$$O(N\cdot n\log^2 n\cdot\log(nN/\varepsilon))\leq n^3\log^3 n\cdot\operatorname{polylog}\left(\tfrac{\log n}{\varepsilon}\right).$$

Note that the use of Glauber dynamics in Sample-k could be replaced by any other polynomial-time approximate sampler for $\mu_{G,\lambda}$, such as the algorithm due to Weitz [33] based on the method of correlation decay. We do however use rapid mixing of the Glauber dynamics in Lemma 8 below to prove correctness of our algorithm, by establishing a lower bound on the probability that a set sampled from $\mu_{G,\lambda}$ has size close to its mean. Note that e.g. a resolution of our Conjecture 5 could imply the necessary probabilistic statement without appealing to the Glauber dynamics, however.

Before we prove Theorem 7, we collect a number of preliminary results that we will use. The first is a bound on the probability of getting an independent set of size close to the mean from the hard-core model when $\lambda<\lambda_c(\Delta)$. We use the notation $n\alpha_G(\lambda)$ for the expected size of an independent set from the hard-core model on G at fugacity λ to avoid ambiguities.

▶ **Lemma 8.** *For $\Delta\geq 3$ and $\alpha<\alpha_c(\Delta)$, there is a unique $\lambda_*<\lambda_c(\Delta)$ so that $\alpha_{K_{\Delta+1}}(\lambda_*)=\alpha$, and the following holds. For any $G\in\mathcal{G}_\Delta$ on n vertices and any $1\leq k\leq\alpha n$, there exists an integer $t\in\{0,1,\dots,\lfloor 2\lambda_* n^2\rfloor\}$ so that*

$$\left|n\alpha_G(t/(2n^2))-k\right|\leq 1/2\,. \tag{2}$$

Moreover, if t satisfies (2) then

$$\mu_{G,t/(2n^2)}(\mathcal{I}_k(G))=\Omega\left(\frac{1}{n\log n}\right).$$

To prove this lemma we need several more results. The first is an extremal bound on $\alpha_G(\lambda)$ for $G\in\mathcal{G}_\Delta$. The statement of the theorem follows from a stronger property proved by Cutler and Radcliffe in [9]; see [12] for discussion.

▶ **Theorem 9** ([9])**.** *For all $G\in\mathcal{G}_\Delta$ and all $\lambda\geq 0$,*

$$\alpha_G(\lambda)\geq\alpha_{K_{\Delta+1}}(\lambda)=\frac{\lambda}{1+\lambda(\Delta+1)}\,.$$

We next rely on a zero-free region for $Z_G(\lambda)$ due to Peters and Regts [28], so that we can apply the subsequent central limit theorem.

▶ **Theorem 10** ([28])**.** *Let $\Delta\geq 3$ and $\xi\in(0,\lambda_c(\Delta))$. Then there exists $\delta>0$ such that for every $G\in\mathcal{G}_\Delta$ the polynomial Z_G has no roots in the complex plane that lie within distance δ of the real interval $[0,\lambda_c(\Delta)-\xi)$.*

The *probability generating function* of a discrete random variable $\mathbf{X}$ distributed on the non-negative integers is the polynomial in z given by $f(z)=\sum_{j\geq 0}\mathbb{P}(\mathbf{X}=j)z^j$, and the above result shows that at subcritical fugacity the probability generating function of $|\mathbf{I}|$ has no zeros close to 1 in $\mathbb{C}$. This lets us use the following result of Michelen and Sahasrabudhe [25].

▶ **Theorem 11** ([25])**.** *For $n\geq 1$ let $\mathbf{X}_n$ be a random variable taking values in $\{0,\dots,n\}$ with mean μ_n, standard deviation σ_n, and probability generating function f_n. If f_n has no roots within distance δ_n of 1 in $\mathbb{C}$, and $\sigma_n\delta_n/\log n\to\infty$, then $(X_n-\mu_n)/\sigma_n$ tends to a standard normal in distribution.*

The final tools we need are simple bounds on the variance of the size of an independent set from the hard-core model.

▶ **Lemma 12.** *Let G be a graph on n vertices and let $\mathbf{I}$ be a random independent set drawn from the hard-core model on G at fugacity λ. Then, if the maximum degree of G is at most Δ and $M \geq n/(\Delta+1)$ is the size of a largest independent set in G, we have*

$$\frac{\lambda}{(1+\lambda)^{2+\Delta}} M \leq \operatorname{var}(|\mathbf{I}|) \leq n^2 \frac{\lambda}{1+\lambda}\,.$$

Proof. For the upper bound note that $|\mathbf{I}|$ is the sum of the indicator random variables $\mathbf{X}_v$ that the vertex $v \in V(G)$ is in $\mathbf{I}$. Then because $\mathbb{P}(\mathbf{X}_v = 1) \leq \lambda/(1+\lambda)$ for all v, from the Cauchy–Schwarz inequality in the form $\operatorname{cov}(\mathbf{X}_u, \mathbf{X}_v)^2 \leq \operatorname{var}(\mathbf{X}_u)\operatorname{var}(\mathbf{X}_v)$ we obtain

$$\operatorname{var}(|\mathbf{I}|) = \sum_{u \in V(G)} \sum_{v \in V(G)} \operatorname{cov}(\mathbf{X}_u, \mathbf{X}_v) \leq n^2 \frac{\lambda}{1+\lambda}\,.$$

For the lower bound, let J be some fixed independent set in G of maximum size M. Now write $\mathbf{X} = |\mathbf{I}|$, and let $\mathbf{K} = \mathbf{I} \setminus J$. By the law of total variance,

$$\operatorname{var}(\mathbf{X}) = \mathbb{E}[\operatorname{var}(\mathbf{X}|\mathbf{K})] + \operatorname{var}(\mathbb{E}[\mathbf{X}|\mathbf{K}]) \geq \mathbb{E}[\operatorname{var}(\mathbf{X}|\mathbf{K})]\,.$$

But we have $\mathbf{X} = |\mathbf{K}| + |\mathbf{I} \cap J|$, and conditioned on $\mathbf{K}$ the set $|\mathbf{I} \cap J|$ is distributed according to the hard-core model on $J \setminus N_G(\mathbf{K})$, the subset of J uncovered by $\mathbf{K}$. Since J is independent, this is a sum of at most $|J|$ independent, identically distributed Bernoulli random variables with probability $\lambda/(1+\lambda)$.

Now, writing $\mathbf{U} = |J \setminus N_G(\mathbf{K})|$ for the number variables in the sum we have

$$\operatorname{var}(\mathbf{X}) \geq \mathbb{E}[\operatorname{var}(\mathbf{X}|\mathbf{K})] = \frac{\lambda}{(1+\lambda)^2}\mathbb{E}\mathbf{U}\,.$$

A vertex $u \in J$ is uncovered by $\mathbf{K}$ precisely when $N(u) \cap \mathbf{K} = \emptyset$. Then by successive conditioning and the maximum degree condition, the probability that u is uncovered by $\mathbf{K}$ is at least $(1+\lambda)^{-\Delta}$. This means $\mathbb{E}\mathbf{U} \geq |J|(1+\lambda)^{-\Delta}$ and hence

$$\operatorname{var}(\mathbf{X}) \geq \frac{\lambda}{(1+\lambda)^{2+\Delta}} M\,.$$

The assertion $M \geq n/(\Delta+1)$ follows from the fact that any n-vertex graph of maximum degree Δ contains an independent set of size at least $n/(\Delta+1)$, which is easy to prove by analyzing a greedy algorithm. ◀

Now we are ready to prove Lemma 8.

Proof of Lemma 8. A standard calculation gives

$$\frac{\partial}{\partial\lambda}\alpha_G(\lambda) = \frac{1}{n}\frac{\partial}{\partial\lambda}\frac{\lambda Z_G'(\lambda)}{Z_G(\lambda)} = \frac{1}{n\lambda}\operatorname{var}(|\mathbf{I}|)\,,$$

and so Lemma 12 gives that $0 < \alpha_G'(\lambda) \leq n$ for all $\lambda > 0$.

Next, let $\lambda_* < \lambda_c(\Delta)$ be the solution to the equation $\alpha_{K_{\Delta+1}}(\lambda_*) = \alpha$. This means

$$\lambda_* = \frac{\alpha}{1-\alpha(\Delta+1)}\,,$$

as defined in Sample-k. The fact that $\lambda_* < \lambda_c(\Delta)$ follows from the fact that $\alpha < \alpha_c(\Delta) = \alpha_{K_{\Delta+1}}(\lambda_c(\Delta))$, and that occupancy fractions are strictly increasing. Then using Theorem 9 we have that

$$\alpha_G(\lambda_*) \geq \alpha_{K_{\Delta+1}}(\lambda_*) = \alpha\,, \tag{3}$$

and so there exists $\lambda \in (0, \lambda_*]$ such that $n\alpha_G(\lambda) = k$. Using the upper bound on $\alpha'_G(\lambda)$, we see that as λ increases over an interval of length $1/(2n^2)$, the function $n\alpha_G(\lambda)$ can increase by at most $1/2$. Hence, there is at least one integer $t \in \{1, \ldots, \lfloor 2\lambda_* n^2 \rfloor\}$ such that $|n\alpha_G(t/(2n^2)) - k| \leq 1/2$.

The second statement of Lemma 8 follows from a central limit theorem for $|\mathbf{I}|$ and rapid mixing of the Glauber dynamics. There is a close connection between zeros of the probability generating function of $|\mathbf{I}|$ and the zeros of the partition function itself. The probability generating function of $|\mathbf{I}|$ is

$$f(z) = \sum_{j\geq 0} \mathbb{P}_\lambda(|\mathbf{I}| = j) z^j = \sum_{j\geq 0} \frac{i_j(G)\lambda^j z^j}{Z_G(\lambda)} = \frac{Z_G(\lambda z)}{Z_G(\lambda)}\,.$$

Then for λ such that $Z_G(\lambda) \neq 0$, z is a root of f if and only if $z\lambda$ is a root of $Z_G(\lambda)$. By our assumptions on t, when $\lambda = t/(2n^2)$ Theorem 10 gives the existence of $\delta > 0$ such that for all $G \in \mathcal{G}_\Delta$ there are no complex zeros of f within distance δ/λ of 1. This is because Theorem 10 means that $Z_G(z\lambda) = 0$ implies $|z\lambda - \lambda| \geq \delta$. The condition of Theorem 11 which states that $\sigma_n\delta_n/\log n \to \infty$ is met because $\lambda < \lambda_c(\Delta) \leq 4$ and so

$$\sigma_n\delta_n \geq \sqrt{\frac{\lambda}{(1+\lambda)^{2+\Delta}}\frac{n}{\Delta+1}} \cdot \frac{\delta}{\lambda} \geq \Omega\Big(\sqrt{n/\lambda}\Big) > \omega(\log n)\,.$$

Now, let $\lambda = t/(2n^2)$ and suppose that (2) holds, meaning that k is within $1/2$ of $n\alpha_G(\lambda)$. The standard deviation of the size of a set drawn from $\mu_{G,\lambda}$ is at least a constant, which follows from the lower bound in Lemma 12 of $\Omega(\sqrt{\lambda n})$ and the fact that $\lambda \geq \Omega(1/n)$. To see this, note that $\alpha_G(\lambda) \leq \lambda/(1+\lambda)$ for any graph and non-negative fugacity λ. This holds because when $\mathbf{I}$ is a random independent set from the hard-core model, conditioned on a vertex v having no neighbors in $\mathbf{I}$, $v \in \mathbf{I}$ with probability $\lambda/(1+\lambda)$. If v has a neighbor in $\mathbf{I}$ then $v \notin \mathbf{I}$ with probability 1, and the bound follows. Then using (2), we have

$$n\frac{\lambda}{1+\lambda} \geq n\alpha_G(\lambda) \geq k - 1/2 \geq 1/2\,,$$

and so $\lambda \geq \Omega(1/n)$. We deduce that k is within some constant number $r > 0$ of standard deviations of the mean size $n\alpha_G(\lambda)$. The central limit theorem and standard properties of the normal distribution mean that there are constants $\rho > 0$ (small enough as a function of r) and n_0 such that for all $n \geq n_0$, with probability at least ρ, $|\mathbf{I}|$ is at least r standard deviations below the mean, and similarly with probability at least ρ it is at least r standard deviations above the mean. So we have $\mathbb{P}_{G,\lambda}(|\mathbf{I}| \geq k) \geq \rho$ and $\mathbb{P}_{G,\lambda}(|\mathbf{I}| \leq k) \geq \rho$.

The transition probabilities when we are at state I in the Glauber dynamics are given by the following random experiment. Choose a vertex $v \in V(G)$ uniformly at random and let

$$I' = \begin{cases} I \cup \{v\} & \text{with probability } \lambda/(1+\lambda)\,, \\ I \setminus \{v\} & \text{with probability } 1/(1+\lambda)\,. \end{cases}$$

Now if I' is independent in G move to state I', otherwise stay in state I. This means that the sequence of sizes of set visited must take consecutive integer values. By Theorem 6, there is a constant C'' such that from an arbitrary starting state, in $C''n\log n$ steps the distribution π of the current state is within total variation distance $\rho/2$ of the hard-core model. Then the following statements hold.

- **(i)** Starting from an independent set of size at most k, with probability at least $\rho/2$ the state after $C''n\log n$ steps is an independent set of size at least k.
- **(ii)** Starting from an independent set of size at least k, with probability at least $\rho/2$ the state after $C''n\log n$ steps is an independent set of size at most k.

Consider starting from an initial state distributed according to $\mu_{G,\lambda}$. Then every subsequent state is also distributed according to $\mu_{G,\lambda}$, and the above facts mean that for any sequence of $C''n\log n$ consecutive steps, with probability at least $\rho/2$ we see a state of size exactly k. Recalling that $\lambda = t/(2n^2)$, this immediately implies that

$$\mu_{G,t/(2n^2)}(\mathcal{I}_k(G)) \geq \frac{\rho}{2C''n\log n}\,,$$

as required. ◀

Proof of Theorem 7. We first prove the theorem under the assumption that each $\hat{\mu}_\lambda$ is exactly the hard-core measure $\mu_{G,\lambda}$, taking note of how many times we sample from any $\hat{\mu}_\lambda$.

We say a *failure* occurs at step i in the FOR loop if either of the following occur:

1. $|n\alpha_G(\lambda) - \kappa| > 1/4$.
2. $|n\alpha_G(\lambda) - k| \leq 1/2$ but the algorithm did not output an independent set of size k in step i.

We show that the probability that a failure occurs at any time during the algorithm is at most $\varepsilon/2$. By a union bound, it is enough to show that the probability of either type of failure at a given step i is at most $\frac{\varepsilon}{4C\log n}$.

Consider an arbitrary step i with its value of λ. To bound the quantity $\mathbb{P}(|n\alpha_G(\lambda) - \kappa| > 1/4)$, note that κ is the mean of N independent samples from $\hat{\mu}_\lambda$, which we currently assume to be $\mu_{G,\lambda}$. Then we have $\mathbb{E}\kappa = n\alpha_G(\lambda)$ and Hoeffding's inequality gives $\mathbb{P}(|n\alpha_G(\lambda) - \kappa| > 1/4) \leq 2e^{-N/(8n^2)}$, so for this to be at most $\varepsilon/(4C\log n)$ we need only $N \geq \Omega\big(n^2\log\big(\frac{\log n}{\varepsilon}\big)\big)$.

To bound the probability that the current step involves λ such that $|n\alpha_G(\lambda) - k| \leq 1/2$, but we fail to get a set of size k in the N samples, observe that we have N independent trials for getting a set of size k, and each trial succeeds with probability $p \geq c/(n\log n)$ by Lemma 8. Then the probability we see no successful trials is $\big(1 - \frac{c}{n\log n}\big)^N$, which is at most $\varepsilon/(4C\log n)$ for $N \geq \Omega\big(n\log n\cdot\log\big(\frac{\log n}{\varepsilon}\big)\big)$. Thus, we can take $N = \Theta\big(n^2\log\big(\frac{\log n}{\varepsilon}\big)\big)$, as in line 6 of Sample-k.

Next we show that in the event that no failure occurs during the running of the algorithm, the algorithm outputs an independent set I with distribution within $\varepsilon/2$ total variation distance of the uniform distribution on $\mathcal{I}_k(G)$.

We first observe that if no failure occurs, the algorithm at some point reaches a value of λ so that $|n\alpha_G(\lambda) - k| \leq 1/2$. This is a simple consequence of Lemma 8, which means there exists some t with this property, and the binary search structure of the algorithm. In particular, in each iteration of the FOR loop, at line (e) the size of the set Λ_i being searched goes down by (at least) half. Conditioned on no failures, the search also proceeds in the correct half of λ_i because we search the upper half only when $\kappa < k - 1/4$ and so conditioned on no failure we have $n\alpha_G(\lambda) \leq \kappa + 1/4 < k$ and hence using a larger value of λ must bring $n\alpha_G(\lambda)$ closer to k. The case $\kappa > k + 1/4$ is similar. This means that, conditioned on no failures, the algorithm must reach a value of λ such that $|n\alpha_G(\lambda) - k| \leq 1/4$.

Note that $\mu_{G,\lambda}$ conditioned on getting a set of size exactly k is precisely the uniform distribution on $\mathcal{I}_k(G)$, hence if the algorithm outputs an independent set of size k during the FOR loop, its distribution is exactly uniform distribution on $\mathcal{I}_k(G)$. Thus, under the assumption that each $\hat{\mu}_\lambda$ is precisely $\mu_{G,\lambda}$ we have shown that with probability at least $1 - \varepsilon/2$ no failures occur, and hence a perfectly uniform sample from $\mathcal{I}_k(G)$ is output during the FOR loop.

We do not have access to an efficient exact sampler for $\mu_{G,\lambda}$, so we make do with the approximate sampler from Theorem 6. One interpretation of total variation distance is that when each $\hat{\mu}_\lambda$ has total variation distance at most ξ from $\mu_{G,\lambda}$, there is a coupling between $\hat{\mu}_\lambda$ and $\mu_{G,\lambda}$ such that the probability they disagree is at most ξ. Then to prove Theorem 7 we consider a third failure condition: that during any of the calls to a sampling algorithm for any $\hat{\mu}_\lambda$ the output differs from what would have been given by $\mu_{G,\lambda}$ under this coupling. Since we make at most $CN \log n$ calls to such sampling algorithms, provided $\xi \leq \varepsilon/(2CN \log n)$ the probability of any failure of this kind is at most $\varepsilon/2$. Together with the above proof for samples distributed exactly according to $\mu_{G,\lambda}$ which successfully returns uniform samples from $\mathcal{I}_k(G)$ with probability $1 - \varepsilon/2$, we have now shown the existence of a sampler that with probability $1 - \varepsilon$ returns uniform samples from $\mathcal{I}_k(G)$, and makes at most $CN \log n$ calls to a $\varepsilon/(2CN \log n)$-approximate sampler for $\mu_{G,\lambda}$ (at various values of λ). Interpreting this in terms of total variation distance, this means we have an ε-approximate sampler for the uniform distribution on $\mathcal{I}_k(G)$ with running time $O(N \log n \cdot T(n, \varepsilon))$. ◀

2.2 Approximate counting

Given a graph $G = (V, E)$ on n vertices and $j \geq 0$, let $f_j(G) = (j+1)i_{j+1}(G)/i_j(G)$. This $f_j(G)$ has an interpretation as the *expected free volume* over a uniform random independent set $\mathbf{J} \in \mathcal{I}_j(G)$, that is, $f_j = \mathbb{E}|V \setminus (\mathbf{J} \cup N(\mathbf{J}))|$. This holds because each vertex in $V \setminus (\mathbf{J} \cup N(\mathbf{J}))$ can be added to $\mathbf{J}$ to make an independent set of size $j+1$, and each such set is counted $j+1$ times in this way. Then by a simple telescoping product we have

$$i_k(G) = \prod_{j=0}^{k-1} \frac{f_j(G)}{j+1}\,, \tag{4}$$

and hence if for $0 \leq j \leq k-1$ we can obtain a relative ε/k approximation to f_j in time polynomial in n and $1/\varepsilon$ then we can obtain a relative ε-approximation to $i_k(G)$ in time polynomial in n and $1/\varepsilon$. By the definition of f_j as an expectation over a uniform random independent set of size j, we can use an efficient sampling scheme for this distribution to approximate f_j, which is provided by Theorem 7. That is, by repeatedly sampling independent sets of size j approximately uniformly and recording the free volume we can approximate the expected free volume $f_j(G)$, and hence the corresponding term of the product in (4). Doing this for all $0 \leq j \leq k-1$ thus provides an approximation to $i_k(G)$. This scheme is an example of *simulated annealing*, which can be used as a general technique for obtaining approximation algorithms from approximate sampling algorithms. For more details, see e.g. [22, 29]. Here the integer j is playing the role of inverse temperature, and we approximate $i_k(G)$ by estimating $f_j(G)$ (by sampling from $\mathcal{I}_j(G)$) with the cooling schedule $j = 0, 1, \ldots, k-1$. We expect that a more sophisticated cooling schedule can be used to decrease the running time of our reduction, see for example [19].

Since this annealing process is standard, we sketch a simple version of the method. Suppose that for all $0 \leq j \leq k-1$ we have a randomized algorithm that with probability at least $1 - \delta'$ returns a relative ε/k-approximation $\hat{t}_j$ to $f_j(G)/(j+1)$ in time T'. Then (4)

implies that with probability at least $1 - k\delta$, the product $\hat{\imath}_k = \prod_{j=0}^{k-1} \hat{t}_j$ is a relative ε-approximation to $i_k(G)$, and this takes time kT' to compute. For the FPRAS in Theorem 1, it therefore suffices to design the hypothetical algorithm with $\delta' = 1/(4k)$ and T' polynomial in n and $1/\varepsilon$.

First, suppose that we have access to an exactly uniform sampler for $\mathcal{I}_j(G)$ for $0 \le j \le k-1$, but impose the smaller failure probability bound of $\delta'/2$. Then, for each j, let $\hat{t}_j$ be the sample mean of m computations of $|V \setminus (\mathbf{J} \cup N(\mathbf{J}))|/(j+1)$ where $\mathbf{J}$ is a uniform random independent set of size j. We note that as a random variable $|V \setminus (\mathbf{J} \cup N(\mathbf{J}))|/(j+1)$ has a range of at most $j\Delta/(j+1)$ in a graph of maximum degree Δ because $0 \le |N(\mathbf{J})| \le j\Delta$, and for $j \le k-1$ and

$$k \le \alpha n < \alpha_c(\Delta) n < \frac{e}{1+e}\frac{n}{\Delta},$$

we have

$$\frac{|V \setminus (\mathbf{J} \cup N(\mathbf{J}))|}{j+1} \ge \frac{n - j(\Delta+1)}{j+1} \ge \frac{\Delta}{e} - 1.$$

Let S_j be the mean of m samples of $|V \setminus (\mathbf{J} \cup N(\mathbf{J}))|/(j+1)$. Then, using that for $\varepsilon' \le 1$ it suffices to ensure $|S_j - \mu| \le \varepsilon'\mu/2$ for S_j to be a relative ε'-approximation to μ, by Hoeffding's inequality,

$$m \ge \Omega(\varepsilon^{-2}k^2 \log(1/\delta')) = \Omega(\varepsilon^{-2}k^2 \log k)$$

samples are sufficient to obtain the required approximation accuracy ε' with the required success probability $1 - \delta'/2$. Since we do not have an exact sampler, we use the approximate sampler obtained in this section with total variation distance $\delta'/2$. Using the coupling between the exact and the approximate sampler that we used in the proof of Theorem 7, this suffices to obtain the required sampling accuracy with failure probability at most δ'. Recalling that $k \le n$, it is now simple to check that the running time of the entire annealing scheme is polynomial in n and $1/\varepsilon$. This completes the proof of Theorem 1a.

3 Hardness

To prove hardness we will use the notion of an "approximation-preserving reduction" from [13]. We reduce the problem of approximating the hard-core partition function $Z_G(\lambda)$ on a Δ-regular graph G, which we recall is hard for $\lambda > \lambda_c$ (see [16, 31]), to the problem of approximating $i_k(G')$ for Δ-regular graph G' that can be constructed in time polynomial in the size of G. In particular, we show that it suffices to find an $\varepsilon/2$-approximation to $i_k(G')$ in order to obtain an ε-approximation to $Z_G(\lambda)$.

Let $\mathrm{IS}(\alpha, \Delta)$ be the problem of computing $i_{\lfloor \alpha n \rfloor}(G)$ for a Δ-regular graph G on n vertices. Let $\mathrm{HC}(\lambda, \Delta)$ be the problem of computing $Z_G(\lambda)$ for a Δ-regular graph G.

▶ **Theorem 13.** *For every $\Delta \ge 3$ and $\alpha \in (\alpha_c(\Delta), 1/2)$, there exists $\lambda > \lambda_c(\Delta)$ so that there is an approximation-preserving reduction from $\mathrm{HC}(\lambda, \Delta)$ to $\mathrm{IS}(\alpha, \Delta)$.*

Theorem 13 immediately implies the hardness part of Theorem 1 as the results of [16, 31] show that there is no FPRAS for $\mathrm{HC}(\lambda, \Delta)$ for any $\lambda > \lambda_c(\Delta)$ unless NP=RP.

Proof of Theorem 13. Fix $\Delta \ge 3$, and let $\alpha \in (\alpha_c(\Delta), 1/2)$ be given. We will construct a Δ-regular graph H on n_H vertices such that for some value $\lambda \in (\lambda_c(\Delta), \infty)$ we have $\alpha_H(\lambda) = \alpha$. Our reduction is then as follows: given a Δ-regular graph G on n vertices and

$\varepsilon > 0$, let G' be the disjoint union of G with rH, the graph of r disjoint copies of H, with $r = \lceil C\Delta n^2/\varepsilon \rceil$ for some absolute constant C. Let $N = |V(G')| = n + rn_H$. We will prove that

$$e^{-\varepsilon/2}\frac{i_k(G')}{i_k(rH)} \le Z_G(\lambda) \le e^{\varepsilon/2}\frac{i_k(G')}{i_k(rH)}\,, \tag{5}$$

where $k = \lfloor \alpha N \rfloor$.

Since G' can be constructed and $i_k(rH)$ computed in time polynomial in n, this provides the desired approximation-preserving reduction. What remains is to construct the graph H satisfying $\alpha_H(\lambda) = \alpha$ and then to prove (5).

Constructing H

The graph $H = H_{a,b}$ will consist of the union of a copies of the complete bipartite graph $K_{\Delta,\Delta}$ and b copies of the clique $K_{\Delta+1}$. Clearly H is Δ-regular. Since the occupancy fraction of any graph is a strictly increasing function of λ, and the relevant occupancy fractions satisfy $\alpha_{K_{\Delta+1}}(\lambda_c(\Delta)) = \alpha_c(\Delta)$ and $\lim_{\lambda\to\infty}\alpha_{K_{\Delta,\Delta}}(\lambda) = 1/2$, we see that there exist integers $a, b \ge 0$ (with at least one positive) and $\lambda > \lambda_c(\Delta)$ so that $\alpha_{H_{a,b}}(\lambda) = \alpha$. A given pair (a, b) provides a suitable $H_{a,b}$ when

$$\alpha_{H_{a,b}}(\lambda_c(\Delta)) < \alpha < \lim_{\lambda\to\infty}\alpha_{H_{a,b}}(\lambda) = \frac{a\Delta + b}{2a\Delta + b(\Delta+1)}\,,$$

and hence it can be shown that for all $\Delta \ge 3$ one of the pairs $(0,1)$, $(1,16)$, $(1,6)$, $(1,3)$, $(2,3)$, $(2,1)$, $(1,0)$ suffices for (a,b), and a suitable pair is easy to find efficiently. This provides us with the desired graph H. From here on, fix these values a, b, λ and let $n_H = 2a\Delta + b(\Delta+1)$.

Proving (5)

We now form G' by taking the union of G (a Δ-regular graph on n vertices) and r copies of H. Let $N = n + rn_H$ be the number of vertices of G', and write $k = \lfloor \alpha N \rfloor$. Let rH be the graph consisting of the disjoint union of r copies of H. We can write:

$$i_k(G') = \sum_{j=0}^{n} i_j(G) i_{k-j}(rH) = i_k(rH)\sum_{j=0}^{n} i_j(G)\frac{i_{k-j}(rH)}{i_k(rH)}\,.$$

Now to prove (5) it suffices to show that for $r \ge C\Delta n^2/\varepsilon$ and $0 \le j \le n$, we have

$$e^{-\varepsilon/2}\lambda^j \le \frac{i_{k-j}(rH)}{i_k(rH)} \le e^{\varepsilon/2}\lambda^j\,. \tag{6}$$

We have the exact formula (for any $0 \le j \le k$)

$$i_{k-j}(rH) = \frac{Z_{rH}(\lambda)}{\lambda^{k-j}}\mathbb{P}_{rH,\lambda}(|\mathbf{I}| = k-j)$$

and so

$$\frac{i_{k-j}(rH)}{i_k(rH)} = \lambda^j\frac{\mathbb{P}_{rH,\lambda}(|\mathbf{I}| = k-j)}{\mathbb{P}_{rH,\lambda}(|\mathbf{I}| = k)}\,,$$

where $\mathbb{P}_{rH,\lambda}$ denotes probabilities with respect to an independent set $\mathbf{I}$ drawn according to the hard-core model on rH at fugacity λ. It is then enough to show

$$e^{-\varepsilon/2} \le \frac{\mathbb{P}_{rH,\lambda}(|\mathbf{I}| = k-j)}{\mathbb{P}_{rH,\lambda}(|\mathbf{I}| = k)} \le e^{\varepsilon/2}\,.$$

This will follow from a local central limit theorem (e.g. [17]) since $|\mathbf{I}|$ is the sum of r i.i.d. random variables and the fact that $\mathbb{E}_{rH,\lambda}|\mathbf{I}|$ is close to both k and $k-j$. The following theorem gives us what we need.

▶ **Theorem 14** (Gnedenko [17]). *Let $X_1, \dots, X_r$ be i.i.d. integer valued random variables with mean μ and variance σ^2, and suppose that the support of X_1 includes two consecutive integers. Let $S_r = X_1 + \cdots + X_r$. Then*

$$\mathbb{P}(S_r = k) = \frac{1}{\sqrt{2\pi r}\sigma} \exp\left[-(k-n\mu)^2/(2r\sigma^2)\right] + o(r^{-1/2}),$$

with the error term $o(r^{-1/2})$ uniform in k.

This immediately implies that with μ and σ^2 the mean and standard deviation of the hard-core model on H at fugacity λ,

$$\frac{\mathbb{P}_{rH,\lambda}(|\mathbf{I}| = k-j)}{\mathbb{P}_{rH,\lambda}(|\mathbf{I}| = k)} = \frac{e^{-[j^2 - 2(k-r\mu)j]/(2r\sigma^2)} + o(e^{(k-r\mu)^2/(2r\sigma^2)}/r)}{1 + o(e^{(k-r\mu)^2/(2r\sigma^2)}/r)}.$$

It therefore suffices to show that for large enough r, namely $r \geq C\Delta n^2/\varepsilon$, we can make $[j^2 - 2(k-r\mu)j]/(2r\sigma^2)$ small compared to ε and show that $(k-r\mu)^2/(2r\sigma^2)$ is bounded above by some absolute constant. Note that $\mu = \alpha n_H$, and by Lemma 12 we have for all $\Delta \geq 3$ (and any choices of α, λ, a, b made according to our conditions),

$$\sigma^2 \geq \frac{\lambda}{(1+\lambda)^{2+\Delta}}(a\Delta + b) \geq \frac{\lambda_c(\Delta)}{(1+\lambda_c(\Delta))^{2+\Delta}}(a\Delta + b) \geq \frac{0.00384}{\Delta}.$$

Since $k = \lfloor \alpha N \rfloor = \lfloor \alpha n + r\alpha n_H \rfloor$, we then have $(k - r\mu)^2 \leq \alpha^2 n^2 < n^2$, and hence $\frac{(k-r\mu)^2}{2r\sigma^2} \leq C'\Delta\frac{n^2}{r}$, where C' is an absolute constant. Now since $0 \leq j \leq n$ we also have

$$\left|\frac{j^2 - 2(k-r\mu)j}{2r\sigma^2}\right| \leq C'\Delta\frac{n^2}{r}.$$

This means that provided we take C to be a large enough absolute constant and $r \geq C\Delta n^2/\varepsilon$, we have (5) as required. ◀

4 Triangle-free graphs

In this section we briefly describe the modifications to the proofs in Sections 2 and 3 to yield Theorem 2, an analogue of Theorem 1 for triangle-free graphs.

4.1 Algorithms

We use the following lower bound on the occupancy fraction of triangle-free graphs.

▶ **Theorem 15** ([11]). *For every $\delta > 0$, there is Δ_0 large enough so that for every $\Delta \geq \Delta_0$, and every triangle-free $G \in \mathcal{G}_\Delta$,*

$$\alpha_G(\lambda_c(\Delta) - 1/\Delta^2) \geq \frac{1-\delta}{\Delta}.$$

This statement follows from [11, Theorem 3] and some asymptotic analysis of the bound for $\lambda = \lambda_c(\Delta) - 1/\Delta^2$ as $\Delta \to \infty$. Now the algorithm for Theorem 2 is essentially the same as for Theorem 1, but since we assume the graph G is triangle free we can use a stronger

lower bound on the occupancy fraction than Theorem 9. Let $\delta > 0$ and $\alpha < (1-\delta)/\Delta$ as in Theorem 2. Then Theorem 15 means that for $\Delta \geq \Delta_0$ and any triangle-free graph $G \in \mathcal{G}_\Delta$ we have

$$\alpha_G(\lambda_c(\Delta) - 1/\Delta^2) \geq \frac{1-\delta}{\Delta} > \alpha\,.$$

But occupancy fractions are continuous and strictly increasing, so with $\lambda_* = \lambda_c(\Delta) - 1/\Delta^2$ there exists $\lambda \in (0, \lambda_*]$ such that $k = n\alpha_G(\lambda)$, as in the proof of Lemma 8 but permitting larger α. The analysis of the algorithm can then proceed exactly as in the proofs of Lemma 8 and Theorem 1, completing the proof of Theorem 2a.

4.2 Hardness

The proof of hardness for triangle-free graphs is the same as that for general graphs, but we replace $K_{\Delta+1}$ with a (constant-sized) random regular graph in the construction. Bhatnagar, Sly, and Tetali [4] showed that the local distribution of the hard-core model on the random regular graph converges to that of the unique translation-invariant hard-core measure on the infinite regular tree for a range of λ including $\lambda = \lambda_c(\Delta)$. This means that if K is a random Δ-regular graph on n vertices and α_{T_Δ} denotes the occupancy fraction of the unique translation-invariant hard-core measure on the infinite Δ-regular tree (see [4, 11]) we have with probability $1 - o_n(1)$,

$$\alpha_K(\lambda_c(\Delta)) = \alpha_{T_\Delta}(\lambda_c(\Delta)) + o_n(1) = \frac{1 + o_{n,\Delta}(1)}{\Delta}\,,$$

where $o_n(1) \to 0$ as $n \to \infty$ and $o_{n,\Delta}(1) \to 0$ as both n and Δ tend to infinity. Thus, for fixed $\delta \in (0,1)$, there is $n_0 = n_0(\delta)$ and $\Delta_0 = \Delta_0(\delta)$ such that with probability at least $1-\delta$ a random Δ-regular graph K on n_0 vertices has $\alpha_G(\lambda_c(\Delta)) \leq (1+\delta)/\Delta$. This means that in time bounded by a function of δ an exhaustive search over Δ-regular graphs on n_0 vertices must yield a graph K with the property $\alpha_K(\lambda_c(\Delta)) \leq (1+\delta)/\Delta$. Now we replace $K_{\Delta+1}$ with the random Δ-regular graph K in the proof above, which for $\Delta \geq \Delta_0$ allows us to work with any $\alpha \in ((1+\delta)/\Delta, 1/2)$ by the above argument. To finish the proof, we require that approximating $Z_G(\lambda)$ is hard for Δ-regular *triangle-free* graphs G when $\lambda > \lambda_c$. This follows directly from the proof of Sly and Sun [31], as their gadget which shows hardness for Δ-regular graphs contains no triangles. Thus, we have the following analogue of Theorem 13, where we let $\mathrm{IS}'(\alpha, \Delta)$ be the problem of computing $i_{\lfloor \alpha n \rfloor}(G)$ for a Δ-regular triangle-free graph G on n vertices.

▶ **Theorem 16.** *Given $\delta > 0$ there exists Δ_0 such that the following holds for all $\Delta \geq \Delta_0$. For every $\alpha \in ((1+\delta)/\Delta, 1/2)$, there exists $\lambda > \lambda_c(\Delta)$ so that there is an approximation-preserving reduction from $\mathrm{HC}(\lambda, \Delta)$ to $\mathrm{IS}'(\alpha, \Delta)$.*

This implies Theorem 2b.

Linear Time Runs Over General Ordered Alphabets

Jonas Ellert
Department of Computer Science, Technical University of Dortmund, Germany

Johannes Fischer
Department of Computer Science, Technical University of Dortmund, Germany

Abstract

A run in a string is a maximal periodic substring. For example, the string `bananatree` contains the runs $\texttt{anana} = (\texttt{an})^{5/2}$ and $\texttt{ee} = \texttt{e}^2$. There are less than n runs in any length-n string, and computing all runs for a string over a linearly-sortable alphabet takes $\mathcal{O}(n)$ time (Bannai et al., SIAM J. Comput. 2017). Kosolobov conjectured that there also exists a linear time runs algorithm for general ordered alphabets (Inf. Process. Lett. 2016). The conjecture was almost proven by Crochemore et al., who presented an $\mathcal{O}(n\alpha(n))$ time algorithm (where $\alpha(n)$ is the extremely slowly growing inverse Ackermann function). We show how to achieve $\mathcal{O}(n)$ time by exploiting combinatorial properties of the Lyndon array, thus proving Kosolobov's conjecture. This also positively answers the at least 29-year-old question whether square-freeness can be tested in linear time over general ordered alphabets (Breslauer, PhD thesis, Columbia University 1992).

1 Introduction and Related Work

A run in a string S is a maximal periodic substring. For example, the string $S = \texttt{bananatree}$ contains exactly the runs $\texttt{anana} = (\texttt{an})^{5/2}$ and $\texttt{ee} = \texttt{e}^2$. Identifying such repetitive structures in strings is of great importance for applications like text compression, text indexing and computational biology (for a general overview see [8]). To name just one example, runs in human genes (called maximal tandem repeats) are involved with a number of neurological disorders [5]. In 1999, Kolpakov and Kucherov showed that the maximum number $\rho(n)$ of runs in a length-n string is bounded by $\mathcal{O}(n)$, and provided a word RAM algorithm that outputs all runs in linear time [18]. The algorithm is based on the Lempel-Ziv factorization and only achieves $\mathcal{O}(n)$ time for *linearly-sortable alphabets*, i.e. alphabets that are totally ordered and for which a sequence of σ alphabet symbols can be sorted in $\mathcal{O}(\sigma)$ time. Since then, it has been an open question whether there exists a linear time runs algorithm for *general ordered alphabets*, i.e. totally ordered alphabets for which the order of any two symbols can be determined in constant time. Any such algorithm must not use the Lempel-Ziv factorization, since for general ordered alphabets of size σ it cannot be constructed in $o(n \lg \sigma)$ time [19].

Kolpakov and Kucherov also conjectured that the maximum number of runs is bounded by $\rho(n) < n$, which started a 15 year-long search for tighter upper bounds of $\rho(n)$. Rytter was the first to give an explicit constant with $\rho(n) < 5n$ [25]. After multiple incremental improvements of this bound (e.g. [7, 9, 24]), Bannai et al. [2] finally proved the conjecture by showing $\rho(n) < n$ for arbitrary alphabets, which was subsequently even surpassed for binary texts [12]. (The current best bound for binary alphabets is $\rho(n) < \frac{183}{193}n$ [17].)

On the algorithmic side, Bannai et al. also provided a new linear time algorithm that computes all the runs [2]. While (just like the algorithm by Kolpakov and Kucherov) it only achieves the time bound for linearly-sortable alphabets, it no longer relies on the Lempel-Ziv factorization. Instead, the main effort of the algorithm lies in the computation of $\Theta(n)$ *longest common extensions (LCEs)*; given two indices $i, j \in [1, n]$, their LCE is the length of the longest common prefix of the suffixes $S[i..n]$ and $S[j..n]$. For linearly-sortable alphabets, we can precompute a data structure in $\mathcal{O}(n)$ time that answers arbitrary LCE queries in constant time (see e.g. [11]), thus yielding a linear time runs algorithm. Kosolobov showed that for general ordered alphabets any batch of $\mathcal{O}(n)$ LCEs can be computed in $\mathcal{O}(n \lg^{2/3} n)$ time, and conjectured the existence of a linear time runs algorithm for general ordered alphabets [20]. Gawrychowski et al. improved this result to $\mathcal{O}(n \lg \lg n)$ time [14]. Finally, Crochemore et al. noted that the required LCEs satisfy a special non-crossing property. They showed how to compute $\mathcal{O}(n)$ non-crossing LCEs in $\mathcal{O}(n\alpha(n))$ time, resulting in an $\mathcal{O}(n\alpha(n))$ time algorithm that computes all runs over general ordered alphabets [10] (where α is the inverse Ackermann function).

This is also the asymptotically fastest known algorithm for testing whether a string is square-free. A square is a substring $\alpha\alpha$ for some non-empty word α. A string is square-free if and only if it contains no runs (because every square is contained in a run, and every run contains at least one square). The question whether square-freeness over general ordered alphabets can be tested in linear time dates back at least to Breslauer's PhD dissertation [4, Section 4.4], which was published almost 30 years ago.[1] Testing for square-freeness over general *unordered* alphabets (where only constant time equality testing of symbols is permitted) takes at least $\Omega(n \lg n)$ symbol comparisons [22].

Our Contributions. We show how to compute the LCEs required by the algorithm by Bannai et al. in $\mathcal{O}(n)$ time and space, resulting in the first linear time runs algorithm for general ordered alphabets. Thus we prove Kosolobov's conjecture, and provide the first linear time algorithm to test for square-freeness over general ordered alphabets. Our solution differs from all previous approaches in the sense that it cannot answer a sequence of *arbitrary* non-crossing LCE queries. Instead, our algorithm is specifically designed *exactly for the LCEs required by the runs algorithm*. This allows us to utilize powerful combinatorial properties of the *Lyndon array* (a definition follows in Section 2) that do not generally hold for arbitrary non-crossing LCE sequences.

Even though the main contribution of our work is the improved asymptotic time bound, it is worth mentioning that our algorithm is also very fast in practice. On modern hardware, computing all runs for a text of length 10^7(= 10MB) takes only one second.

A Note on the Model. As mentioned earlier, our algorithm runs in linear time for *general ordered alphabets*, whereas previous algorithms achieve this time bound only when the alphabet is *linearly-sortable*. This is comparable with the distinction between *comparison-based* and *integer* sorting: while in the comparison-model sorting n items requires $\Omega(n \lg n)$ time, integer sorting is faster ($O(n\sqrt{\lg \lg n})$ time [16] and sometimes even linear, e.g. when the word width w satisfies $w = \mathcal{O}(\lg n)$ and one can use radix sort, or when $w \geq (\lg^{2+\epsilon} n)$ [1]). Whereas it is a major open problem whether integer sorting can always be done in linear time, this paper settles a symmetric open problem for the computation of runs.

[1] We thank the reviewer who kindly pointed out to us that this was an open problem.

The remainder of the paper is structured as follows: First, we introduce the basic notation, definitions, and auxiliary lemmas (Section 2). Then, we give a simplified description of the runs algorithm by Bannai et al. and show how the required LCEs relate to the Lyndon array (Section 3). Our linear time algorithm to compute the LCEs is described in Section 4. We discuss additional practical aspects and experimental results in Section 5.

2 Preliminaries

Our analysis is performed in the word RAM model (see e.g. [15]), where we can perform fundamental operations (logical shifts, basic arithmetic operations etc.) on words of size w bits in constant time. For an input of size n we assume $\lceil \log_2 n \rceil \leq w$. We write $[i,j] = [i,j+1) = (i-1,j] = (i-1,j+1)$ with $i,j \in \mathbb{N}$ to denote the set of integers $\{x \mid x \in \mathbb{N} \wedge i \leq x \leq j\}$.

Strings. Let Σ be a finite and totally ordered set. A *string* S of length $|S| = n$ over the *alphabet* Σ is a sequence $S[1] \dots S[n]$ of n *symbols* (also called *characters*) from Σ. The alphabet is called a *general ordered alphabet* if order testing (i.e. evaluating $\sigma_1 < \sigma_2$ for $\sigma_1, \sigma_2 \in \Sigma$) is possible in constant time. For $i,j \in [1,n]$, we use the interval notation $S[i..j] = S[i..j+1) = S(i-1..j] = S(i-1..j+1)$ to denote the *substring* $S[i] \dots S[j]$. If however $i > j$, then $S[i..j]$ denotes the *empty string* ϵ. The substring $S[i..j]$ is called *proper* if $S[i..j] \neq S$. A *prefix* of S is a substring $S[1..j]$ (including $S[1..0] = \epsilon$), while the *suffix* S_i is the substring $S[i..n]$ (including $S_{n+1} = \epsilon$). Given two strings S and T of length n and m respectively, their concatenation is defined as $ST = S[1] \dots S[n]T[1] \dots T[m]$. For any positive integer k, the k-times concatenation of S is denoted by S^k. Let $\ell_{\max} = \min(n,m)$. The *longest common prefix (LCP)* of S and T has length $\textsc{lcp}(S,T) = \max\{\ell \mid \ell \in [0,\ell_{\max}] \wedge S[1..\ell] = T[1..\ell]\}$, while the *longest common suffix* has length $\textsc{lc-suff}(S,T) = \max\{\ell \mid \ell \in [0,\ell_{\max}] \wedge S_{n-\ell+1} = T_{m-\ell+1}\}$. Let $\ell' = \textsc{lcp}(S,T)$. For a string S of length n and indices $i,j \in [1,n]$, we define the *longest common right-extension (R-LCE) and left-extension (L-LCE)* as $\textsc{lce}_r(i,j) = \textsc{lcp}(S_i,S_j)$ and $\textsc{lce}_\ell(i,j) = \textsc{lc-suff}(S[1..i],S[1..j])$ respectively. The total order on Σ induces a *lexicographical order* $\prec$ on the strings over Σ in the usual way. Given three suffixes, we can deduce properties of their R-LCEs from their lexicographical order:

▶ **Lemma 1.** *Let $S_i \prec S_j \prec S_k$ be suffixes of a string, then it holds $\textsc{lce}_r(i,k) \leq \textsc{lce}_r(i,j)$ and $\textsc{lce}_r(i,k) \leq \textsc{lce}_r(j,k)$.*

Proof. Assume $\ell = \textsc{lce}_r(i,j) < \textsc{lce}_r(i,k)$, then $S_i[1..\ell] = S_j[1..\ell] = S_k[1..\ell]$ and $S_j[\ell+1] \neq S_i[\ell+1] = S_k[\ell+1]$. This implies $S_i \prec S_j \Leftrightarrow S_k \prec S_j$, which contradicts $S_i \prec S_j \prec S_k$. The proof of $\textsc{lce}_r(i,k) \leq \textsc{lce}_r(j,k)$ works analogously. ◀

Repetitions and Runs. Let S be a string and let $S[i..j]$ be a non-empty substring. We say that $p \in \mathbb{N}^+$ is a *period* of $S[i..j]$ if and only if $\forall x \in [i,j-p] : S[x] = S[x+p]$. If additionally $(j-i+1) \geq p$, then $S[i..i+p)$ is called *string period* of $S[i..j]$. Furthermore, p is called *shortest period* of $S[i..j]$ if there is no $q \in [1,p)$ that is also a period of $S[i..j]$. Analogously, a string period of $S[i..j]$ is called *shortest string period* if there is no shorter string period of $S[i..j]$. A *run* is a triple $\langle i,j,p \rangle$ such that p is the shortest period of $S[i..j]$, $(j-i+1) \geq 2p$ (i.e. there are at least two consecutive occurrences of the shortest string period $S[i..i+p)$), and neither $\langle i-1,j,p \rangle$ nor $\langle i,j+1,p \rangle$ satisfies these properties (assuming $i > 1$ and $j < n$, respectively).

Lyndon Words and Nearest Smaller Suffixes. For a length-n string S and $i \in [1, n]$, the string $S_i S[1..i)$ is called *cyclic shift* of S, and *non-trivial cyclic shift* if $i > 1$. A *Lyndon word* is a non-empty string that is lexicographically smaller than any of its non-trivial cyclic shifts, i.e. $\forall i \in [2, n] : S \prec S_i S[1..i)$. The Lyndon array of S identifies the longest Lyndon word starting at each position of S.

▶ **Definition 2** (Lyndon Array). *Given a string S of length n, its Lyndon array $\lambda[1, n]$ is defined by $\forall i \in [1, n] : \lambda[i] = \max\{j - i + 1 \mid j \in [i, n] \wedge S[i..j]$ is a Lyndon word$\}$.*

An alternative representation of the Lyndon array is the next-smaller-suffix array.

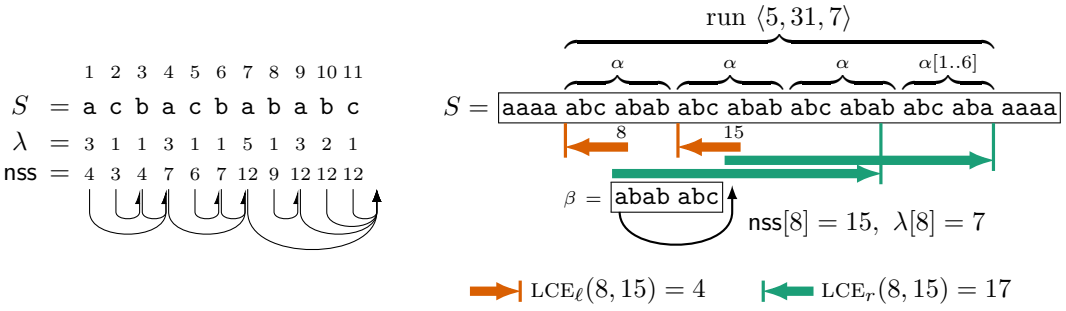
▶ **Definition 3** (Next Smaller Suffixes). *Given a string S of length n, its* next-smaller-suffix (NSS) array *is defined by $\forall i \in [1, n] : \mathsf{nss}[i] = \min\{j \mid j = n + 1 \vee (j \in (i, n] \wedge S_i \succ S_j)\}$. If $\mathsf{nss}[i] \leq n$, then $S_{\mathsf{nss}[i]}$ is called the* next smaller suffix of S_i.

▶ **Lemma 4** (Lemma 15 [13]). *The longest Lyndon word starting at any position $i \in [1, n]$ of a length-n string S is exactly the substring $S[i..\mathsf{nss}[i])$, i.e. $\forall i \in [1, n] : \lambda[i] = \mathsf{nss}[i] - i$.*

An example of the Lyndon and NSS array is provided in Figure 1a. The NSS edges in the example do not intersect. This property also holds in the general case:

▶ **Lemma 5.** *Let $i \in [1, n]$ and $i' \in [i, \mathsf{nss}[i])$. Then it holds $\mathsf{nss}[i'] \leq \mathsf{nss}[i]$.*

Proof. Due to $i' \in [i, \mathsf{nss}[i])$ and Definition 3 it holds $S_{i'} \succ S_{\mathsf{nss}[i]}$. Assume that the lemma does not hold, then we have $\mathsf{nss}[i] \in (i', \mathsf{nss}[i'])$ and Definition 3 implies $S_{i'} \prec S_{\mathsf{nss}[i]}$. ◀



3 The Runs Algorithm Revisited

In this section, we recapitulate the main ideas of the algorithm by Bannai et al. [2], which is the basis of our solution for general ordered alphabets. The key insight is that every run is *rooted* in a longest Lyndon word, allowing us to compute all runs from the Lyndon array.

▶ **Definition 6.** *Let $\langle i, j, p\rangle$ be a run in a string S. We say that $\langle i, j, p\rangle$ is* (lexicographically) decreasing *if and only if $S_i \succ S_{i+p}$. Otherwise, $\langle i, j, p\rangle$ is* (lexicographically) increasing.

▶ **Lemma 7.** *Let $\langle i, j, p\rangle$ be a decreasing run, then there is exactly one index $i_0 \in [i..i + p)$ such that $\lambda[i_0] = p$.*

Proof. Consider any $i_0 \in [i, i+p)$. By the definition of runs, we have $S[i..i_0) = S[i+p..i_0+p)$. Since the run is decreasing it follows $S_i \succ S_{i+p} \iff S[i..i_0)S_{i_0} \succ S[i + p..i_0 + p)S_{i_0+p} \iff S_{i_0} \succ S_{i_0+p}$. This implies $\mathsf{nss}[i_0] \leq i_0 + p$, and due to Lemma 4 also $\lambda[i_0] \leq p$. Next, we show that there is at least one index $i_0 \in [i..i + p)$ such that $S[i_0..i_0 + p)$ is a Lyndon word. Let $\alpha = S[i..i+p)$. Assume that the described index i_0 does not exist, then from $S[i..i+2p) = \alpha\alpha$ follows that no cyclic shift of α is a Lyndon word. Let β be a lexicographically minimal cyclic shift of α, then this shift is not unique (otherwise β would be a Lyndon word), and thus there must be a cyclic shift $\beta_k\beta[1..k) = \beta[1..k)\beta_k$ with $k > 1$. This however implies that β is of the form $\beta = \mu^k$ for some string μ and an integer $k > 1$ (see Lemma 3 in [21]), which contradicts the fact that α is the *shortest* string period of the run. Finally, let $\alpha_k\alpha[1..k)$ with $k \in [1, p]$ be the unique lexicographically smallest cyclic shift of α (and thus a Lyndon word), then it is easy to see that only $i_0 = i + k - 1$ satisfies $\lambda[i_0] = p$. ◀

(a) String $S = \texttt{acbacbababc}$, its Lyndon array λ, and its NSS array nss.

(b) Decreasing run $\langle 5, 31, 7\rangle$ with $S[5..31] = (\texttt{abcabab})^{27/7}$. The run has shortest string period $\alpha = \texttt{abcabab}$, and is rooted in position 8 (with longest Lyndon word $\beta = S[8..15) = \alpha_4\alpha[1..3] = \texttt{abababc}$).

Figure 1 An edge from text position a to text position b indicates $\mathsf{nss}[a] = b$.

▶ **Definition 8** (Root of a Run). *Let $\langle i, j, p\rangle$ be a decreasing run, and let $i_0 \in [i..i + p)$ be the unique index with $\lambda[i_0] = p$ (as described in Lemma 7). We say that $\langle i, j, p\rangle$ is* rooted in i_0.

An example of a decreasing run and its root is provided in Figure 1b. Note that our notion of a root differs from the L-roots introduced by Crochemore et al. [6]. While an L-root is *any* length-p Lyndon word contained in the run, our root is exactly the *leftmost* one.

Given a longest Lyndon word $S[i_0..\mathsf{nss}[i_0])$ of length $p = \mathsf{nss}[i_0] - i_0 = \lambda[i_0]$, it is easy to determine whether i_0 is the root of a decreasing run. We simply try to extend the periodicity as far as possible to both sides by using the LCE functions. For this purpose, we only need to compute $l = \textsc{lce}_\ell(i_0, \mathsf{nss}[i_0])$ and $r = \textsc{lce}_r(i_0, \mathsf{nss}[i_0])$. Let $i = i_0 - l + 1$ and $j = \mathsf{nss}[i_0] + r - 1$, then clearly the substring $S[i..j]$ has smallest period p, and we cannot extend the substring to either side without breaking the periodicity. Thus, if $j - i + 1 \geq 2p$ then $\langle i, j, p\rangle$ is a run. Note that this run is only rooted in i_0 if additionally $i_0 \in [i..i + p)$ (or equivalently $l \leq p$) holds. For the index $i_0 = 8$ in Figure 1b, we have $l = \textsc{lce}_\ell(8, 15) = 4$ and $r = \textsc{lce}_r(8, 15) = 17$. Therefore, the run starts at position $i = 8 - 4 + 1 = 5$ and ends at position $j = 15 + 17 - 1 = 31$. From $l = 4 \leq 7 = p$ follows that 8 is actually the root.

Since each decreasing run is rooted in exactly one index, we can find all decreasing runs by checking for each index whether it is the root of a run. This procedure is outlined in Algorithm 1. First, we compute the NSS array (line 2). Then, we investigate one index $i_0 \in [1, n]$ at a time (line 3), and consider it as the root of a run with period $p = \mathsf{nss}[i_0] - i_0$ (line 4). If the left-extension covers an entire period (i.e. $\textsc{lce}_\ell(i_0, \mathsf{nss}[i_0]) > p$), then we have already investigated the root of the run in an earlier iteration of the for-loop, and no further action is required (line 5). Otherwise, we compute the left and right border of the potential run as described earlier (lines 6–7). If the resulting interval has length at least $2p$, then we have discovered a run that is rooted in i_0 (lines 8–9).

Time and space complexity. The NSS array can be computed in $\mathcal{O}(n)$ time and space for general ordered alphabets [3]. Assume for now that we can answer L-LCE and R-LCE queries in constant time, then clearly the rest of the algorithm also requires $\mathcal{O}(n)$ time and space. The correctness of the algorithm follows from Lemma 7 and the description. We have shown:

Algorithm 1 Compute all decreasing runs.

Input: String S of length n.
Output: Set R of all decreasing runs in S.

```
1: R ← ∅
2: compute array nss
3: for i_0 ∈ [1, n] with nss[i_0] ≠ n + 1 do
4:     p ← nss[i_0] − i_0
5:     if LCE_ℓ(i_0, nss[i_0]) ≤ p then
6:         i ← i_0 − LCE_ℓ(i_0, nss[i_0]) + 1
7:         j ← nss[i_0] + LCE_r(i_0, nss[i_0]) − 1
8:         if j − i + 1 ≥ 2p then
9:             R ← R ∪ {⟨i, j, p⟩}
```

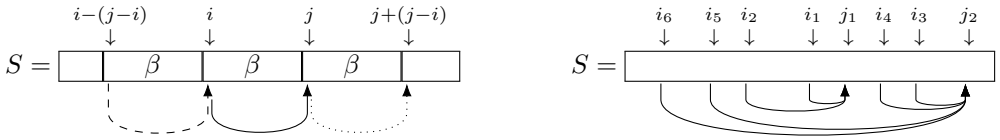
▶ **Lemma 9.** *Let S be a string of length n over a general ordered alphabet, and let* nss *be its NSS array. We can compute all decreasing runs of S in $\mathcal{O}(n) + t(n)$ time and $\mathcal{O}(n) + s(n)$ space, where $t(n)$ and $s(n)$ are the time and space needed to compute $\text{LCE}_\ell(i, \mathsf{nss}[i])$ and $\text{LCE}_r(i, \mathsf{nss}[i])$ for all $i \in [1, n]$ with $\mathsf{nss}[i] \neq n + 1$.*

In order to also find all *increasing* runs, we only need to rerun the algorithm with reversed alphabet order. This way, previously increasing runs become decreasing.

4 Algorithm for Computing the LCEs

In this section, we show how to precompute the LCEs required by Algorithm 1 in linear time and space. Our approach is asymmetric in the sense that we require different algorithms for L-LCEs and R-LCEs (whereas previous approaches usually compute L-LCEs by applying the R-LCE algorithm to the reverse text). However, for both directions we use similar properties of the Lyndon array that are shown in Lemmas 10 and 11 and visualized in Figure 2a.

▶ **Lemma 10.** *Let $i \in [1, n]$ and $j = \mathsf{nss}[i] \neq n + 1$. If $\text{LCE}_r(i, j) \geq (j - i)$, then it holds $\text{LCE}_r(j, j + (j - i)) = \text{LCE}_r(i, j) - (j - i)$ and $\mathsf{nss}[j] = j + (j - i)$.*



Proof. From $\text{LCE}_r(i, j) \geq (j - i)$ follows $\text{LCE}_r(i, j) = (j - i) + \text{LCE}_r(j, j + (j - i))$, which is equivalent to $\text{LCE}_r(j, j + (j - i)) = \text{LCE}_r(i, j) - (j - i)$. It remains to be shown that $\mathsf{nss}[j] = j + (j - i)$. Due to $\mathsf{nss}[i] = j$ it holds $S_i \succ S_j$. Since $S_i \succ S_j$ and $\text{LCE}_r(i, j) \geq (j - i)$, we have $S_{i+(j-i)} \succ S_{j+(j-i)}$, which implies $\mathsf{nss}[j] \leq j + (j - i)$. Note that $\mathsf{nss}[i] = j$ and Lemma 4 imply that $S[i..j) = S[j..j + (j - i))$ is a Lyndon word. Thus it holds $\lambda[j] \geq (j - i)$, or equivalently $\mathsf{nss}[j] \geq j + (j - i)$. ◀

▶ **Lemma 11.** *Let $i \in [1, n]$ and $j = \mathsf{nss}[i] \neq n + 1$. If $\text{LCE}_\ell(i, j) > (j - i)$, then it holds $\text{LCE}_\ell(i - (j - i), i) = \text{LCE}_\ell(i, j) - (j - i)$ and $\mathsf{nss}[i - (j - i)] = i$.*

Proof. Analogous to Lemma 10. ◀

4.1 Computing the R-LCEs

First, we will briefly describe our general technique for computing LCEs, and our method of showing the linear time bound. Assume for this purpose that we want to compute $\ell = \text{LCE}_r(i, j)$ with $i < j$. It is easy to see that we can determine ℓ by performing $\ell + 1$ individual character comparisons (by simultaneously scanning the suffixes S_i and S_j from left

(a) Lemmas 10 and 11. The dotted edge follows from $\text{LCE}_r(i,j) \geq (j-i)$ (Lemma 10). The dashed edge follows from $\text{LCE}_\ell(i,j) > (j-i)$ (Lemma 11).

(b) Relative order of R-LCE computations from first to last: $\text{LCE}_r(i_1,j_1)$, $\text{LCE}_r(i_2,j_1)$, $\text{LCE}_r(i_3,j_2)$, $\text{LCE}_r(i_4,j_2)$, $\text{LCE}_r(i_5,j_2)$, $\text{LCE}_r(i_6,j_2)$.

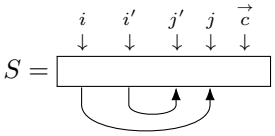


Figure 2 As before, an edge from text position a to text position b indicates $\mathsf{nss}[a] = b$.

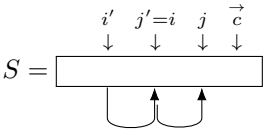
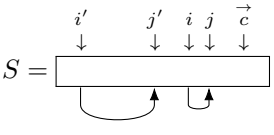
to right until we find a mismatch). Whenever we use this naive way of computing an LCE, we *charge* one character comparison to each of the indices from the interval $[j, j+\ell)$. This way, we account for ℓ character comparisons. Since we want to compute $\mathcal{O}(n)$ R-LCE values in $\mathcal{O}(n)$ time, we can afford a constant time overhead (i.e. a constant number of unaccounted character comparisons) for each LCE computation. Thus, there is no need to charge the $(\ell+1)$-th comparison to any index. At the time at which we want to compute ℓ, we may already know some lower bound $k \leq \ell$. In such cases, we simply skip the first k character comparisons and compute $\ell = k + \text{LCE}_r(i+k, j+k)$. This requires $\ell - k + 1$ character comparisons, of which we charge $\ell - k$ to the interval $[j+k..j+\ell)$.



Ultimately, we will show that all R-LCE values $\text{LCE}_r(i,j)$ with $i \in [1,n]$ and $j = \mathsf{nss}[i] \neq n+1$ can be computed in a way such that each text position gets charged at most once, which results in the desired linear time bound. From now on, we refer to i as the *left index* and j as the *right index* of the R-LCE computation. Our algorithm computes the R-LCEs in the following order (a visualization is provided in Figure 2b): We consider the possible right indices $j \in [2,n]$ one at a time and in *increasing* order. For each right index j, we then consider the corresponding left indices i with $\mathsf{nss}[i] = j$ in *decreasing* order (we will see how to efficiently deduce this order from the Lyndon array later).

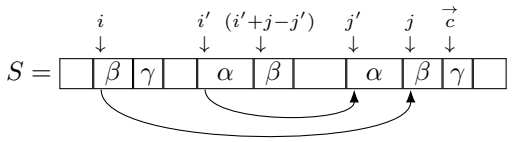
Assume that we are computing the R-LCEs in the previously described order, and let $\ell = \text{LCE}_r(i,j)$ with $j = \mathsf{nss}[i] \neq n+1$ be the next value that we want to compute. The set of indices that we have already considered as left indices for LCE computations is $I = \{x \mid (\mathsf{nss}[x] < j) \vee ((\mathsf{nss}[x] = j) \wedge (i < x))\}$. For example, when we compute $\text{LCE}_r(i_4, j_2)$ in Figure 2b it holds $\{i_1, i_2, i_3\} \subseteq I$. At this point in time, the rightmost text position that we have already inspected is $\overrightarrow{c} = \max_{x \in I}(\mathsf{nss}[x] + \text{LCE}_r(x, \mathsf{nss}[x]))$ if $I \neq \emptyset$, or $\overrightarrow{c} = 1$ otherwise. Due to the nature of our charging method, we have not charged any indices from the interval $[\overrightarrow{c}, n]$ yet. Thus, in order to show that we can compute all LCEs without charging any index twice, it suffices to show how to compute $\ell = \text{LCE}_r(i,j)$ without charging any index from the interval $[1, \overrightarrow{c})$. If $j \geq \overrightarrow{c}$ then we naively compute ℓ and charge the character comparisons to the interval $[j, j+\ell)$, thus only charging previously uncharged indices. The new value of $\overrightarrow{c}$ is $j + \ell$. If however $j < \overrightarrow{c}$, then the computation of ℓ depends on the previously computed LCEs, which we describe in the following.



Let $\ell' = \text{LCE}_r(i', j')$ with $j' = \mathsf{nss}[i']$ be the *most recently* computed R-LCE that satisfies $j' + \ell' = \overrightarrow{c}$. Our strategy for computing ℓ depends on the position of i relative to i' and j'. First, note that $i \notin [i', j')$ because otherwise Lemma 5 implies $j \leq j'$, which contradicts our order of computation. This leaves us with three possible cases (as before, a directed edge from text position a to text position b indicates $\mathsf{nss}[a] = b$):

Case R1: $i < i'$
(possibly $j' = j$)

Case R2: $i = j'$

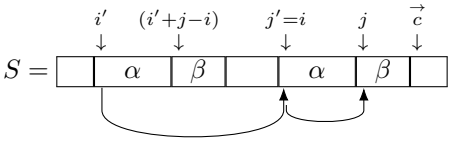


Case R3: $i > j'$

Now we explain the cases in detail. Each case is accompanied by a schematic drawing. We strongly advise the reader to study the drawings alongside the description, since they are essential for an easy understanding of the matter.

Case R1: $i < i'$ (and $j' \leq j < \vec{c}$)**.**

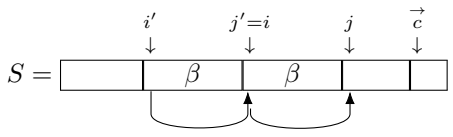
$|\alpha| = j - j'$, $|\beta| = \vec{c} - j$
$\ell' = |\alpha\beta|$, $\ell = |\beta\gamma|$



Due to $i < (i' + j - j') < j = \mathsf{nss}[i]$ we have $S_j \prec S_i \prec S_{i'+j-j'}$. From Lemma 1 follows $\vec{c} - j = \text{LCE}_r(i' + j - j', j) \leq \text{LCE}_r(i, j) = \ell$, i.e. both S_i and S_j start with β. Since now we know a lower bound $\vec{c} - j \leq \ell$ of the desired LCE value, we can skip character comparisons during its computation. Later, we will see that the same bound also holds for most of the other cases. Generally, whenever we can show $\vec{c} - j \leq \ell$ we use the following strategy. We compute $\ell = (\vec{c} - j) + \text{LCE}_r(i + (\vec{c} - j), \vec{c})$ using $\ell - (\vec{c} - j) + 1$ character comparisons, of which we charge $\ell - (\vec{c} - j)$ to the interval $[\vec{c}, j + \ell)$. Thus we only charge previously uncharged positions. We continue with $i' \leftarrow i$, $j' \leftarrow j$, $\ell' \leftarrow \ell$, and $\vec{c} \leftarrow j + \ell$.

Case R2: $i = j'$. We divide this case into two subcases.

Case R2a: $\ell' < j' - i'$.

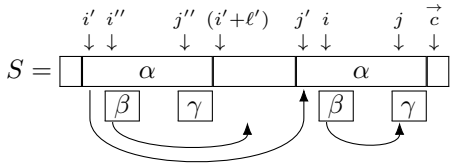


$|\alpha| = j - j'$, $|\beta| = \vec{c} - j$

From $j < \vec{c} \implies j - i < \vec{c} - i = \ell'$ and $\ell' < j' - i'$ follows $i' + j - i < j' = i$. Therefore, $\mathsf{nss}[i'] = i$ and Definition 3 imply $S_i \prec S_{i'+j-1}$. Due to $\mathsf{nss}[i] = j$ we also have $S_j \prec S_i$, such that it holds $S_j \prec S_i \prec S_{i'+j-1}$. It is easy to see that $S_{i'+j-i}$ and S_j share a prefix β of length $\text{LCE}_r(i' + j - i, j) = \vec{c} - j$. In fact, also S_i has prefix β because Lemma 1 implies that $\text{LCE}_r(i' + j - i, j) \leq \text{LCE}_r(i, j) = \ell$. Thus it holds $\vec{c} - j \leq \ell$, which allows us to use the strategy from Case R1.

Case R2b: $\ell' \geq j' - i'$.

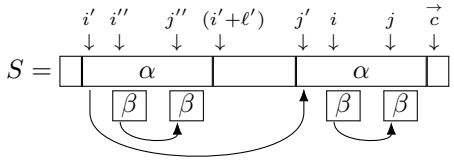
$|\beta| = j' - i'$, $\ell = \ell' - |\beta|$



Due to $\ell' \geq j' - i'$, Lemma 10 implies $j = i + (j' - i')$ and $\ell = \ell' - (j' - i')$. Since i', j', and ℓ' are known, we can compute ℓ in constant time without performing any character comparisons. We continue with $i' \leftarrow i$, $j' \leftarrow j$, and $\ell' \leftarrow \ell$ (leaving $\vec{c}$ unchanged).

Case R3: $i > j'$. This is the most complicated case, and it is best explained by dividing it into three subcases. Let $d = j' - i'$, $i'' = i - d$, $j'' = j - d$, and $\ell'' = \text{LCE}_r(i'', j'')$. (In this situation it is implied that $j'' \leq j'$ because otherwise $\ell' = \text{LCE}_r(i', j')$ would not be the *most recently* computed R-LCE that satisfies $j' + \ell' = \overrightarrow{c}$. However, since our proof does not rely on this property, we will not explain it in more detail.)

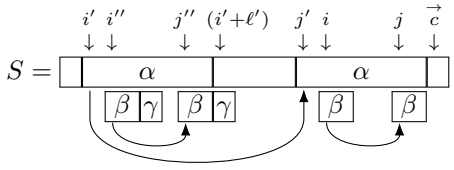
Case R3a: $\mathsf{nss}[i''] \neq j''$:



$|\alpha| = \ell'$, $|\beta| = |\gamma| = \overrightarrow{c} - j$
$\ell'' \geq |\beta|$, $\ell \geq |\beta|$

First, note that $S[i'..i' + \ell') = S[j'..\overrightarrow{c})$ implies $S[i..j) = S[i''..j'')$. From $\mathsf{nss}[i] = j$ follows that $S[i..j) = S[i''..j'')$ is a Lyndon word. Thus, due to Lemma 4 and $\mathsf{nss}[i''] \neq j''$ it holds $\mathsf{nss}[i''] > j''$, which implies $S_{i''} \prec S_{j''}$. Let $\beta = S[i''..i'' + \overrightarrow{c} - j) = S[i..i + \overrightarrow{c} - j)$ and let $\gamma = S[j''..i' + \ell') = S[j..\overrightarrow{c})$. From $S_{i''} \prec S_{j''}$ follows $\beta \preceq \gamma$, while $S_i \succ S_j$ implies $\beta \succeq \gamma$. Thus it holds $\beta = \gamma$, and therefore $\text{LCE}_r(i, j) \geq |\gamma| = \overrightarrow{c} - j$. This means that we can use the strategy from Case R1.

Case R3b: $\mathsf{nss}[i''] = j''$ and $(j'' + \ell'') < (i' + \ell')$:



$|\alpha| = \ell'$, $|\beta| = \ell'' = \ell$

Due to $\ell'' = \text{LCE}_r(i'', j'')$, there is a shared prefix $\beta = S[i''..i'' + \ell'') = S[j''..j'' + \ell'')$ between $S_{i''}$ and $S_{j''}$, and the first mismatch between the two suffixes is $S[i'' + \ell''] \neq S[j'' + \ell'']$. Because of $(j'' + \ell'') < (i' + \ell')$, both the shared prefix and the mismatch are contained in $S[i'..i' + \ell')$ (i.e. in the first occurrence of α). If we consider the substring $S[j'..j' + \ell')$ instead (i.e. the second occurrence of α), then S_i and S_j clearly also share the prefix $\beta = S[i..i + \ell'') = S[j..j + \ell'')$, with the first mismatch occurring at $S[i + \ell''] \neq S[j + \ell'']$. Thus it holds $\ell = \ell''$. Due to $\mathsf{nss}[i''] = j''$ and our order of R-LCE computations, we have already computed ℓ''. Therefore, we can simply assign $\ell \leftarrow \ell''$ and continue without changing i', j', ℓ', and $\overrightarrow{c}$.

Case R3c: $\mathsf{nss}[i''] = j''$ and $(j'' + \ell'') \geq (i' + \ell')$:

$|\alpha| = \ell'$, $|\beta| = \overrightarrow{c} - j$, $|\beta\gamma| = \ell''$
$\ell \geq |\beta|$

This situation is similar to Case R3b. There is a shared prefix $\beta = S[i''..i'' + \overrightarrow{c} - j) = S[j''..i' + \ell')$ between the suffixes $S_{i''}$ and $S_{j''}$. They may share an even longer prefix $\beta\gamma$, but only the first $|\beta| = \overrightarrow{c} - j$ symbols of their LCP are contained in $S[i'..i' + \ell')$ (i.e. in the first occurrence of α). If we consider the substring $S[j'..j' + \ell')$ instead (i.e. the second occurrence of α), then S_i and S_j clearly also share at least the prefix $\beta = S[i..i + \overrightarrow{c} - j) = S[j..\overrightarrow{c})$. Thus it holds $\overrightarrow{c} - j \leq \ell$, and we can use the strategy from Case R1.

We have shown how to compute ℓ without charging any index twice. It follows that the total number of character comparisons for all R-LCEs is $\mathcal{O}(n)$.

A Simple Algorithm for R-LCEs. While the detailed differentiation between the six subcases helps to show the correctness of our approach, it can be implemented in a significantly simpler way (see Algorithm 2). At all times, we keep track of j', $\overrightarrow{c}$ and the distance $d = j' - i'$ (line 1). We consider the indices $j \in [2, n]$ in increasing order (line 2). For each index j, we then consider the indices i with $\mathsf{nss}[i] = j$ in decreasing order (line 3). Each time we want to compute an R-LCE value $\ell = \text{LCE}_r(i, j)$, we first check whether Case R3b applies (line 4). If it does, then we simply copy the previously computed R-LCE value $\text{LCE}_r(i-d, j-d)$ (line 5). Otherwise, we either compute the LCE naively (if $j \geq \overrightarrow{c}$), or we have to apply the strategy from Case R1 (since all other cases except for Case R2b use this strategy; in Case R2b it holds $\overrightarrow{c} - j = \ell$, which means that it can also be solved with the strategy from Case R1). If $j \geq \overrightarrow{c}$ then in lines 7–8 we have $k = 0$, and thus we naively compute $\text{LCE}_r(i, j)$ by scanning. If however $j < \overrightarrow{c}$, then we have $k = \overrightarrow{c} - j$, and we skip k character comparisons. In any case, we update the values j', $\overrightarrow{c}$, and d accordingly (line 9).

Algorithm 2 Compute all R-LCEs.

Input: String S of length n and its NSS array nss.
Output: R-LCE value $\text{LCE}_r(i, \mathsf{nss}[i])$ for each index $i \in [1, n]$ with $\mathsf{nss}[i] \neq n + 1$.

1: $j' \leftarrow 0$; $\overrightarrow{c} \leftarrow 1$; $d \leftarrow 0$
2: **for** $j \in [2, n]$ in increasing order **do**
3: **for** i **with** $\mathsf{nss}[i] = j \neq n + 1$ in decreasing order **do**
4: **if** $\left(\begin{array}{l} i, j \in (j', \overrightarrow{c}) \\ \wedge\ \mathsf{nss}[i-d] = j - d \\ \wedge\ j + \text{LCE}_r(i-d, j-d) < \overrightarrow{c} \end{array}\right)$ **then**
5: $\text{LCE}_r(i, j) \leftarrow \text{LCE}_r(i-d, j-d)$ ▷ retrieve LCE in constant time
6: **else**
7: $k \leftarrow \max(\overrightarrow{c}, j) - j$
8: $\text{LCE}_r(i, j) \leftarrow k + \text{NAIVE-SCAN-LCE}_r(i+k, j+k)$
9: $j' \leftarrow j$; $\overrightarrow{c} \leftarrow j + \text{LCE}_r(i, j)$; $d \leftarrow j - i$

The correctness of the algorithm follows from the description of Cases 1–3. Since for each left index i we have to store at most one R-LCE, we can simply maintain the LCEs in a length-n array, where the i-th entry is $\text{LCE}_r(i, \mathsf{nss}[i])$. This way, we use linear space and can access the R-LCE that is required in line 5 in constant time. Apart from the at most n character comparisons that we charge to the indices, we only need a constant number of additional primitive operations per computed R-LCE. The order of iteration can be realized by first generating all $(i, \mathsf{nss}[i])$-pairs, and then using a linear time radix sorter to sort the pairs in increasing order of their second component and decreasing order of their first component. We have shown:

▶ **Lemma 12.** *Given a string of length n and its NSS array nss, we can compute $\text{LCE}_r(i, \mathsf{nss}[i])$ for all indices $i \in [1, n]$ with $\mathsf{nss}[i] \neq n + 1$ in $\mathcal{O}(n)$ time and space.*

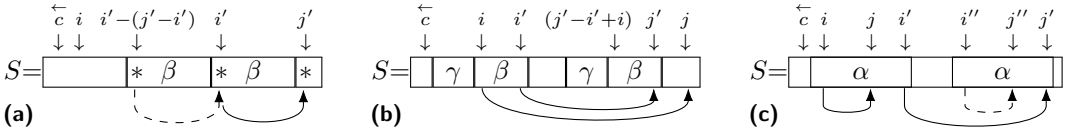


Figure 3 Illustration of the proofs of the three properties in Section 4.2.

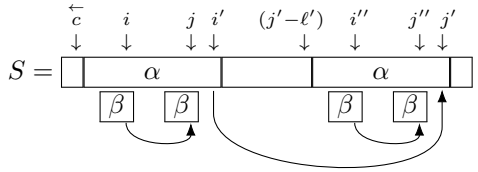
4.2 Computing the L-LCEs

Our solution for the L-LCEs is similar to the one for R-LCEs, but differs in subtle details. We generally compute $\ell = \text{LCE}_\ell(i, j)$ by simultaneously scanning the prefixes $S[1..i]$ and $S[1..j]$ from right to left until we find the first mismatch. This takes $\ell + 1$ character comparisons, of which we charge ℓ comparisons to the interval $(i - \ell, i]$. As before, if some lower bound $k \leq \ell$ is known then we skip k character comparisons. In this case, we compute the L-LCE as $\ell = k + \text{LCE}_\ell(i - k, j - k)$, and charge $\ell - k$ comparisons to the interval $(i - \ell, i - k]$.

Again, we will show how to compute all values $\text{LCE}_\ell(i, \mathsf{nss}[i])$ with $i \in [1, n]$ and $\mathsf{nss}[i] \neq n + 1$ such that each index gets charged at most once. In contrast to the more complex R-LCE iteration order, we can simply compute the L-LCE values in *decreasing* order of i. Thus, when we want to compute $\ell = \text{LCE}_\ell(i, j)$ with $j = \mathsf{nss}[i] \neq n + 1$, we have already considered the indices $I = \{x \mid x \in (i, n] \wedge \mathsf{nss}[x] \neq n + 1\}$ as left indices of L-LCE computations. The leftmost text position that we have already inspected so far at this point is $\overleftarrow{c} = \min_{x \in I}(x - \text{LCE}_\ell(x, \mathsf{nss}[x]))$ if $I \neq \emptyset$, or $\overleftarrow{c} = n$ otherwise. Due to our charging method, we have not charged any index from the interval $[1, \overleftarrow{c}]$ yet. Thus, we only have to show how to compute ℓ without charging indices from $(\overleftarrow{c}, n]$. Let $\ell' = \text{LCE}_\ell(i', j')$ be the most recently computed L-LCE that satisfies $i' - \ell' = \overleftarrow{c}$. If $i \leq \overleftarrow{c}$ then we compute ℓ naively and charge the character comparisons to the interval $(i - \ell, i]$ (thus only charging previously uncharged indices). If however $i > \overleftarrow{c}$, then our strategy is more complicated. Before explaining it in detail, we show three important properties that hold in the present situation.

First, we show that $i \geq i' - (j' - i')$. Assume the opposite (as visualized in Figure 3a), then from $\overleftarrow{c} = i' - \ell' < i$ follows $\ell' > j' - i'$. Thus, Lemma 11 implies $\mathsf{nss}[i' - (j' - i')] = i'$ (dashed edge) and $\text{LCE}_\ell(i' - (j' - i'), i') = \ell' - (j' - i')$. Due to our order of computation and $i < i' - (j' - i')$ we must have already computed this L-LCE. However, it holds $i' - (j' - i') - \text{LCE}_\ell(i' - (j' - i'), i') = \overrightarrow{c}$, which contradicts the fact that $\ell' = \text{LCE}_\ell(i', j')$ is the *most recently* computed L-LCE with $i' - \ell' = \overleftarrow{c}$.

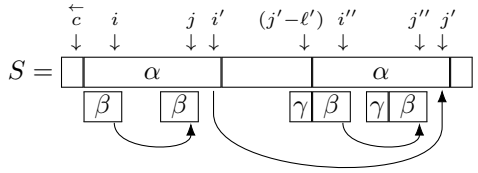


Next, we show that $j \leq i'$. First, note that $j \notin (i', j')$, since due to $i < i'$ we would otherwise contradict Lemma 5. Thus we only have to show $j < j'$. Assume for this purpose that $j \geq j'$ (as visualized in Figure 3b). From $j' - i' + i \in (i, \mathsf{nss}[i])$ and Definition 3 follows $S_i \prec S_{j'-i'+i}$. Because of $\text{LCE}_\ell(i', j') > (i' - i)$ it holds $S[i..i'] = S[j' - i' + i..j'] (= \beta)$. Thus $S_i \prec S_{j'-i'+i}$ implies $S_{i'} \prec S_{j'}$, which contradicts the fact that $\mathsf{nss}[i'] = j'$.

Lastly, let $d = j' - i'$, $i'' = i + d$, and $j'' = j + d$ (as visualized in Figure 3c). Now we show that $\mathsf{nss}[i''] = j''$ (dashed edge in the figure). Because of $\alpha = S(\overleftarrow{c}..i'] = S(j' - \ell'..j']$ it holds $S[i..j) = S[i''..j'')$. From $\mathsf{nss}[i] = j$ and Lemma 4 follows that $S[i''..j'')$ is a Lyndon word, and thus $\mathsf{nss}[i''] \geq j''$. We have already shown that $i \geq i' - (j' - i')$, which implies $i'' \geq i'$. Due to $\mathsf{nss}[i'] = j'$ and $i'' \in [i', j')$ it follows from Lemma 5 that $\mathsf{nss}[i''] \leq j'$. Now assume $\mathsf{nss}[i''] \in (j'', j']$, then $S[i''..\mathsf{nss}[i'']) = S[i..j + (\mathsf{nss}[i''] - j''))$ is a Lyndon word, which contradicts the fact that $S[i..j)$ is the longest Lyndon word starting at position i. Thus, we have ruled out all possible values of $\mathsf{nss}[i'']$ except for j''.

Now we show how to compute ℓ. We keep using the definition of i'' and j'' from the previous paragraph. Furthermore, let $\ell'' = \text{LCE}_\ell(i'', j'')$. There are two possible cases.

Case L1: $(i'' - \ell'') > (j' - \ell')$.

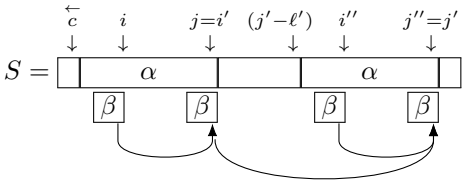


$\ell' = |\alpha|$, $\ell = \ell'' = |\beta|$

Due to $\ell'' = \text{LCE}_\ell(i'', j'')$, the prefixes $S[1..i'']$ and $S[1..j'']$ share the suffix $\beta = S(i'' - \ell''..i''] = S(j'' - \ell''..j'']$, and the first (from the right) mismatch between these prefixes is $S[i'' - \ell''] \neq S[j'' - \ell'']$. Both the shared suffix and the mismatch are contained in $S(j' - \ell'..j']$ (i.e. in the right occurrence of α). If we consider the substring $S(\overleftarrow{c}..i']$ instead (i.e. the left occurrence of α), then $S[1..i]$ and $S[1..j]$ clearly also share the suffix $\beta = S(i - \ell''..i] = S(j - \ell''..j]$, with the first mismatch occurring at $S[i - \ell''] \neq S[j'' - \ell]$. Thus it holds $\ell = \ell''$. Due to $\mathsf{nss}[i''] = j''$ and our order of L-LCE computations, we have already computed ℓ''. Therefore, we can simply assign $\ell \leftarrow \ell''$ and continue without changing i', j', ℓ', and $\overleftarrow{c}$.
(Note that possibly $i'' \neq i' \wedge j'' = j'$. We provide a sketch in Figure 4a.)

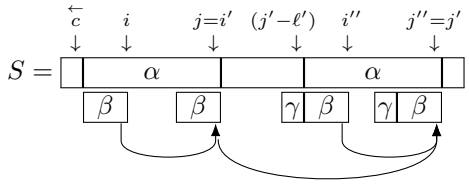
Case L2: $(i'' - \ell'') \leq (j' - \ell')$.

$\ell' = |\alpha|$, $\ell'' = |\beta\gamma|$, $\ell \geq |\beta|$



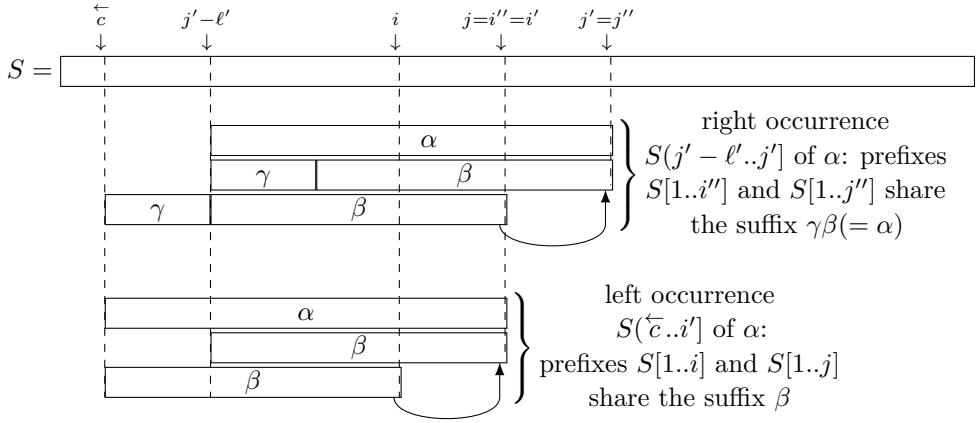
This situation is similar to Case L1. There is a shared suffix $\beta = S(j' - \ell'..i''] = S(j'' - (i - \overleftarrow{c})..j'']$ between the prefixes $S[1..i'']$ and $S[1..j'']$. They may share an even longer suffix $\gamma\beta$, but only the rightmost $|\beta| = i' - \overleftarrow{c}$ symbols of this suffix are contained in $S(j' - \ell'..j']$ (i.e. in the right occurrence of α). If we consider the substring $S(\overleftarrow{c}..i']$ instead (i.e. the left occurrence of α), then $S[1..i]$ and $S[1..j]$ clearly also share the suffix $\beta = S(\overleftarrow{c}..i] = S(j - (i - \overleftarrow{c})..j]$. Thus it holds $i - \overleftarrow{c} \leq \ell$, and we can skip the first $i - \overleftarrow{c}$ character comparisons by computing the LCE as $\ell = (i - \overleftarrow{c}) + \text{LCE}_\ell(\overleftarrow{c}, j + \overleftarrow{c} - i)$. We charge $\ell - (i - \overleftarrow{c})$ character comparisons to the previously uncharged interval $(i - \ell, \overleftarrow{c}]$, and continue with $i' \leftarrow i$, $j' \leftarrow j$, $\ell' \leftarrow \ell$, and $\overleftarrow{c} \leftarrow i - \ell$.
(Note that possibly $i'' \neq i' \wedge j'' = j'$ or even $i'' = i' \wedge j'' = j'$. We provide schematic drawings in Figures 4b and 4c.)

We have shown how to compute ℓ without charging any index twice. It follows that the total number of character comparisons for all LCEs is $\mathcal{O}(n)$. For completeness, we outline a simple implementation of our approach in Algorithm 3. Lines 4–5 correspond to Case L1. If $i \leq \overleftarrow{c}$, then lines 7–9 compute the LCE naively. Otherwise, they correspond to Case L2.



▶ **Lemma 13.** *Given a string of length n and its NSS array* nss*, we can compute* $\text{LCE}_\ell(i, \mathsf{nss}[i])$ *for all indices $i \in [1, n]$ with* $\mathsf{nss}[i] \neq n + 1$ *in $\mathcal{O}(n)$ time and space.*

▶ **Corollary 14.** *Given a string of length n over a general ordered alphabet, we can find all runs in the string in $\mathcal{O}(n)$ time and space.*



Proof. Computing the increasing runs takes $\mathcal{O}(n)$ time and space due to Lemmas 9, 12, and 13. For decreasing runs, we only have to reverse the order of the alphabet and rerun the algorithm. ◀

5 Practical Implementation

We implemented our algorithm for the runs computation in C++17 and evaluated it by computing all runs on texts from the natural, real repetitive, and artificial repetitive text collections of the Pizza-Chili corpus[2]. Additionally, we used the binary run-rich strings proposed by Matsubara et al. [23] as input. Table 1 shows the throughput that we achieve, i.e. the number of input bytes (or equivalently input symbols) that we process per second. On the string `tm29` we achieve the highest throughput of 15.6 MiB/s. The lowest throughput of 8.8 MiB/s occurs on the text `dna`. Generally, we perform better for run-rich strings.

Lastly, it is noteworthy that our new method of LCE computation leads to a remarkably simple implementation of the runs algorithm. In fact, the entire implementation *including the computation of the NSS array* needs only 250 lines of code. We achieve this by interleaving the computation of the R-LCEs with the computation of the NSS array, which also improves the practical performance. For technical details we refer to the source code, which is publicly available on GitHub[3].

6 Conclusion and Open Questions

We have shown the first linear time algorithm for computing all runs over a general ordered alphabet. The algorithm is also very fast in practice and remarkably easy to implement. It is an open question whether our techniques could be used for the computation of runs on tries, where the best known algorithms require super-linear time even for linearly-sortable alphabets (see e.g. [26]).

Abstract

Given an unweighted digraph $G = (V, E)$, undergoing a sequence of edge deletions, with $m = |E|, n = |V|$, we consider the problem of maintaining all-pairs shortest paths (APSP).

Whilst this problem has been studied in a long line of research [ACM'81, FOCS'99, FOCS'01, STOC'02, STOC'03, SWAT'04, STOC'13] and the problem of $(1+\epsilon)$-approximate, weighted APSP was solved to near-optimal update time $\tilde{O}(mn)$ by Bernstein [STOC'13], the problem has mainly been studied in the context of an *oblivious* adversary which fixes the update sequence before the algorithm is started. In this paper, we make significant progress on the problem for an adaptive adversary which can perform updates based on answers to previous queries:

- We first present a *deterministic* data structure that maintains the *exact* distances with total update time $\tilde{O}(n^3)$[1].
- We also present a *deterministic* data structure that maintains $(1+\epsilon)$-approximate distance estimates with total update time $\tilde{O}(\sqrt{m}n^2/\epsilon)$ which for sparse graphs is $\tilde{O}(n^{2+1/2}/\epsilon)$.
- Finally, we present a randomized $(1+\epsilon)$-approximate data structure which works against an adaptive adversary; its total update time is $\tilde{O}(m^{2/3}n^{5/3} + n^{8/3}/(m^{1/3}\epsilon^2))$ which for sparse graphs is $\tilde{O}(n^{2+1/3}/\epsilon^2)$.

Our exact data structure matches the total update time of the best *randomized* data structure by Baswana et al. [STOC'02] and maintains the distance matrix in near-optimal time. Our approximate data structures improve upon the best data structures against an adaptive adversary which have $\tilde{O}(mn^2)$ total update time [JACM'81, STOC'03].

1 Introduction

Shortest paths is a classical algorithmic problem dating back to the 1950s. The two main variants are the all-pairs shortest paths (APSP) problem and the single-source shortest paths (SSSP) problem, both of which have been extensively studied in various models, including the partially and fully-dynamic setting.

A dynamic graph algorithm is an algorithm that maintains information about a graph that is subject to updates such as insertions and deletions of edges or vertices. Such a graph can model real-world networks that change over time, such as road networks where traffic changes and roads are blocked from time to time. We say that a dynamic graph problem is *decremental* if it only allows deletions, *incremental* if it only allows insertions and *fully-dynamic* if it allows both. Incremental and decremental graphs are referred to as being *partially-dynamic*. A dynamic graph algorithm aims to efficiently process a sequence of online updates interspersed with queries about some property of the underlying dynamic graph.

1.1 Problem Definition

In this paper, we consider the *decremental all-pairs shortest-paths* problem where the goal is to efficiently maintain shortest path distances between all pairs of vertices in a decremental directed graph $G = (V, E)$. We shall restrict our attention to the case where G is unweighted. Letting m denote the initial number of edges and $n = |V|$, we want a data-structure which for any $u, v \in V$ supports the following operations:

- $\textsc{Dist}(u, v)$: reports the distance $d_G(u, v)$ from u to v in the current version of G,
- $\textsc{Delete}(u, v)$: deletes an edge (u, v) from E.

We furthermore consider the problem also in its relaxed version where we only aim to maintain *approximate* distance estimates which can then be queried. We denote by $\tilde{d}_G(u, v)$ a distance estimate for the distance from u to v and we say that an APSP algorithm has an *approximation ratio* (or *stretch*) of $t > 1$ if for any $u, v \in V$, we have that $d_G(u, v) \leq \tilde{d}_G(u, v) \leq t \cdot d_G(u, v)$. This paper will be concerned with both the exact and the $(1 + \epsilon)$-approximate version of the problem.

Another focus of this article is the *adversarial model*; the adversarial model defines the model under which the sequence of updates and queries are assumed to be made by an *adversary*. We say that a performance guarantee of an algorithm works against an *oblivious* adversary if the adversary must define the sequence of updates before the algorithm starts for the guarantee to hold. Thus the sequence of updates is independent of any random bits used by the algorithm. This is opposed to algorithms that work against an *adaptive* adversary, where the adversary is allowed to create the update sequence "on the go", e.g. based on answers to previous queries made to the data structure. Depending on the data structure, these choices may not be independent of the random choices made, which may result in the data structure performing poorly. One key advantage of a data structure that works against an adaptive adversary is that it can be used inside an algorithm as a black box, regardless of whether that algorithm adapts its updates to answers to queries. We point out that *deterministic* data structures always work against an adaptive adversary.

The performance of a *partially-dynamic* algorithm is usually measured in terms of the *total update time*. That is, the accumulated time it takes to process all updates (edge deletions). The *query time*, on the other hand, is the time to answer a single distance query. A natural goal is to minimize the total update time while keeping the stretch and query time small. Since all the structures presented in this paper explicitly maintain a distance matrix, the query time is constant.

1.2 Prior Work

The naive approach to dynamic APSP is to recompute the shortest path distances after each update using the best static algorithm. The query time is then constant and the time for a single update is $\tilde{O}(mn)$ for APSP and $\tilde{O}(m)$ for SSSP. At the other end of the spectrum one could achieve optimal update time by simply updating the input graph and only running an SSSP algorithm whenever a query is processed. Running a static algorithm each time, however, fails to reuse any information between updates whatsoever and gives a high query time, motivating more efficient dynamic approaches that do this.

In 1981, Even and Shiloach [6] gave a deterministic data-structure for maintaining a shortest path tree to given depth d in an undirected, unweighted decremental graph in total time $O(md)$. Henzinger and King [7] and King [10] later adapted this to directed graphs with integer weights. Running their structure for each vertex solves the decremental all-pairs shortest paths problem in $O(mn^2W)$ time, where edge weights are integers in $[1, W]$.

Henzinger and King were the first to improve upon this bound, giving an algorithm with total update time $\tilde{O}(mn^{2.5}\sqrt{W})$ [10] which is an improvement for $W = \omega(n)$. Demetrescu and Italiano [4] improved this data structure slightly and showed that the restriction to integral edge weights can be removed. Finally, the same authors [3] presented a data structure with total update time $\tilde{O}(mn^2)$ which is the state of the art for any data structure against an adaptive adversary up to today. In fact, their algorithm can be extended to a fully-dynamic algorithm with $\tilde{O}(n^2)$ amortized update time and which can handle vertex updates[2]. We also point out that this data structure was later simplified and generalized by Thorup [11].

Around the same time Baswana, Hariharan, and Sen [1] gave an *oblivious* Monte-Carlo construction with total update time $\tilde{O}(n^3)$ for *unweighted* graphs. Further, they showed that their data structure could be adapted to give an $(1+\epsilon)$-approximate APSP algorithm for *weighted* graphs with total update time of $\tilde{O}(\sqrt{m}n^2/\varepsilon)$. In the exact setting, the oblivious adversary assumption is only required when paths are to be reported rather than just shortest path distances which are unique. Finally, Bernstein presented a $(1+\epsilon)$-approximate algorithm with total running time $\tilde{O}(mn\log(W)/\epsilon)$ by using a clever approach of shortcutting paths [2]. Whilst his algorithm achieves near-optimal running time, again, the algorithm has to assume an oblivious adversary.

More recently, Karczmarz and Łącki [9] gave a deterministic $(1+\epsilon)$-approximate APSP algorithm for decremental graphs that runs in total time $\tilde{O}(n^3\log(W)/\epsilon)$. They also presented the first non-trivial algorithm for incremental graphs [8] achieving total update time $\tilde{O}(mn^{4/3}\log(W)/\epsilon)$.

We refer the reader to the full version of the paper [5] for a more comprehensive treatment of related work which also includes algorithms for *undirected* graphs and algorithms with larger stretch.

[2] In this case, vertex updates refers to insertions or deletions of vertices with up to $n-1$ incident edges.

1.3 Our Contributions

In this paper, we present three new data structures for the all-pairs shortest paths problem. Our first theorem gives a *deterministic* data structure for the exact variant of the problem with near-optimal $\tilde{O}(n^3)$ total update time. It also matches the best *randomized* algorithm by Baswana et al. [1] and constitutes a significant improvement over the previous best deterministic bound of $\tilde{O}(mn^2)$ which is obtained by running an ES-tree [6] from every source or by the data structure Italiano et al. [3] (that also works in weighted graphs) and improves over all but the sparsest graph densities.

Our exact data structure is near-optimal as there is an $\Omega(n^3)$ lower bound on the total update time of any decremental data structure that explicitly maintains the distance matrix. The lower bound follows by considering an initial undirected, unweighted graph consisting of a simple path $v_0, v_1, v_2, \ldots, v_{n-1}$ plus additional edges (v_i, v_{i+2}) for each even $i \leq n-3$. Deleting these additional edges in any order creates $\Omega(n^3)$ distance matrix changes in total.

▶ **Theorem 1.** *Let G be an unweighted directed graph with n vertices and initially m edges. Then there exists a deterministic data structure which maintains all-pairs shortest path distances in G undergoing an online sequence of edge deletions using a total time of $O(n^3 \log^3 n)$. The $n \times n$ distance matrix is explicitly maintained so that at any point, a shortest path distance query can be answered in constant time. The data structure can report a shortest path between any query pair in time proportional to the length of the path.*

Our second result is concerned with maintaining $(1+\epsilon)$-approximate all-pairs shortest path distances. This constitutes the first deterministic data structure that solves the problem in subcubic time with small approximation error (except for graphs that are not extremely dense).

▶ **Theorem 2.** *Let G be an unweighted directed graph with n vertices and initially m edges. Then given $\epsilon > 0$, there exists a deterministic data structure that maintains all-pairs $(1+\epsilon)$-approximate shortest path distances in G undergoing an online sequence of edge deletions using a total time of $O(\sqrt{m}n^2 \log^2(n)/\epsilon)$. At any point, a $(1+\epsilon)$-approximate shortest path distance query can be answered in constant time and a $(1+\epsilon)$-approximate shortest path between the query pair can be reported in time proportional to the length of the path.*

Our third result gives a data structure achieving a better time bound. While we use randomization to achieve the improved time bound, our algorithm again works against an adaptive adversary.

▶ **Theorem 3.** *Let G be an unweighted directed graph with n vertices and initially m edges. Then given any $\epsilon > 0$, there exists a Las Vegas data structure that maintains all-pairs $(1+\epsilon)$-approximate shortest path distances in G under an online sequence of edge deletions using a total expected time of $\tilde{O}(m^{2/3}n^{5/3}/\epsilon + n^{8/3}/(m^{1/3}\epsilon^2))$. This bound holds w.h.p. and the data structure works against an adaptive adversary. At any point, a $(1+\epsilon)$-approximate shortest path distance query can be answered in constant time.*

We summarize our results as well as previous state-of-the-art results in Table 1.

1.4 Overview

Our overall approach for the deterministic data structures is similar to that of Baswana et al. [1] but with a key difference that allows us to avoid using a randomized hitting set and instead rely on deterministic separators. The idea of the construction by Baswana et

Table 1 Our results and previous state-of-the-art results for decremental APSP.

al. relies on a well-known result which says that if we sample a subset H_i^ρ of the vertices of size $\tilde{O}(n/\rho^i)$ (where ρ is some constant strictly larger than 1), each with uniform probability, then, w.h.p. we "hit" each shortest-path of length $[\rho^i, \rho^{i+1})$ between any pair of vertices in any version of the graph G.

Phrased differently, given vertices $u, v \in V$, we have that if a shortest path from u to v is of length $\ell \in [\rho^i, \rho^{i+1})$, then there is some vertex $w \in H_i^\rho$, such that the concatenation of a shortest path from u to w and a shortest path from w to v is of length ℓ. For each such w, we say w is a *witness* for the tuple (u, v) for distance ℓ.

Now for each $u, v \in V$, if the initial distance from u, v was $\ell \in [\rho^i, \rho^{i+1})$, we can check H_i^ρ to find a witness w. If the length of the path from u to w to v is increased, we can continue our scanning of H_i^ρ to see whether another witness exists. If there is no witness $w \in H_i^\rho$ left at some stage, we know that there is no path of length ℓ left in G w.h.p. and increase our guess by setting $\ell \mapsto \ell + 1$.

Sampling initially a hitting set H_i^ρ for every $i \in [0, \log_\rho n]$, we can find the "right" hitting set for each distance ℓ. Observe now that for each tuple $(u, v) \in V^2$, we have to scan a hitting set of size $\tilde{O}(n/\rho^i)$ for $\rho^{i+1} - \rho^i \sim \rho^{i+1}$ levels before the hitting set index i is increased which only occurs $O(\log n)$ times, thus we only spend time $\tilde{O}(n)$ for each vertex tuple (u, v). Thus, the total running time of the searches for witnesses can be bound by $\tilde{O}(n^3)$.

The Deterministic Exact Data Structure. Our construction is similar in the sense that we maintain witnesses for each distance scale $[\rho^i, \rho^{i+1})$ for every $i \in [0, \log_\rho n]$ such that each distance ℓ is in one such distance scale. The key difference is that instead of using a randomized *global* hitting set H_i^ρ for a distance scale $[\rho^i, \rho^{i+1})$, our construction relies on deterministically maintaining a small local vertex separator $S_i(u)$ for every vertex $u \in V$ of size $\tilde{O}(n/\rho^i)$ separating all shortest paths starting in u with a distance in $[\rho^i, \rho^{i+1})$.

More precisely, for each distance scale $[\rho^i, \rho^{i+1})$ and vertex $u \in V$, we maintain a separator $S_i(u)$ that satisfies the invariant that every shortest path from u to a vertex v at distance at least ρ^i is intersected by a vertex in $S_i(u)$. If this invariant is violated after an adversarial update, then we find such a vertex v and need to add additional vertices to $S_i(u)$ during the time step. The challenge is to take these additional separator vertices such that the total size of $S_i(u)$ is not increased beyond $\tilde{O}(n/\rho^i)$. The separator procedure makes use of sparse layers of BFS trees and here is where we rely on the assumption that the graph is unweighted. We defer the details of the separator procedure to a later section and continue our discussion of the APSP data structure.

Since we need to detect whether vertices have distance less than ρ^i from u or not in G, we further have to use a bottom-up approach to compute distances after an edge deletion, i.e. we start with the smallest possible distance range and update all distances in this range and then update larger distances using the information already computed. This issue did not arise in Baswana et al. [1] but can be handled by a careful approach. The distances computed for one distance scale include all distances to and from witnesses for the next larger distance scale.

It is now easy to see that the scanning for witnesses can be implemented in the same time as in the analysis sketched above by scanning the list of local separator vertices which serve as witnesses instead of the hitting set. Further, we can maintain local vertex separators using careful arguments in total time $\tilde{O}(mn)$ giving our result in Theorem 1.

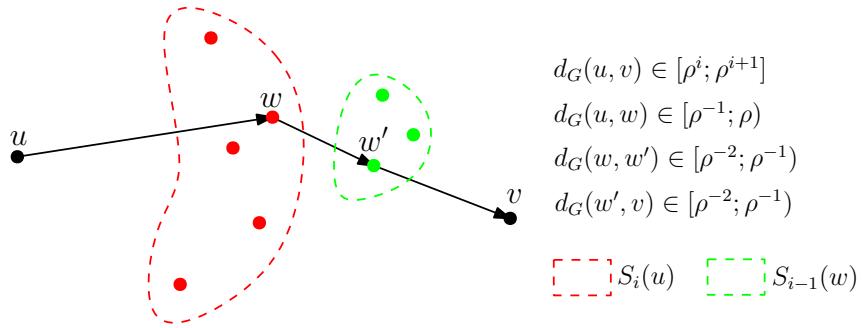

Figure 1 Illustration of separators and path "hierarchy". Here $u \rightsquigarrow v$ goes through a witness w, and $w \rightsquigarrow v$ goes through w'. If the length of the path $w' \rightsquigarrow v$ is increased by Δ, the distance estimates of all 2-hop-paths that use $w' \rightsquigarrow v$ as a sub-path are increased by that amount. In this case, the estimate for $w \rightsquigarrow w' \rightsquigarrow v$ is increased and is propagated to the next level where subsequently the estimate for $u \rightsquigarrow w \rightsquigarrow v$ is possibly increased.

The Deterministic Approximate Data Structure. In order to improve the running time for sparse graphs, we can further focus on only considering distances that are roughly at a $(1+\epsilon)$-multiplicative factor from each other. More concretely, instead of increasing the expected distance from ℓ to $\ell+1$ when we cannot find a witness for some path from u to v for distance ℓ, we can increase the next expected distance level ℓ' to $\sim (1+\epsilon)\ell$ and consider every vertex w a witness if there is a path $u \rightsquigarrow w \rightsquigarrow v$ of length at most ℓ'. Thus, we handle fewer distances and can thereby reduce the time to maintain distances that are at least d in total time $\tilde{O}(n^3/d + mn)$. Again, a careful approach is necessary to ensure that approximations do not add up over distance scales.

This is no faster than the data structure for exact distances when d is small so in order to get Theorem 2, we use the $O(mnd)$ data structure of Even and Shiloach [6] to maintain distances up to d. Picking d such that $mnd = n^3/d$ gives the result of Theorem 2 (the term $\tilde{O}(mn)$ vanishes since it is subsumed by the two other terms, also we assumed $\epsilon > 0$ to be a constant to simplify the presentation).

Maintaining Separators. We now sketch how to deterministically maintain a "small" local separator for a vertex $s \in V$ with some useful invariants.

Let S be the local separator for s. The first invariant that will be useful is that any vertex $t \in V$ that is reachable from s in $G \setminus S$, is "close" to s or roughly within distance d. As edges are deleted from G, the distances from s to such vertices t may increase. If a vertex

t moves too far away from s, the invariant is re-established by growing BFS trees in parallel, one layer at a time, from s in $G \setminus S$ and from t in the graph obtained from $G \setminus S$ by reversing the orientations of all edges. The search halts when a layer (corresponding to the leaves of the BFS tree at the current iteration) that is "thin" is found, and its vertices are added to S; vertices that are on the opposite side of the separator than s are cut off as they must all be too far away from s. Here, "thin" refers to a BFS layer such that the number of vertices added to the separator is only a factor $\tilde{O}(1/d)$ times the number of vertices cut off. It is well known that such a layer exists (cfr. Lemma 5 for the details). Summing up, it follows that $|S| = \tilde{O}(n/d)$ at all times. By marking vertices as they are searched (according to the side of the BFS layer on which they are found), the vertices that are "cut off" from s by the augmented separator will never be searched again, and the cost of searching the edges of either side of the search can be charged to sum of the degree of these vertices, for a total update time of $O(m)$.

For our randomized data structure, we need an additional property that essentially allows us to take a snapshot of the current separator and use it in later updates rather than having to repeatedly update the separator. This will be key to getting an improved randomized time bound. Details can be found in Lemma 6 which states our separator result.

The Randomized Approximate Data Structure. The randomized approximate data structure of Theorem 3 follows the same overall approach but is technically more involved. Instead of keeping track of all 2-hop paths $u \rightsquigarrow s \rightsquigarrow v$[3] for every $s \in S_i(u)$, the randomized data structure samples a subset of these by picking each vertex of $S_i(u)$ independently with some probability p. It only keeps track of approximate shortest path distances going through this subset rather than the full set $S_i(u)$. This will speed up the above since the subset of the separator we need to scan is smaller by a factor p. However, this approach fails once no short 2-hop path intersects the sampled subset. At this point, w.h.p. there should only be short 2-hop paths through $O(\log n/p)$ vertices of $S_i(u)$ so also in this case, the subset can be kept small. However, scanning linearly through $S_i(u)$ to find this small subset will take $\tilde{O}(n/d)$ time and happen over all pairs (u, v).

Our solution is roughly the following. Suppose no sampled vertex certifies an approximate short path from u to v. Then v scans linearly through $S_i(u)$ to find the small size $O(\log n/p)$ subset $S'_i(u)$. Consider the set W of vertices w such that $d_G(w, v)$ is small compared to d, i.e., $d_G(w, v) \leq \epsilon d$ for some small constant $\epsilon > 0$. Then we show that the small subset $S'_i(u)$ found for v can also be used for each vertex $w \in W$. The intuition is that for any vertex $s \in S_i(u) \setminus S'_i(u)$, the approximate shortest path distance from u to w through s must be large since otherwise we get a short path $u \rightsquigarrow s \rightsquigarrow w \rightsquigarrow v$ from u to v through s, contradicting that $s \notin S'_i(u)$.

It follows that if $|W|$ is large, the $\tilde{O}(n/d)$ cost of scanning $S_i(u)$ can be distributed among a large number of vertices of W. Dealing with the case where $|W|$ is small is more technical so we omit it here.

The way we deal with an adaptive adversary is roughly as follows. Consider a deterministic data structure that behaves like the randomized data structure above, except that it maintains 2-hop paths $u \rightsquigarrow s \rightsquigarrow v$ for all $S_i(u)$ rather than only through a sampled subset. The slack from the approximation allows us to round up all "short" approximate distances to the same value. Hence, as long as the randomized data structure has short 2-hop paths, it maintains exactly the same approximate distances as the deterministic structure and hence the approximate distances output to the adversary is independent of the random bits used.

[3] Note that such a path may have more than one intermediate vertex, but it is useful to think of it as a path of two weighted edges/hops (u, s) and (s, v) since this is what is maintained by the data structure.

2 Definitions and Notation

In the following, let $G = (V, E)$ be a directed unweighted graph. The graph $G_{\mathbf{rev}}$ is obtained from G by reversing the orientation of each edge. For any two vertices $u, v \in V$, we denote by $u \rightsquigarrow v$ a shortest path from u to v in G and let $d_G(u, v)$ denote the length of such a path. We extend this notation to sets so that, e.g., $d_G(u, V') = \min\{d_G(u, v) | v \in V'\}$ for $V' \subseteq V$.

We define a BFS-layer to mean the set of nodes at some fixed distance from some v in G. An *in-tree* in G is a BFS tree in $G_{\mathbf{rev}}$.

We will need notation to refer to dynamically changing data at specific points in time. Consider a sequence of updates to some object X where each update takes place at a time step $t \in \mathbb{N}$. We denote by $X^{(t)}$ the object just after update t. Here, X could be a graph, a shortest path distance, etc.

For handling small distances, we rely on the data-structure of Even and Shiloach [6], the properties of which we will state in the following lemma:

▶ **Lemma 4** ([6]). *Given a directed unweighted graph G undergoing a sequence of edge deletions, a source vertex $s \in V$, and $d > 0$, a shortest path tree in G rooted at s can be maintained up to distance d in total time $O(md)$. The structure requires $O(m)$ space and can be constructed in time $O(m + n)$.*

3 Maintaining Separators

Lemma 6 below provides a key tool used in all of our data structures. It gives an efficient data structure that maintains a growing separator set S of small size in a decremental graph G. To prove it, we need the following well-known result.

▶ **Lemma 5.** *Given a directed unweighted n-vertex graph $G = (V, E)$, given $d_1, d_2 \in \mathbb{N}_0$ with $d_2 - d_1 + 1 \geq \lg n$, and given vertices $u, v \in V$ with $d_G(u, v) \geq d_2$, a BFS tree in G with root u contains a layer $L \subseteq V$ with $d_1 \leq d_G(u, L) \leq d_2$ and $|L| \leq |L_-| \lg n/(d_2 - d_1 + 1)$ where $L_- = \{w \in V | d_G(u, w) < d_G(u, L)\}$ is the union of layers closer to u than L.*

Proof. Denote by L_i the ith layer of the BFS tree from u. For each i, let $L_{<i} = \cup_{j<i} L_j$. Let $q = (d_2 - d_1 + 1)/\lg n$. Assume for contradiction that L does not exist. Then for $i = d_1, \ldots, d_2$, $|L_i| > |L_{<i}|/q$ so $|L_{<i+1}| = |L_i| + |L_{<i}| > (1 + 1/q)|L_{<i}|$. Since $q \geq 1$, we have $(1 + 1/q)^q \geq 2$ so

$$|L_{<d_2+1}| > (1 + 1/q)^{d_2-d_1+1} |L_{<d_1}| \geq 2^{(d_2-d_1+1)/q} = n,$$

contradicting that there are only n vertices in G. ◀

We now state and prove Lemma 6. It gives an efficient data structure that maintains a growing separator set S of small size in a decremental graph G with the following guarantees. Let s be a fixed vertex and let d be some given threshold distance. Then at every time step, vertices reachable from s in $G \setminus S$ are of distance slightly less than d from s in G. Conversely, for vertices v not reachable from s in $G \setminus S$, we have $d_G(s, v) = \Omega(d)$; furthermore, if $d_G(s, v)$ is larger than d by some small constant factor then any shortest path $s \rightsquigarrow v$ in G can be decomposed into $s \rightsquigarrow w \rightsquigarrow v$ such that $w \in S$, $d_G(s, w) \leq d$, and $d_G(w, v) \leq d$. In fact, the lemma states that w can be chosen in S^{t_0} where t_0 is the first time step in which $d_G(s, v)$ became (slightly) larger than d; note that this is a stronger statement since S is growing over time.

▶ **Lemma 6.** *Let $G = (V, E)$ be an n-vertex unweighted digraph undergoing a sequence of edge deletions, let $s \in V$ be a source, and let $d \in \mathbb{N}$ with $d > 33 \lg n$. Let $\mathcal{O}$ be a data structure that maintains for each $v \in V$ a distance estimate $\tilde{d}(s, v) \geq d_G(s, v)$ such that if $d_G(s, v) \leq d$ then $\tilde{d}(s, v) \leq \frac{4}{3} d_G(s, v)$. Whenever an estimate $\tilde{d}(s, v)$ grows to a value of at least $\frac{32}{33}d$, $\mathcal{O}$ outputs v. Then there is a data structure $\mathcal{S}$ with access to $\mathcal{O}$ which maintains a growing set $S \subseteq V$ such that for each $v \in V$,*

1. *if v is reachable from s in $G \setminus S$ then $d_G(s, v) < \frac{32}{33}d$ and otherwise $d_G(s, v) > \frac{2}{3}d$,*
2. *if t_0 is a time step in which $d < d_G^{(t_0)}(s, v) \leq \frac{34}{33}d$ then for every time step $t_1 \geq t_0$ in which $d_G^{(t_1)}(s, v) \leq \frac{34}{33}d$, any shortest s-to-v path P in $G^{(t_1)}$ intersects $S^{(t_0)}$ and for the first such intersection vertex w along P, $d_G^{(t_1)}(s, w) \leq d$, and $d_G^{(t_1)}(w, v) \leq d$.*

At any time, $|S| = O(n \log n/d)$ and $\mathcal{S}$ has total update time $O(m)$, excluding the time spent by $\mathcal{O}$.

Proof. Let $\epsilon = \frac{1}{33}$. For each $v \in V$, let $\hat{d}(v)$ be obtained from the degree of v in the initial graph G by rounding up to the nearest multiple of $\Delta = \lceil m/n \rceil$. In the description of $\mathcal{S}$ below, processing one edge takes at most one unit of time.

Data structure $\mathcal{S}$ initializes $S = \emptyset$ and unmarks all vertices of V. Whenever $\mathcal{O}$ outputs an unmarked vertex v (marked output vertices are ignored), $\mathcal{S}$ runs a modified BFS from s in $G_S = G \setminus S$ which for each vertex w spends $\hat{d}(w)$ time to process its outgoing edges; this can always be achieved by busy-waiting at w if needed. In parallel, $\mathcal{S}$ runs a similar modified BFS from v in $G'_S = (G \setminus S)_{\mathbf{rev}}$[4]. The search from s halts if a layer L_s is found such that $\frac{2}{3}d < d_{G_S}(s, L_s) \leq (\frac{2}{3} + \epsilon)d$ and $|L_s| = O((x \log n)/d)$ (for a suitable hidden constant to be specified) where x is the number of vertices visited by the search, excluding L_s. Similarly, the search from v halts if a layer L_v is found such that $d_{G'_S}(v, L_v) < \epsilon d$ and $|L_v| = O((y \log n)/d)$ (again, for a suitable hidden constant) where y is the number of vertices visited by the search excluding L_v. Let L be the first of the two layers found. $\mathcal{S}$ halts both searches when L is found. Then L is added to S and all vertices visited by the search from v in G'_S are marked. The hidden constants are chosen such that the existence of L follows from Lemma 5; this lemma applies since by assumption, $\epsilon d > \lg n$.

Observe that when $\mathcal{O}$ outputs v, we have $d_G(s, v) \geq (1 - \epsilon)d/(4/3) = (\frac{2}{3} + 2\epsilon)d$ as otherwise we have $d_G(s, v) \leq d$ and hence $\tilde{d}(s, v) \leq \frac{4}{3} d_G(s, v) < (1 - \epsilon)d = \frac{32}{33}d$. This shows the existence of L_s and L_v and that no vertex or edge is visited by both searches. We have $d_{G_S}(s, v) \geq d_G(s, v) \geq (\frac{2}{3} + 2\epsilon)d$ and $d_{G_S}(s, L_s) > \frac{2}{3}d$ and for every $w \in L_v$,

$$d_{G_S}(s, w) \geq d_{G_S}(s, v) - d_{G_S}(w, v) \geq \left(\frac{2}{3} + 2\epsilon\right) d - d_{G'_S}(v, w) = \left(\frac{2}{3} + 2\epsilon\right) d - d_{G'_S}(v, L_v)$$
$$> \left(\frac{2}{3} + \epsilon\right) d,$$

implying that $d_{G_S}(s, L_v) > (\frac{2}{3} + \epsilon)d$. Hence $d_{G_S}(s, L) \geq \min\{d_{G_S}(s, L_s), d_{G_S}(s, L_v)\} > \frac{2}{3}d$.

Showing part 1. Let $v \in V$ and consider any point during the sequence of updates. Assume first that v is reachable from s in G_S. Then $\mathcal{O}$ has not yet output v. For suppose otherwise. If v was unmarked when it was output by $\mathcal{O}$, the above procedure would separate v from s with S, making v unreachable from s in G_S. Conversely, if v was marked, v would already be unreachable from s in G_S since a vertex is only marked when it is separated from s in G_S. In both cases, we have a contradiction. It follows that $\mathcal{O}$ did not output v so $d_G(s, v) \leq \tilde{d}(s, v) < \frac{32}{33}d$, as desired.

[4] By "parallel", we mean that $\mathcal{S}$ alternates between spending one unit of time in one search, then one unit of time in the other search, and so on.

Now, assume that v is not reachable from s in G_S. We may assume that there is a shortest path P from s to v in G since otherwise $d_G(s,v) = \infty > \frac{2}{3}d$. Let w be the first vertex of S along P. It suffices to show that for the prefix P' of P from s to w, $|P'| > \frac{2}{3}d$. At some earlier point in time, the procedure added w to S; just prior to this, P' was contained in G_S so from the above, $|P'| > \frac{2}{3}d$, as desired.

Showing part 2. Let $t_0 \leq t_1$ satisfy the second part of the lemma. Since $d_G^{(t_0)}(s,v) > d$ by assumption, the first part of the lemma implies that v is not reachable from s in $G_S^{(t_0)}$ and hence v is also not reachable from s in $G_S^{(t_1)}$.

Let P be a shortest path from s to v in $G^{(t_1)}$. From what we have just shown, P must intersect $S^{(t_0)}$. Let w be the first vertex of $S^{(t_0)}$ along P. Then clearly, $d_G^{(t_1)}(s,v) = d_G^{(t_1)}(s,w) + d_G^{(t_1)}(w,v)$. Since the vertex w' preceding w on P is reachable from s in $G_S^{(t_0)}$, the first part of the lemma implies that $d_G^{(t_0)}(s,w) \leq d_G^{(t_0)}(s,w') + 1 < \frac{32}{33}d + 1$ and $d_G^{(t_0)}(s,w) > \frac{2}{3}d$. The latter implies that $d_G^{(t_1)}(w,v) = d_G^{(t_1)}(s,v) - d_G^{(t_1)}(s,w) \leq \frac{34}{33}d - d_G^{(t_0)}(s,w) < \frac{34}{33}d - \frac{2}{3}d < d$, showing one of the two inequalities in the second part of the lemma.

We show the other inequality by contradiction so assume that $d_G^{(t_1)}(s,w) > d$. Then $d_G^{(t_1)}(s,w) \geq d+1$ so by the above $d_G(s,w)$ would have increased by more than $d + 1 - (\frac{32}{33}d + 1) = \frac{1}{33}d$ from time step t_0 to t_1. Combining this with $d_G^{(t_1)}(s,v) = d_G^{(t_1)}(s,w) + d_G^{(t_1)}(w,v)$, $d_G^{(t_0)}(w,v) \leq d_G^{(t_1)}(w,v)$, and the triangle inequality, we get

$$d_G^{(t_1)}(s,v) - d_G^{(t_0)}(s,v) \geq d_G^{(t_1)}(s,w) + d_G^{(t_1)}(w,v) - (d_G^{(t_0)}(s,w) + d_G^{(t_0)}(w,v)) > \frac{1}{33}d$$

This contradicts the assumption $d < d_G^{(t_0)}(s,v) \leq d_G^{(t_1)}(s,v) \leq \frac{34}{33}d$. We conclude that $d_G^{(t_1)}(s,w) \leq d$ and $d_G^{(t_1)}(w,v) \leq d$ which shows the second part of the lemma.

Bounding $|S|$ and running time. To bound, $|S|$, consider the two parallel searches from s and from v, respectively, in some update. As argued earlier, there cannot be an edge or vertex visited by both searches. Let X resp. Y be the set of vertices visited by the BFS from s resp. v, excluding L_s resp. L_v and let $x = |X|$ and $y = |Y|$.

Assume first that $L = L_s$. Then all vertices in $Y \cup L_v$ become unreachable in G_S once L has been added to S. For each $w \in V$, $\hat{d}(w)/\Delta \geq 1$. Since each BFS spends $\hat{d}(w)$ time to process edges incident to w and since the two searches run in parallel, we have

$$|L| = O((x \log n)/d) = O\left(\frac{\log n}{d} \sum_{w \in X} \frac{\hat{d}(w)}{\Delta}\right) = O\left(\frac{\log n}{d} \sum_{w \in Y \cup L_v} \frac{\hat{d}(w)}{\Delta}\right)$$

Now, assume that $L = L_v$. Then all vertices of $Y \cup L_v$ become unreachable in G_S once L has been added to S so again,

$$|L| = O((y \log n/d) = O\left(\frac{\log n}{d} \sum_{w \in Y \cup L_v} \frac{\hat{d}(w)}{\Delta}\right)$$

In both cases, the cost $|L|$ of adding L to S can be paid for by charging each vertex w no longer reachable from s in G_S a cost of $O(\frac{\log n}{d}\hat{d}(w)/\Delta)$. Since a vertex is only charged once during the course of the algorithm, we get that for the final separator S (and hence for each intermediate separator),

$$|S| = O\left(\frac{\log n}{d}\sum_{w\in V}\frac{\hat{d}(w)}{\Delta}\right) = O\left(\frac{\log n}{d}\sum_{w\in V}\frac{d(w)+\Delta}{\Delta}\right) = O\left(\frac{\log n(m+n\lceil m/n\rceil)}{d\lceil m/n\rceil}\right)$$
$$= O\left(\frac{n\log n}{d}\right)$$

where the last bound follows since we may assume that all vertices are initially reachable from s in G, implying $m \geq n-1$ and hence $\lceil m/n\rceil = \Theta(m/n)$. This shows the desired bound on $|S|$.

The running time cost of any two parallel searches can be charged to the total degree of the vertices that get marked since they all become unreachable in G_S (this is the vertex set Y above). Since a marked vertex is never visited again by a BFS search, the total running time of parallel searches over all updates is $O(m)$, as desired. ◀

The lemma is somewhat technical and its full strength is only needed for the randomized data structure. For the deterministic data structures, the second part of the lemma will only be applied to the current time step $t_1 = t_0$ so it can be simplified to:

2. if $d < d_G(s,v) \leq \frac{34}{33}d$ then any shortest s-to-v path P in G intersects S and for the first such intersection vertex w along P, $d_G(s,w) \leq d$, and $d_G(w,v) \leq d$.

4 Deterministic Decremental APSP

In this section, we present our deterministic data structures for the exact resp. $(1+\epsilon)$-approximate decremental APSP problem and show Theorems 1 and 2. In the following, let $G = (V,E)$ denote the decremental graph.

4.1 Exact distances

Let $\rho = \frac{34}{33}$ and $D_i = \rho^i$ for $i = 0,\ldots,\lfloor \log_\rho n\rfloor$. For each i and each $u \in V$, we give a data structure $\mathcal{D}_i(u)$ which for any query vertex v maintains a value $\tilde{d}_i(u,v) \geq d_G(u,v)$ with equality if $d_G(u,v) \in (D_i, D_{i+1}]$. In each update, these data structures will be updated in order of increasing i.

Handling all-pairs shortest path distances up to at most $33\lg n$ can be done in $O(mn\log n)$ time using the data structure of Even and Shiloach so we only consider i such that $D_i > 33\lg n$. This allows us to apply Lemma 6. Consider such an i and assume that we already have data structures for all values smaller than i.

Data structure $\mathcal{D}_i(u)$ maintains a separator set $S_i(u)$ using an instance $\mathcal{S}_i(u)$ of the data structure of Lemma 6 with $s = u$ and $d = D_i$; inductively, we have an exact data structure for distances smaller than d and this data structure plays the role of $\mathcal{O}$ with $\tilde{d} = d_G$. At the beginning of each update, $\mathcal{S}_i(u)$ updates $S_i(u)$. Then for each v, if $\mathcal{O}$ reports that $\tilde{d}(u,v)$ has increased from a value of at most D_i to a value strictly greater than D_i, $\mathcal{D}_i(u)$ initializes $S_i(u,v)$ to be the current separator set $S_i(u)$; $\mathcal{D}_i(u)$ then initializes a priority queue $Q_i(u,v)$ where elements are all $s \in S_i(u,v)$ with corresponding keys $\tilde{d}_{i-1}(u,s) + \tilde{d}_{i-1}(s,v)$. During updates, whenever $\mathcal{D}_{i-1}(u)$ resp. $\mathcal{D}_{i-1}(s)$ reports that $\tilde{d}_{i-1}(u,s)$ resp. $\tilde{d}_{i-1}(s,v)$ increases, the key value of s in $Q_i(u,v)$ increases by the same amount. Note that after initialization, $S_i(u,v)$ remains fixed and so does $Q_i(u,v)$ (except for key value changes).

For each vertex v, $\mathcal{D}_i(u)$ maintains $\tilde{d}_i(u,v)$ as the min key value in $Q_i(u,v)$ after $Q_i(u,v)$ has been initialized; prior to this, $\tilde{d}_i(u,v) = \infty$. This completes the description of each $\mathcal{D}_i(u)$.

The overall data structure $\mathcal{D}$ maintains a priority queue $Q(u,v)$ for each vertex pair (u,v) with an element for each i of key value $\tilde{d}_i(u,v)$. For i in increasing order, $\mathcal{D}$ updates $\mathcal{D}_i(u)$ for each u. Whenever a data structure $\mathcal{D}_i(u)$ increases a value $\tilde{d}_i(u,v)$, the corresponding key in $Q(u,v)$ is increased accordingly. On a query (u,v), $\mathcal{D}$ reports the min key value in $Q(u,v)$.

Correctness. We prove that for each i, each time step t_1, and each vertex pair (u,v), $\tilde{d}_i(u,v) \geq d_G(u,v)$ with equality if $d_G(u,v) \in (D_i, D_{i+1}]$. The inequality is clear since every estimate corresponds to the length of some path in the current graph. The equality part is shown by induction on i.

The base cases where $D_i < 33 \lg n$ are clear so pick i with $D_i \geq 33 \lg n$ and $d_G^{(t_1)}(u,v) \in (D_i, D_{i+1}]$ and assume that correctness holds for all vertex pairs and time steps for $i-1$. Let $t_0 \leq t_1$ be the first time step such that $d_G^{(t_0)}(u,v) \in (D_i, D_{i+1}]$. Note that $S_i(u,v) = S_i(u)^{(t_0)}$. The induction hypothesis and the second part of Lemma 6 combined with the observation that no key value in $Q_i(u,v)$ is below $d_G(u,v)$, it follows that the min key value in $Q_i(u,v)$ equals $d_G^{(t_1)}(u,v)$. This shows correctness.

Running time. Consider an $i \in \{0, \ldots, \lfloor \log_\rho n \rfloor\}$ with $D_i \geq 33 \lg n$ and a vertex $u \in V$. We will show that maintaining $\mathcal{D}_i(u)$ takes $O(n^2 \log^2 n)$ time using a standard binary heap. Total time over all i and u will thus be $O(n^3 \log^3 n)$. This dominates the $O(n^3 \log^2 n)$ time to maintain priority queues $Q(u,v)$ and the $O(mn \log n)$ time for the data structure of Even and Shiloach for small values of i.

Maintaining $S_i(u)$ takes a total of $O(m)$ time by Lemma 6. The total number of elements in priority queues $Q_i(u,v)$ over all $v \in S_i(u,v)$ is $O(n^2 \log n / D_i)$, again by Lemma 6. The number of increase-key operations for a single priority queue element s of $Q_i(u,v)$ is $O(D_i)$ which takes a total of $O(D_i \log n)$ time. Over all elements of priority queues $Q_i(u,v)$, this is $O(n^2 \log^2 n)$.

Reporting paths. It is easy to extend our data structure to efficiently answer queries for shortest paths (rather than only shortest path distances) between any vertex pair (u,v). Associated with the min element of $Q(u,v)$ is a vertex s such that for the associated index i, $\tilde{d}_i(u,v) = d_G(u,v) = d_G(u,s) + d_G(s,v)$, $\tilde{d}_{i-1}(u,s) = d_G(u,s)$, and $\tilde{d}_{i-1}(s,v) = d_G(s,v)$. Hence, by recursively querying for pairs (u,s) and (s,v), a shortest u-to-v path in G is reported in time proportional to its length.

4.2 Approximate distances

Let $\epsilon > 0$ be given. We now present our deterministic data structure for the $(1+\epsilon)$-approximate variant of the problem.

The data structure is quite similar to the one for the exact variant so we only describe the changes needed. For $i > 0$ and $u \in V$, we describe data structure $\mathcal{D}_i(u)$ and assume that we have data structures for values less than i. As before, we only consider i with $D_i \geq 33 \lg n$.

Let $\epsilon' > 0$ be a value depending on ϵ such that $(1+\epsilon')^c = \rho$ for some $c \in \mathbb{N}$; we will specify ϵ' later. For $j = 0, \ldots, c = \log_{1+\epsilon'} \rho$, let $d_{i,j} = D_i(1+\epsilon')^j$. This partitions each interval $(D_i, D_{i+1}]$ into c sub-intervals $(D_i(1+\epsilon')^j, D_i(1+\epsilon')^{j+1}]$ for $j = 0, \ldots, c-1$.

$\mathcal{D}_i(u)$ maintains $S_i(u)$ as in the exact version. For each $v \in V$, $\mathcal{D}_i(u)$ maintains an initially empty set $S_i(u,v)$. Once $\mathcal{D}_{i-1}(u)$ reports that $\tilde{d}_{i-1}(u,v)$ increased from a value of at most $D_i(1+\epsilon')^i$ to a value strictly greater than $D_i(1+\epsilon')^i$, $\mathcal{D}_i(u)$ sets $S_i(u,v)$ equal to the current set $S_i(u)$.

For each $j = 0, \ldots, c-1$, a data structure $\mathcal{D}_{i,j}(u)$ maintains the following set for each vertex v:

$$Q_{i,j}(u,v) = \left\{ s \in S_i(u,v) \mid \tilde{d}_{i-1}(u,s) + \tilde{d}_{i-1}(s,v) \leq (1+\epsilon')^i d_{i,j} \right\}.$$

$Q_{i,j}(u,v)$ is maintained by $\mathcal{D}_{i,j}(u)$ as a queue in which every $s \in Q_{i,j}(u,v)$ has key $\tilde{d}_{i-1}(u,s) + \tilde{d}_{i-1}(s,v)$ and where s is removed from $Q_{i,j}(u,v)$ (or increased to ∞) when this value exceeds $(1+\epsilon')^i d_{i,j}$.

For each vertex v, define $\tilde{d}_{i,j}(u,v) = (1+\epsilon')^i d_{i,j}$ if $Q_{i,j}(u,v)$ contains at least one element and otherwise $\tilde{d}_{i,j}(u,v) = \infty$.

Data structure $\mathcal{D}_i(u)$ maintains a min-priority queue $Q_i(u,v)$ for each vertex v with an element of key value $\tilde{d}_{i,j}(u,v)$ for each j. On query v, it outputs $\tilde{d}_i(u,v) = \min\{k, \tilde{d}_{i-1}(u,v)\}$ where k is the min-key value of this queue, i.e., $\tilde{d}_i(u,v) = \min\{\tilde{d}_{i-1}(u,v), \min_j \tilde{d}_{i,j}(u,v)\}$.

The overall data structure $\mathcal{D}$ works in the same manner as for the exact data structure.

Correctness. Consider any point during the sequence of edge deletions. We will show that for suitable choice of ϵ', the estimate $\tilde{d}(u,v)$ that $\mathcal{D}$ outputs satisfies $d_G(u,v) \leq \tilde{d}(u,v) \leq (1+\epsilon) d_G(u,v)$ for every vertex pair (u,v).

We first show that $d_G(u,v) \leq \tilde{d}(u,v)$. It suffices to prove by induction on $i \geq 0$ that $d_G(u,v) \leq \tilde{d}_i(u,v)$. The proof holds for small i such that $D_i < 33 \lg n$ since then we use the data structure of Even and Shiloach, implying $\tilde{d}_i(u,v) = d_G(u,v)$. Now, consider an i such that $D_i \geq 33 \lg n$ and assume that the claim holds for smaller values than i. We have $\tilde{d}_i(u,v) = \min\{\tilde{d}_{i-1}(u,v), \min_j \tilde{d}_{i,j}(u,v)\}$ and $\tilde{d}_{i,j}(u,v) \geq (1+\epsilon')^i d_{i,j} \geq \tilde{d}_{i-1}(u,s) + \tilde{d}_{i-1}(s,v)$ for each $s \in Q_{i,j}(u,v)$. Additionally, if $Q_{i,j}(v) = \emptyset$ then $\tilde{d}_{i,j}(u,v) = \infty$. The induction hypothesis now implies $\tilde{d}_i(u,v) \geq d_G(u,v)$, showing the induction step. Thus, $d_G(u,v) \leq \tilde{d}(u,v)$.

To show that $\tilde{d}(u,v) \leq (1+\epsilon) d_G(u,v)$, we prove by induction on $i \geq 0$ that during all updates and for all vertex pairs (u,v), if $d_G(u,v) \in (0, D_{i+1}]$ then $\tilde{d}_i(u,v) \leq (1+\epsilon')^i d_G(u,v)$. If we can show this then picking $\epsilon' \leq \ln(1+\epsilon)/(\lfloor \log_\rho n \rfloor)$ gives $\tilde{d}(u,v) \leq (1+\epsilon')^{\lfloor \log_\rho n \rfloor} d_G(u,v) \leq e^{\epsilon' \lfloor \log_\rho n \rfloor} d_G(u,v) \leq (1+\epsilon) d_G(u,v)$ for every vertex pair (u,v).

We only need to consider i with $D_i \geq 33 \lg n$ since otherwise, we use the data structure of Even and Shiloach. Assume inductively that the claim holds for values less than i.

Let t_1 be the current time step and consider a vertex pair (u,v) with $d_G^{(t_1)}(u,v) \in (0, D_{i+1}]$. By the induction hypothesis, we may assume that $d_G^{(t_1)}(u,v) \in (D_i, D_{i+1}]$. We may further assume that $\tilde{d}_{i-1}^{(t_1)}(u,v) > D_i(1+\epsilon')^i$ since otherwise,

$$\tilde{d}_i^{(t_1)}(u,v) \leq \tilde{d}_{i-1}^{(t_1)}(u,v) \leq D_i(1+\epsilon')^i < (1+\epsilon')^i d_G^{(t_1)}(u,v).$$

Let $t_0 \leq t_1$ be the first time step where $\tilde{d}_{i-1}^{(t_0)}(u,v) > D_i(1+\epsilon')^i$. We must have $d_G^{(t_0)}(u,v) > D_i$ since otherwise, the induction hypothesis would imply $\tilde{d}_{i-1}^{(t_0)}(u,v) \leq d_G^{(t_0)}(u,v)(1+\epsilon')^{i-1} \leq D_i(1+\epsilon')^{i-1}$, contradicting the choice of t_0. Since also $d_G^{(t_0)}(u,v) \leq d_G^{(t_1)}(u,v) \leq D_{i+1}$, Lemma 6 implies that there is a vertex $s \in S_i^{(t_0)}(u) = S_i^{(t_0)}(u,v) = S_i^{(t_1)}(u,v)$ such that $d_G^{(t_1)}(u,v) = d_G^{(t_1)}(u,s) + d_G^{(t_1)}(s,v)$, $d_G^{(t_1)}(u,s) \leq D_i$, and $d_G^{(t_1)}(s,v) \leq D_i$.

Pick j such that $d_G^{(t_1)}(u,v) \in (d_{i,j}, d_{i,j+1}]$. By the induction hypothesis,

$$\tilde{d}_{i-1}^{(t_1)}(u,s) + \tilde{d}_{i-1}^{(t_1)}(s,v) \leq (1+\epsilon')^{i-1} d_G^{(t_1)}(u,v) \leq (1+\epsilon')^{i-1} d_{i,j+1} = (1+\epsilon')^i d_{i,j}.$$

Hence, $Q_{i,j}(u,v)$ is non-empty at time step t_1 so $\tilde{d}_i^{(t_1)}(u,v) \leq \tilde{d}_{i,j}^{(t_1)}(u,v) = (1+\epsilon')^i d_{i,j} \leq (1+\epsilon')^i d_G^{(t_1)}(u,v)$. This shows the induction step.

Running time. The analysis is similar to the one for exact distances. Pick an $i \in \{0, \ldots, \lfloor \log_\rho n \rfloor\}$ with $D_i \geq 33 \lg n$. The total time to maintain $S_i(u)$ over all u is $O(mn)$.

Observe that each approximate distance $\tilde{d}_{i-1}(u_1, u_2)$ is of the form $(1+\epsilon')^{i'} d_{i',j}$ for $i' \leq i-1$. Since each element s in a queue $Q_{i,j}(u,v)$ has key value $\tilde{d}_{i-1}(u,s) + \tilde{d}_{i-1}(s,v)$, it follows that the number of increase-key operations applied to s in $Q_{i,j}(u,v)$ is $O(\log_{1+\epsilon'} D_i) = O(\log D_i/\epsilon') = O(\log n/\epsilon')$. For our purpose, a simplified queue $Q_{i,j}(u,v)$ suffices which keeps a counter of the number of elements of key value at most $(1+\epsilon')^i d_{i,j}$; this follows since the min key value is at most $(1+\epsilon')^i d_{i,j}$ if and only if the counter is strictly greater than 0. Every queue operation for $Q_{i,j}(u,v)$ can then be supported in $O(1)$ time. The number of elements in $Q_{i,j}(u,v)$ over all u, v, and j is $O(cn^3 \log n/D_i) = O(n^3 \log n/(D_i\epsilon'))$ by Lemma 6. This gives a total time bound of $O(mn + n^3 \log^2 n/(D_i(\epsilon')^2))$. This dominates the time spent on maintaining priority queues $Q_i(u,v)$.

Recall from above that $\epsilon' \leq \ln(1+\epsilon)/(\lfloor \log_\rho n \rfloor)$. The only additional constraint on ϵ' is that $(1+\epsilon')^c = \rho$ for some $c \in \mathbb{N}$. This can be achieved with $\epsilon' = \Theta(\ln(1+\epsilon)/(\lfloor \log_\rho n \rfloor))$. Hence, we get a time bound of $O(mn + n^3 \log^4 n/(D_i\epsilon^2))$.

Note that this bound is no better than the exact data structure for small D_i. We thus consider a hybrid data structure that only applies our data structure when D_i is above some distance threshold d and otherwise applies the data structure of Even and Shiloach which takes a total of $O(mnd)$ time. Summing over all $D_i > d$ and applying a geometric sums argument, the total time for our hybrid data structure is

$$O(mnd + \sum_{i:D_i>d} n^3 \log^4 n/(D_i\epsilon^2))) = O(mnd + n^3 \log^4 n/(d\epsilon^2)))$$

Setting $d = n \log^2 n/(\epsilon\sqrt{m})$ gives Theorem 2. Showing the bound for reporting approximate shortest paths in the theorem is done in the same way as in Section 4.1.

5 Randomized Decremental APSP

In this section, we provide a high-level overview of the randomized $(1+\epsilon)$-approximate data structure and analysis to achieve the result presented in Theorem 3. Building on this overview we will then prove the theorem.

Let us start by focusing on maintaining approximate distances close to the value D_i from a single vertex u and for now we assume an oblivious adversary.

Maintaining a sampled separator subset. Instead of maintaining each separator $S_{i,j}(u,v)$ (with associated with priority queue $Q_{i,j}(u,v)$) as the full vertex separator $S_i(u)$, we obtain a speed-up by only maintaining a sampled subset of $S_i(u)$. As long as this sampled subset certifies that there is a short two-hop path from u to v, the data structure proceeds as in the previous section. When this is no longer the case, there might still be a short two-hop path from u to v through a non-sampled vertex s in the full separator set $S_i(u)$. However, since there are no more sampled candidates, the expected number of vertices of $S_i(u)$ that provide a short two-hop path is small and we can update $S_{i,j}(u,v)$ to be this small subset. It follows that in expectation, $S_{i,j}(u,v)$ can be kept small at all times, which is needed to give a speed-up.

A speed-up using shallow in-trees. The problem with the data structure sketched above is that the entire set $S_i(u)$ had to be scanned in order to update $S_{i,j}(u,v)$ which means that the data structure will not be faster than our deterministic structure from the previous section.

To deal with this, consider the following modification. The set $S_{i,j}(u,v)$ is updated as before by scanning over the entire set $S_i(u)$. Now, an in-tree $T(v)$ is grown from v of radius at most $\epsilon' D_i$. Each vertex v' in $T(v)$ then inherits the set of v, i.e., $S_{i,j}(u,v')$ is updated to the set $S_{i,j}(u,v)$ and this update is fast since $S_{i,j}(u,v)$ is small in expectation. This works since v is a proxy for v' in the sense that a short two-hop path from u to v' via $S_{i,j}(u,v)$ can be extended with a short suffix from $T(v)$, giving a short two-hop path from u to v via $S_{i,j}(u,v)$ (as $T(v)$ is an in-tree of small radius). Now, the time spent on the single scan of $S_i(u)$ can be distributed among all vertices of $T(v)$ and the number of such vertices must be at least $\epsilon' D_i + 1$ (if not, v would be within distance $\epsilon' D_i$ from u).

Unfortunately, the time analysis for the above procedure breaks down if the in-trees grown during the sequence of updates overlap too much. We now sketch how to deal with this. Mark vertices of each in-tree grown so far. When the BFS procedure grows a new in-tree $T(v)$, this procedure is modified by having it backtrack at previously marked vertices which thus become leaves of $T(v)$; this set of marked leaves will be referred to as L in the detailed description below.

Case 1, dealing with a large in-tree. If the number of unmarked vertices visited in $T(v)$ is greater than $\epsilon' D_i$, the above procedure and analysis can be applied; this is referred to as Case 1 in the detailed description below.

Case 2, dealing with a small in-tree. Otherwise, we are in Case 2; here we recall that $T(v)$ has small radius and observe that the only way to enter $T(v)$ from $G \setminus T(v)$ is through L. Hence, for every vertex s in the union $\cup_{v' \in L} S_{i,j}(u,v')$, there is a good two-hop path from u to v through s. But since we know that there is only a small number of such vertices left (in expectation), this union must be small. Furthermore, the union must contain a good separator for every vertex in $T(v)$ (again because $T(v)$ has small radius and because $T(v)$ must be entered through L) and we thus have an efficient way to update $S_{i,j}(u,w)$ for all $w \in T(v)$.

Handling an adaptive adversary. Above we assumed an oblivious adversary. When the adversary is adaptive, we need to be more careful since the approximate distances reported might reveal information about which vertices have been sampled. To deal with this, we round up every two-hop distance on a given distance scale to the same upper bound value (this will only increase the weight of each two-hop path by a small factor so that the output to a query will still be $(1+\epsilon)$-approximate). Hence, the rounded up approximate weight of a two-hop path $u \rightsquigarrow s \rightsquigarrow v$ is the same for every choice of "good" separator vertex s regardless of whether it was sampled or not. It follows that our randomized structure outputs the same distance estimates as a slower deterministic algorithm that maintains the full separator sets. Hence, our randomized algorithm works against an adaptive adversary, as desired.

5.1 The data structure

We now make the the overview formal. First, redefine $\rho = \frac{34-\frac{1}{2}}{33} = \frac{67}{66}$ and pick ϵ' such that $(1+\epsilon')^c = \rho$ for some $c \in \mathbb{N}$ and such that $\rho(1+\epsilon') \leq \frac{34}{33}$. For each u and i such that $D_i \geq 33 \lg n$, a separator $S_i(u)$ is maintained with a data structure $\mathcal{S}_i(u)$ as in Section 4.

We extend the range of index j by 1 so that $j \in \{0, \ldots, c+1\}$. Each structure $\mathcal{D}_{i,j}(u)$ maintains a growing set $M_{i,j}(u)$ of marked vertices; this set is initially empty. In the following, let $U_{i,j}(u) = V \setminus M_{i,j}(u)$ denote the set of unmarked vertices and let $G_{U_{i,j}(u)}$ denote the graph with vertex set V and containing the edges of G having at least one unmarked endpoint.

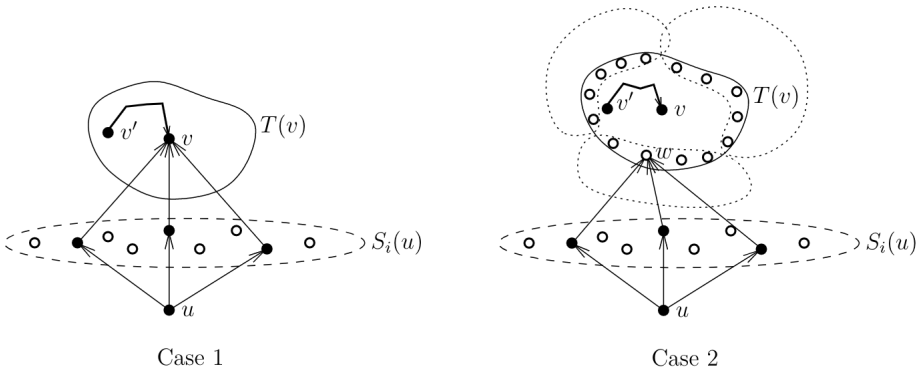

Figure 2 The two cases in the description of the randomized algorithm. Case 1: black vertices of $S_i(u)$ form the subset of vertices s with $\tilde{d}_{i-1}(u,s)+\tilde{d}_{i-1}(s,v) \leq d_{i,j}(1+\epsilon')^{2i}$. For each $v' \in V(T(v))$, $Q_{i,j}(u,v')$ is set to be this subset (with key values adjusted). 2-hop paths from u to v through the subset are shown. Case 2: Vertices of L are shown in white inside $T(v)$. Dotted regions are trees touching $T(v)$. For a $w \in L$, black vertices of $S_i(u)$ form the set $Q_{i,j}(u,w)$ and 2-hop paths from u to w through this set are shown. Q is the union of these sets over all $w \in L$. For each $v' \in V(T(v)) \setminus L$, $Q_{i,j}(u,v')$ is a subset of Q.

In each update, $\mathcal{D}_{i,j}(u)$ maintains $S_{i,j}(u,v)$ and $Q_{i,j}(u,v)$ for $v \in V$ in the following way.

For each $v \in V$ and every vertex s added to $S_i(u)$ in the current update, s is added to $S_{i,j}(u,v)$ with some probability p to be fixed later. Note that only vertices v for which s is actually added to $S_{i,j}(u,v)$ need to be processed. In the full version of the paper [5], we employ a different sampling scheme that avoids having to flip a coin for every vertex $v \in V$ in every update.

For vertices v such that $v \in M_{i,j}(u)$ or such that both $v \in U_{i,j}(u)$ and $\tilde{d}_{i-1}(u,v) \leq D_i(1+\epsilon')^{2i}$, no further processing is done.

Now, assume that $v \in U_{i,j}(u)$ and that $\tilde{d}_{i-1}(u,v) > D_i(1+\epsilon')^{2i}$. If this inequality did not hold in the previous update, each (sampled) vertex of $S_{i,j}(u,v)$ is added to a new min-queue $Q_{i,j}(u,v)$ with key values as in the previous section. Conversely, if the inequality did hold in the previous update, each new (sampled) vertex added to $S_{i,j}(u,v)$ in the current update is added to $Q_{i,j}(u,v)$.

If the min key value of $Q_{i,j}(u,v)$ is greater than $d_{i,j}(1+\epsilon')^{2i}$, $\mathcal{D}_{i,j}(u)$ grows an in-tree $T(v)$ from v in $G_{U_{i,j}(u)}$ up to radius $\epsilon' D_i$.

There are now two cases (see Figure 2): $|V(T(v)) \setminus M_{i,j}(u)| > \epsilon' D_i$ and $|V(T(v)) \setminus M_{i,j}(u)| \leq \epsilon' D_i$.

Case 1: If $|V(T(v)) \setminus M_{i,j}(u)| > \epsilon' D_i$ then $\mathcal{D}_{i,j}(u)$ scans once over $S_i(u)$ to find the subset of vertices $s \in S_i(u)$ for which $\tilde{d}_{i-1}(u,s) + \tilde{d}_{i-1}(s,v) \leq d_{i,j}(1+\epsilon')^{2i}$. For each $v' \in V(T(v))$, $Q_{i,j}(u,v')$ is set to contain exactly this subset of vertices s but with key value $\tilde{d}_{i-1}(u,s) + \tilde{d}_{i-1}(s,v')$.

Case 2: If $|V(T(v)) \setminus M_{i,j}(u)| \leq \epsilon' D_i$ then let $L = V(T(v)) \cap M_{i,j}(u)$ and let $Q = \cup_{v' \in L} Q_{i,j}(u,v')$. For each $v' \in V(T(v)) \setminus L$, $\mathcal{D}_{i,j}(u,v)$ sets $Q_{i,j}(u,v')$ to contain the elements $s \in Q$ with $\tilde{d}_{i-1}(u,s) + \tilde{d}_{i-1}(s,v) \leq d_{i,j}(1+\epsilon')^{2i}$; their key values are $\tilde{d}_{i-1}(u,s) + \tilde{d}_{i-1}(s,v')$.

In both cases, $\mathcal{D}_{i,j}(u)$ then marks all vertices of $T(v)$, i.e., $M_{i,j}(u) \leftarrow M_{i,j}(u) \cup V(T(v))$.

Approximate distances $\tilde{d}_{i,j}(u,v)$ are maintained by $\mathcal{D}_{i,j}(u)$ in a way similar to that in Section 4.2: $\tilde{d}_{i,j}(u,v) = (1+\epsilon')^{2i} d_{i,j}$ if the min key value of $Q_{i,j}(u,v)$ is at most $(1+\epsilon')^{2i} d_{i,j}$ and otherwise $\tilde{d}_{i,j}(u,v) = \infty$.

Data structures $\mathcal{D}_i(u)$ as well as the overall data structure $\mathcal{D}$ work exactly as in Section 4.2.

5.2 Correctness

Consider any point during the sequence of edge deletions. We will show that for suitable choice of ϵ', we have $d_G(u,v) \leq \tilde{d}(u,v) \leq (1+\epsilon) d_G(u,v)$.

We do this by proving that during all updates and for all vertex pairs (u,v), if $d_G(u,v) \in (0, D_{i+1}(1+\epsilon')]$ then $\tilde{d}_i(u,v) \leq (1+\epsilon')^{2i} d_G(u,v)$. By picking $\epsilon' = \ln(1+\epsilon)/(2\lfloor \log_\rho n \rfloor)$, this will give $d_G(u,v) \leq \tilde{d}_G(u,v) \leq (1+\epsilon')^{2\lfloor \log_\rho n \rfloor} d_G(u,v) \leq e^{2\lfloor \log_\rho n \rfloor \epsilon'} d_G(u,v) \leq (1+\epsilon) d_G(u,v)$, as desired.

The proof is by induction on i. The claim is clear for i with $D_i < 33 \lg n$ since then we use the data structure of Even and Shiloach. Now, consider an i with $D_i \geq 33 \lg n$ and assume that the claim holds for values less than i. By the induction hypothesis, we only need to consider pairs (u,v) with $d_G(u,v) \in (D_i(1+\epsilon'), D_{i+1}(1+\epsilon')]$, i.e., $d_G(u,v) \in (d_{i,j}, d_{i,j+1}]$ with $j > 0$.

We first show the following invariant for marked vertices that holds prior to each update over the entire sequence of updates:

▶ **Invariant 7.** *At the end of each update, for every $w \in M_{i,j}(u)$ with $d_G(u,w) \in (d_{i,j}, d_{i,j+1}]$, each shortest u-to-w path in G intersects a vertex $s \in Q_{i,j}(u,w)$ such that $d_G(u,s) \leq D_i$ and $d_G(s,w) \leq D_i$.*

Proof. The invariant is shown by induction on the rank of w in the order in which vertices are marked. Note that this is a proof by induction inside a step of the main proof by induction on i; in addition to the induction hypothesis stated above, we may thus assume that the invariant holds for values less than i. Additionally, for the current value of i, we may assume by induction that the invariant holds for vertices of lower rank than w.

Let t_1 be a time step with $w \in M_{i,j}(u)^{(t_1)}$ and $d_G^{(t_1)}(u,w) \in (d_{i,j}, d_{i,j+1}]$, let $t_0 \leq t_1$ be the time step in which w was marked, and let r be the vertex from which an in-tree $T(r) \ni w$ was grown in time step t_0. Let P be a shortest u-to-w path in $G^{(t_1)}$.

We must have $\tilde{d}_{i-1}^{(t_0)}(u,r) > D_i(1+\epsilon')^{2i}$ since otherwise, no processing would be done for r in time step t_0, contradicting that $T(r)$ is grown in that time step. We also have $d_G^{(t_0)}(u,r) > D_i(1+\epsilon')$ since otherwise the induction hypothesis would give the contradiction $D_i(1+\epsilon') \geq d_G^{(t_0)}(u,r) \geq \tilde{d}_{i-1}^{(t_0)}(u,r)/(1+\epsilon')^{2(i-1)} > D_i(1+\epsilon')^{2i-2(i-1)} = D_i(1+\epsilon')^2$.

By the triangle inequality and the fact that $w \in T(r)$ and $T(r)$ has radius at most $\epsilon' D_i$, we get $d_G^{(t_0)}(u,w) \geq d_G^{(t_0)}(u,r) - d_G^{(t_0)}(w,r) > D_i(1+\epsilon') - \epsilon' D_i = D_i$. Hence, $D_i < d_G^{(t_0)}(u,w) \leq d_G^{(t_1)}(u,w) \leq d_{i,j+1} \leq \frac{34}{33} D_i$ so by Lemma 6, P intersects $S_i^{(t_0)}(u)$ and for the first such intersection vertex s along P, $d_G^{(t_0)}(u,s) \leq d_G^{(t_1)}(u,s) \leq D_i$ and $d_G^{(t_0)}(s,w) \leq d_G^{(t_1)}(s,w) \leq D_i$. We consider the two cases in the description of $\mathcal{D}_{i,j}(u)$ (see Figure 3):

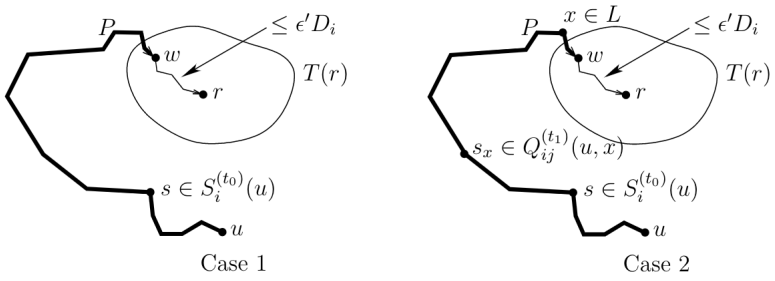

Figure 3 The two cases in the proof of Invariant 7. The path P is marked in bold.

Case 1. It suffices to show that $s \in Q_{i,j}^{(t_1)}(u, w)$. We have $d_G^{(t_0)}(s, r) \leq d_G^{(t_0)}(s, w) + d_G^{(t_0)}(w, r) \leq (1 + \epsilon')D_i$. By the induction hypothesis,

$$\begin{aligned}
\tilde{d}_{i-1}^{(t_0)}(u, s) + \tilde{d}_{i-1}^{(t_0)}(s, r) &\leq (1 + \epsilon')^{2(i-1)} d_G^{(t_0)}(u, r) \\
&\leq (1 + \epsilon')^{2i-2}(d_G^{(t_0)}(u, w) + \epsilon' D_i) \\
&\leq (1 + \epsilon')^{2i-2}(d_G^{(t_1)}(u, w) + \epsilon' D_i) \\
&\leq (1 + \epsilon')^{2i-2}(d_{i,j+1} + \epsilon' d_{i,j+1}) \\
&= (1 + \epsilon')^{2i} d_{i,j},
\end{aligned}$$

so $s \in Q_{i,j}^{(t_0)}(u, w) = Q_{i,j}^{(t_1)}(u, w)$, showing maintenance of the invariant.

Case 2. We first show that P must intersect the set L formed when growing $T(r)$ in time step t_0. Since we are in Case 2, every leaf of $T(r)$ either belongs to L or has no ingoing edges from vertices not in $T(r)$; otherwise, $T(r)$ would contain more than $\epsilon' D_i$ vertices since it is grown up to radius $\epsilon' D_i$. Hence, the only way that P could not intersect L would be if P were fully contained in $T(r)$. But this is not possible since then $T(r)$ would contain at least $|P| + 1 \geq d_{i,j} + 1 > D_i \geq \epsilon' D_i$ unmarked vertices at the beginning of time step t_0, contradicting that we are in Case 2.

Thus, P intersects L and we have $w \notin L$ since w was an unmarked vertex of $T(r)$ when growing this tree. Let x be the last vertex of P belonging to L. Since x was marked earlier than w, the induction hypothesis implies that the subpath of P from u to x intersects $Q_{i,j}^{(t_1)}(u, x) = Q_{i,j}^{(t_0)}(u, x)$ in a vertex s_x such that $d_G^{(t_0)}(u, s_x) \leq d_G^{(t_1)}(u, s_x) \leq D_i$ and $d_G^{(t_0)}(s_x, x) \leq d_G^{(t_1)}(s_x, x) \leq D_i$. The latter implies $d_G^{(t_0)}(s_x, r) \leq (1 + \epsilon')D_i$. By the induction hypothesis, $\tilde{d}_{i-1}^{(t_0)}(u, s_x) + \tilde{d}_{i-1}^{(t_0)}(s_x, r) \leq (1 + \epsilon')^{2(i-1)}(d_G^{(t_0)}(u, s_x) + d_G^{(t_0)}(s_x, r)) = (1 + \epsilon')^{2(i-1)} d_G^{(t_0)}(u, r)$ which by the same calculations as in Case 1 is at most $(1 + \epsilon')^{2i} d_{i,j}$. Inspecting the execution of $\mathcal{D}_{i,j}(u)$ in Case 2, it follows that $s_x \in Q_{i,j}^{(t_0)}(u, w) = Q_{i,j}^{(t_1)}(u, w)$. We have $s_x \in Q_{i,j}^{(t_0)}(u, x) \subseteq S_i^{(t_0)}(u)$. Since s is the first vertex of $S_i^{(t_0)}(u)$ along P, P can thus be decomposed into $u \rightsquigarrow s \rightsquigarrow s_x \rightsquigarrow x \rightsquigarrow w$ and we get $d_G^{(t_1)}(u, s_x) \leq D_i$ (as shown above) and $d_G^{(t_1)}(s_x, w) \leq d_G^{(t_1)}(s, w) \leq D_i$. This shows maintenance of the invariant with s_x in place of s. ◀

Now, we continue with our proof by induction on i. Consider any vertex pair (u, v) at the end of an update with $d_G(u, v) \in (d_{i,j}, d_{i,j+1}]$ and $j > 0$. If $v \notin M_{i,j}(u)$ and $\tilde{d}_{i-1}(u, v) \leq (1 + \epsilon')^{2i} D_i$ then $d_G(u, v) \leq \tilde{d}_{i,j}(u, v) \leq (1 + \epsilon')^{2i} D_i < (1 + \epsilon')^{2i} d_G(u, v)$, as desired.

Now assume that $v \notin M_{i,j}(u)$ and $\tilde{d}_{i-1}(u,v) > (1+\epsilon')^{2i}D_i$. Since v was not marked in the current update, the min key value of $Q_{i,j}(u,v)$ at the end of the update is at most $d_{i,j}(1+\epsilon')^{2i}$ so $d_G(u,v) \leq \tilde{d}_{i,j}(u,v) \leq (1+\epsilon')^{2i}d_{i,j} < (1+\epsilon')^{2i}d_G(u,v)$, as desired.

Finally assume that $v \in M_{i,j}(u)$. By Invariant 7, there is an $s \in Q_{i,j}(u,v)$ such that $d_G(u,v) = d_G(u,s) + d_G(s,v)$, $d_G(u,s) \leq D_i$, and $d_G(s,v) \leq D_i$. By the induction hypothesis, $d_G(u,v) \leq \tilde{d}_i(u,v) \leq \tilde{d}_{i-1}(u,s) + \tilde{d}_{i-1}(s,v) \leq (1+\epsilon')^{2(i-1)}d_G(u,v)$, as desired. This completes the inductive proof and correctness follows.

5.3 Running time

Maintaining separators $S_i(u)$ over all u and i takes $O(mn\log_\rho n) = O(mn\log n)$ time by Lemma 6. For the remaining time analysis, we focus on a single data structure $\mathcal{D}_{i,j}(u)$. It is useful in the following to regard this structure as handling an adversarial sequence of updates consisting of changes to approximate distances maintained by structures $\mathcal{D}_{i'}(v)$ for $i' < i$ and $v \in V$. We will give an expected time bound for $\mathcal{D}_{i,j}(u)$ and we shall rely on the following key lemma; the proof can be found in the full version of the paper [5].

▶ **Lemma 8.** *Let $r \in V$. If at some point in the sequence of updates, $\mathcal{D}_{i,j}(u)$ grows an in-tree from r then at the end of that update, the expected number of vertices $s \in S_i(u)$ satisfying $\tilde{d}_{i-1}(u,s) + \tilde{d}_{i-1}(s,r) \leq D_i(1+\epsilon')^{2i}$ is $O(\ln n/p)$. This bound holds against an adaptive adversary.*

▶ **Corollary 9.** *When a vertex v is marked, $E[|Q_{i,j}(u,v)|] = O(\ln n/p)$ and this bound holds against an adaptive adversary.*

Proof. Consider the update in which v is marked and let r be the root of the in-tree $T(r)$ containing v. If $|T(r)| \geq \epsilon' D_i$ then $Q_{i,j}(u,v) = Q_{i,j}(u,r) \subseteq S_i(u)$ and all $s \in Q_{i,j}(u,r)$ satisfy the inequality of Lemma 8. In the case where $|T(r)| < \epsilon' D_i$, let Q be as defined in the description of the data structure. Then vertices $s \in Q \subseteq S_i(u)$ are only added to $Q_{i,j}(u,v)$ if they satisfy the inequality of Lemma 8. The corollary now follows. ◀

Now, we can bound the time spent by $\mathcal{D}_{i,j}(u)$. The total time spent on growing in-trees is $O(m)$ since every edge (w_1,w_2) visited must have $w_1 \notin M_{i,j}(u)$ at the beginning of the BFS search and $w_1 \in M_{i,j}(u)$ immediately afterwards and a vertex can never be unmarked. This also bounds the time spent on marking vertices.

The total expected number of sampled vertices added to $Q_{i,j}(u,v)$ prior to v being marked is at most xp where x is the size of the set $S_i(u)$ after the final update. By Lemma 6, $x = O(n\log n/D_i)$. By Corollary 9, the expected size of $Q_{i,j}(u,v)$ after v is marked is $O(\ln n/p)$. Using the same argument as in the running time analysis of Section 4.2, the number of increase-key operations applied to a single element of $Q_{i,j}(u,v)$ is $O(\log n/\epsilon')$. Hence, the total expected time spent on operations on $Q_{i,j}(u,v)$ is $O((n\log n \cdot p/D_i + \log n/p)\log^3 n/\epsilon)$.

Whenever $\mathcal{D}_{i,j}(u)$ grows an in-tree $T(r)$ with $|V(T(r)) \setminus M_{i,j}(u,v)| > \epsilon' D_i$, scanning $S_i(u)$ takes $O(n\log n/D_i)$ time by Lemma 6. Since all vertices of $V(T(r)) \setminus M_{i,j}(u,v)$ are marked just after $T(r)$ is grown and since vertices are never unmarked, the number of such trees over the course of the updates is at most $n/(\epsilon' D_i)$ so the total time for all these scans is $O(n^2\log^2 n/(\epsilon D_i^2))$.

Whenever $\mathcal{D}_{i,j}(u)$ grows an in-tree $T(r)$ with $|V(T(r)) \setminus M_{i,j}(u,v)| \leq \epsilon' D_i$, the set $\cup_{x\in L}Q_{i,j}(u,x)$ needs to be computed. Note that for each $x \in L$, $E[|Q_{i,j}(u,x)|] = O(\log n/p)$ by Corollary 9. At least one edge (y,x) ingoing to x belongs to $T(r)$ and this edge is not part of any later grown in-tree since x is marked immediately after $T(r)$ is grown. We charge a cost of $O(\log n/p)$ to (y,x) for computing $Q_{i,j}(u,x)$. Over all $x \in L$, this pays for computing $\cup_{x\in L}Q_{i,j}(u,x)$ and we get a total expected time bound for this part of $O(m\log n/p)$.

Summing the above over all u, v, i, and j, we get a total expected time bound for our data structure of

$$\tilde{O}(mn/\epsilon + \sum_i \sum_j (n^3 \cdot p/(D_i\epsilon) + n^2/(p\epsilon) + n^3/(\epsilon D_i^2) + mn/p).$$

Since this bound is only fast for sufficiently large i, we pick a distance threshold d and apply the algorithm of Even and Shiloach for distances of at most d and our data structure for distances above d. By a geometric sums argument, our hybrid algorithm has a expected total time bound of

$$\begin{aligned}&\tilde{O}(mnd + mn/\epsilon + n^3 \cdot p/(d\epsilon^2) + n^2/(p\epsilon^2) + n^3/(\epsilon^2 d^2) + mn/(p\epsilon))\\ &= \tilde{O}(mnd + n^3 \cdot p/(d\epsilon^2) + n^2/(p\epsilon^2) + n^3/(d^2\epsilon^2) + mn/(p\epsilon))\end{aligned}$$

Setting the second and fifth terms equal to each other, we get $p = \tilde{\Theta}(\sqrt{m\epsilon d}/n)$ and the time bound simplifies to

$$\tilde{O}(mnd + \sqrt{m}n^2/(\sqrt{d}\epsilon^{3/2}) + n^3/(\sqrt{md}\epsilon^{5/2}) + n^3/(d^2\epsilon^2)).$$

We balance the first two terms by setting $d = \tilde{\Theta}(n^{2/3}/(m^{1/3}\epsilon))$ and we get a time bound of

$$\tilde{O}(m^{2/3}n^{5/3}n/\epsilon + n^{8/3}/(m^{1/3}\epsilon^2)),$$

which shows the time bound of Theorem 3.

Abstract

We investigate the polynomial-time approximability of the multistage version of Min-Sum Set Cover (Mult-MSSC), a natural and intriguing generalization of the classical List Update problem. In Mult-MSSC, we maintain a sequence of permutations $(\pi^0, \pi^1, \ldots, \pi^T)$ on n elements, based on a sequence of requests $\mathcal{R} = (R^1, \ldots, R^T)$. We aim to minimize the total cost of updating π^{t-1} to π^t, quantified by the Kendall tau distance $\mathrm{d_{KT}}(\pi^{t-1}, \pi^t)$, plus the total cost of covering each request R^t with the current permutation π^t, quantified by the position of the first element of R^t in π^t.

Using a reduction from Set Cover, we show that Mult-MSSC does not admit an $O(1)$-approximation, unless P = NP, and that any $o(\log n)$ (resp. $o(r)$) approximation to Mult-MSSC implies a sublogarithmic (resp. $o(r)$) approximation to Set Cover (resp. where each element appears at most r times). Our main technical contribution is to show that Mult-MSSC can be approximated in polynomial-time within a factor of $O(\log^2 n)$ in general instances, by randomized rounding, and within a factor of $O(r^2)$, if all requests have cardinality at most r, by deterministic rounding.

1 Introduction

In *Multistage Min-Sum Set Cover* (Mult-MSSC), we are given a universe U on n elements, a sequence of requests $\mathcal{R} = (R_1, \ldots, R_T)$, with $R_t \subseteq U$, and an initial permutation π^0 of the elements of U. We aim to maintain a sequence of permutations $(\pi^0, \pi^1, \ldots, \pi^T)$ of U, so as to minimize the total cost of updating (or moving from) π^{t-1} to π^t in each time step plus the total cost of covering each request R_t with the current permutation π^t. The cost of moving from π^{t-1} to π^t is the number of inverted element pairs between π^{t-1} and π^t, i.e., the Kendall Tau distance $\mathrm{d_{KT}}(\pi^{t-1}, \pi^t)$. The cost $\pi^t(R_t)$ of covering a request R_t with a permutation π^t is the position of the first element of R_t in π^t, i.e., $\pi^t(R_t) = \min\{i \,|\, \pi^t(i) \in R_t\}$. Thus, given $\mathcal{R} = (R_1, \ldots, R_T)$, we aim to minimize $\sum_{t=1}^{T} \left(\mathrm{d_{KT}}(\pi^{t-1}, \pi^t) + \pi^t(R_t)\right)$.

The Mult-MSSC problem is a natural generalization of the (offline version of the) classical *List Update* problem [26], where $|R_t| = 1$ for all requests $R_t \in \mathcal{R}$. The offline version of List Update is NP-hard [2], while it is known that any 5/4-approximation has to resort to *paid exchanges*, where an element different from the requested one is moved forward to the list [24, 28]. Mult-MSSC was introduced in [17] as the multistage extension of Min-Sum Set Cover (MSSC) [15], where we aim to compute a single static permutation π that minimizes the total covering cost $\sum_{t=1}^{T} \pi(R_t)$. [17] presented a (simple polynomial-time) online algorithm for Mult-MSSC with competitive ratio between $\Omega(r\sqrt{n})$ and $O(r^{3/2}\sqrt{n})$ for r-bounded instances, where all requests have cardinality at most r, and posed the polynomial-time approximability of Mult-MSSC as an interesting open question. Mult-MSSC is also related to recently studied time-evolving (a.k.a. multistage or dynamic) optimization problems (e.g., multistage matroid, spanning set and perfect matching maintenance [19], time-evolving Facility Location [14, 3]), where we aim to maintain a sequence of near-optimal feasible solutions to a combinatorial optimization problem, in response to time-evolving underlying costs, without changing too much the solution from one step to the next.

Motivation. Mult-MSSC is motivated by applications, such as web search, news, online shopping, paper bidding, etc., where items are presented to the users sequentially. Then, the item ranking is of paramount importance, because user attention is usually restricted to the first few items in the sequence (see e.g., [27, 13, 16, 10]). If a user does not spot an item fitting her interests there, she either leaves the service (in case of news or online shopping, see e.g., the empirical evidence in [12]) or settles on a suboptimal action (in case of paper bidding, see e.g., [11]). To mitigate such situations and increase user retention, modern online services highly optimize item rankings based on user scrolling and click patterns. Each user t is represented by her set of preferred items (or item categories) R_t . The goal of the service provider is to continually maintain an item ranking π^t, so that the current user t finds one of her favorite items at a relatively high position in π^t. Continual ranking update is dictated by the fact that users with different characteristics and preferences tend to use the online service during the course of the day (e.g., elderly people in the morning, middle-aged people in the evening, young people at the night – similar patterns apply for people from different countries and timezones). Moreover, different user categories react in nonuniform ways to different trends (in e.g., news, fashion, sports, scientific topics). For consistency and stability, however, the ranking should change neither too much nor too frequently. Mult-MSSC makes the (somewhat simplifying) assumptions that the service provider has a relatively accurate knowledge of user preferences and their arrival order, and that its total cost is proportional to how deep in π^t the current user t should reach, before she finds one of her favorite items, and to how much the ranking changes from one user to the next.

From a theoretical viewpoint, Mult-MSSC was used in [17] as a natural benchmark for studying the dynamic competitive ratio of Online Min-Sum Set Cover, where the algorithm updates its permutation online, without any knowledge of future requests. As in Mult-MSSC, the objective is to minimize the total moving plus the total covering cost.

Contribution and Techniques. In this work, we initiate a study of the polynomial-time approximability of Mult-MSSC. Using a reduction from Set Cover, we show (Theorem 7) that Mult-MSSC does not admit a $c \log n$-approximation, for some absolute constant c, unless P = NP. Moreover our reduction establishes that an $o(r)$-approximation for r-bounded instances of Mult-MSSC implies an $o(r)$-approximation for Set Cover, in case each element appears in at most r requests.

Our main technical contribution is to show that Mult-MSSC can be approximated in polynomial-time within a factor of $O(\log^2 n)$ in general instances, by randomized rounding (Theorem 10), and within a factor of $O(r^2)$ in r-bounded instances, by deterministic rounding (Theorem 11).

For both results, we consider a restricted version of Mult-MSSC, inspired by the Move-to-Front (MTF) algorithm for List Update, where in each time step t, we can only move a single element of R_t from its position in π^{t-1} to the first position of π^t. Since such a permutation π^t coves R_t with unit cost, we now aim to select the element of each R_t moved to front of π^t, so as to minimize the total moving cost $\sum_{t=1}^{T} \mathrm{d_{KT}}(\pi^{t-1}, \pi^t)$. It is not hard to see that the optimal cost of serving $\mathcal{R}$ under the restricted Move-to-Front version of Mult-MSSC is within a factor of 4 from the optimal cost under the original, more general, definition of Mult-MSSC.

Hence, approximating Mult-MSSC boils down to determining which element of R_t should become the top element of π^t. To this end, we relax permutations to doubly stochastic matrices and consider a Linear Programming relaxation of the restricted Move-to-Front version of Mult-MSSC, which we call *Fractional-MTF* (see Definition 8). Given the optimal solution of the aforementioned linear program, which is a sequence of doubly stochastic matrices $(A^0, A^1, \ldots, A^T)$, with A^0 corresponding to the initial permutation π^0, our main technical challenge is to round each doubly stochastic matrix A^t to a permutation π^t such that (i) there is an element of R_t at one of the few top positions of π^t; and (ii) the total moving cost $\sum_{t=1}^{T} \mathrm{d_{KT}}(\pi^{t-1}, \pi^t)$ of the rounded solution is comparable to the total moving cost $\sum_{t=1}^{T} \mathrm{d_{FR}}(A^{t-1}, A^t)$ of the optimal solution of Fractional-MTF, where $\mathrm{d_{FR}}$ is a notion of distance equivalent to Spearman's footrule distance on permutations (see Definition 4).

Working towards a randomized rounding approach, we first observe that rounding each doubly stochastic matrix independently may result in a permutation sequence with total moving cost significantly larger than that of Fractional-MTF (see also the discussion after Lemma 9). In Theorem 10, we show that a dependent randomized rounding with logarithmic scaling of entries (Algorithm 1), similar in spirit with the randomized rounding approach [8, 25] for Generalized Min-Sum Set Cover, results in an approximation ratio of $O(\log^2 n)$. Interestingly, Algorithm 1 without the logarithmic scaling results in a permutation sequence with the expected moving cost within a factor of 4 from the optimal moving cost of Fractional-MTF. However, we lose a logarithmic factor in the approximation ratio, because we need to scale up the entries of each doubly stochastic matrix A^t, so as to ensure that some element of R_t appears in the few top positions of π^t with sufficiently large probability. The other logarithmic factor is lost because there could be a logarithmic number of elements allocated to the same position of the resulting permutation by the randomized rounding.

Our deterministic rounding of Algorithm 2 for r-bounded request sequences is motivated by the deterministic rounding for Set Cover and Vertex Cover. We observe that in the optimal solution of Fractional-MTF, in each time step t, there is some element $e \in R_t$ with $A^t_{e1} \geq 1/r$ (i.e., e occupies a fraction of at least $1/r$ of the first position in the "fractional permutation" A^t). Algorithm 2 simply moves any such element to the front of π^t. The most challenging part of the analysis is to establish that for any optimal solution $(A^0, A^1, \ldots, A^T)$ of Fractional-MTF with respect to an r-bounded request sequence, there exists a sequence of doubly stochastic matrices $(A^0, \hat{A}^1, \ldots, \hat{A}^T)$ with the entries of each $\hat{A}^t$ being multiples of $1/r$, such that (i) the moving cost of $(A^0, \hat{A}^1, \ldots, \hat{A}^T)$ is bounded from above by the optimal cost of Fractional-MTF; and (ii) each matrix $\hat{A}^t$ contains in the first position the element that Algorithm 2 keeps in the first position at round t, with mass at least $1/r$. Then we show (Lemma 20) that for any sequence of doubly stochastic matrices $(A^0, \hat{A}^1, \ldots, \hat{A}^T)$ satisfying the above properties, the moving cost of Algorithm 2 is at most the moving cost of the doubly stochastic matrices, $\sum_{t=1}^{T} \mathrm{d_{FR}}(\hat{A}^t, \hat{A}^{t-1})$. The latter is done through the use of an appropriate potential function based on an extension of the Kendall-Tau distance to doubly stochastic matrix with entries being multiples of $1/r$.

A potentially interesting insight is that the technical reason for the quadratic dependence of our approximation ratios on $\log n$ and r is conceptually similar to the reason for the (best possible) approximation ratio of $4 = 2 \cdot 2$ in [15] (see the discussion after Theorem 10). Hence, we conjecture that any $o(\log^2 n)$ (resp. $o(r^2)$) approximation to Mult-MSSC must imply a sublogarithmic (resp. $o(r)$) approximation to Set Cover.

Other Related Work. The MSSC problem generalizes various NP-hard problems, such as Min-Sum Vertex Cover and Min-Sum Coloring and it is well-studied. Feige, Lovasz and Tetali [15] proved that the greedy algorithm, which picks in each position the element that covers the most uncovered requests, is a 4-approximation (that was also implicit in [9]) and that no $(4 - \varepsilon)$-approximation is possible, unless P = NP. In Generalized MSSC (a.k.a. *Multiple Intents Re-ranking*), there is a covering requirement $K(R_t)$ for each request R_t and the cost of covering a request R_t is the position of the $K(R_t)$-th element of R_t in the (static) permutation π. The MSSC problem is the special case where $K(R_t) = 1$ for all requests R_t. Another notable special case of Generalized MSSC is the Min-Latency Set Cover problem [20], which corresponds to the other extreme case where $K(R_t) = |R_t|$ for all requests R_t. Generalized MSSC was first studied by Azar et al. [5], who presented a $O(\log r)$-approximation; later $O(1)$-approximation algorithms were obtained [8, 25, 23, 6].

Further generalizations of Generalized MSSC have been considered, such as the Submodular Ranking problem, studied in [4], which generalizes both Set Cover and MSSC, and the Min-Latency Submodular Cover, studied by Im et al. [22]. We refer to [22, 21] for a detailed discussion on the connections between these problems and their applications.

The online version of MSSC, which generalizes the famous List Update problem, was studied in [17]. They proved that its static deterministic competitive ratio is $\Theta(r)$ and presented a natural memoryless algorithm, called *Move-all-Equally*, with static competitive ratio in $\Omega(r^2)$ and $2^{O(\sqrt{\log n \cdot \log r})}$ and dynamic competitive ratio in $\Omega(r\sqrt{n})$ and $O(r^{3/2}\sqrt{n})$-competitive. Subsequently, [18] considered MSSC from the viewpoint of online learning. Through dimensionality reduction from permutations to doubly stochastic matrices, they obtained randomized (resp. deterministic) polynomial-time online learning algorithms with $O(1)$-regret for Generalized MSSC (resp. $O(r)$-regret for MSSC).

2 Preliminaries and Basic Definitions

The set of elements e is denoted by U with $|U| = n$. A permutation of the elements is denoted by π where π_i denotes the element lying at position i (for $1 \leq i \leq n$) and $\mathrm{Pos}(e, \pi)$ denotes the position of the element $e \in U$ in permutation π.

▶ **Definition 1** (Kendall-Tau Distance). *Given the permutations π^A, π^B, a pair of elements (e, e') is inverted if and only if $\mathrm{Pos}(e, \pi^A) > \mathrm{Pos}(e', \pi^A)$ and $\mathrm{Pos}(e, \pi^B) < \mathrm{Pos}(e', \pi^B)$ or vice versa. The Kendall-Tau distance between the permutations π^A, π^B, denoted by $\mathrm{d_{KT}}(\pi^A, \pi^B)$, is the number of inverted pairs.*

▶ **Definition 2** (Spearman' Footrule Distance). *The FootRule distance between the permutations π^A, π^B is defined as $\mathrm{d_{FR}}(\pi^A, \pi^B) = \sum_{e \in U} |\mathrm{Pos}(e, \pi^A) - \mathrm{Pos}(e, \pi^B)|$.*

The Kendall-Tau distance and FootRule distance are approximately equivalent, $\mathrm{d_{KT}}(\pi^A, \pi^B) \leq \mathrm{d_{FR}}(\pi^A, \pi^B) \leq 2 \cdot \mathrm{d_{KT}}(\pi^A, \pi^B)$. Moreover both of them satisfy the triangle inequality.

▶ **Definition 3.** *An $n \times n$ matrix with positive entries (rows stand for the elements and columns for the positions) is called stochastic if $\sum_{i=1}^{n} A_{ei} = 1$ for all $e \in U$ and doubly stochastic if (additionally) $\sum_{e \in U} A_{ei} = 1$ for all $1 \leq i \leq n$.*

A permutation of the elements π can be equivalent represented by a 0-1 doubly stochastic matrix A, where $A_{ei} = 1$ if element e lies at position i and 0 otherwise. When clear from context, we use the notion of permutation and (0-1) doubly stochastic matrix interchangeably.

The notion of FootRule distance can be naturally extended to stochastic matrices. Given two doubly stochastic matrices A, B consider the min-cost transportation problem, transforming row A_e to the row B_e where the cost of transporting a unit of mass between column i and column j equals $|i - j|$. Formally for each row e, define a complete bipartite graph where on the left part lie the entries (e, i) for $1 \leq i \leq n$ and on the right part the entries (e, j) for $1 \leq j \leq n$. The mass transported from entry (e, i) to entry (e, j) (denoted as f_{ij}^e) costs $f_{ij}^e \cdot |i - j|$ and the total mass *leaving* (e, i) equals A_{ei} and the total mass *arriving* at (e, j) equals B_{ej}.

▶ **Definition 4.** *The FootRule distance between two stochastic matrices A, B, denoted by $\mathrm{d_{FR}}(A, B)$, is the optimal value of the following linear program,*

$$
\begin{aligned}
\textit{min} \quad & \sum_{e \in U} \sum_{i=1}^{n} \sum_{j=1}^{n} |i - j| \cdot f_{ij}^e \\
\textit{s.t} \quad & \sum_{i=1}^{n} f_{ij}^e = B_{ej} \qquad \textit{for all } e \in U \textit{ and } j = 1, \ldots, n \\
& \sum_{j=1}^{n} f_{ij}^e = A_{ei} \qquad \textit{for all } e \in U \textit{ and } i = 1, \ldots, n \\
& f_{ij}^e \geq 0 \qquad\qquad \textit{for all } e \in U \textit{ and } i, j = 1, \ldots, n
\end{aligned}
$$

▶ **Example 5.** Let the stochastic matrices $A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$, $B = \begin{pmatrix} 1/3 & 1/3 & 1/3 \\ 1/2 & 1/2 & 0 \\ 1/4 & 0 & 3/4 \end{pmatrix}$. The FootRule distance $\mathrm{d_{FR}}(A, B) = \underbrace{(0 \cdot 1/3 + 1 \cdot 1/3 + 2 \cdot 1/3)}_{\text{first row}} + \underbrace{(1 \cdot 1/2 + 0 \cdot 1/2 + 1 \cdot 0)}_{\text{second row}} + \underbrace{(2 \cdot 1/4 + 1 \cdot 0 + 0 \cdot 3/4)}_{\text{third row}} = 2$.

Up next we present the formal definition of Multistage Min-Sum Set Cover.

▶ **Definition 6** (Multistage Min-Sum Set Cover)**.** *Given a universe of elements U, a sequence of requests $R_1, \ldots, R_T \subseteq U$ and an initial permutation of the elements π^0. The goal is to select a sequence of permutation $\pi^1, \ldots, \pi^T$ that minimizes*

$$\sum_{t=1}^{T} \pi^t(R_t) + \sum_{t=1}^{T} \mathrm{d_{KT}}(\pi^t, \pi^{t-1})$$

where $\pi^t(R_t)$ is the position of the first element of R_t that we encounter in π^t, $\pi^t(R_t) = \min\{1 \leq i \leq n : \pi^t_i \in R_t\}$.

We refer to $\sum_{t=1}^{T} \pi^t(R_t)$ as **covering cost** and to $\sum_{t=1}^{T} \mathrm{d_{KT}}(\pi^t, \pi^{t-1})$ as **moving cost**. We denote with π^t_{Opt} the permutation of the optimal solution of Mult-MSSC at round t, with o_t the element that the optimal solution uses to cover the request R_t (the element of R_t appearing first in π^t_{Opt}), and with $\mathrm{OPT}_{\text{Mult-MSSC}}$ the cost of the optimal solution. Finally we call an instance of Mult-MSSC *r-bounded* in case the cardinality of the requests is bounded by r, $|R_t| \leq r$.

3 Approximation Algorithms for Dynamic Min-Sum Set Cover

There exists an approximation-preserving reduction from Set − Cover to Mult-MSSC that provides us with the following inapproximability results.

▶ **Theorem 7.**

- *There is no $c \cdot \log n$-approximation algorithm for* Mult-MSSC *(for a sufficiently small constant c) unless* P = NP.
- *For r-bounded sequences, there is no $o(r)$-approximation algorithm for* Mult-MSSC*, unless there is a $o(r)$-approximation algorithm for* Set − Cover *with each element being covered by at most r sets.*

The proof of Theorem 7 is fairly simple, given an instance of Set − Cover we construct an instance of Mult-MSSC in which the initial permutation π^0 contains in the first positions some dummy elements (they do not appear in any of the requests) and in the last positions the sets of the Set − Cover (we consider an element of Mult-MSSC for each set of Set − Cover). Finally each request for Mult-MSSC is associated with an element of the Set − Cover and contains the *elements in* Mult-MSSC*/ sets in* Set − Cover containing it.

Proof. Let the equivalent definition of Set − Cover in which we are given a universe of element $E = \{1, \ldots, n\}$ and sets $S_1, S_2, \ldots, S_m \subseteq E$ and we are asked to select the minimum number of elements covering all the sets (an element e covers set S_i if $e \in S_i$).

Consider the instance of Mult-MSSC with the elements $U = \{1, \ldots, n\} \cup \{d_1, \ldots, d_{n^2m}\}$. The elements $\{d_1, \ldots, d_{n^2m}\}$ are dummy in the sense that they appear in none of the requests R_t. Let the initial permutation π_0 contain in the first n^2m positions the dummy elements and in the last n positions the elements $\{1, \ldots, n\}$, $\pi_0 = [d_1, \ldots, d_{n^2m}, 1, \ldots, n]$ and the request sequence of Mult-MSSC be $S_1, S_2, \ldots, S_m$.

Let a c-approximation algorithm for Mult-MSSC producing the permutation $\pi_1, \ldots, \pi_m$ the cost of which is denoted by Alg. Let also CoverAlg denote the set composed by the element that the c-approximation algorithm uses to cover the requests, CoverAlg = {the element of S_t appearing first in π_t}. Then,

$$\mathrm{Alg} \geq n^2 m \cdot |\mathrm{CoverAlg}|.$$

Now consider the following solution for Mult-MSSC constructed by the optimal solution for Set − Cover. This solution initially moves the elements of the optimal covering set $\mathrm{OPT}_{\mathrm{SetCover}}$ to the first positions and then never changes the permutation. Clearly the cost of this solution is upper bounded by

$$\text{Set} - \text{Cover}_{\text{Mult-MSSC}} \leq \underbrace{|\mathrm{OPT}_{\mathrm{SetCover}}| \cdot (n^2 m + n)}_{\text{moving cost}} + \underbrace{m \cdot |\mathrm{OPT}_{\mathrm{SetCover}}|}_{\text{covering cost}}.$$

In case $\mathrm{Alg} \leq c \cdot \text{Set} - \text{Cover}_{\text{Mult-MSSC}}$, we directly get that $|\mathrm{CoverAlg}| \leq 3c \cdot |\mathrm{OPT}_{\mathrm{SetCover}}|$. There is no polynomial-time approximation algorithm for Set−Cover with approximation ratio better than $\log m$. The latter holds even for instance of Set − Cover for which $m = \mathrm{poly}(n)$ [1] where $\mathrm{poly}(\cdot)$ is a polynomial with degree bounded by a universal constant. Since the number of elements $|U|$, in the constructed instance of Mult-MSSC is $n^2 m$, any $c \cdot \log |U|$-approximation for Mult-MSSC (for c sufficiently small) implies an approximation algorithm for Set − Cover with approximation ratio less than $\log n$. In case there exists an $c = o(r)$-approximation algorithm for Mult-MSSC for requests sequences $R_1, \ldots, R_T$ where $|R_t| \leq r$, we obtain an $o(r)$-approximation for algorithm for Set − Cover for sets with cardinality bounded by r. In the standard form of Set − Cover this is translated into the fact that each element belongs in at most r sets. ◀

Both the $O(\log^2 n)$-approximation algorithm (for requests of general cardinality) and the $O(r^2)$-approximation algorithm for r-bounded requests, that we subsequently present, are based on rounding a linear program called *Fractional Move To Front*. The latter is the linear program relaxation of *Move To Front*, a problem closely related to Multistage Min-Sum Set Cover. MTF asks for a sequence of permutations $\pi^1, \ldots, \pi^T$ such as at each round t, an element of R_t lies on the first position of π^t and $\sum_{t=1}^{T} \mathrm{d}_{\mathrm{FR}}(\pi^t, \pi^{t-1})$ is minimized.

▶ **Definition 8.** *Given a sequence of requests $R_1, \ldots, R_T \subseteq U$ and an initial permutation of the elements π^0, consider the following linear program, called* Fractional − MTF*,*

$$\begin{aligned}
\textit{min} \quad & \sum_{t=1}^{T} \mathrm{d}_{\mathrm{FR}}(A^t, A^{t-1}) \\
\textit{s.t} \quad & \sum_{i=1}^{n} A^t_{ei} = 1 \qquad \textit{for all } e \in U \textit{ and } t = 1, \ldots, T \\
& \sum_{e \in U} A^t_{ei} = 1 \qquad \textit{for all } i = 1, \ldots, n \textit{ and } t = 1, \ldots, T \\
& \sum_{e \in R_t} A^t_{e1} = 1 \qquad \textit{for all } t = 1, \ldots, T \\
& A^0 = \pi^0 \\
& A^t_{ei} \geq 0 \qquad \textit{for all } e \in U,\ i = 1, \ldots, n \textit{ and } t = 1, \ldots, T
\end{aligned}$$

where $\mathrm{d}_{\mathrm{FR}}(\cdot, \cdot)$ is the FootRule distance of Definition 4.

There is an elegant argument (appeared in previous works, e.g., [17]) showing that the optimal solution of MTF is at most $4 \cdot \mathrm{OPT}_{\text{Mult-MSSC}}$. In Lemma 9 we provide the argument and establish that Fractional − MoveToFront is a 4-approximate relaxation of Mult-MSSC.

▶ **Lemma 9.** $\sum_{t=1}^{T} \mathrm{d}_{\mathrm{FR}}(A^t, A^{t-1}) \leq 4 \cdot \mathrm{OPT}_{\text{Mult-MSSC}}$ *where $A^1, \ldots, A^t$ is the optimal solution of* Fractional − MTF*.*

Proof of Lemma 9. Let o_t the element of R_t appearing first in the permutation π^t_{Opt}. Consider the sequence of permutation $\pi^0, \pi^1, \ldots, \pi^T$ constructed by moving at each round t, the element o_t to the first position of the permutation. Notice that $\pi^0, \pi^1, \ldots, \pi^T$ is a feasible solution for both MoveToFront and Fractional $-$ MTF. The first key step towards the proof of Lemma 9 is that

$$\mathrm{d}_{\mathrm{KT}}(\pi^t, \pi^{t-1}) + \mathrm{d}_{\mathrm{KT}}(\pi^t, \pi^t_{\text{Opt}}) - \mathrm{d}_{\mathrm{KT}}(\pi^{t-1}, \pi^t_{\text{Opt}}) \leq 2 \cdot \pi^t_{\text{Opt}}(R_t)$$

To understand the above inequality, let k_t be the position of o_t in permutation π^{t-1}. Out of the $k_t - 1$ elements on the right of o_t in permutation π^{t-1}, let $Left_t$ ($Right_t$) denote the elements that are on the left (right) of o_t in permutation π^{t-1}_{Opt}. It is not hard to see that $\pi^t_{\text{Opt}}(R_t) \geq |Left_t|$, $\mathrm{d}_{\mathrm{KT}}(\pi^t, \pi^{t-1}) = |Left_t| + |Right_t|$ and $\mathrm{d}_{\mathrm{KT}}(\pi^t, \pi^t_{\text{Opt}}) - \mathrm{d}_{\mathrm{KT}}(\pi^{t-1}, \pi^t_{\text{Opt}}) = |Left_t| - |Right_t|$. Using the fact that $\mathrm{d}_{\mathrm{KT}}(\pi^t, \pi^t_{\text{Opt}}) - \mathrm{d}_{\mathrm{KT}}(\pi^{t-1}, \pi^t_{\text{Opt}}) \leq \mathrm{d}_{\mathrm{KT}}(\pi^t_{\text{Opt}}, \pi^{t-1}_{\text{Opt}})$ and the previous inequality we get,

$$\mathrm{d}_{\mathrm{KT}}(\pi^t, \pi^{t-1}) + \mathrm{d}_{\mathrm{KT}}(\pi^t, \pi^t_{\text{Opt}}) - \mathrm{d}_{\mathrm{KT}}(\pi^{t-1}, \pi^{t-1}_{\text{Opt}}) \leq 2 \cdot \pi^t_{\text{Opt}}(R_t) + \mathrm{d}_{\mathrm{KT}}(\pi^t_{\text{Opt}}, \pi^{t-1}_{\text{Opt}})$$

and by a telescopic sum we get $\sum_{t=1}^{T} \mathrm{d}_{\mathrm{KT}}(\pi^t, \pi^{t-1}) \leq 2 \cdot \mathrm{OPT}_{\text{Mult-MSSC}}$. The proof follows by the fact that $\mathrm{d}_{\mathrm{FR}}(\pi^t, \pi^{t-1}) \leq 2 \cdot \mathrm{d}_{\mathrm{KT}}(\pi^t, \pi^{t-1})$. ◀

As already mentioned, our main technical contribution is the design of *rounding schemes* converting the optimal solution, $A^1, \ldots, A^T$, of Fractional $-$ MTF into a sequence of permutations $\pi^1, \ldots, \pi^T$. This is done so as to bound the moving cost of our algorithms by the moving cost $\sum_{t=1}^{T} \mathrm{d}_{\mathrm{FR}}(A^t, A^{t-1})$. We then separately bound the covering cost, $\sum_{t=1}^{T} \pi^t(R_t)$ by showing that always an element of R_t lies on the first positions of π^t.

The main technical challenge in the design of our rounding schemes is ensure to that the moving cost of our solutions $\sum_{t=1}^{T} \mathrm{d}_{\mathrm{KT}}(\pi^t, \pi^{t-1})$ is approximately bounded by the moving cost $\sum_{t=1}^{T} \mathrm{d}_{\mathrm{FR}}(A^t, A^{t-1})$. Despite the fact that the connection between doubly stochastic matrices and permutations is quite well-studied and there are various rounding schemes converting doubly stochastic matrices to probability distributions on permutations (such as the Birkhoff–von Neumann decomposition or the schemes of [8, 25, 6, 17]), using such schemes in a *black-box* manner does not provide any kind of positive results for Mult-MSSC. For example consider the case where $A^1 = \cdots = A^T$ and thus $\sum_{t=1}^{T} \mathrm{d}_{\mathrm{FR}}(A^t, A^{t-1}) = \mathrm{d}_{\mathrm{FR}}(A^1, A^0)$. In case a randomized rounding scheme is applied *independently to each* A^t, there always exists a positive probability that $\pi^t \neq \pi^{t-1}$ and thus the moving cost will far exceed $\mathrm{d}_{\mathrm{FR}}(A^1, A^0)$ as T grows. The latter reveals the need for *coupled rounding schemes* that convert the overall sequence of matrices $A^1, \ldots, A^T$ to a sequence of permutations $\pi^1, \ldots, \pi^T$. Such a rounding scheme is presented in Algorithm 1 and constitutes the back-bone of our approximation algorithm for requests of general cardinality.

The rounding scheme described in Algorithm 1, imposes correlation between the different time-steps by simply requiring that each element e selects α_e once and for all and by breaking ties lexicographically (any consistent tie-breaking rule would also work). In Lemma 12 of Section 4, we show that no matter the sequence of doubly stochastic matrices, the rounding scheme of Algorithm 1 produces a sequence of permutations with overall moving cost at most $4 \log^2 n$ the moving cost of the matrix-sequence[1] and thus establishes that the overall moving cost of Algorithm 1 is bounded by $4 \log^2 n \cdot \mathrm{OPT}_{\text{Mult-MSSC}}$. The $\log n$ multiplication

[1] By omitting the $\log n$-multiplication step of Step 7, one could establish that the moving cost of the produced permutations is at most 4 times the moving cost of the matrix-sequence, however omitting the $\log n$ multiplication could lead in prohibitively high covering cost.

Algorithm 1 A Randomized Algorithm for Mult-MSSC.

Input: A sequence of requests $R_1, \ldots, R_T$ and an initial permutation of the elmenents π^0.
Output: A sequence of permutations $\pi^1, \ldots, \pi^T$.

1: Find the optimal solution $A^0 = \pi^0, A^1, \ldots, A^T$ for Fractional $-$ MTF.
2: **for** each element $e \in U$ **do**
3: Select α_e uniformly at random in $[0, 1]$.
4: **end for**
5: **for** $t = 1 \ldots T$ **do**
6: **for** all elements $e \in U$ **do**
7: $I_e^t := \text{argmin}_{1 \leq i \leq n} \{\log n \cdot \sum_{s=1}^{i} A_{es}^t \geq \alpha_e\}$.
8: **end for**
9: $\pi^t :=$ sort elements according to I_e^t with ties being broken lexicographically.
10: **end for**

in Step 7 serves as a *probability amplifier* ensuring that at least one element of R_t lies in the relatively first positions of π^t and permits us to approximately bound the covering cost $\sum_{t=1}^{T} \mathbb{E}[\pi^t(R_t)]$ by the covering cost of the optimal solution for Mult-MSSC, $\sum_{t=1}^{T} \pi_{\text{Opt}}^t(R_t)$.

▶ **Theorem 10.** *Algorithm 1 is a $O(\log^2 n)$-approximation algorithm for* Mult-MSSC.

Despite the fact that in Step 7 of Algorithm 1, we multiply the entries of A^t with $\log n$ the overall guarantee is $O(\log^2 n)$. At a first glance the latter seems quite strange but admits a rather natural explanation. For most of the positions i, the probability that an element e admits index $I_e^t = i$ is roughly $\log n \cdot A_{ei}^t$, but due to the fact each index $j \leq i$ is on expectation selected by $\log n$ other elements, the expected position of e in the produced permutation is roughly $\log^2 n$ times the expected value of $\text{argmin}_{1 \leq i \leq n} \{\sum_{s=1}^{i} A_{es}^t \geq \alpha_e\}$. This phenomenon relates with the elegant fitting argument given in [15] to prove that the greedy algorithm is 4-approximation for the original *Min-Sum Set Cover* (which is tight unless P = NP). The latter makes us conjecture that the tight inapproximability bound for Mult-MSSC is $\Omega(\log^2 n)$ for requests of general cardinality.

Motivated by the r-approximation LP-based algorithm for instances of Set $-$ Cover in which elements belong in at most r sets, we examine whether the $O(\log^2 n)$ for Mult-MSSC can be ameliorated in case of r-bounded request sequences. Interestingly, the simple *greedy rounding* scheme (described[2] in Algorithm 2) provides such a $O(r^2)$-approximation algorithm.

Algorithm 2 A Greedy-Rounding Algorithm for Mult-MSSC for r-Bounded Sequences.

Input: A request sequence $R_1, \ldots, R_T$ with $|R_t| \leq r$ and an initial permutation π^0.
Output: A sequence of permutations $\pi^1, \ldots, \pi^T$.

1: Find the optimal solution $A^0 = \pi^0, A^1, \ldots, A^T$ for Fractional $-$ MTF.
2: **for** $t = 1 \ldots T$ **do**
3: $\pi^t :=$ in π^{t-1}, move to the first position an element $e \in R_t$ such that $A_{e1}^t \geq 1/r$
4: **end for**

[2] Step 3 of Algorithm 2 is well-defined since $|R_t| \leq r$ and $\sum_{e \in R_t} A_{e1}^t = 1$.

The $O(r^2)$-approximation guarantee of Algorithm 3 is formally stated and proven in Theorem 11. The main technical challenge is that we cannot directly compare the moving cost of Algorithm 2 with $\sum_{t=1}^{T} \mathrm{d_{FR}}(A^t, A^{t-1})$ and thus we deploy a two-step detour.

In the first step (Lemma 19), we prove the existence of a sequence of doubly stochastic matrices $\hat{A}^0 = \pi^0, \hat{A}^1, \ldots, \hat{A}^T$ for which each $\hat{A}^t$ satisfies that **(i)** its entries of are **multiples of $1/r$**, **(ii)** $\hat{A}^t_{e_t 1} \geq 1/r$ where e_t is the element that Algorithm 2 moves to the first position at round t, and **(iii)** the sequence $\hat{A}^0 = \pi^0, \hat{A}^1, \ldots, \hat{A}^T$ admits moving cost at most $\sum_{t=1}^{T} \mathrm{d_{FR}}(A^t, A^{t-1})$. In order to establish the existence of such a sequence, we construct an appropriate linear program (see Definition 18) based on the elements that Algorithm 2 moves to the first position at each round and prove that it admits an optimal solution with values being multiples of $1/r$. To do the latter, we relate the linear program of Definition 18 with a fractional version of the k-Paging [7] problem and based on the optimal eviction policy (*evict the page appearing the furthest in the future*), we design an algorithm producing optimal solutions for the LP with values being multiple of $1/r$.

In the second step (Lemma 20), we show that for any sequence $\hat{A}^0 = \pi^0, \hat{A}^1, \ldots, \hat{A}^T$ satisfying properties **(i)** and **(ii)**, the moving cost of Algorithm 2 is at most $O(r^2) \cdot \sum_{t=1}^{T} \mathrm{d_{FR}}(\hat{A}^t, \hat{A}^{t-1})$. The latter is achieved through the use of an appropriate *potential function* based on a generalization of Kendall-Tau distance to doubly stochastic matrices with entries being multiples of $1/r$ (see Definition 23).

▶ **Theorem 11.** *Algorithm 2 is a $O(r^2)$-approximation algorithm for* Mult-MSSC.

In Section 4 and 5 we provide the basic steps and ideas in the proof of Theorem 10 and 11 respectively.

4 Proof of Theorem 10

The basic step towards the proof of Theorem 10 is Lemma 12, establishing the fact that once two doubly stochastic matrices are given as input to the randomized rounding of Algorithm 1, the expected distance of the produced permutations is approximately bounded by the distance of the respective doubly stochastic matrices.

▶ **Lemma 12.** *Let the doubly stochastic matrices A, B given as input to the rounding scheme of Algorithm 1. Then for the produced permutations π^A, π^B, $\mathbb{E}\left[\mathrm{d_{KT}}(\pi^A, \pi^B)\right] \leq 4 \log^2 n \cdot \mathrm{d_{FR}}(A, B)$.*

Before exhibiting the proof of Lemma 12 we introduce the notion of *neighboring matrices*.

▶ **Definition 13.** *(Neighboring stochastic matrices) The stochastic matrices A, B are neighboring if and only if they differ in exactly two entries lying on the same row and on consecutive columns.*

▶ **Example 14.** Let $A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$, $B = \begin{pmatrix} 1/2 & 1/2 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$ and $C = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}$. The pair of matrices (A, B) and (A, C) are neighboring while (B, C) are not.

Any doubly stochastic matrix A can be converted to another doubly stochastic matrix B through an intermediate sequence of neighboring stochastic matrices all of which are *almost doubly stochastic* and their overall moving cost equals $\mathrm{d_{FR}}(A, B)$.

▷ Claim 15. Given the doubly stochastic matrices A, B, there exists a finite sequence of stochastic matrices, $A^0, \ldots, A^T$ such that

1. $A^0 = A$ and $A^T = B$.
2. A^t and A^{t-1} are neighboring.
3. the column-sum is bounded by 2, $\sum_{e \in U} A^t_{ei} \leq 2$ for all $1 \leq i \leq n$.
4. $\sum_{t=1}^{T} \mathrm{d_{FR}}(A^t, A^{t-1}) = \mathrm{d_{FR}}(A, B)$.

Proof Sketch of Claim 15. Let f^e_{ij} denotes the optimal solution of the linear program of Definition 4 defining the FootRule distance $\mathrm{d_{FR}}(A, B)$. In case $A \neq B$, there exist elements e_1, e_2 and indices $i < j$ such that $f^{e_1}_{i\ell(i)} > 0$ and $f^{e_2}_{j\ell(j)} > 0$ with $\ell(i) >= j$ and $\ell(j) <= i$.
Let $\epsilon = \min(f^{e_1}_{i\ell(i)}, f^{e_2}_{j\ell(j)})$ and consider the sequence of the $|i-j|$ matrices produced by moving ϵ amount of mass in row e_1 from column i to column j. Then consider the sequence of the $|i-j|$ matrices produced by moving ϵ amount of mass in the row e_2 from column j to column i.
In the overall sequence of $2|i-j|$ stochastic matrices, two consecutive matrices are *neighboring*. Furthermore the column-sum of the matrices does not exceed $1 + \epsilon \leq 2$ and the final matrix A' of the sequence is doubly stochastic. Moreover by the fact that $t(i) \geq j$ and $t(j) \leq i$ we get that the overall moving cost of the sequence equals $\mathrm{d_{FR}}(A, A')$ and that $\mathrm{d_{FR}}(A, B) = \mathrm{d_{FR}}(A, A') + \mathrm{d_{FR}}(A', B)$. Applying the same argument inductively, until we reach matrix B, proves Claim 15. ◁

▶ **Example 16.** Let the doubly stochastic matrices $A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$, $B = \begin{pmatrix} 0 & 0 & 1 \\ 1/2 & 1/2 & 0 \\ 1/2 & 1/2 & 0 \end{pmatrix}$. A can be converted to B with the following sequence neighboring stochastic matrices, $\begin{pmatrix} 0 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \begin{pmatrix} 0 & 0 & 1 \\ 1/2 & 1/2 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \begin{pmatrix} 0 & 0 & 1 \\ 1/2 & 1/2 & 0 \\ 1/2 & 1/2 & 0 \end{pmatrix}$. Notice that the above sequence satisfies all the 4 requirements of Claim 15.

The notion of neighboring matrices is rather helpful since Lemma 12 admits a fairly simple proof in case A, B are neighboring stochastic matrices (notice that the rounding scheme of Algorithm 1 is well-defined even for stochastic matrices). The latter is formally stated and proven in Lemma 17 and is the main technical claim of the section.

▶ **Lemma 17.** *Let π^A, π^B the permutations produced by the rounding scheme of Algorithm 1 (given as input) the stochastic matrices A, B that **i)** are neighboring **ii)** their column-sum is bounded by 2, then $\mathbb{E}[\mathrm{d_{KT}}(\pi^A, \pi^B)] \leq 4 \log^2 n \cdot \mathrm{d_{FR}}(A, B)$*

Proof of Lemma 17. Since A, B are neighboring there exists exactly two consecutive entries for which A, B differ, denoted as (e^*, i^*) and $(e^*, i^* + 1)$. Let $\epsilon := A_{e^* i^*} - B_{e^* i^*}$, by the Definition 4 of FootRule distance, we get that $\mathrm{d_{FR}}(A, B) = |\epsilon|$. Without loss of generality we consider $\epsilon > 0$ (the case $\epsilon < 0$ symmetrically follows). We also denote with O_i the set of elements $O_i := \{e \neq e^\star$ such that $I^A_e = i\}$ and with I^A_e, I^B_e the indices in Step 6 of Algorithm 1.
Since A, B are neighboring, the e-th row of A and the e-th row of B are identical for all $e \neq e^\star$. As a result, $I^A_e = I^B_e$ for all $e \neq e^\star$. Furthermore the neighboring property implies that even for e^*, $\sum_{s=1}^{i} A_{e^\star s} = \sum_{s=1}^{i} B_{e^\star s}$ for all $i \neq i^\star$ and thus $\Pr\left[I^A_{e^\star} = i \wedge I^B_{e^\star} = j\right] = 0$ for $(i, j) \neq (i^\star, i^\star + 1)$. Now notice that

$$\Pr\left[I^A_{e^\star}=i^\star, I^B_{e^\star}=i^\star+1\right] \le \Pr\left[\log n\cdot\sum_{s=1}^{i^\star} B_{e^\star s} \le \alpha_e \le \log n\cdot\sum_{s=1}^{i^\star} A_{e^\star s}\right]$$
$$\le \log n\cdot(A_{e^\star i^\star} - B_{e^\star i^\star}) = \log n\cdot\epsilon$$

Notice also that in case $I^A_{e^\star}=I^B_{e^\star}$, $\mathrm{d_{KT}}(\pi_A,\pi_B)=0$. This is due to the fact that in such a case $I^A_e=I^B_e$ for all $e\in U$ and the fact that ties are broken lexicographically. As a result,

$$\begin{aligned}\mathbb{E}\left[\mathrm{d_{KT}}(\pi_A,\pi_B)\right] &= \Pr\left[I^A_{e^\star}\neq I^B_{e^\star}\right]\cdot\mathbb{E}\left[\mathrm{d_{KT}}(\pi_A,\pi_B)|\ I^A_{e^\star}\neq I^B_{e^\star}\right]\\ &= \Pr[I^A_{e^\star}=i^\star, I^B_{e^\star}=i^\star+1]\cdot\mathbb{E}\left[\mathrm{d_{KT}}(\pi_A,\pi_B)|\ I^A_{e^\star}=i^\star, I^B_{e^\star}=i^\star+1\right]\\ &\le \epsilon\log n\cdot(\mathbb{E}\left[|O_{i^\star}|\right]+\mathbb{E}\left[|O_{i^\star+1}|\right])\end{aligned}$$

where the last inequality follows by the fact that once $I^A_{e^*}=i^*$ and $I^B_{e^*}=i^*+1$, the element e^* can move at most by $|O_{i^*}|+|O_{i^*+1}|$ positions and the fact that $I^A_{e^*}, I^B_{e^*}$ and $|O_{i^*}|, |O_{i^*+1}|$ are independent random variables.
We complete the proof we providing a bound on $\mathbb{E}\left[|O_i|\right]$. Notice that for $e\in U/\{e^*\}$,

$$\Pr[e\in O_i] \le \Pr\left[\log n\sum_{s=1}^{i-1} A_{es} \le \alpha_e \le \log n\sum_{s=1}^{i} A_{es}\right] \le \log n\cdot A_{ei}$$

which implies that $\mathbb{E}\left[|O_i|\right]\le\log n\sum_{e\neq e^\star} A_{ei}\le 2\log n$. Finally we overall get,

$$\mathbb{E}\left[\mathrm{d_{KT}}(\pi_A,\pi_B)\right] \le 4\log^2 n\cdot\mathrm{d_{FR}}(A,B)$$ ◀

The proof of Lemma 12 easily follows by Claim 15 and Lemma 17.

Proof of Lemma 12. Given the doubly stochastic matrices A, B, let the sequence $A = A^0, A^1, \ldots, A^T = B$ of neighboring stochastic matrices ensured by Claim 15. Now let $\pi^0, \pi^1, \ldots, \pi^T$ the sequence of permutations that the randomized rounding of Algorithm 1 produces given as input the sequence $A = A^0, A^1, \ldots, A^T = B$. Notice that,

$$\mathbb{E}\left[\mathrm{d_{KT}}(\pi^A,\pi^B)\right] \le \sum_{t=1}^{t}\mathbb{E}\left[\mathrm{d_{KT}}(\pi^t,\pi^{t-1})\right] \le 4\log^2 n\cdot\sum_{t=1}^{T}\mathrm{d_{FR}}(A^t,A^{t-1}) = 4\log^2 n\cdot\mathrm{d_{FR}}(A,B)$$

where the first inequality follows by the triangle inequality, the second by Lemma 17 and the last equality by Case 4 of Claim 15. ◀

We conclude the section with the proof of Theorem 10.

Proof of Theorem 10. By Lemma 12 and Lemma 9,

$$\sum_{t=1}^{T}\mathbb{E}\left[\mathrm{d_{KT}}(\pi^t,\pi^{t-1})\right] \le 4\log^2 n\cdot\sum_{t=1}^{T}\mathrm{d_{FR}}(A^t,A^{t-1}) \le 4\log^2 n\cdot\mathrm{OPT}_{\text{Mult-MSSC}}$$

Up next we bound the expected covering cost $\sum_{t=1}^{T}\mathbb{E}\left[\pi^t(R_t)\right]$. Notice that since $\sum_{e\in R_t} A^t_{e1} = 1$, the only elements that can have index $I^t_e=1$ are the elements $e\in R_t$. As a result, in case there exists some e at round t with $I^t_e=1$ then $\pi^t(R_t)=1$.

$$\begin{aligned}\mathbb{E}\left[\pi^t(R_t)\right] &\le 1+n\cdot\Pr\left[I^t_e>1 \text{ for all } e\in R_t\right]\\ &\le 1+n\cdot\Pi_{e\in R_t}\left(1-\log n\cdot A^t_{e1}\right)\\ &\le 1+n\cdot e^{-\log n\cdot\sum_{e\in R_t} A^t_{e1}} = 2\cdot\pi^t_{\mathrm{Opt}}(R_t)\end{aligned}$$

where the last inequality follows due to the fact that $\sum_{e\in R_t} A^t_{e1}=1$ and $\pi^t_{\mathrm{Opt}}(R_t)\ge 1$. ◀

5 Proof of Theorem 11

In this section we present the basic steps towards the proof of Theorem 11. We remind that $|R_t| \leq r$ and we denote with e_t the element that Algorithm 2 moves in the fist position at round t. As already mentioned, the proof is structured in two different steps.

1. We prove the existence of a sequence of doubly stochastic matrices $\hat{A}^0 = \pi^0, \hat{A}^1, \ldots, \hat{A}^T$ such that **(i)** the entries of each $\hat{A}^t$ are multiples of $1/r$, **(ii)** each $\hat{A}^t$ admits $1/r$ mass for element e_t in first position ($\hat{A}^t_{e_t 1} \geq 1/r$) and **(iii)** $\sum_{t=1}^{T} \mathrm{d_{FR}}(\hat{A}^t, \hat{A}^{t-1}) \leq \sum_{t=1}^{T} \mathrm{d_{FR}}(A^t, A^{t-1})$.
2. We use properties **(i)** and **(ii)** to prove that the moving cost of Algorithm 2 is roughly upper bounded by $\Theta(r^2) \cdot \sum_{t=1}^{T} \mathrm{d_{FR}}(\hat{A}^t, \hat{A}^{t-1})$.

We start with the construction of the sequence $\hat{A}^0 = \pi^0, \hat{A}^1, \ldots, \hat{A}^T$.

▶ **Definition 18.** *For the sequence of elements $e_1, \ldots, e_T \in U$ (the elements that Algorithm 2 moves to the fist position at each round), consider the following linear program,*

$$
\begin{aligned}
\textit{min} \quad & \sum_{t=1}^{T} \mathrm{d_{FR}}(\hat{A}^t, \hat{A}^{t-1}) & \\
\textit{s.t} \quad & \sum_{i=1}^{n} \hat{A}^t_{ei} = 1 & \textit{for all } e \in U \textit{ and } t = 1, \ldots, T \\
& \sum_{e \in U} \hat{A}^t_{ei} = 1 & \textit{for all } i = 1, \ldots, n \textit{ and } t = 1, \ldots, T \\
& \hat{A}^t_{e_t 1} \geq 1/r & \textit{for all } t = 1, \ldots, T \\
& \hat{A}^0 = \pi^0 & \\
& \hat{A}^t_{ei} \geq 0 & \textit{for all } e \in U,\ i = 1, \ldots, n \textit{ and } t = 1, \ldots, T
\end{aligned}
$$

The sequence $\hat{A}^0 = \pi^0, \ldots, \hat{A}^T$ is defined as the optimal solution of the LP in Definition 18 with the entries of each $\hat{A}^t$ being **multiples of $1/r$**. The existence of such an optimal solution is established in Lemma 19.

▶ **Lemma 19.** *There exists an optimal solution $\hat{A} = \pi^0, \hat{A}^1, \ldots, \hat{A}^T$ for the linear program of Definition 19 such that entries of each $\hat{A}^t$ are multiples of $1/r$.*

The proof of Lemma 19 is one of the main technical contributions of this work. Due to lack of space its proof is deferred to the full version of the paper. We remark that the *semi-integrality property*, that Lemma 19 states, is not due to the properties of the LP's polytope and in fact there are simple instances in which the optimal extreme points do not satisfy it. We establish Lemma 19 via the design of an optimal algorithm for the LP of Definition 18 (Algorithm 3) that always produces solutions with entries being multiples of $1/r$. Up next we describe in brief the idea behind Algorithm 3.

Given the matrix $\hat{A}^{t-1}$, Algorithm 3 construct $\hat{A}^t$ as follows. At first it moves $1/r$ mass from the left-most entry (e_t, j) with $\hat{A}^{t-1}_{e_t j} \geq 1/r$ to the entry $(e_t, 1)$. At this point the third constraint of the LP in Definition 18 is satisfied but the column-stochasticity constraints are violated (the first column admits mass $1 + 1/r$ and the j-th column admits mass $1 - 1/r$). Algorithm 3 inductively restores column-stochasticity from left to right. At step i, all the columns on the left of i are restored and the violations concern the column i and j (i's mass is $1 + 1/r$ and j's mass is $1 - 1/r$). Now Algorithm 3 must move a total of $1/r$ mass from column i to column $i + 1$. In case there exists an element e with total amount of mass greater than $2/r$, Algorithm 2 moves the $1/r$ mass from the entry (e, i) to the entry $(e, i + 1)$. The

reason is that even if $e = e_{t'}$ at some future round t', the third constraint only requires $1/r$ mass. In case there is no such element, Algorithm 3 moves the $1/r$ mass from the element appearing the furthest in the sequence $\{e_t, \ldots, e_T\}$. The latter is in accordance with the optimal eviction policy for k − Paging which at each round evicts the page appearing furthest in the future [7]. The optimality of Algorithm 3 is established in Lemma 21 and the fact that produced solution admits values being $1/r$ is inductively established.

To this end, we can show that all of the desired properties of the sequence $\hat{A} = \pi^0, \hat{A}^1, \ldots, \hat{A}^T$ are satisfied. Property **(i)** is established by Lemma 19. Property **(ii)** is enforced by the constraint $\hat{A}^t_{e_t 1} \geq 1/r$. Now for Property **(iii)**, notice that by the definition of Algorithm 2, $A^t_{e_t 1} \geq 1/r$. As a result, the sequence $A^0 = \pi^0, A^1, \ldots, A^T$ is feasible for the linear program of Definition 18 and thus $\sum_{t=1}^{T} \mathrm{d_{FR}}(\hat{A}^t, \hat{A}^{t-1}) \leq \sum_{t=1}^{T} \mathrm{d_{FR}}(A^t, A^{t-1})$.

▶ **Lemma 20.** *Let $\pi^0, \pi^1, \ldots, \pi^T$ the permutations produced by Algorithm 2 and $e_1, \ldots, e_T$ the elements that Algorithm 2 moves to the first position at each round t. For any sequence of doubly stochastic matrices $\hat{A}^0 = \pi^0, \hat{A}^1, \ldots, \hat{A}^T$ for which Property **(i)** and Property **(ii)** are satisfied, $\sum_{t=1}^{T} \mathrm{d_{KT}}(\pi^t, \pi^{t-1}) \leq 2r^2 \cdot \sum_{t=1}^{T} \mathrm{d_{FR}}(\hat{A}^t, \hat{A}^{t-1}) + r \cdot T$.*

The proof of Theorem 11 directly follows by Lemma 19 and 20. In Section 5.2 we present the basic steps for of Lemma 19.

5.1 Proof of Lemma 19

We prove the existence of an optimal solution $\hat{A}^0 = \pi^0, \hat{A}^1, \ldots, \hat{A}^T$ for the linear program of Definition 18 for which the entries of each matrix $\hat{A}^t$ are multiples of $1/r$ though the design of an optimal greedy algorithm illustrated in Algorithm 3.

The fact that Algorithm 3 produces a solution with entries that multiples of $1/r$ easily follows. Algorithm 3 starts with an integral doubly stochastic matrices ($\hat{A}^0 = \pi^0$) and always moves $1/r$ mass from entry to entry. The optimality of Algorithm 3 is established in Lemma 21 the proof of which is presented in the next section since it is quite technically complicated. However the basic idea of the algorithms is very intuitive, once $\hat{A}^{t-1}_{e_t} = 0$ Algorithm 3 moves $1/r$ mass of e_t from its leftmost position (with mass greaer than $1/r$), denoted as Pos of Step 5. At this point of time, Algorithm 3 has violated the column-stochasticity constraints, $1 + 1/r$ for the first column and $1 - 1/r$ for the Pos-th column and Algorithm 3 must move at total of $1/r$ mass from the first position to next positions until $1/r$ mass reaches the Pos position and column-stochasticity is restored (Step 8). Once Algorithm 3 detects an element with aggregated mass (until position j) $\geq 2/r$, it can safely move $1/r$ of each mass to position $j + 1$ since even if this element appears at some point in the future only $1/r$ is necessary to satisfy the constraint $A^t_{e_t 1} \geq 1/r$ and thus the rest is redundant (Step 11). In case such an element does not exist, Algorithm 3 moves the (useful) $1/r$ mass of the element appearing the furthest in the remaining sequence $\{e_t, \ldots, e_T\}$, which is exactly the same optimal *eviction policy* that the well-studied k − Paging suggests.

▶ **Lemma 21.** *Algorithm 3 produces an optimal solution $\hat{A}^0 = \pi^0, \hat{A}^1, \ldots, \hat{A}^T$ for the linear program of Definition 18 while the entries of each $\hat{A}^t$ are multiples of $1/r$.*

5.2 Proof of Lemma 20

In order to prove Lemma 20, we make use of an appropriate potential function that can be viewed as an extension of the Kendall-Tau distance (see Definition 1) to doubly stochastic matrices with entries being multiples of $1/r$.

Algorithm 3 An Optimal Greedy Algorithm for the LP of Definition 18.

Input: The initial permutation π^0 and the sequence of elements $e_1, \ldots, e_T \in U$
Output: An optimal solution of a linear program of Definition 18 where the entries of $\hat{A}^t$ are multiples of $1/r$.

Initially $\hat{A}^0 \leftarrow \pi_0$
for all rounds $t = 1$ to T **do**
  $\hat{A}^t \leftarrow \hat{A}^{t-1}$
  if $\hat{A}^t_{e_t 1} < 1/r$ **then**
    //Move $1/r$ mass of e_t to the first position
      $\text{Pos} \leftarrow \text{argmin}_{1 \le i \le n}\{A^t_{ei} \ge 1/r\}$
      $\hat{A}^t_{e1} \leftarrow \hat{A}^t_{e1} + 1/r, \hat{A}^t_{e\text{Pos}} \leftarrow \hat{A}^t_{e\text{Pos}} - 1/r$
    //Restore the column-stochasticity constraints from left to right
    for $j = 1$ to $\text{Pos} - 1$ **do**
      if there exists $e \in U$ with $\sum_{s=1}^{j} \hat{A}^t_{es} \ge 2/r$ and $\hat{A}^t_{es} \ge 1/r$ **then**
        //Move $1/r$ of its (redundant) mass to the next position
          $\hat{A}^t_{ej} \leftarrow \hat{A}^t_{ej} - 1/r$, $\hat{A}^t_{ej} \leftarrow \hat{A}^t_{ej} + 1/r$
      else
        //Move the $1/r$ mass, of the element appearing furthest in the future, to the next position
          $e^\star \in U \leftarrow$ the element with $\hat{A}^t_{e^\star j} = 1/r$ furthest in $\{e_{t+1}, \ldots, e_T\}$
          $\hat{A}^t_{e^\star j} \leftarrow \hat{A}^t_{e^\star j} - 1/r$, $\hat{A}^t_{e^\star j} \leftarrow \hat{A}^t_{e^\star j} + 1/r$
      end if
    end for
  end if
end for
return $\hat{A}_1, \ldots, \hat{A}_T$

▶ **Definition 22** (***r***-Index). *The r-index of an element $e \in U$ in the doubly stochastic matrix A, $I^A_e := \text{argmin}\{1 \le i \le n : \sum_{s=1}^{i} A_{es} \ge 1/r\}$*

▶ **Definition 23** (Fractional Kendall-Tau Distance). *Given the doubly stochastic matrices A, B, a pair of elements $(e, e') \in U \times U$ is inverted if and only if one of the following condition holds,*

1. $I^A_e > I^A_{e'}$ *and* $I^B_e < I^B_{e'}$.
2. $I^A_e < I^A_{e'}$ *and* $I^B_e > I^B_{e'}$.
3. $I^A_e = I^A_{e'}$ *and* $I^B_e \neq I^B_{e'}$.
4. $I^A_e \neq I^A_{e'}$ *and* $I^B_e = I^B_{e'}$.

The fractional Kendall-Tau distance between two doubly stochastic matrices A, B, denoted as $\text{d}_{\text{KT}}(A, B)$, is the number of inverted pairs of elements.

Notice that in case of $0-1$ doubly stochastic matrices the Fractional Kendall-Tau distance of Definition 23 coincides with the Kendall-Tau distance of Definition 1.

▷ Claim 24. Fractional Kendall-Tau Distance satisfies the triangle inequality, $\text{d}_{\text{KT}}(A, B) \le \text{d}_{\text{KT}}(A, C) + \text{d}_{\text{KT}}(C, B)$.

Proof of Claim 24. Let $X^{AB}_{ee'} = 1$ if (e, e') is inverted pair for the matrices A, B and 0 otherwise (respectively for $X^{AC}_{ee'}, X^{BC}_{ee'}$). By a short case study one can show that once $X^{AB}_{ee'} = 1$ then $X^{AC}_{ee'} + X^{BC}_{ee'} \ge 1$ which directly implies Claim 24. ◁

In the case of doubly stochastic matrices with their entries being multiples of $1/r$, Fractional Kendall-Tau distance relates to FootRule distance of Definition 4.

▶ **Lemma 25.** *Let the doubly stochastic matrices A, B with entries that are multiples of $1/r$. Then $\mathrm{d_{KT}}(A, B) \leq 2r^2 \cdot \mathrm{d_{FR}}(A, B)$.*

Proof of Lemma 25. We construct a doubly stochastic matrix A' for which the following properties hold,

1. The entries of A' are multiples of $\frac{1}{r}$.
2. $\mathrm{d_{FR}}(A, B) = \mathrm{d_{FR}}(A, A') + \mathrm{d_{FR}}(A', B)$.
3. $\mathrm{d_{KT}}(A, A') \leq 2r^2 \cdot \mathrm{d_{FR}}(A, A')$.

Once the above properties are established, Lemma 25 follows by repeating the same construction until matrix B is reached and by using the fact that the *fractional Kendall-Tau distance* of Definition 23 satisfies the triangle inequality.
Before proceeding with the construction of A', we present the following corollary that follows by an easy exchange argument.

▶ **Corollary 26.** *Let the stochastic matrices A, B with entries multiples of $1/r$, the values f_{ij}^e of the optimal solution in the linear program of Definition 4 (the min-cost transportation problem defining the FootRule distance $\mathrm{d_{FR}}(A, B)$) are multiples of $1/r$.*

In order to construct the matrix A' satisfying the Properties 1-3, we consider three different classes of the entries (e, i). In particular, we call an entry (e, i).

1. *right* if and only if $f_{ij}^e > 0$ for some $j > i$.
2. *left* if and only if $f_{ij}^e > 0$ for some $j < i$.
3. *neutral* if and only if $f_{ij}^e = 0$ for all $j \neq i$.

Note that the above classes do not form a partition of the entries since an entry (e, i) can be both *left* and *right* at the same time.

▶ **Corollary 27.** *Given two doubly stochastic matrices $A \neq B$, there exist entries (e, i) and (e', j) such that*

1. *$j > i$*
2. *the entry (e, i) is right*
3. *the entry (e', j) is left*
4. *the entry (α, ℓ) is neutral for all $\alpha \in U$ and $\ell \in \{i + 1, j - 1\}$*

We construct the matrix A' from matrix A as follows. Consider two entries (e, i) and (e', j) with the properties that Corollary 27 illustrates. The doubly stochastic matrix A' is constructed by moving $1/r$ mass from entry (e, i) to entry (e, j) and by moving $1/r$ mass from entry (e', j) to entry (e', i). More formally,

$$A'_{\alpha\ell} = \begin{cases} A_{\alpha\ell} - \frac{1}{r} & \text{if } (\alpha, \ell) = (e, i) \\ A_{\alpha\ell} - \frac{1}{r} & \text{if } (\alpha, \ell) = (e', j) \\ A_{\alpha k} + \frac{1}{r} & \text{if } (\alpha, \ell) = (e', i) \\ A_{\alpha\ell} + \frac{1}{r} & \text{if } (\alpha, \ell) = (e, j) \\ A_{\alpha\ell} & \text{otherwise} \end{cases}$$

Up next we establish the fact that $\mathrm{d_{FR}}(A, B) = \mathrm{d_{FR}}(A, A') + \mathrm{d_{FR}}(A', B)$.

▷ Claim 28. $\mathrm{d_{FR}}(A', A) = 2|j-i|/r$ and $\mathrm{d_{FR}}(A', B) = \mathrm{d_{FR}}(A, B) - 2|j-i|/r$.

Proof. The fact that $\mathrm{d_{FR}}(A', A) = 2|j-i|/r$ is trivial. We thus focus on showing that $\mathrm{d_{FR}}(A', B) = \mathrm{d_{FR}}(A, B) - 2|j-i|/r$.
Since (e, i) is *right*, there exists an index $\ell(i) > i$ such that $f^e_{i\ell(i)} > 0$. Moreover $f^e_{i\ell(i)} \geq 1/r$ since $f^e_{i\ell(i)}$ is multiple of $1/r$. Notice that $\ell(i) \neq \ell$ for $\ell \in \{i+1, j-1\}$ since all the entries (α, ℓ) are *neutral* (otherwise $\sum_{\alpha \in U} B_{\alpha\ell} > 1$). As a result, transfering $1/r$ mass from entry (e, i) to entry (e, j) decreases the FootRule distance between A and B by $1/r \cdot |i-j|$ since the *final destination* of the $1/r$ mass is the entry $(e, \ell(i))$ that is on the right of entry (e, j), $\ell(i) \geq j$. The claim follows by applying the exact same argument for (e', j). ◁

We now establish the last property that is $\mathrm{d_{KT}}(A, A') \leq 2r^2 \cdot \mathrm{d_{FR}}(A, A')$.

▷ Claim 29. $\mathrm{d_{KT}}(A', B) \leq 4r \cdot |i-j|$

Proof. Notice that apart from e, e', the r-index of each element is the same in both A and A' ($I^A_\alpha = I^{A'}_\alpha$ for all $\alpha \in U \setminus \{e, e'\}$). As a result, by Definition 23, we get that the only inverted pairs can be of the form (e, α) or (e', α).
In case $I^A_e \leq i-1$ then $I^A_e = I^{A'}_e$ and there is no inverted pair of the form (e, α). In case $I^A_e = i$ then $i \leq I^{A'}_e \leq j$ and any element α with $I^A_\alpha = I^{A'}_\alpha \in \{1, i-1\} \cup \{j+1, n\}$ cannot form an inverted pair with e. As a result, a pair (e, α) can be inverted only if $i \leq I^A_\alpha = I^{A'}_\alpha \leq j$. Since the entries of A are multiples of $1/r$ and A is doubly stochastic, there are at most r positive entries at each column of A. As a result, there are at most $r \cdot (j-i+1)$ inverted pairs of the form (e, α). With the symmetric argument one can show that there are at most $r \cdot |j-i+1|$ of the form (e', α). Overall there are at most $2r \cdot |j-i+1|$ inverted pairs between A and A' that are less than $4r \cdot |j-i|$ since $j > i$. ◁

◀

We conclude the section with Lemma 30. Then Lemma 20 follows by Lemma 30 and 25.

▶ **Lemma 30.** *Let $\pi^0, \pi^1, \ldots, \pi^T$ the permutations produced by Algorithm 2 and $e_1, \ldots, e_T$ the elements that Algorithm 2 moves to the first position at each round t. For any sequence of doubly stochastic matrices $B^0 = \pi^0, B^1, \ldots, B^T$ with $B^t_{e_t 1} \geq 1/r$,*

$$\sum_{t=1}^{T} \mathrm{d_{KT}}(\pi^t, \pi^{t-1}) \leq \sum_{t=1}^{T} \mathrm{d_{KT}}(B^t, B^{t-1}) + r \cdot T$$

The proof of Lemma 30 is based on the following two inequalities, $\mathrm{d_{KT}}(\pi^t, \pi^{t-1}) + \mathrm{d_{KT}}(\pi^t, B^t) - \mathrm{d_{KT}}(\pi^{t-1}, B^t) \leq r$ and $\mathrm{d_{KT}}(\pi^{t-1}, B^t) - \mathrm{d_{KT}}(\pi^{t-1}, B^{t-1}) \leq \mathrm{d_{KT}}(B^t, B^{t-1})$. The second inequality follows by the triangle inequality established in Claim 24. The first follows by the fact that $I^{B^t}_{e_t} = 1$ and the definition of Fractional Kendall-Tau distance.

Proof of Lemma 30. Since $B^t_{e_t} \geq 1/r$, the r-index of element e_t in matrix B^t is 1, $I^{B^t}_{e_t} = 1$. We first show that,

$$\mathrm{d_{KT}}\left(\pi^t, \pi^{t-1}\right) + \mathrm{d_{KT}}\left(\pi^t, B^t\right) - \mathrm{d_{KT}}\left(\pi^{t-1}, B^t\right) \leq r$$

To simplify notation let k_t the position of e_t in π^{t-1}. Notice that $\mathrm{d_{KT}}\left(\pi^t, \pi^{t-1}\right) = k_t - 1$. Out of the $k_t - 1$ elements lying on the left of e_t in π^{t-1} there are most $r-1$ elements α with $I^{B^t}_\alpha = 1$ (these elements must admit $B^t_{\alpha 1} \geq 1/r$). The rest of the $k_t - 1$ elements admit r-index $I^{B^t}_\alpha \geq 2$ and thus form inverted pairs with e_t when considering π^{t-1} and B^t.

