[2] In the algorithm of Chatterjee and Henzinger [11] red vertices are player-2 vertices where an edge of E is missing. We change this definition slightly, i.e., without changing their algorithm or correctness argument, by saying that player-2 vertices are red if they do not have any outedges in E_i.

Algorithm 5 Determine $W_1(\text{Büchi}(B))$, given a game graph Γ [11].

```
1: procedure BüchiGamesFast(Γ = (V, E, ⟨V_1, V_2⟩), B)
2:     Let j ← 0; U ← ∅; Y_0 ← attr_1(B, Γ); S_0 ← V \ Y_0; D_0 ← attr_2(S_0, Γ); Γ^j ← Γ;
3:     j ← j + 1;
4:     while D_{j−1} ≠ ∅ do
5:         Remove the vertices in D_{j−1} from Γ^{j−1} to obtain Γ^j; and U ← U ∪ D_{j−1};
6:         i ← 1;
7:         repeat
8:             Construct Γ_i^j from Γ^j as described in Definition 18.
9:             Let Z_i^j be the vertices of V^j that are either red or blue;
10:            Y_i^j ← attr_1(B^j ∪ Z_i^j, Γ_i^j);
11:            S_j ← V^j \ Y_i^j;
12:            i ← i + 1
13:        until S_j is nonempty or i ⩾ 1 + log n
14:        if S_j ≠ ∅ then
15:            D_j ← attr_2(S_j, Γ^j)
16:        else
17:            return V \ U
18:        j ← j + 1
```

The definition of a *separating cut* further refines the definition of the winning regions for player 2 in this regard.

Separating cut. A set S of vertices induces a separating cut in a game graph Γ_i or Γ_i^j in Algorithm 5 if

1. the only edges from S to $V \setminus S$ come from player-2 vertices in S
2. every player-2 vertex in S has an edge to another vertex in S
3. every player-1 vertex in S is white and
4. $B \cap S = \emptyset$.

Thus, a separating cut S is a player-1 closed set where (i) player-1 vertices are white and which (ii) does not contain a vertex in B.

The following lemmas are needed to establish the improved running time guarantees in the next section. Detailed proofs can be found in the paper by Chatterjee and Henzinger [11].

Lemma 19 below says that the set S_j is indeed a separating cut in Γ^j (not only in Γ_i^j) and that due to the careful construction of Γ_i^j from the game graph Γ^j in iteration j, S_j does not include a vertex of the player-1 attractor of the Büchi vertices in Γ^j.

▶ **Lemma 19** ([11, Lemma 2.9]). *Let S_j be the non-empty set computed by Algorithm 5 in iteration j. Then, (1) S_j is a separating cut in Γ^j; and (2) $S_j \cap attr_1(B^j, \Gamma^j) = \emptyset$.*

Lemma 20 establishes that the separating cut found in Γ_i^j is indeed the maximum separating cut in Γ_i^j. Also, if Γ_i^j contains a separating cut, Algorithm 5 finds it.

▶ **Lemma 20** ([11, Lemma 2.11]). *Let Γ_i^j be the game graph in iteration j of the outer loop and iteration i of the inner loop. If S induces a separating cut in Γ_i^j, then $S \subseteq S_j$.*

Lemma 21 says that the set S_j is a separating cut in Γ_i^j. This does not follow from Lemma 19(1) because Γ_i^j might have less edges than Γ^j and separating cuts are not preserved if we only consider a subset of edges in Γ^j (property 2 might be violated).

▶ **Lemma 21** ([11, Lemma 2.12]). *Consider an iteration j of the outer loop of Algorithm 5 such that the algorithm stops the inner loop at value i and identifies a non-empty set S_j. Then, S_j is a separating cut in Γ_i^j.*

4.2.2 Faster Algorithm for Bounded Büchi Games

In this section, we give the refined running time analysis of Algorithm 4. We note that Γ^* gets redefined to be $(V^*, E^*, \langle V_2^*, V_1^* \rangle)$ in Algorithm 4 on Line 4. Therefore, from hereon, when we say player 1 (respectively player 2), we mean the player controlling the vertices in V_2^* (respectively, those in V_1^*).

Distinct vertices. We call a set of vertices S in Γ^* *distinct* if, for each pair of vertices $(v, \ell), (v', \ell') \in S$, we have $v \neq v'$.

Copies of a vertex. Let $\mathit{Copies}(v)$ denote the set of "copies" of a vertex $v \in V^*$, i.e., for a layer-0 vertex $(v, 0)$ we have that $\mathit{Copies}((v, 0)) = \{(v, 0)\}$ and for a vertex (v, ℓ), where $\ell > 0$, we have $\mathit{Copies}((v, \ell)) = \{(v, 1), \ldots, (v, d)\}$.

The improved running time guarantee is due to two key ideas.

Key idea 1. When *there is a* vertex (v, ℓ) in D_j then $\mathit{Copies}((v, \ell)) \subseteq D_j$, i.e., *all* its copies are in D_j.

On a very high level, the argument is that if there is a player-2 strategy to go from a vertex to S_j, then there exists a player-2 strategy from all copies of that vertex to S_j. While the idea is simple to state, a complicated machinery is needed to prove it formally. We prove the key idea in Claim 27 building on Definition 25 and Claim 26.

Now, if we follow the original running-time argument [11], then we can only claim that we remove 2^{i-1} vertices in *total* if the inner loop at Line 7 stops at iteration i, but the second key idea states something stronger.

Key idea 2. If the inner loop at Line 7 stops at iteration i^*, we remove 2^{i^*-1} *distinct* vertices.

Combining the key ideas, we remove from the game graph in iteration j all copies of those distinct vertices. The ith iteration of the loop at Lines 7–13 takes time $O(2^i nd)$ for constructing the auxiliary version of $(\Gamma^*)_i$ and performing the attractor computations. The iterations of the loop in Lines 7–13 before $i' < i$ amount to a total running time of $O(2^i nd)$. Thus, we charge the 2^{i-1} removed distinct vertices the cost of the iteration and the iterations before, i.e., each such removed orginal vertex is charged $O(nd)$. As we can remove only n distinct vertices since they correspond to the vertices in the game graph Γ, we have a total cost of $O(n^2 d)$.

For the second key idea to work, we must modify the original bounded Büchi instance (Γ, B, d) carefully. For every vertex in $v \in B$ we add a player-2 vertex v' which is not in B and an edge (v', v). Then we redirect all edges which go to v in the original instance and make them go to v' instead, i.e., for all $v \in B$ we have $V_2 \leftarrow V_2 \cup \{v'\}$ and $E \leftarrow (E \cup \{(v', v)\} \cup \{(u, v') \mid (u, v) \in E\}) \setminus \{(u, v) \in E\}$. Also, we increase d by one, as we increase the distance to all vertices in B by one. Note that this simple modification allows us to assume, without loss of generality, that all vertices in B have incoming edges from player-2 vertices only. Since we swap the player-1 vertices with player-2 vertices in Algorithm 4 we can assume that all incoming edges to a layer-0 vertex are from player-1 vertices. This adds at most n vertices and edges to Γ.

▶ **Observation 22.** *We can assume, without loss of generality, that all layer-*0 *vertices $v \in V^*$ of the auxiliary game graph Γ^* created at Line 4 in Algorithm 4 have no incoming edges from player-2 vertices, i.e., if $(v, 0) \in V^*$ then $\mathit{In}((v, 0)) \cap V_2^* = \emptyset$.*

With the above observation, we can prove the following proposition which is the crux of this section.

▶ **Proposition 23.** *Algorithm 4 runs in time $O(n^2d) = O(n^3)$.*

Proof. In this proof we denote by (Γ^*, B^*) the input of Algorithm 5 at Line 4 of Algorithm 4. The input to Algorithm 4 is (Γ, B, d). If we can show that the running time of the call to Algorithm 5 at Line 4 is in $O(n^2d) = O(n^3)$ we are done, as the rest of the operations of Algorithm 4 are in $O(md)$. This entails constructing (Γ^*, B^*) and going through W. We therefore prove the following lemma.

▶ **Lemma 24.** *The total time Algorithm 4 spends in Algorithm 5 is $O(n^2d) = O(n^3)$.*

Every vertex v in Γ^* has only $O(n)$ out-edges by the definition of the auxiliary game graph. Thus, when we consider the graphs $(\Gamma^*)_i$ of Definition 18 for $1 \leqslant i \leqslant \log n$, we have $(\Gamma^*)_{\log n} = \Gamma^*$. The construction of $(\Gamma^*)_i$ $(1 \leqslant i \leqslant \log n)$ takes time $O(nd \cdot 2^i)$.

We split the running time argument into two parts. In the first part, we bound the running time of all except the last iteration of the while loop at Line 4. In the second part of the analysis, we bound the running time of the last iteration of the same loop.

Running time bound for all iterations of the while loop except the last. Consider iteration j, and assume that Algorithm 5 stops the repeat-until loop at Line 13 with value i^* and it is not the last iteration of the while loop at Line 4. Thus, S_j is not empty. By Lemma 21, the set S_j is a separating cut in $(\Gamma^*)^j_{i^*}$. We make a detour to set up some claims.

We need the following definition because it helps us translate plays and strategies from a vertex to its copies.

▶ **Definition 25.** *If Γ^*_s is an induced subgraph of Γ^* such that for all (u, ℓ_s) in Γ^*_s we have that Copies$((u, \ell_s))$ are also in Γ^*_s, then we say that Γ^*_s has the* induced-symmetry *property or that it is* symmetrically induced*.*

The following claim is about the translation of a strategy from a vertex to its copy.

▷ Claim 26. Suppose Γ^*_s is symmetrically induced. Then, in Γ^*_s, if a player has a strategy to reach a copy of w from a copy of u, then from all copies of u, she has a strategy to reach some copy of w. More formally, in Γ^*_s, if player ρ has a strategy π to reach (w, ℓ_d) from (u, ℓ_s), then for all copies (u, ℓ'_s), she also has a strategy π' to reach (w, ℓ'_d) for some ℓ'_d.

Proof. We define π'. Consider a finite feasible play $\lambda^{(u,\ell'_s)}$ that ends in a player-ρ vertex (v, j). Let $\pi(\text{Shift}(\lambda^{(u,\ell'_s)}, \ell_s)) = (y, p)$. Define $\pi'(\lambda^{(v,\ell'_s)}) = (y, \text{NxtLyr}(v, y, j))$. Now, the play $\text{Shift}(\lambda^{(u,\ell'_s)}, \ell_s)$ is feasible and the strategy π' is well defined because Γ^*_s is symmetrically induced.

We argue why player ρ can reach a copy of w using π'. Let σ' be an arbitrary strategy for the other player, i.e., player $(3 - \rho)$. For any finite feasible play $\lambda^{(u,\ell_s)}$ that ends in a player-$(3 - \rho)$ vertex (v, j), let $\sigma'(\text{Shift}(\lambda^{(u,\ell_s)}, \ell'_s)) = (y, p)$. Define $\sigma(\lambda^{(u,\ell_s)}) = (y, \text{NxtLyr}(v, y, j))$. Again, $\text{Shift}(\lambda^{(u,\ell_s)}, \ell'_s)$ is feasible and σ is well defined because Γ^*_s is symmetrically induced.

Now, it is straightforward to show by induction on k that the first components of $\omega((u, \ell_s), \sigma, \pi)_k$ and $\omega((u, \ell'_s), \sigma', \pi')_k$ are the same. This means that if $\omega((u, \ell_s), \sigma, \pi)_k$ reaches (w, ℓ_d), then $\omega((u, \ell'_s), \sigma', \pi')_k$ reaches (w, ℓ'_d) for some ℓ'_d. ◁

The following claim is a formal version of the first key idea.

▷ Claim 27. If a vertex (v, ℓ) is in D_j, then $\mathit{Copies}((v, \ell)) \subseteq D_j$; and, $(\Gamma^*)^j$ has induced symmetry.

Proof. We prove the claim by induction on j.

Base case, $j = 0$. If $(v, \ell) \in D_0$, then there is a player-2 strategy π_1 to reach $(w, p) \in S_0$. The set $S_0 = V \setminus \mathit{attr}_1(B^*, \Gamma^*)$ is a player-1 closed set by Observation 3: This means that there is a player-2 strategy π_2 to stay inside S_0. By construction of Γ^*, any edge from a non-layer-d vertex goes to the next layer or to layer-0. Then, since $S_0 \cap B^* = \emptyset$, that is, since S_0 does not contain any layer-d vertices, any (infinite) play that stays inside S_0 must eventually return to layer-0. Thus, player 2 can first use π_1 to reach $(w, p) \in S_0$ from (v, ℓ), then use π_2 to reach $(x, 0) \in S_0$ from (w, p); effectively, this gives a player-2 strategy to go to $(x, 0) \in S_0$ from (v, ℓ). Then, by Claim 26, player 2 has a strategy to reach a copy of $(x, 0)$ from (v, ℓ') for any ℓ' because Γ^* itself has induced symmetry. Now, $(x, 0)$ does not have any other copy, this means player 2 has a strategy to reach $(x, 0) \in S_0$ from (v, ℓ'). By induced symmetry of Γ^* again, we have that all copies of (v, ℓ), i.e., $\mathit{Copies}((v, \ell))$ are in Γ^*; moreover, by the above argument, for each of these copies, there is a player-2 strategy to reach S_0, which implies that $\mathit{Copies}((v, \ell)) \subseteq D_0$. Noting that $(\Gamma^*)^0 = \Gamma^*$ has induced symmetry finishes the base case.

Induction step, $j \geqslant 1$. By induction hypothesis, $(\Gamma^*)^{j-1}$ has induced symmetry, and if a vertex (v, ℓ) is in D_{j-1}, then $\mathit{Copies}((v, \ell)) \subseteq D_{j-1}$. This implies that deleting D_{j-1} from $(\Gamma^*)^{j-1}$ to get $(\Gamma^*)^j$ means deleting all copies of a vertex being deleted. Therefore, since $(\Gamma^*)^{j-1}$ has induced symmetry, $(\Gamma^*)^j$ also has induced symmetry.

Since S_j is a separating cut (by Lemma 19), it is a player-1 closed set. Thus, by the same argument as in the base case that uses the induced symmetry of $(\Gamma^*)^j$, if (v, ℓ) is in D_j, then $\mathit{Copies}((v, \ell)) \subseteq D_j$. This completes the induction step and the proof. ◁

The following claim is the formal proof of the second key idea.

▷ Claim 28. The set S_j contains at least 2^{i^*-1} *distinct* vertices.

Proof. The proof is similar to the proof of [11, Lemma 2.13] except that we must now argue that all of the 2^{i^*-1} vertices are distinct. Consider the set S_j in the game graph of the iteration before, i.e., we argue about S_j in $(\Gamma^*)^j_{i^*-1}$. Note that we have the following two cases.

- In the first case, S_j contains a player-1 vertex (x, ℓ) for $1 \leqslant \ell \leqslant d$ that is blue in $(\Gamma^*)^j_{i^*-1}$. Thus, (x, ℓ) has outdegree at least 2^{i^*-1} in $(\Gamma^*)^j_{i^*}$ and none of these edges go to vertices in $V^j \setminus S_j$ in $(\Gamma^*)^j_{i^*}$. Thus, S_j contains at least 2^{i^*-1} vertices. Note that vertex (x, ℓ) can only have edges to vertices which are distinct to (x, ℓ), i.e., for all $((x, \ell), (y, \ell')) \in E^*$ we have $x \neq y$ because the game graph Γ does not have self loops.
- In the second case, all player-1 vertices in S_j are white in $(\Gamma^*)^j_{i^*-1}$. Thus, their outedges in $(\Gamma^*)^j_{i^*}$ and $(\Gamma^*)^j_{i^*-1}$ are identical. We now argue, why a player-2 vertex in S_j exists: Assume for contradiction that no player-2 vertex in S_j exists. Hence, S_j is a separating cut only consisting of player-1 vertices. As S_j is a separating cut in $(\Gamma^*)^j_{i^*}$ we have $S_j \cap B = \emptyset$. Thus, S_j is also a separating cut in $(\Gamma^*)^j_{i^*-1}$. But then, by Lemma 20, the algorithm would have terminated in iteration $i^* - 1$ which is a contradiction because it terminated in iteration i^*.
  Note that repeat-until loop at Lines 7–13 would have stopped in iteration $i^* - 1$ in $(\Gamma^*)^j_{i^*-1}$ as all player-1 vertices in S_j are white.

Consider a player-2 vertex u in S_j. Note that u must have an edge $(u,v) \in (E^*)^j_i$ with $v \in S_j$ because S_j is a separating cut in $(\Gamma^*)^j_{i^*}$ (Lemma 21). Again, there are two possibilities:

- For all player-2 vertices $u \in S_j$ there exists a vertex $v \in S_j$ with $(u,v) \in (E^*)^j_{i^*-1}$. But then S_j would be a separating cut in $(\Gamma^*)^j_{i^*-1}$ as the outedges of player 1 are identical in $(\Gamma^*)^j_{i^*}$ and $(\Gamma^*)^j_{i^*-1}$. By Lemma 20, the separating cut would have been found in iteration i^*-1 of the repeat-until loop at Line 7, which is a contradiction.
- Therefore, there exists a player-2 vertex $u \in S_j$ that has an edge $(u,v) \in (E^*)^j_{i^*}$ to a vertex $v \in S_j$ but this edge is not contained in $(E^*)^j_{i^*-1}$. This can only happen if v has at least 2^{i^*-1} other inedges in $(E^*)^j_{i^*-1}$. Note that u is a player-2 vertex not in $(B^*)^j$ (because all vertices of $(B^*)^j$ belong to Y^j), and hence the edge (u,v) has priority 1 and recall that by the fixed inorder of edges priority-1 edges come before all priority-0 edges. Thus, it follows that since the edge (u,v) is not in $(\Gamma^*)^j_{i^*-1}$, all inedges of v that are in $(\Gamma^*)^j_{i^*-1}$ must have priority 1 by the fixed order of inedges, that is, all the inedges of v in $(\Gamma^*)^j_{i^*-1}$ are from non-Büchi player-2 vertices. Note that $v \in S_j$ and since S_j is a separating cut and, thus, a closed set, all player-2 vertices which are not in B^* with an edge to v are also in S_j. Since v has at least 2^{i^*-1} inedges from player-2 vertices which are not in B^*, the set S_j must contain at least 2^{i^*-1} vertices.

  Furthermore, all incoming edges are from distinct vertices: Note that v cannot be a layer 0 vertex of Γ^*, because by Observation 22 all vertices in B of the given bounded Büchi objective have no incoming edges from a player-2 vertex. Also, layer-d vertices cannot be in S_j as they are in B^* and would be in the player-1 attractor $Y^j_{i^*}$ computed at Line 10. All other vertices in Γ^* have incoming edges only from distinct vertices. Thus, all 2^{i^*-1} such vertices are distinct. ◁

Due to Claim 28, S_j contains at least 2^{i^*-1} distinct vertices, and since $S_j \subseteq D_j$, the set D_j also contains all copies of all vertices in S_j due to Claim 27. All of D_j is deleted. We resume from the detour. The time spent in all graphs $(\Gamma^*)^j_1, \ldots, (\Gamma^*)^j_{i^*}$, i.e., the time spent in the repeat-until loop at Line 7 for the graph construction and the attractor computations, sums up to $O(2^{i^*} \cdot nd)$. We charge $O(nd)$ work to each distinct vertex. This accounts for all the running time except for the last iteration of the outer loop. Since we always remove all copies of a vertex $v \in S_j$, the algorithm deletes at most n distinct vertices throughout a run of the algorithm. Thus, the total time spent over the whole algorithm other than the last iteration is $O(n^2 d)$.

The last iteration of the outer loop. In the last iteration j^* of the outer loop, when no vertex is deleted, the algorithm works on all $\log n$ game graphs, spending time $O(n \cdot 2^i)$ on game graph $(\Gamma^*)^{j^*}_i$. Since each graph $(\Gamma^*)^{j^*}_i$ has at most $nd \cdot 2^{i+1}$ edges and there are $\log n$ graphs, the total number of edges worked in the last iteration is $\sum_{i=1}^{\log n} nd \cdot 2^{i+1} = 4nd \sum_{i=1}^{\log n} 2^{i-1} = 4nd(2^{\log n} - 1) = 4nd(n-1) = O(n^2 d)$. ◀

▶ **Theorem 29.** *The set of winning vertices for the bounded Büchi objective and bounded coBüchi objectives in game graphs can be computed in time $O(n^2 d) = O(n^3)$.*

Inference Systems with Corules for Fair Subtyping and Liveness Properties of Binary Session Types

Luca Ciccone
University of Torino, Italy

Luca Padovani
University of Torino, Italy

Abstract

Many properties of communication protocols stem from the combination of *safety* and *liveness* properties. Characterizing such combined properties by means of a single inference system is difficult because of the fundamentally different techniques (coinduction and induction, respectively) usually involved in defining and proving them. In this paper we show that *Generalized Inference Systems* allow for simple and insightful characterizations of (at least some of) these combined inductive/coinductive properties for dependent session types. In particular, we illustrate the role of *corules* in characterizing weak termination (the property of protocols that can always eventually terminate), fair compliance (the property of interactions that can always be extended to reach client satisfaction) and also fair subtyping, a liveness-preserving refinement relation for session types.

1 Introduction

Session types [21, 22, 4, 23] describe communication protocols at the type level. By making sure that processes use *session channels* according to their session type, a session type system enables the modular enforcement of various desirable properties, including the absence of communication errors, protocol fidelity and in some cases deadlock freedom. These are all examples of *safety properties*, which are informally identified by the motto "nothing bad ever happens" [28]. Less frequent are (session) type systems also enforcing *liveness properties*, those identified by the motto "something good eventually happens". In a network of communicating processes, a typical example of liveness property is the fact that a protocol or a process can always eventually terminate. It is well known that characterizations and proofs of safety and liveness properties rely on fundamentally different (dual) techniques [24, 2, 3, 8]: safety properties are usually based on invariance (coinductive) arguments, whereas liveness properties are usually based on well foundedness (inductive) arguments. As a consequence, it is generally difficult to characterize and enforce complex properties that exhibit a mixture of safety and liveness by means of a single inference system (such as a session type system), in which the inference rules are interpreted either all inductively or all coinductively.

To tame such difficulty, in this work we advocate the use of *Generalized Inference Systems* (GISs) [5, 16]. A GIS allows for the definition of predicates that are a fixed point of the inference operator associated with the inference system, but not necessarily the least or the greatest one. This is made possible by *coaxioms and corules*, whose purpose is to provide an inductive definition of a space within which a coinductive definition is used. A recurring example in the literature of GISs is the predicate $\mathit{maxElem}(l, x)$, asserting that x is the maximum element of a possibly infinite list l. If we consider the inference system

$$\frac{}{\mathit{maxElem}(x :: \Lambda, x)} \qquad \frac{\mathit{maxElem}(l, y)}{\mathit{maxElem}(x :: l, \max\{x, y\})}$$

where Λ denotes the empty list and $::$ is the constructor, we can give two natural interpretations to these rules. The *inductive* one, obtained by taking the least fixed point of the inference operator, restricts the set of derivable judgments to those for which there is a *well-founded* derivation tree. In this case, the *maxElem* predicate is sound but not complete, since it does not hold for any infinite list, even those for which the maximum exists. The *coinductive* interpretation of these rules, obtained by taking the greatest fixed point of the inference operator, allows us to derive judgments by means of *non-well-founded* derivation trees. In this case, the *maxElem* predicate is complete but not sound. In particular, it becomes possible to derive any judgment $\mathit{maxElem}(l, x)$ where x is greater than the elements of the list, but is not an element of the list.

This is one situation in which the sought predicate is neither the least nor the greatest fixed point of a given inference operator, but is somewhere "in between" the two extremes. We can repair the above inference system by adding the following *coaxiom*:

$$\frac{}{\mathit{maxElem}(x :: l, x)}$$

Read naively, this coaxiom seems to assert that the first element of any list is also its maximum. In the context of a GIS, however, its effect is that of ruling out those judgments $\mathit{maxElem}(l, x)$ in which x is *not* an element of the list. In a sense, the coaxiom adds a *well-foundedness element* to the derivability of a judgment $\mathit{maxElem}(l, x)$, by requiring that x must be found in – at some finite distance from the head of – the list l.

The main contribution of this work is the realization that corules can be used to easily characterize properties of session types involving a mixture of coinduction/safety and induction/liveness. We consider three such properties: *weak termination* (the property of protocols that can always eventually terminate), *fair compliance* (the property of client/server interactions that can always be extended to reach client satisfaction) and *fair subtyping* (a liveness-preserving refinement relation for session types). We show how to provide sound and complete characterizations of these properties just by adding a few corules to the inference systems of their "unfair" counterparts, those focusing on safety but neglecting liveness. Not only the added corules shed light on the liveness(-preserving) property of interest, but we can conveniently appeal to the *bounded coinduction principle* of GISs [5] to prove the completeness of the provided characterizations, thus factoring out a significant amount of work. We also make two side contributions. First, the aforementioned characterizations are given for a family of *dependent session types* [33, 34, 32, 14] in which the length and structure of the protocol may depend in non-trivial ways on the *content* of exchanged messages. Thus, we extend previously given characterizations of fair subtyping [29, 30] to a much larger class of protocols. Second, we provide an Agda [27] formalization of all the notions and results stated in the paper. In particular, we give the first machine-checked formalization of a liveness-preserving refinement relation for (dependent) session types.

The rest of the paper is structured as follows. We quickly recall the key definitions of GISs in Section 2 and describe syntax and semantics of (dependent) session types in Section 3. We define and characterize weak termination, fair compliance and fair subtyping in Sections 4–6 and conclude in Section 7. The Agda formalization is accessible from a public repository [15].

2 Generalized Inference Systems

In this section we briefly recall the key notions of Generalized Inference Systems (GISs). In particular, we see how GISs enable the definition of predicates whose purely (co)inductive interpretation does not yield the intended meaning and we review the canonical technique to prove the completeness of a defined predicate with respect to a given specification. Further details on GISs may be found in the existing literature [5, 16].

An *inference system* [1] $\mathcal{I}$ over a *universe* $\mathcal{U}$ of *judgments* is a set of *rules*, which are pairs $\langle pr, j\rangle$ where $pr \subseteq \mathcal{U}$ is the set of *premises* of the rule and $j \in \mathcal{U}$ is the *conclusion* of the rule. A rule without premises is called *axiom*. Rules are typically presented using the syntax

$$\frac{pr}{j}$$

where the line separates the premises (above the line) from the conclusion (below the line).

▶ Remark 2.1. In many cases, and in this paper too, it is convenient to present inference systems using *meta-rules* instead of rules. A meta-rule stands for a possibly infinite set of rules, which are obtained by instantiating the *meta-variables* occurring in the meta-rule. For example, the rules for *maxElem* discussed in Section 1 are meta-rules referring to the meta-variables x, y and l. The actual rules of the discussed inference system result from all possible instantiations of such meta-variables with numbers and (possibly infinite) lists. In the rest of the paper we will not insist on this distinction and we will use "(co)rule" even when referring to meta-(co)rules. If necessary, we will use side conditions to constrain the valid instantiations of the meta-variables occurring in such meta-(co)rules. ⌟

An *interpretation* of an inference system $\mathcal{I}$ identifies a subset of $\mathcal{U}$ whose elements are called *derivable judgments*. To define the interpretation of an inference system $\mathcal{I}$, consider the *inference operator* associated with $\mathcal{I}$, which is the function $F_{\mathcal{I}} : \wp(\mathcal{U}) \to \wp(\mathcal{U})$ such that

$$F_{\mathcal{I}}(X) = \{j \in \mathcal{U} \mid \exists pr \subseteq X : \langle pr, j\rangle \in \mathcal{I}\}$$

for every $X \subseteq \mathcal{U}$. Intuitively, $F_{\mathcal{I}}(X)$ is the set of judgments that can be derived in one step from those in X by applying a rule of $\mathcal{I}$. Note that $F_{\mathcal{I}}$ is a monotone endofunction on the complete lattice $\wp(\mathcal{U})$, hence it has least and greatest fixed points.

▶ **Definition 2.2.** *The* inductive interpretation $\mathsf{Ind}[\![\mathcal{I}]\!]$ *of an inference system* $\mathcal{I}$ *is the least fixed point of* $F_{\mathcal{I}}$ *and the* coinductive interpretation $\mathsf{CoInd}[\![\mathcal{I}]\!]$ *is the greatest one.*

From a proof theoretical point of view, $\mathsf{Ind}[\![\mathcal{I}]\!]$ and $\mathsf{CoInd}[\![\mathcal{I}]\!]$ are the sets of judgments derivable with well-founded and non-well-founded proof trees, respectively.

Generalized Inference Systems enable the definition of (some) predicates for which neither the inductive interpretation nor the coinductive one give the expected meaning.

▶ **Definition 2.3** (generalized inference system)**.** *A* generalized inference system *is a pair* $\langle \mathcal{I}, \mathcal{I}_{\mathsf{co}}\rangle$ *where* $\mathcal{I}$ *and* $\mathcal{I}_{\mathsf{co}}$ *are inference systems whose elements are called* rules *and* corules*, respectively. The interpretation of a generalized inference system* $\langle \mathcal{I}, \mathcal{I}_{\mathsf{co}}\rangle$*, denoted by* $\mathsf{Gen}[\![\mathcal{I}, \mathcal{I}_{\mathsf{co}}]\!]$*, is the greatest post-fixed point of* $F_{\mathcal{I}}$ *that is included in* $\mathsf{Ind}[\![\mathcal{I} \cup \mathcal{I}_{\mathsf{co}}]\!]$*.*

From a proof theoretical point of view, a GIS $\langle \mathcal{I}, \mathcal{I}_{\mathsf{co}} \rangle$ identifies the set of judgments that are derivable with an arbitrary (not necessarily well-founded) proof tree in $\mathcal{I}$ and whose nodes (the judgments occurring in the proof tree) are all derivable with a well-founded proof tree in $\mathcal{I} \cup \mathcal{I}_{\mathsf{co}}$. Recalling *maxElem* from Section 1, the judgments referring to a "maximum" which does not belong to the list are ruled out since they cannot be derived using a well-founded proof tree in the inference system with the coaxiom.

Consider now a *specification* $\mathcal{S} \subseteq \mathcal{U}$ that contains the *valid judgments*. We can relate $\mathcal{S}$ to the interpretation of a (generalized) inference system using one of the following proof principles. The *induction principle* allows us to prove the *soundness* of an inductively defined predicate by showing that $\mathcal{S}$ is *closed* with respect to $\mathcal{I}$. That is, whenever the premises of a rule of $\mathcal{I}$ are all in $\mathcal{S}$, then the conclusion of the rule is also in $\mathcal{S}$.

▶ **Proposition 2.4.** *If* $F_{\mathcal{I}}(\mathcal{S}) \subseteq \mathcal{S}$*, then* $\mathsf{Ind}[\![\mathcal{I}]\!] \subseteq \mathcal{S}$*.*

The *coinduction principle* allows us to prove the *completeness* of a coinductively defined predicate by showing that $\mathcal{S}$ is *consistent* with respect to $\mathcal{I}$. That is, every judgment of $\mathcal{S}$ is the conclusion of a rule whose premises are also in $\mathcal{S}$.

▶ **Proposition 2.5.** *If* $\mathcal{S} \subseteq F_{\mathcal{I}}(\mathcal{S})$*, then* $\mathcal{S} \subseteq \mathsf{Coind}[\![\mathcal{I}]\!]$*.*

The *bounded coinduction principle* allows us to prove the *completeness* of a predicate defined by a generalized inference system $\langle \mathcal{I}, \mathcal{I}_{\mathsf{co}} \rangle$. In this case, one needs to show not only that $\mathcal{S}$ is consistent with respect to $\mathcal{I}$, but also that $\mathcal{S}$ is *bounded* by the inductive interpretation of the inference system $\mathcal{I} \cup \mathcal{I}_{\mathsf{co}}$. Formally:

▶ **Proposition 2.6.** *If* $\mathcal{S} \subseteq \mathsf{Ind}[\![\mathcal{I} \cup \mathcal{I}_{\mathsf{co}}]\!]$ *and* $\mathcal{S} \subseteq F_{\mathcal{I}}(\mathcal{S})$*, then* $\mathcal{S} \subseteq \mathsf{Gen}[\![\mathcal{I}, \mathcal{I}_{\mathsf{co}}]\!]$*.*

Proving the boundedness of $\mathcal{S}$ amounts to proving the completeness of $\mathcal{I} \cup \mathcal{I}_{\mathsf{co}}$ (inductively interpreted) with respect to $\mathcal{S}$. All of the GISs that we are going to discuss in Sections 4–6 are proven complete using the bounded coinduction principle.

3 Syntax and Semantics of Dependent Session Types

We assume a set $\mathbb{V}$ of *values* that can be exchanged in communications. This set may include booleans, natural numbers, strings, and so forth. Hereafter, we assume that $\mathbb{V}$ contains at least *two* elements, otherwise branching protocols cannot be described and the theoretical development that follows becomes trivial. We use x, y, z to range over the elements of $\mathbb{V}$.

We define the set $\mathbb{S}$ of *dependent session types* over $\mathbb{V}$ using coinduction, to account for the possibility that session types (and the protocols they describe) may be infinite.

▶ **Definition 3.1.** *Let* $\mathbb{S}$ *be the largest set such that* $T \in \mathbb{S}$ *implies either* $T = \mathsf{nil}$ *or* $T = ?f$ *or* $T = !f$ *where* $f \in \mathbb{V} \to \mathbb{S}$ *is a total function from* $\mathbb{V}$ *to* $\mathbb{S}$*. We use* T*,* S *and* R *to range over elements of* $\mathbb{S}$ *and* f*,* g *to range over elements of* $\mathbb{V} \to \mathbb{S}$*. We say that* $T \in \mathbb{S}$ *is a* (dependent) session type *over* $\mathbb{V}$ *and that* $f \in \mathbb{V} \to \mathbb{S}$ *is a* continuation *over* $\mathbb{V}$*.*

A session type can be of three forms. An *input session type* $?f$ describes a channel used first for receiving a message $x \in \mathbb{V}$ and then according to $f(x)$. An *output session type* $!f$ describes a channel used first for sending a message $x \in \mathbb{V}$ and then according to $f(x)$. Finally, the session type nil describes an *unusable* session channel. As we will see shortly, we use nil in combination with input and output session types to describe unexpected inputs and impossible outputs. We call the functions f *continuations* since they take as input a message (the one being exchanged on the session channel) and *compute* the session type that describes the usage of the channel after the exchange. Continuations allow us to describe

protocols whose structure *depends* on previously exchanged messages. We do not detail the concrete language in which continuations are specified, but in practice they will be a small subset of the computable functions. For example, in our Agda formalization [15, file `SessionType.agda`] continuations are well-typed Agda functions. This way, we can leverage on Agda and its library [27] for constructing dependent session types.

▶ Remark 3.2. Session types as defined in Definition 3.1 are isomorphic to the possibly infinite trees coinductively generated by the productions

$$S, T \ ::= \ \mathsf{nil} \mid ?\{x : T_x\}_{x \in \mathbb{V}} \mid !\{x : T_x\}_{x \in \mathbb{V}}$$

where we represent continuations f with their graph $\{x : f(x)\}_{x \in \mathbb{V}}$. The structure of session types we have chosen in Definition 3.1, besides suggesting an effective representation of *dependent* session types, is also aimed at streamlining as much as possible not only the syntax but also the semantics of session types. In the end, this choice allowed us to reduce the inevitable complexity bloat that we had to face when formalizing these notions and the related proofs in Agda [15]. ⌟

It is convenient to introduce some notation for presenting session types in a more readable and familiar form. Given a set $X \subseteq \mathbb{V}$ of values, we write $X.T$ for the continuation

$$(X.T)(x) \stackrel{\text{def}}{=} \begin{cases} T & \text{if } x \in X \\ \mathsf{nil} & \text{otherwise} \end{cases}$$

so that we can write session types like $!\mathbb{B}.T$ (send a boolean and continue as T) and $?\mathbb{N}.S$ (receive a natural number and continue as S). We abbreviate $\{x\}$ with x when no confusion may arise. So we write $!\mathsf{true}.T$ instead of $!\{\mathsf{true}\}.T$. We let $?\mathsf{end} \stackrel{\text{def}}{=} ?\emptyset.\mathsf{nil}$ and $!\mathsf{end} \stackrel{\text{def}}{=} !\emptyset.\mathsf{nil}$. Both $?\mathsf{end}$ and $!\mathsf{end}$ describe session channels on which no further communications may occur, although they differ slightly with respect to the session types they can be safely combined with (more on this later). We also define a partial binary operation $\sqcup$ on session types such that $\mathsf{nil} \sqcup T = T \sqcup \mathsf{nil} = T$ and that is undefined otherwise. We extend this operation pointwise to continuations, so that $(f \sqcup g)(x) = f(x) \sqcup g(x)$. It is intended that $f \sqcup g$ is undefined if so is $f(x) \sqcup g(x)$ for some $x \in \mathbb{V}$. We can now express the familiar external and internal choice of session types as the (partial) operations $+$ and $\oplus$ defined by

$$?f + ?g \stackrel{\text{def}}{=} ?(f \sqcup g) \qquad !f \oplus !g \stackrel{\text{def}}{=} !(f \sqcup g)$$

It it easy to see that $+$ and $\oplus$ are commutative and associative and respectively have $?\mathsf{end}$ and $!\mathsf{end}$ as units. We assume that they bind less tightly than the "." in continuations. Finally, we let $\mathsf{dom}(f) \stackrel{\text{def}}{=} \{x \in \mathbb{V} \mid f(x) \neq \mathsf{nil}\}$ be the *proper domain* of the continuation f, namely the set of messages for which f yields a session type other than nil.

▶ **Example 3.3.** The session types T_1 and S_1 that satisfy the equations

$$T_1 = !\mathsf{true}.!\mathbb{N}.T_1 \oplus !\mathsf{false}.?\mathsf{end} \qquad S_1 = !\mathsf{true}.!\mathbb{N}^+.S_1 \oplus !\mathsf{false}.?\mathsf{end}$$

both describe a channel used for sending a boolean. If the boolean is false, the communication stops immediately ($?\mathsf{end}$). If it is true, the channel is used for sending a natural number (a strictly positive one in S_1) and then according to T_1 or S_1 again. Notice how the structure of the protocol after the output of the boolean depends on the *value* of the boolean.

The session types T_2 and S_2 that satisfy the equations

$$T_2 = ?\mathsf{true}.!\mathbb{N}.T_2 + ?\mathsf{false}.?\mathsf{end} \qquad S_2 = ?\mathsf{true}.!\mathbb{N}^+.S_2 + ?\mathsf{false}.?\mathsf{end}$$

differ from T_1 and S_1 in that the channel they describe is used initially for *receiving* a boolean.

As a final example, the session type $T_3 = !f$ where

$$f(0) = T_3 \qquad f(n+1) = !\mathbb{B}.f(n)$$

describes an channel used for sending streams of sequences beginning with a natural number n followed by n boolean messages. ⌟

We define the operational semantics of session types by means of a *labeled transition system*. *Labels*, ranged over by α, β, γ, have either the form $?x$ (input of message x) or the form $!x$ (output of message x). Transitions $T \xrightarrow{\alpha} S$ are defined by the following axioms:

[T-INPUT] [T-OUTPUT]

$$\frac{}{?f \xrightarrow{?x} f(x)} \qquad \frac{}{!f \xrightarrow{!x} f(x)}\ x \in \mathsf{dom}(f)$$

There is a fundamental asymmetry between send and receive operations: the act of sending a message is *active* – the sender may choose the message to send – while the act of receiving a message is *passive* – the receiver cannot cherry-pick the message being received. We model this asymmetry with the side condition $x \in \mathsf{dom}(f)$ in [T-OUTPUT] and the lack thereof in [T-INPUT]: a process that uses a session channel according to $!f$ refrains from sending a message x if $x \notin \mathsf{dom}(f)$, whereas a process that uses a session channel according to $?f$ cannot decide which message x it will receive, but the session channel becomes unusable if an unexpected message arrives. These transition rules allow us to appreciate a little more the difference between !end and ?end. While both describe a session endpoint on which no further communications may occur, !end is "more robust" than ?end since it has no transitions, whereas ?end is "more fragile" than !end since it performs transitions, all of which lead to nil. For this reason, we use !end to flag successful session termination (Section 5), whereas ?end only means that the protocol has ended.

To describe *sequences* of consecutive transitions performed by a session type we use another relation $\stackrel{\varphi}{\Longrightarrow}$ where φ and ψ range over strings of labels. As usual, ε denotes the empty string and juxtaposition denotes string concatenation. The relation $\stackrel{\varphi}{\Longrightarrow}$ is the least one such that $T \stackrel{\varepsilon}{\Longrightarrow} T$ and if $T \xrightarrow{\alpha} S$ and $S \stackrel{\varphi}{\Longrightarrow} R$, then $T \stackrel{\alpha\varphi}{\Longrightarrow} R$.

4 Weak Termination

A session type is weakly terminating if it preserves the possibility of reaching !end or ?end along all of its transitions that do not lead to nil. Weak termination of T does not necessarily imply that there exists an upper bound to the length of communications that follow the protocol T, but it guarantees the absence of "infinite loops" whereby the communication is forced to continue forever.

To formalize weak termination we need the notion of *trace*, which is a finite sequence of actions performed on a session channel while preserving usability of the channel.

▶ **Definition 4.1** (traces and maximal traces). *The* traces *of* T *are defined as* $\mathtt{tr}(T) \stackrel{\text{def}}{=} \{\varphi \mid \exists S : T \stackrel{\varphi}{\Longrightarrow} S \neq \mathsf{nil}\}$. *We say that* $\varphi \in \mathtt{tr}(T)$ *is* maximal *if* $\varphi\psi \in \mathtt{tr}(T)$ *implies* $\psi = \varepsilon$.

For example, we have $\mathtt{tr}(\mathsf{nil}) = \emptyset$ and $\mathtt{tr}(!\mathsf{end}) = \mathtt{tr}(?\mathsf{end}) = \{\varepsilon\}$. Note that !end and ?end have the same traces but different transitions (hence different behaviors). A *maximal trace* is a trace that cannot be extended any further. For example ε is a maximal trace of both !end and ?end but not of $!\mathbb{B}.?\mathsf{end}$ whereas !true and !false are maximal traces of $!\mathbb{B}.?\mathsf{end}$.

$$[\text{NIL}]\ \frac{}{\mathsf{nil}\Downarrow} \qquad [\text{IN}]\ \frac{f(x)\Downarrow \ (\forall x \in \mathbb{V})}{?f\Downarrow} \qquad [\text{OUT}]\ \frac{f(x)\Downarrow \ (\forall x \in \mathbb{V})}{!f\Downarrow}$$

$$[\text{CO-IN}]\ \frac{f(x)\Downarrow}{?f\Downarrow}\ x \in \mathsf{dom}(f) \qquad [\text{CO-OUT}]\ \frac{f(x)\Downarrow}{!f\Downarrow}\ x \in \mathsf{dom}(f)$$

Figure 1 Generalized inference system $\langle \mathcal{T}, \mathcal{T}_{\mathsf{co}} \rangle$ for weak termination.

▶ **Definition 4.2** (weak termination). *We say that T is* weakly terminating *if, for every $\varphi \in \mathtt{tr}(T)$, there exists ψ such that $\varphi\psi \in \mathtt{tr}(T)$ and $\varphi\psi$ is maximal.*

▶ **Example 4.3.** All of the session types presented in Example 3.3 except T_3 are weakly terminating. The session type T_3 is not weakly terminating because no trace of T_3 can be extended to a maximal one. Note that also $S_3 \stackrel{\text{def}}{=} !\mathsf{true}.T_3 \oplus !\mathsf{false}.?\mathsf{end}$ is not weakly terminating, even though there is a path leading to $?\mathsf{end}$, because weak termination must be *preserved* along all possible transitions of the session type, whereas $S_3 \xrightarrow{!\mathsf{true}} T_3$ and T_3 is not weakly terminating. Finally, nil is trivially weakly terminating since it has no trace. ⌟

To find an inference system for weak termination observe that the set $\mathbb{W}$ of weakly terminating session types is the largest one that satifies the following two properties: (1) it must be possible to reach either $!\mathsf{end}$ or $?\mathsf{end}$ from every $T \in \mathbb{W} \setminus \{\mathsf{nil}\}$; (2) the set $\mathbb{W}$ must be closed by transitions, namely if $T \in \mathbb{W}$ and $T \xrightarrow{\alpha} S$ then $S \in \mathbb{W}$. Neither of these two properties, taken in isolation, suffices to define $\mathbb{W}$: the session type S_3 from Example 4.3 enjoys property (1) but is not weakly terminating; the set $\mathbb{S}$ is obviously the largest one with property (2), but not every session type is weakly terminating. This suggests the definition of $\mathbb{W}$ as the largest subset of $\mathbb{S}$ satisfying (2) and whose elements are *bounded* by property (1), which is precisely what corules allow us to specify.

Figure 1 shows a GIS $\langle \mathcal{T}, \mathcal{T}_{\mathsf{co}} \rangle$ for weak termination, where $\mathcal{T}$ consists of all the (singly-lined) rules whereas $\mathcal{T}_{\mathsf{co}}$ consists of all the (doubly-lined) corules (we will follow these naming and syntactic conventions also in the subsequent GISs). The axiom [NIL] indicates that nil is weakly terminating in a trivial way (it has no trace), while rules [IN] and [OUT] indicate that weak termination is closed by transitions. Note that these three rules, interpreted coinductively, are satisfied by all session types, hence $\{T \mid T\Downarrow \in \mathsf{CoInd}[\![\mathcal{T}]\!]\} = \mathbb{S}$.

▶ **Theorem 4.4.** *T is weakly terminating if and only if $T\Downarrow \in \mathsf{Gen}[\![\mathcal{T}, \mathcal{T}_{\mathsf{co}}]\!]$.*

The proof of the "if" part of Theorem 4.4 crucially relies on the corules to extend each trace of T to a maximal one. Indeed, suppose $T\Downarrow \in \mathsf{Gen}[\![\mathcal{T}, \mathcal{T}_{\mathsf{co}}]\!]$ and consider a trace $\varphi \in \mathtt{tr}(T)$. That is, $T \stackrel{\varphi}{\Longrightarrow} S$ for some $S \neq \mathsf{nil}$. Using [IN] and [OUT] we deduce $S\Downarrow \in \mathsf{Gen}[\![\mathcal{T}, \mathcal{T}_{\mathsf{co}}]\!]$ by means of a simple induction on φ. Now $S\Downarrow \in \mathsf{Gen}[\![\mathcal{T}, \mathcal{T}_{\mathsf{co}}]\!]$ implies $S\Downarrow \in \mathsf{Ind}[\![\mathcal{T} \cup \mathcal{T}_{\mathsf{co}}]\!]$ by Definition 2.3. Another induction on the (well-founded) derivation of this judgment, along with the witness messages of [CO-IN] and [CO-OUT], allows us to find ψ such that $\varphi\psi$ is a maximal trace of T.

5 Compliance

In this section we define and characterize two *compliance* relations for session types, which formalize the "successful" interaction between a client and a server connected by a session. The notion of "successful interaction" that we consider is biased towards client satisfaction, but see Remark 6.7 below for a discussion about alternative notions. To formalize compliance we need to model the evolution of a session as client and server interact. To this aim, we represent a session as a term $R \parallel T$ where R describes the behavior of the client and T that of the server. Sessions reduce according to the rule

$$\frac{}{R \parallel T \to R' \parallel S'} \text{ if } R \xrightarrow{\overline{\alpha}} R' \text{ and } T \xrightarrow{\alpha} T'$$

where $\overline{\alpha}$ is the *complementary action* of α defined by $\overline{?x} = !x$ and $\overline{!x} = ?x$. We extend $\overline{\cdot}$ to traces in the obvious way and we write $\Rightarrow$ for the reflexive, transitive closure of $\to$. We write $R \parallel T \to$ if $R \parallel T \to R' \parallel T'$ for some R' and T' and $R \parallel T \not\to$ if not $R \parallel T \to$.

The first compliance relation that we consider requires that, if the interaction in a session stops, it is because the client "is satisfied" and the server "has not failed" (recall that a session type can turn into nil only if an unexpected message is received). Formally:

▶ **Definition 5.1** (compliance). *We say that R is* compliant *with T if $R \parallel T \Rightarrow R' \parallel T' \not\to$ implies $R' = !\mathsf{end}$ and $T' \neq \mathsf{nil}$.*

This notion of compliance is an instance of *safety property* in which the invariant being preserved at any stage of the interaction is that either client and server are able to synchronize further, or the client is satisfied and the server has not failed.

The second compliance relation that we consider adds a *liveness* requirement namely that, no matter how long client and server have been interacting with each other, it is always possible to reach a configuration in which the client is satisfied and the server has not failed.

▶ **Definition 5.2** (fair compliance). *We say that R is* fair compliant *with T if $R \parallel T \Rightarrow R' \parallel T'$ implies $R' \parallel T' \Rightarrow !\mathsf{end} \parallel T''$ with $T'' \neq \mathsf{nil}$.*

It is easy to show that fair compliance implies compliance, but there exist compliant session types that are not fair compliant, as illustrated in the following example.

▶ **Example 5.3.** Recall Example 3.3 and consider the session types R_1 and R_2 such that

$$R_1 = ?\mathsf{true}.?\mathbb{N}.R_1 + ?\mathsf{false}.!\mathsf{end} \qquad R_2 = !\mathsf{true}.(?0.!\mathsf{end} + ?\mathbb{N}^+.R_2)$$

Then R_1 is fair compliant with both T_1 and S_1 and R_2 is compliant with both T_2 and S_2. Even if S_1 exhibits fewer behaviors compared to T_1 (it never sends 0 to the client), at the beginning of a new iteration it can always send false and steer the interaction along a path that leads R_1 to success. On the other hand, R_2 is fair compliant with T_2 but not with S_2. In this case, the client insists on sending true to the server in hope to receive 0, but while this is possible with the server T_2, the server S_2 only sends strictly positive numbers.

This example also shows that weak termination of both client and server is not sufficient, in general, to guarantee fair compliance. Indeed, both R_2 and S_2 are weakly terminating, but they are not fair compliant. The reason is that the sequences of actions leading to !end on the client side are not necessarily the same (complemented) traces that lead to ?end on the server side. Fair compliance takes into account the synchronizations that can actually occur between client and server. ⌟

Figure 2 presents the GIS $\langle \mathcal{C}, \mathcal{C}_{\mathsf{co}} \rangle$ for fair compliance. Rule [WIN] relates a satisfied client with a non-failed server. Rules [IN-OUT] and [OUT-IN] require that, no matter which message is exchanged between client and server, the respective continuations are still fair compliant. The side conditions $\mathsf{dom}(f) \neq \emptyset$ and $\mathsf{dom}(g) \neq \emptyset$ guarantee progress by making sure that the sender is capable of sending at least one message. As we will see, the coinductive interpretation of $\mathcal{C}$, which consists of these three rules, completely characterizes compliance (Definition 5.1). However, these rules do not ensure that the interaction between client and server can always reach a successful configuration as required by Definition 5.2. For this, the corules [CO-IN-OUT] and [CO-OUT-IN] are essential.

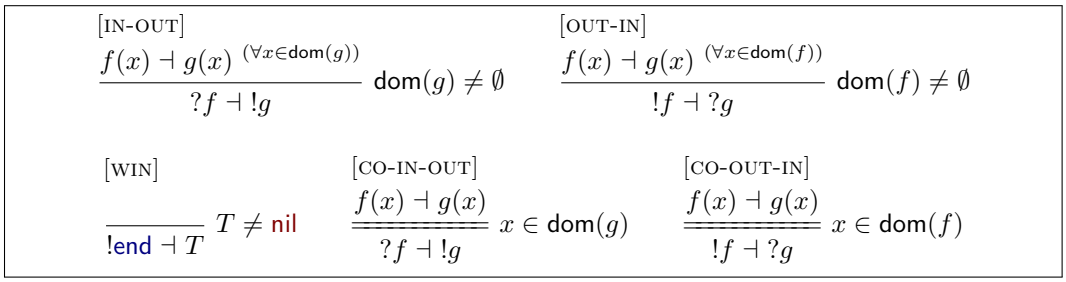

Figure 2 Generalized inference system $\langle \mathcal{C}, \mathcal{C}_{\mathsf{co}} \rangle$ for fair compliance.

▶ **Theorem 5.4** (compliance). *For every $R, T \in \mathbb{S}$, the following properties hold:*

1. *R is compliant with T if and only if $R \dashv T \in \mathsf{CoInd}[\![\mathcal{C}]\!]$;*
2. *R is fair compliant with T if and only if $R \dashv T \in \mathsf{Gen}[\![\mathcal{C}, \mathcal{C}_{\mathsf{co}}]\!]$.*

To illustrate the role of the corules, let us sketch the proof that the GIS in Figure 2 is sound with respect to fair compliance. Suppose that $R \dashv T \in \mathsf{Gen}[\![\mathcal{C}, \mathcal{C}_{\mathsf{co}}]\!]$ and consider a reduction $R \parallel T \Rightarrow R' \parallel T'$. An induction on the length of this reduction, along with [IN-OUT] and [OUT-IN], allows us to deduce $R' \dashv T' \in \mathsf{Gen}[\![\mathcal{C}, \mathcal{C}_{\mathsf{co}}]\!]$. Then we have $R' \dashv T' \in \mathsf{Ind}[\![\mathcal{C} \cup \mathcal{C}_{\mathsf{co}}]\!]$ by Definition 2.3. An induction on this (well-founded) derivation allows us to find a reduction $R' \parallel T' \Rightarrow !\mathsf{end} \parallel T''$ such that $T'' \neq \mathsf{nil}$.

Observe that the corules are at once essential and unsound. For example, without them we would be able to derive the judgment $R_2 \dashv S_2$ despite the fact that R_2 is not fair compliant with S_2 (Example 5.3). At the same time, if we treated corules as plain rules, we would be able to derive the judgment $!\mathbb{N}.!\mathsf{end} \dashv ?0.?\mathsf{end}$ despite the reduction $!\mathbb{N}.!\mathsf{end} \parallel ?0.?\mathsf{end} \to !\mathsf{end} \parallel \mathsf{nil}$ since *there exists* an interaction that leads to the successful configuration $!\mathsf{end} \parallel ?\mathsf{end}$ (if the client sends 0) but none of the others does.

6 Subtyping

The notions of compliance given in Section 5 induce corresponding semantic notions of subtyping, which embed a substitution principle for session types. The key idea is the same used for defining testing equivalences for processes [26, 20, 31], except that we use the term "client" instead of the term "test". Therefore, T is a subtype of S if any client that successfully interacts with T does so with S as well.

▶ **Definition 6.1** (subtyping). *We say that T is a* subtype *of S if R compliant with T implies R compliant with S for every R.*

▶ **Definition 6.2** (fair subtyping). *We say that T is a* fair subtype *of S if R fair compliant with T implies R fair compliant with S for every R.*

According to these definitions, when T is a (fair) subtype of S, a process that behaves according to T can be replaced by a process that behaves according to S without compromising (fair) compliance with the clients of T. At first sight this substitution principle appears to be just the opposite of the expected/intended one, whereby it is safe to use a session channel of type T where a session channel of type S is expected if T is a subtype of S. The mismatch is only apparent, however, and can be explained by looking carefully at the entities being replaced in the substitution principles recalled above (processes in one case, session channels in the other). The interested reader may refer to Gay [18] for a nice study of these two

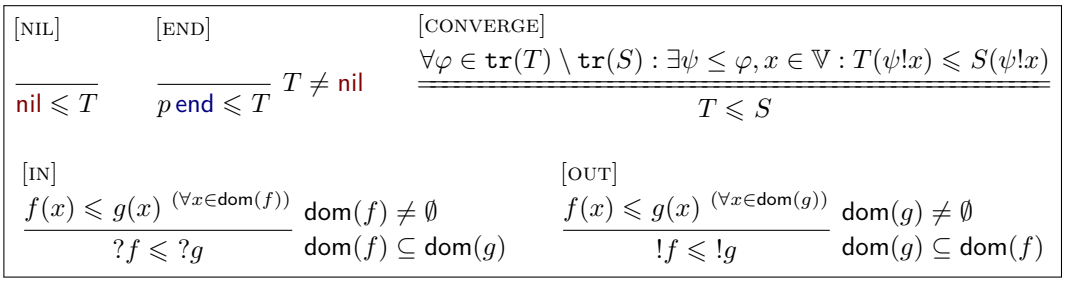

Figure 3 Generalized inference system $\langle \mathcal{F}, \mathcal{F}_{\mathsf{co}} \rangle$ for fair subtyping.

different, yet related viewpoints. What matters here is that the above notions of subtyping are "correct by definition" but do not provide any hint as to the shape of two session types T and S that are related by (fair) subtyping. This problem is well known in the semantic approaches for defining subtyping relations [17, 7] as well as in the aforementioned testing theories for processes [26, 20, 31], which the two definitions above are directly inspired from. Therefore, it is of paramount importance to provide equivalent characterizations of these relations, particularly in the form of inference systems.

The GIS $\langle \mathcal{F}, \mathcal{F}_{\mathsf{co}} \rangle$ for (fair) subtyping is shown in Figure 3 and described hereafter. Rule [NIL] states that nil is the least element of the subtyping preorder, which is justified by the fact that no client successfully interacts with nil. Rule [END] establishes that ?end and !end are the least elements among all session types different from nil. In our theory, this relation arises from the asymmetric form of compliance we have considered: a server $p\,\mathsf{end}$ satisfies only !end, which successfully interacts with any server different from nil. Rules [IN] and [OUT] indicate that inputs are covariant and outputs are contravariant. That is, it is safe to replace a server with another one that receives a superset of messages ($\mathsf{dom}(f) \subseteq \mathsf{dom}(g)$ in [IN]) and, dually, it is safe to replace a server with another one that sends a subset of messages ($\mathsf{dom}(g) \subseteq \mathsf{dom}(f)$ in [OUT]). The side condition $\mathsf{dom}(g) \neq \emptyset$ in [OUT] is important to preserve progress: if the server that behaves according to the larger session type is unable to send any message, the client may get stuck waiting for a message that is never sent. On the other hand, the side condition $\mathsf{dom}(f) \neq \emptyset$ is unnecessary from a purely technical view point, since the rule [IN] without this side condition is subsumed by [END]. We have included the side condition to minimize the overlap between different rules and for symmetry with respect to [OUT]. Overall, these rules are aligned with those of the subtyping relation for session types given by Gay and Hole [19] (see also Remark 6.7).

To discuss the corule [CONVERGE] that characterizes fair subtyping we need to introduce one last piece of notation concerning session types.

▶ **Definition 6.3** (residual of a session type). *Given a session type T and a trace φ of T we write $T(\varphi)$ for the* residual *of T after φ, namely for the session type S such that $T \stackrel{\varphi}{\Longrightarrow} S$.*

The notion of residual is well defined since session types are *deterministic*: if $T \stackrel{\varphi}{\Longrightarrow} S_1$ and $T \stackrel{\varphi}{\Longrightarrow} S_2$, then $S_1 = S_2$. It is implied that $T(\varphi)$ is undefined if $\varphi \notin \mathtt{tr}(T)$.

For the sake of presentation we describe the corule [CONVERGE] incrementally, showing how it contributes to the soundness proof of the GIS in Figure 3. In doing so, it helps bearing in mind that the relation $T \leqslant S$ is meant to preserve fair compliance (Definition 5.2), namely the possibility that any client of T can terminate successfully when interacting with S. As a first approximation observe that, when the traces of T are included in the traces of S, the corule [CONVERGE] boils down to the following coaxiom:

$$\frac{}{T \leqslant S}\ \mathtt{tr}(T) \subseteq \mathtt{tr}(S)$$

Now consider a client R that is fair compliant with T. It must be the case that $R \parallel T \Rightarrow !\mathsf{end} \parallel T'$ for some $T' \neq \mathsf{nil}$, namely that $R \stackrel{\overline{\varphi}}{\Longrightarrow} !\mathsf{end}$ and $T \stackrel{\varphi}{\Longrightarrow} T'$ for some sequence φ of actions. The side condition $\mathtt{tr}(T) \subseteq \mathtt{tr}(S)$ ensures that φ is also a trace of S, therefore $R \parallel S \Rightarrow !\mathsf{end} \parallel S'$ for the $S' \neq \mathsf{nil}$ such that $S \stackrel{\varphi}{\Longrightarrow} S'$. In general, we know from rule [OUT] that S may perform *fewer* outputs than T, hence not every trace of T is necessarily a trace of S. Writing $\leq$ for the prefix order relation on traces, the premises

$$\forall \varphi \in \mathtt{tr}(T) \setminus \mathtt{tr}(S) : \exists \psi \leq \varphi, x \in \mathbb{V} : T(\psi!x) \leqslant S(\psi!x)$$

of [CONVERGE] make sure that, for every trace φ of T that is not a trace of S, there exists a common prefix ψ of T and S and an output action $!x$ shared by both $T(\psi)$ and $S(\psi)$ such that the residuals of T and S after $\psi!x$ are *one level closer*, in the proof tree for $T \leqslant S$, to the residuals of T and S for which trace inclusion holds. The fact that ψ must be followed by an *output* $!x$ is fundamental, since the client R *must* be able to accept all the outputs of T.

Note that the corule is unsound in general. For instance, $!0.?\mathsf{end} \leqslant !\mathbb{N}.?\mathsf{end}$ is derivable by [CONVERGE] since $\mathtt{tr}(!0.?\mathsf{end}) \subseteq \mathtt{tr}(!\mathbb{N}.?\mathsf{end})$, but $!0.?\mathsf{end}$ is *not* a subtype of $!\mathbb{N}.?\mathsf{end}$.

▶ **Example 6.4.** Consider once again the session types T_i and S_i of Example 3.3. It is easy to see that $T_i \leqslant S_i \in \mathsf{CoInd}[\![\mathcal{F}]\!]$ for $i = 1, 2$. In order to derive $T_i \leqslant S_i$ in the GIS $\langle \mathcal{F}, \mathcal{F}_{\mathsf{co}} \rangle$ we must find a well-founded proof tree of $T \leqslant S$ in $\mathcal{F} \cup \mathcal{F}_{\mathsf{co}}$ and the only hope to do so is by means of [CONVERGE], since T_i and S_i share traces of arbitrary length. Observe that every trace φ of T_1 that is not a trace of S_1 has the form $(!\mathsf{true}!p_k)^k !\mathsf{true}!0 \dots$ where $p_k \in \mathbb{N}^+$. Thus, it suffices to take $\psi = \varepsilon$ and $x = 0$, noted that $T_1(!0) = S_1(!0) = ?\mathsf{end}$, to derive

$$\cfrac{\cfrac{}{?\mathsf{end} \leqslant ?\mathsf{end}}}{T_1 \leqslant S_1}$$

with two applications of [CONVERGE]. On the other hand, every trace $\varphi \in \mathtt{tr}(T_2) \setminus \mathtt{tr}(S_2)$ has the form $(?\mathsf{true}!p_k)^k ?\mathsf{true}!0 \dots$ where $p_k \in \mathbb{N}^+$. All the prefixes of such traces that are followed by an output and are shared by both T_2 and S_2 have the form $(?\mathsf{true}!p_k)^k ?\mathsf{true}$ where $p_k \in \mathbb{N}^+$, and $T_2(\psi!p) = T_2$ and $S_2(\psi!p) = S_2$ for all such prefixes and $p \in \mathbb{N}^+$. It follows that we are unable to derive $T_2 \leqslant S_2$ with a well-founded proof tree in $\mathcal{F} \cup \mathcal{F}_{\mathsf{co}}$. This is consistent with the fact that, in Example 5.3, we have found a client R_2 that is fair compliant with T_2 but not with S_2. Intuitively, R_2 insists on poking the server waiting to receive 0. This can eventually happen with T_2, but not with S_2. In the case of T_1 and S_1 no such client can exist, since the server may decide to interrupt the interaction at any time by sending a false message to the client. ⌟

Example 6.4 also shows that fair subtyping is a *context-sensitive* relation in that the applicability of a rule for deriving $T \leqslant S$ may depend on the context in which T and S occur. For instance, in the non-well-founded derivation

$$\cfrac{\cfrac{\cfrac{\vdots}{T_1 \leqslant S_1}}{!\mathbb{N}.T_1 \leqslant !\mathbb{N}^+.S_1}\,[\text{OUT}] \qquad \cfrac{}{?\mathsf{end} \leqslant ?\mathsf{end}}\,[\text{END}]}{T_1 \leqslant S_1}\,[\text{OUT}] \tag{1}$$

the rule [OUT] is used infinitely many times to relate the output session types $!\mathbb{N}.T_1$ and $!\mathbb{N}^+.S_2$. In this context, rule [OUT] can be applied harmlessly. On the contrary, if we attempt to find a derivation for $T_2 \leqslant S_2$ we obtain the non-well-founded tree

$$\dfrac{\dfrac{\dfrac{\vdots}{T_2 \leqslant S_2}}{!\mathbb{N}.T_2 \leqslant !\mathbb{N}^+.S_2}\,[\text{OUT}] \qquad \dfrac{}{?\mathsf{end} \leqslant ?\mathsf{end}}\,[\text{END}]}{T_2 \leqslant S_2}\,[\text{IN}] \tag{2}$$

which is isomorphic to the one shown in Equation (1) with the difference that some applications of [OUT] have been replaced by applications of [IN]. Here too [OUT] is used infinitely many times, but this time to relate the output session types $!\mathbb{N}.T_2$ and $!\mathbb{N}^+.S_2$. This derivation allows us to prove $T_2 \leqslant S_2 \in \mathsf{CoInd}[\![\mathcal{F}]\!]$, but not $T_2 \leqslant S_2 \in \mathsf{Gen}[\![\mathcal{F}, \mathcal{F}_{\mathsf{co}}]\!]$, because [OUT] removes the 0 output from S_2 that a client of T_2 may depend upon.

▶ Remark 6.5. As observed by one reviewer, rule [CONVERGE] is hard not only to understand, but also to formalize in Agda. We have been unable to conceive a sound and complete GIS for fair subtyping that is based on simpler corules, but it should be noted that the property enforced by [CONVERGE] is fundamentally *non-local* and therefore difficult to express in terms of immediate subtrees of a session type. To illustrate the point, consider the following alternative set of corules meant to replace [CONVERGE] in Figure 3:

$$[\text{CO-INC}]\ \dfrac{}{T \leqslant S}\ \mathtt{tr}(T) \subseteq \mathtt{tr}(S) \qquad [\text{CO-IN}]\ \dfrac{f(x) \leqslant g(x)\ {}^{(\forall x \in \mathsf{dom}(f))}}{?f \leqslant ?g} \qquad [\text{CO-OUT}]\ \dfrac{f(x) \leqslant g(x)}{!f \leqslant !g}\ x \in \mathsf{dom}(f) \cap \mathsf{dom}(g)$$

It is easy to see that these rules provide a sound approximation of [CONVERGE], but they are not complete. Indeed, consider the session types $T = ?\mathsf{true}.T + ?\mathsf{false}.(!\mathsf{true}.?\mathsf{end} \oplus !\mathsf{false}.?\mathsf{end})$ and $S = ?\mathsf{true}.S + ?\mathsf{false}.!\mathsf{true}.?\mathsf{end}$. We have $T \leqslant S$ and yet $T \leqslant_{\mathsf{Ind}} S$ cannot be proved with the above corules: it is not possible to prove $T \leqslant_{\mathsf{Ind}} S$ using [CO-INC] because $\mathtt{tr}(T) \not\subseteq \mathtt{tr}(S)$. If, on the other hand, we insist on visiting both branches of the topmost input as required by [CO-IN], we end up requiring a proof of $T \leqslant_{\mathsf{Ind}} S$ in order to derive $T \leqslant_{\mathsf{Ind}} S$. ⌟

▶ **Theorem 6.6.** *For every $T, S \in \mathbb{S}$ the following properties hold:*

1. *T is a subtype of S if and only if $T \leqslant S \in \mathsf{CoInd}[\![\mathcal{F}]\!]$;*
2. *T is a fair subtype of S if and only if $T \leqslant S \in \mathsf{Gen}[\![\mathcal{F}, \mathcal{F}_{\mathsf{co}}]\!]$.*

▶ Remark 6.7. Most session type theories adopt a symmetric form of session type compatibility whereby client and server are required to terminate the interaction at the same time. It is easy to define a notion of *symmetric compliance* (also known as *peer compliance* [7]) by turning $T' \neq \mathsf{nil}$ into $T' = ?\mathsf{end}$ in Definition 5.1. The subtyping relation induced by symmetric compliance has essentially the same characterization of Definition 6.1, except that the axiom [END] is replaced by the more familiar $p\,\mathsf{end} \leqslant q\,\mathsf{end}$ [19]. On the other hand, the analogous change in Definition 5.2 has much deeper consequences: the requirement that client and server must end the interaction at the same time creates a large family of session types that are syntactically very different, but semantically equivalent. For example, the session types T and S such that $T = ?\mathbb{N}.T$ and $S = !\mathbb{B}.S$, which describe completely unrelated protocols, would be equivalent for the simple reason that no client successfully interacts with them (they are not weakly terminating, since they do not contain any occurrence of end). We have not investigated the existence of a GIS for fair subtyping induced by symmetric fair compliance. A partial characterization (which however requires various auxiliary relations) is given by Padovani [30]. ⌟

7 Concluding Remarks

We have shown that generalized inference systems are an effective framework for defining sound and complete proof systems of (some) combined safety and liveness properties of (dependent) session types (Definitions 4.2 and 5.2), as well as of a liveness-preserving subtyping relation (Definition 6.2). We think that this achievement is more than a coincidence. One of the fundamental results in model checking states that every property can be expressed as the conjunction of a safety property and a liveness property [2, 3, 6]. The connections between safety and liveness on one side and coinduction and induction on the other make GISs appropriate for characterizing combined safety and liveness properties.

Murgia [25] studies a wide range of compliance relations for processes and session types, showing that many of them are fixed points of a functional operator, but not necessarily the least or the greatest ones. In particular, he shows that *progress compliance*, which is akin to our compliance (Definition 5.1), is a greatest fixed point and that *should-testing compliance*, which is akin to our fair compliance (Definition 5.2), is an intermediate fixed point. These results are consistent with Theorem 5.4. We have extended these results to subtyping (Definition 6.1) and fair subtyping (Definition 6.2). Previous alternative characterizations of fair subtyping and the related *should-testing preorder* either require several different relations [29, 30] or are denotational in nature [31] and therefore not as insightful as desirable. Using GISs, we have obtained complete characterizations of fair compliance and fair subtyping by simply *adding a few corules* to the proof systems of their "unfair" counterparts.

We have coded all the notions and results discussed in the paper in Agda [27], thus providing the first machine-checked formalization of liveness properties and liveness-preserving subtyping relations for dependent session types. Theorem 4.4 and item (2) of Theorems 5.4 and 6.6 are proved considering $\mathbb{V} = \mathbb{B}$ instead of an arbitrary set of values. This is because the version of the Agda library for GISs [11, 13] used for the formalization does not support (co)rules with infinitely many premises, which are necessary if $\mathbb{V}$ is infinite. However, all of the key aspects of the characterizations of weak termination, fair compliance and fair subtyping already emerge in this simplified setting. The Agda formalization is not entirely constructive since it makes use of three postulates: the *law of excluded middle*, the *extensionality axiom* and the duality between a universally quantified, inductive characterization of *convergence* (see [CONVERGE] in Figure 3) and its negation, which is characterized using an existentially quantified, coinductive definition. Note that the Agda library for GISs is a standalone development [11, 13, 12], on top of which we have built our own [15]. This makes it easy to extend our results to other families of processes or to different properties.

In this paper we have focused on properties of session types alone. The most important piece of future work that we plan to carry out next is the development of a session type system making use of fair subtyping for the enforcement of liveness properties of processes. This problem has remained open for a long time [29, 30] because the integration of fair subtyping into a coinductively-interpreted session type system is (unsurprisingly) challenging. By contrast, session type systems making use of safety-preserving subtyping relations are quite widespread [19, 9, 23, 10]. The achievements described in this paper suggest that GISs could provide just the right framework for defining such type system. Somewhat connected with this future development is also the handling of delegation and therefore of higher-order session types. Previous developments [30] have shown that delegation is orthogonal to the characterizing features of fair subtyping, since the communication of session channels does not (usually) affect the branching structure of session types (but there are a few exceptions [9, 10]). For this reason, we think that this extension can be accounted for without substantial issues.

Deterministic and Game Separability for Regular Languages of Infinite Trees

Lorenzo Clemente

Michał Skrzypczak
University of Warsaw, Poland

Abstract

We show that it is decidable whether two regular languages of infinite trees are separable by a deterministic language, resp., a game language. We consider two variants of separability, depending on whether the set of priorities of the separator is fixed, or not. In each case, we show that separability can be decided in EXPTIME, and that separating automata of exponential size suffice. We obtain our results by reducing to infinite duration games with ω-regular winning conditions and applying the finite-memory determinacy theorem of Büchi and Landweber.

1 Introduction

One of the most intriguing and motivating problems in the field of automata theory is the *membership problem*. For two fixed classes of languages $\mathcal{C}$ (*input class*) and $\mathcal{D}$ (*output class*), the $(\mathcal{C}, \mathcal{D})$-membership problem asks, given a representation of a language in $\mathcal{C}$, whether this language belongs to $\mathcal{D}$. Among the first results of this type is the famous theorem by Schutzenberger [40] and McNaughton-Papert [30], characterising, among all regular languages of finite words, the subclass of languages that can be defined in first-order logic.

In this paper we consider the class $\mathcal{C}$ of regular languages of infinite trees. While there are many semantically equivalent automata models for this class – e.g., Muller, Rabin, and Street automata [27] – *parity automata* are without doubt the most established such model [25]. The most important descriptional complexity measure of a parity automaton is the set of priorities $C \subseteq \mathbb{N}$ it is allowed to use, which is called its *index*. Not only a larger index allows the automaton to recognise more languages [32], but the computational complexity of known procedures for the emptiness problem crucially depends on the index (the current best bound is quasi-polynomial [8]). The most famous open problem in the area of regular languages of infinite trees is the *nondeterministic index membership problem*, which is the $(\mathcal{C}, \mathcal{D})$-membership problem for $\mathcal{D}$ the class of languages recognised by some nondeterministic parity automaton of a fixed index C (cf. [18]). In many cases, the solution of the membership problem relies either on algebraic representations or determinisation, however algebraic structures for regular languages of infinite trees are of limited availability (cf. [2])

and deterministic automata do not capture all regular languages. While on infinite words this problem was essentially solved by Wagner already at the end of the '70s [43], its solution for infinite trees seems still far away.

Known decidability results abound if we restrict either the input class $\mathcal{C}$ or the output class $\mathcal{D}$. Results of the first kind are known for $\mathcal{C}$ being the class of deterministic [35] and, more generally, game automata [26, Theorem 1.2]. Results of the second kind (i.e., when the input class $\mathcal{C}$ is the full class of regular languages) exist for the output class $\mathcal{D}$ being the lower levels of the index hierarchy [29, 44] and of the Borel hierarchy [4], the class of deterministic languages [33], and Boolean combinations of open sets [6]. Other variants of the index membership problem are known to be decidable, including the early result of Urbański showing that it is decidable whether a given deterministic parity tree automaton is equivalent to some nondeterministic Büchi one [42], the weak alternating index problems for the class of deterministic automata [31] and Büchi automata [17, 41], and deciding whether a given parity automaton is equivalent to some nondeterministic co-Büchi automaton [17].

Another problem closely related to membership is separability. The $(\mathcal{C}, \mathcal{D})$-*separability* problem asks, given a pair of languages L, M in $\mathcal{C}$, whether there exists a language S in $\mathcal{D}$ (called a *separator*) s.t. $L \subseteq S$ and[1] $S \perp M$. Intuitively, a separator S provides a certificate of disjointness, yielding information on the structure of L, M up to some chosen granularity. The separability problem is a generalisation of the membership problem if the class $\mathcal{C}$ is closed under complement, since we can always take M to be the complement of L, in which case the only candidate for the separator is L itself. There are many elegant results in computer science, formal logic, and mathematics showing that separators always exist. Instances include Lusin's separation theorem in topology (two disjoint analytic sets are always separable by a Borel set; cf. [28, Theorem 14.7]), a folklore result in computability theory (two disjoint co-recursively enumerable sets are separable by a recursive set), Craig's theorems in logic (jointly contradictory first-order formulas can be separated by a formula containing only symbols in the shared vocabulary [19]) and model theory (two disjoint projective classes are separable by an elementary class [19]); in formal language theory, a generalisation of a theorem suggested by Tarski and proved by Rabin [38, Theorem 29] states that two disjoint Büchi languages of infinite trees are separable by a weak language (cf. [39]).

In this work we study the $(\mathcal{C}, \mathcal{D})$-separability problems where $\mathcal{C}$ is the full class of regular languages of infinite trees, and $\mathcal{D}$ is one of four kinds of sub-classes thereof, depending on whether the automaton is deterministic or game, and depending on whether we fix a finite index $C \subseteq \mathbb{N}$ or we leave it unrestricted $C = \mathbb{N}$. Our main result is that all four kinds of the separability problems above are decidable and in EXPTIME. Moreover, we show that if a separator exists, then there is one of exponential size.

▶ **Theorem 1.** *The deterministic and game separability problems can be solved in EXPTIME, both for a fixed finite index $C \subseteq \mathbb{N}$, and an unrestricted one $C = \mathbb{N}$. Moreover, separators with exponentially many states and polynomially many priorities suffice.*

Our work is permeated by the observation that the separability problem for two languages L, M can be phrased in terms of a game of infinite duration with an ω-regular winning condition. In such a *separability game* there are two players, Separator trying to prove that L, M are separable, and Input with the opposite objective. In the simple case of $(\mathcal{C}, \mathcal{D})$-separability where $\mathcal{C}$ is the class of regular languages of ω-words and $\mathcal{D}$ the subclass induced by deterministic parity automata of finite index C, the i-th round of the game is as follows:

[1] We write $S \perp M$ for $S \cap M = \varnothing$.

- Separator plays a priority $c_i \in C$.
- Input plays a letter a_i from the finite alphabet Σ.

The resulting infinite play $(c_0, a_0)(c_1, a_1) \cdots$ is won by Separator if 1) $a_0 a_1 \cdots \in L$ implies $c_0 c_1 \cdots$ is accepting and 2) $a_0 a_1 \cdots \notin L$ implies $c_0 c_1 \cdots$ is rejecting. Since the winning condition is ω-regular, by the result of Büchi and Landweber [7] we can decide who wins the game and moreover finite-memory strategies for Separator suffice. Thanks to a correspondence between such strategies and deterministic separators, Separator wins such a game iff there exists a deterministic automaton with priorities in C separating L, M. This provides both decidability of the separability problem and an upper-bound on the size of separators. We design analogous games with ω-regular winning conditions for the more involved case of infinite trees for the separability problems mentioned above and apply [7].

The separability problems we consider have been open so far and generalise the corresponding membership problems. A solution for deterministic separability can easily be derived from [34], however our techniques based on games are novel and provide a unified view on all problems. When instantiated to the specific case of membership, our decidability results generalise the deterministic case (for both fixed and unconstrained index) [34, 33] and the game membership case for unconstrained index [26, Theorem 7.12]. We believe the game approach is much more direct than the combinatorial and pattern-based techniques used in the previous solutions, cf. [26, Section 7, pp. 29–37]. The game membership problem for a fixed index C has been open so far.

We are not aware of computation complexity results for separability problems over regular languages of infinite trees, neither of an analysis of the size of separators. Regarding deterministic membership, EXPTIME-completeness is known [34, Corollary 11], as well as EXPTIME upper [33, end of page 12] and lower bounds [44, Theorem 4.1] (cf., also [29]) for computing the optimal deterministic index. Devising non-trivial complexity lower bounds for the separability problem is left for future work, as well as extending our approach to other classes of separators.

Related works. Over finite words, variants of the $(\mathcal{C}, \mathcal{D})$-separability problem have been studied for classes $\mathcal{C}$ both more general than the regular languages, such as the context free languages [23, 45] and higher-order languages [14] (later extended to safe schemes over finite trees [1]), and for classes $\mathcal{D}$ more restrictive than the regular languages, such as in [36, 37]. The separability and membership problems have also been studied for several classes of infinite-state systems, such as vector addition systems [11, 10, 24], well-structured transition systems [22], one-counter automata [21], and timed automata [13, 12]. Recent developments on efficient algorithms solving parity games are based on the ability to find a simple separator, yielding both upper bounds on the problem, and lower bounds for a wide family of algorithms [5, 20, Chapter 3]. Finally, it is worth mentioning that games have already been successfully used to provide several characterisation results, such as in [18, 17, 16, 3, 41, 9].

Outline. In Section 2 we introduce automata and other mathematical preliminaries. In Sections 3–6 we present the game-theoretic characterisations of the separability problems we consider. We believe this is the most interesting aspect of this work. A technical report is available [15] where a detailed complexity analysis is performed and full proofs are provided.

2 Preliminaries

A nonempty finite set Σ of *letters* $a \in \Sigma$ is called an *alphabet*. A (Σ-*labelled*) *tree* is a function $t\colon \{\mathsf{L},\mathsf{R}\}^* \to \Sigma$ assigning to each *node* $u \in \{\mathsf{L},\mathsf{R}\}^*$ a *label* $t(a) \in \Sigma$. The *root* of a tree is denoted ϵ. The set of all Σ-labelled trees is denoted Tr_Σ. The symbols L, R are called *directions* and a *branch* is an infinite sequence thereof $d_0 d_1 \cdots \in \{\mathsf{L},\mathsf{R}\}^\omega$. A tree t is uniquely defined by the set of its *paths* $\mathsf{Path}(t) = \{(a_0,d_0)(a_1,d_1)\cdots \in (\Sigma\times\{\mathsf{L},\mathsf{R}\})^\omega \mid \forall i.\ a_i = t(d_0 d_1 \cdots d_{i-1})\}$, which is extended to languages pointwise as $\mathsf{Path}(L) = \{\mathsf{Path}(t) \mid t \in L\}$.

Automata. Fix a nonempty finite set of *priorities* $C \subseteq \mathbb{N}$. A *(top-down, nondeterministic, parity, tree) automaton* is a tuple $\mathcal{A} = (\Sigma, Q, q_0, \Omega, \Delta)$, where Σ is a finite alphabet, Q is a finite set of *states*, amongst which $q_0 \in Q$ is the *initial state*, $\Omega\colon Q \to C$ assigns a priority to every state, and $\Delta \subseteq Q\times\Sigma\times Q\times Q$ is a set of *transitions*. The priority function Ω is extended to a transition $\delta = (q,_,_,_)$ as $\Omega(\delta) := \Omega(q)$, pointwise to an infinite sequence of states $\Omega(q_0 q_1\cdots) := \Omega(q_0)\Omega(q_1)\cdots \in C^\omega$ and transitions $\Omega(\delta_0\delta_1\cdots) = \Omega(\delta_0)\Omega(\delta_1)\cdots \in C^\omega$. An infinite sequence of priorities $c_0 c_1 \cdots \in C^\omega$ is *accepting* if the maximal priority occurring infinitely often is even. Similarly, an infinite sequence of states $\rho = q_0 q_1 \cdots \in Q^\omega$ or of transitions $\rho = \delta_0\delta_1\cdots \in \Delta^\omega$ is accepting whenever $\Omega(\rho)$ is accepting. We write $\Delta(q,a) = \{(q,a,q_\mathsf{L},q_\mathsf{R}) \in \Delta\}$ for the set of transitions from a state $q \in Q$ over a letter $a \in \Sigma$, and $\Delta(a) = \bigcup\{\Delta(q,a) \mid q \in Q\}$ for all transitions over a. We extend the notation above to an infinite path $b = (a_0,d_0)(a_1,d_1)\cdots \in (\Sigma\times\{\mathsf{L},\mathsf{R}\})^\omega$ by writing $\Delta(b)$ for the set of infinite sequences of transitions $\vec{\delta} = \delta_0\delta_1\cdots \in \Delta^\omega$ of the form $\delta_i = (q_i, a_i, q_{\mathsf{L},i}, q_{\mathsf{R},i})$ for every i, which are *conform to* b in the sense that q_0 is the initial state of the automaton and $q_{i+1} = q_{d_i,i}$.

A *run* of an automaton $\mathcal{A}$ as above over a tree $t \in \mathrm{Tr}_\Sigma$ is a Q-labelled tree $\rho \in \mathrm{Tr}_Q$ s.t. $\rho(\epsilon) = q_0$ is the initial state and for every node in the tree $u \in \{\mathsf{L},\mathsf{R}\}^*$ the quadruple $\big(\rho(u), t(u), \rho(u\mathsf{L}), \rho(u\mathsf{R})\big)$ belongs to Δ. Such a run is *accepting* if for every branch $d_0 d_1 \cdots \in \{\mathsf{L},\mathsf{R}\}^\omega$ the sequence of states $\big(\rho(d_0\cdots d_{i-1})\big)_{i\in\omega}$ is accepting. The set of all trees $t \in \mathrm{Tr}_\Sigma$ s.t. $\mathcal{A}$ has an accepting run over t is denoted $\mathrm{L}(\mathcal{A})$ and is called the *language* recognised by $\mathcal{A}$. The corresponding *path language* is $\mathrm{L}^{\mathsf{path}}(\mathcal{A}) := \mathsf{Path}(\mathrm{L}(\mathcal{A})) \subseteq (\Sigma\times\{\mathsf{L},\mathsf{R}\})^\omega$. If $q \in Q$ is a state of an automaton $\mathcal{A}$ then by $\mathcal{A}_q$ we denote the same automaton as $\mathcal{A}$ but with the initial state q_0 changed to q. Thus, $\mathrm{L}(\mathcal{A}_q)$ is the set of trees over which $\mathcal{A}$ has an accepting run ρ starting at $\rho(\epsilon) = q$. In the rest of the paper we assume that all states q in an automaton are *productive* in the sense that $\mathrm{L}(\mathcal{A}_q) \neq \varnothing$.

Deterministic and game automata. We say that $\mathcal{A}$ is a *game automaton* if, for every $q \in Q$ and $a \in \Sigma$, either we have a *conjunctive transition* $\Delta(q,a) = \{(q,a,q_\mathsf{L},q_\mathsf{R})\}$ or two *disjunctive transitions* $\Delta(q,a) = \{(q,a,q_\mathsf{L},\top),(q,a,\top,q_\mathsf{R})\}$ (cf. [26, Definition 3.2]), where $\top \neq q_0$ represents a distinguished state in Q accepting every tree (i.e., $\mathrm{L}(\mathcal{A}_\top) = \mathrm{Tr}_\Sigma$) and $q_\mathsf{L}, q_\mathsf{R} \neq \top$. An automaton $\mathcal{A}$ is *deterministic* if it is a game automaton with only conjunctive transitions and in this case for every tree $t \in \mathrm{Tr}_\Sigma$ there exists a unique run ρ of $\mathcal{A}$ over t. A tree language L is *deterministic*, resp., *game*, if it can be recognised by some deterministic, resp., game automaton. Game automata can be complemented with very low complexity by just increasing every priority by one and by swapping conjunctive and disjunctive transitions.

▶ **Lemma 2.** *If $\mathcal{A}$ is a game parity tree automaton, then $\mathrm{Tr}_\Sigma\backslash\mathrm{L}(\mathcal{A})$ can be recognised by a game parity tree automaton with the same number of states and priorities.*

Acceptance games. We present a game-theoretic view on accepting runs. This will serve both as an example of the kind of games that we consider throughout paper, and as a technical tool in the proofs from Sections 5 and 6. Let $t \in \mathrm{Tr}_\Sigma$ be a tree. The *acceptance game* $G^{\mathrm{acc}}(\mathcal{A}, t)$ is played in rounds by two players, Automaton and Pathfinder. The goal of Automaton is to show that $t \in \mathrm{L}(\mathcal{A})$; Pathfinder has the complementary objective $t \notin \mathrm{L}(\mathcal{A})$.

Acceptance game $G^{\mathrm{acc}}(\mathcal{A}, t)$

At the i-th round starting at a *position* $v_i = (u_i, q_i) \in V := \{\mathsf{L}, \mathsf{R}\}^* \times Q$:
- [A: δ] Automaton plays a transition $\delta_i = (q_i, t(u_i), q_{\mathsf{L},i}, q_{\mathsf{R},i}) \in \Delta(q_i, t(u_i))$.
- [P: d] Pathfinder plays a direction $d_i \in \{\mathsf{L}, \mathsf{R}\}$.

The next position is $v_{i+1} := (u_i d_i, q_{d_i,i})$.

The initial position is $v_0 := (\epsilon, q_0)$. Automaton *wins* the resulting infinite play $\pi = (\delta_0, d_0)(\delta_1, d_1) \cdots$ if the sequence of transitions $\delta_0 \delta_1 \cdots$ is accepting. Automaton's moves in the acceptance game $G^{\mathrm{acc}}(\mathcal{A}, t)$ are performed according to a *strategy* for Automaton. This is a tuple $\mathcal{M} = (M, \ell_0, \overline{\delta}, \tau)$, where M is a set of *memory states*, of which $\ell_0 \in M$ is the initial memory state, $\overline{\delta} \colon V \times M \to \Delta$ is an output function which in a position (u, q) and a memory state ℓ selects a transition $\overline{\delta}\big((u, q), \ell\big) \in \Delta(q, t(u))$ of $\mathcal{A}$, and $\tau \colon V \times M \times \{\mathsf{L}, R\} \to M$ is a memory update function which, in a given position v, memory state ℓ, and direction d selects the next memory state $\tau(v, \ell, d) \in M$. An infinite play π as above is *conform* to a strategy $\mathcal{M}$ if during the play π Automaton keeps track of the current position v_i and memory state ℓ_i, updating them after each round (i.e., $\ell_{i+1} := \tau(v_i, \ell_i, d_i)$) and her consecutive choices of transitions δ_i are done according to $\overline{\delta}(v_i, \ell_i)$. A strategy $\mathcal{M}$ is *winning* if every play conform to it is winning for Automaton. Automaton wins the acceptance game if she has a winning strategy. The following proposition is folklore.

▶ **Proposition 3.** *Let $t \in \mathrm{Tr}_\Sigma$ and $\mathcal{A}$ be an automaton over the alphabet Σ. Automaton wins the acceptance game $G^{\mathrm{acc}}(\mathcal{A}, t)$ if, and only if, $t \in \mathrm{L}(\mathcal{A})$.*

Disjointness games. Let $\mathcal{A}$ and $\mathcal{B}$ be two nondeterministic automata. We recall a standard game used to characterise whether $\mathrm{L}(\mathcal{A}) \perp \mathrm{L}(\mathcal{B})$. This will be crucial in the correctness proofs throughout Sections 3–6. The *disjointness game* $G^{\mathrm{dis}}(\mathcal{A}, \mathcal{B})$ is played by two players, Automaton and Pathfinder. Automaton's aim is to incrementally build a tree accepted by both $\mathcal{A}$ and $\mathcal{B}$, witnessing $\mathrm{L}(\mathcal{A}) \cap \mathrm{L}(\mathcal{B}) \neq \varnothing$, while Pathfinder has the opposite objective.[2] The set of positions of the game is $Q^{\mathcal{A}} \times Q^{\mathcal{B}}$, and the initial position is $(q_0^{\mathcal{A}}, q_0^{\mathcal{B}})$.

Disjointness game $G^{\mathrm{dis}}(\mathcal{A}, \mathcal{B})$

At the i-th round starting at a position $(q_i^{\mathcal{A}}, q_i^{\mathcal{B}})$:
- [A: a] Automaton plays a letter $a_i \in \Sigma$.
- [A: $\delta^{\mathcal{A}}$] Automaton plays a transition $\delta_i^{\mathcal{A}} = (q_i^{\mathcal{A}}, a_i, q_{\mathsf{L},i}^{\mathcal{A}}, q_{\mathsf{R},i}^{\mathcal{A}}) \in \Delta^{\mathcal{A}}(q_i^{\mathcal{A}}, a_i)$.
- [A: $\delta^{\mathcal{B}}$] Automaton plays a transition $\delta_i^{\mathcal{B}} = (q_i^{\mathcal{B}}, a_i, q_{\mathsf{L},i}^{\mathcal{B}}, q_{\mathsf{R},i}^{\mathcal{B}}) \in \Delta^{\mathcal{B}}(q_i^{\mathcal{B}}, a_i)$.
- [P: d] Pathfinder plays a direction $d_i \in \{\mathsf{L}, \mathsf{R}\}$.

The next position is $(q_{d_i,i}^{\mathcal{A}}, q_{d_i,i}^{\mathcal{B}})$.

[2] The disjointness game could equivalently be phrased as a nonemptiness game for the product automaton $\mathcal{A} \times \mathcal{B}$ recognising $\mathrm{L}(\mathcal{A}) \cap \mathrm{L}(\mathcal{B})$. However, in our technical development it will be more direct to use the disjointness game.

Let the resulting infinite play be $\pi = (a_0, \delta_0^{\mathcal{A}}, \delta_0^{\mathcal{B}}, d_0)(a_1, \delta_1^{\mathcal{A}}, \delta_1^{\mathcal{B}}, d_1)\cdots$. Such a play induces an infinite path $b = (a_0, d_0)(a_1, d_1)\cdots$ and two sequences of transitions $\vec{\delta}^{\mathcal{A}} := \delta_0^{\mathcal{A}}\delta_1^{\mathcal{A}}\cdots$ and $\vec{\delta}^{\mathcal{B}} := \delta_0^{\mathcal{B}}\delta_1^{\mathcal{B}}\cdots$. The rules of the game guarantee that $\vec{\delta}^{\mathcal{A}} \in \Delta^{\mathcal{A}}(b)$ and $\vec{\delta}^{\mathcal{B}} \in \Delta^{\mathcal{B}}(b)$. Automaton wins the play π if both sequences $\vec{\delta}^{\mathcal{A}}$ and $\vec{\delta}^{\mathcal{B}}$ are accepting.

In the rest of the paper it will be more useful to consider Pathfinder's point of view. Since her winning condition can be presented as Rabin condition, whenever she wins, she has a *memoryless* (i.e., $M = \{\ell_0\}$) winning strategy. Such a memoryless strategy for Pathfinder in the disjointness game can be represented by a function $\mathcal{P}\colon \left(\bigcup_{a\in\Sigma} \Delta^{\mathcal{A}}(a) \times \Delta^{\mathcal{B}}(a)\right) \to \{\mathsf{L}, \mathsf{R}\}$, which we call a *pathfinder*.

▶ **Lemma 4.** *If* $\mathrm{L}(\mathcal{A}) \perp \mathrm{L}(\mathcal{B})$ *then there is a pathfinder* $\mathcal{P}$ *which is winning for* Pathfinder *in the disjointness game* $G^{\mathrm{dis}}(\mathcal{A}, \mathcal{B})$.

▶ **Corollary 5.** *Assume that* $\mathrm{L}(\mathcal{A}) \perp \mathrm{L}(\mathcal{B})$ *and let* $\mathcal{P}$ *be a pathfinder as above. Let* $b = (a_0, d_0)(a_1, d_1)\cdots \in (\Sigma \times \{\mathsf{L}, \mathsf{R}\})^\omega$ *be a path and* $\vec{\delta}^{\mathcal{A}} = \delta_0^{\mathcal{A}}\delta_1^{\mathcal{A}}\cdots \in \Delta^{\mathcal{A}}(b)$, $\vec{\delta}^{\mathcal{B}} = \delta_0^{\mathcal{B}}\delta_1^{\mathcal{B}}\cdots \in \Delta^{\mathcal{B}}(b)$ *be two sequences of transitions of these automata that are conform to* b. *If for every* $i \in \omega$ *we have* $\mathcal{P}(\delta_i^{\mathcal{A}}, \delta_i^{B}) = d_i$ *then at least one of the sequences* $\vec{\delta}^{\mathcal{A}}$ *and* $\vec{\delta}^{\mathcal{B}}$ *is rejecting.*

The construction above has a specific property if one of the involved automata (e.g., $\mathcal{A}$) is a game automaton. Since we assume that every state is productive, positions of the form $(\top, q^{\mathcal{B}})$ are losing for Pathfinder in $G^{\mathrm{dis}}(\mathcal{A}, \mathcal{B})$. Therefore, without loss of generality we can assume that the pathfinder $\mathcal{P}$ satisfies the following observation.

▶ Remark 6. Consider a transition $\delta^{\mathcal{A}} = (q^{\mathcal{A}}, a, q_{\mathsf{L}}^{\mathcal{A}}, \top)$ (resp., $\delta^{\mathcal{A}} = (q^{\mathcal{A}}, a, \top, q_{\mathsf{R}}^{\mathcal{A}})$) in a game automaton $\mathcal{A}$. Then, $\mathcal{P}(\delta^{\mathcal{A}}, _)$ is constantly equal to L (resp., R).

3 Separability by deterministic automata with priorities in C

In this section we present a game-theoretic characterisation of separability by deterministic automata over a fixed finite set of priorities $C \subseteq \mathbb{N}$. Let $\mathcal{A}$, $\mathcal{B}$ be two nondeterministic automata over infinite trees. We extend the game from the introduction over ω-words with two additional actions, a *selector* for Separator and a direction for Input.

C-deterministic-separability game $G^{\mathrm{sep}}_{\mathrm{det}}(\mathcal{A}, \mathcal{B}, C)$

At the i-th round:
- [S: c] Separator plays a priority $c_i \in C$.
- [I: a] Input plays a letter $a_i \in \Sigma$.
- [S: f] Separator plays a *selector* $f_i \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{B}}(a_i)}$.
- [I: d] Input plays a direction $d_i \in \{\mathsf{L}, \mathsf{R}\}$.

Intuitively, a selector encodes a direction for each (relevant) transition of $\mathcal{B}$ and this is used for the correctness of the separator. Assume that the resulting infinite play is $\pi = (c_0, a_0, f_0, d_0)(c_1, a_1, f_1, d_1)\cdots$, with the induced infinite path $b := (a_0, d_0)(a_1, d_1)\cdots$. Separator wins the play π if the following two conditions are satisfied:

1. $\pi \in \mathbf{W}_{\mathcal{A}}$: If there exists an accepting sequence of transitions $\vec{\delta}^{\mathcal{A}} = \delta_0^{\mathcal{A}}\delta_1^{\mathcal{A}}\cdots \in \Delta^{\mathcal{A}}(b)$, then $c_0c_1\cdots$ is accepting.
2. $\pi \in \mathbf{W}_{\mathcal{B}}$: If there exists an accepting sequence of transitions $\vec{\delta}^{\mathcal{B}} = \delta_0^{\mathcal{B}}\delta_1^{\mathcal{B}}\cdots \in \Delta^{\mathcal{B}}(b)$ s.t. for every $i \in \omega$ we have $f_i(\delta_i^{\mathcal{B}}) = d_i$, then $c_0c_1\cdots$ is rejecting.

The following lemma states that the separability game correctly characterises the deterministic separability problem.

▶ **Lemma 7.** *Separator wins $G^{\text{sep}}_{\text{det}}(\mathcal{A}, \mathcal{B}, C)$ if, and only if, $\mathrm{L}(\mathcal{A})$, $\mathrm{L}(\mathcal{B})$ can be separated by a deterministic parity tree automaton with priorities in C.*

We present a full proof in order to show the rôle of Separator's selectors.

Soundness. Assume that Separator wins the separability game $G := G^{\text{sep}}_{\text{det}}(\mathcal{A}, \mathcal{B}, C)$ by a finite-memory winning strategy $\mathcal{M} = (M, \ell_0, (\overline{c}, \overline{f}), \tau)$. Strategy $\mathcal{M}$ has two decision functions: $\overline{c}$ assigns to each $\ell \in M$ a priority $\overline{c}(\ell) \in C$, and $\overline{f}$ assigns to each $\ell \in M$ and $a \in \Sigma$ a selector $\overline{f}(\ell, a) \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{B}}(a)}$. Moreover, the type of the memory update function is $\tau \colon M \times \Sigma \times \{\mathsf{L}, \mathsf{R}\} \to M$. Consider a deterministic parity tree automaton $\mathcal{S} := (\Sigma, M, \ell_0, \Omega^{\mathcal{S}}, \Delta^{\mathcal{S}})$ which has the same set of states M and initial state ℓ_0 as $\mathcal{M}$, priorities are induced by the decision function $\overline{c}$ of $\mathcal{M}$ as $\Omega^{\mathcal{S}}(\ell) := \overline{c}(\ell)$, and transitions are of the form $\Delta^{\mathcal{S}} = \{(\ell, a, \tau(\ell, a, \mathsf{L}), \tau(\ell, a, \mathsf{R})) \mid \ell \in M, a \in \Sigma\}$.

We show that $\mathcal{S}$ separates $\mathrm{L}(\mathcal{A})$, $\mathrm{L}(\mathcal{B})$. We first show $\mathrm{L}(\mathcal{A}) \subseteq \mathrm{L}(\mathcal{S})$. Let $t \in \mathrm{L}(\mathcal{A})$ be a tree that is accepted by the automaton $\mathcal{A}$, as witnessed by an accepting run $\rho^{\mathcal{A}}$. Let $\rho^{\mathcal{S}}$ be the unique run of $\mathcal{S}$ over t. Consider any branch $d_0 d_1 \cdots \in \{\mathsf{L}, \mathsf{R}\}^{\omega}$. We need to show that the sequence of priorities $\big(\Omega^{\mathcal{S}}(\rho^{\mathcal{S}}(d_0 \cdots d_{i-1}))\big)_{i \in \omega}$ is accepting. Consider a play π of G where at the i-th round Separator plays according to the strategy $\mathcal{M}$ with current memory state $\ell_i \in M$ and Input plays according to the letters from t and directions $d_0 d_1 \cdots$ fixed above:

- [S: c] Separator plays the priority $c_i := \overline{c}(\ell_i) \in C$.
- [I: a] Input plays the letter $a_i := t(u_i) \in \Sigma$, where $u_i := d_0 \cdots d_{i-1}$.
- [S: f] Separator plays the selector $f_i := \overline{f}(\ell_i, a_i) \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{B}}(a_i)}$ (the selector is irrelevant in this part of the proof).
- [I: d] Input plays the direction $d_i \in \{\mathsf{L}, \mathsf{R}\}$ as fixed above.

The next memory state is $\ell_{i+1} := \tau(\ell_i, a_i, d_i)$. Let the resulting infinite play be $\pi = (c_0, a_0, f_0, d_0)(c_1, a_1, f_1, d_1) \cdots$. By the construction of $\mathcal{S}$ we know that $\ell_i = \rho^{\mathcal{S}}(u_i)$ and therefore $c_i = \Omega^{\mathcal{S}}(\rho^{\mathcal{S}}(u_i))$. Since $t \in \mathrm{L}(\mathcal{A})$, there exists an accepting sequence of transitions $\vec{\delta}^{\mathcal{A}} = \delta^{\mathcal{A}}_0 \delta^{\mathcal{A}}_1 \cdots \in \Delta^{\mathcal{A}}(b)$ along the path $b = (a_0, d_0)(a_1, d_1) \cdots$. Since Separator is winning, $\pi \in \mathbf{W}_{\mathcal{A}}$ and thus the sequence $c_0 c_1 \cdots$ is accepting, as required.

We now argue that $\mathrm{L}(\mathcal{S})$ and $\mathrm{L}(\mathcal{B})$ are disjoint. Towards reaching a contradiction, assume that $t \in \mathrm{L}(\mathcal{S}) \cap \mathrm{L}(\mathcal{B})$ belongs to their intersection. Let $\rho^{\mathcal{S}}$ be the unique run of $\mathcal{S}$ over t, and let $\rho^{\mathcal{B}}$ be an accepting run of $\mathcal{B}$ over t. Consider a play $\pi = (c_0, a_0, f_0, d_0)(c_1, a_1, f_1, d_1) \cdots$ of G where the i-th round is played as above except that Input plays the direction $d_i := f_i(\delta^{\mathcal{B}}_i)$, obtained by applying the selector f_i to the transition $\delta^{\mathcal{B}}_i := \big(\rho^{\mathcal{B}}(u_i), t(u_i), \rho^{\mathcal{B}}(u_i\mathsf{L}), \rho^{\mathcal{B}}(u_i\mathsf{R})\big)$ determined according to the run $\rho^{\mathcal{B}}$. By the choice of directions d_i's, the sequence of transitions $\vec{\delta}^{\mathcal{B}} = \delta^{\mathcal{B}}_0 \delta^{\mathcal{B}}_1 \cdots \in (\Delta^{\mathcal{B}})^{\omega}$ satisfies $f_i(\delta^{\mathcal{B}}_i) = d_i$ for every $i \in \omega$. Since the run $\rho^{\mathcal{B}}$ is accepting, $\vec{\delta}^{\mathcal{B}}$ is accepting. Since Separator is winning, $\pi \in \mathbf{W}_{\mathcal{B}}$ and thus the sequence of priorities $c_0 c_1 \cdots$ is rejecting. However, this is a contradiction, because for each $i \in \omega$ we have $\ell_i = \rho^{\mathcal{S}}(u_i)$ and $c_i = \Omega^{\mathcal{S}}(\ell_i)$ and we assumed that the run $\rho^{\mathcal{S}}$ is accepting. ◀

Completeness. Assume that $\mathcal{S} = (\Sigma, Q^{\mathcal{S}}, q^{\mathcal{S}}_0, \Delta^{\mathcal{S}}, \Omega^{\mathcal{S}})$ is a deterministic automaton with priorities in C separating $\mathrm{L}(\mathcal{A})$, $\mathrm{L}(\mathcal{B})$, and we show that Separator wins the separability game G. Since $\mathcal{S}$ is a separator, we have that $\mathrm{L}(\mathcal{S}) \perp \mathrm{L}(\mathcal{B})$, and by Lemma 4 there exists a pathfinder $\mathcal{P}$. Consider the following strategy of Separator, with memory structure $Q^{\mathcal{S}}$ and initial memory state $q^{\mathcal{S}}_0$. At the i-th round of G, starting with a memory state $q^{\mathcal{S}}_i$,

- [S: c] Separator plays the priority $c_i := \Omega^{\mathcal{S}}(q^{\mathcal{S}}_i) \in C$.
- [I: a] Input plays an arbitrary letter $a_i \in \Sigma$.
- [S: f] Separator plays the selector $f_i := \mathcal{P}(\delta^{\mathcal{S}}_i, _) \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{B}}(a_i)}$, where $\Delta^{\mathcal{S}}(q^{\mathcal{S}}_i, a_i) = \{\delta^{\mathcal{S}}_i\}$.
- [I: d] Input plays an arbitrary direction $d_i \in \{\mathsf{L}, \mathsf{R}\}$.

The next memory state is $q^{\mathcal{S}}_{i+1} := q^{\mathcal{S}}_{d_i,i}$, where $\delta^{\mathcal{S}}_i = (q^{\mathcal{S}}_i, a_i, q^{\mathcal{S}}_{\mathsf{L},i}, q^{\mathcal{S}}_{\mathsf{R},i})$. This concludes the description of the i-th round of G. Let the resulting infinite play be $\pi = (c_0, a_0, f_0, d_0)(c_1, a_1, f_1, d_1)\cdots$, with induced infinite path $b := (a_0, d_0)(a_1, d_1)\cdots$. Let $\vec{\delta}^{\mathcal{S}} := \delta^{\mathcal{S}}_0\delta^{\mathcal{S}}_1\cdots$ be the sequence of transitions used to define the selectors f_i. Clearly $\vec{\delta}^{\mathcal{S}} \in \Delta^{\mathcal{S}}(b)$.

First, we argue that $\pi \in \mathbf{W}_{\mathcal{A}}$ holds. Let $\vec{\delta}^{\mathcal{A}} = \delta^{\mathcal{A}}_0\delta^{\mathcal{A}}_1\cdots \in \Delta^{\mathcal{A}}(b)$ be an accepting sequence of transitions of the automaton $\mathcal{A}$. Since each state of $\mathcal{A}$ is productive, one can construct a tree $t \in \mathrm{L}(\mathcal{A})$ s.t. $b \in \mathsf{Path}(t)$. Since $\mathrm{L}(\mathcal{A}) \subseteq \mathrm{L}(\mathcal{S})$ by the assumption, $t \in \mathrm{L}(\mathcal{S})$ as well, and since $\mathcal{S}$ is deterministic, the unique run of $\mathcal{S}$ over t is accepting. By the definition of Separator's strategy, the sequence of priorities along the branch $d_0d_1\cdots$ of this accepting run is precisely $c_0c_1\cdots$, which thus must be accepting, as required.

Regarding $\mathbf{W}_{\mathcal{B}}$, let $\vec{\delta}^{\mathcal{B}} := \delta^{\mathcal{B}}_0\delta^{\mathcal{B}}_1\cdots \in \Delta^{\mathcal{B}}(b)$ be an accepting sequence of transitions over the path b conform to the selectors f_i, i.e., for every $i \in \omega$ we have $f_i(\delta^{\mathcal{B}}_i) = d_i$. By the definition of f_i, for every $i \in \omega$ we have $d_i = \mathcal{P}(\delta^{\mathcal{S}}_i, \delta^{\mathcal{B}}_i)$. Thus, the assumptions of Corollary 5 are satisfied and at least one of the sequences $\vec{\delta}^{\mathcal{S}}$, $\vec{\delta}^{\mathcal{B}}$ must be rejecting. Since we assumed that $\vec{\delta}^{\mathcal{B}}$ is accepting, it means that $\vec{\delta}^{\mathcal{S}}$ is rejecting, and so is $c_0c_1\cdots$ since $c_i = \Omega^{\mathcal{S}}(\delta^{S}_i)$. ◀

4 Separability by deterministic automata

In this section we present a game-theoretic characterisation of the deterministic separability problem. Notice that here we do not fix in advance a finite set of priorities C. The deterministic-separability game $G^{\mathrm{sep}}_{\mathrm{det}}(\mathcal{A}, \mathcal{B})$ below is a variant of the game with fixed priorities C from Section 3.

Deterministic-separability game $G^{\mathrm{sep}}_{\mathrm{det}}(\mathcal{A}, \mathcal{B})$

At the i-th round:

[I: a] Input plays a letter $a_i \in \Sigma$.

[S: f] Separator plays a selector $f_i \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{B}}(a_i)}$.

[I: d] Input plays a direction $d_i \in \{\mathsf{L}, \mathsf{R}\}$.

Separator wins the resulting infinite play $\pi = (a_0, f_0, d_0)(a_1, f_1, d_1)\cdots$, with induced infinite path $b := (a_0, d_0)(a_1, d_1)\cdots$, if at least one of the two conditions below fails:

1. $\pi \in \mathbf{W}_{\mathcal{A}}$: There exists an accepting sequence of transitions $\vec{\delta}^{\mathcal{A}} = \delta^{\mathcal{A}}_0\delta^{\mathcal{A}}_1\cdots \in \Delta^{\mathcal{A}}(b)$.
2. $\pi \in \mathbf{W}_{\mathcal{B}}$: There exists an accepting sequence of transitions $\vec{\delta}^{\mathcal{B}} = \delta^{\mathcal{B}}_0\delta^{\mathcal{B}}_1\cdots \in \Delta^{\mathcal{B}}(b)$ s.t. for every $i \in \omega$ we have $f_i(\delta^{\mathcal{B}}_i) = d_i$.

Before we prove the equivalence between the game and the existence of a separator, we define a separator candidate, namely the path-closure of $\mathrm{L}(\mathcal{A})$. This is important since it will turn out that if a separator exists, then the path-closure is itself a separator. Given a language of trees L, its *path-closure*, denoted $\forall\mathsf{Path}(L)$, is the set of all trees t s.t. for every path $b \in \mathsf{Path}(t)$ there exists some tree $t' \in L$ s.t. $b \in \mathsf{Path}(t')$ as well. The path-closure operator is directly connected with deterministic automata.

▶ **Lemma 8** (cf. [34, Proposition 1]). *Given a nondeterministic automaton $\mathcal{A}$ one can construct a deterministic automaton $\mathcal{A}^{\mathrm{path}}$ recognising the path closure of $\mathrm{L}(\mathcal{A})$, i.e., $\mathrm{L}(\mathcal{A}^{\mathrm{path}}) = \forall\mathsf{Path}(\mathrm{L}(\mathcal{A}))$. Moreover, $\mathrm{L}(\mathcal{A}^{\mathrm{path}})$ is the smallest deterministic language containing $\mathrm{L}(\mathcal{A})$.*

The following lemma binds together the game $G^{\mathrm{sep}}_{\mathrm{det}}(\mathcal{A}, \mathcal{B})$, separability, and path-closures.

▶ **Lemma 9.** *The following three conditions are equivalent:*

1. *Separator wins the deterministic-separability game $G^{\mathrm{sep}}_{\mathrm{det}}(\mathcal{A}, \mathcal{B})$.*
2. *The automaton $\mathcal{A}^{\mathrm{path}}$ is a deterministic separator for $\mathrm{L}(\mathcal{A})$, $\mathrm{L}(\mathcal{B})$.*
3. *There exists a deterministic separator for $\mathrm{L}(\mathcal{A})$, $\mathrm{L}(\mathcal{B})$.*

Proof sketch. Consider the implication "1 ⇒ 2". Firstly, $\mathrm{L}(\mathcal{A}) \subseteq \mathrm{L}(\mathcal{A}^{\mathrm{path}})$ because the operator $\forall\mathsf{Path}(_)$ is non-decreasing. Moreover, the fact that $\mathrm{L}(\mathcal{A}^{\mathrm{path}}) \perp \mathrm{L}(\mathcal{B})$ is witnessed by the choices of selectors f_i by a winning strategy of Separator in $G^{\mathrm{sep}}_{\mathrm{det}}(\mathcal{A}, \mathcal{B})$. The implication "2 ⇒ 3" is trivial. The proof of the implication "3 ⇒ 1" is similar to the proof of completeness in Lemma 7 – a separating automaton $\mathcal{S}$ can be used to construct a pathfinder $\mathcal{P}$, witnessing that $\mathrm{L}(\mathcal{S})$ and $\mathrm{L}(\mathcal{B})$ are disjoint. Now, one can construct a strategy of Separator in $G^{\mathrm{sep}}_{\mathrm{det}}(\mathcal{A}, \mathcal{B})$ by simulating $\mathcal{S}$ and using $\mathcal{P}$ to choose the selectors f_i. ◀

5 Separability by game automata

In this section we provide a game-theoretic characterisation for the game automata separability problem. Fix two automata $\mathcal{A}$ and $\mathcal{B}$ and consider the following separability game $G^{\mathrm{sep}}_{\mathrm{game}}(\mathcal{A}, \mathcal{B})$. The new ingredient is that Separator can choose a *mode* – a symbol from the set $\{\vee, \wedge\}$. It has two uses. First, in the construction of the separating game automaton, the mode dictates whether there will be a conjunctive or a disjunctive transition. Second, depending on the chosen mode, Separator will have to play a selector for the automaton $\mathcal{A}$ or $\mathcal{B}$, which will guarantee that the constructed automaton is a separator.

Game-separability game $G^{\mathrm{sep}}_{\mathrm{game}}(\mathcal{A}, \mathcal{B})$

At the i-th round:

- [I: a] Input plays a letter $a_i \in \Sigma$.
- [S: m] Separator plays a mode $m_i \in \{\vee, \wedge\}$.
- [S: f] Separator plays either
  - **a.** a selector $f_i \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{A}}(a_i)}$ for $\mathcal{A}$ if $m_i = \vee$ or
  - **b.** a selector $f_i \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{B}}(a_i)}$ for $\mathcal{B}$ if $m_i = \wedge$.
- [I: d] Input plays a direction $d_i \in \{\mathsf{L}, \mathsf{R}\}$.

Separator wins an infinite play $\pi = (a_0, m_0, f_0, d_0)(a_1, m_1, f_1, d_1)\cdots$ inducing a path $b = (a_0, d_0)(a_1, d_1)\cdots$ whenever at least one of the two conditions below fail:

1. $\pi \in \mathbf{W}_{\mathcal{A}}$: There exists an accepting sequence of transitions $\vec{\delta}^{\mathcal{A}} = \delta^{\mathcal{A}}_0\delta^{\mathcal{A}}_1\cdots \in \Delta^{\mathcal{A}}(b)$ s.t. for all $i \in \mathbb{N}$ we have $(m_i = \vee) \Rightarrow f_i(\delta^{\mathcal{A}}_i) = d_i$.
2. $\pi \in \mathbf{W}_{\mathcal{B}}$: There exists an accepting sequence of transitions $\vec{\delta}^{\mathcal{B}} = \delta^{\mathcal{B}}_0\delta^{\mathcal{B}}_1\cdots \in \Delta^{\mathcal{B}}(b)$ s.t. for all $i \in \mathbb{N}$ we have $(m_i = \wedge) \Rightarrow f_i(\delta^{\mathcal{B}}_i) = d_i$.

▶ **Lemma 10.** *Separator wins the separability game $G^{\mathrm{sep}}_{\mathrm{game}}(\mathcal{A}, \mathcal{B})$ if, and only if, there exists a game automaton $\mathcal{S}$ separating $\mathrm{L}(\mathcal{A})$, $\mathrm{L}(\mathcal{B})$.*

In the proof of this lemma we will build separating automata with a more general acceptance condition than the parity condition, which will simplify the technical details. A *generalised game automaton* $\mathcal{A} = (\Sigma, Q, q_0, \Delta, \mathcal{D})$ is just like a game automaton except that the priority mapping Ω is replaced by a deterministic ω-word parity automaton $\mathcal{D}$ over alphabet $\Sigma \times \{\mathsf{L}, \mathsf{R}\}$. A run $\rho \in \mathrm{Tr}_Q$ of such an automaton over a tree $t \in \mathrm{Tr}_\Sigma$ is *accepting* if for every path $b = (a_0, d_0)(a_1, d_1)\cdots \in \mathsf{Path}(t)$ either $\rho(d_0\cdots d_{i-1}) = \top$ for some $i \in \omega$, or $b \in \mathrm{L}(\mathcal{D})$. The acceptance game $G^{\mathrm{acc}}(\mathcal{A}, t)$ can easily be adapted to the case of a generalised game automaton $\mathcal{A}$ by only modifying the winning condition.

▶ **Lemma 11.** *A generalised game automaton $\mathcal{A}$ with a generalised acceptance condition recognised by a deterministic parity automaton $\mathcal{D}$ can be transformed into an equivalent (ordinary) game automaton $\mathcal{B}$ of size polynomial in $\mathcal{A}$ and $\mathcal{D}$.*

We now prove Lemma 10. Its proof is given in full details because, unlike in Sections 3 and 4, it is not obvious how to construct a separator from a winning strategy for Separator.

Soundness. Assume that Separator wins the game-separability game $G := G^{\text{sep}}_{\text{game}}(\mathcal{A}, \mathcal{B})$ and we show that there exists a game automaton $\mathcal{S}$ separating $\mathrm{L}(\mathcal{A})$ from $\mathrm{L}(\mathcal{B})$. Let $\mathcal{M} = (M, \ell_0, (\overline{m}, \overline{f}), \tau)$ be a finite-memory winning strategy of Separator in G.

Before we move to the construction of the separating automaton, we first define its generalised acceptance condition. Let $L_{\mathcal{A}}$ (resp., $L_{\mathcal{B}}$) be the set of those paths $b = (a_0, d_0)(a_1, d_1)\cdots \in (\Sigma \times \{\mathsf{L}, \mathsf{R}\})^\omega$ s.t. the unique play π of G in which Input plays consecutive letters and directions from b and Separator uses her winning strategy $\mathcal{M}$ satisfies the condition $\mathbf{W}_{\mathcal{A}}$ (resp., $\mathbf{W}_{\mathcal{B}}$). Since the strategy $\mathcal{M}$ is winning for Separator, the languages $L_{\mathcal{A}}$ and $L_{\mathcal{B}}$ are disjoint. Moreover, since the strategy $\mathcal{M}$ is finite memory and both $\mathbf{W}_{\mathcal{A}}$, $\mathbf{W}_{\mathcal{B}}$ are ω-regular, so are the languages $L_{\mathcal{A}}$ and $L_{\mathcal{B}}$. Let $\mathcal{D}$ be any deterministic automaton over ω-words that separates $L_{\mathcal{A}}$ from $L_{\mathcal{B}}$ (the simplest case is to take $\mathcal{D}$ recognising the language $L_{\mathcal{A}}$). We build a separating automaton as a generalised game automaton

$$\mathcal{S} := \alpha(\mathcal{M}, \mathcal{D}) := (\Sigma, M \cup \{\top\}, \ell_0, \Delta^{\mathcal{S}}, \mathcal{D}), \text{ where}$$

$$\Delta^{\mathcal{S}}\big(\ell, a\big) := \begin{cases} \{(\ell, a, \ell_{\mathsf{L}}, \top), (\ell, a, \top, \ell_{\mathsf{R}})\} & \text{if } \overline{m}(\ell, a) = \vee, \\ \{(\ell, a, \ell_{\mathsf{L}}, \ell_{\mathsf{R}})\} & \text{if } \overline{m}(\ell, a) = \wedge, \end{cases}$$

for every $\ell \in M$ and $a \in \Sigma$, where for $d \in \{\mathsf{L}, \mathsf{R}\}$ we have $\ell_d := \tau(\ell, a, d)$. We now show that $\mathcal{S}$ separates $\mathrm{L}(\mathcal{A})$ from $\mathrm{L}(\mathcal{B})$. In order to show $\mathrm{L}(\mathcal{A}) \subseteq \mathrm{L}(\mathcal{S})$, let $t \in \mathrm{L}(\mathcal{A})$ as witnessed by an accepting run $\rho^{\mathcal{A}}$. We show that Automaton wins the acceptance game $G_{\mathcal{S}} := G^{\text{acc}}(\mathcal{S}, t)$. To show this we play in parallel the separability game G and the acceptance game $G_{\mathcal{S}}$, maintaining the following invariant: At the i-th round, the current finite path of the input tree t is $(a_0, d_0)\cdots(a_{i-1}, d_{i-1})$, Separator's winning strategy $\mathcal{M}$ in the separability game G is in memory state ℓ_i, the current state of the separating automaton $\mathcal{S}$ in the acceptance game $G_{\mathcal{S}}$ is also ℓ_i, and $\rho^{\mathcal{A}}(d_0 \cdots d_{i-1}) = q_i^{\mathcal{A}}$. The i-th round is then played as follows:

$G.[\mathsf{I}\colon a]$ Input plays the letter $a_i := t(u_i)$ for $u_i := d_0 \cdots d_{i-1}$.

$G.[\mathsf{S}\colon m]$ Separator plays the mode $m_i := \overline{m}(\ell_i, a_i) \in \{\vee, \wedge\}$.

$G.[\mathsf{S}\colon f]$ Separator plays either

- **a.** a selector $f_i := \overline{f}(\ell_i, a_i) \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{A}}(a_i)}$ for $\mathcal{A}$ if $m_i = \vee$ or
- **b.** a selector $f_i := \overline{f}(\ell_i, a_i) \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{B}}(a_i)}$ for $\mathcal{B}$ if $m_i = \wedge$.

$G_{\mathcal{S}}.[\mathsf{A}\colon \delta]$ Automaton plays the transition $\delta_i^{\mathcal{S}} \in \Delta^{\mathcal{S}}(\ell_i, a_i)$, defined as follows. Let $\delta_i^{\mathcal{A}} := \big(\rho^{\mathcal{A}}(u_i), t(u_i), \rho^{\mathcal{A}}(u_i\mathsf{L}), \rho^{\mathcal{A}}(u_i\mathsf{R})\big)$ be the $\mathcal{A}$-transition used in u_i by the run $\rho^{\mathcal{A}}$. We distinguish two cases.

- **a.** In the first case, assume that Separator played $m_i = \vee$ and $f_i \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{A}}(a_i)}$. It means that $\Delta^{\mathcal{S}}\big((\ell_i, q_i), a_i\big)$ contains two disjunctive transitions, $\delta^{\mathcal{S}}_{\mathsf{L},i} := (\ell_i, a_i, \ell_{\mathsf{L},i}, \top)$ and $\delta^{\mathcal{S}}_{\mathsf{R},i} := (\ell_i, a_i, \top, \ell_{\mathsf{R},i})$. Let us put $\delta_i^{\mathcal{S}} := \delta^{\mathcal{S}}_{f_i(\delta_i^{\mathcal{A}}),i}$, i.e., the transition that sends a non-$\top$ state in the direction given by $f_i(\delta_i^{\mathcal{A}})$.
- **b.** In the second case, Separator played $m_i = \wedge$ and $f_i \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{B}}(a_i)}$. It means that $\Delta^{\mathcal{S}}\big(\ell_i, a_i\big)$ contains one conjunctive transition $\delta_i^{\mathcal{S}} := (\ell_i, a_i, \ell_{\mathsf{L},i}, \ell_{\mathsf{R},i})$.

$G_{\mathcal{S}}.[\mathsf{I}\colon d]$ Input plays an arbitrary direction $d_i \in \{\mathsf{L}, \mathsf{R}\}$.

$G.[\mathsf{I}\colon d]$ Input plays the direction $d_i \in \{\mathsf{L}, \mathsf{R}\}$.

If $m_i = \vee$ and $d_i \neq f_i(\delta_i^{\mathcal{A}})$ then the next position of the acceptance game $G_{\mathcal{S}}$ is $(u_i d_i, \top)$, which is a winning position for Automaton. Therefore, w.l.o.g. we assume that:

$$\forall i \in \omega.\ (m_i = \vee) \Rightarrow f_i(\delta_i^{\mathcal{A}}) = d_i. \tag{1}$$

Moreover, the new state of $\mathcal{S}$ in $G_{\mathcal{S}}$ is $\ell_{i+1} := \tau(\ell_i, a_i, d_i)$. Similarly, the new memory state of $\mathcal{M}$ in G is ℓ_{i+1}. This concludes the description of the i-th round of both games. Clearly the invariant is preserved. We argue that Automaton wins the resulting infinite play $(\delta_0^{\mathcal{S}}, d_0)(\delta_1^{\mathcal{S}}, d_1)\cdots$ of the acceptance game $G_{\mathcal{S}}$. Consider the infinite play $\pi = (a_0, m_0, f_0, d_0)(a_1, m_1, f_1, d_1)\cdots$ of the separability game G. Since the run $\rho^{\mathcal{A}}$ is accepting, the infinite sequence of $\mathcal{A}$-transitions $\delta_0^{\mathcal{A}}\delta_1^{\mathcal{A}}\cdots$ is accepting. Thus, (1) implies that $\pi \in \mathbf{W}_{\mathcal{A}}$. Therefore, the infinite path $b := (a_0, d_0)(a_1, d_1)\cdots$ belongs to $L_{\mathcal{A}} \subseteq \mathrm{L}(\mathcal{D})$ and thus the corresponding infinite play $(\delta_0^{\mathcal{S}}, d_0)(\delta_1^{\mathcal{S}}, d_1)\cdots$ of the acceptance game $G_{\mathcal{S}}$ is winning for Automaton, as required. This concludes the argument establishing $\mathrm{L}(\mathcal{A}) \subseteq \mathrm{L}(\mathcal{S})$.

It remains to show that $\mathrm{L}(\mathcal{S}) \perp \mathrm{L}(\mathcal{B})$, which is the same as $\mathrm{L}(\mathcal{B}) \subseteq \mathrm{L}(\mathcal{S}^{\mathrm{c}})$ for the complement game automaton. This follows directly from the construction above via the duality of the game G. ◀

Completeness. Assume that there exists a game automaton $\mathcal{S}$ that separates $\mathrm{L}(\mathcal{A})$ from $\mathrm{L}(\mathcal{B})$. We need to show that Separator wins the separability game $G := G^{\mathrm{sep}}_{\mathrm{game}}(\mathcal{A}, \mathcal{B})$. Let $\mathcal{R} := \mathcal{S}^{\mathrm{c}}$ be the syntactic dual of the game automaton $\mathcal{S}$ as in Lemma 2. Thus, the automata $\mathcal{S}$ and $\mathcal{R}$ share the same set of states. Also, their transitions are related: the conjunctive transitions of $\mathcal{S}$ correspond to disjunctive transitions of $\mathcal{R}$ and vice versa. By slightly rephrasing the separation condition, we have $\mathrm{L}(\mathcal{A}) \perp \mathrm{L}(\mathcal{R})$ and $\mathrm{L}(\mathcal{B}) \perp \mathrm{L}(\mathcal{S})$. This means that Pathfinder wins both disjointness games $G^{\mathrm{dis}}(\mathcal{R}, \mathcal{A})$ and $G^{\mathrm{dis}}(\mathcal{S}, \mathcal{B})$. Thus, we can apply Lemma 4 to obtain pathfinders $\mathcal{P}_{\mathcal{A}}\colon \big(\bigcup_{a\in\Sigma} \Delta^{\mathcal{R}}(a) \times \Delta^{\mathcal{A}}(a)\big) \to \{\mathsf{L}, \mathsf{R}\}$ and $\mathcal{P}_{\mathcal{B}}\colon \big(\bigcup_{a\in\Sigma} \Delta^{\mathcal{S}}(a) \times \Delta^{\mathcal{B}}(a)\big) \to \{\mathsf{L}, \mathsf{R}\}$.

We will now provide a strategy of Separator in G. The constructed strategy uses as its memory states the set of states of $\mathcal{S}$ that are distinct than $\top$. Let the initial memory state be q_0. Assume that the current memory state is q_i and consider the i-th round of the game.

[I: a] Input plays an arbitrary letter $a_i \in \Sigma$.

[S: m] Separator plays the mode $m_i \in \{\vee, \wedge\}$ defined as follows. We consider the following two cases for the mode of the transitions $\Delta^{\mathcal{S}}(q_i, a_i)$.

- **a.** If $\Delta^{\mathcal{S}}(q_i, a_i) = \{\delta_i^{\mathcal{S}}\}$ is a single conjunctive transition $\delta_i^{\mathcal{S}} = (q_i, a_i, q_{\mathsf{L},i}, q_{\mathsf{R},i})$ then we put $m_i := \wedge$ and $f_i := \mathcal{P}_{\mathcal{B}}(\delta_i^{\mathcal{S}}, _)$ is a selector for $\mathcal{B}$.
- **b.** Otherwise, $\Delta^{\mathcal{S}}(q_i, a_i)$ is a pair of disjunctive transitions which means that $\Delta^{\mathcal{R}}(q_i, a_i)$ is a single conjunctive transition $\delta_i^{\mathcal{R}} = (q_i, a_i, q_{\mathsf{L},i}, q_{\mathsf{R},i})$. In this case we put $m_i := \vee$ and $f_i := \mathcal{P}_{\mathcal{A}}(\delta_i^{\mathcal{R}}, _)$ is a selector for $\mathcal{A}$.

[S: f] Separator plays the selector f_i defined above (notice that f_i is either a selector for $\mathcal{A}$ or for $\mathcal{B}$, according to m_i).

[I: d] Input plays an arbitrary direction $d_i \in \{\mathsf{L}, \mathsf{R}\}$.

The next memory state of our strategy is the state $q_{d_i,i}$ taken from one of the transitions $\delta_i^{\mathcal{S}}$ or $\delta_i^{\mathcal{R}}$, see above. We now argue that Separator wins the corresponding infinite play $\pi = (a_0, m_0, f_0, d_0)(a_1, m_1, f_1, d_1)\cdots$. Let $b = (a_0, d_0)(a_1, d_1)\cdots$ be the corresponding path. Consider a number $i \in \omega$. By the construction of the strategy above, we have two cases:

1. If $m_i = \wedge$, then a conjunctive transition $\delta_i^{\mathcal{S}} = (q_i, a_i, q_{\mathsf{L},i}, q_{\mathsf{R},i})$ of $\mathcal{S}$ was used to determine f_i. In this case, define $\delta_i^{\mathcal{R}}$ as the following disjunctive transition of $\mathcal{R}$: if $d_i = \mathsf{L}$ then $\delta_i^{\mathcal{R}} := (q_i, a_i, q_{\mathsf{L},i}, \top)$, otherwise $d_i = \mathsf{R}$ and $\delta_i^{\mathcal{R}} := (q_i, a_i, \top, q_{\mathsf{R},i})$.
2. If $m_i = \vee$, then a conjunctive transition $\delta_i^{\mathcal{R}} = (q_i, a_i, q_{\mathsf{L},i}, q_{\mathsf{R},i})$ of $\mathcal{R}$ was used to determine f_i. In this case, define $\delta_i^{\mathcal{S}}$ as the following disjunctive transition of $\mathcal{S}$: if $d_i = \mathsf{L}$ then $\delta_i^{\mathcal{S}} := (q_i, a_i, q_{\mathsf{L},i}, \top)$, otherwise $d_i = \mathsf{R}$ and $\delta_i^{\mathcal{S}} := (q_i, a_i, \top, q_{\mathsf{R},i})$.

The definitions above provide two sequences of transitions $\vec{\delta}^{\mathcal{S}} := \delta_0^{\mathcal{S}}\delta_1^{\mathcal{S}}\cdots \in \Delta^{\mathcal{S}}(b)$, $\vec{\delta}^{\mathcal{R}} := \delta_0^{\mathcal{R}}\delta_1^{\mathcal{R}}\cdots \in \Delta^{\mathcal{R}}(b)$. Since for every $i \in \omega$ the transitions $\delta_i^{\mathcal{S}}$ and $\delta_i^{\mathcal{R}}$ are from the same state $q_i \neq \top$, $\vec{\delta}^{\mathcal{S}}$ is accepting in $\mathcal{S}$ if, and only if, $\vec{\delta}^{\mathcal{R}}$ is rejecting in $\mathcal{R}$. Assume that $\vec{\delta}^{\mathcal{S}}$ is accepting (the other case is analogous). We will show that $\mathbf{W}_{\mathcal{B}}$ is violated (if $\vec{\delta}^{\mathcal{R}}$ is accepting then $\mathbf{W}_{\mathcal{A}}$ is violated). Assume for the sake of contradiction that $\mathbf{W}_{\mathcal{B}}$ holds, as witnessed by a sequence of $\mathcal{B}$-transitions $\vec{\delta}^{\mathcal{B}} = \delta_0^{\mathcal{B}}\delta_1^{\mathcal{B}}\cdots \in \Delta^{\mathcal{B}}(b)$. By Remark 6 we obtain that whenever $m_i = \vee$ and $\delta_i^{\mathcal{S}}$ is a disjunctive transition of $\mathcal{S}$ then $\mathcal{P}_{\mathcal{B}}(\delta_i^{\mathcal{S}}, _)$ is constantly equal to d_i. By the assumption on $\vec{\delta}^{\mathcal{B}}$ from $\mathbf{W}_{\mathcal{B}}$ we know that whenever $m_i = \wedge$ then $f_i(\delta_i^{\mathcal{B}}) = d_i$. However, if $m_i = \wedge$ then $f_i(\delta_i^{\mathcal{B}}) = \mathcal{P}_{\mathcal{B}}(\delta_i^{\mathcal{S}}, \delta_i^{\mathcal{B}})$. Therefore, in both cases we know that $\mathcal{P}_{\mathcal{B}}(\delta_i^{\mathcal{S}}, \delta_i^{\mathcal{B}}) = d_i$. This means that the assumptions of Corollary 5 are met and at least one of the sequences $\vec{\delta}^{\mathcal{S}}$, $\vec{\delta}^{\mathcal{B}}$ is rejecting – a contradiction, since we assumed both these sequences to be accepting. ◀

6 Separability by game automata with priorities in C

In this section we present our last game-theoretic characterisation, namely game automata separability for a fixed finite set $C \subseteq \mathbb{N}$ of priorities. Fix two automata $\mathcal{A} = (\Sigma, Q^{\mathcal{A}}, q_0^{\mathcal{A}}, \Omega^{\mathcal{A}}, \Delta^{\mathcal{A}})$ and $\mathcal{B} = (\Sigma, Q^{\mathcal{B}}, q_0^{\mathcal{B}}, \Omega^{\mathcal{B}}, \Delta^{\mathcal{B}})$ over the same alphabet Σ. The game is a variation of $G^{\text{sep}}_{\text{game}}(\mathcal{A}, \mathcal{B})$ from Section 5 where Separator additionally plays priorities from C.

C-game-automata separability game $G^{\text{sep}}_{\text{game}}(\mathcal{A}, \mathcal{B}, C)$

At the i-th round:

- [S: c] Separator plays a priority $c_i \in C$.
- [I: a] Input plays a letter $a_i \in \Sigma$.
- [S: m] Separator plays a mode $m_i \in \{\vee, \wedge\}$.
- [S: f] Separator plays either
  - **a.** a selector $f_i \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{A}}(a_i)}$ for $\mathcal{A}$ if $m_i = \vee$, or
  - **b.** a selector $f_i \in \{\mathsf{L}, \mathsf{R}\}^{\Delta^{\mathcal{B}}(a_i)}$ for $\mathcal{B}$ if $m_i = \wedge$.
- [I: d] Input plays a direction $d_i \in \{\mathsf{L}, \mathsf{R}\}$.

Separator wins an infinite play $\pi = (c_0, a_0, m_0, f_0, d_0)(c_1, a_1, m_1, f_1, d_1)\cdots$ inducing a path $b = (a_0, d_0)(a_1, d_1)\cdots$ whenever both conditions below hold:

1. $\pi \in \mathbf{W}_{\mathcal{A}}$: If there exists an accepting sequence of transitions $\vec{\delta}^{\mathcal{A}} = \delta_0^{\mathcal{A}}\delta_1^{\mathcal{A}}\cdots \in \Delta^{\mathcal{A}}(b)$ s.t. for all $i \in \omega$ we have $(m_i = \vee) \Rightarrow f_i(\delta_i^{\mathcal{A}}) = d_i$, then $c_0c_1\cdots$ is accepting.
2. $\pi \in \mathbf{W}_{\mathcal{B}}$: If there exists an accepting sequence of transitions $\vec{\delta}^{\mathcal{B}} = \delta_0^{\mathcal{B}}\delta_1^{\mathcal{B}}\cdots \in \Delta^{\mathcal{B}}(b)$ s.t. for all $i \in \omega$ we have $(m_i = \wedge) \Rightarrow f_i(\delta_i^{\mathcal{B}}) = d_i$, then $c_0c_1\cdots$ is rejecting.

▶ **Lemma 12.** *Separator wins $G^{\text{sep}}_{\text{game}}(\mathcal{A}, \mathcal{B}, C)$ if, and only if, there exists a game automaton $\mathcal{S}$ with priorities in C separating* $\mathrm{L}(\mathcal{A})$, $\mathrm{L}(\mathcal{B})$.

This lemma can be proved similarly as Lemma 10 except for the acceptance condition of the separator which is given by the priorities c_i's as in the proof of Lemma 7.

A Complexity Approach to Tree Algebras: the Bounded Case

Thomas Colcombet
Université de Paris, CNRS, IRIF, F-75006, Paris, France

Arthur Jaquard
Université de Paris, CNRS, IRIF, F-75006, Paris, France

Abstract

In this paper, we initiate a study of the expressive power of tree algebras, and more generally infinitely sorted algebras, based on their asymptotic complexity. We provide a characterization of the expressiveness of tree algebras of bounded complexity.

Tree algebras in many of their forms, such as clones, hyperclones, operads, etc, as well as other kind of algebras, are infinitely sorted: the carrier is a multi sorted set indexed by a parameter that can be interpreted as the number of variables or hole types. Finite such algebras – meaning when all sorts are finite – can be classified depending on the asymptotic size of the carrier sets as a function of the parameter, that we call the complexity of the algebra. This naturally defines the notions of algebras of bounded, linear, polynomial, exponential or doubly exponential complexity...

We initiate in this work a program of analysis of the complexity of infinitely sorted algebras. Our main result precisely characterizes the tree algebras of bounded complexity based on the languages that they recognize as Boolean closures of simple languages. Along the way, we prove that such algebras that are syntactic (minimal for a language) are exactly those in which, as soon as there are sufficiently many variables, the elements are invariant under permutation of the variables.

1 Introduction

Infinitely sorted algebras occur naturally in many contexts of language theory, graph theory or logic. A typical example is the case of tree algebras (such as clones, hyperclones, operads): plugging a subtree into another one requires a mechanism for identifying the leaf/leaves in which the substitution has to be performed. Notions such as variables, hole types, or colors are used for that. Another example is the one of graphs (HR- and VR-algebras [8]) in which basic operations (a) glue graphs together using a set of colors (sometimes called ports) for identifying the glue-points, or (b) add all possible edges between vertices of fixed given colors. In these examples, the algebras are naturally sliced into infinitely many sorts based on the number of variables/hole types/colors that are used simultaneously.

However, a technical difficulty arises immediately when using such algebras. Even when all sorts are finite (what we call a finite algebra), these algebras are not really finite due to the infinite number of sorts. This forbids, for instance, to entirely and explicitly describe the whole algebra in a finite way. And this is of course a problem for describing and using these algebras in an algorithm. Indeed, a concrete algorithm can only maintain a subset of the

© Thomas Colcombet and Arthur Jaquard;
licensed under Creative Commons License CC-BY 4.0

algebra in its memory, say up to some given sort, or resort to other forms of representations, which often means not really working with the algebra. This is particularly annoying since often these objects are used for analyzing properties that admit finite descriptions, such as tree automata or logical formulae (eg in monadic second-order logic for describing properties of graphs).

This hurdle to handle infinitely sorted algebras can, arguably, be seen as one of the causes of the many years that it took before having a good definition of an algebra for infinite trees [2], or the time that it took before it was possible to characterize logically the expressiveness of recognizable properties of graphs under bounded tree-width hypothesis [4]. Also, the long history of results characterizing language families by decidable algebraic properties (initiated by the famous Schützenberger result [11]) has proven hard to extend to these more complex objects, such as trees.

Classifying algebras based on their complexity. In this paper, we initiate a new approach in the study of such algebras, which is to try to understand infinitely sorted algebras in simpler cases. And we define these simpler cases using complexity considerations. Indeed, in each of the above cases, the sorts are naturally indexed by a natural number parameter: the number of variables, or hole types, or colors. Hence, an algebra $\mathcal{A}$ would have a carrier of the form

$$(A_n)_{n\in\mathbb{N}},$$

together with suitable operations that depend on the particular algebra type. This algebra will be called *finite* if all the A_n sets are finite, and, in this case, we naturally define the *complexity map* of the algebra $c_{\mathcal{A}} \colon \mathbb{N} \to \mathbb{N}$ as follows:

$$c_{\mathcal{A}}(n) = |A_n| \ , \qquad \text{for all } n \in \mathbb{N}.$$

Finite algebras can naturally be classified using this map c. Simple classes are then *algebras of bounded complexity* if $c_{\mathcal{A}}$ is bounded, of *polynomial complexity* if $c_{\mathcal{A}}$ is bounded from above by some polynomial in n, etc.

Other interesting complexity classes can be defined using orbits. Indeed, in all of the mentioned examples, there is a natural operation that performs a renaming of the variables/hole types/colors. This renaming is parameterized by a bijection over variables/hole types/colors, and this permutation acts on the corresponding sort. Said differently, in all examples, there is an action of the symmetric group over n elements, $\mathbf{Sym}(n)$, over A_n. It is thus natural to consider the *orbit complexity map* $c^{\circ}_{\mathcal{A}}$ as follows

$$c^{\circ}_{\mathcal{A}}(n) = |A_n/\mathbf{Sym}(n)| \ , \qquad \text{for all } n \in \mathbb{N},$$

and define accordingly what are finite algebras of *bounded orbit complexity*, or *polynomial orbit complexity*, etc.

Related works. As mentioned above, there is a long history of understanding the expressive power of regular languages of words based on algebraic properties. The first work in this direction [11], characterizing star-free languages, intiated a long list of deep results. It was natural to extend this approach to trees. Here, the notion of algebra was less obvious, and several definitions have been used. Some algebras for trees are one sorted, such as deterministic bottom up automata (that can be seen as algebras). Some are two sorted, such as forest algebras [7]. Some others, such as preclones [9], have infinitely many sorts.

Characterizations of classes have been obtained using these approaches [5, 10, 6], but remain very limited due to difficulties inherent to the tree case. The study of algebras for infinite trees renewed the interest in these questions [1, 2, 3]. This line of works also highlights the difficulty to work with tree algebras, and the poor understanding we have so far of the mechanism of recognition for infinite objects.

Contributions of the paper. In this paper we establish some first results in this complexity analysis of infinitely sorted algebras, for the simplest complexity class, bounded complexity. Our results are of two kinds: a characterization of algebras of bounded complexity; and a characterization of the languages that they recognize, meaning we give a syntactic description of the properties that can be recognized by algebras in this class. We more particularly prove:

- A characterization of syntactic finite tree algebras of bounded complexity as those syntactic algebras in which, as soon as there are sufficiently many variables, the elements are invariant under permutation of variables. See Theorem 5.
- A characterization of languages recognized by finite tree algebras of bounded complexity as Boolean closures of simple languages. See Theorem 14.

The second result actually uses the first as a building block in its proof.

Structure of the paper. In Section 2, we recall some classical definitions, and introduce our notions of algebras. In Section 3, we look at the permutations of variables in finite tree algebras, and prove Theorem 5. In Section 4, we study in more depth the bounded complexity case for finite tree algebras, and establish our main result, Theorem 14. Section 5 is our conclusion.

2 Definitions

We denote by $\mathbb{N}$ the set of all non-negative integers. Given $n \in \mathbb{N}$, we write $[n] = \{0, 1, ..., n-1\}$. The symmetric group (resp. alternating group) over $[n]$ is denoted $\mathbf{Sym}(n)$ (resp. $\mathbf{Alt}(n)$), the symmetric group of any set X is denoted $\mathbf{Sym}(X)$. We denote by A^c the complement of a set A.

We fix a finite *ranked alphabet* Σ; the *arity* of a *symbol* $a \in \Sigma$ is denoted $\mathrm{ar}(a)$. It is a *constant* if $\mathrm{ar}(a) = 0$, and is *unary* if $\mathrm{ar}(a) = 1$. For $k \in \mathbb{N}$, we set $\Sigma_k = \{a \in \Sigma \mid \mathrm{ar}(a) = k\}$. A^* is the set of finite words over A, and $A^+ = A^* \setminus \{\varepsilon\}$.

2.1 Trees

In this section, we introduce notions and notations for trees.

We fix a countable set of *variables*. Given a finite set of variables X, a Σ, X-tree is, informally, a tree in which nodes are labelled by elements of Σ and leaves also possibly by variables. All variables have to appear at least once. Formally, a Σ, X*-tree* is a partial map $t \colon \mathbb{N}^* \to \Sigma \uplus X$ such that $\mathrm{dom}(t)$ is non-empty and prefix-closed, and furthermore:

- For all $u \in \mathrm{dom}(t)$ there exists $n \in \mathbb{N}$ such that $\{i \mid ui \in \mathrm{dom}(t)\} = [n]$, and
  - either $t(u) \in \Sigma_n$ (*symbol node*), or
  - $t(u) \in X$ and $n = 0$ (*variable node*). Note that a variable node is always a leaf.
- All variables from X appear in t, i.e. for all $x \in X$, $t(u) = x$ for some $u \in \mathrm{dom}(t)$.
- The root is not a variable, i.e. $t(\varepsilon) \notin X$.

$\Sigma, \emptyset$-trees are simply called Σ-*trees*. The elements in $\mathrm{dom}(t)$ are called *nodes*. The prefix relation over nodes is called the *ancestor relation*. The node ε is called the *root* of the tree. The tree t is *finite* if it has finitely many nodes. A *branch* of a tree t is a maximal set of nodes ordered under the ancestor relation. Let $\mathrm{FiniteTrees}(\Sigma, X)$ bet the set of finite Σ, X-trees, for all finite set of variables X.

Building trees. We introduce now some operations on trees. See Fig. 1.

- $a(x_0, \dots, x_{n-1})$, for $x_0, \dots, x_{n-1}$ variables and $a \in \Sigma_n$, denotes the $\Sigma, \{x_0, \dots, x_{n-1}\}$-tree consisting of a root labelled a, and children $0, \dots, n-1$ labelled with variables $x_0, \dots, x_{n-1}$ respectively.
- $s \cdot_x t$, for two trees $s \in \mathrm{FiniteTrees}(\Sigma, X)$, $t \in \mathrm{FiniteTrees}(\Sigma, Y)$ and a variable $x \in X$, is the $\Sigma, (X \setminus \{x\}) \cup Y$-tree s in which t is substituted for every occurrences of the variable x.
- $\widetilde{\sigma}(t)$, for a tree $t \in \mathrm{FiniteTrees}(\Sigma, X)$ and $\sigma \colon X \to Y$ a surjective map, is the Σ, Y-tree obtained as t in which variable $\sigma(x)$ has been substituted to x for all $x \in X$. Note that $\widetilde{\sigma} \circ \widetilde{\tau} = \widetilde{\sigma \circ \tau}$.
- $t[x_0 \leftarrow t_0, \dots, x_{n-1} \leftarrow t_{n-1}]$ denotes the tree of sort $X \setminus \{x_0, \dots, x_{n-1}\} \cup \bigcup_i Y_i$ obtained from t by simultaneously substituting the tree t_i for the variable x_i for all $i \in [n]$, where t is a tree of sort X, $x_0, \dots, x_{n-1} \in X$, and $t_0, \dots, t_{n-1}$ are trees of sort Y_i for all $i \in [n]$. Note that this operation is equivalent to a combination of the previous ones.
- $a(t_0, ..., t_{n-1})$, for $a \in \Sigma_n$, denotes the tree of root a and children $t_0, \dots, t_{n-1}$ at respective positions $0, \dots, n-1$. Again, this operation is equivalent to a combination of the previous ones.

▶ **Lemma 1.** *All finite trees can be obtained from the $a(x_0, \dots, x_{n-1})$'s using the operation $\cdot$.*

Expressions denoting finite trees. For X a finite set of variables, an FT_Σ-*expression of sort X (over the alphabet Σ)* is an expression built inductively as follows:

- $a(x_0, \dots, x_{n-1})$ is an FT_Σ-expression of sort $\{x_0, \dots, x_{n-1}\}$ for every symbol $a \in \Sigma_n$,
- $S \cdot_x T$ is an FT_Σ-expression of sort $X \setminus \{x\} \cup Y$ for all FT_Σ-expressions S of sort X, all FT_Σ-expressions T of sort Y, and all variables $x \in X$ (*substitution*),
- $\tilde{\sigma}(T)$ is an FT_Σ-expression of sort Y for all FT_Σ-expressions T of sort X, and surjective map $\sigma \colon X \to Y$ (*renaming*).

For an FT_Σ-expression T of sort X, $[\![T]\!]$ denotes its evaluation into a finite Σ, X-tree using the operations of substitution and renaming.