When e_t moves to the first positions (permutation π^t) these inverted pairs are deactivated ($I_{e_t}^{B^t} = 1$) and new inverted pairs are created between e_t and α with $I_\alpha^{B^t} = 1$, but these new inverted pairs are at most r (for any element α with $I_\alpha^{B^t}$, $B_\alpha^t \geq 1/r$). Also notice no additional inverted pairs (e, α) (with $e \neq e_t$) are created since the order between all the other elements is the same in π^t and π^{t-1}. Overall,

$$\underbrace{\mathrm{d_{KT}}\left(\pi^t, \pi^{t-1}\right)}_{k_t - 1} + \underbrace{\mathrm{d_{KT}}\left(\pi^t, B^t\right) - \mathrm{d_{KT}}\left(\pi^{t-1}, B^t\right)}_{\leq -k_t + 1 + r} \leq r$$

Combining the above inequality with $\mathrm{d_{KT}}\left(\pi^{t-1}, B^t\right) - \mathrm{d_{KT}}\left(\pi^{t-1}, B^{t-1}\right) \leq \mathrm{d_{KT}}\left(B^t, B^{t-1}\right)$ which follows from the triangle inequality we get,

$$\mathrm{d_{KT}}\left(\pi^t, \pi^{t-1}\right) + \mathrm{d_{KT}}\left(\pi^t, B^t\right) - \mathrm{d_{KT}}\left(\pi^{t-1}, B^{t-1}\right) \leq \mathrm{d_{KT}}\left(A^t, B^{t-1}\right) + r.$$

Finally a telescopic sum gives $\sum_{t=1}^{T} \mathrm{d_{KT}}\left(\pi^t, \pi^{t-1}\right) \leq \sum_{t=1}^{T} \mathrm{d_{KT}}\left(B^t, B^{t-1}\right) + r \cdot T + \mathrm{d_{KT}}(\pi^0, B^0) - \mathrm{d_{KT}}(\pi^T, B^T)$ where $\mathrm{d_{KT}}(\pi^0, B^0) = 0$. ◀

6 Concluding Remarks

In this work we examine the polynomial-time approximability of Multistage Min-Sum Set Cover. We present $\Omega(\log n)$ and $\Omega(r)$ inapproximability results for general and r-bounded request sequences, while we respectively provide $O(\log^2 n)$ and $O(r^2)$ polynomial-time approximation algorithms. Closing this gap is an interesting question that our work leaves open. Another interesting research direction concerns the competitive ratio in the online version of Dynamic Min-Sum Set Cover. [18] provides an $\Omega(r)$ lower bound and a $\Theta\left(r^{3/2}\sqrt{n}\right)$-competitive online algorithm for r-bounded sequences. Designing online algorithms for a relaxation of the problem (such as the Fractional $-$ MTF) and using the rounding schemes that this work suggests may be a fruitful approach towards closing this gap.

Abstract

The hard-sphere model is one of the most extensively studied models in statistical physics. It describes the continuous distribution of spherical particles, governed by hard-core interactions. An important quantity of this model is the normalizing factor of this distribution, called the *partition function*. We propose a Markov chain Monte Carlo algorithm for approximating the grand-canonical partition function of the hard-sphere model in d dimensions. Up to a fugacity of $\lambda < \mathrm{e}/2^d$, the runtime of our algorithm is polynomial in the volume of the system. This covers the entire known real-valued regime for the uniqueness of the Gibbs measure.

Key to our approach is to define a discretization that closely approximates the partition function of the continuous model. This results in a discrete hard-core instance that is exponential in the size of the initial hard-sphere model. Our approximation bound follows directly from the correlation decay threshold of an infinite regular tree with degree equal to the maximum degree of our discretization. To cope with the exponential blow-up of the discrete instance we use clique dynamics, a Markov chain that was recently introduced in the setting of abstract polymer models. We prove rapid mixing of clique dynamics up to the tree threshold of the univariate hard-core model. This is achieved by relating clique dynamics to block dynamics and adapting the spectral expansion method, which was recently used to bound the mixing time of Glauber dynamics within the same parameter regime.

1 Introduction

Statistical physics models particle systems as probability distributions. One of the most fundamental and mathematically challenging models in this area is the hard-sphere model, which plays a central role in understanding the thermodynamic properties of monoatomic gases and liquids [7, 29]. It is a continuous model that studies the distribution and macroscopic behavior of indistinguishable spherical particles, assuming only hard-core interactions, i.e., no two particles can occupy the same space.

We focus on computational properties of the *grand-canonical ensemble* of the hard-sphere model in a finite d-dimensional cubic region $\mathbb{V} = [0, \ell)^d$ in the Euclidean space. In the grand-canonical ensemble, the system can exchange particles with its surrounding based on a fugacity parameter λ, which is inverse to the temperature of the system. For the rest of the paper, we make the common assumption that the system is normalized such that the particles have unit volume. That means we fix their radii to $r = (1/v_d)^{1/d}$, where v_d is the volume of a unit sphere in d dimensions.

A simple probabilistic interpretation of the distribution of particles in the grand-canonical ensemble is that centers of points that are drawn from a Poisson point process on $\mathbb{V}$ with intensity λ, conditioned on the event that no two particles overlap (i.e., every pair of centers has distance at least $2r$). The resulting distribution over particle configurations in $\mathbb{V}$ is called the *Gibbs distribution* of the model. An important quantity in such models is the so called partition function $Z(\mathbb{V}, \lambda)$, which can be seen as the normalizing constant of the Gibbs distribution. Formally, it is defined as

$$Z(\mathbb{V}, \lambda) = 1 + \sum_{k \in \mathbb{N}_{>0}} \frac{\lambda^k}{k!} \int_{\mathbb{V}^k} D\Big(x^{(1)}, \dots, x^{(k)}\Big) \, \mathrm{d}\nu^{d \times k},$$

where

$$D\Big(x^{(1)}, \dots, x^{(k)}\Big) = \begin{cases} 1 \text{ if } d\big(x^{(i)}, x^{(j)}\big) \geq 2r \text{ for all } i, j \in [k] \text{ with } i \neq j \\ 0 \text{ otherwise} \end{cases}$$

and $\nu^{d \times k}$ is the Lebesgue measure on $\mathbb{R}^{d \times k}$. Commonly, two computational task are associated with the grand-canonical hard-sphere model: (1) approximating its partition function $Z(\mathbb{V}, \lambda)$, and (2) approximately sampling from the Gibbs distribution.

Studying computational aspects of the hard-sphere model carries a historical weight, as in the seminal work of Metropolis [41], the Monte Carlo method was introduced to investigate a two-dimensional hard-sphere model. Approximate-sampling Markov chain approaches have been mainly focused on the canonical ensemble of the model, that is, the system does not exchange particles with its surrounding and thus, the distribution is defined over a fixed number of spheres [31, 36, 34]. Considering the grand canonical ensemble, exact sampling algorithms have appeared in the literature for the two-dimensional model without asymptotic runtime guarantees [37, 38, 43]. A result that is more aligned with theoretical computer science was given in [28], where the authors introduced an exact sampling algorithm for the grand-canonical hard-sphere model in d-dimensions. Their algorithm is based on partial rejection sampling with a runtime linear in the volume of the system $|\mathbb{V}|$ when assuming a continuous computational model and access to a sampler from a continuous Poisson point process. Their approach is guaranteed to apply for $\lambda < 2^{-(d+1/2)}$.

Besides such sampling results, there is an ongoing effort to improve the known fugacity regime where the Gibbs measure is unique and correlations decay exponentially fast [22, 14, 32, 42]. Note that for many discrete spin systems, such as the hard-core model, correlation decay is closely related to the applicability of different methods for efficient approximation of the partition function [50, 24, 54]. Recently, the correlation decay bounds for the hard-sphere model were improved in [32] to $\lambda < 2/2^d$, using probabilistic arguments, and in [42] to $\lambda < \mathrm{e}/2^d$, based on an analytic approach. A common feature of [32] and [42] is that they translated tools originally developed in theoretical computer science for investigating the discrete hard-core model to the continuous domain.

Our work is in line with the computational view on the hard-sphere model but more algorithmic in nature. We investigate the range of the fugacity λ for which an approximation of $Z(\mathbb{V}, \lambda)$ can be obtained efficiently in terms of the volume of the system $|\mathbb{V}|$, assuming a discrete computational model. Our main result is that for all $\lambda < \mathrm{e}/2^d$ there is a randomized algorithm for ε-approximating the partition function in time polynomial in $|\mathbb{V}|$ and $1/\varepsilon$.

▶ **Theorem 1.** *Let $(\mathbb{V}, \lambda)$ be an instance of the continuous hard-sphere model with $\mathbb{V} = [0, \ell)^d$. If there is a $\delta \in (0, 1]$ such that*

$$\lambda \leq (1 - \delta)\frac{\mathrm{e}}{2^d},$$

then for each $\varepsilon \in (0, 1]$ there is a randomized ε-approximation of $Z(\mathbb{V}, \lambda)$ computable in time polynomial in $|\mathbb{V}|^{1/\delta^2}$ and $\frac{1}{\varepsilon}$.

Note that this bound on λ precisely coincides with the best known bound for the uniqueness of the Gibbs measure in the thermodynamic limit, recently established in [42]. For many discrete spin systems, such as the hard-core model or general anti-ferromagnetic 2-state spin systems, the region of efficient approximation of the partition function is closely related to uniqueness of the Gibbs measure. More precisely, it can be shown that the partition function of every graph of maximum degree Δ can be approximated efficiently if the corresponding Gibbs distribution on an infinite Δ regular tree is unique [39, 53]. A detailed discussion for the discrete hard-core model can be found in the next subsection. In a sense, Theorem 1 can be seen as the algorithmic counterpart of the recent uniqueness result for the continuous hard-sphere model. This answers an open question, asked in [42].

The way we prove our result is quite contrary to [32] and [42]. Instead of translating discrete tools from computer science into the continuous domain, we rather discretize the hard-sphere model. By this, existing algorithmic and probabilistic techniques for discrete models become available, and we avoid continuous analysis.

Our applied discretization scheme is fairly intuitive and results in an instance of the discrete hard-core model. This model has been extensively studied in the computer science community. However, as this hard-core instance is exponential in the size of the continuous system $|\mathbb{V}|$, existing approaches for approximating its partition function, such a Markov chain Monte Carlo methods based on Glauber dynamics, are not feasible. We overcome this problem by applying a Markov chain Monte Carlo approach based on clique dynamics, which were introduced in [23] in the setting of abstract polymer models. Previously known conditions for the rapid mixing of clique dynamics were developed for the multivariate version of the hard-core model. Due to this generality, those conditions do not result in the desired bound in our univariate setting. Instead we relate those clique dynamics to another Markov chain, called *block dynamics*. We then prove the desired mixing time for the block dynamics by adapting a recently introduced technique for bounding the mixing time of Markov chains, based on local spectral expansion [2]. Together with a known self-reducibility scheme for clique dynamics, this results in the desired approximation algorithm.

Note that we aim for a rigorous algorithmic result for approximating the partition function of the continuous hard-sphere model. To be in line with commonly used discrete computational models, our Markov chain Monte Carlo algorithm does not assume access to a continuous sampler but instead samples approximately from a discretized version of the Gibbs distribution. Note that sampling from the continuous hard-sphere partition function cannot be done using a discrete computation model as this would involve infinite float pointer precision. For practical matters, our discretization of the Gibbs distribution can be seen as an approximation of the original continuous Gibbs measure. However, a rigorous comparison between both distributions based on total variation distance is not applicable, due to the fact that one is discrete whereas the other is continuous in nature.

Assuming access to a continuous sampler, we believe that our approach can be used to obtain an approximation of the Gibbs distribution of the continuous model within the same fugacity regime, by adding small perturbations to the drawn sphere centers. This would be in line with the relation between the mixing time of continuous heat-bath dynamics and strong spatial mixing, pointed out in [32], combined with the uniqueness bound from [42].

In Sections 1.1–1.3 we discuss our contributions in more detail and explain how they relate to the existing literature. Finally in Section 1.4 we discuss possible extensions and future work. All technical details, statements and proofs are presented the full version of the paper.

1.1 Discretization and hard-core model

Our discretization scheme expresses the hard-sphere partition function as the partition function of an instance of the (univariate) hard-core model. An instance of the hard-core model is a tuple (G, λ) where $G = (V, E)$ is an undirected graph and $\lambda \in \mathbb{R}_{>0}$. Its partition function is defined as

$$Z(G, \lambda) \coloneqq \sum_{I \in \mathcal{I}(G)} \lambda^{|I|},$$

where $\mathcal{I}(G)$ denotes the independent sets of G. A common way to obtain an approximation for the partition function is by applying a Markov chain Monte Carlo algorithm. This involves sampling from the Gibbs distribution $\mu^{(G,\lambda)}$ of (G, λ), which is a probability distribution on $\mathcal{I}(G)$ that assigns each independent set $I \in \mathcal{I}(G)$ the probability

$$\mu^{(G,\lambda)}(I) = \frac{\lambda^{|I|}}{Z(G, \lambda)}.$$

Conditions for efficient approximation of the hard-core partition function have been studied extensively in the theoretical computer science community. Due to hardness results in [50] and [24], it is known that for general graphs of maximum degree $\Delta \in \{3\} \cup \mathbb{N}_{>5}$ there is a critical parameter value $\lambda_c(\Delta) = (\Delta - 1)^{\Delta-1}/(\Delta - 2)^{\Delta}$, such that there is no FPRAS for the partition function of (G, λ) for $\lambda > \lambda_c(\Delta)$, unless RP = NP. On the other hand, in [54] it was proven that there is a deterministic algorithm for approximating the partition function of (G, λ) for $\lambda < \lambda_c(\Delta)$ that runs in time $|V|^{O(\Delta)}$. The critical value $\lambda_c(\Delta)$ is especially interesting, as it precisely coincides with the upper bound on λ for which the hard-core model on an infinite Δ-regular tree exhibits strong spatial mixing and a unique Gibbs distribution [54]. For this reason, it is also referred to as the *tree threshold*. This relation between computational hardness and phase transition in statistical physics is one of the most celebrated results in the area. Both, the hardness results [25, 3] and the approximation algorithms [46, 30] were later generalized for complex λ.

Note that the computational hardness above the tree threshold $\lambda_c(\Delta)$ for general graphs of maximum degree Δ applies to both, randomized and deterministic algorithms. However, in the randomized setting, Markov chain Monte Carlo methods are known to improve the runtime of the algorithm introduced in [54]. Those approaches use the vertex-wise self-reducibility of the hard-core model to construct a randomized approximation of the partition function based on an approximate sampler for the Gibbs distribution. Commonly, a Markov chain on the state space $\mathcal{I}(G)$, called *Glauber dynamics*, is used to construct the sampling scheme. At each step, a vertex $v \in V$ is chosen uniformly at random. With probability $\lambda/(1 + \lambda)$ the chain tries to add v to the current independent set and otherwise it tries to remove it. The resulting Markov chain is ergodic and reversible with respect

to the Gibbs distribution, meaning that it eventually converges to $\mu^{(G,\lambda)}$. A sequence of results has shown that for all $\Delta \geq 3$ there is a family of graphs with maximum degree Δ, such that the Glauber dynamics are torpidly mixing for $\lambda > \lambda_c(\Delta)$, even without additional complexity-theoretical assumptions [17, 27, 45]. Whether the Glauber dynamics are rapidly mixing for the entire regime $\lambda < \lambda_c(\Delta)$ remained a long-standing open problem, until recently the picture was completed [2]. By relating spectral expansion properties of certain random walks on simplicial complexes to the Glauber dynamics, it was shown that the mixing time is polynomial in $|V|$ below the tree threshold. The mixing time was recently further improved in [12] for a broader class of spin systems by combining simplicial complexes with entropy factorization and using the modified log-Sobolev inequality.

By mapping the hard-sphere model to an instance of the hard-core model we can make use of the existing results about approximation and sampling below the tree threshold. Roughly, our discretization scheme restricts the positions of sphere centers to an integer grid, while scaling the radii of spheres and the fugacity appropriately. For a hard-sphere instance $(\mathbb{V}, \lambda)$ with $\mathbb{V} = [0, \ell)^d$ the hard-core representation for resolution $\rho \in \mathbb{R}_{\geq 1}$ is a hard-core instance (G_ρ, λ_ρ) with $G_\rho = (V_\rho, E_\rho)$. Each vertex $v \in V_\rho$ represents a grid point in the finite integer lattice of side length $\rho\ell$. Two distinct vertices in V_ρ are connected by an edge in E_ρ if the Euclidean distance of the corresponding grid points is less than $2\rho r$. Furthermore, we set $\lambda_\rho = \lambda/\rho^d$. We provide the following result on the rate of convergence of $Z(G_\rho, \lambda_\rho)$ to the hard-sphere partition function $Z(\mathbb{V}, \lambda)$ in terms of ρ.

▶ **Lemma 2.** *Let $(\mathbb{V}, \lambda)$ be an instance of the continuous hard-sphere model in d dimensions. For each resolution $\rho \geq 2\sqrt{d}$ it holds that*

$$1 - \rho^{-1}\mathrm{e}^{\Theta(|\mathbb{V}|\ln|\mathbb{V}|)} \leq \frac{Z(\mathbb{V}, \lambda)}{Z(G_\rho, \lambda_\rho)} \leq 1 + \rho^{-1}\mathrm{e}^{\Theta(|\mathbb{V}|\ln|\mathbb{V}|)}.$$

Although proving this rate of convergence involves some detailed geometric arguments, there is an intuitive reason why the partition functions converge eventually as $\rho \to \infty$. Increasing the resolution ρ also linearly increases the side length of the grid and the minimum distance that sphere centers can have. This is equivalent to putting a grid into $\mathbb{V}$ with increasing granularity but fixing the radii of spheres instead. However, only scaling the granularity of this grid increases the number of possible configurations by roughly ρ^d, which would cause the partition function of the hard-core model to diverge as $\rho \to \infty$. To compensate for this, we scale the weight of each vertex in the hard-core model by the inverse of this factor.

Using this discretization approach, the fugacity bound from Theorem 1 results from simply considering Δ_ρ, the maximum degree of G_ρ and comparing λ_ρ with the corresponding tree threshold $\lambda_c(\Delta_\rho)$. Recall that we assume $r = (1/v_d)^{1/d}$. A simple geometric argument shows that Δ_ρ is roughly upper bounded by $2^d\rho^d$ for sufficiently large ρ. Now, observe that

$$\lambda_\rho = \frac{\lambda}{\rho^d} < \lambda_c\big(2^d\rho^d\big),$$

for $\lambda < \rho^d\lambda_c\big(2^d\rho^d\big)$. This follows from the fact that $\rho^d\lambda_c\big(2^d\rho^d\big)$ converges to $\mathrm{e}/2^d$ from above for $\rho \to \infty$. Thus, the approximation bound from Theorem 1 and the uniqueness bound in [42] coincide with the regime of λ, for which λ_ρ is below the tree threshold $\lambda_c(\Delta_\rho)$ in the limit $\rho \to \infty$.

The arguments above show that for a sufficiently high resolution ρ the partition function of the hard-sphere model $Z(\mathbb{V}, \lambda)$ is well approximated by the partition function of our discretization (G_ρ, λ_ρ) and that (G_ρ, λ_ρ) is below the tree threshold for $\lambda < \mathrm{e}/2^d$. However,

this does not immediately imply an approximation algorithm within the desired runtime bounds. Based on Lemma 2, we still need to choose ρ exponentially large in the volume $|\mathbb{V}|$. Note that the number of vertices in G_ρ is roughly $|V_\rho| \in \Theta\big(\rho^d|\mathbb{V}|\big)$. Even without explicitly constructing the graph, this causes problems, as the best bound for the mixing time of the Glauber dynamics is polynomial in $|V_\rho|$ and thus exponential in $|\mathbb{V}|$. Intuitively, the reason for this mixing time is that the Glauber dynamics only change one vertex at each step. Assuming that each vertex should be updated at least once to remove correlations with the initial state, any mixing time that is sublinear in the number of vertices is unlikely. We circumvent this problem by applying dynamics that update multiple vertices at each step but still allow each step to be computed efficiently without constructing the graph explicitly.

1.2 Block and clique dynamics

Most of the results that we discuss from now on apply to the multivariate version of the hard-core model, that is, each vertex $v \in V$ has its own weight λ_v. For a given graph $G = (V, E)$ we denote the set of such vertex weights by $\boldsymbol{\lambda} = \{\lambda_v\}_{v\in V}$ and write $(G, \boldsymbol{\lambda})$ for the resulting multivariate hard-core instance. In the multivariate setting, the contribution of an independent set $I \in \mathcal{I}(G)$ to the partition function is defined as the product of its vertex weights (i.e., $\prod_{v\in I} \lambda_v$), where the contribution of the empty set is fixed to 1. Similar to the univariate hard-core model, the Gibbs distribution assigns a probability to each independent set proportionally to its contribution to the partition function.

As we discussed before, the main problem with approximating the partition function of our discretization (G_ρ, λ_ρ) is that the required graph G_ρ is exponential in the volume of the original continuous system $|\mathbb{V}|$. As the Glauber dynamics Markov chain only updates a single vertex at each step, the resulting mixing time is usually polynomial in the size of the graph, which is not feasible in our case. Various extensions to Glauber dynamics for updating multiple vertices in each step have been proposed in the literature, two of which we discuss in the following.

Clique dynamics

Recently, in [23] a Markov chain, called *clique dynamics*, was introduced in order to efficiently sample from the Gibbs distribution of abstract polymer models. Note that this is similar to our algorithmic problem, as abstract polymer models resemble multivariate hard-core instances. For a given graph $G = (V, E)$, we call a set $\Lambda = \{\Lambda_i\}_{i\in[m]} \subseteq 2^V$ a clique cover of size m if and only if its union covers all vertices V and each $\Lambda_i \in \Lambda$ induces a clique in G. For an instance of the multivariate hard-core model $(G, \boldsymbol{\lambda})$ and a given clique cover Λ of G with size m the clique dynamics Markov chain $\mathcal{C}(G, \boldsymbol{\lambda}, \Lambda)$ is defined as follows. First, a clique $\Lambda_i \in \Lambda$ for $i \in [m]$ is chosen uniformly at random. Let us write $G[\Lambda_i]$ for the subgraph, induced by Λ_i, and $\boldsymbol{\lambda}[\Lambda_i] = \{\lambda_v\}_{v\in\Lambda_i}$ for the corresponding set of vertex weights. Next, an independent set from $\mathcal{I}(G[\Lambda_i])$ is chosen according to the Gibbs distribution $\mu^{(G[\Lambda_i],\boldsymbol{\lambda}[\Lambda_i])}$. Note that, as the vertices Λ_i form a clique, such an independent set is either the empty set or contains a single vertex from $v \in \Lambda_i$. If the empty set is drawn, all vertices from Λ_i are removed from the current independent set. Otherwise, if a single vertex $v \in \Lambda_i$ is drawn, the chain tries to add v to the current independent set.

Using a coupling argument, it was proven in [23] that the so-called *clique dynamics condition* implies that for any clique cover of size m the clique dynamics are mixing in time polynomial in m and $Z_{\max}$, where $Z_{\max} = \max_{i\in[m]}\{Z(G[\Lambda_i], \boldsymbol{\lambda}[\Lambda_i])\}$ denotes the maximum partition function of a clique in Λ. This is important for the application to polymer models, as

they are usually used to model partition functions of other spin systems, which often results in a multivariate hard-core model of exponential size [33, 9, 35, 10, 6, 8, 26]. As discussed in [23], those instances tend to have polynomial size clique covers that arise naturally from the original spin system. In such cases, the mixing time of clique dynamics is still polynomial in the size of original spin system, as long as the clique dynamics condition is satisfied.

This is very similar to our discretization (G_ρ, λ_ρ). To see this, set $a = \frac{2\rho}{\sqrt{d}}r$ and divide the d-dimensional integer lattice of side length $\rho\ell$ into cubic regions of side length a. Every pair of integer points within such a cubic region has Euclidean distance less than $2\rho r$, meaning that the corresponding vertices in G_ρ are adjacent. Thus, each such cubic region forms a clique, resulting in a clique cover of size $(\rho\ell/a)^d \in \mathrm{O}(|\mathbb{V}|)$. This means, there is always a clique cover with size linear in $|\mathbb{V}|$ and independent of the resolution ρ. By showing that, for the univariate hard-core model, the mixing time of clique dynamics is polynomial in the size of the clique cover for all $\lambda_\rho < \lambda_c(\Delta_\rho)$, we obtain a Markov chain with mixing time polynomial in $|\mathbb{V}|$ independent of the resolution ρ. Unfortunately, the clique dynamics condition does not hold for the entire regime up to the tree threshold in the univariate hard-core model. We overcome this problem by proving a new condition for rapid mixing of clique dynamics based on a comparison with block dynamics.

Block dynamics

Block dynamics are a very natural generalization of Glauber dynamics to arbitrary sets of vertices. For a given graph $G = (V, E)$, we call a set $\Lambda = \{\Lambda_i\}_{i\in[m]} \subseteq 2^V$ a block cover of size m if and only if its union covers all vertices V. We refer to the elements of Λ as blocks. Note that the clique cover discussed before is a special case of a block cover, where all blocks are restricted to be cliques. At each step, the block dynamics Markov chain $\mathcal{B}(G, \lambda, \Lambda)$ chooses a block $\Lambda_i \in \Lambda$ uniformly at random. Then, the current independent set is updated on Λ_i based on the projection of the Gibbs distribution onto Λ_i and conditioned on the current independent set outside Λ_i.

In fact, block dynamics are defined for a much more general class of spin systems than the hard-core model. However, due to the fact that each step of the Markov chain involves sampling from a conditional Gibbs distribution, block dynamics are rarely used as an algorithmic tool on its own. Instead, they are usually used to deduce rapid mixing of other dynamics.

For spin systems on lattice graphs, close connections between the mixing time of block dynamics and Glauber dynamics are known [40]. Such connections were for example applied to improve the mixing time of Glauber dynamics of the Monomer Dimer model on torus graphs [51]. Moreover, block dynamics were used to improve conditions for rapid mixing of Glauber dynamics on specific graph classes, such as proper colorings [16, 18, 19, 44] or the hard-core model [18, 44] in sparse random graphs. A very general result for the mixing time of block dynamics was achieved in [4], who proved that for all spin systems on a finite subgraph of the d-dimensional integer lattice the mixing time of block dynamics is polynomial in the number of blocks if the spin system exhibits strong spatial mixing. This result was later generalized in [5] for the Ising model on arbitrary graphs. Very recently, block dynamics based random equally-sized blocks where used in [12] to prove entropy factorization and improve the mixing time of Glauber dynamics for a variety of discrete spin systems up to the tree threshold.

Although our discretization works by restricting sphere positions to the integer lattice, the resulting graph is rather different from the lattice. Thus, results like those in [4] do not apply to our setting. However, on the other hand, we do not need to prove rapid mixing for arbitrary block covers. Instead, in order to obtain rapid mixing for clique dynamics, it is sufficient to establish this result for cases where all blocks are cliques.

Applying block dynamics directly would involve sampling from a conditional Gibbs distribution within each clique. Due to the exponential size of the cliques in our discretization, this would impose additional algorithmic challenges. Instead, similar to the previous literature, we rather use block dynamics as a tool for proving rapid mixing of another Markov chain, namely clique dynamics.

Improved mixing condition for clique dynamics via block dynamics

We analyze the mixing time of clique dynamics for a given clique cover by relating it to the mixing time of block dynamics, using the cliques as blocks. This is done by investigating a notion of pairwise influence between vertices that has also been used to establish rapid mixing of Glauber dynamics up to the tree threshold [2]. Let $\mathbb{P}_G[w]$ denote the probability of the event that a vertex $w \in V$ is in an independent set drawn from $\mu^{(G,\boldsymbol{\lambda})}$. Further, let $\mathbb{P}_G[\overline{w}]$ denote the probability that w is not in an independent set. We extend this abuse of notation to conditional probabilities, so $\mathbb{P}_G[\cdot \mid \overline{w}]$ for example denotes the probability of some event conditioned on w not being in an independent set. For a pair of vertices $v, w \in V$ the influence $\Psi_G(v, w)$ of v on w is defined as

$$\Psi_G(v,w) = \begin{cases} 0 & \text{if } v = w, \\ \mathbb{P}_G[w \mid v] - \mathbb{P}_G[w \mid \overline{v}] & \text{otherwise.} \end{cases}$$

The following condition in terms of pairwise influence is central to our analysis.

▶ **Condition 3.** *Let $(G, \boldsymbol{\lambda})$ be an instance of the multivariate hard-core model. There is a constant $C \in \mathbb{R}_{>0}$ and a function $q\colon V \to \mathbb{R}_{>0}$ such that for all $S \subseteq V$ and $r \in S$ it holds that*

$$\sum_{v \in S} |\Psi_G(r,v)| q(v) \leq C q(r).$$

Note that this condition appeared before in [13], where it was used for bounding the mixing time of Glauber dynamics for anti-ferromagnetic spin systems. Given Condition 3, we obtain the following result for the mixing time of block dynamics based on a clique cover.

▶ **Theorem 4.** *Let $(G, \boldsymbol{\lambda})$ be an instance of the multivariate hard-core model that satisfies Condition 3. Let Λ be a clique cover for G of size m, and let $Z_{\max} = \max_{i \in [m]} \{Z(G[\Lambda_i], \boldsymbol{\lambda}[\Lambda_i])\}$. The mixing time of the block dynamics $\mathcal{B}(G, \boldsymbol{\lambda}, \Lambda)$, starting from $\emptyset \in \mathcal{I}(G)$, is bounded by*

$$\tau_{\mathcal{B}}^{(\emptyset)}(\varepsilon) \leq m^{\mathrm{O}((2+C)C)} Z_{\max}^{\mathrm{O}((2+C)C)} \ln\left(\frac{1}{\varepsilon}\right).$$

Using a bound for the sum of absolute pairwise influences that was recently established in [13], it follows that the univariate hard-core model satisfies Condition 3 up to the tree threshold. As a result, we know that the mixing time of block dynamics is polynomial in m and $Z_{\max}$ for any clique cover of size m. To the best of our knowledge, this is the first result for the mixing time of block dynamics for the univariate hard-core model on general graphs that holds in this parameter range.

As we aim to apply clique dynamics to avoid sampling from the conditional Gibbs distribution in each step, we still need to prove that Theorem 4 also holds in terms of clique dynamics. To this end, we apply a Markov chain comparison argument from [15] to prove that using clique dynamics instead of block dynamics for the same clique cover Λ increases the mixing time by at most a factor $2Z_{\max}$. The following corollary, which is central for proving Theorem 1, follows immediately.

▶ **Corollary 5.** *Let (G, λ) be an instance of the univariate hard-core model such that the degree of G is bounded by Δ. Let Λ be a given clique cover of size m with $Z_{\max} = \max_{i\in[m]}\{Z(G[\Lambda_i], \lambda)\}$. Denote by $\mathcal{C} = \mathcal{C}(G, \lambda, \Lambda)$ the corresponding clique dynamics. If there is some $\delta \in \mathbb{R}_{>0}$ such that $\lambda \leq (1-\delta)\lambda_c(\Delta)$ then the mixing time of the clique dynamics $\mathcal{C}$, starting from $\emptyset \in \mathcal{I}(G)$, is bounded by*

$$\tau_{\mathcal{C}}^{(\emptyset)}(\varepsilon) \leq m^{\mathrm{O}\left(1/\delta^2\right)} Z_{\max}^{\mathrm{O}\left(1/\delta^2\right)} \ln\left(\frac{1}{\varepsilon}\right).$$

A side journey: comparison to multivariate conditions

In fact, Corollary 5 is sufficient for our application to the hard-sphere model. However, we also aim to set Condition 3 in the context of other conditions for rapid mixing of clique dynamics for the multivariate hard-core model. Note that such a rapid mixing result for clique dynamics caries over to Glauber dynamics by taking each vertex as a separate clique of size 1.

To this end, we compare Condition 3 to a strict version of the clique dynamics condition, originally introduced in [23] in the setting of clique dynamics for abstract polymer models. It turns out that this strict version of the clique dynamics condition directly implies Condition 3. This is especially interesting, as the clique dynamics condition was initially introduced as a local condition (only considering the neighborhood of each vertex) and is based on a coupling argument. However, we show that it can as well be understood as a sufficient condition for the global decay of pairwise influence with increasing distance between vertices.

Formally, we say that the strict clique dynamics condition is satisfied for an instance of the multivariate hard-core model $(G, \boldsymbol{\lambda})$ if there is a function $f\colon V \to \mathbb{R}_{>0}$ and a constant $\alpha \in (0, 1)$ such that for all $v \in V$ it holds that

$$\sum_{w\in N(v)} \frac{\lambda_w}{1+\lambda_w} f(w) \leq (1-\alpha) f(v),$$

where $N(v)$ is the neighborhood of v in G. This is a strict version of the clique dynamics condition in that the original clique dynamics condition would correspond to the case $\alpha = 0$ (i.e., the strict clique dynamics condition requires some strictly positive slack α).

The result of our comparison is summarized in the following statement.

▶ **Lemma 6.** *Let $(G, \boldsymbol{\lambda})$ be an instance of the multivariate hard-core model. If $(G, \boldsymbol{\lambda})$ satisfies the strict clique dynamics condition for a function f and a constant α, then it also satisfies Condition 3 for $q = f$ and $C = \frac{1}{\alpha}$.*

Lemma 6 is proven by translating the calculation of pairwise influences to the self-avoiding walk tree of the graph, based on a result in [13], and applying a recursive argument on this tree.

Despite being an interesting relationship between local coupling arguments and global pairwise influence, Lemma 6 also implies that, from an algorithmic perspective, Theorem 4 can be used to produce similar results as those obtained in [23] for abstract polymer models. Further, note that for the univariate model, using pairwise influence yields strictly better results than any coupling approach in the literature. This raises the question if a refined argument based on pairwise influences can be used in the multivariate setting to improve on the clique dynamics condition, leading to better approximation results on abstract polymer models.

1.3 Analyzing spectral expansion

As core technique for obtaining Theorem 4, we adapt an approach for bounding the mixing time that was recently used to prove rapid mixing of Glauber dynamics for the entire regime below the tree threshold for several applications, such as the hard-core model [2], general two-state spin systems [13], and proper colorings [11, 21]. The idea is to map the desired distribution to a weighted simplicial complex.

A simplicial complex X over a groundset U is a set family $X \subseteq 2^U$ such that for each $\tau \in X$ every subset of τ is also in X. We call the elements $\tau \in X$ the faces of X and refer to its cardinality $|\tau|$ as dimensionality.

For a univariate hard-core instance (G, λ), the authors of [2] construct a simplicial complex over a ground set U that contains two elements $x_v, x_{\overline{v}} \in U$ for each vertex $v \in V$. For every independent set $I \in \mathcal{I}(G)$, a face $\tau_I \in X$ is introduced such that $x_v \in \tau_I$ if $v \in I$ and $x_{\overline{v}} \in \tau_I$ otherwise. The simplicial complex is completed by taking the downward closure of these faces. Note that by construction all maximum faces of the resulting complex are $|V|$-dimensional and there is a one-to-one correspondence between the maximum faces and the independent sets in $\mathcal{I}(G)$. By assigning each maximum face $\tau_I \in X$ an appropriate weight, the Glauber dynamics can be represented as a random walk on those maximum faces, which is sometimes referred to as the two-step walk or down-up walk. Using a local-to-global theorem [1], the mixing time of this two-step walk can then be bounded based on certain local expansion properties of the simplicial complex X. It is then proved that such local expansion properties are well captured by the largest eigenvalue of the pairwise influence matrix Ψ_G, which is a $|V| \times |V|$ matrix that contains the pairwise influence $\Psi_G(v, w)$ for all $v, w \in V$. Finally, by bounding those influences a bound on this largest eigenvalue of Ψ_G is obtained. This analysis was later refined and generalized in [13] to general two-state spin systems.

This method was independently extended in [11] and [21] to the non-Boolean domain by applying it to the Glauber dynamics for proper colorings. The main differences to the Boolean domain are that elements of the simplicial complex now represent combinations of a vertex and a color. Furthermore, the bound on the local spectral expansion was obtained by using a different influence matrix, which captures the effect of selecting a certain color for one vertex on the distribution of colors for another vertex.

Although we are dealing with the hard-core model, which is Boolean in nature, the way that we model block dynamics is mainly inspired by the existing work on proper colorings [11]. Assume we have an instance of the multivariate hard-core model $(G, \boldsymbol{\lambda})$ and let Λ be a clique cover for G of size m such that every pair of distinct cliques is vertex-disjoint (i.e., Λ is a partition of G into cliques). We construct a simplicial complex X based on a ground set U that contains one element $x_v \in U$ for each vertex $v \in V$ and one additional element $\emptyset_i$ for each clique $\Lambda_i \in \Lambda$. We introduce a face $\tau_I \in X$ for each independent set $I \in \mathcal{I}(G)$ such that for every $\Lambda_i \in \Lambda$ we have $\emptyset_i \in \tau_I$ if $\Lambda_i \cap I = \emptyset$ and $x_v \in \tau_I$ if $\Lambda_i \cap I = \{v\}$ for some $v \in \Lambda_i$. The simplicial complex is completed by taking the downward closure of these faces. All maximum faces of the resulting complex are m-dimensional and there is a bijection between the maximum faces and the independent sets of G. Furthermore, there is a natural partitioning $\{U_i\}_{i \in [m]}$ of the ground set U, each partition U_i corresponding to a clique Λ_i, such that every maximum face in X contains exactly one element from each partition U_i.

By weighting each maximum face of X by the contribution of the corresponding independent set to the partition function, the block dynamics based on Λ are equivalent to the two-step walk on X. Thus, in order to bound the mixing time of the block dynamics, it is sufficient to study the local expansion properties of X. To this end, we adapt the influence matrix used for proper colorings in [11]. For $x \in U$, let $\mathbb{P}_G[x]$ denote the probability that

$x \in \tau_I$ for an independent set $I \in \mathcal{I}(G)$ drawn from $\mu^{(G,\boldsymbol{\lambda})}$ and corresponding maximum face $\tau_I \in X$. Similarly as for defining pairwise influences, we extend this notation to conditional probabilities. The clique influence matrix $\Phi_{G,\Lambda}$ contains an entry $\Phi_{G,\Lambda}(x,y)$ for each $x, y \in U$ with

$$\Phi_{G,\Lambda}(x,y) = \begin{cases} 0 & \text{if } x,y \in U_i \text{ for some } i \in [m], \\ \mathbb{P}_G[y \mid x] - \mathbb{P}_G[y] & \text{otherwise.} \end{cases}$$

By using similar linear-algebraic arguments as in [11] we prove that the maximum eigenvalue of $\Phi_{G,\Lambda}$ can be used to upper bound the local spectral expansion of X. To obtain Theorem 4 it is then sufficient to relate Condition 3 to the maximum eigenvalue of $\Phi_{G,\Lambda}$. The following lemma establishes this connection.

▶ **Lemma 7.** *Let $(G,\boldsymbol{\lambda})$ be an instance of the multivariate hard-core model that satisfies Condition 3 for a function q and a constant C. For every $S \subseteq V$ and every disjoint clique cover Λ of $G[S]$ it holds that the largest eigenvalue of $\Phi_{G[S],\Lambda}$ is at most $(2+C)C$.*

Note that our simplicial-complex representation is only given under the assumption that the cliques in the clique cover Λ are pairwise disjoint. Indeed, this is a necessary requirement to map the block dynamics to the two-step walk such that the local-global-theorem from [1] can be applied. Thus, Lemma 7 only helps to prove Theorem 4 for disjoint clique covers. However, we relax this requirement by proving that for every clique cover Λ a disjoint clique cover K can be constructed such that the block dynamics $\mathcal{B}(G,\boldsymbol{\lambda},\Lambda)$ and $\mathcal{B}(G,\boldsymbol{\lambda},K)$ have asymptotically the same mixing time. By this comparison argument, we extend Theorem 4 to arbitrary clique covers.

We are aware that, in the case of Glauber dynamics, more recent techniques for combining simplical complex representations with entropy factorization as proposed in [12] yield superior mixing time results. However, in case of the hard-core model, this approach comes with an additional multiplicative factor of $\Delta^{\mathrm{O}(\Delta^2)}$ in the mixing time (see section 8 of [12]). Although negligible for bounded degree graphs, this would be too much for our application, as the degree of our discretization gets exponentially large in the continuous volume $|\mathbb{V}|$ of the system. Thus, directly relating local spectral expansion with the spectral gap of block dynamics is more suitable in our case. We leave as an open question, whether a modification of the approach in [12] can be applied to further improve our mixing time result.

1.4 Outlook

We obtain the fugacity bound from Theorem 1 based on the tree threshold $\lambda_c(\Delta)$ of the hard-core model. An obvious question is whether there are any structural properties of our discretization that can be used to improve this bound. Similar results are known for specific graph classes, such as the 2-dimensional square lattice [48, 52, 54]. In [42] the authors discuss that a generalization of the connective constant to the continuous Euclidean space might be applicable to improve their uniqueness result for the hard-sphere model. A comparable algorithmic result was already established for the discrete hard-core model in [49]. However, any such improvement for our discretization would require the connective constant of G_ρ to be at least by a constant factor small than its maximum degree Δ_ρ. Unfortunately, due to a result in [47], this is not the case. Although this does not necessarily imply that a similar concept does not work in continuous space, it gives a strong evidence that a more specialized tool instead of the connective constant might be required.

A different direction for future work is to see which other quantities and properties of the model are preserved under discretization. This would especially include the thermodynamic pressure and its analyticity. As a matter of fact, non-analytic points of the pressure along the

positive real axis of fugacity in the thermodynamic limit are known to mark phase transitions in infinite volume systems (see for example [42]). One way to approach this could be to prove a relation between zero-freeness of the continuous and the discretized partition function in a complex neighborhood of the real axis by extending our convergence result to the complex domain. Along this line, insights could be gained in how far properties like correlation decay and phase transitions (or their absence) are preserved under sufficiently fine discretization.

From a purely technical point of view, it is interesting to see if our result on the mixing time of block dynamics in Theorem 4 also holds without the requirement of using cliques as blocks. Especially: is the mixing time for block dynamics for the univariate hard-core model polynomial in the number of blocks for any block cover? Most of our techniques that we use for clique covers, such as modeling the distribution as a simplicial complex and relating its local spectral expansion to the clique influence matrix, can be generalized in a straightforward way for different choices of blocks. However, the main difficulty is to relate generalized versions of the clique influence matrix to pairwise influences, as we do in Lemma 7. One way to circumvent this might be to not rely on pairwise influences at all but to rather investigate the influence matrix directly, for example, via different computational-tree methods.

Finally, it would be interesting to see if approaches like ours can be extended to other continuous models from statistical physics (see for example coarse-graining [20]). We believe that the variety of tools that are already established for discrete spin systems are useful in this setting to establish rigorous computational results for different continuous models. We emphasize that clique and block dynamics are a useful computational tool to handle the exponential blow-ups caused by discretization.

Constant-Factor Approximation to Deadline TSP and Related Problems in (Almost) Quasi-Polytime

Zachary Friggstad
Department of Computer Science, University of Alberta, Edmonton, Canada

Chaitanya Swamy
Department of Combinatorics and Optimization, University of Waterloo, Canada

Abstract

We investigate a genre of vehicle-routing problems (VRPs), that we call *max-reward* VRP*s*, wherein nodes located in a metric space have associated rewards that depend on their visiting times, and we seek a path that earns maximum reward. A prominent problem in this genre is *deadline TSP*, where nodes have *deadlines* and we seek a path that visits all nodes by their deadlines and earns maximum reward. Our main result is a *constant-factor approximation* for deadline TSP running in time $O\left(n^{O(\log(n\Delta))}\right)$ in metric spaces with integer distances at most Δ. This is the *first* improvement over the approximation factor of $O(\log n)$ due to Bansal et al. [2] in over 15 years (but is achieved in super-polynomial time). Our result provides the first concrete indication that $\log n$ is unlikely to be a real inapproximability barrier for deadline TSP, and raises the exciting possibility that deadline TSP might admit a polytime constant-factor approximation.

At a high level, we obtain our result by carefully guessing an appropriate sequence of $O(\log(n\Delta))$ nodes appearing on the optimal path, and finding suitable paths between any two consecutive guessed nodes. We argue that the problem of finding a path between two consecutive guessed nodes can be relaxed to an instance of a special case of deadline TSP called *point-to-point (*P2P*) orienteering*. *Any* approximation algorithm for P2P orienteering can then be utilized in conjunction with either a greedy approach, or an LP-rounding approach, to find a good set of paths overall between every pair of guessed nodes. While concatenating these paths does not immediately yield a feasible solution, we argue that it can be covered by a constant number of feasible solutions. Overall our result therefore provides a *novel reduction* showing that any α-approximation for P2P orienteering can be leveraged to obtain an $O(\alpha)$-approximation for deadline TSP in $O\left(n^{O(\log n\Delta)}\right)$ time.

Our results extend to yield the same guarantees (in approximation ratio and running time) for a substantial generalization of deadline TSP, where the reward obtained by a client is given by an arbitrary non-increasing function (specified by a value oracle) of its visiting time. Finally, we discuss applications of our results to variants of deadline TSP, including settings where both end-nodes are specified, nodes have release dates, and orienteering with time windows.

1 Introduction

Vehicle-routing problems (VRPs) constitute a rich class of optimization problems that find a variety of applications and have been extensively studied in the Operations Research and Computer Science literature (see, e.g., [27]) Broadly speaking, vehicle-routing problems can be divided into two categories: one, where we have a *fixed* set of nodes or clients that need to be visited, and we seek the most effective route(s) for visiting these clients (e.g., TSP-style problems [9, 25, 29, 26], minimum-latency problems [5, 23], VRPs with distance bounds [19, 22] and regret bounds [13]); and the other, where, due to resource constraints, we need to *select* which set of clients to visit *and* plan suitable routes for these clients. We investigate a prominent class of VRPs that fall into the second category, wherein nodes have associated rewards that depend on their visiting times, and we seek a path that earns maximum reward. We call this genre of problems *max-reward* VRP*s*, and they constitute a well-studied class of VRPs (see, e.g., [15, 3, 2, 8, 6, 14]).

We consider a fundamental problem in this genre, called the *deadline TSP* problem. In deadline TSP, we are given a (symmetric) metric space $(\{r\} \cup V, c)$ with r being a distinguished starting root node, and each node $v \in V$ has a certain deadline $D_v \geq 0$ and reward $\pi_v \geq 0$. We seek a path starting at r that maximizes the total reward of the nodes on the path that are visited by their deadlines. Since we are in a metric space, by shortcutting, we may assume that all nodes on the path are visited by their deadlines. So equivalently, we seek a maximum-reward r-rooted path that visits all nodes by their deadlines. A simpler problem in the max-reward VRP genre is the *point-to-point (*P2P*) orienteering* problem, wherein we are also given an end-node t, and we seek an r-t path of at most a given length B that collects maximum reward. This is a special case of deadline TSP, which can be seen by setting the deadline of each node v to $B - c_{vt}$.

Max-reward VRPs tend to be more complicated problems than the first category of "fixed-node-set" VRPs mentioned above because of the added combinatorial aspect of selecting which nodes to visit, which is interlinked with the routing decisions, and we have much less of an understanding of max-reward VRPs compared to fixed-node-set VRPs. A constant-factor approximation is known only for P2P orienteering in undirected graphs, which is one of the most rudimentary max-reward VRPs. For other, more-sophisticated, max-reward VRPs – deadline TSP, submodular orienteering, directed orienteering – only logarithmic or polylogarithmic (or worse) approximation factors are known. Furthermore, even for undirected orienteering, the current-best approximation ratio has remained stagnant at $(2 + \epsilon)$ [6] (and fresh LP-based insights were obtained only recently [14]), whereas for s-t path TSP (the corresponding fixed-node-set problem), a steady stream of work [1, 24, 28, 29] has exploited LP-based insights (and other ideas) to improve the approximation ratio to 1.5 [29]. The contrast is even more evident in asymmetric metrics: while $O(1)$-approximation algorithms are now known for asymmetric TSP (ATSP) [26] and s-t path ATSP [17], the best-known guarantee for directed orienteering is an $O(\alpha \log |V|)$-approximation using an LP-relative α-approximation for ATSP [21], which explicitly shows the degradation when moving to the max-reward-VRP version.

Our results. Our main contribution is to provide the *first constant-factor approximation* guarantee for deadline TSP (Theorem 3.1); notably, we obtain a relatively small approximation ratio of $(7.63 + \epsilon)$. We may assume by scaling that all distances in our metric space are integers. Our algorithm runs in time $O\big(n^{O(\log n\Delta)}\big)$, where n is the number of points, and Δ is the diameter of the (scaled) metric space. In particular, for graphical metrics, we obtain a

quasi-polytime (i.e., $O\big(n^{O(\log n)}\big)$-time) constant-factor approximation. Our guarantee yields the *first* improvement over the (polytime) $O(\log n)$ approximation factor obtained by Bansal et al. [2] in over 15 years, even for graphical metrics, but is achieved in super-polynomial time. Prior to our work, it was unclear whether $\log n$ is a real inapproximability barrier for deadline TSP. Our result provides the first concrete indication that this is not the case,[1] and raises the enticing possibility that deadline TSP might admit a polynomial-time constant-factor approximation.

As noted above, constant-factor approximation algorithms are known for P2P orienteering [2, 6, 14], which is a special case of deadline TSP. Our chief technical contribution lies in providing a novel *reduction* showing that *an α-approximation algorithm for* P2P *orienteering can be utilized to obtain an $O(\alpha)$-approximation algorithm for deadline TSP* in $O\big(n^{O(\log n\Delta)}\big)$ time (see Theorem 3.1).

We obtain the *same approximation guarantees* for a substantial generalization of deadline TSP, wherein each node v has a *non-increasing reward function* $\pi_v : \mathbb{R}_+ \mapsto \mathbb{R}_+$, with $\pi_v(x)$ giving the reward of node v if v is visited at time x, and, as before, the goal is to find a path that collects maximum reward. We call this problem *monotone-reward TSP* (Section 4.1). Notice that this problem also captures *discounted-reward TSP*, considered by Blum et al. [3], which is the special case where $\pi_v(x) = \pi_v \cdot \gamma^{-x}$, where $\gamma > 1$ is a discount factor. Our results here only require *value-oracle* access to π_v – an oracle that on input x returns $\pi_v(x)$ – and follow from two distinct approaches (see Theorem 4.1): (a) we show that we can reduce monotone-reward TSP in polytime to deadline TSP with a $(1-\epsilon)$-factor loss; and (b) our algorithm and analysis for deadline TSP readily extend to yield the same guarantees for monotone-reward TSP.

Interestingly, our reduction from orienteering to {deadline, monotone-reward} TSP also applies to *asymmetric metrics* (see Remark 3.8). The recent result of Svensson et al. [26] establishing an $O(1)$-integrality gap for the ATSP LP-relaxation implies (due to the work of [21]) an $O(\log n)$-approximation for directed orienteering; thus our reduction yields an $O(\log n)$-approximation for {deadline, monotone-reward} TSP in asymmetric metrics in $O\big(n^{O(\log n\Delta)}\big)$ time. While this does not improve upon the quasi-polytime $O(\log n)$-approximation for asymmetric deadline TSP that follows from the work of Chekuri and Pál [8], our reduction does show that improved (e.g., constant-factor) approximations to directed orienteering will *directly* translate to analogous improvements for directed deadline TSP in $O\big(n^{O(\log n\Delta)}\big)$ time.

In Section 4.2, we show that our results yield $O(1)$-approximation for some other variants of {deadline, monotone-reward} TSP, namely, settings where: (a) the path must start *and* end at some given nodes; and (b) nodes have release dates but no deadlines, or more generally have a non-decreasing reward function, and we seek a length-bounded path gathering maximum reward (and we are allowed to wait at nodes while traversing a path). We also consider *orienteering with time windows*, wherein we have a time window for each node and we collect its reward if it is visited within its time window. By combining our result for deadline TSP with certain results of Chekuri et al. [6], we obtain an $O\big(\log \frac{L_{\max}}{L_{\min}}\big)$-approximation for orienteering with time windows in $O\big(n^{\log n\Delta}\big)$ time, where $L_{\max}$ and $L_{\min}$ are the lengths of the longest and shortest time windows with non-zero length. This improves upon the approximation guarantee of [6] when the optimum value is large; in particular, if $L_{\max} = O(L_{\min})$, we obtain an $O(1)$-approximation, whereas [6] obtain an $O(\log(\text{optimal value}))$-approximation, but in polynomial time.

[1] More precisely, if $NP \not\subseteq DTIME\,[O\big(n^{O(\log n)}\big)]$, then obtaining an $O(1)$-approximation in graphical metrics cannot be *NP*-hard. Also, any reduction showing *NP*-hardness of an $O(1)$-approximation in general metrics must involve exponentially large distances.

Our techniques. We briefly discuss the techniques that we utilize to obtain our result for deadline TSP (see also "Overview and intuition" in Section 3). We begin by guessing a suitable set of $O(\log n\Delta)$ nodes, which are a subsequence of the nodes encountered along an optimal path P^*. This guessing step requires some care, in light of the fact that we are dealing with *hard* deadlines – i.e., we need to satisfy deadlines *exactly* (and not just approximately) – which rules out certain standard approaches. For instance, a natural attempt would be to view nodes of P^* as being grouped into geometric buckets based on their visiting times and/or deadlines and guess the boundary nodes of the buckets; since nodes in a bucket involve roughly the same visiting time and/or deadline, it is tempting to solve a P2P orienteering instance with the boundary nodes as end-points. But this is too coarse an idea that is incompatible with hard deadlines. Indeed, since one cannot merge similar deadlines/visiting times, any such approach faces the issue that there could be $\Omega(n)$ distinct visiting times and deadlines to consider. Not surprisingly, [7], who take such an approach make the strong assumption that there are only $O(1)$ distinct deadlines. Alternatively, other works on deadline TSP [2, 6] are based on extracting a subset of P^* with a simpler deadline and visiting-time structure, but at the expense of an $O(\log n)$-factor loss in objective.

We seek to avoid both the above bottlenecks, but, as alluded to above, honing in on the correct choice of guessed nodes requires some insight and a more refined approach. At a high level, the sequence of nodes we guess $v_0 := r, v_1, \ldots, v_{\log n\Delta}$ has the property that the length of the v_i-v_{i+1} portion of P^*, which we denote by $P^*_{v_iv_{i+1}}$, is about $c_{v_iv_{i+1}} + \gamma^i$, where γ is some constant (we use $\gamma = 1.5$); equivalently, we say that the v_i-relative regret-length of $P^*_{v_iv_{i+1}}$ is about γ^i. We still obtain P2P-orienteering solutions (with the above distance bound) between consecutive v_i, such that they cumulatively collect enough reward (but they may not have disjoint node-sets). Concatenating these yields a path P that may violate some deadlines. A key insight is that if we were to shortcut past the v_{i-2}-v_i portion of P, then each client visited between v_i and v_{i+1} after shortcutting, *now has its deadline satisfied*: we "save" roughly $\gamma^{i-2} + \gamma^{i-1} \geq \gamma^i$ distance in this shortcutting process, which is enough to guarantee that clients visited between v_i and v_{i+1} in our algorithm have their deadlines satisfied exactly. Thus, we can cover P using a constant number of deadline-TSP solutions. Our eventual algorithm is slightly more involved as we have to account for large leaps in distances as well (thereby requiring us to guess an additional $\log n\Delta$ nodes).

Finally, we consider two approaches for obtaining the P2P-orienteering solutions. The first approach is based on viewing the problem as an instance of the *maximum coverage problem with group budgets* [7], for which a simple greedy algorithm yields a good approximation. The second is a more-sophisticated LP-based approach that yields a somewhat better approximation guarantee. We write an LP to find paths between guessed nodes, and extract from the LP solution a distribution over P2P-orienteering solutions between consecutive guesses. Randomly picking one such path for each v_i will ensure each client is covered with probability proportional to the extent that the LP covers it. While recent LP-based insights [14] for orienteering allow us to obtain a compact LP to obtain such distributions, one can also work with a configuration-style LP that directly encodes the distribution requirement. *Any* P2P-orienteering approximation algorithm can then be used to approximately separate the dual of this LP, and hence yield the desired distributions.

Our $O\big(n^{\log n\Delta}\big)$ running time stems from the need for enumerating $O(\log n\Delta)$ nodes. There is however some hope that this enumeration step and its resulting run-time blowup can be circumvented. At a high level, the search space of our algorithm can be represented by a directed layered graph, whose vertices in layer i encode the various choices for the v_i-v_{i+1} portion of P^*, and arcs encode compatible choices. While we use brute-force enumeration

to find a suitable path in this digraph, one can envisage other means for finding this path, e.g., dynamic programming or linear programming. An important and useful fact to note is that we only have $O(\log n\Delta)$ layers, so that, for $\text{poly}(n, \Delta)$ running time (hence, polytime for graphical metrics), one can afford to take time exponential in the number of layers. (We note that such savings were achieved in the context of another VRP, namely the directed latency problem: Nagarajan and Ravi [20] gave an $O\big(n^{\log n}\big)$-time, $O(\log n)$-approximation based on guessing $O(\log n)$ nodes, and subsequently Friggstad et al. [12] obtained the same approximation in polytime by showing, in essence (roughly speaking), that this guesswork can be eliminated by formulating a suitable LP to provide the guessed nodes.)

Related work. We limit ourselves to a discussion of the work that is most relevant to the max-reward VRP problems we consider; we refer the reader to [27] for more information on vehicle routing problems in general. As mentioned earlier, the current-best approximation factor for deadline TSP is $O(\log n)$ due to Bansal et al. [2]. They also give a bicriteria $O(\log 1/\epsilon)$-approximation that violates deadlines by at most a $(1+\epsilon)$-factor; with integer deadlines this yields an $O(\log D_{\max})$-approximation (where $D_{\max} := \max_v D_v$). Since we obtain $O\big(n^{O(\log n\Delta)}\big)$ running time, it is also relevant to compare our result with the recursive greedy approach of Chekuri and Pál [8]. This is a versatile approach that yields logarithmic approximation guarantees for various problems (including deadline TSP) in quasi-polytime. However, this approach seems hard-pressed to yield anything *better* than logarithmic guarantees (even for deadline TSP); in particular, the $\Omega(\log n)$-inapproximability result for submodular orienteering[2] suggests that one cannot improve their approach to obtain $o(\log n)$ approximation guarantees.

The special case of deadline TSP with uniform node-deadlines is called *rooted orienteering*. Blum et al. [3] obtained the first $O(1)$-approximation algorithm for this problem. Their ideas were refined by [2, 6] to obtain the current-best $(2+\epsilon)$-approximation, which also applies to P2P orienteering [6]. Recently, Friggstad and Swamy [14] developed a different LP-based approach for orienteering, which also yields (slightly inferior) $O(1)$-approximations for these problems. We utilize some of their insights in our work.

Various (other) generalizations of orienteering and deadline TSP have also been studied. Bansal et al. [2] give an $O(\log^2 n)$-approximation for orienteering with time windows, and an $O(\log D_{\max})$ approximation with integer release dates and deadlines. They make the informal remark that a deadline-TSP approximation that relies on an α-approximation for P2P orienteering will translate to an α^2-approximation for orienteering with time windows. However, this comment seems to be in the *specific* context of their approach, and it is unclear if it can be applied with our framework to obtain an $O(1)$-approximation for the time-windows problem in $O\big(n^{O(\log n\Delta)}\big)$; such a result would be quite interesting. Chekuri et al. [6] show that an α-approximation for P2P orienteering yields an $O\big(\alpha \max\{\log \mathsf{opt}, \log \frac{L_{\max}}{L_{\min}}\}\big)$-approximation for orienteering with time windows, where opt is the optimal value, and $L_{\max}$ and $L_{\min}$ are the lengths of the longest and shortest time windows with non-zero length.

Blum et al. [3] considered the special case of monotone-reward TSP called discounted-reward TSP (wherein the reward of node v at time t is $\pi_v\gamma^{-t}$), and devised a 6.753-approximation algorithm. This factor was slightly improved to 5.195 by [10]. Chekuri

[2] Submodular orienteering captures "group orienteering", wherein we are given (disjoint) groups of vertices, and the reward of a path is the number of groups it hits. Using set-cover ideas, one can show that an α-approximation for group orienteering yields an $O(\alpha \log n)$-approximation for the group Steiner tree problem. The $\Omega(\log^2 n)$-inapproximability result for group Steiner tree [16] thus translates to an $\Omega(\log n)$-inapproximability result for submodular orienteering.

and Pál [8] show that their recursive-greedy approach yields a quasi-polytime $O(\log n)$-approximation for a generalization of monotone-reward TSP where the node reward is an *arbitrary* function of time. They obtain the same guarantee for a further generalization of orienteering (even in asymmetric metrics) that they introduce, called *submodular orienteering with time windows*, where the reward of a path is given by a monotone submodular function of the set of nodes visited within their time windows.

In *asymmetric metrics*, Chekuri et al. [6] give an $O(\log^2 \mathsf{opt})$-approximation for P2P orienteering; this also yields guarantees for the time-windows problem via their aforementioned reduction (which also applies to asymmetric metrics). The current-best approximation for directed orienteering is $O(\log n)$, which follows by combining the $O(1)$-integrality gap for the ATSP LP [26] with a result of [21] showing that an LP-relative α-approximation for ATSP yields an $O(\alpha \log n)$-approximation for directed orienteering.

Finally, there is a wealth of literature on fixed-node-set VRPs; we refer the reader to some of the most recent work on these problems [25, 29, 26] for further pointers.

2 Preliminaries and notation

All the problems we consider involve an underlying complete graph $G = (\{r\} \cup V, E)$, where r is a distinguished root node, and metric edge costs $\{c_{uv}\}$. By scaling, we may assume that c_{uv} is an integer for all $u, v \in V \cup \{r\}$. Let $\Delta := \max_{u,v \in V \cup \{r\}} c_{uv}$ be the diameter of the scaled metric space. For a set S of edges, we often use $c(S)$ to denote $\sum_{e \in S} c_e$. We often use V' to denote $\{r\} \cup V$. Let $n = |V'| = |V| + 1$. We call a path P in G rooted if it begins at r. We always think of the nodes on a rooted path P as being ordered in increasing order of their distance along P from r. For any path P and nodes $u, v \in P$, let P_{uv} denote the u-v subpath of P. For a rooted path P and node $v \in P$, the visiting time of v is the distance from r to v along P, which we denote by $c_P(v) := c(P_{rv})$. To avoid excessive notation, we will view a path P sometimes as its edge-set, and sometimes as its node-set; the meaning will be clear from the context.

In *deadline TSP*, each node $v \in V$ has a deadline $D_v \geq 0$ and reward $\pi_v \geq 0$. For notational convenience, set $D_r = \pi_r = 0$. The goal is to find a simple rooted path P such that $c_P(v) \leq D_v$ for all $v \in P$ that maximizes $\sum_{v \in P} \pi_v$. We may assume that $D_v \geq c_{rv}$ for all $v \in V$, as otherwise v can never be visited by a feasible solution and we can simply delete v from our metric space.

Monotone-reward TSP is a substantial generalization of deadline TSP, wherein each node v has a *non-increasing reward function* $\pi_v : \mathbb{R}_+ \mapsto \mathbb{R}_+$. For notational convenience, set $\pi_r(x) = 0$ for all x. The goal is to find a simple rooted path P that maximizes $\sum_{v \in P} \pi_v(c_P(v))$. We assume that each $\pi_v(.)$ is specified via a value oracle, that on input x returns $\pi_v(x)$.

Regret distances. For any $u \in V \cup \{r\}$, and any ordered pair $v, w \in V \cup \{r\}$, define the *regret distance* of (v, w) with respect to u to be $c^{\mathsf{reg}}_u(v, w) := c_{uv} + c_{vw} - c_{uw}$. The regret distances $\{c^{\mathsf{reg}}_u(v, w)\}_{v,w \in V \cup \{r\}}$ form an *asymmetric* metric. The regret-length of a path P with respect to its start node is called the excess of P in [3, 2, 6]. A simple but key insight that we will repeatedly use is that if P is a rooted path, and u, v are nodes on P where u comes before v (recall that nodes on P are ordered by increasing $c_P(\cdot)$), then replacing P_{uv} by the edge uv reduces the length of the path by exactly $c^{\mathsf{reg}}_u(P_{uv}) = c(P_{uv}) - c_{uv}$.

Point-to-point (P2P) orienteering. In P2P orienteering, we have a start node s, *end node* t, and a length bound B, and we seek an s-t path P with $c(P) \leq B$ that maximizes $\sum_{v \in P} \pi_v$. We will often need to restrict the path to only visit nodes from a certain subset $N \subseteq V'$

(where $\{s,t\} \subseteq N$); we refer to this as P2P orienteering with node set N. It will often be convenient to cast the length-bound B, as a regret-bound of $B - c_{st}$ on the regret of P with respect to s, i.e., $c_s^{\mathsf{reg}}(P)$.

Observe that P2P orienteering can be cast as a special case of deadline TSP (with root node s) by setting $D_v = \max\{0, B - c_{vt}\}$ for all $v \in V$: if w is the end-node of a feasible solution to this deadline-TSP instance, then we can always append the edge wt to this path and stay within the length bound of $B = D_t$.

Recently, Friggstad and Swamy [14] devised an LP-based 6-approximation algorithm for P2P orienteering by formulating a polynomial-size LP for the problem and devising an LP-rounding algorithm (see Section 5). Their algorithm yields a distribution of P2P-orienteering solutions that visits each node with probability proportional to the extent it is visited in the LP solution. Our LP-rounding based algorithm (see subroutine LP-Round) for deadline TSP makes use of the latter type of distributional guarantee. In fact, *any* approximation algorithm for P2P orienteering can be used to obtain such a distribution – this follows from [4, 18] – and this leads to our $(7.63+\epsilon)$-approximation algorithm for deadline TSP.

3 Constant-factor approximation for deadline TSP

We now describe our constant-factor approximation algorithm for deadline TSP that runs in time $O\big(n^{O(\log n\Delta)}\big)$. Let P^* be an optimal path, and $\mathsf{opt} = \pi(P^*)$ be the optimal value. We prove the following result.

▶ **Theorem 3.1.** *Algorithm 1 runs in $O\big(n^{O(\log n\Delta)}\big)$ time. Let $\mathcal{A}$ be an α-approximation algorithm for* P2P *orienteering (where $\alpha \geq 1$).*

- **(a)** *Using subroutine* Greedy *in step D1.2 (with algorithm $\mathcal{A}$), Algorithm 1 returns a deadline-TSP solution whose reward is at least $\frac{1}{3(\alpha+1)} \cdot \mathsf{opt}$.*
- **(b)** *Using subroutine* LP-Round *in step D1.2 (with algorithm $\mathcal{A}$), Algorithm 1 returns a deadline-TSP solution with a slightly better expected reward of at least $\frac{1}{3/(1-e^{-1/\alpha})} \cdot \mathsf{opt} \geq \frac{1}{3(\alpha+1)} \cdot \mathsf{opt}$. This guarantee can be derandomized.*

Taking $\alpha = (2+\epsilon)$ above [6], we obtain a $(9+\epsilon)$-approximation using Greedy, and an improved $(7.63+\epsilon)$-approximation using the LP-approach in LP-Round.

Overview and intuition. We first give an overview of the algorithm and convey the underlying intuition; the detailed description appears below as Algorithm 1. Let $\gamma = 1.5$. Note that $\gamma^2 \leq \gamma + 1$.

Let $R^* = c_r^{\mathsf{reg}}(P^*)$ be the regret of P^* with respect to the root r. Set $u_0 := r$. Suppose we "guess" (i.e., enumerate all possible choices for) a sequence of nodes $w_0, u_1, w_1, \ldots$ occurring on P^* (in this order), which are defined as follows. Given u_i for $i \geq 0$, we define w_i, u_{i+1} as follows. Let u_{i+1} be the first node on P^* after u_i such that the regret of $P^*_{u_i u_{i+1}}$ with respect to u_i is at least γ^i. So we have $c_{u_i}^{\mathsf{reg}}(P_{u_i u_{i+1}}) \geq \gamma^i$ and $c_{u_i}^{\mathsf{reg}}(P^*_{u_i v}) < \gamma^i$ for all nodes v prior to u_{i+1} on $P^*_{u_i u_{i+1}}$; since all distances are integers, this implies that $c_{u_i}^{\mathsf{reg}}(P^*_{u_i v}) \leq \lceil \gamma^i \rceil - 1$ for all nodes v prior to u_{i+1} on $P^*_{u_i u_{i+1}}$. Define w_i to be the predecessor of u_{i+1}. If there is no such node u_{i+1}, then u_{i+1} is undefined, and *define* w_i to be the end-node of P^*. Let k be the largest index such that u_k is well defined. Observe that $k = O(\log R^*)$ since for every $i = 0, \ldots, k-1$, we have that $\gamma^i \leq c_{u_i}^{\mathsf{reg}}(P^*_{u_i u_{i+1}}) \leq c_r^{\mathsf{reg}}(P^*_{u_i u_{i+1}})$, and $c_r^{\mathsf{reg}}(P^*) = R^*$. This leads to the $O\big(n^{O(\log n\Delta)}\big)$ running time, since we need to consider $n^{O(\log R^*)}$ guesses for $w_0, \ldots, u_k, w_k$, and $R^* \leq c(P^*) \leq n\Delta$.

We first observe that we can obtain the following lower bound on the deadlines of nodes in $P^*_{u_i w_i}$. The proof of the following lemma is deferred to the analysis.

▶ **Lemma 3.2.** *Consider any index $i = 0, \ldots, k$. The visiting time of a node $v \in P^*_{u_i w_i}$, and hence its deadline D_v, is at least* $\mathsf{lb}_{i,v} := \sum_{j=0}^{i-1} \max\{c_{u_j w_j} + c_{w_j u_{j+1}}, c_{u_j u_{j+1}} + \gamma^j\} + c_{u_i v}$.

Lemma 3.2 implies that the P2P-orienteering instance with node-set $N^i := \{v \in V' : D_v \geq \mathsf{lb}_{i,v}\}$, start node u_i, end node w_i, and regret-bound $\lceil \gamma^i \rceil - 1$ (with respect to u_i), has optimal value at least $\pi(P^*_{u_i w_i})$. (Note that $N^0 = V'$.) Suppose that we are able to find paths $Q^0, Q^1, \ldots, Q^k$, such that:

- **(i)** for every $i = 0, \ldots, k$, we have that Q^i is a u_i-w_i path, visits only nodes of N^i, and $c^{\mathsf{reg}}_{u_i}(Q^i) \leq \lceil \gamma^i \rceil - 1$; and
- **(ii)** $\pi\big(Q^0 \cup \ldots \cup Q^k\big) \geq \rho \cdot \pi(P^*)$, where $0 < \rho \leq 1$ is some constant.

We show that we can use these paths to obtain a deadline-TSP solution of value $\rho \cdot \pi(P^*)/3$; this yields an $O(1)$-approximation for deadline TSP.

Let Z be the path obtained by concatenating all (the nodes of) $Q^0, \ldots, Q^k$. How "far" is Z from being a feasible solution? Assume that the Q^is are node-disjoint (which we can always ensure by shortcutting past all occurrences of a node other than its first occurrence). Consider a node $v \in Q^i$. We can upper bound the visiting time of v by

$$\begin{cases} \sum_{j=0}^{i-1} (c_{u_j w_j} + \lceil \gamma^j \rceil - 1 + c_{w_j u_{j+1}}) & \text{if } v = u_i; \\ \sum_{j=0}^{i-1} (c_{u_j w_j} + \lceil \gamma^j \rceil - 1 + c_{w_j u_{j+1}}) + c_{u_i v} + \lceil \gamma^i \rceil - 1 & \text{otherwise,} \end{cases}$$

where in the latter case, $c_{u_i v} + \lceil \gamma^i \rceil - 1$ upper bounds the time taken to go from u_i to v along Z (as $\lceil \gamma^i \rceil - 1 \geq c^{\mathsf{reg}}_{u_i}(Q^i) \geq c^{\mathsf{reg}}_{u_i}(Q^i_{u_i v})$). For $v \in Q^0$, this shows that its visiting time is at most $c_{u_0 v} = \mathsf{lb}_{0,v}$, which is at most D_v. Nodes in $Q^1 \cup \ldots \cup Q^k$ may however be visited after their deadlines.

The chief insight is that if we replace the u_j-u_{j+1} portion of Z, which currently consists of the node-sequence Q^j, by the direct edge $u_j u_{j+1}$, then we incur a γ^j-savings in the (above upper bound for) visiting times of nodes on Q^i for $i > j$: the term $c_{u_j w_j} + \lceil \gamma^j \rceil - 1 + c_{w_j u_{j+1}}$ in the above upper bound gets replaced by $c_{u_j u_{j+1}}$, and $c^{\mathsf{reg}}_{u_j}(P^*_{u_j w_j}) \leq \lceil \gamma^j \rceil - 1$ implies that

$$c_{u_j w_j} + \lceil \gamma^j \rceil - 1 + c_{w_j u_{j+1}} \geq c(P^*_{u_j w_j}) + c_{w_j u_{j+1}} = c(P^*_{u_j u_{j+1}}) = c^{\mathsf{reg}}_{u_j}(P^*_{u_j u_{j+1}}) + c_{u_j u_{j+1}} \geq \gamma^j + c_{u_j u_{j+1}}.$$

Moreover, since $\gamma^2 \leq \gamma + 1$, this implies that if we "sync up" with P^* at w_{j-1} by visiting w_{j-1} by time $\mathsf{lb}_{j-1,w_{j-1}}$, then deleting the u_j-u_{j+2} portion – i.e., going directly to u_{j+2} from w_{j-1} – ensures that: (a) every $v \in Q^{j+2}$ is visited by its deadline (and, in fact, by $\mathsf{lb}_{j+2,v}$), and (b) we remain in sync with P^* at w_{j+2}. Note also that Z is in sync with P^* at nodes u_0, w_0. Finally, for nodes in Q^1, it suffices to replace the u_0-u_1 portion of Z by the direct edge $u_0 u_1$ in order to visit these nodes by their deadlines, and have w_1 sync up with P^*.

The upshot of these insights is that: (1) for any $\ell \in \{0, 1, 2\}$, the path $Z^{(\ell)}$ given by the node-sequence $r, \{Q^j\}_{0 \leq j \leq k : j = \ell \bmod 3}$ (where r is possibly a duplicated node) is feasible (Lemma 3.3); and (2) together these paths cover all the nodes of Z. Hence, the best of these 3 paths collects reward at least $\pi\big(Q^0 \cup \ldots \cup Q^k\big)/3 \geq \frac{\rho}{3} \cdot \pi(P^*)$.

Finally, we discuss two approaches for finding the $Q^0, \ldots, Q^k$ paths. The first approach is based on observing that the problem of finding these paths to maximize $\pi\big(Q^0 \cup \ldots \cup Q^k\big)$ is an instance of the *maximum coverage problem with group budgets* considered by [7]. Thus, a simple greedy approach (subroutine Greedy) works, where we repeatedly find $Q^0, Q^1, \ldots$ in that order, and to find Q^i, we use a P2P-orienteering α-approximation algorithm with the subset of N^i that has not been covered by Q^j for $j < i$ (or equivalently, we zero out

the rewards of nodes in $Q^0 \cup \ldots \cup Q^{i-1}$). Chekuri and Kumar [7] show that this yields a collection of paths that together obtain reward at least $\mathsf{opt}/(\alpha+1)$; we include the analysis for completeness (Lemma 3.4).

The second approach is a more sophisticated LP-based approach (subroutine LP-Round) that yields a better guarantee. We write a *configuration LP* (Ap-P) to find the Q^i paths. We use variables x^i_v to denote the extent to which v lies in $P^*_{u_i w_i}$, for $i \geq 0$. Let $\mathcal{P}^i := \mathcal{P}^i(u_i, w_i, N^i, \lceil \gamma^i \rceil - 1)$ be the collection of simple u_i-w_i paths of length at most $c_{u_i w_i} + \lceil \gamma^i \rceil - 1$ that visit only nodes of N^i. (Note that if u_i or w_i is not in N^i, then $\mathcal{P}^i = \emptyset$. Also, if $u_i = w_i$ and lies in N^i, then $\mathcal{P}^i$ consists of only the trivial singleton path $\{u_i\}$.) We also have variables $\{z^i_P\}_{P \in \mathcal{P}^i}$, where z^i_P denotes that we choose path $P \in \mathcal{P}^i$. While we cannot solve this LP optimally, we show (see Lemma 3.6) that an α-approximation algorithm for P2P orienteering can be used to obtain a solution $(\overline{x}, \overline{z})$ of objective value at least $OPT_{\text{Ap-P}}$, where each node v is covered by the paths from $\mathcal{P}^i$ to an extent of at least $\overline{x}^i_v/\alpha$. We choose $Q^i \in \mathcal{P}^i$ by sampling from the $\{\overline{z}^i_P\}_{\in \mathcal{P}^i}$ distribution. It is not hard to argue then that $\mathrm{E}\left[\pi\left(\bigcup_{i=2}^k Q^i\right)\right] \geq \left(1 - e^{-1/\alpha}\right) OPT_{\text{Ap-P}}$ (Lemma 3.7), which yields the guarantee stated in Theorem 3.1 (b). We now describe the algorithm in detail and proceed to analyze it.

Algorithm 1 Deadline TSP

Let $\gamma = 1.5$.

Input: metric $(\{r\} \cup V, c)$, deadlines $\{D_v\}_{v \in V}$, rewards $\{\pi_v\}_{v \in V}$; an α-approximation algorithm $\mathcal{A}$ for P2P orienteering.

Output: An r-rooted path P such that every $v \in P$ is visited by time D_v.

D1 Initialize $\mathcal{Q} \leftarrow \emptyset$. Let $u_0 := r$. For $k = 0, 1, \ldots, \frac{\log n\Delta}{\log \gamma}$, and every choice of nodes $w_0, u_1, w_1, \ldots, u_k, w_k$, perform the following steps.

- **D1.1** For $i = 0, \ldots, k$, and $v \in V'$, define $\mathsf{lb}_{i,v} := \sum_{j=0}^{i-1} \max\{c_{u_j w_j} + c_{w_j u_{j+1}}, c_{u_j u_{j+1}} + \gamma^j\} + c_{u_i v}$. Define $N^i := \{v \in V' : D_v \geq \mathsf{lb}_{i,v}\}$. If $u_i \notin N^i$ or $w_i \notin N^i$ for some $i \in \{0, \ldots, k\}$, then reject this guess – i.e., omit steps 12–14 – and move on to the next choice of u_i, w_i nodes.
- **D1.2** Use subroutine Greedy, or subroutine LP-Round below to obtain paths $Q^0, Q^1, \ldots, Q^k$, where each Q^i is a u_i-w_i path with $c^{\mathsf{reg}}_{u_i}(Q^i) \leq \lceil \gamma^i \rceil - 1$ visiting only nodes of N^i.
- **D1.3** For $\ell \in \{0, 1, 2\}$, let $Z^{(\ell)}$ be the path given by the node-sequence $r, \{Q^j\}_{0 \leq j \leq k : j = \ell \bmod 3}$.
- **D1.4** Add the path $Z^{\max} \in \{Z^{(0)}, Z^{(1)}, Z^{(2)}\}$ that gathers maximum reward to $\mathcal{Q}$.

D2 Return the best solution found in $\mathcal{Q}$, shortcutting the path to retain only the first occurrence of each node.

Subroutine Greedy.

G1 For $i = 0, \ldots, k$, use algorithm $\mathcal{A}$ to (approximately) solve the P2P-orienteering instance with start node u_i, end node w_i, node-set $N^i \setminus \left(\bigcup_{j=0}^{i-1} P^j\right)$, and length bound $c_{u_i w_i} + \lceil \gamma^i \rceil - 1$ (and node rewards $\{\pi_v\}_{v \in V'}$), to obtain a simple path P^i (so if $u_i = w_i$, then $P^i = \{u_i\}$ or $P^i = \emptyset$).
Return paths $P^0, \ldots, P^k$.

Subroutine LP-Round.

L1 Let $\mathcal{P}^i := \mathcal{P}^i(u_i, w_i, N^i, \lceil \gamma^i \rceil - 1)$ denote the collection of simple u_i-w_i paths with $c^{\mathsf{reg}}_{u_i}$-length at most $\lceil \gamma^i \rceil - 1$ (so the c-length is at most $c_{u_i w_i} + \lceil \gamma^i \rceil - 1$) and visiting only nodes from N^i. Note that if $u_i = w_i$ and $u_i \in N^i$, then $\mathcal{P}^i$ consists of only the trivial singleton path $\{u_i\}$. Consider the following LP.

$$\max \quad \sum_{i=0}^{k} \sum_{v \in V} \pi_v x^i_v \tag{Ap-P}$$

$$\text{s.t.} \quad \sum_{P \in \mathcal{P}^i} z^i_P \le 1 \qquad \forall i = 0, \dots, k \tag{1}$$

$$x^i_v \le \sum_{P \in \mathcal{P}^i : v \in P} z^i_P \qquad \forall v \in V,\ \forall i = 0, \dots, k \tag{2}$$

$$\sum_{i=0}^{k} x^i_v \le 1 \qquad \forall v \in V \tag{3}$$

$$x^i_{u_i} = x^i_{w_i} = 1 \qquad \forall i = 0, \dots, k \tag{4}$$

$$x, z \ge 0.$$

L2 Use Lemma 3.6 to obtain in polytime a solution $(\overline{x}, \overline{z})$ (with polynomial-size support) such that: (i) $\sum_{i=0}^{k} \sum_{v \in V} \pi_v \overline{x}^i_v \ge OPT_{\text{Ap-P}}$, (ii) $\sum_{P \in \mathcal{P}^i : v \in P} \overline{z}^i_P \ge \overline{x}^i_v / \alpha$ for all $v \in V$ and $i = 0, \dots, k$, and (iii) $(\overline{x}, \overline{z})$ satisfies the remaining constraints of (Ap-P).

L3 For each $i = 0, \dots, k$, sample a random path $P^i \in \mathcal{P}^i$ from the $\{\overline{z}^i_P\}_{P \in \mathcal{P}^i}$ distribution. Return paths $P^0, \dots, P^k$.

Analysis. The running time stated in Theorem 3.1 follows since $k = O(\log n\Delta)$, and for each k, we enumerate over all sequences of $2k$ nodes.

Recall that P^* is an optimal solution. Let $\mathsf{opt} = \pi(P^*)$ be the optimal value. We will assume in the sequel that we have the right choice of k and the u_i, w_i nodes. Recall that $u_0 = r$. That is, w_0 is the last node on P^* such that $c^{\mathsf{reg}}_{u_0}(P_{u_0 w_0}) = 0$. Given u_i, for $i \ge 0$, we have that u_{i+1} is the first node v on P^* after u_i such that $c^{\mathsf{reg}}_{u_i}(P_{u_i v}) \ge \gamma^i$, and w_i is the predecessor of u_{i+1}. If there is no such node u_{i+1}, then u_{i+1} is undefined and w_i is the the end-node of P^*. Also, k is the largest index such that u_k is well defined. Note that $k \ge 0$.

We begin by proving Lemma 3.2.

Proof of Lemma 3.2. For any $j \in \{0, \dots, i-1\}$, we have that $c(P^*_{u_j u_{j+1}}) \ge c(P^*_{u_j w_j}) + c_{w_j u_{j+1}} \ge c_{u_j w_j} + c_{w_j u_{j+1}}$ and also $c(P^*_{u_j u_{j+1}}) = c^{\mathsf{reg}}_{u_j}(P^*_{u_j u_{j+1}}) + c_{u_j u_{j+1}} \ge \gamma^j + c_{u_j u_{j+1}}$, where the inequality follows from the definition of u_{j+1}. The visiting time of $v \in P^*_{u_i w_i}$ is $c_{r u_0} + \sum_{j=0}^{i-1} c(P^*_{u_j u_{j+1}}) + c_{u_i v}$, which, using the above bounds, is at least $\mathsf{lb}_{i,v}$. ◀

Next, Lemma 3.3 shows that the paths $Z^{(\ell)}$ obtained in step D1.3 are feasible. Since these paths together cover $\bigcup_{i=0}^{k} Q^i$, the path $Z^{\max}$ returned in step D1.4 gathers reward at least $\pi\big(\bigcup_{i=0}^{k} Q^i\big)/3$.

▶ **Lemma 3.3.** *Consider $\ell \in \{0, 1, 2\}$, and the path $Z^{(\ell)}$ computed in step D1.3. For every Q^j that is part of $Z^{(\ell)}$, and every $v \in Q^j$, the visiting time of this occurrence of v in $Z^{(\ell)}$ is at most $\mathsf{lb}_{j,v} \le D_v$.*

Proof. Consider any Q^j that is part of $Z^{(\ell)}$. So $0 \le j \le k$ and $j = \ell \bmod 3$. We argue by induction on j that the visiting time (in $Z^{(\ell)}$) of every node $v \in Q^j$ is at most $\mathsf{lb}_{j,v}$.

For the base case, when $j = \ell$, the visiting time of any $v \in Q^\ell$ is at most $c_{u_0u_\ell} + c_{u_\ell v} + \lceil\gamma^\ell\rceil - 1$ since $c^{\mathsf{reg}}_{u_\ell}(Q^\ell_{u_\ell v}) \le c^{\mathsf{reg}}_{u_\ell}(Q^\ell) \le \lceil\gamma^\ell\rceil - 1$. We can check by inspection that this bound is always at most $\mathsf{lb}_{\ell,v}$:

- for $\ell = 0$, the bound is $c_{u_0v} = \mathsf{lb}_{0,v}$;
- for $\ell = 1$, the bound is $c_{u_0u_1} + c_{u_1v} + 1 \le \mathsf{lb}_{1,v}$;
- for $\ell = 2$, the bound is at most $c_{u_0u_2} + c_{u_2v} + \gamma^2 \le (c_{u_0u_1} + 1) + (c_{u_1u_2} + \gamma) + c_{u_2v} \le \mathsf{lb}_{2,v}$.

Now suppose $j > \ell$. The visiting time of any $v \in Q^j$ is at most (visiting time of w_{j-3}) + $c_{w_{j-3}u_j} + c_{u_jv} + \gamma^j$ since the $c^{\mathsf{reg}}_{u_j}$-length of $Q^j_{u_jv}$ is at most $\lceil\gamma^j\rceil - 1 \le \gamma^j$. By our induction hypothesis, the visiting time of w_{j-3} is at most $\mathsf{lb}_{j-3,w_{j-3}}$. Since $\gamma^j \le \gamma^{j-2} + \gamma^{j-1}$, we can upper bound the visiting time of v by

$$\big(\mathsf{lb}_{j-3,w_{j-3}} + c_{w_{j-3}u_{j-2}}\big) + \big(c_{u_{j-2}u_{j-1}} + \gamma^{j-2}\big) + \big(c_{u_{j-1}u_j} + \gamma^{j-1}\big) + c_{u_jv} \le \mathsf{lb}_{j,u_j} + c_{u_jv} \le \mathsf{lb}_{j,v}.$$

The first inequality is because for any index $i \ge 1$, we have $\mathsf{lb}_{i,u_i} \ge \mathsf{lb}_{i-1,w_{i-1}} + c_{w_{i-1}u_i}$ and $\mathsf{lb}_{i,u_i} \ge \mathsf{lb}_{i-1,u_{i-1}} + c_{u_{i-1}u_i} + \gamma^{i-1}$. This completes the induction step and proves the lemma. ◀

Finally, we prove guarantees for the paths returned by subroutine Greedy and subroutine LP-Round.

▶ **Lemma 3.4** (Follows from [7]). *The paths $Q^0, \ldots, Q^k$ returned if we use subroutine* Greedy *in step D1.2 satisfy $\pi\big(Q^0 \cup \ldots \cup Q^k\big) \ge \mathsf{opt}/(\alpha + 1)$.*

Proof. Clearly, for each $i = 0, \ldots, k$, we have that $P^*_{u_iw_i} \setminus \big(\bigcup_{j=0}^{i-1} Q^j\big)$ is a feasible solution to the P2P-orienteering instance that is fed as input to algorithm $\mathcal{A}$ in iteration i. So for each $i = 0, \ldots, k$, we have

$$\pi\Big(Q^i \setminus \big(\bigcup_{j=0}^{i-1} Q^j\big)\Big) \ge \frac{1}{\alpha} \cdot \pi\Big(P^*_{u_iw_i} \setminus \big(\bigcup_{j=0}^{i-1} Q^j\big)\Big). \tag{5}$$

Adding the above for $i = 0, \ldots, k$ yields an inequality whose LHS is $\pi\big(Q^0 \cup \ldots \cup Q^k\big)$, and whose RHS is at least $\frac{1}{\alpha} \cdot \pi\big(P^* \setminus (Q^0 \cup \ldots \cup Q^k)\big) \ge \frac{1}{\alpha} \cdot \big[\pi(P^*) - \pi\big(Q^0 \cup \ldots \cup Q^k\big)\big]$. It follows that $\pi\big(Q^0 \cup \ldots \cup Q^k\big) \ge \pi(P^*)/(\alpha + 1)$. ◀

Combining Lemma 3.4 with Lemma 3.3 leads to the proof of Theorem 3.1 (a).

Part (b) of Theorem 3.1

We now analyze the paths returned by subroutine LP-Round and prove Theorem 3.1 (b).

We first observe in Claim 3.5 that $OPT_{\text{Ap-P}} \ge \pi(P^*) = \mathsf{opt}$. Lemma 3.6 shows that using our P2P-orienteering approximation algorithm, we can obtain in polytime a solution $(\overline{x}, \overline{z})$ satisfying the properties stated in step L2. Given this, Lemma 3.7 proves that the random paths $Q^0, \ldots, Q^k$ returned by subroutine LP-Round satisfy $\mathrm{E}\big[\pi\big(\bigcup_{i=0}^k Q^i\big)\big] \ge \big(1 - e^{-1/\alpha}\big) OPT_{\text{Ap-P}}$. This yields the randomized guarantee stated in Theorem 3.1 (b). We then show how to derandomize the algorithm without affecting its guarantee or running time.

The following claim simply observes that, for each $i = 0, \ldots, k$, setting $z^i_{P^*_{u_iw_i}} = 1$ and x^i to be the indicator vector of the node-set of $P^*_{u_iw_i}$ yields a feasible solution to (Ap-P).

▷ Claim 3.5. We have $OPT_{\text{Ap-P}} \ge \pi(P^*)$.

Lemma 3.6 proves the main result regarding the polytime solvability of (Ap-P). Its proof is a bit technical, and is deferred to the end of this section.

▶ **Lemma 3.6.** *Using algorithm $\mathcal{A}$, we can obtain in polynomial time a solution $(\overline{x}, \overline{z})$ such that: (i) $\sum_{i=0}^{k} \sum_{v \in V} \pi_v \overline{x}_v^i \geq OPT_{Ap\text{-}P}$, (ii) $\sum_{P \in \mathcal{P}^i : v \in P} \overline{z}_P^i \geq \overline{x}_v^i / \alpha$ for all $v \in V$ and $i = 0, \ldots, k$, and (iii) $(\overline{x}, \overline{z})$ satisfies the remaining constraints of* (Ap-P).

▶ **Lemma 3.7.** *The paths $Q^0, \ldots, Q^k$ returned if we use subroutine* LP-Round *in step D1.2 satisfy $\mathrm{E}\big[\pi\big(\bigcup_{i=0}^{k} Q^i\big)\big] \geq \big(1 - e^{-1/\alpha}\big) OPT_{Ap\text{-}P}$.*

Proof. Defining $\rho_v := \Pr[v \in (Q^0 \cup \ldots \cup Q^k)]$ for $v \in V$, we have $\mathrm{E}\big[\pi\big(\bigcup_{i=0}^{k} Q^i\big)\big] = \sum_{v \in V} \pi_v \rho_v$. The paths $Q^0, \ldots, Q^k$ are chosen independently, and $\Pr[v \in Q^i] \geq \overline{x}_v^i / \alpha$ for each $v \in V$ (by Lemma 3.6 (ii)). So for every $v \in V$, we have

$$\rho_v \geq 1 - \prod_{i=0}^{k} \Big(1 - \tfrac{\overline{x}_v^i}{\alpha}\Big) \geq 1 - \Big(1 - \tfrac{\sum_{i=0}^{k} \overline{x}_v^i / \alpha}{k}\Big)^k \geq \Big[1 - \Big(1 - \tfrac{1}{\alpha k}\Big)^k\Big] \cdot \sum_{i=0}^{k} \overline{x}_v^i \geq \big(1 - e^{-1/\alpha}\big) \sum_{i=0}^{k} \overline{x}_v^i$$

which proves the lemma. The second inequality above follows from the AM-GM inequality, and the third uses the fact that the function $f(x) = 1 - \big(1 - \frac{x}{k}\big)^k$ is concave, and so $f(x) \geq x \cdot \frac{f(1/\alpha) - f(0)}{1/\alpha}$ for all $x \leq 1/\alpha$. ◀

Finishing up the proof of Theorem 3.1 (b). We first prove the randomized guarantee. The expected value of the solution returned is $\mathrm{E}\big[\max_{P \in \mathcal{Q}} \pi(P)\big]$, which is at least $\max_{P \in \mathcal{Q}} \mathrm{E}\big[\pi(P)\big]$. We lower bound the latter quantity by focusing on the path in $\mathcal{Q}$ returned for the right choice of k and the u_i-w_i nodes.

Fixing this choice, Claim 3.5 and Lemma 3.7 show that $\mathrm{E}\big[\pi\big(\bigcup_{i=0}^{k} Q^i\big)\big] \geq \big(1 - e^{-1/\alpha}\big)\pi(P^*)$. Since the $Z^{(\ell)}$ paths for $\ell = 0, 1, 2$ are feasible (Lemma 3.3) and together cover $\bigcup_{i=0}^{k} Q^i$, the path $Z^{\max}$ returned in step D1.4 satisfies $\mathrm{E}\big[\pi(Z^{\max})\big] \geq \frac{1 - e^{-1/\alpha}}{3} \cdot \pi(P^*)$.

Derandomization. The above guarantee can be easily derandomized. We use randomization only in sampling, for each $i = 0, \ldots, k$ independently, a random path Q^i from a polynomial-size distribution of u_i-w_i paths. Let $\mathcal{C}^i$ denote the support of this distribution, and for $P \in \mathcal{C}^i$, let λ_P^i denote the probability of choosing path P. The quantity of interest that determines the performance guarantee is $\Phi_0 = \Phi(\lambda^0, \ldots, \lambda^k) := \mathrm{E}\big[\pi\big(\bigcup_{i=0}^{k} Q^i\big)\big]$. For $P \in \mathcal{C}^i$, let $\mathbb{1}_P$ be the distribution that chooses P deterministically with probability 1. We show how to deterministically choose the Q^is so that $\Phi(\mathbb{1}_{Q^0}, \ldots, \mathbb{1}_{Q^k}) \geq \Phi_0$. We have $\Phi = \sum_{v \in V} \pi_v \rho_v$, where

$$\rho_v = \rho_{0,v} + (1 - \rho_{0,v})\rho_{1,v} + \ldots + (1 - \rho_{0,v})(1 - \rho_{1,v}) \cdots (1 - \rho_{k-1}, v)\rho_{k,v},$$
$$\text{and} \quad \rho_{i,v} = \rho_{i,v}(\lambda^0, \ldots, \lambda^k) = \sum_{P \in \mathcal{C}^i} \lambda_P^i \quad \forall i = 0, \ldots, k.$$

It is evident that each ρ_v is linear in λ^i, and therefore Φ is linear in λ^i. Therefore, to derandomize: (1) we choose $Q^0 \in \mathcal{C}^0$ so that $\Phi(\mathbb{1}_{Q^0}, \lambda^1, \ldots, \lambda^k) \geq \Phi_0$; (2) given that we have chosen $Q^0, \ldots, Q^{i-1}$, we choose $Q^i \in \mathcal{C}^i$ so that $\Phi(\mathbb{1}_{Q^0}, \ldots, \mathbb{1}_{Q^i}, \lambda^{i+1}, \ldots, \lambda^k) \geq \Phi(\mathbb{1}_{Q^0}, \ldots, \mathbb{1}_{Q^{i-1}}, \lambda^i, \ldots, \lambda^k)$. ◀

Proof of Lemma 3.6. Since (Ap-P) has an exponential number of variables, we consider the dual (Ap-D). The dual has polynomially many constraints corresponding to the polynomially many x_v^i primal variables, and an exponential number of constraints corresponding to the z_P^i primal variables. Using standard ideas (see, e.g., [13]), we show that we can use algorithm $\mathcal{A}$ to approximately separate over these exponentially many constraints, and hence leverage

the ellipsoid method to obtain the desired primal solution. Let $\theta^i \geq 0$ and $\mu_v^i \geq 0$ denote respectively the dual variables corresponding to constraints (1), (2). The dual constraints corresponding to the z_P^i variables are:

$$\sum_{v \in P} \mu_v^i \leq \theta^i \qquad \forall i = 0, \ldots, k, \ \forall P \in \mathcal{P}^i \tag{P2P}$$

For $b \geq 0$, we let (P2P$_b$) denote (P2P) with the RHS changed to θ^i/b. The effect of this on the primal is that it changes the RHS of (1) to b; let (Ap-P$_b$) denote (Ap-P) with this modified version of (1).

We focus on constraints (P2P) and do not explicitly write down the remaining (polynomially many) dual constraints (including nonnegativity constraints); we collectively denote these constraints by (Ap-D-*). Letting β denote the remaining dual variables, the objective function of (Ap-D) is of the form $\sum_{i=0}^k \theta^i + h^T\beta$, where h is a fixed vector.

Define $\mathcal{K}(\nu; b) := \left\{(\beta, \mu, \theta) : \mu, \theta \geq 0, \ \text{(Ap-D-*)}, \ \text{(P2P}_b\text{)}, \ \sum_{i=0}^k \theta^i + h^T\beta \leq \nu\right\}$. Note that the optimal value of the dual, and hence (Ap-P), is the smallest ν such that $\mathcal{K}(\nu; 1) \neq \emptyset$. Given ν, (β, μ, θ), we can use $\mathcal{A}$ to either show that $(\beta, \mu, \theta) \in \mathcal{K}(\nu; 1)$, or find a hyperplane separating (β, μ, θ) from $\mathcal{K}(\nu; \alpha)$. We first check if $\mu, \theta \geq 0$, (Ap-D-*) and $\sum_{i=0}^k \theta^i + h^T\beta \leq \nu$ hold, and if not use the violated inequality as the separating hyperplane. Next, for each $i = 0, \ldots, k$, we run $\mathcal{A}$ on the P2P-orienteering instance with start and end nodes u_i, w_i respectively, length bound $c_{u_i w_i} + \lceil \gamma^i \rceil - 1$, and node-rewards $\{\mu_v^i\}_{v \in V'}$. If for some i, we obtain a path $P \in \mathcal{P}^i$ with reward greater than θ^i/α, then we return $\sum_{v \in P} \mu_v^i \leq \theta^i/\alpha$ as the separating hyperplane. Otherwise, for all $i = 0, \ldots, k$ and all $P \in \mathcal{P}^i$, we know that $\sum_{v \in P} \mu_v^i \leq \theta^i$, and so $(\beta, \mu, \theta) \in \mathcal{K}(\nu; 1)$. Thus, for a fixed ν, in polynomial time, the ellipsoid method either certifies that $\mathcal{K}(\nu; \alpha) = \emptyset$, or returns a point $(\beta, \mu, \theta) \in \mathcal{K}(\nu; 1)$.

It is easy to find an upper bound UB such that $\mathcal{K}(\text{UB}; 1) \neq \emptyset$. For a given $\epsilon > 0$, we use binary search in the range $[0, \text{UB}]$ to find ν^* such that the ellipsoid method when run for ν^* (with the above separation oracle) returns $(\beta^*, \mu^*, \theta^*) \in \mathcal{K}(\nu^*; 1)$, and when run for $\nu^* - \epsilon$ certifies that $\mathcal{K}(\nu^* - \epsilon; \alpha) = \emptyset$. Since $\mathcal{K}(\nu^*; 1) \neq \emptyset$, we have that $OPT_{\text{Ap-P}} \leq \nu^*$, and $\mathcal{K}(\nu^* - \epsilon; \alpha) = \emptyset$ implies that the optimal value of (Ap-P$_\alpha$) is at least $\nu^* - \epsilon$. For $\nu^* - \epsilon$, the inequalities returned by the separation oracle during the execution of the ellipsoid method together with the inequality $\sum_{i=0}^k \theta^i + h^T\beta \leq \nu^* - \epsilon$ yield a polynomial-size certificate for the emptiness of $\mathcal{K}(\nu^* - \epsilon; \alpha)$. By duality (or Farkas' lemma), this implies that if we restrict (Ap-P$_\alpha$) to only use the (polynomially many) z_P^i variables corresponding to the violated inequalities of type (P2P$_\alpha$) returned during the execution of the ellipsoid method, we obtain a polynomial-size feasible solution $(\overline{x}, \hat{z})$ to (Ap-P$_\alpha$) of value at least $\nu^* - \epsilon$. If we take ϵ to be inverse exponential in the input size, this also implies $(\overline{x}, \hat{z})$ has value at least $\nu^* \geq OPT_{\text{Ap-P}}$. Finally, setting $\overline{z} = \hat{z}/\alpha$, we obtain that $(\overline{x}, \overline{z})$ has the desired properties. ◀

▶ Remark 3.8. It is worthwhile to note that *none* of our arguments above rely on the symmetry of the underlying metric, and so *the reduction in Theorem 3.1 also holds in asymmetric metrics*. Given an asymmetric metric $\{c_{u,v}\}_{u,v \in V \cup \{r\}}$, we define regret distances in the same way – $c_u^{\text{reg}}(v, w) := c_{u,v} + c_{v,w} - c_{u,w}$ – and they continue to form an asymmetric metric.

▶ Remark 3.9. In step D1, we only need to let k go up to $\log_\gamma D_{\max}$ (where $D_{\max} := \max_v D_v \leq n\Delta$), and so the running time is $O\left(n^{\log D_{\max}}\right)$. Also, for any integer $c \geq 1$, we can obtain an $O(c)$-approximation in $O\left(c \cdot n^{\frac{\log D_{\max}}{c}}\right)$ time, as follows. We divide the indices $0, 1, \ldots, k$ (where $k \leq \log_\gamma D_{\max}$) groups of (roughly) $\frac{k}{c}$ consecutive indices, essentially run our algorithm for each group *separately*, and return the best solution found. To elaborate, for a group $\{a, a+1, \ldots, b\}$, we guess the corresponding nodes $u_a, w_a, \ldots, u_b, w_b$, and obtain a

u_i-w_i path Q^i for each $i \in \{a, \ldots, b\}$ such that $c^{\mathsf{reg}}_{u_i}(Q^i) \leq \lceil \gamma^i \rceil - 1$, and $(Q^a \cup \ldots \cup Q^b)$ obtains reward $\Omega\big(\pi(P^*_{u_a w_b})\big)$. Since we are considering each group in isolation and do not know the u_j, w_j nodes for $j < a$, we need to define $\mathsf{lb}_{i,v}$ differently now (which then specifies the node-set N^i that Q^i is allowed to visit); we now define $\mathsf{lb}_{i,v} := \sum_{j=0}^{a-1} \gamma^j + \sum_{j=a}^{i-1} \max\{c_{u_j w_j} + c_{w_j u_{j+1}}, c_{u_j u_{j+1}} + \gamma^j\} + c_{u_i v}$. Similar to before, for $\ell \in \{0, 1, 2\}$, we define $Z^{(\ell)}$ as the path with node-sequence r, $\{Q^j\}_{a \leq j \leq b : j-a = \ell \bmod 3}$, and it is not hard to mimic the earlier arguments to infer that each $Z^{(\ell)}$ is a feasible deadline-TSP solution.

Note that taking $c = \log_\gamma D_{\max}$, this shows that the best of the r, Q^i-paths, for $i = 0, \ldots, \log_\gamma D_{\max}$ yields a (very simple) $O(\log D_{\max})$-approximation in polynomial time.

▶ Remark 3.10. There are a couple of ways of improving the efficiency of algorithm LP-Round, while incurring some associated loss of approximation factor. First, as noted earlier, Friggstad and Swamy [14] gave a polynomial-size LP-relaxation for P2P orienteering, and an LP-rounding 6-approximation algorithm for P2P orienteering. Their algorithm explicitly yields the distributional guarantee proved in Lemma 3.6, namely, it returns a (polynomial-support) distribution of P2P-orienteering solutions that visits each node with probability at least $x^i_v/6$, where x^i_v has the same meaning as above (see Section 5). One could replace the exponential-size LP (Ap-P) in algorithm LP-Round with their compact LP, and sample paths from the distribution output by their algorithm. This yields a much more efficient guarantee relative to an LP upper bound, but the approximation guarantee degrades to $\frac{3}{1-e^{-1/6}} \approx 19.542$. (While this is worse than the guarantee obtained using Greedy and the $(2+\epsilon)$-approximation for orienteering [6], the benefit is that this guarantee is with respect to an LP upper bound; also, the orienteering algorithm in [14] is simpler than the one in [6].)

Second, one can replace the use of the ellipsoid method to approximately solve (Ap-P) by the multiplicative-weights method, incurring a small loss in approximation.

4 Extensions

Our techniques can be applied to handle various extensions, including monotone-reward TSP, which we discuss here, and some other extensions that we discuss in Section 4.2.

4.1 Monotone-reward TSP

Recall that in monotone-reward TSP, each node v has a non-increasing reward function $\pi_v : \mathbb{R}_+ \mapsto \mathbb{R}_+$, where we set $\pi_r(x) = 0$ for all x for notational ease. We overload notation, and for a rooted path P, we now *define* $\pi(P) := \sum_{v \in P} \pi_v(c_P(v))$, and call this the reward of P. The goal is to find a simple rooted path that obtains maximum reward. Each $\pi_v(.)$ function is specified via a value oracle, and we treat each call to this oracle as an elementary operation. Recall that we assume that c_{uv} is an integer for all $u, v \in V \cup \{r\}$.

We show that monotone-reward TSP can be reduced to deadline TSP. This reduction incurs a slight loss and increases the size of the instance. We also show that the algorithms and analysis from Section 3 carry over easily to monotone-reward TSP.

▶ **Theorem 4.1.**

(1) *For any $\epsilon > 0$, given a monotone-reward TSP instance $\mathcal{I}$ with n clients, we can obtain in polytime a deadline-TSP instance $\mathcal{I}'$ with $O\big(\frac{n}{\epsilon} \cdot \log \frac{n}{\epsilon}\big)$ clients such that an α-approximation for $\mathcal{I}'$ yields an $\alpha/(1-2\epsilon)$-approximation to $\mathcal{I}$.*

(2) *The algorithms for deadline TSP described in Section 3 can be easily adapted to monotone-reward TSP and yield the same guarantees as those stated in Theorem 3.1.*

Proof of part (1) of Theorem 4.1. Recall that Δ is the diameter of the metric. In any simple rooted path, each client is visited by time $n \cdot \Delta$; so we define $\pi_v(t) = 0$ for all $t > n\Delta$ for notational ease. In the deadline-TSP instance, we use the same metric, but for each node $v \in V$ and every time $t \in \{0, 1, \ldots, n\Delta\}$, we create a co-located client (v, t) with deadline t and reward $\pi_v(t) - \pi_v(t+1)$ (which is nonnegative since $\pi_v(.)$ is non-increasing). Thus, if v is visited at time t in the original graph, then we collect reward $\pi_v(t)$ in total from its co-located clients $(v, t), (v, t+1), \ldots$. This is a lossless, but pseudo-polytime, reduction.

To make this efficient, we apply a geometric bucketing idea on the rewards. Consider a fixed $\epsilon > 0$. Observe that $\mathsf{LB} := \max_{v \in V} \pi_v(c_{rv})$ is the maximum reward that any solution can collect from node v. Also, we can obtain a path with reward at least LB by considering the path r, v for the node v that attains the maximum. We we have $\mathsf{LB} \leq \mathsf{opt}_{\mathcal{I}} \leq n \cdot \mathsf{LB}$, where $\mathsf{opt}_{\mathcal{I}}$ is the optimal value for the monotone-reward TSP instance $\mathcal{I}$. Now for each $v \in V$, instead of creating $n \cdot \Delta$ co-located clients, we consider each integer $i \geq 0$ such that $(1-\epsilon)^i \geq \frac{\epsilon}{n}$; note that there are at most $O\left(\frac{1}{\epsilon} \cdot \log \frac{n}{\epsilon}\right)$ such values. For each such i, we use binary search (using the value oracle) to find the largest integer $t_{v,i}$ such that $\pi_v(t_{v,i}) \geq (1-\epsilon)^i \cdot \mathsf{LB}$. In the deadline TSP instance $\mathcal{I}'$, we create a client located at v with deadline $t_{v,i}$ and reward $(1-\epsilon)^i \cdot \mathsf{LB} - (1-\epsilon)^{i+1} \cdot \mathsf{LB}$. So, if a path reaches location v by time $t_{v,i}$ it will collect reward at least $(1-\epsilon)^i \cdot \mathsf{LB} - \frac{\epsilon}{n} \cdot \mathsf{LB}$.

Let P^* be an optimum monotone-reward TSP solution. Consider the value of P^* as a solution to the new deadline-TSP instance. Consider each v on P^*, and say v was visited at time t along P^*. We know that $\pi_v(t) \leq \mathsf{LB}$. Let i be the smallest integer such that $(1-\epsilon)^i \cdot \mathsf{LB} \leq \pi_v(t)$; so we also have $(1-\epsilon)^i \cdot \mathsf{LB} \geq (1-\epsilon)\pi_v(t)$. By the construction of $\mathcal{I}'$, we know that $t_{v,i} \geq t$, and so we collect total reward at least $(1-\epsilon)^i \cdot \mathsf{LB} - \frac{\epsilon}{n} \cdot \mathsf{LB} \geq (1-\epsilon)\pi_v(t) - \frac{\epsilon}{n} \cdot \mathsf{LB}$ from the clients co-located at v. So the total reward of P^* when viewing it as a deadline-TSP solution is at least $(1-\epsilon) \cdot \mathsf{opt}_{\mathcal{I}} - \epsilon \cdot \mathsf{LB} \geq (1-2\epsilon) \cdot \mathsf{opt}_{\mathcal{I}}$.

Conversely, any deadline-TSP solution P' when viewed as a monotone-reward TSP solution produces at least as much reward, since for any time t and any client v, $\pi_v(t)$ is at least the total reward that will be collected in instance $\mathcal{I}'$ by visiting the clients located at v at time t. Therefore, a solution to instance $\mathcal{I}'$ of value at least $\mathsf{opt}_{\mathcal{I}'}/\alpha$ yields a monotone-reward TSP solution with value at least $\frac{1-2\epsilon}{\alpha} \cdot \mathsf{opt}_{\mathcal{I}}$. ◀

Proof of part (2) of Theorem 4.1

We briefly sketch the changes to the algorithms and analyses from Section 3. The only changes to Algorithm 1 involve changes to the constituent subroutines Greedy and LP-Round, and entail figuring out what *fixed* node rewards to use when we consider a P2P-orienteering instance in step G1, or in LP (Ap-P). (As before, P^* denotes an optimal solution, and the right choice of u_i, w_i nodes continues to be as defined in Section 3; consequently Lemma 3.2 continues to hold. Also, steps D1.4 and D2 hold as is, given our modified definition of the reward of a path.)

Two observations guide the choice of rewards we use in step G1 and in (Ap-P). First, we know that the visiting time of a node $v \in P^*_{u_i w_i}$ is at least $\mathsf{lb}_{i,v}$. Second, suppose for each i, we obtain a u_i-w_i path Q^i with $c^{\mathsf{reg}}_{u_i}(Q^i) \leq \lceil \gamma^i \rceil - 1$ and construct the paths $\{Z^{(0)}, Z^{(1)}, Z^{(2)}\}$ as in step D1.3; then, by Lemma 3.3, for every $Z^{(\ell)}$, every $Q^j \subseteq Z^{(\ell)}$, and every $v \in Q^j$, we know that the visiting time of this occurrence of v is at most $\mathsf{lb}_{i,v}$. Consequently, in subroutine Greedy and subroutine LP-Round, we use the node rewards $\{\pi_v(\mathsf{lb}_{i,v})\}_{v \in V'}$ for the i-th orienteering instance; also, the node-set N^i is now simply V. Let (MRAp-P) denote the resulting analogue of (Ap-P), where the coefficient multiplying x^i_v in the objective is now $\pi_v(\mathsf{lb}_{i,v})$.

Essentially, all the statements proved for deadline TSP hold here as well, with minor notational tweaks, and for mostly the same reasons. (Recall that for a rooted path P, we now define $\pi(P) := \sum_{v \in P} \pi_v(c_P(v))$, and call this the reward of P.)

Algorithm Greedy is unchanged, and the guarantee of Lemma 3.4 still holds, but it needs to be stated more precisely, and its proof needs to be tweaked. The modified statement is that we have $\sum_{i=0}^{k} \sum_{v \in Q^i \setminus (Q^0 \cup \ldots \cup Q^{i-1})} \pi_v(\mathsf{lb}_{i,v}) \geq \mathsf{opt}/(\alpha+1)$. In the proof, in place of (5), for all $i = 0, \ldots, k$, we now have

$$\sum_{v \in Q^i \setminus (\bigcup_{j=0}^{i-1} Q^j)} \pi_v(\mathsf{lb}_{i,v}) \geq \frac{1}{\alpha} \cdot \sum_{\substack{v \in P^*_{u_i w_i} \\ v \notin \bigcup_{j=0}^{i-1} Q^j}} \pi_v(\mathsf{lb}_{i,v}) \geq \frac{1}{\alpha} \cdot \left[\sum_{v \in P^*_{u_i w_i}} \pi_v\big(c_{P^*}(v)\big) - \sum_{\substack{v \in P^*_{u_i w_i} \\ v \in \bigcup_{j=0}^{i-1} Q^j}} \pi_v(\mathsf{lb}_{i,v}) \right] \quad (6)$$

Consider adding, for all $i = 0, \ldots, k$, the inequality in (6) involving the LHS of (6) and the final RHS of (6). The LHS of the resulting inequality is $\sum_{i=0}^{k} \sum_{v \in Q^i \setminus (Q^0 \cup \ldots \cup Q^{i-1})} \pi_v(\mathsf{lb}_{i,v})$. For a node v, consider its total contribution (across all i) to the negative terms on the final RHS of (6). Node v gets counted at most once among all these negative terms, and if i is the smallest index such that $v \in Q^i$, then the negative term where v is counted is due to some index $j > i$, and so is at least $-\pi_v(\mathsf{lb}_{i,v})$. Therefore, the total contribution of the negative terms on the RHS is at least $-\frac{1}{\alpha} \cdot \sum_{i=0}^{k} \sum_{v \in Q^i \setminus (Q^0 \cup \ldots \cup Q^{i-1})} \pi_v(\mathsf{lb}_{i,v})$. Thus, adding (6) for all $i = 0, \ldots, k$ and simplifying yields the inequality $\sum_{i=0}^{k} \sum_{v \in Q^i \setminus (Q^0 \cup \ldots \cup Q^{i-1})} \pi_v(\mathsf{lb}_{i,v}) \geq \mathsf{opt}/(\alpha+1)$.

Subroutine LP-Round is also unchanged, except for the change in (Ap-P) due to the above-mentioned node rewards and since $N^i = V$. The new LP (MRAp-P) can be approximately solved as in Lemma 3.6. Let $\overline{x}$ denote the values of the x_i^v variables in the solution so obtained. Then we have $\overline{z}$ such that the objective value of $(\overline{x}, \overline{z})$ is at least $OPT_{\text{(MRAp-P)}}$, $\sum_{P \in \mathcal{P}^i : v \in P} \overline{z}^i_P \geq \overline{x}^i_v/\alpha$ for all $v \in V$ and $i = 2, \ldots, k$, and $(\overline{x}, \overline{z})$ satisfies the remaining constraints of (MRAp-P).

Claim 3.5 gets replaced by

$$\sum_{i=0}^{k} \sum_{v \in V} \pi_v(\mathsf{lb}_{i,v}) \overline{x}^i_v \geq \sum_{i=0}^{k} \sum_{v \in P^*_{u_i w_i}} \pi_v(\mathsf{lb}_{i,v}) \geq \sum_{v \in P^*} \pi_v(c_{P^*}(v)) = \mathsf{opt} \quad (7)$$

The guarantee of Lemma 3.7 still holds, but it needs to be stated more precisely and requires a different proof, which we defer to the end of this section.

▶ **Lemma 4.2.** *For each $i = 0, \ldots, k$, let Q^i be a random path obtained such that $\Pr[v \in Q^i] \geq \overline{x}^i_v/\alpha$ for all $v \in V$, for some $\alpha \geq 1$. Then*

$$\mathrm{E}\left[\sum_{i=0}^{k} \sum_{v \in Q^i \setminus (Q^2 \cup \ldots \cup Q^{i-1})} \pi_v(\mathsf{lb}_{i,v})\right] \geq \big(1 - e^{-1/\alpha}\big) \cdot \left(\sum_{i=0}^{k} \sum_{v \in V} \pi_v(\mathsf{lb}_{i,v}) \overline{x}^i_v\right).$$

To finish up the analysis, as before we lower bound $\max_{\ell=0,1,2} \mathrm{E}\big[\pi(Z^{(\ell)})\big]$. Since Lemma 3.3 continues to hold, for every node v, we know that if i is the smallest index such that $v \in Q^i$, then v is visited by some path $Z^{(\ell)}$ by time $\mathsf{lb}_{i,v}$. Therefore, $\max_{\ell=0,1,2} \mathrm{E}\big[\pi(Z^{(\ell)})\big] \geq \frac{1}{3} \cdot \mathrm{E}\big[\sum_{i=0}^{k} \sum_{v \in Q^i \setminus (Q^2 \cup \ldots \cup Q^{i-1})} \pi_v(\mathsf{lb}_{i,v})\big]$. Combining this with Lemma 4.2 and (7), we obtain the same approximation guarantee as in part (b) of Theorem 3.1.

Finally, the derandomization also proceeds as before. Let $\mathcal{C}^i$ denote the polynomial-size support of the distribution from which the u_i-w_i path Q^i is sampled, and let λ^i_P denote the probability of choosing a path $P \in \mathcal{C}^i$. We are now interested in the quantity $\Phi_0 =$

$\Phi(\lambda^0,\ldots,\lambda^k) := \mathrm{E}\big[\sum_{i=0}^{k}\sum_{v\in Q^i\setminus(Q^2\cup\ldots\cup Q^{i-1})}\pi_v(\mathsf{lb}_{i,v})\big]$. We now have $\Phi = \sum_{v\in V}\mathsf{rewd}_v$, where

$$\mathsf{rewd}_v = \rho_{0,v}\pi_v(\mathsf{lb}_{0,v}) + (1-\rho_{0,v})\rho_{1,v}\pi_v(\mathsf{lb}_{1,v}) + \ldots + \Big(\prod_{i=0}^{k}(1-\rho_{i,v})\Big)\rho_{k,v}\pi_v(\mathsf{lb}_{k,v}), \text{ and}$$
$$\rho_{i,v} = \rho_{i,v}(\lambda^0,\ldots,\lambda^k) = \sum_{P\in\mathcal{C}^i}\lambda_P^i \quad \forall i = 0,\ldots,k.$$

Since each rewd_v is linear in λ^i for all i, as before, we can deterministically choose Q^is for all i so that $\Phi(\mathbb{1}_{Q^0},\ldots,\mathbb{1}_{Q^k}) \geq \Phi_0$.

Proof of Lemma 4.2. The following claim will be useful.

▷ Claim 4.3. Let $a_1 \geq a_2 \geq \ldots \geq a_q \geq a_{q+1} := 0$. Let $y \in [0,1]^q$, and $t \geq \sum_{i=1}^{q} y_i$. Define $F(y_1,\ldots,y_q) := y_1a_1 + (1-y_1)y_2a_2 + \ldots + (1-y_1)(1-y_2)\cdots(1-y_{q-1})y_qa_q$. We have: (i) $F(y) \geq (1-e^{-t})\cdot\frac{\sum_{i=1}^{q}a_iy_i}{t}$; and (ii) $F(z) \leq F(y)$ for any z such that $0 \leq z \leq y$.

Proof. The proof of part (i) follows from elementary arguments (see, e.g., [11]). For any $i = 1,\ldots,q$, we have

$$y_1 + (1-y_1)y_2 + \ldots + (1-y_1)(1-y_2)\cdots(1-y_{i-1})y_i = \Big(1-(1-y_1)(1-y_2)\cdots(1-y_i)\Big)$$
$$\geq 1 - \Big(1-\frac{\sum_{j=1}^{i}y_j}{i}\Big)^i \geq \Big[1-\Big(1-\tfrac{t}{i}\Big)^i\Big]\cdot\frac{\sum_{j=1}^{i}y_j}{t} \geq \big(1-e^{-t}\big)\cdot\frac{\sum_{j=1}^{i}y_j}{t}$$

The first inequality is the AM-GM inequality, the second uses the fact that the function $f(x) = 1-\big(1-\frac{x}{i}\big)^i$ is concave, and so $f(x) \geq x\cdot\frac{f(t)-f(0)}{t}$ for $x \leq t$. That is, we have

$$y_1 + (1-y_1)y_2 + \ldots + (1-y_1)(1-y_2)\cdots(1-y_{i-1})y_i \geq \big(1-e^{-t}\big)\cdot\frac{\sum_{j=1}^{i}y_j}{t} \tag{8}$$

Multiplying (8) by $a_i - a_{i+1}$ and adding the resulting inequalities for $i = 1,\ldots,q$ yields the stated bound.

Part (ii) follows from the fact that

$$\frac{\partial F}{\partial y_i} = (1-y_1)\cdots(1-y_{i-1})\Big[a_i - \Big(a_{i+1}y_{i+1} + (1-y_{i+1})y_{i+2}a_{i+2} + \ldots + (1-y_{i+1})\cdots(1-y_{q-1})y_qa_q\Big)\Big]$$

which is nonnegative since $a_i \geq a_{i+1},\ldots,a_q$. ◁

We now have everything to prove Lemma 4.2. Let $\rho_v^i := \Pr[v \in Q^i]$ for $v \in V$, and $i = 0,\ldots,k$. Let Φ denote the quantity on the LHS of the inequality in the lemma. Since $Q^0,\ldots,Q^k$ are chosen independently, we have $\Phi = \sum_{v\in V}\mathsf{rewd}_v$, where

$$\mathsf{rewd}_v = \rho_{0,v}\pi_v(\mathsf{lb}_{0,v}) + (1-\rho_{0,v})\rho_{1,v}\pi_v(\mathsf{lb}_{1,v}) + \ldots + \Big(\prod_{i=0}^{k}(1-\rho_{i,v})\Big)\rho_{k,v}\pi_v(\mathsf{lb}_{k,v})$$
$$\geq \tfrac{\overline{x}_v^0}{\alpha}\cdot\pi_v(\mathsf{lb}_{0,v}) + \Big(1-\tfrac{\overline{x}_v^0}{\alpha}\Big)\tfrac{\overline{x}_v^1}{\alpha}\cdot\pi_v(\mathsf{lb}_{1,v}) + \ldots + \Big(\prod_{i=0}^{k}\Big(1-\tfrac{\overline{x}_v^i}{\alpha}\Big)\Big)\tfrac{\overline{x}_v^k}{\alpha}\cdot\pi_v(\mathsf{lb}_{k,v}).$$

The inequality follows from part (ii) of Claim 4.3 since $\rho_v^i \geq \overline{x}_v^i/\alpha$ for all $i = 0,\ldots,k$. Applying Claim 4.3 with $a_i = \pi_v(\mathsf{lb}_{i,v})$ and $y_i = \frac{\overline{x}_v^i}{\alpha}$ for all $i = 0,\ldots,k$, and $t = \frac{1}{\alpha}$, we therefore obtain that $\mathsf{rewd}_v \geq \big(1-e^{-1/\alpha}\big)\sum_{i=0}^{k}\pi_v(\mathsf{lb}_{i,v})\overline{x}_v^i$. It follows that $\Phi \geq \big(1-e^{-1/\alpha}\big)\cdot\big(\sum_{i=0}^{k}\sum_{v\in V}\pi_v(\mathsf{lb}_{i,v})\overline{x}_v^i\big)$. ◀

4.2 Further extensions of Deadline TSP

Point-to-point {deadline, monotone-reward} TSP. In the point-to-point (P2P) version of {deadline, monotone-reward} TSP, in addition to the root node r, we are also given an end-node t and a length-bound B. The goal is to find an r-t path of length at most B that collects maximum reward.

The P2P-version easily reduces to the standard version of the problem. For deadline TSP, we can incorporate the above requirements by modifying the deadline of each node $v \in V'$ to $D_v^{\mathsf{new}} := \min\{D_v, B - c_{vt}\}$. If P is a rooted path ending at a node s such that all $v \in P$ are visited by time D_v^{new}, then $P' = P, st$ is an r-t path such that all $v \in P'$ are visited by time D_v, and $c(P') \leq D_s^{\mathsf{new}} + c_{st} \leq B$.

Similarly, for monotone-reward TSP, we modify the reward function of each $v \in V'$ to $\pi_v^{\mathsf{new}}(x) = \pi_v(x)$ if $x \leq B - c_{vt}$, and 0 if $x > B - c_{vt}$. As before if P is an r-s path earning a certain modified reward, then $P' = P, st$ is an r-t path of length at most B earning the same reward.

TSP with release dates, and TSP with increasing rewards. In TSP with release dates, each node v has a release date rel_v instead of a deadline, and we have a length bound B. A feasible solution is a rooted path P, and a traversal of P starting from the root node where we are allowed to also wait at nodes, so that the visiting time of each node $v \in P$ is at least rel_v and at most B; we seek a feasible solution that gathers maximum reward. Set $\mathsf{rel}_r = 0$ for notational convenience.

As noted in [2], this can be reduced to deadline TSP as follows. If P is a feasible solution ending at node t, then we must have $\mathsf{rel}_t \leq B$ and $c(P_{vt}) \leq B - \mathsf{rel}_v$ for all $v \in P$. Conversely any r-t path P with $c(P_{vt}) \leq B - \mathsf{rel}_v$ for all $v \in P$ yields a feasible solution, where we wait at r for $B - c(P)$ time and then traverse P without any subsequent waiting. We thus infer that we seek a feasible solution to P2P-deadline TSP (and hence deadline TSP) with start node t, end-node r, length bound B, and deadlines $\{B - \mathsf{rel}_v\}_{v \in V'}$. Trying all possible choices of t completes the reduction.

Analogous to how monotone-reward TSP generalizes deadline TSP, we can consider a generalization of TSP with release dates wherein each node v has a *non-decreasing* reward function $\pi_v : \mathbb{R}_+ \mapsto \mathbb{R}_+$, and we seek a rooted path P with $c(P) \leq B$, and a traversal of P that yields maximum reward. As above, if we know the end-node t of an optimal solution, then this reduces to solving an instance of P2P monotone-reward TSP, where we seek a path starting at t and ending at r path of length at most B, and the reward of node v is given by the *non-increasing* function $\pi'_v(x) = \pi_v(B - x)$.

Orienteering with time windows. Chekuri et al. [6] obtain (among other results) an $O\big(\max\{\log \mathsf{opt}, \log \frac{L_{\max}}{L_{\min}}\}\big)$-approximation for orienteering with time windows, where opt is the optimal value, and $L_{\max}$ and $L_{\min}$ are the lengths of the longest and shortest time windows with non-zero length. The $\log \mathsf{opt}$ term in their guarantee is because they use the logarithmic approximation of [2] for deadline TSP.[3] Replacing this algorithm with our deadline-TSP algorithm therefore yields an $O\big(\log \frac{L_{\max}}{L_{\min}}\big)$-approximation for orienteering with time windows in $O\big(n^{\log n \Delta}\big)$ time.

[3] Chekuri et al. [6] work with $\{0, 1\}$-rewards, and in this setting, the approximation factor obtained in [2] for deadline TSP can be seen to be $O(\log \mathsf{opt})$.

5 LP-rounding algorithm for P2P-orienteering in [14]

We briefly discuss the LP-rounding algorithm for P2P-orienteering by Friggstad and Swamy [14] that directly yields the distributional guarantee utilized in subroutine LP-Round. Recall that $(V' = \{r\} \cup V, c)$ is the underlying metric, and our P2P-orienteering instance $\mathcal{I}$ is specified by node-set $N \subseteq V'$, start and end-nodes $s, t \in N$ respectively, length-bound B, and node-rewards $\{\pi_v\}_{v \in N}$.

Let $D = (N, A)$ denote the complete (bidirected) graph on N, where the cost of an arc $(u, v) \in A$ is set to c_{uv}; thus c induces a metric on D. Let P^* be an optimal solution to $\mathcal{I}$. The idea underlying the LP relaxation is to "guess" the node $v \in P^*$ that maximizes $c_{sv} + c_{vt}$. The LP then searches for an $s \rightsquigarrow v$ path and a $v \rightsquigarrow t$ path – encoded by requiring an s-v flow and v-t flow of value 1 – that visit only nodes $u \in N$ such that $c_{su} + c_{ut} \leq c_{sv} + c_{vt}$, have total length at most B, and together earn the maximum reward. Also, we replace the "guessing" step by having indicator variables z^v_v to denote if v is the node on P^* with maximum $c_{sv} + c_{vt}$ value.

This leads to the following LP. For every $v \in N$, we have the following set of variables (in addition to z^v_v). We use $x_v \in [0, 1]$ to denote the extent to which v is visited. We let y^{sv} denote an s-v flow of value z^v_v, and y^{vt} denotes a v-t flow of value x^v_v. We impose that $y^{sv}\big(\delta^{\text{in}}(u)\big) = y^{vt}\big(\delta^{\text{in}}(u)\big) = 0$ whenever $c_{su} + c_{ut} > c_{sv} + c_{vt}$. We use z^{sv}_u and z^{vt}_u to denote respectively the $s \rightsquigarrow u$ connectivity under x^{sv} and the $v \rightsquigarrow u$ connectivity under x^{vt}. So in an integral solution, z^{sv}_u and z^{vt}_u indicate respectively if u lies on the s-v portion or the v-t portion of the optimum path. We connect the x and z variables by imposing that $x_u = \sum_{v \in N}(z^{sv}_u + z^{vt}_u)$ for every $u \in N$. For nodes $v, p, q \in N$, and $\kappa \geq 0$, define

$$\mathcal{F}_v(p, q, \kappa) := \Big\{ y \in \mathbb{R}^A_+ : \quad y\big(\delta^{\text{out}}(p)\big) = \kappa = y\big(\delta^{\text{in}}(q)\big), \qquad y\big(\delta^{\text{in}}(p)\big) = 0 = y\big(\delta^{\text{out}}(q)\big)$$
$$y\big(\delta^{\text{in}}(w)\big) - y\big(\delta^{\text{out}}(w)\big) = 0 \qquad \forall w \in V' \setminus \{p, q\}$$
$$y\big(\delta^{\text{in}}(w)\big) = 0 \qquad \forall w \in V' : c_{sw} + c_{wt} > c_{sv} + c_{vt} \Big\}$$

Note that if $\kappa > 0$, then $\mathcal{F}(u, u, \kappa) = \emptyset$ for every u.

$$\max \quad \sum_{u,v \in N} \pi_u x_u \tag{P2P-O}$$
$$\text{s.t.} \quad y^{sv} \in \mathcal{F}_v(s, v, z^v_v),\ y^{vt} \in \mathcal{F}_v(v, t, z^v_v) \qquad \forall v \in N$$
$$y^{sv}\big(\delta^{\text{in}}(S)\big) \geq z^{sv}_u \qquad \forall v \in N, S \subseteq N \setminus \{s\}, u \in S \tag{9}$$
$$y^{vt}\big(\delta^{\text{in}}(S)\big) \geq z^{vt}_u \qquad \forall v \in N, S \subseteq N \setminus \{v\}, u \in S \tag{10}$$
$$\sum_{a \in A} c_a(y^{sv}_a + y^{vt}_a) \leq B z^v_v \qquad \forall v \in N \tag{11}$$
$$\sum_{v \in N}(z^{sv}_u + z^{vt}_u) = x_u \qquad \forall u \in N \tag{12}$$
$$\sum_{v \in N} z^v_v = 1, \qquad y, z \geq 0, \quad x \in [0, 1]^N.$$

As noted in [14], we can rephrase the cut constraints (9), (10) using additional flow variables and constraints to obtain a polynomial-size formulation.

Friggstad and Swamy [14] devise the following algorithm for rounding an LP solution (x, y, z). They show that for each $v \in N$, we can utilize y^{sv} to obtain a polynomial collection of s-rooted paths, and weights for these paths such that:

(i) if a path P in the collection ends at a node u, then $P' = P, ut$ is an s-t path with $c(P') \leq B$;
(ii) the total weight of paths in the collection is at most $3z_v^v$; and
(iii) the total weight of paths containing a node u is at least z_u^{sv}, for all $u \in N$.

Similarly, we can utilize y^{vt} to obtain a suitable weighted collection of paths, each of which yields an s-t path of length at most B. Taking these collections for all $v \in N$, we obtain that the total weight of paths is at most 6, and for each $u \in N$, the total weight of paths containing u is at least $\sum_v (z_u^{sv} + z_u^{vt}) = x_u$. The distribution obtained by scaling the weights by 6 yields the desired distribution.

Abstract

With a wide range of applications, stochastic matching problems have been studied in different models, including prophet inequality, Query-Commit, and Price-of-Information. While there have been recent breakthroughs in all these settings for bipartite graphs, few non-trivial results are known for general graphs.

In this paper, we study the random order vertex arrival contention resolution scheme for matching in general graphs, which is inspired by the recent work of Ezra et al. (EC 2020). We design an $\frac{8}{15}$-selectable batched RCRS for matching and apply it to achieve $\frac{8}{15}$-competitive/approximate algorithms for all the three models. Our results are the first non-trivial results for random order prophet matching and Price-of-Information matching in general graphs. For the Query-Commit model, our result substantially improves upon the 0.501 approximation ratio by Tang et al. (STOC 2020). We also show that no batched RCRS for matching can be better than $\frac{1}{2} + \frac{1}{2e^2} \approx 0.567$-selectable.

1 Introduction

Matching is a fundamental object of algorithmic studies, with wide applications. Its recent use in e-commerce often presents two general features: (i) one does not see the entire input graph in the beginning, but there is often prior stochastic information on each edge's value or presence, thanks to accumulated data from the past; depending on the application, the actual value/presence is revealed either according to some order or at the control of the matching algorithm; (ii) in either case, the matching algorithm must be online – that is, once an edge's information is revealed, the algorithm must make an irrevocable decision whether to include the edge in the matching. Examples of such applications include online advertisement [26, 10, 25], kidney exchange [9], and ride-sharing

platforms [4, 19, 20]. Mathematically, this type of scenarios has been modeled as prophet inequality (e.g. [24]), Query-Commit [9], and Price of Information [27] problems, according to the way the information is revealed.

The Online Contention Resolution Scheme (OCRS), first proposed by Feldman et al. [14], is a powerful framework that has found applications in various online decision problems such as prophet inequalities [14, 13], oblivious posted pricing [7], and stochastic probing [17]. Ezra et al. [13] recently proposed a generalization of OCRS, that with batched arrivals, and used it to give prophet inequalities for matching in bipartite graphs when vertices on both sides arrive online.

Our main results are two-fold. We follow Ezra et al. and define a batched OCRS for matching in general graphs with vertex arrival, and give the first non-trivial such OCRS for random arrival order. We then give an alternative perspective on Gamlath et al. [15]'s recent progress for the Query-Commit and Price of Information problems on bipartite matching; viewing their algorithms as reductions to batched OCRS with random batched arrivals, we immediately obtain similar reductions and consequently the first non-trivial results for the Query-Commit and Price of Information problems for matching in general graphs. Before elaborating on these results, we give more background on the connection between contention resolution schemes and online decision problems, and motivate the batched OCRSs we study.

Contention Resolution Schemes (CRSs) are first proposed as rounding algorithms in submodular maximization [8]. Such an algorithm treats a fractional solution $\boldsymbol{x}$ as a product distribution, samples elements according to it so that each element i is *active* independently with probability x_i, and selects a feasible subset of active elements, guaranteeing that each element, when active, is selected with probability at least $\alpha > 0$, which in turn guarantees that the selected subset retains performance comparable in expectation to (typically at least α fraction of) that of $\boldsymbol{x}$. Such a CRS is said to be α-selectable.

The Online Contention Resolution Schemes (OCRSs) were introduced by Feldman et al. [14]. Its difference from a CRS is that the algorithm does not see the set of active elements upfront, but observes each element's status (of being active or not) one by one online as each element arrives. Intuitively, in an online stochastic decision problem, the expected performance of the offline optimal can be calculated as a fractional solution: a realization of the stochastic procedure gives rise to an optimal (integral) solution, and taking expectation over the stochastic procedure is equivalent to taking a convex combination of these solutions, yielding a fractional solution. An online algorithm, to be competitive, emulates the performance of the fractional solution but only sees partial realizations of the stochastic procedure in an online fashion. For example, in the *prophet inequality* problem, one has prior knowledge in the form of a distribution over the elements' values, but the online algorithm only sees an element's value when it arrives and has to decide immediately whether to keep the element in the solution.

From this perspective, while Feldman et al. [14]'s setup of OCRS neatly fits the needs of many online decision problems, for other problems it is natural to go beyond and, as Ezra et al. [13] did, to consider settings in which (i) the elements arrive not necessarily one by one but in batches, and (ii) the elements' being active may not be independent events (which treats the fractional solution as a product distribution) but correlated ones. Ezra et al. [13] termed such schemes *batched OCRSs*. The concrete choices in the batched OCRS should adapt to the underlying online decision problem being solved.

For example, in online matching, it is often interesting to consider vertex arrival rather than edge arrival – with vertex arrival, the vertices arrive one by one, and at the arrival of each vertex, all the edges connecting it to the vertices that have arrived are revealed

in a batch (i.e., simultaneously), whereas with edge arrival, individual edges arrive one by one. Correlation in elements' status (of being active or not) arises naturally when such batch arrivals are allowed. For example, consider prophet inequalities in bipartite matching with vertex arrival: in a given graph $G = (U, V, E)$, each edge $e \in E$ has a value $v_e \geq 0$ drawn independently from a given distribution F_e, and the goal is to obtain a matching with maximum value. The offline (fractional) solution $\boldsymbol{x} \in [0,1]^E$ has x_e representing the probability that edge e is in the maximum value matching. In the standard reduction from edge arrival prophet inequality to OCRS, when an element e arrives and reveals its value v_e, one (re)samples the values of all the other edges according to their distributions, and labels e active if v_e is high enough to make e in the maximum value matching among the sampled edges. Now with vertex arrival, when vertex v arrives, the information of all edges connecting v to the vertices that arrived before v is revealed. Let B_v denote this set of edges. It is natural for the reduction to sample values for all the other edges, and labels at most one edge in B_v as active if that edge is in the maximum value matching among the (re)sampled edges. Here, the status of the edges in B_v in the (batched) OCRS are naturally correlated, even though their values in the original prophet inequality problem are independent.[1]

The batched OCRS we study in this work precisely results from this reduction, when the vertices arrive in an order that is uniformly at random. To be precise, we are given a vector $\boldsymbol{x} \in [0,1]^E$, such that for each vertex v, $\sum_{e \in \delta(v)} x_e \leq 1$, where $\delta(v)$ denotes the set of edges incident to v. Vertices arrive in an order uniformly at random; when vertex v arrives, the status of all edge in B_v are revealed: each edge $e \in B_v$ is active with probability x_e, but at most one of them is active. If an edge is active, we must decide immediately whether to select it into the solution. We must keep the set of selected edges a valid matching and, for as large a constant $\alpha > 0$ as possible, guarantee that any edge is selected with probability at least αx_e. We refer to such an algorithm an *α-selectable batched Random order Contention Resolution Scheme (RCRS)*.[2] The existence of a $\frac{1}{2}$-selectable batched RCRS is known, after all, Ezra et al. [13] constructed a simple $\frac{1}{2}$-selectable batched OCRS for arbitrary vertex arrival order. Their method is very similar to the $\frac{1}{2}$-selectable OCRS for rank 1 matroid due to Alaei [2]. On the contrary, we were unable to generalize existing RCRS (e.g., [23]) to a batched RCRS with a selectability better than $\frac{1}{2}$. Instead, we construct an $\frac{8}{15}$-selectable batched RCRS via a prune-greedy algorithm, which is our main technical result. As with other settings of RCRS, getting beyond the simplest algorithm is technically involved; in contrast with most other RCRS with non-trivial selectability guarantees [23, 1], our batched RCRS is non-adaptive, in the sense that the algorithm's decision to select an edge does not depend on the time when it arrives, besides checking the feasibility of selecting it.

We also show that such batched RCRSs find applications beyond prophet inequalities as in [13]. Recently there is a breakthrough by Gamlath et al. [15] on the Query-Commit and Price of Information problems, where they gave $(1 - \frac{1}{e})$-approximation algorithms for both problems by reducing them to the *prophet secretary* problem in [12, 11]. We notice that the prophet secretary algorithm can be easily replaced by the $(1 - \frac{1}{e})$-selectable RCRS for rank 1 matroid in [23] and still resulting a $(1 - \frac{1}{e})$-approximation algorithm. We find this perspective is not only conceptually simpler, but also powerful in the sense that if we replace RCRS for rank 1 matroid by our batched RCRS, their algorithms (with a slight modification) also apply for general graphs. As a result, we show that our batched RCRSs imply best-known results for Query-Commit and Price of Information for matching in general graphs.

[1] See [13] for details of this reduction.

[2] As explained above, batched OCRS as defined by Ezra et al. is more general. Our shorthand term should cause no confusion, as we consider only one OCRS setting in this work.

In the **Query-Commit** matching problem [9], we are given a graph $G = (V, E)$, a probability p_e for each edge e with which e is present, independently of the other edges, and a value v_e of e if e is present. At each step, we may choose to query an edge, but we must take it if it is present. At all times, we must keep the set of edges taken a valid matching, and our goal is to maximize the expected sum of values of the edges taken. Gamlath et al. [15] gave a clever algorithm that is $(1 - \frac{1}{e})$-competitive for bipartite graphs. Their algorithm solves an offline linear program relaxation and rounds the solution through a prophet secretary algorithm. We show that this rounding algorithm can be seen as a reduction to a batched RCRS with random one-sided vertex arrival. This perspective allows us to directly derive an $\frac{8}{15}$-competitive algorithm on general graphs, using our new batched RCRS.

In the same work, Gamlath et al. [15] gave a $(1 - \frac{1}{e})$-approximation algorithm for the closely related **Price of Information** (PoI) problem for matching in bipartite graphs. The PoI problems were introduced by Singla [27] as a generalization of the Pandora's Box problem from the consumer search literature [29, 22], which in turn is closely related to Bayesian bandits. In the PoI problem for matching [15], we are given a graph $G = (V, E)$, a search cost c_e and a value distribution F_e for each edge e. An invisible value v_e is drawn independently from F_e, and is revealed only when the algorithm chooses to *search* the edge e, at the cost of c_e. Our goal is to maximize, in expectation, the maximum value of matching among searched edges, minus the search costs paid along the way. From a new proof for the optimal algorithm for the Pandora's Box problem, given by Kleinberg et al. [22], surfaced a reduction from PoI with Bernoulli distributions to Query-Commit. This reduction was generalized by Singla [27]. Gamlath et al. [15] showed that their algorithm for Query-Commit admits some modifications that allow it to give a $(1 - \frac{1}{e})$-approximation for the general PoI problem for bipartite matching. Our perspective of their algorithm as a reduction to RCRS with random vertex arrival admits the same modifications, and therefore we immediately obtain an $\frac{8}{15}$-approximation for the PoI problem for matching in general graphs.

Other Related Works. Naturally, the most related work is the recent paper by Gamlath et al. [15]. They studied the query-commit matching problem and the price-of-information problem in *bipartite* graphs and achieved $(1 - \frac{1}{e})$ approximation ratios for both settings. Their paper has a comprehensive review of the related literature, and we only discuss briefly some most related works that are not covered there.

A closely related setting is the oblivious matching problem. It is also a query-commit model, while the input instance is adversarial rather than stochastic. In other words, there is no information about the existence probabilities of edges. Obviously, results in this harder model directly apply to our setting. The celebrated Ranking algorithm by Karp et al. [21] gives a $(1 - \frac{1}{e})$-approximation for the unweighted oblivious matching problem in bipartite graphs. Later, the Ranking algorithm is extended to general graphs and shown to achieve an approximation ratio of 0.526 [6]. Another well-studied algorithm in this literature is called modified randomized greedy. It was introduced by Aronson et al. [3] and shown to be $(0.5 + \Omega(1))$-approximate in general graphs. The approximation ratio was recently improved to 0.531 by Tang et al. [28]. For the edge-weighted case, Tang et al. [28] achieved the first non-trivial 0.501-approximation. As we remarked, this result applies to the Query-Commit setting studied in our current work, but our approximation ratio is significantly larger. Moreover, our techniques are entirely different from the previous papers and we believe they provide novel insights on the problem.

Offline contention resolution schemes for matchings also achieved some progress recently. Bruggmann and Zenklusen [5] gave an optimal monotone contention resolution scheme for bipartite matching with its application to submodular maximization, and Guruganesh and Lee [18] studied the connection between correlation gap and contention resolution scheme.

Gupta et al. [16] introduced a Markovian price of information model and use online contention resolution schemes to round the optimum of linear programming. However, as our RCRS is vertex-arrival model and batched, it can not be directly applied to their result.

2 Preliminaries

Price of Information. In a *Price of Information* problem, we are given a universe U and a feasibility system $\mathcal{F} \subseteq 2^U$. For each element $i \in U$, we are also given a *search cost* $c_i \in \mathbb{R}_+$ and a distribution F_i from which an invisible value $v_i \geq 0$ is independently drawn. In a valid algorithm for the problem, at each step we may choose to terminate the search or to inquire a new element i; when we choose to do the latter, we incur a cost c_i, and the value $v_i \sim F_i$ is revealed. At the termination of the algorithm, if S is the set of elements inquired by the algorithm, our utility is $\max_{A \subseteq S : A \in \mathcal{F}} \sum_{i \in A} v_i - \sum_{i \in S} c_i$. Our goal is to maximize the expected utility, where expectation is taken over both the realization of the values and the internal randomness of our algorithm. In this paper, we focus on the problem where the universe is the set of edges E in a given graph $G = (V, E)$, and $\mathcal{F}$ is the set of all matchings in E. An algorithm is said to be α-approximation if it achieves at least α fraction of the optimal utility. That is, we compare to the optimal algorithm.

The Query-Commit Problem for Matching. In a Query-Commit problem, we are given a universe U, a feasibility system $\mathcal{F} \subseteq 2^U$, and, for each element $i \in U$, a probability $p_i \in [0, 1]$ and a value $v_i \geq 0$. Each element $i \in U$ is *active* independently with probability p_i, but this status can be known only via a *query*. For the Query-Commit problem, at each step our algorithm can choose to query the status of an element; if the queried element is active, it must be accepted to the solution. At all time, we need to make sure that the set of accepted elements is feasible (i.e., in $\mathcal{F}$). Let S be the set of elements accepted by an algorithm by the time it terminates, the performance of the algorithm is $\sum_{i \in S} v_i$, the total value of the accepted elements. An algorithm is *α-competitive* if its performance is at least α fraction of the offline optimal, i.e., the expected performance of an algorithm that knows the set of active elements beforehand. In this work, we focus on the case where the universe U is the edge set E of a given graph $G = (V, E)$, and $\mathcal{F}$ is the set of all matchings in G.

Batched RCRS for Matching in General Graphs. We are given a graph $G = (V, E, \boldsymbol{x})$, where $\boldsymbol{x} \in [0, 1]^E$ satisfies $x_u \stackrel{\text{def}}{=} \sum_{e \in \delta(u)} x_e \leq 1$ for each $u \in V$. All vertices of G arrive online in a uniformly random order. Upon the arrival of a vertex v, the status of the edges connecting v and the vertices that have arrived are sampled and revealed to the algorithm. The sampling is such that, each edge e of these is *active* with probability x_e, and at most one of these edges can be active; that is, these edges' being active are mutually exclusive events. We refer to this sampling scheme as S. A batched random order contention resolution scheme for matching (henceforth batched RCRS) decides, upon the arrival of each vertex, irrevocably whether to select the active edge (if any exists). At any point in time, the selected edges must form a matching. A batched RCRS is *c-selectable* if $\Pr[e \text{ is selected} \mid e \text{ is active}] \geq c$ for every $e \in E$.

Throughout the paper, we use $\delta(u) \subseteq E$ to denote the set of edges incident to a vertex u.

3 Batched RCRS for Matching In General Graphs

In this section we give an $\frac{8}{15}$-selectable batched RCRS for matching in general graphs.

3.1 Batched RCRS and Its Proof Sketch

▶ **Theorem 1.** *There is a polynomial-time computable, $\frac{8}{15}$-selectable batched RCRS for matching in general graphs with random vertex arrival.*

Our proof consists of two steps. Given a graph $G = (V, E, \boldsymbol{x})$. Let S be the corresponding sampling scheme defined in Section 2. An instance is called 1-regular if $x_u = 1$ for all u. We refer to x_u as the degree of u. Our first lemma states that without loss of generality, we can focus on designing batched RCRS for 1-regular instances.

▶ **Lemma 2.** *If c-selectable batched RCRS exists for all 1-regular instances, then c-selectable batched RCRS exists for all instances.*

Proof. Assume c-selectable batched RCRS exists for all 1-regular instances. Consider an arbitrary instance $G = (V, E, \boldsymbol{x})$, we first convert it into a 1-regular instance G' by introducing dummy vertices and edges. Let S be the associated sampling scheme of the instance G. We correspondingly construct a sampling scheme S' on G' from S by simulating the arrival of dummy vertices. Finally, we apply the c-selectable batched RCRS in the converted 1-regular instance to achieve c-selectability in the original instance G.

For the first step, there can be multiple ways of converting a graph into a 1-regular graph. We give a concrete construction below and remark that the reduction does not rely on the details of the construction. Let $n = |V|$ be the number of vertices of G. We introduce n dummy vertices into the graph. For each vertex $u \in V$, we add n dummy edges between u and all dummy vertices, where each edge has active probability $x'_e = \frac{1-x_u}{n}$. Note that now every vertex in V has degree 1 and all dummy vertices have the same degree. Finally, we add a clique to all dummy vertices and set the weight/active probability of those edges appropriately so that all vertices have degree 1.

Recall G' is the converted instance and let $\boldsymbol{x}'$ be the corresponding vector of active probability. Next, we show how to construct the corresponding sampling scheme S' from S. There are $2n$ time slots in total for vertex arrivals. We select uniformly at random n of them to pair with n dummy vertices uniformly at random. Upon the arrival of a dummy vertex, we sample at most one of the edges connecting it to previously arrived vertices with probability consistent with $\boldsymbol{x}'$. Upon the arrival of an empty slot, we pair it with the next vertex arrival in the original instance and call S. If there exists an active edge realized by S, let it also be active in the new instance. Otherwise, we further sample at most one of the dummy edges connecting the current vertex to previously arrived dummy vertices with appropriate probability, so that the overall active probability is consistent with $\boldsymbol{x}'$. This is implementable since the degree of each vertex is exactly 1.

Now, we have defined a sampling scheme S'. Together with G' and $\boldsymbol{x}'$, it is a 1-regular instance and we can apply the c-selectable batched RCRS for 1-regular instances. Whenever an edge of G (i.e., edges between real vertices) is selected by the batched RCRS, we also select it in the real run of the instance. It is straightforward to verify that this is a c-selectable batched RCRS for the original instance. ◀

Next, we design an $\frac{8}{15}$-selectable batched RCRS for 1-regular instances.

▶ **Lemma 3.** *For every 1-regular instance, there exists an $\frac{8}{15}$-selectable batched RCRS.*

Before going into the details of our analysis, we present our algorithm and provide a proof sketch to highlight the essential ideas. The actual proof of Lemma 3 is deferred to Section 3.3.

Proof Sketch. Consider a 1-regular instance $G = (V, E, \boldsymbol{x})$. We apply the following prune-greedy algorithm: 1) Prune the active probability of each edge from x_e to $f(x_e) \stackrel{\text{def}}{=} \frac{3x_e}{3+2x_e}$; 2) Run greedy on the pruned instance.

The first step is a preprocessing step and we refer to it as the pruning step. Before the instance starts, we independently flip a coin for each edge e and decide whether to consider it later. In particular, an edge e survives with probability $\frac{f(x_e)}{x_e}$ and otherwise we would ignore it regardless being active or not in the future. The second step is just a greedy algorithm, that always select an active edge if adding it does not violate the matching constraint. This procedure is equivalent to assuming that each edge is active with probability $f(x_e)$ and we run greedy. For the ease of presentation, in the rest of the proof, we assume that each edge e is active with probability $f(x_e)$. Our specific choice of the function f is to benefit the analysis, and it be explained in the full proof.

For analysis purpose, we use the following interpretation of the random arrival order assumption. Let t_u be the arrival time of each vertex $u \in V$, that is drawn independently from $U[0, 1]$. All vertices arrive in the ascending order of their arrival times.

Fixing an arbitrary edge $(u, v) \in E$, we use $v \to u$ to denote the event that edge (u, v) is selected by our algorithm upon the arrival of vertex v. To prove the selectability, we need a lower bound on $\Pr[v \to u]$. Fixing the arrival time $t_v = t$, since we use a greedy algorithm, this event happens if 1) u arrives before t; 2) u remains unmatched at t; 3) (u, v) is active. Thus,

$$\begin{aligned}\Pr[v \to u \mid t_v = t] &= \Pr[t_u \le t, u \text{ unmatched } @t, (u,v) \text{ active} \mid t_v = t] \\ &= f(x_{uv}) \cdot \Pr[t_u \le t, u \text{ unmatched } @t \mid t_v = t] \\ &= f(x_{uv}) \cdot (t - \Pr[u \text{ matched } @t \mid t_v = t]). \qquad (*)\end{aligned}$$

Consider the following warm-up analysis,

$$\Pr[u \text{ matched } @t \mid t_v = t] = \sum_{z \neq u,v} \Pr[(u,z) \text{ matched before } t \mid t_v = t] \le \sum_{z \neq u,v} t^2 f(x_{uz}) \le t^2,$$

where the inequality follows since the probability that both u, z arrives before t is t^2 and the edge is matched only if it is active, that happens with probability $f(x_{uz})$. Applying this relaxation to equation $(*)$ and integrating over t gives a simple but weak bound of the selectablity of our algorithm, where the ratio is smaller than $\frac{1}{2}$. Observe that the warm-up analysis does not make use of the pruning step, as well as the 1-regularity of the instance.

Instead, we do recursive type of analysis for $\Pr[(u, z) \text{ matched before } t \mid t_v = t]$:

$$\begin{aligned}&\Pr[(u,z) \text{ matched before } t \mid t_v = t] \\ &\qquad = \int_0^t \Big(\Pr[u \to z \mid t_u = s, t_v = t] + \Pr[z \to u \mid t_z = s, t_v = t] \Big) \mathrm{d}s. \qquad (**)\end{aligned}$$

We can thus expand the term $\Pr[u \to z \mid t_v = t, t_u = s]$ as in $(*)$, and we would have a term $\Pr[z \text{ matched before } s \mid t_u = s, t_v = t]$ therein. However, since our final goal is to derive a lower bound of $(*)$, we need a lower bound of this term rather than an upper bound as we derived in the warm-up analysis. This is where we use the 1-regularity of the instance.

Intuitively, the larger the degree of a vertex, the larger the probability it is matched. It is not difficult to construct a counterexample showing that our prune-greedy algorithm is indeed worse than $\frac{1}{2}$-selectable for non 1-regular instances. For technical reasons, we also want to avoid edges with large active probabilities and our pruning step is designed to take care of such edges.

Roughly speaking, $(*)$ together with $(**)$ expands $\Pr[v \to u \mid t_v = t]$ to terms of form $\Pr[u \to z \mid t_u = s, t_v = t]$. The formal analysis recursively applies such expansion for two steps and uses the simple bound in the warm-up analysis in the last step to bound $\Pr[j \text{ matched } @r \mid t_v = t, t_u = s, t_i = r]$. We defer the proof to Section 3.3.

3.2 Hardness

We complement our positive result with a hardness result, showing that no algorithm can be better than $\frac{1}{2} + \frac{1}{2e^2} \approx 0.567$-selectable.

▶ **Theorem 4.** *No batched RCRS for matching is better than $(\frac{1}{2} + \frac{1}{2e^2})$-selectable.*

Proof. Consider a complete graph G with n vertices. Each edge e has $x_e = \frac{1}{n-1}$. Fix an algorithm and let $y_i \cdot n$ be the number of matched vertices after the arrival of the i-th vertex, where $y_i \in [0, 1]$ is increasing and $y_1 = 0$. Notice that all edges are symmetric and every vertex has degree 1, the selectability of the algorithm is thus upper bounded by $\mathbf{E}[y_n]$. Moreover, we have that

$$\mathbf{E}\left[y_{i+1} \mid y_i\right] \leq y_i + 2 \cdot \left(\frac{i}{n-1} - y_i\right),$$

since we can select an edge only if 1) there exists an active edge, which happens with probability $\frac{i}{n-1}$ and 2) the corresponding vertex is unmatched. Taking expectation over y_i, we have that

$$\mathbf{E}\left[y_{i+1}\right] - \mathbf{E}\left[y_i\right] \leq 2 \cdot \left(\frac{i}{n-1} - \mathbf{E}\left[y_i\right]\right).$$

When n goes to infinity, the above family of inequalities converges to $\frac{dz_t}{dt} \leq 2 \cdot (t - z_t)$, where z_t corresponds to $\mathbf{E}[y_{\lfloor t \cdot n \rfloor}]$. Solving the differential equation gives us

$$z_t \leq t - \frac{1}{2} + \frac{1}{2}e^{-2t}, \forall t \in [0, 1] \ .$$

Hence, the total portion of matched vertices is upper bounded by $z_1 \leq \frac{1}{2} + \frac{1}{2e^2}$ when n goes to infinity, that implies no RCRS can be better than $\left(\frac{1}{2} + \frac{1}{2e^2}\right) \approx 0.567$-selectable. ◀

3.3 Proof of Lemma 3

Proof of Lemma 3. Fix an edge (u, v), our goal is to lower bound the probability of

$$\Pr[v \to u] = \int_0^1 \Pr[v \to u \mid t_v = r_v] dr_v. \tag{1}$$

As we discussed in the proof sketch, the probability term on the right side can be expanded as following

$$
\begin{aligned}
&\Pr[v \to u \mid t_v = r_v] \\
&= f(x_{uv}) \cdot (\Pr[u \text{ arrives before } t_v] - \Pr[u \text{ is matched at } t_v]) \\
&= f(x_{uv}) \cdot \left(t_v - \sum_{\substack{(u,i)\in E \\ i \neq u,v}} \Pr[(u,i) \text{ is selected before } t_v \mid t_v = r_v] \right) \\
&= f(x_{uv}) \cdot \left(t_v - \sum_{\substack{(u,i)\in E \\ i \neq u,v}} (\Pr[u \to i \text{ and } t_u \le t_v \mid t_v = r_v] + \Pr[i \to u \text{ and } t_i \le t_v \mid t_v = r_v]) \right).
\end{aligned} \tag{2}
$$

Since both terms in the right side of (2) are symmetric, we will only show how to upper bound the first term $\Pr[u \to i \text{ and } t_u \le t_v \mid t_v = r_v]$. As explained in the sketch, we further recursively expand it in essentially the same way as $\Pr[v \to u \mid t_v = r_v]$.

$$
\begin{aligned}
&\Pr[u \to i \text{ and } t_u \le t_v \mid t_v = r_v] \\
&= \int_0^{t_v} \Pr[u \to i \mid t_v = r_v, t_u = r_u] dr_u \\
&= \int_0^{t_v} f(x_{ui})(t_u - \Pr[i \text{ is matched at } t_u \mid t_v = r_v, t_u = r_u]) dr_u \\
&= f(x_{ui}) \cdot \int_0^{t_v} \left(t_u - \sum_{\substack{(i,j)\in E \\ j \neq i,u,v}} \Pr[(i,j) \text{ is selected before } t_u \mid t_u = r_u, t_v = r_v] \right) dr_u \\
&= f(x_{ui}) \cdot \int_0^{t_v} \Bigg(t_u - \sum_{\substack{(i,j)\in E \\ j \neq i,u,v}} (\Pr[i \to j, t_i \le t_u \mid t_u = r_u, t_v = r_v] \\
&\qquad\qquad + \Pr[j \to i, t_j \le t_u \mid t_u = r_u, t_v = r_v]) \Bigg) dr_u.
\end{aligned} \tag{3}
$$

Now we further expand the last equation and apply similar argument as the warm up analysis in the proof sketch.

$$
\begin{aligned}
&\Pr[i \to j, t_i \le t_u \mid t_u = r_u, t_v = r_v] \\
&= \int_0^{t_u} \Pr[i \to j \mid t_i = r_i, t_u = r_u, t_v = r_v] dr_i \\
&= \int_0^{t_u} f(x_{ij}) \left(t_i - \Pr[j \text{ is matched at } t_i \mid t_i = r_i, t_u = r_u, t_v = r_v] \right) dr_i.
\end{aligned} \tag{4}
$$

As in the proof sketch, we enumerate the vertex k which j is matched to.

$$
\begin{aligned}
&\Pr[j \text{ is matched at } t_i \mid t_i = r_i, t_u = r_u, t_v = r_v] \\
&\qquad = \sum_{\substack{(j,k)\in E \\ k \neq i,j,u,v}} \Pr[(j,k) \text{ is selected before } t_i \mid t_i = r_i, t_u = r_u, t_v = r_v].
\end{aligned} \tag{5}
$$

Notice that if an edge (j,k) is selected by the algorithm R before time t_i, it has to satisfy at least three conditions:

1. j arrives before t_i;
2. k arrives before t_i;
3. the edge is sampled by the sampling scheme S and selected by the algorithm.

One can observe that these three events are independent. In order to bound (4), we can apply the trivial upper bound to (5)

$$\Pr[(j,k) \text{ is selected before } t_i \mid t_i = r_i, t_u = r_u, t_v = r_v] \leq t_i^2 f(x_{jk})$$

and we obtain

$$\begin{aligned}
&\Pr[i \to j, t_i \leq t_u \mid t_u = r_u, t_v = r_v] \\
&\geq f(x_{ij}) \cdot \int_0^{t_u} t_i \left(1 - t_i \sum_{\substack{(j,k)\in E \\ k \neq i,j,u,v}} f(x_{jk})\right) dt_i \\
&\geq f(x_{ij}) \cdot \int_0^{t_u} t_i \cdot (1 - t_i \cdot (1 - x_{ij}))\, dt_i = f(x_{ij}) \cdot \left(\frac{1}{2}t_u^2 - \frac{1}{3}t_u^3(1 - x_{ij})\right).
\end{aligned}$$

Similarly, it also holds that

$$\Pr[j \to i, t_j \leq t_u \mid t_u = r_u, t_v = r_v]) \geq f(x_{ij}) \cdot \left(\frac{1}{2}t_u^2 - \frac{1}{3}t_u^3(1 - x_{ij})\right).$$

Now we start to plug them back to the two-level recursive analysis. First, plugging these two inequalities into (3), we can bound the first term in the right side of (2).

$$\begin{aligned}
&\Pr[u \to i \text{ and } t_u \leq t_v \mid t_v = r_v] \\
&\leq f(x_{ui}) \cdot \int_0^{t_v} \left(t_u - \sum_{\substack{(i,j)\in E \\ j \neq i,u,v}} f(x_{ij}) \cdot \left(t_u^2 - \frac{2}{3}t_u^3(1 - x_{ij})\right)\right) dt_u \\
&= f(x_{ui}) \cdot \left(\frac{1}{2}t_v^2 - \sum_{\substack{(i,j)\in E \\ j \neq i,u,v}} f(x_{ij}) \cdot \left(\frac{1}{3}t_v^3 - \frac{1}{6}t_v^4(1 - x_{ij})\right)\right).
\end{aligned}$$

By symmetry,

$$\Pr[i \to u \text{ and } t_i \leq t_v \mid t_v = r_v] \leq f(x_{ui}) \cdot \left(\frac{1}{2}t_v^2 - \sum_{\substack{(u,j)\in E \\ j \neq i,u,v}} f(x_{uj}) \cdot \left(\frac{1}{3}t_v^3 - \frac{1}{6}t_v^4(1 - x_{uj})\right)\right).$$

Then, by plugging in both terms back to (2), we have

$$\begin{aligned}
(2) \geq f(x_{uv}) \cdot \Bigg(t_v &- \sum_{\substack{(u,i)\in E \\ i \neq u,v}} f(x_{ui}) \cdot \left(\frac{1}{2}t_v^2 - \sum_{\substack{(i,j)\in E \\ j \neq i,u,v}} f(x_{ij}) \cdot \left(\frac{1}{3}t_v^3 - \frac{1}{6}t_v^4(1 - x_{ij})\right)\right) \\
&- \sum_{\substack{(u,i)\in E \\ i \neq u,v}} f(x_{ui}) \cdot \left(\frac{1}{2}t_v^2 - \sum_{\substack{(u,j)\in E \\ j \neq i,u,v}} f(x_{uj}) \cdot \left(\frac{1}{3}t_v^3 - \frac{1}{6}t_v^4(1 - x_{uj})\right)\right)\Bigg).
\end{aligned}$$

Therefore, (1) can be further bounded as follows:

$$
\begin{aligned}
(1) &\geq f(x_{uv}) \cdot \left(\frac{1}{2} - \sum_{\substack{(u,i)\in E \\ i\neq u,v}} f(x_{ui}) \cdot \left(\frac{1}{6} - \sum_{\substack{(i,j)\in E \\ j\neq i,u,v}} f(x_{ij}) \cdot \left(\frac{1}{20} + \frac{1}{30} x_{ij} \right) \right) \right. \\
&\qquad \left. - \sum_{\substack{(u,i)\in E \\ i\neq u,v}} f(x_{ui}) \cdot \left(\frac{1}{6} - \sum_{\substack{(u,j)\in E \\ j\neq i,u,v}} f(x_{uj}) \cdot \left(\frac{1}{20} + \frac{1}{30} x_{uj} \right) \right) \right) \\
&= f(x_{uv}) \cdot \left(\frac{1}{2} - \sum_{\substack{(u,i)\in E \\ i\neq u,v}} f(x_{ui}) \cdot \left(\frac{1}{6} - \sum_{\substack{(i,j)\in E \\ j\neq i,u,v}} \frac{1}{20} x_{ij} \right) - \sum_{\substack{(u,i)\in E \\ i\neq u,v}} f(x_{ui}) \cdot \left(\frac{1}{6} - \sum_{\substack{(u,j)\in E \\ j\neq i,u,v}} \frac{1}{20} x_{uj} \right) \right) \\
&= f(x_{uv}) \cdot \left(\frac{1}{2} - \sum_{\substack{(u,i)\in E \\ i\neq u,v}} f(x_{ui}) \cdot \left(\frac{1}{3} - \frac{1}{20}(1 - x_{ui} - x_{vi}) - \frac{1}{20}(1 - x_{ui} - x_{uv}) \right) \right) \\
&= f(x_{uv}) \cdot \left(\frac{1}{2} - \sum_{\substack{(u,i)\in E \\ i\neq u,v}} f(x_{ui}) \cdot \left(\frac{7}{30} + \frac{1}{20}(2x_{ui} + x_{vi} + x_{uv}) \right) \right).
\end{aligned}
$$

▶ Remark. Note here for the first equality, we use the fact that $f(x)\left(\frac{1}{20} + \frac{1}{30}x\right) = cx$ for $c = \frac{1}{20}$. (Actually, we only need one side that it is larger than cx.) The choice of $f(x) = \frac{3x}{3+2x}$ is to maximize c while keeping $f(x) \leq x$ for all $x \in [0,1]$ so that it is a valid pruning. For the second equality (where again we only need one side), we use the fact that $\sum_{\substack{(i,j)\in E \\ j\neq i,u,v}} x_{i,j} \geq 1 - x_{u,i} - x_{v,i}$ which follows from the 1-regularity of our graph.

Finally we are ready to bound $\Pr[(u,v) \text{ is selected}]$. Without loss of generality, we can assume that $x_{uv} = 0$ for those $(u,v) \notin E$. Recall that $\Pr[(u,v) \text{ is selected}] = \Pr[u \to v] + \Pr[v \to u]$ by definition and we have

$$
\begin{aligned}
&\Pr[(u,v) \text{ is selected}] \\
&\geq f(x_{uv}) \cdot \left(1 - \sum_{i\neq u,v} \left(f(x_{ui}) \cdot \left(\frac{7}{30} + \frac{1}{20}(2x_{ui} + x_{vi} + x_{uv}) \right) + \right. \right. \\
&\qquad \left. \left. f(x_{vi}) \cdot \left(\frac{7}{30} + \frac{1}{20}(2x_{vi} + x_{ui} + x_{uv}) \right) \right) \right) \\
&\geq f(x_{uv}) \cdot \left(1 - \frac{1}{10} x_{uv} - \sum_{i\neq u,v} \left(f(x_{ui}) \cdot \left(\frac{7}{30} + \frac{1}{20}(2x_{ui} + x_{vi}) \right) \right. \right. \\
&\qquad \left. \left. + f(x_{vi}) \cdot \left(\frac{7}{30} + \frac{1}{20}(2x_{vi} + x_{ui}) \right) \right) \right) \\
&\geq f(x_{uv}) \cdot \left(1 - \frac{1}{10} x_{uv} - \sum_{i\neq u,v} \frac{7}{30} \cdot (x_{ui} + x_{vi}) \right) \\
&= f(x_{uv}) \cdot \left(1 - \frac{1}{10} x_{uv} - \frac{7}{30} \cdot (2 - 2x_{uv}) \right) \\
&= \frac{3x_{uv}}{3 + 2x_{uv}} \cdot \left(\frac{8}{15} + \frac{11}{30} x_{uv} \right) \geq \frac{8}{15} x_{uv}.
\end{aligned}
$$

Here the second inequality uses the fact that $\sum_{i\neq u,v} f(x_{ui}) \leq \sum_{i\neq u,v} x_{ui} \leq 1$ and $\sum_{i\neq u,v} f(x_{vi}) \leq \sum_{i\neq u,v} x_{vi} \leq 1$. We are left to prove the third inequality, which we state as the following lemma.

▶ **Lemma 5.** *The inequality*

$$f(x)\cdot\left(\frac{7}{30}+\frac{1}{20}(2x+y)\right)+f(y)\cdot\left(\frac{7}{30}+\frac{1}{20}(2y+x)\right)\leq\frac{7}{30}\cdot(x+y)$$

holds for every $x, y \geq 0$.

Proof. It is equivalent to prove that

$$\frac{1}{20}f(x)(2x+y)+\frac{1}{20}f(y)(2y+x)\leq\frac{7}{30}(x-f(x)+y-f(y)).$$

Expand $f(x)$ and we get

$$\frac{1}{10}\left(\frac{3x^2}{3+2x}+\frac{3y^2}{3+2y}\right)+\frac{1}{20}\left(\frac{3xy}{3+2x}+\frac{3xy}{3+2y}\right)\leq\frac{7}{15}\left(\frac{3x^2}{3+2x}+\frac{3y^2}{3+2y}\right).$$

Rewriting the formula, we find that it's equivalent to prove

$$30x^2+30y^2-54xy+2x^2y+2xy^2\geq 0.$$

Notice that $x, y \geq 0$, thus $2x^2y+2xy^2 \geq 0$. Also, $30x^2+30y^2-54xy \geq 30x^2+30y^2-60xy \geq 30(x-y)^2 \geq 0$, which completes our proof. ◀

This finishes the proof of Lemma 3. ◀

4 Applications

Our definition of the batched RCRS for matching with random vertex arrival is inspired by the standard reduction from prophet matching to online contention resolution schemes. Therefore, Theorem 1 immediately implies the first nontrivial result for prophet matching in general graphs with random vertex arrival.

▶ **Theorem 6.** *There is an* $\frac{8}{15}$*-competitive algorithm for prophet matching in general graphs with random vertex arrival.*

In this section, we mainly discuss the application of our batched RCRS in Query-Commit and Price-of-Information problems for matching. The algorithms below can be seen as reinterpretations of Gamlath et al. [15]'s algorithms for the problems on bipartite matching. For Query-Commit, their algorithm first solves a linear program relaxation of the corresponding problem, then, using characterization of polymatroids, interprets the fractional solution as follows: each vertex u on the left samples a permutation over the edges in δ_u, and *proposes* to query these edges in that order; literally following these proposals for every vertex obviously leads to collisions, and so vertices on the right need to resolve potential collisions by turning down some of the proposals. The algorithm lets the vertices on the left arrive in a uniformly random order to propose their permutations. Each vertex on the right then runs a *prophet secretary* algorithm, which guarantees that, in expectation, the proposed queries turned down by the nodes on the right do not carry too much value. We suggest that, one may bypass the more complex prophet secretary setup, by seeing the last step as an online contention resolution step with random vertex arrival: when vertex u arrives and proposes its permutation, if we let edge $e \in \delta_u$ be *active* if it is the first edge present when we query the edges following the proposed order, then a c-selectable batched RCRS with vertex arrival keeps each active edge with probability at least c, which leads to a c-approximation algorithm. The description at this level omits many details and twists, and the Price-of-Information algorithm has even more of those. Nonetheless, our perspective easily generalizes to the non-bipartite cases, and allows us to use the batched RCRS in Section 3 to these problems. We give the details below.

4.1 The (Weighted) Query-Commit Problem for Matching

We now present an $\frac{8}{15}$-competitive algorithm for the Query-Commit problem by a reduction to batched RCRS.

▶ **Theorem 7.** *There is a polynomial-time computable, $\frac{8}{15}$-competitive algorithm for the Query-Commit problem for weighted matching in graphs not necessarily bipartite.*

4.1.1 Bounding the optimal utility

First we construct a linear program, where for every edge $e \in E$, x_e represents the probability that e is present and included in the solution. We show that the value of the linear program is an upper bound on even the offline optimal. Therefore, if we implement an algorithm so that each edge e is selected with probability at least $\alpha \cdot x_e^*$, then the competitive ratio of the algorithm will be at least α.

Think of x_e as the probability with which edge e is present and included in the offline solution. For a subset of edges $F \subseteq E$, let $f(F)$ be the probability that at least one edge in F exists, i.e., $f(F) = 1 - \prod_{e \in F}(1 - p_e)$. For any $F \subseteq \delta_u$, since in a matching no more than one edge in F can be in the solution, $\sum_{e \in F} x_e$ is the probability any edge in F is in the offline solution, and this should be upper bounded by the probability any edge in F is present. The following linear program $\mathrm{LP}_{\mathrm{QC}}$ therefore upper bounds the offline optimal:

$$\begin{aligned} \text{max:} \quad & \sum_{e \in E} x_e \cdot v_e \\ \text{s.t.} \quad & \sum_{e \in F} x_e \le f(F), && \forall u \in V, F \subseteq \delta_u; \\ & x_e \ge 0, && \forall e \in E. \end{aligned}$$

▶ **Lemma 8** ([15]). *In the edge-weighted Query-Commit problem for matching, the offline optimal is upper bounded by the value of $\mathrm{LP}_{\mathrm{QC}}$. Furthermore, $\mathrm{LP}_{\mathrm{QC}}$ is polynomial-time solvable.*

Lemma 8 is a straightforward generalization of Lemma 2.1 and Lemma 2.2 in [15]. In the following, we need to assume $0 < p_e < 1$ for every $e \in E$ since some proofs requires strict monotonicity and strict submodularity of f. It turns out that we can ignore those edges with zero probabilities and scale down probabilities by $1 - \gamma$ for other edges due to the following lemma.

▶ **Lemma 9** (Lemma 2.3 of [15]). *For $0 < \gamma < 1$, let $\tilde{p}_e = (1 - \gamma)p_e$ for every $e \in E$. Define $\tilde{f}$ using $\tilde{p}$ instead of p. Similarly, define $\widetilde{\mathrm{LP}}_{\mathrm{QC}}$ use $\tilde{p}, \tilde{f}$ instead of of p, f. Then the value of $\widetilde{\mathrm{LP}}_{\mathrm{QC}}$ is at least $(1 - \gamma)$ times the value of $\mathrm{LP}_{\mathrm{QC}}$.*

For any solution $\boldsymbol{x}$ to $\mathrm{LP}_{\mathrm{QC}}$, the following lemma defines a "decomposition into permutations" over (subsets of) δ_u for each $u \in V$. It is essentially Lemma 2.6 in [15] restated on general graphs.

▶ **Lemma 10** ([15]). *Suppose $0 < p_e < 1$ for every $e \in E$. Let $\boldsymbol{x}^*$ be an optimal solution to $\mathrm{LP}_{\mathrm{QC}}$. For every $u \in V$, fix any subset $\delta'_u \subseteq \delta_u$. Then there exists a polynomial-time samplable distribution $\mathcal{D}_u^{\mathrm{QC}}$ over the permutations on subsets of δ'_u, so that, if one queries according to the permutation sampled from $\mathcal{D}_u^{\mathrm{QC}}$, each edge e is the first present one with probability x_e^*.*

The meaning that the permutations are over *subsets of* δ'_u is that some edges may not be present in the permutation (which indicates that they should not be queried).

4.1.2 Rounding with batched RCRS

The game plan becomes clearer with the decomposition from Lemma 10. Ideally, if one may naïvely follow the permutation sampled from $\mathcal{D}_u^{\mathrm{QC}}$ for each u, and take the first present edge, then one may recover the offline optimal. This is of course infeasible, because matching constraints may be violated by collisions caused by doing this for different vertices. Gamlath et al. [15] handled this via a clever application of prophet secretary algorithms. Instead, we replace this with a reduction to the batched RCRS we developed in Section 3.

We may view the naïve algorithm which always commits to the first present edge in $\sigma_u \sim \mathcal{D}_u^{\mathrm{QC}}$ as a sampling scheme S_{QC} that indicates the first present edge as *active*, and apply our batched RCRS. The matching constraint is then respected by the feasibility of RCRS solutions. However, there is one more subtlety: in the Query-Commit problem, we must commit to the edge we just queried, whereas a batched RCRS assumes that it can see an active edge and discards it. Therefore S_{QC} should not query the presence of an edge if the batched RCRS algorithm R would not accept it *even if it is present*. To handle this issue, we need to change the order of the events by modifying the sampling scheme S_{QC}: upon the arrival of each vertex u, S_{QC} first obtains an indicator vector $\boldsymbol{I}$ from the batched RCRS algorithm R, where $I_e = 1$ if and only if R is willing to accept edge e if S_{QC} indicates that e is active. If $I_e = 0$, instead of actual querying the presence of edge e, S_{QC} simply tosses a coin to simulate a query. We remark that Gamlath et al.'s algorithm has a similar argument. Following is the formal description for our reduction from a Query-Commit problem to batched RCRS.

Our algorithm. Our algorithm first solves $\mathrm{LP}_{\mathrm{QC}}$ to get an optimal solution $\boldsymbol{x}^*$. Let R be a batched RCRS instance corresponding to graph $\langle V, E, \boldsymbol{x}^* \rangle$. Let S_{QC} be the sampling scheme to be defined later. Additionally, for each vertex $u \in V$ we sample $t_u \sim U[0,1]$ as its arrival time. We define $\delta'_u = \{(u,w) \in \delta_u \mid t_w < t_u\}$ to be the edges batch that arrives with u.

Our algorithm iterates over all vertices $u \in V$ in the increasing order of t_u. For each vertex u, it first obtains the indicator vector $\boldsymbol{I}$ where I_e indicates whether R is willing to accept e if it is active. Passing $\boldsymbol{I}$ to the sampling scheme S_{QC}, it obtains the active edge $e \in \delta'_u$ for RCRS algorithm R. We commit to e if R accepts it.

The sampling scheme S_{QC}. Let u be the vertex just arrived in batched RCRS. First sample a permutation σ_u from $\mathcal{D}_u^{\mathrm{QC}}$ by Lemma 10, which is a permutation containing a subset of δ'_u. Consider each edge $e = (u,w)$ in the order of σ_u. There are two cases:

- If $I_e = 1$: query if e is active in the query-commit instance. If it is active, report e as the active edge to R and exit; otherwise continue to the next edge.
- If $I_e = 0$: with probability p_e, report e as the active edge to R and exit; otherwise continue to the next edge.

For the analysis, we should first verify that S_{QC} is a valid sampling scheme. First, it will sample at most one active edge for a vertex, and the sampling result is independent from the indicator vector $\boldsymbol{I}$ since when considering an edge e, in both cases it essentially do a coin flip which heads up with probability p_e and use the result to determine whether e is active. Having observed the independency, we can show that x_e^* is the probability of edge e being active in S_{QC} for any arrival times by using Lemma 10.

▶ **Lemma 11.** *Fix arrival times $\{t_u\}_{u \in V}$. For every vertex $u \in V$ and every edge $e \in \delta'_u$, the probability of e being active in S_{QC} upon the arrival of u equals x_e^*.*

Proof. Fixing a vertex $u \in V$, we have that the probability of every edge $e \in \delta'_u$ being the first active edge in the random permutation σ_u equals x^*_e, according to Lemma 10. The problem is that in the second case, the algorithm does not even check whether an edge is active in the query-commit instance.

Nevertheless, in both cases each edge e will be active independently with probability p_e, which is exactly the probability of e being active in the query-commit instance. Therefore, the random process for determining the active edge is identical to finding the first active element in σ_u. And we have the probability of e being active is exactly x^*_e. ◀

At last, $\sum_{e\in\delta_u} x^*_e \le 1$ hold for every $u \in V$ trivially by constraints in $\mathrm{LP}_{\mathrm{QC}}$. We conclude the validity of S_{QC} with Lemma 12.

▶ **Lemma 12.** *S_{QC} is a valid sampling scheme for batched RCRS. In particular, the following three conditions hold:*

1. *each time S_{QC} will sample at most one edge and the result is independent from $\boldsymbol{I}$;*
2. *each edge $e \in E$ will be active with probability x^*_e for any arrival times $\{t_u\}_{u\in V}$;*
3. *$\sum_{e\in\delta_u} x^*_e \le 1$ holds for every $u \in V$.*

We now are ready to prove the competitive ratio for the algorithm by the selectability of the batched RCRS.

Proof of Theorem 7. The validity of batched RCRS is already proven in Lemma 12. We start the rest of the proof by showing the correctness of the reduction. First, those committed edges must form a matching by the correctness of R. And once a query of e has succeed, R will always decide to take e because we only query e when the indicator vector $I_e = 1$. Finally, no edge will be committed without a query since every edge e that has not been queried will be active to R only when $I_e = 0$.

Then we can easily show the ratio of the reduction equals the selectability of the batched RCRS. By Lemma 11 and the fact that $\cup_{u\in V}\delta'_u = E$, the probability of every edge $e \in E$ being active in R is x^*_e. By Theorem 1, the expected utility for our algorithm is at least $\frac{8}{15}\cdot\sum_{e\in E} x^*_e \cdot v_e$. Further by Lemma 8, we conclude it is an $\frac{8}{15}$-competitive algorithm for the query-commit problem on general graphs. ◀

4.2 The Price of Information Problem for Matching

The Price of Information (PoI) problem has search costs but imposes no obligation on an algorithm to immediately accept a queried element regardless of what is revealed. Kleinberg et al. [22] upper bounded the optimal utility using a variant of query-commit, by giving a new proof for the optimal algorithm in the special case where $\mathcal{F}$ is the set of singleton sets (known as the Pandora's Box problem [29]); Singla [27] generalized the bound and proposed approximation algorithms using the bound. Gamlath et al. [15] studied the Price of Information problem for bipartite matching and made use of the upper bound.

Their method converts the original "price-of-information" world to "free-information" world by setting a threshold value τ_i for each element. In "free-information" world, there is no search cost c_i, but the algorithm gets a lower utility $\kappa_i = \min\{v_i, \tau_i\}$ (instead of v_i) for accepting an element i. Intuitively, the $(v_i - \tau_i)_+$ part[3] of the utility pays for the search cost. However, this is only the case if the algorithm accepts element i in the end. If the algorithm queried element i without accepting it, the utility of the algorithm in "free-information" world

[3] $(z)_+$ denotes $\max\{z, 0\}$

will only be an upper bound of that in the "price-of-information" world. In Section 4.2.1, we upper bound the optimal utility in "free-information" world. Therefore, to match this upper bound, the algorithm has to always accept element i whenever element i is queried and $v_i > \tau_i$.

The intuition above is summarized by the following lemma from [27].

▶ **Lemma 13** ([27]). *In any instance of Price of Information problem, for each element $i \in U$, let τ_i be the unique solution to the equation $\mathbf{E}_{v_i \sim F_i}[(v_i - \tau_i)_+] = c_i$, where $(z)_+$ denotes $\max\{z, 0\}$. Let κ_i be $\min\{v_i, \tau_i\}$. Then no algorithm's utility exceeds $\mathbf{E}[\max_{S \in \mathcal{F}} \sum_{i \in S} \kappa_i]$. In particular, in order for algorithm $\mathcal{A}$ to match this upper bound, $\mathcal{A}$ must accept each element i such that i is queried by $\mathcal{A}$ and $v_i > \tau_i$.*

Similar as query-commit setting, our algorithm is essentially the same as that of [15], but we provide the perspective that the use of prophet secretary in [15] can be replaced by batched RCRS and extend their results to general graphs.

▶ **Theorem 14.** *There is a polynomial time, $\frac{8}{15}$-approximate algorithm for the price of information problem for weighted matching in graphs not necessarily bipartite.*

4.2.1 Bounding the optimal utility

We start by presenting the LP which upper bounds the optimal utility in the "free-information" world. Therefore by Lemma 13, it is also an upper bound for the optimal utility in the "price-of-information" world. The LP and the proofs are essentially the same as that in [15] with the only difference that this is for general graph.

Recall in the PoI problem for matching, there is an undirected graph $G = (V, E)$. For each edge $e \in E$, its value is a random variable $v_e \sim F_e$. Then we set τ_e and κ_e as in Lemma 13.

Without loss of generality, we assume that the distributions of κ_e are discrete.[4] Let K_e be the set of possible values of κ_e. For all $u \in V$, let $E_u = \{(e, \kappa) : e \in \delta_u, \kappa \in K_e\}$ be the edge-value pairs incidents to u and $E_{\text{all}} = \cup_{u \in U} E_u$ be the set of all edge-value pairs in the graph. For each $F \subseteq E_u$, we define $f(F)$ be the probability that $\kappa_e = \kappa$ for at least one of the edge-value pair $(e, \kappa) \in F$. Namely $f(F) = \prod_{v \in V}(1 - \sum_{e:(e,\kappa) \in F} p_{e,\kappa})$ where $p_{e,\kappa} = \Pr[\kappa_e = \kappa]$.

For any algorithm $\mathcal{A}$ for the PoI problem for matching, let $x_{e,\kappa}$ be the probability that $\mathcal{A}$ accepts edge e and $\kappa_e = \kappa$. For any $F \subseteq E_u$, similar with Section 4.1, we know that $\sum_{(e,\kappa) \in F} x_{e,\kappa} \leq f(F)$. Therefore it is natural to consider the following LP, which is called LP_{PoI}.

$$\begin{aligned} \max: \quad & \sum_{(e,\kappa) \in E_{\text{all}}} x_{e,\kappa} \cdot \kappa \\ \text{s.t.} \quad & \sum_{(e,\kappa) \in F} x_{e,\kappa} \leq f(F), && \forall u \in V, F \subseteq E_u; \\ & x_e \geq 0, && \forall e \in E_{\text{all}}. \end{aligned}$$

We restate Lemma 3.2 and Lemma 3.3 of [15] below for general graphs.

[4] In the case where the distributions are continuous. We can discretize them by geometric grouping edge weights into classes.

▶ **Lemma 15** ([15]). *In the price of information problem for matching, the optimal expected utility* $\mathrm{OPT}_{\mathrm{PoI}}$ *is upper bounded by the value of* $\mathrm{LP}_{\mathrm{PoI}}$*. Furthermore,* $\mathrm{LP}_{\mathrm{PoI}}$ *is polynomial-time solvable.*

4.2.2 Rounding with batched RCRS

Let $\boldsymbol{x}^*$ be an optimal solution of $\mathrm{LP}_{\mathrm{PoI}}$. We proceed to "round" it to an algorithm for the PoI problem. Let $\langle V, E, \boldsymbol{x}_{\mathrm{PoI}}\rangle$ be the batched RCRS instance. Note the graph of the RCRS instance is the same as the original graph. Before the formal description of S_{PoI}, we first sketch it here:

From the LP solution $\boldsymbol{x}^*$, we first obtain a polynomial-time samplable distribution $\mathcal{D}_u^{\mathrm{PoI}}$ over permutations of edge-value pairs (e,κ). S_{PoI} first draw a permutation σ from $\mathcal{D}_u^{\mathrm{PoI}}$. An edge-value pair (e,κ) is said to be active if $\kappa_e = \kappa$. Roughly speaking, S_{PoI} returns the first active edge-value pair in σ as the active edge. However, as Lemma 15 suggests, our algorithm must accept edge e if e is queried and $v_e = \tau_e$. Therefore, there is an additional requirement that in each σ drawn from $\mathcal{D}_u^{\mathrm{PoI}}$, the edge-value pairs of the same edge should be in decreasing order of their values. Hence (e,τ_e) is always the first pair associated with edge e in σ.

The following lemma formally defines the distribution $\mathcal{D}_u^{\mathrm{PoI}}$. It is a restatement of Lemma 3.6 in [15].

▶ **Lemma 16** ([15]). *Suppose* $0 < p_{e,\kappa} < 1$ *for every* $(e,\kappa) \in E_{\mathrm{all}}$*. Let* $\boldsymbol{x}^*$ *be an optimal solution to* $\mathrm{LP}_{\mathrm{PoI}}$*. For every* $u \in V$*, fix any subset* $\delta'_u \subseteq \delta_u$*, and let* $E'_u = \{(e,\kappa) \in E_u, e \in \delta'_u\}$ *be the corresponding edge-value pairs.*

We call an edge-value pair (e,κ) *active if* $\kappa_e = \kappa$*. Let*

$$y_{e,\kappa} = \Pr_{\sigma \sim \mathcal{D}_u^{\mathrm{PoI}}, \{\kappa_e\}}[(e,\kappa) \text{ is the first active pair in } \sigma].$$

Then there exists a polynomial-time samplable distribution $\mathcal{D}_u^{\mathrm{PoI}}$ *over the permutations on (subsets of)* E'_u *such that the following holds:*

1. *For all permutation* σ *drawn from* $\mathcal{D}_u^{\mathrm{PoI}}$*, if edge-value pair* (e,κ) *appears in* σ*, then the edge-value pair* (e,w) *appears before* (e,κ) *in* σ *for all* $w \in K_e$ *such that* $w \geq \kappa$*.*
2. $\sum_{\kappa \in K_e} y_{e,\kappa} = \sum_{\kappa \in K_e} x^*_{e,\kappa}$ *for all* $e \in \delta'_u$*.*
3. $\sum_{\kappa \in K_e} y_{e,\kappa} \cdot \kappa \geq \sum_{\kappa \in K_e} x^*_{e,\kappa} \cdot \kappa$ *for all* $e \in \delta'_u$*.*

Now we formally define the sampling scheme S_{PoI}. Initially, each vertex $u \in V$ has its arrival time $t_u \sim U[0,1]$. We define $\delta'_u = \{(u,w) \in \delta_u \mid t_w < t_u\}$ to be the edges batch that arrives with u, and let $E'_u = \{(e,\kappa) \mid e \in \delta'_u, \kappa \in K_e\}$ be the corresponding edge-value pairs. When u arrives, using Lemma 16, S_{PoI} draw a permutation σ from $\mathcal{D}_u^{\mathrm{PoI}}$ over (subsets of) E'_u.

The subtlety in S_{QC} still exists in S_{PoI}, i.e., S_{PoI} should not query the value of an edge if batched RCRS algorithm R do not accept it. Therefore, S_{PoI} first obtains an indicator vector $\boldsymbol{I}$ from RCRS algorithm R. $I_e = 1$ if and only if R would accept edge e if S_{PoI} choose it to be active. S_{PoI} draws variables κ'_e from the same distribution of κ_e for all $e \in \delta'_u$. If $I_e = 0$, namely R will not take the edge, instead of query the true κ_e, S_{PoI} simply use κ'_e to replace it. In this way, the exact behavior of S_{PoI} depends on $\boldsymbol{I}$. Nevertheless, the returned edge of S_{PoI} is still independent of $\boldsymbol{I}$.

S_{PoI} handles each pair $\sigma_i = (e_i, \kappa_i)$ in order as follows:

- If $I_{e_i} = 1$: S_{PoI} queries the value of κ_{e_i} if it is not queried before. If $\kappa_{e_i} = \kappa_i$, S_{PoI} returns e_i as active edges. Otherwise, it continues to the next edge.
- If $I_{e_i} = 0$: S_{PoI} looks at κ'_{e_i} instead since R will not accept the edge anyway. If $\kappa'_{e_i} = \kappa_i$, S_{PoI} returns e_i as the active edges. Otherwise, it continues to the next edge.

The proof of validity for S_{PoI} is similar to the proof for S_{QC}.

▶ **Lemma 17.** *S_{PoI} is a valid sampling scheme for batched RCRS. In particular, the following three conditions hold:*

1. *each time S_{PoI} will sample at most one edge and the result is independent from $\boldsymbol{I}$.*
2. *Each edge $e \in E$ is active with probability $x_e = \sum_{\kappa \in K_e} x^*_{e,\kappa}$ for any arrival times $\{t_u\}_{u \in V}$. Specifically, the probability that S_{PoI} returns at edge-value pair (e, κ) is exactly $y_{e,\kappa}$ as defined in Lemma 16.*
3. *$\sum_{e \in \delta_u} x_e \le 1$ for all $u \in V$.*

Proof. Firstly, by the procedure of S_{PoI}, it returns only one edge. Since κ' and κ has the same distribution, the edge returned by S_{PoI} is independent of $\boldsymbol{I}$. Secondly, because of this independence, if we define $y_{e,\kappa}$ as in Lemma 16, the probability of S_{PoI} to return at edge-value pair (e, κ) is exactly $y_{e,\kappa}$. By the definition of x_e and part 2 of Lemma 16, we know that $x_e = \sum_{\kappa \in K_e} y_{e,\kappa} = \sum_{\kappa \in K_e} x^*_{e,\kappa}$. Thirdly, from the definition of LP_{PoI}, when $F = E_u$, we have $\sum_{(e,\kappa) \in E_u} x^*_{e,\kappa} \le 1$. Namely, $\sum_{e \in \delta_u} x_e \le 1$. ◀

In order to let the $(v_e - \tau_e)_+$ part of the utility pays for the search cost, the algorithm must accept an edge e if its v_e is larger than τ_e (which only happens when $\kappa_e = \tau_e$). The definition of S_{PoI} guarantees such property, and it will be useful in the proof of Theorem 14.

▶ **Lemma 18.** *Suppose an edge e is queried by the reduction and $\kappa_e = \tau_e$. Then the edge e is always accepted in the end.*

Proof. Since e is queried by the reduction, we know that $I_e = 1$, namely the RCRS algorithm R is willing to take this edge. By part 1 of Lemma 16, if (e, τ_e) is the first edge-value pair associated with e in σ. Therefore, as e is queried by S_{PoI}, it returns e as the active edge when handling (e, τ_e). Since $I_e = 1$, R accepts edge e as well. ◀

Now we are ready to prove Theorem 14, i.e. the approximation ratio of the algorithm.

Proof of Theorem 14. By Lemma 15, we know the optimum of LP_{PoI} is an upper bound of the optimal utility for the price of information problem for weighted matching. Namely, $\sum_{(e,\kappa) \in E_{\text{all}}} x^*_{e,\kappa} \cdot \kappa \ge \text{OPT}_{\text{PoI}}$. Recall K_e is the set of possible values of κ_e, and let V_e be the set of possible values of v_e.

On the other hand, by Lemma 18 we know when $v_e \ge \tau_e$, the edge is always accepted when queried. Together with the definition of τ_e, we know that the cost of query is

$$\begin{aligned}\sum_{e \in E} \Pr[e \text{ is queried}] \cdot c_e &= \sum_{e \in E} \Pr[e \text{ is queried}] \cdot \mathbf{E}_{v_i \sim F_i}\left[(v_e - \tau_e)_+\right] \\ &= \sum_{e \in E} \Pr[e \text{ is accepted}] \cdot \mathbf{E}_{v_i \sim F_i}\left[(v_e - \tau_e)_+\right].\end{aligned}$$

The utility of our algorithm is therefore

$$\begin{aligned}&\sum_{e \in E} \sum_{v \in V_e} \Pr[e \text{ is accepted and } v_e = v] \cdot v - \sum_{e \in E} \Pr[e \text{ is accepted}] \cdot \mathbf{E}_{v_i \sim F_i}\left[(v_e - \tau_e)_+\right] \\ =&\sum_{e \in E} \sum_{\kappa \in K_e} \Pr[e \text{ is accepted and } \kappa_e = \kappa] \cdot \kappa.\end{aligned}$$

The equality follows from $\kappa_e = v_e - (v_e - \tau_e)_+$. Let $y_{e,\kappa}$ be defined as Lemma 16. By Lemma 17, S_{PoI} is a valid sampling scheme. So we can apply the batched RCRS in Theorem 1. Since the only use of κ_e is to determine the active edge in S_{PoI}, conditioning on e is active, whether e is accepted is independent of κ_e.

Hence

$$\begin{aligned}
&\Pr[e \text{ is accepted and } \kappa_e = \kappa] \\
=\ &\Pr[e \text{ is accepted} \mid e \text{ is active and } \kappa_e = \kappa] \cdot \Pr[e \text{ is active and } \kappa_e = \kappa] \\
=\ &\Pr[e \text{ is accepted} \mid e \text{ is active}] \cdot \Pr[e \text{ is active and } \kappa_e = \kappa] \\
\geq\ &\frac{8}{15} y_{e,\kappa}.
\end{aligned}$$

Then by part 2 of Lemma 16, the utility of our algorithm is

$$\sum_{e \in E} \sum_{\kappa \in K_e} \frac{8}{15} y_{e,\kappa_e} \cdot \kappa \geq \frac{8}{15} \sum_{e \in E} \sum_{\kappa \in K_e} x^*_{e,\kappa} \cdot v = \frac{8}{15} \operatorname{OPT}_{\text{PoI}},$$

where the inequality follows from part 3 of Lemma 16. ◀

Abstract

The ARRIVAL problem is to decide the fate of a train moving along the edges of a directed graph, according to a simple (deterministic) pseudorandom walk. The problem is in NP ∩ coNP but not known to be in P. The currently best algorithms have runtime $2^{\Theta(n)}$ where n is the number of vertices. This is not much better than just performing the pseudorandom walk. We develop a subexponential algorithm with runtime $2^{O(\sqrt{n}\log n)}$. We also give a polynomial-time algorithm if the graph is almost acyclic. Both results are derived from a new general approach to solve ARRIVAL instances.

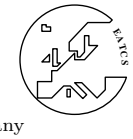
1 Introduction

Informally, the ARRIVAL problem is the following (we quote from Dohrau et al. [6]):



> Suppose that a train is running along a railway network, starting from a designated origin, with the goal of reaching a designated destination. The network, however, is of a special nature: every time the train traverses a switch, the switch will change its position immediately afterwards. Hence, the next time the train traverses the same switch, the other direction will be taken, so that directions alternate with each traversal of the switch.
>
> Given a network with origin and destination, what is the complexity of deciding whether the train, starting at the origin, will eventually reach the destination?

ARRIVAL is arguably the simplest problem in NP ∩ coNP that is not known to be in P. Due to its innocence and at the same time unresolved complexity status, ARRIVAL has attracted quite some attention recently. The train run can be interpreted as a deterministic simulation of a random walk that replaces random decisions at a switch by perfectly fair decisions. Such pseudorandom walks have been studied before under the names of *Eulerian walkers* [17], *rotor-router walks* [12], and *Propp machines* [4]. The reachability question as well as NP and coNP membership are due to Dohrau et al. [6].

Viewed somewhat differently, ARRIVAL is a *zero player game* (a process that runs without a controller); in contrast, three other well-known graph games in NP ∩ coNP that are not known to be in P are two-player (involving two controllers). These are *simple stochastic*

© Bernd Gärtner, Sebastian Haslebacher, and Hung P. Hoang;
licensed under Creative Commons License CC-BY 4.0

games, *mean-payoff games* and *parity games* [3, 21, 13]. Moreover, it is stated in (or easily seen from) these papers that the one-player variants (the strategy of one controller is fixed) have polynomial-time algorithms. In light of this, one might expect a zero-player game such as ARRIVAL to be *really* simple. But so far, no polynomial-time algorithm could be found.

On the positive side, the NP ∩ coNP complexity upper bound could be strengthened in various ways. ARRIVAL is in UP ∩ coUP, meaning that there are efficient verifiers that accept *unique* proofs [10]. A search version of ARRIVAL has been introduced by Karthik C. S. and shown to be in PLS [15], then in CLS [10], and finally in UniqueEOPL [10, 8]. The latter complexity class, established by Fearnley et al. [8], has an intriguing complete problem, but there is no evidence that ARRIVAL is complete for UniqueEOPL.

Concerning complexity lower bounds, there is one result: ARRIVAL is NL-hard [7]. This is not a very strong statement and means that every problem that can be solved by a nondeterministic log-space Turing machine reduces (in log-space) to ARRIVAL.

Much more interesting are the natural one- and two-player variants of ARRIVAL that have been introduced in the same paper by Fearnley et al. [7] and later expanded by Ani et al. [1]. These variants allow a better comparison with the previously mentioned graph games. It turns out that the one-player variants of ARRIVAL are NP-complete, and that the two-player variants are PSPACE-hard [7, 1]. This shows that the p-player variant of ARRIVAL is probably strictly harder than the p-player variants of the other graph games mentioned before, for $p = 1, 2$. This makes it a bit less surprising that ARRIVAL itself ($p = 0$) could so far not be shown to lie in P.

On the algorithmic side, the benchmark is the obvious algorithm for solving ARRIVAL on a graph with n vertices: simulate the train run. This is known to take at most $O(n2^n)$ steps (after this, we can conclude that the train runs forever) [6]. There is also an $\Omega(2^n)$ lower bound for the simulation [6]. The upper bound was improved to $O(p(n)2^{n/2})$ (in expectation) for some polynomial p, using a way to efficiently sample from the run [10]. The same bound was later achieved deterministically [11, 18], and the approach can be refined to yield a runtime of $O(p(n)2^{n/3})$, the currently best one for general ARRIVAL instances [18].

In this paper, we prove that ARRIVAL can be decided in subexponential time $2^{O(\sqrt{n}\log n)}$. While this is still far away from the desired polynomial-time algorithm, the new upper bound is making the first significant progress on the runtime. We also prove that polynomial runtime can be achieved if the graph is close to acyclic, meaning that it can be made acyclic by removing a constant number of vertices.

As the main technical tool from which we derive both results, we introduce a generalization of ARRIVAL. In this *multi-run* variant, there is a subset S of vertices where additional trains may start and also terminate. It turns out that if we start the right numbers of trains from the vertices in S, we also decide the original instance, so the problem is reduced to searching for these right numbers. We show that this search problem is well-behaved and can be solved by systematic guessing, where the number of guesses is exponential in $|S|$, not in n.

We are thus interested in cases where S is small but at the same time allows a sufficiently fast evaluation of a given guess. For the subexponential algorithm, we choose S as a set of size $O(\sqrt{n})$, with the property that a train can only take a subexponential number of steps until it terminates (in S or a destination). For almost acyclic graphs, we choose S as a minimum feedback vertex set, a set whose removal makes the graph acyclic. In this case, a train can visit any vertex only once before it terminates.

The multi-run variant itself is an interesting new approach to the ARRIVAL problem, and other applications of it might be found in the future.

2 ARRIVAL

The ARRIVAL problem was introduced by Dohrau et al. [6] as the problem of deciding whether the train arrives at a given destination or runs forever. Here, we work in a different but equivalent setting (implicitly established by Dohrau et al. already) in which the train always arrives at one of two destinations, and we have to decide at which one. The definitions and results from Dohrau et al. [6] easily adapt to our setting. We still provide independent proofs, derived from the more general setting that we introduce in Section 3.

Given a finite set of vertices V, an origin $o \in V$, two destinations $d, \overline{d} \notin V$ and two functions $s_{even}, s_{odd} : V \to V \cup \{d, \overline{d}\}$, the 6-tuple $A = (V, o, d, \overline{d}, s_{even}, s_{odd})$ is an *ARRIVAL instance*. The vertices $s_{even}(v)$ and $s_{odd}(v)$ are called the even and the odd successor of v.

An ARRIVAL instance A defines a directed graph, connecting each vertex $v \in V$ to its even and its odd successor. We call this the *switch graph* of A and denote it by $G(A)$. To avoid special treatment of the origin later, we introduce an artificial vertex $Y \notin V \cup \{d, \overline{d}\}$ (think of it as the "train yard") that only connects to the origin o. Formally, $G(A) = (V(A), E(A))$ where $V(A) = V \cup \{Y, d, \overline{d}\}$ and $E(A) = \{(Y, o)\} \cup \{(v, s_{even}(v)) : v \in V\} \cup \{(v, s_{odd}(v)) : v \in V\}$. We also refer to $E(A)$ simply as the edges of A. An edge $e \neq (Y, o)$ is called *proper*.

The *run procedure* is the following. For every vertex we maintain a current and a next successor, initially the even and the odd one. We put a token (usually referred to as the train) at o and move it along switch graph edges until it reaches either d or $\overline{d}$. Whenever the train is at a vertex v, we move it to v's current successor and then swap the current and the next successor; see Algorithm 1 for a formal description and Figure 1 for an example.

Algorithm 1 Run Procedure.

Input: ARRIVAL instance $A = (V, o, d, \overline{d}, s_{even}, s_{odd})$
Output: destination of the train: either d or $\overline{d}$
Let s_{curr} and s_{next} be arrays indexed by the vertices of V
for $v \in V$ **do**
  $s_{curr}[v] \leftarrow s_{even}(v)$
  $s_{next}[v] \leftarrow s_{odd}(v)$
$v \leftarrow o$ `/* traversal of edge (Y,o) */`
while $v \neq d$ *and* $v \neq \overline{d}$ **do**
  $w \leftarrow s_{curr}[v]$
  swap($s_{curr}[v]$, $s_{next}[v]$)
  $v \leftarrow w$ `/* traversal of edge (v,w) */`
return v

Algorithm 1 (Run procedure) may cycle, but we can avoid this by assuming that from every vertex $v \in V$, one of d and $\overline{d}$ is reachable along a directed path in $G(A)$. We call such an ARRIVAL instance *terminating*, since it guarantees that either d or $\overline{d}$ is eventually reached.

▶ **Lemma 1.** *Let $A = (V, o, d, \overline{d}, s_{even}, s_{odd})$ be a terminating ARRIVAL instance, $|V| = n$. Let $v \in V$ and suppose that the shortest path from v to a destination in $G(A)$ has length m. Then v is visited (the train is at v) at most 2^m times by Algorithm 1 (Run Procedure).*

Proof. Let $v = v_m, v_{m-1}, \ldots, v_0 \in \{d, \overline{d}\}$ be the sequence of vertices on a shortest path from v to $\{d, \overline{d}\}$. Consider the first 2^m visits to v (if there are less, we are done). Once every two consecutive visits, the train moves on to v_{m-1}, so we can consider the first 2^{m-1} visits to

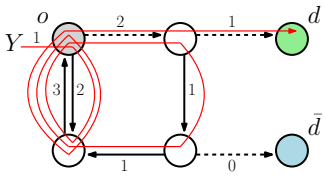


Figure 1 A terminating ARRIVAL instance and the train run. Bold edges go to the even successors, dashed edges to the odd successors. The two successors may coincide (lower left vertex). The numbers indicate how often each edge is traversed by the train.

v_{m-1} and repeat the argument from there to show that v_i is visited at least 2^i times for all i, before v exceeds 2^m visits. In particular, $v_0 \in \{d, \bar{d}\}$ is visited, so the run indeed terminates within at most 2^m visits to v. ◀

▶ **Lemma 2.** *Let $A = (V, o, d, \bar{d}, s_{even}, s_{odd})$ be a terminating ARRIVAL instance, $|V| = n$. Let ℓ be the maximum length of the shortest path from a vertex in V to a destination. Algorithm 1 (Run Procedure) traverses at most $(n - \ell + 2)2^\ell - 2$ proper edges.*

Proof. By Lemma 1, the total number of visits to vertices $v \in V$ is bounded by $\sum_{i=1}^{n} n_i 2^i$, where n_i is the number of vertices with a shortest path of length i to a destination. We have $n_i > 0$ if and only if $i \leq \ell$, and hence the sum is maximized if $n_i = 1$ for all $i < \ell$, and $n_\ell = n - \ell + 1$. In this case, the sum is $(n - \ell + 2)2^\ell - 2$. The number of proper edges being traversed (one after every visit of $v \in V$) is the same. ◀

Given a terminating instance, ARRIVAL is the problem of deciding whether Algorithm 1 (Run Procedure) returns d (YES instance) or $\bar{d}$ (NO instance). It is unknown whether ARRIVAL $\in$ P, but it is in NP $\cap$ coNP, due to the existence of *switching flows* that are certificates for the output of Algorithm 1 (Run Procedure).

2.1 Switching flows

For a vertex v and a set of edges E, we will denote the set of outgoing edges of v by $E^+(v)$. Analogously, we will denote the set of incoming edges of v by $E^-(v)$. Furthermore, for a function $x : E \to \mathbb{N}_0$, we will also use the notation x_e instead of $x(e)$ to denote the value of x at some edge $e \in E$. Lastly, given some vertex v, edges E and a function $x : E \to \mathbb{N}_0$, we will use $x^+(v) := \sum_{e \in E^+(v)} x_e$ to denote the *outflow* of x at v and $x^-(v) := \sum_{e \in E^-(v)} x_e$ to denote the *inflow* of x at v. For two functions $x, x' : E \to \mathbb{N}_0$, we write $x \leq x'$ if this holds componentwise, i.e. $x_e \leq x'_e$ for all $e \in E$.

▶ **Definition 3** (Switching Flow [6]). *Let $A = (V, o, d, \bar{d}, s_{even}, s_{odd})$ be a terminating ARRIVAL instance with edges E. A function $x : E \to \mathbb{N}_0$ is a* switching flow *for A if*

$$\begin{aligned} x^+(Y) &= 1, && \\ x^+(v) - x^-(v) &= 0, && v \in V \quad \textit{(flow conservation)} \\ x_{(v,s_{even}(v))} - x_{(v,s_{odd}(v))} &\in \{0,1\}, && v \in V \quad \textit{(switching behavior).} \end{aligned}$$

Moreover, x is called a switching flow to $t \in \{d, \bar{d}\}$ *if $x^-(t) = 1$.*

Note that due to flow conservation, a switching flow is a switching flow either to d or to $\bar{d}$: exactly one of the destinations must absorb the unit of flow emitted by Y. If we set x_e to the number of times the edge e is traversed in Algorithm 1 (Run Procedure), we obtain

a switching flow to the output; see Figure 1 for an example. Indeed, every time the train enters $v \in V$, it also leaves it; this yields flow conservation. The strict alternation between the successors (beginning with the even one) yields switching behavior.

Hence, the existence of a switching flow to the output is necessary for obtaining the output. Interestingly, it is also sufficient. For that, it remains to prove that we cannot have switching flows to both d and $\overline{d}$ for the same instance.

▶ **Theorem 4** (Switching flows are certificates [6]). *Let $A = (V, o, d, \overline{d}, s_{even}, s_{odd})$ be a terminating ARRIVAL instance, $t \in \{d, \overline{d}\}$. Algorithm 1 (Run Procedure) outputs t if and only if there exists a switching flow to t.*

The switching flow corresponding to the actual train run can be characterized as follows.

▶ **Theorem 5** (The run profile is the minimal switching flow [6]). *Let $A = (V, o, d, \overline{d}, s_{even}, s_{odd})$ be a terminating ARRIVAL instance with edges E. Let $\hat{x}$ be the* run profile *of A, meaning that $\hat{x}_e$ counts the number of times edge e is traversed during Algorithm 1 (Run Procedure). Then $\hat{x} \leq x$ for all switching flows x. In particular, $\hat{x}$ is the unique minimizer of the total flow $\sum_{e \in E} x_e$ over all switching flows.*

We note that this provides the missing direction of Theorem 4. Indeed, $\hat{x}$ is a switching flow and hence either has $\hat{x}^-(d) = 1$ or $\hat{x}^-(\overline{d}) = 1$. By $\hat{x} \leq x$, every switching flow x is to the same destination. In general, there can be switching flows $x \neq \hat{x}$ [6].

We will derive Theorem 5 as a special case of Theorem 8 in the next section.

3 A general framework

In order to solve the ARRIVAL problem, we can simulate Algorithm 1 (Run Procedure) which takes exponential time in the worst case [6]; alternatively, we can try to get hold of a switching flow; via Theorem 4, this also allows us to decide ARRIVAL.

According to Definition 3, a switching flow can be obtained by finding a feasible solution to an integer linear program (ILP); this is a hard task in general, and it is unknown whether switching flow ILPs can be solved more efficiently than general ILPs.

In this section, we develop a framework that allows us to reduce the problem to that of solving a number of more constrained ILPs. At the same time, we provide direct methods for solving them that do not rely on using general purpose ILP solvers.

3.1 The idea

Given a terminating ARRIVAL instance, we consider the switching flow conditions in Definition 3. Given an arbitrary fixed subset $S = \{v_1, \ldots, v_k\} \subseteq V$ of k vertices, we drop the flow conservation constraints at the vertices in S, but at the same time prescribe outflow values $x^+(v_1), \ldots, x^+(v_k)$ that we can think of as guesses for their values in a switching flow.

If we minimize the total flow subject to these guesses, we obtain a unique solution (Theorem 8 (i) below) and hence unique inflow values $x^-(v_1), \ldots, x^-(v_k)$ for the vertices in S. If we happen to stumble upon a fixed point of the mapping $x^+(v_1), \ldots, x^+(v_k) \to x^-(v_1), \ldots, x^-(v_k)$, we recover flow conservation also at S, which means that our guesses were correct and we have obtained a switching flow.

The crucial property is that the previously described mapping is *monotone* (Theorem 8 (ii) below), meaning that the theory of *Tarski fixed points* applies that guarantees the existence of a fixed point as well as efficient algorithms for finding it (Lemma 11 below).

Hence, we reduce the computation of a switching flow to a benign search problem (for a Tarski fixed point), where every search step requires us to solve a "guessing" ILP. We next present a "rail" way of solving the guessing ILP that turns out to be more efficient in the worst case (and also simpler) than general purpose ILP solvers. For suitable switch graphs and appropriate choices of the set S, it will be fast enough to yield the desired runtime results.

3.2 The Multi-Run Procedure

Given $S = \{v_1, \ldots, v_k\} \subseteq V$ and $w \in \mathbb{N}_0^k$ (guesses for the outflows from the vertices in S), we start one train from Y and w_i trains from v_i until they arrive back in S, or at a destination. In this way, we produce inflow values for the vertices in S.

By starting, we mean that we move each of the trains by one step: the one on Y moves to o, while $\lceil w_i/2 \rceil$ of the ones at v_i move to the even successor of v_i, and $\lfloor w_i/2 \rfloor$ to the odd successor. Trains that are now on vertices in $V \setminus S$ are called *waiting* (to move on).

For all $v \in V \setminus S$, we initialize current and next successors as before in Algorithm 1 (Run Procedure). Then we (nondeterministically) repeat the following until there are no more trains waiting.

We pick a vertex $v \in V \setminus S$ where some trains are waiting and call the number of waiting trains $t(v)$. We choose a number $\tau \in \{1, \ldots, t(v)\}$ of trains to move on; we move $\lceil \tau/2 \rceil$ of them to the current successor and $\lfloor \tau/2 \rfloor$ to the next successor. If τ is odd, we afterwards swap the current and the next successor at v.

Algorithm 2 (Multi-Run Procedure) provides the details. For $S = \emptyset$, the procedure becomes deterministic and is equivalent to Algorithm 1 (Run Procedure).

Algorithm 2 Multi-Run Procedure.

Input: Terminating ARRIVAL instance $A = (V, o, d, \overline{d}, s_{even}, s_{odd})$ with edges E; $S = \{v_1, v_2, \ldots, v_k\} \subseteq V$, $w = (w_1, w_2, \ldots, w_k) \in \mathbb{N}_0^k$ (one train starts from Y, and w_i trains start from v_i).
Output: number of trains arriving at $d, \overline{d}$, and in S, respectively
Let t be a zero-initialized array indexed by the vertices of $V \cup \{d, \overline{d}\}$
$t[o] \leftarrow 1$ `/* traversal of` (Y, o) `*/`
for $i = 1, 2, \ldots, k$ **do**
  $t[s_{even}(v_i)] \leftarrow t[s_{even}(v_i)] + \lceil w_i/2 \rceil$ `/*` $\lceil w_i/2 \rceil$ `traversals of` $(v_i, s_{even}(v_i))$ `*/`
  $t[s_{odd}(v_i)] \leftarrow t[s_{odd}(v_i)] + \lfloor w_i/2 \rfloor$ `/*` $\lfloor w_i/2 \rfloor$ `traversals of` $(v_i, s_{odd}(v_i))$ `*/`
Let s_{curr} and s_{next} be arrays indexed by the vertices of $V \setminus S$
for $v \in V \setminus S$ **do**
  $s_{curr}[v] \leftarrow s_{even}(v)$
  $s_{next}[v] \leftarrow s_{odd}(v)$
while $\exists v \in V \setminus S : t[v] > 0$ **do**
  pick $v \in V \setminus S$ such that $t[v] > 0$ and choose $\tau \in \{1, \ldots, t[v]\}$
  $t[v] \leftarrow t[v] - \tau$
  $t[s_{curr}(v)] \leftarrow t[s_{curr}(v)] + \lceil \tau/2 \rceil$ `/*` $\lceil \tau/2 \rceil$ `traversals of` $(v, s_{curr}(v))$ `*/`
  $t[s_{next}(v)] \leftarrow t[s_{next}(v)] + \lfloor \tau/2 \rfloor$ `/*` $\lfloor \tau/2 \rfloor$ `traversals of` $(v, s_{next}(v))$ `*/`
  if τ *is odd* **then**
    swap$(s_{curr}[v], s_{next}[v])$
return $(t[d], t[\overline{d}], t[v_1], t[v_2], \ldots, t[v_k])$

▶ **Lemma 6.** *Algorithm 2 (Multi-Run Procedure) terminates.*

Proof. This is a qualitative version of the argument in Lemma 1. Let $x : E \to \mathbb{N}_0$ record how many times each edge $e \in E$ has been traversed in total, at any given time of Algorithm 2 (Multi-Run Procedure). For $v \in V \setminus S$, we always have $x^+(v) = x^-(v) - t(v)$, where $t(v)$ is the number of trains currently waiting at v. Suppose for a contradiction that the Multi-Run procedure cycles. Then $x^-(v)$ is unbounded for at least one $v \in V \setminus S$, which means that $x^+(v)$ is also unbounded, since $t(v)$ is bounded. This in turn means that $x^-(s_{even}(v))$ and $x^-(s_{odd}(v))$ are unbounded as well, since we distribute $x^+(v)$ evenly between the two successors. Repeating this argument, we see that $x^-(w)$ is unbounded for all vertices w reachable from v. But as $x^-(d)$ and $x^-(\overline{d})$ are bounded (by the number of trains that we started), neither d nor $\overline{d}$ are reachable from v. This is a contradiction to A being terminating. ◀

3.3 Candidate switching flows

After Algorithm 2 (Multi-Run Procedure) has terminated, let $\hat{x}_e$ be the number of times the edge e was traversed. We then have flow conservation at $v \in V \setminus S$, switching behavior at $v \in V$ and outflow w_i from v_i. Indeed, every train that enters $v \in V \setminus S$ eventually also leaves it; moreover, the procedure is designed such that it simulates moving trains out of $v \in V$ individually, strictly alternating between successors. Finally, as we start w_i trains from $v_i \in S$ and stop all trains once they arrive in S, we also have outflow w_i from v_i.

We remark that we do not have any control over how many trains end up at d or $\overline{d}$. Also, $\hat{x}$ could in principle depend on the order in which we pick vertices, and on the chosen τ's. We will show in Theorem 8 below that it does not. So far, we have only argued that $\hat{x}$ is a *candidate switching flow* according to the following definition.

▶ **Definition 7** (Candidate Switching Flow). *Let $A = (V, o, d, \overline{d}, s_{even}, s_{odd})$ be a terminating ARRIVAL instance with edges E, $S = \{v_1, v_2, \ldots, v_k\} \subseteq V$, $w = (w_1, w_2, \ldots, w_k) \in \mathbb{N}_0^k$.*

A function $x : E \to \mathbb{N}_0$ is a candidate switching flow *for A (w.r.t. S and w) if*

$$\begin{array}{rcll} x^+(Y) & = & 1, & \\ x^+(v) - x^-(v) & = & 0, & v \in V \setminus S \quad \textit{(flow conservation at } V \setminus S\textit{)} \\ x^+(v_i) & = & w_i, & i = 1, 2, \ldots, k, \quad \textit{(outflow } w \textit{ at } S\textit{)} \\ x_{(v,s_{even}(v))} - x_{(v,s_{odd}(v))} & \in & \{0,1\}, & v \in V \quad \textit{(switching behavior).} \end{array} \tag{1}$$

▶ **Theorem 8** (Each Multi-Run profile is the minimal candidate switching flow). *Let A, E, S, w be as in Definition 7 and let $\hat{x}$ be a* Multi-Run profile *of A, meaning that $\hat{x}_e$ is the number of times edge $e \in E$ was traversed during some run of Algorithm 2 (Multi-Run Procedure). Then the following statements hold.*

- **(i)** *$\hat{x} \leq x$ for all candidate switching flows x (w.r.t. S and w). In particular, $\hat{x}$ is the unique minimizer of the total flow $\sum_{e \in E} x_e$ over all candidate switching flows.*
- **(ii)** *For fixed A, E, S, define $F(w) = (\hat{x}^-(v_1), \ldots, \hat{x}^-(v_k)) \in \mathbb{N}_0^k$. Then the function $F : \mathbb{N}_0^k \to \mathbb{N}_0^k$ is* monotone*, meaning that $w \leq w'$ implies that $F(w) \leq F(w')$.*

Proof. We prove part (i) by the *pebble argument* [6]: Let x be any candidate switching flow w.r.t. S and w. For every edge e, we initially put x_e pebbles on e, and whenever a train traverses e in Algorithm 2 (Multi-Run Procedure), we let it collect a pebble. If we can show that we never run out of pebbles, $\hat{x} \leq x$ follows. By "running out of pebbles", we concretely mean that we are for the first time trying to collect a pebble from an edge with no pebbles left.

Since x is a candidate switching flow, we cannot run out of pebbles while starting the trains. In fact, we exactly collect all the pebbles on the outgoing edges of $\{Y\} \cup S$. It remains to show that we cannot run out of pebbles while processing a picked vertex $v \in V \setminus S$. For this, we prove that we maintain the following additional invariants (which hold immediately after starting the trains). Let $p : E \to \mathbb{N}_0$ record for each edge e the remaining number of pebbles on e. Then for all $v \in V \setminus S$,

(a) $p^+(v) = p^-(v) + t(v)$, where $t(v)$ is the number of trains waiting at v;

(b) $p((v, s_{curr}(v))) - p((v, s_{next}(v))) \in \{0, 1\}$.

Suppose that these invariants hold when picking a vertex $v \in V \setminus S$. As we have not run out of pebbles before, $p^-(v) \geq 0$ and (a) guarantees that we have $q \geq t(v)$ pebbles on the outgoing edges; by (b), $\lceil q/2 \rceil$ of them are on $(v, s_{curr}(v))$ and $\lfloor q/2 \rfloor$ on $(v, s_{next}(v))$. From the former, we collect $\lceil \tau/2 \rceil$, and from the latter $\lfloor \tau/2 \rfloor$ where $\tau \leq t(v) \leq q$, so we do not run out of pebbles. We maintain (a) at v where both p^+ and t are reduced by τ. We also maintain (a) at the successors; there, the gain in t exactly compensates the loss in p^-. Finally, we maintain (b) at v: If τ is even, both $p((v, s_{curr}(v)))$ and $p((v, s_{next}(v)))$ shrink by $\tau/2$. If τ is odd, we have $p((v, s_{curr}(v))) - p((v, s_{next}(v))) \in \{-1, 0\}$ after collecting one more pebble from $(v, s_{curr}(v))$ than from $(v, s_{next}(v))$, but then we reverse the sign by swapping s_{curr} and s_{next}.

For $S = \emptyset$, this proves Theorem 5, and for general S, we have now proved (i). In particular, the order in which we move trains in Algorithm 2 (Multi-Run Procedure) does not matter.

The proof of (ii) is now an easy consequence; recall that the inflow $F(w)_i$ is the number of trains that arrive at v_i. If $w \leq w'$, we run Algorithm 2 (Multi Run Procedure) with input w' such that it first simulates a run with input w; for this, we keep the extra trains corresponding to $w' - w$ waiting where they are after the start, until all other trains have terminated. At this point, we have inflow $f \geq F(w)$ at S, where $f - F(w)$ corresponds to the extra trains that have already reached S right after the start. We finally run the extra trains that are still waiting, and as this can only further increase the inflows at S, we get $F(w') \geq f \geq F(w)$. ◀

We remark that since the total inflow to the vertices in $\{d, \overline{d}\} \cup S$ equals the total outflow from Y and vertices in S, Theorem 8 (i) implies that the inflows to the vertices in $\{d, \overline{d}\} \cup S$ are the same in every candidate switching flow (w.r.t. S and w). This means that in Theorem 8 (ii), the Multi-Run profile $\hat{x}$ can be replaced by an arbitrary candidate switching flow. This could in principle be easier to compute than the Multi-Run profile, but we currently do not know how.

3.4 Runtime

As we have proved in Theorem 8 (i), the Multi-Run procedure always generates the unique flow-minimal candidate switching flow. But the number of steps depends on the order in which vertices $v \in V \setminus S$ are picked, and on the chosen τ's. We start with an upper bound on the number of edge traversals that generalizes Lemma 2.

▶ **Lemma 9.** *Let $A = (V, o, d, \overline{d}, s_{even}, s_{odd})$ be a terminating ARRIVAL instance, $|V| = n$, $S = \{v_1, v_2, \ldots, v_k\} \subseteq V$, $w = (w_1, w_2, \ldots, w_k) \in \mathbb{N}_0^k$. Let ℓ be the maximum length of the shortest path from a vertex in $V \setminus S$ to a vertex in $\{d, \overline{d}\} \cup S$. Further suppose that at the beginning of some iteration in Algorithm 2 (Multi-Run Procedure), R trains are still waiting. Then all subsequent iterations traverse at most $R((n - \ell + 2)2^\ell - 2)$ edges in total.*

Proof. We continue to run each of the R waiting trains individually and proceed with the next one only when the previous one has terminated. In Algorithm 2 (Multi-Run Procedure), this corresponds to always using $\tau = 1$ and the next vertex v as the head of the previously traversed edge, for each of the R trains. So we effectively perform Algorithm 1 (Run Procedure) for R trains.

As each train terminates once it reaches a vertex in $S \cup \{d, \overline{d}\}$, Lemmata 1 and 2 are easily seen to hold also here, after redefining "destination" as any vertex in $S \cup \{d, \overline{d}\}$. As a consequence, each train traverses at most $(n - \ell + 2)2^\ell - 2$ edges until it reaches a vertex in $\{d, \overline{d}\} \cup S$. This leads to at most $R((n-\ell+2)2^\ell - 2)$ edge traversals overall. By Theorem 8 (i), this upper bound holds for all ways of continuing Algorithm 2 (Multi-Run Procedure). ◀

With $R = W := 1 + \sum_{i=1}^{k} w_i$, we obtain an upper bound for the total number of loop iterations since each iteration traverses at least one edge. But it turns out that we can be significantly faster (and polynomial in the encoding size of W) when we proceed in a greedy fashion, i.e. we always pick the next vertex as the one with the largest number of waiting trains, and move all these trains at once.

▶ **Lemma 10.** *Let A, n, S, w, ℓ as in Lemma 9, and suppose that in each iteration of Algorithm 2 (Multi-Run Procedure), we pick $v \in V \setminus S$ maximizing $t[v]$ and further choose $\tau = t[v]$. Then the number of iterations is at most $(\ln W + n)(n - k)((n - \ell + 2)2^\ell - 2)$, where $W = 1 + \sum_{i=1}^{k} w_i$.*

Proof. As in the proof of Theorem 8, we let each train collect a pebble as it traverses an edge, where we initially put $\hat{x}_e$ pebbles on edge e, with $\hat{x}$ being the unique Multi-Run profile. This means that we eventually collect all pebbles. Now consider an iteration and suppose that $R \leq W$ trains are still waiting. In the greedy algorithm, we move at least $R/(n - k)$ of them in this iteration and collect at least that many pebbles. On the other hand, with R trains still waiting, and with $T = (n - \ell + 2)2^\ell - 2$, there can be no more than RT pebbles left, as all of them will be collected in the remaining at most that many edge traversals, due to Lemma 9.

In summary, the number of pebbles is guaranteed to be reduced by a factor of

$$\left(1 - \frac{1}{(n-k)T}\right)$$

in each iteration, starting from at most WT pebbles before the first iteration. After $s = (\ln W + n)(n - k)T$ iterations, we therefore have at most

$$\left(1 - \frac{1}{(n-k)T}\right)^s WT \leq e^{-\ln W - n} WT < 1$$

pebbles left (using $T < e^n$). Hence, after at most s iterations, the greedy version of Algorithm 2 (Multi-Run Procedure) has indeed terminated. ◀

We remark that essentially the same runtime can be achieved by a round robin version that repeatedly cycles through $V \setminus S$ in some fixed order.

3.5 Tarski fixed points

Tarski fixed points arise in the study of order-preserving functions on complete lattices [19]. For our application, it suffices to consider finite sets of the form $L = \{0, 1, \ldots, N\}^k$ for some $N, k \in \mathbb{N}^+$. For such a set, Tarski's fixed point theorem [19] states that any monotone

function $D : L \to L$ has a fixed point, some $\hat{w} \in L$ such that $D(\hat{w}) = \hat{w}$. Moreover, the problem of finding such a fixed point has been studied: Dang, Qi and Ye [5] have shown that a fixed point can be found using $O(\log^k N)$ evaluations of D. Recently, Fearnley, Pálvölgyi and Savani [9] improved this to $O(\log^{2\lceil k/3 \rceil} N)$.

Via Theorem 8, we have reduced the problem of deciding a terminating ARRIVAL instance to the problem of finding a fixed point of a monotone function $F : \mathbb{N}_0^k \to \mathbb{N}_0^k$, assuming that we can efficiently evaluate F. Indeed, if we have such a fixed point, the corresponding (flow-minimal) candidate switching flow is an *actual* switching flow and hence decides the problem via Theorem 4.

The function F depends on a set $S \subseteq V$ of size k that we can choose freely (we will do so in the subsequent sections).

Here, we still need to argue that we can restrict F to a finite set $L = \{0, 1, \ldots, N\}^k$ so that the Tarski fixed point theorem applies. We already know that outflow (and hence inflow) values never exceed $N = 2^n$ in *some* switching flow, namely the run profile (Lemma 1), so we simply restrict F to this range and at the same time cap the function values accordingly.

▶ **Lemma 11.** *Let $A = (V, o, d, \overline{d}, s_{even}, s_{odd})$ be a terminating ARRIVAL instance, $S = \{v_1, \ldots, v_k\} \subseteq V$, $|V| = n$. Let F be the function defined in Theorem 8 (ii), let $N = 2^n$ and consider the function $D : \{0, 1, \ldots, N\}^k \to \{0, 1, \ldots, N\}^k$ defined by*

$$D(w) = \begin{pmatrix} \min(N, F(w)_1) \\ \min(N, F(w)_2) \\ \vdots \\ \min(N, F(w)_k) \end{pmatrix}, \quad w \in \{0, 1, \ldots, N\}^k.$$

Then D is monotone and has a fixed point $\hat{w}$ that can be found with $O(\log^{2\lceil k/3 \rceil} N)$ evaluations of D. Moreover, $\hat{w}$ is also a fixed point of F, and when we apply Theorem 8 (i) with $w = \hat{w}$, the flow-minimal candidate switching flow resulting from the multi-run procedure is a switching flow for A.

We remark that the switching flow obtained in this way is not necessarily flow-minimal, so we cannot argue that we obtain the run profile of A as defined in Theorem 5. The function D may have several fixed points, each of them leading to a different switching flow; to obtain the run profile, we would have to find a particular fixed point, the one that leads to the unique switching flow of smallest total flow. The known Tarski fixed point algorithms cannot do this, and we do not know of any efficient method for computing the run profile from a given switching flow.

Proof. Monotonicity is clear: if $w \leq w'$, then $F(w) \leq F(w')$ by monotonicity of F; see Theorem 8 (ii). But then also $D(w) \leq D(w')$ for the capped values. Hence, the Tarski fixed point theorem [19] yields a fixed point $\hat{w}$ of D, and the algorithm of Fearnley, Pálvölgyi and Savani [9] finds it using $O(\log^{2\lceil k/3 \rceil} N) = O(n^{2\lceil k/3 \rceil})$ evaluations.

It remains to prove that $\hat{w}$ is a fixed point of F. Suppose for a contradiction that it is not a fixed point. Then $F(\hat{w}) \neq D(\hat{w})$, i.e. some values were actually capped, and so $\hat{w}_j = D(\hat{w})_j = N < F(\hat{w})_j$ for at least one j. As we also have $\hat{w} = D(\hat{w}) \leq F(\hat{w})$, we get

$$\sum_{i=1}^{k} \hat{w}_i < \sum_{i=1}^{k} F(\hat{w})_i. \tag{2}$$

On the other hand, consider the candidate switching flow (1) with $w = \hat{w}$. At most the total flow emitted (at Y and the v_i's) is absorbed at S, so we have

$$\sum_{i=1}^{k} F(\hat{w})_i \leq 1 + \sum_{i=1}^{k} \hat{w}_i. \tag{3}$$

Putting this together with (2), we get an equality in (3). In particular, v_j is the only vertex whose inflow value was capped (by one), all emitted flow is absorbed at S, and no flow arrives at d or $\overline{d}$.

But this is a contradiction to $\hat{w}_j = N = 2^n$: By the same arguments as in the proof of Lemma 1, based on flow conservation (at all $v \neq v_j$) and switching behavior, one of these 2^n outflow units is guaranteed to arrive at $\{d, \overline{d}\}$. ◀

4 Subexponential algorithm for ARRIVAL

In this section, we present our main application of the general framework developed in the previous section.

Given a terminating ARRIVAL instance A with $|V| = n$, the plan is to construct a set $S \subseteq V$ of size $O(\sqrt{n})$ such that from any vertex, the length of the shortest path in $G(A)$ to a vertex in $S \cup \{d, \overline{d}\}$ is also bounded by roughly $O(\sqrt{n})$. Since S is that small, we can find a Tarski fixed point with a subexponential number of F-evaluations; and since shortest paths are that short, each F-evaluation can also be done in subexponential time using the Multi-Run procedure. An overall subexponential algorithm ensues.

▶ **Lemma 12.** *Let $A = (V, o, d, \overline{d}, s_{even}, s_{odd})$ be a terminating ARRIVAL instance with $|V| = n$. Let $\phi \in (0, 1)$ be a real number. In $O(n)$ time, we can construct a ϕ-*set *S, meaning a set $S \subseteq V$ such that*

- **(i)** *$|S| \leq \phi \cdot (n + 2)$;*
- **(ii)** *for all $v \in V$, the shortest path from v to $S \cup \{d, \overline{d}\}$ in $G(A)$ has length at most $\log_2(n + 2)/\phi$.*

Proof. We adapt the ball-growing technique of Leighton and Rao [16], as explained by Trevisan [20].

We first decompose the switch graph $G(A)$ into layers based on the distance of the vertices to a destination [11]. More formally, for $v \in V \cup \{d, \overline{d}\}$, we denote by $\mathrm{dist}(v)$ the length of the shortest path from v to $\{d, \overline{d}\}$ in $G(A)$. Then the layers are defined as $L_i := \{v \in V \cup \{d, \overline{d}\} : \mathrm{dist}(v) = i\}$ for $i \geq 0$. Define $\ell := \max\{\mathrm{dist}(v) : v \in V\}$. We can compute the layer decomposition $(L_0, \ldots, L_\ell)$ using breadth-first search in $O(n)$ time.

Consider Algorithm 3 which computes a ϕ-set as a union of layers. It is clear that the procedure is done in $O(n)$ time. To prove (i), we observe that whenever we add a layer L_i to S, we have $|L_i| < \phi|U|$; moreover, the U's considered in these inequalities are mutually disjoint subsets of $V \cup \{d, \overline{d}\}$. Hence, $|S| < \phi \cdot (n + 2)$.

For (ii), let $v \in V$. Then $v \in L_b$ for some $b \geq 1$. Let $0 \leq a \leq b$ be the largest index such that $L_a \subseteq S \cup \{d, \overline{d}\}$. Then the shortest path from v to a vertex in $S \cup \{d, \overline{d}\}$ has length at most $b - a$. It remains to bound $j := b - a$. The interesting case is $j > 0$.

Consider Algorithm 3. After the a-th iteration, we have $|U| = |L_a| \geq 1$. Moreover, $|L_i| \geq \phi|U|$ for $i = a + 1, \ldots, b$, meaning that for each iteration i in this range, the size of U has grown by a factor of at least $1 + \phi$. Hence, after the b-th iteration, $(1 + \phi)^j \leq |U| \leq n + 2$. This implies $j \leq \log_2(n + 2)/\log_2(1 + \phi) < \log_2(n + 2)/\phi$, where we use the inequality $\log_2(1 + \phi) > \phi$ for $\phi \in (0, 1)$. ◀

Algorithm 3 Procedure to compute a ϕ-set.

Input: ARRIVAL instance with layer decomposition $(L_0, \ldots, L_\ell)$, $\phi \in (0, 1)$
Output: a ϕ-set S
$S \leftarrow \emptyset$
$U \leftarrow L_0$
for $i = 1, \ldots, \ell$ **do**
  if $|L_i| < \phi|U|$ **then**
    $S \leftarrow S \cup L_i$
    $U \leftarrow \emptyset$
  $U \leftarrow U \cup L_i$
return S

▶ **Theorem 13.** *Let $A = (V, o, d, \overline{d}, s_{even}, s_{odd})$ be a terminating ARRIVAL instance with $|V| = n$. A can be decided in time $O(p(n)n^{1.633\sqrt{n}})$, for some polynomial p.*

Proof. By Lemma 12, we can find a ϕ-set S in $O(n)$ time, for any $\phi \in (0, 1)$. As $|S| \leq \phi \cdot (n+2)$, by Lemma 11, we can then decide A with $O(n^{2\lceil \phi \cdot (n+2)/3 \rceil})$ evaluations of the function D. Each evaluation in turn requires us to evaluate the function F in Theorem 8 (ii) for a given $w \in \{0, 1, \ldots, 2^n\}^{|S|}$. We can do this by applying Algorithm 2 (Multi-Run Procedure). By Lemma 10 and the definition of a ϕ-set in Lemma 12, running this algorithm in a greedy fashion requires at most $(\ln W + n)(n - |S|)((n - \ell + 2)2^\ell - 2)$ iterations, where $W = 1 + \sum_{i=1}^{|S|} w_i$ and $\ell = \log_2(n+2)/\phi$. Further, from the choice of w, we have $W \leq 2^n \phi(n+2) + 1$. Therefore, the number of iterations is $O(q(n)n^{1/\phi})$ for some polynomial q. At each iteration, we need to find the vertex with the highest number of waiting trains, as stated in Lemma 10, and move the trains from the chosen vertex. All these operations take polynomial time.

In total, the runtime of the whole process is $O(n^{2\lceil \phi \cdot (n+2)/3 \rceil} \cdot p(n)n^{1/\phi})$ for some polynomial p. Choosing $\phi = \sqrt{3}/\sqrt{2n}$, the runtime becomes $O(p(n)n^{1.633\sqrt{n}})$. ◀

5 Feedback vertex sets

In the previous section, we used our framework to obtain an improved algorithm for ARRIVAL in general. In this section, we will instantiate the framework differently to obtain a polynomial-time algorithm for a certain subclass of ARRIVAL.

A subset $S \subseteq V$ of vertices in a directed graph $G = (V, E)$ is called a *feedback vertex set* if and only if the subgraph induced by $V \setminus S$ is acyclic (i.e. it contains no directed cycle). Karp [14] showed that the problem of finding a smallest feedback vertex set is NP-hard. However, there exists a parameterized algorithm by Chen et al. [2] which can find a feedback vertex set of size k in time $O(n^4 4^k k^3 k!)$ in a directed graph on n vertices, or report that no such set exists.

If we apply Theorem 8 with a feedback vertex set S, it turns out that we can compute the Multi-Run profile in polynomial time, meaning that we get a polynomial-time algorithm for ARRIVAL if there is a feedback vertex set of constant size k.

▶ **Theorem 14.** *Let $A = (V, o, d, \overline{d}, s_{even}, s_{odd})$ be a terminating ARRIVAL instance with graph $G(A)$. If $G(A)$ has a feedback vertex set $S \subseteq V$ of size k (assumed to be fixed as $n = |V| \to \infty$), then A can be decided in time $O(n^{2(\lceil k/3 \rceil + 1)})$.*

Proof. Using the algorithm by Chen et al. [2], we can find a feedback vertex set S in $O(n^4)$ time if it exists. According to Lemma 11, we can then decide A with $O(n^{2\lceil k/3 \rceil})$ evaluations of the function D. Each evaluation in turn requires us to evaluate the function F in Theorem 8 (ii) for a given $w \in \{0, 1, \dots, 2^n\}^k$. To do this, we apply Algorithm 2 (Multi-Run Procedure) where we pick vertices $v \in V \setminus S$ in topological order and choose $\tau = t[v]$ always. As we never send any trains back to vertices that have previously been picked, we terminate within $n - k$ iterations, each of which can be performed in time $O(n)$ as it involves $O(n)$-bit numbers. Hence, $F(w)$ can be computed in $O(n^2)$ time.

Overall, this gives a runtime of $O(n^4 + n^{2(\lceil k/3 \rceil + 1)})$. For $k \geq 1$, the second term dominates the first one. For $k = 0$, we can check if a graph is acyclic, for example, via topological sorting in $O(n)$ time and do not need to employ the algorithm by Chen et al. [2]. The claimed runtime follows. ◀

We remark that even if k is not constant, we can still beat the subexponential algorithm in Section 4, as long as $k = O(n^\alpha)$ for some $\alpha < 1/2$.

Abstract

This paper presents *universal* algorithms for clustering problems, including the widely studied k-median, k-means, and k-center objectives. The input is a metric space containing all *potential* client locations. The algorithm must select k cluster centers such that they are a good solution for *any* subset of clients that actually realize. Specifically, we aim for low *regret*, defined as the maximum over all subsets of the difference between the cost of the algorithm's solution and that of an optimal solution. A universal algorithm's solution SOL for a clustering problem is said to be an (α, β)-approximation if for all subsets of clients C', it satisfies $\text{SOL}(C') \leq \alpha \cdot \text{OPT}(C') + \beta \cdot \text{MR}$, where $\text{OPT}(C')$ is the cost of the optimal solution for clients C' and MR is the minimum regret achievable by any solution.

Our main results are universal algorithms for the standard clustering objectives of k-median, k-means, and k-center that achieve $(O(1), O(1))$-approximations. These results are obtained via a novel framework for universal algorithms using linear programming (LP) relaxations. These results generalize to other ℓ_p-objectives and the setting where some subset of the clients are *fixed*. We also give hardness results showing that (α, β)-approximation is NP-hard if α or β is at most a certain constant, even for the widely studied special case of Euclidean metric spaces. This shows that in some sense, $(O(1), O(1))$-approximation is the strongest type of guarantee obtainable for universal clustering.

1 Introduction

In *universal*[1] approximation (e.g., [8, 9, 10, 16, 20, 22, 27, 39, 40]), the algorithm is presented with a set of *potential* input points and must produce a solution. After seeing the solution, an adversary selects some subset of the points as the actual *realization* of the input, and the

[1] In the context of clustering, universal facility location sometimes refers to facility location where facility costs scale with the number of clients assigned to them. This problem is unrelated to the notion of universal algorithms studied in this paper.

cost of the solution is based on this realization. The goal of a universal algorithm is to obtain a solution that is near-optimal for *every* possible input realization. For example, suppose that a network-based-service provider can afford to deploy servers at k locations around the world and hopes to minimize latency between clients and servers. The service provider does not know in advance which clients will request service, but knows where clients are located. A universal solution provides guarantees on the quality of the solution regardless of which clients ultimately request service. As another example, suppose that a program committee chair wishes to invite k people to serve on the committee. The chair knows the areas of expertise of each person who is qualified to serve. Based on past iterations of the conference, the chair also knows about many possible topics that might be addressed by submissions. The chair could use a universal algorithm to select a committee that will cover the topics well, regardless of the topics of the papers that are submitted. The situation also arises in targeting advertising campaigns to client demographics. Suppose a campaign can spend for k advertisements, each targeted to a specific client type. While the entire set of client types that are potentially interested in a new product is known, the exact subset of clients that will watch the ads, or eventually purchase the product, is unknown to the advertiser. How does the advertiser target her k advertisements to address the interests of any realized subset of clients?

Motivated by these sorts of applications, this paper presents the first universal algorithms for clustering problems, including the classic k-median, k-means, and k-center problems. The input to these algorithms is a metric space containing all locations of *clients* and *cluster centers*. The algorithm must select k cluster centers such that this is a good solution for *any* subset of clients that actually realize.

It is tempting to imagine that, in general, for some large enough value of α, one can find a solution SOL such that for all realizations (i.e., subsets of clients) C', $\text{SOL}(C') \leq \alpha \cdot \text{OPT}(C')$, where $\text{SOL}(C')$ denotes SOL's cost in realization C' and $\text{OPT}(C')$ denotes the optimal cost in realization C'. But this turns out to be impossible for many problems, including the clustering problems we study, and indeed this difficulty may have limited the study of universal algorithms. For example, suppose that the input for the k-median problem is a uniform metric on $k+1$ points, each with a cluster center and client. In this case, for any solution SOL with k cluster centers, there is some realization C' consisting of a single client that is not co-located with any of the k cluster centers in SOL. Then, $\text{SOL}(C') > 0$ but $\text{OPT}(C') = 0$. Since it is not possible to provide a strict approximation guarantee for every realization, we instead seek to minimize the *regret*, defined as the maximum difference between the cost of the algorithm's solution and the optimal cost across all realizations. The solution that minimizes regret is called the *minimum regret solution*, or MRS for short, and its regret is termed *minimum regret* or MR. More formally, $\text{MR} = \min_{\text{SOL}} \max_{C'} [\text{SOL}(C') - \text{OPT}(C')]$. We now seek a solution SOL that achieves, for all input realizations C', $\text{SOL}(C') - \text{OPT}(C') \leq \text{MR}$, i.e., $\text{SOL}(C') \leq \text{OPT}(C') + \text{MR}$. But, obtaining such a solution turns out to be **NP**-hard for many problems, and one has to settle for an approximation: $\text{SOL}(C') \leq \alpha \cdot \text{OPT}(C') + \beta \cdot \text{MR}$. The algorithm is then called an (α, β)-approximate universal algorithm for the problem. Note that in the aforementioned example with $k+1$ points, any solution must pay MR (the distance between any two points) in some realization where $\text{OPT}(C') = 0$ and only one client appears (in which case paying MR might sound avoidable or undesirable). This example demonstrates that stricter notions of regret and approximation than (α, β)-approximation are infeasible in general, suggesting that (α, β)-approximation is the least relaxed guarantee possible for universal clustering.

1.1 Problem Definitions and Results

We are now ready to formally define our problems and state our results. In all the clustering problems that we consider in this paper, the input is a metric space on all the potential client locations C and cluster centers F. The special case where $F = C$ has also been studied in the clustering literature, e.g., in [23, 14], although the more common setting, as in our work, is to not make this assumption. Of course, all results, including ours, without this assumption also apply to the special case. If $F = C$, the constants in our bounds improve, but the results are qualitatively the same. We note that some sources refer to the k-center problem when $F \neq C$ as the k-supplier problem instead, and use k-center to refer exclusively to the case where $F = C$.

Let c_{ij} denote the metric distance between points i and j. The solution produced by the algorithm comprises k cluster centers in F; let us denote this set by SOL. Now, suppose a subset of clients $C' \subseteq C$ realizes in the actual input. Then, the cost of each client $j \in C'$ is given as the distance from the client to its closest cluster center, i.e., $\text{COST}(j, \text{SOL}) = \min_{i \in \text{SOL}} c_{ij}$. The clustering problems differ in how these costs are combined into the overall minimization objective. The respective objectives are given below:

- ***k*-median** (e.g., [14, 25, 5, 34, 11]): $\text{SOL}(C') = \sum_{j \in C'} \text{COST}(j, \text{SOL})$.
- ***k*-center** (e.g., [23, 15, 24, 30, 37]): $\text{SOL}(C') = \max_{j \in C'} \text{COST}(j, \text{SOL})$.
- ***k*-means** (e.g., [35, 28, 33, 21, 1]): $\text{SOL}(C') = \sqrt{\sum_{j \in C'} \text{COST}(j, \text{SOL})^2}$.

We also consider **ℓ_p-clustering** (e.g., [21]) which generalizes all these individual clustering objectives. In ℓ_p-clustering, the objective is the ℓ_p-norm of the client costs for a given value $p \geq 1$, i.e., $\text{SOL}(C') = \left(\sum_{j \in C'} \text{COST}(j, \text{SOL})^p\right)^{1/p}$. Note that k-median and k-means are special cases of ℓ_p-clustering for $p = 1$ and $p = 2$ respectively. k-center can also be defined in the ℓ_p-clustering framework as the limit of the objective for $p \to \infty$; moreover, it is well-known that ℓ_p-norms only differ by constants for $p > \log n$, thereby allowing the k-center objective to be approximated within a constant by ℓ_p-clustering for $p = \log n$.

Our main result is to obtain $(O(1), O(1))$-approximate universal algorithms for k-median, k-center, and k-means. We also generalize these results to the ℓ_p-clustering problem.

▶ **Theorem 1.** *There are $(O(1), O(1))$-approximate universal algorithms for the k-median, k-means, and k-center problems. More generally, there are $(O(p), O(p^2))$-approximate universal algorithms for ℓ_p-clustering problems, for any $p \geq 1$.*

▶ Remark. The bound for k-means is by setting $p = 2$ in ℓ_p-clustering. For k-median and k-center, we use separate algorithms to obtain improved bounds than those provided by the ℓ_p-clustering result. This is particularly noteworthy for k-center where ℓ_p-clustering only gives poly-logarithmic approximation.

Universal Clustering with Fixed Clients. We also consider a more general setting where some of the clients are *fixed*, i.e., are there in any realization, but the remaining clients may or may not realize as in the previous case. (Of course, if no client is fixed, we get back the previous setting as a special case.) This more general model is inspired by settings where a set of clients is already present but the remaining clients are mere predictions. This surprisingly creates new technical challenges, that we overcome to get:

▶ **Theorem 2.** *There are $(O(1), O(1))$-approximate universal algorithms for the k-median, k-means, and k-center problems with fixed clients. More generally, there are $(O(p^2), O(p^2))$-approximate universal algorithms for ℓ_p-clustering problems, for any $p \geq 1$.*

Hardness Results. Next, we study the limits of approximation for universal clustering. In particular, we show that the universal clustering problems for all the objectives considered in this paper are **NP**-hard in a rather strong sense. Specifically, we show that both α and β are separately bounded away from 1, *irrespective of the value of the other parameter*, showing the necessity of both α and β in our approximation bounds. Similar lower bounds continue to hold for universal clustering in Euclidean metrics, even when PTASes are known in the offline (non-universal) setting [4, 31, 33, 37, 1].

▶ **Theorem 3.** *In universal ℓ_p-clustering for any $p \geq 1$, obtaining $\alpha < 3$ or $\beta < 2$ is* **NP***-hard. Even for Euclidean metrics, obtaining $\alpha < 1.8$ or $\beta \leq 1$ is* **NP***-hard. The lower bounds on α (resp., β) are independent of the value of β (resp., α).*

Interestingly, our lower bounds rely on realizations where sometimes as few as one client appears. This suggests that e.g. redefining regret to be some function of the number of clients that appear (rather than just their cost) cannot subvert these lower bounds.

1.2 Techniques

Before discussing our techniques, we discuss why standard approximations for clustering problems are insufficient. It is known that the *optimal* solution for the realization that includes all clients gives a $(1, 2)$-approximation for universal k-median (this is a corollary of a more general result in [29]; we do not know if their analysis can be extended to e.g. k-means), giving universal algorithms for "easy" cases of k-median such as tree metrics. But, the clustering problems we consider in this paper are **NP**-hard in general; so, the best we can hope for in polynomial time is to obtain optimal *fractional* solutions, or *approximate* integer solutions. Unfortunately, the proof of [29] does not generalize to *any* regret guarantee for the optimal *fractional* solution. Furthermore, for all problems considered in this paper, even $(1 + \epsilon)$-approximate (integer) solutions for the "all clients" instance are not guaranteed to be (α, β)-approximations for any finite α, β. These observations fundamentally distinguish universal approximations for **NP**-hard problems like the clustering problems in this paper from those in **P**, and require us to develop new techniques for universal approximations.

In this paper, we develop a general framework for universal approximation based on linear programming (LP) relaxations that forms the basis of our results on k-median, k-means, and k-center (Theorem 1) as well as the extension to universal clustering with fixed clients (Theorem 2).

The first step in our framework is to write an LP relaxation of the regret minimization problem. In this formulation, we introduce a new regret variable that we seek to minimize and is constrained to be at least the difference between the (fractional) solution obtained by the LP and the optimal integer solution *for every realizable instance*. Abstractly, if the LP relaxation of the optimization problem is given by $\min\{\mathbf{c} \cdot \mathbf{x} : \mathbf{x} \in P\}$, then the new *regret minimization* LP is given by

$$\min\{\mathbf{r} : \mathbf{x} \in P; \mathbf{c}(I) \cdot \mathbf{x} \leq \text{OPT}(I) + \mathbf{r}, \ \forall I\}.$$

(For problems like k-means with non-linear objectives, the constraint $\mathbf{c}(I) \cdot \mathbf{x} \leq \text{OPT}(I) + \mathbf{r}$ cannot be replaced with a constraint that is simultaneously linear in $\mathbf{x}, \mathbf{r}$. However, for a fixed value of $\mathbf{r}$, the corresponding non-linear constraints still give a convex feasible region, and so the techniques we discuss in this section can still be used.)

Here, I ranges over all realizable instances of the problem. Hence, the LP is exponential in size, and we need to invoke the ellipsoid method via a separation oracle to obtain an optimal fractional solution. It suffices to design a separation oracle for the new set of constraints

$\mathbf{c}(I)\cdot\mathbf{x} \leq \text{OPT}(I) + \mathbf{r}$, $\forall I$. This amounts to determining the regret of a fixed solution given by $\mathbf{x}$, which unfortunately, is **NP**-hard for our clustering problems. So, we settle for designing an approximate separation oracle, i.e., approximating the regret of a given solution. For k-median, we reduce this to a submodular maximization problem subject to a cardinality constraint, which can then be (approximately) solved via standard greedy algorithms. For k-means, and more generally ℓ_p-clustering, as well as the setting with fixed clients, the situation is more complex, but can still be reduced to submodular maximization.

The next step in our framework is to round these fractional solutions to integer solutions for the regret minimization LP. Typically, in clustering problems such as k-median, LP rounding algorithms give *average* guarantees, i.e., although the overall objective in the integer solution is bounded against that of the fractional solution, individual connection costs of clients are not (deterministically) preserved in the rounding. But, average guarantees are too weak for our purpose: in a realized instance, an adversary may only select the clients whose connection costs increase by a large factor in the rounding thereby causing a large regret. Ideally, we would like to ensure that the connection cost of *every* individual client is preserved up to a constant in the rounding. However, this may be impossible in general. Consider a uniform metric over $k+1$ points. One fractional solution is to make $\frac{k}{k+1}$ fraction of each point a cluster center. In any integer solution, since there are only k cluster centers but $k+1$ points overall, there is one client that has connection cost of 1, which is $k+1$ times its fractional connection cost.

To overcome this difficulty, we allow for a uniform *additive* increase in the connection cost of every client. We show that such a rounding also preserves the regret guarantee of our fractional solution within constant factors. The clustering problem we now solve has a modified objective: for every client, the distance to the closest cluster center is now discounted by the additive allowance, with the caveat that the connection cost is 0 if this difference is negative. This variant is a generalization of a problem appearing in [19], and we call it clustering *with discounts* (e.g., for k-median, we call this problem *k-median with discounts*.) Our main tool in the rounding then becomes an approximation algorithm for ℓ_p^p-clustering with discounts. For k-median, we use a Lagrangian relaxation of this problem to the classic facility location problem to design such an approximation. For k-means and ℓ_p-clustering, extra work is needed to relate the ℓ_p and ℓ_p^p objectives. For k-center, we give a purely combinatorial (greedy) algorithm.

1.3 Related Work

For all previous universal algorithms, the approximation factor corresponds to our parameter α, i.e., these algorithms are $(\alpha, 0)$-approximate. The notion of regret was not considered. As we have explained, however, it is not possible to obtain such results for universal clustering. Furthermore, it may be possible to trade-off some of the large values of α in these results, e.g., $\Omega(\sqrt{n})$ for set cover, by allowing $\beta > 0$.

Universal algorithms have been of large interest in part because of their applications as online algorithms where all the computation is performed ahead of time. Much of the work on universal algorithms has focused on TSP, starting with the seminal work of Jia et al. [26] (later improved by [20]), with following work giving better approximations for Euclidean metrics [39], minor-free metrics [22], and tree metrics [40]. The universal metric Steiner tree problem was also considered by Jia et al. [26], with nearly matching lower bounds [2, 26, 9]. The problem has also been considered for general graphs and minor-free graphs [10]. Finally, for universal (weighted) set cover, Jia et al. [26] (see also [17]) provide an algorithm and an almost matching lower bound.

The problem of minimizing regret has been studied in the context of robust optimization, with a focus on tree metrics. The robust 1-median problem was introduced for tree metrics by Kouvelis and Yu in [32] and several faster algorithms and for general metrics were developed in the following years (e.g. see [7]). For robust k-center, Averbakh and Berman[7] gave a reduction to ordinary k-center problems, which are tractable on tree metrics.

Roadmap. We present the constant approximation algorithms (Theorem 1) for universal k-median, a sketch for k-means, and k-center in Sections 2, 4, and 5 respectively. The k-means result is given in full detail as a more general ℓ_p-clustering result in the full paper. In describing these algorithms, we defer the clustering with discounts algorithms used in the rounding to the appendix. We also give the extension to universal clustering with fixed clients for k-median in Section 3, with the extensions for k-means and k-center in the full paper. Finally, the hardness results (Theorem 3) appear in Section 6.

2 Universal k-Median

In this section, we prove the following theorem:

▶ **Theorem 4.** *There exists a $(27, 49)$-approximate universal algorithm for the k-median problem.*

The algorithm has two components. The first component is a separation oracle for the regret minimization LP based on submodular maximization, which we define below.

Submodular Maximization with Cardinality Constraints. A (non-negative) function $f : 2^E \to \mathbb{R}_0^+$ is said to be *submodular* if for all $S \subseteq T \subseteq E$ and $x \in E$, we have $f(T \cup \{x\}) - f(T) \leq f(S \cup \{x\}) - f(S)$. It is said to be *monotone* if for all $S \subseteq T \subseteq E$, we have $f(T) \geq f(S)$. The following theorem for maximizing monotone submodular functions subject to a cardinality constraint is well-known.

▶ **Theorem 5** (Fisher et al. [38])**.** *For the problem of finding $S \subseteq E$ that maximizes a monotone submodular function $f : 2^E \to \mathbb{R}_0^+$, the natural greedy algorithm that starts with $S = \emptyset$ and repeatedly adds $x \in E$ that maximizes $f(S \cup \{x\})$ until $|S| = k$, is a $\frac{e}{e-1} \approx 1.58$-approximation.*

We give the reduction from the separation oracle to submodular maximization in Section 2.1, and then employ the above theorem.

***k*-median with Discounts.** The second component of our framework is a rounding algorithm that employs the k-median with discounts problem, which we define next. In the k-median with discounts problem, we are given a k-median instance, but where each client j has an additional (non-negative) parameter r_j called its *discount*. Just as in the k-median problem, our goal is to place k cluster centers that minimize the total connection costs of all clients. But, the connection cost for client j can now be discounted by up to r_j, i.e., client j with connection cost c_j contributes $(c_j - r_j)^+ := \max\{0, c_j - r_j\}$ to the objective of the solution.

Let OPT be the cost of an optimal solution to the k-median with discounts problem. We say an algorithm ALG that outputs a solution with connection cost c_j for client j is a (γ, σ)-approximation if:

$$\sum_{j \in C} (c_j - \gamma \cdot r_j)^+ \leq \sigma \cdot \text{OPT}.$$

That is, a (γ, σ)-approximate algorithm outputs a solution whose objective function when computed using discounts $\gamma \cdot r_j$ for all j is at most σ times the optimal objective using discounts r_j. In the case where all r_j are equal, [19] gave a $(9, 6)$-approximation algorithm for this problem based on the classic primal-dual algorithm for k-median. The following lemma generalizes their result to the setting where the r_j may differ:

▶ **Lemma 6.** *There exists a (deterministic) polynomial-time* $(9, 6)$*-approximation algorithm for the* k*-median with discounts problem.*

We give details of the algorithm and the proof of this lemma in the full paper. We note that when all r_j are equal, the constants in [19] can be improved (see e.g. [13]); we do not know of any similar improvement when the r_j may differ. In Section 2.2, we give the reduction from rounding the fractional solution for universal k-median to the k-median with discounts problem, and then employ the above lemma.

2.1 Universal k-median: Fractional Algorithm

The standard k-median polytope (see e.g., [25]) is given by:

$$P = \{(x, y) : \sum_i x_i \leq k; \forall i, j : y_{ij} \leq x_i; \forall j : \sum_i y_{ij} \geq 1; \forall i, j : x_i, y_{ij} \in [0, 1]\}.$$

Here, x_i represents whether point i is chosen as a cluster center, and y_{ij} represents whether client j connects to i as its cluster center. Now, consider the following LP formulation for minimizing regret r:

$$\min\{r : (x, y) \in P; \forall C' \subseteq C : \sum_{j \in C'} \sum_i c_{ij} y_{ij} - \text{OPT}(C') \leq r\}, \tag{1}$$

where $\text{OPT}(C')$ is the cost of the (integral) optimal solution in realization C'. Note that the new constraints: $\forall C' \subseteq C : \sum_{j \in C'} \sum_i c_{ij} y_{ij} - \text{OPT}(C') \leq r$ (we call it the regret constraint set) require that the regret is at most r in all realizations.

In order to solve LP (1), we need a separation oracle for the regret constraint set. Note that there are exponentially many constraints corresponding to realizations C'; moreover, even for a single realization C', computing $\text{OPT}(C')$ is **NP**-hard. So, we resort to designing an *approximate* separation oracle. Fix some fractional solution (x, y, r). Overloading notation, let $S(C')$ denote the cost of the solution with cluster centers S in realization C'. By definition, $\text{OPT}(C') = \min_{S \subseteq F, |S| = k} S(C')$. Then designing a separation oracle for the regret constraint set is equivalent to determining if the following inequality holds:

$$\max_{C' \subseteq C} \quad \max_{S \subseteq F, |S| = k} \left[\sum_{j \in C'} \sum_i c_{ij} y_{ij} - S(C') \right] \leq r.$$

We flip the order of the two maximizations, and define $f_y(S)$ as follows:

$$f_y(S) = \max_{C' \subseteq C} \left[\sum_{j \in C'} \sum_i c_{ij} y_{ij} - S(C') \right].$$

Then designing a separation oracle is equivalent to maximizing $f_y(S)$ for $S \subseteq F$ subject to $|S| = k$. The rest of the proof consists of showing that this function is monotone and submodular, and efficiently computable.

▶ **Lemma 7.** *Fix y. Then, $f_y(S)$ is a monotone submodular function in S. Moreover, $f_y(S)$ is efficiently computable for a fixed S.*

Proof. Let $d(j,S) := \min_{i' \in S} c_{i'j}$ denote the distance from client j to the nearest cluster center in S. If $S = \emptyset$, we say $d(j,S) := \infty$. The value of C' that defines $f_y(S)$ is the set of all clients closer to S than to the fractional solution y, i.e., $\sum_i c_{ij} y_{ij} > \min_{i' \in S} c_{i'j}$. This immediately establishes efficient computability of $f_y(S)$. Moreover, we can equivalently write $f_y(S)$ as follows:

$$f_y(S) = \sum_{j \in C} (\sum_i c_{ij} y_{ij} - d(j,S))^+.$$

A sum of monotone submodular functions is a monotone submodular function, so it suffices to show that for all clients j, the new function $g_{y,j}(S) := (\sum_i c_{ij} y_{ij} - d(j,S))^+$ is monotone submodular.

- $g_{y,j}$ is *monotone*: for $S \subseteq T$, $d(j,T) \leq d(j,S)$, and thus $(\sum_i c_{ij} y_{ij} - d(j,S))^+ \leq (\sum_i c_{ij} y_{ij} - d(j,T))^+$.
- $g_{y,j}$ is submodular if:

  $$\forall S \subseteq T \subseteq F, \forall x \in F : g_{y,j}(S \cup \{x\}) - g_{y,j}(S) \geq g_{y,j}(T \cup \{x\}) - g_{y,j}(T)$$

  Fix S, T, and x. Assume $g_{y,j}(T \cup \{x\}) - g_{y,j}(T)$ is positive (if it is zero, by monotonicity the above inequality trivially holds). This implies that x is closer to client j than any cluster center in T (and hence S too), i.e., $d(j,x) \leq d(j,T) \leq d(j,S)$. Thus, $d(j,x) = d(j, S \cup \{x\}) = d(j, T \cup \{x\})$ which implies that $g_{y,j}(S \cup \{x\}) = g_{y,j}(T \cup \{x\})$. Then we just need to show that $g_{y,j}(S) \leq g_{y,j}(T)$, but this holds by monotonicity. ◀

By standard results (see e.g., GLS [18]), we get an (α, β)-approximate fractional solution for universal k-median via the ellipsoid method if we have an approximate separation oracle for LP (1) that given a fractional solution (x,y,r) does either of the following:

- Declares (x,y,r) feasible, in which case (x,y) has cost at most $\alpha \cdot \text{OPT}(\mathbf{I}) + \beta \cdot r$ in all realizations, or
- Outputs an inequality violated by (x,y,r) in LP (1).

The approximate separation oracle does the following for the regret constraint set (all other constraints can be checked exactly): Given a solution (x,y,r), find an $\frac{e-1}{e}$-approximate maximizer S of f_y via Lemma 7 and Theorem 5. Let C' be the set of clients closer to S than the fractional solution y (i.e., the realization that maximizes $f_y(S)$). If $f_y(S) > r$, the separation oracle returns the violated inequality $\sum_{j \in C'} \sum_i c_{ij} y_{ij} - S(C') \leq r$; else, it declares the solution feasible. Whenever the actual regret of (x,y) is at least $\frac{e}{e-1} \cdot r$, this oracle will find S such that $f_y(S) > r$ and output a violated inequality. Hence, we get the following lemma:

▶ **Lemma 8.** *There exists a deterministic algorithm that in polynomial time computes a fractional $\frac{e}{e-1} \approx 1.58$-approximate solution for* LP (1) *representing the universal k-median problem.*

2.2 Universal k-Median: Rounding Algorithm

Let FRAC denote the $\frac{e}{e-1}$-approximate fractional solution to the universal k-median problem provided by Lemma 8. We will use the following property of k-median, shown by Archer et al. [3].

▶ **Lemma 9** ([3]). *The integrality gap of the natural* LP *relaxation of the k-median problem is at most* 3.

Lemmas 8 and 9 imply that that for any set of clients C',

$$\frac{1}{3} \cdot \text{OPT}(C') \leq \text{FRAC}(C') \leq \text{OPT}(C') + \frac{e}{e-1} \cdot \text{MR}. \tag{2}$$

Our overall goal is to obtain a solution SOL that minimizes $\max_{C' \subseteq C} [\text{SOL}(C') - \text{OPT}(C')]$. But, instead of optimizing over the exponentially many different $\text{OPT}(C')$ solutions, we use the surrogate $3 \cdot \text{FRAC}(C')$ which has the advantage of being defined by a fixed solution FRAC, but still approximates $\text{OPT}(C')$ by Eq. 2. This suggests minimizing the following objective instead: $\max_{C'} [\text{SOL}(C') - 3 \cdot \text{FRAC}(C')]$. Minimizing this objective is equivalent to the k-median with discounts problem, where the discount for client j is $3f_j$. This allows us to invoke Lemma 6 for the k-median with discounts problem.

Thus, our overall algorithm is as follows. First, use Lemma 8 to find a fractional solution $\text{FRAC} = (x, y, r)$. Let $f_j := \sum_i c_{ij} y_{ij}$ be the connection cost of client j in FRAC. Then, construct a k-median with discounts instance where client j has discount $3f_j$, and use Lemma 6 on this instance to obtain the final solution to the universal k-median problem. Theorem 4 follows using the above lemmas; we defer the proof to the full paper.

3 Universal k-Median with Fixed Clients

In this section, we extend the techniques from Section 2 to prove the following theorem:

▶ **Theorem 10.** *If there exists a deterministic polynomial time γ-approximation algorithm for the k-median problem, then for every $\epsilon > 0$ there exists a $(54\gamma + \epsilon, 60)$-approximate universal algorithm for the universal k-median problem with fixed clients.*

By using the derandomized version of the $(2.732 + \epsilon)$-approximation algorithm of Li and Svensson [34] for the k-median problem, and appropriate choice of both ϵ parameters, we obtain the following corollary from Theorem 10.

▶ **Corollary 11.** *For every $\epsilon > 0$, there exists a $(148 + \epsilon, 60)$-approximate universal algorithm for the k-median problem with fixed clients.*

Our high level strategy follows similarly to the previous section. In Section 3.2, we show how to find a good fractional solution by approximately solving a linear program. In Section 3.3, we describe how to round the fractional solution in a manner that preserves its regret guarantee within constant factors. Similar techniques in conjunction with the techniques in Sections 4 and 5 are used for the universal k-means and k-center problems with fixed clients; due to space constraints, we only focus on universal k-median with fixed clients here.

3.1 Preliminaries

In addition to the preliminaries of Section 2, we will use the following tools:

Submodular Maximization over Independence Systems. An *independence system* comprises a ground set E and a set of subsets (called *independent sets*) $\mathcal{I} \subseteq 2^E$ with the property that if $A \subseteq B$ and $B \in \mathcal{I}$ then $A \in \mathcal{I}$ (the *subset closed* property). An independent set S in $\mathcal{I}$ is *maximal* if there does not exist $S' \supset S$ such that $S' \in \mathcal{I}$. Note that one can define an

independence system by specifying the set of maximal independent sets $\mathcal{I}'$ only, since the subset closed property implies $\mathcal{I}$ is simply all subsets of sets in $\mathcal{I}'$. An independence system is a 1-*independence system* (or 1-*system* in short) if all maximal independent sets are of the same size. The following result on maximizing submodular functions over 1-independence systems follows from a more general result given implicitly in [38] and more formally in [12].

▶ **Theorem 12.** *There exists a polynomial time algorithm that given a* 1*-independence system* $(E, \mathcal{I})$ *and a non-negative monotone submodular function* $f : 2^E \to \mathbb{R}^+$ *defined over it, finds a* $\frac{1}{2}$*-maximizer of* f*, i.e. finds* $S' \in \mathcal{I}$ *such that* $f(S') \geq \frac{1}{2} \max_{S \in \mathcal{I}} f(S)$*.*

The algorithm in the above theorem is the natural greedy algorithm, which starts with $S' = \emptyset$ and repeatedly adds to S' the element u that maximizes $f(S' \cup \{u\})$ while maintaining that $S' \cup \{u\}$ is in $\mathcal{I}$, until no such addition is possible.

Incremental ℓ_p-Clustering. We will also use the *incremental ℓ_p-clustering* problem which is defined as follows: Given an ℓ_p-clustering instance and a subset of the cluster centers S (the "existing" cluster centers), find the minimum cost solution to the ℓ_p-clustering instance with the additional constraint that the solution must contain all cluster centers in S. When $S = \emptyset$, this is just the standard ℓ_p-clustering problem, and this problem is equivalent to the standard ℓ_p-clustering problem by the following lemma:

▶ **Lemma 13.** *If there exists a γ-approximation algorithm for the ℓ_p-clustering problem, there exists a γ-approximation for the incremental ℓ_p-clustering problem.*

The lemma follows by an approximation-preserving reduction between the two problems, which simply adds many clients to the locations of cluster centers in S, forcing any low-cost solution to place cluster centers at these locations even in the standard ℓ_p-clustering problem.

3.2 Obtaining a Fractional Solution for Universal k-Median with Fixed Clients

Let $C_f \subseteq C$ denote the set of fixed clients and for any realization of clients C' satisfying $C_f \subseteq C' \subseteq C$, let $\textsc{opt}(C')$ denote the cost of the optimal solution for C'. The same LP we used for universal k-median applies here, except we remove constraints on regret corresponding to realizations $C' \not\subseteq C_f$. Recall that to design an approximate separation oracle, it suffices to find a realization approximately maximizing the regret of the fractional solution.

Let $S(C')$ denote the cost of the solution $S \subseteq F$ in realization C' (that is, $S(C') = \sum_{j \in C'} \min_{i \in S} c_{ij}$). Since $\textsc{opt}(C') = \min_{S : S \subseteq F, |S| = k} S(C')$, exactly deciding the feasibility of the constraints on regret in the LP is equivalent to deciding if the following holds:

$$\forall S : S \subseteq F, |S| = k : \quad \max_{C' : C_f \subseteq C' \subseteq C} \left[\sum_{j \in C'} \sum_{i \in F} c_{ij} y_{ij} - S(C') \right] \leq r. \tag{3}$$

By splitting the terms $\sum_{j \in C'} \sum_{i \in F} c_{ij} y_{ij}$ and $S(C')$ into terms for C_f and $C' \setminus C_f$, we can rewrite Eq. (3) as follows:

$$\forall S \subseteq F, |S| = k : \max_{C^* \subseteq C \setminus C_f} \left[\sum_{j \in C^*} \sum_{i \in F} c_{ij} y_{ij} - S(C^*) \right] \leq S(C_f) - \sum_{j \in C_f} \sum_{i \in F} c_{ij} y_{ij} + r$$

For fractional solution y, let

$$f_y(S) = \max_{C^* : C^* \subseteq C \setminus C_f} \left[\sum_{j \in C^*} \sum_{i \in F} c_{ij} y_{ij} - S(C^*) \right]. \tag{4}$$

Note that we can compute $f_y(S)$ for any S easily since the maximizing value of C^* is the set of clients j for which S has connection cost less than $\sum_{i \in F} c_{ij} y_{ij}$. We already know $f_y(S)$ is submodular. But, the term $S(C_f)$ is not fixed with respect to S, so maximizing $f_y(S)$ does not suffice for separating the LP. To overcome this difficulty, for every possible cost M on the fixed clients, we replace $S(C_f)$ with M and only maximize over solutions S for which $S(C_f) \leq M$ (for convenience, we will call any solution S for which $S(C_f) \leq M$ an *M-cheap* solution):

$$\forall M \in \left\{ 0, 1, \ldots, |C_f| \max_{i,j} c_{ij} \right\} : \max_{S : S \subseteq F, |S| = k, S(C_f) \leq M} f_y(S) \leq M - \sum_{j \in C_f} \sum_{i \in F} c_{ij} y_{ij} + r. \tag{5}$$

Note that this set of inequalities is equivalent to Eq. (3), but it has the advantage that the left-hand side is approximately maximizable and the right-hand side is fixed. Hence, these inequalities can be approximately separated. However, there are exponentially many inequalities; so, for any fixed $\epsilon > 0$, letting $Z_\epsilon := \left\{ 0, 1, 1+\epsilon, \ldots, (1+\epsilon)^{\lceil \log_{1+\epsilon}(|C_f| \max_{i,j} c_{ij}) \rceil + 1} \right\}$ we relax to the following polynomially large set of inequalities:

$$\forall M \in Z_\epsilon : \max_{S : S \subseteq F, |S| = k, S(C_f) \leq M} f_y(S) \leq M - \sum_{j \in C_f} \sum_{i \in F} c_{ij} y_{ij} + r. \tag{6}$$

Separating inequality Eq. (6) for a fixed M corresponds to submodular maximization of $f_y(S)$, but now subject to the constraints $|S| = k$ and $S(C_f) \leq M$ as opposed to just $|S| = k$. Let $\mathcal{S}_M$ be the set of all $S \subseteq F$ such that $|S| = k$ and $S(C_f) \leq M$. Since $f_y(S)$ is monotone, maximizing $f_y(S)$ over $\mathcal{S}_M$ is equivalent to maximizing $f_y(S)$ over the independence system $(F, \mathcal{I}_M)$ with maximal independent sets $\mathcal{S}_M$.

Then all that is needed to approximately separate Eq. (6) corresponding to a fixed M is an oracle for deciding membership in $(F, \mathcal{I}_M)$. Recall that $S \subseteq F$ is in $(F, \mathcal{I}_M)$ if there exists a set $S' \supseteq S$ such that $|S'| = k$ and $S'(C_f) \leq M$. But, even deciding membership of the empty set in $(F, \mathcal{I}_M)$ requires one to solve a k-median instance on the fixed clients, which is in general NP-hard. More generally, we are required to solve an instance of the incremental k-median problem (see Section 3.1) with existing cluster centers in S.

While exactly solving incremental k-median is NP-hard, we have a constant approximation algorithm for it (call it A), by Lemma 13. So, we could define a new system $(F, \mathcal{I}'_M)$ that contains a set $S \subseteq F$ if the output of A for the incremental k-median instance with existing cluster centers S has cost at most M. But, due to the unpredictable behavior of A, $(F, \mathcal{I}'_M)$ may no longer be a 1-system, or even an independence system. To restore the subset closed property, the membership oracle needs to ensure that: (a) if a subset $S' \subseteq S$ is determined to not be in $(F, \mathcal{I}'_M)$, then S is not either, and (b) if a superset $S' \supseteq S$ is determined to be in $(F, \mathcal{I}'_M)$, then so is S.

We now describe the modified greedy maximization algorithm GreedyMax that we use to try to separate one of the inequalities in Eq. (6), which uses a built-in membership oracle that ensures the above properties hold. Pseudocode is given in the full paper, and we informally describe it here. GreedyMax initializes $S_0 = \emptyset$, $F_0 = F$, and starts with a M-cheap k-median solution T_0 (generated by running a γ-approximation on the k-median instance involving only fixed clients C_f). In iteration l, GreedyMax starts with a partial

solution S_{l-1} with $l-1$ cluster centers, and it is considering adding cluster centers in F_{l-1} to S_{l-1}. For each cluster center i in F_{l-1}, GreedyMax generates some k-median solution $T_{l,i}$ containing $S_{l-1} \cup \{i\}$ to determine if $S_{l-1} \cup \{i\}$ is in the independence system. If a previously generated solution, T_0 or $T_{l',i'}$ for any l', i', contains $S_{l-1} \cup \{i\}$ and is M-cheap, then $T_{l,i}$ is set to this solution. Otherwise, GreedyMax runs the incremental k-median approximation algorithm on the instance with existing cluster centers in $S_{l-1} \cup \{i\}$, the only cluster centers in the instance are F_{l-1}, and the client set is C_f. It sets $T_{l,i}$ to the solution generated by the approximation algorithm.

After generating the set of solutions $\{T_{l,i}\}_{i \in F_{l-1}}$, if one of these solutions contains $S_{l-1} \cup \{i\}$ and is M-cheap, then GreedyMax concludes that $S_{l-1} \cup \{i\}$ is in the independence system. This, combined with the fact that these solutions may be copied from previous iterations ensures property (b) holds (as the M-cheap solutions generated by GreedyMax are implicitly considered to be in the independence system). Otherwise, since GreedyMax was unable to find an M-cheap superset of $S_{l-1} \cup \{i\}$, it considers $S_{l-1} \cup \{i\}$ to not be in the independence system. In accordance with these beliefs, GreedyMax initializes F_l as a copy of F_{l-1}, and then removes any i such that it did not find an M-cheap superset of $S_{l-1} \cup \{i\}$ from F_l and thus from future consideration, ensuring property (a) holds. It then greedily adds to S_{l-1} the i in F_l that maximizes $f_y(S_{l-1} \cup \{i\})$ as defined before to create a new partial solution S_l. After the kth iteration, GreedyMax outputs the solution S_k.

Our approximate separation oracle, SepOracle, can then use GreedyMax as a subroutine. Pseudocode is given in the full paper, and we give an informal description of the algorithm here. SepOracle checks all constraints not involving the regret, and then outputs any violated constraints it finds. If none are found, it then runs a k-median approximation algorithm on the instance containing only the fixed clients to generate a solution T_0. For each M in Z_ϵ, if T_0 is M-cheap, it then invokes GreedyMax for this value of M (otherwise, GreedyMax will consider the corresponding independence system to be empty, so there is no point in running it), passing T_0 to GreedyMax. If then checks the inequality $\sum_{j \in C'} \sum_i c_{ij} y_{ij} - S(C') \leq M - \sum_{j \in C_f} \sum_i c_{ij} y_{ij} + r$ for the solution S outputted by GreedyMax, and outputs this inequality if it is violated.

Using the ellipsoid method where SepOracle is used as the separation oracle now gives the following lemma. The proof is deferred to the full paper.

▶ **Lemma 14.** *If there exists a deterministic polynomial-time γ-approximation algorithm for the k-median problem, then for every $\epsilon > 0$ there exists a deterministic algorithm that outputs a $(2\gamma(1+\epsilon), 2)$-approximate fractional solution to the universal k-median problem in polynomial time.*

3.3 Rounding the Fractional Solution for Universal k-Median with Fixed Clients

The rounding algorithm for universal k-median with fixed clients is almost identical to the rounding algorithm for universal k-median without fixed clients. The only difference is that in constructing a k-median with discounts problem, we give the fixed clients a discount of 0 rather than a discount of $3f_j$, as these clients will always appear and thus we want their connection cost to always factor into the cost of the k-median with discounts instance. The cost of a solution ALG to the k-median with discounts instance and the regret of ALG against an adversary with costs $3f_j$ now differs by $\sum_{j \in C_f} 3f_j$ (before, they were equal). However, as before $\sum_{j \in C_f} 3f_j$ is at most some constant times $\text{OPT}(C_f) + \text{MR}$, which lower bounds $\text{OPT}(C') + \text{MR}$ for all realizations $C' \supseteq C_f$. So an analysis of the rounding similar to that in Section 2 still allows us to prove Theorem 10, as the the offset $\sum_{j \in C_f} 3f_j$ (and multiples of it appearing in the analysis) can be absorbed into the (α, β)-approximation guarantee.

4 Universal k-means

In this section, we sketch our universal algorithm for k-means with the following guarantee:

▶ **Corollary 15.** *There exists a* $(108, 412)$*-approximate universal algorithm for the* k*-means problem.*

This follows as a special case of a more general ℓ_p-clustering result, given in the full paper; due to space constraints, we focus on k-means here.

Before describing further details of the universal k-means algorithm, we note a rather unusual feature of the universal clustering framework. Typically algorithms effectively optimize the ℓ_2^2 objective (i.e., sum of squared distances) instead of the k-means objective because these are equivalent in the following sense: an α-approximation for the k-means objective is equivalent to an α^2-approximation for the ℓ_2^2 objective. But, this equivalence fails in the setting of universal algorithms for reasons that we discuss below. Indeed, we first give a universal ℓ_p^p-clustering algorithm, which is a simple extension of the k-median algorithm, and then outline our ℓ_p-clustering algorithm in the setting $p = 2$, which turns out to be much more challenging.

Similar to k-median, we use the primitive of an algorithm for the ℓ_p^p-clustering with discounts problem: In this problem, are given a ℓ_p^p-clustering instance, but where each client j has an additional (non-negative) parameter r_j called its *discount*. Our goal is to place k cluster centers that minimize the total connection costs of all clients. But, the connection cost for client j can now be discounted by up to r_j^p, i.e., client j with connection cost c_j contributes $(c_j^p - r_j^p)^+ := \max\{0, c_j^p - r_j^p\}$ to the objective of the solution. (Note that the k-median with discounts problem that we described in the previous section is a special case of this problem for $p = 1$.)

Let OPT be the cost of an optimal solution to the ℓ_p^p-clustering with discounts problem. We say an algorithm ALG that outputs a solution with connection cost c_j for client j is a (γ^p, σ)-approximation[2] if $\sum_{j \in C}(c_j^p - \gamma^p \cdot r_j^p)^+ \leq \sigma \cdot \text{OPT}$. That is, a (γ^p, σ)-approximate algorithm outputs a solution whose objective function computed using discounts $\gamma \cdot r_j$ for all j is at most σ times the optimal objective using discounts r_j. We give the following result about the ℓ_p^p-clustering with discounts problem (see full paper for details):

▶ **Lemma 16.** *There exists a (deterministic) polynomial-time* $(9^p, \frac{2}{3} \cdot 9^p)$*-approximation algorithm for the* ℓ_p^p*-clustering with discounts problem.*

The rest of this section is dedicated to sketching our algorithm for the universal k-means problem. As for k-median, we have two stages, the fractional algorithm and the rounding algorithm, that we sketch in the next two subsections.

[2] We refer to this as a (γ^p, σ)-approximation instead of a (γ, σ)-approximation to emphasize the difference between the scaling factor for discounts γ and the loss in approximation factor γ^p.

4.1 Universal k-means: Fractional Algorithm

Let us start by describing the fractional relaxation of the universal k-means problem[3] (again, P is the k-median polytope defined as in Section 2.1):

$$\min\{r : (x,y) \in P; \forall C' \subseteq C : \left(\sum_{j \in C'} \sum_i c_{ij}^2 y_{ij}\right)^{1/2} - \textsc{opt}(C') \leq r\}, \tag{7}$$

As described earlier, when minimizing regret, the k-means and ℓ_2^2 objectives are no longer equivalent. For instance, recall that one of the key steps in Lemma 8 was to establish the submodularity of the function $f_y(S)$ denoting the maximum regret caused by any realization when comparing two given solutions: a fractional solution y and an integer solution S. Indeed, the worst case realization had a simple structure: choose all clients that have a smaller connection cost for S than for y. This observation continues to hold for the ℓ_2^2 objective because of the linearity of $f_y(S)$ as a function of the realized clients once y and S are fixed. But, the k-means objective is not linear even after fixing the solutions, and as a consequence, we lose both the simple structure of the maximizing realization as well as the submodularity of the overall function $f_y(S)$. For instance, consider two clients: one at distances 1 and 0, and another at distances $1+\epsilon$ and 1, from y and S respectively. Using the ℓ_p objective, the regret with both clients is $(2+\epsilon)^{1/2} - 1 < 1$, whereas with just the first client the regret is 1.

The above observation results in two related difficulties: first, that $f_y(S)$ is not submodular and hence standard submodular maximization techniques do not apply, but also that given y and S, we cannot even compute the function $f_y(S)$ efficiently. To overcome this difficulty, we further refine the function $f_y(S)$ to a collection of functions $f_{y,Y}(S)$ by also fixing the cost of the fractional solution y to at most a given value Y. Let $\textsc{frac}_2, \textsc{frac}_2^2$ denote the k-means and ℓ_2^2-objectives of a given fractional solution, and S_2, S_2^2 the same for the solution using the set of cluster centers S. We can show that:

$$\max_{C' \subseteq C} \left[\textsc{frac}_2(C') - S_2(C')\right] \simeq_2 \max_Y \max_{C' \subseteq C : \textsc{frac}_2^2(C') \leq Y} \left[\frac{\textsc{frac}_2^2(C') - S_2^2(C')}{Y^{1/2}}\right],$$

where $\simeq_2$ denotes equality to within a factor of 2. In turn, by guessing the maximizing value of Y we can (approximately) reduce maximizing the difference in k-means objectives to maximizing the difference in ℓ_2^2 objectives, subject to the constraint $\textsc{frac}_2^2(C') \leq Y$.

A separation oracle then just needs to (approximately) compute $\max\{\textsc{frac}_2^2(C') - S_2^2(C') : C' \subseteq C, \textsc{frac}_2^2(C') \leq Y\}$ for each fixed (discretized) value of Y. To do so, we show that allowing an adversary to choose *fractional* realizations of clients does not give them an advantage.

▶ **Lemma 17.** *For any two solutions y, S, there exists a global maximum of $\textsc{frac}_2(\mathbf{I}) - S_2(\mathbf{I})$ over fractional realizations $\mathbf{I} \in [0,1]^C$ where all the clients are integral, i.e., $\mathbf{I} \in \{0,1\}^C$. Therefore,*

$$\max_{\mathbf{I} \in [0,1]^C} \left[\textsc{frac}_2(\mathbf{I}) - S_2(\mathbf{I})\right] = \max_{C' \subseteq C} \left[\textsc{frac}_2(C') - S_2(C')\right].$$

[3] The constraints are not simultaneously linear in y and r, although fixing r, we can write these constraints as $\sum_{j \in C'} \sum_i c_{ij}^p y_{ij} \leq (\textsc{opt}(C') + r)^p$, which is linear in y. In turn, to solve this program we bisection search over r, using the ellipsoid method to determine if there is a feasible point for each fixed r.

We then show that $f_{y,Y}(S) := \max\{\text{FRAC}_2^2(\mathbf{I}) - S_2^2(\mathbf{I}) : \mathbf{I} \in [0,1]^C, \text{FRAC}_2^2(\mathbf{I}) \leq Y\}$ is a submodular function. Since we are allowed to use fractional clients, computing $f_{y,Y}(S)$ for a given S is a fractional knapsack problem which can be solved in polynomial time (whereas computing $\max\{\text{FRAC}_2^2(C') - S_2^2(C') : C' \subseteq C, \text{FRAC}_2^2(C') \leq Y\}$ requires solving an integer knapsack problem), giving an efficient separation oracle using the greedy algorithm for submodular maximization.

4.2 Universal k-Means: Rounding Algorithm

At a high level, we use the same strategy for rounding the fractional k-means solution as we did with k-median. Namely, we use Lemma 16 to solve a discounted version of the problem where the discount for each client is equal to the (scaled) cost of the client in the fractional solution. However, if we apply this directly to the k-means objective, we run into several problems. In particular, the linear discounts are incompatible with the non-linear objective defined over the clients. A more promising idea is to use these discounts on the ℓ_2^2 objective, which in fact is defined as a linear combination over the individual client's objectives. But, for this to work, we will first need to relate the regret bound in the ℓ_2^2 objective to that in the k-means objective. We show that, roughly speaking, the realization that maximizes the regret of an algorithm ALG against a fixed solution SOL in both objectives is the same under a "farness" condition:

▶ **Lemma 18.** *Suppose* ALG *and* SOL *are two solutions to a k-means instance, such that there is a subset of clients C^* with the following property: for every client in C^*, the connection cost in* ALG *is greater than* 2 *times the connection cost in* SOL*, while for every client not in C^*, the connection cost in* SOL *is at least the connection cost in* ALG*. Then, C^* is a $1/2$-maximizer of $\text{ALG}_2(C') - \text{SOL}_2(C')$.*

Given any solution SOL, it is easy to define a *virtual* solution $\widetilde{\text{SOL}}$ whose individual connection costs are bounded by 2 times that in SOL, and $\widetilde{\text{SOL}}$ satisfies the farness condition. This allows us to relate the regret of ALG against $\widetilde{\text{SOL}}$ (and thus against 2 times SOL) in the ℓ_2^2 objective to its regret in the k-means objective.

5 Universal k-Center

In this section, we prove the following guarantee for universal k-center:

▶ **Theorem 19.** *There exists a $(3,3)$-approximate algorithm for the universal k-center problem.*

First, note that for every client j, its distance to the closest cluster center in the minimum regret solution MRS is at most $\text{MR}_j := \min_{i \in F} c_{ij} + \text{MR}$; otherwise, in the realization with only client j, MRS would have regret $> \text{MR}$. We first design an algorithm ALG that 3-approximates these distances MR_j, i.e., for every client j, its distance to the closest cluster center in ALG is at most 3MR_j. Since $\min_{i \in F} c_{ij}$ lower bounds $\text{OPT}(C')$ for any C' containing j, this gives a $(3,3)$-approximation. This algorithm actually satisfies a more general property: given *any* value r, it produces a set of cluster centers such that every client j is at a distance $\leq 3r_j$ from its closest cluster center, where $r_j := \min_{i \in F} c_{ij} + r$. Moreover, if $r \geq \text{MR}$, then the number of cluster centers selected by ALG is at most k (for smaller values of r, ALG might select more than k cluster centers).

Our algorithm ALG is a natural greedy algorithm. We order clients j in increasing order of r_j, and if a client j does not have a cluster center within distance $3r_j$ in the current solution, then we add its closest cluster center in F to the solution.

▶ **Lemma 20.** *Given a value r, the greedy algorithm* ALG *selects cluster centers that satisfy the following properties:*

- *every client j is within a distance of $3r_j = 3(\min_{i \in F} c_{ij} + r)$ from their closest cluster center.*
- *If $r \geq$ MR, then* ALG *does not select more than k cluster centers, i.e., the solution produced by* ALG *is feasible for the k-center problem.*

Proof. The first property follows from the definition of ALG. To show that ALG does not pick more than k cluster centers, we map the cluster center i added in ALG by some client j to its closest cluster center i' in MRS. Now, we claim that no two cluster centers i_1, i_2 in ALG can be mapped to the same cluster center i' in MRS. Clearly, this proves the lemma since MRS has only k cluster centers.

Suppose i_1, i_2 are two cluster centers in ALG mapped to the same cluster center i' in MRS. Assume without loss of generality that i_1 was added to ALG before i_2. Let j_1, j_2 be the clients that caused i_1, i_2 to be added; since i_2 was added later, we have $r_{j_1} \leq r_{j_2}$. The distance from j_2 to i_1 is at most the length of the path (j_2, i', j_1, i_1) , which is at most $2r_{j_2} + r_{j_1} \leq 3r_{j_2}$. But, in this case j_2 would not have added a new cluster center i_2, thus arriving at a contradiction. ◀

Theorem 19 follows since there are only polynomially many possibilities for the k-center objective across all realizations (namely, the set of all cluster center to client distances) and thus polynomially many possible values for MR (the set of all differences between all possible solution costs). So we can simply run the algorithm of Lemma 20 with r equal to each of these values, and then choose the solution corresponding to the smallest r that results in the algorithm using at most k cluster centers, which will be at most MR by Lemma 20.

We note that the greedy algorithm described above can be viewed as an extension of the k-center algorithm in [24] to a $(3, 3)$-approximation for the "k-center with discounts" problem, where the discounts are the minimum distances $\min_{i \in F} c_{ij}$.

6 Hardness of Universal Clustering for General Metrics

In this section we give some hardness results to help contextualize the algorithmic results. Much like the hardness results for k-median, all our reductions are based on the NP-hardness of approximating set cover (or equivalently, dominating set) due to the natural relation between the two types of problems. We state our hardness results in terms of ℓ_p-clustering. Setting $p = 1$ gives hardness results for k-median, and setting $p = \infty$ (and using the convention $1/\infty = 0$ in the proofs as needed) gives hardness results for k-center.

The results in this section can be extended to Euclidean metrics by building off the reductions in [36], albeit with worse constants. Due to space constraints, we defer our results for Euclidean metrics to the full paper.

6.1 Hardness of Approximating α

▶ **Theorem 21.** *For all $p \geq 1$, finding an (α, β)-approximate solution for universal ℓ_p-clustering where $\alpha < 3$ is NP-hard.*

Proof. To prove the theorem, given an instance of set cover, we construct the following instance of universal ℓ_p-clustering:

- For each element, there is a corresponding client in the universal ℓ_p-clustering instance.
- For each set S, there is a cluster center which is distance 1 from the clients corresponding to elements in S and 3 from other all clients.

If there is a set cover of size k, the corresponding cluster centers are an optimal solution for any realization of clients, i.e. $\text{MR} = 0$. Furthermore, in any single-client realization, $\text{OPT} = 1$. So an (α, β)-approximate universal ℓ_p-clustering algorithm must find a solution within distance of α of every client to satisfy the regret guarantee in single-client realizations. If $\alpha < 3$, this implies it is distance 1 from every client, in which case its cluster centers also correspond to a set cover. So this algorithm can be used to find set covers of size at most k if they exist, which is an NP-hard task. ◀

Note that for e.g. k-median, we can classically get an approximation ratio of less than 3. So this theorem shows that the universal version of the problem is harder, even if we are willing to use arbitrary large β.

6.2 Hardness of Approximating β

We give the following result on the hardness of universal ℓ_p-clustering.

▶ **Theorem 22.** *For all $p \geq 1$, finding an (α, β)-approximate solution for universal ℓ_p-clustering where $\beta < 2$ is NP-hard.*

Proof. Given an instance of dominating set $G = (V, E)$, we construct the following instance of universal ℓ_p-clustering:

- For each vertex $v \in V$, replace it with a k-clique.
- For each $(u, v) \in E$, add an edge from every vertex in u's clique to every vertex in v's clique.
- To turn this modified graph into a clustering instance, place a client and cluster center at each vertex, and impose the shortest path metric on the clients, where all edges are length 1.

Suppose a dominating set of size k exists in the modified graph (and thus in the original graph). Then the corresponding cluster centers are distance at most 1 from every client. Since any solution is distance 0 from at most k clients and distance at least 1 from all other clients, these cluster centers have regret at most $k^{1/p}$. It now suffices to prove the claim that any k cluster centers that aren't a dominating set have regret at least $2k^{1/p}$ in a realization where OPT has cost 0. The theorem follows since an (α, β)-approximate algorithm would produce a solution with cost at most $\beta k^{1/p}$ in any such realization, i.e. can be used to find dominating sets of size at most k if they exist when $\beta < 2$. The claim follows since if the cluster centers aren't a dominating set, there is a k-clique they are distance 2 or more from. The realization containing exactly the clients in this k-clique satisfies the desired properties. ◀

7 Future Directions

In this paper, we gave the first universal algorithms for clustering problems. While we achieve constant approximation guarantees for these problems, the actual constants are orders of magnitude larger than the best (non-universal) approximations known for these problems. In part to ensure clarity of presentation, we did not attempt to optimize these constants. But it is unlikely that our techniques will lead to *small* constants for the k-median and k-means problems. On the other hand, we show that in general it is **NP**-hard to find an (α, β)-approximation algorithm for a universal clustering problem where α matches the approximation factor for the standard clustering problem. Therefore, it is not entirely clear what one should expect: *are there universal algorithms for clustering with approximation factors of the same order as the classical (non-universal) bounds?*

Another open research direction pertains to Euclidean clustering. Here, we showed that in $\mathbb{R}^d$ for $d \geq 2$, α needs to be bounded away from 1, which is in stark contrast to non-universal clustering problems that admit PTASes in constant-dimension Euclidean space. But for universal clustering on a line, the picture is not as clear. On a line, the lower bounds on α are no longer valid, which brings forth the possibility of (non-bicriteria) approximations of regret. Indeed, there is 2-approximation for universal k-median on a line [29], and even better, an *optimal* algorithm for universal k-center on a line [6]. This raises the natural question: *can we design a PTAS for the universal k-median problem on a line?*

Abstract

Two strings are order isomorphic iff the relative ordering of their characters is the same at all positions. For a given text $T[1, n]$ over an ordered alphabet of size σ, we can maintain an order-isomorphic suffix tree/array in $O(n \log n)$ bits and support (order-isomorphic) pattern/substring matching queries efficiently. It is interesting to know if we can encode these structures in space close to the text's size of $n \log \sigma$ bits. We answer this question positively by presenting an $O(n \log \sigma)$-bit index that allows access to any entry in order-isomorphic suffix array (and its inverse array) in $t_{\mathsf{SA}} = O(\log^2 n / \log \sigma)$ time. For any pattern P given as a query, this index can count the number of substrings of T that are order-isomorphic to P (denoted by occ) in $O((|P| \log \sigma + t_{\mathsf{SA}}) \log n)$ time using standard techniques. Also, it can report the locations of those substrings in additional $O(occ \cdot t_{\mathsf{SA}})$ time.

1 Introduction

An index of a text $T[1, n]$ is a data structure that is capable of counting/reporting all those *substrings* of T that "*match*" (as per the problem specific definition of match) with any pattern P given as a query. We use Σ to denote the alphabet set (of size σ) from which the characters in T are drawn from. WLOG, we assume $T[n] = \$$, a special character that does not appear anywhere else in T. Two fundamental indexes for exact pattern matching are the suffix tree (ST) [23] and the suffix array (SA) [17]. Both takes $\Theta(n \log n)$ bits of space, which could be much larger than the $n\lceil \log \sigma \rceil$ bits needed to store T optimally. The first succinct indexes that use close to $n \log \sigma$ bits are the Compressed Suffix Array (CSA) [13] and the FM-index [7]. The crucial component of FM Index is Burrows-Wheeler Transform (BWT) [2] and its associated operation called the *Last-to-Front* (LF) *mapping*. The subsequent work lead to fully functional suffix trees in succinct space [22]. See [20] for further reading.

The parameterized ST [1, 18] and the order-isomorphic ST [5] are two popular ST variants under the class known as *suffix trees with missing suffix links* [4]. As they do not hold some critical structural properties of the original ST, their compression is challenging. Recently, Ganguly *et al.* showed that it is indeed possible to compress the parameterized suffix arrays. They implemented LF mapping using a BWT-like transformation called the parameterized BWT [10]. However, such a transformation is hard to define for order-isomorphic ST because

LF mapping could lead to multiple changes in the (encoding of) associated suffixes. To that end, we present a novel technique for implementing the LF mapping (named LF *Successor*), leading to the first compact space index for order-isomorphic pattern matching.

1.1 Generalizing the Philosophy of BWT and LF Mapping

We present an overview of our approach using three text indexing problems for (i) traditional/exact matching, (ii) parameterized matching, and (iii) order-isomorphic matching, in that order, to show gradation and successive generalization of the LF mapping approach.

Indexing for Traditional Matching. The classic solution is the suffix tree (ST), which is lexicographic arrangement of all strings in $\mathcal{S} = \{T[t, n] \mid 1 \leq t \leq n\}$ as a compacted trie. We use $\mathsf{path}(u)$ to denote the concatenation of edge labels on the path from the root to node u. Let ℓ_i denotes the ith leftmost leaf. Then, $\mathsf{path}(\ell_i)$ is exactly the ith smallest string in S in the lexicographic order. The suffix array $\mathsf{SA}[1, n]$ is such that $\mathsf{SA}[i] = n + 1 - |\mathsf{path}(\ell_i)|$. Also, its inverse array $\mathsf{SA}^{-1}[1, n]$ is such that $\mathsf{SA}^{-1}[\mathsf{SA}[i]] = i$. For convenience, we use the term "suffix i" for $T[\mathsf{SA}[i], n]$. For all i, where $\mathsf{SA}[i] \neq 1$, we define the Last-to-Front (LF) mapping as $\mathsf{LF}(i) = \mathsf{SA}^{-1}[\mathsf{SA}[i] - 1]$. Therefore, *suffix* $\mathsf{LF}(i)$ is obtained by prepending to *suffix* i the character in T which occurs just before the starting location of suffix i. The Burrows-Wheeler Transform is an array $\mathsf{BWT}[1, n]$, such that $\mathsf{BWT}[i] = T[\mathsf{SA}[i] - 1]$ (define $T[0] = \$$). Computing LF mapping is central to BWT based pattern matching, and in some sense, the BWT enables efficient computation of LF mapping in succinct space. Therefore, once we store the BWT and its associated counting structures, we can replace the costly (space-wise) suffix array with a (cheaper) sampled suffix array [7].

Indexing for Parameterized Matching. Here, P matches with T at position i iff there is one-to-one correspondence between the characters of P and $T[i, i + |P| - 1]$. For example, $xwyx$ can match with $abca$ as x can be mapped to a, b to w, and c to y. However, $abca$ does not match with $xyxw$ because both a and c cannot be mapped to x. Baker [1] presented an encoding called $\mathsf{prev}(S)$ which encodes every character in the string by replacing it by its distance to the previous occurrence of the same character and using 0 if the character has not occurred before. For example, $\mathsf{prev}(xwxyywx) = 0020144$. It is not hard to see that two strings X and Y are a parameterized match iff $\mathsf{prev}(X) = \mathsf{prev}(Y)$. The parameterized ST is a lexicographic arrangement of all strings in $\mathcal{S}' = \{\mathsf{prev}(T[i, n - 1]) \circ \$ \mid 1 \leq i < n\} \cup \{\$\}$ as a compacted trie, where $\circ$ denotes concatenation. The matching of P in T can be performed via exact matching of $\mathsf{prev}(P)$ in this suffix tree. The same notion of LF-mapping can be defined and implemented in succinct space using a BWT-like transform [10].

Indexing for Order-isomorphic Matching. This problem has received significant attention [3, 5, 14, 16, 19] due to its simple formulation and the ability to model complex matching problems in other domains where the relative ordering of characters has to be matched rather than the string itself. Here, there is a total ordering between the symbols in Σ. The pattern P matches with text $T[1, n]$ at position i if for any j, k in $[1, |P|]$, $P[j] < P[k]$ iff $T[i + j - 1] < T[i + k - 1]$. Similar constraints apply for $P[j] > P[k]$ and $P[j] = P[k]$. For example, 1423 can match with 2957 but not with 2657 because $6 < 7$ and $4 > 3$. A new encoding "pred" works in this case. This is a slight modification of the scheme in [5].

▶ **Definition 1** (pred encoding). *Given a character $S[i]$ in string S, its predecessor is a character q which occurs in $S[1, i - 1]$ such that $q \leq S[i]$ and there is no other character r in $S[1, i - 1]$ such that $q < r \leq S[i]$. Given a string S, $\mathsf{pred}(S)[i]$ is defined as follows: let*

alphabet symbol q be the predecessor of $S[i]$ in $S[1, i-1]$ and let position j be the rightmost occurrence of q in $S[1, i-1]$. Then, $\mathsf{pred}(S)[i] = (i-j)$ *if* $q \neq S[i]$, $(i-j)'$ *if* $q = S[i]$, *and* 0 *if q does not exist. Thus* $\mathsf{pred}(S)$ *is a string over the alphabet* $\{0, 1, 1', 2, 2', \ldots, |S|-1, (|S|-1)'\}$.

Thus, in pred encoding, every position (character) in T points to its closest predecessor on the left. For e.g., $\mathsf{pred}(0869514371) = 0\ 1\ 2\ 2\ 4\ 5\ 1\ 2\ 6\ 4'$. We refer to *primed* characters as an *equality* version of their non-primed counterparts. For example, $2'$ is equality variant of 2. It is easy to see that two strings X and Y are order-isomorphic iff $\mathsf{pred}(X) = \mathsf{pred}(Y)$.

The *order-isomorphic* ST [5] of T is a lexicographic arrangement of all strings in $\mathcal{S}'' = \{\mathsf{pred}(T[i, n-1]) \circ \$ \mid 1 \leq i < n\} \cup \{\$\}$ as a compacted trie. We order the encoded characters as: $0 < 1 < 1' < 2 < 2' < \cdots < n-1 < (n-1)' < \$$. Then, the order-isomorphic matching of P in T can be performed via exact matching of $\mathsf{pred}(P)$ in this suffix tree. As earlier, we can define the (order-isomorphic) suffix array SA, its inverse array and the LF mapping.

1.2 Challenges in Implementing (Generalised) LF Mapping Compactly

The challenge here is in deciding what needs to be precomputed and stored, so that $\mathsf{LF}(i)$ for any i can be computed efficiently. At its root, we need to solve the following: given two leaves ℓ_i and ℓ_j with $i < j$, how quickly can we decide whether $\mathsf{LF}(i) < \mathsf{LF}(j)$ or $\mathsf{LF}(i) > \mathsf{LF}(j)$.

In the case of **traditional matching**, the order between $\mathsf{LF}(i)$ and $\mathsf{LF}(j)$ will stay the same if the corresponding suffixes have the same *previous character* (which are $\mathsf{BWT}[i]$ and $\mathsf{BWT}[j]$). It will flip iff the previous character of the suffix corresponding to j is smaller than that of i in the lexicographic order. Therefore pair-wise comparison between such i and j can be computed in "bulk" for i against all j's, enabling "quick" computation of $\mathsf{LF}(i)$ [7].

In the case of **parameterized matching**, this order determination is more sophisticated [10]. Here, it becomes essential to see how prepending the previous character changes the canonical encoding of a suffix and how can this information be stored compactly. For example, consider $T[1, n] = abcabbadcb$ and the suffix $T[4, n] = abbadcb$. Its previous character $T[3]$ is c. When we prepend this character, the suffix (in traditional ST) becomes $cabbadcb$. The string corresponding to $T[4, n]$ in the parameterized suffix tree is $\mathsf{prev}(T[4, n]) = 0013004$. When $T[4, n]$ is prepended with c and prev is applied, apart from the insertion (of 0) at the beginning, there is one change within prev of $T[4, n]$, which is at the first occurrence of c in $T[4, n]$. Thus, the second last character in the encoding switches from 0 to 6, i.e., $\mathsf{prev}(T[3, n]) = 00013064$. Ganguly *et al.* [10] show how to record this change-location for each suffix succinctly using the paramaterized-BWT, which supports LF mapping. Again, as in the case of traditional pattern matching, we can compare two suffixes in terms of their LF mapping by comparing which suffix changes first – in case at least one of them changes before their longest common prefix (LCP). See [11, 15, 9] for some related results.

We now illustrate **order-isomorphic matching** using an example text $T[1, n] = 20869514371\$$. Then, $T[2, n] = 0869514371\$$ and $\mathsf{pred}(T[2, n-1]) \circ \$ = 0\ 1\ 2\ 2\ 4\ 5\ 1\ 2\ 6\ 4'\ \$$. However, pred after prepending $T[1]$, i.e., $\mathsf{pred}(T[1, n-1]) \circ \$$ is $0\ 0\ 2\ 3\ 2\ 5\ 5\ \ 7\ 8\ \ 6\ 4'\ \$$. Observe how the encoding changes when we go from $T[2, n]$ to $T[1, n]$. Apart from the obvious 0 in front, there are "five" other entries whose predecessor changed due to the newly inserted 2. Both earlier problems, traditional and parameterized, incurred only a constant (1 or 2) number of changes per suffix, and hence it was possible to record this information compactly. However, the number of changes here can be as large as σ, which makes it challenging and the existing techniques do not seem adequate.

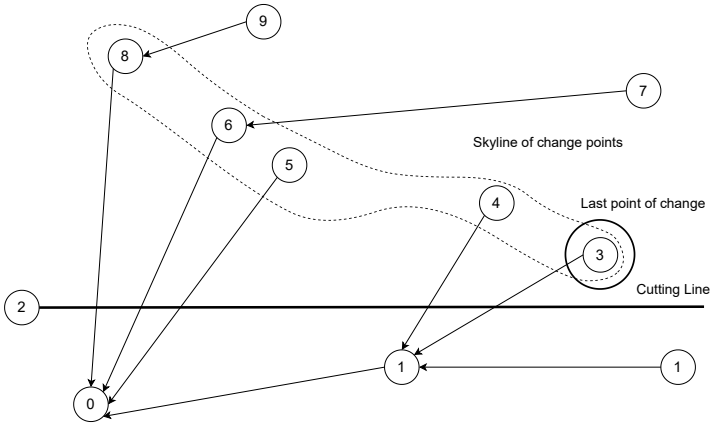

Figure 1 Geometric interpretation of the change in pred encoding of 0869514371 when prepended with 2. The cutting line corresponds to the prepended character.

Our approach. Even though many positions change, and they cannot be explicitly stored, the structural properties of this problem show that the *last point of change* (the rightmost value which changes) during LF is what matters. In the example above, the rightmost character which changes its encoding is 3 and its encoding changes from 2 to 8. The good part is that once we know this, we can deterministically pinpoint which other previous (to the left) locations changed their encoding (we present this formally as Lemma 5). Thus, we can register/store one particular value and all previous changes can be captured based on that. Yet this only gives us existential dependency and not an algorithmic tool.

1.3 Our Contribution

The existing results on compressed text indexing for order-isomorphic pattern matching are partial and conditional. For example, the $O(n \log\log n)$-bit by Gagie et al. [8] can answer only counting queries, that too for short patterns of size $O(\log^{O(1)} n)$. Another result by Decaroli et al. [6] is based on heuristics. We show:

▶ **Theorem 2.** *Let $T[1,n]$ be a given text over an ordered alphabet Σ of size σ. We can encode its order-isomorphic suffix array $\mathsf{SA}[1,n]$ in $O(n \log \sigma)$ bits and answer both $\mathsf{SA}[\cdot]$ and $\mathsf{SA}^{-1}[\cdot]$ queries in $t_{\mathsf{SA}} = O(\log^2 n / \log \sigma)$ time.*

Using the standard binary search algorithm, we can easily answer counting queries in time $O((|P| \log \sigma + t_{\mathsf{SA}}) \log n)$ and then reporting in time t_{SA} per match. At the heart of proving Theorem 2 lies a novel way of implementing LF mapping. We call this as LF Successor. It goes one step beyond the current approach of simulating *Suffix Array using LF mapping*.

2 Structural Properties of the Order Isomorphic Suffixes

In this section we introduce two key lemmas explaining the structural properties of the pred encoding. In other words, we see where the changes occur when a new character is prepended to the suffix. Firstly, we formally define a *change point* as follows,

▶ **Definition 3** (Change Point). *Given a string $T[r,z]$ along with its* pred *encoding* $\mathsf{pred}(T[r,z])$, *point $i \in [r,z]$ is a change point if* $\mathsf{pred}(T[r-1,z])[i-r+2] \neq \mathsf{pred}(T[r,z])[i-r+1]$.

In other words, when a character is prepended to $T[r, z]$ (making it $T[r-1, z]$) the encoding of the character $T[i]$ changes. Here point i means position in the text.

▶ **Definition 4** (Skyline). *A point j in text substring $T[r, z]$ covers a point i iff $j < i$ and $T[j] \leq T[i]$. γ-skyline of $T[r, z]$ is set of all points $i \in [r, z]$ such that $T[i] \geq \gamma$ and i is not covered by any point $j \in [r, i-1]$ such that $T[j] \geq \gamma$. When $\gamma = T[r-1]$, we simply refer to this as skyline of $T[r, z]$. Given a point $d \in T[r, z]$, the skyline induced by d is same as $T[d]$-skyline of $T[r, z]$ (i.e., the one obtained by setting $\gamma = T[d]$).*

Lemma 5 proves that all the change points of $T[r, z]$ are exactly the ones that are on the *skyline* (See Figure 1 for geometric interpretation). Secondly, as mentioned earlier, although there are many change points in the order isomorphic setting, given the rightmost or last change point we can uniquely determine all the previous change points. More formally, it can be stated as follows.

▶ **Lemma 5** (Skyline Lemma). *Given a text substring $T[r, z]$ and it rightmost change point d of the substring, all the change points in $T[r, z]$ can be determined based on d. These are precisely the points in $T[d]$-skyline of $T[r, z]$.*

Proof. Firstly, let's consider any change point $i \in T[r, z]$. Since its pred-encoding changes due to prepending of $T[r-1]$ the new predecessor of point i in $T[r-1, z]$ must be $r-1$ (i.e., $\mathsf{pred}(i) = i - r + 1$). This means $T[i] \geq T[r-1]$. Also if point i was covered by point j such that $j < i$ and $T[j] \geq T[r-1]$, then predecessor of i in $T[r-1, z]$ would still be j.

For the other way around, consider a point i on the skyline of $T[r, z]$. The predecessor of i in $T[r, z]$ cannot be a point j such that $T[j] \geq T[r-1]$ (by definition of cover), Thus, when $T[r-1]$ is prepended, it will become the new predecessor of i. Hence, i is a change point.

Now, if d is the rightmost change point of T then no character value in $T[r-1, z]$ is in between $T[r-1]$ and $T[z]$. That is, there is no $i \in [r, d-1]$ such that $T[r-1] \leq T[i] \leq T[d]$. Thus, this indeed is the same as $T[d]$-skyline. Also, since there are no change points after d they will not be on the skyline. ◀

Next, given two suffixes and their last common change points, all their previous change points will be the same. We state this as a lemma below. Here we define $\mathsf{rank}(x, T[r, z])$ as the number of values in $T[r, z]$ that are less than or equal to x. It follows from the definition of rank that if there are two order isomophic substrings $T[r, r+l-1]$ and $T[s, s+l-1]$, then for any point $1 \leq d \leq l$, $\mathsf{rank}(T[r+d-1], T[r, r+l-1] = \mathsf{rank}(T[s+d-1], T[s, s+l-1]$.

▶ **Lemma 6** (Last Common Point of Change (LCPC) Lemma). *Given two text substrings $T[r, r+l-1]$ and $T[s, s+l-1]$ such that $\mathsf{pred}(T[r, r+l-1]) = \mathsf{pred}(T[s, s+l-1])$, let d be the greatest value such that $r+d-1$ and $s+d-1$ are the change points in $T[r, r+l-1]$ and $T[s, s+l-1]$ respectively. Thus, the dth point is the last common change point of substrings $T[r, r+l-1]$ and $T[s, s+l-1]$. Then for every $e \in [1, d-1]$, $r+e-1$ is a change point in $T[r, r+l-1]$ if and only if $s+e-1$ is a change point in $T[s, s+l-1]$.*

Proof. Firstly, w.l.o.g, let $\mathsf{rank}(T[r-1], T[r, r+l-1]) < \mathsf{rank}(T[s-1], T[s, s+l-1])$. Now, there is no point p such that $1 < p < d$ and $\mathsf{rank}(T[r-1], T[r, r+l-1]) < \mathsf{rank}(T[r+p-1], T[r, r+l-1]) < \mathsf{rank}(T[s-1], T[s, s+l-1])$. This is because if there was such a point p, then d cannot be a change point of $T[r, r+l-1]$, because d will be covered by point p. Secondly, if $e \in [1, d-1]$ is a change point of $T[r, r+l-1]$ and suppose q was the predecessor of e before prepending of the new point $T[r-1]$, then $\mathsf{rank}(T[r+q+1], T[r, r+l-1]) < \mathsf{rank}(T[r-1], T[r, r+l-1]) < \mathsf{rank}(T[r+e+1], T[r, r+l-1])$. Therefore, we can say that

$\mathsf{rank}(T[r+q+1], T[r, r+l-1]) < \mathsf{rank}(T[r-1], T[r, r+l-1]) < \mathsf{rank}(T[s-1], T[s, s+l-1]) < \mathsf{rank}(T[r+e+1], T[r, r+l-1])$. Here if we just consider the ranking orders of $T[s, s+l-1]$, then $\mathsf{rank}(T[s+q+1], T[s, s+l-1]) < \mathsf{rank}(T[s-1], T[s, s+l-1]) < \mathsf{rank}(T[s+e+1], T[s, s+l-1])$ because $\mathsf{pred}(T[r, r+l-1]) = \mathsf{pred}(T[s, s+l-1])$. This implies that $T[s-1]$ is the new predecessor of $T[s+e+1]$, which means e is also a change point of $T[s, s+l-1]$.

The encoding of characters which are not change points will stay the same in $\mathsf{pred}(T[r-1, r+d-1])$ and $\mathsf{pred}(T[s-1, s+d-1])$. On the characters which are change points, their $\mathsf{pred}(\cdot)$ values point to $T[r-1]$ (resp. $T[s-1]$). Since pred encodes distance to the predecessor character, these pred values will be the same for corresponding change points in $T[r-1, r+d-1]$ and $T[s-1, s+d-1]$. Thus, $\mathsf{pred}(\cdot)$ encoding for both agree up to the first $d+1$ characters. ◀

As an example of LCPC, consider two substrings $T[r-1, r+6] = \texttt{dkgcihfe}$ and $T[s-1, s+6] = \texttt{ckfaihdb}$. Now, $T[r, r+6]$ and $T[s, s+6]$ are both order-isomorphic with prev encoding of 0002334 (here we follow the usual ordering of English characters). Considering, the previous values $T[r-1]$ and $T[s-1]$, the change points for $T[r, r+6]$ are $\texttt{k}, \texttt{g}, \texttt{f}, \texttt{e}$ at locations r plus $\{0, 1, 5, 6\}$ within string $T[r, r+6]$ and the change points for $T[s, s+6]$ are $\texttt{k}, \texttt{f}, \texttt{d}$ at locations s plus $\{0, 1, 5\}$ within string $[s, s+6]$. Thus, last common point of change (LCPC) is at location 6 i.e., $T[r+5]$ and $T[s+5]$. Note that $T[r+6]$ is also a change point however it is not a common change point. Also, note that since all the earlier change points in both the strings are at same locations $\{1, 2\}$. All the common change points at locations $\{0, 1, 5\}$ are indeed skylines of $T[r, r+5]$ as well as that of $T[s, s+5]$. Alternatively, these skylines are indeed $T[r+5]$-skyline of $T[r, r+6]$ and $T[s+5]$-skyline of $T[s, s+6]$.

3 LF Successor and Order-Isomorphic Text Indexing

Recall our encoding scheme pred (Definition 1) and the lexicographic order of encoded symbols: $0 < 1 < 1' < 2 < 2' < \cdots < n-1 < (n-1)' < \$$. We will now introduce a few more terminologies related to the order-isomorphic suffix tree (ST). We shall refer to any character on any substring representing an edge label as a "point" in ST. An edge is labeled by a substring represented by that edge in ST. For any point c in ST, let $\mathsf{path}(c)$ denote the concatenation of labels from the root until c. We shall denote $\mathsf{char}(c)$ as an (pred encoded) character represented by point c. We will also refer to nodes in ST as points. In this case, the node will be represented by the character just above it (i.e., the last character of the label of its parent edge). For any point c, $\mathsf{depth}(c)$ is length of $\mathsf{path}(c)$ and $\alpha\mathsf{Depth}(c)$ = number of distinct symbols in $T[r, r+\mathsf{depth}(c)-1]$, where $T[r, n]$ is any suffix passing through c. Note that this $\alpha\mathsf{Depth}$ indeed refers back to the original text instead of encoded text (in terms of encoded text this would be the number of non-primed characters). We call this the alphabet depth of point c. We shall generalize this notion as alphabet length for any string S as $\alpha(S)$ = number of unique alphabet symbols in S. For any two suffixes i and j (i.e., suffixes corresponding to leaves ℓ_i and ℓ_j), let point $v = \mathsf{lca}(i, j)$ be the lowest common ancestor (LCA) of ℓ_i and ℓ_j. Then, the length of their longest common prefix, denoted by $\mathsf{LCP}(i, j)$ is $\mathsf{depth}(v)$. Also $\alpha\mathsf{LCP}(i, j) = \alpha\mathsf{Depth}(v)$.

The locus of a pattern P is the highest node u such that $\mathsf{pred}(P)$ is a prefix of $\mathsf{path}(u)$. Every leaf ℓ_i in the sub-tree of u corresponds to an occurrence of P at a position in T given by $\mathsf{SA}[i]$. Let $[sp, ep]$ be the suffix range of P, where ℓ_{sp} (resp. ℓ_{ep}) is the leftmost (resp. rightmost) suffix in the subtree of u. We note that in order to support pattern matching, we need to **(a)** compute the suffix range $[sp, ep]$ of P and **(b)** decode suffix array values $\mathsf{SA}[i]$, $i \in [sp, ep]$. Using a standard binary search on the suffix array along with the text, we can

find the suffix range. Storing $\mathsf{SA}[i]$ for every leaf ℓ_i is too costly as it will take $\Theta(n \log n)$ bits. The goal is to encode suffix array values in compact space so that they can be decoded efficiently. We show how to achieve this using a *sampled suffix array* and *LF mapping*.

Recall that LF mapping is defined as: $j = \mathsf{LF}(i)$ iff $\mathsf{SA}[j] = \mathsf{SA}[i] - 1$. We explicitly store $\mathsf{SA}[\cdot]$ values belonging to the set $\{1, 1+\Delta, 1+2\Delta, \ldots, n\}$, where Δ is a tunable parameter to be set later. For any suffix i, where $\mathsf{SA}[i]$ has not been stored, we repeatedly apply LF mapping operation (starting from i) until we reach j such that $\mathsf{SA}[j]$ has been sampled. Then, $\mathsf{SA}[i] = \mathsf{SA}[j] + k$, where k is the number of LF operations applied; note that $k \leq \Delta$. Thus, we have reduced the problem to that of computing $\mathsf{LF}(\cdot)$. For SA^{-1} queries, we store $\mathsf{SA}^{-1}[i]$ if i equals n or if i is a multiple of Δ. To compute $\mathsf{SA}^{-1}[j]$, we first find the smallest number $j' \geq j$, such that j' is a multiple of Δ (or $j' = n$). Compute $j'' = \mathsf{SA}^{-1}[j']$ from sampled-SA^{-1} in $O(1)$ time. Let $k = j' - j$. Starting from j'' carry out k successive LF operations and report the final index as $\mathsf{SA}^{-1}[j]$.

To compute LF, we introduce *LF successor*, defined as:

i' is called the LF-successor of i iff $\mathsf{LF}(i') = \mathsf{LF}(i) + 1$

We denote it as $i' = \mathsf{LFS}(i)$. Throughout this paper, we use i' to denote $\mathsf{LFS}(i)$ for any suffix i. Thus, the leaves ℓ_i and $\ell_{i'}$ are mapped by using LF operation to leaves ℓ_j and ℓ_{j+1} respectively. To compute LF mapping, we again use a sampling technique. Specifically, we explicitly store $\mathsf{LF}(\cdot)$ values in the set $\{1, 1+\Delta, 1+2\Delta, \ldots, n\}$, thereby reducing the problem of computing LF mapping to that of computing at most Δ number of LF successors. In Section 4, we show how to compute LF successor in time $t_{\mathsf{LFS}} = O(\log \sigma)$ by using an $O(n \log \sigma)$-bit index. Therefore, LF can be computed in time $t_{\mathsf{LF}} = \Delta \cdot t_{\mathsf{LFS}}$ and $t_{\mathsf{SA}} = O(\Delta \cdot t_{\mathsf{LF}})$. Theorem 2 follows immediately by fixing $\Delta = \log_\sigma n$.

4 Computing LF Successor in Time $O(\log \sigma)$ Using Compact Space

In this section, we shall describe what additional information should be augmented to each leaf of the suffix tree, so that given ith leaf ℓ_i, we can quickly identify which leaf is its LF successor $\mathsf{LFS}(i)$. We shall first describe the data structure and then the query algorithm for computing $\mathsf{LFS}(i)$. We saw earlier that we will be writing SA values and LF values only for n/Δ positions. Thus, this takes $O(n \log \sigma)$-bit space by choosing $\Delta = \log_\sigma n$. What remains to be seen is how to compute LF successor for a given suffix associated with the leaf ℓ_i. If we explicitly write it at all the leaves, it will take $\Theta(\log n)$ bits per leaf. Since there is no sampling here, this will lead to $\Theta(n \log n)$ bits which will defeat our purpose. Our approach is to store only $O(\log \sigma)$ bits per leaf and yet be able to compute the LF successor quickly.

4.1 Four Cases for Suffix and its LF Successor

For the discourse in this section, we use the following terminology. Let the starting position in the text for suffix denoted by leaf ℓ_i be r (i.e, $r = \mathsf{SA}[i]$), and that of $\ell_{i'}$ be r', where $i' = \mathsf{LFS}(i)$. Let $d = |\mathsf{LCP}(i, i')|$, the length of the longest common prefix of $\mathsf{pred}(T[r, n])$ and $\mathsf{pred}(T[r', n])$. Thus, $T[r, r+d-1]$ and $T[r', r'+d-1]$ are order isomorphic. Inevitably, we will also focus on suffixes $\mathsf{LF}(i)$ and $\mathsf{LF}(i')$ which are encodings of text suffixes $T[r-1, n]$ and $T[r'-1, n]$ respectively.

Now, we distinguish two cases with respect to leaf ℓ_i (and its LF successor $\ell_{i'}$) – case (1) if $T[r-1, r+d-1]$ is not order isomorphic with $T[r'-1, r'+d-1]$, and case (2) $T[r-1, r+d-1]$ is order isomorphic with $T[r'-1, r'+d-1]$ i.e., prepending of character $T[r-1]$ (resp., $T[r'-1]$) to the left still maintains order-isomorphism until the LCP i.e., $\mathsf{pred}(T[r-1, r+d-1]) = \mathsf{pred}(T[r'-1, r'+d-1])$.

First, we shall talk about case (1). Let us consider all the change points of $T[r, r+d-1]$ and $T[r', r'+d-1]$. Let e be their last common change point. If $T[r'-1] \neq T[r'+e-1]$ then we call it case (1a) - the *breakaway case*. Else, we call it case (1b) - the *equality case*. In case (1a), let g be the first change point after e for $T[r', r'+d-1]$. To proceed to case (2), we now define LF-image, which generalizes the concept of Wiener links.

▶ **Definition 7** (LF-image). *Let c be any point in the suffix tree and point p above c be such that for at least one of the suffixes $T[r, n]$ passing through c, p is the last change point before c. The LF-image of c with respect to a change point p, denoted by $\mathsf{LF}(c, p, EQBT)$ is a point representing the position of* (pred *encoding of*) $T[r-1, r+\mathsf{depth}(c)-1]$. *EQBT is called the equality bit and is set to* 1 *if p is an equality change point and* 0 *otherwise.*

For any such suffix i passing through c with change point p being the last one above c, $\mathsf{LF}(i)$ passes through $\mathsf{LF}(c, p, \text{EQBT})$. So if $q = \mathsf{LF}(c, p, \text{EQBT})$, $\mathsf{path}(q) = \mathsf{pred}(T[r-1, r+\mathsf{depth}(c)-1])$. Note that the same point c can have multiple LF-images based on which change point above c is taken as the last one and also if that is equality change point or not.

If leaf ℓ_i falls under case 2, we shall again break this case into cases (2a) and (2b). In case (2a) we consider $i < i'$ (we call this *ordered case*) and in case (2b) we consider $i' < i$ (we call this *inverting case*). We say that a suffix l *inverts* over suffix k iff $l < k$ and $\mathsf{LF}(l) > \mathsf{LF}(k)$.

▶ **Lemma 8.** *If suffixes i and $i' = \mathsf{LFS}(i)$ fall in case 2 then they have the same change points (and also the same type of change points - equality or not) until $\mathsf{lca}(i, i')$. Then i cannot have a change point immediately after $\mathsf{lca}(i, i')$. Moreover, if they fall in case (2b) then i' must have a change point immediately after $\mathsf{lca}(i, i')$.*

Proof. Let the point $c = \mathsf{lca}(i, i')$. For case (2) we know that $T[r-1, r+d-1]$ is order isomorphic with $T[r'-1, r'+d-1]$ i.e. $\mathsf{pred}(T[r-1, r+d-1]) = \mathsf{pred}(T[r'-1, r'+d-1])$. This means that i and i' have all the same change points until c.

Now let p be the last common change point of i and i' i.e. $p = \mathsf{LCPC}(i)$. Here, $\mathsf{LCPC}(i)$ denotes the last common point of change of i and its LFS i'. Additionally, suppose $b = \mathsf{LF}(c, p, \text{EQBT})$. So this means that $\mathsf{LF}(i)$ and $\mathsf{LF}(i')$ will pass through b. As per the definition of LF successor we know that, $\mathsf{LF}(i) < \mathsf{LF}(i')$. More specifically, $\mathsf{LF}(i') = \mathsf{LF}(i) + 1$.

Firstly, lets say that i has a change point right after c. It is easy to observe from the structural properties of order-isomorphic suffixes that both i and i' cannot change immediately after c. Hence, if we see all the branches under b, then $\mathsf{LF}(i)$ will fall under the rightmost branch (or just previous branch depending on whether that change point is of equality type or not). This leads to $\mathsf{LF}(i') < \mathsf{LF}(i)$ which is not possible as per the definition of LF successor. Thus, i cannot have a change point immediately after c.

Now, if we take the case (2b), then i' inverts over i because $\mathsf{LF}(i')$ must be greater than $\mathsf{LF}(i)$. For this to happen i' must have a change point immediately after c. ◀

The proof of the lemma above also leads us to the following fact.

▶ **Fact 1.** *Let c be a point immediately above a node v. Let $b = \mathsf{LF}(c, p, EQBT)$, where p is the last common change point (of type equality or non-equality) on $\mathsf{path}(c)$ for two case (2b) suffixes i and $i' = \mathsf{LFS}(i)$ passing through c. Then, i' has a change point immediately after v. Moreover, there cannot be another pair of case (2b) suffixes j and $j' = \mathsf{LFS}(j)$, which have the same last common point of change p, and j' changes immediately after v.*

Proof. If any two of the suffixes i' and j', where $i' = \mathsf{LFS}(i)$ and $j' = \mathsf{LFS}(j)$, passing through v have a change point right after the node v and their last common change point is p, then under the point $b = \mathsf{LF}(c, p, \text{EQBT})$ only one of their LF values (either $\mathsf{LF}(i')$ or $\mathsf{LF}(j')$) can be next to their respective $\mathsf{LF}(i)$ or $\mathsf{LF}(j)$. That implies only one of either $\mathsf{LF}(i') = \mathsf{LF}(i) + 1$ or $\mathsf{LF}(j') = \mathsf{LF}(j) + 1$ can be true. This is a contradiction, implying the fact is true. ◀

4.2 Storing Augmenting Information for each Leaf

We shall describe this section in terms of augmenting information stored with each leaf. However, one can easily see them as arrays that run parallel to the suffix array. We shall show that each of these augmenting fields in all the cases can be stored in $O(\log \sigma)$ bits. For each leaf ℓ_i, we can write in 2 bits which of the above 4 cases it belongs to. We denote this by $\mathsf{CASE}[i]$. We also store the same value with i' and in this case we shall call it $\overline{\mathsf{CASE}}[i']$.

If ℓ_i belongs to case (1b), then we intend to store e which we will denote as $\mathsf{LCPC}[i] = e$. Recall that e is defined as the rightmost (maximum value) common change point for $T[r, r+d-1]$ and $T[r', r'+d-1]$, and LCPC stands for *last common point of change*. Thus, LCPC is an array whose ith entry corresponds to leaf ℓ_i. However, storing the value e directly will require $\log n$ bits. Therefore, instead of e, we store number of distinct alphabet symbols in $T[r, r+e-1]$) (i.e., $\alpha(T[r, r+e-1])$). We will call this value $\alpha\mathsf{LCPC}[i]$. It is worth noting that since change points only occur at new (first occurrence) alphabets in the string, e can be uniquely decoded from $\alpha\mathsf{LCPC}$. We also store a complementary array of $\alpha\mathsf{LCPC}$ denoted as $\overline{\alpha\mathsf{LCPC}}$ such that $\overline{\alpha\mathsf{LCPC}}[i'] = \alpha\mathsf{LCPC}[i]$. Thus, this value is not only stored with leaf i but also replicated in leaf $i' = \mathsf{LFS}(i)$ - albeit under a differently named field.

Recall that for case (1a), g is the first change point after e for $T[r', r'+d-1]$. For the case (1a), we store g which we call the first point of break $\mathsf{FPB}[i]$. Again, we will not store the value g directly but an encoding $\alpha(T[r, r+g-1])$ which takes $\log \sigma$ bits. We will call this value $\alpha\mathsf{FPB}[i]$. Similarly, we store this value with i' as $\overline{\alpha\mathsf{FPB}}[i'] = \alpha\mathsf{FPB}[i]$.

For the case (2a), we maintain $\alpha\mathsf{LCPC}$ and $\overline{\alpha\mathsf{LCPC}}$ as in case (1b). We also maintain an extra-bit EQBT indicating which type of change point LCPC is - whether equality change point (indicated by EQBT = 1) or not. Similarly, we also store $\overline{\mathrm{EQBT}}$. We also store $\alpha(T[r, r+d-1])$ that is the number of distinct alphabet symbol occurring until $\mathsf{LCP}(i, i')$. We shall call it $\alpha\mathsf{LCP}[i]$. Again, we store the same value at leaf $\ell_{i'}$ so that $\overline{\alpha\mathsf{LCP}}[i'] = \alpha\mathsf{LCP}[i]$. Additionally to this, we store $\mathsf{FPC}[i]$ (read as *first point of change post LCA*) which in this case will be defined as the first change point of $T[r, n]$ after $T[r+d-1]$. Note that this point of change cannot be right after LCA at $T[r+d]$ because otherwise i will invert over i' (this would then be case (2b) Lemma 8) during LF mapping operation and $\mathsf{LF}(i)$ will be greater than $\mathsf{LF}(i')$. Once again we define $\overline{\mathsf{FPC}}[i'] = \mathsf{FPC}[i]$ and define $\alpha\mathsf{FPC}[i]$ and $\overline{\alpha\mathsf{FPC}}[i']$ in similar vein. In summary, we maintain $\alpha\mathsf{LCPC}, \mathrm{EQBT}, \alpha\mathsf{LCP}$ and $\alpha\mathsf{FPC}$ for each such leaf which falls in case (2a). We also store these values at their corresponding LF successors. One point to note here is that $\mathsf{FPC}, \mathsf{LCPC}, \mathsf{FPB}$ are all uniquely decodable from $\alpha\mathsf{FPC}, \alpha\mathsf{LCPC}, \alpha\mathsf{FPB}$ since they necessarily fall on the new alphabet which is yet unseen in the suffix. However, the same is not true of $\alpha\mathsf{LCP}$.

As an example, let us look at $T[r-1, n] = \texttt{caghhfbab}$... and $T[r'-1, n] = \texttt{cagjjebae}$.... Then, $\mathsf{pred}(T[r, n]) = \texttt{0111'456'2'}$... and $\mathsf{pred}(T[r', n]) = \texttt{0111'456'3'}$.... Their LCPC is at depth 5 which is encoded as 4 in the encodings of both the suffixes. Their $\alpha\mathsf{LCPC} = 4$, since there are 4 distinct alphabets in both the strings until that point (4 non-prime characters in their pred encoding). Length of their $\mathsf{LCP} = 7$, however the character $\texttt{a}$ which occurs their as encoded character $\texttt{6'}$ is not a new character. Hence, $\alpha\mathsf{LCP} = 5$ which points to character $\texttt{b}$ in both the original strings. If we try to decode $\alpha\mathsf{LCP}$, it will lead us to position 6 rather than 7. Finally, after the LF mapping, the encoded strings are $\texttt{00211'556'2'}$ and $\texttt{00211'556'3'}$.

For case (2b), our solution is more intricate so we only give a brief overview and defer details to Case (2b) section of the proof of correctness. In this case, i' inverts over i. Thus, i' has a change point right after the $\mathsf{lca}(i, i')$ at $T[r'+d]$. Just storing additional augmenting values to the leaves of the suffix tree is not sufficient. Like before, we shall store $\alpha\mathsf{LCPC}$ and $\alpha\mathsf{LCP}$ values. But we shall construct additional data structures called mini-trees and search for i' in an appropriate mini-tree identified by $\alpha\mathsf{LCPC}$ and $\alpha\mathsf{LCP}$ values of i. We will denote this mini-tree as $\tau_{\alpha\mathsf{LCPC}[i], \alpha\mathsf{LCP}[i]}$.

4.3 Query Algorithm

Now, we outline the pseudo-code for our query algorithm.

Computing $\mathsf{LFS}(i)$

- If ℓ_i falls in case (1a),
  $\ell_{i'}$ is the unique leaf under u s.t. $\overline{\mathsf{CASE}}[i'] = \mathsf{CASE}[i]$ and $\overline{\alpha\mathsf{FPB}}[i'] = \alpha\mathsf{FPB}[i]$, where u is the highest ancestor of ℓ_i with $\alpha\mathsf{Depth}(u) \geq \alpha\mathsf{FPB}[i]$
- ElseIf ℓ_i falls in case (1b)
  $\ell_{i'}$ is unique leaf under u s.t. $\overline{\mathsf{CASE}}[i'] = \mathsf{CASE}[i]$ and $\overline{\alpha\mathsf{LCPC}}[i'] = \alpha\mathsf{LCPC}[i]$, where u is the highest ancestor of ℓ_i with $\alpha\mathsf{Depth}(u) \geq \alpha\mathsf{LCPC}[i]$
- ElseIf ℓ_i falls in case (2a)
  Let c = point above $\mathsf{FPC}[i]$ on suffix $T[r, n]$ in the suffix tree. Then $\ell_{i'}$ is leftmost leaf after ℓ_i in the (subtree of $\alpha\mathsf{LCP}[i]$) $\setminus$ (subtree of c) s.t. $\overline{\mathsf{CASE}}[i'] = \mathsf{CASE}[i]$, $\alpha\mathsf{LCP}[i] = \overline{\alpha\mathsf{LCP}}[i']$, $\alpha\mathsf{LCPC}[i] = \overline{\alpha\mathsf{LCPC}}[i']$ and $\mathrm{EQBT}[i] = \overline{\mathrm{EQBT}}[i']$
- Else
  $i' = \mathsf{findSucc}\big(i, \alpha\mathsf{LCPC}[i], \alpha\mathsf{LCP}[i]\big)$, which is to be defined later

Note that all the arrays mentioned above can be represented in $O(n \log \sigma)$ bits, and the implementation uses standard succinct-data-structure techniques (see Section 4.5); the difficulty lies in proving the correctness of the algorithm, which is our focus next.

4.4 Proofs of Correctness

We shall show correctness of each case. In each case, we need to ensure that we would not end up with a wrong answer. This could happen if there is another pair j, j' such that $j' = \mathsf{LFS}(j)$ and this pair shares the same characteristics with the pair i, i'. In this case, pair j, j' may interfere in the search for i' leading to false answer j'.

4.4.1 Case (1a)

Let c be the first point (the character within an edge of ST) on $\mathsf{path}(\ell_i)$ such that $T[r, r + \mathsf{depth}(c) - 1]$ has exactly $\alpha\mathsf{FPB}[i]$ distinct characters. Thus, this is the first (encoded) character where $\mathsf{pred}(T[r-1, n])$ and $\mathsf{pred}(T[r'-1, n])$ differ; in other words, $\mathsf{path}(\ell_{\mathsf{LF}(i)})$ and $\mathsf{path}(\ell_{\mathsf{LF}(i')})$ bifurcate at the position given by $\mathsf{depth}(c) + 1$. Let $\hat{c}$ be the point in ST such that $\mathsf{path}(\hat{c}) = \mathsf{pred}(T[r-1, r + \mathsf{depth}(c) - 1])$ and $\hat{c'}$ be such that $\mathsf{path}(\hat{c'}) = \mathsf{pred}(T[r'-1, r' + \mathsf{depth}(c) - 1])$. These points are on sibling edges going down from the same node. Let v be the node just above $\hat{c}$ and $\hat{c'}$. For example, consider $T[r-1, n] = \texttt{jeabdh}...$ and $T[r'-1, n] = \texttt{gfabdh}....$ Then, $\mathsf{path}(c) = \mathsf{pred}(\texttt{eabdh}) = \mathsf{pred}(\texttt{fabdh}) = \texttt{00114}$. This makes $\mathsf{path}(\hat{c}) = \mathsf{pred}(\texttt{jeabdh}) = \texttt{000114}$. However, $\mathsf{path}(\hat{c'}) = \mathsf{pred}(\texttt{gfabdh}) = \texttt{000115}$. Note that $\texttt{5}$ is the highest encoded character (with an exception of $\texttt{5}'$) which branches out of the node v.

▶ **Lemma 9.** *There is only one pair of leaves i, i' in the subtree of c, such that $\alpha\mathsf{FPB}[i] = \overline{\alpha\mathsf{FPB}}[i'] = \alpha(T[r, r + \mathsf{depth}(c) - 1])$.*

Proof. Consider LF mapping of i and i'. $\mathsf{path}(\ell_{\mathsf{LF}(i)})$ and $\mathsf{path}(\ell_{\mathsf{LF}(i')})$ first bifurcate at points $\hat{c}$ and $\hat{c'}$ respectively. Since $i' = \mathsf{LFS}(i)$, $\mathsf{char}(\hat{c}) < \mathsf{char}(\hat{c'})$. Moreover, $\mathsf{char}(\hat{c'})$ is precisely $\mathsf{depth}(c)$ or its equality version i.e. $(\mathsf{depth}(c))'$. This is the highest (encoded) character, and thus the branch with $\hat{c'}$ will be one of the two rightmost branches among branches (depending on whether the change point c for suffix i' was based on "equality" or not). However, the point $\hat{c}$ will certainly be before the two rightmost branches at v. If there was any other pair j and j' of case (1a) under the subtree of c such that $j' = \mathsf{LFS}(j)$ and $\mathsf{FPB}(j) = \mathsf{FPB}(i)$, then both $\mathsf{LF}(i')$ and $\mathsf{LF}(j')$ will fall under the subtree of $\hat{c'}$ because as per the LCPC lemma all the change points of i' and j' are the same until c (including c). On the contrary, $\mathsf{LF}(i)$ and $\mathsf{LF}(j)$ cannot fall under this subtree as they are under the subtree of $\hat{c}$. Thus, depending on whether $\mathsf{LF}(i') < \mathsf{LF}(j')$ or not, only one pair out of $(\mathsf{LF}(i), \mathsf{LF}(i'))$ or $(\mathsf{LF}(j), \mathsf{LF}(j'))$ can be adjacent. Since, i' is indeed the LF successor of i, such a pair j, j' cannot exist. ◀

4.4.2 Case (1b)

Let c be the first point in ST on $\mathsf{path}(\ell_i)$ such that $T[r, r + \mathsf{depth}(c) - 1]$ has $\alpha\mathsf{LCPC}[i]$ distinct characters. In this case, c is a change point for both i and i'. For i', it is the equality change point while for i it is not (i.e., $T[r' - 1] = T[r' + \mathsf{depth}(c) - 1]$ and $T[r - 1] \neq T[r + \mathsf{depth}(c) - 1]$). Let point $\hat{c}$ correspond to $\mathsf{path}(T[r-1, r+\mathsf{depth}(c)-1])$ and $\hat{c'}$ correspond to $\mathsf{path}(T[r'-1, r'+\mathsf{depth}(c)-1])$. Let v be the node right above $\hat{c}$ (and also $\hat{c'}$) which can be identified by $\mathsf{path}(v) = T[r-1, r+\mathsf{depth}(c)-2]$. In this case, $\hat{c'}$ will fall in the rightmost branch at node v and $\hat{c}$ will fall in the branch previous to that. The character at point $\hat{c'}$ is precisely the equality (prime) version of the character at $\hat{c}$. For example, consider $T[r-1, n] = \mathtt{geabdh}$... and $T[r' - 1, n] = \mathtt{hfabdh}$.... Then, $\mathsf{path}(c) = \mathsf{pred}(\mathtt{eabdh}) = \mathsf{pred}(\mathtt{fabdh}) = \mathtt{00114}$. This makes $\mathsf{path}(\hat{c}) = \mathsf{pred}(\mathtt{geabdh}) = \mathtt{000115}$. However, $\mathsf{path}(\hat{c'}) = \mathsf{pred}(\mathtt{hfabdh}) = \mathtt{000115'}$. Here $\mathtt{5'}$ is the highest encoded character. Again, as in the case (1a), if there were any other pair j, j' falling in case (1b) under subtree of c such that $\mathsf{LCPC}(j) = \mathsf{LCPC}(i)$, then $\mathsf{LF}(j')$ will also fall in the rightmost branch at v while $\mathsf{LF}(j)$ will fall in the previous one. Again, by applying simple interval logic as in case (1a), we can show that only one of the pairs can satisfy the LF-successor definition.

4.4.3 Case (2a)

In this case, post $\mathsf{lca}(i, i')$, branch with ℓ_i is to the left of the branch with $\ell_{i'}$. Let c be the point just above $\mathsf{FPC}[i]$. Let ℓ_k be the rightmost leaf in the subtree of c. Note that since $\mathsf{FPC}[i]$ is not immediately after the $\mathsf{lca}(i, i')$, the subtree of c does not include i'. Therefore, the order between i and i' will not be inverted after taking LF mapping. Let f be the first point in ST on suffix $T[r, n]$ such that $\alpha(\mathsf{path}(f)) = \alpha\mathsf{LCP}[i]$. The actual $\mathsf{LCP}[i]$ will be somewhere in the subtree of f because $\mathsf{LCP}[i]$ is not uniquely decodable from $\alpha\mathsf{LCP}[i]$. Here $\mathsf{LCP}[i]$ denotes the $\mathsf{lcp}(i, i')$. Let j, j' be another pair in the subtree of f such that $j' = \mathsf{LFS}(j)$ and $\alpha\mathsf{LCP}[j] = \alpha\mathsf{LCP}[i]$ and $\mathsf{LCPC}[j] = \mathsf{LCPC}[i]$. All four leaves $\mathsf{LF}(i), \mathsf{LF}(i'), \mathsf{LF}(j), \mathsf{LF}(j')$ will be in the subtree of $\hat{f}$ which is the LF-image $\mathsf{LF}(f, \mathsf{LCPC}[i], \mathrm{EQBT})$. In other words, $\hat{f}$ is the locus of $\mathsf{pred}(T[r - 1, r + \mathsf{depth}(f) - 1])$ in ST.

▶ **Lemma 10.** *There does not exist a pair (j, j') such that $j' = \mathsf{LFS}(j)$, $\alpha\mathsf{LCP}[j] = \alpha\mathsf{LCP}[i]$, $\alpha\mathsf{LCPC}[j] = \alpha\mathsf{LCPC}[i]$ and j' lies in between k and i'.*

Proof. Consider any other pair j, j' in the subtree of f and with the same $\alpha\mathsf{LCPC}$, EQBT and $\alpha\mathsf{LCP}$ values such that $k < j' < i'$. We will show by contradiction that such a j' cannot exist. Firstly, since $i < k < j'$ and ℓ_k being the rightmost leaf in the subtree of c,

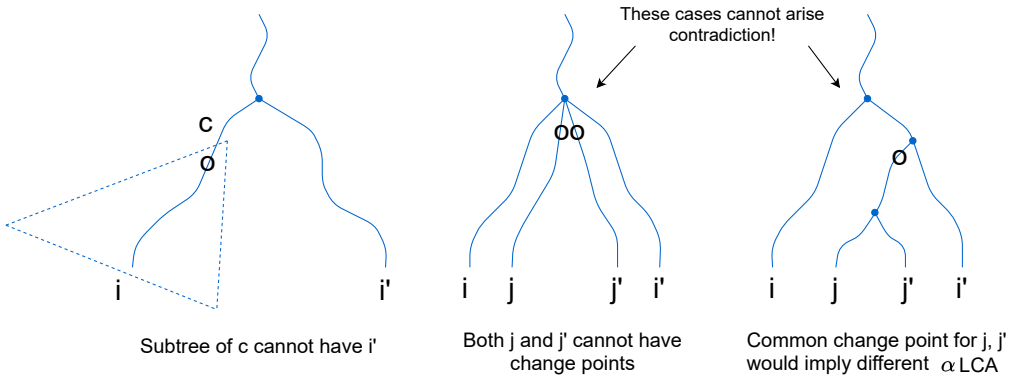

Figure 2 Illustration of case (2a). Small black circles are change points.

i cannot invert over j' after taking LF mapping. This is because c is the point just above $\mathsf{FPC}[i]$. Hence $\mathsf{LF}(i) < \mathsf{LF}(j')$. Also, since $\mathsf{LF}(i') = \mathsf{LF}(i) + 1$, $\mathsf{LF}(j')$ must be greater than $\mathsf{LF}(i')$. Secondly, the pair j, j' falls under case (2a) where $j < j'$ and $\mathsf{LF}(j) < \mathsf{LF}(j')$. Thus, $\mathsf{LF}(i') \leq \mathsf{LF}(j) < \mathsf{LF}(j')$ which means both j and j' invert over i' after LF operation.

Next, $j < j' < i'$ means $\mathsf{lca}(j, i')$ is equal to or above $\mathsf{lca}(j', i')$. Since j and j' invert over i', it must be at $\mathsf{lca}(j, i')$ and $\mathsf{lca}(j', i')$ respectively. If $\mathsf{lca}(j, i')$ is above $\mathsf{lca}(j', i')$, then j inverts above j' and it implies $\mathsf{LF}(j) > \mathsf{LF}(j')$ which is a contradiction. Now if $\mathsf{lca}(j, i') = \mathsf{lca}(j', i')$, then there are two cases. The first case is where j and j' invert from a common branch connecting path of i'. Here, j and j' will have a common change point at this branch which is post $\mathsf{lca}(j', i')$. It implies that there is another common change point for j, j' which leads to $\mathsf{LCPC}[j] > \mathsf{LCPC}[i]$ (a contradiction). In the second case, j and j' branch out at $\mathsf{lca}(j', i')$ but fall in different branches. However, according to Lemma 8, only one of j or j' can have a change point right after the $\mathsf{lca}(i, i')$. Hence, this case also leads to contradiction. Thus, j' does not lie in between k and i'. See Figures 2 and 3 for illustration. ◀

4.4.4 Case (2b)

For the case (2b), we know that suffix i' comes before suffix i in the suffix tree, i.e. $i' < i$. Additionally, for the case (2b), i' has a change point right after the node representing the $\mathsf{lca}(i, i')$. Moreover, under $\mathsf{lca}(i, i')$ the branch containing the suffix i' will be the only one that will have a change point tied with the same LCPC (see Fact 1). Since $i' = \mathsf{LFS}(i)$, after the LF mapping i' will invert over i making $\mathsf{LF}(i') = \mathsf{LF}(i) + 1$. See Figure 3.

As mentioned in Section 4.2, for the case (2b) we store $\alpha\mathsf{LCPC}[i]$ and $\alpha\mathsf{LCP}[i]$ values for each leaf ℓ_i as augmenting information. Additionally, we store their complements $\overline{\alpha\mathsf{LCPC}}[i']$ and $\overline{\alpha\mathsf{LCP}}[i']$ for each leaf $\ell_{i'}$. Now we consider an additional data structure called mini-trees that will help us in finding i' given i. Specifically, a particular mini-tree $\tau_{a,b}$ has set of all leaves ℓ_i and their corresponding LF successors $\ell_{i'}$ from the suffix tree that has $\alpha\mathsf{LCPC}[i] = \overline{\alpha\mathsf{LCPC}}[i'] = a$ and $\alpha\mathsf{LCP}[i] = \overline{\alpha\mathsf{LCP}}[i'] = b$. A particular leaf ℓ_i will not be in any mini-tree if that leaf does not fall under the case (2b). Thus, a leaf can be present in a mini-tree if it falls under case (2b) or it is an LF-successor of some other leaf which falls under the case (2b). Therefore, each leaf in the suffix tree will be in at most two mini-trees and some mini-trees are possibly empty. In other words, a mini-tree is a compacted subtrie of the suffix tree containing only those leaves selected for that mini-tree. Hence, overall size of all the mini-trees combined is $O(n)$.

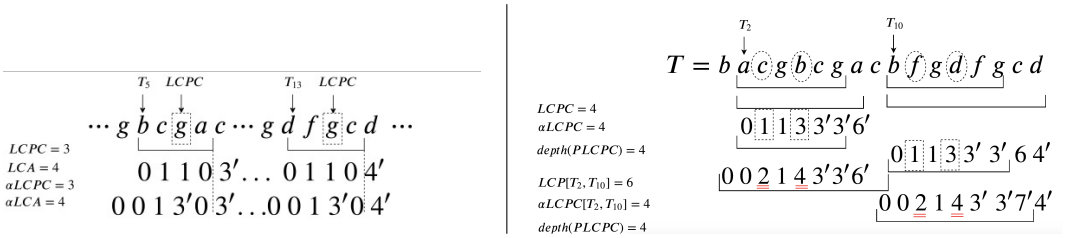

Figure 3 Illustration of case (2a) (left) and case (2b) (right). Red underline shows the character encoding that changes after taking LF.

To draw a correspondence between the leaves of the suffix tree and the leaves of the mini-trees, we use a bit-vector $B[1, n]$, where $B[i] = 1$ iff leaf i falls in case (2b) or leaf i is an LF-successor of the leaf which falls in case (2b). In other words, $B[i] = 1$ if a leaf from the suffix tree is present in at least one of the mini-trees, and $B[i] = 0$ otherwise. Next, we create two character vectors C and $\overline{C}$ as follows. If $B[i] = 0$, then $C[i] = \overline{C}[i] = 0$. Otherwise,

1. $C[i]$ stores an encoding of the pair $\alpha\mathsf{LCPC}[i], \alpha\mathsf{LCP}[i]$ as a combined character from an alphabet of size σ^2; essentially $C[i] = (\sigma - 1) \cdot \alpha\mathsf{LCPC}[i] + \alpha\mathsf{LCP}[i]$
2. $\overline{C}[i] = -C[i]$ if $\alpha\mathsf{LCPC}[i] = \overline{\alpha\mathsf{LCPC}}[i]$ and $\alpha\mathsf{LCP}[i] = \overline{\alpha\mathsf{LCP}}[i]$, and $\overline{C}[i] = (\sigma - 1) \cdot \overline{\alpha\mathsf{LCPC}}[i] + \overline{\alpha\mathsf{LCP}}[i]$ otherwise.

Now given a particular leaf ℓ_i in the suffix tree, for finding the corresponding leaf in the mini-tree, we first check if $B[i] = 1$. Since $a = \alpha\mathsf{LCPC}[i]$ and $b = \alpha\mathsf{LCP}[i]$, we can quickly identify the mini-tree $\tau_{a,b}$ it belongs to as augmenting information $\alpha\mathsf{LCPC}[i]$ and $\alpha\mathsf{LCP}[i]$ is stored for the leaf ℓ_i. To find out which leaf in $\tau_{a,b}$ corresponds to ℓ_i, all we have to do is figure out the number of leaves $j \leq i$ that satisfy $a = \alpha\mathsf{LCPC}[j] = a$ and $b = \alpha\mathsf{LCP}[j]$ or $\overline{\alpha\mathsf{LCPC}}[j] = a$ and $\overline{\alpha\mathsf{LCP}}[j] = b$; this is the same as the number of entries $j \leq i$ in the character vectors C such that $C[j] = C[i]$ plus the number of entries $k \leq i$ in the character vectors $\overline{C}$ such that $\overline{C}[k] = C[i]$. This is because the mini-tree is just a compacted subtrie of the original suffix tree consisting of only those leaves present in a particular mini-tree. To map a leaf from the mini-tree back to the leaf of the original suffix tree, we need to store a character vector for each mini-tree over the leaves of the mini-tree. Let $C_{a,b}$ be the character vector for the mini-tree $\tau_{a,b}$. This character array indicates whether the leaf has $a = \alpha\mathsf{LCPC}[i]$ and $b = \alpha\mathsf{LCP}[i]$ or $a = \overline{\alpha\mathsf{LCPC}}[i]$ and $b = \overline{\alpha\mathsf{LCP}}[i]$ or both. In other words, it simply specifies how the leaf was selected for that mini-tree using techniques similar to that described above. It is to be noted that all character vectors combined need $O(n \log \sigma)$ bits.

4.4.4.1 Identifying i'

We know that $\alpha\mathsf{LCPC}[i] = a$ and $\alpha\mathsf{LCP}[i] = b$. Let p_a be the first point in suffix tree where $\alpha(T[r + \mathsf{depth}(p_a) - 1])) = a$ and p_b be the first point such that $\alpha(T[r + \mathsf{depth}(p_b) - 1]) = b$. Thus, p_a and p_b are the points in suffix tree where $\alpha\mathsf{LCPC}[i]$ and $\alpha\mathsf{LCP}[i]$ are located. Note that p_a is above or the same as p_b. Now consider the mini-tree $\tau_{a,b}$. Let another pair j, j' where $j' = \mathsf{LFS}(j)$ fall under the same mini-tree (i.e., ℓ_j and ℓ'_j are also descendants of p_b and $\alpha\mathsf{LCPC}[j] = \alpha\mathsf{LCPC}[i]$ and $\alpha\mathsf{LCP}[j] = \alpha\mathsf{LCP}[i]$). Here j' will be on the left of j because they fall under the case (2b). We will focus here on searching i' as the first qualifying leaf to the left of i. Another pair j, j' could interfere with our process of searching if j' falls between i' and i. Formally, we say

▶ **Definition 11.** *A pair* j, j' interferes *with* i, i' *if* $i' < j' < i$ *and* $\alpha\mathsf{LCPC}[j] = \alpha\mathsf{LCPC}[i]$ *and* $\alpha\mathsf{LCP}[j] = \alpha\mathsf{LCP}[i]$. *Here,* $i' = \mathsf{LFS}(i)$ *and* $j' = \mathsf{LFS}(j)$

There are two cases of "interference" that can occur with respect to these two pairs – case (2b′) is where both j' and j are in between i' and i i.e. $i' < j' < j < i$ and case (2b*) where j is on the right of i i.e. $i' < j' < i < j$. As we know that $\alpha\mathsf{LCPC}[i] = \alpha\mathsf{LCPC}[j] = a$ and p_a is the first point in the suffix tree where $\alpha(T[r + \mathsf{depth}(p_a) - 1])) = a$. Suppose $x = \mathsf{LF}(\mathsf{lca}(i, i'), p_a, \text{EQBT})$ and $y = \mathsf{LF}(\mathsf{lca}(j, j'), p_a, \text{EQBT})$. Here EQBT is set to 1 if i' has an equality change point and 0 otherwise. Now in the case (2b′), after taking LF-mapping, j' inverts over j under y and i' inverts over all three of j, j', i under x – we call this the *nested case*. In case (2b*), j' and i both together (maintaining same order) invert over j under y and then i' inverts over all of them under x – we call this the *bulk-invert case*. Additionally, we will need to augment this mini-tree further so that we can distinguish the pair i, i' from the pair j, j'.

▶ **Lemma 12.** *If a pair* j, j' *interferes with* i, i'*, then* $\mathsf{lca}(i', i)$ *occurs above* $\mathsf{lca}(j', j)$ *in the suffix tree. Additionally, if* $i < j$*, then* $\mathsf{lca}(j', i)$ *is below* $\mathsf{lca}(j, j')$.

Proof. Note that in bulk invert case since j' and i both invert together over j, $\mathsf{lca}(j', i)$ must be below $\mathsf{lca}(j, j')$. Even though $\alpha\mathsf{LCP}[i] = \alpha\mathsf{LCP}[j]$, it cannot happen that LCAs of both the pairs are on the same node in the suffix tree (i.e. $\mathsf{lca}(i', i) = \mathsf{lca}(j', j)$). This is because from any node only one branch can have a change point at the next character below the node (see Fact 1). But we know that i' has a change point just below the node representing $\mathsf{lca}(i, i')$. Therefore, the branch containing j' cannot have a change point just below that node. This implies $j' \neq \mathsf{LFS}(j)$ since j falls under the case (2b). This holds a contradiction.

Therefore, for the case (2b′), it must be the case that $\mathsf{lca}(j', j)$ is below $\mathsf{lca}(i', i)$, implying that suffixes j' and j belong to the subtree at $\mathsf{lca}(i', i)$. In case (2b*), it cannot happen that $\mathsf{lca}(i', i)$ is below $\mathsf{lca}(j', j)$ because that would mean j' has a change point right below $\mathsf{lca}(j', j)$ which falls above $\mathsf{lca}(i', i)$. This would make $\alpha\mathsf{LCPC}[i]$ different than $\alpha\mathsf{LCPC}[j]$ because the suffixes i and i' will have an extra change point above $\mathsf{lca}(i, i')$ and below the $\mathsf{lca}(j, j')$. Hence, for the case (2b*) this leads to a contradiction and $\mathsf{lca}(j, j')$ cannot be above the $\mathsf{lca}(i, i')$. ◀

If $\mathsf{lca}(i', i)$ and $\mathsf{lca}(j', j)$ are not on the same root-to-leaf path (neither above nor below nor same as each other), then pairs i, i' and j, j' are non-interfering. So we need not consider that case as in some sense for i, our algorithm looks at the closest suffix to the left of i that has the same $\alpha\mathsf{LCP}$ and $\alpha\mathsf{LCPC}$ as the qualifying suffix for $\mathsf{LFS}(i)$.

Finally, from Fact 1 we can say that there exists a unique suffix i' marked with case (2b) under the point at $1 + \mathsf{depth}(\mathsf{lca}(i', i))$ depth such that $\alpha\mathsf{LCP}[i] = \overline{\alpha\mathsf{LCP}}[i']$ and $\alpha\mathsf{LCPC}[i] = \overline{\alpha\mathsf{LCPC}}[i']$, with the constraint that i' has a change point at $1 + \mathsf{depth}(\mathsf{lca}(i', i))$ depth.

4.4.4.2 Searching in Minitree

For any i, if we can identify $\mathsf{lca}(i', i)$ precisely, then i' is the leaf which has the same $\overline{\alpha\mathsf{LCPC}}$ and $\overline{\alpha\mathsf{LCP}}$ values (as that of i) and i' is in the subtree of a branch of $\mathsf{lca}(i', i)$ whose leading character in that branch is a change point. For this, we mark some nodes in the tree. More precisely, for each mini-tree, we mark a node v if a point at $(\mathsf{depth}(\mathsf{parent}(v)) + 1)$ depth is a change point for a suffix i' (in case (2b)) in the subtree of v. Note that only one child of a node can get marked (refer to Fact 1). Also note that there is only one marked node in a path from the root to a leaf because if there were another marked node w for a suffix j', then $\alpha\mathsf{LCPC}[i'] \neq \alpha\mathsf{LCPC}[j']$. But we know that all the leaves in a mini-trie have the same $\alpha\mathsf{LCPC}[i], \alpha\mathsf{LCP}$ (or their complement) values.

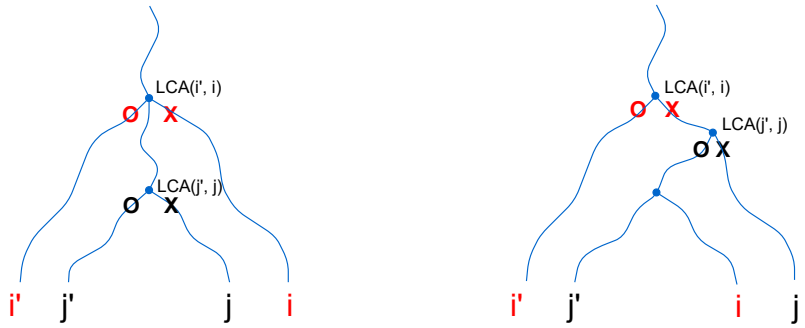

Figure 4 Mini-trees for case (2b). Red (resp. black) circle is the marked node after the change point of i' (resp. j') immediately after $\mathsf{lca}(i', i)$ (resp. $\mathsf{lca}(j', j)$). Red (resp. black) cross is the sibling of the marked node lying on the path from the LCA to the leaf ℓ_i (resp. ℓ_j).

Now lets say that a node x in the mini tree $\tau_{\alpha\mathsf{LCPC}[i],\alpha\mathsf{LCP}[i]}$ is the node corresponding to $\mathsf{lca}(i', i)$ in the suffix tree. Therefore, given i, our task simply becomes locating the leaf ℓ in the mini-tree that corresponds to i. Then, find the lowest ancestor of ℓ that has a marked child before ℓ in pre-order; observe that this lowest ancestor is precisely the node x corresponding to $\mathsf{lca}(i', i)$. Let y be the marked child of x. Within the subtree of y, we can find the unique leaf ℓ' corresponding to i', which can be mapped back to the original suffix tree. To find this unique leaf, we store a unary encoding at the marked node indicating which leaf we looking for; more precisely, if the desired leaf is the z^{th} leftmost leaf under the marked node, then store z in unary at the marked node. Since there is only one marked node from a leaf to root path in a mini-tree, the total length of all such unary encodings combined is bounded by the size of the mini-tree. The mapping to and from the suffix tree to a mini-tree can be carried out using the bit-vector and the character vectors defined earlier.

For the sake of completion, we summarize the discussion in the following findSucc method, which was used by pseudo-code in Section 4.3. See Figure 4 for an illustration.

findSucc(i, a, b)

- Use the bit-vector B and the character vectors C and $\overline{C}$ to identify the leaf ℓ in $\tau_{a,b}$ that corresponds to ℓ_i
- Find the lowest ancestor x of ℓ that has a marked child y before x in pre-order
- Use the unary encoding stored at y to locate the leaf ℓ' in $\tau_{a,b}$ corresponding to $\ell_{i'}$
- Finally, use the character vector $C_{a,b}$ to map ℓ' back to i'

4.5 Implementation and Complexity Analysis

We will rely on the following well-known data structures of Fact 2 and Fact 3.

▶ **Fact 2** (Wavelet Tree [12]). *Given an array $A[1, t]$ over Σ, by using a $t \log |\Sigma| + o(t \log |\Sigma|)$-bit structure, we can compute the following in $O(\log |\Sigma|)$ time:*

- $A[i]$
- $\mathsf{rank}_A(i, x)$ = *number of occurrences of x in $A[1, i]$*
- $\mathsf{select}_A(i, x)$ = *i-th occurrence of x in A*
- $\mathsf{prevValue}_A(i, y)$ = *rightmost position $j < i$ such that $A[j] \leq y$*

We drop the subscript A when the context is clear.

▶ **Fact 3** (Fully-Functional Succinct Tree [21]). *The topology of order-isomorphic suffix tree can be encoded in $O(n)$ bits to support the following operations in $O(1)$ time.*

- $\mathsf{pre\text{-}order}(u)/\mathsf{post\text{-}order}(u)$*: pre-order/post-order rank of node* u
- $\mathsf{parent}(u)$*: parent of node* u
- $\mathsf{nodeDepth}(u)$*: number of edges on the path from the root to* u
- $\mathsf{child}(u, q)$*: qth leftmost child of node* u
- $\mathsf{sibRank}(u)$*: number of children of* $\mathsf{parent}(u)$ *to the left of* u
- $\mathsf{lca}(u, v)$*: lowest common ancestor (LCA) of two nodes* u *and* v
- $\mathsf{sp}(u)/\mathsf{ep}(u)$*: leftmost/rightmost leaf in the subtree of* u
- $\mathsf{levelAncestor}(u, d)$*: ancestor of* u *such that* $\mathsf{nodeDepth}(u) = d$

Moving forward, we assume that any array has been pre-processed using Fact 2. We maintain the topology of the order-isomorphic suffix tree and the mini-trees (Case 2b) using Fact 3. Finally, we explicitly store $\alpha\mathsf{Depth}(u)$ for every node u in the order-isomorphic suffix tree. For the purpose of locating the node immediately below FPB or LCPC, we will rely on the following lemma.

▶ **Lemma 13.** *By maintaining an $O(n \log \sigma)$ bit data structure, given a leaf ℓ_i and an integer W, we can find the highest ancestor w of ℓ_i satisfying $\alpha\mathsf{Depth}(w) \geq W$ in $O(\log \sigma)$ time.*

Proof. Create an array A such that $A[k] = \alpha\mathsf{Depth}(w)$, where w is the node with pre-order rank k. Maintain A as a wavelet tree. Given ℓ_i, find the rightmost entry $r < \mathsf{pre\text{-}order}(\ell_i)$ in A such that $A[r] < W$ using $\mathsf{prevValue}_A(\mathsf{pre\text{-}order}(\ell_i), W-1)$. Let $v' = \mathsf{lca}(\ell_i, v)$, where v is the node with pre-order rank r. Then, $w = \mathsf{levelAncestor}(\ell_i, \mathsf{nodeDepth}(v')+1)$. To see why this is correct, observe that $\alpha\mathsf{Depth}(v') \leq \alpha\mathsf{Depth}(v) < W$. If $\alpha\mathsf{Depth}(w) < W$, the $\mathsf{prevValue}$-query should have returned w instead of v (since $\mathsf{pre\text{-}order}(v) < \mathsf{pre\text{-}order}(w) \leq \mathsf{pre\text{-}order}(\ell_i)$). ◀

4.5.1 Case (1a) and Case (1b)

In case (1a), i' is the only leaf marked with case (1a) in the sub-tree of $\mathsf{FPB}(i)$ that satisfies $\overline{\alpha\mathsf{FPB}}[i'] = \alpha\mathsf{FPB}[i]$. The first task is to find the subtree of $\mathsf{FPB}(i)$, i.e., the node just below $\mathsf{FPB}(i)$. This node, say v, can be found in $O(\log \sigma)$ time using Lemma 13 and by using $\alpha\mathsf{FPB}[i]$. Within the subtree of v, we simply find the only leaf i' marked with 1a such that $\overline{\mathsf{FPB}}[i'] = \mathsf{FPB}[i]$ using Fact 2. Since $\alpha\mathsf{FPB}$ and $\overline{\alpha\mathsf{FPB}}$ entries for case (1a) suffixes are at least one, in order to identify a valid case (1a) suffix, we simply set the $\alpha\mathsf{FPB}$ and $\overline{\alpha\mathsf{FPB}}$ entries for non case (1a) suffixes to zero.

In case (1b), the idea is the same, with the difference that we use $\alpha\mathsf{LCPC}$ and $\overline{\alpha\mathsf{LCPC}}$ arrays (instead of FPB and $\alpha\mathsf{FPB}$ arrays) for finding the node v and then i'. As in the previous case, we set the $\alpha\mathsf{LCPC}$ and $\overline{\alpha\mathsf{LCPC}}$ entries for non case (1b) suffixes to zero.

Note that the wavelet trees for the four arrays need $O(n \log \sigma)$ bits, and a wavelet tree query needs $O(\log \sigma)$ time.

4.5.2 Case (2a)

Let c be the point just above $\mathsf{FPC}[i]$. Let ℓ_k be the rightmost leaf in the subtree of c. By Lemma 10, it is evident that $i' > k$, $\overline{\alpha\mathsf{LCP}}[i'] = \alpha\mathsf{LCP}[i]$, $\overline{\alpha\mathsf{LCPC}}[i'] = \alpha\mathsf{LCPC}[i]$, and $\overline{\mathrm{EQBT}}[i'] = \mathrm{EQBT}[i]$. To properly identify a case (2a) suffix, we maintain a summary vector X defined as follows. For any suffix i lying in case (2a), $X[i] = (\sigma-1) \cdot \alpha\mathsf{LCP}[i] + \alpha\mathsf{LCPC}[i]$ if $\mathrm{EQBT}[i] = 1$, and $X[i] = -(\sigma-1) \cdot \alpha\mathsf{LCP}[i] - \alpha\mathsf{LCPC}[i]$ if $\mathrm{EQBT}[i] = 0$. For any suffix j not in case (2a), we let $X[i] = 0$. Likewise, we define $\overline{X}$ based on $\overline{\alpha\mathsf{LCP}}$, $\overline{\alpha\mathsf{LCPC}}$, and $\overline{\mathrm{EQBT}}$.

Note that any entry in X and $\overline{X}$ is from the set $[0, 2\sigma^2]$; hence, a wavelet over them needs $O(n \log \sigma)$ bits and supports queries in $O(\log \sigma)$ time. Thus, if we can find out the leaf ℓ_k, we can locate i' by using the wavelet-tree over the two summary vectors X and $\overline{X}$ in additional $O(\log \sigma)$ time.

To find ℓ_k, we use Lemma 13 and $\alpha\mathsf{FPB}$ to first find the highest node v such that $\alpha\mathsf{Depth}(v) \geq \alpha\mathsf{FPB}[i]$. Note that ℓ_k is the rightmost leaf in the subtree of $\mathsf{parent}(v)$ if $\mathsf{FPB}[i]$ is the first character of the edge on which it lies, and is the rightmost leaf in the subtree of v otherwise. We explicitly store a bit-vector to distinguish between the cases. Using these, ℓ_k is located in $O(\log \sigma)$ time.

4.5.3 Case (2b)

In our previous discussion, we have already addressed how to map a case (2b) leaf i in the suffix tree to its corresponding leaf in the mini-tree (refer to Section 4.4.4). We have also addressed that given the desired marked node (corresponding to i) in the mini-tree, how we can find the leaf in the mini-tree corresponding to the LF-successor i'. Finally, we also know how to map-back to i' from the mini-tree. Note that all of these can be achieved by storing the character vectors and the bit vector as a wavelet tree, and by using a succinct encoding of the mini trees. What is left to discuss is how to find the marked node. To this end, we present Lemma 14. Using this we can find the desired marked node in $O(1)$ time given the leaf corresponding to i in the mini-tree.

▶ **Lemma 14.** *Consider a tree having t nodes, where each non-leaf node has at least two children. Also, each node is marked or unmarked. By using an $O(t)$-bit data structure, given a leaf x, in $O(1)$ time, we can find the rightmost leaf $y < x$ such that the child of $\mathsf{lca}(y, x)$ on the path to y is marked.*

Proof. Let u be a node. We *associate* 1 with u iff $\mathsf{parent}(u)$ has a child v before u in pre-order, where v is marked. Pre-process the tree with Lemmas 15 and 16.

Given the query x, use Lemma 15 to locate the lowest ancestor u of x associated with a 1. We find the marked sibling v of u to its left using Lemma 16. The time needed is $O(1)$. ◀

▶ **Lemma 15.** *Consider a tree having t nodes, where each non-leaf node has at least two children. Also, each node is associated with a 0 or 1. By using an $O(t)$-bit data structure, in $O(1)$ time, we can find the lowest ancestor of a leaf that is associated with a 1.*

Proof. Starting from the leftmost leaf, every $g = c\lceil \log t \rceil$ leaves form a group, where c is a constant to be decided later. (The last group may have fewer than g leaves.) Mark the lca of the first and last leaf of each group. At each marked node, write the node-depth of its lowest ancestor which is associated with a 1. The space needed is $O(\frac{t}{g} \log t) = O(t)$ bits. Let τ_u be the subtree rooted at a marked node u. Since each node in τ_u is associated with a 0 or 1, the number of possible trees is at most 2^g (because τ_u has fewer than g non-leaf nodes). We store a pointer from u to τ_u. The total space needed for storing all pointers is $O(\frac{t}{g} \log 2^g) = O(t)$ bits. For each possible τ_u, store the following satellite data in an additional array. Consider the kth leftmost leaf ℓ_k in τ_u. Let v be the lowest node on the path from u to ℓ_k associated with a 1. If v exists, store the node-depth of v relative to u, else store -1. The space needed for each τ_u is $O(g \log g) = O(g \log \log t)$ bits. Therefore, the total space for all such trees is $O(2^g g \log \log t)$. By choosing $c = 1/2$, this space is bounded by $o(t)$ bits. Thus, the total space is bounded by $O(t)$ bits.

Given a query leaf ℓ_k, we first locate the lowest marked node $u^* = \mathsf{lca}(1 + g\lfloor k/g \rfloor, \max\{t, g(1 + \lfloor k/g \rfloor)\})$ of ℓ_k. Let d^* be the depth stored at u^*. Let $k' = k - g\lfloor k/g \rfloor$. Check the k'th entry of the satellite array of u^*, and let it be d. If $d = -1$, then assign $D = d^*$, else assign $D = \mathsf{nodeDepth}(u^*) + d$. The lowest ancestor of ℓ_k associated with a 1 is given by $\mathsf{levelAncestor}(\ell_k, D)$. ◀

▶ **Lemma 16.** *Consider a tree of t nodes, where some nodes are marked. By using an $O(t)$-bit data structure, in $O(1)$ time, given a node v, we can find a node u (if any) such that u is the rightmost marked child of $\mathsf{parent}(v)$ and $\mathsf{pre\text{-}order}(u) < \mathsf{pre\text{-}order}(v)$.*

Proof. For each node w, we store a bit-vector $B_w[t_w]$, where t_w is the number of children of w. Assign $B_w[i] = 1$ iff the i^{th} leftmost child of w, given by $\mathsf{child}(w, i)$, is marked. The total space needed is $O(t)$ bits. Given the query node v, we go to the bit vector $B_{v'}$, where $v' = \mathsf{parent}(v)$. Let $r = \mathsf{rank}_{B_{v'}}(\mathsf{sibRank}(v), 1)$. If $r = 0$, then u does not exist; otherwise, $u = \mathsf{child}(v', \mathsf{select}_{B_{v'}}(r, 1))$. ◀

Abstract

In extension problems of partial graph drawings one is given an incomplete drawing of an input graph G and is asked to complete the drawing while maintaining certain properties. A prominent area where such problems arise is that of crossing minimization. For plane drawings and various relaxations of these, there is a number of tractability as well as lower-bound results exploring the computational complexity of crossing-sensitive drawing extension problems. In contrast, comparatively few results are known on extension problems for the fundamental and broad class of simple drawings, that is, drawings in which each pair of edges intersects in at most one point. In fact, the extension problem of simple drawings has only recently been shown to be NP-hard even for inserting a single edge.

In this paper we present tractability results for the crossing-sensitive extension problem of simple drawings. In particular, we show that the problem of inserting edges into a simple drawing is fixed-parameter tractable when parameterized by the number of edges to insert and an upper bound on newly created crossings. Using the same proof techniques, we are also able to answer several closely related variants of this problem, among others the extension problem for k-plane drawings. Moreover, using a different approach, we provide a single-exponential fixed-parameter algorithm for the case in which we are only trying to insert a single edge into the drawing.

Acknowledgements This work was started during the Austrian Computational Geometry Reunion Meeting in Strobl (Austria), August 10 to 14, 2020. We thank all the participants for the nice working atmosphere as well as fruitful discussions on this as well as other topics. The authors would also like to thank Eduard Eiben for his insightful comments.

1 Introduction

The study of the crossing number of graphs, that is, the minimum number of edge crossings necessary to draw a given graph, is a major research direction in the field of computational geometry [10, 33, 36]. More recently, there have been a number of works focusing on minimizing or restricting edge crossings when the task is not to draw a graph from scratch, but rather to extend a partial drawing that is provided on the input. Prominently, Chimani et al. [14] showed that extending a plane drawing with a star in a way that minimizes the number of crossings of the resulting drawing is polynomial-time tractable. Later, Angelini et al. [1] obtained a polynomial-time algorithm for extending plane drawings so that the crossing number remains 0 (i.e., the resulting drawing is plane).

While the two results mentioned above give rise to polynomial-time variants of crossing-minimization extension problems, a number of important cases are known to be NP-hard; a prototypical example is the Rigid Multiple Edge Insertion (RMEI) problem, which asks for a crossing-minimal insertion of k edges into a plane drawing of an n-vertex graph [15, 37]. To deal with this, in recent years the focus has broadened to also consider a weaker notion of tractability, namely, *fixed-parameter tractability* (FPT) [17, 19]. Chimani and Hliněný [15] have shown that RMEI is FPT, i.e., there is an algorithm which solves that problem in time $f(k) \cdot n^{\mathcal{O}(1)}$. Other works have considered various relaxations of crossing minimization; for instance, recently Eiben et al. [20] established the fixed-parameter tractability of extending drawings by k edges in a way which does not minimize the total number of crossings, but rather bounds the number of crossings per edge to at most 1.

For many problems in the intersection of crossing minimization and graph extension, an important goal is that the desired extension should maintain certain properties of the given partial representation. In the problems studied in [1] and [20], the input is a plane or 1-plane[1] drawing, respectively, and the desired extension must maintain the property of being (1-)plane. There have been a plethora of results exploring such extension problems, especially on plane drawings, for a range of other, often more restrictive properties [3, 9, 12, 13, 31, 32, 34].

Beyond planarity, the perhaps most prominent class of drawings with respect to crossing minimization are *simple drawings* (also called *good drawings* [8, 21], *simple topological graphs* [29], or simply *drawings* [26]). A drawing is simple if every pair of edges intersects in at most one point that is either a common endpoint or a proper crossing. Simplicity is an extremely natural restriction that is taken as a basic assumption in a range of settings, e.g., [2, 5, 11, 30], and that constitutes a necessary requirement for crossing-minimal drawings [36].

Contribution. In this work we study the extension problem for simple drawings in the context of crossing minimization. In other words, our aim is to extend a given simple drawing with k new edges while maintaining simplicity and restricting newly created crossings. Naturally, the most obvious way of restricting such crossings is by bounding their number, leading us to our first problem of interest:[2]

[1] A drawing of a graph is ℓ-plane if every edge is involved in at most ℓ crossings.

[2] *Decision* versions of problems are provided purely for complexity-theoretic reasons; every algorithm provided in this article is constructive and can also output a solution as a witness.

Simple Crossing-Minimal Edge Insertion (SCEI)	
Input:	A graph $G = (V, E)$ along with a connected simple drawing $\mathcal{G}$, an integer ℓ, and a set F of k edges of the complement of G.
Question:	Can $\mathcal{G}$ be extended to a simple drawing $\mathcal{G}'$ of the graph $G' = (V, E \cup F)$ such that the number of crossings in $\mathcal{G}'$ that involve an edge of F is at most ℓ?

Note that we require the initial drawing $\mathcal{G}$ to be connected. While this is a natural assumption that is well-justified in many situations, it would certainly also make sense to consider the more general setting in which this is not the case. A short discussion of how the connectivity of $\mathcal{G}$ is used in our proof is provided in Section 4.

SCEI was recently shown to be NP-complete already when $|F| = 1$ and $\ell \geq |E|$ (meaning that the aim is merely to obtain a simple drawing) [7]. On the other hand, dropping the simplicity requirement of the resulting drawing, the problem reduces to RMEI which is FPT.

The main contribution of this article is an FPT algorithm for SCEI parameterized by $k + \ell$. The result is obtained via a combination of techniques recently introduced in [20] and completely new machinery. A high-level overview of challenges posed by the problem and our strategies for overcoming them is provided in the next part of this introduction. Before that, let us mention other natural crossing-sensitive restrictions of simple drawing extension.

Instead of restricting the *total number* of newly created crossings, one may aim to extend $\mathcal{G}$ in a way which bounds the number of crossings involving each of the newly added edges – akin to the restrictions imposed by ℓ-planarity. We call this problem Simple Locally Crossing-Minimal Edge Insertion (SLCEI), where the role of ℓ is that it bounds the maximum number of crossings involving any one particular edge of F. Alternatively, one may simply require that *every* edge in the resulting drawing is involved in at most ℓ crossings, i.e., that the whole $\mathcal{G}'$ is ℓ-plane. This results in the Simple ℓ-Plane Edge Insertion (Sℓ-PEI) problem. Both of these problems are known to be NP-hard when either $\ell = 1$ or $k = 1$, meaning that we can drop neither of our parameters if we wish to achieve tractability.

One key strength of the framework we develop for solving SCEI is its universality. Notably, we obtain the fixed-parameter tractability of SLCEI as an immediate corollary of the proof of our main theorem, while the fixed-parameter tractability of Sℓ-PEI follows by a minor adjustment of the final part of our proof. Moreover, it is trivial to use the framework to solve the considered problems when one drops the requirement that the final drawing is simple – allowing us to, e.g., generalize the previously established fixed-parameter tractability of 1-Planar Edge Insertion [20] to ℓ-Planar Edge Insertion (ℓ-PEI).

Finally, we note that a core ingredient in our approach is the use of Courcelle's theorem [16], and hence the algorithms underlying our tractability results will have an impractical dependency on k. However, for the special case of $|F| = 1$ (i.e., when inserting a single edge), we use so-called *representative sets* to provide a single-exponential fixed-parameter algorithm which is tight under the Exponential Time Hypothesis [27].

Proof Overview. On a high level, our approach follows the general strategy co-developed by a subset of the authors in [20] for solving the problem of inserting k edges into a drawing while maintaining 1-planarity. This general strategy can be summarized as follows:

1. We preprocess G and the planarization of $\mathcal{G}$ to remove parts of $\mathcal{G}$ which are too far away to interact with our solution. This drawing is then translated into a graph representation of bounded *treewidth* [35].
2. We identify a combinatorial characterization that captures how the solution curves will be embedded into $\mathcal{G}$. Crucially, the characterization has size bounded by our parameters.
3. We perform brute-force branching over all characterizations to pre-determine the behavior of a solution in $\mathcal{G}$, and for each such characterization we employ *Courcelle's theorem* [16] to determine whether there exists a solution with such a characterization.

The specific implementation of this strategy differs substantially from the previous work [20] – for instance, the combinatorial characterization of solutions in Step 2 and the use of Courcelle's theorem in Step 3 are both different. But the by far greatest challenge in implementing this strategy occurs in Step 1. Notably, removing the parts of $\mathcal{G}$ required to obtain a bounded-treewidth graph representation creates *holes* in the drawing, and these could disconnect edges intersecting these holes. The graph representation can then lose track of "which edge parts belong to each other", which means we can no longer use it to determine whether the extended drawing is simple. We remark that specifically for Sℓ-PEI and ℓ-PEI, it would be possible to directly adapt Step 1 to ensure that no edge is disconnected in this manner, thus circumventing this difficulty. To handle this problem, we employ an in-depth geometric analysis combined with a careful use of the sunflower lemma and subroutines which invoke Courcelle's theorem to construct a representation which (a) still has bounded treewidth, and (b) contains partial information about which edge parts belong to the same edge in $\mathcal{G}$. A detailed overview of how this is achieved is presented at the beginning of Section 3.

Related Work. There have been two distinct lines of work that recently considered simple drawings in the context of drawing extension problems. The first studied a closely related notion of *saturated* simple drawings [25, 28], while the second studied the computational complexity of the extension problem for simple drawings [6, 7].

Statements where proofs or more details are provided in the full version are marked with ($\star$).

2 Preliminaries

We use standard terminology for undirected and simple graphs [18]. The *length* of a walk or a path is the number of edges it visits. For $r \in \mathbb{N}$, we write $[r]$ as shorthand for the set $\{1, \ldots, r\}$.

A *simple drawing* of a graph G is a drawing $\mathcal{G}$ of G in the plane such that every pair of edges shares at most one point that is either a unique crossing point or a common endpoint. In particular, no tangencies between edges are allowed, edges must not contain any vertices in their relative interior, and no three edges intersect in the same point. Given a simple drawing $\mathcal{G}$ of a graph G and a set of edges F of the complement of G we say that the edges in F can be *inserted* into $\mathcal{G}$ if there exists a simple drawing $\mathcal{G}^+$ of $G^+ = (V(G), E(G) \cup F)$ that contains $\mathcal{G}$ as a subdrawing. The *planarization* of a simple drawing $\mathcal{G}$ of G is the plane graph $\mathcal{G}^\times$ obtained from $\mathcal{G}$ by subdividing the edges of G at the crossing points of $\mathcal{G}$. We call each part of the subdivision of $e \in E(G)$ in $\mathcal{G}^\times$ an *edge segment* (of e). Furthermore, we consider the faces of $\mathcal{G}^\times$ as the *cells* of $\mathcal{G}$ and call $\mathcal{G}$ *connected* if $\mathcal{G}^\times$ is a connected graph.

Sunflower Lemma. One tool we use to obtain our results is the classical sunflower lemma of Erdős and Rado. A *sunflower* in a set family $\mathcal{F}$ is a subset $\mathcal{F}' \subseteq \mathcal{F}$ such that all pairs of elements in $\mathcal{F}'$ have the same intersection.

▶ **Lemma 1** ([22, 23]). *Let $\mathcal{F}$ be a family of subsets of a universe U, each of cardinality at most b, and let $a \in \mathbb{N}$. If $|\mathcal{F}| \geq b!(a-1)^b$, then $\mathcal{F}$ contains a sunflower $\mathcal{F}'$ of cardinality at least a. Moreover, $\mathcal{F}'$ can be computed in time polynomial in $|\mathcal{F}|$.*

Parameterized Complexity. In parameterized complexity [17, 19, 23], the complexity of a problem is studied not only with respect to the input size, but also with respect to some problem parameter(s). The core idea behind parameterized complexity is that the

combinatorial explosion resulting from the NP-hardness of a problem can sometimes be confined to certain structural parameters that are small in practical settings. We now proceed to the formal definitions.

A *parameterized problem* Q is a subset of $\Omega^* \times \mathbb{N}$, where Ω is a fixed alphabet. Each instance of Q is a pair (I, κ), where $\kappa \in \mathbb{N}$ is called the *parameter*. A parameterized problem Q is *fixed-parameter tractable* (FPT) [23, 19, 17], if there is an algorithm, called an FPT-*algorithm*, that decides whether an input (I, κ) is a member of Q in time $f(\kappa) \cdot |I|^{\mathcal{O}(1)}$, where f is a computable function and $|I|$ is the input instance size. The class FPT denotes the class of all fixed-parameter tractable parameterized problems. A parameterized problem Q is FPT-*reducible* to a parameterized problem Q' if there is an algorithm, called an FPT-*reduction*, that transforms each instance (I, κ) of Q into an instance (I', κ') of Q' in time $f(\kappa) \cdot |I|^{\mathcal{O}(1)}$, such that $\kappa' \leq g(\kappa)$ and $(I, \kappa) \in Q$ if and only if $(I', \kappa') \in Q'$, where f and g are computable functions.

Monadic Second Order Logic. We consider *Monadic Second Order* (MSO) logic on (edge-)labeled directed graphs in terms of their incidence structure, whose universe contains vertices and edges; the incidence between vertices and edges is represented by a binary relation. We assume an infinite supply of *individual variables* $x, x_1, x_2, \ldots$ and of *set variables* $X, X_1, X_2, \ldots$. The *atomic formulas* are Vx ("x is a vertex"), Ey ("y is an edge"), Ixy ("vertex x is incident with edge y"), $x = y$ (equality), $P_a x$ ("vertex or edge x has label a"), and Xx ("vertex or edge x is an element of set X"). *MSO formulas* are built up from atomic formulas using the usual Boolean connectives $(\neg, \wedge, \vee, \rightarrow, \leftrightarrow)$, quantification over individual variables ($\forall x$, $\exists x$), and quantification over set variables ($\forall X$, $\exists X$).

Free and bound variables of a formula are defined in the usual way. To indicate that the set of free individual variables of formula Φ is $\{x_1, \ldots, x_\ell\}$ and the set of free set variables of formula Φ is $\{X_1, \ldots, X_q\}$ we write $\Phi(x_1, \ldots, x_\ell, X_1, \ldots, X_q)$. If G is a graph, $v_1, \ldots, v_\ell \in V(G) \cup E(G)$ and $S_1, \ldots, S_q \subseteq V(G) \cup E(G)$ we write $G \models \Phi(v_1, \ldots, v_\ell, S_1, \ldots, S_q)$ to denote that Φ holds in G if the variables x_i are interpreted by the vertices or edges v_i, for $i \in [\ell]$, and the variables X_i are interpreted by the sets S_i, for $i \in [q]$.

The following result (the well-known Courcelle's theorem [16]) shows that if G has bounded treewidth [35] then we can find an assignment φ to the set of free variables $\mathcal{F}$ with $G \models \Phi(\varphi(\mathcal{F}))$ (if one exists) in linear time.

▶ **Theorem 2** (Courcelle's theorem [4, 16]). *Let $\Phi(x_1, \ldots, x_\ell, X_1, \ldots, X_q)$ be a fixed MSO formula with free individual variables $x_1, \ldots, x_\ell$ and free set variables $X_1, \ldots, X_\ell$, and let w a constant. Then there is a linear-time algorithm that, given a labeled directed graph G of treewidth at most w, either outputs $v_1, \ldots, v_\ell \in V(G) \cup E(G)$ and $S_1, \ldots, S_q \subseteq V(G) \cup E(G)$ such that $G \models \Phi(v_1, \ldots, v_\ell, S_1, \ldots, S_q)$ or correctly identifies that no such vertices $v_1, \ldots, v_\ell$ and sets $S_1, \ldots, S_q$ exist.*

We remark that since an understanding of the definition of *treewidth* is not required for our presentation, we merely refer to the literature for a discussion of the notion [17, 19, 35]. We denote the treewidth of a graph G as $\mathrm{tw}(G)$.

Problem Definition and Terminology. We formulate the following generalization of SLCEI in which we allow the numbers of crossings allowed for each newly added edge to differ. Note that this formulation also fixes a parameterization.

Simple Crossing-Restricted Edge Insertion (SCREI) Parameter: $k + \max_{i\in[k]} \ell_i$	
Input:	A graph $G = (V, E)$ along with a connected simple drawing $\mathcal{G}$, a set $F = \{e_1, \dots, e_k\}$ of k edges of the complement of G, and $\ell_1, \dots, \ell_k \in \mathbb{N}$.
Question:	Can $\mathcal{G}$ be extended to a simple drawing $\mathcal{G}'$ of the graph $G' = (V, E \cup F)$ such that the drawing of each edge $e_i \in F$ has at most ℓ_i crossings in $\mathcal{G}'$?

For an instance of SCREI we refer to elements in F as *added edges* and denote the endpoints of e_i as s_i and t_i (where $s_1, t_1 \dots, s_k, t_k$ are not necessarily distinct). For brevity we denote $\ell = \max_{i\in[k]} \ell_i$. Although SCREI is stated as a decision problem, we will want to speak about hypothetical *solutions* of SCREI, which will naturally correspond to the drawings of added edges in $\mathcal{G}'$ (if one exists) as the rest of $\mathcal{G}'$ is predetermined by $\mathcal{G}$. This means that a solution is a set of drawings of added edges in $\mathcal{G}'$ where $\mathcal{G}'$ witnesses the fact that the given instance is a `yes`-instance. If no such $\mathcal{G}'$ exists, then we say that the SCREI-instance *has no solution*.

The reason we focus our presentation on SCREI is that the fixed-parameter tractability of SCREI immediately implies the fixed-parameter tractability of both SLCEI parameterized by the number of added edges and crossings per added edge, and SCEI parameterized by the number of added edges and crossings of all added edges. The former is just a subcase of SCREI. The latter admits a straightforward FPT-reduction to SCREI by branching over the number ℓ_i of crossings each edge $e_i \in F$ is at most involved in. Hence obtaining a fixed-parameter algorithm for SCREI provides a unified reason for the fixed-parameter tractability of both SCEI and SLCEI. Furthermore, we will later show that the result for SCREI can be straightforwardly adapted to solve the other problems mentioned in the introduction.

3 Stitches

Let $\big(G, \mathcal{G}, F, (\ell_i)_{i\in[|F|]}\big)$ be an instance of SCREI. Recalling the Proof Overview provided in Section 1, we want to identify parts of $\mathcal{G}$ that may be considered "unimportant" because they can never be intersected by the drawing of any of the edges $s_it_i \in F$ with at most ℓ_i crossings. Formally, consider the dual G^* of the planarization $\mathcal{G}^\times$ of $\mathcal{G}$, and for each vertex $v \in V(G)$ let $U_v \subseteq G^*$ be the set of vertices that correspond to cells $\mathfrak{c}$ of $\mathcal{G}$ such that v lies on the boundary of $\mathfrak{c}$. We say a cell $\mathfrak{c}$ of $\mathcal{G}$ is *s_it_i-far* if it corresponds to a vertex $v_\mathfrak{c} \in V(G^*)$ at distance more than ℓ_i from U_{s_i} or U_{t_i}, and $\mathfrak{c}$ is *far* if it is s_it_i-far for all $i \in [k]$. Observe that in any solution of SCREI for $\big(G, \mathcal{G}, F, (\ell_i)_{i\in[|F|]}\big)$ no drawing of an edge in F can intersect far cells of $\mathcal{G}$. We refer to maximal unions of far cells in $\mathcal{G}$ which form subsets of $\mathbb{R}^2$ whose interior is connected as *holes*. The interiors of holes are a natural choice for information that is not immediately relevant for the insertion of drawings for F, in the sense that no intersections with these drawings can occur in far cells. However, as mentioned in the Proof Overview, omitting the interior of holes destroys the information about which parts of edges belong to the same edge whenever an edge is disconnected by the removal of a hole.

To transfer this information between different parts of one edge – parts which could be crossed by a hypothetical solution but which are disconnected by holes – we introduce *stitches* into the respective holes. More formally, for a hole H in $\mathcal{G}$ we call an edge e in $E(G)$ *H-torn* if e is split into at least two curves by the removal of the interior of H from $\mathcal{G}$. We call maximal subcurves of an H-torn edge after removing H *(edge) parts* of e and refer to the endpoints of these subcurves as *endpoints* of the corresponding edge part. Stitches will correspond to paths between the endpoints of edge parts of H-torn edges. To construct these paths we introduce so-called *threads* which are edges that we insert into a hole H to connect parts of H-torn edges and derive the stitches from them by considering their planarization.

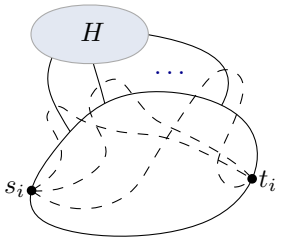

Figure 1 Assuming $\ell_i = 3$, then the potential drawings of s_it_i, depicted as dashed curves, can cross an arbitrary number of H-torn edges.

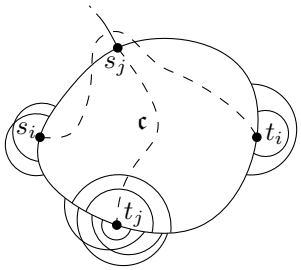

Figure 2 Assuming $\ell_i = \ell_j = 3$, then the drawing of s_jt_j has to go through $\mathfrak{c}$ and the drawing of s_it_i has to revisit cell $\mathfrak{c}$.

To ensure that the obtained combinatorialization of $\mathcal{G}$ has bounded treewidth, the main goal of this section will be to bound the number of stitches for each edge $s_it_i \in F$ and hole H by some function of $k + \ell_i$. We do this by considering which and how many edge parts of H-torn edges any simple s_it_i-curve in a hypothetical solution can cross. Here we face an apparent difficulty: it *is* possible that there is an unbounded number of edge parts which are crossed by drawings of an added edge s_it_i in hypothetical solutions and each edge part belongs to a different H-torn edge (see Figure 1). However, such situations can be safely avoided by restricting our attention to "reasonable" solutions, as we will see in Subsection 3.1. In particular, to specify "reasonable" solutions, we turn our attention to the behavior of drawings of added edges in a hypothetical solution when they *revisit* a cell of $\mathcal{G}$. Then, bounding the number of stitches we introduce for an added edge s_it_i and hole H is equivalent to showing that we can identify all but a bounded number of edges in $E(G)$ which are H-torn and cannot be crossed by a drawing of s_it_i in a "reasonable" hypothetical solution. This is what we focus on in Subsection 3.2.

After adding stitches, we are finally able to define an appropriate combinatorialization of $\mathcal{G}$ in Section 4 which we can use for the final application of Courcelle's theorem in Section 5.

3.1 Detours and Reasonable Solutions

Fix an added edge s_it_i, a hole H, and a cell $\mathfrak{c}$ of the original drawing of G. Note that a drawing of s_it_i in a hypothetical solution might revisit the cell $\mathfrak{c}$ to avoid crossing the drawing of a different added edge s_jt_j. Figure 2 exemplifies such a situation. Understanding how and why a solution might need to revisit a cell is a major component in establishing an upper bound on the number of stitches per hole. In fact, as we will see in this section, avoiding such crossings is the only reason why a cell might have to be revisited.

Let γ_i be a drawing of s_it_i in a hypothetical solution which revisits $\mathfrak{c}$. A $\mathfrak{c}$-*detour* (of γ_i) is a maximal subcurve of γ_i whose interior is disjoint from $\text{int}(\mathfrak{c})$ and has neither s_i nor t_i as an endpoint. Note that a $\mathfrak{c}$-detour might also consist of a singular point. This case occurs when γ_i crosses an edge segment on the boundary of $\mathfrak{c}$ which does not lie on the boundary of another cell. See Figure 3 for an illustration.

▶ **Definition 3.** *Let δ be a $\mathfrak{c}$-detour, and let the embedding $\mathcal{E}$ consist only of δ and the restriction of $\mathcal{G}$ to the boundary of $\mathfrak{c}$. Then δ partitions the boundary of $\mathfrak{c}$ into two connected parts: the part incident to the unbounded (i.e. outer) cell in $\mathcal{E}$, and the* δ-avoided part *which is not incident to the outer cell in $\mathcal{E}$.*

Additionally, we call the subset of $\mathbb{R}^2$ which is enclosed by δ and the δ-avoided part of the boundary of $\mathfrak{c}$ together with the δ-avoided part of the boundary of $\mathfrak{c}$ itself the δ-avoided region.

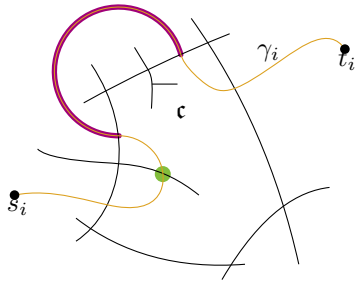

Figure 3 Drawing γ_i of s_it_i in a hypothetical solution with two $\mathfrak{c}$-detours: one is a curve (highlighted in purple) and the other is a point (highlighted in green).

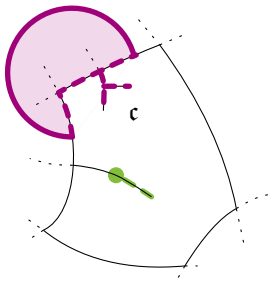

Figure 4 For the single point detour (green), the avoided part of the boundary of $\mathfrak{c}$ and the plane coincide and are dashed green. For the curve detour (purple), the avoided part of the boundary of $\mathfrak{c}$ is dashed purple and the avoided region is shaded purple.

See Figure 4 for an illustration. A $\mathfrak{c}$-detour δ is unremovable *if there exists an added edge s_jt_j with $j \neq i$ such that exactly one of s_j and t_j lies in the δ-avoided region of $\mathcal{G}$. In that case we say that the endpoint (s_j or t_j) in the δ-avoided region is* avoided *by δ, or that δ is* around *the endpoint. We call a $\mathfrak{c}$-detour* removable *if it is not unremovable.*

▶ **Lemma 4 (⋆).** *If there is a solution, then there exists a solution in which no drawing of any added edge contains a removable $\mathfrak{c}'$-detour for any cell $\mathfrak{c}'$ of $\mathcal{G}$.*

Lemma 4 allows us to restrict our attention to solutions which do not contain any removable detours (these are the solutions we intuitively referred to as "reasonable").

3.2 Defining and Finding Stitches

Let $s_it_i \in F$ and H be a hole. Our goal is to compute a, by our parameters, bounded number of edge parts in $E(G)$ which could be crossed by a drawing of s_it_i in some reasonable hypothetical solution. As we obviously do not know any hypothetical solution we cannot compute this set directly. Consequently, we identify and compute a slightly larger set: the set of all edge parts that can be crossed by some so-called *solution curve* for s_i and t_i that is superficially like an s_it_i-curve in a "reasonable" hypothetical solution (but which might induce double-crossings).

▶ **Definition 5.** *A* solution curve *for s_it_i is a simple curve γ_i that (i) starts in s_i and ends in t_i; (ii) produces at most ℓ_i crossings with $\mathcal{G}$; and (iii) whenever γ_i intersects a cell $\mathfrak{c}'$ in more than one maximal connected subcurve there is an added edge s_jt_j with $j \neq i$ such that exactly one of s_j and t_j lies in the ζ-avoided part of $\mathcal{G}$, where ζ is a maximal connected subcurve of γ_i outside of $\mathfrak{c}'$ between two intersections of γ_i with $\mathfrak{c}'$. A part of an H-torn edge $e \in E(G)$ is* crossable *for s_it_i if it is crossed by a solution curve for s_it_i.*

▶ **Lemma 6 (⋆).** *For every hole H and every added edge $s_it_i \in F$ there are less than $\ell_i(2\ell_i+1)! \cdot \left(4k(\ell_i+2)(\ell_i+1)^{\ell_i+1}\right)^{2\ell_i+1}$ parts of H-torn edges that are crossable for s_it_i.*

Proof Sketch. We show that there is a set K of less than $(2\ell_i+1)!\left(4k(\ell_i+2)(\ell_i+1)^{\ell_i+1}\right)^{2\ell_i+1}$ solution curves for s_it_i such that each crossable edge part for s_it_i is crossed by at least one of the curves in K. Then the claim follows as each solution curve crosses at most ℓ_i edges.

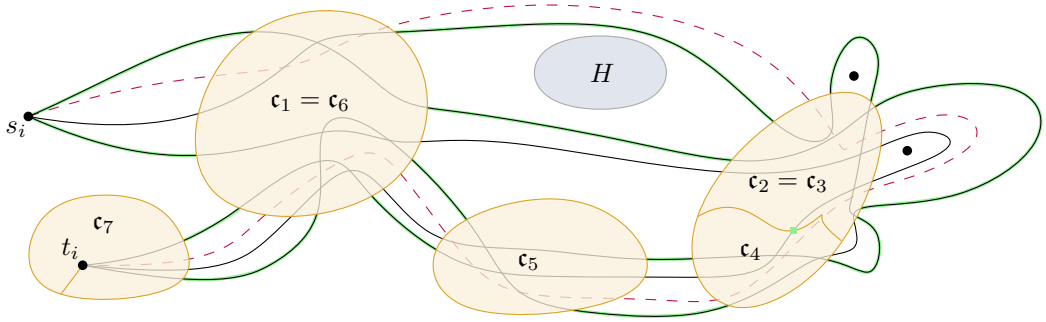

Figure 5 The cells $\mathfrak{c}_1, \ldots, \mathfrak{c}_7$ are in the core of the sunflower. The red dashed s_it_i curve cannot be part of the minimal set of curves K. The extremal subcurves are highlighted in green.

Assume for contradiction that the minimum set K that witnesses crossability of parts of H-torn crossable edges for s_it_i consists of at least $(2\ell_i+1)!\left(4k(\ell_i+2)(\ell_i+1)^{\ell_i+1}\right)^{2\ell_i+1}$ solution curves for s_it_i. Consider the restricted drawing $\mathcal{G}_H$ which is given by $\mathcal{G}$ restricted to the boundary of H, all H-torn edges in $E(G)$, as well as s_i and t_i.

We associate each s_it_i curve in K with the set of cells of $\mathcal{G}_H$ which it intersects and the set of edge segments in $\mathcal{G}_H^\times$ which it crosses. In this way, each curve in K is associated to a set of size at most $2\ell_i+1$. By the minimality of K, no two curves in K are associated to the same set of cells and edge segments. Using the sunflower lemma [22, 23] for the set system given by the sets of cells and edge segments associated to the s_it_i curves in K we obtain a set of at least $4k(\ell_i+2)(\ell_i+1)^{\ell_i+1}$ solution curves $K^\sunflower \subseteq K$ which all intersect pairwise different cells of $\mathcal{G}_H$ and edge segments of $\mathcal{G}_H^\times$, apart from the cells and edge segments in the core of a sunflower, which they all intersect. Moreover, as curves in K intersect at most ℓ_i edges we find at most ℓ_i+1 cells in the core.

By the pigeonhole principle there is a set of at least $4k(\ell_i+2)$ curves in $K^\sunflower$ which all intersect the cells in the core of the sunflower in the same order (taking into account repetitions of cells). Let $K^\sunflower_\sigma \subseteq K^\sunflower$ be such a set of curves and let $\sigma = \mathfrak{c}_1, \ldots, \mathfrak{c}_l$ with $l \leq \ell_i+1$ be the order in which these curves traverse the cells in the core of the sunflower.

As each $\mathfrak{c}_j$ with $j \in [l]$ is a cell in a restriction of $\mathcal{G}$ containing all H-torn edges, no part of an H-torn edge intersects the interior of $\mathfrak{c}_j$. In particular parts of H-torn edges are not crossed by any curve in $K^\sunflower_\sigma$ within $\mathrm{int}(\mathfrak{c}_\mathrm{j})$.

When considering subcurves of curves *between* each $\mathfrak{c}_j$ and $\mathfrak{c}_{j+1}$, we can find at most $4(k-1)$ "extremal" such subcurves which separate all other subcurves from H together with $\mathfrak{c}_j$ and $\mathfrak{c}_{j+1}$. These extremal subcurves together cross any crossable edge part of an H-torn edge intersected by any other considered subcurve. See Figure 5 for an illustration.

In this way we find at least one curve after the removal of which from K the same crossable edge parts of H-torn edges are intersected, contradicting our minimality assumption. ◀

While the fact that the number of crossable edge parts we want to introduce stitches for is bounded by a function in our parameters is reassuring, we need to be able to actually introduce these stitches before being able to give our final MSO encoding of hypothetical solutions. For this we invoke Courcelle's theorem in Lemma 7 independently of its final application. This then allows us to insert the corresponding stitches.

▶ **Lemma 7 (⋆).** *There is a fixed-parameter algorithm parameterized by $k+\ell$ which identifies, for an added edge s_it_i and a hole H, all parts of H-torn edges which are crossable for s_it_i.*

▶ **Definition 8.** *For a hole H in $\mathcal{G}$ and an added edge $s_it_i \in F$, a* thread *is a pair of two endpoints of two distinct edge parts of the same H-torn edge in $e \in E(G)$ satisfying the following properties: (i) both edge parts are crossable for s_it_i, (ii) there is no other crossable edge part between these edge parts along a traversal of e, and (iii) there is no other endpoint of one of the two edge parts along a traversal of e. We denote the set of all threads for H and s_it_i as T_{H,s_it_i}, and define the set of all threads for H as $T_H = \bigcup_{i\in[k]} T_{H,s_it_i}$.*

An embedding of T_H is a set of curves, contained completely in H, which connect each pair of two endpoints of edge parts in T_H.

▶ **Lemma 9 (⋆).** *There is a fixed-parameter algorithm parameterized by $k + \ell$ that computes, for a hole H in $\mathcal{G}$, a simple embedding of T_H.*

For the simple embedding of T_H into H computed in Lemma 9, define the set of *stitches* S_H of H as the planarization of the threads in this embedding.

4 The Patchwork Graph

After identifying a bounded number of stitches in each hole, we are finally able to define the *patchwork graph* and prove desirable properties which we will use in our final application of Courcelle's theorem. An illustration of the patchwork graph is provided in Figure 6. The following definition also doubles as a description of how to construct the patchwork graph from a given drawing. We remark that, unlike $\mathcal{G}$, the patchwork graph might be disconnected.

▶ **Definition 10.** *The* patchwork graph *P and its embedding $\mathcal{P}$ are given by the labeled graph derived from $\mathcal{G}$ in the following steps:*

1. *Planarize $\mathcal{G}$ and label the vertices which are newly introduced by this as* crossing vertices*. Label vertices which correspond to vertices of G as* real vertices*. Additionally label each s_i and t_i with label $i \in [k]$.*
2. *Subdivide each edge e in the planarization $\mathcal{G}^\times$ of $\mathcal{G}$ by k vertices*[3] *$v_1^e, \ldots, v_k^e$ which are labeled as* segment vertices *– each segment vertex of e will represent a possible crossing point of the drawing of one of the k edges in F and e.*
3. *Inside each face f of $\mathcal{G}^\times$, introduce a new vertex v_f and label it as* cell vertex*.*
4. *Inside each face f of $\mathcal{G}^\times$, trace the boundary of f creating a curve at ε-distance and create a vertex labeled as* shadow vertex *on this curve every time an endpoint of an edge in F or a segment vertex is encountered. Insert two edges for each shadow vertex; one connecting the shadow vertex to the corresponding endpoint of an edge in F or segment vertex; and one connecting the shadow vertex to v_f. Note that multiple shadow vertices can be introduced for the same vertex in G (e.g. the orange vertex in Figure 6). Shadow vertices allow to distinguish different ways, more formally positions in the rotation around an endpoint, of accessing that endpoint via the inserted drawing of an edge in F (see Figure 7); this is where the connectivity of $\mathcal{G}$ is used. In this way each shadow vertex of an endpoint corresponds to an* access direction*.*
5. *Delete every vertex that is in the interior of a hole H.*
6. *For each hole H insert all stitches S_H for H into the interior of H and label the inserted vertices as* crossing vertices*.*[4]

[3] If $k = 1$ we subdivide by 2 vertices for reasons that will become clear when we introduce *tracking labels*.
[4] This means they receive the same label as vertices introduced by planarizing $\mathcal{G}$.

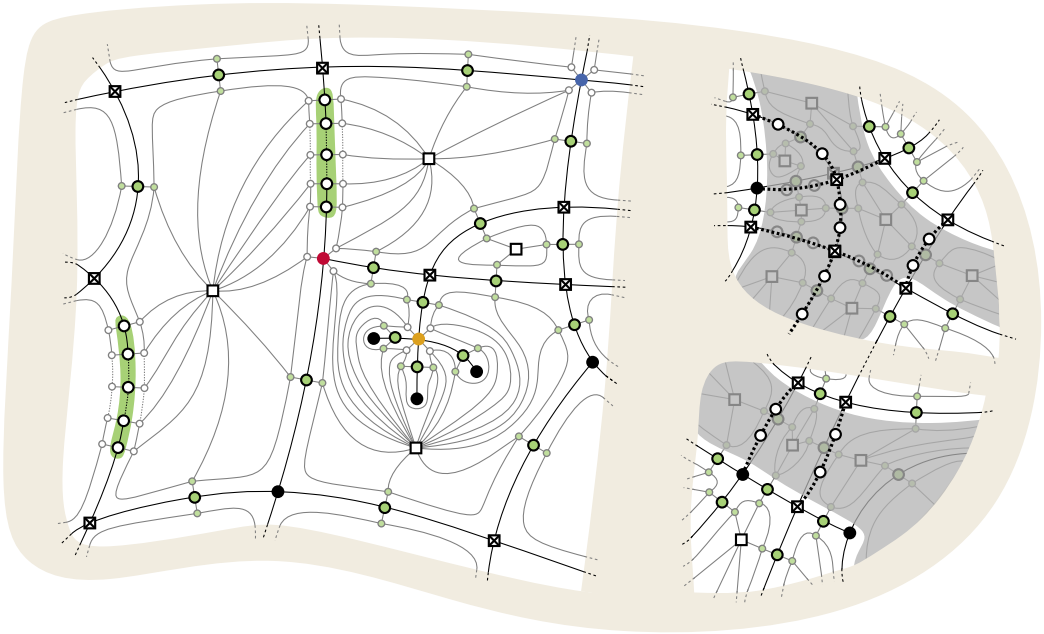

Figure 6 Illustration of a patchwork graph P. The remainder of P is hinted in beige. Black disks are original vertices. Colored disks are endpoints of edges in F. Crossing vertices are crosses. Green and white disks represent the edge segment/shadow vertices. Cell vertices are white squares. Holes are shaded in gray and stitches drawn with thick, dashed curves.

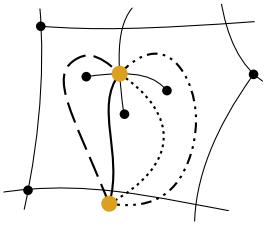

Figure 7 Illustration for different access directions. Each hypothetical drawing (indicated as thick dashes, normal, dotted, and dash-dotted lines) of the added edge between the orange vertices crosses the same edge segment of $\mathcal{G}^\times$ but separates the black vertices differently. In connected initial drawings, ways of separating vertices of the same cell by the drawing of an added edge are completely determined by potential crossing points of that drawing and its positions in the rotations around each of its endpoints. This is not the case for disconnected initial drawings.

7. *For technical reasons which will become apparent later (when we introduce* tracking labels*), we replace each edge in S_H by a path consisting of two vertices and three edges and label the inserted vertices as* segment vertices.[5]

We introduce additional crossability labels for segment vertices in the following way. For every segment vertex v corresponding to an edge segment σ of edge $e \in E(G)$, we label v as *crossable* for some edge $s_it_i \in F$ if one of the following two conditions holds:

- e is not H-torn for any hole H, or
- for *each* hole H in $\mathcal{G}$ for which e is H-torn, σ lies on a part (when considering parts arising from the removal of the interior of H) of e that is crossable for s_it_i.

[5] This means they receive the same label as vertices introduced by subdividing edge segments of the planarization of $\mathcal{G}$.

▶ **Lemma 11 (⋆).** *If there exists a solution for the considered SCREI instance, then there is a solution such that all segment vertices which correspond to edge segments of an edge that is crossed by the drawing of $s_it_i \in F$ in the solution are labeled as crossable for s_it_i.*

Note that Lemmas 7 and 9 and Definition 10 allow us to compute the patchwork graph in FPT time. Two important properties of the patchwork graph are encapsuled in Lemmas 12 and 13. The proof of Lemma 12 relies on obtaining a bound on the diameter of each connected component of the patchwork graph – a task which is intuitively clear, but requires to overcome technical challenges due to the addition of stitches. Lemma 13 later allows us to encode whether two edge segments in P belong to the same edge in $\mathcal{G}$ via an MSO formulation.

▶ **Lemma 12 (⋆).** *The patchwork graph P has treewidth bounded by $3(2 + 4(k-1))(4\ell + 8(kf(k,\ell)-1))$, where $f(k,\ell)$ is the bound on the number of crossable edge parts for a single added edge and hole obtained in Lemma 6.*

▶ **Lemma 13 (⋆).** *Segment vertices which correspond to edge segments of the same edge in $e \in E(G)$ and are labeled as crossable for s_it_i are connected via paths in P consisting only of segment and crossing vertices which correspond to segments and crossings of e and segments and crossings for threads that connect parts of e.*

Ideally, we would like Lemma 13 to lead to an MSO subformula that can check whether two segment vertices in P belong to the same edge – an important component of our algorithm for SCREI. The lemma provides us with a characterization that seems suitable for this task since it is easy to define a path in MSO, but there is an issue if we use P as it is currently defined: a crossing vertex is adjacent to 4 segment vertices, and P (viewed as a graph without an embedding) does not specify which of these segment vertices belong to the same edge. We resolve this by introducing *tracking labels*: for each crossing vertex v in P created by a crossing between edges e and e' in $\mathcal{G}$, we assign the label 1 to the two unique neighbors of v corresponding to e and the label 2 to the remaining two neighbors of v.

▶ **Corollary 14.** *Segment vertices which correspond to edge segments of the same edge in $e \in E(G)$ and are labeled as crossable for s_it_i are connected via paths in P consisting only of segment and crossing vertices with the following property: the two neighbors of each crossing vertex on the path are segment vertices with the same tracking label.*

5 Using the Patchwork Graph

Now that we have constructed the patchwork graph P and established that it has the properties we need, we can proceed to the final stage of our proof. Here, our aim will be to identify a combinatorial characterization which projects the behavior of a solution from $\mathcal{G}$ to P, establish a procedure that allows us to identify (and construct) solutions based on a characterization in P, and finally show how to find such characterizations. To streamline our presentation, at this stage we perform a brute-force branching procedure which will determine, for each $s_it_i \in F$, the number ℓ'_i of crossings between the curve connecting s_i to t_i and edges of $\mathcal{G}$ in the sought-after solution.

Consider a hypothetical solution S, and let f be a curve in S connecting vertex a to b. The *trace* r_f of f is a walk in P starting at a such that:

1. From a, r_f proceeds to the shadow vertex that corresponds to the access direction through which f connects to a, and then to the cell vertex of the first cell $\mathfrak{c}_1$ in $\mathcal{G}$ intersecting f.
2. For each intersection along f with an edge segment q between cells $\mathfrak{c}_i$ and $\mathfrak{c}_{i+1}$, r_f proceeds to the shadow vertex of a segment vertex v in $\mathfrak{c}_i$ on q, then to v, then to its shadow vertex in $\mathfrak{c}_{i+1}$, and then to the cell vertex of $\mathfrak{c}_{i+1}$, where v has the property that the number of

segment vertices of q on either side of v is at least as large as the number of drawings of added edges in F which intersect q on the respective side of its intersection with f. Such a segment vertex v exists, since there are $k = |F|$ segment vertices on q.

3. Finally, r_f continues to the shadow vertex that *corresponds* to the direction through which f enters b, and finally ends in b.

Observe that r_f visits precisely $4\ell'_i + 5$ vertices. Moreover, for two curves f, f' in S, their traces $r_f, r_{f'}$ may only intersect in cell vertices, the real vertices that form the endpoints of the curves, and the associated shadow vertices.

Now, let the *solution trace* (r_S,η_S) of S be a pair where $r_S = \{r_f | f \in S\}$ and η_S describes cyclic orders which will intuitively capture how edges cross into and out of each cell vertex in the solution. Let $R_S = \{v \mid \exists f \in S : v \in r_f\}$ be the set of all vertices occurring in the traces of S. η_S then is a mapping from each cell vertex $c \in R_S$ to a cyclic order $\prec_c$ over the shadow vertices in R_S that are incident to c. Specifically, $\prec_c$ is defined as the cyclic order given by the cycle on the neighborhood of c in P restricted to R_S.

Solution traces describe the way in which a solution can be related to a set of walks and cyclic orders in P. Of course we can abstract away from the explicit reference to a solution and define the more general notion of *preimages* whose combinatorial structure is the same as that of a solution trace but which does not arise and in particular does not even need to correspond to a solution. (Preimages and solution traces relate in a similar way as solution curves and solutions in Section 3.2.)

Formally, a *preimage* (α', β') is a tuple with the following properties. α' is a set of k walks in H which are labeled $\alpha'_1, \ldots, \alpha'_k$, where each α'_i has length $4(\ell_i + 1)$ and visits vertices with the same orders of labels as traces. Similarly, β' is a mapping from each cell vertex c visited by the walks in α' to the cyclic order over its neighbors that occur in α', along the cycle on $N_P(c)$ in P.

Obviously every solution trace is a preimage. Conversely, one can derive a drawing of all edges of F into $\mathcal{G}$ from a preimage (α', β') by the *assembly procedure* **A** introduced below. For each $\alpha'_i \in \alpha'$, **A** will draw a curve u_i that starts and ends at the two vertices labeled i (i.e., the endpoints of $s_i t_i \in F$) as described in the following steps.

1. u_i exits its starting vertex via the access direction given by the first shadow vertex in α'_i.
2. For each cell vertex c such that (e_1, v_1, c, v_2, e_2) forms a subsequence of visited vertices in α'_i, expand u_i by drawing a curve ι in c connecting the edge segment (or the real vertex) e_1 to the edge segment (or the real vertex) e_2 in the following way.
   - Consider an arbitrary other curve drawn in c by **A** up to now, say ζ, that was obtained from some subsequence $(e_1^\zeta, v_1^\zeta, c, v_2^\zeta, e_2^\zeta)$. ι will intersect ζ if and only if the shadow vertices of ι interleave with the shadow vertices of ζ in $\beta(c)$ (i.e., for instance, if $v_1 \prec_c v_1^\zeta \prec_c v_2 \prec_c v_2^\zeta \prec_c v_1$).
   - Such a drawing can be achieved by, e.g., having the curve ι follow the inside boundary of c in a clockwise manner while avoiding all curves it is not supposed to cross (as these will be either completely enveloped by or completely enveloping ι).
   - We remark that v_1 and v_2 may either be shadows of segment vertices or the actual endpoints s_i or t_i.
3. u_i ends by entering the final real vertex in α'_i from the direction specified by the last shadow vertex in α'_i.

The intuition here is that **A** interprets a preimage of a template trace as a specification of precisely which parts of $\mathcal{G}$ should be crossed by the drawings of each added edge (this information is provided in α'), while controlling when and how individual curves in the newly constructed solutions should cross each other (this information is provided in β'). Note that the output of **A** for an arbitrary preimage will in general not be a solution for our edge insertion problem, but – crucially – one can check whether it is in polynomial time.

Observe that, although preimages imply curves in $\mathcal{G}$ for all added edges in F, and we can check for each of them if they are a solution, we cannot iterate over them in FPT time as the number of preimages in P is generally not FPT. We will however be able to distill the structure of preimages, independently of their exact specification in P. For this we define *template traces*. A template trace is a tuple $\tau = (T, \alpha, \beta)$ where:

- T is a graph whose vertices are equipped with a labeling that matches the vertex-labeling used in P (i.e., some may be labeled as segment vertices, some as cell vertices, etc., and in addition some of them may be labeled as the endpoints of added edges in F);
- $\alpha = \{\alpha_1, \ldots, \alpha_k\}$ is a set of walks in T, where each walk α_i has length $4(\ell'_i + 1)$ and the types of vertices visited by α_i match the types of vertices visited by a trace (i.e., α_i starts with a real vertex labeled i, then proceeds with a shadow vertex, a cell vertex, followed by a sequence of ℓ'_i-many subsequences of shadow-, segment-, shadow-, cell vertices, and ends with a shadow vertex followed by a different real vertex labeled i); and
- β is a mapping from each cell vertex in T to a cyclic order over its adjacent shadow vertices.
- For simplicity, we require that each vertex and edge in T occurs in at least one walk in α.

▶ **Proposition 15 (⋆).** *There are at most $(k\ell)^{\mathcal{O}(k\ell)}$ distinct template traces. Moreover, the set of all template traces can be enumerated in time $(k\ell)^{\mathcal{O}(k\ell)}$.*

We say that a template trace (T, α, β) *matches* a preimage (α', β') if there is a label-preserving bijective mapping γ (called the *preimaging*) from the vertices on walks in α' to $V(T)$ such that (1) for each $\alpha'_i \in \alpha'$, $\gamma(\alpha'_i) = \alpha_i$ and (2) $\gamma(\beta')$ maps each c to $\beta(\gamma(c))$. For a template trace τ that matches a preimage (α', β'), we say that (α', β') is a *preimage* of τ. Intuitively, a preimage of a template trace is its firmly embedded counterpart in P. As every solution trace is a preimage, these definitions carry over to solution traces.

The following lemma shows that a template trace τ matching the solution trace of a hypothetical solution contains a sufficient amount of information to *almost* reconstruct a solution using $\mathbf{A}$ on a preimage of τ.

▶ **Lemma 16 (⋆).** *Let S be a solution which matches a template trace $\tau = (T, \alpha, \beta)$, and let (α', β') be a preimage of τ. Let S' be the output of $\mathbf{A}$ applied to (α', β'). Then S' is either a solution, or there exists an edge e of G that intersects some curve in S' more than once.*

Next, we show that the problem of finding a preimage of a template trace (or determining that there is none) can be encoded in Monadic Second Order (MSO) logic. Which is the last ingredient needed to prove our main result.

▶ **Lemma 17 (⋆).** *Let $\tau = (T, \alpha, \beta)$ be a template trace. There exists an MSO formula $\phi_\tau(V(T))$ of size independent of G and $\mathcal{G}$ which is satisfiable in P if and only if there exists a preimage for τ in P. Moreover, if the formula is true, then the interpretation of $V(T)$ defines a* preimaging *between a preimage of τ and τ.*

▶ **Theorem 18 (⋆).** *SCREI is fixed-parameter tractable.*

Theorem 18 implies the fixed-parameter tractability of SCEI and SLCEI parameterized by $k + \ell$. Moreover, the approach can also be used to obtain fixed-parameter tractability of the other problems defined in the introduction, with only minor adaptations required.

▶ **Theorem 19 (⋆).** *Sℓ-PEI, ℓ-PEI and Locally Crossing-Minimal Edge Insertion are fixed-parameter tractable when parameterized by $\ell + k$.*

6 Inserting a Single Edge

In this section we present a single-exponential fixed-parameter algorithm for SCEI parameterized by ℓ in the case where $|F| = 1$; we hereinafter denote this problem SC1EI. We remark that the parameter dependency of this algorithm is tight under the Exponential Time Hypothesis [27], since Arroyo et al. [7] gave a reduction from 3-SAT to the simple drawing extension problem with one extra edge, and the number of edges in the obtained graphs is linear in the size of the 3-SAT instance. We note that in the same work [7], the authors also presented a single-exponential parameterized algorithm for SCEI when $|F| = 1$, however the parameter used there is the total number of crossings in the original drawing.

As a first step we transform SC1EI to the problem of finding a colorful st-path (i.e., a path where no color is repeated) of length at most κ in a vertex-colored graph with coloring χ obtained from $\mathcal{G}^\times$. Using so-called *representative sets*, see e.g. [17, Chapter 12], we can show how to efficiently find a colorful path. Theorem 22 is then an immediate consequence.

▶ **Proposition 20 (⋆).** *There is a linear-time reduction that converts an instance $(G, \mathcal{G}, \{st\}, \ell)$ of SC1EI to an equivalent instance $(G^*, \chi, s, t, 2\ell + 3)$ of* Colorful Short Path.

▶ **Theorem 21 (⋆).** *Colorful Short Path can be solved in time $\mathcal{O}(2^{\mathcal{O}(\kappa)} \cdot |E(G)| \log |V(G)|)$.*

▶ **Theorem 22.** *SC1EI can be solved in time $\mathcal{O}(2^{\mathcal{O}(\ell)} \cdot |\mathcal{G}| \log |E(G)|)$.*

7 Conclusion

In this paper we established the fixed-parameter tractability of inserting a given set of edges into a given drawing while maintaining simplicity and adhering to various restrictions on the number of crossings in the solution. While the presented results make the reasonable assumption that the initial drawing is connected, the problem is of course also interesting in the general case. We believe that our framework and methodology can also be used to handle the extension problem for disconnected drawings, albeit only after overcoming a few additional technical challenges; moreover, the algorithm presented in Section 6 does not require connectivity at all. Other than connectivity, the most glaring question left open concerns the complexity of SCEI parameterized by ℓ alone. Recall that, in contrast to this open question, SLCEI is known to be NP-hard already for $\ell = 1$. Last but not least, while here we focused on the edge insertion problem, it would also be interesting to extend the scope to also allow for the addition of vertices into the drawing.

Abstract

We give a quantum logspace algorithm for powering contraction matrices, that is, matrices with spectral norm at most 1. The algorithm gets as an input an arbitrary $n \times n$ contraction matrix A, and a parameter $T \leq \text{poly}(n)$ and outputs the entries of A^T, up to (arbitrary) polynomially small additive error. The algorithm applies only unitary operators, without intermediate measurements. We show various implications and applications of this result:

First, we use this algorithm to show that the class of quantum logspace algorithms with only quantum memory and with intermediate measurements is equivalent to the class of quantum logspace algorithms with only quantum memory without intermediate measurements. This shows that the deferred-measurement principle, a fundamental principle of quantum computing, applies also for quantum logspace algorithms (without classical memory). More generally, we give a quantum algorithm with space $O(S + \log T)$ that takes as an input the description of a quantum algorithm with quantum space S and time T, with intermediate measurements (without classical memory), and simulates it unitarily with polynomially small error, without intermediate measurements.

Since unitary transformations are reversible (while measurements are irreversible) an interesting aspect of this result is that it shows that any quantum logspace algorithm (without classical memory) can be simulated by a reversible quantum logspace algorithm. This proves a quantum analogue of the result of Lange, McKenzie and Tapp that deterministic logspace is equal to reversible logspace [15].

Finally, we use our results to show non-trivial classical simulations of quantum logspace learning algorithms.

1 Introduction

Quantum computers hold great promise, but in the near future their memory is likely to be limited to a small number of qubits. This motivates the study of quantum complexity classes with bounded space. The most important of these classes is the class of problems solvable in quantum logarithmic space and polynomial time, first studied by Watrous [28].

In the literature, there are several variants of this class. One variant, BQL, is the class of problems solvable in quantum logarithmic space and polynomial time when intermediate measurements are allowed. Another variant, $\mathsf{BQ_UL}$, is the class of problems solvable in quantum logarithmic space and polynomial time when only unitary operators are allowed and intermediate measurements are not allowed. We note that in most previous works, the class BQL allows a quantum algorithm to use both quantum and classical memory (see for example [17, 27, 6]).

Our first main result, Theorem 18, gives a quantum logspace algorithm for powering matrices, a fundamental problem in computational complexity, which is not known to be in classical (deterministic or probabilistic) logspace. Our algorithm uses only unitary operators, without intermediate measurements, and hence it places the problem of powering matrices in the class $\mathsf{BQ_UL}$.

The algorithm gets as an input an arbitrary $n \times n$ matrix A, a parameter $T \leq \mathrm{poly}(n)$ and two indices $i, j \in \{1, \ldots, n\}$ and outputs the entry $(A^T)_{i,j}$, up to an additive error of $\frac{\|A\|^T}{\mathrm{poly}(n)} + \frac{1}{\mathrm{poly}(n)}$, where $\|A\|$ is the spectral norm of the matrix A. In particular, if A is a contraction matrix, that is, a matrix with spectral norm at most 1, the additive error is just $\frac{1}{\mathrm{poly}(n)}$.

We note that by an easy reduction, our algorithm can also solve another fundamental problem in computational complexity, the problem of iterative matrix multiplication. In this problem, the input is T matrices $A_1, \ldots, A_T$ of size $n \times n$ each, and the algorithm outputs the entries of the product $A_1 \cdot \ldots \cdot A_T$.

Besides giving a quantum logspace algorithm for a basic computational problem, our results shed light on several fundamental issues regarding bounded-space quantum computations, and have additional applications.

$\mathsf{BQ_QL}$ is Equal to $\mathsf{BQ_UL}$

We consider the class of quantum logspace algorithms with only quantum memory and with intermediate measurements and refer to it by $\mathsf{BQ_QL}$. We use our algorithm for powering matrices to show that the two classes $\mathsf{BQ_QL}$ and $\mathsf{BQ_UL}$ are exactly equal (Theorem 12). Moreover, the way that this equality is proved is by a *simulation*. Our second main result, Theorem 16, proves that there is a quantum logspace algorithm without intermediate measurements, that is, a $\mathsf{BQ_UL}$ algorithm, that gets the description of a quantum logspace algorithm with intermediate measurements, without classical memory, that is, a $\mathsf{BQ_QL}$ algorithm, and simulates it with polynomially small error. Theorem 16 is even more general and shows how to simulate a quantum logspace algorithm with *unital* channels that are given as an input, while even the very restricted special case of simulating an arbitrary unitary operator within $\mathsf{BQ_UL}$ seems to us interesting.

The Deferred-Measurement Principle

The deferred measurement principle is a fundamental result in quantum computing which states that delaying measurements until the end of a computation doesn't affect the output. In order for the principle to hold, the qubits that were supposed to be measured cannot further participate in the computation from that point on. However, a $\mathsf{BQ_QL}$ algorithm can only store a logarithmic number of qubits, while the number of intermediate measurements is potentially polynomial, and hence excluding the qubits that are supposed to be measured from further participating in the computation is infeasible.

Nevertheless, Theorem 12 and Theorem 16 imply that intermediate measurements are not necessary even when the space used by the quantum algorithm is logarithmic, but the way to eliminate the intermediate measurements is not as straightforward.

Reversible Computation

Landauer introduced the concept of time-reversible computation and argued that any irreversible operation must be accompanied by entropy increase [14] (see also [2]). An interesting aspect of Theorem 12 and Theorem 16 is that they show that any quantum logspace algorithm (without classical memory) can be implemented using only time-reversible operations (except for the final measurement that gives the final output). This is a quantum analogue of the result of Lange, McKenzie and Tapp that deterministic logspace algorithms can be implemented using only time-reversible operations [15].

Classical Simulations of Quantum Learning with Bounded Memory

A line of recent works studied the power of (classical) algorithms for online learning, under memory constraints, where a bounded-space learner tries to learn a concept class from a stream of samples. These works showed that for a large class of online learning problems, any classical learning algorithm requires either super-linear memory size or a super-polynomial number of samples (see for example [24, 26, 22, 13, 21, 18, 1, 8] and the references therein).

Here, we study the relative power of quantum and classical algorithms for online learning, under memory constraints. More concretely, we study the task of distinguishing between two families of distributions over the possible samples. Corollary 23 proves that any quantum algorithm with time T and space S for distinguishing between arbitrary two families of distributions, can be simulated classically in time $\mathrm{poly}(2^{S^2+\log^2 T})$ and space $O(S^2+\log^2 T)$. Moreover, Theorem 24 proves that if one family is a singleton, that is, the task is to distinguish between one distribution over the samples and a family of different distributions, then any quantum learning algorithm with time T and space S can be simulated classically in time $\mathrm{poly}(2^S \cdot T)$ and space $O(S+\log T)$.

Thus, an intriguing open problem is whether any quantum algorithm with time T and space S for distinguishing between two arbitrary families of distributions, can be simulated classically in time $\mathrm{poly}(2^S \cdot T)$ and space $O(S+\log T)$. Theorem 22 proves that this holds if and only if $\mathsf{promiseBQ_UL} = \mathsf{promiseBPL}$.

1.1 Techniques

We start by proving a lemma that shows how to implement an arbitrary contraction matrix A as a subsystem of a unitary quantum circuit (Lemma 6). Since A is not necessarily unitary, rather than implementing A, the lemma implements the unitary matrix

$$U_H = \begin{pmatrix} H & \sqrt{\mathbf{I}_{2m} - H^2} \\ \sqrt{\mathbf{I}_{2m} - H^2} & -H \end{pmatrix}$$

where H is the Hermitian contraction $\begin{pmatrix} & A \\ A^\dagger & \end{pmatrix}$. That is, the lemma shows how to apply the transformation U_H on a unit vector (quantum state) that is also given as an input. The unitary matrix U_H is called a block-encoding of A in some literature [4, 10], which admits various constructions (see [9] for an exhibition). In particular, our construction in Lemma 6 is in unitary quantum logspace.

The proof of Lemma 6 is inspired by, and uses techniques from, Ta-Shma's algorithm that inverts well-conditioned matrices in quantum logspace [27], whose general framework traces back to [12]. In particular, as in [27], the proof goes according to the following lines: Given a Hermitian matrix H,

- First apply the phase estimation over the unitary e^{iH} so that it maps $|u_\lambda\rangle$ to $|u_\lambda\rangle|\lambda\rangle$, where u_λ is an eigenvector of H with eigenvalue λ.
- For each eigenvector apply the unitary transformation $|\lambda\rangle \to \lambda|0\rangle|\lambda\rangle + \sqrt{1-\lambda^2}|1\rangle|\lambda\rangle$ according to the eigenvalue λ. This is where contraction matrices come into play, as the eigenvalues of H are required to be in $[-1, 1]$.
- Uncompute the eigenvalues by reversing the phase estimation over e^{iH}.

As a special case of Lemma 6, when we take the contraction A to be unitary, we get a space-efficient unitary implementation of any unitary matrix (Corollary 7).

We get our algorithms for powering contraction matrices (Theorem 10 and Corollary 15) by iteratively applying the unitary matrix U_H of Lemma 6. However, since Lemma 6 implements the matrix U_H, rather than A, we need to "throw away" the unwanted dimensions introduced by U_H, by permuting them into additional dimensions.

We get our algorithm for powering arbitrary matrices (Theorem 18), by a reduction to the algorithm for powering contraction matrices, by dividing the matrix by its norm. However, the known algorithm for computing the spectral norm of a matrix, by Ta-Shma [27], only works for contraction matrices. To bypass this, we apply Ta-Shma's algorithm on the matrix A divided by its Frobenius norm (which is always larger than the spectral norm).

Finally, we get our algorithms for simulating quantum logspace algorithms with intermediate measurements, or even *unital* channels that are given as an input (Lemma 11 and Theorem 16), by reducing any unital quantum algorithm to the contraction powering problem in the m^2-dimensional space of the $m \times m$ entries of the density matrix, where $m = 2^S$ and S is the space used by the algorithm. Note that this step already doubles the space used. At the end of this step, we only get polynomially small success probability, but that success probability can be amplified to a constant using a Grover-type technique inspired by [6], resulting in Lemma 11 that simulates the computation with constant error. The error is further reduced to be polynomially small in Theorem 16. Interestingly, to reduce the error and prove Theorem 16, we use Theorem 12, so, in a way, the results are used to improve themselves.

1.2 Related Work

Independently of our work, Fefferman and Remscrim have proven closely related results to ours [7]. They took a different route from ours by proving L-reductions between several well-conditioned versions of matrix problems which turned out to be $\mathsf{BQ_UL}$-complete. In particular, they obtained a stronger version of our Theorem 12, showing that $\mathsf{BQL} = \mathsf{BQ_UL}$.

2 Preliminaries

For an integer n, let $[n] = \{0, 1, \ldots, n-1\}$. Let $\mathbb{C}$ denote the set of complex numbers, and $\mathbb{C}^{m\times n}$ denote the set of m by n complex matrices. For a matrix $A \in \mathbb{C}^{m\times n}$, let $\mathrm{vec}(A)$ be the vectorization of A, which is a vector of dimension mn formed by stacking the columns of A on top of each other, that is

$$\mathrm{vec}(A)_{i+jm} = A_{i,j}, \quad \forall i \in [m], j \in [n].$$

Let $\mathcal{U}_m$ be the set of m by m unitary matrices, and $\mathcal{D}_m$ be the set of m by m density matrices, i.e. positive semidefinite Hermitians of trace 1. The m by m identity matrix is denoted by $\mathbf{I}_m$. Let $\|A\|$ denote the spectral norm of a complex matrix A, and $\|A\|_{\mathrm{F}}$ denote the Frobenius norm.

We use ε to denote small real numbers, and $|\epsilon\rangle$ to denote vectors with small norms. When we talk about errors, approximations and ε-closeness of matrices, they are measured in spectral norms.

As we work mostly with complex numbers, we often need corresponding concentration bounds. The following is a direct corollary of the Chernoff-Hoeffding inequality:

▶ **Lemma 1.** *Let X be a random complex number with $|X| \leq 1$, and $X_1, \ldots, X_n$ are n independent copies of X. Then*

$$\Pr\left[\left|\frac{1}{n}(X_1 + \cdots + X_n) - \mathbf{E}[X]\right| \geq \varepsilon\right] \leq 4e^{-2n\varepsilon^2}.$$

2.1 Contraction Matrices

We introduce contraction matrices and provide some useful properties, which can be found in [29, Chapter 6]:

▶ **Definition 2.** *A matrix $A \in \mathbb{C}^{m\times m}$ is a contraction if $\|A\| \leq 1$. Alternatively, A is a contraction if A is in the convex hull of $\mathcal{U}_m$.*

Any eigenvalue λ of a contraction must have $|\lambda| \leq 1$. If $A \in \mathbb{C}^{m\times m}$ is a contraction, then the following matrix is unitary:

$$U_A = \begin{pmatrix} A & \sqrt{\mathbf{I}_m - AA^\dagger} \\ \sqrt{\mathbf{I}_m - A^\dagger A} & -A^\dagger \end{pmatrix}$$

In particular, when $A = a$ is a real number in $[-1, 1]$, $U_a = \begin{pmatrix} a & \sqrt{1-a^2} \\ \sqrt{1-a^2} & -a \end{pmatrix}$ is a reflection. Finally, in a product of multiple contractions, individual errors will not propagate much, as we have the following lemma:

▶ **Lemma 3.** *If $A_1, \ldots, A_k \in \mathbb{C}^{m\times m}$ are contractions, and $B_1, \ldots, B_k \in \mathbb{C}^{m\times m}$ satisfy $\|A_i - B_i\| \leq \varepsilon$ for every i, then $\|A_1 \cdots A_k - B_1 \cdots B_k\| \leq (1+\varepsilon)^k - 1$. Furthermore, if $B_1, \ldots, B_k$ are also contractions, then $\|A_1 \cdots A_k - B_1 \cdots B_k\| \leq k\varepsilon$.*

2.2 Quantum Channels

A quantum channel (or operation), in its most general form, is a *completely-positive trace-preserving* (CPTP) map $\Phi : \mathcal{D}_m \to \mathcal{D}_n$ that maps a density matrix ρ to a density matrix $\Phi(\rho)$. We denote the set of such channels as $\mathcal{C}_{m,n}$. The *Kraus representation* of the quantum channel Φ is a set of matrices $\{E_1, \ldots, E_k\}$ such that $\sum_{i=1}^k E_i^\dagger E_i = \mathbf{I}_m$, and

$$\Phi(\rho) = \sum_{i=1}^k E_i \rho E_i^\dagger.$$

The *natural representation* of Φ, denoted as $K(\Phi)$, is a matrix in $\mathbb{C}^{n^2\times m^2}$ such that $\mathrm{vec}(\Phi(\rho)) = K(\Phi)\mathrm{vec}(\rho)$ for any $\rho \in \mathcal{D}_m$. Given the Kraus representation $\{E_1, \ldots, E_k\}$ of Φ, one can easily compute the natural representation $K(\Phi) = \sum_{i=1}^k \overline{E_i} \otimes E_i$.

A quantum channel Φ is *unital*, if it maps the identity to the identity of the same dimension. The Kraus representation of a unital channel is a set of square matrices $\{E_1, \ldots, E_k\}$ that additionally satisfies $\sum_{i=1}^{k} E_i E_i^\dagger = \mathbf{I}_m$. In the language of natural representation, it is known that Φ is unital if and only if $K(\Phi)$ is a contraction [20]. Notice that unitary operators and projective measurements are all unital. Our paper shows the following: one can construct in logspace a quantum circuit to simulate any arbitrary unital channel with ancillas, but without intermediate measurements.

2.3 Quantum Algorithms

A generic quantum algorithm with time T and space $S = \log m$ is specified by T quantum channels $\Phi_1, \ldots, \Phi_T \in \mathcal{C}_{m,m}$, which might depend on the inputs. We also require the channels $\Phi_1, \ldots, \Phi_T$ to be efficiently constructible, whose meaning may differ for different types of quantum algorithms, and will be specified below.

The algorithm starts from the fixed initial state $\rho_0 = |0^S\rangle\langle 0^S|$, and in the i-th step applies Φ_i on the current state, so that the state after the i-th step can be described as

$$\rho_i = \Phi_i(\rho_{i-1}) = \Phi_i \circ \Phi_{i-1} \circ \cdots \circ \Phi_1(\rho_0).$$

At the end the first qubit of the final state ρ_T is measured in the computational basis of the first qubit, where the measurement can be represented as $M_0 = |0\rangle\langle 0| \otimes \mathbf{I}_{m/2}$. The quantum algorithm outputs 0 with probability $\mathrm{Tr}[\rho_T M_0]$, and 1 with probability $1 - \mathrm{Tr}[\rho_T M_0]$. The quantum algorithm is called unitary (resp. unital), if every channel Φ_i is unitary (resp. unital).

Quantum circuit

Fix a universal quantum gate set $\mathcal{G}$, for instance Hadamard and Toffoli gates [25], and let $\mathcal{G}_S$ be the set of gates in $\mathcal{G}$ on S qubits. Let $\mathcal{M}_S$ be the set of single-qubit measurements on S qubits.

When the input of the problem is from domain X, the quantum circuit is specified by a mapping $\Phi_{\mathrm{D}} : X \times [T] \to \mathcal{G}_S \cup \mathcal{M}_S$ such that $\Phi_{i+1} = \Phi_{\mathrm{D}}(x, i)$ for every $i \in [T]$, where $x \in X$ is the input, and Φ_{D} can be computed deterministically in time $O(T)$ and space $O(S)$. The quantum algorithm decides a function $f : X \to \{0, 1\}$ with error ε if:

$$\forall x \in X, \quad |\mathrm{Tr}[\rho_T M_0] - f(x)| \leq \varepsilon.$$

Now, $\mathsf{BQ_QL}$ is the class of boolean-function families where $f_n : \{0,1\}^n \to \{0,1\}$ can be decided by a quantum circuit with time $\mathrm{poly}(n)$, space $O(\log n)$ and error $1/3$. The function is further in the class $\mathsf{BQ_UL}$ if there is no intermediate measurements, i.e. the range of Φ_{D} is $\mathcal{G}_S$. We define $\mathsf{promiseBQ_QL}$ and $\mathsf{promiseBQ_UL}$ similarly, but the domain of each f_n can be a subset of $\{0,1\}^n$.

Quantum learning algorithm

For a quantum online learning algorithm with Γ being the set of samples, there exists a mapping $\Phi_{\mathrm{L}} : \Gamma \to \mathcal{C}_{m,m}$ such that $\Phi_i = \Phi_{\mathrm{L}}(z_i)$ where $z_i \in \Gamma$ is the sample received in the i-th step, and each entry of $K(\Phi_{\mathrm{L}}(z_i))$ can be computed deterministically in time $O(T)$ and space $O(S)$.

Let $\mathcal{P}(\Gamma)$ be the collection of all probability distributions over Γ. For any distribution $D \in \mathcal{P}(\Gamma)$, let D^T be T i.i.d copies of D, so that $z \sim D^T$ means that each sample z_i is independently drawn from D. Let $\mathcal{X}, \mathcal{Y}$ be two disjoint subsets of $\mathcal{P}(\Gamma)$. The quantum learning algorithm distinguishes $\mathcal{X}$ and $\mathcal{Y}$ with error ε if:

$$\forall D \in \mathcal{X}, \quad \mathop{\mathbf{E}}_{z \sim D^T}[\mathrm{Tr}[\rho_T M_0]] \geq 1 - \varepsilon$$
$$\forall D \in \mathcal{Y}, \quad \mathop{\mathbf{E}}_{z \sim D^T}[\mathrm{Tr}[\rho_T M_0]] \leq \varepsilon.$$

And for $\varepsilon = 1/3$, we simply say that the quantum learning algorithm distinguishes $\mathcal{X}$ and $\mathcal{Y}$.

Other specifications

Notice that even in the unitary algorithms where intermediate measurements are not generally allowed, a constant number of intermediate measurements are still available because of the principle of deferred measurements (see e.g. [19, Section 4.4]), which will only increase the time and space by a constant. This means the error ε in both definitions above can be safely amplified to any constant power, and the specific constant error $1/3$ can be replaced by any constant in $[0, 1/2)$.

For constructible functions $t(n) = \Omega(n)$ and $s(n) = \Omega(\log n)$, define $\mathsf{BPTISP}(t(n), s(n))$ as the class of boolean functions families that can be decided by a classical randomized algorithm with time $O(t(n))$ and space $O(s(n))$, and $\mathsf{promiseBPTISP}(t(n), s(n))$ accordingly. The classical randomized logspace class is defined as $(\mathsf{promise})\mathsf{BPL} = (\mathsf{promise})\mathsf{BPTISP}(\mathrm{poly}(n), \log(n))$.

Phase estimation

Given the dimension m and the error parameter $\varepsilon > 0$, the *phase estimation* circuit (see e.g. [19, Section 5.2]) acts on an input register of dimension m and an estimation register of dimension $2^\ell = O(1/\varepsilon)$. The circuit is with time $O(2^\ell)$ and space $O(\ell + \log m)$, and accesses 2^ℓ oracle calls to the controlled-U gates, where $U \in \mathcal{U}_m$ is an arbitrary unitary matrix. For each $j \in [2^\ell]$, define $\lambda(j) = 2j\pi/2^\ell - \pi$, and for any $\lambda \in [-\pi, \pi]$, let $J(\lambda) = \{j \in [2^\ell] \mid |\lambda(j) - \lambda| \leq \varepsilon\}$. If v is a unit eigenvector of U with eigenvalue $e^{i\lambda}$, the circuit maps $v \otimes |0^\ell\rangle$ to

$$\sum_{j=0}^{2^\ell - 1} \alpha_j v \otimes |j\rangle,$$

so that

$$\sum_{j \in J(\lambda)} |\alpha_j|^2 \geq 1 - \varepsilon^2.$$

Given a Hermitian contraction $H \in \mathbb{C}^{m \times m}$, let P_H be the above phase estimation circuit with $U = e^{iH}$, and $P_{H,\varepsilon}$ be the above phase estimation circuit where U is replaced with the Hamiltonian simulation circuit presented in [27] which differs from e^{iH} by an error of $2^{-\ell}\varepsilon$. Notice that $P_{H,\varepsilon}$ is a unitary quantum circuit with $\mathrm{poly}(m/\varepsilon)$ and space $O(\log(m/\varepsilon))$, and by Lemma 3 we have $\|P_{H,\varepsilon} - P_H\| \leq \varepsilon$.

Since H only has eigenvalues in $[-1, 1]$, we slightly modify the definition of $\lambda(j)$ so that it's truncated at ± 1, that is

$$\lambda(j) = \begin{cases} 2j\pi/2^\ell - \pi & \text{if } 2j\pi/2^\ell - \pi \in [-1, 1] \\ \mathrm{sgn}(2j\pi/2^\ell - \pi) & \text{otherwise} \end{cases}$$

which will only make $J(\lambda)$ larger for $\lambda \in [-1, 1]$.

Every unit eigenvector v of H with eigenvalue λ is also a unit eigenvector of e^{iH} with eigenvalue $e^{i\lambda}$. Therefore for any two unit eigenvectors u, v of H, we have

$$\big(u^\dagger \otimes \langle j|\big) P_H \big(v \otimes |0^\ell\rangle\big) = \begin{cases} \alpha_j & \text{if } u = v \\ 0 & \text{if } u \perp v. \end{cases}$$

In other words, since P_H is unitary,

$$\big(u^\dagger \otimes \langle 0^\ell|\big) P_H^{-1} \big(v \otimes |j\rangle\big) = \begin{cases} \overline{\alpha_j} & \text{if } u = v \\ 0 & \text{if } u \perp v. \end{cases}$$

That means the projection of $P_H^{-1}\big(v \otimes |j\rangle\big)$ onto $\mathbb{C}^m \otimes |0^\ell\rangle$ is along $v \otimes |0^\ell\rangle$ and has amplitude $\overline{\alpha_j}$. Combing the above observations we get the following lemma:

▶ **Lemma 4.** *Given a Hermitian contraction $H \in \mathbb{C}^{m\times m}$ and $\varepsilon > 0$, there is a unitary quantum circuit $P_{H,\varepsilon}$ with time $\mathrm{poly}(m/\varepsilon)$ and space $O(\log(m/\varepsilon))$ that is ε-close to a unitary operator P_H, which satisfies the following: There is a parameter $\ell = O(\log(1/\varepsilon))$, such that if v is a unit eigenvector of H with eigenvalue $\lambda \in [-1, 1]$, then*

$$P_H(v \otimes |0^\ell\rangle) = \sum_{j=0}^{2^\ell - 1} \alpha_j v \otimes |j\rangle, \text{ where } \sum_{j \in J(\lambda)} |\alpha_j|^2 \geq 1 - \varepsilon^2.$$

Moreover, for every $j \in [2^\ell]$,

$$P_H^{-1}(v \otimes |j\rangle) = \overline{\alpha_j} v \otimes |0^\ell\rangle + |\perp\rangle,$$

where $|\perp\rangle$ is a vector orthogonal to $\mathbb{C}^m \otimes |0^\ell\rangle$.

Pure State Preparation

Our results involve the simplest form of the *quantum state preparation* problem, which is to map the initial state $|0^S\rangle$ to a given pure state. With the efficient Solovay-Kitaev Theorem in [17], we have the following:

▶ **Lemma 5.** *Given $m = 2^S$, a unit vector $v \in \mathbb{C}^m$ and $\varepsilon > 0$, there is unitary quantum circuit Q_v on S qubits with time $O(m \cdot \mathrm{polylog}(1/\varepsilon))$ and space $O(\log(m/\varepsilon))$ such that $\|Q_v|0^S\rangle - v\|_2 \leq \varepsilon$.*

3 Quantum Implementations of Contractions

▶ **Lemma 6.** *Given a contraction $A \in \mathbb{C}^{m\times m}$ and $\varepsilon > 0$, there is a unitary quantum circuit Q_A with time $\mathrm{poly}(m/\varepsilon)$ and space $O(\log(m/\varepsilon))$, and a parameter $\ell = O(\log(1/\varepsilon))$, such that for unit vector v of dimension $4m$, $\|Q_A(v \otimes |0^\ell\rangle) - (V_A v) \otimes |0^\ell\rangle\|_2 \leq \varepsilon$, where*

$$V_A = \mathrm{diag}(U_A, U_{A^\dagger}) = \begin{pmatrix} A & \sqrt{\mathbf{I}_m - AA^\dagger} & & \\ \sqrt{\mathbf{I}_m - A^\dagger A} & -A^\dagger & & \\ & & A^\dagger & \sqrt{\mathbf{I}_m - A^\dagger A} \\ & & \sqrt{\mathbf{I}_m - AA^\dagger} & -A \end{pmatrix}$$

Proof. Let H be the Hermitian contraction $\begin{pmatrix} & A \\ A^\dagger & \end{pmatrix}$. Notice that

$$U_H = \begin{pmatrix} H & \sqrt{\mathbf{I}_{2m} - H^2} \\ \sqrt{\mathbf{I}_{2m} - H^2} & -H \end{pmatrix}$$
$$= \begin{pmatrix} & A & & \sqrt{\mathbf{I}_m - AA^\dagger} & \\ A^\dagger & & & & \sqrt{\mathbf{I}_m - A^\dagger A} \\ \sqrt{\mathbf{I}_m - AA^\dagger} & & & & -A \\ & \sqrt{\mathbf{I}_m - A^\dagger A} & & -A^\dagger & \end{pmatrix}$$

which differs from V_A only by permutations:

$$V_A = \begin{pmatrix} \mathbf{I}_m & & & \\ & & & \mathbf{I}_m \\ & \mathbf{I}_m & & \\ & & \mathbf{I}_m & \end{pmatrix} \cdot U_H \cdot \begin{pmatrix} & & \mathbf{I}_m & \\ \mathbf{I}_m & & & \\ & \mathbf{I}_m & & \\ & & & \mathbf{I}_m \end{pmatrix}$$

Since the permutations are only on two qubits, it suffices to implement U_H on v up to error ε.

Let $v = \begin{pmatrix} v_1 \\ v_2 \end{pmatrix}$ where both v_1 and v_2 are of dimension $2m$. Suppose H has the eigen decomposition $H = \sum_{k=1}^{2m} \lambda_k u_k^\dagger u_k$, and v_1, v_2 are decomposed into this eigenbasis as

$$v_1 = \sum_{k=1}^{2m} \omega_k^{(0)} u_k, \quad v_2 = \sum_{k=1}^{2m} \omega_k^{(1)} u_k, \quad \text{where } \sum_{k=1}^{2m} \left|\omega_k^{(0)}\right|^2 + \sum_{k=1}^{2m} \left|\omega_k^{(1)}\right|^2 = 1.$$

Since v can be written as $|0\rangle \otimes v_1 + |1\rangle \otimes v_2$, applying the phase estimation circuit P_{H,ε_1} in Lemma 4 on $v \otimes |0^\ell\rangle$ results in:

$$\sum_{k=1}^{2m} \sum_{j=0}^{2^\ell - 1} \omega_k^{(0)} \alpha_{j,k} |0\rangle \otimes u_k \otimes |j\rangle + \sum_{k=1}^{2m} \sum_{j=0}^{2^\ell - 1} \omega_k^{(1)} \alpha_{j,k} |1\rangle \otimes u_k \otimes |j\rangle + |\epsilon_1\rangle$$
$$= \sum_{k=1}^{2m} \sum_{j \in J(\lambda_k)} \omega_k^{(0)} \alpha_{j,k} |0\rangle \otimes u_k \otimes |j\rangle + \sum_{k=1}^{2m} \sum_{j \in J(\lambda_k)} \omega_k^{(1)} \alpha_{j,k} |1\rangle \otimes u_k \otimes |j\rangle + |\epsilon_2\rangle.$$

where for each k it holds $\sum_{j \in J(\lambda_k)} |\alpha_{j,k}|^2 \geq 1 - \varepsilon_1^2$. Here ε_1 is an error parameter to be determined later, and $\ell = O(\log(1/\varepsilon_1))$. The error vector $|\epsilon_1\rangle$ is introduced due to the difference between P_{H,ε_1} and P_H, and thus $\||\epsilon_1\rangle\|_2 \leq \|P_{H,\varepsilon_1} - P_H\| \leq \varepsilon_1$. The error vector $|\epsilon_2\rangle - |\epsilon_1\rangle$ is a weighted sum of $4m$ orthogonal error vectors, with lengths at most ε_1 and weights $\omega_k^{(0)}, \omega_k^{(1)}$, and thus has length at most ε_1. Therefore $\||\epsilon_2\rangle\|_2 \leq 2\varepsilon_1$.

Now apply the following unitary transformation on the first qubit and last ℓ qubits:

$$|0\rangle|j\rangle \to \lambda(j)|0\rangle|j\rangle + \sqrt{1 - \lambda(j)^2}|1\rangle|j\rangle$$
$$|1\rangle|j\rangle \to \sqrt{1 - \lambda(j)^2}|0\rangle|j\rangle - \lambda(j)|1\rangle|j\rangle$$

which gives

$$\sum_{k=1}^{2m} \sum_{j \in J(\lambda_k)} \omega_k^{(0)} \alpha_{j,k} \left[\lambda(j)|0\rangle + \sqrt{1 - \lambda(j)^2}|1\rangle\right] \otimes u_k \otimes |j\rangle$$
$$+ \sum_{k=1}^{2m} \sum_{j \in J(\lambda_k)} \omega_k^{(1)} \alpha_{j,k} \left[\sqrt{1 - \lambda(j)^2}|0\rangle - \lambda(j)|1\rangle\right] \otimes u_k \otimes |j\rangle + |\epsilon_3\rangle$$

This unitary transformation can be implemented as a serial combination of 2^ℓ single-qubit unitaries $U_{\lambda(j)}$ controlled by the last ℓ qubits representing j. Each one of them can be constructed up to error $2^{-\ell}\varepsilon_1$ in time polylog$(1/\varepsilon_1)$ and space $O(\log(1/\varepsilon_1))$ by [17, Theorem 7]. Therefore by Lemma 3 we have $\||\epsilon_3\rangle\|_2 \le \||\epsilon_2\rangle\|_2 + \varepsilon_1 \le 3\varepsilon_1$.

Finally applying the reverse phase estimation P^{-1}_{H,ε_1} gives the following state, where $|\perp\rangle$ is orthogonal to $\mathbb{C}^2 \otimes \mathbb{C}^{2m} \otimes |0^\ell\rangle$:

$$
\begin{aligned}
&\sum_{k=1}^{2m} \sum_{j\in J(\lambda_k)} |\alpha_{j,k}|^2 \omega_k^{(0)} \left[\lambda(j)|0\rangle + \sqrt{1-\lambda(j)^2}|1\rangle\right] \otimes u_k \otimes |0^\ell\rangle \\
&\quad + \sum_{k=1}^{2m} \sum_{j\in J(\lambda_k)} |\alpha_{j,k}|^2 \omega_k^{(1)} \left[\sqrt{1-\lambda(j)^2}|0\rangle - \lambda(j)|1\rangle\right] \otimes u_k \otimes |0^\ell\rangle + |\epsilon_4\rangle + |\perp\rangle \\
=&\sum_{k=1}^{2m} \sum_{j\in J(\lambda_k)} |\alpha_{j,k}|^2 \omega_k^{(0)} \left[\lambda_k|0\rangle + \sqrt{1-\lambda_k^2}|1\rangle\right] \otimes u_k \otimes |0^\ell\rangle \\
&\quad + \sum_{k=1}^{2m} \sum_{j\in J(\lambda_k)} |\alpha_{j,k}|^2 \omega_k^{(1)} \left[\sqrt{1-\lambda_k^2}|0\rangle - \lambda_k|1\rangle\right] \otimes u_k \otimes |0^\ell\rangle + |\epsilon_5\rangle + |\perp\rangle \\
=&\sum_{k=1}^{2m} \omega_k^{(0)} \left[\lambda_k|0\rangle + \sqrt{1-\lambda_k^2}|1\rangle\right] \otimes u_k \otimes |0^\ell\rangle \\
&\quad + \sum_{k=1}^{2m} \omega_k^{(1)} \left[\sqrt{1-\lambda_k^2}|0\rangle - \lambda_k|1\rangle\right] \otimes u_k \otimes |0^\ell\rangle + |\epsilon_6\rangle + |\perp\rangle \\
=&\sum_{k=1}^{2m} \omega_k^{(0)} \big[U_H(|0\rangle \otimes u_k)\big] \otimes |0^\ell\rangle + \sum_{k=1}^{2m} \omega_k^{(1)} \big[U_H(|1\rangle \otimes u_k)\big] \otimes |0^\ell\rangle + |\epsilon_6\rangle + |\perp\rangle \\
=&\big[U_H(|0\rangle \otimes v_1)\big] \otimes |0^\ell\rangle + \big[U_H(|1\rangle \otimes v_2)\big] \otimes |0^\ell\rangle + |\epsilon_6\rangle + |\perp\rangle \\
=&(U_H v) \otimes |0^\ell\rangle + |\epsilon_6\rangle + |\perp\rangle.
\end{aligned}
$$

Here $\||\epsilon_4\rangle\|_2 \le \||\epsilon_3\rangle\|_2 + \|P^{-1}_{H,\varepsilon_1} - P^{-1}_H\| \le 4\varepsilon_1$. Also, similar to the reasoning for $|\epsilon_2\rangle - |\epsilon_1\rangle$, since for every k, $1-\varepsilon_1^2 \le \sum_{j\in J(\lambda_k)} |\alpha_{j,k}|^2 \le 1$, and for every $j \in J(\lambda_k)$, $\|U_{\lambda(j)} - U_{\lambda_k}\|_2 \le |\lambda(j) - \lambda_k| \le \varepsilon_1$, we have

$$\||\epsilon_6\rangle\|_2 \le \||\epsilon_5\rangle\|_2 + \varepsilon_1^2 \le \||\epsilon_4\rangle\|_2 + \varepsilon_1 + \varepsilon_1^2 \le 6\varepsilon_1.$$

Finally, notice that both $(U_H v) \otimes |0^\ell\rangle$ and $(U_H v) \otimes |0^\ell\rangle + |\epsilon_6\rangle + |\perp\rangle$ are unit vectors, while $|\perp\rangle$ is orthogonal to $(U_H v) \otimes |0^\ell\rangle$, so we have

$$\big|\big((U_H v)^\dagger \otimes \langle 0^\ell|\big)\big((U_H v) \otimes |0^\ell\rangle + |\epsilon_6\rangle + |\perp\rangle\big)\big| = \big|1 + \big((U_H v)^\dagger \otimes \langle 0^\ell|\big)|\epsilon_6\rangle\big| \ge 1 - \||\epsilon_6\rangle\|_2,$$

which implies that $\||\epsilon_6\rangle + |\perp\rangle\|_2 \le \sqrt{2\||\epsilon_6\rangle\|_2}$. Therefore it suffices to take $\varepsilon_1 \le \varepsilon^2/12$, and the theorem follows. ◀

As a by product, when we take the contraction A in Lemma 6 to be unitary, we get the unitary implementation of any unitary matrix, with the number of ancillas only depending on the error:

▶ **Corollary 7.** *Given a unitary matrix $U \in \mathcal{U}_m$ and $\varepsilon > 0$, there is a unitary quantum circuit Q_U with time* poly(m/ε) *and space $O(\log(m/\varepsilon))$, and a parameter $\ell = O(\log(1/\varepsilon))$, such that for any unit vector v of dimension m, $\|Q_U(v \otimes |0^\ell\rangle) - (Uv) \otimes |0^\ell\rangle\|_2 \le \varepsilon$.*

Proof. Use the exact same circuit in Lemma 6 by adding two ancilla qubits to v initialized at $|00\rangle$. Notice that $V_U = \mathrm{diag}(U, -U^\dagger, U^\dagger, -U)$, and thus the output state is ε close to $[V_U(|00\rangle \otimes v)] \otimes |0^\ell\rangle = |00\rangle \otimes (Uv) \otimes |0^\ell\rangle$. Rearranging the order of qubits and the claim follows. ◀

Finally, for permutation matrices, we present a simple unitary implementation without any ancillas by decomposing it into transpositions.

▶ **Lemma 8.** *Given a permutation $\sigma \in S_m$ and $\varepsilon > 0$, there is a unitary quantum circuit U with time $\mathrm{poly}(m/\varepsilon)$ and space $O(\log(m/\varepsilon))$, such that $\|U - P_\sigma\| \le \varepsilon$, where $P_\sigma \in \{0,1\}^{m\times m}$ is the matrix representation of σ.*

4 Contraction Powering in Quantum Logspace

▶ **Definition 9** (Contraction Powering). *Given $m = 2^S$, a contraction $A \in \mathbb{C}^{m\times m}$, a positive integer T in unary, and two vectors $v, w \in \mathbb{C}^m$ with $\|v\|_2 = \|w\|_2 = 1$ as the input, it is promised that $|w^\dagger A^T v|^2$ is either in $[0, 1/3]$ or $[2/3, 1]$, and the goal of the* Contraction-Powering *problem is to distinguish between the two cases.*

▶ **Theorem 10.** *ContractionPowering $\in$ promiseBQ$_{\mathsf{U}}$L. Moreover, given the same input (m, A, T, v, w) but without the promise on $|w^\dagger A^T v|^2$, while also given an error parameter $\varepsilon > 0$, there is a unitary quantum circuit W with time $\mathrm{poly}(mT/\varepsilon)$ and space $S' = O(\log(mT/\varepsilon))$ such that $|\langle 0^{S'}|W|0^{S'}\rangle|^2$ is ε-close to $|w^\dagger A^T v|^2$.*

Proof. First, let Q_v and Q_w be the circuits preparing states v and w with error $\varepsilon/8$ in Lemma 5 respectively. Since

$$\left||\langle 0^S|Q_w^\dagger A^T Q_v|0^S\rangle|^2 - |w^\dagger A^T v|^2\right| \le 4\|Q_v|0^S\rangle - v\|_2 + 4\|Q_w|0^S\rangle - w\|_2 \le \varepsilon/2,$$

in the rest of the proof we can safely assume that $Q_v|0^S\rangle = v$ and $Q_w|0^S\rangle = w$ while halving ε.

Let $\ell = O(\log(T/\varepsilon))$ be the one in Lemma 6 with error parameter $(2T)^{-1}\varepsilon$. The circuit works on three parts of qubits: the counter register C of dimension $2T$, the vector register of dimension m, and ℓ ancilla qubits. The circuit starts by preparing $|0\rangle_C \otimes v \otimes |0^\ell\rangle$ by applying Q_v. Then repeat the following two steps for T times:

1. Apply V_A on the last two qubits of the timer register and the entire vector register by Lemma 6;
2. Apply the permutation $|0\rangle \to |0\rangle$, $|2T-2\rangle \to |1\rangle$, $|2T-1\rangle \to |2\rangle$, $|i\rangle \to |i+2\rangle$, $\forall i = 1, \ldots, 2T-3$. on the counter register by Lemma 8.

Finally, apply $Q_w^\dagger$ on the vector register and measure with the projection onto $|0\rangle_C \otimes |0^S\rangle \otimes |0^\ell\rangle$.

To prove the correctness of the algorithm, we first assume that all the implementations in Lemma 6 and Lemma 8 are errorless, i.e. the evolution is completely within the subspace $\mathbb{C}^{2T} \otimes \mathbb{C}^m \otimes |0^\ell\rangle$. Then it suffices to notice that V_A is block-diagonal, so that step 1 acts locally on the T subspaces spanned by $|2i\rangle_C$ and $|2i+1\rangle_C$. Therefore after the i-th application of V_A, the projection of the current state onto $|j\rangle_C$ is always 0 for $j \ge 2i$, and thus before each application of V_A, the projection onto $|1\rangle_C$ is always 0. So the state after the i-th repetition is $|0\rangle_C \otimes (A^i v) + |\perp\rangle$, where $|\perp\rangle$ is orthogonal to $|0\rangle_C$. The output probability is then

$$\left|\left(\langle 0|_C \otimes \langle 0^S|\right)\left(\mathbf{I}_{2T} \otimes U_w^\dagger\right)\left(|0\rangle_C \otimes (A^T v) + |\perp\rangle\right)\right|^2 = |w^\dagger A^T v|^2.$$

Now each step in the repetition introduces an error of $(2T)^{-1}\varepsilon$. Therefore, by Lemma 3, the total error of the unitary quantum circuit W, compared to the above ideal case, is at most ε. ◀

5 Equivalence of Unital and Unitary Quantum Logspace

5.1 Simulating Unital Quantum Logspace with Constant Error

▶ **Lemma 11.** *Given a unital quantum algorithm with time T and space $S = \log m$ specified by the natural representations $K(\Phi_1), \ldots, K(\Phi_T) \in \mathbb{C}^{m^2 \times m^2}$, and an error parameter $\varepsilon > 0$, there is a unitary quantum circuit with time $\mathrm{poly}(mT/\varepsilon)$ and space $O(\log(mT/\varepsilon))$, such that if the original unital circuit outputs 0 with probability p, then the unitary circuit outputs 0 with probability $\sin^2(p+\alpha)$, where $|\alpha| \le \varepsilon$.*

Proof. We can always assume that S is an odd number and $m \ge \max(4\varepsilon^{-1}, 8)$ by adding dummy dimensions. As each $K(\Phi_i)$ is a contraction, the following matrix A of dimension m^2T is also a contraction:

$$A = \begin{pmatrix} & & & & K(\Phi_T) \\ K(\Phi_1) & & & & \\ & K(\Phi_2) & & & \\ & & \ddots & & \\ & & & K(\Phi_{T-1}) & \end{pmatrix}$$

Since the final state of the unital quantum algorithm is $\rho_T = \Phi_T \circ \cdots \circ \Phi_1(\rho_0)$, we can rewrite the output probability of the unital quantum algorithm as

$$\begin{aligned} p = \mathrm{Tr}[\rho_T M_0] &= \mathrm{vec}(M_0)^\dagger \mathrm{vec}(\rho_T) = \mathrm{vec}(M_0)^\dagger K(\Phi_T) \cdots K(\Phi_1) \mathrm{vec}(\rho_0) \\ &= \left(\mathrm{vec}(M_0)^\dagger \otimes \langle 0|\right) A^T \left(\mathrm{vec}(\rho_0) \otimes |0\rangle\right) \end{aligned}$$

Let $v = \mathrm{vec}(\rho_0) \otimes |0\rangle$ which is already a unit vector. Since $\|\mathrm{vec}(M_0)\|_2 = \sqrt{m/2}$, let $w = \sqrt{\frac{2}{m}}\mathrm{vec}(M_0) \otimes |0\rangle$. Let ε_1 be the error parameter to be determined later. Theorem 10 constructs a unitary quantum algorithm W with time $\mathrm{poly}(mT/\varepsilon_1)$ and space $S' = O(\log(mT/\varepsilon_1))$, such that $|\langle 0^{S'}|W|0^{S'}\rangle|^2$ is ε_1-close to $2p^2/m$. Therefore $|\langle 0^{S'}|W|0^{S'}\rangle|$ is $\sqrt{\varepsilon_1}$-close to $\sqrt{\frac{2}{m}}p$.

Let

$$R = \left(\mathbf{I}_{S'} - 2W|0^{S'}\rangle\langle 0^{S'}|W^\dagger\right)\left(\mathbf{I}_{S'} - 2|0^{S'}\rangle\langle 0^{S'}|\right)$$

be the rotation on the subspace spanned by $|0^{S'}\rangle$ and $W|0^{S'}\rangle$, of degree $2\cos^{-1}|\langle 0^{S'}|W|0^{S'}\rangle|$. By the estimation

$$\frac{\pi}{2} - x - \frac{1}{4}x^3 \le \cos^{-1} x \le \frac{\pi}{2} - x, \forall x \in [0,1],$$

and since $(x+y)^3 \le 4(x^3+y^3)$ for non-negative x, y, it can be calculated that the degree of the rotation R is in the range

$$\left[\pi - 2\sqrt{\frac{2}{m}}p - 4\sqrt{\varepsilon_1} - \frac{4}{m}\sqrt{\frac{2}{m}},\ \pi - 2\sqrt{\frac{2}{m}}p + 2\sqrt{\varepsilon_1}\right].$$

Since S is an odd number, $k = \sqrt{m/8}$ is an integer. Applying R for k times will rotate $|0^{S'}\rangle$ by a degree of $k\pi - p - \alpha$, where $|\alpha| \leq \sqrt{2m\varepsilon_1} + 2m^{-1}$. Therefore the projective measurement of the state $R^k|0^{S'}\rangle$ onto the subspace orthogonal to $|0^{S'}\rangle$ outputs 0 with probability $\sin^2(p+\alpha)$. Let $\varepsilon_1 = (8m)^{-1}\varepsilon^2$, and notice that $2m^{-1} \leq \varepsilon/2$, so that we have $|\alpha| < \varepsilon$, and the circuit R^k is unitary with time $\mathrm{poly}(mT/\varepsilon)$ and space $O(\log(mT/\varepsilon))$. ◀

▶ **Theorem 12.** $\mathsf{BQ_QL} = \mathsf{BQ_UL}$, *and* $\mathsf{promiseBQ_QL} = \mathsf{promiseBQ_UL}$.