Contexts. We define now contexts, which are terms with a specific leaf called the hole. Since we work in a multi-sorted algebra, the hole itself has a sort. Essentially, to a hole of sort X will be substituted a term of sort X. Formally, for fixed finite set of variables Y, an *context of sort X with hole of sort Y* (or simply a FT_Σ-*context*) is defined inductively as an expression of sort X, using the extra construction $\Box_Y$ (the *hole of sort Y*) which is a context of sort Y with hole of sort Y. This new construction may appear multiple times in a context but has to appear at least once.

For C a context of sort X with hole of sort Y, $[\![C]\!] \colon \mathrm{FiniteTrees}(\Sigma, Y) \to \mathrm{FiniteTrees}(\Sigma, X)$ is the function which to a tree of sort Y t associates the tree of sort X obtained by evaluating the operations as above, interpreting $\Box_Y$ as t.

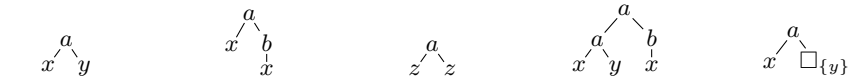

Figure 1 Trees and contexts with their notations. Here $\sigma(x) = \sigma(y) = z$.

2.2 Finite tree algebras

Our notion of tree algebra is the natural notion associated to finite trees equipped with the above operations. We give here a more formal definition, though the detail of identities is more for reference. What matters is that it is defined such that the free algebra coincides with finite trees.

An *FT_Σ-algebra* $\mathcal{A}$ consists of an infinite collection of carrier sets A_X indexed by finite sets of variables X, together with operations:

- $\sigma^{\mathcal{A}} \colon A_X \to A_Y$ for all surjective maps $\sigma \colon X \to Y$,
- $a(x_0, \dots, x_{n-1})^{\mathcal{A}} \in A_{\{x_0,\dots,x_{n-1}\}}$ for all $a \in \Sigma_n$ and variables $x_0, \dots, x_{n-1}$,
- $\cdot_x^{\mathcal{A}} \colon A_X \times A_Y \to A_{X \setminus \{x\} \cup Y}$ for all finite sets of variables X, Y and $x \in X$,

that satisfy the expected identities, i.e. the ones guaranteeing that several ways to describe the same tree yield the same evaluation in the algebra. Formally, for all s, t, u that belong to A_X, A_Y, A_Z respectively,

- $(s \cdot_x^{\mathcal{A}} t) \cdot_y^{\mathcal{A}} u = x \cdot_x^{\mathcal{A}} (t \cdot_y^{\mathcal{A}} u)$ for all $x \in X \cap Z$ and $y \in X \cap Y$ (horizontal associativity), and
- $(s \cdot_x^{\mathcal{A}} t) \cdot_y^{\mathcal{A}} u = x \cdot_x^{\mathcal{A}} (t \cdot_y^{\mathcal{A}} u)$ for all $x \in X$ and $y \in Y \setminus X \cup \{x\}$ (vertical associativity),

for all s, t that belong to A_X, A_Y, $x \in X$ and surjection $\sigma \colon X \to Y$,

- $\sigma^{\mathcal{A}}(s \cdot_x^{\mathcal{A}} t) = \sigma^{\mathcal{A}}(s) \cdot_x^{\mathcal{A}} t$ if $\sigma^{-1}(\sigma(x)) = \{x\}$ and $\sigma(y) = y$ for all $y \in X \cap Y \setminus \{x\}$,
- $\sigma^{\mathcal{A}}(s \cdot_x^{\mathcal{A}} t) = s \cdot_x \sigma^{\mathcal{A}}(t)$ if $\sigma(y) = y$ for all $y \in X \cap Y \setminus \{x\}$,

for all surjective maps $\sigma \colon X \to Y$ and $\tau \colon Y \to Z$, $(\tau \circ \sigma)^{\mathcal{A}} = \tau^{\mathcal{A}} \circ \sigma^{\mathcal{A}}$, and for all surjections $\sigma \colon \{x_0, \dots x_{n-1}\} \to Y$ and $a \in \Sigma_n$, $\sigma^{\mathcal{A}}(a(x_0, \dots, x_{n-1})^{\mathcal{A}}) = a(\sigma(x_0), \dots, \sigma(x_{n-1}))^{\mathcal{A}}$. In practice, we shall not explicitly use these identities, and simply write two elements of the algebra equal as soon as they obviously come from expressions denoting the same trees.

A *morphism of FT_Σ-algebras* from $\mathcal{A}$ to $\mathcal{B}$ is a family of maps $\alpha_X \colon A_X \to B_X$ for all finite sets of variables X which preserves all operations, i.e. $\alpha_Y(\sigma^{\mathcal{A}}(s)) = \sigma^{\mathcal{B}}(\alpha_X(s))$ for all surjective map $\sigma \colon X \to Y$, $\alpha(a(x_0, \dots, x_{n-1})^{\mathcal{A}}) = a(x_0, \dots, x_{n-1})^{\mathcal{B}}$, and $\alpha_{X \setminus \{x\} \cup Y}(s \cdot_x^{\mathcal{A}} t) = \alpha_X(s) \cdot_x^{\mathcal{B}} \alpha_Y(t)$ for all $s \in A_X$, $t \in A_Y$ and $x \in X$.

The FiniteTrees(Σ, X) sets equipped with the operations of substitution and renaming form an FT_Σ-algebra (it is the free FT_Σ-algebra generated by $\emptyset$). For $\mathcal{A}$ a FT_Σ-algebra, its associated *evaluation morphism* is the unique morphism from FiniteTrees(Σ) to $\mathcal{A}$.

A *congruence* $\sim$ over a FT_Σ-algebra $\mathcal{A}$ is a family $\sim$ of equivalence relations over the A_X's (each denoted $\sim$) such that, for any $a \sim b \in A_X$, $c \sim d \in A_Y$, $y \in Y$ and surjective $\sigma \colon X \to Y$: $c \cdot_y a \sim c \cdot_y b$; $c \cdot_y a \sim d \cdot_y a$ and $\widetilde{\sigma}(a) \sim \widetilde{\sigma}(b)$. From such a congruence, one can define the *quotient algebra* $\mathcal{A}/\sim$ in the natural way.

Compact presentation, and complexity. Our definition of algebras does not so far match the one used in the introduction. In the introduction, algebras were considered as using natural numbers as sorts, while here, our sorts are indexed by finite sets. What would be these algebras should be pretty clear. The presentation used here is simpler to present and to use. It is an exercise to show the equivalence.

What matters is that in what follows, a FT_Σ-algebra is of *bounded complexity* if there exists a bound K such that $|A_X| \leqslant K$ for all finite sets of variables X.

2.3 Languages and syntactic algebras

A *language of finite* Σ*-trees* L is a set of Σ-trees. It is *recognized by* an FT_Σ-algebra $\mathcal{A}$ if there is a set $P \subseteq A_\emptyset$ such that $L = \alpha^{-1}(P)$ in which α is the evaluation morphism of $\mathcal{A}$.

The *syntactic congruence* $\sim_L$ *of a language* L of finite Σ-trees is defined in the following way $s \sim_L t$ for s, t finite Σ-trees if, for all FT_Σ-contexts C, $[\![C]\!](s) \in L$ if and only if $[\![C]\!](t) \in L$. It is easy to prove that $\sim_L$ is indeed a congruence. The quotient algebra $\text{FiniteTrees}(\Sigma)/_{\sim_L}$ is called the *syntactic algebra* of L.

▶ **Example 2.** The language of all finite trees in which the symbol a appears has for syntactic FT_Σ-algebra the algebra with sorts $A_X = \{0, 1\}$, for all finite set of variables X, and whose evaluation morphism is such that $\alpha(t) = 1$ if and only if t is a tree in which a appears.

2.4 Tree automata

A *tree automaton* $\mathcal{B} = (Q, I, (\delta_a)_{a\in\Sigma})$ over Σ has a finite set Q of *states*, a set of *accepting states* $I \subseteq Q$ and a *transition relation* $\delta_a \subseteq Q \times Q^{\text{ar}(a)}$ for every symbol $a \in \Sigma$. A *run of* $\mathcal{B}$ over a finite tree t is a mapping $\rho\colon \text{dom}(t) \to Q$ such that, for any vertex $u \in \text{dom}(t)$ with $t(u) = a \in \Sigma$, $(\rho(u), (\rho(u0), ..., \rho(u(\text{ar}(a) - 1)))) \in \delta_a$. A run is *accepting* if $\rho(\varepsilon) \in I$. A language L of finite trees is called *regular* if it is recognized by a tree automaton $\mathcal{B}$, meaning the trees in L are exactly those for which there is an accepting run in $\mathcal{B}$.

Ex. 3 shows the translation from tree automata to tree algebra.

▶ **Example 3** (Automaton algebra)**.** Consider a regular language L of finite trees recognized by the tree automaton $\mathcal{B} = (Q, q_0, (\delta_a)_{a\in\Sigma})$.

Consider some finite set of variables X. An X*-run profile* is a tuple $\tau \in Q \times \mathcal{P}(Q)^X$. For a Σ, X-tree t, $\tau = (p, (U_x)_{x\in X})$ is a *run profile over* t if there exists a run ρ of the automaton over Q such that $\rho(\varepsilon) = p$ and for all variables $x \in X$, U_x is the set of states assumed by ρ at leaves labelled x. We define a tree algebra $\mathcal{A}$ that has as elements of sort X sets of X-run profiles. The definition of the operations is natural, and is such that the image of a Σ, X-tree t under the evaluation morphism yields the set of run profiles over t. It naturally recognizes the language L.

Note that this definition yields an algebra of doubly exponential complexity (and hence, this is an upper bound for regular languages). Of course, in practice, one can restrict the algebra to the reachable elements, and this may dramatically reduce the complexity.

The converse translation is also true, yielding the following classical result (it is for instance proved for preclones in [9]).

▶ **Proposition 4.** *A finite tree language is regular if and only if it is recognized by a finite* FT_Σ*-algebra.*

3 Fundamental results on permutations in tree algebras

This section studies some fundamental phenomena concerning the effect of variable permutations on tree algebras. Its main objective is to prove Theorem 5. It is a characterization of syntactic FT_Σ-algebras of bounded complexity which turns out to be key in the subsequent developments. Beyond that, several intermediate results in this section may also be relevant in the analysis of algebras of unbounded complexity.

In this section, given an FT_Σ-algebra $\mathcal{A}$, $\varphi_X^{\mathcal{A}}\colon \mathbf{Sym}(X) \to \mathbf{Sym}(A_X)$ (or simply φ_X when there is no ambiguity) denotes the group morphism $\sigma \mapsto \sigma^{\mathcal{A}}$, for all finite sets of variables X.

▶ **Theorem 5.** *A finite syntactic FT_Σ-algebra $\mathcal{A}$ is of bounded complexity if and only for all sufficiently large finite set of variables X, $\ker(\varphi_X^{\mathcal{A}}) = \boldsymbol{Sym}(X)$.*

The meaning of $\ker(\varphi_X) = \mathbf{Sym}(X)$ is that permuting the variables has no effect on A_X (i.e. $\sigma^{\mathcal{A}} = \mathrm{Id}_{A_X}$ for every $\sigma \in \mathbf{Sym}(X)$). We fix from now the FT_Σ-algebra $\mathcal{A}$.

Our first step is to define a relation $\equiv_{\mathcal{A}}$ which we show to be a congruence equivalent to the syntactic one (Proposition 6). We set for all $a \in A_X$:

$$\begin{aligned} \langle a \rangle : \quad (A_\emptyset)^X &\to A_\emptyset \\ b &\mapsto a[x_0 \leftarrow b(x_0), ..., x_{n-1} \leftarrow b(x_{n-1})] \ , \end{aligned}$$

in which $X = \{x_0, ..., x_{n-1}\}$. Define now $a \equiv_{\mathcal{A}} a'$, for $a, a' \in A_X$ to hold if $\langle a \rangle = \langle a' \rangle$ (note that it does not depend on the numbering of variables).

▶ **Proposition 6.** *$\equiv_{\mathcal{A}}$ is a congruence. If $\mathcal{A}$ is a syntactic FT_Σ-algebra, then $a = b$ if and only if $a \equiv_{\mathcal{A}} b$, for all a, b in $\mathcal{A}$.*

By a simple counting argument, we obtain the following corollary.

▶ **Corollary 7.** *Let $\mathcal{A}$ be a finite syntactic FT_Σ-algebra, then*

$$|A_X| \leq |A_\emptyset|^{|A_\emptyset|^{|X|}} \ .$$

Recall the following result from finite group theory:

▶ **Proposition 8.** *Let $\varphi \colon \boldsymbol{Sym}(X) \to G$ be a group morphism. If $|X| \geq 5$, then $\ker(\varphi)$ equals either $\boldsymbol{Sym}(X)$, $\boldsymbol{Alt}(X)$ or $\{\mathrm{Id}_X\}$.*

Using Propositions 6 and 8, we prove that, whenever X is large enough, $\ker(\varphi_X)$ may only be $\mathbf{Sym}(X)$ or $\{\mathrm{Id}_X\}$.

▶ **Proposition 9.** *Let $\mathcal{A}$ be a finite syntactic FT_Σ-algebra. There is an integer M such that, for all X of cardinal at least M, either $\ker(\varphi_X) = \boldsymbol{Sym}(X)$ or $\ker(\varphi_X) = \{\mathrm{Id}_X\}$.*

Proof. Let $M = \max(5, |A_\emptyset| + 1)$. Let X be a finite set of variables such that $|X| \geq M$. By Prop. 8, $\ker(\varphi_X)$ is either $\mathbf{Sym}(X)$, $\mathbf{Alt}(X)$ or $\{\mathrm{Id}_X\}$. Assume, for the sake of contradiction, that $\ker(\varphi_X) = \mathbf{Alt}(X)$. This implies that the image of φ_X has exactly 2 elements: permutations of signature $+1$ are sent to Id_{A_X}, and those of signature -1 are sent to another (distinct) element. Let us call τ this permutation of A_X.

Let $t \in \mathbf{Sym}(X)$ be a transposition, let us show that $t^{\mathcal{A}} = \mathrm{Id}_{A_X}$. According to Proposition 6, we only need to prove that $\langle t^{\mathcal{A}}(a) \rangle = \langle a \rangle$ for all $a \in A_X$. Let $b \in (A_\emptyset)^X$, since $n \geq |A_\emptyset| + 1$, there must exists $x \neq y$ in X such that $b(x) = b(y)$, thus: $\langle t^{\mathcal{A}}(a) \rangle(b) = \langle \tau(a) \rangle(b) = \langle (x\ y)^{\mathcal{A}}(a) \rangle(b) = \langle a \rangle(b \circ (x\ y)) = \langle a \rangle(b)$. Since this holds for all $a \in A_X$, $t^{\mathcal{A}} = \mathrm{Id}_{A_X}$. This is a contradiction. ◀

According to Proposition 9, for X large enough, $\ker(\varphi_X)$ may only be $\mathbf{Sym}(X)$ or $\{\mathrm{Id}_X\}$. The next result shows that one of these two cases in fact holds for all sufficiently large X.

▶ **Proposition 10.** *Let $\mathcal{A}$ be a finite syntactic FT_Σ-algebra. There is an integer M such that, either $\ker(\varphi_X) = \boldsymbol{Sym}(X)$ for all X with $|X| \geq M$, or $\ker(\varphi_X) = \{\mathrm{Id}_X\}$ for all X with $|X| \geq M$.*

By simple counting, if $\ker(\varphi_X) = \{\mathrm{Id}_X\}$, then $|\mathbf{Sym}(A_X)| \geq |\mathbf{Sym}(X)|$ and hence $|A_X| \geq |X|$. This yields the following corollary, which is one direction of Theorem 5.

▶ **Corollary 11.** *Let $\mathcal{A}$ be a syntactic FT_Σ-algebra of bounded complexity. There is an integer M such that, for every X with $|X| \geq M$,* $\ker(\varphi_X) = \boldsymbol{Sym}(X)$.

Heading toward the converse implication, we now show that when $\ker(\varphi_X) = \mathbf{Sym}(X)$, then $\langle a \rangle$ can only take very simple forms.

▶ **Lemma 12.** *Let $\mathcal{A}$ be a finite syntactic FT_Σ-algebra, and n be such that* $\ker(\varphi_X) = \boldsymbol{Sym}(X)$ *whenever $|X| \in \{n-1, n\}$. Then, for all $a \in A_X$ with $|X| = n$,*

$$\langle a \rangle(b) = \langle a \rangle(b')$$

for all $b, b' \in A_\emptyset^X$ such that $\mathrm{Im}(b) = \mathrm{Im}(b')$.

Proof. Note first that for $|X| \in \{n-1, n\}$ we have $\ker(\varphi_X) = \mathbf{Sym}(X)$. Hence for for all permutations $\sigma \in \mathbf{Sym}(X)$,

$$\langle a \rangle(b \circ \sigma) = \langle \sigma^{\mathcal{A}}(a) \rangle(b) = \langle a \rangle(b) \ . \tag{$\star$}$$

As a consequence, what matters is to prove that we can "duplicate" some $b(x)$'s. For $Y \subseteq X$ where $Y = \{y_0, ..., y_{k-1}\}$ as well as $h \in (A_\emptyset)^Y$ and $a \in A_X$, we simplify the notation with

$$a[h] = a[y_0 \leftarrow h(y_0), \ldots, y_{k-1} \leftarrow h(y_{k-1})] \ .$$

Let $x, y, z \in X$ be distinct variables and $b, b' \in (A_\emptyset)^X$ be such that b and b' coincide everywhere but for $b(z) = b(y)$ and $b'(z) = b(x)$, we claim that

$$\langle a \rangle(b) = \langle a \rangle(b') \ . \tag{$\star\star$}$$

Indeed, for σ that maps y to z and leaves all other variables unchanged, we have

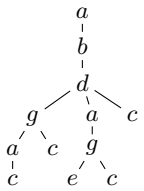
$$\begin{aligned}
a[x \leftarrow d, y \leftarrow d', z \leftarrow d'][h] &= \sigma^{\mathcal{A}}(a)[x \leftarrow d, z \leftarrow d'][h] \\
&= \sigma^{\mathcal{A}}(a)[x \leftarrow d', z \leftarrow d][h] && \text{(by } (\star) \text{ applied to } X \setminus \{y\}) \\
&= a[x \leftarrow d', y \leftarrow d, z \leftarrow d][h] && \text{(by } (\star) \text{ applied to } X) \\
&= a[x \leftarrow d, y \leftarrow d', z \leftarrow d][h] \ .
\end{aligned}$$

in which $d, d' \in A_\emptyset$ and $h \in (A_\emptyset)^{X \setminus \{x,y,z\}}$, from which the claim $(\star\star)$ follows.

At this point, $(\star\star)$ allows to change the value $b(z)$ to another providing that its values before and after the change appear elsewhere in b, and $(\star)$ allows to permute all the $b(x)$'s. Hence, by iterative applications of them, we obtain of $(\star)$ and $(\star\star)$, $\langle a \rangle(b) = \langle a \rangle(b')$ providing that b and b' have same image. ◀

As a consequence of the above lemma, assuming that $\ker(\varphi_X) = \mathbf{Sym}(X)$ for all sufficiently large X, we can bound the number of possible elements in A_X. This yields Corollary 13 below, which is the second direction of Theorem 5.

▶ **Corollary 13.** *A finite syntactic FT_Σ-algebra such that* $\ker(\varphi_X) = \boldsymbol{Sym}(X)$ *for all sufficiently large set of variables X, has bounded complexity.*



Proof. By Lemma 12, we know that, for $a \in A_X$, $\langle a \rangle$ must be chosen in a set of at most $|A_\emptyset|^{2^{|A_\emptyset|}}$ functions, this is an upper bound on the number of elements of A_X that does not depend on $|X|$ for X sufficiently large. ◀

4 Finite tree algebras of bounded complexity

The main theorem of this section, Theorem 14, provides a characterization of the languages recognized by FT_Σ-algebras of bounded complexity as Boolean combinations of simple languages. We proceed as follows. We state Theorem 14 and establish its easier parts in Section 4.1. In Section 4.2, we establish Lemma 22 which essentially amounts to the result for trees with "sufficiently many branches", which is the hardest part of the proof of Theorem 14.

4.1 Statement of the result

The main theorem of this section, Theorem 14, requires some preliminary definitions.

$\mathrm{upref}(t) = ab$ (unary prefix)

$\mathrm{fnu}(t) = d$ (first non-unary symbol)

$\mathrm{symb}(t) = \{a, b, c, d, e, g\}$ (symbols in t)

$\mathrm{pbsymb}(t) = \{a, c, e, g\}$ (post-branching symbols)

Figure 2 A finite tree t and its associated data.

For a given finite tree t, we associate to it some data (see Figure 2 for an illustration). Let n, be the depth of the first node labelled with a non unary symbol; formally, n is the least natural number such that $\mathrm{ar}(t(0^n)) \neq 1$. The *unary prefix* of t, denoted $\mathrm{upref}(t)$ is the word $t(0^1)...t(0^{n-1}) \in \Sigma_1^*$. The *first non-unary symbol of* t is $t(0^n)$, which we denote by $\mathrm{fnu}(t)$. The *set of symbols in* t is $\mathrm{symb}(t) = \{t(u) \mid u \in \mathrm{dom}(t)\}$ and its *set of post-branching symbols* is, if it exists, $\mathrm{pbsymb}(t) = \{t(0^n v) \mid 0^n v \in \mathrm{dom}(t), v \neq \varepsilon\}$.

▶ **Theorem 14.** *For a language of finite trees, the following properties are equivalent:*

1. *being recognized by a FT_Σ-algebra of bounded complexity,*
2. *having its syntactic FT_Σ-algebra of bounded complexity,*
3. *being equal to a Boolean combination of languages of the following kinds:*
   - **a.** *The language of finite trees with unary prefix in a given regular language of words $L \subseteq \Sigma_1^*$.*
   - **b.** *The language of finite trees with first non-unary symbol a for a fixed non-unary symbol a.*
   - **c.** *The language of finite trees with post-branching symbols B, for $B \subseteq \Sigma$.*
   - **d.** *A regular language K of* bounded branching*, meaning that there exists a natural number k such that all trees $t \in K$ have at most k branches.*

Let us establish the easiest parts of this statement. To start with, it is a generic fact– generic meaning independent of the type of algebras under consideration–that the syntactic FT_Σ-algebra of a language divides[1] any FT_Σ-algebra that recognizes the same language. Hence, each sort of the syntactic FT_Σ-algebra has a lesser size than the same sort in any other FT_Σ-algebra recognizing the same language. Thus 1 implies 2.

We now prove the second easiest implication, 3 implies 1. For this, it is sufficient to prove that the languages of kind 3a to 3d are recognized by FT_Σ-algebras of bounded complexity, and that FT_Σ-algebras of bounded complexity are closed under all the Boolean connectives. This is stated in Lemmas 15 to 17 below. All are straightforward.

[1] Divides in the morphism sense: being a quotient of a sub-algebra.

Given a regular language of words $L \subseteq \Sigma_1^*$, a non unary symbol a and a set $B \subseteq \Sigma$ of symbols, let us denote by $\mathrm{UPref}(L)$, $\mathrm{FNU}(a)$ and $\mathrm{PBSymb}(B)$, respectively the language of trees with unary prefix in L, the language of trees with first non-unary symbol c, and the language of trees t with $\mathrm{pbsymb}(t) = B$. Lemma 15 shows that these languages are recognized by algebras of bounded complexity, i.e. it treats Cases 3a to 3c.

▶ **Lemma 15.** *Given a regular language of words L, a non unary symbol $a \in \Sigma_{\neq 1}$ and a set of symbols $B \subseteq \Sigma$, the languages* $\mathrm{UPref}(L)$, $\mathrm{FNU}(a)$ *and* $\mathrm{PBSymb}(B)$ *are recognized by FT_Σ-algebras of bounded complexity.*

Proof. For space considerations, we only detail the case of $\mathrm{UPref}(L)$, which is arguably the hardest one. Let $\varphi\colon \Sigma_1^* \to M$ be a monoid morphism that recognizes L, meaning there exists $P \subseteq M$ such that $\varphi^{-1}(P) = L$. Define on $\mathrm{FiniteTrees}(\Sigma)$ the relation $\sim$ by $s \sim t$ if $\varphi(\mathrm{upref}(s)) = \varphi(\mathrm{upref}(t))$, this relation is easily seen to be a congruence, and $\mathrm{UPref}(L)$ is obviously recognized by the quotient algebra $\mathrm{FiniteTrees}(\Sigma)/\sim$. Because $\sim$ only has $|M|$ equivalence classes in every sort, we just described a FT_Σ-algebra recognizing $\mathrm{UPref}(L)$ of bounded complexity. ◀

Next we deal with the languages that have bounded branching, i.e. Case 3d. It is done with a modification of the automaton algebra of Example 3 so that it is also able to count the number of branches of a tree up to the bound k. The key observation is that a tree with k different variables must have at least k branches. This means that the sort A_X where X is a finite set of variables such that $|X| > k$ can be collapsed to one element only. Note that this is tightly related to our assumption that every variable from X must occur in all Σ, X-trees. We do not give any further detail here.

▶ **Lemma 16.** *The regular languages of finite trees of bounded branching are recognized by FT_Σ-algebras of bounded complexity.*

Finally, using standard constructions, we can provide the last ingredient of the proof that 3 implies 1 in Theorem 14:

▶ **Lemma 17.** *The languages recognized by FT_Σ-algebras of bounded complexity are closed under Boolean operations.*

4.2 Trees with many branches

In this section, we fill the missing gap in the proof of Theorem 14, namely the implication from 2 to 3.

Given two finite trees s and t and a FT_Σ-algebra $\mathcal{A}$ with evaluation morphism α, let $s \simeq_{\mathcal{A}} t$ hold if $\alpha(s) = \alpha(t)$. We omit the sub- and superscript $\mathcal{A}$ when it is clear from the context. Our goal is to prove Lemma 22 which states that if $\mathcal{A}$ is of bounded complexity, then for all trees s and t with sufficiently many branches, if $\mathrm{upref}(s) = \mathrm{upref}(t)$, $\mathrm{fnu}(s) = \mathrm{fnu}(t)$ and $\mathrm{pbsymb}(s) = \mathrm{pbsymb}(t)$, then $s \simeq_{\mathcal{A}} t$

Given an $\Sigma, X \uplus \{\gamma_1, \ldots, \gamma_n\}$-tree t in which the γ_i's only appear once, and given trees $t_1, \ldots, t_n$, we denote $t(t_1, \ldots, t_n)$ the tree $t[\gamma_1 \leftarrow t_1, \ldots, \gamma_n \leftarrow t_n]$. We will use these distinguished variables γ_i's in this section.

The results we prove throughout this section are consequences of the properties of permutations in FT_Σ-algebras of bounded complexity and, more particularly, consequences of Corollary 11. Our first objective is to show that if there are sufficiently many branches in a tree, it is possible to exchange any two subtrees which are not related by the ancestor

relationwithout changing evaluation in the algebra (see Lemma 20). Lemma 18 is a first step towards this goal: it says that, in a syntactic algebra, whenever a tree has many branches, it is possible to exchange *some* of its subtrees. More precisely:

▶ **Lemma 18.** *For every syntactic FT_Σ-algebras $\mathcal{A}$ of bounded complexity, there exists an integer N_0 such that, for all finite trees $t(t_1, t_2)$ such that t has at least N_0 branches,*

$$t(t_1, t_2) \simeq_{\mathcal{A}} t(t_2, t_1) \ .$$

Proof. Let N_0 be the integer introduced in Corollary 11. Assume that t is a $\Sigma, X \uplus \{\gamma_1, \gamma_2\}$-tree that has at least N_0 branches. Let s be a $\Sigma, X \uplus \{\gamma_1, \gamma_2\} \uplus \{x_1, ..., x_{N_0-2}\}$-tree and let s_0, ..., s_{N_0-2} be trees such that $s[x_1 \leftarrow s_1, ..., x_{N_0-2} \leftarrow s_{N_0-2}] = t$. As such, s has at least N_0 variables. Hence by Corollary 11, $t' \simeq_{\mathcal{A}} \sigma^{\mathcal{A}}(t')$ in which σ is the transposition of γ_1 and γ_2. We now compute:

$$\begin{aligned} t(t_1, t_2) &\simeq_{\mathcal{A}} s[\gamma_1 \leftarrow t_1, \gamma_2 \leftarrow t_2][x_1 \leftarrow s_1, ..., x_{N_0-2}] \\ &\simeq_{\mathcal{A}} \sigma^{\mathcal{A}}(s)[\gamma_1 \leftarrow t_1, \gamma_2 \leftarrow t_2][x_1 \leftarrow s_1, ..., x_{N_0-2}] \\ &= s[\gamma_1 \leftarrow t_2, \gamma_2 \leftarrow t_1][x_1 \leftarrow s_1, ..., x_{N_0-2}] = t(t_2, t_1) \ . \end{aligned}$$

◀

Here, notice the similarity between this proof and the observations we made in the proof of Lemma 12: this is the exact same argument, we just used the fact that a tree with many branches can always be obtained from some tree with many variables. Taking this similarity further, we may apply the other arguments we used in the proof of Lemma 12 to prove Lemma 19, and change the number of occurrences of plugged subtrees.

▶ **Lemma 19.** *For every syntactic FT_Σ-algebras $\mathcal{A}$ of bounded complexity, there exists an integer N_1 such that, for any finite tree $t(t_1, t_2, t_2)$ such that t has at least N_1 branches,*

$$t(t_1, t_2, t_2) \simeq_{\mathcal{A}} t(t_1, t_1, t_2) \ .$$

The next step is to establish Lemma 20, which is very similar to the previous Lemma 18 but for the fact that it is sufficient to have many branches in $t(t_1, t_2)$ instead of many branches in t to be allowed to swap t_1 and t_2. It is obtained by repeated and careful applications of Lemma 18.

▶ **Lemma 20.** *For all syntactic FT_Σ-algebras $\mathcal{A}$ of bounded complexity, there is an integer N_3 such that, for any finite tree $t(t_1, t_2)$ where $t(t_1, t_2)$ has at least N_3 branches,*

$$t(t_1, t_2) \simeq_{\mathcal{A}} t(t_2, t_1) \ .$$

As such, we may exchange two subtrees of a tree with many branches without changing evaluation in the algebra. We will use this result to prove that two trees with the same unary prefix, first non-unary symbol and set of post-branching symbols are not distinguished by the algebra (Lemma 22).

Using Lemmas 19 and 20, we first establish Lemma 21 that allows in some situation to make a symbol "appear" or "disappear".

▶ **Lemma 21.** *For all syntactic FT_Σ-algebras $\mathcal{A}$ of bounded complexity, there exists an integer N_4 that has the following property. For all finite trees $s(\gamma_1, \gamma_2)$, all finite trees t with at least N_4 branches, and all symbols $c, d \in \mathrm{symb}(t)$, c constant,*

$$s(t, c) \simeq_{\mathcal{A}} s(t, d(c, \dots, c)) \ .$$

In combination with Lemmas 19 and 20, it means that under the same assumptions, $s(t, c) \simeq_{\mathcal{A}} s(t, t')$ for all finite trees t' that use only symbols appearing in t. This building block, used iteratively, allows to shuffle and change the number of occurrences of all symbols that appear below a first non-unary symbol as soon as there are sufficiently many branches. This is our key Lemma 22.

▶ **Lemma 22.** *Let $\mathcal{A}$ be a syntactic FT_Σ-algebra of bounded complexity. There is an integer N, such that, for all finite trees s and t, both of which have at least N branches, if* $\mathrm{upref}(s) = \mathrm{upref}(t)$, $\mathrm{fnu}(s) = \mathrm{fnu}(t)$ *and* $\mathrm{pbsymb}(t) = \mathrm{pbsymb}(t)$, *then $t \simeq_{\mathcal{A}} s$.*

Putting everything together we establish the last implication in Theorem 14:

▶ **Lemma 23.** *A language of finite trees L recognized by a FT_Σ-algebra of bounded complexity can be written as a Boolean combination of languages of kinds 3a-3d in Theorem 14.*

The idea behind this last proof is as follows. Given a regular word language $K \subseteq \Sigma_1^*$, a non-unary symbol a, and a set of symbols B, let $L_{K,a,B}$ be the set of trees t such that $\mathrm{upref}(t) \in K$, $\mathrm{fnu}(t) = a$ and $\mathrm{pbsymb}(t) = B$. Such languages can be written as the intersection of $\mathrm{UPref}(K)$, $\mathrm{FNU}(a)$ and $\mathrm{PBSymb}(B)$ which are of the kinds 3a-3d in Theorem 14. Let N be the value from Lemma 22.

In a first step, we construct finitely many tuples (K_i, a_i, B_i), such that L and $\bigcup_i L_{K_i,a_i,B_i}$ coincide over all trees with sufficiently many branches. For this, for all $t \in L$ with at least N branches, consider the least language $K_t \subseteq \Sigma_1^*$ recognized by $A_{\{x\}}$ such that $\mathrm{upref}(t) \in K_t$ (in which $\mathrm{upref}(t)$ is recognized by $A_{\{x\}}$ when seen as a tree made of unary symbols and the variable x). The language K_t is regular and has the property that exchanging the unary prefix of t for any other word in K_t leaves the tree in L. We use as the (K_i, a_i, B_i)'s all the tuples $(K_t, \mathrm{fnu}(t), \mathrm{pbsymb}(t))$ for t ranging over the trees in L with at least N branches (note that since all the K_t's are recognized by $A_{\{x\}}$, there are finitely many of them). One can show using Lemma 22 that, as claimed, L and $\bigcup_i L_{K_i,a_i,B_i}$ coincide over all trees with at least N branches. In a second step one defines L_i to be the set of trees in L_{K_i,a_i,B_i} that have at least N branches. Let also L' be L restricted to trees with less than N branches. One gets

$$L = L' \cup \bigcup_i L_i \ ,$$

and this is by construction a Boolean combination of languages of the kinds 3a-3d.

This concludes our proof of Lemma 23, and hence Theorem 14.

5 Conclusion

In this paper, we initiated a complexity analysis of the expressiveness of infinitely sorted algebras. Our main result gives a descriptive characterization of the languages of finite trees recognized by algebras of bounded complexity, Theorem 14. In this work, we made a design choice in the definition of tree algebras. Indeed, we require that in a tree of sort X, every variable occurs at least once. Removing this assumption would change our bounded complexity characterization result, yielding only Boolean combinations of languages of the form "the root symbol is a". Another possible variant is to allow trees restricted to a single variable: in this case our results remain unchanged.

Extensions to infinite trees. We also obtained a similar characterization for algebras for infinite trees. We did not include it in this short abstract for space considerations (this was in fact our original question). In this case, the algebras have to include an extra iterating construct that allows to build all infinite regular trees (i.e. unfolding of finite graphs). By Rabin's lemma, regular languages of infinite trees are entirely characterized by the regular trees they contain, and as a consequence such algebras describe regular languages of infinite trees. Our result characterizes such algebras of bounded complexity along the same line as Theorem 14. We show that over infinite trees, such algebras can express two extra things (1) the existence of subtrees of unary shape that belong to a prescribed prefix-invariant regular language of infinite words, and (2) the existence of subtrees in which a set of letters C appears densely, i.e. every letter in C appears in every subtree.

Future work. The next simplest cases seem to be the algebras of polynomial complexity and of bounded orbit complexity. An example in this case is the language of Σ-trees such that the leftmost branch does not contain the symbol a (we assume the existence of other symbols of arity 0, and at least 2). It is recognized by an algebra which is both of polynomial complexity and bounded orbit complexity. So far, we do not even know whether these two classes differ.

Improved Lower Bounds for Reachability in Vector Addition Systems

University of Warsaw, Poland

Abstract

We investigate computational complexity of the reachability problem for vector addition systems (or, equivalently, Petri nets), the central algorithmic problem in verification of concurrent systems. Concerning its complexity, after 40 years of stagnation, a non-elementary lower bound has been shown recently: the problem needs a tower of exponentials of time or space, where the height of tower is linear in the input size. We improve on this lower bound, by increasing the height of tower from linear to exponential. As a side-effect, we obtain better lower bounds for vector addition systems of fixed dimension.

1 Introduction

Petri nets [38] are a long established model of concurrency, with extensive applications in modelling and analysis of hardware [6, 25], software [16, 5, 20] and database [3, 4] systems, as well as chemical [1], biological [37, 2] and business [43, 31] processes (the references on applications are illustrative). The model admits various alternative but essentially equivalent presentations, most notably *vector addition systems* (VAS) [22], and *vector addition systems with states* (VASS) [17, Sec.5], [19]. The central algorithmic problem for this model is reachability: whether from the given initial configuration there exists a sequence of valid execution steps that reaches the given final configuration. Each of the alternative presentations admits its own formulation of the reachability problem, all of them being equivalent due to straightforward polynomial-time translations that preserve reachability; for further details, see e.g. Schmitz's survey [42, Section 2.1]. For instance, in terms of VAS, the problem is stated as follows: given a finite set T of integer vectors in d-dimensional space and two d-dimensional vectors $\mathbf{v}$ and $\mathbf{w}$ of nonnegative integers, does there exist a walk from $\mathbf{v}$ to $\mathbf{w}$ such that it stays within the nonnegative orthant, and its every step modifies the current position by adding some vector from T? Emphasizing VASS, a natural extension of VAS with finite control, in the sequel we use the name 'VASS reachability problem'.

Importance of the problem is widespread, as a plethora of problems from formal languages [8], logic [21, 11, 10, 7], concurrent systems [15, 13], process calculi [35], linear algebra [18] and other areas (the references are again illustrative) are known to admit reductions from the VASS reachability problem; for more such problems and a wider discussion, we refer to [42].

State of the art. The complexity of the VASS reachability problem was remaining unsettled over the past half century. The late 1970s and the early 1980s saw the initial burst of activity. After an incomplete proof by Sacerdote and Tenney [40], decidability of the problem was established by Mayr [33, 34], whose proof was then simplified by Kosaraju [23]. Building on the further refinements made by Lambert in the 1990s [24], there has been substantial progress over the past ten years [26, 27, 28], culminating in the first upper bound on the complexity [29], recently improved to Ackermannian [30].

In contrast to the progress on refining the proof of decidability and obtaining upper bounds on the complexity, Lipton's landmark result that the VASS reachability problem requires exponential space [32] has remained the state of the art on lower bounds for over 40 years. Moreover, in conjunction with an apparent tightness of Lipton's construction, this has led to the conjecture that the problem is ExpSpace-complete becoming common in the community. The conjecture has been falsified by a recent breakthrough construction of [9] that shows the VASS reachability problem is hard for the class Tower of all decision problems that are solvable in time or space bounded by a tower of exponentials whose height is an elementary (bounded by a tower of exponentials of fixed height) function of the input size.

Contribution. This paper provides a further improvement on the lower bound. The construction of [9] proves hardness of the VASS reachability problem for the class Tower, with respect to elementary reductions. However, in terms of the more fine-grained hierarchy defined with respect to polynomial-time reductions only, the result states that the problem needs a tower of exponentials of time or space, where the height of tower is linear in input size. As our primary result we increase the height of the tower from linear to exponential, namely we prove that the problem actually needs a tower of exponentials of time or space, where the height of the tower is itself exponential in input size:

$$\left.2^{2^{2^{\cdots^{n}}}}\right\} \text{ height } \mathcal{O}(n) \qquad \rightsquigarrow \qquad \left.2^{2^{2^{\cdots^{n}}}}\right\} \text{ height } 2^{\mathcal{O}(n)}.$$

In addition, as a side effect of our improved construction we obtain better lower bounds for VASS of fixed dimension. It has been known, as shown in [9], that the reachability problem for VASS in dimension d is $\mathcal{O}(d)$-ExpSpace-hard (specifically: d-ExpSpace-hardness for dimension $d + 13$). We show that the reachability problem for VASS in dimension d is $2^{\mathcal{O}(d)}$-ExpSpace-hard (specifically: 2^d-ExpSpace-hardness for dimension $2d + 13$).

Clearly, these new lower bounds do not formally exclude the VASS reachability problem from still being in Tower (and hence being Tower-complete with respect to elementary reductions). However, we believe that the result makes this less likely. Intuitively speaking, we rule out a natural algorithmic scheme of solving the reachability problem, where each additional control state or dimension leads to an additional exponential blowup of time or space. Presently, the most optimistic scheme must suffer, for each additional control state or dimension, from at least *doubling* of the number of exponentials.

Organisation of the paper. We start by defining the model, in Section 2, and then the reachability problem, in Section 3. In the latter section we also recall the lower bounds of [9] and formally formulate our improved ones. The following two sections are devoted to proofs. First, in Section 4 we show 2^d-ExpSpace-hardness of the reachability problem for VASS of dimension $2d + 13$, as a preparation before Section 5, in which we prove our primary result: without restriction on dimension, the problem needs a tower of exponentials of time or space, of height exponential in input size.

2 Counter programs

As mentioned in the introduction, Petri nets [38], VAS [22], and VASS [17, 19] are alternative presentations of the same model of concurrent processes, in the sense that between each pair there exist straightforward polynomial-time translations that preserve reachability [42, Sec. 2.1]. Following [12] and [9], instead of working directly with VASS, as our primary language we choose imperative nondeterministic programs operating on variables called counters, that range over nonnegative integers. These programs may be seen as user-friendly presentations of VASS.

Counter programs. A counter program is a sequence of commands, each of which is of one of the following three types:

$\mathsf{x} \mathrel{+}= 1$	(increment counter x)
$\mathsf{x} \mathrel{-}= 1$	(decrement counter x)
goto L **or** L'	(jump to either line L or line L')

except that the last command is of the form:

halt if $\mathsf{x}_1, \ldots, \mathsf{x}_l = 0$ (terminate provided all the listed counters are zero).

Counters are only allowed to have nonnegative values, they may be incremented or decremented but, notably, counters may not be zero-tested. As an illustration, consider the following program:

1: **goto** 7 **or** 2
2: $\mathsf{x} \mathrel{+}= 1$
3: $\mathsf{x}' \mathrel{-}= 1$
4: $\mathsf{y} \mathrel{+}= 1$
5: $\mathsf{y} \mathrel{+}= 1$
6: **goto** 1
7: **halt if** $\mathsf{x}' = 0$.

It repeats the block of three commands in lines 2–5 some number of times chosen nondeterministically (possibly zero, although not infinite because x' is decreasing and hence its initial value bounds the number of iterations) and then halts provided counter x' is zero.

We emphasise that counters are not permitted to have negative values. In the example above, that is why the decrement in line 3 works also as a non-zero test.

We assume that initially all counters are set to 0. A run of a counter program is a sequence of commands, as expected. We say that such a run is *halting* if, and only if it has successfully executed its **halt** command (which is necessarily the program's last); otherwise, the run is either *partial* or *infinite*. Observe that, due to a decrement that would cause a counter to become negative, or due to an unsuccessful terminal check for zero, a partial run may fail to continue because it is blocked from further execution. Moreover, due to nondeterministic jumps, the same program may have various runs in each of the three categories: halting runs, maximal partial runs, and infinite runs.

By the *size* of a program we mean the number of commands in it, and by its *dimension* we mean the number of counters. We sometimes speak also of *program fragments*, which are not ended with a **halt** command.

3 The reachability problem

Counter programs can be seen as presentations of VASS, where the latter are required to start with all vector components zero and to finish with vector components zero as specified by the **halt** command, and hence the VASS reachability problem can be stated as:

VASS REACHABILITY PROBLEM
Input: A counter program.
Question: Does it have a halting run?

We remark that restricting further to programs where no counter is required to be zero finally (i.e., where the last command is just **halt**) turns this problem into the VASS *coverability* problem, which is concerned with reachability of just a control location, with no requirement on the final values of counters. Lipton's EXPSPACE lower bound [32] holds already for the coverability problem, which is in fact EXPSPACE-complete [39].

For stating our results we recall the standard complexity classes bases on exponential hierarchy of fast-growing functions. We write $\mathcal{T}(n)$ for a tower of exponentials:

$$\mathcal{T}_2(k,n) \;=\; 2^{2^{2^{\cdots^{n}}}} \Big\} \text{ height } k \qquad\qquad \mathcal{T}(n) \;=\; \mathcal{T}_2(n,n) \;=\; 2^{2^{2^{\cdots^{n}}}} \Big\} \text{ height } n.$$

Formally, let $\mathcal{T}_2(0,n) = n$ and $\mathcal{T}_2(k+1,n) = 2^{\mathcal{T}_2(k,n)}$. For a fixed positive integer k, the class k-EXPSPACE contains all decision problems solvable in space $\mathcal{T}_2(k, \text{poly}(n))$. The class TOWER contains all decision problems solvable in time or space bounded by a tower of exponentials whose height is an elementary function of the input size, namely

$$\text{TOWER} \;=\; \bigcup_{f \text{ elementary}} \text{SPACE}(\mathcal{T}(f(n)))$$

with $f(_)$ ranging over all *elementary* functions, i.e., functions bounded by $\mathcal{T}_2(k,_)$ for some k. TOWER is thus closed under elementary reductions.

For the results of this paper we need a fine-grained hierarchy inside TOWER, with respect to dependency of the height of exponentials on the input size. For a fixed elementary function f, let $f(n)$-TOWER denote the class of all decision problems solvable in (time or) space $\mathcal{T}(f(\text{poly}(n)))$, i.e., in (time or) space bounded by a tower of exponentials of height $f(n^k)$, for some k, where n is the input size:

$$f(n)\text{-TOWER} \;=\; \bigcup_{k\in\mathbb{N}} \text{SPACE}(\mathcal{T}(f(n^k))).$$

Each class $f(n)$-TOWER is a strict subclass of TOWER as it is closed under polynomial-time reductions but, contrarily to TOWER, not under arbitrary elementary reductions.

We recall the results of [9]. First, once one fixes the dimension of VASS, the reachability problem requires a tower of exponentials of space, where the height of the tower is linear in the dimension:

▶ **Theorem 1** ([9], Cor. 5). *For any positive integer d, the* VASS *reachability problem in dimension $d+13$ is d-*EXPSPACE*-hard, with respect to polynomial-time*[1] *reductions.*

[1] All results mentioned in this section are actually shown using linear-time reductions.

The main result of [9] is a non-elementary lower bound of the VASS reachability problem: TOWER-hardness with respect to elementary reductions. The construction of [9] shows that the problem requires a tower of exponentials of space, where the height of tower is linear in the input size, and hence the result can be stated in terms of the fine-grained hierarchy as follows:

▶ **Theorem 2** ([9], Thm. 4). *The* VASS *reachability problem is hard for* n-TOWER*, with respect to polynomial-time reductions.*

As our first main result, we improve the lower bound of Theorem 1, namely we prove that solving the VASS reachability problem in dimension $2d + 13$ requires at least $\mathcal{T}_2(2^d, n)$ space:

▶ **Theorem 3.** *For any positive integer* d*, the* VASS *reachability problem in dimension* $2d + 13$ *is* 2^d*-*EXPSPACE*-hard.*

Clearly, without restriction of dimension, Theorem 3 does not exclude membership of the problem in TOWER, neither it excludes its membership in n-TOWER. Our primary result excludes the latter possibility: it states that the VASS reachability problem requires a tower of exponentials of space, where the height of tower is exponential in the input size, thus improving the bound of Theorem 2:

▶ **Theorem 4.** *The* VASS *reachability problem is hard for* 2^n*-*TOWER*, with respect to polynomial-time reductions.*

Again, Theorem 4 does not formally exclude membership of the VASS reachability problem in TOWER, it makes it however less imaginable as mentioned in the introduction.

Theorems 3–4 are proved in the following two sections. The proofs are a refinement and an optimisation of the construction of [9], involving certain amount of programming effort in the setting of counter programs.

4 Proof of Theorem 3

In this and in the next section we proceed by reductions from space-bounded variants of the halting problem for the standard model of (deterministic) Minsky machines [36]. The reader is referred to [14, Theorem 3.1] for translations between space-bounded 3-counter Minsky machines and Turing machines.

Following [9], for technical reasons we prefer to work with factorials instead of exponentials. We write $\mathcal{F}(k, _)$ for the tower of factorials of height k: $\mathcal{F}(0, n) = n$ and $\mathcal{F}(k+1, n) = \mathcal{F}(k, n)!$. We note that all the complexity classes from the previous section are robust with respect to the choice of the fast-growing function hierarchy: exponential function can be equivalently replaced by factorial [41, Section 4.1].

Our proof is a refinement of the reduction of [9], from the following bounded version of the halting problem for Minsky machines with 3 counters, which is $(k-1)$-EXPSPACE-complete for any fixed positive integer k:

k-EXP-BOUNDED HALTING PROBLEM

Input: A 3-counter Minsky machine $\mathcal{M}$ of size n.

Question: Does it have a halting run where all counters are bounded by $\mathcal{F}(k, n)$?

Let h be a fixed positive integer. Given a 3-counter Minsky machine $\mathcal{M}$ of size n, the reduction of [9, Lem. 6] transforms $\mathcal{M}$, in time $\mathcal{O}(n+h)$, into a counter program $\mathcal{P}$ with $h+13$ counters, including $h+2$ counters $\mathsf{x}_{-1}, \mathsf{x}_0, \mathsf{x}_1, \ldots, \mathsf{x}_h$ which are required to be zero by the final **halt** command, plus 11 other counters, of the form[2]

$$\underbrace{\mathcal{H}_{-1}}_{\text{size } \mathcal{O}(n)} \quad \underbrace{\mathcal{H}_0 \quad \mathcal{H}_1 \quad \cdots \quad \mathcal{H}_h}_{\text{constant size each}} \quad \underbrace{\mathcal{H}_{h+1}}_{\text{size } \mathcal{O}(n)} \quad \textbf{halt if } \mathsf{x}_{-1}, \mathsf{x}_0, \ldots, \mathsf{x}_h = 0,$$

for some program fragments $\mathcal{H}_{-1}, \mathcal{H}_0, \ldots, \mathcal{H}_{h+1}$ (for technical convenience, the indexing starts at -1). We refer to the program fragments $\mathcal{H}_{-1}, \mathcal{H}_0, \ldots, \mathcal{H}_{h+1}$ as *segments*. Furthermore, the first segment $\mathcal{H}_{-1}$ and the last one $\mathcal{H}_{h+1}$ are of size $\mathcal{O}(n)$, the remaining ones are of constant size, and the reduction is correct due to:

▷ Claim 5 (Correctness). $\mathcal{M}$ has a halting run with all counters bounded by $\mathcal{F}(h+1, n)$ if, and only if, $\mathcal{P}$ has a halting run.[3]

Moreover, the counter program $\mathcal{P}$ has the following two crucial properties:

(i) Each counter x_j appearing in the final **halt** command appears in segments $\mathcal{H}_j$ and $\mathcal{H}_{j+1}$ only, for $j = -1, 0, \ldots, h$:

$$\underbrace{\mathcal{H}_{-1}}_{\mathsf{x}_{-1} \text{ only here}} \quad \overbrace{\underbrace{\mathcal{H}_0}_{\mathsf{x}_1 \text{ only here}} \quad \mathcal{H}_1}^{\mathsf{x}_0 \text{ only here}} \quad \overbrace{\mathcal{H}_2 \quad \mathcal{H}_3}^{\mathsf{x}_2 \text{ only here}} \quad \ldots \quad \underbrace{\mathcal{H}_{h-1}}_{\mathsf{x}_{h-1} \text{ only here}} \quad \overbrace{\mathcal{H}_h \quad \mathcal{H}_{h+1}}^{\mathsf{x}_h \text{ only here}}.$$

We say, to some extent informally, that $\mathcal{P}$ is a *relay-race* with respect to counters $\mathsf{x}_{-1}, \mathsf{x}_0, \ldots, \mathsf{x}_h$, by which we mean the last appearance of every counter x_j, for $j < h$, is in the same segment as the first appearance of the next counter x_{j+1}, and counters x_j and x_{j+2}, for $j < h-1$, never appear in the same segment.

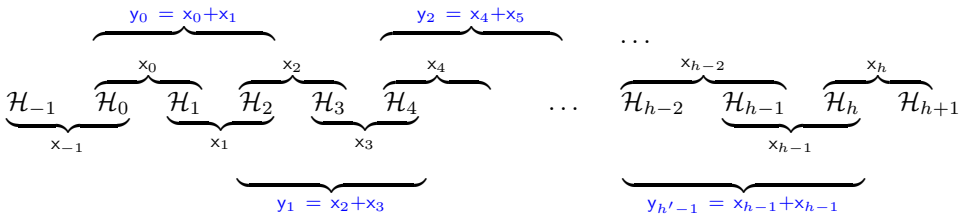
(ii) Each segment $\mathcal{H}_j$, for $j = 0, 1, \ldots, h$, is obtained from the same[4] program fragment $\mathcal{H}$, not using counters $\mathsf{x}_{-1}, \mathsf{x}_0, \ldots, \mathsf{x}_h$, by replacing a counter x appearing in $\mathcal{H}$ by x_{j-1}, and another counter x' appearing in $\mathcal{H}$ by x_j. We denote the replacement as:

$$\mathcal{H}_j \quad = \quad \mathcal{H}[\mathsf{x} \mapsto \mathsf{x}_{j-1},\ \mathsf{x}' \mapsto \mathsf{x}_j]. \tag{1}$$

Let $h = 2^d$ for some positive integer d. We prove Theorem 3 by transforming $\mathcal{P}$ into an equivalent counter program $\widetilde{\mathcal{P}}$ of (slightly larger) size $\mathcal{O}(n + d \cdot 2^d)$, but of exponentially smaller dimension $2d+13$. We will rely on the relay-race property with respect to h counters $\mathsf{x}_0, \mathsf{x}_1, \ldots, \mathsf{x}_{h-1}$ (call these counters *relay-race counters*), and thus the transformation will not affect counters x_{-1} and x_h. The intuitive idea is to re-cycle counters $\mathsf{x}_0, \mathsf{x}_1, \ldots, \mathsf{x}_{h-1}$ appearing in segments $\mathcal{H}_0, \mathcal{H}_1, \ldots, \mathcal{H}_h$. Our transformation proceeds in $(d-1)$ steps, in each step reducing by half the number of relay-race counters and adding two additional fresh counters.

---

[2] Whenever convenient we compose counter program fragments horizontally, for the ease of presentation.



[3] Roughly speaking, $\mathcal{H}_{-1}$ simply computes n, then the sequence of segments $\mathcal{H}_0, \mathcal{H}_1, \ldots, \mathcal{H}_h$ is responsible for computation of $(h+1)$th iterate of factorial of n, which is then used in $\mathcal{H}_{h+1}$ for simulating $\mathcal{M}$.

[4] For the ease of presentation we slightly simplify the structure of $\mathcal{P}$; in fact, in order to rigorously express the construction of [9] one needs to use two different program fragments instead of just one $\mathcal{H}$, one of them for even j and the other one for odd j. As will be clear later, this simplification is inessential.

The first step. We split the first step of the transformation into two sub-steps. As the first sub-step, consider the following transformation of $\mathcal{P}$. Let $h' = \frac{1}{2}h = 2^{d-1}$. We introduce h' additional fresh counters $\mathsf{y}_0, \ldots, \mathsf{y}_{h'-1}$, initially set to 0, with the idea that counter y_k invariantly equals to the sum of counters $\mathsf{x}_{2k} + \mathsf{x}_{2k+1}$. This is achieved by adding, immediately after each command anywhere in fragments $\mathcal{H}_0, \mathcal{H}_1, \ldots, \mathcal{H}_{h-1}$ that operates on counter x_j, for $j = 0, \ldots, h-1$, an additional command operating in the same way on $\mathsf{y}_{j \text{ div } 2}$:

$$\mathsf{x}_j \mathrel{*}= 1 \qquad \mapsto \qquad \mathsf{x}_j \mathrel{*}= 1 \quad \mathsf{y}_{j \text{ div } 2} \mathrel{*}= 1,$$

where j div 2 is the largest nonnegative integer k such that $2k \leq j$, and $* \in \{+, -\}$. This addition yields a counter program $\mathcal{P}'$ (recall that both h and h' are even):

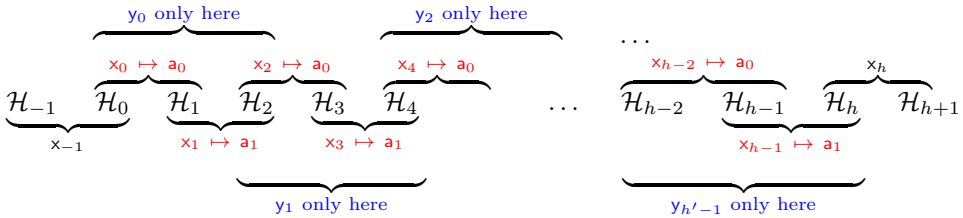
(2)

Furthermore, we remove counters $\mathsf{x}_0, \mathsf{x}_1, \ldots, \mathsf{x}_{h-1}$ from the **halt** command, and put counters $\mathsf{y}_0, \mathsf{y}_1, \ldots, \mathsf{y}_{h'-1}$ instead:

$$\textbf{halt if } \mathsf{x}_{-1}, \mathsf{x}_0, \ldots, \mathsf{x}_h = 0 \qquad \mapsto \qquad \textbf{halt if } \mathsf{x}_{-1}, \mathsf{x}_h, \mathsf{y}_0, \mathsf{y}_1, \ldots, \mathsf{y}_{h'-1} = 0.$$

▷ Claim 6. $\mathcal{P}'$ satisfies invariantly $\mathsf{y}_k = \mathsf{x}_{2k} + \mathsf{x}_{2k+1}$, for $k = 0, 1, \ldots, h'-1$.

We use that claim for entailing:



▷ Claim 7 (Correctness). $\mathcal{P}$ has a halting run if, and only if, $\mathcal{P}'$ has one.

Proof. We show that halting runs of $\mathcal{P}$ are in one-to-one correspondence with halting runs of $\mathcal{P}'$, using Claim 6 in both directions. In one direction, every halting run of $\mathcal{P}$, ending with all counters $\mathsf{x}_{-1}, \mathsf{x}_0, \ldots, \mathsf{x}_h$ equal 0, has a corresponding halting run of $\mathcal{P}'$ ending with $\mathsf{x}_{-1}, \mathsf{x}_h$ and all added counters $\mathsf{y}_0, \mathsf{y}_1, \ldots, \mathsf{y}_{h'-1}$ equal 0 as well. For the opposite direction consider any halting run of $\mathcal{P}'$. As every counter y_k is 0 at the end of the run, the sum of every two consecutive counters $\mathsf{x}_{2k} + \mathsf{x}_{2k+1}$ is 0 at the end, and hence also each individual counter x_j is *forced* to be 0 as well (without even checking that it is so, in the final **halt** command). Therefore, dropping operations on the added counters yields a halting run of $\mathcal{P}$. ◁

As the second sub-step, we introduce two fresh counters a_0, a_1, and replace each operation on every counter x_j, for $j = 0, 1, \ldots, h-1$, anywhere in segments $\mathcal{H}_0, \mathcal{H}_1, \ldots, \mathcal{H}_{h-1}$, by the analogous operation on $\mathsf{a}_{j \text{ mod } 2}$.

$$\mathsf{x}_j \mathrel{*}= 1 \qquad \mapsto \qquad \mathsf{a}_{j \text{ mod } 2} \mathrel{*}= 1. \tag{3}$$

The replacement removes h counters $\mathsf{x}_0, \mathsf{x}_1, \ldots, \mathsf{x}_{h-1}$ definitely from $\mathcal{P}'$, yielding a counter program $\mathcal{P}''$:

(4)

with the same **halt** command as $\mathcal{P}'$. Note that the size of $\mathcal{P}''$ is larger by $\mathcal{O}(2^d)$ than the size of $\mathcal{P}$, but its dimension decreased from $2^d + 13$ to $2^{d-1} + 15$, as $h = 2^d$ counters have been removed and another $h' + 2 = 2^{d-1} + 2$ counters have been introduced instead.

We have thus completed the description of a transformation $\mathcal{P} \mapsto \mathcal{P}''$. Formally, by composing the two sub-steps, we see that $\mathcal{P}''$ has the form:

$$\underbrace{\mathcal{H}_{-1}}_{\text{size } \mathcal{O}(n)} \quad \underbrace{\mathcal{H}''_0 \quad \mathcal{H}''_1 \quad \cdots \quad \mathcal{H}''_h}_{\text{constant size each}} \quad \underbrace{\mathcal{H}_{h+1}}_{\text{size } \mathcal{O}(n)} \quad \textbf{halt if } \mathsf{x}_{-1}, \mathsf{x}_h, \mathsf{y}_0, \mathsf{y}_1, \ldots, \mathsf{y}_{h'-1} = 0,$$

where each segment $\mathcal{H}''_i$ is obtained from $\mathcal{H}_i$ by the simultaneous substitution, for all $j = 0, 1, \ldots, h-1$:

$$\mathsf{x}_j \mathrel{*}= 1 \qquad \mapsto \qquad \mathsf{a}_{j \bmod 2} \mathrel{*}= 1 \quad \mathsf{y}_{j \operatorname{div} 2} \mathrel{*}= 1. \tag{5}$$

The following fact is crucial for correctness, i.e., for proving that the second sub-step, and hence also the whole step, preserves reachability:

▷ Claim 8. In every halting run of $\mathcal{P}''$, $\mathsf{a}_{j \bmod 2} = 0$ at the end of $\mathcal{H}''_{j+1}$ for every $j \in \{0, \ldots, h-1\}$.

Proof. Consider any halting run of $\mathcal{P}''$. By induction on j we prove that for every *even* $j \in \{0, 1, \ldots, h-1\}$, $\mathsf{a}_0 = 0$ at the end of $\mathcal{H}''_{j+1}$, and $\mathsf{a}_1 = 0$ at the end of $\mathcal{H}''_{j+2}$.

Let $j \geq 0$ and asssume the claim holds for smaller values of j. Let $v_0 \in \mathbb{N}$ (resp. $v_1 \in \mathbb{N}$) denote the value of counter a_0 (resp. counter a_1), at the beginning of fragment $\mathcal{H}''_j$ (resp. $\mathcal{H}''_{j+1}$). By induction assumption (or due to initial 0 values of counters) we have $v_0 = v_1 = 0$. According to the substitution (5), every operation on a_0 in $\mathcal{H}''_j$ and $\mathcal{H}''_{j+1}$ (recall that these are the only fragments where x_j appears) is also performed on $\mathsf{y}_{j \operatorname{div} 2}$. Likewise, every operation on a_1 in $\mathcal{H}''_{j+1}$ and $\mathcal{H}''_{j+2}$ (these are the only fragments where x_{j+1} appears) is also performed on $\mathsf{y}_{j \operatorname{div} 2}$. Also according to (5), these are the only operations on $\mathsf{y}_{j \operatorname{div} 2}$ performed along the run. Therefore, denoting by v'_0 (resp. v'_1) the value of counter a_0 (resp. counter a_1), at the end of fragment $\mathcal{H}''_{j+1}$ (resp. $\mathcal{H}''_{j+2}$), we know that the value of counter $\mathsf{y}_{j \operatorname{div} 2}$ at the end of the run is $(v'_0 - v_0) + (v'_1 - v_1) = v'_0 + v'_1$. As the counter $\mathsf{y}_{j \operatorname{div} 2}$ is checked to be 0 by the final **halt** command, we deduce $v'_0 + v'_1 = 0$. Finally, since both values are necessarily nonnegative, we deduce $v'_0 = v'_1 = 0$, as required. ◁

▷ Claim 9 (Correctness). $\mathcal{P}'$ has a halting run if, and only if, $\mathcal{P}''$ has one.

Proof. We show that halting runs of $\mathcal{P}'$ are in one-to-one correspondence with halting runs of $\mathcal{P}''$. As $\mathcal{P}''$ is obtained from $\mathcal{P}'$ by merging all counters x_j, for even j, to one counter a_0, and all counters x_j, for odd j, to one counter a_1, every halting run of $\mathcal{P}'$ has a corresponding halting run of $\mathcal{P}''$ such that a_0 is the sum of values of all counters x_j for even j and a_1 is the sum of values of all counters x_j for odd j. For the opposite direction we rely on Claim 8. According to the claim, replacing in a halting run of $\mathcal{P}''$ each operation on $\mathsf{a}_{j \bmod 2}$ in $\mathcal{H}''_j$ and $\mathcal{H}''_{j+1}$ by the same operation on x_j is safe, namely it is guaranteed that counters x_j stay nonnegative. Therefore we get a halting run of $\mathcal{P}''$. ◁

Iterating steps. A crucial but simple observation, cf. (4), is that the so described step of the transformation preserves the relay-race property, and hence can be iterated:

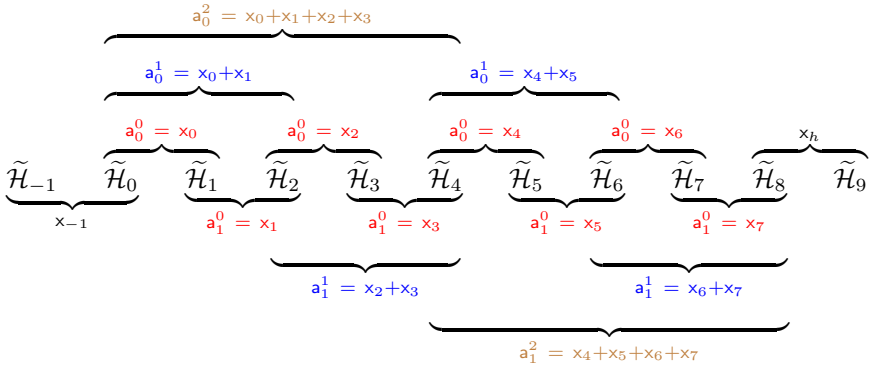
▷ Claim 10 (Relay-race preservation). The counter program $\mathcal{P}''$ is a relay-race with respect to counters $\mathsf{y}_0, \mathsf{y}_1, \ldots, \mathsf{y}_{h'-1}$.

Proof. According to the substitution (5), each counter y_k only appears in three consecutive segments $\mathcal{H}''_{2k}, \mathcal{H}''_{2k+1}$ and $\mathcal{H}''_{2k+2}$. Therefore the relay-race condition is satisfied: the last appearance of every counter y_k, for $k+1 < h'$, is in the same segment $\mathcal{H}''_{2k+2}$ as the first appearance of the next counter y_{k+1}, and counters y_k and y_{k+2}, for $k+2 < h'$, never appear in the same segment. ◁

We apply the transformation step $d-1$ times. Initially, $\mathcal{P}$ has 2^d relay-race counters, and 13 other counters including x_{-1} and x_h. Each ith iteration, for $i = 0, 1, \ldots, d-2$, decreases the number of relay-race counters twice, from 2^{d-i} to 2^{d-i-1}, and adds two additional counters a^i_0 and a^i_1. Therefore, after $d-1$ iterations[5] we arrive at a counter program $\widetilde{\mathcal{P}}$ with just two relay-race counters, say $\mathsf{z}_0, \mathsf{z}_1$, plus $2(d-1)$ added counters, say a^i_0, a^i_1 for $i = 0, 1, \ldots, d-2$, and 13 remaining counters, of the form:

$$\underbrace{\mathcal{H}_{-1}}_{\text{size } \mathcal{O}(n)} \quad \underbrace{\widetilde{\mathcal{H}}_0 \quad \widetilde{\mathcal{H}}_1 \quad \cdots \quad \widetilde{\mathcal{H}}_h}_{\text{size } \mathcal{O}(d) \text{ each}} \quad \underbrace{\mathcal{H}_{h+1}}_{\text{size } \mathcal{O}(n)} \qquad \textbf{halt if } \mathsf{x}_{-1}, \mathsf{x}_h, \mathsf{z}_0, \mathsf{z}_1 = 0. \tag{6}$$

By iterating the substitution (5), one sees that $\widetilde{\mathcal{H}}_i$ is actually obtained from $\mathcal{H}_i$ by the following simultaneous substitution, for $* \in \{+, -\}$ and $j = 0, 1, \ldots, h-1$



$$\mathsf{x}_j \mathrel{*}= 1 \qquad \mapsto \qquad \mathsf{a}^0_{j_0} \mathrel{*}= 1 \quad \mathsf{a}^1_{j_1} \mathrel{*}= 1 \quad \ldots \quad \mathsf{a}^{d-2}_{j_{d-2}} \mathrel{*}= 1 \quad \mathsf{z}_{j_{d-1}} \mathrel{*}= 1, \tag{7}$$

where $j_{d-1} \ldots j_1 j_0 = \text{BIN}(j)$ is the binary representation of j using d bits, in the order of decreasing significance of bits. Indeed, observe that $j_0 = j \bmod 2$, $j_1 = (j \operatorname{div} 2) \bmod 2$, $j_2 = ((j \operatorname{div} 2) \operatorname{div} 2) \bmod 2$, and so on. Therefore, by iterating the substitution (5), we first replace x_j by $\mathsf{a}^0_{j_0}$ and a relay-race counter $\mathsf{y}_{j \operatorname{div} 2}$, then replace $\mathsf{y}_{j \operatorname{div} 2}$ by $\mathsf{a}^1_{j_1}$ and some further relay-race counter $\mathsf{z}_{(j \operatorname{div} 2) \operatorname{div} 2}$, and so on. In the sequel we uniformly write a^{d-1}_b instead of z_b appearing in (6) and (7), for $b = 0, 1$. Let $\overline{b} = 1 - b$ denote bit negation.

▷ Claim 11. In every halting run of $\widetilde{\mathcal{P}}$, $\mathsf{a}^i_b = 0$ at the end of $\widetilde{\mathcal{H}}_j$ for every $j \in \{1, \ldots, h\}$ such that $j_i = \overline{b}$ and $j_{i-1} = \ldots = j_0 = 0$.

Proof. Follows by iterating the substitution (5) and Claim 8. ◁

▶ **Example 12.** As an illustration consider $d = 3$, and hence $h = 8$. The construction yields a counter program $\widetilde{\mathcal{P}}$ with 6 added counters $\mathsf{a}^0_0, \mathsf{a}^0_1, \mathsf{a}^1_0, \mathsf{a}^1_1, \mathsf{a}^2_0, \mathsf{a}^2_1$, and hence of dimension 19. Halting runs of $\mathcal{P}$ and $\widetilde{\mathcal{P}}$ are in one-to-one correspondence, and the values of counters $\mathsf{x}_0, \mathsf{x}_1, \ldots, \mathsf{x}_7$ in a halting run of $\mathcal{P}$ are related, via the equalities depicted below, to the values of counters $\mathsf{a}^0_0, \mathsf{a}^0_1, \mathsf{a}^1_0, \mathsf{a}^1_1, \mathsf{a}^2_0, \mathsf{a}^2_1$ in the corresponding halting run of $\widetilde{\mathcal{P}}$.

[5] One additional dth iteration could be also performed, which would however result in replacing 2 counters by 3 other ones, and hence the dimension would increase.

Indeed, iterating the proof of Claims 7 and 9 three times, we learn that a_b^i is the sum of values of all counters x_j where $j_i = b$, for instance $\mathsf{a}_0^1 = \mathsf{x}_0 + \mathsf{x}_1 + \mathsf{x}_4 + \mathsf{x}_5$. However, according to Claim 11, we have $\mathsf{a}_0^1 = 0$ at the end of $\widetilde{\mathcal{H}}_2$, and hence $\mathsf{a}_0^1 = \mathsf{x}_4 + \mathsf{x}_5$ in $\widetilde{\mathcal{H}}_4 \dots \widetilde{\mathcal{H}}_6$.

In particular, we obtain (cf. Claim 14 below) 8-ExpSpace-hardness for VASS in dimension 19 which, according to Theorem 1, has been known before to be 6-ExpSpace-hard. ⌟

▷ Claim 13 (Correctness). $\mathcal{P}$ has a halting run if, and only if, $\widetilde{\mathcal{P}}$ has one.

Proof. Iterating Claims 7 and 9 we deduce that halting runs of $\mathcal{P}$ are in one-to-one correspondence with halting runs of $\widetilde{\mathcal{P}}$. In one direction, every halting run of $\mathcal{P}$ has a corresponding halting run of $\widetilde{\mathcal{P}}$ where each counter a_b^i, for $i = 0, 1, \dots, d-2$ and $b = 0, 1$, invariantly equals to the sum of all counters x_j with $j_i = b$: $\mathsf{a}_b^i = \sum_{j \,:\, j_i = b} \mathsf{x}_j$. For the opposite direction we deduce, using Claim 11, that dropping operations on the added counters in every halting run of $\widetilde{\mathcal{P}}$, and replacing each operation on $\mathsf{a}_{j \bmod 2}$ in $\widetilde{\mathcal{H}}_j$ and $\widetilde{\mathcal{H}}_{j+1}$ by the same operation on x_j, yields a halting run of $\mathcal{P}$. ◁

The dimension of $\widetilde{\mathcal{P}}$ is $2d + 13$. The size of every segment $\widetilde{\mathcal{H}}_j$, for $j = 0, 1, \dots, h$, is $\mathcal{O}(d)$ times the constant size of $\mathcal{H}_j$, therefore the size of $\widetilde{\mathcal{P}}$ is $\mathcal{O}(n + d \cdot 2^d)$.

Due to Claims 5 and 13, the reduction $\mathcal{M} \mapsto \mathcal{P}$ of [9], composed with the transformation $\mathcal{P} \mapsto \widetilde{\mathcal{P}}$ just described, yield the required reduction $\mathcal{M} \mapsto \widetilde{\mathcal{P}}$:

▷ Claim 14. Let d be a positive integer. Given a 3-counter Minsky machine $\mathcal{M}$ of size n, one can compute in time $\mathcal{O}(n + d \cdot 2^d)$ a counter program $\widetilde{\mathcal{P}}$ of dimension $2d + 13$ such that $\mathcal{M}$ has a halting run with counters bounded by $\mathcal{F}(2^d + 1, n)$ if, and only if, $\widetilde{\mathcal{P}}$ has a halting run.

For every fixed d the reduction is computable in linear time with respect to the input size n, and hence the VASS reachability problem in dimension $2d + 13$ is 2^d-ExpSpace-hard.

5 Proof of Theorem 4

In order to prove Theorem 4 we refine further our reduction from Section 4. The refinement involves certain amount of low-level programming with counter programs.

Formally, we will set up a linear-time reduction from the following problem:

EXP-TOWER HALTING PROBLEM
Input: A 3-counter Minsky machine $\mathcal{M}$ of size n.
Question: Does it have a halting run where all counters are bounded by $\mathcal{F}(2^n, n)$?

We argue, similarly as before, that the problem is complete for the class 2^n-Tower, with respect to polynomial-time reductions, cf. [14, Theorem 3.1] and [41, Section 4.1].

In this section we strongly rely on condition (ii) from Section 4: each segment $\mathcal{H}_j$ in (6), for $j = 0, 1, \dots, h$, is obtained by the substitution (1) applied to the same program fragment $\mathcal{H}$ of constant size. Combining this substitution with the substitution (7) we deduce that each $\widetilde{\mathcal{H}}_j$, for $j = 0, 1, \dots, h$, is obtained from $\mathcal{H}$ by applying the following two substitutions:

$$\begin{array}{lcl} \mathsf{x} \mathrel{*}= 1 & \mapsto & \mathcal{C}^*_{j-1} \\ \mathsf{x}' \mathrel{*}= 1 & \mapsto & \mathcal{C}^*_{j} \end{array} \tag{8}$$

where program fragments $\mathcal{C}^*_j$ are defined, for $* \in \{+, -\}$ and $j = 0, 1, \dots, h-1$, as the sequence of commands:

$$\mathcal{C}^*_j \quad = \quad \mathsf{a}^0_{j_0} \mathrel{*}= 1 \quad \mathsf{a}^1_{j_1} \mathrel{*}= 1 \quad \dots \quad \mathsf{a}^{d-2}_{j_{d-2}} \mathrel{*}= 1 \quad \mathsf{a}^{d-1}_{j_{d-1}} \mathrel{*}= 1.$$

We apply here the proviso that the former substitution, referring to x, is not applied when $j = 0$, and the latter one, referring to x', is not applied when $j = h$. Indeed, recalling (1) and (4), x in $\mathcal{H}_0$ refers actually to x_0, and likewise x' in $\mathcal{H}_j$ refers actually to x_{h+1}.

Relying on the substitutions (8) we are going to optimise the counter program $\widetilde{\mathcal{P}}$, as defined in (6), by replacing all segments $\widetilde{\mathcal{H}}_1, \ldots, \widetilde{\mathcal{H}}_{h-1}$ by a *single* program fragment $\overline{\mathcal{G}}$ of size $\mathcal{O}(d)$, and thus obtaining the final counter program $\overline{\mathcal{P}}$ (see (11) below).

We start by defining a single program fragment $\mathcal{C}^*$ of size $\mathcal{O}(d)$ that achieves the effect of any $\mathcal{C}^*_j$ in a way parametric with respect to j. The program fragment $\mathcal{C}^*$ uses a bit-wise representation of the value of j, ranging over $0, \ldots, h-1$. To this aim we introduce d new counters $\mathsf{b}_0, \mathsf{b}_1, \ldots, \mathsf{b}_{d-1}$ to represent the binary representation $\textsc{bin}(j) = j_{d-1} \ldots j_0$ of current value j; thus these counters will only take values 0 or 1. In addition, we introduce another d counters $\overline{\mathsf{b}}_0, \overline{\mathsf{b}}_1, \ldots, \overline{\mathsf{b}}_{d-1}$ to represent negations of bits $\mathsf{b}_0, \mathsf{b}_1, \ldots, \mathsf{b}_{d-1}$. We are going to enforce the following equalities to hold invariantly:

$$\mathsf{b}_i + \overline{\mathsf{b}}_i = 1 \qquad (\text{for } i = 0, \ldots, d-1). \tag{9}$$

In particular, as expected, counters b_i are initialised to 0, while counters $\overline{\mathsf{b}}_i$ are incremented to 1 at the start of $\overline{\mathcal{P}}$. Having (9), one easily implements a conditional construct

$$\textbf{if } \mathsf{b}_i = 1 \textbf{ then } \mathcal{G} \textbf{ else } \mathcal{G}' \tag{10}$$

that executes one of program fragments $\mathcal{G}$, $\mathcal{G}'$ depending on the value of the ith bit b_i:

1: **goto** 2 **or** 5
2: b_i $-{=}$ 1 $\quad$ b_i $+{=}$ 1
3: $\mathcal{G}$
4: **goto** 7
5: $\overline{\mathsf{b}}_i$ $-{=}$ 1 $\quad$ $\overline{\mathsf{b}}_i$ $+{=}$ 1
6: $\mathcal{G}'$
7: ...

Note that exactly one of the two branches fails (because of $\mathsf{b}_i = 0$ or $\overline{\mathsf{b}}_i = 0$) and the other one succeeds. Line 2 is a non-zero test on b_i, while line 5 is, due to the equality (9), a *zero-test* on b_i. The original values of counters $\mathsf{b}_i, \overline{\mathsf{b}}_i$ are retrieved by increments in lines 2 and 5. The conditional construct allows us to write the code for $\mathcal{C}^*$:

if $\mathsf{b}_0 = 1$ **then** $\mathsf{a}_1^0 *{=} 1$ **else** $\mathsf{a}_0^0 *{=} 1$
if $\mathsf{b}_1 = 1$ **then** $\mathsf{a}_1^1 *{=} 1$ **else** $\mathsf{a}_0^1 *{=} 1$
...
if $\mathsf{b}_{d-1} = 1$ **then** $\mathsf{a}_1^{d-1} *{=} 1$ **else** $\mathsf{a}_0^{d-1} *{=} 1$

Also, using the above conditional construct (10) as a building block, one writes down two further program fragments $\mathcal{I}nc$ and $\mathcal{D}ec$, both of size $\mathcal{O}(d)$. Fragment $\mathcal{I}nc$ (resp. $\mathcal{D}ec$) increments (resp. decrements) the current value j represented by counters $\mathsf{b}_0, \ldots, \mathsf{b}_{d-1}$, assuming that this value is below $h-1$ (resp. above 0), by means of bit operations. In order to keep the invariant (9), every increment b_i $+{=}$ 1 of ith bit is accompanied by the corresponding decrement $\overline{\mathsf{b}}_i$ $-{=}$ 1, and symmetrically every decrement b_i $-{=}$ 1 of ith bit is accompanied by the increment $\overline{\mathsf{b}}_i$ $+{=}$ 1.

Let $\overline{\mathcal{H}}$ denote the result of applying the following substitutions to $\mathcal{H}$, for $* \in \{+, -\}$:

$$\mathsf{x} *{=} 1 \quad \mapsto \quad \mathcal{D}ec \;\; \mathcal{C}^* \;\; \mathcal{I}nc$$
$$\mathsf{x}' *{=} 1 \quad \mapsto \quad \mathcal{C}^*$$

This exactly implements substitutions (8): assuming the current value of j is represented in counters b_i and $\overline{\mathsf{b}}_i$, as described above, execution of the program fragment $\mathcal{C}^*$ has the same effect as execution of $\mathcal{C}_j^*$; and execution of $\mathcal{D}ec\ \mathcal{C}^*\ \mathcal{I}nc$ has the same effect as decrementing j, executing $\mathcal{C}_j^*$, and incrementing j to retrieve its actual current value, which is equivalent to execution of $\mathcal{C}_{j-1}^*$.

The size of $\overline{\mathcal{H}}$ is $\mathcal{O}(d)$. It remains to wrap up this program fragment inside a loop that increments the value j, represented by counters $\mathsf{b}_0, \ldots, \mathsf{b}_{d-1}$, from 0 to $h-1$. Using an aggregated conditional construct **if** $\mathsf{b}_0 = \mathsf{b}_1 = \ldots = \mathsf{b}_{d-1} = 1$ **then goto** L of size $\mathcal{O}(d)$, defined as expected, we write down the following program fragment $\overline{\mathcal{G}}$, again of size $\mathcal{O}(d)$:[6]

1: $\mathcal{I}nc$
2: **if** $\mathsf{b}_0 = \mathsf{b}_1 = \ldots = \mathsf{b}_{d-1} = 1$ **then goto** 6
3: $\overline{\mathcal{H}}$
4: $\mathcal{I}nc$
5: **goto** 2
6: ...

Assuming the initial values $\mathsf{b}_i = 0$ and $\overline{\mathsf{b}}_i = 1$ for all $j = 0, \ldots, d-1$, $\overline{\mathcal{G}}$ sets values $\mathsf{b}_i = 1$ and $\overline{\mathsf{b}}_i = 0$ for all $j = 0, \ldots, d-1$, once line 6 is reached. We use $\overline{\mathcal{G}}$ as a part of the final counter program $\overline{\mathcal{P}}$. As the substitutions (8) apply fully only when $j = 1, \ldots, h-1$, we keep the first and the last segments $\widetilde{\mathcal{H}}_0$ and $\widetilde{\mathcal{H}}_h$ as defined in (6)–(7), and replace all others by $\overline{\mathcal{G}}$. The counter program $\overline{\mathcal{P}}$ has the following form:

$$\underbrace{\mathcal{H}_{-1}}_{\text{size } \mathcal{O}(n)} \quad \underbrace{\widetilde{\mathcal{H}}_0}_{\text{size } \mathcal{O}(d)} \quad \underbrace{\overline{\mathcal{G}}}_{\text{size } \mathcal{O}(d)} \quad \underbrace{\widetilde{\mathcal{H}}_h}_{\text{size } \mathcal{O}(d)} \quad \underbrace{\mathcal{H}_{h+1}}_{\text{size } \mathcal{O}(n)} \quad \textbf{halt if } \mathsf{x}_{-1}, \mathsf{x}_h, \mathsf{a}_0^{d-1}, \mathsf{a}_1^{d-1} = 0. \tag{11}$$

Its size is $\mathcal{O}(n+d)$ and its dimension is larger by $2d$ than the dimension of $\widetilde{\mathcal{P}}$.

▷ Claim 15 (Correctness). $\widetilde{\mathcal{P}}$ has a halting run if, and only if, $\overline{\mathcal{P}}$ has one.

Proof. Again, halting runs of $\widetilde{\mathcal{P}}$ are in one-to-one correspondence with halting runs of $\overline{\mathcal{P}}$. Indeed, a halting run of $\widetilde{\mathcal{P}}$ is faithfully simulated in $\overline{\mathcal{P}}$ by iterating through $j = 0, 1, \ldots, h-1$ in $\overline{\mathcal{G}}$. Conversely, by the very construction of $\overline{\mathcal{P}}$, its every halting run simulates in this way some halting run of $\widetilde{\mathcal{P}}$. Note that $\overline{\mathcal{P}}$ has also other runs which are necessarily partial (i.e., they fail to reach the **halt** command), because of choosing a failing branch in some of the conditional constructs (10). ◁

The optimisation $\mathcal{P} \mapsto \widetilde{\mathcal{P}}$ described above yields a reduction $\mathcal{M} \mapsto \overline{\mathcal{P}}$, whose correctness follows by Claims 5, 13 and 15:

▷ Claim 16. Given a 3-counter Minsky machine $\mathcal{M}$ of size n and a positive integer d, one can compute in time $\mathcal{O}(n+d)$ a counter program $\overline{\mathcal{P}}$ of dimension $4d+13$ such that $\mathcal{M}$ has a halting run with counters bounded by $\mathcal{F}(2^d+1, n)$ if, and only if, $\overline{\mathcal{P}}$ has a halting run.

Putting $d = n$, we obtain a linear-time reduction from the EXP-TOWER HALTING PROBLEM. In consequence, the VASS reachability problem is 2^n-TOWER-hard, with respect to polynomial-time reductions.

[6] As remarked in the footnote 4 in Section 4, $\overline{\mathcal{G}}$ adapts straightforwardly if, instead of just one $\mathcal{H}$, two different program fragments are used, say $\mathcal{H}_0$ and $\mathcal{H}_1$, one of them for even j and the other one for odd j. It is enough to replace line 3 by **if** $\mathsf{b}_0 = 1$ **then** $\overline{\mathcal{H}}_1$ **else** $\overline{\mathcal{H}}_0$

New Techniques for Universality in Unambiguous Register Automata

Abstract

Register automata are finite automata equipped with a finite set of registers ranging over the domain of some relational structure like $(\mathbb{N}; =)$ or $(\mathbb{Q}; <)$. Register automata process words over the domain, and along a run of the automaton, the registers can store data from the input word for later comparisons. It is long known that the universality problem, i.e., the problem to decide whether a given register automaton accepts all words over the domain, is undecidable. Recently, we proved the problem to be decidable in 2-ExpSpace if the register automaton under study is over $(\mathbb{N}; =)$ and unambiguous, i.e., every input word has at most one accepting run; this result was shortly after improved to 2-ExpTime by Barloy and Clemente. In this paper, we go one step further and prove that the problem is in ExpSpace, and in PSpace if the number of registers is fixed. Our proof is based on new techniques that additionally allow us to show that the problem is in PSpace for single-register automata over $(\mathbb{Q}; <)$. As a third technical contribution we prove that the problem is decidable (in ExpSpace) for a more expressive model of unambiguous register automata, where the registers can take values nondeterministically, if defined over $(\mathbb{N}; =)$ and only one register is used.

1 Introduction

Certainly, determinism plays a central role in the research about computation models. Recently, a lot of active research work [1, 6, 3, 16, 14] is devoted to its weaker form: *unambiguity*. A system is *unambiguous* if for every input word there is at most one accepting run. Unambiguous systems exhibit elegant properties; in particular many natural computational problems turn out to be easier compared to the general case. A prominent example is the *universality problem* for finite automata, *i.e.*, the problem of deciding whether a given automaton accepts *every* input word. It is in PTime [18] and even in NC^2 [19] in the unambiguous case, as opposed to PSpace-complete in the general case.

In his seminal overview article about unambiguity, Colcombet [5] states some very natural conjectures about unambiguous systems that are so fundamental that one can be surprised that they are still open. An example conjecture, motivated by the fact that the universality problem for unambiguous finite automata is in PTime, was that for every unambiguous finite automaton the complement of its language can be accepted by another unambiguous finite automaton with at most polynomial size with respect to the size of the original automaton. This conjecture was surprisingly resolved negatively by Raskin [17], who provided a family of automata where a blowup $\Theta(n^{\log\log\log(n)})$ is unavoidable. Still, a lot of other natural questions remain unresolved. Some of them are not algorithmic (as the above one), while others ask for the existence of faster algorithms in the unambiguous case.

Usually one cannot hope for designing more efficient algorithms for the emptiness problem, as it is often easy to transform a nondeterministic system to a deterministic (and thus unambiguous) system which has empty language if and only if the accepted language of the original system is empty. Indeed, it is often sufficient to change the labelling of every transition of the system to its unique transition name. This transformation preserves the emptiness property, but not much more. Therefore there is a hope that the unambiguity assumption may result in faster solving of problems like universality, equivalence and language containment. Recently there was a substantial amount of research in this area [11, 4, 7, 14, 6, 1]. The considered problem is often the universality problem. Indeed, the universality problem is probably the easiest nontrivial problem for which there is a hope to obtain an improvement in the unambiguous case. Equivalence and containment are often not much harder, even though sometimes a bit more involved techniques are needed.

For *register automata*, this line of research was started in [14]. Register automata (RA, for short) extend finite automata with a finite set of registers that take values from an infinite data domain for later comparisons. More detailed, RA are defined over a relational structure, like $(\mathbb{N};=)$ or $(\mathbb{Q};<,=)$; they process finite words over the domain of the relational structure, and the registers can store values from the input word for comparing them using the relations provided by the relational structure. In the more expressive model of register automata *with guessing* (GRA) the registers can even take arbitrary values. In [14] it is shown that for unambiguous RA (URA) over $(\mathbb{N};=)$ the containment problem is in 2-ExpSpace and in ExpSpace for a fixed number of registers. Without the unambiguity assumption, this problem is known to be much harder. Concretely, the universality problem is undecidable as soon as the automaton uses two registers [12, 15, 9], and Ackermann-complete in the one-register case [10]. In the case of GRA even the one-register case is undecidable.[1] The result for URA in [14] was improved by Barloy and Clemente [1] who have shown that the problem is in 2-ExpTime and in ExpTime for a fixed number of registers, using very different tools such as linear recursive sequences in two dimensions.

Our contribution

Our result improves statements of Barloy and Clemente [1] even further. We provide three results shown by two different techniques. Our first technique is to show that in some cases one can assume that only a linear or exponential number of different configurations can be reached via an input word. This claim immediately provides an improved upper bound compared to [1].

[1] A proof for undecidability can be done using a reduction from the undecidable reachability problem for Minsky machines, following the lines of the proof of Theorem 5.2 in [8]. The nondeterministic guessing can be used to express that there exists some decrement for which there is no matching preceding increment.

▶ **Theorem 1.** *The containment problem $L(\mathcal{A}) \subseteq L(\mathcal{B})$ is in* ExpSpace*, if $\mathcal{A}$ is an* RA *and $\mathcal{B}$ is a* URA *over $(\mathbb{N}; =)$. The containment problem is in* PSpace *on inputs $\mathcal{A}, \mathcal{B}$ both having a bounded number of registers.*

This approach can also be applied to unambiguous one-register automata over $(\mathbb{Q}; <, =)$.

▶ **Theorem 2.** *The universality problem for one-register* URA *over $(\mathbb{Q}; <, =)$ is in* PSpace*.*

Our techniques used to show Theorems 1 and 2 differ from techniques used previously in [14]. In [14] a reached configuration was compressed if it was too big. More concretely, if two different data values were equivalent in a certain sense with respect to the current configuration, one of them was eliminated from the configuration, and the resulting configuration was equivalent. In that way, a compressed configuration had only non-equivalent data values and therefore its size was bounded. In this work, we analyse a reachable configuration much more locally, looking only at states with the same location. We show that if there are too many states with the same location in a certain configuration, then it is not possible that the considered unambiguous automaton is universal. In that quite different way we provide a bound on the size of a reachable configuration in an unambiguous universal automaton.

However, we will see that the techniques for URA do not work for unambiguous GRA (GURA), not even in the one-register case. In that case we solve the universality problem, and even the containment problem, with the use of more sophisticated analysis, closer related to the technique from [14]. In short, we show that we can modify the set of reachable configurations such that it becomes small and equivalent in some sense, which also allows us to obtain a more efficient algorithm.

▶ **Theorem 3.** *The containment problem $L(\mathcal{A}) \subseteq L(\mathcal{B})$ is in* ExpSpace*, if $\mathcal{A}$ is a* GRA *over $(\mathbb{N}; =)$ and $\mathcal{B}$ is a one-register* GURA *over $(\mathbb{N}; =)$.*

Independently from our work, Bojańczyk, Klin and Moerman [2] have recently published a result about orbit-finite vector spaces, which, for GURA with register values comparable wrt. a linear order, implies an algorithm that works in ExpTime if the number of registers is not fixed, and in PTime if the number of registers is fixed. However, we believe that our contribution does not only provide an improved complexity of the considered problem (compared with previous results), but also techniques that can be useful in future research on unambiguous systems.

2 Preliminaries

In this section, we define *register automata*, introduced by Kaminski et al. [12, 13]. We start with some basic notions used throughout the paper. We use Σ to denote a finite alphabet, and $\mathbb{N}$ and $\mathbb{Q}$ denote the set of non-negative integers and rational numbers, respectively. Given $a, b \in \mathbb{N}$ with $a \leq b$, we write $[a, b]$ to denote the set $\{a, a+1, \ldots, b\}$.

A *relational structure* is a tuple $\mathcal{D} = (\mathbb{D}; R_1, \ldots, R_k)$, where $\mathbb{D}$ is an infinite domain, and $R_1, \ldots, R_k$ are binary relations over $\mathbb{D}$, and we assume that R_k is the equality relation. In this paper, we are mainly interested in the relational structures $(\mathbb{N}; =)$ of the non-negative integers with equality, and $(\mathbb{Q}; <, =)$ of the rationals with the usual order and equality relations.

A *data word* is a finite sequence $(\sigma_1, d_1) \ldots (\sigma_k, d_k) \in (\Sigma \times \mathbb{D})^*$. If $\Sigma = \{\sigma\}$ is a singleton set, we may write $d_1 \cdot d_2 \cdot \ldots \cdot d_k$ shortly for $(\sigma, d_1)(\sigma, d_2) \ldots (\sigma, d_k)$. We use ε to denote the empty data word. A *data language* is a set of data words. We use $\mathrm{data}(w)$ to denote the set $\{d_1, \ldots, d_k\}$ of all data occurring in w.

Let $\mathbb{D}_\perp$ denote the set $\mathbb{D} \cup \{\perp\}$, where $\perp \notin \mathbb{D}$. We let $\perp \neq d$ for all $d \in \mathbb{D}$, and $\perp$ is incomparable with respect to $\leq$ to all $d \in \mathbb{D}$. We use boldface lower-case letters like $\boldsymbol{a}, \boldsymbol{b}, \ldots, \boldsymbol{u} \ldots$ to denote tuples in $\mathbb{D}_\perp^n$, where $n \in \mathbb{N}$. Given a tuple $\boldsymbol{a} \in \mathbb{D}_\perp^n$, we write a_i for its i-th component, and $\mathrm{data}(\boldsymbol{a})$ denotes the set $\{a_1, \ldots, a_n\} \subseteq \mathbb{D}_\perp$ of all data occurring in $\boldsymbol{a}$.

Let $\mathcal{R} = \{r_1, \ldots, r_n\}$ be a finite set of *registers*. A *register valuation* is a mapping $\boldsymbol{u} : \mathcal{R} \to \mathbb{D}_\perp$; we may write u_i as shorthand for $\boldsymbol{u}(r_i)$. Let $\mathbb{D}_\perp^{\mathcal{R}}$ denote the set of all register valuations. A *register constraint over $\mathcal{D}$ and $\mathcal{R}$* is defined by the grammar

$$\phi ::= \texttt{true} \mid R(t_1, t_2) \mid \neg\phi \mid \phi \wedge \phi$$

where R is a binary relation symbol from the relational structure $\mathcal{D}$, and $t_i \in \{\#\} \cup \{r, \dot{r} \mid r \in \mathcal{R}\}$. Here $\#$ is a symbol representing the current input datum, r refers to the current value of the register r, and $\dot{r}$ refers to the future value of the register r. We use $\Phi(\mathcal{D}, \mathcal{R})$ to denote the set of all register constraints over $\mathcal{D}$ and $\mathcal{R}$. The satisfaction relation $\models$ on $\mathbb{D}_\perp^{\mathcal{R}} \times \mathbb{D} \times \mathbb{D}_\perp^{\mathcal{R}}$ is defined by structural induction as follows. We only give some atomic cases; the other cases can be derived easily. We have $(\boldsymbol{u}, d, \boldsymbol{v}) \models \phi$ if

- ϕ is of the form $\texttt{true}$,
- ϕ is of the form $R(r_i, \#)$ and $\mathcal{D} \models R(u_i, d)$,
- ϕ is of the form $R(\dot{r}_i, r_i)$ and $\mathcal{D} \models R(v_i, u_i)$,
- ϕ is of the form $R(\dot{r}_i, \#)$ and $\mathcal{D} \models R(v_i, d)$.

For example, $\phi := \neg(r = \#) \wedge (\dot{r} = r)$ is a register constraint over $(\mathbb{N}; =)$ and $\mathcal{R} = \{r\}$, and we have $(1, 2, 1) \models \phi$, whereas $(1, 2, 3) \not\models \phi$.

It is important to note that only register constraints of the form $\dot{r} = r$ and $\dot{r} = \#$ uniquely determine the new value of r. In absence of such a register constraint, the register r can nondeterministically take any of infinitely many data values from $\mathbb{D}$, with the following restrictions: the register constraint $\neg(\dot{r} = \#)$ requires that the new value of r is different from the current input datum, so that r may take any datum in $\mathbb{D}$ except for the input datum. Likewise, the register constraint $\neg(\dot{r} = r)$ requires that r takes any datum in $\mathbb{D}$ except for the current value of r. Register automata that allow for such nondeterministic *guessing* of future register values are also called *register automata with guessing*. Formally, a register automaton with guessing (GRA) over $\mathcal{D}$ and Σ is a tuple $\mathcal{A} = (\mathcal{R}, \mathcal{L}, \ell_{\mathrm{init}}, \mathcal{L}_{\mathrm{acc}}, E)$, where

- $\mathcal{R}$ is a finite set of registers,
- $\mathcal{L}$ is a finite set of locations,
- $\ell_{\mathrm{init}} \in \mathcal{L}$ is the initial location,
- $\mathcal{L}_{\mathrm{acc}} \subseteq \mathcal{L}$ is the set of accepting locations,
- $E \subseteq \mathcal{L} \times \Sigma \times \Phi(\mathcal{D}, \mathcal{R}) \times \mathcal{L}$ is a finite set of edges.

If every edge of $\mathcal{A}$ contains some constraint of the form $\dot{r} = r$ or $\dot{r} = \#$, for every $r \in \mathcal{R}$, so that the future value of every register is uniquely determined, then we simply speak of *register automata* (RA, for short), *i.e.*, register automata without guessing. If the number of registers of a GRA (RA, respectively) is fixed to $k \in \mathbb{N}$, then we speak of k-GRA (k-RA, respectively).

A *state* of $\mathcal{A}$ is a pair $(\ell, \boldsymbol{u}) \in \mathcal{L} \times \mathbb{D}_\perp^{\mathcal{R}}$, where ℓ is the current location and $\boldsymbol{u}$ is the current register valuation. Abusing notation a bit, we usually write $\ell(\boldsymbol{u})$ instead of $(\ell, \boldsymbol{u})$. The state $\ell_{\mathrm{init}}(\boldsymbol{u}_{\mathrm{init}})$, where $\boldsymbol{u}_{\mathrm{init}}$ maps every register $r \in \mathcal{R}$ to $\perp$, is called the *initial state*, and a state $\ell(\boldsymbol{u})$ is called *accepting* if $\ell \in \mathcal{L}_{\mathrm{acc}}$. Given two states $\ell(\boldsymbol{u})$ and $\ell'(\boldsymbol{u'})$ and some input letter $(\sigma, d) \in \Sigma \times \mathbb{D}$, we postulate a transition $\ell(\boldsymbol{u}) \xrightarrow{\sigma,d}_{\mathcal{A}} \ell'(\boldsymbol{u'})$ if there exists some edge $(\ell, \sigma, \phi, \ell') \in E$ such that $(\boldsymbol{u}, d, \boldsymbol{u'}) \models \phi$. A *run* of $\mathcal{A}$ on the data word $(\sigma_1, d_1) \ldots (\sigma_k, d_k)$ is a sequence $\ell_0(\boldsymbol{u^0}) \xrightarrow{\sigma_1,d_1}_{\mathcal{A}} \ell_1(\boldsymbol{u^1}) \xrightarrow{\sigma_2,d_2}_{\mathcal{A}} \ldots \xrightarrow{\sigma_k,d_k}_{\mathcal{A}} \ell_k(\boldsymbol{u^k})$ of such transitions. We say that a run as above *starts in* $\ell_0(\boldsymbol{u^0})$; similarly, the run *ends in* $\ell_k(\boldsymbol{u^k})$. A state $\ell(\boldsymbol{u})$ is *reachable*

in $\mathcal{A}$ if there exists a run that ends in $\ell(\boldsymbol{u})$. A run is *initialized* if it starts in the initial state, and a run is *accepting* if it ends in some accepting state. A data word w is *accepted from* $\ell(\boldsymbol{u})$ if there exists an accepting run on w that starts in $\ell(\boldsymbol{u})$. The data language *accepted* by $\mathcal{A}$, denoted by $L(\mathcal{A})$, is the set of data words that are accepted from the initial state.

A GRA is *unambiguous* if for every input data word w there is at most one initialized accepting run. Note that unambiguity is a semantic condition; it can be checked in polynomial time [5]. We write GURA and URA to denote unambiguous GRA and RA, respectively.

▶ **Example 4.** Let us study the behaviour of the 1-GRA depicted in Figure 1. The GRA is over $(\mathbb{N}; =)$ and the singleton alphabet $\Sigma = \{\sigma\}$ (we omit the letter σ from all transitions in the figure). Suppose the first input letter is d_1. In order to satisfy the constraint of the transition from ℓ_1 to ℓ_2, the automaton has to nondeterministically guess some datum $d' \neq d_1$ and store it into its register r. Being in the state $\ell_1(d')$, the automaton can only move to the accepting location ℓ_2 if the next input datum is equal to d' (indicated by the constraint $r = d$); for every other input letter, the automaton satisfies the constraint $\neg(r = d)$ and stays in ℓ_1, and it keeps the register value to satisfy the constraint $\dot{r} = r$. In this way, the automaton accepts the language $\{d_1 \cdot \ldots \cdot d_k \mid \exists k \geq 2\ \forall 1 \leq i < k.\ d_i \neq d_k\}$. Note that the automaton is unambiguous: for every input data word there is only one accepting run. We remark that the accepted data language cannot be accepted by any RA (without guessing) [13]. Hence, GRA are more expressive than RA.

In this paper, we study the *universality problem*: given a GRA $\mathcal{A}$, is $\mathcal{A}$ universal, *i.e.*, does $L(\mathcal{A}) = (\Sigma \times \mathbb{D})^*$ hold? In Table 1, we give an overview of the decidability status for register automata over $(\mathbb{N}; =)$, in bold the new results for unambiguous register automata that we present in this paper.

3 Basic Notions for Deciding Universality

For many computational models, a standard approach for solving the universality problem is to explore the (potentially infinite) state space of the automaton under study. Starting from the initial state, the basic idea is to input one letter after the other, and keep track of the *sets of states* that are reached, building a reachability graph whose nodes are the reached sets of states (per input letter). The key property of this state space is that it contains sufficient information to decide whether the automaton under study is universal: this is the case if, and only if, every node of the graph contains an accepting state. Let us formalize this intuition for register automata.

Fix a k-GRA $\mathcal{A} = (\mathcal{R}, \mathcal{L}, \ell_{\text{init}}, \mathcal{L}_{\text{acc}}, E)$ over $\mathcal{D}$ and Σ, for some $k \in \mathbb{N}$. A *configuration of* $\mathcal{A}$ is a subset of $\mathcal{L} \times \mathbb{D}_\perp^k$. The set C_{init}, denoting the singleton set containing the initial state of $\mathcal{A}$, is a configuration, henceforth called the *initial configuration*. Let C be a configuration, and let $(\sigma, d) \in (\Sigma \times \mathbb{D})$. We use $\text{Succ}_{\mathcal{A}}(C, (\sigma, d))$ to denote the *successor of* C *on the input* (σ, d), formally defined by

$$\mathrm{Succ}_{\mathcal{A}}(C,(\sigma,d)) := \{\ell(\boldsymbol{u}) \mid \exists\, \ell'(\boldsymbol{u'}) \in C\ \ell'(\boldsymbol{u'}) \xrightarrow{\sigma,d}_{\mathcal{A}} \ell(\boldsymbol{u})\}.$$

In order to extend this definition to data words, we define inductively $\mathrm{Succ}_{\mathcal{A}}(C,\varepsilon) := C$ and $\mathrm{Succ}_{\mathcal{A}}(C, w\cdot(\sigma,d)) := \mathrm{Succ}_{\mathcal{A}}(\mathrm{Succ}_{\mathcal{A}}(C,w),(\sigma,d))$. We say that a configuration C is *reachable in $\mathcal{A}$ by the data word w* if $C = \mathrm{Succ}_{\mathcal{A}}(C_{\mathrm{init}}, w)$; we say that C is *reachable in $\mathcal{A}$* if there exists some data word w such that C is reachable in $\mathcal{A}$ by w. We say that C is *coverable* if there exists some $C' \supseteq C$ such that C' is reachable in $\mathcal{A}$. Given a configuration C, we use $\mathrm{data}(C)$ to denote the set $\bigcup_{\ell(\boldsymbol{u})\in C}\mathrm{data}(\boldsymbol{u})$ of data occurring in C. Notice that every configuration reachable in an RA (without guessing) is necessarily finite. In contrast, the configuration $\{\ell_1(d') \mid d' \in \mathbb{N}, d' \neq d_1\}$ is reachable in the GRA in Figure 1 by the single-letter data word (σ, d_1). If $C = \{\ell(\boldsymbol{u})\}$ is a singleton set, then we may, in slight abuse of notation, omit the curly brackets and write $\ell(\boldsymbol{u})$.

We say that a configuration C is *accepting* if there exists $\ell(\boldsymbol{u}) \in C$ such that $\ell \in \mathcal{L}_{\mathrm{acc}}$; otherwise we say that C is *non-accepting*. Clearly, $\mathcal{A}$ is universal if, and only if, every configuration reachable in $\mathcal{A}$ is accepting. This suggests to reduce the universality problem to a reachability problem for the state space corresponding to the given input GRA. However, the state space of a GRA is infinite, in two different aspects.

First of all, the state space is *infinitely branching*, as each of the infinite data in $\mathbb{D}$ may give rise to a unique successor configuration. The standard approach for solving this complication is to abstract from concrete data, using the simple observation that, *e.g.*, the data word $3\cdot 4$ is accepted from the state $\ell(4)$ if, and only if, $5\cdot 2$ is accepted from the state $\ell(2)$. This is formalized in the following paragraph.

A *partial isomorphism of $\mathcal{D}_\perp$* is an injective mapping $\pi\colon D \to \mathbb{D}_\perp$ with domain $\mathrm{dom}(\pi) := D \subseteq \mathbb{D}$ such that:

- for every relation R of $\mathcal{D}$ and $a, b \in \mathrm{dom}(\pi)$, we have $(a,b) \in R \Leftrightarrow (\pi(a),\pi(b)) \in R$,
- if $\perp \in D$ then $\pi(\perp) = \perp$.

Let π be a partial isomorphism of $\mathcal{D}_\perp$ and let C be a configuration such that $\mathrm{data}(C) \subseteq \mathrm{dom}(\pi)$. We define the configuration $\pi(C) := \{\ell(\pi(d_1),\dots,\pi(d_k))) \mid \ell(d_1,\dots,d_k) \in C\}$; likewise, if $\{d_1,\dots,d_k\} \subseteq \mathrm{dom}(\pi)$, we define the data word $\pi(w) = (\sigma_1,\pi(d_1))\dots(\sigma_k,\pi(d_k))$. We write $\langle C, w\rangle \sim \langle C', w'\rangle$ if there exists a partial isomorphism of $\mathcal{D}_\perp$ such that $\pi(C) = C'$ and $\pi(w) = w'$.

▶ **Proposition 5.** *Let $\mathcal{A}$ be a* GRA*. If $\langle C, w\rangle \sim \langle C', w'\rangle$, then $\mathrm{Succ}_{\mathcal{A}}(C,w) \sim \mathrm{Succ}_{\mathcal{A}}(C',w')$.*

Secondly, there can be infinitely many reachable configurations even up to the equivalence relation $\sim$. As an example, consider the GURA in Figure 1. For every $n \geq 1$, the configuration $C_n := \{\ell_1(d') \mid d' \in \mathbb{N}\backslash\{d_1,\dots,d_n\}\} \cup \{\ell_2(d_n)\}$ with pairwise distinct data values $d_1,\dots,d_n$ is reachable by the data word $d_1\cdot d_2\cdot\ldots\cdot d_n$, and $C_n \not\sim C_{n'}$ for $n \neq n'$. There are similar examples also for URA, cf. [14].

In order to obtain our results, we will prove that one can solve the reachability problem for the state space of $\mathcal{A}$ by focussing on a subset of configurations reachable in the automaton under study. The concrete methods are different for URA and GURA, however, for both models we will take advantage of Proposition 5 and its simple consequence (cf. [14]).

▶ **Corollary 6.** *Let $\mathcal{A}$ be a* GRA*. If $\langle C, w\rangle \sim \langle C', w'\rangle$ and $\mathrm{Succ}_{\mathcal{A}}(C,w)$ is non-accepting (accepting, respectively), then $\mathrm{Succ}_{\mathcal{A}}(C',w')$ is non-accepting (accepting, respectively).*

4 The Universality Problem for URA over $(\mathbb{N}; =)$

In this section, we study the complexity of the universality problem for URA over the relational structure $(\mathbb{N}; =)$. We prove the following theorem.

▶ **Theorem 7.** *The universality problem is*
- *in* PSpace *for* k-URA *for any fixed* $k \in \mathbb{N}$,
- *in* ExpSpace *for* URA.

We start by showing that we can assume URA to have a specific form that simplifies the coming proofs. Given some k-URA $\mathcal{A}$, we say that $\mathcal{A}$ is *pruned* if for every state $\ell(\boldsymbol{u})$ that is reachable in $\mathcal{A}$ there exists a data word w that is accepted from $\ell(\boldsymbol{u})$, and $u_i \neq u_j$ for all $1 \leq i < j \leq k$, *i.e.*, no datum appears more than once in $\boldsymbol{u}$. The proof of the following proposition is simple and omitted.

▶ **Proposition 8.** *For every* k-URA *one can compute in polynomial time an equivalent pruned* k-URA.

In the following we always assume that a k-URA is pruned, even if we do not explicitly mention it. For simplicity, we also assume that the alphabet of the URA we consider are singletons. The techniques we develop can be easily lifted to the more general case where Σ is not a singleton.

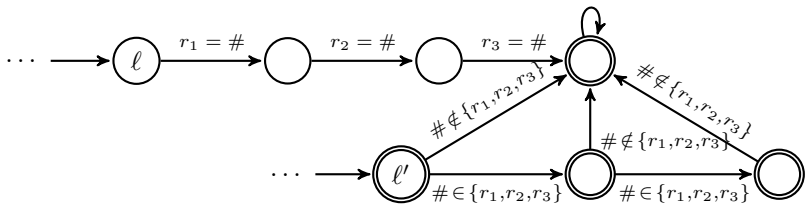
We introduce some constants that bound from above the number of states with the same location occurring in a configuration reachable in a universal URA. Let $\mathcal{A}$ be a k-URA. For a configuration C of $\mathcal{A}$, define $M_C \in \mathbb{N}$ to be the maximal number M such that in C there are M different states with the same location. Define $M_{\mathcal{A}} \in \mathbb{N} \cup \{\infty\}$ to be the supremum of M_C, for C ranging over all the configurations C reachable in $\mathcal{A}$, if $\mathcal{A}$ is a *universal* k-URA, *i.e.*, $L(\mathcal{A}) = \mathbb{D}^*$. In the sequel, we show that $M_{\mathcal{A}} < \infty$. In order to do so, for $k \in \mathbb{N}$, define $\mathbf{M}_k \in \mathbb{N} \cup \{\infty\}$ to be the supremum of all the $M_{\mathcal{A}}$, for $\mathcal{A}$ ranging over pruned and universal k-URA. The main technical result of this section is showing that $\mathbf{M}_k$ is finite and moreover upper-bounded by an exponential function of k.

Let n be the number of locations of $\mathcal{A}$. First observe that showing $\mathbf{M}_k \in \mathbb{N}$ easily implies the existence of a NPSpace algorithm deciding whether $\mathcal{A}$ is universal. Indeed, if $\mathbf{M}_k < \infty$, then every configuration C reachable in $\mathcal{A}$ has size at most $n \cdot \mathbf{M}_k$, as otherwise C contains more than $\mathbf{M}_k$ states with the same location. Thus, in order to decide whether $\mathcal{A}$ is not universal, we can apply the following algorithm:
- By Corollary 6, $\mathcal{A}$ is not universal iff $\mathcal{A}$ does not accept some data word $(\sigma_1, d_1)(\sigma_2, d_2)\ldots$, where $d_i \in \{0, \ldots, i\}$ for all i.
- Guess, letter by letter, an input data word $(\sigma_1, d_1)(\sigma_2, d_2)\ldots$, where $d_i \in \{0, \ldots, i\}$.
- For each $i \geq 1$, define $C_i := \mathrm{Succ}_{\mathcal{A}}(C_{i-1}, (\sigma_i, d_i))$, where $C_0 = C_{\mathrm{init}}$.
- If for some $i \geq 1$, the configuration C_i is not accepting or its size exceeds $n \cdot \mathbf{M}_k$, we know that $\mathcal{A}$ is not universal.
- Otherwise we keep the configuration in the space linear with respect to n and count the length of the word. If the length exceeds the number of possible configurations, then this run is not accepting. The length counter can be also kept in linear space.

The above is hence a PSpace-algorithm for deciding non-universality for k-URA. By Savitch's theorem, there also exists one for deciding universality for k-URA. Moreover, if we show that $\mathbf{M}_k$ is exponential in k, then the above algorithm works in space exponential with respect to k, so is in ExpSpace even without fixing the number of registers k. Therefore, in order to show Theorem 7, it is enough to prove that $\mathbf{M}_k$ is bounded by some exponential function of k. The rest of this Section is devoted mainly to showing the following lemma.

▶ **Lemma 9.** $\mathbf{M}_k \leq (k \cdot 4^k \cdot k!)^k$.

We first give here an argument showing that $\mathbf{M}_k$ is bounded by some doubly-exponential function in k. We show this argument in order to illustrate the techniques, which needed to be refined in our proof of Lemma 9. First recall that the *Ramsey number* $R_m(n)$ is the smallest number of vertices k of the graphs such that any clique of k vertices with its edges coloured on m different colours contain a monochromatic subgraph G of n vertices, namely such that all the edges in G are of the same colour. It can be shown by induction that $R_m(n)$ is finite, and indeed its growth is bounded by $2^{n^{O(m)}}$.



▶ **Proposition 10.** *Every set $T \subseteq \mathbb{D}_\perp^k$ of size at least $R_{k+1}(4^k(k+1)!+1)$ contains a k-full subset of size at least $k+1$.*

Proof. Construct a graph with vertices being tuples from T and edge between $\boldsymbol{t}$ and $\boldsymbol{t'}$ be coloured by the number of data values that $\boldsymbol{t}$ and $\boldsymbol{t'}$ have in common. Clearly the colour belongs to the set $\{0, \ldots, k\}$, so there are $k+1$ colours. Because $|S| \geq R_{k+1}(4^k(k+1)!+1)$ we know from Ramsey's theorem that there are at least $4^k(k+1)!+1$ tuples such that every intersection is of the same size - assume this size to be m. Let S be a set of $4^k(k+1)!+1$ such tuples and let $\boldsymbol{s} \in S$ be one of them. Let $\boldsymbol{s} = (d_1, \ldots, d_k)$. Divide all the other tuples $\boldsymbol{s'}$ into $\binom{k}{m}^2 \cdot m!$ sets depending on which m data values from $\{d_1, \ldots, d_k\}$ belong to $\boldsymbol{s'}$ (there are $\binom{k}{m}$ options), on which positions they are located in $\boldsymbol{s'}$ (also $\binom{k}{m}$ options) and in which order ($m!$ options). It is easy to see that $\binom{k}{m}^2 \cdot m! \leq 4^k k!$, as $\binom{k}{m} \leq 2^k$ and $m! \leq k!$. We divide $4^k(k+1)!$ tuples (we omit $\boldsymbol{s}$) into at most $4^k k!$ sets, so by the pigeonhole principle at least one of them contains at least $k+1$ elements: let these elements be $\boldsymbol{s^1}, \ldots, \boldsymbol{s^{k+1}}$. Notice now that the tuples $\boldsymbol{s^1}, \ldots, \boldsymbol{s^{k+1}}$ form a k-full set: indeed on positions on which they have the m shared data they are identical and on the other positions all the data values are totally different. Thus T contains a k-full set of size $k+1$, which finishes the proof. ◀

Before refining our argument to give an exponential bound, we remark that these techniques alone *cannot* be used to lower even more the complexity of the universality problem for k-URA or for URA. This is because $\mathbf{M}_k \geq k!$, which is the subject of the following lemma.

▶ **Lemma 11.** $\mathbf{M}_k \geq k!$.

Proof. We define a family of pruned universal k-URA $(\mathcal{A}_k)_{k\geq 1}$ over $\Sigma = \{\sigma\}$ such that $M_{\mathcal{A}_k} \geq k!$. Consider the following part of a pruned universal k-URA $\mathcal{A}_k$ (shown for the case $k = 3$):

The rest of the automaton makes sure that the configuration

$$\{\ell(\boldsymbol{u}) \mid \boldsymbol{u} \in \{1, \ldots, k\}^k \text{ is a permutation}\} \cup \{\ell'(1, \ldots, k)\}$$

is reachable in $\mathcal{A}_k$ by the k-letter data word $1 \cdot 2 \cdot \ldots \cdot k$ (*e.g.*, each $\ell(\boldsymbol{u})$ is reached by a path storing the input data in a different order). By taking the (disjoint) union with an unambiguous automaton accepting every data word of length $< k$ and every k letter word that has a repeated data value, we obtain a universal automaton. ◀

Our main tool to prove Lemma 9 is a structural observation, which delivers an understanding of how reachable configurations in universal k-URA can look like. Before diving into it we present an intuition by the following example.

▶ **Example 12.** Let C be a configuration reachable in some universal 2-URA $\mathcal{A}$ over $\Sigma = \{\sigma\}$ by some data word w, and assume that C contains three states $\ell(1,2)$, $\ell(3,4)$ and $\ell(5,6)$ sharing the same location ℓ. We will argue that this is impossible. Assume that from $\ell(1,2)$ the data word $1 \cdot 2 \cdot 7$ is accepted. Then clearly also $3 \cdot 4 \cdot 7$ is accepted from $\ell(3,4)$, and $5 \cdot 6 \cdot 7$ is accepted from $\ell(5,6)$. Let us now consider the data word $8 \cdot 9 \cdot 7$, where 8 and 9 are *fresh* data values, that is, they do not occur in w. Since A is universal, the data word $8 \cdot 9 \cdot 7$ must be accepted from some state $\ell'(d_1, d_2)$ in C. The set $\{d_1, d_2\}$ has only two elements, and so the intersection with at least one of the sets $\{1,2\}$, $\{3,4\}$ and $\{5,6\}$ must be empty. For instance, assume that $\{d_1, d_2\} \cap \{1,2\} = \emptyset$ and $(d_1, d_2) = (3,6)$. Note that $\langle \ell'(3,6), 8 \cdot 9 \cdot 7 \rangle \sim \langle \ell'(3,6), 1 \cdot 2 \cdot 7 \rangle$, so that by Corollary 6, the data word $1 \cdot 2 \cdot 7$ is accepted from state $\ell'(3,6)$, too. But then that there are two accepting runs for $w \cdot 1 \cdot 2 \cdot 7$, a contradiction to the unambiguity of $\mathcal{A}$. Below we generalise this reasoning, in particular to the case where some registers in the reached states keep the same value (*i.e.*, not all are different, as 1, 2, 3, 4, 5 and 6 in the above example). However the intuition stays the same.

We say that a set of tuples $T \subseteq \mathbb{D}_\perp^m$ is *m-full* (or simply *full* if m is clear from the context) if there exists a set of indices $I \subseteq [1,m]$ such that:

- all the tuples in T are identical in indices from I, namely for all $i \in I$ and all $\boldsymbol{t}, \boldsymbol{t'} \in T$ we have $t_i = t'_i$;
- all the data values occurring in tuples in T on indices outside I are different, namely for all $i \notin I$, all $j \in \{1, \ldots, m\}$, and all $\boldsymbol{t}, \boldsymbol{t'} \in T$ we have $t_i \neq t'_j$ unless both $\boldsymbol{t} = \boldsymbol{t'}$ and $i = j$. Note that in particular, this condition applies to the case $\boldsymbol{t'} = \boldsymbol{t}$, and thus $t_i \neq t_j$ whenever $i \notin I$ and $j \in \{1, \ldots, m\}$ are different.

For instance, the set containing the tuples $(1,3,2,4), (1,3,5,6), (1,3,7,8)$ is a 4-full set with $I = \{1,2\}$, and the set $\{(3,7,2,10,8)\}$ is a 5-full set, where $I \subseteq [1,5]$ can be chosen arbitrarily. In contrast, $\{(1,2),(3,1)\}$ is *not* a full set.

For a location ℓ and set of tuples $T \subseteq \mathbb{D}_\perp^k$ we write $\ell(T) = \{\ell(\boldsymbol{t}) \mid \boldsymbol{t} \in T\}$. The following lemma delivers the key observation, which uses the notion of k-full sets.

▶ **Lemma 13.** *If $\mathcal{A}$ is a pruned universal k-URA, then there exists no configuration C reachable in $\mathcal{A}$ such that $\ell(T) \subseteq C$ for some location $\ell \in \mathcal{L}$ and some k-full set of tuples $T \subseteq \mathbb{D}_\perp^k$ of size more than k.*

Proof. Let $\mathcal{A}$ be a pruned universal k-URA, and suppose towards contradiction that there exists a configuration C reachable in $\mathcal{A}$ such that $\ell(T) \subseteq C$ for some location ℓ and some k-full set $T \subseteq \mathbb{D}_\perp^k$ of size more than k. Let w be the data word such that $C = \mathrm{Succ}_{\mathcal{A}}(C_{\mathrm{init}}, w)$. Assume without loss of generality that the indices on which tuples from T are identical are $I = \{1, \ldots, n\}$ for some $n \leq k$. Let us choose some $k+1$ tuples from T, let the i-th of it be of the form $\boldsymbol{t}^i = (c_1, \ldots, c_n, o_1^i, \ldots, o_m^i)$, where $n + m = k$. We call the c_j the *common* data values and the o_j^i the *own* data values of $\boldsymbol{t}^i$. $\mathcal{A}$ is pruned and $\ell(\boldsymbol{t}^1)$ is reachable in $\mathcal{A}$, so there must exist a data word $w_1 \in (\Sigma \times \mathbb{D})^*$ that is accepted from $\ell(\boldsymbol{t}^1)$. Without loss of generality we can assume that w_1 does not contain the own data values of any of the other tuples $\boldsymbol{t}^2, \ldots, \boldsymbol{t}^{k+1}$. Indeed, if this is the case, we can replace synchronously all occurrences of such a data value by a *fresh* data value not occurring in $\mathrm{data}(w)$; the resulting data word is still accepted from $\ell(\boldsymbol{t}^1)$. For every $i \in [2, k+1]$, let w_i be the word w_1 in which for each $j \in [1,m]$ the own data value o_j^1 is replaced by the data value o_j^i. Clearly, for every $i \in [2, k+1]$ $\langle \ell(\boldsymbol{t}^1), w_1 \rangle \sim \langle \ell(\boldsymbol{t}^i), w_i \rangle$, so that by Corollary 6 the data word w_i is accepted from $\ell(\boldsymbol{t}^i)$.

Let us now consider the data word w_{fresh} that is obtained from w_1 by replacing synchronously every occurrence of every o^1_j by some fresh data value each. As $\mathcal{A}$ is universal, also the data word w_{fresh} needs to be accepted from some state in C. Let $q_{\text{fresh}} = \ell'(e_1, \ldots, e_k)$ be the state in C from which w_{fresh} is accepted. Notice that we do not enforce $\ell \neq \ell'$, similarly e_i may be equal to some of the c_i or o^j_i, but this does not have an effect on our reasoning. For each tuple $\boldsymbol{t}^i = (c_1, \ldots, c_n, o^i_1, \ldots, o^i_m)$, let the set of its own data values be $O_i = \{o^i_1, \ldots, o^i_m\}$. By assumption all the sets $O_1, \ldots, O_{k+1}$ are pairwise disjoint. As there are $k+1$ of them, we know that at least one of them is disjoint from the set of data values in the state q_{fresh}, namely with $E = \{e_1, \ldots, e_k\}$. So let $1 \leq i \leq k+1$ be such that $O_i \cap E = \emptyset$. Then we have $\langle q_{\text{fresh}}, w_i\rangle \sim \langle q_{\text{fresh}}, w_{\text{fresh}}\rangle$, so that by Corollary 6 w_i is also accepted from q_{fresh}. In consequence, there are at least two accepting runs over w_i from configuration C, one from $\ell(\boldsymbol{t}^1)$ and one from q_{fresh}. Hence there are at least two initialized accepting runs over $w \cdot w_i$. This is a contradiction to the unambiguity of $\mathcal{A}$. ◀

The following result directly implies Lemma 9, when setting $B = n = k$.

▶ **Lemma 14.** *Every set $T \subseteq \mathbb{D}^n_\perp$ of size at least $(B \cdot 4^n \cdot n!)^n + 1$ contains an n-full subset of size larger than B.*

Proof. Let us denote by $D_{B,n}$ the maximal size of the set of n-tuples such that any n-full subset has size at most B; in other words, $D_{B,n}$ is the least integer such that if X is a set of n-tuples of size $D_{B,n}+1$, then X contains an n-full subset of size $B+1$. Our aim is to show that $D_{B,n} \leq (B \cdot 4^n \cdot n!)^n$. We show it by induction on n.

For the induction base assume $n = 1$. Then any set of data values is a full set, so clearly $D_{B,1} \leq B \leq B \cdot 4^1 \cdot 1!$.

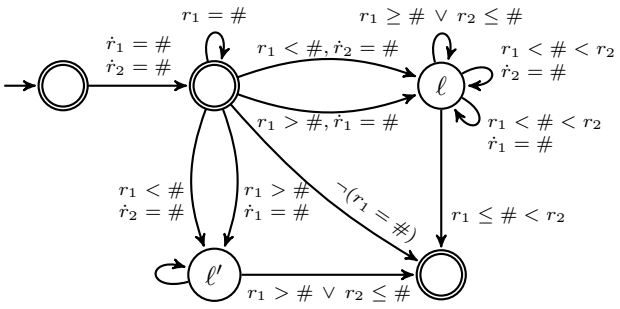
Assume now that $D_{B,m} \leq (B \cdot 4^m \cdot m!)^m$ for all $m < n$ and consider some set $T \subseteq \mathbb{D}^n_\perp$ of n-tuples. Assume that T contains no n-full subset of size larger than B. Pick some tuple $\boldsymbol{t} = (d_1, \ldots, d_n) \in T$. We first show that there can be at most $4^n \cdot n! \cdot D_{B,n-1}$ tuples in T whose data intersect data($\boldsymbol{t}$). Let us denote $N = 4^n \cdot n! \cdot D_{B,n-1}$. Let S be the set of those tuples, assume towards contradiction that the size of S exceeds the bound N. For each tuple $\boldsymbol{s} \in S$ there are at most $2^n - 1$ choices for data($\boldsymbol{s}$) $\cap$ data($\boldsymbol{t}$), so by the pigeonhole principle there are more than $2^n \cdot n! \cdot D_{B,n-1}$ tuples which have the same set data($\boldsymbol{s}$) $\cap$ data($\boldsymbol{t}$). Those data values can occur in tuples from S on at most 2^n different sets of indices, and in at most $n!$ different orders, so by the pigeonhole principle more than $D_{B,n-1}$ tuples from S have the same data values shared with $\boldsymbol{t}$ on the same indices. After ignoring the indices shared with $\boldsymbol{t}$ at most $n-1$ indices remain on these tuples. So by induction assumption there is some full set of size more than B among these tuples, which leads to a contradiction to the assumption that for more than N tuples from T their data intersects data($\boldsymbol{t}$).

Therefore we know that all the tuples but the mentioned N ones have data disjoint with data($\boldsymbol{t}$). Let use denote $\boldsymbol{t^1} = \boldsymbol{t}$ and T_1 to be the set of tuples with data disjoint from data($\boldsymbol{t^1}$). Let $\boldsymbol{t^2} \in T_1$. We now repeat the argument for $\boldsymbol{t^2}$ similarly as for $\boldsymbol{t^1}$ and get that there are at most N tuples with data intersecting data($\boldsymbol{t^2}$). Repeating this argument we get a sequence of tuples $\boldsymbol{t^1}, \boldsymbol{t^2}, \ldots, \boldsymbol{t^m}$ such that for each $i \neq j$ we have data($\boldsymbol{t^i}$) $\cap$ data($\boldsymbol{t^j}$) $= \emptyset$. After adding each tuple $\boldsymbol{t^j}$ to the sequence we define the set T_{j+1} of elements, which have disjoint data with all the tuples $\boldsymbol{t^1}, \ldots, \boldsymbol{t^j}$. As long as T_{j+1} is nonempty we can continue the process. It is easy to see that $|T_{j+1}| \geq |T_j| - N$. Assume now towards contradiction that $D_{B,n} > (B \cdot 4^n \cdot n!)^n$, which implies that $D_{B,n} > (B \cdot 4^n \cdot n!) \cdot D_{B,n-1} = B \cdot N$. We can see now that $|T_B| > 0$, which means that we can construct tuples $\boldsymbol{t^1}, \boldsymbol{t^2}, \ldots, \boldsymbol{t^B}, \boldsymbol{t^{B+1}}$ such that for each $i \neq j$ we have data($\boldsymbol{t^i}$) $\cap$ data($\boldsymbol{t^j}$) $= \emptyset$. This however means that $\{\boldsymbol{t^1}, \ldots, \boldsymbol{t^{B+1}}\}$ is a full set of size $B+1$, which is more than B. This contradicts the assumption, which shows that $D_{B,n} \leq (B \cdot 4^n \cdot n!)^n$ and finishes the proof. ◀

We can now apply a reduction from containment to universality provided by Barloy and Clemente (Lemma 8 in [1]) to obtain Theorem 1 from the introduction.

5 Universality for URA over $(\mathbb{Q}; <, =)$

In this section, we prove Theorem 2 by using the techniques developed in the preceding section. Let us define constants $\mathbf{M}_k^{\mathcal{O}}$ for k-URA with order similarly as $\mathbf{M}_k$ for k-URA. The main technical lemma is the following; Theorem 2 follows.



▶ **Lemma 15.** $\mathbf{M}_1^{\mathcal{O}} = 1$.

Proof. Towards contradiction suppose that for some pruned universal 1-URA $\mathcal{A}$ with order there is a configuration C reachable in $\mathcal{A}$ by a data word $w_{\text{pref}} \in (\Sigma \times \mathbb{Q})^*$, such that $\ell(d_1), \ell(d_2) \in C$ for some location ℓ and data values $d_1 < d_2$. Because $\mathcal{A}$ is pruned, there exists a data word $w_1 \in (\Sigma \times \mathbb{Q})^*$ that is accepted from $\ell(d_1)$. Without loss of generality we can assume that w_1 does not contain any data in $(d_1, d_2]$. Indeed, if w_1 contains some datum in $(d_1, d_2]$, then we can replace it synchronously by some datum greater than d_2, while taking care that that the relative order of all data in w_1 is preserved, so that, for the resulting data word w, we have $\langle \ell(d_1), w_1 \rangle \sim \langle \ell(d_1), w \rangle$. By Corollary 6, the resulting data word w is also accepted from $\ell(d_1)$. Notice that for similar reasons, also the data word w_2 obtained from w_1 by replacing every occurrence of d_1 by d_2 is accepted from $\ell(d_2)$. Now, if w_1 does not contain d_1, then $w_1 = w_2$. Hence w_1 is accepted from both $\ell(d_1)$ and $\ell(d_2)$, contradiction to unambiguity of $\mathcal{A}$. So let us assume w_1 contains d_1. Pick some data value d_{fresh} that is fresh, *i.e.*, it does not occur in w_{pref}, and additionally $d_1 < d_{\text{fresh}} < d_2$. We clearly can choose such a fresh data value, as there are infinitely many rational numbers between d_1 and d_2 and only finitely many of them occur in w_{pref}. Let w_{fresh} be the word obtained from w_1 by synchronously replacing every occurrence of d_1 by d_{fresh}. The word w_{fresh} is accepted from some configuration in C, let it be $\ell'(d')$. Notice now that if $d' < d_{\text{fresh}}$, then $\langle \ell'(d'), w_{\text{fresh}} \rangle \sim \langle \ell'(d'), w_2 \rangle$, so that $\ell'(d')$ accepts also w_2 by Corollary 6; in the other case, *i.e.*, if $d' > d_{\text{fresh}}$, then we have $\langle \ell'(d'), w_{\text{fresh}} \rangle \sim \langle \ell'(d'), w_1 \rangle$, so that $\ell'(d')$ also accepts w_1. Therefore in the first case automaton $\mathcal{A}$ has two accepting runs over $w_{\text{pref}} \cdot w_2$ and in the second case over $w_{\text{pref}} \cdot w_1$. This is a contradiction to the unambiguity of $\mathcal{A}$. ◀

The following lemma shows that our techniques by themselves are not sufficient to solve the case of 2-URA with order.

▶ **Lemma 16.** $\mathbf{M}_2^{\mathcal{O}} = \infty$.

Proof. For all $n \geq 1$, consider the configuration $C_n := \{\ell'(1, n)\} \cup \{\ell(1, 2), \ldots, \ell(n-1, n)\}$, which is for all $n \geq 1$ a subset of a configuration reachable in the following pruned universal 2-URA.

The state $\ell'(d_1, d_2)$ keeps track of the first two distinct data read, with $d_1 < d_2$. It is responsible for accepting any datum d outside the interval $[d_1, d_2)$. The state $\ell(x, y)$ is such that $d_1 \leq x < y \leq d_2$ and it is responsible for accepting every datum d' in the interval $[x, y)$. Moreover, if $d' \in (x, y)$, then $\ell(x, y)$ splits into $\ell(x, d')$ and $\ell(d', y)$. The automaton ensures that no two intervals $[x, y), [x', y')$ overlap, and that all the intervals $[x, y)$ present in a configuration cover the interval $[d_1, d_2)$, thus the automaton is unambiguous and universal. ◀

6 Containment for GURA over $(\mathbb{N}; =)$

In this section, we aim to prove the decidability of the universality problem for the more expressive model of GURA. Let us first argue that the techniques developed in Section 4 do not work for GURA.

▶ **Example 17.** One can easily construct a universal 1-GURA with reachable configuration C containing $\ell(0), \ell(1)$, and $\{\ell'\} \times \{n \in \mathbb{N} \mid n \neq 0, 1\}$. If from both ℓ and ℓ' there are outgoing edges with constraint $r = \#$ to some accepting state, then every data word n is accepted from C. In particular, the word 0 is accepted from $\ell(0)$, but we cannot replace 0 by some *fresh* datum to obtain a contradiction as in Example 12.

The example shows that we need more sophisticated methods to solve the universality problem. Moreover, and in contrast to the result for RA, we cannot rely on the reduction from containment to universality by Barloy and Clemente [1], as it holds for RA without guessing only. We hence present a direct proof for containment as stated in Theorem 3. The idea is based on exploring a sufficiently big part of the infinite *synchronized state space* of both automata $\mathcal{A}$ and $\mathcal{B}$, following the approach in [14]. The main difference with [14] lies in the complications that arise due to the fact that a configuration of a GURA may be *infinite*.

6.1 Synchronized Configurations and Bounded Supports

For the rest of this section, let $\mathcal{A} = (\mathcal{R}^{\mathcal{A}}, \mathcal{L}^{\mathcal{A}}, \ell^{\mathcal{A}}_{\text{init}}, \mathcal{L}^{\mathcal{A}}_{\text{acc}}, E^{\mathcal{A}})$ be a GRA with $\mathcal{R}^{A} = \{r_1, \ldots, r_m\}$, and let $\mathcal{B} = (\mathcal{R}^{\mathcal{B}}, \mathcal{L}^{\mathcal{B}}, \ell^{\mathcal{B}}_{\text{init}}, \mathcal{L}^{\mathcal{B}}_{\text{acc}}, E^{\mathcal{B}})$ be a GURA with a single register r.

We aim to reduce the containment problem $L(\mathcal{A}) \subseteq L(\mathcal{B})$ to a reachability problem in $(\mathbb{S}, \Rightarrow)$ where:

- $\mathbb{S}$ is the set of *synchronized configurations* $(\ell(\boldsymbol{d}), C)$, where $\ell(\boldsymbol{d}) \in (\mathcal{L}^{\mathcal{A}} \times \mathbb{N}_{\perp}^{\mathcal{R}^{\mathcal{A}}})$ is a single state of $\mathcal{A}$, and C is a configuration of $\mathcal{B}$,
- $(\ell(\boldsymbol{d}), C) \Rightarrow (\ell'(\boldsymbol{d'}), C')$ if there exists a letter $(\sigma, d) \in (\Sigma \times \mathbb{N})$ such that $\ell(\boldsymbol{d}) \xrightarrow{\sigma, d}_{\mathcal{A}} \ell'(\boldsymbol{d'})$, and $\text{Succ}_{\mathcal{B}}(C, (\sigma, d)) = C'$.

We define $S_{\text{init}} := (\ell^{\mathcal{A}}_{\text{init}}(\boldsymbol{v}_{\text{init}}), C_{\text{init}})$ to be the *initial synchronized configuration of* $\mathcal{A}$ *and* $\mathcal{B}$. We say that a synchronized configuration S' is *reachable* from S if there is a $\Rightarrow$-path from S to S'. S is *reachable* if it is reachable from S_{init}. Call a synchronized configuration $(\ell(\boldsymbol{d}), C)$ *bad* if $\ell \in \mathcal{L}^{\mathcal{A}}_{\text{acc}}$ is an accepting location and C is non-accepting, *i.e.*, $\ell' \notin \mathcal{L}^{\mathcal{B}}_{\text{acc}}$ for all $(\ell', u) \in C$. Thus, a bad synchronized configuration is reachable iff $L(\mathcal{A}) \not\subseteq L(\mathcal{B})$.

We extend the equivalence relation $\sim$ defined in Section 3 to synchronized configurations in a natural manner, *i.e.*, $(\ell(\boldsymbol{d}), C) \sim (\ell(\boldsymbol{d'}), C')$ if there exists a partial isomorphism π of $\mathbb{N}_{\perp}$ such that $\text{data}(\boldsymbol{d}) \cup \text{data}(C) \subseteq \text{dom}(\pi)$ and satisfying $\pi(\boldsymbol{d}) = \boldsymbol{d'}$ and $\pi(C) = C'$. Clearly, an analogue of Corollary 6 holds for this extended relation. In particular, we have the following:

▶ **Proposition 18.** *Let S, S' be two synchronized configurations of $(\mathbb{S}, \Rightarrow)$ such that $S \sim S'$. If S reaches a bad synchronized configuration, so does S'.*

The *support* of a configuration C of $\mathcal{B}$ is the set $\mathrm{supp}(C)$ of data d' such that at least one of the following two conditions holds:

- $\ell(d') \in C$ for some $\ell \in \mathcal{L}$ such that $(\{\ell\} \times \mathbb{D}) \cap C$ is finite,
- $\ell(d') \notin C$ for some $\ell \in \mathcal{L}$ such that $(\{\ell\} \times \mathbb{D}) \cap C$ is cofinite.

Note that $\mathrm{supp}(C) \subseteq \mathrm{data}(w)$ whenever $C = \mathrm{Succ}_{\mathcal{B}}(C_{\mathrm{init}}, w)$.

Let $S = (\ell(\boldsymbol{d}), C)$ be a synchronized configuration, and let $a, b \in \mathrm{supp}(C)$ be two data values in the support of C. We say that *a and b are indistinguishable in S*, written $a \equiv_S b$, if $a, b \notin \mathrm{data}(\boldsymbol{d})$ and $\{\ell \in \mathcal{L} \mid \ell(a) \in C\} = \{\ell \in \mathcal{L} \mid \ell(b) \in C\}$.

Given a configuration C of $\mathcal{B}$, we define for every datum $d \in \mathbb{N}$ the sets $C_d^+ := \{\ell(d) \in \mathcal{L} \times \{d\} \mid \ell(d) \in C \text{ and } \mathrm{data}(C \cap (\{\ell\} \times \mathbb{N})) \text{ is finite}\}$, and $C_d^- := \{\ell(d) \in \mathcal{L} \times \{d\} \mid \ell(d) \notin C \text{ and } \mathrm{data}(C \cap (\{\ell\} \times \mathbb{N})) \text{ is infinite}\}$.

We give here an example for the definition of C_d^+ and C_d^-.

▶ **Example 19.** Let $C = \{\ell_1(0), \ell_1(1)\} \cup \{\ell_2(d) \mid d \in \mathbb{N}\backslash\{1,2\}\} \cup \{\ell_3(d) \mid d \in \mathbb{N}\backslash\{0,1\}\}$. Then

$$\begin{array}{lll} C_0^+ = \{\ell_1(0)\} & C_1^+ = \{\ell_1(1)\} & C_2^+ = \emptyset \\ C_0^- = \{\ell_3(0)\} & C_1^- = \{\ell_2(1), \ell_3(1)\} & C_2^- = \{\ell_2(2)\} \end{array}$$

We say that a configuration C is *essentially coverable* if for every two $\ell(u), \ell'(u') \in C$, the set $\{\ell(u), \ell'(u')\}$ is coverable.

▶ **Proposition 20.** *Let C be an essentially coverable configuration, and let $b \in \mathrm{supp}(C)$. Then $(C\backslash C_b^+) \cup C_b^-$ is essentially coverable, too.*

Proof. Let $\ell(c), \ell'(c') \in ((C\backslash C_b^+) \cup C_b^-)$. If $\ell(c), \ell'(c') \in C\backslash C_b^+$, then $\{\ell(c), \ell'(c')\}$ is coverable by essential coverability of C. Suppose $\ell(c), \ell'(c') \in C_b^-$. By definition of C_b^-, $c = c' = b$. Pick some value $e \in \mathbb{N}\backslash\{b\}$ such that $\ell(e), \ell'(e) \in C$. Note that such a value e must exist, as by definition of C_b^-, the sets $\mathrm{data}((\{\ell\} \times \mathbb{N}) \cap C)$ and $\mathrm{data}((\{\ell'\} \times \mathbb{N}) \cap C)$ are cofinite, and hence their intersection is non-empty. By essential coverability of C, $\{\ell(e), \ell'(e)\}$ is coverable. There must thus exist some data word w such that $\{\ell(e), \ell'(e)\} \subseteq \mathrm{Succ}(\ell_{\mathrm{init}}(\bot), w)$. Let π be any partial isomorphism satisfying $\pi(e) = b$ and whose domain contains $\mathrm{data}(w)$. Clearly, $\{\ell(b), \ell'(b)\} \subseteq \mathrm{Succ}(\ell_{\mathrm{init}}(\bot), \pi(w))$, and hence $\{\ell(b), \ell'(b)\}$ is coverable. Finally, suppose $\ell(c) \in C \setminus C_b^+$ and $\ell'(c') \in C_b^-$. By definition, we have $c \neq b = c'$. Since $\mathrm{data}((\ell' \times \mathbb{N}) \cap C)$ is cofinite, there is $d \neq c$ such that $\ell'(d) \in C$. By essential coverability of C, there exists a data word w such that $\{\ell(c), \ell'(d)\} \subseteq \mathrm{Succ}(\ell_{\mathrm{init}}(\bot), w)$. By picking a partial isomorphism π such that $\pi(d) = c'$ and $\pi(c) = c$, we obtain that $\{\ell(c), \ell'(c')\} \subseteq \mathrm{Succ}(\ell_{\mathrm{init}}(\bot), \pi(w))$, which concludes the proof. ◀

The following is the main technical result of this section.

▶ **Proposition 21.** *Let $S = (\ell^{\mathcal{A}}(\boldsymbol{d}), C)$ be a synchronized configuration of $\mathcal{A}$ and $\mathcal{B}$ such that C is essentially coverable, and let $a \neq b$ be such that $a, b \in \mathrm{supp}(C)$ and $a \equiv_S b$. Then S reaches a bad configuration in $(\mathbb{S}, \Rightarrow)$ if, and only if, $S' := (\ell^{\mathcal{A}}(\boldsymbol{d}), (C \setminus C_b^+) \cup C_b^-)$ reaches a bad configuration in $(\mathbb{S}, \Rightarrow)$.*

Proof. ($\Leftarrow$) Suppose there exists some data word w such that there exists an accepting run of $\mathcal{A}$ on w that starts in $\ell^{\mathcal{A}}(\boldsymbol{d})$, and $\mathrm{Succ}_{\mathcal{B}}(C\backslash C_b^+ \cup C_b^-, w)$ is non-accepting. We assume in the following that $\mathrm{Succ}_{\mathcal{B}}(C_b^+, w)$ is accepting; otherwise we are done. Let $\ell^+(b) \in C_b^+$ be the unique state such that $\mathrm{Succ}_{\mathcal{B}}(\ell^+(b), w)$ is accepting. In the following, we prove that we can without loss of generality assume that w does not contain any a's. Pick some $a' \in \mathbb{N}$ such that $a' \notin \mathrm{data}(w) \cup \mathrm{supp}(C) \cup \mathrm{data}(\boldsymbol{d})$. Let π be the isomorphism defined by $\pi(a) = a'$,

$\pi(a') = a$, and $\pi(d) = d$ for all $d \in \mathbb{N}_\perp \backslash \{a, a'\}$. Then $\pi\langle \ell^{\mathcal{A}}(\boldsymbol{d}), w\rangle = \langle \ell^{\mathcal{A}}(\boldsymbol{d}), \pi(w)\rangle$ (as $a \notin \mathrm{data}(\boldsymbol{d})$ by $a \equiv_S b$), and $\pi\langle \ell^+(b), w\rangle = \langle \ell^+(b), \pi(w)\rangle$. By Corollary 6, there exists an accepting run of $\mathcal{A}$ on $\pi(w)$ that starts in $\ell^{\mathcal{A}}(\boldsymbol{d})$, and $\mathrm{Succ}_{\mathcal{B}}(\ell^+(b), \pi(w))$ is accepting. We prove that $\mathrm{Succ}_{\mathcal{B}}(\ell(c), \pi(w))$ is non-accepting, for every $\ell(c) \in C \setminus \{\ell^+(b)\} \cup C_b^-$: first, let $\ell(c) \in C \setminus \{\ell^+(b)\}$. By essential coverability of C, $\{\ell^+(b), \ell(c)\}$ is coverable. By unambiguity of $\mathcal{B}$, $\mathrm{Succ}_{\mathcal{B}}(\ell(c), \pi(w))$ must be non-accepting. Second, let $\ell(c) \in C_b^-$. But then $c = b$, and hence $\pi\langle \ell(c), w\rangle = \langle \ell(c), \pi(w)\rangle$. By assumption, $\mathrm{Succ}_{\mathcal{B}}(\ell(c), w)$ is non-accepting, so that by Corollary 6, $\mathrm{Succ}_{\mathcal{B}}(\ell(c), \pi(w))$ is non-accepting, too. Note that $\pi(w)$ indeed does not contain any a's. We can hence continue the proof assuming that w does not contain any a's.

Next, we prove that if we replace all b's occurring in w by some fresh datum not occurring in $\mathrm{supp}(C) \cup \mathrm{data}(w) \cup \mathrm{data}(\boldsymbol{d})$, we obtain a data word that guides S to a bad synchronized configuration. Formally, pick some datum $b' \notin \mathrm{data}(w) \cup \mathrm{supp}(C) \cup \mathrm{data}(\boldsymbol{d})$, and let π be the partial isomorphism defined by $\pi(b) = b'$, $\pi(b') = b$, and $\pi(d) = d$ for all $d \in \mathbb{N}_\perp \backslash \{b, b'\}$. Note that $\pi(w)$ does not contain any a's or b's. Clearly, $\pi\langle \ell^{\mathcal{A}}(\boldsymbol{d}), w\rangle = \langle \ell^{\mathcal{A}}(\boldsymbol{d}), \pi(w)\rangle$. By Corollary 6, there still exists an accepting run of $\mathcal{A}$ on $\pi(w)$ that starts in $\ell^{\mathcal{A}}(\boldsymbol{d})$. We prove that $\mathrm{Succ}_{\mathcal{B}}(C, \pi(w))$ is non-accepting. Let $\ell(c) \in C$. We distinguish three cases.

1. Let $c \notin \{b, b'\}$. Then $\pi\langle \ell(c), w\rangle = \langle \ell(c), \pi(w)\rangle$. Since $\mathrm{Succ}_{\mathcal{B}}(\ell(c), w)$ is non-accepting by assumption, so that by Corollary 6 also $\mathrm{Succ}_{\mathcal{B}}(\ell(c), \pi(w))$ is non-accepting.
2. Let $c = b$. By $a \equiv_C b$, the state $\ell(a)$ is in C and $\ell(a), \pi(w) \sim \ell(c), \pi(w)$ since a and c do not appear in w. By essential coverability of C, $\{\ell(a), \ell(c)\} \subseteq C$ is coverable. By unambiguity of $\mathcal{B}$, we obtain that $\mathrm{Succ}_{\mathcal{B}}(\ell(c), \pi(w))$ is non-accepting.
3. Let $c = b'$. Note that $\pi\langle \ell(b), w\rangle = \langle \ell(b'), \pi(w)\rangle$. Recall that $b' \notin \mathrm{supp}(C)$. This implies that $\mathrm{data}(C \cap (\{\ell\} \times \mathbb{N}_\perp))$ is cofinite. We distinguish two cases.
   - $b \in \mathrm{data}(C \cap (\{\ell\} \times \mathbb{N}_\perp))$, i.e., $\ell(b) \in C$. But note that $\ell(b) \notin C_b^+$ by cofiniteness of $\mathrm{data}(C \cap (\{\ell\} \times \mathbb{N}_\perp))$. Hence $\ell(b) \in C \backslash \{\ell^+(b)\}$.
   - $b \notin \mathrm{data}(C \cap (\{\ell\} \times \mathbb{N}_\perp))$, i.e., $\ell(b) \in C_b^-$.