Proof. Clearly $\mathsf{BQ_QL} \supseteq \mathsf{BQ_UL}$, and $\mathsf{promiseBQ_QL} \supseteq \mathsf{promiseBQ_UL}$. To prove the other direction, notice that quantum circuits are unital, therefore by Lemma 11 with $\varepsilon = 0.01$ they can be simulated by unitary quantum circuits with polynomial time and logarithmic space. Since the original output probability p is promised to be in $[0, 1/3]$ or $[2/3, 1]$, the value of $\sin^2(p+\alpha)$ is in $[0, 0.12]$ or $[0.37, 1]$ respectively, and thus it suffices to perform a constant rounds of amplification in order to bring the error down to less than $1/3$. ◀

▶ Remark 13. Though we proved Theorem 12 via the contraction powering algorithm, the unitary quantum circuit that simulates a given quantum circuit with intermediate measurements can be more simply constructed without using Lemma 6. In details, given a channel Φ in the quantum circuit, we can directly write out the natural representations $K(\Phi)$, and apply the matrix on the vectorized density matrix $\mathrm{vec}(\rho)$:

- If Φ is a unitary quantum gate U, then $K(\Phi) = \overline{U} \otimes U$ which can be implemented by applying U and then $\overline{U}$;
- If Φ is a single-qubit measurement, then $K(\Phi)$ is a diagonal matrix with diagonal entries in $\{0, 1\}$. It can be implemented using a similar "permute and throw away" technique as in Theorem 10, which after applied T times increases the dimension (instead of the space!) by a factor of T.

And the resulting circuit can be amplified in the same way as in Lemma 11.

5.2 Simulating Unital Quantum Logspace with Small Error

Now we can improve the result in Lemma 11 to arbitrarily small error (namely the probability of outputting 0 is $(p+\alpha)$ instead of $\sin^2(p+\alpha)$). Interestingly, the improvement relies on a stronger version of Theorem 10, which in turn relies on Theorem 12. In a way, we use these results to improve themselves!

We start with the stronger version of Theorem 10, which outputs the numerical value of $|w^\dagger A^T v|^2$ instead of outputting 0 with such probability. Here the quantum circuit outputs a number by a final measurement over the computational basis.

▶ **Lemma 14.** *Given $m = 2^S$, a contraction $A \in \mathbb{C}^{m\times m}$, a positive integer T, two unit vectors $v, w \in \mathbb{C}^m$ and an error parameter $\varepsilon > 0$, there is a unitary quantum circuit with time* $\mathrm{poly}(mT/\varepsilon)$ *and space* $O(\log(mT/\varepsilon))$ *such that with probability* $1 - 2^{-\mathrm{poly}(mT/\varepsilon)}$*, it outputs* $|w^\dagger A^T v|^2$ *with additive error* ε*.*

Proof. Theorem 10 provides a unitary quantum circuit W with time $\mathrm{poly}(mT/\varepsilon)$ and space $O(\log(mT/\varepsilon))$ which outputs 0 with probability p such that $\left|p - |w^\dagger A^T v|^2\right| \leq \varepsilon/2$. By Marriott-Watrous amplification [16, Theorem 3.3], there is a quantum circuit W' with time $\mathrm{poly}(mT/\varepsilon)$ and space $O(\log(mT/\varepsilon))$ *with* intermediate measurements, that uses W and W^{-1} as sub-circuits, and with probability $1 - \delta = 1 - 2^{-\mathrm{poly}(mT/\varepsilon)}$ outputs a value $\tilde{p}$ such that $|\tilde{p} - p| \leq \varepsilon/4$.

Since the resulting circuit W' is not unitary, we would like to use Theorem 12 to compute unitarily each bit in the output value $\tilde{p}$ of W'. Furthermore, using the result in [5] that $\mathsf{BQ_UL} = \mathsf{Q_UL}(1 - 2^{-\mathrm{poly}(n)}, 2^{-\mathrm{poly}(n)})$ (which stands for unitary quantum logspace with exponentially small error) the total error probability can be reduced down to $2^{-\mathrm{poly}(mT/\varepsilon)}$. Assuming that every bit in $\tilde{p}$ is 0 with probability either in $[0, 1/3]$ or $[2/3, 1]$, then for $1 \leq i \leq \lceil \log(1/\varepsilon) \rceil + 2$, we let W_i be the unitary quantum circuit that computes the i-th bit of $\tilde{p}$ with exponentially small error. Ideally, the outputs of W_i combined together would ε-approximate $|w^\dagger A^T v|^2$.

However, the value $\tilde{p}$ outputted by the Marriott-Watrous amplification might be different in each W_i, so the final approximation assembled can be totally wrong (for instance, when $p = 0.5$, the outputs $\tilde{p} = \overline{0.1000\ldots}$ and $\tilde{p} = \overline{0.0111\ldots}$ might be assembled to $\overline{0.1111\ldots}$). Moreover, the error reduction in [5] may have unpredictable results, as the promises on the distributions of the bits in $\tilde{p}$ are not guaranteed (again when $p = 0.5$, the most significant bit of $\tilde{p}$ is equally distributed on 0 and 1).

Fortunately, we can solves both problems by computing from the most significant bit to the least significant bit. We maintain a value $q \in [0, 1]$ which is initialized to 0. For each $i = 1$ to $\lceil \log(1/\varepsilon) \rceil + 2$ do the following: Run the modified circuit W_i which outputs the i-th bit of $(\tilde{p} - q)$ instead of $\tilde{p}$. To deal with case when $\tilde{p} - q$ is outside of $[0, 2^{-i+1})$, if $\tilde{p} - q < 0$ it outputs 0, and if $\tilde{p} - q \geq 2^{-i+1}$ it outputs 1. Let the output bit be b_i and update q to $q + b_i \cdot 2^{-i}$.

We claim that with probability $1 - 2^{-\mathrm{poly}(mT/\varepsilon)}$, $|q - p| \leq \varepsilon/2$. First notice that, if every bit in $\tilde{p}$ is 0 with probability in $[0, 2\delta] \cup [1 - 2\delta, 1]$, then the error reduction will work as intended, while with probability $1 - O(\delta \log(1/\varepsilon)) = 1 - 2^{-\mathrm{poly}(mT/\varepsilon)}$ the value $\tilde{p}$ is the same in each circuit W_i, so that q is also the same as $\tilde{p}$.

Now let i be the first index such that the i-th bit of $\tilde{p}$ is 0 with probability in $[2\delta, 1 - 2\delta]$. As the Marriott-Watrous amplification outputs incorrectly with probability at most δ, it means that there are two valid outputs $\tilde{p}_1$ and $\tilde{p}_2$, both are $\varepsilon/4$-close to p, and they coincide in the first $i - 1$ bits but differs at the i-th bit. Let q_i be the value of q at that step, which consists of the first $i - 1$ bits of $\tilde{p}_1$ and $\tilde{p}_2$, then $|q_i + 2^{-i} - p| \leq \varepsilon/4$. Therefore the remaining bits of q could only be $\overline{011\ldots11}$, $\overline{100\ldots00}$ or $\overline{100\ldots01}$, which means $|q_i + 2^{-i} - q| \leq \varepsilon/4$ and thus $|q - p| \leq \varepsilon/2$. Notice that on the i-th (and the last bit when $b_i = 1$) the error reduction may fail and arbitrarily output 0 or 1, but it does not matter as both 0 and 1 are viable in these cases.

As a conclusion, the value q is an ε-approximation of $|w^\dagger A^T v|^2$ with probability $1 - 2^{-\mathrm{poly}(mT/\varepsilon)}$. The above circuit that outputs q is clearly with time $\mathrm{poly}(mT/\varepsilon)$ and space $O(\log(mT/\varepsilon))$ as we use constructions in Theorem 12 and [5]. Finally, the the circuit is unitary since the $O(\log(1/\varepsilon))$ measurements that output b_i's can be deferred, and each W_i can be uncomputed by implementing the circuit in reverse. ◀

▶ **Corollary 15.** *Given $m = 2^S$, a contraction $A \in \mathbb{C}^{m \times m}$, a positive integer T, two unit vectors $v, w \in \mathbb{C}^m$ and an error parameter $\varepsilon > 0$, there is a unitary quantum circuit with time $\mathrm{poly}(mT/\varepsilon)$ and space $O(\log(mT/\varepsilon))$ such that with probability $1 - 2^{-\mathrm{poly}(mT/\varepsilon)}$, it outputs $w^\dagger A^T v$ with additive error ε.*

Proof. Let $A_1 = \begin{pmatrix} A & \\ & 1 \end{pmatrix}$, $v_1 = \begin{pmatrix} v/\sqrt{2} \\ 1/\sqrt{2} \end{pmatrix}$, $v_1' = \begin{pmatrix} v/\sqrt{2} \\ \mathrm{i}/\sqrt{2} \end{pmatrix}$ and $w_1 = \begin{pmatrix} w/\sqrt{2} \\ 1/\sqrt{2} \end{pmatrix}$. Since we have

$$w^\dagger A^T v = \frac{1}{2}\left(4|w_1^\dagger A_1^T v_1|^2 - |w^\dagger A^T v|^2 - 1\right) + \frac{\mathrm{i}}{2}\left(4|w_1^\dagger A_1^T v_1'|^2 - |w^\dagger A^T v|^2 - 1\right),$$

computing $|w^\dagger A^T v|^2$, $|w_1^\dagger A_1^T v_1|^2$ and $|w_1^\dagger A_1^T v_1'|^2$ each up to error $\varepsilon/2$ gives $w^\dagger A^T v$ with error ε. ◀

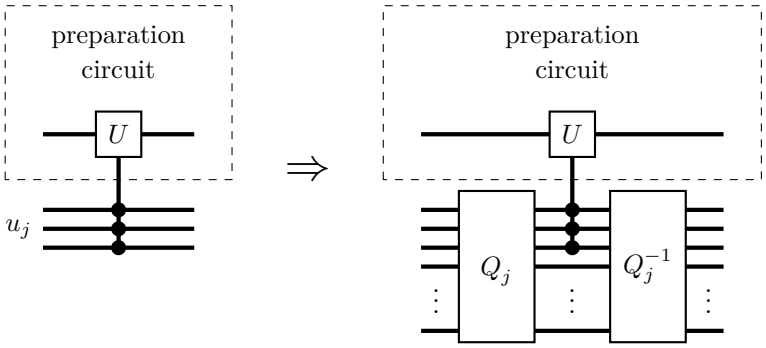

Figure 1 The quantum operator U in the preparation circuit controlled by an entry u_j of u, in binary representation with classical bits. We replace the classical control by first implementing the circuit Q_j, applying the controlled-U operator, and implementing Q_j in reverse.

Notice that one can instead achieve $1/\text{poly}(mT/\varepsilon)$ error probability without using the exponential error reduction in [5], by simply repeating the decision circuit in $\mathsf{BQ_UL}$ for $O(\log(mT/\varepsilon))$ rounds. Nevertheless, it is enough for proving the following theorem, which states that unitary quantum circuits can simulate any unital quantum algorithm by computing its output distribution with arbitrarily small error.

▶ **Theorem 16.** *Given a unital quantum algorithm with time T and space $S = \log m$ specified by the natural representations $K(\Phi_1), \ldots, K(\Phi_T) \in \mathbb{C}^{m^2 \times m^2}$, where $\rho_T = \Phi_T \circ \Phi_{T-1} \circ \cdots \circ \Phi_1(|0^S\rangle\langle 0^S|)$ is its final state, a multi-outcome measurement $\{M_0, \ldots, M_{r-1}\}$ over the computational basis, and an error parameter $\varepsilon > 0$, there is a unitary quantum circuit W with time $\text{poly}(mT/\varepsilon)$ and space $S' = O(\log(mT/\varepsilon))$ such that if $w \in \mathbb{C}^{2^{S'}}$ is the vector representation of $W|0^{S'}\rangle$ in computational basis, for every $j \in [r]$ it holds that $\left||w_j|^2 - \text{Tr}[\rho_T M_j]\right| \leq \varepsilon$.*

Proof. For every $j \in [r]$, let m_j be the dimension of the subspace that M_j projects onto. In other words, $m_j = \|\text{vec}(M_j)\|_2^2$. As in the proof of Lemma 11, we can construct a contraction $A \in \mathbb{C}^{m^2T \times m^2T}$ and unit vectors $v, w \in \mathbb{C}^{m^2T}$ such that $w^\dagger A^T v = \text{Tr}[\rho_T M_j]/\sqrt{m_j}$. By Corollary 15, for every $j \in [r]$ there is a unitary quantum circuit Q_j with time $\text{poly}(mT/\varepsilon)$ and space $O(\log(mT/\varepsilon))$ such that with probability $1 - 2^{-\text{poly}(mT/\varepsilon)}$, it gives an $(2m)^{-3}\varepsilon^2$-approximation of $\text{Tr}[\rho_T M_j]/\sqrt{m_j}$, which implies an $(2m)^{-1}\varepsilon$-approximation of $\sqrt{\text{Tr}[\rho_T M_j]}$.

Consider the preparation circuit constructed in Lemma 5 which prepares the unit vector

$$u = \left(\sqrt{\text{Tr}[\rho_T M_0]}, \sqrt{\text{Tr}[\rho_T M_1]}, \ldots, \sqrt{\text{Tr}[\rho_T M_{r-1}]}\right).$$

with error $\varepsilon/2$. By construction, the preparation circuit can be viewed as a composition of $r-1$ unitary operators, each controlled by a different entry in u. Since u is not explicitly given, we instead control these unitary operators with the output qubits of Q_j, but without measurements. Each circuit Q_j is applied in reverse after the control, so that the space can be reused.

It is clear that the entire circuit is with time $\text{poly}(mT/\varepsilon)$ and space $O(\log(mT/\varepsilon))$. The error introduced by replacing each of th $r-1$ unitary operators is at most $(2m)^{-1}\varepsilon + 2^{-\text{poly}(mT/\varepsilon)}$, therefore the total error is at most $\varepsilon/2 + (r-1)((2m)^{-1}\varepsilon + 2^{-\text{poly}(mT/\varepsilon)}) < \varepsilon$. See Figure 1 for an illustration. ◀

The measurement $\{M_0, \ldots, M_{r-1}\}$ in Theorem 16 could be over any subset of the qubits. In particular, when it is a two-outcome measurement over one qubit, we have the following direct corollary which improves Lemma 11:

▶ **Corollary 17.** *Given a unital quantum algorithm with time T and space $S = \log m$ specified by the natural representations $K(\Phi_1), \ldots, K(\Phi_T) \in \mathbb{C}^{m^2 \times m^2}$, and an error parameter $\varepsilon > 0$, there is a unitary quantum circuit with time $\mathrm{poly}(mT/\varepsilon)$ and space $O(\log(mT/\varepsilon))$, such that if the original unital circuit outputs 0 with probability p, then the unitary circuit outputs 0 with probability $p + \alpha$, where $|\alpha| \leq \varepsilon$.*

6 Powering of Non-Contraction Matrices

In this section we extend the result of Corollary 15 to matrices that may not necessarily be contractions. We state the result for general square matrices, while the additive error can be exponentially large with respect to the spectral norm:

▶ **Theorem 18.** *Given $m = 2^S$, an arbitrary matrix $A \in \mathbb{C}^{m \times m}$, a positive integer T, two unit vectors $v, w \in \mathbb{C}^m$ and an error parameter $\varepsilon > 0$, there is a unitary quantum circuit W with time $\mathrm{poly}(mT/\varepsilon)$ and space $O(\log(mT/\varepsilon))$ such that with probability $1 - 2^{-\mathrm{poly}(mT/\varepsilon)}$, it outputs $w^\dagger A^T v$ with additive error $\varepsilon \cdot \max(1, \|A\|^T)$.*

Proof. Ideally, we would like to apply the contraction powering algorithm on $A/\|A\|$ and multiply the result by $\|A\|^T$. However, the current best quantum algorithm for computing the spectral norm is [27, Theorem 5.2] which approximates $\|A\|$ with additive error ε_1 within time $\mathrm{poly}(m/\varepsilon_1)$ and space $O(\log(m/\varepsilon_1))$ and only works for contractions A. We use this algorithm to approximate $\|A\|$ for arbitrary A with multiplicative error as follows[1]: First compute $\|A\|_{\mathrm{F}}$ in $O(\log m + \log \|A\|_F) = O(\log(m\|A\|_2))$ space. Notice that $A/\|A\|_{\mathrm{F}}$ is a contraction since $\|A\|_{\mathrm{F}} \geq \|A\|$. Therefore, let σ be the approximation of $\|A/\|A\|_{\mathrm{F}}\|$ with additive error ε_1 by [27], then $\sigma\|A\|_F$ approximates $\|A\|$ since

$$\left|\sigma\|A\|_F - \|A\|\right| = \|A\|_F \cdot \left|\sigma - \left\|A/\|A\|_F\right\|\right| \leq \sqrt{m}\varepsilon_1\|A\|.$$

Let $\varepsilon_1 = (3T\sqrt{m})^{-1}$, and let $\alpha = (1 - \sqrt{m}\varepsilon_1)^{-1}\sigma\|A\|_F$. Then

$$\|A\| \leq \alpha \leq \frac{1 + \sqrt{m}\varepsilon_1}{1 - \sqrt{m}\varepsilon_1}\|A\| \leq (1 + T^{-1})\|A\|.$$

Now let $\widetilde{A} = \alpha^{-1}A$ so that $\widetilde{A}$ is always a contraction. Applying the contraction powering algorithm in Corollary 15 on $\widetilde{A}$ with error $\varepsilon/3$ results in a unitary quantum circuit with time $\mathrm{poly}(mT/\varepsilon)$ and space $O(\log(mT/\varepsilon))$ which outputs $w^\dagger \widetilde{A}^T v$ with additive error $\varepsilon/3$. Multiplying it by α^T gives the desired result, while the error is at most $\alpha^T\varepsilon/3 \leq \varepsilon \cdot \|A\|^T$. ◀

7 Classical Simulation of Quantum Learning

7.1 Equivalence of Classical Simulation in Decision and Learning

▶ **Theorem 19.** *If there are functions $t(\cdot,\cdot)$ and $s(\cdot,\cdot)$, such that every unitary quantum learning algorithm with time T and space S can be simulated classically with time $t(T,S)$ and space $s(T,S)$, then*

$$\mathsf{promiseBQ_UL} \subseteq \mathsf{promiseBPTISP}(t(\mathrm{poly}(n), O(\log n)), s(\mathrm{poly}(n), O(\log n))).$$

[1] During the analysis we assume without loss of generality that $\|A\| \geq 1$, since otherwise it can always be relaxed to 1 whenever necessary.

Specifically, if every unitary quantum learning algorithm in time T and space S can be simulated classically with time $\mathrm{poly}(2^S T)$ *and space* $O(S + \log T)$*, then* $\mathsf{promiseBQ_UL} = \mathsf{promiseBPL}$.

Proof. Suppose that we have a unitary quantum circuit with time $T(n) = \mathrm{poly}(n)$ and space $S(n) = O(\log n)$ that decides a partial function $f : X \to \{0,1\}$, where $X \subseteq \{0,1\}^n$. Let $\Phi_{\mathrm{D}}(x,i)$ be the unitary gate at the i-th step of the decision algorithm with input x, which can be constructed in time $\mathrm{poly}(n)$ and space $O(\log n)$.

We can convert the quantum circuit to a learning algorithm as follows. Use X directly as the sample space, while the samples are always constant x for some fixed $x \in X$. The learning task is to distinguish between $x \in f^{-1}(0)$ or $x \in f^{-1}(1)$. Upon receiving the sample x, the learning algorithm simply applies the following unitary operator on $\mathbb{C}^{2^{S(n)}} \otimes \mathbb{C}^{T(n)}$:

$$|\psi\rangle|i\rangle \to \big(\Phi_{\mathrm{D}}(x,i)|\psi\rangle\big)|(i+1) \bmod T(n)\rangle$$

so that after $T(n)$ steps it computes in the first register the same state as in the quantum circuit. Therefore it computes $f(x)$ and distinguishes between the two cases. Using the premises, we have a classical learning algorithm with time $t(\mathrm{poly}(n), O(\log n))$ and space $s(\mathrm{poly}(n), O(\log n))$ that accomplishes the same task. The classical learning algorithm can be viewed as a randomized decision algorithm that computes $f(x)$ by self-constructing the stochastic matrices in the same time and space. ◀

▶ **Theorem 20.** *If* $\textsc{ContractionPowering} \in \mathsf{promiseBPTISP}(t(n), s(n))$*, where* $t(n) \geq \Omega(n)$ *and* $s(n) \geq \Omega(\log n)$*, then every unital quantum learning algorithm with time T and space S can be simulated classically with time* $t(\mathrm{poly}(2^S T))$ *and space* $s(\mathrm{poly}(2^S T))$.

Proof. Suppose that we have a unital quantum learning algorithm with time T and space $S = \log m$ that distinguishes between two distribution families $\mathcal{X}$ and $\mathcal{Y}$. Let $\Phi_{\mathrm{L}}(z)$ be the unital channel applied when receiving the sample z. With the sample distribution D, let $A = \mathop{\mathbf{E}}_{z\sim D}[K(\Phi_{\mathrm{L}}(z))]$. We note that A is a contraction matrix of dimension $m^2 \times m^2$ as every $K(\Phi_{\mathrm{L}}(z))$ is a contraction. Similar to proof of Lemma 11, the probability of the learning algorithm outputting 0 is

$$\mathop{\mathbf{E}}_{z\sim D^T}\left[\mathrm{vec}(M_0)^\dagger K(\Phi_T)\cdots K(\Phi_1)\mathrm{vec}(\rho_0)\right] = \mathrm{vec}(M_0)^\dagger A^T \mathrm{vec}(\rho_0).$$

What's different from Lemma 11 is that here A is not explicitly given. Instead, by Lemma 1, each time an entry of A is requested, it takes $\mathrm{poly}(mT)$ samples z to approximate the entry to at most $O((m^{2.5}T)^{-1})$ error, so that the approximated matrix $\widetilde{A}$ differs from the actual matrix A by at most $\|\widetilde{A} - A\| \leq O((\sqrt{m}T)^{-1})$. By Lemma 3 it means that $\|\widetilde{A}^T - A^T\| \leq O(m^{-1/2})$. Therefore applying the contraction powering algorithm on $\widetilde{A}$ gives a classical learning algorithm that distinguishes $\mathcal{X}$ and $\mathcal{Y}$ in time $t(\mathrm{poly}(mT))$ and space $s(\mathrm{poly}(mT))$.

The above scheme has two problems. First, a fixed matrix $\widetilde{A}$ cannot be directly stored, and if every time the same entry is requested, the entry is approximated as the average of a different batch of samples, it may result in different requested values for the same entry (even though the difference is small with high probability), similar to the problem in Lemma 14. However, unlike the case in Lemma 14, here the classical contraction powering algorithm is not explicitly given, and may not be robust against changing inputs.

The solution to this problem is the *shift and truncate* method by Saks and Zhou[23], which has found numerous applications in space-bounded algorithms [27] and derandomizations [3, 11]. Concretely, let $P = t(\mathrm{poly}(mT))$ be the largest number of possible requests to entries

of A in the contraction powering algorithm, and take a uniform random number $\zeta \in [8L]$. For simplicity let $L = 12\sqrt{2m}T$ and $N = 24m^{2.5}T$. When the entry A_{jk} is requested, the algorithm takes $t(\mathrm{poly}(mT))$ samples z_i and calculate the average value a of the (j,k)-entries of $K(\Phi_{\mathrm{L}}(z_i))$, so that $|a - A_{jk}| < \frac{1}{8NP}$ with probability at least $1 - 2^{-P}$. The value fed back for the request is

$$\widetilde{A}_{jk} = \frac{1}{N}\left\lfloor N \cdot \mathrm{Re}(a) + \frac{\zeta}{8P} \right\rfloor + \frac{\mathrm{i}}{N}\left\lfloor N \cdot \mathrm{Im}(a) + \frac{\zeta}{8P} \right\rfloor.$$

We claim that with high probability, this value coincides with the fixed value

$$\frac{1}{N}\left\lfloor N \cdot \mathrm{Re}(A_{jk}) + \frac{\zeta}{8P} \right\rfloor + \frac{\mathrm{i}}{N}\left\lfloor N \cdot \mathrm{Im}(A_{jk}) + \frac{\zeta}{8P} \right\rfloor.$$

For the real part, as $|N \cdot \mathrm{Re}(a) - N \cdot \mathrm{Re}(A_{jk})| < \frac{1}{8P}$, there is at most one possibility for ζ such that $\left\lfloor N \cdot \mathrm{Re}(a) + \frac{\zeta}{8P} \right\rfloor \neq \left\lfloor N \cdot \mathrm{Re}(A_{jk}) + \frac{\zeta}{8P} \right\rfloor$, which is of probability $\frac{1}{8P}$, and the same holds for the imaginary part. By the union bound on the bad events during all L requests, with probability

$$1 - \left(2^{-P} + \frac{1}{4P}\right) P \geq \frac{2}{3}$$

for every (j,k) the value $\widetilde{A}_{jk}$ are always the same, and $|\widetilde{A}_{jk} - A_{jk}| \leq \frac{\sqrt{2}}{N} = \frac{1}{m^2 L}$, so $\|\widetilde{A} - A\| \leq L^{-1}$.

The second problem is that because of the approximation error, $\widetilde{A}$ might not be a contraction matrix. This is easily fixed by using the matrix $\widetilde{A}' = \frac{L}{L+1} \cdot \widetilde{A}$ as the input. Since $\|\widetilde{A} - A\| \leq L^{-1}$ with probability $2/3$, it is implied that

$$\|\widetilde{A}'\| = \frac{L}{L+1} \cdot \|\widetilde{A}\| \leq \frac{L}{L+1} \cdot \left(1 + L^{-1}\right) = 1,$$

$$\|\widetilde{A}' - A\| \leq \|\widetilde{A} - A\| + \frac{1}{L+1}\|\widetilde{A}\| \leq \frac{2}{L}.$$

Since $\|\mathrm{vec}(M_0)\|_2 = \sqrt{m/2}$, $\|\mathrm{vec}(\rho_0)\|_2 = 1$, in this case we have (by Lemma 3)

$$\left|\mathrm{vec}(M_0)^\dagger (\widetilde{A}'^T - A^T)\mathrm{vec}(\rho_0)\right| \leq \frac{\sqrt{2m}T}{L} = \frac{1}{12}.$$

Since the error of the original quantum learning algorithm can be amplified to $1/4$ so that $\mathrm{vec}(M_0)^\dagger A^T \mathrm{vec}(\rho_0)$ is in $[0, 1/4]$ or $[3/4, 1]$, we conclude that with probability $5/6$,

$$\mathrm{vec}(M_0)^\dagger \widetilde{A}'^T \mathrm{vec}(\rho_0) \in [0, 1/3] \text{ or } [2/3, 1]$$

Therefore the two cases can be distinguished by the classical contraction powering algorithms on $\widetilde{A}'$, and it can be repeated for constant rounds so that the total error rate is brought down to $1/3$. ◀

▶ **Corollary 21.** *If* ContractionPowering $\in$ promiseBPL*, then every unital quantum learning algorithm with time T and space S can be simulated classically with time* $\mathrm{poly}(2^S T)$ *and space* $O(S + \log T)$*.*

Since by Theorem 10 we already know ContractionPowering $\in$ promiseBQ$_{\mathsf{U}}$L, combined with Theorem 19, we get the equivalence between efficient simulations of decision problems and learning problems:

▶ **Theorem 22.** *Every (unital) quantum learning algorithm with time T and space S can be simulated classically with time* $\mathrm{poly}(2^S T)$ *and space* $O(S + \log T)$*, if and only if* $\mathsf{promiseBQ_UL} = \mathsf{promiseBPL}$.

Also, as we already know $\mathsf{promiseBQ_UL} \subseteq \mathsf{promiseL^2}$ [28], we have the following unconditional result:

▶ **Corollary 23.** *Every unital quantum learning algorithm with time T and space S can be simulated classically with time* $2^{O(S^2+\log^2 T)}$ *and space* $O(S^2 + \log^2 T)$.

7.2 Classical Simulation when One Family is Singleton

▶ **Theorem 24.** *If $\mathcal{Y} = \{Y\}$, then any quantum learning algorithm that distinguishes between $\mathcal{X}$ and $\mathcal{Y}$ within time T and space S can be simulated classically in time* $\mathrm{poly}(2^S T)$ *and space* $O(S + \log T)$.

Abstract

Online bipartite matching with edge arrivals remained a major open question for a long time until a recent negative result by Gamlath et al., who showed that no online policy is better than the straightforward greedy algorithm, i.e., no online algorithm has a worst-case competitive ratio better than 0.5. In this work, we consider the bipartite matching problem with edge arrivals in a natural stochastic framework, i.e., Bayesian setting where each edge of the graph is independently realized according to a known probability distribution.

We focus on a natural class of prune & greedy online policies motivated by practical considerations from a multitude of online matching platforms. Any prune & greedy algorithm consists of two stages: first, it decreases the probabilities of some edges in the stochastic instance and then runs greedy algorithm on the pruned graph. We propose prune & greedy algorithms that are 0.552-competitive on the instances that can be pruned to a 2-regular stochastic bipartite graph, and 0.503-competitive on arbitrary stochastic bipartite graphs. The algorithms and our analysis significantly deviate from the prior work. We first obtain analytically manageable lower bound on the size of the matching, which leads to a non-linear optimization problem. We further reduce this problem to a continuous optimization with a constant number of parameters that can be solved using standard software tools.

1 Introduction

Matching theory is a central area in combinatorial optimization with a big range of applications [28]. Many market models for jobs, commercial products, dating, healthcare, etc., rely on matching as a fundamental mathematical primitive. These examples often aim to describe environments that evolve in real time and thus are relevant to the area of online bipartite matching initiated by a seminal paper of Karp, Vazirani and Vazirani [26]. In this work they consider the one-sided vertex-arrival model within the competitive analysis framework, i.e., vertices only on one side of a bipartite graph appear online and each new vertex reveals all its

incident edges. The algorithm immediately and irrevocably decides to which vertex (if any) the new arrival is matched. They studied the worst-case performance of online algorithms and solved the problem optimally with an elegant $(1 - 1/e)$-competitive algorithm, named RANKING. Later, the proof of the result has been simplified by a series of papers [6, 19, 13].

The interest in matching models and online bipartite matching problems in particular has been on the rise since a decade ago due to emergence of the internet advertisement industry and online market platforms [32]. With the large amount of available data on many online platforms from the day-to-day user activities, more recent literature has shifted more towards *stochastic* models, also called Bayesian in the economically oriented work. In particular, Feldman, Mehta, Mirrokni and Muthukrishnan [16] proposed a stochastic model in which online vertices are drawn i.i.d. from a known distribution and improved[1] the competitive ratio of the classic result by Karp, Vazirani and Vazirani to 0.67. The competitive ratio has been further improved by a series of papers [3, 30, 24] to 0.706. Another line of work [25, 29] studied the model in which online vertices arrive in a random order and showed that the RANKING algorithm is 0.696-competitive.

The aforementioned results and other works, e.g., [33, 7, 12, 36, 18, 22, 23, 2], have made remarkable progress on different online matching settings with vertex arrivals, i.e., models where all incident edges of a new vertex are reported to the algorithm. However, more general arrival models are much less understood. E.g., one of the most natural and nonrestrictive extensions of online bipartite matching to the model where edges appear online and must be immediately matched or discarded was not known to have a competitive ratio better than the greedy algorithm for a long time. Only a recent negative result by Gamlath et al. [18] closed this tantalizing question showing that no online algorithm can be better than 0.5-competitive in the worst case. Algorithms with better performance are only known for quite special family of graphs, e.g., bounded-degree graphs [8] and forests [32, 8], or under strong assumptions on the edge arrival order, e.g., random arrival order [21].

It might seem that the edge-arrival model is too general to allow non-trivial theoretical results without strong assumptions on the instance. Thus it is not very surprising that practically motivated models do not usually consider online setting with edge arrivals. On the other hand, most of the specific applications posses additional structure and extra information that might allow to break the theoretical barrier. The edge-arrival online model besides pure theoretical interest and clean mathematical formulation, is indeed relevant to practical problems not unlike the examples we discuss below.

Practical Motivation: Edge Arrivals

Imagine any online matching platform for job search, property market, or even online dating. All these instances can be viewed as online matching processes in bipartite graphs. They also share a common trait that the realization of any particular edge is not instantaneous, often consumes significant effort and time from one or both sides of the potential match, and may exhibit complex concurrent behavior across different parties of the market. The platform can be thought of as an online matching algorithm, if it has any degree of control to intervene in the process of edge formation at any point.[2] However, the platform does not have enough power to control the order in which edges are realized. Hence, using arbitrary edge arrival order seems to be an appropriate modeling choice in these situations.

---

[1] Their result holds under the assumption that the expected number of vertices for each type is an integer.

[2] Even if the platform cannot directly prohibit an edge formation or disallow certain matches, it usually can affect outcome indirectly by restricting access/information exchange between certain pairs of agents, so that they never consider each other as potential matches.

Another notable feature of these instances is the vast amount of historical data accumulated over time. The data enables the platform to estimate the probability of a potential match between any pair of given agents. Thus the Bayesian (stochastic) approach widely adapted in economics seems to be another reasonable modeling choice. This raises the following natural question that to the best of our knowledge has not been considered before: *Is there an online matching algorithm for stochastic bipartite graphs with edge arrivals that is better than greedy?* This question is the main focus of our work. Let us first specify the model in more details.

Our Model: Edge Arrivals in Stochastic Graphs

We call our model *online stochastic matching with edge arrivals*. It is a relaxation of the standard edge-arrival model that performs on a random bipartite graph. In particular, we assume the input graph G is stochastic. That is, each edge e exists (is realized) in G independently with probability p_e and the probabilities $(p_e)_{e\in E(G)}$ are known to the online algorithm.[3] The algorithm observes a sequence of edges arriving online in a certain (unknown) order. Upon the arrival of an edge e, we observe the realization of e and if e exists, then the algorithm immediately and irrevocably decides whether to add e to the matching. We assume that the arrival order of the edges is chosen by an *oblivious* adversary, i.e., an adversary who does not observe the realization of the edges and algorithm's decisions, which is a standard assumption in the literature on online algorithms in stochastic settings (see, e.g., [27]). We compare the expected performance of our algorithm with the maximum matching in hindsight, i.e., the expected size of a maximum matching over the randomness of all edges.

1.1 Comparison with Other Stochastic Models

Our model is closely connected to two existing theoretical lines of works on stochastic bipartite matching and prophet inequality in algorithmic game theory. Below we compare our model with the most relevant results in each of these lines of works.

Stochastic Probing Model

It has the same ingredient as our model: the underlying stochastic graph. That is, the input is also a bipartite graph with the stochastic information on existence probability of every edge e. On the other hand, it is an offline model under the query-commit framework, i.e., the algorithm can check the existence of the edges in any order. However, if an edge exists, it has to be included into the solution. For this model, an adaptation of the RANKING algorithm by Karp, Vazirani and Vazirani is $(1-1/e)$-competitive. Costello, Tetali and Tripathi [11] provided a 0.573-approximation algorithm on general (non-bipartite) graphs and showed that no algorithm can have an approximation ratio larger than 0.898. Recently, Gamlath, Kale and Svensson [17] designed a $(1-1/e)$-approximation algorithm for the edge-weighted version of this problem.

[3] Note that some independence assumption across the edges is necessary. If we allow arbitrary probability distribution over the sets of realized edges, the model would be as difficult as the worst case online setting.

Prophet Inequality for Bipartite Matching

Consider a bipartite graph, where all edges have random values independently sampled from given probability distributions. Upon the arrival of an edge, we see the realization of its value and decide immediately whether to include this edge if possible in the matching. This model was originally proposed by Kleinberg and Weinberg [27] for a more general setting of intersection of k matroids. Gravin and Wang [20] studied explicitly the setting of bipartite matching and provided a $\frac{1}{3}$-approximation. Ezra et al. [15] later improved this ratio to 0.337. Our model can be viewed as an unweighted version of this prophet setting. Indeed, we assume that each edge has value either 0 or 1 and, hence, the probability distribution is a product of Bernoulli random variables summarized by existence probabilities $(p_e)_{e\in E(G)}$. Note that the weighted case is strictly harder than the unweighted one. Gravin and Wang [20] provided a 1/2.25 hardness result for the weighted setting while our goal is to design an online algorithm with a competitive ratio strictly better than 1/2. After all, the simple greedy algorithm achieves a competitive ratio of 1/2 for unweighted graphs.

1.2 Our Results and Techniques

We study a specific family of algorithms, named *Prune & Greedy*. The algorithm consists of two steps: (i) prune the graph by removing or decreasing probabilities of certain edges in G; (ii) greedily take every edge in the pruned instance. In particular, upon the arrival of an edge, we always drop it with certain probability so that its realization probability is consistent with the pruned graph.

We argue that the family of *Prune & Greedy* algorithms is of independent interest due to their practical relevance. Indeed, in those market applications we discussed above, the online platform often cannot prevent the matching between two parties (pair of vertices) once they realized their compatibility. But the platform usually possesses all the stochastic information about the graph and thus is fully capable of implementing pruning step by restricting information to its users. After that participants naturally implement greedy matching by exploring compatibilities with the other side of the graph exposed to them by the platform in an arbitrary order.

As our first result (Theorem 5 and Theorem 14), we identify a class of graphs on which greedy algorithm performs better than the worst-case competitive ratio of 1/2. We compare the size of the matching to the total number of vertices, a stronger benchmark than the expected size of maximum matching. As the pruning step naturally decreases the expected size of the maximum matching, the change of the benchmark is indeed necessary. Specifically, we find that on log-normalized[4] c-regular graphs with small $c = 2$ the greedy algorithm matches at least 0.552 vertices. This result immediately implies that if initial stochastic graph has a 2-regular bipartite spanning subgraph, then *Prune & Greedy* algorithm is 0.552-competitive.

Second, we propose a 0.503-competitive *Prune & Greedy* algorithm for any bipartite stochastic graph (Theorem 8). This result confirms that the edge-arrival model is theoretically interesting in the stochastic framework. A complementary hardness result (Theorem 15) shows that no online algorithm can be better than 2/3-competitive.

[4] For any vertex in a log-normalized c-regular graph, the probability that it has at least an adjacent edge is $1 - e^{-c}$. The definition is given in Section 3. Informally, a log-normalized c-regular graph is a c-regular graph where all edges have weights $\varepsilon \approx 0$.

Our techniques

We first build some intuition by analyzing the greedy algorithm on log-normalized c-regular graphs. One of the main challenges is that different events such as "edge e is matched", or "vertex u is matched" may have complex dependencies. This makes it very difficult to write the performance of the greedy algorithm in an explicit analytical form. We consider simpler to analyze events: "there exists a vertex u whose first realized edge is the edge (uv)", which guarantee that vertex v is matched at the end of the algorithm. This relaxation allows us to break the analysis into independent optimization problems per each vertex. We derive a guarantee $f(c)$ on the fraction of vertices matched by the greedy algorithm for any c-regular stochastic graph, where the function $f(c)$ has a single peak around $c = 2$ with $f(2) \approx 0.532$. I.e., we develop an analytically tractable relaxation on the performance of greedy that we later generalize to non-regular case. Interestingly, the greedy algorithm may perform worse on log-normalized c-regular graphs for larger c. In particular, greedy is not better than 0.5-competitive on c-regular graphs as $c \to \infty$.

However, this relaxation alone is not sufficient for the general case of non-regular graphs, since such analysis is not tailored in any way to the expected size of optimal matching. To this end, we consider an LP relaxation (an upper bound) on the expected optimal matching in stochastic graphs proposed in [17]. This LP gives a set of values $(x_e)_{e\in E(G)}$ with the objective $\sum_{e\in E(G)} x_e$ which satisfy a set of constraints that could be conveniently added to our optimization problem. Our analysis for regular graphs prompted us to the strategy of pruning each edge of the graph to $2 \cdot x_e$ so that the pruned graph is similar to a 2-regular graph. Unfortunately, this might not be a feasible operation when p_e (realization probability of e) is smaller than $2 \cdot x_e$. For these edges, it is then natural to keep their original existence probability. Our analysis can be similarly localized to an optimization problem for individual vertices, albeit the optimization becomes more complex. The main technical challenge is to solve an unwieldy optimization problem due to the "irregular" edges. Note that even a simpler optimization problem for c-regular graphs has a continuous optimal solution (i.e., is a limit of increasing discrete instances), which required computer assisted calculations to obtain the bound.

Finally, building on top of the relaxation we discussed above, we provide a more refined analysis for the case of 2-regular graphs. Namely, we consider second-order events that also witness the matching status of a vertex. We prove that the greedy algorithm is at least 0.552-competitive on 2-regular graphs, improving on the easier $f(2) \approx 0.532$ bound. We note that the same approach could in principle be extended to general *Prune & Greedy* algorithm for arbitrary graphs with optimization part still localizable to individual vertices. However, the optimization problem becomes too complicated to solve analytically. We leave it as an interesting open question to have a better analysis of the *Prune & Greedy* algorithms. On the positive side, the improved analysis for 2-regular graphs suggests that performance of *Prune & Greedy* algorithms should be noticeably better than what we proved in this paper.

1.3 Other Related Works

The edge-arrival setting is also studied under the free-disposal assumption, i.e., the algorithm is able to dispose of previously accepted edges. McGregor [31] gave a deterministic $\frac{1}{3+2\sqrt{2}} \approx 0.171$-competitive algorithm for weighted graphs. Varadaraja [35] proved the optimality of this result among deterministic algorithms. Epstein, Levin, Segev and Weimann [14] gave a $\frac{1}{5.356} \approx 0.186$-competitive randomized algorithm later and proved a hardness result of $\frac{1}{1+\ln 2} \approx 0.591$ for unweighted graphs. Recently, the hardness bound is improved to $2 - \sqrt{2} \approx 0.585$ by Huang et al. [23]. We remark that the question of designing an algorithm that beats 0.5-competitive remains open.

One of the earlier work on stochastic matching is due to Chen et al. [9]. They proposed stochastic model with edge probing motivated by real life matching applications such as kidney exchange. This model is more complex than the stochastic probing model we discussed before, since it has an additional constraint per each vertex v on how many times edges incident to v can be queried. Another difference is that a weaker benchmark than the optimal offline matching has to be used in this setting. Chen et al. developed a $\frac{1}{4}$-approximation algorithm. Bansal et al. [4] considered the weighted version and provided a $\frac{1}{3}$-approximation and a $\frac{1}{4}$-approximation for bipartite graphs and general graphs respectively. The ratio for general graphs was further improved to $\frac{1}{3.709}$ by Adamczyk, Grandoni and Mukherjee [1], and then to $\frac{1}{3.224}$ by Baveja et al. [5].

There has been prior work in the online matching literature on regular graphs [3, 25, 34, 21, 10]. However, the notion of stochastic regular graphs we defined is very different from the notion of standard regular graphs, the previous techniques are not directly applicable.

2 Preliminaries

The bipartite graph $G = (L, R, E)$ consists of left and right sides denoted respectively L and R. The graph G is a multigraph, i.e., E is a multiset that may have multiple parallel edges between the same pair of vertices. We use E_v to denote the multiset of edges incident to vertex v and E_{uv} to denote the multiset of edges connecting u and v. We consider the Bayesian model, where each edge $e \in E$ is realized with probability $p_e \in [0, 1]$, which is known in advance. The realizations of different edges are independent. We are interested in online matching algorithms with the objective of maximizing the expected size of the matching. We assume that all edges in E arrive one by one according to some fixed unknown order (i.e., oblivious adversarial order). Upon arrival of the edge e, the algorithm observes whether or not e is realized. If the edge exists, the algorithm immediately and irrevocably decides whether to include e into the matching; the algorithm does nothing, if the edge is not realized. We compare the performance of the algorithm with the performance of the optimal offline algorithm, also known as the *prophet*, who knows the realization of the whole graph in hindsight, i.e., $\mathsf{OPT} = \mathbf{E}[\text{size of maximum matching}]$.

A natural online matching strategy is the greedy algorithm: Take every available edge $e = (u, v)$ whenever both vertices u and v have not yet been matched. Obviously, the greedy algorithm is a 0.5-approximation, since it selects a *maximal* matching in all possible realizations of the graph, which is always a 0.5-approximation to the *maximum* matching.

Paper Roadmap

In Section 3, we introduce the notion of stochastic regular graphs and establish an analytical bound on the competitive ratio of the greedy algorithm on c-regular graphs. In Section 4, we design a Prune & Greedy algorithm that is 0.503-competitive for general inputs. Section 5 provides a more refined analysis of the greedy algorithm on 2-regular graphs. In Section 6, we give a simple impossibility result showing that no online algorithm can do better than $\frac{2}{3}$ of the expected optimum. Omitted proofs are in the full version.

3 Warm-up: Regular Graphs

A regular graph is a graph whose vertices have the same degree. But how do we define vertex degrees in a stochastic graph? One standard way is to use the expected vertex degree, i.e., $\sum_{e \in E_u} p_e$ for the degree of a vertex $u \in L$. However, the expectation alone does not

contain all the important information about a degree distribution. Consider for example a vertex a having only one incident edge (a, b) with $p_{(a,b)} = 1$ and a vertex u having 2 incident parallel edges $e = (u, v)$ with probability $p_e = 0.5$ for each $e \in E_u$. Both vertices a and u have the same expected degree, but while a always has exactly one incident edge, u gets no incident edges with 0.25 probability. On the other hand, u may have 2 incident edges in some realizations, which is almost the same for our purposes as having only a single incident edge.

A good way to reconcile this difference is to substitute each edge (u, v) by multiple parallel edges $e_i = (u, v)$ with small probabilities such that $p_{(u,v)}$ matches the probability that at least one of e_i edges exists. Alternatively, we can define a *log-normalized weight* for each edge e as $w_e \stackrel{\text{def}}{=\!=} -\ln(1 - p_e)$, i.e., given an input instance $G = (L, R, E)$ we construct a one-to-one correspondence between vectors of probabilities $\mathbf{p} = (p_e)_{e\in E}$ and vectors of log-normalized weights $\mathbf{w} = (w_e)_{e\in E}$. In particular, if we split an edge with log-normalized weight w_e into two edges $e_1 = e_2 = (u, v)$ with $w_{e_1} + w_{e_2} = w_e$, then the new instance gets only harder, i.e., any online algorithm for the new instance can be easily adapted to the original instance with the same or better performance. Indeed, notice that the probability that at least one of the edges e_1, e_2 exists equals $1 - e^{-w_{e_1}} \cdot e^{-w_{e_2}} = 1 - e^{-w_e}$, the probability that e exists, i.e., there is a probability coupling between the event that e exists with the event that at least one of e_1, e_2 exists. Then, we can substitute e in any arrival order with a pair of consecutive edges e_1 and e_2 and match e whenever the online algorithm matches e_1 or e_2 in the modified instance. Thus the log-normalized weight is the correct notion for us to do additive operations over the existence probabilities and leads to the following definition of the regular stochastic graph.

▶ **Definition 1.** *A graph G is a* log-normalized c-regular graph *if for every $v \in L \cup R$, $\sum_{e\in E_v} w_e = c$.*

We restrict our attention to log-normalized regular graphs in the remainder of this section. Our goal is to analyze the performance of Greedy on log-normalized c-regular graphs for a small constant c. Remarkably, it is not easy to give a precise answer and produce a tight worst-case estimate even for a specific value $c = 1$.

We first introduce a few short hand notations for the events that will be frequently used throughout the paper.

▶ **Definition 2.** *Fix an arbitrary edge arrival order σ and an edge $e \in E_{uv}$, define the following events:*

1. *$\exists e$: the event that e is realized.*
2. *$M_u(e)$: the event that u is matched right before e arrives.*
3. *$Q_u(e)$: the event that no edge of E_u is realized before e arrives. Let $q_u(e) \stackrel{\text{def}}{=\!=} \mathbf{Pr}[Q_u(e)]$.*
4. *$F_u(e) \stackrel{\text{def}}{=\!=} Q_u(e) \cap \exists e$: the event that e is the first realized edge of vertex u.*

The following lemma gives a lower bound on the matching probability of any vertex. This analytically tractable bound will allow us to reduce the global optimization for the competitive ratio of our algorithm to the local optimization per individual vertex. The lemma will also be useful for the general case, i.e., for not necessarily regular graphs, which we discuss in Section 4. To be consistent with the notations of the next section, let $x_e = \frac{w_e}{c}$ and $y_e = 1 - e^{-w_e}$. We have the property that $\sum_{e\in E_v} x_e = 1$ for every $v \in V$ and y_e equals the probability that e is realized ($\exists e$). We state the following lemma with the weaker condition of $\sum_{e\in E_v} x_e \leqslant 1$ for more general use in later sections.

▶ **Lemma 3.** *For any $v \in R$, if $\sum_{e\in E_v} x_e \leqslant 1$, then*

$$\mathbf{Pr}\left[v \text{ is matched}\right] \geqslant \mathbf{Pr}\left[\bigcup_{e=(u,v)\in E_v} F_u\left(e\right)\right] \geqslant \sum_{e=(u,v)\in E_v} x_e \cdot \left(1-\exp\left(-\frac{q_u(e)\cdot y_e}{x_e}\right)\right). \quad (1)$$

Proof. For each edge $e \in E_v$, consider the case when edge $e = (u, v)$ arrives and the event $F_u(e) = Q_u(e) \cap \exists e$ happens. At this moment, either v is already matched, or e will be included in the matching by Greedy. Therefore, whenever $\exists u \in L$ such that there is an edge $e \in E_{uv}$ making $F_u(e)$ happen, v is covered by Greedy.

Next, the events $\left\{\bigcup_{e\in E_{uv}} F_u(e)\right\}_{u\in L}$ are mutually independent, since (i) the event $\bigcup_{e\in E_{uv}} F_u(e)$ only depends on the random realization of the edges in E_u and (ii) $E_u \cap E_{u'} = \varnothing$ when $u \neq u'$.[5]

Lastly, $F_u(e_1) \cap F_u(e_2) = \varnothing$ for any $e_1, e_2 \in E_{uv}$, and thus $\mathbf{Pr}[\bigcup_{e\in E_{uv}} F_u(e)] = \sum_{e\in E_{uv}} q_u(e) \cdot y_e$. Putting the above observations together, we have

$$\begin{aligned}
\mathbf{Pr}\left[v \text{ is matched}\right] &\geqslant \mathbf{Pr}\left[\bigcup_{e\in E_v} F_u\left(e\right)\right] = 1-\mathbf{Pr}\left[\bigcap_{e\in E_v} \overline{F_u\left(e\right)}\right] = 1-\prod_u \mathbf{Pr}\left[\bigcap_{e\in E_{uv}} \overline{F_u\left(e\right)}\right] \\
&= 1-\prod_u\left(1-\sum_{e\in E_{uv}} q_u(e)\cdot y_e\right) \geqslant 1-\prod_u \exp\left(-\sum_{e\in E_{uv}} q_u(e)\cdot y_e\right) \\
&= 1-\exp\left(-\sum_{e\in E_v} q_u(e)\cdot y_e\right) \geqslant \sum_{e\in E_v} x_e\cdot\left(1-\exp\left(-\frac{q_u(e)\cdot y_e}{x_e}\right)\right),
\end{aligned}$$

where the second inequality follows from the fact that $1 - z \leqslant e^{-z}$ and the last inequality follows from Jensen's inequality and the concavity of function $1 - \exp(-z)$ (recalling $\sum_{e\in E_v} x_e \leqslant 1$). ◀

Thus, we may think of the quantity $x_e \cdot \left(1-\exp\left(-\frac{q_u(e)\cdot y_e}{x_e}\right)\right)$ as the contribution of edge e in the algorithm.[6] Observe that this contribution depends on the event $Q_u(e)$ for $u \in L$. We sum the (1) bound over all $v \in R$ and change the order of summations.

$$\begin{aligned}
\mathsf{ALG} = \sum_{v\in R}\mathbf{Pr}\left[v \text{ is matched}\right] &\geqslant \sum_{v\in R}\sum_{e=(u,v)\in E_v} x_e\cdot\left(1-\exp\left(-\frac{q_u(e)\cdot y_e}{x_e}\right)\right) \\
&= \sum_{u\in L}\sum_{e=(u,v)\in E_u} x_e\cdot\left(1-\exp\left(-\frac{q_u(e)\cdot y_e}{x_e}\right)\right). \quad (2)
\end{aligned}$$

▶ **Lemma 4.** *For all $u \in L$,*

$$\sum_{e\in E_u} x_e\cdot\left(1-\exp\left(-\frac{q_u(e)\cdot y_e}{x_e}\right)\right) \geqslant \int_0^1 \left(1-e^{-ce^{-cz}}\right)\mathrm{d}z.$$

Proof. Let u be any fixed vertex in L and $e_1, e_2, \ldots, e_k$ be the edges of E_u enumerated according to their arrival order. For notation simplicity, we use q_i, x_i and y_i to denote $q_u(e_i), x_{e_i}$ and y_{e_i} respectively. Then we have

$$Q_u\left(e_i\right) = \bigcap_{j<i}\overline{\exists e_j} = \bigcap_{j<i}\nexists e_j; \qquad q_i = \mathbf{Pr}\left[Q_u\left(e_i\right)\right] = \prod_{j<i}(1-y_j) = \prod_{j<i} e^{-c\cdot x_j} = e^{-c\cdot\sum_{j<i} x_j}.$$

[5] It is the only place where we use that G is bipartite. Indeed, our result can be generalized to triangle-free graphs.

[6] Note that this quantity is not necessarily a lower bound of the probability that edge e is matched.

Since $\int_0^{x_i} c \cdot e^{-cz} \mathrm{d}z = 1 - e^{-cx_i} = y_i$ and $1 - \exp(-q_i \cdot z)$ is a concave function of z , we can apply Jensen's inequality to get

$$1 - e^{-\frac{q_i \cdot y_i}{x_i}} = 1 - \exp\left(-q_i \cdot \frac{1}{x_i} \int_0^{x_i} c \cdot e^{-cz} \mathrm{d}z\right) \geqslant \frac{1}{x_i} \int_0^{x_i} \left(1 - \exp\left(-q_i \cdot c \cdot e^{-cz}\right)\right) \mathrm{d}z$$
$$= \frac{1}{x_i} \int_0^{x_i} \left(1 - \exp\left(-c \cdot e^{-c \cdot \sum_{j<i} x_j} \cdot e^{-cz}\right)\right) \mathrm{d}z = \frac{1}{x_i} \int_{\sum_{j<i} x_j}^{\sum_{j \leqslant i} x_j} \left(1 - e^{-ce^{-cz}}\right) \mathrm{d}z.$$

Summing this inequality over $i \in [k]$, we have

$$\sum_{e \in E_u} x_e \cdot \left(1 - \exp\left(-\frac{q_u(e) \cdot y_e}{x_e}\right)\right) = \sum_{i=1}^{k} x_i \cdot \left(1 - \exp\left(-\frac{q_i \cdot y_i}{x_i}\right)\right)$$
$$\geqslant \sum_{i=1}^{k} \int_{\sum_{j<i} x_j}^{\sum_{j \leqslant i} x_j} \left(1 - e^{-ce^{-cz}}\right) \mathrm{d}z = \int_0^1 \left(1 - e^{-ce^{-cz}}\right) \mathrm{d}z. \quad \blacktriangleleft$$

Let us denote the lower bound in the Lemma 4 as $h_1(c) \stackrel{\text{def}}{=\!=} \int_0^1 \left(1 - e^{-ce^{-cz}}\right) \mathrm{d}z$.

▶ **Theorem 5.** *The competitive ratio of* Greedy *on c-regular graphs is at least $h_1(c)$, which is at least* 0.532 *when $c = 2$.*

Proof. By equation (2) and Lemma 4, we have

$$\mathsf{ALG} \geqslant \sum_{u \in L} \sum_{e \in E_u} x_e \cdot \left(1 - \exp\left(-\frac{q_u(e) \cdot y_e}{x_e}\right)\right) \geqslant \sum_{u \in L} h_1(c).$$

This concludes the theorem by noticing that $|L|$ is an upper bound of OPT. $\blacktriangleleft$

▶ Remark. When $c = 2$, the competitive ratio is at least $h_1(c) \geqslant 0.532$. Notice that h_1 has a peak at $c \approx 2.1$, but it gets smaller again for $c > 3$ (see the full version for a plot) and our analysis gives relatively weak results for large c. One reason is because of the relaxation from Lemma 3. On the other hand, Greedy indeed does not perform well on c-regular graphs when c is large. In particular, Greedy is no better than 0.5-competitive on c-regular graphs when c goes to infinity.

▶ **Theorem 6.** *Greedy is at most* 0.5*-competitive on log-normalized c-regular graphs when $c \to \infty$.*

Proof. Consider the graph shown in Figure 1. We use $L_1 = \{u_i\}_{i=1}^{n+1}, R_1 = \{v_j\}_{j=1}^{n+1}, L_2 = \{u'_i\}_{i=1}^{n}$ and $R_2 = \{v'_j\}_{j=1}^{n}$ to denote the vertices in the graph. The edges are defined as the following:

1. For each $i \in [n+1]$, there is a (red solid) edge (u_i, v_i) with existence probability $1 - \varepsilon$.
2. For each pair of $(u, v) \in (L_2 \times R_1) \cup (L_1 \times R_2)$, there is a (green/blue dashed) edge (u, v) with existence probability $1 - \varepsilon$.

It is easy to verify the graph is log-normalized regular. When $\varepsilon \to 0$, with high probability, the graph admits a perfect matching with size $2n + 1$. On the other hand, consider the case when the red edges arrive first. With high probability, all these edges exist and Greedy matches $n + 1$ edges. This finishes the proof since $\frac{n+1}{2n+1} \to \frac{1}{2}$ when $n \to \infty$. $\blacktriangleleft$

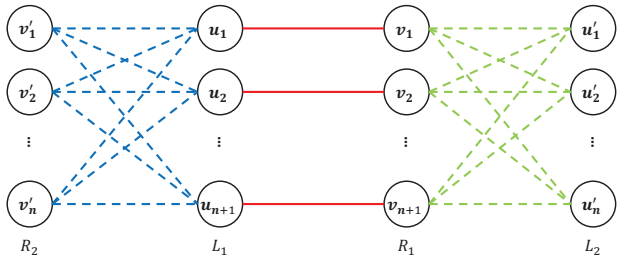

Figure 1 Hard instance for GREEDY on regular graphs.

4 Prune & Greedy: General Graphs

The fact that GREEDY beats half on log-normalized $c = 2$ regular graphs lends itself to the following natural two step adaptation for general graphs: (i) prune (remove or decrease probabilities of certain edges in G) such that the log-normalized degree of each vertex in the remaining graph is 2; (ii) greedily take every edge in the pruned instance G_c. Specifically, upon the arrival of an edge e, we first adjust its probability by dropping e so that its realization probability is consistent with e's log-normalized weight in G_c, then we match the realized edge if none of e's endpoints are currently matched. This approach would already yield the desired result for the dense graphs that can be pruned to the log-normalized 2-regular graph G_c. However, such a direct strategy fails for the graphs that have a few small degree vertices.

Before we proceed with the fix for the general graphs, let us take a closer look at the proof of Theorem 5. Note that in the theorem we actually compare our algorithm with a stronger benchmark, half the total number of vertices in G. The problem with such a benchmark, is that it may be too strong for any algorithm to approximate. To address this issue, we have to adjust our algorithm and analysis to handle low degree vertices. To this end, we can calculate x_e, the probability that e appears in the maximum matching of the random graph for every e, as the first step of our algorithm. By definition, $\mathsf{OPT} = \sum_{e\in E} x_e$ is the right benchmark to compare with. Alternatively, we can solve the following LP introduced by Gamlath, Kale and Svensson [17].[7]

$$\begin{aligned} \underset{(x_e \geqslant 0)_{e\in E}}{\text{maximize}} \quad & \sum_{e\in E} x_e \\ \text{subject to} \quad & \sum_{e\in F} x_e \leqslant 1 - \prod_{e\in F}(1-p_e), \quad \forall v \in L \cup R,\ \forall F \subseteq E_v. \end{aligned} \tag{3}$$

The constraints of the LP simply state that for each vertex v and subset $F \subseteq E_v$ of edges incident to v, the probability that an edge of F appears in the maximum matching is at most the probability that at least one edge of F is realized. Note that the value of each variable x_e in the LP (3) does not necessarily match the exact probability of e to appear in the maximum matching. However, $\sum_{e\in E} x_e$ still serves as a valid upper bound on OPT. As a matter of fact, our analysis works for either benchmark: the solution to LP (3), or for each x_e being the probability of e to appear in the optimal matching. We choose the LP (3) formulation in the description of the algorithm and the following analysis, since the LP optimal solution is a stronger benchmark and important constraints are explicitly stated in the LP.

[7] The LP is polynomial-time solvable. See [17] for the details.

A natural approach for general graphs would be to prune the graph according to the LP solution $(x_e)_{e\in E}$. To build some intuition let us consider what happens if we directly use x_es instead of p_es:

1. prune the graph by decreasing the probabilities of each edge from p_e to x_e,
2. run Greedy on the pruned instance.

Consider a special case of complete bipartite graph $K_{n,n}$ where each edge is realized with probability 1. The optimal solution to LP (3) is $x_e = \frac{1}{n}$ for all $e \in E$, as the maximum matching has size $n = \sum_{e\in E} x_e$. As $-\ln(1-x) \approx x$ when x is small, we effectively run Greedy on log-normalized 1-regular graph after pruning $K_{n,n}$. Theorem 3 from previous section gives $h_1(1) \approx 0.459 < 0.5$ in this case. Moreover, a simple computer aided simulation suggests that Greedy matches no more than 0.5 fraction of all vertices in this case. In this simulation we consider a regular complete graph G with $|L| = |R| = n$, where each edge has probability $\frac{1}{n}$; the edges arrive in random (uniformly distributed) order. In particular, we run 10^5 number of trials for $n = 3000$ and the ratio between ALG and n equals 0.50002. See the full version of this paper for more details of our experiment.

This means that pruning probabilities directly to x_e is too much and we need a more conservative pruning step. In particular, Theorem 5 suggests to prune the graph so that the log-normalized weight of edge e becomes $c \cdot x_e$. On the other hand, for some edges, p_e can be as small as x_e, in which case we have a cap on the existence probability. For those edges, it is reasonable to keep the existence probability as the original graph. Formally, we consider the following algorithm.

Algorithm 1 Prune & Greedy.

1: Solve LP (3) and let $\{x_e\}_{e\in E}$ be the optimal solution.
2: Prune the graph by decreasing the probabilities of each edge from p_e to $y_e = \min(p_e, 1 - e^{-c\cdot x_e})$.
3: Run Greedy on the pruned instance.

In an easy case when $y_e = 1 - e^{-c\cdot x_e}$ for all edges $e \in E$, we can adapt our analysis for c-regular graphs with a similar performance guarantee. On the other hand, if $y_e = x_e$ for all edges, then the algorithm might not be better than 0.5-competitive according to the previous discussion. However, the constraints from LP (3) guarantee that this cannot happen for all e.

Note that Lemma 3 and equation (2) apply to our Prune & Greedy algorithm with the $\{x_e, y_e\}$ defined in this section. We shall prove Lemma 7 an analog of Lemma 4 to conclude Theorem 8, which is the main result of this section.).

▶ **Lemma 7.** *For all $u \in L$, when $c = 1.7$,*

$$\sum_{e\in E_u} x_e \cdot \left(1 - \exp\left(-\frac{q_u(e)\cdot y_e}{x_e}\right)\right) \geqslant 0.503 \cdot \sum_{e\in E_u} x_e$$

▶ **Theorem 8.** *Prune & Greedy is 0.503-competitive when $c = 1.7$.*

Proof. We write the lower bound on the performance of Greedy using Lemma 3.

$$\begin{aligned}
\mathsf{ALG} &\geqslant \sum_{u\in L}\sum_{e\in E_u} x_e \cdot \left(1 - \exp\left(-\frac{q_u(e)\cdot y_e}{x_e}\right)\right) && \text{(by Equation (2))}\\
&\geqslant \sum_{u\in L} 0.503 \cdot \sum_{e\in E_u} x_e = 0.503 \cdot \sum_{e\in E} x_e \geqslant 0.503 \cdot \mathsf{OPT}. && \text{(by Lemma 7)}
\end{aligned}$$

◀

4.1 Proof of Lemma 7

The proof of Lemma 7 is highly technical and requires us to solve a rather non-trivial optimization. Let $\{e_1, e_2, \cdots, e_k\}$ be all edges incident to u and enumerated in their arrival order. To simplify notations, let p_i, x_i, y_i and q_i denote $p_{e_i}, x_{e_i}, y_{e_i}$ and $q_u(e_i)$ respectively.

The optimization problem (4) captures the ratio that we want to study.

$$\min_{(p_i \leqslant 1),(x_i \geqslant 0)} \sum_{i=1}^{k} x_i \cdot \left(1 - e^{-\frac{q_i \cdot y_i}{x_i}}\right) \Big/ \sum_{i=1}^{k} x_i \tag{4}$$
$$\text{s.t. } y_i = \min(p_i, 1 - e^{-c \cdot x_i}), \quad \forall i \in [k]$$
$$q_i = \prod_{j<i}(1 - y_j), \quad \forall i \in [k]$$
$$\sum_{i \in S} x_i \leqslant 1 - \prod_{i \in S}(1 - p_i), \ \forall S \subseteq [k]$$

$$\min_{(p_i \leqslant 1),x \geqslant 0} \sum_{i=1}^{k} x \cdot \left(1 - e^{-\frac{q_i \cdot y_i}{x}}\right) \Big/ (kx) \tag{5}$$
$$\text{s.t. } y_i = \min(p_i, 1 - e^{-cx}), \quad \forall i \in [k]$$
$$q_i = \prod_{j<i}(1 - y_j), \quad \forall i \in [k]$$
$$|S| \cdot x \leqslant 1 - \prod_{i \in S}(1 - p_i), \ \forall S \subseteq [k]$$

The first family of constraints in (4) comes from the design of our algorithm. The second family of constraints characterizes the probability that u has no realized edge before e_i. The last family of constraints follows from LP (3).

We first decrease the value of optimization (4) by increasing the size k of the instance and get a simpler optimization problem (5). The fact that we can construct more regular instance with all $x_i = x$ and smaller or equal objective value follows from the "subdivision" Lemma 9 below.

▶ **Lemma 9.** *Let $(x_j, p_j)_{j \in [k]}$ be any feasible solution to (4). Let e_i be any edge $i \in [k]$ which we subdivide into two consecutive parallel edges e' and e''. Then there is a feasible solution to the new instance of (4) with the same $(x_j, p_j)_{j \neq i}$ and $x_{e'} + x_{e''} = x_i$, and smaller objective value. Moreover, $x_{e'} \geqslant 0$ and $x_{e''} \geqslant 0$ can be set to have any values subject to $x_{e'} + x_{e''} = x_i$.*

Proof. We fix feasible solution $(x_j, p_j)_{j \in [k]}$ to (4), edge e_i, and particular $x_{e'} \geqslant 0$ and $x_{e''} \geqslant 0$ such that $x_{e'} + x_{e''} = x_i$. Let $\beta = \frac{x_{e'}}{x_i}$. Note that $0 \leqslant \beta \leqslant 1$. We need to define $p_{e'}$,$p_{e''}$. Consider two cases depending on the value of y_i:

Case 1. If $y_i = 1 - e^{-c \cdot x_i}$, then we let $p_{e'} = p_{e''} = 1$.

Case 2. If $y_i = p_i$, then we let $p_{e'} = 1 - (1 - p_i)^{\beta}$ and $p_{e''} = 1 - (1 - p_i)^{1-\beta}$.

In the first case, $y_{e'} = 1 - e^{-cx_{e'}}$ and $y_{e''} = 1 - e^{-cx_{e''}}$. In the second case, we verify that

$$p_{e'} \leqslant 1 - e^{-cx_{e'}} \iff 1 - (1 - p_i)^{\beta} \leqslant 1 - e^{-cx_{e'}} \iff p_i \leqslant 1 - e^{-cx_i}.$$

Similarly, $p_{e''} \leqslant 1 - e^{-cx_{e''}}$ and we have that $y_{e'} = p_{e'}$ and $y_{e''} = p_{e''}$. In both cases, we have that $(1 - y_{e'})(1 - y_{e''}) = 1 - y_i$. Consequently, the value of q_j does not change by our subdivision for all $j \neq i$. Next, we examine the change to the numerator of the objective function.

$$
\begin{aligned}
&x_{e'} \cdot \left(1 - e^{-q_i \cdot \frac{y_{e'}}{x_{e'}}}\right) + x_{e''} \cdot \left(1 - e^{-q_i \cdot \frac{(1-y_{e'})y_{e''}}{x_{e''}}}\right) - x_i \cdot \left(1 - e^{-q_i \cdot \frac{y_i}{x_i}}\right) \\
=&x_i \cdot \left(\frac{x_{e'}}{x_i} \cdot \left(1 - e^{-q_i \cdot \frac{y_{e'}}{x_{e'}}}\right) + \frac{x_{e''}}{x_i} \cdot \left(1 - e^{-q_i \cdot \frac{(1-y_{e'})y_{e''}}{x_{e''}}}\right)\right) - x_i \cdot \left(1 - e^{-q_i \cdot \frac{y_i}{x_i}}\right) \\
\leqslant&x_i \cdot \left(1 - e^{-\frac{q_i}{x_i} \cdot (y_{e'} + (1-y_{e'})y_{e''})}\right) - x_i \cdot \left(1 - e^{-q_i \cdot \frac{y_i}{x_i}}\right) = 0,
\end{aligned}
$$

where the inequality holds by Jensen's inequality for the concave function $1 - e^{-x}$, and the last equality is due to the fact that $(1-y_{e'})(1-y_{e''}) = 1-y_i$. Thus, the subdivision decreases the objective function. We are left to verify that all inequality constraints in (4) for $S \subseteq [k]$ are satisfied.

First, we consider **Case 1**, when $y_i = 1 - e^{-c \cdot x_i}$. We have $p_{e'} = p_{e''} = 1$. Then

- if $e', e'' \notin S$, the constraint trivially holds (none of x_j, p_j change);
- if $e' \in S$ or $e'' \in S$, the right-hand side of the constraint becomes 1.

Next, in **Case 2**, $y_i = p_i$, $y_{e'} = p_{e'}$, $y_{e''} = p_{e''}$, and $(1 - y_{e'})(1 - y_{e''}) = 1 - y_i$. Then

- if $e', e'' \notin S$, the constraint still holds (none of x_j, p_j change);
- if both $e', e'' \in S$, the inequality holds since $x_{e'} + x_{e''} = x_i$ and $(1 - p_{e'})(1 - p_{e''}) = 1 - p_i$;
- if exactly one of $e', e'' \in S$, we may assume w.l.o.g. that $e' \in S, e'' \notin S$ (as the other case $e'' \in S, e' \notin S$ is symmetric). Let $T \subseteq [k] - \{i\}$ be any set of indexes. Then

$$
\begin{aligned}
&1 - (1 - p_{e'}) \prod_{j \in T}(1 - p_j) = 1 - (1 - p_i)^{\beta} \prod_{j \in T}(1 - p_j) \geqslant 1 - (1 - \beta p_i) \prod_{j \in T}(1 - p_j) \\
&= \beta \left(1 - (1 - p_i) \prod_{j \in T}(1 - p_j)\right) + (1 - \beta) \left(1 - \prod_{j \in T}(1 - p_j)\right) \\
&\qquad \geqslant \beta \left(x_i + \sum_{j \in T} x_j\right) + (1 - \beta) \sum_{j \in T} x_j = \beta x_i + \sum_{j \in T} x_j = x_{e'} + \sum_{j \in T} x_j,
\end{aligned}
$$

where to get the first inequality we used the fact $(1 - x)^{\beta} \leqslant 1 - x \cdot \beta$, for any $x > -1$, $0 \leqslant \beta \leqslant 1$; the second inequality holds due to the original constraints in (4) for $S = T \cup \{i\}$ and $S = T$.

This concludes our proof. ◀

To get (5), we can start with the optimal solution to (4) for any given k, then apply multiple times Lemma 9 to every edge e_i, $i \in [k]$ getting an instance with $k' \gg k$ edges and a feasible solution with the same value, where almost all $x_j = x$ and at most k edges have $x_e < x$ (x may depend on k'). Finally, we can remove all edges with $x_e < x$, keep the rest x_j and p_j untouched and redefine (q_j) according to the recurrent formula. The impact of the change to q_j's before the removal of edges $x_e < x$ can be made vanishingly small as $k' \to \infty$. At the end, we get a feasible solution to (4) of the form (5) (for bigger k) with almost the same value as the optimum of (4) for the initial k. Thus we can analyze (5) without loss of generality instead of (4).

We prove the following lemma that describes the optimal solution to problem (5).

▶ **Lemma 10.** *For an optimal solution to* (5)*: (i)* $(y_i)_{i \in [k]}$ *are decreasing; (ii)* $\exists$ *cut-off point* $\ell \in [k]$ *such that* $y_i = cx$ *for* $i \leqslant \ell$ *and* $y_i = p_i$ *for* $i > \ell$*; (iii) constraints* $|S| \cdot x \leqslant 1 - \prod_{i \in S}(1 - p_i)$ *are tight for all* $S = [j..k]$*, where* $j > \ell$*.*

Proof. We prove the three statements sequentially. Let (p_i) be the optimal solution. If $y_i < y_{i+1}$ for an $i \in [k]$. Consider swapping p_i and p_{i+1} in the instance and the other $(p_j)_{j\neq i,i+1}$ remain the same. Note that the last family of constraints are preserved since the constraints are invariant under any permutation of p_j's. It is easy to see that q_j's are not changed for all $j \neq i+1$ and $q'_{i+1} = q_i(1-y_{i+1})$. Moreover, $y'_i = y_{i+1}$ and $y'_{i+1} = y_i$. Therefore, to prove that the swap decreases the objective, it suffices to show

$$1 - e^{-\frac{q_i \cdot y_i}{x}} + 1 - e^{-\frac{q_i(1-y_i)\cdot y_{i+1}}{x}} < 1 - e^{-\frac{q_i \cdot y_{i+1}}{x}} + 1 - e^{-\frac{q_i(1-y_{i+1})\cdot y_i}{x}}.$$

Observe that $q_i y_{i+1} > q_i y_i$, $q_i y_{i+1} > q_i(1-y_i)y_{i+1}$ and $q_i y_i + q_i(1-y_i)y_{i+1} = q_i y_{i+1} + q_i(1-y_{i+1})y_i$. The above inequality is true due to the convexity of the function $\exp(-z)$. A contradiction that concludes the proof of (i), the monotonicity of y_i's.

The second statement follows immediately from (i) according to our definition of $y_i = \min(p_i, cx)$ which is a monotone function with respect to p_i.[8] Let ℓ be the cut-off point such that $y_i = cx$ for $i \leqslant \ell$ and $y_i = p_i$ for $i > \ell$.

We are left to prove (iii). Given the statement (ii), we safely assume that $p_i = 1$ for all $i \leqslant \ell$ since this would not affect all y_i, q_i's and only trivialize the last family of constraints when $S \cap [\ell] \neq \varnothing$, since in this case the right-hand side of the constraint equals 1. Since $p_i = 1$ for $i \in [\ell]$ and $1 \geqslant p_i = y_i$ for $i > \ell$, we can assume that $(p_i)_{i\in[k]}$ are decreasing as well.

Given the monotonicity of p_i's, we note that "critical" inequality constraints $|S| \cdot x \leqslant 1 - \prod_{i\in S}(1-p_i)$ are those where $S = \{j, j+1, \cdots, k\}$, i.e., the remaining (non-critical) inequality constrains for other sets S are automatically satisfied, if the constraints for $S = \{j, j+1, \cdots, k\}$ hold. Indeed, when restricting to S with a fixed cardinality s, the left-hand side of each constraint is the same $|S| \cdot x$, while the right-hand side is minimized when S consists of the s smallest p_i, i.e., $\{p_j, p_{j+1} \ldots, p_k\}$. We are going to prove (iii), that the critical constraints for $j > \ell$ are tight.

Now, suppose to the contrary that a critical constraint is not tight for an $S = \{\bar{i}, \bar{i}+1, \ldots, k\}$ for $\bar{i} > \ell$, while all critical constraints for each $S = \{i, i+1, \ldots, k\}$ where $i > \bar{i}$ are tight (if $\bar{i} = k$, we don't require any constraints to be tight). We first consider a non-degenerate case when $1 > p_{\bar{i}-1}$, which also means that $\bar{i} - 1 > \ell$ (otherwise $y_{\bar{i}-1} = cx$ and we would set $p_{\bar{i}-1} = 1$). Before that we prove the following fact.

▷ Claim 11. If $1 > p_i = p_{i+1}$ for $i \in (\ell..k)$, then inequality $|S| \cdot x < 1 - \prod_{j\in S}(1-p_j)$ for $S = \{i+1, \ldots, k\}$ is strict.

Proof. Suppose to the contrary that the inequality is an equality, that is

$$(1-p_{i+1}) = \frac{\prod_{j>i}(1-p_j)}{\prod_{j>i+1}(1-p_j)} = \frac{1-(k-i)x}{\prod_{t>i+1}(1-p_j)}.$$

The inequality constraint for $S = \{i, \ldots, k\}$ gives:

$$(1-p_i)(1-p_{i+1}) = \frac{\prod_{j\geqslant i}(1-p_j)}{\prod_{j>i+1}(1-p_j)} \leqslant \frac{1-(k-i+1)x}{\prod_{j>i+1}(1-p_j)}.$$

[8] Notice that $cx \approx 1 - e^{-cx}$ when $x \approx 0$ in (5).

Putting the two equations together and by the assumption that $p_i = p_{i+1}$, we have

$$\left(\frac{1-(k-i)x}{\prod_{j>i+1}(1-p_j)}\right)^2 \leqslant \frac{1-(k-i+1)x}{\prod_{j>i+1}(1-p_j)}$$
$$\Longrightarrow \frac{(1-(k-i)x)^2}{(1-(k-i+1)x)} \leqslant \prod_{j>i+1}(1-p_j) \leqslant 1-(k-i-1)x,$$

where the last inequality follows from the constraint for $S = \{i+2, \dots, k\}$ (if $i+2 > k$, the inequality still holds, as $i = k-1$, $1-(k-i-1)x = 1$, and $\prod_{j>i+1}(1-p_j) = 1$).

Thus $(1-(k-i+1)x)(1-(k-i-1)x) = (1-(k-i)x)^2 - x^2 \geqslant (1-(k-i)x)^2$, a contradiction. ◁

Case 1 ($1 > p_{\bar{i}-1}$). We will get a contradiction by providing an instance with a strictly smaller objective's value. Let $\underline{i}$ be the smallest index so that $p_{\underline{i}} = p_{\underline{i}+1} = \cdots = p_{\bar{i}-1}$. So $p_{\underline{i}-1} > p_{\underline{i}}$, if $\underline{i} > 1$. Recall that we consider the case $1 > p_{\bar{i}-1} = p_{\underline{i}}$ and thus $\ell < \underline{i}$ (otherwise $y_{\underline{i}} = cx$ and we should have set $p_{\underline{i}} = 1$). By Claim 11, each inequality in (5) for $S = \{i, i+1, \dots, k\}$ with $\underline{i}+1 \leqslant i \leqslant \bar{i}-1$ must be strict. On the other hand, a contra-positive statement to Claim 11 gives us that $p_{\bar{i}}$ cannot be equal to $p_{\bar{i}+1}$ (if $\bar{i} = k$, this also is true). Thus $p_{\bar{i}} > p_{\bar{i}+1}$ (if $\bar{i} < k$). If $\bar{i} = k$, then $p_{\bar{i}} > 0$ (otherwise, we can decrease k in (5)).

We consider the following modification $(\mathbf{p}', x)$ of (5)'s feasible solution: slightly increase $p_{\underline{i}}$ and decrease $p_{\bar{i}}$ so that $(1-p_{\underline{i}})(1-p_{\bar{i}})$ remains the same; all other p_i for $i \neq \underline{i}, \bar{i}$ and x are the same in $(\mathbf{p}', x)$ and original optimum $(\mathbf{p}, x)$; $\mathbf{y}', \mathbf{q}'$ are redefined according to the formula in (5). Note that we can always do such modification when $1 > p_{\underline{i}} > p_{\bar{i}} > 0$.

For any sufficiently small such perturbation of $p_{\bar{i}}$ and $p_{\underline{i}}$, $(p'_i)_{i\in[k]}$ remain monotone and all constraints in (5) are satisfied. Indeed, we only need to check the critical constraints in (5) for monotone $\mathbf{p}'$: $\mathbf{p}'$ and $\mathbf{p}$ are the same for $S = \{i, i+1, \dots, k\}$ for $i \in (\bar{i}..k]$; all inequalities for $S = \{i, i+1, \dots, k\}$ where $i \in [\underline{i}+1, \bar{i}]$ are strict and, therefore, for sufficiently small perturbation of $p_{\bar{i}}$ and $p_{\underline{i}}$ they still hold; for $S = \{i, i+1, \dots, k\}$ where $i \in (\ell..\underline{i}]$, the right-hand side of each critical constraint does not change, because $(1-p_{\bar{i}})(1-p_{\underline{i}}) = (1-p'_{\bar{i}})(1-p'_{\underline{i}})$.

Now we examine the changes to q_i. Observe that each $q'_i = q_i$ and $y'_i = y_i$ for any $i < \underline{i}$, as $(p'_i)_{i<\underline{i}}$ and $(p_i)_{i<\underline{i}}$ are the same. For $i \geqslant \bar{i}$, we also have $q'_i = q_i$ and $y'_i = y_i$ since $(1-y_{\underline{i}})(1-y_{\bar{i}}) = (1-y'_{\underline{i}})(1-y'_{\bar{i}})$. Moreover, we notice that

$$\sum_{i\in[\underline{i}..\bar{i}]} q_i y_i = q_{\underline{i}}\left(1 - \prod_{i\in[\underline{i}..\bar{i}]}(1-y_i)\right) = \sum_{i\in[\underline{i}..\bar{i}]} q'_i y'_i.$$

In the interval $i \in [\underline{i}, \bar{i}]$, we notice that by increasing $p_{\underline{i}}$ and decreasing $p_{\bar{i}}$ we increase $q_{\underline{i}} y_{\underline{i}}$ and decrease each $q_i y_i$ for $i \in (\underline{i}..\bar{i})$, since each q_i deceases. Moreover,

$$q'_{\bar{i}} y'_{\bar{i}} = \left[\prod_{\substack{j<\bar{i},\\ j\neq\underline{i}}}(1-y_j)\right]\cdot(1-y'_{\underline{i}})\cdot y'_{\bar{i}} = \left[\prod_{\substack{j<\bar{i},\\ j\neq\underline{i}}}(1-y_j)\right]\cdot(1-y'_{\underline{i}}-(1-y'_{\bar{i}})(1-y'_{\underline{i}}))$$
$$< \left[\prod_{\substack{j<\bar{i},\\ j\neq\underline{i}}}(1-y_j)\right]\cdot(1-y_{\underline{i}}-(1-y_{\bar{i}})(1-y_{\underline{i}})) = q_{\bar{i}} y_{\bar{i}},$$

since $y'_{\underline{i}} > y_{\underline{i}}$ while $(1-y'_{\underline{i}})(1-y'_{\bar{i}}) = (1-y_{\underline{i}})(1-y_{\bar{i}})$. Hence, due to convexity of the function $\exp(-z)$, we conclude that the objective $\sum_i(1-\exp(-\frac{q_i y_i}{x}))$ decreases when we substitute $(\mathbf{q},\mathbf{y})$ with $(\mathbf{q}',\mathbf{y}')$. Indeed, $q_{\underline{i}}y_{\underline{i}}$, the largest number among $\{q_i y_i\}_{i=\underline{i}}^{\bar{i}}$, increases, while all other affected $q_i y_i$ in $[\underline{i},\bar{i}]$ decrease.

Case 2 ($p_{\bar{i}-1} = 1$). Now we consider a degenerate case when $p_{\bar{i}-1} = 1$. In this case, $p_{\bar{i}}$ only appears in the critical constraint for $S = \{\bar{i}, \bar{i}+1, \dots, k\}$, which we assume to be not tight. Note that $p_{\bar{i}} > p_{\bar{i}+1}$ if $\bar{i} < k$ by Claim 11 and also that $p_{\bar{i}} > 0$ if $\bar{i} = k$ (otherwise, we can decrease k in (5)). Thus, sightly decreasing $p_{\bar{i}}$ shall not violate any constraint. Furthermore, since $\bar{i} > \ell$, $p_{\bar{i}} < cx$, we can also slightly increase $p_{\bar{i}}$ without violating any constraints. Now, we fix all p_i for $i \neq \bar{i}$ and consider $y_{\bar{i}} = p_{\bar{i}}$ as a locally free variable that we can slight increase or decrease. We study the objective of (5) as a function of $y_{\bar{i}} = p_{\bar{i}}$.

Observe that any change to $y_{\bar{i}}$ only affects the terms $(1-e^{-\frac{q_i y_i}{x}})$ for $i \geqslant \bar{i}$. Furthermore, for $i = \bar{i}$, $(1-e^{-\frac{q_{\bar{i}} y_{\bar{i}}}{x}})$ is a strictly concave function of $y_{\bar{i}}$; and for $i > \bar{i}$

$$1-\exp\left(-\frac{q_i y_i}{x}\right) = 1-\exp\left(-(1-y_{\bar{i}})\cdot\frac{\prod_{j<i, j\neq\bar{i}}(1-y_j)\cdot y_i}{x}\right)$$

is also a concave function of $y_{\bar{i}}$.

Thus, the objective function of (5) is a strictly concave function of $y_{\bar{i}} = p_{\bar{i}}$, at least in some neighborhood of $p_{\bar{i}}$. Note that the minimum of a strictly concave function is always achieved on the boundary of its domain. Therefore, some small perturbation of $p_{\bar{i}}$ and consequently $y_{\bar{i}} = p_{\bar{i}}$ (either slightly increase or decrease $p_{\bar{i}}$ such that all constraint in (5) are still satisfied) would strictly decrease the objective. This contradicts the optimality of $\mathbf{p}$. ◀

Now we can write explicit formula for p_i for $i > \ell$. By (iii) of Lemma 10, we have $\prod_{j=i+1}^{k}(1-p_j) = 1-(k-i)x$ and $\prod_{j=i}^{k}(1-p_j) = 1-(k-i+1)x$. Thus, if $i > \ell$, then $y_i = p_i = \frac{x}{1-(k-i)x}$ and

$$\begin{aligned} q_i = \prod_{j<i}(1-y_j) = (1-cx)^{\ell}\cdot\prod_{j=\ell+1}^{i-1}(1-p_i) &= (1-cx)^{\ell}\cdot\frac{\prod_{j=\ell+1}^{k}(1-p_i)}{\prod_{j=i}^{k}(1-p_i)} \\ &= (1-cx)^{\ell}\cdot\frac{1-(k-\ell)x}{1-(k-i+1)x}. \end{aligned}$$

Let $t = (k-\ell)x$ and $s = \ell x$ for notation simplicity. We have, for small x

$$\frac{q_i y_i}{x} = \begin{cases} \frac{1-e^{-cx}}{x}(1-cx)^{i-1} \approx c\cdot e^{-c\cdot(i-1)x}, & i \leqslant \ell \\ (1-cx)^{\ell}\cdot\frac{(1-t)}{(1-(k-i)x)\cdot(1-(k-i+1)x)} \approx e^{-c\cdot s}\frac{(1-t)}{(1-t+(i-\ell)x)^2}, & i > \ell \end{cases}$$

Consequently, we have that for small x

$$\begin{aligned} \sum_{i=1}^{k} x\cdot\left(1-e^{-\frac{q_i y_i}{x}}\right) &= \sum_{i=1}^{\ell} x\cdot\left(1-e^{-\frac{q_i y_i}{x}}\right) + \sum_{i=\ell+1}^{k} x\cdot\left(1-e^{-\frac{q_i y_i}{x}}\right) \\ &= \sum_{i=1}^{\ell} x\cdot\left(1-e^{-c\cdot e^{-c\cdot(i-1)x}}\right) + \sum_{i=\ell+1}^{k} x\cdot\left(1-e^{-e^{-c\cdot s}\frac{(1-t)}{(1-t+(i-\ell)x)^2}}\right) \\ &\geqslant \int_0^s 1-e^{-ce^{-cz}}\,\mathrm{d}z + \int_0^t 1-e^{-e^{-cs}\cdot\frac{1-t}{(1-t+z)^2}}\,\mathrm{d}z \end{aligned}$$

Furthermore, since $\frac{x}{1-t} \approx \frac{x}{1-(k-\ell-1)x} = p_{\ell+1} \leqslant 1-e^{-cx} \approx cx$, we have $t \leqslant 1-\frac{1}{c}$.

To finish the proof, it suffices to lower bound the following function

$$h_2(s,t) \stackrel{\text{def}}{=\!=} \left(\int_0^s 1 - e^{-ce^{-cz}}\,\mathrm{d}z + \int_0^t 1 - e^{-e^{-cs}\cdot\frac{1-t}{(1-t+z)^2}}\,\mathrm{d}z\right) / (s+t)\,,$$

subject to $s \in [0,1], t \in \left[0, 1-\frac{1}{c}\right], s+t \in (0,1]$.

We use numerical methods to show $h_2(s,t) \geqslant h_2\left(\frac{1}{c}, 1-\frac{1}{c}\right) > 0.503$ when $c = 1.7$. The details are in the full version.

5 Improved Analysis: Regular Graphs

In this section, we prove a stronger performance guarantee of Greedy for regular graphs. According to the definition of log-normalized regular graph, each edge with log-normalized weight w_e can be substituted by a set of consecutive "small" edges with the same total log-normalized weight. For the ease of presentation, we assume that all edges are infinitesimal within this section. Let $x_e = \frac{w_e}{c}$ and $y_e = 1 - e^{-w_e}$ for all $e \in E$ as defined in Section 3.

Define the following two types of contributions of each edge $e \in E_{vu}$, where $u \in L$ and $v \in R$:

$$\mathrm{I}(e) \stackrel{\text{def}}{=\!=} x_e \cdot \left(1 - \exp\left(-\frac{q_u(e)\cdot y_e}{x_e}\right)\right);$$

and $\mathrm{II}(e) \stackrel{\text{def}}{=\!=} y_e \cdot \left(\mathbf{Pr}\left[\overline{M_u}(e)\right] - \mathbf{Pr}\left[Q_u\left(e\right)\right]\right).$

In Section 3, we estimated performance of Greedy with a lower bound of $\sum_{e\in E} \mathrm{I}(e)$. Recall that this bound corresponds to the event that edge e is the first realized edge of u. It turns out that we can add an extra term $\mathrm{II}(e)$ on top of $\mathrm{I}(e)$ to have a better bound on the probability that edge e is matched. The term $\mathrm{II}(e)$ corresponds to the event that e is not the first realized edge of u, but u is still unmatched before e. Formally, we have the following Lemma 12, where coefficient $e^{-c-ce^{-c}}$ in front of $\mathrm{II}(e)$ ensures that the event from which we get extra gain is disjoint with the events from which we obtain the contribution of the first kind. I.e., we avoid double counting.

Within this section, we use computer assisted calculations in several places. We state all our lemmas in the case when $c = 2$ to highlight the improvement of our analysis over the competitive ratio of 0.532. We remark that our analysis generalizes for a wide range of the parameter c. The proofs of Lemmas 12 and 13 can be found in the full version.

▶ **Lemma 12.** *When $c = 2$,*

$$\mathsf{ALG} \geqslant \sum_{e\in E}\left(I(e) + e^{-c-ce^{-c}}\cdot II(e)\right). \tag{6}$$

By Lemma 4, the $\mathrm{I}(e)$ term alone is sufficient to show that Greedy is 0.532-competitive for 2-regular graphs. Next, we study the $\mathrm{II}(e)$ term.

Let $\delta_u = \mathbf{Pr}[\overline{M_u}] - \mathbf{Pr}[Q_u]$ for each vertex $u \in L$ at the end of algorithm's execution. Note that $\mathbf{Pr}[\overline{M_u}(e)] \geqslant \mathbf{Pr}[Q_u(e)]$ for all $e \in E_u$, because u cannot be matched at the moment of edge e arrival, if u had no realized edges. Thus $\delta_u \geqslant 0$. Similar to Lemma 3, we fix a vertex $u \in L$ and study the sum of $\mathrm{II}(e)$ for all edges $e \in E_u$.

▶ **Lemma 13.** *For any vertex $u \in L$, when $c = 2$,*

$$\sum_{e\in E_u} II(e) = \sum_{e\in E_u} y_e \cdot \left(\mathbf{Pr}\left[\overline{M_u}(e)\right] - \mathbf{Pr}\left[Q_u(e)\right]\right) \geqslant 1.98\cdot\delta_u^2.$$

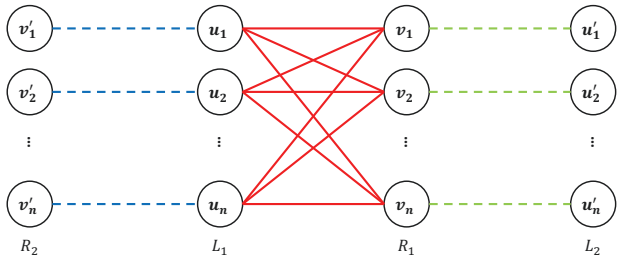

Figure 2 Hard instance for any algorithm.

▶ **Theorem 14.** *GREEDY is 0.552-competitive on 2-regular graphs.*

Proof. We have that

$$\mathsf{ALG} = \sum_{u\in L} \mathbf{Pr}\left[M_u\right] = \sum_{u\in L} \left(1 - \mathbf{Pr}\left[\overline{M_u}\right]\right) = \sum_{u\in L} \left(1 - e^{-c} - \delta_u\right).$$

We recall definition of $h_1(c) \stackrel{\text{def}}{=\!=} \int_0^1 \left(1 - e^{-ce^{-cz}}\right) \mathrm{d}z$ from Section 3. Then,

$$\begin{aligned}
&|L| \cdot (1 - e^{-c}) - \sum_{u\in L} \delta_u \\
\geqslant &\sum_{e\in E} \left(\mathrm{I}(e) + e^{-c-ce^{-c}} \cdot \mathrm{II}(e)\right) && \text{(by Lemma 12)} \\
\geqslant &\sum_{u\in L} \left(h_1(c) + e^{-c-ce^{-c}} \cdot 1.98 \cdot \delta_u^2\right) && \text{(by Lemma 4, 13)} \\
\geqslant &h_1(c) \cdot |L| + 1.98 \cdot e^{-c-ce^{-c}} \cdot \frac{\left(\sum_{u\in L} \delta_u\right)^2}{|L|}. && \text{(by Cauchy-Schwarz inequality)}
\end{aligned}$$

Let $\Delta = \frac{\sum_{u\in L} \delta_u}{|L|}$. We rearrange the above inequality and get the following for $c = 2$.

$$(1 - e^{-2} - h_1(2)) \geqslant \Delta + 1.98 \cdot e^{-2-2e^{-2}} \cdot \Delta^2.$$

Solving the inequality numerically, we have that $\Delta \leqslant 0.312$. Therefore,

$$\mathsf{ALG} = (1 - e^{-2} - \Delta) \cdot |L| \geqslant (1 - e^{-2} - 0.312) \cdot |L| \geqslant 0.552 \cdot |L|.$$ ◀

6 Problem Hardness

In this section, we present an upper bound of $\frac{2}{3} \approx 0.667$ for all online algorithms. Consider the graph shown in Figure 2. We use $L_1 = \{u_i\}_{i=1}^n, R_1 = \{v_j\}_{j=1}^n, L_2 = \{u'_i\}_{i=1}^n$ and $R_2 = \{v'_j\}_{j=1}^n$ to denote the vertices in the graph. The edges are defined as the following:

1. For each pair of $(u, v) \in L_1 \times R_1$, let there be an edge (u, v) with existence probability 1. We call them type-1 edges (red solid edges).
2. For each $i \in [n]$, let there be an edge (u_i, v'_i) with existence probability $\frac{1}{2}$. We call them type-2 edges (blue dashed edges).
3. For each $i \in [n]$, let there be an edge (u'_i, v_i) with existence probability $\frac{1}{2}$. We call them type-3 edges (green dashed edges).

Let the type-1 edges arrive first and then type-2 and type-3 edges.

▶ **Theorem 15.** *No algorithm is better than* $\frac{2}{3}$*-competitive.*

Proof. Note that there is no randomness for type-1 edges. If an algorithm matches k of them, there will be $\frac{n-k}{2}$ possible type-2 edges and $\frac{n-k}{2}$ type-3 edges in expectation. Thus any online algorithm matches no more than $k + \frac{n-k}{2} + \frac{n-k}{2} = n$ in expectation.

On the other hand, with high probability, there are at least $(0.5 - o(1)) \cdot n$ realized type-2 edges and at least $(0.5 - o(1)) \cdot n$ realized type-3 edges. In this case, the prophet can match $(0.5 - o(1)) \cdot n$ type-2 and type-3 edges respectively and then $0.5 \cdot n$ type-1 edges. In total, the prophet matches $(1.5 - o(1)) \cdot n$ edges with high probability. That is, $\mathsf{OPT} \geqslant (1.5 - o(1)) \cdot n$ when $n \to \infty$. ◀

Faster Monotone Min-Plus Product, Range Mode, and Single Source Replacement Paths

Abstract

One of the most basic graph problems, All-Pairs Shortest Paths (APSP) is known to be solvable in $n^{3-o(1)}$ time, and it is widely open whether it has an $O(n^{3-\epsilon})$ time algorithm for $\epsilon > 0$. To better understand APSP, one often strives to obtain subcubic time algorithms for structured instances of APSP and problems equivalent to it, such as the Min-Plus matrix product.

A natural structured version of Min-Plus product is Monotone Min-Plus product which has been studied in the context of the Batch Range Mode [SODA'20] and Dynamic Range Mode [ICALP'20] problems. This paper improves the known algorithms for Monotone Min-Plus Product and for Batch and Dynamic Range Mode, and establishes a connection between Monotone Min-Plus Product and the Single Source Replacement Paths (SSRP) problem on an n-vertex graph with potentially negative edge weights in $\{-M, \ldots, M\}$.

SSRP with positive integer edge weights bounded by M can be solved in $\tilde{O}(Mn^{\omega})$ time, whereas the prior fastest algorithm for graphs with possibly negative weights [FOCS'12] runs in $O(M^{0.7519}n^{2.5286})$ time, the current best running time for directed APSP with small integer weights. Using Monotone Min-Plus Product, we obtain an improved $O(M^{0.8043}n^{2.4957})$ time SSRP algorithm, showing that SSRP with constant negative integer weights is likely easier than directed unweighted APSP, a problem that is believed to require $n^{2.5-o(1)}$ time.

Complementing our algorithm for SSRP, we give a reduction from the Bounded-Difference Min-Plus Product problem studied by Bringmann et al. [FOCS'16] to negative weight SSRP. This reduction shows that it might be difficult to obtain an $\tilde{O}(Mn^{\omega})$ time algorithm for SSRP with negative weight edges, thus separating the problem from SSRP with only positive weight edges.

1 Introduction

The All-Pairs Shortest Paths problem (APSP) is one of the most well-known problems in graph algorithms. Following the classical Floyd–Warshall algorithm that solves APSP in $O(n^3)$ time in n-vertex edge-weighted graphs, a long list of papers have been dedicated to improving the APSP running time. The current best algorithm by Williams [26] runs in $n^3/2^{\Theta(\sqrt{\log n})}$ time. It is a big open problem whether a truly sub-cubic, $O(n^{3-\epsilon})$-time for $\epsilon > 0$, algorithm for APSP exists. In fact, the popular APSP hypothesis from Fine-Grained Complexity [23] asserts that this is not the case.

In the Min-Plus Product problem, one is given two $n \times n$ integer matrices A, B and is required to compute an $n \times n$ matrix $C = A \star B$ such that $C_{i,j} = \min_k\{A_{i,k} + B_{k,j}\}$. Fischer and Meyer [12] showed that Min-Plus Product is equivalent to APSP, in the sense that a $T(n)$ time algorithm for either of the problems immediately implies an $O(T(n))$ time algorithm for the other. The APSP hypothesis thus states that computing the min-plus product of $n \times n$ integer matrices requires $n^{3-o(1)}$ time[1].

Structured Min-Plus Products. To better understand the complexity of APSP, much research focuses on improving the running time for Min-Plus Product when one or both of the matrices have some structure, with the hope that eventually all instances can be handled. As a fundamental problem, Min-Plus Product can be used to solve many other problems. It turns out that in many cases a structured version of Min-Plus Product suffices [25, 4]. Thus, studying structured instances of Min-Plus Product has the potential to speed up the running times for many applications.

Alon, Galil and Margalit [3] first studied the Min-Plus Product of structured matrices. They showed, following ideas of Yuval [30], that if all entries of two $n \times n$ matrices A, B are integers in $\{-M, \ldots, M\} \cup \{\infty\}$, then one can compute the min-plus product of A and B in $\tilde{O}(Mn^\omega)$ time[2], where $\omega \in [2, 2.373)$ denotes the best possible exponent of square matrix multiplication [22, 17, 1].

Yuster [28] considered Min-Plus Product when one of the matrices has a small number of distinct entries in each row, generalizing [3]. Bringmann et al. [4] studied Min-Plus Product of bounded-difference matrices, generalizing [3, 28]. An integer matrix is called to have *bounded differences* if all pairs of adjacent entries (both horizontally and vertically) differ by at most $O(1)$. Bringmann et al. [4] gave an $O(n^{2.8244})$ time algorithm for computing the Min-Plus Product between two bounded-difference matrices. When $\omega = 2$, their algorithm runs in $O(n^{2.7554})$ time. They also studied variants of this problem including the case when only one matrix is guaranteed to have bounded differences, and the bounded-differences are only in the rows or only in the columns.

[1] In fine-grained complexity one needs to fix the model of computation for each hardness hypothesis, and the APSP hypothesis is typically stated for a word RAM with $O(\log n)$ bit words, which is the model the algorithms in our paper are in.

[2] Throughout the paper the $\tilde{O}$ notation hides subpolynomial factors.

Chan [5] gave a truly sub-cubic time algorithm for the min-plus product between *geometrically weighted* matrices using a geometric tool called the *partition theorem*. Recently, Vassilevska Williams and Xu [25] combined the approach of Bringmann et al. [4] and a geometric data structure to give a truly subcubic Min-Plus Product algorithm for integer matrices where one of the matrices has constant $O(1)$-approximate rank, further generalizing the results of [4] and partially [5].

Our contribution. In this work, we study the Min-Plus Product of a *monotone* integer matrix with an arbitrary[3] integer matrix. We defer the general definition of *Monotone Min-Plus Product* to Section 2. For now let us focus on an interesting special case: We are given an arbitrary $n \times n$ integer matrix A and an $n \times n$ matrix B whose entries are positive integers bounded by $O(n)$, and such that each row of B is non-decreasing.

The above special case already subsumes the Min-Plus Product of bounded-difference matrices studied by Bringmann et al.: Suppose we are asked to compute the min-plus product of matrices A and B where B has bounded differences. In other words, all pairs of adjacent entries (both horizontally and vertically) differ by at most some constant M. We can create a matrix B' so that $B'_{k,j} = B_{k,j} - B_{1,1} + jM$. It is easy to check that the matrix B' satisfies the above-mentioned special case definition of monotone matrix. Thus, we can use our algorithm to compute the min-plus product $C' = A \star B'$. Then it is easy to recover $C = A \star B$ by setting $C_{i,j} = C'_{i,j} + B_{1,1} - jM$. Therefore, Monotone Min-Plus Product is more general than the Min-Plus Product of an arbitrary matrix with a bounded-difference matrix.

Monotone Min-Plus Product was first studied by Vassilevska Williams and Xu [25] as a tool to give a fast algorithm for the *Batch Range Mode* problem. In their work, the authors devise a black-box reduction from Monotone Min-Plus Product to their Min-Plus Product algorithm for matrices with a small $O(1)$-approximate rank. Their algorithm runs in $\tilde{O}(n^{(15+\omega)/6}) = O(n^{2.8955})$ time for the above-mentioned special case. We improve and generalize their algorithm. Below is a special case of our main theorem, which will be introduced in Section 3.

▶ **Theorem 1.** *The min-plus product $A \star B$ of two $n \times n$ matrices where entries of B are non-negative integers bounded by $O(n)$ and each row of B is non-decreasing can be computed deterministically in $\tilde{O}(n^{\frac{12+\omega}{5}})$ time. Using the current best bound on fast rectangular matrix multiplication the running time improves to $O(n^{2.8653})$.*

If $\omega = 2$, our improvement is from $\tilde{O}(n^{17/6}) \leq O(n^{2.8334})$ time to $\tilde{O}(n^{14/5}) = \tilde{O}(n^{2.8})$ time. We provide several interesting applications of our improved algorithm for Monotone Min-Plus Product.

1.1 Applications

Single Source Replacement Paths. The main contribution of this paper is establishing a relationship between Monotone Min-Plus Product and the Single-Source Replacement Paths (SSRP) problem. In the SSRP problem, one is given a directed edge-weighted graph G and a source vertex s, and is asked to compute for each edge e, $d_G(s, v, e)$'s, the shortest path distances from s to each vertex v in $G \setminus \{e\}$. Note that the interesting case is when e belongs to a shortest paths tree rooted at s, so that there are only $O(n^2)$ distances to report.

[3] Throughout the paper we assume the entries of the matrices are polylog(n)-bit integers or ∞ unless otherwise stated.

The trivial algorithm for SSRP runs in $\tilde{O}(n^3)$ time: For each edge e on the shortest path tree rooted at s, run Dijkstra's algorithm on the graph with e removed. Negative edge weights can be handled with Johnson's trick [16], without increasing the asymptotic complexity. Vassilevska Williams and Williams [24] showed that APSP and SSRP are sub-cubically equivalent. Hence, assuming the APSP hypothesis, there is no $O(n^{3-\epsilon})$ time algorithm for SSRP in graphs with arbitrary integer weights, for any $\epsilon > 0$. There seems to be little hope to improve upon the trivial algorithm for the general case.

Grandoni and Vassilevska Williams [14] studied SSRP in graphs with integer edge weights of small absolute value. They gave an algorithm that solves SSRP in directed n-vertex graphs with edge weights in $\{-M, \ldots, M\}$ in $\tilde{O}(M^{\frac{1}{4-\omega}} n^{2+\frac{1}{4-\omega}})$ time, which would become $\tilde{O}(M^{0.5} n^{2.5})$ if $\omega = 2$. For positive weights only, they reduce the runtime to $\tilde{O}(Mn^{\omega})$.

Let us consider the special case $M = 1$. Here, the algorithms of [14] solve SSRP with positive weights 1 in $\tilde{O}(n^{\omega})$ time, while the $\tilde{O}(n^{2+\frac{1}{4-\omega}})$ runtime for SSRP with weights in $\{-1, 0, 1\}$ is the same as the runtime for APSP with weights in $\{-1, 0, 1\}$.

As APSP in graphs with arbitrary integer weights is fine-grained equivalent to SSRP with arbitrary integer weights [24], it is possible that APSP with weights in $\{-1, 0, 1\}$ could be fine-grained equivalent to SSRP with weights in $\{-1, 0, 1\}$.

It is believed that APSP in directed graphs with weights in $\{-1, 0, 1\}$ (and even for unweighted graphs) requires $n^{2.5-o(1)}$ time [19, 27], as the best known algorithm by Zwick [31] would run in $\Omega(n^{2.5})$ time even if $\omega = 2$. As SSRP with small *positive* weights is in $O(n^{2.5-\varepsilon})$ time for $\varepsilon > 0$ [14], it is likely not fine-grained equivalent to directed unweighted APSP. Beating the APSP runtime for SSRP with *negative* weights is an open problem.

This leads to the following interesting questions.

(1) Is SSRP with negative weights inherently harder than SSRP with only positive weights?
(2) Or, is it possible to improve the running time of SSRP with negative weights, possibly below $n^{2.5}$, thus showing that it is likely not as hard as directed unweighted APSP?

Quite surprisingly, we give positive answers to both of these questions. First, we improve over the running time of [14] for negative weights.

▶ **Theorem 2.** *There is a randomized algorithm that solves SSRP in a directed n-vertex graph with edge weights in $\{-M, \ldots, M\}$ in $\tilde{O}(M^{\frac{5}{17-4\omega}} n^{\frac{36-7\omega}{17-4\omega}})$ time, with high probability. Using the current best bound on fast rectangular matrix multiplication the running time improves to $O(M^{0.8043} n^{2.4957})$.*

Notably, when M is small enough, the running time $O(M^{0.8043} n^{2.4957})$ is polynomially faster than $n^{2.5}$, and hence faster than the best known running time of APSP in directed unweighted graphs which is $\Omega(n^{2.5})$ even if $\omega = 2$. This answers our question (2) above. If $\omega = 2$, our running time for SSRP with negative weights is $\tilde{O}(M^{5/9} n^{22/9}) \leq O(M^{0.556} n^{2.445})$.

APSP in directed graphs with edge weights in $\{-1, 0, 1\}$ is one of long list of so-called *intermediate* graph and matrix problems [19, 27], whose running time lies between $\tilde{O}(n^{\omega})$ and $\tilde{O}(n^3)$ and becomes $\tilde{O}(n^{2.5})$ when $\omega = 2$. Our result shows that SSRP with bounded negative integer weights is not an intermediate problem. We remark that recently Grandoni et al. [13] showed that another (ex-)candidate intermediate problem, All-Pairs LCA in DAGs, can actually be solved faster than $O(n^{2.5})$ time.

We prove Theorem 2 by improving the runtime of the so-called *subpath problem*, which is the bottleneck in the algorithm of [14]. Grandoni and Vassilevska Williams solve it by reducing to APSP in directed graphs with edge weights in $\{-M, \ldots, M\}$, and applying Zwick's APSP algorithm [31]. We show that the APSP computation can be rearranged so that certain min-plus products that appear throughout involve monotone matrices.

Next, we identify an obstacle to obtaining a $\tilde{O}(Mn^{\omega})$ time algorithm for SSRP with negative weights, addressing our question (1).

▶ **Theorem 3.** *If there exists a $T(n)$ time algorithm for SSRP in n-vertex graphs with edge weights in $\{-1, 0, 1\}$, then there exists an $O(T(n)\sqrt{n})$ time algorithm for the Bounded-Difference Min-Plus Product of $n \times n$ matrices.*

Theorem 3 gives the following argument why SSRP with negative weights might be hard. The current best algorithm for Bounded-Difference Min-Plus Product runs in $O(n^{2.7554})$ time even if $\omega = 2$. If SSRP with weights $\{-1, 0, 1\}$ could be solved in $\tilde{O}(n^2)$ time (when $\omega = 2$), then Bounded-Difference Min-Plus Product could be solved in $\tilde{O}(n^{2.5})$ time, which would be a breakthrough in structured Min-Plus Product algorithms.

Recently replacement paths problems have received increased attention [8, 2, 9, 10]. None of these works is directly related to ours, because they focus either on the s-t Replacement Paths problem (with both source and target nodes fixed), or on combinatorial algorithms (i.e. without fast matrix multiplication) for sparse graphs.

Range Mode. Given an array a of elements, a range mode query asks for the most frequent element in a contiguous interval of a. In the Batch Range Mode problem the array a is fixed and all range mode queries are given in advance. In the Dynamic Range Mode problem one starts with an empty array and has to support insertions and deletions, and handle queries in an online fashion.

Vassilevska Williams and Xu [25] were the first to use structured Min-Plus Product in range mode algorithms. They reduced Batch Range Mode to a Min-Plus Product instance where both matrices have some monotone structures. Their techniques give an $O(n^{1.4854})$ time algorithm for Batch Range Mode on an array of size n and n queries. Since we improve over their Monotone Min-Plus Product algorithm, we naturally obtain a faster Batch Range Mode algorithm.

▶ **Theorem 4.** *The Batch Range Mode problem can be solved deterministically in time $\tilde{O}(n^{\frac{21+2\omega}{15+\omega}})$. Using the current best bound on fast rectangular matrix multiplication the running time improves to $O(n^{1.4805})$.*

There are multiple algorithms that solve Dynamic Range Mode in $\tilde{O}(n^{2/3})$ time per update and query on an array of size bounded by n [6, 11]. Recently, Sandlund and Xu [21] improved both update and query time to $O(n^{0.6560})$ by using a so-called *Min-Plus-Query-Witness* problem. During the preprocessing phase of the Min-Plus-Query-Witness problem, one is given two matrices A, B. During the query phase, given two indices i, j and a set S, one is asked to compute $\arg\min_{k \notin S}\{A_{i,k} + B_{k,j}\}$, where the set S can be viewed as the set of elements recently deleted in the array. In the Min-Plus-Query-Witness instances reduced from Dynamic Range Mode, the matrices A, B have the monotone property, so our techniques for Monotone Min-Plus Product can also apply to these Min-Plus-Query-Witness instances, leading to a faster Dynamic Range Mode algorithm.

▶ **Theorem 5.** *The Dynamic Range Mode problem can be solved deterministically in $\tilde{O}(n^{\frac{\omega+9}{\omega+15}})$ worst-case time per query with $\tilde{O}(n^{\frac{3\omega+39}{2\omega+30}})$ space. Using the current best bound on fast rectangular matrix multiplication improves the running time to $O(n^{0.6524})$ and the space complexity to $O(n^{1.3262})$.*

1.2 Overview of the Monotone Min-Plus Product Algorithm

Our improvement is achieved by extending Vassilevska Williams and Xu's [25] framework so that it can handle the more general monotone matrices. The algorithm has three phases. Say we would like to compute the min-plus product $C = A \star B$, where B is a monotone matrix.

In Phase 1, we compute a matrix $\tilde{C}$ which is close in ℓ_∞ norm to the desired output C. This can be done by, e.g., computing the min-plus product of $\lfloor \frac{A}{W} \rfloor$ and $\lfloor \frac{B}{W} \rfloor$, the downscaled versions of A and B, for some small parameter W.

In Phase 2, we repeatedly sample columns of B, and create new matrices A^r and B^r (for $r = 1, 2, \ldots$) whose entries are simple linear combinations of A, B and $\tilde{C}$. We replace large-magnitude entries of A with ∞, so that all finite entries of A^r are of small absolute values, and that the min-plus product $A^r \star B^r$ can be computed efficiently. The results are collected in a way such that by the end of Phase 2, we have found, for every pair (i, j),

$$\min_k \{A_{i,k} + B_{k,j} : A^r_{i,k} \neq \infty \text{ for some } r\}.$$

In Phase 3, we deal with (i, k) such that $A^r_{i,k} = \infty$ for all r. Such (i, k) are called *uncovered*. It can be shown that the number of *relevant* triples (i, k, j) with (i, k) uncovered is small, and we can afford enumerating all such triples. The enumeration is done by performing a witness-listing version of min-plus product of the downscaled versions of A and B.

We base on the fact that, when a monotone matrix B has very small entries, the number of *changes*, i.e. pairs (k, j) for which $B_{k,j} \neq B_{k,j+1}$, can be upper-bounded. Then for each fixed i we let j iterate through its range, and we maintain the set $\{A_{i,k} + B_{k,j}\}$ during the iteration. The total number of updates to the set is exactly the number of changes. This gives us an efficient way to compute min-plus product (and its witness-listing version) of the downscaled matrices, and leads to an efficient running time for Phases 1 and 3.

What makes our improvement possible is that we focus directly on the structure of monotone matrices, instead of going through a lossy black-box reduction to the Min-Plus Product of bounded-difference matrices, like the previous work [25] did.

2 Preliminaries

▶ **Definition 6** (Rectangular Matrix Multiplication Exponent). *Let α, β, γ be non-negative real numbers. Define $\omega(\alpha, \beta, \gamma)$ to be the smallest number such that the product of an $n^\alpha \times n^\beta$ matrix by an $n^\beta \times n^\gamma$ matrix can be computed in $\tilde{O}(n^{\omega(\alpha,\beta,\gamma)})$ time.*

▶ **Definition 7.** *Let α, β, γ, θ be non-negative real numbers. Define $g(\alpha, \beta, \gamma, \theta)$ to be the smallest number such that the min-plus product of an $n^\alpha \times n^\beta$ matrix whose entries are in $\{-n^\theta, \ldots, n^\theta\} \cup \{\infty\}$ by an arbitrary $n^\beta \times n^\gamma$ matrix can be computed in $\tilde{O}(n^{g(\alpha,\beta,\gamma,\theta)})$ time.*

▶ **Definition 8** (Bounded-Difference Matrix). *An $n \times m$ matrix A is called a bounded-difference matrix if $|A_{i,j} - A_{i,j+1}| \leq 1$ for every $1 \leq i \leq n, 1 \leq j < m$ and $|A_{i,j} - A_{i+1,j}| \leq 1$ for every $1 \leq i < n, 1 \leq j \leq m$.*

▶ **Problem 9** (Bounded-Difference Min-Plus Product). *Given two bounded-difference integer matrices A and B, compute $A \star B$.*

▶ **Definition 10** (Monotone Matrix). *An $n^\beta \times n^\gamma$ matrix B is called monotone if for every $k \in [n^\beta]$, $B_{k,j}$ is non-decreasing in $j \in [n^\gamma]$. For a monotone matrix B, we define its total range as $\sum_{k \in [n^\beta]} (\max_{j \in [n^\gamma], B_{k,j} \neq \infty} B_{k,j} - B_{k,1} + 1)$.*

▶ **Problem 11** (Monotone Min-Plus Product). *Given an $n^\alpha \times n^\beta$ matrix A and an $n^\beta \times n^\gamma$ matrix B where B is monotone and has total range $O(n^{\beta+\eta})$, where α, β, γ, η are non-negative real numbers, compute the min-plus product $A \star B$.*

▶ **Definition 12.** *Define $m(\alpha, \beta, \gamma, \eta)$ to be the smallest number such that Monotone Min-Plus Product with parameters α, β, γ, η, can be computed in $\tilde{O}(n^{m(\alpha,\beta,\gamma,\eta)})$ time.*

In our applications, we only need the case $\alpha = \gamma$. Because $m(c\alpha, c\beta, c\gamma, c\eta) = cm(\alpha, \beta, \gamma, \eta)$ for any $c \geq 0$, it suffices to consider only the case $\alpha = \gamma = 1$.

2.1 Upper bounds for g

We prove some useful upper bound for the function $g(\cdot, \cdot, \cdot, \cdot)$ introduced in Definition 7. We use the following bound from [7], which is a straightforward generalization of Theorem 1.2 from [25] to the case of rectangular matrices.

▶ **Lemma 13.** *For any non-negative real numbers $\alpha, \beta, \gamma, \theta$,*

$$g(\alpha, \beta, \gamma, \theta) \leq \min_{0 \leq \delta \leq \beta} \max\{\omega(\alpha, \beta, \beta + \gamma - \delta) + \theta, \delta + \alpha + \gamma\}. \tag{1}$$

We only need the following special cases of (1).

▶ **Corollary 14.** *For any non-negative real numbers β and θ,*

$$g(1, \beta, 1, \theta) \leq \frac{1}{2}(2 + \beta + \omega(1, \beta, 1) + \theta), \tag{2}$$

$$g(1, 1, 1, \theta) \leq \min_{0 \leq \delta \leq 1} \max\{\omega(1, 1, 2 - \delta) + \theta, 2 + \delta\}. \tag{3}$$

Proof. Consider the term $\omega(\alpha, \beta, \beta + \gamma - \theta)$ in (1). By splitting matrix B into $n^{\beta-\delta}$ matrices along its second dimension and computing $n^{\beta-\delta}$ independent instances of matrix multiplications, we get

$$\omega(\alpha, \beta, \beta + \gamma - \delta) \leq \omega(\alpha, \beta, \gamma) + \beta - \delta. \tag{4}$$

We plug (4) into (1), and take $\delta = \min\{\beta, \frac{1}{2}(\omega(\alpha, \beta, \gamma) + \beta + \theta - \alpha - \gamma)\}$, to get

$$g(\alpha, \beta, \gamma, \theta) \leq \max\{\omega(\alpha, \beta, \gamma) + \theta, \frac{1}{2}(\alpha + \beta + \gamma + \omega(\alpha, \beta, \gamma) + \theta)\}. \tag{5}$$

However, if $\omega(\alpha, \beta, \gamma) + \theta \geq \frac{1}{2}(\alpha + \beta + \gamma + \omega(\alpha, \beta, \gamma) + \theta)$, then both sides of (5) are at least $\alpha + \beta + \gamma$, and we can compute the min-plus product in $O(n^{\alpha+\beta+\gamma})$ time using a trivial algorithm. Therefore we get (2).

(3) is a simple substitution $\alpha = \beta = \gamma = 1$ to (1). ◀

▶ Remark 15. In the rectangular case $\alpha = \gamma = 1$, we use (4) so that in the final expression (2) we only need to deal with terms of the form $\omega(1, \beta, 1)$, whose value can be bounded by [18]. We know of no handy upper bounds for $\omega(\alpha, \beta, \gamma)$ when all three parameters are distinct.

In the square case $\alpha = \beta = \gamma = 1$, we do not need to use the simplification (4). This is because the upper bound of $\omega(1, \beta, 1)$ in [18] is by a bilinear algorithm. Thus by [15], the same upper bound works for $\omega(1, 1, \beta)$.

3 Monotone Min-Plus Product

▶ **Theorem 16.** *The min-plus product of an $n \times n^\beta$ matrix A and an $n^\beta \times n$ matrix B where B is monotone with total range $O(n^{\beta+\eta})$ can be deterministically computed, for any $\theta \in [0, \eta]$, in time $\tilde{O}(n^{\max\{1+\beta+\eta-\theta, \frac{1}{2}(2+\beta+g(1,\beta,1,\theta))\}})$. In other words,*

$$m(1,\beta,1,\eta) \le \min_{0\le\theta\le\eta} \max\{1+\beta+\eta-\theta, \frac{1}{2}(2+\beta+g(1,\beta,1,\theta))\}.$$

Proof. Proof of Theorem 16 follows the three-phase framework of [4, 25], which we have briefly described in Section 1.2. Here we present the full algorithm.

Phase 1. Let $\theta \in [0, \eta]$ be a parameter, and let $W = \lfloor n^\theta \rfloor$. We define two matrices $\tilde{A}$ and $\tilde{B}$ as $\tilde{A}_{i,k} = \lfloor \frac{A_{i,k}}{W} \rfloor$ and $\tilde{B}_{k,j} = \lfloor \frac{B_{i,k}}{W} \rfloor$. We compute the min-plus product $\tilde{A} \star \tilde{B}$ and let $\tilde{C}_{i,j} = (\tilde{A} \star \tilde{B})_{i,j} W$. Then $||\tilde{C} - C||_\infty \le 2W$.

We compute $\tilde{A} \star \tilde{B}$ using the following lemma, which is a simple algorithm that works fast when the total range is very small.

▶ **Lemma 17.** $m(\alpha, \beta, \gamma, \eta) \le \max\{\alpha+\gamma, \beta+\gamma, \alpha+\beta+\eta\}$.

Proof. Say we would like to compute $C = A \star B$. For a fixed row $i \in [n^\alpha]$, we iterate through columns $j \in [n^\gamma]$, maintaining the multi-set $\{A_{i,k} + B_{k,j} : k \in [n^\beta]\}$.

Each time j increases, we need to update the multi-set for those k where $B_{k,j} \ne B_{k,j-1}$. The total number of (k, j) satisfying $B_{k,j} \ne B_{k,j-1}$ is $O(n^{\beta+\eta})$ by monotonicity and the bound on total range.

For each $i \in [n^\alpha]$, we need to make $O(n^{\beta+\eta})$ updates and $O(n^\gamma)$ queries for the minimum number in the multi-set. We can use a balanced BST to maintain the multi-set so that each update and query costs $\tilde{O}(1)$ time. The total running time is $\tilde{O}(n^{\max\{\alpha+\gamma, \beta+\gamma, \alpha+\beta+\eta\}})$. ◀

Total range of $\tilde{B}$ is $O(n^{\beta+\eta-\theta})$, so running time of Phase 1 is $\tilde{O}(n^{\max\{2, 1+\beta+\eta-\theta\}})$.

Phase 2. In Phase 2 we compute a matrix $\hat{C}$ which upper bounds $C = A \star B$ and agrees with it on most entries. Initially, let $\hat{C}_{i,j} \leftarrow \infty$ for all $i, j \in [n]$.

Phase 2 consists of $(10+\beta)n^\rho \log n$ *rounds*, for a parameter $\rho \ge 0$ to be chosen later. In the r-th round, we choose $j^r \in [n]$ uniformly at random[4]. Define matrix A^r and B^r as

$$A^r_{i,k} = \begin{cases} A_{i,k} + B_{k,j^r} - \tilde{C}_{i,j^r} & \text{if } A_{i,k} + B_{k,j^r} - \tilde{C}_{i,j^r} \le 3W \text{ and } A^{r'}_{i,k} = \infty \forall r' < r, \\ \infty & \text{otherwise,} \end{cases}$$

$$B^r_{k,j} = \begin{cases} B_{k,j} - B_{k,j^r} & \text{if } B_{k,j^r} \ne \infty, \\ 0 & \text{otherwise.} \end{cases}$$

We compute $C^r = A^r \star B^r$ using Corollary 14 because A^r has bounded entries. Finally, for all $i, j \in [n]$, we make the update $\hat{C}_{i,j} \leftarrow \min\{\hat{C}_{i,j}, C^r_{i,j} + \tilde{C}_{i,j^r}\}$.

In other words, in the end we have $\hat{C}_{i,j} = \min_r\{C^r_{i,j} + \tilde{C}_{i,j^r}\}$. If $A^r_{i,k} \ne \infty$, then for all j, we have $\hat{C}_{i,j} \le C^r_{i,j} + \tilde{C}_{i,j^r} \le A^r_{i,k} + B^r_{i,k} + \tilde{C}_{i,j^r} = A_{i,k} + B_{k,j}$. Thus in this case we have effectively updated $\hat{C}_{i,j}$'s using $A_{i,k} + B_{k,j}$ for all j.

[4] For simplicity of presentation, we use randomness here. The derandomization is deferred to the full version of the paper.

Following [25], we make the following definitions: a triple $(i,k,j) \in [n] \times [n^\beta] \times [n]$ is *strongly relevant*, if $A_{i,k} + B_{k,j} = C_{i,j}$; *weakly relevant*, if $A_{i,k} + B_{k,j} - \tilde{C}_{i,j} \leq 3W$; *covered*, if $A^r_{i,k} \neq \infty$ for some r; *uncovered*, if it is not covered. We use the following lemma from [25].

▶ **Lemma 18** ([25, Lemma 4.3]). *With probability $1 - n^{-9}$, the number of triples that are weakly relevant and uncovered is at most $n^{2+\beta-\rho}$.*

Proof. Fix some pair of (i,k). If the number of j such that (i,k,j) is weakly relevant is at least $n^{1-\rho}$, then with probability at least $1 - (1-n^{-\rho})^{(10+\beta)n^\rho \log n} \geq 1 - n^{-10-\beta}$, we will sample a j^r such that (i,k,j^r) is weakly relevant. If so, $A^r_{i,k} \neq \infty$ for some r and thus (i,k,j) will be covered for all j. Therefore, with probability at least $1 - n^{-9}$, all (i,k) that are in at least $n^{1-\rho}$ weakly relevant triples will be covered. The number of remaining weakly relevant triples is at most $n^{2+\beta-\rho}$. ◀

Each round costs $\tilde{O}(n^{g(1,\beta,1,\theta)})$ time. Phase 2 costs $\tilde{O}(n^{\rho+g(1,\beta,1,\theta)})$ time in total.

Phase 3. We define a triple (i,k,j) to be *moderately relevant* if $\tilde{A}_{i,k} + \tilde{B}_{k,j} \leq (\tilde{A} \star \tilde{B})_{i,j} + 1$. In Phase 3, we enumerate over moderately relevant and uncovered triples to complete matrix C.

▶ **Lemma 19.** *Every strongly relevant triple is also moderately relevant.*

Proof. Suppose (i,k,j) is strongly relevant. If $\tilde{A}_{i,k'} + \tilde{B}_{k',j} = (\tilde{A} \star \tilde{B})_{i,j}$ for some k', then because $A_{i,k} + B_{k,j} \leq A_{i,k'} + B_{k',j}$, we have

$$\tilde{A}_{i,k} + \tilde{B}_{k,j} \leq \tilde{A}_{i,k'} + \tilde{B}_{k',j} + 1 = (\tilde{A} \star \tilde{B})_{i,j} + 1.$$

Hence (i,k,j) is moderately relevant. ◀

▶ **Lemma 20.** *Every moderately relevant triple is also weakly relevant.*

Proof. Suppose (i,k,j) is moderately relevant. Then

$$\begin{aligned} A_{i,k} + B_{k,j} - \tilde{C}_{i,j} &\leq (\tilde{A}_{i,k} + 1)W + (\tilde{B}_{k,j} + 1)W - (\tilde{A} \star \tilde{B})_{i,j}W \\ &\leq (\tilde{A}_{i,k} + \tilde{B}_{k,j} - (\tilde{A} \star \tilde{B})_{i,j})W + 2W \leq 3W. \end{aligned}$$

Hence (i,k,j) is weakly relevant. ◀

By Lemma 19, it suffices to enumerate over moderately relevant and uncovered triples to recover all of C. By Lemmas 18 and 20, the number of moderately relevant and uncovered triples is at most $O(n^{2+\beta-\rho})$, with high probability.

▶ **Lemma 21.** *With high probability, it takes time $\tilde{O}(n^{\max\{2,1+\beta+\eta-\theta,2+\beta-\rho\}})$ to enumerate all moderately relevant and uncovered triples.*

Proof. Define matrix $\check{A}$ as $\check{A}_{i,k} = \tilde{A}_{i,k}$ if (i,k) is uncovered; and $\check{A}_{i,k} = \infty$ otherwise.

We proceed on computing $\check{A} \star \tilde{B}$ in a way similar to Lemma 17 from Phase 1. For each row i, we maintain the set $\{(\check{A}_{i,k} + \tilde{B}_{k,j}, k) : k \in [n^\beta]\}$ as j iterates over $[n]$. Each time j increases, we need to update the multi-set for those k where $\tilde{B}_{k,j} \neq \tilde{B}_{k,j-1}$. The total number of (k,j) satisfying $\tilde{B}_{k,j} \neq \tilde{B}_{k,j-1}$ is $O(n^{\beta+\eta-\theta})$.

For each (i,j), we enumerate the elements in the multi-set in the increasing order, and stop as soon as we observe a k where $\check{A}_{i,k} + \tilde{B}_{k,j} > (\tilde{A} \star \tilde{B})_{i,j} + 1$. Therefore we enumerate exactly the moderately relevant uncovered triples. The running time is the running time from Lemma 17, plus the number of triples emitted, which, with high probability, is at most $O(n^{2+\beta-\rho})$, by Lemma 18. ◀

Phase 3 runs in time $\tilde{O}(n^{\max\{2,1+\beta+\eta-\theta,2+\beta-\rho\}})$.

Summary. Overall running time of our algorithm is $\tilde{O}(n^{\max\{2,1+\beta+\eta-\theta,\rho+g(1,\beta,1,\theta),2+\beta-\rho\}})$. Note that $g(1,\beta,1,\theta) \leq 2+\beta$. So we can take $\rho = \frac{1}{2}(2+\beta-g(1,\beta,1,\theta))$. Also note that $\rho + g(1,\beta,1,\theta) \geq 2$, so the 2 in the max expression can be ignored. In the end we get $\tilde{O}(n^{\max\{1+\beta+\eta-\theta,\frac{1}{2}(2+\beta+g(1,\beta,1,\theta))\}})$ as claimed. ◀

As a benchmark, let us consider the case $\alpha = \beta = \gamma = \eta = 1$.

▶ **Theorem 1.** *The min-plus product $A \star B$ of two $n \times n$ matrices where entries of B are non-negative integers bounded by $O(n)$ and each row of B is non-decreasing can be computed deterministically in $\tilde{O}(n^{\frac{12+\omega}{5}})$ time. Using the current best bound on fast rectangular matrix multiplication the running time improves to $O(n^{2.8653})$.*

Proof. In this case, Theorem 16 simplifies (via (3)) to

$$\begin{aligned} m(1,1,1,1) &\leq \min_{0\leq\theta\leq 1} \max\{3-\theta, \frac{1}{2}(3+g(1,1,1,\theta))\} \\ &\leq \min_{0\leq\theta\leq 1} \max\{3-\theta, \frac{1}{2}(3+\min_{0\leq\delta\leq 1} \max\{\omega(1,1,2-\delta)+\theta, 2+\delta\})\}. \end{aligned} \tag{6}$$

Without using rectangular matrix multiplication, we can use $\omega(1,1,2-\delta) \leq 1-\delta+\omega$ and take $\theta = \frac{3-\omega}{5}$ and $\delta = \frac{2\omega-1}{5}$, so (6) takes value $\frac{12+\omega}{5}$.

Using the rectangular matrix multiplication upper bounds in [18] (see also Remark 15), we find that when $\theta = 0.1348$, $\delta = 0.7305$, expression (6) takes value ≤ 2.8653. ◀

4 Single Source Replacement Paths

We show our algorithm and lower bound for SSRP in this section. We use $d_G(u,v)$ to denote the length of a shortest path from u to v in a graph G, and we use $d_G(u,v,e)$ as a shorthand for $d_{G\setminus\{e\}}(u,v)$. When it is clear from the context, we sometimes omit G.

4.1 Algorithm

In this section we present our improved algorithm for SSRP, proving Theorem 2.

▶ **Theorem 2.** *There is a randomized algorithm that solves SSRP in a directed n-vertex graph with edge weights in $\{-M,\ldots,M\}$ in $\tilde{O}(M^{\frac{5}{17-4\omega}} n^{\frac{36-7\omega}{17-4\omega}})$ time, with high probability. Using the current best bound on fast rectangular matrix multiplication the running time improves to $O(M^{0.8043}n^{2.4957})$.*

To this end we improve the bottleneck in Grandoni-Vassilevska Williams algorithm [14], hence let us begin with a high level overview of that algorithm. This is however just to give a context and intuition, and our formal proof of Theorem 2 follows from a black-box[5] application of Lemmas 23 and 27.

[5] See end of the proof of Lemma 27 for a discussion why the $\tilde{O}(Mn^{\omega})$ component from Lemma 23 can be omitted.

Algorithm overview and the subpath problem. The algorithm first computes a shortest paths tree (from the source vertex s), and splits it into a subpolynomial number of subtrees. By using balanced separators, the subtrees can be roughly of the same size. Then, for each such subtree T, values $d_G(s, v, e)$ such that both vertex v and edge e belong to T are deferred to a recursive call on a graph obtained from G by carefully compressing its parts outside T. The only remaining interesting values $d_G(s, v, e)$ (i.e. such that they might be different from $d_G(s, v)$) are such that vertex v belongs to subtree T and edge e lies on the path from s to the root of T in the shortest paths tree. The problem of computing those remaining values is called *subpath problem*, which we now define formally.

▶ **Definition 22** (Subpath problem). *Given an n-vertex directed graph G with edge weights in $\{-M, \ldots, M\}$, a source vertex s, and a tree T which is a subtree of a shortest paths tree from s, compute $d_G(s, v, e)$ for every $v \in T$ and every e on the path from s to the root t of T in the shortest paths tree.*

Using the ideas outlined above, Grandoni and Vassilevska Williams formally reduce SSRP to the subpath problem.

▶ **Lemma 23** (Lemma 5.1 in [14]). *Given an algorithm that solves the subpath problem in time $\tilde{O}(M^\alpha n^\beta)$, with high probability, for constants $\beta \geq \alpha + 1 \geq 1$, there is an algorithm that solves SSRP in time $\tilde{O}(Mn^\omega + M^\alpha n^\beta)$, with high probability.*

Jumping paths and departing paths. We proceed to show how to solve the subpath problem. Let $P = (s = s_1 \to s_2 \to \cdots \to s_{|P|} = t)$ be the s-t path in the shortest paths tree. A replacement path witnessing $d_G(s, v, e)$ has to depart from P somewhere before e and then can either (1) join P back somewhere after e, and thus reach v through t, or (2) never use any other edge of P after departing. Paths of the first type are called *jumping paths*, and of the second type – *departing paths*. Grandoni and Vassilevska Williams [14] use the fact that jumping paths can be found by solving the *s-t replacement paths* problem, i.e. computing all $d_G(s, t, e)$'s for fixed t, which can be computed in $\tilde{O}(Mn^\omega)$ time (see Lemma 24). We just follow their approach in that regard.

▶ **Lemma 24** (Theorem 1.1 in [14]). *There is a randomized algorithm that solves s-t replacement paths problem in $\tilde{O}(Mn^\omega)$ time, with high probability.*

Improved algorithm for departing paths. Let $\widetilde{G}$ denote the graph obtained from G by removing all edges on path P. Note that the length of a shortest departing replacement path to v avoiding $e = (s_i, s_{i+1})$ equals to $\min_{j \leq i} d_G(s, s_j) + d_{\widetilde{G}}(s_j, v)$. Grandoni and Vassilevska Williams [14] simply feed $\widetilde{G}$ to Zwick's APSP algorithm [31], running in time $\tilde{O}(M^{\frac{1}{4-\omega}} n^{2+\frac{1}{4-\omega}})$, to compute all $d_{\widetilde{G}}(s_j, v)$'s. We take a different approach and employ our truly subcubic algorithm for Monotone Min-Plus Product. We remark that any truly subcubic algorithm would yield an improvement.

Let $\zeta \in [0, 1]$ be a parameter to be determined later. We say that a departing replacement path is *hop-long* if it visits at least n^ζ nodes after departing P, otherwise it is *hop-short*. We handle the two types of paths separately.

Hop-short paths. To find hop-short paths we use a modification of Zwick's APSP algorithm [31], already described in [14]. Zwick's algorithm consists of $O(\log n)$ iterations, and in the i-th iteration it computes the shortest paths which use at most $(3/2)^i$ nodes. By running only first few iterations we can compute all hop-short shortest paths in time $\tilde{O}(Mn^{\zeta+\omega(1,1-\zeta,1)})$, which is faster than it would take to compute all shortest paths (given that ζ is small enough). For a formal proof of this statement we refer to [14].

▶ **Lemma 25** (Corollary 3.1 in [14]). *The distances between all pairs of nodes that have shortest paths on at most n^ζ nodes can be computed in time $\tilde{O}(Mn^{\zeta+\omega(1,1-\zeta,1)})$, with high probability.*

Hop-long paths. To find hop-long paths, first we sample (with replacement) $c \cdot n^{1-\zeta} \ln n$ nodes, for a large enough constant c. Let $B \subseteq V$ denote the set of sampled nodes. For the sake of analysis let us fix a set $\mathcal{S}$ of shortest hop-long departing replacement for all nodes $v \in T$ and all edges $e \in P$. When there is more than one such path of the smallest length for a given pair (v, e), we choose an arbitrary one. Note that for paths in $\mathcal{S}$, we only include the portions after they depart P so that they only contain edges in $\widetilde{G}$. Since the definition of hop-long paths only concerns the length of the part of a path after it departs P, all paths in $\mathcal{S}$ have length at least n^ζ. By a standard proof, with high probability, every path in $\mathcal{S}$ contains a node from B which lies in that path's middle third part.

Then we construct Yuster-Zwick distance oracle for graph $\widetilde{G}$ (see Lemma 26 below) and use it compute all $\tilde{O}(n \cdot n^{1-\zeta})$ shortest paths to and from B using at least $(1/3) \cdot n^\zeta$ nodes. In total it takes time $\tilde{O}(Mn^\omega + n^{3-2\zeta})$.

▶ **Lemma 26** (implicit in [29], Lemma 2.3 in [14]). *Given an n-vertex directed graph G, with edge weights in $\{-M, \ldots, M\}$, one can compute in $\tilde{O}(Mn^\omega)$ time an $n \times n$ matrix D, so that the (i, j)-th entry of the min-plus product $D \star D$ is the distance from node i to j in G. Furthermore, by the properties of D, the length of a shortest $i \rightsquigarrow j$ path containing at least n^ζ nodes can be computed in $\tilde{O}(n^{1-\zeta})$ extra time, with high probability.*

Let $d^{YZ}(\cdot, \cdot)$ denote such computed distances. The length of a shortest hop-long departing replacement path to v avoiding $e = (s_i, s_{i+1})$ equals $\min_{j \le i} \min_{b \in B} d_G(s, s_j) + d^{YZ}(s_j, b) + d^{YZ}(b, v)$.

We create two matrices A and B, of dimensions at most $n \times |B|$ and $|B| \times n$, respectively, such that

$$A_{i,b} = \min_{j \le i} d_G(s, s_j) + d^{YZ}(s_j, b), \quad \text{and} \quad B_{b,v} = d^{YZ}(b, v).$$

We need to compute $A \star B$. Note that $A_{i+1,b} \le A_{i,b}$, i.e. columns of A are monotone. Moreover, finite entries of A are of absolute value at most $2 \cdot nM$, so we can compute $A \star B = (B^T \star A^T)^T$ in time $\tilde{O}(n^{m(1,1-\zeta,1,1+\log_n M)})$.

Wrap-up and runtime analysis. Now we can sum up the running time and then balance the terms. The proof of the following lemma is deferred to the full version of the paper.

▶ **Lemma 27.** *There is a randomized algorithm that solves the subpath problem in a directed n-vertex graph with edge weights in $\{-M, \ldots, M\}$ in $\tilde{O}(M^{\frac{5}{17-4\omega}} n^{\frac{36-7\omega}{17-4\omega}})$ time, with high probability. Using fast rectangular matrix multiplication improves the running time to $O(M^{0.8043} n^{2.4957})$.*

4.2 Lower Bound

In this section, we prove our conditional lower bound for SSRP.

▶ **Theorem 3.** *If there exists a $T(n)$ time algorithm for SSRP in n-vertex graphs with edge weights in $\{-1, 0, 1\}$, then there exists an $O(T(n)\sqrt{n})$ time algorithm for the Bounded-Difference Min-Plus Product of $n \times n$ matrices.*

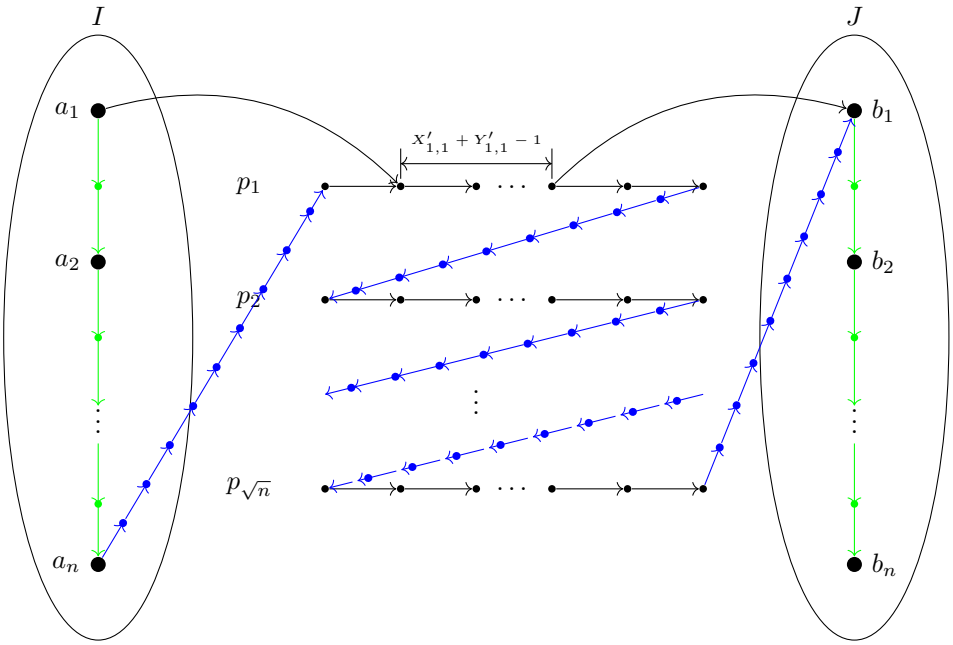

Figure 1 Reduction from Bounded-Difference Min-Plus Product to Ham-APSP (Lemma 29). Most edges between the parts I, J and the middle paths $p_1, \ldots, p_{\sqrt{n}}$ are omitted for clarity. The green portions are the first type paths, and the blue portions are the second type paths.

We first reduce Bounded-Difference Min-Plus Product to a problem called Ham-APSP, then we further reduce Ham-APSP to SSRP.

▶ **Problem 28** (Ham-APSP). *Given a directed unweighted graph G with vertex set $\{v_1, \ldots, v_n\}$ and a Hamiltonian path $v_1 \to \cdots \to v_n$ of G, compute all pairs shortest path distances in G.*

The key idea in the following reduction was used by Chan et al. [7] for a reduction from Min-Plus Product with small integer weights to unweighted directed APSP.

▶ **Lemma 29.** *If there exists a $T(n)$ time algorithm for Ham-APSP in a graph with n vertices, then there exists an $O(T(n)\sqrt{n})$ time algorithm for Bounded-Difference Min-Plus Product of $n \times n$ matrices.*

Proof. Given two $n \times n$ bounded-difference matrices A and B, we first split the columns of A and rows of B to $O(\sqrt{n})$ pieces. For each pair of pieces, we need to compute the min-plus product of an $n \times \sqrt{n}$ bounded-difference matrix X and a $\sqrt{n} \times n$ bounded-difference matrix Y. We will use a single call of the assumed $T(n)$ time algorithm for Ham-APSP to compute the min-plus product between each pair of pieces, yielding an $O(T(n)\sqrt{n})$ overall running time.

We create a new matrix X' such that $X'_{i,k} = X_{i,k} - X_{i,1}$. Since $|X_{i,k} - X_{i,k+1}| \leq 1$ for any i, k, all entries of X' are bounded by $\sqrt{n}$. We can create Y' similarly by setting $Y'_{k,j} = Y_{k,j} - Y_{1,j}$ so that all entries of Y' are bounded by $\sqrt{n}$ as well. We will later use the Ham-APSP algorithm to compute $X' \star Y'$, which immediately gives $X \star Y$ via the relation $(X \star Y)_{i,j} = (X' \star Y')_{i,j} + X_{i,1} + Y_{1,j}$.

In [7], Min-Plus Product of an $n \times \sqrt{n}$ and a $\sqrt{n} \times n$ matrices with weights up to $\sqrt{n}$ is reduced to unweighted directed APSP on n-node graphs. Here is a description of that reduction. We create a vertex set I of n vertices $\{a_1, \ldots, a_n\}$ and a vertex set J of n vertices $\{b_1, \ldots, b_n\}$. We also create $\sqrt{n}$ paths $p_1, \ldots, p_{\sqrt{n}}$ each of length $2\sqrt{n}$. From each a_i to p_k,

we add a directed edge from a_i to the $(\sqrt{n} - X'_{i,k})$-th node on p_k; similarly, from each p_k to b_j, we add a directed edge from the $(\sqrt{n} + Y'_{k,j})$-th node on p_k to b_j. Then we can see that the distance from a_i to b_j equals $(X' \star Y')_{i,j} + 2$.

In order to have a Hamiltonian path in the graph, we need to add two types of additional paths.

For the first type, we add paths of length 2 from a_i to a_{i+1} and from b_i to b_{i+1} for every $1 \le i < n$. Clearly, we only add $O(n)$ vertices and $O(n)$ edges. Now consider the shortest path from a_i to b_j for some i, j. The shortest path has the option to go to some $a_{i'}$ for $i' \ge i$, then choose some path p_k in the middle, then go to $b_{j'}$ for $j' \le j$, and finally reach b_j. The cost of this path would be $2(i' - i) + 1 + X'_{i',k} + Y'_{k,j'} + 1 + 2(j - j')$. Because X and Y have bound differences, we have that $2(i' - i) + X'_{i',k} \ge X'_{i,k}$ and $Y'_{k,j'} + 2(j - j') \ge Y'_{k,j}$. Therefore, in one of the shortest paths from a_i to b_j, we have $i' = i$ and $j' = j$. Thus, the distance from a_i to b_j is exactly $2 + (X' \star Y')_{i,j}$, so we can recover $X' \star Y'$ by computing all the pairwise distances.

For the second type of paths, we add $O(\sqrt{n})$ paths of lengths $3\sqrt{n}$ to connect I, J and each p_k, as shown in Figure 1. The total number of vertices and number of edges added are both $O(n)$. Since all distances we care about are at most $2\sqrt{n} + O(1)$, adding those paths won't affect these distances.

This graph now has a Hamiltonian path: we can travel from a_1 to a_n via the first type of paths. Then we use the second type of paths to travel from a_n to the beginning of p_1 and then we can easily travel to the end of p_1 by using edges of p_1. Similarly, we can go through all vertices in $p_2, \ldots, p_{\sqrt{n}}$. Finally, we travel from the end of $p_{\sqrt{n}}$ to b_1 via the second type of paths, and then use the first type of paths to travel to b_n. ◀

In the following lemma, we further reduce Ham-APSP to SSRP.

▶ **Lemma 30.** *If there exists a $T(n)$ time algorithm for SSRP in a graph with n vertices whose edge weights are in $\{-1, 0, 1\}$, then there exists an $O(T(n))$ time algorithm for Ham-APSP in a graph with n vertices.*

Proof. Let G be an instance of the Ham-APSP problem. We first create a graph G' whose vertex set is $\{v'_0, v'_1, \ldots, v'_n, v'_{n+1}\} \cup \{v_1, \ldots, v_n\}$. Then we add the following three types of edges to G, as depicted in Figure 2:

1. We add an edge from v'_i to v'_{i-1} of weight -1 for every $1 \le i \le n + 1$;
2. We add an edge from v'_i to v_i of weight 0 for every $1 \le i \le n$;
3. We add an edge from v_i to v_j of weight 1 for every $(v_i, v_j) \in E(G)$. This part essentially pastes a copy of G to G'.

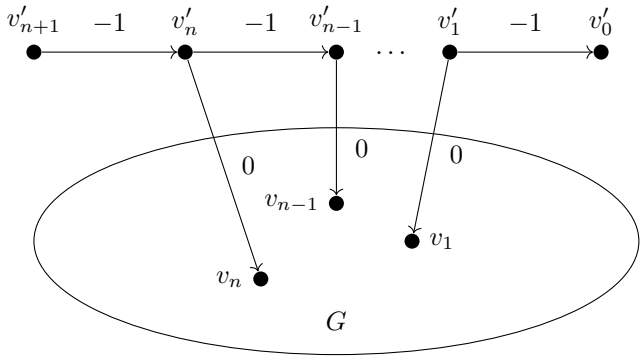

Figure 2 Reduction from Ham-APSP to SSRP with weights in $\{-1, 0, 1\}$ (Lemma 30).

If we cut the edge (v'_i, v'_{i-1}) in the graph G', then the shortest path from v'_{n+1} to v_j for some $1 \le j \le n$ must move from v'_{n+1} to v'_k for some $i \le k \le n$, then take the weight 0 edge to v_k, and finally move to v_j in the copy of graph G. Therefore, $d_{G'}(v'_{n+1}, v_i, (v'_i, v'_{i-1})) = \min_{i \le k \le n}(k - n - 1) + d_G(v_k, v_j)$. We show that $\min_{i \le k \le n}(k - n - 1) + d_G(v_k, v_j) = (i - n - 1) + d_G(v_i, v_j)$. Clearly, $\min_{i \le k \le n}(k - n - 1) + d_G(v_k, v_j) \le (i - n - 1) + d_G(v_i, v_j)$ since the right hand side is one of the terms we are minimizing over.

To show the other direction, we fix an arbitrary $k \in [i, n]$. By triangle inequality, $d_G(v_i, v_k) + d_G(v_k, v_j) \ge d_G(v_i, v_j)$. Since G has a Hamiltonian path $v_1 \to \cdots \to v_n$, it holds that $d_G(v_i, v_k) \le k - i$. Hence,

$$(k - n - 1) + d_G(v_k, v_j) \ge (k - n - 1) + d_G(v_i, v_j) - d_G(v_i, v_k) \ge (i - n - 1) + d_G(v_i, v_j).$$

We have shown that $d_{G'}(v'_{n+1}, v_i, (v'_i, v'_{i-1})) = (i - n - 1) + d_G(v_i, v_j)$. Thus, we can infer the pairwise distances in G by querying the assumed $T(n)$ time SSRP algorithm on graph G' since $d_G(v_i, v_j) = d_{G'}(v'_{n+1}, v_i, (v'_i, v'_{i-1})) - (i - n - 1)$. ◀

5 Range Mode

In this section, we show our improved algorithms for Batch Range Mode and Dynamic Range Mode.

5.1 Batch Range Mode

▶ **Theorem 4.** *The Batch Range Mode problem can be solved deterministically in time* $\tilde{O}(n^{\frac{21+2\omega}{15+\omega}})$. *Using the current best bound on fast rectangular matrix multiplication the running time improves to* $O(n^{1.4805})$.

Proof. Via a binary search, Sandlund and Xu [21] showed that the Batch Range Mode problem can be reduced to finding the frequencies of the most frequent elements for all queries (with an $\tilde{O}(1)$ factor overhead), which is in turn reduced to Monotone Min-Plus Product in [21, Theorem 6.1], leading to a deterministic

$$\tilde{O}(n^{\min_{0 \le \tau \le 1} \max\{m(1-\tau, 1-\tau, 1-\tau, \tau), 1+\tau\}})$$

time algorithm for Batch Range Mode.

Expanding the expression using Theorem 16 and (3), we have

$$\begin{aligned}
&\min_{0 \le \tau \le 1} \max\{m(1-\tau, 1-\tau, 1-\tau, \tau), 1+\tau\} \\
&= \min_{0 \le \tau \le 1} \max\{(1-\tau)m(1, 1, 1, \frac{\tau}{1-\tau}), 1+\tau\} \\
&\le \min_{0 \le \tau \le 1} \max\{(1-\tau) \min_{0 \le \theta \le \frac{\tau}{1-\tau}} \max\{2 + \frac{\tau}{1-\tau} - \theta, \frac{1}{2}(3 + g(1, 1, 1, \theta))\}, 1+\tau\} \\
&= \min_{\substack{0 \le \tau \le 1 \\ 0 \le \theta \le \frac{\tau}{1-\tau}}} \max\{\tau + (1-\tau)(2-\theta), \frac{1-\tau}{2}(3 + g(1, 1, 1, \theta)), 1+\tau\} \\
&\le \min_{\substack{0 \le \tau \le 1 \\ 0 \le \theta \le \frac{\tau}{1-\tau} \\ 0 \le \delta \le 1}} \max\{\tau + (1-\tau)(2-\theta), \frac{1-\tau}{2}(3 + \max\{\omega(1, 1, 2-\delta) + \theta, 2 + \delta\}), 1+\tau\}.
\end{aligned} \tag{7}$$

By using $\omega(1, 1, 2-\delta) \le 1 - \delta + \omega$ and taking $\delta = \frac{4\omega-3}{9}, \theta = \frac{3-\omega}{9}, \tau = \frac{6+\omega}{15+\omega}$, we can upper bound (7) by $\frac{21+2\omega}{15+\omega}$. Using the upper bounds in [18], we find that when $\tau = 0.4804$, $\theta = 0.0754$, $\delta = 0.6984$, expression (7) takes value ≤ 1.4805. ◀

5.2 Dynamic Range Mode

▶ **Theorem 5.** *The Dynamic Range Mode problem can be solved deterministically in $\tilde{O}(n^{\frac{\omega+9}{\omega+15}})$ worst-case time per query with $\tilde{O}(n^{\frac{3\omega+39}{2\omega+30}})$ space. Using the current best bound on fast rectangular matrix multiplication improves the running time to $O(n^{0.6524})$ and the space complexity to $O(n^{1.3262})$.*

Our strategy is to improve [21, Lemma 11]. The following Min-Plus-Query-Witness problem defined in [21, Problem 7] plays a key role in the algorithm for Dynamic Range Mode.

▶ **Problem 31** (Min-Plus-Query-Witness problem)**.** *We are given two matrices A and B and are able to perform preprocessing before the first query. For each query, we are given two indices i, j and a set S of indices, and we must output an index $k^* \notin S$ such that*

$$A_{i,k^*} + B_{k^*,j} = \min_{k \notin S}\{A_{i,k} + B_{k,j}\}.$$

We recall the following lemma from [21].

▶ **Lemma 32** ([21, Lemma 9])**.** *Let β and θ be non-negative real numbers. The Min-Plus-Query-Witness problem where A is an $n \times n^\beta$ matrix whose entries are in $\{-n^\theta, \ldots, n^\theta\} \cup \{\infty\}$ and B is an $n^\beta \times n$ matrix can be solved with*

- *$\tilde{O}(n^{\theta+\omega(1,\beta,1)+\beta-\sigma})$ preprocessing time,*
- *$\tilde{O}(|S| + n^\sigma)$ worst-case time per query,*
- *and $\tilde{O}(n^{\max\{2+\beta+\theta, 1+2\beta\}-\sigma})$ space,*

for every $0 \le \sigma \le \beta$.

The following is our key lemma for the dynamic range mode algorithm.

▶ **Lemma 33.** *The Min-Plus-Query-Witness problem where A is an $n \times n^\beta$ matrix, B is an $n^\beta \times n$ monotone matrix with total range $O(n^{\beta+\eta})$, and the size of S for each query is $O(n^\lambda)$, can be solved with*

- *$\tilde{O}(n^{\max\{1+\beta+\eta-\theta, \rho+\theta+\omega(1,\beta,1)+\beta-\sigma, 2+\beta-\rho\}})$ preprocessing time,*
- *$\tilde{O}(n^\lambda + n^{\rho+\sigma})$ worst-case time per query,*
- *and $\tilde{O}(n^{\max\{1+\beta+\eta-\theta, \rho+\max\{2+\beta+\theta, 1+2\beta\}-\sigma, 2+\beta-\rho\}})$ space,*

for any constants $0 \le \theta \le \eta$, $\rho \ge 0$ and $0 \le \sigma \le \beta$.

Proof. Preprocessing is in three steps, corresponding to the three phases of the algorithm for Theorem 16.

Preprocessing Step 1. This step is slightly more complicated than Phase 1 of Theorem 16. Let $0 \le \theta \le \eta$ be a parameter to be chosen. Let $W = \lfloor n^\theta \rfloor$. Define two matrices $\tilde{A}$ and $\tilde{B}$ as $\tilde{A}_{i,k} = \lfloor \frac{A_{i,k}}{W} \rfloor$ and $\tilde{B}_{k,j} = \lfloor \frac{B_{k,j}}{W} \rfloor$.

We iterate through $j \in [n]$, and in each iteration j, maintain for each $i \in [n]$ the set $L_{i,j} := \{(\tilde{A}_{i,k} + \tilde{B}_{k,j}, k) : k \in [n^\beta]\}$ using a *persistent* balanced BST.

Using the maintained information, we can compute a matrix $\tilde{C}'$, where each entry $\tilde{C}'_{i,j}$ is defined as W times the $(n^\lambda + 1)$-th smallest element in $\{\tilde{A}_{i,k} + \tilde{B}_{k,j} : k \in [n^\beta]\}$. Furthermore, for each (i, j) and for any t, we can enumerate the t smallest elements in $L_{i,j}$ in $\tilde{O}(t)$ time.

Time complexity and space complexity of this step are both $\tilde{O}(n^{\max\{2, 1+\beta+\eta-\theta\}})$.

Preprocessing Step 2. As in Phase 2 of Theorem 16, we sample $j^r \in [n]$ for $r \in [\tilde{O}(n^\rho)]$ for some parameter ρ to be chosen, and compute matrices A^r and B^r as

$$A^r_{i,k} = \begin{cases} A_{i,k} + B_{k,j^r} - \tilde{C}'_{i,j^r} & \text{if } |A_{i,k} + B_{k,j^r} - \tilde{C}'_{i,j^r}| \le 3W \text{ and } A^{r'}_{i,k} = \infty \forall r' < r, \\ \infty & \text{otherwise,} \end{cases}$$

$$B^r_{k,j} = \begin{cases} B_{k,j} - B_{k,j^r} & \text{if } B_{k,j^r} \neq \infty, \\ 0 & \text{otherwise.} \end{cases}$$

Then for each r, we apply the data structure in Lemma 32 to A^r and B^r. Running time for this step is $\tilde{O}(n^{\rho+\theta+\omega(1,\beta,1)+\beta-\sigma})$. Space complexity for this step is $\tilde{O}(n^{\rho+\max\{2+\beta+\theta,1+2\beta\}-\sigma})$.

We note that this part can be derandomized as well.

Preprocessing Step 3. For a pair (i,k) if $A^r_{i,k} \neq \infty$ for some r, we call (i,k) *covered*; otherwise we call it *uncovered*. We call a triple (i,k,j) *almost relevant* if $0 \le \tilde{A}_{i,k} + \tilde{B}_{k,j} - \frac{1}{W}\tilde{C}'_{i,j} \le 1$. Note that for such triples, we must have $|A_{i,k} + B_{k,j} - \tilde{C}'_{i,j}| \le 3W$. So the number of uncovered and almost relevant triples is $\tilde{O}(n^{2+\beta-\rho})$.

We run an algorithm similar to Lemma 21 to enumerate all uncovered and almost relevant triples (i,k,j). Then for each $i,j \in [n]$, we use a balanced BST to store the set $T_{i,j} := \{(A_{i,k} + B_{k,j}, k) : (i,k,j) \text{ is uncovered and almost relevant}\}$.

Running time for this step is $\tilde{O}(n^{\max\{2,1+\beta+\eta-\theta,2+\beta-\rho\}})$. Space complexity for this step is $\tilde{O}(n^{2+\beta-\rho})$.

Query. Now let us describe how to handle a query. Let (S,i,j) be a query, and k^* be an optimal index, i.e., $A_{i,k^*} + B_{k^*,j} = \min_{k \notin S}\{A_{i,k} + B_{k,j}\}$. There are three cases.

Case 1: (i,k^*) is covered. For each r, we query the data structure (Lemma 32) for A^r and B^r with (S_r,i,j) where $S_r = S \cap \{k : A^r_{i,k} \neq \infty\}$. Because finite entries of A^r are disjoint for different r, we have $\sum_r |S_r| = |S|$. So the total query time for this case is $\tilde{O}(|S| + n^{\rho+\sigma})$.

Case 2: (i,k^*) is uncovered and almost relevant. In this case k^* must be among the $(|S|+1)$ smallest elements in $T_{i,j}$. We deal with this case by enumerating the $(|S|+1)$ smallest elements in $T_{i,j}$. The query time for this case is $\tilde{O}(|S|)$.

Case 3: (i,k^*) is uncovered and not almost relevant. Note that by definition of $\tilde{C}'_{i,j}$, in this case we must have $\tilde{A}_{i,k^*} + \tilde{B}_{k^*,j} - \frac{1}{W}\tilde{C}'_{i,j} \le -1$. Therefore k^* must be among the $(n^\lambda + 1)$ smallest elements in $L_{i,j}$. We deal with this case by enumerating the $(n^\lambda+1)$ smallest elements in $L_{i,j}$. The query time for this case is $\tilde{O}(n^\lambda)$.

Summary. Total preprocessing time is $\tilde{O}(n^{\max\{1+\beta+\eta-\theta,\rho+\theta+\omega(1,\beta,1)+\beta-\sigma,2+\beta-\rho\}})$. Space complexity is $\tilde{O}(n^{\max\{1+\beta+\eta-\theta,\rho+\max\{2+\beta+\theta,1+2\beta\}-\sigma,2+\beta-\rho\}})$. Each query costs $\tilde{O}(n^\lambda + n^{\rho+\sigma})$ time. ◀

Proof of Theorem 5. The algorithm is exactly the same as in [21], except for replacing [21, Lemma 11] with Lemma 33. We skip most of the algorithm description and focus on analyzing the time and space complexity.

For the algorithm we need to choose three constants $t_1, t_2, t_3 \in [0,1]$. The algorithm has three parts.

Part 1: Infrequent values. In the first part, we handle values that appear at most n^{1-t_1} times. By maintaining n^{1-t_1} balanced BSTs, this part can be done in $\tilde{O}(n^{2-2t_1})$ time per operation. Space complexity is $\tilde{O}(n^{2-t_1})$.

Part 2: Newly modified values. We maintain a data structure holding frequent values that rebuilds every n^{t_2} operations. The data structure is discussed in Part 3. In Part 2, we deal with values that have been modified in the last n^{t_2} operations. This part can be done in $\tilde{O}(n^{t_2})$ time and $\tilde{O}(n^{t_2})$ space.

Part 3: Data structure. In Part 3, we build the data structure. For this part, we call Lemma 33 where A is an $n^{1-t_3} \times n^{t_1}$ matrix, B is an $n^{t_1} \times n^{1-t_3}$ monotone matrix with total range $O(n)$, and in the queries we have $|S| = O(n^{t_2})$. The dimensions $\alpha = \gamma = 1 - t_3$ come from choosing n^{1-t_3} evenly spaced points in $[n]$, and $\beta = t_1$ comes from the $O(n^{t_1})$ values which appear more than n^{1-t_1} times. In a query we pick the maximum interval whose endpoints are chosen points inside the query interval, and S is the set of values modified in the last n^{t_2} operations.

Rebuilding costs $\tilde{O}(n^{(1-t_3)\max\{1+\beta+\eta-\theta,\rho+\theta+\omega(1,\beta,1)+\beta-\sigma,2+\beta-\rho\}-t_2})$ time per operation[6], where $\beta = \frac{t_1}{1-t_3}$, $\eta = \frac{1-t_1}{1-t_3}$, and $0 \le \theta \le \eta$, $\rho \ge 0$, $0 \le \sigma \le \beta$ are constants to be chosen. One query in Lemma 33 costs $\tilde{O}(n^{t_2} + n^{(1-t_3)(\rho+\sigma)})$ time. Besides the above, we also need $\tilde{O}(n^{t_3})$ time per operation to deal with elements not covered by the maximum interval of chosen points inside the query interval.

Space cost of the data structure is $\tilde{O}(n^{(1-t_3)\max\{\rho+\max\{2+\beta+\theta,1+2\beta\}-\sigma,2+\beta-\rho\}})$.

Summary. Running time per operation is

$$\tilde{O}(n^{2-2t_1} + n^{t_2} + n^{(1-t_3)\max\{1+\beta+\eta-\theta,\rho+\theta+\omega(1,\beta,1)+\beta-\sigma,2+\beta-\rho\}-t_2} + n^{(1-t_3)(\rho+\sigma)} + n^{t_3}),$$

subject to $t_1, t_2, t_3 \in [0,1]$, $\beta = \frac{t_1}{1-t_3}$, $\eta = \frac{1-t_1}{1-t_3}$, $0 \le \theta \le \eta$, $\rho \ge 0$, $0 \le \sigma \le \beta$.

Space cost is $\tilde{O}(n^{2-t_1} + n^{t_2} + n^{(1-t_3)\max\{\rho+\max\{2+\beta+\theta,1+2\beta\}-\sigma,2+\beta-\rho\}})$.

As an observation, in the optimum case we have $\beta \ge 1$, so we may use $\omega(1,\beta,1) \le \omega+\beta-1$. As a result, we can set $t_1 = \frac{\omega+21}{2\omega+30}, t_2 = t_3 = \frac{\omega+9}{\omega+15}, \theta = \frac{3-\omega}{6}, \rho = \frac{3-\omega}{4}$ and $\sigma = \frac{5\omega+9}{12}$ to upper bound the running time by $\tilde{O}(n^{\frac{\omega+9}{\omega+15}})$. The space complexity is dominated by Part 1, which is $\tilde{O}(n^{2-t_1}) = \tilde{O}(n^{\frac{3\omega+39}{2\omega+30}})$.

Taking $t_1 = 0.67385$, $t_2 = t_3 = 0.6523$, $\theta = 0.1239$, $\rho = 0.1859$, $\sigma = 1.6902$ and using fast rectangular matrix multiplication we get $O(n^{0.6524})$ running time per operation. The space complexity is again dominated by Part 1, which is $\tilde{O}(n^{2-t_1}) = O(n^{1.3262})$. ◀

Constructing a Distance Sensitivity Oracle in $O(n^{2.5794}M)$ Time

Yong Gu

Abstract

We continue the study of *distance sensitivity oracles* (DSOs). Given a directed graph G with n vertices and edge weights in $\{1, 2, \ldots, M\}$, we want to build a data structure such that given any source vertex u, any target vertex v, and any failure f (which is either a vertex or an edge), it outputs the length of the shortest path from u to v not going through f. Our main result is a DSO with preprocessing time $O(n^{2.5794}M)$ and constant query time. Previously, the best preprocessing time of DSOs for directed graphs is $O(n^{2.7233}M)$, and even in the easier case of undirected graphs, the best preprocessing time is $O(n^{2.6865}M)$ [Ren, ESA 2020]. One drawback of our DSOs, though, is that it only supports distance queries but not path queries.

Our main technical ingredient is an algorithm that computes the inverse of a degree-d polynomial matrix (i.e. a matrix whose entries are degree-d univariate polynomials) modulo x^r. The algorithm is adapted from [Zhou, Labahn and Storjohann, *Journal of Complexity*, 2015], and we replace some of its intermediate steps with faster rectangular matrix multiplication algorithms.

We also show how to compute *unique* shortest paths in a directed graph with edge weights in $\{1, 2, \ldots, M\}$, in $O(n^{2.5286}M)$ time. This algorithm is crucial in the preprocessing algorithm of our DSO. Our solution improves the $O(n^{2.6865}M)$ time bound in [Ren, ESA 2020], and matches the current best time bound for computing all-pairs shortest paths.

We would also like to thank an anonymous reviewer for suggesting the title of Section 5, and another anonymous reviewer for pointing out a subtle issue regarding the invertibility of polynomial matrices (and fixing the issue).

1 Introduction

In this paper, we consider the problem of constructing a *distance sensitivity oracle* (DSO). A DSO is a data structure that preprocesses a directed graph $G = (V, E)$ with n vertices and m edges, and supports queries of the following form: Given a source vertex u, a target vertex v, and a failure f (which can be either a vertex or an edge), output the length of the shortest path from u to v that does not go through f.

One motivation for constructing DSOs is the fact that real-life networks often suffer from failures. Consider a communication network among n servers. When a server u wants to send a message to another server v, the most efficient way would be to send the message along the

© Yong Gu and Hanlin Ren;
licensed under Creative Commons License CC-BY 4.0

shortest path from u to v. However, if a failure happens in a server or a link between two servers, we would need to recompute the shortest path with the failure taken into account. It may be too slow to compute the shortest path from scratch each time a failure happens. A better solution is to construct a DSO for the communication network, and invoke the query algorithm of the DSO whenever a failure happens.

1.1 Related Work

The problem of constructing DSOs has received a lot of attention in the literature. A naïve solution is to precompute the answers for every possible query (u, v, f), but it requires $\Omega(n^2 m)$ space to store this DSO. Demetrescu et al. [11] constructed a DSO with $O(n^2 \log n)$ space that answers a query in constant time. However, the preprocessing time of the DSO in [11] is $O(mn^2 + n^3 \log n)$, which is inefficient for large networks. Subsequently, Bernstein and Karger improved the preprocessing time to $\tilde{O}(n^2\sqrt{m})$ [5], and finally $\tilde{O}(mn)$ [6].[1] The preprocessing time $\tilde{O}(mn)$ matches the current best time bound for the easier problem of computing *all-pairs shortest paths* (APSP), and it is conjectured that APSP requires $mn^{1-o(1)}$ time [20]. In this sense, the $\tilde{O}(mn)$ time bound of [6] is optimal. Duan and Zhang [14] improved the space complexity of the DSO to $O(n^2)$, eliminating the last $\log n$ factor, while preserving constant query time and $\tilde{O}(mn)$ preprocessing time.

However, for dense graphs (i.e. $m = \Theta(n^2)$) with edge weights in $[-M, M]$, it is possible to compute APSP in time faster than $\tilde{O}(mn) = \tilde{O}(n^3)$. The best APSP algorithm for undirected graphs runs in $\tilde{O}(n^\omega M)$ time [27, 30], and the best APSP algorithm for directed graphs runs in $O(n^{2.5286}M)$ time [4, 42]. (Here $\omega < 2.3728596$ is the exponent of matrix multiplication [2, 9, 19, 32, 37].) Therefore, it is natural to ask whether one can beat $\tilde{O}(n^3)$ preprocessing time for DSOs in this regime.

The answer turned out to be *yes*. Weimann and Yuster [36] showed that for any constant $0 < \alpha < 1$, there is a DSO with $\tilde{O}(n^{1-\alpha+\omega}M)$ preprocessing time and $\tilde{O}(n^{1+\alpha})$ query time. Subsequently, Grandoni and Williams [16] showed that for any constant $0 < \alpha < 1$, there is a DSO with $\tilde{O}(n^{\omega+1/2}M + n^{\omega+\alpha(4-\omega)}M)$ preprocessing time and $\tilde{O}(n^{1-\alpha})$ query time. Recently, Chechik and Cohen [8] constructed the first DSO that achieves both sub-cubic ($O(n^{2.873}M)$) preprocessing time and poly-logarithmic query time simultaneously. For the case that edge weights are positive, Ren [22] improved the previous results by presenting a much simpler DSO with $\tilde{O}(n^{2.7233}M)$ preprocessing time and constant query time.

Note that most DSOs mentioned above are randomized. Recently, there are also some efforts on derandomizing these DSOs, see e.g. [3, 23].

1.2 Our Results

Our main result is an improved DSO for directed graphs with integer edge weights in $[1, M]$. In particular, our DSO has preprocessing time $O(n^{2.5794}M)$ and constant query time.

▶ **Theorem 1.1** (Main). *Given as input a directed graph $G = (V, E)$ with edge weights in $\{1, 2, \ldots, M\}$, we can construct a DSO with $O(n^{2.5794}M)$ preprocessing time and constant query time. With high probability over the randomized preprocessing algorithm, the DSO answers every possible query correctly.*

[1] $\tilde{O}$ hides polylog(n) factors.

▶ Remark 1.2. Our preprocessing algorithm uses fast *rectangular* matrix multiplication algorithms. To express our time bound as a function of ω, we could also simulate rectangular matrix multiplications by square matrix multiplications, e.g. multiply an $n \times m$ matrix and an $m \times n$ matrix by $\lceil m/n \rceil$ square matrix multiplications of dimension n. In this case, the preprocessing time becomes $\tilde{O}(n^{2+1/(4-\omega)}M) < O(n^{2.6146}M)$.

▶ Remark 1.3 (Comparison with Prior Works). The biggest advantage of our DSO is, of course, its fast preprocessing algorithm. In fact, the preprocessing time bound is only an $O(n^{0.051})$ factor away from the current best time bound for APSP. Our DSO is also the first one to break a barrier of $\tilde{\Omega}(n^{8/3})$ preprocessing time, while keeping constant query time.[2] However, our DSO has two drawbacks. First, it can only return the length of the shortest path. It does not suggest an efficient way to produce this path. Second, it does not support negative edge weights.

We highlight two technical ingredients that are crucial for the preprocessing algorithm of our DSO.

Inverting a polynomial matrix modulo x^r

Let r be an integer parameter, and $\mathbf{F}$ be a polynomial matrix of degree d (i.e. each entry of $\mathbf{F}$ is a degree-d polynomial over some formal variable x) that is invertible. We show how to compute $\mathbf{F}^{-1} \bmod x^r$ in time

$$\tilde{O}(dn^\omega) + (r^2/d) \cdot \mathsf{MM}(n, nd/r, nd/r) \cdot n^{o(1)}.$$

(That is, we only preserve the monomials in $\mathbf{F}^{-1}$ with degrees at most $r-1$.) Here, $\mathsf{MM}(n_1, n_2, n_3)$ is the time complexity of multiplying an $n_1 \times n_2$ matrix and an $n_2 \times n_3$ matrix.

It is shown in [40] that we can compute the full $\mathbf{F}^{-1}$ (instead of $\mathbf{F}^{-1} \bmod x^r$) in $\tilde{O}(n^3 d)$ time. We examine their algorithm carefully, and adapt it to our case where we only want to compute $\mathbf{F}^{-1} \bmod x^r$. We modulo each polynomial in the intermediate steps of the algorithm by x^r, and use fast rectangular matrix multiplication to speed up the algorithm.

▶ **Theorem 1.4.** *Let r be an integer, $\mathbb{F}$ be a finite field. Let $\mathbf{F} \in \mathbb{F}[x]^{n \times n}$ be an $n \times n$ matrix over the ring of univariate polynomials $\mathbb{F}[x]$, and let $d \geq 1$ be an upper bound on the degrees of entries of $\mathbf{F}$. If $\mathbf{F}$ is invertible over $(\mathbb{F}[x]/\langle x^r \rangle)^{n \times n}$, the number of field operations to compute $\mathbf{F}^{-1} \bmod x^r$ is at most*

$$\tilde{O}(dn^\omega) + (r^2/d) \cdot \mathsf{MM}(n, nd/r, nd/r) \cdot n^{o(1)}.$$

▶ Remark 1.5. The idea of using polynomial matrices to capture distances is a common technique in graph algorithms. It has found many applications in static algorithms [24], fault-tolerant algorithms [35], and dynamic algorithms [25, 33, 34].

[2] There are three previous DSOs with both sub-cubic preprocessing time and constant query time: [16], [8], and [22]. (The query time of the first two DSOs can be brought down to constant using Observation 2.1 of [22]. In the case of [16], this increases the preprocessing time by an additive factor of $\tilde{O}(n^{3-\alpha})$.) Even when $\omega = 2$, the preprocessing time bounds of these DSOs are $\tilde{O}(n^{8/3})$ (setting α appropriately), $\tilde{O}(n^{14/5})$, and $\tilde{O}(n^{8/3})$ respectively.

Computing consistent shortest path trees

Our DSO needs to invoke [22, Observation 2.1] (see also [6]), which needs a *consistent* set of (incoming and outgoing) shortest path trees rooted at each vertex. Here, by *consistent*, we mean that for every pair of vertices u, v and any two shortest path trees T_1 and T_2 (from the $2n$ trees; recall they are *directed* rooted trees), if u can reach v in both T_1 and T_2, then the $u \rightsquigarrow v$ paths in T_1 and T_2 are the same path. In other words, we want to specify a *unique* shortest path between each pair of vertices, such that for every vertex v, the shortest paths starting from v (or ending at v, respectively) form a tree.

Note that this problem is quite nontrivial in small-weighted graphs. There may be many shortest paths between two vertices, and it is not obvious how to pick one shortest path for each vertex pair, while guaranteeing consistency. Also, we cannot randomly perturb the edge weights by small values, as that would break the property that edge weights are small integers. It is also unclear how to construct such a set of shortest path trees from the APSP algorithm in [42]. Previously, combining ideas in [10, Section 3.4] and an algorithm in [13], [22] showed how to compute such shortest path trees in $\tilde{O}(n^{(3+\omega)/2}M) \leq O(n^{2.6865}M)$ time; unfortunately, this time bound is worse than our claimed time bound $O(n^{2.5794}M)$ in Theorem 1.1.

In this paper, we show how to construct consistent shortest paths trees in $O(n^{2.5286}M)$ time, matching the currently best time bound for APSP [42]. Below is an informal statement, see Theorem 5.1 for the precise version.

▶ **Theorem 1.6** (Informal Version). *Given a directed graph $G = (V, E)$ with edge weights in $\{1, 2, \ldots, M\}$, we can compute a set of incoming and outgoing shortest path trees rooted at each vertex that are consistent, in $O(n^{2.5286}M)$ time.*

1.3 Warm-Up: DSO in $\tilde{O}(n^{(3+\omega)/2}M)$ Preprocessing Time

Actually, the ideas in [35] of maintaining the *adjoint* of the *symbolic adjacency matrix* (see Section 3), together with ideas in [22], already give us a DSO with $\tilde{O}(n^{(3+\omega)/2}M)$ preprocessing time and constant query time. As a warm-up, we briefly describe this DSO before we proceed into the details of Theorem 1.1.

An *r-truncated DSO* [22] is a DSO that only needs to be correct for the queries (u, v, f) whose answer (i.e. length of the corresponding shortest path) is at most r. If the answer is greater than r, it should return r instead. In what follows, we will describe how to construct an r-truncated DSO in $\tilde{O}(rn^{\omega})$ preprocessing time and $\tilde{O}(r)$ query time. Using techniques in [22] (see also Section 3.3), this implies a DSO with $\tilde{O}(n^{(3+\omega)/2}M)$ preprocessing time and constant query time.

Let $\mathbb{F}$ be a sufficiently large finite field, and $\mathbf{A}$ be the following matrix. For every vertices u, v, if there is an edge from u to v with weight l, then let $\mathbf{A}_{u,v} = a_{u,v}x^l$, where $a_{u,v}$ is a random element in $\mathbb{F}$, and x is an indeterminate. Furthermore, for every vertex v, let $\mathbf{A}_{v,v} = 1$. It is well-known [24] that with high probability over the choices of $a_{u,v}$, the *adjoint* matrix of $\mathbf{A}$ encodes the shortest path information of the input graph, as follows. Let $\mathrm{adj}(\mathbf{A})$ be the adjoint matrix of $\mathbf{A}$, and u, v be two vertices, then the lowest degree of $\mathrm{adj}(\mathbf{A})_{u,v}$ is exactly the distance from u to v. For example, if $\mathrm{adj}(\mathbf{A})_{u,v} = 7x^8 + 6x^5 - 9x^4$, then the distance from u to v is 4.

A big advantage of the adjoint matrix, exploited in [35] and also this work, is that it is easy to perform *low-rank* updates, by the Sherman-Morrison-Woodbury formula (see Theorem 3.2). Given a matrix $\mathbf{A}$, its adjoint $\mathrm{adj}(\mathbf{A})$, and a low-rank matrix $\mathbf{B}$, we can compute a specific element of $\mathrm{adj}(\mathbf{A}+\mathbf{B})_{u,v}$, in time much faster than brute force. Therefore,

we answer a query (u, v, f) as follows: We first express the failure as a *rank-one* matrix $\mathbf{F}$, such that $\mathbf{A} + \mathbf{F}$ is the matrix corresponding to the graph with f removed. Then we can compute $\text{adj}(\mathbf{A} + \mathbf{F})_{u,v}$ quickly. Given this element (a polynomial over $\mathbb{F}$), we can easily compute the answer to the query.

What is the time complexity of this DSO? Recall that we only want to construct an r-truncated DSO, so we can modulo every entry in the process of computing $\text{adj}(\mathbf{A})$ by the polynomial x^r. Every arithmetic operation in the commutative ring $\mathbb{F}[x]/x^r$ only takes $\tilde{O}(r)$ time. Computing the adjoint of a matrix reduces to inverting that matrix, which takes $\tilde{O}(n^\omega)$ arithmetic operations [7]. Therefore it takes $\tilde{O}(rn^\omega)$ time to compute $\text{adj}(\mathbf{A}) \bmod x^r$. A close inspection of the Sherman-Morrison-Woodbury formula shows that each query can be completed in $O(1)$ arithmetic operations, i.e. $\tilde{O}(r)$ time.

The $\tilde{O}(rn^\omega)$-time algorithm for inverting a polynomial matrix modulo x^r is not optimal; the time bound in Theorem 1.4 is better. In Section 4, we use fast rectangular matrix multiplication algorithms to speed up the algorithm in [40], obtaining a faster algorithm for inverting polynomial matrices modulo x^r.

2 Preliminaries

In this paper, we say an event happens *with high probability* (w.h.p.) if it happens with probability at least $1 - 1/n^c$, for a constant c that can be made arbitrarily large. Our DSOs (or r-truncated DSOs) will have a randomized preprocessing algorithm and a deterministic query algorithm. We say a DSO is *correct with high probability* if w.h.p. over its (randomized) preprocessing algorithm, it answers every possible query (u, v, f) correctly.

Notation

We use the following notation in [12, 22].

- Let p be a path, we use $|p|$ to denote the number of edges in p, and use $\|p\|$ to denote the length of p (i.e. total weight of edges in p).
- Let u, v be two vertices, we define $\|uv\|$ as the length of the shortest path from u to v. Furthermore, let f be a failure (which is either an edge or a vertex), we define $\|uv \diamond f\|$ as the length of the shortest path from u to v that does not go through f.
- Let u, v be two vertices, we define $|uv|$ as the number of edges in the shortest path from u to v. In the case that there are many shortest paths from u to v, it turns out that the following definition will be convenient in Section 5: We define $|uv|$ as the *largest* number of edges in any shortest path from u to v.

Fast matrix multiplication

Let ω be the exponent of matrix multiplication; the current best upper bound is $\omega \leq 2.3728596$ [2]. For positive integers n_1, n_2, n_3, let $\mathsf{MM}(n_1, n_2, n_3)$ denote the minimum number of arithmetic operations needed to multiply an $n_1 \times n_2$ matrix and an $n_2 \times n_3$ matrix. We define $\omega(a, b, c)$ to be the exponent of multiplying an $n^a \times n^b$ matrix and an $n^b \times n^c$ matrix, i.e.

$$\omega(a, b, c) = \inf\{w : \mathsf{MM}(n^a, n^b, n^c) = O(n^w)\}.$$

It is a classical result that $\omega(1, 1, \lambda) = \omega(1, \lambda, 1) = \omega(\lambda, 1, 1)$ for any real number $\lambda > 0$ [21]; we denote $\omega(\lambda) = \omega(1, 1, \lambda)$.

We will need the following lemmas about the exponent of rectangular matrix multiplication. We refer the reader to the full version of this paper for their proofs.

▶ **Lemma 2.1.** *Let a, b, c, r be positive real numbers, then $r + \omega(a, b, c) \leq \omega(a, b + r, c + r)$.*

▶ **Lemma 2.2.** *Consider the function $f(\tau) = \omega(1, 1 - \tau, 1 - \tau)$, where $\tau \in [0, 1]$. Then $\tau + f(\tau)$ is monotonically non-increasing in τ, and $2\tau + f(\tau)$ is monotonically non-decreasing in τ.*

Polynomial operations

Let $p, q \in \mathbb{F}[x]$ be two polynomials of degree d. It is easy to compute $p + q$ or $p - q$ in $O(d)$ field operations. We can also compute $p \cdot q$ in $\tilde{O}(d)$ field operations using fast Fourier transform. (Here, $\tilde{O}$ hides polylog(d) factors.) When p is invertible, it is also possible to compute $p^{-1} \bmod x^d$ in $\tilde{O}(d)$ field operations [1, Section 8.3].

3 Constructing a DSO in $O(n^{2.5794}M)$ Time

In this section, we show how to preprocess a distance sensitivity oracle in $O(n^{2.5794}M)$ time, such that every query can be answered in constant time. Our preprocessing algorithm is randomized; with high probability over the preprocessing algorithm, the query algorithm always returns the correct answer.

3.1 Preliminaries

First, our preprocessing algorithm will use the following algorithm for inverting a polynomial matrix. A sketch of this algorithm will be given in Section 4.

▶ **Theorem 1.4.** *Let r be an integer, $\mathbb{F}$ be a finite field. Let $\mathbf{F} \in \mathbb{F}[x]^{n \times n}$ be an $n \times n$ matrix over the ring of univariate polynomials $\mathbb{F}[x]$, and let $d \geq 1$ be an upper bound on the degrees of entries of $\mathbf{F}$. If $\mathbf{F}$ is invertible over $(\mathbb{F}[x]/\langle x^r \rangle)^{n \times n}$, the number of field operations to compute $\mathbf{F}^{-1} \bmod x^r$ is at most*

$$\tilde{O}(dn^\omega) + (r^2/d) \cdot \mathsf{MM}(n, nd/r, nd/r) \cdot n^{o(1)}.$$

Let G be a directed graph whose edge weights are integers in $[1, M]$. We define its *symbolic adjacency matrix* $\mathsf{SA}(G)$ as (see [24])

$$\mathsf{SA}(G)_{i,j} = \begin{cases} 1 & \text{if } i = j, \\ z_{i,j}x^l & \text{if there is an edge from } i \text{ to } j \text{ with weight } l \text{ in } G, \\ 0 & \text{otherwise,} \end{cases}$$

where $z_{i,j}$ are unique variables corresponding to edges of G.

It will be inefficient to deal with these variables $z_{i,j}$, therefore we will pick a suitably large field $\mathbb{F}$, and substitute each variable $z_{i,j}$ by a random element in $\mathbb{F}$. However, we still keep the indeterminate x. Now, let $\mathbf{Z}$ be a matrix where each $\mathbf{Z}_{i,j} \in \mathbb{F}$, we will use $\mathsf{SA}_{\mathbf{Z}}(G)$ to denote the matrix $\mathsf{SA}(G)$ with each formal variable $z_{i,j}$ substituted by the field element $\mathbf{Z}_{i,j}$. Note that $\mathsf{SA}_{\mathbf{Z}}(G)$ is a polynomial matrix where every entry is a polynomial over x with degree at most M.

We recall the definition of *adjoint* matrix that will be crucial to our algorithm. Let $\mathbf{A}$ be an $n \times n$ matrix, $i, j \in [n]$. We denote by $\mathbf{A}^{i,j}$ the matrix $\mathbf{A}$ with every element in the i-th row and the j-th column set to zero, except that $(\mathbf{A}^{i,j})_{i,j} = 1$. The adjoint matrix of $\mathbf{A}$, denoted as $\mathrm{adj}(\mathbf{A})$, is an $n \times n$ matrix such that $\mathrm{adj}(\mathbf{A})_{i,j} = \det(\mathbf{A}^{j,i})$ for every $i, j \in [n]$. A basic fact about $\mathrm{adj}(\mathbf{A})$ is that if $\det(\mathbf{A}) \neq 0$, then $\mathrm{adj}(\mathbf{A}) = \det(\mathbf{A}) \cdot \mathbf{A}^{-1}$.

There is a close relationship between the distances in the graph G, and the entries in the adjoint of $\mathsf{SA}(G)$. Let p be a multivariate polynomial, we define $\deg_x^*(p)$ as the lowest degree of the variable x in any monomial of p. If $p = 0$, then we define $\deg_x^*(p) := +\infty$. We have:

▶ **Theorem 3.1** ([24, Lemma 4]). *Let G be a directed graph with positive integer weights, i, j be two vertices. Then the distance from i to j in G is $\deg_x^*(\mathrm{adj}(\mathsf{SA}(G))_{i,j})$.*

We need the following theorem that allows us to maintain the adjoint of a matrix under *rank*-1 queries. (This theorem is a special case of [35, Lemma 1.6].)

▶ **Theorem 3.2.** *Let $\mathcal{R}$ be an arbitrary commutative ring, $\mathbf{A} \in \mathcal{R}^{n\times n}$ be an invertible matrix, $\mathbf{u}, \mathbf{v} \in \mathcal{R}^n$ be column vectors, and $\gamma = 1 + \mathbf{v}^\mathsf{T}\mathbf{A}^{-1}\mathbf{u}$. Suppose γ is invertible, then $\mathbf{A} + \mathbf{u}\mathbf{v}^\mathsf{T}$ is also invertible, and*

$$\mathrm{adj}(\mathbf{A} + \mathbf{u}\mathbf{v}^\mathsf{T}) = \det(\mathbf{A})(\gamma\mathbf{A}^{-1} - (\mathbf{A}^{-1}\mathbf{u}\mathbf{v}^\mathsf{T}\mathbf{A}^{-1})).$$

Proof Sketch. By the matrix determinant lemma, we have

$$\det(\mathbf{A} + \mathbf{u}\mathbf{v}^\mathsf{T}) = \gamma \cdot \det(\mathbf{A}).$$

Since γ is invertible, we can use the Sherman-Morrison-Woodbury formula [29, 38]:

$$(\mathbf{A} + \mathbf{u}\mathbf{v}^\mathsf{T})^{-1} = \mathbf{A}^{-1} - \gamma^{-1}(\mathbf{A}^{-1}\mathbf{u}\mathbf{v}^\mathsf{T}\mathbf{A}^{-1}).$$

The theorem is proved by multiplying the above two formulas together. ◀

We need the Schwartz-Zippel lemma that guarantees the correctness of our randomized algorithm.

▶ **Theorem 3.3** (Schwartz-Zippel Lemma, [26, 41]). *Let $p(x_1, x_2, \ldots, x_m)$ be a non-zero polynomial of (total) degree d over a field $\mathbb{F}$. Let S be a finite subset of $\mathbb{F}$, and $r_1, r_2, \ldots, r_m$ be independently and uniformly sampled from S. Then*

$$\Pr[p(r_1, r_2, \ldots, r_m) = 0] \leq \frac{d}{|S|}.$$

We also need the following algorithm that computes the determinant of a polynomial matrix.

▶ **Theorem 3.4** ([18, 31]). *Let $\mathbf{B} \in \mathbb{F}[x]^{n\times n}$ be a matrix of degree at most d, then we can compute $\det(\mathbf{B})$ in $\tilde{O}(dn^\omega)$ field operations.*

3.2 Constructing an r-Truncated DSO

Recall that for a failure f (which is either a vertex or an edge), $\|uv \diamond f\|$ denotes the length of the shortest path from u to v that avoids f. An *r-truncated* DSO, as defined in [22], is a DSO that given a query (u, v, f), outputs the value $\min\{\|uv \diamond f\|, r\}$. The main result of this subsection is that given an integer r and an input graph G, an r-truncated DSO can be constructed in time

$$\tilde{O}(n^\omega M) + r^2/M \cdot \mathsf{MM}(n, nM/r, nM/r) \cdot n^{o(1)}.$$

Preprocessing algorithm

Let C be a large enough constant. First, we choose a prime $p \in [n^C, 2n^C]$ and let $\mathbb{F} = \mathbb{Z}_p$. Then we let $\mathbf{Z}$ be an $n \times n$ matrix over $\mathbb{F}$, where every $\mathbf{Z}_{i,j}$ is sampled independently from $\mathbb{F}$ uniformly at random. We substitute $\mathbf{Z}$ into $\mathsf{SA}(G)$ to obtain the matrix $\mathsf{SA}_{\mathbf{Z}}(G)$. Recall that each element of $\mathsf{SA}_{\mathbf{Z}}(G)$ is a polynomial over x with coefficients in $\mathbb{F}$, whose degree is at most M. Then we compute $\mathsf{SA}_{\mathbf{Z}}(G)^{-1}$ and $\det(\mathsf{SA}_{\mathbf{Z}}(G))$ using Theorem 1.4 and Theorem 3.4 respectively.

Since we only want an r-truncated DSO, we only need to compute $\mathsf{SA}_{\mathbf{Z}}(G)^{-1}$ modulo x^r, i.e. we only preserve the monomials with degree less than r in every entry of $\mathsf{SA}_{\mathbf{Z}}(G)^{-1}$. Note that $\mathsf{SA}_{\mathbf{Z}}(G)$ is of the form $\mathbf{I} + x\mathbf{M}$ for some matrix $\mathbf{M} \in \mathbb{F}[x]^{n\times n}$, therefore its determinant is of the form $1 + x \cdot p(x)$ for some polynomial $p(x)$. As the determinant is invertible modulo x^r, $\mathsf{SA}_{\mathbf{Z}}(G)$ is also invertible modulo x^r. By Theorem 1.4, we can compute $\mathsf{SA}_{\mathbf{Z}}(G)^{-1} \bmod x^r$ in time

$$\tilde{O}(n^\omega M) + (r^2/M) \cdot \mathsf{MM}(n, nM/r, nM/r) \cdot n^{o(1)}.$$

By Theorem 3.4, we can compute $\det(\mathsf{SA}_{\mathbf{Z}}(G))$ in $\tilde{O}(n^\omega M)$ time. Again, we only need to store the polynomial $\det(\mathsf{SA}_{\mathbf{Z}}(G)) \bmod x^r$. This concludes the preprocessing algorithm.

For the following query algorithms, we use $\mathbf{e}_i$ to denote the i-th standard unit vector, i.e. $(\mathbf{e}_i)_i = 1$, and $(\mathbf{e}_i)_j = 0$ for every index $j \neq i$.

Query algorithm for an edge failure

A query consists of vertices $u, v \in V$ and a failed edge e. We assume that e goes from vertex a to vertex b, and has weight l. Let G' be the graph obtained by removing e from G, then we have $\mathsf{SA}(G') = \mathsf{SA}(G) + \mathbf{u}\mathbf{v}^\mathsf{T}$, where $\mathbf{u} = \mathbf{e}_a$ and $\mathbf{v} = -z_{a,b}x^l\mathbf{e}_b$. Let

- $\gamma = 1 + \mathbf{v}^\mathsf{T}\mathsf{SA}(G)^{-1}\mathbf{u} = 1 - z_{a,b}x^l\mathsf{SA}(G)^{-1}_{b,a}$,
- $\beta = (\mathsf{SA}(G)^{-1}\mathbf{u}\mathbf{v}^\mathsf{T}\mathsf{SA}(G)^{-1})_{u,v} = -\mathsf{SA}(G)^{-1}_{u,a}z_{a,b}\mathsf{SA}(G)^{-1}_{b,v}x^l$, and
- $\alpha = \det(\mathsf{SA}(G))(\gamma \cdot \mathsf{SA}(G)^{-1}_{u,v} - \beta)$,

then by Theorem 3.2, we have $\alpha = \mathrm{adj}(\mathsf{SA}(G'))_{u,v}$. (Note that since $l \geq 1$, γ is always invertible.)

Query algorithm for a vertex failure

A query consists of vertices $u, v \in V$ and a failed vertex $f \in V$. It suffices to remove every outgoing edge from f (and we do not need to also remove incoming edges to f), as f already cannot appear as an intermediate vertex in every path from u to v. Therefore, we need to compute $\mathrm{adj}(\mathsf{SA}(G'))_{u,v}$, where G' is obtained by removing all outgoing edges from f in G. Let $\mathbf{u} = \mathbf{e}_f$, and $\mathbf{v}$ be the negation of the transpose of the f-th row of $\mathsf{SA}(G)$, except that $\mathbf{v}_f = 0$, i.e.,

$$\mathbf{v}_j = \begin{cases} -z_{f,j}x^l & \text{if there is an edge from } f \text{ to } j \text{ with weight } l \text{ in } G, \\ 0 & \text{otherwise,} \end{cases}$$

It is easy to see $\mathsf{SA}(G') = \mathsf{SA}(G) + \mathbf{u}\mathbf{v}^\mathsf{T}$. To compute $\mathrm{adj}(\mathsf{SA}(G'))_{u,v}$ using Theorem 3.2, we let

- $\gamma = 1 + \mathbf{v}^\mathsf{T}\mathsf{SA}(G)^{-1}\mathbf{u}$. Note that $(\mathbf{e}_f - \mathbf{v})^\mathsf{T}$ is exactly the f-th row of $\mathsf{SA}(G)$, so $(\mathbf{e}_f - \mathbf{v})^\mathsf{T}\mathsf{SA}(G)^{-1} = \mathbf{e}_f^\mathsf{T}$, and $\mathbf{v}^\mathsf{T}\mathsf{SA}(G)^{-1} = \mathbf{e}_f^\mathsf{T}\mathsf{SA}(G)^{-1} - \mathbf{e}_f^\mathsf{T}$. We have $\gamma = 1 + \mathbf{e}_f^\mathsf{T}\mathsf{SA}(G)^{-1}\mathbf{u} - \mathbf{e}_f^\mathsf{T}\mathbf{u} = \mathsf{SA}(G)^{-1}_{f,f}$;

- $\beta = (\mathsf{SA}(G)^{-1}\mathbf{u}\mathbf{v}^{\mathsf{T}}\mathsf{SA}(G)^{-1})_{u,v} = (\mathbf{e}_u^{\mathsf{T}}\mathsf{SA}(G)^{-1}\mathbf{u})(\mathbf{v}^{\mathsf{T}}\mathsf{SA}(G)^{-1}\mathbf{e}_v)$
  $= \mathsf{SA}(G)^{-1}_{u,f}(\mathbf{e}_f^{\mathsf{T}}\mathsf{SA}(G)^{-1}\mathbf{e}_v) = \mathsf{SA}(G)^{-1}_{u,f}\mathsf{SA}(G)^{-1}_{f,v}$;
- and $\alpha = \det(\mathsf{SA}(G))(\gamma \cdot \mathsf{SA}(G)^{-1}_{u,v} - \beta)$,

then we have $\alpha = \mathrm{adj}(\mathsf{SA}(G'))_{u,v}$. (Note that γ is always invertible since the constant term of $\mathsf{SA}(G)^{-1}_{f,f}$ must be 1.)

In the actual query algorithm, we will substitute each formal variable $z_{i,j}$ by $\mathbf{Z}_{i,j}$. Let $\gamma_{\mathbf{Z}}$ denote the resulting polynomial after this substitution. Note that $\gamma_{\mathbf{Z}}$ is a polynomial in $\mathbb{F}[x]$. Similarly we can define $\beta_{\mathbf{Z}}$ and $\alpha_{\mathbf{Z}}$. If $\alpha_{\mathbf{Z}} \not\equiv 0 \pmod{x^r}$, then our query algorithm outputs $\deg^*_x(\alpha_{\mathbf{Z}})$; otherwise it outputs r.

From the above formulas, we can compute $\gamma_{\mathbf{Z}}$, $\beta_{\mathbf{Z}}$, and $\alpha_{\mathbf{Z}}$ in $O(1)$ arithmetic operations over polynomials. Note that we only need to compute these polynomials modulo x^r, so each such arithmetic operation takes $\tilde{O}(r)$ time. The total query time is thus $\tilde{O}(r)$.

▶ Remark 3.5 (Query Algorithm for Undirected Graphs). Our r-truncated DSO can also deal with undirected graphs, but the details are a bit different from the case of directed graphs. To remove an undirected edge, we need to update two entries in $\mathsf{SA}(G)$, which corresponds to a rank-2 update to $\mathsf{SA}(G)$. To remove a vertex, we need to update one row and one column in $\mathsf{SA}(G)$, which is also a rank-2 update to $\mathsf{SA}(G)$. Therefore, we need to use the rank-2 version of Theorem 3.2 (see [35, Lemma 1.6]). Actually, our r-truncated DSOs also support deleting f failures, and the query time is $\tilde{O}(f^\omega r)$. We omit the details here and refer the interested readers to [35].

▶ **Theorem 3.6.** *For every integer r, we can construct an r-truncated DSO with preprocessing time*

$$\tilde{O}(n^\omega M) + r^2/M \cdot \mathsf{MM}(n, nM/r, nM/r) \cdot n^{o(1)},$$

and query time $\tilde{O}(r)$. Our r-truncated DSO is correct w.h.p.

(Recall that by saying our r-truncated DSO is correct w.h.p, we mean that w.h.p. over its randomized preprocessing algorithm, it answers every query correctly.)

Proof of Theorem 3.6. We only need to prove the correctness of our r-truncated DSO. Consider a query (u, v, f) where f is an edge or a vertex, and let G' be the graph obtained by removing f from G. By Theorem 3.2, we have $\alpha_{\mathbf{Z}} = \mathrm{adj}(\mathsf{SA}_{\mathbf{Z}}(G'))_{u,v}$. (Note that the constant term of $\gamma_{\mathbf{Z}}$ is always 1, so $\gamma_{\mathbf{Z}}$ is always invertible.)

If $\|uv \diamond f\| \geq r$, then by Theorem 3.1, $\mathrm{adj}(\mathsf{SA}(G'))_{u,v}$ must be a polynomial whose minimum degree over x is at least r. In this case, we have $\alpha_{\mathbf{Z}} \equiv 0 \pmod{x^r}$ for every $\mathbf{Z}$. Therefore, our algorithm returns r, which is correct.

If $\|uv \diamond f\| = k < r$, then by Theorem 3.1, $\mathrm{adj}(\mathsf{SA}(G'))_{u,v}$ must be a polynomial whose minimum degree is exactly k. In this case, the coefficient of x^k in α is a polynomial of $z_{i,j}$ with (total) degree at most n. (This is because $\mathrm{adj}(\mathsf{SA}(G'))_{u,v}$ is the determinant of a certain $n \times n$ matrix in which every entry has total degree at most one in the variables $z_{i,j}$.) If this polynomial is nonzero at $\mathbf{Z}$, then $\deg^*_x(\alpha_{\mathbf{Z}}) = k$ and our query algorithm is correct. By Theorem 3.3, this polynomial is 0 with probability at most $1/n^{C-1}$. Therefore, our query algorithm returns the correct answer k with probability at least $1 - 1/n^{C-1}$.

In conclusion, for every fixed query (u, v, f), our query algorithm is correct with probability $1-1/n^{C-1}$ over the choice of $\mathbf{Z}$. By a union bound over $O(n^4)$ possible queries, the probability (over our randomized preprocessing algorithm) that every query is answered correctly is at least $1 - 1/\Theta(n^{C-5})$, which is a high probability. ◀

3.3 Constructing the Full DSO

Now we have constructed an r-truncated DSO, which we denote by $\mathcal{D}^{\mathsf{start}}$. In this subsection, we will extend it to a *full* DSO using the techniques in [22]. Specifically, we use the following two algorithms from [22].

The first algorithm transforms an (r-truncated) DSO with a possibly large query time into an (r-truncated) DSO with query time $O(1)$. More precisely:

▶ **Lemma 3.7** ([22, Observation 2.1]). *Given an r-truncated DSO $\mathcal{D}$ with preprocessing time P and query time Q, we can build an r-truncated DSO $\mathsf{Fast}(\mathcal{D})$ with query time $O(1)$ which is correct w.h.p. The preprocessing algorithm of $\mathsf{Fast}(\mathcal{D})$ is as follows:*

- *It needs the all-pairs distance matrix of the input graph G, as well as the set of* consistent *(incoming and outgoing) shortest path trees rooted at each vertex in G. By Theorem 1.6, these shortest path trees can be computed in $O(n^{2.5286}M)$ time. For details, see Section 5.*
- *It invokes the preprocessing algorithm of $\mathcal{D}$ on the input graph G once, and makes $\tilde{O}(n^2)$ queries to $\mathcal{D}$. The preprocessing time is $P + \tilde{O}(n^2)Q$.*

The second algorithm we use is implicit in the argument of [22, Section 2.3]. We formalize it as the following lemma.

▶ **Lemma 3.8.** *Given an r-truncated DSO $\mathcal{D}$ with preprocessing time P and query time $O(1)$, we can build a $(3/2)r$-truncated DSO $\mathsf{Extend}(\mathcal{D})$ with preprocessing time $P + O(n^2)$ and query time $\tilde{O}(nM/r)$. The new DSO is correct w.h.p.*

Now, we are ready to explain our algorithm to build a full DSO. Given an r-truncated DSO $\mathcal{D}^{\mathsf{start}}$, we first obtain an r-truncated DSO $\mathcal{D}_0$ with query time $O(1)$ by applying Lemma 3.7.

Let $i^\star = \lfloor \log_{3/2}(nM/r) \rfloor$. For every $0 \le i \le i^\star$, we construct an $r(3/2)^{i+1}$-truncated DSO $\mathcal{D}_{i+1}$ by applying Lemma 3.8 and Lemma 3.7 sequentially on $\mathcal{D}_i$, i.e. $\mathcal{D}_{i+1} = \mathsf{Fast}(\mathsf{Extend}(\mathcal{D}_i))$. Let the resulting DSO be $\mathcal{D}^{\mathsf{final}} = \mathcal{D}_{i^\star+1}$, since $r(3/2)^{i^\star+1} \ge nM$, $\mathcal{D}^{\mathsf{final}}$ is a full DSO.

We can also summarize our construction algorithm in one formula:

$$\mathcal{D}^{\mathsf{final}} = \underbrace{\mathsf{Fast}(\mathsf{Extend}(\mathsf{Fast}(\mathsf{Extend}(\cdots \mathsf{Fast}(\mathcal{D}^{\mathsf{start}})))))}_{O(\log(nM/r)) \text{ times}}.$$

Complexity of our DSO

Let $r = Mn^\alpha$, where $\alpha \in [0, 1]$ is a parameter to be determined. By Theorem 3.6, the preprocessing time of $\mathcal{D}^{\mathsf{start}}$ is

$$\tilde{O}(n^\omega M) + r^2/M \cdot \mathsf{MM}(n, nM/r, nM/r) \cdot n^{o(1)} \le \tilde{O}(n^\omega M) + n^{2\alpha+\omega(1,1-\alpha,1-\alpha)+o(1)}M,$$

and the query time of $\mathcal{D}^{\mathsf{start}}$ is $\tilde{O}(r) = \tilde{O}(n^\alpha M)$. By Lemma 3.7, the preprocessing time of $\mathcal{D}_0$ is

$$\tilde{O}(n^{2+\alpha}M + n^\omega M) + n^{2\alpha+\omega(1,1-\alpha,1-\alpha)+o(1)}M.$$

Now consider the preprocessing algorithm of $\mathcal{D}^{\mathsf{final}}$. We need to compute the all-pairs distance matrix and in/out shortest path trees of G as required by Lemma 3.7, which takes $\tilde{O}(n^{2+\mu}M)$ time by Theorem 1.6. We also need to run the preprocessing algorithm of $\mathcal{D}_0$. Also, for every $0 \le i \le i^\star$, we need to preprocess the oracle $\mathcal{D}_{i+1}$, which takes $n^2 \cdot \tilde{O}(nM/(r(3/2)^{i+1})) = \tilde{O}\left(\frac{n^{3-\alpha}M}{(3/2)^i}\right)$ time.

Therefore, the preprocessing time of $\mathcal{D}^{\mathsf{final}}$ is:

$$\tilde{O}(n^{2+\alpha}M + n^{\omega}M + n^{2+\mu}M) + n^{2\alpha+\omega(1,1-\alpha,1-\alpha)+o(1)}M + \sum_{i=0}^{\lfloor \log_{3/2}(nM/r)\rfloor} \tilde{O}\left(\frac{n^{3-\alpha}M}{(3/2)^i}\right)$$
$$\leq n^{\max\{2+\alpha,2+\mu,3-\alpha,2\alpha+\omega(1,1-\alpha,1-\alpha)\}+o(1)}M.$$

Let $\alpha = 0.420645$, $\beta = \frac{1}{1-\alpha}$, then $1.5 < \beta < 1.75$. Recall that for any real number λ, $\omega(\lambda)$ is a shorthand for $\omega(1,1,\lambda)$. We have

$$\begin{aligned}
\omega(1,1-\alpha,1-\alpha) &= (1-\alpha)\omega(\beta) \\
&\leq (1-\alpha)\cdot\frac{(1.75-\beta)\omega(1.5)+(\beta-1.5)\omega(1.75)}{1.75-1.5} && (1)\\
&\leq 0.579355\cdot 4\cdot(0.023943\cdot\omega(1.5)+0.226058\cdot\omega(1.75)) \\
&\leq 1.738094. && (2)
\end{aligned}$$

Here, Equation (1) uses the convexity of the $\omega(\cdot)$ function [21], and Equation (2) uses the recent bounds in [15] that $\omega(1.5) \leq 2.796537$ and $\omega(1.75) \leq 3.021591$. We can see that

$$\max\{2+\alpha, 2+\mu, 3-\alpha, 2\alpha+\omega(1,1-\alpha,1-\alpha)\} = 2\alpha+\omega(1,1-\alpha,1-\alpha) \leq 2.579384.$$

By Lemma 3.7, the query time of $\mathcal{D}^{\mathsf{final}}$ is $O(1)$. Therefore, we can construct a DSO with $O(n^{2.5794}M)$ preprocessing time and $O(1)$ query time.

As the DSOs constructed in Lemma 3.7 always have size $\tilde{O}(n^2)$, our final DSO only occupies $\tilde{O}(n^2)$ space. However, we remark that the preprocessing algorithm of our DSO requires $\tilde{O}(rn^2) = O(n^{2.4207})$ space (in particular, to store $\mathsf{SA}_{\mathbf{Z}}(G)^{-1} \bmod x^r$).

4 Inverting a Polynomial Matrix Modulo x^r

As we see in Section 3, the algorithm in Theorem 1.4 for inverting a polynomial matrix modulo x^r is very crucial for our results.

▶ **Theorem 1.4.** *Let r be an integer, $\mathbb{F}$ be a finite field. Let $\mathbf{F} \in \mathbb{F}[x]^{n\times n}$ be an $n\times n$ matrix over the ring of univariate polynomials $\mathbb{F}[x]$, and let $d \geq 1$ be an upper bound on the degrees of entries of $\mathbf{F}$. If $\mathbf{F}$ is invertible over $(\mathbb{F}[x]/\langle x^r\rangle)^{n\times n}$, the number of field operations to compute $\mathbf{F}^{-1} \bmod x^r$ is at most*

$$\tilde{O}(dn^{\omega}) + (r^2/d)\cdot \mathsf{MM}(n, nd/r, nd/r)\cdot n^{o(1)}.$$

Our algorithm is essentially the algorithm in [40]. In fact, the only difference is that we only consider polynomials modulo x^r. This allows us to invert the polynomial matrix in time faster than $\tilde{O}(n^3 d)$ using fast rectangular matrix multiplication algorithms.

In this section, we provide a very brief exposition of the algorithm in [40], and justify the time bound in Theorem 1.4. A detailed description of the algorithm can be found in the full version.

Let $\mathbf{F}$ be an input polynomial matrix where each entry has degree at most d. Suppose $\mathbf{F}$ is invertible over $(\mathbf{F}[x]/\langle x^r\rangle)^{n\times n}$. We will compute a *kernel basis decomposition* of $\mathbf{F}$, which is a chain of matrices $\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_{\log n}$ and a diagonal matrix $\mathbf{B}$, such that

$$\mathbf{F}^{-1} = \mathbf{A}_1\mathbf{A}_2\ldots\mathbf{A}_{\log n}\mathbf{B}^{-1}. \quad (3)$$

Then, to compute $\mathbf{F}^{-1}$, we simply multiply the above matrices. Note that $\mathbf{B}$ is a diagonal matrix, so its inverse is easy to compute.[3]

To start, we write $\mathbf{F} = \begin{bmatrix}\mathbf{F}_{\mathsf{U}}\\ \mathbf{F}_{\mathsf{D}}\end{bmatrix}$, where each $\mathbf{F}_{\mathsf{U}}$ or $\mathbf{F}_{\mathsf{D}}$ is an $(n/2) \times n$ matrix. Then we compute two $n \times (n/2)$ matrices $\mathbf{N}_{\mathsf{R}}$ and $\mathbf{N}_{\mathsf{L}}$ with full rank, such that $\mathbf{F}_{\mathsf{U}}\mathbf{N}_{\mathsf{R}} = \mathbf{0}$, and $\mathbf{F}_{\mathsf{D}}\mathbf{N}_{\mathsf{L}} = \mathbf{0}$. (This can be done by [39, Theorem 4.2].) Let $\mathbf{A}_1 = \begin{bmatrix}\mathbf{N}_{\mathsf{L}} & \mathbf{N}_{\mathsf{R}}\end{bmatrix}$, then $\mathbf{A}_1$ has full rank, and

$$\mathbf{F} \cdot \mathbf{A}_1 = \begin{bmatrix}\mathbf{F}_{\mathsf{U}}\mathbf{N}_{\mathsf{L}} & \mathbf{F}_{\mathsf{U}}\mathbf{N}_{\mathsf{R}}\\ \mathbf{F}_{\mathsf{D}}\mathbf{N}_{\mathsf{L}} & \mathbf{F}_{\mathsf{D}}\mathbf{N}_{\mathsf{R}}\end{bmatrix} = \begin{bmatrix}\mathbf{F}_{\mathsf{U}}\mathbf{N}_{\mathsf{L}} & \\ & \mathbf{F}_{\mathsf{D}}\mathbf{N}_{\mathsf{R}}\end{bmatrix}.$$

Therefore, $\mathbf{F} \cdot \mathbf{A}_1$ is a block diagonal matrix with two blocks, each of size $(n/2) \times (n/2)$. We can then recursively invoke the kernel basis decomposition of these two blocks, and form the matrices $\mathbf{A}_2, \ldots, \mathbf{A}_{\log n}$. The diagonal matrix $\mathbf{B}$ is created at the base case of the recursion, where the diagonal blocks of $\mathbf{F} \cdot \mathbf{A}_1 \cdot \cdots \cdot \mathbf{A}_{\log n}$ are of size 1×1. It is shown in [40] that the kernel basis decomposition takes only $\tilde{O}(dn^{\omega})$ time to compute.

We still need to compute Equation (3). From the above algorithm, we can see that each $\mathbf{A}_i$ is a block-diagonal matrix, which consists of 2^{i-1} blocks of size $(n/2^{i-1}) \times (n/2^{i-1})$. Now we *assume* that each entry in $\mathbf{A}_i$ also has degree at most $d \cdot 2^{i-1}$. (In reality, the behavior of degrees in $\mathbf{A}_i$ may be complicated, and we need the notion of *shifted column degree* to control them; see the full version of this paper for more details.)

To compute Equation (3), we define $\mathbf{M}_i = \mathbf{A}_1\mathbf{A}_2 \ldots \mathbf{A}_i$, and compute each $\mathbf{M}_i$ by the formula

$$\mathbf{M}_{i+1} = \mathbf{M}_i\mathbf{A}_{i+1}. \tag{4}$$

The degree of each entry in $\mathbf{M}_i$ will be at most $O(2^i \cdot d)$. As we only need the results modulo x^r, we can assume the degrees are actually $O\big(\min\{r, 2^i \cdot d\}\big)$. Note that $\mathbf{A}_{i+1}$ consists of 2^i blocks, each of size $(n/2^i) \times (n/2^i)$, and the degree of each (nonempty) entry in $\mathbf{A}_{i+1}$ is also $O\big(\min\{r, 2^i \cdot d\}\big)$. Therefore, we can compute Equation (4) in

$$O\big(\min\{r, 2^i \cdot d\}\big) \cdot 2^i \cdot \mathsf{MM}(n, n/2^i, n/2^i) \tag{5}$$

time. (It is basically 2^i matrix products of size $n \times (n/2^i)$ and $(n/2^i) \times (n/2^i)$; we need to multiply another factor of $\min\{r, 2^i \cdot d\}$ which is the degree of polynomials in these matrices.)

Now, it is easy to see that the bottleneck of this algorithm occurs when $r = 2^i \cdot d$, and the time for computing Equation (4) is:

$$(5) = (r^2/d) \cdot \mathsf{MM}(n, nd/r, nd/r).$$

5 Computing Unique Shortest Paths in Directed Graphs

In this section, we show how to compute *unique* shortest paths in a directed graph in $\tilde{O}(n^{2+\mu}M)$ time, matching the current best time bound for computing the all-pairs distances [42]. Here $\mu < 0.5286$ is the solution of $\omega(1, 1, \mu) = 1 + 2\mu$ [15]. This algorithm is needed before we use Lemma 3.7.

[3] Every diagonal element of $\mathbf{B}$ is a divisor of the *largest invariant factor* of $\mathbf{F}$ (see [40, Section 5.1]), which is (again) a divisor of $\det(\mathbf{F})$. Since $\det(\mathbf{F})$ is invertible modulo x^r, every diagonal element of $\mathbf{B}$ is also invertible modulo x^r.

We may assume that before we proceed, we have already computed the all-pairs distances $\|uv\|$ for every $u, v \in V$, using the APSP algorithm in [42].

Our tie-breaking method requires a (random) permutation π of all vertices, or equivalently a bijection between the vertex set V and $[n]$, i.e. $\pi : V \to [n]$. According to π, for every graph G on V and every $u, v \in V$, we will specify a shortest path $\rho_G(u, v)$ in G from u to v in a certain way. These shortest paths will be *consistent* and *easy to compute*, which is captured by the following theorem. (See also [22, Theorem 1.3 and 1.4].)

▶ **Theorem 5.1.** *Given a graph G on V, a representation of the set of shortest paths $\{\rho_G(u, v)\}_{u,v\in V}$ can be computed in $\tilde{O}(n^{2+\mu}M)$ time, with high probability over the random choice of permutation π, such that the following hold.*

(Property a) *Let G be a graph on V. For every $u', v' \in \rho_G(u, v)$ such that u' appears before v', the portion of $u' \rightsquigarrow v'$ in $\rho_G(u, v)$ coincides with the path $\rho_G(u', v')$.*

(Property b) *Let G be a graph on V, $u, v \in V$, and G' be a subgraph of G. Suppose $\rho_G(u, v)$ is completely contained in G', then $\rho_{G'}(u, v) = \rho_G(u, v)$.*

From (Property a), for every vertex u, the shortest paths from u to every other vertex in G form a tree, and we call this tree the *outgoing shortest path tree* rooted at u, denoted as $T^{\mathsf{out}}(u)$. Similarly, the shortest paths to u from every other vertex in G also form a tree, and we call this tree the *incoming shortest path tree* rooted at u, denoted as $T^{\mathsf{in}}(u)$. Actually, the "representation" computed is exactly the set of n outgoing shortest path trees $\{T^{\mathsf{out}}(u)\}_{u\in V}$ and the set of n incoming shortest path trees $\{T^{\mathsf{in}}(u)\}_{u\in V}$.

The rest of this section

We first define the paths $\rho_G(u, v)$ in Section 5.1. Then we explain how to compute them efficiently in Section 5.2, by presenting an algorithm that computes the incoming and outgoing shortest path trees in $\tilde{O}(Mn^{2+\mu})$ time. Finally, we prove (Property a) and (Property b) in Section 5.3.

5.1 Defining $\rho_G(u, v)$

Let G be an input graph, and $\pi : V \to [n]$ be a (random) bijection. Let $u, v \in V$, P be a path from u to v, we will say that any vertex on P that is neither u nor v is an *internal vertex of P*.

Recall that we defined $|uv|$ as the *largest* number of edges in any shortest path from u to v. In particular:

- $|uv| = 0$ if and only if $u = v$;
- $|uv| = 1$ if and only if the edge (u, v) is the *only* shortest path from u to v;
- $|uv| = \infty$ if there is no path from u to v in G;
- otherwise, we have $2 \le |uv| < \infty$.

We claim that the set of vertices mapped to small values by π is a good "hitting set" w.h.p:

▷ Claim 5.2. Fix the graph G. For some large constant C, with high probability over the choice of π, the following holds. For every pair of vertices $u, v \in V$ such that $2 \le |uv| < \infty$, there is a shortest path $\rho'(u, v)$ from u to v, and an internal vertex z on $\rho'(u, v)$, such that $\pi(z) \le CMn \ln n/\|uv\|$.

Proof. Fix two vertices $u, v \in V$, and any shortest path $\rho'(u, v)$ from u to v. Denote $r = \|uv\|$, if $r \leq M \ln n$ then the claim is trivial. Otherwise, there are at least $r/1.1M$ vertices on $\rho'(u, v)$. Therefore, the probability over a random bijection $\pi : V \to [n]$ that π maps every vertex on $\rho'(u, v)$ to an integer greater than $CMn \ln n/r$ is at most

$$(1 - CM \ln n/r)^{r/1.1M} \leq 1/n^{C/1.1}.$$

Thus by a union bound, the probability that the above condition holds (for every u, v) is at least $1 - 1/n^{C/1.1-2}$, which is a high probability. ◁

Let $u, v \in V$ such that $2 \leq |uv| < \infty$. Define $w(u, v)$ as the intermediate vertex with the smallest label in any shortest path from u to v, i.e.

$$w(u, v) = \arg_w \min\{\pi(w) : \|uv\| = \|uw\| + \|wv\|, w \neq u \text{ and } w \neq v\}. \tag{6}$$

Claim 5.2 states that w.h.p. for every vertices $u, v \in V$ such that $2 \leq |uv| < \infty$, we have that

$$\pi(w(u, v)) \leq CMn \ln n/\|uv\|. \tag{7}$$

In the rest of this section, we assume that Equation (7) holds for every vertices $u, v \in V$ such that $2 \leq |uv| < \infty$. Now we define the paths $\rho_G(u, v)$.

▶ **Definition 5.3.** *Let $u, v \in V$ such that $|uv| \neq \infty$. The path $\rho_G(u, v)$ is recursively defined as follows.*

- *If $u = v$, then $\rho_G(u, v)$ is the empty path that starts and ends at u.*
- *If $|uv| = 1$, then $\rho_G(u, v)$ consists of a single edge, i.e. the edge from u to v.*
- *Otherwise, let $w = w(u, v)$, then $\rho_G(u, v)$ is the concatenation of $\rho_G(u, w)$ and $\rho_G(w, v)$.*

For every u, v such that $2 \leq |uv| < \infty$, since w is an intermediate vertex on some shortest path from u to v, it is easy to see that $|uw| < |uv|$ and $|wv| < |uv|$. Therefore $\rho_G(u, v)$ is well defined – it is inductively defined in the nondecreasing order of $|uv|$.

5.2 Computing Shortest Path Trees in $\tilde{O}(Mn^{2+\mu})$ Time

We will need the following classical algorithm for computing distance products:

▶ **Lemma 5.4** ([42]). *Let A be an $n \times m$ matrix, and B be an $m \times n$ matrix. Suppose every entry in A or B is either $+\infty$ or an integer with absolute value at most M. Then the distance product of A and B can be computed in $\tilde{O}(M \cdot \mathsf{MM}(n, m, n))$ time.*

Computing $w(u, v)$

We first show how to compute $w(u, v)$ for every $u, v \in V$ such that $2 \leq |uv| < \infty$ in $\tilde{O}(Mn^{2+\mu})$ time. Then we use the values of all $w(u, v)$ to compute the incoming and outgoing shortest path trees in $\tilde{O}(n^2)$ additional time. Our strategy for computing $w(u, v)$ is to mimic the algorithm in [17, 28] for computing maximum witness of Boolean matrix multiplication. In particular, we divide the possible witnesses into blocks, and use fast matrix multiplication algorithms to find the block containing $w(u, v)$, for every u, v. After that, we use brute force to find $w(u, v)$ inside that block. Details follow.

Let $r = 2^k$ be a parameter, we show how to compute $w(u, v)$ for every pair of vertices $u, v \in V$ such that $r \leq \|uv\| < 2r$. Let

$$\mathcal{H}_r = \{z \in V : \pi(z) \le CMn \ln n/r\}.$$

By Claim 5.2, for every vertices u, v such that $\|uv\| \in [r, 2r)$, we have $w(u, v) \in \mathcal{H}_r$.

We define an $n \times |\mathcal{H}_r|$ matrix A and an $|\mathcal{H}_r| \times n$ matrix B as follows. For every $u \in V$ and $z \in \mathcal{H}_r$, we define

$$A[u, z] = \begin{cases} \|uz\| & \text{if } \|uz\| \le 2r \text{ and } u \ne z \\ +\infty & \text{otherwise} \end{cases}, \text{ and } B[z, u] = \begin{cases} \|zu\| & \text{if } \|zu\| \le 2r \text{ and } u \ne z \\ +\infty & \text{otherwise} \end{cases}.$$

Then we compute the *minimum witness* of the distance product $A \star B$. To be more precise, we compute the matrix $W[\cdot, \cdot]$ such that for every $u, v \in V$,

$$W[u, v] = \arg_z \min\{\pi(z) : \|uv\| = A[u, z] + B[z, v]\}.$$

Correctness. Fix $u, v \in V$, where $\|uv\| \in [r, 2r)$. We will show that if $|uv| = 1$, then $W[u, v]$ does not exist; otherwise $W[u, v]$ coincides with $w(u, v)$ defined in Equation (6).

First, suppose $|uv| = 1$, then there are no intermediate vertex z such that $\|uv\| = \|uz\| + \|zv\|$, which means $W[u, v]$ does not exist.

Now we assume $|uv| \ge 2$. Since $\|uv\| \ge r$, by Claim 5.2, there is an intermediate vertex $z \in \mathcal{H}_r$ such that $\|uz\| + \|zv\| = \|uv\|$. Since $\|uz\|, \|zv\| \le \|uv\| < 2r$, we can see that $\|uv\| = A[u, z] + B[z, v]$, therefore $W[u, v]$ exists. Let $z = W[u, v]$, then by Equation (6), $\pi(w(u, v)) \le \pi(z)$. On the other hand, Claim 5.2 shows that $w(u, v) \in \mathcal{H}_r$, so by the definition of $z = W[u, v]$, we have $\pi(z) \le \pi(w(u, v))$. Therefore $z = w(u, v)$ and we have established the correctness of $W[\cdot, \cdot]$.

Time complexity. Now we show how to compute the matrix $W[\cdot, \cdot]$ efficiently.

Let $s = n^\mu$, where $\mu \in (0, 1)$ is a parameter to be determined later. If $|\mathcal{H}_r| < s$, then we can compute the matrix W by brute force in $\tilde{O}(n^2 s)$ time. Otherwise, we partition $\mathcal{H}_r$ into blocks of size s, where the i-th block contains vertices that are mapped by π to values between $(i-1) \cdot s + 1$ and $i \cdot s$. For every block i, we compute the distance product of A and B where only vertices in block i are allowed as witnesses. In other words, we compute the following matrix

$$D^i[u, v] = \min\{A[u, z] + B[z, v] : (i-1) \cdot s + 1 \le \pi(z) \le i \cdot s\}.$$

By Lemma 5.4, this matrix can be computed in $\tilde{O}(r \cdot \mathsf{MM}(n, s, n))$ time. There are $O(|\mathcal{H}_r|/s) = \tilde{O}(Mn/(rs))$ blocks, and we need to compute a distance product D^i for each block i. Therefore the total time for computing all these distance products is

$$\tilde{O}(r \cdot \mathsf{MM}(n, s, n) \cdot Mn/(rs)) = \tilde{O}(M \cdot (n/s) \cdot \mathsf{MM}(n, s, n)).$$

Now for every $u, v \in V$ such that $\|uv\| \in [r, 2r)$ and $|uv| \ge 2$, we want to compute $W[u, v]$, which is the vertex $z \in \mathcal{H}_r$ with the minimum $\pi(z)$, such that $\|uv\| = A[u, z] + B[z, v]$. First, we find the smallest i such that $D^i[u, v] = \|uv\|$, and we know that $W[u, v]$ is in the i-th block. (If such i does not exist, then $W[u, v]$ does not exist either, and $|uv| = 1$.) This step takes $\tilde{O}(Mn/(rs))$ time. Then we iterate through the vertices in this block, and find the vertex z with the smallest $\pi(z)$ such that $A[u, z] + B[z, v] = \|uv\|$. This step takes $O(s)$ time.

It follows that the time complexity for computing every $w(u,v)$ where $\|uv\| \in [r, 2r)$ is

$$\begin{aligned}&\tilde{O}(M \cdot \mathsf{MM}(n,s,n) \cdot (n/s) + n^2 \cdot Mn/(rs) + n^2 s)\\ \leq\ &\tilde{O}(M \cdot \mathsf{MM}(n,s,n) \cdot (n/s) + n^2 s) \qquad (8)\\ \leq\ &\tilde{O}(M \cdot n^{\omega(1,\mu,1)+1-\mu} + n^{2+\mu}).\end{aligned}$$

Here, Equation (8) is because $n^2 \cdot Mn/(rs) \leq n^2 \cdot M \cdot (n/s) \leq M \cdot \mathsf{MM}(n,s,n) \cdot (n/s)$.

Let μ be the solution to $\omega(1,\mu,1) = 1 + 2\mu$, then $\mu < 0.5286$ ([15,42]). It follows that the time complexity for computing every $w(u,v)$, where $r \leq \|uv\| < 2r$, is at most $\tilde{O}(Mn^{2+\mu})$.

Putting it together. We run the above algorithm for k from 0 to $\lfloor \log(nW) \rfloor$, and for each k, we update the values $w(u,v)$ where $\|uv\| \in [2^k, 2^{k+1})$. The total time to compute $w(u,v)$ for all u, v is thus $\tilde{O}(Mn^{2+\mu})$.

From $w(u,v)$ to unique shortest paths

For every $u, v \in V$, we will compute the parent of u in the tree $T^{\mathsf{in}}(v)$, denoted as $\mathsf{parent}_v(u)$. In other words, $\mathsf{parent}_v(u)$ is the second vertex in the path $\rho_G(u,v)$ (the first being u). After computing $\mathsf{parent}_v(u)$ for every $u, v \in V$, it is easy to construct $T^{\mathsf{in}}(v)$ for every vertex v. We can compute every $T^{\mathsf{out}}(u)$ in a symmetric fashion.

We proceed by nondecreasing order of $\|uv\|$. Suppose that for every (u', v') such that $\|u'v'\| < \|uv\|$, we have already computed $\mathsf{parent}_{v'}(u')$. Now we compute $\mathsf{parent}_v(u)$ as follows. Let $w = w(u,v)$. If w does not exist, let $\mathsf{parent}_v(u) = v$; otherwise $\mathsf{parent}_v(u) = \mathsf{parent}_w(u)$.

This algorithm (that given every $w(u,v)$, computes every $\mathsf{parent}_v(u)$) clearly runs in $\tilde{O}(n^2)$ time. Notice that if w exists, then w is an intermediate vertex in $\rho_G(u,v)$, thus $\|uw\| < \|uv\|$, and the second vertex in the path $\rho_G(u,v)$ coincides with the second vertex in the path $\rho_G(u,w)$. Hence, the correctness of the algorithm can be easily proved by induction on $\|uv\|$.

5.3 Proof of Theorem 5.1

▶ **Theorem 5.1.** *Given a graph G on V, a representation of the set of shortest paths $\{\rho_G(u,v)\}_{u,v\in V}$ can be computed in $\tilde{O}(n^{2+\mu}M)$ time, with high probability over the random choice of permutation π, such that the following hold.*

(Property a) *Let G be a graph on V. For every $u', v' \in \rho_G(u,v)$ such that u' appears before v', the portion of $u' \rightsquigarrow v'$ in $\rho_G(u,v)$ coincides with the path $\rho_G(u',v')$.*

(Property b) *Let G be a graph on V, $u, v \in V$, and G' be a subgraph of G. Suppose $\rho_G(u,v)$ is completely contained in G', then $\rho_{G'}(u,v) = \rho_G(u,v)$.*

In this subsection, for any path P and vertices $u', v' \in P$ such that u' appears before v' on P, we use $P[u', v']$ to denote the portion of $u' \rightsquigarrow v'$ on the path P.

Proof of (Property a). We prove it by induction on the number of edges of $\rho_G(u,v)$. Let $P = \rho_G(u,v)$. If $u = v$ or P has only one edge, (Property a) is trivial. Now suppose P has k edges where $k > 1$. Let $w = w(u,v)$, then w must lie on P. Consider the following three cases:

- Suppose u' appears after (or coincides with) w on P. By definition, $P[w,v] = \rho_G(w,v)$. Then $P[u',v'] = \rho_G(u',v')$ by induction hypothesis on $\rho_G(w,v)$ since it has fewer edges than $\rho_G(u,v)$.
- Suppose v' appears before (or coincides with) w. This case is symmetric to the above case.

- Otherwise, w lies between u' and v' on P.

  First, we claim that $w = w(u', v')$. As w lies on some shortest path from u' to v' (i.e. $P[u', v']$), we have $\pi(w(u', v')) \leq \pi(w)$. On the other hand, suppose there exists w' such that $\pi(w') < \pi(w)$ and w' is on some shortest path from u' to v'. Then w' also lies on some shortest path from u to v, so it is a better candidate for $w(u, v)$, contradicting the definition of w.

  Second, by induction hypothesis on $\rho_G(u, w)$, which has fewer edges than $\rho_G(u, v)$, we have $P[u', w] = \rho_G(u', w)$. Similarly, $P[w, v'] = \rho_G(w, v')$. Therefore, by definition, $P[u', v'] = P[u', w] \circ P[w, v'] = \rho_G(u', v')$. ◀

Proof of (Property b). We prove it by induction on the number of edges of $\rho_G(u, v)$. Let $P = \rho_G(u, v)$. If $u = v$ or P has only one edge, (Property b) is trivial.

Now suppose P has more than one edge. Let $w = w_G(u, v)$ (i.e. the vertex $w(u, v)$ defined in Equation (6) in graph G), we claim that w coincides with $w_{G'}(u, v)$ (i.e. the vertex $w(u, v)$ defined in Equation (6) in graph G'). Since P is also a shortest path from u to v in G', we have $\pi(w_{G'}(u, v)) \leq \pi(w)$. On the other hand, suppose there exists w' such that $\pi(w') < \pi(w)$ and w' is on some shortest path from u to v in G'. Then w' also lies on some shortest path from u to v in G, so it is a better candidate for $w_G(u, v)$, contradicting the definition of w.

Since $\rho_G(u, w)$ has fewer edges than $\rho_G(u, v)$, and $\rho_G(u, w)$ is completely contained in G', we can use induction hypothesis on $\rho_G(u, w)$ to conclude that $P[u, w] = \rho_{G'}(u, w)$. Similarly, we can use the induction hypothesis on $\rho_G(w, v)$ to conclude that $P[w, v] = \rho_{G'}(w, v)$. Therefore, by definition, $\rho_{G'}(u, v) = \rho_{G'}(u, w) \circ \rho_{G'}(w, v) = P$. ◀

6 Conclusions and Open Problems

We presented an improved DSO for directed graphs with integer weights in $[1, M]$. The preprocessing time is $O(n^{2.5794}M)$ and the query time is $O(1)$. However, there is still a small gap between the preprocessing time of our DSO and the current best time bound for the APSP problem in directed graphs, which is $\tilde{O}(n^{2+\mu}M) \leq O(n^{2.5286}M)$ [42]. Can we improve the preprocessing time to $\tilde{O}(n^{2+\mu}M)$, matching the latter time bound? Another interesting problem is to investigate the complexity of preprocessing a DSO in undirected graphs – here, the best time bound for APSP is $\tilde{O}(n^{\omega}M)$ [27, 30]. Can we preprocess a DSO in $\tilde{O}(n^{\omega}M)$ time on undirected graphs?

Compared to other DSOs [8, 16, 36], our oracle has two drawbacks. First, our query algorithm only outputs the shortest distance, but we do not know how to find the actual shortest paths. So another open problem is whether we can find the actual shortest path with additional $O(l)$ query time, where l is the number of edges in the returned shortest path. Second, since we used [22, Observation 2.1], our oracle can only deal with positive edge weights. Can we extend our oracle to also deal with negative edge weights?

For every parameter f, the r-truncated DSO in Section 3.2 can actually handle f edge/vertex deletions in $\tilde{O}(f^{\omega}r)$ query time. (See also [35].) However, as far as we know, [22, Observation 2.1] only works for one failure. It would be exciting to extend [22, Observation 2.1] or our (full) DSO to also handle f failures.

Abstract

This paper considers approximation algorithms for generalized k-median problems. This class of problems can be informally described as k-median with a constant number of extra constraints, and includes k-median with outliers, and knapsack median. Our first contribution is a pseudo-approximation algorithm for generalized k-median that outputs a 6.387-approximate solution with a constant number of fractional variables. The algorithm is based on iteratively rounding linear programs, and the main technical innovation comes from understanding the rich structure of the resulting extreme points.

Using our pseudo-approximation algorithm, we give improved approximation algorithms for k-median with outliers and knapsack median. This involves combining our pseudo-approximation with pre- and post-processing steps to round a constant number of fractional variables at a small increase in cost. Our algorithms achieve approximation ratios $6.994 + \epsilon$ and $6.387 + \epsilon$ for k-median with outliers and knapsack median, respectively. These both improve on the best known approximations.

1 Introduction

Clustering is a fundamental problem in combinatorial optimization, where we wish to partition a set of data points into *clusters* such that points within the same cluster are more similar than points across different clusters. In this paper, we focus on generalizations of the *k-median* problem. Recall that in this problem, we are given a set F of facilities, a set C of clients, a metric d on $F \cup C$, and a parameter $k \in \mathbb{N}$. The goal is to choose a set $S \subset F$ of k facilities to open to minimize the sum of *connection costs* of each client to its closest open facility. That is, to minimize the objective $\sum_{j \in C} d(j, S)$, where we define $d(j, S) = \min_{i \in S} d(i, j)$.

The k-median problem is well-studied from the perspective of approximation algorithms, and many new algorithmic techniques have been discovered while studying it. Examples include linear program rounding [3, 13], primal-dual algorithms [10], and local search [1].

Recently, there has been significant interest in generalizations of the k-median problem [4, 11]. One such generalization is the *knapsack median* problem. In knapsack median, each facility has a non-negative weight, and we are given budget $B \geq 0$. The goal is to choose a set of open facilities of total weight at most B (instead of having cardinality at most k) to minimize the same objective function. That is, the open facilities must satisfy a knapsack constraint. Another commonly-studied generalization is *k-median with outliers*, also known as *robust k-median*. Here we open k facilities S, as in basic k-median, but we no longer have to serve all clients; now, we are only required to serve at least m clients $C' \subset C$ of our choice. Formally, the objective function is now $\sum_{j \in C'} d(j, S)$.

Both knapsack median and k-median with outliers have proven to be much more difficult than the standard k-median problem. Algorithmic techniques that have been successful in approximating k-median often lead to only a pseudo-approximation for these generalizations – that is, they violate the knapsack constraint or serve fewer than m clients [2, 4, 6, 9]. Obtaining "true" approximation algorithms requires new ideas beyond those of k-median. Currently the best approximation ratio for both problems is $7.081 + \epsilon$ due to the beautiful iterative rounding framework of Krishnaswamy, Li, and Sandeep [12]. The first and only other true approximation for k-median with outliers is a local search algorithm due to Ke Chen [5].

Generalized k-Median

Both knapsack median and k-median with outliers maintain the salient features of k-median; that is, the goal is to open facilities to minimize the connection costs of served clients. These variants differ in the way we put constraints on the open facilities and served clients. For example, in k-median with outliers, we are constrained to open at most k facilities, and serve at least m clients.

In this paper, we consider a further generalization of k-median that we call *generalized k-median (GKM)*. As in k-median, our goal is to open facilities to minimize the connection costs of served clients. In GKM, the open facilities must satisfy r_1 given knapsack constraints, and the served clients must satisfy r_2 given coverage constraints. We define $r = r_1 + r_2$ to be the number of side constraints overall.

For each knapsack constraint, we have a unique non-negative budget and each facility has a non-negative cost with respect to that budget. The open facilities satisfy all budgets. Similarly, for each coverage constraint, we have a unique non-negative quota and each client has a non-negative value with respect to that quota. Then the served clients must satisfy all quotas.

1.1 Our Results

The main contribution of this paper is a refined iterative rounding algorithm for GKM. Specifically, we show how to round the natural linear program (LP) relaxation of GKM to ensure all except $O(r)$ of the variables are integral, and the objective function is increased by at most a 6.387-factor. It is not difficult to show that the iterative rounding framework in [12] can be extended to show a similar result. Indeed, a 7.081-approximation for GKM with at most $O(r)$ fractional facilities is implicit in their work. The improvement in this work is the smaller loss in the objective value.

▶ **Theorem 1** (Pseudo-Approximation for GKM). *There exists a poly-time pseudo-approximation for GKM that outputs a solution of cost at most $6.387 \cdot Opt$ with at most $O(r)$ fractional facilities.*

Our improvement relies on analyzing the extreme points of certain set-cover-like LPs. These extreme points arise at the intermediate steps of our iterative rounding, and by using their structural properties, we obtain our improved pseudo-approximation for GKM. This work reveals some of the structure of such extreme points, and it shows how this structure can lead to improvements.

Our second contribution is improved "true" approximation algorithms for two special cases of GKM: knapsack median and k-median with outliers. For both problems, applying the pseudo-approximation algorithm for GKM gives a solution with $O(1)$ fractional facilities. Thus, the remaining work is to round a constant number of fractional facilities to obtain an integral solution. To achieve this goal, we apply known sparsification techniques [12] to pre-process the instance, and then develop new post-processing algorithms to round the final $O(1)$ fractional facilities.

We show how to round these remaining variables for knapsack median at arbitrarily small loss, giving a $6.387 + \epsilon$-approximation, improving on the best $7.081 + \epsilon$-approximation. For k-median with outliers, a more sophisticated post-processing is needed to round the $O(1)$ fractional facilities. This procedure loses more in the approximation ratio. In the end, we obtain a $6.994 + \epsilon$-approximation, modestly improving on the best known $7.081 + \epsilon$-approximation.

▶ **Theorem 2** (Approximation for Knapsack Median). *For any $\epsilon > 0$, there exists a $n^{(1/\epsilon)}$-time $(6.387 + \epsilon)$-approximation for knapsack median.*

▶ **Theorem 3** (Approximation for k-Median with Outliers). *For any $\epsilon > 0$, there exists a $n^{(1/\epsilon)}$-time $(6.994 + \epsilon)$-approximation for k-median with outliers.*

Organization

In this paper, we develop and analyze the pseudo-approximation algorithm for GKM guaranteed by Theorem 1. We defer the "true" approximation algorithms guaranteed by Theorems 2 and 3 to the full version of this paper [8], §6.

1.2 Overview of Techniques

To illustrate our techniques, we first introduce a natural LP relaxations for GKM. The problem admits an integer program formulation, with variables $\{x_{ij}\}_{i\in F, j\in C}$ and $\{y_i\}_{i\in F}$, where x_{ij} indicates that *client j connects to facility i* and y_i indicates that *facility i is open*. Relaxing the integrality constraints gives the linear program relaxation LP_1. We focus on only LP_1 for now.

$$
\begin{array}{lll|lll}
(LP_1)\ \min_{x,y} & \sum_{i\in F}\sum_{j\in C} d(i,j)\, x_{ij} & & (LP_2): \quad \min_{y} & \sum_{j\in C}\sum_{i\in F_j} d(i,j)\, y_i & \\
& \sum_{i\in F} x_{ij} \le 1 & \forall j \in C & & y(F_j) \le 1 & \forall j \in C \\
& x_{ij} \le y_i & \forall i \in F, j \in C & & & \\
& Wy \le b & & & Wy \le b & \\
& \sum_{j\in C} a_j(\sum_{i\in F} x_{ij}) \ge c & & & \sum_{j\in C} a_j y(F_j) \ge c & \\
& x_{ij}, y_i \in [0,1] & \forall i \in F, j \in C & & y_i \in [0,1] & \forall i \in F
\end{array}
$$

The linear program LP_1 is the standard k-median LP with the extra side constraints. Note that $\sum_{i\in F} x_{ij} \le 1$ may seem opposite to the intuition that we want clients to get "enough" coverage from the facilities, but that will be guaranteed by the coverage constraints below.

The constraint $Wy \le b$ corresponds to the r_1 knapsack constraints on the facilities y, where $W \in \mathbb{R}_+^{r_1 \times F}$ and $b \in \mathbb{R}_+^{r_1}$. These r_1 packing constraints can be thought of as a multidimensional knapsack constraint over the facilities, and ensure that "few" facilities

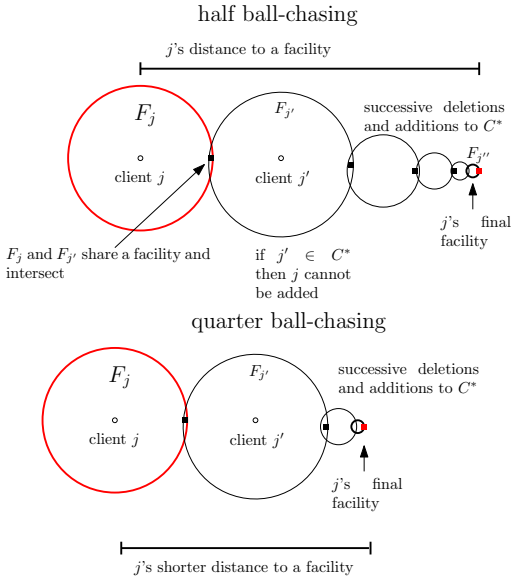

Figure 1 Half and quarter ball chasing.

are opened. Next, $\sum_{j\in C} a_j(\sum_i x_{ij}) \geq c$ corresponds to the r_2 coverage constraints on the clients, where $a_j \in \mathbb{R}_+^{r_2}$ for all $j \in C$ and $c \in \mathbb{R}_+^{r_2}$. These coverage constraints ensure that "enough" clients are served. E.g., having one packing constraint $\sum_{i\in F} y_i \leq k$ and one covering constraint $\sum_{j\in C}\sum_{i\in F} x_{ij} \geq m$ ensures that at least m clients are covered by at most k facilities; this is the k-median with outliers problem.

1.2.1 Constructing LP_2

The idea from [12] is to prescribe a set $F_j \subseteq F$ of permissible facilities for each client j such that x_{ij} is implicitly set to $y_i\mathbf{1}(i \in F_j)$. The procedure to construct these F_j's is given in Proposition 4. Using this procedure, LP_2 is also a relaxation for GKM. Note that in LP_2, we use the notation $y(F') = \sum_{i\in F'} y_i$ for $F' \subset F$.

Now consider solving LP_2 to obtain an optimal extreme point $\bar{y}$. There must be $|F|$ linearly independent tight constraints at $\bar{y}$. The tight constraints of interest are the $y(F_j) \leq 1$ constraints; in general, there are at most $|C|$ such tight constraints, and we have little structural understanding of the F_j-sets.

1.2.2 Prior Iterative Rounding Framework

Consider the family of F_j-sets corresponding to tight constraints, so $\mathcal{F} = \{F_j \mid j \in C, \bar{y}(F_j) = 1\}$. If $\mathcal{F}$ is a family of disjoint sets , then the tight constraints of LP_2 form a face of a partition matroid polytope intersected with at most r side constraints (the knapsack and coverage constraints.) Using ideas from, e.g., [12, 7], we can show that $\bar{y}$ has at most $O(r)$ fractional variables.

Indeed, the goal of the iterative rounding framework in [12] is to control the set family $\mathcal{F}$ to obtain an optimal extreme point where $\mathcal{F}$ is a disjoint family. To achieve this goal, they iteratively round an auxiliary LP based on LP_2, where they have the constraint $y(F_j) = 1$ for all clients j in a special set $C^* \subset C$. Roughly, they regulate what clients are added to C^* and delete constraints $y(F_j) \leq 1$ for some clients. The idea is that a client j whose constraint is deleted must be close to some client j' in C^*. Since $y(F_{j'}) = 1$ we can serve j with the facility for j'; the cost is small if j''s facility is close to j.

To get intuition, assume each client j can pay the farthest distance to a facility in F_j, and call this the *radius* of F_j. (Precisely, clients may not be able to afford this distance, but we use this assumption to highlight the ideas behind our algorithmic decisions.) For simplicity, assume every F_j-set is a ball whose radius is a power of two. Over time, this radius shrinks if some y-variables in F_j are set to zero. Consider applying the following iterative steps until none are applicable, in which case C^* corresponds to the tight constraints: (1) delete a constraint for $j \notin C^*$ if the radius of F_j is at least that of some $F_{j'}$ for $j' \in C^*$ and $F_j \cap F_{j'} \neq \emptyset$. (2) add $j \notin C^*$ to C^* if $y(F_j) \leq 1$ is tight and for every $j' \in C^*$ such that $F_j \cap F_{j'} \neq \emptyset$ it is the case that $F_{j'}$ has a radius strictly larger than F_j. If added then remove all j' from C^* where j's radius is *half* or less of the radius of j' and $F_j \cap F_{j'} \neq \emptyset$.

The approximation ratio is bounded by how much a client j with a deleted constraint pays to get to a facility serving a client in C^*. After removing j's constraint, the case to worry about is if j's closest client $j' \in C^*$ is later removed from C^*. This happens only if j'' is added to C^*, with $F_{j''}$ having half the radius of $F_{j'}$. Thus every time we remove j's closest client in C^*, we guarantee that j's cost only increases geometrically. The approximation ratio is proportional to the total distance that j must travel and can be directly related to the distance of "ball-chasing" though these F_j sets. When we remove a client j from C^* due to $j' \in C^*$ such that $F_{j'} \cap F_j \neq \emptyset$ and j' has radius at most half of j, we call this a *half-chasing step*. See Figure 1.

1.2.3 New Framework via Structured Extreme Points

The target of our framework is to ensure that the radius decreases in the ball-chasing at a faster rate, in particular *one-quarter*. This gives closer facilities for clients whose constraints are deleted. See Figure 1. To achieve this *quarter-chasing step*, we can simply change half to one-quarter in step (2) above.

Making this change immediately decreases the approximation ratio; however, the challenge is that $\mathcal{F}$ is no longer disjoint. Indeed, it can be the case that $j, j' \in C^*$ such that $F_j \cap F_{j'} \neq \emptyset$ if their radii differ by only a one half factor. Instead, our quarter ball-chasing algorithm maintains that $\mathcal{F}$ is not disjoint, but has a *bipartite intersection graph*.

The main technical challenge is obtaining an extreme point with $O(r)$ fractional variables, which is no longer guaranteed as when $\mathcal{F}$ was disjoint. Indeed, if $\mathcal{F}$ has bipartite intersection graph, then the tight constraints form a face of the intersection of two partition matroid polytopes intersected with at most r side constraints. In general, we *cannot upper bound the number of fractional variables* arising in the extreme points of such polytopes. However, such extreme points have a nice combinatorial structure: the intersection graph can be decomposed into $O(r)$ disjoint paths. We exploit this "chain decomposition" of extreme points arising in our iterative rounding to discover clients j that can be removed from C^* even if there is not a $j' \in C^*$ where $F_{j'}$ has one quarter of the radius of F_j. We continue this procedure until we are left with only $O(r)$ fractional variables.

The main technical contribution of this work is showing how the problem can be reduced to structural characterization of extreme points corresponding to bipartite matching. This illustrates some of the structural properties of polytopes defined by k-median-type problems. We hope that this helps lead to other structural characterizations of these polytopes and ultimately improved algorithms.

2 Auxiliary LP for Iterative Rounding

In this section, we construct the auxiliary LP, LP_{iter}. We note that we use the same relaxation used in [12]. Recall the two goals of iterative rounding, outlined in the technical overview; we want to maintain a set of clients $C^* \subset C$ such that $\{F_j \mid j \in C^*\}$ has bipartite intersection graph, and C^* should provide a good set of open facilities for the clients that are not in C^*. Thus, we want to define LP_{iter} to accommodate moving clients in and out of C^*, while having the LP faithfully capture how much we think the clients outside of C^* should pay in connection costs.

2.1 Defining F-balls

Our starting point is LP_2, so we assume that we have sets $F_j \subset F$ for all $j \in C$. The next proposition states that such sets can be found efficiently so that LP_2 is a relaxation of GKM.

▶ **Proposition 4.** *There is a poly-time algorithm that given GKM instance $\mathcal{I}$ outputs sets $F_j \subseteq F$ for $j \in C$ such that $Opt(LP_2) \leq Opt(\mathcal{I})$.*

Proof. Let $\mathcal{I}$ be the given instance of GKM and (x^*, y^*) be an optimal solution to LP_1.

Observe that if $x^*_{ij} \in \{0, y^*_i\}$ for all $i \in F, j \in C$, then we can define $F_j = \{i \in F \mid x^*_{ij} > 0\}$ for all $j \in C$. It is easy to verify in this case that y^* is feasible for LP_2 and achieves the same objective value in LP_2 as (x^*, y^*) achieves in LP_1, which completes the proof.

Thus our goal is to duplicate facilities in F and re-allocate the x- and y-values appropriately until $x^*_{ij} \in \{0, y^*_i\}$ for all $i \in F, j \in C$. To prevent confusion, let F denote the original set of facilities, and let F' denote the modified set of facilities, where make $n = |C|$ copies of each facility in F, so for each $i \in F$, we have copies $i_1, \ldots, i_n \in F'$.

Now we define $x' \in [0,1]^{F' \times C}$ and $y' \in [0,1]^{F'}$ with the desired properties. For each $i \in F$, we assume without loss of generality that $0 \leq x_{i1} \leq x_{i2} \leq \cdots \leq x_{in} \leq y_i$. We define $x'_{i_1 1}, \ldots, x'_{i_n n}$ and $y'_{i_1}, \ldots, y'_{i_n}$ recursively:

Let $y'_{i_1} = x_{i1}$ and $x'_{i_1 j} = x_{ij}$ for all $j \in [n]$.

Now for $k > 1$, let $y'_{i_k} = x_{ik} - x_{i(k-1)}$ and $x'_{i_k j} = \begin{cases} 0 & , j < k \\ y'_{i_k} & , j \geq k \end{cases}$ for all $j \in [n]$.

It is easy to verify that (x', y') is feasible for LP_1 (after duplicating facilities) and $x'_{ij} \in \{0, y'_i\}$ for all $i \in F', j \in C$, as required. Further, it is clear that this algorithm is polynomial time. ◀

In the technical overview, we assumed the radii of the F_j sets were powers of two. To formalize this idea, we discretize the distances to powers of $\tau > 1$ (up to some random offset.) The choice of τ is to optimize the final approximation ratio. The main ideas of the algorithm remain the same if we discretize to powers of, say 2, with no random offset. Our discretization procedure is the following:

Fix some $\tau > 1$ and sample the random offset $\alpha \in [1, \tau)$ such that $\log_e \alpha$ is uniformly distributed in $[0, \log_e \tau)$. Without loss of generality, we may assume that the smallest non-zero inter-point distance is 1. Then we define the possible discretized distances, $L(-2) = -1, L(-1) = 0, \ldots, L(\ell) = \alpha\tau^\ell$ for all $\ell \in \mathbb{N}$. For each $p, q \in F \cup C$, we round $d(p,q)$ *up* to the next largest discretized distance. Let $d'(p,q)$ denote the rounded distances. Observe that $d(p,q) \leq d'(p,q)$ for all $p, q \in F \cup C$. The next proposition bounds the cost of discretization.

▶ **Proposition 5.** *For all $p, q \in F \cup C$, we have $\mathbb{E}[d'(p,q)] = \frac{\tau - 1}{\log_e \tau} d(p,q)$*

Proof. If $d(p,q) = 0$, then the claim is trivial. Suppose $d(p,q) \geq 1$. We can rewrite $d(p,q) = \tau^{\ell+f}$ for some $\ell \in \mathbb{N}, f \in [0,1)$. Also, for convenience we define $\beta = \log_\tau \alpha$. Because $\log_e \alpha$ is uniformly distributed in $[0, \log_e \tau)$, it follows that β is uniformly distributed in $[0,1)$.

It follows, $d(p,q)$ is rounded to $\alpha\tau^\ell = \tau^{\ell+\beta}$ exactly when $\beta \geq f$, and otherwise $d(p,q)$ is rounded to $\tau^{\ell+\beta+1}$ when $\beta < f$. Thus we compute:

$$\begin{aligned}
\mathbb{E}[d'(p,q)] &= \int_{\beta=0}^{f} \tau^{\ell+\beta+1}\, d\beta + \int_{\beta=f}^{1} \tau^{\ell+\beta}\, d\beta \\
&= \frac{1}{\log_e \tau}(\tau^{\ell+\beta+1}|_{\beta=0}^{f} + \tau^{\ell+\beta}|_{\beta=f}^{1}) \\
&= \frac{1}{\log_e \tau}(\tau^{\ell+f+1} - \tau^{\ell+1} + \tau^{\ell+1} - \tau^{\ell+f}) \\
&= \frac{1}{\log_e \tau}(\tau^{\ell+f+1} - \tau^{\ell+f}) \\
&= \frac{\tau-1}{\log_e \tau} d(p,q).
\end{aligned}$$

◀

Now using the discretized distances, we can define the *radius level* of F_j for all $j \in C$ by:

$$\ell_j = \min_{\ell \geq -1} \{\ell \mid d'(j,i) \leq L(\ell) \quad \forall i \in F_j\}.$$

One should imagine that F_j is a ball of radius $L(\ell_j)$ in terms of the d'-distances. Thus, we will often refer to F_j as the *F-ball of client j*. Further, to accommodate "shrinking" the F_j sets, we define the *inner ball of F_j* by:

$$B_j = \{i \in F_j \mid d'(j,i) \leq L(\ell_j - 1)\}.$$

Note that we defined $L(-2) = -1$ so that if $\ell_j = -1$, then $B_j = \emptyset$.

2.2 Constructing LP_{iter}

Our auxiliary LP will maintain three sets of clients: C_{part}, C_{full}, and C^*. C_{part} consists of all clients, whom we have not yet decided whether we should serve them or not. Then for all clients in C_{full} and C^*, we decide to serve them fully. The difference between the clients in C_{full} and C^* is that for the former, we remove the constraint $y(F_j) = 1$ from the LP, while for the latter we still require $y(F_j) = 1$. Thus although we commit to serving C_{full}, such clients rely on C^* to find an open facility to connect to. Using the discretized distances, radius levels, inner balls, and these three sets of clients, we are ready to define LP_{iter}:

$$\begin{aligned}
\min_{y} \quad & \sum_{j \in C_{part}} \sum_{i \in F_j} d'(i,j) y_i + \sum_{j \in C_{full} \cup C^*} \Big(\sum_{i \in B_j} d'(i,j) y_i + (1 - y(B_j)) L(\ell_j) \Big) && (LP_{iter}) \\
\text{s.t.} \quad & y(F_j) \leq 1 \quad \forall j \in C_{part} \\
& y(B_j) \leq 1 \quad \forall j \in C_{full} \\
& y(F_j) = 1 \quad \forall j \in C^* \\
& Wy \leq b \\
& \sum_{j \in C_{part}} a_j y(F_j) \geq c - \sum_{j \in C_{full} \cup C^*} a_j \\
& 0 \leq y \leq 1
\end{aligned}$$

This completes the construction of LP_{iter}. Note that we use the *rounded* distances in the definition of LP_{iter} rather than the original distances. Keeping this in mind, if $C_{part} = C$ and $C_{full}, C^* = \emptyset$, then LP_{iter} is the same as LP_2 up to the discretized distances, so the following lemma is immediate. The algorithm described by the lemma is exactly the steps we took in this section.

▶ **Lemma 6.** *There exists a poly-time algorithm that takes as input a GKM instance $\mathcal{I}$ and outputs LP_{iter} such that $\mathbb{E}[Opt(LP_{iter})] \leq \frac{\tau-1}{\log_e \tau} Opt(\mathcal{I})$.*

The remainder of the paper shows how to iterative round LP_{iter} to obtain our pseudo-approximation for GKM.

2.3 Understanding LP_{iter}

Initially, all clients are in C_{part}. For clients in C_{part}, we are not sure yet whether we should serve them or not. Thus for these clients, we simply require $y(F_j) \leq 1$, so they can be served any amount, and in the objective, the contribution of a client from C_{part} is exactly its connection cost (up to discretization) to F_j.

The clients in C_{full} correspond to the "deleted" constraints in the technical overview. Importantly, for $j \in C_{full}$, we do not require that $y(F_j) = 1$; rather, we relax this condition to $y(B_j) \leq 1$. Recall that we made the assumption that every client can pay the radius of its F_j set. To realize this idea, we require that each $j \in C_{full}$ pays its connection costs to B_j in the objective. Then, to serve j fully, j must find $(1 - y(B_j))$ units of open facility to connect to beyond B_j. Now j truly pays its radius, $L(\ell_j)$, for this $(1 - y(B_j))$ units of connections in LP_{iter}, so we can do ball-chasing to C^* to find these facilities. In this case, we say that we *re-route* the client j to some *destination*.

Note that using the discretized distances, a half-chasing step corresponds to intersecting a neighboring ball of one radius level smaller, and a quarter-chasing step is analogously defined.

For clients in C^*, we require $y(F_j) = 1$. Note that the contribution of a $j \in C^*$ to the objective of LP_{iter} is exactly its connection cost to F_j. The purpose of C^* is to provide destinations for C_{full}.

Finally, because we have decided to fully serve all clients in C_{full} and C^*, regardless of how much they are actually served in their F-balls, we imagine that they every $j \in C_{full} \cup C^*$ contributes a_j to the coverage constraints, which is reflected in LP_{iter}.

3 Basic Iterative Rounding Phase

In this section, we describe the iterative rounding phase of our algorithm. This phase has two main goals: (a) to simplify the constraint set of LP_{iter}, and (b) to decide which clients to serve and how to serve them. To make these two decisions, we repeatedly solve LP_{iter} to obtain an optimal extreme point, and then use the structure of tight constraints to update LP_{iter}, and reroute clients accordingly.

Throughout our algorithm, we will modify the data of LP_{iter} - we will move clients between C_{part}, C_{full}, and C^* and modify the F-balls and radius levels. The key property that we wish to maintain is the *Distinct Neighbors Property*.

▶ **Definition 7** (Distinct Neighbors Property). *For all $j_1, j_2 \in C^*$, if $F_{j_1} \cap F_{j_2} \neq \emptyset$, then $|\ell_{j_1} - \ell_{j_2}| = 1$. In words, if the F-balls of two clients in C^* intersect, then they differ by exactly one radius level.*

This simple property will enable quarter-chasing and a structural characterization of the extreme points of LP_{iter} - both of which are crucial to our improved algorithm.

3.1 The Algorithm

Our algorithm repeatedly solves LP_{iter} to obtain an optimal extreme point $\bar{y}$, and then performs one of the following three possible updates, based on the tight constraints:

1. If some facility i is set to zero in $\bar{y}$, we delete it from the instance.
2. If constraint $\bar{y}(F_j) \leq 1$ is tight for some $j \in C_{part}$, then we decide to fully serve client j by moving j to either C_{full} or C^*. Initially, we add j to C_{full} then run Algorithm 2 to decide if j should be in C^* instead.
3. If constraint $\bar{y}(B_j) \leq 1$ is tight for some $j \in C_{full}$, we shrink F_j by one radius level (so j's new F-ball is exactly B_j.) Then we possibly move j to C^* by running Algorithm 2 for j.

These steps are made formal in Algorithms 1 (IterativeRound) and 2 (ReRoute). IterativeRound relies on the subroutine ReRoute, which gives our criterion for moving a client to C^*. This criterion for adding clients to C^* is the key way in which our algorithm differs from that of [12]. In [12], the criterion used ensures that $\{F_j \mid j \in C^*\}$ is a family of disjoint sets. In contrast, we allow F-balls for clients in C^* to intersect, as long as they satisfy the Distinct Neighbors Property. Thus, our algorithm allows for rich structures in the set system $\{F_j \mid j \in C^*\}$.

Algorithm 1 IterativeRound.

Input: LP_{iter}
Result: Modifies LP_{iter} and outputs an optimal extreme point of LP_{iter}

repeat
  Solve LP_{iter} to obtain optimal extreme point $\bar{y}$.
  if *there exists a facility* $i \in F$ *such that* $\bar{y}_i \geq 0$ *is tight* **then**
    Delete i from F.
  else if *there exists a client* $j \in C_{part}$ *such that* $y(F_j) \leq 1$ *is tight* **then**
    Move j from C_{part} to C_{full}.
    ReRoute(j)
  else if *there exists a client* $j \in C_{full}$ *such that* $\bar{y}(B_j) \leq 1$ *is tight* **then**
    Update $F_j \leftarrow B_j$ and decrement ℓ_j by 1.
    Update $B_j \leftarrow \{i \in F_j \mid d'(j,i) \leq L(\ell_j - 1)\}$.
    ReRoute(j)
  else
    Output $\bar{y}$ and Terminate.
until *termination*

The modifications made by IterativeRound do not increase $Opt(LP_{iter})$, so upon termination of our algorithm, we have an optimal extreme point $\bar{y}$ to LP_{iter} such that LP_{iter} is still a relaxation of GKM and no non-negativity constraint, C_{part}-constraint, or C_{full}-constraint is tight for $\bar{y}$. Further, it is easy to check that the Distinct Neighbors Property is maintained.

Algorithm 2 ReRoute.

Input: Client $j \in C_{full}$
Result: Decide whether to move j to C^* or not
if $\ell_j \leq \ell_{j'} - 1$ *for all* $j' \in C^*$ *such that* $F_j \cap F_{j'} \neq \emptyset$ **then**
  Move j from C_{full} to C^*.
  For all $j' \in C^*$ such that $F_j \cap F_{j'} \neq \emptyset$ and $\ell_{j'} \geq \ell_j + 2$, move j' from C^* to C_{full}.

3.2 Sketch of Analysis

Recall the goals from the beginning of the section: procedure IterativeRound achieves goal (a) of making $\{F_j \mid j \in C^*\}$ simpler while maintaining the Distinct Neighbors Property. Since we moved facilities between C^* and C_{full}, achieving goal (b) means deciding which facilities to open, and guaranteeing that each client has a "close-by" open facility. (Recall from §2 that C^* is the set of clients such that their F_j-balls are guaranteed to contain an open facility, and C_{full} are the clients which are guaranteed to be served but using facilities opened in C^*.)

To achieve goal (b), we observe that ReRoute always gives quarter-chasing steps. That is, if we move a client j from C^* to C_{full}, then we are guaranteed a neighboring client $j' \in C^*$ with radius level at least two smaller than j. Thus, each time we re-route j to a further destination (i.e. if j' is subject to another quarter-chasing step), the extra distance j must travel decreases geometrically. In the end, we can show that j will have an open facility within $O(1)$ times its radius.

4 Iterative Operation for Structured Extreme Points

In this section, we achieve two goals: (a) we show that the structure of the extreme points of LP_{iter} obtained from IterativeRound are highly structured, and admit a *chain decomposition*. Then, (b) we exploit this chain decomposition to define a *new* iterative operation that is applicable whenever $\bar{y}$ has "many" (i.e., more than $O(r)$) fractional variables. We emphasize that this characterization of the extreme points is what enables the new iterative rounding algorithm.

4.1 Chain Decomposition

A chain is a sequence of clients in C^* where the F-ball of each client j contains exactly two facilities – one shared with the previous ball and other with the next.

▶ **Definition 8** (Chain). *A* chain *is a sequence of clients* $(j_1, \ldots, j_p) \subseteq C^*$ *satisfying:*
- $|F_{j_q}| = 2$ *for all* $q \in [p]$, *and*
- $F_{j_q} \cap F_{j_{q+1}} \neq \emptyset$ *for all* $q \in [p-1]$.

Our chain decomposition is a partition of the *fractional* C^*-clients given in the next theorem, which is our main structural characterization of the extreme points of LP_{iter}. (We say a client j is fractional if all facilities in F_j are fractional; we denote the fractional clients in C^* by $C^*_{<1}$.) We defer the proof of the next structural theorem to the full version of this paper [8] §8, and instead focus on how to apply it.

▶ **Theorem 9** (Chain Decomposition). *Upon termination of* IterativeRound, *there exists a partition of* $C^*_{<1}$ *into at most* $3r$ *chains, along with a set of at most* $2r$ *violating clients (clients that are not in any chain.)*

The proof relies on analyzing the extreme points of LP_{iter} satisfying the Distinct Neighbors Property. We show that this boils down to analyzing a bipartite matching polytope with r side constraints.

4.2 Iterative Operation for Chain Decompositions

Leveraging Theorem 9, consider an optimal extreme point $\bar{y}$ of LP_{iter}, and its chain decomposition. We show that if the number of fractional variables in $\bar{y}$ is sufficiently large, there exists a useful structure in the chain decomposition, which we call a *candidate configuration*.

▶ **Definition 10** (Candidate Config). *Let $\bar{y}$ be an optimal extreme point of LP_{iter}. A candidate configuration is a pair of two clients $(j, j') \subset C^*_{<1}$ such that:*

1. $F_j \cap F_{j'} \neq \emptyset$
2. $\ell_{j'} \leq \ell_j - 1$
3. *Every facility in F_j and $F_{j'}$ is in at exactly two F-balls for clients in C^**
4. $|F_j| = 2$ *and* $|F_{j'}| = 2$

One should imagine that a candidate configuration is two neighboring balls on a sufficiently long chain.

▶ **Lemma 11.** *If* IterativeRound *outputs an extreme point that has at least $15r$ fractional facilities, then there exist a candidate configuration in $C^*_{<1}$.*

To prove Lemma 11, which bounds the number of fractional facilities needed to have a candidate configuration, we first prove a bound on the number of factional clients needed. The bound on the number of facilities will follow by a dimension argument.

▶ **Proposition 12.** *Suppose LP_{iter} satisfies the Distinct Neighbors Property. Then each facility is in at most two F-balls for clients in C^*.*

Proof. Assume for contradiction that there exists a facility i such that $i \in F_{j_1} \cap F_{j_2} \cap F_{j_3}$ for distinct clients $j_1, j_2, j_3 \in C^*$. Then j_1 and j_2 differ by one radius level, and j_2 and j_3 differ by one radius level. However, now it cannot be the case that j_1 and j_3 also differ by one radius level. This contradicts the Distinct Neighbors Property. ◀

▶ **Lemma 13.** *Suppose LP_{iter} satisfies all Basic Invariants, and let $\bar{y}$ be an optimal extreme point of LP_{iter} such that no C_{part}-, C_{full}-, or non-negativity constraint is tight. If $|C^*_{<1}| \geq 14r$, then there exist a candidate configuration in $C^*_{<1}$.*

Proof. We claim that in order for $C^*_{<1}$ to have a candidate configuration, it suffices to have a chain of length at least four in $C^*_{<1}$. To see this, let $(j_1, j_2, j_3, j_4, \dots) \subset C^*_{<1}$ be a chain of length at least four. Then $F_{j_2} \cap F_{j_3} \neq \emptyset$, and by the Distinct Neighbors Property, either $\ell_{j_3} = \ell_{j_2} - 1$ or $\ell_{j_2} = \ell_{j_3} - 1$.

We only consider the former case, because both cases are analogous. Thus, if $\ell_{j_3} = \ell_{j_2} - 1$, then we claim that (j_2, j_3) forms a candidate configuration. We already have the first two properties of a candidate configuration. Now we verify the last two. Because j_2 and j_3 are part of a chain, we have $|F_{j_2}| = 2$ and $|F_{j_3}| = 2$. Further, j_2 has neighbors j_1 and j_3 along the chain. By Proposition 12, each facility in F_{j_2} is in at most two F-balls for clients in C^*. In particular, one of the facilities in F_{j_2} is shared by F_{j_1} and F_{j_2}, and the other must be shared by F_{j_2} and F_{j_3}. Thus, each facility in F_{j_2} is in exactly two F-balls for clients in C^*. An analogous argument holds for F_{j_3}, so (j_2, j_3) satisfies all properties of a candidate configuration, as required.

Now suppose $|C^*_{<1}| \geq 14r$. By Theorem 9, $C^*_{<1}$ admits a chain decomposition into at most $3r$ chains and a set of at most $2r$ violating clients. Then at least $12r$ of the clients in $C^*_{<1}$ belong to the $3r$ chains. By averaging, there must exist a chain with size at least $\frac{12r}{3r} = 4$, as required. ◀

Now we relate the number of fractional facilities with the number of fractional C^*-clients by a dimension argument.

▶ **Lemma 14.** *Let $\bar{y}$ be an extreme point of LP_{iter} such that no C_{part}-, C_{full}-, or non-negativity constraint is tight. Then the number of fractional facilities in $\bar{y}$ satisfies $|F_{<1}| \leq |C^*_{<1}| + r$ (recall that r is the number of side constraints.)*

Proof of Lemma 14. We construct a basis $\bar{y}$. First, for each integral facility $i \in F_{=1}$, we add the integrality constraint $\bar{y}_i \leq 1$ to our basis. Thus we currently have $|F_{=1}|$ constraints in our basis.

It remains to choose $|F_{<1}|$ further linearly independent constraints to add to our basis. Note that we have already added all tight integrality constraints to our basis, and no non-negativity constraint is tight. Then the only remaining tight constraints we can add are the C^*-constraints and the r side constraint.

We claim that we cannot add any $C^*_{=1}$-constraints, because every $C^*_{=1}$-constraint is of the form $y(F_j) = y_{i_j} = 1$ for the unique integral facility $i_j \in F_1$. Note that here we used the fact that there is no facility that is set to zero. Thus every $C^*_{=1}$-constraint is linearly dependent with the tight integrality constraints, which we already chose.

It follows, the only possible constraints we can choose are the $C^*_{<1}$-constraints and the r side constraints so:

$$|F_{<1}| \leq |C^*_{<1}| + r.$$ ◀

Lemma 11 is immediate by composing the above two lemmas.

Proof of Lemma 11. By Lemma 13, it suffices to show that $|F_{<1}| \geq 15r$ implies that $|C^*_{<1}| \geq 14r$. Applying Lemma 14, we have:

$$15r \leq |F_{<1}| \leq |C^*_{<1}| + r.$$ ◀

Our new iterative operation is easy to state. Find a candidate configuration (j, j') and move j from C^* to C_{full}.

Algorithm 3 ConfigReRoute.

Input: An optimal extreme point $\bar{y}$ to LP_{iter} s.t. there exists a candidate configuration
Result: Modify LP_{iter}
1 Let $(j, j') \subset C^*_{<1}$ be any candidate configuration.
2 Move j from C^* to C_{full}.

It is easy to check that ConfigReRoute maintains the Distinct Neighbors Property and weakly decreases $Opt(LP_{iter})$.

4.3 Sketch of Analysis

The first two properties of candidate configurations are used to re-route j to j'. Observe a key difference between ReRoute and ConfigReRoute: In the former, we always guarantee quarter-chasing steps. On the other hand, in ConfigReRoute, we only guarantee a neighboring client of at least one radius level smaller, which corresponds to a half-chasing step. This raises the worry that if all re-routings are due to ConfigReRoute, any potential gains by ReRoute are not realized in the worst case. However we show that, roughly speaking, the last two properties of candidate configurations guarantee that the half-chasing steps of ConfigReRoute happen at most half the time.

In particular, suppose client j is re-routed via ConfigReRoute to j' , which is exactly one radius level smaller. If j' is later re-routed via ReRoute, then we can re-route j to j' and then this new destination. This gives one half- and one quarter-chasing step. The concern is if j' is later re-routed via ConfigReRoute, which would give j two half-chasing steps in a row. By analyzing the interactions between ReRoute and ConfigReRoute, we show that there must exist a j'' that gives j a quarter-chasing step. See Figure 2.

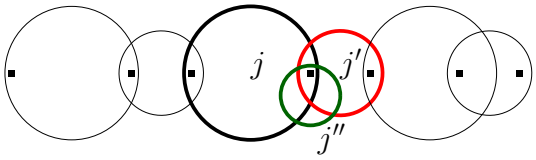

Figure 2 A chain of balls in C^*, where squares indicate facilities. First j is removed from C^* as part of candidate configuration (j, j'), so j' has strictly smaller radius than j. Then j'' is added to C^*, which has strictly smaller radius than j'. This gives j a destination that is at least two radius levels smaller.

5 Pseudo-Approximation Algorithm for GKM

The pseudo-approximation algorithm for GKM combine the iterative rounding algorithm IterativeRound from §3 with the re-routing operation ConfigReRoute from §4 to construct a solution to LP_{iter}. PseudoApproximation is the algorithm guaranteed by Theorem 1.

Algorithm 4 PseudoApproximation.

Input: LP_{iter}
Result: Modifies LP_{iter} and outputs an optimal extreme point of LP_{iter}

```
repeat
    Run IterativeRound to obtain an optimal extreme point ȳ of LP_iter
    if there exists a candidate configuration then
        Run ConfigReRoute
    else
        Output ȳ and Terminate
until Termination
```

5.1 Sketch of Analysis

There are two main components to analyzing PseudoApproximation. First, we show that the output extreme point has $O(r)$ fractional variables, which follows from Lemma 11. Second, we bound the re-routing cost, which follows from the sketches in §3 and §4. In particular, for each client, we can charge each of its half-chasing steps to a quarter-chasing step. This improves on [12], where every re-routing is via half-chasing steps. Optimizing the choice of τ (the discretization factor) gives our final approximation ratio.

5.2 Analysis of PseudoApproximation

In this section, we prove that PseudoApproximation satisfies the guarantees of Theorem 1. We begin by analyzing the runtime and number of fractional facilities.

▶ **Lemma 15.** *PseudoApproximation is a polynomial time algorithm that maintains the Distinct Neighbors Property, weakly decreases $Opt(LP_{iter})$, and outputs an optimal extreme point of LP_{iter} with at most $15r$ fractional variables.*

Proof of Lemma 15. We first show that both IterativeRound and ReRoute are polynomial time. It is clear that the latter runs in polynomial time. For IterativeRound, it suffices to show that the number of iterations of IterativeRound is polynomial. In each iteration, we make one of three actions. We either delete a facility from F, move a client from C_{part} to C_{full} or shrink a F-ball by one radius level for a client in $j \in C_{full}$.

We can delete each facility from F at most once, so we make at most $|F|$ deletions. Each client can move from C_{part} to C_{full} at most once, because we never move clients back from C_{full} to C_{part}, so we do this operations at most $|C|$ times. Finally, observe that $\ell_j \geq -1$ for all $j \in C$ over all iterations. We conclude that we can shrink each F-ball only polynomially many times.

For the runtime of PseudoApproximation, it suffices to show that the number of calls to IterativeRound and ConfigReRoute is polynomial.

In every iteration of PseudoApproximation, either we terminate or we are guaranteed to move a client from C^* to C_{full} in ConfigReRoute. Each client can be removed from C^* only polynomially many times, because each time a client is removed, in order to be re-added to C^*, it must be the case that we shrunk the F-ball of that client. However, again because $\ell_j \geq -1$ for all $j \in C$, we can shrink each F-ball only polynomially many times.

It is easy to check that both IterativeRound and ReRoute maintain the Distinct Neighbors Property and weakly decrease $Opt(LP_{iter})$.

Finally, upon termination of PseudoApproximation, there is no candidate configuration, so Lemma 11 implies that $\bar{y}$ has at most $15r$ fractional variables. ◀

5.3 Analysis of Re-Routing Cost

We now bound the re-routing cost by analyzing how C^* evolves throughout PseudoApproximation. This is one of the main technical contributions of our paper, and it is where our richer C^*-set and relaxed re-routing rules are used. [12] prove an analogous result about the re-routing cost of their algorithm. In the language of the following theorem statement, they show that $\alpha = \frac{\tau+1}{\tau-1}$ for the case $\beta = 1$. We improve on this factor by analyzing the interactions between ReRoute and ConfigReRoute. Interestingly, analyzing each of ReRoute and ConfigReRoute separately would not yield any improvement over [12] in the worst case, even with our richer set C^*. It is only by using the properties of candidate configurations and analyzing sequences of calls to ReRoute and ConfigReRoute that we get an improvement.

▶ **Theorem 16** (Re-Routing Cost). *Upon termination of* PseudoApproximation*, let $S \subset F$ be a set of open facilities and $\beta \geq 1$ such that $d(j,S) \leq \beta L(\ell_j)$ for all $j \in C^*$. Then for all $j \in C_{full} \cup C^*$, $d(j,S) \leq (2+\alpha)L(\ell_j)$, where $\alpha = \max(\beta, 1+\frac{1+\beta}{\tau}, \frac{\tau^3+2\tau^2+1}{\tau^3-1})$.*

We will need the following discretized version of the triangle inequality.

▶ **Proposition 17.** *Let $j, j' \in C$ such that F_j and $F_{j'}$ intersect. Then $d(j,j') \leq L(\ell_j)+L(\ell_{j'})$.*

Proof. Let $i \in F_j \cap F_{j'}$. Then using the triangle inequality we can bound:

$$d(j,j') \leq d(j,i) + d(i,j') \leq d'(j,i) + d'(i,j') \leq L(\ell_j) + L(\ell_{j'}).$$ ◀

The next lemma analyzes the life-cycle of a client that enters C^* at some point in PseudoApproximation. Our improvement over [12] comes from this lemma.

▶ **Lemma 18.** *Upon termination of* PseudoApproximation*, let $S \subset F$ be a set of open facilities and $\beta \geq 1$ such that $d(j,S) \leq \beta L(\ell_j)$ for all $j \in C^*$. Suppose client j is added to C^* at radius level ℓ during* PseudoApproximation *(it may be removed later.) Then upon termination of* PseudoApproximation*, we have $d(j,S) \leq \alpha L(\ell)$, where $\alpha = \max(\beta, 1+\frac{1+\beta}{\tau}, \frac{\tau^3+2\tau^2+1}{\tau^3-1})$.*

Proof. Consider a client j added to C^* with radius level ℓ. If j remains in C^* until termination, the lemma holds for j because $\alpha \geq \beta$. Thus, consider the case where j is later removed from C^* in PseudoApproximation. Note that the only two operations that can possibly cause this removal are ReRoute and ConfigReRoute. We prove the lemma by induction on $\ell = -1, 0, \ldots$. If $\ell = -1$, then j remains in C^* until termination because it has the smallest possible radius level and both ReRoute and ConfigReRoute remove a client from C^* only if there exists another client with strictly smaller radius level.

Similarly, if $\ell = 0$, we note that ReRoute removes a client from C^* only if there exists another client with radius level at least two smaller, which is not possible for j. Thus, if j does not remain in C^* until termination, there must exist some j' that is later added to C^* with radius level at most $\ell - 1 = -1$ such that $F_j \cap F_{j'} \neq \emptyset$. We know that j' remains in C^* until termination since it is of the lowest radius level. Thus:

$$d(j,S) \leq d(j,j') + d(j',S) \leq L(0) + L(-1) + \beta L(-1) = L(0).$$

Now consider $\ell > 0$ where j can possibly be removed from C^* by either ReRoute or ConfigReRoute. In the first case, j is removed by ReRoute, so there exists j' that is added to C^* such that $\ell_{j'} \leq \ell - 2$ and $F_j \cap F_{j'} \neq \emptyset$. Applying the inductive hypothesis to j', we can bound:

$$d(j,S) \leq d(j,j') + d(j',S) \leq L(\ell) + L(\ell-2) + \alpha L(\ell-2) \leq (1 + \frac{1+\alpha}{\tau^2})L(\ell).$$

It is easy to verify by routine calculations that $1 + \frac{1+\alpha}{\tau^2} \leq \alpha$ given that $\alpha \geq \frac{\tau^3+2\tau^2+1}{\tau^3-1}$.

For our final case, suppose j is removed by ConfigReRoute. Then there exists $j' \in C^*$ such that $F_j \cap F_{j'} \neq \emptyset$ and $\ell_{j'} \leq \ell - 1$. Further, $|F_{j'}| = 2$. If j' remains in C^* until termination, then:

$$d(j,S) \leq d(j,j') \leq L(\ell) + L(\ell-1) + \beta L(\ell-1) \leq (1 + \frac{1+\beta}{\tau})L(\ell).$$

Otherwise, j' is removed by ReRoute at an even later time because some j'' is added to C^* such that $\ell_{j''} \leq \ell_{j'} - 2$ and $F_{j'} \cap F_{j''} \neq \emptyset$. Applying the inductive hypothesis to j'', we can bound:

$$d(j,S) \leq d(j,j') + d(j',j'') + d(j'',S) \leq (1 + \frac{2}{\tau} + \frac{1+\alpha}{\tau^3})L(\ell).$$

where $\alpha \geq \frac{\tau^3+2\tau^2+1}{\tau^3-1}$ implies $1 + \frac{2}{\tau} + \frac{1+\alpha}{\tau^3} \leq \alpha$.

Now, we consider the case where j' is later removed by ConfigReRoute. To analyze this case, consider when j was removed by ConfigReRoute. At this time, we have $|F_{j'}| = 2$ by definition of Candidate Configuration. Because $F_j \cap F_{j'} \neq \emptyset$, consider any facility $i \in F_j \cap F_{j'}$. When j is removed from C^* by ConfigReRoute, we have that i is in exactly two F-balls for clients in C^*, exactly F_j and $F_{j'}$. However, after removing j from C^*, i is only in one F-ball for clients in C^* - namely $F_{j'}$.

Later, at the time j' is removed by ConfigReRoute, it must be the case that $|F_{j'}| = 2$ still, so $F_{j'}$ is unchanged between the time that j is removed and the time that j' is removed. Thus the facility i that was previously in $F_j \cap F_{j'}$ must still be present in $F_{j'}$. Then this facility must be in exactly two F-balls for clients in C^*, one of which is j'. It must be the case that the other F-ball containing i, say $F_{j''}$, was added to C^* between the removal of j and j'.

Note that the only operation that adds clients to C^* is ReRoute, so we consider the time between the removal of j and j' when j'' is added to C^*. Refer to Figure 2. At this time, we have $j' \in C^*$, and $F_{j'} \cap F_{j''} \neq \emptyset$ because of the facility i. Then it must be the case that j'' has strictly smaller radius level than j', so $\ell_{j''} \leq \ell_{j'} - 1 \leq \ell - 2$. To conclude the proof, we note that $F_j \cap F_{j''} \neq \emptyset$ due to the facility i, and apply the inductive hypothesis to j'':

$$d(j, S) \leq d(j, j'') + d(j'', S) \leq (1 + \frac{1+\alpha}{\tau^2})L(\ell,)$$

which is at most $\alpha L(\ell)$. ◀

Now using the above lemma, we can prove Theorem 16.

Proof of Theorem 16. Consider any client j that is in $C_{full} \cup C^*$ upon termination of PseudoApproximation. It must be the case that ReRoute(j) was called at least once during PseudoApproximation. Consider the time of the last such call to ReRoute(j). If j is added to C^* at this time, note that its radius level from now until termination remains unchanged, so applying Lemma 18 gives that $d(j, S) \leq \alpha L(\ell_j)$, as required. Otherwise, if j is not added to C^* at this time, then there must exist some $j' \in C^*$ such that $F_j \cap F_{j'} \neq \emptyset$ and $\ell_{j'} \leq \ell_j$. Then applying Lemma 18 to j', we have:

$$d(j, S) \leq d(j, j') + d(j', S) \leq L(\ell_j) + L(\ell_{j'}) + \alpha L(\ell_{j'}) \leq (2 + \alpha)L(\ell_j).$$ ◀

5.4 Putting it all Together: Pseudo-Approximation for GKM

In this section, we prove Theorem 1. In particular, we use the output of PseudoApproximation to construct a setting of the x-variables with the desired properties.

Proof of Theorem 1. Given as input an instance $\mathcal{I}$ of GKM, our algorithm is first to run the algorithm guaranteed by Lemma 6 to construct LP_{iter} from LP_1 such that $\mathbb{E}[Opt(LP_{iter})] \leq \frac{\tau-1}{\log_e \tau} Opt(\mathcal{I})$. Note that we will choose $\tau > 1$ later to optimize our final approximation ratio. Then we run PseudoApproximation on LP_{iter}, so by Theorem 15, PseudoApproximation outputs in polynomial time LP_{iter} along with an optimal solution $\bar{y}$ with $O(r)$ fractional variables.

Given $\bar{y}$, we define a setting $\bar{x}$ for the x-variables: for all $j \in C_{part}$, connect j to all facilities in F_j by setting $\bar{x}_{ij} = \bar{y}_i$ for all $i \in F_j$. For all $j \in C^*$, we have $\bar{y}(F_j) = 1$, so connect j to all facilities in F_j. Finally, to connect every $j \in C_{full}$ to one unit of open facilities, we use the following modification of Theorem 16:

▶ **Proposition 19.** *When* PseudoApproximation *terminates, for all* $j \in C_{full} \cup C^*$*, there exists one unit of open facilities with respect to* $\bar{y}$ *within distance* $(2+\alpha)L(\ell_j)$ *of* j*, where* $\alpha = \max(1, 1+\frac{2}{\tau}, \frac{\tau^3+2\tau^2+1}{\tau^3-1})$.

The proof of the above proposition is analogous to that of Theorem 16 in the case $\beta = 1$, so we omit it. To see this, note that for all $j \in C^*$, we have $\bar{y}(F_j) = 1$. This implies that each $j \in C^*$ has one unit of fractional facility within distance $L(\ell_j)$. Following an analogous inductive argument as in Lemma 18 gives the desired result.

By routine calculations, it is easy to see that $\alpha = \frac{\tau^3+2\tau^2+1}{\tau^3-1}$ for all $\tau > 1$. Now, for all $j \in C_{full}$, we connect j to all facilities in B_j. We want to connect j to one unit of open facilities, so to find the remaining $1 - \bar{y}(B_j)$ units, we connect j to an arbitrary $1 - \bar{y}(B_j)$ units of open facilities within distance $(2+\alpha)L(\ell_j)$ of j, whose existence is guaranteed by Proposition 19. This completes the description of $\bar{x}$.

It is easy to verify that $(\bar{x}, \bar{y})$ is feasible for LP_1, because $\bar{y}$ satisfies all knapsack constraints, and every client's contribution to the coverage constraints in LP_1 is exactly its contribution in LP_{iter}. Thus it remains to bound the cost of this solution. We claim that $LP_1(\bar{x}, \bar{y}) \leq (2+\alpha)Opt(LP_{iter})$, because each client in C_{part} and C^* contributes the same amount to LP_1 and LP_{iter} (up to discretization), and each client $j \in C_{full}$ has connection cost at most $2+\alpha$ times its contribution to LP_{iter}.

In conclusion, the expect cost of the solution $(\bar{x}, \bar{y})$ to LP_1 is at most:

$$(2+\alpha)\,\mathbb{E}[Opt(LP_{iter})] \leq \frac{\tau-1}{\log_e \tau}\left(2 + \frac{\tau^3+2\tau^2+1}{\tau^3-1}\right) Opt(\mathcal{I}).$$

Choosing $\tau > 1$ to minimize $\frac{\tau-1}{\log_e \tau}(2 + \frac{\tau^3+2\tau^2+1}{\tau^3-1})$ gives $\tau = 2.046$ and $\frac{\tau-1}{\log_e \tau}(2 + \frac{\tau^3+2\tau^2+1}{\tau^3-1}) = 6.387$. ◀

5.5 From Pseudo-Approximation to True Approximation

To extend PseudoApproximation to a true approximation algorithm for the special cases of knapsack median and k-median with outliers, we need to round the final $O(1)$ fractional facilities from the output of PseudoApproximation. To do so, we wrap PseudoApproximation with pre-processing and post-processing algorithms. The pre-processing involves enumeration to overcome the unbounded integrality gap, and the post-processing rounds the final $O(1)$ fractional facilities. See [8], §6 for details.

Abstract

We study the store-and-forward packet routing problem for simultaneous multicasts, in which multiple packets have to be forwarded along given trees as fast as possible.

This is a natural generalization of the seminal work of Leighton, Maggs and Rao, which solved this problem for unicasts, i.e. the case where all trees are paths. They showed the existence of asymptotically optimal $O(C + D)$-length schedules, where the congestion C is the maximum number of packets sent over an edge and the dilation D is the maximum depth of a tree. This improves over the trivial $O(CD)$ length schedules.

We prove a lower bound for multicasts, which shows that there do not always exist schedules of non-trivial length, $o(CD)$. On the positive side, we construct $O(C + D + \log^2 n)$-length schedules in any n-node network. These schedules are near-optimal, since our lower bound shows that this length cannot be improved to $O(C + D) + o(\log n)$.

1 Introduction

We study how to efficiently schedule multiple simultaneous multicasts in the store-and-forward model.

Unicasts and multicasts are two of the most basic and important information dissemination primitives in modern communication networks. In a unicast a source sends information to a receiver and in a multicast a source sends information to several receivers. Typically, many such primitives are run simultaneously, causing these primitives to contend for the same resources, most notably the bandwidth of communication links.

The store-and-forward model has been the classic model for developing a clean theoretical understanding of how to most efficiently schedule many such primitives contending for the same link bandwidth. In the store-and-forward model, a network is modeled as a simple undirected graph $G = (V, E)$ with n nodes. Time proceeds in synchronous rounds during which nodes trade packets. In each round a node can send packets it holds to neighbors in G, but at most one packet is allowed to be sent along an edge in each round. Nodes can copy packets and send duplicate packets to neighbors, again subject to the constraint that at most one packet crosses an edge each round.

The store-and-forward model, in turn, enables a formal definition of the problem of scheduling many simultaneous multicasts or unicasts. A simultaneous multicast instance is given by a set of rooted trees $\mathcal{T}$ – one for each multicast – on a store-and-forward network G. Each $T_i \in \mathcal{T}$ has root r_i and leaves L_i along with a packet (a.k.a. message) m_i, initially only known to r_i. A schedule instructs nodes what packets to send in which rounds, subject to the constraint that m_i can only be sent over edges in T_i. The quality of a schedule is its *length*; i.e., the number of rounds until all nodes in L_i have received m_i for every i. A simultaneous unicast instance is the simple case of a simultaneous multicast where all T_i are paths. The goal of past work and this work is to understand the length of the shortest schedule.

The most important parameters in understanding the length of the shortest schedule has been the *congestion* $C = \max_e |\{T_i \ni e\}|$, i.e., the maximum number of packets that need to be routed over any edge in G and the *dilation* $D = \max_i \text{depth}(T_i)$, i.e., the maximum depth of any multicast-tree or the maximum length of any path in the case of simultaneous unicast. It is easy to see that any schedule requires at least $\max(C, D) = \Omega(C + D)$ rounds: a tree with depth D requires at least D rounds to deliver its message and any edge with congestion C requires at least C rounds to forward all packets that need to be sent over it. On the other hand, any instance can easily be scheduled in $O(CD)$ rounds in a greedy manner: in each round and for each edge $e = (u, v)$, forward m_i from u to v where T_i is an arbitrary tree such that $e \in T_i$ and u knows m_i but v does not; it is easy to verify that this schedule takes $O(CD)$ rounds.

Classic results of Leighton, Maggs, and Rao [30] improve upon this trivial $O(CD)$ bound for the case of simultaneous unicast. They showed that introducing a simple independent random delay for each packet at its source suffices to obtain schedules of length $O(C + D \cdot \log n)$ or $O((C + D) \cdot \frac{\log n}{\log \log n})$. A similar strategy can be shown to also work for simultaneous multicasts [12]. More surprisingly, Leighton et al. show how an intricate repeated application of the Lovász Local Lemma [1] proves the existence of length $O(C + D)$ for any simultaneous unicast instance. This seminal paper initiated a long line of followup work [39, 36, 43, 5, 28, 6, 35, 38, 34, 2, 12, 33], some of which even showed these $O(C + D)$-length schedules are efficiently computable [31], even by *distributed* algorithms [34, 38].

In contrast, essentially nothing beyond the above trivial $O(CD)$ and simple random delay bounds of $O(C+D\cdot\log n)$ and $O((C+D)\cdot\frac{\log n}{\log\log n})$ is known for simultaneous multicast, despite ample practical and theoretical motivation. In particular, simultaneous multicast forms an important component of practical content-delivery systems [25, 8], as well as numerous recent theoretical advances in distributed computing [9, 16, 13, 14, 18, 19, 20, 17, 21, 29, 27, 15].

The length of the optimal simultaneous multicast schedule is made all the more intriguing by the work of Ghaffari [12]. This work studied a natural generalization of simultaneous multicast, namely how to schedule many simultaneous distributed algorithms, which corresponds to scheduling the routing of messages on directed acyclic graphs (DAGs). Ghaffari showed that in this setting no $O(C + D)$ schedules exist and, in fact, (up to $O(\log\log n)$ factors) the random delay upper bound of $O(C + D \cdot \log n)$ is the closest that one can get to

an $O(C + D)$ bound. Given that multicasts are more general than unicasts but less general than DAGs, it has remained an interesting open question whether an $O(C + D)$ schedule comparable to those for unicasts is also possible for multicasts or whether, like for DAGs, a multiplicative $O(\log n)$ overhead is required.

1.1 Our Contributions

We show that, unlike in the unicast setting where $O(C + D)$ schedules are possible, for multicasts the trivial $O(CD)$ upper bound cannot be improved without introducing a dependence on the number of nodes, n.

▶ **Theorem 1.1.** *For any $C, D, n \in \mathbb{Z}_+$ such that $C2^{D+1} \leq \log n$ there exists a simultaneous multicast instance on an n-node graph with congestion C and dilation D whose optimal schedule requires at least $\frac{CD}{2}$ rounds.*

We note that our lower bound also implies a new lower bound of $\Omega(CD)$ for the DAGs case studied by Ghaffari [12] since the DAGs case generalizes simultaneous multicasts.

On the positive side, we show that if one allows a schedule's length to depend on n then, unlike in the DAGs case where $O(C + D \cdot \log n)$ is the closest one can get to $O(C + D)$, one can get $O(C + D)$ with a mere *additive* $O(\log^2 n)$.

▶ **Theorem 1.2.** *Each simultaneous multicast instance with congestion C and dilation D in an n-node network admits a schedule of length at most $O(C + D + \log^2 n)$.*

We also verify that these schedules are efficiently computable both by a deterministic, centralized polynomial-time algorithm and by a randomized distributed algorithm in the CONGEST model. Our centralized algorithms are a straightforward extension of our constructions while our distributed algorithms will be based on exponentially decreasing the number of messages that must be sent by using a "rank-decomposition" idea from the union find data structure; we defer the details of our algorithms to Section 7.

Complementing our proof that shows the existence of $O(C + D + \log^2 n)$ schedules, we extend our lower bound to show that any schedule with purely additive dependence on C, D and any function of n incurs at least an additive $\Omega(\log n)$ term. This implies that the additive $\log^2 n$ in Theorem 1.2 is essentially optimal.

▶ **Theorem 1.3.** *Suppose there is a function f such that for any simultaneous multicast instance with congestion C and dilation D, there is a schedule delivering all packets in $O(C + D) + f(n)$ steps. Then $f(n) = \Omega(\log n)$.*

In summary, our results give an essentially optimal characterization of what simultaneous multicast schedules are possible and cleanly separate the complexity of simultaneous multicast schedules from those of simultaneous unicasts and DAGs.

2 Related Work

While we have already mentioned the most relevant previous work, we give some additional related work below.

The seminal work of Leighton et al. [30] initiated a series of works aimed at showing short simultaneous unicast schedules exist. For example, [40, 36] improved the constants in the $O(C + D)$ schedules of Leighton et al., with [36] also generalizing this result to edges with non-unit transit times and bandwidth. Rothvoss [39] presented a simplified proof compared to that of [30] by way of the "method of conditional expectations", and also increased the constant in the $\Omega(C + D)$ lower bound.

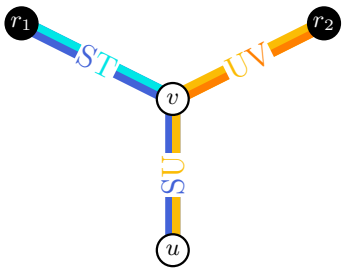
In addition to the mentioned work of Ghaffari [12], there is a variety of work in scheduling of specific distributed algorithms. A classic result of Topkis [44] shows that h-hop broadcast of k messages from different sources can be done in $O(k+h)$ rounds. This is a special case of simultaneous multicast, where k multicast instances are to be scheduled along edges of trees with congestion $C \leq k$ and depth D. So, for this special case of simultaneous multicast a $O(C+D)$-length schedule always exists. More recently, Holzer and Wattenhofer [22] showed that n BFSs can be performed from different nodes in $O(n)$ rounds. This was generalized by Lenzen and Peleg [32] who showed that k many h-hop BFSs from different sources can be done in $O(k+h)$ rounds.

Another line of work on simultaneous unicast and related problem focused on *computing* optimal or near-optimal schedules efficiently, starting with work of Leighton et al. [31]. There has been work on simultaneous unicast focused on "local-control" or distributed algorithms, where at each step each node makes decisions on which packets to move forward along their paths, based only on the routing information that the packets carry and on the local history of execution. The $O(C + D \cdot \log n)$ algorithm of Leighton et al. [30], for example, is such a distributed simultaneous unicast algorithm. Rabani and Tardos [38] improved this bound to $O(C) + D \cdot (\log^* n)^{O(\log^* n)}$ rounds, which was then further improved by Ostrovsky and Rabani [34] to $O(C + D + \log^{1+\epsilon} n)$ rounds for any constant $\epsilon > 0$. Another series of works also studied centralized algorithms for simultaneous unicast where the source and sink pairs are fixed but the algorithm is free to choose what paths it uses to deliver packets from sources to sinks. Notably, Srinivasan and Teo [43] gave a constant approximation for this problem. Bertsimas and Gamarnik [5] then provided an asymptotically-optimal algorithm, outputting a schedule of length $OPT + (\sqrt{n \cdot OPT})$; i.e., $OPT(1 + o(1))$ for sufficiently large OPT. Lastly, there has been work in computing schedules for single multicasts [4, 10] and even simultaneous multicasts [23, 24] in models fundamentally different from the store-and-forward model we study.

3 Intuition and Overview of Techniques

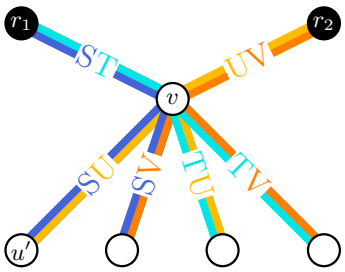
We now give an overview of and intuition for the techniques we use in proving the impossibility of good simultaneous multicast schedules and our nearly matching upper bound.

3.1 $\Omega(CD)$ Lower Bound



The goal of our lower $\Omega(CD)$ lower bound construction is to repeatedly "accumulate" delays by combining together already delayed multicast trees. Here, we build some intuition for this strategy .

Consider a simultaneous multicast instance consisting of two trees S and T using a single edge as in Figure 1. Since at most one message crosses this edge each round, we know that after one round at least one of our trees' messages will be delayed by 1 round, i.e., will not have crossed the edge. More generally, if C trees all use a single edge e then for any fixed schedule one of these trees will require at least C rounds until its message crosses e.



If we knew, a priori, for any C-congested edge which multicast tree was delayed by C, producing a hard multicast instance would be easy as we could repeatedly combine together the multicast trees delayed by C in each congested edge. For instance, consider the following example, illustrated in Figure 2a where $C = 2$. We have four multicast trees S, T, U and V where S and T have root r_1 and U and V have root r_2. Both roots connect to a vertex v where (r_1, v) is used by S and T and (r_2, v) is used by U and V. If we knew that after a single round T and V used edges (r_1, v) and (r_2, v) respectively, then we could "combine" S

Figure 1 A congested edge example on multicast trees S and T. Root of both trees given by black node. Each multicast tree given in a different color and edges labeled by which multicast trees use them.

(a) Accumulating delays if S and U delayed.

(b) Guessing the delayed trees.

Figure 2 Illustration of how one can "guess" which trees are delayed. Roots given by black nodes. Each multicast tree given in a different color and edges labeled by which multicast trees use them.

and U into a new edge (v, u). Then, the messages for S and U wouldn't arrive at v until at least two rounds have passed and since both S and U use the edge (v, u), one of the messages of either S or U wouldn't arrive at u until four rounds have passed, despite the fact that u is only two hops from the root of each tree. We might hope, then, to recursively repeat this strategy, combining together such gadgets to accumulate larger and larger delays.

However, we, of course, do not always know which trees are delayed and so combining together the most delayed tree is not a feasible strategy. That is, we must provide a construction which requires many rounds for *every possible* simultaneous multicast schedule, not many rounds for one fixed schedule.

We overcome this challenge by using the fact that trees, unlike paths, branch. In particular, we will use the branching of trees to "guess" which tree was delayed for every congested edge. As a concrete example of this strategy consider the simultaneous multicast instance given in Figure 2b. We have the instance as in Figure 2a but now instead of vertex u, we have four vertices, one for each possible guess of which pair of elements in $\{S, T\} \times \{U, V\}$ are delayed at (r_1, v) and (r_2, v). Now notice that for any fixed simultaneous multicast schedule for this instance we know that after one round only one of S and T's messages will cross (r_1, v) and only one of U and V's message will cross (r_2, v). Without loss of generality suppose S and U do not cross (r_1, v) and (r_2, v) respectively in the first round. We then know that one of the edges (v, u') corresponding to one of our guesses – in this case the edge used by S and U – is such that the trees which use this edge will not deliver the their messages to v until two rounds have passed. Similarly, we know that at most one of S and U's messages arrive at u' by the third round – without loss of generality U's message. Thus, S will not successfully deliver its message to all leaves until at least four rounds have passed, despite the fact that all leaves of S are only two hops from S's root. More generally, if we repeated this construction with a larger congestion C we would have that some multicast tree requires at least $2C$ rounds to deliver its message to all leaves, despite the fact that $C + D = C + 2$.

Our lower bound construction will recursively stack trees like those in Figure 2b to guess which multicast trees a schedule chooses to delay and accumulate a larger and larger delay by combining together these delayed trees. We will guarantee that some sub-graph is always correct in its guesses. We will also make use of the observation that if C trees all use a single edge e then by Markov's inequality at least $\frac{C}{2}$ of these trees will require $\frac{C}{2}$ rounds until their message crosses e to reduce the amount of guessing we must do; this will allow us to expand the possible values of C and D we can use when constructing our lower bound graph which will aid in the proof of Theorem 1.3. We elaborate on our $\Omega(CD)$ construction in Section 4 and then extend it in Section 6 to show that additive $\Omega(\log n)$ is necessary for length $O(C + D)$ schedules.

3.2 Existence of $O(C + D + \log^2 n)$ Simultaneous Multicast Schedules

The main intuition underlying our $O(C+D+\log^2 n)$-length simultaneous multicast schedules is that every instance of multicast can be reduced to a series of unicast instances and, as Leighton et al. [30] showed, unicast instances admit schedules of length linear in their congestion and dilation. Our goal then is to gracefully reduce a simultaneous multicast to a series of simultaneous unicasts.

Here, we discuss two natural approaches for such a reduction, argue that they fail and extract intuition for our upper bound from this failure. In the first approach, for each multicast tree T_i we define $|L_i|$ unicast instances, where for each leaf $l \in L_i$ we have a unicast instance on the root-to-leaf path from r_i to l. While this simultaneous unicast instance has dilation $D' = D$, it also has congestion potentially as high as $C' = \Omega(n)$: unicasts corresponding to the same tree are run independently, and each edge in T_i is contained in every root-to-leaf unicast path. Relying on the existence of schedules of length $O(C' + D')$ guaranteed by [30], then, could yield schedules of length as bad as $\Omega(D + n)$. In the second approach, we define a separate unicast instance for each edge in each T_i. We then run a simultaneous unicast schedule for all edges from roots of multicast trees to their children, then from roots' children to their children, and so on and so forth. Here we have at least obtained a sequence of simultaneous unicast instances with lower dilation – $D' = 1$ – and congestion no larger than what we started with – $C' \leq C$. [30] guarantees the existence of schedules of length $O(C' + D')$ for each such simultaneous unicast instance. Unfortunately, we must concatenate together the schedules of D such simultaneous unicast instances to solve the simultaneous multicast instance, which would yield schedules of length $\Omega(D(C' + D')) = \Omega(CD)$; i.e., no better than the trivial schedule.

Thus, the challenge in reducing simultaneous multicast to simultaneous unicast is finding a suitable way of balancing between these two approaches. In the first reduction, we were able to solve a single simultaneous unicast problem with dilation D but one whose congestion was much larger than the congestion of the simultaneous multicast problem with which we started. In the second extreme, we were able to solve simultaneous unicast instances with dilation and congestion only 1 and C but we had to solve many such problems.

Our goal, then, is to find a way of reducing simultaneous multicast to simultaneous unicast in a way that keeps the dilation and congestion of the resulting simultaneous unicast instances small but does not require solving too many simultaneous unicasts. We strike such a balance by computing what we call a $(\log n, \log n)$-*short path decomposition* of each multicast tree. This decomposition is based on subdividing paths in the heavy path decompositions of [42]. By using such a decomposition on each multicast tree along with random delays determining when to schedule each path in the decomposition, we obtain a sequence of $\frac{C}{\log n} + \frac{D}{\log n} + \log n$ many simultaneous unicast instance whose congestion C' and dilation

D' are both at most $O(\log n)$ with high probability. Relying on the $O(C' + D')$ schedules guaranteed by [30] for these simultaneous unicast instances, we find that every simultaneous multicast instance admits a schedules of length $O(C + D + \log^2 n)$. We elaborate on this in Section 5. We also provide centralized and distributed algorithms for the computation of these schedules in Section 7.

4 $\Omega(CD)$ Lower Bound

This section is dedicated to the proof of our $\Omega(CD)$ lower bound. We begin this section by providing the family of instances we use to show this lower bound. We proceed to show how this family requires $\Omega(CD)$ rounds, showing that $O(C+D)$ simultaneous multicast schedules are generally impossible and that the trivial $O(CD)$ schedule is the best simultaneous multicast schedule without a dependence on n. Specifically, we prove the following.

▶ **Theorem 1.1.** *For any $C, D, n \in \mathbb{Z}_+$ such that $C2^{D+1} \leq \log n$ there exists a simultaneous multicast instance on an n-node graph with congestion C and dilation D whose optimal schedule requires at least $\frac{CD}{2}$ rounds.*

4.1 Multicast Instance

We will describe how our instance is constructed in a top-down manner. For the remainder of this section we fix a desired congestion C and dilation D. We will recursively construct a graph in which every edge receives C "labels" where the graph induced by each label is a distinct multicast tree.[1] As each label corresponds to a multicast tree, each label will also have a root corresponding to it which will be the root of the corresponding multicast tree. Ultimately, our instance corresponding to a fixed C and D will contain $C \cdot 2^{D-1}$ multicast trees and so throughout this section we will imagine we have $C \cdot 2^{D-1}$ distinct labels. Throughout this section we will also let capital letters correspond to labels; e.g. $\{S, T, U, V, W, X, Y, Z\}$ is a set of 8 labels. Before moving onto specific details, we refer the reader to Figure 5 for a visual preview of our lower bound construction.

4.1.1 Interleaving Labels

In order to rigorously define what it means to guess which multicast trees are delayed, we introduce the idea of "interleaving" the sets of labels corresponding to our multicast trees.

Given sets S_1 and S_2, each consisting of C labels, we let the interleaving of S_1 and S_2 be $I(S_1, S_2) := \{S_1' \cup S_2' : S_i' \subseteq S_i, |S_i'| = C/2\}$ be all subsets which take $C/2$ labels from S_1 and $C/2$ labels from S_2. For example, if $C = 2$ and $S_1 = \{S, T\}$ and $S_2 = \{U, V\}$ then $I(S_1, S_2) = \{\{S, U\}, \{S, V\}, \{T, U\}, \{T, V\}\}$. S_1 and S_2 will correspond to two adjacent edges, each in a disjoint set of C multicast trees each and so $I(S_1, S_2)$ will correspond to all ways of guessing which C trees, taking $C/2$ trees from one edge and $C/2$ trees from the other edge, are delayed among the $2C$ multicast trees which use one of the two edges.

Let $\mathcal{S} = (S_i)_{i=1}^{2^{D-1}}$ be a tuple partitioning our $C \cdot 2^{D-1}$ distinct labels into sets of size C. That is, each S_i is a set (with associated index i) containing C distinct labels and $S_i \cap S_j = \emptyset$ for $i \neq j$. We call two sets in $\mathcal{S}$ adjacent if the index of one is $2i - 1$ and the index of the other is $2i$ for some $i \in \mathbb{Z}_{\geq 1}$. Finally, we let

$$I(\mathcal{S}) := \bigtimes_{i=1}^{|\mathcal{S}|/2} I(S_{2i-1}, S_{2i})$$

[1] The graph induced by a label χ on graph G is the subgraph of edges from G labeled χ.

be all possible interleavings of adjacent sets in $\mathcal{S}$ where $\bigtimes$ denotes an $|S|/2$-wise Cartesian product. This tuple $\mathcal{S}$ will correspond to all edges of our construction at height D while a pair of adjacent sets S_{2i-1} and S_{2i} will correspond to two adjacent edges, each in disjoint sets of C multicast trees; thus $\mathcal{I}(\mathcal{S})$ will correspond to all possible ways to guess how, among all pairs of adjacent edges at height D, which C trees, taking $C/2$ trees from one edge and $C/2$ trees from the other edge, are delayed in each pair.

We give a concrete example of our notation where $C = 2$ and $D = 3$. Let $\mathcal{S} = (S_1, S_2, S_3, S_4) = (\{S,T\}, \{U,V\}, \{W,X\}, \{Y,Z\})$. Then $I(\mathcal{S})$ corresponds to all ways of combining S_1 and S_2 by taking one element from each and all ways of combining S_3 and S_4 by taking one element from each. In particular, we have

$$\begin{aligned} I(\mathcal{S}) &= I(S_1, S_2) \times I(S_3, S_4) \\ &= \big\{\{S,U\}, \{S,V\}, \{T,U\}, \{T,V\}\big\} \times \big\{\{W,Y\}, \{W,Z\}, \{X,Y\}, \{X,Z\}\big\}, \end{aligned}$$

Notice that each $\mathcal{S}' \in I(\mathcal{S})$ is a tuple of sets, each of C labels, and the number of distinct labels across all sets in $\mathcal{S}'$ is exactly half of the number of labels across all sets in $\mathcal{S}$. Each $\mathcal{S}' \in I(\mathcal{S})$ will correspond to a single recursive call in our construction.

4.1.2 Our Instance

With the above notation in hand, we now describe how we recursively construct our multicast instance for a fixed C and D. Let $\mathcal{S} = (S_i)_{i=1}^{2^{D-1}}$ be an arbitrary partition of our $C \cdot 2^{D-1}$ distinct labels into sets of size C as above. Our recursion will be on D; that is, we will recursively construct several instances of simultaneous multicast with dilation $D-1$ and congestion C and then combine together these instances into a single instance with congestion C and dilation D (in fact, every edge will have congestion exactly C and every tree will have depth exactly D). We let $M_{\mathcal{S}}$ be the simultaneous multicast instance we construct from $\mathcal{S}$ and let $G_{\mathcal{S}}$ be its corresponding graph. As can easily be seen by induction on our recursive depth, each root will inductively only be incident on a single edge and so we let $\chi(r)$ be the set of labels of the one edge incident to root r.

- **Base case ($D = 1$):** In this case we have $\mathcal{S} = (S_1)$. We let $M_{\mathcal{S}}$ consist of one edge (r, v) which receives every label in S_1 and let r be the root of every label/tree.
- **Inductive case ($D > 1$):** We construct $M_{\mathcal{S}}$ in three steps. See Figures 3, 4 and 5 for an illustration of the results of steps one, two and three respectively; we defer the former two to the appendix. In the example in these figures $C = 2$, $D = 3$ and $\mathcal{S} = (S_1, S_2, S_3, S_4) = (\{S,T\}, \{U,V\}, \{W,X\}, \{Y,Z\})$; roots of multicast trees are indicated by black nodes and edges are colored according to their label/tree.
  1. First, for each pair of adjacent sets S_{2i-1} and S_{2i} in $\mathcal{S}$ we introduce vertices r_{2i-1}, r_{2i} and v_i and edges $e_{2i-1} = (r_{2i-1}, v_i)$ and $e_{2i} = (r_{2i}, v_i)$. We let r_j be the root of all trees with a label in S_j and e_j receive all labels in S_j for every j (Figure 3).
  2. Next, we "guess" which trees will be delayed on the e_js. In particular, we add to our graph the disjoint union of $G_{\mathcal{S}'}$ for each $\mathcal{S}' \in \mathcal{I}(\mathcal{S})$; each of the new connected components in our graph at this point corresponds to some instance $M_{\mathcal{S}'}$; each edge inherits the C labels it received in $M_{\mathcal{S}'}$ (Figure 4).
  3. Finally, we connect up our guesses to the corresponding parents. In particular, for each vertex r that was a root in $M'_{\mathcal{S}}$ if $\chi(r) \in I(S_{2i-1}, S_{2i})$, we identify r and v_i as the same vertex (Figure 5).

It is easy to verify by induction on our recursive depth that, indeed, each label and its root induce a tree in the returned graph and so $M_{\mathcal{S}}$ is an instance of simultaneous multicast.

Figure 3 The result of step one of our lower bound construction. Notice that we have an edge for each set S_i and each pair of adjacent S_i are joined together at a vertex. We outline in red and green v_1 and v_2 respectively. Left-to-right black nodes are r_1, r_2, r_3 and r_4.

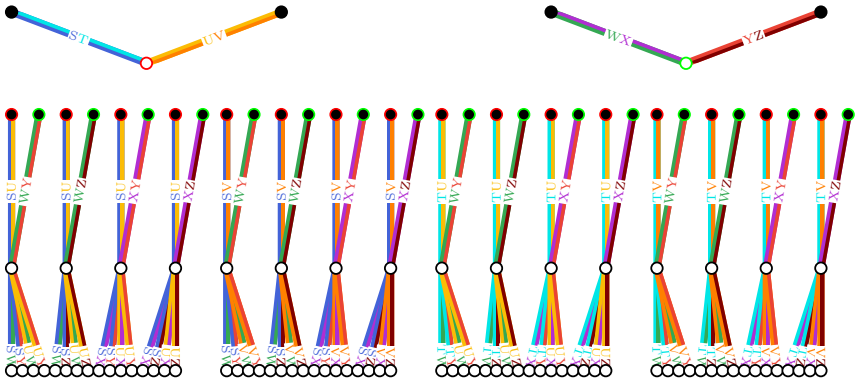


Figure 4 The result of step two of our construction. Notice that we now have a new connected component for each $\mathcal{S}' \in I(\mathcal{S})$, each of which corresponds to a guess for which trees will be delayed at v_1 and v_2. We outline in red and green the vertices which in step three we identify with v_1 and v_2 respectively.

▶ **Lemma 4.1.** *Let $\mathcal{S} = (S_i)_i^{2^{D-1}}$ be a partition of $C \cdot 2^{D-1}$ distinct labels as above. Then each label in $\bigcup_i S_i$ induces a rooted tree in $G_{\mathcal{S}}$.*

Proof. We prove this by induction on D. Let T_χ be the graph induced by label χ and let r_χ be χ's root. We will prove the slightly stronger claim that T_χ is a tree containing r_χ and for any two labels $\chi \neq \chi'$ we have $r_\chi \in T_{\chi'}$ only if $r_\chi = r_{\chi'}$. Call this latter property ⊛.

As a base case suppose that $D = 1$. We then have that $\mathcal{S} = (S_1)$ is a single set of labels and so by definition of $M_{\mathcal{S}}$ we have that our graph will consist of a single edge (r, v) where r is the root for every label and (r, v) is labeled by every label in S_1. Since each label induces the edge (r, v) where r is the root for this label, clearly every label induces a rooted tree containing its root. Moreover, ⊛ holds since every label has the same root.

As an inductive hypothesis suppose that for any $D' < D$ and $\mathcal{S}'$ of size $C \cdot 2^{D'-1}$, we have that every label in $M_{\mathcal{S}'}$ induces a tree containing the label's root and all induced trees in $M_{\mathcal{S}'}$ satisfy ⊛. Thus, our inductive hypothesis tells us that every label in $M_{\mathcal{S}'}$ for $\mathcal{S}' \in I(\mathcal{S})$ induces a tree containing the label's root where all labels satisfy ⊛.

We will first verify that each T_χ is a tree containing r_χ. Clearly, since the edge leaving r_χ is labeled χ, we have that $r_\chi \in T\chi$. Let $\mathcal{T}'_\chi$ be all trees induced by label χ in $M'_{\mathcal{S}}$ for $\mathcal{S}' \in I(\mathcal{S})$. $M_{\mathcal{S}}$ is created by taking the disjoint union of $G_{\mathcal{S}'}$ for $\mathcal{S}' \in I(\mathcal{S})$, identifying several roots of $M_{\mathcal{S}'}$ trees and then adding new roots and edges. Notice that for any χ this identifying of nodes as the same nodes does not cause any cycles in a T_χ since by ⊛ we identify exactly one node from each tree in $\mathcal{T}'_\chi$ with another node. Next, to see that ⊛ still holds notice that if a node is designated a root in $M_{\mathcal{S}}$ then it is incident to a single edge and is a root for every label this edge was assigned. ◀

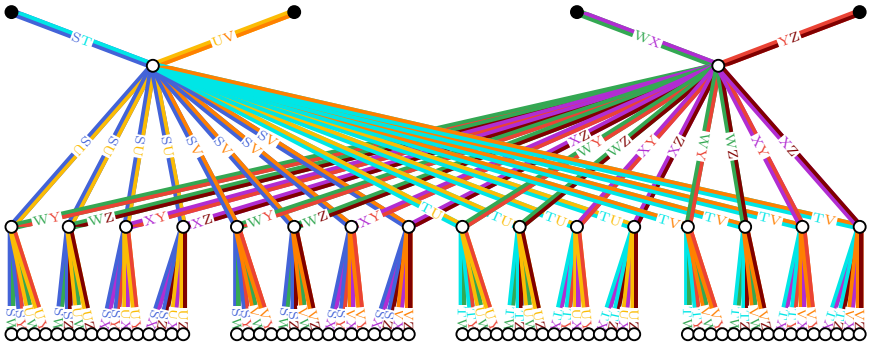

Figure 5 Our construction (i.e. the result of step three) for $\mathcal{S} = (S_1, S_2, S_3, S_4) = (\{S,T\}, \{U,V\}, \{W,X\}, \{Y,Z\})$, $C = 2$ and $D = 3$. Notice that we have modified the graph in Figure 4 by adding one edge for each S_{2i-1} (resp. S_{2i}) colored by the labels in S_{2i-1} (resp. S_{2i}) going from root r_{2i-1} (resp. r_{2i}) to v_i.

4.2 Proof of $\Omega(CD)$ Lower Bound

An induction on D demonstrates that our simultaneous multicast instance has the appropriate congestion and dilation.

▶ **Lemma 4.2.** *$M_{\mathcal{S}}$ has congestion C and dilation D.*

Proof. As each edge receives C labels in our construction, each of which corresponds to a multicast tree, clearly the congestion is C. For the dilation, we prove by induction on D. As a base case notice that if D is 1 then $|\mathcal{S}|$ is 1 and so G consists of a single edge used by all all trees, giving a dilation of 1. Suppose that for $D' < D$ we have that the dilation of $M_{\mathcal{S}'}$ is D' where $|\mathcal{S}'| = C \cdot 2^{D-1}$. The claim follows by simply noticing that each tree in $M_{\mathcal{S}}$ extends the root of every tree in $M_{\mathcal{S}'}$ by 1 edge. ◀

Another simple induction on D and standard approximations allows us to bound the number of nodes in our lower bound graph.

▶ **Lemma 4.3.** $|V(G_{\mathcal{S}})| \leq 2^{C(2^{D+1})}$.

Proof. Clearly, to upper bound the total number of vertices it suffices to upper bound the total number of edges introduced. Thus, we will count the number of edges introduced at each level of our recursion.

Fix C. Define $m_D := |E(G_{\mathcal{S}})|$. We claim by induction on D that $m_D \leq 2^{C(2^D)+D}$. As a base case notice that when $D = 1$ we have $m_1 = 1 \leq 2^{C(2^D)+D}$. For our inductive step consider $G_{\mathcal{S}}$. $G_{\mathcal{S}}$ is constructed by introducing 2^{D-1} edges and unioning together $G_{\mathcal{S}'}$ for $\mathcal{S}' \in I(\mathcal{S})$ of which there are $\binom{C}{C/2}^{2^{D-1}}$, each of which have m_{D-1} edges. Thus, we have

$$
\begin{aligned}
m_D &= 2^{D-1} + \binom{C}{C/2}^{2^{D-1}} m_{D-1} \\
&\leq 2^{D-1} + 2^{C2^{D-1}} 2^{C2^{D-1}+D-1} && \left(\text{By } \binom{C}{C/2} \leq 2^C \text{ and inductive hypothesis}\right) \\
&\leq 2^{D-1} + 2^{C2^D+D-1} \\
&\leq 2^{C2^D+D} && \left(\text{By } 2^{D-1} \leq 2^{C2^D+D-1}\right)
\end{aligned}
$$

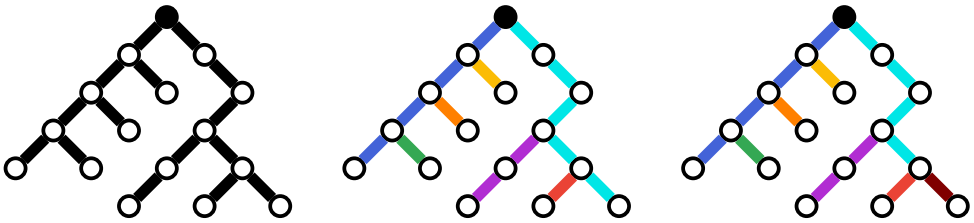
Finally, we conclude the (somewhat loose) bound of $2^{C2^{D+1}}$ on the number of vertices in our graph since $D \leq C \cdot 2^D$. ◀

Having established the basic properties of our instance, we now argue that (asymptotically) the best one can hope for on our instance is the trivial $O(CD)$-round schedule. As discussed in Section 3.1, we will prove this by arguing that for any fixed schedule, some sub-graph in G was correct in "guessing" which multicast trees were slowed down. In particular, we will argue that for any fixed schedule there is some smaller instance of simultaneous multicast which this schedule must solve as a sub-problem which takes at least $\frac{C(D-1)}{2}$ rounds but which the schedule does not start making progress towards solving until at least $\frac{C}{2}$ rounds have passed.

▶ **Lemma 4.4.** *The optimal schedule on $M_{\mathcal{S}}$ is of length at least $\frac{CD}{2}$.*

Proof. Fix an arbitrary simultaneous multicast schedule. We will prove by induction on D that $M_{\mathcal{S}}$ requires at least $\frac{CD}{2}$ rounds. The base case of $D = 1$ is trivial, as in this case $M_{\mathcal{S}}$ is a single edge with congestion C and so clearly requires at least $C \geq \frac{CD}{2}$ rounds.

For the inductive step, $D > 1$, suppose that for any partition $\mathcal{S}'$ of $C \cdot 2^{D-1}$ distinct labels into sets of size C, we have that $M_{\mathcal{S}'}$ requires at least $\frac{C(D-1)}{2}$ rounds. By definition of $M_{\mathcal{S}}$, any schedule which solves $M_{\mathcal{S}}$ can be projected in the natural way onto $M_{\mathcal{S}'}$ as a schedule which solves $M_{\mathcal{S}'}$ for any $\mathcal{S}' \in I(\mathcal{S})$. For example, any schedule which solves the instance in Figure 5 induces a schedule which when projected onto Figure 4 solves $M_{\mathcal{S}'}$ for each of the recursively constructed $M_{\mathcal{S}'}$. Even stronger, notice that $M_{\mathcal{S}}$ is created by combining the union of all $M_{\mathcal{S}'}$ for $\mathcal{S}' \in I(\mathcal{S})$ in such a way that any schedule which solves $M_{\mathcal{S}}$ must also send all messages from roots of trees in $M_{\mathcal{S}}$ to corresponding roots of trees in $M_{\mathcal{S}'}$ and solve $M_{\mathcal{S}'}$. That is, let r' be an arbitrary root for $M_{\mathcal{S}'}$ and let $\chi(r')$ be the labels associated with the one edge for root r' in $M_{\mathcal{S}'}$. Then, if we identify r' with v_i when constructing $M_{\mathcal{S}}$ then a schedule for $M_{\mathcal{S}}$ must both send r' the C messages of $\chi(r')$ from r_{2i-1} and r_{2i} and solve $M_{\mathcal{S}'}$. Thus, clearly the time our schedule takes is at least the time it takes to send one message in $\chi(r')$ to r' from r_{2i-1} and r_{2i} for some root in $M_{\mathcal{S}'}$ plus the time it takes to solve $M_{\mathcal{S}'}$. For example, if we let $\mathcal{S}' = (\{S, U\}, \{W, Y\})$ then any schedule which solves Figure 5 solves $M_{\mathcal{S}'}$ but before doing so must clearly send at least one message of $\{S, U\}$ to v_1 or at least one message $\{W, Y\}$ to v_2.



We now define $\bar{\mathcal{S}}'$ where $\bar{\mathcal{S}}' \in I(\mathcal{S})$ so that $M_{\bar{\mathcal{S}}'}$ is an instance of simultaneous multicast embedded in $M_{\mathcal{S}}$ which our fixed schedule must solve in order to solve $M_{\mathcal{S}}$ but which it does not start start solving until at least $C/2$ rounds have passed. In particular, consider what our fixed schedule does in the first $C/2$ rounds. As C messages must cross each edge e_j and only one such message can cross per rounds, there are some $C/2$ multicast trees whose message cannot cross e_j before $C/2$ rounds have passed; let S'_j be these "slow" trees for edge e_j and let

$$\bar{\mathcal{S}}' := (S'_{2i-1} \cup S'_{2i})_{i=1}^{2^{D-2}}$$

be a partition of the labels corresponding to these slow edges into sets of size C.

The tuple $\bar{S}'$ belongs to $I(\mathcal{S})$ and so, as discussed above, the fixed schedule must first send at least one message to a root in $M_{\bar{S}'}$ and then solve $M_{\bar{S}'}$. By definition of $\bar{S}'$, no messages arrive at roots of trees in $M_{\bar{S}'}$ until at least $\frac{C}{2}$ rounds have passed. On the other hand, by the inductive hypothesis, the latter sub-instance takes at least $\frac{C(D-1)}{2}$ additional rounds. Thus, the schedule must use at least $\frac{C(D-1)}{2} + \frac{C}{2} = \frac{CD}{2}$ rounds. ◀

Combining Lemmas 4.2, Lemma 4.3 and 4.4 and noting that we can always add dummy nodes to increase the number of vertices in our graph to a desired n immediately yields Theorem 1.1.

(a) Multicast tree T_i. **(b)** Heavy-light decomposition. **(c)** Cut heavy paths.

Figure 6 Our decomposition for multicast tree T_i. Each heavy path in Figure 6b and short path in Figure 6c drawn in different colors. Notice the far right path is cut into two short paths since its length is $5 > \log_2 n = 4$.

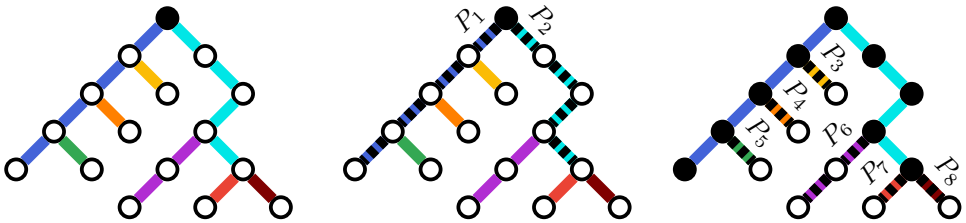
5 Existence of $O(C + D + \log^2 n)$-Length Schedules

Here we demonstrate that length $O(C + D + \log^2 n)$ simultaneous multicast schedules always exist. For this result we rely on heavy path decompositions, introduced by Sleator and Tarjan [42].

▶ **Defintion 5.1** (Heavy path decomposition [42]). *A* heavy path decomposition *of a rooted tree T is obtained as follows. First, each non-leaf node selects one* heavy *edge, which is an edge to a child with the greatest number of descendants (breaking ties arbitrarily). Other edges are termed* light. *We consider inclusion-wise maximal paths consisting of heavy edges, and for each highest node v of such a path p, we add to the path p the edge from v to its parent (if any). The obtained paths form the heavy path decomposition.*

It is easy to see that this is indeed a decomposition of the tree; that is, that each edge belongs to exactly one path in the heavy path decomposition. Moreover, each root-to-leaf path intersects at most $\log_2 n$ heavy paths, as each such path can have at most $\log_2 n$ light edges because the number of nodes in a subtree decreases by at least a factor of two every time one traverses down a light edge. This will allow us to decompose the trees into "short paths" such that each root-to-leaf path intersects few short paths. Specifically, we define a refinement of this decomposition in a top-down fashion, by breaking up each heavy path into short paths of length at most $\log_2 n$; that is, starting from the top of a heavy path of length l, we cut it into $\lceil l/\log n \rceil$ short paths. See Figure 6. Both the decomposition and its refinement exist, and are even computable deterministically in linear time.

As each root-to-leaf path intersects at most $\log_2 n$ heavy paths, this refined decomposition has each root-to-leaf path intersect at most $\frac{D}{\log_2 n} + \log_2 n$ short paths. We will refer to such a decomposition as a $(\log n, \log n)$-short (path) decomposition. We use this particular name as we generalize this notion further in Section 7 and the full version to (l, k)-decompositions for any integers k and l. This refined path decomposition together with some additional random delays will allow us to reduce the task of simultaneous multicast to that of $O\big(\frac{C}{\log n} + \frac{D}{\log n} + \log n\big)$ many simultaneous unicast instances with congestion and dilation $O(\log n)$, from which we obtain the following result. We illustrate the schedules in this result in Figure 7.



▶ **Theorem 1.2.** *Each simultaneous multicast instance with congestion C and dilation D in an n-node network admits a schedule of length at most $O(C + D + \log^2 n)$.*

Proof. We prove this result by means of the probabilistic method. First, we consider a $(\log n, \log n)$ decomposition of each multicast tree. For each short path p in the $(\log n, \log n)$-decomposition of a tree, we say p is at *level* j if there are exactly $j - 1$ other short paths

between p's root and the tree's root. That is, if we were to schedule a particular tree by forwarding along all paths of level $j = 1, 2, \ldots$ during $R = O(\log n)$ rounds, the path of level j would be scheduled in rounds $((j-1) \cdot R, j \cdot R]$, which we refer to as the j-th *frame*. Our goal will be to schedule the sets of short paths with limited congestion in parallel, using simultaneous unicast schedules guaranteed by [30].

In order to break up simultaneous multicast to multiple simultaneous unicasts, we shift the levels of each tree T_i by a random offset X_{T_i} chosen uniformly in $[C/\log n]$. Now a short path of level j in tree T_i will be scheduled during frame $j + X_{T_i}$. Since each edge e has congestion C, the expected number of paths of different trees that use e during any given frame is at most $O(\log n)$. So, by standard Chernoff concentration inequalities, the congestion of each edge during any frame is at most $O(\log n)$ w.h.p. Therefore, applying a union bound over all edges and time frames, we find that w.h.p., all edges have congestion at most $O(\log n)$ for all (shifted) frames $j = 1, 2, \ldots, \frac{C}{\log n} + \frac{D}{\log n} + \log n$ (recall that each root-to-leaf path intersects at most $\frac{D}{\log n} + \log n$ paths of length at most $\log n$). In particular, there exist random delays such that each time frame consists of a simultaneous unicast instance with congestion $C' = O(\log n)$ and dilation $D' = O(\log n)$. Therefore, by [30, 31], there exists a schedule of length $O(C' + D') = O(\log n)$ for these time frames' simultaneous unicasts. Combining these schedules one time frame after another, we obtain a schedule of length

$$\left(\frac{C+D}{\log n} + \log n\right) \cdot O(\log n) = O(C + D + \log^2 n). \qquad \blacktriangleleft$$

(a) Wait for T_i's random delay. **(b)** Run LMR on P_1, P_2. **(c)** Run LMR on $P_3, \ldots, P_8$.

Figure 7 Our multicast schedule on T_i using the decomposition from Figure 6. Nodes with m_i colored in black. Short unicast paths are dashed in black. "LMR" is the schedule given by [30].

The above proof can be made algorithmic, deterministic, and even allows for efficient distributed algorithms. See Section 7 for details.

6 Additive $\Omega(\log n)$ Necessary

In this section we use our $\Omega(CD)$ lower bound (Theorem 1.1) to show that any simultaneous multicast bound of the form $O(C + D) + f(n)$ must have $f(n) = \Omega(\log n)$ (Theorem 1.3). This result demonstrates the near optimality of the length $O(C + D + \log^2 n)$ schedules we gave in the previous section.

▶ **Theorem 1.3.** *Suppose there is a function f such that for any simultaneous multicast instance with congestion C and dilation D, there is a schedule delivering all packets in $O(C + D) + f(n)$ steps. Then $f(n) = \Omega(\log n)$.*

Proof of Theorem 1.3. Assume for the sake of contradiction that every simultaneous multicast instance admitted a schedule of length $\alpha(C+D)+f(n)$ for constant α and $f(n) = o(\log n)$.

Let $D = 4\alpha$ and let $C = \frac{\log n}{2^{4\alpha+1}}$ for n to be fixed later. Consider the simultaneous multicast instance given by $M_{\mathcal{S}}$ on graph $G_{\mathcal{S}}$ as defined in Section 4 whose properties are given by Theorem 1.1. Notice that $C2^{D+1} = \frac{\log n}{2^{4\alpha+1}} 2^{4\alpha+1} = \log n$ and so indeed we may apply Theorem 1.1.

Furthermore, by Theorem 1.1 we have that the optimal schedule of this simultaneous multicast instance with congestion C, dilation D and n nodes has length at least

$$L := \frac{CD}{2} = \frac{\alpha}{2^{4\alpha}} \log n.$$

But, by our assumption for contradiction we have that this instance admits a schedule of length at most

$$U := \alpha(C + D) + f(n) = \frac{\alpha}{2^{4\alpha+1}} \log n + 4\alpha^2 + f(n).$$

We then have a contradiction because $U < L$. In particular for n sufficiently large,

$$U - L = -\frac{\alpha}{2^{4\alpha+1}} \log n + 4\alpha^2 + o(\log n) < 0. \quad \blacktriangleleft$$

7 Algorithmic Results

In this section we present centralized and distributed algorithms for the computation of simultaneous multicast schedules of length $O(C + D + \log^2 n)$, as guaranteed to exist by Theorem 1.2.

7.1 Centralized Algorithm

It is easy to see that the probabilistic method proof in Theorem 1.2 yields a randomized algorithm which succeeds with high probability. Moreover, by standard limited independence methods [41], one can make this algorithm deterministic.

▶ **Theorem 7.1.** *There exists a deterministic, centralized algorithm which, given a simultaneous multicast instance, outputs a schedule of length $O(C + D + \log^2 n)$ in time polynomial in $|\mathcal{T}|$ and n.*

Proof. Let us begin by explaining why the proof of Theorem 1.2 immediately yields a polynomial-time randomized algorithm which succeeds with high probability. Recall that the schedules in Theorem 1.2 were produced by taking a heavy path decomposition of each T_i, delaying each T_i by $X_{T_i} \sim [C/\log n]$ and then concatenating together unicast schedules given by [30]. As noted in Section 5, a heavy path decomposition can be computed deterministically in polynomial (in fact, linear) time. Clearly, drawing a random delay from $[C/\log n]$ for each T_i is also doable in polynomial time by a randomized algorithm. Lastly, by [31], the schedules of [30] can be computed deterministically in polynomial time. By Theorem 1.2 the resulting schedule is of the appropriate length.

Let us now explain how this algorithm can be made deterministic. Let $n' = n + |\mathcal{T}|$. The only randomization used in the above algorithm is the random delays drawn from $[C/\log n]$. As with most proofs that show concentration by Chernoff bounds, it is easy to see that each X_{T_i} need only be $\frac{1}{\text{poly}n'}$-approximate, $O(\log n')$-wise independent for the above algorithm to succeed with high probability in n'. (For more background on limited independence, see [41].) Recalling that one can generate polynomially-many binary $\frac{1}{\text{poly}n'}$-approximate $O(\log n')$-wise independent random variables with only $O(\log n')$ random bits, our deterministic algorithm can simply brute force over all possible assignments to these $O(\log n')$ bits, and check if each resulting schedule is of the appropriate length. The result is a deterministic algorithm which is polynomial-time in $|\mathcal{T}|$ and n and outputs a schedule of the stated length. $\blacktriangleleft$

7.2 Distributed Algorithm

In this section we outline our distributed simultaneous multicast algorithm in the CONGEST model. Please see the full version for additional details.

In the classic CONGEST model of distributed communication [37], a network is modeled as an undirected simple n-node graph $G = (V, E)$. Communication is conducted over discrete, synchronous rounds. During each round each node can send an $O(\log n)$-bit message along each of its incident edges. Every node has an arbitrary and unique ID of $O(\log n)$ bits, first only known to itself (this is the KT_0 model of Awerbuch et al. [3]).

In the CONGEST model in a simultaneous multicast instance, each node initially knows a unique ID associated with each tree T_i to which it belongs, as well as which of its incident edges occur in which trees. We think of m_i in this setting as being an $O(\log n)$-bit message, which is therefore transmittable along an edge in a single round. As in the centralized version of the problem, initially only r_i knows m_i.

In the full version of this work we show CONGEST algorithms with the following guarantees exists.

▶ **Theorem 7.2.** *For any constant $\epsilon > 0$, there exists a CONGEST algorithm which given access to shared randomness solves simultaneous multicast in time*

$$O\left((C+D)\cdot\left(1+\frac{\log\min\{C,D\}}{\log\log n}\right)+\log^{2+\epsilon} n\right).$$

with high probability. If nodes also know their depth in each tree, then there exists another CONGEST algorithm which solves simultaneous multicast in $O(C + D + \log^{2+\epsilon})$ time.

As noted in the introduction, simultaneous multicast has proven to be a crucial subroutine in many recent algorithms in CONGEST for fundamental problems like MST, shortest path and approximate min cut. Therefore, improving simultaneous multicast in the CONGEST model is an important step towards obtaining better algorithms for many of these fundamental problems. Furthermore, in the above applications of simultaneous multicast the parameters C and D are equal to the diameter of the graph up to polylogarithmic in n terms, provided the input graph has certain structure such as being planar [14, 18, 16, 19]. If C and D are sufficiently large polylogarithmic terms, i.e., $\max\{C, D\} = \Omega(\log^{2+\epsilon} n)$, then, assuming nodes know their heights, our distributed algorithm gives an optimal $O(C + D)$ time distributed algorithm. Thus, we view our distributed algorithm as an important step towards obtaining better algorithms for many distributed problems, including MST, shortest path and approximate minimum cut.

Before proceeding, let us discuss the preprocessing assumptions in Theorem 7.2. Our distributed algorithms assume nodes have access to shared randomness or to their height in each of their incident multicast trees. Both of these assumptions can be dispensed with provided nodes are allowed to do some preprocessing: see [11] for how to share randomness and note that nodes can compute their heights by a single simultaneous multicast computation where we could, for example, use the aforementioned $O(C + D \log n)$ length schedules. If this preprocessing is performed only once and many simultaneous multicasts are performed, the preprocessing step's cost amortizes away. Thus, provided nodes share randomness we have that after a preprocessing step equivalent to the current state of the art distributed simultaneous multicast algorithm, subsequent simultaneous multicasts can be performed in time $O(C + D + \log^{2+\epsilon} n)$, which as discussed earlier, is essentially as close as one can get to a bound of $O(C + D)$.

7.2.1 Intuition and Overview

Here we provide an intuition for and an overview of our distributed algorithms. As mentioned earlier, Ostrovsky and Rabani [34] provided a distributed algorithm for simultaneous unicast using $O(C+D+\log^{1+\epsilon} n)$ rounds. Since our centralized algorithm has shown that simultaneous multicast can be reduced to simultaneous unicast by way of a $(\log n, \log n)$-short decomposition (i.e. a heavy path decomposition), the focus of our distributed algorithm is the efficient distributed computation of a $(\log n, \log n)$-short decomposition.

The challenge of computing such a decomposition in a distributed manner is that it seems as hard as solving simultaneous multicast. In particular, computing a heavy path decomposition requires that every node in a T_i aggregate information from all of its children. It is not hard to see that performing such a "convergecast" at every node can be seen as performing a multicast on every T_i in reverse. Even worse, the message size sent by nodes to their parents in such a convergecast to compute a heavy path decomposition must consist of $\log_2 n$ bits to count the size of their sub-tree; i.e. sending just one such message fully uses the bandwidth of a CONGEST link in one round. Thus, it seems that if we want to solve simultaneous multicast by using a $(\log n, \log n)$-short decomposition, then we must circularly solve a simultaneous convergecast – i.e. simultaneous multicast in reverse – in which large messages must be sent.

However, we show that, in fact, one can compute what is essentially a $(\log n, \log n)$-short decomposition more efficiently than one can solve simultaneous multicast. In particular, we show how to efficiently compute what we call a $(\log^{1+\epsilon} n, \log n)$-short decomposition. We formally define these decompositions in the full version of this work but for now note that they are a simple relaxation of heavy path decompositions. We demonstrate that a $(\log^{1+\epsilon} n, \log n)$-short decomposition for every T_i can be efficiently computed in a distributed fashion by using what we call a rank-decomposition – defined in the full version. Computing a rank-decomposition will require nodes to send exponentially fewer bits to their parents than computing a heavy path decomposition. That is, it will require that each node send only $O(\log \log n)$ bits to its parent rather than the $O(\log n)$ bits needed to encode the size of a subtree by requiring nodes to send information about their "rank" rather than their subtree size. By exploiting this exponential decrease in the total number of bits that must be passed, we are able to efficiently pack rank information into messages and compute a $(\log^{1+\epsilon} n, \log n)$-short decomposition. Specifically, by using random delays each edge transmits a message for $O(\log n/\log \log n)$ trees to which it belongs with high probability. Thus, we are able to to transmit the $O(\log \log n)$ bits of $O(\log n/\log \log n)$ trees for each edge using the $O(\log n)$ bits of one round of CONGEST. This becomes more challenging if an edge does not know which trees' messages are being sent which is what incurs the $\log(\min\{C, D\})/\log \log n)$ factor. After computing the above decomposition in this way we are then able to translate our centralized algorithm to the distributed setting by making use of the distributed simultaneous unicast algorithms of [34].

8 Future Directions

We conclude our paper with future directions for work in the scheduling of simultaneous multicasts. Of course, one can try and tighten the polylogarithmic additive terms in our results. More interestingly, one could extend the simultaneous multicast setting in ways similar to how the simultaneous unicast scheduling work of Leighton et al. [30, 31] has been extended.

We give two notable examples. First, one could study what sort of approximation algorithms are possible if one is permitted to choose the trees over which multicast is performed as was done in the simultaneous unicast setting [43, 5, 28]. Roughly speaking, this corresponds to a depth-bounded version of the multicast congestion problem [45, 7, 26]. We point out that choices of trees with optimal congestion + dilation (or nearly-optimal, up to constant multiplicative and additive polylogarithmic terms) combined with our algorithm to output length $O(C + D + \log^2 n)$-length schedules would imply near-optimal simultaneous multicasts for this setting. Second, we note that our schedules have logarithmic-sized edge queues. That is, messages may have to wait up to $\Theta(\log n)$ rounds before being sent over an edge. This is not due to our use of the schedules of Leighton et al. [30], whose queue sizes are constant, but rather due to $\Theta(\log n)$ messages arriving to a node by the end of simultaneous unicast frames used in our schedules. An interesting open question is whether there exist efficient simultaneous multicast schedules which minimize both time and edges' queue sizes.

Abstract

The smooth heap is a recently introduced self-adjusting heap [Kozma, Saranurak, 2018] similar to the pairing heap [Fredman, Sedgewick, Sleator, Tarjan, 1986]. The smooth heap was obtained as a heap-counterpart of Greedy BST, a binary search tree updating strategy conjectured to be *instance-optimal* [Lucas, 1988], [Munro, 2000]. Several adaptive properties of smooth heaps follow from this connection; moreover, the smooth heap itself has been conjectured to be instance-optimal within a certain class of heaps. Nevertheless, no general analysis of smooth heaps has existed until now, the only previous analysis showing that, when used in *sorting mode* (n insertions followed by n delete-min operations), smooth heaps sort n numbers in $O(n \lg n)$ time.

In this paper we describe a simpler variant of the smooth heap we call the *slim heap*. We give a new, self-contained analysis of smooth heaps and slim heaps in unrestricted operation, obtaining amortized bounds that match the best bounds known for self-adjusting heaps. Previous experimental work has found the pairing heap to dominate other data structures in this class in various settings. Our tests show that smooth heaps and slim heaps are competitive with pairing heaps, outperforming them in some cases, while being comparably easy to implement.

1 Introduction

A heap (priority queue) data structure stores a collection of items, each with an associated real-valued key (priority). Operations include inserting an item, deleting an item with smallest key, decreasing the key of an item, or melding (merging) two heaps. Heaps are among the most basic and well-studied structures in computer science, with applications in sorting, event simulation, graph algorithms, and many other settings (see e.g. [2, 17] and the references therein).

Williams' implicit binary heap [27] and its variants remain the simplest, and in many applications, the fastest implementation. Carefully engineered *sequence-based* heaps [22] tend to be even faster in several (although not all) practical scenarios, because of their better use of caching.

To implement efficient *meld* and to obtain theoretically optimal running times for *insert* and *decrease-key*, more sophisticated data structures have been proposed. The Fibonacci heap [10] was the first heap implementation to obtain the asymptotically optimal amortized bounds of $O(\lg n)$ time for *delete-min* and *delete* in a size-n heap, and $O(1)$ time for all other operations. (We denote by lg the base-two logarithm.) A large number of alternative designs that match these bounds have been explored throughout the years, see e.g. [11] and the references therein. Due to their relatively complex implementation, Fibonacci heaps and other theoretically optimal heaps have been found to be slower in practice than simpler heaps with sub-optimal guarantees [17].

Self-adjusting heaps. Is it possible to design data structures that are simple and efficient in practice but also efficient in theory, at least in an amortized sense? Self-adjusting data structures attempt to achieve this goal by allowing a very flexible structure with no (or very little) bookkeeping. They react to user operations with local structural readjustments, attempting to bring the data structure into a more favorable state for future operations. Examples include the *splay tree* [24], a self-adjusting binary search tree, and the *pairing heap* [9], a self-adjusting heap.

A pairing heap is a rooted, ordered tree (the children of each node are ordered) whose nodes are the heap items, arranged in (*min-*)*heap* order: the parent of a node x has key no greater than that of x. Heap order implies that the root has minimum key. A *delete-min* operation deletes the root, thereby making each of its children into a root. These new roots retain the order they had when they were children of the deleted root. The *delete-min* combines the new roots into a single tree by *linking* them two at a time. One link operation combines two adjacent roots, making the one with larger key the new *leftmost* child of the other. In its original variant, the pairing heap combines roots by first linking pairs of adjacent roots (the first and second, the third and fourth, etc.) from left to right, and then linking the remaining roots consecutively from right to left. This variant performs all operations in $O(\lg n)$ amortized time [9]. Although it was originally conjectured that pairing heaps match the theoretical guarantees of Fibonacci-heaps, Fredman [8] and Iacono and Özkan [14] showed that the amortized time of *decrease-key* in pairing heaps is $\Omega(\lg \lg n)$, and that the same lower bound holds for broader classes of self-adjusting heaps.

The exact amortized complexity of the *decrease-key* operation in pairing heaps remains unknown [13, 21, 5][1]. In practice, however, pairing heaps have been found to dominate Fibonacci heaps and other theoretically optimal heaps across a wide range of experimental settings, and for some specific types of workloads (e.g. with a high frequency of *decrease-key* operations) they even compare favorably with implicit heaps [17]. The pairing heap can thus be considered a "robust choice" [23] in a variety of applications.

In addition, pairing heaps and other self-adjusting data structures hold the promise of *adaptivity*, i.e. the ability to take advantage of regularities or biases in the usage pattern, which may give improved performance in specific scenarios. The adaptivity of splay trees has inspired a long line of research and is the subject of the *dynamic optimality conjecture* [24, 18]. Adaptivity in heaps is relatively less studied (see e.g. [16] and references therein).

Smooth heaps and slim heaps. The recently introduced *smooth heap* [16] is a self-adjusting heap with a structure similar to that of the pairing heap. Like pairing heaps, smooth heaps are built of rooted, ordered trees combined by links. The two data structures differ however,

[1] The lack of structure of self-adjusting data structures makes their analysis both difficult and interesting.

both in the order in which they do links, and in the implementation of the linking primitive itself. Smooth heaps use *stable linking*: when linking two adjacent roots, the one with larger key becomes the leftmost – or the *rightmost* – child of the other, depending on the original left-to-right order of siblings.

The smooth heap was obtained from a correspondence between heaps and binary search trees. In sorting mode (n insertions followed by n delete-min operations), the smooth heap has the same asymptotic running time as Greedy BST, a self-adjusting binary search tree strategy[2]. Greedy BST was proposed as a candidate *dynamically optimal* search tree implementation [19, 20, 4]. In its original form, Greedy BST needs information about *future* queries. Remarkably, this requirement can be removed (with a constant factor slowdown) [4]. Nonetheless, Greedy BST should be seen as a theoretical "proof of concept" that is largely impractical, as compared to splay trees, which are simple and widely used in practice. Surprisingly, despite its correspondence to Greedy BST, the smooth heap is simple and easy to implement. In particular, operations do not require knowledge of the future. The pointer structure and low-level complexity of operations in smooth heaps are comparable to those in pairing heaps.

In [16], several bounds were shown for the time of operations on smooth heaps used in sorting mode, by transferring results known for Greedy BST. The correspondence with Greedy BST breaks down when additional operations are supported, or even when *insert* and *delete-min* operations are intermixed. The smooth heap may be a viable general-purpose data structure, but so far it has lacked a complete, self-contained analysis that covers unrestricted operations.

In this paper we provide such an analysis. We begin by describing the implementation of all standard heap operations, some of which were not fully specified in [16]. We also describe and analyze the variant of smooth heaps that uses unstable (classical) linking, which we call the *slim heap*. The bounds we obtain for smooth heaps and slim heaps match the best known bounds for any self-adjusting heap, and differ from those of Fibonacci heaps only in the $O(\lg \lg n)$ bound (versus $O(1)$) for *decrease-key* (see Table 1). Despite the similarities between pairing heaps, smooth heaps, and slim heaps, the analysis of pairing heaps does not directly transfer to smooth heaps or slim heaps, since the behaviours of the data structures differ. Indeed, even minor variants of the standard pairing heap are difficult to analyze, with open questions remaining. See e.g. [5]. On the other hand, our analysis of smooth heaps and slim heaps does use a variant of the potential function used to analyze pairing heaps.

Our $O(\lg \lg n)$ bound for *decrease-key* in smooth heaps and slim heaps matches the lower bounds of Fredman [8] and Iacono and Özkan [14], but our implementation, which is based on Elmasry's [6] implementation for pairing heaps, violates the assumptions of these bounds, so they do not in fact apply to our algorithm. It remains open whether these lower bounds can be extended to encompass an Elmasry-type implementation. A related question is whether there is *any* self-adjusting heap with an $O(\lg \lg n)$ bound for *decrease-key* that satisfies the assumptions of these lower bounds. The *sort heap* [14] satisfies the assumptions of the Iacono-Özkan bound, but its analysis is flawed [15], [12, § 6]. We also give a simple implementation of *decrease-key* in smooth heaps and slim heaps based on the original implementation for pairing heaps. This implementation satisfies the assumptions of both lower bounds.

We complement our theoretical results with a brief experimental study (Section 6). Since the pairing heap was previously found to have good experimental performance and has been extensively compared with other heaps, we limit ourselves to comparing smooth heaps and

[2] The correspondence is subtle: going from the smooth heap to Greedy BST involves *inverting* and *reversing* the permutation that is being sorted.

slim heaps with pairing heaps. Our initial results show that smooth heaps and slim heaps are competitive with pairing heaps, outperforming pairing heaps in some cases, particularly for some structured usage patterns. This aligns with the adaptive properties shown previously in an asymptotic sense for smooth heaps. Our results suggest the smooth heap or slim heap as a drop-in alternative heap in applications where the pairing heap works well.

2 Smooth Heaps and Slim Heaps

In this section, we introduce the smooth heap and its variant, the slim heap, and state our efficiency bounds. Both of these data structures store a collection of nodes, each node having a real-valued key (not necessarily distinct for different nodes). They support the following standard heap operations:

- *make-heap*(h): Create a new, empty heap h.
- *find-min*(h): Return a node of smallest key in heap h, or null if h is empty.
- *insert*(x, h): Insert node x with predefined key into heap h. Node x must be in no other heap.
- *delete-min*(h): Delete from h the node that would be returned by *find-min*(h).
- *meld*(h, h'): Meld node-disjoint heaps h and h'.
- *decrease-key*(x, k, h): Decrease to k the key of node x in heap h, assuming that x is a node in h and k is no larger than the current key of x. (Operation *decrease-key* is given a pointer to node x in heap h, not just its key or some other identifier.)
- *delete*(x, h): Delete node x from heap h, assuming that x is a node in heap h. Again, *delete* is given a pointer to x in h.

Table 1 The best time bounds known for smooth, slim, Fibonacci, and pairing heaps. All bounds are amortized. Smooth heaps are competitive with the best variants of pairing heaps. They fall short of Fibonacci heaps on *decrease-key* (though self-adjusting heaps often perform better in practice [17]). In all cases, *make-heap* and *find-min* take $O(1)$ time, and *delete* takes $O(\lg n)$ time. Strict Fibonacci heaps [3] achieve the same bounds as Fibonacci heaps, but without amortization.

	insert	*delete-min*	*meld*	*decrease-key*
Smooth Heaps (this paper)	$O(1)$	$O(\lg n)$	$O(1)$	$O(\lg \lg n)$
Slim Heaps (this paper)	$O(1)$	$O(\lg n)$	$O(1)$	$O(\lg \lg n)$
Fibonacci Heaps [10]	$O(1)$	$O(\lg n)$	$O(1)$	$O(1)$
Pairing Heaps [9, 25, 13]	$O(1)$	$O(\lg n)$	$O(1)$	$O(\lg n)$
Alternative Analysis (Pettie [21])	$O(4^{\sqrt{\lg \lg n}})$	$O(\lg n)$	$O(4^{\sqrt{\lg \lg n}})$	$O(4^{\sqrt{\lg \lg n}})$
Elmasry Pairing Heaps [6][3]	$O(1)$	$O(\lg n)$	$O(\lg \lg n)$	$O(\lg \lg n)$

2.1 Efficiency

Table 1 states our time bounds for smooth heaps and summarizes known results for some competing heaps. In stating these bounds, we assume that $n \geq 4$, so that $\lg \lg n \geq 1$: if $n < 4$ all operations take $O(1)$ time. We shall prove the following theorem:

[3] Elmasry [6] also claims a *meld* time of $O(1)$ with a *delete-min* time of $O(\lg n + \lg \lg N)$, where N is the number of items in all heaps.

▶ **Theorem 1.** *In a smooth heap or slim heap,* delete-min *and* delete *take* $O(\lg n)$ *amortized time,* decrease-key *takes* $O(\lg \lg n)$ *amortized time, and* make-heap*,* find-min*,* insert*, and* meld *take* $O(1)$ *time, where there are* n *nodes in the heap at the time of operation.*

In some applications, a large number of nodes may be inserted and then never accessed, for example if one inserts many nodes with large keys, and then repeatedly inserts and deletes a few nodes with small keys. For this case, we shall prove the following theorem, which states that nodes that are never deleted do not slow down deletions:

▶ **Theorem 2.** *Operations* delete-min *and* delete *take* $O(\lg t)$ *amortized time, with the other amortized bounds unchanged, where* t *is the number of nodes in the heap at the time of the operation that will be deleted in the future.*

2.2 Data structures and terminology

A smooth heap or slim heap consists of a forest of rooted, ordered trees whose nodes are the nodes of the heap. Each tree is (min-)heap ordered: the key of a non-root node is no less than that of its parent. The roots of the trees are stored in a list, with a root of minimum key, the *min-root*, first. Each node stores a list of its children. For both the root list and the lists of children, we identify the front of the list with "left" and the back of the list with "right", so that nodes early in the list are considered left of nodes later in the list.

The forest is altered by *linking* pairs of *adjacent* nodes in the list of roots or in a list of children. A link makes the node with smaller key (the *winner* of the link) the parent of the node of larger key (the *loser* of the link). If the keys are equal, the node on the right is the winner. The link is a *left link* if the loser is originally left of the winner, a *right link* if the loser is originally right of the winner.

The only difference between smooth and slim heaps is the position of the loser in its list of new siblings after a link. (See Figure 1.) Slim heaps use *one-sided* links: the loser of the link becomes the new leftmost child of the winner. This is the type of linking used in Fibonacci heaps, pairing heaps, and many other similar data structures.

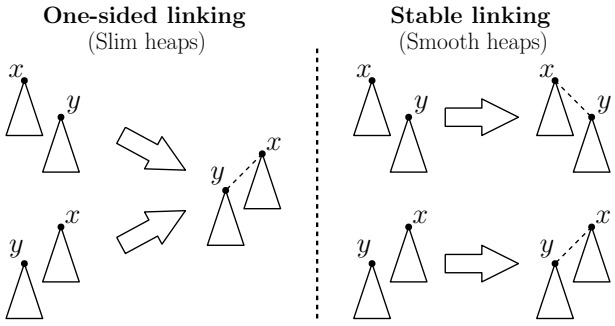

Figure 1 The result of a link of adjacent nodes x and y, where x has the smaller key, using one-sided linking (left) and stable linking (right). A one-sided link always adds the child on the left, whereas a stable link preserves left-to-right order. Slim heaps use one-sided links, smooth heaps use stable links. In both smooth and slim heaps, all links are between adjacent nodes.

Smooth heaps use *stable* links: the loser becomes the new leftmost or rightmost child of the winner, depending on whether the link is a left link or a right link. Stable links maintain the left-to-right order of nodes (although *insert*, *meld*, and *decrease-key* operations perturb it, as we shall see). A child of a node is either a *left* child or a *right* child, depending on whether it was left or right of its parent just before they were linked. In a smooth heap all left children in a list of children precede all right children; in a slim heap, left and right children are in general intermixed.

2.3 Operations

In this subsection we describe the implementation of all the heap operations except *decrease-key* and *delete*; we cover these in Section 4. The description of smooth heaps in [16] did not include a find-min operation, nor was the implementation of *decrease-key* fully specified. In addition to adding these operations, we have changed some details of the original presentation.

As noted in the last subsection, slim heaps differ from smooth heaps only in the linking method. The following descriptions apply to both smooth heaps and slim heaps if links are done using the appropriate linking method, stable for smooth heaps, one-sided for slim heaps.

We store the root list of a heap in a circular singly-linked list, with the min-root first (leftmost). Access is via the min-root. Circular linking supports melding in $O(1)$ time. We store each list of children in a singly-linked list, circular for smooth heaps. In a slim heap, access to a list of children is via the leftmost child. In a smooth heap, access to such a list is via the *rightmost* child; circular linking allows a new child to be added as the leftmost or rightmost in $O(1)$ time. Each node needs two pointers: to its right adjacent root or sibling, and to its leftmost (slim heap) or rightmost (smooth heap) child. To support *delete* and *decrease-key* we shall add a third pointer per node. See Section 4.

- *make-heap*(h): Create and return an empty heap.
- *find-min*(h): Return the min-root of h.
- *insert*(x, h): Make x into a one-node tree and insert x into the root list of h, in first or second position depending on whether its key is less than or not less than that of the min-root of h; in the former case x becomes the new min-root.
- *meld*(h, h'): Catenate the root lists of h and h'; set the min-root of the melded heap to that of h or h', whichever has smaller key.
- *delete-min*(h): Delete the min-root x of h. Replace x in the list of roots of h by the list of children of x, in the order they occur in the list of children. These *new roots* precede all the undeleted (*old*) roots in the root list. Repeatedly link pairs of adjacent roots until there is only one root remaining, using the *leftmost locally maximum linking rule* given below. Make the remaining root the min-root of h.

The main novelty in smooth heaps and slim heaps is the leftmost locally maximum linking rule used in *delete-min*. It is: find the leftmost node v in the root list whose key is no less than those of both adjacent nodes, say u and w, and link v with whichever of u and w has larger key, breaking a tie in favor of the node left of v. As special cases, if the leftmost root has key no less than that of the right adjacent root, link these roots (the right one is the winner); if the keys of all the roots are in strictly increasing order left-to-right, link the rightmost root with the left adjacent root (the left one is the winner). One can eliminate the special cases by adding dummy leftmost and rightmost nodes, both with key minus infinity, and applying the leftmost locally maximum linking rule until there is only one non-dummy root.)

To implement leftmost locally maximum linking, start at the leftmost root and proceed rightward until finding a root v whose key is not less than that of its right adjacent root w, or until reaching the rightmost root. In the latter case, link the two rightmost roots and repeat until there is only one root, completing the linking. In the former case, link v with whichever of the adjacent roots has higher key, choosing the left adjacent node in case of a tie and linking with w (the right adjacent node) if v is the leftmost root. Then repeat, but starting from the winner of the link: all roots preceding this winner are in strictly decreasing order by key, left to right, and hence none is the leftmost local maximum.

Leftmost locally maximum linking *treapifies* the list of roots: it arranges the roots into a binary tree symmetrically ordered by root list order and heap-ordered by key, with ties broken in favor of nodes on the right: if x is a node, its new left child, if any, has no smaller key, and its new right child, if any, has strictly greater key.

In both linking and in the definition of "leftmost local maximum" our tie-breaking rule in key comparisons is that the node on the right is treated as having smaller key. Other tie-breaking rules work equally well: what is required is consistency (the outcome of a key comparison between two nodes must remain the same throughout a *delete-min*) and transitivity (if x, y, and z have equal keys and the tie-breaking rule declares that x has smaller key than y and y has smaller key than z, then it must declare that x has smaller key than z). An alternative tie-breaking rule with these properties is to break ties by node identifier. The tie-breaking rule can depend on the keys, the nodes, and the position of the nodes in the root list. Leftmost locally maximum linking is easy to implement, but a more general linking rule does the same links if the tie-breaking rule is the same: Find *any* locally maximum root v (a root with key greater than those of both adjacent roots); link it with the adjacent node of greater key; repeat until one root remains.

Smooth heaps and slim heaps are efficient for two reasons. The first is that locally maximum linking guarantees that a node acquires at most two new children during a *delete-min* operation (Lemma 3). Pairing heaps do not have this property: in the second, right-to-left linking pass during a pairing heap *delete-min*, a node can acquire an arbitrary number of new children (see Figure 2). The second is that insertions and melds are lazy (they do no links), but *delete-min* operations are eager (they do as many links as possible). Pairing heaps are eager: except in the middle of an operation, a pairing heap consists of a single tree, and insertions and melds are done by single links. We do not know whether it is possible to obtain our bounds for a single-tree smooth heap or pairing heap.

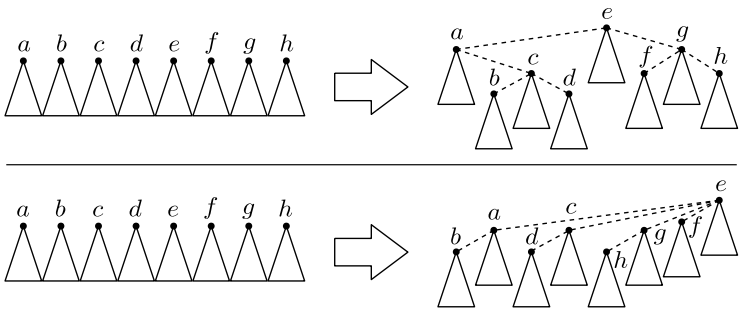

Figure 2 A possible linking of roots during a *delete-min* in a smooth heap (above) and a pairing heap (below), assuming key order e, a, g, c, b, d, f, h from smallest to largest.

▶ **Lemma 3.** *During a* delete-min*, a root wins at most one left link and at most one right link. Hence during a* delete-min *each node acquires at most one new left child and at most one new right child.*

Proof. Consider a link of the leftmost locally maximum node v during a *delete-min*. Node v is linked with either the left adjacent node u or the right adjacent node w. Suppose the link is with u. Then u has key strictly less than that of v; otherwise, u has locally maximum key and is left of v, contradicting the choice of v. The link is a right link won by u. After this link, either u is the rightmost node in the list or the node w adjacent to u on the right has no larger key, and the node adjacent to u on the left, if any, has key strictly smaller than

that of u. This makes u the leftmost local maximum, so u will participate in the next link and lose it: if the link is with w, w will win by the link tie-breaking rule if the keys of u and w are equal. Hence after the link of u and v, u cannot win another link, either left or right.

Suppose the link of v is with w. Since the key of w is no greater than that of v, w wins the link, by the link tie-breaking rule if the keys of v and w are equal. The link is a left link. After the link, the node u adjacent to w on the left, if it exists, has key strictly smaller than that of w by the tie-breaking rule for choosing whether to link v with u or with w. Node u cannot become a leftmost local maximum until w loses a link. Hence w cannot win another left link, since it would be with u. ◀

3 Efficiency of operations

With the two-pointer-per-node representation in Section 2.3, each *make-heap*, *find-min*, *insert*, and *meld* operation takes $O(1)$ time worst-case: catenation of the two root lists during *meld* takes two pointer changes, and each link, whether one-sided or stable, takes O(1) time. The time for a *delete-min* is O(1) plus at most a constant times the number of links. We normalize this time to be one plus the number of links. The number of links is one less than the number of roots, new and old, after deletion of the min-root. We shall prove a bound of $O(\lg n)$ on the amortized time of *delete-min* and of $O(1)$ on the amortized times of the other operations by using the *potential method* [26].

The previous analysis of smooth heaps [16] was restricted to *sorting mode*, and made use of a *geometric view* of binary search trees [4]. Our analysis is free of such restrictions and is self-contained.

3.1 Potential method

In the potential method, we assign to each state of the data structure a real-valued potential. We define the *amortized time* of an operation to be its actual time plus the potential of the structure after the operation minus the potential of the structure before it. That is, the amortized time is the actual time plus the net increase in potential caused by the operation. If we sum the amortized times of the operations in a sequence, the sum of the potential differences telescopes: the sum of the actual times of the operations equals the sum of their amortized times, plus the final potential (after the last operation), minus the initial potential (before the first operation). If the initial potential is 0 (corresponding to an empty data structure) and the final potential is non-negative, then the sum of the amortized times of the operations is an upper bound on the sum of their actual times, allowing us to use the former as a conservative bound on the latter.

3.2 Definition of the potential

The analyses of slim heaps and smooth heaps differ slightly. We develop them both at the same time and point out the differences.

For each node x having children, we define the *link order* of the children to be the order in which these children lost links to x, latest first, earliest last. This is exactly the order of the children in the list of children of x if the heap is a slim heap, but not necessarily if the heap is a smooth heap: in the latter, the link order is a merge of the left children in their order in the list of children of x and of the right children in the reverse of their order in the list of children of x.

We define the size $size(x)$ of a node x in a heap to be the number of its descendants, including itself. We define the mass $mass(x)$ of a child x to be the sum of the sizes of x and of all its siblings after it in link order (those linked to their common parent before x). (We do not need to define the masses of roots.)

We define the potential of a root x to be $2 + 2 \lg size(x)$. In a slim heap, we define the potential of a child x to be 0 if x is the first or second child of its parent, $\lg mass(x)$ otherwise (at least two children were linked to the parent of x after x). In a smooth heap, we define the potential of a child x to be 0 if it is the leftmost left child or rightmost right child in its sibling list, $\lg mass(x)$ otherwise. We define the potential of a collection of heaps to be the sum of the potentials of their nodes.

The slim heap potential is closely related to the one used in the original analysis of pairing heaps [9], which assigns $\lg size(x)$ potential to each root x and $\lg mass(x)$ potential to each child x. Here we give (at most) two children of a node zero potential. This limits the increase in potential caused by a link in a *delete-min* to the logarithm of the size of the winner *before* the *delete-min*. Our analysis relies on this limit.

3.3 Amortized bounds

The amortized time of a *make-heap*, *find-min*, *insert*, or *meld* is $O(1)$, since the worst-case time of each is $O(1)$, and only an *insert* changes the potential, increasing it by 2.

We shall show that the amortized time of a *delete-min* is $O(\lg n)$.

Let x be the min-root. After its deletion, the list of roots consists of new roots, those that were children of x, followed by old roots, those that were roots before the deletion of x. See Figure 3. We separately analyze links won by old roots and links won by new roots.

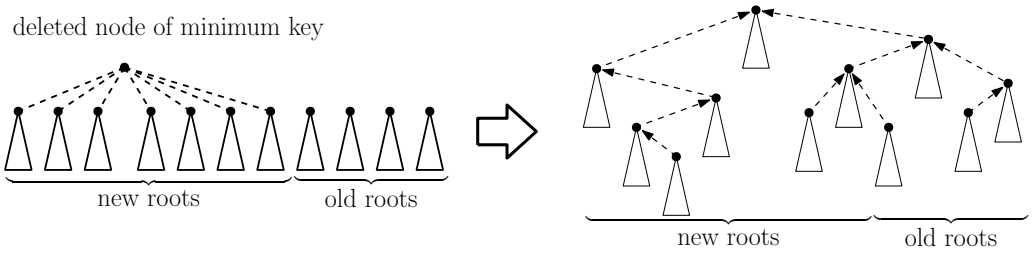

Figure 3 The result of the delete-min operation. The root with smallest key is deleted, its children become the new roots in its place, and then all roots are linked in a binary tree.

Each old root u has potential $2 + 2 \lg size(u)$, where $size(u)$ is the size of u just before the *delete-min*. This potential covers the actual time (1 or 2) of the link or links that u wins during the *delete-min*, if there are any, plus the increase in the potential of children of u when u wins a link or two: if v and w respectively are the at most two children of u that have potential zero before the *delete-min*, then when u wins one link, the potential of one of v and w increases from 0 to $\lg mass(w) < \lg size(u)$, and when u wins a second link the potential of the other of v and w increases from 0 to $\lg mass(v) < \lg size(u)$.

The heart of the analysis, the hard part, is that of links won by new roots. Let the masses of the new roots be their masses before the deletion of x. Before this deletion, x has potential $2 + 2 \lg size(x)$. The deletion of x frees its potential. We transfer $\lg size(x)$ of this potential from x to each of the at most two new roots with zero potential. Then every new root u has a potential of at least $\lg mass(u)$.

Each new root u can acquire one or two new children by winning one or two links during the *delete-min*. By the argument we used for old roots, the increase in potential of the children of u when u wins a link is less than $\lg size(u)$ per link, where $size(u)$ is the size of u

just before the *delete-min*. We shall show that the sum of the base-two logarithms of the masses of the new roots, which is at most the sum of their potentials after x is deleted and its freed potential is transferred, plus $2 + \lg size(x)$ for a slim heap or $2 + 2\lg size(x)$ for a smooth heap, is at least the sum of the increases in potential of the children of these roots, plus at least 2 per new root that wins a link. The extra 2 pays for the actual time of the links won by new roots during the *delete-min*.

The first step is to shift some of the potential of the new roots so that each new root u has at least $\lg mass(u)$ potential for each link it wins during the *delete-min*. This shifting is different for slim heaps and smooth heaps. In slim heaps, for each new root u except the last one in link order, if the root v after u in link order wins a left link, we shift $\lg mass(u) \geq \lg mass(v)$ from u to v. See Figure 4.

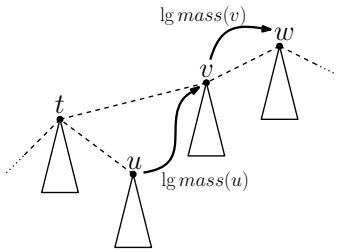

Figure 4 An example of shifting potential among new roots in a slim heap. The dotted lines represent links made during delete-min, with the losers are pictured lower than the winners, and curved lines represent shifted potential. New root u gives potential to its adjacent sibling v because v wins a left link with t and v gives potential to w because w wins a left link with v.

▶ **Lemma 4.** *After the potentials are shifted in a slim heap, each new root u has potential at least* $\lg mass(u)$ *if it wins one link during the* delete-min*, at least* $2\lg mass(u)$ *if it wins two.*

Proof. Consider a new root v that wins one or two links during the *delete-min*. If v wins a left link, it acquires at least $\lg mass(v)$ potential from the root before it in link order. For v to lose potential to the node w after it in link order, w must win a left link. But then v cannot win a right link, since if this link occurs before the left link that w wins, w must be the loser, and hence cannot later win a link, and if this link occurs after the left link that w wins, v must be the loser, and cannot later win a link. We conclude that if v wins both a left link and a right link, it acquires at least $\lg mass(v)$ potential from the node before it in link order and retains its own potential of at least $\lg mass(v)$; if v wins only a right link, it retains its own potential of at least $\lg mass(v)$; and if v wins only a left link, it acquires at least $\lg mass(v)$ potential from the node before it in link order, although it may lose its own potential. Hence the lemma holds. ◀

In the case of smooth heaps, we call a new root a *left* or *right* root depending on whether it was a left or right child of x before x was deleted. We must shift the potential of left and right roots separately, since the link order of the latter is the reverse of their order on the list of children of x before x was deleted. Specifically, for each left root u except the last in link order, if the next left root v in link order wins a left link, we shift $\lg mass(u) \geq \lg mass(v)$ from u to v; for each right root u except the last in link order, if the next right root v in link order wins a right link, we shift $\lg mass(u) \geq \lg mass(v)$ from u to v. In addition, if the first right root u in link order wins a (right) link with an old root, we give u $\lg size(u) \leq \lg size(x)$ of the $2 + 2\lg size(x)$ extra potential allocated to the *delete-min*. This accounts for the extra potential needed in the analysis for smooth heaps: since all the new roots precede all the

old roots, a new root can only win a right link with an old root, not a left link. This is a problem only when shifting potential to cover right links, which does not happen in slim heaps. See Figure 5.

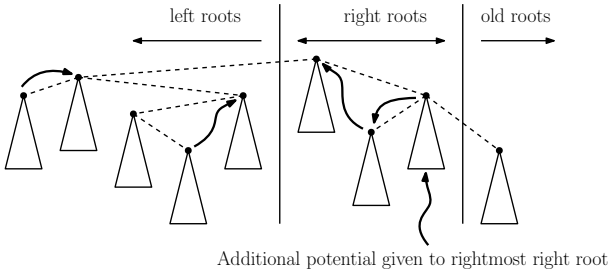

Figure 5 An example of shifting potential in a smooth heap. Every curved line represents a transfer of potential equal to the logarithm of the mass of the new root at the start of the line. Left roots transfer potential in the same way as a slim heap. Right roots transfer potential in the symmetric way, and the rightmost right root receives additional potential to pay for a right link.

▶ **Lemma 5.** *After the potentials are shifted in a smooth heap, each new root u has potential at least* $\lg mass(u)$ *if it wins one link during the* delete-min*, at least* $2 \lg mass(u)$ *if it wins two.*

Proof. The proof is that of Lemma 4 applied separately to left roots and right roots. Consider a left root v that wins one or two links during the *delete-min*. If v wins a left link, it acquires at least $\lg mass(v)$ potential from the left root preceding it in link order: there must be such a root since if v wins a left link it must be with a left root. For v to lose potential, it must be to the left root w after it in link order, and w must win a left link. But then v cannot win a right link, since if this link occurs before the left link that w wins, w must be the loser, and hence cannot later win a link, and if this link occurs after the left link that w wins, v must be the loser, and cannot later win a link. We conclude that if v wins both a left link and a right link, it acquires at least $\lg mass(v)$ potential from the left root preceding it in link order and retains its own potential of at least $\lg mass(v)$; if v wins only a right link, it retains its own potential of at least $\lg mass(v)$; and if v wins only a left link, it acquires at least $\lg mass(v)$ potential from the left root preceding it in link order, although it may lose its own potential. The symmetric argument applies to right roots, except that the first right root in link order may win a right link (with an old root), and not receive any potential for it. The additional $\lg size(x)$ potential allocated to a smooth heap *delete-min* covers this. Hence the lemma holds. ◀

By Lemmas 4 and 5, every new root has enough potential to cover the increase in the potential of its children if it wins one or two links. For each new root u that wins two links during the linking, we allocate $\lg size(u)$ potential from u to the child whose potential increases when the second link occurs. Each new root u that wins at least one link retains at least $\lg mass(u)$ potential. We shall show that if we add $2 + \lg size(x)$ additional potential, there are at least two units of extra potential per new root u that wins at least one link, in addition to the increase in potential of a child of u when u first wins a link. The latter is less than $\lg size(u)$. We consider new roots that win at least one link from first to last in link order. We maintain the invariant that the next root u that wins a link has at least $2 \lg mass(u)$ potential. To establish the invariant for the first such root u, we give it $\lg mass(u) < \lg size(x)$ of the $2 + \lg size(x)$ additional potential.

Let u be the current root under consideration and let v be the next new root after u that wins a link. Node u currently has potential at least $2 \lg \mathit{mass}(u)$. Since $\mathit{mass}(u) \geq \mathit{size}(u) + \mathit{mass}(v)$, the inequality $2 \lg(\mathit{size}(u) + \mathit{mass}(v)) \geq \lg \mathit{size}(u) + \lg \mathit{mass}(v) + 2$ allows us to move $\lg \mathit{size}(u)$ potential from u to its child whose potential increases when u first wins a link, and to move $\lg \mathit{mass}(u)$ potential from u to v, establishing the invariant for v, with at least two units of potential left over to pay for the link or links that u wins during the *delete-min*. This argument covers all but the last new root w in link order that wins at least one link, but w ends up with potential at least $2 \lg \mathit{mass}(w)$, more than enough to cover the increase in potential of one of its children when it first wins a link. We use the two units of remaining added potential to pay for the actual time of the one or two links won by w.

The single root remaining after all the linking has a potential of $2 + 2 \lg n$. We conclude that the amortized time of a *delete-min* is at most $5 + 3 \lg n$ in a slim heap, at most $5 + 4 \lg n$ in a smooth heap: the links are covered by potential decreases, we added $2 + \lg n$ or $2 + 2 \lg n$ extra potential, the remaining root needs potential $2 + 2 \lg n$, and the *delete-min* takes time 1 in addition to the links. This finishes the proof that *delete-min* takes $O(\lg n)$ amortized time.

4 Implementation of *decrease-key* and *delete*

In this section we implement *decrease-key* and *delete*. We give two implementations of *decrease-key*, a simple one for which it is easy to prove an $O(\lg n)$ amortized bound, and a more complicated one based on Elmasry's for pairing heaps, which has an $O(\lg \lg n)$ bound.

Our implementations of *decrease-key* and *delete* require adding a third pointer to each node. If x is a child that is not leftmost on its list of siblings, its third pointer indicates its previous sibling; if it is leftmost, its third pointer indicates its parent. If x is a root, its third pointer indicates the left adjacent root on the root list, or the rightmost root on the root list if x is the min-root. This makes the lists of children and the list of roots doubly linked, and supports deletion of a node (and its subtree) from such a list in $O(1)$ time.

4.1 Key decrease

A simple implementation of *decrease-key*(x, k, h) is the one used in pairing heaps: Set the key of x to k. If x is not a root, cut x (and its subtree) from the list of children containing it, and add x to the root list. Update the min-root. This takes O(1) actual time. Cutting x from its parent and making it a root increases the potential only of x, by at most $2 + 2 \lg \mathit{size}(x)$. Thus the amortized time of *decrease-key* is $O(\lg n)$. A much more complicated argument based on Pettie's proof of the same method for *decrease-key* in pairing heaps gives a stronger amortized bound. For lack of space, we have omitted this proof from this version of our paper.

We obtain a smaller amortized bound for *decrease-key* if we use Elmasry's implementation for pairing heaps [6]. We maintain a *buffer* that contains roots whose keys have been decreased. The buffer of a new heap is initially empty. To do *decrease-key*(x, k, h), we set the key of x to k. If x is not a root, we first cut x (and its subtree) from its sibling list L. Second, if x has a child, we cut its leftmost child y (and its subtree) from x, and replace x by y in L. Third, we add x to the buffer. If the buffer contains at least $\lg n$ roots, we empty it. Whether or not x was a root, we finish the *decrease-key* by updating the min-root.

When doing a *delete-min*, we begin by emptying the buffer. When doing a *meld*, we empty the buffer of the smaller heap; the buffer of the larger heap becomes the buffer of the melded heap.

To empty the buffer, we sort the roots in the buffer in non-increasing order by key, and link them using leftmost locally maximum linking, which makes each root the leftmost child of the one of next-smaller key, whether the heap is a slim heap or a smooth heap. Each link is a left link. We add to the root list the root remaining after the roots in the buffer are linked.

To support *find-min* in $O(1)$-time, we maintain the min-root of the buffer as well as the min-root of the roots not in the buffer. This adds $O(1)$ time to each operation. We also need to store with each heap the number of nodes it contains. This is easy to maintain in $O(1)$ time per operation.

This way of doing *decrease-key* reduces the amortized time to $O(\lg\lg n)$. To prove this we use the potential function of Section 3.2, with three changes:

- **(i)** If x is a root in the buffer that lost a child y when its key was decreased, we give its children the potential they had before y was cut from x. Since y is the leftmost child of x before it is cut, if the heap is a slim heap y has zero potential. If the heap is a smooth heap, y has zero potential unless y and all the children of x are right children, not left children. In the latter case, x has at most one child of zero potential both before and after y is cut. We conclude that after y is cut, x has at most one child of zero potential, its most recently acquired child if the heap is a slim heap; its most recently acquired right child if the heap is a smooth heap. This allows x to win a new left link without increasing the potential of any of its children, including its new one.
- **(ii)** To pay for emptying the buffer when it is full, we give each root u in the buffer a potential of $4 + \lg\lg n$, rather than the $2 + \lg \mathit{size}(u)$ potential it would have if it were in the root list.
- **(iii)** To pay for emptying the buffer of a heap when it is melded with a larger heap, we give each heap of n nodes an extra potential of $4\lg n$.

The actual time to decrease the key of a node x is $O(1)$. After x is cut from its sibling list and its leftmost child is cut from it, its children have exactly the potential they need when x is in the buffer. Replacing x by the first child of x does not increase the potential of any node in the tree previously containing x. Thus the potential increase caused by a *decrease-key* is at most the potential of the new root in the buffer, which is $4 + \lg\lg n$, making the amortized time of the *decrease-key* $O(\lg\lg n)$ unless the buffer becomes full and is emptied.

The actual time to empty the buffer is $O(\lg\lg n)$ per root in the buffer, with the sorting time dominant. The potential of $\lg\lg n$ per root in the buffer covers this time. Because of the sorting, each root in the buffer acquires at most one new left child, which does not increase the potential of any node in any of the trees rooted at these nodes. One root, say u, remains after the roots in the buffer are linked. This node needs potential $2 + 2\mathit{size}(u) \leq 4\lg n$ when it is added to the root list. Since the buffer is full when it is emptied in a *decrease-key*, u acquires the needed potential from the extra 4 units of potential per root in the buffer before these roots are linked. Hence *decrease-key* takes $O(\lg\lg n)$ time whether or not the buffer is emptied.

If the buffer is emptied during a *delete-min*, the root formed by linking the roots in the buffer needs potential at most $2 + 2\lg n$, increasing the amortized time of the *delete-min* by this amount, but the amortized time remains $O(\lg n)$.

It remains to consider *insert* and *meld*. Insertion is just a special case of meld, in which one of the heaps contains only one item and an empty buffer. Consider a meld of two heaps, with the larger heap, say h, containing n nodes. The heap resulting from the meld has size at most $2n$. The heap potential of the smaller heap covers the potential of the root formed

by linking the roots in its buffer when it is emptied. The heap potential of the new heap is at most $4\lg(2n) = 4\lg n + 4$, which is an increase of at most 4 of the heap potential of h. Let $k \leq \lg n$ be the number of roots in the buffer of h. The meld increases the sum of the potentials of these roots by at most

$$k(\lg\lg(2n) - \lg\lg n) \leq (\lg n)\lg\left(\frac{\lg n + 1}{\lg n}\right) = (\lg n)\lg(1 + 1/\lg n) \leq (\lg n)(\lg e)/\lg n = \lg e$$

by the inequality $\lg(1 + 1/\lg n) \leq \lg e/\lg n$ if $n \geq 2$. We conclude that the amortized times of *insert* and *meld* remain $O(1)$.

4.2 Arbitrary deletion

To delete a node x in a heap h, if x is the min-root of h, we merely do *delete-min*(h). If x is not the min-root of h, we offer three ways of doing the deletion. One is to decrease the key of x to minus infinity and then do *delete-min*(h). Using either of our implementations of *decrease-key*, this takes $O(\lg n)$ amortized time, with the *delete-min* time dominating. An alternative that does not use *decrease-key* is to repeatedly link adjacent children of x using leftmost locally maximum linking until x has only one child, and then replace x by its only child in the root list, or in its list of siblings if x is not a root. This implementation of *delete* also takes $O(\lg n)$ time, by an analysis like that of *delete-min* in Section 3.3. A third alternative is to delay linking the children of the deleted node, by merely replacing the deleted node in its list of siblings (or in the root list if it is a root) by its list of children. This also takes $O(\lg n)$ amortized time, by an extension of the analysis in Section 3.3: we must add $O(\lg n)$ additional potential to each group of siblings whose parent is deleted, to help pay for the links they eventually win.

5 Permanent nodes do not count

In this section we prove Theorem 2, which states that nodes that are never deleted do not slow down operations:

▶ **Theorem 2.** *Operations* delete-min *and* delete *take* $O(\lg t)$ *amortized time, with the other amortized bounds unchanged, where* t *is the number of nodes in the heap at the time of the operation that will be deleted in the future.*

Proof. Call a node *temporary* if it will eventually be deleted, and *permanent* otherwise. The total time of a sequence of operations is O(1) per operation plus the number of links. All the links except at most one per *decrease-key* operation are done during *delete-min* operations and when a buffer of nodes whose keys have decreased is emptied. Thus it suffices to count links. We separately count links won by permanent nodes and those won by temporary nodes. A link won by a permanent node either remains permanent, or is cut by a subsequent *decrease-key operation*: such links cannot be cut by deletions. It follows that there is at most one such link per *insert* and at most two per *decrease-key*.

It remains to count links won by temporary nodes. To do this we redefine the size of a node to be the number of temporary nodes in its subtree, and we redefine mass and potential accordingly, except that we give a root with size 0 potential 2 and a child with mass 0 potential 0. It is easy to check that with the new potential function *make-heap*, *find-min*, *insert*, and *meld* still take constant amortized time, and *decrease-key* still takes $O(\lg\lg n)$ amortized time.

We make a few small changes to adapt the analysis of *delete-min* to the new potential function. We apply the analysis of links won by old roots only to those that are temporary. We add and shift potentials only among temporary new roots. The additional potential needed for the analysis to work is $O(\lg t)$ rather than $O(\lg n)$. Thus we obtain an $O(\lg t)$ amortized time bound for *delete-min*. We also obtain an $O(\lg t)$ amortized time bound for either implementation of arbitrary deletion that does not use *decrease-key*; for the implementation that uses *decrease-key*, the bound is $O(\lg t + \lg\lg n)$. ◀

6 Experimental evaluation

We implemented the pairing heap, the smooth heap, and the slim heap in Python 3, with the same generic heap interface. We compared their performance in two scenarios: sorting and Dijkstra's single-source shortest paths algorithm. In both tasks we counted two types of logical operations: *comparisons* between keys and *links* between nodes. Note that in pairing heaps comparisons and links occur together, making the two counts equal. By contrast, in smooth heaps and slim heaps the number of comparisons is larger than the number of links by a factor of at most two (see [16])[4]. In practice, links are typically costlier than comparisons, requiring several pointer changes. Thus the number of links is expected to be indicative of the actual running time. We summarize the experimental setup and findings (Figures 6, 7, 8) and refer to [12] for further experiments.[5]

Sorting. Given a list of roots containing the keys $\pi_1, \ldots, \pi_n$ of an input permutation π, we execute n *delete-min* operations, sorting π. It has been hypothesized that the smooth heap performs particularly well on structured inputs. To test this experimentally, we considered, besides uniformly random inputs, classes of *semi-random* permutations. We tested four families of input permutations:

- **(a)** *Uniformly random*: We generated permutations of sizes $n = 2, 2^2, \ldots, 2^{17}$ using the pseudo-random *random.shuffle* function of Python, with 5 independent runs for each size.
- **(b)** *Separable:* Starting with the sequence $1, \ldots, n$, for $n = 2, 2^2, \ldots, 2^{17}$, we did the following shuffling: reverse the sequence with probability $1/2$, then recursively process the first half and second half of the sequence in the same way, doing 20 independent runs for each size. The permutations obtained are *separable* (see e.g. [1]).
- **(c)** *Localized:* We generated a sequence of length $n = 10000$ where each element is drawn from a Gaussian normal distribution centered at its index, with standard deviation proportional to a parameter ε, doing 10 independent runs for each value $\varepsilon = 0, 0.01, \ldots, 0.3$.
- **(d)** *Sorted blocks:* Starting with a uniform random permutation of size $n = 10000$, we sorted contiguous blocks of elements, where the block sizes are chosen uniformly at random from the range $[1, \ldots B]$, with 20 independent runs for each value $B = 100, 200, \ldots, 2000$.

Shortest paths. For all three heaps we used a similar multi-tree implementation of *insert* and *decrease-key* that simply adds the respective node to the end of the root list. (This is *not* the standard pairing heap implementation, which maintains a single tree, and the

[4] In the worst case $2k - \Theta(\lg k)$ comparisons are necessary to combine k roots during *delete-min*, since the outcome corresponds to one of $\Theta(4^k/k^{3/2})$ possible binary trees.

[5] The scripts used can be found at `https://git.imp.fu-berlin.de/hlm/smooth-heap-pub`.

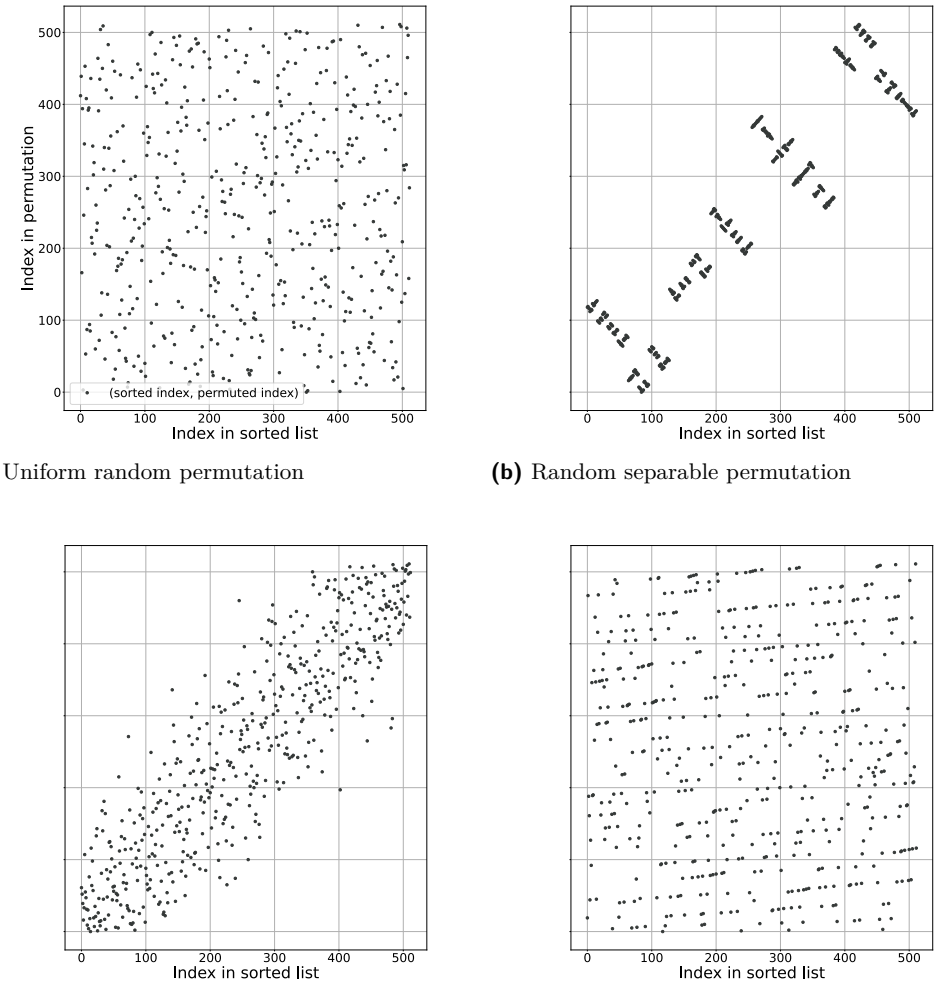
implementation of *decrease-key* in smooth heaps and pairing heaps is the simple one.) Since these structures differ only in the restructuring during delete-min, we counted the number of links and comparisons only for delete-mins, taking averages over 10 independent runs. We considered two families of undirected input graphs, with edge weights in both cases chosen uniformly at random from $\{1, \ldots, 10000\}$:

(e) *Random graphs:* with $n = 500$ vertices, generated according to the Erdős-Rényi model, with edges present with probability p (for values $p = 0, 0.05, \ldots, 1$), and
(f) *Random* 10*-regular graphs:* with $n = 500, 1000, \ldots, 10000$ vertices.

Findings. In (a) the number of comparisons (and links) done by the pairing heap is a small factor (≈ 1.2) above the information-theoretical lower bound of $\lg(n!)$. On our largest test, the smooth (slim) heap performs about 22% (44%) more comparisons. In turn, the pairing heap performs about 47% (11%) more links than the smooth (slim) heap.

In (b) the number of operations appears to be $O(n)$ for all data structures. This is consistent with the fact that there are $2^{O(n)}$ such permutations of size n. In fact, for the smooth heap, it is known [16] that sorting separable permutations takes time $O(n)$, as implied by more general results for Greedy BST. It can be observed that the pairing heap performs on average both more comparisons and more links than the smooth and slim heaps. The differences in the number of comparisons are small, but in the number of links the overhead of pairing heaps is about 58% (65%) in our largest test. One can further notice that there is less variation in the number of operations in smooth/slim heaps, whereas the pairing heap is sensitive to the exact choice of input permutation.

In (c) the situation is similar to the uniformly random case, with the ordering slim, smooth, pairing in the number of comparisons, and pairing, slim, smooth in the number of links. Although the overall costs are smaller to (a), the smooth/slim heaps do not appear to have a particular advantage in adapting to this type of structure.



In (d) the smooth/slim heaps have a clearer advantage. When the input permutation consists of just about 10 sorted blocks, the pairing heap performs about 7 comparisons and links per key, whereas both smooth and slim heaps perform about 6 comparisons and 4 links per key. The advantage diminishes as the sizes of the sorted blocks decrease.

In the densest case of (e), the smooth (slim) heaps perform about 40% (45%) more comparisons than the pairing heap, while the pairing heap performs about 22% (14%) more links than the smooth (slim) heaps. In the largest case of (f), the smooth (slim) heaps perform about 36% (48%) more comparisons, while the pairing heap performs about 23% (6%) more links.

7 Remarks

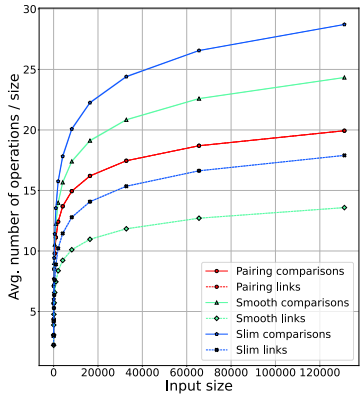
Self-adjusting data structures are simple to describe and implement but hard to analyze. Developing new approaches and tools for analyzing such data structures remains an exciting field, with many questions still open. Our design of slim heaps and our analysis of smooth and slim heaps (Theorems 1 and 2) add to what we know about such structures.

One property that makes smooth heaps and slim heaps efficient is that each *delete-min* links at most two new children to each node. Neither the original version of pairing heaps nor any of the proposed variants has this property, but there is one variant that does: the *pure pairing heap*, in which the heap is a forest instead of a single tree, *insert* and *meld* are done lazily by catenating the root lists, and *delete-min* performs a single pairing pass: after the min-root is deleted, the remaining roots are linked in pairs, first and second, third and fourth, and so on. During a *delete-min*, each node acquires at most *one* new child. We offer

(a) Uniform random permutation

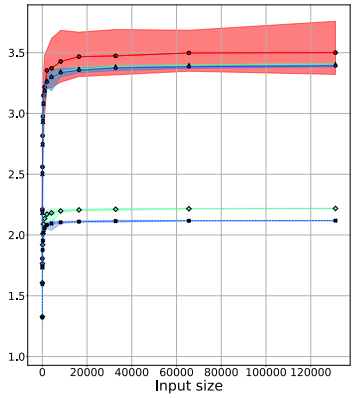
(b) Random separable permutation

(c) Random permutation with locality parameter $\varepsilon = 0.15$



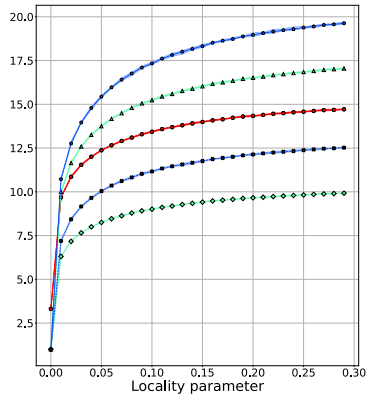
(d) Random permutation with average sorted blocks of length 15

Figure 6 Sample permutations of size 512 generated for the different families of permutations.

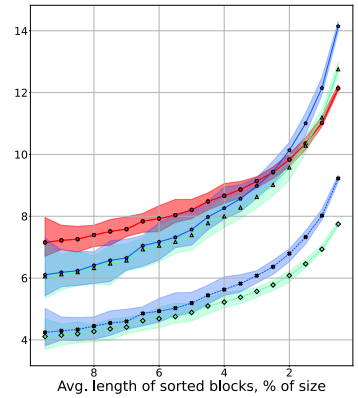


the pure pairing heap as a data structure for further study: our analysis fails, because this structure does not have the second property that makes smooth and slim heaps efficient; a *delete-min* can result in a list of roots rather than a single one.

We have proved that the simple method of doing *decrease-key* in smooth and slim heaps, by merely cutting the node whose key decreases and adding it to the root list, takes $O(\lg n)$ amortized time. For pairing heaps, Pettie has shown that the same method takes $O(4^{\sqrt{\lg \lg n}})$ amortized time. We think that his techniques will give a similar bound for smooth and slim heaps, and we are currently working on this question.

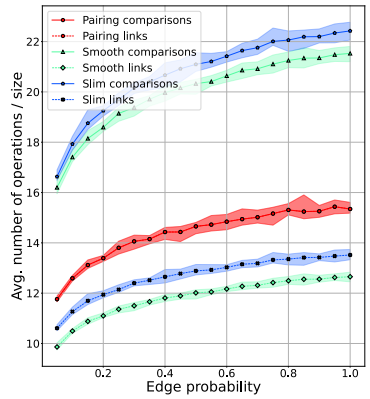


Similarly to other self-adjusting data structures, smooth heaps and slim heaps are expected to be *adaptive*, i.e. to show greater efficiency on some specific inputs. Through the connection with Greedy BST [16], smooth heaps are known to be highly adaptive in sorting mode, but these results do not seem easy to transfer to slim heaps. Adaptivity in general operation sequences is much less understood. Our Theorem 2 can be seen as a first result in this direction. We expect that other adaptive bounds, e.g. similar to those in [7] can also be shown. A possible way for proving such bounds is to generalize the analysis in this paper to

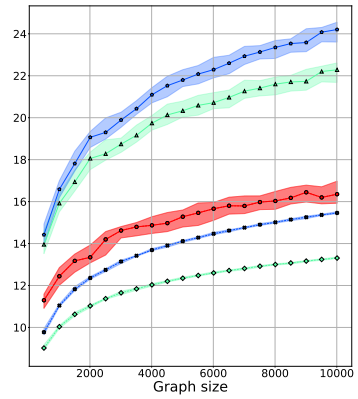


(a) Uniform random permutations.

(b) Random separable permutations.



(c) Random permutations of size 10^4 with locality parameter ε.



(d) Random permutations of size 10^4 with sorted blocks.

Figure 7 Average number of links (dashed lines) and average number of comparisons (continuous lines) for sorting permutations using pairing heap (red), smooth heap (green), and slim heap (blue); note that for pairing heaps the two counts are equal. Shaded areas indicate ranges between minimum and maximum costs.

(a) Random graphs with varying edge probability.

(b) Random regular graphs of varying size.

a weighted setting, much in the spirit of splay trees [24]. Such an extension of Theorem 1 is indeed possible, but with the current potential function it does not appear to yield nontrivial new bounds. A weighted analysis combined with a *linear* potential function, i.e. $O(n)$ rather than $O(n \lg n)$ may lead to such results.

Abstract

We devise the first constant-factor approximation algorithm for finding an integral multi-commodity flow of maximum total value for instances where the supply graph together with the demand edges can be embedded on an orientable surface of bounded genus. This extends recent results for planar instances. Our techniques include an uncrossing algorithm, which is significantly more difficult than in the planar case, a partition of the cycles in the support of an LP solution into free homotopy classes, and a new rounding procedure for freely homotopic non-separating cycles.

1 Introduction

Multi-commodity flows, or *multiflows* for short, are well-studied objects in combinatorial optimization; see, e.g., Part VII of [34]. A multiflow of maximum total value can be found in polynomial time by linear programming. Often, a multiflow must be integral, and then the problem is much harder; the well-known edge-disjoint paths problem is a special case. Recently, constant-factor approximation algorithms have been found for maximum edge-disjoint paths and integral multiflows in *fully planar instances*, i.e., when $G + H$, the supply graph together with the demand edges, can be embedded in the plane [21, 16]. We generalize these results to surfaces of bounded genus and devise the first constant-factor approximation algorithm for that case.

Beyond using some ideas of [16, 21], we need several new ingredients. Like [16], we start by computing an optimal (fractional) multiflow and "uncross" the cycles in its support as much as possible, but uncrossing is significantly more complicated on general surfaces than in the plane. Next, we need to deal with two cases separately: depending on whether most of the fractional multiflow is on separating cycles (that case is similar to the planar case)

or on non-separating cycles. In the latter case we partition the cycles into free homotopy classes and define a cyclic order in each free homotopy class, which is possible due to the uncrossing and allows for a simple greedy algorithm.

1.1 Our results

The (fractional) *maximum multiflow problem* can be described as follows. An instance consists of an undirected graph $(V, D \dot\cup E)$ whose edge set is partitioned into *demand edges*, in D, and *supply edges*, in E. We write $G = (V, E)$, $H = (V, D)$, and $G + H = (V, D \dot\cup E)$. Moreover we have a function $u : D \dot\cup E \to \mathbb{Z}_{>0}$ which defines a *capacity* $u(e)$ for each supply edge $e \in E$ and a *demand* $u(d)$ for each demand edge $d \in D$. The goal is to satisfy as much of the demand as possible by routing flow on supply edges. More precisely, we ask for an s-t-flow f^d of value at most $u(d)$ for every demand edge $d = \{t, s\}$ such that the total flow on each supply edge is at most its capacity and the total value of all those flows is maximum.

It is well known that every s-t-flow can be decomposed into flow on s-t-paths and on cycles, and for integral flows there is an integral decomposition. The cycles in such a decomposition do not contribute to the value of the s-t-flow and can be ignored. An s-t-path in (V, E) together with the demand edge $d = \{t, s\}$ forms a *D-cycle*: a cycle in $G + H$ that contains exactly one demand edge. If we let $\mathcal{C}$ denote the set of all D-cycles in $G + H$, we can write the maximum multiflow problem equivalently as

$$\max \sum_{C \in \mathcal{C}} f_C \quad \text{s.t.} \quad \begin{cases} \sum_{C \in \mathcal{C} : C \ni e} f_C \leqslant u(e) & \text{for all } e \in D \dot\cup E \\ f_C \geqslant 0 & \text{for all } C \in \mathcal{C} \end{cases} \tag{1}$$

In some previous works, the problem has been defined with $u(d) = \infty$ for $d \in D$, and this variant is easily seen to be equivalent. We call the linear program (1) the *maximum multiflow LP*. The *maximum integral multiflow* problem is identical, except that the flow must be integral:

$$\max \sum_{C \in \mathcal{C}} f_C \quad \text{s.t.} \quad \begin{cases} \sum_{C \in \mathcal{C} : C \ni e} f_C \leqslant u(e) & \text{for all } e \in D \dot\cup E \\ f_C \in \mathbb{Z}_{\geqslant 0} & \text{for all } C \in \mathcal{C} \end{cases} \tag{2}$$

The special case where $u(e) = 1$ for every edge $e \in D \dot\cup E$ is known as the *maximum edge-disjoint paths* problem. Even that special case is unlikely to have a constant-factor approximation algorithm for general graphs (see Section 1.2). Our main result is a constant-factor approximation algorithm in the case when $G + H$ can be embedded on an orientable surface of bounded genus.

▶ **Theorem 1.** *There is a polynomial-time algorithm which takes as input an instance (G, H, u) of the maximum integral multiflow problem such that $G + H$ is embedded on an orientable surface of genus g, and which outputs an integral multiflow whose value is at most a factor $O(g^2 \log g)$ smaller than the value of any fractional multiflow.*

See Section 3 for an outline of the algorithm and the proof. In the full version of the paper, we explain how to improve the approximation ratio of the algorithm to $O(g^2)$. It is worth pointing out that almost all known hardness results for the maximum edge-disjoint paths problem hold even when G is planar (see Section 1.2). Theorem 1, along with the two recent papers [16, 21], highlight that for tractability one needs more than the planarity of G alone. The topology of $G + H$ together plays an important role.

The dual LP of (1) is:

$$\min \sum_{e \in D \dot\cup E} u(e) y_e \quad \text{s.t.} \quad \begin{cases} \sum_{e \in C} y_e \geqslant 1 & \text{for all } C \in \mathcal{C} \\ y_e \geqslant 0 & \text{for all } e \in D \dot\cup E \end{cases} \tag{3}$$

and this may be called the *minimum fractional multicut problem*. The *minimum multicut problem* results from replacing the inequality $y_e \geqslant 0$ in (3) by $y_e \in \{0,1\}$ for all edges $e \in D \dot\cup E$. Again, many previous works considered the equivalent special case where $u(d) = \infty$ for $d \in D$, in which case no dual variables for demand edges are needed. By weak duality, the value of any multiflow is at most the capacity of any multicut. Using Theorem 1 and a previous result of [36], we obtain (in Section 9):

▶ **Corollary 2.** *For any instance (G, H, u) of the maximum integral multiflow problem such that $G + H$ is embedded on an orientable surface of genus g, the minimum capacity of a multicut is at most $O(g^{3.5} \log g)$ times the maximum value of an integral multiflow.*

In general the integral multiflow-multicut gap[1], and even the integrality gap of (1), can be as large as $\Theta(|D|)$, even when G is planar and $G + H$ is embedded in the projective plane [18]. In this paper we consider orientable surfaces only. Corollary 2 states that the gap becomes constant when $G + H$ has bounded genus. So far very few such constant integral multiflow-multicut gaps are known, for example when G is a tree [18], or when $G + H$ is planar, as recently shown in [16, 21].

1.2 Related Work

Approximation algorithms and hardness for integral multiflows. Most of the hardness results for the maximum integral multiflow problem follow from the special case of the maximum edge-disjoint paths problem (EDP). The decision version of EDP is one of Karp's original NP-complete problems [22], and remains NP-complete even in many special cases [30], including the case of interest in this paper, namely even when $G + H$ is planar [28]. In terms of approximation, EDP is APX-hard [2]. Assuming that $\mathrm{NP} \not\subseteq \mathrm{DetTIME}(n^{O(\log n)})$, where $n = |V|$, there is no $n^{o(1/\sqrt{\log n})}$ approximation for EDP, even when G is planar and sub-cubic [6]. Assuming that for some positive δ, $\mathrm{NP} \not\subseteq \mathrm{RandTIME}(2^{n^\delta})$, there is no $n^{O(1/(\log\log n)^2)}$ approximation for EDP, even when G is planar and sub-cubic [7]. As far as we know, no stronger hardness result is known for integral mutliflows.

On the positive side, EDP can be solved in polynomial time when the number of demand edges is bounded by a constant [33]. The same holds for integral multiflows when $G + H$ is planar [35]. For exact algorithms in various special cases, see the survey [30]. In general, the best known approximation guarantee for EDP and maximum integral multiflows is $O(\sqrt{n})$ [4]. Approximation algorithms with better approximation ratios for various special cases have been designed. We refer the readers to the survey [10] and to [18, 23, 30] and the references therein.

Recent work on the planar case. Recently, [16] and [21] gave constant-factor approximation algorithms for maximum integer multiflows when $G + H$ is planar. Both papers proceed by first obtaining a half-integral multiflow and then using the four color theorem to round it to an integral solution (similar to Section 6). The main difference of the two works is the way such half-integral multiflows are obtained. In [16], it is constructed by uncrossing a fractional multiflow (see Section 5 for a definition) to construct a certain network matrix, which is known to be totally unimodular; in [21], such a half-integral multiflow is obtained

[1] There is a closely related, but different, notion of integral flow-cut gap introduced in [5]: they study the smallest constant c such that whenever $u(C \cap E) \geqslant u(C \cap D)$ for every cut C (the cut condition), there is an integral multiflow satisfying all demands and violating capacities by at most a factor c.

by rounding a feasible solution of a related problem in the planar dual graph of $G+H$. Both approaches do not extend to higher genus graphs in a straightforward way, because the dual of a cycle is no longer a cut in general and cycles cannot always be uncrossed.

Minimum multicut problem. The minimum multicut problem is NP-hard even when there are only three demand edges [11]. In general, assuming that the Unique Games conjecture holds, there is no $O(1)$-approximation [3], but a $O(\log |D|)$-approximation algorithm [17]. Better approximations also have been shown for special cases; see [18, 36] and the references therein. In particular, when $G+H$ is planar, [25] gave an approximation scheme. When G has genus g, an FPT-approximation scheme with parameters of g and $|D|$ has been proposed [8].

Tools from topology. The design of multiflows on surfaces is closely related to the properties of sets of curves on a surface. In a recent breakthrough, Przytycki [31] proved that the maximum number of essential curves on a closed surface of genus g such that no two of them are freely homotopic or intersect more than once is $O(g^3)$, improving on the previous exponential upper bound by [27]. Very recently, this number was shown to be $O(g^2 \log g)$ by [19], which almost matches the lower bound $\Omega(g^2)$ on the size of such sets [27]. We will use this result in Section 7.

2 Preliminaries

Consider an instance (G, H, u) of the maximum integral multiflow problem, and let $G+H = (V, E \dot\cup D)$ be the graph whose edge set is the disjoint union of the edge sets of the supply graph $G = (V, E)$ and the demand graph $H = (V, D)$. Throughout the paper, we assume that the graph $G+H$ is connected, otherwise we can run the algorithm on each of its connected components.

Graphs on surfaces. Surfaces are either orientable or non-orientable; in this paper we only consider closed orientable surfaces. A closed orientable surface of genus g can be seen as a connected sum of g tori, or equivalently a sphere with g handles attached on it, where g is called the *genus* of the surface. Given an integer $g \geqslant 0$, all closed surfaces with genus g are mutually homeomorphic, and we refer to any one of them as $\mathbb{S}_g$. For instance, $\mathbb{S}_0$ is the sphere and $\mathbb{S}_1$ is the torus.

A (multi)graph has *genus* g or is a *genus-g graph*, if it can be drawn on $\mathbb{S}_g$ without edge crossings, but not on $\mathbb{S}_{g-1}$. A genus-g graph may have several non-equivalent embeddings on $\mathbb{S}_g$, but all of them satisfy the same invariant, called the *Euler characteristic*: #Faces − #Edges + #Vertices $= 2 - 2g$.

A simple application of Euler's formula gives the following upper bound on the coloring number of genus-g graphs, when $g \geqslant 1$.

▶ **Theorem 3** (Map color theorem)**.** *A genus-g graph can be colored in polynomial time with at most $\chi_g \leqslant \lfloor \frac{7+\sqrt{1+48g}}{2} \rfloor$ colors.*

For $g = 0$, this is an algorithmic version of the 4-color theorem [32]. For $g \geqslant 1$, the coloring is obtained in polynomial time by a simple recursive algorithm that removes a vertex of minimum degree and colors the remaining graph [20]. For additional details and results about graphs on surfaces see e.g. [29, 9].

Combinatorial embeddings. Given a graph, let $\delta(v)$ denote the set of edges incident to a vertex v, and $\delta(U)$ the set of edges with exactly one endpoint in vertex set U. Given an embedding of a graph on an orientable surface, and an arbitrary orientation of this surface, for each vertex v, a clockwise cyclic order can be defined on the edges of $\delta(v)$. Note that contracting an edge $e = \{u, v\}$ results in removing e from $\delta(u)$ and from $\delta(v)$ and concatenating the orders to obtain the clockwise cyclic order of the edges around the vertex created by the contraction. Using these orders together with the incidence relation between edges and faces, embeddings become purely combinatorial objects. For additional details see, e.g., [29], Chapter 4.

Graph duality. Given an embedding of a genus-g graph G on $\mathbb{S}_g$, there exists a uniquely defined dual graph, denoted as G^*. This graph can be embedded on the same surface as G. There exists a bijection between the faces of G and the vertices of G^*, a bijection between the vertices of G and the faces of G^*, and a bijection between the edge sets of G and of G^*. Moreover, the embeddings of G and G^* are consistent: with this bijection, every edge only crosses its dual edge, every face only contains its corresponding dual vertex and reciprocally. For notational simplicity, the latter bijection is implicit.

Cycles and cuts. A *path* in a graph G is a sequence $(v_0, e_1, v_1, \dots, e_k, v_k)$ for some $k \geqslant 0$, where $v_0, \dots, v_k$ are distinct vertices and $e_i = \{v_{i-1}, v_i\}$ is an edge for all $i = 1, \dots, k$. A *cycle* in a graph G is a sequence $(v_0, e_1, v_1, \dots, e_k, v_k)$ such that $v_1, \dots, v_k$ are distinct vertices, $\{v_{i-1}, v_i\}$ is an edge for all $i = 1, \dots, k$, and $v_0 = v_k$. Sometimes we view cycles as edge sets or as graphs. A *cut* is an edge set $\delta(U)$ for some proper subset $\emptyset \neq U \subset V$. A cut $\delta(U)$ is *simple* if both U and $V \setminus U$ are connected.

We say that an edge set F in a graph is a (simple) *dual cut* if the corresponding set of edges F^* in the dual is a (simple) cut. A cycle C in G is called *separating* if it is a dual cut, and *non-separating* otherwise. Note that every separating cycle is a simple dual cut.

Homotopy. Given a surface $\mathbb{S}$, a (simple) *topological cycle* is a continuous injective map γ from the unit cycle $S^1 := \{z \in \mathbb{C},\ ||z|| = 1\}$ to $\mathbb{S}$. Two topological cycles γ_1 and γ_2 are *freely homotopic* if there exists a continuous function $\varphi : [0, 1] \times S^1 \to \mathbb{S}$ such that $\varphi(0, \cdot) = \gamma_1$ and $\varphi(1, \cdot) = \gamma_2$. Intuitively, cycle γ_1 is transformed into cycle γ_2 by continuously moving it on the surface. Free homotopy is an equivalence relation.

Given an embedding of the graph $G + H$ on $\mathbb{S}$, we say that a cycle C in $G + H$ *is represented*[2] *by* a topological cycle γ of $\mathbb{S}$ if the image of γ is the embedding of C on $\mathbb{S}$. Two cycles in $G + H$ are freely homotopic if and only if they can be represented by two freely homotopic topological cycles. In the sequel, we use the following well-known fact.

▶ **Fact 4.** *If two cycles C and C' are freely homotopic, then their symmetric difference is a dual cut. If C and C' are additionally disjoint and non-separating, then their union is a simple dual cut.*

Intuitively, the image of the continuous homotopy function from C to C' on the surface forms an annulus [12]. See Figure 1 for an illustration.

[2] Topological cycles are considered up to orientation-preserving reparameterization. Therefore, a cycle in $G + H$ may be represented by a topological cycle from two classes, one for each orientation: the class of γ and the class of γ' where $\gamma'(e^{i\theta}) = \gamma(e^{-i\theta})$.

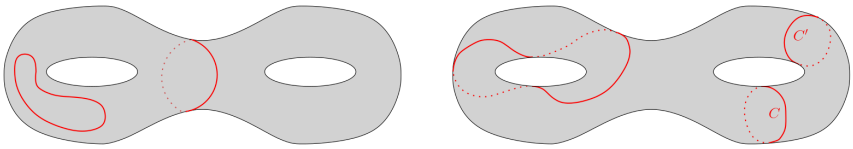

Figure 1 Some cycles on an orientable surface of genus 2. On the left, two *separating* cycles. On the right, three *non-separating* cycles. C and C' are *freely homotopic* and their union disconnects the surface.

3 Overview

In this section, we give an overview of our constant-factor approximation algorithm for the maximum integral multiflow problem when $G+H$ is embedded on an orientable surface $\mathbb{S}_g$ of genus g, where g is bounded by a constant (Theorem 1). Again, without loss of generality, we assume that $G+H$ is connected. Here is the main algorithm. Steps 1,2,3,4 will be described in detail in Sections 4,5,6,7, respectively.

1. Solve the linear program (1) to obtain a (fractional) multiflow f^*.
2. Construct another multiflow $\overline{f}$ such that any two cycles in the support of $\overline{f}$ cross at most once (Lemma 7). See Definition 6 for the definition of "crossing."
3. If at least half of the total value of $\overline{f}$ is contributed by separating cycles, these cycles now form a laminar family. Construct a half-integral multiflow f^{half} (Theorem 10), and from there, using the map color theorem (Theorem 3), compute an integral multiflow f' (Lemma 11), which is the output.
4. Otherwise, partition the non-separating cycles in the support of $\overline{f}$ into free homotopy classes. Pick the class $\mathcal{H}$ with largest total flow value. Remove the flow on all other cycles and greedily construct an integral multiflow (Lemmas 20 and 17), which is the output.

It can be proved that we only lose a constant factor at every step of the algorithm: see Section 8 for the analysis of the above algorithm, proving Theorem 1.

4 Finding a fractional multiflow (Step 1)

A feasible solution f to the maximum multiflow LP (1) will be simply called a *multiflow*. Recall that $\mathcal{C}$ denotes the set of all D-cycles, i.e., all cycles in $G+H$ that contain precisely one demand edge. We denote by $|f| = \sum_{C\in\mathcal{C}} f_C$ the *value* of f, and by $\mathcal{C}(f) := \{C \in \mathcal{C} \mid f_C > 0\}$ the *support* of f. Although formulation (1) has an exponential number of variables, it is well known that it can be reformulated by polynomially many flow variables and constraints (see, e.g., [15, 1]) and thereby solved in polynomial time:

▶ **Proposition 5.** *There is an algorithm that finds an optimal solution f^* to the maximum multiflow LP (1) such that $|\mathcal{C}(f^*)| \leqslant |D||E|$. Its running time is polynomial in the size of the input graph.*

Proof. By introducing flow variables $x_e^d := \sum_{C\in\mathcal{C}:d,e\in C} f_C$ for all $d \in D$ and $e \in D \dot\cup E$ we can maximize the total value $\sum_{d\in D} x_d^d$ subject to nonnegativity and flow conservation constraints (for each $d \in D$ and for each vertex). This is a linear program of polynomial size. By flow decomposition, one can then construct a feasible solution to (1) of the same value and with support at most $|D||E|$. ◀

Later we will restrict a multiflow to subsets of D-cycles. For $\mathcal{C}' \subseteq \mathcal{C}$ we define a multiflow f' by $f'_C := f_C$ for $C \in \mathcal{C}'$ and $f'_C := 0$ for $C \in \mathcal{C} \setminus \mathcal{C}'$, and write $f(\mathcal{C}') := f'$.

5 Making a fractional flow minimally crossing (Step 2)

In this section we show that for a given embedding, we can "uncross" a multiflow in such a way that any two D-cycles in the support cross at most once. While doing this we will lose only an arbitrarily small fraction of the multiflow value.

Uncrossing is a well-known technique in combinatorial optimization, but in most cases it is applied to families of subsets of a ground set U. Such a family is said to be cross-free if, for any two of its sets, A and B, at least one of the four sets $A \setminus B$, $B \setminus A$, $A \cap B$, and $U \setminus (A \cup B)$ is empty. Here we want to uncross D-cycles in the topological sense, and this can be reduced to the above (with some extra care) only if all these cycles are separating (which, for example, is always the case if $G + H$ is planar; cf. [16]).

▶ **Definition 6.** *We say that two D-cycles C_1 and C_2* cross *if there exists a path P (possibly a single vertex), which is a subpath of both C_1 and C_2, and such that in the embedding, after contracting the edges of P, the vertex v thus obtained is incident to two edges of C_1 and to two edges of C_2, all distinct, and in the embedding the restriction of the cyclic order of $\delta(v)$ to those four edges alternates between an edge of C_1 and an edge of C_2.*

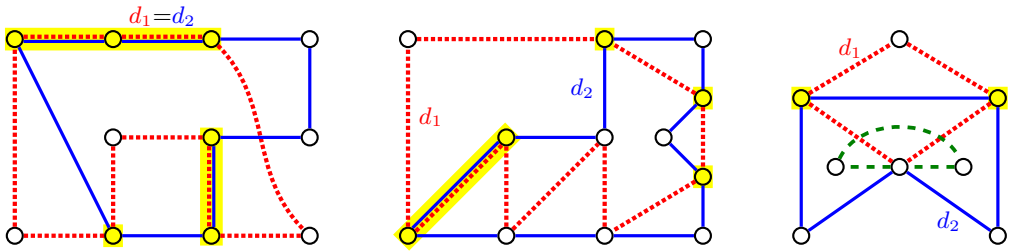

Figure 2 Each of the two figures on the left show two D-cycles, C_1 (red, dotted) and C_2 (blue, solid). The edges belonging to D are marked as d_1 and d_2. Edges are arranged at every vertex in the order of their embedding. Crossings are marked by yellow shade. The two D-cycles on the left cross three times. The two D-cycles in the middle cross four times. The figure on the right shows two D-cycles C_1 and C_2 that cross twice, and a third D-cycle C_3 (green, dashed) that crosses neither C_1 nor C_2. Uncrossing C_1 and C_2 here generates a crossing of C_3 with a new D-cycle (namely with the triangle containing d_2).

Two cycles may cross multiple times. We denote by $cr(C, C')$ the number of times that C and C' cross. See Figure 2 for three examples. In contrast to the planar case, it is possible that two cycles cross exactly once and cannot be uncrossed. The third example in Figure 2 shows another difficulty: when uncrossing two D-cycles it might be necessary to generate new crossings with other cycles.

▶ **Lemma 7.** *Let $\epsilon > 0$ be fixed. Given a multiflow f whose support has size at most $|E||D|$, there is a polynomial-time algorithm to construct another multiflow $\overline{f}$, of value at least $|\overline{f}| \geqslant (1 - \epsilon)|f|$, and such that any two cycles in the support of $\overline{f}$ cross at most once.*

Proof. First we discretize the multiflow, losing an ϵ fraction in value; then we iteratively modify it, without changing its value, to reduce the number of crossings or the total amount of flow on all edges; finally, we analyze the process and argue that the number of iterations is polynomially bounded.

Discretization. The statement is trivial if $|f| = 0$. Otherwise, before uncrossing, we round down the flow on every D-cycle to integer multiples of $\frac{\epsilon|f|}{|E||D|}$. That is, we define $f'_C := \frac{\epsilon|f|}{|E||D|}\left\lfloor \frac{|E||D|f_C}{\epsilon|f|} \right\rfloor$ for all $C \in \mathcal{C}$. Note that f' is a multiflow. We claim that $|f'| \geqslant (1-\epsilon)|f|$. Indeed,

$$|f'| = \sum_{C\in\mathcal{C}} f'_C \geqslant \sum_{C\in\mathcal{C}(f)} \left(f_C - \frac{\epsilon|f|}{|E||D|} \right) = |f| - |\mathcal{C}(f)|\frac{\epsilon|f|}{|E||D|} \geqslant |f| - \epsilon|f|.$$

The discretized multiflow f' can be represented by a multi-set $\mathcal{S}$ of unweighted D-cycles: if $f'_C = k\frac{\epsilon|f|}{|E||D|}$, then k identical copies of cycle C are added to $\mathcal{S}$. The number of cycles in $\mathcal{S}$ (counting multiplicities) is at most $\frac{|E||D|}{\epsilon}$ because $|\mathcal{S}| = \sum_{C\in\mathcal{C}} f'_C \frac{|E||D|}{\epsilon|f|} \leqslant \sum_{C\in\mathcal{C}} f_C \frac{|E||D|}{\epsilon|f|} = \frac{|E||D|}{\epsilon}$.

Uncrossing. To construct $\overline{f}$, we perform a sequence of transformations of the multiflow. We will modify $\mathcal{S}$ while maintaining the following invariants:

(a) The number of elements of $\mathcal{S}$ (counting multiplicities) remains constant.

(b) For every $e \in D \dot\cup E$, the number of elements of $\mathcal{S}$ (counting multiplicities) that contain e never increases.

Thanks to (b), at any stage, $\overline{f}$ is a multiflow, where $\overline{f}$ is defined by $\overline{f}_C = k\frac{\epsilon|f|}{|E||D|}$ for $C \in \mathcal{C}$, where k is the multiplicity of C in $\mathcal{S}$. Initially $\overline{f} = f'$. Thanks to (a), the value of the multiflow is preserved. In the following we work only with $\mathcal{S}$.

While there exist two cycles C_1 and C_2 in $\mathcal{S}$ that cross at least twice, do the following *uncrossing* operation (on one copy of C_1 and one copy of C_2). Let d_1 be the edge in $C_1 \cap D$, and let d_2 be the edge in $C_2 \cap D$. Let P and Q be two of the paths where C_1 and C_2 cross (cf. Definition 6), such that Q contains only edges of E. Orient C_1 so that in that orientation, when traversing the entirety of P and then walking towards Q, edge d_1 is traversed before reaching Q. Let $\vec{C}_1$ denote the resulting directed cycle. Let a be the first vertex on P in the orientation of $\vec{C}_1$, and let b be an arbitrary vertex on Q. Vertices a and b partition $\vec{C}_1$ into a path C_1^+ from a to b that contains d_1 and a path C_1^- from b to a that does not contain d_1.

Case 1: P contains an edge of D. Then this edge is $d_1 = d_2$. We orient C_2 so that the orientation on P agrees with the orientation of $\vec{C}_1$ on P. Let $\vec{C}_2$ denote the resulting directed cycle. Then the vertices a and b also partition $\vec{C}_2$ into a path C_2^+ from a to b that contains d_2 and a path C_2^- from b to a that does not contain d_2.

Case 2: P contains edges of E only. Then we orient C_2 so that in that orientation, when traversing the entirety of P and then walking towards Q, edge d_2 is traversed before reaching Q. Let $\vec{C}_2$ denote the directed cycle. With that orientation, vertices a and b also partition $\vec{C}_2$ into a path C_2^+ from a to b that contains d_2 and a path C_2^- from b to a that does not contain d_2.

To obtain C'_1, we concatenate C_1^+ and C_2^-, remove any cycle that does not contain d_1, and remove the orientation. To obtain C'_2, we concatenate C_2^+ and C_1^-, remove any cycle that does not contain d_2, and remove the orientation. Note that C'_1 and C'_2 are D-cycles because each of C_1^+ and C_2^+ contains exactly one demand edge, and C_1^- and C_2^- contain no demand edge.

See Figure 3 for two examples, one for each case.

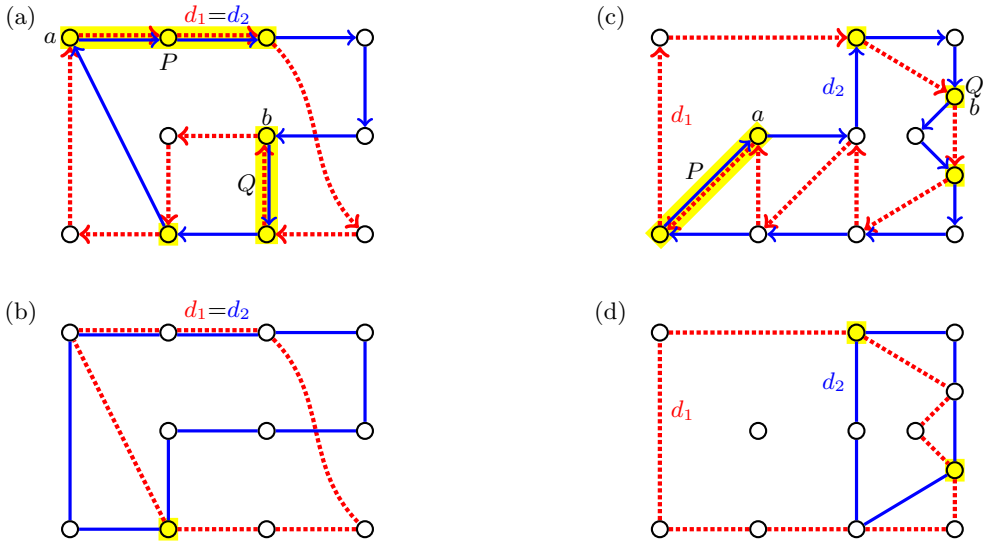

Figure 3 Uncrossing the pairs of D-cycles from Figure 2. (a) and (b) show an example for Case 1, (c) and (d) an example for Case 2. The initial situation (C_1 red, dotted, and C_2 blue, solid) and a possible choice of P, Q, a, b and the resulting orientation is shown in (a) and (c). As the result of the uncrossing operation, shown in (b) and (d), we have the new D-cycles C_1' (red, dotted) and C_2' (blue, solid) with fewer crossings among each other.

Analysis. From the construction it follows that C_1' and C_2' are D-cycles and $C_1' \dot\cup C_2' \subseteq C_1 \dot\cup C_2$. Hence removing one copy of C_1 and C_2 from $\mathcal{S}$ and adding one copy of C_1' and C_2' to $\mathcal{S}$ maintains the invariants (a) and (b).

To show that the after a polynomial number of uncrossing operations any pair of cycles in $\mathcal{S}$ crosses at most once, we consider the total number of edges $\Phi_1 = \sum_{C \in \mathcal{S}} |C|$ (counting multiplicities) and the total number of crossings $\Phi_2 = \sum_{C,C' \in \mathcal{S}} cr(C, C')$ (where we again count multiplicities). Note that $|\mathcal{S}|$ remains constant by invariant (a), and Φ_1 never increases by invariant (b). Moreover $0 \leqslant \Phi_1 \leqslant |V||\mathcal{S}|$ and $0 \leqslant |\Phi_2| \leqslant |V||\mathcal{S}|^2$.

▷ Claim 8. Each uncrossing operation either decreases Φ_1 or leaves Φ_1 unchanged and decreases Φ_2.

To prove Claim 8, consider an uncrossing operation that replaces C_1 and C_2 by C_1' and C_2', and suppose that Φ_1 remains the same, so C_1' consists of C_1^+ plus C_2^-, and C_2' consists of C_2^+ plus C_1^-. We first observe that $cr(C_1', C_2') < cr(C_1, C_2)$. Indeed, the crossings at P and at Q go away, and no new crossing arises.

Finally we need to show that for any cycle $C \in \mathcal{C}$,

$$cr(C, C_1') + cr(C, C_2') \leqslant cr(C, C_1) + cr(C, C_2). \tag{4}$$

To show (4), consider a crossing of C and $C' \in \{C_1', C_2'\}$ at a path R. Let $e_1' = \{v_0, v_1\}, \dots, e_k' = \{v_{k-1}, v_k\}$ be the edges of R ($k \geqslant 0$), and let $e_0, e_{k+1}, e_0', e_{k+1}'$ be edges such that $e_0, e_1', \dots, e_k', e_{k+1}$ are subsequent on C and $e_0', e_1', \dots, e_k', e_{k+1}'$ are subsequent on C'. After contracting R, the incident edges $e_0, e_0', e_{k+1}, e_{k+1}'$ are embedded in this cyclic order. (Note that $e_0 = e_{k+1}$ or $e_0' = e_{k+1}'$ is possible if $k \geqslant 1$, then contracting R yields a loop.) See Figure 4 (a).

Now e_0' belongs to C_1 or C_2, say C_1. If R contains neither a nor b, then $e_0', \dots, e_{k+1}'$ all belong to C_1, and C_1 crosses C at R. If R contains either a or b, say at v_i, then $e_0', \dots, e_i'$ belong to C_1 and $e_{i+1}', \dots, e_{k+1}'$ belong to C_2. Moreover C_1 and C_2 cross at a path containing

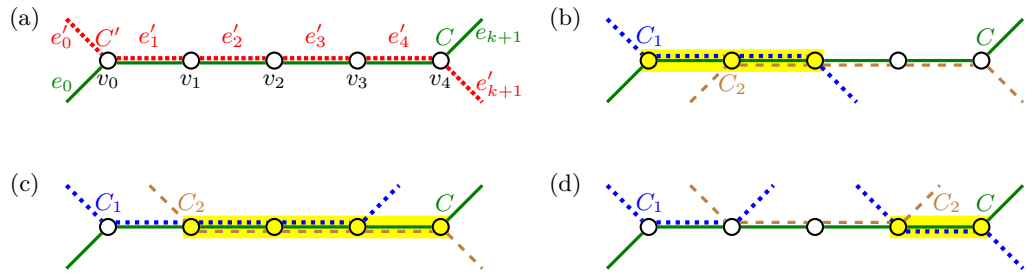

Figure 4 For each crossing of C with a new cycle $C' \in \{C'_1, C'_2\}$ at a path R there is a crossing of C with one of the old cycles C_1 and C_2 at a subpath of R. This crossing is marked with yellow shade in the three examples.

v_i, so either C_1 crosses C at a subpath of R (Figure 4(b)) or C_2 crosses C at a subpath of R (Figure 4(c)). Finally, if R contains a and b, say at v_i and v_j for $0 \leqslant i < j \leqslant k$, then $e'_0, \ldots, e'_i$ and $e'_{j+1}, \ldots, e'_{k+1}$ belong to C_1 and $e'_{i+1}, \ldots, e'_j$ belong to C_2 (Figure 4(d)). Again, C_1 or C_2 crosses C at a subpath of R. This concludes the proof of Claim 8.

We can now conclude the proof of Lemma 7 because Φ_1 decreases at most $|V||\mathcal{S}|$ times, and while Φ_1 is constant, Φ_2 decreases at most $|V||\mathcal{S}|^2$ times, so the total number of uncrossing operations is at most $|V|^2|\mathcal{S}|^3 \leqslant \frac{|V|^2|E|^3|D|^3}{\epsilon^3}$. ◀

6 Separating cycles: routing an integral flow (Step 3)

Let $\overline{f}$ result from Lemma 7, and let $\mathcal{C}_{\text{sep}}$ denote the set of separating cycles in the support of $\overline{f}$. We now consider the case when the separating cycles contribute at least half to the total flow value, i.e., $|\overline{f}(\mathcal{C}_{\text{sep}})| \geqslant \frac{1}{2}|\overline{f}|$.

This branch of our algorithm consists of two steps:

1. Given $\overline{f}(\mathcal{C}_{\text{sep}})$, construct a half-integral multiflow f^{half} of value at least $|\overline{f}|/2$;
2. Given f^{half}, construct an integral multiflow of value at least $|f^{\text{half}}|/\Theta(\sqrt{g})$.

6.1 Obtaining a half-integral multiflow

To obtain a half-integral multiflow, we follow the technique used by [16] for the case where $G + H$ is planar. By the Jordan curve theorem, any cycle in a planar graph is separating. As for the plane, the following property is easy to check for higher genus surfaces.

▶ **Proposition 9.** *If C and C' are two cycles embedded on a surface, and C' is a separating cycle, then C and C' must cross an even number of times.*

Proof. C' is separating the surface into two sides. While walking along C from a vertex v, we go from one side to the other each time we cross C'. When we return at v, we are on the same side where we started so the number of crossing is even. ◀

Since any pair of cycles in the support of $\overline{f}$ crosses at most once, $\mathcal{C}_{\text{sep}}$ must be a non-crossing family by Proposition 9. In particular, we can show that $\mathcal{C}_{\text{sep}}$ have a laminar structure.

We say that a family of subsets of the dual vertex set V^* is laminar if any two members either are disjoint or one contains the other. Let us take any face of $G + H$ that we call ∞. For any cycle $C \in \mathcal{C}_{\text{sep}}$ we define $\text{in}(C)$ and $\text{out}(C)$ to be the two connected components of $(G + H)^* \setminus C^*$, such that $\infty \in \text{out}(C)$. We claim that the family $\mathcal{L} := \{\text{in}(C) : C \in \mathcal{C}_{\text{sep}}\}$ is laminar.

Indeed, take any two cycles C and C' in $\mathcal{C}_{\text{sep}}$. Since they do not cross, either (i) $(C' \setminus C)^* \subseteq \text{in}(C)$ or, (ii) $(C' \setminus C)^* \subseteq \text{out}(C)$. In case (i) we must have $\text{in}(C') \subseteq \text{in}(C)$. In case (ii), we have either (ii.a) $\text{in}(C) \subseteq \text{in}(C')$ or (ii.b) $\text{in}(C) \cap \text{in}(C') = \emptyset$, hence laminarity.

Using the terminology in [16], we say that a multiflow f is *laminar* if $\{C^* : C \in \mathcal{C},\ f_C > 0\} = \{\delta(U) : U \in \mathcal{L}\}$ where $\mathcal{L}$ is a laminar family (of subsets of V^*). Thus, $\overline{f}(\mathcal{C}_{\text{sep}})$ is laminar and we can apply the following result to get f^{half}.

▶ **Theorem 10** ([16]). *If f is a laminar multiflow, then there exists a laminar half-integral multiflow f' such that $\mathcal{C}(f') \subseteq \mathcal{C}(f)$ of value $|f'| \geqslant \frac{1}{2}|f|$. Such a multiflow can be computed in polynomial time.*

6.2 Obtaining an integral multiflow

In this section we show the following result, which is an extension of a result from [21, 16], who proved it for planar graphs.

▶ **Lemma 11.** *Let (G, H, u) be an instance of the maximum multiflow problem such that $G+H$ has genus g, and let f^{half} be a laminar half-integral multiflow whose support $\mathcal{C}(f^{\text{half}})$ contains only separating cycles. Then there exists an integral multiflow f' of value $|f'| \geqslant 2|f^{\text{half}}|/\chi_g$ (such that $\mathcal{C}(f') \subseteq \mathcal{C}(f^{\text{half}})$). Such a multiflow can be found in polynomial time.*

Our proof follows the same outline as the proof of Theorem 1 of Fiorini et al. [14]. Let $\mathcal{C}^{\text{half}} := \mathcal{C}(f^{\text{half}})$ be the set of D-cycles C such that $f^{\text{half}}_C > 0$. We first reduce the problem to the case where all cycles in $\mathcal{C}^{\text{half}}$ have flow value $\frac{1}{2}$ and every edge has capacity 1. To do that, we reduce the flow f^{half}_C by $\lfloor f^{\text{half}}_C \rfloor$ for each cycle $C \in \mathcal{C}^{\text{half}}$, and reduce edge capacities accordingly. Then, since now f^{half} is small, we can further reduce demands and capacities to $u'(e) = \min\{u(e), |\mathcal{C}(f^{\text{half}})|\}$ for each $e \in E \cup D$, so that $\sum_{e \in D \dot\cup E} u(e)$ is polynomially bounded. We can then replace each edge e by $u(e)$ parallel edges of unit capacity. Given a cycle C such that $f^{\text{half}}_C = \frac{1}{2}$, we replace each edge $e \in C$ by one of its parallel edges. This can be done while ensuring that the resulting flow is still feasible and laminar. To facilitate the proof, we still denote this graph by $G + H$ and keep all other notations.

Recall that cycles in $\mathcal{C}^{\text{half}} \subseteq \mathcal{C}_{\text{sep}}$ are separating and do not cross each other, so that the family $\{\text{in}(C), C \in \mathcal{C}^{\text{half}}\}$ is laminar. We partially order $\mathcal{C}^{\text{half}}$ with the following relation: $C \prec C'$ if $\text{in}(C) \subset \text{in}(C')$. We have the following simple property:

▶ **Lemma 12.** *If $C_1, C_2, C' \in \mathcal{C}^{\text{half}}$ are such that $C_1 \prec C'$ and $C_2 \not\prec C'$, then C_1 and C_2 are edge-disjoint.*

For the proof, see the full version of the paper. Our goal is to get a large subset $\mathcal{C}' \subseteq \mathcal{C}^{\text{half}}$ such that any two cycles in $\mathcal{C}'$, are edge-disjoint. This is equivalent to finding a large independent set in a properly defined graph $\text{Int}(\mathcal{C}^{\text{half}})$ with vertex set $\mathcal{C}^{\text{half}}$ and such that two cycles are adjacent if they share at least one edge. Using Lemma 12 we can show:

▶ **Lemma 13.** *Given a graph embedded in $\mathbb{S}_g$, let $\mathcal{C}^{half}$ be defined as above. Let $Int(\mathcal{C}^{half})$ be the graph with vertex set $\mathcal{C}^{half}$ and such that two cycles are adjacent if they share at least one edge. Then $Int(\mathcal{C}^{half})$ is a genus-g graph.*

Proof. We prove the statement by induction on $g + |\mathcal{C}^{\text{half}}|$. When $g + |\mathcal{C}^{\text{half}}| \leqslant 2$, it is trivial. Otherwise let G be a connected genus-g graph, embedded on $\mathbb{S}_g$, and $\mathcal{C}^{\text{half}}$ a family as described above.

Suppose first that $\{\text{in}(C) \mid C \in \mathcal{C}^{\text{half}}\}$ are pairwise disjoint. Then, contract in G^* each set $\text{in}(C)$ into a single node. Two cycles C and C' share an edge if and only if in this contracted graph, the nodes corresponding to $\text{in}(C)$ and $\text{in}(C')$ are adjacent. This means that $\text{Int}(\mathcal{C}^{\text{half}})$ is a minor of G^*, and in particular has genus less than or equal to the genus of G^*.

The case where there is one cycle $\bar{C}$ such that $C \prec \bar{C}$ for all $C \in \mathcal{C}^{\text{half}} \setminus \bar{C}$ and $\{\text{in}(C) \mid C \in \mathcal{C}^{\text{half}} \setminus \bar{C}\}$ are pairwise disjoint works similarly; here we contract $\text{out}(\bar{C})$.

Otherwise there exists a triple $C_1, C_2, C \in \mathcal{C}^{\text{half}}$ such that $C_1 \prec C$ and $C_2 \not\prec C$. The separating cycle C divides $\mathbb{S}_g$ into two sides. Each side can be closed – by identifying the boundary of a disk with the boundary form by C – so that they are homeomorphic to $\mathbb{S}_{g_{\text{in}}}$ and $\mathbb{S}_{g_{\text{out}}}$, respectively. The connected sum of these two surfaces is homeomorphic to $\mathbb{S}_g$, and in particular we have $g_{\text{in}} + g_{\text{out}} = g$. This equality can easily be checked with Euler's formula.

Let G_{in} (*resp.* G_{out}) be the subgraph of G induced by the vertices embedded on the side corresponding to $\mathbb{S}_{g_{\text{in}}}$ (*resp.* $\mathbb{S}_{g_{\text{out}}}$), such that both contain C. The embedding of G in $\mathbb{S}_g$ induces an embedding of G_{in} in $\mathbb{S}_{g_{\text{in}}}$ and an embedding of G_{out} in $\mathbb{S}_{g_{\text{out}}}$. Thus, $\text{genus}(G_{\text{in}}) + \text{genus}(G_{\text{out}}) \leqslant g$.

Now we define $\mathcal{C}^{\text{half}}_{\preceq C} := \{C' \in \mathcal{C}^{\text{half}} | C' \prec C\} \cup \{C\}$ and $\mathcal{C}^{\text{half}}_{\not\prec C} := \{C' \in \mathcal{C}^{\text{half}} | C' \not\prec C\} \cup \{C\}$. The choice of C implies that these two families are proper subsets of $\mathcal{C}^{\text{half}}$. Since the cycles in $\mathcal{C}^{\text{half}}$ do not cross, we have $\{C \in \mathcal{C}^{\text{half}} : C \subseteq G_{\text{in}}\} = \mathcal{C}^{\text{half}}_{\preceq C}$ and $\{C \in \mathcal{C}^{\text{half}} : C \subseteq G_{\text{out}}\} = \mathcal{C}^{\text{half}}_{\not\prec C}$.

By the induction hypothesis, $\text{Int}(\mathcal{C}^{\text{half}}_{\preceq C})$ and $\text{Int}(\mathcal{C}^{\text{half}}_{\not\prec C})$ can be embedded on $\mathbb{S}_{g_{\text{in}}}$ and $\mathbb{S}_{g_{\text{out}}}$, respectively. By Lemma 12, the graph $\text{Int}(\mathcal{C}^{\text{half}})$ arises from $\text{Int}(\mathcal{C}^{\text{half}}_{\preceq C})$ and $\text{Int}(\mathcal{C}^{\text{half}}_{\not\prec C})$ by identifying the two vertices that correspond to C.

Finally we prove that $\text{Int}(\mathcal{C}^{\text{half}})$ can be embedded on a surface genus $g_{\text{in}} + g_{\text{out}} \leqslant g$. To see that, remove small disks D_{in} and D_{out} in $\mathbb{S}_{g_{\text{in}}}$ and $\mathbb{S}_{g_{\text{out}}}$, respectively, around the point that corresponds to vertex C and that intersects only edges incident to C, and glue them together by identifying boundaries of D_{in} and D_{out}. The surface obtained is homeomorphic to $\mathbb{S}_{g_{\text{in}}+g_{\text{out}}}$ It is easy to see that C, and the edges incident to C, can be re-embedded in this surface without intersecting any other edges. This terminates the proof of Lemma 13. ◀

Using Theorem 3, this lemma ensures that one can compute in polynomial time a subset $\mathcal{C}' \subseteq \mathcal{C}^{\text{half}}$ of at least $|\mathcal{C}^{\text{half}}|/\chi_g$ pairwise edge-disjoint D-cycles. From this set, we define an integral multiflow by setting $f'_C = 1$ for $C \in \mathcal{C}'$ and $f'_C = 0$ for $C \in \mathcal{C} \setminus \mathcal{C}'$. It is easy to check that f' is a multiflow that satisfies the properties of Lemma 11.

7 Non-separating cycles: routing an integral multiflow (Step 4)

If the separating cycles contribute less than half to the total value of the multiflow $\overline{f}$ obtained by Lemma 7, we consider the non-separating cycles in the support of $\overline{f}$. We first partition them into *free homotopy classes*. The next theorem gives an upper bound on the number of such classes.

▶ **Theorem 14** ([19]). *Let $\mathbb{S}_g$ be an orientable surface of genus g. Then there are at most $O(g^2 \log g)$ topological cycles such that any two of them are in different free homotopy classes and cross each other at most once.*

▶ **Corollary 15.** *The D-cycles in the support of $\overline{f}$ can be partitioned into $O(g^2 \log g)$ free homotopy classes in polynomial time.*

Proof. Take pairs of cycles in the support of $\overline{f}$ and check whether they are freely homotopic, for example as in [13, 26]. ◀

7.1 Greedy algorithm

Let $\mathcal{H}$ be a free homotopy class of non-separating cycles whose total flow value $|\overline{f}(\mathcal{H})|$ is largest. We will run the following simple greedy algorithm (Algorithm 1) on $\mathcal{H}$ to get an integral multiflow.

Algorithm 1 Greedy algorithm for integral multiflows.

Input: a sequence $C_1, \dots, C_k$ of D-cycles of $\mathcal{C}(\overline{f})$.
Output: an integral multiflow f.
$f \leftarrow$ the all-zero multiflow;
for $i = 1$ *to* k **do**
  Set f_{C_i} to be the greatest integer such that f remains feasible.

The value of the integral multiflow returned by this algorithm depends on the order of the D-cycles in the input. If it is ordered according to the following definition, then we show that we lose only a constant fraction of the flow value.

▶ **Definition 16.** *A family of cycles $\{C_1, C_2, \dots, C_k\}$ is* cyclically ordered*, or has a* cyclic order *if, whenever two cycles C_a and C_b share an edge, where $a < b$, then this edge is:*

1. *shared by all cycles $C_a, C_{a+1}, \dots, C_{b-1}, C_b$,*
2. *or shared by all cycles $C_b, C_{b+1}, \dots, C_k, C_1, \cdots, C_{a-1}, C_a$.*

The following lemma establishes the approximation ratio of Algorithm 1 on cyclically ordered input.

▶ **Lemma 17.** *Let $\overline{f}$ be a multiflow and $\mathcal{H} = \{C_1, C_2, \dots, C_k\}$ a cyclically ordered family of $\mathcal{C}(\overline{f})$. Then Algorithm 1 returns in polynomial time an integral multiflow of value at least $|\overline{f}(\{C_1, \dots, C_k\})|/2$.*

Proof. Let $\overline{f}$ be a multiflow and $\mathcal{H} = \{C_1, C_2, \dots, C_k\}$ a cyclically ordered family of $\mathcal{C}(\overline{f})$. It is clear that Algorithm 1 runs in polynomial time and returns an integral multiflow. Let f be this flow. We show that its value is at least $|\overline{f}(\mathcal{H})|/2$.

Let us define $\mathcal{H}_{a,b} = \{C_a, C_{a+1}, \dots, C_{b-1}\}$ and $\mathcal{H}_{b,a} = \{C_b, C_{b+1}, \dots, C_k, C_1, \dots, C_{a-1}\}$ for all $1 \leqslant a \leqslant b \leqslant k$. Additionally, for all edges $e \in \bigcup_{C \in \mathcal{H}} C$, we define $\mathcal{H}^e := \{C \in \mathcal{H} \mid e \in C\}$. Since we assumed that $\mathcal{H}$ is cyclically ordered, we know that for each $e \in \bigcup_{C \in \mathcal{H}} C$, there are indexes $1 \leqslant a, b \leqslant k$, such that $\mathcal{H}^e = \mathcal{H}_{a,b}$.

We call i_0 the smallest index $1 \leqslant i \leqslant k$ such that there exists an edge $e \in C_i$ such that $f(\mathcal{H}_{1,i+1})(e) = u(e)$ and $\mathcal{H}_{i,1} \subseteq \mathcal{H}^e$. Remark that in particular, for all $i > i_0$, we must have $f_{C_i} = 0$, and thus $|f| = |f(\mathcal{H}_{1,i_0+1})|$.

We first show by induction that for all $1 \leqslant i < i_0$ we have $|f(\mathcal{H}_{1,i+1})| \geqslant |\overline{f}(\mathcal{H}_{1,i+1})|$. For $i = 1$, we have $|f(\mathcal{H}_{1,i+1})| = |f(\mathcal{H}_{1,2})| = f_{C_1} = \min\{u(e) | e \in C_1\} \geqslant \overline{f}_{C_1} = |\overline{f}(\mathcal{H}_{1,2})|$.

Assume now that at some iteration $1 < i < i_0$ of the algorithm we set $f_{C_i} = x$. By the choice of x, we know that there is an edge $e \in C_i$ such that $u(e) = f(\mathcal{H}_{1,i+1})(e)$. In particular, notice that $|f(\mathcal{H}^e)| = |f(\mathcal{H}^e \cap \mathcal{H}_{1,i+1})| = u(e)$. By feasibility of $\overline{f}$, we have

$$|f(\mathcal{H}^e \cap \mathcal{H}_{1,i+1})| = u(e) \geqslant |\overline{f}(\mathcal{H}^e)|. \tag{5}$$

Now, let a, b be the two indexes such that $\mathcal{H}_{a,b} = \mathcal{H}^e$. Since we assumed that $i < i_0$, we must have $i < b \leqslant k$. There are two cases: either $1 \leqslant a \leqslant i < b$ or $1 < i < b < a$.

If $1 \leqslant a \leqslant i < b$, then equation (5) becomes $|f(\mathcal{H}_{a,i+1})| \geqslant |\overline{f}(\mathcal{H}^e)| \geqslant |\overline{f}(\mathcal{H}_{a,i+1})|$. Together with the induction hypothesis we obtain:

$$|f(\mathcal{H}_{1,i+1})| = |f(\mathcal{H}_{1,a})| + |f(\mathcal{H}_{a,i+1})| \geqslant |\overline{f}(\mathcal{H}_{1,a})| + |\overline{f}(\mathcal{H}_{a,i+1})| = |\overline{f}(\mathcal{H}_{1,i+1})|.$$

Otherwise if $1 < i < b < a$, then $\mathcal{H}_{1,i+1} \subseteq \mathcal{H}^e$, and thus the inequality claimed follows directly from equation (5). We have established the induction. In particular, we have proved that $|f| = |f(\mathcal{H}_{1,i_0+1})| \geqslant |f(\mathcal{H}_{1,i_0})| \geqslant |\overline{f}(\mathcal{H}_{1,i_0})|$. To conclude the proof of Lemma 17, it remains to show that $|f| \geqslant |\overline{f}(\mathcal{H}_{i_0,1})|$.

By definition of i_0, we know that there exists an edge $e \in C_{i_0}$ such that $f(e) = u(e)$ and such that $\mathcal{H}_{i_0,1} \subseteq \mathcal{H}^e$. By feasibility of $\overline{f}$, we deduce that $|\overline{f}(\mathcal{H}_{i_0,1})| \leqslant u(e) = f(e) \leqslant |f|$. This concludes the proof. ◀

▶ Remark 18. The analysis of Algorithm 1 for cyclically ordered inputs is tight. To see this, imagine that $\mathcal{H} = \{C_1, \ldots, C_{2k-1}\}$, and there are two edges e_1, e_2, both of capacity k, such that $\{C \in \mathcal{H} \mid e_1 \in C\} = \{C_1, \ldots, C_k\}$ and $\{C \in \mathcal{H} \mid e_2 \in C\} = \{C_{k+1}, \ldots, C_{2k-1}, C_1\}$. Then Algorithm 1 may only set $f_{C_1} = k$ while $\overline{f}$ could be such that $\overline{f}_C = 1$ for all $C \in \mathcal{H}$, for a total value $2k - 1$.

7.2 Computing a cyclic order

Lemma 20, the second main result of the section, states that a family $\mathcal{H}$ of pairwise freely homotopic cycles crossing at most once can be cyclically ordered in polynomial time. One key ingredient in the proof is that cycles in $\mathcal{H}$ are pairwise non-crossing. This fact uses the assumption that the surface is orientable. In a non-orientable surface, two freely homotopic cycles may cross exactly once.

Recall that $\overline{f}$ denotes the minimally-crossing multiflow obtained by Lemma 7.

▶ **Lemma 19.** *Two freely homotopic cycles in $\mathcal{C}(\overline{f})$ do not cross.*

For the proof of this simple topological fact, see the full version.

▶ **Lemma 20.** *A family of non-separating, pairwise non-crossing and freely homotopic cycles of a graph embedded in an orientable surface can be cyclically ordered. Such a cyclic order can be found in polynomial time.*

This result holds more generally for a family of *non-contractible*[3], pairwise non-crossing and freely homotopic cycles. For simplicity, we only consider the special case of non-separating cycles, which is sufficient for our main result.

Proof. Let $\mathcal{H}$ be a set of non-separating, pairwise freely homotopic and non-crossing cycles. We first order the cycles in $\mathcal{H}$ and then prove that this is a cyclic order. We assume that $|\mathcal{H}| \geqslant 3$, otherwise any order on $\mathcal{H}$ is a cyclic order.

In topology it is usually more convenient to work with disjoint cycles. If two (graph) cycles do not cross, but may share common edges, it is possible to continuously deform by free homotopy one of them, into an arbitrarily small open neighborhood so that the two resulting (topological) cycles are now disjoint.

In the context of graph cycles, we now give a reduction from the setting of Lemma 20 to the special case where the cycles are disjoint. Initially, $Q = G + H$.

[3] all cycles that are not freely homotopic to a point on the surface.

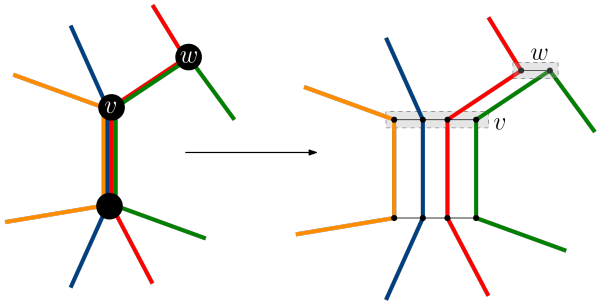

Figure 5 Construction of Q.

Step 1: If an edge is shared by s cycles, replace it s parallel edges. Each of these edges corresponds to a different cycle so that the resulting set of cycles is still pairwise non-crossing. Now the cycles are pairwise edge-disjoint but may still share some vertices.

Step 2: Let v be a vertex shared by two cycles C and C'. Edges incident to v are embedded around v in the cyclic order $e_1, a_1, \dots, a_i, e_2, b_1, \dots, b_j$ where $C \cap \delta(v) = \{e_1, e_2\}$. Since C and C' do not cross, we have $C' \cap \delta(v) \subseteq \{a_1, \dots, a_i\}$ or $C' \cap \delta(v) \subseteq \{b_1, \dots, b_j\}$. Then replace v by two adjacent vertices v', v'' and distribute the incident edges so that $\delta(v') = (e_1, a_1, \dots, a_i, e_2, \{v', v''\})$ and $\delta(v'') = (\{v', v''\}, b_1, \dots, b_j)$. Repeat step 2 until all cycles are vertex-disjoint.

It is easy to see that this graph is connected (since $G + H$ is connected) and can be embedded in the same surface $\mathbb{S}_g$. Figure 5 illustrates the construction of Q. Moreover, a cyclic ordering of the resulting cycles naturally induces a cyclic ordering of H. This completes the reduction. For simplicity, let us also call $\mathcal{H}$ the family of cycles in Q.

In the dual Q^*, let $\mathcal{K}$ denote the set of connected components of $Q^* \setminus \left(\bigcup_{C \in \mathcal{H}} C^*\right)$. They correspond to the connected components of $\mathbb{S}_g \setminus \left(\bigcup_{C \in \mathcal{H}} C\right)$. We say that a cycle $C \in \mathcal{H}$ is *incident* to a connected component $K \in \mathcal{K}$ if there is an edge in C^* with one endpoint in K. Consider the bipartite graph B that has a vertex for each cycle in $\mathcal{H}$ and a vertex for each element of $\mathcal{K}$, and whose edges represent the incidence relation. Next we show that the graph B is a cycle, and we order the D-cycles in $\mathcal{H}$ according to the cyclic order induced by B.

▷ Claim 21. B is a cycle.

The connectivity of B follows by construction from the connectivity of Q. Then it is enough to prove that this graph is 2-regular.

We first prove that each vertex of B that corresponds to a cycle in $\mathcal{H}$ has degree two in B. Since the cycles in $\mathcal{H}$ are disjoint, each cycle C has one component on its left, and one on its right, when we walk along the cycle. Assume, for a contradiction, that they are the same component: C is incident to only one component of $\mathbb{S}_g \setminus \left(\bigcup_{C \in \mathcal{H}} C\right)$. This cycle is also incident to only one component of $\mathbb{S}_g \setminus (C \cup C')$ where C' is any other cycle in $\mathcal{H}$. By Fact 4, we know that $\mathbb{S}_g \setminus (C \cup C')$ has two connected components. But since C is incident to only one connected component of $\mathbb{S}_g \setminus (C \cup C')$, $\mathbb{S}_g \setminus C'$ must also have two connected components, which contradicts the assumption that C' is non-separating. Thus, each cycle in B must have degree two.

Now we prove that each element of $\mathcal{K}$ has degree two. For a contradiction, assume that an element of $\mathcal{K}$ is incident to three cycles C, C', C'' or more. Then one component of $Q^* \setminus (C \cup C' \cup C'')$ is also incident to C, C' and C'', and $Q^* \setminus (C \cup C' \cup C'')$ has two or three components in total. If it has three components, then one of the other two components

would be incident to exactly one cycle, which would mean that this cycle is separating, a contradiction. If $Q^* \setminus (C \cup C' \cup C'')$ has exactly two connected components, then $Q^* \setminus (C \cup C')$ must be connected which contradicts Fact 4. Thus, each component is incident to exactly two cycles. This concludes the proof of the claim.

It remains to show that the order induced by B satisfies the property of Definition 16. If an edge $e = \{u, v\}$ of $G + H$ is shared by some cycles $C'_1, \ldots, C'_\ell$, then the vertex v can be mapped to a path $P = (v_1, \ldots, v_\ell)$ in Q, so that $C'_i \cap P = \{v_i\}, 1 \leqslant i \leqslant \ell$. See Figure 5. It follows that for all $1 \leqslant i \leqslant \ell - 1$, C'_i and C'_{i+1} are both incident the same connected component of $Q^* \setminus \left(\bigcup_{C \in \mathcal{H}} C\right)$ that contains the edge $\{v_i, v_{i+1}\}^*$. In particular, C'_i and C'_{i+1} are consecutive in the order induced by B. ◀

8 Proof of Theorem 1

By construction, the output of the algorithm is a feasible solution. We now analyze the value of the output. Since (1) is a relaxation of the maximum integral multiflow problem, $|f^*| \geqslant \mathrm{OPT}$. By Lemma 7, $|\overline{f}| \geqslant (1 - \epsilon)|f^*|$. For $\epsilon = \frac{1}{2}$ we have $|\overline{f}| \geqslant \frac{1}{2}|f^*|$.

Consider the multiflow restricted to separating cycles, $\overline{f}_{\mathrm{sep}}$. If $|\overline{f}_{\mathrm{sep}}| \geqslant \frac{1}{2}|\overline{f}|$, then by Theorem 10, Lemma 11, and Theorem 3 we obtain an integral flow of value at least $|\overline{f}_{\mathrm{sep}}|/\Theta(\sqrt{g})$.

Otherwise, by Theorem 14 there exists a free homotopy class $\mathcal{H}$ of non-separating cycles such that $|\overline{f}(\mathcal{H})| \geqslant |\overline{f}|/\Theta(g^2 \log g)$. Use Lemmas 17 and 20 to obtain that the output has value at least $|f^*|/\Theta(g^2 \log g)$.

Finally, we analyze the running time. As observed in Section 4, an optimum fractional multiflow f^* can be found in polynomial time. (Discretizing and) uncrossing is done in time polynomial in $|E||D|$ by Lemma 7. Partitioning into free homotopy classes is done by Corollary 15. Finally, the operations of Theorem 10, Theorem 3, Lemma 11, Lemma 17 and Lemma 20 can all be done in polynomial time, hence polynomial running time overall.

9 Proof of Corollary 2

In this section, we observe how Corollary 2 follows from Theorem 1 and the following result by Tardos and Vazirani [36] (based on work by Klein, Plotkin and Rao [24]).

▶ **Theorem 22** ([36]). *Let (G, H, u) be a multiflow instance and $\gamma > 1$ such that the supply graph G does not have a $K_{\gamma,\gamma}$ minor. Then the minimum capacity of a multicut is $O(\gamma^3)$ times the maximum value of a (fractional) multiflow.*

The following is well known.

▷ Claim 23. If a graph G has genus at most g, where $g \geqslant 1$, then it has no $K_{\gamma,\gamma}$ minor for any $\gamma > 2(\sqrt{g} + 1)$.

Proof. Suppose that such a minor $K_{\gamma,\gamma}$ exists in G. As the three operations for obtaining a minor (deleting edges/vertices and contracting edges) do not increase the genus, $K_{\gamma,\gamma}$ has genus at most g. Furthermore, K has 2γ vertices, γ^2 edges, and at most $\frac{\gamma^2}{2}$ faces (since there is no odd cycle in a bipartite graph). By Euler's formula, $2 - 2g \leqslant 2\gamma - \gamma^2 + \frac{\gamma^2}{2}$, which implies $\gamma \leqslant 2(\sqrt{g} + 1)$. ◁

By Claim 23 and Theorem 22, the ratio between the minimum capacity of a multicut and the maximum value of a (fractional) multiflow is $O(g^{1.5})$. This, combined with Theorem 1, proves Corollary 2.

Minimum-Norm Load Balancing Is (Almost) as Easy as Minimizing Makespan

Abstract

We consider the *minimum-norm load-balancing* (MinNormLB) problem, wherein there are n jobs, each of which needs to be assigned to one of m machines, and we are given the processing times $\{p_{ij}\}$ of the jobs on the machines. We also have a monotone, symmetric norm $f : \mathbb{R}^m \to \mathbb{R}_{\geq 0}$. We seek an assignment σ of jobs to machines that minimizes the f-norm of the induced load vector $\overrightarrow{\mathsf{load}}_\sigma \in \mathbb{R}^m_{\geq 0}$, where $\mathsf{load}_\sigma(i) = \sum_{j:\sigma(j)=i} p_{ij}$. This problem was introduced by [4], and the current-best result for MinNormLB is a $(4+\epsilon)$-approximation [5]. In the stochastic version of MinNormLB, the job processing times are given by nonnegative random variables X_{ij}, and jobs are independent; the goal is to find an assignment σ that minimizes the *expected* f-norm of the induced random load vector.

We obtain results that (essentially) *match* the best-known guarantees for deterministic makespan minimization (MinNormLB with ℓ_∞ norm). For MinNormLB, we obtain a $(2+\epsilon)$-approximation for unrelated machines, and a PTAS for identical machines. For stochastic MinNormLB, we consider the setting where the X_{ij}s are *Poisson* random variables, denoted PoisNormLB. Our main result here is a novel and powerful reduction showing that, for any machine environment (e.g., unrelated/identical machines), *any* α-approximation algorithm for MinNormLB in that machine environment yields a randomized $\alpha(1+\epsilon)$-approximation for PoisNormLB in that machine environment. Combining this with our results for MinNormLB, we immediately obtain a $(2+\epsilon)$-approximation for PoisNormLB on unrelated machines, and a PTAS for PoisNormLB on identical machines. The latter result substantially generalizes a PTAS for makespan minimization with Poisson jobs obtained recently by [6].

1 Introduction

In the *minimum-norm load-balancing* (MinNormLB) problem, we are given a set J of n jobs, a set of m machines, and nonnegative job processing times (or sizes) $\{p_{ij}\}_{i\in[m],j\in J}$. We use $[m]$ to denote $\{1,\ldots,m\}$. We are also given a *monotone, symmetric norm* $f : \mathbb{R}^m \mapsto \mathbb{R}_{\geq 0}$. Recall that f being a norm means that: (i) $f(x) = 0$ iff $x = 0$; (ii) $f(x+y) \leq f(x) + f(y)$ for all $x, y \in \mathbb{R}^m$, and (iii) $f(\theta x) = |\theta| f(x)$ for all $x \in \mathbb{R}^m, \theta \in \mathbb{R}$. A monotone norm f satisfies $f(x) \leq f(y)$ for all $0 \leq x \leq y$, and symmetry is the property that permuting the coordinates of x does not change its norm. An assignment $\sigma : J \to [m]$ of jobs to machines induces the machine-load vector $\overrightarrow{\mathsf{load}}_\sigma = \big(\mathsf{load}_\sigma(i)\big)_{i\in[m]} \in \mathbb{R}^m_{\geq 0}$, where $\mathsf{load}_\sigma(i) := \sum_{j:\sigma(j)=i} p_{ij}$. The goal in MinNormLB is to find an assignment σ that minimizes the f-norm of $\overrightarrow{\mathsf{load}}_\sigma$.

This problem was first considered by [4], as a natural problem in the genre of minimum-norm optimization problems that they introduce. They gave a $(38+\varepsilon)$-approximation algorithm for MinNormLB, and the approximation factor was subsequently improved to $(4+\varepsilon)$ by [5]. Ibrahimpur and Swamy [12] introduced the genre of *stochastic* minimum-norm optimization, and considered StochNormLB, the stochastic generalization of MinNormLB, as a prominent problem in this genre. In StochNormLB, the job processing times are given by nonnegative random variables $\{X_{ij}\}_{i\in[m],j\in J}$ with specified distributions, and the jobs are independent (but X_{ij} and $X_{i'j}$ could be correlated); the goal is to find an assignment that minimizes the *expected* f-norm of the induced random load vector. As discussed in these works, one of the chief motivations and benefits of working with the rather broad class of monotone, symmetric norms is that it captures a variety of appealing objectives, including the frequently-considered (in both deterministic and stochastic settings) min-max (ℓ_∞) and min-sum (ℓ_1) objectives, general ℓ_p-norms, as also another important class of norms called Top_ℓ*norms* (for $x \geq 0$, $\mathsf{Top}_\ell(x)$ is the sum of the ℓ largest coordinates of x). Moreover, by exploiting the closure properties of monotone, symmetric norms, one can also model seemingly more general settings, such as when we have *multiple* monotone-symmetric-norm budget constraints $f_\ell(x) \leq B_\ell$ (a flexibility we leverage in Section 3).

The special case of MinNormLB where $f = \ell_\infty$ yields the classical (deterministic) *makespan-minimization* problem, which has been well studied for various machine environments. For unrelated machines, a 2-approximation is known [17, 23], and improving this factor remains a longstanding open problem, while various PTAS'es are known for identical and related machines [11, 10, 13, 14]. Similar guarantees are known for MinNormLB with (general) ℓ_p norms [2, 16, 20, 1]. Stochastic load balancing is less well-understood than its deterministic counterpart (even for the makespan objective). Constant-factor approximations are known for stochastic makespan minimization on identical [15] and unrelated [8] machines, StochNormLB with ℓ_p norms [22] and Top_ℓ norms [12], and StochNormLB with (an arbitrary f and) Bernoulli job sizes [12]. A common shortcoming of all these works is that the approximation factors obtained are quite large, at least in the 100s (although these works were not aiming to optimize the constant). With an eye towards obtaining small approximation factors, Goel and Indyk [7] considered stochastic makespan minimization on identical machines with structured distributions. They obtained (among other results) a 2-approximation for StochNormLB with Poisson job sizes – i.e., where each X_{ij} is a Poisson random variable – and very recently, this was improved to a PTAS [6].

Our contributions. As suggested by the title of the paper, we obtain results for both deterministic and stochastic load balancing with *approximation factors that (essentially) match the best-known approximation factors for the deterministic makespan-minimization problem.* Our salient results are as follows.

- For MinNormLB, we devise a $(2+\epsilon)$-approximation for unrelated machines (Theorem 4.1), and a PTAS for identical machines (Theorem 5.1).
  For unrelated machines, this improves upon the previous-best $(4+\epsilon)$-approximation [5].
- We consider StochNormLB with Poisson job sizes, denoted PoisNormLB, and give a novel, clean, and fairly general reduction showing that, for any machine environment (e.g., unrelated/identical machines), *any* α-approximation algorithm for MinNormLB in that machine environment can be used to obtain a randomized $\alpha(1+\epsilon)$-approximation for PoisNormLB in that machine environment (Theorem 3.1). Combining this with our results for MinNormLB, we obtain a $(2+\epsilon)$-approximation for PoisNormLB on unrelated machines, and a PTAS for PoisNormLB on identical machines.

Our approximation factors (which are for general monotone, symmetric norms) are *considerably* smaller than the factors known (even) for stochastic makespan minimization with general distributions. Our PTAS for PoisNormLB on identical machines substantially generalizes the PTAS by [6] for stochastic makespan minimization with Poisson jobs. Our techniques are quite different, and our approach, based on the reduction to MinNormLB, while being more general, is in fact also simpler and cleaner than the one in [6].

All our algorithms require only a *value oracle* for the norm f. (In contrast, the results of [4, 5] need more-sophisticated oracle access to f.)

Our techniques. We briefly discuss the key techniques underlying some of our results.