   In both cases, we have proved above that $\mathrm{Succ}(\ell(b), w)$ is non-accepting. By $\pi\langle \ell(b), w\rangle = \langle \ell(b'), \pi(w)\rangle$ and Corollary 6, $\mathrm{Succ}_{\mathcal{B}}(\ell(b'), \pi(w))$ is non-accepting, too.

Altogether we have proved that $\mathrm{Succ}_{\mathcal{B}}(C, \pi(w))$ is non-accepting, while there exists some accepting run of $\mathcal{A}$ on $\pi(w)$ starting in $\ell^{\mathcal{A}}(\boldsymbol{d})$. This concludes the proof for the ($\Leftarrow$)-direction.

($\Rightarrow$) Suppose there exists some data word w such that there exists some accepting run of $\mathcal{A}$ on w starting in $\ell^{\mathcal{A}}(\boldsymbol{d})$, and $\mathrm{Succ}_{\mathcal{B}}(C, w)$ is non-accepting. We assume in the following that $\mathrm{Succ}_{\mathcal{B}}(C \setminus C_b^+ \cup C_b^-, w)$ is accepting; otherwise we are done. Let $\ell^-(b)$ be a state in C_b^- such that $\mathrm{Succ}_{\mathcal{B}}(\ell^-(b), w)$ is accepting. Pick some datum $a' \in \mathbb{N}_\perp$ such that $a' \notin \mathrm{data}(w) \cup \mathrm{supp}(C) \cup \mathrm{data}(\boldsymbol{d})$. Let π be the isomorphism defined by $\pi(b) = a$, $\pi(a) = a'$, $\pi(a') = b$, and $\pi(d) = d$ for all $d \in \mathbb{N} \backslash \{a, b, a'\}$. Clearly, $\pi\langle \ell^{\mathcal{A}}(\boldsymbol{d}), w\rangle = \langle \ell^{\mathcal{A}}(\boldsymbol{d}), \pi(w)\rangle$, so that by Corollary 6, there exists some accepting run of $\mathcal{A}$ on $\pi(w)$ starting in $\ell^{\mathcal{A}}(\boldsymbol{d})$. We prove that $\mathrm{Succ}_{\mathcal{B}}(C \backslash C_b^+ \cup C_b^-, \pi(w))$ is non-accepting. Let $\ell(c) \in C \backslash C_b^+ \cup C_b^-$. We distinguish the following cases:

1. Let $c = a$, i.e., $\ell(a) \in C$. By $a \equiv_S b$, we also have $\ell(b) \in C$. Note that $\pi\langle \ell(b), w\rangle = \langle \ell(a), \pi(w)\rangle$ and that $\ell(b) \neq \ell^-(b)$. By assumption, $\mathrm{Succ}_{\mathcal{B}}(\ell(b), w)$ is non-accepting. By Corollary 6, $\mathrm{Succ}_{\mathcal{B}}(\ell(a), \pi(w))$ is non-accepting, too.
2. Let $c \neq a$. Note that also $\pi\langle \ell^-(b), w\rangle = \langle \ell^-(a), \pi(w)\rangle$. Recall that $\mathrm{Succ}_{\mathcal{B}}(\ell^-(b), w)$ is accepting. By Corollary 6, $\mathrm{Succ}_{\mathcal{B}}(\ell^-(a), \pi(w))$ is accepting. We prove below that $\{\ell^-(a), \ell(c)\}$ is coverable. By unambiguity of $\mathcal{B}$, this directly implies that $\mathrm{Succ}_{\mathcal{B}}(\ell(c), \pi(w))$ is non-accepting.

   Recall that $\{d \in \mathbb{N} \mid \ell^-(d) \in C\}$ is cofinite. Pick some datum $d \in \mathbb{N} \backslash \{c\}$ such that $\ell^-(d) \in C$. We distinguish two cases.

- Assume $\ell(c) \in C \backslash C_b^+$. Since C is essentially coverable, the set $\{\ell^-(d), \ell(c)\}$ is coverable. Hence there must exist some data word u such that $\{\ell^-(d), \ell(c)\} \subseteq \mathrm{Succ}_{\mathcal{B}}(\ell_{\mathrm{init}}(\bot), u)$. Let π' be a partial isomorphism satisfying $\pi'(d) = a$, $\pi'(a) = d$, and $\pi'(e) = e$ for all $e \in \mathrm{data}(u) \cup \{c\}$. Then $\{\ell^-(a), \ell(c)\} \subseteq \mathrm{Succ}_{\mathcal{B}}(\ell_{\mathrm{init}}(\bot), \pi'(u))$, hence $\{\ell^-(a), \ell(c)\}$ is coverable.
- Second suppose $\ell(c) \in C_b^-$, i.e., $c = b$. This implies that $\{e \in \mathbb{N} \mid \ell(e) \in C\}$ is cofinite. Pick some datum $e \in \mathbb{N} \backslash \{d\}$ such that $\ell(e) \in C$. Since C is essentially coverable, the set $\{\ell^-(d), \ell(e)\}$ is coverable. Hence there must exist some data word u such that $\{\ell^-(d), \ell(e)\} \subseteq \mathrm{Succ}_{\mathcal{B}}(\ell_{\mathrm{init}}(\bot), u)$. Let π' be a partial isomorphism satisfying $\pi'(d) = a$, $\pi'(a) = d$, $\pi'(b) = e$, $\pi'(e) = b$, and $\pi'(f) = f$ for all $f \in \mathrm{data}(u)$. Then $\{\ell(b), \ell^-(a)\} \subseteq \mathrm{Succ}_{\mathcal{B}}(\ell_{\mathrm{init}}(\bot), \pi'(u))$, hence $\{\ell(c), \ell^-(a)\}$ is coverable.

Altogether we have proved that $\mathrm{Succ}_{\mathcal{B}}((C \backslash C_b^+) \cup C_b^-, \pi(w))$ is non-accepting, while there is an accepting run of $\mathcal{A}$ on $\pi(w)$ starting in $\ell^{\mathcal{A}}(\boldsymbol{d})$. This finishes the proof for the ($\Rightarrow$)-direction, and thus the proof of the Proposition. ◀

The Theory of Concatenation over Finite Models

Abstract

We propose FC, a new logic on words that combines finite model theory with the theory of concatenation – a first-order logic that is based on word equations. Like the theory of concatenation, FC is built around word equations; in contrast to it, its semantics are defined to only allow finite models, by limiting the universe to a word and all its factors. As a consequence of this, FC has many of the desirable properties of FO on finite models, while being far more expressive than FO[<]. Most noteworthy among these desirable properties are sufficient criteria for efficient model checking, and capturing various complexity classes by adding operators for transitive closures or fixed points.

Not only does FC allow us to obtain new insights and techniques for expressive power and efficient evaluation of document spanners, but it also provides a general framework for logic on words that also has potential applications in other areas.

1 Introduction

This paper proposes a finite model version of the theory of concatenation: FC, a new logic that is designed to describe properties of words and to query them. While the idea of using logic on words is by no means new, the advantage of FC is its combination of expressive power and tractable model checking and evaluation.

Logic on words. A common way of using logic on words is *monadic second-order logic* (MSO) over a linear order (e. g. [53]). That is, a word w is seen as a sequence of positions, and predicates $\mathsf{P}_a(x)$ express "letter a at position x of w". This approach comes with two disadvantages for querying. The first is that factors (continuous subwords) cannot be expressed directly. Consider the query "return all factors of w". As variables refer to positions, the query would not return a factor u directly, but represent it as a set (or tuple) of positions that describe a specific occurrence of u in w. If u occurs more than once, the query result would contain each occurrence – unless the logic is powerful enough to prevent this.

This leads us to the second disadvantage, namely that MSO cannot compare factors of unbounded length. That is, while MSO can express queries like "return the positions of factors of length k that occur twice in w" for a fixed length k, it is impossible to express "return the positions of factors that occur twice in w"; or non-regular languages, like that of all words ww with $w \in \{\mathtt{a}, \mathtt{b}\}^*$. As a result, many natural relations on factors of w are inexpressible in MSO, in particular the concatenation $x = yz$.

Another approach to logic on words is the *theory of concatenation* (short: C). First defined by Quine [48], this logic is built on *word equations*, that is, equations of the form $xx \doteq yyy$, where variables like x and y stand for words over a finite alphabet Σ. While less prominent than FO or MSO, the theory of concatenation has been studied extensively since the 1970s, with particular emphasis on word equations. A fairly recent survey on the satisfiability of word equations is [14]. More current research on word equations and the theory of concatenation can be found in e. g. [7, 10, 11, 12, 44, 50].

In contrast to MSO, the logic C allows us to treat words as words (instead of intervals of positions) and a position in w can be expressed as the corresponding prefix of w. More importantly, C can express properties like "u is a factor of v" or concatenation like $x = yz$. This expressive power comes at a price – even limited use of negation leads to an undecidable theory (i. e., satisfiability is undecidable, see [17, 48]). Contrast this to *first-order logic* (FO) over finite models: By Trakhtenbrot's theorem, satisfiability is undecidable; but the model checking problem is not just decidable, but can even be made tractable (see e. g. [18, 36]).

Another situation where using queries for words together with an open universe causes problems occurs in *string databases*, see [4, 5, 27, 28]. These query languages treat words as entries of the database instead of operating on a single word. Furthermore, they offer transformation operations that assume an infinite universe. As a result, these query language usually express Turing-complete functions from words to words.

Introducing FC. The new logic FC aims to bring the advantages of FO on finite models to the theory of concatenation. The universe for C is usually assumed to be Σ^*, which means that there is no meaningful distinction between satisfiability and model checking. The key idea of FC is changing universe from Σ^* to the set of all factors of a word w; comparable to how the universe for MSO consists of all positions of a word w.

As FC-formulas are based on word equations, concatenation is straightforward to use. For example, "return all factors that occur twice in w" can be expressed as

$$\varphi_1(x) := \exists p_1, p_2, s_1, s_2 \colon \big(\mathfrak{u} \doteq p_1\, x\, s_1 \wedge \mathfrak{u} \doteq p_2\, x\, s_2 \wedge \neg p_1 \doteq p_2\big),$$

where $\mathfrak{u}$ represents w. In detail, φ_1 expresses that there are two different ways of decomposing w into $w = p\, x\, s$. If we also wanted to know the positions of these occurrences, we could return p_1 and p_2 (by removing their quantifiers), as these encode the start of each occurrence in w. This formula does not rely on the requirement that variables can only be mapped to factors of w, as the $\mathfrak{u}$ on the left side of the equations ensures this already. Instead, consider

$$\varphi_2(x) := \exists y, z \colon y \doteq x\, z\, x,$$

which returns all factors x that have two non-overlapping occurrences in w. As we not need to know where in w the factor xzx occurs, $\mathfrak{u}$ is not needed in the formula.

The restriction to a finite universe allows us to translate various classical results from FO to FC. Most importantly, model checking becomes not only decidable, but upper bounds can be lowered in the same way as for FO (Section 4.1). In fact, FC can be extended with iteration operators to characterize complexity classes from L to PSPACE, analogously to FO

on ordered structures; which allows us to define a version of Datalog on words that includes concatenation (Section 4.3). Furthermore, Section 5 also describes how FC can be extended with *constraints* (aka *predicates*), while still keeping model checking tractable.

Spanners. An immediate application of FC is as a logic for *document spanners* (or just *spanners*). Spanners are a rule-based framework for information extraction that was proposed by Fagin, Kimelfeld, Reiss, and Vansummeren [19] to study the formal properties of the query language AQL of IBM's SystemT for information extraction. They can be understood as a combination of regular expressions and relational algebra.

In the last years, spanners have received considerable attention in the database theory community. The two main areas of interest are expressive power [19, 22, 23, 41, 43, 45, 47, 52] and efficient evaluation [3, 21, 24, 41, 42, 45, 46, 52]; further topics include updates [3, 25, 37], cleaning [20], distributed query planning [15], and a weighted variant [16].

But most of these articles do not focus on the full class of spanners that was introduced by Fagin et al. (called *core spanners*, as they describe the core of AQL), but a much smaller subclass, the *regular spanners*. The difference between these is that regular spanners cannot express equality of factors. Hence, techniques for finite automata and MSO often work on regular spanners; but they rarely work for core spanners. Furthermore, although spanners are conceptually similar to relational algebra, many canonical approaches for relational databases and the underlying FO are not viable in the spanner setting. In particular, while *acyclic conjuctive queries* are well-known to be tractable for FO (see e. g. [1]), this does not hold for the corresponding class of spanners (see [24]).

Although "pure" FC is not powerful enough to express core spanners, extending it with constraints that decide regular languages results in a logic that captures core spanners (Section 5.2). In addition to providing us with a rich and natural class of tractable spanners, this connection also allows us to develop a new inexpressibility method (Section 5.3).

2 Preliminaries

Let ε denote the *empty word*. We use $|x|$ for the length of a word, a formula, or a regular expression x, or the number of elements of a finite set x. A word v is a *factor* of a word w, written $v \sqsubseteq w$, if there exists (possibly empty) words p, s with $w = pvs$. For words x and y, let $x \sqsubseteq_{\mathsf{p}} y$ (x is a *prefix* of y) if $y = xs$ for some s, and $x \sqsubset_{\mathsf{p}} y$ if $x \sqsubseteq_{\mathsf{p}} y$ and $x \neq y$.

For alphabets A, B, a *morphism* is a function $h\colon A^* \to B^*$ with $h(u \cdot v) = h(u) \cdot h(v)$ for all $u, v \in A^*$. To define h, it suffices to define $h(a)$ for all $a \in A$. Let Σ be a finite *terminal alphabet*, and let Ξ be an infinite *variable alphabet* with $\Sigma \cap \Xi = \emptyset$. We assume Σ is fixed and $|\Sigma| \geq 2$, unless stated otherwise. As a convention, we use typewriter letters (like $\mathtt{a}$ and $\mathtt{b}$) for terminals.

Patterns and the theory of concatenation. A *pattern* is a word from $(\Sigma \cup \Xi)^*$. For every pattern $\eta \in (\Sigma \cup \Xi)^*$, let $\mathsf{Var}(\eta)$ denote the set of variables that occur in η. A *pattern substitution* (or just *substitution*) is a partial morphism $\sigma\colon (\Sigma \cup \Xi)^* \to \Sigma^*$ with $\sigma(\mathtt{a}) = \mathtt{a}$ for all $\mathtt{a} \in \Sigma$. When applying a substitution σ to a pattern η, we assume σ is defined on $\mathsf{Var}(\eta)$, that is, $\mathsf{Dom}(\sigma) \supseteq \mathsf{Var}(\eta)$. A *word equation* is a pair of patterns, that is, a pair (η_L, η_R) with $\eta_L, \eta_R \in (\Sigma \cup \Xi)^*$. We also write $\eta_L \doteq \eta_R$, and call η_L and η_R the *left side* and the *right side* of the equation. A *solution* of $\eta_L \doteq \eta_R$ is a substitution σ with $\sigma(\eta_L) = \sigma(\eta_R)$.

The theory of concatenation combines word equations with first-order logic. First the syntax: The set C of formulas of the *theory of concatenation* uses word equations $(\eta_L \doteq \eta_R)$ with $\eta_L, \eta_R \in (\Sigma \cup \Xi)^*$ as atoms. The connectives are conjunction, disjunction, negation, and quantifiers with variables from Ξ. For every $\varphi \in \mathsf{C}$, we define its set of *free variables* $\mathsf{free}(\varphi)$ by $\mathsf{free}(\eta_L \doteq \eta_R) := \mathsf{Var}(\eta_L) \cup \mathsf{Var}(\eta_R)$; extending this canonically.

The semantics build on solutions of word equations: For all $\varphi \in \mathsf{C}$ and all pattern substitutions σ with $\mathsf{Dom}(\sigma) \supseteq \mathsf{free}(\varphi)$, we define $\sigma \models \varphi$ as follows: Let $\sigma \models (\eta_L \doteq \eta_R)$ if $\sigma(\eta_L) = \sigma(\eta_R)$. For the quantifiers, we say $\sigma \models \exists x\colon \varphi$ (or $\sigma \models \forall x\colon \varphi$) if $\sigma_{x \mapsto w} \models \varphi$ holds for an (or all) $w \in \Sigma^*$, where $\sigma_{x \mapsto w}$ is defined by $\sigma_{x \mapsto w}(x) := w$ and $\sigma_{x \mapsto w}(y) := \sigma(y)$ for all $y \in (\Sigma \cup \Xi) - \{x\}$. The connectives' semantics are defined canonically.

▶ **Example 2.1.** Let $\varphi := x\mathtt{abc}y \doteq y\mathtt{bca}x \wedge \neg(x \doteq \varepsilon \vee y \doteq \varepsilon)$. Then $\sigma \models \varphi$ if and only if $\sigma(x\mathtt{abc}y) = \sigma(y\mathtt{bca}x)$, $\sigma(x) \neq \varepsilon$, and $\sigma(y) \neq \varepsilon$. For example, if $\sigma(x) = \mathtt{abca}$ and $\sigma(y) = \mathtt{a}$.

We freely add and omit parentheses as long as the meaning stays clear. E-C, the *existential fragment* of C, consists of those formulas that do not use universal quantifiers and that apply negation only to word equations. The *existential-positive fragment* EP-C allows neither universal quantifiers, nor negation. We also use this notation for other logics that we define.

3 Finite models in the theory of concatenation

The new logic *finite model version of the theory of concatenation*, namely FC, is built around word equations; similarly to the theory of concatenation C. The latter can be understood as first-order logic over the universe Σ^* with concatenation – see for example [29], which refers to C as $\mathsf{FO}(A^*, \cdot)$. In other words, for C, we can consider the universe to be fixed (for a given terminal alphabet Σ). The key idea of FC is to replace the universe Σ^* with a single word and all its factors. In the formulas, this word is represented by a distinguished variable:

▶ **Definition 3.1.** *We distinguish a variable* $\mathfrak{u} \in \Xi$ *and call it the* universe variable.

As the universe variable represents the universe (hence its name), it has a special role in both syntax and semantics of FC. The *syntax of FC* restricts the syntax of C in two ways:

▶ **Definition 3.2.** *The set* FC *of* FC-formulas *is defined recursively: The atoms are word equations* $(\eta_L \doteq \eta_R)$ *with* $\eta_L \in \Xi$ *and* $\eta_R \in (\Sigma \cup \Xi)^*$*. These can be combined using disjunction* $(\varphi \vee \psi)$*, conjunction* $(\varphi \wedge \psi)$*, negation* $\neg\varphi$*, and quantifiers* $\exists x\colon \varphi$ *and* $\forall x\colon \varphi$ *with* $x \in \Xi - \{\mathfrak{u}\}$.

In other words, firstly, every word equation has a single variable on its left side. Secondly, the universe variable $\mathfrak{u}$ may not be bound by quantifiers. The reason for the first restriction is a bit subtle; we shall discuss it after defining the semantics. But the other follows immediately from the intuition that $\mathfrak{u}$ shall represent the universe – hence, binding it would make no sense. For the same reason, we also exclude $\mathfrak{u}$ from the free variables of FC-formulas:

▶ **Definition 3.3.** *The set* $\mathsf{free}(\varphi)$ *of free variables of an* FC*-formula* φ *is defined as for* C*-formulas, with the exception that* $\mathfrak{u}$ *is not considered a free variable.*

The *semantics of FC* combine those of C with the additional condition that the universe consists only of factors of the content of the universe variable $\mathfrak{u}$:

▶ **Definition 3.4.** *For* $\varphi \in \mathsf{FC}$ *and a pattern substitution* σ *with* $\mathsf{Dom}(\sigma) \supseteq \mathsf{free}(\varphi) \cup \{\mathfrak{u}\}$*, we define* $\sigma \models \varphi$ *as for* C*, but with the additional condition that* $\sigma(x) \sqsubseteq \sigma(\mathfrak{u})$ *for all* $x \in \mathsf{Dom}(\sigma)$.

To highlight the special role of $\mathfrak{u}$, we also write $(w, \sigma) \models \varphi$ if $\sigma \models \varphi$ and $w = \sigma(\mathfrak{u})$. We may shorten this to $w \models \varphi$ if φ is a *sentence* – that is, if $\mathsf{free}(\varphi) = \emptyset$. We write $\varphi(\vec{x})$ to denote that $\vec{x}$ is a tuple of free variables of φ.

▶ **Example 3.5.** Define $\varphi_1(y) := \exists x\colon x \doteq \mathtt{papaya}\, y\, \mathtt{banana}$ and $\varphi_2 := \exists x\colon (x \doteq \mathtt{papaya} \vee x \doteq \mathtt{banana})$. Then $(w, \sigma) \models \varphi_1$ if and only if $\sigma(y)$ occurs in w between $\mathtt{papaya}$ and $\mathtt{banana}$, and $w \models \varphi_2$ if and only if w contains $\mathtt{papaya}$ or $\mathtt{banana}$ as factor. Finally, let $\varphi_3(x) := \exists p, s\colon \big(\mathfrak{u} \doteq p\, x\, s \wedge \neg \exists \hat{p}, \hat{s}\colon (\mathfrak{u} \doteq \hat{p}\, x\, \hat{s} \wedge \neg \hat{p} \doteq p)\big)$. Then $(w, \sigma) \models \varphi_3$ if and only if $\sigma(x)$ occurs exactly once in w.

When applying σ to an FC-formula, $\sigma(\mathfrak{u})$ always needs to be defined – otherwise, we would have no universe to work with. But FC-formulas do not need to contain $\mathfrak{u}$. As a rule of thumb, $\mathfrak{u}$ is only required when referring to some "global" property of w. If we describe properties that are more "local" (as in the next example), we usually do not need to use $\mathfrak{u}$.

▶ **Example 3.6.** Let $\varphi^{\sqsubseteq_\mathsf{p}}(x, y) := \exists z\colon y \doteq xz$. Then $\sigma \models \varphi$ if and only if $\sigma(x)$ and $\sigma(y)$ are factors of $\sigma(\mathfrak{u})$ with $\sigma(x) \sqsubseteq_\mathsf{p} \sigma(y)$. In other words, $\varphi^{\sqsubseteq_\mathsf{p}}$ expresses $x \sqsubseteq_\mathsf{p} y$. Consequently, we can express $x \sqsubset_\mathsf{p} y$ through $\varphi^{\sqsubset_\mathsf{p}}(x, y) := \varphi^{\sqsubseteq_\mathsf{p}}(x, y) \wedge \neg x \doteq y$.

In fact, $\sqsubset_\mathsf{p}$ and inequality can be expressed without negation (or universal quantifiers). First, define $\varphi(x)^{\neq\varepsilon} := \exists y\colon \bigvee_{\mathtt{a}\in\Sigma} x \doteq \mathtt{a}\, y$ to express $x \neq \varepsilon$ – that is, $\sigma \models \varphi^{\neq\varepsilon}$ if and only if $\sigma(x) \sqsubseteq \sigma(\mathfrak{u})$ and $\sigma(x) \neq \varepsilon$. We use this in $\psi^{\sqsubset_\mathsf{p}}(x, y) := \exists z\colon (y \doteq x\, z \wedge \varphi^{\neq\varepsilon}(z))$. Like $\varphi^{\sqsubset_\mathsf{p}}$, this expresses $x \sqsubset_\mathsf{p} y$; but without negation.

Finally, let $\varphi^{\neq}(x, y) := \psi^{\sqsubset_\mathsf{p}}(x, y) \vee \psi^{\sqsubset_\mathsf{p}}(y, x) \vee \bigvee_{\mathtt{a},\mathtt{b}\in\Sigma,\mathtt{a}\neq\mathtt{b}} \exists x_1, y_1, z\colon (x \doteq z\, \mathtt{a}\, x_1 \wedge y \doteq z\, \mathtt{b}\, y_1)$. This states that $x \sqsubset_\mathsf{p} y$, $y \sqsubset_\mathsf{p} x$, or x and y differ after a common prefix z – that is, $x \neq y$.

We say $\varphi, \psi \in \mathsf{FC}$ are *equivalent*, written $\varphi \equiv \psi$, if for all σ with $\mathsf{Dom}(\sigma) \supseteq \mathsf{free}(\varphi) \cup \mathsf{free}(\psi) \cup \{\mathfrak{u}\}$, we have that $\sigma \models \varphi$ holds if and only if $\sigma \models \psi$. Thus, in Example 3.6, we have $\varphi^{\sqsubset_\mathsf{p}} \equiv \psi^{\sqsubset_\mathsf{p}}$. If $\varphi \in \mathsf{FC}$ is a sentence, we define its language as $\mathcal{L}(\varphi) := \{w \mid w \models \varphi\}$.

▶ **Example 3.7.** A language is called *star-free* if it is defined by a regular expression α that is constructed from the empty set $\emptyset$, terminals $\mathtt{a} \in \Sigma$, concatenation $\cdot$, union $\cup$, and complement $\overline{\alpha}$. Given such an α, we define $\varphi^\alpha := \exists x\colon (\mathfrak{u} \doteq x \wedge \psi^\alpha(x))$, where $\psi^\alpha(x)$ is defined recursively by $\psi^\emptyset(x) := \neg(x \doteq x)$, $\psi^\mathtt{a}(x) := (x \doteq \mathtt{a})$, $\psi^{(\alpha_1 \cdot \alpha_2)}(x) := \exists x_1, x_2\colon \big(x \doteq x_1\, x_2 \wedge \psi^{\alpha_1}(x_1) \wedge \psi^{\alpha_2}(x_2)\big)$, $\psi^{(\alpha_1 \cup \alpha_2)}(x) := \psi^{\alpha_1}(x) \vee \psi^{\alpha_1}(x)$, and $\psi^{\overline{\alpha}}(x) := \neg\psi^\alpha(x)$. Then $\sigma \models \psi^\alpha$ if and only if $\sigma(x) \in \mathcal{L}(\alpha)$ and $\sigma(x) \sqsubseteq \sigma(\mathfrak{u})$. Thus, $\mathcal{L}(\varphi^\alpha) = \mathcal{L}(\alpha)$.

We are now ready to discuss why Definition 3.2 restricts the left sides of word equations to single variables. Assume we allowed, for instance, the word equation $xy \doteq yx$ in an FC-formula, and consider the case of $\sigma(\mathfrak{u}) = \mathtt{a}^3$ and $\sigma(x) = \sigma(y) = \mathtt{a}^2$. Then $\sigma(x) \sqsubseteq \sigma(\mathfrak{u})$, $\sigma(y) \sqsubseteq \sigma(\mathfrak{u})$, and $\sigma(xy) = \sigma(yx)$ hold, but $\sigma(xy) = \mathtt{a}^4$ is not a factor of $\sigma(\mathfrak{u})$, which means that it is not in the universe.

There are two straightforward ways of allowing arbitrary word equations $\eta_L \doteq \eta_R$ in FC without changing the underlying universe. The first is adding the additional requirements $\sigma(\eta_L) \sqsubseteq \sigma(\mathfrak{u})$ and $\sigma(\eta_R) \sqsubseteq \sigma(\mathfrak{u})$ to the definition of $\sigma \models (\eta_L \doteq \eta_R)$. This can also be understood as declaring the concatenation as undefined if its result is not a factor of $\sigma(\mathfrak{u})$. The second is interpreting $\eta_L \doteq \eta_R$ as syntactic sugar for $\exists x\colon (x \doteq \eta_L \wedge x \doteq \eta_R)$, where x is a new variable.

On the other hand, this re-interpretation of the solutions of word equations can be considered non-intuitive, which makes formulas that rely on these easy to misunderstand. To avoid these issues, this paper restricts every left side to a single variables, even though this is not strictly necessary.

4 Properties of FC

In this section we analyze FC dynamically by discussing its *evaluation problem* – given a formula $\varphi \in \mathsf{FC}$ and a pattern substitution σ, decide whether $\sigma \models \varphi$. We call the special case where φ is a sentence the *model checking problem*. We also consider the *satisfiability problem* – given $\varphi \in \mathsf{FC}$, decide whether there is a pattern substitution σ with $\sigma \models \varphi$. After that, we also consider aspects of optimization of formulas.

4.1 Model checking vs satisfiability

For C, the model checking problem is undecidable. This is due to two reasons. Firstly, the satisfiability problem for C is undecidable by Quine [48]. Secondly, for C, satisfiability reduces to model checking – from a given $\varphi \in \mathsf{C}$, we can construct a C-sentence φ' by binding all free variables of φ existentially. Then φ is satisfiable if and only if $\sigma \models \varphi'$, no matter which substitution σ we choose. In contrast to this, the finite universe of FC drastically reduces the complexity of model checking.

▶ **Theorem 4.1.** *Evaluation is* PSPACE*-complete for* FC *and* NP*-complete for* EP-FC*.*

In fact, the proof shows that the lower bounds hold even in the special case of model checking $\mathsf{a} \models \varphi$. Both the drop in complexity and the fact a very simple structure suffice are comparable to FO on finite relations (see e. g. [36]), and the proofs are equally straightforward. For both logics, the hardness of the problem comes from parameters of the formula and not of the word or the relational structure. FO provides us with another parameter to lower the complexity of model checking. We define the *width* $\mathsf{wd}(\varphi)$ of a formula φ as the maximum number of free variables in any of its subformulas.

▶ **Theorem 4.2.** *Model checking for* FC *can be solved in time* $O(k|\varphi|n^{2k})$*, for* $k := \mathsf{wd}(\varphi)$ *and* $n := |\sigma(\mathfrak{u})|$*.*

The proof also shows that this is only a rough upper bound; taking properties of variables into account lowers the exponent. In principle, we can apply various structure parameters for first-order formulas (see e. g. Adler and Weyer [2]) to FC. This assumes that we treat word equations as atomic formulas, which is certainly possible – but we can do better than that.

Decomposing patterns. Using a word equation $x \doteq \alpha$ as an atom results in a formula that has a width of at least $|\mathsf{Var}(\alpha)|$. Our goal is to lower that bound, by decomposing the pattern into a formula. Technically, a pattern $\alpha = \alpha_1 \cdots \alpha_n$ with $\alpha_i \in (\Xi \cup \Sigma)$ is a term $f(\alpha_1, \ldots, \alpha_n)$, where the function f is the n-ary concatenation. But there is a syntactic criterion that allows us to decompose α into a conjunction of binary concatenations. This builds on a result from combinatorics on words and formal languages, where a pattern α is also treated as generators of the *pattern languages* $\mathcal{L}(\alpha)$; the set of images of α under pattern substitutions. In this context, Reidenbach and Schmid [49] started a series of articles on classes of *pattern languages* with a polynomial time membership problem (surveyed in [40]), most of which rely on the following definition (see [8] for the definition of treewidth).

▶ **Definition 4.3.** *The* standard graph *of a pattern* $\alpha = \alpha_1 \cdots \alpha_n$ *with* $n \geq 1$ *and* $\alpha_i \in (\Sigma \cup \Xi)$ *is* $\mathcal{G}_\alpha := (V_\alpha, E_\alpha)$ *with* $V_\alpha := \{1, \ldots, n\}$ *and* $E_\alpha := E_\alpha^{<} \cup E_\alpha^{=}$*, where* $E_\alpha^{<}$ *is the set of all* $\{i, i+1\}$ *with* $1 \leq i < n$*, and* $E_\alpha^{=}$ *is the set of all* $\{i, j\}$ *such that* α_i *is some* $x \in \Xi$*, and* α_j *is the next occurrence of* x *in* α*. Then* $\mathsf{tw}(\alpha)$*, the* treewidth *of* α*, is the treewidth of* $\mathcal{G}_\alpha$*.*

As artificial (but simple) example, consider the sequence of patterns $\alpha_n := x_1x_1x_2x_2 \cdots x_nx_n$. Then $|\mathsf{Var}(\alpha_n)| = n$, affecting the width of formulas that use α_n accordingly, but $\mathsf{tw}(\alpha_n) = 1$. Using tree decompositions, we can rewrite patterns of bounded treewidth into formulas of bounded width (similar to the proof of Kolaitis and Vardi [34] for variable bounded FO).

▶ **Theorem 4.4.** *Let $\varphi := \exists x_1, \dots, x_m \colon y \doteq \alpha$. Then there exists $\psi \in$ EP-FC with $\psi \equiv \varphi$ and $\mathsf{wd}(\psi) \leq 2\mathsf{tw}(\alpha) + v$, where $v = 2 + |\mathsf{free}(y \doteq \alpha) - \{x_1, \dots, x_m\}|$.*

For every fixed k, given φ with $\mathsf{tw}(\alpha) \leq k$, we can compute ψ in polynomial time.

Combining Theorems 4.2 and 4.4 yields a (slightly) different proof of the polynomial time decidability of the membership problem for classes of patterns with bounded treewidth from [49]. As pointed out in [9], bounded treewidth does not cover all pattern languages with a polynomial time membership problem, like e. g. patterns α^k where $\mathsf{tw}(\alpha)$ is bounded. But these languages can be expressed by $\exists x \colon (\mathfrak{u} \doteq x^k \wedge \varphi_\alpha(x))$, where $\varphi_\alpha(x)$ is a formula that expresses $x \in \mathcal{L}(\alpha)$, thus increasing the width by one. We leave a systematic examination whether all criteria for patterns with a tractable membership problem map to FC-formulas of bounded width for future work.

Satisfiability. Another parallel to FO is that satisfiability is undecidable for FC, even if we use only few variables. Let FC^k denote the set of formulas with width at most k.

▶ **Proposition 4.5.** *Satisfiability for FC^3 is undecidable if $|\Sigma| \geq 2$.*

The problem is trivial for FC^0 (see the proof of Theorem 4.8) and open for FC^1 and FC^2.

4.2 Static optimization

Apart from the width, Theorem 4.2 highlights the length of a formula as another parameter that influences the complexity of model checking. While the length of the patterns in the word equations might not seem to be factor that is overly important, there are patterns where straightforward optimizations can lead to an exponential advantage.

▶ **Example 4.6.** For $k \geq 1$, let $\varphi_k(y) := \exists x \colon y \doteq x^{2^k}$. Then $\varphi_k \equiv \psi_k := \exists x_1, \dots, x_k \colon \big(y \doteq x_1x_1 \wedge \bigwedge_{i=1}^{k-1} x_i \doteq x_{i+1}x_{i+1}\big)$, and $|\varphi_k|$ is exponential in k, while $|\psi_k|$ is linear in k. We can also rewrite ψ_k into a formula of width 3 by pulling quantifiers inwards and reusing variables. More specifically, we first rewrite each ψ_k into the equivalent formula

$$\exists x_1 \colon (y \doteq x_1x_1 \wedge (\exists x_2 \colon x_1 \doteq x_2x_2 \wedge \cdots (\exists x_{k-1} \colon x_k \doteq x_{k-1}x_{k-1}) \cdots)).$$

Then we replace every variable x_i with x_1 if i is odd or x_2 if i is even. The resulting formula has width 3 (due to y), is equivalent to φ_k, and has the same length.

This raises the questions whether we can computably minimize formulas and whether some fragments are more succinct than others. We address these questions in order.

▶ **Theorem 4.7.** *There is no algorithm that, given $\varphi \in$ FC, computes an equivalent ψ such that $|\psi|$ is minimal. This holds even if we restrict this to minimization within $\mathsf{EP\text{-}FC}^4$.*

This leaves open the decidability of, given $\varphi \in$ FC (or $\varphi \in$ EP-FC) and $k > 0$, is there an equivalent $\psi \in \mathsf{FC}^k$. But without suitable inexpressibility methods (see Section 5.3), we cannot even show that a language is inexpressible in FC^k for some $k > 0$, which complicates tackling this problem. The proof of Theorem 4.7 is actually more general and also demonstrates the undecidability of other common problems, like containment and equivalence.

Via Hartmanis' [30] meta theorem, certain undecidability results provide insights into the relative succinctness of models (see [35] or e. g. [23] for details). For two logics $\mathcal{F}_1$ and $\mathcal{F}_2$, the *tradeoff* from $\mathcal{F}_1$ to $\mathcal{F}_2$ is *non-recursive* if, for every computable $f\colon \mathbb{N} \to \mathbb{N}$, there exists some $\varphi \in \mathcal{F}_1$ that is expressible in $\mathcal{F}_2$, but $|\psi| \geq f(|\varphi|)$ holds for every $\psi \in \mathcal{F}_2$ with $\psi \equiv \varphi$.

▶ **Theorem 4.8.** *There are non-recursive tradeoffs from* EP-FC^4 *to regular expressions and* FC^0*; and from* FC^4 *to* EP-FC*, patterns, and singleton sets* $\{w\}$*.*

Note in particular that patterns can be parts of word equations. Hence, where Example 4.6 showed an exponential advantage in the rewriting, Theorem 4.8 shows FC^4 can obtain far larger advantages on certain classes of patterns.

4.3 Iteration and recursion

Iteration and recursion have been extensively studied in finite model theory and database theory. In particular, FO[<] that is extended with operators for transitive closure or fixed points captures various complexity classes (see e. g. [18, 36]). This is also closely connected to the recursive query language Datalog (see e. g. [1]). In this section, we shall define FC-Datalog, an FC-analog of Datalog. On the way, we shall also see that using transitive closures or fixed points on FC instead of FO[<] characterizes the same complexity classes.

Iteration. The definitions of these operators and the resulting extensions of FC are straightforward adaptions of their FO[<]-versions (see e. g. [36] or [18]). But as they are also rather lengthy, we only give the intuitions behind them (detailed definitions can be found in the full version of this paper).

For $k \geq 1$, an FC-formula with $2k$ free variables can be viewed as generator of a relation over $R \subseteq S^k \times S^k$, where S is the universe (the set of factors of $\mathfrak{u}$). The operator tc computes the *transitive closure* $\mathsf{tc}(R)$ of R. If we view R as edge set of a directed graph over S^k, then tc computes the reachability relation in this graph. The *deterministic transitive closure* dtc is defined analogously, with the additional restriction that dtc stops at nodes with more than one outgoing edge. FC$^{\mathsf{tc}}$ and FC$^{\mathsf{dtc}}$ extend FC with tc and dtc, respectively.

For fixed points, we introduce special relation symbols as part of inductive definitions. Inside a fixed point operator, a formula φ may use a symbol $\dot{R}$ and at the same time also define the relation R inductively. We start with $R_0 := \emptyset$ and let R_1 be the relation that is defined by φ if $\dot{R}$ represents R_0. This is repeated, each R_i giving rise to R_{i+1}, until a fixed point is reached. For *least fixed points*, we ensure $R_i \subseteq R_{i+1}$ for all i. For *partial fixed points*, this is not required. We use FC$^{\mathsf{lfp}}$ and FC$^{\mathsf{pfp}}$ for the respective extensions of FC.

Complexity classes are commonly defined as classes of languages; and as we can treat FC and its extensions as language generators, connecting these two worlds is straightforward. We say that a logic $\mathcal{F}$ *captures* a complexity class $\mathbb{C}$ if $\mathbb{C}$ is the class of languages that are $\mathcal{F}$-definable – that is, $\mathbb{C} = \{\mathcal{L}(\varphi) \mid \varphi \in \mathcal{F}\}$.

The following result mirrors that for the respective extensions of FO[<]:

▶ **Theorem 4.9.** FC$^{\mathsf{dtc}}$*,* FC$^{\mathsf{tc}}$*,* FC$^{\mathsf{lfp}}$*,* FC$^{\mathsf{pfp}}$ *capture* L*,* NL*,* P*,* PSPACE*, respectively.*

The result holds even if the formulas are required to be existential-positive. Thus, FC and even EP-FC behave under fixed-points and transitive closures like FO[<].

Recursion. This connection immediately suggests another: Recall that FO with least-fixed point operators can be used to define Datalog (see e. g. Part D of [1]). Analogously, we define FC-Datalog, a version of Datalog that is based on word equations.

An FC-Datalog-program is a tuple $P := (\mathcal{R}, \Phi, \mathsf{Ans})$, where $\mathcal{R}$ is a set of relation symbols that contains a special output symbol Ans, each $R \in \mathcal{R}$ has an arity $\mathsf{ar}(R)$, and Φ is a finite set of rules $R(\vec{x}) \leftarrow \varphi_1(\vec{y}_1), \dots, \varphi_m(\vec{y}_m)$ with $R \in \mathcal{R}$, $m \geq 1$, each φ_i is an FC-word equation, and each x of $\vec{x}$ appears in some $\vec{y}_i$.

We define $[\![P]\!](w)$ incrementally, initializing the relations of all $R \in \mathcal{R}$ to $\emptyset$. For each rule $R(\vec{x}) \leftarrow \varphi_1(\vec{y}_1), \dots, \varphi_m(\vec{y}_m)$, we enumerate all σ with $\sigma(\mathfrak{u}) = w$ and check if $\sigma \models \exists \vec{y}\colon \bigwedge_{i=1}^{m} \varphi_i$, where $\vec{y} := (\bigcup_{i=1}^{m} \vec{y}_i) - \vec{x}$. If this holds, we add $\sigma(\vec{x})$ to R. This is repeated until all relations have stabilized. Then $[\![P]\!](w)$ is the content of the relation Ans.

▶ **Example 4.10.** Define an FC-Datalog-program $(\{\mathsf{Ans}, E\}, \Phi)$, where $\mathsf{ar}(\mathsf{Ans}) = 0$, $\mathsf{ar}(E) = 3$, and Φ consists of the rules $\mathsf{Ans}() \leftarrow \mathfrak{u} \doteq xyz, E(x, y, z)$, and $E(x, y, z) \leftarrow x \doteq \varepsilon, y \doteq \varepsilon, z \doteq \varepsilon$, and $E(x, y, z) \leftarrow x \doteq \hat{x}\mathtt{a}, y \doteq \hat{y}\mathtt{b}, z \doteq \hat{z}\mathtt{c}, E(\hat{x}, \hat{y}, \hat{z})$. This defines the language $\{\mathtt{a}^n\mathtt{b}^n\mathtt{c}^n \mid n \geq 0\}$.

▶ **Theorem 4.11.** FC-Datalog *captures* P.

This is unsurprising, considering Datalog on ordered structures captures P, see e. g. [36], and the analogous result for spanners with recursion [47]. But it allows us to use word equations as a basis for Datalog on words. This provides potential applications for future insights into acyclicity for patterns, which could be combined with existing techniques for Datalog.

FC-Datalog can also be seen as a generalization of *range concatenation grammars (RCGs)*, see [6, 31], to use outputs and relations. There has been some work on parsing of RCGs (see [32] and its references). In the future, these might help identify tractable fragments of FC-Datalog. Vice versa, insights into the latter might lead to new approaches to RCG-parsing.

5 FC as a logic for document spanners

Fagin et al. [19] introduced *document spanners* (or just *spanners*) as a formal model of information extraction that is based on relational algebra (see e. g. [1]). This section connects spanners to FC. After stating the necessary definitions (Section 5.1), we extend FC into a logic for spanners (Section 5.2) and then use this for an inexpressibility proof (Section 5.3).

5.1 Spans and document spanners

A *span* of $w := \mathtt{a}_1 \cdots \mathtt{a}_n$ with $n \geq 1$ is an interval $[i, j\rangle$ with $1 \leq i \leq j \leq n + 1$. It describes the factor $w_{[i,j\rangle} = \mathtt{a}_i \cdots \mathtt{a}_{j-1}$. For finite $V \subset \Xi$ and $w \in \Sigma^*$, a (V, w)-*tuple* is a function μ that maps each variable in V to a span of w. A *spanner* with variables V is a function P that maps every $w \in \Sigma^*$ to a set $P(w)$ of (V, w)-tuples. We use $\mathsf{Var}(P)$ for the variables of a spanner P. Accordingly, a spanner P is a function that takes an input word w and computes a relation $P(w)$ of $(\mathsf{Var}(P), w)$-tuples.

Like [19], we base spanners on *regex formulas*; regular expressions with variable bindings $x\{\alpha\}$. This matches the same words as the expression α and assigns the corresponding span of w to the variable x. For the purpose of this article, this informal definition shall suffice. Detailed definitions of the syntax and semantics of regex formulas can be found in [19] (the original definition that uses parse trees) and [22] (a more lightweight definition that uses the ref-words from Schmid [51]).

A regex formula is *functional* if on every word, every match has exactly one assignment for each variable. The set of functional regex formulas is RGX. For $\alpha \in \mathsf{RGX}$, we define the spanner $[\![\alpha]\!]$ as follows. Every match on $w \in \Sigma^*$ defines a $(\mathsf{Var}(\alpha), w)$-tuple μ, where each $\mu(x)$ is the span assigned to x; and $[\![\alpha]\!](w)$ is the set of all these μ.

▶ **Example 5.1.** We consider the regex formula $\alpha := \Sigma^*\big(x\{\texttt{banana}\} \cup x\{\texttt{papaya}\}\big)\Sigma^*$, which matches every word w that contains an occurrence of `banana` or `papaya`. The corresponding spanner $[\![\alpha]\!](w)$ contains all spans $[i, j\rangle$ with $w_{[i,j\rangle} \in \{\texttt{banana}, \texttt{papaya}\}$. Next, we define $\beta := \Sigma^* x\{\Sigma^*\}\Sigma^* y\{\Sigma^*\}\Sigma^*$. For every $w \in \Sigma^*$, we have that $[\![\beta]\!](w)$ contains those μ where $\mu(x)$ refers to a span to the left of $\mu(y)$.

We use the spanner operations union $\cup$, natural join $\bowtie$, projection π, set difference $-$, and equality selection $\zeta^=$. For spanners P_1 and P_2 with $\mathsf{Var}(P_1) = \mathsf{Var}(P_2)$, *union* and *set difference* are defined by $(P_1 \cup P_2)(w) := P_1(w) \cup P_2(w)$ and $(P_1 - P_2)(w) := P_1(w) - P_2(w)$ on all $w \in \Sigma^*$. Furthermore, the *projection* $\pi_V P$ for a spanner P and a set of variables $V \subset \mathsf{Var}(P)$ is obtained for every $w \in \Sigma^*$ by restricting the domain of every $\mu \in P(w)$ to V.

The *natural join* $P_1 \bowtie P_2$ combines spanner results by merging tuples that agree on the common variables. That is, $(P_1 \bowtie P_2)(w)$ contains those $(\mathsf{Var}(P_1) \cup \mathsf{Var}(P_2), w)$-tuples μ for which there exist $\mu_1 \in P_1(w)$ and $\mu_2 \in P_2(w)$ such that $\mu_1(x) = \mu_2(x)$ for all $x \in \mathsf{Var}(P_1) \cap \mathsf{Var}(P_2)$. An important consequence of this definition is that join is defined using spans (and thereby positions in the input word), not using the factors that occur in the spans. To compare factors, we use the *equality selection* $\zeta^=_{x,y} P$ with $x, y \in \mathsf{Var}(P)$. This is defined by $\zeta^=_{x,y} P(w) := \{\mu \in P(w) \mid w_{\mu(x)} = w_{\mu(y)}\}$ for $w \in \Sigma^*$.

By combining regex formulas with symbols for spanner operations, we obtain *spanner representations*; and their semantics are defined by applying the operations. The class of *generalized core spanner representations* $\mathsf{RGX}^{\mathsf{gcore}}$ consists of combinations of RGX and any of the five operators; the *core spanner representations* $\mathsf{RGX}^{\mathsf{core}}$ exclude set difference. According to Fagin et al. [19], "core spanners" capture the core functionality of IBM's SystemT.

▶ **Example 5.2.** Let α and β be the regex formulas from Example 5.1. We define the spanner representation $\varrho_1 := \alpha(x) \bowtie \alpha(y) \bowtie \beta(x, y)$. Then $\mathsf{Var}(\varrho_1) = \{x, y\}$, and $[\![\varrho_1]\!](w)$ contains those μ where $\mu(x)$ occurs before $\mu(y)$ in w and each of $w_{\mu(x)}$ and $w_{\mu(y)}$ is `banana` or `papaya`. Now let $\varrho_2 := \zeta^=_{x,y}\varrho_1$. Then $[\![\varrho_2]\!](w)$ is the subset of $[\![\varrho_1]\!](w)$ that also has $w_{\mu(x)} = w_{\mu(y)}$.

We identify spanners and their representations; e. g. by referring to a representation ϱ as a spanner (technically, $[\![\varrho]\!]$ is the spanner) or by calling the elements of $\mathsf{RGX}^{\mathsf{core}}$ *core spanners*.

5.2 Adding expressive power to FC

As core spanners are based on regular expressions, they can define all regular languages. This makes them more powerful than EP-FC. To prove this, we first connect FC to C.

▶ **Lemma 5.3.** *Given $\varphi \in \mathsf{FC}$, we can construct in polynomial time $\psi \in \mathsf{C}$ such that $\sigma \models \varphi$ if and only if $\sigma \models \psi$. This also preserves the properties existential and existential-positive.*

Hence, EP-FC is not more expressive than EP-C, which cannot express all regular languages – not even comparatively "harmless" languages like e. g. $\{\mathtt{a}, \mathtt{b}\}^*\mathtt{c}$ (see Karhumäki, Mignosi, Plandowski [33]). While we could define this specific language using negation, we shall address the issue in a way that generalizes far beyond regular languages and that does not require us to leave the existential-positive fragment (and its friendlier upper bounds). Complexity is also a reason why we do not use MSO or define a second-order version of FC.

Instead, take inspiration from C (see Diekert [13]). The *theory of concatenation with regular constraints*, C[REG], extends C by allowing *regular constraints* $x \mathrel{\dot\in} \alpha$ as atoms, where $x \in \Xi$, α is a regular expression, and $\sigma \models x \mathrel{\dot\in} \alpha$ if $\sigma(x) \in \mathcal{L}(\alpha)$. We define FC[REG] analogously, where $\sigma \models x \mathrel{\dot\in} \alpha$ has the additional condition that $\sigma(x) \sqsubseteq \sigma(\mathfrak{u})$ must hold.

▶ **Theorem 5.4.** *Theorem 4.1 and Theorem 4.2 also hold if we replace* FC *with* FC[REG] *and* EP-FC *with* EP-FC[REG].

In other words, evaluation is PSPACE-complete for FC[REG] and NP-complete for EP-FC[REG], and formula width can be used as parameter to bound model checking for FC[REG]. This generalizes to all constraints that can be decided in polynomial time, which allows us to adapt FC to other settings as well.

For example, string solvers often use *length constraints*. There are predicates that compare words by applying arithmetic to their lengths, like $|x| + |y| = |z|$. While the applications of EP-C in a string solver context usually rely on deciding satisfiability, cases where model checking suffices could benefit from using FC with appropriate constraints.

Regarding prior work, the C[REG]-fragments SpLog and $\mathsf{SpLog}^{\neg}$ were introduced in [22] as alternatives to $\mathsf{RGX}^{\mathsf{core}}$ and $\mathsf{RGX}^{\mathsf{gcore}}$, respectively. As these ensure the finite universe purely through syntax, they are more cumbersome than FC and do not generalize as nicely.

Before we connect FC[REG] to spanners, we take a brief look at restricted regular expressions that can be expressed in FC. We call a regular expression *simple* if the operator * is only applied to terminal words or to Σ (a shorthand for $\bigcup_{\mathtt{a}\in\Sigma}\mathtt{a}$). That is, if $\Sigma = \{\mathtt{a}, \mathtt{b}, \mathtt{c}\}$, then $(\mathtt{abc})^*\Sigma^*$ is simple, but $(\mathtt{a} \cup \mathtt{b})^*$ and $(\mathtt{a}(\mathtt{b})^*)^*$ are not.

▶ **Lemma 5.5.** *For every simple regular expression α, there is $\varphi^\alpha(x) \in$ EP-FC such that $(w, \sigma) \models \varphi^\alpha$ if and only if $\sigma(x) \in \mathcal{L}(\alpha)$ and $\sigma(x) \sqsubseteq w$.*

The proof uses the characterization of commuting words (see e. g. Lothaire [38]). We shall use this Lemma in the proof of Theorem 5.14, to replace regular constraints.

FC[REG] and Spanners. As we want to use FC[REG] for spanners, we still need to close a formal gap, namely that spanners reason over positions in a word, while FC[REG] reasons over words. We bridge this gap through the notion of one *realizing* the other, which [22] introduced for the logic SpLog. We begin with formulas that realize spanners.

▶ **Definition 5.6.** *A substitution σ* expresses *a (V, w)-tuple μ if $\mathsf{Dom}(\sigma) \supseteq \{x^P, x^C \mid x \in V\}$ and, for all $x \in V$, we have $\sigma(x^P) = w_{[1,i\rangle}$ and $\sigma(x^C) = w_{[i,j\rangle}$ for $[i, j\rangle = \mu(x)$.*

A formula $\varphi \in$ FC[REG] realizes *a spanner P if $\mathsf{free}(\varphi) = \{x^P, x^C \mid x \in \mathsf{Var}(P)\}$ and, for all $w \in \Sigma^*$, we have $(w, \sigma) \models \varphi$ if and only if σ expresses some $\mu \in P(w)$.*

In other words, x^C is $w_{\mu(x)}$ (the content of x), and x^P is the prefix of w before $w_{\mu(x)}$.

▶ **Example 5.7.** In Example 5.1, we defined $\alpha := \Sigma^*\big(x\{\mathtt{banana}\} \cup x\{\mathtt{papaya}\}\big)\Sigma^*$. Its spanner $[\![\alpha]\!]$ is realized by $\varphi(x^P, x^C) := \exists y\colon \mathfrak{u} \doteq x^P x^C y \wedge \big(x^C \doteq \mathtt{banana} \vee x^C \doteq \mathtt{papaya}\big)$.

Then $(w, \sigma) \models \varphi$ if σ expresses some $\mu \in [\![\alpha]\!](w)$. That is, $\sigma(x^C)$ contains $w_{\mu(x)}$ (i. e., banana or papaya), and $\sigma(x^P)$ contains the prefix in w before it.

To show that FC[REG] cannot express more than the classes of spanners that we consider, we also define the notion of spanners that realize formulas.

▶ **Definition 5.8.** *A spanner P* realizes *$\varphi \in$ FC[REG] if $\mathsf{Var}(P) = \mathsf{free}(\varphi)$ and, for all $w \in \Sigma^*$, we have $\mu \in P(w)$ if and only if $(w, \sigma) \models \varphi$ for the σ with $\sigma(x) := w_{\mu(x)}$ for all $x \in \mathsf{Var}(P)$.*

There are *polynomial-time conversions* from a class of formulas (or spanners) A to a class of spanners (or formulas) B if, given $x \in A$, we can compute in polynomial time $y \in B$ that realizes x. We write $A \equiv_{\mathsf{poly}} B$ if there are polynomial-time conversions from A to B and from B to A.

▶ **Theorem 5.9.** $\mathsf{FC[REG]} \equiv_{\mathsf{poly}} \mathsf{RGX}^{\mathsf{gcore}}$ *and* $\mathsf{EP\text{-}FC[REG]} \equiv_{\mathsf{poly}} \mathsf{RGX}^{\mathsf{core}}$.

5.3 Inexpressibility for FC, FC[REG], and spanners

There are currently only few inexpressibility methods for FC and FC[REG], as there are only few such methods for related models like spanners or the theory of concatenation. A detailed discussion from the point of view of $\mathsf{RGX}^{\mathsf{core}}$ and SpLog can be found in Section 6 of [22]. These techniques do not account for negation, which makes them inapplicable for FC or FC[REG]. A standard tool for FO-inexpressibility are Ehrenfeucht–Fraïssé games (e. g. [36]). But as concatenation acts as a generalized addition, using these for FC or FO[EQ] is far from straightforward. Another standard tool is the Feferman-Vaught theorem (see [39]). While this can be used for FC, the factor universe of FC makes decomposing the structure into disjoint sets inconvenient. Instead of following down this road, we introduce FO[EQ], an extension of FO[<] that has the same expressive power as FC.

Connecting FC to FO[<]. In this section, we establish connections between FC and "classical" relational first-order logic. It is probably safe to say that in finite model theory, the most common way of applying first-order logic to words is the logic FO[<] (and the more general MSO). This uses the equality $\doteq$ and a vocabulary that consists of a binary relation symbol $<$ and unary relation symbols $\mathsf{P}_\mathtt{a}$ for each $\mathtt{a} \in \Sigma$. Every word $w = a_1 \cdots a_n \in \Sigma^+$ with $n \geq 1$ is represented by a structure $\mathcal{A}_w$ with universe $\{1, \ldots, n\}$. For every $\mathtt{a} \in \Sigma$, the relation $\mathsf{P}_\mathtt{a}$ consists of those i that have $a_i = \mathtt{a}$. To simplify dealing with ε, we slightly deviate from this standard structure. For every $w \in \Sigma^*$, we extend $\mathcal{A}_w$ to $\mathcal{A}'_w$ by adding an additional "letter-less" node $|w| + 1$ that occurs in no $\mathsf{P}_\mathtt{a}$. Then we have a one-to-one correspondence between pairs (i, j) with $i \leq j$ from the universe of $\mathcal{A}'_w$ and the spans $[i, j\rangle$ of w (see Section 5.1), and $w = \varepsilon$ does not require a special case.

▶ **Definition 5.10.** FO[EQ] *extends* FO[<] *with constants* min *and* max*, the binary relation symbol* succ*, and the 4-ary relation symbol* Eq*. For every* $w \in \Sigma^*$ *and the corresponding structure* $\mathcal{A}'_w$*, these symbols express* $\mathsf{min} = 1$*,* $\mathsf{max} = |w| + 1$*,* $\mathsf{succ} = \{(i, i+1) \mid 1 \leq i \leq |w|\}$*, and* Eq *contains those* (i_1, j_1, i_2, j_2) *with* $i_1 \leq j_1$ *and* $i_2 \leq j_2$ *such that* $w_{[i_1,j_1\rangle} = w_{[i_2,j_2\rangle}$*. We write* $(w, \alpha) \models \varphi$ *to denote that* α *is a satisfying assignment for* φ *on* $\mathcal{A}'_w$*.*

▶ **Example 5.11.** The FO[EQ]-formula $\exists x \colon \mathsf{Eq}(\mathsf{min}, x, x, \mathsf{max})$ defines $\{ww \mid w \in \Sigma^*\}$.

Technically, we do not need the symbols min, max, or succ, as these can be directly expressed in FO[<]. But these constants allows us to better preserve the structural similarities when converting between various fragments of FC and FO[EQ].

When comparing FC to FO[EQ], we need to address that one operates on words and the other on positions. We can handle this in a way that is similar to the situation between FC and spanners; and this can be used to show that there are polynomial time conversions between FC and FO[EQ] that preserve the properties existential and existential-positive, and only marginally increase the width of the formulas.

In fact, these transformations show that one could choose FO[EQ] over FC as a logic for words (or for spanners, if one extends FO[EQ] with regular constraints or generalizes it to MSO with Eq). This is a valid choice, if one prefers writing $\exists x_1, \ldots, x_6 \colon \big(\mathsf{P}_\mathtt{p}(x_1) \wedge \mathsf{P}_\mathtt{a}(x_2) \wedge \mathsf{P}_\mathtt{p}(x_3) \wedge \mathsf{P}_\mathtt{a}(x_4) \wedge \mathsf{P}_\mathtt{y}(x_5) \wedge \mathsf{P}_\mathtt{a}(x_6) \wedge \bigwedge_{i=1}^{5} \mathsf{succ}(x_i, x_{i+1})\big)$ over $\exists x \colon x \doteq \mathtt{papaya}$ or if one wants to express $x \doteq yz$ as $\exists x^m \colon \big(\mathsf{Eq}(x^o, x^m, y^o, y^c) \wedge \mathsf{Eq}(x^m, x^c, z^o, z^c)\big)$ instead.

Details on these conversions (and the required definitions) can be found in the full version of this paper. For the sake of finding an inexpressibility result, we only require the following.

▶ **Lemma 5.12.** *A language is definable in* FC *if and only if it is definable in* FO[EQ].

Proving inexpressibility. Lemma 5.12 allows us to use Feferman-Vaught theorem, at least when considering languages that are restricted enough.

▶ **Lemma 5.13.** *There is no* FC*-formula that defines* $\{\mathtt{a}^n\mathtt{b}^n \mid n \geq 1\}$.

Moreover, we can show that regular constraints offer no help for defining this language.

▶ **Theorem 5.14.** FC[REG] *cannot express the equal length relation* $|x| = |y|$.

As FC[REG] has the same expressive power as $\mathsf{RGX}^{\mathsf{gcore}}$, this is the first inexpressible result for $\mathsf{RGX}^{\mathsf{gcore}}$ on non-unary alphabets. The proof has two parts, which both rely on the limited structure of the language $\mathtt{a}^n\mathtt{b}^n$. One part is using Lemma 5.13, wich applies the Feferman-Vaught theorem. The other is using Lemma 5.5 to eliminate the regular constraints, which is based on combinatorics on words. The authors expect that a more general inexpressibility method for FC (or even FC[REG]) would need to combine more advanced techniques from combinatorics on words (like those in [33]) with methods from logic.

6 Conclusions and future work

On words, concatenation is one of the most natural operations. But as seen for C, using concatenation with first-order logic quickly becomes undecidable. Restricting the universe to a word and all its factors changes the situation drastically. In contrast to C, the resulting logic FC has a meaningful distinction between satisfiability and model checking; and the latter is not only decidable, but we can use the structure of the formula to derive upper bounds in the same way as for FO over finite structures. In addition to this, FC can also replace FO[<] as "base" logic for characterizing complexity classes. Hence, while one might certainly make a case against the claim that FC is *the* finite model version of the theory of concatenation, the results leave little doubt that it is at least *a* valid approach.

FC also provides an extendable framework for querying and model checking words, in particular for scenarios that rely on expressing that factors appear multiple times. If more expressive power is needed, FC is easily extended with constraints, without affecting the lower bounds on evaluation and model checking. In particular, we can translate core and generalized core spanners to FC[REG] and then analyze or optimize these formulas with respect to parameters like width. To a degree, this was also possible the spanner logic SpLog, but FC is more elegant, easier to use, and behaves much more like FO on relational databases.

Future work

Many fundamental questions remain open, in particular for model checking and related problems, like evaluation and enumeration.

Compilation into tractable fragments. One promising direction is the compiling of formulas into equivalent formulas of a fragment where these problems can be solved more efficiently. For example, Theorem 4.2 shows that bounding the width of the formulas leads to tractable model checking. Theorem 4.4 then provides us with a sufficient criterion for formulas that can be rewritten into formulas with a lower width, by decomposing the pattern of word equations. It is likely that this approach can be further refined by not just rewriting single patterns, but taking the larger formula into account. This approach can also be used with other structure parameter for formulas (like acyclicity and bounded tree width), by developing a corresponding variant of Theorem 4.4. One example of this is [26], which adapts the concept of acyclic conjunctive queries to FC.

A more fundamental question is whether all tractable fragments of FC can be explained through the criterion of bounded width (or are subset of a larger tractable fragment that is explained through it). A good starting point for this line of investigation is the question whether all classes of pattern languages with a polynomial time membership problem can be explained through bounded width.

Model checking as parsing. Another approach – that is not investigated in the present paper – is the connection to parsing algorithms. This is a natural question, as model-checking EP-FC-formulas can be understood as a parsing problem (where variables are mapped to factors of the input word). Promising starting points for this are parsing algorithms for RCGs (recall Section 4.3) and related grammars, and the extraction grammars from [45].

Data structures. Model checking algorithms will likely benefit from specialized data structures. For example, a naive representation of all factors of a word of length n would contain about $O(n^2)$ elements, and if these are just represented directly as words, this would take $O(n^3)$ memory. But using data structures like suffix trees and suffix arrays, one can create in time $O(n)$ a data structure that allows us to enumerate all factors with constant delay (see [26], which also examines small word equations).

While these optimizations do not matter if one considers polynomial time efficient enough, it would be very useful to know which fragments can be model-checked in time $O(n^k)$ for small k, or even in sub-quadratic time.

Inexpressibility and satisfiability. Our results on inexpressibility also leave many questions open. Lemma 5.13 heavily relies on the limited structure of the language. This is the same situation as in Section 6.1 of [22], which describes an inexpressibility technique for EP-FC[REG]. Although these two approaches provide us with some means of proving inexpressibility, they only cover special cases, and much remains to be done. It seems likely that a more general method will need to combine approaches from finite model theory (like the Feferman-Vaught theorem that we used for Lemma 5.13) with techniques from combinatorics on words (like those in [33] that [22] uses). A related problem that is still open is whether EP-FC has the same expressive power as EP-C.

Of particular interest is finding a method to prove inexpressibility in FC^k for some $k > 0$. This problem relates to the open questions whether there are algorithms that minimize the width of a formula, and for which k the fragment FC^{k+1} is more expressive than FC^k. The authors conjecture that this holds for all $k \geq 0$, which would contrast with FO[<], where the fragment of formulas with width three has the same expressive power as the full logic. Finally, it remains open whether satisfiability is decidable for FC^1 or FC^2.

Beyond FC. Using FC as a logic for spanners (and other models, potentially) raises further questions. For example, while every tractable fragment of FC[REG] maps to a tractable fragment of core spanners (namely, those that are obtained by converting the formulas), there is no guarantee that the obtained fragment is natural. Hence, a more detailed investigation into conversions between FC[REG] and $\mathsf{RGX}^{\mathsf{core}}$ is justified.

There are many other possible directions. For example, one could easily define a second-order version of FC and adapt various results from SO. Moreover, FC could be examined from an algebra point of view, or related to rational and regular relations.

Uniform Elgot Iteration in Foundations

Sergey Goncharov
University Erlangen-Nürnberg, Germany

Abstract

Category theory is famous for its innovative way of thinking of concepts by their descriptions, in particular by establishing *universal properties*. Concepts that can be characterized in a universal way receive a certain quality seal, which makes them easily transferable across application domains. The notion of partiality is however notoriously difficult to characterize in this way, although the importance of it is certain, especially for computer science where entire research areas, such as *synthetic* and *axiomatic domain theory* revolve around it. More recently, this issue resurfaced in the context of (constructive) *intensional type theory*. Here, we provide a generic categorical iteration-based notion of partiality, which is arguably the most basic one. We show that the emerging free structures, which we dub *uniform-iteration algebras* enjoy various desirable properties, in particular, yield an *equational lifting monad*. We then study the impact of classicality assumptions and choice principles on this monad, in particular, we establish a suitable categorial formulation of the *axiom of countable* choice entailing that the monad is an *Elgot monad*.

2012 ACM Subject Classification Theory of computation → Categorical semantics; Theory of computation → Constructive mathematics

Keywords and phrases Elgot monad, partiality monad, delay monad, restriction category

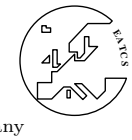
1 Introduction



Natural numbers form a prototypical domain for programming and reasoning. Both in *category theory* and in *type theory* they are characterized by a universal property, which consists of two parts: a definitional principle – *(structural) primitive recursion* and a reasoning principle – *induction*. Dualization yields respectively *co-natural numbers*, *co-recursion* and *co-induction*. Amid these two structuralist extremes, here, we analyse the challenging case of non-structural recursion in the form of iteration, which arises as follows. A map

$$h\colon S \to X + S$$

presents the simplest possible model of a computation process: with S regarded as a state space, h sends any state either to a successor *state* or to a terminal *value* in X. We wish to be able to form an object KX of *denotations* potentially reachable via such processes. Besides the values of X reachable in a finite number of steps, KX must also contain a designated value for divergence, generated by the right injection $h = \mathsf{inr}$. We then ask: what would be the generic universal characterization of KX and what properties it would imply? Somewhat surprisingly, this question has not been addressed yet on a level of generality, sufficiently close to the settings where the question can be posed, although many similar closely related questions have been addressed, mostly couched in type-theoretic terms.

The question trivializes whenever one of the two following perspectives is adopted.

- *intensional perspective:* the domain KX keeps track not only of results, but also of the number of steps needed to reach them. This leads to the identification of KX as the final coalgebra $DX = \nu\gamma.\ X + \gamma$, known as *Capretta's monad* or the *delay monad* [10].
- *non-constructive perspective:* assuming non-constructive principles, such as the *law of excluded middle*, leads to the identification of KX as the *maybe-monad* $X + 1$.

Here, we generally keep aloof from these interpretations of KX and work both extensionally and generically, using the language of the category theory to analyse the issue in the abstract, and keeping the potential class of models possibly large.

We introduce KX as a certain free structure, equipped with an iteration operator, which sends any $f\colon S \to KX + S$ to $f^\sharp\colon S \to KX$, and satisfies the following two basic and uncontroversial principles:

- *fixpoint:* $f^\sharp$ is in an obvious sense a fixpoint of f;
- *uniformity:* the structure of the state space S is ineffective (i.e. merging or adding new states done coherently does not influence the result).

We dub such structures *uniform-iteration algebras* and show that on a high level of generality (in any extensive category with finite limits and a stable natural number object) if KX exists then it satisfies a number of other properties: K extends to a monad $\mathbf{K}$, which is an equational lifting monad [9], the Kleisli category of K is enriched over partial orders and monotone maps, and the iteration operator is a least fixpoint operator w.r.t. this order; moreover, the iteration operator satisfies an additional principle, previously dubbed *compositionality* [2].

In some environments, such as *homotopy type theory (HoTT)*, $\mathbf{K}$ can be constructed directly, by using *higher inductive types*. One can then define a universal map from the delay monad $\mathbf{D}$ to $\mathbf{K}$ and regard it is a form of *extensional collapse*. However, proving $\mathbf{K}$ to be a quotient of $\mathbf{D}$ seems to be impossible without using (weak) choice principles [11, 5, 16]. We interpret this categorically, first by introducing a categorical *limited principle of omniscience (LPO)* under which $\mathbf{K}$ turns out to be isomorphic to the *maybe-monad* $(- + 1)$ and also turns out to be an *Elgot monad*. This generalizes slightly previous results [17] obtained for *hyper-extensive categories* [3]. Second, we identify other cases of $\mathbf{K}$ being a quotient of $\mathbf{D}$ and additionally being an (initial) Elgot monad, by introducing certain coequalizer preservation conditions, abstractly capturing the corresponding instances of the axiom of countable choice.

From the type-theoretic perspective, in our work we revisit the familiar waymarks of using/avoiding principles of classical/constructive mathematics in view of the tradoffs in expressive power of the corresponding constructions. Our present approach of uniform-iteration algebras as a fundamental primitive is entirely new, though. Moreover, we would like to emphasize that our results, being generic, apply to a wide range of categories, whose objects need not be like sets, or types in any conventional sense. This has a massive impact on the underlying proof methods. In topos theory, calculations are facilitated by existence of the subobject classifier Ω, which is used as a global parent space for propositions. Predicative theories, such as HoTT make do without Ω, but it is still possible to form predicative types of propositions per universe, implying that the style of proofs can to a significant extent be maintained, with Ω intuitively regarded as "scattered" over the cumulative universe hierarchy. Contrastingly, here we do not assume any kind of general reference spaces for propositions, which results in completely different proof methods. Nevertheless, we conjecture that our results can be implemented in HoTT. This is clear for the universe of sets, which in HoTT form a *pretopos* [30], and hence directly satisfy our assumptions. For types of higher homotopy levels this should be possible by using existing recipes of formalizing *precategories of types* [33].

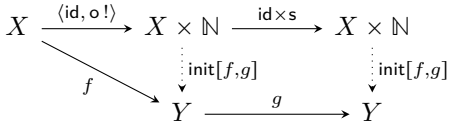
Previous related work. We relate to the work on iteration theories, starting from a seminal paper of Elgot [15], who identified iteration as a fundamental unifying notion. Equational properties of Elgot iteration were extensively explored by Bloom and Ésik [8] with the initial iteration structure playing a prominent role, however, since the whole setup therein is inherently classical, most of our present agenda is essentially moot there. The uniformity property occurred under the name *functorial dagger implication* in Bloom and Ésik's monograph, and is an established and powerful principle, thus notably recognized in Simpson and Plotkin's work [32], in the context of generic recursion (as opposed to the present dual case of generic iteration). Adámek et al [2] introduced axioms of *(guarded) Elgot algebras*, and it follows from their results that these axioms are complete w.r.t. the algebras of the delay monad. Uniform-iteration algebras are generally a proper weakening of Elgot algebras, but we show that KX as a free uniform-iteration algebra over X is in fact also an Elgot algebra.

Another line of research we relate to is concerned with notions of partiality, via *dominances*, in particular the *Rosolini dominance* in *synthetic domain* theory [31], via *equational lifting monads* [9], and via *restriction categories* [13]. We remark that these approaches are rather concerned with specifying a notion of partiality than with defining it. This distinction is particularly significant in the context of constructive type theories, such as HoTT, which revitalized the interest to defining a notion of partiality both predicatively and constructively and to understanding the impact of (restricted) choice principles. Chapman et al [11] provided a construction of a partiality monad as a quotient of the delay monad assuming countable choice. Also, Uustalu and Veltri [35] explored universal properties of the obtained quotient as an initial *ω-complete pointed classifying monad*. Altenkirch et al [5] directly based on ω-complete partial orders to obtain a partiality monad in HoTT as a certain *quotient inductive-inductive type* without using any choice whatsoever, but established an equivalence with the delay monad quotient under countable choice. Chapman et al [12] subsequently used more basic *quotient inductive types* for the same purpose.

Recently, Escardó and Knapp [16] reinforced the issue of discrepancy between the quotient of the delay monad and partiality monads, by showing that the quotient precisely captures extensions of Turing computable values, whereas in the absence of any choice, the reasonable partiality monads seem to yield proply larger carriers. The latter view is particularly fine grained, and involves a monad, which is essentially our monad $\mathbf{K}$. According to them, showing the desired connection between $\mathbf{K}$ and the delay monad still amounts to (very weak) choice principles (albeit still not natively available in HoTT), while equivalence to more expressive monads would again require countable choice. Further relevant details of type-theoretic analysis of partiality can be found in recent theses [37, 25]. A comparison of various lifting monads in type theory using a unifying notion of *container* was recently provided by Uustalu and Veltri [36].

2 Categories and Monads

We assume familiarity with standard categorical concepts [28, 6]. In what follows, we generally work in an ambient extensive category $\mathbf{C}$ with finite products, a stable natural number object $\mathbb{N}$ and exponentials $X^{\mathbb{N}}$. By $|\mathbf{C}|$ we refer to the objects of $\mathbf{C}$. We often drop indices of natural transformations to avoid clutter. For the same purpose, we juxtaposition of morphisms as composition. Let us clarify this and fix some conventions.



Extensive categories and pointful reasoning. Extensiveness means existence of disjoint finite coproducts and stability of them under pullbacks (which must exist). Every extensive category is *distributive*, that is, every morphism $[\mathsf{id}\times\mathsf{inl}, \mathsf{id}\times\mathsf{inr}]\colon X\times Y + X\times Z \to X\times(Y+Z)$ is an isomorphism whose inverse we denote $\mathsf{dstr}\colon X\times(Y+Z)\to X\times Y + X\times Z$. Let $\mathsf{dstl}\colon (X+Y)\times Z \to X\times Z + Y\times Z$ be the obvious dual to dstr.

In order to simplify reasoning, we occasionally use a rudimentary pointful notation for stating equalities in $\mathbf{C}$, most notably we use the case distinction operator case, e.g. we write

$$f(x) = \mathsf{case}\, g(x)\, \mathsf{of}\, \mathsf{inl}\, y \mapsto h(y);\ \mathsf{inr}\, z \mapsto u(z)$$

meaning $f = [h,u]\ g$ where $f\colon X\to W$, $g\colon X\to Y+Z$, $h\colon Y\to W$ and $u\colon Z\to W$.

Natural numbers and primitive recursion. A *stable natural number object* (NNO) in a Cartesian category $\mathbf{C}$, is an object $\mathbb{N}$ equipped with two morphisms $\mathsf{o}\colon 1\to\mathbb{N}$ (*zero*) and $\mathsf{s}\colon\mathbb{N}\to\mathbb{N}$ (*successor*) such that for any $X, Y\in|\mathbf{C}|$ and any $f\colon X\to Y$ and $g\colon Y\to Y$ there is unique $\mathsf{init}[f,g]\colon X\times\mathbb{N}\to Y$ such that

commutes. This combines two separate properties: there exists an initial $(1+-)$-algebra $(\mathbb{N}, [\mathsf{o},\mathsf{s}]\colon 1+\mathbb{N}\to\mathbb{N})$, and $(X\times\mathbb{N}, [\langle\mathsf{id},\mathsf{o}\,!\rangle, \mathsf{id}\times\mathsf{s}]\colon X + X\times\mathbb{N}\to X\times\mathbb{N})$ is an initial $(X+-)$-algebra. The latter property follows from the former in Cartesian closed categories.

More generally, we need the derivable Lawvere's internalization of *primitive recursion* [27]: Given $f\colon X\to Y$ and $g\colon Y\times X\times\mathbb{N}\to Y$ there is unique $\mathsf{p\text{-}rec}(f,g)\colon X\times\mathbb{N}\to Y$ such that

$$\mathsf{p\text{-}rec}(f,g)(x,\mathsf{o}) = f(x), \qquad \mathsf{p\text{-}rec}(f,g)(x,\mathsf{s}\,n) = g(\mathsf{p\text{-}rec}(f,g)(x,n),x,n).$$

We thus say that $\mathsf{p\text{-}rec}(f,g)$ is *defined* by (primitive) recursion, whereas *induction* is a *proof principle*, stating that $\mathsf{p\text{-}rec}(f,g) = w$ for any $w\colon X\times\mathbb{N}\to Y$ satisfying the same equations.

Exponentials $X^{\mathbb{N}}$ are adjoint to products $X\times\mathbb{N}$, meaning that there is an isomorphism $\mathsf{curry}\colon \mathbf{C}(X\times\mathbb{N}, Y)\to\mathbf{C}(X, Y^{\mathbb{N}})$ natural in X. This induces an evaluation morphism $\mathsf{ev} = \mathsf{curry}^{-1}\,\mathsf{id}\colon X^{\mathbb{N}}\times\mathbb{N}\to X$ with the standard properties.

Strong functors and monads. A functor T is strong if it is equipped with a natural transformation *strength* $\tau_{X,Y}\colon X\times TY\to T(X\times Y)$, satisfying standard coherence conditions w.r.t. the monoidal structure $(1,\times)$ of $\mathbf{C}$ [26]. This induces the obvious dual $\hat\tau_{X,Y}\colon TX\times Y\to T(X\times Y)$. A natural transformation $\alpha\colon F\to G$ between two strong functors is itself *strong* if it preserves strength in the obvious sense, i.e. $\alpha\ \tau = \tau\ (\mathsf{id}\times\alpha)$.

A monad $\mathbf{T}$ (in the form of a Kleisli triple) consists of an endomap $T\colon|\mathbf{C}|\to|\mathbf{C}|$, a family of morphisms $(\eta_X\in\mathbf{C}(X,TX))_{X\in|\mathbf{C}|}$ and a lifting operation $(-)^\star\colon\mathbf{C}(X,TY)\to\mathbf{C}(TX,TY)$, satisfying standard laws [29]. It then follows that T is an endofunctor with $Tf = (\eta\ f)^\star$, η extends to a natural transformation, and the *multiplication* transformation $\mu\colon TT\to T$ is definable as $\mathsf{id}^\star$. For every monad $\mathbf{T}$, whose underlying functor T is strong, η and μ are strong (with id being a strength of Id and $(T\tau)\ \tau$ being a strength of μ). Such monad $\mathbf{T}$ is then called *strong* if both η and μ are strong. A strong monad is *commutative* if $\tau^\star\ \hat\tau = \hat\tau^\star\ \tau$.

We adopt Moggi's perspective [29] to strong monads as carriers of computational effects, and thus say that a morphism $f\colon X\to TY$ *computes a value in* Y. Since, the only effect we deal with here is divergence, f can either produce a value or diverge (modulo the inherent linguistic inaccuracy of the excluded middle law baked into the natural language).

Functor algebras and monad algebras. For an endofunctor T, we distinguish T-algebras, which are pairs $(A, a\colon TA \to A)$, from $\mathbf{T}$-algebras, which can only be formed for monads $\mathbf{T}$ on T: a $\mathbf{T}$-algebra is a T-algebra (A, a), which additionally satisfies $a\ \eta = \mathsf{id}$ and $a\ \mu = a\ Ta$. Both T- and $\mathbf{T}$-algebras form categories under the standard structure preserving morphisms, the latter fully embeds into the former.

With our assumptions on $\mathbf{C}$, we mean to cover the following (classes of) categories.

1. Zermello-Fraenkel set theory with choice (ZFC) and further variants of set theory: ETCS, ZF, CZF, etc.
2. Toposes satisfying countable choice, e.g. the *topological topos* [23].
3. Toposes not satisfying countable choice, e.g. *nominal sets*.
4. Pretoposes, e.g. ΠW-pretoposes, compact Hausdoff spaces.
5. The category of topological spaces **Top**, and its subcategories, such as the category of directed complete sets **dCpo**.

3 Basic Properties of the Delay Monad

The final coalgebras $DX = \nu\gamma.\, X + \gamma$ jointly yield a monad $\mathbf{D}$, called the *delay monad* [10]. Capretta [10] showed that $\mathbf{D}$ is strong, which remains valid in our setting. By Lambek's lemma, the final coalgebra structure $\mathsf{out}\colon DX \to X + DX$ is an isomorphism. Its inverse $\mathsf{out}^{-1} = [\mathsf{now}, \mathsf{later}]\colon X + DX \to DX$ is composed of the morphisms, conventionally called now and later, of which the first one is the monad unit, and the effect of the second one is intuitively to postpone the argument computation by one time unit. In what follows, we will write $\triangleright$ instead of later for the sake of succinctness. As a final coalgebra, DX comes together with a *coiteration operator*: for any $f\colon Y \to X + Y$, $\mathsf{coit}\, f\colon Y \to DX$ is the unique morphism, such that $\mathsf{out}\ (\mathsf{coit}\, f) = (\mathsf{id} + \mathsf{coit}\, f)\ f$.

We denote $D1$ by $\bar{\mathbb{N}}$, and think of it as an object of co-natural or possibly infinite natural numbers. Note that the initial algebra structure $[\langle \mathsf{id}, \mathsf{o}\,! \rangle, \mathsf{id} \times \mathsf{s}]\colon X + X \times \mathbb{N} \to X \times \mathbb{N}$, is an isomorphism, and thus yields a D-coalgebra structure on $X \times \mathbb{N}$. This induces a unique D-coalgebra morphism $\iota_X\colon X \times \mathbb{N} \to DX$. Alternatively, we can regard ι_X as defined by primitive recursion:

$$\iota_X(x, \mathsf{o}) = \mathsf{now}(x) \qquad\qquad \iota_X(x, \mathsf{s}(n)) = \triangleright(\iota_X(x, n))$$

Let $\hat{\iota}\colon \mathbb{N} \to \bar{\mathbb{N}}$ be ι_1 modulo the obvious isomorphism.

In our setting, DX need not be postulated, for it is in fact definable as a retract of the object $(X + 1)^{\mathbb{N}}$ of *infinite streams*, which is elaborated in detail by Chapman et al [11]. This also entails that ι is a componentwise monic. Intuitively, DX consists of precisely those streams, which contain at most one element of the form $\mathsf{inl}\, x$. This intuition becomes precise in (possibly non-classical) set theory, where

$$\mathsf{now}\, x = (\mathsf{inl}\, x, \mathsf{inr}\, \star, \mathsf{inr}\, \star, \ldots) \qquad\qquad \triangleright\, (e_1, e_2, \ldots) = (\mathsf{inr}\, \star, e_1, e_2, \ldots)$$

This explains why classically, more precisely, under the *law of excluded*, DX is isomorphic to $X \times \mathbb{N} + 1$. We provide a stronger result to this effect further below. Let us record some general facts about $\mathbf{D}$ first.

▶ **Proposition 1.** *The monad* **D** *admits the following characterization:*

1. *unit* $\mathsf{now}\colon X \to DX$ *of* **D** *satisfies* $\mathsf{out} \;\; \mathsf{now} = \mathsf{inl}$*;*
2. *Kleisli lifting of* $f\colon X \to DY$ *is the unique morphism* $f^\star\colon DX \to DY$*, for which the diagram*

$$\begin{array}{ccc} DX & \xrightarrow{\quad f^\star \quad} & DY \\ {\scriptstyle \mathsf{out}}\downarrow & & \downarrow{\scriptstyle \mathsf{out}} \\ X + DX & \xrightarrow{[\mathsf{out}\, f,\ \mathsf{inr}\, f^\star]} & Y + DY \end{array}$$

   commutes;
3. *strength* $\tau\colon X \times DY \to D(X \times Y)$ *is a unique such morphism that the diagram*

$$\begin{array}{ccccc} X \times DY & & \xrightarrow{\qquad\qquad \tau \qquad\qquad} & & D(X \times Y) \\ {\scriptstyle \mathsf{id}\times\mathsf{out}}\downarrow & & & & \downarrow{\scriptstyle \mathsf{out}} \\ X \times (Y + DY) & \xrightarrow{\mathsf{dstr}} & X \times Y + X \times DY & \xrightarrow{\mathsf{id}+\tau} & Y + DY \end{array}$$

   commutes.

Proof. (1) and (2) follow from a more general characterization by Uustalu [34]; (3) is established in [19]. ◀

▶ **Proposition 2.** **D** *is commutative.*

Let us proceed with a characterization of the situations when $DX \cong X \times \mathbb{N} + 1$. Recall that a monic σ is called *complemented* if there exists $\sigma'\colon X' \hookrightarrow Y$, such that Y is a coproduct of X and X' with σ and σ' as coproduct injections. The *law of excluded middle* states that any monic is complemented. We involve a rather more specific property.

▶ **Proposition 3.** *The monic* $\hat{\iota}\colon \mathbb{N} \hookrightarrow \bar{\mathbb{N}}$ *is complemented iff* $DX \cong X \times \mathbb{N} + 1$*.*

Proof (Sketch). The necessity is obvious. Let us proceed with the sufficiency. Using extensiveness of **C** one can obtain the following pullback:

$$\begin{array}{ccc} X \times \mathbb{N} & \xrightarrow{\quad \mathsf{snd} \quad} & \mathbb{N} \\ {\scriptstyle \iota}\downarrow & \lrcorner & \downarrow{\scriptstyle \hat{\iota}} \\ DX & \xrightarrow{\quad D\,! \quad} & \bar{\mathbb{N}} \end{array}$$

By assumption, $\hat{\iota}$ is complemented, and since **C** is extensive, so is ι. We obtain that $DX \cong \mathbb{N} \times X + R$ for some R, and then it follows from finality of DX that $R \cong 1$. ◀

The property of $\hat{\iota}\colon \mathbb{N} \hookrightarrow \bar{\mathbb{N}}$ to be complemented is a categorical formulation of the *limited principle of omniscience (LPO)*, which is rejected in constructive mathematics. Informally, LPO states that every infinite bit-stream either contains 1 at some position or contains only 0 everywhere (the constraint that the stream contains *at most one* 1, does not make a difference). We say that **C** is an LPO category if $\hat{\iota}\colon \mathbb{N} \hookrightarrow \bar{\mathbb{N}}$ is complemented.

▶ **Corollary 4.** *Suppose that (i)* **C** *has countable products and (ii) given a family* $(\sigma_i\colon A_i \to A)_{i\in\omega}$ *of complemented pairwise disjoint monos, the induced universal morphism* $\coprod_i A_i \to A$ *is complemented. Then* **C** *satisfies LPO and hence* $DX \cong X \times \mathbb{N} + 1$*.*

Proof. It is folklore that in categories with countable products $\mathbb{N}$ is isomorphic to the sum of ω copies of 1. Thus $\hat{\iota}\colon \mathbb{N} \to \bar{\mathbb{N}}$ is the induced universal map, which is complemented by (ii). ◀

▶ **Example 5.** As expected, Proposition 3 does not apply to models, designed with constructivist principles in mind, such as intensional type theories, or realizability toposes, although, it is technically possible to design a realizability topos, satisfying LPO [7], in which thus $DX \cong X \times \mathbb{N} + 1$. Another class of examples to which Proposition 3 does not apply stems from topology. In **Top**, $\bar{\mathbb{N}}$ is a subspace of the *Cantor space* $2^{\mathbb{N}}$ whose topology is generated by the base of opens of the form $\{sr \mid r \in \{0,1\}^{\omega}\}$ with $s \in 2^{\star}$. Then $\bar{\mathbb{N}}$ is isomorphic to a *one-point compactification* of $\mathbb{N}$, i.e. it is the set $\mathbb{N} \cup \{\infty\}$, whose opens are all subsets of $\mathbb{N}$ and additionally all complements of finite subsets of $\mathbb{N}$ in $\mathbb{N} \cup \{\infty\}$. Clearly, $\bar{\mathbb{N}} \ncong \mathbb{N} + 1$. This kind of arguments is inherited by higher order topology-based models, such as Johnstone's *topological topos* [23], which is a Grothendieck topos not satisfying LPO.

▶ **Example 6.** Proposition 3 and Corollary 4 cover quite a few models constructed in the scope of classical mathematics. Every set theory satisfying the law of excluded middle satisfies LPO. Every presheaf topos (w.r.t. a classical set theory) inherits countable coproducts from **Set** and those satisfy (ii) of Corollary 4. As we indicated in Example 5, a Grothendieck topos generally need not satisfy LPO, but, e.g. *Schanuel topos* (aka the topos of nominal sets) does satisfy it, because this topos is Boolean. As we indicated in Example 5, **Top** does not satisfy LPO, but curiously the full subcategory of directed complete partial orders **dCpo** (under Scott topology) does. Both **Top** and **dCpo** have countable coproducts, but **Top** fails to satisfy condition (ii), of Corollary 4, while **dCpo** does satisfy it. This can be read as a manifestation of (undesirable) effects, which motivated synthetic domain theory [21].

Conditions (i) and (ii) in Corollary 4 are essentially the axioms of *hyper-extensive categories* by Adámek et al [3] (modulo our background extensiveness assumption). An example of an LPO category that fails (i) is Lawvere's ETCS. Another example of a Grothendieck topos that fails (ii) can be rendered as a certain category of *Jónsson-Tarski algebras* [3].

The above examples indicate that in models developed w.r.t. constructive foundations LPO fails by design, while in models developed w.r.t. classical foundations, depending on the purposes, constructively questioned principles may leak in from the metalogic level inside of the category, possibly in a weakened form, resulting in an explicit expression for DX.

4 Unguarded Elgot Algebras

Recall the following notion from [2] where the term *complete Elgot algebra over H* is used.

▶ **Definition 7** (Guarded Elgot Algebras). *Given an endofunctor H, an* (H-)guarded Elgot algebra *is a tuple $(A, a\colon HA \to A, (\text{–})^{\sharp})$ where the* iteration $f^{\sharp}\colon X \to A$ *for every given $f\colon X \to A + HX$, satisfies the following axioms:*

- (**Fixpoint**) *for every $f\colon X \to A + HX$, $f^{\sharp} = [\mathsf{id}, a\ Hf^{\sharp}]\ f$;*
- (**Uniformity**) *for every $f\colon X \to A + HX$ every $g\colon Y \to A + HY$ and every $h\colon X \to Y$, $(\mathsf{id} + Hh)\ f = g\ h$ implies $f^{\sharp} = g^{\sharp}\ h$;*
- (**Compositionality**) *for every $h\colon Y \to X + HY$ and $f\colon X \to A + HX$, $((f^{\sharp} + \mathsf{id})\ h)^{\sharp} = \big([(\mathsf{id} + H\,\mathsf{inl})\ f, \mathsf{inr}\ (H\,\mathsf{inr})]\ [\mathsf{inl}, h]\colon X + Y \to A + H(X + Y)\big)^{\sharp}\ \mathsf{inr}$.*

H-guarded Elgot algebras form a category together with iteration preserving *morphisms defined as follows: a morphism h from $(A, a, (\text{–})^{\sharp})$ to $(B, b, (\text{–})^{\sharp})$ is a morphism $h\colon A \to B$ between carriers, such that $h\ f^{\sharp} = ((h + \mathsf{id})\ f)^{\sharp}$ for every $f\colon X \to A + HX$ (this entails $h\ a = b\ (Hh)$ [2, Lemma 5.2]).*

The **Compositionality** axiom is the most sophisticated one. It intuitively states that running h in a loop over Y as the state space, and subsequently running f in a loop over X as the state space, equivalently corresponds to running a certain term constructed from f and g in a single loop over the combined state $X + Y$.

The axioms of guarded Elgot algebras are complete in the following sense.

▶ **Theorem 8** ([2, Theorem 5.4, Corollary 5.7, Theorem 5.8])**.** *For every X, a final coalgebra $\nu\gamma.\, X + H\gamma$ is a free H-guarded algebra over X, in particular, existence of final coalgebras is equivalent to existence of free H-guarded Elgot algebras. The categories of H-guarded Elgot algebras and algebras of the monad $\nu\gamma.\, X + H\gamma$ are isomorphic.*

By Theorem 8, free algebras of the delay monad are thus precisely the free Id-guarded Elgot algebras. We then introduce *un-guarded Elgot algebras* as a certain subcategory of Id-guarded ones.

▶ **Definition 9** (Unguarded Elgot Algebras)**.** *We call* Id*-guarded Elgot algebras of the form* $(A, \mathsf{id}\colon A \to A, (\text{–})^\sharp)$ unguarded Elgot algebras*, or simply* Elgot algebras *if no confusion arises. Given two Elgot algebras A and B, we call $f\colon X \times A \to B$ right iteration preserving if*

$$f(\mathsf{id} \times h^\sharp) = \big(X \times Z \xrightarrow{\mathsf{id}\times h} X \times (A + Z) \xrightarrow{\mathsf{dstr}} X \times A + X \times Z \xrightarrow{f+\mathsf{id}} B + X \times Z\big)^\sharp$$

for any $h\colon Z \to A + Z$. This generalizes Elgot algebra morphisms under $X = 1$.

We write simply "iteration preserving" instead of "right iteration preserving" in the sequel if the decomposition of $X \times A$ into the Elgot algebra part A and the parameter part X is clear from the context. Parametrization will be needed later for characterizing stability of free algebras (Lemma 18).

The unguarded Elgot algebras thus differ from the Id-guarded ones in that the Id-algebra structures $a\colon A \to A$ in the former case are forced to be trivial. This has an impact on forming the corresponding free structures: in the guarded case, the Id-algebra structures must be maximally unrestricted, which is the reason why we obtain a free Id-guarded Elgot algebra DX with the Id-algebra structure playing the role of delays. Intuitively, a free unguarded Elgot algebra must be a quotient of a free guarded one under removing delays, which is indeed what happens for LPO categories, as we show later. Otherwise, the situation is much more subtle, and it is one of our goals to demonstrate that free unguarded Elgot algebras are exactly the semantic carriers generated by unguarded iteration.

In the unguarded case **Compositionality** can be replaced by a simpler looking new law that we dub **Folding**:

▶ **Proposition 10.** *Given $A \in |\mathbf{C}|$, $(A, (\text{–})^\sharp)$ is an Elgot algebra iff $(\text{–})^\sharp$ satisfies*

- (**Fixpoint**) *for every $f\colon X \to A + X$, $f^\sharp = [\mathsf{id}, f^\sharp]\ f$;*
- (**Uniformity**) *for every $f\colon X \to A + X$ every $g\colon Y \to A + Y$ and every $h\colon X \to Y$, $(\mathsf{id} + h)\ f = g\ h$ implies $f^\sharp = g^\sharp\ h$;*
- (**Folding**) *for every $h\colon Y \to X + Y$ and $f\colon X \to A + X$, $(f^\sharp + h)^\sharp = [(\mathsf{id} + \mathsf{inl})\ f, \mathsf{inr}\ h]^\sharp$.*

The laws of Elgot algebras are summarised in Fig. 1 in the style of string diagrams, akin to those, which are used for axiomatizing traced symmetric monoidal categories [24]. In contrast to the latter, here we essentially can only form traces of morphisms of the form $X + Y \to A + Y$ where A is an Elgot algebra. Merging wires is to be interpreted as calling codiagonal morphisms $\nabla\colon X + X \to X$.

As expected, products and exponents of Elgot algebras can be formed in a canonical way.

▶ **Lemma 11.** *Given two Elgot algebras $(A, (\text{–})^\sharp)$ and $(B, (\text{–})^\sharp)$ and an object $X \in |\mathbf{C}|$,*

1. *$(A \times B, (\text{–})^{\hat\sharp})$ is an Elgot algebra with $h^{\hat\sharp} = \langle((\mathsf{fst} + \mathsf{id})\ h)^\sharp, ((\mathsf{snd} + \mathsf{id})\ h)^\sharp\rangle$ for any $h\colon Z \to A \times B + Z$.*
2. *If A^X exists then $(A^X, (\text{–})^{\hat\sharp})$ is an Elgot algebra with $h^{\hat\sharp} = \mathsf{curry}((\mathsf{ev} + \mathsf{id})\ \mathsf{dstl}\ (h \times \mathsf{id}))^\sharp$ for any $h\colon Z \to A^X + Z$.*

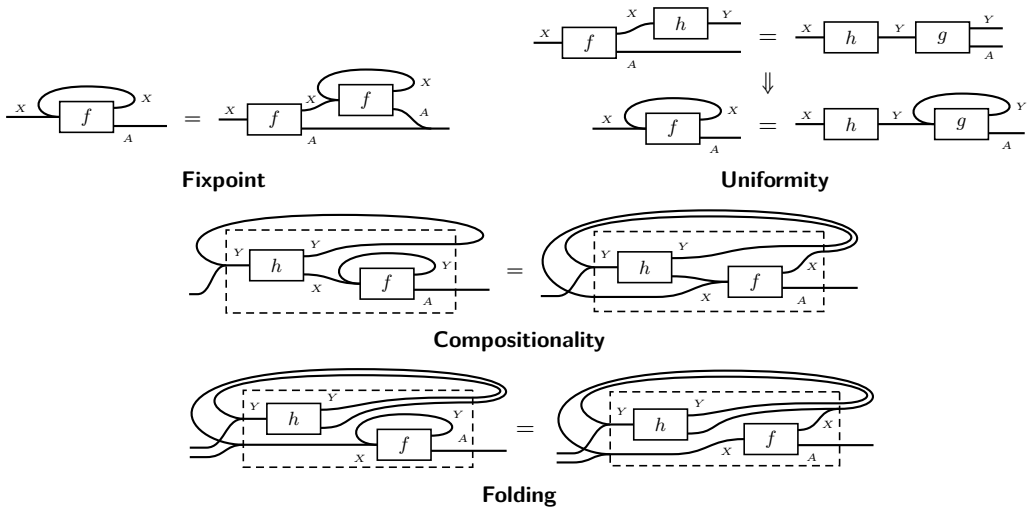


Figure 1 Laws of (unguarded) Elgot algebras.

Every Elgot algebra $(A, (-)^\sharp)$ comes together with a divergence constant $\bot\colon 1 \to A = (\mathsf{inr}\colon 1 \to A + 1)^\sharp$. Note that $\bot$ is automatically preserved by Elgot algebra morphisms.

By omitting the not entirely self-motivating **Compositionality** (or **Folding**) law, we obtain what we dub *uniform-iteration algebras*. As we see later, this law is automatic for free uniform-iteration algebras.

▶ **Definition 12** (Uniform-Iteration Algebras). *A* uniform-iteration algebra *is a tuple* $(A, (-)^\sharp)$ *as in Definition 9 but* $(-)^\sharp$ *is only required to satisfy* **Fixpoint** *and* **Uniformity**. *Morphisms of uniform-iteration algebras are defined in the same way.*

5 The Initial Pre-Elgot Monad

The goal of this section is to show that free uniform-iteration algebras coincide with free Elgot algebras (Theorem 29), and enjoy a number of other characteristic properties. In particular, we characterize the functor sending any X to a free uniform-iteration algebra on X as an initial pre-Elgot monad. We define pre-Elgot monads as follows.

▶ **Definition 13** (Pre-Elgot Monads). *We call a monad* $\mathbf{T}$ pre-Elgot *if every* TX *is equipped with an Elgot algebra structure, in such a way that* $h^\star\ f^\sharp = ((h^\star + \mathsf{id})\ f)^\sharp$ *for any* $f\colon Z \to TX + Z$ *and any* $h\colon X \to TY$. *A pre-Elgot monad* $\mathbf{T}$ *is* strong pre-Elgot *if* $\mathbf{T}$ *is strong as a monad and strength is iteration preserving.*

Pre-Elgot monads are to be compared with Elgot monads, which support a stronger type profile for the iteration operator, and satisfy more sophisticated axioms.

▶ **Definition 14** (Elgot Monads [15, 4]). *A monad* $\mathbf{T}$ *is an* Elgot monad *if it is equipped with an iteration operator sending each* $f\colon X \to T(Y + X)$ *to* $f^\dagger\colon X \to TY$ *and satisfying:*

- (**Fixpoint**) $f^\dagger = [\eta, f^\dagger]^\star\ f$;
- (**Naturality**) $g^\star\ f^\dagger = ([(T\,\mathsf{inl})\ g, \eta\ \mathsf{inr}]^\star\ f)^\dagger$ *for* $f\colon X \to T(Y + X)$, $g\colon Y \to TZ$;
- (**Codiagonal**) $(T[\mathsf{id}, \mathsf{inr}]\ f)^\dagger = f^{\dagger\dagger}$ *for* $f\colon X \to T((Y + X) + X)$;
- (**Uniformity**) $f\ h = T(\mathsf{id}+h)\ g$ *implies* $f^\dagger\ h = g^\dagger$ *for* $f\colon X \to T(Y+X)$, $g\colon Z \to T(Y+Z)$ *and* $h\colon Z \to X$.

If $\mathbf{T}$ *is additionally strong then* $\mathbf{T}$ *is strong Elgot if moreover:*

- (**Strength**) $\tau\ (\mathsf{id} \times f^\dagger) = ((T\,\mathsf{dstr})\ \tau\ (\mathsf{id} \times f))^\dagger$ *for any* $f\colon X \to T(Y + X)$.

▶ **Proposition 15.** *(Strong) Elgot monads are (strong) pre-Elgot under* $f^\sharp = ([T\,\mathsf{inl}, \eta\,\mathsf{inr}]\ f)^\dagger$.

It has been argued [17, 20] that strong Elgot monads are minimal semantic structures for interpreting effectful while-languages. In that sense, we acknowledge an expressivity gap between Elgot and pre-Elgot monads, which generally happen to be too weak. We will consider approaches to close this gap, in particular by drawing on some versions of the axiom of countable choice. Even though, in general, the gap presumably cannot be closed, we regard the initial pre-Elgot monad to be an important notion, which arises from first principles and carries a very clear operational intuition. The discrepancy between pre-Elgot monads and Elgot monads seems to represent a very basic form of discrepancy between operational and denotational semantics. We thus find it important to conceptually delineate between Elgot monads and pre-Elgot monads, no matter how desirable it is to have them to be equivalent.

▶ **Lemma 16.** *If for every* $X \in |\mathbf{C}|$ *a free uniform-iteration algebra* KX *exists then* K *extends to a monad* $\mathbf{K}$ *whose algebras are precisely uniform-iteration algebras.*

As in the case of natural numbers, one cannot make much progress without stability.

▶ **Definition 17** (Stable Free Uniform-Iteration Algebras)**.** *A free uniform-iteration algebra* KY *over* Y *is* stable *if for every* $X \in |\mathbf{C}|$, $\mathsf{fst}\colon X \times KY \to X$ *is a free uniform-iteration algebra in the slice category* $\mathbf{C}/X$.

▶ **Lemma 18.** *For* $Y \in |\mathbf{C}|$, KY *is stable iff for every uniform-iteration* A *and every* $f\colon X \times Y \to A$, *there is unique iteration preserving* $f^\sharp\colon X \times KY \to A$ *such that* $f = f^\sharp\ (\mathsf{id} \times \eta)$.

Using Lemma 11, it is easy to show that in Cartesian closed categories every KX is stable. For the rest of the section, we assume that all free uniform-iteration algebras KX exist and are stable.

▶ **Proposition 19.** *The monad* $\mathbf{K}$ *is strong, with the components of strength* $\tau\colon X \times KY \to K(X \times Y)$ *uniquely identified by the conditions:*

$$\tau\ (\mathsf{id} \times \eta) = \eta, \qquad \tau\ (\mathsf{id} \times h^\sharp) = ((\tau + \mathsf{id})\ \mathsf{dstr}\ (\mathsf{id} \times h))^\sharp \qquad (h\colon Z \to KY + Z)$$

Proof. In the notation of Lemma 18 we define strength of $\mathbf{K}$ as $(\eta\colon X \times Y \to K(X \times Y))^\sharp$. The axioms of strength are easy to verify. ◀

As a next step, we show that $\mathbf{K}$ is an equational lifting monad in the sense of Bucalo et al [9]. This means precisely that $\mathbf{K}$ is commutative and satisfies the equational law:

$$\tau\ \Delta = K\langle \eta, \mathsf{id}\rangle. \tag{1}$$

This law is rather restrictive, and roughly means that some form of non-termination is the only possible effect of the monad. Proving (1) is nontrivial. The key step is the following property, which allows for splitting a loop involving a product of algebras into two loops.

▶ **Lemma 20.** *Given uniform-iteration algebras* A *and* B, $f\colon Z \to A \times B + Z$ *and* $h\colon A \times B \to C$, $((h + \mathsf{id})\ f)^\sharp = ((h + \mathsf{id})\ \mathsf{dstr}\ (\mathsf{id} \times (\mathsf{snd} + \mathsf{id})\ f))^\sharp\ \langle((\mathsf{fst} + \mathsf{id})\ f)^\sharp, \mathsf{id}\rangle$.

▶ **Lemma 21.** *Given* $X, Z \in |\mathbf{C}|$, *and* $h\colon Z \to KX + Z$, *then* $\tau\ \langle h^\sharp, h^\sharp\rangle = ((\tau\ \Delta + \mathsf{id})\ h)^\sharp$.

Proof. It follows from Lemma 20 that $((\tau + \mathsf{id})\ \mathsf{dstr}\ (\mathsf{id} \times h))^\sharp\ \langle h^\sharp, \mathsf{id}\rangle = ((\tau\ \Delta + \mathsf{id})\ h)^\sharp$. On the other hand, by Proposition 19, $((\tau + \mathsf{id})\ \mathsf{dstr}\ (\mathsf{id} \times h))^\sharp\ \langle h^\sharp, \mathsf{id}\rangle = \tau\ \langle h^\sharp, h^\sharp\rangle$. By combining the last two identities, we obtain the goal. ◀

▶ **Theorem 22.** **K** *is an equational lifting monad.*

Proof. Let us sketch the proof of (1). Since $K\langle\eta,\mathsf{id}\rangle = (\eta\ \langle\eta,\mathsf{id}\rangle)^\star$, using the definition of Kleisli star for K, it suffices to show that $\tau\ \Delta$ is a unique iteration preserving morphism for which $\eta\ \langle\eta,\mathsf{id}\rangle = \tau\ \Delta\ \eta$. Indeed, $\tau\ \Delta\ \eta = \tau\ (\mathsf{id}\times\eta)\ \langle\eta,\mathsf{id}\rangle = \eta\ \langle\eta,\mathsf{id}\rangle$, and $\tau\ \Delta$ is iteration preserving by Lemma 21. ◀

The fact that **K** is an equational lifting monad has a number of implications, in particular, the Kleisli category of **K** is a *restriction category* [13]. That is, we can calculate the *domain (of definiteness)*, represented by an idempotent Kleisli morphism as follows: given $f\colon X\to KY$,

$$\mathsf{dom}\ f = (K\,\mathsf{fst})\ \tau\ \langle\mathsf{id}, f\rangle\colon X\to KX,$$

We additionally use the notation $f\mathbin{\downharpoonleft} g = \mathsf{fst}^\star\ \tau\ \langle f,g\rangle$, meaning: restrict f to the domain of g. It is easy to see that $\mathsf{dom}\ f = \eta\mathbin{\downharpoonleft} f$ and $f\mathbin{\downharpoonleft} g = f^\star\ (\mathsf{dom}\ g)$. Let $f\sqsubseteq g$ abbreviate $f = g\mathbin{\downharpoonleft} f$. Under this definition, every $\mathbf{C}(X,KY)$ is partially ordered, which is a general fact about restriction categories. In our case, moreover, this partial order additionally has a bottom element $\bot = \mathsf{inr}^\sharp$; $\mathsf{dom}(\eta\ f) = \eta$ for any $f\colon X\to KY$, and $\mathsf{dom}\ f\sqsubseteq\eta$ for any f.

▶ **Proposition 23.** *The Kleisli category of* **K** *is enriched over pointed partial orders and strict monotone maps. Moreover, strength preserves* $\bot$ *and* $\sqsubseteq$ *as follows:*

$$\tau\ (\mathsf{id}\times\bot) = \bot \qquad\qquad f\sqsubseteq g \quad \textit{implies} \quad \tau\ (\mathsf{id}\times f)\sqsubseteq\tau\ (\mathsf{id}\times g)$$

▶ **Corollary 24.** $K\emptyset\cong 1$.

Proof. Since $!\bot = \mathsf{id}\colon 1\to 1$ and $\bot! = \mathsf{id}\colon K\emptyset\to K\emptyset$, we obtain an isomorphism $K\emptyset\cong 1$. ◀

▶ **Proposition 25.** *The monad* **K** *is* copyable *and* weakly discardable *[18], i.e.:* $\hat\tau^\star\ \tau\ \Delta = K\Delta$ *and* $(K\,\mathsf{fst})\ \hat\tau^\star\ \tau\ \langle f,g\rangle\sqsubseteq f$ *for* $f\colon X\to KY$ *and* $g\colon X\to KZ$.

▶ **Definition 26** (Bounded Iteration)**.** *Let* A *be a* pointed object*, i.e. an object with a canonical map* $\bot\colon 1\to A$*. Then we define* bounded iteration $(\text{–})^{\langle\sharp\rangle}\colon\mathbf{C}(X,A+X)\to\mathbf{C}(X\times\mathbb{N},A)$ *by primitive recursion as follows:*

$$f^{\langle\sharp\rangle}(x,\mathsf{o}) = \bot \qquad\qquad f^{\langle\sharp\rangle}(x,\mathsf{s}\,n) = \mathsf{case}\ f(x)\ \mathsf{of}\ \mathsf{inl}\ a\mapsto a;\ \mathsf{inr}\ y\mapsto f^{\langle\sharp\rangle}(y,n).$$

Intuitively, $f^{\langle\sharp\rangle}(x,n)$ behaves as $f^\sharp(x)$ except that at each iteration the counter n is decreased, and $\bot$ is returned once $n=\mathsf{o}$. We next show that $f^\sharp(x)$ is in a suitable sense a limit of the $f^{\langle\sharp\rangle}(x,n)$ as n tends to infinity. This is, of course, a form of *Kleene fixpoint theorem*.

▶ **Theorem 27** (Kleene Fixpoint Theorem)**.** *Given* $f\colon X\to KY+X$*, and* $g\colon X\to KY$*, (i)* $f^{\langle\sharp\rangle}\sqsubseteq f^\sharp\ \mathsf{fst}$*, and (ii)* $f^{\langle\sharp\rangle}\sqsubseteq g\ \mathsf{fst}$ *implies* $f^\sharp\sqsubseteq g$.

▶ **Corollary 28.** *Given* $f\colon X\to KY+X$*,* $f^\sharp\colon X\to KY$ *is the least pre-fixpoint of the map* $[\mathsf{id},\text{–}]\ f\colon\mathbf{C}(X,KY)\to\mathbf{C}(X,KY)$.

Finally, we obtain

▶ **Theorem 29.** **K** *is an initial pre-Elgot monad and an initial strong pre-Elgot monad.*

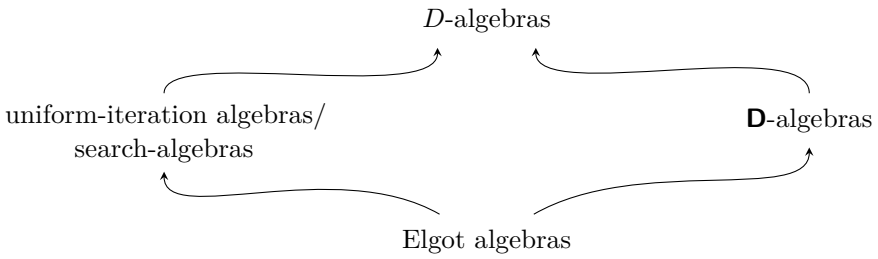

Figure 2 Connections between classes of D-algebras.

6 Quotienting the Delay Monad

By Theorem 8, Id-guarded Elgot algebras are precisely the **D**-algebras. We proceed to characterize uniform-iteration and Elgot algebras as certain D-algebras, which we dub *search-algebras*. Intuitively, modulo identification of DA with a set of streams from $(A+1)^{\mathbb{N}}$, a search-algebra structure $a\colon DA \to A$ is guaranteed to find the first element in the stream of the form $\mathsf{inl}\, a$ if it exists. We expect that this notion can be formulated more generally, but we do not pursue it here.

▶ **Definition 30** (Search-Algebra)**.** *We call a D-algebra $(A, a\colon DA \to A)$ a* search-algebra *if it satisfies the conditions: $a\ \mathsf{now} = \mathsf{id}$, $a \triangleright = a$. Search-algebras form a full subcategory of the category of all D-algebras.*

Uniform-iteration algebras capture the structure of search-algebras independently of the assumption that D exists. This and further connections between categories of D-algebras illustrated in Fig. 2 (arrows indicate full embeddings of categories) are formalized as follows.

▶ **Proposition 31.**

1. *The categories of uniform-iteration algebras and search-algebras are isomorphic under:*

$$(A, (-)^\sharp) \mapsto (A,\ \mathsf{out}^\sharp\colon DA \to A),$$
$$(A, a\colon DA \to A) \mapsto (A,\ a\ \ \mathsf{coit}(-)\colon \mathbf{C}(X, A+X) \to \mathbf{C}(X, A)).$$

2. *Elgot algebras are precisely those D-algebras, which are search-algebras and* **D***-algebras.*

▶ **Lemma 32.** *Every Elgot algebra $(DA, a\colon DA \to A)$ satisfies $a\ \iota^\star = a\ (D\,\mathsf{fst})$.*

We proceed to model the construction of quotienting **D** by weak bisimilarity $\approx$, previously described in type-theoretic terms [11]. Modulo identification of DX with the object of those streams $\sigma\colon \mathbb{N} \to X+1$ for which $\sigma(n) \neq \mathsf{inr}\star$ for at most one n, $\approx$ can be described as follows: $\sigma \approx \sigma'$ if for every a, $\sigma(n) = a$ for some n iff $\sigma'(n) = a$ for some n.

Recall the embedding $\iota\colon X \times \mathbb{N} \hookrightarrow DX$, and define the quotient of DX by the coequalizer

$$D(X \times \mathbb{N}) \underset{D\,\mathsf{fst}}{\overset{\iota^\star}{\rightrightarrows}} DX \xrightarrow{\ \rho_X\ } \widetilde{D}X \tag{2}$$

which we assume to exist and be preserved by products. It is then straightforward that $\widetilde{D}$ is a functor and ρ_X is natural in X. It also follows that $X \xrightarrow{\mathsf{now}} DX \xrightarrow{\rho} \widetilde{D}X$ is strong. Following tradition, we denote $\widetilde{D}1$ as Σ.

▶ **Lemma 33.** $\rho \triangleright = \rho$.

Defining ρ as a coequalizer of $\triangleright$ and id in the first place does not seem to be sufficient, though, in particular, for showing the following property. We leave open the question of identifying conditions under which it is possible.

▶ **Proposition 34.** *The following is a coequalizer:*

$$D(X + (X \times \mathbb{N} + X \times \mathbb{N})) \underset{[\eta,[\eta\ \ \mathsf{fst},\iota\ \ (\mathsf{id}\times\mathsf{s})]]^\star}{\overset{[\eta,[\iota\ \ (\mathsf{id}\times\mathsf{s}),\eta\ \ \mathsf{fst}]]^\star}{\rightrightarrows}} DX \xrightarrow{\rho_X} \widetilde{D}X \tag{3}$$

The last proposition brings the definition of ρ in accordance with the intuition; the coproduct $X + (X \times \mathbb{N} + X \times \mathbb{N})$ covers three alternatives for $\sigma \approx \sigma'$: either $\sigma = \sigma'$, or σ terminates earlier than σ' by a specified number, or the other way around. It can be verified that the embedding $D(X + (X \times \mathbb{N} + X \times \mathbb{N})) \hookrightarrow DX \times DX$ is an internal equivalence relation.

▶ **Theorem 35.** *The following conditions are equivalent:*

1. *for every X, coequalizer (2) is preserved by D;*
2. *every $\widetilde{D}X$ extends to a search-algebra, so that each ρ_X is a D-algebra morphism;*
3. *for every X, $(\widetilde{D}X, \rho\ \mathsf{now}\colon X \to \widetilde{D}X)$ is a stable free Elgot algebra on X, ρ_X is a D-algebra morphism and $\rho_X = ((\rho_X\ \ \mathsf{now} + \mathsf{id})\ \ \mathsf{out})^\sharp$;*
4. *$\widetilde{D}$ extends to a strong monad, so that ρ is a strong monad morphism.*

If the equivalent conditions of Theorem 35 are satisfied, we obtain an explicit construction of the initial pre-Elgot monad $\mathbf{K}$, which we explored previously. Let us consider concrete examples.

▶ **Example 36** (Maybe-Monad)**.** Suppose that $\mathbf{C}$ is an LPO category, and recall that DX is isomorphic to $X \times \mathbb{N} + 1$. It is then easy to check that (2) exists, it is preserved by products, $\widetilde{D}X \cong X + 1$ and $\rho = \mathsf{fst} + \mathsf{id}\colon X + 1 \to X \times \mathbb{N} + 1$. Since D is the composition of $(- \times \mathbb{N})$ and $(- + 1)$, and both these functors preserve coequalizers (first as a left adjoint, and second by extensiveness of $\mathbf{C}$), D preserves (2). We thus obtain that the maybe-monad is an initial pre-Elgot monad. This covers instances of LPO categories from Example 6. Moreover, the initial pre-Elgot monad is in fact an initial Elgot monad in this case: the profiles of the iteration operators $(-)^\sharp$ and $(-)^\dagger$ agree up to rearrangement of summands, and the axioms of Definition 14 become the axioms of Definition 13, except for **Codiagonal**, which can be checked directly.

Note that Example 36 entails that the maybe-monad is the initial Elgot monad in $\mathbf{dCpo}$. This is a result of our assumption that $\mathbf{dCpo}$ is developed w.r.t. a classical set theory, which entails that $\mathbf{dCpo}$ is an LPO category. This would not be the case if we defined $\mathbf{dCpo}$ internally to a non-classical environment, which is indeed the core idea of synthetic domain theory.

Another direction for obtaining an Elgot monad from (2) is by using a suitable instance of the *axiom of countable choice*. In our setting this takes the following form.

▶ **Theorem 37.** *Suppose that the coequalizers (2) are preserved by the exponentiation $(-)^{\mathbb{N}}$.*

1. *The equivalent conditions of Theorem 35 hold, in particular, $\mathbf{K}$ is an initial (strong) pre-Elgot monad.*
2. *If every (3) is an effective quotient, i.e. $D(X + (X \times \mathbb{N} + X \times \mathbb{N}))$ is a kernel pair of ρ_X, then $\mathbf{K}$ is a strong Elgot monad with $f^\dagger$ being the least fixpoint of $[\eta, -]^\star\ f\colon \mathbf{C}(X, TY) \to \mathbf{C}(X, TY)$ for any $f\colon X \to T(Y + X)$.*

The effectiveness assumption in clause 2. is satisfied in any exact category (e.g. in any pretopos) – by definition, every internal equivalence relation there is effective.

▶ **Example 38.** Theorem 37 applies to **Top**, yielding a concrete description for **K**. Recall that in **Top**, coequalizers are computed as in **Set** and are equipped with the quotient topology. Note that DX is the set $X \times \mathbb{N} \cup \{\infty\}$ whose base opens are $\{(x,n) \mid x \in O\}$ and $\{(x,k) \mid x \in X, k \geqslant n\} \cup \{\infty\}$ with $n \in \mathbb{N}$ and O ranging over the opens of X. The collapse $\widetilde{D}X$ computed with (2) is thus the set $X \cup \{\infty\}$, whose opens are those of X and additionally the entire space $X \cup \{\infty\}$, in particular, $\widetilde{D}1$ is the *Sierpiński space*.

To obtain that (2) is preserved by $(-)^{\mathbb{N}}$, it suffices to show that the opens of $(X \cup \{\infty\})^{\mathbb{N}}$ are precisely those, whose inverse images under $\rho^{\mathbb{N}}$ are open. This is in fact true for any regular epi in **Top**. The effectiveness condition in 2. is not vacuous for **Top**, which is not an exact category (and not even regular), but it can be checked manually.

In every pretopos, preservation of (2) by $(-)^{\mathbb{N}}$ is a proper instance of the *internal axiom of countable choice*, or *internal projectivity of* $\mathbb{N}$, which means preservation of epis by $(-)^{\mathbb{N}}$, roughly because every pretopos is *exact* and our quotienting morphism ρ is associated with an internal equivalence relation by Proposition 34. Theorem 37 can thus be related to the existing result in synthetic domain theory, that Rosolini dominance, i.e. our Σ, is indeed a dominance [31], which applies to Hyland's *effective topos* [22], as it satisfies countable choice. Contrastingly, we cannot apply Theorem 37 to nominal sets, which falsify countable choice, however, as a Boolean topos, nominal sets fall into the scope of Example 36.

We currently do not have a concrete example of **K** being definable, but not being an Elgot monad. Theorem 37 and Example 36 indicate that a category to witness this must neither support excluded middle nor the axiom of countable choice.

7 Conclusions and Further Work

Iteration and iteration theories emerged as unifying concepts for computer science semantics and reasoning. By interpreting iteration suitably, one obtains a basic extensible equational logic of programs, shown to be sound and complete across various models [8]. Elgot monads implement this inherently algebraic view in the general categorical realm of abstract data types and effects. The class of Elgot monads (over a fixed category) is stable under various categorical constructions (monad transformers), and thus one can build new Elgot monads from old, but the simplest Elgot monad, the initial one, does not arise in this way.

Here, we proposed an approach to defining an initial iteration structure from first principles, characterized it in various ways, analysed conditions, under which it can be concretely described, and to yield an Elgot monad. Unsurprisingly, these conditions generally cannot be lifted, as the previous research in type theory indicates. We consider broadening the scope in which results about notions of partiality apply, and unifying both classical and non-classical models, as an important part of our contribution. Universal properties play a central role in category theory, but many important concepts are not covered by them. One example is Sierpiński space, which is fundamental in topology, duality theory and domain theory. It follows from our results, that it is in fact a free uniform-iteration algebra on one generator. We believe that the structure of our results can be reused in more sophisticated setting, such as semantics of *hybrid systems*, which require a notion of partiality, combined with continuous evolution, and rise semantic issues, structurally similar to those, we considered here [14]. Another potential for taking further the present work is to consider more general shapes of the basic functor (instead of the current $(X + -)$), prospectively leading to more sophisticated (non-)structural recursion scenarios (see e.g. [1]).

Powerset-Like Monads Weakly Distribute over Themselves in Toposes and Compact Hausdorff Spaces

Abstract

The powerset monad on the category of sets does not distribute over itself. Nevertheless a weaker form of distributive law of the powerset monad over itself exists and it essentially stems from the canonical Egli-Milner extension of the powerset to the category of relations. On the other hand, any regular category yields a category of relations, and some regular categories also possess a powerset-like monad, as is the Vietoris monad on compact Hausdorff spaces. We derive the Egli-Milner extension in three different frameworks : sets, toposes, and compact Hausdorff spaces. We prove that it corresponds to a monotone weak distributive law in each case by showing that the multiplication extends to relations but the unit does not. We provide an application to coalgebraic determinization of alternating automata.

1 Introduction

Composing monads is usually achieved using distributive laws. Unfortunately, sometimes these do not exist. It is known since the work of Varacca [24] that there is no distributive law between the monad $\mathbf{D}$ of probability distributions and the powerset monad $\mathbf{P}$. The proof, attributed to Plotkin, relies on a manipulation of the naturality squares of the unit of $\mathbf{D}$. More recently, [14] showed that there is no distributive law of the powerset $\mathbf{P}$ over itself, and even more nor over its iterations. More negative results for other Set-based algebraic theories are presented in [26].

One way to circumvent such negative results is to compose monads using weaker forms of distributive laws. In the definition of a distributive law between monads we have four axioms specifying the interactions of the law with the units, respectively with the multiplications of the two monads. In a weak distributive law, an axiom involving the unit of one of the monads is dropped. In our previous paper [11] we exhibited a canonical weak distributive law between the monads $\mathbf{D}$ and $\mathbf{P}$. It comes as no surprise that the axiom that is dropped from the definition of such a law is the one involving the unit of $\mathbf{D}$ – on which the argument of Plotkin relied. Our work in turn, was based on Garner's results [10]. In loc. cit. he exhibited a weak distributive law between the powerset monad and the ultrafilter monad $\boldsymbol{\beta}$. This leads to a weak lifting of the powerset to the category of Eilenberg-Moore algebras of $\boldsymbol{\beta}$, that is,

© Alexandre Goy, Daniela Petrişan, and Marc Aiguier;
licensed under Creative Commons License CC-BY 4.0

to the category of compact Hausdorff spaces KHaus. This weak lifting is the Vietoris monad and is indeed the closest there is to a powerset-like monad on KHaus. In [10] it is also shown that the powerset monad on Set weakly distributes over itself.

The weak distributive laws in [10] and [11] were all of the form $\mathbf{TP} \to \mathbf{PT}$, where $\mathbf{P}$ is the powerset monad on Set. The recipe for obtaining these laws was based on the monotone weak extension of the monad $\mathbf{T}$ to the category of relations, this is, the Kleisli category of $\mathbf{P}$.

The motivation of the present paper is to understand composition of monads via weak distributive laws in other settings than for Set-based monads. In particular our aim here is to build the technology necessary for combining various forms of nondeterminism (ordinary and probabilistic) in a continuous setting.

An obvious starting point is to consider the category of compact Hausdorff spaces KHaus, where we have the Vietoris monad $\mathbf{V}$ whose Kleisli category $\mathsf{Kl}(\mathbf{V})$ can be seen as a category of relations satisfying additional continuity constraints. The first question we have asked ourselves is whether the Vietoris monad $\mathbf{V}$ weakly distributes over itself. Can we extend Garner's result from Set to KHaus? It turns out the answer is positive, see Theorem 24. In the process we have used various results from the literature, in particular, the work of [7] for extending functors on a regular category C to the category of relations $\mathsf{Rel}(\mathsf{C})$. Nevertheless, the results are far from immediate since $\mathsf{Kl}(\mathbf{V})$ is only a subcategory of $\mathsf{Rel}(\mathsf{KHaus})$, hence some additional work is needed to obtain the canonical extension of $\mathbf{V}$ to $\mathsf{Kl}(\mathbf{V})$. We also notice that despite the fact that the Vietoris functor does not preserve pullbacks (see also [6]), it nearly preserves pullbacks, and this is exactly the condition needed in [7] to provide the relational extension. Once the monotone extension of the monad $\mathbf{V}$ to $\mathsf{Kl}(\mathbf{V})$ is found, we can provide the weak distributive law via the same mechanism as in [10].

Another extension we provide is for the powerset-like monad on a topos C. This monad is defined on objects as Ω^X where Ω is the subobject classifier of the topos. Notice that we are not considering the contravariant powerset-like functor usually appearing in topos theory, but rather the monad $\mathbf{\exists}$ of [19]. Its Kleisli category is simply $\mathsf{Rel}(\mathsf{C})$ and, as far as the underlying functor is concerned, a monotone extension is obtained again by leveraging the work in [7]. To obtain the extension of the *monad* $\mathbf{\exists}$, we need to investigate the properties of its unit and of its multiplication. As far as the multiplication is concerned, we can internalize the proof from the Set case, using the internal logic of the topos. As far as the unit is concerned, we show that it has the required property for obtaining a strong extension of the monad, only when the topos is degenerate. In all other meaningful cases, we thus only obtain a weak extension of $\mathbf{\exists}$ to $\mathsf{Kl}(\mathbf{\exists})$, and hence a weak distributive law of $\mathbf{\exists}$ over itself, see Theorem 13.

The paper is structured as follows. In Section 2 we recall the necessary preliminaries on weak distributive laws and relations in regular categories. In Section 3 we recall the weak distributive law of the powerset over itself and provide an application to coalgebraic determinization of alternating automata. We find it instructive to understand the proofs first in Set, as they will serve as a basis for the generalization to toposes, performed in Section 4. In Section 5 we provide the weak distributive law of the Vietoris functor over itself and we conclude with a summary and directions for future work in Section 6.

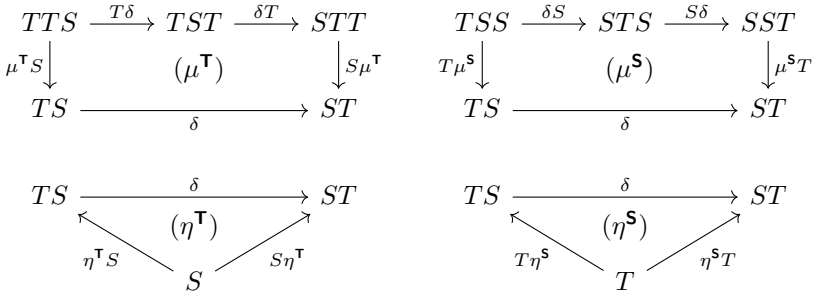
2 Preliminaries

Notations

For a relation $R \subseteq X \times Y$ between two sets and $A \subseteq X$, $B \subseteq Y$, we write $R[A] = \{y \in Y \mid (x, y) \in R \text{ and } x \in A\}$ and $R^{-1}[B] = \{x \in X \mid (x, y) \in R \text{ and } y \in B\}$. The complement of $A \subseteq X$ is denoted by A^c. In the whole paper, C denotes a generic category, $F, G : \mathsf{C} \to \mathsf{C}$ denote functors and $\alpha : F \to G$ denotes a natural transformation. Identity morphisms, functors and natural transformations will all be denoted by 1.

2.1 (Weak) Extensions, (Weak) Distributive Laws, (Weak) Liftings

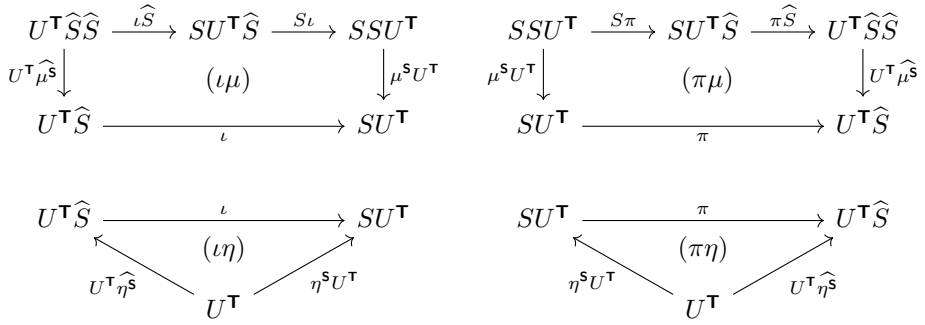
We assume the reader is familiar with the basic theory of monads, and fix here some notations. A *monad* is a triple $\mathbf{T} = (T, \eta^{\mathbf{T}}, \mu^{\mathbf{T}})$ where $T : \mathsf{C} \to \mathsf{C}$ is a functor, $\eta^{\mathbf{T}} : 1 \to T$ and $\mu^{\mathbf{T}} : TT \to T$ are natural transformations called respectively unit and multiplication and equations $\mu^{\mathbf{T}} \circ T\eta^{\mathbf{T}} = 1 = \mu^{\mathbf{T}} \circ \eta^{\mathbf{T}}T$, $\mu^{\mathbf{T}} \circ T\mu^{\mathbf{T}} = \mu^{\mathbf{T}} \circ \mu^{\mathbf{T}}T$ hold. In the following we fix two monads $\mathbf{T}$ and $\mathbf{S}$ on C. The *Kleisli category* of $\mathbf{S}$ is denoted by $\mathsf{Kl}(\mathbf{S})$. A morphism in $\mathsf{Kl}(\mathbf{S})$ will be denoted by $X \nrightarrow Y$ and corresponds to a morphism $X \to SY$ in C. The Kleisli free and forgetful functor are denoted respectively by $F_{\mathbf{S}} : \mathsf{C} \to \mathsf{Kl}(\mathbf{S})$ and $U_{\mathbf{S}} : \mathsf{Kl}(\mathbf{S}) \to \mathsf{C}$. The *Eilenberg-Moore category* of $\mathbf{T}$ is denoted by $\mathsf{EM}(\mathbf{T})$, objects are algebras (X, x) where X is an object of C and $x : TX \to X$ satisfies $x \circ \eta^{\mathbf{T}}_X = 1_X$ and $x \circ \mu^{\mathbf{T}}_X = x \circ Tx$. The Eilenberg-Moore free and forgetful functor are denoted respectively by $F^{\mathbf{T}} : \mathsf{C} \to \mathsf{EM}(\mathbf{T})$ and $U^{\mathbf{T}} : \mathsf{EM}(\mathbf{T}) \to \mathsf{C}$.



▶ **Example 1.** The *powerset monad* $\mathbf{P}$ on the category of sets and functions Set is defined as follows. The functor P maps a set X to the set of its subsets and acts on functions by taking direct images. Unit is given by the singleton operation $\eta^{\mathbf{P}}_X(x) = \{x\}$ and multiplication by union $\mu^{\mathbf{P}}_X(\mathcal{A}) = \bigcup \mathcal{A}$.

Monads are not stable under composition. However, Beck introduced the framework of distributive laws [1] as a tool to generate composite monads. Distributive laws are actually one face of a three-sided coin comprising also extensions and liftings. Interestingly enough, each component of this triptych can be weakened in such a way that the correspondence still stands between weak distributive laws, weak extensions and weak liftings [10]. The rest of this section aims at jointly recalling both the usual and the weakened framework.

An extension of F to $\mathsf{Kl}(\mathbf{S})$ is a functor $\overline{F} : \mathsf{Kl}(\mathbf{S}) \to \mathsf{Kl}(\mathbf{S})$ such that $\overline{F}F_{\mathbf{S}} = F_{\mathbf{S}}F$. Similarly, an extension of $\alpha : F \to G$ is a natural transformation $\overline{\alpha} : \overline{F} \to \overline{G}$ such that the equation $\overline{\alpha}F_{\mathbf{S}} = F_{\mathbf{S}}\alpha$ holds.

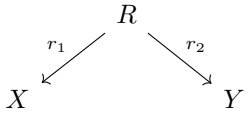


▶ **Definition 2** (Extension). *An* extension *of* $\mathbf{T}$ *to* $\mathsf{Kl}(\mathbf{S})$ *is a monad* $\overline{\mathbf{T}}$ *on* $\mathsf{Kl}(\mathbf{S})$ *whose functor, unit and multiplication are extensions of those of* $\mathbf{T}$*. A* weak extension *only requires the extension of the functor and of the multiplication of* $\mathbf{T}$*.*

▶ **Definition 3** (Distributive law). *A* distributive law *of type* $\mathbf{TS} \to \mathbf{ST}$ *is a natural transformation* $\delta : TS \to ST$ *such that the four following diagrams commute*

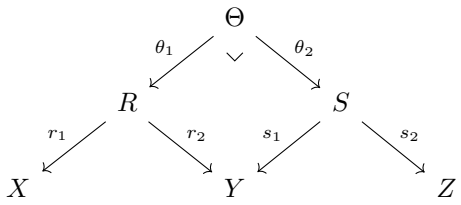
A weak distributive law *only requires the* $(\eta^{\mathbf{S}})$, $(\mu^{\mathbf{S}})$ *and* $(\mu^{\mathbf{T}})$ *diagrams.*

▶ **Definition 4** (Lifting). *A* lifting *of* $\mathbf{S}$ *to* $\mathsf{EM}(\mathbf{T})$ *is a monad* $\widehat{\mathbf{S}} : \mathsf{EM}(\mathbf{T}) \to \mathsf{EM}(\mathbf{T})$ *such that* $U^{\mathbf{T}}\widehat{S} = SU^{\mathbf{T}}$, $U^{\mathbf{T}}\widehat{\eta^{\mathbf{S}}} = \eta^{\mathbf{S}}U^{\mathbf{T}}$ *and* $U^{\mathbf{T}}\widehat{\mu^{\mathbf{S}}} = \mu^{\mathbf{S}}U^{\mathbf{T}}$. *A* weak lifting *of* $\mathbf{S}$ *on* $\mathbf{T}$ *is a monad* $\widehat{\mathbf{S}} : \mathsf{EM}(\mathbf{T}) \to \mathsf{EM}(\mathbf{T})$ *along with two natural transformations* $\pi : SU^{\mathbf{T}} \to U^{\mathbf{T}}\widehat{S}$, $\iota : U^{\mathbf{T}}\widehat{S} \to SU^{\mathbf{T}}$ *such that* $\pi \circ \iota = 1$ *and the following diagrams commute:*



Recall that an idempotent morphism $e : X \to X$ *splits* if there is an object Y and morphisms $f : X \to Y$, $g : Y \to X$ such that $g \circ f = e$ and $f \circ g = 1_Y$.

▶ **Theorem 5** ([1, 10]). *There is a bijective correspondence between extensions of* $\mathbf{T}$ *to* $\mathsf{Kl}(\mathbf{S})$, *distributive laws of type* $\mathbf{TS} \to \mathbf{ST}$, *and liftings of* $\mathbf{S}$ *to* $\mathsf{EM}(\mathbf{T})$. *This extends to a bijective correspondence between weak extensions, weak distributive laws, and (if all idempotents split in* C*) weak liftings.*



2.2 Relations in Regular Categories

From now on, we make the assumption that C is a *regular* category, this is, finitely complete with pullback-stable image factorizations. (Note that in a regular category, regular epis and strong epis coincide; notions will be phrased in terms of strong epis, as in [7].) In particular, C has all pullbacks: in this context, a *weak pullback* (resp. *near pullback*) is a commutative square such that the mediating morphism into the pullback is a split epi (resp. strong epi). The functor F is *weakly cartesian* (resp. *nearly cartesian*) if it maps pullbacks into weak pullbacks (resp. near pullbacks), and α is weakly cartesian (resp. nearly cartesian) if its naturality squares are weak pullbacks (resp. near pullbacks). Note that in the literature, strong epis are sometimes called *covers*, and within this terminology a nearly cartesian functor is a functor that *covers pullbacks* [22].

Regular categories have a (strong epi, mono) factorization system. In such a factorization $f = m \circ e$ we recall that the subobject defined by the mono m is the *image* of the morphism f. Note that these factorizations imply that idempotents split in C, so that Theorem 5 can be fully applied. As explained in [7], one can build a category $\mathsf{Rel}(\mathsf{C})$ whose morphisms will stand for relations. The objects of $\mathsf{Rel}(\mathsf{C})$ are the objects of C. A morphism $r : X \rightsquigarrow Y$ in $\mathsf{Rel}(\mathsf{C})$ is a subobject of $X \times Y$ in C and is called a relation – the notation $\rightsquigarrow$ tells relations apart from morphisms in C. We will not distinguish monomorphisms from their equivalence classes, hence a relation is equivalently a jointly monic span

The composition of relations $r = \langle r_1, r_2 \rangle : R \to X \times Y$ and $s = \langle s_1, s_2 \rangle : S \to Y \times Z$ is obtained using a pullback Θ, by taking the image of the morphism $\Theta \to X \times Z$ below:

This relational composition of r and s will be denoted by $s.r$. Identities are obtained via the diagonal monomorphism $\langle 1_X, 1_X \rangle : X \to X \times X$. There is a contravariant involution $-^\circ : \mathsf{Rel}(\mathsf{C})^{\mathsf{op}} \to \mathsf{Rel}(\mathsf{C})$ given by $X^\circ = X$ and $\langle r_1, r_2 \rangle^\circ = \langle r_2, r_1 \rangle$. The graph functor $\mathcal{G} : \mathsf{C} \to \mathsf{Rel}(\mathsf{C})$ is defined by $\mathcal{G}X = X$ and $\mathcal{G}f = \langle 1_X, f \rangle$ for any $f : X \to Y$. These two fundamental functors have a nice interplay, as for every $r : X \rightsquigarrow Y$ we have $r = \mathcal{G}r_2.(\mathcal{G}r_1)^\circ$. Most of the time, the mention of $\mathcal{G}$ will be omitted, e.g. the previous equation writes $r = r_2.r_1^\circ$ and functoriality of $\mathcal{G}$ writes $g.f = g \circ f$. Given two relations $r : R \to X \times Y$ and $s : S \to X \times Y$, the subobject order is defined by:

$$r \leq s \iff \exists h : R \to S, r = s \circ h \tag{1}$$

Accordingly, a functor $H : \mathsf{Rel}(\mathsf{C}) \to \mathsf{Rel}(\mathsf{C})$ is called *monotone* if $r \leq s \Rightarrow Hr \leq Hs$.

A *relational extension* of F is a monotone functor $\mathsf{Rel}(F) : \mathsf{Rel}(\mathsf{C}) \to \mathsf{Rel}(\mathsf{C})$ such that $\mathsf{Rel}(F)\mathcal{G} = \mathcal{G}F$. This actually forces $\mathsf{Rel}(F)X = FX$ and

$$\mathsf{Rel}(F)r = (Fr_2).(Fr_1)^\circ \tag{2}$$

so that F has at most one relational extension. Similarly, a relational extension of $\alpha : F \to G$ is a natural transformation $\mathsf{Rel}(\alpha) : \mathsf{Rel}(F) \to \mathsf{Rel}(G)$ such that $\mathsf{Rel}(\alpha)\mathcal{G} = \mathcal{G}\alpha$, and α has at most one such extension. Collecting results from the literature ([7, §4.3], [21, Corollary 1.5.7]) we get the following existence theorem

▶ **Theorem 6** (Existence of relational extensions). *A functor $F : \mathsf{C} \to \mathsf{C}$ on a regular category C has a (unique) relational extension if and only if F preserves strong epis and F is nearly cartesian. Provided these conditions hold for both F and G, a natural transformation $\alpha : F \to G$ has a (unique) relational extension if and only if α is nearly cartesian.*

Note that whenever $\mathsf{Rel}(F)$ and $\mathsf{Rel}(G)$ exist, then $\mathsf{Rel}(G)\mathsf{Rel}(F) = \mathsf{Rel}(GF)$ (see also [7, §4.4]).

3 Sets

There is no distributive law of type $\mathbf{PP} \to \mathbf{PP}$ on Set [14]. However, there is a weak distributive law recently described by Garner [10]. In this section, we detail how this law is obtained using Theorem 6. Our aim is twofold. First, we lay the ground for Sections 4 and 5 where we will generalize this reasoning in two different directions. Second, as an application we present how this weak distributive law allows to retrieve a known procedure that transforms alternating automata into non-deterministic automata [13].

In this section, C is the (regular) category Set of sets and functions and $\mathbf{S}$ is the powerset monad $\mathbf{P}$ defined in Example 1. It turns out that both $\mathsf{Kl}(\mathbf{P})$ and $\mathsf{Rel}(\mathsf{Set})$ can be identified to the category Rel of sets and relations. Under this identification we have $F_{\mathbf{P}} = \mathcal{G}$. In this

context a relation $R : X \nrightarrow Y$ is just a subset of the product $R \subseteq X \times Y$ and composition is defined by the usual formula $S \circ R = \{(x, z) \in X \times Z \mid (x, y) \in R \text{ and } (y, z) \in S\}$. A relational extension of a functor is nothing but a (Kleisli) extension that is monotone with respect to relation inclusion. The axiom of choice yields that all epis are split, henceforth any functor automatically preserves strong epis, and near pullbacks coincide with weak pullbacks. Theorem 6 therefore boils down to saying that F (resp. α) extends to Rel iff F (resp. α) is weakly cartesian – this is [10, Proposition 15].

Let $\mathbf{T}$ also be the powerset monad $\mathbf{P}$. The following example is essentially in [10] – however the proofs there are done with $\mathbf{T}$ being the *finite* powerset monad. An obvious consequence of the above paragraph is that $\mathbf{P}$ has a weak extension to Rel iff P and $\mu^{\mathbf{P}}$ are weakly cartesian, which both are known results, see e.g. [23] for P and [10] for $\mu^{\mathbf{P}}$. Further, the unit $\eta^{\mathbf{P}}$ is not nearly cartesian [10], so that the weak extension is not an extension. We recall these proofs here because they will be used in the next sections.

▶ **Proposition 7.** *The powerset functor P is weakly cartesian.*

Proof. Equivalently, P being nearly cartesian amounts to showing that for every $f : X \to Z$, $g : Y \to Z$ and $(A, B) \in PX \times PY$ such that $f[A] = g[B]$, there is $C \subseteq P := \{(x, y) \in X \times Y \mid f(x) = g(y)\}$ such that $\pi_1[C] = A$ and $\pi_2[C] = B$, where $\pi_1 : P \to X$, $\pi_2 : P \to Y$ are the projections from the pullback. One can easily check that $C = \pi_1^{-1}(A) \cap \pi_2^{-1}(B)$ completes the proof. ◀

▶ **Proposition 8.** *The unit $\eta^{\mathbf{P}}$ is not weakly cartesian.*

Proof. Consider the naturality square for the unique map $! : \{0, 1\} \to \{0\}$. The corresponding pullback $\{(0, \{0\}), (0, \{1\}), (0, \{0, 1\})\}$ has cardinality 3, so there cannot be a surjective map from $\{0, 1\}$ into it. ◀

▶ **Proposition 9.** *The multiplication $\mu^{\mathbf{P}}$ is weakly cartesian.*

Proof. For any $f : X \to Y$ and $(A, \mathcal{B}) \in PX \times PPY$ such that $f[A] = \bigcup \mathcal{B}$, we must find $\mathcal{A} \in PPX$ such that $\bigcup \mathcal{A} = A$ and $(Pf)[\mathcal{A}] = \mathcal{B}$. Take $\mathcal{A} = \{A \cap f^{-1}(B) \mid B \in \mathcal{B}\}$ and check

$$(Pf)[\mathcal{A}] = \{f[A \cap f^{-1}(B)] \mid B \in \mathcal{B}\} = \{f[A] \cap B \mid B \in \mathcal{B}\} = \{B \mid B \in \mathcal{B}\} = \mathcal{B}$$
$$\bigcup \mathcal{A} = A \cap f^{-1}\left(\bigcup \mathcal{B}\right) = A \cap f^{-1}(f[A]) = A$$ ◀

Computing the weak extension of $\mathbf{P}$ to Rel using equation (2) yields the well-known Egli-Milner relation

$$\overline{P}R = \{(A, B) \in PX \times PY \mid \forall x \in A, \exists y \in B, (x, y) \in R \text{ and } \forall y \in B, \exists x \in A, (x, y) \in R\} \quad (3)$$

The corresponding weak distributive law $\lambda : \mathbf{PP} \to \mathbf{PP}$ is given by

$$\lambda_X(\mathcal{A}) = \left\{B \in PX \mid B \subseteq \bigcup \mathcal{A} \text{ and } \forall A \in \mathcal{A}, A \cap B \neq \emptyset\right\} \quad (4)$$

The corresponding weak lifting of $\mathbf{P}$ to the category of complete join semi-lattices $\mathsf{EM}(\mathbf{P})$ is as follows: $\widehat{P}(X, x) = (S, s)$ has underlying set $S = \{A \in PX \mid \forall B \subseteq A, B \neq \emptyset \Rightarrow x(B) \in A\}$ with join given for every $\mathcal{A} \in PS$ by $s(\mathcal{A}) = \{x(\{a_A \mid A \in \mathcal{A}\}) \mid \forall A \in \mathcal{A}, a_A \in A\}$. The morphism $\pi_{(X,x)} : PX \to S$ sends a subset $A \subseteq X$ to its closure under non-empty join $\{x(B) \mid B \in P(A) \setminus \{\emptyset\}\}$, whereas $\iota_{(X,x)} : S \to PX$ is just the inclusion. Practically speaking, disposing of such a weak lifting allows to perform generalized determinization of PP-coalgebras as in [11, Section 5].

An *F-coalgebra* (X, c) is a morphism $c : X \to FX$, and a morphism of F-coalgebras $f : (X, c) \to (Y, d)$ is a morphism $f : X \to Y$ such that $Ff \circ c = d \circ f$. Let $\mathsf{Coalg}(F)$ be the category of F-coalgebras. Generalized determinization of PP-coalgebras is a transformation into a P-coalgebra via a process that factors through $\widehat{P}$-coalgebras as follows:

$$\begin{array}{ccccc} \mathsf{Coalg}(PP) & \longrightarrow & \mathsf{Coalg}(\widehat{P}) & \longrightarrow & \mathsf{Coalg}(P) \\ \downarrow & & \downarrow & & \downarrow \\ \mathsf{Set} & \xrightarrow{F^{\mathbf{P}}} & \mathsf{EM}(\mathbf{P}) & \xrightarrow{U^{\mathbf{P}}} & \mathsf{Set} \end{array} \tag{5}$$

More precisely, this construction maps a coalgebra $X \xrightarrow{c} PPX$ to

$$c^+ = PX \xrightarrow{Pc} PPPX \xrightarrow{\lambda_{PX}} PPPX \xrightarrow{P\mu^{\mathbf{P}}_X} PPX \tag{6}$$

so $c^+(A) = \left\{ \bigcup_{x \in A} B_x \mid \forall x \in A, B_x \in \overline{c(x)} \right\}$ where $\overline{c(x)}$ is the closure of $c(x)$ under non-empty unions. See Figure 1 for a concrete example. An interesting view is to interpret P-coalgebras as non-deterministic automata and PP-coalgebras as alternating automata, meaning a transition from a state $x \in X$ consists in choosing non-deterministically a set $U \in c(x)$, then going simultaneously into every state $y \in U$. Alternating automata have been introduced in [8] and have known some difficulties to be properly modelled as PP-coalgebras ([2, 13]). In particular, this non-standard transformation of alternating automata was already described in [13], but did not fit very well into any general framework. There, λ was only identified as a non-distributive law, because the $(\eta^{\mathbf{T}})$ diagram does not commute – which in this case is equivalent to $\eta^{\mathbf{P}}$ not being weakly cartesian. We hereby pinpoint that this automata transformation is canonical in the sense that it comes from the unique monotone weak extension of $\mathbf{P}$ to Rel.

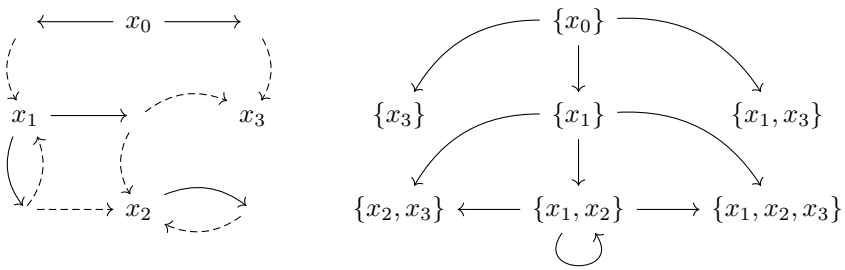


Figure 1 On the left, an alternating automaton: a transition consists in going in one of the solid lines, then in all of the available dashed lines. On the right, a portion of the non-deterministic automaton obtained after the process described in (5).