Consider first the reduction from PoisNormLB to MinNormLB. Let $\mathsf{Pois}(\lambda)$ denote a Poisson random variable with parameter λ; recall that this has mean λ. The sum $\mathsf{Pois}(\lambda_1) + \mathsf{Pois}(\lambda_2)$ of independent Poisson random variables is a $\mathsf{Pois}(\lambda_1 + \lambda_2)$ random variable. So given an assignment $\sigma : J \to [m]$, the load on any machine i is a $\mathsf{Pois}(\Lambda_i^\sigma)$ random variable, where Λ_i^σ is the expected load on machine i, and the objective value of σ is $g(\Lambda^\sigma) := \mathbf{E}\left[f(\mathsf{Pois}(\Lambda_1^\sigma), \mathsf{Pois}(\Lambda_2^\sigma), \ldots, \mathsf{Pois}(\Lambda_m^\sigma))\right]$. It is known that if $\mathsf{Top}_i(y) \leq \mathsf{Top}_i(y')$ for all $i \in [m]$ then $g(y) \leq g(y')$ (Theorem 3.3). We argue that g is *subhomogeneous*, i.e., $g(\theta y) \leq \theta \cdot g(y)$ for any $\theta \geq 1$, and so one can generalize the above statement to say that if $\mathsf{Top}_i(y) \leq \theta \cdot \mathsf{Top}_i(y')$ for all $i \in [m]$, then $g(y) \leq \theta \cdot g(y')$. Let Λ^* denote the Λ-vector of an optimal solution. The idea now is to "guess" $\mathsf{Top}_\ell(\Lambda^*)$ within a $(1+\varepsilon)$-factor for all ℓ in a certain sparse set $\mathsf{POS} \subseteq [m]$; let B_ℓ^* denote such an overestimate of $\mathsf{Top}_\ell(\Lambda^*)$. We now seek a solution σ such that $\mathsf{Top}_\ell(\Lambda^\sigma) \leq \alpha B_\ell^*$ for all $\ell \in \mathsf{POS}$, for some $\alpha \geq 1$; this will imply that $\mathsf{Top}_i(\Lambda^\sigma) \leq \alpha\big(1 + O(\varepsilon)\big)\mathsf{Top}_i(\Lambda^*)$ for all $i \in [m]$, and hence $g(\Lambda^\sigma) \leq \alpha(1 + O(\varepsilon))g(\Lambda^*)$. This is where the generality of monotone, symmetric norms comes in handy. *We can cast this multiple-*Top_ℓ*-norm-budgets problem as a* MinNormLB *problem, with* $\{\lambda_{ij}\}$ *job sizes, and monotone, symmetric norm given by* $h(v) := \max_{\ell \in \mathsf{POS}} \mathsf{Top}_\ell(v)/B_\ell^*$; we can now use an α-approximation algorithm for MinNormLB, say $\mathcal{A}^{\mathsf{Det}}$, to find σ.

Note that the versatility afforded by MinNormLB as a model is crucial for the reduction, and we really need $\mathcal{A}^{\mathsf{Det}}$ to work for an arbitrary monotone, symmetric norm. We need to have fine-grained control of the Λ^σ vector (as dictated by the multiple Top_ℓ-norm budget constraints), and we define a suitable (monotone, symmetric) norm h to enforce this. In contrast, De et al. [6], who devise a PTAS for stochastic makespan minimization with Poisson jobs follow a completely different approach, based on proving suitable concentration results.

Our $(2+\epsilon)$-approximation for MinNormLB on unrelated machines (Section 4) is based on rounding the solution to a novel LP-relaxation for the problem. Let σ^* be an optimal solution, $\vec{o}$ be the induced load vector, and $\mathsf{OPT} = f(\vec{o})$. It suffices to obtain an assignment σ such that $\mathsf{Top}_\ell(\overrightarrow{\mathsf{load}}_\sigma) \leq \big(2 + O(\delta)\big)\mathsf{Top}_\ell(\vec{o})$ for all $\ell \in \mathsf{POS}$ (see Theorem 2.4 and Claim 2.6). Roughly speaking, for all $\ell \in \mathsf{POS}$, we guess the ℓ-th largest entry of $\vec{o}$, and use this to linearly encode the constraint that $\mathsf{Top}_\ell(\overrightarrow{\mathsf{load}}_\sigma) \leq \mathsf{Top}_\ell(\vec{o})$. LP-rounding algorithms for the special case of makespan minimization typically return a guarantee where the load on a machine is at most its LP-load + (maximum cost (i.e., size) of a job assigned to it). In order to bound the f-norm of the portion of the load-vector, say P, arising from the most-costly jobs, we also consider the vector $\overrightarrow{\mathsf{JL}^*}$ comprising the costs of the m most-costly jobs under σ^*. In [5], it is shown that $f(\overrightarrow{\mathsf{JL}^*}) \leq \mathsf{OPT}$. We indirectly encode that $f(P) \leq f(\overrightarrow{\mathsf{JL}^*})$ by guessing the ℓ-th largest entry, say ζ_ℓ, of $\overrightarrow{\mathsf{JL}^*}$ and encoding that there are at most $\ell - 1$ jobs of higher cost, for all $\ell \in \mathsf{POS}$. We round a fractional solution to the resulting LP using *iterative rounding* to obtain two types of guarantees *simultaneously* (see Lemma 4.3):

(i) similar to above, the load on machine i is at most its LP-load + $(1+\delta)\times$(maximum cost of a job assigned to i); and (ii) the number of jobs having cost larger then ζ_ℓ is at most $(1+\delta)\ell - 1$. The LP constraints explicitly encode that the Top_ℓ-norms of the LP-load vector are roughly speaking at most $\mathsf{Top}_\ell(\vec{o})$, for all $\ell \in \mathsf{POS}$; guarantee (ii) allows us to argue that $f(P) \leq \big(1 + O(\delta)\big)\mathsf{OPT}$. Together, these imply a $(2+\epsilon)$-approximation.

We remark that the approach taken in the GAP-rounding algorithm of [23] (and also used for Top_ℓ-norm minimization in [4]), wherein the problem is essentially reduced to a bipartite matching problem, does not seem to be helpful in obtaining a $(2+\epsilon)$-approximation for MinNormLB. This approach "hard-codes" the distinction between the most-costly job assigned to a machine and the remaining jobs as a means of bounding the load on a machine by its LP-load + (maximum cost of a job assigned to it). However, bounding $f(P)$ then entails solving (to within a $(1+\epsilon)$-factor) a (bipartite) matching problem with $|\mathsf{POS}| = O(\log m)$ side-constraints, or essentially a min-norm matching problem, but neither of these has (even) an $O(1)$-approximation. Instead, iterative rounding seems crucial for simultaneously obtaining guarantees (i) and (ii) above, and (ii) allows us to obtain a sufficiently-tight bound on the Top_ℓ-norms (and hence the f-norm) of P and thereby obtain our $(2+\epsilon)$-approximation.

2 Preliminaries

For a vector $v \in \mathbb{R}^m_{\geq 0}$, we use $v^\downarrow$ to denote v with its coordinates sorted in non-increasing order; i.e., we have $v^\downarrow_i = v_{\pi(i)}$, where π is a permutation of $[m]$ such that $v_{\pi(1)} \geq v_{\pi(2)} \geq \ldots \geq v_{\pi(m)}$. We say that v is non-increasing if $v_1 \geq \ldots \geq v_m$ (i.e., $v = v^\downarrow$). Whenever we say norm in the sequel, we always mean a monotone, symmetric norm. The following claim from [12] will be useful in obtaining bounds on the optimal value.

▷ Claim 2.1 (Claim 3.2 in [12]). Let $h : \mathbb{R}^m \mapsto \mathbb{R}_{\geq 0}$ be a monotone, symmetric norm. For any $v \in \mathbb{R}^m_{\geq 0}$, we have $\frac{\sum_{i\in[m]} v_i}{m} \leq \max_{i\in[m]} v_i \leq \frac{h(v)}{h(1,0,\ldots,0)} \leq \sum_{i\in[m]} v_i$.

As established in prior work on minimum-norm optimization [4, 12], we can control the norm of a vector by controlling all its Top_ℓ norms, which are defined below. Theorem 2.4 makes this notion precise. For $x \in \mathbb{R}$, we use $(x)^+$ to denote $\max\{0, x\}$.

▶ **Definition 2.2.** Let $\ell \in [m]$. The Top_ℓ *norm* is defined as follows: for $v \in \mathbb{R}^m_{\geq 0}$, $\mathsf{Top}_\ell(v)$ is the sum of the ℓ largest coordinates of v, i.e., $\mathsf{Top}_\ell(v) = \sum_{i=1}^{\ell} v^\downarrow_i$.

The following ways of reformulating the Top_ℓ-norm will be useful. For a vector $v \in \mathbb{R}^m$ and $\theta \in \mathbb{R}$, define $N^{>\theta}(v) := \big|\{i \in [m] : v_i > \theta\}\big|$.

▷ Claim 2.3. Let $v \in \mathbb{R}^m_{\geq 0}$, and $\ell \in [m]$. Then

$$\mathsf{Top}_\ell(v) = \min_{t\geq 0}\big(\ell t + \sum_{i\in[m]} (v_i - t)^+\big) = \ell v^\downarrow_\ell + \sum_{i\in[m]} (v_i - v^\downarrow_\ell)^+ = \int_0^\infty \min\{\ell, N^{>\theta}(v)\} d\theta.$$

▶ **Theorem 2.4** (Follows from structural result in [4], or majorization theory of [9]). *If $x, y \in \mathbb{R}^m_{\geq 0}$ are such that $\mathsf{Top}_\ell(x) \leq \alpha\mathsf{Top}_\ell(y) + \beta$ for all $\ell \in [m]$, where $\alpha, \beta \geq 0$, then $h(x) \leq \alpha \cdot h(y) + \beta \cdot h(1, 0, \ldots, 0)$ for any monotone, symmetric norm $h : \mathbb{R}^m \mapsto \mathbb{R}_{\geq 0}$.*

Theorem 2.4 will be our chief means for reasoning about the norm of a vector. Our algorithms will "guess" (i.e., enumerate) the Top_ℓ norms (or certain associated quantities) of the load vector $\vec{o}$ induced by an optimal solution, and will aim to obtain a solution whose induced load vector $\overrightarrow{\mathsf{load}}$ satisfies $\mathsf{Top}_\ell(\overrightarrow{\mathsf{load}}) = O\big(\mathsf{Top}_\ell(\vec{o})\big)$. However, to make this approach

polynomial time, we will only be able to enumerate the Top_ℓ norms for a certain *sparse* subset of indices $\mathsf{POS} \subseteq [m]$. The next few definitions and results make this precise, and show that the move to this sparse subset only incurs the loss of a small factor.

Let $\delta > 0$ be a parameter. We define $\mathsf{POS}_{m,\delta} \subseteq [m]$ iteratively as follows: include the index 1 in $\mathsf{POS}_{m,\delta}$; as long as the largest index $\ell \in \mathsf{POS}_{m,\delta}$ is such that $\lceil (1+\delta)\ell \rceil \leq m$, include $\lceil (1+\delta)\ell \rceil$ (which is larger than ℓ) in $\mathsf{POS}_{m,\delta}$. (This definition is mathematically slightly more convenient to work with than the one in [4], where $\mathsf{POS}_{m,\delta}$ is defined as $\left\{\min\{\lceil (1+\delta)^s \rceil, m\} : s \in \mathbb{Z}_{\geq 0}\right\}$, but this change is not crucial.)

▷ Claim 2.5. We have $|\mathsf{POS}_{m,\delta}| \leq 1 + \log_{1+\delta} m = O\left(\frac{\log m}{\delta}\right)$.

We frequently abbreviate $\mathsf{POS}_{m,\delta}$ to POS in the remainder of this section, and whenever m, δ are clear from the context. For $i \in [m]$, let $\mathsf{next}(i)$ be the smallest index in POS (strictly) larger than i; if no such index exists, then we define $\mathsf{next}(i) := m+1$ for notational convenience. Similarly, let $\mathsf{prev}(i)$ be the largest index in POS (strictly) smaller than i; set $\mathsf{prev}(1) := 0$. It is immediate from the definition of POS that $\mathsf{next}(\ell) - 1 \leq (1+\delta)\ell$ for all $\ell \in \mathsf{POS}$; it follows also that $\mathsf{next}(i) - 1 \leq (1+\delta)i$ for all $i \in [m]$. Claim 2.6 and Lemma 2.7 show that focusing on only the indices in POS only results in a $(1+\delta)$-factor loss.

▷ Claim 2.6. Let $u, v \in \mathbb{R}^m_{\geq 0}$ be such that $\mathsf{Top}_\ell(u) \leq \mathsf{Top}_\ell(v)$ for all $\ell \in \mathsf{POS}_{m,\delta}$. Then we have $h(u) \leq (1+\delta)h(v)$ for any monotone, symmetric norm $h : \mathbb{R}^m \mapsto \mathbb{R}_{\geq 0}$.

Proof. Let $i \in [m] \setminus \mathsf{POS}$, and $\ell = \mathsf{prev}(i)$. Then $i \leq (1+\delta)\ell$, and therefore $\mathsf{Top}_i(u) \leq (1+\delta)\mathsf{Top}_\ell(u) \leq (1+\delta)\mathsf{Top}_\ell(v) \leq (1+\delta)\mathsf{Top}_i(v)$. The claim now follows from Theorem 2.4. ◁

▶ **Lemma 2.7.** *Let $u, v \in \mathbb{R}^m_{\geq 0}$ be such that $u^\downarrow_\ell \leq v^\downarrow_\ell$ for all $\ell \in \mathsf{POS}_{m,\delta}$. Then, we have $h(u) \leq (1+\delta)h(v)$ for any monotone, symmetric norm $h : \mathbb{R}^m \mapsto \mathbb{R}_{\geq 0}$.*

Proof. By Theorem 2.4, it suffices to show that $\mathsf{Top}_i(u) \leq (1+\delta)\mathsf{Top}_i(v)$ for all $i \in [m]$. So fix $i \in [m]$. We mimic the proof of Lemma 4.2 in [4]. Define vectors $\alpha, \beta \in \mathbb{R}^m_{\geq 0}$ as follows:

$$\alpha_k = \begin{cases} u^\downarrow_k; & \text{if } k \in \{1, \ldots, i\} \\ 0 & \text{otherwise} \end{cases} \qquad \beta_k = \begin{cases} v^\downarrow_k; & \text{if } k \in \{1, \ldots, i\} \\ 0 & \text{otherwise.} \end{cases}$$

Clearly, both α and β are non-increasing vectors. For notational convenience, set $\alpha_k := 0, \beta_k := 0$ for any $k > m$. We have

$$\begin{aligned} \mathsf{Top}_\ell(u) = \sum_{k=1}^{m} \alpha_k &= \sum_{\ell \in \mathsf{POS}} \sum_{k=\ell}^{\mathsf{next}(\ell)-1} \alpha_k \\ &\leq \sum_{\ell \in \mathsf{POS}} \alpha_\ell \big((\mathsf{next}(\ell) - 1) - (\ell - 1) \big) = \sum_{\ell \in \mathsf{POS}} \big(\mathsf{next}(\ell) - 1 \big)(\alpha_\ell - \alpha_{\mathsf{next}(\ell)}) \end{aligned}$$

where the inequality follows because α is a non-increasing vector. Now using the fact that $\mathsf{next}(\ell) - 1 \leq (1+\delta)\ell$ for all $\ell \in \mathsf{POS}$, and $\alpha_\ell \leq \beta_\ell$ for all $\ell \in \mathsf{POS}$, we obtain that

$$\begin{aligned} \mathsf{Top}_\ell(u) &\leq (1+\delta) \sum_{\ell \in \mathsf{POS}} \ell(\alpha_\ell - \alpha_{\mathsf{next}(\ell)}) = (1+\delta) \sum_{\ell \in \mathsf{POS}} \alpha_\ell \big(\ell - \mathsf{prev}(\ell) \big) \leq (1+\delta) \sum_{\ell \in \mathsf{POS}} \beta_\ell \big(\ell - \mathsf{prev}(\ell) \big) \\ &\leq (1+\delta) \sum_{\ell \in \mathsf{POS}} \sum_{k=\mathsf{prev}(\ell)+1}^{\ell} \beta_k \leq (1+\delta) \sum_{k=1}^{m} \beta_i = (1+\delta)\mathsf{Top}_\ell(v). \end{aligned}$$

The third inequality above follows because β is a non-increasing vector. ◀

In our algorithms, we work with estimates of $\{\vec{o}_\ell^{\downarrow}\}_{\ell \in \mathsf{POS}}$, where $\vec{o}$ is the load vector induced by an optimal solution. We show that these estimates then allow us to infer an estimate of $h(\vec{o})$ for any monotone, symmetric norm h. We need the following notation. Given a non-increasing vector $v \in \mathbb{R}^{\mathsf{POS}}_{\geq 0}$, we define its *expansion* to be the vector $v^{\mathsf{exp}} \in \mathbb{R}^m_{\geq 0}$ given by $v_i^{\mathsf{exp}} := v_i$ for $i \in \mathsf{POS}$, and $v_i^{\mathsf{exp}} = v_{\mathsf{prev}(i)}$ for $i \in [m] \setminus \mathsf{POS}$.

▶ **Lemma 2.8.** *Let $u \in \mathbb{R}^m_{\geq 0}$, and $v \in \mathbb{R}^{\mathsf{POS}}_{\geq 0}$ be a non-increasing vector. Let $h : \mathbb{R}^m \mapsto \mathbb{R}_{\geq 0}$ be a monotone, symmetric norm. Let $\varepsilon, \kappa > 0$.*

(a) *If $u_\ell^{\downarrow} \leq v_\ell$ for all $\ell \in \mathsf{POS}$, then $\mathsf{Top}_i(u) \leq \mathsf{Top}_i(v^{\mathsf{exp}})$ for all $i \in [m]$, and hence, $h(u) \leq h(v^{\mathsf{exp}})$.*

(b) *If $v_\ell \leq (1+\varepsilon)u_\ell^{\downarrow} + \kappa$ for all $\ell \in \mathsf{POS}$, then $\mathsf{Top}_i(v^{\mathsf{exp}}) \leq (1+\delta)(1+\varepsilon)\mathsf{Top}_i(u) + i\kappa$ for all $i \in [m]$, and hence, $h(v^{\mathsf{exp}}) \leq (1+\delta)(1+\varepsilon)h(u) + m\kappa \cdot h(1,0,\ldots,0)$.*

(c) *Let v be as in part (b). Let $\delta \leq 1$ (in $\mathsf{POS} = \mathsf{POS}_{m,\delta}$). Let $\alpha \in \mathbb{R}^m$ be such that $\alpha_1^{\downarrow} \leq v_1$ and $N^{>v_\ell}(\alpha) \leq (1+\delta)\ell - 1$ for all $\ell \in \mathsf{POS}$. Then, $\mathsf{Top}_i(\alpha) \leq (1+4\delta)(1+\varepsilon)\mathsf{Top}_i(u) + 5i\kappa$ for all $i \in [m]$. Hence, $h(\alpha) \leq (1+4\delta)(1+\varepsilon)h(u) + 5m\kappa \cdot h(1,0,\ldots,0)$.*

Lemma 2.8 (c) can be seen as a generalization of Lemma 2.8 (b): the vector v^{exp} satisfies $N^{>v_\ell}(v^{\mathsf{exp}}) \leq \ell - 1$ for all $\ell \in \mathsf{POS}$, while the vector α satisfies a relaxed version of this bound.

Proof. The inequalities involving $h(.)$ in parts (a)–(c) follow from the corresponding bounds on the Top_i-norms, using Theorem 2.4. So we focus on the proving the bounds for the Top_i-norms.

Let $\gamma = v^{\mathsf{exp}}$. Part (a) follows immediately from the fact that $u^{\downarrow} \leq \gamma$. For part (b), define $\beta \in \mathbb{R}^m_{\geq 0}$ to be the expansion of $(u_\ell^{\downarrow})_{\ell \in \mathsf{POS}}$. Then, we have $\gamma \leq (1+\varepsilon)\beta + \kappa \cdot \mathbf{1}$, where $\mathbf{1}$ is the vector of all 1s, and hence, $\mathsf{Top}_i(\gamma) \leq (1+\varepsilon)\mathsf{Top}_i(\beta) + i\kappa$, for any $i \in [m]$. Observe that $\beta_\ell \leq u_\ell^{\downarrow}$ for all $\ell \in \mathsf{POS}$. Therefore, by Lemma 2.7, we have $\mathsf{Top}_i(\beta) \leq (1+\delta)\mathsf{Top}_i(u)$ for any $i \in [m]$.

For part (c), consider an index $i \in [m]$. We use the reformulation $\mathsf{Top}_i(\alpha) = \int_0^\infty \min\{i, N^{>\theta}(\alpha)\}d\theta$ stated in Claim 2.3. Since $N^{>v_1}(\alpha) = 0$, we only need to go up to v_1 in the above integral. Let $\overline{\ell} = i$ if $i \in \mathsf{POS}$, and $\overline{\ell} = \mathsf{prev}(i)$ otherwise. Observe that $i \leq (1+\delta)\overline{\ell}$. We have the following chain of inequalities.

$$\begin{aligned}
\mathsf{Top}_i(\alpha) &\leq \int_0^{v_{\overline{\ell}}} i d\theta + \sum_{\ell \in \mathsf{POS}: 1 < \ell \leq \overline{\ell}} \int_{v_\ell}^{v_{\mathsf{prev}(\ell)}} N^{>\theta}(\alpha) d\theta \leq i \cdot v_{\overline{\ell}} + \sum_{\ell \in \mathsf{POS}: 1 < \ell \leq \overline{\ell}} (v_{\mathsf{prev}(\ell)} - v_\ell) N^{>v_\ell}(\alpha) \\
&\leq i \cdot v_{\overline{\ell}} + \sum_{\ell \in \mathsf{POS}: 1 < \ell \leq \overline{\ell}} (v_{\mathsf{prev}(\ell)} - v_\ell)\big((1+\delta)\ell - 1\big) \\
&\leq i \cdot v_{\overline{\ell}} + \sum_{\ell \in \mathsf{POS}: 1 < \ell \leq \overline{\ell}} (v_{\mathsf{prev}(\ell)} - v_\ell)\big((1+\delta)^2 \mathsf{prev}(\ell) + \delta\big). \qquad (1)
\end{aligned}$$

The second inequality is because $N^{>\theta}(\alpha)$ is non-increasing in θ; the third is from condition (ii) in the lemma statement; and the final inequality (1) follows since $\ell - 1 \leq (1+\delta)\mathsf{prev}(\ell)$. Recall that $\mathsf{prev}(1) = 0$. Continuing, since $i \leq (1+\delta)\overline{\ell} \leq (1+\delta)^2\overline{\ell}$, the RHS of (1) is at most

$$\begin{aligned}
&(1+\delta)^2 \sum_{\ell \in \mathsf{POS}: \ell \leq \overline{\ell}} v_\ell\big(\ell - \mathsf{prev}(\ell)\big) + \delta v_1 \\
&\leq (1+\delta)^2 \sum_{\ell \in \mathsf{POS}: \ell \leq \overline{\ell}} \big((1+\varepsilon)u_\ell^{\downarrow} + \kappa\big)\big(\ell - \mathsf{prev}(\ell)\big) + \delta(1+\varepsilon) \cdot \mathsf{Top}_i(u) + \delta\kappa
\end{aligned}$$

$$\ldots \le (1+\delta)^2(1+\varepsilon)\sum_{i'=1}^{\overline{\ell}} u^{\downarrow}_{i'} + (1+\delta)^2\overline{\ell}\kappa + \delta(1+\varepsilon)\cdot \mathsf{Top}_i(u) + \delta\kappa$$
$$\le (1+4\delta)(1+\varepsilon)\mathsf{Top}_i(u) + 5i\kappa. \qquad \text{(since } \delta \le 1\text{)}$$ ◀

Our algorithms will often need to estimate a non-increasing vector α (such as $(\vec{o}^{\downarrow}_\ell)_{\ell\in\mathsf{POS}}$). We show that if we have suitable bounds on the coordinates of α, then one can identify a (polynomially bounded) set containing a vector close to α.

▶ **Lemma 2.9.** *Let $\mathcal{L} \subseteq [m]$ be an index-set. Let $\alpha \in \mathbb{R}^{\mathcal{L}}_{\ge 0}$ be a non-increasing vector, i.e., $\alpha_\ell \ge \alpha_{\ell'}$ for indices $\ell, \ell' \in \mathcal{L}$, $\ell < \ell'$. Let ub be such that $\alpha_\ell \le \mathsf{ub}$ for all $\ell \in \mathcal{L}$. Let $\varepsilon, \kappa > 0$, and $\varepsilon' = \min\{1, \varepsilon\}$.*

(a) *Let $N_1 := (2e)^{|\mathcal{L}|} + \left(\frac{\mathsf{ub}}{\kappa}\right)^{O(\frac{1}{\varepsilon'})}$. We can construct a set $\mathcal{T} \subseteq \mathbb{R}^{\mathcal{L}}_{\ge 0}$ with $|\mathcal{T}| \le N_1$ in $O(N_1)$ time, containing a non-increasing vector $v \in \mathbb{R}^{\mathcal{L}}_{\ge 0}$, such that $\alpha_\ell \le v_\ell \le (1+\varepsilon)\alpha_\ell + \kappa$ for all $\ell \in \mathcal{L}$.*

(b) *Suppose that we also have $\alpha_\ell \ge \mathsf{lb}$ for all $\ell \in \mathcal{L}$, where $\mathsf{lb} > 0$. Let $N_2 := (2e)^{|\mathcal{L}|} + \left(\frac{\mathsf{ub}}{\mathsf{lb}}\right)^{O(\frac{1}{\varepsilon'})}$. We can construct $\mathcal{T} \subseteq \mathbb{R}^{\mathcal{L}}_{\ge 0}$ with $|\mathcal{T}| \le N_2$ in $O(N_2)$ time, containing a non-increasing vector $v \in \mathbb{R}^{\mathcal{L}}_{\ge 0}$, such that $\alpha_\ell \le v_\ell \le (1+\varepsilon)\alpha_\ell$ for all $\ell \in \mathcal{L}$.*

Proof. We utilize the following standard result, lifted from [4], that gives a bound on the number of non-increasing vectors with bounded coordinates.

▷ Claim 2.10. There are at most $(2e)^{\max\{M,k\}}$ non-increasing sequences of k integers chosen from $\{0, \ldots, M\}$.

For part (a), consider the set

$$\mathcal{T} := \Big\{\vec{t} \in \mathbb{R}^{\mathcal{L}}_{\ge 0} : \ \vec{t} \text{ is a non-increasing vector,}$$
$$\forall \ell \in \mathcal{L}, \quad t_\ell = \tfrac{\mathsf{ub}}{(1+\varepsilon)^k}, \text{ where } k \in \mathbb{Z}_{\ge 0}, \quad t_\ell \ge \tfrac{\kappa}{1+\varepsilon}\Big\}.$$

Each $\vec{t} \in \mathcal{T}$ is a non-increasing vector, and there are $I := 1 + \left\lfloor \log_{1+\varepsilon} \frac{(1+\varepsilon)\mathsf{ub}}{\kappa} \right\rfloor = O\big(\frac{\log(\mathsf{ub}/\kappa)}{\varepsilon'}\big)$ choices for $\log_{1+\varepsilon} \frac{\mathsf{ub}}{t_\ell}$ for every $\ell \in \mathsf{POS}$. (Recall that $\varepsilon' = \min\{\varepsilon, 1\}$.) So Claim 2.10 implies that $|\mathcal{T}| \le (2e)^{\max\{|\mathcal{L}|, I\}}$. We have $(2e)^I \le \left(\frac{\mathsf{ub}}{\kappa}\right)^{O(\frac{1}{\varepsilon'})}$, so this yields the bound on $|\mathcal{T}|$ and the time to construct $\mathcal{T}$.

Consider the vector $v \in \mathbb{R}^{\mathcal{L}}_{\ge 0}$, where for every $\ell \in \mathcal{L}$, v_ℓ is the smallest number of the form $\mathsf{ub}/(1+\varepsilon)^k$, $k \in \mathbb{Z}_{\ge 0}$ that is at least $\max\{\kappa/(1+\varepsilon), \alpha_\ell\}$. Then, v is a non-increasing vector, $v \in \mathcal{T}$, and $\alpha_\ell \le v_\ell \le (1+\varepsilon)\alpha_\ell + \kappa$ for all $\ell \in \mathcal{L}$.

Part (b) is proved very similarly. We now take $\mathcal{T}$ to be the set of all non-increasing vectors $\vec{t} \in \mathbb{R}^{\mathcal{L}}_{\ge 0}$ satisfying $t_\ell \ge \mathsf{lb}$, $t_\ell = \frac{\mathsf{ub}}{(1+\varepsilon)^k}$ where $k \in \mathbb{Z}_{\ge 0}$, for all $\ell \in \mathcal{L}$. As before, one can infer that the size of $\mathcal{T}$ and the time taken to construct it are bounded by $(2e)^{|\mathcal{L}|} + \left(\frac{\mathsf{ub}}{\mathsf{lb}}\right)^{O(\frac{1}{\varepsilon'})}$. Now if $v \in \mathbb{R}^{\mathcal{L}}_{\ge 0}$ is such that, for every $\ell \in \mathcal{L}$, v_ℓ is the smallest number of the form $\mathsf{ub}/(1+\varepsilon)^k$, $k \in \mathbb{Z}_{\ge 0}$ that is at least α_ℓ, then, v is a non-increasing vector, $v \in \mathcal{T}$, and $\alpha_\ell \le v_\ell \le (1+\varepsilon)\alpha_\ell$ for all $\ell \in \mathcal{L}$. ◀

Poisson random variables. A discrete random variable Z is said to have a Poisson distribution with parameter $\lambda \ge 0$, denoted $Z \sim \mathsf{Pois}(\lambda)$, if $\mathbf{Pr}\big[Z = k\big] = e^{-\lambda}\lambda^k/k!$ for all $k \in \mathbb{Z}_{\ge 0}$.

▶ **Fact 2.11.** *The following facts about Poisson random variables are well known.*

(a) *The mean and variance of $\mathsf{Pois}(\lambda)$ are both equal to λ.*

(b) *Let $\{Z_j\}_j$ be a collection of independent Poisson variables with parameters $\{\lambda_j\}_j$. Then, $S = \sum_j Z_j$ is distributed as $\mathsf{Pois}(\sum_j \lambda_j)$.*

3 Stochastic Minimum Norm Load Balancing with Poisson Jobs

We now consider StochNormLB with Poisson job sizes, denoted PoisNormLB, wherein the processing time of a job j on machine i is a $\mathsf{Pois}(\lambda_{ij})$ random variable and we seek to minimize the expected f-norm of the load vector. Jobs are independent, but processing times of the same job could be correlated across machines. Our main result is a novel, clean, and versatile *black-box reduction* from PoisNormLB to the deterministic problem, MinNormLB, showing that, for any machine environment (i.e., unrelated/identical machines), guarantees obtained for MinNormLB translate to yield essentially the same guarantees for PoisNormLB.

▶ **Theorem 3.1.** *Let $\mathcal{I}^{\mathsf{Pois}} = (J, [m], \{\lambda_{ij}\}, f)$ be an instance of* PoisNormLB*, and $\mathcal{A}^{\mathsf{Det}}$ be an ρ-approximation algorithm for* MinNormLB*-instances with job-set J, machine-set $[m]$, and $\{\lambda_{ij}\}_{i\in[m],j\in J}$ job sizes. For any $\varepsilon, \eta > 0$, we can utilize $\mathcal{A}^{\mathsf{Det}}$ to obtain an $\rho\big(1+O(\varepsilon)\big)$-approximate solution to* PoisNormLB *with probability at least $1-\eta$, in time $\mathrm{poly}\big(m^{1/\varepsilon}, n, \frac{1}{\eta}\big)$. The run time also bounds the number of calls to $\mathcal{A}^{\mathsf{Det}}$ and the sample size.*

We emphasize that: (a) the above reduction preserves the machine environment: for instance, if we have identical machines ($\lambda_{ij} = \lambda_j$ for all i, j), we only need $\mathcal{A}^{\mathsf{Det}}$ to work for identical machines; and (b) algorithm $\mathcal{A}^{\mathsf{Det}}$ is required to work for an arbitrary monotone, symmetric norm (and not just the norm f): this generality is *crucial* for the above reduction and brings to the fore a prime benefit of working at the level of generality of monotone, symmetric norms. Combining the above reduction with our results for MinNormLB in Sections 4 and 5 *immediately* yields the following results as corollaries. (We do not explicitly indicate the failure probability η below; the sample size, for a fixed ε, is $\mathrm{poly}(m)/\eta$.)

▶ **Theorem 3.2.**

(a) **(Follows from Theorems 3.1 and 4.1)** *For any $\varepsilon > 0$, there is a randomized $\big(2+O(\varepsilon)\big)$-approximation algorithm for* PoisNormLB *on unrelated machines .*

(b) **(Follows from Theorems 3.1 and 5.1)** *There is a randomized PTAS for* PoisNormLB *on identical machines.*

We discuss the chief ideas behind the reduction in Theorem 3.1, deferring some details to the full version of the paper. Since the sum of independent Poisson random variables is another Poisson random variable (Fact 2.11 (b)), the objective value of an assignment $\sigma : J \to [m]$ depends only the aggregate λ-vector $\Lambda^\sigma = (\Lambda^\sigma_i)_{i\in[m]}$, where $\Lambda^\sigma_i := \sum_{j:\sigma(j)=i} \lambda_{ij}$ for all $i \in [m]$. We drop σ in Λ^σ if the assignment σ is clear from the context. Overloading notation, for a vector $y \in \mathbb{R}^m_{\geq 0}$, we use $\mathsf{Pois}(y)$ to denote the random vector $\big(\mathsf{Pois}(y_1), \ldots, \mathsf{Pois}(y_m)\big)$ of *independent* Poisson random variables. Defining $g(y) := \mathbf{E}\big[f(\mathsf{Pois}(y))\big]$ for $y \in \mathbb{R}^m_{\geq 0}$, the goal in PoisNormLB is to find an assignment σ that minimizes $g(\Lambda^\sigma)$. The function g is *not* convex, but it satisfies the following inequality [21] (see Chapter 11, Proposition E.6), which is closely related to a property called *Schur convexity* that is satisfied by all symmetric convex functions. Theorem 3.3 provides a means for controlling $g(y)$, by bounding the Top_ℓ-norms of y, and is key to our approach. We give a self-contained proof of Theorem 3.3 in the full version.

▶ **Theorem 3.3.** *Let $y, y' \in \mathbb{R}^m_{\geq 0}$. If $\mathsf{Top}_i(y) \leq \mathsf{Top}_i(y')$ for all $i \in [m]$, then $g(y) \leq g(y')$.*

To keep notation simple, we assume that f is normalized so that $f(1, 0, \ldots, 0) = 1$; clearly, this is without loss of generality. Let σ^* be an optimal solution to the PoisNormLB-instance $\mathcal{I}^{\mathsf{Pois}}$. Let $\Lambda^* := \Lambda^{\sigma^*}$. The idea underlying our reduction is strikingly simple. Given Theorem 3.3, we aim to (ideally) find an assignment σ such that $\mathsf{Top}_i(\Lambda^\sigma) \leq \mathsf{Top}_i(\Lambda^*)$ for all $i \in [m]$. One of our chief insights is that *this amounts to solving a deterministic*

min-norm load balancing problem with job sizes $\{\lambda_{ij}\}_{i,j}$, and the monotone, symmetric norm $h : \mathbb{R}^m \to \mathbb{R}_{\geq 0}$ given by $h(v) := \max_{i\in[m]} \mathsf{Top}_i(v)/\mathsf{Top}_i(\Lambda^*)$. Now σ^* yields a solution to this MinNormLB-instance of cost 1, and so solving this MinNormLB problem optimally, and utilizing Theorem 3.3, would yield the desired solution.

Further ingredients are needed to make this idea work. We do not know the $\mathsf{Top}_i(\Lambda^*)$ values, and cannot "guess" these values for all $i \in [m]$; moreover, we cannot solve the MinNormLB problem optimally. We utilize the sparsification tools from Section 2, and, with a small loss in approximation, move to the sparse set $\mathsf{POS} = \mathsf{POS}_{m,\delta}$ (for, say, $\delta = \min\{0.5, \varepsilon\}$) and work with estimates B_ℓ of $\mathsf{Top}_\ell(\Lambda^*)$ for all $\ell \in \mathsf{POS}$; so the norm in the MinNormLB instance is now $h(v) := \max_{\ell\in\mathsf{POS}} \mathsf{Top}_\ell(v)/B_\ell$. Now, using the algorithm $\mathcal{A}^{\mathsf{Det}}$ with the correct estimate-vector $B^* \in \mathbb{R}^{\mathsf{POS}}_{\geq 0}$ (where each B^*_ℓ overestimates $\mathsf{Top}_\ell(\Lambda^*)$ within a $(1+\delta)$-factor), we obtain an assignment σ such that $\mathsf{Top}_i(\Lambda^\sigma) \leq \alpha' \mathsf{Top}_i(\Lambda^*)$ for all $i \in [m]$, where $\alpha' = \alpha\big(1 + O(\varepsilon)\big)$. Theorem 3.3 then shows that $g(\Lambda^\sigma) \leq g(\alpha'\Lambda^*)$, but we need a bound in terms of $g(\Lambda^*)$. To this end, we prove the important property that g is *subhomogeneous* (Lemma 3.5): $g(\theta y) \leq \theta \cdot g(y)$ for any $\theta \geq 1$. Finally, we cannot quite identify the correct B^*, but we can isolate it in a polynomial-size set. We show how to estimate $g(y)$ using polynomially many samples (Lemma 3.6), and utilize this estimator to find (loosely speaking) the best solution among those computed for each candidate estimate-vector in this set. Combining these various ingredients yields Theorem 3.1.

▶ **Lemma 3.4.** *Let $y \in \mathbb{R}^m_{\geq 0}$. We have $\max\{f(y), 1 - e^{-\mathsf{Top}_m(y)}\} \leq g(y) \leq \mathsf{Top}_m(y)$.*

Proof. To prove the upper bound on g we use Claim 2.1 (recall that f is normalized) and Fact 2.11 (a): $\mathbf{E}\big[f(\mathsf{Pois}(y))\big] \leq \mathbf{E}\big[\mathsf{Top}_m(\mathsf{Pois}(y))\big] = \mathbf{E}\big[\sum_{i\in[m]} \mathsf{Pois}(y_i)\big] = \mathsf{Top}_m(y)$. The first lower bound follows from convexity of norms: $\mathbf{E}\big[f(\mathsf{Pois}(y))\big] \geq f(\mathbf{E}\big[\mathsf{Pois}(y)\big]) = f(y)$. Lastly, for the second lower bound, we use Claim 2.1:

$$\begin{aligned}\mathbf{E}\big[f(\mathsf{Pois}(y))\big] \geq \mathbf{E}\big[\mathsf{Top}_1(\mathsf{Pois}(y))\big] &\geq \mathbf{Pr}\big[\mathsf{Top}_1(\mathsf{Pois}(y)) > 0\big] \\ &= 1 - \prod_{i\in[m]} \mathbf{Pr}\big[\mathsf{Pois}(y_i) = 0\big] = 1 - e^{-\mathsf{Top}_m(y)}.\end{aligned}$$ ◀

▶ **Lemma 3.5** (Subhomogeneity). *For any $y \in \mathbb{R}^m_{\geq 0}$ and scalar $\theta \geq 1$, we have $g(\theta y) \leq \theta \cdot g(y)$.*

Proof. We prove this for rational θ. The proof for general θ then follows from a continuity argument, which we defer to the full version. Let $\theta = a/b$ for integers $a > b \geq 1$. (If $a = b$, there is nothing to be shown.) Observe that $g(\theta y) = g(az)$ and $g(y) = g(bz)$, where $z = y/b$. So, for the rational case, it suffices to prove that $g(az) \leq \frac{a}{b} g(bz)$ holds for all $z \in \mathbb{R}^m_{\geq 0}$ and integers $a > b \geq 1$. Fix some $z \in \mathbb{R}^m_{\geq 0}$. Let $Z^{(0)}, Z^{(1)}, \ldots, Z^{(a-1)}$ be a independent random vectors that are identically distributed copies of $\mathsf{Pois}(z)$ (so each $Z_i^{(j)}$ is an independent $\mathsf{Pois}(z_i)$ random variable). For any $i \in [m]$, $\mathsf{Pois}(az_i)$ is identically distributed as $\sum_{j=0}^{a-1} Z_i^{(j)}$ (Fact b), so $g(az) = \mathbf{E}\big[f\big(\mathsf{Pois}(az)\big)\big] = \mathbf{E}\big[f\big(\sum_{j=0}^{a-1} Z^{(j)}\big)\big]$. Also, for any subset $S \subseteq \{0, 1, \ldots, a\}$ with $|S| = b$, we have $\mathbf{E}\big[f\big(\sum_{j\in S} Z^{(j)}\big)\big] = g(bz)$. Define size-$b$ index sets $S_k := \{(k+j) \bmod a : j = 0, \ldots, b-1\}$, for $k = 0, 1, \ldots, a-1$. Note that each $j \in \{0, \ldots, a-1\}$ is contained in exactly b of these sets.

$$g(az) = \mathbf{E}\big[f\big(\sum_{j=0}^{a-1} Z^{(j)}\big)\big] = \mathbf{E}\big[f\big(\tfrac{1}{b} \cdot \sum_{k=0}^{a-1} \sum_{j\in S_k} Z^{(j)}\big)\big] \leq \frac{1}{b} \cdot \sum_{k=0}^{a-1} \mathbf{E}\big[f\big(\sum_{j\in S_k} Z^{(j)}\big)\big] = \frac{a}{b} \cdot g(bz).$$ ◀

▶ **Lemma 3.6.** *Let $\varepsilon, \eta > 0$. Let $y \in \mathbb{R}^m_{\geq 0}$ be such that $\mathsf{Top}_m(y) \geq \varepsilon$. Let $N := 2\max\{m^2, 4/\varepsilon\}/(\varepsilon^2\eta)$. Using at most N independent samples from $\mathsf{Pois}(y)$, we can compute an estimate γ satisfying $\mathbf{Pr}\big[\gamma \in [(1-\varepsilon)g(y), (1+\varepsilon)g(y)]\big] \geq 1 - \eta$.*

Proof. Let $x^{(1)}, \dots, x^{(N)}$ be N independent samples from $\mathsf{Pois}(y)$, and let $\gamma := \frac{1}{N}\sum_{j=1}^{N} f(x^{(j)})$ denote the sample f-average. We show that γ is the desired estimator by using Chebyshev's concentration inequality. To this end, we need a bound on the variance of the real-valued random variable $f(\mathsf{Pois}(y))$. We have $\mathrm{Var}\big[f(\mathsf{Pois}(y))\big] \le \mathbf{E}\big[f^2(\mathsf{Pois}(y))\big] \le \mathbf{E}\big[\mathsf{Top}_m^2(\mathsf{Pois}(y))\big]$ by Claim 2.1, and $\mathbf{E}\big[\mathsf{Top}_m^2(\mathsf{Pois}(y))\big] = \mathrm{Var}\big[\mathsf{Pois}(\mathsf{Top}_m(y))\big] + \big(\mathbf{E}\big[\mathsf{Pois}(\mathsf{Top}_m(y))\big]\big)^2$. By Fact b, $\mathsf{Top}_m(\mathsf{Pois}(y))$ is distributed as $\mathsf{Pois}(\mathsf{Top}_m(y))$. As the variance of a Poisson variable with mean λ is λ, we obtain that

$$\mathrm{Var}\big[f(\mathsf{Pois}(y))\big] \le \mathrm{Var}\big[\mathsf{Pois}(\mathsf{Top}_m(y))\big] + \big(\mathbf{E}\big[\mathsf{Pois}(\mathsf{Top}_m(y))\big]\big)^2 \le 2\mathsf{Top}_m(y)\max(1, \mathsf{Top}_m(y)).$$

Since γ is an average of $f(\mathsf{Pois}(y))$ over N independent samples, we have $\mathrm{Var}\big[\gamma\big] = \mathrm{Var}\big[f(\mathsf{Pois}(y))\big]/N$. By Chebyshev's inequality,

$$\mathbf{Pr}\big[|\gamma - g(y)| > \varepsilon g(y)\big] \le \frac{\mathrm{Var}\big[\gamma\big]}{\varepsilon^2 g^2(y)} \le \frac{2}{N\varepsilon^2}\cdot\frac{\mathsf{Top}_m(y)\max(1,\mathsf{Top}_m(y))}{g^2(y)} \le \frac{2\max\{m^2, 4/\varepsilon\}}{N\epsilon^2} \le \eta$$

It remains to justify the penultimate inequality used above. First, observe that $\mathsf{Top}_m(y)/g(y) \le m$ for any $y \in \mathbb{R}^m_{\ge 0}$, so the inequality holds when $\mathsf{Top}_m(y) \ge 1$. Suppose $\mathsf{Top}_m(y) \in [\varepsilon, 1]$. We have $g(y) \ge 1 - e^{-\mathsf{Top}_m(y)}$ (by Lemma 3.4), which is at least $\mathsf{Top}_m(y)(1 - \mathsf{Top}_m(y)/2) \ge \mathsf{Top}_m(y)/2$. This finishes the proof of the lemma. ◀

Proof of Theorem 3.1. Set $\epsilon' = \delta = \min\{0.5, \varepsilon\}$. Let σ^{sum} be the assignment that minimizes the expected sum of machine loads, so $\sigma^{\mathsf{sum}}(j) = \mathrm{argmin}_i \lambda_{ij}$ for all jobs j. Let $\Lambda^{\mathsf{sum}} := \Lambda^{\sigma^{\mathsf{sum}}}$, and $\mathsf{UB} := \mathsf{Top}_m(\Lambda^{\mathsf{sum}})$. If $\mathsf{UB} \le \epsilon'$, then we claim that σ^{sum} is a $(1+\epsilon')$-approximate solution to PoisNormLB. This is because we have $\mathsf{Top}_m(\Lambda^*) \ge \mathsf{UB}$, and so by Lemma 3.4, we have that $g(\Lambda^{\mathsf{sum}}) \le \mathsf{UB}$ and $g(\Lambda^*) \ge 1 - e^{-\mathsf{UB}} \ge \mathsf{UB}(1 - \mathsf{UB}/2) \ge \mathsf{UB}/(1+\epsilon')$, where we use that $\mathsf{UB} \le \epsilon' \le 1$.

So suppose that $\mathsf{UB} \ge \epsilon'$ (and so $\mathsf{Top}_m(\Lambda^\sigma) \ge \epsilon'$ for every assignment σ). We have $\mathsf{Top}_1(\Lambda^*) \ge \mathsf{Top}_m(\Lambda^*)/m \ge \mathsf{UB}/m$. Also, $\mathsf{Top}_m(\Lambda^*) \le m\mathsf{Top}_1(\Lambda^*)$, and we have $\mathsf{Top}_1(\Lambda^*) \le f(\Lambda^*) \le g(\Lambda^*) \le g(\Lambda^{\mathsf{sum}}) \le \mathsf{UB}$; here, we have used Claim 2.1, Lemma 3.4 (twice), and the optimality of σ^*. So we obtain that $\mathsf{Top}_m(\Lambda^*) \le m \cdot \mathsf{UB}$.

Now consider the non-increasing vector u which is $(\Lambda^*_\ell)_{\ell \in \mathsf{POS}}$ with its coordinates listed in *decreasing* order of ℓ. We apply Lemma 2.9 (b) on u, taking $\mathcal{L} = \mathsf{POS}$, and upper and lower bounds $m \cdot \mathsf{UB}$ and UB/m respectively, to obtain a $\mathrm{poly}(m^{1/\delta})$-size set $\mathcal{T} \subseteq \mathbb{R}^{\mathsf{POS}}_{\ge 0}$ containing a vector B^* such that $\mathsf{Top}_\ell(\Lambda^*) \le B^*_\ell \le (1+\delta)\mathsf{Top}_\ell(\Lambda^*)$ for all $\ell \in \mathsf{POS}$.

For each $B \in \mathcal{T}$, we do the following. Let $h_B : \mathbb{R}^m \to \mathbb{R}_{\ge 0}$ be the monotone, symmetric norm defined as $h_B(v) := \max_{\ell \in \mathsf{POS}} \mathsf{Top}_\ell(v)/B_\ell$. We run $\mathcal{A}^{\mathsf{Det}}$ on the MinNormLB instance with $\{\lambda_{ij}\}_{i\in[m], j\in J}$ job sizes and norm h_B, to obtain an assignment σ^B. Let $\Lambda^B = \Lambda^{\sigma^B}$. We use Lemma 3.6 to compute an estimate γ^B such that $\mathbf{Pr}\big[\gamma^B \in [(1-\epsilon')g(\Lambda^B), (1+\epsilon')g(\Lambda^B)]\big] \ge 1 - \frac{\eta}{|\mathcal{T}|}$. We output the assignment $\sigma^{B'}$ with smallest $\gamma^{B'}$ value among all $B' \in \mathcal{T}$.

We argue that this is an $\rho\big(1+O(\varepsilon)\big)$-approximation with probability at least $1-\eta$. By the union bound, with probability at least $1-\eta$, we have that $\gamma^B \in [(1-\epsilon')g(\Lambda^B), (1+\epsilon')g(\Lambda^B)]$ for all $B \in \mathcal{T}$; we assume that this event happens. Consider the correct guess $B^* \in \mathcal{T}$. We have $h_{B^*}(\Lambda^*) \le 1$, and so the solution σ^{B^*} satisfies $\mathsf{Top}_\ell(\Lambda^{B^*}) \le \rho B^*_\ell \le \rho(1+\delta)\mathsf{Top}_\ell(\Lambda^*)$ for all $\ell \in \mathsf{POS}$. Using Claim 2.6, we have $\mathsf{Top}_i(\Lambda^{B^*}) \le \rho(1+\delta)^2\mathsf{Top}_i(\Lambda^*)$ for all $i \in [m]$. By Theorem 3.3 and Lemma 3.5, we then obtain that $g(\Lambda^{B^*}) \le \rho(1+\delta)^2 g(\Lambda^*)$. Accounting for the error due to the γ^B estimates, yields $g(\Lambda^{B'}) \le \frac{1+\epsilon'}{1-\epsilon'} \cdot g(\Lambda^{B^*}) \le \rho(1+15\epsilon')g(\Lambda^*)$. ◀

4 A $(2+\epsilon)$-approximation for MinNormLB on unrelated machines

▶ **Theorem 4.1.** *For any $\varepsilon > 0$, there is a $\big(2+O(\varepsilon)\big)$-approximation algorithm for* MinNormLB *on unrelated machines.*

Our algorithm yielding the above theorem is based on LP-rounding. Our relaxation is different from the LP used in [4] and the convex program used in [5] for MinNormLB. The latter relaxation, which was used to obtain the previous best $(4+\varepsilon)$-approximation has an integrality gap of (roughly) 4 [3], and therefore we need new ideas to obtain our $(2+\varepsilon)$-approximation algorithm. Indeed, our LP and rounding algorithm leverage and build upon the ideas used in the above works in a novel fashion.

Let $n = |J|$ be the number of jobs. Let σ^* denote an optimal solution, $\vec{o} := \big(\overrightarrow{\mathsf{load}}_{\sigma^*}\big)$ be the load vector induced by σ^*, and let $\mathsf{OPT} = f(\vec{o})$ denote the optimal value. Define the cost of a job j under σ^* to be $p_{\sigma^*(j)j}$. For any set $S \subseteq J$ of jobs, define the job-cost vector $\overrightarrow{P^*_S} = \overrightarrow{P^{\sigma^*}_S} := \big(p_{\sigma^*(j)j}\big)_{j\in S}$. Let $\varepsilon > 0$ be a parameter, and let $\delta = \min\{\varepsilon, 1\}$. Recall that we abbreviate $\mathsf{POS}_{m,\delta}$ to POS. We may assume that $n \geq \lceil 2(1+\delta)/\delta^3 \rceil$ as otherwise we can simply exhaustively search for the optimal assignment.

LP relaxation. As is standard, our LP has variables x_{ij} for every machine i and job j denoting if job j is assigned to machine i (or, fractionally, the extent of j assigned to machine i). Constraints (2) enforce that every job is assigned to a machine.

We are guided by Theorem 2.4, which shows that to obtain a solution whose load vector has f-norm equal to $O(\mathsf{OPT})$, it suffices to show that the Top_ℓ-norm of the load vector is $O\big(\mathsf{Top}_\ell(\vec{o})\big)$ for all $\ell \in [m]$; also, by Claim 2.6, one can focus on indices $\ell \in \mathsf{POS}$. We work with "guesses" (i.e., estimates) t_ℓ of $\vec{o}^{\downarrow}_\ell$, for all $\ell \in \mathsf{POS}$. Our LP seeks a fractional solution such that the resulting load vector has Top_ℓ-norm at most $\mathsf{Top}_\ell(\vec{o})$ for all $\ell \in \mathsf{POS}$. Using Claim 2.3 and our estimates, we encode this via the constraint $\ell t_\ell + \sum_i \big(\sum_j p_{ij}x_{ij} - t_\ell\big)^+ \leq \mathsf{Top}_\ell(\overrightarrow{t^{\mathsf{exp}}})$ for all $\ell \in \mathsf{POS}$; constraints (3), (4) linearize these. (Recall that $\overrightarrow{t^{\mathsf{exp}}} \in \mathbb{R}^m_{\geq 0}$ is defined by $t^{\mathsf{exp}}_i = t_i$ for $i \in \mathsf{POS}$, and $t^{\mathsf{exp}}_i = t_{\mathsf{prev}(i)}$ for $i \in [m] \setminus \mathsf{POS}$.)

The last set of constraints of our LP is motivated by an insight in [5]. They show that if $\overrightarrow{\mathsf{JL}^*} \in \mathbb{R}^m_{\geq 0}$ is the vector comprising the costs of the m most costly jobs under σ^*, then we have $f(\overrightarrow{\mathsf{JL}^*}) \leq \mathsf{OPT}$, which also implies that $f(\overrightarrow{P^*_S}) \leq \mathsf{OPT}$ for any set S of m jobs. Chakrabarty and Swamy [5] include this (convex) constraint directly in their convex program, and it plays a crucial role in obtaining their $(4+\varepsilon)$-approximation for MinNormLB. We also utilize this constraint, but incorporate it (loosely speaking) in our LP in a more subtle fashion. We work with guesses ζ_ℓ of $\overrightarrow{\mathsf{JL}^*}^{\downarrow}_\ell$ for all $\ell \in \mathsf{POS}$, and encode (see constraints (5)) that there are at most $\ell - 1$ jobs whose cost is larger than ζ_ℓ, for all $\ell \in \mathsf{POS}$. This can be seen as an indirect way of capturing $f(\overrightarrow{\mathsf{JL}^*}) \leq \mathsf{OPT}$, and this indirect way is crucial for us because we show that we can round a fractional solution x with only a $(1+\delta)$-factor violation of these constraints. For technical reasons, to facilitate this, we use another partial enumeration step. Let ℓ_0 be the smallest index in POS that is at least $\frac{2}{\delta^3}$. Note that $\ell_0 \leq \lceil 2(1+\delta)/\delta^3 \rceil \leq n$. We will guess the ℓ_0 most costly jobs under σ^* and their σ^*-assignments. Let $C = \{(i_1, j_1), (i_2, j_2), \ldots, (i_{\ell_0}, j_{\ell_0})\}$ denote our guess of these jobs and their σ^*-assignments. Note that given C, we know that $\overrightarrow{\mathsf{JL}^*}^{\downarrow}_\ell$ is the ℓ-th largest value in $\{p_{ij} : (i,j) \in C\}$ for all $\ell \in [\ell_0]$, and we therefore set $\zeta_\ell = \overrightarrow{\mathsf{JL}^*}^{\downarrow}_\ell$ for all $\ell \in \mathsf{POS}$ with $\ell \leq \ell_0$. An important consequence of this enumeration step, which will be crucial in the analysis (see the proof of Lemma 4.3), is that this *fixes* the assignment of all jobs whose cost under σ^* is larger than ζ_{ℓ_0}; we encode this in our LP via constraints (6).

This yields the following LP, which is a feasibility LP depending on $\vec{t}$, $\vec{\zeta}$, and C. Throughout, we use i to index $[m]$, and j to index J.

$$
\begin{aligned}
& x \geq 0, \quad \sum_i x_{ij} = 1 && \forall j \in J && (2)\\
& \ell t_\ell + \sum_i W_i^\ell \leq \mathsf{Top}_\ell(\overrightarrow{t^{\mathsf{exp}}}) && \forall \ell \in \mathsf{POS} && (3)\\
(\mathsf{LP}(\vec{t},\vec{\zeta},C)) \qquad & W_i^\ell \geq 0, \quad W_i^\ell \geq \sum_j p_{ij}x_{ij} - t_\ell && \forall i \in [m],\ \ell \in \mathsf{POS} && (4)\\
& \sum_{i,j:p_{ij}>\zeta_\ell} x_{ij} \leq \ell - 1 && \forall \ell \in \mathsf{POS} && (5)\\
& x_{ij} = \begin{cases} 1 & \text{if } (i,j) \in C \\ 0 & \text{otherwise.} \end{cases} && \forall i \in [m], j \in J \text{ s.t. } p_{ij} > \zeta_{\ell_0} && (6)
\end{aligned}
$$

▷ Claim 4.2. $(\mathsf{LP}(\vec{t},\vec{\zeta},C))$ is feasible whenever: (i) $t_\ell \geq \vec{o}^{\downarrow}_\ell$, $\zeta_\ell \geq \overrightarrow{\mathsf{JL}^*}^{\downarrow}_\ell$ for all $\ell \in \mathsf{POS}$; and (ii) C is the correct guess of the ℓ_0 most costly jobs under σ^* and their σ^*-assignments.

Rounding algorithm. Assume that $(\mathsf{LP}(\vec{t},\vec{\zeta},C))$ is feasible and $(\overline{x},\overline{W})$ is a feasible solution. We consider the following auxiliary LP (Aux) for rounding $\overline{x}$.

$$x \geq 0, \quad \sum_i x_{ij} = 1 \ \ \forall j \in J, \quad \sum_j p_{ij}x_{ij} \leq \sum_j p_{ij}\overline{x}_{ij} \ \ \forall i \in [m], \quad \sum_{i,j:p_{ij}>\zeta_\ell} x_{ij} \leq \ell - 1 \quad \forall \ell \in \mathsf{POS}.$$

Clearly, $\overline{x}$ is a feasible solution to (Aux). We show that this can be rounded to an integer solution $\widetilde{x}$ so that $\sum_i \widetilde{x}_{ij} = 1$ for every job j, the load on each machine is at most its $\overline{x}$-load $+ (1+\delta)\times$(cost of the most-costly job assigned to it), and the remaining constraints are violated by a small factor. More precisely, in the analysis, we prove the following result.

▶ **Lemma 4.3.** *We can round $\overline{x}$ efficiently to an integer solution $\widetilde{x}$ satisfying the following.*
(a) *$\widetilde{x}_{ij} = \overline{x}_{ij}$ for all i,j such that $\overline{x}_{ij} \in \{0,1\}$;*
(b) *$\sum_i \widetilde{x}_{ij} = 1$ for each job j;*
(c) *$\sum_j p_{ij}\widetilde{x}_{ij} \leq \sum_i p_{ij}\overline{x}_{ij} + (1+\delta)\max_{j:\widetilde{x}_{ij}=1} p_{ij}$ for every machine i;*
(d) *$\sum_{i,j:p_{ij}>\zeta_\ell} \widetilde{x}_{ij} \leq \ell - 1$ for all $\ell \in \mathsf{POS}$ with $\ell \leq \ell_0$; and*
(e) *$\sum_{i,j:p_{ij}>\zeta_\ell} \widetilde{x}_{ij} \leq (1+\delta)\ell - 1$ for all $\ell \in \mathsf{POS}$ with $\ell > \ell_0$.*

We apply the above lemma, and due to Lemma 4.3 (a), the integer solution $\widetilde{x}$ yields an assignment $\widetilde{\sigma}$ of jobs to machines; we return this assignment.

Analysis. We assume again that f is normalized. Lemma 4.3 is the main technical result that we need to prove. Its proof utilizes an *iterative-rounding* result of independent interest (Theorem 4.6) that is very similar to Corollary 11 in [19], wherein iterative rounding is used to round a point that lies in the base polytope of one matroid $\mathcal{M}_0$ and satisfies various other matroid-independence and knapsack constraints, to a basis of $\mathcal{M}_0$ that is "approximately independent" in the other matroids and violates the knapsack constraints by a certain additive factor. In (Aux), the job assignment constraints correspond to the base-polytope constraints (of a partition matroid), and the remaining constraints correspond to knapsack constraints. First, we establish that, assuming Lemma 4.3, we obtain the stated guarantee.

Suppose that we have the correct set C, and that $\vec{t}$ and $\vec{\zeta}$ are "good" estimates of $(\vec{o}^{\downarrow}_{\ell})_{\ell\in\mathsf{POS}}$ and $(\overrightarrow{\mathsf{JL}^*}^{\downarrow}_{\ell})_{\ell\in\mathsf{POS}}$ respectively (we make this precise later). We analyze the load vector $\overrightarrow{\mathsf{load}}_{\widetilde{\sigma}}$ by considering two vectors $L=(L_i)_{i\in[m]}$ and $P=(P_i)_{i\in[m]}$. For each $i\in[m]$, define $L_i=\sum_j p_{ij}\bar{x}_{ij}$, and $P_i=\max_{j:\widetilde{\sigma}(j)=i} p_{ij}$; note that $P_i=0$ if there is no job assigned by $\widetilde{\sigma}$ to machine i. By Lemma 4.3 (c), we have that $\overrightarrow{\mathsf{load}}_{\widetilde{\sigma}}\le L+(1+\delta)P$, and we bound both $f(L)$ and $f(P)$ by roughly OPT. Constraints (3), (4) of our LP immediately allow us to bound $\mathsf{Top}_\ell(L)$ by $\mathsf{Top}_\ell(\overrightarrow{t^{\mathsf{exp}}})$ for all $\ell\in\mathsf{POS}$, which suffices since $\vec{t}$ well estimates $(\vec{o}^{\downarrow}_{\ell})_{\ell\in\mathsf{POS}}$ (see Lemma 4.4). For the vector P, parts (d) and (e) of Lemma 4.3 yield the desired bound on $f(P)$, due to Lemma 2.8 (c) (see Lemma 4.5). Before proving Lemmas 4.4 and 4.5, we justify, and make precise, the assumption that we have the correct set C (specifying the ℓ_0 most costly jobs under σ^* and their σ^*-assignments), and good estimates $\vec{t}$, $\overrightarrow{\mathsf{JL}^*}$. There are at most $\binom{n}{\ell_0}\cdot m^{\ell_0}$ choices for the set C. As noted earlier, for all $\ell\in\mathsf{POS}$ with $\ell\le\ell_0$, this then fixes $\zeta_\ell=\zeta^*_\ell=\overrightarrow{\mathsf{JL}^*}^{\downarrow}_{\ell}$ to be the ℓ-th largest entry in $\{p_{ij}:(i,j)\in C\}$. Using Claim 2.1, if we consider the assignment σ^{sum} that minimizes the sum of the machine loads – so $\sigma^{\mathsf{sum}}(j)=\mathrm{argmin}_i p_{ij}$ for all jobs j – and set $\mathsf{UB}:=\sum_i \mathsf{load}_{\sigma^{\mathsf{sum}}}(i)$, then we obtain that $\frac{\mathsf{UB}}{m}\le\mathsf{OPT}\le\mathsf{UB}$, and so $\vec{o}_1,\overrightarrow{\mathsf{JL}^*}_1\le\mathsf{UB}$. Set $\kappa=\varepsilon\mathsf{UB}/m^2$. Let $\mathsf{POS}_{>}:=\{\ell\in\mathsf{POS}:\ell>\ell_0\}$. So using Lemma 2.9 (a) (and since $|\mathsf{POS}|=O(\log m/\delta)$), we can identify polynomial-size sets containing vectors $\vec{t}=\vec{t^*}$ and $(\zeta_\ell)_{\ell\in\mathsf{POS}_{>}}=(\zeta^*_\ell)_{\ell\in\mathsf{POS}_{>}}$ such that:

(1) $\vec{o}^{\downarrow}_{\ell}\le t^*_\ell\le(1+\varepsilon)\vec{o}^{\downarrow}_{\ell}+\kappa$ for all $\ell\in\mathsf{POS}$, and $\vec{t^*}$ is a non-increasing vector; and

(2) $\overrightarrow{\mathsf{JL}^*}^{\downarrow}_{\ell}\le\zeta^*_\ell\le(1+\varepsilon)\overrightarrow{\mathsf{JL}^*}^{\downarrow}_{\ell}+\kappa$ for all $\ell\in\mathsf{POS}_{>}$, and $\zeta^*=(\zeta^*_\ell)_{\ell\in\mathsf{POS}}$ is non-increasing.

For (1), we take $\mathcal{L}=\mathsf{POS}$, $\mathsf{ub}=\mathsf{UB}$, and κ as above; for (2), we take $\mathcal{L}=\mathsf{POS}_{>}$, $\mathsf{ub}=\overrightarrow{\mathsf{JL}^*}_{\ell_0}$, and κ as above.) Recall that $\delta=\min\{\varepsilon,1\}$.

▶ **Lemma 4.4.** *We have* $f(L)\le(1+\delta)(1+\varepsilon)\mathsf{OPT}+m\kappa\le(1+\delta+3\varepsilon)\mathsf{OPT}$.

Proof. We show that $\mathsf{Top}_i(L)\le\mathsf{Top}_i(\overrightarrow{t^{*\mathsf{exp}}})$ for *all* $i\in[m]$. For any $\ell\in\mathsf{POS}$, this follows quite directly from constraints (3), (4) of our LP $(\mathsf{LP}(\vec{t},\vec{\zeta},C))$: we have $\mathsf{Top}_\ell(L)\le\ell t^*_\ell+\sum_{i'\in[m]}(L_{i'}-t^*_\ell)^+\le\mathsf{Top}_\ell(\overrightarrow{t^{*\mathsf{exp}}})$. For any $i\in[m]\setminus\mathsf{POS}$, taking $\ell=\mathsf{prev}(i)$, this then implies that

$$\mathsf{Top}_i(L)\le it^*_\ell+\sum_{i'\in[m]}(L_{i'}-t^*_\ell)^+\le\mathsf{Top}_\ell(\overrightarrow{t^{*\mathsf{exp}}})+(i-\ell)t^*_\ell=\mathsf{Top}_i(\overrightarrow{t^{*\mathsf{exp}}}),$$

where the final equality follows because $t^{*\mathsf{exp}}_{i'}=t^*_\ell$ for all $i'\in\{\ell,\ell+1,\dots,\mathsf{next}(\ell)-1\}$. Hence, by Theorem 2.4, we have that $f(L)\le f(\overrightarrow{t^{*\mathsf{exp}}})$.

Since $t^*_\ell\le(1+\varepsilon)\vec{o}^{\downarrow}_{\ell}+\kappa$ for all $\ell\in\mathsf{POS}$, by Lemma 2.8 (b), taking $u=\vec{o}$ and $v=\vec{t^*}$, we obtain that $f(\overrightarrow{t^{*\mathsf{exp}}})\le(1+\delta)(1+\varepsilon)f(\vec{o})+m\kappa$. The final inequality in the lemma statement follows because $m\kappa\le\varepsilon\mathsf{OPT}$ and $(1+\delta)(1+\varepsilon)\le(1+\delta+2\varepsilon)$ as $\delta\le1$. ◀

▶ **Lemma 4.5.** *We have* $f(P)\le(1+4\delta+5\varepsilon)f(\overrightarrow{\mathsf{JL}^*})+5m\kappa\le(1+4\delta+10\varepsilon)\mathsf{OPT}$.

Proof. We apply Lemma 2.8 (c), taking $u=\overrightarrow{\mathsf{JL}^*}$, $\alpha=P$, and $v=(\zeta^*_\ell)_{\ell\in\mathsf{POS}}$. The conditions in Lemma 2.8 (c) hold due to parts (d) and (e) of Lemma 4.3. This yields that $f(P)\le(1+4\delta)(1+\varepsilon)f(\overrightarrow{\mathsf{JL}^*})+5m\kappa$. The lemma follows since $\delta\le1$, $m\kappa\le\varepsilon\mathsf{OPT}$, and $f(\overrightarrow{\mathsf{JL}^*})\le\mathsf{OPT}$. ◀

Proof of Theorem 4.1. Recall that $\widetilde{\sigma}$ is the assignment returned by the algorithm. Lemmas 4.4 and 4.5 together with the fact that $\overrightarrow{\mathsf{load}}_{\widetilde{\sigma}}\le L+(1+\delta)P$ immediately yield that

$$f(\overrightarrow{\mathsf{load}}_{\widetilde{\sigma}})\le(1+\delta+3\varepsilon)\mathsf{OPT}+(1+\delta)(1+4\delta+10\varepsilon)\mathsf{OPT}\le(2+10\delta+23\varepsilon)\mathsf{OPT}.$$ ◀

Proof of Lemma 4.3

We reproduce the system (Aux) below for easy reference.

$$\text{(Aux)}\quad \begin{aligned} x \geq 0, \quad \sum_i x_{ij} &= 1 && \forall j \in J && (7)\\ \sum_j p_{ij} x_{ij} &\leq \sum_j p_{ij} \overline{x}_{ij} && \forall i \in [m] && (8)\\ \sum_{i,j: p_{ij} > \zeta_\ell} x_{ij} &\leq \ell - 1 && \forall \ell \in \mathsf{POS} && (9) \end{aligned}$$

We utilize the following iterative-rounding result that is quite similar to Corollary 11 in [19].

▶ **Theorem 4.6** (Similar to Corollary 11 in [19]). *Let $\mathcal{M}_s = (N_s, \mathcal{I}_s)$, for $s = 0, \ldots, k$ be $(k+1)$ matroids, where each N_s is a subset of $N := N_0$. Let r_s be the rank function of matroid $\mathcal{M}_s$, for $s = 0, \ldots, k$. Let $w \in \mathbb{R}^N$, $A \in \mathbb{R}^{d \times N}_{\geq 0}$, $b \in \mathbb{R}^d_{\geq 0}$. Consider the following LP.*

$$\begin{aligned} \max \quad & w^T x && && (\mathrm{LP}_{\mathrm{matkn}})\\ \textit{s.t.} \quad & x(N) = r_0(N), \quad x(T) \leq r_0(T) && \forall T \subseteq N\\ & x(T) \leq r_s(T) && \forall s = 1, \ldots, k, \forall T \subseteq N_i\\ & Ax \leq b, \quad x \geq 0. \end{aligned}$$

Let $q_1, \ldots, q_k \geq 1$ be integers, and $\mu_1, \ldots, \mu_d \in \mathbb{R}_{\geq 0}$ be such that:

$$\sum_{s \in [k]: e \in N_s} \frac{1}{q_s} + \sum_{s \in [d]: A_{se} > 0} \frac{1}{\mu_s} \leq 1 \qquad \forall e \in N. \tag{10}$$

If $(\mathrm{LP}_{\mathrm{matkn}})$ is feasible, then we can efficiently obtain a basis R of $\mathcal{M}_0$ such that:

- **(i)** *$|T| \leq q_s r_s(T)$ for all $s \in [k]$ and $T \subseteq R \cap N_s$;*
- **(ii)** *$\sum_{e \in R} A_{se} \leq b_s + \mu_s \cdot \max_{e \in R} A_{se}$ for all $s \in [d]$; and*
- **(iii)** *$w(R) \geq \mathsf{OPT}_{LP_{\mathrm{matkn}}}$.*

▶ Remark 4.7. The statement of Theorem 4.6 differs from that of Corollary 11 in [19] in three respects. In [19]: (1) $\mu_1, \ldots, \mu_d$ are assumed to be positive integers (but their proof does not need the integrality requirement); (2) condition (10) is replaced by the *weaker* condition, $\sum_{s \in [k]: e \in N_s} \frac{1}{q_s} + \sum_{s \in [d]} \frac{A_{se}}{(\max_{e \in N} A_{se})\mu_s} \leq 1$ for all $e \in N$; and (3) one obtains the slightly *weaker* additive error of $\mu_s \cdot \max_{e \in N} A_{se}$ in (ii) for the knapsack constraint for index $s \in [d]$. The proof of Corollary 11 in [19] is however easily adapted to yield the above statement; we include the proof of Theorem 4.6 in the full version.

For our purposes, we only need a simpler version of Theorem 4.6, where we have only one matroid $\mathcal{M}_0$ and other knapsack constraints. We include the more general statement above (with its subtly stronger guarantee for the knapsack constraints, which turns out to be crucial for us; see Remark 4.8) because we believe that this is of independent interest.

Before delving into the details of how we apply Theorem 4.6 to prove our lemma, we briefly discuss the main idea, which will also elucidate why we need the partial enumeration step of "guessing" the set C specifying the ℓ_0 most costly jobs under σ^* and their σ^*-assignments.

We can cast (Aux) as an instance of $(\mathrm{LP}_{\mathrm{matkn}})$ as follows. Let $U = [m] \times J$. The weight vector w is irrelevant. The matroid $\mathcal{M}_0$ is the partition matroid over U encoding that each job j is assigned to at most one machine. It is immediate that (7) shows that

$\overline{x}$ lies in the base polytope of $\mathcal{M}_0$. Constraints (8) correspond to knapsack constraints in (LP_{matkn}). Constraints (9) can be incorporated into (LP_{matkn}) in three ways: (i) as matroid-independence constraints in the (single) laminar matroid formed by the nested family of sets $\{(i,j) \in U : p_{ij} > \zeta_\ell\}_{\ell \in \mathsf{POS}}$; (ii) as multiple matroid-independence constraints, where for each $\ell \in \mathsf{POS}$, we have a matroid encoding the cardinality bound from $\{(i,j) \in U : p_{ij} > \zeta_\ell\}$; or (iii) as additional knapsack constraints.

But utilizing Theorem 4.6 directly on the above system does not quite work for us. To elaborate, in order to obtain the guarantee in 4.3 (c), we need to set the μ_is for the knapsack constraints (8) to $(1+\delta)$. But then if we view (9) as matroid independence constraints (in one laminar matroid, or multiple matroids), we need to set the q_s value for the corresponding matroid(s) to be at least 2 in order to satisfy (10) resulting in (at least) a multiplicative factor-2 violation of constraints (9), which is too large a violation. Suppose we incorporate (9) as knapsack constraints and, for some constant ρ, take $\mu_\ell = \rho\ell$ for constraint (9) for index ℓ. But to satisfy (10), we need ρ to be at least $\left(1 - \frac{1}{1+\delta}\right)^{-1} \cdot \sum_{\ell' \in \mathsf{POS}:\ell' > 1} \frac{1}{\ell'} = \Omega\left(\frac{1}{\delta^2}\right)$, which again yields too large a violation of (9). (A more accurate estimate of $\sum_{\ell' \in \mathsf{POS}:\ell' > 1}$ is $\ln(\lceil 1/\delta \rceil) + 1 + \delta$, but this still requires ρ to be large.)

However, a tweak of the latter approach does work, by noting that if x_{ij} first appears in constraint (9) for index $\ell \in \mathsf{POS}$, then to satisfy (10), we really need that $\rho \geq \left(1 - \frac{1}{1+\delta}\right)^{-1} \cdot \sum_{\ell' \in \mathsf{POS}:\ell' \geq \ell} \frac{1}{\ell'}$; the RHS is at most $\frac{(1+\delta)^2}{\delta^2 \ell}$, which is at most δ for *large enough* ℓ. *This is precisely where the enumeration of* C *turns out to be key, since it allows us to eliminate constraints* (9) *for* $\ell \leq \ell_0$. Recall that C specifies the ℓ_0 most-costly jobs under σ^* and their σ^*-assignments, where ℓ_0 is the smallest index in POS that is at least $\frac{2}{\delta^3}$. Due to this enumeration, $\overline{x}$ is integral whenever $p_{ij} > \zeta_\ell$, and so if we drop integral variables and corresponding constraints from (Aux), we are left with constraints (9) for indices $\ell > \ell_0$ in POS. Now we can take $\mu_\ell = \delta\ell$ for all $\ell \in \mathsf{POS}$, $\ell > \ell_0$, and these values satisfy (10), since each $\ell > \ell_0$ is large.

We now describe precisely how we utilize Theorem 4.6 to prove our lemma. We apply Theorem 4.6 to (Aux) after getting rid of all integral variables, and modifying or dropping constraints to take into account the integral variables. Recall that $U = [m] \times J$. Let $E = \{(i,j) \in U : \overline{x}_{ij} \in (0,1)\}$. We retain only the variables in E, and only these will be rounded, so this takes care of part (a) of the lemma. We drop any constraint that contains only integral variables. Thus, the POS-constraints (9) for all $\ell \in \mathsf{POS}$, $\ell \leq \ell_0$ are dropped, and so part (d) holds. Let J' be the set of jobs corresponding to the remaining constraints (7); note that all jobs in J' are completely assigned by (the variables in) E, and the remaining jobs are completely assigned by the integral variables. Let $I \subseteq [m]$ index the machine-constraints (8) that remain, and $I^{\mathsf{POS}} \subseteq \{\ell \in \mathsf{POS} : \ell > \ell_0\}$ index the POS-constraints (9) that remain. This yields the following system of constraints.

$$\text{(P')} \quad \begin{cases} \displaystyle\sum_{i:(i,j)\in E} x_{ij} = 1 & \forall j \in J' \\ \displaystyle\sum_{j:(i,j)\in E} p_{ij} x_{ij} \leq \sum_j p_{ij}\overline{x}_{ij} - \sum_{j:\overline{x}_{ij}=1} p_{ij} & \forall i \in I \\ \displaystyle\sum_{(i,j)\in E:p_{ij}>\zeta_\ell} x_{ij} \leq \ell - 1 - \left|\{(i,j) : p_{ij} > \zeta_\ell, \overline{x}_{ij} = 1\}\right| & \forall \ell \in I^{\mathsf{POS}} \\ x \geq 0. \end{cases}$$

Clearly, $(\overline{x}_{ij})_{(i,j)\in E}$ is a feasible solution to (P'). We apply Theorem 4.6 to (P'), taking $\mathcal{M}_0$ to be the partition matroid now with ground set E encoding that every job in J' is assigned to at most one machine, and treating both the machine constraints indexed by I, and the POS-constraints indexed by I^{POS} as knapsack constraints. The weight vector w is irrelevant. We take $\mu_i = (1+\delta)$ for all $i \in I$, and $\mu_\ell = \delta\ell$ for all $\ell \in I^{\mathsf{POS}}$, and we claim that this satisfies condition (10). To see this, consider any $(i,j) \in E$. Let ℓ be the smallest index in I^{POS} whose POS-constraint contains the variable x_{ij}. Then, x_{ij} appears possibly in the machine constraint for machine i, and the POS-constraints for indices $\ell' \in \mathsf{POS}$, $\ell' \geq \ell$. We have

$$\sum_{\ell' \in I^{\mathsf{POS}}: \ell' \geq \ell} \frac{1}{\mu_{\ell'}} \leq \sum_{\ell' \in \mathsf{POS}: \ell' \geq \ell} \frac{1}{\delta \ell'} \leq \frac{1}{\delta\ell} \cdot \sum_{k \geq 0} (1+\delta)^{-k} = \frac{1}{\delta\ell} \cdot \frac{1+\delta}{\delta} \leq \frac{1}{\delta^2 \ell_0} \leq \frac{\delta}{2}.$$

Since $\frac{1}{1+\delta} + \frac{\delta}{2} \leq 1$, it follows that (10) is satisfied for (i,j).

Finally, we argue that applying Theorem 4.6 with the above parameters yields the lemma. Let $\widetilde{x}$ be the solution obtained by concatenating the integral portion of $\overline{x}$, and the integer solution returned by Theorem 4.6. Part (b) holds because we return a basis of $\mathcal{M}_0$, and the jobs not in J' are completely assigned by the integral portion of $\overline{x}$. Parts (c) and (e) follow directly from our choice of the μ values. ◀

▶ Remark 4.8. We note that the subtly stronger guarantee obtained for the knapsack constraint for index s, in Theorem 4.6, versus Corollary 11 in [19] – i.e., an additive error of $\mu_s \cdot \max_{e \in R} A_{se}$ versus an additive error of $\mu_s \cdot \max_{e \in N} A_{se}$ – is crucial for us. The weaker guarantee would yield, after dropping integral (and hence 0-valued) variables, that the load on each machine i is at most $\sum_j p_{ij}\overline{x}_{ij} + (1+\delta)\max_{j:\overline{x}_{ij}>0} p_{ij}$. But it is hard to obtain a bound on the f-norm of the vector $\{\max_{j:\overline{x}_{ij}>0} p_{ij}\}_{i\in[m]}$, since multiple coordinates here could correspond to the same job, and therefore constraints (9) do not help.

5 A PTAS for MinNormLB on identical machines

We now consider the oft-studied and important special case where all machines are identical – that is, we have $p_{ij} = p_j$ for all jobs j and machines i – and devise a PTAS in this setting.

▶ **Theorem 5.1.** *There is a PTAS for* MinNormLB *on identical machines.*

The above result substantially generalizes the well-known PTAS by Hochbaum and Shmoys for minimizing makespan (i.e., the special case of ℓ_∞ norm) on identical machines [11]. We utilize some of their insights, but need to combine them with various novel ideas to handle the substantial richness of arbitrary monotone, symmetric norms. In the full version, we show that our PTAS extends to a further generalization of MinNormLB, wherein each machine incurs a *cost* given by a "bounded-growth" convex, non-decreasing function μ of its load, and we seek to minimize the f-norm of the *machine-cost vector*. We also observe that Graham's list-scheduling rule – considering jobs in any sequence, schedule the next job on the currently least-loaded machine – yields a simple 2-approximation algorithm.

▶ **Theorem 5.2.** *Graham's list-scheduling rule yields a* 2*-approximation for* MinNormLB *on identical machines.*

We defer the proof of Theorem 5.2 to the full version, and discuss the PTAS for MinNormLB here. It is useful to first recall how the PTAS in [11] for makespan works. Their algorithm considers a "guess", say $t_1 \geq \max_j p_j$, of the optimal makespan, *opt*. We classify jobs as large or small, based on whether $p_j \geq \varepsilon t_1$ (large jobs) or $p_j < \varepsilon t_1$ (small jobs). A key insight is

that since the large jobs have $p_j \in [\varepsilon t_1, t_1]$, rounding their p_js to the nearest power of $(1+\varepsilon)$ yields $O\big(\log_{1+\varepsilon} \frac{1}{\varepsilon}\big)$ distinct rounded job sizes, and a constant (depending on ε) number of distinct possibilities, called *configurations*, for assigning large jobs to a machine so that its rounded load is at most $(1+\varepsilon)t_1$. One can write an *integer program*, with a (ε-dependent) constant number of variables, to determine which configurations are used on the machines, which can be solved in time $\text{poly}(m,n)$ for any fixed $\varepsilon > 0$ using the algorithm of Lenstra [18]. If $opt \le t_1$, then this yields an assignment of large jobs having makespan at most $(1+\varepsilon)t_1$. Finally, one can argue that either the small jobs can be packed (arbitrarily) on the machines while maintaining a makespan of at most $(1+\varepsilon)t_1$, or we have $opt > t_1$.

Now consider MinNormLB. We may assume that $n > m$ as otherwise it is easy to see that an optimal solution is to assign each job to a separate machine. Clearly, we may also assume that $p_j > 0$ for all jobs j. Recall that $\vec{o}$ is an optimal load vector, and $\mathsf{OPT} = f(\vec{o})$. As before, we assume that f is normalized. Since all machines are identical, it will be convenient to re-index machines so that $\vec{o} = \vec{o}^{\downarrow}$. Since we now need to control all Top_ℓ norms, following a common theme, it is natural that we now work with guesses t_ℓ of o_ℓ (which is $\vec{o}^{\downarrow}_\ell$) for all $\ell \in \mathsf{POS}$. The chief issue that arises is: *how do we now define large and small jobs given the multiple t_ℓs*? Suppose we choose a threshold of εt_ℓ, for some $\ell \in \mathsf{POS}$, for this purpose. For indices $\ell' < \ell$, the problem then is that we need to consider all jobs with $p_j \in [\varepsilon t_\ell, t_{\ell'}]$; this would yield a *non-constant number* of job types, and hence a non-constant number of configurations for machines $i < \ell$. Machines $i > \ell$ also present a problem: the packing of small jobs may cause us to exceed the target load of o_i (or rather t_i^{exp}) by εt_ℓ, which can create too large an error compared to the target load.

We circumvent these issues as follows. We select a *specific* optimal solution. Given distinct vectors $u, v \in \mathbb{R}^m$, we say that u is *lexicographically smaller* than v, denoted $u \prec_{\mathsf{lex}} v$ if there exists some index $i \in [m]$ such that $u_{i'} = v_{i'}$ for all $i' = 1, \ldots, i-1$, and $u_i < v_i$. Let $\vec{o}^{\downarrow}$ be the *lexicographically smallest* sorted load-vector among all optimal solutions, i.e., $\vec{o}^{\downarrow} \prec_{\mathsf{lex}} (\overrightarrow{\mathsf{load}}_\sigma)^{\downarrow}$ for every optimal solution σ. As before, we may assume that $\vec{o} = \vec{o}^{\downarrow}$. Let σ^* be an optimal solution yielding the load-vector $\vec{o}$. Let i^* be the smallest index such that machine i^* has at least two jobs assigned to it under σ^*; this is well defined since $n > m$.

▷ Claim 5.3. Let $\vec{o}$, σ^* and i^* be as defined above. Then we have $o_i \ge o_{i^*}/2$ for all $i \ge i^*$.

In addition to our guess $\vec{t}$ of $(o_\ell)_{\ell \in \mathsf{POS}}$, we now also guess i^* and the load o_{i^*}, and use εo_{i^*} as the threshold demarcating large and small jobs. The small jobs are now indeed small compared to the target load of o_i for $i \ge i^*$. Also, since machines $i < i^*$ only have one job assigned to them, we can infer that these machines are assigned the $i^* - 1$ largest jobs.

We describe our algorithm below, and conclude with its analysis.

▶ **Algorithm 1 (PTAS for MinNormLB on identical machines).**
Input: a non-increasing vector $\vec{t} \in \mathbb{R}^{\mathsf{POS}}_{\ge 0}$, an index $i^* \in [m]$, $\theta \in \mathbb{R}_{\ge 0}$ intended to be a good overestimate of o_{i^*}, and a parameter $0 < \varepsilon \le 1$. We set $\delta = \varepsilon$ in the definition $\mathsf{POS} = \mathsf{POS}_{m,\delta}$.
Output: an assignment $\widetilde{\sigma}$ such that $(\overrightarrow{\mathsf{load}}_{\widetilde{\sigma}})^{\downarrow}_\ell \le (1+\varepsilon)t_\ell + \varepsilon\theta$ for all $\ell \in \mathsf{POS}$, or that $(\vec{t}, i^*, \theta)$ is an invalid guess.

P1. Perform the following checks, and if any of these fail, then declare that $(\vec{t}, i^*, \theta)$ is invalid and return. Define $t_{m+1} := 0$ for notational convenience.
- **(a)** If $i^* \in \mathsf{POS}$, then check that $\theta = t_{i^*}$, otherwise check that $t_{\mathsf{next}(i^*)} \le \theta \le t_{\mathsf{prev}(i^*)}$.
- **(b)** For all $\ell \in \mathsf{POS}$, $\ell \le i^*$, check that there are at most $\ell - 1$ jobs with $p_j > t_\ell$.
- **(c)** Check that there are at most $i^* - 1$ jobs with $p_j > \theta$.

P2. Assign the $i^* - 1$ largest jobs to machines $1, \ldots, i^* - 1$, assigning the largest job to machine 1, the second-largest job to machine 2, and so on. Let J' be the remaining set of jobs. Note that check (c) in step P1 implies that $p_j \le \theta$ for all $j \in J'$.

P3. Let $J'_L := \{j \in J' : p_j \geq \varepsilon\theta\}$, and $J'_S := \{j \in J' : p_j < \varepsilon\theta\}$. We refer to the jobs in J'_L and J'_S as large and small jobs respectively.

P4. Round the processing time of each large job to the nearest power of $(1+\varepsilon)$, i.e., for each $j \in J'_L$, round its processing time to $p'_j := (1+\varepsilon)^{\lceil \log_{1+\varepsilon} p_j \rceil}$. Let $R = \{p'_j : j \in J'_L\}$ be the distinct rounded processing times, and $N = |R|$; note that $N \leq 1 + \log_{1+\varepsilon}\left(\frac{1}{\varepsilon}\right)$. For a budget $B \geq 0$, define $\mathcal{C}(B) := \left\{\nu \in \mathbb{Z}^R_{\geq 0} \setminus \{\vec{0}\} : \sum_{p\in R} \nu_p \cdot p \leq B\right\}$ as the set of non-trivial *configurations* that yield a total rounded load of at most B. (Observe that $\mathcal{C}(0) = \emptyset$.)

Recall that $\overrightarrow{t^{\mathsf{exp}}} \in \mathbb{R}^m_{\geq 0}$ is the expansion of $\vec{t}$, defined by $t^{\mathsf{exp}}_i = t_i$ for $i \in \mathsf{POS}$, and $t^{\mathsf{exp}}_i = t_{\mathsf{prev}(i)}$ for $i \in [m] \setminus \mathsf{POS}$. For notational convenience, define $t^{\mathsf{exp}}_{m+1} := 0$. For $i \in \{i^*, \ldots, m+1\}$, define its load budget to be $B_i = (1+\varepsilon)\min\{\theta, t^{\mathsf{exp}}_i\}$. (Note that $B_{m+1} = 0$.) For any $0 \leq B \leq B_{i^*}$, any $\nu \in \mathcal{C}(B)$ and $p \in R$, we have $\nu_p \leq B/p \leq \frac{1+\varepsilon}{\varepsilon}$; so $|\mathcal{C}(B)| \leq \left(\frac{1}{\varepsilon}+2\right)^N$, and we can enumerate the configurations in $\mathcal{C}(B)$ in polynomial time. Assign the large jobs by using the algorithm of Lenstra [18] to solve the integer program (Config-IP), wherein the integer variable x_ν specifies the number of machines in $\{i^*, \ldots, m\}$ for which configuration $\nu \in \mathcal{C}(B_{i^*})$ is used.

$$\sum_{\nu \in \mathcal{C}(B_{i^*})} \nu_p \cdot x_\nu = \left|\{j \in J'_L : p'_j = p\}\right| \qquad \forall p \in R \tag{11}$$

(Config-IP)
$$\sum_{\nu \in \mathcal{C}(B_{i^*}) \setminus \mathcal{C}(B_\ell)} x_\nu \leq \ell - i^* \qquad \forall \ell \in \mathsf{POS} \cup \{m+1\} : \ell > i^* \tag{12}$$

$$x_\nu \in \mathbb{Z}_{\geq 0} \qquad \forall \nu \in \mathcal{C}(B_{i^*}) \tag{13}$$

If (Config-IP) is infeasible, declare that $(\vec{t}, i^*, \theta)$ is invalid and return. Otherwise, suppose that $\widetilde{x}$ is a feasible solution to (Config-IP). Obtain an assignment of the large jobs to machines $i^*, i^*+1, \ldots, m$ from $\widetilde{x}$ as follows. Let $\widetilde{\mathcal{C}}$ be the *multiset* of configurations where we have $\widetilde{x}_\nu$ copies of each configuration $\nu \in \mathrm{supp}(\widetilde{x})$. We map each $\nu \in \widetilde{\mathcal{C}}$ to a disjoint set A_ν of large jobs, comprising ν_p large jobs with $p'_j = p$ for every $p \in R$, so that $(A_\nu)_{\nu \in \widetilde{\mathcal{C}}}$ forms a partition of J'_L. Constraint (11) shows that this is always possible.

We go over the configurations $\nu \in \widetilde{\mathcal{C}}$ in non-increasing order of their load, $\sum_{p\in S} \nu_p \cdot p$, and assign one configuration each to machines $i^*, i^*+1, \ldots, i^* + |\widetilde{\mathcal{C}}| - 1$ in this order, where by assigning a configuration ν to a machine i, we mean that we assign the jobs in A_ν to machine i. Note that $|\widetilde{\mathcal{C}}| = \sum_{\nu \in \mathcal{C}(B_{i^*})} \widetilde{x}_\nu \leq m + 1 - i^*$ due to constraint (12) for index $m+1$.

P5. We assign the small jobs to the machines in $\{i^*, \ldots, m\}$ arbitrarily while ensuring that the total actual load (i.e., under the p_j processing times) on each machine i is at most $B_i + \varepsilon\theta$. If we are unable to assign all small jobs this way, then we declare that $(\vec{t}, i^*, \theta)$ is invalid, and return.

P6. Return the assignment $\widetilde{\sigma}$ computed in steps P2, P4, and P5.

Analysis. Recall that σ^* is the optimal solution yielding the sorted load vector $\vec{o}^{\downarrow} = \vec{o}$. We first assume that $(\vec{t}, i^*, \theta)$ is such that $\vec{t} \geq (o_\ell)_{\ell \in \mathsf{POS}}$, we have the right i^*, $\theta \geq o_{i^*}$, and $(\vec{t}, i^*, \theta)$ passes the check in step P1(a). Under these assumptions, we show that the algorithm returns an assignment $\widetilde{\sigma}$, and $\overrightarrow{\mathsf{load}}^{\downarrow}_{\widetilde{\sigma}}$ is "close" to $\overrightarrow{t^{\mathsf{exp}}}$. This will then imply Theorem 5.1, since we can find in polytime $(\vec{t^*}, i^*, \theta^*)$ satisfying the above properties, and such that $t^*_\ell \leq (1+\varepsilon)o_\ell$ for all $\ell \in [m]$, and $\theta^* \leq (1+\varepsilon)o_{i^*}$.

We begin by observing in Claim 5.4 that (under the above assumptions), $(\vec{t}, i^*, \theta)$ passes checks (b) and (c) in step P1, and that step P2 is valid. Then, in Lemmas 5.5 and 5.6, we argue that steps P4 and P5 are successful.

▷ Claim 5.4. (i) $(\vec{t}, i^*, \theta)$ passes checks (b) and (c) in step P1. (ii) The optimal solution σ^* assigns the $i^* - 1$ largest jobs to machines $1, \ldots, i^* - 1$, assigning one job per machine.

▶ **Lemma 5.5.** *Step P4 successfully returns an assignment of large jobs such that every machine $i \in \{i^*, \dots, m\}$ has (rounded and actual) load at most B_i.*

Proof. Consider the following solution to (Config-IP). Each machine $i \in \{i^*, \dots, m\}$ that has jobs assigned to it under σ^* naturally maps to a corresponding configuration ν, where ν_p is the number of large jobs assigned to i with $p'_j = p$. We have

$$\sum_{p \in R} \nu_p \cdot p = \sum_{j \in J'_L : \sigma^*(j) = i} p'_j \leq (1+\varepsilon) \sum_{j : \sigma^*(j) = i} p_j = (1+\varepsilon) o_i \leq (1+\varepsilon) \min\{\theta, t_i^{\mathsf{exp}}\} = B_i$$

where the first inequality is because $p'_j \leq (1+\varepsilon) p_j$ for all $j \in J'_L$. Thus, each machine $i \in \{i^*, \dots, m\}$ maps to a configuration in $\mathcal{C}(B_i) \subseteq \mathcal{C}(B_{i^*})$. Let $\hat{x} \in \mathbb{Z}_{\geq 0}^{\mathcal{C}(B_{i^*})}$ be the integral vector, where $\hat{x}_\nu$ is the number of machines that map to configuration ν, for each $\nu \in \mathcal{C}(B_{i^*})$. By construction, it is easy to see that constraints (11) are satisfied. It is also clear that constraint (12) holds for index $\ell = m+1$. So consider constraint (12) for some index $\ell \in \mathsf{POS}$, $\ell > i^*$. A configuration ν with $\hat{x}_\nu > 0$ whose load is larger than B_ℓ corresponds to a machine in $\{i^*, \dots, m\}$ whose actual load is larger than $B_\ell/(1+\varepsilon) \geq o_\ell$. There are at most $\ell - i^*$ such machines, so (12) holds for index ℓ.

Since (Config-IP) is feasible, it follows that we return an assignment of large jobs to machines $i^*, i^*+1, \dots, m$ where every machine has rounded (and hence, actual) load at most B_{i^*}. Consider a machine $i \in \{i^*, \dots, m\}$ that is assigned a configuration. Let $\ell = i$ if $i \in \mathsf{POS} \cup \{i^*\}$, and $\ell = \max\{i^*, \mathsf{prev}(i)\}$ otherwise; note that $B_i = B_\ell$. If $\ell = i^*$, then $B_i = B_{i^*}$, and there is nothing left to prove. So suppose $\ell \neq i^*$. Then $\ell \in \mathsf{POS}$, $\ell > i^*$. By constraint (12) there are at most $\ell - i^* \leq i - i^*$ configurations in $\widetilde{\mathcal{C}}$ with load larger than B_ℓ. By the way in which we assign configurations to machines, it follows that machine i is *not* assigned one of these configurations. Therefore, the total rounded (and hence, actual) load on machine i is at most $B_\ell = B_i$. ◀

▶ **Lemma 5.6.** *Step P5 successfully assigns all small jobs. At the end of this step every machine $i \in \{i^*, \dots, m\}$ has total actual load at most $B_i + \varepsilon\theta$.*

Proof of Theorem 5.1. We can find $(\vec{t^*}, i^*, \theta^*)$ in polytime such that $o_\ell \leq t^*_\ell \leq (1+\varepsilon) o_\ell$ for all $\ell \in \mathsf{POS}$, we have the right i^*, $o_{i^*} \leq \theta^* \leq (1+\varepsilon) o_{i^*}$, and $(\vec{t^*}, i^*, \theta^*)$ clears check P1 (a). We prove this momentarily, but first show that this yields the desired performance guarantee.

Recall that $\varepsilon \leq 1$ and $\delta = \varepsilon$. By Lemma 2.8 (b), taking $u = \vec{o}$ and $v = \vec{t^*}$, we obtain that $f(\overrightarrow{t^{*\mathsf{exp}}}) \leq (1+\delta)(1+\varepsilon) f(\vec{o})$. Our analysis shows that the algorithm run with input $(\vec{t^*}, i^*, \theta^*)$ returns an assignment $\widetilde{\sigma}$. Since we pass checks (b) and (c) in step P1, each machine $i \in \{1, \dots, i^*-1\}$ has load (due to the one job assigned to it) $o_i \leq {t^*}_i^{\mathsf{exp}}$. Lemmas 5.5 and 5.6 show that the total load on each machine $i \in \{i^*, \dots, m\}$ is at most

$$B_i + \varepsilon\theta^* \leq (1+\varepsilon) {t^*}_i^{\mathsf{exp}} + \varepsilon(1+\varepsilon) o_{i^*} \leq (1+\varepsilon) {t^*}_i^{\mathsf{exp}} + 4\varepsilon o_i \leq (1+5\varepsilon) {t^*}_i^{\mathsf{exp}}.$$

The second inequality follows from Claim 5.3 and since $\varepsilon \leq 1$, and the last one since $\vec{t^*} \geq (o_\ell)_{\ell \in \mathsf{POS}}$ (and therefore $\overrightarrow{t^{*\mathsf{exp}}} \geq o$). It follows that $\overrightarrow{\mathsf{load}}_{\widetilde{\sigma}} \leq (1+5\varepsilon) t^{*\mathsf{exp}}$, and so $f(\overrightarrow{\mathsf{load}}_{\widetilde{\sigma}}) \leq (1+5\varepsilon) f(\overrightarrow{t^{*\mathsf{exp}}})$. Combining this with the bound on $f(\overrightarrow{t^{*\mathsf{exp}}})$, and simplifying, we obtain that $f(\overrightarrow{\mathsf{load}}_{\widetilde{\sigma}}) \leq (1+23\varepsilon) f(\vec{o})$.

We complete the proof by showing how to find $(\vec{t^*}, i^*, \theta^*)$ in polynomial time satisfying the properties stated at the beginning of the proof. There are only m choices for i^*. Given the correct i^*, we know that the load on each machine $i < i^*$ is the processing time of the i-th largest job. So we know $o_1, \dots, o_{i^*-1}$ exactly, and can set $t^*_\ell = o_\ell$ for all $\ell \in \mathsf{POS}$, $\ell < i^*$. Let $\mathsf{POS}' = \{i^*\} \cup \{\ell \in \mathsf{POS} : \ell > i^*\}$. Let J' be the set of jobs excluding the

$i^* - 1$ largest jobs. Let $\mathsf{UB}' := \sum_{j \in J'} p_j$. The jobs in J' are assigned by σ^* to machines in $\{i^*, \ldots, m\}$, and we have $o_{i^*} \geq o_i \geq o_{i^*}/2$ for all $i \geq i^*$ (Claim 5.3). It follows that $\frac{\mathsf{UB}'}{m-i^*+1} \leq o_{i^*} \leq T := \min\{\frac{2\mathsf{UB}'}{m-i^*+1}, o_{i^*-1}\}$. So by Lemma 2.9 (b), taking $\mathcal{L} = \mathsf{POS}'$, $\mathsf{ub} = T$, and $\mathsf{lb} = \frac{\mathsf{UB}'}{2(m-i^*+1)}$, we can identify a set of size $O\big(m^{O(\frac{1}{\varepsilon})}\big)$ containing a non-increasing vector $v \in \mathbb{R}^{\mathsf{POS}'}_{\geq 0}$ such that $o_\ell \leq v_\ell \leq \min\{(1+\varepsilon)o_\ell, T\}$ for all $\ell \in \mathsf{POS}'$. So the vector $\vec{t^*} = \big((o_\ell)_{\ell \in \mathsf{POS}:\ell < i^*}, (v_\ell)_{\ell \in \mathsf{POS}:\ell \geq i^*}\big)$ and $\theta^* = v_{i^*}$ have the desired properties. ◀

Abstract

In a recent landmark result [Ji *et al.*, arXiv:2001.04383 (2020)], it was shown that approximating the value of a two-player game is undecidable when the players are allowed to share quantum states of unbounded dimension. In this paper, we study the computational complexity of two-player games when the dimension of the quantum systems is bounded by T. More specifically, we give a semidefinite program of size $\exp\big(\mathcal{O}\big(T^{12}(\log^2(AT)+\log(Q)\log(AT))/\epsilon^2\big)\big)$ to compute additive ϵ-approximations on the value of two-player free games with $T\times T$-dimensional quantum entanglement, where A and Q denote the number of answers and questions of the game, respectively. For fixed dimension T, this scales polynomially in Q and quasi-polynomially in A, thereby improving on previously known approximation algorithms for which worst-case run-time guarantees are at best exponential in Q and A. For the proof, we make a connection to the quantum separability problem and employ improved multipartite quantum de Finetti theorems with linear constraints that we derive via quantum entropy inequalities.

1 Introduction

Thanks to the celebrated discovery by John Bell [4], it is well-known that quantum correlations can be used to overcome locality constraints, which was one of the earliest examples of advantages provided by quantum correlations over classical correlations. This led to the development of numerous quantum information processing tasks which make use of quantum correlations as a resource to outperform their classical analogues. In general, understanding the differences in the performance of distinct correlation sets for a given task is important both fundamentally and practically. A common way to measure the quantitative advantages

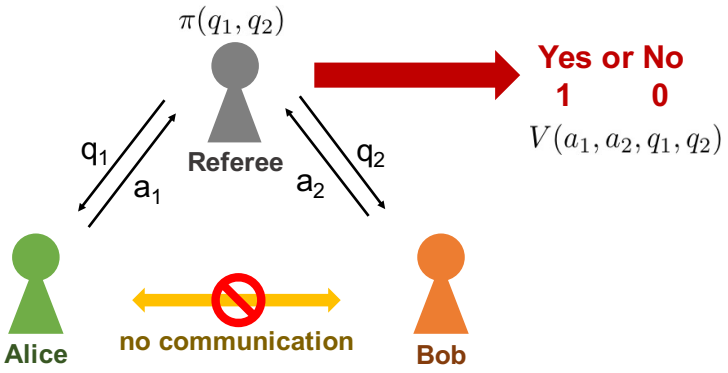

Figure 1 Two-player games. The referee gives Alice and Bob questions $q_1 \in Q_1$ and $q_2 \in Q_2$ according to the question probability distribution $\pi(q_1, q_2)$, and then Alice and Bob give answers $a_1 \in A_1$ and $a_2 \in A_2$ back to the referee depending on the questions they received. The referee decides whether Alice and Bob win or lose according to the rule function $V : A_1 \times A_2 \times Q_1 \times Q_2 \to \{0, 1\}$, where 0 denotes losing the game, and 1 denotes winning the game. Alice and Bob cannot communicate with each other during the game, but they can agree on a strategy beforehand. We are interested in determining the values of the game, i.e., the maximum achievable winning probabilities, for different classes of strategies. For simplicity, we assume that $|Q_1| = |Q_2| = Q$ and $|A_1| = |A_2| = A$.

of different sets of correlations is via a two-player game G (illustrated in Figure 1). In a two-player game, the performance of a given correlation set is quantified by the maximum achievable winning probability. For example, the classical value $\omega_C(G)$ is the maximum winning probability that can be achieved using shared randomness between the two players, while the quantum value $\omega_Q(G)$ is the maximum winning probability that can be achieved by sharing arbitrary quantum states between the players.

In general, it is hard to compute $\omega_C(G)$ and $\omega_Q(G)$ for the given description of a two-player game G. Approximating $\omega_C(G)$ within some constant multiplicative factor is NP-hard [2, 3], while approximating $\omega_Q(G)$ has recently been shown not to be possible for an algorithm running in finite time [20]. Despite these general hardness results, there are some special classes of two-player games for which $\omega_C(G)$ and $\omega_Q(G)$ can be approximated in polynomial time [10, 21, 1, 9]. In particular, for *free games*, i.e., games where the questions for the two players are chosen independently, there exists a quasi-polynomial time algorithm that can approximate $\omega_C(G)$ within any constant additive error [1, 9]. Also, in practice, the Navascués-Pironio-Acín (NPA) hierarchy [27, 29] provides semidefinite programming (SDP) upper bounds on $\omega_Q(G)$ which give approximately tight bounds for many games of interest.

1.1 Contributions

In this paper, we study the dimension-bounded quantum value $\omega_{Q(T)}(G)$ – the maximum winning probability that can be achieved by sharing quantum states of fixed dimension $T \times T$. It is easy to see that $\omega_{Q(1)}(G) = \omega_C(G)$ and $\omega_Q(G) = \sup_{T \geq 1} \omega_{Q(T)}(G)$. Computing $\omega_{Q(T)}(G)$ is of particular interest since it can be used as a *dimension witness* for an underlying system in semi-device-independent quantum information processing protocols, see for example [15]. SDP upper bounds have been derived for $\omega_{Q(T)}(G)$ in [25, 28, 26]. In [25], the authors exploit a connection to the quantum separability problem, and in [28, 26], the authors employ a moment matrix technique similar to the NPA hierarchy to derive SDP relaxations with better performance than the ones in [25]. However, the worst case runtime guarantees for these works is either not analytically quantified or is at best exponential in the number of questions Q and the number of answers A of the game G.

In our work, we provide approximation algorithms for $\omega_{Q(T)}(G)$ whose runtime has an improved dependence on both A and Q. More specifically, we construct a new hierarchy of SDP relaxations, providing a sequence of upper bounds for $\omega_{Q(T)}(G)$ for a given game G, and then derive analytical bounds on the convergence speed. This gives an upper bound on the computational complexity of calculating $\omega_{Q(T)}(G)$ in terms of the size of the game G. For the case of free games, a semidefinite program of size

$$\exp\left(\mathcal{O}\left(\frac{T^{12}}{\epsilon^2}\log(AT)\left(\log(Q)+\log(AT)\right)\right)\right) \tag{1}$$

is sufficient for computing additive ϵ-approximations of $\omega_{Q(T)}(G)$, where A and Q denote the number of answers and questions, respectively. The dependence is quasi-polynomial in A and polynomial in Q thus improving on the best previously known approximation algorithms [25, 28, 26], for which only exponential bounds in A and Q are known. In the classical limit ($T = 1$), our result recovers the quasi-polynomial time approximation scheme for computing $\omega_C(G)$ for two-player free games – which has a matching hardness result assuming the Exponential Time Hypothesis [1, 9]. Besides analysing free games, we give an algorithm for general games as well, leading to approximation algorithms that are still quasi-polynomial in A but exponential in Q.

We construct our SDP relaxations by drawing a connection to a variant of the quantum separability problem where the optimisation variables are additionally subject to some linear constraints. Similar variants of the quantum separability problem have been studied in [35, 34, 6]. The main tool we use to obtain the analytical convergence speed is improved multipartite quantum de Finetti theorems with linear constraints, which we derive in our work. One of the contributions towards this result, which we believe is of independent interest, is an improved version of the optimal loss in distinguishability relative to quantum side information.

1.2 Preliminaries on two-player games

A non-local game is a mathematical formulation for the correlations between distant parties. In this paper, we will consider *two-player games* where only two distant parties are involved. In this formulation, the correlation between two parties is considered to be a resource to win the games.

In a two-player game G, two spatially separated agents, Alice and Bob, need to provide correct answers $a_1 \in A_1$ and $a_2 \in A_2$ to the referee depending on the questions $q_1 \in Q_1$ and $q_2 \in Q_2$ they received (see Figure 1). The correct answers are determined by a given rule function of G

$$V : A_1 \times A_2 \times Q_1 \times Q_2 \to \{0, 1\}, \tag{2}$$

where 0 means the answer is incorrect, and 1 means the answer is correct. The questions q_1 and q_2 are chosen by the referee according to a given probability distribution $\pi(q_1, q_2)$ of G. A specific two-player game G can be represented by the pair of rule function $V(a_1, a_2, q_1, q_2)$ and question probability distribution $\pi(q_1, q_2)$, and hereafter we will denote a game G as (V, π). Alice and Bob cannot communicate with each other during the game, but they can agree on a strategy beforehand as well as make use of systems whose correlations lie within a given class. When only classical shared randomness is allowed, the correlations take the form

$$p(a_1, a_2|q_1, q_2) = e(a_1|q_1)d(a_2|q_2), \tag{3}$$

where $e(a_1|q_1)$ and $d(a_2|q_2)$ are conditional probability distributions for Alice and Bob respectively. That is, $\sum_{a_1} e(a_1|q_1) = 1\ \forall q_1 \in Q_1$, and $\sum_{a_2} d(a_2|q_2) = 1\ \forall q_2 \in Q_2$. When quantum resources are allowed, the correlations have a more general form

$$p(a_1, a_2|q_1, q_2) = \operatorname{tr}\left[\rho_{T\hat{T}}\left(E_T(a_1|q_1) \otimes D_{\hat{T}}(a_2|q_2)\right)\right], \tag{4}$$

where $\rho_{T\hat{T}}$ is a possibly entangled quantum state shared by Alice and Bob, and $\{E_T(a_1|q_1)\}_{a_1}$ and $\{D_{\hat{T}}(a_2|q_2)\}_{a_2}$ are positive-operator valued measurements (POVMs) performed by Alice and Bob respectively for given q_1 and q_2, i.e., $\sum_{a_1} E_T(a_1|q_1) = \mathbb{I}_T\ \forall q_1 \in Q_1$ and $\sum_{a_2} D_{\hat{T}}(a_2|q_2) = \mathbb{I}_{\hat{T}}\ \forall q_2 \in Q_2$.

The quantitative advantage of each set of correlations can be captured by the maximum winning probabilities achievable using the given correlation set. For a given two-player game $G = (V, \pi)$, the classical value is defined as

$$\omega_C(V, \pi) := \max_{(e,d)} \sum_{a1,q1,a2,q2} \pi(q_1, q_2) V(a_1, a_2, q_1, q_2) e(a_1|q_1) d(a_2|q_2), \tag{5}$$

and the quantum value is given by

$$\omega_Q(V, \pi) := \sup_{\substack{(E\otimes D,\rho)\\ \text{on } \mathcal{H}_{T\hat{T}}}} \sum_{\substack{a1,q1\\ a2,q2}} \pi(q_1, q_2) V(a_1, a_2, q_1, q_2) \operatorname{tr}\left[\rho_{T\hat{T}}\left(E_T(a_1|q_1) \otimes D_{\hat{T}}(a_2|q_2)\right)\right]. \tag{6}$$

Here, the optimisation is taken over not only states and measurements but also the Hilbert space $\mathcal{H}_{T\hat{T}}$. We can define the dimension-bounded quantum value as

$$\omega_{Q(T)}(V, \pi) := \max_{\substack{(E\otimes D,\ \rho)\\ \text{on}\\ \mathbb{C}^T\otimes\mathbb{C}^T}} \sum_{\substack{a1,q1\\ a2,q2}} \pi(q_1, q_2) V(a_1, a_2, q_1, q_2) \operatorname{tr}\left[\rho_{T\hat{T}}\left(E_T(a_1|q_1) \otimes D_{\hat{T}}(a_2|q_2)\right)\right], \tag{7}$$

which is the central object of investigation in this paper.

If not stated otherwise, we assume that the choice of questions for Alice and Bob are independent, i.e., $\pi(q_1, q_2) = \pi_1(q_1)\pi_2(q_2)$, which corresponds to *free games*. We denote $\mathcal{H}_A^{\otimes n}$ as A^n, and $\dim(\mathcal{H}_A)$ as $|A|$. For simplicity, we assume that $|Q_1| = |Q_2| = Q$ and $|A_1| = |A_2| = A$.

2 Derivation of semidefinite programming relaxations

2.1 Connection with quantum separability

Quantum separability problems are a special type of optimisation problems, where the optimisation is taken over the set of separable quantum states. We show that computing $\omega_{Q(T)}(V, \pi)$ for a given two-player game (V, π) can be rephrased as an instance of the tripartite quantum separability problem subject to additional linear constraints.

▶ **Lemma 1.** *For a two-player free game with $V(a_1,a_2,q_1,q_2)$, $\pi(q_1,q_2)=\pi_1(q_1)\pi_2(q_2)$, and $|T|^2$-dimensional quantum correlation, we have*

$$\begin{aligned}
\omega_{Q(T)}(V,\pi) = |T|^2 \cdot \max_{(E,D,\rho)} \ & \mathrm{tr}\left[\left(V_{A_1A_2Q_1Q_2}\otimes\Phi_{T\hat{T}|S\hat{S}}\right)\left(E_{A_1Q_1T}\otimes D_{A_2Q_2\hat{T}}\otimes\rho_{S\hat{S}}\right)\right] \\
s.t. \quad & \rho_{S\hat{S}}\geq 0\,, \qquad \mathrm{tr}\left[\rho_{S\hat{S}}\right]=1 \\
& E_{A_1Q_1T}=\sum_{a_1,q_1}\pi_1(q_1)\,|a_1q_1\rangle\langle a_1q_1|_{A_1Q_1}\otimes\frac{E_T(a_1|q_1)}{|T|}\geq 0 \\
& D_{A_2Q_2\hat{T}}=\sum_{a_2,q_2}\pi_2(q_2)\,|a_2q_2\rangle\langle a_2q_2|_{A_2Q_2}\otimes\frac{D_{\hat{T}}(a_2|q_2)}{|T|}\geq 0 \\
& \mathrm{tr}_{A_1}\left[E_{A_1Q_1T}\right]=\sum_{q_1}\pi_1(q_1)\,|q_1\rangle\langle q_1|_{Q_1}\otimes\frac{\mathbb{I}_T}{|T|} \\
& \mathrm{tr}_{A_2}\left[D_{A_2Q_2\hat{T}}\right]=\sum_{q_2}\pi_2(q_2)\,|q_2\rangle\langle q_2|_{Q_2}\otimes\frac{\mathbb{I}_{\hat{T}}}{|T|},
\end{aligned} \tag{8}$$

where $\Phi_{T\hat{T}|S\hat{S}}=|\Phi\rangle\langle\Phi|_{T\hat{T}|S\hat{S}}$ is the (non-normalised) maximally-entangled state, $|\Phi\rangle_{T\hat{T}|S\hat{S}}=\sum_i|i\rangle_{T\hat{T}}|i\rangle_{S\hat{S}}$, and $V_{A_1A_2Q_1Q_2}$ is a diagonal matrix whose entries are given by the rule function $V(a_1,a_2,q_1,q_2)$.

To prove Lemma 1, we need a slightly modified version of the swap trick.

▶ **Lemma 2.** *Let M_{AB} be a linear operator on $\mathcal{H}_A\otimes\mathcal{H}_B$, and N_A be a linear operator on $\mathcal{H}_A$. Then, it holds that*

$$\mathrm{tr}\left[(N_A\otimes\mathbb{I}_B)M_{AB}\right]=\mathrm{tr}\left[\left(F_{\hat{A}|A}\otimes\mathbb{I}_B\right)\left(N_{\hat{A}}\otimes M_{AB}\right)\right], \tag{9}$$

where $F_{\hat{A}|A}$ denotes the swap operator between $\hat{A}$ and A.

Proof. By inspection, we have that

$$\begin{aligned}
& \mathrm{tr}\left[\left(F_{\hat{A}|A}\otimes\mathbb{I}_B\right)\left(N_{\hat{A}}\otimes M_{AB}\right)\right] \\
=\,& \mathrm{tr}\left[\left(F_{\hat{A}|A}\otimes\mathbb{I}_B\right)\left(\sum_{i,j}n_{ij}\,|i\rangle\langle j|_{\hat{A}}\otimes\sum_{k,\ell,s,t}m_{(k\ell)(st)}\,|k\rangle\langle\ell|_A\otimes|s\rangle\langle t|_B\right)\right] \\
=\,& \mathrm{tr}\left[\sum_{i,j,k,\ell,s,t}n_{ij}\,m_{(k\ell)(st)}\,|k\rangle\langle j|_{\hat{A}}\otimes|i\rangle\langle\ell|_A\otimes|s\rangle\langle t|_B\right] \\
=\,& \sum_{i,j,s,t}n_{ij}\,m_{(ji)(st)}=\mathrm{tr}\left[(N_A\otimes\mathbb{I}_B)M_{AB}\right],
\end{aligned} \tag{10}$$

where we used $N_{\hat{A}}=\sum_{i,j}n_{ij}\,|i\rangle\langle j|_{\hat{A}}$ and $M_{AB}=\sum_{k,\ell,s,t}m_{(k\ell)(st)}\,|k\rangle\langle\ell|_A\otimes|s\rangle\langle t|_B$. ◀

Proof of Lemma 1. Let us start from the expression for $\omega_{Q(T)}$ in Eq. (7). For free games, i.e. $\pi(q_1, q_2) = \pi_1(q_1)\pi_2(q_2)$, we can write

$$\omega_{Q(T)}(V,\pi) = |T|^2 \max_{E,D,\rho} \operatorname{tr}\left[\left(V_{A_1A_2Q_1Q_2} \otimes \rho_{T\hat{T}}\right)\left(E_{A_1Q_1T} \otimes D_{A_2Q_2\hat{T}}\right)\right] \tag{11}$$

$$\begin{aligned}
\text{s.t.}\quad & \rho_{T\hat{T}} \geq 0\,, \qquad \operatorname{tr}\left[\rho_{T\hat{T}}\right] = 1 \\
& E_{A_1Q_1T} = \sum_{a_1,q_1} \pi_1(q_1)\, |a_1q_1\rangle\langle a_1q_1|_{A_1Q_1} \otimes \frac{E_T(a_1|q_1)}{|T|} \geq 0 \\
& D_{A_2Q_2\hat{T}} = \sum_{a_2,q_2} \pi_2(q_2)\, |a_2q_2\rangle\langle a_2q_2|_{A_2Q_2} \otimes \frac{D_{\hat{T}}(a_2|q_2)}{|T|} \geq 0 \\
& \operatorname{tr}_{A_1}\left[E_{A_1Q_1T}\right] = \sum_{q_1} \pi_1(q_1)\, |q_1\rangle\langle q_1|_{Q_1} \otimes \frac{\mathbb{I}_T}{|T|} \\
& \operatorname{tr}_{A_2}\left[D_{A_2Q_2\hat{T}}\right] = \sum_{q_2} \pi_2(q_2)\, |q_2\rangle\langle q_2|_{Q_2} \otimes \frac{\mathbb{I}_{\hat{T}}}{|T|},
\end{aligned}$$

where we define $V_{A_1A_2Q_1Q_2} := \sum_{a_1,a_2,q_1,q_2} V(a_1,a_2,q_1,q_2)\, |a_1,a_2,q_1,q_2\rangle\langle a_1,a_2,q_1,q_2|$. Then, using Lemma 2 we can rewrite the objective function in Eq. (11) as

$$\begin{aligned}
& \operatorname{tr}\left[\left(V_{A_1A_2Q_1Q_2} \otimes \rho_{T\hat{T}}\right)\left(E_{A_1Q_1T} \otimes D_{A_2Q_2\hat{T}}\right)\right] \\
&= \operatorname{tr}\left[\left(\mathbb{I}_{A_1A_2Q_1Q_2} \otimes \rho_{T\hat{T}}\right)\left(\left(V_{A_1A_2Q_1Q_2} \otimes \mathbb{I}_{T\hat{T}}\right)\left(E_{A_1Q_1T} \otimes D_{A_2Q_2\hat{T}}\right)\right)\right] \\
&= \operatorname{tr}\left[\left(\mathbb{I}_{A_1A_2Q_1Q_2} \otimes F_{T\hat{T}|S\hat{S}}\right)\left(\left(\left(V_{A_1A_2Q_1Q_2} \otimes \mathbb{I}_{T\hat{T}}\right)\left(E_{A_1Q_1T} \otimes D_{A_2Q_2\hat{T}}\right)\right) \otimes \rho_{S\hat{S}}\right)\right] \\
& \qquad\qquad \text{(by Lemma 2)} \\
&= \operatorname{tr}\left[\left(\left(V_{A_1A_2Q_1Q_2} \otimes F_{T\hat{T}|S\hat{S}}\right)\left(E_{A_1Q_1T} \otimes D_{A_2Q_2\hat{T}} \otimes \rho_{S\hat{S}}\right)\right)\right],
\end{aligned} \tag{12}$$

which has a similar form to the objective function in Lemma 1 with the exception that $F_{T\hat{T}|S\hat{S}}$ replaces $\Phi_{T\hat{T}|S\hat{S}}$. To complete the proof, we write the swap operator $F_{A|\hat{A}}$ in terms of the (non-normalised) maximally-entangled state $\Phi_{A|\hat{A}} = |\Phi\rangle\langle\Phi|_{A|\hat{A}}$, where $|\Phi\rangle_{A|\hat{A}} = \sum_{i=1}^{d_A} |i\rangle_A\, |i\rangle_{\hat{A}}$. Namely, we have $F_{A|\hat{A}} = \Phi_{A|\hat{A}}^{T_A}$, where T_A denotes the transposition over the A subsystem. Redefining the variable ρ as ρ^T, we then immediately obtain Eq. (8) as this last step leaves the constraints invariant. ◀

In Lemma 1, the optimisation is now taken over all product states with respect to the tripartition $A_1Q_1T|A_2Q_2\hat{T}|S\hat{S}$ satisfying the stated linear constraints. Since product states are extreme points in the set of separable states, we can equivalently think of the above as an optimisation over the convex hull of the feasible states, where the feasible states are all product states satisfying the linear constraints. This gives the claimed connection to the quantum separability problem.

2.2 Hierarchy of semidefinite programming relaxations

In the previous section, we showed that $\omega_{Q(T)}(V,\pi)$ can be rephrased as a variant of the quantum separability problem which is subject to additional linear constraints. However, solving quantum separability problems is known to be NP-hard [16, 17], and our mapping does not necessarily make the problem more approachable. Fortunately, there are well-known

relaxations for the quantum separability condition; the Doherty-Parrilo-Spedalieri (DPS) hierarchy [12] based on extendibility, which is strongly related to the notion of monogamy of entanglement [33].

▶ **Definition 3** (Extendibility). *A bipartite quantum state ρ_{AB} is n-extendible if there exists a multipartite quantum state ρ_{AB^n} such that*

$$\mathrm{tr}_{B^{n-1}}\left[\rho_{AB^n}\right] = \rho_{AB}, \quad \left(\mathcal{I}_A \otimes \mathcal{U}^{\pi}_{B^n}\right)\left(\rho_{AB^n}\right) = \rho_{AB^n} \quad \forall \pi \in \mathcal{S}(B^n), \tag{13}$$

where $\mathcal{S}(B^n)$ is the symmetric group over B^n, $\mathcal{U}^{\pi}_{B^n}(\cdot) = U^{\pi}_{B^n}(\cdot)(U^{\pi}_{B^n})^{\dagger}$ is the adjoint representation of the group, and $U^{\pi}_{B^n}$ is a unitary permutation operator acting on B^n.

Extendible states have two main advantages. Firstly, deciding if a state is n-extendible can be done efficiently via SDPs [11, 12]; for fixed n, the computation resources scale polynomially in the system dimension. Secondly, it is shown that a quantum state is n-extendible for all $n \geq 2$ if and only if the state is separable [14, 30]. Thus, the set of n-extendible states is a good outer approximation for the separable set and converges to the separable set when $n \to \infty$. The same idea can be generalised to the tripartite case as well; (n_1, n_2)-extendible states ρ_{ABC} with the two-fold extension $\rho_{AB^{n_1}C^{n_2}}$. As in the bipartite case, the set of (n_1, n_2)-extendible states converges to the set of tripartite separable states when $n_1 \to \infty$ and $n_2 \to \infty$ [13].

To derive SDP relaxations for $\omega_{Q(T)}(V, \pi)$ in Eq. (8), we can simply replace the optimisation variables with (n, n)-extendible states with respect to the appropriate tripartition.

$$\mathrm{sdp}_n(V, \pi, T) := |T|^2 \max_{\rho} \mathrm{tr}\left[\left(V_{A_1A_2Q_1Q_2} \otimes \Phi_{T\hat{T}|S\hat{S}}\right)\rho_{(A_1Q_1T)(A_2Q_2\hat{T})(S\hat{S})}\right] \tag{14}$$

$$\text{s.t.} \quad \rho_{(A_1Q_1T)(A_2Q_2\hat{T})^n(S\hat{S})^n} \geq 0\,, \quad \mathrm{tr}\left[\rho_{(A_1Q_1T)(A_2Q_2\hat{T})^n(S\hat{S})^n}\right] = 1 \tag{15}$$

$$\rho_{(A_1Q_1T)(A_2Q_2\hat{T})^n(S\hat{S})^n} \text{ perm. inv. on } (A_2Q_2\hat{T})^n \text{ wrt } (A_1Q_1T)(S\hat{S})^n \tag{16}$$

$$\rho_{(A_1Q_1T)(A_2Q_2\hat{T})^n(S\hat{S})^n} \text{ perm. inv. on } (S\hat{S})^n \text{ wrt } (A_1Q_1T)(A_2Q_2\hat{T})^n \tag{17}$$

$$\mathrm{tr}_{A_1}[\rho_{(A_1Q_1T)(A_2Q_2\hat{T})^n(S\hat{S})^n}] = \left(\sigma_{Q_1} \otimes \frac{\mathbb{I}_T}{|T|}\right) \otimes \rho_{(A_2Q_2\hat{T})^n(S\hat{S})^n} \tag{18}$$

$$\mathrm{tr}_{A_2}[\rho_{(A_1Q_1T)(A_2Q_2\hat{T})^n(S\hat{S})^n}] = \left(\sigma_{Q_2} \otimes \frac{\mathbb{I}_{\hat{T}}}{|T|}\right) \otimes \rho_{(A_1Q_1T)(A_2Q_2\hat{T})^{(n-1)}(S\hat{S})^n} \tag{19}$$

$$\rho^{T_{A_1Q_1T}}_{(A_1Q_1T)(A_2Q_2\hat{T})^n(S\hat{S})^n} \geq 0\,, \quad \rho^{T_{(A_2Q_2\hat{T})^n}}_{(A_1Q_1T)(A_2Q_2\hat{T})^n(S\hat{S})^n} \geq 0, \ \dots\,, \tag{20}$$

where $\sigma_{Q_i} = \sum_{q_i} \pi_i(q_i)\,|q_i\rangle\langle q_i|_{Q_i}$ for $i = 1, 2$, and the last line Eq. (20) contains all positive partial transpose (PPT) conditions with respect to all the cuts

$$A_1Q_1T : A_2^1Q_2^1\hat{T}^1 : \cdots : A_2^nQ_2^n\hat{T}^n : S^1\hat{S}^1 : \cdots : S^n\hat{S}^n. \tag{21}$$

Note that in addition to the n-extendibility conditions Eq. (16)–(17) enforced by the DPS hierarchy, we arrive at the additional linear constraints, Eq. (18)–(19), originating from the constraints in Eq. (8). These additional constraints are crucial in order to obtain the improved complexity bounds. Furthermore, we are able to combine our SDPs with the NPA constraints [27], so that our new hierarchy is guaranteed to produce at least as good outputs as the ones produced by the NPA hierarchy (see the full version [19, Section 5]),

$$\mathrm{sdp}^{\mathrm{NPA}}_n(V, \pi, T) := \mathrm{sdp}_n(V, \pi, T) \text{ with } \Gamma_n\left(\rho_{(A_1Q_1T)(A_2Q_2\hat{T})^n(S\hat{S})^n}\right) \geq 0, \tag{22}$$

where $\Gamma_n(\rho)$ denotes the n-th level NPA matrix.

It is worth noting that $\mathrm{sdp}_n(V, \pi, T)$ in Eq. (14) is naturally upper bounded by 1.

▶ **Proposition 4.** *Let $sdp_n(V,\pi,T)$ be the n-th level SDP relaxation for the two-player free game with rule matrix V, probability distribution $\pi(q_1,q_2)=\pi_1(q_1)\pi_2(q_2)$, and $|T|^2$-dimensional quantum correlation. Then, we have that*

$$0 \leq sdp_n(V,\pi,T) \leq 1. \tag{23}$$

The proof can be found in the full version [19, Proposition 5].

3 Convergence of the hierarchy

3.1 Tripartite quantum de Finetti theorem with additional linear constraints

Quantum de Finetti theorems provide a quantitative bound on how close n-extendible states are to the set of separable states in trace distance as a function of both n and the system's dimensions. This information can be converted to the upper bound on the accuracy of our SDP relaxations. However, since the quantum separability problem for $\omega_{Q(T)}(V,\pi)$ in Eq. (8) is subject to the additional linear constraints, we cannot directly exploit the standard quantum de Finetti theorem and need an adapted version (we refer to [6, Example 3.7] for a discussion of counterexamples). What we need is an upper bound on how close n-extendible states satisfying the linear constraints are to the separable states satisfying the same linear constraints.

In this paper, we derive improved multipartite quantum de Finetti theorems with additional linear constraints employing the information-theoretic proof technique based on quantum entropy inequalities [8, 9]. Using this adapted quantum de Finetti theorems is crucial to obtain the improved complexity bounds on approximating $\omega_{Q(T)}(V,\pi)$ in the next section. Here, we state the tripartite version of the theorem.

▶ **Theorem 5.** *Let $\rho_{AB^{n_1}C^{n_2}}$ be a quantum state which is invariant under permutations on B^{n_1} with respect to AC^{n_2} and on C^{n_2} with respect to AB^{n_1}, satisfying for linear maps $\mathcal{E}_{A\to\tilde{A}}$, $\Lambda_{B\to\tilde{B}}$, and $\Gamma_{C\to\tilde{C}}$ and operators $\mathbf{X}_{\tilde{A}}$, $\mathbf{Y}_{\tilde{B}}$, and $\mathbf{Z}_{\tilde{C}}$ that*

$$\left(\mathcal{E}_{A\to\tilde{A}}\otimes\mathcal{I}_{B^{n_1}C^{n_2}}\right)\left(\rho_{AB^{n_1}C^{n_2}}\right)=\mathbf{X}_{\tilde{A}}\otimes\rho_{B^{n_1}C^{n_2}} \qquad \text{linear constraint on } A \tag{24}$$

$$\left(\Lambda_{B\to\tilde{B}}\otimes\mathcal{I}_{B^{n_1-1}C^{n_2}}\right)\left(\rho_{B^{n_1}C^{n_2}}\right)=\mathbf{Y}_{\tilde{B}}\otimes\rho_{B^{n_1-1}C^{n_2}} \qquad \text{linear constraint on } B \tag{25}$$

$$\left(\mathcal{I}_{B^{n_1}C^{n_2-1}}\otimes\Gamma_{C\to\tilde{C}}\right)\left(\rho_{B^{n_1}C^{n_2}}\right)=\mathbf{Z}_{\tilde{C}}\otimes\rho_{B^{n_1}C^{n_2-1}} \qquad \text{linear constraint on } C. \tag{26}$$

Then, there exist a probability distribution $\{p_i\}_{i\in I}$ and sets of quantum states $\{\sigma_A^i\}_{i\in I}$, $\{\omega_B^i\}_{i\in I}$ and $\{\tau_C^i\}_{i\in I}$ such that we have that

$$\begin{aligned}&\left\|\rho_{ABC}-\sum_{i\in I}p_i\sigma_A^i\otimes\omega_B^i\otimes\tau_C^i\right\|_1\\&\qquad\leq\min\left\{18^{3/2}\sqrt{|ABC|},4|BC|\right\}\times\sqrt{2\ln 2}\left(\sqrt{\frac{\log|A|+8\log|B|}{n_2}+\frac{\log|A|}{n_1}}\right)\end{aligned} \tag{27}$$

$$\mathcal{E}_{A\to\tilde{A}}\left(\sigma_A^i\right)=\mathbf{X}_{\tilde{A}},\quad \Lambda_{B\to\tilde{B}}\left(\omega_B^i\right)=\mathbf{Y}_{\tilde{B}},\quad \Gamma_{C\to\tilde{C}}\left(\tau_C^i\right)=\mathbf{Z}_{\tilde{C}}\qquad\forall i\in I. \tag{28}$$

Like any other de Finetti theorem, Theorem 5 can be understood as a statement on the monogamy of entanglement; a multipartite system, described by an extendible state, cannot possess much entanglement between any tripartition. Instead of directly working with the

trace distance, we prove the above theorem via quantum entropy inequalities and chain rules. This approach allows us to carefully quantify how correlations are divided between different partitions of the extendible states.

For k given quantum systems $A_1, ..., A_k$ and a classical system R described by the global state $\rho_{A_1A_2\cdots A_kR}$, the conditional multipartite quantum mutual information is defined as

$$I(A_1 : A_2 : \ldots : A_k|R) := \sum_{i=1}^{k} S(A_iR) - S(A_1A_2 \ldots A_kR) - S(R), \tag{29}$$

where $S(A_i) = -\operatorname{tr}[\rho_{A_i} \log \rho_{A_i}]$ is the von Neumann entropy [23] of the marginal state ρ_{A_i}. This quantity has a few useful mathematical properties. One is its relation to the bipartite ones [9, Lemma 3]

$$I(A_1 : \ldots : A_k|R) = I(A_1 : A_2|R) + I(A_1A_2 : A_3|R) + \ldots + I(A_1 \ldots A_{k-1} : A_k|R), \tag{30}$$

and another one is the chain rule

$$I(AB : C|D) = I(B : C|D) + I(A : C|BD). \tag{31}$$

The conditional multipartite quantum mutual information is mathematically equivalent to the relative entropy distance between the state and the tensor product of its conditional marginals

$$I(A_1 : A_2 : \ldots : A_k|R) = D(\rho_{A_1\cdots A_k|R} \| \rho_{A_1|R} \otimes \ldots \otimes \rho_{A_k|R}), \tag{32}$$

where $\rho_{A_i|R}$ is the marginal state of the conditional $\rho_{A_1\cdots A_k|R} = \rho_R^{-1/2}\rho_{A_1\cdots A_k}\rho_R^{-1/2}$, and $D(\rho||\sigma) = \operatorname{tr}[\rho(\log\rho - \log\sigma)]$ is the relative entropy between ρ and σ whenever $\operatorname{supp}(\rho) \subset \operatorname{supp}(\sigma)$. The relative entropy can be further related to the trace distance via Pinsker's inequality. As the tensor product of marginal states is a separable state, if we can find an upper bound on the conditional multipartite quantum mutual information of an extendible state $\rho_{AB^{n_1}C^{n_2}}$, we can show Eq. (27) in Theorem 5.

For the first ingredient, we derive a general upper bound on the conditional multipartite quantum mutual information of a state with classical subsystems.

▶ **Lemma 6.** *Consider a quantum state $\rho_{AZ^{n_1}W^{n_2}}$ classical on the Z- and W-systems. Then, there exist $0 \le \bar{m} < n_1$ and $0 \le \bar{l} < n_2$ such that*

$$I(A : Z_{\bar{m}+1} : W_{\bar{l}+1}|Z^{\bar{m}}W^{\bar{l}}) \le \frac{\log|A|}{n_1} + \frac{\log|A| + \log|Z|}{n_2}. \tag{33}$$

Moreover, by Pinsker's inequality, this implies that

$$\mathbb{E}_{z^{\bar{m}}w^{\bar{l}}} \left\{ \left\| \rho_{AZ_{\bar{m}+1}W_{\bar{l}+1}|z^{\bar{m}}w^{\bar{l}}} - \rho_{A|z^{\bar{m}}w^{\bar{l}}} \otimes \rho_{Z_{\bar{m}+1}|z^{\bar{m}}w^{\bar{l}}} \otimes \rho_{W_{\bar{l}+1}|z^{\bar{m}}w^{\bar{l}}} \right\|_1^2 \right\} \tag{34}$$
$$\le 2\ln 2 \left(\frac{\log|A|}{n_1} + \frac{\log|A| + \log|Z|}{n_2} \right).$$

Here, we use the notation $\rho_{A|z}$ for the conditional state after measurement on classical system Z when the measurement outcome is z, i.e.,

$$\rho_{A|z} := \frac{\operatorname{tr}_Z[\rho_{AZ}(\mathbb{I}_A \otimes |z\rangle\langle z|_Z)]}{\operatorname{tr}[\rho_{AZ}(\mathbb{I}_A \otimes |z\rangle\langle z|_Z)]}. \tag{35}$$

The proof of Lemma 6 is as follows.

Proof of Lemma 6. The multipartite quantum mutual information $I(A : Z_{\bar{m}+1} : W_{\bar{l}+1}|Z^{\bar{m}}W^{\bar{l}})$ can be expressed in terms of bipartite ones using Eq. (30):

$$I(A : Z_{\bar{m}+1} : W_{\bar{l}+1}|Z^{\bar{m}}W^{\bar{l}}) = I(A : Z_{\bar{m}+1}|Z^{\bar{m}}W^{\bar{l}}) + I(AZ_{\bar{m}+1} : W_{\bar{l}+1}|Z^{\bar{m}}W^{\bar{l}}). \tag{36}$$

The two terms in the right hand side (RHS) are the bipartite mutual information between quantum and classical systems, and this allows us to find an upper bound for each term using the chain rule in Eq. (31). Additionally, we also make use of a general upper bound

$$I(A : Z|X) \leq \log|A| \tag{37}$$

for a classical-quantum state ρ_{AZX} with classical Z and X systems [19, Lemma 13].

First term: For any l, it holds that

$$I(A : Z^{n_1}|W^l) = \sum_{m=0}^{n_1-1} I(A : Z_{m+1}|Z^m W^l) \leq \log|A|, \tag{38}$$

where the first equality is the chain rule in Eq. (31) and the second inequality is found by applying Eq. (37) to $I(A : Z^{n_1}|W^l)$. Then, summing over all l gives us

$$\sum_{m=0}^{n_1-1}\sum_{l=0}^{n_2-1} I(A : Z_{m+1}|Z^m W^l) \leq n_2 \log|A|. \tag{39}$$

Second term: Using the same argument, for any m, it holds that

$$I(AZ_{m+1} : W^{n_2}|Z^m) = \sum_{l=0}^{n_2-1} I(AZ_{m+1} : W_{l+1}|Z^m W^l) \leq \log|AZ_{m+1}|, \tag{40}$$

and summing over m gives us

$$\sum_{m=0}^{n_1-1}\sum_{l=0}^{n_2-1} I(AZ_{m+1} : W_{l+1}|Z^m W^l) \leq n_1 \left(\log|A| + \log|Z|\right). \tag{41}$$

Combining Eq. (39) and Eq. (41) gives

$$\begin{aligned} &n_2 \log|A| + n_1 \left(\log|A| + \log|Z|\right) \\ &\geq \sum_{m=0}^{n_1-1}\sum_{l=0}^{n_2-1} \left[I(A : Z_{m+1}|Z^m W^l) + I(AZ_{m+1} : W_{l+1}|Z^m W^l)\right] \\ &\geq n_1 n_2 \left[I(A : Z_{\bar{m}+1}|Z^{\bar{m}}W^{\bar{l}}) + I(AZ_{\bar{m}+1} : W_{\bar{l}+1}|Z^{\bar{m}}W^{\bar{l}})\right], \end{aligned} \tag{42}$$

where $\bar{m}$ and $\bar{l}$ are the indices of the smallest element in the sum. Dividing both sides by $n_1 n_2$ gives us the desired relation,

$$\begin{aligned} I(A : Z_{\bar{m}+1} : W_{\bar{l}+1}|Z^{\bar{m}}W^{\bar{l}}) &= I(A : Z_{\bar{m}+1}|Z^{\bar{m}}W^{\bar{l}}) + I(AZ_{\bar{m}+1} : W_{\bar{l}+1}|Z^{\bar{m}}W^{\bar{l}}) \\ &\leq \frac{\log|A|}{n_1} + \frac{\log|A| + \log|Z|}{n_2}. \end{aligned} \tag{43}$$

This ends the proof of Eq. (33). Then, using Eq. (32) and Pinsker's inequality we can obtain Eq. (34). ◀

As another ingredient, we derive two different types of informationally complete measurements that achieve the optimal loss in distinguishability.

▶ **Lemma 7.**

1. ([8, Lemma 14]) *There exist fixed measurements $\mathcal{M}_A$, $\mathcal{M}_B$, and $\mathcal{M}_C$ with at most $|A|^8$, $|B|^8$, and $|C|^8$ outcomes, respectively, such that for every traceless Hermitian operator γ_{ABC} on $\mathcal{H}_{ABC}$ we have*

$$\|\gamma_{ABC}\|_1 \leq 18^{3/2}\sqrt{|ABC|}\cdot\|(\mathcal{M}_A\otimes\mathcal{M}_B\otimes\mathcal{M}_C)(\gamma_{ABC})\|_1. \tag{44}$$

2. *There exists a fixed measurement $\mathcal{M}_B$ with at most $|B|^6$ outcomes such that for every traceless Hermitian operator γ_{AB} on $\mathcal{H}_{AB}$ we have*

$$\|\gamma_{AB}\|_1 \leq 2|B|\cdot\|(\mathcal{I}_A\otimes\mathcal{M}_B)(\gamma_{AB})\|_1. \tag{45}$$

The first part is straightforward from [8, Lemma 14]. We remark that when a traceless Hermitian operator already has a classical subsystem, i.e., γ_{ABCZ} with classical Z-system, the dimension factor only includes the dimension of the quantum systems

$$\|\gamma_{ABCZ}\|_1 \leq 18^{3/2}\sqrt{|ABC|}\cdot\|(\mathcal{M}_A\otimes\mathcal{M}_B\otimes\mathcal{M}_C\otimes\mathcal{I}_Z)(\gamma_{ABCZ})\|_1. \tag{46}$$

This follows easily as $\|\sum_z \rho_A^z\otimes|z\rangle\langle z|\|_1 = \sum_z\|\rho_A^z\|_1$ for classical-quantum states ρ_{AZ}.

The proof of the second part is given in Section 5. The main idea is to identify the one-way quantum teleportation protocol as a candidate for the optimal measurement and is largely inspired by [22, Theorem 16]. Our result improves on the factor $\sqrt{18}B^{3/2}$ given in [9, Eq.(68)]. Moreover, as there exist quantum states ρ_{AB} and σ_{AB} such that [24]

$$\|\rho_{AB}-\sigma_{AB}\|_1 = 2 \quad\text{and}\quad \sup_{\mathcal{M}_B}\|(\mathcal{I}_A\otimes\mathcal{M}_B)(\rho_{AB}-\sigma_{AB})\|_1 = \frac{2}{|B|+1}, \tag{47}$$

our result establishes that the dimension dependence for the optimal loss in distinguishability relative to quantum side information is $\Theta(|B|)$. This answers a question left open in [6].

Then, for the extendible state $\rho_{AB^{n_1}C^{n_2}}$ in Theorem 5, applying the optimal measurement $\mathcal{M}$ as specified in Lemma 7 to the state (to make it partially classical), and applying Lemma 6 to the resulting classical-quantum state allows us to derive Theorem 5.

Proof of Theorem 5. Let $\mathcal{M}_{B\to Y}$ be a quantum-to-classical measurement from B to the classical system Y, and $\mathcal{M}_{C\to Z}$ be a quantum-to-classical measurement from C to the classical system Z. We apply these measurements to the quantum state $\rho_{AB^{n_1}C^{n_2}}$ and will denote the outcome classical-quantum state as $\rho_{AY^{n_1}Z^{n_2}}$. Then, according to Lemma 6, there exist $m\in\{0,\cdots,n_1-1\}$ and $\ell\in\{0,\cdots,n_2-1\}$ such that

$$\mathbb{E}_{y^m z^\ell}\left\{\left\|\rho_{AY_{m+1}Z_{\ell+1}|y^m z^\ell}-\rho_{A|y^m z^\ell}\otimes\rho_{Y_{m+1}|y^m z^\ell}\otimes\rho_{Z_{\ell+1}|y^m z^\ell}\right\|_1^2\right\} \leq 2\ln 2\left(\frac{\log|A|}{n_1}+\frac{\log|A|+\log|Y|}{n_2}\right). \tag{48}$$

As $\rho_{AB^{n_1}C^{n_2}}$ is invariant under permutations of the systems B^{n_1} and C^{n_2}, we can always find m and l satisfying Eq. (48).

Now, let us define

$$\gamma_{ABC}\equiv\rho_{AB_{m+1}C_{\ell+1}|y^m z^\ell}-\rho_{A|y^m z^\ell}\otimes\rho_{B_{m+1}|y^m z^\ell}\otimes\rho_{C_{\ell+1}|y^m z^\ell}. \tag{49}$$

Note that

$$\mathcal{I}_A\otimes\mathcal{M}_{B\to Y}\otimes\mathcal{M}_{C\to Z}(\gamma_{ABC}) = \rho_{AY_{m+1}Z_{\ell+1}|y^m z^\ell}-\rho_{A|y^m z^\ell}\otimes\rho_{Y_{m+1}|y^m z^\ell}\otimes\rho_{Z_{\ell+1}|y^m z^\ell}. \tag{50}$$

Using the second part of Lemma 7 iteratively, we can obtain

$$\begin{aligned}\|\gamma_{ABC}\|_1 &\leq 2|C|\|(\mathcal{I}_{AB}\otimes\mathcal{M}_{C\to Z})(\gamma_{ABC})\|_1\\ &\leq 2|B|\times 2|C|\|(\mathcal{I}_{AC}\otimes\mathcal{M}_{B\to Y})(\mathcal{I}_{AB}\otimes\mathcal{M}_{C\to Z})(\gamma_{ABC})\|_1\\ &= 4|BC|\|(\mathcal{I}_A\otimes\mathcal{M}_{B\to Y}\otimes\mathcal{M}_{C\to Z})(\gamma_{ABC})\|_1,\end{aligned} \tag{51}$$

with $|Y|\leq|B|^6$. We can also exploit the first part of Lemma 7 to obtain

$$\begin{aligned}\|\gamma_{ABC}\|_1 &\leq \sqrt{18^3|ABC|}\,\|(\mathcal{M}_A\otimes\mathcal{M}_{B\to Y}\otimes\mathcal{M}_{C\to Z})(\gamma_{ABC})\|_1\\ &\leq \sqrt{18^3|ABC|}\,\|(\mathcal{I}_A\otimes\mathcal{M}_{B\to Y}\otimes\mathcal{M}_{C\to Z})(\gamma_{ABC})\|_1\end{aligned} \tag{52}$$

with $|Y|\leq|B|^8$, where the second inequality follows from the monotonicity of the trace norm under completely positive and trace preserving (CPTP) maps. Depending on the dimensions, we can freely choose the tighter bound between the two cases. Combining Eq. (48) with the above two results we obtain

$$\begin{aligned}&\mathbb{E}_{y^m z^\ell}\left\{\left\|\rho_{AB_{m+1}C_{\ell+1}|y^m z^\ell}-\rho_{A|y^m z^\ell}\otimes\rho_{B_{m+1}|y^m z^\ell}\otimes\rho_{C_{\ell+1}|y^m z^\ell}\right\|_1^2\right\}\\ &\quad\leq\min\left\{\sqrt{18^3|ABC|},4|BC|\right\}^2\times 2\ln 2\left(\frac{\log|A|}{n_1}+\frac{\log|A|+8\log|B|}{n_2}\right).\end{aligned} \tag{53}$$

Then, we have

$$\begin{aligned}&\left\|\rho_{AB_{m+1}C_{\ell+1}}-\mathbb{E}_{y^m z^\ell}\left\{\rho_{A|y^m z^\ell}\otimes\rho_{B_{m+1}|y^m z^\ell}\otimes\rho_{C_{\ell+1}|y^m z^\ell}\right\}\right\|_1\\ &\leq\ \mathbb{E}_{y^m z^\ell}\left\{\left\|\rho_{AB_{m+1}C_{\ell+1}|y^m z^\ell}-\rho_{A|y^m z^\ell}\otimes\rho_{B_{m+1}|y^m z^\ell}\otimes\rho_{C_{\ell+1}|y^m z^\ell}\right\|_1\right\}\\ &\leq\ \sqrt{\mathbb{E}_{y^m z^\ell}\left\{\left\|\rho_{AB_{m+1}C_{\ell+1}|y^m z^\ell}-\rho_{A|y^m z^\ell}\otimes\rho_{B_{m+1}|y^m z^\ell}\otimes\rho_{C_{\ell+1}|y^m z^\ell}\right\|_1^2\right\}}\\ &\leq\ \min\left\{\sqrt{18^3|ABC|},4|BC|\right\}\times\sqrt{2\ln 2}\left(\sqrt{\frac{\log|A|}{n_1}+\frac{\log|A|+8\log|B|}{n_2}}\right),\end{aligned} \tag{54}$$

where we used the triangular inequality for Schatten p-norms in the second line and the concavity of the square function in the third line. As $\mathbb{E}_{y^m z^\ell}\left\{\rho_{A|y^m z^\ell}\otimes\rho_{B_{m+1}|y^m z^\ell}\otimes\rho_{C_{\ell+1}|y^m z^\ell}\right\}$ is a separable state with respect to the tripartition $A|B|C$, this proves the first half of the theorem.

The remaining part is to check whether $\rho_{A|y^m z^\ell}$, $\rho_{B_{m+1}|y^m z^\ell}$ and $\rho_{C_{\ell+1}|y^m z^\ell}$ satisfy the desired linear constraints. Let us denote $M_{B_i}^{y_i}$ and $M_{C_i}^{z_i}$ as the POVM elements of the measurements $\mathcal{M}_{B_i\to Y_i}$ and $\mathcal{M}_{C_i\to Z_i}$ corresponding to the measurement outcomes y_i and z_i, respectively. Then, we find

$$\begin{aligned}&\mathcal{E}_{A\to\tilde{A}}\left(\sigma_A^i\right)=\mathcal{E}_{A\to\tilde{A}}\left(\rho_{A|y^m z^\ell}\right)\\ &=\frac{\mathrm{Tr}_{B^m C^\ell}\left[(\mathbb{I}_A\otimes M_{B_1}^{y_1}\otimes\cdots\otimes M_{B_m}^{y_m}\otimes M_{C_1}^{z_1}\otimes\cdots\otimes M_{C_\ell}^{z_\ell})\mathcal{E}_{A\to\tilde{A}}\left(\rho_{AB^m C^\ell}\right)\right]}{\mathrm{Tr}\left[(\mathbb{I}_A\otimes M_{B_1}^{y_1}\otimes\cdots\otimes M_{B_m}^{y_m}\otimes M_{C_1}^{z_1}\otimes\cdots\otimes M_{C_\ell}^{z_\ell})\rho_{AB^m C^\ell}\right]}\\ &=\frac{\mathrm{Tr}_{B^m C^\ell}\left[(\mathbb{I}_A\otimes M_{B_1}^{y_1}\otimes\cdots\otimes M_{B_m}^{y_m}\otimes M_{C_1}^{z_1}\otimes\cdots\otimes M_{C_\ell}^{z_\ell})\left(\mathcal{X}_{\tilde{A}}\otimes\rho_{B^m C^\ell}\right)\right]}{\mathrm{Tr}\left[(\mathbb{I}_A\otimes M_{B_1}^{y_1}\otimes\cdots\otimes M_{B_m}^{y_m}\otimes M_{C_1}^{z_1}\otimes\cdots\otimes M_{C_\ell}^{z_\ell})\rho_{AB^m C^\ell}\right]}\\ &=\mathcal{X}_{\tilde{A}}.\end{aligned} \tag{55}$$

$$\begin{aligned}
&\Lambda_{B\to\tilde{B}}\left(\omega_B^i\right) = \Lambda_{B\to\tilde{B}}\left(\rho_{B_{m+1}|y^m z^\ell}\right) \qquad (56)\\

\end{aligned}$$

Theorem 5 describes a general setting; both the extendible state and the linear constraints do not have any refined structures. However, in our case, we have more information about the state and the constraints. The extendible state $\rho_{(A_1Q_1T)(A_2Q_2\hat{T})^n(S\hat{S})^n}$ in $\mathrm{sdp}_n(V,\pi,T)$ to which we apply the de Finetti theorem already has some classical subsystems, and the linear constraints are partial trace constraints. We can exploit this information to obtain a better bound in the quantum de Finetti theorem. We state this special case as a lemma.

▶ **Lemma 8.** *Let $\rho_{(AX\tilde{X})B^{n_1}(CZ\tilde{Z})^{n_2}}$ be a quantum state with classical $X\tilde{X}$- and $Z\tilde{Z}$-systems invariant under permutation on B^{n_1} and $(CZ\tilde{Z})^{n_2}$ with respect to the other systems, satisfying*

$$\mathrm{tr}_X\left[\rho_{(AX\tilde{X})B^{n_1}(CZ\tilde{Z})^{n_2}}\right] = \mathcal{X}_{A\tilde{X}}\otimes\rho_{B^{n_1}(CZ\tilde{Z})^{n_2}} \qquad (58)$$

$$\mathrm{tr}_Z\left[\rho_{(AX\tilde{X})B^{n_1}(CZ\tilde{Z})^{n_2}}\right] = \mathcal{Z}_{C\tilde{Z}}\otimes\rho_{(AX\tilde{X})B^{n_1}(CZ\tilde{Z})^{n_2-1}} \qquad (59)$$

for some operators $\mathcal{X}_{A\tilde{X}}$, and $\mathcal{Z}_{C\tilde{Z}}$. Then, there exist a probability distribution $\{p_i\}_{i\in I}$ and sets of quantum states $\{\sigma^i_{AX\tilde{X}}\}_{i\in I}$, $\{\omega^i_B\}_{i\in I}$ and $\{\tau^i_{CZ\tilde{Z}}\}_{i\in I}$ such that

$$\begin{aligned}
&\left\|\rho_{(AX\tilde{X})B(CZ\tilde{Z})} - \sum_{i\in I} p_i\,\sigma^i_{AX\tilde{X}}\otimes\omega^i_B\otimes\tau^i_{CZ\tilde{Z}}\right\|_1\\
&\leq \min\left\{18^{3/2}\sqrt{|ABC|}, 4|BC|\right\}\times\sqrt{4\ln 2}\left(\sqrt{\frac{\log|X|+8\log|B|}{n_2}}+\frac{\log|X|}{n_1}\right) \qquad (60)
\end{aligned}$$

with $\mathrm{tr}_X\left[\sigma^i_{AX\tilde{X}}\right] = \mathcal{X}_{A\tilde{X}}$ and $\mathrm{tr}_Z\left[\tau^i_{CZ\tilde{Z}}\right] = \mathcal{Z}_{C\tilde{Z}}$ for all $i\in I$.

The proof of Lemma 8 is similar to the one of Theorem 5 apart from the following two ingredients – leading to the tighter bound in Eq. (60) in comparison to Eq. (27):

- The partial trace constraints allow us to use a stronger bound on the conditional quantum mutual information in the proof of Lemma 6 (instead of Eq. (37)). Namely, for a quantum state ρ_{ABCD} satisfying $\mathrm{tr}_A[\rho_{ABCD}] = \rho_B\otimes\rho_{CD}$, we have that

$$I(AB:C|D)_\rho = I(B:C|D) + I(A:C|DB) \leq 2\log|A|. \qquad (61)$$

  Using this results in a better bound with $|X|$ instead of $|AX\tilde{X}|$ in the square root part of Eq. (60). Please see Section 4.2, especially Lemma 6 and Lemma 7, in the full version [19] for a more detailed discussion.

- As we remarked in Eq. (46) after Lemma 7, the dimension factor only comes from the measurements on the quantum systems. This is why there is no $|X\tilde{X}Z\tilde{Z}|$ contribution in the first part of Eq. (60).

3.2 Convergence of the hierarchy

Lemma 8 allows us to find an upper bound on the accuracy of the SDP relaxations in Eq. (14). We derive analytical bounds on the convergence speed of our SDP hierarchy in terms of the dimension $|T|$ and the size of the game.

▶ **Theorem 9.** *Let $sdp_n(V,\pi,T)$ be the n-th level SDP relaxation for the two-player free game with rule matrix V, probability distribution $\pi(q_1,q_2)=\pi_1(q_1)\pi_2(q_2)$, and quantum correlation of dimension $|T|^2$. Then, we have*

$$0 \leq sdp_n(V,\pi,T) - \omega_{Q(T)}(V,\pi) \leq O\left(|T|^6\sqrt{\frac{\log|T||A|}{n}}\right). \tag{62}$$

Hence, we have $\omega_{Q(T)}(V,\pi) = \lim_{n\to\infty} sdp_n(V,\pi,T)$.

Proof. Let $\rho_{A_1Q_1TA_2Q_2\hat{T}S\hat{S}}$ be the optimal state of the n-th level relaxation $\mathrm{sdp}_n(V,\pi,T)$. The state should be (n,n)-extendible since all feasible states must be (n,n)-extendible states satisfying the linear constraints. Then, we have

$$\begin{aligned}
&\mathrm{sdp}_n(V,\pi,T) = |T|^2 \operatorname{tr}\left[\left(V_{A_1A_2Q_1Q_2}\otimes\Phi_{T\hat{T}|S\hat{S}}\right)\rho_{A_1Q_1TA_2Q_2\hat{T}S\hat{S}}\right]\\
&= |T|^2 \operatorname{tr}\left[\left(V_{A_1A_2Q_1Q_2}\otimes\Phi_{T\hat{T}|S\hat{S}}\right)\left(\sum_i p_i\,\sigma^i_{A_1Q_1T}\otimes\omega^i_{A_2Q_2\hat{T}}\otimes\tau^i_{S\hat{S}}\right)\right]\\
&\quad + |T|^2 \operatorname{tr}\left[\left(V_{A_1A_2Q_1Q_2}\otimes\Phi_{T\hat{T}|S\hat{S}}\right)\left(\rho_{A_1Q_1TA_2Q_2\hat{T}S\hat{S}} - \sum_i p_i\,\sigma^i_{A_1Q_1T}\otimes\omega^i_{A_2Q_2\hat{T}}\otimes\tau^i_{S\hat{S}}\right)\right]\\
&\leq \omega_{Q(T)}(V,\pi)\\
&\quad + |T|^2 \operatorname{tr}\left[\left(V_{A_1A_2Q_1Q_2}\otimes\Phi_{T\hat{T}|S\hat{S}}\right)\left(\rho_{A_1Q_1TA_2Q_2\hat{T}S\hat{S}} - \sum_i p_i\,\sigma^i_{A_1Q_1T}\otimes\omega^i_{A_2Q_2\hat{T}}\otimes\tau^i_{S\hat{S}}\right)\right],
\end{aligned} \tag{63}$$

where $\sum_i p_i\,\sigma^i_{A_1Q_1T}\otimes\omega^i_{A_2Q_2\hat{T}}\otimes\tau^i_{S\hat{S}}$ is one of the close separable states to $\rho_{A_1Q_1TA_2Q_2\hat{T}S\hat{S}}$ specified by Lemma 8. As $\mathrm{sdp}_n(V,\pi,T)$ is an upper bound for $\omega_{Q(T)}(V,\pi)$ we obtain

$$\begin{aligned}
&\left|\mathrm{sdp}_n(V,\pi,T) - \omega_{Q(T)}(V,\pi)\right|\\
&\leq |T|^2\left|\operatorname{tr}\left[\left(V_{A_1A_2Q_1Q_2}\otimes\Phi_{T\hat{T}|S\hat{S}}\right)\left(\rho_{A_1Q_1TA_2Q_2\hat{T}S\hat{S}} - \sum_i p_i\,\sigma^i_{A_1Q_1T}\otimes\omega^i_{A_2Q_2\hat{T}}\otimes\tau^i_{S\hat{S}}\right)\right]\right|\\
&\leq |T|^2\left\|V_{A_1A_2Q_1Q_2}\otimes\Phi_{T\hat{T}|S\hat{S}}\right\|_\infty\left\|\rho_{A_1Q_1TA_2Q_2\hat{T}S\hat{S}} - \sum_i p_i\,\sigma^i_{A_1Q_1T}\otimes\omega^i_{A_2Q_2\hat{T}}\otimes\tau^i_{S\hat{S}}\right\|_1\\
&\qquad\qquad\qquad

$$= |T|^4 \left\| \rho_{A_1Q_1TA_2Q_2\hat{T}S\hat{S}} - \sum_i p_i \, \sigma^i_{A_1Q_1T} \otimes \omega^i_{A_2Q_2\hat{T}} \otimes \tau^i_{S\hat{S}} \right\|_1$$

$$\left(\text{by } \|V_{A_1A_2Q_1Q_2}\|_\infty = 1, \ \left\|\Phi_{T\hat{T}|S\hat{S}}\right\|_\infty = |T|^2 \right)$$

$$\leq |T|^4 \left[18^{3/2} |T|^2 \left(\sqrt{2 \ln 2}\right) \left(\sqrt{\frac{\log |A_1| + 8 \log |S\hat{S}|}{n}} + \frac{\log |A_1|}{n} \right) \right] \qquad \text{(by Lemma 8)}$$

$$= 18^{3/2} |T|^6 \left(\sqrt{2 \ln 2}\right) \left(\sqrt{\frac{\log |A| + 16 \log |T|}{n}} + \frac{\log |A|}{n} \right). \tag{64}$$

Here, we set $A = T$, $X = A_1$, $\tilde{X} = Q_1$ $B = S\hat{S}$, $C = \hat{T}$, $Z = A_2$, and $\tilde{Z} = Q_2$ when we applied Lemma 8. ◀

It is worth noting that neither the PPT nor NPA constraints are used to derive this convergence speed.

Theorem 9 allows us to provide an upper bound on the computational complexity of calculating $\omega_{Q(T)}(V, \pi)$ for two-player free games. To achieve a constant error ϵ, it is sufficient to go up to the following level of the hierarchy:

$$\mathcal{O}\left(|T|^6 \sqrt{\frac{\log |TA|}{n}} \right) \leq \epsilon \qquad \Longleftrightarrow \qquad n \geq \mathcal{O}\left(|T|^{12} \frac{\log |TA|}{\epsilon^2} \right). \tag{65}$$

The resulting size of the program is stated in Eq. (1), where the dependence is quasi-polynomial in A and polynomial in Q. Our result is the quantum extension of the quasi-polynomial time approximation scheme for computing classical values $\omega_C(V, \pi)$ of two-player free games developed in [1, 9].

3.2.1 General games

We hitherto assume that the choice of questions for Alice and Bob is independent, i.e., $\pi(q_1, q_2) = \pi_1(q_1)\pi_2(q_2)$, which corresponds to free games. We can use the same protocol that we used for free games to derive upper bounds on the computational complexity of calculating $\omega_{Q(T)}(V, \pi)$ of general games, when $\pi(q_1, q_2) \neq \pi_1(q_1)\pi_2(q_2)$. The key difference is that for general games we absorb $\pi(q_1, q_2)$ into the rule matrix $V(a_1, a_2, q_1, q_2)$ instead of $E_{A_1Q_1T}$ and $D_{A_2Q_2\hat{T}}$ when we connect $\omega_{Q(T)}(V, \pi)$ to the quantum separability problem in Lemma 1. This leaves some additional factor $|Q_1||Q_2|$ in the objective function, which leads to a worse upper bound on the computational complexity. For a general two-player game with $|T|^2$-dimensional quantum correlation, we can compute additive ϵ-approximations of $\omega_{Q(T)}(V, \pi)$ with a semidefinite program of size

$$\exp\left(\mathcal{O}\left(\frac{|T|^{12} |Q|^4 \left(\log^2 |A||T| + \log |A||T| \log |Q| \right)}{\epsilon^2} \right) \right), \tag{66}$$

where $|A|$ and $|Q|$ are the number of possible answers and questions, respectively. The dependence is still quasi-polynomial in $|A|$, but exponential in $|Q|$ in contrast to the case of free games in Eq. (1). The detailed derivation can be found in Appendix C of the full version [19, Appendix C].

4 Conclusions

In this paper, we study the characterisation of quantum correlations of fixed dimension and, more specifically, provide a converging hierarchy of SDP relaxations with improved analytical convergence speed for the set of fixed-dimensional quantum correlations. This is done by employing a variant of the quantum separability problem and multipartite quantum de Finetti theorems with additional linear constraints. Our result leads to an upper bound on the computational complexity of additive ϵ-approximation for $\omega_{Q(T)}(V,\pi)$ of two-player free games with $T \times T$-dimensional quantum correlation.

We conclude with a few remarks on possible future studies. Firstly, for a given level n, $\mathrm{sdp}_n(V,\pi,T)$ has a relatively large-sized optimisation variable. One possible way to improve this aspect is to exploit the symmetry embedded in the program to reduce the size of the optimisation variable. We could employ some existing symmetry-finding programs such as [31] to achieve this. Secondly, it is still not certain whether the T-dependence in Eq. (1) is optimal. In the classical limit ($T = 1$), our result matches the best-known classical result for free games in terms of A and Q – which also has a matching hardness result [1]. This implies that the dependence on A and Q in Eq. (1) is optimal, but there could be more efficient approximation algorithm in terms of T-dependence. For example, one could explore ϵ-net based methods as in [7, 32].

5 Proof of Lemma 7

In this section, we prove the second part of Lemma 7 which states that for a traceless Hermitian operator γ_{AB} on $\mathcal{H}_{AB}$, there exists a measurement $\mathcal{M}_B$ on $\mathcal{H}_B$ with at most $|B|^6$ outcomes such that $\|(\mathcal{I}_A \otimes \mathcal{M}_B)(\gamma_{AB})\|_1 \geq \frac{1}{2|B|}\|\gamma_{AB}\|_1$. The proof is inspired by [22, Theorem 16].

Proof of the second part of Lemma 7. Let us start with the maximally entangled state

$$\Phi_{A'|B'} = |\Phi\rangle\langle\Phi|_{A'|B'} \text{ where } |\Phi\rangle_{A'|B'} = \frac{1}{|A'||B'|}\sum_i |i\rangle_{A'}|i\rangle_{B'}, \text{ and } |A'| = |B'|. \tag{67}$$

We can create a separable state $\omega_{A'B'}$ by mixing $\Phi_{A'|B'}$ with another separable state $\sigma_{A'B'} = \frac{\mathbb{I}_{A'B'} - \Phi_{A'|B'}}{|B'|^2-1}$ as

$$\omega_{A'B'} = \frac{1}{|B'|}\Phi_{A'B'} + \frac{|B'|-1}{|B'|}\sigma_{A'B'} \in \mathrm{SEP(A':B')}, \tag{68}$$

where SEP(A':B') denotes the set of separable states with respect to the bipartition $A'|B'$. Hence, we can write $\omega_{A'B'} = \sum_i p_i \omega^i_{A'} \otimes \omega^i_{B'}$ for some probability distribution $\{p_i\}_i$ and states $\{\omega^i_{A'}\}_i$ and $\{\omega^i_{B'}\}_i$ with at most $|A'B'|^2$ elements [18]. Next, we define a measurement $\mathcal{M}_B$ with operators $\{\tilde{M}_B(i,k)\}_{i,k}$, as well as a set of measurements $\{\mathcal{M}^{i,k}_A\}_{i,k}$ with operators $\{\tilde{M}^{i,k}_A(j)\}_j$ as

$$\tilde{M}_B(i,k) = \mathrm{tr}_{B'}\left[p_i U^\dagger_B(k)\sqrt{\omega^i_{B'}}\Phi_{BB'}\sqrt{\omega^i_{B'}}U_B(k)\right] \quad \text{and} \tag{69}$$

$$\tilde{M}^{i,k}_A(j) = \mathrm{tr}_{A'}\left[\sqrt{\omega^i_{A'}}U^\dagger_{A'}(k)N_{AA'}(j)U_{A'}(k)\sqrt{\omega^i_{A'}}\right], \tag{70}$$

where $U(k)$ denote generalised Pauli operators, $\omega^i_{A'}$ and $\omega^i_{B'}$ are the elements of the decomposition of $\omega_{A'B'}$, and $\{N_{AA'}(j)\}_j$ are measurement operators defined later. We can check that both definitions indeed correspond to valid measurements:

$$\sum_{i,k} \tilde{M}_B(i,k) = \mathbb{I}_B,\ \sum_j \tilde{M}_A^{i,k}(j) = \mathbb{I}_A, \text{ and } \tilde{M}_B(i,k), \tilde{M}_A^{i,k}(j) \geq 0 \ \ \forall i,k,j. \tag{71}$$

The goal is to show that $\mathcal{M}_B$ defined in Eq. (69) gives rise to Eq. (45). Before showing that, however, it is helpful to understand where these measurements came from. They are related to the quantum teleportation protocol [5]. Without loss of generality, let us assume that $|A| \geq |B| = |A'| = |B'|$. Then, the quantum teleportation protocol from B to A is a quantum channel defined as [5]

$$\tau_{ABA'B'\to AA'}(\cdot) = \sum_{k=1}^{|B|^2} U_{A'}(k) \operatorname{tr}_{BB'} \left[(\cdot) \left(\mathbb{I}_{AA'} \otimes U_B(k) \Phi_{BB'} U_B^\dagger(k) \right) \right] U_{A'}^\dagger(k). \tag{72}$$

For a traceless Hermitian operator γ_{AB}, we then consider

$$\left\| \tau_{ABA'B'\to AA'} \left(\gamma_{AB} \otimes \omega_{A'B'} \right) \right\|_1 = \sum_j \left| \operatorname{tr} \left[N_{AA'}(j) \left(\tau_{ABA'B'\to AA'} \left(\gamma_{AB} \otimes \omega_{A'B'} \right) \right) \right] \right|, \tag{73}$$

where we used the expression $\|X_A\|_1 = \max_{\{M_A(i)\}_i} \sum_i |\operatorname{tr}[M_A(i) X_A]|$ for the trace norm with corresponding arg max $\{N_{AA'}(j)\}_j$ to be used in Eq. (70). Then, we have

$$\begin{aligned}
&\left\| \tau_{ABA'B'\to AA'} \left(\gamma_{AB} \otimes \omega_{A'B'} \right) \right\|_1 \\
&= \sum_j \left| \sum_k \operatorname{tr} \left[N_{AA'}(j) \left(U_{A'}(k) \operatorname{tr}_{BB'} \left[\left(\gamma_{AB} \otimes \omega_{A'B'} \right) \left(\mathbb{I}_{AA'} \otimes U_B(k) \Phi_{BB'} U_B^\dagger(k) \right) \right] U_{A'}^\dagger(k) \right) \right] \right| \\
&= \sum_j \left| \sum_k \operatorname{tr} \left[\left(U_{A'}^\dagger(k) N_{AA'}(j) U_{A'}(k) \otimes \mathbb{I}_{BB'} \right) \left(\left(\gamma_{AB} \otimes \omega_{A'B'} \right) \left(\mathbb{I}_{AA'} \otimes U_B(k) \Phi_{BB'} U_B^\dagger(k) \right) \right) \right] \right| \\
&= \sum_j \left| \sum_k \operatorname{tr} \left[\left(U_{A'}^\dagger(k) N_{AA'}(j) U_{A'}(k) \otimes U_B^\dagger(k) \Phi_{BB'} U_B(k) \right) \left(\gamma_{AB} \otimes \left(\sum_i p_i \omega_{A'}^i \otimes \omega_{B'}^i \right) \right) \right] \right| \\
&= \sum_j \left| \sum_{i,k} \operatorname{tr} \left[\left(\left(\sqrt{\omega_{A'}^i} U_{A'}^\dagger(k) N_{AA'}(j) U_{A'}(k) \sqrt{\omega_{A'}^i} \right) \right. \right. \right. \\
&\qquad \left. \left. \left. \otimes \left(p_i U_B^\dagger(k) \sqrt{\omega_{B'}^i} \Phi_{BB'} \sqrt{\omega_{B'}^i} U_B(k) \right) \right) \left(\gamma_{AB} \otimes \mathbb{I}_{A'B'} \right) \right] \right| \\
&= \sum_j \left| \sum_{i,k} \operatorname{tr} \left[\gamma_{AB} \left(\tilde{M}_A^{i,k}(j) \otimes \tilde{M}_B(i,k) \right) \right] \right|.
\end{aligned} \tag{74}$$

The measurement $\mathcal{M}_B$ defined in Eq. (69) now gives rise to

$$\left\| \left(\mathcal{I}_A \otimes \mathcal{M}_B \right) \left(\gamma_{AB} \right) \right\|_1 \tag{75}$$

$$= \sum_{i,k} \left\| \operatorname{tr}_B \left[\left(\mathbb{I}_A \otimes \tilde{M}_B(i,k) \right) \gamma_{AB} \right] \right\|_1 \tag{76}$$

$$= \sum_{i,k} \max_{\{M_A^{i,k}(j)\}_j} \sum_j \left| \operatorname{tr} \left[\left(M_A^{i,k}(j) \otimes \tilde{M}_B(i,k) \right) \gamma_{AB} \right] \right| \tag{77}$$

$$\geq \sum_{i,k} \sum_j \left| \operatorname{tr} \left[\left(\tilde{M}_A^{i,k}(j) \otimes \tilde{M}_B(i,k) \right) \gamma_{AB} \right] \right| \tag{78}$$

$$\geq \sum_j \left| \sum_{i,k} \operatorname{tr} \left[\left(\tilde{M}_A^{i,k}(j) \otimes \tilde{M}_B(i,k) \right) \gamma_{AB} \right] \right| \tag{79}$$

$$= \left\|\tau_{ABA'B'\to AA'}\left(\gamma_{AB}\otimes\omega_{A'B'}\right)\right\|_1 \qquad \text{(by Eq. (74))} \tag{80}$$

$$= \left\|\tau_{ABA'B'\to AA'}\left(\gamma_{AB}\otimes\left(\frac{1}{|B|}\Phi_{A'B'}+\frac{|B|-1}{|B|}\sigma_{A'B'}\right)\right)\right\|_1 \tag{81}$$

$$= \left\|\frac{1}{|B|}\tau_{ABA'B'\to AA'}\left(\gamma_{AB}\otimes\Phi_{A'B'}\right)+\frac{|B|-1}{|B|}\tau_{ABA'B'\to AA'}\left(\gamma_{AB}\otimes\sigma_{A'B'}\right)\right\|_1 \tag{82}$$

$$\geq \frac{1}{|B|}\left\|\tau_{ABA'B'\to AA'}\left(\gamma_{AB}\otimes\Phi_{A'B'}\right)\right\|_1 - \left\|\tau_{ABA'B'\to AA'}\left(\gamma_{AB}\otimes\left(\frac{|B|-1}{|B|}\sigma_{A'B'}\right)\right)\right\|_1, \tag{83}$$

where in the third line we substituted the measurement operators $\{\tilde{M}_A^{i,k}(j)\}_j$ instead of the maximisation, and in the last line we used the reverse triangular inequality. Note that the first term in the last line is equivalent to $\|\gamma_{AB}\|_1$ since $\Phi_{A'B'}$ is the maximally entangled state. Let us investigate the second term more closely. We have a chain of elementary implications

$$\frac{|B|-1}{|B|}\sigma_{A'B'} \leq \frac{|B|-1}{|B|}\sigma_{A'B'}+\frac{1}{|B|}\Phi_{A'B'} = \omega_{A'B'}$$

$$\gamma_{AB}\otimes\frac{|B|-1}{|B|}\sigma_{A'B'} \leq \gamma_{AB}\otimes\omega_{A'B'}$$

$$\left\|\tau_{ABA'B'\to AA'}\left(\gamma_{AB}\otimes\left(\frac{|B|-1}{|B|}\sigma_{A'B'}\right)\right)\right\|_1 \leq \left\|\tau_{ABA'B'\to AA'}\left(\gamma_{AB}\otimes\omega_{A'B'}\right)\right\|_1$$

$$\left\|\tau_{ABA'B'\to AA'}\left(\gamma_{AB}\otimes\left(\frac{|B|-1}{|B|}\sigma_{A'B'}\right)\right)\right\|_1 \leq \sum_j\left|\sum_{i,k}\operatorname{tr}\left[\gamma_{AB}\left(\tilde{M}_A^{i,k}(j)\otimes\tilde{M}_B(i,k)\right)\right]\right| \qquad \text{(by Eq. (74))}$$

$$\left\|\tau_{ABA'B'\to AA'}\left(\gamma_{AB}\otimes\left(\frac{|B|-1}{|B|}\sigma_{A'B'}\right)\right)\right\|_1 \leq \left\|\left(\mathcal{I}_A\otimes\mathcal{M}_B\right)\left(\gamma_{AB}\right)\right\|_1 \qquad \text{(by Eq. (79))} \tag{84}$$

and substituting this into Eq. (83) yields the claim

$$\left\|\left(\mathcal{I}_A\otimes\mathcal{M}_B\right)\left(\gamma_{AB}\right)\right\|_1 \geq \frac{1}{|B|}\left\|\gamma_{AB}\right\|_1 - \left\|\left(\mathcal{I}_A\otimes\mathcal{M}_B\right)\left(\gamma_{AB}\right)\right\|_1. \tag{85}$$

It remains to quantify the number of measurement outcomes of $\mathcal{M}_B$ with measurement operators $\{\tilde{M}_B(i,k)\}_{i,k}$ defined in Eq. (70). The index i came from the number of elements in the separable state $\omega_{A'B'}$, which is at most $|A'B'|^2 = |B|^4$, and the index k came from the number of generalised Pauli operators, which is $|B|^2$. Therefore, the number of outcomes is at most $|B|^6$. ◀

Fully Dynamic Algorithms for Minimum Weight Cycle and Related Problems

Adam Karczmarz
Institute of Informatics, University of Warsaw, Poland

Abstract

We consider the directed minimum weight cycle problem in the fully dynamic setting. To the best of our knowledge, so far no fully dynamic algorithms have been designed specifically for the minimum weight cycle problem in general digraphs. One can achieve $\widetilde{O}(n^2)$ amortized update time by simply invoking the fully dynamic APSP algorithm of Demetrescu and Italiano [J. ACM '04]. This bound, however, yields no improvement over the trivial recompute-from-scratch algorithm for sparse graphs.

Our first contribution is a very simple deterministic $(1+\epsilon)$-approximate algorithm supporting vertex updates (i.e., changing all edges incident to a specified vertex) in conditionally near-optimal $\widetilde{O}(m \log(W)/\epsilon)$ amortized time for digraphs with real edge weights in $[1, W]$. Using known techniques, the algorithm can be implemented on planar graphs and also gives some new sublinear fully dynamic algorithms maintaining approximate cuts and flows in planar digraphs.

Additionally, we show a Monte Carlo randomized exact fully dynamic minimum weight cycle algorithm with $\widetilde{O}(mn^{2/3})$ worst-case update that works for real edge weights. To this end, we generalize the exact fully dynamic APSP data structure of Abraham et al. [SODA'17] to solve the *multiple-pairs shortest paths* problem, where one is interested in computing distances for some k (instead of all n^2) fixed source-target pairs after each update. We show that in such a scenario, $\widetilde{O}((m+k)n^{2/3})$ worst-case update time is possible.

1 Introduction

The all-pairs shortest paths problem (APSP) is one of the most fundamental graph problems. Given a real-weighted *directed* graph G with n vertices, the goal is to compute the distance matrix between all pairs of vertices u, v in G. APSP can be computed in $\widetilde{O}(nm)$ time [29, 41], which is clearly near-optimal for sparse graphs (since the output consists of n^2 numbers), but is also conjectured to be optimal for the entire range of possible graph sparsities. Some of the other core directed graph problems such as computing the diameter, the radius, or the minimum weight cycle[1] can be trivially reduced to APSP in $O(n^2)$ time by simply inspecting the entries of the distance matrix. In fact, as shown by Vassilevska Williams and Williams [47], for dense graphs APSP is known to be subcubically equivalent to many problems which look easier at first sight, especially because their output is just a single

[1] Also called the *girth*, or the *weighted girth* of a digraph. For simplicity, in this paper we very often use *minimum weight cycle* to refer to the *length* of such a cycle rather than to the actual cycle. Moreover, throughout this paper, our focus is on computing/maintaining that length instead of the actual cycle. The obtained algorithms, however, can be easily extended to return a sought cycle with no additional asymptotic overhead.

number (as opposed to n^2 numbers in APSP). These include e.g., the radius, the minimum weight cycle, and the second shortest simple s, t path problems. For all these problems, just like for APSP, the best known algorithms run in $\widetilde{O}(nm)$ time. Lincoln et al. [36] gave some compelling reasons why improving upon this bound may also be impossible.

In this paper, our focus is on *fully dynamic* graph algorithms. Fully dynamic graph algorithms allow updating the graph under both edge insertions and deletions, as opposed to *partially dynamic* algorithms that allow either only insertions (*incremental* setting) or only deletions (*decremental* setting). Fully dynamic APSP has been widely studied in the past. Demetrescu and Italiano [18] showed that the distance matrix can be *explicitly* maintained in $\widetilde{O}(n^2)$ *amortized* time under *vertex updates* which are allowed to change all edges incident to a single vertex at once. Thorup [45] simplified and slightly improved their algorithm. Clearly, if the algorithm is required to maintain all distances explicitly, one cannot break through the $O(n^2)$ time barrier since even a *single* edge update may change *all* the n^2 pairwise distances. Much of the work in this topic [2, 24, 46] has been devoted to obtaining good *worst-case* bounds on the time needed to recompute the distance matrix and it is known that $\widetilde{O}(n^{2+2/3})$ worst-case update time is possible [2, 24]. Interestingly, none of the known fully dynamic algorithms for *real-weighted* dynamic APSP has $o(n^2)$ update time and a non-trivial query procedure running in $o(m)$ time. Such an algorithm, with $\widetilde{O}(m\sqrt{n})$ amortized update time and $\widetilde{O}(n^{3/4})$ query time, has so far been only described for sparse enough unweighted graphs by Roditty and Zwick [43].

The algorithm of Demetrescu and Italiano [18] immediately implies $\widetilde{O}(n^2)$ amortized update bound for fully dynamic variants of all the most fundamental problems "trivially reducible" to APSP – the aforementioned diameter, radius, or minimum weight cycle. Surprisingly, as shown in [3], such an update bound is likely to be the best possible for maintaining both the diameter and the radius (conditionally on so-called Strong Exponential Time- and Hitting Set hypotheses [1, 26]), even if the graph remains sparse at all times and $(3/2 - \epsilon)$-approximation is allowed.

It is thus natural to ask whether there exist fully dynamic algorithms for the *minimum weight cycle problem* that improve upon the reduction to fully dynamic APSP for sparse graphs, possibly allowing some small multiplicative approximation. The fundamental difference between the minimum weight cycle and diameter/radius problems is that the trivial reduction of minimum weight cycle requires reading only m entries of the distance matrix, as opposed to all n^2 in the case of radius and diameter. As a result, by using the aforementioned fully dynamic algorithm of Roditty and Zwick [43], one immediately gets $\widetilde{O}(mn^{3/4})$ amortized update bound but merely for *unweighted* graphs. Note that this bound is always better than recompute-from-scratch, and is truly subquadratic for sparse graphs. It is however not clear whether such a bound can be obtained for real-weighted graphs, nor whether a much better bound is attainable if we allow approximation.

Motivated by the above, in this paper we initiate the study of the directed minimum weight cycle problem in the fully dynamic setting. To the best of our knowledge, this problem has not been explicitly studied in the literature before. It is worth noting, however, that a non-trivial fully dynamic algorithm has been shown for *undirected planar* graphs [37].

1.1 Our results

A fully dynamic approximate minimum weight cycle algorithm. Our first contribution is a simple deterministic fully dynamic algorithm maintaining a $(1 + \epsilon)$-approximation of the minimum weight $\phi(G)$ of a cycle in a real-weighted directed graph G. If G has a negative

cycle, then we define $\phi(G) = -\infty$, thus allowing the sought cycle to be non-simple. Note that if we wanted the minimum weight cycle to be simple and simultaneously allowed negative edge weights, the problem would become NP-hard via a reduction from Hamiltonian cycle.

▶ **Theorem 1.** *Let G be an initially empty fully dynamic real-weighted digraph such that the weight of each positive weight cycle in G always belongs to the interval $[c, C]$, $c, C \in \mathbb{R}$.*

There exists an algorithm maintaining an estimate ϕ' satisfying $\phi(G) \leq \phi' \leq (1+\epsilon)\phi(G)$ under vertex updates to G with amortized update time $O((m + n \log n) \cdot \log(C/c)/\epsilon)$.

By Theorem 1, a simpler amortized update time bound of $O((m + n \log n) \cdot \log(nW)/\epsilon)$ for the fully dynamic $(1+\epsilon)$-approximate minimum weight cycle problem can be obtained in two special cases:

- if G has real-weights in $\{0\} \cup [1, W]$,
- if G has integer weights in $(-\infty, W]$.

Via known conditional lower bounds on the static approximate minimum weight cycle problem, the update time bound in Theorem 1 – as a function of m *alone* – is near-optimal for both vertex and edge updates if we allow approximation factor less than 2 and $O(m^{2-\delta})$ preprocessing time (for some $\delta > 0$). Indeed, Dalirrooyfard and Vassilevska Williams [17] proved that under so-called k-Cycle hypothesis [3], one cannot approximate the minimum weight cycle within factor less than 2 in $O(m^{2-\delta})$ time, for any $\delta > 0$. Clearly, if there was, say, a dynamic 3/2-approximate minimum weight cycle algorithm with $O(m^{2-\delta})$ preprocessing time, $O(m^{1-\delta})$ update time, and the same interface as our algorithm, m edge/vertex updates would be sufficient to obtain a static 3/2-approximate minimum weight cycle algorithm running in $O(m^{2-\delta})$ time. This would refute the k-Cycle hypothesis.

Observe that the $\Omega(m^{2-o(1)})$ conditional lower bound [17] (which implies that the $\Omega(mn^{1-o(1)})$ bound holds for *some* sparsity m) on the complexity of static approximate minimum weight cycle problem does not rule out dynamic vertex update bounds of the form $\widetilde{O}(n^{\alpha} \cdot m^{1-\alpha})$ for some $\alpha \in (0, 1]$ or $\widetilde{O}(m^{1+\beta}/n^{2\beta})$ for some $\beta \in (0, 1/2]$, e.g., $\widetilde{O}(n)$, $\widetilde{O}(\sqrt{nm})$, or $\widetilde{O}(m^{3/2}/n)$. However, if we limit ourselves to *"combinatorial"* algorithms that do not rely on fast matrix multiplication, such $O(m^{1-\epsilon})$ bounds are ruled out for infinitely many sparsities of the form $m = \Theta(n^{1+2/(k-1)})$, where $k \geq 3$ is an odd integer [17, 36].

We stress that the aforementioned static conditional lower bounds do not rule out $\widetilde{O}(n)$ or even $\widetilde{O}(\sqrt{nm})$ amortized update time in the *edge update* model. In this case, for similar reasons, only combinatorial approximate algorithms with amortized update time that is sublinear in n for many sparsities, e.g., $\widetilde{O}(m^{\beta} \cdot n^{1-2\beta})$ for $\beta \in (0, 1/2]$, are unlikely to exist.

Fully dynamic cycles, flows, and cuts in planar graph. Interestingly, if we limit our attention to the case of single edge updates (as opposed to vertex updates) and real weights in $\{0\} \cup [1, W]$, the amortized update cost of the data structure of Theorem 1 can always be charged to the cost of performing a single edge update plus a single distance query on $O(\log(nW)/\epsilon)$ fully dynamic *exact* distance oracles, each maintaining some subgraph of G. For general digraphs, this amounts to running Dijkstra's algorithm in each of these subgraphs since no non-trivial fully dynamic distance oracles with both update and query time $o(m)$ are known. However, such dynamic distance oracles are well-known to exist for planar digraphs [21, 31, 34] which immediately leads to the following result.

▶ **Theorem 2.** *Let G be a planar digraph G with real weights in $\{0\} \cup [1, W]$. There exists an algorithm maintaining an $(1+\epsilon)$-approximate estimate of $\phi(G)$ under planarity preserving edge insertions and deletions with amortized update time $\widetilde{O}(n^{2/3} \log(W)/\epsilon)$.*

Previously, no sublinear fully dynamic algorithm for minimum weight cycle in planar directed graphs has been described. An *exact* algorithm for planar *undirected* graphs with $\widetilde{O}(n^{5/6})$ update time was given by Łącki and Sankowski [37].

There is a well-known correspondence between simple cuts in an undirected plane graph G, and simple cycles in its dual G^*. The correspondence, in a way, extends to *directed* planar graphs (see e.g. [35, 38]). Nevertheless, currently the best known min s,t-cut algorithms in planar digraphs [9, 19] are less efficient and use entirely different techniques than their counterparts for planar undirected graphs [28]. Generally speaking, for cut/flow applications, undirected planar graphs proved much more friendly to work with (see e.g., the discussion in [19] or [38]). As an example of this phenomenon, an *exact* fully dynamic max s,t-flow *oracle* (accepting s,t as query parameters) with $\widetilde{O}(n^{2/3})$ update and query time exists for undirected plane graphs [28], whereas no such dynamic algorithm has been described for *directed* plane graphs, even allowing approximation and just a single fixed source-sink pair.

It is known that in a plane digraph G, an s,t-flow of value f can be routed iff the dual $G^*_{s,t,f}$ of a certain augmentation of $G_{s,t,f}$ depending on s,t and f contains no negative cycles [19, 30, 39]. Roughly speaking, since the algorithm of Theorem 2 supports negative weights, by running it on $G^*_{s,t,f}$ for $O(\log(nW)/\epsilon)$ distinct values of f, we obtain the following.

▶ **Theorem 3.** *Let G be a plane embedded digraph with real edge capacities in $\{0\} \cup [1, W]$ and a* fixed *source/sink pair s,t. There exists an algorithm maintaining a $(1-\epsilon)$-approximate estimate of the value of maximum s,t-flow in G under* embedding preserving *edge insertions and deletions with $\widetilde{O}(n^{2/3}\log(W)/\epsilon)$ amortized update time.*

To the best of our knowledge, the above constitutes the first known fully dynamic maximum s,t-flow algorithm for plane directed graphs with a sublinear update time bound.

Exact fully dynamic minimum weight cycle and MPSP. Finally, we consider maintaining the minimum weight cycle *exactly* in a fully dynamic *real-weighted* digraph. We show:

▶ **Theorem 4.** *Let G be a real-weighted digraph. There exists a Monte Carlo randomized fully dynamic algorithm maintaining $\phi(G)$ under vertex updates with $O((m+n\log n)n^{2/3}\log^{4/3} n)$ worst-case update time. The answers produced are correct with high probability.*[2]

Note that for sparse graphs, Theorem 4 allows recomputing the minimum weight cycle in $\widetilde{O}(n^{5/3})$ time, i.e., polynomially faster than recompute-from-scratch and the dynamic algorithm of Demetrescu and Italiano [18]. However, observe that [18] yields a better amortized update bound for $m = \omega(n^{4/3})$.

In order to obtain Theorem 4, we generalize the fully dynamic APSP algorithm of Abraham et al. [2] in a non-trivial way to solve what we call the *multiple pairs shortest paths* problem (*MPSP*). In the MPSP problem, which may be of independent interest, one requires to maintain only k fixed entries of the distance matrix, i.e., after each update we are interested in distances between some source-target pairs (s_i, t_i) for $i = 1, \ldots, k$. Recall that the minimum weight cycle of a directed graph can be computed by inspecting distances for m source-target pairs. We obtain the following bound for the fully dynamic MPSP problem.

▶ **Theorem 5.** *Let G be a real-weighted digraph. There exists a Monte Carlo randomized fully dynamic MPSP data structure supporting vertex updates with $O((m+n\log n+k)n^{2/3}\log^{4/3} n)$ worst-case update time. The answers produced are correct with high probability.*

[2] That is, with probability at least $1 - 1/n^c$ for any chosen constant $c \geq 1$.

Note that the aforementioned data structure of Roditty and Zwick [43] trivially implies an MPSP data structure for *unweighted* digraphs with $\widetilde{O}(m\sqrt{n} + kn^{3/4})$ amortized update bound. Our result shows that a better (even worst-case) bound for (even real-weighted) sparse graphs can be achieved if the set of source-target pairs is fixed throughout.

Actually, just as the worst-case update time of the data structure of Abraham et al. [2] can be very easily improved to $\widetilde{O}(n^{2.5})$ for *unweighted* graphs [2, Section 4.2], an unweighted variant of our MPSP data structure has $\widetilde{O}((m+k)\sqrt{n})$ worst-case update time.

Interestingly, it seems that the other known approaches to fully dynamic APSP in real-weighted graphs [18, 23, 45], if adjusted, cannot easily yield subquadratic (in n) update times for "sparse" instances of MPSP where $m, k = O(n)$. This is because they all reconstruct shortest paths in a hierarchical manner, by inductively stitching [23] or extending [18, 45] paths recomputed earlier in the process. Even though the number of input source-target pairs of interest may be small, these may require answers for $\Theta(n^2)$ distinct source-target pairs at lower levels of the hierarchy. The data structure of Abraham et al. [2], on the contrary, does not use a hierarchical approach and can be thought as using a single "stitching layer".

Since the algorithm behind Theorem 4 (Theorem 5) is exact, the maintained information, i.e., the minimum weight of a cycle (the entries of the distance matrix of interest, resp.) is unique. Therefore, if we are interested in maintaining the corresponding weight (distances, resp.) only, the bounds in Theorems 4 and 5 hold against an adaptive adversary. However, if we are required to output some actual minimum weight cycle (edges on some of the desired shortest paths, resp.) we have to assume an oblivious adversary.[3]

1.2 Related work

Computing minimum weight cycles statically. The best known algorithm for computing the minimum weight cycle in sparse graphs exactly runs in $O(nm)$ time [40]. One can improve upon this for graphs with small integer weights using matrix multiplication [16, 27, 42]. A subcubic-time $(1+\epsilon)$-approximation can also be achieved this way [10, 48]. Much of the recent work regarded approximating the minimum weight cycle within factor at least 2 [13, 14, 17].

Dynamic APSP. Apart from the fully dynamic setting, APSP has also been widely studied in partially dynamic settings. There exist efficient exact algorithms for *unweighted* digraphs with $\widetilde{O}(n^3)$ total update time in both incremental [4] and decremental [5, 20] settings. The fully dynamic APSP algorithm [18, 45] is known to have total update time $\widetilde{O}(n^3)$ in the decremental setting for real-weighted digraphs, but only when each update removes *all* edges incident to a vertex (and thus there are at most $\leq n$ updates). For weighted digraphs, a nearly optimal $\widetilde{O}(nm\log(W)/\epsilon)$ total update time partially dynamic algorithm is known in the $(1+\epsilon)$-approximate setting [7]. This algorithm assumes an oblivious adversary though. Less efficient algorithms that are either deterministic or assume an adaptive adversary are known [20, 33, 32]. Note that many of the above algorithms maintain the distance matrix explicitly so they can be obviously used to maintain the minimum weight cycle (possibly approximately) in the respective partially dynamic scenarios.

Dynamic APSP has also been studied in undirected graphs [6, 8, 12, 15, 23, 25, 44].

[3] Abraham et al. [2] show how to extend their data structure so that it is capable of tracking lexicographically smallest shortest paths and thus works against an adaptive adversary, even when returning actual paths is required. Out of the box, this additional feature costs $\Omega(n^2)$ extra time per update, though. Adapting this idea to minimum weight cycle and MPSP is an interesting possible further step.

1.3 Organization of the paper

The rest of this paper is organized as follows. In Section 2 we fix the notation. In Section 3 we show a fully dynamic *threshold cycle detection* data structure that constitutes the heart of the fully dynamic $(1+\epsilon)$-approximate minimum weight cycle algorithm of Theorem 1 proved in Section 4. The applications of Theorem 1 to planar graph algorithms, in particular the proofs of Theorems 2 and 3, are covered in detail in Section 5. In Section 6 we describe the exact fully dynamic minimum weight cycle and fully dynamic MPSP algorithms. Due to space constraints, Section 6 contains merely an overview of the adjustments we make to the fully dynamic APSP algorithm of [2], and the details can be found in the full version.

2 Preliminaries

In this paper we deal with *real-weighted directed* graphs. We write $V(G)$ and $E(G)$ to denote the sets of vertices and edges of G, respectively. We denote by n and m numbers of vertices and edges (resp.) in the input graph. A graph H is a *subgraph* of G, which we denote by $H \subseteq G$, if and only if $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. We write $uv \in E(G)$ when referring to edges of G and use $w_G(uv)$ to denote the weight of uv.

For an edge set F, we sometimes write $G + F$ to denote the graph $(V(G), E(G) \cup F)$. If F contains an edge uv of weight x and $uv \in E(G)$, then we assume that $w_{G+F}(uv) = \min(w_G(uv), x)$. For an edge e we sometimes use $G + e$ to denote $G + \{e\}$. For a subset $D \subseteq V$, we define $G \setminus D$ to be the graph G with all edges incident to vertices in D removed.

A sequence of edges $P = e_1 \dots e_k$, where $k \geq 1$ and $e_i = u_i v_i \in E(G)$, is called an $s \to t$ path in G if $s = u_1$, $v_k = t$ and $v_{i-1} = u_i$ for each $i = 2, \dots, k$. For brevity we sometimes also express P as a sequence of $k+1$ vertices $u_1 u_2 \dots u_k v_k$ or as a subgraph of G with vertices $\{u_1, \dots, u_k, v_k\}$ and edges $\{e_1, \dots, e_k\}$. A path P is *simple* if $u_i \neq u_j$ for $i \neq j$. A *cycle* is a path such that $u_1 = v_k$. A *simple cycle* is a cycle that is a simple path.

The *hop-length* of P is the number of edges in P. We also say that P is a *k-hop path*. The *length* of the path $\ell(P)$ is defined as $\ell(P) = \sum_{i=1}^{k} w_G(e_i)$. For convenience, we sometimes consider a single edge uv as a path of hop-length 1. If P_1 is a $u \to v$ path and P_2 is a $v \to w$ path, we denote by $P_1 \cdot P_2$ (or simply $P_1 P_2$) a path obtained by concatenating P_1 with P_2.

The *distance* $\delta_G(u, v)$ between the vertices $u, v \in V(G)$ is the length of the shortest $u \to v$ path in G, or ∞, if no $u \to v$ path exists in G.

Note that the distance is well-defined only if G contains no negative cycles. It is well known that G has no negative cycles if and only if there exists a *feasible price function* $p : V \to \mathbb{R}$ satisfying $w_G(e) + p(u) - p(v) \geq 0$ for all $uv = e \in E(G)$. It is well-known that, given a feasible price function of G, one can compute single-source shortest paths in G using Dijkstra's algorithm even if G has edges with negative weights.

Define $\phi(G)$ to be the infimum of $\ell(C)$ through all cycles $C \subseteq G$. Note that here C is not necessarily a simple cycle: in general finding minimum weight simple cycles with arbitrary negative weights is NP-hard. In particular, if G contains no cycles at all, then we define $\phi(G) := \infty$. If G contains a negative cycle, then $\phi(G) = -\infty$. On the other hand, if $\phi(G) \geq 0$, then G contains a simple cycle C' with $\ell(C') = \phi(G)$. We call any such cycle C' a *minimum weight cycle*. Observe that if $\phi(G) \geq 0$, then $\phi(G) = \min_{uv \in E(G)} \{\delta_G(v, u) + w_G(uv)\}$.

▶ **Observation 6.** *Let H be a non-negatively weighted digraph and let v be its vertex. The minimum weight of a cycle in H that goes through v can be computed in $O(m + n \log n)$ time.*

Proof. First compute single-source shortest paths from v using Dijkstra's algorithm. Note that the minimum weight cycle through v has length $\min_{uv \in E(H)} \{\delta_H(v, u) + w_H(uv)\}$. ◀

When characterizing dynamic graph algorithms, we use the term *edge update* to refer to a graph update that changes (i.e., inserts, removes, or alters the weight) a single edge of G. On the other hand, a *vertex update* can change all edges incident (incoming or outgoing) to a single chosen vertex $v \in V(G)$. In this case, we say that such a vertex update is *centered* at v.

3 Fully dynamic threshold cycle detection

Consider the following decision variant of the fully dynamic minimum weight cycle problem. Suppose we would like to maintain the information whether the minimum weight $\phi(G)$ of a cycle in a real-weighted digraph G is below some threshold $\mu \geq 0$. In this section we show:

▶ **Theorem 7.** *Let G be an initially empty real-weighted digraph and let $\mu \geq 0$. There exist a fully dynamic algorithm maintaining the information whether $\phi(G) < \mu$ and supporting vertex updates in $O(m + n \log n)$ amortized time.*

The idea is to keep the edge set E partitioned into two subsets E_0 and E_1 such that the following two invariants are satisfied:
(1) For $G_0 = (V, E_0)$ we have $\phi(G_0) \geq \mu$.
(2) If $E_1 \neq \emptyset$, then $\phi(G) < \mu$.
Observe that by the above invariants, $\phi(G) < \mu$ *if and only if* $E_1 \neq \emptyset$.

Let us first consider the case when G has non-negative edges only. Then we can assume $\mu > 0$ since the answer for $\mu = 0$ is trivially "no".

We store E_1 partitioned into subsets $E_1(v)$ for $v \in V$, so that each edge $uv \in E_1$ is stored in either $E_1(u)$ or $E_1(v)$ (this choice is arbitrary). Since the data structure is initialized with an empty graph, initially $E_0 = \emptyset$ and $E_1(v) = \emptyset$ for all $v \in V$.

We also store the vertices v with $E_1(v) \neq \emptyset$ of G in a list Q sorted by the time when the last insertion around v happened, i.e., at the end of Q we have a vertex that has been most recently subject to insertion of edges around v.

Let us now describe an auxiliary procedure `update`(v) that will be used to fix the invariants. `update`(v) does the following. We assume that $E_1(v) \neq \emptyset$. We compute the minimum weight x of a cycle going through v in $G_0 + E_1(v) = (V, E_0 \cup E_1(v))$ as described in Observation 6. If $x \geq \mu$, the edges $E_1(v)$ are moved to E_0, and the set $E_1(v)$ is emptied. This change is reflected in Q by removing v from Q.

To handle and insertion of a set F_v of edges centered at some vertex v, we simply add the edges F_v to $E_1(v)$, move v to the end of Q, and, if $Q = \{v\}$, run `update`(v).

To handle a deletion of an arbitrary set of edges $F \subseteq E$, we first remove each edge $f \in F$ from E_0 or some set $E_1(w)$, wherever f resides. If some $E_1(w)$ is emptied this way, w is removed from Q accordingly. Next, while $Q \neq \emptyset$, we repeatedly run `update`(v) for the first element $v \in Q$ and stop if `update`(v) fails to empty the respective set $E_1(v)$.

We now prove the correctness of the algorithm, whose pseudocode is given in Algorithm 1.

▶ **Observation 8.** *Suppose $\phi(G_0) \geq \mu$ and let $v \in V$. Then $\phi(G_0 + E_1(v)) < \mu$ if and only if the shortest cycle going through v in $G_0 + E_1(v)$ has weight less than μ.*

Proof. By $\phi(G_0) \geq \mu$, a cycle of weight less than μ in $G_0 + E_1(v)$ has to go through an edge of $E_1(v)$. All of these edges are incident to the vertex v. ◀

Clearly, E_0 and E_1 form a partition of E after each insertion or deletion: the procedure `update` only moves edges from E_1 to E_0.

Algorithm 1 Detecting a cycle of weight less than μ.

procedure `update`(v)

```
1: x := the minimum weight of a cycle going through v in G_0 + E_1(v)
2: if x ≥ μ then
3:     E_0 := E_0 ∪ E_1(v)
4:     E_1(v) := ∅
5:     Q := Q \ {v}
```

procedure `insert`$(F_v \neq \emptyset)$

```
1: E_1(v) := E_1(v) ∪ F_v
2: move-to-back(Q, v)
3: if Q = {v} then
4:     update(v)
```

procedure `delete`$(F \subseteq E(G))$

```
1: E_0 := E_0 \ F
2: for uv = e ∈ F do
3:     for w ∈ {u, v} do
4:         E_1(w) := E_1(w) \ {e}
5:         if E_1(w) = ∅ then
6:             Q := Q \ {w}
7: while Q ≠ ∅ do
8:     v := front(Q)
9:     update(v)
10:    if E_1(v) ≠ ∅ then
11:        break
```

function `cycle-below-threshold`$()$

```
1: return Q ≠ ∅
```

▶ **Lemma 9.** *Invariant (1) is maintained throughout the updates.*

Proof. Note that no edge is added to E_0 outside the `update` procedure. As a result, since invariant (1) cannot be broken by removing edges from G_0, to establish that invariant (1) is maintained, it is enough to see that `update` only adds edges to E_0 if $\phi(G_0) \geq \mu$ afterwards. ◀

▶ **Lemma 10.** *Invariant (2) is maintained throughout the updates.*

Proof. Let G', G'_0, E'_1 denote G, G_0, E_1 respectively *before* the graph update. Suppose that after processing the update, invariant (2) is broken. Equivalently, $E_1 \neq \emptyset$ and $\phi(G) \geq \mu$.

Suppose the update was insertion of edges F_v centered at v. Since adding edges can only decrease the minimum weight of a cycle, $\phi(G') \geq \mu$. As invariant (2) was satisfied before, $E'_1 = \emptyset$. So after F_v is moved to $E_1(v)$, we indeed have $Q = \{v\}$. Since $\phi(G_0 + E_1(v)) \geq \phi(G) \geq \mu$, $E_1(v)$ should have been moved to E_0 by `update`(v). But $E_1 = E_1 \setminus E'_1 \subseteq E_1(v) = \emptyset$, so $E_1 = \emptyset$, a contradiction.

Now assume that the update deleted an arbitrary subset of edges. If after some `update`(v) call we have $E_1(v) \neq \emptyset$, then $\phi(G_0 + E_1(v)) < \mu$, which implies $\phi(G) < \mu$, a contradiction. If no such v exists, then Q is emptied, i.e., $E_1(v) = \emptyset$ for all $v \in V$ after the deletion is processed. It follows that $E_1 = \emptyset$, which again leads to a contradiction. ◀

Now let us analyze the running time of our algorithm.

▶ **Lemma 11.** *Each insertion is processed in $O(m + n \log n)$ worst-case time.*

Proof. An insertion adds $O(n)$ edges to a single set $E_1(v)$ and causes at most a single `update` call. The running time of `update` is dominated by the time needed to find the minimum weight of a cycle going through some vertex v in some subgraph of the current graph G. By Observation 6, this time is no more than $O(m + n \log n)$. ◀

▶ **Lemma 12.** *The total time needed to process arbitrary k updates is $O\left(\sum_{i=1}^{k}(m_i + n \log n)\right)$, where m_i is the number of edges in G when the i-th update happened. In other words, the amortized update time is $O(m + n \log n)$.*

Proof. By Lemma 11, we only need to prove that the deletions take $O\left(\sum_{i=1}^{k}(m_i + n \log n)\right)$ time in total. The cost of removing the edges from the sets E_0 and $E_1(w)$, $w \in V$, can be charged to the insertions which added those edges to the graph.

After updating the edge set, a deletion is handled using a number of `update`(v) runs, in the order in which vertices v appear in Q. At most one of these runs leaves $E_1(v)$ non-empty afterwards. We charge the cost of this run to the considered deletion. For all other `update`(v) runs during that deletion, they empty the set $E_1(v)$ that previously was non-empty. As a result, we can charge the cost of that run to the last insertion of edges centered at v that happened before the considered deletion.

We need to prove two things. First of all, to see that no insertion is charged twice, note that after an insertion is charged for the first time, $E_1(v)$ is emptied. So, before `update`(v) is called next time when handling a deletion, new edges have to be added to $E_1(v)$, which can only happen during another later insertion centered at v.

We also have to prove that just before $E_1(v)$ is emptied in `update`(v), the number of edges in $G_0 + E_1(v)$ is $O(|E'|)$, where E' is the edge set of G immediately after the last insertion I centered at v happened. To this end, we prove $E(G_0) \cup E_1(v) \subseteq E'$.

We clearly had $E_1(v) \subseteq E'$ immediately after I. Afterwards no more elements were added to $E_1(v)$ (albeit some might have been removed), so we still have $E_1(v) \subseteq E'$.

Now suppose there is an edge $e \in E(G_0)$ with $e \notin E'$. Then, since $G_0 \subseteq G$, e was inserted into G after the insertion I, as a result of a later insertion I' centered at some $w \neq v$. The edge e could have been added to G_0 only if $E_1(w)$ was emptied inside `update`(w) immediately afterwards, but before `update`(v) was called. Since I was the last insertion centered at v before `update`(v) was called, both v and w were in Q when `update`(w) was called. This is a contradiction: `update` is always called on the earliest element of Q, whereas the fact that I happened before I' implies that v lied earlier than w in Q when `update`(w) was called. ◀

▶ Remark 13. When handling a deletion, we could in principle call `update`(v) for vertices v with $E_1(v) \neq \emptyset$ in arbitrary order, as opposed to in the order of least recent centered insertions. However, then one could only show a weaker total update time bound of $O(k(m_{\max} + n \log n))$, where $m_{\max}$ is the maximum number of edges in G during the first k updates.

3.1 Negative weights

In this section we extend the obtained basic algorithm to also work with negative edges. Recall that we still assume $\mu \geq 0$. Note that the case $\mu = 0$ is equivalent to dynamically maintaining whether G has a negative cycle. Recall that if G has a negative cycle, $\phi(G) = -\infty$.

Unfortunately, in presence of negative weights or cycles we cannot simply use the algorithm behind Observation 6 to find the minimum weight cycle through a vertex v in $G_0 + E_1(v)$ as we did in `update`(v). Instead, we use the following lemma.

▶ **Lemma 14.** *Let H be a digraph with no negative cycles. Let $p : V \to \mathbb{R}$ be a feasible price function of H. Let F be a set of edges centered at some vertex v.*

Then in $O(m + n \log n)$ time one can find the minimum weight of a cycle going through v in $H + F$. Moreover, if $H + F$ contains no negative cycles, within the same time bound one can produce a feasible price function on $H + F$.

Proof. Clearly, since H has no negative cycles, a negative cycle in $H+F$ has to go through v. Let E_v^+ be the set of edges in $H + F$ incoming to v. Note that $H' = H + F - E_v^+$ has no negative cycles. Moreover, since H' differs from H by edges incident to v, the edge costs reduced by p are non-negative for all edges of H' possibly except the outgoing edges of v. However, since v has no incoming edges in H', a price function p' obtained from p by sufficiently increasing $p(v)$ (e.g., to $\max\{p(u) - w(vu) : vu \in E(H')\}$) is a feasible price function of H'. With price function p' in hand, we can compute distances from v in H' using Dijkstra's algorithm in $O(m + n \log n)$ time.

Now let $x = \min_{uv \in E_v^+}\{\delta_{H'}(v, u) + w_{H'}(uv)\}$. Observe that x is indeed the minimum weight of a simple cycle in $H + F$. Moreover, $x \geq 0$ implies that $p^*(y) := \delta_{H'}(v, y) = \delta_{H+F}(v, y)$ is a feasible price function on the induced subgraph of $(H + F)[R]$ reachable from v. To extend that price function p^* on $R \subseteq V$ to entire V, it is enough to set $p^*(z) = p(z) + M$ for all $z \in V \setminus R$, where M is a sufficiently large number. To see that, note that p^* is clearly a feasible price function on $(H + F)[R]$, $(H + F)[V \setminus R]$, and there are no edges from R to $V \setminus R$ in $H + F$. For edges $zy \in E(H + F) \cap ((V \setminus R) \times R)$ we have $w_{H+F}(zy) + p^*(z) - p^*(y) = w_{H+F}(zy) + p(z) + M - p^*(y)$. For

$$M = \max\{p^*(y) - p(z) - w_{H+F}(zy) : zy \in E(H + F) \cap ((V \setminus R) \times R)\},$$

all the required reduced costs are non-negative. ◀

Now, given Lemma 14, we modify the basic algorithm as follows. In addition to the partition of E into E_0 and E_1, we always maintain a feasible price function p_0 on G_0. Then, in `update`(v), we use Lemma 14 to find the minimum weight x of a cycle in $G_0 + E_1(v)$. If the edges $E_1(v)$ are moved to E_0 (and thus $x \geq 0$ since $\phi(G_0 + E_1(v)) \geq \mu \geq 0$), we update the price function p_0 to that produced by Lemma 14. Since the worst-case cost of running the algorithm from Lemma 14 matches that of Observation 6, the time analysis remains unchanged. Lemmas 9, 10, 12 and 14 together imply Theorem 7.

▶ Remark 15. For the problem of fully dynamically maintaining the information whether G contains a *negative* cycle (i.e., the special case $\mu = 0$) there exists a better algorithm with $O(m + n \log n)$ *worst-case* (as opposed to only amortized) update time bound (see Theorem 23). In fact, we make use of that algorithm when obtaining exact algorithms with good worst-case bounds in Section 6. The main idea is to generalize the problem to maintaining a minimum cost circulation in the graph G with imposed unit vertex/edge capacities (the details can be found in the full version). This resembles Gabow's reduction of single-source shortest paths with negative weights to the minimum cost perfect matching problem [22]. However, the min-cost circulation based algorithm is not as robust when it comes to obtaining fully dynamic algorithms for planar graphs (described in Section 5).

4 A fully dynamic $(1 + \epsilon)$-approximate algorithm

In this section we show how Lemma 12 can be used to obtain an $(1+\epsilon)$-approximate minimum weight cycle algorithm, for any $\epsilon \in (0, 1]$. Suppose $c \in \mathbb{R}$ ($C \in \mathbb{R}$) is a lower bound (an upper bound, respectively) on the weight of a *positive* cycle in G.

Suppose first that G has positively weighted edges. In order to convert the decision version from Section 3, all we have to do is to run it simultaneously with $\mu = (1+\epsilon)^k$ for all integers $k = \lceil \log_{1+\epsilon}(c) \rceil, \ldots, \lceil \log_{1+\epsilon}(C) \rceil$. . To maintain an approximate minimum weight of a cycle G, one only needs to keep track of the minimum k such that the fully dynamic decision algorithm for $(1+\epsilon)^k$ returns yes. If no such k exists, G is acyclic since $\phi(G) < \infty$ implies $\phi(G) \leq C$. Otherwise, we have $(1+\epsilon)^{k-1} \leq \phi(G) < (1+\epsilon)^k$, so indeed $(1+\epsilon)^k$ approximates $\phi(G)$ with multiplicative error no more than $(1+\epsilon)$. Since each of the $O(\log_{1+\epsilon}(C) - \log_{1+\epsilon}(c)) = O(\log(C/c)/\epsilon)$ decision algorithms has $O(m + n\log n)$ amortized update time, the amortized time of the approximate algorithm is $O((m+n\log n)\log(C/c)/\epsilon)$.

The same bound can be achieved even if G has non-positive edges (without, however, changing the definition of c and C) by extending each threshold data structure as described in Section 3.1. Apart from the data structures for thresholds $\mu = (1+\epsilon)^k$, we also need two more threshold cycle detection data structures: one for $\mu = 0$ to detect a negative cycle, and one for $\mu = c$ to detect whether $\phi(G) = 0$. We have thus proved Theorem 1.

▶ **Theorem 1.** *Let G be an initially empty fully dynamic real-weighted digraph such that the weight of each positive weight cycle in G always belongs to the interval $[c, C]$, $c, C \in \mathbb{R}$.*

There exists an algorithm maintaining an estimate ϕ' satisfying $\phi(G) \leq \phi' \leq (1+\epsilon)\phi(G)$ under vertex updates to G with amortized update time $O((m + n\log n) \cdot \log(C/c)/\epsilon)$.

5 Dynamic algorithms for cycles, cuts and flows in planar graphs

In this section we argue that the fully dynamic threshold cycle detection algorithm can be implemented on planar directed graphs using the known dynamic distance oracles on planar graphs. Since the reduction in Section 4 uses the threshold data structure in a black-box way, this will imply an $(1+\epsilon)$-approximate minimum weight cycle algorithm.

Using known reductions based on plane duality, this will yield fully dynamic $(1+\epsilon)$-approximate algorithms for maintaining (1) the capacity of a global min-cut in a plane digraph, (2) the value of maximum s,t-flow in a plane digraph.

The algorithms in this section handle *edge updates*, as opposed to more general vertex updates as was the case in the previous sections. Observe that achieving sublinear update time for vertex updates is not possible in general since a vertex update may need up to $\Theta(n)$ space to be described. More concretely, we will allow a single update to either insert or remove a single edge uv, provided that this update preserves planarity of G. In the cut/flow applications we will additionally need to assume that the edge insertions are *embedding preserving*, i.e., u and v lie on a single face of the current embedding of G.

Kaplan et al. [31], based on earlier work [21, 34], showed a dynamic distance oracle for real-weighted plane graphs undergoing edge weight updates. As argued in [11], their bound also holds if arbitrary, not necessarily embedding-preserving, edge updates are allowed.

▶ **Theorem 16** ([11, 21, 31, 34])**.** *Let G be a real-weighted planar digraph. There exists a fully dynamic algorithm supporting edge insertions and deletions in $\widetilde{O}(n^{2/3})$ worst-case time, such that for any query vertices s, t, the shortest $s \to t$ path in G can be computed in $\widetilde{O}(n^{2/3})$ time. If an edge insertion creates a negative cycle in G, the update algorithm reports it and refuses to perform that insertion. Edge insertions are not required to be embedding preserving.*

Fully dynamic threshold- and minimum weight cycles. Consider using the fully dynamic threshold cycle detection algorithm of Section 3 in the edge update scenario. Suppose that that algorithm attempts to moves edges from E_1 to E_0 single edge at a time. This does not

influence correctness; the efficiency of processing a *node update* could deteriorate though (which we do not mind). Then, the *amortized* update time to process the update involving an edge uv can be actually bounded by the sum of times needed to:

1. update the set $E_1(u)$ to reflect the graph update,
2. if uv is deleted, remove uv from G_0,
3. for some $xy \in E$, find the minimum weight of a cycle going through xy in $G_0 + xy$,
4. if $\phi(G_0 + xy) \geq \mu$, insert the edge xy into G_0.

Clearly, item 1 takes constant time. If we store the (planar) graph G_0 in the data structure of Theorem 16, items 2-4 above all require $\widetilde{O}(n^{2/3})$ time. Indeed, items 2 and 4 translated to a single edge update to that data structure, whereas item 3 amounts to computing $\delta_{G_0}(y, x) + w_G(xy)$ using a single query. We thus obtain the following analogue of Theorem 7.

▶ **Theorem 17.** *Let G be a real-weighted planar digraph and let $\mu \geq 0$. There exist a fully dynamic algorithm maintaining whether $\phi(G) < \mu$ and supporting planarity-preserving edge insertions and deletions in $\widetilde{O}(n^{2/3})$ amortized time.*

Since Theorem 1 uses the threshold data structure in a black-box way, we obtain:

▶ **Theorem 18.** *Let G be a fully dynamic real-weighted planar digraph G such that the weight of any positive cycle in G always lies in the interval $[c, C]$.*

There exists an algorithm maintaining the minimum weight cycle in G under planarity preserving edge insertions and deletions with amortized update time $\widetilde{O}(n^{2/3} \log(C/c)/\epsilon)$.

Note that Theorem 18 immediately implies Theorem 2.

Fully dynamic directed cuts and flows. Let G be a *plane embedded* digraph with real edge capacities in $\{0\} \cup [1, W]$. Wlog. we assume that every edge e in G has its reverse e^R of capacity 0 embedded into the same curve. We can then think of any edge as traversable in both directions, but the cost of such a traversal is 0 if the edge is traversed in the reverse direction. This assumption clearly does not influence values of max-flows or min-cuts in G, but makes the dual graph G^* possess certain useful properties. We call a cycle in G^* *non-trivial* if it is not of the form ee^R for some edge $e \in E(G^*)$ and its reverse e^R.

We now state well-known properties relating flows/cuts in G to cycles in the dual G^*.

▶ **Lemma 19** (see e.g. [35])**.** *The global minimum cut in a plane graph G corresponds to the minimum weight non-trivial cycle in G^*.*

▶ **Lemma 20** ([19, 30, 39])**.** *Let G be a plane digraph with some fixed source s and sink t. For $f \geq 0$, let $G_{P,f}$ be a plane graph obtained from G adding an embedded $s \to t$ path P such that for each edge e of P, the capacity of e is f, whereas the capacity of e^R is $-f$.*

There exists an s,t-flow of value f in G if and only if the dual $G^*_{P,f}$ of $G_{P,f}$ does not contain negative cycles.

By Lemma 19, maintaining the (approximate) global min-cut dynamically under edge *embedding preserving* insertions/deletions can be reduced to maintaining the (approximate) minimum weight non-trivial cycle in the dual under vertex splits and edge contractions.

Let us now explain how such operations can be simulated using $O(1)$ updates to the data structure of Theorem 18 maintained on a certain augmented version G^*_1 of G^*, so that the minimum weights of a non-trivial cycle in G^* and G^*_1 are equal. A similar reduction has been previously described in [28, 35]. Each vertex v of the dual G^* corresponds in G^*_1 to a path P_v of $\deg_{G^*}(v)$ vertices connected using 0-weight edges traversable in both directions. For an edge $vu \in E(G^*)$ that is the i-th in (some) clockwise edge ring of v, and j-th in (some)

clockwise edge ring of u, the i-th vertex of P_v is connected by an edge of weight $w_{G^*}(vu)$ with the j-th vertex of P_u. This way, (1) each vertex of G_1^* has constant degree, (2) each non-trivial cycle in G^* has a corresponding non-trivial cycle of the same weight in G_1^*, (3) no additional (with respect to G^*) non-trivial cycles are introduced in G_1^*.

It is not hard to verify that each edge contraction or vertex split in G^* can be reflected using $O(1)$ edge insertions or deletions issued to G_1^*.

Observe that the additional constraint that the minimum weight cycle is non-trivial does not introduce any difficulties: in the data structure of Theorem 17 we compute the minimum weight cycle through some edge e by issuing a distance query to a graph that *does not contain* that edge. However, since a minimum weight non-trivial cycle through e in $G_0 + e$ can traverse e in any of the two directions, we need to issue two distance queries instead of one.

We thus obtain the following theorem.

▶ **Theorem 21.** *Let G be a plane digraph with real capacities in $\{0\} \cup [1, W]$. There is an algorithm maintaining a $(1+\epsilon)$-approximate estimate of the capacity of the global min-cut of G under* embedding preserving *edge updates with $\widetilde{O}(n^{2/3} \log W/\epsilon)$ amortized update time.*

To obtain a dynamic max s,t-flow algorithm, we use Lemma 20. We keep track of whether there exists a negative cycle (i.e., we set $\mu = 0$) in the dual of a graph a $G_{P,f}$, where $f = (1+\epsilon)^k$, for each $k = 0, \ldots, \lceil \log_{1+\epsilon}(nW) \rceil$. Similarly as was the case for global min-cut, one can simulate the effect that an embedding preserving edge update in G has on the negative cycles of the dual of $G_{P,f}$ using $O(1)$ updates to the data structure of Theorem 17 maintained on an analogous augmentation $(G_{P,f})_1^*$ of $G_{P,f}^*$.

There is one subtle detail about how $G_{P,f}$ is updated when G is subject to embedding preserving edge insertions and deletions. Note that Lemma 20 requires us to embed any additional simple $s \to t$ path P into G. Embedding P into G subdivides some of the original faces of G. As a result, an edge uv to be inserted inside some face F of G may cross some edges of the currently used path P in $G_{P,f}$. We deal with this problem as follows. We maintain an additional invariant that (the embedding of) the simple path P crosses each face of G at most once.

Now, when a new edge uv is inserted inside F, and P has an edge $e = xy$ inside F that would cross uv, we first remove e from $G_{P,f}$ to allow the insertion of uv. This insertion splits F into two faces F_1, F_2 such that x lies on F_1 and y lies on F_2. We now reconnect the path P by embedding two edges xu, uy with appropriate capacities as required by Lemma 20.

On the other hand, when an edge uv is removed, two faces F_1 of F_2 of G are merged into a single face F. If at most one of them F_1, F_2 contained an edge of P, we do not have to do anything. Otherwise, suppose wlog. that F_1 contains an edge $xy = e_1 \in P$, and F_2 contains an edge $ab = e_2 \in P$, such that e_1 appears before e_2 on P. Then, we remove e_1, e_2, and all edges between e_1 and e_2 on P from $G_{P,f}$, and replace them with a single edge xb embedded in F. Afterwards, the invariant is satisfied and P remains a simple path.

Finally, observe that each update to G adds $O(1)$ new edges to P in the *worst case*. An edge deletion may remove a superconstant number of edges from P, but these removals can be charged to the corresponding additions of new edges to P. To conclude, an edge update to G translates to $O(1)$ amortized edge updates to $G_{P,f}$, and as a result, to $O(1)$ amortized operations on the data structure of Theorem 17 run on the augmented dual $(G_{P,f})_1^*$. We have thus proved:

▶ **Theorem 3.** *Let G be a plane embedded digraph with real edge capacities in $\{0\} \cup [1, W]$ and a* fixed *source/sink pair s, t. There exists an algorithm maintaining a $(1-\epsilon)$-approximate estimate of the value of maximum s,t-flow in G under* embedding preserving *edge insertions and deletions with $\widetilde{O}(n^{2/3} \log(W)/\epsilon)$ amortized update time.*

6 Exact fully dynamic algorithm for minimum weight cycle

In this section we argue that using a variant of the fully dynamic APSP algorithm of Abraham et al. [2] one can achieve subquadratic update bounds for dynamic minimum weight cycle.

We will in fact first solve a slightly more general problem that we call the *fully dynamic multiple-pairs shortest paths* (fully dynamic MPSP for short). Our goal is to have a data structure that maintains distances $\delta_G(s_i, t_i)$ for some *fixed* (throughout the course of the algorithm) k source-target pairs $(s_1, t_1), \ldots, (s_k, t_k)$ subject to fully dynamic vertex updates. Obviously, the classical fully dynamic APSP corresponds to the case $k = n^2$.

In the following we sketch the approach of [2] to fully dynamic APSP. The presentation is however directed towards our goal of obtaining an MPSP data structure. Some details and proofs can be found only in [2]; we focus on the details of our adjustments.

Reduction to batch-deletion MPSP data structure. The first step is to reduce the fully dynamic problem to a certain decremental problem, called the *batch-deletion MPSP*. In this problem, we want to preprocess the input digraph G, so that one can efficiently compute MPSP in $G \setminus D$ for a subset $D \subseteq V$ that constitutes the query parameter. We assume that if $G \setminus D$ has a negative cycle, the data structure has to report its existence instead.

▶ **Lemma 22.** *Suppose we have a batch-deletion MPSP data structure with preprocessing time $T_{\mathrm{pre}}(n, m, k)$ and worst-case query time $T_{\mathrm{q}}(n, m, k, d)$, where $d = |D|$ is the size of the removed vertex set. Then, for any integer $\Delta > 0$, there exists a fully dynamic MPSP algorithm with worst-case update time $O(T_{\mathrm{pre}}(n, m, k)/\Delta + T_{\mathrm{q}}(n, m, k, \Delta) + \Delta(m + k + n \log n))$.*

Proof sketch. To obtain an amortized (as opposed to worst-case) bound from the statement, we split the timeline into phases of Δ updates. When a new phase starts, we rebuild the batch-deletion data structure from scratch on the graph G_0 at the start of the phase; this clearly incurs $O(T_{\mathrm{pre}}(n, m_0, k)/\Delta)$ amortized time cost per update, where $m_0 = |E(G_0)|$. At some point of a phase, let $D \subseteq V$, $|D| \leq \Delta$, be the vertices touched by updates in this phase. To compute MPSP at that point, we first compute MPSP in $G_0 \setminus D = G \setminus D$ in $O(T_{\mathrm{q}}(n, m_0, k, |D|)) = O(T_{\mathrm{q}}(n, m_0, k, \Delta))$ time. To obtain MPSP in G, we need to check if paths going through D in G improve upon those in $G \setminus D$, i.e., we compute MPSP in G according to the equation $\delta_G(s_i, t_i) = \min\left(\delta_{G_0 \setminus D}(s_i, t_i), \min_{v \in D}\{\delta_G(s_i, v) + \delta_G(v, t_i)\}\right)$.

Observe that all distances of the form $\delta_G(\cdot, v)$ or $\delta_G(v, \cdot)$ for $v \in D$ can be obtained by running Dijkstra's algorithm to/from each such v, in $O(\Delta(m + n \log n))$ total time, as long as a feasible price function of G is given. A feasible price function can be maintained in $O(m + n \log n)$ worst-case time after a vertex update using the following theorem, whose proof is deferred to the full version.

▶ **Theorem 23.** *Let G be an initially empty real-weighted digraph. There exists an algorithm maintaining the information whether G has a negative cycle and supporting vertex updates in $O(m + n \log n)$* worst-case *time. Additionally, whenever $\phi(G) \geq 0$, the algorithm maintains a feasible price function p of G.*

Theorem 23 is also used to keep track of whether the current G has a negative cycle. Once these distances are available, the distances $\delta_G(s_i, t_i)$ can be computed in $O(\Delta \cdot k)$ time.

Unfortunately, the above argument is fully valid only if either the number of edges m is of the same order throughout, i.e., $m_0 = O(m)$, or it cannot drop by more than a constant factor during a single phase, e.g., $m = \Omega(n\Delta)$. If, say, $T_{\mathrm{pre}}(n, m, k) = \Theta(nm)$, $\Delta = n^{1/3}$ and $m = n^{5/4} = m_0$ at the beginning of the phase, and during $n^{1/4}$ first updates in that phase m

gets decreased to $O(n)$, then the total update cost coming from the preprocessing in this phase is $\Theta(nm_0) = \Theta(n^{9/4})$. If the amortized update time coming from the preprocessing was indeed $O(T_{\text{pre}}(n, m, k)/\Delta)$, the the total update cost coming from these terms in that phase would be $O(n^{1/4} \cdot nm_0/\Delta + \Delta \cdot n^2/\Delta) = O(n^{13/6})$, i.e., polynomially less.

We circumvent this problem[4] as follows. We build the batch-deletion MPSP data structure on the graph $G'_0 = G_0 \setminus D^*$ instead of G_0, where D^* is the set of Δ vertices of G_0 with highest degree. Then, Dijkstra's algorithm is used to separately compute shortest paths through $D \cup D^*$ in G, as opposed to only through D. Clearly, the cost of such computation remains $O(\Delta(m + k + n \log n))$. However, the update cost coming from the batch-deletion MPSP data structure is decreased to $O(T_{\text{pre}}(n, m'_0, k)/\Delta + T_{\text{q}}(n, m'_0, k, \Delta))$, where m'_0 is the number of edges in G'_0. It is hence enough to observe that $m'_0 \leq m$ throughout this phase. Indeed, the updates centered at vertices D cannot remove more than $\sum_{v \in D} \deg_{G_0}(v)$ edges out of those originally contained in G_0. As a result, $m \geq m_0 - \sum_{v \in D} \deg_{G_0}(v)$. On the other hand, by removing D^* from G_0 we remove at least $\frac{1}{2} \sum_{v \in D^*} \deg_{G_0}(v)$ edges from G_0, i.e, $m'_0 \leq m_0 - \frac{1}{2} \sum_{v \in D^*} \deg_{G_0}(v)$. We obtain $m'_0 \leq m$ as follows:

$$m'_0 \leq m_0 - \frac{1}{2} \sum_{v \in D^*} \deg_{G_0}(v) \leq m_0 - \frac{1}{2} \sum_{v \in D} \deg_{G_0}(v) \leq m_0 + \frac{1}{2}(m - m_0) = \frac{1}{2} m'_0 + \frac{1}{2} m.$$

Since the amortization comes only from a (costly) rebuilding step after every Δ updates, turning the amortized bound into a worst-case one is standard, see e.g., [2, Section 2]. ◀

The batch-deletion data structure. Abraham et al [2] showed a batch-deletion APSP data structure with $\widetilde{O}(n^3)$ preprocessing time and $\widetilde{O}(n^2\sqrt{nd})$ query time which, by Lemma 22, implies $\widetilde{O}(n^{2+2/3})$ worst-case update time for fully dynamic APSP. Their batch-deletion data structure is Monte Carlo randomized and produces answers correct with high probability. We generalize this data structure to MPSP and non-dense graphs.

▶ **Theorem 24.** *There exists a Monte Carlo randomized batch-deletion MPSP data structure with $O((m + k)n \log^2 n)$ preprocessing and $O((m + n \log n + k)\sqrt{nd} \log n)$ query time. The answers produced are correct with high probability.*

Before we prove Theorem 24, let us show how it can be used to obtain fully dynamic MPSP and minimum weight cycle algorithms.

By choosing $\Delta = n^{1/3} \log^{2/3} n$, and applying Lemma 22, we obtain:

▶ **Theorem 5.** *Let G be a real-weighted digraph. There exists a Monte Carlo randomized fully dynamic MPSP data structure supporting vertex updates with $O((m+n \log n+k)n^{2/3} \log^{4/3} n)$ worst-case update time. The answers produced are correct with high probability.*

Now consider the fully dynamic minimum weight cycle problem. The minimum weight of a cycle in G is given by $\phi(G) = \min_{uv \in E(G)}\{\delta_G(v, u) + w_G(uv)\}$. As a result, after each update it is enough to recompute distances $\delta_G(s_l, t_l)$ in G for $k = m$ pairs (s_l, t_l) such that $t_l s_l \in E(G)$. If the edge set of G was fixed (and, for example, the updates were only allowed to change edge weights), so would be the set of source-target pairs of our interest. Hence, we could simply use the fully dynamic MPSP data structure of Theorem 5 in a black-box way. However, in general, $E(G)$ is not fixed and we need to be more careful.

[4] This problem does not arise in [2], since there m is assumed to be $\Theta(n^2)$ throughout.

We proceed as follows. In the reduction of Lemma 22, we will always build a batch-deletion MPSP data structure with the set of source-target pairs equal to the edge set used to build that data structure reversed. This means that at any point of the phase, we can compute the minimum weight cycle in $G \setminus (D^* \cup D) = G_0 \setminus (D^* \cup D)$ in $O(T_{\mathrm{pre}}(n,m,m)/\Delta + T_{\mathrm{q}}(n,m,m,\Delta)) = O((m+n\log n)n^{2/3}\log^{4/3} n)$ worst-case time. Since $G_0 \setminus (D^* \cup D)$ contains only a subset of edges of G_0, reading the subset of entries of the distance matrix of $G_0 \setminus (D^* \cup D)$ corresponding to reversed edges of $E(G_0)$ is enough to this end. In order to find the minimum weight cycle going through some vertex of $D^* \cup D$ in G, we just run the algorithm of Observation 6 (or, more generally, in presence of negative edges – the algorithm of Lemma 14 with a feasible price function maintained by the algorithm of Theorem 23) $|D^* \cup D| = O(\Delta)$ times. This costs $O(\Delta(m + n\log n)) = \widetilde{O}(mn^{1/3})$ time.

▶ **Theorem 4.** *Let G be a real-weighted digraph. There exists a Monte Carlo randomized fully dynamic algorithm maintaining $\phi(G)$ under vertex updates with $O((m+n\log n)n^{2/3}\log^{4/3} n)$ worst-case update time. The answers produced are correct with high probability.*

6.1 Overview of the batch-deletion MPSP data structure

Let us now sketch the idea behind our generalization of the batch-deletion data structure of [2]. Due to space constraints, the detailed description can be found in the full version.

We first need to refer to some details of the construction of Abraham et al. [2]. The batch-deletion data structure separately handles recomputing shortest paths of hop-length at least $\sqrt{n/d}$ ("long" paths), and separately "short" shortest paths – with hop-lengths in the intervals of the form $[h/2, h)$ for $O(\log n)$ values $h = 2^1, 2^2, \ldots, \sqrt{n/d}$.

The main difficulty lies in handling short paths, whereas handling long paths is an easier task. The key idea (which dates back to Thorup [46]) is to compute an ordered subset $\{v_1, \ldots, v_\ell\} \subseteq V$ with the following properties. Let $G_i = G \setminus \{v_1, \ldots, v_{i-1}\}$. Let $\mathcal{P}_i$ be the set of shortest $\leq h$-hop paths from/to v_i in G_i. Then:

(1) For any $s, t \in V$, an $s \to t$ path not longer than the shortest $\leq h$-hop $s \to t$ path in G can be obtained by stitching, for some $i \in \{1, \ldots, \ell\}$, the $s \to v_i$ and $v_i \to t$ paths of $\mathcal{P}_i$.
(2) For any $x \in V$, x lies on at most $\widetilde{O}(hn)$ paths from $\bigcup_{i=1}^{\ell} \mathcal{P}_i$.

Such an ordering, along with the paths $\mathcal{P}_i$, can be computed in $\widetilde{O}(nmh)$ time deterministically (then we have $\ell = n$), or in $\widetilde{O}(nm)$ time using randomization (then $\ell = \widetilde{O}(n/h)$). Each subsequent vertex v_i in the ordering is picked to be, roughly speaking, the "most congested" one out of $V \setminus \{v_1, \ldots, v_{i-1}\}$, i.e., the one that has not been picked yet and appears most often on the previously constructed paths $\bigcup_{j=1}^{i-1} \mathcal{P}_j$.

Given the above, Abraham et al. [2] show that after removing any $D \subseteq V$ from G, the "short" paths in G can be recomputed by:

(1) constructing a number of *sketch graphs* $H_1, \ldots, H_\ell$, where $H_i \subseteq G_i \setminus D$,
(2) rebuilding destroyed (by the removal of D) paths from $\mathcal{P}_i$ by running Dijkstra's algorithm from/to v_i on H_i,
(3) stitching the reconstructed paths back to obtain paths at leas as good as the actual shortest $\leq h$-hop paths in G.

Abraham et al. [2] prove that if we denote by U_i the set of vertices u such that either of the paths $u \to v_i$ or $v_i \to u$ from $\mathcal{P}_i$ has been destroyed by removing D, $d = |D|$, then we have $\sum_{i=1}^{\ell} |U_i| = \widetilde{O}(hnd)$, and the total number of edges M in the sketch graphs is

$$M = O\left(\sum_{i=1}^{\ell}\left(n + \sum_{u \in U_i} \deg_G(u)\right)\right).$$

It is easy to see that $M = \Omega(n\ell)$, and $M = \tilde{O}(hn^2 d)$. Moreover, for each rebuilt path $u \to v_i$ or $v_i \to u$, stitching takes additional $\Theta(n)$ time – as one needs to traverse through $\Theta(n)$ source-target pairs that might benefit from this – for a total of $\widetilde{O}(hn^2 d)$ time. Since h ranges from $O(1)$ to $\Theta\left(\sqrt{n/d}\right)$, rebuilding short paths takes $\Omega(n^2)$ and $\widetilde{O}(n^2\sqrt{nd})$ time as claimed.