4 Toposes

The category Set is a special case of the more general notion of topos. Our contribution in this section is to generalize the results of Section 3 to arbitrary toposes. Some standard references about the theory of toposes are [12], [16], and our approach will be close to the one of [19]. Our presentation of toposes will be self-contained, with the exception of internal logic. In short, toposes are sufficiently set-behaved to internalize a logic in which one may reason as if they were picking elements in sets, and accommodate internally constructive proofs,

i.e., not using either the law of excluded middle or the axiom of choice. For more details about the internal logic, see [12, Part D], [16, Section VI.5] or the more accessible [20], [18, Chapters 14-16].

A *topos* is a finitely complete cartesian closed category with a subobject classifier Ω. Having a subobject classifier means that there is a morphism out of the terminal object $\mathsf{true} : 1 \to \Omega$ such that for every subobject $m : A \hookrightarrow X$, there is a unique morphism $\chi_m : X \to \Omega$ (called the characteristic morphism of m) such that the following diagram is a pullback:

$$\begin{array}{ccc} A & \xrightarrow{!_A} & 1 \\ {\scriptstyle m}\downarrow & \lrcorner & \downarrow{\scriptstyle \mathsf{true}} \\ X & \xrightarrow[\chi_m]{} & \Omega \end{array}$$

Note that $!_A$ denotes the unique morphism of type $A \to 1$. Toposes are finitely cocomplete. Every topos is regular, and conversely a regular category C is a topos if and only if the graph functor $\mathcal{G} : \mathsf{C} \to \mathsf{Rel}(\mathsf{C})$ has a right adjoint ([19, §6.1.1], [9, §1.911]). This adjunction yields a monad $\mathbf{\exists} : \mathsf{C} \to \mathsf{C}$ which is the generalization of the powerset monad on the topos Set – as hinted by the equality $\exists X = \Omega^X$ in C similar to $PX = 2^X$ in Set. In the internal logic of the topos, the data of $\mathbf{\exists}$ can be expressed as

$$\exists f(a) = \{y : Y \mid \exists x : X, x \in a \wedge f(x) = y\} \qquad \text{[20, Proposition 4.9]}$$
$$\eta^{\mathbf{\exists}}_X(x) = \{x' : X \mid x = x'\} \qquad \text{[20, Proposition 4.17]}$$
$$\mu^{\mathbf{\exists}}_X(t) = \{x : X \mid \exists s : \Omega^X, x \in s \wedge s \in t\} \qquad \text{[20, Proposition 4.19]}$$

Another view on $\eta^{\mathbf{\exists}}_X : X \to \Omega^X$ is that it is the exponential transpose of the characteristic morphism $X \times X \to \Omega$ of the diagonal monomorphism $\langle 1_X, 1_X \rangle : X \hookrightarrow X \times X$ ([12, page 86]).

The Kleisli category of $\mathbf{\exists}$ is nothing but the category $\mathsf{Rel}(\mathsf{C})$ ([19, §6.1.10]), with again the identification $F_{\mathbf{\exists}} = \mathcal{G}$ and relational extensions being exactly monotone (Kleisli) extensions. Given the similarities with Set, a natural question is whether the results of the previous section extend to any topos: is there a weak distributive law of type $\mathbf{\exists\exists} \to \mathbf{\exists\exists}$?

Some of the ingredients required for obtaining such a law are already in the literature:

▶ **Proposition 10** ([19, Proposition 6.5.1])**.** *The functor $\exists$ is weakly cartesian and preserves strong epis.*

De Moor [19] deduces that the *functor* $\exists$ is a *relator*, i.e., it has a monotone extension to $\mathsf{Rel}(\mathsf{C})$. One can compute this generalized Egli-Milner formula using equation (2) and the internal logic notations, although it is not relevant for the subsequent developments.

The extension $\overline{\exists}$ corresponds to a distributive law between the *functor* $\exists$ and the monad $\mathbf{\exists}$ of type $\exists\mathbf{\exists} \to \mathbf{\exists}\exists$, called *cross-operator* in [19], meaning that the $(\eta^{\mathbf{S}})$ and $(\mu^{\mathbf{S}})$ diagrams relative to the inner $\mathbf{\exists}$ commute. We provide the missing results:

▶ **Proposition 11.** *The unit $\eta^{\mathbf{\exists}}$ is nearly cartesian if and only if C is degenerate, i.e., the initial object 0 and the terminal object 1 are isomorphic.*

Proof sketch. If C is degenerate, then C is the category with a single object and a single arrow, and every natural transformation is nearly cartesian in such a category. Conversely, assume $\eta^{\mathbf{\exists}}$ is nearly cartesian. As $\eta^{\mathbf{\exists}}$ components are mono (see [16, Lemma 1 p.166]), this induces that $\eta^{\mathbf{\exists}}$ is cartesian, i.e., naturality squares are pullbacks. In particular, the left square below is a pullback. (Note that this square is the one that appears in the proof of

Proposition 8, because in Set we have $\{0\} \cong 1$ and $\{0,1\} \cong \Omega$.) Let $p : 1 \to \Omega^\Omega$ be the morphism that picks the maximal subobject $\Omega \subseteq \Omega$. The pasting law for pullbacks yields that $\Theta \cong \Phi$, where Θ and Φ are defined by the pullback squares on the right:

$$\begin{array}{ccc} \Omega & \xrightarrow{!_\Omega} & 1 \\ {\scriptstyle \eta^{\exists}_\Omega}\downarrow & \lrcorner & \downarrow{\scriptstyle \eta^{\exists}_1} \\ \Omega^\Omega & \xrightarrow[\exists !_\Omega]{} & \Omega \end{array} \qquad \begin{array}{ccc} \Theta & \longrightarrow & \Omega \\ {\scriptstyle !_\Theta}\downarrow & \lrcorner & \downarrow{\scriptstyle \eta^{\exists}_\Omega} \\ 1 & \xrightarrow[p]{} & \Omega^\Omega \end{array} \qquad \begin{array}{ccc} \Phi & \xrightarrow{!_\Phi} & 1 \\ {\scriptstyle !_\Phi}\downarrow & \lrcorner & \downarrow{\scriptstyle \eta^{\exists}_1} \\ 1 & \xrightarrow[\exists !_\Omega \circ p]{} & \Omega \end{array}$$

We can prove additionally that $\Theta \cong \Theta \times \Omega$ and $\Phi \cong 1$. Combining these results yields $\Omega \cong 1$, and this in turn implies that the topos is degenerate. ◀

▶ **Proposition 12.** *The multiplication $\mu^{\exists}$ is weakly cartesian.*

Proof. Mimicking the computation of Proposition 9 in the internal logic of C produces a valid proof, because the latter is a constructive intuitionistic proof, i.e., does not use either the axiom of choice or the law of excluded middle. ◀

▶ **Theorem 13.** *In any topos, there is a unique monotone weak distributive law of type $\exists\exists \to \exists\exists$, which is a distributive law exactly when the topos is degenerate.*

Proof. By Theorem 6, Propositions 10, 11, 12 and the fact that $F_{\exists} = \mathcal{G}$, the generalized Egli-Milner relation defines the unique monotone weak extension of $\exists$ to $\mathsf{Kl}(\exists)$, and is a monad extension iff the topos is degenerate. Applying Theorem 5 completes the proof. ◀

There is also a weak lifting of $\exists$ to the category $\mathsf{EM}(\exists)$ of internal complete join semi-lattices, implying in particular that the generalized determinization procedure described in Section 3 can be applied to $\exists\exists$-coalgebras in arbitrary toposes.

5 Compact Hausdorff Spaces

In this section, C is the category of compact Hausdorff spaces and continuous functions KHaus. As recalled in [10], KHaus is isomorphic to the Eilenberg-Moore category of the ultrafilter monad $\beta : \mathsf{Set} \to \mathsf{Set}$. This yields that KHaus is regular, complete, and that limits can be computed as in Set and given the initial topology afterwards. As KHaus is a pretopos (see, e.g., [17]), strong epis are just epis, that is, (continuous) surjections. Given an object X of KHaus, we denote its carrier set also by X and its topology by τ_X. Define VX to be the set of all closed subsets of X equipped with the *Vietoris topology*, i.e., the topology generated by the subbase

$$\Box U = \{A \in VX \mid A \subseteq U\} \qquad \Diamond U = \{A \in VX \mid A \cap U \neq \emptyset\} \tag{7}$$

where U ranges over τ_X. The mapping $X \mapsto VX$ extends into a monad $\mathbf{V}$ on KHaus called the *Vietoris monad* [10] in the same way as the powerset in Set. In concrete terms, V maps a continuous function $f : X \to Y$ to its direct image $Vf : VX \to VY$, $\eta^{\mathbf{V}} : 1 \to V$ takes singletons and $\mu^{\mathbf{V}} : VV \to V$ takes unions.

▶ Remark 14. It turns out that there is a monotone weak extension of β to $\mathsf{Kl}(\mathbf{P}) \cong \mathsf{Rel}$ and that the corresponding weak lifting is the Vietoris monad on $\mathsf{EM}(\beta) \cong \mathsf{KHaus}$. This is the main result of Garner's paper [10].

As KHaus is not a topos but only a pretopos, $\mathbf{V}$ cannot be obtained using the graph functor $\mathsf{KHaus} \to \mathsf{Rel}(\mathsf{KHaus})$ as a left adjoint. This is closely related to the fact that VX, being only part of a *weak* lifting, does not contain *all* subsets of X. Actually, $\mathsf{Rel}(\mathsf{KHaus})$ and $\mathsf{Kl}(\mathbf{V})$ correspond to the two essential ways of embedding KHaus into a relational category (see [4], where they are denoted by $\mathsf{KHaus}^{\mathsf{R}}$ and $\mathsf{KHaus}^{\mathsf{C}}$). Let X, Y be compact Hausdorff spaces and $R \subseteq X \times Y$ be a relation. Consider the following properties of R:

(i) $\forall A \in VX, R[A] \in VY$
(ii) $\forall B \in VY, R^{-1}[B] \in VX$
(iii) $\forall U \in \tau_Y, R^{-1}[U] \in \tau_X$

The relation R is *closed* if it satisfies properties (i) and (ii), or equivalently, if R is a closed subset of the product topology $\tau_{X\times Y}$. The relation R is *continuous* if it satisfies properties (i), (ii) and (iii). Note that these properties are preserved by the usual composition of relations and satisfied by identity relations. The following are straightforward results:

▶ **Proposition 15.** *The category of compact Hausdorff spaces and closed relations is isomorphic to* $\mathsf{Rel}(\mathsf{KHaus})$.

▶ **Proposition 16** (see [3, 4])**.** *The category of compact Hausdorff spaces and continuous relations is isomorphic to* $\mathsf{Kl}(\mathbf{V})$.

As a summary, we have the wide subcategory inclusions

$$\mathsf{KHaus} \xrightarrow[F_{\mathbf{V}}]{} \mathsf{Kl}(\mathbf{V}) \xrightarrow[\text{(iii)}]{\text{forget}} \mathsf{Rel}(\mathsf{KHaus}), \qquad \mathsf{KHaus} \xrightarrow{\mathcal{G}} \mathsf{Rel}(\mathsf{KHaus})$$

Any endofunctor on $\mathsf{Rel}(\mathsf{KHaus})$ that preserves continuous relations – i.e. preserves property (iii) – therefore restricts to an endofunctor on $\mathsf{Kl}(\mathbf{V})$. Similarly, given two such endofunctors on $\mathsf{Rel}(\mathsf{KHaus})$, any natural transformation whose components are continuous relations (e.g. every $\mathsf{Rel}(\alpha)$) automatically restricts to a natural transformation between their restrictions on $\mathsf{Kl}(\mathbf{V})$. Putting this together with Theorem 6 and the definition of monad extensions, we get

▶ **Proposition 17.** *Assume that T preserves continuous surjections, that T and $\mu^{\mathbf{T}}$ are nearly cartesian, and that $\mathsf{Rel}(T)$ preserves continuous relations. Then there is a monotone weak extension of $\mathbf{T}$ to $\mathsf{Kl}(\mathbf{V})$, and this is an extension if and only if $\eta^{\mathbf{T}}$ is nearly cartesian.*

Now we fix $\mathbf{T} = \mathbf{V}$ and proceed to verify the assumptions of Proposition 17.

▶ **Proposition 18.** *The Vietoris functor V preserves continuous surjections.*

Proof. For such a continuous surjective $f : X \to Y$, $Vf : VX \to VY$ is surjective because any $C \in VY$ satisfies $Vf(f^{-1}(C)) = C$, with $f^{-1}(C) \in VX$. ◀

▶ **Proposition 19.** *The Vietoris functor V is nearly cartesian.*

Proof. This is the same proof as for Proposition 7, with an additional check that if $A \in VA$ and $B \in VB$ then $C = \pi_1^{-1}(A) \cap \pi_2^{-1}(B)$ indeed is in VR, by continuity of π_1, π_2. ◀

▶ **Proposition 20.** *The unique relational extension $\mathsf{Rel}(V)$ preserves continuous relations.*

Proof. Assume that $R \subseteq X \times Y$ is a closed relation that satisfies condition (iii), denote its projections by $r_1 : R \to X$, $r_2 : R \to Y$ and show that $\mathsf{Rel}(V)R$ satisfies condition (iii). Sets of the form $\Box U_0 \cap \bigcap_{1\leq i\leq n} \Diamond U_i$ with $n \in \omega$ and $U_i \in \tau_Y$ form a base of τ_{VY}, therefore the identity (8) below suffices to conclude because R satisfying condition (iii) makes the right-hand side an element of τ_{VY}.

$$(\mathsf{Rel}(V)R)^{-1}\left[\Box U_0 \cap \bigcap_{1\leq i\leq n} \Diamond U_i\right] = \Box R^{-1}[U_0] \cap \bigcap_{1\leq i\leq n} \Diamond R^{-1}[U_0 \cap U_i] \tag{8}$$

We now prove (8). A subset $C \in VX$ belongs to the left-hand side iff there exists $D \in VY$ such that

1. $\forall x \in C, \exists y \in D, (x, y) \in R$
2. $\forall y \in D, \exists x \in C, (x, y) \in R$
3. $D \subseteq U_0$
4. $\forall i \in \{1, ..., n\}, D \cap U_i \neq \emptyset$

A subset $C \in VX$ belongs to the right-hand side iff

5. $\forall x \in C, \exists y \in U_0, (x, y) \in R$
6. $\forall i \in \{1, ..., n\}, \exists (x_i, y_i) \in R, x_i \in C, y_i \in U_0 \cap U_i$

Let $C \in VX$ and $D \in VY$ such that $1. - 4.$ are satisfied. For any $x \in C$, using 1. and 3., we can find $y \in U_0$ such that $(x, y) \in R$, so that 5. holds. For any $i \in \{1, ..., n\}$, using 3. and 4. we find $y_i \in U_0 \cap U_i$, then using 2. we find $x_i \in C$ such that $(x_i, y_i) \in R$, so that 6. holds.

For the other direction we note that every compact Hausdorff space is regular and use the following property

▶ **Lemma 21** ([25, Theorem 14.3]). *A topological space Y is regular if and only if for every $U \in \tau_Y$ and every $y \in U$, there is a $W \in \tau_Y$ such that $y \in W$ and $\overline{W} \subseteq U$.*

Let $C \in VX$ such that $5. - 6.$ hold. For every $x \in C$ we fix $y_x \in U_0$ such that $(x, y_x) \in R$. For every $i \in \{1, ..., n\}$ we fix $(x_i, y_i) \in R$ such that $x_i \in C$ and $y_i \in U_0 \cap U_i$. Apply Lemma 21 to get $W_x \in \tau_Y$ such that $y_x \in W_x$ and $\overline{W_x} \subseteq U_0$ and $W_i \in \tau_Y$ such that $y_i \in W_i$ and $\overline{W_i} \subseteq U_0 \cap U_i$. For every $x \in C$, $(x, y_x) \in R$ and $y_x \in W_x$ so $x \in R^{-1}[W_x]$, hence $C \subseteq \bigcup_{x\in C} R^{-1}[W_x]$. As C is closed in a compact space, it is compact and we can extract a finite subcover $C \subseteq \bigcup_{1\leq k\leq m} R^{-1}[W_{x_k}]$. Define the closed set

$$K = \bigcup_{1\leq i\leq n} \overline{W_i} \cup \bigcup_{1\leq k\leq m} \overline{W_{x_k}} \in VY \tag{9}$$

and consider $D = Vr_2((C \times K) \cap R) \in VY$. For any $x \in C$, there is $k \in \{1, ..., m\}$ and $y \in W_{x_k} \subseteq K$ such that $(x, y) \in R$, hence $y \in D$ and property 1. holds. Property 2. is immediate from the expression of D. As $\overline{W_i}, \overline{W_{x_k}} \subseteq U_0$, we have $D \subseteq K \subseteq U_0$ and property 3. holds. For any $i \in \{1, ..., n\}$, $(x_i, y_i) \in (C \times K) \cap R$ so $y_i \in D \cap U_i$ and property 4. holds. This achieves the proof. ◀

▶ **Proposition 22.** *The Vietoris unit $\eta^{\mathbf{V}}$ is not nearly cartesian.*

Proof. The counterexample of Proposition 8 still works by endowing the sets with the discrete topology. Note that the discrete topology on a finite set is always compact Hausdorff. ◀

A consequence is that there is no relational extension of $\mathbf{V}$ to $\mathsf{Rel}(\mathsf{KHaus})$, hence also no distributive law of type $\mathbf{VV} \to \mathbf{VV}$ can be obtained via Proposition 17. Further, there is no possible distributive law of this type because the counter-example for $\mathbf{PP} \to \mathbf{PP}$ presented in [14, Theorem 2.4] uses only finite sets: it is still valid in KHaus by endowing every set with the discrete topology again.

▶ **Proposition 23.** *The Vietoris multiplication $\mu^{\mathbf{V}}$ is nearly cartesian.*

Proof. Consider $f : X \to Y$ and let P be the pullback of its $\mu^{\mathbf{V}}$ naturality square. Surjectivity of the mediating map $h : VVX \to P$ amounts to proving that for every $C \in VX$ and $\mathcal{D} \in VVY$ such that $Vf(C) = {\mu^{\mathbf{V}}}_Y(\mathcal{D})$, there is a $\mathcal{C} \in VVX$ such that ${\mu^{\mathbf{V}}}_X(\mathcal{C}) = C$ and $VVf(\mathcal{C}) = \mathcal{D}$. However, our usual candidate $\mathcal{A} = \{C \cap f^{-1}(D) \mid D \in \mathcal{D}\}$ may not be a closed subset of VX. In its place we take

$$\mathcal{C} = (Vf)^{-1}(\mathcal{D}) \cap (\Diamond(C^c))^c \in VVX \tag{10}$$

Note that $\mathcal{C} = \{K \in VX \mid Vf(K) \in \mathcal{D} \text{ and } K \subseteq C\}$. Inclusions ${\mu^{\mathbf{V}}}_X(\mathcal{C}) \subseteq C$ and $VVf(\mathcal{C}) \subseteq \mathcal{D}$ are immediate. For the other ones, note that $\mathcal{A} \subseteq \mathcal{C}$, hence $C = {\mu^{\mathbf{P}}}_X(\mathcal{A}) \subseteq {\mu^{\mathbf{V}}}_X(\mathcal{C})$ and $\mathcal{D} = PPf(\mathcal{A}) \subseteq VVf(\mathcal{C})$. ◀

▶ **Theorem 24.** *There is a monotone weak distributive law of type* $\mathbf{VV} \to \mathbf{VV}$ *defined by*

$$\lambda_X(\mathcal{A}) = \left\{B \in VX \mid B \subseteq \bigcup \mathcal{A} \text{ and } \forall A \in \mathcal{A}, A \cap B \neq \emptyset\right\} \tag{11}$$

Proof. Use Proposition 17 together with Propositions 18, 19, 20, 22, 23 to get that there is a monotone weak extension of $\mathbf{V}$ to $\mathsf{Kl}(\mathbf{V})$ defined by

$$\overline{V}R = \{(A, B) \in VX \times VY \mid \forall x \in A, \exists y \in B, (x, y) \in R \text{ and } \forall y \in B, \exists x \in A, (x, y) \in R\}$$

By Theorem 5, this corresponds to a weak distributive law with the wanted expression. ◀

Again, we also have a weak lifting of $\mathbf{V}$ to the category $\mathsf{EM}(\mathbf{V})$ – i.e., to continuous lattices, see [10, § 2.3] – whose existence notably allows generalized determinization of VV-coalgebras.

▶ Remark 25. The Vietoris monad restricts to the full subcategory of Stone spaces and continuous functions $\mathsf{Stone} \hookrightarrow \mathsf{KHaus}$, which regularly attracts the interest of the coalgebraic community ([15], [6]). Equation (11) clearly still defines a weak distributive law in Stone, which may be useful to understand better double Vietoris coalgebras as described in [5].

6 Conclusion

In this article, we have detailed how to obtain a triptych weak extension - weak distributive law - weak lifting using powerset-like monads. First we assembled results in the literature to show that the usual method for obtaining weak extensions from Set to Rel can be adapted to obtain weak extensions from any regular category C to its category of relations. We proved that weak self-distributivity of the Set powerset monad – known since the paper of Garner [10] – can actually be understood at the deeper level of toposes. Then we treated compact Hausdorff spaces, for which the Vietoris monad plays the role of a powerset. This case is particularly interesting because the category of closed relations and the Kleisli category of the Vietoris monad do not have exactly the same morphisms. In every case, we find that the unique monotone weak extension can be expressed with an Egli-Milner-shaped formula. Using the corresponding weak distributive law, we provide an application to automata theory: generalized determinization of alternating automata into non-deterministic automata. Here alternating automata are to be understood as double powerset coalgebras, living in any category previously considered.

To our knowledge, all previous examples of interesting weak distributive laws that are not distributive laws were exhibited in the category Set. Our work provides some first instances of such laws outside of Set. It would be an interesting research direction to find useful weak

distributive laws that do not come from the extension result of Theorem 6, or that do not live into a set-like category. However, categories of relations being a rich framework, looking for more laws of the form $\mathbf{TP} \to \mathbf{PT}$ is also a promising direction. In particular, the category KHaus possesses a probability monad $\mathbf{R}$ called the Radon monad. Maybe is it possible to generalize the weak distributive law of type $\mathbf{DP} \to \mathbf{PD}$ presented in [11] (where $\mathbf{D}$ is the finitely supported distribution monad) to a continuous version $\mathbf{RV} \to \mathbf{VR}$ in KHaus. We leave this to future work.

Finally, we thank reviewers for bringing up the following remark. Although KHaus is not a topos, the Vietoris monad $\mathbf{V}$ may be thought of as classifying subobjects, in the sense that global elements of VX correspond to subobjects of X. It is an interesting question whether our weak distributive law can be generalized to (regular) categories admitting a monad classifying subobjects in this element-wise sense.

Elementary Equivalence Versus Isomorphism in Semiring Semantics

Erich Grädel
RWTH Aachen University, Germany

Lovro Mrkonjić
RWTH Aachen University, Germany

Abstract

We study the first-order axiomatisability of finite semiring interpretations or, equivalently, the question whether elementary equivalence and isomorphism coincide for valuations of atomic facts over a finite universe into a commutative semiring. Contrary to the classical case of Boolean semantics, where every finite structure is axiomatised up to isomorphism by a first-order sentence, the situation in semiring semantics is rather different, and depends on the underlying semiring. We prove that for a number of important semirings, including min-max semirings, and the semirings of positive Boolean expressions, there exist finite semiring interpretations that are elementarily equivalent but not isomorphic. The same is true for the polynomial semirings that are universal for the classes of absorptive, idempotent, and fully idempotent semirings, respectively. On the other side, we prove that for other, practically relevant, semirings such as the Viterby semiring $\mathbb{V}$, the tropical semiring $\mathbb{T}$, the natural semiring $\mathbb{N}$ and the universal polynomial semiring $\mathbb{N}[X]$, all finite semiring interpretations are first-order axiomatisable, and thus elementary equivalence implies isomorphism.

1 Introduction

Semiring semantics is based on the idea to evaluate logical statements not just by *true* or *false*, but by values in some commutative semiring $(K, +, \cdot, 0, 1)$. In this context, the standard semantics appears as the special case when the Boolean semiring $\mathbb{B} = (\{\bot, \top\}, \vee, \wedge, \bot, \top)$ is used. Valuations in other semirings provide additional information, beyond the truth or falsity of a statement: the Viterbi-semiring $\mathbb{V} = ([0,1]_{\mathbb{R}}, \max, \cdot, 0, 1)$ models *confidence scores*, the tropical semiring $\mathbb{T} = (\mathbb{R}^{\infty}_{+}, \min, +, \infty, 0)$ is used for *cost analysis*, and min-max-semirings $(K, \max, \min, a, b)$ for a totally ordered set $(K, <)$ can model, for instance, different *access levels*. More generally, semirings of polynomials, such as $\mathbb{N}[X]$ or $\mathbb{B}[X]$, allow us to track the role of specific atomic facts for the evaluation of a logical statement, to describe evaluation strategies for a formula, and to determine which combinations of literals prove the truth of a formula.

Some of the motivation for the study of semiring semantics comes from the successful development of semiring provenance in database theory and related fields (see e.g. [5, 6, 9, 14, 15, 18, 19, 20]), and the fact that the typical applications of provenance analysis, such as confidence scores, cost analysis, proof counting, and the understanding of evaluation strategies are of importance in many other areas of logic as well. However, semiring provenance analysis for database queries had originally been largely confined to positive query languages, such as conjunctive queries, positive relational algebra, and Datalog, and the treatment

© Erich Grädel and Lovro Mrkonjić;
licensed under Creative Commons License CC-BY 4.0

of negation poses non-trivial algebraic problems. Only recently, provenance analysis via semiring semantics has been extended to logics with negation, and in particular to full first-order logic [12, 13], by means of new algebraic constructions based on quotient semirings. Semiring semantics has also been studied for other logics, including modal logics, description logics, guarded logics, and fixed-point logic [1, 2, 3, 4], and this paper is part of a larger project devoted to a systematic study of semiring semantics for various logics. An important objective in this context is the understanding of the *model theory of semiring semantics*, and the development of model-theoretic methods for semiring interpretations.

It turns out that this is much more involved and diverse than for Boolean semantics. In the standard semantics, a model $\mathfrak{A}$ assigns to each (instantiated) atomic formula a Boolean value, whereas K-interpretations π, for a suitable semiring K, generalise this by assigning to each literal a semiring value in K, where 0 is interpreted as *false* and all other semiring values as *nuances of true*. Interpreting disjunction by $+$ and conjunction by $\cdot$, we can extend π to provide semiring valuations $\pi[\![\varphi]\!] \in K$ for all first-order sentences φ, written in negation normal form. Semiring semantics thus gives a finer distinction of logical statements, and formulae that are equivalent in the Boolean sense (i.e. in the Boolean semiring) may have different valuations in other semirings. As a consequence, standard facts of classical (finite) model theory may lead to interesting and sometimes rather difficult questions in semiring semantics, and the answer may strongly depend on algebraic properties of the underlying semiring. Specific such questions that we study here concern the first-order axiomatisability of finite K-interpretations or, what amounts to the same, the relationship between isomorphism and elementary equivalence in this context.

It is a rather trivial fact of finite model theory that every finite structure $\mathfrak{A}$ (with a finite vocabulary τ) can be axiomatised, up to isomorphism, by a first-order sentence $\chi_{\mathfrak{A}}$. In particular, two finite τ-structures $\mathfrak{A}$ and $\mathfrak{B}$ are isomorphic if, and only if, they are elementarily equivalent, in short $\mathfrak{A} \equiv \mathfrak{B}$, which means that they cannot be distinguished by any first-order sentence. Is this also the case for semiring interpretations? Notice that standard notions such as isomorphism and elementary equivalence generalise in a natural way from τ-structures to semiring interpretations, which raises, for any given semiring K, the following

▶ **Questions.**

1. *Are elementarily equivalent, finite K-interpretations always isomorphic?*
2. *Is every finite K-interpretation π_A first-order axiomatisable, in the sense that there is a set of axioms $\Phi_A \subseteq$ FO such that whenever $\pi_B[\![\varphi]\!] = \pi_A[\![\varphi]\!]$ for all $\varphi \in \Phi_A$, then $\pi_B \cong \pi_A$?*
3. *Does every finite K-interpretation admit an axiomatisation by a* finite *set of axioms?*
4. *Can every finite K-interpretation be axiomatised by a single first-order sentence?*

Clearly, the first two questions are equivalent, and a positive answer to the third question implies also positive ones to the first two. The converse is not necessarily true, because a first-order axiomatisation of a finite semiring interpretation might require an infinite collection of sentences, and, contrary to the Boolean case, it is a priori also not clear that an axiomatisation by a finite set of sentences implies an axiomatisation by a single sentence, because from the value of a conjunction we cannot necessary infer the values of its components.

We shall prove that the answers to these questions strongly depend on the chosen semiring. There are in fact rather simple semirings, such as min-max semirings with at least three elements, for which one can construct examples of non-isomorphic K-interpretations which are, however, elementarily equivalent. The standard method for proving elementary equivalence in model theory, the Ehrenfeucht–Fraïssé method, seems not really available in

semiring semantics, an aspect that we shall discuss at the end of this paper. To establish elementary equivalence, we shall hence develop new methods based on classes of semiring homomorphisms and reduction arguments. Elementarily equivalent but non-isomorphic semiring interpretations also exist for powerful polynomial semirings, such as $\mathbb{S}[X]$ and $\mathbb{B}[X]$, which are universal for the classes of absorptive and idempotent semirings, respectively. On the other side, there are practically relevant semirings, such as the Viterby semring $\mathbb{V}$, the tropical semiring $\mathbb{T}$, the natural semiring $\mathbb{N}$ and the universal polynomial semiring $\mathbb{N}[X]$, for which any finite K-interpretation is first-order axiomatisable, thus elementary equivalence does indeed imply isomorphism. At least for $\mathbb{V}$ and $\mathbb{T}$, finite axiomatisations are always possible, but not axiomatisations by a single sentence, so there exist semirings where the answers to questions (3) and (4) are different.

2 Semiring Interpretations

We briefly summarise semiring semantics for first-order logic, as introduced in [12].

▶ **Definition 1** (Semiring). A commutative semiring $\mathbb{K} = (K, +, \cdot, 0, 1)$ is an algebraic structure with two binary operations such that $(K, +, 0)$ and $(K, \cdot, 1)$ are commutative monoids, multiplication distributes over addition and multiplication with zero annihilates elements. We may identify $\mathbb{K}$ with its universe K if the operations are clear from the context.

In this paper, we only consider commutative semirings and simply call them "semirings" for convenience. Any class of semirings is implicitly restricted to commutative semirings only.

Let τ denote a finite relational vocabulary. We write $\mathrm{Lit}_n(\tau)$ for the set of atoms $R\overline{z}$ and negated atoms $\neg R\overline{z}$ with $R \in \tau$ and where $\overline{z}$ is any tuple of variables taken from $\{x_1, \dots, x_n\}$. For a universe A, we write $\mathrm{Lit}_A(\tau)$ for the set of *instantiated* τ-literals $R\overline{a}$ and $\neg R\overline{a}$ with $\overline{a} \in A^{\mathrm{arity}(R)}$.

▶ **Definition 2** (K-interpretation). For a semiring K, a mapping $\pi\colon \mathrm{Lit}_A(\tau) \to K$ is called a *K-interpretation* over the universe A with signature τ. We call π *model-defining* if exactly one of the values $\pi(L)$ and $\pi(\overline{L})$ is zero for all pairs of opposing literals $L, \overline{L} \in \mathrm{Lit}_A(\tau)$. In that case, π *induces* the classical model $\mathfrak{A}_\pi$ with $\mathfrak{A}_\pi \models L$ if, and only if, $\pi(L) \neq 0$.

▶ **Definition 3** (Isomorphism). K-interpretations $\pi_A\colon \mathrm{Lit}_A(\tau) \to K$ and $\pi_B\colon \mathrm{Lit}_B(\tau) \to K$ are *isomorphic*, denoted as $\pi_A \cong \pi_B$, if there is a bijective mapping $\sigma\colon A \to B$ such that $\pi_A(L) = \pi_B(\sigma(L))$ for all $L \in \mathrm{Lit}_A(\tau)$, where $\sigma(L) \in \mathrm{Lit}_B(\tau)$ is defined by replacing each $a \in A$ occurring in L with $\sigma(a) \in B$. The mapping $\sigma\colon \pi_A \xrightarrow{\sim} \pi_B$ is called an *isomorphism*.

Given a K-interpretation $\pi\colon \mathrm{Lit}_A(\tau) \to K$, a formula $\varphi(\overline{x}) \in \mathrm{FO}(\tau)$ in negation normal form and an assignment $\overline{a} \subseteq A$, the semiring semantics $\pi[\![\varphi(\overline{a})]\!]$ is straightforwardly defined by induction on $\mathrm{FO}(\tau)$. Equalities are simply mapped to their truth values by $\pi[\![a = b]\!] := 1$ if $a = b$ and 0 otherwise, and vice versa for inequalities. Similarly to the semantics of weighted logics introduced in [7], disjunctions and existential quantifiers are interpreted as sums, and conjunctions and universal quantifiers as products:

$$\pi[\![\psi(\overline{a}) \vee \vartheta(\overline{a})]\!] := \pi[\![\psi(\overline{a})]\!] + \pi[\![\vartheta(\overline{a})]\!] \qquad \pi[\![\psi(\overline{a}) \wedge \vartheta(\overline{a})]\!] := \pi[\![\psi(\overline{a})]\!] \cdot \pi[\![\vartheta(\overline{a})]\!]$$
$$\pi[\![\exists x \vartheta(\overline{a}, x)]\!] := \sum_{a \in A} \pi[\![\vartheta(\overline{a}, a)]\!] \qquad \pi[\![\forall x \vartheta(\overline{a}, x)]\!] := \prod_{a \in A} \pi[\![\vartheta(\overline{a}, a)]\!].$$

Our goal is to analyse classical model-theoretic concepts under semiring semantics.

▶ **Definition 4** (Elementary Equivalence). Two K-interpretations $\pi_A\colon \mathrm{Lit}_A(\tau) \to K$ and $\pi_B\colon \mathrm{Lit}_B(\tau) \to K$ are *elementarily equivalent*, denoted as $\pi_A \equiv \pi_B$, if $\pi_A[\![\psi]\!] = \pi_B[\![\psi]\!]$ holds for all sentences $\psi \in \mathrm{FO}(\tau)$.

Clearly, the notions of isomorphism and elementary equivalence of K-interpretations are natural generalisations of the corresponding definitions for τ-structures. Further, it is obvious that, as in classical semantics, isomorphism implies elementary equivalence.

▶ **Lemma 5** (Isomorphism Lemma). *Let $\pi_A\colon \mathrm{Lit}_A(\tau) \to K$ and $\pi_B\colon \mathrm{Lit}_B(\tau) \to K$ be two K-interpretations, $\overline{a} \in A^k$ and $\overline{b} \in B^k$ be k-tuples and $\sigma\colon \pi_A \xrightarrow{\sim} \pi_B$ an isomorphism with $\sigma(\overline{a}) = \overline{b}$. Then, $\pi_A[\![\varphi(\overline{a})]\!] = \pi_B[\![\varphi(\overline{b})]\!]$ holds for all $\varphi(\overline{x}) \in \mathrm{FO}(\tau)$ with k free variables.*

Coarser definitions may be conceivable in semirings K with more than two elements, such as replacing equality by a congruence relation $\sim\, \subseteq K \times K$. However, Definition 4 indirectly covers these variants, since any non-trivial congruence relation $\sim$ on K induces a semiring homomorphism $h_\sim\colon K \to K/\!\sim$, which is compatible with FO-semantics as follows [12].

▶ **Lemma 6** (Fundamental Property). *Let $\pi\colon \mathrm{Lit}_A(\tau) \to K$ be a K-interpretation and $h\colon K \to L$ a semiring homomorphism. Then, $(h \circ \pi)$ is an L-interpretation such that $(h \circ \pi)[\![\varphi(\overline{a})]\!] = h(\pi[\![\varphi(\overline{a})]\!])$ holds for all $\varphi(\overline{x}) \in \mathrm{FO}(\tau)$ and $\overline{a} \subseteq A$.*

3 Polynomial Semirings and the Universal Property

Semiring homomorphisms and the fundamental property open the possibility to reduce semiring semantics to the evaluation of polynomials. For a finite set X of abstract provenance tokens that are used to track atomic facts, consider the semiring $\mathbb{N}[X]$ of multivariate polynomials with indeterminates from X and coefficients from $\mathbb{N}$, whose generality is formalised by the following *universal property* [14].

▶ **Lemma 7** (Universal Property). *For each commutative semiring K, every assignment $e\colon X \to K$ induces a unique homomorphism $h_e\colon \mathbb{N}[X] \to K$ with $h_e(x) = e(x)$ for $x \in X$.*

This property can be used to save computation resources, for example, if we would like to evaluate a sentence $\psi \in \mathrm{FO}$ under several interpretations $(\pi_i)_{i\in I}$ sharing the same set of true literals. In such a scenario, we may build an $\mathbb{N}[X]$-interpretation π that assigns a unique variable $x \in X$ to each positive literal. After computing the polynomial $p := \pi[\![\psi]\!]$ once, the semiring semantics $\pi_i[\![\psi]\!]$ for each $i \in I$ may be computed by plugging the positive literals' values into their corresponding variables and evaluating the polynomial p instead of starting from scratch.

The universality of $\mathbb{N}[X]$ also makes it relevant for model theory. Crucially, more restricted polynomial semirings can be used to capture smaller classes of semirings in the sense of the universal property. This is formalised in the following and summarised by Figure 1.

▶ **Definition 8** (Idempotence and Absorption). A semiring K is called *idempotent* if $a + a = a$ holds for all $a \in K$, that is, if addition is idempotent. It is *multiplicatively idempotent* if $a \cdot a = a$ for all $a \in K$. If both properties hold, we call K *fully idempotent*. Finally, a semiring K is *absorptive* if $a + ab = a$ holds for all $a, b \in K$.

- By dropping coefficients from $\mathbb{N}[X]$, we get the semiring $\mathbb{B}[X]$ whose elements are finite sets of monomials. It has the universal property for the class of idempotent semirings.

- By collapsing exponents in $\mathbb{B}[X]$, we get the semiring $\mathbb{W}[X]$ of finite sums of monomials that are linear in each argument. It is sometimes called the Why-semiring. While $\mathbb{W}[X]$ is not fully idempotent itself due to $(x+y)\cdot(x+y) = x+xy+y$, it still holds the universal property for fully idempotent semirings.
- For absorptive semirings, we require absorptive polynomials as introduced in [5]. An absorptive polynomial is a sum of distinct monomials over a finite set of variables X, with absorption among monomials: "shorter" monomials absorb "longer" monomials. More formally, m_1 absorbs m_2, denoted $m_1 \succeq m_2$, if it has smaller exponents, i.e. $m_2 = m \cdot m_1$ for some monomial m. For example, $xy^2 \succeq x^3y^2$ and $x \succeq xy$, but x^2y and xy^2 are incomparable. Applying absorption after each operation induces the semiring of absorptive polynomials $\mathbb{S}[X]$, which is universal for the class of all absorptive semirings.
- By collapsing exponents in $\mathbb{S}[X]$, we obtain yet another polynomial semiring $\mathsf{PosBool}[X]$, which is universal for the fully idempotent and absorptive semirings. Those are precisely the semirings induced by distributive lattices, as shown in [17]. Incidentally, $\mathsf{PosBool}[X]$ is the distributive lattice freely generated by the set X.

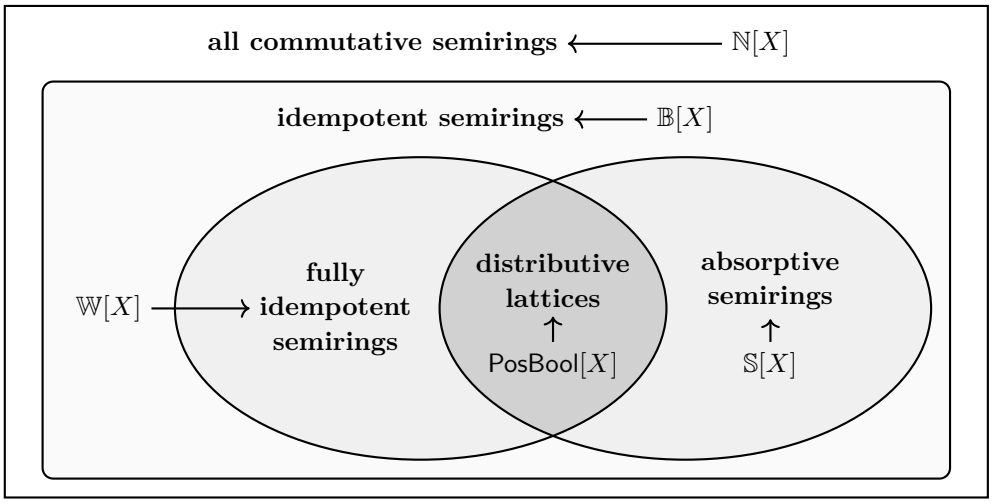

Figure 1 Relationships between some classes of commutative semirings and their respective universal polynomial semirings, adapted from [17].

4 Separating Elementary Equivalence from Isomorphism

We shall now, for certain semirings K, provide examples of finite, non-isomorphic K-interpretations that are, however, elementarily equivalent. We thus provide negative answers to Question (1) from the introduction, and hence also to Questions (2) to (4). For instance, we claim that the following two K_4-interpretations over the min-max-semiring with four elements, $K_4 = \{0,1,2,3\}$, are elementarily equivalent, but not isomorphic.

π_{PQ} :

A	P	Q	$\neg P$	$\neg Q$
a	1	3	0	0
b	2	1	0	0
c	3	2	0	0

π_{QP} :

A	P	Q	$\neg P$	$\neg Q$
a	3	1	0	0
b	1	2	0	0
c	2	3	0	0

Observe that π_{QP} is obtained from π_{PQ} by permuting the relations P and Q, or visually, by permuting the "columns". Moreover, for both interpretations, the Q-column can be obtained by permuting the P-column. Informally, these properties ensure that the two interpretations are "sufficiently similar" so that no first-order sentence can distinguish them.

Clearly, π_{PQ} is not isomorphic to π_{QP}, as intended. However, the only tool we presented so far for proving elementary equivalence under semiring semantics is the Isomorphism Lemma itself, which is not directly applicable for obvious reasons. Hence, we shall develop another tool for proving elementary equivalence that enables the indirect use of the Isomorphism Lemma after switching to a different semiring via homomorphisms.

4.1 Separating Pairs of Homomorphisms

The central idea of the reduction technique is to "decompose" the semiring K via homomorphisms. Observe that if $\pi_A \not\equiv \pi_B$, then there is a witnessing sentence $\psi \in \mathrm{FO}(\tau)$ with $\pi_A[\![\psi]\!] \neq \pi_B[\![\psi]\!]$, hence a pair of distinct elements $a, b \in K$ with $\pi_A[\![\psi]\!] =: a \neq b := \pi_B[\![\psi]\!]$ exists. If we can find two homomorphisms $h_A, h_B \colon K \to K'$ with $h_A(a) \neq h_B(b)$, but we are sure that the corresponding K'-interpretations $(h_A \circ \pi_A)$ and $(h_B \circ \pi_B)$ are elementarily equivalent, then we can exclude (a, b) as a witness for $\pi_A \not\equiv \pi_B$. If we are able to provide enough pairs of homomorphisms so that each distinct pair (a, b) can be excluded, then $\pi_A \equiv \pi_B$ must hold. The following definition formalises the required properties.

▶ **Definition 9** (Separating Homomorphism Pairs)**.** A set $S \subseteq \mathrm{Hom}^2(K, K')$ of homomorphism pairs $h_A, h_B \colon K \to K'$ is called *separating* if for all $a, b \in K$ with $a \neq b$, there is a pair $(h_A, h_B) \in S$ such that $h_A(a) \neq h_B(b)$. S is called *diagonal* if $h_A = h_B$ for all pairs $(h_A, h_B) \in S$. In that case, we may write S as a subset of $\mathrm{Hom}(K, K')$.

Note that a single *injective* homomorphism $h \colon K \to K'$ induces the diagonal separating set $S := \{(h, h)\}$ with just one element. Moreover, some semirings, such as $\mathsf{PosBool}[X]$, can be completely decomposed into $K' := \mathbb{B}$ using a diagonal separating set of semiring homomorphisms as follows. Any subset $Y \subseteq X$ induces a unique homomorphism $h_Y \colon \mathsf{PosBool}[X] \to \mathbb{B}$ by $h_Y(x) = \top$ for $x \in Y$ and $h_Y(x) = \bot$ for $x \in X \setminus Y$. Clearly, for any $p \in \mathsf{PosBool}[X]$, we have that $h_Y(p) = \top$ if, and only if, p contains a monomial with only variables from Y.

▶ **Lemma 10.** *The set $S := \{h_Y \mid Y \subseteq X\} \subseteq \mathrm{Hom}(\mathsf{PosBool}[X], \mathbb{B})$ is a diagonal separating set of homomorphisms.*

Proof. Consider $p, q \in \mathsf{PosBool}[X]$ such that $p \neq q$. Among the monomials that appear in one of the two polynomials p, q but not in the other, let m be one whose set Y of variables is minimal. By symmetry, we can assume that m appears in p but not in q. It follows that $h_Y(p) = \top$. We claim that $h_Y(q) = \bot$. Otherwise q must contain a monomial m' with only variables from Y. Since m' has less variables than m, m' must also be contained in p. But m' absorbs m, so m does not occur in p, a contradiction. ◀

On the other side, $\mathbb{N}[X]$, among other semirings, cannot be decomposed into $\mathbb{B}$ by a diagonal separating set. For example, $h(x + xy) = h(x) \vee (h(x) \wedge h(y)) = h(x)$ for all homomorphisms $h \colon \mathbb{N}[X] \to \mathbb{B}$, but $x + xy \neq x$. The reason why a decomposition into $\mathbb{B}$ would be useful for model theory is given by the following reduction technique.

▶ **Proposition 11** (Reduction Technique)**.** *Let $\pi_A \colon \mathrm{Lit}_A(\tau) \to K$ and $\pi_B \colon \mathrm{Lit}_B(\tau) \to K$ be two K-interpretations, $\overline{a} \in A^k$ and $\overline{b} \in B^k$ be k-tuples and $S \subseteq \mathrm{Hom}^2(K, K')$ a separating set of homomorphism pairs. Then, for any formula $\varphi(x_1, \ldots, x_k) \in \mathrm{FO}(\tau)$, we have that whenever $(h_A \circ \pi_A)[\![\varphi(\overline{a})]\!] = (h_B \circ \pi_B)[\![\varphi(\overline{b})]\!]$ for all $(h_A, h_B) \in S$, then also $\pi_A[\![\varphi(\overline{a})]\!] = \pi_B[\![\varphi(\overline{b})]\!]$.*

Proof. We show the contraposition. Suppose that $\pi_A[\![\varphi(\overline{a})]\!] \neq \pi_B[\![\varphi(\overline{b})]\!]$. Then, by definition of S, there exists a pair $(h_A, h_B) \in S$ such that $h_A(\pi_A[\![\varphi(\overline{a})]\!]) \neq h_B(\pi_B[\![\varphi(\overline{b})]\!])$. Applying the fundamental property yields $(h_A \circ \pi_A)[\![\varphi(\overline{a})]\!] \neq (h_B \circ \pi_B)[\![\varphi(\overline{b})]\!]$. ◀

▶ **Corollary 12.** *For S as above, $(h_A \circ \pi_A) \equiv (h_B \circ \pi_B)$ for all $(h_A, h_B) \in S$ implies $\pi_A \equiv \pi_B$.*

With the target semiring $K' \coloneqq \mathbb{B}$, the corollary shows that proving equivalence in K may be reduced to proving equivalence in $\mathbb{B}$, which permits using results from standard semantics.

4.2 Applications to PosBool$[X]$ and $\mathbb{W}[X]$

Consider the following two PosBool$[X]$-interpretations π_{xy}, π_{yx} with $X \coloneqq \{x, y\}$ over the universe $A \coloneqq \{a, b, c, d\}$ with four elements and a signature $\tau \coloneqq \{P, Q\}$ with two unary relation symbols.

π_{xy} :

A	P	Q	$\neg P$	$\neg Q$
a	0	y	x	0
b	x	0	0	y
c	y	x	0	0
d	0	0	y	x

π_{yx} :

A	P	Q	$\neg P$	$\neg Q$
a	y	0	0	x
b	0	x	y	0
c	x	y	0	0
d	0	0	x	y

Thanks to Lemma 10, the four homomorphisms $S = \{h_\varnothing, h_{\{x\}}, h_{\{y\}}, h_{\{x,y\}}\}$ induce a separating set on PosBool$[X]$ and with Corollary 12, it suffices to show that $(h \circ \pi_{xy}) \equiv (h \circ \pi_{yx})$ in $\mathbb{B}$ for all $h \in S$ in order to prove $\pi_{xy} \equiv \pi_{yx}$ on PosBool$[X]$. Indeed, Figure 2 demonstrates that $(h \circ \pi_{xy}) \cong (h \circ \pi_{yx})$ holds for all $h \in S$.

Thus, we conclude that $\pi_{xy} \equiv \pi_{yx}$ and due to $\pi_{xy} \ncong \pi_{yx}$, this shows that for finite PosBool$[X]$-interpretations, elementary equivalence does not necessarily imply isomorphism. Moreover, similar examples can be constructed for any distributive lattice semiring K thanks to the universal property of PosBool$[X]$, by assigning $r, s \in K$ to the variables x, y.

π_{rs} :

A	P	Q	$\neg P$	$\neg Q$
a	0	s	r	0
b	r	0	0	s
c	s	r	0	0
d	0	0	s	r

π_{sr} :

A	P	Q	$\neg P$	$\neg Q$
a	s	0	0	r
b	0	r	s	0
c	r	s	0	0
d	0	0	r	s

Clearly, $\pi_{rs} \equiv \pi_{sr}$ holds as above, and the only requirement for $\pi_{rs} \ncong \pi_{sr}$ is that r and s must be distinct. This yields the following theorem.

▶ **Theorem 13.** *For any distributive lattice semiring K with at least three elements, there is a pair of finite K-interpretations π_{rs}, π_{sr} over a universe with four elements and a signature with two unary relation symbols such that $\pi_{rs} \equiv \pi_{sr}$, but $\pi_{rs} \ncong \pi_{sr}$.*

Note that the two K_4-interpretations π_{PQ} and π_{QP} from the opening example of this section can be shown to be elementarily equivalent using a similar technique as above. In fact, the above theorem even shows that the opening example was not minimal and a counterexample with only three semiring elements in $K_3 = \{0, 1, 2\}$ exists.

We shall strengthen the result of Theorem 13 to the class of all fully idempotent semirings by simply regarding π_{xy} and π_{yx} as $\mathbb{W}[X]$-interpretations instead of PosBool$[X]$-interpretations. However, the proof that $\pi_{xy} \equiv \pi_{yx}$ becomes more involved, since a diagonal separating set for $\mathbb{W}[X]$ into $\mathbb{B}$ does not exist. Nevertheless, a suitable separating set can

$h_\varnothing \circ \pi_{xy}$:

A	P	Q	$\neg P$	$\neg Q$
a	$\bot$	$\bot$	$\bot$	$\bot$
b	$\bot$	$\bot$	$\bot$	$\bot$
c	$\bot$	$\bot$	$\bot$	$\bot$
d	$\bot$	$\bot$	$\bot$	$\bot$

$h_\varnothing \circ \pi_{yx}$:

A	P	Q	$\neg P$	$\neg Q$
a	$\bot$	$\bot$	$\bot$	$\bot$
b	$\bot$	$\bot$	$\bot$	$\bot$
c	$\bot$	$\bot$	$\bot$	$\bot$
d	$\bot$	$\bot$	$\bot$	$\bot$

$h_{\{x\}} \circ \pi_{xy}$:

A	P	Q	$\neg P$	$\neg Q$
a	$\bot$	$\bot$	$\top$	$\bot$
b	$\top$	$\bot$	$\bot$	$\bot$
c	$\bot$	$\top$	$\bot$	$\bot$
d	$\bot$	$\bot$	$\bot$	$\top$

$h_{\{x\}} \circ \pi_{yx}$:

A	P	Q	$\neg P$	$\neg Q$
a	$\bot$	$\bot$	$\bot$	$\top$
b	$\bot$	$\top$	$\bot$	$\bot$
c	$\top$	$\bot$	$\bot$	$\bot$
d	$\bot$	$\bot$	$\top$	$\bot$

$h_{\{y\}} \circ \pi_{xy}$:

A	P	Q	$\neg P$	$\neg Q$
a	$\bot$	$\top$	$\bot$	$\bot$
b	$\bot$	$\bot$	$\bot$	$\top$
c	$\top$	$\bot$	$\bot$	$\bot$
d	$\bot$	$\bot$	$\top$	$\bot$

$h_{\{y\}} \circ \pi_{yx}$:

A	P	Q	$\neg P$	$\neg Q$
a	$\top$	$\bot$	$\bot$	$\bot$
b	$\bot$	$\bot$	$\top$	$\bot$
c	$\bot$	$\top$	$\bot$	$\bot$
d	$\bot$	$\bot$	$\bot$	$\top$

$h_X \circ \pi_{xy}$:

A	P	Q	$\neg P$	$\neg Q$
a	$\bot$	$\top$	$\top$	$\bot$
b	$\top$	$\bot$	$\bot$	$\top$
c	$\top$	$\top$	$\bot$	$\bot$
d	$\bot$	$\bot$	$\top$	$\top$

$h_X \circ \pi_{yx}$:

A	P	Q	$\neg P$	$\neg Q$
a	$\top$	$\bot$	$\bot$	$\top$
b	$\bot$	$\top$	$\top$	$\bot$
c	$\top$	$\top$	$\bot$	$\bot$
d	$\bot$	$\bot$	$\top$	$\top$

Figure 2 Illustrations of $h \circ \pi_{xy}$ next to $h \circ \pi_{yx}$ for all $h \in S = \{h_\varnothing, h_{\{x\}}, h_{\{y\}}, h_{\{x,y\}}\}$.

be obtained by exploiting homomorphisms into $\mathbb{W}[X]$ itself. Consider any permutation $\sigma\colon X \to X$ of the variables. Surely, it induces an automorphism h_σ of $\mathbb{W}[X]$. In the previous example, if σ swaps the variables x and y, then applying h_σ to π_{xy} yields an interpretation that is isomorphic to π_{yx}, as illustrated below.

$(h_\sigma \circ \pi_{xy})$:

A	P	Q	$\neg P$	$\neg Q$
a	0	x	y	0
b	y	0	0	x
c	x	y	0	0
d	0	0	x	y

π_{yx} :

A	P	Q	$\neg P$	$\neg Q$
a	y	0	0	x
b	0	x	y	0
c	x	y	0	0
d	0	0	x	y

With this insight, we can construct a suitable separating set $S \subseteq \mathrm{Hom}^2(\mathbb{W}[X], \mathbb{W}[X])$, starting with the pair $(h_\sigma, h_{\mathrm{id}}) \in S$. This pair alone does not separate $\mathbb{W}[X]$, since we have $x \neq y$ in $\mathbb{W}[X]$, but $h_\sigma(x) = y = h_{\mathrm{id}}(y)$. Hence, we add more homomorphisms by annihilating some variables, similarly to the construction for $\mathsf{PosBool}[X]$ in Lemma 10. Fixing a permutation $\sigma\colon X \to X$, we want to construct a homomorphism h^Y_σ that annihilates all variables in $X \setminus Y$ and permutes the variables in Y. Observe that for each $x \in Y$ there is a minimal number $r(x) \geq 1$ such that $\sigma^{r(x)}(x) \in Y$. Formally, we define $\sigma^Y\colon X \to Y \cup \{0\}$ by setting $\sigma^Y(x) \coloneqq \sigma^{r(x)}(x)$ for $x \in Y$, and $\sigma^Y(x) \coloneqq 0$ for $x \in X \setminus Y$. Note that σ^Y induces a homomorphism $h^Y_\sigma\colon \mathbb{W}[X] \to \mathbb{W}[X]$.

▶ **Lemma 14.** *$S \coloneqq \{(h^Y_\sigma, h^Y_{\mathrm{id}}) \mid Y \subseteq X\} \subseteq \mathrm{Hom}^2(\mathbb{W}[X], \mathbb{W}[X])$ is a separating set of homomorphism pairs.*

Proof. Suppose that $p \neq q$ for a pair $p, q \in \mathbb{W}[X]$. A monomial in $\mathbb{W}[X]$ can be identified with the set of its variables. Thus, without loss of generality, there is some $Y \subseteq X$ with $Y \in p$ and $Y \notin q$. Surely, $h^Y_\sigma(p)$ contains the monomial $h^Y_\sigma(Y) = Y$, but $h^Y_{\mathrm{id}}(q)$ only contains monomials from q, hence it does not contain Y and $h^Y_\sigma(p) \neq h^Y_{\mathrm{id}}(q)$. ◀

Before applying the reduction technique to obtain $\pi_{xy} \equiv \pi_{yx}$ from Corollary 12, it only remains to show that $(h^Y_\sigma \circ \pi_{xy}) \equiv (h^Y_{\mathrm{id}} \circ \pi_{yx})$ for all $Y \subseteq X := \{x, y\}$. Since we have already illustrated $(h^X_\sigma \circ \pi_{xy}) \cong (h^X_{\mathrm{id}} \circ \pi_{yx})$, we only need to consider the cases where $Y \subsetneq X$. But then, at most one variable is contained in Y and the remaining variables are annihilated by h^Y_σ and h^Y_{id}, thus $(h^Y_\sigma \circ \pi_{xy}) \cong (h^Y_{\mathrm{id}} \circ \pi_{yx})$ clearly follows. The reduction technique then implies that $\pi_{xy} \equiv \pi_{yx}$ on $\mathbb{W}[X]$, which can naturally be lifted to all fully idempotent semirings thanks to the universal property.

▶ **Theorem 15.** *For any fully idempotent semiring K with at least three elements, there is a pair of finite K-interpretations π_{rs}, π_{sr} over a universe with four elements and a signature with two unary relation symbols such that $\pi_{rs} \equiv \pi_{sr}$, but $\pi_{rs} \not\cong \pi_{sr}$.*

In conclusion, the proof of $\pi_{xy} \equiv \pi_{yx}$ on $\mathsf{PosBool}[X]$ illustrates how elementary equivalence in semiring semantics can be reduced to elementary equivalence on $\mathbb{B}$ by completely decomposing $\mathsf{PosBool}[X]$ to $\mathbb{B}$ with homomorphisms. Moreover, the proof of elementary equivalence on $\mathbb{W}[X]$ shows that it may even pay off to use separating sets of homomorphisms from $\mathbb{W}[X]$ to $\mathbb{W}[X]$ itself.

5 Characteristic Sentences

The results of the previous section raise the question whether it is possible to construct a similar example of non-isomorphic, but elementarily equivalent interpretations also for the most general semiring $\mathbb{N}[X]$, and lift it to all commutative semirings with at least three elements. In order to show that this is not possible, we draw inspiration from classical semantics, where for each finite τ-structure $\mathfrak{A}$ with universe $A = \{a_1, \ldots, a_n\}$ one can construct a *characteristic sentence* $\chi_{\mathfrak{A}}$ such that $\mathfrak{B} \models \chi_{\mathfrak{A}}$ if, and only if, $\mathfrak{A} \cong \mathfrak{B}$. The characteristic sentence is explicitly defined as

$$\chi_{\mathfrak{A}} := \exists x_1 \ldots \exists x_n (\varphi(\overline{x}) \wedge \psi(\overline{x})) \quad \text{with}$$
$$\varphi(\overline{x}) := \bigwedge_{1 \leq i < j \leq n} x_i \neq x_j \wedge \forall y \bigvee_{i \leq n} y = x_i \quad \text{and} \quad \psi(\overline{x}) := \bigwedge \{L(\overline{x}) \in \mathrm{Lit}_n(\tau) \mid \mathfrak{A} \models L(\overline{a})\}.$$

The subformula $\varphi(\overline{x})$ of this sentence asserts that the universe has precisely n elements assigned to the variables $\overline{x}$. Since $\varphi(\overline{x})$ uses only equalities and inequalities it can be used as-is for semiring semantics in any semiring.

▶ **Lemma 16.** *For every K-interpretation $\pi_B \colon \mathrm{Lit}_B(\tau) \to K$ into an arbitrary semiring K and every tuple $\overline{b} = (b_1, \ldots, b_n)$, we have that $\pi_B[\![\varphi(\overline{b})]\!] = 1$ if $B = \{b_1, \ldots, b_n\}$ and $b_i \neq b_j$ for $i \neq j$, and $\pi_B[\![\varphi(\overline{b})]\!] = 0$, otherwise.*

Proof. Semiring interpretations evaluate equalities and inequalities to 0 and 1, so

$$\pi_B[\![\varphi(\overline{b})]\!] = \prod_{i<j} \pi_B[\![b_i \neq b_j]\!] \cdot \prod_{b \in B} \Big(\sum_{i \leq n} \pi_B[\![b = b_i]\!]\Big)$$

evaluates to 1 if $b_1, \ldots, b_n$ is a distinct enumeration of all elements of B, and to 0 otherwise. ◀

On the other side, $\psi(\overline{a})$ is the conjunction of all true literals in $\mathfrak{A}$. Since $\mathfrak{A}$ satisfies precisely one literal out of each pair of opposing literals L and $\overline{L}$, it is clear that $\psi(\overline{a})$ describes $\mathfrak{A}$ up to isomorphism. However, this approach does not lift to arbitrary semiring interpretations π_A, since different literals in π_A may have different non-zero values, but conjunctions are interpreted as products, and it is in general impossible to trace the result back to the contributions of the literals.

5.1 The Viterbi Semiring

The Viterbi semiring $\mathbb{V} = ([0,1]_{\mathbb{R}}, \max, \cdot, 0, 1)$ is used in confidence analysis, probabilistic parsing, and Hidden Markov Models (see [8, 10]). It is isomorphic to the tropical semiring $\mathbb{T} = (\mathbb{R}_+^\infty, \min, +, \infty, 0)$, used for instance for cost analysis and performance evaluation, via $x \mapsto e^{-x}$. Hence, all results that we establish for the Viterbi semiring also hold for the tropical semiring. We can illustrate the shortcomings of the characteristic sentences in their classical form by very simple $\mathbb{V}$-interpretations with one element.

π_{19} :

A	P	Q	$\neg P$	$\neg Q$
a	0.1	0.9	0	0

π_{91} :

A	P	Q	$\neg P$	$\neg Q$
a	0.9	0.1	0	0

They are clearly not isomorphic, but trying to construct χ_{19} from π_{19} as above would yield $\chi_{19} = \exists x(\varphi(x) \wedge \psi(x))$ with $\psi(x) = Px \wedge Qx$, hence $\pi_{19}[\![\chi_{19}]\!] = 0.1 \cdot 0.9 = 0.9 \cdot 0.1 = \pi_{91}[\![\chi_{19}]\!]$.

However, under semiring semantics, and especially on the Viterbi semiring $\mathbb{V}$, multiplication need not be idempotent; hence we can hope to distinguish two interpretations by simply repeating one of the literals. In the given example, we can set $\psi(x) \coloneqq Px \wedge (Qx)^2$, which is short for $Px \wedge Qx \wedge Qx$, to obtain $\pi_{19}[\![\chi_{19}]\!] = 0.1 \cdot 0.9^2 \neq 0.9 \cdot 0.1^2 = \pi_{91}[\![\chi_{19}]\!]$. We now generalise this idea to arbitrary finite $\mathbb{V}$-interpretations. We shall associate with every finite $\mathbb{V}$-interpretation $\pi_A \colon \mathrm{Lit}_A(\tau) \to \mathbb{V}$ and every $\varepsilon \in \mathbb{R}^+$ a characteristic sentence

$$\chi_{\pi_A,\varepsilon} \coloneqq \exists x_1 \ldots \exists x_n(\varphi(\overline{x}) \wedge \psi_\varepsilon(\overline{x})),$$

with $n \coloneqq |A|$ and $\varphi(x)$ as before, but a more involved construction of $\psi_\varepsilon(\overline{x})$:

Let $\overline{a} = (a_1, \ldots, a_n)$ be some fixed order on A and $L_1(\overline{a}), \ldots, L_k(\overline{a})$ an arbitrary enumeration of the "true" literals in $\mathrm{Lit}_A(\tau)$ with $\pi_A(L_i(\overline{a})) \neq 0$. Further, fix a sequence $f(1), \ldots, f(k)$ of "exponents" in $\mathbb{N}$, where $f(1) = 1$ and $f(i+1)$ is chosen large enough so that

$$(*) \qquad (1-\varepsilon)^{f(i+1)} < \varepsilon^{f(1)+\cdots+f(i)}.$$

Then, put $\psi_\varepsilon(\overline{x}) \coloneqq \bigwedge_{i=1}^k L_i(\overline{x})^{f(i)}$, where "exponentiation" denotes repetition of a literal.

The idea is that $\chi_{\pi_A,\varepsilon}$ should characterise π_A up to isomorphism by repeating the literals in $\psi_\varepsilon(\overline{x})$ "sufficiently often" so that the contribution of each literal can be distinguished and changing the value for one literal surely alters the final value of $\psi_\varepsilon(\overline{x})$. Since the elements of $\mathbb{V}$ are from $[0,1]_{\mathbb{R}}$, the values of the literals can change by an arbitrarily small amount, hence the "exponents" $f(i)$ must depend on the "smallest possible change" ε. This intuition is formalised as follows.

▶ **Proposition 17.** *Let $\pi_A \colon \mathrm{Lit}_A(\tau) \to \mathbb{V}$ and $\pi_B \colon \mathrm{Lit}_B(\tau) \to \mathbb{V}$ be two finite, model-defining $\mathbb{V}$-interpretations, which induce the finite set of values*

$$V \coloneqq \{\pi_A(L) \mid L \in \mathrm{Lit}_A(\tau)\} \cup \{\pi_B(L) \mid L \in \mathrm{Lit}_B(\tau)\}.$$

Then, for every $\varepsilon \in \mathbb{R}$ bounded by $0 < \varepsilon \leq \min\{|r-s| \mid r,s \in V, r \neq s\}$, we have that $\pi_A[\![\chi_{\pi_A,\varepsilon}]\!] = \pi_B[\![\chi_{\pi_A,\varepsilon}]\!]$ implies $\pi_A \cong \pi_B$.

Proof. Assume $\pi_A[\![\chi_{\pi_A,\varepsilon}]\!] = \pi_B[\![\chi_{\pi_A,\varepsilon}]\!]$. By construction, $\pi_A[\![\chi_{\pi_A,\varepsilon}]\!] > 0$, so $\pi_B[\![\chi_{\pi_A,\varepsilon}]\!] > 0$ as well. By Lemma 16, together with the fact that the existential quantifiers $\exists x_1 \dots \exists x_n$ in $\chi_{\pi_A,\varepsilon}$ are interpreted as max in the Viterbi semiring $\mathbb{V}$, this implies that $|A| = |B|$, and that we have enumerations $\overline{a} = (a_1, \dots, a_n)$ and $\overline{b} = (b_1, \dots, b_n)$ of the elements of A and B, such that

$$\pi_A[\![\chi_{\pi_A,\varepsilon}]\!] = \pi_A[\![\psi_\varepsilon(\overline{a})]\!] = \pi_B[\![\psi_\varepsilon(\overline{b})]\!] = \pi_B[\![\chi_{\pi_A,\varepsilon}]\!].$$

Recall that $\pi_A[\![\psi_\varepsilon(\overline{a})]\!] = \prod_{i=1}^{k} \pi_A(L_i(\overline{a}))^{f(i)} > 0$, hence $\pi_A(L_1(\overline{a})), \dots, \pi_A(L_k(\overline{a}))$ are all positive. Accordingly, $\pi_B[\![\psi_\varepsilon(\overline{b})]\!] = \prod_{i=1}^{k} \pi_B(L_i(\overline{b}))^{f(i)} > 0$, so that $\pi_B(L_1(\overline{b})), \dots, \pi_B(L_k(\overline{b}))$ are positive as well. Given that π_A and π_B share the same signature and universe size, any permutations $\overline{a}$, $\overline{b}$ of their elements yield the same number of positive literals, which is k by definition. We infer that all remaining literals in both interpretations are mapped to zero. Hence, for $i = 1, \dots, k$, let $r_i \coloneqq \pi_A(L_i(\overline{a})) > 0$ and $s_i \coloneqq \pi_B(L_i(\overline{b})) > 0$ be the values of the positive literals, then it only remains to show that $r_i = s_i$ for all $i \leq k$ in order to conclude that $\overline{a} \mapsto \overline{b}$ is indeed an isomorphism from π_A to π_B.

Towards a contradiction, assume that this is not the case and let j be the maximal index among $1, \dots, k$ with $r_j \neq s_j$. We can assume that $r_j < s_j$. Since the difference between the two values is at least ε and since $s_j \leq 1$, it follows that $r_j \leq s_j - \varepsilon \leq s_j - \varepsilon s_j = (1-\varepsilon)s_j$. Further, we have $\varepsilon \leq s_i, r_i \leq 1$ for all i. It follows that

$$r_1^{f(1)} \cdots r_j^{f(j)} \leq r_j^{f(j)} \leq (1-\varepsilon)^{f(j)} s_j^{f(j)} \overset{*}{<} \varepsilon^{f(1)+\cdots+f(j-1)} \cdot s_j^{f(j)} \leq s_1^{f(1)} \cdots s_j^{f(j)}.$$

However, since $r_i = s_i$ for $i = j+1, \dots, k$, this would imply that

$$\pi_A[\![\psi_\varepsilon(\overline{a})]\!] = \prod_{i \leq k} r_i^{f(i)} \neq \prod_{i \leq k} s_i^{f(i)} = \pi_B[\![\psi_\varepsilon(\overline{b})]\!]$$

and hence $\pi_A[\![\chi_{\pi_A,\varepsilon}]\!] \neq \pi_B[\![\chi_{\pi_A,\varepsilon}]\!]$. ◀

Notice that none of the sentences $\chi_{\pi_A,\varepsilon}$ characterises π_A alone, but the countable set $X_{\pi_A} \coloneqq \{\chi_{\pi_A,\varepsilon} \mid \varepsilon \in \mathbb{Q}^+\}$ does so. No infinite $\mathbb{V}$-interpretation π_B agrees with π_A on any of the ε-characteristic sentences $\chi_{\pi_A,\varepsilon}$ due to $\varphi(\overline{x})$, whereas for each finite $\mathbb{V}$-interpretation π_B, one can calculate an $\varepsilon \in \mathbb{Q}$ to apply the proposition just proved.

▶ **Theorem 18.** *For finite $\mathbb{V}$-interpretations π_A and π_B, $\pi_A \equiv \pi_B$ implies $\pi_A \cong \pi_B$.*

As a consequence, there are indeed interesting semirings beyond the Boolean semiring $\mathbb{B}$, where elementary equivalence implies isomorphism on finite interpretations.

5.2 Finite Axiomatisability

The characteristic set X_{π_A} raises the question whether a finite set of sentences suffices to characterise a $\mathbb{V}$-interpretation π_A. We will answer this question positively using two observations. By Proposition 17, we observe that $\chi_{\pi_A,\varepsilon}$ characterises π_A up to isomorphism inside the class of $\mathbb{V}$-interpretations that only use values in $V = \{\pi_A(L) \mid L \in \mathrm{Lit}_A(\tau)\}$, with $\varepsilon \coloneqq \min\{|r-s| \mid r, s \in V, r \neq s\}$. Hence, π_A can be characterised by adding sentences to ensure that no values outside of V are used.

We will show that this is possible by building sentences that fix particular values $\pi_A(L)$.

▶ **Definition 19.** Let $\pi\colon \mathrm{Lit}_A(\tau) \to \mathbb{V}$ be a finite $\mathbb{V}$-interpretation over a universe A with n elements and $\varphi(\overline{x}) \in \mathrm{FO}(\tau)$ a formula with $k \in \mathbb{N}$ free variables. The sequence $(s^i_{\pi,\varphi})_{1 \leq i \leq n^k}$ is defined as the non-increasingly sorted sequence of the values $\pi[\![\varphi(\overline{a})]\!]$ for $\overline{a} \in A^k$.

In particular, $s^1_{\pi,\varphi}$ is the largest possible value $\pi[\![\varphi(\overline{a})]\!]$; further, $s^2_{\pi,\varphi} \leq s^1_{\pi,\varphi}$ is either the second largest one, or equal to $s^1_{\pi,\varphi}$ if the maximal value is shared by two distinct tuples $\overline{a}, \overline{b} \in A^k$, and so on. We construct a series of sentences that fix the values $(s^i_{\pi,\varphi})_{1 \leq i \leq n^k}$.

▶ **Lemma 20** (Sorting Lemma). *For $\varphi(\overline{x}) \in \mathrm{FO}(\tau)$ with k free variables and $1 \leq i \leq n^k$, let*

$$\psi^i_\varphi \coloneqq \exists \overline{x}_1 \ldots \exists \overline{x}_i \Big(\bigwedge_{1 \leq j < \ell \leq i} \overline{x}_j \neq \overline{x}_\ell \wedge \bigwedge_{j=1}^{i} \varphi(\overline{x}_j) \Big)$$

where $\overline{x}_1, \ldots \overline{x}_i$ are k-tuples of variables. Then, for any $\mathbb{V}$-interpretation $\pi \colon \mathrm{Lit}_A(\tau) \to \mathbb{V}$ over a universe with n elements, we have that

$$\pi[\![\psi^i_\varphi]\!] = \prod_{1 \leq j \leq i} s^j_{\pi,\varphi} \quad \text{for } 1 \leq i \leq n^k.$$

Proof. Recall that existential quantifiers are interpreted as max on $\mathbb{V}$. Due to monotonicity of multiplication, the maximum $\pi[\![\psi^i_{\pi,\varphi}]\!]$ is achieved by picking the i pairwise distinct tuples $\overline{a}_1, \ldots, \overline{a}_i$ that yield the largest values $\pi[\![\varphi(\overline{a}_j)]\!] = s^j_{\pi,\varphi}$ and inserting them for $\overline{x}_1, \ldots, \overline{x}_i$. Clearly, this yields $\pi[\![\psi^i_\varphi]\!] = \prod_{1 \leq j \leq i} s^j_{\pi,\varphi}$. ◀

By observing that $\mathbb{V}$ is cancellative, i.e. $ab = ac$ implies $b = c$ for all $a, b, c \in \mathbb{V}$ with $a \neq 0$, we may disentangle the products $\prod_{1 \leq j \leq i} s^j_{\pi,\varphi}$ to draw the following conclusion.

▶ **Corollary 21.** *Let $\varphi(\overline{x})$ be as above, and consider two $\mathbb{V}$-interpretations $\pi \colon \mathrm{Lit}_A(\tau) \to \mathbb{V}$ and $\pi' \colon \mathrm{Lit}_B(\tau) \to \mathbb{V}$ with $|A| = |B| = n$. If π and π' agree on $\Psi \coloneqq \{\psi^i_\varphi \mid 1 \leq i \leq n^k\}$, then $s^i_{\pi,\varphi} = s^i_{\pi',\varphi}$ for all $1 \leq i \leq n^k$. In other words, the values $\pi[\![\varphi(\overline{a})]\!]$ for $\overline{a} \in A^k$ and $\pi'[\![\varphi(\overline{b})]\!]$ for $\overline{b} \in B^k$ are the same, up to permutation.*

If $R \in \tau$ is a k-ary relation, pick $\varphi(\overline{x}) \coloneqq R\overline{x}$ and construct $\Psi_R \coloneqq \{\psi^i_{R\overline{x}} \mid 1 \leq i \leq n^k\}$ according to the Sorting Lemma. Similarly, construct $\Psi_{\neg R}$ from $\varphi(\overline{x}) \coloneqq \neg R\overline{x}$. Then, define

$$\Psi_\tau \coloneqq \bigcup_{R \in \tau} \Psi_R \cup \bigcup_{R \in \tau} \Psi_{\neg R}.$$

Clearly, any two $\mathbb{V}$-interpretations over τ that agree on Ψ_τ use the same set of values from $\mathbb{V}$. Putting this together with the characteristic sentences $\chi_{\pi_A,\varepsilon}$ from Proposition 17 provides a finite axiomatisation of any $\mathbb{V}$-interpretation.

▶ **Theorem 22.** *Let $\pi \colon \mathrm{Lit}_A(\tau) \to \mathbb{V}$ be a finite $\mathbb{V}$-interpretation. Then, $\Psi_\tau \cup \{\chi_{\pi,\varepsilon}\}$ is a finite axiomatisation of π up to isomorphism, where $\varepsilon \coloneqq \min\{|r - s| \mid r, s \in \pi(\mathrm{Lit}_A(\tau)), r \neq s\}$.*

Proof. Let $\pi' \colon \mathrm{Lit}_B(\tau) \to \mathbb{V}$ agree with π on all sentences in $\Psi_\tau \cup \{\chi_{\pi,\varepsilon}\}$. Due to the construction of $\chi_{\pi,\varepsilon}$, π' is finite and $|A| = |B|$. Since π' agrees with π on Ψ_τ, we have $\{\pi(L) \mid L \in \mathrm{Lit}_A(\tau)\} = \{\pi'(L) \mid L \in \mathrm{Lit}_B(\tau)\}$. Thus, we can invoke Proposition 17 by observing that $V = \pi(\mathrm{Lit}_A(\tau))$ and conclude that $\pi[\![\chi_{\pi,\varepsilon}]\!] = \pi'[\![\chi_{\pi,\varepsilon}]\!]$ implies $\pi \cong \pi'$. ◀

Under classical semantics, any finite axiom system $\Phi \subseteq \mathrm{FO}(\tau)$ can be collapsed to a single axiom $\psi \coloneqq \bigwedge \Phi$, but this is not the case in semiring semantics. To illustrate this, we shall show that there are $\mathbb{V}$-interpretations that cannot be axiomatised up to isomorphism by a single sentence.

▶ **Proposition 23.** *There exist $\mathbb{V}$-interpretations $\pi \colon \mathrm{Lit}_A(\tau) \to \mathbb{V}$ such that, for every sentence $\psi \in \mathrm{FO}(\tau)$, there exists an interpretation $\pi' \colon \mathrm{Lit}_A(\tau) \to \mathbb{V}$ such that $\pi \ncong \pi'$, but $\pi[\![\psi]\!] = \pi'[\![\psi]\!]$.*

Proof. Take an interpretation with just two atoms Pa and Qa and with values $\pi(Pa) = p$ and $\pi(Qa) = q$ such that $0 < p, q < 1$ are multiplicatively independent real numbers, i.e. $k = \ell = 0$ is the only solution to $p^k q^\ell = 1$ with $k, \ell \in \mathbb{Z}$. Let $\pi_{\mathbb{B}}$ be the corresponding $\mathbb{B}[x, y]$-interpretation, with $\pi_{\mathbb{B}}(Pa) = x$ and $\pi_{\mathbb{B}}(Qa) = y$. A sentence $\psi \in \mathrm{FO}$ is evaluated under $\pi_{\mathbb{B}}$ to a polynomial $\pi_{\mathbb{B}}[\![\psi]\!] \in \mathbb{B}[x, y]$, and by the universal property for idempotent semirings, the homomorphism $h\colon \mathbb{B}[x, y] \to \mathbb{V}$ induced by $h(x) = p$ and $h(y) = q$ maps $\pi_{\mathbb{B}}[\![\psi]\!]$ to $\pi[\![\psi]\!]$. Writing $\pi_{\mathbb{B}}[\![\psi]\!]$ as a sum of monomials $m = x^i y^j$, we conclude that $\pi[\![\psi]\!] = p^i q^j$ is the maximal value $m(p, q)$ for the monomials m occuring in $\pi_{\mathbb{B}}[\![\psi]\!]$. Since p, q are multiplicatively independent, no other monomial can take the same value, i.e. $m'(p, q) < m(p, q)$ for all other monomials m' in $\pi_{\mathbb{B}}[\![\psi]\!]$. We now can certainly find a value $r \neq p$ that is sufficiently close to p, and a value s such that $r^i s^j = p^i q^j$, i.e. $m(r, s) = m(p, q)$, but $m'(r, s) < m(r, s)$ for all other monomials m' in $\pi_{\mathbb{B}}[\![\psi]\!]$. For the $\mathbb{V}$-interpretation π' with $\pi'(Pa) = r$ and $\pi'(Qa) = s$ this implies that $\pi'[\![\psi]\!] = r^i s^j = p^i q^j = \pi[\![\psi]\!]$, but clearly, $\pi' \not\cong \pi$. ◀

This result can be strengthened in many directions. It holds, in fact, for almost all $\mathbb{V}$-interpretations, as long as they do not map all literals to either 0 or 1. Further, we shall exploit the isomorphism of $\mathbb{V}$ and $\mathbb{T}$ in order to prove explicit lower bounds on the number of axioms that are needed to characterise an interpretation, depending on the number of literals mapped to multiplicatively independent values.

5.3 Lower Bound for Axiomatisations of $\mathbb{T}$- and $\mathbb{V}$-interpretations

Recall that $\mathbb{V} = ([0, 1]_{\mathbb{R}}, \max, \cdot, 0, 1)$ is isomorphic to $\mathbb{T} = (R_+^\infty, \min, +, \infty, 0)$ via isomorphisms $\sigma_{\mathbb{V}\to\mathbb{T}}(a) = -\log_b(a)$ for any fixed base $b \in \mathbb{R}_{>1}$, and the corresponding inverse isomorphisms $\sigma_{\mathbb{T}\to\mathbb{V}}(a) = b^{-a}$ for any fixed $b \in \mathbb{R}_{>1}$. We formulate our result in terms of $\mathbb{T}$.

▶ **Theorem 24.** *Let $\pi\colon \mathrm{Lit}_A(\tau) \to \mathbb{T}$ be any finite, model-defining $\mathbb{T}$-interpretation with $|A| = n$ and $|\mathrm{Lit}_A(\tau)| = 2\ell$, such that its finite values $\pi(\mathrm{Lit}_A(\tau)) \setminus \{\infty\}$ are linearly independent over $\mathbb{Q}$. Then, for any set of sentences $\Psi \subseteq \mathrm{FO}(\tau)$ with $|\Psi| < \ell$, there is an interpretation $\pi'\colon \mathrm{Lit}_A(\tau) \to \mathbb{T}$ such that $\pi[\![\psi]\!] = \pi'[\![\psi]\!]$ for all $\psi \in \Psi$, but $\pi \not\cong \pi'$.*

Proof. Since π is model-defining, there are ℓ literals L in $\mathrm{Lit}_A(\tau)$ with $\pi(L) \neq \infty$, which we call the positive literals. Choose $X \coloneqq \{x_1, \ldots, x_\ell\}$ and construct the $\mathbb{B}[X]$-interpretation $\pi_{\mathbb{B}}\colon \mathrm{Lit}_A(\tau) \to \mathbb{B}[X]$ by assigning a unique variable to each of the positive literals. Clearly, there is a homomorphism $h\colon \mathbb{B}[X] \to \mathbb{T}$ with $h \circ \pi_{\mathbb{B}} = \pi$ induced by mapping each variable to the original value $\pi(L)$ of the corresponding literal.

Enumerate $\Psi = \{\psi_1, \ldots, \psi_j\}$ arbitrarily with $j < \ell$ and construct the polynomials $p_i \coloneqq \pi_{\mathbb{B}}[\![\psi_i]\!] \in \mathbb{B}[X]$ for $1 \leq i \leq j$. By the fundamental property, $\pi[\![\psi_i]\!] = h(p_i)$ holds for $1 \leq i \leq j$.

We assume without loss of generality that $p_i \neq 0$ for all $1 \leq i \leq j$, and we will construct π' with the same positive literals as π. Thus, p_i contains a monomial m_i so that $h(m_i)$ is minimal among $\{h(m) : m \in p_i\}$. This monomial is unique thanks to the linear independence of the values of π, which guarantees that $h(m) \neq h(m')$ for $m \neq m'$. Suppose for a contradiction that $h(m) = h(m')$. We may write

$$h(m) = h\left(\prod_{i=1}^{\ell} x_i^{m(x_i)}\right) = \sum_{i=1}^{\ell} m(x_i) \cdot h(x_i),$$

which implies that $h(m)$ is a linear combination of the values of π. In particular, $h(m) = h(m')$ implies that $h(m - m') = 0$, hence $m(x_i) - m'(x_i) = 0$ for all $1 \leq i \leq j$ due to linear independence.

We conclude that there is a sufficiently small $\varepsilon \in \mathbb{R}_{>0}$ such that changing the numbers $h(x_i)$ by less than ε does not affect the monomial order. In other words, view the values $\overline{v} \coloneqq (h(x_1), \dots, h(x_\ell)) \in \mathbb{R}^\ell_{\geq 0}$ as a vector and notice that any $\overline{w} \in \mathbb{R}^\ell_{\geq 0}$ with $|\overline{v} - \overline{w}| < \varepsilon$ preserves the monomial order, so that if we construct $h' \colon \mathbb{B}[X] \to \mathbb{T}$ induced by $h'(x_i) = w_i$ for $1 \leq i \leq \ell$, we have $h(m) < h(m')$ if, and only if, $h'(m) < h'(m')$.

To complete the proof, it remains to ensure that $h'(p_i) = h(p_i)$ stays the same for all $1 \leq i \leq j$. By the above considerations, it suffices to ensure that $h'(m_i) = h(m_i)$ for the corresponding maximal monomials $m_1, \dots, m_j$. Each of these monomials induces one condition $h(m_i) - h'(m_i) = 0$, which translates to a linear equation

$$h(m_i) - h'(m_i) = \sum_{i=1}^{\ell} m_i(x_i)(h(x_i) - h'(x_i)) = \sum_{i=1}^{\ell} m_i(x_i) \cdot (v_i - w_i) = 0$$

on $(\overline{v} - \overline{w})$.

Since there are only $j < \ell$ equations and ℓ variables, the solution space is at least one-dimensional, meaning that we can pick $\overline{w} \neq \overline{v}$ adequately with $|\overline{v} - \overline{w}| < \varepsilon$ to satisfy all equations and obtain $h'(p_i) = h(p_i)$ for all $1 \leq i \leq j$. Note that due to linear independence, none of the entries from $\overline{v}$ was zero, hence it is possible to ensure that $\overline{w}$ only has positive entries. We thus can pick $\pi' \coloneqq h' \circ \pi_{\mathbb{B}}$ with the desired properties. ◀

This result translates to $\mathbb{V}$ thanks to isomorphism. Linear independence of values from $\mathbb{T}$ as $\mathbb{Q}$-vectors translates to multiplicative independence of the corresponding values from $\mathbb{V}$.

5.4 The Semirings $\mathbb{N}$ and $\mathbb{N}[X]$

We will now provide a similar analysis of axiomatisablity for the most general semiring $\mathbb{N}[X]$ by taking a detour via $\mathbb{N}$. For the construction of the characteristic sentences for $\mathbb{N}$, we shall need the following combinatorial lemma.

▶ **Lemma 25.** *For any two natural numbers k, c with $c > 1$, there exists a exponent e such that, for any two non-decreasing sequences $r_1 \leq r_2 \leq \dots \leq r_k$ and $s_1 \leq s_2 \leq \dots \leq s_k$ of k natural numbers, with $r_k, s_k < c$, the equation $r_1^e + \dots + r_k^e = s_1^e + \dots + s_k^e$ implies that the two sequences are the same, i.e. $r_i = s_i$ for all $i \leq k$.*

Proof. Choose e large enough so that $(c/(c-1))^e > k$. Towards a contradiction, assume that there are two *distinct* sequences $r_1 \leq r_2 \leq \dots r_k < c$ and $s_1 \leq s_2 \leq \dots s_k < c$ such that $r_1^e + \dots + r_k^e = s_1^e + \dots + s_k^e$. Let j be the maximal index with $r_j \neq s_j$. Thanks to additive cancellation, we can remove the summands with index $i > j$ to obtain that $r_1^e + \dots + r_j^e = s_1^e + \dots + s_j^e$. By symmetry we can assume that $r_j < s_j$. Since $s_j < c$, it follows that $s_j > (c/(c-1))r_j$ and hence $s_j^e > k \cdot r_j^e$. But this implies that

$$r_1^e + \dots + r_j^e \leq j \cdot r_j^e \leq k \cdot r_j^e < s_j^e \leq s_1^e + \dots + s_j^e,$$

contradicting the equation above. ◀

▶ **Lemma 26.** *Let $(r_1, \dots r_k), (s_1, \dots, s_k) \in \mathbb{N}^k$ be strictly bounded by c, that is $r_i, s_i < c$ for all $i \leq k$. Then, there is an exponent e depending only on c and k such that*

$$\sum_{i=1}^{k} r_i^e = \sum_{i=1}^{k} s_i^e$$

implies that there is a permutation $\sigma \in S_k$ such that $r_i = s_{\sigma(i)}$ for all $1 \leq i \leq k$.

Proof. Sort both sequences non-decreasingly, that is, permute them with $\rho, \tau \in S_k$ so that $r_{\rho(1)} \leq \ldots \leq r_{\rho(k)}$ and $s_{\tau(1)} \leq \ldots \leq s_{\tau(k)}$. By the previous Lemma, there is a suitable e such that $r_{\rho(i)} = s_{\tau(i)}$ for all $i \leq k$. Then, $\sigma \coloneqq \tau \circ \rho^{-1}$ is the desired permutation. ◀

We are now ready to construct characteristic sentences for finite $\mathbb{N}$-interpretations $\pi_A \colon \mathrm{Lit}_A(\tau) \to \mathbb{N}$. For $n = |A|$, let $L_1(\overline{x}), \ldots, L_k(\overline{x})$ be an enumeration of all literals in $\mathrm{Lit}_n(\tau)$. For any constant $q \in \mathbb{N}$ we define the *q-characteristic sentence* $\chi_{\pi_A,q}$ as

$$\chi_{\pi_A,q} \coloneqq \exists x_1 \ldots \exists x_n (\varphi(\overline{x}) \wedge \psi_q(\overline{x}))^e, \quad \text{with } \psi_q(\overline{x}) \coloneqq \bigvee_{i=1}^{k} q^{i-1} \cdot L_i(\overline{x}),$$

with $\varphi(\overline{x})$ as given before and e is an exponent that depends on q, n and τ, according to Lemma 26. The notation $q^{i-1} \cdot L_i(\overline{x})$ denotes a disjunctive repetition of the literal $L_i(\overline{x})$ for q^{i-1} times.

The idea of this construction is similar to the one for the Viterbi semiring. While ε-characteristic sentences work for $\mathbb{V}$-interpretations where the differences of two distinct values are at least ε, q-characteristic sentences work for $\mathbb{N}$-interpretations with values less than q. With this in mind, we can explain the construction of $\psi_q(\overline{x})$ as follows. If all values in π_A are less than q, we can picture the value

$$\pi_A[\![\psi_q(\overline{a})]\!] = \sum_{i=1}^{k} q^{i-1} \pi_A(L_i(\overline{a})),$$

to be in a number system with radix q, hence the values $\pi_A(L_i(\overline{a}))$ can be seen as digits. Thus, it is immediately clear that for any $\mathbb{N}$-interpretation π_B with universe enumerated by $\overline{b}$ and values less than q, $\pi_A[\![\psi_q(\overline{a})]\!] = \pi_B[\![\psi_q(\overline{b})]\!]$ implies that $\overline{a} \xrightarrow{\sim} \overline{b}$ is an isomorphism between π_A and π_B, since the corresponding "digits" $\pi_A(L_i(\overline{a}))$ and $\pi_B(L_i(\overline{b}))$ for each $1 \leq i \leq k$ have to be the same.

The only remaining problem is the fact that existential quantifiers $\exists x_1 \ldots \exists x_n$ from $\chi_{\pi_A,q}$ are interpreted as a sum in $\mathbb{N}$. Thus, the value $\pi_A[\![\chi_{\pi_A,q}]\!]$ is not induced by a single variable assignment $\overline{a}$. The exponent e is used to separate the contributions of different variable assignments to the sum on the basis of Lemma 26.

▶ **Theorem 27.** *Let π_A and π_B are finite $\mathbb{N}$-interpretations with values less than q. Then $\pi_A[\![\chi_{\pi_A,q}]\!] = \pi_B[\![\chi_{\pi_A,q}]\!]$ implies that $\pi_A \cong \pi_B$.*

Proof. Clearly, $\varphi(\overline{x})$ takes care of the number of elements, hence we can assume $\overline{a}$ and $\overline{b}$ enumerate the universes of π_A and π_B. Now, we have

$$\pi_A[\![\chi_{\pi_A,q}]\!] = \sum_{\sigma \in S_n} \pi_A[\![\psi_q(\sigma(\overline{a}))]\!]^e = \sum_{\sigma \in S_n} \pi_B[\![\psi_q(\sigma(\overline{b}))]\!]^e = \pi_B[\![\chi_{\pi_A,q}]\!].$$

Recall that $\psi_q(\overline{x})$ is constructed as a number with k "digits", where the digits are the values of the literals $\pi_A(L_i(\overline{a}))$ and $\pi_B(L_i(\overline{b}))$, which are bounded by q. Hence, $\pi_A[\![\psi_q(\sigma(\overline{a}))]\!]$ and $\pi_B[\![\psi_q(\sigma(\overline{b}))]\!]$ are less than $c \coloneqq q^k$, which only depends on q, n and τ. By Lemma 26, there is a sufficiently large e so that $\sum_{\sigma \in S_n} \pi_A[\![\psi_q(\sigma(\overline{a}))]\!]^e = \sum_{\sigma \in S_n} \pi_B[\![\psi_q(\sigma(\overline{b}))]\!]^e$ implies that both sums share the same summands. In particular, there are permutations $\sigma_A, \sigma_B \in S_n$ such that $\pi_A[\![\psi_c(\sigma_A(\overline{a}))]\!] = \pi_B[\![\psi_c(\sigma_B(\overline{b}))]\!]$.

Thanks to the construction of $\psi_c(\overline{x})$, this yields $\pi_A(L_i(\sigma_A(\overline{a})) = \pi_B(L_i(\sigma_B(\overline{b}))$ for all literals L_i of $\mathrm{Lit}_n(\tau)$. Thus, $\sigma_B \circ (\overline{a} \mapsto \overline{b}) \circ \sigma_A^{-1}$ is an isomorphism from π_A to π_B. ◀

We can further use the q-characteristic sentences also for $\mathbb{N}[X]$-interpretations instead of $\mathbb{N}$-interpretations. Let $X_k = \{x_1, \dots, x_k\}$, and let $\mathbb{N}[X_k](C, n)$ denote the set of polynomials $p \in \mathbb{N}[X_k]$ with coefficients less than C and exponents less than n. If we choose a suitable variable assignment $X_k \to \mathbb{N}$, we can obtain a homomorphism that assigns unique values to all polynomials in $\mathbb{N}[X_k](C, n)$.

▶ **Lemma 28.** *The variable assignment $x_i \mapsto C^{n^{i-1}}$ for $1 \leq i \leq k$ defines a homomorphism $h\colon \mathbb{N}[X_k] \to \mathbb{N}$ which induces a bijection from $\mathbb{N}[X_k](C, n)$ to $\{0, \dots, c-1\} \subseteq \mathbb{N}$ where $c \coloneqq C^{n^k}$.*

Proof. We proceed by induction on the number of variables $k \in \mathbb{N}$. The base case $k = 0$ is trivial, since $\mathbb{N}[\varnothing] \cong \mathbb{N}$ and the empty assignment induces the corresponding isomorphism. For $k > 0$, notice that $\mathbb{N}[X_k] \cong \mathbb{N}[X_{k-1}][x_k]$. Hence, each $p \in \mathbb{N}[X_k](C, n)$ may be written as

$$p = \sum_{i=0}^{n-1} q_i x_k^i, \quad \text{where } q_i \in \mathbb{N}[X_{k-1}](C, n).$$

Thus, applying the induced homomorphism h yields

$$h(p) = \sum_{i=0}^{n-1} h(q_i) h(x_k)^i = \sum_{i=0}^{n-1} h'(q_i)(C^{n^{k-1}})^i,$$

where $h'\colon \mathbb{N}[X_{k-1}] \to \mathbb{N}$ is induced by $x_i \mapsto C^{n^{i-1}}$ for $1 \leq i < k$. By induction hypothesis the restriction $h'|_{\mathbb{N}[X_{k-1}](C,n)}$ is a bijection from $\mathbb{N}[X_{k-1}](C, n)$ to $\{0, \dots, C^{n^{k-1}} - 1\}$. Clearly, $h(p)$ may be seen as a number with n digits $h'(q_i) \in \{0, \dots, C^{n^{k-1}} - 1\}$ for $0 \leq i < n$ in the number system with radix $C^{n^{k-1}}$. Thus, any number in $\{0, \dots, C^{n^k} - 1\}$ can be uniquely represented as $h(p)$ for $p \in \mathbb{N}[X_k](C, n)$, which completes the proof. ◀

▶ **Corollary 29.** *For finite $\mathbb{N}[X]$-interpretations π_A and π_B whose values are contained in $\mathbb{N}[X](C, n)$, $\pi_A[\![\chi_{\pi_A,c}]\!] = \pi_B[\![\chi_{\pi_A,c}]\!]$ implies $\pi_A \cong \pi_B$ with $c \coloneqq C^{n^{|X|}}$.*

Proof. Transform π_A and π_B to $\mathbb{N}$-interpretations $\pi'_A \coloneqq h \circ \pi_A$ and $\pi'_B \coloneqq h \circ \pi_B$ by applying the homomorphism from above. The fundamental property yields $\pi'_A[\![\chi_{\pi_A,c}]\!] = \pi'_B[\![\chi_{\pi_A,c}]\!]$. Since $h|_{\mathbb{N}[X](C,n)}$ is a bijection from $\mathbb{N}[X](C, n)$ to $\{0, \dots, c\}$, the values of π'_A and π'_B are less than c, hence we can invoke Theorem 27 to conclude $\pi'_A \cong \pi'_B$. Now, the injectivity of h on $\mathbb{N}[X](C, n)$ yields $\pi_A \cong \pi_B$. ◀

Similarly to the implications of Proposition 17 on the Viterbi semiring $\mathbb{V}$, we conclude that finite $\mathbb{N}[X]$-interpretations π_A are characterised by a the set $X_{\pi_A} \coloneqq \{\chi_{\pi_A,c} \mid c \in \mathbb{N}, c > 1\}$ of characteristic sentences. The obvious consequence is that no counterexamples exist on $\mathbb{N}[X]$.

▶ **Theorem 30.** *For finite $\mathbb{N}[X]$-interpretations π_A and π_B, $\pi_A \equiv \pi_B$ implies $\pi_A \cong \pi_B$.*

These results highlight the importance of cancellation for the construction of characteristic sentences. $\mathbb{V}$ and $\mathbb{N}[X]$ allow multiplicative cancellation, and $\mathbb{N}[X]$ even allows additive cancellation. We shall use this observation in the search for counterexamples on semirings that do *not* admit cancellation.

6 Cancellation

There are indeed counterexamples for a large class of semirings that break cancellation, including the polynomial semirings $\mathbb{B}[X]$ and $\mathbb{S}[X]$.

▶ **Definition 31.** *Let K be an idempotent semiring. A witness that K breaks cancellation is a triple $a, b, c \in K \setminus \{0\}$ such that*
(1) $a + b = a + c = a$ *and*
(2) $ab = ac$, *but* $b \neq c$.[1]

For any such triple, we define the following two non-isomorphic K-interpretations.

π_b :

A	R	$\neg R$
d	a	0
e	b	0

π_c :

A	R	$\neg R$
d	a	0
e	c	0

▶ **Lemma 32.** *The K-interpretations π_b and π_c are elementarily equivalent.*

Proof. Consider the $\mathbb{B}[X]$ interpretation

π :

A	R	$\neg R$
d	x	0
e	y	0

Let $h_b, h_c \colon \mathbb{B}[X] \to K$ be the unique homomorphisms induced by $x \mapsto a, y \mapsto b$ and $x \mapsto a, y \mapsto c$ respectively. Obviously, $\pi_b = h_b \circ \pi$ and $\pi_c = h_c \circ \pi$, hence, for each sentence $\psi \in \mathrm{FO}(\{R\})$, the fundamental property yields $\pi_b[\![\psi]\!] = h_b(\pi[\![\psi]\!])$ and $\pi_c[\![\psi]\!] = h_c(\pi[\![\psi]\!])$. In fact, if we set $p \coloneqq \pi[\![\psi]\!]$, we have $\pi_b[\![\psi]\!] = h_b(p)$ and $\pi_c[\![\psi]\!] = h_c(p)$, hence both interpretations evaluate the same polynomial p under their own homomorphism.

It remains to show that $h_b(p) = h_c(p)$. The automorphism $\overline{h}$ of $\mathbb{B}[X]$ induced by swapping the variables x and y yields the $\mathbb{B}[X]$-interpretation

$\overline{h} \circ \pi = \overline{\pi}$:

A	R	$\neg R$
d	y	0
e	x	0

Clearly, $\pi \cong \overline{\pi}$ by swapping d and e, hence $p = \pi[\![\psi]\!] = \overline{\pi}[\![\psi]\!] = \overline{h}(\pi[\![\psi]\!]) = \overline{h}(p)$. In other words, p is invariant under swapping variables, so for each pair i, j we have that $x^i y^j \in p$ if, and only if, $x^j y^i \in p$. In particular, $x^i \in p \Leftrightarrow y^i \in p$ $(*)$.

Since p is finite and all exponents are less than some $d \in \mathbb{N}$, we may write p as

$$p = \sum_{i,j<d, x^i y^j \in p} x^i y^j = \sum_{i<d, x^i \in p} x^i + \sum_{j<d, y^j \in p} y^j + \sum_{0<i,j<d, x^i y^j \in p} x^i y^j.$$

Set $I \coloneqq \{i < d \mid x^i \in p\} \overset{*}{=} \{j < d \mid y^j \in p\}$ and $M \coloneqq \{x^i y^j \mid 0 < i, j < d, x^i y^j \in p\}$. Then,

$$p = \sum_{i \in I} (x^i + y^i) + \sum_{m \in M} m.$$

For each $m \in M$, $h_b(m) = a^i b^j = a^i c^j = h_c(m)$ due to condition (2) and $i > 0$. More precisely, if $i > 0$, we can invoke (2) inductively to transform ab^j into ac^j due to commutativity of multiplication. We now invoke condition (1) for each $i \in I$. For $z \in \{b, c\}$ and using idempotence of K (i), this yields

[1] Strictly speaking, condition (2) suffices for breaking cancellation. Condition (1) imposes a further restriction on the witness, which is needed for the proof of Lemma 32.

$$a^i + z^i \overset{(1)}{=} (a+z)^i + z^i = \sum_{j=0}^{i} a^{i-j} z^j + z^i = \sum_{j=0}^{i-1} a^{i-j} z^j + z^i + z^i$$
$$\overset{(i)}{=} \sum_{j=0}^{i-1} a^{i-j} z^j + z^i = a^i.$$

Hence, $h_b(x^i + y^i) = a^i + b^i = a^i = a^i + c^i = h_c(x^i + y^i)$ for each $i \in I$ holds as well. Together, we have

$$h_b(p) = \sum_{i \in I} h_b(x^i + y^i) + \sum_{m \in M} h_b(m) = \sum_{i \in I} h_c(x^i + y^i) + \sum_{m \in M} h_c(m) = h_c(p),$$

which completes the proof, since ψ was arbitrary and $\pi_b[\![\psi]\!] = h_b(p) = h_c(p) = \pi_c[\![\psi]\!]$. ◀

Since $\pi_b \not\cong \pi_c$ clearly holds for π_b and π_c from Definition 31, we can apply Lemma 32 to construct counterexamples in many idempotent semirings, such as $\mathbb{B}[X]$ itself and $\mathbb{S}[X]$. The only requirement for this approach is the existence of an appropriate witness (a, b, c).

▶ **Theorem 33.** *For $X \supseteq \{x, y\}$, there exists a pair of elementarily equivalent, but non-isomorphic K-interpretations in the shape of π_b and π_c for both $K = \mathbb{B}[X]$ and $K = \mathbb{S}[X]$.*

Proof. For $\mathbb{B}[X]$, choose $a \coloneqq x + y + x^2 + xy + y^2$, $b \coloneqq x^2 + y^2$ and $c \coloneqq x^2 + xy + y^2$ to obtain the following pair of $\mathbb{B}[X]$-interpretations.

π_b :

A	R	$\neg R$
d	$x + y + x^2 + xy + y^2$	0
e	$x^2 + y^2$	0

π_c :

A	R	$\neg R$
d	$x + y + x^2 + xy + y^2$	0
e	$x^2 + xy + y^2$	0

To prove the desired properties, we only have to check conditions (1) and (2) from Definition 31 and then invoke Lemma 32. Condition (1) is obvious, and for (2), it suffices to expand the products ab and ac to calculate that

$$ab = ac = x^3 + xy^2 + x^2y + y^3 + x^4 + x^3y + x^2y^2 + xy^3 + y^4.$$

In $\mathbb{S}[X]$, we may use the "absorptive versions" $a \coloneqq x + y$, $b \coloneqq x^2 + y^2$ and $c \coloneqq x^2 + xy + y^2$ and apply the same argument. ◀

Finally, we will apply Lemma 32 to the Łukasiewicz semiring $\mathbb{L} = ([0,1]_{\mathbb{R}}, \max, \star, 0, 1)$, which is used in many-valued logic. A witness that $\mathbb{L}$ breaks cancellation is easy to obtain due to the multiplication $\star$ being defined as $a \star b \coloneqq \max\{0, a + b - 1\}$, which "cuts off" at 0.

▶ **Theorem 34.** *There exists a pair of elementarily equivalent, but non-isomorphic $\mathbb{L}$-interpretations.*

Proof. $\mathbb{L}$ is idempotent and the triple $a \coloneqq 1/2, b \coloneqq 1/3, c \coloneqq 1/4 \in \mathbb{L}$ satisfies the conditions (1) and (2) from Definition 31. Together with Lemma 32, we conclude that the $\mathbb{L}$-interpretations π_b and π_c, as constructed in the definition from the triple (a, b, c), are elementarily equivalent, but non-isomorphic. ◀

7 Conclusion and Outlook

Our analysis of first-order axiomatisations and elementary equivalence of finite semiring interpretations has revealed some remarkable differences between semiring semantics and classical Boolean semantics. Depending on the underlying semiring, there may exist finite semiring interpretations that are elementarily equivalent without being isomorphic. Indeed, this phenomenon happens already in very simple cases such as for min-max semirings with three elements. On the other side, there are relevant semirings, used for instance in provenance analysis in databases such as the tropical semiring or the Viterbi semiring, where every finite interpretation is first-order axiomatisable, and in fact even by a finite set of axioms. However, and this is again an interesting difference to Boolean semantics, a finite axiomatisation does not imply an axiomatisation by a single axiom.

Also for the semirings of polynomials, fundamental for a general provenance analysis that reveals which combinations of atomic facts are responsible for the truth of a logical statement, the picture is not unique. While the most general semiring $\mathbb{N}[X]$, freely generated by X, admits axiomatisations of all finite interpretations, so that elementary equivalence implies isomorphism, this is not the case for the semirings $\mathsf{PosBool}[X]$, $\mathbb{S}[X]$, $\mathbb{B}[X]$ and $\mathbb{W}[X]$ which are universal for important subclasses of semirings.

In the study of elementary equivalence for semiring semantics, it turns out that there is no *straightforward* adaptation of Ehrenfeucht–Fraïssé games, or their generalisations such as Hellas bijective pebble game [16], to semiring interpretations. Whatever the specific protocol of possible moves in such games may be, they always result in a *localisation*, in the sense that some tuples in the two structures are picked that are indistinguishable on the atomic level. As shown by the very simple example of the interpretations π_{PQ} and π_{QP} at the beginning of Sect. 4, this is not possible in semiring semantics. Although the two interpretations are elementarily equivalent, no element of the first "looks the same" as any element of the second, so any kind of localisation would result in a winning play of the Spoiler. It is an intriguing open question how elementary equivalence of semiring interpretations can be captured by a different notion of comparison games or back-and-forth systems à la Fraïssé. This not being available (yet), we have established elementary equivalence by different methods, based on homomorphisms, which we believe to be of independent interest.

There are many other model-theoretic issues that deserve to be studied in semiring semantics. While we have limited ourselves here to *finite* semiring interpretations, the study of semiring semantics over infinite universes is of course very interesting as well. It requires certain restrictions on the underlying semirings, concerning existence and appropriate algebraic properties of infinite sums and products, but there are useful semirings satisfying such properties. A particularly interesting question is what kind of compactness and preservation results are possible in such contexts.

We finally remark that an altogether different approach to semiring interpretations would consider them as two-sorted structures, one sort being a finite or infinite structure (or just a set), the second one consisting of the semiring, with functions from the first to the second sort giving the semiring interpretation of the literals. This is very similar to the approach of metafinite model theory [11], and to get a reasonable logical theory it is important that the elements of the second sort, here the semiring, are treated differently than the elements of the first sort. In particular, quantifiers should range only over the first sort, and operations on the second sort are just the algebraic semiring operations and their aggregates, together with equalities between terms. Such an approach is certainly useful for a number of questions and permits the study of semiring interpretations via classical Boolean semantics. In particular,

once semiring values are directly accessible in the logic, the construction of characteristic sentences, axiomatising a finite structure up to isomorphism, can easily be translated into such a setting. However, such an internalisation of the semiring values, from the meta-level of truth values into the structures under consideration, does not really capture the essence of semiring semantics.

Logarithmic Weisfeiler-Leman Identifies All Planar Graphs

Martin Grohe
RWTH Aachen University, Germany

Sandra Kiefer
University of Warsaw, Poland
RWTH Aachen University, Germany

Abstract

The Weisfeiler-Leman (WL) algorithm is a well-known combinatorial procedure for detecting symmetries in graphs and it is widely used in graph-isomorphism tests. It proceeds by iteratively refining a colouring of vertex tuples. The number of iterations needed to obtain the final output is crucial for the parallelisability of the algorithm.

We show that there is a constant k such that every planar graph can be identified (that is, distinguished from every non-isomorphic graph) by the k-dimensional WL algorithm within a logarithmic number of iterations. This generalises a result due to Verbitsky (STACS 2007), who proved the same for 3-connected planar graphs.

The number of iterations needed by the k-dimensional WL algorithm to identify a graph corresponds to the quantifier depth of a sentence that defines the graph in the $(k+1)$-variable fragment C^{k+1} of first-order logic with counting quantifiers. Thus, our result implies that every planar graph is definable with a C^{k+1}-sentence of logarithmic quantifier depth.

1 Introduction

The Weisfeiler-Leman (WL) algorithm is a combinatorial procedure for detecting symmetries in graphs. It is widely used in approaches to tackle the graph-isomorphism problem, both from a theoretical ([4, 5, 24]) and from a practical perspective ([7, 23, 31, 32]). The algorithm is derived from a technique called *naïve vertex classification* (or *Colour Refinement*), which may be viewed as the 1-dimensional version WL^1 of the WL algorithm. For every $k \geq 1$, the k-dimensional WL algorithm (WL^k) iteratively colours k-tuples of vertices of a graph by propagating local information until it reaches a *stable colouring*. Weisfeiler and Leman introduced the 2-dimensional version WL^2, today known as the *classical WL algorithm*, in [37]. The algorithm WL^k can be implemented to run in time $O(n^{k+1} \log n)$ on graphs of order n [22].

The algorithm has striking connections to numerous areas of mathematics and computer science, which surely is a reason why research on it has been active since its introduction over half a century ago. For example, there are tight connections to linear and semidefin-

ite programming [2, 3, 20], homomorphism counting [8, 10], and the algebra of coherent configurations [6]. Most recently, the WL algorithm has been applied in several interesting machine-learning contexts [1, 16, 33, 34, 39].

A very strong and highly exploited link between the algorithm and logic was established by Immerman and Lander [22] and Cai, Fürer, and Immerman [5]: WL^k assigns the same colour to two k-tuples of vertices if and only if these tuples satisfy the same formulas of the $(k+1)$-variable fragment C^{k+1} of first-order logic with counting quantifiers. Cai, Fürer, and Immerman [5] used this correspondence and an Ehrenfeucht-Fraïssé game that characterises equivalence for the logic C^{k+1} to prove that, for every k, there are non-isomorphic graphs of order $O(k)$ that are not distinguished by WL^k. Here we say that WL^k *distinguishes* two graphs if WL^k computes different stable colourings on them, that is, there is some colour such that the numbers of k-tuples of that colour differ in the two graphs.

We say that WL^k *identifies* a graph G if it distinguishes G from all graphs G' that are not isomorphic to G. It has been shown that for suitable constants k, the algorithm WL^k identifies all planar graphs [13], all graphs of bounded tree width [18], and all graphs in many other natural graph classes [12, 14, 15, 17, 19]. For some of these classes, fairly tight bounds for the optimal value of k, called the *Weisfeiler-Leman (WL) dimension*, are known. Notably, interval graphs have WL dimension 2 [12], graphs of tree width k have WL dimension in the range $\lceil k/2 \rceil - 3$ to k [26], and, most relevant for us, planar graphs have WL dimension 2 or 3 [27].

Another parameter of the WL algorithm that has received recent attention is the number of iterations it needs to reach its final, stable colouring. Since a set of size n^k can only be partitioned $n^k - 1$ times, a natural upper bound on the number of iterations to reach the final output is $n^k - 1$ (n always denotes the number of vertices of the input graph). This bound cannot be improved for WL^1, since there are infinitely many graphs on which the algorithm takes $n - 1$ iterations to compute its final output [25]. However, for WL^2, it was shown that the bound $\Theta(n^2)$ is asymptotically not tight [28]. Currently, the best upper bound on the iteration number for WL^2 is $O(n \log n)$ [30].

The number of iterations of WL^k is crucial for the parallelisability of the algorithm: for $\ell \geq \log n$, it holds that ℓ iterations of WL^k can be simulated in $O(\ell)$ steps on a PRAM with $O(n^k)$ processors [21, 29]. In particular, if for a class $\mathcal{C}$ of graphs, all $G, G' \in \mathcal{C}$ (of order n) can be distinguished by WL^k in $O(\log n)$ iterations, then the isomorphism problem for graphs in $\mathcal{C}$ is in the complexity class AC^1. Grohe and Verbitsky [21] proved that this is the case for all classes of graphs of bounded tree width and all maps (graphs embedded into a surface together with a rotation system specifying the embedding), and Verbitsky [36] proved it for the class of 3-connected planar graphs.

Our results

We say that WL^k distinguishes two graphs *in ℓ iterations* if the colouring obtained by WL^k in the ℓ-th iteration differs among the two graphs, and we say WL^k identifies a graph *in ℓ iterations* if it distinguishes the graph from every non-isomorphic graph in ℓ iterations.

▶ **Theorem 1.** *There is a constant k such that WL^k identifies every n-vertex planar graph in $O(\log n)$ iterations.*

The correspondence between WL^k and the logic C^{k+1} can be refined to a correspondence between the number of iterations and the quantifier depth: WL^k assigns the same colour to two k-tuples of vertices in the ℓ-th iteration if and only if these two k-tuples satisfy the same C^{k+1}-formulas of quantifier depth ℓ. Thus, the following theorem is equivalent to Theorem 1.

▶ **Theorem 2.** *There is a constant k such that for every n-vertex planar graph G, there is a C^k-sentence of quantifier depth $O(\log n)$ that identifies G (that is, characterises G up to isomorphism).*

We exploit the logical characterisation of the WL algorithm in our proof, so it is actually Theorem 2 that we prove. We first show that every planar graph G has a tree decomposition of logarithmic height where each bag consists of at most four 3-connected components of G and the adhesion is at most 6. Then we inductively construct a formula to identify G by ascending through the tree, encoding all information about isomorphism types of the parsed subgraphs in subformulas. At each node of the tree, we use Verbitsky's result to deal with the 3-connected components.

2 Preliminaries

All graphs in this paper are finite, simple, and undirected. For a graph G, we denote by $V(G)$ and $E(G)$ its set of vertices and edges, respectively. The *order* of G is $|G| \coloneqq |V(G)|$. We write edges without parenthesis, as in vw. For $v \in V(G)$, we let $N_G(v) \coloneqq \{w \mid vw \in E(G)\}$.

A *subgraph* of G is a graph H with $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. We set $N_G(H) \coloneqq \bigcup_{v \in V(H)} N_G(v) \setminus V(H)$. We call a graph H a *topological subgraph* of G if a subdivision of H (i.e., a graph obtained from H by replacing some edges with paths) is a subgraph of G. For $W \subseteq V(G)$, we let $G[W] \coloneqq (W, E(G) \cap \{uv \mid u, v \in W\})$ and, for arbitrary sets W, we let $G \setminus W \coloneqq G[V(G) \setminus W]$.

A graph G is *k-connected* if $|G| > k$ and there is no set $S \subseteq V(G)$ with $|S| \leq k-1$ such that $G \setminus S$ is disconnected.

2.1 Logic

We denote by C the extension of first-order logic FO by *counting quantifiers* $\exists^{\geq m} x$ with the obvious meaning. C is only a syntactical extension of FO, because $\exists^{\geq m} x \varphi(x)$ is equivalent to $\exists x_1 \dots \exists x_m \Big(\bigwedge_{i \neq j} x_i \neq x_j \wedge \bigwedge_i \varphi(x_i) \Big)$. However, we are mainly interested in the fragments C^k of C consisting of all formulae with at most k variables (which can, however, be reused within the formula). If $m > k$, then $\exists^{\geq m} x$ cannot be expressed in the k-variable fragment of FO, this is why we add the counting quantifiers.

We write $\varphi(x_1, \dots, x_\ell)$ to indicate that the free variables of φ are among $x_1, \dots, x_\ell$. Then for a graph G and vertices $u_1, \dots, u_\ell \in V(G)$, we write $G \models \varphi(u_1, \dots, u_\ell)$ to denote that G satisfies φ if, for all i, the variable x_i is interpreted by u_i. Moreover, we write $\varphi[G, u_1, \dots, u_i, x_{i+1}, \dots, x_\ell]$ to denote the set of all $(\ell - i)$-tuples $(u_{i+1}, \dots, u_\ell)$ such that $G \models \varphi(u_1, \dots, u_\ell)$.

The *quantifier depth* $\operatorname{qd}(\varphi)$ of a formula $\varphi \in \mathsf{C}$ is its depth of quantifier nesting. More formally,

- if φ is atomic, then $\operatorname{qd}(\varphi) = 0$.
- $\operatorname{qd}(\neg\varphi) = \operatorname{qd}(\varphi)$.
- $\operatorname{qd}(\varphi_1 \vee \varphi_2) = \operatorname{qd}(\varphi_1 \wedge \varphi_2) = \max\{\operatorname{qd}(\varphi_1), \operatorname{qd}(\varphi_2)\}$.
- $\operatorname{qd}(\exists^{\geq p} x \varphi) = \operatorname{qd}(\varphi) + 1$.

We denote the set of all C^k-formulas of quantifier depth at most ℓ by C^k_ℓ.

It will often be convenient to use asymptotic notation, such as $\mathsf{C}^{O(1)}_{O(\log n)}$. The parameter n always refers to the order of the input graph, and we will typically make assertions such as: *For every n, there exists a $\mathsf{C}^{O(1)}_{O(\log n)}$-formula $\varphi^{(n)}(x)$ such that for all graphs G of order $|G| = n$ and all $v \in V(G)$, [something holds].* What this means is that *there is a constant k and a function $\ell(n) \in O(\log n)$ such that for every n, there exists a $\mathsf{C}^k_{\ell(n)}$-formula $\varphi^{(n)}(x)$ such that for all graphs G of order $|G| = n$ and all $v \in V(G)$, [something holds].*

Throughout this paper, we will have to express properties of graphs and their vertices using $\mathsf{C}^{O(1)}_{O(\log n)}$-formulas. The basic building blocks that we use are connectivity statements with formulas of logarithmic quantifier depth, as illustrated in the following example.

▶ **Example 3.** For every $k \geq 0$, we define a $\mathsf{C}^3_{\lceil \log n \rceil}$-formula $\mathsf{dist}_{\leq k}$ such that for every graph G of order at most n and all vertices $u, u' \in V(G)$, it holds that $G \models \mathsf{dist}_{\leq k}(u, u')$ if and only if u and u' have distance at most k in G. We let

$$\mathsf{dist}'_{\leq k}(x, x') \coloneqq \begin{cases} x = x' & \text{if } k = 0 \\ E(x, x') \vee x = x' & \text{if } k = 1 \\ \exists y_k \big(\mathsf{dist}'_{\leq \lfloor \frac{k}{2} \rfloor}(x, y_k) \wedge \mathsf{dist}'_{\leq \lceil \frac{k}{2} \rceil}(y_k, x') \big) & \text{otherwise.} \end{cases}$$

Thus, for $k \leq n$, the quantifier depth of $\mathsf{dist}'_{\leq k}$ is bounded by $\lceil \log n \rceil$. Now, it suffices to note that we can actually get by with the three variables x, x', y_k by reusing them in the subformulas that are defined inductively. We hence obtain the desired $\mathsf{C}^3_{\lceil \log n \rceil}$-formula $\mathsf{dist}_{\leq k}$. Note that, for $k \geq 1$, the $\mathsf{C}^3_{\lceil \log n \rceil}$-formula $\mathsf{dist}_{=k}(x, x') \coloneqq \mathsf{dist}_{\leq k}(x, x') \wedge \neg \mathsf{dist}_{\leq k-1}(x, x')$ states that x and x' have distance exactly k. Moreover, in every graph of order at most n, the $\mathsf{C}^3_{\lceil \log n \rceil}$-formula $\mathsf{comp}(x, x') \coloneqq \mathsf{dist}_{\leq n-1}(x, x')$ states that x and x' lie in the same connected component and the $\mathsf{C}^3_{\lceil \log n \rceil}$-sentence $\mathsf{conn}_n \coloneqq \forall x \forall x' \mathsf{dist}_{\leq n-1}(x, x')$ states that the graph is connected. ⌟

2.2 The WL Algorithm

We briefly review the WL algorithm. For details, we refer to the recent survey [24].

Let $k \geq 1$. The *atomic type* $\mathrm{atp}(G, \bar{u})$ of a k-tuple $\bar{u} = (u_1, \ldots, u_k)$ of vertices of a graph G is the set of all atomic facts satisfied by these vertices, that is, all adjacencies and equalities between the vertices. Hence, tuples $\bar{u} = (u_1, \ldots, u_k)$ and $\bar{v} = (v_1, \ldots, v_k)$ of vertices of graphs G, H, respectively, have the same atomic type if and only if the mapping $u_i \mapsto v_i$ is an isomorphism from the graph $G[\{u_1, \ldots, u_k\}]$ to $H[\{v_1, \ldots, v_k\}]$.

The algorithm WL^k (the *k-dimensional Weisfeiler-Leman algorithm*) takes a graph G as input and computes the following sequence of *colourings* wl^k_i of $V(G)^k$ for $i \geq 0$, until it returns $\mathsf{wl}^k_\infty \coloneqq \mathsf{wl}^k_i$ for the smallest i such that, for all $\bar{u}, \bar{v}$, it holds that $\mathsf{wl}^k_i(\bar{u}) = \mathsf{wl}^k_i(\bar{v}) \iff \mathsf{wl}^k_{i+1}(\bar{u}) = \mathsf{wl}^k_{i+1}(\bar{v})$. Set $\mathsf{wl}^k_0(\bar{u}) \coloneqq \mathrm{atp}(G, \bar{u})$. In the $(i+1)$-st *iteration*, the colouring wl^k_{i+1} is defined by $\mathsf{wl}^k_{i+1}(\bar{u}) \coloneqq \big(\mathsf{wl}^k_i(\bar{u}), M_i(\bar{u})\big)$, where, for $\bar{u} = (u_1, \ldots, u_k)$, we let $M_i(\bar{u})$ be the multiset

$$\Big\{\!\!\Big\{ \big(\mathrm{atp}(G, (u_1, \ldots, u_k, v)), \mathsf{wl}^k_i(u_1, \ldots, u_{k-1}, v), \\ \mathsf{wl}^k_i(u_1, \ldots, u_{k-2}, v, u_k), \ldots, \mathsf{wl}^k_i(v, u_2, \ldots, u_k) \big) \mid v \in V \Big\}\!\!\Big\}$$

The algorithm WL^k *distinguishes* two graphs G, H *in ℓ iterations* if there is a colour c in the range of wl^k_ℓ such that the number of tuples $\bar{u} \in V(G)^k$ with $\mathsf{wl}^k_\ell(\bar{u}) = c$ is different from the number of tuples $\bar{v} \in V(H)^k$ with $\mathsf{wl}^k_\ell(\bar{v}) = c$. In this case, we say WL^k_ℓ *distinguishes G and H*. Moreover, WL^k_ℓ *identifies* G if it distinguishes G from all graphs H that are not isomorphic to G.

▶ **Theorem 4** ([5, 22])**.** *Let $k \in \mathbb{N}$. Let G and H be graphs with $|G| = |H|$ and let $\bar{u} \coloneqq (u_1, \ldots, u_k) \in V(G)^k$ and $\bar{v} \coloneqq (v_1, \ldots, v_k) \in V(H)^k$. Then, for all $i \in \mathbb{N}$, the following are equivalent.*

1. $\mathsf{wl}^k_i(\bar{u}) = \mathsf{wl}^k_i(\bar{v})$.
2. $G \models \varphi(u_1, \ldots, u_k) \iff H \models \varphi(v_1, \ldots, v_k)$ *holds for every C^{k+1}_i-formula $\varphi(x_1, \ldots, x_k)$.*

3 3-Connected Planar Graphs

Verbitsky [36] proved that $\mathsf{WL}^{O(1)}_{O(\log n)}$ distinguishes any two 3-connected planar graphs. Before we discuss the specific version of this result that we need here, let us briefly review some background on planar graphs. Intuitively, a *plane graph* is a graph drawn into the plane with no edges crossing. A *planar graph* is an abstract graph G isomorphic to a plane graph; an isomorphism from G to a plane graph is a *planar embedding* of G. Now suppose G is a plane graph. If we cut the plane along all edges of the graph, the pieces that remain are the *faces* of G (note that one of these faces is unbounded). The closed walk along the vertices and edges in the boundary of a face is the *facial walk* associated with this face. If G is 2-connected, then every facial walk is a cycle. If G is 3-connected, we can describe the facial cycles combinatorially: a cycle C is a facial cycle of G if and only if C is an induced subgraph of G and $G \setminus V(C)$ is connected. (This is the statement of *Whitney's Theorem* [38].) This implies that all planar embeddings of a 3-connected planar graph have the same facial cycles, which can be interpreted as saying that, combinatorially, all planar embeddings of the graph are the same. Another way of describing a planar embedding combinatorially is by specifying, for each vertex, the cyclic order in which the edges incident to this vertex appear. This is what is known as a *rotation system*. It is easy to see that a rotation system determines all facial walks, and, conversely, the facial walks determine the rotation system. One last fact that we need to know about plane graphs is *Euler's formula*: if G is a connected plane graph with n vertices, m edges, and f faces, then $n - m + f = 2$. (For details and more background, we refer the reader to [9].)

Let us now turn to the version of Verbitsky's theorem about 3-connected planar graphs that we need here. It says that, in a 3-connected planar graph, we can find three vertices such that once these vertices are fixed, we can identify every other vertex by a $\mathsf{C}^{O(1)}_{O(\log n)}$-formula.

▶ **Theorem 5** ([36]). *Let $n \in \mathbb{N}$ and let G be a 3-connected planar graph of order $|G| \leq n$ and $v_1v_2 \in E(G)$. Then there is a $v_3 \in N_G(v_2)$ and for every $w \in V(G)$ a $\mathsf{C}^{O(1)}_{O(\log n)}$-formula $\mathsf{id}_w(x_1, x_2, x_3, y)$ such that $G \models \mathsf{id}_w(v_1, v_2, v_3, w)$ and $G \not\models \mathsf{id}_w(v_1, v_2, v_3, w')$ for all $w' \in V(G) \setminus \{w\}$.*

The key step in Verbitsky's proof is to define the rotation system underlying the unique planar embedding of a 3-connected planar graph. To state this formally, we use the terminology of [13, 15]. An *angle* of a plane graph G *at* a vertex v is a triple (w, v, w') of vertices such that vw and vw' are successive edges in a facial walk of G. Two angles (v_1, v_2, v_3) and (w_1, w_2, w_3) are *aligned* if $w_1 = v_2$ and $w_2 = v_3$ and both angles appear in the same facial walk. Observe that, if we know all angles at a vertex v, we can define the cyclic permutation of the edges incident with v induced by the embedding. If we know all angles of G and the alignment relation between them, we can define the rotation system. By Whitney's Theorem, all planar embeddings of a 3-connected planar graph G have the same angles; we call them *the angles of* G. Similarly, we can define abstractly if two angles of a 3-connected planar graph are aligned.

▶ **Lemma 6** ([36]). *There are $\mathsf{C}^{O(1)}_{O(\log n)}$-formulas $\mathsf{ang}^{(n)}(x_1, x_2, x_3)$ and $\mathsf{aln}^{(n)}(x_1, x_2, x_3, x_4)$ such that for all 3-connected planar graphs G of order $|G| = n$ and all $v_1, v_2, v_3, v_4 \in V(G)$, we have*

$$G \models \mathsf{ang}^{(n)}(v_1, v_2, v_3) \iff (v_1, v_2, v_3) \text{ is an angle of } G,$$
$$G \models \mathsf{aln}^{(n)}(v_1, \ldots, v_4) \iff (v_1, v_2, v_3), (v_2, v_3, v_4) \text{ are aligned angles of } G.$$

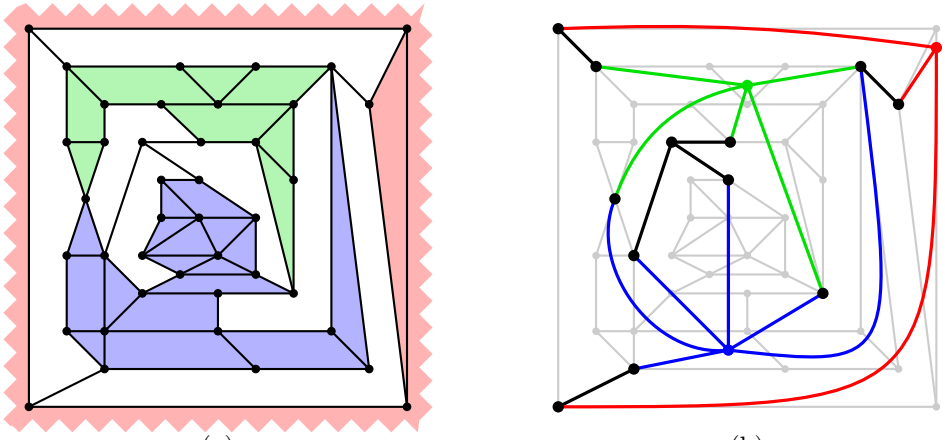

Figure 1 Defining the faces of a 3-connected planar graph: (a) shows a 3-connected planar graph G with 3 regions formed by faces with at most 6 edges in their boundary; (b) shows the derived graph $G^{(1)}$; the faces of $G^{(1)}$ are in one-to-one correspondence to the white faces of G.

This lemma is an easy consequence of the results in [36, Section 4]. The terminology there is different, the notion corresponding to (aligned) angles is that of a *layout system*. Verbitsky's proof is based on a careful (and tedious) analysis of how two paths between the neighbours of a vertex may intersect.

To give the reader some intuition about the lemma, we sketch an alternative proof, which is based on ideas from [14] (also see [15, Section 10.4]). Let G be a 3-connected planar graph, and let us think of G as being embedded in the plane. It follows from Euler's formula that in every plane graph of minimum degree 3, a constant fraction of the edges is contained in facial walks of length at most 6. Using Whitney's Theorem, we can define the set of all 6-tuples that determine a facial cycle of length at most 6 using a C^9-formula of logarithmic quantifier depth. This gives us all the angles associated with these cycles and the alignment relation on these angles. The faces corresponding to these facial cycles of size at most 6 can be partitioned into *regions*, where two faces belong to the same region if their boundaries share an edge (see Figure 1(a)).

We define a new graph $G^{(1)}$ as follows: for every region R of G, we delete all vertices contained in the interior of R, all vertices on the boundary of R that have no neighbours outside the region, and all edges that are either in the interior or on the boundary of the region. Then we add a fresh vertex v_R and edges from v_R to all vertices that remain in the boundary of the region R (see Figure 1(b)). Each face of $G^{(1)}$ corresponds to a face of G that we have not found yet. Applying Euler's formula again, we can prove that a constant fraction of the edges of G that remain edges of $G^{(1)}$ are contained in facial walks of $G^{(1)}$ that contain at most six vertices of degree ≥ 3. We can define the facial walks of the corresponding edges in G, again using Whitney's Theorem to test if a cycle is facial. Note that, for this, we do not need $G^{(1)}$ to be 3-connected (in general, it is not); we always define facial cycles in the original graph G. The new facial cycles together with those found in the first step give us new regions (covering more faces of G), and from these, we construct a graph $G^{(2)}$. Iterating the construction, we obtain a sequence of graphs $G^{(i)}$. The construction stops once we have found all facial walks of G. Since we always use a constant fraction of the edges, this happens after at most logarithmically many iterations. This completes our proof sketch of Lemma 6.

Proof of Theorem 5. Let G be a 3-connected planar graph of order $|G| = n$. For angles $\overline{v} = (v_1, v_2, v_3)$, $\overline{w} = (w_1, w_2, w_3)$, we write $\overline{v} \curvearrowright \overline{w}$ if $\overline{v}, \overline{w}$ are aligned, and we write $\overline{v} \between \overline{w}$ if $w_1 = v_3$ and $w_2 = v_2$ and $w_3 \neq v_1$. Note that, for every angle $\overline{v}$, there is a unique $\overline{w}$ such that $\overline{v} \curvearrowright \overline{w}$, because, by the 3-connectedness of G, every angle is in the boundary of a unique face, and the aligned angle belongs to the same face. There is also a unique $\overline{w}'$ such that $\overline{v} \between \overline{w}'$, determined by the cyclic order of the edges and faces around a vertex. An *angle walk* is a sequence $\overline{v}_0, \dots, \overline{v}_\ell$ of angles such that for all $i \in [\ell]$, we have $\overline{v}_{i-1} \curvearrowright \overline{v}_i$ or $\overline{v}_{i-1} \between \overline{v}_i$. The *direction* of the angle walk $\overline{v}_0, \dots, \overline{v}_\ell$ is the tuple $\overline{\delta} = (\delta_1, \dots, \delta_\ell) \in \{\curvearrowright, \between\}^\ell$ such that for every $i \in [\ell]$, we have $\overline{v}_{i-1}\delta_i\overline{v}_i$. Using Lemma 6, it is straightforward to prove that for every $\overline{\delta} \in \{\curvearrowright, \between\}^{\leq n}$, there is a $\mathsf{C}^{O(1)}_{O(\log n)}$-formula $\mathsf{awalk}^{(n)}_{\overline{\delta}}(\overline{x}, \overline{y})$ such that for all $\overline{v}, \overline{w} \in V(G)^3$, we have $G \models \mathsf{awalk}^{(n)}_{\overline{\delta}}(\overline{v}, \overline{w})$ if and only if there is an angle walk of direction $\overline{\delta}$ from $\overline{v}$ to $\overline{w}$. Now let $v_1v_2 \in E(G)$. Then there is a v_3 such that (v_1, v_2, v_3) is an angle. Let $\overline{v} := (v_1, v_2, v_3)$. Note that, for every $w \in V(G) \setminus \{v_1, v_2, v_3\}$, there is an angle walk of length at most n from $\overline{v}$ to some $\overline{w} = (w_1, w_2, w_3)$ with $w_3 = w$, simply because every path in G can be extended to an angle walk. Let $\Delta(w)$ be the set of all directions $\overline{\delta}$ of length at most n such that there is an angle walk of direction $\overline{\delta}$ from $\overline{v}$ to some $\overline{w} = (w_1, w_2, w_3)$ with $w_3 = w$. Note that the sets $\Delta(w)$ for $w \in V(G) \setminus \{v_1, v_2, v_3\}$ are mutually disjoint. Let $\mathsf{id}_{\overline{\delta}}(x_1, x_2, x_3, y) := \exists y_1 \exists y_2 \mathsf{awalk}^{(n)}_{\overline{\delta}}(x_1, x_2, x_3, y_1, y_2, y)$. Then for $\overline{\delta} \in \Delta(w)$, we have $G \models \mathsf{id}_{\overline{\delta}}(v_1, v_2, v_3, w)$ and $G \not\models \mathsf{id}_{\overline{\delta}}(v_1, v_2, v_3, w')$ for all $w' \neq w$. ◀

4 Decomposition into Blocks

Let G be a graph. A *tree decomposition* of G is a pair (T, β) where T is a tree and $\beta \colon V(T) \to 2^{V(G)}$ is a function such that for every $v \in V(G)$, the set $\{t \in V(T) \mid v \in \beta(t)\}$ is non-empty and induces a connected subgraph in T, and for every $e \in E(G)$, there is a $t \in V(T)$ such that $e \subseteq \beta(t)$. For $t \in V(T)$, we call $\beta(t)$ a *bag* of (T, β). The *adhesion* of (T, β) is $\mathrm{ad}(T, \beta) := \max\{|\beta(t) \cap \beta(u)| \mid tu \in E(T)\}$ (or 0 if $E(T) = \emptyset$). The *width* of (T, β) is $\mathrm{wd}(T, \beta) := \max_{t \in V(T)} |\beta(t)| - 1$.

We denote the root of a rooted tree T by r^T. For better readability, if the rooted tree is referred to as T^*, we set $r^* := r^{T^*}$. The *height* of T is the maximum length of a path from r^T to a leaf of T. We denote the descendant order of T by $\trianglelefteq^T$. That is, $t \trianglelefteq^T u$ if t occurs on the path from r^T to u. A *rooted tree decomposition* is a tree decomposition where the tree is rooted.

▶ **Lemma 7** (Folklore). *Let T be a tree and $\chi \colon V(T) \to \mathbb{R}_{\geq 0}$. Then there is a node $t \in V(T)$ such that for every connected component C of $T \setminus \{t\}$, it holds that*

$$\sum_{t \in V(C)} \chi(t) \leq \frac{1}{2} \sum_{t \in V(T)} \chi(t).$$

Proof. Orient all edges towards the larger sum of χ-weights in the connected components that the removal of the edge would induce, breaking ties arbitrarily. There will be a node such that all incident edges are oriented towards it. This node has the desired property. ◀

The following lemma is known in its essence (for example, [11]), though we are not aware of a reference where it is stated in this precise form, which we will need later.

▶ **Lemma 8.** *Let T be a tree, and let $B \subseteq V(T)$ be a set of size $|B| \leq 3$. Then there is a rooted tree decomposition (T^*, β^*) of T with $B \subseteq \beta^*(r^*)$ and the following additional properties:*

(i) *The height of* T^* *is at most* $2\log|T|$.
(ii) *The width of* (T^*, β^*) *is at most* 3.
(iii) *The adhesion of* (T^*, β^*) *is at most* 3.
(iv) *For every* $t^* \in V(T^*)$ *and every child* u^* *of* t^**, the graph* $T\left[\left(\bigcup_{v^* \trianglerighteq^{T^*} u^*} \beta^*(v^*)\right) \setminus \beta^*(t^*)\right]$ *is connected.*

Proof. Condition (iv) is something that we can easily achieve for every rooted tree decomposition: if, for the rooted subtree at some node, the subgraph induced by the bags in this subtree is not connected, we simply create one copy of the subtree for each connected component and only keep the vertices of that connected component in the copy. Moreover, the adhesion of a tree decomposition of width 3 can only be larger than 3 if there are adjacent nodes with the same bag. If this is the case, we can simply contract the edge between the nodes. Repeating this, we can turn the decomposition into a decomposition of adhesion at most 3. So we only need to take care of Conditions (i) and (ii).

The proof is by induction on $n := |T|$. We prove a slightly stronger statement; in addition to $B \subseteq \beta^*(r^*)$, we require $|\beta^*(r^*) \setminus B| \leq 1$.

The base case $n \leq 4$ is easy: for $n = 1$, the 1-node tree decomposition of height 0 has all the desired properties, and for $2 \leq n \leq 4$, we can take a 2-node tree decomposition of height 1 where the root bag is B and the leaf bag is $V(T)$.

For the inductive step, suppose $n > 4$.

Case 1: $|B| < 3$.

By Lemma 7, there is a node $b \in V(T)$ such that for every connected component C of $T \setminus \{b\}$, it holds that $|V(C)| \leq \frac{n}{2}$.

Let $C_1, \ldots, C_m$ be the vertex sets of the connected components of $T \setminus \{b\}$. For every $i \in [m]$, let c_i be the unique neighbour of b in C_i, and let $B_i := (B \cap V(C_i)) \cup \{c_i\}$. Note that $|B_i| \leq 3$.

By the induction hypotheses, for every i, there is a rooted tree decomposition (T_i, β_i) of C_i with the desired properties. In particular, the height of T_i is at most $2\log(n/2) = 2\log n - 2$.

For every i, let r_i be the root of T_i. We form a new tree T^* by taking the disjoint union of all the T_i, adding fresh nodes r^* and r_i^* for $i \leq m$, and adding edges $r^* r_i^*$, $r_i^* r_i$ for all $i \in [m]$. We define $\beta^* \colon V(T^*) \to 2^{V(T)}$ by

$$\beta^*(t) := \begin{cases} B \cup \{b\} & \text{if } t = r^*, \\ B_i \cup \{b\} & \text{if } t = r_i^*, \\ \beta_i(t) & \text{if } t \in V(T_i). \end{cases}$$

Then (T^*, β^*) is a tree decomposition of T of width at most 3 and height at most $2\log n$.

Case 2: $|B| = 3$.

By Lemma 7 applied to the characteristic function of B, there is a node $b \in V(T)$ such that for every connected component C of $T \setminus \{b\}$, it holds that $|V(C) \cap B| \leq 1$.

Let $C_1, \ldots, C_\ell$ be the connected components of $T \setminus \{b\}$, and for every i, let $B_i := B \cap V(C_i)$. Then $|B_i| \leq 1$.

▷ Claim 9. For every $i \in [\ell]$, there is a tree decomposition (T_i, β_i) of width at most 3 such that the height of T_i is at most $2\log n - 1$ and for the root r_i of T_i it holds that $B_i \subseteq \beta_i(r_i)$ and $|\beta(r_i)| \leq 2$.

Proof. Let $\in [\ell]$ and $n_i := |C_i|$. By Lemma 7, there is a $c \in V(C_i)$ such that for every connected component D of $C_i \setminus \{c\}$, it holds that $|D| \leq n_i/2$. Choose such a c and let $D_1, \ldots, D_m$ be the connected components of $C_i \setminus \{c\}$. For every $j \in [m]$, let d_j be the unique neighbour of c in D_j. Let $B_{ij} := (B_i \cap D_j) \cup \{d_j\}$. Then $|B_{ij}| \leq 2$.
By the induction hypotheses, for every j, there is a rooted tree decomposition (T_{ij}, β_{ij}) of D_j of width 3 such that the height of T_{ij} is at most $2 \log |D_i| \leq 2 \log(n_i/2) \leq 2 \log n - 2$. Furthermore, for the root r_{ij} of T_{ij}, it holds that $B_{ij} \subseteq \beta_{ij}(r_{ij})$ and $|\beta_{ij}(r_{ij}) \setminus B_{ij}| \leq 1$. This implies $|\beta_{ij}(r_{ij})| \leq 3$.
We form a new tree T_i by taking the disjoint union of all the T_{ij} for $j \in [m]$, adding a fresh node r_i, and adding edges r_{ij} for all $j \in [m]$. We define $\beta_i \colon V(T_i) \to 2^{V(C_i)}$ by

$$\beta_i(t) := \begin{cases} B_i \cup \{c\} & \text{if } t = r_i, \\ \beta_{ij}(r_{ij}) \cup \{c\} & \text{if } t = r_{ij}, \\ \beta_{ij}(t) & \text{if } t \in V(T_{ij}) \setminus \{r_{ij}\}. \end{cases}$$

Then (T_i, β_i) is a tree decomposition of C_i with the desired properties. ◁

To complete the proof of the lemma, we form a new tree T^* by taking the disjoint union of the T_i of Claim 9 for $i \in [\ell]$, adding a fresh node r^*, and adding edges $r^* r_i$ for all $i \in [\ell]$. We define $\beta^* \colon V(T^*) \to 2^{V(T)}$ by

$$\beta^*(t) := \begin{cases} B \cup \{b\} & \text{if } t = r^*, \\ \beta(r_i) \cup \{b\} & \text{if } t = r_i, \\ \beta_i(t) & \text{if } t \in V(T_i) \setminus \{r_i\}. \end{cases}$$

Then (T^*, β^*) is a tree decomposition of T of width at most 3 and height at most $2 \log n$. ◀

Let us now turn to decompositions of a graph into its 3-connected components. We need a few more definitions. In the following, let G be a connected graph and $X \subseteq V(G)$. The *torso* of X is the graph $G[\![X]\!]$ with vertex set X and edge set

$$\left\{ vw \in \binom{X}{2} \;\middle|\; vw \in E(G) \text{ or } v, w \in N_G(C) \text{ for some connected component } C \text{ of } G \setminus X \right\}.$$

The *adhesion* of X is the maximum of $|N_G(C)|$ for all connected components C of $G \setminus X$. It is easy to see that if the adhesion of X is at most 2, then the torso $G[\![X]\!]$ is a topological subgraph of G and if the adhesion of X is at most 1, then the torso $G[\![X]\!]$ is just the induced subgraph $G[X]$.

A *block*[1] of G is a set $B \subseteq V(G)$ such that

- either $G[\![B]\!]$ is 3-connected and the adhesion of B is at most 2,
- or $G[\![B]\!]$ is a complete graph of order 3 and the adhesion of B is at most 2,
- or $G[\![B]\!]$ is a complete graph of order 2 and the adhesion of B is at most 1.

We call blocks with 3-connected torsos *proper blocks* and blocks of cardinality at most 3 *degenerate blocks* of *order* 3 and 2, respectively. It is easy to see that for distinct blocks B, B', neither $B \subseteq B'$ nor $B' \subseteq B$ holds and, furthermore, $|B \cap B'| \leq 2$. A *block separator*

[1] Our usage of the term "block" is non-standard. If anything, what we call a "block" might better be called "2-block". But just using "block" is more convenient.

is a set $S \subseteq V(G)$ such that there are distinct blocks B, B' with $S = B \cap B'$, and the two sets $B \setminus S$ and $B' \setminus S$ belong to different connected components of $G \setminus S$. Note that by the definition of blocks, block separators have cardinality at most 2.

Observe that the torsos of all blocks of a graph are topological subgraphs. As all topological subgraphs of a planar graph are planar, the torsos of the blocks of a planar graph are planar. In particular, the torsos of proper blocks are 3-connected planar graphs. This will be important later.

Call a tree decomposition (T, β) *small* if for all distinct nodes $t, u \in V(T)$, it holds that $\beta(t) \not\subseteq \beta(u)$.

▶ **Lemma 10** ([35]). *Every connected graph G has a small tree decomposition (T, β) of adhesion at most 2 such that for all $t \in V(T)$, the bag $\beta(t)$ is a block of G.*

The decomposition in this lemma is essentially Tutte's well-known decomposition of a graph into its 3-connected components described in a slightly non-standard way. The two main differences are that, normally, the decomposition is only described for 2-connected graphs, whereas arbitrary connected graphs are first decomposed into their 2-connected components. We merge these decompositions into one. The second difference is that Tutte decomposes a 2-connected graph into 3-connected pieces (our proper blocks) and cycles. Instead of cycles, we only allow triangles, i.e., degenerate blocks of order 3. This is possible because every cycle can be decomposed into triangles. What we lose with our form of decomposition is the canonicity: a graph may have several structurally different decompositions of the form described in the lemma.

In the following, we apply Lemma 8 to the tree of the decomposition of Lemma 10 and obtain a decomposition of logarithmic height that is still essentially a decomposition into 3-connected components.

▶ **Lemma 11.** *Every connected graph G has a rooted tree decomposition (T^*, β^*) with the following properties.*

- **(i)** *The height of T^* is at most $2 \log |G|$.*
- **(ii)** *For every $t^* \in V(T^*)$, there are sets $B_1, \dots, B_4$ (not necessarily distinct or disjoint) such that $\beta^*(t^*) = \bigcup_{i=1}^{4} B_i$ and each B_i is either a block or a block separator.*
- **(iii)** *The adhesion of (T^*, β^*) is at most 6.*
- **(iv)** *For every $t^* \in V(T^*)$ and every child u^* of t^*, the induced subgraph*

$$G\left[\Big(\bigcup_{v^* \trianglerighteq^{T^*} u^*} \beta^*(v^*)\Big) \setminus \beta^*(t^*)\right]$$

is connected.

Proof. Let (T, β) be the decomposition of G into its blocks obtained from Lemma 10. Let (T^*, β^*_T) be the rooted tree decomposition of T obtained from Lemma 8. Let r^* be the root of T^*, and let $\trianglelefteq^* := \trianglelefteq^{T^*}$ be the partial descendant order associated with T^*. For every $t^* \in V(T^*)$, let

$$\gamma^*_T(t^*) := \bigcup_{u^* \trianglerighteq^* t^*} \beta^*_T(u^*)$$

and

$$\sigma^*_T(t^*) := \begin{cases} \emptyset & \text{if } t^* = r^*, \\ \beta^*_T(s^*) \cap \beta^*_T(t^*) & \text{for the parent } s^* \text{ of } t^* \text{ in } T^*, \text{ otherwise}. \end{cases}$$

For every $t \in V(T)$, we let $\min^*(t)$ be the unique $\trianglelefteq^*$-minimal node $t^* \in V(T^*)$ such that $t \in \beta_T^*(t^*)$. The uniqueness follows from the fact that the set of all $t^* \in V(T^*)$ with $t \in \beta_T^*(t^*)$ is connected in T^*.

Let us call $t \in V(T)$ *active* in $t^* \in V(T^*)$ if $t \in \beta_T^*(t^*)$ and $t^* \neq \min^*(t)$ and there is a $u \in N_T(t)$ such that $t^* \trianglelefteq \min^*(u)$. We call u an *activator* of t in t^*.

▷ Claim 12. Suppose that $t \in V(T)$ is active in $t^* \in V(T^*)$. Then there is a unique activator of t in t^*.

Proof. Since $t \in \beta_T^*(t^*)$ and $t^* \neq \min^*(t)$, we have $\min^*(t) \triangleleft t^*$ and $t \in \beta_T^*(\min^*(t)) \cap \beta_T^*(t^*) \subseteq \sigma_T^*(t^*)$. Moreover, for every activator u of t, it holds that $t^* \trianglelefteq \min^*(u)$, which implies $u \in \gamma_T^*(t^*) \setminus \sigma_T^*(t^*)$.

Suppose towards a contradiction that t has two activators u_1, u_2 in t^*. Then $u_1, u_2 \in N_T(t) \cap \big(\gamma_T^*(t^*) \setminus \sigma_T^*(t^*)\big)$. By Lemma 8(iv), the induced subgraph $T[\gamma_T^*(t^*) \setminus \sigma_T^*(t^*)]$ is connected. Thus, there is a path from u_1 to u_2 in $T[\gamma_T^*(t^*) \setminus \sigma_T^*(t^*)]$. As $u_1, u_2 \in N_T(t)$ and $t \in \sigma_T^*(t^*)$, there is a cyle in T, which is a contradiction. ◁

Hence, in the following we can speak of *the* activator of a node. Observe that if t is active in t^*, then t is also active in all u^* with $\min^*(t) \triangleleft u^* \triangleleft t^*$, with the same activator.

Now we are ready to define our tree decomposition (T^*, β^*) of G. The tree T^* is the same as in the decomposition (T^*, β_T^*) of T. We define $\beta^* \colon V(T^*) \to 2^{V(G)}$ by letting $\beta^*(t^*)$ for $t^* \in V(T^*)$ be the union of the following sets:

- for all $t \in \beta_T^*(t^*)$ such that $t^* = \min^*(t)$: the block $\beta(t)$, and
- for all $t \in \beta_T^*(t^*)$ such that t is active in t^* with activator u: the block separator $\beta(t) \cap \beta(u)$.

▷ Claim 13. (T^*, β^*) is a tree decomposition of G.

Proof. Every edge $e \in E(G)$ is contained in some bag $\beta(t)$, and $\beta(t) \subseteq \beta^*(\min^*(t))$.

Now consider a vertex $v \in V(G)$. Let

$$S_v \coloneqq \{t \in V(T) \mid v \in \beta(t)\},$$
$$S_v^* \coloneqq \{t^* \in V(T^*) \mid S_v \cap \beta_T^*(t^*) \neq \emptyset\}.$$

Since (T, β) is a tree decomposition, S_v is connected in T, and as (T^*, β_T^*) is a tree decomposition, S_v^* is connected in T^*. Thus, there is a unique $\trianglelefteq^*$-minimal node s^* in S_v^*. Let $s \in S_v \cap \beta_T^*(s^*)$. Then $s^* = \min^*(s)$ and therefore $v \in \beta^*(s^*)$.

Let $t^* \in V(T^*)$ such that $v \in \beta^*(t^*)$. We shall prove that $v \in \beta^*(v^*)$ for all v^* on the path from t^* to s^*. This will prove that the set of all t^* for which $v \in \beta^*(t^*)$ holds is connected in T^*.

By the definition of β^*, since $v \in \beta^*(t^*)$, there is a $t \in \beta_T^*(t)$ such that $v \in \beta(t)$ and either $t^* = \min^*(t)$ or t is active in t^*. We choose such a t. Then $t \in S_v$ and therefore $t^* \in S_v^*$. By the minimality of s^*, this implies $s^* \trianglelefteq^* t^*$.

The proof that $v \in \beta^*(v^*)$ holds for all v^* on the path from t^* to s^* is by induction on the distance d between t^* and s^*. The base case $d = 0$ is trivial. So let us assume that $d \geq 1$. It follows from the definition of β^* that $v \in \beta^*(v^*)$ holds for all v^* on the path from t^* to $\min^*(t)$. Thus, without loss of generality, we may assume that $t^* = \min^*(t)$.

Let $t = t_1, \ldots, t_m = s$ be the path from t to s in T. Note that $v \in \beta(t_i)$ holds for all $i \in [m]$. The edge $tt_2 = t_1t_2$ must be covered by some bag $\beta_T^*(u^*)$ that contains both t and t_2. Since $t^* = \min^*(t)$, we have $t^* \trianglelefteq^* u^*$. As the pre-image of the path $t_1, \ldots, t_m$ in T^* is connected and $s^* \trianglelefteq^* t^* \trianglelefteq^* u^*$, there is an $i > 1$ such that $t_i \in \beta^*(t^*)$. If $\min^*(t_i) = t^*$, we find a $j > i$ such that $t_j \in \beta^*(t)$, and, repeating this, we eventually arrive at a $t_k \in \beta^*(t)$ such

that $\min^*(t_k) \lhd t^*$. Arguing as above, we find that $v \in \beta^*(v^*)$ holds for all v^* on the path from t^* to $\min^*(t_k)$. Since $\min^*(t_k)$ is closer to s^* than t^*, we can now apply the induction hypothesis to conclude that $v \in \beta^*(v^*)$ holds for all v^* on the path from $\min^*(t_k)$ to s^*. ◁

Let us turn to proving that the tree decomposition (T^*, β^*) has the desired properties.

Since (T, β) is a small decomposition, we have $|T| \leq |G|$. Thus, Condition (i) follows from Lemma 8(i). Also, Condition (ii) follows from Lemma 8(ii) and the definition of $\beta^*(t)$.

To prove Condition (iii), let u^* be a child of t^*. Let us assume that $\beta^*_T(t^*) = \{t_1, \dots, t_4\}$ and $\beta^*_T(u^*) = \{u_1, \dots, u_4\}$ with $t_1 = u_1, t_2 = u_2$, and $t_3 = u_3$ and $t_4 \neq u_i, u_4 \neq t_i$ for $i \in [4]$. The cases of smaller bags $\beta^*_T(t^*)$, $\beta^*_T(u^*)$ or a smaller intersection between them can be dealt with similarly.

Let us first deal with the common elements $t_i = u_i$ for $i \in [3]$. Note that $\min^*(t_i) \trianglelefteq t^* \lhd u^*$. If t_i is not active in u^*, then it does not contribute to the $\beta^*(u^*)$ and hence not to the intersection of the two bags. If t_i is active in u^*, say, with activator v_i, then the block separator $S_i \coloneqq \beta(t_i) \cap \beta(v_i)$ is contained in $\beta^*(u^*)$. To simplify the notation, in the following, we let $S_i \coloneqq 0$ if t_i is not active in u^*.

Either t_i is active in t^* as well with the same activator and we have $S_i \subseteq \beta^*(t^*)$, or $t^* = \min^*(t_i)$ and $S_i \subseteq \beta(t_i) \subseteq \beta^*(t^*)$. In both cases,

$$S_i \subseteq \beta^*(t^*) \cap \beta(u^*). \tag{1}$$

Next, let us look at the contribution of t_4 and u_4. The contribution of t_4 to $\beta^*(t^*)$ is contained in $\beta(t_4)$, and the contribution of u_4 to $\beta^*(u^*)$ is contained in $\beta(u_4)$. Since the only neighbour of t_i in $\gamma^*_T(u^*) \setminus \sigma^*_T(u^*) = \gamma^*_T(u^*) \setminus \{t_1, t_2, t_3\}$ is v_i (if t_i is active in u^*, otherwise there is no neighbour), all paths from t_i to u_4 go through v_i. This implies that

$$\beta(t_i) \cap \beta(u_4) \subseteq \beta(t_i) \cap \beta(v_i) = S_i. \tag{2}$$

All paths from t_4 to u_4 go through t_1, t_2, t_3, and therefore

$$\beta(t_4) \cap \beta(u_4) \subseteq \bigcup_{i=1}^{3} \beta(t_i) \cap \beta(u_4) \subseteq S_1 \cup S_2 \cup S_3. \tag{3}$$

Thus, overall, we have $\beta^*(t^*) \cap \beta^*(u^*) \subseteq S_1 \cup S_2 \cup S_3$.

To prove that Condition (iv) holds, let $t^* \in V(T^*)$ and and let u^* be a child of t^*. To simplify the notation, let $\sigma^*(u^*) \coloneqq \beta(u^*) \cap \beta^*(t^*)$ and

$$\gamma^*(u^*) \coloneqq \bigcup_{v^* \trianglerighteq u^*} \beta^*(v^*). \tag{4}$$

We need to prove that $G[\gamma^*(u^*) \setminus \sigma^*(u^*)]$ is connected. The key observation is that

$$\gamma^*(u^*) \setminus \sigma^*(u^*) = \bigcup_{t \in \gamma^*_T(u^*) \setminus \sigma^*_T(u^*)} \beta(t). \tag{5}$$

The reason for this is that, for all $t \in \gamma^*_T(u^*) \setminus \sigma^*_T(u^*)$, it holds that $u^* \trianglelefteq \min^*(t)$, which implies that $\beta(t) \subseteq \beta^*(\min^*(t))$ appears on the right-hand side of (4). It follows from Lemma 8(iv) that the set $\gamma^*_T(u^*) \setminus \sigma^*_T(u^*)$ is connected in T, and this implies that the union on the right-hand side of (5) is connected. ◀

Our next goal will be to define the decomposition in the logic $\mathsf{C}^{O(1)}_{O(\log n)}$. The following lemma yields a way to define blocks via triplets of vertices.

▶ **Lemma 14.** *Let G be a graph, and let B be a proper block of G. Let $b_1, b_2, b_3 \in B$ be pairwise distinct vertices. Then B is the set of all $v \in V(G)$ such that there is no set $S \subseteq V(G) \setminus \{v\}$ of cardinality at most 2 separating v from $\{b_1, b_2, b_3\}$.*

Proof. Let $v \in B$. Since $G[\![B]\!]$ is 3-connected, there are paths $P_i \subseteq G[\![B]\!]$ from v to b_i that are internally disjoint, that is, $V(P_i) \cap V(P_j) = \{v\}$ for $i \neq j$. As $G[\![B]\!]$ is a topological subgraph of G, these paths can be expanded to paths P'_i from v to b_i in G, and the P'_i are still internally disjoint. Since every $S \subseteq V(G) \setminus \{v\}$ of cardinality at most 2 has an empty intersection with at least one of the paths P'_i, it does not separate v from $\{b_1, b_2, b_3\}$.

Conversely, let $v \in V(G) \setminus B$, and let C be the connected component of $G \setminus B$ with $v \in V(C)$, and let $S := N_G(C)$. Then $|S| \leq 2$. Then S separates v from $\{b_1, b_2, b_2\}$. ◀

Let G be a graph and $S, X \subseteq V(G)$. We say that S *separates* X if there are two distinct connected components C_1, C_2 of $G \setminus S$ such that $X \cap V(C_i) \neq \emptyset$ for both $i = 1, 2$.

▶ **Lemma 15.** *Let G be a graph, and let $b_1, b_2, b_3 \in V(G)$ be mutually distinct. Then there is a proper block B with $b_1, b_2, b_3 \in B$ if and only if there is a vertex $b_4 \in V(G) \setminus \{b_1, b_2, b_3\}$ such that no set $S \subseteq V(G)$ of cardinality at most 2 separates $\{b_1, b_2, b_3, b_4\}$.*

Proof. For the forward direction, suppose that B is a proper block with $b_1, b_2, b_3 \in B$. Let $b_4 \in B \setminus \{b_1, b_2, b_3\}$. Then it follows from Lemma 14 that there is no S of cardinality at most 2 that separates $\{b_1, b_2, b_3, b_4\}$.

For the backward direction, let B be the set of all $v \in V(G)$ such that no set $S \subseteq V(G) \setminus \{v\}$ of cardinality at most 2 separates v from $\{b_1, b_2, b_3\}$. Then $b_1, b_2, b_3 \in B$ and $|B| \geq 4$. It is easy to prove that B is a block. ◀

▶ **Lemma 16.** *For all $n \in \mathbb{N}$, there exist $\mathsf{C}^{O(1)}_{O(\log n)}$-formulas $\mathsf{block}^{(n)}(x_1, x_2, x_3, y)$ and $\mathsf{torso}^{(n)}(x_1, x_2, x_3, y, z)$ such that for all graphs G of order at most n and all $b_1, b_2, b_3, v \in V(G)$, we have*

$$G \models \mathsf{block}^{(n)}(b_1, b_2, b_3, v)$$

if and only if one of the following holds:

- *either $\{b_1, b_2, b_3\}$ is a degenerate block and $v \in \{b_1, b_2, b_3\}$,*
- *or b_1, b_2, b_3 are mutually distinct and there is a proper block B such that $b_1, b_2, b_3, v \in B$.*

Moreover, for all $b_1, b_2, b_3, v, w \in V(G)$, we have

$$G \models \mathsf{torso}^{(n)}(b_1, b_2, b_3, v, w)$$

if and only if $G \models \mathsf{block}^{(n)}(b_1, b_2, b_3, v)$ and $G \models \mathsf{block}^{(n)}(b_1, b_2, b_3, w)$ and vw is an edge of the torso of the block determined by b_1, b_2, b_3.

Proof. It is easy to express in $\mathsf{C}^{O(1)}_{O(\log n)}$ that $\{b_1, b_2, b_3\}$ is a degenerate block. For proper blocks, we use Lemmas 14 and 15. ◀

As an immediate consequence, we obtain a formula to define a block separator.

▶ **Corollary 17.** *For all $n \in \mathbb{N}$, there exists a $\mathsf{C}^{O(1)}_{O(\log n)}$-formula $\mathsf{blocksep}^{(n)}(x_1, x_2)$ such that for all graphs G of order at most n and all $s_1, s_2 \in V(G)$, we have*

$$G \models \mathsf{blocksep}^{(n)}(s_1, s_2)$$

if and only if $\{s_1, s_2\}$ is a block separator of G.

We are ready to define the formula that yields the decomposition from Lemma 11.

▶ **Lemma 18.** *For all $h \geq 0$, $n \geq 1$, there is a $\mathsf{C}^{O(1)}_{O(h+\log n)}$-formula $\mathsf{dec}^{(n)}_h(x^j_i, y_k \mid i \in [4], j \in [3], k \in [6])$ such that the following holds. Let G be a graph of order $|G| \leq n$ and $b^j_i, s_k \in V(G)$ for $i \in [4], j \in [3], k \in [6]$ (not necessarily distinct). Then*

$$G \models \mathsf{dec}^{(n)}_h(b^j_i, s_k \mid i \in [4], j \in [3], k \in [6])$$

if and only if the following conditions are satisfied.

- **(i)** *For all $i \in [4]$, either $B_i := \{b^1_i, b^2_i, b^3_i\}$ is a block separator or $B_i := \{b^1_i, b^2_i, b^3_i\}$ is a degenerate block or b^1_i, b^2_i, b^3_i are mutually distinct and there is a (unique) block B_i that contains b^1_i, b^2_i, b^3_i.*
  Let $B := B_1 \cup \ldots \cup B_4$.
- **(ii)** *$S := \{s_1, \ldots, s_6\} \subset B$.*
- **(iii)** *There is a (unique) connected component C of $G \setminus S$ such that $B \subseteq S \cup V(C)$.*
- **(iv)** *The induced subgraph $G[S \cup V(C)]$ has a rooted tree decomposition (T^*, β^*) of height at most h with $B = \beta^*(r^*)$ for the root r^* of T^*.*
- **(v)** *The tree decomposition (T^*, β^*) satisfies Conditions* (ii)–(iv) *of Lemma 11, where all blocks are blocks of the graph G (rather than of the subgraph $G[S \cup C]$).*

Proof. The proof is by induction on $h \geq 0$.

However, before we begin the induction, we observe that using Lemma 16 and Corollary 17, we can write a formula in the variables x^j_i that expresses Condition (i). It is straightforward to express Condition (ii), and, again using Lemma 16, to express Condition (iii). So in the induction, we will focus on Conditions (iv) and (v).

For the case $h = 0$, observe that a decomposition of height 0 consists of a single node that covers the whole graph. So we need to express that for the component C we obtain in (iii), we have $V(C) \cup S = B$. Then the 1-node tree decomposition of $G[B]$ satisfies (iv) and (v).

For a 1-node decomposition, Conditions (iii) and (iv) of Lemma 11 are void, and Condition (ii) of Lemma 11 follows from Condition (i) of this lemma.

For the inductive step $h \to h+1$, suppose we have a graph G and elements b^j_i, s_k satisfying Conditions (i)–(iii) for suitable sets B, S, C. It suffices to express that for each connected component C' of $G[S \cup V(C)] \setminus B$, we can find a decomposition of height h that covers C' and attaches to B in a way that satisfies the conditions of Lemma 11.

So let $G' := G[S \cup V(C)]$, and let C' be a connected component of $G' \setminus B$. Let $S' := N_G(C')$. If $|S'| > 6$, then there definitely is no decomposition with the desired properties. Suppose that $S' = \{s'_1, \ldots, s'_6\}$. Then, if there are $b'^j_i \in S' \cup V(C')$ such that $G \models \mathsf{dec}^{(n)}_h(b'^j_i, s'_k \mid i \in [4], j \in [3], k \in [6])$, the desired decomposition that covers C' exists by the induction hypothesis. If this is the case for all C', we can combine the decompositions to form the desired decomposition of G'. Conversely, if there is a decomposition of $G[S' \cup V(C')]$ of height h in the sense of Lemma 11 such that for the root u^*, the bag $\beta^*(u^*)$ contains S', then there are blocks or block separators $B'_1, \ldots, B'_4$ such that $\beta^*(u^*) = B'_1 \cup \ldots \cup B'_4$. From the B'_i, we obtain b'^j_i such that $G \models \mathsf{dec}^{(n)}_h(b'^j_i, s'_k \mid i \in [4], j \in [3], k \in [6])$, again by the induction hypothesis.

To conclude, in addition to the subformulas taking care of Conditions (i)–(iii), the formula $\mathsf{dec}^{(n)}_{h+1}$ must have a subformula stating that, for all connected components C' of $G' \setminus B$, there exist $s'_k \in B$ for $k \in [6]$ and $b'^j_i \in S' \cup V(C')$ for $i \in [4]$, $j \in [3]$ such that $\{s'_1, \ldots, s'_6\} = N_G(C')$ and $\mathsf{dec}^{(n)}_h(b'^j_i, s'_k \mid i \in [4], j \in [3], k \in [6])$

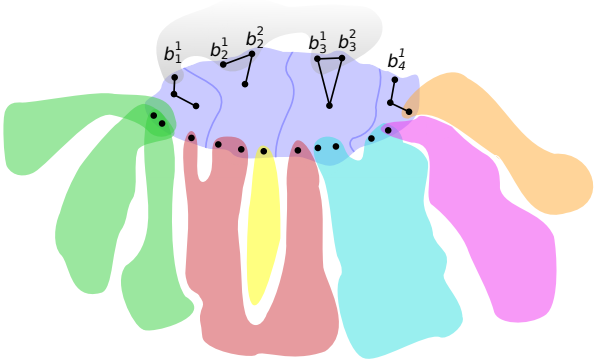

Figure 2 A (simplified) schematic visualisation of the rooted tree decomposition (T^*, β^*) from Lemma 11. For simplicity, all B_i in the bag of the purple node are depicted as distinct proper blocks.

Note that, in each step $h \to h+1$, we need to use formulas of quantifier depth $O(\log n)$ to express the desired connectivity conditions, for example to speak about components C', and to express that the b_i^j define blocks. However, the formula $\mathsf{dec}_h^{(n)}$ occurs only in the scope of constantly many (19, to be precise) quantifiers ranging over an element of the component(s) C' and the $b_i'^j, s_k'$. Overall, the quantifier depth will be $O(h) + O(\log n)$. ◀

5 Canonisation

In this section, we finally prove Theorems 1 and 2. By the logical characterisation of the WL algorithm given in Theorem 4, we obtain Theorem 1 as a corollary from Theorem 2, which we prove below.

In the following, for a graph G and a list of vertices $v_1, \dots, v_\ell \in V(G)$, we denote by $(G, v_1, \dots, v_\ell)$ the graph G with *individualised* vertices $v_1, \dots, v_\ell$. That is, $(G, v_1, \dots, v_\ell)$ and $(G', v_1', \dots, v_{\ell'}')$ have the same isomorphism type if and only if $\ell = \ell'$ and there is an isomorphism from G to G' that maps v_i to v_i' for every $i \in [\ell]$.

▶ **Lemma 19.** *For all $h \geq 0$, $n \geq 1$ and all connected planar graphs G of order $|G| \leq n$, and all $b_i^j, s_k \in V(G)$ for $i \in [4], j \in [3], k \in [6]$ (not necessarily distinct) such that*

$$G \models \mathsf{dec}_h^{(n)}(b_i^j, s_k \mid i \in [4], j \in [3], k \in [6]),$$

there is a $\mathsf{C}^{O(1)}_{O(h+\log n)}$-formula $\mathsf{iso}_h^{(n)}(x_i^j, y_k \mid i \in [4], j \in [3], k \in [6])$ (which depends on the b_i^j and the s_k) such that the following holds. Let H be a connected graph of order $|H| \leq n$ and $b_i'^j, s_k' \in V(H)$ for $i \in [4], j \in [3], k \in [6]$ (not necessarily distinct) and assume $H \models \mathsf{dec}_h^{(n)}(b_i'^j, s_k' \mid i \in [4], j \in [3], k \in [6])$. Then

$$H \models \mathsf{iso}_h^{(n)}(b_i'^j, s_k' \mid i \in [4], j \in [3], k \in [6])$$

if and only if for the connected components C_G, C_H that Lemma 18 yields for G and H, it holds that $\big(H[\{s_1', \dots, s_6'\} \cup V(C_H)], (b_i'^j, s_k' \mid i \in [4], j \in [3], k \in [6])\big) \cong \big(G[\{s_1, \dots, s_6\} \cup V(C_G)], (b_i^j, s_k \mid i \in [4], j \in [3], k \in [6])\big)$.

Proof. For the following arguments, see also Figure 2 for a better intuition.

Let $n \in \mathbb{N}$ and let G be a connected planar graph with $|G| \leq n$. The proof is by induction on $h \geq 0$.

First, given a second connected graph H of order at most $|G|$ that satisfies the $\mathsf{dec}_h^{(n)}$-formula, we can assume that the first four triplets of vertices form the same types of blocks and block separators (of corresponding sizes), respectively, in H as in G, since otherwise we can distinguish the graphs using the formulas from Lemma 16 and Corollary 17.

Note that there is a formula $\mathsf{bag}^{(n)}(x_1^1,\dots,x_4^3,y) \in \mathsf{C}^{O(1)}_{O(\log n)}$ such that for all graphs H of order at most n and all $b_1'^1, b_1'^2, b_1'^3, \dots, b_4'^1, b_4'^2, b_4'^3, v \in V(H)$, it holds that $H \models \mathsf{bag}^{(n)}(b_1'^1,\dots,b_4'^3,v)$ if and only if each set $\{b_i'^j \mid j \in [3]\}$ for $i \in [4]$ is a block separator B_i or a degenerate block B_i or contained in a proper block B_i of H and v is in $B \coloneqq \bigcup_{i=1}^4 B_i$.

The case that $h = 0$ follows analogously as the formula for the isomorphism type of the root bag in the inductive step. We therefore focus on the inductive step. Assume that for every list of vertices $(b_i'^j, s_k' \mid i \in [4], j \in [3], k \in [6]) \in V(G)^{18}$, where

$$G \models \mathsf{dec}_h^{(n)}(b_i'^j, s_k' \mid i \in [4], j \in [3], k \in [6]),$$

there is a $\mathsf{C}^{O(1)}_{O(h+\log n)}$-formula

$$\mathsf{iso}_{G,(b_i'^j, s_k' \mid i\in[4], j\in[3], k\in[6])}(x_1'^1,\dots,x_4'^3,y_1',\dots,y_6')$$

that defines the isomorphism type of $(G[\{s_1',\dots,s_6'\} \cup V(C')], (b_i'^j, s_k' \mid i \in [4], j \in [3], k \in [6]))$, where C' is the connected component from Parts (iii)–(v) in Lemma 18.

Let $(b_i^j, s_k \mid i \in [4], j \in [3], k \in [6]) \in V(G)^{18}$ be a list of vertices such that

$$G \models \mathsf{dec}_{h+1}^{(n)}(b_i^j, s_k \mid i \in [4], j \in [3], k \in [6]).$$

For $B_1, B_2, B_3, B_4, B, C, S$ as described in Lemma 18, let (T^*, β^*) be the rooted tree decomposition from Condition (iv) in Lemma 18. Let r^* be the root of T^*. By Condition (iv) in Lemma 18, it holds that $\beta^*(r^*) = B = \bigcup_{i=1}^4 B_i$. Consider a B_i with $|B_i| \geq 4$. Then B_i is a proper block, in which, by Theorem 5, we can find vertices v_i^1, v_i^2, v_i^3 such that for all $w \in B_i$, there is a $\mathsf{C}^{O(1)}_{O(\log n)}$-formula $\mathsf{id}'_w(x_i^1, x_i^2, x_i^3, y)$ such that $G[[B_i]] \models \mathsf{id}'_w(v_i^1, v_i^2, v_i^3, w)$ and $G[[B_i]] \not\models \mathsf{id}'_w(v_i^1, v_i^2, v_i^3, w')$ for every $w' \in B_i \setminus \{v\}$. (In every B_i with $|B_i| \leq 3$, such vertex-identifying formulas with four free variables exist trivially and they also identify the vertex the entire graph G.)

For simplicity, first assume that for all i with $|B_i| \geq 4$, the vertex v_i^j equals b_i^j for $j \in [3]$. Then by replacing in $\mathsf{id}'_v(x_i^1, x_i^2, x_i^3, y)$ every subformula of the form $\exists^{\geq k} x \psi$ with $\exists^{\geq k} x(\psi \wedge \mathsf{block}^{(n)}(x_i^1, x_i^2, x_i^3, x))$ and every $E(x,y)$ with $\mathsf{torso}^{(n)}(x_i^1, x_i^2, x_i^3, x, y)$, we easily obtain for each $v \in B$ a $\mathsf{C}^{O(1)}_{O(\log n)}$-formula $\mathsf{id}_v(x_1^1,\dots,x_4^3,y)$ with $\mathsf{id}_v[G, b_1^1,\dots,b_4^3, y] = \{v\}$.

Now we can use these formulas to address each vertex individually. More formally, we can define the edge relation of $G[B]$ by setting, for $v, w \in B$ with $v \neq w$,

$$\varphi_{v,w}(x,y) \coloneqq \begin{cases} E(x,y) & \text{if } vw \in E(G), \\ \neg E(x,y) & \text{otherwise.} \end{cases}$$

Then the $\mathsf{C}^{O(1)}_{O(\log n)}$-formula

$$\begin{aligned} \mathsf{iso}_B(x_1^1,\dots,x_4^3) \coloneqq \bigwedge_{v,w\in B} \exists^{=1} x \Big(\mathsf{id}_v(x_1^1,\dots,x_4^3,x) \wedge \exists^{=1} x' \big(\mathsf{id}_w(x_1^1,\dots,x_4^3,x') \wedge \varphi_{v,w}(x,x') \big) \Big) \\ \wedge \neg \exists x \Big(\mathsf{bag}^{(n)}(x_1^1,\dots,x_4^3,x) \to \bigwedge_{w\in B} \neg \mathsf{id}_w(x_1^1,\dots,x_4^3,x) \Big) \wedge \\ \bigwedge_{v\neq w\in B} \neg \exists x \Big(\mathsf{id}_v(x_1^1,\dots,x_4^3,x) \wedge \mathsf{id}_w(x_1^1,\dots,x_4^3,x) \Big) \end{aligned}$$

defines the isomorphism type of $(G[B], b_1^1,\dots,b_4^3)$ (see the purple bag in Figure 2).

We now construct a formula that describes how the connected components of $G[S \cup V(C)] \setminus B$ are attached to $G[B]$. Let $G' \coloneqq G[S \cup V(C)]$. By Condition (iii) in Lemma 11, for every connected component C' of $G' \setminus B$, it holds that $|N_G(C')| \leq 6$ (see the coloured shapes attached to the purple one in Figure 2). Hence, we iterate over all tuples $(s'_1, \dots, s'_6) \in B^6$: let $\mathcal{M}^{s'_1,\dots,s'_6}$ be the multiset of isomorphism types of the graphs $(G[S' \cup C'], s'_1, \dots, s'_6)$, where $S' \coloneqq \{s'_i \mid i \in [6]\}$ and C' is a connected component of $G' \setminus B$ with $N_G(C') = S'$.

Since $G \models \mathsf{dec}^{(n)}_{h+1}(b^j_i, s_k \mid i \in [4], j \in [3], k \in [6])$, for every $(s'_1, \dots, s'_6) \in B^6$ and every connected component C' of $G' \setminus B$ with $N_G(C') = \{s'_1, \dots, s'_6\}$, there exist vertices $(b'^j_i \mid i \in [4], j \in [3]) \in (S' \cup V(C'))^{12}$ such that

$$G[S' \cup V(C')] \models \mathsf{dec}^{(n)}_h(b'^j_i, s'_k \mid i \in [4], j \in [3], k \in [6]).$$

So, by the induction hypothesis, there is a formula $\mathsf{iso}_M(x'^1_1, \dots, x'^3_4, y'_1, \dots, y'_6) \in \mathsf{C}^{O(1)}_{O(h+\log n)}$ for the isomorphism type M of $(G[\{s'_1, \dots, s'_6\} \cup V(C')], (b'^j_i, s'_k \mid i \in [4], j \in [3], k \in [6]))$. Note that by Condition (ii) in Lemma 18, at least one of the vertices b'^j_i will lie outside B. Using the counting quantifiers, we can use the iso_M to make sure that every isomorphism type appears with the correct multiplicity. More precisely, we first group all components with equal isomorphism types. The fact that they are of the same size enables us to define their number (e.g. the three green shapes in Figure 2). This then allows us to build a formula $\mathsf{iso}'_{\mathcal{M}}(y'_1, \dots, y'_6)$ which identifies the graph $(G[S' \cup \bigcup_{C' : N_G(C') = S'} V(C')], s'_1, \dots, s'_6)$ (where $\mathcal{M} \coloneqq \mathcal{M}^{s'_1,\dots,s'_6}$ and the C' are connected components of $G' \setminus B$). Using the $\mathsf{dec}^{(n)}_h$-formula, we can turn $\mathsf{iso}'_{\mathcal{M}}(y'_1, \dots, y'_6)$ into a formula $\mathsf{iso}_{\mathcal{M}}(x^1_1, \dots, x^3_4, y_1, \dots, y_6, y'_1, \dots, y'_6)$ that ensures that $\mathsf{iso}_{\mathcal{M}}(b^1_1, \dots, b^3_4, s_1, \dots, s_6, s'_1, \dots, s'_6)$ describes for $S' \coloneqq \{s'_1, \dots, s'_6\}$ the subgraph $(G[S' \cup \bigcup_{C' : N_G(C') = S'} V(C')], s'_1, \dots, s'_6)$, where the C' are connected components of $G' \setminus B$, up to isomorphism.

Hence, it suffices to conjugate $\mathsf{iso}_B(x^1_1, \dots, x^3_4)$ with a conjunction over all $(s'_1, \dots, s'_6) \in B^6$ of the following formula

$$\exists y'_1 \dots \exists y'_6 \left(\bigwedge_{i=1}^{6} \mathsf{id}_{s'_i}(x^1_1, \dots, x^3_4, y'_i) \wedge \mathsf{iso}_{\mathcal{M}}(x^1_1, \dots, x^3_4, y_1, \dots, y_6, y'_1, \dots, y'_6) \right),$$

where $\mathcal{M} \coloneqq \mathcal{M}^{s_1,\dots,s_6}$, to obtain the desired $\mathsf{iso}_{G,(b^j_i, s_k \mid i \in [4], j \in [3], k \in [6])}(x^1_1, \dots, x^3_4, y_1, \dots, y_6)$.

We now consider the general case where it does not necessarily hold for all i, j that $v^j_i = b^j_i$. We assume for notational simplicity that for all i, the b^1_i, b^2_i, b^3_i define a block. It is easy to adapt the following construction to the situation that block separators are present.

We introduce one nested existential quantifier $\exists \tilde{x}^j_i$ for each of the v^j_i so that our resulting formula $\mathsf{iso}_{G,(b^j_i, s_k \mid i \in [4], j \in [3], k \in [6])}(x^1_1, \dots, x^3_4, y_1, \dots, y_6)$ looks as follows:

$$\exists \tilde{x}^1_1 \dots \exists \tilde{x}^3_4 \Bigg(\bigwedge_{j=1}^{3} \bigwedge_{i=1}^{4} \mathsf{block}^{(n)}(x^1_i, x^2_i, x^3_i, \tilde{x}^j_i) \wedge \mathsf{iso}_B(\tilde{x}^1_1, \dots, \tilde{x}^3_4) \wedge \bigwedge_{(s'_1,\dots,s'_6) \in B^6} \exists y'_1 \dots \exists y'_6 \Bigg(\bigwedge_{i=1}^{6} \mathsf{id}_{s'_i}(\tilde{x}^1_1, \dots, \tilde{x}^3_4, y'_i) \wedge \mathsf{iso}_{\mathcal{M}}(x^1_1, \dots, x^3_4, y_1, \dots, y_6, y'_1, \dots, y'_6) \Bigg) \Bigg).$$

The bounds on the quantifier depth and the number of variables follow similarly as in the proof of Lemma 18. ◀

Applying Lemma 8, we can deduce Theorem 2.

Proof of Theorem 2. Let $n \in \mathbb{N}$ and let G be a planar graph with order $|G| = n$. If G is not connected, we construct one formula for each connected component of G (as described in the following) and join them to obtain the identifying sentence.

So suppose G is connected. Then by Lemma 11, G has a rooted tree decomposition (T^*, β^*) of logarithmic height and adhesion at most 6 for which every bag is a union of four (not necessarily distinct) blocks or block separators and also Condition (iv) of the lemma holds. Let $b_1^1, \dots, b_4^3$ be vertices that determine the blocks and block separators in the root bag B of (T^*, β^*).

If there is a vertex $s \in B$ such that there is a unique connected component C of $G \setminus \{s\}$ with $B \subseteq \{s\} \cup V(C)$, then there are vertices b_i^j, s_k for $i \in [4], j \in [3], k \in [6]$ (e.g. $s_k = s$ for all k) such that G satisfies $\mathsf{dec}^{(n)}_{2\log|G|}(b_i^j, s_k \mid i \in [4], j \in [3], k \in [6])$. Then the sentence

$$\exists x_1^1 \dots \exists x_4^3 \exists y_1 \dots \exists y_6 \mathsf{iso}_{G,(b_i^j, s_k \mid i\in[4], j\in[3], k\in[6])}(x_1^1, \dots, x_4^3, y_1, \dots, y_6)$$

identifies G, where $\mathsf{iso}_{G,(b_i^j, s_k \mid i\in[4], j\in[3], k\in[6])}$ is the formula from Lemma 19.

Otherwise, let $s \in B$ be a vertex such that $G \setminus \{s\}$ has multiple connected components C_i and let $G_i \coloneqq G[V(C_i) \cup \{s\}]$. Then the restriction of (T^*, β^*) to each G_i still satisfies the conditions of Lemma 11, because the block structure of G_i is just the block structure induced by G on $V(G_i)$ (that is, the blocks of G_i are precisely those blocks of G contained in $V(G_i)$, and similarly for the block separators). This yields by Lemma 19 an identifying formula $\varphi_i(y)$ for each (G_i, s), which we can join by isomorphism type of (G_i, s) to obtain an identifying sentence. ◀

We can directly deduce Theorem 1.

Proof of Theorem 1. The theorem follows from Theorems 2 and 4. ◀

6 Conclusion

We prove that planar graphs are identified by the WL algorithm with constant dimension in a logarithmic number of iterations, thereby completing a project started by Verbitsky fourteen years ago with his proof of the same result in the special case of 3-connected planar graphs. Our proof is based on the careful analysis of a novel logarithmic-depth decomposition of graphs into their 3-connected components.

It is unclear which dimension of the WL algorithm is necessary to identify planar graphs in logarithmically many iterations and if there is a (provable) trade-off between dimension and iteration number. This is not only interesting for planar graphs, and many questions remain open.

We leave it as another interesting open project whether our result can be extended to graph classes of bounded genus. As it stands, our proof heavily relies on properties of 3-connected planar graphs that are not shared by 3-connected graphs of higher genus. Similarly, we pose as a challenge to find good bounds on the iteration number of the WL algorithm on other parameterised graph classes, such as graphs with a certain excluded minor or graphs of bounded rank width.

Abstract

We display an application of the notions of kernelization and data reduction from parameterized complexity to proof complexity: Specifically, we show that the existence of data reduction rules for a parameterized problem having (a). a small-length reduction chain, and (b). small-size (extended) Frege proofs certifying the soundness of reduction steps implies the existence of subexponential size (extended) Frege proofs for propositional formalizations of the given problem.

We apply our result to infer the existence of subexponential Frege and extended Frege proofs for a variety of problems. Improving earlier results of Aisenberg et al. (ICALP 2015), we show that propositional formulas expressing (a stronger form of) the Kneser-Lovász Theorem have quasipolynomial size Frege proofs for each constant value of the parameter k.

Another notable application of our framework is to impossibility results in computational social choice: we show that, for any fixed number of agents, propositional translations of the Arrow and Gibbard-Satterthwaite impossibility theorems have subexponential size Frege proofs.

1 Introduction

The central task of *proof complexity* [10, 30] is that of understanding (and distinguishing) the relative power of various propositional proof systems. Proving lower bounds for stronger and stronger proof systems might (in principle) be a way to eventually confirm the various conjectures of computational complexity. Yet we are far from being able to prove exponential lower bounds for some concrete problems in strong proof systems.

One of the most important open problems in this area, explicitly raised by Bonet, Buss and Pitassi [6] is that of separating the complexity of Frege proof systems ("textbook style propositional proofs") from that of extended Frege proof systems (which in addition can introduce new variables as substitutes for arbitrary propositional formulas). That is, we would like to find explicit classes of propositional formulas that have extended Frege proofs of polynomial size but have exponential lower bounds on the size of the shortest Frege proofs.

Many classes of problems that are candidates for separating the two systems have been proposed, e.g. statements based on linear algebra [24,36], propositional encodings of the Paris-Harrington independence results [11], Ramsey's theorem [31], central theorems from extremal combinatorics [1, 34], or the Kneser-Lovász formula from combinatorial topology [2, 27]).

So far most of the proposed examples have turned out to have sub-exponential Frege proofs (only a couple of candidate formula classes for the purported separation have been advanced, such as local improvement principles [28], or truncations of the octahedral Tucker lemma [2]). On the other hand many of the tractability results listed above have been obtained using techniques that are highly problem-specific, with relatively little transferability to more general classes of formulas. The existence of such general methods would be highly desirable: such general results could guide the search for examples witnessing the desired separation by pointing to structural properties one needs to avoid in order to construct them.

The purpose of this paper is to present a more general approach for proving sub-exponential upper bounds for the Frege and extended Frege proof complexity of some classes of propositional formulas. We point out that concepts from the theory of parameterized complexity [18], specifically those of *data reduction* and *kernelization* [19] may be relevant to proof complexity as well[1]. We give a metatheorem that translates a data reduction for the original problem whose soundness can be witnessed by polynomial size (extended) Frege proofs into subexponential proofs for the corresponding propositional translation of the original problem. The exact size of these proofs is controlled by three factors: the length of the data reduction chain, the nature and size of the proofs witnessing the soundness of the reduction rules, and the size of proofs of unsatisfiability for the formulas in the kernel.

We give several applications of our metatheorem. The use of kernelization techniques does not only allow to tackle the complexity of new problems, but also to improve existing results: In [2] it was shown that propositional formulas $Kneser_{n,k}$ expressing a principle from topological combinatorics known as *the Kneser-Lovász theorem* have, for every fixed value of parameter k, quasipolynomial size Frege proofs. We improve this result by showing quasipolynomial upper bounds for a principle stronger than the Kneser-Lovász theorem, known as Schrijver's theorem. Other applications of our metatheorem concern several (mostly graph-theoretic) problems whose kernelization had previously been studied in the theory of parameterized algorithms. The problems we study are well-known examples satisfying two conditions: First, their negative instances have natural formulations as unsatisfiable CNF formulas. Second, they have efficient kernelizations, often with a small kernel. The problems we have chosen illustrate an important point: *several techniques used in the literature to prove the existence of a kernelization can often be efficiently simulated by (extended) Frege proofs.* Perhaps the most interesting set of applications of our general metatheorem comes, however, from the theory of computational social choice [7]: as it was recently observed, various propositional formalizations of impossibility principles in the theory of computational social choice have computer-assisted proofs that reduce the task of mathematically proving these theorems to the verification of a finite number of cases of unsatisfiability of propositional formulas (using SAT solvers; see [22] for a fairly recent overview)[2]. **We obtain subexponential upper bounds on the complexity of Frege proofs for propositional formulations of Arrow's theorem and the Gibbard-Satterthwaite theorem: quasipolynomial in general, polynomial for a fixed number of agents.**

[1] This is not the first time a connection between parameterized complexity and proof complexity was made; see e.g. [5, 16]. However, our concerns are rather different.

[2] A similar phenomenon had been independently uncovered for the Kneser-Lovász theorem [2].

2 Preliminaries

We assume basic familiarity with concepts from three distinct areas: proof complexity, parameterized algorithms and computational social choice. We refer the reader to [7, 19, 30] for book-length treatments of these topics. Nevertheless, for purposes of readability we review a couple of relevant notions in the sequel:

▶ **Definition 1.** *A* Frege proof system *is a sound and complete propositional proof systems having a finite number of axioms and inference rules. An* extended Frege proof *augments Frege proofs by allowing new variables to substitute complex formulas.*

All Frege proof systems are equivalent up to polynomial transformations [15]. Therefore, for concreteness, we will employ a standard "textbook proof style" system having *modus ponens* as the unique inference rule. In both cases we measure the length of a proof by the number of steps in it. Thus the effect of the extension rule in extended Frege proofs is reducing proof length.

We use the shorthand $[m]$ for the set $\{1, 2, \ldots, m\}$, $[i : j]$ for $\{i, i+1, \ldots, j\}$, and write $A \cong B$ when sets A, B have the same cardinality. Function $f(\cdot)$ is called *quasipolynomial* if there exists $k > 0$ such that $f(n) = O(2^{O(\log^k(n))})$. We will need the following simple

▶ **Lemma 2.** *Suppose C is a CNF formula and $Z_1, \ldots, Z_m$ are literals s.t. $C \wedge (Z_1 \wedge Z_2 \wedge \ldots \wedge Z_m)$ is unsatisfiable, as witnessed by a resolution (Frege) proof of length k. Then one can derive from C clause $\overline{Z_1} \vee \overline{Z_2} \vee \ldots \vee \overline{Z_m}$ via a resolution (Frege) proof of size at most k.*

▶ **Definition 3** (Parameterized problem)**.** *Let Σ be an alphabet. L is a* parametrized problem *over Σ^* iff $L \subseteq \Sigma^* \times \mathbb{N}$. Define the support of L, by $supp(L) = \{x \in \Sigma^* | (\exists k \in \mathbb{N}) : (x, k) \in L\}$.*

Let L be a parameterized problem in co-NP. Let ϕ be a "canonical" reduction of L to $\overline{SAT}$. When ϕ is clear from the context, we identify L with the set of pairs $\phi(L) := \{(\phi(x, k), k) : (x, k) \in L\}$, slightly abusing notation, and writing L instead of $\phi(L)$.

▶ **Example 4** (Graph colorability)**.** Let $COL = \{(G, i) \mid \chi(G) \leq i\}$. We can encode instances (G, k) of COL as SAT instances $(\phi(G, k), k)$ by the reduction ϕ informally defined by:

- For $v \in V(G)$ and $1 \leq i \leq k$ define boolean $X_{v,i}$ =TRUE iff v is colored with color i.
- For every pair of distinct vertices $v, w \in G$ we define variable $Y_{v,w}$. The semantics is that $Y_{v,w} = TRUE$ means that v and w are connected by an edge. Thus, for all sets $\{v, w\}$ that correspond to an edge we add to $\phi(G, k)$ the unit clause $Y_{v,w}$. On the other hand, for sets $\{v, w\}$ that correspond to non-edges we add to $\phi(G, k)$ the unit clause $\overline{Y_{v,w}}$.
- For every $v \in V$ add $X_{v,1} \vee X_{v,2} \vee \ldots \vee X_{v,k}$. ("$v$ must be colored with one of colors 1 to k")
- For $v \in V$ and $1 \leq i < j \leq k$ add $\overline{X_{v,i}} \vee \overline{X_{v,j}}$. ("$v$ cannot be colored with both i and j")
- For every set $v, w \in V$ and $i \in 1 \ldots k$, add clause $\overline{Y_{v,w}} \vee \overline{X_{v,i}} \vee \overline{X_{w,i}}$. ("if v and w are connected then they cannot both be colored with color i")

▶ **Definition 5.** *Define graph, $Kn_{n,k}$, parameterized by an integer $k \geq 1$: The vertex set of $Kn_{n,k}$ is $\binom{n}{k}$, the set of subsets of $\{1, 2, \ldots, n\}$ with k elements. Two sets A, B represent adjacent vertices iff $A \cap B = \emptyset$.*

The Kneser-Lovász theorem (see e.g. [17]) is a statement about the chromatic number of $Kn_{n,k}$, equivalently restated as $\chi(Kn_{n,k}) > n - 2k + 1$[3]. It is expressed as a parameterized problem as follows: $L_{Kn} = \left\{(Kn^k_n, i) : n \geq 2k > 1,\ i \leq n - 2k + 1\right\}$. Note that $L_{Kn} \subseteq$

[3] actually $\chi(Kn_{n,k}) = n - 2k + 2$. However, the existence of a $(n - 2k + 2)$-coloring is easy [17].

$\overline{COL}$, hence we can use the translation from Example 4 to canonically translate L_{Kn} as a set of unsatisfiable propositional formulas. Similar propositional translations of other constraint satisfaction problems appear e.g. in [25, 33].

The next problem is just the graph coloring problem, but with a different parameterization:

▶ **Definition 6.** *An instance of the Dual Coloring problem is a pair (G, k), where G is a graph with n vertices and k is an integer. To decide: is $\chi(G) \leq n - k$? That is, let $DualCol = \{(G, k) : \chi(G) \leq n - k\}$. We have $(G, k) \in DualCOL \Leftrightarrow (G, n - k) \in COL$. For this reason the translation of $\overline{DualCOL}$ into $\overline{SAT}$ modifies the one from $\overline{COL}$ to $\overline{SAT}$ in Example 4 in an obivious way.*

Given graph G, a *vertex cover in* G is a set $S \subseteq V(G)$ such that for every edge $e = (v, w)$, $v \in S$ or $w \in S$. We denote by $vc(G)$ the size of the smallest vertex cover of G.

▶ **Example 7** (Vertex Cover). Let $\overline{VC} = \{(G, i) \mid i < vc(G)\}$ be the set of unsatisfiable instances of Vertex Cover. We can encode (negative) instances (G, k) of VC as instances $\phi(G, k)$ of SAT by the reduction ϕ informally defined as follows:

- For every $v \neq w \in V$, $(v, w) \in E$ add new unit clause $Y_{v,w}$ to the formula. For $(v, w) \notin E$ add new unit clause $\overline{Y_{v,w}}$, to the formula.
- For $v \in V(G)$ and $i \in 1 \dots k$ define boolean variable $X_{v,i}$ with the informal semantics $X_{v,i}$ is TRUE when vertex v is the i'th vertex in a vertex cover of size k. To encode this semantics add to the formula, for every $v \in V$ and $i \in 1, \dots, k$, clause $\overline{X_{v,i}} \vee (\bigvee_{w \neq v} Y_{v,w})$. This ensures that if v is chosen in the vertex cover then it covers some edge (v, w). With some extra technical complications one can do away with adding these clauses.
- For every $i = 1, \dots, k$ we add to the formula clause $\bigvee_{v \in V} X_{v,i}$.
- For every $v \neq w \in V$ and $1 \leq i \leq k$ we add to the formula clause $\overline{X_{v,i}} \vee \overline{X_{w,i}}$.
- For every $v \in V$ and $1 \leq i < j \leq k$ we add to the formula clause $\overline{X_{v,i}} \vee \overline{X_{v,j}}$.
- For $v \neq w \in V$ add to the formula clause $\overline{Y_{v,w}} \vee X_{v,1} \vee \ldots \vee X_{v,k} \vee X_{w,1} \vee \ldots \vee X_{w,k}$.

▶ **Definition 8** (Kernelization). *Let L be a parametrized problem. A* kernelization algorithm *(or, shortly, kernelization) Ker for the problem L is an algorithm that works as follows: on input (x, k), Ker outputs (in time polynomial in $|(x, k)|$) a pair (x', k'), such that the following are true: $(x, k) \in L$ iff $(x', k') \in L$, and $|x'|, k' \leq g(k)$, where g is a computable function. Pair (x', k') is called* the kernel of (x, k), *while $g(k)$ is called* the size of the kernel.

One can convert a kernelization into an algorithm by solving kernel instances by other means (e.g. brute force). A kernelization is often the reflexive, transitive closure of a finite set of *data reduction rules*: we apply the rules as long as possible, until we are left with an instance, the kernel, to which no rule can be applied anymore.

▶ **Definition 9** (Data reduction rule). *Let L be a parameterized problem. A* ***data reduction rule for L*** *is an algorithm A that maps (in time polynomial in $|x| + k$) an instance (x, k) of L to an instance (x', k') such that $(x, k) \in L$ iff $(x', k') \in L$ (we say that the two instances are* equivalent*, or that the reduction rule is* safe*), and $|x'| \leq |x|$. In practice, a data reduction rule may be well-defined only for $|x| \geq f(k)$, for some function $f(\cdot)$, as we can simply extend it to smaller instances (x, k) by defining $A(x, k) = (x, k)$. All kernelizations in this paper have this nature, and we will assume this to be true for all the results we give in the sequel.*

▶ **Definition 10** (Data reduction chain). *Given parameterized problem L kernelizable via data reductions $(A_1, A_2, \dots, A_r)$, a* ***data reduction chain*** *for instance (x, k) of L is a sequence $(x_0, k_0), (x_1, k_1), \dots, (x_m, k_m)$, where $(x_0, k_0) = (x, k)$, $A_t(x_m, k_m) = (x_m, k_m)$, for all $t = 1, \dots r$ and, for all $i = 1, \dots, m$ there exists $j \in 1, \dots, r$ such that $(x_i, k_i) = A_j(x_{i-1}, k_{i-1})$.*

▶ **Example 11** (Data reduction for Kneser instances:). Reductions $(Kn^2_n, a) \to (Kn^2_{n-1}, a-1)$ and $(Kn^3_n, a) \to (Kn^3_{n-1}, a-1)$ were used in [27] to give polynomial size extended Frege upper bounds for Kneser formulas for $k = 2, 3$.

- For $k \geq 2$ there exists $N(k) \leq k^4$ such that for $n > N(k)$ $(\mathcal{K}^k_n, a) \to (\mathcal{K}^k_{n-1}, a-1)$. This was used in [2] to give polynomial size extended Frege upper bounds for Kneser formulas.
- For $k \geq 2$ there exists $N(k) \leq k^4$ such that for $n > N(k)$ $(Kn^k_n, a) \to (Kn^k_{n-\frac{n}{2k}}, a - \frac{n}{2k})$. This was used in [2] to give quasipolynomial size Frege proofs for Kneser formulas.

Our results will work by formalizing *data reductions* which solve the decision for an instance X_1 of a parameterized problem by reducing it to a smaller instance X_2 of the same problem. This will map, propositionally, to witnessing the soundness of an implication $\Phi_1 \vdash \Phi_2$. However, to make Φ_2 a propositional tranlation of an instance of the same problem, we will need to use variable substitutions $Y = \Xi[X]$. That is, the reduction we witness is actually $\Phi_1[X] \vdash \Phi_2[Y]$. When we will refer to the proof complexity of witnessing an implication $\Phi_1 \vdash \Phi_2$ using (extended) Frege proofs, what we mean is that one can derive the clauses of $\Phi_2[Y]$ using the clauses of $\Phi_1[X]$ as axioms. Since they use substitutions, these are extended Frege proofs. To convert them into Frege proofs one needs to unwind the definitions of newly defined variables.

▶ **Definition 12.** *A **crown decomposition of a graph G** (see e.g. Fig. 1 (b).) is a decomposition of $V(G)$ into three subsets C, H, R, $C \neq \emptyset$ such that (1). C is an independent set. (2). No vertex in C is adjacent to a vertex in R. (3). There exists a matching of H in C, i.e. a set of disjoint edges covering H with the other endpoint in C.*

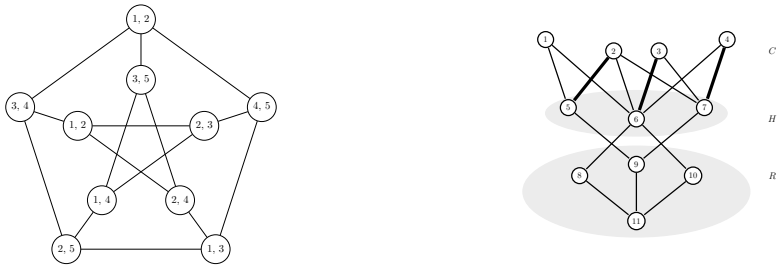

Figure 1 (a). The Kneser graph $Kn_{5,2}$. (b). A crown decomposition of a graph.

Given a set S and $T \subseteq S$, we will denote, as in [37,38], by S_{-T} the set $S \setminus T$. We will also write S_{-a} instead of $S_{-\{a\}}$. When $S = [m]$, of course $[m]_{-T} \cong [m - |T|]$ for every $T \subseteq [m]$.

▶ **Definition 13.** *Given a set of m objects, identified with the set $[m]$, a* preference profile *is a linear ordering of $[m]$, i.e. a permutation $\pi \in S_m$. Given $a, b \in [m]$ we say that a* is preferred to *b (written $a <_\pi b$) iff $\pi^{-1}(a) < \pi^{-1}(b)$. **Note that preferred objects are lower in the ordering.** We denote by $top(\pi)$ the object $\pi^{-1}(1)$, i.e. the object that is preferred in π to all others. Given a preference profile π and $T \subseteq [m]$, denote by π_{-T} the restriction of π to $[m]_{-T}$, and by π^{+T} the preference profile derived from π by making all elements $a \in T$ less preferred than any other $b \in [m]$ (with an arbitrary fixed order among them, e.g. the order induced on $[m]$ by the identical permutation).*

▶ **Definition 14.** *Given a set of m objects, identified with the set $[m]$ and a set of n agents, a **social choice function** (SCF) is a mapping $s : S^n_m \to Z$. Z is a set equal to S_m (for Arrow's theorem) and to $[m]$ (for the Gibbard-Satterthwaite theorem). A SCF is **dictatorial***

if there exists $i \in [m]$ such that for all $R_1, R_2, \ldots, R_n \in S_m$, $s(R_1, R_2, \ldots, R_n) = R_i$ ($s(R_1, R_2, \ldots, R_n) = top(R_i)$ for the Gibbard-Satterthwaite theorem). A SCF is ***unanimous*** *if whenever a is preferred to b in all profiles $R_1, R_2, \ldots, R_n$ then a is preferred to b in profile $s(R_1, R_2, \ldots, R_n)$. SCF s satisfies the* ***independence of irrelevant alternatives (IIA) axiom*** *(for Arrow's theorem) if whenever $a, b \in [m]$ are two different objects and $(R_1, R_2, \ldots, R_n) \in S_m^n$ and $(R'_1, R'_2, \ldots, R'_n) \in S_m^n$ are two vectors of preference profiles such that, for all $i = 1, \ldots m$, R_i and R'_i agree in their relative preference of a or b, then $s(R_1, R_2, \ldots, R_n)$ and $s(R'_1, R'_2, \ldots, R'_n)$ agree in their relative preference of a or b. A SCF is* ***onto*** *iff it is onto as a function. Finally, for every pair (R, o), $R = (R_1, \ldots, R_n)$ and player $1 \leq i \leq m$, denote by $pr(i, o, R)$ the set of objects o' s.t. $R_i^{-1}(o) \leq R_i^{-1}(o')$ (i.e. i weakly prefers o to o' in R_i). A SCF s is* ***strategyproof*** *(for the Gibbard-Satterthwaite theorem) iff, for every strategy profile R, if o is the outcome of preference profile R then i cannot misrepresent its preferences as $\pi \in S_m, \pi \neq R_i$ so that the social choice for the resulting profile $s(i, R, \pi)$ is an o' that i strictly prefers to o.*

Given an *SCF* $W : [m]^n \to Z$ and $B \subseteq [m]$ we define function $W_{-B} : [m]^n_{-B} \to Z$ to be defined as follows: $W_{-B}(R_1, R_2, \ldots, R_n) = W(R_1^{+B}, R_2^{+B}, \ldots, R_n^{+B})_{-B}$. In other words, we extend profiles $R_1, R_2, \ldots, R_n$ by making objects in B less preferred than all other objects, apply W on the resulting profiles, then drop objects from B from the result.

3 Main (Meta)Theorem and Applications

In the next definition we formalize the complexity of simulating data reduction steps by (extended) Frege proofs. Clearly, we want to encode the scenario where each such step can be simulated by efficient proofs. Our main result will allow a slightly more general setting, where the safety of each reduction step can be established by a "case by case argument with a limited number of cases". This will lead not to a chain but to a *tree* of logical reductions:

▶ **Definition 15.** *Given reduction rule $\mathcal{A}$ for problem L and function $h(\cdot)$,* ***the soundness of $\mathcal{A}$ has (extended) Frege proofs of size $h(\cdot)$*** *iff there is an integer $R \geq 1$ s.t. for every $(x, k) \notin L$ and every step $(x_i, k_i) \to (x_{i+1}, k_{i+1})$ in the reduction chain the following are true:*

- *There exists $r'_i \leq R$, tautology $\Xi_i := \bigvee_{t=1}^{r'_i} \Xi_{i,t}$ and formulas $\eta_{i,1}, \ldots \eta_{i,r'_i}$ isomorphic (up to a variable renaming) to $\Phi(x_{i+1}, k_{i+1})$ s.t. for $t = 1, \ldots, r'_i$, $\Phi(x_i, k_i) \wedge \Xi_{i,t} \vdash \eta_{i,t}$.*
- *Proving the soundness of Ξ_i and of all reductions $\Phi(x_i, k_i) \wedge \Xi_{i,t} \vdash \eta_{i,t}$ can be accomplished by (extended) Frege proofs of* ***total*** *size at most $h(|\Phi(x, k)|)$.*

In other words, the kernelization may encode a case-by-case construction with a constant number, at most R, of cases. Each case will lead to a different reduced formula. The consistency of all those reductions is witnessed by proofs with a common polynomial upper bound. Given this definition, our main (meta)theorem is:

▶ **Theorem 16.** *Let L be a parameterized problem that is kernelizable via a finite number of data reduction rules $(A_1, A_2, \ldots, A_r)$ with kernel size $g(\cdot)$.*

1. *Assume that negative instance (x, k) of L has a data reduction chains of length $C(x, k)$, and that the soundness of each reduction rule $A_1, A_2, \ldots, A_r$ can be witnessed using extended Frege proofs of size at most $h(|\Phi(x, k)|)$, for some function $h(\cdot)$. Then L has extended Frege proofs of size $O((\sum_{i=0}^{C(x,k)} R^i)[h(|\Phi(x, k)|) + 2^{O(poly(g(k)))}])$. In particular, if $R = 1$ and for every fixed k we have $C(x, k) = O(poly(|\Phi(x, k)|))$ then, for every fixed k, negative instances $\Phi(x, k)$ of L have extended Frege proofs of size polynomial in $|\Phi(x, k)|$.*

2. *Assume that negative instances (x,k) of L have data reduction chains of length $C(x,k) = O(1)$ ($O(log(|\Phi(x,k)|))$, respectively), where the constant may depend on k, and that the safety of each reduction $\Phi(x_i,k_i) \vdash \Phi(x_{i+1},k_{i+1})$ is witnessed by Frege proofs of size $\leq p(|\Phi(x,k)|)$, for some fixed polynomial $p(\cdot)$ Then for every fixed k, negative instances $(\Phi(x,k),k)$ of L have Frege proofs of size polynomial (quasipolynomial) in $|\Phi(x,k)|$.*

Proof.

1. Given an instance (x,k) of L, and data reduction chain $(x,k) = (x_0,k_0),(x_1,k_1),,\ldots(x_m,k_m)$, an extended Frege proof for $\Phi(x,k)$ is obtained by concatenating the proofs for statements $\Phi(x_{i-1},k_{i-1}) \vdash \Phi(x_i,k_i)$ with an extended Frege proof of the kernel instance. There is one complication, though, induced by the fact that we allow at most R cases in the reduction: the reduction chain maps to a **tree** of propositional proofs, since for each node $\Phi(x_i,k_i)$ we have $r_i' \leq R$ children $\Xi_{i,t}$, all isomorphic to $\Phi(x_{i+1},k_{i+1})$ (but different). The total number of nodes in this tree is at most $\sum_{t=0}^{C(x,k)} R^t$.

   Then the whole chain of reductions from $\Phi(x,k)$ to $\Phi(x_m,k_m)$ can be proved to be sound by proofs of length $(\sum_{t=0}^{C(x,k)} R^t) \cdot h(|\Phi(x,k)|)$. There are at most $R^{C(x,k)}$ copies of the kernel instance. Each of them can be proved (in brute force) in size $O(2^{|\Phi(x_m,k_m)|}) = O(2^{poly(g(k))})$, since $(x_m,k_m) \in ker(L)$ and any unsatisfiable formula Ξ with n variables has Frege proofs of size $O(2^n)$.

   The length of the total proof is thus $O(\sum_{t=0}^{C(x,k)} R^t \cdot [h(|\Phi(x,k)|) + 2^{poly(g(k))})]$. We infer the desired result when $C(x,k) = O(poly(|\Phi(x,k)|))$.

2. We unwind the substitions implicit in the extended Frege proofs. For $R = 1$ (i.e. a reduction chain), arguing that the blow-up due to making substitutions is quasipolynomial as long as the chain length is logarithmic is identical to similar arguments made in [9], [2] for other problems, and we omit further details.

   In our case the complication arises since we no longer have a chain but a tree. However, we can upper bound the complexity of Frege proofs by $R^{C(x,k)}$ times the complexity of a single chain (a root-to-leaf path in this tree). As long as $C(x,k) = O(\log(|\Phi(x,k)|))$, the term $R^{C(x,k)}$ has a magnitude polynomial in $|\Phi(x,k)|$. Multiplying this polynomial by the quasipolynomial complexity of each chain still yields a proof of complexity quasipolynomial in $|\Phi(x,k)|$. ◀

▶ **Observation 17.** *There is an important uniformity aspect of kernelization that we haven't used in the preceding proof:* the fact that data reductions are specified by polynomial time algorithms. *This issue will be important in applying the above result: often the existence of a data reduction is proved by an algorithm whose soundness (for all instances) would be rather cumbersome to simulate in propositional proofs. This is the case when results involve general techniques for developing kernelizations, such as the Crown Decomposition Lemma or the Sunflower Lemma. As long as we do not insist, however, on* actually generating *the proof, but merely on* proving its existence*, we can get away with proving the soundness of individual instances. That is, if we can prove the soundness of* an individual application of a propositional reduction rule*, $\Phi(x,k) \vdash \Phi(x',k')$, taking for granted the existence/definition of (x',k'), we can prove the existence of efficient proofs,* ***without actually having to generate a propositional proof of the soundness of the reduction techniques.***

Next we highlight some applications of our main (meta)theorem:

3.1 Proof Complexity of (Dual) Coloring

▶ **Theorem 18.** *There exists a kernelization that reduces instances (G,k) of DUALCOL to a kernel of size at most $3k-2$. The length of reduction chain in this kernelization is $O(k)$. The soundness of each reduction step can be witnessed by polynomial size Frege proofs. Hence, for every fixed k, negative instances (G,k) of DUALCOL have Frege proofs of size polynomial in $|\Phi_{G,k}|$.*

Proof. The kernelization is a variant of the classical one from the parameterized complexity literature, based on *crown decompositions* (Definition 12). It consists of three data reductions:

(a). Let $All(G)$ be the set of vertices v adjacent to all other vertices in G. If $All(G) \neq \emptyset$ then $(G,k) \in DualCol \Leftrightarrow (G \setminus All(G), k - |All(G)|) \in DualCol$.

(b). If $All(G) = \emptyset$ but $\overline{G}$ has a matching of size k, $x_1, y_1, \ldots, x_k, y_k$, with x_i being matched to y_i for $i = 1, \ldots, k$, then $(G,k) \in DualCol$ (so reduce it to an arbitrary positive instance).

(c). Assume that rules (a),(b) do not apply. Let (C,H,R) be a crown decomposition of the graph $\overline{G}$. Reduce (G,k) to (G',k'), by deleting $H \cup C$ from G and $k' = k - |H|$.

Without loss of generality, we will only apply rule (c). to crown decompositions where $|H| \neq \emptyset$ and all nodes in C are matched to some node in H. This is possible for the following reason: if $|H| \neq \emptyset$ and the original crown decomposition had other vertices in C, just move them to R. If, on the other hand $|H| = \emptyset$ then all vertices in C would be connected to all vertices in $C \cup R$, hence to all vertices of G. But this cannot happen, since the case $All(G) \neq \emptyset$ is covered by the first data reduction rule.

The Crown Decomposition Lemma (Lemma 4.5 of [19]) makes sure that at least one of reduction rules (a),(b),(c) applies to every graph with more than $3k-2$ vertices.

The safety of reduction rule (c) can be informally justified as follows: since vertices in a crown decomposition of $\overline{G}$ are matched in a matching m, vertices $v \in H$ and $m(v)$ is C are not connected in G, hence they can be colored with the same color. At the same time, $m(v)$ is connected in G to all the vertices of G', hence must assume a color different from all the colors of vertices of G'. Also $m(v_1)$ and $m(v_2)$ are connected, so must assume distinct colors. In conclusion, vertices of C must use $|C|$ different colors, and G is $n-k$ colorable if and only if G' is $n-k-|C|$ colorable. But $|G'| = n - 2|C|$, so G is $n-k$ colorable if and only if G' is $|G'| - (k - |C|)$ colorable.

Rule (b). does not apply to unsatisfiable instances of DualCol. Hence we have to argue about the size of Frege proofs witnessing the soundness of rules (a) and (c), namely: Let $\Phi_{v,1}[\overline{Y}]$ be the formula $\wedge_{w \neq v} Y_{v,w}$ (informally, $v \in All(G)$). We need to provide proofs that witness that

$$\Phi(G,k) \wedge \Phi_{v,1}[\overline{Y}] \vdash \Phi(G \setminus \{v\}, k-1), \text{ and}$$

$$\Phi(G,k) \vdash \Phi(G',k').$$

For the first implication, define new variables $Z_{w,i}$ via the substitution, for $w \neq v \in V(G)$, $Z_{w,i'} \leftrightarrow X_{w,i} \wedge X_{v,l}$, where $i' = i$ for $i < l$, $i' = i-1$ for $i > l$.

We start by deriving, by resolving unit literals $Y_{v,w}$ (which are part of the formula), for all $w \neq v \in V(G)$ and i, clauses $\overline{X_{v,i}} \vee \overline{X_{w,i}}$. Then we derive, for every $w \neq v \in V(G)$ and i, clauses $\overline{X_{v,i}} \vee (\vee_{j \neq i} X_{w,j})$. This is done by resolving $(\vee_{j=1}^{k} X_{w,j})$ and $\overline{X_{v,i}} \vee \overline{X_{w,i}}$. We then derive clauses $\overline{X_{v,i}} \vee (\vee_{i'=1}^{k-1} Z_{w,i'})$. By resolving all these clauses against $\vee_{i=1}^{k} X_{v,i}$ we derive $(\vee_{i'=1}^{k-1} Z_{w,i'})$. Similar tricks allow deriving clauses $\overline{Z_{w,i}} \vee \overline{Z_{w,j}}$ and $\overline{Y_{v,w}} \vee \overline{Z_{v,i}} \vee \overline{Z_{w,i}}$ from the corresponding clauses in the X variables.

As for the second reduction rule, intuitively we want to encode the fact that if a vertex $v \in G'$ is colored with color i in G, then coloring it with color $i - less(v)$, where $less(v)$ is the number of nodes in H colored with a color smaller than i, yields a legal coloring of G'. This is true since all nodes in H must get colors (in G) different from all colors in G'.

For an arbitrary vertex $v \in G'$, let $less(v)$ be the number of nodes $w \in C$ (here C refers to the class of the crown decomposition of $\overline{G}$) such that $col(w) < col(v)$. One can compute the binary representation of number $less(v)$ using Frege proofs as follows: we create a boolean variable $T_{v,w}$ which will be true iff $col(w) < col(v)$. One can compute $T_{v,w}$ as

$$T_{v,w} := \bigvee_{i<j} X_{w,i} \wedge X_{v,j}.$$

Now we simply use the predicate $COUNT(T_{v,w})_{w \in C}$ to compute the binary representation of $less(v)$. Here COUNT is the Buss counting predicate [8]. We will also derive the following formulas:

$$\overline{X_{v,i}} \vee \bigvee_{t=1}^{i} [less[v] = t] \tag{1}$$

To accomplish that, we use the pigeonhole principle PHP_i^{i+1} to prove that

$$\overline{X_{v,i}} \vee [COUNT((X_{w,j})_{w \in C, j<i}) \leq i] \tag{2}$$

Indeed, assuming $X_{v,i} = TRUE$ we can derive any disjunction of length $i+1$ consisting of literals of type $\overline{X_{w,j}}$, with $w \in C$, $j < i$. This is because for all $w_1 \neq w_2 \in C$, $k_1 \neq k_2$ $\overline{X_{w_1,k_1}} \vee \overline{X_{w_2,k_1}}$ and $\overline{X_{w_1,k_1}} \vee \overline{X_{w_1,k_2}}$ are clauses of $\Phi(G,k)$. By Lemma 2 we can derive equation (2). Next, simple arguments along the lines of [8] establishes the equivalence between formulas $U \leq i$ and $\bigvee_{k=1}^{i}[U = k]$. Here U is a bit vector of appropriate length to represent i. We use (2) and this to derive (1).

Now, for every $v \in V(G') = R$ we define a new variable $Z_{v,i}$, designed to be true iff the color of v in the induced coloring on G' is j. We will enforce this by making the substitutions

$$Z_{v,j} := \bigvee_{j=1}^{i} X_{v,i} \wedge [less(v) = i - j] \tag{3}$$

First note that Z respects the color classes of G: if v_1, v_2 have the same color in G then they have the same color in G'. Furthermore, the substitution does not collapse two different color classes of G into a single color class in G': it simply relabels the colors of vertices in G' with elements of $1, 2, \ldots, k'$. Therefore, if $Z_{v_1,j} = Z_{v_2,j} = TRUE$ then there exists an unique i_0 such that $X_{v_1,i_0} = X_{v_2,i_0} = TRUE$.

We need to derive clauses $\bigvee_{t=1}^{k'} Z_{v,t}$ as well as, for $vw \in E(G')$, $\overline{Z_{v,j}} \vee \overline{Z_{w,j}}$. Deriving the first type of clauses is easy: we use formulas (1) and $X_{v,1} \vee X_{v,2} \vee \ldots \vee X_{v,k}$.

As for the second one, nota that all clauses $\overline{X_{v,i}} \vee \overline{X_{w,i}}$ are part of $\Phi(G,k)$. Given the observation we made above and this fact, assuming $Z_{v,j} = Z_{w,j} = TRUE$ we can derive a contradiction. By Lemma 2 we can, therefore, derive (with the same complexity) clause $\overline{Z_{v,j}} \vee \overline{Z_{w,j}}$.

◀

3.2 Proof Complexity of Schrijver's Theorem

In this section we deal with the proof complexity of a stronger version of the Kneser-Lovász theorem known as Schrijver's Theorem [35]. This is a statement about the chromatic number of the so-called *stable Kneser graph* $SKn_{n,k}$, defined as follows:

▶ **Definition 19.** *Call a set* $A \subseteq \binom{n}{k}$ stable *if* A *does not contain two elements that are consecutive (we also consider* n *and* 1 *as consecutive). Denote the set of stable sets by* $\binom{n}{k}_{st}$. *The* stable Kneser graph $SKn_{n,k}$ *is the subgraph of* $Kn_{n,k}$ *induced by the set* $\binom{n}{k}_{st}$.

Schrijver's theorem asserts that the chromatic number of the stable Kneser graph $SKn_{n,k}$ is $n-2k+2$. We are, of course, interested mainly in the harder part of this result, the lower bound $\chi(SKn_{n,k}) > n-2k+1$. Since $SKn_{n,k}$ is the subset of the Kneser graph (see e.g. Figure 1, where the central star is the stable Kneser graph $SKn_{5,2}$), this strengthens the (harder part of the) Kneser-Lovász theorem. The propositional translation of Schrijver's theorem is immediate, and the resulting unsatisfiable formulas, that we will denote by $\text{Schrijver}_{n,k}$ are subformulas of formulas $Kneser_{n,k}$. We have the following:

▶ **Theorem 20.** *For every fixed* k, *formulas* $Schrijver_{n,k}$ *have Frege proofs of size quasipolynomial in* n.

For the (somewhat more involved) proof of this theorem, we refer the reader to [26].

3.3 Buss Meets Buss: the Proof Complexity of Vertex Cover

In this subsection we study the proof complexity of Vertex Cover, the "drosophila of parameterized complexity" [20]. We apply our result to a variation of the standard kernelization of VC (called in [20] *the Buss reduction*, hence the title of this subsection) to prove:

▶ **Theorem 21.** *Instances* (G,k) *of VC have a kernelization with a data reduction chain of length* $O(k)$ *to a kernel with at most* k^2 *vertices. The soundness of each step in this data reduction can be witnessed by Frege proofs of size polynomial in* $|\Phi(G,k)|$. *Hence, for every fixed* k *negative instances* $\Phi(G,k)$ *of VC have Frege proofs of size polynomial in* $|\Phi(G,k)|$.

Proof. Informally, we will use the following two data reduction rules:

(a). if G has a vertex v of degree larger than k then G has a VC of size $\leq k$ if and only if $G \setminus \{v\}$ has a VC of size $\leq k-1$. Indeed, v must be part of any VC of G of size $\leq k$.

(b). if $Isolated(G)$ denotes the set vertices v in G that are isolated then G has a VC of size $\leq k$ iff $G \setminus Isolated(G)$ has a VC of size $\leq k$.

The kernel of these two reduction rules, the set of instances (G,k) of VC such that none of the two rules applies is composed of graphs of at most k^2 vertices only [19].

To encode the soundness of these rules by polynomial-size Frege proofs we use the predicate $COUNT^n_k(x_1,x_2,\ldots,x_n)$ from [8]. Formula $COUNT^n_k(x_1,x_2,\ldots,x_n)$ is TRUE if and only if at least k of the variables $x_1,x_2,\ldots,x_n$ are true. For every fixed k, $COUNT^n_k$ can be computed by polynomial size Frege proofs.

We will define a sequence of formulas:

1. For $v \in V$, $\Phi_{v,1}(\overline{Y}) = COUNT^{n-1}_k((Y_{v,w})_{w \neq v \in V})$. Informally, $\Phi_{v,1}$ is true in graph G iff the degree of v is at least k.
2. For $v \in V$, $\Phi_{v,2}(\overline{X},\overline{Y}) = (\bigwedge_{i=1}^{k} \overline{X_{v,i}}) \wedge \Phi_{v,1}(\overline{Y}) \wedge \Phi_{VC}(G,k)[\overline{X},\overline{Y}]$.

For every neighbor w of v, by resolving $Y_{v,w}$ with clause $\overline{Y_{v,w}} \vee X_{v,1} \vee \ldots \vee X_{v,k} \vee X_{w,1} \vee \ldots \vee X_{w,k}$. of $\Phi_{v,2}$ we derive clause $X_{v,1} \vee \ldots \vee X_{v,k} \vee X_{w,1} \vee \ldots \vee X_{w,k}$. By resolving successively with $\overline{X_{v,1}},\ldots,\overline{X_{v,k}}$ we derive clause $X_{w,1} \vee \ldots \vee X_{w,k}$.

Formula $\bigwedge_{w \in N(v)} (X_{w,1} \vee \ldots \vee X_{w,k})$ is isomorphic to the Pigeonhole Principle $PHP^k_{|N(v)|}$ which has polynomial-size Frege refutations [8]. Plugging in this proof of this statement into our argument, we conclude that that the implication $\Phi_{v,2}(X, \overline{Y}) \vdash \Box$ can be witnessed by polynomial size Frege proofs, hence, by Lemma 2, so does the implication $\Phi_{v,1}(\overline{Y}) \wedge \Phi_{VC}(G,k)[\overline{X}, \overline{Y}] \vdash \bigvee_{i=1}^{k} X_{v,i}$.

As for the second reduction rule, it is just as easy: for every vertex $v \in V$ which is isolated and every $i = 1, \ldots, k$, we first derive by resolution (using negative clauses $\overline{Y_{v,w}}$ and clause $\overline{X_{v,i}} \vee (\bigvee_{w \neq v} Y_{v,w})$ unit clauses $\overline{X_{v,i}}$. We then use these clauses to resolve away every other occurrence of $X_{v,i}$ from the formula, obtaining a formula isomorphic to $\Phi(G \setminus Isolated(G), k)$. ◀

3.4 Proof Complexity of Edge Clique Cover

In this section we study the proof complexity of the following problem:

▶ **Definition 22** (Edge Clique Cover). *Given graph G and integer k, to decide is whether one can find sets of vertices $V_1, V_2, \ldots, V_k \subseteq V$ s.t. each V_i induces a clique, and for every edge $e = (v,w) \in E$ there exists $1 \leq i \leq k$ s.t. $v, w \in V_i$ ("each edge is covered by some clique"). We represent instance (G,k) of Edge Clique Cover by propositional formula $\Phi_{G,k}$ as follows:*

- *For every pair of distinct vertices $v, w \in V$ define a variable $Y_{v,w}$. For every edge $(v,w) \in E(G)$ add unit clause $Y_{v,w}$. For $(v,w) \notin E(G)$ add unit clause $\overline{Y_{v,w}}$.*
- *For $v \in V$ and $1 \leq i \leq k$ define boolean variable $X_{v,i} = TRUE$ iff $v \in V_i$.*
- *For $v, w \in V$ and $1 \leq i \leq k$ add $\overline{X_{v,i}} \vee \overline{X_{w,i}} \vee Y_{v,w}$ ("if $v, w \in V_i$ then $vw \in E(G)$") and $\overline{Y_{v,w}} \vee (\vee_{j=1}^{k}(X_{v,j} \wedge X_{w,j}))$. Of course, as written above the latter formula is not CNF, but it can be converted easily by expanding the last disjunction.*

The following is our result for the Edge Clique Cover problem. The main technical novelty is reducing the length of the data reduction chain (compared to the usual kernelization) from linear to logarithmic, so that we can get quasipolynomial-size Frege proofs:

▶ **Theorem 23.** *There exists a kernelization that reduces instances (G,k) of problem EDGE CLIQUE COVER with graph G having n vertices to a kernel with at most 2^k nodes. The length of the data reduction chain is $O(\log_{1+\frac{1}{2^k-1}}(n))$. The soundness of each reduction step can be witnessed by polynomial size Frege proofs. Consequently, for fixed k, negative instances (G,k) of EDGE CLIQUE COVER have extended Frege proofs of polynomial size and Frege proofs of quasipolynomial size in $|\Phi_{G,k}|$.*

Proof. We use the following data reduction rules:

(a). If $|Isolated(G)| \geq \frac{n}{2^k}$ then reduce (G,k) to $(G \setminus Isolated(G), k)$.

(b). If there exists a set $S \subseteq V$, $|S| \geq \frac{n}{2^k}$ such that vertices in S induce a clique in G, and for all $v, w \in S$ we have $N[v] = N[w]$, where $N[v]$ stands for *the closed neighborhood* of v, then reduce G to (G', k'), where G' is the graph obtained by identifying vertices v, w, and $k' = k$ whenever $N[v] = N[w] \neq \emptyset$, $k' = k - 1$, otherwise.

The soundness of the first reduction rule, $\Phi(G,k) \vdash \Phi(G \setminus Isolated(G), k)$ can be witnessed by efficient Frege proofs similar to those for the vertex cover problem.

As for the second rule, the formula

$$\Xi_S(G) := \wedge_{w,v \in S} \wedge_{r \in V} (Y_{v,r} \leftrightarrow Y_{w,r})$$

(where, of course, $A \leftrightarrow B$ can be equivalently rewritten as $(\overline{A} \vee B) \wedge (A \vee \overline{B})$) expresses the fact that $N[v] = N[w]$ for all $v, w \in S$. So we need to prove the soundness of the rule

$$\Phi(G,k) \wedge \Xi_S(G) \vdash \Phi(G',k'). \tag{4}$$

Without loss of generality we will only deal with the case $N[v] \neq \emptyset$ for all $v \in S$, (the other case, $N[v] = \emptyset$ for all $v \in S$, can be handled with minor modifications to this argument). By slightly abusing notation, we will denote by S the vertex of G' obtained by contraction. Let $s \in S$ be an arbitrary vertex.

We define substitutions: $Y'_{v,w} := Y_{v,w}$ for all $v, w \in G'$, $v, w \neq S$. If, say, $v = S$ we define $Y'_{S,w} := Y_{s,w}$. Also define $X'_{v,i} := X_{v,i}$ for $v \neq S$, $X'_{S,i} := X_{s,i}$. The substitution yields a formula isomorphic to $\Phi(G',k')$, and the proof of the safety is basically trivial.

To obtain the result note that the number of vertices goes down geometrically, by a ratio of $1 - \frac{1}{2^k}$ at each step.

▶ **Lemma 24.** *Rules (a). (b). are safe. Also, for every graph G with $n > 2^k$ vertices one of rules (a). (b). applies.*

Proof. Let G be a graph to which rules (a). (b). do not apply and which has an edge clique cover of size k. Consider an encoding $b(v)$ of every vertex v on k bits such that for every $v \in V$, $b(v)$ is a bit vector whose i'th bit is one iff v is a part of the i'th clique.

There must be a set of vertices $S \subset V$, $|S| \geq \frac{n}{2^k}$ such that for all $u, v \in S$, $b(u) = b(v) = b$, for some $b \in \{0,1\}^k$.

If $b = 0^k$ then, since every edge in G must be covered by one of the k cliques, it follows that every $v \in S$ is an isolated vertex. Hence rule (a). applies.

If, on the other hand $b \neq 0^k$, say $b_i \neq 0$, then every $v \in S$ must belong to the i'th clique. Hence S induces a clique in G. ◀

◀

3.5 Proof Complexity of the Hitting set problem

In the d-Hitting Set problem we are given an universe U and a family $\mathcal{A}$ of subsets of U, all of cardinality at most d, as well as an integer k. To decide is whether there exists a set $H \subseteq U$ containing at most k elements, such that H intersects every $P \in \mathcal{A}$.

A formalization of the d-Hitting set problem as an instance of SAT is obtained as follows:

▶ **Example 25.** Let $P = (U, \mathcal{A}, k)$ be an instance of d-Hitting set. Define formula Φ_P by:

- For $i \in U$, $j = 1, \ldots, k$ add variable $X_{i,j}$, TRUE iff i is the j'th chosen element.
- For $i \neq i' \in U$, $1 \leq j \leq k$ add clauses $\vee_{i \in U} X_{i,j}$ ("some i is the j'th chosen element") and $\overline{X_{i,j}} \vee \overline{X_{i',j}}$ ("at most one i can be the j'th chosen element").
- For $A \in \mathcal{A}$ add $(\vee_{i \in A}(\vee_{j=1,\ldots k} X_{i,j}))$ ("some element of A is among the k chosen elements")

Our result, which only guarantees polynomial size *extended* Frege proofs, is:

▶ **Theorem 26.** *There exists a kernelization mapping instances $(U, \mathcal{A}, k)$ of d-HittingSet with $|U| = n$ elements to a kernel with at most $d \cdot d! \cdot k^d$ sets (hence at most $d^2 \cdot d! \cdot k^d$ elements). The data reductions chains in this kernelization have length $O(n^d/k)$, and their soundness can be witnessed by polynomial-size Frege proofs. Hence for every fixed k, d, unsatisfiable instances $\Phi_{(U,\mathcal{A},k)}$ of d-HittingSet have extended Frege proofs of size $O(poly(|\Phi_{(U,\mathcal{A},k)}|))$.*

Proof. We employ the standard kernelization of d-Hitting set based on sunflowers [19]:

▶ **Definition 27.** *A* sunflower with k-petals and core Y *is a colection of sets $S_1, \ldots, S_k$, all different from Y, such that for $1 \leq i < j \leq k$, $S_i \cap S_j = Y$.*

We are going to propositionally encode the following informally stated data reduction rule: let $(U, \mathcal{A}, k)$ be an instance of the d-Hitting set such that $\mathcal{A}$ contains a sunflower $\mathcal{S} = \{S_1, S_2, \ldots, S_{k+1}\}$ of cardinality $k+1$ with core Y. We reduce $(U, \mathcal{A}, k)$ to the instance $(U', \mathcal{A}', k)$, where $\mathcal{A}' = (\mathcal{A} \setminus \mathcal{S}) \cup \{Y\}$ and $U' = \cup_{X \in \mathcal{A}'} X$. Indeed, consider a hitting set H for $(U, \mathcal{A}, k)$. By definition, H meets every element of $\mathcal{A} \setminus \mathcal{S}$. If H did not meet Y then it would have to meet each of the $k+1$ disjoint petals $S_j \setminus Y$. Hence $|H| \leq k$ iff H meets Y.

To simulate this argument propositionally, define for $i \in U'$ substitutions $X'_{i,j} := X_{i,j}$. We need to (a). derive clause $(\vee_{i \in Y}(\vee_{j=1,\ldots k} X_{i,j}))$ (b). for every $j = 1, \ldots, k$, derive clauses $\vee_{i \in U'} X_{i,j}$.

For the first clause we show that $\Phi(U, \mathcal{A}, k) \wedge (\wedge_{i \in Y}(\wedge_{j=1,\ldots k} \overline{X_{i,j}})) \vdash \emptyset$ and then we invoke Lemma 2. To do that we first derive, for $l = 1, \ldots, k+1$ (by resolving literals $\overline{X_{i,j}}$) clauses $(\vee_{i \in S_l \setminus Y}(\vee_{j=1,\ldots k} X_{i,j}))$.

Substituting each variable $X_{i,j}$, where $i \in S_j \setminus Y$ to a new variable $Y_{i,j}$ yields a formula isomorphic to PHP^k_{k+1} which has polynomial size Frege proofs [8]. Putting all these things together we get polynomial-size Frege proofs witnessing the soundness of one step of the data reduction.

The number of clauses drops at every reduction step by k, so the length of the data reduction chain is $O(n^d/k)$. ◀

4 Proof Complexity of principles in Computational Social Choice

A great number of applications come from the theory of Social Choice [7]: motivated by pioneering work of [38], a significant amount of research in Artificial Intelligence has investigated the provability of such results in logical settings (see [22] for a recent survey). We show that the most interesting of these results (Arrow's theorem and the Gibbard-Satterthwaite theorem) have proof complexity counterparts: the unsatisfiability of formulas encoding them can be certified by Frege proofs of subexponential length. A first example of application is Arrow's Theorem. The formulas encoding the nonexistence of a social welfare function satisfying the conditions of Arrow's theorem are rather large. Nevertheless, such an encoding exists, and was used explicitly in [38] to give a computer-assisted proof of Arrow's theorem[4]:

▶ **Definition 28.** *Consider an instance with n agents and m objects to rank. There are $(m!)^n$ possible profiles for the complete rankings of the m objects, and $m!$ possible aggregate orderings of the m objects. Formula $Arrow_{m,n}$ (unsatisfiable for $m, n \geq 3$) has $(m!)^{n+1}$ variables $X_{R,\pi}$, one for each possible pair (R, π) consisting of ranking profile R, and an aggregate ordering $\pi \in S_m$. The constraints are the following:*

- *For every $R \in \mathcal{R}$ and $\pi_1 \neq \pi_2 \in S_m$ add clauses $\bigvee_{\pi \in S_m} X_{R,\pi}$ ("every profile is aggregated to some ordering") and $\overline{X_{R,\pi_1}} \vee \overline{X_{R,\pi_2}}$ ("no profile is aggregated to more than one ordering")*
- *For $i = 1, \ldots, n$ we add to $Arrow_{m,n}$ clauses $\bigvee_{R \in \mathcal{R}} \overline{X_{R,R_i}}$. These forbid aggregations that always output the ordering given by the i'th agent, i.e. dictatorial rank aggregations.*
- *For every two objects a, b let $S^m_{a,b}$ be the set of orderings π where for all $i = 1, \ldots n$, $\pi^{-1}(a) < \pi^{-1}(b)$ (i.e. a is preferred to b in ordering π). Let $\mathcal{R}_{a,b}$ be the set of profiles such that for every $i = 1, \ldots, n$, $R_i \in S^m_{a,b}$ (i.e. all agents prefer a to b). For every $R \in \mathcal{R}_{a,b}$ add to $Arrow_{m,n}$ clauses $\bigvee_{\pi \in S^m_{a,b}} X_{R,\pi}$. These constraints encode unanimity (if all agents prefer object a to b then a is preferred to b in the aggregated ranking).*

[4] For encodings of Arrow's Theorem in more powerful logical frameworks see [14, 23].

- *For all profiles $R, R' \in \mathcal{R}$ and objects a, b such that all players rank a, b in the same way in both R, R' and all pairs $\pi_1, \pi_2 \in S^m$ that rank a, b in a different way (i.e. $\pi_1^{-1}(a) < \pi_1^{-1}(b)$ but $\pi_2^{-1}(a) > \pi_2^{-1}(b)$ or viceversa) we add to $Arrow_{m,n}$ clauses $\overline{X_{R,\pi_1}} \vee \overline{X_{R',\pi_2}}$. These encode independence of irrelevant alternatives (if R, R' coincide with respect to the relative ordering of a, b then their aggregate orderings also rank a, b in the same way).*

Results in [38] yield a kernelization for $Arrow_{m,n}$ with a reduction chain of length $O(m+n)$. We improve them by providing a kernelization with reduction chains whose length only depends on n, implying the existence of polynomial size Frege proofs for constant values of n:

▶ **Theorem 29.** *Formulas $Arrow_{m,n}$ have a kernelization with data reduction chains of length $\leq C(n+1)$, with constant C independent from m, n, whose safety is witnessed by polynomial-size Frege proofs. Hence (a) formulas $Arrow_{m,n}$ have Frege proofs of size quasipolynomial in $|Arrow_{m,n}|$). (b). For every fixed $n \geq 3$ there exists a polynomial $p_n(\cdot)$ such that for all $m \geq 3$ formulas $Arrow_{m,n}$ have Frege proofs of size at most $p_n(|Arrow_{m,n}|)$.*

Proof. The kernelization has two data reduction rules, described informally as follows:

(a). If $n \geq 2, m \geq 6$ and $W : [S_m]^n \to [S_m]$ is a function that is non-dictatorial, IIA and unanimous then there exists an $T \subseteq [m]$, $|T| = m - 5$ such that $W_{-T} : [S_{[m]_{-T}}]^n \to [S_{[m]_{-T}}]$ (see the end of Section 2) has the same properties. In other words, one can reduce in one step the set of alternatives from $[m]$ (which has m elements) to $[m]_{-T}$ (which has 5).

(b). See [38]: If $n, m \geq 3$ and $W : [S_m]^n \to [S_m]$ is non-dictatorial, IIA and unanimous then at least one of the functions $W_{1,2}, W_{1,3}, W_{2,3} : [S_m]^{n-1} \to [S_m]$ defined as follows: $W_{i,j}(R_1, R_2, \ldots, \widehat{R_i}, \ldots, R_n) = W(R'_1, \ldots, R'_n)$ is non-dictatorial, IIA and unanimous. Here $R'_i = R_j$, $R'(k) = R_k, k \neq i$. In other words, one can reduce in one step the number of agents by one.

▶ **Lemma 30.** *If W is unanimous, IIA and non-dictatorial then for every $B \subseteq [m]$, function W_{-B} is unanimous and IIA.*

Proof. Suppose that $a, a' \in [m]_{-B}$ and $a <_{R_i} a'$ for all $i \in [m]_{-B}$. Then $a <_{R_i^{+B}} a'$. By unanimity of W, $a <_{W(R_1^{+B}, \ldots, R_n^{+B})} a'$. Since a, a' were arbitrary, it follows that W_{-B} is unanimous. As for IIA, let $a, a' \in [m]_{-B}$ and $(R_1, R_2, \ldots, R_n)$ and $(R'_1, R'_2, \ldots, R'_n)$ be preference profiles such that, for every $i = 1, \ldots, n$, R_i and R'_i agree with respect to the relative ordering of a, a'. Then for every $i = 1, \ldots, n$, R_i^{+B} and $R_i'^{,+B}$ agree with respect to the relative ordering of a, a'. By the IIA axiom for W, $W(R_1^{+B}, R_2^{+B}, \ldots, R_n^{+B})$ and $W(R_1'^{,+B}, R_2'^{,+B}, \ldots, R_n'^{,+B})$ agree with respect to the relative ranking of a, a'. Hence so do $W_B(R_1, R_2, \ldots, R_n)$ and $W_B(R'_1, R'_2, \ldots, R'_n)$. ◀

▶ **Lemma 31.** *Reduction (a). is safe.*

Proof. Consider an arbitrary set $T \subseteq [m]$ of cardinality $m - 6$, e.g. $T = \{7, \ldots, m\}$. Let $x \notin T$, e.g. $x = 6$ and $U = T \cup \{x\}$. If W_{-U} is non-dictatorial we are done. Otherwise, assume w.l.o.g. that agent 1 is a dictator for W_{-U}. Since 1 is not a dictator for W, there must exist indices $c \neq d \in [m]$ and preference profiles $<_1, \ldots, <_n$ on $[m]$ such that $c <_1 d$ but $d <_{W(<_1, \ldots, <_n)} c$. Let $y, a, b \notin T$, different from x, c, d, and let $V \subseteq [m]$, $|V| = m - 5$, $a, b, c, d, x \notin V$, $y \in V$. Such a V exists, since $m \geq 6$. Clearly $V \neq U$, since $y \in V \setminus U$. We claim that function W_{-V} is not dictatorial.

First note that 1 cannot be a dictator for W_{-V}. Indeed, consider $<_{i,-V}$ the restriction of $<_i$ to $[m]_{-V}$. We have $c <_{1,-V} d$ but $d <_{W_{-V}(<_{1,-V}, \ldots, <_{n,-V})} c$. The first relation holds because $c <_1 d$ and $c, d \notin V$. The second relation holds because to compare c, d according to

$W_{-V}(<_{1,-V},\ldots,<_{n,-V})$ we apply function W on $(<^{+V}_{1,-V},\ldots,<^{+V}_{n,-V})$. But since $c,d\notin V$, $<^{+V}_{i,-V}$ coincides with $<_i$ with respect to the ordering of c,d for $i=1,\ldots,n$. Invoking the IIA property of W for tuples $(<_1,\ldots,<_n)$ and $(<^{+V}_{1,-V},\ldots,<^{+V}_{n,-V})$ justifies the second relation.

Assume now that another agent, say 2, were a dictator for W_{-V}. Let $<_1,<_2$ be preference profiles on $[m]$ s.t. $a<_1 b$ but $b<_2 a$, and $<_3,\ldots,<_n$ be arbitrary preference profiles. First, invoking the first relation, the fact that W_{-U} is computed using W, and that 1 is a dictator for W_{-U} we get that $a<_{W_{-U}(<_{1,-U},<_{2,-U},\ldots,<_{n,-U})} b$. Invoking the IIA property of W on tuples $(<_{1,-U},<_{2,-U},\ldots,<_{n,-U})$ and $(<_1,<_2,\ldots,<_n)$ we get that $a<_{W(<_1,<_2,\ldots,<_n)} b$. Using a similar reasoning for the function W_{-V} we get that $b<_{W(<_1,<_2,\ldots,<_n)} a$, a contradiction. ◀

The safety of reduction (b) was (mathematically) proved in [38]. Next we outline how to simulate these mathematical arguments using polynomial-size Frege proofs. First, note that formula $Arrow_{m,n}$ has $(m!)^{n+1}$ variables, all of them appearing explicitly in the formula. But $n=O(log((m!)^{n+1}))$, so indeed a reduction chain of length $O(n)$ has length logarithmic in $|Arrow_{m,n}|$. Invoking our metatheorem yields a proof of point (a) of Theorem 29. Point (b) follows by invoking point 2 of the same metatheorem.

First reduction rule: Define, for $Q\subseteq[m]$, $|Q|=m-5$, and $i=1,\ldots,n$ formulas

$$Nondict_{-Q,i}:=\bigvee_{R\in\mathcal{R}_{-Q}}\overline{X_{R^{+Q},R_i^{+Q}}}$$

(informally, formula $Nondict_{-Q,i}$ is true iff i is not a dictator for W_{-Q}).

$$Unanimous_{-Q}:=\bigwedge_{a,b\in[m]_{-Q}}\bigvee_{\substack{R\in\mathcal{R}_{a,b,-Q}\\ \pi\in S^m_{a,b}}}X_{R^{+Q},\pi^{+Q}}.$$

$$IIA_{-Q}:=\bigwedge_{(R,R',\pi,\pi')\in\mathcal{R}_{-Q}}(\overline{X_{R^{+Q},\pi_1^{+Q}}}\vee\overline{X_{R'^{,+Q},\pi_2^{+Q}}})$$

(where, for simplicity, we have ommitted the IIA restrictions on R,R',π_1,π_2, see Definition 28). Note that $Arrow_{m,n}=Unanimous_{-\emptyset}\wedge IIA_{-\emptyset}\wedge\bigwedge_{i=1}^n Nondict_{-\emptyset,i}$.
We will prove that

$$Arrow_{m,n}\wedge\bigwedge_{i=1}^n Nondict_{-[6:m],i}\vdash Arrow_{5,n}\tag{5}$$

and, for $i=1,\ldots,n$

$$Arrow_{m,n}\wedge\bigvee_{i=1}^n\bigwedge_{R\in\mathcal{R}_{-[6:m]}}X_{R^{+[6:m]},R_i^{+[6:m]}}\vdash Arrow_{5,n}\tag{6}$$

Employing tautology $\bigwedge_{i=1}^n Nondict_{-[6:m],i})\vee\bigvee_{i=1}^n(\bigwedge_{R\in\mathcal{R}_{-[6:n]}}X_{R^{+[6:m]},top(R_i^{+[6:m]})})$ and substitutions implicit in (5) and (6) we conclude that $Arrow_{m,n}\vdash P_1\vee P_2$, where both P_1,P_2 are formulas isomorphic to $Arrow_{5,n}$. Thus we are in the framework of our metatheorem with $R=2$.
We need to specify the substitutions implicit in (5) and (6). First, formalizing the mathematical argument in Lemma 30 we show that $Arrow_{m,n}\vdash IIA_{-Q}\wedge Unanimous_{-Q}$. The propositional content of this implication is trivial: the clauses of $Unanimous_{-Q}$ and IA_{-Q} are simply subclauses of $Arrow_{m,n}$.
Because of this, the substitution witnessing implication (5) is quite simple: it replaces a restricted variable $X'_{R,\pi}$ of $Arrow_{5,n}$ with the variable $X_{R^{+[6;m]},\pi^{+[6:m]}}$ of $Arrow_{m,n}$.

As for (6), define, for all $c < d \in [5]$ and $i = 1, \ldots, n$, formulas

$$Witness_{c,d,i} := \bigvee_{\substack{R \in \mathcal{R}: R_i \in S^m_{c,d} \\ \pi \in S^m_{d,c}}} X_{R,\pi} \tag{7}$$

Informally, formula $Witness_{c,d,i}$ is true when pair (c, d) acts as a witness that agent i is not a dictator for W, since $c <_{R_i} d$ but $d <_{W(R)} c$.

A next step is to prove that $Arrow_{m,n} \wedge \bigwedge_{R \in \mathcal{R}_{-[6:m]}} X_{R^{+[6:m]}, R_i^{+[6:m]}} \vdash \bigvee_{c<d \in [5]} Witness_{c,d,i}$. This is easy: we use literals $X_{R^{+[6:m]}, R_i^{+[6:m]}}$ to prove (by resolution)

$$Arrow_{m,n} \wedge \bigwedge_{R \in \mathcal{R}_{-[6:m]}} X_{R^{+[6:m]}, R_i^{+[6:m]}} \wedge \bigwedge_{c<d \in [5]} \bigwedge_{\substack{R \in \mathcal{R}: R_i \in S^m_{c,d} \\ \pi \in S^m_{d,c}}} \overline{X_{R,\pi}} \vdash \square \tag{8}$$

(the last conjunction negates formulas $Witness_{c,d,i}$) and then invoke Lemma 2 to get a proof of the same length of the implication we claimed.

Now we prove, for all $j = 1, \ldots, n$ that $Arrow_{m,n} \wedge Witness(c, d, i) \vdash Nondict_{-V,j}$, where V is defined as in the proof of Lemma 31.

The proof of the implication for $j = i$ uses unit literal X_{R,R_j} (negation of one from $Nondict_{-V,i}$) and $\overline{X_{R,\pi}} \vee \overline{X_{R^{+V}_{-V}, \pi_2}}$ (part of the IIA part of $Arrow_{m,n}$) to derive clauses $\overline{X_{R^{+V}_{-V}, \pi_2}}$ for all π_2 that rank c, d in a different way than π. Resolving away these literals from clause $\bigvee_{\pi \in S_m} X_{R^{+V}_{-V}, \pi}$ (part of $Arrow_{m,n}$) derives clause $Nondict_{-V,i}$.

As for the case $j \neq i$, we want to show that

$$Arrow_{m,n} \wedge Witness(c, d, i) \wedge \bigwedge_{R \in \mathcal{R}_{[5]}} X_{R^{+[6:m]}, R_j^{+[6:m]}} \vdash \square \tag{9}$$

By Lemma 2 this will imply $Nondict_{-V,j}$. Let $R = (R_1, R_2, \ldots, R_n)$ be a profile on $[5]$ such that $a <_{R_1} b$ but $b <_{R_2} a$ ($a, b \in [5]$ are defined as in Lemma 31). Combining the derivations of $Nondict_{-V,j}$ in (9) with the ones of $Unanimous_{-V}$ and IIA_{-V} (outlined before), plus a bijective identification of of $[m]_{-V}$ and $[5]$ yields a substitution that proves $Arrow_{5,n}$, completing the proof of (6).

Second reduction rule: We refer to Lemma 2 of [38] for (mathematical) details of the reduction. What is important is that the soundness of the statement that at least one of $W_{1,2}, W_{2,3}, W_{1,3}$ is non-dictatorial is established by a case-by-case analysis. It is first proved that it cannot be that all these functions have the same dictator. Then it is established that if i is the dictator of $W_{1,2}$, j the dictator of $W_{1,3}$, k the dictator of $W_{2,3}$ then $i \in \{2, 3\}$, $j \in \{2, 3\}$, $k \in \{1, 3\}$. For all eight possible cases for triplets (i, j, k) we obtain a contradiction: either we explicitly provide a profile R showing that triplet (i, j, k) cannot represent the set of dictators for the three function, or we employ an argument similar to the one in the case $i = j = k$. ◀

As for the Gibbard-Satterthwaite theorem, we use the following formalization:

▶ **Definition 32.** *Consider an instance with n agents and m objects. There are $(m!)^n$ possible profiles for the complete rankings of the m objects, and m possible outcomes. Formula $GS_{m,n}$ has $(m!)^n \times m$ variables $X_{R,o}$, one for each possible pair consisting of a strategy profile R and a value $o \in [m]$, the value of the SCF on profile R. The constraints are the following:*

- *For $R \in \mathcal{R}$ add clauses $\bigvee_{o\in[m]} X_{R,o}$ ("every joint profile is aggregated to some object") and $\overline{X_{R,o_1}} \vee \overline{X_{R,o_2}}$ ("no joint profile is aggregated to more than one object").*
- *For $i = 1, \ldots, n$ we add to $GS_{m,n}$ clauses $\bigvee_{R\in\mathcal{R}} \overline{X_{R,top(R_i)}}$. They forbid social choice functions that always output the top preference of the i'th agent, i.e. dictatorial aggregations.*
- *For $i = 1, \ldots, n$ add $\bigvee_{R\in\mathcal{R}} X_{R,o}$. This eliminates social choice functions that are not onto.*
- *Add, for every pair (R, o), player $1 \leq i \leq m$ and $\pi \in S_m$, $\overline{X_{R,o}} \vee (\bigvee_{o'\in pr(i,o,R)} X_{s(i,R,\pi),o'})$. These clauses state that the social choice function is strategyproof.*

▶ **Theorem 33.** *For every fixed m formulas $GS_{n,m}$ have a kernelization of length $O(n)$ whose soundness has polynomial time Frege proofs. Hence, formulas $GS_{n,m}$ expressing the Gibbard-Satterthwaite theorem have (a). Frege proofs of size quasipolynomial in $|GS_{n,m}|$, (b). for every fixed n, Frege proofs of size polynomial in $|GS_{n,m}|$.*

Proof. The argument is very similar to that of Arrow's theorem: We use the following two data reductions: (a). for $n \geq 2, m \geq 4$, if $W : [m]^n \to [m]$ is a social choice function that is onto, non-dictatorial and strategy-proof then there exists $T \subseteq [m]$, $|T| = m - 3$ such that function $W_{-T} : ([m]_{-T})^n \to [m]_{-T}$ is onto, non-dictatorial and strategyproof, and (b). [37] if $W : [m]^n \to [m]$ is a social choice function that is onto, non-dictatorial and strategy-proof then one of functions $W_{1,2}, W_{1,3}, W_{2,3} : [S_m]^{n-1} \to [m]$ defined by $W_{a,b}(R_1, R_2, \ldots, \widehat{R_a}, \ldots, R_n) = W(R'_1, \ldots, R'_n)$ is non-dictatorial, onto and strategy-proof. Here $R'_a = R_b$, $R'(k) = R_k$ for $k \neq a$.

First, it is not obvious that, as formulated in the paragraph, W_{-B} is well-defined. The reason is that $W_{-B}(R)$ invokes W on profile R^{+B}, and it is not obvious that if R is a profile on $[m]_{-B}$ the the outcome of W is an element of $[m]_{-B}$, as needed by the definition.

Suppose that $W_{-B}(R) = W(R^{+B}) \in B$ for some profile R on $[m]_{-B}$. We claim that $W(S) \in B$ for every profile $S = (S_1, S_2, \ldots, S_n)$, contradicting the hypothesis that W is onto. Indeed, if $W_{-B}(R) = W(R^{+B}) \in B$ then $W_{-B}(R_{-1}, S_1) = W(R_{-1}^{+B}, S_1^{+B}) \in B$, otherwise agent 1 would have an opportunity to manipulate at profile R^{+B} by misrepresenting its preference as S_1^{+B}. Applying this argument inductively for agents $2, 3, \ldots, n$ (replacing R_i by S_i) we infer that $W(S) \in B$, which is what we claimed.

▶ **Lemma 34.** *If $W : S_m^n \to [m]$ is onto, strategyproof and non-dictatorial then for every $B \subseteq [m]$, function W_{-B} is onto and strategyproof.*

Proof. Suppose there exists some profile R and agent $i \in [n]_{-B}$ such that i could manipulate $W_{-B}(R)$ by misrepresenting its profile as R'_i. This means that i could manipulate W on profile R^{+B} by misrepresenting its profile as $R_i'^{,+B}$, contradicting the fact that W is strategy-proof. Hence W_{-B} is strategy-proof.

Suppose now that $a \in [m]_{-B}$. Since W is onto, there must exist a profile R such that $W(R) = a$. Consider the profile R'_i that modifies R by moving a to the top of preference profile R_i. We claim that $W(R'_i) = a$. Indeed, if this was not the case then i could manipulate on profile R'_i by misrepresenting its preferences. Continuing the argument inductively for all agents we infer that if $\overline{R}$ is the profile that modifies R by moving a to the top of all profile preferences then $W(\overline{R}) = a$. This means that W is unanimous, hence W_{-B} also is. But then there is a profile $\underline{R}$ such that $W_{-B}(\underline{R}) = a$: simply make a the top of all profiles. Since a was arbitrary, it follows that W_{-B} is onto. ◀

We next prove the safety of reduction rule (a) (for (b) see [37]). We show that there exists $T \subseteq [m]$, $|T| = m-3$ such that W_{-T} is non-dictatorial. Together with Lemma 34 this establishes the safety of rule a.

Step 1. Given two different sets T_1, T_2 of size $m-3$, $|T_1 \cap T_2| = m-4$ (in other words, $|\overline{T_1}| = |\overline{T_2}| = 3$, $|\overline{T_1} \cap \overline{T_2}| = 2$), we show that functions W_{-T_1}, W_{-T_2} must have the same dictator, if they have one.

Suppose, indeed, that W_{-T_1} has dictator i, W_{-T_2} has dictator $j \neq i$. Let $d \in T_2 \setminus T_1$, $c \in T_1 \setminus T_2, a, b \in \overline{T_1} \cap \overline{T_2}$. Define profiles

$$R_s = a < b < \ldots < sorted(T_2) < c, \text{ for } s \neq j$$

$$R_j = b < a < \ldots < sorted(T_2) < c.$$

$W(R) = a$, since i is a dictator for W_{-T_1}. Now, if we replace R_i by

$$R'_i = a < b < \ldots < c < sorted(T_2).$$

obtaining profile R', then $W(R') = a$, otherwise agent i could manipulate by reporting profile R_i instead. We continue changing iteratively profiles $R_s, s \neq j$ to $R'_s = a < b < \ldots < c < sorted(T_2)$, one profile at a time, until all profiles R_s except R_j have been replaced by R'_s. Call this profile $\underline{R}$. That is, $\underline{R}_s = a < b < \ldots < c < sorted(T_2)$ for $s \neq j$, while $\underline{R}_j = b < a < \ldots < sorted(T_2) < c$.

Since no agent $s \neq j$ had an opportunity to manipulate, it must be that $W(\underline{R}) = a$. Consider now profile $\underline{R}'_j = b < a < \ldots < c < sorted(T_2)$. Since W_{-T_2} has agent j as a dictator, $W(\underline{R}_1, \ldots, \underline{R}'_j, \ldots, \underline{R}_n) = W_{-T_2}(\underline{R}_{1,-T_2}, \ldots, \underline{R}'_{j,-T_2}, \underline{R}_{n,-T_2}) = b$. So agent j has an opportunity to manipulate at profile $(\underline{R}_1, \ldots, \underline{R}'_j, \ldots, \underline{R}_n)$ by reporting instead $\underline{R}'_j$.

Step 2. Either there exists a set T of size $m-3$ such that W_{-T} is not dictatorial, or all functions $W_{-T}, |T| = m-3$ must have the same dictator. Indeed, we can "interpolate" between any two sets of cardinality $m-3$ by a sequence of sets falling under step 1.

Step 3. We show that it is not possible that all functions W_{-T}, $|T| = m-3$ have the same dictator i. Since W is not dictatorial, there exists a profile R such that $b = W(R)$ is different from $a = top(R_i)$. Let $T \subseteq [m], |T| = m-3, a, b \notin T$ and consider a profile R' that modifies R by moving $b, sorted(T)$ to the bottom of all preferences (in this order), that is $R' = (R_{-b}^{+b})_{-sorted(T)}^{+sorted(T)}$.

We have $W(R') = W_{-T}(R'_{-T}) = top(R'_i) = a$, since W_{-T} has i as dictator and $top(R'_i) = a$. Let us create a path between R and R' by changing one profile R_s at a time to R'_s, the last move being R_i. The value of W does not change at any step s, since W_{-T} has i as dictator, and the relative orders of elements in $[m]_{-T}$ does not change at any profile as a result of a change $R_s \to R'_s$, $s \neq i$, or agent s would have an opportunity of manipulation at one of the two profiles, using R_s, R'_s, whichever yields a result ranked lower in R_s, R'_s. But this yields a contradiction, since $W(R) = b$ and $W(R') = a \neq b$.

For some details on the propositional simulations we refer to [26]. ◀

5 Conclusions and open problems

We believe that the most important contribution of our paper is to show that several techniques for proving kernelization can sometimes be simulated by efficient extended Frege proofs. The proof techniques in this list includes: crown decomposition, the sunflower lemma, ad-hoc methods. It is an interesting challenge to enlarge the list of methods and problems that have such a simulation or, conversely, show limits of some of these methods.

It is rewarding to note that methods from algebraic topology can be used to reframe and extend results in both Topological Combinatorics and Computational Social Choice: Arrow's theorem has topological proofs [4, 12, 13]. On the other hand the original results on Kneser's conjecture [32] have been strengthened using more advanced topological methods, e.g. [3] (see [29] for a book-length treatment). The results in [2, 38] can be interpreted as stating that in both cases one can bypass topological arguments by purely combinatorial arguments (plus computer-assisted verification of finitely many cases). It is an interesting question whether this is still true for the results requiring more sophisticated topological methods as well.

In Theorem 26 we have only obtained polynomial size extended Frege proofs. Similarly, in Theorems 29, 33 we have only obtained polynomial-size Frege proofs when the number of agents is fixed. We leave open the issue of improving these results. On the other hand, our results have only touched on the most basic topics on the proof complexity of statements in computational social choice. There has been significant progress in this area (see e.g. [22]) and we believe that our framework may be applicable to some of this work (e.g. to the Preservation Theorem of [21]). It would be interesting to see if this is really the case.

Dominique Unruh
University of Tartu, Estonia

Abstract

We present a variant of the quantum relational Hoare logic from (Unruh, POPL 2019) that allows us to use "expectations" in pre- and postconditions. That is, when reasoning about pairs of programs, our logic allows us to quantitatively reason about how much certain pre-/postconditions are satisfied that refer to the relationship between the programs inputs/outputs.

1 Introduction

Relational Hoare logics (RHL) are logics that allow us to reason about the relationship between two programs. Roughly speaking, they can express facts like "if the variable $\mathbf{x}$ in program $\mathfrak{c}$ is equal to $\mathbf{x}$ in program $\mathfrak{d}$, then after executing $\mathfrak{c}$ and $\mathfrak{d}$, respectively, the content of variable $\mathbf{y}$ in program $\mathfrak{c}$ is greater than that of $\mathbf{y}$ in $\mathfrak{d}$." RHL was introduced in the deterministic case by [6], and generalized to probabilistic programs by [4] (pRHL) and to quantum programs by [17] (qRHL). RHLs have proven especially useful in the context of verification of cryptographic schemes. For example, the CertiCrypt tool [4, 3] and its successor EasyCrypt [2, 1] use pRHL to create formally verified cryptographic proofs. And [16] implements a tool for verifying quantum cryptographic proofs based on qRHL.

On the other hand, "normal" (i.e., not relational) quantum Hoare logics have been developed in the quantum setting, starting with the predicate transformers from [10], see [11, 18, 7, 12]. Out of these, [10, 11, 18] use "expectations" instead of "predicates" for the pre- and postconditions of the Hoare judgments. To understand the difference, consider the case of classical probabilistic programs. Here, a predicate is (logically equivalent to) a set of program states (and a program state is a function from variables to values). In contrast, an

expectation is a function from program states to real numbers, basically assigning a value to each program state. Probabilistic Hoare logic with expectations, implicit in [13], uses expectations as the pre- and postconditions of a Hoare judgment. Then, roughly speaking, the preexpectation tells us what the expected value of the postexpectation is after running the program. This can be used to express much more fine-grained properties of probabilistic programs, giving quantitative guarantees about their probabilistic behavior, instead of just qualitative (a certain final state can or cannot occur). As [10] showed, the same approach can be used for quantum programs. Here, an expectation is modeled by a self-adjoint operator A on the space of all program states. The "value" of a given program state ρ is then computed as the trace $\operatorname{tr}\mathsf{A}\rho$. While at the first glance not as obvious as the meaning of classical expectations, this formalism has nice mathematical properties and is also equivalent to taking the expectation value of the outcome of a real-valued measurement. By using this approach, [10, 11, 18] can express more fine-grained judgments about quantum programs, by not just expressing which final states are possible, but also with what probabilities.

Yet, qRHL [17] did not follow this approach (only mentioning it as possible future work). As a consequence, qRHL does not enable as fine-grained reasoning about probabilities as the non-relational quantum Hoare logics. On the other hand, the non-relational quantum Hoare logics do not allow us to reason about the relationship between programs.

In this work, we combine the best of two worlds. We present a variant of qRHL, expectation-qRHL, that reasons about pairs of programs, and at the same time supports expectations as the pre- and postconditions, thus being as expressive as the calculi from [10, 11, 18] when it comes to the probabilistic behavior of the programs.

Related work. The relevant prior work has already been discussed above. Concurrently and independently, [5] presented a different formalization of expectation-qRHL. (The first versions on arXiv appeared within two months of each other.) The biggest difference is the definition of couplings which in our setting are separable quantum states, and in their setting nonseparable quantum states. Therefore, the soundness proofs are totally different in [5] and in the present paper, even for the same rules. As a consequence, we can avoid having to reason about judgments with side-conditions, making compositional reasoning about more complex programs much easier.

Organization. In Section 2 we introduce notation and preliminaries, including the concept of expectations. In Section 3 we give syntax and semantics of the imperative quantum programming language that we study. In Section 4 we give the definition of expectation-qRHL. In Section 5, we present sound rules for reasoning about expectation-qRHL judgments. And in Section 6, we analyze the quantum Zeno effect as an example of using our logic.

In the full version, we give a detailed comparison of our logic with [5] and full proofs of our results.

2 Preliminaries: Variables, Memories, and Predicates

In this section, we introduce some fundamental concepts and notations needed for this paper, and recap some of the needed quantum background as we go along. When introducing some notation X, the place of definition is marked like this: X. For further mathematical background we recommend [8, 9], and for an introduction to quantum mechanics [15].

Variables. Before we introduce the syntax and semantics of programs, we first need to introduce some basic concepts. A *variable* is described by a variable name $\mathbf{x}, \mathbf{y}, \mathbf{z}$ that identifies the variable, and a nonempty type T. The *type* of $\mathbf{x}$ is simply the nonempty set of all (classical) values the variable can take. E.g., a variable might have type $\{0,1\}$, or $\mathbb{N}$.[1] Lists or sets of variables will be denoted $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$. Given a list $\mathbf{X} = \mathbf{x}_1 \dots \mathbf{x}_n$ of variables, we say its *type* is $T_1 \times \cdots \times T_n$ if T_i is the type of $\mathbf{x}_i$. We write $\mathbf{XY}$ for the concatenation/disjoint union of lists/sets of variables $\mathbf{X}, \mathbf{Y}$.

Memories and quantum states. An *assignment* assigns to each variable a classical value. Formally, for a set $\mathbf{X}$, the *assignments over* $\mathbf{X}$ are all functions m with domain $\mathbf{X}$ such that: for all $\mathbf{x} \in \mathbf{X}$ with type $T_{\mathbf{x}}$, $\mathsf{m}(\mathbf{x}) \in T_{\mathbf{x}}$. That is, assignments can represent the content of classical memories.

To model quantum memories, we simply consider superpositions of assignments: A *(pure) quantum memory* is a superposition of assignments. Formally, $\ell^2[\mathbf{X}]$, the set of all quantum memories over $\mathbf{X}$, is the Hilbert space with basis[2] $\{|\mathsf{m}\rangle\}_{\mathsf{m}}$ where m ranges over all assignments over $\mathbf{X}$. Here $|\mathsf{m}\rangle$ simply denotes the basis vector labeled m. We often write $|\mathsf{m}\rangle_{\mathbf{X}}$ to stress which space we are talking about. We call a quantum memory ψ *normalized* iff $\|\psi\| = 1$. Intuitively, a normalized quantum memory over $\mathbf{X}$ represents a state a quantum computer with variables $\mathbf{X}$ could be in. We also consider quantum states over arbitrary sets X (as opposed to sets of assignments). Namely, $\ell^2(X)$ denotes the Hilbert space with orthonormal basis $\{|x\rangle\}_{x\in X}$. (In that notation, $\ell^2[\mathbf{X}]$ is simply $\ell^2(A)$ where A is the set of all assignments on $\mathbf{X}$.) Normalized elements of $\ell^2[\mathbf{X}]$ represent quantum states.

We often treat elements of $\ell^2(T)$ and $\ell^2[\mathbf{X}]$ interchangeably if T is the type of $\mathbf{X}$ since there is a natural isomorphism between those spaces.

In many situations, we additionally need an additional symbol $\bot$ that denotes that a memory is not available because the program did not terminate. A *quantum $\bot$-memory over* $\mathbf{X}$ is an element of $\ell^2[\mathbf{X}]^\bot := \ell^2(A \cup \{\bot\})$ where A is the set of all assignments on $\mathbf{X}$. That is, a quantum $\bot$-memory is a superposition between a quantum memory and $|\bot\rangle$.

The tensor product $\otimes$ combines two quantum states $\psi \in \ell^2(X), \phi \in \ell^2(Y)$ into a joint system $\psi \otimes \phi \in \ell^2(X \times Y)$. In the case of quantum memories ψ, ϕ over $\mathbf{X}, \mathbf{Y}$, respectively, $\psi \otimes \phi \in \ell^2[\mathbf{XY}]$. (And in this case, $\psi \otimes \phi = \phi \otimes \psi$ since we are composing "named" systems.)

We will need to consider entangled pairs of memories. Specifically, a *quantum bimemory* over $\mathbf{X}_1, \mathbf{X}_2$ is an element of $\ell^2[\mathbf{X}_1] \otimes \ell^2[\mathbf{X}_2] = \ell^2[\mathbf{X}_1\mathbf{X}_2]$. Similarly, a *quantum $\bot$-bimemory* is an element of $\ell^2[\mathbf{X}_1]^\bot \otimes \ell^2[\mathbf{X}_2]^\bot$, i.e., a tensor product of two quantum $\bot$-memories. (Note: "one-sided-$\bot$" states such as $|\mathsf{m}\rangle \otimes |\bot\rangle$ are included in this.) For clarity, we often write $|\bot_1\rangle, |\bot_2\rangle$ instead of $\bot$ to emphasize whether we are talking about elements of $\ell^2[\mathbf{X}_1]^\bot$ or $\ell^2[\mathbf{X}_2]^\bot$.

For a vector (or operator) a, we write a^* for its adjoint. (In the finite dimensional case, the adjoint is simply the conjugate transpose of a vector/matrix. The literature also knows the notation $a^\dagger$.) The adjoint of a vector $|x\rangle$ is also written as $\langle x|$. We abbreviate $\mathsf{proj}(\psi) := \psi\psi^*$. This is the projector onto ψ when $\|\psi\| = 1$.

[1] We stress that we do not assume that the type is a finite or even a countable set. Consequently, the Hilbert spaces considered in this paper are not necessarily finite dimensional or even separable. However, all results can be informally understood by thinking of all sets as finite and hence of all Hilbert spaces as $\mathbb{C}^N$ for suitable $N \in \mathbb{N}$.

[2] When we say "basis", we always mean an orthonormal Hilbert-space basis.

Mixed quantum memories. In many situations, we need to model probabilistic quantum states (e.g., a quantum state that is $|0\rangle$ with probability $\frac{1}{2}$ and $|1\rangle$ with probability $\frac{1}{2}$). This is modeled using *mixed states* (a.k.a. *density operators*). Having normalized state ψ_i with probability p_i is represented by the operator $\rho := \sum_i p_i \mathsf{proj}(\psi_i)$.[3] In particular, $\mathsf{proj}(\psi)$ is the density operator of a pure quantum state ψ. Then ρ encodes all observable information about the distribution of the quantum state (that is, two distributions of quantum states have the same ρ iff they cannot be distinguished by any physical process). And $\operatorname{tr}\rho$ is the total probability $\sum_i p_i$. Note that we do not formally impose the condition $\operatorname{tr}\rho = 1$ or $\operatorname{tr}\rho \leq 1$ unless explicitly specified. We call a mixed state *normalized* iff $\operatorname{tr}\rho = 1$. We will often need to consider mixed states of quantum memories (i.e., mixed states with underlying Hilbert space $\ell^2[\mathbf{X}]$). We call them *mixed (quantum) memories* over $\mathbf{X}$. Analogously, we define *mixed bimemories* and *mixed $\bot$-bimemories* as mixed states of quantum ($\bot$-)bimemories.

Let $P_\bot := \mathsf{proj}(|\bot\rangle)$ and $P_{\not\bot} := \mathsf{id} - P_\bot$. We can easily access the terminating and non-terminating part of a mixed $\bot$-memory: $\downarrow_\bot(\rho) := P_\bot \rho P_\bot$ and $\downarrow_{\not\bot}(\rho) := P_{\not\bot}\rho P_{\not\bot}$ are the memory ρ after measuring that we have termination or do not have termination, respectively.

For a mixed ($\bot$-)bimemory ρ over $\mathbf{X}_1\mathbf{X}_2$ the *partial trace* $\operatorname{tr}_i \rho$ ($i = 1, 2$) is the result of throwing away the left/right memory (i.e., it is a mixed memory over $\mathbf{X}_i$). Formally, tr_i is defined as the continuous linear function satisfying $\operatorname{tr}_1(\sigma \otimes \tau) := \tau \cdot \operatorname{tr}\sigma$, $\operatorname{tr}_2(\sigma \otimes \tau) := \sigma \cdot \operatorname{tr}\tau$.

A mixed memory ρ is $(\mathbf{X}, \mathbf{Y})$-*separable* (i.e., not entangled between $\mathbf{X}$ and $\mathbf{Y}$) iff it can be written as $\rho = \sum_i \rho_i \otimes \rho'_i$ for mixed memories ρ_i, ρ'_i over $\mathbf{X}, \mathbf{Y}$, respectively. (Potentially infinite sum.) When $\mathbf{X}, \mathbf{Y}$ are clear from the context, we simply say *separable*.

In this paper, when we write infinite sums of operators, convergence is always with respect to the trace norm: $\|A\|_{\operatorname{tr}} := \operatorname{tr}\sqrt{AA^\dagger}$. (In the finite-dimensional case, the choice of norm is irrelevant since all norms are equivalent then.)

Operations on quantum states. An operation in a closed quantum system is modeled by an isometry U on $\ell^2(X)$.[4] If we apply such an operation on a mixed state ρ, the result is $U\rho U^*$. In particular, denote by id the identity operation, i.e. $\mathsf{id}\psi = \psi$ for all pure states ψ in this space.

An operator A on $\ell^2[\mathbf{X}]$ can be interpreted as an operator on $\ell^2[\mathbf{X}]^\bot$ by setting $A|\bot\rangle := 0$. To avoid confusion, we often write $A \oplus 0_\bot$ for the operator on $\ell^2[\mathbf{X}]^\bot$. Similarly, an operator A on $\ell^2[\mathbf{X}_1] \otimes \ell^2[\mathbf{X}_2]$ can be seen as an operator on $\ell^2[\mathbf{X}_1]^\bot \otimes \ell^2[\mathbf{X}_2]^\bot$, we write $A \oplus 0_{\bot\bot}$ for the operator on $\ell^2[\mathbf{X}_1]^\bot \otimes \ell^2[\mathbf{X}_2]^\bot$.

Most often, isometries will occur in the context of operations that are performed on a single variable or list of variables, i.e., an isometry U on $\ell^2[\mathbf{X}]$. Then U can also be applied to $\ell^2[\mathbf{Y}]$ with $\mathbf{Y} \supseteq \mathbf{X}$: we identify U with $U \otimes \mathsf{id}_{\mathbf{Y}\setminus\mathbf{X}}$. Furthermore, if $\mathbf{X}$ has type T, then an isometry U on $\ell^2(T)$ can be seen as an isometry on $\ell^2[\mathbf{X}]$ since we identify $\ell^2(T)$ and $\ell^2[\mathbf{X}]$. If we want to make $\mathbf{X}$ explicit, we write $U\,\mathbf{on}\,\mathbf{X}$ for the isometry U on $\ell^2[\mathbf{Y}]$. For example, if U is a 2×2-matrix and $\mathbf{x}$ has type bit, then $U\,\mathbf{on}\,\mathbf{x}$ can be applied to quantum memories over $\mathbf{xy}$, acting on $\mathbf{x}$ only. This notation is not limited to isometries, of course, but applies to other operators, too. (By *operator* we always mean a bounded linear operator in this paper.)

---

[3] Mathematically, density operators are positive Hermitian trace-class operators on $\ell^2(X)$. The requirement "trace-class" ensures that the trace exists and can be ignored in the finite-dimensional case.

[4] That is, a norm-preserving linear operation. Often, one models quantum operations as unitaries instead because in the finite-dimensional case an isometry is automatically unitary. However, in the infinite-dimensional case, unitaries are unnecessarily restrictive. Consider, e.g., the isometry $|i\rangle \mapsto |i+1\rangle$ with $i \in \mathbb{N}$ which is a perfectly valid quantum operation but not a unitary.

In slight overloading of notation, we also write $U \mathbf{on} \mathbf{X}$ for U acting on $\bot$-memories, where $(U \mathbf{on} \mathbf{X})|\bot\rangle = 0$. (That is, $U \mathbf{on} \mathbf{X}$ is short for the more precise $(U \mathbf{on} \mathbf{X}) \oplus 0_\bot$.) We also write $U \mathbf{on} \mathbf{X}_1$ for U acting on $\bot$-bimemories. In this case, we simply have $U \mathbf{on} \mathbf{X}_1 := (U \mathbf{on} \mathbf{X}_1) \otimes \mathsf{id}$. In particular, $(U \mathbf{on} \mathbf{X}_1)(|\mathsf{m}\rangle \otimes |\bot\rangle) = (U \mathbf{on} \mathbf{X}_1)|\mathsf{m}\rangle \otimes |\bot\rangle$ but $(U \mathbf{on} \mathbf{X}_1)(|\bot\rangle \otimes |\mathsf{m}\rangle) = 0$. Analogously for $U \mathbf{on} \mathbf{X}_2$.

We will use only binary measurements in this paper. A *binary measurement* M on $\ell^2[\mathbf{X}]$ has outcomes $\mathsf{true}, \mathsf{false}$ and is described by two bounded operators M_{true}, M_{false} on $\ell^2[\mathbf{X}]$ that satisfy $M_{\mathsf{true}}^* M_{\mathsf{true}} + M_{\mathsf{false}}^* M_{\mathsf{false}} = \mathsf{id}$, its *Krauss operators*. Given a mixed memory ρ, the probability of measurement outcome t is $p_t := \operatorname{tr} M_t \rho M_t^*$, and the post-measurement state is $M_t \rho M_t^* / p_t$.

Expectations. In this work, we will use expectations as pre- and postconditions in Hoare judgments. The idea of using expectations originated in [13] for reasoning about (classical) probabilistic programs. Intuitively, an expectation is a quantitative predicate, that is for any memory (or bimemory, in our case), it does not tell us whether the memory satisfies the predicate but *how much* it satisfies the predicate. Thus, classically, an expectation is simply a function from assignments to reals. By analogy, in the quantum setting, one might want to define expectations, e.g., as functions f from quantum bimemories to reals (i.e., an expectation would be a function $\ell^2[\mathbf{X}] \to \mathbb{R}_{\geq 0}$). However, such expectations might behave badly, for example, it is not clear how to compute the expected value $f(\psi)$ for a random ψ if the distribution of ψ is given in terms of a density operator. A better approach was introduced by [10]. Following their approach, we define an *expectation* as a positive operator A on quantum bimemories.[5] (We use letters $\mathsf{A}, \mathsf{B}, \mathsf{C}, \ldots$ for expectations in this paper.) This expectation then assigns the value $\psi^* \mathsf{A} \psi$ to the quantum memory ψ (equivalently, $\operatorname{tr} \mathsf{A}\, \mathsf{proj}(\psi)$). To understand this, it is best to first look at the special case where A is a projector. Then $\psi^* \mathsf{A} \psi = 1$ iff ψ is in the image of A, and $\psi^* \mathsf{A} \psi = 0$ iff ψ is orthogonal to the image of A. Such an A is basically a predicate (by outputting 1 for states that satisfy the predicate). Of course, states that neither satisfy the predicate nor are orthogonal to it will output a value between 0 and 1. Any expectation A can be written as $\sum_i p_i \mathsf{A}_i$ with projectors A_i. Thus, A would give p_i "points" for satisfying the predicate A_i. In this respect, expectations in the quantum setting are similar to classical ones: classical expectations give a certain amount of "points" for each possible classical input.

The nice thing about this formalism is that, given a density operator $\rho = \sum p_i \mathsf{proj}(\psi_i)$, we can easily compute the expected value of the expectation A. More precisely, the expected value of $\psi^* \mathsf{A} \psi = \operatorname{tr} \mathsf{A} \mathsf{proj}(\psi)$ with $\psi := \psi_i$ with probability p_i. That expected value is $\sum p_i \operatorname{tr} \mathsf{A} \mathsf{proj}(\psi_i) = \operatorname{tr} \mathsf{A} (\sum p_i \mathsf{proj}(\psi_i)) = \operatorname{tr} \mathsf{A} \rho$. This shows that we can evaluate how much a density operator satisfies the expectation A by just computing $\operatorname{tr} \mathsf{A} \rho$. This formula will be the basis for our definitions!

Analogously, we define $\bot$-*expectations* on quantum $\bot$-bimemories. However, we add one restriction: The value of a $\bot$-expectation should not change if we measure whether the $\bot$-bimemory is in $|\bot\rangle$ or not. Formally, a $\bot$-expectation is a positive operator on quantum $\bot$-bimemories that is invariant under $\mathcal{E}_\bot \otimes \mathcal{E}_\bot$ where $\mathcal{E}_\bot(\rho) := P_\bot \rho P_\bot + P_\not\bot \rho P_\not\bot$. ($\mathcal{E}_\bot$ corresponds to measuring and forgetting whether a given mixed $\bot$-memory is $|\bot\rangle$ or not.) Note that for an expectation A, the operator $\mathsf{A} \oplus 0_{\bot\bot}$ is a $\bot$-expectation. We can thus see expectations as special cases of $\bot$-expectations.

[5] Recall from page 4 that operators are always bounded in our context. This means that A is bounded, too. This means that the values that an expectation A can assign to states are between 0 and B for some finite B.

A very simple example of an expectation would be the matrix $\mathsf{A} := \begin{pmatrix} 1 & \\ & \frac{1}{2} \end{pmatrix}$ that assigns 1 to $|0\rangle$, and $\frac{1}{2}$ to $|1\rangle$. And given the density operator $\rho = \frac{1}{2}\mathsf{id}$ (representing a uniform qubit), $\operatorname{tr} \mathsf{A}\rho = \frac{3}{4}$ are intuitively expected.

Quantum equality. In [17], a specific predicate $\mathbf{X}_1 \equiv_{\mathfrak{q}} \mathbf{X}_2$ was introduced to describe the fact that two quantum variables (or list of quantum variables) have the same state. Formally, $\mathbf{X}_1 \equiv_{\mathfrak{q}} \mathbf{X}_2$ is the subspace consisting of all quantum memories in $\ell^2[\mathbf{X}_1\mathbf{X}_2]$ that are invariant under $\mathsf{SWAP}_{\mathbf{X}_1\mathbf{X}_2}$, the unitary that swaps variables $\mathbf{X}_1$ and $\mathbf{X}_2$.[6] Or equivalently, $\mathbf{X}_1 \equiv_{\mathfrak{q}} \mathbf{X}_2$ denotes the subspace spanned by all quantum memories of the form $\phi \otimes \phi$ with $\phi \in \ell^2[\mathbf{X}_1] = \ell^2[\mathbf{X}_2]$. We write $\mathsf{EQUAL}\,\mathbf{on}\,\mathbf{X}_1\mathbf{X}_2$ for the projector onto $\mathbf{X}_1 \equiv_{\mathfrak{q}} \mathbf{X}_2$.

3 Quantum programs

Syntax. We will now define a small imperative quantum language.[7] The set of all programs is described by the following syntax:

$$\mathfrak{c},\mathfrak{d} ::= \underline{\mathbf{apply}}\ U\ \underline{\mathbf{to}}\ \mathbf{X} \mid \mathbf{X} \leftarrow \psi \mid \underline{\mathbf{if}}\ M[\mathbf{X}]\ \underline{\mathbf{then}}\ \mathfrak{c}\ \underline{\mathbf{else}}\ \mathfrak{d} \mid \underline{\mathbf{while}}\ M[\mathbf{X}]\ \underline{\mathbf{do}}\ \mathfrak{c} \mid \mathfrak{c};\mathfrak{d} \mid \underline{\mathbf{skip}} \mid \underline{\mathbf{abort}}$$

Here $\mathbf{X}$ is a list of variables and U an isometry on $\ell^2[\mathbf{X}]$, $\psi \in \ell^2[\mathbf{X}]$ a normalized state, and M is a binary measurement on $\ell^2[\mathbf{X}]$. (There are no fixed sets of allowed U and ψ, any isometry/state that we can describe can be used here).[8]

Intuitively, $\underline{\mathbf{apply}}\ U\ \underline{\mathbf{to}}\ \mathbf{X}$ means that the operation U is applied to the quantum variables $\mathbf{X}$. E.g., $\underline{\mathbf{apply}}\ H\ \underline{\mathbf{to}}\ \mathbf{x}$ would apply the Hadamard gate to the variable $\mathbf{x}$ (we assume that H denote the Hadamard matrix). It is important that we can apply U to several variables $\mathbf{X}$ simultaneously, otherwise no entanglement between variables can ever be produced.

The program $\mathbf{X} \leftarrow \psi$ initializes the variables $\mathbf{X}$ with the quantum state ψ. The program $\underline{\mathbf{if}}\ M[\mathbf{X}]\ \underline{\mathbf{then}}\ \mathfrak{c}\ \underline{\mathbf{else}}\ \mathfrak{d}$ will measure the variables $\mathbf{X}$ with the measurement M, and, if the outcome is true, execute $\mathfrak{c}$, otherwise execute $\mathfrak{d}$.

The program $\underline{\mathbf{while}}\ M[\mathbf{X}]\ \underline{\mathbf{do}}\ \mathfrak{c}$ measures $\mathbf{X}$, and if the outcome is true, it executes $\mathfrak{c}$. This is repeated until the outcome is false.

Finally, $\mathfrak{c};\mathfrak{d}$ executes $\mathfrak{c}$ and then $\mathfrak{d}$. And $\underline{\mathbf{skip}}$ does nothing. We will always implicitly treat ";" as associative and $\underline{\mathbf{skip}}$ as its neutral element. $\underline{\mathbf{abort}}$ never terminates.

Semantics. The *denotational semantics* of our programs $\mathfrak{c}$ are represented as completely positive trace-reducing maps $[\![\mathfrak{c}]\!]$ on the mixed memories over $\mathbf{X}^{\mathbf{all}}$, defined by recursion on the structure of the programs. Here $\mathbf{X}^{\mathbf{all}}$ is a fixed set of program variables, and we will assume that all variables under consideration are contained in this set. The obvious cases are $[\![\underline{\mathbf{skip}}]\!] := \mathsf{id}$ and $[\![\mathfrak{c};\mathfrak{d}]\!] := [\![\mathfrak{d}]\!] \circ [\![\mathfrak{c}]\!]$ and $[\![\underline{\mathbf{abort}}]\!](\rho) := 0$. And application of an isometry U is also fairly straightforward given the syntactic sugar introduced above: $[\![\underline{\mathbf{apply}}\ U\ \underline{\mathbf{to}}\ \mathbf{X}]\!](\rho) := (U\,\mathbf{on}\,\mathbf{X})\rho(U\,\mathbf{on}\,\mathbf{X})^*$. (The notation $U\,\mathbf{on}\,\mathbf{X}$ was introduced on page 4.)

---

[6] That is, $\mathsf{SWAP}_{\mathbf{X}_1\mathbf{X}_2}(\psi \otimes \phi) = \phi \otimes \psi$ for $\psi \in \ell^2[\mathbf{X}_1]$, $\phi \in \ell^2[\mathbf{X}_2]$.

[7] Very similar to [18], except that we replace their case-statement by an if-statement and allow initialization with arbitrary states instead of just $|0\rangle$.

[8] We will assume throughout the paper that all programs satisfy those well-typedness constraints. In particular, rules may implicitly impose type constraints on the variables and constants occurring in them by this assumption.

Initialization of quantum variables is slightly more complicated: $\mathbf{X} \leftarrow \psi$ initializes the variables $\mathbf{X}$ with ψ, which is the same as removing $\mathbf{X}$, and then creating a new variable $\mathbf{X}$ with content ψ. Removing $\mathbf{X}$ is done by the operation $\mathrm{tr}_{\mathbf{X}}$ (partial trace, see page 4). And creating new variables $\mathbf{X}$ in state ψ is done by the operation $\otimes\mathsf{proj}(\psi)$. Thus we define $[\![\mathbf{X} \leftarrow \psi]\!](\rho) := \mathrm{tr}_{\mathbf{X}}\, \rho \otimes \mathsf{proj}(\psi)$.

The if-command first performs a measurement and then branches depending on the outcome. We then have that the state after measurement (without renormalization) is $(M_t \,\mathbf{on}\, \mathbf{X})\rho(M_t \,\mathbf{on}\, \mathbf{X})^*$ for outcome $t = \mathsf{true}, \mathsf{false}$. Then $\mathfrak{c}$ or $\mathfrak{d}$ is applied to that state and the resulting states are added together to get the final mixed state. Altogether:

$$[\![\underline{\mathbf{if}}\ M[\mathbf{X}]\ \underline{\mathbf{then}}\ \mathfrak{c}\ \underline{\mathbf{else}}\ \mathfrak{d}]\!](\rho) := [\![\mathfrak{c}]\!]\big(\downarrow_{\mathsf{true}}(\rho)\big) + [\![\mathfrak{d}]\!]\big(\downarrow_{\mathsf{false}}(\rho)\big)$$
$$\text{where} \qquad \downarrow_t(\rho) := (M_t \,\mathbf{on}\, \mathbf{X})\rho(M_t \,\mathbf{on}\, \mathbf{X})^*$$

While-commands are modeled similarly: In an execution of a while statement, we have $n \geq 0$ iterations of "measure with outcome true and run $\mathfrak{c}$" (which applies $[\![\mathfrak{c}]\!] \circ \downarrow_{\mathsf{true}}$ to the state), followed by "measure with outcome false" (which applies $\downarrow_{\mathsf{false}}$ to the state). Adding all those branches up, we get the definition:

$$[\![\underline{\mathbf{while}}\ M[\mathbf{X}]\ \underline{\mathbf{do}}\ \mathfrak{c}]\!](\rho) := \sum_{n=0}^{\infty} \downarrow_{\mathsf{false}}\big(([\![\mathfrak{c}]\!] \circ \downarrow_{\mathsf{true}})^n(\rho)\big)$$

We call a program $\mathfrak{c}$ *terminating* iff $\mathrm{tr}[\![\mathfrak{c}]\!](\rho) = \mathrm{tr}\,\rho$ for all ρ.

Semantics with explicit non-termination. $[\![\mathfrak{c}]\!]$ is not trace-preserving if $\mathfrak{c}$ is not terminating. For technical reasons, we will need a variant of this function that is trace-preserving. This can be achieved by outputting a mixed state that has an explicit state $\mathsf{proj}(|\bot\rangle)$ to denote non-termination. This semantic function $[\![\mathfrak{c}]\!]^\bot$ takes mixed $\bot$-memories to mixed $\bot$-memories and can be easily derived from $[\![\mathfrak{c}]\!]$:

$$[\![\mathfrak{c}]\!]^\bot(\rho) := [\![\mathfrak{c}]\!](\downarrow_{\not\bot}(\rho)) + \big(\mathrm{tr}\,\rho - \mathrm{tr}[\![\mathfrak{c}]\!](\downarrow_{\not\bot}(\rho))\big)\mathsf{proj}(|\bot\rangle).$$

($P_\bot, P_{\not\bot}$ are defined on page 4.) Operationally, $[\![\mathfrak{c}]\!]^\bot$ first measures if the state is $\bot$. If so, nothing happens. Otherwise, $\mathfrak{c}$ is applied. If $\mathfrak{c}$ does not terminate, the final output memory is set to be $\bot$. $[\![\mathfrak{c}]\!]^\bot$ is easily seen to be trace-preserving. Moreover, we have the composition property $[\![\mathfrak{c};\mathfrak{d}]\!]^\bot = [\![\mathfrak{d}]\!]^\bot \circ [\![\mathfrak{c}]\!]^\bot$, since

$$\begin{aligned}
&[\![\mathfrak{d}]\!]^\bot([\![\mathfrak{c}]\!]^\bot(\rho)) = [\![\mathfrak{d}]\!]^\bot\,[[\![\mathfrak{c}]\!](\rho_{\not\bot}) + (\mathrm{tr}\,\rho - \mathrm{tr}[\![\mathfrak{c}]\!](\rho_{\not\bot}))\mathsf{proj}(|\bot\rangle)] \\
&= [\![\mathfrak{d}]\!]([\![\mathfrak{c}]\!](\rho_{\not\bot})) + \big[\mathrm{tr}[\![\mathfrak{c}]\!]^\bot(\rho) - \mathrm{tr}[\![\mathfrak{d}]\!]([\![\mathfrak{c}]\!](\rho_{\not\bot}))\big]\,\mathsf{proj}(|\bot\rangle) \\
&= [\![\mathfrak{c};\mathfrak{d}]\!](\rho_{\not\bot}) + (\mathrm{tr}\,\rho - \mathrm{tr}[\![\mathfrak{c};\mathfrak{d}]\!](\rho_{\not\bot}))\mathsf{proj}(|\bot\rangle) = [\![\mathfrak{c};\mathfrak{d}]\!]^\bot(\rho).
\end{aligned}$$

4 qRHL with expectations

Defining the logic. We now present our definition of expectation-qRHL. We follow the approach from [17] to use separable couplings to describe the relationship between programs. A *coupling* between two mixed states ρ_1 and ρ_2 is a mixed state ρ that has ρ_1 and ρ_2 as marginals. (That is, $\mathrm{tr}_{\mathbf{X}_2}\,\rho = \rho_1$ and $\mathrm{tr}_{\mathbf{X}_1}\,\rho = \rho_2$ if ρ_1, ρ_2 are over $\mathbf{X}_1, \mathbf{X}_2$, respectively.) This is analogous to probabilistic couplings: a coupling of distributions μ_1, μ_2 is a distribution μ with marginals μ_1, μ_2. Note that couplings trivially always exist if ρ_1 and ρ_2 have the same trace (namely, $\rho := \rho_1 \otimes \rho_2 / \mathrm{tr}\,\rho_1$). Couplings become interesting when we put additional

constraints on the state ρ. For example, if we require the support of ρ to be in the subspace $C := \mathrm{span}\{|00\rangle, |11\rangle\}$, then $\rho_1 = \mathsf{proj}(|0\rangle)$ and $\rho_2 = \mathsf{proj}(|0\rangle)$ have a coupling (namely, $\rho = \mathsf{proj}(|00\rangle)$), as do $\rho_1 = \mathsf{proj}(|1\rangle)$ and $\rho_2 = \mathsf{proj}(|1\rangle)$ (namely, $\rho = \mathsf{proj}(|11\rangle)$), but not $\rho_1 = \mathsf{proj}(|0\rangle)$ and $\rho_2 = \mathsf{proj}(|1\rangle)$. Things become particularly interesting when ρ_1, ρ_2 are not pure states. E.g., $\rho_1 = \frac{1}{2}\mathsf{proj}(|0\rangle) + \frac{1}{2}\mathsf{proj}(|1\rangle)$ and $\rho_2 = \frac{1}{2}\mathsf{proj}(|0\rangle) + \frac{1}{2}\mathsf{proj}(|1\rangle)$ have such a coupling as well (namely, $\rho = \frac{1}{2}\mathsf{proj}(|00\rangle) + \frac{1}{2}\mathsf{proj}(|11\rangle)$ but $\rho := \rho_1 \otimes \rho_2$ is not a coupling with support in C).

Thus, a subspace such as C can be seen as a predicate describing the relationship of ρ_1, ρ_2. The states ρ_1, ρ_2 satisfy C iff there is a coupling with support in C. This idea leads to the following tentative definition of qRHL:

▶ **Definition 1** (qRHL, tentative, without expectations). *For subspaces A, B (i.e., spaces of quantum memories over $\mathbf{X}_1^{\mathbf{all}}\mathbf{X}_2^{\mathbf{all}}$), $\{A\}\,\mathfrak{c} \sim \mathfrak{d}\,\{B\}$ holds iff for any ρ_1, ρ_2 that have a coupling with support in A, the final states $[\![\mathfrak{c}]\!](\rho_1), [\![\mathfrak{d}]\!](\rho_2)$ have a coupling with support in B.*

However, it was noticed in [17] that the definition becomes easier to handle if we impose another condition on the couplings. Namely, the coupling should be separable, i.e., there should be no entanglement between the two systems corresponding to ρ_1, ρ_2. That is, the definition of qRHL used in [17] is Definition 1 with "coupling" replaced by "separable coupling". We will also adopt the separability condition in our definition of expectation-qRHL.[9]

So far, we have basically recapped the definition from [17]. However, that definition only allows us to express Hoare judgments that do not involve expectations since A and B in Definition 1 are subspaces (predicates), not expectations. To define expectation-qRHL, we follow the same idea, but instead of quantifying over only the initial states satisfying the precondition, we quantify over all initial states, and merely require that (the coupling of) the final states satisfies the postexpectation at least as much as (the coupling of the) initial states satisfy the preexpectation. That is:

▶ **Definition 2** (Expectation-qRHL (eqRHL), first attempt). *For expectations A, B, $\{A\}\,\mathfrak{c} \sim \mathfrak{d}\,\{B\}$ holds iff for any ρ_1, ρ_2 with separable coupling ρ, the final states $[\![\mathfrak{c}]\!](\rho_1), [\![\mathfrak{d}]\!](\rho_2)$ have a separable coupling ρ' such that $\mathrm{tr}\,\mathsf{A}\rho \leq \mathrm{tr}\,\mathsf{B}\rho'$. (Recall that $\mathrm{tr}\,\mathsf{A}\rho$ indicates how much ρ satisfies A, and analogously $\mathrm{tr}\,\mathsf{B}\rho'$, cf. Section 2.)*

For terminating programs $\mathfrak{c}, \mathfrak{d}$, this definition already works well. Unfortunately, if $\mathfrak{c}, \mathfrak{d}$ do not terminate with probability 1, we have some undesired effects: For example, assume that $\mathfrak{c} = \underline{\mathbf{skip}}$, and $\mathfrak{d}$ is a program that with probability $1-\varepsilon$ does nothing ($\underline{\mathbf{skip}}$), and but with probability ε does not terminate ($\underline{\mathbf{abort}}$). Then $\{\mathsf{A}\}\,\mathfrak{c} \sim \mathfrak{d}\,\{\mathsf{B}\}$ does not hold *for any* A, B. Why? The final states $[\![\mathfrak{c}]\!](\rho_1), [\![\mathfrak{d}]\!](\rho_2)$ have trace 1 and $1-\varepsilon$, respectively. Therefore there exists no coupling ρ' of $[\![\mathfrak{c}]\!](\rho_1), [\![\mathfrak{d}]\!](\rho_2)$. (It follows from the definition of couplings that the coupling must have the same trace as its marginals.) Hence $\{\mathsf{A}\}\,\mathfrak{c} \sim \mathfrak{d}\,\{\mathsf{B}\}$ does not hold. Similarly, $\{\mathsf{A}\}\,\mathfrak{c} \sim \mathfrak{d}\,\{\mathsf{B}\}$ does not hold whenever there are two input states ρ_1, ρ_2 such that $\mathfrak{c}, \mathfrak{d}$ terminate with different probabilities. (Even if this nontermination only occurs for input states for which A evaluates to 0!) This makes it near impossible to reason about non-terminating programs.[10]

[9] [17] was not able to prove the Frame rule without adding this separability condition. Our reasons for adopting the separability condition are slightly different: we do not have a Frame rule anyway, but for other elementary rules such as the rule Equal in [17] with quantum expectations and quantum variables, it is unclear how to prove them without the separability condition.