Now, to obtain our improved $\widetilde{O}((m+k)\sqrt{nd})$ bound on batch deletion for sparse graphs and small number k of source-target paths (s_i, t_i) of interest, we make two main adjustments.

First of all, we show that even smaller sketch graphs H_i – with $O\left(\sum_i^\ell \sum_{u\in U_i} \deg_G(u)\right)$ edges in total – can be used, thus eliminating the $\Omega(n\ell)$ term, which for small h is $\Omega(n^2)$.

More importantly, we use a different *weighted* scheme for picking the ordered subset $\{v_1, \ldots, v_\ell\}$. Let us denote by K the undirected graph on V whose edges correspond to the source-target pairs (s_i, t_i) of interest. In our scheme, the congestion that a previously computed $\le h$-hop path $P = v_i \to u$ (or $P = u \to v_i$) incurs upon some vertex x with $x \in V(P)$ is $\deg_G(u) + \log n + \deg_K(u)$, as opposed to 1 in [2]. This makes the total congestion of each vertex x in the process possibly increase to $\tilde{\Theta}(h(m + n\log n + k))$, as opposed to $\widetilde{O}(hn)$ in [2]. However, we show that the total cost of running Dijkstra's algorithm on our (more compact) sketch graphs $H_1, \ldots, H_\ell$ can be charged to the part of the total congestion of removed vertices D coming from the $[\deg_G(u) + \log n]$ terms, which is $\widetilde{O}(dh(m + n\log n))$. A similar argument applies to the cost of restitching, which we prove to be $\widetilde{O}(dhk)$.

Coboundary and Cosystolic Expansion from Strong Symmetry

Abstract

Coboundary and cosystolic expansion are notions of expansion that generalize the Cheeger constant or edge expansion of a graph to higher dimensions. The classical Cheeger inequality implies that for graphs edge expansion is equivalent to spectral expansion. In higher dimensions this is not the case: a simplicial complex can be spectrally expanding but not have high dimensional edge-expansion. The phenomenon of high dimensional edge expansion in higher dimensions is much more involved than spectral expansion, and is far from being understood. In particular, prior to this work, the only known bounded degree cosystolic expanders were derived from the theory of buildings that is far from being elementary.

In this work we study high dimensional complexes which are *strongly symmetric*. Namely, there is a group that acts transitively on top dimensional cells of the simplicial complex [e.g., for graphs it corresponds to a group that acts transitively on the edges]. Using the strong symmetry, we develop a new machinery to prove coboundary and cosystolic expansion.

It was an open question whether the recent elementary construction of bounded degree spectral high dimensional expanders based on coset complexes give rise to bounded degree cosystolic expanders. In this work we answer this question affirmatively. We show that these complexes give rise to bounded degree cosystolic expanders in dimension two, and that their links are (two-dimensional) coboundary expanders. We do so by exploiting the strong symmetry properties of the links of these complexes using a new machinery developed in this work.

Previous works have shown a way to bound the co-boundary expansion using strong symmetry in the special situation of "building like" complexes. Our new machinery shows how to get coboundary expansion for *general* strongly symmetric coset complexes, which are not necessarily "building like", via studying the (Dehn function of the) presentation of the symmetry group of these complexes.

Extended abstract

High dimensional expansion is a vibrant emerging field that has found applications to PCPs [5] and property testing [10], to counting problems and matroids [1], to list decoding [4], and recently to a breakthrough construction of decodable quantum error correcting codes that outperform the state-of-the art previously known codes [7]. We refer the reader to [16] for a recent (but already outdated) survey.

The term high dimensional expander means a simplicial complex that has expansion properties that are analogous to expansion in a graph. Nevertheless, the question of what is a high dimensional expander is still unclear. There is a spectral definition of high dimensional expanders that generalizes the spectral definition of expander graphs and a geometrical/topological definition that generalizes the notion of edge expansion (or Cheeger constant) of a graph. For a graph the spectral and the geometric definitions of expansion are known to be equivalent (via the celebrated Cheeger inequality) while in high dimensions the spectral and geometric definitions are known to be NOT equivalent (see [9, Theorem 4] and [19]).

The aim of this paper is to present elementary constructions of new families of 2-dimensional simplicial complexes with high dimensional edge expansion, and in particular, of new elementary *bounded degree* families of cosystolic expanders (see exact definition below). The question of giving an elementary construction of a family of bounded degree spectrally high dimensional expanders got recently a satisfactory answer. Namely, it was understood that such a family needs to obey a specific local spectral criterion and in [11] we used this understanding in order to construct elementary families of high dimensional *spectrally* expanding families (prior non-elementary constructions were known). Here, we further study the examples of [11], and show that they also give rise to bounded degree cosystolic expanders:

▶ **Theorem 1** (New cosystolic expanders, Informal, see also Theorem 22)**.** *For every large enough odd prime power q, the family of 2-skeletons of the 3-dimensional local spectral expanders constructed in [11] using elementary matrices over $\mathbb{F}_q[t]$ is a family of bounded degree cosystolic expanders.*

Prior to this work, the known examples of bounded degree cosystolic expanders arose from the theory of Bruhat-Tits buildings and were far from being elementary.

Relying on the work of the first named author and Evra (see Theorem 11 below), the proof of this Theorem boils down to proving that the links of our construction are coboundary expanders and that their coboundary expansion can be bounded independently of q (i.e., that the coboundary does not deteriorate as q increases). Thus, the real problem is bounding the coboundary expansion of the links. This goal is achieved utilizing the fact that the links are strongly symmetric coset complexes.

Coboundary expansion for strongly symmetric (coset) complexes

We call a simplicial complex strongly symmetric if it has a symmetry group acting transitively on top dimensional simplices. As noted above, our problem is to show that the links in our examples are coboundary expanders. In the graph setting, there is a classical Theorem (see Theorem 12 below) stating that for a strongly symmetric graph the Cheeger constant can be bounded from below by $\frac{1}{2D}$, where D denotes the diameter of the graph.

We generalize this idea: we define a high dimensional notion of radius and show that for strongly symmetric complexes, this radius can be used to bound the coboundary expansion. We then show that this radius can be bounded using filling constants of the complex. These ideas of bounding the coboundary expansion for symmetric complexes using filling constants already appeared implicitly in Gromov's work [8] and in the work of Lubotzky, Meshulam and Mozes [17]. However, these previous works considered the setting of spherical buildings and "building-like complexes" and thus bounding the filling constants in these examples were relatively simple due to the existence of apartments in the building (or "apartment-like" sub-complexes in "building-like" complexes). In our setting, we consider a more general situation (not assuming "apartment-like" sub-complexes) and thus bounding the filling constants becomes a much harder task.

What helps to solve this harder problem of bounding the filling constants is working with strongly symmetric *coset complexes* (see Definition 16). We note that this is not a very restrictive assumption - under some mild assumptions, every strongly symmetric complex is a coset complex (see proof in [13]). For a coset complex one can fully reconstruct the complex via its symmetry group and its subgroup structure. Thus every geometrical/topological property of a coset complex (including coboundary expansion) is encoded in some way in the presentation of its symmetry group. Using this philosophy, we are able to prove a bound for filling constants for two dimensional coset complex in terms of the presentation of its symmetry group (namely, in terms on its Dehn function - see definition below). Thus, for two dimensional coset complexes, we get a bound on the coboundary expansion in terms of presentation-theoretic properties of the symmetry group.

Coboundary expansion of the links in our construction

If follows from our work described above that in order to show that the links in our construction are coboundary expanders, we should verify a presentation-theoretic property for their symmetry group (namely, to bound its Dehn function). Luckily for us, the symmetry group of the links in our construction is a generalization of the group of unipotent groups over finite fields. For the finite field case, the presentation of these unipotent groups was studied by Biss and Dasgupta [2]. Using their ideas, we are able to show that the symmetry groups of links in our construction fulfil the presentation-theoretic condition that allows us to bound their coboundary expansion. Namely, we prove the following:

▶ **Theorem 2** (New coboundary expanders, Informal, see also Theorem 21)**.** *For every odd prime power q, the links of the 3-dimensional local spectral expanders constructed in [11] using elementary matrices over $\mathbb{F}_q[t]$ are coboundary expanders and their coboundary expansion can be bounded from below independent of q.*

Simplicial complexes

An n-dimensional simplicial complex X is a hypergraph whose maximal hyperedges are of size $n+1$, and which is closed under containment. Namely, for every hyperedge τ (called a face) in X, and every $\eta \subset \tau$, it must be that η is also in X. In particular, $\emptyset \in X$. For example, a graph is a 1-dimensional simplicial complex. Let X be a simplicial complex, we fix the following terminology/notation:

1. X is called *pure n-dimensional* if every face in X is contained in some face of size $n+1$.
2. The set of all k-faces (or k-simplices) of X is denoted $X(k)$, and we will be using the convention in which $X(-1) = \{\emptyset\}$.
3. For $0 \leq k \leq n$, the k-skeleton of X is the k-dimensional simplicial complex $X(0) \cup X(1) \cup ... \cup X(k)$. In particular, the 1-skeleton of X is the graph whose vertex set is $X(0)$ and whose edge set is $X(1)$.
4. For a simplex $\tau \in X$, the link of τ, denoted X_τ is the complex

   $$\{\eta \in X : \tau \cup \eta \in X, \tau \cap \eta = \emptyset\}.$$

   We note that if $\tau \in X(k)$ and X is pure n-dimensional, then X_τ is pure $(n-k-1)$-dimensional.
5. A family of pure n-dimensional simplicial complexes $\{X^{(s)}\}_{s\in\mathbb{N}}$ is said to have bounded degree if there is a constant $L > 0$ such that for every $s \in \mathbb{N}$ and every vertex v in $X^{(s)}$, v is contained in at most L n-dimensional simplices of $X^{(s)}$.

The coboundary/cosystolic expansion and high order Cheeger constants

Let us recall the geometric notion of expansion in graphs known as the edge expansion or Cheeger constant of a graph:

▶ **Definition 3** (Cheeger constant of a graph). *For a graph $X = (V, E)$:*

$$h(X) := min_{A \neq \emptyset, V} \frac{|E(A, \bar{A})|}{min\{w(A), w(\bar{A})\}},$$

where for a set of vertices $U \subsetneq V$, $w(U)$ denotes is the sum of the degrees of the vertices in U.

The generalization of the Cheeger constant to higher dimensions originated in the works of Linial, Meshulam and Wallach ([15], [18]) and independently in the work of Gromov ([8]) and is now known as *coboundary expansion*. Later, a weaker variant of high dimensional edge expansion known as *cosystolic expansion* arose in order to answer questions regarding topological overlapping.

In order to define coboundary and cosystolic expansion, we also need some terminology. Let X be an n-dimensional simplicial complex. Fix the following notations/definitions:

1. The space of k-cochains denoted $C^k(X) = C^k(X, \mathbb{F}_2)$ is the $\mathbb{F}_2$-vector space of functions from $X(k)$ to $\mathbb{F}_2$.
2. The *coboundary map* $d_k : C^k(X, \mathbb{F}_2) \to C^{k+1}(X, \mathbb{F}_2)$ is defined as:

$$d_k(\phi)(\sigma) = \sum_{\tau \subset \sigma, |\tau| = |\sigma| - 1} \phi(\tau),$$

3. The spaces of k-coboundaries and k-cocycles are subspaces of $C^k(X)$ defined as:
   $B^k(X) = B^k(X, \mathbb{F}_2) = \text{Image}(d_{k-1}) =$ the space of k-coboundaries.
   $Z^k(X) = Z^k(X, \mathbb{F}_2) = \text{Ker}(d_k) =$ the space of k-cocycles.
4. The function $w : \bigcup_{k=-1}^{n} X(k) \to \mathbb{R}_+$ is defined as

$$\forall \tau \in X(k), w(\tau) = \frac{|\{\sigma \in X(n) : \tau \subseteq \sigma\}|}{\binom{n+1}{k+1}|X(n)|}.$$

   We note that $\sum_{\tau \in X(k)} w(\tau) = 1$.
5. For every $\phi \in C^k(X)$, $w(\phi)$ is defined as

$$w(\phi) = \sum_{\tau \in \text{supp}(\phi)} w(\tau).$$

6. For every $0 \leq k \leq n-1$, define the following k-expansion constants:

$$\text{Exp}_b^k(X) = \min \left\{ \frac{w(d_k \phi)}{\min_{\psi \in B^k(X)} w(\phi + \psi)} : \phi \in C^k(X) \setminus B^k(X) \right\}.$$

$$\text{Sys}^k(X) = \min \left\{ w(\psi) : \psi \in Z^k(X) \setminus B^k(X) \right\},$$

and

$$\text{Exp}_z^k(X) = \min \left\{ \frac{w(d_k \phi)}{\min_{\psi \in Z^k(X)} w(\phi + \psi)} : \phi \in C^k(X) \setminus Z^k(X) \right\}.$$

After these notations, we can define coboundary/cosystolic expansion:

▶ **Definition 4** (Coboundary expansion). *Let $\varepsilon > 0$ be a constant. We say that X is an ε-coboundary expander if for every $0 \leq k \leq n-1$, $\mathrm{Exp}_b^k(X) \geq \varepsilon$.*

▶ Remark 5. We leave it for the reader to verify that in the case where X is a graph, i.e., the case where $n = 1$, $\mathrm{Exp}_b^0(X)$ is exactly the Cheeger constant of X. Thus, we think of $\mathrm{Exp}_b^k(X)$ as the k-dimensional Cheeger constant of X.

▶ **Definition 6** (Cosystolic expansion). *Let $\varepsilon > 0, \mu > 0$ be constants and X an n-dimensional simplicial complex X. We say that X is a (ε, μ)-cosystolic expander if for every $0 \leq k \leq n-1$, $\mathrm{Exp}_z^k(X) \geq \varepsilon$ and $\mathrm{Sys}^k(X) \geq \mu$.*

▶ Remark 7. We note that if $\mathrm{Exp}_b^k(X) > 0$, then it can be shown that $B^k(X) = Z^k(X)$ and thus $\mathrm{Exp}_b^k(X) = \mathrm{Exp}_z^k(X)$. However, there are examples of simplicial complexes with $\mathrm{Exp}_b^k(X) = 0$ and $\mathrm{Exp}_z^k(X) > 0, \mathrm{Sys}^k(X) > 0$.

As in expander graphs, we are mainly interested in a family of bounded degree cosystolic expanders (and not a single complex that is a cosystolic expander):

▶ **Definition 8** (A family of bounded degree cosystolic expanders). *A family of n-dimensional simplicial complexes $\{Y^{(s)}\}_{s\in\mathbb{N}}$ is a family of bounded degree cosystolic expanders if:*

- *The number of vertices of $Y^{(s)}$ tends to infinity with s.*
- *$\{Y^{(s)}\}_{s\in\mathbb{N}}$ has bounded degree.*
- *There are universal constants $\varepsilon > 0, \mu > 0$ such that for every s, $Y^{(s)}$ is a (ε, μ)-cosystolic expander.*

▶ Remark 9. The motivation behind the definition of a family of cosystolic expanders is to proved a family of bounded degree complexes that have the topological overlapping property (see [13] for the exact definition).

The Evra-Kaufman criterion for cosystolic expansion

In [6], Evra and the first named author gave a criterion for cosystolic expansion. In order to state this criterion, we will need the following definition:

▶ **Definition 10** (Local spectral expansion). *For $\lambda \geq 0$, a pure n-dimensional simplicial complex X is called a (one-sided) λ-local spectral expander if for $-1 \leq k \leq n-2$ and every $\tau \in X(k)$, the one-skeleton of X_τ is a connected graph and the second largest eigenvalue of the random walk on the one-skeleton of X_τ is less or equal to λ.*

The idea behind the Evra-Kaufman criterion for cosystolic expansion is the following: We can deduce cosystolic expansion from local spectral expansion and local coboundary expansion (i.e., coboundary expansion in the links) given that the local spectral expansion is "strong enough" so it "beats" the local coboundary expansion. More formally:

▶ **Theorem 11** ([6, Theorem 1] Evra-Kaufman criterion for cosystolic expansion). *For every $\varepsilon' > 0$ and $n \geq 3$ there are $\mu(n, \varepsilon') > 0, \varepsilon(n, \varepsilon') > 0$ and $\lambda(n, \varepsilon') > 0$ such that for every pure n-dimensional simplicial complex if*

- *X is a λ-local spectral expander.*
- *For every $0 \leq k \leq n-2$ and every $\tau \in X(k)$, X_τ is a ε'-coboundary expander.*

Then the $(n-1)$-skeleton of X is a (ε, μ)-cosystolic expander.

Thus, in order to prove cosystolic expansion in examples, we should verify two things: local spectral expansion and coboundary expansion in the links. In our examples from [11] described below, local spectral expansion is already known and we are left with proving coboundary expansion for the links. In order to do so, we will develop machinery to prove coboundary expansion for symmetric complexes of a special type called coset complexes.

Coboundary expansion for strongly symmetric simplicial complexes

As noted above, unlike the case of graphs, in simplicial complexes a high dimensional version of Cheeger inequality does not hold. Thus, there is a need to develop machinery in order to prove coboundary expansion that does not rely on spectral arguments. For graphs such machinery is available, under the assumptions that the graph has a large symmetry group. A discussion regarding the Cheeger constant of symmetric graphs appear in [3, Section 7.2] and in particular, the following Theorem is proven there:

▶ **Theorem 12** ([3, Theorem 7.1]). *Let X be a finite connected graph such that there is a group G acting transitively on the edges of X. Denote $h(X)$ to be the Cheeger constant of X and D to be the diameter of X. Then $h(X) \geq \frac{1}{2D}$.*

▶ Remark 13. Note that the inequality stated in the Theorem does not hold without the assumption of symmetry. For instance, let X_N be the graph that is the ball of radius N in the 3-regular infinite tree. Then the diameter of X is $2N+1$ and $h(X_N)$ is of order $O(\frac{1}{2^N})$.

In this paper, using the ideas of [8] and [17], we prove a generalization of Theorem 12 to the setting of (strongly) symmetric simplicial complexes. We first define the notion of strongly symmetric simplicial complexes.

▶ **Definition 14** (Strongly symmetric complex). *A simplicial complex X is called* strongly symmetric *if there is a group that acts simply transitively on its top dimensional faces. E.g., For graphs (one dimensional complexes) we require a group that acts simply transitively on the edges.*

We then define a high dimensional notion of radius which we call a cone radius, but this definition is a little technical and thus appears in Section 2 (see Definition 28). We then prove the following:

▶ **Theorem 15** (Informal, see Theorem 30 for the formal statement). *Let X be a strongly symmetric simplicial complex. If the k-dimensional (cone) radius of X is bounded by D, then $\mathrm{Exp}_b^k(X) \geq \frac{1}{\binom{n+1}{k+1}D}$, i.e., the k-coboundary expansion is bounded from below as a function of the k-th radius.*

Bounding the high dimensional radius for coset complexes

By Theorem 15, in order to prove coboundary expansion for strongly symmetric complexes, it is enough to bound their high dimensional radius. Following the ideas of Gromov [8], we bound the radius by bounding certain filling constants, that we will not define here. In order to bound these filling constants and thus the high dimensional radius, we will assume that our strongly symmetric complex is of a special type, namely that it is a coset complex:

▶ **Definition 16** (Coset complex). *Given a group G with subgroups $K_{\{i\}}, i \in \mathrm{I}$, where I is a finite set. The coset complex $X = X(G, (K_{\{i\}})_{i\in \mathrm{I}})$ is a simplicial complex defined as follows:*

1. *The vertex set of X is composed of disjoint sets $S_i = \{gK_{\{i\}} : g \in G\}$.*
2. *For two vertices $gK_{\{i\}}, g'K_{\{j\}}$ where $i, j \in \mathrm{I}, g, g' \in G$, $\{gK_{\{i\}}, g'K_{\{j\}}\} \in X(1)$ if $i \neq j$ and $gK_{\{i\}} \cap g'K_{\{j\}} \neq \emptyset$.*
3. *The simplicial complex X is the clique complex spanned by the 1-skeleton defined above, i.e., $\{g_0K_{\{i_0\}}, ..., g_kK_{\{i_k\}}\} \in X(k)$ if for every $0 \leq j, j' \leq k$, $g_jK_{\{i_j\}} \cap g_{j'}K_{\{i_{j'}\}} \neq \emptyset$.*

Although this Definition may seem daunting at first, we note that it is very natural in examples. Namely, in [13] we shows that under some mild assumptions, strongly symmetric simplicial complexes are actually coset complexes.

As noted above, for coset complexes, every property of the complex should be reflected in some way in its symmetry group and its subgroup structure. Following this philosophy, we prove that for coset complexes, the 0-th and 1-th dimensional coboundary expansion can be bounded using the presentation of the group from which the complex arose.

In order to describe our result, we recall some definitions from group theory. Given a group G, a generating set $S \subseteq G$ is a set of elements of G such that every element in G can be written as a finite product (or sum if G is commutative) of elements of S. One can always take $S = G$, but usually one can make due with a smaller set. For example, for the group G of addition of integers modulo n, $G = (\mathbb{Z}/n\mathbb{Z}, +)$, one can take $S = \{\pm 1\}$. Given a group G with a generating set S, a word with letters in S is called trivial if it equal to the identity. For example, in $G = (\mathbb{Z}/n\mathbb{Z}, +)$ with $S = \{\pm 1\}$, the words $1 + 1 + (-1) + (-1)$ and $1 + ... + 1$ (n summands) $= n \cdot 1$ are trivial.

We say that a group G has a presentation $G = \langle S|R\rangle$, if S is a generating set of G and R is a set of trivial words called relations such that every trivial word in G can be written using the words in $R \cup \{ss^{-1}, s^{-1}s : s \in S\}$ (allowing products, conjugations and inverses). Again, one can always take $S = G \setminus \{e\}$ and R to be the entire multiplication table of G, i.e., all the words of the form $g_1 g_2 g_3^{-1} = e$, where $g_1 g_2 = g_3$. However, in concrete examples, one can usually make due with fewer generators and relations. For example, for the group $G = (\mathbb{Z}/n\mathbb{Z}, +)$ it is sufficient to take $S = \{\pm 1\}$ and the single relation $n \cdot 1$. We note that it is not always easy to determine if a set of relations gives a presentation of G.

Given a presentation $G = \langle S|R\rangle$, the Dehn function for this presentation is a function $\mathrm{Dehn} : \mathbb{N} \to \mathbb{N}$ such that $\mathrm{Dehn}(m)$ describes how many elements of $R \cup \{ss^{-1}, s^{-1}s : s \in S\}$ does one need to write a trivial word in G of length $\leq m$. With this terminology, we prove the following:

▶ **Theorem 17.** *Let G be a finite group with subgroups $K_{\{i\}}, i \in \{0,1,2\}$. Denote $X = X(G, (K_{\{i\}})_{i\in\{0,1,2\}})$. Assume that G acts strongly transitively on X.*

For every $i \in \{0,1,2\}$, denote R_i to be all the non-trivial relations in the multiplication table of $K_{\{i\}}$, i.e., all the relations of the form $g_1 g_2 g_3 = e$, where $g_1, g_2, g_3 \in K_{\{i\}} \setminus \{e\}$. Assume that $G = \langle \bigcup_i K_{\{i\}} | \bigcup_i R_i \rangle$ and let Dehn *denote the Dehn function of this presentation.*

Then:

1. *For*
$$N_0' = 1 + \max_{g\in G} \min \left\{ l : g = g_1 ... g_l \text{ and } g_1, ..., g_l \in \bigcup_i K_{\{i\}} \right\},$$
it holds that $\mathrm{Exp}_b^0(X) \geq \frac{1}{3N_0'}$.
2. *There is a universal polynomial $p(x, y)$ independent of X such that*
$$\mathrm{Exp}_b^1(X) \geq \frac{1}{3p(2N_0' + 1, \mathrm{Dehn}(2N_0' + 1))}.$$

Our construction

So far, we described general tools that we developed in order to prove coboundary and cosystolic expansion. Now we will describe our construction from [11] on which we aim to apply these tools.

In [11], we used coset complexes to construct n-dimensional spectral expanders. Below, we only describe the construction for $n = 3$: Fix $s \in \mathbb{N}, s > 4$ and q be a prime power. Denote $G_q^{(s)}$ to be the group of 4×4 matrices with entries in $\mathbb{F}_q[t]/\langle t^s \rangle$ generated by the set

$$\{e_{1,2}(a + bt), e_{2,3}(a + bt), e_{3,4}(a + bt), e_{4,1}(a + bt) : a, b \in \mathbb{F}_q\}.$$

For $0 \leq i \leq 2$, define $H_{\{i\}}$ to be the subgroup of $G_q^{(s)}$ generated by

$$\{e_{j,j+1}(a+bt), e_{4,1}(a+bt) : a,b \in \mathbb{F}_q, 1 \leq j \leq 3, j \neq i+1\}$$

and define $H_{\{3\}}$ to be the subgroup of $G^{(s)}$ generated by

$$\{e_{1,2}(a+bt), e_{2,3}(a+bt), e_{3,4}(a+bt) : a,b \in \mathbb{F}_q\}.$$

Denote $X_q^{(s)} = X(G_q^{(s)}, (H_{\{i\}})_{i\in\{0,\ldots,3\}})$ to be the coset complex as defined above.

The main result of [11] applied to $\{X_q^{(s)}\}_{s>4}$ above can be summarized as follows:

1. The family $\{X_q^{(s)}\}_{s>4}$ has bounded degree (that depends on q).
2. The number of vertices of $X_q^{(s)}$ tends to infinity with s.
3. For every s, $X_q^{(s)}$ is $\frac{1}{\sqrt{q}-3}$-local spectral expander.

In light of Theorem 17, we will also need some facts regrading the links of $X_q^{(s)}$. We give the following explicit description of the links in our construction: We note that for every fixed q it holds that there is a complex X such that for every $s > 4$ and every vertex $v \in X_q^{(s)}$, there is a coset complex denoted $X_{link,q}$ such that the link of v is isomorphic to $X_{link,q}$ (all the links are isomorphic).

The complex $X_{link,q}$ can be described explicitly as follows: Denote the group $G_{link,q}$ to be a subgroup of 4×4 invertible matrices with entries in $\mathbb{F}_q[t]$ in generated by the set $\{e_{i,i+1}(a+bt) : a,b \in \mathbb{F}_q, 1 \leq i \leq 4\}$. More explicitly, an 4×4 matrix A is in $G_{link,q}$ if and only if

$$A(i,j) = \begin{cases} 1 & i = j \\ 0 & i > j \\ a_0 + a_1 t + \ldots + a_{j-i} t^{j-i} & i < j, a_0, \ldots, a_{j-i} \in \mathbb{F}_q \end{cases},$$

(observe that all the matrices in G are upper triangular).

For $0 \leq i \leq 3$, define a subgroup $K_{\{i\}} < G$ as

$$K_{\{i\}} = \langle e_{j,j+1}(a+bt) : j \in \{1,\ldots,4\} \setminus \{i+1\}, a,b \in \mathbb{F}_q \rangle.$$

Define $X_{link,q}$ to be the coset complex $X_{link,q} = X(G_{link,q}, (K_{\{i\}})_{i\in\{0,1,2\}})$. As noted above, for every $s > 4$, all the 2-dimensional links of $X_q^{(s)}$ are isomorphic to $X_{link,q}$. Also,

▶ **Theorem 18** ([12, Theorems 2.4, 3.5]). *The complex $X_{link,q}$ above is strongly symmetric, namely the group $G_{link,q}$ of unipotent matrices described above acts transitively on the triangles of $X_{link,q}$.*

New coboundary and cosystolic expanders

Finally, we describe how the general machinery we developed can be applied in our construction.

First, by applying Theorem 11 on the family $\{X_q^{(s)}\}_{s\in\mathbb{N}}$ yields the following Corollary:

▶ **Corollary 19.** *Let $\{X_q^{(s)}\}_{s\in\mathbb{N}}$ be the family of n-dimensional simplicial complexes from [11]. Assume there is a constant $\varepsilon' > 0$ such that for every odd q, every s, every $0 \leq k \leq n-2$ and every $\tau \in X(k)$, X_τ is a ε'-coboundary expander. Denote $Y_q^{(s)}$ to be the $(n-1)$-skeleton of $X_q^{(s)}$. Then for any sufficiently large odd prime power q, the family $\{Y_q^{(s)}\}_{s\in\mathbb{N}}$ is a family of bounded degree cosystolic expanders.*

Thus, by this Corollary, in order to prove Theorem 1 it is enough to show that for every odd q, there is a constant $\varepsilon' > 0$ such that for every odd q and every $s \in \mathbb{N}$, the 2-skeleton of the link of every vertex v in $X_q^{(s)}$ is a ε' coboundary expander.

As we noted, the links are strongly transitive coset complexes which we denoted $X_{q,link}$ and described explicitly above. By Theorem 17, in order to bound the coboundary expansion of the links, we need to consider the presentation of their symmetry group $G_{link,q}$ defined above. Generalizing on the work of Biss and Dasgupta [2] we prove the following:

▶ **Theorem 20.** *For any prime power q denote $G_{q,link}, K_{\{0\}}, K_{\{1\}}, K_{\{2\}}$ as above and for every $i \in \{0,1,2\}$, denote R_i to be all the non-trivial relations in the multiplication table of $K_{\{i\}}$. Then*

- $$\sup_{q \text{ odd prime power}} \left(\max_{g \in G_{q,link}} \min \left\{ l : g = g_1 ... g_l \text{ and } g_1, ..., g_l \in \bigcup_i K_{\{i\}} \right\} \right) < \infty.$$
- *For every odd q it holds that*

$$G_{q,link} = \langle \bigcup_i K_{\{i\}} | \bigcup_i R_i \rangle$$

and the Dehn function of this presentation is bounded independently of q.

This Theorem combined with Theorem 17 gives:

▶ **Theorem 21** (First Main Theorem - new explicit two dimensional coboundary expanders)**.** *For every odd prime power q, $X_{link,q}$ is a coboundary expander and $\mathrm{Exp}_0(X), \mathrm{Exp}_1(X)$ are bounded from below by a constant that is independent of q.*

Applying Corollary 19 it follows that:

▶ **Theorem 22** (Second Main Theorem - elementary two dimensional bounded degree cosytolic expanders)**.** *Let $s \in \mathbb{N}, s > 4$ and q be a prime power and $X_q^{(s)}$ as above. For every s, let $Y_q^{(s)}$ be the 2-skeleton of $X_q^{(s)}$, i.e., the 2-dimensional complex $Y_q^{(s)} = X_q^{(s)}(0) \cup X_q^{(s)}(1) \cup X_q^{(s)}(2)$. For any sufficiently large odd prime power q, the family $\{Y_q^{(s)}\}_{s \in \mathbb{N}, s>4}$ is a family of bounded degree cosystolic expanders.*

Technical details of the paper

In Section 1, we give the precise definitions and notations regarding (co)homology. In Section 2, we define the cone radius of a simplicial complex and prove that for symmetric simplicial complexes, the cone radius can be used to bound the coboundary expansion.

The other technical details of the paper are available in its Arxiv version [13]. Namely, in [13] the reader can find the following:

- A precise definition of the filling constants of a simplicial complex and a proof that the filling constants of the complex can be used to bound the cone radius.
- A review the idea of coset complexes and a proof that our assumption of strong symmetry combined with some extra assumptions on a complex imply that it is a coset complex.
- A bound on the first two filling constants for a coset complex in terms of algebraic properties of the presentation of the group and subgroups from which it arises.
- New examples of coboundaries expanders arising from coset complexes of unipotent groups.
- New examples of bounded degree cosystolic and topological expanders.
- A proof that the existence of a cone function is equivalent to the vanishing of (co)homology.

1 Homological and Cohomological definitions and notations

The aim of this section is to recall a few basic definitions regarding homology and cohomology of simplicial complexes that we will need below.

Let X be an n-dimensional simplicial complex. A simplicial complex X is called *pure* if every face in X is contained in some face of size $n+1$. The set of all k-faces of X is denoted $X(k)$, and we will be using the convention in which $X(-1) = \{\emptyset\}$.

We denote by $C_k(X) = C_k(X, \mathbb{F}_2)$ the $\mathbb{F}_2$-vector space with basis $X(k)$ (or equivalently, the $\mathbb{F}_2$-vector space of subsets of $X(k)$), and $C^k(X) = C^k(X, \mathbb{F}_2)$ the $\mathbb{F}_2$-vector space of functions from $X(k)$ to $\mathbb{F}_2$.

The *boundary map* $\partial_k : C_k(X, \mathbb{F}_2) \to C_{k-1}(X, \mathbb{F}_2)$ is:

$$\partial_k(\sigma) = \sum_{\tau \subset \sigma, |\tau| = |\sigma|-1} \tau,$$

where $\sigma \in X(k)$, and the *coboundary map* $d_k : C^k(X, \mathbb{F}_2) \to C^{k+1}(X, \mathbb{F}_2)$ is:

$$d_k(\phi)(\sigma) = \sum_{\tau \subset \sigma, |\tau| = |\sigma|-1} \phi(\tau),$$

where $\phi \in C^k$ and $\sigma \in X(k+1)$.

For $A \in C_k(X)$ and $\phi \in C^k(X)$, we denote

$$\phi(A) = \sum_{\tau \in A} \phi(\tau),$$

Thus, for $\phi \in C^k(X)$ and $A \in C_{k+1}(X)$

$$(d_k \phi)(A) = \phi(\partial_{k+1} A)$$

We sometimes refer to k-chains as subsets of $X(k)$, e.g., the 0-chain $\{u\} + \{v\}$ will be sometimes referred to as the set $\{\{u\}, \{v\}\}$. For $A \in C_k(X)$, we denote $|A|$ to be the size of A as a set.

Well known and easily calculated equations are:

$$\partial_k \circ \partial_{k+1} = 0 \text{ and } d_{k+1} \circ d_k = 0 \tag{1}$$

Thus, if we denote: $B_k(X) = B_k(X, \mathbb{F}_2) = \text{Image}(\partial_{k+1}) =$ the space of k-boundaries.
$Z_k(X) = Z_k(X, \mathbb{F}_2) = \text{Ker}(\partial_{k+1}) =$ the space of k-cycles.
$B^k(X) = B^k(X, \mathbb{F}_2) = \text{Image}(d_{k-1}) =$ the space of k-coboundaries.
$Z^k(X) = Z^k(X, \mathbb{F}_2) = \text{Ker}(d_k) =$ the space of k-cocycles.
We get from (1)

$$B_k(X) \subseteq Z_k(X) \subseteq C_k(X) \text{ and } B^k(X) \subseteq Z^k(X) \subseteq C^k(X).$$

Define the quotient spaces $\widetilde{H}_k(X) = Z_k(X)/B_k(X)$ and $\widetilde{H}^k(X) = Z^k(X)/B^k(X)$, the k-homology and the k-cohomology groups of X (with coefficients in $\mathbb{F}_2$).

2 Cone radius as a bound on coboundary expansion

Below, we define a generalized notion of diameter (or more precisely radius) of a simplicial complex. We will later show that in symmetric simplicial complexes a bound on this radius yields a bound on the coboundary expansion of the complex.

▶ **Definition 23** (Cone function). *Let X be a pure n-dimensional simplicial complex. Let $-1 \leq k \leq n-1$ be a constant and v be a vertex of X. A k-cone function with apex v is a linear function $\mathrm{Cone}_k^v : \bigoplus_{j=-1}^{k} C_j(X) \to \bigoplus_{j=-1}^{k} C_{j+1}(X)$ defined inductively as follows:*

1. *For $k=-1$, $\mathrm{Cone}_{-1}^v(\emptyset) = \{v\}$.*
2. *For $k \geq 0$, $\mathrm{Cone}_k^v|_{\bigoplus_{j=-1}^{k-1} C_j(X)}$ is a $(k-1)$-cone function with an apex v and for every $A \in C_k(X)$, $\mathrm{Cone}_k^v(A) \in C^{k+1}(X)$ is a $(k+1)$-chain that fulfills the equation*

$$\partial_{k+1} \mathrm{Cone}_k^v(A) = A + \mathrm{Cone}_k^v(\partial_k A).$$

▶ **Observation 24.** *By linearity, the condition that*

$$\partial_{k+1} \mathrm{Cone}_k^v(A) = A + \mathrm{Cone}_k^v(\partial_k A), \forall A \in C^k(X)$$

is equivalent to the condition:

$$\partial_{k+1} \mathrm{Cone}_k^v(\tau) = \tau + \mathrm{Cone}_k^v(\partial_k \tau), \forall \tau \in X(k).$$

▶ Remark 25. We note that by linearity, a k-cone function is needs only to be defined on k-simplices, but it gives us homological fillings for every k-cycle in X: for every $A \in Z_k(X)$,

$$\partial_{k+1} \mathrm{Cone}_k^v(A) = A + \mathrm{Cone}_k^v(\partial_k A) = A + \mathrm{Cone}_k^v(0) = A,$$

i.e., $\partial_{k+1} \mathrm{Cone}_k^v(A) = A$. This might be computationally beneficial for other needs (apart from the results of this paper), since usually there are exponentially more k-cycles than k-simplices.

▶ **Example 26** (0-cone example). Let X be an n-dimensional simplicial complex. Fix some vertex v in X. By definition, for every $\{u\} \in X(0)$, $\mathrm{Cone}_0^v(\{u\})$ is a 1-chain such that $\partial_0 \mathrm{Cone}_0^v(\{u\}) = \{u\} + \{v\}$.

If the 1-skeleton of X is connected, we can define $\mathrm{Cone}_0^v(\{u\})$ to be a 1-chain that consists of a sum of edges that form a path between $\{u\}$ and $\{v\}$. If the 1-skeleton of X is not connected, a 0-cone function does not exist: for $\{u\} \in X(0)$ that is not in the connected component of $\{v\}$, $\mathrm{Cone}_0^v(\{u\})$ cannot be defined. Assuming that the 1-skeleton of X is connected, we note that the construction of Cone_0^v is usually not unique: different choices of paths between $\{u\}$ and $\{v\}$ give different 0-cone functions.

▶ **Example 27** (1-cone example). Let X be an n-dimensional simplicial complex. Assume that the 1-skeleton of X is connected and define a 0-cone function as in the example above and define Cone_2^v on $C_0(X)$ as that 0-cone function. We note that for every $\{u,w\} \in X(1)$, $\{u,w\} + \mathrm{Cone}_0^v(\{u\}) + \mathrm{Cone}_0^v(\{w\})$ forms a closed path, i.e., a 1-cycle, in X. If $\widetilde{H}_1(X) = 0$, we can deduce that $\{u,w\} + \mathrm{Cone}_1^v(\{u\}) + \mathrm{Cone}_1^v(\{w\})$ is a boundary. Therefore, for every $\{u,w\} \in X(1)$, we can choose $\mathrm{Cone}_1^v(\{u,w\}) \in X(2)$ such that

$$\partial_2 \mathrm{Cone}_1^v = \{u,w\} + \mathrm{Cone}_1^v(\{u\}) + \mathrm{Cone}_1^v(\{w\}).$$

▶ **Definition 28** (Cone radius). *Let X be an n-dimensional simplicial complex, $-1 \leq k \leq n-1$ and v a vertex of X. Given a k-cone function Cone_k^v define the volume of Cone_k^v as*

$$\mathrm{Vol}(\mathrm{Cone}_k^v) = \max_{\tau \in X(k)} |\mathrm{Cone}_k^v(\tau)|.$$

Define the k-th cone radius of X to be

$$\mathrm{Crad}_k(X) = \min\{\mathrm{Vol}(\mathrm{Cone}_k^v) : \{v\} \in X(0), \mathrm{Cone}_k^v \text{ is a } k\text{-cone function}\}.$$

If k-cone functions do not exist, we define $\mathrm{Crad}(X) = \infty$.

▶ Remark 29. The reason for the name "cone radius" is that in the case where $k = 0$, $\mathrm{Crad}_0(X)$ is exactly the (graph) radius of the 1-skeleton of X. Indeed, for $k = 0$, choose $\{v\} \in X(0)$ such that for every $\{v'\} \in X(0)$,

$$\max_{\{u\} \in X(0)} \mathrm{dist}(v, u) \leq \max_{\{u\} \in X(0)} \mathrm{dist}(v', u),$$

where dist denotes the path distance. For such a $\{v\} \in X(0)$, define $\mathrm{Cone}_0^v(\{u\})$ to be the edges of a shortest path between v and u. By our choice of v, it follows that $\mathrm{Vol}(\mathrm{Cone}_0^v)$ is the radius of the one-skeleton of X and we leave it to the reader to verify that this choice gives $\mathrm{Crad}_0(X) = \mathrm{Vol}(\mathrm{Cone}_0^v)$.

The main result of this section is that in a symmetric simplicial complex X, the k-th cone radius gives a lower bound on $\mathrm{Exp}_b^k(X)$:

▶ **Theorem 30.** *Let X be a pure finite n-dimensional simplicial complex. Assume that X is strongly symmetric, i.e., that there is a group G of automorphisms of X acting transitively on $X(n)$. For every $0 \leq k \leq n-1$, if $\mathrm{Crad}_k(X) < \infty$, then $\mathrm{Exp}_b^k(X) \geq \frac{1}{\binom{n+1}{k+1}\mathrm{Crad}_k(X)}$.*

Theorem 30 stated above generalizes a result of of Lubotzky, Meshulam and Mozes [17] in which coboundary expansion was proven for symmetric simplicial complexes given that they are "building-like", i.e., that they have have sub-complexes that behave (in some sense) as apartments in a Bruhat-Tits building.

We note that the notion of a cone function is already evident in Gromov's original work [8]. Gromov considered what he called "random cones", which was a probability over a family of cone functions and show that the expectancy of the occurrence of a simplex in the support of this family bounds $\mathrm{Exp}_b^k(X)$ (see also the work of Kozlv and Meshulam [14, Theorem 2.5]). Using Gromov's terminology, in the proof of the Theorem above, we show that under the assumption of symmetry a single cone function yields a family of random cones and the needed expectancy is bounded by the cone radius. In the sake of completeness, we will not prove the Theorem without using Gromov's results.

In order to prove Theorem 30, we will need some additional lemmas.

▶ **Lemma 31.** *For $-1 \leq k \leq n-1$ and a k-cone function Cone_k^v with apex v. Define the contraction operator $\iota_{\mathrm{Cone}_k^v}$,*

$$\iota_{\mathrm{Cone}_k^v} : \bigoplus_{j=-1}^{k} C^{j+1}(X) \to \bigoplus_{j=-1}^{k} C^j(X)$$

as follows: for $\phi \in C^{j+1}(X)$ and $A \in C_j(X)$, we define

$$(\iota_{\mathrm{Cone}_k^v}\phi)(A) = \phi(\mathrm{Cone}_k^v(A)).$$

Then for every $\phi \in C^k(X)$,

$$\iota_{\mathrm{Cone}_k^v} d_k \phi = \phi + d_{k-1}\iota_{\mathrm{Cone}_k^v}\phi.$$

Proof. Let $A \in C_k(X)$, then

$$\iota_{\mathrm{Cone}_k^v} d_k \phi(A) = (d_k\phi)(\mathrm{Cone}_k^v(A)) =$$
$$\phi(\partial_{k+1}(\mathrm{Cone}_k^v(A))) = \phi(A + (\mathrm{Cone}_k^v(\partial_k A))) =$$
$$\phi(A) + (\iota_{\mathrm{Cone}_k^v}\phi)(\partial_k A) = \phi(A) + (d_{k-1}\iota_{\mathrm{Cone}_k^v}\phi)(A),$$

as needed. ◀

Naively, it might seem that this Lemma gives a direct approach towards bounding the coboundary expansion: if one could find is some constant $C = C(n, k, \mathrm{Crad}_k(X))$ such that $w(\iota_{\mathrm{Cone}_k^v} d_k\phi) \leq C w(d_k\phi)$, then for every ϕ,

$$\frac{w(d_k\phi)}{\min_{\psi \in B^k(X)} w(\phi+\psi)} \geq \frac{1}{C}\frac{w(\iota_{\mathrm{Cone}_k^v} d_k\phi)}{w(\phi + d_{k-1}\iota_{\mathrm{Cone}_k^v}\phi)} = \frac{1}{C}.$$

However, by Remark 13, we note that without symmetry, the existence of a k-cone function cannot give an effective bound on the coboundary expansion.

Our proof strategy below is to improve on this naive idea by using the symmetry of X: we will show that for a group G that acts on X, the group G also acts on k-cone functions and we will denote this action by ρ. We then show that when G acts transitively on $X(n)$, we can average the action on the k-cone function that realizes the cone radius and deduce that

$$\frac{1}{|G|}\sum_{g\in G} w(\iota_{\rho(g).\,\mathrm{Cone}_k^v} d_k\phi) \leq \binom{n+1}{k+1}\mathrm{Crad}_k(X) w(d_k\phi).$$

Thus, using an averaged version of the naive argument above will get a bound on the coboundary expansion.

We start by defining an action on k-cone functions. Assume that G is a group acting simplicially on X. For every $g \in G$ and every k-cone function Cone_k^v define

$$(\rho(g).\,\mathrm{Cone}_k^v)(A) = g.(\mathrm{Cone}_k^v(g^{-1}.A)), \forall A \in \bigoplus_{j=-1}^{k} C_j(X).$$

▶ **Lemma 32.** *For $g \in G$, $-1 \leq k \leq n-1$ and a k-cone function Cone_k^v with apex v, $\rho(g).\,\mathrm{Cone}_k^v$ is a k-cone function with apex $g.v$ and $\mathrm{Vol}(g.\,\mathrm{Cone}_k^v) = \mathrm{Vol}(\mathrm{Cone}_k^v)$. Moreover, ρ defines an action of G on the set of k-cone functions.*

Proof. If we show that $g.\,\mathrm{Cone}_k^v$ is a k-cone function the fact that $\mathrm{Vol}(g.\,\mathrm{Cone}_k^v) = \mathrm{Vol}(\mathrm{Cone}_k^v)$ will follow directly from the fact that G acts simplicially.

The proof that $\rho(g).\,\mathrm{Cone}_k^v$ is a k-cone function is by induction on k. For $k = -1$,

$$(\rho(g).\,\mathrm{Cone}_{v,-1})(\emptyset) = g.\,\mathrm{Cone}_{v,-1}(g^{-1}.\emptyset) = g.\,\mathrm{Cone}_{v,-1}(\emptyset) = g.\{v\} = \{g.v\},$$

then $\rho(g).\,\mathrm{Cone}_{v,-1}$ is a (-1)-cone function with an apex $g.v$.

Assume the assertion of the lemma holds for $k-1$. Thus, $\rho(g).\,\mathrm{Cone}_k^v|_{\bigoplus_{j=-1}^{k-1} C_j(X)}$ is a $(k-1)$-cone function with an apex $g.v$ and, by Observation 24, we are left to check that for every $\tau \in X(k)$,

$$\partial_{k+1}(\rho(g).\,\mathrm{Cone}_k^v)(\tau) = \tau + \rho(g).\,\mathrm{Cone}_k^v(\partial_k\tau).$$

Note that the G acts simplicially on X and thus the action of G commutes with the ∂ operator. Therefore, for every $\tau \in X(k)$,

$$\partial_{k+1}(\rho(g).\operatorname{Cone}_k^v)(\tau) = \partial_{k+1}(g.(\operatorname{Cone}_k^v(g^{-1}.\tau))) = g.\left(\partial_{k+1}\operatorname{Cone}_k^v(g^{-1}.\tau)\right) = g.\left(g^{-1}.\tau + \operatorname{Cone}_k^v(\partial_k g^{-1}.\tau)\right) = \tau + g.\operatorname{Cone}_k^v(g^{-1}.\partial_k\tau) = \tau + \rho(g).\operatorname{Cone}_k^v(\partial_k\tau).$$

The fact that ρ is an action is straight-forward and left for the reader. ◀

Applying our proof strategy above, will lead us to consider the constant $\theta(\eta)$ defined in the Lemma below.

▶ **Lemma 33.** *Assume that G is a group acting simplicially on X and that this action is transitive on n-simplices. Let $0 \le k \le n-1$ and assume that $\operatorname{Crad}_k(X) < \infty$. Fix Cone_k^v to be a k-cone function such that $\operatorname{Crad}_k(X) = \operatorname{Vol}(\operatorname{Cone}_k^v)$. For every $\eta \in X(k+1)$, denote*

$$\theta(\eta) = \frac{1}{w(\eta)|G|}\sum_{g\in G}\sum\{w(\tau) : \tau \in X(k), \eta \in (\rho(g).\operatorname{Cone}_k^v)(\tau))\}.$$

Then for every $\eta \in X(k+1)$, $\theta(\eta) \le \binom{n+1}{k+1}\operatorname{Crad}_k(X)$.

Proof. Fix some $\eta \in X(k+1)$. First, we note that G acts transitively on $X(n)$ and therefore $\bigcup_{gG_\eta}\{g.\sigma : \sigma \in X(n), \eta \subseteq \sigma\} = X(n)$. This yields that

$$|X(n)| \le \frac{|G|}{|G_\eta|}|\{\sigma \in X(n) : \eta \subseteq \sigma\}|,$$

and therefore $|G_\eta| \le |G|\binom{n+1}{k+1}w(\eta)$.

Second, we note that for every $g \in G$, and every $\eta \in X(k+1)$,

$$\eta \in (\rho(g).\operatorname{Cone}_k^v)(\tau) \Leftrightarrow \eta \in g.(\operatorname{Cone}_k^v(g^{-1}.\tau)) \Leftrightarrow g^{-1}.\eta \in \operatorname{Cone}_k^v(g^{-1}.\tau).$$

Thus,

$$\begin{aligned}
\theta(\eta) &= \frac{1}{w(\eta)|G|}\sum_{g\in G}\sum\{w(\tau) : \tau \in X(k), \eta \in (\rho(g).\operatorname{Cone}_k^v)(\tau))\} = \\
&\frac{1}{w(\eta)|G|}\sum_{g\in G}\sum\{w(\tau) : \tau \in X(k), g^{-1}.\eta \in \operatorname{Cone}_k^v(g^{-1}.\tau)\} = \\
&\frac{1}{w(\eta)|G|}\sum_{g\in G}\sum\{w(g^{-1}.\tau) : \tau \in X(k), g^{-1}.\eta \in \operatorname{Cone}_k^v(g^{-1}.\tau)\} = \\
&\frac{1}{w(\eta)|G|}\sum_{g\in G}\sum\{w(\tau) : \tau \in X(k), g^{-1}.\eta \in \operatorname{Cone}_k^v(\tau)\} = \\
&\frac{1}{w(\eta)|G|}\sum_{g\in G}\sum_{\tau\in X(k)}\sum_{g^{-1}.\eta\in\operatorname{Cone}_k^v(\tau)} w(\tau) = \\
&\frac{1}{w(\eta)}\sum_{\tau\in X(k)} w(\tau)\sum_{g\in G}\sum_{g^{-1}.\eta\in\operatorname{Cone}_k^v(\tau)}\frac{1}{|G|} \le \\
&\frac{1}{w(\eta)}\sum_{\tau\in X(k)} w(\tau)|\operatorname{Cone}_k^v(\tau)|\frac{|G_\eta|}{|G|} \le \\
&\frac{1}{w(\eta)}\sum_{\tau\in X(k)} w(\tau)\operatorname{Crad}_k(X)\binom{n+1}{k+1}w(\eta) = \\
&\binom{n+1}{k+1}\operatorname{Crad}_k(X)\sum_{\tau\in X(k)} w(\tau) = \binom{n+1}{k+1}\operatorname{Crad}_k(X),
\end{aligned}$$

as needed. ◀

We turn now to prove Theorem 30:

Proof. Assume that G is a group acting simplicially on X such that the action is transitive on $X(n)$. Let $0 \leq k \leq n-1$ and assume that $\mathrm{Crad}_k(X) < \infty$. For $\phi \in C^k(X)$, we denote

$$[\phi] = \{\phi + \psi : \psi \in B^k(X)\}, \text{ and } w([\phi]) = \min_{\phi' \in [\phi]} w(\phi').$$

Thus, we need to prove that for every $\phi \in C^k(X)$,

$$\frac{1}{\binom{n+1}{k+1}\mathrm{Crad}_k(X)} w([\phi]) \leq w(d_k\phi),$$

or equivalently,

$$|G|w([\phi]) \leq |G|w(d_k\phi)\left(\binom{n+1}{k+1}\mathrm{Crad}_k(X)\right).$$

Fix Cone_k^v to be a k-cone function such that $\mathrm{Crad}_k(X) = \mathrm{Vol}(\mathrm{Cone}_k^v)$. By Lemma 32, for every $g \in G$, $\rho(g).\mathrm{Cone}_k^v$ is a k-cone function.

In the notation of Lemma 31, for every $g \in G$, denote $\iota_g = \iota_{\rho(g).\mathrm{Cone}_k^v}$. By Lemma 31, for every $g \in G$, $w([\phi]) \leq w(\iota_g d_k \phi)$ and therefore

$$\begin{aligned}
|G|w([\phi]) &\leq \sum_{g\in G} w(\iota_g d_k\phi) = \sum_{g\in G}\sum \{w(\tau) : \tau \in \mathrm{supp}(\iota_g d_k\phi)\} = \\
&\sum_{g\in G}\sum \{w(\tau) : \tau \in X(k), d_k\phi(\rho(g).\mathrm{Cone}_k^v(\tau)) = 1\} \leq \\
&\sum_{g\in G}\sum \{w(\tau) : \tau \in X(k), \mathrm{supp}(d_k\phi) \cap \rho(g).\mathrm{Cone}_k^v(\tau) \neq \emptyset\} \leq \\
&\sum_{\eta\in\mathrm{supp}(d_k\phi)}\sum_{g\in G}\sum \{w(\tau) : \tau \in X(k), \eta \in \rho(g).\mathrm{Cone}_k^v(\tau)\} = \\
\sum_{\eta\in\mathrm{supp}(d_k\phi)} |G|w(\eta)\theta(\eta) &\leq^{\text{Lemma 33}} |G|w(d_k\phi)\left(\binom{n+1}{k+1}\mathrm{Crad}_k(X)\right),
\end{aligned}$$

as needed. ◀

The converse of Theorem 30 is also true, i.e., the existence of a cone function is equivalent to vanishing of (co)homology and thus to coboundary expansion (for a proof see [13]).

Maximum Matchings and Popularity

Telikepalli Kavitha
Tata Institute of Fundamental Research, Mumbai, India

Abstract

Let G be a bipartite graph where every node has a strict ranking of its neighbors. For any node, its preferences over neighbors extend naturally to preferences over matchings. A maximum matching M in G is a *popular max-matching* if for any maximum matching N in G, the number of nodes that prefer M is at least the number that prefer N. Popular max-matchings always exist in G and they are relevant in applications where the size of the matching is of higher priority than node preferences. Here we assume there is also a cost function on the edge set. So what we seek is a min-cost popular max-matching. Our main result is that such a matching can be computed in polynomial time.

We show a compact extended formulation for the popular max-matching polytope and the algorithmic result follows from this. In contrast, it is known that the popular matching polytope has near-exponential extension complexity and finding a min-cost popular matching is NP-hard.

1 Introduction

We consider a matching problem in a bipartite graph $G = (A \cup B, E)$ on n nodes and m edges where every node has a strict ranking of its neighbors. The bipartite graph G need not be complete. This is a very well-studied model in two-sided matching markets. This model has been used to match students to schools and colleges [1, 4] and doctors to residencies in hospitals [6, 28].

The goal is to find an optimal matching in G. The classical notion of optimality in such an instance is *stability*. A matching M is stable if there is no edge that *blocks* M; an edge (a, b) blocks M if a and b prefer each other to their respective assignments in M. Stable matchings always exist in G and one such matching can be computed in linear time by the Gale-Shapley algorithm [17].

In several applications, along with node preferences, the definition of optimality may involve attributes such as size, e.g., consider the problem of assigning doctors to hospitals during a pandemic. For instance, during the Covid-19 pandemic in Mumbai, public hospitals were overwhelmed with a rising number of patients and were severely short-staffed; so doctors associated with private clinics were asked to also work in public hospitals[1] [3, 22]. We want the maximum number of doctors to get assigned to hospitals, i.e., we do not wish to

[1] In the doctors-hospitals setting, one typically seeks a many-to-one matching since a hospital may need several doctors. Here we focus on one-to-one matchings.

compromise at all on the size of our matching. Thus the size of the matching is of higher priority here than node preferences. We refer to [5] for more such applications: these include school placement [1] and the assignment of sailors to billets [29, 34]. So the set of admissible solutions in all these applications is the set of maximum matchings and among all maximum matchings, we wish to find a *best* matching as per node preferences.

Note that a stable matching need not have maximum size. It is known that all stable matchings match the same set of nodes [18]. When stable matchings are not admissible, a natural alternative would be to seek a maximum matching with the least number of blocking edges. However this is an NP-hard problem [5] and as shown there, this is NP-hard to approximate within $n^{1-\varepsilon}$, for any $\varepsilon > 0$.

Observe that stability empowers every edge with the "veto power" to block a matching. Thus stability is a very strong notion and the notion of *popularity* is a meaningful relaxation of stability that captures collective welfare. We say node u prefers matching M to matching N if u prefers its assignment in M to its assignment in N; being unmatched is the worst choice for any node. We can compare any pair of matchings M and N by holding an election between them where nodes are voters.

Let $\phi(M, N)$ be the number of nodes that prefer M to N and similarly, let $\phi(N, M)$ be the number of nodes that prefer N to M. We say N is more popular than M if $\phi(N, M) > \phi(M, N)$.

▶ **Definition 1.** *A matching M is popular if $\Delta(M, N) \geq 0$ for all matchings N in G, where $\Delta(M, N) = \phi(M, N) - \phi(N, M)$.*

Thus a matching M is popular if there is no matching that is more popular than M. Every stable matching is popular[2] [19]. One of the main merits of popularity is that it allows larger matchings compared to stable matchings. Since a stable matching is a maximal matching, its size is at least $|M_{\max}|/2$ (where $M_{\max}$ is a maximum matching in G) and there are easy examples where this bound is tight. It is known that there is always a popular matching of size at least $2|M_{\max}|/3$ and there are simple instances with no larger popular matching [23].

Since a popular matching need not be maximum, a natural alternative is to ask for a maximum matching M that is popular *within* the set of maximum matchings, i.e., no maximum matching is more popular than M. Since it is only maximum matchings that are admissible and we are not willing to replace a maximum matching with a smaller one, elections that involve *non-maximum* or inadmissible matchings are not relevant here. Hence a natural candidate for a best maximum matching is a *popular max-matching* defined below.

▶ **Definition 2.** *Call a maximum matching M in $G = (A \cup B, E)$ a popular max-matching if $\Delta(M, N) \geq 0$ for all maximum matchings N in G.*

Thus what we seek is a *weak Condorcet winner* [7, 27] in the voting instance where maximum matchings are candidates and nodes are voters. The relation "more popular than" is not transitive and weak Condorcet winners need not exist in every voting instance. The question of whether every instance admits a popular max-matching was considered in [23] where it was shown that popular max-matchings always exist in $G = (A \cup B, E)$ and one such matching can be computed in $O(mn)$ time.

[2] In an election between a stable matching S and any matching M, if node u prefers M to S then the node $M(u)$ has to prefer S to M, otherwise $(u, M(u))$ blocks S, which is forbidden. Hence $\phi(M, S) \leq \phi(S, M)$.

In several applications there is a cost function $c : E \to \mathbb{R}$ and for any matching M, its cost $c(M) = \sum_{e \in M} c(e)$. So among all popular max-matchings in G, what we seek is a *min-cost* popular max-matching. There are no previous algorithmic/hardness results known for this problem. We know that it is NP-hard to find a min-cost popular matching [13].

Finding a min-cost popular max-matching is a natural and interesting problem in discrete optimization. Solving this problem efficiently implies efficient algorithms for a whole host of popular max-matching problems such as finding one with forced/forbidden edges or one with max-utility or one with min-regret. In general, a cost function allows us to "access" the entire set of popular max-matchings; note that G may have more than 2^n such matchings [32].

Let $\mathcal{M}_G$ denote the popular max-matching polytope of G, i.e., this polytope is the convex hull of the edge incidence vectors of popular max-matchings in G. A compact description of $\mathcal{M}_G$ (or some extension[3] of it) implies a polynomial time algorithm to compute a min-cost popular max-matching. Our main result is that the polytope $\mathcal{M}_G$ has a compact extended formulation. So unlike the min-cost popular matching problem, interestingly and quite surprisingly, the min-cost popular max-matching problem is tractable.

▶ **Theorem 3.** *Given $G = (A \cup B, E)$ where nodes have strict preferences and $c : E \to \mathbb{R}$, a min-cost popular max-matching can be computed in polynomial time.*

So Theorem 3 shows that a natural variant of the min-cost popular matching problem (which is NP-hard) admits a polynomial time algorithm. We also consider *Pareto-optimality* – this is a far more relaxed notion than popularity that any reasonable matching in this domain should satisfy. If M is a matching that is not Pareto-optimal then there is a matching N such that no node is worse-off in N than in M and at least one node is better-off.

The *unpopularity factor* of M is defined as follows [26]: $u(M) = \max_{N \neq M} \frac{\phi(N,M)}{\phi(M,N)}$. Observe that a popular matching M satisfies $u(M) \leq 1$. A matching M is Pareto-optimal if $u(M) < \infty$. A maximum matching M that satisfies $u(M) < \infty$ is a Pareto-optimal max-matching. We show the following hardness result here.

▶ **Theorem 4.** *Given $G = (A \cup B, E)$ with strict preferences and edge costs in $\{0, 1\}$, it is NP-hard to compute a min-cost Pareto-optimal matching/max-matching in G. Moreover, it is NP-hard to approximate this within any multiplicative factor.*

1.1 Background

The notion of popularity was introduced by Gärdenfors [19] in 1975 where he observed that every stable matching is popular. Many algorithmic questions in popular matchings have been investigated in the last 10-15 years and we refer to [8] for a survey. In the domain of popular matchings with two-sided preferences (every node has a preference order ranking its neighbors), other than a handful of positive results [10, 20, 23, 25], most optimization problems have turned out to be NP-hard [13].

Computing a min-cost *quasi-popular* matching M, i.e., $u(M) \leq 2$, is also NP-hard [12]. Compact extended formulations for the *dominant* matching[4] polytope [10, 12] and the popular fractional matching polytope [24] are known but the popular matching polytope has near-exponential extension complexity [12].

[3] A polytope Q that linearly projects to a polytope P is an *extension* of P and a linear description of Q is an *extended formulation* for P. The minimum size of an extension of P is the *extension complexity* of P.

[4] These are popular matchings that are more popular than all larger matchings.

Though an $O(mn)$ time algorithm to find a popular max-matching in G is known [23], there are no previous results on its *optimization* variant, i.e., to find a min-cost or max-utility popular max-matching. It is common in this domain to have an efficient algorithm to find a max-size matching in some class – say, popular matchings [20, 23] or Pareto-optimal matchings for one-sided preferences (only nodes in A have preferences) studied in [2], however finding a min-cost matching in these classes is NP-hard [2, 13]; Theorem 4 also shows such a hardness result. Thus an efficient algorithm to find some popular max-matching was no guarantee on the tractability of the min-cost popular max-matching problem.

There are several polynomial time algorithms to compute a min-cost stable matching and some variants of this problem [11, 14, 15, 16, 21, 30, 31, 33]. Moreover, the stable matching polytope of G has a linear-size description in $\mathbb{R}^m$ [30]. Thus in contrast to stable matchings, the landscape of popular matchings has only a few positive results.

1.2 Our Techniques

An algorithm called the "$|A|$-level Gale-Shapley algorithm" was given in [23] to find a popular max-matching in $G = (A \cup B, E)$. As we show in Section 2, this algorithm is equivalent to running the Gale-Shapley algorithm in an auxiliary instance G^* with $|A|$ copies of each node in A. The proof in [23] can be easily adapted to show that there is a map from the set of stable matchings in G^* to the set of popular max-matchings in G (see Theorem 6). Our novel contribution here is to show that this map is *surjective*, i.e., every popular max-matching in G is the image of a stable matching in G^*.

Loosely speaking, the instance G^* is made up of $|A|$ copies of G and is inspired by an instance from [10] that is made up of two copies of G. So our instance G^* is much larger than the instance used in [10]. In order to realize a popular max-matching in G as the image of a stable matching in G^*, rather than be guided by blocking edges (as done in [10]), we need a "global handle" over the given popular max-matching, i.e., we seek a function from $A \cup B$ to $\{0, \ldots, |A| - 1\}$ that guides us in how to "place" this matching in the instance G^*.

LP-duality gives us such a handle in terms of dual certificates. Dual certificates for popular matchings are well-understood: these are in $\{0, \pm 1\}^n$ [24]. To show a compact extended formulation for $\mathcal{M}_G$ (unlike the popular matching polytope), finding the right dual certificates is crucial. Our proof consists of two parts: when G admits a perfect matching, it is the easy case. We use total unimodularity, complementary slackness, and the fact that G has a perfect matching to show that the given popular max-matching M has a dual certificate $\vec{\alpha}$ where $\alpha_a \in \{0, -2, -4, \ldots\}$ for $a \in A$ and $\alpha_b \in \{0, 2, 4, \ldots\}$ for $b \in B$. Such an $\vec{\alpha}$ can be neatly used to realize M as the image of a stable matching in G^* (see Theorem 8).

The general case. When G does not admit a perfect matching, things are more complicated. The primal LP will not be as simple as (LP1) whose constraints describe the perfect matching polytope. So we reduce the general case to the case when M is a perfect matching, i.e., we use the dual solution $\vec{\alpha} \in \{0, \pm 2, \pm 4, \ldots\}^{2n_0}$ that certifies M's optimality in the subgraph $G' = G \setminus \{\text{nodes not matched in } M\}$ on $2n_0 = 2|M|$ nodes.

We need to update $\vec{\alpha}$ so that it certifies M's optimality in the entire graph G. Our main technical novelty is in how we update $\vec{\alpha}$ using certain rules (see Theorem 9). Let $A' \cup B'$ be the node set of G' and let U be the set of nodes not matched in M.

We use the fact that M is a maximum matching to prove that our update procedure terminates with a dual certificate $\vec{\alpha}$ for M in G' where $\alpha_a \in \{0, -2, -4, \ldots, -2(n_0 - 1)\}$ for $a \in A'$ and $\alpha_b \in \{0, 2, 4, \ldots, 2(n_0 - 1)\}$ for $b \in B'$ such that the neighbors of nodes in U take

the highest possible α-values, i.e., (i) $\alpha_a = 0$ for $a \in A' \cap \mathsf{Nbr}(U)$ and (ii) $\alpha_b = 2(n_0 - 1)$ for $b \in B' \cap \mathsf{Nbr}(U)$. Roughly speaking, such an $\vec{\alpha}$ will *take care* of the edges of G missing in G' and will allow us to realize M as the image of a stable matching in G^* (see Theorem 10).

2 Popular Max-Matchings

In this section we first show a simple characterization of popular max-matchings. Then we show a method to construct matchings that satisfy this characterization. Let M be any matching in $G = (A \cup B, E)$. The following edge weight function wt_M will be useful here. For any $(a, b) \in E$:

$$\text{let } \mathsf{wt}_M(a,b) = \begin{cases} 2 & \text{if } (a,b) \text{ blocks } M; \\ -2 & \text{if } a \text{ and } b \text{ prefer their assignments in } M \text{ to each other;} \\ 0 & \text{otherwise.} \end{cases}$$

So $\mathsf{wt}_M(e) = 0$ for every $e \in M$. For any edge e, $\mathsf{wt}_M(e)$ is the sum of votes (each vote is in $\{0, \pm 1\}$) of the endpoints of e for each other versus their respective assignments in M.

For any cycle/path ρ in G, let $\mathsf{wt}_M(\rho) = \sum_{e \in \rho} \mathsf{wt}_M(e)$. Theorem 5 uses this edge weight function to characterize popular max-matchings. Recall that an alternating path (resp., cycle) with respect to matching M is a path (resp., cycle) whose alternate edges are in M.

▶ **Theorem 5.** *For any maximum matching M in G, M is a popular max-matching if and only if (1) there is no alternating cycle C wrt M such that $\mathsf{wt}_M(C) > 0$ and (2) there is no alternating path p with an unmatched node as an endpoint such that $\mathsf{wt}_M(p) > 0$.*

Proof. Let M be a popular max-matching. We need to show that conditions (1) and (2) given in the theorem statement hold. Suppose not. Then there exists either an alternating path with an unmatched node as an endpoint or an alternating cycle wrt M (call this path/cycle ρ) such that $\mathsf{wt}_M(\rho) > 0$. Since $\mathsf{wt}_M(e) \in \{0, \pm 2\}$, $\mathsf{wt}_M(\rho) \geq 2$.

Consider $N = M \oplus \rho$. This is a maximum matching in G and observe that $\Delta(N, M) \geq \mathsf{wt}_M(\rho) - 1$. We are subtracting 1 here to count for that endpoint of ρ (when ρ is a path) that is matched in M but will become unmatched in N. Since $\mathsf{wt}_M(\rho) \geq 2$, $\Delta(N, M) \geq 1$. So N is more popular than M; this is a contradiction to M's popularity within the set of maximum matchings. Thus conditions (1) and (2) have to hold.

To show the converse, suppose M is a maximum matching that obeys conditions (1) and (2). Consider the symmetric difference $M \oplus N$, where N is any maximum matching in G and let C be any alternating cycle here. We know from (1) that $\mathsf{wt}_M(C) \leq 0$. Let p be any alternating path in $M \oplus N$. Since M and N are maximum matchings, p is an alternating path with exactly one node not matched in M as an endpoint. We know from (2) that $\mathsf{wt}_M(p) \leq 0$. So we have $\Delta(N, M) \leq \sum_{\rho \in M \oplus N} \mathsf{wt}_M(\rho) \leq 0$. Thus no maximum matching is more popular than M. ◀

A new instance. We will now construct a new instance $G^* = (A^* \cup B^*, E^*)$ such that every stable matching in G^* maps to a maximum matching in G that satisfies properties (1) and (2) given in Theorem 5. As mentioned earlier, the structure of the instance G^* is inspired by an instance from [10] whose stable matchings map to dominant matchings in G.

We first describe the node sets A^* and B^*. Let $n_0 = |A|$. For every $a \in A$, the set A^* has n_0 copies of a: call them $a_0, \ldots, a_{n_0 - 1}$. So $A^* = \cup_{a \in A} \{a_0, \ldots, a_{n_0 - 1}\}$.

Let $B^* = \cup_{a \in A}\{d_1(a), \ldots, d_{n_0-1}(a)\} \cup \{\tilde{b} : b \in B\}$, where $\tilde{B} = \{\tilde{b} : b \in B\}$ is a copy of the set B. So along with nodes in $\tilde{B}$, the set B^* also contains $n_0 - 1$ nodes $d_1(a), \ldots, d_{n_0-1}(a)$ for each $a \in A$. These will be called *dummy* nodes. The purpose of $d_1(a), \ldots, d_{n_0-1}(a)$ is to ensure that in any stable matching in G^*, at most one node among $a_0, \ldots, a_{n_0-1}$ is matched to a neighbor in $\tilde{B}$.

The edge set. For each $(a, b) \in E$, the edge set E^* contains n_0 edges $(a_i, \tilde{b})$ for $0 \leq i \leq n_0 - 1$. For each $a \in A$ and $i \in \{1, \ldots, n_0 - 1\}$, E^* also has $(a_{i-1}, d_i(a))$ and $(a_i, d_i(a))$.

Preference orders. Let a's preference order in G be $b_1 \succ \cdots \succ b_k$. Then a_0's preference order in G^* is $\tilde{b}_1 \succ \cdots \succ \tilde{b}_k \succ d_1(a)$, i.e., it is analogous to a's preference order in G with $d_1(a)$ added as a_0's last choice.

- For $i \in \{1, \ldots, n_0 - 2\}$, the preference order of a_i in G^* is as follows: $d_i(a) \succ \tilde{b}_1 \succ \cdots \succ \tilde{b}_k \succ d_{i+1}(a)$. So a_i's top choice is $d_i(a)$ and last choice is $d_{i+1}(a)$.
- The preference order of a_{n_0-1} is $d_{n_0-1}(a) \succ \tilde{b}_1 \succ \cdots \succ \tilde{b}_k$.

For each $i \in \{1, \ldots, n_0 - 1\}$, the preference order of $d_i(a)$ is $a_{i-1} \succ a_i$. Since each of $a_0, \ldots, a_{n_0-2}$ and $d_1(a), \ldots, d_{n_0-1}(a)$ is a top choice neighbor for some node, every stable matching in G^* has to match all these nodes. So the only node among $a_0, \ldots, a_{n_0-1}, d_1(a), \ldots, d_{n_0-1}(a)$ that can possibly be left unmatched in a stable matching in G^* is a_{n_0-1}.

Consider any $b \in B$ and let its preference order in G be $a \succ \cdots \succ z$. Then the preference order of $\tilde{b}$ in G^* is

$$\underbrace{a_{n_0-1} \succ \cdots \succ z_{n_0-1}}_{\text{all subscript } n_0-1 \text{ neighbors}} \succ \underbrace{a_{n_0-2} \succ \cdots \succ z_{n_0-2}}_{\text{all subscript } n_0-2 \text{ neighbors}} \succ \cdots \succ \underbrace{a_0 \succ \cdots \succ z_0}_{\text{all subscript 0 neighbors}}$$

That is, $\tilde{b}$'s preference order in G^* is all its subscript $n_0 - 1$ neighbors, followed by all its subscript $n_0 - 2$ neighbors, so on, and finally, all its subscript 0 neighbors. For each $i \in \{0, \ldots, n_0 - 1\}$: within all subscript i neighbors, the order of preference for $\tilde{b}$ in G^* is the same as b's order of preference in G.

The set S'. For any stable matching S in G^*, define $S' \subseteq E$ to be the set of edges obtained by deleting edges in S that are incident to dummy nodes and replacing any edge $(a_i, \tilde{b}) \in S$ with the original edge $(a, b) \in E$. Since S matches at most one node among $a_0, \ldots, a_{n_0-1}$ to a neighbor in $\tilde{B}$, the set S' is a matching in G.

The proof of Theorem 6 is based on the proof of correctness of the $|A|$-level Gale-Shapley algorithm (from [23]) in the original instance G.

▶ **Theorem 6.** *Let S be a stable matching in G^*. Then S' is a popular max-matching in G.*

Proof. Partition the set A into $A_0 \cup \cdots \cup A_{n_0-1}$ where for $0 \leq i \leq n_0 - 2$: $A_i = \{a \in A : (a_i, \tilde{b}) \in S \text{ for some } \tilde{b} \in \tilde{B}\}$, i.e., a_i is matched in S to a neighbor in $\tilde{B}$. The left-out nodes in A, i.e., those in $A \setminus (A_0 \cup \cdots \cup A_{n_0-2})$, form the set A_{n_0-1} (see Fig. 1).

Similarly, partition B into $B_0 \cup \cdots \cup B_{n_0-1}$ where for $1 \leq i \leq n_0 - 1$: $B_i = \{b : (a_i, \tilde{b}) \in S \text{ for some } a \in A_i\}$, i.e., $\tilde{b}$'s partner in S is a subscript i node. Let $B_0 = B \setminus (B_1 \cup \cdots \cup B_{n_0-1})$ be the set of left-out nodes in B.

The following properties hold: (these are proved below)

1. $S' \subseteq \cup_{i=0}^{n_0-1}(A_i \times B_i)$. Moreover, S' restricted to each set $A_i \cup B_i$ is stable.
2. For any i and edge (a, b) where $a \in A_{i+1}, b \in B_i$: we have $\mathsf{wt}_{S'}(a, b) = -2$.

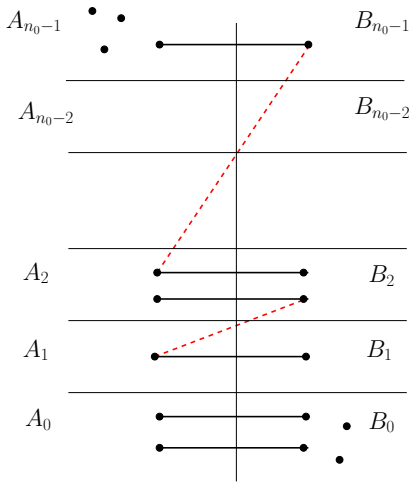

Figure 1 $A = A_0 \cup \cdots \cup A_{n_0-1}$ and $B = B_0 \cup \cdots \cup B_{n_0-1}$. The matching $S' \subseteq \cup_{i=0}^{n_0-1}(A_i \times B_i)$. All nodes unmatched in S' are in $A_{n_0-1} \cup B_0$. The dashed edges are blocking edges to S'.

3. G has no edge in $A_i \times B_j$ where $i \geq j+2$.
4. Any blocking edge to S' has to be in $A_i \times B_j$ where $i \leq j-1$.
5. All nodes that are unmatched in S' are in $A_{n_0-1} \cup B_0$.
6. S' is a maximum matching in G.

Properties 1–4 imply that for any alternating cycle C wrt S', $\mathtt{wt}_{S'}(C) \leq 0$. Similarly, properties 1–5 imply that for any alternating path p with one unmatched node as an endpoint, $\mathtt{wt}_{S'}(p) \leq 0$. We refer to [23, Theorem 2] for more details. Property 6 states that S' is a maximum matching in G. Hence S' is a popular max-matching in G (by Theorem 5). ◀

Properties 1-6. These six properties are proved below.

1. The inclusion $S' \subseteq \cup_{i=0}^{n_0-1}(A_i \times B_i)$ follows from the definition of the sets $B_0, \ldots, B_{n_0-1}$. Recall that for $1 \leq i \leq n_0 - 1$, B_i is the set of nodes b such that $(a_i, \tilde{b}) \in S$ for some $a \in A_i$. Also, B_0 contains all nodes b such that $(a_0, \tilde{b}) \in S$ for some $a \in A_0$. Thus $S' \subseteq \cup_{i=0}^{n_0-1}(A_i \times B_i)$.
   The stability of S' restricted to each set $A_i \cup B_i$ is by $\tilde{b}$'s preference order in G^*. Recall that within subscript i neighbors, the order of preference for $\tilde{b}$ in G^* is b's order of preference in G. Thus the stability of S in G^* implies the stability of S' restricted to $A_i \cup B_i$ for each i.
2. Let $a \in A_{i+1}$. Then $(a_{i+1}, d_{i+1}(a)) \notin S$. So it has to be the case that $(a_i, d_{i+1}(a)) \in S$. Recall that $d_{i+1}(a)$ is a_i's least preferred neighbor in G^*. So a_i prefers $\tilde{b}$ to its partner in S. Hence it follows from the stability of S in G^* that $\tilde{b}$ prefers its partner in S (this is a subscript i node z_i) to a_i, i.e., b prefers z to a.
   Since $\tilde{b}$ prefers subscript $i+1$ nodes to subscript i nodes, $\tilde{b}$ prefers a_{i+1} to its partner z_i in S. It follows from the stability of S in G^* that a_{i+1} has to prefer its partner $\tilde{w}$ in S to $\tilde{b}$, otherwise $(a_{i+1}, \tilde{b})$ would block S. Hence a prefers w to b. Thus $\mathtt{wt}_{S'}(a, b) = -2$.
3. Suppose $a \in A_i$ where $i \geq j+2$ and $b \in B_j$. So the edge $(a_{j+1}, d_{j+2}(a)) \in S$. Since $d_{j+2}(a)$ is a_{j+1}'s least preferred neighbor in G^*, the stability of S implies that $\tilde{b}$ prefers its partner in S to a_{j+1}. However $b \in B_j$ and so $\tilde{b}$'s partner in S is a subscript j node z_j. This contradicts $\tilde{b}$'s preference order that it prefers any subscript $j+1$ neighbor to a subscript j neighbor. Thus there is no edge (a, b) in G with $a \in A_i$ and $b \in B_j$ where $i \geq j+2$.

4. Property 4 follows from properties 1, 2, and 3 given above. Properties 2 and 3 tell us that there is no blocking edge in $A_i \times B_j$ where $i \geq j+1$. Property 1 tells us that there is no blocking edge in $A_i \times B_i$ for any i. So any blocking edge to S' has to be in $A_i \times B_j$ where $i \leq j-1$.
5. Property 5 follows from the definitions of the sets $A_0, \ldots, A_{n_0-2}$ and $B_1, \ldots, B_{n_0-1}$. For each $a \in A_i$ where $0 \leq i \leq n_0-2$: we have $(a_i, \tilde{b}) \in S$ for some $\tilde{b} \in \tilde{B}$ and thus $(a,b) \in S'$. Similarly, for each $b \in B_j$ where $1 \leq j \leq n_0-1$: we have $(a_j, \tilde{b}) \in S$ for some $a \in A_j$ and thus $(a,b) \in S'$. Hence all nodes unmatched in S' are in $A_{n_0-1} \cup B_0$.
6. Suppose S' is not a maximum matching in G. Then there is an augmenting path ρ with respect to S'. Let us refer to an edge e that satisfies $\mathsf{wt}_{S'}(e) = -2$ as a *negative* edge. The endpoints of a negative edge prefer their respective partners in S' to each other.
   We know from property 5 above that all the nodes in A that are unmatched in S' are in A_{n_0-1} and all the nodes in B that are unmatched in S' are in B_0. We also know that $S' \subseteq \cup_i (A_i \times B_i)$ (by property 1 above). Moreover, all the edges e in $A_{j+1} \times B_j$ are negative edges (by property 2) and there is no edge in $A_i \times B_j$ where $i \geq j+2$ (by property 3).
   Thus the path ρ starts in A_{n_0-1} at an unmatched node a and since there cannot be any negative edge incident to an unmatched node, all of a's neighbors have to be in B_{n_0-1}: this is because every edge e in $A_{n_0-1} \times B_{n_0-2}$ is a negative edge. The matched partners of a's neighbors are in A_{n_0-1}. Then the next node can be in B_{n_0-2} (this is by property 3) and its partner is in A_{n_0-2} and so on. Finally, there is no edge from A_1 to an unmatched node in B_0: this is because there is no negative edge incident to an unmatched node and we know all edges in $A_1 \times B_0$ are negative edges (by property 2).
   So the *shortest* alternating path ρ from an unmatched $a \in A_{n_0-1}$ to an unmatched $b \in B_0$ moves across sets as follows: $A_{n_0-1} - B_{n_0-1} - A_{n_0-1} - B_{n_0-2} - A_{n_0-2} - B_{n_0-3} - \cdots - A_1 - B_0 - A_0 - B_0$. This implies there are at least n_0+1 nodes in A. However $|A| = n_0$. So there is no such alternating path, i.e., there is no augmenting path with respect to S'. In other words, S' is a maximum matching in G. This finishes our proof of these six properties.

Theorem 6 shows that every stable matching in G^* maps to a popular max-matching in G. In fact, as we show next, *every* popular max-matching in G has to be realized in this manner. This is the tough part of the proof and as mentioned earlier, we will use LP-duality here. We will see that appropriate dual certificates capture a very useful feature of popular max-matchings.

3 Proving Surjectivity in a Special Case

In this section we consider the case when G admits a perfect matching. Let M be a popular perfect matching in G. So no perfect matching in G is more popular than M.

Consider the following linear program (LP1) that computes a max-weight (wrt wt_M) perfect matching in G. For any node u, let $\delta(u)$ be the set of edges incident to u.

$$\text{maximize} \quad \sum_{e \in E} \mathsf{wt}_M(e) \cdot x_e \qquad \text{(LP1)}$$

$$\text{subject to}$$

$$\sum_{e \in \delta(u)} x_e = 1 \quad \forall\, u \in A \cup B \qquad \text{and} \qquad x_e \geq 0 \quad \forall\, e \in E.$$

It follows from the definition of the function wt_M that the optimal value of (LP1) is $\max_N \Delta(N, M)$ where N is a perfect matching in G. So if M is a popular perfect matching then the optimal value of (LP1) is 0, which is $\Delta(M, M)$, i.e., the edge incidence vector of M is an optimal solution to (LP1). The linear program (LP2) is the dual of (LP1). Hence if M is a popular perfect matching then there exists a dual feasible $\vec{\alpha}$ such that $\sum_{u \in A \cup B} \alpha_u = 0$.

$$\text{minimize} \sum_{u \in A \cup B} y_u \qquad \text{(LP2)}$$

$$\text{subject to}$$

$$y_a + y_b \geq \mathsf{wt}_M(a,b) \quad \forall\, (a,b) \in E.$$

Let $\vec{\alpha}$ be an optimal solution to (LP2). Observe that there exists an integral optimal solution to (LP2) since the constraint matrix is totally unimodular. Thus we can assume that $\vec{\alpha} \in \mathbb{Z}^{2n_0}$, where $n_0 = |A| = |B|$.

▶ **Lemma 7.** *If M is a popular perfect matching in G then there exists an optimal solution $\vec{\alpha}$ to* (LP2) *such that $\alpha_a \in \{0, -2, -4, \ldots, -2(n_0-1)\}$ for all $a \in A$ and $\alpha_b \in \{0, 2, 4, \ldots, 2(n_0-1)\}$ for all $b \in B$.*

Proof. The dual feasibility constraints are $\alpha_a + \alpha_b \geq \mathsf{wt}_M(a,b)$ for all $(a,b) \in E$. For each edge $(a,b) \in M$: $\alpha_a + \alpha_b = \mathsf{wt}_M(a,b) = 0$ by complementary slackness. Since $\alpha_b = -\alpha_a$ for $(a,b) \in M$ and because $\mathsf{wt}_M(e) \in \{0, \pm 2\}$ for each edge e, we can assume that in the sorted order of distinct α-values taken by nodes in A, for any two consecutive values $\alpha_{a'}, \alpha_{a''}$, where $\alpha_{a'} > \alpha_{a''}$, we have $\alpha_{a'} - \alpha_{a''} = 2$.

Thus we can assume that $\alpha_a \in \{k, k-2, k-4, \ldots, k-2(n_0-1)\}$ for all $a \in A$ and $\alpha_b \in \{-k, -k+2, -k+4, \ldots, -k+2(n_0-1)\}$ for all $b \in B$, for some $k \in \mathbb{Z}$. Observe that k has no impact on the objective function $\sum_{u \in A \cup B} \alpha_u$. This is because $|A| = |B|$ and so k's and $-k$'s cancel each other out.

Let us update $\vec{\alpha}$ as follows: $\alpha_a = \alpha_a - k$ for every $a \in A$ and $\alpha_b = \alpha_b + k$ for every $b \in B$. The updated vector $\vec{\alpha}$ continues to be dual feasible since $\alpha_a + \alpha_b$, for any edge (a,b), is unchanged by this update. Thus there is an optimal solution $\vec{\alpha}$ to (LP2) such that $\alpha_a \in \{0, -2, \ldots, -2(n_0-1)\}$ for all $a \in A$ and $\alpha_b \in \{0, 2, \ldots, 2(n_0-1)\}$ for all $b \in B$. ◀

Let M be a popular perfect matching in G. In order to define a stable matching S in G^* such that $M = S'$ (the set S' is defined above Theorem 6), we will use the vector $\vec{\alpha}$ described in Lemma 7. Since M is perfect, we know that for any $a \in A$, there is an edge $(a,b) \in M$ for some neighbor b of a. Recall that $\alpha_a + \alpha_b = \mathsf{wt}_M(a,b) = 0$ by complementary slackness. We will include the edge $(a_i, \tilde{b})$ in S where $\alpha_a = -2i$ and $\alpha_b = 2i$. Thus we define S as follows:

$$S = \cup_{i=0}^{n_0-1} \{(a_i, \tilde{b}) : (a,b) \in M \text{ and } \alpha_a = -2i, \alpha_b = 2i\} \cup \{\text{necessary edges incident to dummy nodes in } G^*\}.$$

In more detail, the edges incident to dummy nodes that are present in S are as follows: for each $a \in A$, these edges are $(a_j, d_{j+1}(a))$ for $0 \leq j \leq i-1$ and $(a_j, d_j(a))$ for $i+1 \leq j \leq n_0-1$, where $\alpha_a = -2i$.

Since $(a_i, \tilde{b}) \in S$, all the n_0 nodes $a_0, \ldots, a_{n_0-1}$ and the dummy nodes $d_1(a), \ldots, d_{n_0-1}(a)$ corresponding to a in G^* are matched in S. This holds for every $a \in A$. Also every $\tilde{b} \in \tilde{B}$ is matched in S since M is a perfect matching in G. Thus S is a perfect matching in G^*. It is easy to check that $S' = M$. What we need to prove is the stability of S in G^*.

▶ **Theorem 8.** *The matching S is stable in G^*.*

Proof. We need to show there is no edge in G^* that blocks S. There is no blocking edge incident to a dummy node: this is because a dummy node $d_i(a)$ has only two neighbors and when $d_i(a)$ is matched in S to its second choice neighbor a_i, its top choice neighbor a_{i-1} prefers its partner in S to $d_i(a)$.

Let us now show that no node in $a_0, \ldots, a_{n_0-1}$ has a blocking edge incident to it, for any $a \in A$. Let $(a_i, \tilde{b}) \in S$ where $(a, b) \in M$. All of $a_{i+1}, \ldots, a_{n_0-1}$ are matched to their respective top choice neighbors $d_{i+1}(a), \ldots, d_{n_0-1}(a)$. So there is no blocking edge incident to any of $a_{i+1}, \ldots, a_{n_0-1}$.

All of $a_0, \ldots, a_{i-1}$ are matched to their last choice neighbors – these are the dummy nodes $d_1(a), \ldots, d_i(a)$, respectively. Consider any neighbor $w \in B$ of a. We need to show that $\tilde{w} \in \tilde{B}$ is matched in S to a neighbor preferred to all of $a_0, \ldots, a_{i-1}$. We have $\alpha_a + \alpha_w \geq \mathsf{wt}_M(a, w)$. Since $\alpha_a = -2i$ and $\mathsf{wt}_M(e) \geq -2$ for every edge e, it follows that $\alpha_w \geq 2i - 2$.

So $(z, w) \in M$ for some neighbor z of w such that $\alpha_z = -\alpha_w \leq -(2i-2)$. Equivalently, $(z_j, \tilde{w}) \in S$ where $j \geq i-1$. Thus there is no blocking edge between $\tilde{w}$ and any of $a_0, \ldots, a_{i-2}$ by $\tilde{w}$'s preference order in G^*. We will now show that $(a_{i-1}, \tilde{w})$ cannot be a blocking edge.

- If $j \geq i$ then by $\tilde{w}$'s preference order in G^*, $\tilde{w}$ prefers z_j to a_{i-1} and so $(a_{i-1}, \tilde{w})$ does not block S.
- If $j = i-1$ then $\mathsf{wt}_M(a, w) \leq \alpha_a + \alpha_w = -2i + 2i - 2 = -2$. So both a and w prefer their respective partners in M to each other. Thus $\tilde{w}$ prefers z_{i-1} to a_{i-1}. So $(a_{i-1}, \tilde{w})$ does not block S.

Finally, we need to show there is no blocking edge incident to a_i. By the above arguments, we only need to consider edges $(a_i, \tilde{w})$ where $(z_i, \tilde{w}) \in S$. So $\mathsf{wt}_M(a, w) \leq \alpha_a + \alpha_w = -2i + 2i = 0$. Hence either $(a, w) \in M$ or at least one of a, w prefers its partner in M to the other. So either $(a_i, \tilde{w}) \in S$ or at least one of $a_i, \tilde{w}$ prefers its partner in S to the other; thus the edge $(a_i, \tilde{w})$ does not block S. Hence S is a stable matching in G^*. ◀

4 The General Case

We showed that when G has a perfect matching, our mapping from the set of stable matchings in G^* to the set of popular max-matchings in G is surjective. Now we look at the general case, i.e., G need not have a perfect matching. Let M be a popular max-matching in G.

Let $U \subseteq A \cup B$ be the set of nodes left unmatched in M. Consider (LP3) that computes a max-weight perfect matching (with respect to wt_M) in the subgraph G' induced on $V = (A \cup B) \setminus U$. Let E' be the edge set of G'. For any $v \in V$, let $\delta'(v) = \delta(v) \cap E'$.

$$\text{maximize} \quad \sum_{e \in E'} \mathsf{wt}_M(e) \cdot x_e \qquad \text{(LP3)}$$

$$\text{subject to}$$

$$\sum_{e \in \delta'(v)} x_e = 1 \quad \forall\, v \in V \qquad \text{and} \qquad x_e \geq 0 \quad \forall\, e \in E'.$$

The optimal value of (LP3) is $\max_N \Delta(N, M)$ where N is a perfect matching in G'. Any perfect matching in G' is a maximum matching in G and since M is a popular max-matching in G, $\Delta(N, M) \leq 0$ for any perfect matching N in G'. Since $\Delta(M, M) = 0$, the edge incidence vector of M is an optimal solution to (LP3). The linear program (LP4) is the dual of (LP3).

$$\text{minimize} \sum_{u \in V} y_u \qquad \text{(LP4)}$$

$$\text{subject to}$$

$$y_a + y_b \;\geq\; \mathsf{wt}_M(a,b) \quad \forall\, (a,b) \in E'.$$

Since M is a popular max-matching, the optimal value of (LP3) is 0. So there exists an optimal solution $\vec{\alpha}$ to (LP4) such that $\sum_{u \in V} \alpha_u = 0$. Moreover, we can assume the following (see Lemma 7) where $A' = A \setminus U$ and $B' = B \setminus U$. Here $|A'| = |B'| = n_0$.

1. $\alpha_a \in \{0, -2, -4, \ldots, -2(n_0 - 1)\}$ for all $a \in A'$
2. $\alpha_b \in \{0, 2, 4, \ldots, 2(n_0 - 1)\}$ for all $b \in B'$.

For any $T \subseteq A \cup B$, let $\mathsf{Nbr}(T)$ be the set of neighbors in G of nodes in T. Theorem 9 is our main technical result here. Let $U_A = U \cap A$ and $U_B = U \cap B$.

▶ **Theorem 9.** *Let M be a popular max-matching in G and let U be the set of nodes left unmatched in M. There exists an optimal solution $\vec{\alpha}$ to* (LP4) *such that*

- $\alpha_a \in \{0, -2, \ldots, -2(n_0 - 1)\}$ *for* $a \in A'$ *and* $\alpha_b \in \{0, 2, \ldots, 2(n_0 - 1)\}$ *for* $b \in B'$
- *(i)* $\alpha_a = 0$ *for* $a \in \mathsf{Nbr}(U_B)$ *and (ii)* $\alpha_b = 2(n_0 - 1)$ *for* $b \in \mathsf{Nbr}(U_A)$.

Let us first finish our proof of surjectivity by assuming Theorem 9. Then we will prove Theorem 9. Let M be any popular max-matching in G. Corresponding to M, there is a vector $\vec{\alpha}$ as given in Theorem 9. We will use this vector $\vec{\alpha}$ to construct $S = \cup_{i=0}^{n_0 - 1} \{(a_i, \tilde{b}) : (a,b) \in M$ and $\alpha_a = -2i, \alpha_b = 2i\} \cup \{$necessary edges incident to dummy nodes in $G^*\}$.

The edges in S incident to dummy nodes are: $(a_j, d_{j+1}(a))$ for $0 \leq j \leq n_0 - 2$ for $a \in U_A$. For $a \in A \setminus U_A$, these are $(a_j, d_{j+1}(a))$ for $0 \leq j \leq i-1$ and $(a_j, d_j(a))$ for $i+1 \leq j \leq n_0 - 1$, where $\alpha_a = -2i$. It is easy to see that S is a matching in G^* and $S' = M$.

▶ **Theorem 10.** *The matching S is stable in G^*.*

Proof. Let E' be the edge set of G', where G' is the subgraph of G induced on $(A \cup B) \setminus U$. Consider any edge $(a_j, \tilde{w})$ in G^* where $(a,w) \in E'$ and $0 \leq j \leq n_0 - 1$. The proof of Theorem 8 shows that $(a_j, \tilde{w})$ does not block S.

Consider any edge (a,w) in $E \setminus E'$. Such an edge has a node in U as an endpoint. A useful observation is that every node in $\mathsf{Nbr}(U)$ has to be matched in M to some neighbor that it prefers to all its neighbors in U. Otherwise M would not be a popular max-matching.

- Suppose $a \in U_A$. So $w \in \mathsf{Nbr}(U_A)$ and $\alpha_w = 2(n_0 - 1)$ by property (ii) in Theorem 9. So $(z_{n_0 - 1}, \tilde{w}) \in S$ for some neighbor z that w prefers to a. Thus $(a_{n_0 - 1}, \tilde{w})$ does not block S. For $i \in \{0, \ldots, n_0 - 2\}$, none of the edges $(a_i, \tilde{w})$ can block S (by $\tilde{w}$'s preference order).
- Suppose $w \in U_B$. So $a \in \mathsf{Nbr}(U_B)$ and $\alpha_a = 0$ by property (i) in Theorem 9. Thus $(a_0, \tilde{b}) \in S$ for some neighbor b that a prefers to w. Hence $(a_0, \tilde{w})$ does not block S. Moreover, none of the edges $(a_i, \tilde{w})$ for $i \in \{1, \ldots, n_0 - 1\}$ can block S since $a_1, \ldots, a_{n_0 - 1}$ are matched to their respective top choice neighbors $d_1(a), \ldots, d_{n_0 - 1}(a)$.

Finally, no edge incident to a dummy node blocks S (by the same argument as given in the proof of Theorem 8). Hence S is a stable matching in G^*. ◀

Thus Theorem 9 allows us to show that for any popular max-matching M in G, there is a stable matching S in G^* such that $M = S'$. We will now prove Theorem 9.

Proof of Theorem 9. We know there is an optimal solution $\vec{\alpha}$ to (LP4) where $\alpha_a \in \{0, -2, \ldots, -2(n_0 - 1)\}$ for $a \in A'$ and $\alpha_b \in \{0, 2, \ldots, 2(n_0 - 1)\}$ for $b \in B'$. We now update $\vec{\alpha}$ so that it remains an optimal solution to (LP4) in the above format and it also satisfies properties (i) and (ii) given in the theorem statement.

Property (ii). Suppose the vector $\vec{\alpha} \in \{0, \pm 2, \ldots, \pm 2(n_0 - 1)\}^{2n_0}$ does not satisfy property (ii). So we have to update $\vec{\alpha}$ so that property (ii) is satisfied. First, we increase the α-values of the nodes in $\mathsf{Nbr}(U_A)$ to $2(n_0 - 1)$ and decrease the α-values of their partners in M to $-2(n_0 - 1)$. Now $\vec{\alpha}$ may no longer be a feasible solution to (LP4).

We use the following three update rules for all $a \in A'$ to make $\vec{\alpha}$ feasible again. Let $\alpha_a = -2i$ where $i \in \{0, \ldots, n_0 - 1\}$. Suppose there is some $(a, b) \in E'$ with $\alpha_a + \alpha_b < \mathsf{wt}_M(a, b)$. Let $M(b)$ be b's partner in M.

- *Rule 1.* If $\mathsf{wt}_M(a, b) = 0$ then update $\alpha_b = 2i$ and $\alpha_{M(b)} = -2i$.
- *Rule 2.* If $\mathsf{wt}_M(a, b) = -2$ then update $\alpha_b = 2(i - 1)$ and $\alpha_{M(b)} = -2(i - 1)$.
- *Rule 3.* If $\mathsf{wt}_M(a, b) = 2$ then update $\alpha_b = 2(i + 1)$ and $\alpha_{M(b)} = -2(i + 1)$.

At the onset, $\vec{\alpha}$ was a feasible solution to (LP4), so $\alpha_a + \alpha_b \geq \mathsf{wt}_M(a, b)$ for $(a, b) \in E'$. Then we moved the nodes in $\mathsf{Nbr}(U_A)$ and their partners in M to sets B_{n_0-1} and A_{n_0-1}, respectively, where $A_i = \{a \in A' : \alpha_a = -2i\}$ and $B_i = \{b \in B' : \alpha_b = 2i\}$ for all i. The subscript i will be called the *level* of nodes in $A_i \cup B_i$.

The nodes that moved to A_{n_0-1} have a lower α-value than earlier and it is these nodes that "pull" their neighbors upwards to higher levels as given by rules 1-3. Let a be a new node in level i and let b be a neighbor of a such that $\alpha_a + \alpha_b < \mathsf{wt}_M(a, b)$. Then b and $M(b)$ move to: (1) level i if $\mathsf{wt}_M(a, b) = 0$, (2) level $i - 1$ if $\mathsf{wt}_M(a, b) = -2$, else (3) level $i + 1$, i.e., if $\mathsf{wt}_M(a, b) = 2$.

In turn, the nodes in A' that have moved to these higher levels by rules 1-3 pull their neighbors and the partners of these neighbors upwards to higher levels by these rules. Thus we may get further new nodes in B_{n_0-1}, A_{n_0-1} and so on. While any of rules 1-3 is applicable, we apply that rule. So a rule may be applied many times to the same edge in E'.

Claim 11 (proved in Section 4.1) shows a useful property. We show in its proof that such a blocking edge creates a *forbidden* alternating cycle/path wrt M, as given in Theorem 5.

▷ Claim 11. By applying the above rules, suppose a node $v_0 \in A'$ moves to A_{n_0-1}. Then there is no blocking edge (e such that $\mathsf{wt}_M(e) = 2$) incident to v_0.

Applying rules 1-3 increases the α-values of some nodes in B' and it never decreases the α-value of any node in B'. The nodes in B' with increased α-values and their partners have moved to higher levels (see Fig. 1). This upwards movement of nodes has to terminate at level $n_0 - 1$. For the α-value of any $b \in B'$ to be increased beyond $2(n_0 - 1)$, we need a blocking edge (a, b) where $a \in A_{n_0-1}$ – this would cause rule 3 to be applied which would increase α_b to $2n_0$. However there is no such blocking edge (by Claim 11).

Since there are n_0 levels and because $|B'| = n_0$, there can be at most n_0^2 applications of these rules. When no rule is applicable, $\vec{\alpha}$ is a feasible solution to (LP4). Moreover, $\sum_{u \in V} \alpha_u$ is invariant under this update of α-values, since we maintain $\alpha_a + \alpha_b = 0$ for every $(a, b) \in M$. Hence $\vec{\alpha}$ is an optimal solution to (LP4). Thus for every popular max-matching M, there is an optimal solution $\vec{\alpha}$ to (LP4) in the desired format that satisfies property (ii).

Property (i). We now have an optimal solution $\vec{\alpha} \in \{0, \pm 2, \ldots, \pm 2(n_0 - 1)\}^{2n_0}$ to (LP4), where $\alpha_a \leq 0$ for all $a \in A'$ and $\alpha_b \geq 0$ for all $b \in B'$, such that $\alpha_b = 2(n_0 - 1)$ for all $b \in \mathsf{Nbr}(U_A)$. Suppose property (i) is not satisfied.

Then we increase α-values of certain nodes in A' – this moves these nodes *downwards* with respect to their level (see Fig. 1) and ensures that property (i) holds. First, we increase the α-values of the nodes in $\mathsf{Nbr}(U_B)$ to 0 and their partners also have α-values updated to 0. Now $\vec{\alpha}$ may no longer be a feasible solution to (LP4).

So we will use the following three update rules for all $b \in B'$. Let $\alpha_b = 2i$ where $i \in \{0, \ldots, n_0 - 1\}$. Suppose there is an edge $(a, b) \in E'$ such that $\alpha_a + \alpha_b < \mathsf{wt}_M(a, b)$. Let $M(a)$ be a's partner in M.

- *Rule 4.* If $\mathsf{wt}_M(a, b) = 0$ then update $\alpha_a = -2i$ and $\alpha_{M(a)} = 2i$.
- *Rule 5.* If $\mathsf{wt}_M(a, b) = -2$ then update $\alpha_a = -2(i + 1)$ and $\alpha_{M(a)} = 2(i + 1)$.
- *Rule 6.* If $\mathsf{wt}_M(a, b) = 2$ then update $\alpha_a = -2(i - 1)$ and $\alpha_{M(a)} = 2(i - 1)$.

Applying rules 4-6 increases the α-values of some nodes in A' and it never decreases the α-value of any node in A'. The nodes in A' with increased α-values and their partners have moved to lower levels. Moreover, the movement of nodes downwards has to stop at level 0 since no blocking edge can be incident to any node that moves to B_0 (analogous to Claim 11). While any of the above three rules is applicable, we apply that rule.

When no rule is applicable, $\vec{\alpha}$ is a feasible solution to (LP4). Since $\sum_{u \in V} \alpha_u = 0$, $\vec{\alpha}$ is an optimal solution to (LP4). So there is an optimal solution $\vec{\alpha}$ to (LP4) in the desired format that satisfies property (i).

Properties (i) and (ii). Note that we cannot claim straightaway that the above $\vec{\alpha}$ satisfies both property (i) and property (ii). This is because applying rules 4-6 may have caused $\alpha_b < 2(n_0 - 1)$ for some $b \in \mathsf{Nbr}(U_A)$. Claim 12 shows this is not possible.

▷ Claim 12. The above $\vec{\alpha}$ satisfies property (ii), i.e., $\alpha_b = 2(n_0 - 1)$ for $b \in \mathsf{Nbr}(U_A)$.

Claim 12 is proved in Section 4.1. So we have an optimal solution $\vec{\alpha}$ to (LP4) in the desired format that satisfies both property (i) and property (ii). ◀

4.1 Proofs of Claim 11 and Claim 12

The proofs of Claim 11 and Claim 12 use the fact that certain alternating cycles/paths are forbidden for popular max-matchings. These include the ones given in Theorem 5 and also augmenting paths (since M is a maximum matching).

Proof of Claim 11. Let v_0 be the first node that moves to A_{n_0-1} with a blocking edge incident to it. Recall our update procedure – we initially added nodes in $\mathsf{Nbr}(U_A)$ and their partners in M to B_{n_0-1} and A_{n_0-1}, respectively. Then we applied rules 1-3 in some order and this resulted in the node v_0 moving to A_{n_0-1}. Corresponding to these rules, we will construct an alternating path $p = v_0 - M(v_0) - v_1 - M(v_1) - v_2 - \cdots - v_k - M(v_k) - u$ between v_0 and some node $u \in U_A$.

The path p can be partitioned into $k + 1$ pairs of edges for some $k \geq 0$. For $0 \leq i \leq k - 1$: the i-th pair consists of the matching edge $(v_i, M(v_i))$ of weight 0 and the non-matching edge $e_i = (M(v_i), v_{i+1})$ where v_{i+1} is the node that pulled $M(v_i)$ and v_i to their current level due to the application of one of the above three rules. Rule 1 implies $\mathsf{wt}_M(e_i) = 0$ while rule 2 implies $\mathsf{wt}_M(e_i) = -2$ and rule 3 implies $\mathsf{wt}_M(e_i) = 2$.

Observe that rule 1 places $M(v_i)$ in the same level as v_{i+1} while rule 2 places $M(v_i)$ one level lower than v_{i+1} and rule 3 places $M(v_i)$ one level higher than v_{i+1}. The last pair of edges in p are $(v_k, M(v_k)) \in A_{n_0-1} \times B_{n_0-1}$ and $(M(v_k), u)$, where the latter edge has weight 0. The node v_0 is in level $n_0 - 1$ and the node $M(v_k)$ is also in level $n_0 - 1$. So v_0 and v_k are at the same level, hence the number of edges in p of weight -2 is exactly the same as the number of edges of weight 2, thus $\mathsf{wt}_M(p) = 0$.

Suppose there is a blocking edge (v_0, w). If w belongs to p, then it is easy to see that the alternating cycle C obtained by joining the endpoints of the v_0-w subpath in p with the edge (v_0, w) satisfies $\mathsf{wt}_M(C) \geq 2$. This contradicts Theorem 5 since M is a popular max-matching. Hence w does not belong to path p. So let us add the 2-edge path $M(w) - w - v_0$ as a prefix to the v_0-u path p and call this alternating path q: we have $\mathsf{wt}_M(q) = \mathsf{wt}_M(p) + \mathsf{wt}_M(v_0, w) = 2$. Since $\mathsf{wt}_M(q) > 0$ and the unmatched node u is an endpoint of q, this again contradicts Theorem 5. Hence there is no blocking edge incident to v_0. ◁

Proof of Claim 12. Suppose there is a node $w_1 \in \mathsf{Nbr}(U_A)$ such that $\alpha_{w_1} < 2(n_0 - 1)$. So there is some $u \in U_A$ such that $(u, w_1) \in E$ and though $\alpha_{w_1} = 2(n_0 - 1)$ just before we started applying rules 4-6, the application of these rules caused α_{w_1} to become less than $2(n_0 - 1)$.

Initially we added nodes in $\mathsf{Nbr}(U_B)$ and their partners in M to A_0 and B_0, respectively. Then we repeatedly applied rules 4-6 and this resulted in w_1 moving to a level lower than $n_0 - 1$. Corresponding to what caused w_1 to be "pulled" downwards, we will construct an alternating path $p = w_1 - M(w_1) - w_2 - M(w_2) - \cdots - w_r - M(w_r) - u'$ between w_1 and a node $u' \in U_B$.

The path p will consist of r pairs of edges for some $r \geq 1$. For $1 \leq i \leq r - 1$: the i-th pair of edges is $(w_i, M(w_i))$ and $(M(w_i), w_{i+1})$ where w_{i+1} is the node that pulled $M(w_i)$ and w_i to their current level due to the application of one of rules 4-6. The last pair of edges in p is $(w_r, M(w_r))$ and $(M(w_r), u')$, where $w_r \in B_0, M(w_r) \in A_0$, and $u' \in U_B$. Thus we have an alternating path p between w_1 and $u' \in U_B$.

By adding the edge (u, w_1) as a prefix to the path p, we get an augmenting path $u - w_1 - \cdots - M(w_r) - u'$ with respect to M. However there cannot be any augmenting path wrt M since M is a maximum matching in G. Thus $\vec{\alpha}$ satisfies property (ii). ◁

This finishes the proof of Theorem 9. So the stable matching polytope of G^* yields a compact extended formulation for the popular max-matching polytope of G (by Theorem 6 and Theorem 10). This formulation is described in Section 4.2.

Linear programming on this formulation with $\min \sum_{e \in E} c(e) \cdot x_e$ as the objective function computes a min-cost popular max-matching in G in polynomial time. Equivalently, we can compute a min-cost stable matching S in G^* and return the corresponding matching S' in G. It follows from Theorem 6 and Theorem 10 that S' is a min-cost popular max-matching in G. This proves Theorem 3 stated in Section 1.

4.2 An Extended Formulation for the Popular Max-Matching Polytope

For any node u in G^*, let $\{v' \succ_u v\}$ be the set of all neighbors of u in G^* that it prefers to v. Let $\delta^*(u)$ denote the set of edges incident to u in G^*.

Let $T = \cup_{a \in A}(\{a_0, \ldots, a_{n_0-2}\} \cup \{d_1(a), \ldots, d_{n_0-1}(a)\})$. Every node in T is a top choice neighbor for some node, so every node in T has to be matched in all stable matchings in G^*. The constraints given below describe the stable matching polytope of G^*, as shown in [30].

$$\sum_{w \succ_{a_i} \tilde{b}} x_{(a_i,w)} + \sum_{z \succ_{\tilde{b}} a_i} x_{(z,\tilde{b})} + x_{(a_i,\tilde{b})} \geq 1 \qquad \forall (a_i, \tilde{b}) \in E^*$$

$$\sum_{e \in \delta^*(u)} x_e = 1 \qquad \forall\, u \in T$$

$$\sum_{e \in \delta^*(u)} x_e \leq 1 \quad \forall u \in A^* \cup B^* \qquad \text{and} \qquad x_e \geq 0 \qquad \forall e \in E^*.$$

1. The topmost constraint captures the *stability* constraint for edge $(a_i, \tilde{b}) \in E^*$ where $(a, b) \in E$ and $0 \leq i \leq n_0 - 1$.
2. The constraint in the second line for $u = a_{i-1}$ captures the stability constraint for the edge $(a_{i-1}, d_i(a))$ and for $u = d_i(a)$ captures the stability constraint for the edge $(a_i, d_i(a))$.
3. The constraints in the third line capture that $\vec{x}$ belongs to the matching polytope of G^*.

Consider the equations $x_{(a,b)} = \sum_{i=0}^{n_0-1} x_{(a_i,\tilde{b})}$ for all $(a, b) \in E$. It follows from Theorem 6 and Theorem 10 that these m equations along with the constraints of the stable matching polytope of G^* given above describe an extended formulation for the popular max-matching polytope $\mathcal{M}_G$. So the extension complexity of the polytope $\mathcal{M}_G$ is $O(mn)$.

5 A Hardness Result

In this section we show that it is NP-hard to compute a min-cost Pareto-optimal matching and a min-cost Pareto-optimal max-matching in an instance $G = (A \cup B, E)$ with edge costs in $\{0, 1\}$.

Given a 3SAT formula ψ, we will build an instance G_ψ with edge costs in $\{0, 1\}$ such that G_ψ admits a Pareto-optimal matching of cost 0 if and only if ψ is satisfiable. Any Pareto-optimal matching of cost 0 would have to be a perfect matching in G_ψ. Hence this will prove the NP-hardness of both the min-cost Pareto-optimal matching problem and the min-cost Pareto-optimal max-matching problem.

Our reduction resembles a hardness reduction from [9] that showed the NP-hardness of deciding if an instance G has a stable matching M that is also dominant. As done in this reduction, we will first transform ψ so that every clause contains either only positive literals or only negative literals; moreover, there will be a single occurrence of each negative literal in the transformed ψ. This is easy to achieve:

- let $X_1, \ldots, X_n$ be the starting variables. For $i \in [n]$: replace all occurrences of $\neg X_i$ with the same variable X_{n+i} (a new one) and add the two clauses $(X_i \vee X_{n+i}) \wedge (\neg X_i \vee \neg X_{n+i})$ to capture $\neg X_i \equiv X_{n+i}$. Thus there are $2n$ variables in the transformed ψ.

We build the graph G_ψ as follows. There are two types of gadgets: those that correspond to positive clauses and those that correspond to negative clauses. Fig. 2 (resp., Fig. 3) shows how a positive (resp., negative) clause gadget looks like.

We now describe the preference lists of nodes in a positive clause $C_\ell = x \vee y \vee z$ (see Fig. 2). The nodes a_x, a'_x, b_x, b'_x occur in x's gadget and a_y, a'_y, b_y, b'_y occur in y's gadget and a_z, a'_z, b_z, b'_z occur in z's gadget: these gadgets are in the ℓ-th clause gadget C_ℓ. Every occurrence of a literal has a separate gadget.

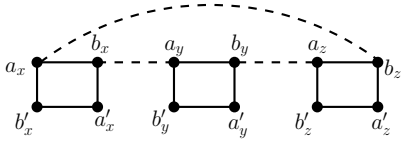

Figure 2 The clause gadget for a positive clause $C_\ell = x \vee y \vee z$. Every occurrence of a literal in ψ has a separate gadget. So we ought to use labels such as $a_{x,\ell}, b_{x,\ell}, \ldots$ here; for the sake of simplicity, we used the labels $a_x, b_x, \ldots$ here.

a_x	a'_x	a_y	a'_y	a_z	a'_z
b_z	b_x	b_x	b_y	b_y	b_z
b_x	b'_x	b_y	b'_y	b_z	b'_z
d'_x	–	d'_y	–	d'_z	–
b'_x	–	b'_y	–	b'_z	–

Here a_x's top choice is b_z, second choice b_x, third choice d'_x, fourth choice b'_x, and similarly for other nodes. For every occurrence of a positive literal x: there will be a pair of *consistency edges* – the pair (a_x, d'_x) and (b'_x, c_x) in Fig. 4 – between this gadget of x and the unique gadget of $\neg x$. In our preferences, the neighbors on consistency edges are marked in red.

b_x	b'_x	b_y	b'_y	b_z	b'_z
a_y	a'_x	a_z	a'_y	a_x	a'_z
a_x	c_x	a_y	c_y	a_z	c_z
a'_x	a_x	a'_y	a_y	a'_z	a_z

The preference lists of nodes that occur in a clause gadget with 2 positive literals will be totally analogous to the preference lists of nodes in a clause gadget with 3 positive literals.

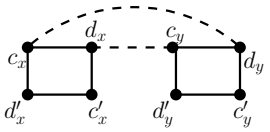

Figure 3 A clause gadget corresponding to a negative clause $D_k = \neg x \vee \neg y$; due to our transformation of ψ, every negative clause has only 2 literals.

We will now describe the preference lists of nodes in a negative clause k – the overall picture here is given in Fig. 3.

c_x	c'_x	c_y	c'_y
d_y	d_x	d_x	d_y
d_x	d'_x	d_y	d'_y
$b'_{x,i}$	–	$b'_{y,i'}$	–
$\cdots$	–	$\cdots$	–
$b'_{x,j}$	–	$b'_{y,j'}$	–
d'_x	–	d'_y	–

d_x	d'_x	d_y	d'_y
c_y	c'_x	c_x	c'_y
c_x	$a_{x,i}$	c_y	$a_{y,i'}$
c'_x	$\cdots$	c'_y	$\cdots$
–	$a_{x,j}$	–	$a_{y,j'}$
–	c_x	–	c_y

The nodes c_x, c'_x, d_x, d'_x and c_y, c'_y, d_y, d'_y occur in the gadgets of $\neg x$ and $\neg y$, respectively. The nodes $b'_{x,i}, \ldots, b'_{x,j}$ (resp., $b'_{y,i'}, \ldots, b'_{y,j'}$) in the preference lists above are the b'-nodes in the x-gadgets (resp., y-gadgets) in the various clauses that x (resp., y) occurs in. Similarly, $a_{x,i}, \ldots, a_{x,j}$ (resp., $a_{y,i'}, \ldots, a_{y,j'}$) are the a-nodes in the x-gadgets (resp., y-gadgets) in the

various clauses that x (resp., y) occurs in. The preference order among the b'-nodes and among the a-nodes in these lists is not important. The consistency edges between a gadget of x and the gadget of $\neg x$ are shown in Fig. 4.

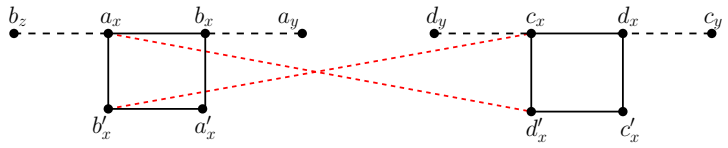

Figure 4 For the sake of simplicity, we use a_x, b_x, a'_x, b'_x to denote the 4 nodes in the gadget of x in the ℓ-th clause; c_x, d_x, c'_x, d'_x are the 4 nodes in the unique gadget of $\neg x$. The consistency edges are the red dashed edges.

Edge costs. For each edge e in G_ψ, we will set $\mathsf{cost}(e) \in \{0, 1\}$ as follows.

- For each variable $r \in \{X_1, \ldots, X_{2n}\}$: set $\mathsf{cost}(e) = 0$ where e is any of the 4 edges in any literal gadget $\langle a_r, b_r, a'_r, b'_r\rangle$ of r or any of the 4 edges in the gadget $\langle c_r, d_r, c'_r, d'_r\rangle$ of $\neg r$.
- For all other edges e, set $\mathsf{cost}(e) = 1$.

In particular, for any edge e in the consistency pair for any variable, we have $\mathsf{cost}(e) = 1$. In our figures, all dashed edges have cost 1 and all solid edges have cost 0.

Let M be a Pareto-optimal matching in G_ψ with $\mathsf{cost}(M) = 0$. So M has to use only cost 0 edges. Thus M is forbidden to use any edge other than the 4 edges in the gadget of any literal. Moreover, since M is Pareto-optimal, M cannot leave two adjacent nodes unmatched. Thus for $r \in \{X_1, \ldots, X_{2n}\}$:

1. From a gadget of r (say, on nodes a_r, b_r, a'_r, b'_r), either (i) $(a_r, b_r), (a'_r, b'_r)$ are in M or (ii) $(a_r, b'_r), (a'_r, b_r)$ are in M.
2. From the gadget of $\neg r$ (the nodes are c_r, d_r, c'_r, d'_r), either (i) $(c_r, d_r), (c'_r, d'_r)$ are in M or (ii) $(c_r, d'_r), (c'_r, d_r)$ are in M.

Thus any Pareto-optimal matching in G_ψ of cost 0 is a perfect matching. Lemma 13 will be useful to us.

▶ **Lemma 13.** *Let M be a Pareto-optimal matching in G_ψ. For any $r \in \{X_1, \ldots, X_{2n}\}$, both (a_r, b'_r) and (c_r, d'_r) cannot simultaneously be in M.*

Proof. The preferences of the nodes are set such that if both (a_r, b'_r) and (c_r, d'_r) are in M then both the non-matching edges (a_r, d'_r) and (b'_r, c_r) in the alternating cycle $\rho = a_r - (d'_r, c_r) - (b'_r, a_r) - d'_r$ are blocking edges to M. Consider $M \oplus \rho$ versus M. All the 4 nodes a_r, b'_r, c_r, d'_r prefer $M \oplus \rho$ to M while the other nodes are indifferent between $M \oplus \rho$ and M. Thus $\phi(M \oplus \rho, M) = 4$ and $\phi(M, M \oplus \rho) = 0$, so $u(M) = \infty$. This means M is not Pareto-optimal, a contradiction. Thus for any $r \in \{X_1, \ldots, X_{2n}\}$, we cannot have both (a_r, b'_r) and (c_r, d'_r) in M. ◀

Theorem 14 is our main result here.

▶ **Theorem 14.** *G_ψ has a Pareto-optimal matching M with $\mathsf{cost}(M) = 0$ if and only if ψ is satisfiable.*

Proof. Suppose G_ψ has a Pareto-optimal matching M with $\mathsf{cost}(M) = 0$. For any variable $r \in \{X_1, \ldots, X_{2n}\}$, consider the edges in $\neg r$'s gadget that are in M. If $(c_r, d'_r), (c'_r, d_r)$ are in M then set $r = \mathsf{false}$ else set $r = \mathsf{true}$.

Lemma 13 tells us that when we set r to false, the edges $(a_{r,i}, b_{r,i}), (a'_{r,i}, b'_{r,i})$ from r's gadget in the i-th clause have to be in M (where $a_{r,i}, b_{r,i}, a'_{r,i}, b'_{r,i}$ are the 4 nodes from r's gadget in the i-th clause).

▷ Claim 15. The above assignment satisfies ψ.

Claim 15 uses the Pareto-optimality of M to show that every clause has at least one literal set to true. Its proof is given after the proof of Theorem 14. Hence if G_ψ admits a Pareto-optimal matching M with $\mathsf{cost}(M) = 0$, then ψ is satisfiable.

The converse. We will now show that if ψ is satisfiable then there is a Pareto-optimal matching M in G_ψ such that $\mathsf{cost}(M) = 0$. There is a natural way of constructing the matching M – we will use the satisfying assignment for ψ to choose edges from each literal gadget. For any variable r, include the following edges in the matching M:

- if $r =$ true then take the edges $(c_r, d_r), (c'_r, d'_r)$ from $\neg r$'s gadget and the edges $(a_{r,i}, b'_{r,i})$, $(a'_{r,i}, b_{r,i})$ from r's gadget in clause i (for every clause i that r belongs to).
- if $r =$ false then take the edges $(c_r, d'_r), (c'_r, d_r)$ from $\neg r$'s gadget and the edges $(a_{r,i}, b_{r,i})$, $(a'_{r,i}, b'_{r,i})$ from r's gadget in clause i (for every clause i that r belongs to).

It is easy to see that $\mathsf{cost}(M) = 0$. Since M is a perfect matching, there is no alternating path ρ wrt M such that $\phi(M, M \oplus \rho) = 0$. This is because for every alternating path ρ wrt M, we have $|M \oplus \rho| < |M|$ and the nodes matched in M and unmatched in $M \oplus \rho$ prefer M to $M \oplus \rho$, so $\phi(M, M \oplus \rho) > 0$. Hence in order to prove M's Pareto-optimality, what we need to show is Claim 16.

▷ Claim 16. There is no alternating cycle ρ with respect to M such that $\phi(M \oplus \rho, M) > 0$ and $\phi(M, M \oplus \rho) = 0$.

The proof of Claim 16 is given below. This finishes the proof of Theorem 14. ◀

Proof of Claim 15. Suppose this assignment does not satisfy ψ. We have 3 cases here.

1. Let $C_i = x \vee y \vee z$. Suppose all the three variables x, y, z are in false state. Consider the following alternating cycle ρ wrt M:

   $$b_{z,i} - (a_{x,i}, b_{x,i}) - (a_{y,i}, b_{y,i}) - (a_{z,i}, b_{z,i}) - a_{x,i}.$$

   All non-matching edges in this alternating cycle, i.e., the edges $(b_{z,i}, a_{x,i})$, $(b_{x,i}, a_{y,i})$, $(b_{y,i}, a_{z,i})$, are blocking edges with respect to M. In the $M \oplus \rho$ versus M comparison, these 6 nodes $a_{x,i}, b_{x,i}, a_{y,i}, b_{y,i}, a_{z,i}, b_{z,i}$ prefer $M \oplus \rho$ to M while all other nodes in G_ψ are indifferent between $M \oplus \rho$ and M. Thus we have $\phi(M \oplus \rho, M) = 6$ and $\phi(M, M \oplus \rho) = 0$. Hence $u(M) = \infty$, contradicting the Pareto-optimality of M.
2. Let $C_j = x \vee y$, i.e., this is a positive clause with 2 literals. Suppose both x and y are in false state. Consider the following alternating cycle ρ wrt M:

   $$b_{y,j} - (a_{x,j}, b_{x,j}) - (a_{y,j}, b_{y,j}) - a_{x,j}.$$

   In the $M \oplus \rho$ versus M comparison, the 4 nodes $a_{x,j}, b_{x,j}, a_{y,j}, b_{y,j}$ prefer $M \oplus \rho$ to M while all the other nodes in G_ψ are indifferent between $M \oplus \rho$ and M. Thus $\phi(M \oplus \rho, M) = 4$ and $\phi(M, M \oplus \rho) = 0$. Hence $u(M) = \infty$, contradicting the Pareto-optimality of M.
3. Let $D_k = \neg x \vee \neg y$. Suppose both $\neg x$ and $\neg y$ are in false state. Consider the following alternating cycle ρ wrt M:

   $$d_y - (c_x, d_x) - (c_y, d_y) - c_x.$$

In the $M \oplus \rho$ versus M comparison, the 4 nodes c_x, d_x, c_y, d_y prefer $M \oplus \rho$ to M while all the other nodes in G_ψ are indifferent between $M \oplus \rho$ and M. So $\phi(M \oplus \rho, M) = 4$ and $\phi(M, M \oplus \rho) = 0$. Hence $u(M) = \infty$, contradicting the Pareto-optimality of M.

Thus every clause in ψ has at least one literal in true state. ◁

Proof of Claim 16. We need to show there is no alternating cycle ρ with respect to M such that $\phi(M \oplus \rho, M) > 0$ and $\phi(M, M \oplus \rho) = 0$. Every non-matching edge in such an alternating cycle ρ has to be a blocking edge wrt M.

First, we argue that every consistency edge is a *non-blocking* edge to M; say, this is a consistency edge corresponding to variable r in clause i. It follows from our construction of M that M contains either:

1. $(a_{r,i}, b'_{r,i}), (a'_{r,i}, b_{r,i})$ and $(c_r, d_r), (c'_r, d'_r)$ or
2. $(a_{r,i}, b_{r,i}), (a'_{r,i}, b'_{r,i})$ and $(c_r, d'_r), (c'_r, d_r)$.

- case 1: the node d'_r prefers $M(d'_r) = c'_r$ to $a_{r,i}$ and the node c_r prefers $M(c_r) = d_r$ to $b'_{r,i}$.
- case 2: the node $a_{r,i}$ prefers $M(a_{r,i}) = b_{r,i}$ to d'_r and the node $b'_{r,i}$ prefers $M(b'_{r,i}) = a'_{r,i}$ to c_r.

Thus in both cases, the consistency edges $(a_{r,i}, d'_r)$ and $(b'_{r,i}, c_r)$ are non-blocking edges to M. Let H be the subgraph of G_ψ obtained by preserving only the edges that are in M and also blocking edges wrt M. Thus no non-blocking edge (other than edges in M) is included in H – so no consistency edge belongs to H.

Since there are no consistency edges in H, any alternating cycle in H has to be contained within a single clause. We will now show there is no such cycle in H by using the fact that we constructed M using a satisfying assignment for ψ: thus every clause has at least one literal set to true.

Let $C = x \vee y \vee z$ and suppose $y = \mathsf{true}$ in ψ. Then (a_y, b'_y) and (a'_y, b_y) are in M, however the edge (a'_y, b'_y) is non-blocking wrt M and hence it is missing in H. Thus there is no alternating cycle in H that is contained within the clause C. Now consider a negative clause $D = \neg x \vee \neg y$ and suppose $x = \mathsf{false}$ in ψ. Then (c_x, d'_x) and (c'_x, d_x) are in M, however the edge (c'_x, d'_x) is non-blocking wrt M and it is missing in H. Thus there is no alternating cycle in H that is contained within the clause D.

Consider the 4 edges of any literal gadget (say, r) in G_ψ: if $(a_r, b_r) \in M$ then (a_r, b'_r) is a non-blocking edge wrt M and if $(a'_r, b_r) \in M$ then (a'_r, b'_r) is a non-blocking edge wrt M. Similarly, in the gadget of $\neg r$: if $(c_r, d_r) \in M$ then (c_r, d'_r) is a non-blocking edge wrt M and if $(c'_r, d_r) \in M$ then (c'_r, d'_r) is a non-blocking edge wrt M. Thus there is no alternating cycle wrt M in H. So there is no alternating cycle ρ in G_ψ such that $\phi(M \oplus \rho, M) > 0$ and $\phi(M, M \oplus \rho) = 0$. ◁

Since any Pareto-optimal matching in G_ψ of cost 0 is a perfect matching, Theorem 14 shows that the min-cost Pareto-optimal matching problem and the min-cost Pareto-optimal max-matching problem are NP-hard. Moreover, these problems are NP-hard to approximate to any multiplicative factor. Thus we have shown Theorem 4 stated in Section 1.

Abstract

A map is a 2-cell decomposition of a closed compact surface, i.e., an embedding of a graph such that every face is homeomorphic to an open disc. An automorphism of a map can be thought of as a permutation of the vertices which preserves the vertex-edge-face incidences in the embedding. When the underlying surface is orientable, every automorphism of a map determines an angle-preserving homeomorphism of the surface. While it is conjectured that there is no "truly subquadratic" algorithm for testing map isomorphism for unconstrained genus, we present a linear-time algorithm for computing the generators of the automorphism group of a map, parametrized by the genus of the underlying surface. The algorithm applies a sequence of local reductions and produces a uniform map, while preserving the automorphism group. The automorphism group of the original map can be reconstructed from the automorphism group of the uniform map in linear time. We also extend the algorithm to non-orientable surfaces by making use of the antipodal double-cover.

1 Introduction

The graph isomorphism problem asks whether or not two given graphs are isomorphic. It is one of the most fundamental problems in the theory of algorithms. It is probably the most notorious problem whose computational complexity is still a huge open question, even after Babai's recent quasipolynomial-time breakthrough [2]. While some complexity theoretic results indicate that this problem is unlikely NP-complete (if it was, the polynomial hierarchy would collapse to its second level, see [28]), no polynomial-time algorithm is known, even with extended resources like randomization or quantum computing.

On the other hand, there is a number of important classes of graphs on which the graph isomorphism problem is known to be solvable in polynomial time. These include graphs with bounded degree [23, 9], bounded eigenvalue multiplicity [3], bounded tree-width [22, 10], excluded small minors [11], etc.

In this paper, we are interested in planar graphs and, more generally, graphs of bounded genus. In 1966, Weinberg [30] gave a very simple quadratic algorithm for the graph isomorphism of planar graphs. This was improved by Hopcroft and Tarjan [16] to $\mathcal{O}(n \log n)$. Building, on this earlier work, Hopcroft and Wong [17] published in 1974 a paper, where they described a linear-time algorithm for isomorphism testing of planar graphs.

For graphs on surfaces of higher genus, the graph isomorphism problem seems much harder. This can be perhaps explained in the following way. We can rather easily reduce the problem to 3-connected graphs. For planar graphs, the famous result of Whitney [31] says that embeddings of 3-connected planar graphs in the plane are (combinatorially) unique. But for every simply connected surface, there exist 3-connected graphs with exponentially many embeddings. This makes an essential difference between planar graphs and graphs of higher genus.

For quite a long time it has been known that the isomorphism of bounded genus graphs can be solved in time $n^{\mathcal{O}(g)}$, where g is the genus of the underlying surface; see for example [27]. However, an interesting question is whether the result of Hopcroft and Wong [17] can be generalized also for the bounded genus graphs, i.e., whether the isomorphism problem for graphs of bounded genus can be solved in time $f(g) \cdot n$, for some computable function f. This motivates the study of the isomorphism problem for embedded graphs first.

By a *topological map* we mean a 2-cell decomposition of a closed compact surface, i.e., an embedding of a graph into a surface such that every face is homeomorphic to an open disc. An *isomorphism* of two maps is an isomorphism of the underlying graphs, which preserves the vertex-edge-face incidences. In particular, a map isomorphism induces a homeomorphism of the underlying surfaces. Our main result reads as follows.

▶ **Theorem 1.** *Let M_1 and M_2 be maps on a surface of genus g. The set of all isomorphisms* $\mathrm{Iso}(M_1, M_2)$ *from M_1 to M_2 can be determined in time $f(g) \cdot (\|M_1\| + \|M_2\|)$, where f is some computable function and $\|M\|$ denotes the size of the map M.*

In [21], two of the authors deal with a much weaker version of this problem, where only testing isomorphism is considered instead of constructing the whole set $\mathrm{Iso}(M_1, M_2)$. Recently, a linear-time algorithm was announced [19] for testing isomorphism of bounded genus graphs and the proposed approach heavily relies on our result. It should be also mentioned, that an algorithm with running time $n^{\mathcal{O}((\log g)^c)}$ for bounded genus graphs follows from [26], however, this result is based on completely different techniques.

Determining the set of all isomorphisms between two maps is closely related to finding the generators of the automorphism group $\mathrm{Aut}(M)$ of a map M, where an automorphism of M is just an isomorphism $M \to M$. More precisely, the set of all isomorphisms $M_1 \to M_2$ can be expressed as a composition $\psi \cdot \mathrm{Aut}(M_1)$ where $\psi : M_1 \to M_2$ is any isomorphism. Thus, our first result goes hand-in-hand with the following.

▶ **Theorem 2.** *Let M be a map on a surface of genus g. The generators of the automorphism group* $\mathrm{Aut}(M)$ *of M can be computed in time $f(g) \cdot \|M\|$, where f is some computable function and $\|M\|$ denotes the size of the map M.*

Colbourn and Booth [7] proposed a way to modify the Hopcroft-Wong algorithm [17] to compute the generators of the automorphism group of a spherical map. However, they state the following: "*We ... base our automorphism algorithms on the Hopcroft-Wong algorithm. Necessarily, we will only be able to sketch our procedure. A more complete description and a*

proof of correctness would require a more thorough analysis of the Hopcroft-Wong algorithm than has yet appeared in the literature." Sadly, the situation has not changed since, and the only available description of the Hopcroft-Wong algorithm is the extended abstract [17], which contains no proof of correctness and running time.[1] Our contribution also fills in this gap and we obtain much better insight into the Hopcroft-Wong algorithm by solving the problem in a much greater generality; see [20] as well.

Roughly speaking, the key idea of the Hopcroft-Wong algorithm is to try to apply contractions of edges to obtain two smaller isomorphic maps. In order to do this, edges must be chosen canonically, which is not always possible. Since Hopcroft and Wong consider only the spherical case, this situation occurs only in one special case. However, on the surfaces of higher genus, this situation is quite common and requires a completely different, more systematic, approach. As a consquence of considering the problem on the higher genus, our approach turnes out to be much simpler even for planar graphs than the approach originally proposed by Colbourn and Booth [7].

The Hopcroft-Wong algorithm reduces spherical maps to maps having the same degrees of vertices and also the same degrees of faces (e.g. Platonic solids). These maps are then treated separately. We, however, relax this condition and instead reduce our map to a map having the same cyclic vector of face sizes at each vertex (e.g. on sphere these also include Archimedean solids). The number of such maps is bounded for surfaces of genus $g > 1$, and for surfaces of genus $g \leq 1$ we give some special algorithms. This, surprisingly, allows a much more unified method of reducing the map, while preserving its automorphisms and isomorphisms.

Simultaneous conjugation problem. The problems of testing isomorphism of maps and computing the generators of the automorphism group of a map are related to the problem of *simultaneous conjugation*. In the latter problem, the input consists of two sets of permutations $\alpha_1, \ldots, \alpha_d$ and $\beta_1, \ldots, \beta_d$ on the set $\{1, \ldots, n\}$, each of which generates a transitive subgroup of the symmetric group. The goal is to find a permutation γ such that $\gamma\alpha_i\gamma^{-1} = \beta_i$, for $i = 1, \ldots, d$. Let us observe that this problem is a generalization of the map isomorphism problem. If α_1 and β_1 are involutions, $d = 2$, and the set $\{1, \ldots, n\}$ is identified with the set of darts of a map on a surface (see Section 2 for definitions), then this problem is exactly the map isomorphism problem. If further $\alpha_1 = \beta_1$ and $\alpha_2 = \beta_2$, we get the map automorphism problem.

Since mid 1970s it has been known that the simultaneous conjugation problem can be solved in time $\mathcal{O}(dn^2)$ [8, 15]. A faster algorithm, with running time $\mathcal{O}(n^2 \log d/\log n + dn \log n)$, was found only recently [6]. This implies an $\mathcal{O}(n^2/\log n)$ algorithm for the isomorphism and automorphism problems for maps of unrestricted genus. In complexity theory, this is not considered to be a "truly subquadratic" algorithm. This motivates the following conjecture.

▶ **Conjecture 3.** *There is no $\varepsilon > 0$ for which there is an algorithm for testing isomorphism of maps of unrestricted genus in time $\mathcal{O}(n^{2-\varepsilon})$.*

An interesting open subproblem is to prove a conditional "truly superlinear" lower bound for any of the mentioned problems. There has been some progress in the direction of providing a lower bound. In particular it is known that the communication complexity of the simultaneous conjugation problem is $\Omega(dn \log(n))$, for $d > 1$, and that under the decision tree model the search version of the simultaneous conjugation problem has lower bound of $\Omega(n \log n)$ [5].

[1] The PhD thesis of Wong also does not bring any new information compared to [17].

2 Preliminaries

A *map* M is an embedding $\iota\colon X \to S$ of a connected graph X to a closed connected compact surface S such that every connected component of $S \setminus \iota(X)$ is homeomorphic to an open disc. The connected components are called *faces*. By $V(M)$, $E(M)$, and $F(M)$ we denote the sets of vertices, edges, and faces of M, respectively. We put $v(M) := |V(M)|$, $e(M) := |E(M)|$, and $f(M) := |F(M)|$.

Recall that closed connected compact surfaces are characterized by two invariants: orientability and the Euler characteristic χ. For the orientable surfaces, the latter can be replaced by the *(orientable) genus* $g \geq 0$, which is the number of tori in the connected sum decomposition of the surface, and for the non-orientable surfaces by the *non-orientable genus* $\gamma \geq 1$, which is the number of real projective planes in the connected sum decomposition of the surface. The following is well-known.

▶ **Theorem 4** (Euler-Poincaré formula). *Let M be a map on a surface S. Then $v(M) - e(M) + f(M) = \chi(S) = 2 - 2g$ if S has genus g and $\chi(S) = 2 - \gamma$ if S has non-orientable genus γ.*

We give an algebraic description of a map, where a map is defined by means of three fixed-point-free involutions acting on *flags*. A flag is a triple representing a vertex-edge-face incidence. The involutions are simply instructions on how to join the flags together to form a map. There are several advantages: (i) in such a form, maps can be easily passed to an algorithm as an input, (ii) verifying whether a mapping is an automorphism reduces to checking three commuting rules, and (iii) group theory techniques can be applied to obtain results about maps. For more details see for example [18] and [13, Section 7.6].

Oriented maps. Even though our main concern is in general maps, a large part of our algorithm deals with maps on orientable surfaces, where the algebraic description is simpler. An *oriented map* is a map on an orientable surface with a fixed global orientation. Every oriented map can be combinatorially described as a triple (D, R, L). Here, D is the set of *darts*. By a dart we mean an edge endowed with one of two possible orientations. Hence, each edge gives rise to two darts. The permutation $R \in \mathrm{Sym}(D)$, called *rotation*, is the product $R = \Pi_{v \in V} R_v$, where each R_v cyclically permutes the darts originating at $v \in V$, following the chosen orientation around v. The *dart-reversing involution* $L \in \mathrm{Sym}(D)$ is an involution of D that, for each edge, swaps the two oppositely oriented darts arising from the edge.

Formally, a *combinatorial oriented map* is any triple $M = (D, R, L)$, where D is a finite non-empty set of *darts*, R is any permutation of darts, L is a fixed-point-free involution of D, and the group $\langle R, L\rangle \leq \mathrm{Sym}(D)$ is transitive on D. By the size $\|M\|$ of the map, we mean the number of darts $|D|$. We require transitivity because the maps are connected by definition.

The group $\langle R, L\rangle$ is called the *monodromy group* of M. The vertices, edges, and faces of M are in one-to-one correspondence with the cycles of the permutations R, L, $R^{-1}L$, respectively. By the phrase "a dart x is incident to a vertex v" we mean that $x \in R_v$. Similarly, "x is incident to a face f" means that x belongs to the boundary walk of f defined by the respective cycle of $R^{-1}L$. By the *degree of a face* we mean the length of its boundary walk. A face of degree d will be called a d-face. Note that each dart is incident to exactly one face. For convenience, we frequently use a shorthand notation $x^{-1} = Lx$, for $x \in D$. The *dual* of an oriented map $M = (D, R, L)$ is the oriented map $M^* = (D, R^{-1}L, L)$.

Apart from standard map theory references, we need to introduce labeled maps. A *planted tree* is a rooted tree embedded in the sphere, i.e., a planted tree is a spherical map having exactly one face. We say that a planted tree is *integer-valued* if an integer is assigned to each vertex. A *dart-labeling* of an oriented map $M = (D, R, L)$ is a mapping $\ell\colon D \to \mathcal{T}$, where $\mathcal{T}$ is the set of integer-valued planted trees. A *labeled oriented map* M is a 4-tuple (D, R, L, ℓ). The *dual map* is the map M^* defined as $M^* = (D, R^{-1}L, L, \ell)$.

Two labeled oriented maps $M_1 = (D_1, R_1, L_1, \ell_1)$ and $M_2 = (D_2, R_2, L_2, \ell_2)$ are *isomorphic*, in symbols $M_1 \cong M_2$, if there exists a bijection $\psi\colon D_1 \to D_2$, called an *orientation-preserving isomorphism* from M_1 to M_2, such that

$$\psi R_1 = R_2\psi, \quad \psi L_1 = L_2\psi, \quad \text{and} \quad \ell_1 = \ell_2\psi. \tag{1}$$

The *set of orientation-preserving isomorphisms* from M_1 to M_2 is denoted by $\mathrm{Iso}^+(M_1, M_2)$. The *orientation-preserving automorphism group* of M is the set $\mathrm{Aut}^+(M) := \mathrm{Iso}^+(M, M)$. The following statement, which can be easily seen for unlabeled maps, extends also to labeled maps.

▶ **Theorem 5.** *Let M_1 and M_2 be labeled oriented maps with sets of darts D_1 and D_2, respectively. For every $x \in D_1$ and every $y \in D_2$, there exists at most one isomorphism $M_1 \to M_2$ mapping x to y. In particular, $\mathrm{Aut}^+(M_1)$ is fixed-point-free on D_1.*

▶ **Corollary 6.** *Let M_1 and M_2 be labeled oriented maps with sets of darts D_1 and D_2, respectively. If $x \in D_1$ and $y \in D_2$, then it can be checked in time $\mathcal{O}(|D_1| + |D_2|)$ whether there is an isomorphism mapping x to y.*

Chirality. The *mirror image* of an oriented map $M = (D, R, L)$ is the oriented map $M^{-1} = (D, R^{-1}, L)$. Similarly, the *mirror image* of labeled oriented map $M = (D, R, L, \ell)$ is the map $M^{-1} = (D, R^{-1}, L, \ell^{-1})$, where $\ell^{-1}(x)$ is the mirror image of $\ell(x)$ for each $x \in D$.

An oriented map M is called *reflexible* if $M \cong M^{-1}$. Otherwise the maps M and M^{-1} form a *chiral pair*. For example, all the Platonic solids are reflexible. The set of *all isomorphisms* from M_1 to M_2 is defined as $\mathrm{Iso}(M_1, M_2) := \mathrm{Iso}^+(M_1, M_2) \cup \mathrm{Iso}^+(M_1, M_2^{-1})$. Similarly, we put $\mathrm{Aut}(M) := \mathrm{Iso}(M, M)$.

Maps on all surfaces. Let M be a map on any, possibly non-orientable, surface. In general, a *combinatorial non-oriented map* is a quadruple (F, λ, ρ, τ), where F is a finite non-empty set of *flags*, and $\lambda, \rho, \tau \in \mathrm{Sym}(F)$ are fixed-point-free[2] involutions such that $\lambda\tau = \tau\lambda$ and the group $\langle \lambda, \rho, \tau \rangle$ acts transitively on F. By the *size* $\|M\|$ of the map M we mean the number of flags $|F|$.

Each flag corresponds uniquely to a vertex-edge-face incidence triple (v, e, f). Geometrically, it can be viewed as the triangle defined by v, the center of e, and the center of f. The group $\langle \lambda, \rho, \tau \rangle$ is called the *non-oriented monodromy group* of M. The vertices, edges, and faces of M correspond uniquely to the orbits of $\langle \rho, \tau \rangle$, $\langle \lambda, \tau \rangle$, and $\langle \rho, \lambda \rangle$, respectively. Similarly, an *isomorphism* of two non-oriented maps M_1 and M_2 is a bijection $\psi\colon F_1 \to F_2$ which commutes with λ, ρ, τ. The even-word subgroup $\langle \rho\tau, \tau\lambda \rangle$ has index at most two in the monodromy group of M. If it is exactly two, the map M is called *orientable*. For every oriented map (D, R, L) it is possible to construct the corresponding non-oriented map

[2] It is possible to extend the theory to maps on surfaces with boundaries by allowing fixed points of λ, ρ, τ.

(F, λ, ρ, τ). Conversely, from an orientable non-oriented map (F, λ, ρ, τ) it is possible to construct two oriented maps (D^+, R, L) and (D^-, R^{-1}, L), where D^+ and D^- are the two orbits of the even word subgroup, and $L = \tau\lambda$, $R = \rho\tau$.

Test of orientability. For a non-oriented map $M = (F, \lambda, \rho, \tau)$, it is possible to test in linear time if M is orientable [12, 24]. The *barycentric subdivision* B of M is constructed by placing a new vertex in the center of every edge and face, and then joining the centers of faces with the incident vertices and with the center of the incident edges. The dual of B is a 3-valent map, i.e., every vertex is of degree 3.

▶ **Theorem 7.** *A map $M = (F, \lambda, \rho, \tau)$ is orientable if and only if the underlying 3-valent graph of the dual of the barycentric subdivision of M is bipartite.*

Light vertices. A map is called *face-normal*, if all its faces are of degree at least three. It is well-known that every face-normal map on the sphere or on the projective plane has a vertex of degree at most 5. The next theorem generalizes this for other surfaces.

▶ **Theorem 8.** *Let S be a closed compact surface with Euler characteristic $\chi(S) \leq 0$ and let M be a face-normal map on S. Then there is a vertex of valence at most $6(1 - \chi(S))$.*

Proof. A bound for maximum degree is achieved by a triangulation, thus we may assume that M is a triangulation. We have $f = 2e/3$. By plugging this in the Euler-Poincaré formula and using the Handshaking lemma, we obtain $3v - \overline{d}v/2 = 3\chi(S)$, where $\overline{d}$ is the average degree. By manipulating the equality, we get $\overline{d} - 6 = -6\chi(S)/v$. Since $\chi(S) \leq 0$, the right hand side is maximized for $v = 1$. We conclude that $\overline{d} \leq 6(1 - \chi(S))$. ◀

A vertex is called *light* if it is of minimum degree, otherwise it is called *heavy*.

Uniform and homogeneous maps. Given a map on an orientable surface, the cyclic vector of degrees of faces incident with a vertex v, induced by the chosen global orientation, is called the *local type* of v. A map is *uniform*[3] if the local types of all vertices are the same. A map is *homogeneous* of type $\{k, \ell\}$ if every vertex is of degree k and every face is of degree ℓ.

A *dipole* is a 2-vertex spherical map dual to a spherical cycle. *A bouquet* is a one-vertex map that is a dual of a *planted star* (a tree with at most one vertex of degree > 1).

▶ **Example 9.** The face-normal uniform spherical maps are: the 5 Platonic solids, the 13 Archimedean solids, pseudo-rhombicuboctahedron, prisms, antiprisms, and cycles of length at least 3. It easily follows from Euler's formula that the spherical homogeneous maps are the 5 Platonic solids, cycles, and dipoles.

3 Overview of the algorithm

We provide a high-level overview of the whole algorithm determining the automorphism group of a map. The input consists of a non-oriented map given by the quadruple $N = (F, \lambda, \rho, \tau)$.

First, using Theorem 7, we test whether N is orientable or not. If the map is orientable, then we know that the underlying surface is orientable and we fix a global orientation of the surface. We construct two oriented maps $M = (D, R, L)$ and $M^{-1} = (D, R^{-1}, L)$ representing N.

[3] In [1] Babai uses the term semiregular instead of uniform.

We start by determining $\mathrm{Aut}^+(M)$. On the map M, we perform a sequence of elementary local reductions (Section 4). There are two types of reductions: normalization and elimination of vertices of minimum degree. The normalization is of the highest priority and its purpose is to ensure that the resulting map is face-normal. In a face-normal map, it is guaranteed by Theorem 8 that there is a vertex of small degree. The second elementary reduction replaces a vertex of minimum degree by a polygon connecting its higher-degree neighbours and reconnecting the other incident edges (see Figure 3). These two reductions are applied until we are left with a map which has all vertices of degree k. Now, we observe that our reductions do not really depend on the degrees of vertices, but rather on some vertex-labelling (not related to dart labelling) which is linearly ordered. At this stage we can no longer distinguish vertices based on their degreee. We refine the procedure by using the local types instead of degrees. Note that the local types can be linearly ordered. It follows from Theorem 8 that the number of local types sufficient to consider is bounded. Thus, our reduction can be applied in the same way, but instead of degrees we use local types. The result is a labeled face-normal uniform oriented map $M' = (D', R', L', \ell')$ with $\mathrm{Aut}^+(M) \cong \mathrm{Aut}^+(M')$ and $D' \subseteq D$; for more details see Section 4.

The number of face-normal uniform oriented map M' on a surface of genus $g > 1$ is bounded by a fucntion of g (Proposition 13), which means that a brute-force approach is sufficient to determine $\mathrm{Aut}^+(M')$. For the case of sphere and torus, the problem is non-trivial since there are infinite families of face-normal uniform maps and a special treatment is necessary; for more details see Section 5. Now, since $\mathrm{Aut}^+(M)$ acts fixed-point-freely on D and $D' \subseteq D$, there is a unique way to extend $\mathrm{Aut}^+(M')$ to $\mathrm{Aut}^+(M)$. Finally, to construct $\mathrm{Aut}(M)$, we run the whole algorithm again to determine $\mathrm{Iso}(M, M^{-1})$.

If the map is N is non-orientable, we construct its oriented antipodal double-cover $\widetilde{M} = (D, R, L) = (F, \rho\tau, \tau\lambda)$. We show that $\mathrm{Aut}(N) \leq \mathrm{Aut}^+(\widetilde{M})$, and therefore, we can again apply our algorithm to determine $\mathrm{Aut}^+(\widetilde{M})$. Here, the most difficult part is to determine $\mathrm{Aut}(N)$ within $\mathrm{Aut}^+(\widetilde{M})$. For the case of projective plane and Klein bottle the problem is highly non-trivial and a special treatment is again needed, while for the other cases, again, a brute force approach is sufficient; for more details see Section 6.

4 From oriented maps to uniform oriented maps

In this section, we describe a set of elementary reductions defined on labeled oriented maps, given by a quadruple (D, R, L, ℓ), in detail. The output of each elementary reduction is always a quadruple (D', R', L', ℓ'), satisfying $D' \subseteq D$, $v(M') + e(M') < v(M) + e(M)$, and $\mathrm{Aut}^+(M') \cong \mathrm{Aut}^+(M)$. If none of the reductions apply, the map is a uniform oriented map. The procedure defines a function which assigns to a given oriented map M a unique labeled oriented map U with $\mathrm{Aut}^+(M) \cong \mathrm{Aut}^+(U)$. Since the darts of U form a subset of the darts of M, by semiregularity, every generator of $\mathrm{Aut}^+(U)$ can be extended to a generator of $\mathrm{Aut}^+(M)$ in linear time. We deal with the uniform oriented maps in Section 5.

After every elementary reduction, to ensure that $\mathrm{Aut}^+(M') = \mathrm{Aut}^+(M)$, we need to define a new labeling ℓ'. To this end, in the whole section, we assume that we have an injective function $\mathbf{Label}\colon \mathbb{N} \times \bigcup_{k=1}^{\infty} \mathcal{T}^k \to \mathcal{T}$, where $\mathcal{T}$ is the set of all integer-valued planted trees. Moreover, we assume that the root of $\mathbf{Label}(t, T_1, \ldots, T_k)$ contains the integer t, corresponding to the current step of the reduction procedure. After every elementary reduction, this integer is increased by one; see the full version for more details.

Even though we defined our reductions only based on the minimum degree, it can be easily seen that we are only using the fact that natural numbers are linearly ordered. Thus, our reduction really works with any vertex lables, which are linearly ordered. In particular,

if we replace degrees with local types together with a natural lexicographic linear ordering, our reductions are well-defined. The consequence is thet every irreducible map with respect to these reductions is a face-normal uniform map.

Normalization. By Theorem 8, there is always a light vertex in a face-normal map. The purpose of the following reduction is to remove faces of degree one and two. This reduction is of the highest priority and it is applied until the map is one of the following: (i) face-normal, (ii) bouquet, (iii) dipole. In the cases (ii) and (iii), the whole reduction procedure stops with a uniform map. In the case (i), the reduction procedure continues with further reductions. We describe the reduction formally.

For technical reasons we split the reduction into two parts: deletion of loops, denoted by $\mathbf{Loops}(M)$, and replacement of a dipole by an edge, denoted by $\mathbf{Dipoles}(M)$.

Reduction Loops. If $M = (D, R, L, \ell)$ with $v(M) > 1$ contains loops, we remove them. Let $\mathcal{L}$ be the list of all maximal sequences of darts of the form $s = \{x_1, x_1^{-1}, \dots, x_k, x_k^{-1}\}$, where $Rx_i = x_i^{-1}$, for $i = 1, \dots, k$, $Rx_i^{-1} = x_{i+1}$ for $i = 1, \dots, k-1$, and $Rx_k^{-1} \neq x_1$. By definition, $R^{-1}Lx_i = x_i$, hence x_i bounds a 1-face, for $i = 1, \dots, k-1$; see Figure 1. Moreover, for each such sequence s, all the darts x_i are incident to the same vertex $v \in V(M)$. We say that the unique vertex v with $R_v = (x_0, x_1, x_1^{-1}, \dots, x_k, x_k^{-1}, x_{k+1}, \dots)$ is *incident* to s. We call the darts x_0 and x_{k+1} the *bounding darts* of the sequence s.

The new map $M' = (D'; R', L', \ell') =: \mathbf{Loops}(M)$ is defined as follows. First, we put $D' := D \setminus \bigcup_{s \in \mathcal{L}} s$, and $L' := L_{\restriction D'}$. Let $s = \{x_1, x_1^{-1}, \dots, x_k, x_k^{-1}\} \in \mathcal{L}$ with bounding darts x_0 and x_{k+1}. If v is incident to s, then we put $R'_v := (x_0, x_{k+1}, \dots)$, else we put $R'_v := R_v$. Moreover, we put $\ell'(x_0) := \mathbf{Label}(t, a_0, \dots, a_k)$ and $\ell'(x_{k+1}) := \mathbf{Label}(t, a_{k+1}, b_k, \dots, b_1)$, where t is the current step, $a_i = \ell(x_i)$, for $i = 0, \dots, k+1$, and $b_i = \ell(x_i^{-1})$, for $i = 1, \dots, k$. For every $x \in D'$ which is not a bounding dart in M, we put $\ell'(x) := \ell(x)$. We obtain a well-defined map M' with no faces of valence one; see Figure 1.

▶ **Lemma 10.** *Let $M_i = (D_i, R_i, L_i, \ell_i)$, $i = 1, 2$ where $D_1 \cap D_2 = \emptyset$, be labeled oriented maps. Let $M'_1 := \mathbf{Loops}(M_1)$ and $M'_2 := \mathbf{Loops}(M_2)$. Then $\mathrm{Iso}^+(M_1, M_2)_{\restriction D'_1} = \mathrm{Iso}^+(M'_1, M'_2)$. In particular, $\mathrm{Aut}^+(M_1)_{\restriction D'_1} = \mathrm{Aut}^+(M'_1)$.*

Reduction Dipoles. If $M = (D, R, L, \ell)$ with $v(M) > 2$ contains dipoles. Let $\mathcal{L}$ be the list of all maximal sequences $s = (x_1, \dots, x_k)$ of darts, $k > 1$, satisfying $Rx_i = x_{i+1}$, $(R^{-1}L)^2 x_i = x_i$, and either $Rx_k \neq x_1$ or $Rx_1^{-1} \neq x_k^{-1}$; see Figure 2. Let $s^{-1} := (x_k^{-1}, \dots, x_1^{-1}) \in \mathcal{L}$ be the *inverse* sequence. There are vertices u and v such that $R_u = (y_1, s, y_2, \dots)$ and

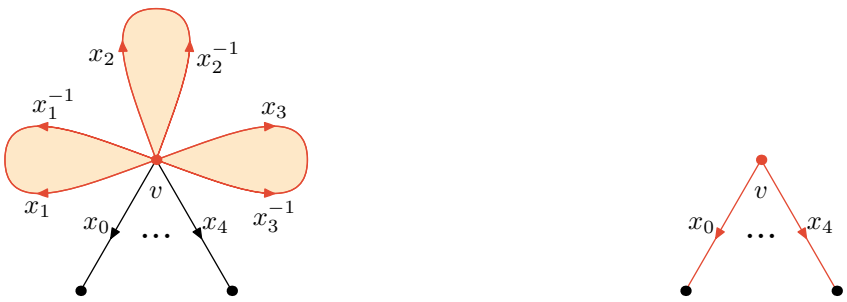

Figure 1 A sequence of darts $x_1, x_1^{-1}, x_2, x_2^{-1}, x_3, x_3^{-1}$ with bounding darts x_0 and x_4.

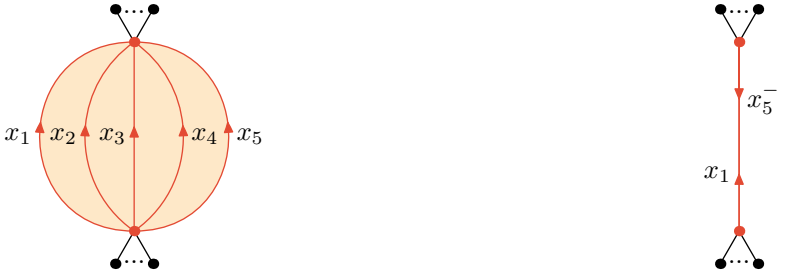

Figure 2 A sequence of darts $x_1, \dots, x_5$ forming a dipole.

$R_v = (z_1, s^{-1}, z_2, \dots)$, for some $y_1, y_2, z_1, z_2 \in D$. At least one of the sets $\{y_1, y_2\}$, $\{z_1, z_2\}$ is non-empty since otherwise $v(M) = 2$ and M is a dipole. We say that u, v are *incident* to s, s^{-1}, respectively; see Figure 2

The new map $M' = (D', R', L', \ell') =: \mathbf{Dipoles}(M)$ is defined as follows. First, we put

$$D' := D \setminus \bigcup_{(x_1,\dots,x_k)\in\mathcal{L}} \{x_2, \dots, x_k\} \cup \{x_1^{-1}, \dots, x_{k-1}^{-1}\}.$$

Let $s = (x_1, \dots, x_k) \in \mathcal{L}$. If u and v are incident to s and s^{-1}, respectively, then we put $R'_u := (y_1, x_1, y_2 \dots)$ and $R'_v := (z_1, x_k^{-1}, z_2, \dots)$, else we put $R'_u := R_u$. Next, we put $L'x_1 := x_k^{-1}$, $L'x_k^{-1} := x_1$, and $L'x := Lx$ if $x \notin s \in \mathcal{L}$. Finally, we put $\ell'(x_1) := \mathbf{Label}(t, a_1, \dots, a_k)$ and $\ell'(x_k^{-1}) := \mathbf{Label}(t, b_k, \dots, b_1)$, where t is the current step, $a_i = \ell(x_i)$ and $b_i = \ell(x_i^{-1})$, for $i = 1, \dots, k$. We put $\ell'(x) := \ell(x)$ for $x \notin s \in \mathcal{L}$. We obtain a well-defined map M' with no 2-faces; see Figure. 2.

▶ **Lemma 11.** *Let $M_i = (D_i, R_i, L_i, \ell_i)$, $i = 1, 2$ where $D_1 \cap D_2 = \emptyset$, be labeled oriented maps. Let $M'_1 := \mathbf{Dipoles}(M_1)$ and $M'_2 := \mathbf{Dipoles}(M_2)$. Then $\mathrm{Iso}^+(M_1, M_2)_{\restriction D'_1} = \mathrm{Iso}^+(M'_1, M'_2)$. In particular, $\mathrm{Aut}^+(M_1)_{\restriction D'_1} = \mathrm{Aut}^+(M'_1)$.*

Face-normal maps. The input is a labeled face-normal oriented map $M = (D, R, L, \ell)$ and a list $\mathcal{L}$ of all light vertices of degree d which have at least one heavy neighbour. For every vertex $v \in \mathcal{L}$, we denote by $u_0, \dots, u_{k-1}$, for some $1 \le k \le d$, the cyclic sequence of all heavy neighbours of v, following the prescribed orientation of the underlying surface. Denote by $x_0, x_1, \dots, x_{k-1}$ the darts based at $u_0, u_1, \dots, u_{k-1}$, joining u_j to v for $j = 0, \dots, k-1$. Let $R_{u_i} = (y_i, x_i, z_i, \dots)$, for $i = 0, \dots, k-1$, and let

$$R_v = (x_0^{-1}, A_0, x_1^{-1}, A_1, \dots, x_{k-1}^{-1}, A_{k-1}),$$

where each A_i is a (possibly empty) sequence of darts.

The new map $M' = (D', R', L', \ell') =: \mathbf{Delete}(M)$ is defined as follows. We set $D' := D$ and $L' := L$. For a heavy vertex w with no light neighbour, we have $R'_w := R_w$. If $v \in \mathcal{L}$, with the above notation, we set $R'_{u_i} := (y_i, A_i, x_i, x_{i-1}^{-1}, z_i, \dots)$. Moreover, we set $\ell'(x_i) := \mathbf{Label}(t, \ell(x_i))$ and $\ell'(x_i^{-1}) := \mathbf{Label}(t, \ell(x_i^{-1}))$, where t is the current step number; see Figure 3.

▶ **Lemma 12.** *Let $M_i = (D_i, R_i, L_i, \ell_i)$, $i = 1, 2$ where $D_1 \cap D_2 = \emptyset$, be labeled oriented maps. Let $M'_1 := \mathbf{Delete}(M_1)$ and $M'_2 := \mathbf{Delete}(M_2)$. Then $\mathrm{Iso}^+(M_1, M_2) = \mathrm{Iso}^+(M'_1, M'_2)$. In particular, $\mathrm{Aut}^+(M_1) = \mathrm{Aut}^+(M'_1)$.*

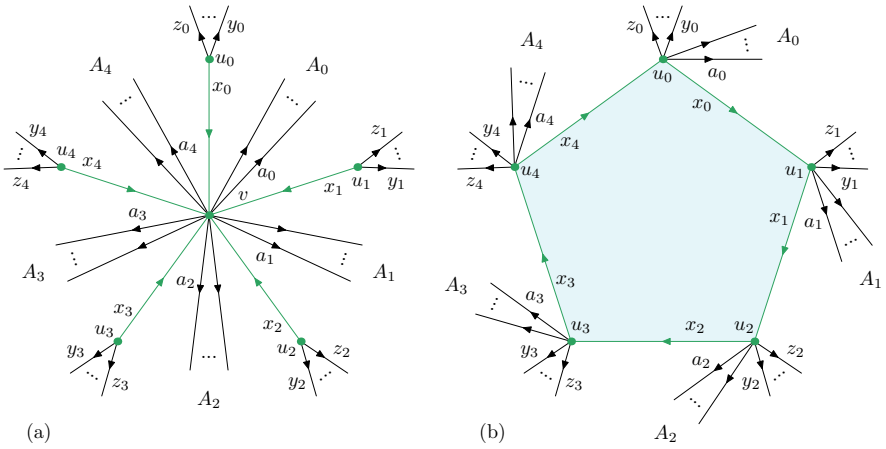

Figure 3 An example of the reduction deleting a vertex.

Proof. Let $\psi\colon M_1 \to M_2$ be an isomorphism. We prove that ψ is also an isomorphism of M_1' and M_2'. We check the commuting rules (1) for ψ. We have $L_i' = L_i$, for $i = 1, 2$, so $L_1'\psi = \psi L_2'$. For R_1' and R_2', we need to check the commuting rules only at $x_i, x_i^{-1}, y_i, a_i \in D_1'$, for $i = 0, \ldots, k-1$, where a_i is the last dart in the sequence A_i. We have

$$\psi R_1' x_i = \psi R_1^{-1} L_1 x_i = R_2^{-1} L_2 \psi x_i = R_2' \psi x_i,$$

$$\psi R_1' x_i^{-1} = \psi R_1 L_1 x_i^{-1} = R_2 L_2 \psi x_i^{-1} = R_2' \psi x_i^{-1}.$$

It remains to check the commuting rules at each y_i and a_i. Note that if A_i is empty there is nothing to check. We have

$$\psi R_1' y_i = \psi R_1 L_1 R_1 y_i = R_2 L_2 R_2 \psi y_i = R_2' \psi y_i.$$

Further, using the relations $R_1' a_i = x_i = L_1 R_1^q a_i$, for some $q > 0$, we get

$$\psi R_1' a_i = \psi x_i = \psi L_1 R_1^q a_i = L_2 R_2^q \psi a_i = R_2' \psi a_i.$$

Putting it together, we proved that $\psi R_1' = R_2' \psi$. Clearly, $\ell_1'(x_i) = \ell_2'(\psi x_i)$ if and only if $\ell_1(x_i) = \ell_2(\psi x_i)$. Similarly for x_i^{-1}.

For the converse, we assume that $\psi R_1' = R_2' \psi$ and $\psi L_1' = L_2' \psi$ and we prove $\psi R_1 = R_2 \psi$ and $\psi L_1 = L_2 \psi$. Similarly as above, we need to check the commuting rules for $x_i, x_i^{-1}, y_i, a_i \in D_1$.

- By the definition of M_1' and M_2', we have $R_1 x_i = z_i = (R_1')^2 x_i$. Since **Label** is injective, we have $R_2 \psi x_i = \psi z_i = (R_2')^2 \psi x_i$. Using these relations, we get

$$\psi R_1 x_i = \psi (R_1')^2 x_i = (R_2')^2 \psi x_i = R_2 \psi x_i.$$

- By the definition of M_1' and M_2', we have $R_1 x_i^{-1} = R_1'^m L_1' x_i^{-1}$, for some m. Since **Label** is injective, we have $R_2 \psi x_i^{-1} = R_2'^m L_2' \psi x_i^{-1}$. Using these relations, we get

$$\psi R_1 x_i^{-1} = \psi R_1'^m L_1 x_i^{-1} = R_1'^m L_2' \psi x_i^{-1} = R_2 \psi x_i^{-1}.$$

- By the definition of M_1' and M_2', we have $R_1 y_i = x_i = R_1'^m y_i$, for some m. Since **Label** is injective, $R_2 \psi y_i = \psi x_i = R_2'^m \psi y_i$. Using these relations, we get

$$\psi R_1 y_i = \psi R_1'^m y_i = R_2'^m \psi y_i = R_2 \psi y_i.$$

- By the definition of M_1' and M_2', we have $R_1 a_i = L_1' R_1'^{-1} L_1' R_1' a_i$. Since **Label** is injective, $R_2 \psi a_i = L_2' R_2'^{-1} L_2' R_2' \psi a_i$. Using these relations, we get

$$\psi R_1 a_i = \psi L_1' R_1'^{-1} L_1' R_1' a_i = L_2' R_2'^{-1} L_2' R_2' \psi a_i = R_2 \psi a_i.$$

Putting it togehter, we proved that $\psi R_1 = R_2 \psi$, which implies that ψ is an isomorphism $M_1 \to M_2$. This completes the proof. ◀

5 Irreducible maps on orientable surfaces

In this section, we provide an algorithm computing the automorphism group of irreducible oriented maps, with fixed Euler characteristic, in linear time. The proof splits into three parts: maps of negative Euler characteristic, maps on the sphere, and maps on torus.

Surfaces of negative Euler characteristic. If the Euler characteristic χ is negative, the irreducible maps are exactly all the uniform face-normal maps. We prove that the number of uniform face-normal maps is bounded by a function of χ. Therefore, generators of the automorphism group can be computed by a brute force approach. Note that the following lemma does not require the underlying surface to be orientable, it only requires χ to be negative.

▶ **Proposition 13.** *The number of edges of a uniform face-normal map on a closed compact surface S with Euler characteristic $\chi(S) < 0$ is bounded by a function of $\chi(S)$.*

Proof. Babai noted in [1, Theorem 3.3] that the Hurwitz Theorem (see, e.g. [4] or [12]) implies that the number of vertices of a uniform map M on S is at most $84|\chi(S)|$. By Theorem 8, the degree of a vertex of M is bounded by a function of $\chi(S)$ as well. Therefore, the number of edges is also bounded by a function of $\chi(S)$ and the theorem follows. ◀

▶ **Corollary 14.** *Let $M = (D, R, L)$ be a uniform face-normal map $M = (D, R, L)$ on an orientable surface S with $\chi(S) < 0$. Then $\mathrm{Aut}(M)$ can be computed in time $f(\chi(S))|D|$, for some computable function f.*

Sphere. By the definition of the reductions in Section 4, the irreducible spherical maps are the five Platonic maps, 13 Archimedean maps, pseudo-rhombicuboctahedron, prisms, antiprisms, cycles, dipoles, and bouquets.

In the first three cases, the automorphism group can be computed by a brute force approach. We show that for (labeled) prisms, antiprisms, dipoles and bouquets, the problem can be reduced to computing the automorphism group of a vertex-labeled cycle.

▶ **Theorem 15** ([17])**.** *If $M = (D, R, L)$ is an irreducible spherical map, then the generators of $\mathrm{Aut}(M)$ can be computed in time $\mathcal{O}(|D|)$.*

Torus. The toroidal irreducible maps are uniform face-normal maps. The universal covers of uniform toroidal maps are uniform tilings (infinite maps with finite vertex and face degrees) of the Euclidean plane. There are 12 of such tilings; see [14, page 63]. The corresponding local types are $(3,3,3,3,3,3)$, $(4,4,4,4)$, $(6,6,6)$, $2 \times (3,3,3,3,6)$, $(3,3,3,4,4)$, $(3,3,4,3,4)$, $(3,4,6,4)$, $(3,6,3,6)$, $(3,12,12)$, $(4,6,12)$, and $(4,8,8)$. One type occurs in two forms, one of the respective tilings is the mirror image of the other. Each of these tilings T gives rise to an infinite family of toroidal uniform maps as follows. It is well-known that $\mathrm{Aut}^+(T)$ is

isomorphic either to the triangle group $\Delta(4,4,2)$ or to $\Delta(6,3,2)$. Each of these contains an infinite subgroup H of translations generated by two shifts. Every finite uniform toroidal map of the prescribed local type can be constructed as the quotient T/K, where K is a subgroup of H of finite index.

First, our algorithm reduces a uniform map to one of the two homogeneous types $\{4,4\}$ and $\{6,3\}$, while preserving the automorphism group. Then, the algorithm computes the generators of the automorphism groups of a labeled homogeneous toroidal map M of type $\{4,4\}$ or $\{3,6\}$. For technical reasons, we transform the dart-labelling to a vertex-labelling of M. These transformations can be done easily by, for a given vertex, encoding the lables of the outgoing darts into the vertex. The following lemma describes some important properties of $\mathrm{Aut}^+(M)$.

▶ **Lemma 16** ([29]). *Let M be a toroidal map of type $\{4,4\}$ or $\{6,3\}$. The orientation-preserving automorphism group of a labeled map M is a semidirect product $T \rtimes H$, where T is a direct product of two cyclic groups, and $|H| \leq 6$. Moreover, the action of T is regular on the vertices of M.*

Since the order of H is bounded by a constant, it takes linear time to check whether every element of H is a label-preserving automorphism. The main difficulty is to find T. The subgroup T is generated by α and β, where α is the horizontal, and β is the vertical shift by the unit distance. Now the meaning of the parameters r, s, t is the following: $|\alpha| = r$, $\alpha^t = \beta^s$, and s is the least power of β such that $\beta^s \in \langle\alpha\rangle$. The following lemma shows that T can always be written as a direct product of two cyclic groups.

▶ **Lemma 17.** *There exists δ and γ such that $T = \langle\delta\rangle \times \langle\gamma\rangle$. Moreover, δ and γ can be computed in time $\mathcal{O}(rs)$.*

Lemma 17 can be viewed as a transformation of the shifted grid $\mathcal{G}$ to the orthogonal grid $\mathcal{G}^\perp$. Note that the underlying graph may change, but both $\mathcal{G}$ and $\mathcal{G}^\perp$ are Cayley graphs based on the group T, therefore, the vertex-labeling naturally transfers. Thus, we may assume that $t = 0$ and $T = \langle\alpha\rangle \times \langle\beta\rangle \cong \mathbb{Z}_r \times \mathbb{Z}_s$. We need to compute generators of the label-preserving subgroup of T.

From now on, we assume that we are given a *cyclic orthogonal grid* $\mathcal{G}$ of size rs, which is graph with vertices identified with $(i,j) \in G$, where $G = \mathbb{Z}_r \times \mathbb{Z}_s$. For every (i,j), there is an edge between (i,j) and $(i+1 \mod r, j)$, and between (i,j) and $(i, j+1 \mod s)$. Moreover, we are given an integer-labeling ℓ of the vertices of $\mathcal{G}$. Clearly, $\mathcal{G}$ determines the *ℓ-preserving subgroup* H of G, namely

$$H = \{(x,y) : \forall (i,j) \in G, \ell(i,j) = \ell(i+x, j+y)\}.$$

The goal is to find the generators of H in time $\mathcal{O}(rs)$.

We give a description of any subgroup of the direct product of G that is suitable for our algorithm. First, we define four important mappings. The two *projections* $\pi_1 \colon G \to \mathbb{Z}_r$ and $\pi_2 \colon G \to \mathbb{Z}_s$ are defined by $\pi_1(x,y) = x$ and $\pi_2(x,y) = y$, respectively. The two *inclusions* $\iota_1 \colon \mathbb{Z}_r \to G$ and $\iota_2 \colon \mathbb{Z}_s \to G$ are defined by $\iota_1(x) = (x,0)$ and $\iota_2(y) = (0,y)$, respectively.

▶ **Lemma 18.** *Let $G = \mathbb{Z}_r \times \mathbb{Z}_s$ for $r, s \geq 1$, and let H be a subgroup of G. Then there are $a, c \in \mathbb{Z}_r$ and $b \in \mathbb{Z}_s$ such that*

$$H = \{(ia + jc, jb) : i, j \in \mathbb{Z}\} = \langle (a,0), (c,b) \rangle,$$

where $\langle a\rangle = \iota_1^{-1}(H)$, $\langle b\rangle = \pi_2(H)$, and $c < a$ is the minimum integer such that $(c,b) \in H$.

This description suggests an algorithm to find the generators of the given subgroup H of $\mathbb{Z}_r \times \mathbb{Z}_s$. In our setting, the subgroup H is given on the input by a labeling function ℓ, defined on the vertices of the $r \times s$ orthogonal grid. The subgroup H is the ℓ-preserving subgroup of $\mathbb{Z}_r \times \mathbb{Z}_s$.

To compute the generators of H, it suffices, by Lemma 18, to determine $a, c \in \mathbb{Z}_r$ and $b \in \mathbb{Z}_s$ such that $\langle a \rangle = \iota_1^{-1}(H)$, $\langle b \rangle = \pi_2(H)$, and c is the smallest integer such that $(c, b) \in H$. Then $H = \langle (a, 0), (c, b) \rangle$.

▶ **Lemma 19.** *There is an $\mathcal{O}(rs)$-time algorithm which computes the integers a, b, c such that $\iota_1^{-1}(H) = \langle a \rangle$, $\pi_2(H) = \langle b \rangle$ and $c < a$ is the smallest integer such that $(c, b) \in H$.*

The results of this subsection are summarized by the following.

▶ **Theorem 20.** *If $M = (D, R, L, \ell)$ is a uniform face-normal labeled toroidal map, then the generators of $\mathrm{Aut}(M)$ can be computed in time $\mathcal{O}(|D|)$.*

6 Non-orientable surfaces

For a map M on a non-orientable surface S, we reduce the problem of computing the generators of $\mathrm{Aut}(M)$ to the problem of computing the generators of $\mathrm{Aut}^+(\widetilde{M})$, for some orientable map $\widetilde{M}$. In particular, the map $\widetilde{M}$ is the antipodal double cover of M.

Given a map $M = (F, \lambda, \rho, \tau)$ on a non-orientable surface of genus γ, we define the antipodal double cover $\widetilde{M} = (D, R, L)$ by setting $D := F$, $R := \rho\tau$, and $L := \tau\lambda$. Since M is non-orientable, we have $\langle R, L \rangle = \langle \lambda, \rho, \tau \rangle$, so $\langle R, L \rangle$ is transitive and $\widetilde{M}$ is well-defined. For more details on this construction see [25]. We note that $\widetilde{\chi} = 2\chi$, where $\widetilde{\chi}$ and χ is the Euler characteristic of the underlying surface of $\widetilde{M}$ and M, respectively.

▶ **Lemma 21.** *We have $\mathrm{Aut}(M) \leq \mathrm{Aut}^+(\widetilde{M})$.*

Proof. Let $\varphi \in \mathrm{Aut}(M)$. Then we have $R^\varphi = (\rho\tau)^\varphi = \rho^\varphi\tau^\varphi = \rho\tau = R$ and $L^\varphi = (\tau\lambda)^\varphi = \tau^\varphi\lambda^\varphi = \tau\lambda = L$. ◀

▶ **Lemma 22.** *We have $\mathrm{Aut}(M) = \{\varphi \in \mathrm{Aut}^+(\widetilde{M}) : \varphi\tau = \tau\varphi\}$.*

Proof. Let $\varphi \in \mathrm{Aut}^+(\widetilde{M})$. We have $\varphi R\varphi^{-1} = R$ and $\varphi L\varphi^{-1} = L$. By plugging in $R = \rho\tau$ and $L = \tau\lambda$, we obtain

$$\varphi(\rho\tau)\varphi^{-1} = \rho\tau \quad \text{and} \quad \varphi(\tau\lambda)\varphi^{-1} = \lambda\tau.$$

From there, by rearranging the left-hand sides of the equations, we get

$$(\varphi\rho\varphi^{-1})(\varphi\tau\varphi^{-1}) = \varphi(\rho\tau)\varphi^{-1} = \rho\tau \quad \text{and} \quad (\varphi\tau\varphi^{-1})(\varphi\lambda\varphi^{-1}) = \varphi(\tau\lambda)\varphi^{-1} = \tau\lambda.$$

Finally, we obtain

$$\varphi\rho\varphi^{-1} = \rho\tau(\varphi\tau\varphi^{-1}) \quad \text{and} \quad \varphi\lambda\varphi^{-1} = (\varphi\tau\varphi^{-1})\tau\lambda.$$

If $\varphi \in \mathrm{Aut}(M)$, then, in particular, it commutes with τ. On the other hand, if φ commutes with τ, then the last two equations imply that it also must commute with ρ and λ, i.e., $\varphi \in \mathrm{Aut}(M)$. ◀

The previous lemmas are key and suggest an approach for computing the generators of the automorphism group of M. In particular, it is necessary to check which automorphisms of $\widetilde{M}$ commute with τ. The cases when the underlying surface is the projective plane, or the Klein bottle, must be treated separately.

▶ **Theorem 23.** *Let $M = (F, \lambda, \rho, \tau)$ be a map on a non-orientable a non-orietable surface of genus γ. Then it is possible to compute the generators of $\mathrm{Aut}(M)$ in time $f(\gamma)|F|$.*

Lower Bounds on Dynamic Programming for Maximum Weight Independent Set

Tuukka Korhonen
Department of Computer Science, University of Helsinki, Finland

Abstract

We prove lower bounds on pure dynamic programming algorithms for maximum weight independent set (MWIS). We model such algorithms as tropical circuits, i.e., circuits that compute with max and + operations. For a graph G, an MWIS-circuit of G is a tropical circuit whose inputs correspond to vertices of G and which computes the weight of a maximum weight independent set of G for any assignment of weights to the inputs. We show that if G has treewidth w and maximum degree d, then any MWIS-circuit of G has $2^{\Omega(w/d)}$ gates and that if G is planar, or more generally H-minor-free for any fixed graph H, then any MWIS-circuit of G has $2^{\Omega(w)}$ gates. An MWIS-formula is an MWIS-circuit where each gate has fan-out at most one. We show that if G has treedepth t and maximum degree d, then any MWIS-formula of G has $2^{\Omega(t/d)}$ gates. It follows that treewidth characterizes optimal MWIS-circuits up to polynomials for *all* bounded degree graphs and H-minor-free graphs, and treedepth characterizes optimal MWIS-formulas up to polynomials for all bounded degree graphs.

1 Introduction

In this paper, we prove lower bounds for *tropical circuits* computing the weight of a maximum weight independent set (MWIS) of a graph. A tropical circuit is a circuit with Max and Plus operations as gates. In particular, we consider *MWIS-circuits* of graphs. An MWIS-circuit of a graph G is a tropical circuit whose inputs correspond to the vertices of G and which computes the weight of a maximum weight independent set of G for any assignment of weights to the inputs. An MWIS-formula is an MWIS-circuit where each gate has fan-out at most one.

Our motivation for proving lower bounds for MWIS-circuits is that many algorithmic techniques for maximum weight independent set implicitly build an MWIS-circuit of the input graph, and therefore the running time of any algorithm resulting from such a technique is bounded from below by the minimum size of an MWIS-circuit of the graph. Examples of algorithmic techniques that build MWIS-circuits are dynamic programming over different kinds of decompositions of graphs [3, 8, 16] and dynamic programming over potential maximal cliques [10, 17, 29]. Examples of algorithmic techniques that build MWIS-formulas are branching [20, 34] and maximal independent set enumeration [32].

1.1 Our Results

We prove unconditional lower bounds for sizes of MWIS-circuits and MWIS-formulas parameterized by graph parameters treewidth and treedepth, respectively. The lower bounds are exponential in treewidth and treedepth, and therefore well-known algorithms yield matching upper bounds for them [3, 18]. We emphasize that our lower bounds are not worst-case bounds over graph classes, but instead hold for each individual graph.

MWIS-Circuits and Treewidth

First we characterize optimal MWIS-circuits of bounded degree graphs.

▶ **Theorem 1.** *Let G be any graph with treewidth w and maximum degree d. Any MWIS-circuit of G has $2^{\Omega(w/d)}$ gates.*

Theorem 1 is optimal up to a factor d in the sense that for each pair w, d we can construct a graph with treewidth $\Omega(w)$ and maximum degree $O(d)$ that admits an MWIS-formula with $d2^{w/d}$ gates.

Then we extend the result to some graphs that may have high-degree vertices. A graph H is a *minor* of a graph G if it can be obtained from G by vertex deletions, edge deletions, and edge contractions. If H can be obtained by only vertex deletions and edge contractions, then it is an *induced minor*.

▶ **Theorem 2.** *Let G be any graph that contains an induced minor with treewidth w and maximum degree d. Any MWIS-circuit of G has $2^{\Omega(w/(d4^d))}$ gates.*

In Theorem 2 it is essential to require an induced minor instead of a minor because a complete graph with n vertices admits an MWIS-circuit of size $O(n)$, but contains all n-vertex graphs as minors.

A graph G is H-minor-free if it does not contain the graph H as a minor.

▶ **Corollary 3.** *Let H be any fixed graph and G any H-minor-free graph with treewidth w. Any MWIS-circuit of G has $2^{\Omega(w)}$ gates.*

Proof. For any fixed H, every H-minor-free graph of treewidth w contains an $\Omega(w) \times \Omega(w)$-grid as an induced minor [13][1]. An $\Omega(w) \times \Omega(w)$-grid has treewidth $\Omega(w)$ and maximum degree 4, so the result follows from Theorem 2. ◀

Corollary 3 implies a $2^{\Omega(w)}$ lower bound for all planar graphs because planar graphs are K_5-minor-free [27].

The following corollary follows from Theorem 1, Corollary 3, constant-factor treewidth approximation in $2^{O(w)}n^{O(1)}$ time [36], and dynamic programming over a tree decomposition [3].

▶ **Corollary 4.** *There is an algorithm which, given a bounded degree or H-minor-free graph G whose smallest MWIS-circuit has τ gates, constructs an MWIS-circuit of G with $\tau^{O(1)}$ gates in $\tau^{O(1)}$ time.*

In particular, a property analogous to automatizability of proof systems [6] holds for MWIS-circuits on bounded degree graphs and H-minor-free graphs.

[1] The stated result in [13] is that such a grid is a minor, but the same proof works directly to show that the constructed grid minor is also an induced minor. In particular, the proof in [13] does not use any edge deletions, and the corresponding result for bounded-genus graphs that it depends on [14] is already stated in terms of contraction to a graph that can be turned into a grid by removing vertices without decreasing treewidth by more than a constant factor.

MWIS-Formulas and Treedepth

We characterize optimal MWIS-formulas of bounded degree graphs.

▶ **Theorem 5.** *Let G be any graph with treedepth t and maximum degree d. Any MWIS-formula of G has $2^{\Omega(t/d)}$ gates.*

Again, Theorem 5 is optimal up to a factor d by the same construction as Theorem 1. As formulas can be thought of as bounded space analogies of circuits, Theorem 5 gives further evidence (in addition to e.g. [9, 26, 35]) supporting that while treewidth is the right parameter for CSP-like problems when equipped with unlimited space, treedepth is the right parameter when dealing with bounded space.

Obtaining a constant-factor single-exponential time parameterized approximation algorithm for treedepth is a well-known open problem [12], so while we know that the converse of Theorem 5 existentially holds in bounded degree graphs, we currently do not know how to construct such MWIS-formulas without having the treedepth decomposition as an input.

1.2 Techniques

Our main circuit complexity tool is an adaptation of a circuit decomposition lemma used in e.g. [22, 23, 37]. In particular, we show that this lemma can be adapted so that given an MWIS-circuit with τ gates of a graph with treewidth w it extracts a family of τ vertex separators each of size $\Omega(w)$. Once this family has been extracted, the main challenge for proving Theorem 1 is to show that if this family of separators is too small, there exists an independent set that intersects all of the separators. For this we use the lopsided Lovász Local Lemma [15], though we note that more elementary arguments would suffice to prove the theorem with a worse dependency on d. To extend the result from bounded degree graphs to H-minor-free graphs we use the minor model of the bounded degree induced minor with high treewidth to further control the structure of these separators.

For MWIS-formulas parameterized by treedepth t we similarly extract a family of 2τ vertex sets each of size $\Omega(t)$ from a τ-gate MWIS-formula, showing that if an independent set intersects all of these vertex sets the formula cannot compute it. The same application of the Local Lemma is used to prove that such an independent set indeed exists in low degree graphs if τ is too small. The argument for extracting the family from the formula is more ad-hoc than the argument for circuits.

1.3 Related Work

The convention of modeling dynamic programming algorithms as tropical circuits originates from the recent works of Jukna [24, 25], although some earlier results in monotone arithmetic circuit complexity apply also to tropical circuits [23]. In general, tropical circuit lower bounds imply lower bounds for monotone arithmetic circuits, but not necessarily the other way around [24]. In addition to the works of Jukna, the other works explicitly giving lower bounds for tropical circuits or formulas that we are aware of are [30, 31]. We are not aware of prior works on lower bounds for tropical circuits or formulas considering maximum weight independent set or the graph parameters treewidth or treedepth.

There are multiple worst-case hardness results related to different formulations of the independent set polynomial. In [7] it was shown that the multivariate independent set polynomial is VNP-complete. The univariate independent set polynomial is #P-hard to evaluate at every non-zero rational point [5], and more fine-grainedly its evaluation has $2^{\Omega(n/\log^3 n)}$ worst-case complexity assuming #ETH [21].

Chvátal has shown that a certain proof system for maximum independent set which naturally corresponds to branching algorithms requires exponential size proofs on almost all graphs that have the number of edges linear in the number of vertices [11].

Multiple worst-case lower bounds of form $n^{\Omega(w)}$ in limited models of computation for graph homomorphism problems of a pattern graph with treewidth w to a graph with n vertices are known [4, 26, 28]. In particular, recently it was shown that the worst-case monotone arithmetic circuit complexity of homomorphism polynomial is $\Theta(n^{w+1})$, and the worst-case monotone arithmetic formula complexity is $\Theta(n^t)$, where t is the treedepth of the pattern graph [26].

Recently, a lower bound of $2^{\Omega(w)}$ was shown for DNNF-compilation of monotone CNFs with primal treewidth w and bounded degree and arity, applying to all such CNFs [2]. We note that after the acceptance of this paper, we became aware of a reduction from MWIS-circuits to DNNFs that allows to prove a weaker version of our Theorem 1 via the result of [2]. In particular, the techniques of [2] yield an exponent of form $\Omega(w/2^d)$ instead of the best possible $\Omega(w/d)$ given in Theorem 1.

1.4 Organization

In Section 2 we present preliminaries on graph theory, define MWIS-circuits and prove simple lemmas on them, and discuss the lopsided Lovász Local Lemma and prove a lemma using it. In Section 3 we prove the lower bounds for MWIS-circuits parameterized by treewidth, i.e., Theorems 1 and 2. In Section 4 we prove the lower bound for MWIS-formulas parameterized by treedepth, i.e., Theorem 5. In Section 5 we give the construction that shows the optimality of Theorems 1 and 5 up to a factor d. We conclude and discuss future work in Section 6.

2 Preliminaries

2.1 Graphs

The vertex set of a graph G is denoted by $V(G)$ and the edge set by $E(G)$. The set of neighbors of a vertex v is denoted by $N(v)$ and the neighborhood of a vertex set X by $N(X) = \bigcup_{v\in X} N(v) \setminus X$. Closed neighborhoods are denoted by $N[v] = N(v) \cup \{v\}$ and $N[X] = N(X) \cup X$. The subgraph $G[X]$ induced by a vertex set $X \subseteq V(G)$ has $V(G[X]) = X$ and $E(G[X]) = \{\{u, v\} \in E(G) \mid u \in X \wedge v \in X\}$. We also use $G \setminus X = G[V(G) \setminus X]$ to denote induced subgraphs. An independent set of G is a vertex set I such that $G[I]$ has no edges. In particular, an empty set is an independent set.

A tree decomposition of a graph G is a tree T whose each vertex $i \in V(T)$ corresponds to a bag $B_i \subseteq V(G)$, satisfying that

1. $V(G) = \bigcup_{i\in V(T)} B_i$,
2. for each $\{u, v\} \in E(G)$ there is a bag B_i with $\{u, v\} \subseteq B_i$, and
3. for each $v \in V(G)$ the subtree of T induced by bags containing v is connected.

The width of a tree decomposition is $\max |B_i| - 1$ and the treewidth $tw(G)$ of a graph G is the minimum width over its tree decompositions.

A treedepth decomposition of a graph G is a rooted forest F with vertex set $V(F) = V(G)$, satisfying for each $\{u, v\} \in E(G)$ that u and v have an ancestor-descendant relation in F. The depth of F is the maximum number of vertices on a simple path from a root to a leaf in F. The treedepth $td(G)$ of a graph G is the minimum depth over its treedepth decompositions. Note that $tw(G) + 1 \leq td(G)$.

2.2 MWIS-Circuits

We start by giving a formal definition of a tropical circuit. Our definition is non-standard in that it does not allow any other input constants than 0, which we can w.l.o.g. assume in the context of maximum weight independent set. For a comprehensive treatment of tropical circuits and their relations to monotone Boolean and monotone arithmetic circuits see [24].

▶ **Definition 6.** A tropical circuit over variables X is a directed acyclic graph with in-degree of each vertex either 0 or 2. The vertices are called gates, the in-degree of a gate is called fan-in, and the out-degree of a gate is called fan-out. Each gate with fan-in 0 is labeled with a variable $x_i \in X$ or the constant 0 and each gate with fan-in 2 is labeled with either max or $+$. One gate is designated as the output gate. A tropical formula is a tropical circuit where each gate has fan-out at most 1.

With an assignment of real numbers to the variables X, a tropical circuit outputs a number computed by the output gate by natural semantics, i.e., a gate labeled with a variable x_i computes the value of x_i, a gate labeled with 0 computes 0, a gate labeled with $+$ computes the sum of the values computed by its children, and a gate labeled with max computes the maximum of the values computed by its children. In particular, a tropical circuit computes a tropical polynomial in the variables X over the tropical $(\mathbb{R} \cup \{-\infty\}, \max, +)$ semiring. In the tropical semiring max corresponds to addition and $+$ corresponds to multiplication, with $-\infty$ as the zero and 0 as the unit. We will refer to max as addition and to $+$ as multiplication.

We define an *MWIS-polynomial* with the following simple lemma.

▶ **Lemma 7.** *Let G be a graph. A tropical circuit over variables $V(G)$ computes the weight of a maximum weight independent set of G for any assignment of real weights to the inputs if and only if for the tropical polynomial f computed by the circuit it holds that*

1. *each monomial of f is of form $v_1 \cdot \ldots \cdot v_l$, where $\{v_1, \ldots, v_l\}$ is an independent set of G and*
2. *for each independent set $\{v_1, \ldots, v_l\}$ of G there is a monomial $v_1 \cdot \ldots \cdot v_l$ in f, including the empty independent set corresponding to the empty product 0.*

Proof. For the if-direction, (1) guarantees that the value computed by the circuit is at most the weight of a maximum weight independent set and (2) guarantees that the value is at least the weight of a maximum weight independent set.

For the only if-direction, if some monomial would not be multilinear, i.e., include a factor v^2 for some vertex v, the output would be incorrect when assigning weight 1 to v and 0 to other vertices. If some monomial would be of form $v_1 \cdot \ldots \cdot v_l$, where $\{v_1, \ldots, v_l\}$ is not an independent set the output would be incorrect when assigning weight 1 to those v_i and 0 to others. Finally, if the output polynomial would not include $v_1 \cdot \ldots \cdot v_l$ as a monomial for some independent set $\{v_1, \ldots, v_l\}$ then the circuit would be incorrect when assigning weight 1 to vertices of this independent set and -1 to others. ◀

An MWIS-polynomial of a graph G is a polynomial f satisfying (1) and (2) in Lemma 7. An MWIS-circuit of G is a tropical circuit that computes an MWIS-polynomial of G. An MWIS-formula of G is an MWIS-circuit of G that is a tropical formula.

We note that requiring the circuit to work for all real weights is not a strong assumption: Any MWIS-circuit that works for weights $\{0, 1\}$ can be turned into an MWIS-circuit that works for weights $\mathbb{R} \cup \{-\infty\}$ by replacing each input variable v_i by $\max(v_i, 0)$. In particular, the weight of an empty independent set is 0, so negative weights will never be used. Our assumption that the only constant available to the circuit is 0 can be justified by noting

that if an output monomial would contain a positive constant the circuit would be incorrect on the all-zero input, and that if an output monomial would contain a negative constant it should also occur without the constant. In particular, any other constants than 0 could be replaced by 0.

Next we make some simple observations on the structure of MWIS-circuits.

▶ **Definition 8.** A partial MWIS-polynomial is a polynomial f satisfying (1) in Lemma 7. A partial MWIS-circuit is a tropical circuit computing a partial MWIS-polynomial.

Note that by monotonicity of $(\max, +)$ computations we can assume that each gate of an MWIS-circuit computes a partial MWIS-polynomial and therefore each subcircuit is a partial MWIS-circuit.

▶ **Definition 9.** Let f be a partial MWIS-polynomial. We denote by $\mathrm{Sup}(f)$ the support of f, that is, the variables that occur in the monomials of f.

We also use $\mathrm{Sup}(g)$ for a gate g to denote the support of the polynomial computed by the gate. Note that each monomial of f corresponds to an independent set of $G[\mathrm{Sup}(f)]$.

The following property is the basis for proving lower bounds for MWIS-circuits.

▶ **Lemma 10.** *Let $f = g \cdot h$ be a partial MWIS-polynomial of a graph G. The sets $N[\mathrm{Sup}(g)]$ and $\mathrm{Sup}(h)$ are disjoint.*

Proof. If there was a vertex $v \in \mathrm{Sup}(g) \cap \mathrm{Sup}(h)$ then f would contain a monomial with a factor v^2. If there was a vertex $v \in \mathrm{Sup}(g)$ and $u \in \mathrm{Sup}(h)$ with $\{u, v\} \in E(G)$, then there would be a monomial in f containing a factor $u \cdot v$. ◀

We will say that a partial MWIS-polynomial f or a circuit computing f *computes* an independent set I if f contains the monomial $\prod_{v_i \in I} v_i$. In particular, an MWIS-polynomial computes every independent set.

2.3 Lopsided Lovász Local Lemma

The lopsided Lovász Local Lemma [15] (see [1] for the general version) is a method for showing that there is a non-zero probability that none of the events in a collection of events hold. In particular, we use it to show that independent sets satisfying certain requirements exist.

▶ **Definition 11.** Let $\mathcal{E}_1, \ldots, \mathcal{E}_n$ be events in a probability space. A graph Γ is a negative dependency graph of the events if its vertices are $V(\Gamma) = \{\mathcal{E}_1, \ldots, \mathcal{E}_n\}$ and for all events $\mathcal{E}_i$ and subsets $J \subseteq V(\Gamma) \setminus N(\mathcal{E}_i)$ it holds that $\Pr[\bigcup_{j \in J} \mathcal{E}_j \mid \mathcal{E}_i] \geq \Pr[\bigcup_{j \in J} \mathcal{E}_j]$.

In words, the negative dependency graph should capture all negative correlations between the events.

▶ **Proposition 12** ([1])**.** *Let $\mathcal{E}_1, \ldots, \mathcal{E}_n$ be a collection of events with a negative dependency graph Γ. If there exists real numbers $x_1, \ldots, x_n$ with $0 < x_i < 1$ such that for each i it holds that $\Pr[\mathcal{E}_i] \leq x_i \prod_{\mathcal{E}_j \in N(\mathcal{E}_i)} (1 - x_j)$, then $\Pr[\bigcap_{i=1}^{n} \overline{\mathcal{E}_i}] > 0$.*

2.4 Hitting Vertex Sets with Independent Sets

We prove a lemma which captures our use of the Local Lemma in Theorems 1 and 5. We spell out the constants to emphasize that they are not particularly high, although noting that a more careful proof could improve them a bit.

▶ **Lemma 13.** *Let G be a graph with maximum degree d and $\mathcal{F}$ a family of vertex subsets of G, each member of $\mathcal{F}$ containing at least k vertices. If $6|\mathcal{F}| \leq e^{k/(6d)}$, then there exists an independent set of G that intersects all sets in $\mathcal{F}$.*

Proof. We assume $d \geq 2$ as the lemma is easy to verify for $d \leq 1$. We use the Local Lemma to construct such an independent set. We let each vertex be in the independent set with probability $p = 1/(2d)$. Our bad events are $\mathcal{E}_e$ for each each edge e indicating that both endpoints of e are selected in the independent set, and $\mathcal{E}_A$ for each $A \in \mathcal{F}$ indicating that the independent set does not intersect A. The negative dependency graph is a bipartite graph connecting $\mathcal{E}_e$ to $\mathcal{E}_A$ if at least one of the endpoints of e is in A. In particular, note that the edge events $\mathcal{E}_e$ have non-negative correlation with each other and the vertex set events $\mathcal{E}_A$ also have non-negative correlation with each other. For all edge events $\mathcal{E}_e$ we choose $x_e = 1/(3d^2+1)$ and for all vertex set events $\mathcal{E}_A$ we choose $x_A = 1/(5|\mathcal{F}|+1)$. Now, by Proposition 12, it suffices to verify that

$$\Pr[\mathcal{E}_e] = p^2 \leq x_e(1-x_A)^{|\mathcal{F}|} \tag{1}$$

and

$$\Pr[\mathcal{E}_A] = (1-p)^{|A|} \leq x_A(1-x_e)^{|A|d} \tag{2}$$

hold whenever $6|\mathcal{F}| \leq e^{|A|/6d}$.

For (1), a lower bound for the right hand side is $e^{-1/5}/(3d^2+1)$, which can be verified to be greater than $p^2 = 1/(4d^2)$ when $d \geq 2$. For (2), an upper bound for the left hand side is $e^{-|A|/(2d)}$, and a lower bound for the right hand side is $x_A e^{-|A|d/(3d^2)}$, implying that (2) holds if $e^{-|A|/(2d)}e^{|A|/(3d)} \leq x_A$. This simplifies to $e^{-|A|/(6d)} \leq x_A \Leftrightarrow e^{|A|/(6d)} \geq 5|\mathcal{F}|+1$. ◀

3 Treewidth and MWIS-Circuits

In this section we prove lower bounds for MWIS-circuits parameterized by treewidth, i.e., Theorems 1 and 2.

We use a witness of high treewidth due to Robertson-Seymour treewidth approximation algorithm [36]. A separation of a graph G is an ordered triple of vertex sets (A,S,B) such that A,S,B are disjoint, $A \cup S \cup B = V(G)$, and no vertex of A is adjacent to a vertex of B. The order of a separation (A,S,B) is $|S|$. A separation (A,S,B) is a balanced separation of a vertex set $X \subseteq V(G)$ if $|A \cap X| \leq 2|X|/3$ and $|B \cap X| \leq 2|X|/3$.

▶ **Lemma 14** ([36])**.** *If a graph G has treewidth at least $4k$, then there is a vertex set $X \subseteq V(G)$ such that any balanced separation of X in G has order at least k.*

The next lemma is our main tool to connect circuit complexity with treewidth. This lemma is an adaptation of a classical circuit decomposition lemma (e.g. Theorem 1 in [22], Lemma 3 in [37]). In our applications the vertex set X will be the set given by Lemma 14.

▶ **Lemma 15.** *Let G be a graph and $X \subseteq V(G)$ with $|X| \geq 2$. If there is an MWIS-circuit of G with τ gates, then we can write an MWIS-polynomial of G as $g_1 \cdot h_1 + \ldots + g_\tau \cdot h_\tau$, where for all i it holds that $|Sup(g_i) \cap X| \leq 2|X|/3$ and $|Sup(h_i) \cap X| \leq 2|X|/3$.*

Proof. Let $f + e$ be an MWIS-polynomial of G, where f can be computed by a tropical circuit with τ gates. (The term e is here for the induction argument. In the first step we can assume it to be empty.) We will show that there is an MWIS-polynomial $f' + g \cdot h + e$ of G, where f' can be computed by a tropical circuit with $\tau - 1$ gates, and $|\mathrm{Sup}(g) \cap X| \leq 2|X|/3$ and $|\mathrm{Sup}(h) \cap X| \leq 2|X|/3$. The lemma follows from this by induction.

If $|\mathrm{Sup}(f) \cap X| \leq 2|X|/3$ we are done. Otherwise, we traverse the circuit computing f down starting from the output gate, always choosing the one of the two child gates whose support has larger intersection with X, until we reach a gate v computing a polynomial f_v with $|X|/3 \leq |\mathrm{Sup}(f_v) \cap X| \leq 2|X|/3$. Let $f_{v=-\infty}$ be the polynomial computed by the circuit when the value of the gate v is set to $-\infty$. Now we can write an MWIS-polynomial of G as $f_{v=-\infty} + f_v \cdot g + e$, for example by letting g be an MWIS-polynomial of $G \setminus N[\mathrm{Sup}(f_v)]$. Now, we observe that $f_{v=-\infty}$ can be computed by a circuit with $\tau - 1$ gates. We also observe that the supports of f_v and g cannot intersect, and therefore $|\mathrm{Sup}(g) \cap X| \leq 2|X|/3$. ◀

3.1 Proof of Theorem 1

Now we complete the proof of Theorem 1 by putting Lemmas 13, 14, and 15 together.

▶ **Lemma 16.** *Let G be a graph with maximum degree d and treewidth at least $4k$. Any MWIS-circuit of G has at least $e^{k/(6d)}/6$ gates.*

Proof. Suppose there is an MWIS-circuit of G with τ gates. By Lemma 14 there is a vertex set $X \subseteq V(G)$ that does not admit a balanced separation of order less than k. By Lemma 15 we can write an MWIS-polynomial of G as $g_1 \cdot h_1 + \ldots + g_\tau \cdot h_\tau$, where for all i it holds that $|\mathrm{Sup}(g_i) \cap X| \leq 2|X|/3$ and $|\mathrm{Sup}(h_i) \cap X| \leq 2|X|/3$. Now, by Lemma 10 each multiplication $g_i \cdot h_i$ defines a balanced separation $(\mathrm{Sup}(g_i), V(G) \setminus \mathrm{Sup}(g_i \cdot h_i), \mathrm{Sup}(h_i))$ of X. The order of such a separation is $|V(G) \setminus \mathrm{Sup}(g_i \cdot h_i)|$, and therefore $|V(G) \setminus \mathrm{Sup}(g_i \cdot h_i)| \geq k$. Note that $g_i \cdot h_i$ does not compute an independent set I if I intersects $V(G) \setminus \mathrm{Sup}(g_i \cdot h_i)$. Therefore, by letting $\mathcal{F}$ be the collection of vertex sets $\{V(G) \setminus \mathrm{Sup}(g_1 \cdot h_1), \ldots, V(G) \setminus \mathrm{Sup}(g_\tau \cdot h_\tau)\}$, Lemma 13 shows that if $6\tau \leq e^{k/(6d)}$ we can construct an independent set that is not computed by any of the multiplications, contradicting the assumption that we have an MWIS-circuit. ◀

3.2 Proof of Theorem 2

An *induced minor model* of a graph H in a graph G is a function $f : V(H) \to 2^{V(G)} \setminus \{\emptyset\}$, where $2^{V(G)}$ denotes the power set of $V(G)$, satisfying that

1. the sets $f(u)$ and $f(v)$ are disjoint for $u \neq v$,
2. for each $v \in V(H)$ the induced subgraph $G[f(v)]$ is connected, and
3. $\{u, v\} \in E(H)$ if and only if $N(f(u))$ intersects $f(v)$.

A graph G contains a graph H as an induced minor if and only if there is an induced minor model of H in G. For $v \in V(H)$ we call the induced subgraphs $G[f(v)]$ *clusters*.

First, we ensure that the maximum degree of each cluster is bounded.

▶ **Lemma 17.** *Let G be a graph that contains a graph H with maximum degree d as an induced minor. There is an induced minor model f of H in G such that the maximum degree of each cluster $G[f(v)]$ is at most d.*

Proof. Consider an induced minor model f of H in G and a cluster $G[f(v)]$ for some $v \in V(H)$. Because the degree of H is at most d, we can assign the cluster a set of at most d terminal vertices whose connectivity should be preserved in order to satisfy that f is an induced minor model of H in G. Now, we can remove from the cluster any vertices as long as the terminals stay connected. In particular, if there is a vertex u with degree $> d$ in $G[f(v)]$, then we can consider the shortest paths from u to the terminals, and remove from $G[f(v)]$ the vertices of $N(u) \cap G[f(v)]$ that do not participate in the shortest paths. This makes the degree of u in $G[f(v)]$ at most d. ◀

We also need the following lemma.

▶ **Lemma 18.** *Let I be an independent set selected uniformly at random from the set of all independent sets of a graph G with maximum degree d. For all $v \in V(G)$ it holds that* $\Pr[v \in I] \geq 1/2^{d+1}$.

Proof. For any set $J \subseteq N(v)$ it holds that $\Pr[I \cap N(v) = J] \leq \Pr[I \cap N(v) = \emptyset]$ because we can map any independent set I with $I \cap N(v) = J$ into an independent set $I \setminus N(v)$. Therefore $\Pr[I \cap N(v) = \emptyset] \geq 1/2^d$, so by observing that $\Pr[v \in I \mid I \cap N(v) = \emptyset] \geq 1/2$ we get $\Pr[v \in I] \geq 1/2^{d+1}$. ◀

Next we finish the proof with similar arguments as in the proof of Theorem 1, but with a different kind of construction of the independent set with the Local Lemma. In this case the constants involved appear to be impractical.

▶ **Lemma 19.** *Let G be a graph that contains a graph H with maximum degree d and treewidth $4k$ as an induced minor. Any MWIS-circuit of G has $2^{\Omega(k/(d4^d))}$ gates.*

Proof. Let f be the induced minor model of H in G. First, by Lemma 17 we can assume that the maximum degree of each cluster $G[f(v)]$ is at most d. Now, by Lemma 14 we let X' be a vertex set of H that has no balanced separation of order less than k. Then we let X be a vertex set of G created by mapping each $v \in X'$ to an element of $f(v)$. For each balanced separation (A, S, B) of X in G, the set S must intersect at least k different clusters, because otherwise we could map it into a balanced separation of X' of order $< k$ in H. Therefore, by assuming that G has an MWIS-circuit with τ gates and applying Lemma 15 with the set X we write an MWIS-polynomial of G as $g_1 \cdot h_1 + \ldots + g_\tau \cdot h_\tau$, observing that for each i the set $S_i = V(G) \setminus \mathrm{Sup}(g_i \cdot h_i)$ intersects at least k different clusters. Now it remains to show that if τ is too small we can construct an independent set of G that intersects S_i for all i.

By removing vertices from each S_i we can assume that S_i contains only vertices in clusters, and moreover contains exactly one vertex from each cluster that it intersects. We use the Local Lemma to construct the independent set. First we select each cluster independently with probability $p = 1/(4d2^d)$, and then for each selected cluster $G[f(v)]$ we select an independent set uniformly at random from the set of all independent sets of $G[f(v)]$. By Lemma 18 each vertex of G that is in some cluster will appear in the independent set with probability at least $p/2^{d+1}$. Vertices in different clusters appear in it independently of each other.

Now our bad events are $\mathcal{E}_{\{u,v\}}$ for all $\{u, v\} \in E(H)$ indicating that both clusters $G[f(u)]$ and $G[f(v)]$ have been selected and $\mathcal{E}_i$ for each S_i indicating that the set S_i does not intersect the independent set. Our negative dependency graph has edges connecting each $\mathcal{E}_{\{u,v\}}$ to each $\mathcal{E}_i$ such that S_i intersects $f(u)$ or $f(v)$. It also has all edges between all events $\mathcal{E}_i$ because $\mathcal{E}_i$ and $\mathcal{E}_j$ can be negatively correlated if S_i and S_j intersect a common cluster.

For edges $\{u, v\} \in E(H)$ we let $x_{\{u,v\}} = 1/(15d^2 4^d + 1)$ and for sets S_i we choose $x_i = 1/(20\tau + 1)$. Now it suffices to verify that

$$\Pr[\mathcal{E}_{\{u,v\}}] = p^2 \leq x_{\{u,v\}}(1 - x_i)^\tau \tag{3}$$

and

$$\Pr[\mathcal{E}_i] \leq (1 - p/2^{d+1})^{|S_i|} \leq x_i(1 - x_i)^\tau (1 - x_{\{u,v\}})^{|S_i|d} \tag{4}$$

hold whenever $30\tau \leq e^{7|S_i|/(120d4^d)}$. We also assume that $d \geq 3$ since if $d \leq 2$ then the treewidth of H is at most 2.

For (3), a lower bound for the right hand side is $e^{-1/20}/(15d^2 4^d + 1)$, which is greater than $p^2 = 1/(16d^2 4^d)$ when $d \geq 2$. For (4), a lower bound for the right hand side is $x_i e^{-1/20} e^{-|S_i|d/(15d^2 4^d)}$ and an upper bound for the left hand side is $e^{-|S_i|/(8d4^d)}$, so it holds whenever $e^{-|S_i|/(8d4^d)} \leq x_i e^{-1/20} e^{-|S_i|d/(15d^2 4^d)}$ holds, which we can simplify to $e^{|S_i|(1/(15d4^d)-1/(8d4^d))} \leq x_i e^{-1/20}$, and finally to $e^{-7|S_i|/(120d4^d)} \leq 1/(20\tau+1)e^{-1/20}$, which holds whenever $30\tau \leq e^{7|S_i|/(120d4^d)}$. ◀

4 Treedepth and MWIS-Formulas

For treedepth we are not aware of linear high-treedepth witnesses similar to what Lemma 14 is for treewidth. However, it turns out that we can use very basic properties of treedepth decompositions to establish the connection to formula complexity.

Recall that we denote the treedepth of a graph G with $td(G)$. The following properties follow from the definition of treedepth.

▶ **Proposition 20.** *Let G be a graph with treedepth $td(G)$. It holds that*
1. *$td(G \setminus \{v\}) \geq td(G) - 1$ for any $v \in V(G)$ and*
2. *$td(G)$ is the maximum of $td(G[C])$ over the connected components C of G.*

For our proof we need to introduce two definitions on MWIS-formulas. We start by defining *typical* independent sets of a partial MWIS-formulas.

▶ **Definition 21.** Let F be a partial MWIS-formula of a graph G. An independent set I of G is a typical independent set of F if for each multiplication gate g with $td(G[\mathrm{Sup}(g)]) \geq td(G)/2$ it holds that I intersects a connected component C of $G[\mathrm{Sup}(g)]$ with $td(G[C]) = td(G[\mathrm{Sup}(g)])$.

Note that by the property 2 of Proposition 20 such component indeed exists.

We also define the *separator* $\mathrm{Sep}(g)$ of a gate g. Note that an MWIS-formula forms a tree rooted at the output gate, so we will use standard tree terminology (parent, child, ancestor, descendant).

▶ **Definition 22.** The separator of the output gate o is $\mathrm{Sep}(o) = V(G) \setminus \mathrm{Sup}(o)$. The separator of a gate g whose parent p is a multiplication gate is $\mathrm{Sep}(g) = \mathrm{Sep}(p)$. The separator of a gate g whose parent p is a sum gate is $\mathrm{Sep}(g) = \mathrm{Sep}(p) \cup \mathrm{Sup}(p) \setminus \mathrm{Sup}(g)$.

With the definitions of typical independent sets and separators of gates, we can state the following lemma which will be applied with Lemma 13 to prove our lower bound.

▶ **Lemma 23.** *Let G be a graph with $td(G) \geq 2$ and F a partial MWIS-formula of G. If I is a typical independent set of F and intersects $Sep(g)$ for each gate g with $|Sep(g)| \geq td(G)/2$, then F does not compute I.*

Proof. Let F be such a formula and I such an independent set. We say that a gate g of F is redundant if F computes I if and only if F without g computes I. First, note that all gates g such that I intersects $\mathrm{Sep}(g)$ are redundant because by the definition of separator there is an ancestor gate g' of g with a sum gate parent p such that none of the monomials M contributed from g' to p have $M = \prod_{v_i \in I \cap \mathrm{Sup}(p)} v_i$, implying that g' is redundant and thus all of its descendants are redundant.

Now, we prove by induction starting from the leaves that every gate g of F for which $|\mathrm{Sep}(g)| + td(G[\mathrm{Sup}(g)]) \geq td(G)$ holds is redundant. First, for all such gates g with $td(G[\mathrm{sup}(g)]) \leq td(G)/2$, including all leaves, we have that $|\mathrm{Sep}(g)| \geq td(G)/2$, making g redundant by our definition of I. For a sum gate g and its child c we have by property 1

of Proposition 20 that $td(G[\mathrm{Sup}(c)]) \geq td(G[\mathrm{Sup}(g)]) - |\mathrm{Sup}(g) \setminus \mathrm{Sup}(c)|$, rearranging to $td(G[\mathrm{Sup}(c)] \geq td(G[\mathrm{Sup}(g)]) - |\mathrm{Sep}(c)| + |\mathrm{Sep}(g)|$, and finally to $td(G[\mathrm{Sup}(c)]) + |\mathrm{Sep}(c)| \geq td(G[\mathrm{Sup}(g)]) + |\mathrm{Sep}(g)|$. This implies that if $|\mathrm{Sep}(g)| + td(G[\mathrm{Sup}(g)]) \geq td(G)$ then both children of g are redundant, making g redundant. For a multiplication gate g with $td(G[\mathrm{Sup}(g)]) \geq td(G)/2$ it follows from the typicality assumption that there is a child c of g with $td(G[\mathrm{Sup}(c)]) + |\mathrm{Sep}(c)| = td(G[\mathrm{Sup}(g)]) + |\mathrm{Sep}(g)|$ such that g is redundant if c is redundant. Therefore the induction works, and because $|\mathrm{Sep}(o)| + td(G[\mathrm{Sup}(o)]) \geq td(G)$ holds for the output gate o, the output gate is redundant and therefore the formula does not compute I. ◀

Now the only thing left to complete the proof of Theorem 5 is to show that if a formula has less than $2^{\Omega(td(G)/d)}$ gates then we can construct an independent set that is typical for the formula and intersects $\mathrm{Sep}(g)$ whenever $|\mathrm{Sep}(g)| \geq td(G)/2$. For an independent set to be typical it suffices that it intersects $\mathrm{Sup}(g)$ for all gates g with $|\mathrm{Sup}(g)| \geq td(G)/2$. Therefore it suffices to apply Lemma 13 with $\mathcal{F}$ consisting of $\mathrm{Sep}(g)$ for all $|\mathrm{Sep}(g)| \geq td(G)/2$ and $\mathrm{Sup}(g)$ for all $|\mathrm{Sup}(g)| \geq td(G)/2$. This yields a lower bound of $e^{td(G)/(12d)}/12$ for the number of gates.

5 Optimality of Theorems 1 and 5

We show that for each pair w, d we can construct a graph with treewidth $\Omega(w)$ and maximum degree $O(d)$ that admits an MWIS-formula with $d2^{w/d}$ gates.

If $d > w$ then a d-clique does the job. Otherwise, we take a bounded degree expander with w/d vertices, having treewidth $\Omega(w/d)$, constructible by e.g. [19]. We replace each vertex of the expander with a d-clique (which will be referred to as cluster) such that each vertex of a cluster is connected to each vertex of the clusters of the adjacent vertices. We denote the constructed graph with $G_{w,d}$

▶ **Proposition 24.** *The graph $G_{w,d}$ has treewidth $\Omega(w)$, maximum degree $O(d)$, and admits an MWIS-formula with $d2^{w/d}$ gates.*

Proof. The maximum degree is at most $(d+1)$ times the maximum degree of the original bounded degree expander. The treewidth is $\Omega(w)$ because if a balanced separator contains one vertex from a cluster it must contain all vertices of the cluster.

Note that by a simple recursion any n-vertex graph admits an MWIS-formula with at most 2^n gates, so the original expander admits an MWIS-formula with $2^{w/d}$ gates. We can construct an MWIS-formula of $G_{w,d}$ by taking the MWIS-formula of the original expander and replacing each leaf corresponding to a vertex v with a d-gate construction computing the maximum over the vertices of the cluster of v. ◀

6 Conclusions and Future Work

We investigated the tropical circuit complexity of maximum weight independent set. Our initial motivation for this was the fact that lower bounds for tropical circuits imply lower bounds for many actual algorithmic techniques for maximum weight independent set that are widely used in both theory and practice. We showed that in bounded degree graphs optimal MWIS-circuits are characterized by treewidth and optimal MWIS-formulas are characterized by treedepth. We generalized the result for MWIS-circuits to apply beyond bounded degree

graphs, to a graph class that includes all planar graphs, and more generally all H-minor-free graphs. The constants hidden by the Ω-notation in Theorems 1 and 5 are somewhat practical even though we did not specifically optimize them. For example, Theorem 1 shows that any MWIS-circuit of the 5000×5000-grid has at least 10^{21} gates.

We identify some technical barriers for extending the results. First, we note that Lemma 13 is not effective in graphs with maximum degree higher than k: If $|N(v)| \geq k$, we can add $N(v)$ to $\mathcal{F}$ to force the independent set to avoid v, essentially forcing us to work with $G \setminus \{v\}$. Indeed an example of a graph with high treewidth and no small MWIS-circuits for which Lemma 13 is unsuitable is a clique with each edge subdivided. In some cases, including H-minor-free graphs and the subdivided clique, this barrier can be circumvented with Theorem 2 by using a bounded degree induced minor with high treewidth. We also note that our proofs do not exploit the fact that the separators given by Lemma 15 are balanced beyond just the size bound.

The subdivided clique does not exclude any fixed graph as a minor, so the fact that Theorem 2 works also for proving a lower bound for it seems to indicate that Theorem 2 is more powerful than what is captured by Corollary 3. We are in fact not aware of graph families for which a $2^{\Omega(w)}$ lower bound can be proved but Theorem 2 does not apply.

An interesting general direction for future work could be to prove Corollary 4 for as large graph classes as possible, starting by extending the $2^{\Omega(w)}$ lower bound as far as possible. In particular, H-topological-minor-free graphs generalize both bounded degree and H-minor-free graphs [33], so proving a $2^{\Omega(w)}$ lower bound for them seems like a natural next step. Even more generally, it could be that such a lower bound could even apply to all bounded degeneracy graphs. We hope that this line of work will lead to new insights on the structure of independent sets that could even be useful for positive results on algorithms for maximum weight independent set.

Abstract

We build boolean circuits of size $\mathcal{O}(nm^2)$ and depth $\mathcal{O}(\log(n) + m\log(m))$ for sorting n integers each of m-bits. We build also circuits that sort n integers each of m-bits according to their first k bits that are of size $\mathcal{O}(nmk(1 + \log^*(n) - \log^*(m)))$ and depth $\mathcal{O}(\log^3(n))$. This improves on the results of Asharov et al. [3] and resolves some of their open questions.

1 Introduction

Sorting undoubtedly plays a central role in computer science. Great many problems can be solved using sorting as a subcomponent. There are many practical variants of sorting based either on what we sort (integers, rational numbers, strings, etc.) or how we sort (in parallel, in distributed fashion, in external memory, etc.). Despite lots of research there are still many basic questions about sorting unanswered.

The classical comparison based sorting takes time $\mathcal{O}(n\log(n))$ when sorting n integers. Well known lower bound postulates that this is optimal for comparison based sorting. However, this is a great over-simplification and the picture is much more nuanced: sorting integers from a domain of size M can be done using binary search trees in time $\mathcal{O}(n\log|M|)$, thus sorting for example m-bit integers only needs $\mathcal{O}(nm)$ comparisons. Such an algorithm can be implemented on a pointer machine, for example. In the RAM model, with the word size m we can sort even faster: When $m = O(\log(n))$ one can sort in time $\mathcal{O}(n)$ using radix sort, and when $m = \Omega(\log^3(n))$ one can also sort in linear time using the algorithm of Andersson [2]. When $m = O(\log^3(m))$ one can sort in expected time $\mathcal{O}\left(n\sqrt{\log\frac{m}{\log(n)}}\right)$ and linear space using the algorithm of Han and Thorup [4]. It is an easy exercise to design Turing machines that sort m-bit integers in time $\mathcal{O}(nm^2)$.

In many cryptographic applications there is an interest in oblivious algorithms, algorithms in which the sequence of the operations is independent of the processed data. Sorting plays an important role in construction of oblivious RAM. An oblivious comparison based parallel model of computation intended for sorting are *sorting networks*. Numbers in a sorting network are thought of as signals which can only be compared. The seminal paper by Ajtai,

Komlós, and Szemerédi [1] gives an asymptotically optimal sorting network of logarithmic depth and thus having $\mathcal{O}(n \log(n))$ comparators matching the comparison based lower bound. The AKS network has immense applications in theoretical computer science, and we use it in this paper, too.

Another oblivious model of computation heavily used throughout theoretical computer science are boolean circuits. One can turn the AKS sorting network into a circuit of size $\mathcal{O}(nm \log(n))$ and depth $\mathcal{O}(\log(m) \log(n))$ (see Section 4). However, when building boolean circuits for sorting it is not clear whether one can take any advantage of some of the faster algorithms for RAM or Turing machines as simulating random access memory or Turing machine tapes by circuits requires substantial overhead. Asharov et al. [3] asked the question whether one can sort m-bit integers in time $o(nm \log(n))$ when $m = o(\log(n))$. They provide an answer to this question by constructing circuits for sorting m-bit integers of size $\mathcal{O}(nm^2(1 + \log^*(n) - \log^*(m))^{2+\varepsilon})$ and polynomial depth, for any $\varepsilon > 0$. We improve their results: We build boolean circuits for sorting m-bit integers of size $\mathcal{O}(nm^2)$ and depth $\mathcal{O}(\log(n) + m \log(m))$. Pending some unexpected breakthrough this size seems optimal. The depth is provably optimal whenever $m = O(\log(n)/\log\log(n))$.

Asharov et al. [3] solve even a more general problem as their circuits partially sort n numbers each of m bits by their first k bits using a circuit of size $\mathcal{O}(nmk(1 + \log^*(n) - \log^*(m))^{2+\varepsilon})$. We improve on this result as well by presenting circuits that sort m-bit integers according to their first k bits of size $\mathcal{O}(nmk(1 + \log^*(n) - \log^*(m)))$ and depth $\mathcal{O}(\log^3(n))$. Our small circuits of poly-logarithmic depth answer some of the open questions of Asharov et al. [3]. In a work subsequent to ours, Lin and Shi [7] get circuits of depth $\mathcal{O}(\log(n) + \log(k))$ and size $\mathcal{O}(nkm \cdot \mathrm{poly}(\log^*(n) - \log^*(m)))$ whenever $n > 2^{4k+7}$. They use substantially different approach. We state our results in the next section.

1.1 Our Results

We provide a family of boolean circuits that sort m-bit strings. Our circuits are smaller than the circuits directly derived from the AKS sorting network, and they improve on the result of Asharov et al. [3]. Our circuits achieve optimal logarithmic depth whenever $m \log(m) \leq \log(n)$. Pending some unexpected breakthrough, their size seems also optimal.

▶ **Theorem 1.** *For any integers $n, m \geq 1$ there is a size $\mathcal{O}(nm^2)$ and depth $\mathcal{O}(\log(n) + m \log(m))$ circuit that sorts n integers of m bits each.*

For $m \geq \Omega(\log(n))$, the existence of such a circuit directly follows from AKS sorting networks. Our contribution is the construction of such circuits for $m \leq o(\log(n))$. Our construction also uses a sorting network as a building block. We use the AKS sorting network as one of our primitives but in principle, we could use any sorting network or sorting circuit. In particular, we could use any circuit sorting n numbers of $\log(n)$ bits each in our construction. Any improvement of asymptotic complexity of sorting of $\log(n)$-bit numbers would give us improved complexity of sorting short numbers.

The main idea behind our construction is to *compress* the input by computing the number of occurrences of each m-bit integer. This gives a vector of 2^m integers, each of size $\mathcal{O}(\log(n))$. Decompressing this vector back gives the sorted input. Combining the counting and decompressing circuit gives us a circuit that sorts. The main technical lemma is our counting circuit which is of independent interest.

▶ **Lemma 2.** *For any integers $n, m \geq 1$ where $m \leq \log(n)/10$ there is a circuit*

$$FAST_COUNT_{n,m} \colon \{0,1\}^{n \cdot m} \to \{0,1\}^{\lceil 1+\log(n) \rceil 2^m}$$

which given a sequence of n strings of m bits each outputs the number of occurrences of each possible m-bit string among the inputs, that is for input $x_1, x_2, \ldots, x_n \in \{0,1\}^m$ it outputs $n_{0^m}, n_{0^{m-1}1}, \ldots, n_{1^m}$ where for each string $y \in \{0,1\}^m$, $n_y \in \{0,1\}^{\lceil 1+\log(n) \rceil}$ represents $|\{j \in [n] \mid x_j = y\}|$ in binary. The size of the circuit $FAST_COUNT_{n,m}$ is $\mathcal{O}(nm^2)$ and depth $\mathcal{O}(\log(n) + m\log(m))$.

We also provide a family of boolean circuits which sort the input integers by their first k bits only. One can view this as sorting (key, value) pairs, where keys have k bits and values have $m - k$ bits. For the special case of $k = 1$ (that is partially sorting the numbers by a single bit) the problem is equivalent to routing in *super-concentrators* (see Section 1.2), and we use super-concentrators of Pippenger [8] as our building block. We get size improvement over the result of Asharov et al. [3] while achieving also poly-logarithmic depth.

▶ **Theorem 3.** *For any integers $n, m, k \geq 1$ where $k \leq m$ and $k \leq \log(n)/11$ there is a circuit*

$$SORT_{n,m,k} \colon \{0,1\}^{nm} \to \{0,1\}^{nm}$$

which partially sorts n numbers each of m bits by their first k bits. The circuit $SORT_{n,m,k}$ has size $\mathcal{O}(knm(1 + \log^*(n) - \log^*(m)))$ and depth $\mathcal{O}(\log^3(n))$.

1.2 Our Techniques

One can take AKS sorting networks and turn them into circuits of size $\mathcal{O}(nm\log(n))$ and depth $\mathcal{O}(\log(m)\log(n))$. For $m = o(\log(n))$ this is sub-optimal as shown by Asharov et al. [3]. Asharov et al. show how to reduce the problem of sorting m-bit integers according to the first k bits into the problem of sorting m-bit integers according to just single bit. Sorting according to single bit is essentially equivalent to routing in super-concentrators.

Super-concentrators have been studied originally by Valiant with the aim of proving circuit lower bounds. A super-concentrator is a graph with two disjoint subsets of vertices $A, B \subseteq V(G)$, called inputs and outputs, with the property that for any set $S \subseteq A$ and $T \subseteq B$ of the same size there is a set of vertex disjoint paths from each vertex of S to some vertex of T. Pippenger [8] constructs super-concentrators with a linear number of edges and an algorithm that on input describing S and T outputs the list of edges forming the disjoint paths between S and T. This can be turned into a circuit of size $\mathcal{O}(n\log(n))$ and depth $\mathcal{O}(\log^2(n))$.

The result of Pippenger [8] can be used to build a circuit sorting by one bit, but the circuit will be larger than we want (see Corollary 18.) Thus, Asharov et al. [3] used the technique of Pippenger rather than his result to design a circuit sorting by one bit, and iterate it to sort by k bits. Our technique differs substantially from that of Asharov et al. yet, we use the circuits from AKS networks and from Pippenger's super-concentrators as black box.

To sort m-bit integers for $2^m \ll n$ our approach is to count the number of occurrences of each number in the input. This compresses the input from nm bits into $2^m \log(n)$ bits. We can then decompress the vector back to get the desired output. So the main challenge is to construct counting (compressing) circuits of size $\mathcal{O}(nm^2)$. Interestingly, we use the sorting circuits derived from AKS networks to do that. But to avoid the size blow-up we don't use them on all of the integers at once but on blocks of integers of size 2^{8m}. Then the $\mathcal{O}(\log(n))$ overhead of the circuits turns into the acceptable $\mathcal{O}(m)$ overhead. Each sorted

block is then subdivided into parts of size 2^{2m}. Clearly, most parts in each block will be monochromatic, they will contain copies of the same integer. There will be at most 2^m non-monochromatic parts. We *move* the parts within a block to one side using another application of the AKS sorting circuit. Then we can afford to build a fairly expensive counting circuit for the small fraction of non-monochromatic parts, while cheaply counting the monochromatic parts. Summing the results by linear size circuit gives us the desired compression. Our decompression essentially mirrors the compression.

We also design a circuit to sort according to a single bit improving the parameters of Asharov et al. [3]. We take the circuit of Pippenger as basis and apply it iteratively to larger and larger blocks of inputs. Again we start from blocks of size $2^{O(m)}$, and increase the size of the blocks exponentially at each iteration. We use Pippenger's circuit to sort each block by the bit. When we split the block into parts, only one will be monochromatic. Merging multiple blocks into one gives a mega-block with only a small fraction of non-monochromatic parts. These non-monochromatic parts can be separated from monochromatic ones, re-sorted, and re-partitioned to give only one non-monochromatic part in the mega-block. Each part takes on the role of an "m"-bit integer in the next iteration. Iterating this process leads to the desired result.

To sort according to the first k bits we use the one-bit sorting similarly to Asharov et al. [3]. Thanks to our efficient sorting circuits for m-bit integers to sort the k-bit keys, we can avoid the use of median finding circuits.

Organization

In the next section we review our notation. We provide basic construction tools including naïve constructions of counting and decompression circuits in Section 3. In Section 4 we recall basic facts on AKS sorting networks and related sorting circuits. In Section 5 we prove our main result by constructing efficient counting and decompression circuits. Finally, we provide a construction of partial sorting circuits for Theorem 3 in Section 6.

2 Notation

In this paper $\mathbb{N}$ denotes the set of natural numbers, and for $1 \leq a \leq b \in \mathbb{N}$, $[a,b] = \{a, a+1, \ldots, b\}$ and $[a] = \{1, \ldots, a\}$. All logarithms are base two unless stated otherwise. For $m \in \mathbb{N}$, $\{0,1\}^m$ is the set of all binary strings of length m. A string $x \in \{0,1\}^m$, $x = x_1 x_2 \cdots x_m$, represents the number $\sum_{j\in[m]} x_j 2^{m-j}$ in binary, and we often identify the string with that number. (As the same integer has multiple binary representations differing in the number of leading zeroes, the number of leading zeroes should be clear from the context.) The most significant bit of $x = x_1 x_2 \cdots x_m$ is x_1 and the least significant bit of x is x_m. Symbol $\circ$ denotes the concatenation of two strings. For strings $x, y \in \{0,1\}^m$, $x \oplus y$ denotes the bit-wise XOR of x and y, $x \wedge y$ denotes the bit-wise AND, and $x \vee y$ the bit-wise OR.

We assume the reader is familiar with boolean circuits (see for instance the book of Jukna [5]). We assume boolean circuits consist of gates computing binary AND and OR, and unary gates computing negation. For us, boolean circuits might have multiple outputs so a circuit with n inputs and m outputs computes a function $f\colon \{0,1\}^n \to \{0,1\}^m$. We usually index a circuit family by multiple integral parameters. Inputs and outputs of boolean circuits are often interpreted as sequences of substrings, e.g., a circuit $C_{n,m}\colon \{0,1\}^{nm} \to \{0,1\}^{nm}$ is viewed as taking n binary strings of length m as its input, and similarly for its output. We say a circuit family $(C_n)_{n\in\mathbb{N}}$ is uniform, if there is an algorithm that on input 1^n outputs the description of the circuit C_n in time polynomial in n.

3 Preliminaries

Here we review some of the circuits for basic primitives that we will use in our later constructions. Most of them are well known facts but for the others we provide proofs for the sake of completeness.

▶ **Lemma 4** (Addition). *There is a uniform family of boolean circuits* $ADD_m\colon \{0,1\}^{2m} \to \{0,1\}^{m+1}$ *that given* $x, y \in \{0,1\}^m$ *representing two numbers in binary outputs their sum* $x + y \in \{0,1\}^{m+1}$. *The circuit* ADD_m *has size* $\Theta(m)$ *and depth* $\Theta(\log(m))$.

▶ **Lemma 5** (Subtraction). *There is a uniform family of boolean circuits* $SUB_m\colon \{0,1\}^{2m} \to \{0,1\}^m$ *that given* $x, y \in \{0,1\}^m$ *representing two numbers in binary outputs the absolute value of their difference* $|x - y| \in \{0,1\}^m$. *The circuit* SUB_m *has size* $\Theta(m)$ *and depth* $\Theta(\log(m))$.

▶ **Lemma 6** (Summation). *There is a uniform family of boolean circuits*

$$SUM_{n,m}\colon \{0,1\}^{n\cdot m} \to \{0,1\}^{\lceil \log(n) \rceil + m}$$

that given $x_1, x_2, \ldots, x_n \in \{0,1\}^m$ *interpreted as* n *numbers, each of* m *bits, outputs their sum* $\sum_{j=1}^{n} x_j$. *The circuit* $SUM_{n,m}$ *has size* $\Theta(nm)$ *and depth* $\Theta(\log(n) + \log(m))$.

Proof. We sketch the construction following the technique of Wallace [9]. Given three numbers $x, y, z \in \{0,1\}^k$ in constant depth and using $\Theta(k)$ gates we can compute $p, q \in \{0,1\}^{k+1}$ such that $x + y + z = p + q$. Here, p is the coordinate-wise addition without carry, i.e., $0 \circ (x \oplus y \oplus z)$, and q is the carry, i.e., $((x \wedge y) \vee (x \wedge z) \vee (y \wedge z)) \circ 0$. Thus as long as there are at least three numbers to sum we can use this to transform x, y, z which takes $3k$ bits into p, q which take $2k + 2$ bits and continue summing those. Doing this in parallel for disjoint triples of summants after $\mathcal{O}(\log_{3/2}(n)) = \mathcal{O}(\log(n))$ rounds we are left with just two numbers and we sum those using Lemma 4. ◀

▶ **Lemma 7** (Comparator). *There is a uniform family of boolean circuits*

$$SWITCH_m\colon \{0,1\}^{2m} \to \{0,1\}^{2m}$$

that given two numbers $x, y \in \{0,1\}^m$ *outputs these two numbers sorted as integers, i.e.,* $\min(x, y) \circ \max(x, y)$. *The size of the circuit* $SWITCH_m$ *is* $\Theta(m)$ *and depth is* $\Theta(\log(m))$.

Technique similar to the proof of the next lemma will be used also later in the proofs of Lemma 2 and Lemma 16 in order to achieve smaller circuit size. The main idea is to split inputs into smaller blocks and process the blocks independently by smaller circuits.

▶ **Lemma 8** (Binary to unary). *There is a uniform family of boolean circuits*

$$ONES_b\colon \{0,1\}^{b+1} \to \{0,1\}^{2^b}$$

such that for any number $x \in \{0,1\}^{b+1}$ *represented in binary the output consists of* x *ones followed by* $2^b - x$ *zeroes, provided* $x \leq 2^b$. *The circuit* $ONES_b$ *has size* $\Theta(2^b)$ *and depth* $\Theta(\log(b))$.

Proof. We first show how to construct a uniform family of boolean circuits (ONES'$_b$) which computes the same function, has the same size but depth $\mathcal{O}(b)$. Then we use ONES'$_{\log(b)}$ to construct the desired circuit ONES$_b$.

The main idea of the construction of ONES'$_b$ is to recursively split the number x into two numbers x_L, x_R which describe how many bits set to one there should be in the first and the second half of the output.