[10] Even if we are interested in a Hoare logic with total correctness, this behavior is undesired. Instead, we want that a nontermination with small probability simply introduces some small penalty in the expectations. For example, in the case of non-relational Hoare with total correctness, $\{(1-\varepsilon)\mathsf{id}\}\,\mathsf{A}\,\{\mathsf{id}\}$ means that A is nonterminating with probability $\leq \varepsilon$.

There are a number of approaches how one can circumvent this problem. E.g., one could allow ρ' to be a "subcoupling" instead of a coupling (i.e., its marginals do not have to equal $[\![\mathfrak{c}]\!](\rho_1), [\![\mathfrak{d}]\!](\rho_2)$ but only lower bound them);[11] the subcoupling always exists, even if the traces are not equal. However, we find that adding such "hacks" to the definition makes it more difficult to understand what the definition exactly does in case of non-terminating programs.

Instead, we choose an approach that makes non-termination explicit. That is, when a program does not terminate, we assign a specific state $|\bot\rangle$ to its output, and we allow expectation to explicitly refer to it (e.g., an expectation could assign value 1 to nontermination, and value 0 to termination). The denotation $[\![\mathfrak{c}]\!]^\bot$ defined on page 7 does exactly that. And expectations that live on a space that has an explicit nontermination-state $|\bot\rangle$ were introduced as $\bot$-expectations on page 5. This leads to the following definition:

▶ **Definition 3** (Expectation-qRHL, informal). *For $\bot$-expectations A, B, $\{A\}\,\mathfrak{c} \sim \mathfrak{d}\,\{B\}$ holds iff for any ρ_1, ρ_2 with separable coupling ρ, the final states $[\![\mathfrak{c}]\!]^\bot(\rho_1), [\![\mathfrak{d}]\!]^\bot(\rho_2)$ have a separable coupling ρ' such that $\operatorname{tr} \mathsf{A}\rho \le \operatorname{tr} \mathsf{B}\rho'$.*

Note that a coupling of $[\![\mathfrak{c}]\!]^\bot(\rho_1), [\![\mathfrak{d}]\!]^\bot(\rho_2)$ always exists since $[\![\cdot]\!]^\bot$ is trace-preserving. (Below, we will derive certain specific variants of eqRHL such as eqRHL with total correctness as specific cases of this definition. Also, we will see that subcouling-based definitions can be recovered as special cases in Lemma 9.) By plugging in the definition of couplings into Definition 3, we get the following precise definition:

▶ **Definition 4** (Expectation-qRHL, generic). *Let A, B be $\bot$-expectations and $\mathfrak{c}$, $\mathfrak{d}$ programs. Then $\{\mathsf{A}\}\,\mathfrak{c} \overset{\text{gen}}{\approx} \mathfrak{d}\,\{\mathsf{B}\}$ holds iff for any separable mixed $\bot$-bimemory ρ over $\mathbf{X}_1^{\mathbf{all}}, \mathbf{X}_2^{\mathbf{all}}$, there is a separable mixed $\bot$-bimemory ρ' over $\mathbf{X}_1^{\mathbf{all}}, \mathbf{X}_2^{\mathbf{all}}$ such that*

- $\operatorname{tr}_2 \rho' = [\![\mathfrak{c}]\!]^\bot(\operatorname{tr}_2 \rho)$.
- $\operatorname{tr}_1 \rho' = [\![\mathfrak{d}]\!]^\bot(\operatorname{tr}_1 \rho)$.
- $\operatorname{tr} \mathsf{A}\rho \le \operatorname{tr} \mathsf{B}\rho'$.

In this definition, $\mathbf{X}_1^{\mathbf{all}}, \mathbf{X}_2^{\mathbf{all}}$ are isomorphic copies of the set $\mathbf{X}^{\mathbf{all}}$ of variables. That is, while strictly speaking, $[\![\mathfrak{c}]\!]^\bot$ maps mixed $\bot$-memories over $\mathbf{X}^{\mathbf{all}}$ to mixed $\bot$-memories over $\mathbf{X}^{\mathbf{all}}$, we can also see it as mapping mixed $\bot$-memories over $\mathbf{X}_1^{\mathbf{all}}$ to mixed $\bot$-memories over $\mathbf{X}_1^{\mathbf{all}}$. Analogously for $\mathfrak{d}$ and $\mathbf{X}_2^{\mathbf{all}}$. We make use of this in the preceding definition when we apply $[\![\mathfrak{c}]\!]^\bot, [\![\mathfrak{d}]\!]^\bot$ to ρ_1, ρ_2, respectively. In the rest of the paper, we simply call a mixed state (ρ_1, ρ_2)-*coupling* if it is separable and has marginals ρ_1 and ρ_2.

Note that we defined $\bot$-expectations to be invariant under $\mathcal{E}_\bot \otimes \mathcal{E}_\bot$ (page 5), i.e., that they implicitly measure first whether the quantum memories are $|\bot\rangle$. Otherwise, we would not even have $\{\mathsf{A}\}\,\underline{\mathbf{skip}} \overset{\text{gen}}{\approx} \underline{\mathbf{skip}}\,\{\mathsf{A}\}$ (rule Skip below), for example if $\mathsf{A} := \mathsf{proj}(\frac{1}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|\bot\rangle)$. This is because even the program $\underline{\mathbf{skip}}$ measures whether the memory is $|\bot\rangle$ (by definition of $[\![\cdot]\!]^\bot$), so it may change the state if the memory is in a superposition between $|\bot\rangle$ and something else.

Partial/total correctness. The generic definition of eqRHL (Definition 4) allows us to explicitly express in our pre-/postexpectations how nontermination should be treated. While this allows for maximal generality, in practice it might be cumbersome to always have to specify explicitly how the expectations behave on $|\bot\rangle$. Instead, we define below three special cases of eqRHL that hardcode the treatment of $|\bot\rangle$.

[11] This is explored further in Section 4 for special cases of our definition.

The simplest case is eqRHL with total correctness: Here, nontermination is "forbidden", i.e., we assign value 0 to it. Recall from page 4 that for an expectation A, $\mathsf{A} \oplus 0_{\bot\bot}$ is the corresponding $\bot$-expectation. It assigns 0 to a state that has $|\bot\rangle$ in the left or right memory. Hence, eqRHL with total correctness simply means that all pre/postconditions are of the form $\mathsf{A} \oplus 0_{\bot\bot}$. The following definition specifies convenient syntax for this special case:

▶ **Definition 5** (Expectation-qRHL, total)**.** *Let* A, B *be expectations and* $\mathfrak{c}$, $\mathfrak{d}$ *programs. Then* $\{\mathsf{A}\}\,\mathfrak{c} \overset{\text{tot}}{\sim} \mathfrak{d}\,\{\mathsf{B}\}$ *iff* $\{\mathsf{A} \oplus 0_{\bot\bot}\}\,\mathfrak{c} \overset{\text{gen}}{\sim} \mathfrak{d}\,\{\mathsf{B} \oplus 0_{\bot\bot}\}$.

A second common variant of Hoare logic is "partial correctness". Here we allow nontermination, i.e., if a program does not terminate, we assign the value 1. That is, we use pre/postexpectations of the form $(\mathsf{A} \oplus 0_{\bot\bot}) + T$ where T assigns value 1 when the left or right memory is in state $|\bot\rangle$:

▶ **Definition 6** (Expectation-qRHL, partial)**.** *Let* A, B *be expectations and* $\mathfrak{c}$, $\mathfrak{d}$ *programs. Then* $\{\mathsf{A}\}\,\mathfrak{c} \overset{\text{par}}{\sim} \mathfrak{d}\,\{\mathsf{B}\}$ *iff* $\{(\mathsf{A} \oplus 0_{\bot\bot}) + T\}\,\mathfrak{c} \overset{\text{gen}}{\sim} \mathfrak{d}\,\{(\mathsf{B} \oplus 0_{\bot\bot}) + T\}$ *where* $T := \big(\mathsf{proj}(|\bot_1\rangle) \otimes P_{\not\downarrow}\big) + \big(P_{\not\downarrow} \otimes \mathsf{proj}(|\bot_2\rangle)\big) + \mathsf{proj}(|\bot_1\rangle \otimes |\bot_2\rangle)$.

Unfortunately, this definition does not necessarily behave as we would like. E.g., if both $\mathfrak{c}$ and $\mathfrak{d}$ terminate with probability $\leq \frac{1}{2}$ on all inputs, then $\{\mathsf{A}\}\,\mathfrak{c} \overset{\text{par}}{\sim} \mathfrak{d}\,\{\mathsf{B}\}$ holds for any $\mathsf{A} \leq \mathsf{id}$, B. That is, any property holds with probability $\frac{1}{2}$ for those programs which is not what we would expect! Why does this happen? Since $[\![\mathfrak{c}]\!]^{\bot}(\rho_1), [\![\mathfrak{d}]\!]^{\bot}(\rho_2)$ are 50% nontermination, we can "match up" the nonterminating part of $[\![\mathfrak{c}]\!]^{\bot}(\rho_1)$ with the terminating part of $[\![\mathfrak{d}]\!]^{\bot}(\rho_2)$ and vice versa in the coupling ρ' of the output states. Then $\operatorname{tr} T\rho' = 1$ and thus $\{\mathsf{A}\}\,\mathfrak{c} \overset{\text{par}}{\sim} \mathfrak{d}\,\{\mathsf{B}\}$ holds. The problem here is that we treat nontermination as a "wildcard" that is allowed to match any behavior of the other program. While there may be valid use cases for such a notation, we believe that in most cases this is not what we want.

Instead, we define a notion we call "semipartial". In this eqRHL-variant, we allow nontermination, but only when it occurs in the two programs "in sync". I.e., we consider pre/postexpectations that assign 1 to $|\bot\rangle \otimes |\bot\rangle$, but 0 to a state where one program has nonterminated and the other has terminated. Formally:

▶ **Definition 7** (Expectation-qRHL, semipartial)**.** *Let* A, B *be expectations and* $\mathfrak{c}$, $\mathfrak{d}$ *programs. Then* $\{\mathsf{A}\}\,\mathfrak{c} \overset{\text{semi}}{\sim} \mathfrak{d}\,\{\mathsf{B}\}$ *iff*

$$\{(\mathsf{A} \oplus 0_{\bot\bot}) + \mathsf{proj}(|\bot_1\rangle \otimes |\bot_2\rangle)\}\,\mathfrak{c} \overset{\text{gen}}{\sim} \mathfrak{d}\,\{(\mathsf{B} \oplus 0_{\bot\bot}) + \mathsf{proj}(|\bot_1\rangle \otimes |\bot_2\rangle)\}.$$

Pure initial states. In many cases, it is much easier to work with the definition of eqRHL correctness if one can assume that the initial states of $\mathfrak{c}, \mathfrak{d}$ are pure states, and that the initial coupling is the tensor product of those states. (No nontrivial correlations.) The following lemma shows that we can do so without loss of generality:

▶ **Lemma 8.** *Let* A, B *be* $\bot$*-expectations and* $\mathfrak{c}$, $\mathfrak{d}$ *programs. Then* $\{\mathsf{A}\}\,\mathfrak{c} \overset{\text{gen}}{\sim} \mathfrak{d}\,\{\mathsf{B}\}$ *holds iff*

- *for all unit quantum memories* ψ_1, ψ_2 *over* $\mathbf{X}_1$, $\mathbf{X}_2$, *respectively, there is a separable* $\bot$*-mixed bimemory* ρ' *over* $\mathbf{X}_1, \mathbf{X}_2$ *such that*
  - $\operatorname{tr}_2 \rho' = [\![\mathfrak{c}]\!]^{\bot}(\mathsf{proj}(\psi_1))$.
  - $\operatorname{tr}_1 \rho' = [\![\mathfrak{d}]\!]^{\bot}(\mathsf{proj}(\psi_2))$.
  - $\operatorname{tr} \mathsf{A}\,\mathsf{proj}(\psi_1 \otimes \psi_2) \leq \operatorname{tr} \mathsf{B}\rho'$.[12]

[12] Or equivalently, $\|\sqrt{\mathsf{A}}(\psi_1 \otimes \psi_2)\| \leq \operatorname{tr} \mathsf{B}\rho'$. Or $(\psi_1 \otimes \psi_2)^* \mathsf{A}(\psi_1 \otimes \psi_2) \leq \operatorname{tr} \mathsf{B}\rho'$.

- *for all unit quantum memories* ψ_1 *over* $\mathbf{X}_1$*, we have* $\operatorname{tr} \mathsf{A} \operatorname{proj}(\psi_1 \otimes |\bot_2\rangle) \leq \operatorname{tr} \mathsf{B}\big([\![\mathfrak{c}]\!]^\bot(\operatorname{proj}(\psi_1)) \otimes \operatorname{proj}(|\bot_2\rangle)\big)$.
- *for all unit quantum memories* ψ_2 *over* $\mathbf{X}_2$*, we have* $\operatorname{tr} \mathsf{A} \operatorname{proj}(|\bot_1\rangle \otimes \psi_2) \leq \operatorname{tr} \mathsf{B}\big(\operatorname{proj}(|\bot_1\rangle) \otimes [\![\mathfrak{d}]\!]^\bot(\operatorname{proj}(\psi_2))\big)$.
- $\operatorname{tr} \mathsf{A} \operatorname{proj}(|\bot_1\rangle \otimes |\bot_2\rangle) \leq \operatorname{tr} \mathsf{B} \operatorname{proj}(|\bot_1\rangle \otimes |\bot_2\rangle)$.

Equivalent reformulations. As discussed after Definition 2, an alternative means of trying to circumvent the problem that Definition 2 does handle nonterminating programs well is to use subcouplings instead of couplings.

Here, we show that the notions of eqRHL with partial and total correctness can be equivalently restated in terms of subcouplings (instead of the extended semantics $[\![\cdot]\!]^\bot$ over $\bot$-memories). However, we do not know such an equivalent reformulation for semipartial correctness.

▶ **Lemma 9.** *Let* A, B *be expectations and* $\mathfrak{c}$, $\mathfrak{d}$ *programs. Then* $\{\mathsf{A}\}\,\mathfrak{c} \overset{\text{tot}}{\sim} \mathfrak{d}\,\{\mathsf{B}\}$ *iff for any separable mixed bimemory* ρ *over* $\mathbf{X}_1^{\mathbf{all}}, \mathbf{X}_2^{\mathbf{all}}$*, there is a separable mixed bimemory* ρ' *over* $\mathbf{X}_1^{\mathbf{all}}, \mathbf{X}_2^{\mathbf{all}}$ *such that*

- $\operatorname{tr}_2 \rho' \leq [\![\mathfrak{c}]\!](\operatorname{tr}_2 \rho)$.
- $\operatorname{tr}_1 \rho' \leq [\![\mathfrak{d}]\!](\operatorname{tr}_1 \rho)$.
- $\operatorname{tr} \mathsf{A}\rho \leq \operatorname{tr} \mathsf{B}\rho'$.

▶ **Lemma 10.** *Let* A, B *be expectations and* $\mathfrak{c}$, $\mathfrak{d}$ *programs. Then* $\{\mathsf{A}\}\,\mathfrak{c} \overset{\text{par}}{\sim} \mathfrak{d}\,\{\mathsf{B}\}$ *holds iff for any separable mixed bimemory* ρ *over* $\mathbf{X}_1^{\mathbf{all}}, \mathbf{X}_2^{\mathbf{all}}$*, there is a separable mixed bimemory* ρ' *over* $\mathbf{X}_1^{\mathbf{all}}, \mathbf{X}_2^{\mathbf{all}}$ *such that*

- $\operatorname{tr}_2 \rho' \leq [\![\mathfrak{c}]\!](\operatorname{tr}_2 \rho)$.
- $\operatorname{tr}_1 \rho' \leq [\![\mathfrak{d}]\!](\operatorname{tr}_1 \rho)$.
- $\operatorname{tr} \rho' \geq \operatorname{tr}[\![\mathfrak{c}]\!](\operatorname{tr}_2 \rho) + \operatorname{tr}[\![\mathfrak{d}]\!](\operatorname{tr}_1 \rho) - \operatorname{tr} \rho$.
- $\operatorname{tr} \mathsf{A}\rho \leq \operatorname{tr} \mathsf{B}\rho' + \operatorname{tr} \rho - \operatorname{tr} \rho'$.

In this definition, $\operatorname{tr} \rho - \operatorname{tr} \rho' \geq 0$ is describe the nonterminating probability. Lemma 9 and Lemma 10 mean that total and partial correctness can be alternatively defined using the concept of subcouplings, without considering the $\bot$-extension of the expectations and programs.

▶ **Lemma 11.** *Let* A, B *be expectations and* $\mathfrak{c}$, $\mathfrak{d}$ *programs. Then* $\{\mathsf{A}\}\,\mathfrak{c} \overset{\text{tot}}{\sim} \mathfrak{d}\,\{\mathsf{B}\}$ *(resp.* $\{\mathsf{A}\}\,\mathfrak{c} \overset{\text{par}}{\sim} \mathfrak{d}\,\{\mathsf{B}\}$*) holds iff for all unit quantum memories* ψ_1*,* ψ_2 *over* $\mathbf{X}_1^{\mathbf{all}}$*,* $\mathbf{X}_2^{\mathbf{all}}$*, respectively, there is a separable mixed bimemory* ρ *over* $\mathbf{X}_1\mathbf{X}_2$ *such that*

- $\operatorname{tr}_2 \rho \leq [\![\mathfrak{c}]\!](\operatorname{proj}(\psi_1))$.
- $\operatorname{tr}_1 \rho \leq [\![\mathfrak{d}]\!](\operatorname{proj}(\psi_2))$.
- $\operatorname{tr} \mathsf{A}\operatorname{proj}(\psi_1 \otimes \psi_2) \leq \operatorname{tr} \mathsf{B}\rho$.[13]

  (resp. $\operatorname{tr} \mathsf{A}\operatorname{proj}(\psi_1 \otimes \psi_2) \leq \operatorname{tr} \mathsf{B}\rho + 1 - \operatorname{tr} \rho$ *and* $1 + \operatorname{tr} \rho \geq \operatorname{tr}[\![\mathfrak{c}]\!](\operatorname{proj}(\psi_1)) + \operatorname{tr}[\![\mathfrak{d}]\!](\operatorname{proj}(\psi_2))$*.)*

5 Description of the rules

We describe the rules of our logic one by one here. Recall that we essentially have four different logics: partial, semipartial, total, and the general case from which the former three are derived. To keep things readable, we only describe the rules for the partial, semipartial, and total case here. (Listed in Figure 1.) In the full version, we state and prove the rules

[13] Or equivalently, $\|\sqrt{\mathsf{A}}(\psi_1 \otimes \psi_2)\| \leq \operatorname{tr} \mathsf{B}\rho$. Or $(\psi_1 \otimes \psi_2)^* \mathsf{A}(\psi_1 \otimes \psi_2) \leq \operatorname{tr} \mathsf{B}\rho$.

$$\frac{\{\mathsf{A}_T\}\,\mathfrak{c}_T \overset{\text{any}}{\simeq} \mathfrak{d}\,\{\mathsf{B}\}\qquad \{\mathsf{A}_F\}\,\mathfrak{c}_F \overset{\text{any}}{\simeq} \mathfrak{d}\,\{\mathsf{B}\}}{\{\downarrow^*_{\mathsf{true}}(\mathsf{A}_T)+\downarrow^*_{\mathsf{false}}(\mathsf{A}_F)\}\,\underline{\mathbf{if}}\ M[\mathbf{X}]\ \underline{\mathbf{then}}\ \mathfrak{c}_T\ \underline{\mathbf{else}}\ \mathfrak{c}_F \overset{\text{any}}{\simeq} \mathfrak{d}\,\{\mathsf{B}\}}$$

JointIf9
$$\frac{\{\mathsf{A}_{t,u}\}\,\mathfrak{c}_t \overset{\text{any}}{\simeq} \mathfrak{d}_u\,\{\mathsf{B}\}\text{ for }t,u\in\{\mathsf{true},\mathsf{false}\}}{\Big\{\sum_{t,u\in\{\mathsf{true},\mathsf{false}\}}\downarrow^*_{t,u}(\mathsf{A}_{t,u})\Big\}\,\underline{\mathbf{if}}\ M[\mathbf{X}]\ \underline{\mathbf{then}}\ \mathfrak{c}_{\mathsf{true}}\ \underline{\mathbf{else}}\ \mathfrak{c}_{\mathsf{false}} \overset{\text{any}}{\simeq} \underline{\mathbf{if}}\ N[\mathbf{Y}]\ \underline{\mathbf{then}}\ \mathfrak{d}_{\mathsf{true}}\ \underline{\mathbf{else}}\ \mathfrak{d}_{\mathsf{false}}\,\{\mathsf{B}\}}$$

JointIf
$$\frac{\{\mathsf{A}_{\mathsf{true}}\}\,\mathfrak{c}_{\mathsf{true}} \overset{\text{any}}{\simeq} \mathfrak{d}_{\mathsf{true}}\,\{\mathsf{B}\}\qquad \{\mathsf{A}_{\mathsf{false}}\}\,\mathfrak{c}_{\mathsf{false}} \overset{\text{any}}{\simeq} \mathfrak{d}_{\mathsf{false}}\,\{\mathsf{B}\}}{\Big\{\downarrow^*_{\mathsf{true},\mathsf{true}}(\mathsf{A}_{\mathsf{true}})+\downarrow^*_{\mathsf{false},\mathsf{false}}(\mathsf{A}_{\mathsf{false}})\Big\}\,\underline{\mathbf{if}}\ M[\mathbf{X}]\ \underline{\mathbf{then}}\ \mathfrak{c}_{\mathsf{true}}\ \underline{\mathbf{else}}\ \mathfrak{c}_{\mathsf{false}} \overset{\text{any}}{\simeq} \underline{\mathbf{if}}\ N[\mathbf{Y}]\ \underline{\mathbf{then}}\ \mathfrak{d}_{\mathsf{true}}\ \underline{\mathbf{else}}\ \mathfrak{d}_{\mathsf{false}}\,\{\mathsf{B}\}}$$

While1
$$\frac{\big\{\mathsf{A}\big\}\,\mathfrak{c} \overset{\text{any}}{\simeq} \underline{\mathbf{skip}}\,\big\{\downarrow^*_{\mathsf{true}}(\mathsf{A})+\downarrow^*_{\mathsf{false}}(\mathsf{B})\big\}\qquad \underline{\mathbf{while}}\ M[\mathbf{X}]\ \underline{\mathbf{do}}\ \mathfrak{c}\text{ is terminating}}{\big\{\downarrow^*_{\mathsf{true}}(\mathsf{A})+\downarrow^*_{\mathsf{false}}(\mathsf{B})\big\}\,\underline{\mathbf{while}}\ M[\mathbf{X}]\ \underline{\mathbf{do}}\ \mathfrak{c} \overset{\text{any}}{\simeq} \underline{\mathbf{skip}}\,\{\mathsf{B}\}}$$

JointWhile
$$\frac{\begin{array}{c}\{\mathsf{A}\}\,\mathfrak{c} \overset{\text{any}}{\simeq} \mathfrak{d}\,\{\downarrow^*_{\mathsf{true},\mathsf{true}}(\mathsf{A})+\downarrow^*_{\mathsf{false},\mathsf{false}}(\mathsf{B})\}\\ \underline{\mathbf{while}}\ M[\mathbf{X}]\ \underline{\mathbf{do}}\ \mathfrak{c}\text{ or }\underline{\mathbf{while}}\ N[\mathbf{Y}]\ \underline{\mathbf{do}}\ \mathfrak{d}\text{ is terminating}\end{array}}{\{\downarrow^*_{\mathsf{true},\mathsf{true}}(\mathsf{A})+\downarrow^*_{\mathsf{false},\mathsf{false}}(\mathsf{B})\}\,\underline{\mathbf{while}}\ M[\mathbf{X}]\ \underline{\mathbf{do}}\ \mathfrak{c} \overset{\text{any}}{\simeq} \underline{\mathbf{while}}\ N[\mathbf{Y}]\ \underline{\mathbf{do}}\ \mathfrak{d}\,\{\mathsf{B}\}}$$

Figure 1 Rules for total/semipartial/partial eqRHL. In these rules, "any" can be any of "tot", "semi", "par". For any = par, the termination condition in While1 can be replaced by $\mathsf{A}\le\mathsf{id}$, and for any = par, semi the termination condition in JointWhile can be replaced by $\mathsf{A}\le\mathsf{id}$. We refer to the symmetric rules of Apply1, Init1, If1, and While1 (obtained by applying Sym) as Apply2, Init2, If2, and While2.

in the general case. The rules in Figure 1 are then simple consequences of the rules in the general case. The sole exception are rules related to while-loops: here not all of the partial, semipartial, total case follow directly from the general while rule. Those cases that do not follow are proved separately.

5.1 Structural rules

First, we mention the "structural" rules, i.e., rules that do not related to a specific language construct. There is Sym for exchanging the two programs. (In this rule, $\mathsf{SWAP} : \ell^2[\mathbf{X}_2^{\mathbf{all}}] \otimes \ell^2[\mathbf{X}_1^{\mathbf{all}}] \mapsto \ell^2[\mathbf{X}_1^{\mathbf{all}}] \otimes \ell^2[\mathbf{X}_2^{\mathbf{all}}]$ is the unitary operator $\mathsf{SWAP}_\perp : (\psi \otimes \phi) = \phi \otimes \psi.$) ExFalso allows us to show anything from an impossible preexpectation. Seq allows us to analyze the sequential composition of programs. Conseq allows us to weaken a judgment. (The preexpectation can be replaced by a smaller preexpectation, and the postexpectation can be replaced by a larger preexpectation. $\leq$ is the Loewner order). And finally, Scale allows us to scale pre- and postexpectations by a scalar factor.

5.2 One-sided rules

Conceptually simplest are the one-sided rules, i.e., rules that have **skip** on the right (or left) hand side. By combining them with Seq, we can prove facts about pairs of programs one statement at the time. Here, we only describe the rules with **skip** on the right side, the other case is analogous.

Apply: First, consider the Apply1 rule. It is stated (like all our rules), in a backward reasoning style, i.e., for any postexpectation A, the tells us the corresponding preexpectation, here $(U \mathbf{on} \mathbf{X}_1)^* \mathsf{A} (U \mathbf{on} \mathbf{X}_1)$. (Recall that $U \mathbf{on} \mathbf{X}_1$ denotes U applied to $\mathbf{X}_1$.) This is quite intuitive: the left program applies $U \mathbf{on} \mathbf{X}_1$, so the preexpectation corresponding to the postexpectation A is what we get if we apply $U \mathbf{on} \mathbf{X}_1$ and then compute the preexpectation, i.e., $(U \mathbf{on} \mathbf{X}_1)^* \mathsf{A} (U \mathbf{on} \mathbf{X}_1)$. (And it is $(U \mathbf{on} \mathbf{X}_1)^* \mathsf{A} (U \mathbf{on} \mathbf{X}_1)$ and not $\mathsf{A}(U \mathbf{on} \mathbf{X}_1)$ because the latter is not Hermitian and thus not a valid expectation.)

A toy example how to apply this rule: we want to what $\mathbf{x}$ has to be so that it will be $|0\rangle$ after applying a Hadamard H. Thus our postexpectation is $\mathsf{proj}(|0\rangle) \mathbf{on} \mathbf{x}_1$. Applying rule Apply1, we get that $\{\mathsf{B}\}\, \underline{\mathbf{apply}}\ H\ \underline{\mathbf{to}}\ \mathbf{x} \overset{\text{any}}{\sim} \underline{\mathbf{skip}}\, \{\mathsf{proj}(|0\rangle) \mathbf{on} \mathbf{x}_1\}$ for $\mathsf{B} := (H \mathbf{on} \mathbf{x}_1)^* (\mathsf{proj}(|0\rangle) \mathbf{on} \mathbf{x}_1)(H \mathbf{on} \mathbf{x}_1)$. (Here $\overset{\text{any}}{\sim}$ can be any of $\overset{\text{tot}}{\sim}$, $\overset{\text{semi}}{\sim}$, $\overset{\text{par}}{\sim}$.) A simple calculation reveals: $\mathsf{B} = \big(H^* \mathsf{proj}(|0\rangle) H\big) \mathbf{on} \mathbf{x}_1 = \mathsf{proj}(|+\rangle) \mathbf{on} \mathbf{x}_1$. Thus we learned (unsurprisingly) that to get $|0\rangle$, we need to start out with $|+\rangle$.

Init: The rule Init1 rule stated in a similar backwards reasoning way as Apply1, but the preexpectation is somewhat less intuitive. We will illustrate it with a toy example. Assume we want to know what the probability is to measure $|0\rangle$ after initializing a variable $\mathbf{x}$ with $|+\rangle$. That is, our postexpectation is $\mathsf{A} := \mathsf{proj}(|0\rangle) \mathbf{on} \mathbf{x}_1$ and our left program is $\mathbf{x} \leftarrow |+\rangle$. We ask for a suitable preexpectation B in $\{\mathsf{B}\}\, \mathbf{x} \leftarrow |+\rangle \overset{\text{any}}{\sim} \underline{\mathbf{skip}}\, \{\mathsf{A}\}$. The Init1 rule gives us $\mathsf{B} = \mathsf{id}_{\mathbf{x}_1} \otimes \big(\langle +| \otimes \mathsf{id}_{\neg \mathbf{x}_1}\big) \mathsf{A} \big(|+\rangle \otimes \mathsf{id}_{\neg \mathbf{x}_1}\big)$. (Here, $\neg \mathbf{X}_1 := \mathbf{X}_1^{\mathbf{all}} \mathbf{X}_2^{\mathbf{all}} \setminus \mathbf{X}_1$.) By definition of A, we have that $\big(\langle +| \otimes \mathsf{id}_{\neg \mathbf{x}_1}\big) \mathsf{A} \big(|+\rangle \otimes \mathsf{id}_{\neg \mathbf{x}_1}\big) = \langle +|\mathsf{proj}(|0\rangle)|+\rangle \otimes \mathsf{id}_{\neg \mathbf{x}_1} = \frac{1}{2} \mathsf{id}_{\neg \mathbf{x}_1}$. Note that this is not an expectation in our sense because it is an operator on all variable *but* $\mathbf{x}_1$. But by tensoring with $\mathsf{id}_{\mathbf{x}_1}$, we get the expectation $\mathsf{B} = \frac{1}{2}\mathsf{id}$. Thus the preexpectation is $\frac{1}{2}\mathsf{id}$ which intuitively means that, no matter what the initial state, the probability of measuring $|0\rangle$ will be $\frac{1}{2}$, as we would expect.

If: The rule rule If1 allows us to prove a judgment about an if-statement from judgments about the then- and the else-branch. If the preexpectations from the then- and else-branch are A_T and A_F, then the preexpectations for the if-statement is $\downarrow^*_{\mathsf{true}}(\mathsf{A}_T) + \downarrow^*_{\mathsf{false}}(\mathsf{A}_F)$. (Here

$\downarrow_t^*(A) := (M_t \,\mathbf{on}\, \mathbf{X}_1)^* A (M_t \,\mathbf{on}\, \mathbf{X}_1)$.) This is natural since $\downarrow_{\mathsf{true}}^*(\mathsf{A}_T)$ is A_T restricted to the case where the conditional holds, and $\downarrow_{\mathsf{false}}^*(\mathsf{A}_F)$ is A_F restricted to the case where the conditional does not hold.

A toy example: We want to show $\{\mathsf{id}\}$ **if** $M[\mathbf{x}]$ **then apply** X **to** $\mathbf{x}$ **else skip** $\overset{\text{any}}{\sim}$ **skip** $\{\mathsf{B}\}$ with $\mathsf{B} := \mathsf{proj}(|0\rangle) \,\mathbf{on}\, \mathbf{x}_1$. Here M is a computational basis measurement ($M_{\mathsf{true}} = \mathsf{proj}(|1\rangle)$, $M_{\mathsf{false}} = \mathsf{proj}(|0\rangle)$), and X is the pauli-X matrix (quantum bit flip). That is, with probability 1 (preexpectation is id), if we measure $\mathbf{x}$ in the computational basis, and, in case of outcome 1 flip it, we get $|0\rangle$ (postexpectation B). We derive easily (using rules Apply1 and Skip) that $\{\mathsf{proj}(|1\rangle) \,\mathbf{on}\, \mathbf{x}_1\}$ **apply** X **to** $\mathbf{x}$ $\overset{\text{any}}{\sim}$ **skip** $\{\mathsf{B}\}$ and $\{\mathsf{proj}(|0\rangle) \,\mathbf{on}\, \mathbf{x}_1\}$ **skip** $\overset{\text{any}}{\sim}$ **skip** $\{\mathsf{B}\}$. From the If1 rule, we then get $\{\mathsf{A}\}$ **if** $M[\mathbf{x}]$ **then apply** X **to** $\mathbf{x}$ **else skip** $\overset{\text{any}}{\sim}$ **skip** $\{\mathsf{B}\}$ with $\mathsf{A} = \downarrow_{\mathsf{true}}^*(\mathsf{proj}(|1\rangle) \,\mathbf{on}\, \mathbf{x}_1) + \downarrow_{\mathsf{false}}^*(\mathsf{proj}(|0\rangle) \,\mathbf{on}\, \mathbf{x}_1)$. Thus $\mathsf{A} = \mathsf{proj}(|1\rangle) \,\mathbf{on}\, \mathbf{x}_1 + \mathsf{proj}(|0\rangle) \,\mathbf{on}\, \mathbf{x}_1 = \mathsf{id}$, as desired.

While: The While1 rule is similar to the If1 rule. (The preexpectation in the conclusion has the same form.) The main difference is that we need to guess the invariant A because the postexpectation in the premise contains A. The rule also requires us to prove first that the loop is terminating (except in the case of partial correctness). Since this is a statement about a single program (non-relational), it can be shown using existing approaches (e.g., [14]) and is outside the scope of this paper.

5.3 Two-sided rules

The one-sided rules discussed in the previous section allow us to analyze two programs one statement at a time. However, they are not sufficient if want to analyze the relationship of two programs that go in lockstop. (E.g., two while loops that always take the same decision whether to terminate.) For handling if- and while-statements that are in sync, our logic provides the two-sided rules JointIf9, JointIf, and JointWhile. Notice that there are not two-sided analogues to Apply1 and Init1. This is because the resulting rule would be no different from using the one-sided rule twice. However, when random choices happen, two-sided rules are useful. In our case, this happens in if- and while-statements because the measurement of the loop-condition introduces randomness.

If: The JointIf9 rule allows us to compute the preexpectation of two if-statements. It is analogous to the If1 rule, except that the resulting preexpectation is of the form $\sum_{t,u\in\{\mathsf{true},\mathsf{false}\}} \downarrow_{t,u}^*(\mathsf{A}_{t,u})$. (Here $\downarrow_{t,u}^*(\mathsf{A}) := \big((M_t \,\mathbf{on}\, \mathbf{X}_1) \otimes (N_t \,\mathbf{on}\, \mathbf{Y}_2)\big)^* \mathsf{A} \big((M_t \,\mathbf{on}\, \mathbf{X}_1) \otimes (N_t \,\mathbf{on}\, \mathbf{Y}_2)\big)$.) That is, the preexpectations are restricted to all four combinations of true/false for the two if-conditions. And, consequently, we have a premise for each of those four cases. (The rule is called JointIf9 because, in the general case, there are nine cases, due to explicit treatment of non-terminating cases.) For convenience, we additionally state rule JointIf which considers only the cases where the two if-statements are in sync (true/true or false/false).

While: Similar to JointIf, the JointWhile rule allows us to reason about while loops that are in sync. Like with While1, in contrast to JointIf, we need to guess the invariant A. For an example, see Section 6. One difference with the While1 rule is that While1 requires us to prove termination in the semipartial and total case (not in the partical case), while JointWhile requires us to prove termination only in the total case. (Intuitively, this is because in the semipartial case, termination is not required, it is only required that both programs terminate with the same probability.)

6 Example: Quantum Zeno effect

Motivation. In this section, we study (one specific incarnation of) the quantum Zeno effect as an example of application of our logic. The Zeno effect implies that the following processes have the same effect:

- Start with a qubit in state $|0\rangle$. Apply a continuous rotation (with angular velocity ω) to it. (Thus, after time t, the state will have rotated by angle ωt.)
- Start with a qubit in state $|0\rangle$. Continuously observe the state. Namely, at time t, measure whether the qubit has rotated by angle ωt.

The quantum Zeno effect implies that in both processes, the state evolves in the same way (and that the measurement in the second situation always gives answer "yes"). Notice that this means that the measurements can be used to rotate the state.

In our formalization, we will consider the discrete version of this phenomenon: The rotation is split into n rotations by a small angle, and the continuous measurement consists of n measurements. In the limit $n \to \infty$, both processes yield the same state, but if we consider the situation for a concrete value of n, the result of the processes will be slightly different. (And the difference can be quantified in terms of n.) This makes this example a prime candidate for our logic: We want to compare two processes (hence we need relational Hoare logic), but the processes are not exactly equivalent (hence we cannot use qRHL from [17]) but only close to equivalent (and the "amount of equivalence" can be expressed using expectations).

Formalizing the processes. We now formalize the two processes as programs in our language. Let $n \geq 1$ be an integer.

In the first process, we have a continuous rotation, broken down into n small rotations. For simplicity, we will rotate by the angle $\pi/2$ within n steps, thus each small rotation rotates by angle $\frac{\pi}{2n}$. This is described by the rotation matrix $R := \begin{pmatrix} \cos\frac{\pi}{2n} & -\sin\frac{\pi}{2n} \\ \sin\frac{\pi}{2n} & \cos\frac{\pi}{2n} \end{pmatrix}$. Let $\mathbf{y}$ be a variable of type $\{0,1\}$ (i.e., the qubit that is rotated). In order to apply the rotation n times, we will need a counter $\mathbf{x}$ for the while loop. Let $\mathbf{x}$ be a variable of type $\mathbb{Z}$. We will have a loop that continues while (informally speaking) $\mathbf{x} < n$. This is formalized by the projector $P_{<n}$ onto states $|i\rangle$ with $i < n$. I.e., $P_{<n} := \sum_{-\infty<i<n} \mathsf{proj}(|i\rangle)$. In slight abuse of notation, we also write $P_{<n}$ for the binary measurement with Kraus operators $\{P_{<n}, \mathsf{id} - P_{<n}\}$. Furthermore, we need to increase the counter. For this let INCR be the unitary on $\ell^2(\mathbb{Z})$ with $\mathsf{INCR}|i\rangle \mapsto |i+1\rangle$ Then the program that initializes $\mathbf{y}$ with $|0\rangle$ and then applies the rotation R n times can be written as:

$$\mathbf{c} := \mathbf{x} \leftarrow |0\rangle;\ \mathbf{y} \leftarrow |0\rangle;\ \underline{\textbf{while}}\ P_{<n}[\mathbf{x}]\ \underline{\textbf{do}}\ (\underline{\textbf{apply}}\ \mathsf{INCR}\ \underline{\textbf{to}}\ \mathbf{x};\ \underline{\textbf{apply}}\ R\ \underline{\textbf{to}}\ \mathbf{y}) \tag{1}$$

In the second process, instead of applying R, we measure the state in each iteration of the loop. In the first iteration, we expect the original state $\phi_0 := |0\rangle$, and after the i-th iteration, we expect the state $\phi_i := R\phi_{i-1}$ for $i \geq 1$. This can be done using the program $\underline{\textbf{if}}\ \mathsf{proj}(\phi_i)[\mathbf{y}]\ \underline{\textbf{then}}\ \underline{\textbf{skip}}\ \underline{\textbf{else}}\ \underline{\textbf{skip}}$ where we again write in slight abuse of notation $\mathsf{proj}(\phi_i)$ for the corresponding binary measurement. Since the if-statement first measures $\mathbf{y}$ and then executes one of the $\underline{\textbf{skip}}$-branches, this is effectively just a measurement. We abbreviate this as $\underline{\textbf{if}}\ \mathsf{proj}(\phi_i)[\mathbf{y}]$.

However, we cannot simply write $\underline{\textbf{if}}\ \mathsf{proj}(\phi_i)[\mathbf{y}]$ in our loop body, because i should be the value of $\mathbf{x}$. So we need to define the projector that projects onto ϕ_i when $\mathbf{x} = |i\rangle$. This is done by the following projector on $\ell^2[\mathbf{xy}]$: $P_\phi := \sum_i \mathsf{proj}(|i\rangle \otimes \phi_i)$. Then $\underline{\textbf{if}}\ P_\phi[\mathbf{y}]$ will measure whether $\mathbf{y}$ contains ϕ_i whenever $\mathbf{x}$ contains $|i\rangle$.

Armed with that notation, we can now formulate the second process as a program:

$$\mathfrak{d} := \mathbf{x} \leftarrow |0\rangle;\ \mathbf{y} \leftarrow |0\rangle;\ \underline{\textbf{while}}\ P_{<n}[\mathbf{x}]\ \underline{\textbf{do}}\ (\underline{\textbf{apply}}\ \mathsf{INCR}\ \underline{\textbf{to}}\ \mathbf{x};\ \underline{\textbf{if}}\ P_\phi[\mathbf{xy}]) \tag{2}$$

Equivalence of the programs. We claim that the two processes, i.e., the programs $\mathfrak{c}, \mathfrak{d}$ have approximately the same final state in $\mathbf{y}$. Having the same state can be expressed using the "quantum equality" described in Section 2. Specifically, the postexpectation $\mathsf{EQUAL}\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2$ corresponds to $\mathbf{y}_1$ and $\mathbf{y}_2$ having the same state. For example, $\{\mathsf{id}\}\,\mathfrak{c} \overset{\text{tot}}{\sim} \mathfrak{d}\,\{\mathsf{EQUAL}\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2\}$ implies that the final state of $\mathfrak{c}$ and $\mathfrak{d}$ is the same (if we trace out all variables except $\mathbf{y}_1, \mathbf{y}_2$).[14] The fact that the final states are approximately equal can be expressed by multiplying the preexpectation with a real number close to 1. Specifically, in our case we claim that

$$\{\varepsilon^n \cdot \mathsf{id}\}\,\mathfrak{c} \overset{\text{tot}}{\sim} \mathfrak{d}\,\{\mathsf{EQUAL}\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2\} \tag{3}$$

Here $\varepsilon := (\cos\frac{\pi}{2n})^2$. This indeed means that the final states of $\mathfrak{c}$ and $\mathfrak{d}$ are the same asymptotically since $\varepsilon^n = (\cos\frac{\pi}{2n})^{2n} \xrightarrow{n\to\infty} 1$.

Warm up. Before we prove (3), we investigate a simpler case as a warm up. We investigate the special where $n = 3$, and instead of a while-loop, we simply repeat the loop body three times.

$$\begin{aligned}\mathfrak{c}' &:= \mathbf{y} \leftarrow |0\rangle;\underline{\textbf{apply}}\ R\ \underline{\textbf{to}}\ \mathbf{y};\underline{\textbf{apply}}\ R\ \underline{\textbf{to}}\ \mathbf{y};\underline{\textbf{apply}}\ R\ \underline{\textbf{to}}\ \mathbf{y}\\ \mathfrak{d}' &:= \mathbf{y} \leftarrow |0\rangle;\underline{\textbf{if}}\ \mathsf{proj}(\phi_1)[\mathbf{y}];\ \underline{\textbf{if}}\ \mathsf{proj}(\phi_2)[\mathbf{y}];\ \underline{\textbf{if}}\ \mathsf{proj}(\phi_3)[\mathbf{y}]\end{aligned} \tag{4}$$

We claim:

$$\{\varepsilon^3 \cdot \mathsf{id}\}\,\mathfrak{c}' \overset{\text{tot}}{\sim} \mathfrak{d}'\,\{\mathsf{EQUAL}\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2\} \tag{5}$$

First, we strengthen the postcondition. Let $\mathsf{A}_3 := (\mathsf{proj}(\phi_3 \otimes \phi_3)\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2)$. (This postcondition is intuitively what we expect to (approximately) hold at the end of the execution. It means that $\mathbf{y}_1$ and $\mathbf{y}_2$ are both in state ϕ_3, the result by rotating three times using R. Since $\phi_3 \otimes \phi_3$ is in the image of the projector EQUAL, it follows that $\mathsf{A}_3 \le (\mathsf{EQUAL}\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2)$. By rule Conseq it is thus sufficient to show $\{\varepsilon^3 \cdot \mathsf{id}\}\,\mathfrak{c}' \overset{\text{tot}}{\sim} \mathfrak{d}'\,\{\mathsf{A}_3\}$. And by rule Seq, we can show that by the following sequence of Hoare judgments for some $\mathsf{A}_0, \mathsf{A}_1, \mathsf{A}_2$:

$$\left\{\varepsilon^3 \cdot \mathsf{id}\right\} \underset{\text{tot}}{\sim} \left\{\mathsf{A}_0\right\} \underset{\text{tot}}{\sim} \left\{\mathsf{A}_1\right\} \underset{\text{tot}}{\sim} \left\{\mathsf{A}_2\right\} \underset{\text{tot}}{\sim} \left\{\mathsf{A}_3\right\} \tag{6}$$

$$\begin{array}{l}\mathbf{y} \leftarrow |0\rangle\\ \mathbf{y} \leftarrow |0\rangle\end{array}\qquad \begin{array}{l}\underline{\textbf{apply}}\ R\ \underline{\textbf{to}}\ \mathbf{y}\\ \underline{\textbf{if}}\ \mathsf{proj}(\phi_1)[\mathbf{y}]\end{array}\qquad \begin{array}{l}\underline{\textbf{apply}}\ R\ \underline{\textbf{to}}\ \mathbf{y}\\ \underline{\textbf{if}}\ \mathsf{proj}(\phi_2)[\mathbf{y}]\end{array}\qquad \begin{array}{l}\underline{\textbf{apply}}\ R\ \underline{\textbf{to}}\ \mathbf{y}\\ \underline{\textbf{if}}\ \mathsf{proj}(\phi_3)[\mathbf{y}]\end{array}$$

(These are four judgments, we just use a more compact notation to put them in one line.) We will derive suitable values $\mathsf{A}_0, \mathsf{A}_1, \mathsf{A}_2$ by applying our rules backwards from the postcondition.

By applying rule Apply1, we get $\left\{\mathsf{A}_3'\right\}\underline{\textbf{apply}}\ R\ \underline{\textbf{to}}\ \mathbf{y} \overset{\text{tot}}{\sim} \underline{\textbf{skip}}\left\{\mathsf{A}_3\right\}$ where $\mathsf{A}_3' := (R^\dagger\,\mathbf{on}\,\mathbf{y}_1) \circ \mathsf{A}_3$ and where we use $A \circ B$ as an abbreviation for $ABA^\dagger$. And by rule If2 (using rule Skip for its premises), we get

$$\left\{(\mathsf{proj}(\phi_3)\,\mathbf{on}\,\mathbf{y}_2) \circ \mathsf{A}_3' + (1 - \mathsf{proj}(\phi_3)\,\mathbf{on}\,\mathbf{y}_2) \circ \mathsf{A}_3'\right\}\underline{\textbf{skip}} \overset{\text{tot}}{\sim} \underline{\textbf{if}}\ \mathsf{proj}(\phi_3)[\mathbf{y}]\left\{\mathsf{A}_3'\right\}.$$

[14] This is seen as follows: The judgment implies that the finals states are marginals of a state that is invariant under the projector $\mathsf{EQUAL}\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2$, i.e., a state with support in the space $\mathbf{Y}_1 \equiv_{\mathsf{q}} \mathbf{Y}_2$. That means that this state is invariant under swapping $\mathbf{Y}_1, \mathbf{Y}_2$, and thus the marginals corresponding to $\mathbf{Y}_1$ and $\mathbf{Y}_2$ are equal.

The precondition is lower bounded by $A_2 := (\mathsf{proj}(\phi_3)\,\mathbf{on}\,\mathbf{y}_2) \circ \mathsf{A}'_3$. (The second term corresponds to the measurement failing to measure ϕ_3, in this case all is lost anyway, so we remove that term.) Hence (with rules Seq and Conseq), $\{\mathsf{A}_2\}$ **apply** R **to** $\mathbf{y} \overset{\text{tot}}{\sim}$ **if** $\mathsf{proj}(\phi_3)[\mathbf{y}]\,\{\mathsf{A}_3\}$ as desired in (6).

Analogously, we can instantiate

$$\mathsf{A}_1 := (\mathsf{proj}(\phi_2)\,\mathbf{on}\,\mathbf{y}_2) \circ (R^*\,\mathbf{on}\,\mathbf{y}_1) \circ \mathsf{A}_2 \quad \text{and} \quad \mathsf{A}_0 := (\mathsf{proj}(\phi_1)\,\mathbf{on}\,\mathbf{y}_2) \circ (R^*\,\mathbf{on}\,\mathbf{y}_1) \circ \mathsf{A}_1$$

in (6). We can simplify the expressions for $\mathsf{A}_0, \mathsf{A}_1, \mathsf{A}_2$ some more. We have

$$\begin{aligned}\mathsf{A}_2 &= (\mathsf{proj}\big(\phi_3\big)\,\mathbf{on}\,\mathbf{y}_2) \circ (R^*\,\mathbf{on}\,\mathbf{y}_1) \circ \big(\mathsf{proj}(\phi_3 \otimes \phi_3)\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2\big) \\ &= \mathsf{proj}\big(R^*\phi_3 \otimes \mathsf{proj}(\phi_3)\phi_3\big)\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2 = \mathsf{proj}(\phi_2 \otimes \phi_3)\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2\end{aligned}$$

And

$$\begin{aligned}\mathsf{A}_1 &= (\mathsf{proj}\big(\phi_2\big)\,\mathbf{on}\,\mathbf{y}_2) \circ (R^*\,\mathbf{on}\,\mathbf{y}_1) \circ \big(\mathsf{proj}(\phi_2 \otimes \phi_3)\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2\big) \\ &= \mathsf{proj}\big(R^*\phi_2 \otimes \mathsf{proj}(\phi_2)\phi_3\big)\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2 = \varepsilon\,\mathsf{proj}(\phi_1 \otimes \phi_2)\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2.\end{aligned}$$

(Note the slight difference: instead of $\mathsf{proj}(\phi_3)\phi_3$ have $\mathsf{proj}(\phi_2)\phi_3$ here, which simplifies to $\phi_2 \cdot \phi_2^*\phi_3 = \phi_2 \cdot \sqrt{\varepsilon}$.) Analogously

$$\mathsf{A}_0 = \varepsilon^2\,\mathsf{proj}(\phi_0 \otimes \phi_1)\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2.$$

It is left to show the first judgment in (6), namely $\{\varepsilon^3 \cdot \mathsf{id}\}\,\mathbf{y} \leftarrow |0\rangle \overset{\text{tot}}{\sim} \mathbf{y} \leftarrow |0\rangle\,\{\mathsf{A}_0\}$. By rules Init1 and Init2 (starting from the right), we have

$$\begin{aligned}\Big\{\varepsilon^3 \cdot \mathsf{id}\Big\} &\overset{(**)}{=} \Big\{\mathsf{id}_{\mathbf{y}_2} \otimes \big(\langle 0|_{\mathbf{y}_2} \otimes \mathsf{id}_{\neg\mathbf{y}_2}\big) \circ \varepsilon^2(\mathsf{proj}(\phi_1)\,\mathbf{on}\,\mathbf{y}_2)\Big\}\ \underline{\mathbf{skip}}\ \overset{\text{tot}}{\sim} \mathbf{y} \leftarrow |0\rangle \\ &\Big\{\varepsilon^2(\mathsf{proj}(\phi_1)\,\mathbf{on}\,\mathbf{y}_2)\Big\} \overset{(*)}{=} \Big\{\mathsf{id}_{\mathbf{y}_1} \otimes \big(\langle 0|_{\mathbf{y}_1} \otimes \mathsf{id}_{\neg\mathbf{y}_1}\big) \circ \mathsf{A}_0\Big\}\,\mathbf{y} \leftarrow |0\rangle \overset{\text{tot}}{\sim} \underline{\mathbf{skip}}\,\Big\{\mathsf{A}_0\Big\}. \quad (7)\end{aligned}$$

Here $(*)$ uses that $\phi_0 = |0\rangle$ and thus $\langle 0|\mathsf{proj}(\phi_0)|0\rangle = 1$, and $(**)$ uses that $\phi_1^*\phi_0 = \sqrt{\varepsilon}$ and thus $\langle 0|\mathsf{proj}(\phi_1)|0\rangle = \varepsilon$.

The first judgment in (6) then follows by rule Seq.

This completes the analysis, we have shown (5).

Analysis of the while-programs. Given the experiences from the analysis of the special case (the programs from (4)), we now can solve the original problem, namely analyzing the programs $\mathfrak{c}, \mathfrak{d}$ from (1),(2).

As before, we can replace the postcondition in (3) by the stronger postcondition $\mathsf{B} := (\mathsf{proj}(|n\rangle) \otimes |n\rangle \otimes \phi_n \otimes \phi_n)\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2\mathbf{y}_1\mathbf{y}_2)$. By rule Conseq, it is sufficient to show $\{\varepsilon^n \cdot \mathsf{id}\}\,\mathfrak{c} \overset{\text{tot}}{\sim} \mathfrak{d}\,\{\mathsf{B}\}$. By rule Seq, this follows if we can show

$$\Big\{\varepsilon^n \cdot \mathsf{id}\Big\}\ \begin{matrix}\mathbf{x} \leftarrow |0\rangle \\ \overset{\text{tot}}{\sim}\ \mathbf{x} \leftarrow |0\rangle\end{matrix}\ \Big\{\mathsf{D}\Big\}\ \begin{matrix}\mathbf{y} \leftarrow |0\rangle \\ \overset{\text{tot}}{\sim}\ \mathbf{y} \leftarrow |0\rangle\end{matrix}\ \Big\{\mathsf{C}\Big\}\ \begin{matrix}\text{while}_{\mathfrak{c}} \\ \overset{\text{tot}}{\sim}\ \text{while}_{\mathfrak{d}}\end{matrix}\ \Big\{\mathsf{B}\Big\} \quad (8)$$

with

$$\begin{aligned}\text{while}_{\mathfrak{c}} &:= \underline{\mathbf{while}}\ P_{<n}[\mathbf{x}]\ \underline{\mathbf{do}}\ (\underline{\mathbf{apply}}\ \mathsf{INCR}\ \underline{\mathbf{to}}\ \mathbf{x};\ \underline{\mathbf{apply}}\ R\ \underline{\mathbf{to}}\ \mathbf{y}) \\ \text{while}_{\mathfrak{d}} &:= \underline{\mathbf{while}}\ P_{<n}[\mathbf{x}]\ \underline{\mathbf{do}}\ (\underline{\mathbf{apply}}\ \mathsf{INCR}\ \underline{\mathbf{to}}\ \mathbf{x};\ \underline{\mathbf{if}}\ P_\phi[\mathbf{xy}])\end{aligned}$$

for suitably chosen expectations C, D.

To prove the last judgment $\{\mathsf{C}\}\,\text{while}_{\mathfrak{c}} \overset{\text{tot}}{\sim} \text{while}_{\mathfrak{d}}\,\{\mathsf{B}\}$ in (8), we use rule JointWhile. This rule requires us to come up with a loop invariant A. To understand what the right loop invariant is, we draw from our experiences in the special case. There, we had defined the expectations $\mathsf{A}_0, \dots, \mathsf{A}_3$, where A_i described the state of the programs right after the i-th application of $\underline{\textbf{apply}}\ R\ \underline{\textbf{to}}\ \mathbf{y}$ and $\underline{\textbf{if}}\ \mathsf{proj}(\phi_i)[\mathbf{y}]$. We had

$$\mathsf{A}_i = \varepsilon^{2-i}\,\mathsf{proj}(\phi_i \otimes \phi_{i+1})\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2 \text{ for } i = 0,1,2 \qquad \text{and} \qquad \mathsf{A}_3 = \mathsf{proj}(\phi_3 \otimes \phi_3)\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2$$

One sees easily that this would generalize as

$$\mathsf{A}_i = \varepsilon^{n-i-1}\,\mathsf{proj}(\phi_i \otimes \phi_{i+1})\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2 \qquad \text{for } i < n$$
$$\text{and} \qquad \mathsf{A}_n = \mathsf{proj}(\phi_n \otimes \phi_n)\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2$$

for values $n \neq 3$. Thus we expect that these expectations A_i also hold in the programs $\text{while}_{\mathfrak{c}}$, $\text{while}_{\mathfrak{d}}$ after the i-th iteration (or before the $(i+1)$-st iteration). Additionally, we keep track of the counter $\mathbf{x}$, which should be $|i\rangle$ after the i-th iteration (or before the $(i+1)$-st iteration). This would be expressed by the expectation $\mathsf{proj}(|i\rangle \otimes |i\rangle)\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2$. Thus, for the i-th iteration, we use the "conjunction"

$$\mathsf{A}_i^{\mathbf{x}} := \mathsf{A}_i \cdot (\mathsf{proj}(|i\rangle \otimes |i\rangle)\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2)$$
$$= \begin{cases} \varepsilon^{n-i-1}\,\mathsf{proj}(|i\rangle \otimes |i\rangle \otimes \phi_i \otimes \phi_{i+1})\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2\mathbf{y}_1\mathbf{y}_2 & (i < n) \\ \mathsf{proj}(|n\rangle \otimes |n\rangle \otimes \phi_n \otimes \phi_n)\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2\mathbf{y}_1\mathbf{y}_2 & (i = n) \end{cases}$$

(Note that $\cdot$ is not generally a sensible operation on expectations. But in this case, $\mathsf{fv}(\mathsf{A}_i) = \mathbf{y}_1\mathbf{y}_2$ and $\mathsf{fv}(\mathsf{proj}(|i\rangle \otimes |i\rangle)\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2) = \mathbf{x}_1\mathbf{x}_2$, so the expectations commute and their product is again an expectation.)

The final loop invariant A is then the "disjunction" of the $\mathsf{A}_i^{\mathbf{x}}$ for $i = 0, \dots, n-1$, meaning that in every iteration, one of the A_i should hold. (We do not include $\mathsf{A}_i^{\mathbf{x}}$ with $i = n$ here because when applying the JointWhile rule, we only need the invariant to hold when the loop guard was passed.) We define $\mathsf{A} := \sum_{i=0}^{n} \mathsf{A}_i^{\mathbf{x}}$. (In general, summation is not a sensible operation representation of "disjunction", but in the present case, all summands are orthogonal.)

We have now derived a suitable candidate for the invariant A to use in rule JointWhile. We stress that the above argumentation (involving words like "disjunction" and "conjunction" of expectations, and claims that an expectation "holds" at a certain point) was not a formally well-defined argument, merely an explanation how we arrived at our specific choice for A. From the formal point of view, all we will need in the following are the definitions of $\mathsf{A}, \mathsf{A}_i^{\mathbf{x}}$. The rest of the argument above was semi-formal motivation.

We will now show the rightmost judgment in (8), namely $\{\mathsf{C}\}\,\text{while}_{\mathfrak{c}} \overset{\text{tot}}{\sim} \text{while}_{\mathfrak{d}}\,\{\mathsf{B}\}$ (for some suitable C). If we apply rule JointWhile (with A as defined above) to this, we get the premise[15]

$$\Big\{\mathsf{A}\Big\}\ \overbrace{\underbrace{\underline{\textbf{apply}}\ \mathsf{INCR}\ \underline{\textbf{to}}\ \mathbf{x};\ \underline{\textbf{apply}}\ R\ \underline{\textbf{to}}\ \mathbf{y}}_{\overset{\text{tot}}{\sim}\ \underline{\textbf{apply}}\ \mathsf{INCR}\ \underline{\textbf{to}}\ \mathbf{x};\ \underline{\textbf{if}}\ P_\phi[\mathbf{xy}]}}^{=:\text{body}_{\mathfrak{c}}}\ \Big\{\underbrace{P^{\text{both}}_{<n} \circ \mathsf{A} + (P^{\text{none}}_{<n}) \circ \mathsf{B}}_{=:\mathsf{C}'}\Big\} \tag{9}$$
$$=:\text{body}_{\mathfrak{d}}$$

[15] We also additionally get the premise that $\text{while}_{\mathfrak{c}}$ is terminating. This can be shown with techniques from prior work (e.g., [14]) and is quite obvious in the present case. Alternatively, we could have stated this example with respect to partial correctness instead of total correctness. In that case, we do not need to prove termination.

with $P^{\text{both}}_{<n} := P_{<n} \otimes P_{<n}\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2$ and $P^{\text{none}}_{<n} := (\mathsf{id} - P_{<n}) \otimes (\mathsf{id} - P_{<n})\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2$. (Here we write $A \circ B$ as an abbreviation for $ABA^\dagger$.) By applying rules If2, Apply2, and twice Apply1 (with Seq in between), we get

$$\big\{(\mathsf{INCR}\,\mathbf{on}\,\mathbf{x}_1) \circ (R\,\mathbf{on}\,\mathbf{y}_1) \circ (\mathsf{INCR}\,\mathbf{on}\,\mathbf{x}_2) \circ \mathsf{B}_2\big\}\,\mathrm{body}_{\mathfrak{c}} \overset{\text{tot}}{\sim} \mathrm{body}_{\mathfrak{d}}\,\big\{\mathsf{C}'\big\}$$

where $\mathsf{B}_2 := (P_\phi\,\mathbf{on}\,\mathbf{x}_2\mathbf{y}_2) \circ \mathsf{C}' + (\mathsf{id} - P_\phi\,\mathbf{on}\,\mathbf{x}_2\mathbf{y}_2) \circ \mathsf{C}'$. Since $\mathsf{B}_2 \geq (P_\phi\,\mathbf{on}\,\mathbf{x}_1\mathbf{y}_1) \circ \mathsf{C}'$, by rule Conseq we can weaken this to

$$\big\{\mathsf{A}'\big\}\,\mathrm{body}_{\mathfrak{c}} \overset{\text{tot}}{\sim} \mathrm{body}_{\mathfrak{d}}\,\big\{\mathsf{C}'\big\} \qquad \text{with} \qquad \mathsf{A}' := \underbrace{(\mathsf{INCR}\,\mathbf{on}\,\mathbf{x}_1) \circ (R\,\mathbf{on}\,\mathbf{y}_1) \circ (\mathsf{INCR}\,\mathbf{on}\,\mathbf{x}_2) \circ (P_\phi\,\mathbf{on}\,\mathbf{x}_2\mathbf{y}_2)}_{=:L} \circ \mathsf{C}'$$

If we can show that $\mathsf{A} \leq \mathsf{A}'$ then we have proven (9). By definition of $\mathsf{A}^{\mathbf{x}}_i$, L, R, P_ϕ, INCR, $P^{\text{both}}_{<n}$, we have

$$\begin{aligned} L \circ P^{\text{both}}_{<n} \circ \mathsf{A}^{\mathbf{x}}_i &= \varepsilon^{n-i-1}\,\mathsf{proj}(\mathsf{INCR}^*|i\rangle \otimes \mathsf{INCR}^*|i\rangle \otimes R^*\phi_i \otimes \mathsf{proj}(\phi_i)\phi_{i+1})\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2\mathbf{y}_1\mathbf{y}_2 \\ &= \varepsilon^{n-i}\,\mathsf{proj}(|i-1\rangle \otimes |i-1\rangle \otimes \phi_{i-1} \otimes \phi_i)\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2\mathbf{y}_1\mathbf{y}_2 = \mathsf{A}^{\mathbf{x}}_{i-1}. \end{aligned}$$

And $L \circ P^{\text{both}}_{<n} \circ \mathsf{A}^{\mathbf{x}}_n = 0$ since $P^{\text{both}}_{<n} \circ \mathsf{A}^{\mathbf{x}}_n = 0$. Thus $L \circ P^{\text{both}}_{<n} \circ \mathsf{A} = \sum_{i=0}^{n-1} A^{\mathbf{x}}_{i-1} \geq \sum_{i=0}^{n-2} A^{\mathbf{x}}_i$. And by definition of B, L, R, P_ϕ, INCR, $P^{\text{none}}_{<n}$, we have

$$\begin{aligned} L \circ P^{\text{none}}_{<n} \circ \mathsf{B} &= \mathsf{proj}\big(\mathsf{INCR}^*|n\rangle \otimes \mathsf{INCR}^*|n\rangle \otimes R^*\phi_n \otimes \mathsf{proj}(\phi_n)\phi_{n+1}\big)\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2\mathbf{y}_1\mathbf{y}_2 \\ &= \mathsf{proj}\big(|n-1\rangle \otimes |n-1\rangle \otimes \phi_{n-1} \otimes \phi_n\big)\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2\mathbf{y}_1\mathbf{y}_2 = \mathsf{A}^{\mathbf{x}}_{n-1}. \end{aligned}$$

Thus $\mathsf{A}' = L \circ \mathsf{C}' \geq \sum_{i=0}^{n-2} A^{\mathbf{x}}_i + A^{\mathbf{x}}_{n-1} = \mathsf{A}$. Thus we have proven (9). By rule JointWhile, this implies $\{\mathsf{C}'\}\,\mathrm{while}_{\mathfrak{c}} \overset{\text{tot}}{\sim} \mathrm{while}_{\mathfrak{d}}\,\{\mathsf{B}\}$ with C' as defined in (9). With $\mathsf{C} := A^{\mathbf{x}}_0 \leq \mathsf{C}'$, $\{\mathsf{C}\}\,\mathrm{while}_{\mathfrak{c}} \overset{\text{tot}}{\sim} \mathrm{while}_{\mathfrak{d}}\,\{\mathsf{B}\}$ follows by rule Conseq. This is the rightmost judgment in (8).

Using rules Init1, Init2, and Seq, we get $\{\mathsf{D}\}\,\mathbf{y} \leftarrow |0\rangle \overset{\text{tot}}{\sim} \mathbf{y} \leftarrow |0\rangle\,\{\mathsf{C}\}$ with $\mathsf{D} := \varepsilon^n \cdot (\mathsf{proj}(|0\rangle \otimes |0\rangle)\,\mathbf{on}\,\mathbf{x}_1\mathbf{x}_2)$. (This is done very similarly to (7).) This shows the middle judgment in (8).

Also using rules Init1, Init2, and Seq, we get $\{\varepsilon^n \cdot \mathsf{id}\}\,\mathbf{x} \leftarrow |0\rangle \overset{\text{tot}}{\sim} \mathbf{x} \leftarrow |0\rangle\,\{\mathsf{D}\}$. This shows the leftmost judgment in (8).

Thus we have shown the three judgments in (8). By rule Seq, it follows that $\{\varepsilon^n \cdot \mathsf{id}\}\,\mathfrak{c} \overset{\text{tot}}{\sim} \mathfrak{d}\,\{\mathsf{B}\}$. Since $\mathsf{B} \leq (\mathsf{EQUAL}\,\mathbf{on}\,\mathbf{y}_1\mathbf{y}_2)$, by rule Conseq, we get (3).

Playing Stochastically in Weighted Timed Games to Emulate Memory

Abstract

Weighted timed games are two-player zero-sum games played in a timed automaton equipped with integer weights. We consider optimal reachability objectives, in which one of the players, that we call Min, wants to reach a target location while minimising the cumulated weight. While knowing if Min has a strategy to guarantee a value lower than a given threshold is known to be undecidable (with two or more clocks), several conditions, one of them being the divergence, have been given to recover decidability. In such weighted timed games (like in untimed weighted games in the presence of negative weights), Min may need finite memory to play (close to) optimally. This is thus tempting to try to emulate this finite memory with other strategic capabilities. In this work, we allow the players to use stochastic decisions, both in the choice of transitions and of timing delays. We give for the first time a definition of the expected value in weighted timed games, overcoming several theoretical challenges. We then show that, in divergent weighted timed games, the stochastic value is indeed equal to the classical (deterministic) value, thus proving that Min can guarantee the same value while only using stochastic choices, and no memory.

1 Introduction

Real-time aspects are often inherent in the behaviour of critical software systems. *Timed automata* [2] extend finite-state automata with timing constraints, providing an automata-theoretic framework to model and verify real-time systems. While this has lead to the development of mature verification tools, the design of programs verifying some real-time specifications remains a notoriously difficult problem. One way to avoid the need to a posteriori debugging is to automatise the process as much as possible. To do so, the situation is modelled into a *timed game*, played by a *controller* and an antagonistic *environment*: they act, in a turn-based fashion, over a timed automaton. A simple, yet realistic, objective for the controller is to reach a target location. We are thus looking for a *strategy* of the controller, that is a recipe dictating how to play so that the target is reached no matter how the environment plays. Reachability timed games are decidable [4], and EXPTIME-complete [19].

For many applications, this qualitative setting is often too coarse to model faithfully the system. This motivated a shift to a quantitative setting, based on weighted extensions of the models considered so far. Weighted extensions of these timed automata and games have thus been considered in order to measure the quality of the winning strategy for the controller [11, 1]: when the controller has several winning strategies, the quantitative version of the game helps choosing a good one with respect to some metrics. More precisely, the controller, which we now call player Min, wants to reach the target while *minimising* the cumulated weight. The model we consider, called *weighted timed game* (WTG for short), is defined as follows: the game takes place over a weighted (or priced) timed automaton [5, 3], where locations are split among the two players, transitions are equipped with weights, and locations with rates of weights (the cost is then proportional to the time spent in this location, with the rate as proportional coefficient). In this setting, the possibility to use negative weights on transitions and locations is crucial when one wants to model energy or other resources that can grow or decrease during the execution of the system under study.

While solving the optimal reachability problem on weighted timed automata has been shown to be PSPACE-complete [8] (i.e. the same complexity as the non-weighted version), WTGs are known to be undecidable [13]. Many restrictions have then been considered in order to regain decidability, the first and most interesting one being the class of strictly non-Zeno cost with only non-negative weights (in transitions and locations) [11]: this hypothesis requires that every execution of the timed automaton that follows a cycle of the region automaton has a weight far from 0 (in interval $[1, +\infty)$, for instance). This setting has been extended in the presence of negative weights in transitions and locations [16]: in the so-called *divergent WTGs*, each execution that follows a cycle of the region automaton has a weight in $(-\infty, -1] \cup [1, +\infty)$. A triply-exponential-time algorithm allows one to compute the values and almost-optimal strategies, while deciding the divergence of a WTG is PSPACE-complete.

When studying optimal reachability objectives with both positive and negative weights, it is known that strategies of player Min require memory to play optimally (see [15] for the case of finite games). More precisely, the memory needed is pseudo-polynomial (i.e. polynomial if constants are encoded in unary). For WTGs, the memory needed even becomes exponential. An important challenge is thus to find ways to avoid using such complex strategies, e.g. by proposing alternative classes of strategies that are more easily amenable to implementation.

Strategies considered so far are deterministic. Though the game has no stochastic edges, it is possible to allow players to use stochastic strategies. This approach has been recently studied in the setting of finite games [20], where it is shown that memory may indeed be emulated using randomness in finite reachability games with integer weights. More precisely, the minimal value Min can achieve using memoryless stochastic strategies is the same as the value achievable using deterministic strategies. In the present work, we lift the results obtained in [20] for finite games to the timed setting.

A first important challenge is to analyse how to play stochastically in WTGs. To our knowledge, this has not been studied before. Starting from a notion of stochastic behaviours in a timed automaton considered in [7] (for the one-player setting), we propose a new class of stochastic strategies. Compared with [7], our class is larger in the sense that we allow Dirac distributions for delays, which subsumes the setting of deterministic strategies. However, in order to ensure that strategies yield a well-defined probability distribution on sets of executions, we need measurability properties stronger than the one considered in [7] (we actually provide an example showing that their hypothesis was not strong enough).

Then, we turn our attention towards the expected cumulated weight of the set of plays conforming to a pair of stochastic strategies. We first prove that under the previous measurability hypotheses, this expectation is well-defined when restricting to the set of plays

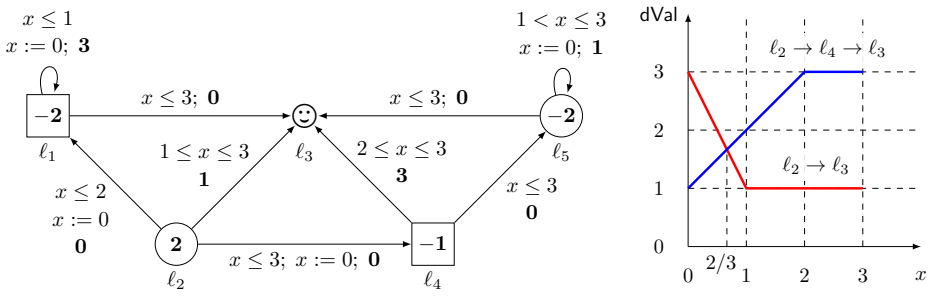

Figure 1 On the left, a weighted timed game. Locations belonging to Min (resp. Max) are depicted by circles (resp. squares). The target location is ℓ_3. Location ℓ_1 (resp. ℓ_5) has (deterministic) value $+\infty$ (resp. $-\infty$). As a consequence, the value in ℓ_4 is determined by the edge to ℓ_3, and depicted in blue on the right. In location ℓ_2, the value associated with the transition to ℓ_3 is depicted in red, and the deterministic value in ℓ_2 is obtained as the minimum of these two curves.

following a finite sequence of transitions. In order to have the convergence of the global expectation, we identify another property of strategies of Min, which intuitively ensures that the set of target locations is reached quickly enough. This allows us to define a notion of stochastic value (resp. memoryless stochastic value) of the game, i.e. the best value Min can achieve using stochastic strategies (resp. memoryless stochastic strategies), when Max uses stochastic strategies (resp. memoryless stochastic strategies) too.

In a second step, we aim at adapting the proof techniques of [20] from finite to infinite games. It is well-known that the classical region abstraction of timed automata is not suited to analyse WTGs (there are cases in which one has to split regions). In order to obtain positive results, we focus on the class of divergent WTGs. We prove that the notion of optimal deterministic switching strategy, which was central in the approach of [20], can be adapted to divergent WTGs. Our main result is then to show that for these games, the two versions of stochastic values are equal to the deterministic value. In other terms, we show that Min can emulate memory using randomisation, and vice versa. Moreover, combining memory and randomisation does not increase Min's capabilities. Due to the lack of space, detailed proofs of all results can be found in the long version [21].

2 Weighted timed games

We let $\mathcal{C}$ be a finite set of variables called clocks. A valuation is a mapping $\nu \colon \mathcal{C} \to \mathbb{R}_{\geq 0}$. For a valuation ν, a delay $t \in \mathbb{R}_{\geq 0}$ and a subset $Y \subseteq \mathcal{C}$ of clocks, we define the valuation $\nu + t$ as $(\nu + t)(x) = \nu(x) + t$, for all $x \in \mathcal{C}$, and the valuation $\nu[Y := 0]$ as $(\nu[Y := 0])(x) = 0$ if $x \in Y$, and $(\nu[Y := 0])(x) = \nu(x)$ otherwise. The valuation $\mathbf{0}$ assigns 0 to every clock. A (non-diagonal) guard on clocks of $\mathcal{C}$ is a conjunction of atomic constraints of the form $x \bowtie c$, where $\bowtie \in \{\leq, <, =, >, \geq\}$ and $c \in \mathbb{N}$. A valuation $\nu \colon \mathcal{C} \to \mathbb{R}_{\geq 0}$ satisfies an atomic constraint $x \bowtie c$ if $\nu(x) \bowtie c$. The satisfaction relation is extended to all guards g naturally, and denoted by $\nu \models g$. We let $\mathsf{Guards}(\mathcal{C})$ denote the set of guards over $\mathcal{C}$.

▶ **Definition 1.** *A weighted timed game (WTG) is a tuple* $\mathcal{G} = \langle L_{\mathsf{Min}}, L_{\mathsf{Max}}, L_T, \Delta, \mathsf{wt} \rangle$ *where* L_{Min}, L_{Max}, L_T *are finite disjoint subsets of* Min *locations,* Max *locations, and target locations, respectively (we let* $L = L_{\mathsf{Min}} \uplus L_{\mathsf{Max}} \uplus L_T$*),* $\Delta \subseteq L \times \mathsf{Guards}(\mathcal{C}) \times 2^{\mathcal{C}} \times L$ *is a finite set of transitions,* $\mathsf{wt} \colon \Delta \uplus L \to \mathbb{Z}$ *is the weight function.*

Without loss of generality, we suppose the absence of deadlocks except on target locations, i.e. for each location $\ell \in L \backslash L_T$ and valuation ν, there exists $(\ell, g, Y, \ell') \in \Delta$ such that $\nu \models g$, and no transitions start in L_T. The semantics of a WTG $\mathcal{G}$ is defined in terms of a game played on an infinite transition system whose vertices are configurations of the WTG. A configuration is a pair (ℓ, ν) with a location and a valuation of the clocks. Configurations are split into players according to the location. A configuration is final if its location is a target location of L_T. The alphabet of the transition system is given by $\Delta \times \mathbb{R}_{\geq 0}$: a pair (δ, t) encodes the delay t that a player wants to spend in the current location, before firing transition δ. For every delay $t \in \mathbb{R}_{\geq 0}$, transition $\delta = (\ell, g, Y, \ell') \in \Delta$ and valuation ν, there is an edge $(\ell, \nu) \xrightarrow{\delta, t} (\ell', \nu')$ if $\nu + t \models g$ and $\nu' = (\nu + t)[Y := 0]$. The weight of such an edge e is given by $t \times \mathsf{wt}(\ell) + \mathsf{wt}(\delta)$. An example is depicted on Figure 1.

A *finite play* is a finite sequence of consecutive edges $\rho = (\ell_0, \nu_0) \xrightarrow{\delta_0, t_0} (\ell_1, \nu_1) \xrightarrow{\delta_1, t_1} \cdots (\ell_k, \nu_k)$. We sometimes denote such a play $(\ell_0, \nu_0) \xrightarrow{(\delta_0, t_0) \cdots (\delta_{k-1}, t_{k-1})}$, since intermediate locations and valuations are uniquely defined by the initial configuration and the sequence of transitions and delays. We denote by $|\rho|$ the length k of ρ. The concatenation of two finite plays ρ_1 and ρ_2, such that ρ_1 ends in the same configuration as ρ_2 starts, is denoted by $\rho_1 \rho_2$. We denote by $I(\rho, \delta)$ the interval of delays t such that the play ρ can be extended with the edge $\xrightarrow{\delta, t}$. We let FPlays be the set of all finite plays, whereas $\mathsf{FPlays}_{\mathsf{Min}}$ (resp. $\mathsf{FPlays}_{\mathsf{Max}}$) denote the finite plays that end in a configuration of Min (resp. Max). A *play* is then a maximal sequence of consecutive edges (it is either infinite or it reaches L_T).

We call *path* a finite or infinite sequence π of transitions of $\mathcal{G}$. Each play ρ of $\mathcal{G}$ is associated with a unique path π (by projecting away everything but the transitions): we say that ρ *follows* the path π. A *target path* is a finite path ending in the target set L_T. We denote by TPaths the set of target paths. We let TPaths_ρ (resp. TPaths^n_ρ) the subset of target paths that start from the last location of the finite play ρ (resp. containing n transitions). A path is said to be *maximal* if it is infinite or if it is a target path.

A *deterministic strategy* for Min (resp. Max) is a mapping $\sigma \colon \mathsf{FPlays}_{\mathsf{Min}} \to \Delta \times \mathbb{R}_{\geq 0}$ (resp. $\tau \colon \mathsf{FPlays}_{\mathsf{Max}} \to \Delta \times \mathbb{R}_{\geq 0}$) such that for all finite plays $\rho \in \mathsf{FPlays}_{\mathsf{Min}}$ (resp. $\rho \in \mathsf{FPlays}_{\mathsf{Max}}$) ending in non-target configuration (ℓ, ν), there exists an edge $(\ell, \nu) \xrightarrow{\sigma(\rho)} (\ell', \nu')$. We let $\mathsf{dStrat}_{\mathsf{Min}}$ and $\mathsf{dStrat}_{\mathsf{Max}}$ denote the set of deterministic strategies in $\mathcal{G}$ for players Min and Max, respectively. A play or finite play $\rho = (\ell_0, \nu_0) \xrightarrow{\delta_0, t_0} (\ell_1, \nu_1) \xrightarrow{\delta_1, t_1} \cdots$ conforms to a deterministic strategy σ of Min (resp. Max) if for all k such that (ℓ_k, ν_k) belongs to Min (resp. Max), we have that $(\delta_k, t_k) = \sigma((\ell_0, \nu_0) \xrightarrow{\delta_0, t_0} \cdots (\ell_k, \nu_k))$. For all deterministic strategies σ and τ of players Min and Max, respectively, and for all configurations (ℓ_0, ν_0), we let $\mathsf{Play}((\ell_0, \nu_0), \sigma, \tau)$ be the outcome of σ and τ, defined as the unique maximal play conforming to σ and τ and starting in (ℓ_0, ν_0).

The objective of Min is to reach a target configuration, while minimising the cumulated weight up to the target. Hence, we associate to every finite play $\rho = (\ell_0, \nu_0) \xrightarrow{\delta_0, t_0} (\ell_1, \nu_1) \xrightarrow{\delta_1, t_1} \cdots (\ell_k, \nu_k)$ its cumulated weight, taking into account both discrete and continuous costs: $\mathsf{wt}_\Sigma(\rho) = \sum_{i=0}^{k-1} [t_i \times \mathsf{wt}(\ell_i) + \mathsf{wt}(\delta_i)]$. Then, the weight of a maximal play ρ, denoted by $\mathsf{wt}(\rho)$, is defined by $+\infty$ if ρ is infinite (does not reach L_T), and $\mathsf{wt}_\Sigma(\rho)$ if it ends in (ℓ_T, ν) with $\ell_T \in L_T$.

A deterministic strategy $\sigma \in \mathsf{dStrat}_{\mathsf{Min}}$ guarantees a certain value, against all possible strategies of the opponent: for all locations ℓ and valuations ν, we let $\mathsf{dVal}^\sigma_{\ell,\nu} = \sup_{\tau \in \mathsf{dStrat}_{\mathsf{Max},\mathcal{G}}} \mathsf{wt}(\mathsf{Play}((\ell, \nu), \sigma, \tau))$. Then, for all locations ℓ and valuations ν, we let $\mathsf{dVal}_{\ell,\nu}$ be the *deterministic value* of $\mathcal{G}$ in (ℓ, ν), defined as $\mathsf{dVal}_{\ell,\nu} = \inf_{\sigma \in \mathsf{dStrat}_{\mathsf{Min}}} \mathsf{dVal}^\sigma_{\ell,\nu}$. We say that a deterministic strategy σ of Min is *ε-optimal wrt the deterministic value* if $\mathsf{dVal}^\sigma_{\ell,\nu} \leq \mathsf{dVal}_{\ell,\nu} + \varepsilon$ for all (ℓ, ν). It is said optimal if this holds for $\varepsilon = 0$.

As usual in related work [1, 11, 12, 16], we assume that all clocks are *bounded* by a constant $M \in \mathbb{N}$, i.e. every transition of the WTG is equipped with a guard g such that $\nu \models g$ implies $\nu(x) \leq M$ for all clocks $x \in \mathcal{C}$. We denote by $w^L_{\max}$ (resp. $w^\Delta_{\max}$, $w^e_{\max}$) the maximal weight in absolute values of locations (resp. of transitions, edges) of $\mathcal{G}$, i.e. $w^L_{\max} = \max_{\ell \in L} |\mathsf{wt}(\ell)|$ (resp. $w^\Delta_{\max} = \max_{\delta \in \Delta} |\mathsf{wt}(\delta)|$, $w^e_{\max} = M w^L_{\max} + w^\Delta_{\max}$).

In the following, we rely on the crucial notion of regions, as introduced in the seminal work on timed automata [2]. A game $\mathcal{G}$ can be populated with the region information, without loss of generality, as described formally in [16], e.g. The *region automaton, or region game*, $\mathcal{R}(\mathcal{G})$ is thus the WTG with locations $S = L \times \mathsf{Reg}(\mathcal{C}, M)$ and all transitions $((\ell, r), g'', Y, (\ell', r'))$ with $(\ell, g, Y, \ell') \in \Delta$ such that the model of guard g'' (i.e. all valuations ν such that $\nu \models g''$) is a region r'', time successor of r such that r'' satisfies the guard g, and r' is the region obtained from r'' by resetting all clocks of Y. Distribution of locations to players, final locations, and weights are inherited from $\mathcal{G}$. We call *region path* a finite or infinite sequence of transitions in this automaton, and we again denote by π such paths. A play ρ in $\mathcal{G}$ is projected on a region path π, with a similar definition as the projection on paths: we again say that ρ *follows* the region path π. It is important to notice that, even if π is a *cycle* (i.e. starts and ends in the same location of the region game), there may exist plays following it in $\mathcal{G}$ that are not cycles, due to the fact that regions are sets of valuations.

As shown in previous work [11, 16], knowing whether $\mathsf{dVal}_{\ell,\nu} = +\infty$ for a certain configuration is a purely qualitative problem that can be decided easily by using the region game: indeed, $\mathsf{dVal}_{\ell,\nu} = +\infty$ if and only if Min has no strategies that guarantee reaching the target L_T. This is thus a reachability objective, where weights are useless. Moreover, Max has a strategy that guarantees that no plays reach the target L_T from any configuration (ℓ, ν) such that $\mathsf{dVal}_{\ell,\nu} = +\infty$. In this situation, considering stochastic choices is not interesting. **We thus rule out this case by supposing in the following that no configurations of $\mathcal{G}$ have a value $+\infty$**: such configurations can be removed in the region game by strengthening the guard on transitions.

3 Playing stochastically in WTGs

Our first contribution consists in allowing both players to use stochastic choices in their strategies. From a game theory point of view, this seems natural. From a controller synthesis point of view, we claim that the question is natural too, especially because player Min may require exponential memory to play optimally in WTGs. This is already the case even without clocks (such games are then sometimes called *shortest-path games*) where it has been shown in [20] that the memory required by Min could be traded for stochastic choices instead (and vice versa). We aim at extending this result in the context of weighted timed games. Before doing so, we must introduce stochastic strategies in the context of weighted timed games, which has never been explored until now, as far as we are aware of. We will however strongly rely on a recent line of works aiming at studying stochastic timed automata [7, 9, 6, 10], thus extending the results in the context of two-player games (instead of model-checking) and with weights, which indeed represents the main challenge in order to give a meaning to the expected payoff.

Naturally, deterministic strategies for Min are extended to more general stochastic strategies as mappings $\eta \colon \mathsf{FPlays}_{\mathsf{Min}} \to \mathsf{Dist}(\Delta \times \mathbb{R}_{\geq 0})$ where each finite play is associated to a probability distribution over the set of pairs of transition and delay. Here, we let $\mathsf{Dist}(S)$ the set of all probability distributions over a set S (equipped with an underlying σ-algebra). Since Δ is a finite set, this is equivalent to letting first Min choose a transition

via $\eta_\Delta : \mathsf{FPlays}_{\mathsf{Min}} \to \mathsf{Dist}(\Delta)$, and then, knowing the chosen transition, choose a delay via $\eta_{\mathbb{R}^+} : \mathsf{FPlays}_{\mathsf{Min}} \times \Delta \to \mathsf{Dist}(\mathbb{R}_{\geq 0})$, the support of the distribution $\eta_{\mathbb{R}^+}(\rho, \delta)$ being included in the interval $I(\rho, \delta)$ of valid delays. We can then recombine η_Δ and $\eta_{\mathbb{R}^+}$ to obtain the distribution $\eta(\rho)$. Similar definitions hold for Max whose general strategies are denoted by θ.

Notice that deterministic strategies are a special case of strategies, where the distributions are chosen to be Dirac distributions. Another useful restriction over strategies is the non-use of memory: a strategy η is *memoryless* if for all finite plays ρ, ρ' ending in the same configuration, we have that $\eta(\rho) = \eta(\rho')$. A similar definition holds for Max.

Probability measure on plays. We fix two strategies η and θ for both players, and an initial configuration (ℓ_0, ν_0). Our goal is to define a probability measure on plays. To do so, and following the contribution of [7] for stochastic timed automata, the set of plays of a WTG $\mathcal{G}$ starting from (ℓ_0, ν_0) and conforming to η and θ can naturally be equipped with a structure of σ-algebra whose generators are all subsets of plays that start with a finite prefix following the same finite path π (remember that paths are sequences of transitions, with no information on the delayed time) with some Borel-measurable constraints on the delays taken along π. The a priori idea is thus to define a probability measure $\mathbb{P}^{\eta,\theta}_{\ell_0,\nu_0}$ on such generators which extends uniquely as a probability measure over the whole σ-algebra, by Carathéodory's extension theorem.

Consider thus a finite path π, starting in location ℓ, and a play ρ ending in the same location ℓ. We define the probability $\mathbb{P}^{\eta,\theta}_\rho(\pi)$ taking into account all possible plays that start with ρ and continue according to π (we leave the Borel-measurable constraints on the delays for now, but discuss them later). It is defined by induction on the length of π by $\mathbb{P}^{\eta,\theta}_\rho(\varepsilon) = 1$, and for all transitions $\delta = (\ell, g, Y, \ell') \in \Delta$, $\mathbb{P}^{\eta,\theta}_\rho(\delta\pi) = \int_{I(\rho,\delta)} \eta_\Delta(\rho)(\delta) \times \mathbb{P}^{\eta,\theta}_{\rho \xrightarrow{\delta,t}}(\pi)\, \mathrm{d}\eta_{\mathbb{R}^+}(\rho, \delta)(t)$. This definition is very similar to the one in [7] except that we choose to decouple the distribution on pairs of $\Delta \times \mathbb{R}_{\geq 0}$ by first selecting a transition and then delay, whereas authors of [7] consider independent choices, the one on transitions being described by some weights on transitions (depending on the current region).

For modelling purposes, authors of [7] enforce that probability distributions on delays do not forbid any delays of the interval $I(\rho, \delta)$ of possible delays, thus ruling out singular distributions like Dirac ones that would consider taking a single possible delay (like deterministic strategies do). More formally, they require $\eta_{\mathbb{R}^+}(\rho, \delta)$ to be absolutely continuous (i.e. equivalent to the Lebesgue measure) on interval $I(\rho, \delta)$. We claim that even with this assumption, the previous definition of the probability may not be well-founded, as demonstrated by the example given in [21, Appendix A]. From this example, we see the importance to moreover enforce that the distributions $\eta_\Delta(\rho)$ and $\eta_{\mathbb{R}^+}(\rho, \delta)$ are "measurable wrt the sequence of delays along the play ρ". This is easy to define for the transition part. For delays, since we want deterministic strategies to be a subset of stochastic strategies, we must be able to choose delays by using Dirac distributions, and by extension discrete distributions (that are not absolutely continuous, as [7] requires). This results in the following hypothesis:

▶ **Hypothesis 1.** *A strategy η satisfies this hypothesis if*

1. *for all transitions $\delta_0, \ldots, \delta_k, \delta$, the mapping*

$$(t_0, \ldots, t_{k-1}) \mapsto \eta_\Delta\big((\ell_0, \nu_0) \xrightarrow{(\delta_0,t_0)\cdots(\delta_{k-1},t_{k-1})} \big)(\delta)$$

is measurable; and

2. *for all plays ρ and transition δ, the probability distribution $\eta_{\mathbb{R}^+}(\rho,\delta)$ (of the random variable t) is described by a cumulative distribution function (CDF) that is the sum of an absolutely continuous function $G(\rho,\delta)$ and Heaviside functions*[1] *$t \mapsto \sum_i \alpha_i(\rho,\delta)H(t - a_i(\rho,\delta))$. Moreover, for all transitions $\delta_0,\dots,\delta_{k-1},\delta$, the mappings $(t_0,\dots,t_{k-1},t) \mapsto G(\rho,\delta)(t)$, $(t_0,\dots,t_{k-1}) \mapsto \alpha_i(\rho,\delta)$, and $(t_0,\dots,t_{k-1}) \mapsto a_i(\rho,\delta)$ must be measurable (where we use notation ρ to denote the play $(\ell_0,\nu_0) \xrightarrow{(\delta_0,t_0)\cdots(\delta_{k-1},t_{k-1})}$).*

This hypothesis allows us to obtain :

▶ **Lemma 2.** *If η and θ are strategies satisfying Hypothesis 1, the probabilities $\mathbb{P}^{\eta,\theta}_\rho(\pi)$ of following a path π after the play ρ are well defined. It can be extended into a probability distribution over maximal paths π starting in the last location of ρ.*

Apart from the well-definition that is new, the rest of the proof is very close to the one of [7]. The probability measure easily extends to unions of maximal paths: in particular, $\mathbb{P}^{\eta,\theta}_{\ell_0,\nu_0}(\mathsf{TPaths}_{\ell_0,\nu_0})$ is set as the sum $\sum_{\pi\in\mathsf{TPaths}_{\ell_0,\nu_0}} \mathbb{P}^{\eta,\theta}_{\ell_0,\nu_0}(\pi)$ of probabilities of all paths reaching L_T from ℓ_0. Authors of [7] go one step further, by using Carathéodory's theorem to extend the probability measure on paths ($\mathbb{P}^{\eta,\theta}_\rho(\pi)$) to a measure on plays ($\mathbb{P}^{\eta,\theta}_\rho$), whose σ-algebra is generated by maximal plays with Borel-measurable constraints on the delays. We do not formally need this further extension and will only use such extension to give an intuitive introduction of the expected payoff below. In the following, we let $\mathsf{Strat}_{\mathsf{Min}}$ and $\mathsf{Strat}_{\mathsf{Max}}$ be the sets of (stochastic) strategies satisfying Hypothesis 1, for both players. We let $\mathsf{mStrat}_{\mathsf{Min}}$ and $\mathsf{mStrat}_{\mathsf{Max}}$ be the respective subsets of memoryless strategies.

Expected payoff of plays. As explained before, by Carathéodory's theorem, the set of plays can be equipped with a probability distribution, and we are interested in the expectation of the random variable $\mathsf{wt}(\rho)$ (where ρ conforms with two fixed strategies η and θ). This only makes sense if the probability to reach a target location is equal to 1, since otherwise, the expected weight will intuitively be $+\infty$ (there is a non-zero probability to not reach the target location, the weight of all such plays being $+\infty$). We thus now require that $\mathbb{P}^{\eta,\theta}_{\ell_0,\nu_0}(\mathsf{TPaths}_{\ell_0,\nu_0}) = 1$ (i.e. the probability to follow an infinite path is 0). We will see afterwards that this is not a sufficient condition to ensure that the expected weight is finite.

We would like to define the expected weight to reach the target as (we write $\mathbb{E}^{\eta,\theta}_{\ell_0,\nu_0}$ instead of $\mathbb{E}^{\eta,\theta}_{\ell_0,\nu_0}(\mathsf{wt})$, since we only consider the expectation of the weight wt): $\mathbb{E}^{\eta,\theta}_{\ell_0,\nu_0} = \int_\rho \mathsf{wt}(\rho)\,\mathrm{d}\mathbb{P}^{\eta,\theta}_{\ell_0,\nu_0}(\rho)$ where the integral is over all plays ρ that start in (ℓ_0,ν_0) and reach the target L_T (such restriction is again justified by the fact that the probability mass of all other plays is 0). This is problematic a priori (and we will see below an example where this indeed would be a problem) since the cumulated weight is not known to be a measurable function of the play, wrt the measure $\mathbb{P}^{\eta,\theta}_{\ell_0,\nu_0}$.

To overcome this challenge, we follow a different approach, consisting in mimicking the construction of the probability before: first define the expected payoff of all plays following a given path, and then sum over all possible paths.

▶ **Definition 3.** *We define the expected weight $\mathbb{E}^{\eta,\theta}_\rho(\pi)$ of plays that can extend ρ (the weight of ρ is thus not counted in the expectation) and that follow the path π. It is defined by induction on the length of π by $\mathbb{E}^{\eta,\theta}_\rho(\varepsilon) = 0$ and for all transitions $\delta = (\ell,g,Y,\ell')$:*

$$\mathbb{E}^{\eta,\theta}_\rho(\delta\pi) = \int_{I(\rho,\delta)} \eta_\Delta(\rho)(\delta)\Big[\big(t\,\mathsf{wt}(\ell) + \mathsf{wt}(\delta)\big)\mathbb{P}^{\eta,\theta}_{\rho\xrightarrow{\delta,t}}(\pi) + \mathbb{E}^{\eta,\theta}_{\rho\xrightarrow{\delta,t}}(\pi)\Big]\,\mathrm{d}\eta_{\mathbb{R}^+}(\rho,\delta)(t)$$

We then define the expected weight $\mathbb{E}^{\eta,\theta}_\rho = \sum_{\pi\in\mathsf{TPaths}_\rho} \mathbb{E}^{\eta,\theta}_\rho(\pi)$, when this sum converges.

[1] We let H denote the mapping from $\mathbb{R}$ to $[0,1]$ such that $H(t) = 0$ if $t < 0$ and $H(t) = 1$ otherwise. Recall that it is the CDF of the Dirac distribution choosing $t = 0$.

Hypothesis 1 is sufficient to show the well-definition of all expectations $\mathbb{E}^{\eta,\theta}_{\rho}(\pi)$:

▶ **Lemma 4.** *If $\eta \in \mathsf{Strat}_{\mathsf{Min}}$ and $\theta \in \mathsf{Strat}_{\mathsf{Max}}$, $\mathbb{E}^{\eta,\theta}_{\rho}(\pi)$ is well-defined for all ρ and π.*

However, the infinite sum in $\mathbb{E}^{\eta,\theta}_{\rho}$ can be problematic. We thus need a stronger hypothesis to ensure its convergence. We adopt here an asymmetrical point of view, relying only on hypothesis on the strategy η of Min. Our choice is grounded in our controller synthesis view, Min being the controller desiring to reach a target location with minimum expected payoff, while Max is an uncontrollable environment.

▶ **Definition 5.** *A strategy $\eta \in \mathsf{Strat}_{\mathsf{Min}}$ of Min is said* proper *if for all finite plays ρ and strategies $\theta \in \mathsf{Strat}_{\mathsf{Max}}$, $\mathbb{P}^{\eta,\theta}_{\rho}(\mathsf{TPaths}_{\rho}) = 1$ and the infinite sum $\sum_{\pi \in \mathsf{TPaths}_{\rho}} \mathbb{E}^{\eta,\theta}_{\rho}(\pi)$ converges.*

We let $\mathsf{Strat}^{\mathsf{P}}_{\mathsf{Min}}$ be the set of proper strategies of Min, $\mathsf{mStrat}^{\mathsf{P}}_{\mathsf{Min}}$ the subset of memoryless proper strategies. Notice that a deterministic strategy of Min is proper as soon as it guarantees to reach the target set of locations (remember that we have ruled out configurations with a deterministic value $\mathsf{dVal}(\ell,\nu) = +\infty$ where Min cannot deterministically guarantee to reach the target L_T): this shows that proper strategies exist (even without using memory). For stochastic strategies, we have seen above that reaching the target set of locations with probability 1 is a necessary but not sufficient condition to be proper. Not only Max must reach the target almost surely, but he must do it *quickly enough* so that the expectation converges. We now give a sufficient condition for a strategy to be proper, that we will use in the rest of this article.

▶ **Hypothesis 2.** *A strategy $\eta \in \mathsf{Strat}_{\mathsf{Min}}$ of Min satisfies this hypothesis if there exist $m \in \mathbb{N}$ and $\alpha \in (0,1]$ such that for all finite plays ρ and strategies $\theta \in \mathsf{Strat}_{\mathsf{Max}}$, $\mathbb{P}^{\eta,\theta}_{\rho}(\bigcup_{n \leq m} \mathsf{TPaths}^{n}_{\rho}) \geq \alpha$.*

This hypothesis is indeed a sufficient condition for a strategy to be proper:

▶ **Lemma 6.** *All strategies of Min satisfying Hypothesis 2 are proper.*

Sketch of proof. The idea is to decompose $\mathbb{E}^{\eta,\theta}_{\rho}$ for all ρ as $\mathbb{E}^{\eta,\theta}_{\rho} = \sum_{n=0}^{\infty} \sum_{\pi \in \mathsf{TPaths}^{n}_{\rho}} \mathbb{E}^{\eta,\theta}_{\rho}(\pi)$. Since $\mathsf{TPaths}^{n}_{\rho}$ is a finite set, only the first sum must be shown to be converging. It is done by noticing that the weight of plays of length n grows linearly wrt n, while the probability $\sum_{\pi \in \mathsf{TPaths}^{n}_{\rho}} \mathbb{P}^{\eta,\theta}_{\rho}(\pi)$ decreases exponentially wrt n (thanks to Hypothesis 2). More precisely, we show for all $n \in \mathbb{N}$ and all $\rho \in \mathsf{FPlays}$, that

1. for all $\pi \in \mathsf{TPaths}^{n}_{\rho}$, $|\mathbb{E}^{\eta,\theta}_{\rho}(\pi)| \leq \mathbb{P}^{\eta,\theta}_{\rho}(\pi)\, n\, w^{e}_{\max}$; and
2. $\sum_{\pi \in \mathsf{TPaths}^{n}_{\rho}} \mathbb{P}^{\eta,\theta}_{\rho}(\pi) \leq (1-\alpha)^{\lfloor n/m \rfloor}$.

This allows us to show that $\mathbb{P}^{\eta,\theta}_{\rho}(\mathsf{TPaths}_{\rho}) = 1$ and that the sum $\mathbb{E}^{\eta,\theta}_{\rho} = \sum_{\pi \in \mathsf{TPaths}_{\rho}} \mathbb{E}^{\eta,\theta}_{\rho}(\pi)$ converges. ◀

Now that we have associated an expected payoff to each convenient pair of strategies, we are able to mimic the classical definition of *value* to stochastic strategies. Let ℓ be a location and ν be a valuation. For all $\eta \in \mathsf{Strat}^{\mathsf{P}}_{\mathsf{Min}}$ and $\theta \in \mathsf{Strat}_{\mathsf{Max}}$, we let $\mathsf{Val}^{\eta}_{\ell,\nu} = \sup_{\theta \in \mathsf{Strat}_{\mathsf{Max}}} \mathbb{E}^{\eta,\theta}_{\ell,\nu}$. Then, we let $\mathsf{Val}_{\ell,\nu}$ be the value of $\mathcal{G}$ in (ℓ,ν), defined as the best expected payoff Min can hope for: $\mathsf{Val}_{\ell,\nu} = \inf_{\eta \in \mathsf{Strat}^{\mathsf{P}}_{\mathsf{Min}}} \mathsf{Val}^{\eta}_{\ell,\nu}$. Both definitions can be generalised by replacing configurations (ℓ,ν) by finite plays ρ: we let $\mathsf{Val}^{\eta}_{\rho}$ and Val_{ρ} be the generalised versions. We also define the *memoryless values* mVal^{η} and mVal, where all strategies are taken memoryless.

Our main contribution, presented in details in Section 5, is to compare the memoryless (stochastic) value, the deterministic value and the stochastic value, showing their equality for a fragment of WTGs. Along the way, we will need the following result showing that when Min plays with a proper strategy, Max always has a *best response* strategy that is deterministic:

▶ **Lemma 7.** *Let $\eta \in \mathsf{Strat}^{\mathsf{p}}_{\mathsf{Min}}$ and $\varepsilon > 0$. There exists a deterministic strategy $\tau \in \mathsf{dStrat}_{\mathsf{Max}}$ such that for all finite plays ρ, $\mathbb{E}^{\eta,\tau}_{\rho} \geq \mathsf{Val}^{\eta}_{\rho} - \varepsilon$. If $\eta \in \mathsf{mStrat}^{\mathsf{p}}_{\mathsf{Min}}$ is memoryless, then there exists a deterministic strategy $\tau \in \mathsf{dStrat}_{\mathsf{Max}}$ such that for all finite plays ρ, $\mathbb{E}^{\eta,\tau}_{\rho} \geq \mathsf{mVal}^{\eta}_{\rho} - \varepsilon$.*

4 Divergent weighted timed games

As we have already seen in the introduction, interesting fragments of WTGs have been designed, in order to regain decidability of the problem of determining whether the value of a WTG is below a certain threshold. One such fragment is obtained by enforcing a semantical property of divergence (originally called *strictly non-Zeno cost* when only dealing with non-negative weights [11]): it asks that every play following a cycle in the region automaton has weight far from 0. We will consider this restriction in the following, since it allows for a large class of decidable WTGs, with no limitations on the number of clocks. Formally, a cyclic region path π of $\mathcal{R}(\mathcal{G})$ is said to be a positive cycle (resp. a negative cycle) if every finite play ρ following π satisfies $\mathsf{wt}_{\Sigma}(\rho) \geq 1$ (resp. $\mathsf{wt}_{\Sigma}(\rho) \leq -1$).

▶ **Definition 8** ([16])**.** *A WTG is divergent if every cyclic region path is positive or negative.*

In [16], it is shown that this definition is equivalent to requiring that for all strongly connected components (SCC) S of the graph of $\mathcal{R}(\mathcal{G})$, either every cycle π inside S is positive (we say that the SCC is positive), or every cycle π inside S is negative (we say that the SCC is negative). The best computability result in this setting is:

▶ **Theorem 9** ([16])**.** *The deterministic value of a divergent WTG can be computed in triply-exponential-time.*

We explain how to recover from Theorem 9 the needed shape of ε-optimal strategies, since this is one of the new technical ingredient we need afterwards.

Switching strategies for Min. Theorem 9 is obtained in [16] by using a *value iteration algorithm* (originally described in [1] for acyclic timed automata). If V represents a value function, i.e. a mapping $L \times \mathbb{R}^{\mathcal{C}}_{\geq 0} \to \mathbb{R}_{\infty}$, we denote by $V_{\ell,\nu}$ the image $V(\ell,\nu)$, for better readability. One step of the game is summarised in the following operator $\mathcal{F}$ mapping each value function V to the value function defined for all $(\ell,\nu) \in L \times \mathbb{R}^{\mathcal{C}}_{\geq 0}$ by $\mathcal{F}(V)_{\ell,\nu} = 0$ if $\ell \in L_T$, $\mathcal{F}(V)_{\ell,\nu} = \sup_{(\ell,\nu) \xrightarrow{\delta,t} (\ell',\nu')} \left[t \times \mathsf{wt}(\ell) + \mathsf{wt}(\delta) + V_{\ell',\nu'}\right]$ if $\ell \in L_{\mathsf{Max}}$, and $\mathcal{F}(V)_{\ell,\nu} = \inf_{(\ell,\nu) \xrightarrow{\delta,t} (\ell',\nu')} \left[t \times \mathsf{wt}(\ell) + \mathsf{wt}(\delta) + V_{\ell',\nu'}\right]$ if $\ell \in L_{\mathsf{Min}}$, where $(\ell,\nu) \xrightarrow{\delta,t} (\ell',\nu')$ ranges over valid edges in $\mathcal{G}$. Then, starting from V^0 mapping every configuration to $+\infty$, except for the targets mapped to 0, we let $V^i = \mathcal{F}(V^{i-1})$ for all $i > 0$. The value function V^i is intuitively what Min can guarantee when forced to reach the target in at most i steps.

The value computation of Theorem 9 is then obtained in two steps. First, configurations (ℓ,ν) of value $\mathsf{dVal}_{\ell,\nu} = -\infty$ are found by using a decomposition of the region game $\mathcal{R}(\mathcal{G})$ into strongly-connected components (SCC). Indeed, in divergent WTGs, configurations of value $-\infty$ are all the ones from which Min has a strategy to visit infinitely many times configurations of a single location (ℓ,r) of $\mathcal{R}(\mathcal{G})$ contained in a negative SCC. This is thus a Büchi objective on the region game, that can easily be solved with some attractor computations. Notice that if a configuration (ℓ,ν) has value $-\infty$, this implies that all configurations (ℓ,ν') with ν' in the same region as ν have value $-\infty$. As we explained at the end of Section 2 for the values $+\infty$, we can then remove configurations of value $-\infty$ by strengthening the guards on transitions, while letting unchanged other finite values.

Then, the (finite) value dVal is obtained as an iterate V^H of the previous operator, with H polynomial in the size of the region game and the maximal weights of $\mathcal{G}$. This means that playing for only a bounded number of steps is equivalent to the original game. In particular, at horizon H, we have that $\mathcal{F}(V^H) = V^{H+1} = \mathsf{dVal}$ so that dVal is a fixpoint of $\mathcal{F}$. As a side effect, this allows one to decompose the clock space $\mathbb{R}^{\mathcal{C}}_{\geq 0}$ into a finite number α of *cells* (a refinement of the classical regions) such that dVal is affine on each cell.

Based on this, we can construct good strategies for Min that have a special form, the so-called *switching strategies* (introduced in [15] in the untimed setting, further extended in the timed setting with only one-clock in [14]).

▶ **Definition 10.** *A switching strategy σ is described by two deterministic memoryless strategies σ^1 and σ^2, as well as a switching threshold K. The strategy σ then consists in playing strategy σ^1 until either we reach a target location, or the finite play has length at least K, in which case we switch to strategy σ^2.*

Our new contribution is as follows:

▶ **Theorem 11.** *In a divergent WTG, for all $\varepsilon > 0$ and $N \in \mathbb{N}$, there exists a switching strategy σ for Min, for which the two components σ^1 and σ^2 satisfy Hypothesis 1, such that for all configurations (ℓ, ν), $\mathsf{dVal}^{\sigma}_{\ell,\nu} \leq \max(-N, \mathsf{dVal}_{\ell,\nu}) + \varepsilon$.*

In particular, if all configurations have a finite deterministic value, **there exists an ε-optimal switching strategy wrt the deterministic value**. In the presence of a configuration with a deterministic value $-\infty$, we build from Theorem 11 a family of switching strategies (indexed by the parameter N) whose value tends to $-\infty$.

The proof of Theorem 11 requires to build both strategies σ^1 and σ^2, as well as a switching threshold K. The second strategy σ^2 only consists in reaching the target and is thus obtained as a deterministic memoryless strategy from a classical attractor computation in the region game $\mathcal{R}(\mathcal{G})$. It is easy to choose σ^2 smooth enough so that it fulfils Hypothesis 1. In contrast, the first strategy σ^1 requires more care. We build it so that it fulfils two properties, that we summarise in saying that σ^1 is *fake-ε-optimal* wrt the deterministic value:

1. each finite play conforming to σ^1 from (ℓ, ν) and reaching the target has a cumulated weight at most $\mathsf{dVal}_{\ell,\nu} + |\rho|\,\varepsilon$ (in particular, if $\mathsf{dVal}_{\ell,\nu} = -\infty$, no such plays should exist);
2. each finite play conforming to σ^1 following a *long enough* cycle in the region game $\mathcal{R}(\mathcal{G})$ has a cumulated weight at most -1.

Here, "fake" means that σ^1 is not obliged to guarantee reaching the target, but if it does so, it must do it with a cumulated weight close to $\mathsf{dVal}_{\ell,\nu}$, the error factor depending linearly on the size of the play. The second property ensures that playing long enough σ^1 without reaching the target results in diminishing the cumulated weight. Then, if the switch happens at horizon K big enough, ($K = (w^e_{\max}|\mathcal{R}(\mathcal{G})|(|L|\alpha + 2) + N)(|\mathcal{R}(\mathcal{G})|(|L|\alpha + 1) + 1)$ suffices for instance), Min is sure that the cumulated weight so far is low enough so that the rest of the play to reach a target location (following σ^2 only) will not make the weight increase too much. In the absence of values $-\infty$ in dVal, the first property allows one to obtain a $K\varepsilon$-optimal strategy even in the case where the switch does not occur (because we reach the target prematurely). The construction of a fake-ε/K-optimal strategy σ^1 (the linear dependency on the length of the play in the first property of fake-optimality is thus taken care by a division by K here) relies on the fact that $\mathcal{F}(\mathsf{dVal}) = \mathsf{dVal}$ to play almost-optimally at horizon 1. More formally:

- For all configurations of value $-\infty$, σ^1 is built as a winning strategy for the Büchi objective "visit infinitely often configurations of a location (ℓ, r) of $\mathcal{R}(\mathcal{G})$ contained in a negative SCC". By definition, all cyclic paths following σ^1 will be inside a negative

SCC, and thus be of cumulated weight at most -1, by divergence of the WTG. Moreover, no plays conforming to σ^1 from such a configuration of value $-\infty$ will reach a target location, since the chosen negative SCC is a trap controlled by Min. It is easy to choose σ^1 smooth enough so that it fulfils Hypothesis 1.

- For the remaining configurations of finite value, we rely upon operator $\mathcal{F}$, letting σ^1 choose a decision that minimises the value at horizon 1. However, because of the guards on clocks, infimum/supremum operators in $\mathcal{F}$ are not necessarily minima/maxima, and we thus need to allow for a small error at each step of the strategy: this is the main difference with the untimed setting, which by the way explains why our definition of switching strategy needed to be adapted. We will use the $\operatorname{arginf}^{\varepsilon}$ operator defined for all mappings $f\colon A \to \mathbb{R}$ and $B \subseteq A$ by $\operatorname{arginf}^{\varepsilon}_B f = \{a \in B \mid f(a) \leq \inf_B f + \varepsilon\}$. Then, for all configurations $(\ell, \nu) \in L_{\mathsf{Min}} \times \mathbb{R}^{\mathcal{C}}_{\geq 0}$, we choose $\sigma^1(\ell, \nu)$ as a pair (δ, t) in

$$\operatorname{arginf}^{\varepsilon/K}_{(\ell,\nu) \xrightarrow{\delta,t} (\ell',\nu')} (t\,\mathsf{wt}(\ell) + \mathsf{wt}(\delta) + \mathsf{dVal}_{\ell',\nu'})$$

  This set is non empty since dVal is a fixpoint of operator $\mathcal{F}$ in this case. Moreover, knowing that the mapping dVal_ℓ is piecewise affine by the results shown in [16], it is possible to choose σ^1 so that it fulfils the measurability (even piecewise continuity) conditions of Hypothesis 1. More precisely, we can consider it to take the same kind of decision for all configurations of a same cell: same transition, and either no delay or a delay jumping to the same border of cell.

The strategy σ^1 thus built makes a small error wrt the optimal at each step. But once again strongly relying on the divergence of the WTG, we can nevertheless show that σ^1 is fake-ε/K-optimal wrt the deterministic value.

Memoryless strategies for Max. WTGs are known to be determined [14], i.e. the deterministic value is also equal to $\mathsf{dVal}_{\ell,\nu} = \sup_{\tau \in \mathsf{dStrat}_{\mathsf{Max}}} \inf_{\sigma \in \mathsf{dStrat}_{\mathsf{Min}}} \mathsf{wt}(\mathsf{Play}((\ell,\nu),\sigma,\tau))$. In this setting, we can turn our study to the point of view of Max, looking for good strategies for this other player. A deterministic strategy τ of Max has an associated value: $\mathsf{dVal}^{\tau}_{\ell,\nu} = \inf_{\sigma \in \mathsf{dStrat}_{\mathsf{Min}}} \mathsf{wt}(\mathsf{Play}((\ell,\nu),\sigma,\tau))$. It is ε-optimal wrt the deterministic value if $\mathsf{dVal}^{\tau}_{\ell,\nu} \geq \mathsf{dVal}_{\ell,\nu} - \varepsilon$ for all (ℓ,ν).

As Max does not wish to go to the target, we show that no switch is necessary to play ε-optimally: memoryless strategies are sufficient to guarantee a value as close as wanted to the deterministic value. For a configuration with a value equal to $-\infty$, all the deterministic strategies for Max are equivalent where they are all equally bad. Without loss of generality, we can therefore suppose that there are no configurations in $\mathcal{G}$ with a value equal to $-\infty$. Then, it is shown in [16] that remaining values are bounded in absolute value by $w^{e}_{\max}|\mathcal{R}(\mathcal{G})|$, since *optimal plays* have no cycles. We use that fact to build a memoryless deterministic strategy τ analogous to strategy σ^1 before:

▶ **Theorem 12.** *In a divergent WTG, there exists a memoryless ε-optimal strategy for player* Max *wrt the deterministic value (that moreover satisfies Hypothesis 1).*

5 Emulate memory with randomness, and vice versa

The main contribution of this article, apart from defining a notion of expected value in weighted timed games, is to relate the different notions of values. In divergent WTGs, memory can thus be fully emulated with stochastic choices, and combining memory and stochastic choices does not bring more power to players, which we summarise by:

▶ **Theorem 13.** *In all divergent WTGs, for all* (ℓ, ν), $\mathsf{dVal}_{\ell,\nu} = \mathsf{Val}_{\ell,\nu} = \mathsf{mVal}_{\ell,\nu}$.

The proof of this result is decomposed into several inequalities on these values. One is easier, and holds for all WTGs: the stochastic value is at most equal to the deterministic value, using the inclusion of deterministic strategies into stochastic ones, and Lemma 7.

▶ **Lemma 14.** *In all WTGs* $\mathcal{G}$*, for all configurations* (ℓ, ν), $\mathsf{Val}_{\ell,\nu} \leq \mathsf{dVal}_{\ell,\nu}$.

We show in the rest of this section the inequalities comparing the deterministic value with the other values: first we show that memoryless stochastic strategies can emulate deterministic ones ($\mathsf{mVal}_{\ell,\nu} \leq \mathsf{dVal}_{\ell,\nu}$); then we show that deterministic strategies can emulate stochastic ones ($\mathsf{dVal}_{\ell,\nu} \leq \mathsf{Val}_{\ell,\nu}$ and $\mathsf{dVal}_{\ell,\nu} \leq \mathsf{mVal}_{\ell,\nu}$).

Simulating deterministic strategies with memoryless strategies. We focus here on showing that, for all configurations (ℓ, ν), $\mathsf{mVal}_{\ell,\nu} \leq \mathsf{dVal}_{\ell,\nu}$. We build a memoryless strategy of Min at least as good as a deterministic strategy. By Theorem 11, we can start from a switching strategy for Min. For $N \in \mathbb{N}$ and $\varepsilon > 0$, we thus consider a switching strategy $\sigma = (\sigma^1, \sigma^2, K)$ of value $\mathsf{dVal}^{\sigma}_{\ell,\nu} \leq \max(-N, \mathsf{dVal}_{\ell,\nu}) + \varepsilon$, and simulate it with a memoryless strategy for Min, denoted η^p, with a probability parameter $p \in (0,1)$. This new strategy is a probabilistic superposition of the two memoryless deterministic strategies σ^1 and σ^2.

Formally, we define $\eta^p(\ell, \nu)$, with $\ell \in L_{\mathsf{Min}}$, depending on the sign of the SCC containing the location (ℓ, r), with r the region of ν, of the region game $\mathcal{R}(\mathcal{G})$.

In a positive SCC, Min always chooses to play σ^1, thus looking for a negative cycle in the next SCCs (in topological order) if any. Formally, letting $(\delta_1, t_1) = \sigma^1(\ell, \nu)$, we define $\eta^p_{\Delta}(\ell, \nu) = \mathsf{Dirac}_{\delta_1}$ and $\eta^p_{\mathbb{R}^+}((\ell, \nu), \delta_1) = \mathsf{Dirac}_{t_1}$.

In a negative SCC, we let $\eta^p(\ell, \nu)$ be the distribution picking $\sigma^1(\ell, \nu)$ with probability p, and $\sigma^2(\ell, \nu)$ with probability $1-p$. Formally, η^p_{Δ} chooses the transition given by $\sigma^1(\ell, \nu)$ with probability p and of σ^2, with probability $1-p$, except if those transitions are equal, in which case η^p_{Δ} chooses it with probability 1. If transitions chosen by σ^1 and σ^2 are distinct, $\eta^p_{\mathbb{R}^+}$ is a Dirac distribution over the corresponding delay. Otherwise, $\eta^p_{\mathbb{R}^+}$ chooses with probability p the delay given by σ^1, and with probability $1-p$ the one given by σ^2.

Theorem 11 ensuring that strategies σ^1 and σ^2 satisfy Hypothesis 1, the superposition η^p also satisfies these hypotheses. Moreover, we use the sufficient condition in Hypothesis 2 to show that η^p is also proper:

▶ **Lemma 15.** *For all* $p \in (0,1)$*, the strategy* η^p *satisfies Hypothesis 2.*

To show the expected result, we prove that $\mathsf{mVal}^{\eta^p}_{\ell,\nu} \leq \max(-N, \mathsf{dVal}_{\ell,\nu}) + 3\varepsilon$ for all (ℓ, ν), for p *close enough to* 1: we conclude that $\mathsf{mVal}_{\ell,\nu} \leq \mathsf{dVal}_{\ell,\nu}$ by taking the limit when N tends to $+\infty$ and ε tends to 0. We get that inequality by showing the following result, paired with the fact that $\mathsf{dVal}^{\sigma}_{\ell,\nu} \leq \max(-N, \mathsf{dVal}_{\ell,\nu}) + \varepsilon$.

▶ **Proposition 16.** *For all configurations* (ℓ, ν) *and* $\varepsilon > 0$ *small enough, there exists* $\tilde{p} \in (0,1)$ *so that for all* $p \in [\tilde{p}, 1)$, $\mathsf{mVal}^{\eta^p}_{\ell,\nu} \leq \mathsf{dVal}^{\sigma}_{\ell,\nu} + 2\varepsilon$.

Proof. Lemma 7 allows us to limit ourselves to deterministic strategies for Max. For all deterministic strategies τ of Max, we compute a lower bound on p independent of τ such that $\mathbb{E}^{\eta^p,\tau}_{\ell,\nu} \leq \mathsf{dVal}^{\sigma}_{\ell,\nu} + 3\varepsilon/2$. By Lemma 7 (with $\varepsilon/2$), we obtain the desired $\mathsf{mVal}^{\eta^p}_{\ell,\nu} \leq \mathsf{dVal}^{\sigma}_{\ell,\nu} + 2\varepsilon$.

The case where the whole region game only contains positive SCCs is easy, since then η^p chooses the transition and delay given by σ^1 with probability 1. By divergence, $\mathcal{G}$ then contains no negative cycles. A play conforming to η^p is also conforming to the deterministic

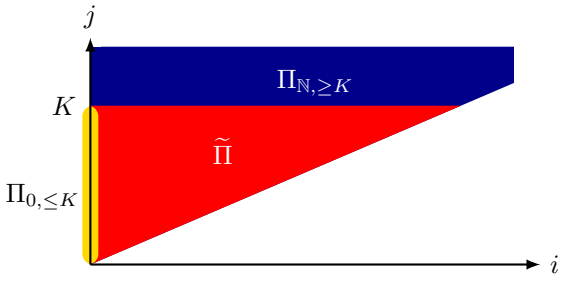

Figure 2 Partition of paths TPaths.

strategy σ^1, so it must be acyclic. In particular, there exists only one play ρ conforming to η^p and τ. This one is also conforming to σ and thus reaches the target with a cumulated weight $\mathsf{wt}_\Sigma(\rho) = \mathbb{E}^{\eta^p,\tau}_{\ell,\nu} \leq \mathsf{dVal}^\sigma_{\ell,\nu}$ as expected.

Now, suppose that the region graph contains at least a negative SCC. Thus, we let $c > 0$ be the maximal size of an elementary cycle of the region game (that visits a pair (ℓ, r) at most once) and $w^- > 0$ be the opposite of the maximal cumulated weight of an elementary negative cycle in $\mathcal{R}(\mathcal{G})$ (necessarily bounded by $w^e_{\max}|\mathcal{R}(\mathcal{G})|$).

We partition the set $\mathsf{FPlays}^{\eta^p,\tau}_{\ell,\nu}$ into subsets $\Pi_{i,j}$ according to the number i of choices of probability $1-p$ along the play (the probability as described previously with the product of the probabilities given by η^p_Δ and $\eta^p_{\mathbb{R}_+}$), and their length j (we always have $i \leq j$). The partition is depicted in Figure 2:

- $\Pi_{\mathbb{N},\geq K}$, depicted in blue, contains all plays with a length greater than K (the switching threshold)
- $\Pi_{0,\leq K}$, depicted in yellow, contains all plays without any probability $1-p$, with a length at most K;
- $\widetilde{\Pi}$, depicted in red, contains the rest of the plays.

We can use the particular shape of the memoryless strategy η^p for Min, and the fact that we fixed a deterministic strategy τ for Max, to decompose the expectation $\mathbb{E}^{\eta^p,\tau}_\rho$ on the partition. Indeed, notice that the set of plays conforming to η^p and τ, from a particular configuration (ℓ, ν), is countable. Moreover, we can associate a probability to each *play* (instead of a probability to a *path*). For a finite play $\rho = (\ell_0, \nu_0) \xrightarrow{\delta_0,t_0} \cdots (\ell_{k-1}, \nu_{k-1})$ conforming to η^p and τ, we let

$$\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\rho) = \prod_{i=0}^{k-1} p_i$$

where, for all $i \in \{0, \ldots, k-1\}$

$$p_i = \begin{cases} 1 & \text{if } \ell_i \in L_{\mathsf{Max}} \\ \eta^p_\Delta(\ell_i, \nu_i)(\delta_i) \times \eta^p_{\mathbb{R}_+}((\ell_i, \nu_i), \delta_i)(t_i) & \text{if } \ell_i \in L_{\mathsf{Min}} \end{cases}$$

This definition allows us to recover the probability of a path π using the probability of all plays following π. Then, we obtain easily

$$\mathbb{E}^{\eta^p,\tau}_{\ell,\nu} = \underbrace{\sum_{\rho\in\Pi_{0,\leq K}} \mathsf{wt}(\rho)\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\rho)}_{\gamma_{0,\leq K}} + \underbrace{\sum_{\rho\in\Pi_{\mathbb{N},\geq K}} \mathsf{wt}(\rho)\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\rho)}_{\gamma_{\mathbb{N},\geq K}} + \underbrace{\sum_{\rho\in\widetilde{\Pi}} \mathsf{wt}(\rho)\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\rho)}_{\widetilde{\gamma}} \tag{1}$$

We now compute and bound the three expectations $\gamma_{0,\leq K}$, $\gamma_{\mathbb{N},\geq K}$ and $\widetilde{\gamma}$. In the following, for a set Π of plays, we let $\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\Pi) = \sum_{\rho\in\Pi}\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\rho)$.

Red zone is such that $\widetilde{\gamma} \leq \varepsilon/4$. All plays in $\widetilde{\Pi}$ have a length at most K: so the cumulated weight of all such play is at most $Kw^e_{\max}$. So, we have

$$\widetilde{\gamma} = \sum_{\rho\in\widetilde{\Pi}} \mathsf{wt}(\rho)\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\rho) \leq \sum_{\rho\in\widetilde{\Pi}} Kw^e_{\max}\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\rho) = Kw^e_{\max}\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\widetilde{\Pi})$$

But, all plays $\rho \in \bigcup_{j\leq K}\Pi_{i,j}$ with $i \leq K$ take i transitions of probability $1-p$. In particular, by bounding all other probabilities by 1, and since there are at most 2^K plays in $\bigcup_{j\leq K}\Pi_{i,j}$, we obtain (using that $1-(1-p)^K \leq 1$)

$$\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\widetilde{\Pi}) \leq 2^K \sum_{i=1}^{K-1}(1-p)^i = 2^K\frac{(1-p)(1-(1-p)^K)}{p} \leq 2^K\frac{1-p}{p} \longrightarrow_{p\to 1} 0 \tag{2}$$

If we suppose that

$$p \geq \frac{1}{1+\varepsilon/(4\times 2^K K w^e_{\max})}$$

we obtain as desired

$$\widetilde{\gamma} \leq 2^K K w^e_{\max}\frac{1-p}{p} \leq \frac{\varepsilon}{4}$$

Yellow and blue zones are such that $\gamma_{0,\leq K} + \gamma_{\mathbb{N},\geq K} \leq \mathsf{dVal}^\sigma_{\ell,\nu} + 5\varepsilon/4$. All plays in $\Pi_{0,\leq K}$ reach the target without taking any probability $1-p$ from η^p_Δ, so they are conforming to σ^1. In the case where $\mathsf{dVal}_{\ell,\nu} = -\infty$, $\Pi_{0,\leq K} = \emptyset$ and $\gamma_{0,\leq K} = 0$, since no play conforming to σ^1 from (ℓ,ν) reaches the target. In this case, Min can stay in a cycle with a negative cumulated weight as long as he wants. Now, if $\mathsf{dVal}_{\ell,\nu}$ is finite, Theorem 11 (see [21, Lemma 19]) allows us to show that the cumulated weight of a play in $\Pi_{0,\leq K}$ is at most $\mathsf{dVal}_{\ell,\nu} + K\varepsilon/K = \mathsf{dVal}_{\ell,\nu} + \varepsilon$, as $\mathsf{dVal}_{\ell,\nu} = \inf_{\sigma\in\mathsf{dStrat}_{\mathsf{Min}}}\mathsf{dVal}^\sigma_{\ell,\nu} \leq \mathsf{dVal}^\sigma_{\ell,\nu}$. Therefore, in both cases, we can write

$$\gamma_{0,\leq K} \leq \left(\mathsf{dVal}^\sigma_{\ell,\nu} + \varepsilon\right)\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\Pi_{0,\leq K})$$

Let ρ be a play in $\Pi_{i,j}$ with $0 \leq i$ and $j \geq K$. Since η^p only allows cycles in negative SCCs, all region cycles in ρ have a cumulated weight at most -1. By definition of K and the proof of Theorem 11, $\mathsf{wt}(\rho) \leq \mathsf{dVal}^\sigma_{\ell,\nu} \leq \mathsf{dVal}^\sigma_{\ell,\nu} + \varepsilon$.

By summing up the contribution of yellow and blue zones, we get

$$\gamma_{0,\leq K} + \gamma_{\mathbb{N},\geq K} \leq \left(\mathsf{dVal}^\sigma_{\ell,\nu} + \varepsilon\right)\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\Pi_{0,\leq K}\cup\Pi_{\mathbb{N},\geq K}) \tag{3}$$

We distinguish two cases.

- If $\mathsf{dVal}^\sigma_{\ell,\nu} \geq -5\varepsilon/4$, having $\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\Pi_{0,\leq K}\cup\Pi_{\mathbb{N},\geq K}) \leq 1$, we get

$$\gamma_{0,\leq K} + \gamma_{\mathbb{N},\geq K} \leq \left(\mathsf{dVal}^\sigma_{\ell,\nu} + \frac{5\varepsilon}{4}\right)\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\Pi_{0,\leq K}\cup\Pi_{\mathbb{N},\geq K}) \leq \mathsf{dVal}_{\ell,\nu} + \frac{5\varepsilon}{4}$$

- If $\mathsf{dVal}^\sigma_{\ell,\nu} < -5\varepsilon/4$, then by (2),

$$\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\Pi_{0,\leq K}\cup\Pi_{\mathbb{N},\geq K}) = 1 - \mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\widetilde{\Pi}) \geq 1 - 2^K\frac{1-p}{p} \longrightarrow_{p\to 1} 1$$

If we suppose that

$$p \geq \frac{2^K}{2^K + 1 - \frac{\mathsf{dVal}^\sigma_{\ell,\nu} + 5\varepsilon/4}{\mathsf{dVal}^\sigma_{\ell,\nu} + \varepsilon}} \in (0,1)$$

then

$$\mathbb{P}^{\eta^p,\tau}_{\ell,\nu}(\Pi_{0,\leq K} \cup \Pi_{\mathbb{N},\geq K}) \geq \frac{\mathsf{dVal}^\sigma_{\ell,\nu} + 5\varepsilon/4}{\mathsf{dVal}^\sigma_{\ell,\nu} + \varepsilon}$$

and, by negativity of $\mathsf{dVal}^\sigma_{\ell,\nu} + \varepsilon$, we can rewrite (3) as

$$\gamma_{0,\leq K} + \gamma_{\mathbb{N},\geq K} \leq \left(\mathsf{dVal}^\sigma_{\ell,\nu} + \varepsilon\right) \frac{\mathsf{dVal}^\sigma_{\ell,\nu} + 5\varepsilon/4}{\mathsf{dVal}^\sigma_{\ell,\nu} + \varepsilon} = \mathsf{dVal}^\sigma_{\ell,\nu} + \frac{5\varepsilon}{4}$$

In all cases, we have $\gamma_{0,\leq K} + \gamma_{\mathbb{N},\geq K} \leq \mathsf{dVal}^\sigma_{\ell,\nu} + 5\varepsilon/4$.

Gathering all constraints on p. We gather all the lower bounds over p that we need in the proof:

$$\tilde{p} = \begin{cases} \max\left(\frac{1}{1+\varepsilon/(4\times 2^K K w^e_{\max})}, \frac{1}{2}\right) & \text{if } \mathsf{dVal}^\sigma_{\ell,\nu} \geq -5\varepsilon/4 \\ \max\left(\frac{1}{1+\varepsilon/(4\times 2^K K w^e_{\max})}, \frac{1}{2}, \frac{2^K}{2^K+1-\frac{\mathsf{dVal}^\sigma_{\ell,\nu}+5\varepsilon/4}{\mathsf{dVal}^\sigma_{\ell,\nu}+\varepsilon}}\right) & \text{otherwise} \end{cases}$$

Then, for $p \in (\tilde{p}, 1)$, we have $\mathbb{E}^{\eta^p,\tau}_{\ell,\nu} \leq \mathsf{dVal}^\sigma_{\ell,\nu} + 3\varepsilon/2$. Since $\tilde{p}$ does not depend on τ, we conclude that for $p \in (\tilde{p}, 1)$, we have $\mathsf{mVal}^{\eta^p}_{\ell,\nu} \leq \mathsf{dVal}^\sigma_{\ell,\nu} + 2\varepsilon$. ◀

Simulating (stochastic) strategies with deterministic strategies. Finally, we show that, for all configurations (ℓ,ν), $\mathsf{dVal}_{\ell,\nu} \leq \mathsf{Val}_{\ell,\nu}$ and $\mathsf{dVal}_{\ell,\nu} \leq \mathsf{mVal}_{\ell,\nu}$. To do so, we consider a proper strategy $\eta \in \mathsf{Strat}^{\mathsf{p}}_{\mathsf{Min}}$ of Min and an initial configuration (ℓ,ν). We build a deterministic strategy σ such that $\mathsf{dVal}^\sigma_{\ell,\nu} \leq \mathsf{Val}^\eta_{\ell,\nu} + \varepsilon$. Thus, in the case where $\mathsf{Val}_{\ell,\nu} \neq -\infty$, we can consider η to be an ε-optimal strategy so that $\mathsf{dVal}^\sigma_{\ell,\nu} \leq \mathsf{Val}_{\ell,\nu} + 2\varepsilon$ which allows us to conclude. In the case where $\mathsf{Val}_{\ell,\nu} = -\infty$, then, for all $N \in \mathbb{N}$, we can consider η to be such that $\mathsf{Val}^\eta_{\ell,\nu} \leq -N$. Then, $\mathsf{dVal}^\sigma_{\ell,\nu} \leq -N + \varepsilon$, which implies that $\mathsf{dVal}_{\ell,\nu} = -\infty$, by taking the limit when N tends to $+\infty$.

The deterministic strategy σ uses the same kind of *memory* as η (in particular, it will be memoryless if η is memoryless). However, we want this strategy to be relatively simple to define, independent of the memory of η. Intuitively, we want to build a switching strategy (as in Section 4) on a game induced by the memory of η, i.e. a deterministic strategy σ^1 that uses the memory capabilities of η, a memoryless deterministic strategy σ^2 obtained by an attractor in the region game, and a threshold K. Strategy σ then consists in playing σ^1 for at most K steps, before switching to strategy σ^2. The construction of σ^1 is done in a similar way as in the deterministic case, Min always choosing the best possible candidate according to the choices of η, thus trying to minimise the immediate reward obtained in one turn. Under this condition, we verify that σ^1 satisfies some properties similar to the fake-ε-optimality encountered in Section 4. Then, by mimicking the techniques of Theorem 11, we obtain that the switching strategy η obtained from η^1 satisfies the desired inequality $\mathsf{dVal}^\sigma_{\ell,\nu} \leq \mathsf{Val}^\eta_{\ell,\nu} + \varepsilon$.

6 Conclusion

We have introduced stochastic strategies for WTGs, showing that, in divergent games, Min can use randomisation to emulate memory, and vice versa. We aim at extending our study to more general WTGs. As a first step, we may consider the class of almost-divergent WTGs (adding the possibility for an execution following a region cycle to have weight *exactly 0*), used in [12, 17] to obtain an approximation schema of the optimal value. We wonder if similar ε-optimal switching strategies may exist also in this context, one of the crucial argument in order to extend our emulation result. Another question concerns the implementability of the randomised strategies: even if they use no memory, they still need to know the precise current clock valuation. In (non-weighted) timed games, previous work [18] aimed at removing this need for precision, by using stochastic strategies where the delays are chosen with probability distributions that do not require exact knowledge of the clocks measurements. In our setting, we aim at further studying the implementability of the randomised strategies of Min in WTGs, e.g. by requiring them to be robust against small imprecisions.

Abstract

We prove that relational structures admitting specific polymorphisms (namely, canonical pseudo-WNU operations of all arities $n \geq 3$) have low relational width. This implies a collapse of the bounded width hierarchy for numerous classes of infinite-domain CSPs studied in the literature. Moreover, we obtain a characterization of bounded width for first-order reducts of unary structures and a characterization of MMSNP sentences that are equivalent to a Datalog program, answering a question posed by Bienvenu *et al.*. In particular, the bounded width hierarchy collapses in those cases as well.

1 Introduction

Local consistency checking is an algorithmic technique that is central in computer science. Intuitively speaking, it consists in propagating local information through a structure so as to infer global information (consider, e.g., computing the transitive closure of a relation as deriving global information from local one). Local consistency checking has a prominent role in the area of constraint satisfaction, where one is given a set of variables V and constraints and one has to find a satisfying assignment $h\colon V \to D$ for the constraints. In this setting, the local consistency algorithm can be used to decrease the size of the search space efficiently or even to correctly solve some constraint satisfaction problems in polynomial time (for example, 2-SAT or Horn-SAT). However, the use of local consistency methods is not limited to constraint satisfaction. Indeed, local consistency checking is also used for such problems as the graph isomorphism problem, where it is is known as the Weisfeiler-Leman algorithm. Again, the technique can be used to derive implied constraints that an isomorphism between two graphs has to satisfy so as to narrow down the search space, but local consistency is in fact powerful enough to solve the graph isomorphism problem over any non-trivial minor-closed class of graphs [36]. Notably, the best algorithm for graph isomorphism to date also uses local consistency as a subroutine [3]. Finally, local consistency can be used to solve games involved in formal verification such as parity games and mean-payoff games [16].

One of the reasons for the ubiquity of local consistency is that its underlying principles can be described in many different languages, such as the language of category theory [1], in the language of finite model theory (by Spoiler-Duplicator games [38] or by homomorphism duality [2]), and logical definability (in Datalog, or infinitary logics with bounded number of variables). For constraint satisfaction problems over a finite template, the power of local consistency checking can additionally be characterised algebraically. More precisely, there are conditions on the set of *polymorphisms* of a template $\mathbb{A}$ such that local consistency correctly solves its constraint satisfaction problem $\mathrm{CSP}(\mathbb{A})$ if, and only if, the polymorphisms of $\mathbb{A}$ satisfy these conditions. Moreover, whenever local consistency correctly solves $\mathrm{CSP}(\mathbb{A})$, where $\mathbb{A}$ is finite, then in fact only a very restricted form of local consistency checking is needed [4]. This fact is known as the *collapse of the bounded width hierarchy*, and it has strong consequences both for complexity and logic. On the one hand, the collapse gives efficient algorithms that are able to solve *all* the CSPs that are solvable by local consistency methods, and in fact this gives a polynomial-time algorithm solving instances of the *uniform CSP*. On the other hand, this collapse induces collapses in all the areas mentioned at the beginning of this paragraph.

Many natural problems from computer science can only be phrased as CSPs where the template is infinite. This is the case for linear programming, some reasoning problems in artificial intelligence such as ontology-mediated data access, or even problems as simple to formulate as the digraph acyclicity problem. In order to understand the power of local consistency in more generality it is thus necessary to consider its use for infinite-domain CSPs. Infinite-domain CSPs with an ω-categorical template form a very general class of problems for which the algebraic approach from the finite case can be extended, and numerous results in the recent years have shown the power of this approach. An algebraic characterisation of local consistency checking for infinite-domain CSPs is, however, missing. In fact, the negative results of [19], refined in [35], show that no purely algebraic description of local consistency is possible for CSPs with ω-categorical templates; this is even the case for temporal CSPs [20]. These negative results are to be compared with the recent result by Mottet and Pinsker [45] that did provide an algebraic description of local consistency for several subclasses of ω-categorical templates.

In the finite, the algebraic characterisation of local consistency relies on a set of algebraic tools whose development eventually led to the solutions of the Feder-Vardi dichotomy conjecture. Bulatov's proof of the Feder-Vardi conjecture [30] builds on his theory of edge-colored algebras, that were also used in his characterisation of bounded width [29]; Zhuk's proof [50, 51] relies on the concept of absorption, which was developed by Barto and Kozik in their effort to prove the bounded width conjecture [5, 7]. Comparable algebraic tools, or a general theory, are at the moment missing in the theory of infinite-domain CSPs, even with an ω-categorical template. The most general results obtained so far use *canonical operations*, which behave like operations on finite sets, and for which it is sometimes possible to mimic the universal-algebraic approach to finite-domain CSPs. Canonical operations alone do not seem to be sufficient in full generality and a characterisation of their applicability is also missing, but on the positive side their applicability covers a vast majority of the results that were proved in the area. The application of canonical operations to approach the question of local consistency for infinite-domain CSPs has only been started recently [18, 45, 49].

1.1 Results

In the present paper, we focus on applying the theory of canonical functions to study the power of local consistency checking for constraint satisfaction problems over ω-categorical templates. Our objective is two-fold: on the one hand, we wish to obtain generic sufficient conditions that imply that local consistency solves a given CSP, and on the other hand we wish to understand the amount of locality needed for local consistency to solve the CSP, as measured by the so-called *relational width*. The definitions of all concepts mentioned in this section can be found in the preliminaries.

In order to solve the first objective, we build on recent work by Mottet and Pinsker [45] and expand the use of their *smooth approximations* to fully suit *equational (non-)affineness*, which is roughly the algebraic situation imposed by local consistency solvability. The main technical contribution is a new *loop lemma* that exploits deep algebraic tools from the finite [6] and, assuming the use of canonical functions is unfruitful, allows to obtain the existence of polymorphisms of every arity $n \geq 2$ and satisfying certain strong symmetry conditions. Using this loop lemma, we are able to obtain a characterisation of bounded width for particular classes of templates, namely for first-order reducts of unary structures and for certain structures related to the logic MMSNP. In particular, we obtain a decidable necessary and sufficient condition for an MMSNP sentence to be equivalent to a Datalog program, solving an open problem from [11, 34].

▶ **Theorem 1.** *The Datalog-rewritability problem for MMSNP is decidable, and is 2NExpTime-complete.*

In order to solve the second objective, we prove that sufficiently locally consistent instances of a given CSP can be turned into locally consistent instances of a finite-domain CSP. If the finite-domain CSP has bounded width then it has relational width $(2, 3)$ by [4], which allows us to obtain a collapse of bounded width for structures whose clone of canonical polymorphisms satisfy suitable identities, thus obtaining a similar collapse as in the finite case. In particular, it turns out that the relational width of a structure then only depends on certain simple parameters of the structure whose automorphism group is considered in the notion of canonicity.

▶ **Theorem 2.** *Let $k, \ell \geq 1$, and let $\mathbb{A}$ be a first-order reduct of a k-homogeneous ℓ-bounded ω-categorical structure $\mathbb{B}$.*

- *If the clone of $\mathrm{Aut}(\mathbb{B})$-canonical polymorphisms of $\mathbb{A}$ contains pseudo-WNUs modulo $\overline{\mathrm{Aut}(\mathbb{B})}$ of all arities $n \geq 3$, then $\mathbb{A}$ has relational width $(2k, \max(3k, \ell))$.*
- *If the clone of $\mathrm{Aut}(\mathbb{B})$-canonical polymorphisms of $\mathbb{A}$ contains pseudo-totally symmetric operations modulo $\overline{\mathrm{Aut}(\mathbb{B})}$ of all arities, then $\mathbb{A}$ has relational width $(k, \max(k+1, \ell))$.*

Note that every finite structure $\mathbb{A}$ with domain $\{a_1, \ldots, a_n\}$ is a first-order reduct of the structure $(\{a_1, \ldots, a_n\}; \{a_1\}, \ldots, \{a_n\})$, which is easily seen to be 1-homogeneous and 2-bounded. Thus the width obtained in Theorem 2 coincides with the width given by Barto's collapse result from [4].

As a corollary of Theorem 2, we obtain a collapse of the bounded width hierarchy for first-order reducts of the unary structures mentioned above, as well as of numerous other structures studied in the literature [22, 18, 17, 39].

▶ **Corollary 3.** *Let $\mathbb{A}$ be a structure that has bounded width. If $\mathbb{A}$ is a first-order reduct of:*

- *the universal homogeneous graph $\mathbb{G}$ or tournament $\mathbb{T}$, or of a unary structure, then $\mathbb{A}$ has relational width at most $(4, 6)$;*
- *the universal homogeneous K_n-free graph $\mathbb{H}_n$, where $n \geq 3$, then at most $(2, n)$;*
- *$(\mathbb{N}; =)$, the countably infinite equivalence relation with infinitely many equivalence classes $\mathbb{C}^\omega_\omega$, or the universal homogeneous partial order $\mathbb{P}$, then at most $(2, 3)$.*

Proof. A first-order reduct of $\mathbb{G}$ or $\mathbb{T}$ has bounded width if and only if the algebraic condition in the first item of Theorem 2 is satisfied [45]. Since both $\mathbb{G}$ and $\mathbb{T}$ are 2-homogeneous and 3-bounded our claim follows. First-order reducts of $\mathbb{H}_n$, $(\mathbb{N}; =)$ or $\mathbb{C}^\omega_\omega$ have bounded width if and only if the condition in the second item of Theorem 2 is satisfied, by [17], [14] and [26], respectively. Since $\mathbb{H}_n$ is 2-homogeneous and n-bounded, and since both $(\mathbb{N}; =)$ and $\mathbb{C}^\omega_\omega$ are 2-homogeneous and 3-bounded, the claimed bound follows.

By appeal to Theorems 2 and 23 in the present paper our claim holds for first-order reducts of unary structures.

Finally, a first-order reduct of $\mathbb{P}$ with bounded width is either homomorphically equivalent to a first-order reduct of $(\mathbb{Q}; <)$ or it satisfies the algebraic condition in the second item of Theorem 2 [39]. In the latter case we are done by Theorem 2, in the former we appeal to the syntactical characterization of first-order reducts of $(\mathbb{Q}; <)$. Indeed, such a structure has bounded width iff it is definable by a conjunction of so-called Ord-Horn clauses [20]. It then follows by [28] that a first-order reduct of $(\mathbb{Q}; <)$ with bounded width has relational width $(2, 3)$. The result for $\mathbb{P}$ follows. ◀

The following example shows that for some of the structures under consideration, the bounds on relational width provided by Corollary 3 are tight.

▶ **Example 4.** To show the tightness of the first bound in the case of the universal homogeneous graph, we exhibit a first-order reduct $\mathbb{A}$ such that for all $i \leq j$ with $1 \leq j < 4$ or $1 \leq i < 6$ there exists a non-trivial, (i, j)-minimal instance of $\mathrm{CSP}(\mathbb{A})$ that has no solution. Let $\mathbb{B} := (A; E)$ be the universal homogeneous graph with edge relation E, and let $N := (A^2 \setminus E) \cap \neq$. Consider the first-order reduct $\mathbb{A} := (A; R_=, R_\neq)$ of $\mathbb{B}$, where $R_= := \{(a, b, c, d) \in A^4 \mid E(a, b) \wedge E(c, d)$ or $N(a, b) \wedge N(c, d)\}$ and $R_\neq := \{(a, b, c, d) \in A^4 \mid E(a, b) \wedge N(c, d)$ or $N(a, b) \wedge E(c, d)\}$.

It can be seen that $\mathbb{A}$ has bounded width, so that Theorem 2 implies that $\mathbb{A}$ has relational width $(4, 6)$. It is easy to see that the instance

$$\Phi = R_=(v_1, v_2, v_3, v_4) \wedge R_\neq(v_1, v_2, v_3, v_4)$$

is non-trivial, (i,j)-minimal for all $i \leq j$ with $1 \leq i \leq 3$, and has no solution. Moreover, the $(4,5)$-minimal instance equivalent to the instance

$$\Psi = R_{=}(v_1, v_2, v_3, v_4) \wedge R_{\neq}(v_3, v_4, v_5, v_6) \wedge R_{\neq}(v_1, v_2, v_5, v_6)$$

is non-trivial and has no solution. It follows that the exact relational width of $\mathbb{A}$ is $(4,6)$.

The bounds on relational width provided by the second and third item of Corollary 3 are easily seen to be tight as well. Indeed, let $n \geq 3$, let $\mathbb{B} := (A; E)$ be the universal homogeneous K_n-free graph, let $N := (A^2 \setminus E) \cap \neq$ and let $\mathbb{A} := (A; E, N)$. $\mathbb{A}$ is preserved by canonical pseudo-totally symmetric operations modulo $\overline{\mathrm{Aut}(\mathbb{B})}$ of all arities and has therefore relational width $(2,n)$ by Theorem 2. But the non-trivial, $(2, n-1)$-minimal instance

$$\Phi = \bigwedge_{1 \leq i \neq j \leq n} E(v_i, v_j)$$

has no solution; moreover, the instance $\Psi = E(v_1, v_2) \wedge N(v_1, v_2)$ is non-trivial, $(1,j)$-minimal for every $j \geq 1$ and has no solution either.

For the other structures from Corollary 3, the tightness of the bound can be shown similarly.

1.2 Related results

Local consistency for ω-categorical structures was studied for the first time in [13] where basic notions were introduced and some basic results provided. First-order reducts of certain k-homogeneous ℓ-bounded structures with bounded width were characterized in [45, 20].

A structure $\mathbb{A}$ has *bounded strict width* [33] if not only $\mathrm{CSP}(\mathbb{A})$ is solvable by local consistency, but moreover every partial solution of a locally consistent instance can be extended to a total solution. The articles [49] and [48] give the upper bound $(2,\ell)$ on the relational width for some classes of 2-homogeneous, ℓ-bounded structures under the stronger assumption of bounded strict width; it also follows from [49] that first-order reducts of $\mathbb{H}_n$ with bounded width have relational width at most $(2,n)$.

1.3 Organisation of the present article

In Section 2 we provide the basic notions and definitions. The reduction to the finite using canonical functions which leads to the collapse of the bounded width hierarchy is given in Section 3. We then extend the algebraic theory of smooth approximations in Section 4 before applying it to first-order reducts of unary structures and MMSNP in Section 5. For lack of space, some proofs are omitted and can be found in the full version of the paper.

2 Preliminaries

2.1 Structures and model-theoretic notions

For sets B, I, the *orbit* of a tuple $b \in B^I$ under the action of a permutation group $\mathcal{G}$ on B is the set $\{\alpha(b) \mid \alpha \in \mathcal{G}\}$. A countable structure $\mathbb{B}$ is *ω-categorical* if its automorphism group $\mathrm{Aut}(\mathbb{B})$ is *oligomorphic*, i.e., for all $n \geq 1$, the number of orbits of the action of $\mathrm{Aut}(\mathbb{B})$ on n-tuples is finite. For $\ell \geq 1$, we say that $\mathbb{B}$ is *ℓ-bounded* if for every finite $\mathbb{X}$, if all substructures $\mathbb{Y}$ of $\mathbb{X}$ of size at most ℓ embed in $\mathbb{B}$, then $\mathbb{X}$ embeds in $\mathbb{B}$. For $k \geq 1$, we say that $\mathbb{B}$ is *k-homogeneous* if for all tuples a, b of arbitrary finite length, if all k-subtuples of a

and b are in the same orbit under $\mathrm{Aut}(\mathbb{B})$, then a and b are in the same orbit under $\mathrm{Aut}(\mathbb{B})$. We say that $\mathbb{B}$ is *unary* if all relations in its signature are unary. A *first-order reduct* of a structure $\mathbb{B}$ is a structure on the same domain whose relations have a first-order definition in $\mathbb{B}$.

2.2 Polymorphisms, clones and identities

A *polymorphism* of a relational structure $\mathbb{A}$ is a homomorphism from some finite power of $\mathbb{A}$ to $\mathbb{A}$. The set of all polymorphisms of a structure $\mathbb{A}$ is denoted by $\mathrm{Pol}(\mathbb{A})$; it is a *function clone*, i.e., a set of finitary operations on a fixed set which contains all projections and which is closed under arbitrary compositions.

If $\mathcal{C}$ is a function clone, then we denote the domain of its functions by C; we say that $\mathcal{C}$ *acts on* C. The clone $\mathcal{C}$ also naturally acts (componentwise) on C^l for any $l \geq 1$, on any invariant subset S of C (by restriction), and on the classes of any invariant equivalence relation $\sim$ on an invariant subset S of C (by its action on representatives of the classes). We write $\mathcal{C} \curvearrowright C^l$, $\mathcal{C} \curvearrowright S$ and $\mathcal{C} \curvearrowright S/\!\sim$ for these actions. Any action $\mathcal{C} \curvearrowright S/\!\sim$ is called a *subfactor* of $\mathcal{C}$, and we also call the pair $(S, \sim)$ a subfactor. A subfactor $(S, \sim)$ is *minimal* if $\sim$ has at least two classes and no proper subset of S intersecting at least two $\sim$-classes is invariant under $\mathcal{C}$. For a clone $\mathcal{C}$ acting on a set X and $Y \subseteq X$ we write $\langle Y \rangle_{\mathcal{C}}$ for the smallest $\mathcal{C}$-invariant subset of X containing Y.

For $n \geq 1$, a k-ary operation f defined on the domain C of a permutation group $\mathcal{G}$ is *n-canonical* with respect to $\mathcal{G}$ if for all $a_1, \ldots, a_k \in C^n$ and all $\alpha_1, \ldots, \alpha_k \in \mathcal{G}$ there exists $\beta \in \mathcal{G}$ such that $f(a_1, \ldots, a_k) = \beta \circ f(\alpha_1(a_1), \ldots, \alpha_k(a_k))$. In particular, f induces an operation on the set $C^n/\mathcal{G}$ of $\mathcal{G}$-orbits of n-tuples. If all functions of a function clone $\mathcal{C}$ are n-canonical with respect to $\mathcal{G}$, then $\mathcal{C}$ acts on $C^n/\mathcal{G}$ and we write $\mathcal{C}^n/\mathcal{G}$ for this action; if $\mathcal{G}$ is oligomorphic then $\mathcal{C}^n/\mathcal{G}$ is a function clone on a finite set. A function is *canonical* with respect to a permutation group $\mathcal{G}$ if it is n-canonical with respect to $\mathcal{G}$ for all $n \geq 1$. We say that it is *diagonally canonical* if it satisfies the definition of canonicity in case $\alpha_1 = \cdots = \alpha_k$.

We write $\mathcal{G}_{\mathcal{C}}$ to denote the largest permutation group contained in a function clone $\mathcal{C}$, and say that $\mathcal{C}$ is oligomorphic if $\mathcal{G}_{\mathcal{C}}$ is oligomorphic. For $n \geq 1$, the *n-canonical (canonical) part* of $\mathcal{C}$ is the clone of those functions of $\mathcal{C}$ which are n-canonical (canonical) with respect to $\mathcal{G}_{\mathcal{C}}$. We write $\mathcal{C}^{\mathrm{can}}_n$ and $\mathcal{C}^{\mathrm{can}}$ for these sets which form themselves function clones.

For a set of functions $\mathcal{F}$ over the same fixed set C we write $\overline{\mathcal{F}}$ for the set of those functions g such that for all finite subsets F of C, there exists a function in $\mathcal{F}$ which agrees with g on F. We say that f *locally interpolates* g modulo $\mathcal{G}$, where f, g are k-ary functions and $\mathcal{G}$ is a permutation group all of which act on the same domain, if $g \in \overline{\{\beta \circ f(\alpha_1, \ldots, \alpha_k) \mid \beta, \alpha_1, \ldots, \alpha_k \in \mathcal{G}\}}$. Similarly, we say that f *diagonally interpolates* g modulo $\mathcal{G}$ if f locally interpolates g with $\alpha_1 = \cdots = \alpha_k$. If $\mathcal{G}$ is the automorphism group of a *Ramsey structure* in the sense of [12], then every function on its domain locally (diagonally) interpolates a canonical (diagonally canonical) function modulo $\mathcal{G}$ [25, 21]. We say that a clone $\mathcal{D}$ locally interpolates a clone $\mathcal{C}$ modulo a permutation group $\mathcal{G}$ if for every $g \in \mathcal{D}$ there exists $f \in \mathcal{C}$ such that g locally interpolates f modulo $\mathcal{G}$. A clone $\mathcal{C}$ is a *model-complete core* if its unary functions are equal to $\overline{\mathcal{G}_{\mathcal{C}}}$. A structure $\mathbb{A}$ is called a model- complete core if its polymorphism clone is.

A function f is *idempotent* if $f(x, \ldots, x) = x$ for all values x of its domain; a function clone is idempotent if all of its functions are. A k-ary operation w is called a *weak near-unanimity (WNU)* operation if it satisfies the set of identities containing an equation for each pair of terms in $\{w(x, \ldots, x, y), w(x, y, \ldots, x), \ldots, w(y, x, \ldots, x)\}$. It is called *totally symmetric* if $w(x_1, \ldots, x_k) = w(y_1, \ldots, y_k)$ whenever $\{x_1, \ldots, x_k\} = \{y_1, \ldots, y_k\}$ (where $1 \leq |\{x_1, \ldots, x_k\}| \leq k$). Each set of identities also has a *pseudo*-variant obtained by composing each term appearing in the identities with a distinct unary function symbol. For example,

a ternary pseudo-WNU operation f satisfies the identities: $e_1 \circ f(y,x,x) = e_2 \circ f(x,y,x)$, $e_3 \circ f(y,x,x) = e_4 \circ f(x,x,y)$ and $e_5 \circ f(x,y,x) = e_6 \circ f(x,x,y)$. If $\mathcal{C}$ is a function clone and $\mathcal{U} \subseteq \mathcal{C}$ is a set of unary functions, then $\mathcal{C}$ *satisfies a set of pseudo-identities modulo* $\mathcal{U}$ if it satisfies the identities in such a way that the unary function symbols are assigned values in $\mathcal{U}$.

An arity-preserving map $\xi\colon \mathcal{C} \to \mathcal{D}$ between function clones is called a *clone homomorphism* if it preserves projections, i.e., maps every projection in $\mathcal{C}$ to the corresponding projection in $\mathcal{D}$, and compositions, i.e., it satisfies $\xi(f \circ (g_1,\dots,g_n)) = \xi(f) \circ (\xi(g_1),\dots,\xi(g_n))$ for all $n,m \geq 1$ and all n-ary $f \in \mathcal{C}$ and m-ary $g_1,\dots,g_n \in \mathcal{C}$. An arity-preserving map ξ is a *minion homomorphism* if it preserves compositions with projections, i.e., compositions where $g_1,\dots,g_n$ are projections. We say that a function clone $\mathcal{C}$ is *equationally trivial* if it has a clone homomorphism to the clone $\mathcal{P}$ of projections over the two-element domain, and *equationally non-trivial* otherwise. We also say that $\mathcal{C}$ is *equationally affine* if it has a clone homomorphism to an *affine clone*, i.e., a clone of affine maps over a finite module. It is known that a finite idempotent clone is either equationally affine or it contains WNU operations of all arities $n \geq 3$ ([43], this stronger version is attributed to E. Kiss in [40, Theorem 2.8]). Similarly, if $\mathbb{A}$ is an ω-categorical model-complete core, then $\mathrm{Pol}(\mathbb{A})^{\mathrm{can}}$ is either equationally affine, or it contains pseudo-WNU operations modulo $\overline{\mathrm{Aut}(\mathbb{A})}$ of all arities $n \geq 3$ (see [24, 45] for the lift of the corresponding result from the finite).

If $\mathcal{C}$, $\mathcal{D}$ are function clones and $\mathcal{D}$ has a finite domain, then a clone (or minion) homomorphism $\xi\colon \mathcal{C} \to \mathcal{D}$ is *uniformly continuous* if for all $n \geq 1$ there exists a finite subset F of C^n such that $\xi(f) = \xi(g)$ for all n-ary $f,g \in \mathcal{C}$ which agree on F.

A first-order formula is called a *primitive-positive* (pp-)formula if it is built exclusively from atomic formulae, existential quantifiers, and conjunction. A relation is pp-definable in a structure $\mathbb{B}$ if it is first-order definable by a pp-formula; in that case, it is invariant under $\mathrm{Pol}(\mathbb{B})$. Any ω-categorical model-complete core pp-defines all orbits of n-tuples with respect to its own automorphism group, for all $n \geq 1$.

2.3 CSP, Relational Width, Minimality

A *CSP instance* over a set A is a pair $\mathcal{I} = (\mathcal{V}, \mathcal{C})$, where $\mathcal{V}$ is a finite set of variables, and $\mathcal{C}$ is a set of *constraints*; each constraint $C \in \mathcal{C}$ is a subset of A^U for some non-empty $U \subseteq \mathcal{V}$ (U is the *scope* of C). We say that $\mathcal{I}$ is an *instance of* $\mathrm{CSP}(\mathbb{A})$ if for every $C \in \mathcal{C}$ with scope U, there exists an enumeration $u_1,\dots,u_k$ of the elements of U and a k-ary relation R of $\mathbb{A}$ such that for all $f\colon U \to A$ we have $f \in C \Leftrightarrow (f(u_1),\dots,f(u_k)) \in R$. Given a constraint $C \subseteq A^U$ and $K \subseteq U$, the *projection of* C *onto* K is defined by $C|_K := \{f|_K \colon f \in C\}$.

▶ **Definition 5.** *Let $1 \leq k \leq \ell$. We say that an instance $\mathcal{I}$ over $\mathcal{V}$ of* $\mathrm{CSP}(\mathbb{A})$ *is* (k,ℓ)-minimal *if both of the following hold:*

- *every non-empty subset of at most ℓ variables in $\mathcal{V}$ is the scope of some constraint in $\mathcal{I}$;*
- *for every at most k-element subset of variables $K \subseteq \mathcal{V}$ and any two constraints $C_1, C_2 \in \mathcal{I}$ whose scopes contain K, the projections of C_1 and C_2 onto K coincide.*

We say that an instance $\mathcal{I}$ of the CSP is *non-trivial* if it does not contain any empty constraint. Otherwise, $\mathcal{I}$ is *trivial*.

Let $1 \leq k \leq \ell$. Clearly not every instance $\mathcal{I}$ over variables $\mathcal{V}$ of $\mathrm{CSP}(\mathbb{A})$ is (k,ℓ)-minimal. However, every instance $\mathcal{I}$ is *equivalent* to a (k,ℓ)-minimal instance $\mathcal{I}'$ in the sense that $\mathcal{I}$ and $\mathcal{I}'$ have the same set of solutions. In particular we have that if $\mathcal{I}'$ is trivial, then $\mathcal{I}$ has no solutions. Moreover, if $\mathbb{A}$ is ω-categorical, then $\mathcal{I}'$ can be computed in time polynomial in the size of $\mathcal{I}$. Indeed, it is enough to introduce a new constraint A^L for every set $L \subseteq \mathcal{V}$ with

at most ℓ elements to satisfy the first condition. Then the algorithm removes tuples (in fact, orbits of tuples with respect to $\mathrm{Aut}(\mathbb{A})$) from the constraints in the instance as long as the second condition is not satisfied. Since $\mathbb{A}$ is ω-categorical and thus every relation in $\mathcal{I}$ is a union of a finite number of orbits of tuples with respect to $\mathrm{Aut}(\mathbb{A})$, the algorithm terminates.

▶ **Definition 6.** *Let $1 \leq k \leq \ell$. A relational structure $\mathbb{A}$ has* relational width (k, ℓ) *if every non-trivial (k, ℓ)-minimal instance of $\mathbb{A}$ has a solution. $\mathbb{A}$ has* bounded width *if it has relational width (k, ℓ) for some natural numbers $k \leq \ell$.*

▶ **Theorem 7** ([7])**.** *Let $\mathcal{I}$ be a non-trivial $(2, 3)$-minimal CSP instance over a finite set. Suppose that the constraints of $\mathcal{I}$ are preserved by WNUs of all arities $m \geq 3$. Then $\mathcal{I}$ has a solution.*

▶ **Theorem 8** ([32, 33])**.** *Let $\mathcal{I}$ be a non-trivial $(1, 1)$-minimal CSP instance over a finite set. Suppose that the constraints of $\mathcal{I}$ are preserved by totally symmetric polymorphisms of all arities. Then $\mathcal{I}$ has a solution.*

2.4 Smooth Approximations

We are going to apply the fundamental theorem of smooth approximations [45] to lift an action of a function clone to a larger clone.

▶ **Definition 9.** (Smooth approximations) *Let A be a set, $n \geq 1$, and let $\sim$ be an equivalence relation on a subset S of A^n. We say that an equivalence relation η on some set S' with $S \subseteq S'$* approximates *$\sim$ if the restriction of η to S is a (possibly non-proper) refinement of $\sim$. We call η an* approximation *of $\sim$.*

For a permutation group $\mathcal{G}$ acting on A and leaving η as well as the $\sim$-classes invariant, we say that the approximation η is smooth *if each equivalence class C of $\sim$ intersects some equivalence class C' of η such that $C \cap C'$ contains a $\mathcal{G}$-orbit.*

▶ **Theorem 10** (The fundamental theorem of smooth approximations [45])**.** *Let $\mathcal{C} \subseteq \mathcal{D}$ be function clones on a set A, and let $\mathcal{G}$ be a permutation group on A such that $\mathcal{D}$ locally interpolates $\mathcal{C}$ modulo $\mathcal{G}$. Let $\sim$ be a $\mathcal{C}$-invariant equivalence relation on $S \subseteq A$ with $\mathcal{G}$-invariant classes and finite index, and η be a $\mathcal{D}$-invariant smooth approximation of $\sim$ with respect to $\mathcal{G}$. Then there exists a uniformly continuous minion homomorphism from $\mathcal{D}$ to $\mathcal{C} \curvearrowright S/\sim$.*

3 Collapses in the Relational Width Hierarchy

▶ **Definition 11.** *Let $\mathcal{I} = (\mathcal{V}, \mathcal{C})$ be a CSP instance over A. Let $\mathcal{G}$ be a permutation group on A, let $k \geq 1$, and let $\mathcal{O}$ be the set of orbits of k-tuples under $\mathcal{G}$. Let $\mathcal{I}_{\mathcal{G},k}$ be the following instance over $\mathcal{O}$:*

- *The variable set of $\mathcal{I}_{\mathcal{G},k}$ is the set $\binom{\mathcal{V}}{k}$ of k-element subsets of $\mathcal{V}$. Thus, every variable K of $\mathcal{I}_{\mathcal{G},k}$ is meant to take a value in $\mathcal{O}$, and we consider that the values for K are K-orbits, i.e., orbits of maps $f\colon K \to A$ under the natural action of $\mathcal{G}$.*
- *For every constraint $C \subseteq A^U$ in $\mathcal{I}$, $\mathcal{I}_{\mathcal{G},k}$ contains the constraint $C_{\mathcal{G},k} \subseteq \mathcal{O}^{\binom{U}{k}}$ defined by*

$$C_{\mathcal{G},k} = \left\{ g\colon \binom{U}{k} \to \mathcal{O} \mid \exists f \in C \ \ \forall K \in \binom{U}{k} \ \ (f|_K \in g(K)) \right\}.$$

Note that the notation $f|_K \in g(K)$ makes sense precisely because $g(K)$ is a K-orbit.

Observe that if $\mathcal{I}$ is non-trivial, then so is $\mathcal{I}_{\mathcal{G},k}$.

▶ **Lemma 12.** *Let $1 \leq a \leq b$. If $\mathcal{I}$ is (ak, bk)-minimal, then $\mathcal{I}_{\mathcal{G},k}$ is (a, b)-minimal.*

Note that for every solution h of $\mathcal{I}$, the map $\chi_h \colon \binom{\mathcal{V}}{k} \to \mathcal{O}$ defined by $K \mapsto \{\alpha h|_K \mid \alpha \in \mathcal{G}\}$ defines a solution to $\mathcal{I}_{\mathcal{G},k}$. The next lemma proves that every solution to $\mathcal{I}_{\mathcal{G},k}$ is of the form χ_h for some solution h of $\mathcal{I}$, provided that $\mathcal{I}$ is (k, ℓ)-minimal and that $\mathcal{G} = \mathrm{Aut}(\mathbb{B})$ for some ℓ-bounded k-homogeneous structure $\mathbb{B}$.

▶ **Lemma 13.** *Let $1 \leq k < \ell$. Let $\mathbb{B}$ be ℓ-bounded and k-homogeneous, let $\mathbb{A}$ be a first-order reduct of $\mathbb{B}$, and let $\mathcal{I}$ be a (k, ℓ)-minimal instance of $\mathrm{CSP}(\mathbb{A})$. Then every solution to $\mathcal{I}_{\mathrm{Aut}(\mathbb{B}),k}$ lifts to a solution of $\mathcal{I}$.*

Proof. Let $h \colon \binom{\mathcal{V}}{k} \to \mathcal{O}$ be a solution to $\mathcal{I}_{\mathrm{Aut}(\mathbb{B}),k}$. Recall that for any $K \in \binom{\mathcal{V}}{k}$, we view $h(K)$ as a K-orbit, and one can therefore restrict $h(K)$ to any $L \subseteq K$ by setting $h(K)|_L := \{f|_L \mid f \in h(K)\}$. Note that since $\mathcal{I}$ is (k, k)-minimal, we have $h(K)|_{K \cap K'} = h(K')|_{K \cap K'}$ for all $K, K' \in \binom{\mathcal{V}}{k}$.

We now define an equivalence relation $\sim$ on $\mathcal{V}$. Suppose first that $k = 1$. Then every orbit of $\mathbb{B}$ must be a singleton (for any orbit with two elements a, b, the pairs (a, a) and (a, b) are not in the same orbit but their entries are, so that $\mathbb{B}$ is not 1-homogeneous). In that case, we identify $\mathcal{O}$ with the domain B itself, and set $x \sim y$ if and only if $h(\{x\}) = h(\{y\})$; that is, $\sim$ is essentially the kernel of h.

Suppose next that $k \geq 2$, and set $x \sim y$ iff there is $K \in \binom{\mathcal{V}}{k}$ containing x, y such that $h(K)|_{\{x,y\}}$ consists of constant maps. It can be seen that one could equivalently ask that this holds for *all* K containing x, y by 2-minimality, and that this is indeed an equivalence relation by $(2, 3)$-minimality of $\mathcal{I}$. Moreover, h descends to $\binom{\mathcal{V}/\sim}{k}$: if $K' = \{[v_1]_\sim, \ldots, [v_k]_\sim\}$ is a k-element set, define $\tilde{h}(K') := h(\{v_1, \ldots, v_k\})$. The definition of $\tilde{h}$ does not depend on the choice of representatives, by the very definition of $\sim$.

Define a finite structure $\mathbb{C}$ with domain $\mathcal{V}/\sim$ in the signature of $\mathbb{B}$ as follows. Let $K = \{[v_1]_\sim, \ldots, [v_k]_\sim\}$. The orbit $\tilde{h}(K)$ describes an atomic type on the elements of K; one defines $\mathbb{C}$ such that its substructure induced by K has the same atomic type. This is a well-defined construction by the previous paragraphs.

Finally, note that all substructures of $\mathbb{C}$ of size at most ℓ embed into $\mathbb{B}$. Indeed, let $\mathbb{L}$ be an ℓ-element substructure of $\mathbb{C}$, and let $L' \subseteq V$ be an ℓ-element set containing one representative for each element of $\mathbb{L}$. By (k, ℓ)-minimality of $\mathcal{I}$, there exists $C \subseteq A^{L'}$ in $\mathcal{I}$, and a corresponding $C_{\mathrm{Aut}(\mathbb{B}),k} \subseteq \mathcal{I}_{\mathrm{Aut}(\mathbb{B}),k}$. Thus, $h|_{\binom{L'}{k}} \in C_{\mathrm{Aut}(\mathbb{B}),k}$, so that there exists $g \in C$ such that for all $K \in \binom{L'}{k}$, $g|_K \in h(K)$. Thus g corresponds to an embedding of every k-element substructure of $\mathbb{L}$ into $\mathbb{B}$, and since $\mathbb{B}$ is k-homogeneous, g is an embedding of $\mathbb{L}$ into $\mathbb{B}$. Finally, since $\mathbb{B}$ is ℓ-bounded, it follows that there exists an embedding e of $\mathbb{C}$ into $\mathbb{B}$.

It remains to check that the composition of e with the canonical projection $\mathcal{V} \to \mathcal{V}/\sim$ is a solution to $\mathcal{I}$, which is trivial since the relations of $\mathbb{A}$ are definable in $\mathbb{B}$. ◀

Every operation f that is canonical with respect to a group $\mathcal{G}$ induces an operation on the set orbits of k-tuples under $\mathcal{G}$, by definition. We denote this operation by $f_{\mathcal{G},k}$.

▶ **Lemma 14.** *Let f be a polymorphism of $\mathbb{A}$ that is canonical with respect to $\mathcal{G}$. Every constraint $C_{\mathcal{G},k}$ in $\mathcal{I}_{\mathcal{G},k}$ is preserved under $f_{\mathcal{G},k}$.*

Finally, this allows us to prove Theorem 2 from the introduction.

Proof of Theorem 2. Suppose that the assumption of the first item of Theorem 2 is satisfied. Let $\mathcal{I}$ be a non-trivial $(2k, \max(3k, \ell))$-minimal instance of $\mathrm{CSP}(\mathbb{A})$, and let $\mathcal{I}_{\mathrm{Aut}(\mathbb{B}),k}$ be the associated instance of Definition 11. By Lemma 12, $\mathcal{I}_{\mathrm{Aut}(\mathbb{B}),k}$ is a $(2, 3)$-minimal instance,

and it is non-trivial by definition. The constraints of $\mathcal{I}_{\mathrm{Aut}(\mathbb{B}),k}$ are preserved by WNUs of all arities $m \geq 3$ (Lemma 14). By Theorem 7, $\mathcal{I}_{\mathrm{Aut}(\mathbb{B}),k}$ admits a solution and since $\mathcal{I}$ is $(k, \max(3k, \ell))$-minimal, this solution lifts to a solution of $\mathcal{I}$ by Lemma 13. Thus, $\mathbb{A}$ has width $(2k, \max(3k, \ell))$.

Suppose now that the assumption in the second item is satisfied. By the same reasoning but using Theorem 8 instead of Theorem 7, given a $(k, \max(k+1, \ell))$-minimal instance $\mathcal{I}$, the associated instance $\mathcal{I}_{\mathrm{Aut}(\mathbb{B}),k}$ is $(1,1)$-minimal and therefore has a solution. Since $\mathcal{I}$ is $(k, \max(k+1, \ell))$-minimal, this solution lifts to a solution of $\mathcal{I}$. ◀

4 A New Loop Lemma for Smooth Approximations

We refine the algebraic theory of smooth approximations from [45]. Building on deep algebraic results from [6] on finite idempotent algebras that are equationally non-trivial, we lift some of the theory from binary symmetric relations to cyclic relations of arbitrary arity.

4.1 The loop lemma

▶ **Definition 15.** *The* linkedness congruence *of a binary relation $R \subseteq A \times B$ is the equivalence relation λ_R on $\mathrm{proj}_{(2)}(R)$ defined by $(b, b') \in \lambda_R$ iff there are $k \geq 0$ and $a_0, \ldots, a_{k-1} \in A$ and $b = b_0, \ldots, b_k = b' \in B$ such that $(a_i, b_i) \in R$ and $(a_i, b_{i+1}) \in R$ for all $i \in \{0, \ldots, k-1\}$. We say that R is* linked *if it is non-empty and λ_R relates any two elements of $\mathrm{proj}_{(2)}(R)$.*

If A is a set and $m \geq 2$, then we call a relation $R \subseteq A^m$ cyclic *if it is invariant under cyclic permutations of the components of its tuples. The* support *of R is its projection on any argument. We apply the same terminology as above to any cyclic R, viewing R as a binary relation between $\mathrm{proj}_{(1,\ldots,m-1)}(R)$ and $\mathrm{proj}_{(m)}(R)$.*

If R is invariant under an oligomorphic group action on $A \times B$, then there is an upper bound on the length k to witness $(b, b') \in \lambda_R$, and therefore λ_R is pp-definable from R; in particular, it is invariant under any function clone acting on $A \times B$ and preserving R.

▶ **Definition 16.** *Let $\mathcal{G}$ be a permutation group on a set A. A* pseudo-loop with respect to $\mathcal{G}$ *is a tuple of elements of A all of whose components belong to the same $\mathcal{G}$-orbit [46, 9, 10]. If $\mathcal{G}$ contains only the identity function, then a pseudo-loop is called a* loop.

▶ **Theorem 17** (Consequence of the proof of Theorem 4.2 in [6])**.** *Let $\mathcal{C}$ be an idempotent function clone on a finite domain that is equationally non-trivial. Then any $\mathcal{C}$-invariant cyclic linked relation on its domain contains a loop.*

The following is a generalization of [45, Theorem 10] from binary symmetric relations to arbitrary cyclic relations.

▶ **Proposition 18.** *Let $n \geq 1$, and let $\mathcal{D}$ be an oligomorphic function clone on a set A which is a model-complete core. Let $\mathcal{C} \subseteq \mathcal{D}^{\mathrm{can}}_n$ be such that $\mathcal{C}^n/\mathcal{G}_\mathcal{D}$ is equationally non-trivial. Let $(S, \sim)$ be a minimal subfactor of the action $\mathcal{C}^n$ with $\mathcal{G}_\mathcal{D}$-invariant $\sim$-classes. Then for every $\mathcal{D}$-invariant cyclic relation R with support $\langle S \rangle_\mathcal{D}$ one of the following holds:*

1. *The linkedness congruence of R is a $\mathcal{D}$-invariant approximation of $\sim$.*
2. *R contains a pseudo-loop with respect to $\mathcal{G}_\mathcal{D}$.*

Proof. Let R be given, and denote its arity by m. Assuming that (1) does not hold, we prove (2).

Denote by $\mathcal{O}$ the set of orbits of n-tuples under the action of $\mathcal{G}_\mathcal{D}$ thereon. Let R' be the relation obtained by considering R as a relation on $\mathcal{O}$, i.e.,

$$R' := \{(O_1, \dots, O_m) \in \mathcal{O}^m \mid R \cap (O_1 \times \cdots \times O_m) \neq \emptyset\}.$$

Thus, R' is an m-ary cyclic relation with support $S' \subseteq \mathcal{O}$, and R' contains a loop if and only if R satisfies (2).

By assumption, the action $\mathcal{C}^n/\mathcal{G}_\mathcal{D}$ is equationally non-trivial; moreover, it is idempotent since $\mathcal{D}$ is a model-complete core. Note also that R', and in particular S', are preserved by this action. It is therefore sufficient to show that R' is linked and apply Theorem 17.

Recall that we consider R also as a binary relation between $\mathrm{proj}_{m-1}(R)$ and $\langle S\rangle_\mathcal{D}$; similary, we consider R' as a binary relation between $\mathrm{proj}_{m-1}(R')$ and S'. By the oligomorphicity of $\mathcal{D}$, the linkedness congruence λ_R of R is invariant under $\mathcal{D}$.

By our assumption that (1) does not hold, there exist $c, d \in S$ which are not $\sim$-equivalent and such that $\lambda_R(c, d)$ holds; otherwise, λ_R would be an approximation of $\sim$. This implies that the orbits O_c, O_d of c, d are related via $\lambda_{R'}$. By the minimality of $(S, \sim)$, we have that $\langle S\rangle_\mathcal{D} = \langle\{c, d\}\rangle_\mathcal{D}$. Since $\mathcal{D}$ is a model-complete core, it preserves the $\mathcal{G}_\mathcal{D}$-orbits, and it follows that any tuple in $\langle S\rangle_\mathcal{D} = \langle\{c, d\}\rangle_\mathcal{D}$ is λ_R-related to a tuple in the orbit of c. Hence, $\lambda_{R'} = (S')^2$, and thus R' is linked. Theorem 17 therefore implies that R' contains a loop, and hence R contains a pseudo-loop with respect to $\mathcal{G}_\mathcal{D}$, which is what we had to show. ◀

The following is a generalization of Lemma 12 in [45] from binary relations and functions to relations and functions of higher arity.

▶ **Lemma 19.** *Let $n \geq 1$, and let $\mathcal{D}$ be an oligomorphic polymorphism clone on a set A that is a model-complete core. Let $\sim$ be an equivalence relation on a set $S \subseteq A^n$ with $\mathcal{G}_\mathcal{D}$-invariant classes. Let $m \geq 1$, and let P be an m-ary relation on $\langle S\rangle_\mathcal{D}$. Suppose that every m-ary $\mathcal{D}$-invariant cyclic relation R on $\langle S\rangle_\mathcal{D}$ which contains a tuple in P with components in at least two $\sim$-classes contains a pseudo-loop with respect to $\mathcal{G}_\mathcal{D}$.*

Then there exists an m-ary $f \in \mathcal{D}$ such that for all $a_1, \dots, a_m \in A^n$ we have that if the tuple $(f(a_1, \dots, a_m), f(a_2, \dots, a_m, a_1), \dots, f(a_m, a_1, \dots, a_{m-1}))$ is in P, then it intersects at most one $\sim$-class.

5 Applications: Collapses of the bounded width hierachies for some classes of infinite structures

We now apply the algebraic results of Section 4 and the theory of smooth approximations to obtain a characterisation of bounded width for CSPs of first-order reducts of unary structures ($k = 2, \ell = 2$) and for CSPs in MMSNP (where k and ℓ are arbitrarily large). Moreover, the results of Section 3 then imply a collapse of the bounded width hierarchy for such CSPs.

5.1 Unary Structures

▶ **Lemma 20** (Proposition 6.5 in [18]). *Let $\mathbb{A}$ be a first-order expansion of a stabilized partition $(\mathbb{N}; V_1, \dots, V_r)$. For every $f \in \mathrm{Pol}(\mathbb{A})$ there exists $g \in \mathrm{Pol}(\mathbb{A})^{\mathrm{can}}$ which is locally interpolated by f modulo $\mathrm{Aut}(\mathbb{A})$.*

▶ **Proposition 21** (Proposition 6.6 in [18]). *Let $\mathbb{A}$ be a first-order expansion of a stabilized partition $(\mathbb{N}; V_1, \dots, V_r)$, and assume it is a model-complete core. Suppose that $\mathrm{Pol}(\mathbb{A})$ contains a binary operation whose restriction to V_i is injective for all $1 \leq i \leq r$. Then the following are equivalent:*

- *$\mathrm{Pol}(\mathbb{A})^{\mathrm{can}}$ is equationally affine;*
- *$\mathrm{Pol}(\mathbb{A})^{\mathrm{can}} \curvearrowright \mathbb{N}/\mathrm{Aut}(\mathbb{A})$ is equationally affine.*

▶ **Lemma 22** (Subset of the proof of Proposition 6.6 [18]). *Let $\mathbb{A}$ be a first-order expansion of a stabilized partition $(\mathbb{N}; V_1, \dots, V_r)$, and assume it is a model-complete core. If $\mathrm{Pol}(\mathbb{A})$ has no continuous clone homomorphism to $\mathcal{P}$, then it contains operations of all arities whose restrictions to V_i are injective for all $1 \leq i \leq r$.*

▶ **Theorem 23.** *Let $\mathbb{A}$ be a first-order reduct of a unary structure, and assume that $\mathbb{A}$ is a model-complete core. Then one of the following holds:*

- $\mathrm{Pol}(\mathbb{A})^{\mathrm{can}}$ *is not equationally affine, or equivalently, it contains pseudo-WNUs modulo* $\mathrm{Aut}(\mathbb{A})$ *of all arities $n \geq 3$;*
- $\mathrm{Pol}(\mathbb{A})$ *has a uniformly continuous minion homomorphism to an affine clone.*

In the first case, $\mathbb{A}$ has relational width $(4, 6)$ by Theorem 2, and in the second case it does not have bounded width by results from [23, 41]. Theorem 23 gives a characterization of bounded width for *all* first-order reducts of unary structures, since this class is closed under taking model-complete cores by Lemma 6.7 in [18].

The two items of Theorem 23 are invariant under expansions of $\mathbb{A}$ by a finite number of constants. Thus, by Proposition 6.8 in [18], one can assume that $\mathbb{A}$ is a first-order expansion of $(\mathbb{N}; V_1, \dots, V_r)$ where $V_1, \dots, V_r$ form a partition of $\mathbb{N}$ in which every set is either a singleton or infinite. Such partitions were called *stabilized partitions* in [18], and we shall also call the structure $(\mathbb{N}; V_1, \dots, V_r)$ a stabilized partition.

Proof of Theorem 23. Let $\mathbb{A}$ as in Theorem 23 be given; by the remark preceding this proof, we may without loss of generality assume that $\mathbb{A}$ is a first-order expansion of a stabilized partition $(\mathbb{N}; V_1, \dots, V_r)$. Assume henceforth that $\mathrm{Pol}(\mathbb{A})^{\mathrm{can}}$ is equationally affine; we show that $\mathrm{Pol}(\mathbb{A})$ has a uniformly continuous minion homomorphism to an affine clone.

If $\mathrm{Pol}(\mathbb{A})$ has a continuous clone homomorphism to $\mathcal{P}$, then we are done. Assume therefore the contrary; then by Lemma 22, $\mathrm{Pol}(\mathbb{A})$ contains for all $k \geq 2$ a k-ary operation whose restriction to V_i is injective for all $1 \leq i \leq r$. In particular, Proposition 21 applies, and thus $\mathrm{Pol}(\mathbb{A})^{\mathrm{can}} \curvearrowright \mathbb{N}/\mathrm{Aut}(\mathbb{A})$ is equationally affine. Let $(S, \sim)$ be a minimal subfactor of $\mathrm{Pol}(\mathbb{A})^{\mathrm{can}}$ such that $\mathrm{Pol}(\mathbb{A})^{\mathrm{can}}$ acts on the $\sim$-classes as an affine clone; the fact that this exists is well-known (see, e.g., Proposition 3.1 in [47]).

Let R be any $\mathrm{Pol}(\mathbb{A})$-invariant cyclic relation with support $\langle S \rangle_{\mathrm{Pol}(\mathbb{A})}$, containing a tuple with components in pairwise distinct $\mathrm{Aut}(\mathbb{A})$-orbits and which intersects at least two $\sim$-classes. By Proposition 18, R either gives rise to a $\mathrm{Pol}(\mathbb{A})$-invariant approximation of $\sim$, or it contains a pseudo-loop with respect to $\mathrm{Aut}(\mathbb{A})$. In the first case, the presence of the tuple required above implies smoothness of the approximation: if $t \in R$ is such a tuple, $c \in S$ appears in t, and $d \in S$ belongs to the same $\mathrm{Aut}(\mathbb{A})$-orbit as c, then there exists an element of $\mathrm{Aut}(\mathbb{A})$ which sends c to d and fixes all other elements of t. Hence, c and d are linked in R, and the entire $\mathrm{Aut}(\mathbb{A})$-orbit of c is contained in a class of the linkedness relation of R. Thus, $\mathrm{Pol}(\mathbb{A})$ admits a uniformly continuous minion homomorphism to an affine clone by Theorem 10.

Hence we may assume that for any R as above the second case holds. We are now going to show that this leads to a contradiction, finishing the proof of Theorem 23. By Lemma 19 applied with any $m \geq 2$ and P the set of m-tuples with entries in pairwise distinct $\mathrm{Aut}(\mathbb{A})$-orbits within $\langle S \rangle_{\mathrm{Pol}(\mathbb{A})}$, we obtain an m-ary function $f \in \mathrm{Pol}(\mathbb{A})$ with the property that the tuple $(f(a_0, \dots, a_{m-1}), \dots, f(a_1, \dots, a_{m-1}, a_0))$ intersects at most one $\sim$-class whenever it has entries in pairwise distinct $\mathrm{Aut}(\mathbb{A})$-orbits, for all $a_0, \dots, a_{m-1} \in S$. Let $(\mathbb{A}, <)$ be the expansion of $\mathbb{A}$ by a linear order that is convex with respect to the partition $V_1, \dots, V_r$ and dense and without endpoints on every infinite set of the partition. The structure $(\mathbb{A}, <)$ can be seen to be a *Ramsey structure*, since $\mathrm{Aut}(\mathbb{A}, <)$ is isomorphic as a permutation group to

the action of the product $\prod_{i=1}^{r} \mathrm{Aut}(V_i;<)$, and each of the groups of the product is either trivial or the automorphism group of a Ramsey structure [37]. By diagonal interpolation we may assume that f is diagonally canonical with respect to $\mathrm{Aut}(\mathbb{A},<)$. Let $a, a' \in A^m$ be so that a_i, a'_i belong to the same orbit with respect to $\mathrm{Aut}(\mathbb{A})$ for all $1 \leq i \leq m$. Then there exists $\alpha \in \mathrm{Aut}(\mathbb{A},<)$ such that $\alpha(a) = \alpha(a')$, and hence $f(a)$ and $f(a')$ lie in the same $\mathrm{Aut}(\mathbb{A})$-orbit by diagonal canonicity; hence f is 1-canonical with respect to $\mathrm{Aut}(\mathbb{A})$. Applying Lemma 20, we obtain a canonical function $g \in \mathrm{Pol}(\mathbb{A})^{\mathrm{can}}$ which acts like f on $\mathbb{N}/\mathrm{Aut}(\mathbb{A})$. The property of f stated above then implies for g that $g(a_0,\dots,a_{m-1}) \sim g(a_1,\dots,a_{m-1},a_0)$ for all $a_0,\dots,a_{m-1} \in S$ such that the values $g(a_0,\dots,a_{m-1}),\dots,g(a_{m-1},a_0,\dots,a_{m-2})$ lie in pairwise distinct $\mathrm{Aut}(\mathbb{A})$-orbits.

By the choice of $(S,\sim)$ we have that $\mathrm{Pol}(\mathbb{A})^{\mathrm{can}}$ acts on $S/\!\sim$ by affine functions over a finite module. We use the symbols $+,\cdot$ for the addition and multiplication in the corresponding ring, and also $+$ for the addition in the module and $\cdot$ for multiplication of elements of the module with elements of the ring. We denote by 1 the multiplicative identity of the ring, by -1 its additive inverse, and identify their powers in the additive group with the non-zero integers. The domain of the module is $S/\!\sim$, and we denote the identity element of its additive group by $[a_0]_\sim$. Pick an arbitrary element $[a_1]_\sim \neq [a_0]_\sim$ from $S/\!\sim$, and let $m \geq 2$ be its order in the additive group of the module, i.e., the minimal positive number such that $m \cdot [a_1]_\sim = [a_0]_\sim$. Let $g \in \mathrm{Pol}(\mathbb{A})^{\mathrm{can}}$ be the m-ary operation obtained in the preceding paragraph. If the values $g(a_0,\dots,a_{m-1}),\dots,g(a_{m-1},a_0,\dots,a_{m-2})$ lie in pairwise distinct $\mathrm{Aut}(\mathbb{A})$-orbits, then computing indices modulo m we have that $g([a_0]_\sim,\dots,[a_{m-1}]_\sim),\dots,g([a_{m-1}]_\sim,\dots,[a_{m+m-1}]_\sim)$ are all equal. If on the other hand they do not, then $g([a_k]_\sim,\dots,[a_{k+m-1}]_\sim) = g([a_{k+j}]_\sim,\dots,[a_{k+j+m-1}]_\sim)$ for some $0 \leq k < m$ and $1 \leq j < m$. Hence, in either case we may assume the latter equation holds. By assumption, g acts on $S/\!\sim$ as an affine map, i.e., as a map of the form $(x_0,\dots,x_{m-1}) \mapsto \sum_{i=0}^{m-1} c_i \cdot x_i$, where $c_0,\dots,c_{m-1}$ are elements of the ring which sum up to 1. We compute (with indices to be read modulo m)

$$\begin{aligned}
[a_0]_\sim &= g([a_{k+j}]_\sim,\dots,[a_{k+j+m-1}]_\sim) \;+\; (-1)\cdot g([a_k]_\sim,\dots,[a_{k+m-1}]_\sim)\\
&= \sum_{i=0}^{m-1} c_i \cdot [a_{k+j+i}]_\sim \;+\; (-1)\cdot \sum_{i=0}^{m-1} c_i \cdot [a_{k+i}]_\sim\\
&= \sum_{i=0}^{m-1} c_i \cdot (k+i+j) \cdot [a_1]_\sim \;+\; (-1)\cdot \sum_{i=0}^{m-1} c_i \cdot (k+i) \cdot [a_1]_\sim\\
&= \left(\sum_{i=0}^{m-1} c_i\right) \cdot j \cdot [a_1]_\sim = j \cdot [a_1]_\sim.
\end{aligned}$$

But $j \cdot [a_1]_\sim \neq [a_0]_\sim$ since the order of $[a_1]_\sim$ equals $m > j$, a contradiction. ◀

5.2 MMSNP

MMSNP is a fragment of existential second order logic that was discovered by Feder and Vardi in their seminal paper [33]. We prefer not to define the syntax of MMSNP, and rather define it using a correspondence between MMSNP sentences and certain coloring problems. We refer to [15] for a precise definition of all the terms employed here.

Let τ be a relational signature, let σ be a unary signature whose relations are called the *colors*, and let $\mathcal{F}$ be a finite set of finite connected $(\tau \cup \sigma)$-structures whose vertices have exactly one color. We call $\mathcal{F}$ a *colored obstruction set* in the following. The problem $\mathrm{FPP}(\mathcal{F})$ takes as input a τ-structure $\mathbb{G}$ and asks whether there exists a $(\tau\cup\sigma)$-expansion $\mathbb{G}^*$ of $\mathbb{G}$ whose

vertices are all colored with exactly one color and such that for every $\mathbb{F} \in \mathcal{F}$, there exists no homomorphism from $\mathbb{F}$ to $\mathbb{G}^*$. The connection between MMSNP and FPP is shown in [42, Corollary 3.7]: every MMSNP sentence Φ is equivalent to a union $\mathrm{FPP}(\mathcal{F}_1) \cup \cdots \cup \mathrm{FPP}(\mathcal{F}_p)$, in the sense that a τ-structure $\mathbb{G}$ satisfies Φ iff it is a yes-instance for one of the problems $\mathrm{FPP}(\mathcal{F}_i)$. We say Φ is *connected* if it is equivalent to a single $\mathrm{FPP}(\mathcal{F})$.

Every set $\mathcal{F}$ as above has a *strong normal form* $\mathcal{G}$ such that $\mathrm{FPP}(\mathcal{F}) = \mathrm{FPP}(\mathcal{G})$. We say $\mathcal{F}$ is *precolored* if for every symbol $M \in \sigma$, there is an associated unary symbol $P_M \in \tau$, and moreover if $\mathcal{F}$ contains for every $M \neq M'$ a 1-element structure whose vertex belongs to P_M and M'. Every $\mathcal{F}$ has a *standard precoloration*, obtained by enlarging τ with the necessary symbols and enlarging $\mathcal{F}$ with the associated obstructions.

It was shown in [15, Definition 4.3] that for every set $\mathcal{F}$ in strong normal form, there exists an ω-categorical τ-structure $\mathbb{A}_\mathcal{F}$ such that for any finite τ-structure $\mathbb{B}$, $\mathbb{B}$ is a yes-instance of $\mathrm{FPP}(\mathcal{F})$ iff there exists an injective homomorphism from $\mathbb{B}$ to $\mathbb{A}_\mathcal{F}$, and such that:

- If $\mathcal{F}$ is precolored, then the orbits of the elements of $\mathbb{A}_\mathcal{F}$ under $\mathrm{Aut}(\mathbb{A}_\mathcal{F})$ correspond to the colors of $\mathcal{F}$ and to the corresponding predicates in τ. In particular, the action of $\mathrm{Pol}(\mathbb{A}_\mathcal{F})^{\mathrm{can}}_1$ on $\mathrm{Aut}(\mathbb{A}_\mathcal{F})$-orbits of elements is idempotent [15, Proposition 7.1].
- Every $f \in \mathrm{Pol}(\mathbb{A}_\mathcal{F})$ locally interpolates an operation $g \in \mathrm{Pol}(\mathbb{A}_\mathcal{F})^{\mathrm{can}}_1$, and there exists a linear order $<$ on $\mathbb{A}_\mathcal{F}$ such that every f diagonally interpolates an operation f' that is diagonally canonical with respect to $\mathrm{Aut}(\mathbb{A}_\mathcal{F}, <)$.

We finally solve the Datalog-rewritability problem for MMSNP and prove that a connected sentence Φ is equivalent to a Datalog-program iff the action of $\mathrm{Pol}(\mathbb{A}_\mathcal{F})^{\mathrm{can}}_1$ on $\mathrm{Aut}(\mathbb{A}_\mathcal{F})$-orbits of elements is not equationally affine, where $\mathcal{F}$ is any strong normal form for Φ.

The following proposition is proved in [15] in the case where $m = 2$. Only small alterations to the proof are needed to prove the more general version, so we omit it.

▶ **Proposition 24.** *Let $\mathcal{F}$ be a precolored obstruction set and in normal form. Let $\mathbb{B}$ have a homomorphism to $\mathbb{A}_\mathcal{F}$ and let $m \geq 1$. There exists an embedding e of $\{1, \ldots, m\} \times \mathbb{B}$, the disjoint union of m copies of $\mathbb{B}$, into $\mathbb{A}_\mathcal{F}$ such that $(e(i_1, a_1), \ldots, e(i_m, a_m))$ and $(e(j_1, b_1), \ldots, e(j_m, b_m))$ are in the same orbit under $\mathrm{Aut}(\mathbb{A}_\mathcal{F}, <)$ provided that:*

- *a_k and b_k are in the same color for all $k \in \{1, \ldots, m\}$*
- *a_k and a_ℓ are in distinct colors for all $k \neq \ell$,*
- *$\{i_1, \ldots, i_m\} = \{j_1, \ldots, j_m\} = \{1, \ldots, m\}$.*

The following proposition shows that for the question of Datalog-rewritability, one can reduce to the precolored case without loss of generality. The same proposition was shown in [15] for the P/NP-complete dichotomy, with $\mathcal{P}$ replacing affine clones in the statement.

▶ **Proposition 25.** *Let $\mathcal{F}$ be a colored obstruction set in strong normal form and let $\mathcal{G}$ be its standard precoloration. There is a uniformly continuous minion homomorphism from $\mathrm{Pol}(\mathbb{A}_\mathcal{G})$ to an affine clone if and only if there is a uniformly continuous minion homomorphism from $\mathrm{Pol}(\mathbb{A}_\mathcal{F})$ to an affine clone.*

Proof. It is shown in [15] that $\mathrm{Pol}(\mathbb{A}_\mathcal{G})$ has a uniformly continuous minion homomorphism to $\mathrm{Pol}(\mathbb{A}_\mathcal{F})$ and that $\mathrm{Pol}(\mathbb{A}_\mathcal{F}, \neq)$ has a uniformly continuous minion homomorphism to $\mathrm{Pol}(\mathbb{A}_\mathcal{G})$. Thus, it suffices to show that if $\mathrm{Pol}(\mathbb{A}_\mathcal{F}, \neq)$ has a uniformly continuous minion homomorphism to an affine clone, then so does $\mathrm{Pol}(\mathbb{A}_\mathcal{F})$.

Let $p \geq 2$ be prime and let R_0 and R_1 be the relations defined by $\{(x, y, z) \in \mathbb{Z}_p \mid x + y + z = i \bmod p\}$ for $i \in \{0, 1\}$. For an arbitrary ω-categorical structure $\mathbb{B}$, it is known that the existence of a uniformly continuous minion homomorphism $\mathrm{Pol}(\mathbb{B})$ to an affine clone is equivalent to the existence of a p such that the relational structure $(\mathbb{Z}_p; R_0, R_1)$ has a *pp-construction* in $\mathbb{B}$.

Suppose that $(\mathbb{Z}_p; R_0, R_1)$ has a pp-construction in $(\mathbb{A}_\mathcal{F}, \neq)$. Thus, there is $n \geq 1$ and pp-formulas $\phi_0(\mathbf{x}, \mathbf{y}, \mathbf{z}), \phi_1(\mathbf{x}, \mathbf{y}, \mathbf{z})$ defining relations S_0, S_1 such that $(A^n; S_0, S_1)$ and $(\mathbb{Z}_p; R_0, R_1)$ are homomorphically equivalent; we take n to be minimal with the property that such pp-formulas exist. Since R_0 and R_1 are totally symmetric relations (i.e., the order of the entries in a tuple does not affect its membership into any of R_0 or R_1), we can assume that S_0 and S_1 are, too, and that the formulas pp-defining them are syntactically invariant under permutation of the block of variables $\mathbf{x}$, $\mathbf{y}$, and $\mathbf{z}$.

We first claim that ϕ_i does not contain any equality atom or any inequality atom $x_j \neq y_j$ for $j \in \{1, \dots, n\}$ (so that by symmetry, also $y_j \neq z_j$ and $x_j \neq z_j$ do not appear). Let $h\colon (\mathbb{Z}_p; R_0, R_1) \to (A^n; S_0, S_1)$ be a homomorphism. Since $(0,0,0) \in R_0$, we have that $(h(0), h(0), h(0))$ satisfies ϕ_0, and therefore the listed inequality atoms cannot appear. The same holds for ϕ_1, by considering $(h(0), h(0), h(1))$ and its permutations.

In order to rule out equalities, we proceed as in [15]. Suppose that ϕ_0 contains $x_i = x_j$ for $i \neq j$. Then the entries i and j of $h(q)$ are equal, for any $q \in \{0, \dots, p-1\}$, since every q belongs to the support of R_0. Thus, one can also add $x_i = x_j$ to ϕ_1, since the structure defined by the modified formula still admits a homomorphism from $(\mathbb{Z}_p; R_0, R_1)$. By existentially quantifying x_j, y_j, z_j in ϕ_0 and ϕ_1, one obtains a pp-construction of some $(A^{n-1}; S_0', S_1')$ that is still homomorphically equivalent to $(\mathbb{Z}_p; R_0, R_1)$, a contradiction to the minimality of n. If ϕ_0 contains $x_i = y_j$ for $j \neq i$, then it also contains $y_j = z_i$ and $z_i = x_j$ since we enforced that ϕ_0 is syntactically symmetric. By transitivity, we obtain that $x_i = x_j$ is implied by ϕ_0 and we are back in the first case. Suppose now that ϕ_0 contains $x_i = y_i$. Then the ith entry of $h(0)$ and $h(q)$ are equal, for all $q \in \{0, \dots, p-1\}$, since for all q there exists r such that $(0, q, r) \in R_0$. Thus we can again reduce n by fixing the ith coordinate.

Let ψ_i be the formula obtained from ϕ_i by removing the possible inequality literals, and let T_i be defined by ψ_i in $\mathbb{A}_\mathcal{F}$. We claim that $(A^n; T_0, T_1)$ and $(A^n; S_0, S_1)$ are homomorphically equivalent, which concludes the proof. Since ϕ_i implies ψ_i, we have that $(A^n; S_0, S_1)$ is a (non-induced) substructure of $(A^n; T_0, T_1)$, and therefore it homomorphically maps to $(A^n; T_0, T_1)$ by the identity map. For the other direction, we prove the result by compactness and show that every finite substructure $\mathbb{B}$ of $(A^n; T_0, T_1)$ has a homomorphism to $(A^n; S_0, S_1)$. Let $\mathbf{b}^1, \dots, \mathbf{b}^m$ be the elements of $\mathbb{B}$. Let $\mathbb{C}$ be the τ-structure over precisely $n \cdot m$ elements $\{c^i_j \mid i, j\}$ corresponding to the entries of $\mathbf{b}^i_j$, whose relations are pulled back from $\mathbb{A}_\mathcal{F}$ under the map $\pi\colon c^i_j \mapsto b^i_j$. Note that no structure from $\mathcal{F}$ has a homomorphism to $\mathbb{C}$ (otherwise, we would obtain a homomorphism to $\mathbb{A}_\mathcal{F}$ by composition with π), and thus $\mathbb{C}$ admits an injective homomorphism g to $\mathbb{A}_\mathcal{F}$. We claim that if $(\mathbf{b}^i, \mathbf{b}^j, \mathbf{b}^k) \in T_0$ then $(g(\mathbf{c}^i), g(\mathbf{c}^j), g(\mathbf{c}^k)) \in S_0$. Indeed, suppose that $(\mathbf{b}^i, \mathbf{b}^j, \mathbf{b}^k)$ satisfies ψ_0. Then by construction $(g(\mathbf{c}^i), g(\mathbf{c}^j), g(\mathbf{c}^k))$ satisfies ψ_0. Moreover, by injectivity of g, we have $g(c^i_r) \neq g(c^j_s)$ as long as $i \neq j$ or $r \neq s$. Consider any inequality atom in ϕ_0. By our first claim, it is not of the form $x_r \neq y_r$, and therefore it is satisfied by $(g(\mathbf{c}^i), g(\mathbf{c}^j), g(\mathbf{c}^k))$. Thus, $(g(\mathbf{c}^i), g(\mathbf{c}^j), g(\mathbf{c}^k))$ satisfies ϕ_0. The same reasoning for ϕ_1 shows that g induces a homomorphism $\mathbb{B} \to (A^n; S_0, S_1)$ by mapping $\mathbf{b}^i$ to $g(\mathbf{c}^i)$. ◀

▶ **Lemma 26.** *Let $(S, \sim)$ be a subfactor of $\mathrm{Pol}(\mathbb{A}_\mathcal{F})^{(\mathrm{can})}_1$ with $\mathrm{Aut}(\mathbb{A}_\mathcal{F})$-invariant $\sim$-classes. Let $m \geq 2$, and let $f \in \mathrm{Pol}(\mathbb{A}_\mathcal{F})$ be as in Lemma 19: for all $a_1, \dots, a_m \in A_\mathcal{F}$ we have that if the entries of the tuple $(f(a_1, \dots, a_m), f(a_2, \dots, a_m, a_1), \dots, f(a_m, a_1, \dots, a_{m-1}))$ all belong to different colors, then it intersects at most one $\sim$-class. Let $O_0, \dots, O_{m-1} \in S$ be pairwise distinct orbits under $\mathrm{Aut}(\mathbb{A}_\mathcal{F})$. There exists $g \in \mathrm{Pol}(\mathbb{A}_\mathcal{F})^{(\mathrm{can})}_1$ that is locally interpolated by f and that satisfies*

$$g(O_k, \dots, O_{k+m-1}) \sim g(O_{j+k}, \dots, O_{j+k+m-1}) \tag{$\star$}$$

for some $0 \leq k < m$ and $1 \leq j < m$.

Proof. Recall that the expansion of $\mathbb{A}_\mathcal{F}$ by a generic linear order is a Ramsey structure [15]. Thus, f diagonally interpolates a function $g \in \mathrm{Pol}(\mathbb{A}_\mathcal{F})$ with the same properties and which is diagonally canonical with respect to $\mathrm{Aut}(\mathbb{A}_\mathcal{F}, <)$, and without loss of generality we can therefore assume that f is itself diagonally canonical.

Let $\mathbb{B} := \{0, \dots, m-1\} \times \mathbb{A}_\mathcal{F}$ be the disjoint union of m copies of $\mathbb{A}_\mathcal{F}$ and let e be an embedding of $\{0, \dots, m-1\} \times \mathbb{B}$ into $\mathbb{A}_\Phi$ with the properties stated in Proposition 24. Let $e_i(x) := e(i, x)$, which is a self-embedding of $\mathbb{A}_\mathcal{F}$. Consider $f'(x_0, \dots, x_{m-1}) := f(e_0 x_0, \dots, e_{m-1} x_{m-1})$, and note that f' is 1-canonical when restricted to m-tuples where all entries are in pairwise distinct orbits. Let g be obtained by canonising f' with respect to $\mathrm{Aut}(\mathbb{A}_\mathcal{F}, <)$. In particular $g \in \mathrm{Pol}(\mathbb{A}_\mathcal{F})^{\mathrm{can}}_1$ and $g(O_k, \dots, O_{k+m-1})$ and $f'(O_k, \dots, O_{k+m-1})$ are in S and $\sim$-equivalent for all k.

As in the proof of Theorem 23, there are suitable $0 \leq k < m$ and $1 \leq j < m$ such that

$$f(e_k O_k, \dots, e_{k+m-1} O_{k+m-1}) \sim f(e_{k+j} O_{k+j}, \dots, e_{k+j+m-1} O_{j+k+m-1})$$

holds, where indices are computed modulo m. Then

$$\begin{aligned} g(O_k, \dots, O_{k+m-1}) &\sim f(e_0 O_k, \dots, e_{m-1} O_{k+m-1}) \\ &\sim f(e_k O_k, \dots, e_{k+m-1} O_{k+m-1}) && (\star) \\ &\sim f(e_{k+j} O_{k+j}, \dots, e_{k+j+m-1} O_{k+j+m-1}) \\ &\sim f(e_0 O_{k+j}, \dots, e_{m-1} O_{k+j+m-1}) && (\star) \\ &\sim g(O_{k+j}, \dots, O_{k+j+m-1}), \end{aligned}$$

where the equivalences marked $(\star)$ hold by the fact that f is diagonally canonical with respect to $\mathrm{Aut}(\mathbb{A}_\mathcal{F}, <)$ and by Proposition 24. ◀

The following theorem gives a characterization of Datalog-rewritability in terms of precolored normal forms. The proof is similar to that of Theorem 23.

▶ **Theorem 27.** *Let Φ be a connected MMSNP τ-sentence, let $\mathcal{F}$ be an equivalent colored obstruction set and suppose that $\mathcal{F}$ is precolored and in strong normal form. The following are equivalent:*

1. *$\neg\Phi$ is equivalent to a Datalog program;*
2. *$\mathrm{Pol}(\mathbb{A}_\mathcal{F})$ does not have a uniformly continuous minion homomorphism to an affine clone;*
3. *The action of $\mathrm{Pol}(\mathbb{A}_\mathcal{F})^{\mathrm{can}}_1$ on $\mathrm{Aut}(\mathbb{A}_\mathcal{F})$-orbits of elements is not equationally affine;*
4. *$\mathbb{A}_\mathcal{F}$ has relational width $(k, \max(k+1, \ell))$, where k and ℓ are such that $\mathbb{A}_\mathcal{F}$ is k-homogeneous ℓ-bounded.*

Proof. (1) implies (2) by general principles [41, 8].

(2) implies (3). We do the proof by contraposition. The proof is essentially the same as in the case of reducts of unary structures (Theorem 23). Suppose that $\mathrm{Pol}(\mathbb{A}_\mathcal{F})^{\mathrm{can}}_1 \curvearrowright \mathbb{A}_\mathcal{F}/\mathrm{Aut}(\mathbb{A}_\mathcal{F})$ is equationally affine and let $(S, \sim)$ be a minimal module for this action.

Let $m \geq 2$ and let R be an m-ary cyclic relation invariant under $\mathrm{Pol}(\mathbb{A}_\mathcal{F})$ and containing a tuple $(a_1, \dots, a_m)$ whose entries are pairwise distinct. By Proposition 18, either the linkedness congruence of R defines an approximation of $\sim$, or R contains a pseudoloop modulo $\mathrm{Aut}(\mathbb{A}_\mathcal{F})$. In the first case, the approximation is smooth and we obtain a uniformly continuous minion homomorphism from $\mathrm{Pol}(\mathbb{A}_\mathcal{F})$ to a clone of affine maps. Any such clone admits a uniformly continuous minion homomorphism to $\mathbb{Z}_p$ for some p, and by composition this gives us a uniformly continuous minion homomorphism $\mathrm{Pol}(\mathbb{A}_\mathcal{F}) \to \mathbb{Z}_p$.

So let us assume that for all $m \geq 2$, every such relation R contains a pseudoloop. By applying Lemma 19, we obtain a polymorphism f such that for all $a_1, \dots, a_m$, if $f(a_1, \dots, a_m), \dots, f(a_m, a_0, \dots, a_{m-1})$ are pairwise distinct, then they intersect at most one $\sim$-class. As in the proof of Theorem 23, pick an arbitrary $a_1 \in S$ such that $[a_1]_\sim$ is not the zero element of the module $S/\sim$. Let $m \geq 2$ be its order, and let O_i be the orbit of $i \cdot [a_1]_\sim$, for $i \in \{0, 1, \dots, m-1\}$. By Lemma 26, we obtain $g \in \mathrm{Pol}(\mathbb{A}_\mathcal{F})^{\mathrm{can}}_1$ such that

$$g(O_k, \dots, O_{k+m-1}) \sim g(O_{j+k}, \dots, O_{j+k+m-1})$$

for some $k \in \{0, \dots, m-1\}$ and $j \in \{1, \dots, m-1\}$. The same computation as in Theorem 23 then gives a contradiction and concludes the proof.

(3) implies (4). First, note that $\mathbb{A}_\mathcal{F}$ is infinite, and therefore $k \geq 2$. Let $\mathcal{I}$ be a non-trivial $(k, \max(k+1, \ell))$-minimal instance of $\mathbb{A}_\mathcal{F}$. Let $\mathcal{G}$ be $\mathrm{Aut}(\mathbb{A}_\mathcal{F})$. Consider the instance $\mathcal{I}_{\mathcal{G},1}$ as in Definition 11. Thus, the variables of $\mathcal{I}_{\mathcal{G},1}$ are the same as the variables of $\mathcal{I}$ (up to the natural bijection between $\mathcal{V}$ and $\binom{\mathcal{V}}{1}$) and the values for the variables are taken from the set of colors of $\mathcal{F}$. By Lemma 12, $\mathcal{I}_{\mathcal{G},1}$ is $(2,3)$-minimal, and from (3) and Lemma 14 we obtain that it has a solution h. Note that we cannot use Lemma 13 to obtain a solution to $\mathcal{I}$, since we only considered $\mathcal{I}_{\mathcal{G},1}$. Let $\mathbb{B}$ be the τ-structure described by $\mathcal{I}$ (i.e., $\mathbb{B}$ is the *canonical database* of $\mathcal{I}$). Let $\mathbb{B}^*$ be the $(\tau \cup \sigma)$-expansion of $\mathbb{B}$ obtained by coloring the vertices of $\mathbb{B}$ according to h. Since $\mathcal{I}$ is (k, ℓ)-minimal, it can be seen that $\mathbb{B}^*$ does not contain any homomorphic copy of $\mathbb{F} \in \mathcal{F}$, so that $\mathbb{B}$ admits a homomorphism to $\mathbb{A}_\mathcal{F}$, i.e., $\mathcal{I}$ has a solution in $\mathbb{A}_\mathcal{F}$.

(4) implies (1). Trivial. ◀

Combining Proposition 25, Theorem 27, and known facts about MMSNP and normal forms [15], this allows us to obtain Theorem 1 from the introduction.

▶ **Theorem 1.** *The Datalog-rewritability problem for MMSNP is decidable, and is 2NExpTime-complete.*

Proof. Let Φ be an MMSNP sentence, which is equivalent to a disjunction $\Phi_1 \vee \dots \vee \Phi_p$ of connected MMSNP sentences [15, Proposition 3.2]. Moreover, if p is minimal then $\neg\Phi$ is equivalent to a Datalog program iff every $\neg\Phi_i$ is equivalent to a Datalog program (see, e.g., Proposition 3.3 in [15], for a proof of a similar fact).

By Theorem 4.3 in [15], one can compute for every Φ_i a coloured obstruction set $\mathcal{F}_i$ that is in strong normal form. Let $\mathcal{G}_i$ be the standard precoloration of $\mathcal{F}_i$. By Proposition 25, one has a uniformly continuous minion homomorphism from $\mathrm{Pol}(\mathbb{A}_{\mathcal{G}_i})$ to an affine clone iff one has one from $\mathrm{Pol}(\mathbb{A}_{\mathcal{F}_i})$ to an affine clone. Then, by Theorem 27, we get that deciding Datalog-rewritability for $\mathcal{G}_i$ is equivalent to deciding whether $\mathrm{Pol}(\mathbb{A}_{\mathcal{G}_i})^{\mathrm{can}}_1 \curvearrowright \mathbb{A}_{\mathcal{G}_i}/\mathrm{Aut}(\mathbb{A}_{\mathcal{G}_i})$ is equationally non-affine, which is known to be decidable in polynomial time since $\mathrm{Pol}(\mathbb{A}_{\mathcal{G}_i})^{\mathrm{can}}_1 \curvearrowright \mathbb{A}_{\mathcal{G}_i}/\mathrm{Aut}(\mathbb{A}_{\mathcal{G}_i})$ is idempotent.

The computation of a strong normal form is costly and can be performed in 2-ExpSpace. In order to obtain a 2NExpTime-algorithm, we rather compute a normal form $\mathcal{F}_i$ for Φ_i (by Lemma 3.1 in [15]), which can be done in doubly exponential-time. The consequence of not working with a strong normal form is that the clone $\mathrm{Pol}(\mathbb{A}_{\mathcal{F}_i})^{\mathrm{can}}_1 \curvearrowright \mathbb{A}_{\mathcal{F}_i}/\mathrm{Aut}(\mathbb{A}_{\mathcal{F}_i})$ is not a core; its core is the action considered for the strong normal form. Deciding whether such a clone admits a minion homomorphism to an affine clone is in NP [31, Corollary 6.8]. We obtain overall a 2NExpTime algorithm. The complexity lower bound is Theorem 18 in [27]. ◀

Abstract

This paper introduces a new automata-theoretic class of string-to-string functions with polynomial growth. Several equivalent definitions are provided: a machine model which is a restricted variant of pebble transducers, and a few inductive definitions that close the class of regular functions under certain operations. Our motivation for studying this class comes from another characterization, which we merely mention here but prove elsewhere, based on a λ-calculus with a linear type system.

As their name suggests, these *comparison-free polyregular functions* form a subclass of polyregular functions; we prove that the inclusion is strict. We also show that they are incomparable with HDT0L transductions, closed under usual function composition – but not under a certain "map" combinator – and satisfy a comparison-free version of the pebble minimization theorem.

On the broader topic of polynomial growth transductions, we also consider the recently introduced layered streaming string transducers (SSTs), or equivalently k-marble transducers. We prove that a function can be obtained by composing such transducers together if and only if it is polyregular, and that k-layered SSTs (or k-marble transducers) are closed under "map" and equivalent to a corresponding notion of $(k+1)$-layered HDT0L systems.

2012 ACM Subject Classification Theory of computation → Transducers

Keywords and phrases pebble transducers, HDT0L systems, polyregular functions

1 Introduction

The theory of transducers (as described in the surveys [21, 29]) has traditionally dealt with devices that take as input strings of length n and output strings of length $O(n)$. However, several recent works have investigated function classes going beyond linear growth. We review three classes in this landscape below.

- *Polyregular functions* (§2.3) are thus named because they have (at most) polynomial growth and include regular functions (§2.2) (the most expressive of the traditional string-to-string transduction classes). They were defined in 2018 [4] by four equivalent computational models, one of which – the *pebble transducers* – is the specialization to strings of a tree transducer model that existed previously in the literature [28] (this specialization had been investigated earlier in [17, 14]). A subsequent work [8] gave a logical characterization based on Monadic Second-Order logic (MSO). They enjoy two nice properties:

© Lê Thành Dũng (Tito) Nguyễn, Camille Noûs, and Cécilia Pradic;
licensed under Creative Commons License CC-BY 4.0

  - *preservation of regular languages (by preimage)*: if $f : \Gamma^* \to \Sigma^*$ is polyregular and $L \subseteq \Sigma^*$ is regular, then $f^{-1}(L) \subseteq \Gamma^*$ is regular;
  - *closure under function composition*: if $f : \Gamma^* \to \Delta^*$ and $g : \Delta^* \to \Sigma^*$ are both polyregular, then so is $g \circ f : \Gamma^* \to \Sigma^*$.
- *HDT0L transductions* (§2.1) form another superclass of regular functions, whose output size may be at most exponential in the input size. They are older than polyregular functions, and we shall discuss their history in Section 2.1; suffice to say for now, they also admit various equivalent characterizations scattered in several papers [20, 22, 13]. These functions preserve regular languages by preimage, but are *not* closed under composition (the growth rate of a composition of HDT0L transductions may be a tower of exponentials).
- Very recently, the polynomially bounded HDT0L transductions (§2.3) have been characterized using two transducer models [13]. One of them, the *k-marble transducers* (where $k \in \mathbb{N}$ depends on the function to be computed), is obtained by putting a syntactic constraint on the model of *(unbounded) marble transducers* [13] which computes HDT0L transductions. But it can also be seen as a restricted variant of pebble transducers; it follows (although this is not explicitly stated in [13]) that a HDT0L transduction has polynomial growth if and only if it is polyregular. Moreover, as claimed in [13, Section 6], the functions computed by k-marble transducers are not closed under composition either, and thus form a strict subclass of polyregular functions.

A new subclass of polyregular functions. In this paper, we start by proving a few results on the above classes (Section 3). For instance, we supply a proof for the aforementioned claim of [13, Section 6], and show that the polyregular functions are exactly those computable by compositions of k-marble transducers. Those complements are not particularly difficult nor surprising and are included mostly for the sake of giving a complete picture.

But our main contribution is the introduction of a new class, giving its title to the paper; as we show, it admits three equivalent definitions:

- two ways to inductively generate the class (Sections 4 and 6 respectively):
  - by closing regular functions under a certain "composition by substitution" operation;
  - by combining regular functions and a certain kind of *squaring* functions (less powerful than the squaring plus underlining functions used to characterize general poyregular functions) with usual function composition;
- a restriction on pebble transducers (Section 5) – we disallow comparing the positions of a transducer's multiple reading heads, hence the name *comparison-free polyregular functions* (henceforth abbreviated as *cfp*).

Properties. By the third definition above, comparison-free polyregular functions are indeed polyregular, while the second one implies that our new class contains the regular functions and is closed under composition. (In fact, in the proof that our first definition is equivalent to the second one, most of the work goes into showing that the former enjoys closure under composition.) We rule out inclusions involving the other classes that we mentioned by proving some *separation results* (Section 8): there exist

- comparison-free polyregular functions that are not HDT0L (we take one example from [13]),
- and polynomially bounded HDT0L transductions which are not comparison-free:
  - one of our examples follows from a precise characterization of cfp functions over unary input alphabets (extending a known result for regular functions with unary inputs [10]), which we give in Section 9;
  - another example shows that unlike (poly)regular functions, cfp functions are *not* closed under a certain counterpart of the "map" operation in functional programming.

We summarize the inclusions and separations between classes that we get in Figure 1.

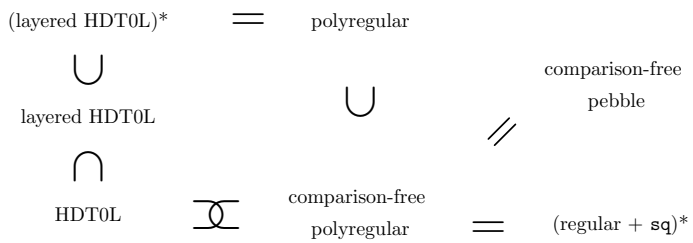

Figure 1 Summary of the known relationships between superlinear transduction classes, taking our results into account. Inclusions $\subset$ are strict, and $\between$ means that there is no inclusion either way. Finally C^* denotes the composition closure of the class C.

Finally, we show in Section 7 that the number of pebbles required to compute a function using a comparison-free transducer is related to its growth rate. The analogous result for pebble transducers was proved recently, with a whole paper dedicated to it [25]; we adapt its arguments to our setting, resulting in our longest and most technical proof. There is a similar property for k-marble transducers [13], but it is proved using very different tools.

Motivations. Although this is the first proper paper to introduce comparison-free pebble transducers, we were told that they had already been considered by several colleagues (Mikołaj Bojańczyk, personal communication). But in fact, the starting point in our investigation was a characterization of regular functions using a linear λ-calculus (in the sense of linear logic) that we had previously obtained [30]; this was part of a research programme relating automata and functional programming that we initiated in [31]. As we reported in a previous version of the present paper (version 1 of the full paper archived on HAL), by tweaking a parameter in this characterization, one gets the cfp functions instead; we initially defined the latter using composition by substitution, and only later realized the connection with pebble transducers. One interesting feature of the λ-calculus characterization is that it is trivially closed under composition, and this led us to take inspiration from the category-theoretic machinery that we used in [30] for our standalone composition proof in this paper.

2 Preliminaries

Notations. The set of natural numbers is $\mathbb{N} = \{0, 1, \dots\}$. We write $|w|$ for the length of a string $w \in \Sigma^*$; for $\Pi \subseteq \Sigma$, we write $|s|_\Pi$ for the number of occurrences of letters from Π in w; and for $c \in \Sigma$, we abbreviate $|w|_{\{c\}}$ as $|w|_c$. The i-th letter of $w \in \Sigma^*$ is denoted by either w_i or $w[i]$ (for $i \in \{1, \dots, |w|\}$). Given monoids M and N, $\mathrm{Hom}(M, N)$ is the set of monoid morphisms. We write ε for the empty word and $\underline{\Sigma} = \{\underline{a} \mid a \in \Sigma\}$ for a disjoint copy of the alphabet Σ made of "underlined" letters.

2.1 HDT0L transductions and streaming string transducers

L-systems were originally introduced by Lindenmayer [26] in the 1960s as a way to generate formal languages, with motivations from biology. While this language-centric view is still predominant, the idea of considering variants of L-systems as specifications for string-to-string functions – whose range are the corresponding languages – seems to be old. For instance, in a paper from 1980 [18], one can find (multi-valued) string functions defined by ET0L systems.

More recently, Ferté, Marin and Sénizergues [20] provided alternative characterizations[1] (by catenative recurrent equations and higher-order pushdown transducers of level 2) of the string-to-string functions that *HDT0L systems* can express – what we call here *HDT0L transductions*. Later work by Filiot and Reynier [22] and then by Douéneau-Tabot, Filiot and Gastin [13] – that does not build on [36, 20] – proved the equivalence with, respectively, copyful SSTs (Definition 2.3) and unbounded marble transducers (not presented here).

▶ **Definition 2.1** (following [22]). *A* HDT0L system *consists of:*

- *an input alphabet* Γ*, an output alphabet* Σ*, and a working alphabet* Δ *(all* finite*);*
- *an initial word* $d \in \Delta^*$*;*
- *for each* $c \in \Gamma$*, a* monoid morphism $h_c \in \mathrm{Hom}(\Delta^*, \Delta^*)$*;*
- *a final morphism* $h' \in \mathrm{Hom}(\Delta^*, \Sigma^*)$*.*

It defines the transduction taking $w = w_1 \dots w_n \in \Gamma^*$ *to* $h' \circ h_{w_1} \circ \dots \circ h_{w_n}(d) \in \Sigma^*$*.*

(The definition of HDT0L systems given in [36, 20] makes slightly different choices of presentation[2].) To define the equivalent model of copyful streaming string transducers, we must first introduce the notion of register assignment.

▶ **Definition 2.2.** *Fix a finite alphabet* Σ*. Let* R *and* S *be two finite sets* disjoint from Σ*; we shall consider their elements to be "register variables".*

For any word $\omega \in (\Sigma \cup R)^*$*, we write* $\omega^\dagger : (\Sigma^*)^R \to \Sigma^*$ *for the map that sends* $(u_r)_{r\in R}$ *to* ω *in which every occurrence of a register variable* $r \in R$ *is replaced by* u_r *– formally, we apply to* ω *the morphism* $(\Sigma \cup R)^* \to \Sigma^*$ *that maps* $c \in \Sigma$ *to itself and* $r \in R$ *to* u_r*.*

A register assignment[3] α *from* R *to* S *(over* Σ*) is a map* $\alpha : S \to (\Sigma \cup R)^*$*. It induces the action* $\alpha^\dagger : \vec{u} \in (\Sigma^*)^R \mapsto (\alpha(s)^\dagger(\vec{u}))_{s\in S} \in (\Sigma^*)^S$ *(which indeed goes "from* R *to* S*").*

▶ **Definition 2.3** ([22]). *A (deterministic copyful)* streaming string transducer *(SST) with input alphabet* Γ *and output alphabet* Σ *is a tuple* $\mathcal{T} = (Q, q_0, R, \delta, \vec{u}_I, F)$ *where*

- Q *is a finite set of* states *and* $q_0 \in Q$ *is the* initial state*;*
- R *is a finite set of* register variables*, that we require to be* disjoint from Σ*;*
- $\delta : Q \times \Gamma \to Q \times (R \to (\Sigma \cup R)^*)$ *is the* transition function *– we abbreviate* $\delta_{\mathrm{st}} = \pi_1 \circ \delta$ *and* $\delta_{\mathrm{reg}} = \pi_2 \circ \delta$*, where* π_i *is the projection from* $X_1 \times X_2$ *to its* i*-th component* X_i*;*
- $\vec{u}_I \in (\Sigma^*)^R$ *describes the* initial register values*;*
- $F : Q \to (\Sigma \cup R)^*$ *describes how to recombine the final values of the registers, depending on the final state, to produce the output.*

The function $\Gamma^* \to \Sigma^*$ *computed by* $\mathcal{T}$ *is*

$$w_1 \dots w_n \quad \mapsto \quad F(q_n)^\dagger \circ \delta_{\mathrm{reg}}(q_{n-1}, w_n)^\dagger \circ \dots \circ \delta_{\mathrm{reg}}(q_0, w_1)^\dagger(\vec{u}_I)$$

where the sequence of states $(q_i)_{0\le i\le n}$ *(sometimes called the* run *of the transducer over the input word) is inductively defined, starting from the fixed initial state* q_0*, by* $q_i = \delta_{\mathrm{st}}(q_{i-1}, w_i)$*.*

---

[1] Those characterizations had previously been announced in an invited paper by Sénizergues [36]. Some other results announced in [36] are proved in [9].

[2] The family $(h_c)_{c\in\Gamma}$ is presented as a morphism $H : \Gamma^* \to \mathrm{Hom}(\Delta^*, \Delta^*)$ (whose codomain is indeed a monoid for function composition). And an initial *letter* is used instead of an initial word; this is of no consequence regarding the functions that can be expressed (proof sketch: consider $\Delta' = \Delta \cup \{x\}$ with a new letter $x \notin \Delta$, take x as the initial letter and let $h_c(x) = h_c(w)$, $h'(x) = h'(w)$).

[3] Some papers e.g. [11, 13] call register assignments *substitutions*. We avoid this name since it differs from its meaning in the context of our "composition by substitution" operation.

▶ **Example 2.4.** Let $\Sigma = \Gamma \cup \underline{\Gamma}$. We consider a SST $\mathcal{T}$ with $Q = \{q\}$, $R = \{X, Y\}$ and

$$\vec{u}_I = (\varepsilon)_{r\in R} \qquad F(q) = Y \qquad \forall c \in \Gamma,\ \delta(q, c) = (q,\ (X \mapsto cX,\ Y \mapsto \underline{c}XY))$$

If we write (v, w) for the family $(u_r)_{r\in R}$ with $u_X = v$ and $u_Y = w$, then the action of the register assignments may be described as $(X \mapsto cX,\ Y \mapsto \underline{c}XY)^\dagger(v, w) = (c \cdot v,\ \underline{c} \cdot v \cdot w)$.

Let $\mathtt{1}, \mathtt{2}, \mathtt{3}, \mathtt{4} \in \Gamma$. After reading $\mathtt{1234} \in \Gamma^*$, the values stored in the registers of $\mathcal{T}$ are

$$(X \mapsto \mathtt{4}X,\ Y \mapsto \underline{\mathtt{4}}XY)^\dagger \circ \ldots \circ (X \mapsto \mathtt{1}X,\ Y \mapsto \underline{\mathtt{1}}XY)^\dagger(\varepsilon, \varepsilon) = (\mathtt{4321}, \underline{\mathtt{4}}\mathtt{321}\underline{\mathtt{3}}\mathtt{21}\underline{\mathtt{2}}\mathtt{11})$$

Since $F(q) = Y$, the function defined by $\mathcal{T}$ maps $\mathtt{1234}$ to $\underline{\mathtt{4}}\mathtt{321}\underline{\mathtt{3}}\mathtt{21}\underline{\mathtt{2}}\mathtt{11} \in (\Gamma \cup \underline{\Gamma})^* = \Sigma^*$.

This gives us an example of HDT0L transduction $\Gamma^* \to (\Gamma \cup \underline{\Gamma})^*$, since:

▶ **Theorem 2.5** ([22]). *A function $\Gamma^* \to \Sigma^*$ can be computed by a copyful SST if and only if it can be specified by a HDT0L system.*

▶ Remark 2.6. As observed in [22, Lemma 3.3], there is a natural translation from HDT0L systems to SSTs whose range is composed precisely of the *single-state* SSTs whose transitions and final output function *do not access the letters of their output alphabet* – those are called *simple SSTs* in [13, §5.1]. This involves a kind of reversal: the initial register values correspond to the final morphisms, while the final output function corresponds to the initial word. Thus, Theorem 2.5 is essentially a state elimination result; a direct translation from SSTs to single-state SSTs has also been given by Benedikt et al. [2, Proposition 8]. However, it does *not* preserve the subclass of *copyless* SSTs (this would contradict Proposition 3.7).

The lookahead elimination theorem for macro tree transducers [19, Theorem 4.21] arguably generalizes this to trees. Indeed, while those transducers are generally presented as a top-down model, their formal definition can also be read as bottom-up register tree transducers in the style of [7, §4], and top-down lookahead corresponds to bottom-up states.

2.2 Regular functions

▶ **Definition 2.7** (Alur and Černý [1]). *A register assignment $\alpha : S \to (\Sigma \cup R)^*$ from R to S is said to be* copyless *when each $r \in R$* occurs at most once among all the strings $\alpha(s)$ for $s \in S$, *i.e. it does not occur at least twice in some $\alpha(s)$, nor at least once in $\alpha(s)$ and at least once in $\alpha(s')$ for some $s \neq s'$. (This restriction does not apply to the letters in Σ.)*

A streaming string transducer is copyless *if all the assignments in the image of its transition function are copyless. In this paper, we take computability by copyless SSTs as the definition of* regular functions *(but see Theorem 5.3 for another standard definition).*

▶ Remark 2.8. Thanks to Theorem 2.5, every regular function is a HDT0L transduction.

▶ Remark 2.9. The SST of Example 2.4 is *not* copyless: in a transition $\alpha = \delta_{\mathrm{reg}}(q, c)$, the register X appears twice, once in $\alpha(X) = cX$ and once in $\alpha(Y) = \underline{c}XY$; in other words, its value is *duplicated* by the action $\alpha^\dagger$. In fact, it computes a function whose output size is quadratic in the input size, while regular functions have linearly bounded output.

▶ **Example 2.10** (Iterated reverse [4, p. 1]). The following single-state SST is copyless:

$$\Gamma = \Sigma \text{ with } \# \in \Sigma \qquad Q = \{q\} \qquad R = \{X, Y\} \qquad \vec{u}_I = (\varepsilon)_{r\in R} \qquad F(q) = XY$$

$$\delta(q, \#) = (q,\ (X \mapsto XY\#,\ Y \mapsto \varepsilon)) \qquad \forall c \in \Sigma \setminus \{\#\},\ \delta(q, c) = (q,\ (X \mapsto X,\ Y \mapsto cY))$$

For $u_1, \ldots, u_n \in (\Sigma \setminus \{\#\})^*$, it maps $u_1\# \ldots \#u_n$ to $\mathtt{reverse}(u_1)\# \ldots \#\mathtt{reverse}(u_n)$.

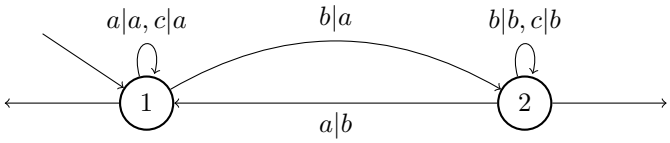

Figure 2 An example of sequential transducer.

The concrete SSTs (copyless or not) that we have seen for now are all single-state. As a source of stateful copyless SSTs, one can consider the translations of *sequential transducers*. These are usual finite automata, whose transitions additionally produce a word catenated to the end of the would-be output function. For instance, the one in Figure 2 computes the function $\{a, b, c\}^* \to \{a, b\}^*$ that replaces each c in its input by the closest non-c letter on its left (or a if no such letter exists). We do not give a detailed definition (which can be found e.g. in [33, Chapter V]) here, but for our purpose, it suffices to observe any sequential transducer can be translated into a copyless SST with the same set of states and a single register.

2.3 Polynomial growth transductions

Next, we recall one way to define Bojańczyk's *polyregular functions* [4].

▶ **Definition 2.11** ([4]). *The class of* polyregular functions *is the smallest class of string-to-string functions closed under composition containing:*

- *the functions computed by sequential transducers (for instance, the one of Figure 2);*
- *the* iterated reverse *function of Example 2.10, over any finite alphabet containing #;*
- *the* squaring with underlining *functions* $\texttt{squaring}_\Gamma : \Gamma^* \to (\Gamma \cup \underline{\Gamma})^*$*, for any finite* Γ*, illustrated by* $\texttt{squaring}_\Gamma(1234) = \underline{1}234\underline{12}341\underline{23}41\underline{234}$.

As mentioned in the introduction, the intersection between the above class and HDT0L transductions has been recently characterized by Douéneau-Tabot et al. [13].

▶ **Theorem 2.12** ([13]). *Let* $f : \Gamma^* \to \Sigma^*$*. The following conditions are equivalent:*

- *f is both a polyregular function and a HDT0L transduction;*
- *f is a HDT0L transduction and has at most polynomial growth: $f(|w|) = |w|^{O(1)}$;*
- *there exists $k \in \mathbb{N}$ such that f is computed by some k-*layered SST*, defined below.*

(Another equivalent model, the *k-marble transducers*, was mentioned in the introduction, but we will not use it in the rest of the paper.) Those k-layered SST propose a compromise between copyful and copyless SSTs: duplication is controlled, but not outright forbidden.

▶ **Definition 2.13** ([13]). *A register assignment $\alpha : R \to (\Sigma \cup R)^*$ is* k-layered *(for $k \in \mathbb{N}$) with respect to a partition $R = R_0 \sqcup \ldots \sqcup R_k$ when for $0 \leq i \leq k$,*

- *for $r \in R_i$, we have $\alpha(r) \in (\Sigma \cup R_0 \cup \ldots \cup R_i)^*$;*
- *each register variable in R_i appears at most once among all the $\alpha(r)$ for $r \in R_i$ (however, those from $R_0 \sqcup \ldots \sqcup R_{i-1}$ may appear an arbitrary number of times).*

A SST is k-layered *if its registers can be partitioned in such a way that all assignments in the transitions of the SST are k-layered.*

Beware: with this definition, the registers of a k-layered SST are actually divided into $k + 1$ layers, not k. In particular, a SST is copyless if and only if it is 0-layered. (We chose this convention for backwards compatibility with [13]; see also Remark 5.4.)

For instance, the transducer of Example 2.4 is 1-layered with $R_0 = \{X\}$ and $R_1 = \{Y\}$. There also exist register assignments that cannot be made k-layered no matter the choice of partition, such as $X \mapsto XX$. Using such assignments, one can indeed build SSTs that compute functions f such that e.g. $|f(w)| = 2^{|w|}$.

▶ Remark 2.14. There is arguably an old precursor to this recent characterization of HDT0L transductions with polynomial growth by a syntactic "layering" condition: Schützenberger's theorem on polynomially bounded $\mathbb{Z}$-rational series, which dates back to the 1960s (see for instance [3, Chapter 9, Section 2] – the preface of the same book describes this theorem as "one of the most difficult results in the area"). Let us give a brief exposition.

A *$\mathbb{Z}$-rational series* $f : \Sigma^* \to \mathbb{Z}$ is a function of the form $f : w \in \Sigma^* \mapsto X^T \cdot \Phi(w) \cdot Y$ where $X, Y \in \mathbb{Z}^R$ and Φ is a morphism from Σ^* to the multiplicative monoid of R-indexed square matrices over $\mathbb{Z}$, where R is a finite set. This data (X, Φ, Y) has a clear interpretation as a "simple SST" (cf. Remark 2.6) with register set R, whose register values are integers rather than strings. Schützenberger's theorem says that any $\mathbb{Z}$-rational series f with polynomial growth (i.e. $|f(w)| = |w|^{O(1)}$ where $|\cdot|$ on the left is the absolute value) can be written as $f : w \mapsto X^T \cdot \Phi(w) \cdot Y$ where

(i) the image of Φ has a block triangular structure;
(ii) the projection of this image on each diagonal block is a finite monoid.

The first item gives us a partition of the register into layers where each layer "depends" only on the ones below them. The finiteness condition in the second item is equivalent to having bounded coefficients, which means that the register assignments within each layer are *bounded-copy*, while in a layered SST, they would be *copyless* instead – but bounded-copy SSTs are known to be equivalent to copyless SSTs (see e.g. [11]). The theorem also states a relationship between the number of blocks and the growth rate; compare this to Remark 7.2.

Via the canonical isomorphism $\{a\}^* \cong \mathbb{N}$, HDT0L transductions with unary output alphabet are the same thing as $\mathbb{N}$-*rational series*. The counterpart of Schützenberger's theorem over $\mathbb{N}$ is thus a corollary of the results of [13] on layered SSTs.

2.4 Transition monoids for streaming string transducers

To wrap up the preliminaries, let us recall some algebraic tools for working with SSTs (this technical section can be safely skipped on a first reading). Let us start by putting a monoid structure on register assignments (Definition 2.2).

▶ **Definition 2.15.** *Let $\mathcal{M}_{R,\Sigma} = R \to (\Sigma \cup R)^*$ for $R \cap \Sigma = \varnothing$. We endow it with the following composition operation, that makes it into a monoid:*

$$\alpha \bullet \beta = \alpha^{\odot} \circ \beta \quad \text{where } \alpha^{\odot} \in \mathrm{Hom}((\Sigma \cup R)^*, (\Sigma \cup R)^*),\ \alpha^{\odot}(x) = \begin{cases} \alpha(x) & \text{for } x \in R \\ x & \text{for } x \in \Sigma \end{cases}$$

The monoid $\mathcal{M}_{R,\Sigma}$ thus defined is isomorphic to a submonoid of $\mathrm{Hom}((\Sigma \cup R)^*, (\Sigma \cup R)^*)$ with function composition. It admits a submonoid of *copyless* assignments.

▶ **Definition 2.16.** *We write $\mathcal{M}^{\mathrm{cl}}_{R,\Sigma}$ for the set of all $\alpha \in \mathcal{M}_{R,\Sigma}$ such that each letter $r \in R$ occurs at most once among all the $\alpha(r')$ for $r' \in R$.*

▶ **Proposition 2.17.** *$\mathcal{M}^{\mathrm{cl}}_{R,\Sigma}$ is a submonoid of $\mathcal{M}_{R,\Sigma}$. In other words, copylessness is preserved by composition (and the identity assignment is copyless).*

The following proposition ensures that this composition does what we expect. Recall from Definition 2.2 that $(-)^\dagger$ sends $\mathcal{M}_{R,\Sigma}$ to $(\Sigma^*)^R \to (\Sigma^*)^R$.

▶ **Proposition 2.18.** *For all $\alpha, \beta \in \mathcal{M}_{R,\Sigma}$, we have $(\alpha \bullet \beta)^\dagger = \beta^\dagger \circ \alpha^\dagger$.*

To incorporate information concerning the states of an SST, we define below a special case of the *wreath product* of transformation monoids.

▶ **Definition 2.19.** *Let M be a monoid whose multiplication is denoted by $m, m' \mapsto m \cdot m'$. We define $M \wr Q$ as the monoid whose set of elements is $Q \to Q \times M$ and whose monoid multiplication is, for $\mu, \mu' : Q \to Q \times M$,*

$$(\mu \bullet \mu') : q \mapsto (\pi_1 \circ \mu' \circ \pi_1 \circ \mu(q),\ (\pi_2 \circ \mu(q)) \cdot (\pi_2 \circ \mu' \circ \pi_1 \circ \mu(q)))$$

where $\pi_1 : Q \times M \to Q$ and $\pi_2 : Q \times M \to M$ are the projections.

For instance, if M is the trivial monoid with one element, $Q \wr M$ is isomorphic to $Q \to Q$ with *reverse* composition as the monoid multiplication: $f \bullet g = g \circ f$.

▶ **Proposition 2.20.** *Let $(Q, q_0, R, \delta, \vec{u}_I, F)$ be an SST that computes $f : \Gamma^* \to \Sigma^*$ (using the notations of Definition 2.3). For all $c \in \Gamma$, we have $\delta(-, c) \in \mathcal{M}_{R,\Sigma} \wr Q$, and the SST is copyless if and only if $\{\delta(-, c) \mid c \in \Gamma\} \subseteq \mathcal{M}^{\mathrm{cl}}_{R,\Sigma} \wr Q$. Furthermore, for all $w_1 \dots w_n \in \Gamma^*$,*

$$f(w_1 \dots w_n) \quad = \quad F(g(q_0))^\dagger(\alpha^\dagger(\vec{v})) \quad \text{where} \quad (g, \alpha) = \delta(-, w_1) \bullet \dots \bullet \delta(-, w_n)$$

Finally, it will sometimes be useful to consider monoids of assignments over an *empty* output alphabet. This allows us to keep track of how the registers are shuffled around by transitions.

▶ **Proposition 2.21.** *Let R and Σ be disjoint finite sets. There is a monoid morphism $\mathcal{M}_{R,\Sigma} \to \mathcal{M}_{R,\varnothing}$, that sends the submonoid $\mathcal{M}^{\mathrm{cl}}_{R,\Sigma}$ to $\mathcal{M}^{\mathrm{cl}}_{R,\varnothing}$. For any Q, this extends to a morphism $\mathcal{M}_{R,\Sigma} \wr Q \to \mathcal{M}_{R,\varnothing} \wr Q$ that sends $\mathcal{M}^{\mathrm{cl}}_{R,\Sigma} \wr Q$ to $\mathcal{M}^{\mathrm{cl}}_{R,\varnothing} \wr Q$. We shall use the name $\mathtt{erase}_\Sigma$ for both morphisms (R and Q being inferred from the context).*

▶ Remark 2.22. Consider an SST with a transition function δ. Let $\varphi_\delta \in \mathrm{Hom}(\Gamma^*, \mathcal{M}^{\mathrm{cl}}_{R,\varnothing} \wr Q)$ be defined by $\varphi_\delta(c) = \mathtt{erase}_\Sigma(\delta(-, c))$ for $c \in \Gamma$. The range $\varphi_\delta(\Gamma^*)$ is precisely the *substitution transition monoid (STM)* defined in [11, Section 3].

▶ **Proposition 2.23.** *For any finite R, the monoid $\mathcal{M}^{\mathrm{cl}}_{R,\varnothing}$ is* finite. *As a consequence, the substitution transition monoid of any* copyless *SST is finite.*

Proof idea. For all $\alpha \in \mathcal{M}^{\mathrm{cl}}_{R,\varnothing}$ and $r \in R$, observe that $|\alpha(r)| \leq |R|$. ◀

3 Complements on HDT0L systems, SSTs and polyregular functions

Before embarking on the study of our new comparison-free polyregular functions, we state some minor results that consolidate our understanding of pre-existing classes.

Layered HDT0L systems. Let us transpose the layering condition from SSTs to HDT0L systems. The hierarchy of models that we get corresponds *with an offset* to layered SSTs.

▶ **Definition 3.1.** *A HDT0L system $(\Gamma, \Sigma, \Delta, d, (h_c)_{c \in \Gamma}, h')$ is* k-layered *if its working alphabet can be partitioned as $\Delta = \Delta_0 \sqcup \dots \sqcup \Delta_k$ such that, for all $c \in \Gamma$ and $i \in \{0, \dots, k\}$:*

- *for $r \in \Delta_i$, we have $h_c(r) \in (\Delta_0 \sqcup \dots \sqcup \Delta_i)^*$;*
- *each letter in Δ_i appears at most once among all the $\alpha(r)$ for $r \in \Delta_i$ (but those in $\Delta_0 \sqcup \dots \sqcup \Delta_{i-1}$ may appear an arbitrary number of times).*

▶ **Theorem 3.2.** *For $k \in \mathbb{N}$, a function can be computed by a k-layered SST if and only if it can be specified by a $(k+1)$-layered HDT0L system.*

In particular, regular functions correspond to 1-layered HDT0L systems.

The obvious translation from HDT0L systems to SSTs preserves 1-layeredness and produces a single-state machine, so one may sacrifice copylessness to eliminate states for SSTs.

▶ **Corollary 3.3.** *Every regular function can be computed by a single-state 1-layered SST.*

The converse to this corollary does not hold: the single-state 1-layered SST of Example 2.4 computes a function which is not regular (cf. Remark 2.9).

Polyregular functions vs layered SSTs. By applying some results from [4], we can state a variant of Definition 2.11 which is a bit more convenient for us.

▶ **Proposition 3.4.** *Polyregular functions are the smallest class closed under composition that contains the regular functions and the squaring with underlining functions* $\texttt{squaring}_\Gamma$.

This allows us to show that composing HDT0L transductions with at most polynomial growth yields the polyregular functions. One direction of this equivalence is proved by encoding $\texttt{squaring}_\Gamma$ as a composition of two SSTs, one of which is Example 2.4. More precisely:

▶ **Theorem 3.5.** *Let $f : \Gamma^* \to \Sigma^*$. The following are equivalent:*

(i) *f is polyregular;*
(ii) *f can be obtained as a composition of layered SSTs;*
(iii) *f can be obtained as a composition of single-state 1-layered SSTs.*

But layered SSTs by themselves are *strictly less expressive* than polyregular functions, as we shall see later in Theorem 8.1. Therefore, as promised in the introduction:

▶ **Corollary 3.6** (claimed in [13, Section 6])**.** *Layered SSTs are* not *closed under composition.*

The importance of being stateful. One interesting aspect of Theorem 3.2 is that 1-layered HDT0L systems can be seen, through Remark 2.6, as a kind of one-way transducer model for regular functions that does not use an explicit control state. This is in contrast with copyless SSTs, whose expressivity critically depends on the states (unlike copyful SSTs).

▶ **Proposition 3.7.** *The sequential (and therefore regular) function defined by the transducer of Figure 2 (Section 2.2)* cannot *be computed by a* single-state copyless SST.

In fact, the knowledgeable reader can verify that this counterexample belongs to the *first-order letter-to-letter sequential functions*, one of the weakest classical transduction classes.

Closure under map. The pattern of Example 2.10 (iterated reverse) can be generalized:

▶ **Definition 3.8.** *Let $f : \Gamma^* \to \Sigma^*$ and suppose that $\# \notin \Gamma \cup \Sigma$. We define the function* $\mathbf{map}(f) : w_1\# \dots \# w_n \in (\Gamma \cup \{\#\})^* \mapsto f(w_1)\# \dots \# f(w_n) \in (\Sigma \cup \{\#\})^*$.

▶ **Proposition 3.9.** *If f is an HDT0L transduction, then so is* $\mathbf{map}(f)$. *For each $k \geq 1$, the functions that can be computed by k-layered HDT0L systems are also closed under* **map**.

As an immediate corollary, closure under **map** holds for both regular and polyregular functions, but this was already known. In fact, $\texttt{map}(f, [x_1, \dots, x_n]) = [f(x_1), \dots, f(x_n)]$ is an essential primitive in the *regular list functions* [6] and *polynomial list functions* [4, §4], two list-processing programming languages that characterize regular and polyregular functions respectively. We will come back to this point in Corollary 8.5 and the subsequent remark.

4 Composition by substitution

At last, we now introduce the class of *comparison-free polyregular functions*. The simplest way to define them is to start from the regular functions.

▶ **Definition 4.1.** *Let $f : \Gamma^* \to I^*$, and for each $i \in I$, let $g_i : \Gamma^* \to \Sigma^*$. The* composition by substitution *of f with the family $(g_i)_{i\in I}$ is the function*

$$\mathrm{CbS}(f, (g_i)_{i\in I}) \quad : \quad w \mapsto g_{i_1}(w) \dots g_{i_k}(w) \quad \text{where } i_1 \dots i_k = f(w)$$

That is, we first apply f to the input, then every letter i in the result of f is substituted by the image of the original input by g_i. Thus, $\mathrm{CbS}(f, (g_i)_{i\in I})$ is a function $\Gamma^* \to \Sigma^*$.

▶ **Definition 4.2.** *The smallest class of string-to-string functions closed under* CbS *and containing all regular functions is called the class of* comparison-free polyregular functions.

▶ **Example 4.3.** The following variant of "squaring with underlining" (cf. Definition 2.11) is comparison-free polyregular: $\mathtt{cfsquaring}_\Gamma : \mathtt{123} \in \Gamma^* \mapsto \underline{1}123\underline{2}123\underline{3}123 \in (\Gamma \cup \underline{\Gamma})^*$.

Indeed, it can be expressed as $\mathtt{cfsquaring}_\Gamma = \mathrm{CbS}(f, (g_i)_{i\in I})$ where $I = \Gamma \cup \{\#\}$, the function $f : w_1 \dots w_n \mapsto w_1 \# \dots w_n \#$ is regular (more than that, a morphism between free monoids) and $g_\# = \mathrm{id}$, $g_c : w \mapsto \underline{c}$ for $c \in \Gamma$ are also regular. Its growth rate is quadratic, while regular functions have at most linear growth. Other examples that also require a single composition by substitution are given in Theorem 8.1.

We can already justify the latter half of the name of our new class. Using the "polynomial list functions" mentioned at the end of the previous section, we prove:

▶ **Theorem 4.4.** *Polyregular functions are closed under composition by substitution.*

▶ **Corollary 4.5.** *Every comparison-free polyregular function is, indeed, polyregular.*

Fundamentally, Definition 4.2 is inductive: it considers the functions generated from the base case of regular functions by applying compositions by substitution. The variant below with more restricted generators is sometimes convenient.

▶ **Definition 4.6.** *A string-to-string function is said to be:*

- *of* rank at most 0 *if it is regular;*
- *of* rank at most $k+1$ (for $k \in \mathbb{N}$) *if it can be written as $\mathrm{CbS}(f, (g_i)_{i\in I})$ where $f : \Gamma^* \to I^*$ is* regular *and each $g_i : \Gamma^* \to \Sigma^*$ is of rank at most k.*

▶ **Proposition 4.7.** *A function f is comparison-free polyregular if and only if there exists some $k \in \mathbb{N}$ such that f has rank at most k. In that case, we write $\mathrm{rk}(f)$ for the least such k and call it the* rank *of f. If $(g_i)_{i\in I}$ is a family of comparison-free polyregular functions,*

$$\mathrm{rk}(\mathrm{CbS}(f, (g_i)_{i\in I})) \leq 1 + \mathrm{rk}(f) + \max_{i\in I} \mathrm{rk}(g_i)$$

A straightforward consequence of this definition is that, just like regular functions, cfp functions are closed under *regular conditionals* and concatenation.

▶ **Proposition 4.8.** *Let $f, g : \Gamma^* \to \Sigma^*$ be comparison-free polyregular functions and $L \subseteq \Gamma^*$ be a regular language. The function that coincides with f on L and with g on $\Gamma^* \setminus L$ is cfp, and so is $w \in \Gamma^* \mapsto f(w) \cdot g(w)$; both have rank at most $\max(\mathrm{rk}(f), \mathrm{rk}(g))$.*

5 Comparison-free pebble transducers

We now characterize our function class by a machine model that will explain our choice of the adjective "comparison-free", as well as the operational meaning of the notion of rank we just defined. It is based on the *pebble transducers* first introduced for trees by Milo, Suciu and Vianu [28] and later investigated in the special case of strings by Engelfriet and Maneth [17, 14]. However, the definition using composition by substitution will remain our tool of choice to prove further properties, so the next sections do not depend on this one.

▶ **Definition 5.1.** *Let $k \in \mathbb{N}$ with $k \geq 1$. Let Γ, Σ be finite alphabets and $\triangleright, \triangleleft \notin \Gamma$.*

*A k-*pebble stack *on an input string $w \in \Gamma^*$ consists of an ordered list of p positions in the string $\triangleright w \triangleleft$ (i.e. of p integers between 1 and $|w|+2$) for some $p \in \{1, \dots, k\}$. We therefore write $\mathrm{Stack}_k = \mathbb{N}^0 \cup \mathbb{N}^1 \cup \cdots \cup \mathbb{N}^k$, keeping in mind that given an input w, we will be interested in "legal" values bounded by $|w|+2$.*

A comparison-free k-pebble transducer (k-CFPT) *consists of a finite set of states Q, an initial state $q_I \in Q$ and a family of transition functions*

$$Q \times (\Gamma \cup \{\triangleright, \triangleleft\})^p \to Q \times (\mathbb{N}^p \to \mathrm{Stack}_k) \times \Sigma^* \quad \text{for } 1 \leq p \leq k$$

where the $\mathbb{N}^p$ on the left is considered as a subset of Stack_k. For a given state and given letters $(c_1, \dots, c_p) \in (\Gamma \cup \{\triangleright, \triangleleft\})^p$, the allowed values for the stack update function $\mathbb{N}^p \to \mathrm{Stack}_k$ returned by the transition function are:

(identity)	$(i_1, \dots, i_p)$	$\mapsto$	$(i_1, \dots, i_p)$	$\in$	$\mathbb{N}^p$
(move left, only allowed when $c_p \neq \triangleright$)	$(i_1, \dots, i_p)$	$\mapsto$	$(i_1, \dots, i_p - 1)$	$\in$	$\mathbb{N}^p$
(move right, only allowed when $c_p \neq \triangleleft$)	$(i_1, \dots, i_p)$	$\mapsto$	$(i_1, \dots, i_p + 1)$	$\in$	$\mathbb{N}^p$
(push, only allowed when $p \leq k-1$)	$(i_1, \dots, i_p)$	$\mapsto$	$(i_1, \dots, i_p, 1)$	$\in$	$\mathbb{N}^{p+1}$
(pop, only allowed when $p \geq 1$)	$(i_1, \dots, i_p)$	$\mapsto$	$(i_1, \dots, i_{p-1})$	$\in$	$\mathbb{N}^{p-1}$

(Note that the codomains of all these functions are indeed subsets of Stack_k.)

The run of a CFPT over an input string $w \in \Gamma^*$ starts in the initial configuration comprising the initial state q_I, the initial k-pebble stack $(1) \in \mathbb{N}^1$, and the empty string as an initial output log. As long as the current stack is non-empty a new configuration is computed by applying the transition function to q and to $((\triangleright w \triangleleft)[i_1], \dots, (\triangleright w \triangleleft)[i_p])$ where $(i_1, \dots, i_p)$ is the current stack; the resulting stack update function is applied to $(i_1, \dots, i_p)$ to get the new stack, and the resulting output string in Σ^* is appended to the right of the current output log. If the CFPT ever terminates by producing an empty stack, the *output associated to w* is the final value of the output log.

This amounts to restricting in two ways[4] the definition of *pebble transducers* from [4, §2]:

- in a general pebble transducer, one can *compare positions*, i.e. given a stack $(i_1, \dots, i_p)$, the choice of transition can take into account whether[5] $i_j \leq i_{j'}$ (for any $1 \leq j, j' \leq p$);
- in a "push", new pebbles are initialized to the leftmost position ($\triangleright$) for a CFPT, instead of starting at the same position as the previous top of the stack (the latter would ensure the equality of two positions at some point; it is therefore an implicit comparison that we must relinquish to be truly "comparison-free").

[4] There is also an inessential difference: the definition given in [4] does not involve end markers and handles the edge case of an empty input string separately. This has no influence on the expressiveness of the transducer model. Our use of end markers follows [15, 25].

[5] One would get the same computational power, with the same stack size, by only testing whether $i_j = i_p$ for $j \leq p-1$ as in [28] (this is also essentially what happens in the nested transducers of [25]).

This limitation is similar to (but goes a bit further than) the "invisibility" of pebbles in a transducer model introduced by Engelfriet et al. [16] (another difference, unrelated to position comparisons, is that their transducers use an unbounded number of invisible pebbles).

▶ Remark 5.2. Our definition guarantees that "out-of-bounds errors" cannot happen during the run of a comparison-free pebble transducer. The sequence of successive configurations is therefore always well-defined. But it may be infinite, that is, it may happen that the final state is never reached. Thus, a CFPT defines a *partial* function.

That said, the set of inputs for which a given pebble tree transducer does not terminate is always a regular language [28, Theorem 4.7]. This applies *a fortiori* to CFPTs. Using this, it is possible[6] to extend any partial function $f : \Gamma^* \rightharpoonup \Sigma^*$ computed by a k-CFPT into a total function $f' : \Gamma^* \to \Sigma^*$ computed by another k-CFPT for the same $k \in \mathbb{N}$, such that $f'(x) = f(x)$ for x in the domain of f and $f'(x) = \varepsilon$ otherwise. This allows us to *only consider CFPTs computing total functions* in the remainder of the paper.

A special case of particular interest is $k = 1$: the transducer has a single reading head, push and pop are always disallowed.

▶ **Theorem 5.3** ([1])**.** *Copyless SSTs and 1-CFPTs – which are more commonly called* two-way (deterministic) finite transducers (2DFTs) *– are equally expressive.*

Since we took copyless SSTs as our reference definition of regular functions, this means that 2DFTs characterize regular functions. But putting it this way is historically backwards: the equivalence between 2DFTs and MSO transductions came first [15] and made this class deserving of the name "regular functions" before the introduction of copyless SSTs.

▶ Remark 5.4. There are two different numbering conventions for pebble transducers. In [4, 25], 2DFTs are 1-pebble transducers, which is consistent with our choice. However, several other papers (e.g. [28, 17, 14, 16, 12]) consider that a 2DFT is a *0-pebble* transducer (likewise, in [13], 2DFTs are 0-marble transducers). This is because they think of a pebble automaton not as a restricted multi-head automaton, but as an enriched 2DFA that can drop stationary markers (called pebbles) on input positions, with a single moving head that is not a pebble.

Let us now show the equivalence with Definition 4.2. The reason for this is similar to the reason why k-pebble transducers are equivalent to the *k-nested transducers*[7] of [25], which is deemed "trivial" and left to the reader in [25, Remark 6]. But in our case, one direction (Theorem 5.6) involves an additional subtlety compared to in [25]; to take care of it, we use the fact that the languages recognized by pebble automata are regular (this is also part of [28, Theorem 4.7]) together with regular conditionals (Proposition 4.8).

▶ **Proposition 5.5.** *If f is computed by a k-CFPT, and the g_i are computed by l-CFPTs, then $\mathrm{CbS}(f, (g_i)_{i\in I})$ is computed by a $(k + l)$-CFPT.*

▶ **Theorem 5.6.** *If $f : \Gamma^* \to \Sigma^*$ is computed by a k-CFPT, for $k \geq 2$, then there exist a finite alphabet I, a regular function $h : \Gamma^* \to I^*$ and a family $(g_i)_{i\in I}$ computed by $(k-1)$-CFPTs such that $f = \mathrm{CbS}(h, (g_i)_{i\in I})$.*

▶ **Corollary 5.7.** *For all $k \in \mathbb{N}$, the functions computed by $(k + 1)$-CFPTs are exactly the comparison-free polyregular functions of rank at most k.*

---

[6] Proof idea: do a first left-to-right pass to determine whether the input leads to non-termination of the original CFPT; if so, terminate immediately with an empty output; otherwise, move the first pebble back to the leftmost position and execute the original CFPT's behavior. This can be implemented by adding finitely many states, including those for a DFA recognizing non-terminating inputs.

[7] Remark: nested transducers should yield a machine-independent definition of polyregular functions as the closure of regular functions under a CbS-like operation that relies on *origin semantics* [29, §5].

6 Composition of basic functions

Another possible definition of cfp functions consists in swapping out $\mathtt{squaring}_\Gamma$ for some other function in Proposition 3.4:

▶ **Theorem 6.1.** *The class of comparison-free polyregular functions is the smallest class closed under usual function composition and containing both all regular functions and the functions* $\mathtt{cfsquaring}_\Gamma$ *(cf. Example 4.3) for all finite alphabets* Γ*.*

The hard part is to show that cfp functions are closed under composition. We exploit the following combinatorial phenomenon, often applied to the study of copyless SSTs: a copyless register assignment, i.e. an element of $\mathcal{M}^{\mathrm{cl}}_{R,\Delta}$ (cf. Section 2.4), can be specified by

- a "shape" described by an element of the *finite* monoid $\mathcal{M}^{\mathrm{cl}}_{R,\varnothing}$ (Proposition 2.23),
- plus finitely many "labels" in Σ^* (where Σ is the output alphabet) describing the constant factors that will be concatenated with the old register contents to give the new ones.

▶ **Proposition 6.2.** *There is a bijection*

$$\mathcal{M}^{\mathrm{cl}}_{R,\Delta} \quad\cong\quad \left\{ \left(\alpha, \vec{\ell}\right) \;\middle|\; \alpha \in \mathcal{M}^{\mathrm{cl}}_{R,\varnothing},\ \vec{\ell} \in \prod_{r\in R} (\Delta^*)^{|\alpha(r)|+1} \right\}$$

through which $\mathtt{erase}_\Delta : \mathcal{M}^{\mathrm{cl}}_{R,\Delta} \to \mathcal{M}^{\mathrm{cl}}_{R,\varnothing}$ *can be seen as simply removing the "labels"* $\vec{\ell}$*.*

Proof idea. Let $\beta \in \mathcal{M}^{\mathrm{cl}}_{R,\Delta}$. For each $r \in R$, one can write $\beta(r) = w_0 r'_1 w_1 \dots r'_n w_n$ with $w_0, \dots, w_n \in \Delta^*$ and $r'_1, \dots, r'_n \in R$ such that $r'_1 \dots r'_n = \mathtt{erase}_\Delta(\beta)(r) \in R^*$. ◀

This provides a clear way to represent a copyless register assignment inside the working memory of an SST: store the shape in the state and the labels in registers. Another important fact for us is that given two assignments $\beta, \beta' \in \mathcal{M}^{\mathrm{cl}}_{R,\Delta}$ the labels of $\beta \bullet \beta'$ can be obtained as a *copyless* recombination of the labels of β and β'.

(There is a subtlety worth mentioning here: while the set of stateful transitions $\mathcal{M}^{\mathrm{cl}}_{R,\Delta} \wr Q$ also admits a "shape + labels" representation, its monoid multiplication does *not* have this copylessness property. This prevents a naive proof of the closure under composition of copyless SSTs from working. Nevertheless, the composition of two regular functions *is* always regular, and we rely on this fact to prove Theorem 6.1.)

The rest of the proof of Theorem 6.1 is relegated to the technical appendix.

7 Rank vs asymptotic growth

Our next result is the comparison-free counterpart to recent work on polyregular functions by Lhote [25], whose proof techniques (in particular the use of Ramsey's theorem) we reuse. Compare item (ii) below to the main theorem of [25] and item (iii) – which provides yet another definition of cfp functions – to [25, Appendix A].

▶ **Theorem 7.1.** *Let* $f : \Gamma^* \to \Sigma^*$ *and* $k \in \mathbb{N}$*. The following are equivalent:*

(i) *f is comparison-free polyregular with rank at most k;*

(ii) *f is comparison-free polyregular and $|f(w)| = O(|w|^{k+1})$;*

(iii) *there exists a regular function $g : (\{0, \dots, k\} \times \Gamma)^* \to \Sigma^*$ such that $f = g \circ \mathtt{cfpow}^{(k+1)}_\Gamma$, with the following inductive definition: $\mathtt{cfpow}^{(0)}_\Gamma : w \in \Gamma^* \mapsto \varepsilon \in (\varnothing \times \Gamma)^*$ and*

$$\mathtt{cfpow}^{(n+1)}_\Gamma \quad : \quad w \mapsto (n, w_1) \cdot \mathtt{cfpow}^{(n)}_\Gamma(w) \cdot \ldots \cdot (n, w_{|w|}) \cdot \mathtt{cfpow}^{(n)}_\Gamma(w)$$

To make (ii) $\implies$ (i) more precise, if f is cfp with $\mathrm{rk}(f) \geq 1$, then it admits a sequence of inputs $w_0, w_1, \ldots \in \Gamma^*$ such that $|w_n| \to +\infty$ and $|f(w_n)| = \Omega(|w_n|^{\mathrm{rk}(f)+1})$.

Note that $\mathtt{cfpow}^{(2)}_\Gamma$ and $\mathtt{cfsquaring}_\Gamma$ are the same up to a bijection $\{0,1\} \times \Gamma \cong \Gamma \cup \underline{\Gamma}$.

▶ Remark 7.2. The growth of an HDT0L transduction is also related, in a very similar way to item (ii) above, to the number of layers required in any SST that computes it [13, §5].

Some proof elements. Let us present a few definitions and lemmas to give an idea of the ingredients that go into the proof. Those technical details take up the rest of this section.

Lhote's paper [25] makes a heavy use of *factorizations* of strings that depend on a morphism to a finite monoid. This is also the case for our proof, but we have found that a slightly different definition of the kind of factorization that we want works better for us.

▶ **Definition 7.3** (similar but not equivalent to [25, Definition 19])**.** *An* r-split *of a string* $s \in \Gamma^*$ *according to a morphism* $\varphi : \Gamma^* \to M$ *is a tuple* $(u, v_1, \dots, v_r, w) \in (\Gamma^*)^{r+2}$ *such that:*

- $s = uv_1 \dots v_n w$ *with* v_i *non-empty for all* $i \in \{1, \dots, r\}$*;*
- $\varphi(u) = \varphi(uv_1) = \cdots = \varphi(uv_1v_r)$*;*
- $\varphi(w) = \varphi(v_r w) = \cdots = \varphi(v_1 \dots v_r w)$*.*

▶ **Proposition 7.4** (immediate from the definition)**.** $(u, v_1, \dots, v_r, w)$ *is an* r*-split if and only if, for all* $i \in \{1, \dots, r\}$*,* $(uv_1 \dots v_{i-1}, v_i, v_{i+1} \dots v_r w)$ *is a 1-split.*

The difference with the $(1, r)$*-factorizations* of [25, Definition 19] is that we have replaced the equality and idempotency requirements on $\varphi(v_1), \dots, \varphi(v_n)$ by the "boundary conditions" involving $\varphi(u)$ and $\varphi(w)$ (actually, $(1, r+2)$-factorizations induce r-splits). This change allows us to establish a subclaim used in the proof of Lemma 7.7 in an elementary way.

The point of r-splits is that given a split of an input string according to the morphism that sends it to the corresponding transition in a SST, we have some control over what happens to the output of the SST if we pump a middle factor in the split. Furthermore, it suffices to consider a quotient of the transition monoid which is finite when the SST is copyless (this is similar to Proposition 2.23). More precisely, we have the key lemma below, which is used pervasively throughout our proof of Theorem 7.1:

▶ **Lemma 7.5.** *Let* $f : \Gamma^* \to \Sigma^*$ *be a regular function. There exist a morphism to a* finite *monoid* $\nu_f : \Gamma^* \to \mathcal{N}(f)$ *and, for each* $c \in \Sigma$*, a set of* producing triples $P(f, c) \subseteq \mathcal{N}(f)^3$ *such that, for any* 1-split *according to* ν_f *composed of* $u, v, w \in \Gamma^*$ *– i.e.* $\nu_f(uv) = \nu_f(u)$ *and* $\nu_f(vw) = \nu_f(w)$ *– we have:*

- *if* $(\nu_f(u), \nu_f(v), \nu_f(w)) \in P(f, c)$*, then* $|f(uvw)|_c > |f(uw)|_c$*;*
- *otherwise (when the triple is not producing),* $|f(uvw)|_c = |f(uw)|_c$*.*

Furthermore, in the producing case, we get as a consequence that $\forall n \in \mathbb{N},\ |f(uv^n w)|_c \geq n$*.*

▶ **Definition 7.6.** *We fix once and for all a choice of* $\mathcal{N}(f)$*,* ν_f *and* $P(f, c)$ *for each* $c \in \Sigma$ *and regular* $f : \Gamma^* \to \Sigma^*$*. We say that a 1-split* (u, v, w) *is* producing with respect to (f, c) *when* $(\nu_f(u), \nu_f(v), \nu_f(w)) \in P(f, c)$*. For* $\Pi \subseteq \Sigma$*, we also set* $P(f, \Pi) = \bigcup_{c \in \Pi} P(f, c)$*.*

Something like Lemma 7.5 (but not exactly) appears in the proof of [25, Lemma 18]. We first apply it to prove the following lemma, which is morally a counterpart to the "$k = 1$ case" of the central Dichotomy Lemma from [25], with r-splits instead of (k, r)-factorizations.

▶ **Lemma 7.7.** *Let* $f : \Gamma^* \to \Sigma^*$ *be regular and* $\varphi : \Gamma^* \to M$ *be a morphism with* M *finite. Suppose that* $\pi \circ \varphi = \nu_f$ *for some other morphism* $\pi : M \to \mathcal{N}(f)$*. Let* $r \geq 1$ *and* $\Pi \subseteq \Sigma$*.*

We define $L(f, \Pi, \varphi, r)$ *to be the set of strings that admit an* r*-split* $s = uv_1 \dots v_r w$ *according to* φ *such that all the triples* $(uv_1 \dots v_{i-1}, v_i, v_{i+1} \dots v_r w)$ *are producing with respect to* (f, Π) *– let us call this a producing* r*-split with respect to* (f, Π, φ)*.*

Then $L(f, \Pi, \varphi, r)$ *is a regular language, and* $\sup\{|f(s)|_\Pi \mid s \in \Gamma^* \setminus L(f, \Pi, \varphi, r)\} < \infty$*.*

Our proof of the above lemma uses the proposition below, analogous to [25, Claim 20]. Its statement is a bit stronger than necessary for this purpose, but it will be reused in the proof of Theorem 8.3; as for its proof, this is where a standard Ramsey argument occurs.

▶ **Proposition 7.8.** *Let Γ be an alphabet, M be a finite monoid and $\varphi : \Gamma^* \to M$ be a morphism. There exists $N \in \mathbb{N}$ such that any string $s = uvw \in \Gamma^*$ such that $|v| \geq N$ admits an r-split $s = u'v'_1 \dots v'_r w'$ according to φ in which u is a prefix of u' and w is a suffix of w'.*

To leverage Lemma 7.7, we combine it with an elementary property of composition by substitution that does not depend on the previous technical development. (Compare the assumptions of the lemma below with the conclusion of Lemma 7.7.)

▶ **Lemma 7.9.** *Let $g : \Gamma^* \to I^*$ be a regular function and, for each $i \in I$, let $h_i : \Gamma^* \to \Sigma^*$ be comparison-free polyregular of rank at most k. Suppose that $\sup_{s \in \Gamma^*} |g(s)|_J < \infty$ where*

$$J = \begin{cases} \{i \in I \mid \mathrm{rk}(h_i) = k\} & \text{when } k \geq 1 \\ \{i \in I \mid |h_i(\Gamma^*)| = \infty\} & \text{when } k = 0 \end{cases}$$

(Morally, regular functions with finite range play the role of "comparison-free polyregular functions of rank -1".) Then $\mathrm{rk}(\mathrm{CbS}(g, (h_i)_{i \in I})) \leq k$.

The above lemma can be compared to [25, Claim 22], but it also seems to be related to the way the "nested transducer" R_{k+1} is defined in the proof of the Dichotomy Lemma in [25]: indeed, R_{k+1} can call either a k-nested subroutine or a $(k-1)$-nested one.

The remainder of the proof of Theorem 7.1 consists mainly of a rather technical induction on the rank, which we present in the appendix.

8 Separation results

Let us now demonstrate that the class of cfp functions is incomparable with the class of HDT0L transductions and is a strict subclass of polyregular functions.

▶ **Theorem 8.1.** *There exist comparison-free polyregular functions which are not HDT0L:*
- **(i)** *the function $a^n \in \{a\}^* \mapsto (a^n b)^{n+1} \in \{a, b\}^*$ for $a \neq b$;*
- **(ii)** *the function $w \in \Sigma^* \mapsto w^{|w|}$ for $|\Sigma| \geq 2$ (a simplification of Example 4.3);*
- **(iii)** (from [13, §6]) *the cfp functions that map $a^n \# w \in \Sigma^*$ to $(w\#)^n$ for $a, \# \in \Sigma$, $a \neq \#$.*

▶ Remark 8.2. The first example in [13, §5] shows that $a^n \mapsto a^{n \times n}$ is HDT0L (via the equivalent model of marble transducers), hence the necessity of $|\Sigma| \geq 2$ above. More generally, Douéneau-Tabot has shown very recently that *every polyregular function with unary output alphabet is HDT0L* [12]. So polyregular functions with unary output coincide with *polynomial growth* $\mathbb{N}$*-rational series* (cf. Remark 2.14), and the latter admit several algebraic characterizations in the literature (see [32] and [3, Chapter 9, Exercise 1.2]).

▶ **Theorem 8.3.** *Some HDT0L transductions are polyregular but not comparison-free:*
- **(i)** *$f : a^n \in \{a\}^* \mapsto ba^{n-1}b \dots baabab$ (with $f(\varepsilon) = \varepsilon$ and $f(a) = b$);*
- **(ii)** $\mathbf{map}(a^n \mapsto a^{n \times n}) : a^{n_1} \# \dots \# a^{n_k} \mapsto a^{n_1 \times n_1} \# \dots \# a^{n_k \times n_k}$ *(cf. Definition 3.8).*

▶ Remark 8.4. The function $a^{n_1} \# \dots \# a^{n_k} \mapsto a^{n_1 \times n_1 + \dots + n_k \times n_k}$ obtained by erasing the #s in the output of $\mathbf{map}(a^n \mapsto a^{n \times n})$ is also *not* comparison-free. This result implies the second item of Theorem 8.3 by composition with the erasing morphism; we do not prove it here, but it appears in Douéneau-Tabot's aforementioned paper [12]. Therefore, according to [12], *not* every polyregular function with unary output is comparison-free.

To see why the first of the two functions in Theorem 8.3 is HDT0L, observe that it is Example 2.4 for $\Gamma = \{a\}$ (taking $b = \underline{a}$). As for the second one, combine Proposition 3.9 and the first observation in Remark 8.2.

The non-membership parts of Theorems 8.1 and 8.3 require more work. For the former, we use pumping arguments on HDT0L systems. Item (ii) of Theorem 8.3 is handled by first appealing to Theorem 7.1 to reduce to showing that $\mathbf{map}(a^n \mapsto a^{n\times n}) \neq \mathrm{CbS}(g, (h_i)_{i\in I})$ when g and all the h_i are *regular* functions; a combination of pumping and of a combinatorial argument then shows that inputs with $|I|$ occurrences of # suffice to discriminate the two sides of the inequality. This result also has the following consequence:

▶ **Corollary 8.5.** *Comparison-free polyregular functions are not closed under* **map**.

▶ Remark 8.6. Contrast with Proposition 3.9. The discussion that follows that proposition lends some significance to the above corollary: the latter rules out the obvious conjectures for a characterization of cfp functions in the style of regular/polynomial list functions.

As for item (i) of Theorem 8.3, it concerns a function whose domain consists of words over a unary alphabet, i.e., up to isomorphism, a *sequence*. This motivates the study of such sequences, which is the subject of the next section.

9 Comparison-free polyregular sequences

From now on, we identify $\mathbb{N}$ with the set of words $\{a\}^*$ and freely speak, for instance, of cfp sequences $\mathbb{N} \to \Gamma^*$ instead of cfp functions $\{a\}^* \to \Gamma^*$. It turns out that cfp sequences admit a characterization as finite combinations of what we call *poly-pumping sequences*.

▶ **Definition 9.1.** *A* poly-pumping sequence *is a function of the form* $[\![e]\!] : \mathbb{N} \to \Sigma^*$ *where*
- *e is a* polynomial word expression *generated by* $e ::= w \mid e \cdot e' \mid e^*$ *where* $w \in \Sigma^*$*;*
- $[\![w]\!](n) = w$, $[\![e \cdot e']\!](n) = [\![e]\!](n)[\![e']\!](n)$ *and* $[\![e^*]\!](n) = ([\![e]\!](n))^n$.

The star-height *of a polynomial word expression is defined in the usual way.*

▶ **Theorem 9.2.** *Let* $s : \mathbb{N} \to \Sigma^*$ *and* $k \in \mathbb{N}$. *The sequence s is comparison-free polyregular with* $\mathrm{rk}(s) \leq k$ *if and only if there exists* $p > 0$ *such that, for any* $m < p$, *there is a polynomial word expression e of star-height at most* $k + 1$ *such that* $\forall n \in \mathbb{N},\ s((n + 1)p + m) = [\![e]\!](n)$.

In short, the cfp sequences are exactly the *ultimately periodic combinations* of poly-pumping sequences. Our proof strategy is an induction on k.

The base case $k = 0$ says that regular sequences are ultimately periodic combinations of *pumping sequences* $n \mapsto u_0(v_1)^n \dots (v_l)^n u_l$. An essentially equivalent result is stated with a proof sketch using 2DFTs in [10, p. 90]; we propose an alternative proof using copyless SSTs. (Non-deterministic two-way transducers (2NFTs) taking unary inputs have also been studied [23]; furthermore, the notion of "k-iterative language" that appears in a pumping lemma for general 2NFTs [35] is related to the shape of the above pumping sequences.)

To make the inductive step go through, it is enough to synchronize the periods of the different poly-pumping sequences involved and to observe that $\mathrm{CbS}([\![e]\!], ([\![e'_i]\!])_{i\in I})$ is realized by an expression obtained by substituting the e'_i for i in e.

Coming back to Theorem 8.3, we show that $a^n \mapsto ba^{n-1}b \dots bab$ is not comparison-free polyregular by proving that its subsequences are *not* poly-pumping: for every poly-pumping sequence $s : \mathbb{N} \to \{a, b\}^*$, there is a uniform bound on the number of distinct contiguous subwords of the shape $baa \dots ab$ occuring in each $s(n)$ for $n \in \mathbb{N}$. Another consequence of Theorem 9.2 that we establish by induction over expressions contrasts with Corollary 8.5:

▶ **Corollary 9.3.** *If* $f : \Gamma^* \to \Sigma^*$ *and* $s : \mathbb{N} \to (\Gamma \cup \{\#\})^*$ *are cfp, so is* $\mathbf{map}(f) \circ s$.

10 Further topics

Functional programming. We mentioned in the introduction a forthcoming characterization of cfp functions using Church-encoded strings in a λ-calculus with linear types, in the vein of our previous results [31, 30]. Meanwhile, Corollary 8.5 could be understood as negative result in the search for another kind of functional programming characterization (cf. Remark 8.6).

It is also worth noting that the copying discipline of layered SSTs is very similar to what happens in the *parsimonious λ-calculus* [27]: a datum of type $!\tau$ cannot be duplicated into two copies of the same type $!\tau$, but it may yield an arbitrary number of copies of type τ without the modality "!". Since the function classes defined following the methodology of [31, 30] are automatically closed under composition, Theorem 3.5 leads us to conjecture that polyregular functions can be characterized in a variant of the parsimonious λ-calculus.

First-order interpretations. As we already said, regular and polyregular functions both admit logical characterizations using Monadic Second-Order Logic [15, 8]. The basic conceit behind these definitions is that a string w may be regarded as a finite model $\mathfrak{M}(w)$ over a signature containing the order relation $\leq$ on positions and predicates encoding their labeling.

The classes obtained by replacing MSO with first-order logic (FO) are to (poly)regular functions what star-free languages are to regular languages, see [11, 4]. We expect that in the same way, replacing regular functions (i.e. MSO transductions) by FO transductions in Definition 4.2 and Theorem 6.1 results in the same class in both cases, which would then be the natural FO counterpart of cfp functions. Furthermore, we believe it can be defined logically. Given a finite model $\mathfrak{U} = (U, R, \ldots)$, we write $\mathfrak{U}^k$ for the k^{th} power $(U^k, R_1, \ldots, R_k, \ldots)$ where $R_i(x_1, \ldots, x_m)$ of arity m is defined as $R(\pi_i(x_1), \ldots, \pi_i(x_m))$ for $1 \leq i \leq k$.

▶ **Conjecture 10.1.** *A function $f : \Gamma^* \to \Sigma^*$ is "FO comparison-free polyregular" if and only if there exists $k \in \mathbb{N}$ and a one-dimensional FO interpretation φ such that for every $w \in \Gamma^*$ with $|w| \geq 2$, there is an isomorphism of structures $\mathfrak{M}(f(w)) \simeq \varphi\left(\mathfrak{M}(w)^k\right)$.*

On an intuitive level, this seems to capture the inability to compare the positions of two heads of comparison-free pebble transducers. However, as mentioned to us by M. Bojańczyk, the naive transposition of this conjecture to MSO fails because the direct product, generalized to Henkin structures, does not preserve *standard* second-order models.

Integer sequences. Recall from Remarks 8.2 and 8.4 that for unary outputs, polyregular and layered HDT0L transductions coincide, but comparison-free polyregular functions form a strictly smaller class (those results come from [12]). If we also restrict to unary inputs – in other words, if we consider sequences $\mathbb{N} \to \mathbb{N}$ – then we are fairly confident at this stage that the three classes collapse to a single one, and that this can be shown by routine methods:

▷ Claim 10.2. The classes of polyregular, comparison-free polyregular and layered HDT0L functions coincide on sequences of natural numbers.

Note that we already have a description of cfp integer sequences by specializing Theorem 9.2.

Membership and equivalence. We presented comparison-free polyregular functions as a strict subclass of polyregular functions. This leads to a natural *membership problem*, for which partial results were recently obtained by Douéneau-Tabot [12]:

▷ Problem 10.3. Is there an algorithm taking as input a (code for a) pebble transducer which decides whether the corresponding function $\Sigma^* \to \Gamma^*$ is comparison-free or not?

There are many similar problems of interest on the frontier between comparison-free and general polyregular functions. We hope that investigating such issues may also lead to machine/syntax-free characterizations of the containment between the two classes.

Finally, a major open problem on polyregular functions is the *equivalence problem*:

▷ Problem 10.4. Is there an algorithm taking as input two pebble transducers which decides whether they compute the same function?

Interestingly, a positive answer is known for HDT0L transductions. There is an short proof using Hilbert's basis theorem [24], which is now understood to be an example of a general approach using polynomial grammars (see e.g. [2, 5]). One could hope that a restriction to comparison-free pebble transducers also puts the equivalence problem within reach of known tools. Unfortunately, the extended polynomial grammars that would serve as the natural target for a reduction from 2-CFPT equivalence already have an undecidable zeroness problem (this was shown recently by Schmude [34]). This does *not* extend, however, to an undecidability proof for the CFPT equivalence problem, so the latter is still open.

Higher-Order Model Checking Step by Step

Paweł Parys
Institute of Informatics, University of Warsaw, Poland

Abstract

We show a new simple algorithm that solves the model-checking problem for recursion schemes: check whether the tree generated by a given higher-order recursion scheme is accepted by a given alternating parity automaton. The algorithm amounts to a procedure that transforms a recursion scheme of order n to a recursion scheme of order $n-1$, preserving acceptance, and increasing the size only exponentially. After repeating the procedure n times, we obtain a recursion scheme of order 0, for which the problem boils down to solving a finite parity game. Since the size grows exponentially at each step, the overall complexity is n-EXPTIME, which is known to be optimal. More precisely, the transformation is linear in the size of the recursion scheme, assuming that the arity of employed nonterminals and the size of the automaton are bounded by a constant; this results in an FPT algorithm for the model-checking problem.

Our transformation is a generalization of a previous transformation of the author (2020), working for reachability automata in place of parity automata. The step-by-step approach can be opposed to previous algorithms solving the considered problem "in one step", being compulsorily more complicated.

1 Introduction

Recursion schemes are faithful and algorithmically manageable abstractions of the control flow of programs involving higher-order functions [19]. Such functions are nowadays widely used not only in functional programming languages such as Haskell and the OCAML family, but also in mainstream languages such as Java, JavaScript, Python, and C++. Simultaneously, the formalism of recursion schemes is equivalent via direct translations to simply-typed λY-calculus [28]. Collapsible pushdown systems [15] and ordered tree-pushdown systems [10] are other equivalent formalisms. Recursion schemes cover some other models such as indexed grammars [1] and ordered multi-pushdown automata [3].

The most celebrated algorithmic result in the analysis of recursion schemes is the decidability of the *model-checking problem* against regular properties of trees: given a recursion scheme $\mathcal{G}$ and a parity tree automaton $\mathcal{A}$, one can decide whether the tree generated by $\mathcal{G}$ is accepted by $\mathcal{A}$ [23]. This fundamental result has been reproved several times, that is, using collapsible higher-order pushdown automata [14], intersection types [20], Krivine machines [26], and it has been extended in diverse directions such as global model checking [7], logical reflection [5], effective selection [9], and a transfer theorem via models of lambda-

calculus [27]. The model-checking problem for recursion schemes of order n is complete for n-fold exponential time [23]. Despite this hardness result, the model-checking problem can be solved efficiently on multiple nontrivial examples, thanks to the development of several recursion-scheme model checkers [13, 21, 29] (including some model checkers that work only for automata models weaker than parity tree automata [17, 18, 6, 22, 25]).

In this paper, we give a new simple algorithm solving the model-checking problem for recursion schemes, mentioned above. The algorithm amounts to a procedure that transforms a recursion scheme of order n to a recursion scheme of order $n-1$, preserving acceptance, and increasing the size only exponentially. After repeating the procedure n times, we obtain a recursion scheme of order 0, for which acceptance boils down to winning a finite parity game. Since the size grows exponentially at each step, we reach the optimal overall complexity of n-fold exponential time. In a more detailed view, the complexity looks even better: the size growth is exponential only in the arity of types appearing in the recursion scheme, and in the size of the parity automaton; if these two parameters are bounded by a constant, the transformation is linear in the size of the recursion scheme. Since solving a finite parity game is FPT in the number of priorities [8], our algorithm for the the model-checking algorithm is FTP in the two parameters.[1]

The main difference between our algorithm and all the others is that we solve the problem step by step, repeatedly reducing the order by one, while most previous algorithms work "in one step", being compulsorily more complicated. The only algorithms that have been reducing the order by one, were algorithms using collapsible pushdown automata [14, 5, 9]. Notice, however, that these algorithms: first, are very technical; second, are contained only in unpublished appendices and in an arXiv paper [4]; third, if we want to use them for recursion schemes, it is necessary to employ a (nontrivial) translation from recursion schemes to collapsible pushdown automata [15, 28, 9]. A reduction of order was also possible for a subclass of recursion schemes, called *safe* recursion schemes [16], but it was not known how to extend it to all recursion schemes.

The transformation presented in this paper generalizes of a previous transformation of the author [24], working for reachability automata in place of parity automata. It has also a close relationship with a transformation given by Asada and Kobayashi [2].

2 Preliminaries

For a number $k \in \mathbb{N}$ we write $[k]$ for $\{1, \dots, k\}$. For any relation $\longrightarrow$ we write $\longrightarrow^*$ for the reflexive transitive closure of $\longrightarrow$.

For a function Z we write $Z[z \mapsto r]$ to denote the function that maps z to r while all other elements of the domain of Z are mapped as in Z. Likewise, we write $Z[z_i \mapsto r_i \mid i \in I]$ to denote the function that maps z_i to r_i for all $i \in I$, while all other elements of the domain of Z are mapped as in Z. We also use this notation without the "Z" part, for a function Z with empty domain.

Recursion schemes. The set of *(simple) types* is constructed from a unique ground type o using a binary operation $\to$; namely o is a type, and if α and β are types, so is $\alpha \to \beta$. By convention, $\to$ associates to the right, that is, $\alpha \to \beta \to \gamma$ is understood as $\alpha \to (\beta \to \gamma)$.

[1] This is not new. Actually, most previous algorithms reduce the model-checking problem to the problem of solving a parity game whose size is polynomial (for a polynomial of a fixed degree, for some algorithms just linear) in the size of the input, assuming that the arity of types appearing in the recursion scheme and the size of the parity automaton are fixed. Thus, only the method introduced by us is new, not the complexity results.

We often abbreviate $\underbrace{\alpha \to \cdots \to \alpha}_{\ell} \to \beta$ as $\alpha^{\ell} \to \beta$. The *order* of a type α, denoted $\mathsf{ord}(\alpha)$, is defined by induction: $\mathsf{ord}(\alpha_1 \to \cdots \to \alpha_k \to \mathsf{o}) = \max(\{0\} \cup \{\mathsf{ord}(\alpha_i) + 1 \mid i \in [k]\})$; for example $\mathsf{ord}(\mathsf{o}) = 0$, $\mathsf{ord}(\mathsf{o} \to \mathsf{o} \to \mathsf{o}) = 1$, and $\mathsf{ord}((\mathsf{o} \to \mathsf{o}) \to \mathsf{o}) = 2$.

Having a set of typed nonterminals $\mathcal{X}$, a set of typed variables $\mathcal{Y}$, and a set of symbols Σ, *terms* over $(\mathcal{X}, \mathcal{Y}, \Sigma)$ are defined by induction:

- nonterminal: every nonterminal $X \in \mathcal{X}$ of type α is a term of type α;
- variable: every variable $y \in \mathcal{Y}$ of type α is a term of type α;
- node constructor: if $K_1, \ldots, K_k$ are terms of type o and $a \in \Sigma$, then $\langle a, K_1, \ldots, K_k \rangle$ is a term of type o;
- application: if K is a term of type $\alpha \to \beta$, and L is a term of type α, then $K\,L$ is a term of type β.

The type of a term K is denoted $\mathsf{tp}(K)$. The order of a term K, written $\mathsf{ord}(K)$, is defined as the order of its type.

A *(higher-order) recursion scheme* is a tuple $\mathcal{G} = (\mathcal{X}, X_0, \Sigma, \mathcal{R})$, where $\mathcal{X}$ is a finite set of typed nonterminals, and $X_0 \in \mathcal{X}$ is a *starting nonterminal* of type o, and Σ is a finite set of symbols (called an *alphabet*), and $\mathcal{R}$ is a function assigning to every nonterminal $X \in \mathcal{X}$ a *rule* of the form $X\,y_1\,\ldots\,y_k \to R$, where $\mathsf{tp}(X) = (\mathsf{tp}(y_1) \to \cdots \to \mathsf{tp}(y_k) \to \mathsf{o})$, and R is a term of type o over $(\mathcal{X}, \{y_1, \ldots, y_k\}, \Sigma)$. The order of a recursion scheme, $\mathsf{ord}(\mathcal{G})$, is defined as the maximum of orders of its nonterminals.

Having a recursion scheme $\mathcal{G} = (\mathcal{X}, X_0, \Sigma, \mathcal{R})$, for every set of variables $\mathcal{Y}$ we define a *reduction relation* $\longrightarrow_{\mathcal{G}}$ between terms over $(\mathcal{X}, \mathcal{Y}, \Sigma)$ as the least relation such that

- $X\,K_1\,\ldots\,K_k \longrightarrow_{\mathcal{G}} R[K_1/y_1, \ldots, K_k/y_k]$ if the rule for X is $X\,y_1\,\ldots\,y_k \to R$, where $R[K_1/y_1, \ldots, K_k/y_k]$ denotes the term obtained from R by substituting K_i for y_i for all $i \in [k]$.

A (potentially infinite) *tree* over an alphabet Σ is defined by coinduction: every tree over Σ is of the form $\langle a, T_1, \ldots, T_k \rangle$, where $a \in \Sigma$ and $T_1, \ldots, T_k$ are again trees over Σ (for an introduction to coinductive definitions and proofs see, e.g., Czajka [12]). We employ the usual notions of nodes, children, branches, etc. Formally, we can define nodes as sequences of natural numbers; then for a tree $T = \langle a, T_1, \ldots, T_k \rangle$, the empty sequence $()$ is a node of T labeled by a, and any longer sequence $(i_1, i_2, \ldots, i_n)$ is a node of T labeled by b if $i_1 \in [k]$ and $(i_2, \ldots, i_n)$ is a node of T_{i_1} labeled by b. For a tree T and its node v, we write $T{\restriction_v}$ for the subtree of T starting at v.

Again by coinduction, we define the tree *generated* by a recursion scheme $\mathcal{G} = (\mathcal{X}, X_0, \Sigma, \mathcal{R})$ from a term M of type o (over $(\mathcal{X}, \varnothing, \Sigma)$), denoted $\mathsf{BT}_{\mathcal{G}}(M)$:

- if $M \longrightarrow_{\mathcal{G}}^{*} \langle a, K_1, \ldots, K_k \rangle$, then $\mathsf{BT}_{\mathcal{G}}(M) = \langle a, \mathsf{BT}_{\mathcal{G}}(K_1), \ldots, \mathsf{BT}_{\mathcal{G}}(K_k) \rangle$;
- otherwise, $\mathsf{BT}_{\mathcal{G}}(M) = \langle \omega \rangle$ for a special symbol $\omega \notin \Sigma$.

The tree generated by $\mathcal{G}$ (without mentioning a term), denoted $\mathsf{BT}(\mathcal{G})$, is defined as $\mathsf{BT}_{\mathcal{G}}(X_0)$.

Parity games. As already said, in the model-checking problem we are given a recursion scheme $\mathcal{G}$ and an alternating parity automaton $\mathcal{A}$, and we are asked whether the tree $T_{\mathcal{G}}$ generated by $\mathcal{G}$ is accepted by $\mathcal{A}$. One can, however, create a product of $\mathcal{G}$ and $\mathcal{A}$, which is a recursion scheme $\mathcal{G}_{\mathcal{A}}$ generating the tree of all possible runs of $\mathcal{A}$ on $T_{\mathcal{G}}$. This tree is a parity game; the game is won by Eve if and only if $\mathcal{A}$ accepts $T_{\mathcal{G}}$ (see Appendix A of the full version for more details). Due to this reduction, it is enough to work with recursion schemes generating parity games, and consider the problem of finding a winner in such games.

For every $d \in \mathbb{N}_+$ we consider the alphabet $\Sigma_d = \{\mathrm{Adam}, \mathrm{Eve}\} \times [d]$. A *parity tree* is a tree over Σ_d where every node has at least one child. A *parity recursion scheme* is a recursion scheme generating a parity tree (in particular the generated tree cannot have nodes

without children, including ω-labeled nodes). For a node labeled by $(\wp, p) \in \Sigma_d$, we say that it *belongs* to the player $\wp$, and that it has *priority* p. For trees and terms we write $\langle \wp, p, K_1, \ldots, K_k \rangle$ instead of $\langle (\wp, p), K_1, \ldots, K_k \rangle$, avoiding excessive brackets.

A branch ξ in a parity tree T is *won by Eve* (*Adam*) if the greatest priority appearing infinitely often on ξ is even (odd, respectively). A *strategy* ρ of a player $\wp \in \{\text{Adam}, \text{Eve}\}$ in a parity tree T is a function that assigns numbers to nodes of T belonging to the player $\wp$; if a node v has k children, we require that $\rho(v) \in [k]$. A branch ξ *agrees* with ρ if for every node v on ξ that belongs to $\wp$, the next node of ξ is the $\rho(v)$-th child of v. A strategy ρ of $\wp$ is *winning* if all branches that agree with ρ are winning for $\wp$. Finally, $\wp$ *wins* in T if $\wp$ has a winning strategy in T; otherwise $\wp$ *loses* in T. It is a standard result that in every parity tree T exactly one of the players wins.

It is useful to consider the following order $\preceq$ on positive natural numbers (priorities): $\cdots \preceq 5 \preceq 3 \preceq 1 \preceq 2 \preceq 4 \preceq 6 \preceq \ldots$ (first we have odd numbers in the reversed order, and then positive even numbers). We use the words *worse* and *better* to say that a priority is, respectively, earlier or later in this order. The intuition is that while playing a parity game, Eve always prefers to see better priorities.