Each of the two numbers x_L, x_R will be represented by b bits with the convention that if the most significant bit is equal to one then the number is a power of two (corresponding to all output bits in this part of the output set to one). We recursively split the numbers x_L, x_R in the same fashion until the numbers are represented by a single bit each at which point they will represent the output bits. We set

$$x_L = \min(2^{b-1}, x)$$
$$x_R = \min(2^{b-1}, \max(0, x - 2^{b-1}))$$

note that if the number x is represented by $b+1$ bits ($x \in \{0,1\}^{b+1}$) then the numbers x_L, x_R can be represented by b bits ($x_L, x_R \in \{0,1\}^b$) as both of them represent at most half of x. Given $x \in \{0,1\}^{b+1}$ we can compute the maximum and minimum defining x_L, x_R by inspecting the two most significant bits of x:

- If the most significant bit of x is set to one (thus $x \geq 2^b$) we set $x_L = x_R = x/2$ each a power of two with the most significant bit set to one (and represented by a binary string 10^{b-1}).
- If the most significant bit of x is set to zero and the second most significant bit is set to one, then x_L will be set to the binary number 10^{b-1} and x_R will be $x - x_L$ (a copy of x without the second most significant bit of x).
- If the two most significant bits of x are equal to zero then $x_L = x$ (represented by one less bit than x) and $x_R = 0$.

See Figure 1 for an example of splitting of x into x_L, x_R.

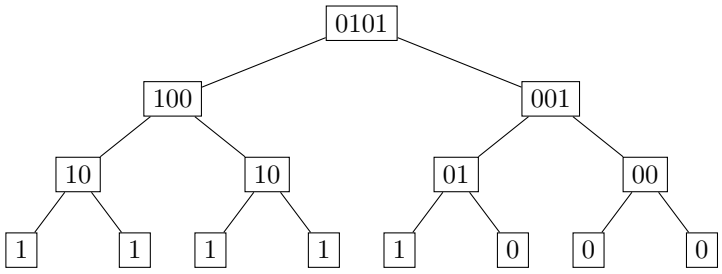

Figure 1 An example of splitting numbers where $b = 3$. The input number $x = 5$ is represented as 0101 and is split into $x_L = 100, x_R = 001$ which are themselves split recursively. The bottom nodes form the output.

Thus we can compute the transformation $x \mapsto (x_L, x_R)$ where $x \in \{0,1\}^{b+1}$ and $x_L, x_R \in \{0,1\}^b$ using a circuit of size $\Theta(b)$ and depth $\Theta(1)$. Then each of the numbers x_L, x_R is again split into two, etc. until we get single bit numbers which represent the final output. The depth of the circuit ONES'$_b$ is $\Theta(b)$ as each splitting can be done in constant depth. If the circuit splitting $b+1$ bits into two b-bit numbers has size $s(b) \leq cb + d$, for some universal constants c and d, then the circuit ONES'$_b$ has size:

$$\begin{aligned} s(b+1) + 2s(b) + 4s(b-2) + \ldots + 2^b s(1) &= \sum_{j=0}^{b} 2^j s(b-j) \\ &\leq \sum_{j=0}^{b} 2^j c(b-j) + 2^j d \\ &\leq c\left(2^{b+2} - b - 1\right) + 2^{b+1} d \\ &= O(2^b) \end{aligned}$$

To build the circuit ONES_b of depth $\mathcal{O}(\log(b))$ we proceed as follows. For any $y > 1$ we denote the largest power of two that is at most y by $\ell(y) = \max\left\{2^j \mid j \in \mathbb{N}, 2^j \leq y\right\}$. We divide the output bits into blocks of $\ell(b)$ bits and for each block $j \in \left[\frac{2^b}{\ell(b)}\right]$ of output bits with positions $[(j-1)\ell(b)+1, j\ell(b)]$ (counting positions from one) we compute if it should be constant (that is either constant zero when $x \leq (j-1)\ell(b)$ or constantly equal to one when $x > j\ell(b)$). This check for constant values can be done in each block by a circuit of size $\Theta(b)$ and depth $\Theta(\log(b))$. We compute $\mathrm{ONES'}_{\log(\ell(b))}$ with the input being the $\log(\ell(b))$ least significant bits of x. This circuit is of size $\mathcal{O}(b)$ and depth $\mathcal{O}(\log(b))$. In each block if the block should not be monochromatic then we use the output of that circuit as the output of the block, otherwise we use the appropriate constant one or zero copied $\ell(b)$-times as the output of the block. ◀

We will need a primitive that counts the number of occurrences of each string in the input. A counting similar to Lemma 9 appears in Appendix A of the paper of Asharov et al. [3]. The construction of the counting circuit is rather straightforward, we just compare each input string x_j with a given string y getting an indicator bit set to one for equality and to zero for inequality and then sum the indicator bits.

▶ **Lemma 9** (Count). *There is a uniform family of boolean circuits $COUNT_{n,m}\colon \{0,1\}^{n\cdot m} \to \{0,1\}^{2^m\lceil 1+\log(n)\rceil}$ that given $x_1, x_2, \ldots, x_n \in \{0,1\}^m$ counts the number of occurrences of each $y \in \{0,1\}^m$ among the inputs, i.e., the circuit outputs $n_{0^m}, n_{0^{m-1}1}, \ldots, n_{1^m}$ where for each $y \in \{0,1\}^m$, n_y represents in binary $|\{j \in [n] \mid y = x_j\}|$ using $\lceil 1 + \log(n)\rceil$ bits. The size of the circuit $COUNT_{n,m}$ is $\mathcal{O}(nm2^m)$ and depth $\mathcal{O}(\log(n) + \log(m))$.*

Proof. For each $y \in \{0,1\}^m$ we build a sub-circuit computing the number of times y occurs among the inputs $x_1, \ldots, x_n$. This is done by comparing y to each x_i in parallel, $i \in [n]$, to get an indicator bit whether they are equal. We obtain n_y by summing up the indicator bits using the circuit $\mathrm{SUM}_{n,1}$ of size $\Theta(n)$ and depth $\Theta(\log(n))$ from Lemma 6. Comparing y to x_i can be done by a circuit of size $\mathcal{O}(m)$ and depth $\mathcal{O}(\log(m))$. So we get n_y using a circuit of size $\Theta(nm)$ and depth $\Theta(\log(n) + \log(m))$. Doing this for each $y \in \{0,1\}^m$ in parallel we get a circuit of size $\Theta(nm2^m)$ and depth $\Theta(\log(n) + \log(m))$. ◀

We will need also an inverse operation for the counting. To construct a circuit that decompresses the counts we would like to first compute the interval where a given string x should appear and then get indicator bits for this interval. We can compute the interval using prefix sums of the counts. To get the indicator bits for the interval we utilize the circuit from Lemma 8 which outputs a given number of bits set to one followed by bits set to zero.

▶ **Lemma 10** (Decompress). *There is a uniform family of boolean circuits*

$$DECOMPRESS_{n,m}\colon \{0,1\}^{\lceil 1+\log(n)\rceil 2^m} \to \{0,1\}^{n\cdot m}$$

that decompresses its input *that is on input numbers* $n_{0^m}, n_{0^{m-1}1}, \ldots, n_{1^m}$*, each represented in binary by* $\lceil 1+\log(n)\rceil$ *bits, where* $\sum_{x\in\{0,1\}^m} n_x = s \le n$*, outputs the string*

$$(\underbrace{0\cdots0}_{m})^{n_{0\cdots0}} \circ (\underbrace{0\cdots0}_{m-1}1)^{n_{0\cdots01}} \circ (\underbrace{0\cdots0}_{m-2}10)^{n_{0\cdots010}} \circ (\underbrace{0\cdots0}_{m-2}11)^{n_{0\cdots011}} \circ \cdots \circ (\underbrace{1\cdots1}_{m})^{n_{1\cdots1}} \circ (0^m)^{n-s}.$$

When $s > n$ *the output might be arbitrary. The size of the circuit* $DECOMPRESS_{n,m}$ *is* $\mathcal{O}(nm2^m + 2^{2m}\log(n))$ *and depth* $\mathcal{O}(m + \log\log(n))$*.*

Proof. Given $n_{0^m}, n_{0^{m-1}1}, \ldots, n_{1^m}$ we can compute the total sum $s = \sum_{x\in\{0,1\}^m} n_x$ and for each $y \in \{0,1\}^m$, the number p_y of binary strings before the first occurrence of y, i.e., $p_y = \sum_{x\in\{0,1\}^m\colon x<y} n_x$. Each of the numbers p_y can be computed using the circuit $\mathrm{SUM}_{y,\lceil 1+\log(n)\rceil}$ from Lemma 6 of size $\mathcal{O}(2^m\log(n))$ and depth $\mathcal{O}(m+\log\log(n))$. Similarly for s. Thus we can get all numbers p_y in parallel by a circuit of size $\mathcal{O}(2^{2m}\log(n))$. A given string $y \in \{0,1\}^m$, $y \neq 1^m$, should appear at each position $j \in [p_y+1, p_{y+1}]$. Let $I_y \in \{0,1\}^n$ be the indicator vector of positions where y should appear in the output. We can use $\mathrm{ONES}_{\lceil 1+\log(n)\rceil}(p_y) \oplus \mathrm{ONES}_{\lceil 1+\log(n)\rceil}(p_{y+1})$ to calculate I_y for each $y \neq 1^m$. For $y = 1^m$, $I_y = \mathrm{ONES}_{\lceil 1+\log(n)\rceil}(p_y) \oplus \mathrm{ONES}_{\lceil 1+\log(n)\rceil}(s)$. The size of $\mathrm{ONES}_{\lceil 1+\log(n)\rceil}$ is $\Theta(n)$. As there are 2^m different y's, we need a circuit of size $\Theta(n2^m)$ and depth $\Theta(\log\log(n))$ to calculate all I_y's.

If $x_1, x_2, \ldots, x_n$ are the output integers, for each output position $j \in [n]$, we calculate the k-bit of x_j as

$$\bigvee_{y\in\{0,1\}^m} ((I_y)_j \wedge y_k)$$

To compute all these ORs we need a circuit of total size $\Theta(nm2^m)$ and depth $\Theta(m)$. ◀

4 Sorting Circuits from AKS Sorting Networks

In this section we recall the construction of circuits for sorting from the Ajtai-Komlós-Szemerédi sorting networks. They will serve as the basic primitive for our later constructions.

Sorting networks

Sorting networks model parallel algorithms that sort values using only comparisons. A sorting network consists of n wires and s comparators. The wires extend from left to right in parallel. Each wire carries an integer from left to right. Any two wires can be connected by a comparator at any point along their length. The comparator swaps the values carried along the two wires if the higher wire carries a higher value at that point otherwise it has no effect. The sorting network should be such when we input arbitrary integers to the wires on the left, the integers always exit in sorted order from top to bottom. The *depth* of a sorting network is the maximum number of comparators a value can encounter on its way. A figure of a small sorting network is given in Figure 2. For a formal definition see, e.g., [1]. Observe that if the depth of a sorting network is d and the number of inputs is n then there are at most $s \le nd$ comparators. Ajtai, Komlós and Szemerédi [1] established the existence of sorting networks of logarithmic depth.

▶ **Theorem 11** (AKS [1]). *For any integer* $n \ge 1$*, there is a sorting network for* n *integers of depth* $\mathcal{O}(\log(n))$*.*

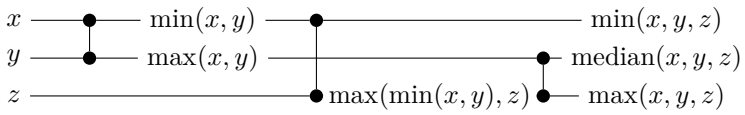

Figure 2 An example of a sorting network with three inputs (the horizontal lines), three comparators (the vertical lines), and depth three. The inputs on the left are numbers x, y, z and after each comparator we noted what is on the horizontal line. Note that the bottom most output is $\max(\max(x,y), \max(\min(x,y),z)) = \max(x,y,z)$ and the middle one is $\min(\max(x,y), \max(\min(x,y),z))$ which is the median.

Sorting circuits

Here we give a precise definition of sorting by a circuit. First we consider a circuit sorting n integers, each of them m bits long.

▶ **Definition 12** (Sort). *Let $n, m \in \mathbb{N}$, and $(C_{n,m})$ be a family of boolean circuits. We say that the* circuit $C_{n,m} \colon \{0,1\}^{nm} \to \{0,1\}^{nm}$ sorts its input *interpreted as n integers $x_1, x_2, \ldots, x_n$ each represented by m bits if it outputs $y_1, y_2, \ldots, y_n \in \{0,1\}^m$ such that:*

1. *The outputs are sorted: For any $i < j \in [n]$, $y_i \leq y_j$.*
2. *The inputs and outputs form the same multiset: For each $j \in [n]$, $|\{i \in [n] \mid y_i = x_j\}| = |\{i \in [n] \mid x_i = x_j\}|$.*

An immediate consequence of the existence of AKS sorting networks is the existence of shallow sorting circuits, since by Lemma 7, each comparator can be replaced by a small circuit:

▶ **Corollary 13.** *There is a family of boolean circuits $AKS_{n,m} \colon \{0,1\}^{n \cdot m} \to \{0,1\}^{n \cdot m}$ that on an input $x_1, x_2, \ldots, x_n \in \{0,1\}^m$ sorts these numbers. The size of the circuit $AKS_{n,m}$ is $\mathcal{O}(nm \log(n))$ and depth $\mathcal{O}(\log(n) \log(m))$.*

We also need circuits that sort the n input integers, each of m bits, by the k most significant bits where $k < m$. Such sorting can be thought of as sorting (key, value) pairs, where keys are k-bit long and values $(m-k)$-bit long. Formally it can be defined as follows:

▶ **Definition 14** (Partial Sort). *Let $n, m, k \in \mathbb{N}$, be such that $k < m$, and let $(C_{n,m,k})$ be a family of boolean circuits. We say that the* circuit $C_{n,m,k} \colon \{0,1\}^{nm} \to \{0,1\}^{nm}$ partially sorts by the first k bits its input *interpreted as n integers $x_1, x_2, \ldots, x_n$ each represented by m bits if it outputs $y_1, y_2, \ldots, y_n \in \{0,1\}^m$ such that:*

1. *The outputs are partially sorted: For any $i < j$, $(y_i)_1 (y_i)_2 \cdots (y_i)_k \leq (y_j)_1 (y_j)_2 \cdots (y_j)_k$.*
2. *The inputs and outputs form the same multiset: For each $j \in [n]$, $|\{i \in [n] \mid y_i = x_j\}| = |\{i \in [n] \mid x_i = x_j\}|$.*

Using a circuit of size $\mathcal{O}(m)$ and depth $\mathcal{O}(\log(k))$ implementing a comparator which swaps two m-bit integers based only on the first k bits we get the following variant of the previous corollary.

▶ **Corollary 15.** *There is a family of boolean circuits $PARTIAL_AKS_{n,m,k} \colon \{0,1\}^{n \cdot m} \to \{0,1\}^{n \cdot m}$, for $k \leq m$ and $k \leq \log(n)$, that on input $x_1, x_2, \ldots, x_n \in \{0,1\}^m$ partially sorts these numbers according to their k most significant bits. That is if y_i, y_j are two output numbers where $i < j$ then we have $\lfloor y_i / 2^{m-k} \rfloor \leq \lfloor y_j / 2^{m-k} \rfloor$. The size of the circuit $PARTIAL_AKS_{n,m,k}$ is $\mathcal{O}(nm \log(n))$ and depth $\mathcal{O}(\log(n) \log(k))$.*

5 Sorting n Binary Strings of Length m

Here we present a sorting circuit for short numbers. The construction consists of two circuits. The first circuit counts the number of occurrences of various strings (as stated in Lemma 2) and the second circuit decompresses these counts. Both of these constructions use heavily the following technique: we divide the problem into blocks which can be efficiently sorted using the AKS-based circuit. These blocks will be of size between $2^{O(m)}$ and $n/2^{O(m)}$ where m is the binary length of the input integers.

Thus when we sort the numbers inside each block and subdivide the block into parts, then by the pigeon-hole principle, most of the parts will be monochromatic (containing copies of a single string only). We can then separately count the strings in monochromatic parts (count the first string and then multiply that by the length of the part) and in the non-monochromatic parts (there are not that many strings in total in non-monochromatic parts). However a priori we do not know which parts will be monochromatic and which will be not. To save on circuitry we use sorting (on whole parts) to move the non-monochromatic parts aside. We build the (expensive) counting circuits only for non-monochromatic parts.

Proof of Lemma 2. For the sake of simplicity let us assume that n is a power of two so, it is divisible by 2^{8m}. (By our assumption $n \geq 2^{10m}$, thus if n is not a power of two take the circuit for the closest power of two larger than n and feed ones for the extra input bits.) We partition the input into $n/2^{8m}$ blocks each consisting of 2^{8m} numbers. We sort each block by the circuit $\mathrm{AKS}_{2^{8m},m}$ of size $\mathcal{O}(2^{8m}m\log(2^{8m})) = \mathcal{O}(2^{8m}m^2)$ and depth $\mathcal{O}(m\log(m))$ as given in Corollary 13 . Thus for this phase we need a circuit of total size $\mathcal{O}(nm^2)$.

Then we subdivide each block into 2^{6m} parts each consisting of 2^{2m} numbers. Observe that most of these parts are monochromatic: a part is monochromatic if it contains 2^{2m} copies of a single m-bit number. We can upper bound the number of non-monochromatic parts by 2^m. We can add a single indicator bit to each part indicating whether this part is monochromatic. As the parts are sorted it is enough to compare the first and last number in each part and set the bit to 1 if the numbers are equal and to 0 otherwise. We sort the parts prefixed by their indicator bit using the circuit $\mathrm{PARTIAL_AKS}_{2^{6m},1+m2^{2m},1}$ from Corollary 15 to move all non-monochromatic parts to the front of each block. Thus the total size of the circuit sorting parts inside each block is $\mathcal{O}\left(\frac{n}{2^{8m}}(2^{6m})(1+m2^{2m})6m\right) = \mathcal{O}(nm^2)$ and depth $\mathcal{O}(m)$. We call the first 2^m parts of each block *potentially non-monochromatic*. The other parts are *definitely monochromatic*.

From each definitely monochromatic part we take the first m-bit number and we count them. This can be done by the circuit $\mathrm{COUNT}_{\frac{n}{2^{8m}}(2^{6m}-2^m),m}$ from Lemma 9 of size $\mathcal{O}\left(\left(\frac{n}{2^{2m}} - \frac{n}{2^{7m}}\right)m2^m\right) \leq \mathcal{O}(nm)$ and depth $\mathcal{O}(\log(n)+\log(m))$. By multiplying each count by 2^{2m} (that is by appending $2m$ zeroes) we get the number of occurrences of each number in the definitely monochromatic parts.

As there are relatively few (exactly $\frac{n}{2^{8m}}2^m2^{2m}$) numbers overall in potentially non-monochromatic parts we can use the circuit $\mathrm{COUNT}_{n/2^{5m},m}$ from Lemma 9 to count those numbers by a circuit of size $\mathcal{O}\left(\frac{n}{2^{5m}}m2^m\right) \leq \mathcal{O}(nm)$ and depth $\mathcal{O}(\log(n)+\log(m))$.

Thus we get two vectors of counts for numbers in potentially non-monochromatic and definitely monochromatic blocks. Finally, we add the two vectors of 2^m numbers each consisting of at most $\lceil 1+\log(n)\rceil$ bits to get the resulting counts. This uses a circuit of size $\mathcal{O}(m2^m) = O(n)$ and depth $\mathcal{O}(\log\log(n))$. Thus, the overall size of the circuit is $\mathcal{O}(nm^2)$ and depth $\mathcal{O}(\log(n)+m\log(m))$. ◀

▶ **Lemma 16.** *For integers $n, m \geq 1$ such that $m \leq \log(n)/11$, there is a family of boolean circuits*

$$FAST_DECOMPRESS_{n,m} \colon \{0,1\}^{\lceil 1+\log(n)\rceil 2^m} \to \{0,1\}^{n\cdot m}$$

that decompresses its input as in Lemma 10. The size of $FAST_DECOMPRESS_{n,m}$ is $\mathcal{O}(nm^2)$ and its depth is $\mathcal{O}(m\log(m) + \log\log(n))$.

The construction of the decompression circuit mirrors the counting circuit albeit it is somewhat simpler with a different choice of parameters. We separately decompress monochromatic blocks (by decompressing just a single string from each block and then creating the right number of copies) and the strings from non-monochromatic blocks (as there are not many of those). We then use partial sorting to rearrange the blocks in the proper order to construct a sorted sequence.

Proof. For the sake of simplicity let us assume that n is a power of two and let us set $k = n/2^{8m}$. (Thus k is an integer.) We will think of the output as partitioned into 2^{8m} blocks of size k. As in the proof of Lemma 10 we compute the prefix sums

$$p_x = \sum_{y\in\{0,1\}^m \colon y<x} n_y \qquad \text{for each } x \in \{0,1\}^m$$

and we set $p_{2^m} = n$. (Here, we identify m-bit strings x and y with integers they represent.) We can compute each p_x using the circuit $\mathrm{SUM}_{2^m,1+\log(n)}$, thus computing all of them using a circuit of size $\mathcal{O}(\log(n)2^{2m}) \leq \mathcal{O}(n)$ (by the assumption $m \leq \log(n)/11$) and depth $\mathcal{O}(m+\log\log(n))$. Thus the string $x \in \{0,1\}^m$ should appear at output positions $[p_x+1, p_{x+1}]$. For any $x \in \{0,1\}^m$ we set:

$$r_x = ((k - (p_x \mod k)) \mod k) + (p_{x+1} \mod k)$$
$$q_x = \frac{n_x - r_x}{k}$$

The meaning is that if we partition the output into blocks of k consecutive numbers, then for any $x \in \{0,1\}^m$ the number r_x tells the number of times the string x appears in non-monochromatic blocks. (These occurrences are located in at most two non-monochromatic blocks.) The number q_x tells us in how many monochromatic blocks the string $x \in \{0,1\}^m$ appears. Observe that q_x is an integer. Since n is a power of two, so is k, furthermore, k is fixed for given n and m, and thus computing mod k and division by k corresponds to selecting appropriate bits from the binary representation of numbers. All numbers p_x, q_x and r_x are integers represented by $1 + \log(n)$ bits. Hence, each q_x and r_x can be computed from n_x and p_x by one circuit $\mathrm{ADD}_{1+\log(n)}$ and two $\mathrm{SUB}_{1+\log(n)}$. The circuit computing values q_x and r_x for all x has total size $\mathcal{O}(2^m\log(n))$ and depth $\mathcal{O}(\log\log(n))$.

The following holds:

$$n_x = kq_x + r_x$$
$$\sum_{x\in\{0,1\}^m} q_x = \sum_{x\in\{0,1\}^m} \frac{n_x - r_x}{k} \leq n/k = 2^{8m}$$
$$\sum_{x\in\{0,1\}^m} r_x \leq 2k2^m = 2n/2^{7m}$$

We use circuit $\mathrm{DECOMPRESS}_{2^{8m},m}(q_{0^m}, q_{0^{m-1}1}, \ldots, q_{1^m})$ from Lemma 10 of size $\mathcal{O}\left(m2^{9m}\right)$ and depth $\mathcal{O}\left(m\right)$ to decompress monochromatic blocks. We then just copy each resulting number k times to create sorted monochromatic blocks. Last $2^{8m} - \sum_{x\in\{0,1\}^m} q_x$ blocks contain zero padding corresponding to the numbers in non-monochromatic blocks. They will be merged with the non-monochromatic blocks obtained next.

In order to properly match the non-monochromatic blocks to the padded zeroes we adjust the count r_{0^m}:

$$r'_{0^m} = \left(2n/2^{7m}\right) - \sum_{x\in\{0,1\}^m:\, x\neq 0^m} r_x$$

using circuit $\mathrm{SUM}_{2^m,1+\log(n)}$ and $\mathrm{SUB}_{1+\log(n)}$ of size $\mathcal{O}(n)$ and depth $\mathcal{O}(m+\log\log(n))$. We use the circuit $\mathrm{DECOMPRESS}_{2n/2^{7m},m}(r'_{0^m}, r_{0^{m-1}1}, \ldots, r_{1^m})$ from Lemma 10 to decompress the non-monochromatic blocks. The circuit is of size

$$\mathcal{O}\left(\left(2n/2^{7m}\right)m2^m + 2^{2m}\log\left(2n/2^{7m}\right)\right) \leq \mathcal{O}\left(nm/2^{6m}\right)$$

and of depth $\mathcal{O}(m+\log\log(n))$. (Here, we used our assumption $m \leq \log(n)/11$, to bound $n \geq 2^{11m}$ and $2^{2m} \leq n^{3/4}/2^{6m}$.)

Finally, we compute the bit-wise OR of the last 2^{m+1} blocks of the output from the previous step (monochromatic decompression) with the current output (non-monochromatic decompression). This way we get a sequence of n numbers partitioned into blocks where each block corresponds to one of the blocks in the desired output. However, we still need to rearrange the blocks in the proper order. We will use partial sorting of the whole blocks to do that.

For a given block let x be the first number in that block. We prefix the block by a number $2x$ (represented by $m+1$ bits) if the block is monochromatic or the number $2x+1$ if the block is non-monochromatic. To determine whether the block is monochromatic we compare for equality the first and last number inside the block. We do this for each block. Thus each block of k numbers is prefixed by an $m+1$ bit number. Computing these prefixes requires a circuit of total size $\mathcal{O}(2^{8m}m) = O(n)$ and depth $\mathcal{O}(\log(m))$. We then use the $\mathrm{PARTIAL_AKS}_{2^{8m},(m+1)+km,m+1}$ circuit of size $\mathcal{O}(nm^2)$ and depth $\mathcal{O}(m\log(m))$ to sort the blocks. Finally, we ignore the $m+1$ bit prefixes of each block to get the desired output. ◀

Proof of Theorem 1. This is just a combination of Lemma 2 with Lemma 16. ◀

Observe that the proofs of Lemma 2 and Lemma 16 do not depend on using specifically the AKS sorting. In particular for the case of Lemma 2 if there is a circuit that sorts input numbers that is linear in the number of input bits then there is a linear size circuit that counts these numbers.

6 Partial Sorting by the First k Bits in Poly-logarithmic Depth

Here we design a family of boolean circuits that partially sorts by the first k bits out of m bits which is asymptotically smaller than $\mathrm{PARTIAL_AKS}_{n,m,k}$. We will need super-concentrators for our construction.

A directed acyclic graph $G = (V, E, A, B)$, where V is the set of vertices, E is the set of directed edges, and A and B are disjoint subsets of vertices of the same size, is a *super-concentrator* if the following hold: The vertices in A (*inputs*) have in-degree zero, vertices in B (*outputs*) have out-degree zero, and for any $S \subseteq A$ and for any $T \subseteq B$: $|S| = |T|$ there is a set of pairwise vertex disjoint paths connecting each vertex from S to some vertex in T.

We parametrize the super-concentrator by the number of input vertices n, and we measure its size by the number of edges. We want the graph to have as few edges as possible. The depth of the super-concentrator is the number of edges on the longest directed path.

Pippenger [8] shows a construction of super-concentrators of linear size and logarithmic depth. He constructs a family of super-concentrators S_n for n being the number of inputs, where the in-degree and out-degree of each vertex is bounded by some universal constant, the number of edges is linear in n, and the depth is $\mathcal{O}(\log(n))$. Moreover there are finite automatons which for any $S \subset A, T \subset B$: $|S| = |T|$ when put on the vertices of the super-concentrator find the set of vertex disjoint paths from S to T in $\mathcal{O}(\log(n))$ iterations, each taking $\mathcal{O}(\log(n))$ steps, for the total number of $\mathcal{O}(n)$ steps of the automatons. We describe this construction using the language of circuits. The circuit on input of characteristic vector of S and T computes the set of $|T|$ vertex disjoint paths connecting S and T. The circuit outputs the characteristic vector of the set of edges participating in the paths.

▶ **Theorem 17** (Pippenger [8]). *There is a family of super-concentrators S_n as described above and boolean circuits $ROUTE_n\colon \{0,1\}^{2n} \to \{0,1\}^{|S_n|}$ of size $\mathcal{O}(n\log(n))$ and depth $\mathcal{O}(\log^2(n))$ that on input characteristic vector of any set $T \subseteq [n]$ and characteristic vector of any $S \subseteq [n]$ where $|T| = |S|$, outputs the characteristic vector of edges that form $|T|$ vertex disjoint paths between S and T.*

By routing m bits along each path in the super-concentrator we can use the above circuit to build a circuit that partially sorts m-bit integers by their most significant bit.

▶ **Corollary 18.** *There is a family of boolean circuits*

$$PIPPENGER_SORT_{n,m,1}\colon \{0,1\}^{n\cdot m} \to \{0,1\}^{n\cdot m}$$

that on input $x_1, x_2, \ldots, x_n \in \{0,1\}^m$ partially sort these numbers according to their first most significant bit. The size of the circuit $PIPPENGER_SORT_{n,m,1}$ is $\mathcal{O}(nm + n\log(n))$ and depth $\mathcal{O}(\log^2(n))$.

Proof. We give a sketch of the proof. First, we will use the graph S_n to get all inputs starting with one to the proper place. Then, using the same construction we will move all inputs starting by 0 to the proper place. We transform the graph S_n into a circuit by replacing each vertex of in-degree d by a *routing gadget* (circuit) which takes d m-bit inputs together with d control bits, one bit for each of the m-bit inputs, and outputs the bit-wise OR of inputs for which their control bit is set to 1. Such a routing gadget of size $\mathcal{O}(dm)$ and depth $\mathcal{O}(\log(d))$ can be easily constructed. If (u, v) is the j-th incoming edge of v in S_n, we connect the j-th block of m input bits of the routing gadget corresponding to v to the output of the routing gadget of u. The routing gadgets of input vertices of S_n are connected directly to the appropriate inputs of the sorting circuit. The routing gadget will be used with at most single control bit set to one, thus it will route the corresponding input.

It remains to calculate paths that will route the integers starting with 1 in the above circuit in the desired way. For that, we calculate the sum s of the most significant bits by which we are sorting using $\mathrm{SUM}_{n,1}$ from Lemma 6, we expand it back using $\mathrm{ONES}_{\lceil\log(n)\rceil+1}(s)$, and reverse it to get the characteristic vector of a set T, where we want to route to. Together with the most significant bits of each input integer (which form the characteristic vector of S from which we route) we feed this as an input to ROUTE_n. The output bits of ROUTE_n are connected to the appropriate control bits of our routing gadgets. The sorted output will be obtained as the output of the n routing gadgets corresponding to the output vertices of S_n.

The size of the ROUTE_n is $\mathcal{O}(n \log(n))$ and the total size of the circuits implementing the routing gadgets is $\mathcal{O}(mn)$. These two terms dominate the overall size of the circuit. The depth of the circuit is dominated by the depth of the ROUTE_n. ◀

We can use the above circuit in an iterative fashion to build a smaller circuit for the same primitive.

▶ **Lemma 19.** *There is a family of boolean circuits* $ITERATIVE_SORT_{n,m,1}\colon \{0,1\}^{n \cdot m} \to \{0,1\}^{n \cdot m}$ *that on input* $x_1, x_2, \ldots, x_n \in \{0,1\}^m$ *partially sort these numbers according to their first most significant bit. The size of the circuit* $ITERATIVE_SORT_{n,m,1}$ *is* $\mathcal{O}(nm(1 + \log^*(n) - \log^*(m)))$ *and its depth is* $\mathcal{O}(\log^2(n))$.

Proof. Assume $m \leq \log(n)/11$ otherwise use Corollary 18. We will build the circuit iteratively using the circuit from Corollary 18 for blocks of various sizes. We will start with small blocks of items and we will iteratively sort larger and larger number of items organized into mostly monochromatic blocks. Without loss of generality we assume that m is a power of two, and we will ignore the rounding issues. We will have two parameters m_i and $n_i = 2^{3m_i}$, where $m_0 = m$ and $m_{i+1} = 2^{m_i}$ for $i \geq 0$. At iteration i, all the items will be partitioned into *parts* of consecutive numbers, each part will be either *monochromatic* containing all zeros, all ones, or it will be *mixed*. (Here we refer to the most significant bits of the numbers in the part.) For each part we will maintain two indicator bits which of the three possibilities occurs: an indicator which is one if the block is mixed, and another *color* indicator which specifies the highest order bit of the integers if the block is monochromatic. (For the latter we could use the first bit of the first integer in the part.) At each iteration $i > 0$, m_i will denote the number of items in each part. n_i/m_i consecutive parts form a *block*, so each block contains n_i items. The blocks partition the input. We will maintain an invariant that the fraction of mixed parts in each block is at most $2/m_i^3$.

At iteration 0 we apply $\mathrm{PIPPENGER_SORT}_{n_0,m,1}$ to consecutive blocks of n_0 input integers. Afterwards, the block is partitioned into parts of size m_1 and for each part we determine its status by comparing the most significant bits of the first and last integer in the part. It is clear that each block of size n_0 contains at most one mixed part. As the number of parts in the block is m_1^3, the fraction of mixed parts in each block is at most $2/m_1^3$, and this is also true for blocks of size n_1.

At iteration $i > 0$, we divide the current sequence of parts of size m_i into blocks containing n_i/m_i parts, and we proceed in three steps:

Step 1. Sort the parts in each block using $\mathrm{PIPPENGER_SORT}_{n_i/m_i,2+m_i \cdot m,1}$ according to the mixed indicator. Hence, all the mixed parts will move to the end of the block. There are at most $2n_i/m_i^3$ mixed parts in each block, the remaining parts must be monochromatic.

Step 2. In each block, sort all the m-bit integers in the last $2n_i/m_i^3$ parts according to their most significant bit using $\mathrm{PIPPENGER_SORT}_{2n_i/m_i^2,m,1}$. This sorts together all the integers in the mixed parts (and perhaps few other parts). Repartition them into parts of m_i consecutive numbers and determine their indicator bits. Only one of the parts should be mixed at this point. Swap it with the last part in the block. (We provide details of the swap later.)

Step 3. In each block, sort all the parts except for the last one according to their color indicator using $\mathrm{PIPPENGER_SORT}_{(n_i/m_i)-1,2+m_i \cdot m,1}$. This moves all the parts of color 0 to the front. Repartition all the numbers in the block into parts of m_{i+1} consecutive integers and determine their indicator bits, where the last part is marked as mixed. At

most two of the new parts should be mixed at this point. Notice, that out of m_{i+1}^3 parts in each block, at most two are marked as mixed so the invariant applies. We can move to the next iteration.

We iterate the algorithm until $m_i \geq \log(n)/4$. Once $m_i \geq \log(n)/4$, the number of integers in mixed parts is at most $2n/m_i^2 \leq O(n/\log^2(n))$, remaining items are in monochromatic parts. At this point we cannot form a block of size n_i, but we can still perform the same type of actions as in Steps 1-3: We can bring the monochromatic parts forward as in Step 1, sort the last $32n/\log^2(n)$ integers belonging to the mixed parts, move the remaining mixed part to the end, sort the monochromatic parts and swap the mixed part with the first monochromatic part of color 1.

To swap a single mixed part with the last part we can copy the mixed part into a buffer by AND-ing every part bit-wise with the indicator whether that is the mixed part, and OR-ing all the results together. This copies the mixed part into a buffer. In a similar fashion we can copy the last part into the now unused part by letting each part bit-wise copy to its place either its original content or the content of the last part, again conditioning on an appropriate indicator bit. Hence, the swap can be implemented by a circuit of size proportional to the total size of the parts and depth logarithmic in the number of parts.

Now we will bound the total size of the circuit we constructed. Step 1 requires n/n_i circuits of size $\mathcal{O}(n_i m + n_i/m_i \log(n_i/m_i)) = \mathcal{O}(n_i m)$, as $\log(n_i) = O(m_i)$, and of depth at most $\mathcal{O}(\log^2(n_i))$. Step 2 requires n/n_i sorting circuits of size $\mathcal{O}(mn_i/m_i^2 + 2n_i/m_i^2 \log(2n_i/m_i^2)) = \mathcal{O}(n_i)$ and of depth at most $\mathcal{O}(\log^2(n_i))$, together with a circuit of total linear size $\mathcal{O}(n)$ to recalculate the parts and do the swaps. The last step requires the same amount of circuitry as the first step.

Hence, each step requires circuits of total size $\mathcal{O}(nm)$. The same goes for the initial sort at iteration 0, and the final sorts at the end. As there are at most $\log^*(n) - \log^*(m)$ iterations, the resulting size is $\mathcal{O}(nm(\log^*(n) - \log^*(m)))$. Each step requires a circuit of depth $\mathcal{O}(\log^2(n_i))$, recall that by our choice $n_i = 2^{4m_i}$, thus $\log(n_i) = 4m_i$. Since $m_{i+1} = 2^{m_i}$ and for each i we have $m_i \leq \log(n)/4$, thus the total depth is dominated by the last iteration where we use a circuit of depth $\mathcal{O}(\log^2(n))$. ◀

Proof of Theorem 3. We assume that $k \leq \log(n)/11$ otherwise we can use Corollary 15 to sort the elements. Without loss of generality we assume n is a power of two. We think of the input as organized into an array. We extract the first k bits (*key*) from each input element and we sort the keys using the circuit from Theorem 1 of size $\mathcal{O}(nk^2)$ and depth $\mathcal{O}(\log(n) + k\log(k))$.

We will build recursively a circuit that will sort the input array of n elements according to the first k bits when the input is augmented with the array of sorted keys. Now our goal is to split the input array into two equal sized parts L and R where all elements in L are less or equal to elements in R when comparing only the keys.

To do that we take the *median*, the $n/2$-th element among the keys, and we partition the array according to it. We split the input array into three arrays L, M, and R of length n with elements less than, equal to, and greater than the median, resp., and we mark the unused elements as *dummy* using an extra bit associated to each element. We sort L and M so that all non-dummy elements are to the left and R so that all non-dummy elements are to the right. We use three circuits ITERATIVE_SORT$_{n,m+1,1}$ to do that. Now, we flip the first half of elements in M, i.e., swap the i-th element with the element in position $(n/2) - i + 1$, and we replace the dummy elements in the first half of L by the corresponding elements in M.

By one application of ITERATIVE_SORT$_{n,m+1,1}$ we move all the remaining non-dummy elements in M to the left, and we merge those elements with the second half of R. We discard the second and first half of L and R, respectively. (They contain only dummy elements.)

If the highest order bit of the median is set to 0 then all the elements in L have the highest order bit set to 0, otherwise all the elements in R have the highest order bit set to 1. In either case we reduced the problem to one problem of sorting half of the elements according to $k-1$ bits and the other half according to k-bits. We recursively build a circuit to sort SORT$_{n/2,m,k-1}$ and SORT$_{n/2,m,k}$ when the input is augmented with the sorted array of keys. We pass to each of the sorting sub-circuits the appropriate sub-problem and we re-route the results from them to form the final output.

Not counting the two sub-circuits SORT$_{n/2,m,k-1}$ and SORT$_{n/2,m,k}$, this step requires four copies of the circuit ITERATIVE_SORT$_{n,m+1,1}$ and additional $\mathcal{O}(nm)$ gates to do the moves and element comparison with the median. Denote the size of this part of the circuit by $L_m(n) = \mathcal{O}(nm(1+\log^*(n)-\log^*(m)))$. The depth of the resulting circuit to perform all those operations is $\mathcal{O}(\log^2(n))$ as the move operations are done in parallel (again, not counting the depth of SORT$_{n/2,m,k-1}$ and SORT$_{n/2,m,k}$). If we denote by $S_{m,k}(n)$ the size of the circuit SORT$_{n,m,k}$ we get the following recurrence:

$$\begin{aligned}
S_{m,k}(1) &= \mathcal{O}(m)\\
S_{m,1}(n) &= \mathcal{O}(nm(1+\log^*(n)-\log^*(m)))\\
S_{m,k}(n) &\leq L_m(n) + S_{m,k-1}\left(\frac{n}{2}\right) + S_{m,k}\left(\frac{n}{2}\right)
\end{aligned}$$

when we iterate the recurrence:

$$\begin{aligned}
S_{m,k}(n) &= L_m(n) + S_{m,k-1}(n/2) + S_{m,k}(n/2)\\
&= L_m(n) + S_{m,k-1}(n/2) + L_m(n/2) + S_{m,k-1}(n/4) + S_{m,k}(n/4)\\
&= L_m(n) + S_{m,k-1}(n/2) + L_m(n/2)\\
&\quad + S_{m,k-1}(n/4) + L_m(n/4) + S_{m,k-1}(n/8) + S_{m,k}(n/8)\\
&= \dots\\
&= (L_m(n) + L_m(n/2) + \dots + L_m(1))\\
&\quad + (S_{m,k-1}(n/2) + S_{m,k-1}(n/4) + \dots + S_{m,k-1}(1)) + S_{m,k}(1)\\
&\leq L_m(2n) + S_{m,k-1}(n) + \mathcal{O}(m)
\end{aligned}$$

which gives us

$$\begin{aligned}
S_{m,k}(n) &= kL_m(2n) + (k-1)S_{m,k}(1) + S_{m,1}(n)\\
&= kL_m(2n) + \mathcal{O}(nm(1+\log^*(n)-\log^*(m)))\\
&= \mathcal{O}(knm(1+\log^*(n)-\log^*(m)))
\end{aligned}$$

To bound the depth $D_{m,k}(n)$ we use the following recurrence:

$$\begin{aligned}
D_{m,k}(1) &= \mathcal{O}(1)\\
D_{m,k}(n) &\geq D_{m,k-1}(n)\\
D_{m,1}(n) &= \mathcal{O}(\log^2(n))\\
D_{m,k}(n) &= \mathcal{O}(\log^2(n)) + \max\left(D_{m,k}(n/2) + D_{m,k-1}(n/2)\right)\\
&\leq \mathcal{O}(\log^2(n)) + D_{m,k}(n/2)\\
&\leq \mathcal{O}(\log^3(n))
\end{aligned}$$

◀

7 Conclusion

We have provided improved sorting circuits. Our technique used in the proof of Theorem 1 can be viewed as information compression and decompression. This technique might prove useful for other related problems. We list some open problems:

- Most of our circuits are uniform. The non-uniform part is due to the use of the AKS circuits and Pippenger's super-concentrators. Can one make uniform circuits of the same size?
- Kospanov [6] shows that there is a family of sorting circuits with depth $\mathcal{O}(\log(n)+\log(m))$ and size $\mathcal{O}(mn^2)$ that sorts n numbers each of m bits. Is there a circuit family for sorting with circuits of depth $\mathcal{O}(\log(n)+\log(m))$ and size $\mathcal{O}(nm^2)$? In other words can we get rid of the $m\log(m)$ factor in the circuit depth from Theorem 1 while keeping the $\mathcal{O}(nm^2)$ size?
- Is it possible to partially sort n numbers of m bits each by their first bit using a circuit of size $\mathcal{O}(nm)$ and depth $\mathcal{O}(\log(n))$?

Improving Gebauer's Construction of 3-Chromatic Hypergraphs with Few Edges

Jakub Kozik
Theoretical Computer Science Department, Faculty of Mathematics and Computer Science, Jagiellonian University, Kraków, Poland

Abstract

In 1964 Erdős proved, by randomized construction, that the minimum number of edges in a k-graph that is not two colorable is $O(k^2\,2^k)$. To this day, it is not known whether there exist such k-graphs with smaller number of edges. Known deterministic constructions use much larger number of edges. The most recent one by Gebauer requires $2^{k+\Theta(k^{2/3})}$ edges. Applying a derandomization technique we reduce that number to $2^{k+\widetilde{\Theta}(k^{1/2})}$.

1 Introduction

In 1964 Erdős proved in [3] that $(1+o(1))\frac{e\ln(2)}{4}k^2 2^k$ edges are sufficient to build a k-graph[1] which is not two colorable. To this day that result provides the best known upper bound for the minimum number of edges in such hypergraph. The Erdős' bound results from the fact that random k-graph with that number of edges, built on a set of $k^2/2$ vertices can not be colored properly with two colors with high probability. In some sense this value is not far from being optimal since a straightforward probabilistic argument shows that any k-graph with at most 2^{k-1} edges is two colorable. Using random recoloring method, introduced by Beck in [1], Radhakrishnan and Srinivasan in [8] extended this result to k-graphs with at most $\Theta(\sqrt{k/\log(k)}2^k)$ edges (see also [2] for a simplified proof).

The best known deterministic construction of a k-graph that is not two colorable has been obtained by Gebauer [5]. It requires $2^{k+\Theta(k^{2/3})}$ edges. It is also the first construction in which the number of edges is $2^{k+o(k)}$. The main result of the current paper is an upgrade of this construction that allows to cut down the number of edges to $2^{k+\Theta((k\log(k))^{1/2})}$.

Within the whole paper, log(.) stands for binary logarithm. We are only concerned with vertex two coloring of hypergraphs. However, just like in the construction from [5], the presented method naturaly generalizes to any fixed number of colors and gives analogous improvement. Vertex coloring is *proper* if no edge is monochromatic. Following common convention we use colors *red* and *blue*.

2 Gebauer's construction

We start with recalling the construction of [5], as we are going to modify it. The whole procedure is parameterized by $t = t(k)$ that takes value roughly k^α for some optimized positive $\alpha < 1$. It it convenient to organize the vertices of the constructed hypergraph into a rectangular matrix $\mathbb{M}$ of $2t-1$ rows and s columns. In particular, the vertex set of the hypergraphs has $(2t-1)\cdot s$ elements. The value of s will be a subject of optimization and in the final construction we are going to chose $s = \lceil \mathrm{e}\,(k/t)\,2^t \rceil$. Slightly abusing the notation, we use $\mathbb{M}$ for both the matrix and the set of vertices. We use the same convention for submatrices of $\mathbb{M}$.

2.1 Preliminary choice of rows

As the vertices of constructed hypergraph are identified with the entries of $\mathbb{M}$, vertex coloring can be seen as assigning colors to the entries of the matrix. A color is *dominating* in a row if at least half of its entries are colored with it (there can be two dominating colors). A matrix for which one of the colors is dominating in all rows will be called *consistently dominated*. The main part of the construction is designed to work with a consistently dominated submatrix of $\mathbb{M}$ with t rows. Wlog we always assume that red is the dominating color in such a matrix.

Let $\mathcal{M}$ denote the set of submatrices of $\mathbb{M}$ built of every t rows. For every $M \in \mathcal{M}$ we apply the *main construction* described in the next section. The construction outputs hypergraph H_M. The union of the edge sets of these hypergraphs forms the edge set of the resulting hypergraph. For every coloring of $\mathbb{M}$ at least one submatrix $M \in \mathcal{M}$ is consistently dominated. The main construction guarantees that in such a case, H_M contains a monochromatic edge.

2.2 Main construction

Let $M \in \mathcal{M}$, recall that M has t rows. Our goal is to build a hypergraph H_M on the vertex set M such that for every consistently dominated coloring of M, there exists a monochromatic edge in H_M. For $(\sigma_1, \ldots, \sigma_t) \in [s]^t$, we denote by $M(\sigma_1, \ldots, \sigma_t)$ matrix M in which for every $i \in [t]$, the i-th row has been cyclically shifted by σ_i. The construction proceeds as follows.

For every
1. *sequence of shifts* $\sigma \in [s]^t$,
2. and *set of indices* $I \subset [s]$ of size k/t,

add to H_M an edge built from all elements of the columns of $M(\sigma)$ with indices in I.

Note that the edges of H_M are of size k as required.

Let us fix a consistently dominated coloring of M. We assume wlog that red is the dominating color of the rows. When the sequence of shifts is chosen randomly, the probability that some fixed column is red is at least 2^{-t}. As a consequence, for $s \geqslant (k/t)\,2^t$ the expected number of red columns is at least k/t. In particular, for some sequence of shifts, there exists a set of k/t red columns. Hence the edge built for these shifts and columns is monochromatic.

2.3 Counting

We have

$$\binom{2t-1}{t} < 2^{2t}$$

choices for the subset of rows in the preliminary step. Then, in the main construction, every sequence of t elements of $[s]$ and a subset of k/t elements of $[s]$ is used to build an edge. The number of choices is

$$s^t \cdot \binom{s}{k/t} \leqslant s^t \cdot \left(\frac{\mathrm{e}s}{k/t}\right)^{k/t}.$$

For $s = (k/t)\, 2^t$ (we assume for simplicity that it is an integer) we obtain

$$(k/t)^t\, 2^{t^2} \cdot \mathrm{e}^{k/t}\, 2^k = 2^{t\log(k/t)+t^2+k/t\log(\mathrm{e})+k}.$$

The total number of edges is smaller than

$$2^{2t+t\log(k/t)+t^2+k/t\log(\mathrm{e})+k}.$$

Finally we choose t so that the above exponent is minimized. That happens for $t = \Theta(k^{1/3})$. In the end we obtain that the total number of edges is $2^{k+\Theta(k^{2/3})}$.

3 Improved construction

We modify only the main construction. Recall that we work with matrix M with t rows. For a fixed consistently dominating coloring of M, sequence of shifts $\sigma \in [s]^t$ is called *good* if $M(\sigma)$ contains at least $s\, 2^{-t}$ red columns. The set of good sequences for a coloring $\mathcal{C}$ of M is denoted by $\mathcal{G}(\mathcal{C})$.

If we fix a consistently dominating coloring of M and choose the sequence of shifts $\sigma \in [s]^t$ uniformly at random, the expected number of red columns in $M(\sigma)$ is $s\, 2^{-t}$. That observation was used to justify that there exists a good sequence. However, it also suggests that a large number of shift sequences might be good. For the constructed hypergraph not to be two colorable, it is sufficient that for every consistently dominated coloring of M, at least one such sequence is used in the main construction.

We apply derandomization techniques to construct relatively small set of sequences of shifts that can be used in the main construction instead of $[s]^t$. For a family of sets $\mathcal{F}$, a set that intersects every element of that family is called a *hitting set* for $\mathcal{F}$. In these terms we are looking for a small hitting set for family $\mathcal{G}_M = \{\mathcal{G}(\mathcal{C}) : \mathcal{C} \text{ is a consistently dominating coloring of } M\}$.

3.1 Sequential choice of shifts

We start with estimating the size of the set of good shift sequences. While it is not directly used in our construction, it provides a good opportunity to introduce some tools. It will also allow us to derive a probabilistic argument that small hitting sets actually exist.

The property of being good is generalized to prefixes in the straightforward way – sequence of shifts $(\sigma_1, \ldots, \sigma_i)$ is *good* if the matrix trimmed to the first i rows and shifted according to the sequence, has at least $s\, 2^{-i}$ red columns.

Suppose that $(\sigma_1, \ldots, \sigma_i)$ is good. We want to estimate the number of possible choices of σ_{i+1} for which $(\sigma_1, \ldots, \sigma_i, \sigma_{i+1})$ is good as well. If the coloring of the $(i+1)$-th row was "random", then about half of the choices would be right, and almost all of the choices would be almost right. That property does not hold in the worst case scenario and hence we are going to work with relaxed definitions.

For $\varepsilon > 0$, a sequence of shifts $(\sigma_1, \ldots, \sigma_i)$ is *ε-good* if the number of red columns in the shifted matrix trimmed to the first i rows is at least $s\left(\frac{1-\varepsilon}{2}\right)^i$. Then, every ε-good sequence of shifts of length t gives a shifted matrix with at least

$$s\frac{(1-\varepsilon)^{t-1}}{2^t}$$

red columns. For $s \geqslant \mathrm{e}\,(k/t)\,2^t$ and $\varepsilon = 1/t$, the number of red columns is at least k/t as needed. In the modified construction we set s to $\lceil \mathrm{e}\,(k/t)\,2^t \rceil$.

We also define $\mathcal{G}^\varepsilon(\mathcal{C})$ as the set of ε-good sequences for a coloring $\mathcal{C}$ of M and $\mathcal{G}^\varepsilon_M$ as $\{\mathcal{G}^\varepsilon(\mathcal{C}) : \mathcal{C}$ is a consistently dominating coloring of $M\}$.

The following proposition is used to derive a lower bound for the number of ε-good sequences. It is formulated in more general terms that needed here, but we are going to use it again later. For a set $A \subset [s]$ and a number x, set $A + x$ is defined as the set A shifted cyclically within $[s]$ by x, formally $A + x = \{(a - 1 + x)(\mod s) + 1 : a \in A\}$.

▶ **Proposition 1.** *For any positive $\varepsilon < 1$ and sets $A, B \subset [s]$, let $\alpha = |B|/s$, there exist at least*

$$\frac{\varepsilon}{1-(1-\varepsilon)\alpha}\,\alpha s$$

elements $x \in [s]$ for which $|(A + x) \cap B| \geqslant (1-\varepsilon)\alpha|A|$.

Proof. Let random variable X denote the size of $(A+x)\cap B$, when $x \in [s]$ is chosen uniformly at random. By the fact that $|B| = \alpha s$ and linearity of expectation we obtain

$$\mathbb{E}(X) = \alpha|A|.$$

From the definition of X, we get also

$$X \leqslant |A|.$$

We can observe now that a distribution that minimizes $\Pr[X > (1-\varepsilon)\alpha|A|]$ and satisfies the above conditions, is supported only by values $(1-\varepsilon)\alpha|A|$ and $|A|$. There is only one such distribution that satisfies $\mathbb{E}(X) = \alpha|A|$. Straightforward calculations give

$$\Pr[X > (1-\varepsilon)\alpha|A|] \geqslant \frac{\varepsilon\alpha}{1-(1-\varepsilon)\alpha}.$$ ◀

For $|B| \geqslant s/2$ we get that there exist at least

$$\frac{2\varepsilon}{1+\varepsilon}\,s/2$$

elements $x \in [s]$ for which $|(A + x) \cap B| \geqslant (1-\varepsilon)|A|/2$.

Applying the proposition iteratively, we obtain that the number of ε-good sequences of length j is at least

$$\left(\frac{\varepsilon}{1+\varepsilon}\,s\right)^j.$$

(For a fixed j, and some ε-good sequence σ of length $j-1$, let A be the set of indices of the red columns in the matrix trimmed to the first $j-1$ rows and shifted according to σ, and B be the set of indices of red entries of the j-th row.)

For $j = t$ we get a lower bound for the number of ε-good sequences. Once we have that bound, a typical application of the probabilistic method (along the lines of the proof from [3]) allows to proof that there exists a hitting set for $\mathcal{G}_M^\varepsilon$ of size $2^{O(t\log(t))}$. That argument is briefly described below.

Recall that, for a fixed consistently dominated coloring of matrix M with t rows, the volume of ε-good sequences is at least

$$p = \left(\frac{\varepsilon}{1+\varepsilon}\right)^t.$$

The volume is exactly the probability that uniformly random sequence is ε-good. Let S be a set built from m uniformly and independently sampled random sequences from $[s]^t$. (Since, the sequences are sampled with repetitions, it may happen that $|S| < m$.) The following formula upperbounds the expected number of consistently dominated colorings of M, for which the set of ε-good sequences is not hit by S

$$2^{st} \cdot (1-p)^m < \exp(st\ln(2) - mp).$$

Therefore, whenever $st\ln(2) - mp \leqslant 0$, some set of m sequences hits all the sets of ε-good sequences for consistently dominating colorings. For $s = \lceil \mathrm{e}\,(k/t)\,2^t \rceil$ and $\varepsilon = 1/t$ it is sufficient to take m of the order $2^{O(t\log(t))}$ to satisfy the inequality. As a consequence there exists a hitting set for $\mathcal{G}_M^\varepsilon$ of size $2^{O(t\log(t))}$.

3.2 Expanders for hitting sets

Linial, Luby, Saks and Zuckerman [6] worked on deterministic constructions of small hitting sets for combinatorial rectangles. We summarize in this section, their results that are relevant for our developments. We follow closely their definitions.

Graph $G = (V, E)$ is an (m, Δ, α)-*expander* if it has m vertices, maximum degree Δ and for any $A \subset V$, the fraction of vertices in $V - A$ that have a neighbor in A is at least $\alpha|A|/m$. For a fixed graph G let W_r denote the set of walks in G of length r. Let $W_{r,d}$ be the set of subsequences of elements of W_r of length d (not necessarily subsequences of consecutive elements). Set $R \subset [m]^d$ is a *combinatorial rectangle* if it is of a form $R_1 \times \ldots \times R_d$ for some $R_1, \ldots, R_d \subset [m]$. The volume of rectangle R, denoted as $vol(R)$, is defined as $|R|/m^d$.

▶ **Lemma 2** ([6]). *Let m, d be positive integers and R be a rectangle in $[m]^d$. Suppose G is an (m, Δ, α)-expander with $1/2 > \alpha > 0$. If $r = 1 + (4/\alpha)(d + \log(1/vol(R)))$, then $W_{r,d}$ contains a point from R.*

The above lemma implies that a specific set of sequences $W_{r,d}$ hits every combinatorial rectangle in $[m]^d$ of sufficiently large volume.

The following rough estimations for the size of $W_{r,t}$ will be sufficient for our needs. We have

$$|W_r| \leqslant m(\Delta+1)^r$$

and

$$|W_{r,d}| < 2^r|W_r| \leqslant m\,(2(\Delta+1))^r.$$

Lemma 2 leaves some space for the choice of expander graph. Authors of [6] used the construction of Margulis [7] (see also [4]) which allows to build an expander with $\Delta = 8$ and $\alpha = (2-\sqrt{3})/4$. A minor inconvenience is that the construction requires the number

of vertices to be a perfect square. However, as observed already in [6], we can consider the rectangles of our interest as subsets of a larger space $[m']^d$, and apply the lemma in that space. For every m we can choose number m' that is a perfect square and satisfies $m \leqslant m' \leqslant 2m$. While that change affects the volumes of rectangles, they get smaller at most by a factor of 2^{-d}. For our purposes this cost is negligible.

When we are interested in rectangles of volume at least $\mathcal{V}$, Lemma 2 instructs to take

$$r = r(d, \mathcal{V}) = 1 + (4/\alpha)(d + \log(2^d/\mathcal{V})).$$

For some specific constant $\hat{C}$ and for all positive d and $\mathcal{V}$ we have

$$r(d, \mathcal{V}) \leqslant \hat{C}(d + \log(1/\mathcal{V})).$$

▶ **Corollary 3.** *There exists a constant $C > 0$ such that, for every integers m, d, and $\mathcal{V} > 0$ there exists an efficiently constructible subset of $[m]^d$ of size at most*

$$m \cdot 2^{C(d+\log(1/\mathcal{V}))},$$

that intersects every combinatorial rectangle in $[m]^d$ of volume at least $\mathcal{V}$.

We apply that result, to construct a small hitting set for $\mathcal{G}^{\varepsilon}_M$. That set is then used in the modified main construction instead of the set of all shift sequences.

3.3 Under false assumption

Unfortunately, for a fixed consistently dominating coloring of M, the set of good or ε-good shift sequences does not need to form a combinatorial rectangle. It is instructive to pretend for a moment that it does. We assume (falsely) in this subsection that $\mathcal{G}^{\varepsilon}_M$ contains only combinatorial rectangles.

By the discussion that follows Proposition 1, for every consistently dominating coloring of M, the set of ε-good shift sequences has volume at least

$$\nu = \left(\frac{\varepsilon}{2(1+\varepsilon)}\right)^t.$$

By Corollary 3 there exists a hitting set HS for all rectangles of volume ν of size $s \cdot 2^{C(t+\log(1/\nu))}$. For $\varepsilon = 1/t$ and $s = \lceil \mathrm{e}\ (k/t)\ 2^t \rceil$, the size of HS is at most $2^{2Ct\log(t)}$ (assuming that t is sufficiently large). Note that in the original construction all possible shift sequences were used. Using set HS instead of $[s]^t$ and choosing $t = (k\log(k))^{1/2}$, the total number of edges becomes

$$2^{k+O((k\log(k))^{1/2})}.$$

3.4 Decomposing good shift sequences

We showed in Section 3.1 that, for every consistently dominating coloring of M, the set of ε-good shift sequences is large. While, in general, it does not have a structure of combinatorial rectangle, in some sense it can be decomposed into a small number of such. We start by altering the way that the sequences of shifts are represented. For the clarity of the exposition we assume that t is a power of 2.

Let T be a rooted plane complete binary tree with t leaves[2]. A subtree rooted at some internal node of T consists of that node and all its descendants. A node of T is *at level* j if its distance to the set of leaves is j. Let S_j be the set of inner nodes at level j. Note that $|S_j| = t\ 2^{-j}$, we denote that value by d_j. For $h = \log(t)$, the tree has $h+1$ levels with all the leaves on level 0.

We associate leaves of T with rows of M in such a way that the i-th leaf from the left, corresponds to the i-th row. Inner nodes of the tree are going to be labeled by elements of $[s]$. These labels represent the relative shifts between neighboring rows of M. For an inner node v, if l is the rightmost leaf of the left subtree of v and r is the leftmost leaf of the right subtree of v, then the label of v describes how row r is shifted wrt l.

Labeling of a subtree rooted at node v is ε-good, if for r being the number of descendant leaves of v, the submatrix of the rows that correspond to these leaves, shifted according to the labels of the inner nodes of the subtree, has at least $s\ ((1-\varepsilon)/2)^r$ red columns. Note that ε-good labellings of the whole tree correspond to ε-good sequences (up to a cyclic shift of the whole matrix, which is clearly redundant in the original construction).

We order the nodes of S_j from left to right and represent labellings of the nodes of S_j as elements of $[s]^{d_j}$. We are going to work bottom up and label inner nodes in groups consisting of the nodes of the same level. A labeling of T is *ε-good up to level j* if all the subtrees rooted at level at most j are ε-good. In all the places where we use this definition, it can be assumed that the labeling is undefined for the nodes of higher levels. Suppose that τ is a labeling of T that is ε-good up to level $j-1$. Then, a sequence of labels $\sigma \in [s]^{d_j}$ is called *an ε-good level j extension (of τ)* if the labeling τ in which the labels of the nodes of level j has been set to σ is ε-good up to level j.

▶ **Proposition 4.** *Suppose, that a labelling of T is ε-good up to level $j-1$. Then, the set of its ε-good level j extensions forms a combinatorial rectangle of volume at least*

$$\nu_j = \left(\varepsilon\ ((1-\varepsilon)/2)^{-2^{j-1}}\right)^{d_j}.$$

Proof. Fix j and suppose that labeling τ is ε-good up to level $j-1$. We want to assign labels to the nodes of S_j in such a way that all the subtrees rooted at depth j are ε-good shift trees as well. Note that for any pair of distinct nodes of level j, the property of the corresponding subtrees of being ε-good shift trees is determined by disjoint sets of rows of the underlying matrix. That justify that the set of ε-good level j extensions forms a combinatorial rectangle.

Let v be a node of S_j and let A and B be the sets of indices of red columns respectively in the shifted submatrices corresponding to the left and right subtrees of v. By the assumptions we know that both these sets have cardinality at least

$$s\ ((1-\varepsilon)/2)^{-2^{j-1}}.$$

We need to estimate the number of $x \in [s]$ for which the set $A \cap (B+x)$ has cardinality at least

$$s\ ((1-\varepsilon)/2)^{-2^{j}}.$$

Proposition 1 gives that there exist at least

$$\varepsilon\ ((1-\varepsilon)/2)^{-2^{j-1}}\ s$$

[2] i.e. all the internal nodes of T have two children (left and right) and all the leaves are of the same distance from the root

such values. We obtain that the volume of combinatorial rectangle of ε-good level j extensions is at least

$$\left(\varepsilon\left((1-\varepsilon)/2\right)^{-2^{j-1}}\right)^{d_j}$$ ◀

By Corollary 3, there exists a set HS_j of cardinality

$$s \cdot 2^{C(d_j+\log(1/\nu_j))},$$

that is a hitting set for the family of ε-good level j extensions for labellings that are ε-good up to level $j-1$. That implies the following proposition.

▶ **Proposition 5.** *Set $HS = HS_1 \times \ldots \times HS_h$ is a hitting set for the family of sets of ε-good labellings of T.*

It remains to estimate the size of HS. We have

$$\begin{aligned}|HS| &\leqslant \prod_{j=1\ldots h} s \cdot 2^{C(d_j+\log(1/\nu_j))} \\ &= s^{\log(t)} \cdot 2^{C\sum_{j=1\ldots h}(d_j+\log(1/\nu_j))} \\ &< s^{\log(t)} \cdot 2^{Ct} \cdot 2^{C\sum_{j=1\ldots h}\log(1/\nu_j)},\end{aligned}$$

and

$$\begin{aligned}\sum_{j=1\ldots h}\log(1/\nu_j) &= \sum_{j=1\ldots h} d_j(\log(1/\varepsilon) + 2^{j-1}\log(2/(1-\varepsilon))) \\ &< t\log(1/\varepsilon) + t\sum_{j=1\ldots h}\log(4) \quad (\text{for } \varepsilon < 1/2) \\ &= t\cdot\log(1/\varepsilon) + 2t\cdot\log(t)\end{aligned}$$

Therefore, for our parametrization (i.e. $s = \lceil \mathrm{e}\,(k/t)\,2^t \rceil$ and $\varepsilon = 1/t$), and for all sufficiently large t we get

$$|HS| \leqslant 2^{4t\log(t)}.$$

3.5 Modified main construction

Let HS be the set from Proposition 5. As we already observed labellings of T correspond to shift sequences up to a cyclic shift of the whole matrix. For a labeling τ let $\sigma(\tau)$ be a shift sequence that is compatible with τ. Observe, that if τ is an ε-good labeling, then $\sigma(\tau)$ is ε-good shift sequence. Recall that we chose $s = \mathrm{e}\,(k/t)\,2^t$ so that if σ is an ε-good sequence for some consistently dominated coloring of M, then $M(\sigma)$ has at least k/t red columns. The modified main construction proceeds as follows.

`For every`
1. `labeling of the tree` $\tau \in HS$`,`
2. `and set of indices` $I \subset [s]$ `of size` k/t`,`

`add to` H_M `an edge build from all elements of the columns of` $M(\sigma(\tau))$ `with indices in` I`.`

By Proposition 5 for every consistently dominated coloring of M, at least one ε-good labeling τ is used in the construction. Then, for every such coloring, matrix M shifted according to $\sigma(\tau)$ has at least k/t red columns. As a consequence at least one of the edges of H_M is monochromatic.

Counting

Just like in the original construction, we have less than 2^{2t} choices for the subset of rows in the preliminary step. Then, in the modified main construction, we use every sequence of HS with every subset of k/t elements of $[s]$ to build an edge. The number of choices is smaller than

$$2^{4t\log(t)} \cdot \binom{s}{k/t} < 2^{4t\log(t)} \cdot \left(\frac{\mathrm{e}s}{k/t}\right)^{k/t}.$$

Substituting the value of s we obtain a value that is smaller than

$$2 \cdot 2^{4t\log(t)} \cdot \mathrm{e}^{2k/t} 2^k = 2^{1+4t\log(t)+(2k/t)\log(\mathrm{e})+k}.$$

The bound is multiplied by 2 to compensate for the ceiling in the definition of s. Taking into account preliminary choices of rows, the total number of edges is smaller than

$$2^{2t+1+4t\log(t)+(2k/t)\log(\mathrm{e})+k}.$$

For $t = (k/\log(k))^{1/2}$, the total number of edges becomes $2^{k+\Theta((k\log(k))^{1/2})}$.

Abstract

We study the rank of the Sum of Squares (SoS) hierarchy over the Boolean hypercube for Symmetric Quadratic Functions (SQFs) in n variables with roots placed in points $k-1$ and k. Functions of this type have played a central role in deepening the understanding of the performance of the SoS method for various unconstrained Boolean hypercube optimization problems, including the Max Cut problem. Recently, Lee, Prakash, de Wolf, and Yuen proved a lower bound on the SoS rank for SQFs of $\Omega(\sqrt{k(n-k)})$ and conjectured the lower bound of $\Omega(n)$ by similarity to a polynomial representation of the n-bit OR function.

Leveraging recent developments on Chebyshev polynomials, we refute the Lee–Prakash–de Wolf–Yuen conjecture and prove that the SoS rank for SQFs is at most $O(\sqrt{nk}\log(n))$.

We connect this result to two constrained Boolean hypercube optimization problems. First, we provide a degree $O(\sqrt{n})$ SoS certificate that matches the known SoS rank lower bound for an instance of Min Knapsack, a problem that was intensively studied in the literature. Second, we study an instance of the Set Cover problem for which Bienstock and Zuckerberg conjectured an SoS rank lower bound of $n/4$. We refute the Bienstock–Zuckerberg conjecture and provide a degree $O(\sqrt{n}\log(n))$ SoS certificate for this problem.

1 Introduction

Semialgebraic proof systems, also called certificates of nonnegativity, are systematic methods to prove nonnegativity of polynomials over semialgebraic sets. One of the most successful approaches for constructing theoretically efficient algorithms for polynomial optimization problems is the Sum of Squares (SoS) certificate [17, 38, 39, 46],

For a wide variety of combinatorial optimization problems, SoS provides the best available algorithms [1, 14, 5, 19, 34]. The strength of this method has also come to light for Max CSP [32] and problems in robust estimation [21], dictionary learning [3, 45], tensor completion and decomposition [4, 20, 41], and problems arising from statistical physics [13].

However, the SoS algorithm also admits certain weaknesses. It is known to struggle with solving certain combinatorial optimization problems, e.g., [7, 10, 18, 26, 49]. In a seminal example, Grigoriev showed that a $\Omega(n)$ degree SoS certificate is needed to detect a simple integrality argument for the Knapsack problem [15], see also [16, 24, 31]. A degree $n^{\Omega(\varepsilon)}$ SoS algorithm was proved to be unable to asymptotically certify an upper bound smaller than 2 times the optimal value for Sherrington-Kirkpatric Hamiltonian [23, 13]. Moreover, the degree $\Omega(\sqrt{n})$ SoS hierarchy was proved to have problems scheduling unit size jobs on a single machine to minimize the number of late jobs, see [27], even though the problem is known to be solvable in polynomial time using the Moore-Hodgson algorithm [36]. Finally, various examples where the SoS hierarchy fares very badly have been shown for the planted clique [2, 35] and Max CSP problems [22, 48].

The discrepancy between the excellent performance of the SoS hierarchy and its severe weaknesses has been studied extensively throughout the last decade. Thus, a natural question arises: what factors determine the difficulty of solving a problem for the SoS method?

A prominent example that was studied through the lens of this question is the Max Cut problem, which not only lies at the center of SoS research but was also one of the first problems for which lower bounds of the SoS rank were studied. Grigoriev proved that SoS needs at least degree $\lfloor \frac{n}{2} \rfloor$ to certify the size of the maximum cut in an odd clique of n vertices [15], for alternative proofs see also [16, 24, 31]. In a breakthrough paper nearly two decades later, Parrilo showed that the Grigoriev lower bound is tight by proving that every n-variate polynomial of degree 2, nonnegative over Boolean hypercube has an SoS certificate of degree at most $\lceil \frac{n}{2} \rceil$, see [12]. Subsequently, the analog of the results by Grigoriev and Parrilo for higher degree symmetric functions recently appeared in [25, 44], respectively.

Many of the problem instances with large lower bounds of the SoS rank target known limitations of the SoS method such as an issue with dealing with integrality constraints. Indeed, certifying the size of the maximum cut in a clique can be transformed into the problem of proving nonnegativity of the *Symmetric Quadratic Function* (SQF) of the form $q_{\lceil \frac{n}{2} \rceil}(\mathbf{x})$ over the Boolean hypercube, where, throughout this paper, $q_k : \{0,1\}^n \to \mathbb{R}$ is a multivariate polynomial of the form

$$q_k(\mathbf{x}) := (|\mathbf{x}| - k)(|\mathbf{x}| - k + 1). \tag{1.1}$$

The optimization of degree 2 polynomials over the Boolean hypercube plays a central role in Theoretical Computer Science. This claim is supported by the fact that high degree optimization problems attracted limited attention, especially since solving an NP-complete problem can be reduced in polynomial time to proving nonnegativity of a degree-4 even form [37]. Moreover, if an SQF has a complex root with a corresponding conjugate root, the polynomial is globally nonnegative and admits an SoS certificate of degree 2. Similarly, there exists an SoS certificate of nonnegativity of degree 2 for SQFs over the Boolean hypercube if the roots are real and placed outside the interval $[0, n]$. Hence, the only interesting case is when the roots are real and located within some interval $[k-1, k]$ for $k \in \{1, \ldots, n\}$.

Finding an SoS representation of the symmetric function q_k has gained significant attention in the SoS community. However, up to this day, the exact SoS rank for q_k is not known. The most recent result towards a characterization of the SoS rank of q_k provides a lower and upper bound of the SoS degree that approximates the function q_k with SoS polynomials in l_1 and l_∞ norm [33]. However, since finding an exact SoS certificate is at least as difficult as providing an approximate SoS representation, the result implies that for $k \geqslant 2$, q_k does not admit an SoS certificate of degree smaller than $\Omega\left(\sqrt{k(n-k)}\right)$. Moreover, in [33], Lee, Prakash, de Wolf, and Yuen conjectured that the lower bound of the SoS approximate representation with error

at most ε in the l_∞ norm is expected to be $\Omega\left(\sqrt{k(n-k)}+\sqrt{n\log(1/\varepsilon)}\right)$. They support the conjecture by arguing about similarity with approximating n-bit OR functions [40, 50]. This conjecture, if true, would imply a lower bound on the exact SoS certificate for SQFs of $\Omega(n)$, even for small, constant values of k. Proving this conjecture is left as an open question in [33]. In this paper, we refute the Lee–Prakash–de Wolf–Yuen (LPdWY) conjecture. We show that certifying SQFs is easier than representing n-bit OR functions. More specifically, we prove the following theorem.

▶ **Theorem 1.** *For any $k \in \{2,\dots,\lceil\frac{n}{2}\rceil\}$, there exists a degree $O(\sqrt{nk}\log(n))$ SoS certificate of nonnegativity for the Boolean function q_k as in* (1.1).

We motivate the research on the SoS degree of the SQFs q_k by connecting it to two combinatorial optimization problems. We first consider the instance of the Min Knapsack (MK) problem. For $P \geqslant 2$, the problem is defined as:

$$\text{MK:} \qquad \min \sum_{i\in[n]} x_i \qquad \text{s.t.} \quad \sum_{i\in[n]} x_i \geqslant \frac{1}{P}, \qquad \mathbf{x}\in\{0,1\}^n. \tag{1.2}$$

For $P=2$, the problem was previously considered by Cook and Dash [11]. They proved that the Lovasz-Schrijver hierarchy rank is n. For the Sherali-Adams hierarchy, Laurent proved that the rank is also equal to n and raised the open question to find the rank for the SoS hierarchy [30]. For $n=2$, they also proved that the SoS rank is 2, but the discussion of general n was left as an open question. Currently, it is known that the SoS rank of the MK problem falls within $\Omega(\sqrt{n})$ and $\lceil\frac{n+4\lceil\sqrt{n}\rceil}{2}\rceil$, see [28]. In this paper, we prove an upper bound on the SoS rank for the MK problem.

▶ **Theorem 2.** *The SoS rank for the MK problem is $\Omega(\sqrt{n}\log(P))$.*

The existing lower bound for general P (see Lemma 14 of [28]) is $\Omega(\sqrt{n\log(P)})$, so this is tight when P is constant, though for larger P there is a gap of $O(\sqrt{\log(P)})$.

We also consider the following instance of the Set Cover (SC) problem:

$$\text{SC:} \qquad \min \sum_{i\in[n]} x_i \qquad \text{s.t.} \quad \sum_{i\in[n]\setminus\{j\}} x_i \geqslant 1 \qquad \forall j\in[n], \qquad \mathbf{x}\in\{0,1\}^n. \tag{1.3}$$

This instance was considered in [8] and it is known that the SoS hierarchy cannot solve this problem with a degree smaller than $\Omega(\sqrt{n})$ [28]. In [8], Bienstock and Zuckerberg raised the question of what the actual SoS rank of this polytope is, conjecturing that, based on numerical experiments, the SoS rank is at least $\frac{n}{4}$. In this paper, using the SoS certificate for SQFs in Theorem 1, we refute the Bienstock–Zuckerberg conjecture and provide a nearly tight SoS rank for the SC problem:

▶ **Theorem 3.** *The SoS rank for the SC problem is at most $O(\sqrt{n}\log(n))$.*

2 Preliminaries

For $n\in\mathbb{N}$, let $[n]=\{1,\dots,n\}$. For $\mathbf{x}\in\mathbb{R}^n$, let $\mathbb{R}[\mathbf{x}]=\mathbb{R}[x_1,\dots,x_n]$ be the ring of *n-variate real polynomials*. For a set of polynomials $\mathcal{G}\subseteq\mathbb{R}[x]$, the corresponding *semialgebraic set* is

$$\mathcal{G}_+ \;:=\; \{\mathbf{x}\in\mathbb{R}^n \mid g(\mathbf{x})\geqslant 0 \text{ for all } g\in\mathcal{G}\}\subseteq\mathbb{R}^n.$$

Throughout this paper, we consider optimization problems on the Boolean hypercube $\{0,1\}^n$ and therefore, for $\mathcal{H}:=\{\pm(x_1^2-x_1),\dots,\pm(x_n^2-x_n)\}$, we assume that $\mathcal{G}$ is of the form

$$\mathcal{G} \;:=\; \mathcal{H}\cup\{g_1,\dots,g_m:\; g_i\in\mathbb{R}[\mathbf{x}] \text{ for all } \; i\in[m]\},$$

where $m \in \mathbb{N}_{>0}$. This implies that $\mathcal{G}_+ \subseteq \{0,1\}^n$. Moreover, define the *cone of nonnegative polynomials with respect to a given semialgebraic set, $\mathcal{G}_+$,* as

$$\mathcal{K}(\mathcal{G}_+) \;:=\; \{f \in \mathbb{R}[\mathbf{x}] \mid f(\mathbf{x}) \geqslant 0 \text{ for all } \mathbf{x} \in \mathcal{G}_+\}.$$

For given $f \in \mathbb{R}[\mathbf{x}]$ and $\mathcal{G} \subseteq \mathbb{R}[\mathbf{x}]$, define the corresponding *Constrained Polynomial Optimization Problem* (CPOP) as

$$f^* \;:=\; \min\{f(\mathbf{x}) \mid \mathbf{x} \in \mathcal{G}_+\} \;=\; \max\{\lambda \in \mathbb{R} \mid f - \lambda \in \mathcal{K}(\mathcal{G}_+)\}.$$

Generally, since CPOP is NP-hard, it is desirable to find a proper subset that is a good inner approximation of $\mathcal{K}(\mathcal{G}_+)$ such that the corresponding program is computationally *tractable*.

The *SoS method* approximates the cone $\mathcal{K}(\mathcal{G}_+)$ by using the set of *sum of square polynomials*. We define the set of finite sum of squares polynomials as $\Sigma := \{s \mid s = \sum_{i=1}^k s_i^2, s_i \in \mathbb{R}[\mathbf{x}]\ \forall i \in [k], k \in \mathbb{N}_{>0}\}$ and let $\Sigma_{n,d} := \{s \mid s = \sum_{i=1}^k s_i^2, s_i \in \mathbb{R}[\mathbf{x}] \wedge \deg(s_i) \leqslant d\ \forall i \in [k], k \in \mathbb{N}_{>0}\}$ denote the polynomials which are sums of squares of polynomials of degree at most d. We define the *hierarchy of certificates of nonnegativity depending on $d, n \in \mathbb{N}$* as

$$\Sigma_{n,d}^{\mathcal{G}} := \left\{ s_0 + \sum_{i=1}^m s_i g_i \mid s_i \in \Sigma_{n,d},\ g_i \in \mathcal{G}\ \forall i \in [m] \text{ and } s_0 \in \Sigma_{n,2\left\lceil \frac{2d+\deg(\mathcal{G})}{2} \right\rceil} \right\},$$

where $\deg(\mathcal{G}) = \max\{\deg(g) \mid g \in \mathcal{G}\}$. The *degree d SoS certificate* for f being nonnegative over $\mathcal{G}_+$ is $f \in \Sigma_{n,d}^{\mathcal{G}}$. Moreover, throughout the paper we say that a multivariate polynomial f is *a degree d SoS modulo Boolean axioms* if $f \in \Sigma_{n,d}^{\mathcal{H}}$. The *degree d SoS program* for CPOP is

$$f_\Sigma^d \;:=\; \max\{\lambda \in \mathbb{R} \mid f - \lambda \in \Sigma_{n,d}^{\mathcal{G}}\} \tag{2.1}$$

and is called *exact* if $f_\Sigma^d = f^*$. The smallest degree d such that the degree d SoS program is exact is called the *SoS rank*. Over the Boolean hypercube, the degree d SoS program can be solved via a *semidefinite program* (SDP) of size $O(m \sum_{k=0}^d \binom{n}{k})$. Moreover, the degree n SoS program is exact, see, e.g., [6, 29, 30].

Throughout this paper, we often encounter the following type of multivariate polynomials.

▶ **Definition 4.** *A polynomial $f : \{0,1\}^n \to \mathbb{R}$ is* symmetric *if there exists a univariate polynomial $\tilde{f} : \mathbb{R} \to \mathbb{R}$ such that $f(\mathbf{x}) = \tilde{f}\left(\sum_{i=1}^n x_i\right)$ for all $\mathbf{x} \in \{0,1\}^n$.*

With this in mind, let $|\mathbf{x}| := \sum_{i=1}^n x_i$ for any $\mathbf{x} \in \{0,1\}^n$. To prove SoS rank upper bounds, we consider symmetric multivariate polynomials over $\{0,1\}^n$ as univariate polynomials over $[0,n]$ and apply one of the many results on SoS certificates for univariate polynomials.

▶ Remark 5. Throughout this paper, we make frequent use of the fact that SoS certificates for polynomials over $[0,n]$ translate to SoS certificates for symmetric polynomials over $\{0,1\}^n$. More formally, if a univariate polynomial $\tilde{f} : \mathbb{R} \to \mathbb{R}$ has an univariate SoS certificate of degree d on $[0,n]$, then the multivariate polynomial $f : \{0,1\}^n \to \mathbb{R}$ such that $f(\mathbf{x}) := \tilde{f}(|\mathbf{x}|)$ has a degree d SoS certificate of nonnegativity over the Boolean hypercube.

In this paper, we use the following theorem to prove the SoS rank for univariate polynomials.

▶ **Theorem 6** ([9, Theorem 3.72])**.** *Let $a < b$. Then the univariate polynomial $p(x)$ is nonnegative on $[a,b]$ if and only if it can be written as*

$$\begin{cases} p(x) = s(x) + (x-a)(b-x) \cdot t(x) & \text{if } \deg(p) \text{ is even,} \\ p(x) = (x-a) \cdot s(x) + (b-x) \cdot t(x) & \text{if } \deg(p) \text{ is odd,} \end{cases}$$

where s, t are sum of squares. In the first case, we have $\deg(p) = 2d$, $\deg(s) \leqslant 2d$, and $\deg(t) \leqslant 2d-2$. In the second, $\deg(p) = 2d+1$, $\deg(s) \leqslant 2d$, and $\deg(t) \leqslant 2d-2$.

Finally, throughout the paper we use degree-d Chebyshev polynomials of the first type, which were used is several applications for bounds of sum of squares ranks, i.e., [28, 47, 42]. We frequently use the following lemma.

▶ **Lemma 7.** *Let $n, d \in \mathbb{N}$ such that $d \leqslant n$. Then,*

1. *For all $c \in [0, n]$, $T_d^2\left(-1-\frac{c}{n}\right) \geqslant \frac{1}{4}\left(-1-\sqrt{\frac{2c}{n}}\right)^{2d}$ and $T_d^2\left(-1-\frac{c}{n}\right) \leqslant \left(-1-2\sqrt{\frac{2c}{n}}\right)^{2d}$. Moreover, for constant c and n big enough, $T_d^2\left(-1-\frac{c}{n}\right) \leqslant \left(-1-\sqrt{\frac{2c+1}{n}}\right)^{2d}$.*
2. *For all $c \in (n, \infty)$, $T_d^2\left(-1-\frac{c}{n}\right) \leqslant \left(-1-3\frac{c}{n}\right)^{2d}$.*

Proof. It holds that:

1. Consider the characterization of Chebyshev polynomials given in [43, Equation 1.12]: $T_d(x) = \frac{1}{2}\left(\left(x-\sqrt{x^2-1}\right)^d + \left(\sqrt{x^2-1}+x\right)^d\right)$. For $x = -1-\frac{c}{n}$ and $c \in [0, n]$, we have $T_d^2\left(-1-\frac{c}{n}\right) \geqslant \frac{1}{4}\left(\left(-1-\frac{c}{n}\right)-\sqrt{\left(-1-\frac{c}{n}\right)^2-1}\right)^{2d} \geqslant \frac{1}{4}\left(-1-\sqrt{\frac{2c}{n}}\right)^{2d}$ and
$$\begin{aligned} T_d^2\left(-1-\frac{c}{n}\right) &\leqslant \left(\left(-1-\frac{c}{n}\right)-\sqrt{\left(-1-\frac{c}{n}\right)^2-1}\right)^{2d} \\ &\leqslant \left(\left(-1-\frac{c}{n}\right)-\sqrt{\frac{2c}{n}+\frac{c^2}{n^2}}\right)^{2d} \\ &\leqslant \left(-1-\sqrt{\frac{c}{n}}-\sqrt{\frac{2c}{n}+\frac{c}{n}}\right)^{2d} \leqslant \left(-1-2\sqrt{\frac{2c}{n}}\right)^{2d}. \end{aligned} \tag{2.2}$$
Moreover, we have $T_d^2\left(-1-\frac{c}{n}\right) \leqslant \left(\left(-1-\frac{c}{n}\right)-\sqrt{\left(-1-\frac{c}{n}\right)^2-1}\right)^{2d} \leqslant \left(-1-\sqrt{\frac{2c+1}{n}}\right)^{2d}$, where the last inequality holds for n large compared to c.
2. For $x = -1-\frac{c}{n}$ and $c \in (n, \infty)$, we have
$$\begin{aligned} T_d^2\left(-1-\frac{c}{n}\right) &\leqslant \left(\left(-1-\frac{c}{n}\right)-\sqrt{\left(-1-\frac{c}{n}\right)^2-1}\right)^{2d} \\ &\leqslant \left(\left(-1-\frac{c}{n}\right)-\sqrt{\frac{2c}{n}+\frac{c^2}{n^2}}\right)^{2d} \\ &\leqslant \left(-1-\frac{c}{n}-\sqrt{\frac{2c^2}{n^2}+\frac{c^2}{n^2}}\right)^{2d} \leqslant \left(-1-3\frac{c}{n}\right)^{2d}. \end{aligned} \tag{2.3}$$

◀

3 SoS rank for SQFs

In this section, we refute the LPdWY conjecture stated in [33] by proving Theorem 1. To prove Theorem 1, it is sufficient to prove the following theorem.

▶ **Theorem 8.** *For all $n \in \mathbb{N}$ and all $k \in [n]$, there exists a polynomial $s(x)$ of degree $O(\sqrt{kn}\log(n))$ such that*

1. *$s\left(\sum_{i=1}^n x_i\right)$ is a sum of squares (modulo the Boolean axioms).*
2. *For all $x \in [0, n]$, $(x-k+1)(x-k) - s(x) \geqslant 0$.*

Indeed, by Theorem 8 and Theorem 6, there exist sum of squares polynomials s, s_1 and s_2 of degree $O(\sqrt{kn}\log(n))$ s.t.

$$(x-k+1)(x-k) = s(x) + s_1(x) + s_2(x)x(n-x).$$

We now make the following observations:

1. By Theorem 8, $s(\sum_{i=1}^n x_i)$ is a sum of squares polynomial modulo the Boolean axioms.
2. $s_1(\sum_{i=1}^n x_i)$, $s_2(\sum_{i=1}^n x_i)$ are sum of squares polynomials.
3. $\sum_{i=1}^n x_i = \sum_{i=1}^n x_i^2 - \sum_{i=1}^n \left(x_i^2 - x_i\right)$ is a sum of squares polynomial modulo the Boolean axioms.
4. $n - \sum_{i=1}^n x_i = \sum_{i=1}^n (1-x_i) = \sum_{i=1}^n \left((x_i-1)^2 - \left(x_i^2 - x_i\right)\right)$ is a sum of squares polynomial modulo the Boolean axioms.

Putting everything together, the multivariate polynomial $q_k(\mathbf{x})$ has an $O(\sqrt{kn}\log(n))$ SoS certificate modulo the Boolean axioms of the form

$$q_k(\mathbf{x}) = s\left(\sum_{i=1}^n x_i\right) + s_1\left(\sum_{i=1}^n x_i\right) + s_2\left(\sum_{i=1}^n x_i\right)\left(\sum_{i=1}^n x_i\right)\left(n - \sum_{i=1}^n x_i\right).$$

Before we prove Theorem 8, we make the following observation which shows that our upper bound for $q_k(x)$ applies for any symmetric quadratic function with roots in $[k-1,k]$.

▶ **Corollary 9.** *For any $k \in \{1,\dots,\lceil n/2\rceil\}$ and any $a \leqslant b \in [k-1,k]$, a polynomial $f_k := (x-a)(x-b)$ admits an SoS certificate over the Boolean hypercube of degree at most the degree of an SoS certificate over the Boolean hypercube for polynomial q_k.*

Proof. We have $f_k(x) \geqslant \left((k-a)(b-k+1) + (k-b)(a-k+1)\right) q_k(x)$ as

$$\begin{aligned}
&(|x|-a)(|x|-b)\\
&= \left((k-a)(|x|-k+1) + (a-k+1)(|x|-k)\right)\left((k-b)(|x|-k+1) + (b-k+1)(|x|-k)\right)\\
&= (k-a)(k-b)(|x|-k+1)^2 + (a-k+1)(b-k+1)(|x|-k)^2\\
&+ \left((k-a)(b-k+1) + (k-b)(a-k+1)\right)(|x|-k+1)(x-|k|)
\end{aligned}$$

and invoke Theorem 1 to conclude the proof. ◀

3.1 Proof of Theorem 8

We construct $s(x)$ in two steps. We first construct a polynomial $s_1(x)$ which is a sum of squares (modulo the Boolean axioms), is less than or equal to $(x-k+1)(x-k)$ on the interval $[0,2k-1]$, and is not too large on the interval $[2k-1,n]$. We then construct a polynomial $s_2(x)$ which is a sum of squares, is less than or equal to 1 on the intervals $[0,k-1]$ and $[k,2k-1]$, is greater than or equal to 1 on the interval $[k-1,k]$, and is very small on the interval $[2k-1,n]$. We then take $s(x) = s_1(x)s_2(x)$. More precisely, we have the following conditions on s_1 and s_2:

1. $s_1\left(\sum_{i=1}^n x_i\right)$ is a sum of squares (modulo the Boolean axioms) and $s_2(x)$ is a sum of squares.
2. For all $x \in [k-1,k]$, $\frac{s_1(x)}{(x-k+1)(x-k)} \geqslant 1$ and $s_2(x) \geqslant 1$.
3. For all $x \in [0,k-1] \cup [k,2k-1]$, $\frac{s_1(x)}{(x-k+1)(x-k)} \leqslant 1$ and $s_2(x) \leqslant 1$.
4. For all $x \in [2k-1,n]$, $\left|\frac{s_1(x)}{(x-k+1)(x-k)}\right| \leqslant n^{40k}$ and $s_2(x) \leqslant n^{-40k}$.
5. $s_1(x)$ has degree $O(k)$ and $s_2(x)$ has degree $O(\sqrt{nk}\log(n))$.

▶ **Proposition 10.** *If $s_1(x)$ and $s_2(x)$ satisfy the above conditions and we take $s(x) = s_1(x)s_2(x)$ then $s\left(\sum_{i=1}^n x_i\right)$ is a sum of squares (modulo the Boolean axioms) and for all $x \in [0, n]$, $(x-k+1)(x-k) - s(x) \geqslant 0$.*

Proof. We make the following observations:

1. Since $s_1\left(\sum_{i=1}^n x_i\right)$ is a sum of squares (modulo the Boolean axioms) and $s_2(x)$ is a sum of squares, the product $s\left(\sum_{i=1}^n x_i\right) = s_1\left(\sum_{i=1}^n x_i\right) s_2\left(\sum_{i=1}^n x_i\right)$ is a sum of squares (modulo the Boolean axioms).
2. For all $x \in [0, k-1] \cup [k, 2k-1]$, since $(x-k+1)(x-k) \geqslant 0$, $\frac{s_1(x)}{(x-k+1)(x-k)} \leqslant 1$, and $0 \leqslant s_2(x) \leqslant 1$,
$$(x-k+1)(x-k) - s(x) = (x-k+1)(x-k)\left(1 - s_2(x)\frac{s_1(x)}{(x-k+1)(x-k)}\right) \geqslant 0.$$
3. For all $x \in [k-1, k]$, since $(x-k+1)(x-k) \leqslant 0$, $\frac{s_1(x)}{(x-k+1)(x-k)} \geqslant 1$, and $s_2(x) \geqslant 1$,
$$(x-k+1)(x-k) - s(x) = (x-k+1)(x-k)\left(1 - s_2(x)\frac{s_1(x)}{(x-k+1)(x-k)}\right) \geqslant 0.$$
4. For all $x \in [2k-1, n]$, since $(x-k+1)(x-k) \geqslant 0$, $\left|\frac{s_1(x)}{(x-k+1)(x-k)}\right| \leqslant n^{40k}$ and $|s_2(x)| \leqslant n^{-40k}$,
$$(x-k+1)(x-k) - s(x) = (x-k+1)(x-k)\left(1 - s_2(x)\frac{s_1(x)}{(x-k+1)(x-k)}\right) \geqslant 0. \quad ◀$$

Thus, we have an SoS proof of degree $O(\sqrt{kn}log(n))$ that $(|x|-k+1)(|x|-k) \geqslant 0$.

3.1.1 Constructing the polynomial $s_1(x)$

We now construct the polynomial $s_1(x)$.

▶ **Lemma 11.** *For $n \in \mathbb{N}$ and all $k \in [n]$, there exists a polynomial $s_1(x)$ such that*

1. *$s_1\left(\sum_{i=1}^n x_i\right)$ has a degree $O(k)$ sum of squares (modulo the Boolean axioms) certificate.*
2. *For all $x \in [k-1, k]$, $\frac{s_1(x)}{(x-k+1)(x-k)} \geqslant 1$.*
3. *For all $x \in [0, k-1] \cup [k, 2k-1]$, $\frac{s_1(x)}{(x-k+1)(x-k)} \leqslant 1$.*
4. *For all $x \in [2k-1, n]$, $\left|\frac{s_1(x)}{(x-k+1)(x-k)}\right| \leqslant n^{40k}$.*

Proof. For $k = 1$, we can take $s_1(x) = x(x-1)$ so we can assume that $n \geqslant k \geqslant 2$. For $k \geqslant 2$, we use the following construction.[1]

▶ **Definition 12.** *For all natural numbers $k \geqslant 2$, define $g_k(x)$ to be the polynomial*
$$g_k(x) = x^{16k}(x-2k+1)^{16k} \prod_{i \in \{0,\ldots,2k-1\} \setminus \{k-1,k\}} (x-i).$$

▶ **Definition 13.** *Given a natural number n and $k \in \{2, 3, \ldots, n\}$, we define $s_1(x)$ as follows:*

1. *If k is odd, then we define $s_1(x) = \frac{g_k(x)}{g_k(k-1)}(x-k+1)(x-k)$.*
2. *If k is even, then we define $s_1(x) = -\frac{g_k(x)(x+1)(x-2k)}{g_k(k-1)k(k+1)}(x-k+1)(x-k)$.*

[1] Definitions 12 and 13 are only used in the current section, Section 3.

We verify the desired properties. We first show that $s_1\left(\sum_{i=1}^n x_i\right)$ is a sum of squares (modulo the Boolean axioms). If k is odd, then since $g_k(k-1) > 0$, $\prod_{i=0}^{2k-1}\left(\left(\sum_{i=1}^n x_i\right) - i\right)$ is a sum of squares (modulo the Boolean axioms), and by [33, Lemma 4.4],

$$s_1\left(\sum_{i=1}^n x_i\right) = \frac{\left(\sum_{i=1}^n x_i\right)^{16k}\left(\left(\sum_{i=1}^n x_i\right) - 2k + 1\right)^{16k}}{g_k(k-1)} \prod_{i=0}^{2k-1}\left(\left(\sum_{i=1}^n x_i\right) - i\right)$$

is a sum of squares (modulo the Boolean axioms). If k is even, then since $g_k(k-1) < 0$, $\left(\sum_{i=1}^n x_i\right) + 1$ and $\prod_{i=0}^{2k}\left(\left(\sum_{i=1}^n x_i\right) - i\right)$ are sum of squares (modulo the Boolean axioms),

$$s_1\left(\sum_{i=1}^n x_i\right) = -\frac{\left(\sum_{i=1}^n x_i\right)^{16k}\left(\left(\sum_{i=1}^n x_i\right) - 2k + 1\right)^{16k}}{g_k(k-1)k(k+1)}\left(\left(\sum_{i=1}^n x_i\right) + 1\right)\prod_{i=0}^{2k}\left(\left(\sum_{i=1}^n x_i\right) - i\right)$$

is a sum of squares (modulo the Boolean axioms). Finally, to argue about the degree, note that by [33, Lemma 4.4], $\prod_{i=0}^{2k-1}\left(\left(\sum_{i=1}^n x_i\right) - i\right)$ has a sum of squares (modulo the Boolean axioms) certificate of degree $2k$ and thus, for all k, $s_1\left(\sum_{i=1}^n x_i\right)$ has a sum of squares (modulo the Boolean axioms) certificate of degree $O(k)$.

For the fourth property, observe that for $x \in [0, n]$, every term in the numerator (except for $(x+1)$ when k is even) has magnitude at most n, every term in the denominator has magnitude at least 1, and there are less than $40k$ terms in the numerator.

The second and third properties follow immediately from the following lemma.

▶ **Lemma 14.** *For all natural numbers $k \geqslant 2$, $g_k(x)$ satisfies the following properties:*

1. *For all $x \in [0, 2k-1]$, $g_k(2k-1-x) = g_k(x)$.*
2. *For all $x \in [k-1, k]$, $\frac{g_k(x)}{g_k(k-1)} \geqslant 1$.*
3. *For all $x \in [0, k-1] \cup [k, 2k-1]$, $\left|\frac{g_k(x)}{g_k(k-1)}\right| \leqslant 1$.*

Proof. Since the first and second properties hold for every term in the product $g_k(x) = (-1)^{k-1}\left(x(x-2k+1)\right)^{16k}\left(\prod_{i=0}^{k-2}(x-i)(2k-1-x-i)\right)$, they hold for $g_k(x)$ as well.

By symmetry, it suffices to show the third property for $x \in [0, k-1]$. For $x \in \{0, 1, \ldots, k-2\}$, $g_k(x) = 0$ and for $x \in (k-2, k-1)$, the third property holds for every term in this product, so it holds for $g_k(x)$ as well. To show that the third property holds for $x \in [0, k-2]\backslash\{0, 1, \ldots, k-2\}$, we compare $g_k(x-m)$ and $g_k(x)$, where $x \in (k-2, k-1)$ and $m \in \{0, 1, \ldots, k-2\}$. For this, we decompose $g_k(x)$ as $g_k(x) = a_k(x)b_k(x)^{16k}$, where $a_k(x) = \prod_{i \in \{0,\ldots,2k-1\}\backslash\{k-1,k\}}(x-i)$ and $b_k(x) = x(2k-1-x)$.

▶ **Lemma 15.** *Let $a_k(x) = \prod_{i \in \{0,\ldots,2k-1\}\backslash\{k-1,k\}}(x-i) = \left(\prod_{i=0}^{k-2}(x-i)\right)\left(\prod_{i=k+1}^{2k-1}(x-i)\right)$. For all $x \in (k-2, k-1)$ and all $m \in \{1, \ldots, k-2\}$, $\left|\frac{a_k(x-m)}{a_k(x)}\right| \leqslant e^{\frac{16m^2}{k}}$.*

Proof. Observe that

$$\begin{aligned}
\left|\frac{a_k(x-m)}{a_k(x)}\right| &= \left|\frac{\prod_{j=1}^m (x-k+2-j)}{\prod_{j=1}^m (x+1-j)} \cdot \frac{\prod_{j=1}^m (x-2k+1-j)}{\prod_{j=1}^m (x-k-j)}\right| \\
&= \left|\frac{\prod_{j=1}^m (k-2-x+j)}{\prod_{j=1}^m (k-x+j)} \cdot \frac{\prod_{j=1}^m (2k-x-1+j)}{\prod_{j=1}^m (x-m+j)}\right| \\
&\leqslant \left|\prod_{j=1}^m \left(\frac{k+1+j}{k-2-m+j}\right)\right|.
\end{aligned}$$

We distinguish between two cases.

1. If $m \leqslant \frac{3k}{4} - 1$, observe that

$$\left|\prod_{j=1}^{m}\left(\frac{k+1+j}{k-2-m+j}\right)\right| = \prod_{j=1}^{m}\left(1+\frac{m+3}{k-2-m+j}\right)$$
$$\leqslant \prod_{j=1}^{m}\left(1+\frac{m+3}{k-m-1}\right) \leqslant \prod_{j=1}^{m} e^{\frac{m+3}{k-m-1}} = e^{\frac{m(m+3)}{(k-m+1)}} \leqslant e^{\frac{16m^2}{k}}.$$

2. If $m > \frac{3k}{4} - 1$, then $m \geqslant \frac{3k}{4} - \frac{3}{4} \geqslant \frac{3k}{8}$ (as $k \geqslant 2$). Thus,

$$\left|\prod_{j=1}^{m}\left(\frac{k+1+j}{k-2-m+j}\right)\right| \leqslant \prod_{j=1}^{k-2}\left(\frac{k+1+j}{j}\right) = \frac{(2k-1)!}{(k-2)!(k+1)!} \leqslant 2^{2k-1} \leqslant e^{\frac{16m^2}{k}}. \quad \blacktriangleleft$$

▶ **Lemma 16.** *Let $b_k(x) = x(2k-1-x)$. For $x \in (k-2, k-1)$ and $m \in [k-2]$, $\left|\frac{b_k(x-m)}{b_k(x)}\right| \leqslant e^{-\frac{m^2}{k^2}}$.*

Proof. Observe that

$$\frac{b_k(x-m)}{b_k(x)} = \frac{(x-m)(2k-1+m-x)}{x(2k-1-x)} = \frac{x(2k-1-x)-(2k-1-2x)m-m^2}{x(2k-1-x)}$$
$$\leqslant 1 - \frac{m^2}{x(2k-1-x)} \leqslant 1 - \frac{m^2}{k^2} \leqslant e^{-\frac{m^2}{k^2}}. \quad \blacktriangleleft$$

▶ **Corollary 17.** *For all $x \in (k-2, k-1)$ and $m \in \{1, \ldots, k-2\}$, $\left|\frac{g_k(x-m)}{g_k(x)}\right| \leqslant 1$.*

Proof. By Lemmas 15 and 16, $\left|\frac{g_k(x-m)}{g_k(x)}\right| = \left|\frac{a_k(x-m)}{a_k(x)}\right| \left|\frac{b_k(x-m)}{b_k(x)}\right|^{16k} \leqslant e^{\frac{16m^2}{k}} \left(e^{-\frac{m^2}{k^2}}\right)^{16k} = 1.$ $\blacktriangleleft$

$\blacktriangleleft$

$\blacktriangleleft$

3.1.2 Constructing the polynomial $s_2(x)$

We now construct the polynomial $s_2(x)$.

▶ **Lemma 18.** *For all $n \in \mathbb{N}$ and all $k \in [n]$, there exists a polynomial $s_2(x)$ of degree $O(\sqrt{kn}log(n))$ satisfying the following properties:*

1. *$s_2(x)$ is a sum of squares.*
2. *For all $x \in [k-1, k]$, $s_2(x) \geqslant 1$.*
3. *For all $x \in [0, k-1] \cup [k, 2k-1]$, $s_2(x) \leqslant 1$.*
4. *For all $x \in [2k-1, n]$, $s_2(x) \leqslant n^{-40k}$.*

Proof.

▶ **Lemma 19.** *For $C := e^{8\sqrt{3}}$ and $k \in \{0, \ldots, \lceil n/2 \rceil\}$, $H_k = T^2_{\sqrt{\frac{n}{k}}}\left(2\frac{x}{n} - 1 - 2\frac{2k-1}{n}\right)$ satisfies the following properties:*

1. *For all $x \in [2k-1, n]$, $H_k(x) \leqslant 1$.*
2. *For all $k \in [0, 2k-1]$, $H_k'(x) < 0$.*
3. *$H_k(0) \leqslant C$.*
4. *$H_k(k) \geqslant 1.5$.*

Proof. Note that $H_k(x) = T^2_{\sqrt{\frac{n}{k}}}\left(2\frac{x}{n} - 1 - 2\frac{2k-1}{n}\right)$. Hence, $H_k(2k-1) = T^2_{\sqrt{\frac{n}{k}}}(-1) = 1$ and $H_k(n) = T^2_{\sqrt{\frac{n}{k}}}\left(1 - 2\frac{2k-1}{n}\right) \leqslant 1$, which implies the first property. We prove Properties (2) and (3). By Lemma 7, for k such that $4k-2 \leqslant n$, we have

$$H_k(0) = T^2_{\sqrt{\frac{n}{k}}}\left(-1 - \frac{4k-2}{n}\right) \leqslant \left(1 + \sqrt{\frac{32k-16}{n}}\right)^{2\sqrt{\frac{n}{k}}} \leqslant e^{2\sqrt{\frac{32k-16}{k}}} \leqslant e^{8\sqrt{3}}$$

and for k such that $4k-2 \geqslant n$, by Lemma 7, for $c \geqslant n$, we have

$$H_k(0) = T^2_{\sqrt{\frac{n}{k}}}\left(-1 - \frac{4k-2}{n}\right) \leqslant \left(1 + \frac{12k}{n}\right)^{2\sqrt{\frac{n}{k}}} \leqslant \left(1 + \sqrt{\frac{12k}{n}}\right)^{4\sqrt{\frac{n}{k}}} \leqslant e^{4\sqrt{\frac{12k}{k}}} \leqslant e^{8\sqrt{3}}.$$

Moreover, by Lemma 7 we have

$$H_k(k) = T^2_{\sqrt{\frac{n}{k}}}\left(-1 - \frac{2k-2}{n}\right) \geqslant \frac{1}{4}\left(1 + \sqrt{\frac{4k-4}{n}}\right)^{2\sqrt{\frac{n}{k}}} \geqslant \frac{1}{4}\left(1 + \sqrt{\frac{2k}{n}}\right)^{2\sqrt{\frac{n}{k}}},$$

where the last inequality holds because $k \geqslant 2$. Finally, since $n \geqslant 2k$,

$$\frac{1}{4}\left(1 + \sqrt{\frac{2k}{n}}\right)^{2\sqrt{\frac{n}{k}}} \geqslant \frac{1}{4}2^{2\sqrt{\frac{n}{k}}\sqrt{\frac{2k}{n}}} = \frac{1}{4}2^{2\sqrt{2}} \geqslant 1.5.$$ ◀

▶ **Lemma 20.** *For any constants a, b, C such that $1.5 \leqslant a < b < C$, there is a sum of squares polynomial $p_{a,b,C}(x)$ of degree at most $8\lceil C^2 \rceil$ such that the following hold:*

1. *For all $x \in [a, b]$, $p_{a,b,C}(x) \geqslant 1$.*
2. *For all $x \in [0, 1]$, $|p_{a,b,C}(x)| \leqslant \frac{1}{2}$.*
3. *For all $x \in [0, a] \cup [b, C]$, $|p_{a,b,C}(x)| \leqslant 1$.*

Proof. We can take the polynomial

$$p_{a,b,C}(x) = \left(1 - \frac{(x-a)(x-b)}{C^2}\right)^{4\lceil C^2 \rceil}.$$

We now make the following observations:

1. For all $x \in [a, b]$, $1 - \frac{(x-a)(x-b)}{C^2} \geqslant 1$ so $p_{a,b,C}(x) \geqslant 1$.
2. For all $x \in [0, 1]$, $|1 - \frac{(x-a)(x-b)}{C^2}| \leqslant 1 - \frac{1}{4C^2}$ so $|p_{a,b,C}(x)| \leqslant \left(1 - \frac{1}{4C^2}\right)^{4\lceil C^2 \rceil} \leqslant \frac{1}{2}$.
3. For all $x \in [0, a] \cup [b, C]$, $|1 - \frac{(x-a)(x-b)}{C^2}| \leqslant 1$ so $|p_{a,b,C}(x)| \leqslant 1$. ◀

We construct the polynomial $s_2(x)$. For $k \in \{2, \ldots, \lceil n/2 \rceil\}$, let $s_2(x) := p_{a,b,C}\left(H_k(x)\right)^{40\lceil k \log(n) \rceil}$, where $a = H_k(k)$, $b = H_k(k-1)$, and $C = e^{8\sqrt{3}}$ is the constant given by Lemma 19.

▶ **Lemma 21.** *For any $k \in \{2, \ldots, \lceil n/2 \rceil\}$, $s_2(x)$ satisfies the properties in Lemma 18.*

Proof. We make the following observations:

1. For all $x \in [0, k-1] \cup [k, 2k-1]$, $H_k(x) \in [0, H_k(k)] \cup [H_k(k-1), C]$ so $|p_{a,b,C}(H_k(x))| \leqslant 1$ and thus $s_2(x) = p_{a,b,C}\left(H_k(x)\right)^{40\lceil k \log(n) \rceil} \leqslant 1$.
2. For all $x \in [k-1, k]$, $H_k(x) \in [H_k(k), H_k(k-1)]$ so $p_{a,b,C}(H_k(x)) \geqslant 1$ and thus $s_2(x) = p_{a,b,C}\left(H_k(x)\right)^{40\lceil k \log(n) \rceil} \geqslant 1$.
3. For all $x \in [2k-1, n]$, $H_k(x) \in [0, 1]$ so $|p_{a,b,C}(H_k(x))| \leqslant 1$ and thus, $s_2(x) = p_{a,b,C}\left(H_k(x)\right)^{40\lceil k \log(n) \rceil} \leqslant n^{-40k}$. ◀

◀

4 SoS rank upper bound for the MK problem via SQF certification

In this section, we prove an upper bound of $O(\sqrt{n}\log(P))$ on the SoS rank for the MK problem, which, together with the lower bound presented in [28], constitutes proof of Theorem 2.

We first discuss the necessary properties a candidate SoS certificate for the MK problem has to satisfy. A degree d SoS certificate for the MK problem is of the form $\sum_{i\in[n]} x_i - 1 = s_0(\mathbf{x}) + s_1(\mathbf{x})\left(\sum_{i\in[n]} x_i - \frac{1}{P}\right)$, where s_0, s_1 are SoS polynomials of degree $2d+2$ and $2d$, respectively. Through permutation of indices, the existence of an SoS certificate for the MK problem implies the existence of an SoS certificate such that s_1 is symmetric, that is, there exists $\tilde{s}_1 : \mathbb{R} \to \mathbb{R}$ such that $s_1(\mathbf{x}) = \tilde{s}_1(|\mathbf{x}|)$ for all $\mathbf{x} \in \{0,1\}^n$. Since s_0 is globally nonnegative, $\tilde{s}_1$ needs to satisfy

$$|\mathbf{x}| - 1 \geqslant \tilde{s}_1(|\mathbf{x}|)\left(|\mathbf{x}| - \frac{1}{P}\right) \qquad \text{for all } \mathbf{x} \in \{0,1\}^n. \tag{4.1}$$

Thus, $\tilde{s}_1(0) \geqslant P$, $\tilde{s}_1(1) = 0$, and $\tilde{s}_1(x) \leqslant \frac{x-1}{x-\frac{1}{P}}$ for $x \in \{2,\dots,n\}$.

We will construct a sum of squares polynomial $\tilde{s}_1$ which satisfies the following slightly stronger conditions:

1. $\tilde{s}_1(0) > P$
2. For all $x \in [1,2]$, $\tilde{s}_1(x) \leqslant \frac{x-1}{2}$
3. For all $x \in [2,n]$, $\tilde{s}_1(x) \leqslant \frac{1}{2}$

We will then observe that these conditions imply that

$$\tilde{s}_0(|x|) = |x| - 1 - \tilde{s}_1(|x|)\left(|x| - \frac{1}{P}\right)$$

is positive for all $x \in \{0\} \cup (1,n]$ which is sufficient to show that $\tilde{s}_0(x)$ is a sum of squares modulo the Boolean constraints.

A polynomial $T_{2\sqrt{n}}(\frac{x-1+r_0}{n} - 1)$, where r_0 is the smallest root of the polynomial $T_{2\sqrt{n}}(\frac{x}{n} - 1)$, which for $P = 2$ satisfies similar requirements was constructed in [28, Lemma 15] using properties of Chebyshev polynomials.

To obtain our polynomial $\tilde{s}_1(x)$, we generalize this construction using three parameters, the degree d of the Chebyshev polynomial, a scaling factor α, and an even power m.

▶ **Definition 22.** *Given an $\alpha > 0$, a natural number d, and an even natural number m, define $\tilde{s}_{\alpha,d,m}(x) := \alpha T_d\left(\frac{x-1+r_0}{n} - 1\right)^m$, where r_0 is the smallest root of the polynomial $T_d\left(\frac{x}{n} - 1\right)$.*

▶ **Lemma 23.** $r_0 \leqslant \frac{\pi^2 n}{4d^2}$.

Proof. Observe that $T_d(x) = \cos(d\cos^{-1}(x))$ so the first zero of $T_d(x)$ is $\cos\left(-\pi + \frac{\pi}{2d}\right) \leqslant -1 + \frac{\pi^2}{4d^2}$. Thus, the first zero of $T_d\left(\frac{x}{n} - 1\right)$ is at most $\frac{\pi^2 n}{4d^2}$. ◀

▶ **Lemma 24.** *For $d > \frac{\pi}{2}\sqrt{n}$ the polynomial $\tilde{s}_{\alpha,d,m}(x)$ satisfies the following properties:*

1. *For all $x \in [1,n]$, $\tilde{s}_{\alpha,d,m}(x) \leqslant \min\left\{\frac{\alpha d^2}{n}(x-1), \alpha\right\}$.*
2. $\tilde{s}_{\alpha,d,m}(0) \geqslant \alpha\left(\frac{1}{4}\left(1 + \sqrt{\frac{2(1-r_0)}{n}}\right)^d\right)^m$.

Proof. For the first statement, observe that by the Markov Brothers' Theorem, since $|T_d(x)| \leqslant 1$ for all $x \in [-1,1]$, $|T_d'(x)| \leqslant d^2$ for all $x \in [-1,1]$. This implies that $\left|T_d'\left(\frac{x-1+r_0}{n} - 1\right)\right| \leqslant \frac{d^2}{n}$ for all $x \in [1-r_0, 2n+1-r_0]$. Since $T_d\left(\frac{x-1+r_0}{n} - 1\right) = 0$, when $x = 1$, $\left|T_d\left(\frac{x-1+r_0}{n} - 1\right)\right| \leqslant \min\{\frac{d^2(x-1)}{n}, 1\}$ for all $x \in [1,n]$, which implies the result.

For the second statement, by Lemma 7, if $0 \leqslant c \leqslant n$ then $|T_d(-1-\frac{c}{n})| \geqslant \frac{1}{4}\left(1+\sqrt{\frac{2c}{n}}\right)^d$. Applying this lemma with $c = 1 - r_0$, the result follows. ◀

▶ **Corollary 25.** *If the conditions*

1. $d \geqslant 3\sqrt{n}$,
2. $\alpha \leqslant \frac{n}{2d^2} \leqslant \frac{1}{2}$,
3. $m > \frac{\ln(P) - ln(\alpha)}{d\ln\left(1+\sqrt{\frac{2(1-r_0)}{n}}\right) - \ln(4)}$,

are satisfied, then the following properties hold:

1. $\tilde{s}_{\alpha,d,m}(0) > P$.
2. *For all* $x \in [1,2]$, $\tilde{s}_{\alpha,d,m}(x) \leqslant \frac{x-1}{2}$.
3. *For all* $x \in [2,n]$, $\tilde{s}_{\alpha,d,m}(x) \leqslant \frac{1}{2}$.

Thus, $(x-1) - \tilde{s}_{\alpha,d,m}(x)(x - \frac{1}{P}) > 0$ *whenever* $x \in \{0\} \cup (1,n]$.

Proof. The first statement follows from algebraic manipulations provided that $\frac{1}{4}\left(1+\sqrt{\frac{2(1-r_0)}{n}}\right)^d \geqslant 1$. To confirm that this holds, observe that $r_0 \leqslant \frac{\pi^2 n}{4d^2} \leqslant \frac{1}{2}$. Thus,

$$\left(1+\sqrt{\frac{2(1-r_0)}{n}}\right)^d \geqslant \left(1+\frac{1}{\sqrt{n}}\right)^d \geqslant 2^{\frac{d}{\sqrt{n}}} \geqslant 8.$$

For the second and third statements, we use the facts that for all $x \in [1,n]$, $\tilde{s}_{\alpha,d,m}(x) \leqslant \frac{\alpha d^2}{n}(x-1)$ and $\tilde{s}_{\alpha,d,m}(x) \leqslant \alpha$, respectively.

To show that $(x-1) - \tilde{s}_{\alpha,d,m}(x)(x - \frac{1}{P}) > 0$ whenever $x \in \{0\} \cup (1,n]$, we make the following observations:

1. For $x = 0$, $-1 - \tilde{s}_{\alpha,d,m}(0)(-\frac{1}{P}) > -1 - P\left(-\frac{1}{P}\right) = 0$.
2. For $x \in (1,2]$, $(x-1) - \tilde{s}_{\alpha,d,m}(x)(x - \frac{1}{P}) \leqslant (x-1) - \frac{x-1}{2}\left(x - \frac{1}{P}\right) > 0$.
3. For $x \in [2,n]$, $(x-1) - \tilde{s}_{\alpha,d,m}(x)(x - \frac{1}{P}) \leqslant (x-1) - \frac{1}{2}\left(x - \frac{1}{P}\right) > 0$. ◀

We now confirm that

$$\tilde{s}_0 = (x-1) - \tilde{s}_{\alpha,d,m}(x)\left(x - \frac{1}{P}\right)$$

is a sum of squares modulo the Boolean axioms. To see this, observe that since $\tilde{s}_0(x) > 0$ for $x \in \{0\} \cup (1,n]$, $\tilde{s}_0(x)$ must have an even number of roots in $(0,1]$ and no other roots in $[0,n]$. Thus, we can write

$$\tilde{s}_0(x) = p\prod_{i=1}^{l}(x-a_i)(x-b_i)$$

for some polynomial p which is positive on $[0,n]$ and some real roots $a_1, \ldots, a_l, b_1, \ldots, b_l \in (0,1]$. Since p is positive on $[0,n]$, p is a sum of squares modulo the Boolean axioms. By Corollary 9, since $|x|(|x|-1)$ is a sum of squares modulo the Boolean axioms, for each $i \in [l]$, $(x-a_i)(x-b_i)$ is also a sum of squares modulo the Boolean axioms. Thus, $\tilde{s}_0(x)$ is a sum of squares modulo the Boolean axioms.

Finally, we observe that we can satisfy the required conditions on d, α, and m by taking $d = \lceil 3\sqrt{n} \rceil$, $\alpha = \frac{1}{2d^2} \approx \frac{1}{18n}$, and $m = O(\log(P))$, which gives a sum of squares certificate of degree $O(\sqrt{n}\log(P))$.

5 SoS rank upper bound for the SC problem via SQF certification

In this section, we refute the Bienstock–Zuckenberg conjecture for the SC problem. We provide a degree $O(\sqrt{n}\log(n))$ SoS certificate for the SC problem on the Boolean hypercube, thus proving Theorem 3. For this proof, we use the SoS rank for certifying SQFs for $k = 2$ in Theorem 1. We present an alternative direct proof in Section 6.

We begin this section with a discussion on the properties necessary for an SoS polynomial s to even be considered as a possible candidate for an SoS certificate for the SC problem. An SoS certificate for the SC problem is of the form $\sum_{i\in[n]} x_i - 2 = s_0(\mathbf{x}) + \sum_{i\in[n]} s_i(\mathbf{x})g_i(\mathbf{x})$, where $g_i(\mathbf{x}) = \left(\sum_{j\in[n]\setminus\{i\}} x_j - 1\right)$. As opposed to the discussion in Section 4, an SoS certificate for the SC problem not only has multiple constraints but also displays a certain type of asymmetry, which is present in the formulation of the polynomials g_i for $i \in [n]$. One could hope to abuse this asymmetry by constructing different SoS polynomials $s_i \in \Sigma_{n,d}$ for certain $d \in [n]$, but for this proof, we proceed in a similar fashion as for the MK problem and instead construct only one symmetric SoS polynomial $s : \{0,1\}^n \to \mathbb{R}$ and look for the certificate of the form $\sum_{i\in[n]} x_i - 2 = s_0(\mathbf{x}) + \sum_{i\in[n]} s(\mathbf{x})g_i(\mathbf{x})$. Through permutation of indices, the existence of an SoS certificate for the SC problem implies the existence of an SoS certificate such that s is symmetric, that is, there exists an $\tilde{s} : \mathbb{R} \to \mathbb{R}$ such that $s(\mathbf{x}) = \tilde{s}(|\mathbf{x}|)$ for all $\mathbf{x} \in \{0,1\}^n$. As for the MK problem, we are interested in the requirements that polynomial $\tilde{s}$ needs to satisfy such that s constitutes part of an SoS certificate for the SC problem. Let $g(\mathbf{x}) := \sum_{i\in[n]} g_i(\mathbf{x}) = (n-1)(\sum_{i=1}^n x_i) - n$ and note that g is a symmetric polynomial; there exists a univariate polynomial $\tilde{g}$ such that $\tilde{g}(|\mathbf{x}|) = g(\mathbf{x})$ for all $\mathbf{x} \in \{0,1\}^n$. Since s_0 is globally nonnegative, this implies that s needs to satisfy

$$\begin{aligned} |\mathbf{x}| - 2 &\geqslant \tilde{s}(|\mathbf{x}|)\left(|\mathbf{x}|(|\mathbf{x}|-2) + (n-|\mathbf{x}|)(|\mathbf{x}|-1)\right) \\ &= \tilde{s}(|\mathbf{x}|)((n-1)|\mathbf{x}| - n) = \tilde{s}(|\mathbf{x}|)\tilde{g}(|\mathbf{x}|) \qquad \text{for all } \mathbf{x} \in \{0,1\}^n. \end{aligned} \tag{5.1}$$

This implies that $\tilde{s}(0) \geqslant \frac{2}{n}$, $\tilde{s}(1) \geqslant 1$, $\tilde{s}(2) = 0$ and $\tilde{s}(x) \leqslant \frac{x-2}{3(n-1)x-n}$ for all $x \in \{3, 4, \ldots, n\}$. We will construct a sum of squares polynomial $\tilde{s}(x)$ which satisfies the following slightly stronger conditions:

1. $\tilde{s}(x) \geqslant 1$ for all $x \in [0,1]$.
2. For all $x \in [1,2)$, $\frac{\tilde{s}(x)}{x-2} < 0$ and $\frac{\tilde{s}(x)}{x-2}$ is increasing.
3. $\tilde{s}(x) \leqslant \frac{(x-2)}{2n}$ for all $x \in [2,3]$.
4. $\tilde{s}(x) \leqslant \frac{1}{2n}$ for all $x \in [3,n]$.

We will then observe that these conditions imply that $\tilde{s}_0(x) = x - 2 - \tilde{s}(x)((n-1)x - n)$ is positive for $x \in [0,1) \cup (2,n]$ and has exactly two zeros in the interval $[1,2]$, one of which is $x = 2$. We can then use Theorem 1 and Corollary 9 to show that $\tilde{s}_0$ is a sum of squares of degree $\deg(\tilde{s}) + O(\sqrt{n}\log(n))$ modulo the Boolean axioms.

▶ **Lemma 26.** *For $d = 3\sqrt{n}$, $\alpha = \frac{1}{18n}$, and $m = 2\lceil \log_2(\sqrt{18n}) \rceil$ the polynomial $\tilde{s}(x) = \tilde{s}_{\alpha,d,m}(x-1)$ satisfies the following properties:*

1. *$\tilde{s}(x) \geqslant 1$ for all $x \in [0,1]$.*
2. *For all $x \in [1,2)$, $\frac{\tilde{s}(x)}{x-2} < 0$ and $\frac{\tilde{s}(x)}{x-2}$ is increasing.*
3. *$\tilde{s}(x) \leqslant \frac{(x-2)}{2n}$ for all $x \in [2,3]$.*
4. *$\tilde{s}(x) \leqslant \frac{1}{2n}$ for all $x \in [3,n]$.*

Proof. For the first statement, just as in the proof of Corollary 25, $r_0 \leqslant \frac{\pi^2 n}{4d^2} \leqslant \frac{1}{2}$. Thus,

$$\left(1+\sqrt{\frac{2(1-r_0)}{n}}\right)^d \geqslant \left(1+\frac{1}{\sqrt{n}}\right)^d \geqslant 2^{\frac{d}{\sqrt{n}}} \geqslant 8$$

Hence, by Lemma 24, $\tilde{s}(1) = \tilde{s}_{\alpha,d,m}(0) \geqslant \alpha 2^m \geqslant 1$. Since $deg(\tilde{s})$ is even, all roots of $\tilde{s}$ are real and the smallest root of $\tilde{s}$ is 2, $\tilde{s}$ is positive and decreasing when $x < 2$ so $\tilde{s}(x) \geqslant 1$ whenever $x \in [0,1]$, as needed.

For the second statement, observe that since $\deg(\tilde{s})$ is even, all roots of $\tilde{s}$ are real and the smallest root of $\tilde{s}$ is 2, $\frac{\tilde{s}(x)}{x-2}$ is negative and increasing whenever $x < 2$.

For the third statement, observe that by Lemma 24, for all $x \in [2,3]$, $\tilde{s}(x) = \tilde{s}_{\alpha,d,m}(x-1) \leqslant \alpha\frac{d^2}{n}(x-2) \leqslant \frac{x-2}{2n}$.

For the fourth statement, observe that by Lemma 24, for all $x \in [3,n]$, $\tilde{s}(x) = \tilde{s}_{\alpha,d,m}(x-1) \leqslant \alpha < \frac{1}{2n}$. ◀

▶ **Corollary 27.** *For $d = 3\sqrt{n}$, $\alpha = \frac{1}{n}$, $m = 2\lceil\log_2(n)\rceil$, and $\tilde{s}(x) = \tilde{s}_{\alpha,d,m}(x-1)$ the polynomial $\tilde{s}_0(x) = x-2-\tilde{s}(x)((n-1)x-n)$ is positive for $x \in [0,1)\cup(2,n]$ and has exactly two zeros in the interval $[1,2]$, one of which is $x = 2$.*

Proof. We make the following observations:

1. For all $x \in [0,1)$,

$$\tilde{s}_0(x) = x-2-\tilde{s}(x)((n-1)x-n) \geqslant x-2-((n-1)x-n) = (n-2)(1-x) > 0.$$

2. For all $x \in [1,2]$, $\frac{\tilde{s}_0}{x-2} = 1-((n-1)x-n)\frac{\tilde{s}}{x-2}$. When $x \in [\frac{n}{n-1},2]$, $((n-1)x-n)\frac{\tilde{s}}{x-2} \leqslant 0$ so $\frac{\tilde{s}}{x-2} > 0$. When $x \in [1,\frac{n}{n-1})$, both $((n-1)x-n)$ and $\frac{\tilde{s}}{x-2}$ are negative and increasing so $((n-1)x-n)\frac{\tilde{s}}{x-2}$ is positive and decreasing and thus $\frac{\tilde{s}_0}{x-2}$ is increasing. Since $\frac{\tilde{s}_0(1)}{1-2} \leqslant 0$ and $\frac{\tilde{s}_0(\frac{n}{n-1})}{\frac{n}{n-1}-2} > 0$, $\frac{\tilde{s}_0(x)}{x-2}$ must have exactly one zero in the interval $[1,\frac{n}{n-1}]$.
3. For all $x \in (2,3]$, $\tilde{s}_0(x) = x-2-\tilde{s}(x)((n-1)x-n) \geqslant x-2-\frac{(n-1)x-n}{2n}(x-2) > 0$.
4. For all $x \in [3,n]$, $\tilde{s}_0(x) = x-2-\tilde{s}(x)((n-1)x-n) \geqslant x-2-\frac{(n-1)x-n}{2n} > \frac{x}{2}-\frac{3}{2} \geqslant 0$.

◀

▶ **Corollary 28.** *$\tilde{s}_0(|x|)$ is a sum of squares of degree $O(\sqrt{n}\log(n))$ modulo the Boolean axioms.*

Proof. Since $\tilde{s}_0(x) = x-2-\tilde{s}(x)((n-1)x-n)$ is positive for $x \in [0,1)\cup(2,n]$ and has exactly two zeros in the interval $[1,2]$, one of which is $x = 2$, we can write

$$\tilde{s}_0(x) = \tilde{p}(x-a)(x-2),$$

for some $a \in [1,2)$ where $\tilde{p}(x)$ is positive for has no real roots in the interval $[0,n]$. Since $\tilde{p}(x)$ is positive and has no real roots in the interval $[0,n]$, $\tilde{p}(|x|)$ is a sum of squares modulo the Boolean axioms. By Theorem 1 and Corollary 9, $(x-a)(x-2)$ is a sum of squares of degree $O(\sqrt{n}\log(n))$ modulo the Boolean axioms. ◀

Thus, there exists a degree $O(\sqrt{n}\log(n))$ SoS certificate of nonnegativity for the SC problem.

6 Alternative Proof for the SoS rank upper bound for the SC problem

In this section, we provide an alternative proof of Theorem 3. More precisely, we prove an $O(\sqrt{n}\log(n))$ upper bound on the SoS rank for the SC problem without using Theorem 1.

By the problem formulation, Definition (1.2), and Equation (2.1), the SoS rank for the SC Problem is the smallest d for which there exist SoS polynomials $s_0 \in \Sigma_{n,2d+2}$ and $s_i \in \Sigma_{n,2d}$ for $i \in [n]$ such that

$$\sum_{i=1}^{n} x_i - 2 = s_0(\mathbf{x}) + \sum_{i=1}^{n} s_i \left(\sum_{\substack{j=1 \\ j\neq i}}^{n} x_j - 1 \right).$$

Equivalently, it is the smallest positive integer d such that $\sum_{i=1}^{n} x_i - 2 \in \Sigma^{\mathcal{G}}_{n,d}$.

To prove the SoS rank upper bound for the SC problem, we define the polynomials $h_1(\mathbf{x}) := |\mathbf{x}| - 1$ and $h_2(\mathbf{x}) := |\mathbf{x}| \left(|\mathbf{x}| - 2\right)$ and require the following lemma, in which we use the asymmetry inherent to the constraints of the SC problem.

▶ **Lemma 29.** *For polynomials h_1, h_2 it holds that $h_1(\mathbf{x}) \in \Sigma^{\mathcal{G}}_{n,0}$ and $h_2(\mathbf{x}) \in \Sigma^{\mathcal{G}}_{n,1}$.*

Proof. Consider the first polynomial, h_1, and note that

$$\sum_{i=1}^{n} x_i - 1 = \frac{1}{n-1} \sum_{i=1}^{n} \left(\sum_{\substack{j=1 \\ j\neq i}}^{n} x_j - 1 \right) + \frac{1}{n-1} \in \Sigma^{\mathcal{G}}_{n,0}.$$

Polynomial h_2 can be written as

$$\begin{aligned} \sum_{j=1}^{n} x_j \left(\sum_{i=1}^{n} x_i - 2 \right) &= \sum_{j=1}^{n} \left(x_j \left(\sum_{i=1}^{n} x_i - x_j - 1 \right) + (x_j^2 - x_j) \right) \\ &= \sum_{j=1}^{n} \left(x_j^2 \left(\sum_{\substack{i=1 \\ i\neq j}}^{n} x_i - 1 \right) - (x_j^2 - x_j) \left(\sum_{\substack{i=1 \\ i\neq j}}^{n} x_i - 1 \right) + (x_j^2 - x_j) \right) \in \Sigma^{\mathcal{G}}_{n,1}. \end{aligned}$$

◀

Although Lemma 29 uses asymmetry in the constraints of the SC problem, both h_1 and h_2 are symmetric polynomials. We can thus define polynomials $\tilde{h}_1,\ \tilde{h}_2 : \mathbb{R} \to \mathbb{R}$ such that $\tilde{h}_1(|\mathbf{x}|) = h_1(\mathbf{x})$, and $\tilde{h}_2(|\mathbf{x}|) = h_2(\mathbf{x})$, respectively. We are working towards a proof of the existence of polynomials $p_1, p_2 : \mathbb{R} \to \mathbb{R}$ such that

$$(x-2) - p_1(x)\tilde{h}_1(x) - p_2(x)\tilde{h}_2(x) \geqslant 0 \qquad \text{for all } x \in [0, n]. \tag{6.1}$$

6.1 Construction of polynomials $\mathbf{p_1}, \mathbf{p_2}$

We consider necessary, but not sufficient requirements that the polynomials p_1 and p_2 have to satisfy, that is, $p_1(2)\tilde{h}_1(2) + p_2(2)\tilde{h}_2(2) = 0$, $\left[p_1\tilde{h}_1 + p_2\tilde{h}_2\right]'(2) = 1$, and $\left[p_1\tilde{h}_1 + p_2\tilde{h}_2\right]''(2) < 0$. It is easy to check that these requirements are satisfied if p_1 has a double root at $x = 2$, $p_2(2) = 1/2$, and $1 + 4p_2'(2) + 2\frac{p_1(2)}{(x-2)^2} < 0$. We use these guidelines to construct polynomials

$$\begin{aligned} p_1(x) &:= \frac{1}{2n^2 c_1} (x-2)^2 \, T^2_{2\sqrt{n}\log(n)} \left(2\frac{x-2}{n} - 1 \right), \\ p_2(x) &:= \frac{1}{2nc_2} \, T^2_{2\sqrt{n}\log(n)} \left(2\frac{x-3}{n} - 1 \right), \end{aligned} \tag{6.2}$$

where c_1 and c_2 are constants equal to $\frac{1}{2n^2}T^2_{2\sqrt{n}\log(n)}\left(-\frac{2}{n}-1\right)$ and $\frac{1}{n}\,T^2_{2\sqrt{n}\log(n)}\left(-\frac{2}{n}-1\right)$, respectively, such that $p_1(1)=1$ and $p_2(2)=1/2$.

▶ **Lemma 30.** *There exists $C\in\mathbb{N}$ such that for $n\geqslant C$, the polynomial p_1 satisfies the following properties:*

1. $p_1(x)\geqslant 4$ *for* $x\in[0,\frac{1}{2}]$.
2. $p_1(x)\leqslant\left(-0.9(x-1)+1\right)(x-2)^2$ *for* $x\in[1,2]$.
3. $p_1(x)\leqslant\frac{1}{2n^2}(x-2)^2$ *for* $x\in[2,n]$.

Proof. Since $p_1(x)$ is decreasing for $x\leqslant 1$, to prove Property (1) it is enough to show that $p_1(\frac{1}{2})\geqslant 4$. By Lemma 7 and for sufficiently big n, it holds

$$p_1(1/2)=\frac{\frac{9}{4}\,T^2_{2\sqrt{n}\log(n)}\left(\frac{-3}{n}-1\right)}{T^2_{2\sqrt{n}\log(n)}\left(-\frac{2}{n}-1\right)}\geqslant\frac{1}{2}\left(\frac{1+\sqrt{\frac{6}{n}}}{1+\sqrt{\frac{5}{n}}}\right)^{4\sqrt{n}\log(n)}.$$

Since $\frac{1}{2}\left(\frac{1+\sqrt{\frac{6}{n}}}{1+\sqrt{\frac{5}{n}}}\right)^{4\sqrt{n}\log(n)}\geqslant 4$ for $n\geqslant 32$ and by monotonicity, Property (1) is satisfied.

To prove Property (3), note that for every $x\in[2,n]$ and $d\in\mathbb{N}$ we have $T^2_d(2\frac{x-2}{n}-1)\leqslant 1$ and for every $n\geqslant 2$, by Lemma 7, we have $c_1=\frac{1}{2n^2}\,T^2_{2\sqrt{n}\log(n)}\left(-\frac{2}{n}-1\right)\geqslant\frac{1}{2n^2}\frac{1}{4}\left(1+\sqrt{\frac{4}{n}}\right)^{4\sqrt{n}\log(n)}\geqslant 1$.

To prove Property (2), we show that $\frac{1}{2n^2}T^2_{2\sqrt{n}\log(n)}\left(2\frac{x-2}{n}-1\right)\leqslant\left(-0.9(x-1)+1\right)$ for every $x\in[1,2]$. By construction, it is satisfied for $x=1$ and by Property (3), it is satisfied for $x=2$. Since the function $T^2_{2\sqrt{n}\log(n)}\left(2\frac{x-2}{n}-1\right)$ is convex in the interval $[1,2]$, the property is satisfied for $x\in[1,2]$. ◀

▶ **Lemma 31.** *There exists a constant $C\in\mathbb{N}$ such that for $n\geqslant C$, the polynomial p_2 satisfies the following properties:*

1. $p_2(x)\geqslant 4$ *for* $x\in[0,1]$.
2. $p_2(2)=\frac{1}{2}$.
3. $p_2'(x)\leqslant -1$ *for* $x\in[1,2]$.
4. $p_2(x)\leqslant -0.45(x-2)+\frac{1}{2}$ *for* $x\in[2,3]$.
5. $p_2(x)\leqslant\frac{1}{2n}$ *for* $x\in[3,n]$.

Proof. Since $p_2(x)$ is decreasing for $x\leqslant 1$, to prove Property (1), it is enough to show that $p_2(1)\geqslant 4$. For sufficiently big n we get:

$$p_2(1):=\frac{\frac{1}{2}\,T^2_{2\sqrt{n}\log(n)}\left(-\frac{4}{n}-1\right)}{T^2_{2\sqrt{n}\log(n)}\left(-\frac{2}{n}-1\right)}\geqslant\frac{1}{8}\left(\frac{-1-\sqrt{\frac{8}{n}}}{-1-\sqrt{\frac{5}{n}}}\right)^{4\sqrt{n}\log(n)}.$$

Since $\frac{1}{8}\left(\frac{-1-\sqrt{\frac{8}{n}}}{-1-\sqrt{\frac{5}{n}}}\right)^{4\sqrt{n}\log(n)}\geqslant 4$ for $n\geqslant 13$ and by monotonicity, Property (1) is satisfied.

Property (2) is satisfied by construction.

Since for every $x\in[3,n]$ and $d\in\mathbb{N}$ we have $\left|T_d(2\frac{x-3}{n}-1)\right|\leqslant 1$ and for every $n\geqslant 2$, by Lemma 7, we have $c_2=\frac{1}{n}\,T^2_{2\sqrt{n}\log(n)}\left(-\frac{2}{n}-1\right)\geqslant\frac{1}{n}\frac{1}{4}\left(-1-\sqrt{\frac{4}{n}}\right)^{4\sqrt{n}\log(n)}\geqslant 1$, Property (5) is satisfied.

Since $p_2(x)$ is convex for $x \in [1,2]$, to prove Property (3), it is enough to show $p_2^{'}(2) \leqslant -1$. Note that $\frac{\partial T_d(x)}{\partial x} = dU_{d-1}(x)$ and $\frac{\partial T_d^2(x)}{\partial x} = 2dT_d(x)U_{d-1}(x)$, where $U_d(x)$ is a Chebyshev polynomial of the second type. Thus,

$$p_2^{'}(x) = \frac{4\log(n)T_{2\sqrt{n}\log(n)}\left(\frac{2(x-3)}{n} - 1\right)U_{2\sqrt{n}\log(n)-1}\left(\frac{2(x-3)}{n} - 1\right)}{\sqrt{n}T_{2\sqrt{n}\log(n)}\left(-1-\frac{2}{n}\right)},$$

which implies that

$$p_2^{'}(2) = \frac{4\log(n)U_{2\sqrt{n}\log(n)-1}\left(-1-\frac{2}{n}\right)}{\sqrt{n}T_{2\sqrt{n}\log(n)}\left(-1-\frac{2}{n}\right)} = \left[\frac{\partial}{\partial x}\frac{T_{2\sqrt{n}\log(n)}\left(2\frac{x-3}{n} - 1\right)}{T_{2\sqrt{n}\log(n)}\left(-1-\frac{2}{n}\right)}\right](2)\,.$$

Since $T_{2\sqrt{n}\log(n)}\left(2\frac{x-3}{n} - 1\right)$ for $x = 2.5$ takes at most half of the value for $x = 2$ and since $T_{2\sqrt{n}\log(n)}\left(2\frac{x-3}{n} - 1\right)$ is convex in the interval $[2,3]$, $p_2^{'}(x) \leqslant -1$. By Lemma 7,

$$\frac{T^2_{2\sqrt{n}\log(n)}\left(-\frac{2}{n} - 1\right)}{T^2_{2\sqrt{n}\log(n)}\left(-\frac{1}{n} - 1\right)} \geqslant \frac{1}{4}\left(\frac{-1-\sqrt{\frac{4}{n}}}{-1-\sqrt{\frac{3}{n}}}\right)^{2\sqrt{n}\log(n)}.$$

Since $\frac{1}{4}\left(\frac{-1-\sqrt{\frac{4}{n}}}{-1-\sqrt{\frac{3}{n}}}\right)^{2\sqrt{n}\log(n)} \geqslant 2$ for $n \geqslant 100$ and by monotonicity, Property (3) is satisfied.

By Property (2), Property (4) holds for $x = 2$. By Property (5), it holds for $x = 3$ and $n \geqslant 10$. Since $p_2(x)$ is convex for $x \in [2,3]$, the property holds for $x \in [2,3]$. ◀

Now we are ready to prove the main lemma of this section.

▶ **Lemma 32.** *It holds that*

$$f(x) := x - 2 - p_1(x)h_1(x) - p_2(x)h_2(x) \geqslant 0 \qquad \text{for } x \in [0,n]. \tag{6.3}$$

Proof. Note that $h_1(x),\ h_2(x) \leqslant 0$ for $x \in [0,1]$. For all $x \in [0,\frac{1}{2}]$, $p_1(x)$ is decreasing and $h_1(x)$ is increasing in x. Thus, by Property (1), for $x \in [0,\frac{1}{2}]$, $f(x) \geqslant x - 2 - p_1(x)h_1(x) \geqslant -2 - p_1(1/2)h_1(1/2) \geqslant -2 + 4\cdot\frac{1}{2} \geqslant 0$. For $x \in [\frac{1}{2},1]$, both $p_2(x)$ and $h_2(x)$ are decreasing. Thus, for $x \in [\frac{1}{2},1]$ and by Property (1), $f(x) \geqslant x - 2 - p_2(x)h_2(x) \geqslant -\frac{3}{2} - p_2(1)h_2(1/2) \geqslant -\frac{3}{2} + 4\cdot\frac{3}{4} \geqslant 0$. To prove the statement for $x \in [1,2]$, we show that for every $a \in [0,1]$, we have $f(2-a) \geqslant 0$. By construction, we have $f(2) = 0$. Thus, the property holds for $a = 0$. By Property (2), for polynomial p_1, we have $p_1(2-a) \leqslant (0.9a + 0.1)a^2$. By Properties (2) and (3), for polynomial p_2, we have $p_2(2-a) \geqslant 1/2 + a$. Thus, $f(2-a) \geqslant -a - (0.9a+0.1)a^2(1-a) + (1/2+a)a(2-a) = a^2((0.9a-1.8)a+1.4)$, which is nonnegative for $a \in [0,1]$. This proves the statement for $x \in [1,2]$.

To prove the statement for $x \in [2,3]$ we show that for every $a \in [0,1]$, it holds that $f(2+a) \geqslant 0$. By Property (3), for $x \in [2,3]$ and $n \geqslant 2$, we get $p_1(2+a) \leqslant \frac{1}{4}a^2$. By Property (4), we get that $p_2(2+a) \leqslant -0.45a + \frac{1}{2}$. Thus, $f(2+a) \geqslant a - \frac{1}{4}a^2(1+a) - \left(-0.45a + \frac{1}{2}\right)(2+a)a = (0.15 + 0.2a)a^2$, which is non-negative for $a \in [0,1]$. This proves the statement for $x \in [2,3]$. Finally, for $x \in [3,n]$, we have $f(x) \geqslant x - 2 - \frac{1}{2n^2}(x-2)^2(x-1) - \frac{1}{2n}x(x-2) \geqslant 0$. ◀

6.2 Proof of Theorem 3

By Lemma 32, $x - 2 - p_1(x)h_1(x) - p_2(x)h_2(x) \geqslant 0$ for $x \in [0,n]$ and the degree of the polynomial on the LHS is at most $O(\sqrt{n}\log(n))$. Thus, by Theorem 6, there exist SoS polynomials s_0, s_1 such that $x - 2 - p_1(x)h_1(x) - p_2(x)h_2(x) = s_0(x) + x(n-x)s_1(x)$. Thus, $x - 2 = s_0(x) + x(n-x)s_1(x) + p_1(x)h_1(x) + p_2(x)h_2(x)$. Remark 5 and the fact that $|\mathbf{x}|(n - |\mathbf{x}|)$ has a degree 1 SoS certificate over the Boolean hypercube imply the existence of a degree $O(\sqrt{n}\log(n))$ certificate over the Boolean hypercube for the polynomial $\sum_{i=1}^n x_i - 2$.

Abstract

We study the problem of counting the number of homomorphisms from an input graph G to a fixed (quantum) graph $\bar{H}$ in any finite field of prime order $\mathbb{Z}_p$. The subproblem with graph H was introduced by Faben and Jerrum [ToC'15] and its complexity is still uncharacterised despite active research, e.g. the very recent work of Focke, Goldberg, Roth, and Zivný [SODA'21]. Our contribution is threefold.

First, we introduce the study of quantum graphs to the study of modular counting homomorphisms. We show that the complexity for a quantum graph $\bar{H}$ collapses to the complexity criteria found at dimension 1: graphs. Second, in order to prove cases of intractability we establish a further reduction to the study of bipartite graphs. Lastly, we establish a dichotomy for all bipartite ($K_{3,3}\backslash\{e\}$, *domino*)-free graphs by a thorough structural study incorporating both local and global arguments. This result subsumes all results on bipartite graphs known for all prime moduli and extends them significantly. Even for the subproblem with $p = 2$ this establishes new results.

1 Introduction

The study of graph homomorphisms represents one of the classic bodies of work in both discrete mathematics and computer science but remains a very active research area. These homomorphisms play a crucial role in the study of graph limits and networks [4, 19, 20, 47], in the study of databases [11, 33, 39, 40], and in the study of spin-systems in statistical physics [2, 5]. Formally, a graph-homomorphism from G to H is a map from $V(G)$ to $V(H)$ that preserves edges. Many classic problems studied in computer science can be expressed with graph homomorphisms. Examples range from the *decision* problem of determining the chromatic number of a graph, through the problem of *counting* the number of independent

sets, to the problem of *counting* the number of k-colourings using all k colours. The latter can be expressed by a *linear combination* of the number of graph homomorphisms to a set of non-isomorphic graphs.

Graph homomorphisms are a prime example of a very general class of problems that frequently yields complexity dichotomies with structural characterisations, where the properties of a graph implying (in)tractibility are easily computable. However, the dichotomy itself is hard to establish and by Ladner [37] not obvious to exist. Hell and Nešetřil studied the *decision* problem HomsToH with fixed image graph H, that asks whether there exists a homomorphism from an input graph G to H. In [35] they showed that the problem HomsToH can be solved in polynomial time if H contains a loop or is bipartite; otherwise it is NP-complete. Dyer and Greenhill introduced the *counting* problem #HomsToH with fixed image graph H, that asks for the number of homomorphisms from an input graph G to H. In their seminal work [16] they showed that #HomsToH can be solved in polynomial time if the connected components of H are complete bipartite graphs or reflexive complete graphs; otherwise it is # P-complete.

Lovász [38] observed that there are many graph parameters that can only be expressed by a linear combination of computational problems #HomsToH for a set of at least two graphs $H \in \mathcal{H}$. Examples are the class of *vertex surjective homomorphisms* and *compactions* studied in this context by Focke, Goldberg, and Zivný [24]. Lovász [38] introduced the notion of a *quantum graph* for a linear combination of finitely many graphs called its *constituents*. We refer by the dimension of a quantum graph to its number of constituents and find the set of graphs at dimension 1. With every increase of dimension, the set of graph parameters expressible by #HomsToH increases as well. For a quantum graph $\bar{H}$ the counting problem #HomsTo$\bar{H}$ denotes then *linear combination* of problems #HomsToH for all constituents H of $\bar{H}$. Chen, Curticapean and Dell [12] studied the complexity of #HomsTo$\bar{H}$ and showed that the complexity is inherited from the complexity of #HomsToH for all constituents H of $\bar{H}$, which is given by the criterion of Dyer and Greenhill. Motivated by this strong connection, Chen et al. raised the question of whether techniques based on quantum graphs can advance the state of the art of open problems regarding modular counting homomorphisms.

We study the complexity of the problem $\#_p$HomsTo$\bar{H}$ for any prime p and answer the question of Chen et al. in the affirmative, where the problem $\#_p$HomsTo$\bar{H}$ asks for the value of #HomsTo$\bar{H}$ in the finite field $\mathbb{Z}_p$. Our contribution is threefold. First, we obtain results for the whole class of quantum graphs by showing that the complexity of $\#_p$HomsTo$\bar{H}$ is inherited from the complexity $\#_p$HomsToH. Second, we reduce the study of $\#_p$HomsToH to a study of bipartite graphs by establishing a reduction to a restricted homomorphism problem. Finally, we employ a structural analysis on the set of ($K_{3,3}\backslash\{e\}$, *domino*)-free graphs and establish a dichotomy for these.

The line of research on modular counting homomorphisms was initiated with the study of the parity of #HomsToH by Faben and Jerrum [21]. Despite the clear picture on the non-modular version #HomsToH the modulus implies additional cases of tractibility as structures in H implying intractibility for #HomsToH get "cancelled" when counting in a finite field $\mathbb{Z}_p$. Faben and Jerrum [21] showed that automorphisms of order p capture a subset of these "cancellations" and reduced the study to a structural analysis of parameter graphs H that do not enjoy such automorphisms. These graphs are called *order p reduced*. In particular, for $p = 2$ they conjectured that automorphisms of order 2 capture all cancellations and that $\#_2$HomsToH for an order 2 reduced graph enjoys the same complexity criterion as the non-modular version #HomsToH given by Dyer and Greenhill. Despite a growing line of research by Göbel, Goldberg, and Richerby [26, 27] and the very recent work of Focke,

Table 1 History of the study of $\#_p$HomsToH on **bipartite** graphs H. (Note that the complexity study can be restricted to bipartite graphs by the bipartization result of this paper.) Crosses denote that the result incorporates the dichotomy for the graphclass, a p denotes that the result holds for all primes. Parenthesis denote that the result is not intrinsic but given by additional argumentation.

	Mod	Trees	Cactus	Square-free	K_4-minor-free	$(K_{3,3}\backslash\{e\}, domino)$-free

Goldberg, Roth, and Zivný [23] the conjecture remains open. The body of work is dominated by a study of structures as the modulus commands incorporating not only the local but also global properties of the graph H.

The research on $\#_p$HomsToH for arbitrary primes p was already suggested by Faben and Jerrum [21] as they showed that their results concerning automorphisms of order p apply for any prime p. However, Valiant [48] showed the existence of computational counting problems that enjoy a change of complexity with respect to different moduli. Therefore, a uniform complexity criterion for $\#_p$HomsToH would emphasize the special role of graph homomorphisms even more. The study of $\#_p$HomsToH was finally initiated by Göbel, Lagodzinski, and Seidel [28] and followed by Kazeminia and Bulatov [36]. In light of the richer structure due to the higher moduli far less is known about the complexity of $\#_p$HomsToH compared to $\#_2$HomsToH. Even though Faben and Jerrum [21] as well as Göbel et al. [28] considered an extension of the conjecture to all prime moduli and the results so far suggest it, no one has gone that far yet. We illustrate the individual contributions and the state of the art in Table 1.

1.1 Contribution

We establish a plethora of technical results, which we believe to be a major asset to future works on the complexity of $\#_p$HomsToH and may be of independent interest to different lines of research. The main contributions are given in the following and discussed in more depth in the subsequent subsection.

Quantum Homomorphisms

We introduce the study of quantum graphs to the study of $\#_p$HomsToH. For any quantum graph $\bar{H}$ we find that $\#_p$HomsTo$\bar{H}$ is equivalent to $\#_p$HomsTo$\bar{H}'$, where $\bar{H}'$ is a quantum graph whose constituents are order p reduced with coefficients in $\mathbb{Z}_p^* = \mathbb{Z}_p\backslash\{0\}$. We call these constituents the *p-constituents* of $\bar{H}'$. Focusing on these "reduced" quantum graphs we obtain the following inheritance theorem.

▶ **Theorem 1.1.** *Let p be a prime and $\bar{H} = \sum_{H\in\mathcal{H}} \alpha_H H$ be a quantum graph with p-constituents $\mathcal{H} = \{H_1, \dots, H_r\}$ that are order p reduced pairwise non-isomorphic graphs and a set of associated constants $\{\alpha_H\}_{H\in\mathcal{H}}$ that are in $\mathbb{Z}_p^*$. Then,*

- *if there exists a graph $H \in \mathcal{H}$ such that $\#_p$HomsToH is $\#_p$P-hard, then $\#_p$HomsTo$\bar{H}$ is $\#_p$P-hard;*
- *if, for all $H \in \mathcal{H}$, $\#_p$HomsToH is solvable in polynomial time, then $\#_p$HomsTo$\bar{H}$ is also solvable in polynomial time.*

This shows that the complexity of $\#_p\text{HOMSTO}\bar{H}$ collapses to the complexity of $\#_p\text{HOMSTO}H$. Even though the set of graph parameters expressible by $\#\text{HOMSTO}\bar{H}$ is arbitrarily larger compared to the parameters expressible by $\#\text{HOMSTO}H$, the complexity behaviour is captured at dimension $r = 1$, i.e. graphs.

In the same spirit, we show that the reduction technique applied to show Theorem 1.1 yields a universal technique that can be applied to obtain so-called *pinning* in classes of graph-homomorphisms closed under the composition. This technique is helpful for our study as we also obtain pinning for the restricted class of homomorphisms introduced in the following.

Bipartization

We restrict the study of $\#_p\text{HOMSTO}H$ to the study of bipartite graphs by a restricted class of homomorphisms. For two bipartite graphs $G = (L_G, R_G, E_G)$ and $H = (L_H, R_H, E_H)$ with fixed bipartition we say that a homomorphism from G to H *preserves the order of the bipartition* if the homomorphism maps L_G to L_H and R_G to R_H. The problem $\#_p\text{BIPHOMSTO}H$ with fixed bipartite graph H then asks for the number of these homomorphisms to H. It allows us to restrict the study of $\#_p\text{HOMSTO}H$ to the study of bipartite graphs by the following theorem.

▶ **Theorem 1.2.** *For any prime p and any graph H, there exists a bipartite graph H' such that*

- *if $\#_p\text{BIPHOMSTO}H'$ is $\#_p\,\mathsf{P}$-hard then $\#_p\text{HOMSTO}H$ is $\#_p\,\mathsf{P}$-hard;*
- *if $\#_p\text{BIPHOMSTO}H'$ is solvable in polynomial time then $\#_p\text{HOMSTO}H$ is solvable in polynomial time.*

This implies that a dichotomy for $\#_p\text{BIPHOMSTO}H'$ yields a dichotomy for $\#_p\text{HOMSTO}H$. As we will later show, the graph H' is a collection of complete bipartite graphs if and only if H satisfies the Dyer and Greenhill criterion. An additional feature of Theorem 1.2 is that it allows for the graph H to contain loops whereas the bipartite graph H' is always loop-less by definition. So far no study of $\#_p\text{HOMSTO}H$ allowed for loops. The structural implications of a bipartite graph H are also heavily exploited in the following analysis.

Hardness in Bipartite $(K_{3,3}\backslash\{e\}$, *domino*$)$-Free Graphs

In the longest and most technically involved part of the paper we study bipartite graphs H not satisfying the Dyer and Greenhill criterion with the goal of finding enough structural information to establish hardness of $\#_p\text{BIPHOMSTO}H$. We find that it suffices to study bipartite graphs in the class denoted $\mathcal{G}^{*p}_{\text{bip}}$ consisting of bipartite graphs without automorphisms of order p, that preserve the order of the bipartition. To this end, we conduct a rigorous structural analysis of the class of bipartite graphs that contain no induced subgraph isomorphic to $K_{3,3}\backslash\{e\}$ or *domino* (see Figure 1 for an illustration). Our insights on the structure of bipartite graphs allow us to establish the following theorem.

▶ **Theorem 1.3.** *Let p be a prime and $H \in \mathcal{G}^{*p}_{\text{bip}}$ be a $(K_{3,3}\backslash\{e\}$, *domino*$)$-free graph. If there exists a connected component of H that is not a complete bipartite graph, then $\#_p\text{BIPHOMSTO}H$ is $\#_p\,\mathsf{P}$-hard.*

In many cases, a *domino* as induced subgraph yields a pair of vertices x, y where x *dominates* y. The class of bipartite domination-free $K_{3,3}\backslash\{e\}$-free graphs is one of the focal points of the seminal work by Feder and Vardi [22]. They showed that the class of *graph*

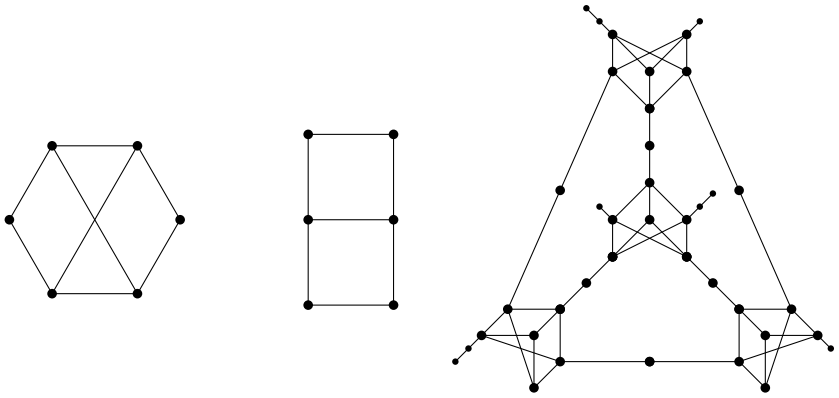

Figure 1 From left to right: $K_{3,3}\backslash\{e\}$; *domino*; Example of a bipartite ($K_{3,3}\backslash\{e\}$, *domino*)-free and asymmetric graph containing locally and globally K_4 as a minor.

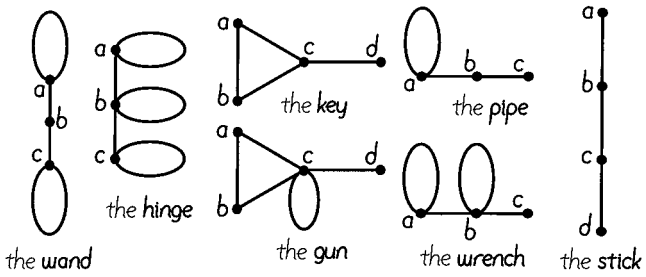

Figure 2 Depiction of the seven minimal fertile graphs as given in Brightwell and Winkler [5, Fig. 6].

retract problems – a notion equivalent to a partially labelled graph homomorphism – to the class of bipartite domination-free $K_{3,3}\backslash\{e\}$-free graphs contains as much computational power as the whole class of *constraint satisfaction problem*s (CSP's), i.e. every CSP is polynomially equivalent to a partially labelled graph homomorphism problem, where the image is a bipartite domination-free $K_{3,3}\backslash\{e\}$-free graph.

Consider the graphs studied in the work of Brightwell and Winkler [5] shown in Figure 2. The set of graph homomorphisms to these graphs played a key role in their study of spin systems in statistical physics. Prior results incorporate only two out of the seven minimal fertile graphs: "the stick" and "the key". Following the line of argumentation, our results incorporate the previous and three additional minimal fertile graphs. The only missing ones are "the hinge" and "the gun" as the construction used for bipartization yields graphs that are not *domino*-free. In fact, the class of bipartite ($K_{3,3}\backslash\{e\}$, *domino*)-free graphs captures all the classes of bipartite graphs studied in previous works on $\#_2\text{HomsTo}H$ and $\#_p\text{HomsTo}H$ except for the recent work by Focke et al. [23] on K_4-minor-free graphs. Clearly, every biclique with at least 3 vertices in each part contains a K_4 as minor, as is the case with $K_{3,3}\backslash\{e\}$. A *domino* is K_4-minor-free. Hence, our result given by a local property is orthogonal to the result of Focke et al. [23] given by a global property. An example is depicted in Figure 1.

1.2 Technical Overview

We are going to explain our results and argumentative routes in more detail. Due to their length, details are omitted but can be found in the full version.

In this work, hardness for modular counting problems is indicated by reducing from problems that are $\#_p\,\mathsf{P}$-hard. The class $\#_p\,\mathsf{P}$ contains functions of the form "$f \mod p$", where $f \in \#\,\mathsf{P}$. Notably, for the case $p = 2$ the whole polynomial hierarchy reduces to problems in $\#_2\,\mathsf{P}$ by Toda [46].

We briefly discuss the insights by Faben and Jerrum [21]. For a pair of graphs G, H we denote by $\mathrm{Hom}(G \to H)$ the set of homomorphisms from G to H. By $\hom(G \to H)$ we denote the cardinality $|\mathrm{Hom}(G \to H)|$ and, for a modulus p, by $\hom_p(G \to H)$ we denote $\hom(G \to H) \pmod p$. The computational problem $\#\textsc{HomsTo}H$ with parameter H then asks to compute $\hom(G \to H)$ for an input G. Similarly, $\#_p\textsc{HomsTo}H$ asks to compute $\hom_p(G \to H)$. A central point in the study of $\#_p\textsc{HomsTo}H$ is the (non)-existence of automorphisms of order p, where for $p = 2$ these automorphisms are called *involutions*. Given an automorphism ϱ of order p acting as a derangement on the subset $V' \subseteq V(H)$, Faben and Jerrum [21] showed that the number of homomorphisms σ from any input graph G to H is equivalent to 0 in $\mathbb{Z}_p$ if the image of σ intersects V'. They deduced that, for the subgraph H^ϱ of H induced by the fixpoints $V(H)\backslash V'$, there exists a parsimonious reduction from $\#_p\textsc{HomsTo}H^\varrho$ to $\#_p\textsc{HomsTo}H$. Iteratively applying this reduction, one ends up with a subgraph H^{*p} of H that admits no automorphism of order p called the *order p reduced* form of H. This subgraph is also unique up to ismomorphism and thus well defined by [21, Theorem 3.7]. The study of $\#_p\textsc{HomsTo}H$ focusses on graphs H that do not admit automorphisms of order p, which are called *order p reduced*.

1.2.1 Quantum Homomorphisms

It has been observed by Borgs, Chayes, Kahn, and Lovász [3] that the study of linear combinations of homomorphisms provides great insights especially on the comparability of pairs of graphs, for instance if one is a subgraph of the other. Lovász [38] introduced the term *quantum graph*, denoted $\bar{H}$, for a linear combination of finitely many graphs and calls the set of pairwise non-isomorphic graphs $\mathcal{H}$ with coefficient $\alpha_H \neq 0$ in $\bar{H}$ its *constituents*:

$$\bar{H} = \sum_{H \in \mathcal{H}} \alpha_H\, H.$$

A computational problem on $\bar{H}$ translates into the linear combination of computational problems on entities H in $\mathcal{H}$ with coefficient α_H. By Lovász [38] every graph parameter has – if any – a unique expression by a linear combination of finitely many graph homomorphisms up to isomorphisms.

We establish a polynomial time reduction from $\#_p\textsc{HomsTo}H$ to $\#_p\textsc{HomsTo}\bar{H}$, for any quantum graph $\bar{H}$ and any constituent H in $\bar{H}$. Such a polynomial time reduction is commonly referred to as a *pinning*-reduction because it enables us to consider the subproblem where a partially mapping is already fixed. One of the main problems of reduction algorithms on modular counting problems is the loss of control of summations in a finite field because we cannot infer from a number of non-zero summands that the sum is non-zero. For instance, let $p = 2$ and $\bar{H}$ be the quantum graph consisting of the two graphs H_1 and H_2 with coefficients $\alpha_{H_1} = \alpha_{H_2} = 1$, where H_1 is an asymmetric tree and H_2 is the disjoint union of a copy of H_1 and an isolated vertex. Let G be a connected graph and input for $\#\textsc{HomsTo}\bar{H}$, then we obtain $\hom(G \to H_2) = \hom(G \to H_1) + \hom(G \to K_1)$. Consequently, when computing $\hom(G \to H_1) + \hom(G \to H_2)$ in $\mathbb{Z}_2$ the term referring to H_1 vanishes and this amounts to computing $\hom(G \to K_1)$, which is polynomial time solvable. However, Theorem 1.1 yields that $\#_2\textsc{HomsTo}\bar{H}$ is $\#_2\,\mathsf{P}$-hard. The reason is that the split into $\hom(G \to H_1) + \hom(G \to K_1)$ only works if G is connected and by utilizing disconnected graphs the additional vertex in H_2 yields enough information to distinguish between H_1 and H_2. Therefore, we can extract $\hom_p(G \to H_1)$ from $\hom_p(G \to \bar{H})$.

In finite fields, reduction algorithms usually rely heavily on multiplication. We find that the beautiful insight on specific matrices defined on families $\mathcal{F}$ of simple graphs provided by Borgs, Chayes, Kahn, and Lovász [3, Lemma 4.2] is able to lift us above this hurdle. In order to adapt this result we first extend it to allow for graphs that contain loops. Then, we translate the result to counting in a finite field of prime order. A straightforward application of the modulo operator is not sufficient as the graphs in $\mathcal{F}$ might contain a number of automorphisms that is a multiple of p. We restrict to order p reduced graphs and argue why this allows for an application of the modulo operator. In this way, we show the following.

▶ **Corollary 1.4.** *Let $k \geqslant 1$ and let $\mathcal{F} = \{F_1, \ldots, F_k\}$ be a finite family of non-isomorphic order p reduced graphs closed under surjective homomorphic image, that contain no multi-edge. Then the matrix*

$$M_{hom} = \left[\hom_p(F_i \to F_j)\right]_{i,j=1}^{k}$$

is nonsingular.

The strength of this result for our purposes is twofold. First, it allows us to show Theorem 1.1 in a concise manner. Given a quantum graph $\bar{F}$ with set of p-constituents $\mathcal{F} = (F_1, \ldots, F_r)$ closed under surjective homomorphic image, we obtain by Corollary 1.4 that any system of linear equations of the form $\bar{x}\, M_{hom} = \bar{v}$ has a unique solution in the field $\mathbb{Z}_p$. Therefore, for any vector $\bar{v}$ with entries $(v_i)_{i\in[k]}$ there exists a unique linear combination of entities in $\mathcal{F}$ with coefficients α_F that yield the vector $\bar{v}$. In fact, we observe that this corresponds to a quantum graph $\bar{F}'$ with $\hom_p(\bar{F}' \to F_i) = v_i$ that *implements* the vector $\bar{v}$. In particular, there exists a quantum graph $\bar{F}'$ implementing the i-th standard vector allowing us to "pick" the i-th entry of $\mathcal{F}$, i.e. $\hom_p(\bar{F}' \to F_j) = 1$ if $j = i$ and $\hom_p(\bar{F}' \to F_j) = 0$ otherwise. Given an input graph G for $\hom_p(G \to \bar{F})$, we then construct a quantum graph $\bar{F}^*$ from G and $\bar{F}'$ such that $\hom_p(\bar{F}^* \to \bar{F}) = \hom_p(G \to F_i)$. The main problem for this application is then that the set $\mathcal{F}$ of p-constituents might not be closed under surjective homomorphic image. Given any quantum graph $\bar{H}$ with set of p-constituents $\mathcal{H}$, we need to define a suitable family $\mathcal{F}$ that contains all the image graphs needed. We find that the subgraphs of the maximal closure are sufficient for this purpose and obtain Theorem 1.1.

The second strength is the adaptability to subproblems of homomorphisms. The main property needed is that the subset of homomorphisms has to be closed under composition, i.e. the subset is actually a *subgroup* of the group of homomorphisms. Examples are *vertex surjective homomorphisms* and *compactions* as studied by Focke et al. [24]. A homomorphism $\sigma \in \mathrm{Hom}(G \to H)$ is *vertex surjective* if the image-set of σ is the whole set $V(H)$. The homomorphism σ is a *compaction* if it is vertex surjective and every non-loop edge e is in the image of σ. A closely related example is the problem of counting *partially labelled* homomorphisms $\#\textsc{PartLabHomsTo}H$, that are homomorphisms from an input graph G to H that have to respect a given mapping from a subset $V_G \subset V(G)$ to a subset $V_H \subset V(G)$ and are also referred to as *retractions* (see e.g. Focke et al. [24]). The reduction from $\#_p\textsc{PartLabHomsTo}H$ to $\#_p\textsc{HomsTo}H$ is a building stone of every paper in the study of $\#_p\textsc{HomsTo}H$ and can be obtained in a swift manner due to the strength of Corollary 1.4. A third example will be discussed in the next subsection.

1.2.2 Bipartization

Chen et al. [12] employed the tensor product $H \otimes K_2 = H'$ to reduce to $\#\textsc{HomsTo}H$ from $\#\textsc{HomsTo}H'$, where H' is bipartite. The main problem when adapting this construction to modular counting $\#_p\textsc{HomsTo}H$ is that for every graph G the number of homomorphisms

$\hom_2(G \to K_2)$ is 0 and thus the tensor product with K_2 annihilates seemingly any structure that might imply hardness. Instead of branching the study of $\#_p\text{HomsTo}H$ into one studying the modulus 2 and one studying the modulus of odd primes, we solve this issue in a uniform way for all prime moduli.

The key insight towards this is that for an involution-free graph H the tensor product $H' = H \otimes K_2$ only yields involutions on H' that exchange the parts of the bipartition. A very important example is the graph H consisting of a single edge with one loop, for which it is known that $\#\text{HomsTo}H$ is equivalent to counting the number of independent sets. The graph $H' = H \otimes K_2$ is then the path with 4 vertices (see Figure 2), that admits only the reflection across the middle edge. It is known that $\#\text{HomsTo}H'$ is equivalent to counting the number of bipartite independent sets #BIS and also that $\#_4\text{HomsTo}H'$ is $\#_2$ P-hard (see [28]) whereas $\#_2\text{HomsTo}H'$ is polynomial time solvable. In order to evade the artificial involutions yielded by the tensor product with K_2 we introduce the study on the problem of counting homomorphisms between bipartite graphs that preserve the order of the bipartition denoted $\#\text{BipHomsTo}H$. For example, if H is the path with 4 vertices then $\#_2\text{BipHomsTo}H$ is equivalent to $\#_4\text{HomsTo}H$.

▶ **Lemma 1.5.** *Let p be a prime, let H be a graph, and let $H' = H \otimes K_2$. Then, $\#_p\text{BipHomsTo}H'$ reduces to $\#_p\text{HomsTo}H$ under parsimonious reduction.*

We note that the graph $H' = H \otimes K_2$ is a collection of complete bipartite graphs if and only if H satisfies the Dyer and Greenhill criterion, for these graphs $\#_p\text{BipHomsTo}H'$ is solvable in polynomial time.

The reduction from $\#_p\text{BipHomsTo}H$ has the downside that the machinery developed over the course of multiple papers on $\#_p\text{HomsTo}H$ is not stated for the subgroup of homomorphisms counted by $\#_p\text{BipHomsTo}H$. We remedy this. First, by the strong adaptability of Corollary 1.4 and the subsequent reduction algorithm we obtain pinning for the problem $\#_p\text{BipHomsTo}H$. Second, using automorphisms of order p that preserve the order of the bipartition we reduce the bipartite graph H to a *part-wise order p reduced* bipartite graph $(H)^{*p}$. We deduce that the goal towards a dichotomy for $\#\text{HomsTo}H$ is captured by Theorem 1.2. The chain of reductions is displayed below.

$$\#_p\text{BipPartLabHomsTo}H^* =_P \#_p\text{BipHomsTo}H^* \leq_{pars}^{(H^* = (H')^{*p})} \#_p\text{BipHomsTo}H' \leq_{pars}^{(H' = H \otimes K_2)} \#_p\text{HomsTo}H$$

We employ a gadgetry that establishes a reduction to $\#_p\text{BipHomsTo}H$ from a variant of #BIS with weights on both types of vertices. Such a gadgetry yielding hardness is called a *p-hardness gadget*. By an adaptation of the dichotomy for #BIS with weights on the vertices *in* the independent set given in [28] this reduction establishes hardness when counting in $\mathbb{Z}_p$ if and only if none of the weights is equivalent to 0 in $\mathbb{Z}_p$. The problem of #BIS with weights on the vertices in the independent set is established as terminal problem yielding hardness in the study of $\#_p\text{HomsTo}H$ [28, 36] as the bigger modulus implies a richer structure compared to the study of $\#_2\text{HomsTo}H$ that traditionally focusses on counting the number of independent sets.

1.2.3 Hardness in Bipartite $(K_{3,3}\backslash\{e\}, \textit{domino})$-Free Graphs

A central argument in the work of Chen et al. [12] is that for a bipartite graph H and the problem $\#\text{HomsTo}H$ there exists a simple reduction from $\#\text{HomsTo}B$, where B is the ball of radius 2 around a vertex v in H denoted $B_2(v)$, i.e. vertices of distance at most 2 from v.

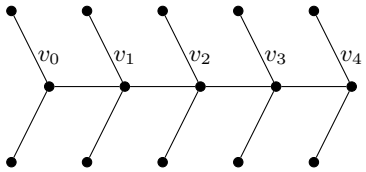

Figure 3 For $p = 3$ the tree H contains no ball of radius 2 around any vertex with enough structure to yield hardness even though $\#_3\text{HomsTo}H$ is $\#_3$ P-hard.

By an iterative application of this argument they establish a reduction from $\#\text{HomsTo}P$, where P is a generalization of the path with 4 vertices. Even though the reduction argument can be made valid for $\#_p\text{HomsTo}H$ and $\#_p\text{BipHomsTo}H$ the restriction to a substructure might destroy the properties that yield hardness already for trees H, a class of graphs for which the dichotomy is proved (see [21, 28]). An example is depicted in Figure 3.

In a nutshell, the induced subgraphs of radius at most 2 can admit too many automorphisms of order p. In Figure 3 we observe that the problem originates from too many instances of complete bipartite graphs $K_{1,b}$, where $b \equiv 0 \pmod 3$ or $b \equiv 1 \pmod 3$. The way to overcome this is to also consider the global structure. In the case displayed in Figure 3 the number of walks of length 4 from v_4 to a vertex v in the neighbourhood of v_1 is 0 (mod 3) if $v = v_2$ and 1 else. The goal is then to construct a reduction restricting the study to $B_2(v_0)\backslash\{v_2\}$, a graph that yields hardness. We do this in a general form by a second type of gadgetry called (B, p)-*gadget* that reduces $\#_p\text{BipHomsTo}H$ from $\#_p\text{BipHomsTo}B$.

As we have argued, one of the main obstacles for the study on $\#_p\text{HomsTo}H$ are complete bipartite graphs. The graph $K_{3,3}\backslash\{e\}$ denotes the graph obtained from $K_{3,3}$ by deleting an edge, and the graph *domino* denotes the graph obtained from $K_{3,3}$ by deleting two edges without introducing a cut-vertex (see Figure 1). By the restriction to ($K_{3,3}\backslash\{e\}$, *domino*)-free bipartite graphs we study exactly the case of a great many of complete bipartite induced subgraphs. To this end, we observe that for every vertex $v \in H$ the induced subgraph $B_2(v)$ splits into connected components obtained from deleting v. The *split* of $B_2(v)$ at v corresponds to the set of these connected components, where every component contains a copy of v. By the absence of induced subgraphs isomorphic to $K_{3,3}\backslash\{e\}$ or *domino* we deduce that the blocks containing v in these components have to be complete bipartite.

The overall line of argumentations towards Theorem 1.3 is then the following. First, we establish the dichotomy for all ($K_{3,3}\backslash\{e\}$, *domino*)-free bipartite graphs H of radius at most 2 by a combination of (B, p)- and p-hardness gadgets. This is done by a careful structural study of the split of H at a central vertex v. An important first result is then that any bipartite graph H in $\mathcal{G}_{\text{bip}}^{*p}$ that contains a vertex v where $B_2(v)$ falls into the hard cases of the dichotomy, is itself such that $\#_p\text{BipHomsTo}H$ is $\#_p$ P-hard. Second, we study graphs H of radius larger than 2 in order to establish enough structural information of H allowing us to construct either a p-hardness gadget for H or a (B, p)-gadget such that $\#_p\text{BipHomsTo}B$ is $\#_p$ P-hard. This second step is very long and technically involved because the class of ($K_{3,3}\backslash\{e\}$, *domino*)-free graphs allows for many cases commanding us to explore the global structure of H. Before we shed more light on how we proceed towards the second step, we display the chain of reduction arguments below, where the intermediate steps for H_i refer to H itself or an induced subgraph obtained by a (H_i, p)-gadget.

$$\#_p\text{BIS}^{\kappa_\ell,\kappa_r}_{\lambda_\ell,\lambda_r} \leq_P \#_p\text{BipHomsTo}H_k \leq_P \cdots \leq_P \#_p\text{BipHomsTo}H_1 \leq_P \#_p\text{BipHomsTo}H$$

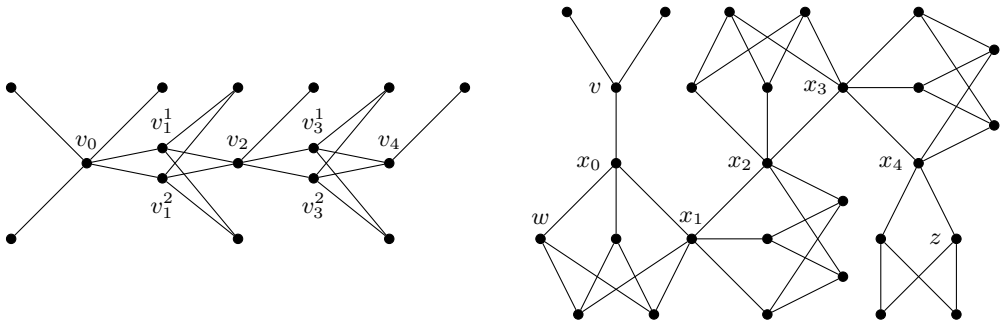

Figure 4 For $p = 3$ the left figure depicts an example of a generalized hardness path and the right figure depicts an example of a p-mosaic path.

Informally, we split the study of bipartite $(K_{3,3}\backslash\{e\}, \textit{domino})$-free graphs of radius larger than 2 into two broad cases: graphs with no pair of vertices that have a multiple of p common neighbours, and graphs with such a pair of vertices. Focusing on the first case, if the graph H contains a cycle of length at least 6 we argue that the cycle provides enough structure to show hardness. Otherwise, the more restricted structure of H renders the graph "tree-like". The "leafs" of H are vertices v, such that the split of $B_2(v)$ at v contains at most one component adjacent to a vertex not in $B_2(v)$. We call such a vertex a *dead end* and traverse the graph H along a path P starting at a dead end v. The path P is constructed such that it allows us to establish hardness depending only on the local properties of its endvertices, we call such a path P a *generalized hardness path*; an example is depicted in Figure 4. The first broad case is then established by showing that H contains a generalized hardness path whose endvertices are such that P yields hardness.

Turning towards the second broad case, we traverse the graph H again along a path P. Contrary to the first case, we can encounter a pair of vertices with a multiple of p common neighbours. For our purposes, it is important to evade such pairs of vertices. We argue that by the property of H being in $\mathcal{G}_{\text{bip}}^{*p}$ we are always able to do so. This leads to a structure we call *p-mosaic path* that, similar to a generalized hardness path, provides enough structural information towards establishing hardness depending only on the local properties of its endvertices. An example is shown in Figure 4. We find that if a p-mosaic path is a cycle then this cycle satisfies the same properties we found to be sufficient to yield hardness in the first broad case. Interestingly, we show that if the p-mosaic path does not yield hardness the only remaining option for an endvertex of a p-mosaic path is to also be the endvertex of a generalized hardness path. We conclude that H has to contain a concatenation of generalized hardness paths and p-mosaic paths. Arguing by the finiteness of H we show that this concatenation has to yield hardness.

1.2.4 Beyond $(K_{3,3}\backslash\{e\}, \textit{domino})$-Free Graphs

In light of our findings we conjecture that for a bipartite graph H in $\mathcal{G}_{\text{bip}}^{*p}$ the problem $\#_p\textsc{BipHomsTo}H$ is $\#_p\,\mathsf{P}$-hard if H is not a collection of complete bipartite graphs. This conjecture then extends towards a conjecture on $\#_p\textsc{HomsTo}H$ and also incorporates the conjecture of Faben and Jerrum.

▶ **Conjecture 1.6.** *Let p be a prime and H a graph with order p reduced form H^{*p}. Then, $\#_p\textsc{HomsTo}H$ is solvable in polynomial time if the connected components of H^{*p} are complete bipartite or reflexive complete. Otherwise, $\#_p\textsc{HomsTo}H$ is $\#_p\,\mathsf{P}$-complete.*

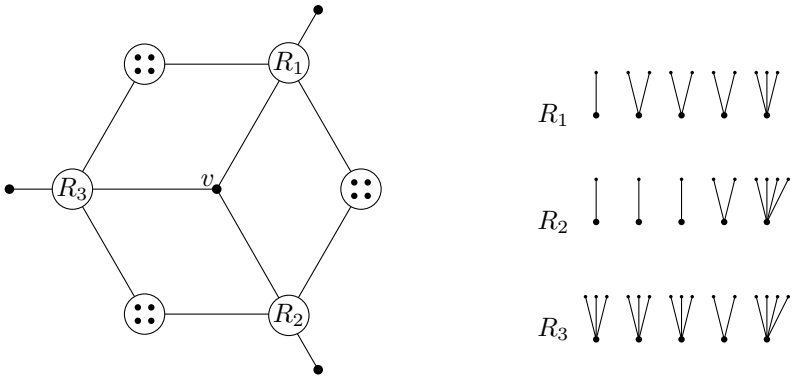

Figure 5 Illustration of a 5-Catherine wheel. Edges to encircled sets illustrate edges to every vertex in the set. The smaller substructure in the sets $R_1, \ldots, R_5$ is illustrated to the right, where the vertices in the sets R_i are the more prominent ones at the bottom of the row.

We emphasize this conjecture by a study of the set of *partially surjective homomorphisms* from a graph G to a graph H denoted $\mathrm{PartSurj}(G \to H)$. Partially surjective homomorphisms have to be surjective on a set of distinguished vertices $V^{\mathrm{dist}} \subseteq V(H)$ and a set of distinguished edges $E^{\mathrm{dist}} \subseteq E(H)$. We deduce that it suffices to study graphs H without automorphisms of order p acting bijectively on V^{dist} and E^{dist}. However, this reduction does not capture all cancellations because the graph H might still admit too many general automorphisms.

By our results on quantum graphs and an application of the inclusion-exclusion principle we find that the dichotomy presented in Conjecture 1.6 extends to a dichotomy on the whole class of partially surjective homomorphisms. Contrary to the non-modular version established in [12], this dichotomy does not state a clear structural characterisation of the hard instances due to the mentioned possibility of additional cancellations. For the special cases in which the parameter graph H is order p reduced we amplify the dichotomy such that it states clear structural characterisations. Two examples for this case are the problems $\#_p\textsc{VertSurjHomsTo}H$ and $\#_p\textsc{CompTo}H$ of counting in $\mathbb{Z}_p$ the number of vertex surjective homomorphisms and compactions, respectively. We obtain the following criteria analogous to the criteria in the non-modular setting given by Focke et al. [24].

▶ **Corollary 1.7.** *Let p be a prime and H be a graph. The problem $\#_p\textsc{VertSurjHomsTo}H$ is solvable in polynomial time if either H admits an automorphism of order p, or every connected component of H is a complete bipartite graph or a reflexive complete graph.*

The problem $\#_p\textsc{CompTo}H$ is solvable in polynomial time if either H admits an automorphism of order p, or every connected component of H is an irreflexive star or a reflexive complete graph of size at most two.

Assuming Conjecture 1.6 both problems are $\#_p\,\mathsf{P}$-hard in every other case.

In order to prove Conjecture 1.6, we need to study bipartite graphs that contain $K_{3,3}\backslash\{e\}$ or *domino* as an induced subgraph. The strong restrictions on the structure of the graphs under study are a double-edged sword. On one hand, it is more plausible to find enough structure that yields hardness. On the other hand, it is more difficult to pin the structural analysis down to a handful of cases. Furthermore, the higher moduli imply even more complexity of the structural analysis. We illustrate an especially difficult example in Figure 5.

We call such a graph as illustrated in Figure 5 a *p-Catherine wheel*. Even though these graphs are 2-connected and of radius 2 their highly symmetric global structure together with the lack of small structure in the sets R_i makes it difficult to identify sources for hardness.

Here, the case displayed in Figure 5 where the sets R_i only yield a collection of trees and the sum of degrees of the vertices in the sets is $0 \pmod p$ is especially difficult. We note that such a graph cannot be part-wise order p reduced for $p = 2, 3$, which highlights the gain of complexity due to higher moduli.

1.3 Related Literature

Before we conclude the introduction, we mention related bodies of work. The study of homomorphisms under the point of view of *parameterized algorithms* has been long established (see Diaz, Serna, and Thilikos [18]) but enriched by the work of Amini, Fomin, and Saurabh [1] and by Curticapean, Dell, and Marx [13], who also introduced linear combinations of graph homomorphisms to the study and motivated subsequent works, for instance Roth and Wellnitz [41].

The study of homomorphisms from the point of view of *extremal combinatorics* incorporates important conjectures like *Sidorenko's conjecture* [43, 44], which states a universal lower bound on the number of homomorphisms from a bipartite graph and, in a weaker version, can be found in the work of Simonovits [45]. Until today the conjecture remains open but still enjoys new contributions like the recent article by Shams, Ruozzi, and Csikvári [42].

This leads to the body of work studying *approximation algorithms* including the work of Goldberg and Jerrum [30] on tree homomorphisms and the work of Galanis, Goldberg, and Jerrum [25], who showed that approximating the number of homomorphisms to a fixed graph H is #BIS-hard, a notorious complexity class in this body of work. These findings yield an interesting connection to ours in the form of the reduction from (versions of) #BIS.

The body of studies concerning different versions of homomorphism problems is vast. It contains dichotomies for the affiliated problem, where the pre-image is from a fixed class of graphs, given by Dalmau and Jonsson [14] and Grohe [32]. Turning towards versions of the problem with fixed image, Focke, Goldberg, and Zivný [24] gave a dichotomy for surjective homomorphisms and compactions, and Dyer, Goldberg, and Paterson [15] gave a dichotomy for directed homomorphisms if the target is acyclic. The line of research towards the dichotomy for the generalization of #HomsToH allowing weights by Cai, Chen, and Lu [9] incorporates works by Bulatov and Grohe [7] and Goldberg, Grohe, Jerrum, and Thurley [29]. Recently, Govorov, Cai, and Dyer [31] extended this research body.

The connection of homomorphisms and CSP's was already shown by Feder and Vardi [22]. Bulatov [6] showed that the problem of counting satisfying assignments to a CSP enjoys a dichotomy theorem, a result on which Dyer and Richerby [17] shed more light. Furthermore, a complete dichotomy for directed homomorphism can be found in the dichotomy on counting weighted versions of CSP's by Cai and Chen [8]. Guo, Huang, Lu, and Xia [34] gave a dichotomy for the associated modular problem.

Finally, the recent work by Cai and Govorov [10] studied the power of expression of the class of homomorphisms. By studying algebras of quantum graphs they provide a general technique and showed, for instance, that the problem of counting perfect matchings cannot be expressed by counting homomorphisms to a fixed graph H regardless of possible weights.

Minimum Stable Cut and Treewidth

Michael Lampis
Université Paris-Dauphine, PSL University, CNRS, LAMSADE, 75016, Paris, France

Abstract

A stable or locally-optimal cut of a graph is a cut whose weight cannot be increased by changing the side of a single vertex. Equivalently, a cut is stable if all vertices have the (weighted) majority of their neighbors on the other side. Finding a stable cut is a prototypical PLS-complete problem that has been studied in the context of local search and of algorithmic game theory.

In this paper we study Min Stable Cut, the problem of finding a stable cut of minimum weight, which is closely related to the Price of Anarchy of the Max Cut game. Since this problem is NP-hard, we study its complexity on graphs of low treewidth, low degree, or both. We begin by showing that the problem remains weakly NP-hard on severely restricted trees, so bounding treewidth alone cannot make it tractable. We match this hardness with a pseudo-polynomial DP algorithm solving the problem in time $(\Delta \cdot W)^{O(\mathrm{tw})} n^{O(1)}$, where tw is the treewidth, Δ the maximum degree, and W the maximum weight. On the other hand, bounding Δ is also not enough, as the problem is NP-hard for unweighted graphs of bounded degree. We therefore parameterize Min Stable Cut by both tw and Δ and obtain an FPT algorithm running in time $2^{O(\Delta \mathrm{tw})}(n + \log W)^{O(1)}$. Our main result for the weighted problem is to provide a reduction showing that both aforementioned algorithms are essentially optimal, even if we replace treewidth by pathwidth: if there exists an algorithm running in $(nW)^{o(\mathrm{pw})}$ or $2^{o(\Delta \mathrm{pw})}(n + \log W)^{O(1)}$, then the ETH is false. Complementing this, we show that we can, however, obtain an FPT *approximation scheme* parameterized by treewidth, if we consider almost-stable solutions, that is, solutions where no single vertex can unilaterally increase the weight of its incident cut edges by more than a factor of $(1 + \varepsilon)$.

Motivated by these mostly negative results, we consider Unweighted Min Stable Cut. Here our results already imply a much faster exact algorithm running in time $\Delta^{O(\mathrm{tw})} n^{O(1)}$. We show that this is also probably essentially optimal: an algorithm running in $n^{o(\mathrm{pw})}$ would contradict the ETH.

1 Introduction

In this paper we study problems related to *stable cuts* in graphs. A *stable* cut of an edge-weighted graph $G = (V, E)$ is a partition of V into two sets V_0, V_1 that satisfies the following property: for each $i \in \{0, 1\}$ and $v \in V_i$, the total weight of edges incident on v whose other endpoint is in V_{1-i} is at least half the total weight of all edges incident on v. In other words, a cut is stable if all vertices have the (weighted) majority of their incident edges cut.

The notion of stable cuts has been very widely studied from two different points of view. First, in the context of local search, a stable cut is a locally optimal cut: switching the side of any single vertex cannot increase the total weight of the cut. Hence, stable cuts have

been studied with the aim to further our understanding of the basic local search heuristic for Max Cut. Second, in the context of algorithmic game theory a Max Cut game has often been considered, where each vertex is an agent whose utility is the total weight of edges connecting it to the other side. In this game, a stable cut corresponds exactly to the notion of a Nash equilibrium, that is, a state where no agent has an incentive to change her choice. The complexity of producing a Nash stable or locally optimal cut of a given edge-weighted graph has been heavily studied under the name Local Max Cut. The problem is known to be PLS-complete, under various restrictions (we give detailed references below).

In this paper we focus on a different but closely related optimization problem: given an edge-weighted graph we would like to produce a stable cut *of minumum total weight*. We call this problem Min Stable Cut. In addition to being a fairly natural problem on its own, we believe that Min Stable Cut is interesting from the perspective of both local search and algorithmic game theory. In the context of local search, Min Stable Cut is the problem of bounding the performance of the local search heuristic on a particular instance. It is folklore (and easy to see) that in general there exist graphs where the smallest stable cut has size half the maximum cut (e.g. consider a C_4) and this is tight since any stable cut must cut at least half the total edge weight. However, for most graphs this bound is far from tight. Min Stable Cut therefore essentially asks to estimate the ratio between the largest and smallest stable cut for a given specific instance. Similarly, in the context of algorithmic game theory, solving Min Stable Cut is essentially equivalent to calculating the Price of Anarchy of the Max Cut game on the given instance, that is, the ratio between the smallest stable cut and the maximum cut. Since we will mostly focus on cases where Max Cut is tractable, Min Stable Cut can, therefore, be seen as the problem of computing either the approximation ratio of local search or the Price of Anarchy of the Max Cut game on a given graph.

Our results. It appears that little is currently known about the complexity of Min Stable Cut. However, since finding a (not necessarily minimum) stable cut is PLS-complete, finding the minimum such cut would be expected to be hard. Our focus is therefore to study the parameterized complexity of Min Stable Cut using structural parameters such as treewidth and the maximum degree of the input graph[1]. Our results are the following.

- First, we show that bounding only one of the two mentioned parameters is not sufficient to render the problem tractable. This is not suprising for the maximum degree Δ, where a reduction from Max Cut allows us to show the problem is NP-hard for $\Delta \leq 6$ even in the unweighted case (Theorem 4). It is, however, somewhat more disappointing that bounded treewidth also does not help, as the problem remains weakly NP-hard on trees of diameter 4 (Theorem 1) and bipartite graphs of vertex cover 2 (Theorem 3).
- These hardness results point to two directions for obtaining algorithms for Min Stable Cut: first, since the problem is "only" weakly NP-hard for bounded treewidth one could hope to obtain a pseudo-polynomial time algorithm in this case. We show that this is indeed possible and the problem is solvable in time $(\Delta \cdot W)^{O(\mathrm{tw})} n^{O(1)}$, where W is the maximum edge weight (Theorem 5). Second, one may hope to obtain an FPT algorithm when both tw and Δ are parameters. We show that this is also possible and obtain an algorithm with complexity $2^{O(\Delta \mathrm{tw})}(n + \log W)^{O(1)}$ (Theorem 6).
- These two algorithms lead to two further questions. First, can the $(\Delta \cdot W)^{O(\mathrm{tw})} n^{O(1)}$ algorithm be improved to an FPT dependence on tw, that is, to running time $f(\mathrm{tw})(nW)^{O(1)}$? And second, can the $2^{\Delta \mathrm{tw}}$ parameter dependence of the FPT algorithm be improved,

[1] We assume familiarity with the basics of parameterized complexity as given in standard textbooks [21].

for example to $2^{O(\Delta+\mathrm{tw})}$ or even $\Delta^{O(\mathrm{tw})}$? We show that the answer to both questions is negative, even if we replace treewidth with pathwidth: under the ETH there is no algorithm running in $(nW)^{o(\mathrm{pw})}$ or $2^{o(\Delta \mathrm{tw})}(n + \log W)^{O(1)}$ (Theorem 8).

- Complementing the above, we show that the problem does become FPT by treewidth alone if we allow the notion of approximation to be used in the concept of stability: there exists an algorithm which, for any $\varepsilon > 0$, runs in time $(\mathrm{tw}/\varepsilon)^{O(\mathrm{tw})}(n + \log W)^{O(1)}$ and produces a cut with the following properties: all vertices are $(1 + \epsilon)$-stable, that is, no vertex can unilaterally increase its incident cut weight by more than a factor of $(1 + \varepsilon)$; the cut has weight at most equal to that of the minimum stable cut.
- Finally, motivated by the above mostly negative results, we also consider Unweighted Min Stable Cut, the restriction of the problem where all edge weights are uniform. Our previous results give a much faster algorithm with parameter dependence $\Delta^{O(\mathrm{tw})}$, rather than $2^{\Delta \mathrm{tw}}$ (Corollary 12). However, this poses the natural question if in this case the problem finally becomes FPT by treewidth alone. Our main result in this part is to answer this question in the negative and show that, under the ETH, Unweighted Min Stable Cut cannot be solved in time $n^{o(\mathrm{pw})}$ (Theorem 13).

Taken together, our results paint a detailed picture of the complexity of Min Stable Cut parameterized by tw and Δ. All our exact algorithms (Theorems 5, 6) are obtained using standard dynamic programming on tree decompositions, the only minor complication being that for Theorem 6 we edit the decomposition to make sure that for each vertex some bag contains all of its neighborhood (this helps us verify that a cut is stable). The main technical challenge is in proving our complexity lower bounds. It is therefore perhaps somewhat surprising that the lower bounds turn out to be essentially tight, as this indicates that for Min Stable Cut and Unweighted Min Stable Cut, the straightforward DP algorithms are essentially optimal, if one wants to solve the problem exactly.

For the approximation algorithm, we rely on two rounding techniques: one is a rounding step similar to the one that gives an FPTAS for Knapsack by truncating weights so that the maximum weight is polynomially bounded. However, Min Stable Cut is more complicated than Knapsack, as an edge which is light for one of its endpoints may be heavy for the other. We therefore define a more general version of the problem, allowing us to decouple the contribution each edge makes to the stability of each endpoint. This helps us bound the largest stability-weight by a polynomial, but is still not sufficient to obtain an FPT algorithm, as the lower bound of Theorem 8 applies to polynomially bounded weights. We then go on to apply a technique introduced in [46] (see also [2, 10, 43, 44]) which allows us to obtain FPT approximation algorithms for problems which are W-hard by treewidth by applying a different notion of rounding to the dynamic program. This allows us to produce a solution that is simultaneously of optimal weight (compared to the best stable solution) and almost-stable, using essentially the same algorithm as in Theorem 5. However, it is worth noting that in general there is no obvious way to transform almost-stable solutions to stable solutions [11, 17], so our algorithm is not immediately sufficient to obtain an FPT approximation for Min Stable Cut if we insist on obtaining a cut which is exactly stable.

Related work. From the point of view of local search algorithms, there is an extensive literature on the Local Max Cut problem, which asks us to find a stable cut (of any size). The problem has long been known to be PLS-complete [42, 52]. It remains PLS-complete for graphs of maximum degree 5 [27], but becomes polynomial-time solvable for graphs of maximum degree 3 [48, 51]. The problem remains PLS-complete if weights are assigned to vertices, instead of edges, and the weight of an edge is defined simply as the product of the

weights of its endpoints [31]. Even though the problem is PLS-complete, it has long been observed that local search quickly finds a stable solution in most practical instances. One theoretical explanation for this phenomenon was given in a recent line of work which showed that Local Max Cut has quasi-polynomial time smoothed complexity [3, 12, 18, 29]. Local Max Cut is of course polynomial time solvable if all weights are polynomially bounded in n, as local improvements always increase the size of the cut.

In algorithmic game theory much work has been done on the complexity of computing Nash equilibria for the cut game and the closely related *party affiliation game*, in which players, represented by vertices, have to pick one of two parties and edge weights indicate how much two players gain if they are in the same party [6, 7, 19, 30, 35]. Note that for general graphical games finding an equilibrium is PPAD-hard on trees of constant pathwidth [25]. Because computing a stable solution is generally intractable, approximate equilibria have also been considered [11, 17]. Note that the notion of approximate equilibrium corresponds exactly to the approximation guarantee given by Theorem 11, but unlike the cited works, Theorem 11 produces a solution that is both approximately stable and as good as the optimal.

The problem we consider in this paper is more closely related to the problem of computing the *worst* (or best) Nash equilibrium, which in turn is closely linked to the notion of Price of Anarchy. For most problems in algorithmic game theory this type of question is usually NP-hard [13, 20, 26, 32, 34, 37, 53] and hard to approximate [5, 16, 22, 39, 49]. Even though these results show that finding a Nash equilibrium that maximizes an objective function is NP-hard under various restrictions (e.g. graphical games of bounded degree), to the best of our knowledge the complexity of finding the worst equilibrium of the Max Cut game (which corresponds to the Min Stable Cut problem of this paper) has not been considered.

Finally, another topic that has recently attracted attention in the literature is that of MinMax and MaxMin versions of standard optimization problems, where we search the worst solution which cannot be improved using a simple local search heuristic. The motivation behind this line of research is to provide bounds and a refined analysis of such basic heuristics. Problems that have been considered under this lens are Max Min Dominating Set [8, 24], Max Min Vertex Cover [15, 54],Max Min Separator [38], Max Min Cut [28], Min Max Knapsack [4, 33, 36], Max Min Edge Cover [45], Max Min Feedback Vertex Set [23]. Some problems in this area also arise naturally in other forms and have been extensively studied, such as Min Max Matching (also known as Edge Dominating Set [41]) and Grundy Coloring, which can be seen as a Max Min version of Coloring [1, 9].

2 Definitions – Preliminaries

We generally use standard graph-theoretic notation and consider edge-weighted graphs, that is, graphs $G = (V, E)$ supplied with a weight function $w : E \to \mathbb{N}$. For a vertex $v \in V$, The weighted degree of a vertex $v \in V$ is $d_w(v) = \sum_{uv \in E} w(uv)$. A cut of a graph is a partition of V into V_0, V_1. A cut is *stable* for vertex $v \in V_i$ if $\sum_{vu \in E \wedge u \in V_{1-i}} w(vu) \geq \frac{d_w(v)}{2}$, that is, if the total weight of edges incident on v crossing the cut is at least half the weighted degree of v. In the Min Stable Cut problem we are given an edge-weighted graph and are looking for a cut that is stable for all vertices that minimizes the sum of weights of cut edges (that is, edges with endpoints on both sides of the cut). In Unweighted Min Stable Cut we restrict the problem so that the w function returns 1 for all edges. When describing stable cuts we will sometimes say that we "assign" value 0 (or 1) to a vertex; by this we mean that we place this vertex in V_0 (or V_1 respectively).

For the definitions of treewidth, pathwidth, and the related (nice) decompositions we refer to [21]. We will use as a complexity assumption the Exponential Time Hypothesis (ETH) [40] which states that there exists a constant $c > 1$ such that 3-SAT with n variables and m clauses cannot be solved in time c^{n+m}. In fact, we will use the slightly weaker and simpler form of the ETH which states that 3-SAT cannot be solved in time $2^{o(n+m)}$.

3 Weighted Min Stable Cut

In this section we present our results on exact algorithms for (weighted) Min Stable Cut. We begin with some basic NP-hardness reductions in Section 3.1, which establish that the problem remains (weakly) NP-hard when either the treewidth or the maximum degree are bounded. These set the stage for two algorithms, given in Section 3.2, solving the problem in pseudo-polynomial time for constant treewidth; and in FPT time parameterized by $\mathrm{tw} + \Delta$. In Section 3.3 we present a more fine-grained hardness argument, based on the ETH, which shows that the dependence on tw and Δ of our two algorithms is essentially optimal.

3.1 Basic Hardness Proofs

▶ **Theorem 1.** *Min Stable Cut is weakly NP-hard on trees of diameter* 4.

Proof. We describe a reduction from Partition. Recall that in this problem we are given n positive integers $x_1, \ldots, x_n$ such that $\sum_{i=1}^{n} x_i = 2B$ and are asked if there exists $S \subseteq [n]$ such that $\sum_{i \in S} x_i = B$. We construct a star with n leaves and subdivide every edge once. For each $i \in [n]$ we select a distinct leaf of the tree and set the weight of both edges in the path from the center to this leaf to x_i. We claim that the graph has a stable cut of weight $3B$ if and only if there is a partition of $x_1, \ldots, x_n$ into two sets with the same sum.

For the first direction, suppose $S \subseteq [n]$ is such that $\sum_{i \in S} x_i = B$. For each $i \in S$ we select a degree two vertex of the tree whose incident edges have weight x_i and assign it value 1. We assign all other degree two vertices value 0 and assign to all leaves the opposite of the value of their neighbor. We give the center value 0. This partition is stable as the center has edge weight exactly B towards each side, and all degree two vertices have a leaf attached that is placed on the other side and contributes half their total incident weight. The total weight cut is $2B$ from edges incident on leaves, plus B from half the weight incident on the center.

For the converse direction, observe that in any stable solution all edges incident on leaves are cut, contributing a weight of $2B$. As a result, in a stable cut of size $3B$, the weight of cut edges incident on the center is at most B. However, this weight is also at least B, since the edge weight incident on the center is $2B$. We conclude that the neighborhood of the center must be perfectly balanced. From this we can infer a solution to the Partition instance. ◀

▶ Remark 2. Theorem 1 is tight, because Min Stable Cut is trivial on trees of diameter at most 3.

▶ **Theorem 3.** *Min Stable Cut is weakly NP-hard on bipartite graphs with vertex cover* 2.

▶ **Theorem 4.** *Unweighted Min Stable Cut is strongly NP-hard and APX-hard on bipartite graphs of maximum degree* 6.

3.2 Algorithms

▶ **Theorem 5.** *There is an algorithm which, given an instance of Min Stable Cut with n vertices, maximum weight W, and a tree decomposition of width* tw*, finds an optimal solution in time $(\Delta \cdot W)^{O(\mathrm{tw})} n^{O(1)}$.*

▶ **Theorem 6.** *There is an algorithm which, given an instance of* Min Stable Cut *with n vertices, maximum weight W, maximum degree Δ and a tree decomposition of width* tw*, finds an optimal solution in time $2^{O(\Delta \mathrm{tw})}(n + \log W)^{O(1)}$.*

Proof. We describe an algorithm which works in a way similar to the standard algorithm for Max Cut parameterized by treewidth, except that we work in a tree decomposition that is essentially a decomposition of the square of G. More precisely, before we begin, we do the following: for each $v \in V$ we add to every bag of the decomposition that contains v all the vertices of $N(v)$. It is not hard to see that we now have a decomposition of width at most $(\Delta + 1)(\mathrm{tw} + 1)$ and also that the new decomposition is still a valid tree decomposition. Crucially, we now also have the following property: for each $v \in V$ there exists at least one bag of the decomposition that contains all of $N[v]$.

The algorithm now performs dynamic programming by storing for each bag the value of the best solution for each partition of B_t. As a result, the size of the DP table is $2^{O(\Delta \mathrm{tw})}$. The only difference with the standard Max Cut algorithm (beyond the fact that we are looking for a cut of minimum weight) is that when we consider a bag that contains all of $N[v]$, for some $v \in V$, we discard all partitions which are unstable for v. Since the bag contains all of $N[v]$, this can be checked in time polynomial in n and $\log W$ (assuming weights are given in binary). ◀

3.3 Tight ETH-based Hardness

We first give a reduction from 3-Set Splitting to Min Stable Cut whose main properties are laid out in Lemma 7. This reduction gives the lower bound of Theorem 8.

▶ **Lemma 7.** *There is a polynomial-time algorithm which, given a 3-Set Splitting instance $H = (V, E)$ with n elements, produces a Min Stable Cut instance G with the following properties: (i) G is a Yes instance if and only if H is a Yes instance; (ii) if Δ is the maximum degree of G and* pw *its pathwidth, then $\Delta = O(\log n)$ and $\mathrm{pw} = O(n/\log n)$; (iii) the maximum weight of G is $W = O(2^{\Delta})$.*

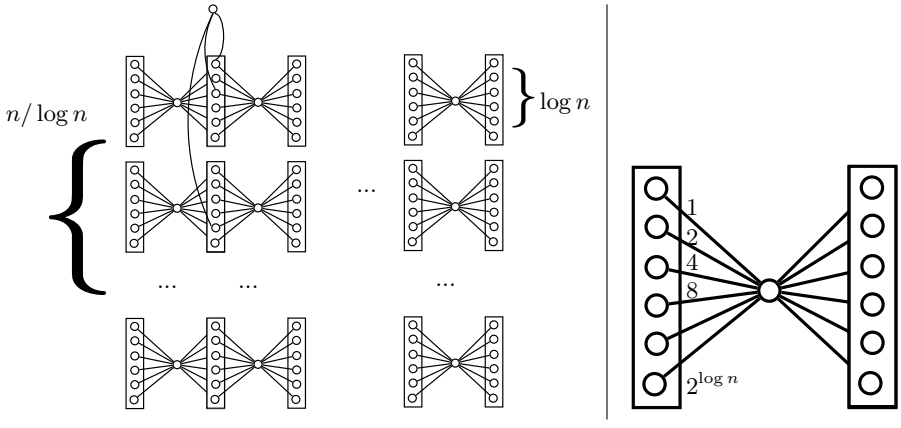

Figure 1 Sketch of the construction of Lemma 7. On the left, the general architecture: m columns, each with n vertices, partitioned into groups of size $\log n$. On each column we add a checker vertex (on top). Between the same groups of consecutive columns we add propagator vertices. On the right, more details about the exponentially increasing weights of edges incident on propagators.

Proof. Let $H = (V, E)$ be the given 3-Set Splitting instance, $V = \{v_0, \ldots, v_{n-1}\}$ and suppose that E contains e_2 sets of size 2 and e_3 sets of size 3, where $|E| = e_2 + e_3$ will be denoted by m. Assume without loss of generality that n is a power of 2 (otherwise add some dummy elements to V). Let $\delta = \log n$. We construct a graph by first making m copies of V, call them $V_j, j \in [m]$ and label their vertices as $V_j = \{v_{(i,j)} \mid i \in \{0, \ldots, n-1\}\}$. Intuitively, the vertices $\{v_{(i,j)} \mid j \in [m]\}$ are all meant to represent the element v_i of H. We now add to the graph the following:

1. Checkers: Suppose that the j-th set of E contains elements $v_{i_1}, v_{i_2}, v_{i_3}$. Then we construct a vertex c_j and connect it to $v_{(i_1,j)}, v_{(i_2,j)}, v_{(i_3,j)}$ with edges of weight 1. If the j-th set has size two, we do the same (ignoring v_{i_3}).
2. Propagators: For each $j \in [m-1]$ we construct $\rho = \lceil n/\delta \rceil$ vertices labeled $p_{(i,j)}, i \in \{0, \ldots, \rho - 1\}$. Each $p_{(i,j)}$ is connected to (at most) δ vertices of V_j and δ vertices of V_{j+1} with edges of exponentially increasing weight. Specifically, for $i \in \{0, \ldots, \rho-1\}, \ell \in \{0, \ldots, \delta - 1\}$, we connect $p_{(i,j)}$ to $v_{(i\delta+\ell,j)}$ and to $v_{(i\delta+\ell,j+1)}$ (if they exist) with an edge of weight 2^ℓ.
3. Stabilizers: For each $j \in [m], i \in \{0, \ldots, n-1\}$ we attach to $v_{(i,j)}$ a leaf. The edge connecting this leaf to $v_{(i,j)}$ has weight $3 \cdot 2^{(i \bmod \delta)}$.

This completes the construction of the graph. Let L_w be the total weight of edges incident on leaves and P be the total weight of edges incident on Propagator vertices $p_{(i,j)}$. We set $B = L_w + \frac{P}{2} + e_2 + 2e_3$ and claim that the new instance has a stable cut of weight B if and only if H can be split.

For the forward direction, suppose that H can be split by the partition of V into $L, R = V \setminus L$. We assign the following values for our new instance: for each $j \in [m]$ odd, we set $v_{(i,j)}$ to value 0 if and only if $v_i \in L$; for each $j \in [m]$ even, we set $v_{(i,j)}$ to value 0 if and only if $v_i \in R$. In other words, we use the same partition for all copies of V, but flip the roles of $0, 1$ between consecutive copies. We place leaves on the opposite side from their neighbors and greedily assign values to all other vertices of the graph to obtain a stable partition. Observe that all vertices $v_{(i,j)}$ are stable with the values we assigned, since the edge connecting each such vertex to a leaf has weight at least half its total incident weight.

In the partition we have, we observe that (i) all edges incident on leaves are cut (total weight L_w) (ii) all Propagator vertices have balanced neighborhoods, so exactly half of their incident weight is cut (total weight $P/2$) (iii) since L, R splits all sets of E, each checker vertex will have exactly one neighbor on the same side (total weight $e_2 + 2e_3$). So, the total weight of the cut is B.

For the converse direction, suppose we have a stable cut of size B in the constructed instance. Because of the stability condition, this solution must cut all edges incident on leaves (total weight L_w); at least half of the total weight of edges incident on Propagators (total weight $P/2$); and for each checker vertex all its incident edges except at most one (total weight at least $e_2 + 2e_3$). We conclude that, in order to achieve weight B, the cut must properly balance the neighborhood of all Propagators and make sure that each Checker vertex has one neighbor on its own side.

We now argue that because the neighborhood of each Propagator is balanced we have for all $i \in \{0, \ldots, n-1\}, j \in [m-1]$ that $v_{(i,j)}, v_{(i,j+1)}$ are on different sides of the partition. To see this, suppose for contradiction that for two such vertices this is not the case and to ease notation consider the vertices $v_{(i\delta+\ell,j)}, v_{(i\delta+\ell,j+1)}$, where $0 \leq \ell \leq \delta - 1$. Among all such pairs select one that maximizes ℓ. Both vertices are connected to the Propagator $p_{(i,j)}$ with edges of weight 2^ℓ. But now $p_{(i,j)}$ has strictly larger edge weight connecting it to the side of the

partition that contains $v_{(i\delta+\ell,j)}$ and $v_{(i\delta+\ell,j+1)}$ than to the other side because (i) for neighbors of $p_{(i,j)}$ connected to it with edges of higher weight, the neighborhood of $p_{(i,j)}$ is balanced by the maximality of ℓ (ii) the total weight of all other edges is $2 \cdot (2^{\ell-1} + 2^{\ell-2} + \ldots + 1) < 2 \cdot 2^{\ell}$.

We thus have that for all i, j, $v_{(i,j)}, v_{(i,j+1)}$ must be on different sides, and therefore all V_j are partitioned in the same way (except some have the roles of 0 and 1 reversed). From this, we obtain a partition of V. To conclude this direction, we argue that this partition of V must split all sets. Indeed, if not, there will be a checker vertex such that all its neighbors are on the same side, which, as we argued, means that the cut must have weight strictly more than B.

Finally, let us show that the constructed instance has the claimed properties. The maximum degree is $\Delta = 2\delta = O(\log n)$ in the Propagators vertices (all other vertices have degree at most 4); the maximum weight is $O(2^{\delta}) = O(2^{\Delta})$. Let us also consider the pathwidth of the constructed graph. Let G_j be the subgraph induced by V_j and its attached leaves, the Checker c_j, and all Propagators adjacent to V_j. We claim that we can build a path decomposition of G_j that contains all Propagators adjacent to V_j in all bags and has width $O(n/\log n)$. Indeed, if we place all the (at most $\lceil 2n/\delta \rceil$) Propagators and c_j in all bags, we can delete them from G_j, and all that is left is a union of isolated edges, which has pathwidth 1. Now, since the union of all G_j covers all vertices and edges, we can construct a path decomposition of the whole graph of width $O(n/\log n)$ by gluing together the decompositions of each G_j, that is, by connecting the last bag of the decomposition of G_j to the first bag of the decomposition of G_{j+1}. ◀

▶ **Theorem 8.** *If the ETH is true then (i) there is no algorithm solving* Min Stable Cut *in time* $(nW)^{o(\mathrm{pw})}$ *(ii) there is no algorithm solving* Min Stable Cut *in time* $2^{o(\Delta \mathrm{pw})}(n + \log W)^{O(1)}$. *These statements apply even if we restrict the input to instances where weights are written in unary and the maximum degree is* $O(\log n)$.

4 Approximately Stable Cuts

In this section we present an algorithm which runs in FPT time parameterized by treewidth and produces a solution that is $(1+\varepsilon)$-stable and has weight upper bounded by the weight of the optimal stable cut. Before we proceed, we will need to define a more general version of our problem. In Extended Min Stable Cut we are given as input: a graph $G = (V, E)$; a cut-weight function $w : E \to \mathbb{N}$; and a stability-weight function $s : E \times V \to \mathbb{N}$. For $v \in V$ we denote $d_s(v) = \sum_{vu \in E} s(vu, v)$, which we call the stability degree of v. If we are also given an error parameter $\rho > 1$, we will then be looking for a partition of V into V_0, V_1 which satisfies the following: (i) each vertex is ρ-stable, that is, for each $i \in \{0, 1\}$ and $v \in V_i$ we have $\sum_{vu \in E \wedge u \in V_{1-i}} s(vu, v) \geq \frac{d_s(v)}{2\rho}$ (ii) the total cut weight $\sum_{u \in V_0, v \in V_1, uv \in E} w(uv)$ is minimum. Observe that this extended version of the problem contains Min Stable Cut as a special case if $\rho = 1$ and for all $uv \in E$ we have $s(uv, v) = s(uv, u) = w(uv)$.

The generalization of Min Stable Cut is motivated by three considerations. First, the algorithm of Theorem 5 is inefficient because it has to store exact weight values to satisfy the stability constraints; however, it can efficiently store the total weight of the cut. We therefore decouple the contribution of an edge to the size of the cut (given by w) from a contribution of an edge to the stability of its endpoints (given by s). Second, our strategy will be to truncate the values of s so that the DP of the algorithm of Theorem 5 can be run more efficiently. To do this we will first simply divide all stability-weights by an appropriate value. However, a problem we run into if we do this is that the edge uv could simultaneously be one of the heavier edges incident on u and one of the lighter edges incident on v, so it

is not clear how we can adjust its weight in a way that minimizes the distortion for both endpoints. As a result it is simpler if we allow edges to contribute different amounts to the stability of their endpoints. In this sense, $s(uv, u)$ is the amount that the edge uv contributes to the stability of u if the edge is cut. Observe that with the new definition, if we set a new stability-weight function for a specific vertex u as $s'(uv, v) = c \cdot s(uv, v)$ for all $v \in N(u)$, that is, if we multiply the stability-weight of all edges incident on u by a constant c and leave all other values unchanged, we obtain an equivalent instance, and this does not affect the stability of other vertices. Finally, the parameter ρ allows us to consider solutions where a vertex is stable if its cut incident edges are at least a $(\frac{1}{2\rho})$-fraction of its stability degree.

Armed with this intuition we can now explain our approach to obtaining our FPT approximation algorithm. Given an instance of the extended problem, we first adjust the s function so that its maximum value is bounded by a polynomial in n. We achieve this by dividing $s(uv, u)$ by a value that depends only on $d_s(u)$ and n. This allows us to guarantee that near-stable solutions are preserved. Then, given an instance where the maximum value of s is polynomially bounded, we apply the technique of [46], using the algorithm of Theorem 5 as a base, to obtain our approximation. We give these separate steps in the Lemmas below.

▶ **Lemma 9.** *There is an algorithm which, given a graph $G = (V, E)$ on n vertices and a stability-weight function $s : E \times V \to \mathbb{N}$ with maximum value S, runs in time polynomial in $n + \log S$ and produces a stability-weight function $s' : E \times V \to \mathbb{N}$ with the following properties: (i) the maximum value of s' is $O(n^2)$ (ii) for all partitions V into V_0, V_1, $i \in \{0, 1\}$, $v \in V_i$ we have*

$$\left(\frac{\sum_{vu \in E, u \in V_{1-i}} s(vu, v)}{d_s(v)}\right) / \left(\frac{\sum_{vu \in E, u \in V_{1-i}} s'(vu, v)}{d_{s'}(v)}\right) \in [1 - 1/n, 1 + 1/n]$$

Using Lemma 9 we can assume that all stability-weights are bounded by $O(n^2)$. The most important part is that Lemma 9 guarantees us that almost-optimal solutions are preserved in both directions, as for any cut and for each vertex the ratio of stability weight going to the other side over the total stability-degree of the vertex does not change by more than a factor $(1 + \frac{1}{n})$. Let us now see the second ingredient of our algorithm.

▶ **Lemma 10.** *There is an algorithm which takes as input a graph $G = (V, E)$, a cut-weight function $w : E \to \mathbb{N}$ with maximum W, a stability-weight function $s : E \times V \to \mathbb{N}$ with maximum S, a tree decomposition of G of width* tw*, and an error parameter $\varepsilon > 0$ and returns a $(1+2\varepsilon)$-stable solution that has cut-weight at most equal to that of the minimum $(1+\epsilon)$-stable solution. If $S = O(n^2)$, then the algorithm runs in time $(\mathrm{tw}/\varepsilon)^{O(\mathrm{tw})}(n + \log W)^{O(1)}$.*

Proof. We use the methodology of [46]. Before we proceed, let us explain that we are actually aiming for an algorithm with running time roughly $(\log n/\varepsilon)^{O(\mathrm{tw})}$. This type of running time implies the time stated in the lemma using a standard Win/Win argument: if $\mathrm{tw} \leq \sqrt{\log n}$ then $(\log n)^{O(\mathrm{tw})}$ is $n^{o(1)}$, so the $(\log n)^{O(\mathrm{tw})}$ factor is absorbed in the $n^{O(1)}$ factor; while if $\log n \leq \mathrm{tw}^2$, then an algorithm running in $(\log n)^{\mathrm{tw}}$ actually runs in time $(\mathrm{tw})^{O(\mathrm{tw})}$.

To be more precise, if the given tree decomposition has height H, then we will formulate an algorithm with running time $(H \log S/\varepsilon)^{O(\mathrm{tw})}(n + \log W)^{O(1)}$. This running time achieves parameter dependence $(\log n/\varepsilon)^{O(\mathrm{tw})}$ if we use the fact that $S = O(n^2)$ and a theorem due to [14] which proves that any tree decomposition can be edited (in polynomial time) so that its height becomes $O(\log n)$, without increasing its width by more than a constant factor.

The basis of our algorithm will be the algorithm of Theorem 5, appropriately adjusted to the extended version of the problem. Let us first sketch the modifications to the algorithm of Theorem 5 that we would need to do to solve this more general problem, since the details

are straightforward. First, we observe that in solution signatures we would now take into account stability-weights, and signatures would have values going up to S. Second, in Forget nodes, since we are happy with a $(1+\varepsilon)$-stable solution, we would only discard solutions which violate this constraint. With these modifications, we can run this exact algorithm to return the minimum $(1+\varepsilon)$-stable solution in time $(2S)^{O(\mathrm{tw})}(n+\log W+\log(1/\varepsilon))^{O(1)}$.

The idea is to modify this algorithm so that the DP tables go from size $(2S)^{\mathrm{tw}}$ to roughly $(H\log S)^{\mathrm{tw}}$. To do this, we define a parameter $\delta=\frac{\varepsilon}{5H}$. We intend to replace every value x that would be stored in the signature of a solution in the DP table, with the next larger integer power of $(1+\delta)$, that is, to construct a DP table where x is replaced by $(1+\delta)^{\lceil \log_{(1+\delta)} x\rceil}$.

More precisely, the invariant we maintain is the following. Consider a node t of the decomposition at height h, where $h=0$ corresponds to leaves. We maintain a collection of solution signatures such that: (i) each signature contains a partition of B_t and for each $v\in B_t$ an integer that is upper-bounded by $\lceil \log_{(1+\delta)} d_s(v)\rceil$; (ii) Soundness: for each stored signature there exists a partition of $B_t^{\downarrow}$ which approximately corresponds to it. Specifically, the partition and the signature agree exactly on the assignment of B_t and the total cut-weight; the partition is $(1+2\varepsilon)$-stable for all vertices of $B_t^{\downarrow}\setminus B_t$; and for each $v\in B_t$, if the signature stores the value $x(v)$ for v, that is, it states that v has approximate stability-weight $(1+\delta)^{x(v)}$ towards its own side in $B_t^{\downarrow}\setminus B_t$, then in the actual partition the stability-weight of v to its own side of $B_t^{\downarrow}\setminus B_t$ is at most $(1+\delta)^h(1+\delta)^{x(v)}$. (iii) Completeness: conversely, for each partition of $B_t^{\downarrow}$ that is $(1+\varepsilon)$-stable for all vertices of $B_t^{\downarrow}\setminus B_t$ there exists a signature that approximately corresponds to it. Specifically, the partition and signature agree on the assignment of B_t and the total cut-weight; and for each $v\in B_t$, if the stability-weight of v towards its side of the partition of $B_t^{\downarrow}\setminus B_t$ is $y(v)$, and the signature stores the value $x(v)$, then $(1+\delta)^{x(v)}\le(1+\delta)^h y(v)$.

In more simple terms, the signatures in our DP table store values $x(v)$ so that we estimate that in the corresponding solution v has approximately $(1+\delta)^{x(v)}$ weight towards its own side in $B_t^{\downarrow}$, that is, we estimate that the DP of the exact algorithm would store approximately the value $(1+\delta)^{x(v)}$ for this solution. Of course, it is hard to maintain this relation exactly, so we are happy if for a node at height h the "true" value which we are approximating is at most a factor of $(1+\delta)^h$ off from our approximation.

Now, the crucial observation is that the approximate DP tables can be maintained because our invariant allows the error to increase with the height. For example, suppose that t is a Forget node at height h and let $u\in B_t$ be a neighbor of the vertex v we forget. The exact algorithm would construct the signature of a solution in t by looking at the signature of a solution in its child node, and then adding to the value stored for u the weight $s(vu,u)$ (if u,v are on the same side). Our algorithm will take an approximate signature from the child node, which may have a value at most $(1+\delta)^{h-1}$ the correct value, add to it $s(vu,u)$ and then, perhaps, round-up the value to an integer power of $(1+\delta)$. The new approximation will be at most $(1+\delta)^h$ larger than the value that the exact algorithm would have calculated. Similar argumentation holds for Join nodes. Furthermore, in Forget nodes we will only discard a solution if according to our approximation it is not $(1+2\varepsilon)$-stable. We may be over-estimating the stability-weight a vertex has to its own side of the cut by a factor of at most $(1+\delta)^h\le(1+\frac{\varepsilon}{5H})^H\le 1+\frac{\varepsilon}{2}$ so if for a signature our approximation says that the solution is not $(1+2\varepsilon)$-stable, the solution cannot be $(1+\varepsilon)$-stable, because $(1+\varepsilon)(1+\frac{\varepsilon}{2})<1+2\varepsilon$ (for sufficiently small ε).

Finally, to estimate the running time, the maximum value we have to store for each vertex in a bag is $\log_{(1+\delta)} S=\frac{\log S}{\log(1+\delta)}\le O(\frac{\log n}{\delta})=O(\frac{H\log n}{\varepsilon})$. Using the fact that $H=O(\log n)$ we get that the size of the DP table is $(\log n/\varepsilon)^{O(\mathrm{tw})}$. ◀

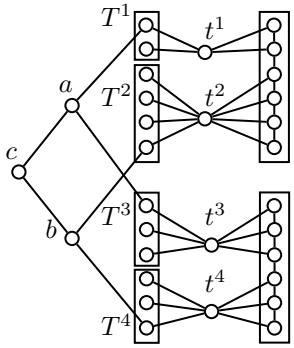

Figure 2 Checker gadget for Theorem 13. On the right two Selector gadgets. This Checker verifies that we have not taken an edge which has endpoints $(2, 3)$, hence t^1, t^3 are connected to the first 2 and 3 vertices of the Selectors.

▶ **Theorem 11.** *There is an algorithm which, given an instance of* Min Stable Cut *$G = (V, E)$ with n vertices, maximum weight W, a tree decomposition of width* tw*, and a desired error $\varepsilon > 0$, runs in time $(\mathrm{tw}/\varepsilon)^{O(\mathrm{tw})}(n + \log W)^{O(1)}$ and returns a cut with the following properties: (i) for all $v \in V$, the total weight of edges incident on v crossing the cut is at least $(1 - \varepsilon)\frac{d_w(v)}{2}$ (ii) the cut has total weight at most equal to the weight of the minimum stable cut.*

5 Unweighted Min Stable Cut

In this section we consider Unweighted Min Stable Cut. We first observe that applying Theorem 5 gives a parameter dependence of $\Delta^{O(\mathrm{tw})}$, since $W = 1$. We then show that this algorithm is essentially optimal, as the problem cannot be solved in $n^{o(\mathrm{pw})}$ under the ETH.

▶ **Corollary 12.** *There is an algorithm which, given an instance of* Unweighted Min Stable Cut *with n vertices, maximum degree Δ, and a tree decomposition of width* tw*, returns an optimal solution in time $\Delta^{O(\mathrm{tw})}n^{O(1)}$.*

We now first state our hardness result, then describe the construction of our reduction, and finally go through a series of lemmas that establish its correctness.

▶ **Theorem 13.** *If the ETH is true then no algorithm can solve* Unweighted Min Stable Cut *on graphs with n vertices in time $n^{o(\mathrm{pw})}$. Furthermore,* Unweighted Min Stable Cut *is W[1]-hard parameterized by pathwidth.*

To prove Theorem 13 we will describe a reduction from k-Multi-Colored Independent Set, a well-known W[1]-hard problem that cannot be solved in $n^{o(k)}$ time under the ETH [21]. In this problem we are given a graph $G = (V, E)$ with V partitioned into k color classes $V_1, \ldots, V_k$, each of size n, and we are asked to find an independent set of size k which selects one vertex from each V_i. In the remainder we use m to denote the number of edges of E and assume that vertices of V are labeled $v_{(i,j)}, i \in [k], j \in [n]$, where $V_i = \{v_{(i,j)} \mid j \in [n]\}$.

Before we proceed, let us give some intuition. Our reduction will rely on a $k \times m$ grid-like construction, where each row represents the selection of a vertex in the corresponding color class of G and each column represents an edge of G. The main ingredients will be a Selector gadget, which will represent a choice of an index in $[n]$; a Propagator gadget which will make sure that the choice we make in each row stays consistent throughout; and a Checker gadget which will verify that we did not select the two endpoints of any edge. Each Selector gadget

will contain a path on (roughly) n vertices such that any reasonable stable cut will have to cut exactly one edge of the path. The choice of where to cut this path will represent an index in $[n]$ encoding a vertex of G.

In our construction we will also make use of a simple but important gadget which we will call a "heavy" edge. Let $A = n^5$. When we say that we connect u, v with a heavy edge we will mean that we construct A new vertices and connect them to both u and v. The intuitive idea behind this gadget is that the large number of degree two vertices will force u and v to be on different sides of the partition (otherwise too many edges will be cut). We will also sometimes attach leaves on some vertices with the intention of making it easier for this vertex to achieve stability (as its attached leaves will always be on the other side of the partition).

Let us now describe our construction step-by-step.

1. Construct two "palette" vertices p_0, p_1 and a heavy edge connecting them. Note that all heavy edges we will add will be incident on at least one palette vertex.
2. For each $i \in [k], j \in [m]$ construct the following Selector gadget:
   a. Construct a path on $n+1$ vertices $P_{(i,j)}$ and label its vertices $P^1_{(i,j)}, \ldots, P^{n+1}_{(i,j)}$.
   b. If j is odd, then add a heavy edge from $P^1_{(i,j)}$ to p_1 and a heavy edge from $P^{n+1}_{(i,j)}$ to p_0. If j is even, then add a heavy edge from $P^1_{(i,j)}$ to p_0 and a heavy edge from $P^{n+1}_{(i,j)}$ to p_1.
   c. Attach 5 leaves to each $P^\ell_{(i,j)}$ for $\ell \in \{2, \ldots, n\}$. Attach $A+5$ leaves to $P^1_{(i,j)}$ and $P^{n+1}_{(i,j)}$.
3. For each $i \in [k], j \in [m-1]$ construct a new vertex connected to all vertices of the paths $P_{(i,j)}$ and $P_{(i,j+1)}$. This vertex is the Propagator gadget.
4. For each $j \in [m]$ consider the j-th edge of the original instance and suppose it connects $v_{(i_1,j_1)}$ to $v_{(i_2,j_2)}$. We construct the following Checker gadget (see Figure 2)
   a. We construct four vertices $t^1_j, t^2_j, t^3_j, t^4_j$. These are connected to existing vertices as follows: t^1_j is connected to $\{P^1_{(i_1,j)}, \ldots, P^{j_1}_{(i_1,j)}\}$ (that is, the first j_1 vertices of the path $P_{(i_1,j)}$); t^2_j is connected to $\{P^{j_1+1}_{(i_1,j)}, \ldots, P^{n+1}_{(i_1,j)}\}$ (that is, the remaining $n+1-j_1$ vertices of $P_{i_1,j}$); similarly, t^3_j is connected to $\{P^1_{(i_2,j)}, \ldots, P^{j_2}_{(i_2,j)}\}$; and finally t^4_j is connected to $\{P^{j_2+1}_{(i_2,j)}, \ldots, P^{n+1}_{(i_2,j)}\}$.
   b. We construct four independent sets $T^1_j, T^2_j, T^3_j, T^4_j$ with respective sizes $j_1, n+1-j_1, j_2, n+1-j_2$. We connect t^1_j to all vertices of T^1_j, t^2_j to T^2_j, t^3_j to T^3_j, and t^4_j to T^4_j. We attach two leaves to each vertex of $T^1_j \cup T^2_j \cup T^3_j \cup T^4_j$.
   c. We construct three vertices a_j, b_j, c_j. We connect c_j to both a_j and b_j. We connect a_j to an arbitrary vertex of T^1_j and an arbitrary vertex of T^3_j. We connect b_j to an arbitrary vertex of T^2_j and an arbitrary vertex of T^4_j.

Let L_1 be the number of leaves of the construction we described above and L_2 be the number of degree two vertices which are part of heavy edges. We set $B = L_1 + L_2 + km + k(m-1)(n+1) + m(2n+6)$.

▶ **Lemma 14.** *If G has a multi-colored independent set of size k, then the constructed instance has a stable cut of size at most B.*

▶ **Lemma 15.** *If the constructed instance has a stable cut of size at most B, then G has a multi-colored independent set of size k.*

▶ **Lemma 16.** *The constructed graph has pathwidth $O(k)$.*

6 Conclusions

Our results paint a clear picture of the complexity of Min Stable Cut with respect to tw and Δ. As directions for further work one could consider stronger notions of stability such as demanding that switching sets of k vertices cannot increase the cut, for constant k. We conjecture that, since the structure of this problem has the form $\exists\forall_k$, its complexity with respect to treewidth will turn out to be double-exponential in k [47]. Another direction is to consider *hedonic games* where vertices self-partition into an unbounded number of groups. The complexity of finding a stable solution in such games parameterized by $\text{tw} + \Delta$ has already been considered by Peters [50], whose algorithm runs in time exponential in $\Delta^5\text{tw}$. Can we bridge the gap between this complexity and the $2^{O(\Delta\text{tw})}$ complexity of Min Stable Cut?

Testing Triangle Freeness in the General Model in Graphs with Arboricity $O(\sqrt{n})$

Reut Levi
Efi Arazi School of Computer Science, The Interdisciplinary Center Herzliya, Israel

Abstract

We study the problem of testing triangle freeness in the general graph model. This problem was first studied in the general graph model by Alon et al. (SIAM J. Discret. Math. 2008) who provided both lower bounds and upper bounds that depend on the number of vertices and the average degree of the graph. Their bounds are tight only when $d_{\max} = O(d)$ and $\bar{d} \leq \sqrt{n}$ or when $\bar{d} = \Theta(1)$, where $d_{\max}$ denotes the maximum degree and $\bar{d}$ denotes the average degree of the graph. In this paper we provide bounds that depend on the arboricity of the graph and the average degree. As in Alon et al., the parameters of our tester is the number of vertices, n, the number of edges, m, and the proximity parameter ϵ (the arboricity of the graph is not a parameter of the algorithm). The query complexity of our tester is $\tilde{O}(\Gamma/\bar{d} + \Gamma) \cdot \text{poly}(1/\epsilon)$ on expectation, where Γ denotes the arboricity of the input graph (we use $\tilde{O}(\cdot)$ to suppress $O(\log \log n)$ factors). We show that for graphs with arboricity $O(\sqrt{n})$ this upper bound is tight in the following sense. For any $\Gamma \in [s]$ where $s = \Theta(\sqrt{n})$ there exists a family of graphs with arboricity Γ and average degree $\bar{d}$ such that $\Omega(\Gamma/\bar{d} + \Gamma)$ queries are required for testing triangle freeness on this family of graphs. Moreover, this lower bound holds for any such Γ and for a large range of feasible average degrees [1].

1 Introduction

Testing triangle-freeness is one of the most basic decision problems on graphs. The existence of triangles in a graph is often a crucial property for various applications. In the realm of property testing, decision problems are relaxed so that a tester for a property $\mathcal{P}$ is only required to distinguish between graphs that have the property $\mathcal{P}$ from graphs which are "far" according to some predetermined distance measure, from having the property $\mathcal{P}$, which in our case are graphs which are far from being triangle free.

Testing triangle freeness is known to be possible with query complexity which only depends on the proximity parameter, ϵ, in graphs which are either dense or sparse. More specifically, Alon, Fischer, Krivelevich and Szegedy [2] showed that in the dense-graphs model [8] it is possible to test triangle-freeness with query complexity which is independent

[1] For a graph, G, whose arboricity is Γ, the number of edges is at most $n \cdot \Gamma$ and at least Γ^2. Thus, the average degree of G is at least Γ^2/n and at most Γ.

of the size of the graph but has a tower-type dependence in $1/\epsilon$. In the other extreme, Goldreich and Ron [9] observed that in the bounded-degree model [9] it is possible to test triangle-freeness with query complexity $O(1/\epsilon)$ given that the maximum degree of the input graph is constant.

Alon, Kaufman, Krivelevich, Ron [3] were the first to study this problem in the general-graphs model [12, 11]. This model is more stringent in the sense that we do not assume anything on the density of the graph and the distance is measured with respect to the actual number of edges in the graph (instead of the maximum possible number of edges). They provided several upper bounds which apply for almost the entire range of average degrees. They also provided lower bounds that show that their upper bounds are at most quadratic in the optimal bounds. Shortly after, Rast [13] and Gugelmann [10] improved their upper bounds and lower bounds, respectively, for some ranges of the parameters.

Although there is a fairly significant gap between the known upper bounds and lower bounds for the vast range of parameters, there has been no progress on this question since then. In this paper we provide an upper bound and several lower bounds which are tight for a large range of parameters. Surprisingly, our bounds depend on the arboricity of the graph although it is not a parameter of our algorithm.

1.1 Results

We provide an upper bound whose running time complexity is $\tilde{O}(\Gamma/\bar{d} + \Gamma) \cdot \mathrm{poly}(1/\epsilon)$ on expectation. Therefore, for $m \leq n$ our upper bound is $\tilde{O}(\Gamma/\bar{d})$ and when $m > n$ our upper bound is $\tilde{O}(\Gamma)$ (ignoring polynomial dependencies in $1/\epsilon$).

We provide three lower bounds, each suitable for a different range of parameters.

1. For any Γ and any feasible $m \geq 1$, we provide a lower bound of $\Omega((\Gamma n)/m) = \Omega(\Gamma/\bar{d})$ queries. Therefore our upper bound is tight when $m \leq n$ (up to polynomial dependencies in $1/\epsilon$ and $O(\log \log n)$ factors).
2. For any Γ and any feasible $m \geq \Gamma^3$ we provide a lower bound of $\Omega(\Gamma)$ queries. Therefore, our upper bound is also essentially tight as long as $m \geq \Gamma^3$ (notice that since $m \leq n \cdot \Gamma$, it is implied that this lower bound applies only for graphs in which $\Gamma = O(n^{1/3})$). Since we may assume that $m \geq n$ (otherwise we already have essentially tight lower bound), one implication of this lower bound is that our upper bound is tight in the strong sense for graphs with arboricity $O(n^{1/3})$ (namely it is tight for any feasible m) as it is always the case that $m \geq \Gamma^3$ for $\Gamma = O(n^{1/3})$.
3. For any $\Gamma \leq (n/2)^{1/2}$ and any feasible $n \leq m \leq \Gamma^3$ we provide a lower bound of $\Omega(m^{1/3})$ queries. Since it is always the case that $m \geq \Gamma^2$, a lower bound of $\Omega(\Gamma^{2/3})$ queries is also implied.

To summarize, for graphs of arboricity $\Gamma = O(n^{1/2})$ we obtain that our upper bound is tight for a large range of average degrees. Additionally, for the range of average degrees in which we do not provide tight bounds, our upper bound is essentially $O(\Gamma)$ while our lower bound is $\Omega(\Gamma^{2/3})$ in the worst case.

1.2 Related Work

1.2.1 Property testing of triangle freeness

As mentioned above, testing triangle freeness, in the context of property testing, was first studied by Alon et al. [2] in the dense graphs model. They showed that triangle freeness can be tested in time which is independent of the size of the graph. However, their upper bound has tower-type dependence in $1/\epsilon$. Alon [1] showed that the query complexity of this problem in the dense-graphs model is indeed super-polynomial in $1/\epsilon$.