3 Transformation

In this section we present a transformation, called *order-reducing transformation*, resulting in the main theorem of this paper:

▶ **Theorem 3.1.** *For any $n \geq 1$, there exists a transformation from order-n parity recursion schemes to order-$(n-1)$ parity recursion schemes, and a polynomial p_n such that, for any order-n parity recursion scheme $\mathcal{G}$, the winner in the tree generated by the resulting recursion scheme $\mathcal{G}^\dagger$ is the same as in the tree generated by $\mathcal{G}$, and $|\mathcal{G}^\dagger| \leq 2^{p_n(|\mathcal{G}|)}$.*

Intuitions. Let us first present intuitions behind our transformation. While reducing the order, we have to replace, in particular, order-1 functions by order-0 terms. Consider for example a tree T generated from a term $K\,L$ of type o, where K has type $\mathsf{o} \to \mathsf{o}$. Essentially, T consists of a context C_K, generated by K, where the tree T_L generated by L is inserted in some "holes". Instead of playing in T, we propose the following modification of the game. At the beginning, we ask Eve a question: how is she going to reach subtrees T_L while playing in T? She may declare that, according to her winning strategy,

- she is able to ensure that the greatest priority seen before reaching T_L will not be worse than r, for some number r of her choice, or
- she will not reach subtrees T_L at all, which amounts to choosing for r an even number greater than d, say $r = 2d$.

Then, we ask Adam if he believes in this declaration. If so, we simply read the declared worst-case priority r, and we continue playing in T_L (this possibility is unavailable for Adam, if Eve declared that she will not visit T_L). Otherwise, we check the declaration: we start playing in C_K; while reaching a place where T_L should be placed, Eve immediately wins (loses) if her declaration is fulfilled (not fulfilled, respectively).

We can see that such a modification of the game (even applied in infinitely many places of the considered tree) does not change the winner. A subtle point is that, in the modified game, Eve has to make a declaration on the priority r before actually starting the game in the tree generated from $K\,L$, and it is not completely obvious why the need for the declaration introduces no disadvantage for Eve. Nevertheless, for a fixed Eve's winning strategy, the worst greatest priority seen before reaching T_L is fixed, so that Eve can declare it as r.

In the transformation, we change the order-1 term K into several order-0 terms: K_r for $r \in \{1, \ldots, d, 2d\}$ (where d is a bound on priorities in the considered parity recursion scheme $\mathcal{G}$). These terms generate trees of the same shape as the context C_K generated by K but with some fixed trees substituted in place of the holes of C_K (where originally trees generated by the argument L were attached). The generated trees correspond to particular declarations made by Eve, as described above. Namely, we consider some fixed trees $\bot$ and $\top$ in which Eve loses and wins, respectively. Then, in the tree generated by K_r, the tree $\top$ is placed in holes such that the greatest priority on the path from the root to the hole is not worse than r, and the tree $\bot$ is placed in the remaining holes. In particular, the tree $\bot$ is placed in all holes of the tree generated by K_{2d}, because all priorities actually appearing in the tree are worse than $2d$. Finally, we replace $K\,L$ by $\langle \mathrm{Eve}, 1, K_1^L, K_2^L, \ldots, K_d^L, K_{2d}\rangle$, where $K_r^L = \langle \mathrm{Adam}, 1, K_r, \langle \mathrm{Eve}, r, L\rangle\rangle$. In this way we realize the modified game described above: first Eve chooses a declaration r and then Adam either proceed to K_r or to L after seeing priority r (the latter possibility is disabled for $r = 2d$). The priority 1 of the newly created tree nodes should be seen as a neutral priority; higher priorities visited later will be more important anyway.

When a term K of order 1 takes multiple arguments (instead of one argument L), we proceed in the same way, allowing Eve to make declarations for each of the arguments.

While applying the above-described transformation to recursion schemes, it is possible that the term K considered above contains some nonterminals or variables. Then, in order to realize the transformation, we need to create multiple copies of these nonterminals and variables, corresponding to particular declarations of Eve.

For example, say that in a recursion scheme we have (among others) the following two rules:

$$\mathsf{X} \to \mathsf{Y}\,\mathsf{Z},$$
$$\mathsf{Y}\,\mathsf{z} \to \langle \mathrm{Eve}, 1, \mathsf{z}, \langle \mathrm{Eve}, 2, \mathsf{z}\rangle\rangle.$$

Here X and Z are of type o, and Y is of type $\mathsf{o} \to \mathsf{o}$, so $\mathsf{Y}\,\mathsf{Z}$ is an application that should be replaced by the transformation. Assuming $d = 2$, we should obtain the following rules:

$$\mathsf{X}' \to \langle \mathrm{Eve}, 1, \langle \mathrm{Adam}, 1, \mathsf{Y}_1, \langle \mathrm{Eve}, 1, \mathsf{Z}'\rangle\rangle, \langle \mathrm{Adam}, 1, \mathsf{Y}_2, \langle \mathrm{Eve}, 2, \mathsf{Z}'\rangle\rangle, \mathsf{Y}_4\rangle,$$
$$\mathsf{Y}_1 \to \langle \mathrm{Eve}, 1, \overline{\top}, \langle \mathrm{Eve}, 2, \overline{\top}\rangle\rangle,$$
$$\mathsf{Y}_2 \to \langle \mathrm{Eve}, 1, \underline{\bot}, \langle \mathrm{Eve}, 2, \overline{\top}\rangle\rangle,$$
$$\mathsf{Y}_4 \to \langle \mathrm{Eve}, 1, \underline{\bot}, \langle \mathrm{Eve}, 2, \underline{\bot}\rangle\rangle,$$

where $\underline{\bot}$ and $\overline{\top}$ are nonterminals from which the trees $\bot$ and $\top$ (in which Eve loses and wins, respectively) are generated.

Another possibility is that in the original recursion scheme we have $\mathsf{y}\,\mathsf{Z}$ instead of $\mathsf{Y}\,\mathsf{Z}$:

$$\mathsf{S} \to \mathsf{T}\,\mathsf{Y},$$
$$\mathsf{T}\,\mathsf{y} \to \mathsf{y}\,\mathsf{Z}.$$

Then, the single parameter y gets transformed into three parameters:

$$\mathsf{S}' \to \mathsf{T}'\,\mathsf{Y}_1\,\mathsf{Y}_2\,\mathsf{Y}_4,$$
$$\mathsf{T}'\,\mathsf{y}_1\,\mathsf{y}_2\,\mathsf{y}_4 \to \langle \mathrm{Eve}, 1, \langle \mathrm{Adam}, 1, \mathsf{y}_1, \langle \mathrm{Eve}, 1, \mathsf{Z}'\rangle\rangle, \langle \mathrm{Adam}, 1, \mathsf{y}_2, \langle \mathrm{Eve}, 2, \mathsf{Z}'\rangle\rangle, \mathsf{y}_4\rangle.$$

Formal definition. We now formalize the above intuitions. Fix a parity recursion scheme $\mathcal{G} = (\mathcal{X}, X_0, \Sigma_d, \mathcal{R})$; in particular fix a bound d on priorities appearing in $\mathcal{G}$.

A set D_d of Eve's *declarations* is defined as $D_d = \{1, \dots, d, 2d\}$. For a priority $p \in [d]$ and a declaration $r \in D_d$ we define a *shifted* declaration $r{\restriction_p}$ (obtained from r after seeing priority p):

$$r{\restriction_p} = \begin{cases} p+1 & \text{if } p \text{ is odd and } p > r, \\ p-1 & \text{if } p \text{ is even and } p \geq r, \\ r & \text{otherwise.} \end{cases}$$

We remark that the same definition appears in Tsukada and Ong [30] (where shifts are called left-residuals); a slightly different representation is present also in Salvati and Walukiewicz [26] (with declarations called residuals and shifts called liftings).

The *leader* ("most important priority") of a sequence of priorities π is the greatest priority appearing in π, or 1 if π is empty. A sequence of priorities π *fulfils* a declaration $r \in D_d$ if r is worse or equal than the leader of π (where "worse" refers to the $\preceq$ order defined in Section 2). For example, $1, 4, 2$, and $1, 1, 1$, both fulfil 3, but $1, 5, 4$ does not. The empty sequence fulfils r exactly when r is odd. No sequence of priorities from $[d]$ fulfils $2d$. The following lemma is obtained by a direct analysis (see Appendix B of the full version):

▶ **Lemma 3.2.** *A sequence of priorities $p_1, p_2, \dots, p_k \in [d]$ fulfils a declaration $r \in D_d$ if and only if $p_2, \dots, p_k$ fulfils $r{\restriction_{p_1}}$.*

Having a type, we are interested in cutting off its suffix of order 1. Thus, we use the notation $\alpha_1 \to \cdots \to \alpha_k \Rightarrow \mathsf{o}^\ell \to \mathsf{o}$ for a type $\alpha_1 \to \cdots \to \alpha_k \to \mathsf{o}^\ell \to \mathsf{o}$ such that either $k = 0$ or $\alpha_k \neq \mathsf{o}$. Notice that every type α can be uniquely represented in this form. We remark that some among the types $\alpha_1, \dots, \alpha_{k-1}$ (but not α_k) may be o. For a type α we write $\mathsf{gar}(\alpha)$ ("ground arity") for the number ℓ for which we can write $\alpha = (\alpha_1 \to \cdots \to \alpha_k \Rightarrow \mathsf{o}^\ell \to \mathsf{o})$; we also extend this to terms: $\mathsf{gar}(M) = \mathsf{gar}(\mathsf{tp}(M))$.

We transform terms of type α to terms of type $\alpha^{\dagger_d}$, which is defined by induction:

$$(\alpha_1 \to \cdots \to \alpha_k \Rightarrow \mathsf{o}^\ell \to \mathsf{o})^{\dagger_d} = \left((\alpha_1^{\dagger_d})^{|D_d|^{\mathsf{gar}(\alpha_1)}} \to \cdots \to (\alpha_k^{\dagger_d})^{|D_d|^{\mathsf{gar}(\alpha_k)}} \to \mathsf{o} \right).$$

Thus, we remove all trailing order-0 arguments, and we multiplicate (and recursively transform) remaining arguments. The number of copies depends on the bound d on priorities appearing in the considered parity recursion scheme.

For a finite set S, we write D_d^S for the set of functions $A \colon S \to D_d$. Moreover, we assume some fixed order on functions in D_d^S, and we write $P\,(Q_A)_{A \in D_d^S}$ for an application $P\,Q_{A_1} \dots Q_{A_{|D_d|^{|S|}}}$, where $A_1, \dots, A_{|D_d|^{|S|}}$ are all the functions from D_d^S listed in the fixed order. The only function in $D_d^\varnothing$ is denoted $\varnothing$.

For every variable y and for every function $A \in D_d^{[\mathsf{gar}(y)]}$ we consider a variable $y_A^{\dagger_d}$ of type $(\mathsf{tp}(y))^{\dagger_d}$. Likewise, for every nonterminal X of $\mathcal{G}$ and for every function $A \in D_d^{[\mathsf{gar}(X)]}$ we consider a nonterminal $X_A^{\dagger_d}$ of type $(\mathsf{tp}(X))^{\dagger_d}$. As the new set of nonterminals we take $\mathcal{X}^{\dagger_d} = \{X_A^{\dagger_d} \mid X \in \mathcal{X}, A \in D_d^{[\mathsf{gar}(X)]}\} \cup \{\underline{\bot}, \overline{\top}\}$.

We now define a function tr_d transforming terms. Its value $\mathsf{tr}_d(A, Z, M)$ is defined when M is a term over $(\mathcal{X}, \mathcal{Y}, \Sigma_d)$ for some set of variables $\mathcal{Y}$, and $A \in D_d^{[\mathsf{gar}(M)]}$, and $Z \colon \mathcal{Y} \rightharpoonup D_d$ is a partial function such that $\mathrm{dom}(Z)$ contains only variables of type o. The intention is that A specifies Eve's declarations for trailing order-0 arguments, and Z specifies them for order-0 variables (among those in $\mathrm{dom}(Z)$). The transformation is defined by induction on the structure of M, as follows:

(1) $\mathsf{tr}_d(A, Z, X) = X_A^{\dagger_d}$ for $X \in \mathcal{X}$;
(2) $\mathsf{tr}_d(A, Z, y) = y_A^{\dagger_d}$ for $y \in \mathcal{Y} \setminus \mathrm{dom}(Z)$;
(3) $\mathsf{tr}_d(\varnothing, Z, z) = \overline{\top}$ if $Z(z)$ is odd;
(4) $\mathsf{tr}_d(\varnothing, Z, z) = \underline{\bot}$ if $Z(z)$ is even;
(5) $\mathsf{tr}_d(\varnothing, Z, \langle \wp, p, K_1, \dots, K_k\rangle) = \langle \wp, p, \mathsf{tr}_d(\varnothing, Z{\restriction_p}, K_1), \dots, \mathsf{tr}_d(\varnothing, Z{\restriction_p}, K_k)\rangle$, where $Z{\restriction_p}$ is the function defined by $Z{\restriction_p}(z) = (Z(z)){\restriction_p}$ for all $z \in \mathrm{dom}(Z)$;
(6) $\mathsf{tr}_d(A, Z, K\,L) = \langle \mathrm{Eve}, 1, K_1^L, K_2^L, \dots, K_d^L, K_{2d}\rangle$ if $\mathsf{tp}(K) = (\mathsf{o}^{\ell+1} \to \mathsf{o})$, where $K_r^L = \langle \mathrm{Adam}, 1, K_r, \langle \mathrm{Eve}, r, \mathsf{tr}_d(\varnothing, Z{\restriction_r}, L)\rangle\rangle$ for $r \in [d]$ and $K_r = \mathsf{tr}_d(A[\ell+1 \mapsto r], Z, K)$ for $r \in D_d$;
(7) $\mathsf{tr}_d(A, Z, K\,L) = (\mathsf{tr}_d(A, Z, K))\,(\mathsf{tr}_d(B, Z, L))_{B \in D_d^{[\mathsf{gar}(L)]}}$ if $\mathsf{tp}(K) = (\alpha_1 \to \cdots \to \alpha_k \Rightarrow \mathsf{o}^{\ell} \to \mathsf{o})$ with $k \geq 1$.

In Cases (3), (4), and (5) the term is of type o, so the "A" argument is necessarily $\varnothing$ (a function with an empty domain).

For every rule $X\,y_1 \dots y_k\,z_1 \dots z_\ell \to R$ in $\mathcal{R}$, where $\ell = \mathsf{gar}(X)$, and for every function $A \in D_d^{[\ell]}$, to $\mathcal{R}^{\dagger_d}$ we take the rule

$$X_A^{\dagger_d}\,(y_{1,B}^{\dagger_d})_{B \in D_d^{[\mathsf{gar}(y_1)]}} \dots (y_{k,B}^{\dagger_d})_{B \in D_d^{[\mathsf{gar}(y_k)]}} \to \mathsf{tr}_d(\varnothing, [z_i \mapsto A(\ell+1-i) \mid i \in [\ell]], R).$$

In the function A it is more convenient to count arguments from right to left (then we do not need to shift the domain in Case (6) above), but it is more natural to have variables $z_1, \dots, z_\ell$ numbered from left to right; this is why in the rule for $X_A^{\dagger_d}$ we assign to z_i the value $A(\ell+1-i)$, not $A(i)$. Additionally, in $\mathcal{R}^{\dagger_d}$ we have rules $\underline{\bot} \to \langle \mathrm{Eve}, 1, \underline{\bot}\rangle$ and $\overline{\top} \to \langle \mathrm{Eve}, 2, \overline{\top}\rangle$. Then Eve loses (wins) in the tree $\bot$ ($\top$) generated by $\mathcal{G}^\dagger$ from $\underline{\bot}$ ($\overline{\top}$, respectively).

Finally, the resulting recursion scheme $\mathcal{G}^\dagger$ is $(\mathcal{X}^{\dagger_d}, X_{0,\varnothing}^{\dagger_d}, \Sigma_d, \mathcal{R}^{\dagger_d})$. This finishes the definition of the transformation. In the next section we analyze its complexity, and in Section 5 we justify its correctness.

▶ Remark 3.3. Let us briefly compare our transformation with a transformation by Broadbent et al. [4] reducing the order of a collapsible pushdown automaton by one while preserving the winner of the generated parity game. Although their transformation seems technically more complicated, its overall idea is quite similar to what we do in this paper. Their transformation is split into three independent steps. First, they make the automaton "rank-aware", which means that it knows what was the highest priority visited between creation of a collapse link and its usage. This corresponds to adding the parameters A and Z to our transformation, so that we know whether a declaration is fulfilled when a variable z is used. Second, they eliminate collapse links of order n, which in our case corresponds to removing trailing arguments of order 0 and introducing the gadget asking Eve for a declaration. Third, they reduce the order of the automaton by one, which we also do for recursion schemes.

4 Complexity

In this section we analyze complexity of our transformation. First, we formally define the *size* of a recursion scheme. The size of a term is defined by induction on its structure:

$$|X| = |y| = 1, \qquad |K\,L| = 1 + |K| + |L|,$$
$$|\langle a, K_1, \dots, K_k\rangle| = 1 + |K_1| + \cdots + |K_k|.$$

Then $|\mathcal{G}|$, the size of $\mathcal{G}$, is defined as the sum of $|R| + k$ over all rules $X\,y_1 \dots y_k \to R$ of $\mathcal{G}$. In Asada and Kobayashi [2] such a size is called *Curry-style* size; it does not include sizes of types of employed variables.

We say that a type α *appears in the definition* of a type β if either $\alpha = \beta$, or $\beta = (\beta_1 \to \beta_2)$ and α appears in the definition of β_1 or of β_2. We write $A_{\mathcal{G}}$ for the largest arity of types appearing in the definition of types of nonterminals in a recursion scheme $\mathcal{G}$. Notice that types of other objects used in $\mathcal{G}$, namely variables and subterms of right-hand sides of rules, appear in the definition of types of nonterminals, hence their arity is also bounded by $A_{\mathcal{G}}$. It is reasonable to consider large recursion schemes, consisting of many rules, where simultaneously the maximal arity $A_{\mathcal{G}}$ is respectively small.

While the exponential bound mentioned in Theorem 3.1 is obtained by applying the order-reducing transformation to an arbitrary parity recursion scheme, the complexity becomes slightly better if we first apply a preprocessing step. This is in particular necessary, if we want to obtain linear dependence in the size of $\mathcal{G}$ (and exponential only in the maximal arity $A_{\mathcal{G}}$). The preprocessing, making sure that the recursion scheme is in a *simple form* (defined below), amounts to splitting large rules into multiple smaller rules. A similar preprocessing is present already in prior work [19, 2, 11, 24].

An *application depth* of a term R is defined as the maximal number of applications on a single branch in R, where a compound application $K\,L_1\,\ldots\,L_k$ counts only once. More formally, we define by induction:

$$\mathsf{ad}(\langle a, K_1, \ldots, K_k\rangle) = \max\{\mathsf{ad}(K_i) \mid i \in [k]\},$$
$$\mathsf{ad}(X\,K_1\,\ldots\,K_k) = \mathsf{ad}(y\,K_1\,\ldots\,K_k) = \max(\{0\} \cup \{\mathsf{ad}(K_i) + 1 \mid i \in [k]\}).$$

We say that a recursion scheme $\mathcal{G}$ is in a *simple form* if the right-hand side of each its rule has application depth at most 2. We have the following:

▶ **Lemma 4.1** ([24, Lemma 4.1])**.** *For every recursion scheme $\mathcal{G}$ there exists a recursion scheme $\mathcal{G}'$ being in a simple form, generating the same tree as $\mathcal{G}$, and such that $\mathsf{ord}(\mathcal{G}') = \mathsf{ord}(\mathcal{G})$, and $A_{\mathcal{G}'} \le 2A_{\mathcal{G}}$, and $|\mathcal{G}'| = \mathcal{O}(A_{\mathcal{G}} \cdot |\mathcal{G}|)$. The recursion scheme $\mathcal{G}'$ can be created in time linear in its size.*

We now state and prove the main lemma of this section:

▶ **Lemma 4.2.** *For every parity recursion scheme $\mathcal{G} = (\mathcal{X}, X_0, \Sigma_d, \mathcal{R})$ in a simple form, the recursion scheme $\mathcal{G}^\dagger$ (i.e., the result of the order-reducing transformation) is also in a simple form, and $\mathsf{ord}(\mathcal{G}^\dagger) = \max(0, \mathsf{ord}(\mathcal{G}) - 1)$, and $A_{\mathcal{G}^\dagger} \le A_{\mathcal{G}} \cdot (d+1)^{A_{\mathcal{G}}}$, and $|\mathcal{G}^\dagger| = \mathcal{O}(|\mathcal{G}| \cdot (d+1)^{5 \cdot A_{\mathcal{G}}})$. Moreover, $\mathcal{G}^\dagger$ can be created in time linear in its size.*

Proof. The part about the running time is obvious. It is also easy to see by induction that $\mathsf{ord}(\alpha^{\dagger_d}) = \max(0, \mathsf{ord}(\alpha) - 1)$. It follows that the order of the recursion scheme satisfies the same equality, because nonterminals of $\mathcal{G}^\dagger$ have type $\alpha^{\dagger_d}$ for α being the type of a corresponding nonterminal of $\mathcal{G}$.

Recall that in the type $\alpha^{\dagger_d}$ obtained from $\alpha = (\alpha_1 \to \cdots \to \alpha_k \to \mathsf{o})$, every α_i either disappears or becomes (transformed and) repeated $|D_d|^{\mathsf{gar}(\alpha_i)}$ times, that is, at most $(d+1)^{A_{\mathcal{G}}}$ times. This implies the inequality concerning $A_{\mathcal{G}^\dagger}$.

Every compound application can be written as $f\,K_1\,\ldots\,K_k\,L_1\,\ldots\,L_\ell$, where f is a nonterminal or a variable, and $\ell = \mathsf{gar}(f)$. In such a term, every K_i (after being transformed) gets repeated $|D_d|^{\mathsf{gar}(K_i)}$ times, that is, at most $(d+1)^{A_{\mathcal{G}}}$ times. Then, for every L_i we replicate the outcome $d+1$ times, and we append a small prefix; this replication happens ℓ times (and $\ell \le A_{\mathcal{G}}$). In consequence, we easily see by induction that while transforming a term of application depth c, its size gets multiplicated by at most $O((d+1)^{2c \cdot A_{\mathcal{G}}})$. Moreover, every nonterminal X is repeated $|D_d|^{\mathsf{gar}(X)}$ times, that is, at most $(d+1)^{A_{\mathcal{G}}}$ times. Because the application depth of right-hand sides of rules is at most 2, this bounds the size of the new recursion scheme by $\mathcal{O}(|\mathcal{G}| \cdot (d+1)^{5 \cdot A_{\mathcal{G}}})$.

Looking again at the above description of the transformation, we can notice that the application depth cannot grow; in consequence the property of being in a simple form is preserved. ◀

Thus, if we want to check whether Eve wins in the tree generated by a parity recursion scheme $\mathcal{G}$ of order n, we can first convert $\mathcal{G}$ to a simple form, and then apply the order-reducing transformation n times. This gives us a parity recursion scheme of order 0, which can be seen as a finite parity game with d priorities. Such a game can be solved in time $O(N^4 \cdot 2^d)$, where N is its size [8]. Thus, by Lemmata 4.1 and 4.2, the whole algorithm works in time n-fold exponential in $A_{\mathcal{G}}$ and d, and polynomial (quartic) in $|\mathcal{G}|$.

If $\mathcal{G}$ is created as a product of a recursion scheme $\mathcal{H}$ and an alternating parity automaton $\mathcal{A}$, the running time is n-fold exponential in $A_{\mathcal{H}}$ and $|\mathcal{A}|$, and quartic in $|\mathcal{H}|$ (cf. Appendix A of the full version).

5 Correctness

In this section we finish a proof of Theorem 3.1 by showing that the winner in the tree generated by the recursion scheme $\mathcal{G}^\dagger$ resulting from transforming a recursion scheme $\mathcal{G}$ is the same as in the tree generated by the original recursion scheme $\mathcal{G}$. Our proof consists of three parts. First, we show that reductions performed by $\mathcal{G}$ can be reordered, so that we can postpone substituting for (trailing) variables of order 0. To store such postponed substitutions, called *explicit substitutions*, we introduce *extended trees*. Second, we show that such reordered reductions in $\mathcal{G}$ are in a direct correspondence with reductions in $\mathcal{G}^\dagger$. Finally, we show how winning strategies of particular players from the tree generated by $\mathcal{G}^\dagger$ can be transferred to the tree generated by $\mathcal{G}$.

Extended trees and terms. In the sequel, trees and terms defined previously are sometimes called non-extended trees and non-extended terms, in order to distinguish them from extended trees and extended terms defined below. Having a set $\mathcal{Z}$ of variables of type o and a set of symbols Σ, (potentially infinite) *extended trees* over $(\mathcal{Z}, \Sigma)$ are defined by coinduction: every extended tree over $(\mathcal{Z}, \Sigma)$ is of the form either

- $\langle a, T_1, \dots, T_k \rangle$, where $a \in \Sigma$ and $T_1, \dots, T_k$ are again extended trees over Σ, or
- z for some variable $z \in \mathcal{Z}$, or
- $T(\!|U/z|\!)$, where $z \notin \mathcal{Z}$ is a variable of type o, and T is an extended tree over $(\mathcal{Z} \cup \{z\}, \Sigma)$, and U is an extended tree over $(\mathcal{Z}, \Sigma)$.

The construction of the form $T(\!|U/z|\!)$ is called an *explicit substitution*. Intuitively, it denotes the tree obtained by substituting U for z in T. Notice that the variable z being free in T becomes bound in $T(\!|U/z|\!)$.

Likewise, having a set of typed nonterminals $\mathcal{X}$, a set $\mathcal{Z}$ of variables of type o, and a set of symbols Σ, *extended terms* over $(\mathcal{X}, \mathcal{Z}, \Sigma)$ are defined by induction:

- if $z \notin \mathcal{Z}$ is a variable of type o, and E is an extended term over $(\mathcal{X}, \mathcal{Z} \cup \{z\}, \Sigma)$, and L is a non-extended term of type o over $(\mathcal{X}, \mathcal{Z}, \Sigma)$, then $E(\!|L/z|\!)$ is an extended term over $(\mathcal{X}, \mathcal{Z}, \Sigma)$;
- every non-extended term of type o over $(\mathcal{X}, \mathcal{Z}, \Sigma)$ is an extended term over $(\mathcal{X}, \mathcal{Z}, \Sigma)$.

Notice that explicit substitutions can be placed anywhere inside an extended tree, while in an extended term they are allowed only to surround a non-extended term.

Of course an extended tree over $(\mathcal{Z}, \Sigma)$ can be also seen as an extended tree over $(\mathcal{Z}', \Sigma)$, where $\mathcal{Z}' \supseteq \mathcal{Z}$; likewise for extended terms. In the sequel, such extending of the set of variables is often performed implicitly.

Having a recursion scheme $\mathcal{G} = (\mathcal{X}, X_0, \Sigma, \mathcal{R})$, for every set $\mathcal{Z}$ of variables of type o we define an *ext-reduction* relation $\rightsquigarrow_{\mathcal{G}}$ between extended terms over $(\mathcal{X}, \mathcal{Z}, \Sigma)$, as the least relation such that

- $X\,K_1\,\ldots\,K_k\,L_1\,\ldots\,L_\ell \;\rightsquigarrow_{\mathcal{G}}\; R[K_1/y_1, \ldots, K_k/y_k, z'_1/z_1, \ldots, z'_\ell/z_\ell](\!|L_1/z'_1|\!)\ldots(\!|L_\ell/z'_\ell|\!)$ if $\ell = \mathsf{gar}(X)$, and $\mathcal{R}(X) = (X\,y_1\,\ldots\,y_k\,z_1\,\ldots\,z_\ell \to R)$, and $z'_1, \ldots, z'_\ell$ are fresh variables of type o not appearing in $\mathcal{Z}$.

Then, we define by coinduction the extended tree (over $(\mathcal{Z}, \Sigma)$) *ext-generated* by $\mathcal{G}$ from an extended term E (over $(\mathcal{X}, \mathcal{Z}, \Sigma)$), denoted $\mathsf{BT}^{\mathsf{ext}}_{\mathcal{G}}(E)$:

- if $E \rightsquigarrow^*_{\mathcal{G}} \langle a, F_1, \ldots, F_k\rangle$, then $\mathsf{BT}^{\mathsf{ext}}_{\mathcal{G}}(E) = \langle a, \mathsf{BT}^{\mathsf{ext}}_{\mathcal{G}}(F_1), \ldots, \mathsf{BT}^{\mathsf{ext}}_{\mathcal{G}}(F_k)\rangle$;
- if $E \rightsquigarrow^*_{\mathcal{G}} F(\!|L/z|\!)$, then $\mathsf{BT}^{\mathsf{ext}}_{\mathcal{G}}(E) = \mathsf{BT}^{\mathsf{ext}}_{\mathcal{G}}(F)(\!|\mathsf{BT}^{\mathsf{ext}}_{\mathcal{G}}(L)/z|\!)$;
- otherwise, $\mathsf{BT}^{\mathsf{ext}}_{\mathcal{G}}(E) = \langle\omega\rangle$.

The extended tree ext-generated by $\mathcal{G}$ (without mentioning a term), denoted $\mathsf{BT}^{\mathsf{ext}}(\mathcal{G})$, is defined as $\mathsf{BT}^{\mathsf{ext}}_{\mathcal{G}}(X_0)$. Formally, the ext-generated extended tree is not unique, because arbitrary fresh names may be used for bound variables; we should thus identify extended trees differing only in names of bound variables.

Finally, we say how to convert extended trees to trees, by performing all postponed substitutions. To this end, having fixed a set Σ of symbols, we define a *simplification* relation $\mapsto$ between extended trees over $(\varnothing, \Sigma)$ as the least relation such that

- $\langle a, T_1, \ldots, T_k\rangle(\!|L_1/z_1|\!)\ldots(\!|L_\ell/z_\ell|\!) \mapsto \langle a, T_1(\!|L_1/z_1|\!)\ldots(\!|L_\ell/z_\ell|\!), \ldots, T_k(\!|L_1/z_1|\!)\ldots(\!|L_\ell/z_\ell|\!)\rangle$, and
- $z_i(\!|L_1/z_1|\!)\ldots(\!|L_\ell/z_\ell|\!) \mapsto L_i(\!|L_{i+1}/z_{i+1}|\!)\ldots(\!|L_\ell/z_\ell|\!)$.

Then, we define by coinduction the *expansion* of an extended tree T over $(\varnothing, \Sigma)$, being a tree over Σ, and denoted $\mathsf{BT}^{\mathsf{s}}(T)$:

- if $T \mapsto^* \langle a, T_1, \ldots, T_k\rangle$, then $\mathsf{BT}^{\mathsf{s}}(T) = \langle a, \mathsf{BT}^{\mathsf{s}}(T_1), \ldots, \mathsf{BT}^{\mathsf{s}}(T_k)\rangle$;
- otherwise, $\mathsf{BT}^{\mathsf{s}}(T) = \langle\omega\rangle$.

The following lemma says that instead of generating a tree, we can first ext-generate an extended tree, and then expand all the explicit substitutions:

▶ **Lemma 5.1.** *For every recursion scheme $\mathcal{G}$ it holds that* $\mathsf{BT}(\mathcal{G}) = \mathsf{BT}^{\mathsf{s}}(\mathsf{BT}^{\mathsf{ext}}(\mathcal{G}))$.

The lemma can be proved in a standard way; a proof is contained in Appendix C of the full version (similar lemmata appear in previous work [2, Lemma 18], [24, Lemma 5.1]).

Transforming extended parity trees. An *extended parity tree* is an extended tree whose expansion is a parity tree. We now show how the transformation, defined previously for terms, can be applied to extended parity trees. Namely, we define $\mathsf{tr}^{\mathsf{t}}_d(Z, T)$ when T is an extended tree over $(\mathcal{Z}, \Sigma_d)$ for some set $\mathcal{Z}$ of variables of type o, and $Z\colon \mathcal{Z} \to D_d$ (we do not need an "A" argument, used previously to store declarations for arguments, because extended trees have no arguments). The definition is by coinduction:

(3') $\mathsf{tr}^{\mathsf{t}}_d(Z, z) = \top$ if $Z(z)$ is odd;
(4') $\mathsf{tr}^{\mathsf{t}}_d(Z, z) = \bot$ if $Z(z)$ is even;
(5') $\mathsf{tr}^{\mathsf{t}}_d(Z, \langle \wp, p, K_1, \ldots, K_k\rangle) = \langle \wp, p, \mathsf{tr}^{\mathsf{t}}_d(Z\restriction_p, K_1), \ldots, \mathsf{tr}^{\mathsf{t}}_d(Z\restriction_p, K_k)\rangle$;
(8') $\mathsf{tr}^{\mathsf{t}}_d(Z, T(\!|U/z|\!)) = \langle \mathrm{Eve}, 1, T_1^U, T_2^U, \ldots, T_d^U, T_{2d}\rangle$, where we take $T_r^U = \langle \mathrm{Adam}, 1, T_r, \langle \mathrm{Eve}, r, \mathsf{tr}^{\mathsf{t}}_d(Z\restriction_r, U)\rangle\rangle$ for $r \in [d]$ and $T_r = \mathsf{tr}^{\mathsf{t}}_d(Z[z \mapsto r], T)$ for $r \in D_d$.

Notice that tr_d transforms a term z to nonterminals $\overline{\top}$ or $\underline{\bot}$, while $\mathsf{tr}^{\mathsf{t}}_d$ transforms an extended tree z to trees $\top$ or $\bot$, generated from those nonterminals.

In the next lemma we observe that the tree generated by the transformed recursion scheme $\mathcal{G}^\dagger$ can be obtained by transforming the extended tree ext-generated by the original recursion scheme $\mathcal{G}$:

▶ **Lemma 5.2.** *For every parity recursion scheme $\mathcal{G}$ it holds that* $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, \mathsf{BT}^{\mathsf{ext}}(\mathcal{G})) = \mathsf{BT}(\mathcal{G}^\dagger)$.

The proof is purely syntactical, and is contained in Appendix D of the full version.

Transforming strategies. We finish our correctness proof by showing the following lemma:

▶ **Lemma 5.3.** *Let T be an extended parity tree over $(\varnothing, \Sigma_d)$. If a player $\wp \in \{\text{Adam}, \text{Eve}\}$ wins in $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$, then $\wp$ wins also in $\mathsf{BT}^{\mathsf{s}}(T)$.*

Recall that the goal of this section is to prove that the winner in $\mathsf{BT}(\mathcal{G}^\dagger)$ is the same as in $\mathsf{BT}(\mathcal{G})$, for every parity recursion scheme $\mathcal{G}$. This follows from the above lemma used for $T = \mathsf{BT}^{\mathsf{ext}}(\mathcal{G})$, because $\mathsf{BT}(\mathcal{G}^\dagger) = \mathsf{tr}^{\mathsf{t}}_d(\varnothing, \mathsf{BT}^{\mathsf{ext}}(\mathcal{G}))$ by Lemma 5.2 and $\mathsf{BT}(\mathcal{G}) = \mathsf{BT}^{\mathsf{s}}(\mathsf{BT}^{\mathsf{ext}}(\mathcal{G}))$ by Lemma 5.1.

We now come to a proof of Lemma 5.3. In the sequel we assume a fixed extended parity tree T over $(\varnothing, \Sigma_d)$. Suppose first that it is Eve who wins in $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$; thus, we also fix her winning strategy ρ in this tree. Our goal is to construct Eve's winning strategy ρ' in $\mathsf{BT}^{\mathsf{s}}(T)$.

In the proof, we use two additional notions. First, we say that a sequence of priorities $r_1, \dots, r_k$ is a $\preceq$-*contraction* of a sequence of priorities $p_1, \dots, p_n$ if the latter can be split at some indices $i_0, i_1, \dots, i_k$, where $0 = i_0 \le i_1 \le \cdots \le i_k = n$, so that for every $j \in [k]$ the infix $p_{i_{j-1}+1}, p_{i_{j-1}+2}, \dots, p_{i_j}$ fulfils declaration r_j. Likewise we define $\preceq$-contractions for infinite sequences, only there are infinitely many splitting indices (which necessarily tend to infinity, meaning that the whole infinite sequence is split).

Notice that we allow empty infixes, so one can arbitrarily insert odd numbers r_j (i.e., numbers r_j fulfilled by the empty sequence) to the $\preceq$-contraction. For example, $3, 4, 2$ is a $\preceq$-contraction of $4, 3, 2, 3, 4$ because the empty sequence fulfils 3, and $4, 3$ fulfils 4, and $2, 3, 4$ fulfils 2. On the other hand, $3, 4, 2$ is not a $\preceq$-contraction of $4, 3, 2, 3$. The idea of $\preceq$-contractions is to describe what happens when we move from $\mathsf{BT}^{\mathsf{s}}(T)$ to $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$. Indeed, if T has a subtree of the form $U(\!|V/z|\!)$, then in $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$ the play can continue to V after playing only an Eve's declaration r (skipping completely U), while in $\mathsf{BT}^{\mathsf{s}}(T)$ before reaching V we traverse through U, where visited priorities are intended to fulfil r.

It is easy to see that $\preceq$-contractions are transitive, and that they can make the situation only worse for Eve:

▶ **Lemma 5.4.** *If a sequence π_1 is a $\preceq$-contraction of a sequence π_2, which is in turn a $\preceq$-contraction of a sequence π_3, then π_1 is a $\preceq$-contraction of π_3.*

▶ **Lemma 5.5.** *If an infinite sequence π_1 is a $\preceq$-contraction of an infinite sequence π_2, and the greatest priority appearing infinitely often in π_1 is even, then the greatest priority appearing infinitely often in π_2 is even as well.*

We now introduce the second notion (it concerns only finite sequences, and is relative to the bound d on priorities): for a declaration $r \in D_d$ and two sequences π_1, π_2 of priorities from $[d]$ we say that π_1 is an r-*extension* of π_2 if for every sequence π_3 of priorities from $[d]$ that fulfils the declaration r, the sequence π_1 is a $\preceq$-contraction of the concatenation $\pi_2 \cdot \pi_3$.

For example, the sequence $3, 4, 4$ is a 5-extension of the sequence $4, 3, 6$ (independently from the value of $d \ge 6$), because the empty sequence fulfils 3, and $4, 3$ fulfils 4, and $6, p_1, \dots, p_k$ fulfils 4 whenever $p_1, \dots, p_k$ fulfils 5 (i.e., the maximum among $p_1, \dots, p_k$ is either even or at most 5). Notice, moreover, that every sequence is a $2d$-extension of every sequence, because no sequence of priorities from $[d]$ can fulfil the declaration $2d$.

The following lemma is a direct consequence of the definition and of Lemma 3.2:

▶ **Lemma 5.6.** *If a sequence π is an r-extension of a sequence $p_1, \dots, p_n$, then π is also an $r{\restriction_{p_{n+1}}}$-extension of $p_1, \dots, p_n, p_{n+1}$ for every priority $p_{n+1} \in [d]$.*

Additionally, for a node v (of some parity tree) we write $\pi(v)$ for the sequence of priorities in ancestors of v (not including the priority in v).

We now come back to the proof, showing how to construct the new strategy ρ', winning for Eve in $\mathsf{BT}^{\mathsf{s}}(T)$. In order to describe ρ', we play simultaneously in both trees, $\mathsf{BT}^{\mathsf{s}}(T)$ and $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$, and we use moves in one tree to choose moves in the other tree. Namely, at every moment of the play, we remember

- a current node v in $\mathsf{BT}^{\mathsf{s}}(T)$,
- nodes $w_0, w_1, \dots, w_\ell$ in $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$, for some $\ell \in \mathbb{N}$,
- variables $z_1, \dots, z_\ell$ of type o,
- functions $Z_0, Z_1, \dots, Z_\ell$ storing Eve's declarations, where $Z_i \colon \{z_{i+1}, \dots, z_\ell\} \to D_d$ for every i, and
- extended trees $U_0, U_1, \dots, U_\ell$, where every U_i is over $(\{z_{i+1}, \dots, z_\ell\}, \Sigma_d)$.

They satisfy the following invariant:

(a) $\mathsf{BT}^{\mathsf{s}}(T){\restriction_v} = \mathsf{BT}^{\mathsf{s}}(U_0(\!|U_1/z_1|\!) \dots (\!|U_\ell/z_\ell|\!))$,
(b) $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T){\restriction_{w_i}} = \mathsf{tr}^{\mathsf{t}}_d(Z_i, U_i)$ for all $i \in \{0, 1, \dots, \ell\}$,
(c) $\pi(w_0)$ is a $\preceq$-contraction of $\pi(v)$, and
(d) $\pi(w_j)$ is a $Z_i(z_j)$-extension of $\pi(w_i)$, for all i, j such that $0 \le i < j \le \ell$.

We start with $\ell = 0$, with v and w_0 at the root of $\mathsf{BT}^{\mathsf{s}}(T)$ and $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$, respectively, with $Z_0 = \varnothing$, and with $U_0 = T$. The invariant is clearly satisfied.

Then, during the play, we have one of three cases, depending on the shape of U_0:

1. First, assume that $U_0 = \langle \wp, p, T_1, \dots, T_k \rangle$. Then

$$\mathsf{BT}^{\mathsf{s}}(T){\restriction_v} = \langle \wp, p, \mathsf{BT}^{\mathsf{s}}(T_1(\!|U_1/z_1|\!) \dots (\!|U_\ell/z_\ell|\!)), \dots, \mathsf{BT}^{\mathsf{s}}(T_k(\!|U_1/z_1|\!) \dots (\!|U_\ell/z_\ell|\!)) \rangle;$$
$$\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T){\restriction_{w_0}} = \langle \wp, p, \mathsf{tr}^{\mathsf{t}}_d(Z_0, T_1), \dots, \mathsf{tr}^{\mathsf{t}}_d(Z_0, T_k) \rangle.$$

If $\wp$ = Adam, Adam chooses some child of v in $\mathsf{BT}^{\mathsf{s}}(T)$, and we choose the same child of w_0 in $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$. If $\wp$ = Eve, Eve chooses some child of w_0 in $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$, according to her strategy ρ, and in ρ' we choose the same child of v. Thus, in both cases, we move both v and w_0 to their c-th child, for some $c \in [k]$. We also take $Z_0{\restriction_p}$ as the new Z_0 and T_c as the new U_0. Lemma 5.6 ensures that Item (d) of the invariant is preserved.

2. Another possibility is that U_0 is a variable, that is, $U_0 = z_c$ for some $c \in [\ell]$. Then $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T){\restriction_{w_0}}$ (i.e., $\mathsf{tr}^{\mathsf{t}}_d(Z_0, U_0)$) is either $\bot$ or $\top$, depending on the parity of $Z_0(z_c)$. But our play in $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$ follows an Eve's winning strategy, so it will be won by Eve, thus the subtree cannot be $\bot$, in which Eve is losing. In consequence $Z_0(z_c)$ is odd, so the empty sequence fulfils $Z_0(z_c)$. This implies that $\pi(w_c)$, being an $Z_0(z_c)$-extension of $\pi(w_0)$, is its $\preceq$-contraction, and thus also an $\preceq$-contraction of $\pi(v)$ (by Lemma 5.4). We discard w_i, z_i, Z_i, U_i for $i < c$ (so that w_c becomes now w_0, etc.).

3. Finally, assume that $U_0 = V(\!|W/z|\!)$. Then $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T){\restriction_{w_0}} = \langle \mathrm{Eve}, 1, V_1^W, \dots, V_d^W, V_{2d} \rangle$, where $V_r^W = \langle \mathrm{Adam}, 1, V_r, \langle \mathrm{Eve}, r, \mathsf{tr}^{\mathsf{t}}_d(Z_0{\restriction_r}, W) \rangle \rangle$ for $r \in [d]$ and $V_r = \mathsf{tr}^{\mathsf{t}}_d(Z_0[z \mapsto r], V)$ for $r \in D_d$. In such a node w_0 Eve, according to her strategy ρ, chooses a declaration r by going to an appropriate subtree V_r^W (or V_r if $r = 2d$). We then update our memory as follows:

- We leave v and w_i, z_i, Z_i, U_i for $i \ge 1$ unchanged.
- We move w_0 to the root of V_r (this adds once or twice priority 1 to $\pi(w_0)$, hence Item (c) of the invariant is preserved).

- Let $r' = r$ if $r \in [d]$, and $r' = 1$ if $r = 2d$.
- We add an additional node $w_{0.5}$ between w_0 and w_1 (saying this differently, we shift w_i for $i \geq 1$ by one, and we insert the new node in place of w_1). For $w_{0.5}$ we choose the root of $\mathsf{tr}^{\mathsf{t}}_d(Z_0{\restriction}_{r'}, W)$. Notice that $\pi(w_{0.5})$ is an r-extension of $\pi(w_0)$ (for $r \in [d]$ because $\pi(w_{0.5})$ is obtained from $\pi(w_0)$ by appending the priority $r' = r$, and for $r = 2d$ because no sequence of priorities from $[d]$ fulfils $2d$), and that every $\pi(w_j)$ for $1 \leq j \leq \ell$ is a $Z_0{\restriction}_{r'}(z_j)$-extension of $\pi(w_{0.5})$ (by Lemma 5.6).
- As Z_0, U_0, $z_{0.5}$, $Z_{0.5}$, and $U_{0.5}$ we take $Z_0[z \mapsto r]$, V, z, $Z_0{\restriction}_{r'}$, and W, respectively.

Observe that after finitely many repetitions of Cases 2 and 3 necessarily Case 1 has to occur, where the play advances in $\mathsf{BT}^{\mathsf{s}}(T)$. Indeed, $U_0(\!|U_1/z_1|\!)\dots(\!|U_\ell/z_\ell|\!)$ has to generate the next node of $\mathsf{BT}^{\mathsf{s}}(T)$ in finitely many steps; in particular, the number of explicit substitution at the head of U_0 has to be finite.

We have to prove that the infinite branch ξ of $\mathsf{BT}^{\mathsf{s}}(T)$ obtained this way is won by Eve. To this end, consider the corresponding sequence of "w_0" nodes in the construction and observe that this sequence converges to some infinite branch ζ in $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$. Indeed, whenever the sequence enters to a subtree of the form $\mathsf{tr}^{\mathsf{t}}_d(Z_0, V(\!|W/z|\!))$ and stays there forever, then either it enters to the subtree $V_r = \mathsf{tr}^{\mathsf{t}}_d(Z_0[z \mapsto r], V)$ for some r and stays there forever, or, after some time, it enters to the subtree $\mathsf{tr}^{\mathsf{t}}_d(Z_0{\restriction}_r, W)$ for some r and stays there forever. Moreover, the sequence of priorities on ζ is a $\preceq$-contraction of the sequence of priorities on ξ (the function from elements of the former sequence to infixes of the latter sequence, as needed for $\preceq$-contraction, is obtained as the limit of such functions witnessing that always $\pi(w_0)$ is a $\preceq$-contraction of $\pi(v)$). Since ζ agrees with the strategy ρ, it is won by Eve, hence by Lemma 5.5 also ξ is won by Eve, as required. This finishes the proof in the case of Eve winning in $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$.

Suppose now that it is Adam who wins in $\mathsf{tr}^{\mathsf{t}}_d(\varnothing, T)$. The proof in this case is similar, so we only list differences. First, $\succeq$-*contraction* is defined like $\preceq$-contraction, but for every infix $p_{i_{j-1}+1}, p_{i_{j-1}+2}, \dots, p_{i_j}$ in the split we require that r_j is $\succeq$ (instead of $\preceq$) than the leader of the infix. Second, we say that a sequence π_1 of priorities from $[d]$ is an *r-neg-extension* of a sequence π_2 of priorities from $[d]$ if for every sequence π_3 of priorities from $[d]$ that does NOT fulfil the declaration r, the sequence π_1 is a $\succeq$-contraction of the concatenation $\pi_2 \cdot \pi_3$. In Items (c) and (d) of the invariant we replace $\preceq$-contraction by $\succeq$-contraction, and r-extension by r-neg-extension. Then, in Case 1 of the construction we only swap the role of Eve and Adam. In Case 2 we now have that the play is won by Adam, so $Z_0(z_c)$ is even, that is, not fulfilled by the empty sequence; this implies that $\pi(w_c)$, being an $Z_0(z_c)$-neg-extension of $\pi(w_0)$, is also its $\succeq$-contraction. The main difference is in Case 3. For every $r \in [d]$ we know Adam's decision in the root of V_r^W, according to his winning strategy. Take the worst $r \in [d]$ such that in V_r^W Adam goes to the left subtree, or $r = 2d$ if he goes right everywhere; in both cases, Adam's strategy allows to enter V_r. Let also s be the best among priorities that are worse than r; in V_s^W Adam goes to the right subtree (if there are no priorities worse than r, we choose s arbitrarily, e.g., $s = 1$). Then as the new w_0 we take the root of V_r, and as $w_{0.5}$ we take the root of $\mathsf{tr}^{\mathsf{t}}_d(Z{\restriction}_s, W)$. Notice that $\pi(w_{0.5})$ is an r-neg-extension of $\pi(w_0)$: s is better or equal than the leader of every sequence not fulfilling r (also when r is the worst priority, because no such a sequence exists), which ensures that the invariant is preserved.

6 Final remarks

We have presented a new, simple model-checking algorithm for higher-order recursion schemes. One may ask whether this algorithm can be used in practice. Of course the complexity n-EXPTIME for recursion schemes of order n is unacceptably large (even if we take into

account the fact that we are n-fold exponential only in the arity of types and in the size of an automaton, not in the size of a recursion scheme), but one has to recall that there exist tools solving the considered problem in such a complexity. The reason why these tools work is that the time spent by them on "easy" inputs is much smaller than the worst-case complexity (and many "typical inputs" are indeed easy). Unfortunately, this is not the case for our algorithm: the size of the recursion scheme resulting from our transformation is always large. Moreover, it seems unlikely that any simple analysis of the resulting recursion scheme (like removing useless nonterminals or some control flow analysis) may help in reducing its size. Indeed, one can see that if no nonterminals nor arguments were useless in the original recursion scheme, then also no nonterminals nor arguments are useless in the resulting recursion scheme. Thus, our algorithm is mainly of a theoretical interest.

It seems feasible that a transformation similar to the one presented in this paper can be used to solve the simultaneous unboundedness problem (aka. diagonal problem) [11] for recursion schemes. Developing such a transformation is a possible direction for further work.

Fluted Logic with Counting

Ian Pratt-Hartmann
Department of Computer Science, University of Manchester, UK
Institute of Computer Science, University of Opole, Poland

Abstract

The fluted fragment is a fragment of first-order logic in which the order of quantification of variables coincides with the order in which those variables appear as arguments of predicates. It is known that the fluted fragment possesses the finite model property. In this paper, we extend the fluted fragment by the addition of counting quantifiers. We show that the resulting logic retains the finite model property, and that the satisfiability problem for its $(m+1)$-variable sub-fragment is in m-NExpTime for all positive m. We also consider the satisfiability and finite satisfiability problems for the extension of any of these fragments in which the fluting requirement applies only to sub-formulas having at least three free variables.

1 Introduction

The *fluted fragment*, $\mathcal{FL}$, is a fragment of first-order logic in which, *very* roughly, the order of quantification of variables coincides with the order in which those variables appear as arguments of predicates, for example:

No student admires every professor
$$\forall x_1(\mathrm{std}(x_1) \to \neg\forall x_2(\mathrm{prof}(x_2) \to \mathrm{admr}(x_1, x_2))) \tag{1}$$

No lecturer introduces any professor to every student
$$\forall x_1(\mathrm{lectr}(x_1) \to \neg\exists x_2(\mathrm{prof}(x_2) \wedge \forall x_3(\mathrm{std}(x_3) \to \mathrm{intro}(x_1, x_2, x_3)))). \tag{2}$$

More precisely, in fluted formulas, all atoms are of the form $p(x_\ell, \ldots, x_m)$, with a contiguous sequence of variables as their arguments, Boolean combinations can only be formed from formulas whose last free variable is the same, and only the last free variable in a formula may be quantified. Equality is not present. It is known that $\mathcal{FL}$ has the finite model property, and that its m-variable sub-fragment, $\mathcal{FL}^m$, is $\lfloor m/2 \rfloor$-NExpTime-hard for all $m \geq 2$ and in $(m-2)$-NExpTime for all $m \geq 3$ [17]. Hence, the satisfiability problem for $\mathcal{FL}$ is Tower-complete in the system of trans-elementary complexity classes of [24]. (It was incorrectly claimed in [20] that this problem is in NExpTime.)

Counting quantifiers are expressions of the form $\exists_{[\leq M]}$, $\exists_{[\geq M]}$ and $\exists_{[=M]}$, where M is a positive integer, with the interpretations "there exist at most/at least/exactly M ...". We investigate the addition of counting quantifiers and equality to the fluted fragment:

At most three lecturers introduce a professor to at least five students
$$\exists_{[\leq 3]}x_1(\mathrm{lectr}(x_1) \wedge \exists x_2(\mathrm{prof}(x_2) \wedge \exists_{[\geq 5]}x_3(\mathrm{std}(x_3) \wedge \mathrm{intro}(x_1, x_2, x_3)))) \tag{3}$$

Every absent-minded professor introduces some student to himself
$$\forall x_1(\text{abs-mnd}(x_1) \wedge \mathrm{prof}(x_1) \to \exists x_2\exists x_3(\mathrm{std}(x_3) \wedge x_2 = x_3 \wedge \mathrm{intro}(x_1, x_2, x_3))). \tag{4}$$

We denote this extension of $\mathcal{FL}$ by $\mathcal{FLC}$, and its m-variable sub-fragment by $\mathcal{FLC}^m$. We also consider the corresponding fragments $\mathcal{SFC}$ and $\mathcal{SFC}^m$, in which the fluting restriction is waived for sub-formulas with at most two variables. (Formal definitions are given in Sec. 2.)

The definition of $\mathcal{FL}$ employed here is that given by Purdy [19], who traces its origins to Quine [22]. (The term "fluted" is actually Quine's.) While it is unclear whether the quantification patterns specified by Purdy are really those that Quine had in mind, it is Purdy's definition which has established itself, and indeed which is – from the point of view of recent work in computational logic – of greater interest. In particular, two-variable fluted logic with counting, $\mathcal{FLC}^2$ includes (under a simple translation) the description logic $\mathcal{ALCHOQ}$, whose sub-fragments have been the focus of intensive investigation over recent decades; and its semi-fluted extension, $\mathcal{SFC}^2$ coincides with $\mathcal{C}^2$, the two-variable fragment of first-order logic with counting quantifiers, whose satisfiability and finite satisfiability problems are known to be NExpTime-complete [6, 12, 15]. Of course, $\mathcal{FL}$ is not limited in the number of variables formulas can contain, a property it shares with the *guarded fragment* [1], which also has the finite model property, and whose satisfiability problem is in 2-ExpTime [5]. In fact, our logic $\mathcal{SFC}$ extends $\mathcal{C}^2$ with fluted formulas in much the same way as the so-called *triguarded fragment* [23] extends the two-variable fragment of first-order logic (without equality) with guarded formulas. The triguarded fragment has recently been shown to have the finite model property [10]; its satisfiability problem is 2-NExpTime-complete, but becomes undecidable in the presence of equality. We note that negation can be applied freely in $\mathcal{FLC}$ and $\mathcal{SFC}$. Thus, these fragments are not subject to any type of guardedness restrictions: for example, (2) is not guarded or even negation-guarded [2].

In this extended abstract, we show that $\mathcal{FLC}$ has the finite model property, and that the satisfiability problem for $\mathcal{FLC}^{m+1}$ is in m-NExpTime for all $m \geq 1$. We also show that the satisfiability and finite satisfiability problems for $\mathcal{SFC}$ remain decidable.

2 Preliminaries

In the context of fluted formulas, logical variables are taken from the sequence $\bar{x}_\omega = x_1, x_2, \ldots$, and all signatures are purely relational, i.e., there are no individual constants or function symbols; however, we allow 0-ary relations (proposition letters). We employ the syntax of counting quantifiers $\exists_{[\leq M]}$, $\exists_{[\geq M]}$ and $\exists_{[=M]}$, where M is a (numeral denoting a) positive integer, under the expected semantics. A *multiset* over some carrier set X is a function f from X to cardinal numbers, where, for each $x \in X$, $f(x)$ is the *multiplicity* with which x occurs in f. Informally, we identify multisets differing only by elements of multiplicity 0. Almost all mulitplicities we encounter will be finite.

We begin with the syntax of the logics considered here. Define the sets of formulas $\mathcal{FLC}^{[m]}$, for all $m \geq 0$, by simultaneous structural recursion as follows:

- **(i)** any atom $p(x_\ell, \ldots, x_m)$, where $x_\ell, \ldots, x_m$ is a contiguous subsequence of $\bar{x}_\omega$ and p a predicate of arity $m - \ell + 1$, is in $\mathcal{FLC}^{[m]}$;
- **(ii)** $\mathcal{FLC}^{[m]}$ is closed under boolean combinations;
- **(iii)** if φ is in $\mathcal{FLC}^{[m+1]}$, then $\exists x_{m+1}.\varphi$ and $\forall x_{m+1}.\varphi$ are in $\mathcal{FLC}^{[m]}$,
- **(iv)** if φ is in $\mathcal{FLC}^{[m+1]}$ and M a non-negative integer, then $\exists_{[\leq M]} x_{m+1}.\varphi$, $\exists_{[\geq M]} x_{m+1}.\varphi$ and $\exists_{[=M]} x_{m+1}.\varphi$ are in $\mathcal{FLC}^{[m]}$.

It is intended that Clause (i) allows the case $\ell = m + 1$ (empty sequence of arguments), so that the atoms in question are proposition letters; and when $m = \ell + 1$ (exactly two arguments), we allow p to be the equality predicate. We define the sets of formulas $\mathcal{FL}^{[m]}$ similarly, except that we do not allow the equality predicate in Clause (i), and Clause (iv) is

dropped altogether. The *fluted fragment* is the set of formulas $\mathcal{FL} = \bigcup_{m\geq 0} \mathcal{FL}^{[m]}$, and the *fluted fragment with counting and equality*, the set of formulas $\mathcal{FLC} = \bigcup_{m\geq 0} \mathcal{FLC}^{[m]}$. Finally, we define $\mathcal{FL}^m$ to be the fragment of $\mathcal{FL}$ in which at most the variables $x_1, \ldots, x_m$ appear (free or bound); and similarly for $\mathcal{FLC}^m$. Thus, (1) is in $\mathcal{FL}^2$, and (2) in $\mathcal{FL}^3$, while (3) and (4) are in $\mathcal{FLC}^3$. Do not confuse $\mathcal{FLC}^m$ with $\mathcal{FLC}^{[m]}$: all of (1)–(4) are in $\mathcal{FLC}^{[0]}$. By *sentence*, we mean a formula with no free variables.

Denote by $\mathcal{C}^2$ the *two-variable fragment of first-order logic with counting*, i.e. the set of first-order formulas with (equality and) counting quantifiers over a purely relational signature, and featuring only two logical variables. (We may without loss of useful expressive power assume that all predicates have arity at most 2.) Formulas of $\mathcal{C}^2$ are not required to be fluted. For example, $\forall x_1 \exists x_2 . r(x_1, x_2) \wedge \forall x_2 \exists_{[\leq 1]} x_1 . r(x_1, x_2) \wedge \exists x_2 \forall x_1 \neg r(x_1, x_2)$ is a formula of $\mathcal{C}^2$, but not of $\mathcal{FLC}^2$. It is straightforward to see that this formula is satisfiable, but only in infinite models. Thus, $\mathcal{C}^2$ lacks the finite model property. It is well-known that the satisfiability and finite satisfiability problems for the three-variable fragment of first-order logic (even without with counting) are undecidable.

In the context of $\mathcal{FLC}$, the possibility arises of waiving the fluting restrictions on sub-formulas featuring at most two free variables. Define the sets of formulas $\mathcal{SFC}^{[m]}$ in the same way as $\mathcal{FLC}^{[m]}$, but with the additional clauses (for $m \geq 2$):

(v) Any $\mathcal{C}^2$-formula ψ, whose set of free variables is equal to one of $\{x_{m-1}, x_m\}$, $\{x_m\}$ or $\emptyset$, is in $\mathcal{SFC}^{[m]}$.

We then take the *semi-fluted fragment with counting* to be the set of formulas $\mathcal{SFC} = \bigcup_{m\geq 0} \mathcal{SFC}^{[m]}$, denoting its m-variable sub-fragment by $\mathcal{SFC}^m$. If φ is a formula of any of the above fragments, we take its *size*, $\|\varphi\|$, to be the number of bits required to write it, on the understanding that numerical subscripts are encoded as binary strings. Since $\mathcal{SFC}$ contains $\mathcal{C}^2$, it lacks the finite model property. We can now state our main results.

▶ **Theorem 1.** *The logic $\mathcal{FLC}$ has the finite model property. The satisfiability problem for $\mathcal{FLC}^{m+1}$ is in m-NExpTime for all $m \geq 1$.*

▶ **Theorem 2.** *The satisfiability and finite satisfiability problems for $\mathcal{SFC}$ are decidable.*

Assuming, as we shall, that the arity of any predicate is fixed in advance, variables in fluted logic convey no information at all, and therefore can be omitted. (This may have been part of the motivation for Quine [21].) The same applies to fluted formulas with counting quantifiers. For example, (3) and (4) can be written, respectively, as:

$$\exists_{[\leq 3]}(\text{lectr} \wedge \exists(\text{prof} \wedge \exists_{[\geq 5]}(\text{std} \wedge \text{intro}))) \tag{5}$$

$$\forall(\text{abs-mnd} \wedge \text{prof} \rightarrow \exists\exists(\text{std} \wedge = \wedge \text{intro})). \tag{6}$$

It is straightforward to reconstruct (3) and (4) (up to a shift of variable indices) from (5) and (6). Consequently, we employ variable-free notation for $\mathcal{FLC}$ in the sequel, as it is more compact, though formulas such as "std $\wedge = \wedge$ intro" admittedly take some getting used to. It is important to realize that, with variable-free notation, any formula of $\mathcal{FLC}^{[m]}$ is, *without lexical change*, also a formula of $\mathcal{FLC}^{[m+1]}$. For example, the sub-formula $\exists(\text{prof} \wedge \exists_{[\geq 5]}(\text{std} \wedge \text{intro}))$ of (5) may be reconstructed as the $\mathcal{FLC}^{[1]}$-formula $\varphi(x_1) := \exists x_2(\text{prof}(x_2) \wedge \exists_{[\geq 5]} x_3(\text{std}(x_3) \wedge \text{intro}(x_1, x_2, x_3)))$, or alternatively as the $\mathcal{FLC}^{[2]}$-formula $\varphi'(x_1, x_2) := \exists x_3(\text{prof}(x_3) \wedge \exists_{[\geq 5]} x_4(\text{std}(x_4) \wedge \text{intro}(x_2, x_3, x_4)))$, and so on.

Thus, using variable-free notation, the sets $\mathcal{FLC}^{[m]}$ are the minimal family of sets of formulas satisfying:

(i) any predicate p of arity less than or equal to m is in $\mathcal{FLC}^{[m]}$;
(ii) $\mathcal{FLC}^{[m]}$ is closed under boolean combinations;
(iii) if φ is in $\mathcal{FLC}^{[m+1]}$, then $\exists\varphi$ and $\forall\varphi$ are in $\mathcal{FLC}^{[m]}$,
(iv) if φ is in $\mathcal{FLC}^{[m+1]}$ and M a non-negative integer, then $\exists_{[\leq M]}\varphi$, $\exists_{[\geq M]}\varphi$ and $\exists_{[=M]}\varphi$ are in $\mathcal{FLC}^{[m]}$.

We also use the term *sentence* in this context to mean a formula of $\mathcal{FLC}^{[0]}$, and we continue to use the notation $\mathcal{FLC}^m$ to denote the same set of formulas as defined above, but written without variables. We remark that there is no difference between a *quantifier-free* formula of $\mathcal{FLC}^m$ and a *quantifier-free* formula of $\mathcal{FLC}^{[m]}$; it is just a Boolean combination of predicates (including equality) of arity at most m.

If $\varphi \in \mathcal{FLC}^{[m]}$, and $\bar{a} = a_1, \ldots, a_m$ is an m-tuple of elements from some structure $\mathfrak{A}$ interpreting the signature of φ, we write $\mathfrak{A} \models \varphi[\bar{a}]$ as usual to indicate that $\bar{a}$ satisfies φ in $\mathfrak{A}$, under the assignments $x_1 \mapsto a_1, \ldots, x_m \mapsto a_m$. Observe that this notation remains meaningful even with variable-free notation. Indeed, if $\bar{a} \in A^m$ and $a \in A$, then $\mathfrak{A} \models \varphi[\bar{a}]$ if and only if $\mathfrak{A} \models \varphi[a\bar{a}]$. (This trick is important, because it will be used at various points in Sec. 4.) The notation $\forall^m$ stands for a block $\forall \cdots \forall$ of m universal quantifiers.

Of course, we cannot – without further ado – use variable-free notation for $\mathcal{SFC}$.

The analysis of decidable fragments is often simplified by the use of normal forms in the style of [25]. Here, we adapt the normal forms for $\mathcal{FL}$ from [17, Lemma 4.1].

▶ **Lemma 3.** *Let φ be a formula of $\mathcal{FLC}^{m+1}$ $(m \geq 1)$. Then we may compute, in time bounded by a polynomial function of $\|\varphi\|$, an $\mathcal{FLC}^{m+1}$-sentence satisfiable over the same domains as φ, and having the form*

$$\bigwedge_{s\in S} \forall^m(\mu_s \to \exists_{[=M_s]}\zeta_s) \wedge \bigwedge_{t\in T} \forall^m(\nu_t \to \forall\eta_t) \wedge \forall^{m+1}\theta, \tag{7}$$

where S and T are index sets, the μ_s and ν_t are quantifier-free $\mathcal{FLC}^m$-formulas, the ζ_s, η_t and θ are quantifier-free $\mathcal{FLC}^{m+1}$-formulas, and the M_s are positive integers.

Proof. By prepending existential quantifiers if necessary, we may assume that φ is a sentence. Call a quantifier of the form $\exists_{[=M]}$ an *equality quantifier*. Somewhat counter-intuitively, we first remove all equality quantifiers from φ. Let $\varphi_0 := \varphi$, and suppose φ_0 possesses a sub-formula $\theta = \exists_{[=M]}\chi$, such that χ contains no equality quantifiers. Let ℓ be the smallest number such that $\theta \in \mathcal{FLC}^{[\ell]}$. Let p, q be fresh predicates or arity ℓ, and define $\varphi_1 := \varphi_0[\theta/(p \wedge q)]$ and

$$\psi_1 := \forall^\ell(p \leftrightarrow \exists_{[\geq M]}\chi) \wedge \forall^\ell(q \leftrightarrow \exists_{[\leq M]}\chi).$$

It is obvious that φ_0 and $\varphi_1 \wedge \psi_1$ are satisfiable over the same domains Now process φ_1 in the same way to obtain φ_2, until we eventually obtain a sentence φ_n containing no equality quantifiers. This process evidently terminates in polynomial time. Since φ and $\varphi_n \wedge \psi_n \wedge \cdots \wedge \psi_1$ are satisfiable over the same domains, we may simply assume, henceforth, that φ contains no equality quantifiers.

Since there are no equality quantifiers in φ we may move negations inward in the usual way, so that they apply to atomic formulas. At this point, we may follow the proof of the analogous theorem for $\mathcal{FL}$ presented in [17, pp. 174], obtaining, in polynomial time, a sentence satisfiable over the same domains as φ, and having the form

$$\bigwedge_{s\in S} \forall^m(\mu_s \to \exists_{[\bowtie_s M_s]}\zeta_s) \wedge \bigwedge_{t\in T} \forall^m(\nu_t \to \forall\eta_t) \wedge \forall^{m+1}\theta,$$

where each $\bowtie_s$ is one of the symbols $\leq$ or $\geq$. We now eliminate all occurrences of $\leq$ and $\geq$ with $=$. For any conjunct $\forall^m(\mu_s \to \exists_{[\leq M_s]}\zeta_s)$, we let q_s be a new predicate of arity $m+1$ and replace this conjunct with

$$\forall^m(\mu_s \to \exists_{[=M_s]}q_s) \wedge \forall^{m+1}(\zeta_s \to q_s).$$

The case $\geq$ is treated similarly. ◀

We refer to formulas of the forms (7) as *normal-form* formulas of $\mathcal{FLC}^{m+1}$.

The following notions are useful for analysing $\mathcal{FLC}$-formulas. Let Σ be a finite relational signature. A *fluted literal over* Σ is an expression p or $\neg p$, where $p \in \Sigma \cup \{=\}$. (Remember that, under variable-free notation, we think of p as an atom $p(x_\ell, \ldots, x_m)$ of $\mathcal{FLC}^{[m]}$.) The *arity* of the literal is the arity of the underlying predicate. A *fluted m-type* τ (*over* Σ) is a maximal consistent set of fluted literals over Σ having arity at most m. We call τ *reflexive* if it contains the literal $=$. We silently identify fluted m-types with their conjunctions, thus regarding them as quantifier-free $\mathcal{FL}^m$-formulas. Obviously, if τ is a fluted m-type and ψ a quantifier-free $\mathcal{FLC}^m$-formula over the same signature, then either $\models \tau \to \psi$ or $\models \tau \to \neg\psi$. Suppose $\mathfrak{A}$ is a structure over domain A interpreting Σ, and $\bar{a}$ an m-tuple of elements from A ($m \geq 1$). Then there is a unique fluted m-type τ such that $\mathfrak{A} \models \tau[\bar{a}]$. We denote τ by $\mathrm{ftp}^{\mathfrak{A}}[\bar{a}]$, and call it the fluted m-type of $\bar{a}$.

A *fluted star-type* σ of *dimension* m *over* Σ is a multiset of fluted $(m+1)$-types over Σ at most one of which (counting multiplicities) is reflexive. The term "star-type" comes from [15]; in the present paper,we concern ourselves either with *fluted* star-types or *semi-fluted* star-types (defined below). Since we may list the fluted $(m+1)$-types over Σ as $\tau_1, \ldots, \tau_J$ in some fixed order ($J \leq 2^{|\Sigma|+1}$), we can regard any fluted star-type σ over Σ as a vector $(\sigma(\tau_1), \ldots, \sigma(\tau_J))$ of cardinal numbers. We say that σ is *M-bounded* if $|\sigma| = \sigma(\tau_1) + \cdots + \sigma(\tau_J) \leq M$. If ζ is a quantifier-free $\mathcal{FLC}^{m+1}$-formula over Σ, the *retract* of σ to ζ is the fluted star-type $\sigma{\restriction}\zeta$ given by:

$$(\sigma{\restriction}\zeta)(\tau) = \begin{cases} \sigma(\tau) & \text{if } \models \tau \to \zeta \\ 0 & \text{otherwise.} \end{cases}$$

Thus, when performing a retract to ζ, we remove from σ all occurrences of those fluted $(m+1)$-types inconsistent with ζ (i.e. set their multiplicities to 0). We say that σ is a *fluted ζ-star-type* if $\sigma = \sigma{\restriction}\zeta$. Suppose $\mathfrak{A}$ is a structure over domain A interpreting Σ, and $\bar{a}$ an m-tuple of elements from A ($m \geq 1$). If ζ is any quantifier-free formula of $\mathcal{FLC}^{m+1}$ over Σ, we may define a fluted ζ-star-type σ of dimension m by setting, for each fluted $(m+1)$-type τ over Σ, $\sigma(\tau) = |\{b \in A : \mathfrak{A} \models \tau[\bar{a}b] \text{ and } \mathfrak{A} \models \zeta[\bar{a}b]\}|$. We denote σ by $\mathrm{fst}^{\mathfrak{A}}_{\zeta}[\bar{a}]$, and call it the *fluted ζ-star-type of $\bar{a}$ in $\mathfrak{A}$*. As an aide to intuition, think of $\bar{a}$ as emitting various "ζ-rays", each absorbed by some element $b \in A$ such that $\mathfrak{A} \models \zeta[\bar{a}b]$. Every ζ-ray has a "colour" specified by some fluted $(m+1)$-type τ such that $\models \tau \to \zeta$. The fluted star-type $\mathrm{fst}^{\mathfrak{A}}_{\zeta}[\bar{a}]$ simply counts how many rays of each colour arise in this way. To grasp the utility of these notions, let φ be a normal-form formula (7), and suppose $\mathfrak{A} \models \varphi$. Now let $\mathfrak{B}$ be a structure such that, for every m-tuple $\bar{b}$ from B, there exists an m-tuple $\bar{a}$ from A satisfying: (i) $\mathrm{ftp}^{\mathfrak{B}}[\bar{b}] = \mathrm{ftp}^{\mathfrak{A}}[\bar{a}]$; (ii) $\mathrm{fst}^{\mathfrak{B}}_{\zeta_s}[\bar{b}] = \mathrm{fst}^{\mathfrak{A}}_{\zeta_s}[\bar{a}]$ for every s such that $\mathfrak{B} \models \mu_s[\bar{b}]$, and (iii) for every $b' \in B$, there exists $a' \in A$ such that $\mathrm{ftp}^{\mathfrak{B}}[\bar{b}b'] = \mathrm{ftp}^{\mathfrak{A}}[\bar{a}a']$. Then $\mathfrak{B} \models \varphi$.

We mentioned earlier that the logic $\mathcal{C}^2$ lacks the finite model property, but that its satisfiability and finite satisfiability problems are in NExpTime – these being relatively non-trivial results. The following lemma illustrates the comparative weakness of its fluted sub-fragment, $\mathcal{FLC}^2$ by establishing that this has the finite model property. In fact, we adapt a well-known proof (see [8, pp. 77 ff.], [9]) of the corresponding statement for the monadic fragment of first-order logic [11].

▶ **Lemma 4.** *If φ is a satisfiable formula of $\mathcal{FLC}^2$, then φ has a model of size bounded by an exponential function of $\|\varphi\|$. The satisfiablity problem for $\mathcal{FLC}^2$ is in NExpTime.*

Proof. By Lemma 3, we may assume that φ is of the form (7), over a signature Σ, where $m = 1$. We may further assume that Σ features no predicates of arity 0, since their truth-values can be guessed. Let $M = \sum_{s\in S} M_s$, and suppose $\mathfrak{A} \models \varphi$. For each fluted 1-type π (over Σ) realized in $\mathfrak{A}$, let B_π be a set of cardinality $\min(M+1, |\{a \in A \mid \mathrm{ftp}^{\mathfrak{A}}[a] = \pi\}|)$ and let $B = \bigcup_\pi B_\pi$. Thus, $|B| \leq (M+1)2^{|\Sigma|+1}$. We define a structure $\mathfrak{B}$ with domain B and show that $\mathfrak{B} \models \varphi$. For each $b \in B_\pi$, set $\mathrm{ftp}^{\mathfrak{B}}[b] = \pi$. These fluted 1-types involve only unary predicates, and so may be assigned independently of each other. To complete the definition of $\mathfrak{B}$ we fix the extensions of binary predicates so as to determine $\mathrm{ftp}^{\mathfrak{B}}[bb']$ for any ordered pair of elements $\langle b, b'\rangle \in B^2$.

Pick any $b \in B$, and let $a \in A$ be such that $\mathrm{ftp}^{\mathfrak{A}}[a] = \mathrm{ftp}^{\mathfrak{B}}[b] = \pi$, say. Write $S' = \{s \in S : \mathfrak{A} \models \mu_s[a]\}$ and $\zeta' = \bigvee_{s\in S'} \zeta_s$, and let A' be the set of elements $a' \in A \setminus \{a\}$ such that $\mathfrak{A} \models \zeta'[aa']$, say $A' = \{a_1, \ldots, a_k\}$, with $k \leq M$. Thus we may choose a subset $B' = \{b_1, \ldots, b_k\} \subseteq B \setminus \{b\}$ such that, for all i $(1 \leq i \leq k)$, $\mathrm{ftp}^{\mathfrak{B}}[b_i] = \mathrm{ftp}^{\mathfrak{A}}[a_i]$. However this is done, we are guaranteed that, for every $b' \in B \setminus (B' \cup \{b\})$, we can find some $a' \in A \setminus (A' \cup \{a\})$ such that $\mathrm{ftp}^{\mathfrak{A}}[a'] = \mathrm{ftp}^{\mathfrak{B}}[b']$. Now set $\mathrm{ftp}^{\mathfrak{B}}[bb] = \mathrm{ftp}^{\mathfrak{A}}[aa]$ and $\mathrm{ftp}^{\mathfrak{B}}[bb_i] = \mathrm{ftp}^{\mathfrak{A}}[aa_i]$ for all i $(1 \leq i \leq k)$. Further, for all $b' \in B \setminus (B' \cup \{b\})$, pick some $a' \in A \setminus (A' \cup \{a\})$ such that $\mathrm{ftp}^{\mathfrak{A}}[a'] = \mathrm{ftp}^{\mathfrak{B}}[b']$, and set $\mathrm{ftp}^{\mathfrak{B}}[bb'] = \mathrm{ftp}^{\mathfrak{A}}[aa']$. Observe that, in the latter case, $\mathfrak{A} \not\models \zeta'[aa']$, and therefore $\mathfrak{B} \not\models \zeta'[bb']$. Hence, $\mathrm{fst}^{\mathfrak{B}}_{\zeta'}[b] = \mathrm{fst}^{\mathfrak{A}}_{\zeta'}[a]$, so that $\mathrm{fst}^{\mathfrak{B}}_{\zeta_s}[b] = \big(\mathrm{fst}^{\mathfrak{B}}_{\zeta'}[b]\big)\restriction\zeta_s = \big(\mathrm{fst}^{\mathfrak{A}}_{\zeta'}[a]\big)\restriction\zeta_s = \mathrm{fst}^{\mathfrak{A}}_{\zeta_s}[a]$ for every $s \in S'$. By carrying out this construction for every $b \in B$, we fully define $\mathfrak{B}$. Note that the *fluted* 2-types assigned in this process never clash with the fluted 1-types already assigned, and never clash with each other. Thus, for every element $b \in B$ there exists $a \in A$ such that: (i) $\mathrm{ftp}^{\mathfrak{B}}[b] = \mathrm{ftp}^{\mathfrak{A}}[a]$; (ii) $\mathrm{fst}^{\mathfrak{B}}_{\zeta_s}[b] = \mathrm{fst}^{\mathfrak{A}}_{\zeta_s}[a]$ for every s such that $\mathfrak{B} \models \mu_s[b]$, and (iii) for every element $b' \in B$, there exists $a' \in A$ such that $\mathrm{ftp}^{\mathfrak{B}}[bb'] = \mathrm{ftp}^{\mathfrak{A}}[aa']$. Hence $\mathfrak{B} \models \varphi$. ◀

At various points in the ensuing argument, we need to vary the signatures interpreted by structures. The following notation and terminology is standard. If $\mathfrak{A}^+$ is any structure interpreting a signature Σ^+, and $\Sigma \subseteq \Sigma^+$, we denote by $\mathfrak{A}^+\restriction\Sigma$ the structure obtained by forgetting the predicates in $\Sigma^+ \setminus \Sigma$. We call $\mathfrak{A} = \mathfrak{A}^+\restriction\Sigma$ the *reduct* of $\mathfrak{A}^+$ to Σ, and say that $\mathfrak{A}^+$ is an *expansion* of $\mathfrak{A}$.

3 Existential Presburger quantifiers

In view of Lemma 4, a natural strategy for proving Theorem 1 suggests itself: reduce the satisfiability problem for $\mathcal{FLC}^{m+1}$ to that for $\mathcal{FLC}^m$. This is *nearly* the strategy we follow. To make it work, however, we must generalize the notion of counting quantifiers. Denote the natural numbers $\{0, 1, 2, \ldots\}$ by $\mathbb{N}$. A *linear Diophantine inequality* is an expression $a_1v_1 + \cdots + a_nv_n + b \leq c_1v_1 + \cdots + c_nv_n + d$, with coeffecients in $\mathbb{N}$. If $\mathcal{E}(\bar{v})$ is a system of linear Diophantine inequalities in variables $\bar{v}$, a *solution* of $\mathcal{E}$ is an assignment of natural numbers $\bar{a}$ to the variables $\bar{v}$ which make all inequalities of $\mathcal{E}$ true. It was shown in [4] that one can bound the values occurring in the solutions of such systems. (Various such bounds are available: see, e.g. [13].) The following is adequate for our purposes:

▶ **Theorem 5** (from [14], Corollary 1)**.** *Let $\mathcal{E}$ be a system of m linear Diophantine inequalities in n variables, with maximum coefficient M. If $\mathcal{E}$ has a solution, then it has one in which all values are bounded by $(2 + (n+1)M)^{n+m}$.*

By *Presburger arithmetic*, we understand the set of first-order formulas (with equality) over the signature $\{\mathbb{N}, +, \leq, \cdot\}$ whose atomic sub-formulas are linear Diophantine inequalities. We interpret these symbols over the domain $\mathbb{N}$ in the standard way (with the constants $\mathbb{N}$ interpreted as themselves), and say that a tuple of natural numbers $\bar{a}$ *satisfies* a formula of Presburger arithmetic $\Theta(\bar{v})$ if $\mathbb{N} \models \Theta[\bar{a}]$. The *size* of Θ, denoted $\|\Theta\|$, is the number of bits required to write it in the usual way, under the assumption that the individual constants (i.e. coefficients of the linear Diophantine inequalities) are encoded as bit-strings. By *existential Presburger arithmetic*, we mean the set of formulas of Presburger arithmetic of the form $\Theta(\bar{v}) = \exists \bar{u}.\Xi(\bar{v}, \bar{u})$, where Ξ is quantifier-free. Theorem 5 immediately yields (see also, e.g. [7, Table 1]):

▶ **Corollary 6.** *There is a non-deterministic procedure which, given a formula $\Theta(\bar{v})$ of existential Presburger arithmetic and tuple $\bar{a}$ of natural numbers bounded by M with the same arity as $\bar{v}$, has a successful run if and only if $\bar{a}$ satisfies $\Theta(\bar{v})$. This procedure runs in time bounded by a polynomial function of $\|\Theta\| + \log M$.*

Now for our generalization of counting quantifiers.

Fix some $m \geq 1$, and let Σ be a purely relational signature, M a positive integer and Θ a formula of existential Presburger arithmetic in variables $\bar{v} = v_1, \ldots, v_J$ corresponding to the fluted $(m+1)$-types $\tau_1, \ldots, \tau_J$ over Σ. We call an expression $\mathsf{Q}\langle \Sigma, M, \Theta \rangle$ a *fluted existential Presburger quantifier* (or: *fluted ep-quantifier*). If ζ is a quantifier-free formula of $\mathcal{FLC}^{m+1}$, we allow formulas φ of the form $\mathsf{Q}\langle \Sigma, M, \Theta \rangle \zeta$, with semantics given by declaring, for any structure $\mathfrak{A}$ interpreting a signature $\Sigma' \supseteq \Sigma$ and any m-tuple $\bar{a}$ of elements from A:

$$\mathfrak{A} \models \varphi[\bar{a}] \text{ if and only if } \mathrm{fst}_{\zeta}^{(\mathfrak{A} \restriction \Sigma)}[\bar{a}] \text{ is } M\text{-bounded and satisfies } \Theta(\bar{v}). \tag{8}$$

Recall in this connection that we regard a star-type over Σ as a vector with entries in $\mathbb{N}$; the star-type in question is M-bounded if the sum of those entries is at most M. By way of maintaining some contact with familiar territory, the $\mathcal{FLC}$-formula $\exists_{[=M]}\zeta$ can be written in the new syntax as $\mathsf{Q}\langle \Sigma, M, \Theta \rangle \zeta$, where Θ is the single equation $v_1 + \cdots + v_J = M$. (Of course: this equation is just a conjunction of two linear inequalities, and so counts as a formula of Presburger arithmetic). Note that there is no existential quantification in this case.

We define $\mathcal{FLC}^{m+1}_{\mathrm{ep}}$ to be the set of formulas φ given by

$$\bigwedge_{s \in S} \forall^m (\mu_s \to \mathsf{Q}\langle \Sigma, M_s, \Theta_s \rangle \zeta_s) \wedge \bigwedge_{t \in T} \forall^m (\nu_t \to \forall \eta_t) \wedge \forall^{m+1} \theta, \tag{9}$$

where Σ is a relational signature, the μ_s and ν_t are quantifier-free $\mathcal{FLC}^m$-formulas over Σ, the ζ_s, η_t and θ are quantifier-free $\mathcal{FLC}^{m+1}$-formulas over Σ, the M_s are positive integers and the Θ_s are formulas of existential Presburger arithmetic with free variables corresponding to the fluted $(m+1)$-types over Σ. We remark that we have *defined* $\mathcal{FLC}^{m+1}_{\mathrm{ep}}$ directly interms of fomulas of the form (9), rather than establishing an analogue of Lemma 3 for a language extending $\mathcal{FLC}^{m+1}$. This is intentional: formulas in which $\mathsf{Q}\langle \Sigma, M_s, \Theta_s \rangle \zeta$ appears with negative polarity might not be *succinctly* expressible in the form (9). We define the *effective size* of φ, denoted $\#(\varphi)$, to be the quantity $\log(\|\varphi\|) + |S| + |T| + \log M + |\Sigma|$, where $M = \sum_{s \in S} M_s$. Informally: when measuring the effective size of φ, we do not mind if $\|\varphi\|$ becomes exponentially large, as long as Σ, S, T and the number of bits required to write the various M_s do not.

We stress that fluted ep-quantifiers give us no additional expressive power beyond the standard counting quantifiers. Indeed, if ζ is a quantifier-free formula of $\mathcal{FLC}^{m+1}$ over a signature Σ, and supposing the fluted $(m+1)$-types over Σ to be enumerated as $\tau_1, \ldots, \tau_J$, any formula $\mathsf{Q}\langle \Sigma, M, \Theta \rangle \zeta$ is logically equivalent to the huge disjunction

$$\bigvee \left\{ \bigwedge_{j=1}^{J} \exists_{[=\sigma(\tau_j)]}\tau_j \;\middle|\; \sigma \text{ is an } M\text{-bounded fluted } \zeta\text{-star-type over } \Sigma \text{ satisfying } \Theta \right\}. \quad (10)$$

However, fluted ep-quantifiers can be more compact, and we require the added strength of the following routine extension of Lemma 4.

▶ **Lemma 7.** *If φ is a satisfiable formula of $\mathcal{FLC}^2_{\text{ep}}$, then φ has a model of size bounded by an exponential function of $\#(\varphi)$. The satisfiability problem for $\mathcal{FLC}^2_{\text{ep}}$ is in NExpTime, measured in terms of the effective size of the input.*

Proof. For the first statement, let a formula φ of $\mathcal{FLC}^2_{\text{ep}}$ be given. By definition, φ is in the form (9) with $m = 1$. Now construct $\mathfrak{B}$ as in the proof of Lemma 4. Still we have $\mathfrak{B} \models \varphi$, since it does not matter whether the permitted star-types are specified by means of standard counting quantifiers or fluted ep-quantifiers. Further, $|B| \leq (M+1)2^{|\Sigma|+1}$ and thus is bounded by an exponential function of $\#(\varphi)$. For the second statement, we may simply guess a structure $\mathfrak{B}$ subject to this size bound and check that it satisfies φ. It follows from Lemma 5 that, for any $b \in B$ and $s \in S$ such that $\mathfrak{B} \models \mu_s[b]$, we may check, in *non-deterministic* time bounded by an exponential function of $\#(\varphi)$, that $\text{fst}^{\mathfrak{B}}_{\zeta_s}[b]$, satisfies Θ_s. Checking the remaining conditions of φ involves standard model-checking, and requires only (deterministic) time bounded by an exponential function of $\#(\varphi)$. ◀

4 Proof of main result

In this section we prove Theorems 1 and 2, proceeding via the logics $\mathcal{FLC}^m_{\text{ep}}$. Fix some $\mathcal{FLC}^{m+1}_{\text{ep}}$-formula φ as given in (9), with $m \geq 2$. We show how to construct an $\mathcal{FLC}^m_{\text{ep}}$-formula φ', such that φ and φ' are satisfiable over the same domains. The formula φ' employs a signature Σ' formed by removing from Σ all $(m+1)$-ary predicates, while adding a fresh $(m-1)$-ary predicate $p_{S',T'}$ and a fresh m-ary predicate $q_{S',T'}$ for each $S' \subseteq S$ and each $T' \subseteq T$. It is obvious that $|\Sigma'| \leq |\Sigma| + 2^{|S|+|T|+1}$. The maximal arity of predicates in Σ is $m+1$, and in Σ' is m. In addition to Σ and Σ', we consider the signatures $\Sigma^+ = \Sigma \cup \Sigma'$ and $\Sigma^- = \Sigma \cap \Sigma'$. As explained in Sec. 2, we assume some fixed enumeration $\tau_1, \ldots, \tau_J$ of the $J = 2^{|\Sigma|+1}$ fluted $(m+1)$-types over Σ. We write $\tau^+_1, \ldots, \tau^+_{J^+}$ for the corresponding enumeration of fluted $(m+1)$-types over Σ^+; likewise we enumerate the fluted m-types over Σ' as $\tau'_1, \ldots, \tau'_{J'}$, and over Σ^- as $\tau^-_1, \ldots, \tau^-_{J^-}$.

Our essential problem is to get rid of the $(m+1)$-ary predicates appearing in φ without affecting satisfiability. The following device will help. Let ψ be any quantifier-free $\mathcal{FLC}^{m+1}$-formula over Σ. Clearly, there is, up to logical equivalence, a unique strongest quantifier-free $\mathcal{FLC}^m$-formula over Σ^- entailed by ψ, i.e. a quantifier-free $\mathcal{FLC}^m$-formula ψ° over Σ^- satisfying: (i) $\models \psi \to \psi^\circ$; and (ii) for all quantifier-free $\mathcal{FLC}^m$-formulas χ over Σ^- such that $\models \psi \to \chi$, we have $\models \psi^\circ \to \chi$. Indeed, since there are only finitely many such χ (ignoring logical equivalents), we can take ψ° to be their conjunction. Strictly, of course, ψ° is only defined up to logical equivalence, and in fact there are various ways to construct it. Thus, for example, [16, 17] employ resolution theorem-proving; however, the procedure in the following proof requires only basic propositional logic.

▶ **Lemma 8.** *Let ψ be a quantifier-free $\mathcal{FLC}^{m+1}$-formula over Σ. Then we can compute ψ° in time bounded by an exponential function of $\|\psi\| + |\Sigma|$. Moreover, if τ^- is a fluted m-type over Σ^- such that $\models \tau^- \to \psi^\circ$, then there exists a fluted $(m+1)$-type τ over Σ extending τ^- such that $\models \tau \to \psi$.*

Proof. We begin by writing ψ, equivalently, in disjunctive normal form. Thus, $\psi \equiv \bigvee\{\tau \mid \tau \in D\}$, where D is a set of fluted $(m+1)$-types (over Σ). For each $\tau \in D$, let τ° be the fluted m-type over Σ^- obtained by deleting from τ all conjuncts involving predicates not in Σ^-, and define ψ° to be $\bigvee\{\tau^\circ \mid \tau \in D\}$. Note that, since by assumption $m \geq 2$, we will never delete equality-literals. It is evident that this construction can be carried out in time bounded by an exponential function of $\|\psi\|+|\Sigma|$. Since $\models \tau \to \tau^\circ$ for any $(m+1)$-type τ, it is immediate that $\models \psi \to \psi^\circ$. On the other hand, suppose χ is a quantifier-free $\mathcal{FLC}^m$-formula over Σ^- entailed by ψ; without loss of generality, χ is in disjunctive normal form. We claim that τ° is a disjunct of χ for all $\tau \in D$. For if not, we have $\models \psi \to \neg\tau^\circ$, whence $\models \psi \to \neg\tau$, contradicting the supposition that $\psi \equiv \bigvee\{\tau \mid \tau \in D\}$. Hence, $\models \psi^\circ \to \chi$. Given the above construction of ψ°, the second statement of the lemma is completely trivial. ◀

Also in this connection, we define a further operation on fluted star-types. Suppose that σ is an m-dimensional fluted star-type over Σ. The *reduct of σ to Σ^-*, denoted σ/Σ^-, is the $(m-1)$-dimensional fluted star-type over Σ^- given by

$$(\sigma/\Sigma^-)(\tau^-) = \sum\{\sigma(\tau) : \tau \text{ a fluted } (m+1)\text{-type over } \Sigma \text{ such that } \models \tau \to \tau^-\},$$

where τ^- is any fluted m-type over Σ^-. Thus, when forming a reduct to Σ^-, we merge together fluted $(m+1)$-types which look identical in the smaller signature.

To explain the intuition behind the construction of φ', we first describe how a putative model $\mathfrak{A} \models \varphi$ can be expanded to a structure, $\mathfrak{A}^+$, interpreting $\Sigma^+ = \Sigma \cup \Sigma'$. Taking $\mathfrak{A}'$ to be the reduct of $\mathfrak{A}^+$ to Σ' (i.e. with all the $(m+1)$-ary predicates removed), we observe in (13), (14) and (15) that the formulas which will eventually form the conjuncts of φ' are all true in $\mathfrak{A}'$. We begin with the predicates $p_{S',T'}$ for $S' \subseteq S$ and $T' \subseteq T$. Let $\bar{a} \in A^{m-1}$ be any $(m-1)$-tuple of elements, and consider what φ tells us about the relationship of $\bar{a}$ to other elements in the structure. Since φ is fluted, and bearing in mind the form (9), what really matters here are the different subsets $S' \subseteq S$ and $T' \subseteq T$ for which there exists an element a such that $\mathfrak{A} \models \mu_s[a\bar{a}]$ for all $s \in S'$ and $\mathfrak{A} \models \nu_t[a\bar{a}]$ for all $t \in T'$. The $(m-1)$-ary predicates $p_{S',T'}$ will simply record which pairs S', T' are realized in this way. That is, we set, for every $S' \subseteq S$ and $T' \subseteq T$,

$$p^{\mathfrak{A}^+}_{S',T'} = p^{\mathfrak{A}'}_{S',T'} = \{\bar{a} \in A^{m-1} : \text{for some } a \in A,\ \mathfrak{A} \models \mu_s[a\bar{a}] \text{ for all } s \in S' \text{ and } \mathfrak{A} \models \nu_t[a\bar{a}] \text{ for all } t \in T'\}. \quad (11)$$

The predicates $q_{S',T'}$ are only slightly more complicated. Fix $S' \subseteq S$ and $T' \subseteq T$ for the moment, and suppose that $\mathfrak{A}^+ \models p_{S',T'}[\bar{a}]$. By construction, there exists $a \in A$ such that $\mathfrak{A} \models \mu_s[a\bar{a}]$ for all $s \in S'$ and $\mathfrak{A} \models \nu_t[a\bar{a}]$, for all $t \in T'$. So pick *any* such a and denote it by $\dot{a}$. The formula φ then guarantees that, for each $s \in S'$, the m-tuple $\dot{a}\bar{a}$ satisfies the formula $\mathsf{Q}\langle\Sigma, M_s, \Theta_s\rangle\zeta_s$. Defining $B_{\bar{a}} = \{b \in A : \mathfrak{A} \models \zeta_s[\dot{a}\bar{a}b] \text{ for some } s \in S'\}$, we set

$$q^{\mathfrak{A}^+}_{S',T'} = q^{\mathfrak{A}'}_{S',T'} = \{\bar{a}b \in A^m : \mathfrak{A}^+ \models p_{S',T'}[\bar{a}] \text{ and } b \in B_{\bar{a}}\}. \quad (12)$$

Thus, $B_{\bar{a}}$ serves to pick out the witnesses required by the various fluted ep-quantifiers $\mathsf{Q}\langle\Sigma, M_s, \Theta_s\rangle$ for the tuple $\dot{a}\bar{a}$, as s varies over S'. Letting $\zeta_{S'} = \bigvee_{s\in S'}\zeta_s$, we see that $B_{\bar{a}}$ is the set of elements absorbing $\zeta_{S'}$-rays emitted by $\dot{a}\bar{a}$. Observe, in particular, that $|B_{\bar{a}}| \leq \sum_{S'} M_s$. The whole construction is illustrated in Fig. 1. Here we see, arranged in a horizontal strip, the m-tuple $\dot{a}\bar{a}$, which satisfies μ_s for all $s \in S'$ and ν_t for all $t \in T'$. The elements $b \in B_{\bar{a}}$ absorbing the $\zeta_{S'}$-rays emitted by $\dot{a}\bar{a}$, are taken to lie on the periphery of the fan-shaped region. Each of these elements b absorbs a ζ_s-ray, for at least one (in general

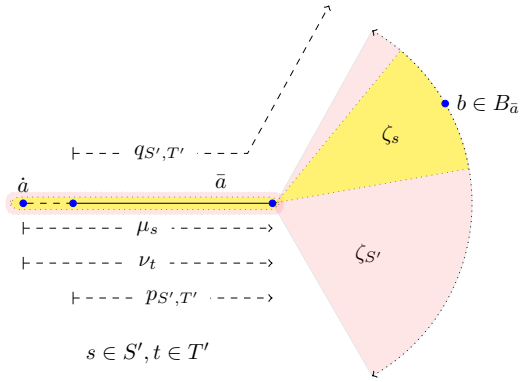

Figure 1 Intended interpretations of the predicates $p_{S',T'}$ and $q_{S',T'}$ in $\mathfrak{A}^+$ (and $\mathfrak{A}'$).

several) values of $s \in S'$. Discarding the element $\dot{a}$, we take the new predicate $p_{S',T'}$ to apply to the $(m-1)$-tuple $\bar{a}$ and the new predicate $q_{S',T'}$ to apply to the m-tuples $\bar{a}b$, where $b \in B_{\bar{a}}$.

We now construct the promised formula φ' in three steps, guided by the structure $\mathfrak{A}'$ just described. The first step is to write formulas reflecting the intended interpretations of the predicates $p_{S',T'}$. Indeed, we see immediately that, for all $S' \subseteq S$ and $T' \subseteq T$,

$$\mathfrak{A}' \models \forall^m \big(\bigwedge_{s \in S'} \mu_s \wedge \bigwedge_{t \in T'} \nu_t \to p_{S',T'} \big). \tag{13}$$

The second step is to write formulas reflecting the intended interpretations of the predicates $q_{S',T'}$, and specifically, the fact that they identify *all* $\zeta_{S'}$-witnesses for m-tuples of interest. Concretely, select an $(m-1)$-tuple $\bar{a}$ from A and suppose $\mathfrak{A} \models p_{S',T}[\bar{a}]$. Now let $\dot{a}$ and $B_{\bar{a}}$ be as chosen in the definition of $q^{\mathfrak{A}'}_{S',T'}$. Then $b \notin B_{\bar{a}}$ implies that $\dot{a}\bar{a}b$ does not satisfy ζ_s for any $s \in S'$. On the other hand, $\dot{a}\bar{a}b$ satisfies η_t for every $t \in T'$ as well as θ. Thus, writing, say, ψ for $(\bigwedge_{s \in S'} \neg\zeta_s \wedge \bigwedge_{t \in T'} \eta_t \wedge \theta)$, we see that $\mathfrak{A} \models \psi[\dot{a}\bar{a}b]$. Recalling that ψ° denotes the strongest quantifier-free formula over Σ^- entailed by ψ, we obviously have $\mathfrak{A}^- \models \psi^\circ[\dot{a}\bar{a}b]$, where $\mathfrak{A}^-$ denotes the reduct $\mathfrak{A}|\Sigma^- = \mathfrak{A}'|\Sigma^-$. But ψ° involves no predicates of arity $m+1$, whence $\mathfrak{A}^- \models \psi^\circ[\bar{a}b]$. (Observe how we are here exploiting variable-free notation: while ψ° is indeed a formula of $\mathcal{FLC}^{[m+1]}$, it involves only predicates in Σ^- , and therefore is simultaneously a formula of $\mathcal{FLC}^{[m]}$, which cannot "see" the element $\dot{a}$ in the tuple $\dot{a}\bar{a}b$.) Thus, since ψ° is also a formula over the signature Σ', we have shown that, for all $S' \subseteq S$ and $T' \subseteq T$,

$$\mathfrak{A}' \models \forall^{m-1} \big(p_{S',T'} \to \forall \big(\neg q_{S',T'} \to \big(\bigwedge_{s \in S'} \neg\zeta_s \wedge \bigwedge_{t \in T'} \eta_t \wedge \theta \big)^\circ \big) \big). \tag{14}$$

The final step in the construction of φ' requires us to define, for all subsets $S' \subseteq S$, a fluted ep-quantifier $\mathsf{Q}\langle \Sigma', M_{S'}, \Theta_{S'} \rangle$. To motivate the definition, let $\bar{a}$ again be any $(m-1)$-tuple from A, let S', T' be such that $\mathfrak{A}^+ \models p_{S',T'}[\bar{a}]$, and let $\dot{a}$ be the element selected in the definition of $q^{\mathfrak{A}^+}_{S',T'}$, so that we have

$$B_{\bar{a}} = \{b \in A : \mathfrak{A} \models \zeta_s[\dot{a}\bar{a}b] \text{ for some } s \in S'\} = \{b \in A : \mathfrak{A}' \models q_{S',T'}[\bar{a}b]\}.$$

Remembering that $\zeta_{S'} = \bigvee_{s \in S'} \zeta_s$, define the fluted star-types $\sigma = \mathrm{fst}^{\mathfrak{A}}_{\zeta_{S'}}[\dot{a}\bar{a}]$ (m-dimensional, over Σ) and $\sigma' = \mathrm{fst}^{\mathfrak{A}'}_{q_{S',T'}}[\bar{a}]$ ($(m-1)$-dimensional, over Σ'). Define in addition the $(m-1)$-dimensional fluted star-type over Σ^- by setting, for any fluted m-type τ^- over Σ^-,

$$\sigma^-(\tau^-) = |\{b \in B_{\bar{a}} : \mathfrak{A}^- \models \tau^-[\bar{a}b]\}|.$$

We see immediately by consideration of the set $B_{\bar{a}}$ that $\sigma/\Sigma^- = \sigma^- = \sigma'/\Sigma^-$. Warning: it will not in general be the case that σ^- arises as $\mathrm{fst}^{\mathfrak{A}^-}_{\zeta^-}[\bar{a}]$ for any quantifier-free formula ζ^- over the signature Σ^-. Indeed, $\mathfrak{A}^-$ interprets neither the predicate $q_{S',T'}$ nor the predicates of $\zeta_{S'}$, and is therefore insensitive to the extension of $B_{\bar{a}}$ used to define σ^-. Nevertheless, we have established:

$$\sigma/\Sigma^- = \sigma'/\Sigma^-. \tag{L1}$$

A little thought shows that σ satisfies various further properties. Fix some $s \in S'$. Since $\models \zeta_s \to \zeta_{S'}$, we see that the retract $\sigma{\restriction}\zeta_s$ is equal to the fluted star-type $\mathrm{fst}^{\mathfrak{A}}_{\zeta_s}[\dot{a}\bar{a}]$ and hence (from the fact that $\mathfrak{A} \models \varphi$), is M_s-bounded and satisfies Θ_s. Thus, we have:

$$\text{for all } s \in S',\ \sigma{\restriction}\zeta_s \text{ is } M_s\text{-bounded and satisfies } \Theta_s. \tag{L2}$$

Now fix some $t \in T'$. Since $\mathfrak{A} \models \varphi$, it follows immediately that, for every $b \in B_{\bar{a}}$, $\mathfrak{A} \models \eta_t[\dot{a}\bar{a}b]$, and indeed $\mathfrak{A} \models \theta[\dot{a}\bar{a}b]$, whence:

$$\text{for all } t \in T \text{ and all } \tau \text{ such that } \sigma(\tau) > 0,\ \models \tau \to \eta_t. \tag{L3}$$

$$\text{for all } \tau \text{ such that } \sigma(\tau) > 0,\ \models \tau \to \theta. \tag{L4}$$

Casting this discussion in terms of $\sigma' = \mathrm{fst}^{\mathfrak{A}'}_{q_{S',T'}}[\bar{a}]$ and writing $M_{S'} = \sum_{s\in S'} M_s$, we see that σ' is $M_{S'}$-bounded and satisfies the property that there exists a fluted star-type σ such that (L1)–(L4) hold. Crucially, this property can be naturally formulated using a formula of existential Presburger arithmetic. Letting $\bar{v}$ be a tuple of variables corresponding to the fluted $(m+1)$-types over Σ and $\bar{v}'$ a tuple of variables corresponding to the fluted m-types over Σ', we see that (L1) is a system of equations $A\bar{v} = A'\bar{v}'$, where A, A' are matrices with entries in $\{0,1\}$ depending only on the fixed ordering of the fluted $(m+1)$-types over Σ and the fixed ordering of the fluted m-types over Σ' and Σ^-. And certainly, (L3) and (L4) can be expressed as a single equation setting certain values in $\bar{v}$ to zero. Let us write $\Lambda(\bar{v},\bar{v}')$ for the conjunction of all the equations expressing (L1), (L3) and (L4). Considering that any retract $\sigma{\restriction}\zeta_s$ amounts to the zeroing of certain entries in σ, we may assume without loss of generality that the corresponding variables do not occur in Θ_s. (If they do, we may replace them by 0.) And in that case, (L2) is expressed by the conjunction $\bigwedge_{s\in S'}\Theta_s(\bar{v})$. Thus, we may formulate the above conditions on σ' as the requirement that (considered as a vector $\bar{v}'$ of length J' over $\mathbb{N}$) it satisfies the formula of Presburger arithmetic $\exists\bar{v}\big(\Lambda(\bar{v},\bar{v}') \wedge \bigwedge_{s\in S'}\Theta_s(\bar{v})\big)$. Writing $\Theta_s(\bar{v})$ as $\exists\bar{u}_s.\Xi_s(\bar{u}_s,\bar{v})$ for each $s \in S$, we obtain, by renaming variables to avoid clashes, the equivalent existential Presburger formula $\Theta_{S'}(\bar{v}') \equiv \exists\bar{v}\bar{u}\big(\Lambda(\bar{v},\bar{v}') \wedge \bigwedge_{s\in S'}\Xi_s(\bar{u}_s,\bar{v})\big)$, where $\bar{u}$ is the concatenation of the (disjoint) tuples $\bar{u}_s$ for $s \in S'$. Thus, we have shown:

$$\mathfrak{A}' \models \forall^{m-1}(p_{S',T'} \to \mathsf{Q}\langle\Sigma', M_{S'}, \Theta_{S'}\rangle q_{S',T'}). \tag{15}$$

Now we are ready to define φ' as the conjunction of the following formulas:

$$\bigwedge_{S'\subseteq S}\bigwedge_{T'\subseteq T}\forall^m\Big(\bigwedge_{s\in S'}\mu_s \wedge \bigwedge_{t\in T'}\nu_t \to p_{S',T'}\Big) \tag{16}$$

$$\bigwedge_{S'\subseteq S}\bigwedge_{T'\subseteq T}\forall^{m-1}(p_{S',T'} \to \mathsf{Q}\langle\Sigma', M_{S'}, \Theta_{S'}\rangle q_{S',T'}) \tag{17}$$

$$\bigwedge_{S'\subseteq S}\bigwedge_{T'\subseteq T}\forall^{m-1}\big(p_{S',T'} \to \forall\big(\neg q_{S',T'} \to \big(\bigwedge_{s\in S'}\neg\zeta_s \wedge \bigwedge_{t\in T'}\eta_t \wedge \theta\big)^\circ\big)\big). \tag{18}$$

By re-ordering of conjuncts, we see that φ' is an $\mathcal{FLC}^m_{\mathrm{ep}}$-formula. Moreover, it follows from (13), (14) and (15) that $\mathfrak{A}' \models \varphi'$. Hence, we have proved:

▶ **Lemma 9.** *If φ is satisfiable over some domain A, then so is φ'.*

We now prove a converse to Lemma 9. Suppose $\mathfrak{B}' \models \varphi'$, where $\mathfrak{B}'$ has domain B. We proceed to construct a model $\mathfrak{B} \models \varphi$ over the same domain. Let $\mathfrak{B}^- = \mathfrak{B}' \restriction \Sigma^-$. Notice that $\mathfrak{B}^-$ features no predicates of arity $m+1$, and none of the "new" predicates $p_{S',T'}$ or $q_{S',T'}$. We shall expand $\mathfrak{B}^-$ to a structure $\mathfrak{B}$ and then show that $\mathfrak{B} \models \varphi$. It suffices to specify, for every $a, b \in B$ and $\bar{a} \in B^{m-1}$, whether the tuple $a\bar{a}b$ is in the extension of each $(m+1)$-ary predicate of Σ. Equivalently, we must specify the fluted $(m+1)$-type of every tuple $a\bar{a}b$ in $\mathfrak{B}$.

Fix $a \in B$ and $\bar{a} \in B^{m-1}$. Let $S' = \{s \in S \mid \mathfrak{B}^- \models \mu_s[a\bar{a}]\}$, $T' = \{t \in T \mid \mathfrak{B}^- \models \nu_t[a\bar{a}]\}$ and $\zeta_{S'} = \bigvee_{s \in S'} \zeta_s$. Since all the μ_s and ν_t are Σ^--formulas, we could equivalently have replaced $\mathfrak{B}^-$ by $\mathfrak{B}'$ in the definitions of S' and T'. Define $\sigma' = (v'_1, \ldots, v'_{J'}) = \mathrm{fst}^{\mathfrak{B}'}_{q_{S',T'}}[\bar{a}]$ and $B_{a\bar{a}} = \{b \in B \mid \mathfrak{B}' \models q_{S',T'}[\bar{a}b]\}$. Notice that, since the sets S' and T' depend on a as well as $\bar{a}$, then so does the set $B_{a\bar{a}}$. It follows from (16) that $\mathfrak{B}' \models p_{S',T'}[\bar{a}]$, and from (17), that σ' is $M_{S'}$-bounded and satisfies the existential Presburger formula $\Theta_{S'}(\bar{v}') \equiv \exists \bar{v} \bar{u} \big(\Lambda(\bar{v}, \bar{v}') \wedge \bigwedge_{s \in S'} \Xi_s(\bar{u}_s, \bar{v}) \big)$. But $\Theta_{S'}(\bar{v}')$ asserts that $\bar{v}'$ is the vector representation of a fluted star-type σ' (over Σ') for which there exists an m-dimensional fluted star-type σ (over Σ) satisfying conditions (L1)–(L4). Letting $\sigma^- = \sigma'/\Sigma^-$, it follows from (L1) that $\sigma^- = \sigma/\Sigma^-$. We proceed to set the fluted $(m+1)$-type of all tuples $a\bar{a}b$, as b ranges over B; we shall do this in such a way that $\mathrm{fst}^{\mathfrak{B}}_{\zeta_{S'}}[a\bar{a}] = \sigma$. The plan is first to find all the required witnesses in the set $B_{a\bar{a}}$, and then to ensure that no unwanted witnesses appear outside this set.

We begin with the elements $b \in B_{a\bar{a}}$. We first partition $B_{a\bar{a}}$ into groups which are indistinguishable from the point of view of the signature Σ^-. Specifically, we write $\sigma^- = (v^-_1, \ldots, v^-_{J^-})$, and for each j^- $(1 \leq j^- \leq J^-)$, we let $B_{j^-} = \{b \in B_{a\bar{a}} \mid \mathfrak{B}^- \models \tau^-_{j^-}[\bar{a}, b]\}$. Writing $J^-_{a\bar{a}}$ for the set of indices j^- for which B_{j^-} is non-empty, we see that $|B_{j^-}| = v_{j^-}$ for all j^- $(1 \leq j^- \leq J^-)$, $v_{j^-} = 0$ for all $j^- \notin J^-_{a\bar{a}}$, and the family of sets $\{B_{j^-} \mid j^- \in J^-_{a\bar{a}}\}$ forms a partition of $B_{a\bar{a}}$.

Now consider just one cell of this partition, say B_{j^-}. We have

$$B_{j^-} = \{b \in B_{a\bar{a}} \mid \mathfrak{B}^- \models \tau^-_{j^-}[\bar{a}, b]\} = \{b \in B_{a\bar{a}} \mid \mathfrak{B}' \models \tau_{j'}[\bar{a}, b] \text{ for some } j' \text{ s.t. } \models \tau'_{j'} \to \tau^-_{j^-}\}.$$

And since $v^-_{j^-} = |B_{j^-}|$, we obtain

$$v^-_{j^-} = \sum \{v_{j'} \mid 1 \leq j' \leq J' \text{ and } \models \tau'_{j'} \to \tau^-_{j^-}\} = \sum \{v_j \mid 1 \leq j \leq J \text{ and } \models \tau_j \to \tau^-_{j^-}\},$$

the second equality arising from the fact that $\sigma/\Sigma^- = \sigma'/\Sigma^-$. Thus, we may choose, for each j such that $\models \tau_j \to \tau^-_{j^-}$, a fresh collection $B_{j^-,j}$ of v_j elements of B_{j^-}, and for each of these elements, b, set $\mathrm{ftp}^{\mathfrak{B}}[a\bar{a}b] = \tau_j$. Because $\models \tau_j \to \tau^-_{j^-}$, the only predicates being defined afresh here have arity $(m+1)$, so that these assignments represent an expansion of $\mathfrak{B}^-$. Once these assignments are made, the set B_{j^-} will contain v_j elements b such that $\mathrm{ftp}^{\mathfrak{B}}[a\bar{a}b] = \tau_j$ for all j such that $\models \tau_j \to \tau^-_{j^-}$. Repeating this procedure for every $j^- \in J^-_{a\bar{a}}$, and writing $J_{a\bar{a}} = \{j \mid 1 \leq j \leq J \text{ and } \models \tau_j \to \tau^-_{j^-} \text{ for some } j^- \in J^-_{a\bar{a}}\}$, we see that the set $B_{a\bar{a}}$ will contain v_j elements b such that $\mathrm{ftp}^{\mathfrak{B}}[a\bar{a}b] = \tau_j$ for all $j \in J_{a\bar{a}}$. On the other hand, $\sigma' = (v'_1, \ldots, v'_{J'}) = \mathrm{fst}^{\mathfrak{B}'}_{q_{S',T'}}[\bar{a}]$, so that $j^- \notin J^-_{a\bar{a}}$ implies $v^-_{j^-} = 0$ and hence

$$\sum \{v_j \mid 1 \leq j \leq J \text{ and } \models \tau_j \to \tau^-_{j^-}\} = 0,$$

since $\sigma \restriction \Sigma^- = \sigma^-$. That is, $v_j = 0$ for all $j \notin J_{a\bar{a}}$, and we have shown that $B_{a\bar{a}}$ contains v_j elements b such that $\mathrm{ftp}^{\mathfrak{B}}[a\bar{a}b] = \tau_j$, for all j $(1 \leq j \leq J)$.

Next, we deal with the elements $b \in B \setminus B_{a\bar{a}}$. By definition, $\mathfrak{B}' \not\models q_{S',T'}[\bar{a}b]$, so that, abbreviating $\bigwedge_{s\in S'} \neg\zeta_s \wedge \bigwedge_{t\in T'} \eta_t \wedge \theta$ by ψ, (18) yields $\mathfrak{B}' \models \psi^\circ[\bar{a}b]$. Writing $\tau^- = \mathrm{ftp}^{\mathfrak{B}^-}[\bar{a}, b]$, and noting that ψ° is a Σ^--formula, we have $\models \tau^- \to \psi^\circ$. By Lemma 8, let $\tilde{\tau}$ be a fluted $(m+1)$-type over Σ extending τ^- such that $\models \tilde{\tau} \to \psi$, and set $\mathrm{ftp}^{\mathfrak{B}}[a\bar{a}b] = \tilde{\tau}$. In particular, $\mathfrak{B} \not\models \zeta_{S'}[a\bar{a}b]$. Thus, we have set the fluted $(m+1)$-type of all $(m+1)$-tuples $a\bar{a}b$, as b ranges over B. Repeating this process for each m-tuple $a\bar{a}$, which we may do independently, the structure $\mathfrak{B}$ will have been completely defined. In the course of this construction, we have shown that, for every $b \notin B_{a\bar{a}}$, $\mathfrak{B} \not\models \zeta_{S'}[a\bar{a}b]$. But we showed above that the number of elements $b \in B_{a\bar{a}}$ such that $\mathfrak{B} \models \tau_j[a\bar{a}b]$ is v_j, where $\sigma = (v_1, \ldots, v_J)$. It follows that $\mathrm{fst}^{\mathfrak{B}}_{\zeta_{S'}}[a\bar{a}] = \sigma$, as required.

In constructing $\mathfrak{B}$, we have secured the following property. Take any m-tuple $a\bar{a}$ with $a \in B$ and $\bar{a} \in B^{m-1}$, and define $S' = \{s \in S \mid \mathfrak{B}^- \models \mu_s[a\bar{a}]\}$, $T' = \{t \in T \mid \mathfrak{B}^- \models \nu_t[a\bar{a}]\}$, $\zeta_{S'} = \bigvee_{s\in S'} \zeta_s$ and $\sigma' = \mathrm{fst}^{\mathfrak{B}'}_{q_{S',T'}}[\bar{a}]$. Then $\mathrm{fst}^{\mathfrak{B}}_{\zeta_{S'}}[a\bar{a}] = \sigma$, where σ is some fluted star-type over Σ satisfying (L1)–(L4), whose existence is guaranteed by the fact that σ' satisfies the existential Presburger formula $\Theta_{S'}$. We have used (L1) in the construction of $\mathfrak{B}$. We now use (L2)–(L4) to ensure that $\mathfrak{B} \models \varphi$.

We first show that, for all $s \in S$, $\mathfrak{B} \models \forall^m(\mu_s \to \mathsf{Q}\langle\Sigma, M_s, \mathcal{L}_s\rangle\zeta_s)$. For consider any m-tuple $a\bar{a}$ with $a \in B$ and $\bar{a} \in B^{m-1}$ such that $\mathfrak{B} \models \mu_s[a\bar{a}]$, and let S', $\zeta_{S'}$, and σ be as just defined. Since $s \in S'$, we have $\models \zeta_s \to \zeta_{S'}$, and hence $\mathrm{fst}^{\mathfrak{B}}_{\zeta_s}[a\bar{a}] = \sigma{\restriction}\zeta_s$, which, by (L2), is M_s-bounded and satisfies $\Theta_{S'}$. We next show that, for all $t \in T$, $\mathfrak{B} \models \forall^m(\nu_t \to \forall\eta_t)$. Again, consider any m-tuple $a\bar{a}$ with $a \in B$ and $\bar{a} \in B^{m-1}$ such that $\mathfrak{B} \models \nu_t[a\bar{a}]$, and let S', T' and σ be as just defined. Pick any $b \in B$. If b is in the set $B_{a\bar{a}}$ used in the construction of $\mathfrak{B}$, then $\sigma(\mathrm{ftp}^{\mathfrak{B}}[a\bar{a}b]) > 0$, whence by (L3), we have $\mathfrak{B} \models \eta_t[a\bar{a}b]$. On the other hand, if $b \notin B_{a\bar{a}}$, then $\mathrm{ftp}^{\mathfrak{B}}[a\bar{a}b]$ was set to some $\tilde{\tau}$ entailing $\bigwedge_{s\in S'} \neg\zeta_s \wedge \bigwedge_{t\in T'} \eta_t \wedge \theta$, so that, again $\mathfrak{B} \models \eta_t[a\bar{a}b]$. Finally, to show that $\mathfrak{B} \models \forall^{m+1}\theta$, we proceed as in the previous case, but using (L4) instead of (L3). Thus we have proved:

▶ **Lemma 10.** *If φ' is satisfiable over some domain B, then so is φ.*

▶ **Lemma 11.** *The formula φ' can be computed in time bounded by an exponential function of $\|\varphi\|$. Moreover, $\#(\varphi')$ is bounded by an exponential function of $\#(\varphi)$.*

Proof. Recalling that φ has the form

$$\bigwedge_{s\in S} \forall^m(\mu_s \to \mathsf{Q}\langle\Sigma, M_s, \Theta_s\rangle\zeta_s) \wedge \bigwedge_{t\in T} \forall^m(\nu_t \to \forall\eta_t) \wedge \forall^{m+1}\theta$$

over signature Σ', let $M = \sum_{s\in S} M_s$. Writing φ' given by (16)–(18) in the same form, over signature Σ', we notice first of all that the sizes of the index sets certainly only increase by an exponential. Let M' be the sum of all the numbers occurring in the fluted ep-quantifiers of φ', i.e. $\sum\{2^{|T|} \cdot M_{S'} \mid S' \subseteq S\}$, whence $\log M' \leq |S| + |T| + \log M \leq \#(\varphi)$. We noted above that $|\Sigma'| \leq |\Sigma| + 2^{|S|+|T|+1} \leq \#(\varphi) + 2^{\#(\varphi)+1}$. To show that $\log\|\varphi'\|$ is also bounded by an exponential function of $\#(\varphi)$, we need only show that $\log\|\Theta_{S'}\|$ is bounded by an exponential function of $\#(\varphi)$, for each $S' \subseteq S$. Fix some $S' \subseteq S$, then, and recall that

$$\Theta_{S'}(\bar{v}') \equiv \exists\bar{v}\{\bar{u}_s\}_{s\in S'}\big(\Lambda(\bar{v}, \bar{v}') \wedge \bigwedge_{s\in S'} \Xi_s(\bar{u}_s, \bar{v})\big).$$

Let e be the maximum number of existentially quantified variables in any Θ_s as s ranges over S; certainly, $e \leq \|\varphi\|$. The number of free variables in $\Theta_{S'}$ is simply the number of fluted m-types over Σ' and hence at most $2^{|\Sigma'|+1}$. The number of existentially quantified variables in in $\Theta_{S'}$ is bounded by $|S'|.e + 2^{|\Sigma|+1}$. Moreover, Λ consists of $2^{|\Sigma^-|+1}$ equations

featuring at most $2^{|\Sigma|+1} + 2^{|\Sigma'|+1}$ terms. Finally we evidently have $\|\bigwedge_{s\in S'} \Theta_s\| \leq |S'| \cdot \|\varphi\|$. Adding all of these together, we see that $\log\|\Theta_{S'}\|$ is bounded by an exponential function of $\#(\varphi)$, as required. ◀

▶ **Lemma 12.** *Let $m \geq 1$. Any satisfiable formula of $\mathcal{FLC}^{m+1}_{\text{ep}}$ has a finite model. Moreover, the satisfiability problem for $\mathcal{FLC}^{m+1}_{\text{ep}}$ is in m-NExpTime, measured in terms of the effective size of the input.*

Proof. The case $m = 1$ is Lemma 4. The inductive step is from Lemmas 9, 10 and 11. ◀

We may now prove Theorem 1. Let a formula φ of $\mathcal{FLC}^{m+1}$ be given. By Lemma 3, we may suppose without loss of generality that φ is in normal form (7). Further, we may replace any sub-formula $\exists_{[=M_s]}\zeta_s$ in φ by the equivalent sub-formula $\mathsf{Q}\langle\Sigma, M_s, \Theta_s\rangle\zeta_s$, where Θ_s is simply the equation $v_1 + \cdots + v_J = M_s$, thus obtaining, in time bounded by an exponential function of $\|\varphi\|$, an $\mathcal{FLC}^{m+1}_{\text{ep}}$-formula φ_0 equivalent to φ. Note that $\#(\varphi_0)$ is bounded by a polynomial function of $\|\varphi\|$. The result then follows from Lemma 12.

5 The semi-fluted fragment

Finally, we consider the semi-fluted fragment with counting, $\mathcal{SFC}$. The analysis proceeds largely as for $\mathcal{FLC}$. We remind the reader that variable-free notation is no longer available in this case. Of course, we could employ predicate-functor-style syntax here; however, for the little material remaining, this seems excessive.

Let Σ be a purely relational signature and m a positive integer. A *semi-fluted m-atom* over Σ is a formula of the form $p(\bar{x})$ or its negation where either: (i) $p \in \Sigma$ and $\bar{x}$ is a contiguous sequence of variables $x_\ell, \ldots, x_m$, or (ii) $p \in \Sigma \cup \{=\}$ and $\bar{x}$ is a sequence of at most two variables chosen (repeats allowed) from the set $\{x_{m-1}, x_m\}$. A *semi-fluted m-literal* is either a semi-fluted m atom or its negation. Thus, we have the same restriction on argument patterns as in fluted logic generally, except that semi-fluted m-literals of arity at most 2 may feature the variables x_{m-1} and x_m in any order we like. A *semi-fluted m-type* (over Σ) is a maximal consistent set of semi-fluted m-literals (over Σ). For these purposes, consistency takes account of the special meaning of the equality predicate: thus, $\{p(x_1), \neg p(x_2), x_1 = x_2\}$ is not consistent. As before, where convenient, we identify a semi-fluted m-type τ with the conjunction of its members and call τ *reflexive* if it contains $x_{m-1} = x_m$. We remark that semi-fluted 1- and 2-types are simply maximal consistent sets of literals (atomic formulas or their negations) in the variables x_1 and x_2, and are usually referred to in the literature simply as 1- and 2-*types*. If τ is a semi-fluted literal of arity $m \geq 2$, define $\text{tp}_1(\tau)$ to be the set of literals in τ featuring only the variable x_{m-1}. (Note that replacing the variable x_{m-1} in $\text{tp}_1(\tau)$ by x_1 would yield a 1-type.) A *semi-fluted star-type of dimension m over Σ* is a multiset of semi-fluted $(m+1)$-types over Σ at most one of which is reflexive, subject to the additional condition that the value $\text{tp}_1(\tau)$ is the same for all τ occurring (i.e. having non-zero multiplicity) in σ. A semi-fluted star-type is M-bounded if the sum of its multiplicities is M. By enumerating the semi-fluted $(m+1)$-types over Σ in some fixed order, we may regard any semi-fluted star-type as a vector of cardinal numbers.

If $\mathfrak{A}$ is a structure interpreting Σ, and $\bar{a}$ is an m-tuple of elements from A (repeats allowed), there is a unique semi-fluted m-type satisfied by $\bar{a}$; we denote this by $\text{sftp}^{\mathfrak{A}}[\bar{a}]$. If, in addition, ζ is a quantifier-free formula of $\mathcal{SFC}^{m+1}$, then we may define a semi-fluted star-type σ of dimension m by setting, for each semi-fluted $(m+1)$-type τ over Σ, $\sigma(\tau) = |\{b \in A : \mathfrak{A} \models \tau[\bar{a}b] \text{ and } \mathfrak{A} \models \zeta[\bar{a}b\}]|$. Notice incidentally that for all τ occurring in σ, we have $\mathfrak{A} \models \text{tp}_1(\tau)[a]$, where a is the last element of $\bar{a}$, whence these 1-types are indeed

all the same. We call σ the *semi-fluted ζ-star-type of $\bar{a}$ in $\mathfrak{A}$*, and denote it by $\mathrm{sfst}^{\mathfrak{A}}_{\zeta}[\bar{a}]$. As with fluted ζ-star-types, so with their semi-fluted cousins, we can think of the tuple $\bar{a}$ as "emitting" various "ζ-rays", which are "absorbed" by various elements of $\mathfrak{A}$. The principal difference is that the (non-empty) semi-fluted ζ-star-type of $\bar{a}$ gives us the 1-type satisfied by the final element a of $\bar{a}$, and indeed of the full 2-types (not just the fluted 2-types) of the pairs ab, for b an element absorbing one of the ζ-rays emitted by $\bar{a}$.

Normal forms analogous to those of Lemma 3 are easily obtainable:

▶ **Lemma 13.** *Let φ be a formula of $\mathcal{SFC}^{m+1}$ ($m \geq 1$). Then we may compute, in time bounded by a polynomial function of $\|\varphi\|$, an $\mathcal{SFC}^{m+1}$-sentence satisfiable over the same domains as φ, and having the form*

$$\bigwedge_{s\in S} \forall x_1 \ldots \forall x_m(\mu_s \to \exists_{[=M_s]} x_{m+1}.\zeta_s) \wedge \bigwedge_{t\in T} \forall x_1 \ldots \forall x_m(\nu_t \to \forall \eta_t) \wedge \forall x_{m+1}.\theta, \tag{19}$$

where S and T are index sets, the μ_s and ν_t are quantifier-free $\mathcal{SFC}^m$-formulas, the ζ_s, η_t and θ are quantifier-free $\mathcal{SFC}^{m+1}$-formulas, and the M_s are positive integers.

The proof proceeds as for Lemma 3, almost verbatim.

Extending the notion of ep-quantifiers to the semi-fluted case is again routine. If ζ is a quantifier-free formula of $\mathcal{SFC}^{m+1}$, we allow formulas φ of the form $\mathsf{Q}\langle\Sigma, M, \Theta\rangle\zeta$. For any structure $\mathfrak{A}$ interpreting a signature $\Sigma' \supseteq \Sigma$ and any m-tuple $\bar{a}$ of elements from A, we declare:

$$\mathfrak{A} \models \varphi[\bar{a}] \text{ if and only if } \mathrm{sfst}^{(\mathfrak{A}\restriction\Sigma)}_{\zeta}[\bar{a}] \text{ is } M\text{-bounded and satisfies } \Theta(\bar{v}), \tag{20}$$

just as with (8). We then define $\mathcal{SFC}^{m+1}_{\mathrm{ep}}$ to be the set of formulas φ given by

$$\bigwedge_{s\in S} \forall x_1 \ldots \forall x_m(\mu_s \to \mathsf{Q}\langle\Sigma, M_s, \Theta_s\rangle x_{m+1}.\zeta_s) \wedge \bigwedge_{t\in T} \forall x_1 \ldots \forall x_m(\nu_t \to \forall x_{m+1}.\eta_t) \wedge \forall x_1 \ldots \forall x_{m+1}.\theta, \tag{21}$$

where Σ is a relational signature, the μ_s and ν_t are quantifier-free $\mathcal{SFC}^m$-formulas over Σ, the ζ_s, η_t and θ are quantifier-free $\mathcal{SFC}^{m+1}$-formulas over Σ, the M_s are positive integers and the Θ_s are formulas of existential Presburger arithmetic with free variables corresponding to the semi-fluted $(m+1)$-types over Σ. Of course, this parallels the definition of $\mathcal{FLC}^{m+1}_{\mathrm{ep}}$ given in (9). Again, semi-fluted ep-quantifiers give us no expressive power beyond the ordinary counting quantifiers, since the translation (10) (with the counting quantifier taken to bind the variable x_{m+1}) holds also when ζ is only semi-fluted. We may define the *effective size*, $\#(\varphi)$ of an $\mathcal{SFC}^m_{\mathrm{ep}}$-formula φ exactly as with $\mathcal{FLC}^m_{\mathrm{ep}}$-formulas.

At this point, we are in a position to sketch the proof of Theorem 2. Let an $\mathcal{SFC}^{m+1}$-formula φ be given ($m \geq 1$). By Lemma 13, we may assume without loss of generality that φ is in the form (19). Clearly, this may be converted, in time bounded by an exponential function of $\|\varphi\|$, and with at most a polynomial increase in $\#(\varphi)$, into an $\mathcal{SFC}^{m+1}_{\mathrm{ep}}$-formula of the form (21). The reduction described in Sec. 4 can then be repeated almost verbatim, since the transformation of φ into φ' never affects the two final variables. Lemmas 9, 10 and 11 then continue to hold. This allows us to transform any formula of $\mathcal{SFC}^{m+1}$ ($m \geq 2$) eventually into a formula of $\mathcal{SFC}^2_{\mathrm{ep}}$ satisfiable over the same domains. But we have already argued that any $\mathcal{SFC}^2_{\mathrm{ep}}$-formula can be translated into equivalent formula of $\mathcal{C}^2$. Since the satisfiability and finite satisfiability problems for $\mathcal{C}^2$ are in NExpTime, we thus obtain Theorem 2, as promised.

The complexity bound we may extract from the above argument is rather weak. The translation given above from a $\mathcal{SFC}^2_{\text{ep}}$-formula φ to an equivalent $\mathcal{C}^2$-formula ψ' runs in time bounded by a doubly exponential function of $\|\varphi\|$, and hence a triply exponential function of $\#(\varphi)$. Since the satisfiability and finite satisfiability problems for $\mathcal{C}^2$ are in NExpTime, this means that the corresponding problems for $\mathcal{SFC}^2_{\text{ep}}$ are in non-deterministic time bounded by quadruply exponential time as a function of $\#(\varphi)$. This results in an upper complexity bound of $(m+3)$-NExpTime for the satisfiability and finite satisfiability problems for $\mathcal{SFC}^{m+1}_{\text{ep}}$ $(m \geq 1)$. We claim that the satisfiability and finite satisfiability problems for $\mathcal{SFC}^{m+1}$ in fact remain in m-NExpTime. However, the proof appears to require a modified version of existing proofs of the complexity bounds for $\mathcal{C}^2$, in order to accommodate semi-fluted ep-quantifiers. Such a reconstruction is beyond the scope of the current paper.

6 Discussion

For $m \geq 2$, the upper complexity bound of m-NExpTime for $\mathcal{FLC}^{m+1}$ in Theorem 1 is laxer than the corresponding upper complexity bound of $(m-1)$-NExpTime for $\mathcal{FL}^{m+1}$ from [17]. The best known lower complexity bound on satisfiability for both logics is $\lfloor (m+1)/2 \rfloor$-NExpTime-hard, from the same source. It is currently not known how to close this gap. It is plausible that, for $m \geq 2$, the upper bound given in this extended abstract for $\mathcal{FLC}^{m+1}$ could be reduced by one exponential, by adapting the procedure of in [17] for $\mathcal{FL}^3$. The probable difficulty of doing so coupled with the fact that a complexity gap would remain for $\mathcal{FLC}^5$ and above acts, however, as a deterrent to trying.

It is shown in [18] that the satisfiability and finite satisfiability problems for the fluted fragment, $\mathcal{FL}$ remain decidable even in the presence of a distinguished binary predicate required to be interpreted as a transitive relation (equality is also permitted); with just two transitive relations (or three transitive relations without equality), however, decidability is lost. The question arises as to whether a single transitive relation can be added to $\mathcal{FLC}$ without losing decidability of satisfiability. The argumentation of Sec. 4 will reduce this problem (with blow-up given by the same towers of exponentials) to the corresponding problem for $\mathcal{FLC}^2$ with a single transitive relation. However, this latter problem appears to be open.

We noted above that the fluted ep-quantifiers introduced here do not extend the expressive power of ordinary counting quantifiers. In this regard, they do less work than the "existential Presburger formulas" of [3], which strictly extend the expressive power of $\mathcal{C}^2$, permitting, saliently, counting *modulo* k for $k \geq 2$. The objects referred to as "*behaviours*" in that paper play a role very similar to the fluted star-types considered here, except that the values they assign are not integers, but *semi-linear sets* of integers. Unifying these approaches seems therefore to be a natural line of future enquiry.

Abstract

Guarded Kleene Algebra with Tests (GKAT) is an efficient fragment of KAT, as it allows for almost linear decidability of equivalence. In this paper, we study the (co)algebraic properties of GKAT. Our initial focus is on the fragment that can distinguish between unsuccessful programs performing different actions, by omitting the so-called *early termination axiom*. We develop an operational (coalgebraic) and denotational (algebraic) semantics and show that they coincide. We then characterize the behaviors of GKAT expressions in this semantics, leading to a coequation that captures the covariety of automata corresponding to these behaviors. Finally, we prove that the axioms of the reduced fragment are sound and complete w.r.t. the semantics, and then build on this result to recover a semantics that is sound and complete w.r.t. the full set of axioms.

1 Introduction

Kleene algebra with tests (KAT) [17] was introduced in the early 90's as an extension of Kleene algebra (KA), the algebra of regular expressions. The core idea of the extension was simple: consider regular languages over a two-sorted alphabet, in which one sort represents Boolean tests and the other denotes basic program actions. This seemingly simple extension enables an important application for regular languages in reasoning about imperative programs with basic control flow structures like branches (**if-then-else**) and loops (**while**). KAT largely inherited the properties of KA: a language model [22], a Kleene theorem [19], a sound and complete axiomatization [22], and a PSPACE decision procedure for equivalence [8].

In 2014, a specialized KAT called NetKAT [4] was proposed to program software-defined networks. NetKAT was later extended with a probabilistic choice operator that enabled the modelling of randomized protocols [9]. Interestingly, there exists a decision procedure for NetKAT program equivalence that enables practical verification of reachability in networks

with thousands of nodes and links, which seems to scale almost linearly despite the PSPACE-completeness of this problem [10, 35]. This raised the question: do practical NetKAT programs belong to a fragment of KAT that has more favorable properties than the full language?

Recently, this question was answered positively [34], in the form of *Guarded Kleene Algebra with Tests* (GKAT), a fragment of KAT obtained by adding a Boolean guard to the non-deterministic choice and iteration operators so that they correspond exactly to the standard **if-then-else** and **while** constructs. GKAT is expressive enough to capture all programs used in network verification while allowing for almost linear time[1] decidability of equivalence, thereby explaining the experimental results observed in NetKAT.

The use of GKAT as a framework for program analysis also raises further questions about recovering the properties of KAT on the level of GKAT. Is there a class of automata that provides a Kleene theorem? Is there a sound and complete axiomatization of GKAT equivalence? The original paper [34] gave incomplete answers to these questions. First, it proposed a class of *well-nested* automata that can be used to describe the semantics of all GKAT programs, but left open whether this class covered all automata that accept the behaviors of GKAT programs. Second, GKAT was axiomatized under the assumption of *early termination*: intuitively, referring to a semantics of imperative programs where programs that fail immediately are equated to programs that fail eventually. This semantics, though useful, is too coarse in contexts where program behavior prior to failure matters.

In this paper, we take a new perspective on the semantics of GKAT programs and their corresponding automata, using coequations. Coequations provide the right tool to characterize fragments of languages as they enable a precise way to remove unwanted traces. We are then able to give a precise characterization of the behaviors of GKAT programs and prove a completeness theorem for each of the fragments of interest.

Our contributions. In a nutshell, the contributions of this paper are the following:

1. We give a denotational model for GKAT without early termination by representing the behavior as a certain kind of tree. This allows us to design two coequations: one characterizing the behaviors denoted by GKAT expressions, and another capturing only the behaviors of GKAT expressions that terminate early.
2. We obtain two completeness results for GKAT: one for the model of the previous item and the axiomatization of [34] without the early termination axiom; and building on this, another for the full axiomatization. The former is new; the latter provides an alternative proof to the completeness theorem presented in [34].
3. A concrete example of a well-nested GKAT automaton with a non-well-nested quotient. This settles an open question of [34] and closes the door on an alternative proof of completeness based on well-nested automata.

2 Guarded Kleene Algebra with Tests

At its heart, *Guarded Kleene Algebra with Tests* (GKAT) is an algebraic theory of imperative programs. Expressions in GKAT are concise formulas for WHILE programs [23], which are built inductively from actions and tests with sequential composition and the classic programming constructs of branches and loops: **if** b **then** e **else** f and **while** b **do** e.

[1] $O(n\alpha(n))$, where $\alpha(n)$ is the inverse of Ackermann's function

Union Axioms

U1. $e +_b e \equiv e$

U2. $e +_b f \equiv f +_{\bar{b}} e$

U3. $(e +_b f) +_c g \equiv e +_{b \wedge c} (f +_c g)$

U4. $e +_b f \equiv b \cdot e +_b f$

U5. $e \cdot g +_b f \cdot g \equiv (e +_b f) \cdot g$

Sequence Axioms

S1. $(e \cdot f) \cdot g \equiv e \cdot (f \cdot g)$

S2. $0 \cdot e \equiv 0$

S3. $e \cdot 0 \equiv 0$

S4. $1 \cdot e \equiv e$; S5. $e \equiv e \cdot 1$

S6. $b \cdot c \equiv b \wedge c$

Loop Axioms

W1. $e^{(b)} \equiv e \cdot e^{(b)} +_b 1$

W2. $(ce)^{(b)} \equiv (e +_c 1)^{(b)}$

W3. $\dfrac{E(e) \equiv 0 \quad g \equiv eg +_b f}{g \equiv e^{(b)} \cdot f}$

Figure 1 Axioms for GKAT-expressions. Here, $e, f, g \in \mathrm{Exp}$ and $b, c \in \mathrm{BExp}$.

Formally, these expressions are drawn from a two-sorted language of *tests* and *programs*. The tests are built from a finite set of ***primitive tests*** T, as follows:

$$\mathrm{BExp} \ni b, c ::= 0 \mid 1 \mid t \in T \mid \bar{b} \mid b \wedge c \mid b \vee c.$$

Here, 0 and 1 are understood as the constant tests **false** and **true** respectively, $\bar{b}$ denotes the negation of b, and $\wedge$ and $\vee$ are conjunction and disjunction, respectively. We will use A to denote the set of ***atomic tests*** (or just ***atoms***), Boolean expressions of the form $d_1 \wedge \cdots \wedge d_l$, where $d_i \in \{t_i, \bar{t}_i\}$ for each $i \leqslant l$ and $\{t_i \mid i \leqslant l\}$ is a fixed enumeration of T. It is well known that any $b \in \mathrm{BExp}$ can be written equivalently as the disjunction of the atoms $a \in A$ that imply b under the laws of Boolean algebra. We will often identify each Boolean expression $b \in \mathrm{BExp}$ with this set of atoms and write $b \subseteq A$ or $a \in b$.

Programs are built from tests and a finite set of ***primitive programs*** or ***actions*** Σ, disjoint from T. Formally, programs are generated by the grammar

$$\mathrm{Exp} \ni e, f ::= b \in \mathrm{BExp} \mid p \in \Sigma \mid e \cdot f \mid e +_b f \mid e^{(b)}$$

Here, a test b abbreviates the statement **assert** $\boldsymbol{b}$, the operator $\cdot$ is sequential composition, $e +_b f$ is shorthand for **if** $\boldsymbol{b}$ **then** $\boldsymbol{e}$ **else** $\boldsymbol{f}$ and $e^{(b)}$ is shorthand for **while** $\boldsymbol{b}$ **do** $\boldsymbol{e}$.

GKAT programs satisfy standard properties of imperative programs. For instance, swapping the branches of an **if-then-else** construct should not make a difference, provided that we also negate the condition; that is, the semantics of $e +_b f$ should coincide with that of $f +_{\bar{b}} e$. The rules in Figure 1 axiomatize equivalences between programs. Together with the axioms of Boolean algebra, these generate a congruence $\equiv$ on Exp.

Some remarks are in order for axiom W3. The right-hand premise states that an expression g has some self-similarity in the sense that it is equivalent to checking whether b holds, in which case it runs e followed by recursing at g, and otherwise running f. Intuitively, this says that g is loop-like, matching the conclusion that g is equivalent to $e^{(b)} \cdot f$. However, this conclusion may not make sense when based on just the second premise. Specifically, if we choose e, f, g and b to be 1, we can show that the premise holds and derive $1 \equiv 1^{(1)} \cdot 1$, which is to say that **assert true** is equivalent to **(while true do assert true); assert true**. Intuitively, this should be false: the first program terminates successfully and immediately, but the second program does not. The problem is that the loop body does not perform any actions that affect the state and make progress towards the end of the loop.

This is remedied by the left-hand premise, which distinguishes loop bodies that can accept immediately from those that cannot. It plays the same role as the *empty word property* in Salomaa's axiomatization of the algebra of regular events [31]. Formally, given $e \in \mathrm{Exp}$, the Boolean expression $E(e)$ is defined inductively by setting $E(p) = 0$, $E(b) = b$, and

$$E(e \cdot f) = E(e) \wedge E(f) \qquad E(e +_b f) = (b \wedge E(e)) \vee (\bar{b} \wedge E(f)) \qquad E(e^{(b)}) = \bar{b}$$

We call e ***productive*** if $E(e) \equiv 0$. Axioms W2 and W3 are analogues of Salomaa's axioms A_{11} and R2 [31]. Specifically, W2 says that non-productive loop iterations do not contribute to the semantics. This allows the use of W3 to reason about loops in general, for instance to prove $e^{(b)} \equiv e^{(b)} \cdot \overline{b}$, which says that the loop condition is false when a loop ends [34].

Axiom S3 identifies a program that fails eventually with the program that fails immediately. As a consequence, $\equiv$ cannot distinguish between processes that loop forever, like $p^{(1)}$ and $q^{(1)}$, even though they perform different actions [34]. Consequently, GKAT can be seen as a theory of *computation* schemata, i.e., programs that need to halt successfully to be meaningful.

In contrast, it is also useful to be able to reason about *process* schemata, i.e., programs that perform meaningful tasks, even when they do not terminate successfully. To this end, we define the ***reduced congruence*** $\equiv_0$ generated by the axioms of Figure 1 except S3.

Let $[\![-]\!] : \mathrm{Exp} \to S$ be a semantics of GKAT. We say that $[\![-]\!]$ is ***sound w.r.t.*** $\equiv$ if for all $e, f \in \mathrm{Exp}$ with $e \equiv f$, it holds that $[\![e]\!] = [\![f]\!]$. Similarly, $[\![-]\!]$ is ***sound w.r.t.*** $\equiv_0$ if $e \equiv_0 f$ implies that $[\![e]\!] = [\![f]\!]$.

Since $\equiv$ encodes common program laws, one might wonder whether there is a single interpretation in which programs are related by $\equiv$ if and only if they have the same image. Such an interpretation is called ***free w.r.t.*** $\equiv$. This question is not just of theoretical interest: a free interpretation can help decide whether programs are provably equivalent, and hence the same under any sound interpretation, by checking whether their free semantics coincide. Naturally, the same question can be asked for $\equiv_0$: is there a semantics that is ***free w.r.t.*** $\equiv_0$, i.e., where $e \equiv_0 f$ if and only if e and f have the same interpretation?

The remainder of this paper is organized as follows. In Section 3, we describe the operational structure for GKAT expressions in terms of GKAT-automata, as in [34]. In Section 4, we provide an explicit construction of a GKAT-automaton in which all other automata can be uniquely interpreted. We then build a semantics that is sound w.r.t. $\equiv_0$ in Section 5. In Section 6 we relate our coequational description of GKAT expressions to the *well-nested* GKAT-*automata* of [34]. In Section 7, we prove that this semantics is in fact complete w.r.t. $\equiv_0$ and, building on this, obtain a semantics that is complete w.r.t. $\equiv$. Omitted proofs are included in the extended version [32].

3 An operational model: GKAT-automata

In this section we discuss the small-step operational model for GKAT programs from [34]. The operational perspective provides us with the tools to describe a semantics that is complete w.r.t. $\equiv_0$ and paves the way to a decision procedure.

We can think of a GKAT-program as a machine that evolves as it reads a string of atomic tests. Depending on the most recently observed atomic test, the program either accepts, rejects, or emits an action label and changes to a new state. For example, feeding **if** b **do** p **else** q an atomic test $a \in b$ causes it to perform the action p and then terminate successfully.

▶ **Definition 3.1.** *A* GKAT**-automaton** *[34, 23] is a pair $\mathcal{X} = (X, \delta)$, where X is a set of* **states** *and $\delta : X \times A \to 2 + \Sigma \times X$ is a* **transition function**. *We use $x \xrightarrow{a|p}_{\mathcal{X}} x'$ as a notation for $\delta(x, a) = (p, x')$. Similarly, $x \Rightarrow_{\mathcal{X}} a$ denotes that $\delta(x, a) = 1$, and $x \downarrow_{\mathcal{X}} a$ denotes that $\delta(x, a) = 0$. We drop the subscript $\mathcal{X}$ when the automaton is clear from context.*

Intuitively, X represents the states of an abstract machine running a GKAT program, with dynamics encoded in δ. When the machine is in state $x \in X$ and observes $a \in A$, there are three possibilities: if $x \downarrow a$, the machine rejects; if $x \Rightarrow a$, it accepts; and if $x \xrightarrow{a|p} x'$, it performs the action p followed by a transition to the state x'.

$$\frac{a \in b}{b \Rightarrow a} \qquad \frac{}{p \xrightarrow{a|p} 1} \qquad \frac{a \in b \qquad e \Rightarrow a}{e +_b f \Rightarrow a} \qquad \frac{a \in \bar{b} \qquad f \Rightarrow a}{e +_b f \Rightarrow a} \qquad \frac{a \in b \qquad e \xrightarrow{a|p} e'}{e +_b f \xrightarrow{a|p} e'} \qquad \frac{a \in \bar{b} \qquad f \xrightarrow{a|p} f'}{e +_b f \xrightarrow{a|p} f'}$$

$$\frac{e \Rightarrow a \qquad f \Rightarrow a}{e \cdot f \Rightarrow a} \qquad \frac{e \Rightarrow a \qquad f \xrightarrow{a|p} f'}{e \cdot f \xrightarrow{a|p} f'} \qquad \frac{e \xrightarrow{a|p} e'}{e \cdot f \xrightarrow{a|p} e' \cdot f} \qquad \frac{a \in b \qquad e \xrightarrow{a|p} e'}{e^{(b)} \xrightarrow{a|p} e' \cdot e^{(b)}} \qquad \frac{a \in \bar{b}}{e^{(b)} \Rightarrow a}$$

Figure 2 The transition structure of $\mathcal{E}$. Here, $e, e', f, f' \in \mathrm{Exp}$, $b \subseteq A$, $a \in A$, and $p \in \Sigma$. Transitions that are not explicitly defined above are assumed to be failed termination.

▶ Remark 3.2. The reader familiar with coalgebra will recognize that GKAT-automata are precisely coalgebras for the functor $G = (2 + \Sigma \times \mathsf{Id})^A$ [34]. Indeed, the notions relating to GKAT-automata, such as homomorphism, bisimulation, and semantics to follow are precisely those that arise from G as prescribed by universal coalgebra [27].

We can impose an automaton structure on Exp yielding the ***syntactic* GKAT-*automaton*** $\mathcal{E} = (\mathrm{Exp}, D)$, where D is the transition map given by Brzozowski derivatives [34] as specified in Figure 2. For instance, the operational behavior of $p^{(b)}$ as a state of $\mathcal{E}$ could be drawn as follows, where $x \xrightarrow{b|p} y$ denotes that $x \xrightarrow{a|p} y$ for every $a \in b$ and rejecting transitions $x \downarrow a$ are left implicit:

$$\bar{b} \Longleftarrow p^{(b)} \xrightarrow{b|p} 1 \cdot p^{(b)} \Longrightarrow \bar{b} \qquad (1)$$

The operational structure of $\mathcal{E}$ is connected to $\equiv_0$ as follows.

▶ **Theorem 3.3** (Fundamental theorem of GKAT). *For any $e \in \mathrm{Exp}$, $e \equiv_0 1 +_{E(e)} D(e)$ where*

$$D(e) = \bigplus_{e \xrightarrow{a|p_a} e_a} p_a \cdot e_a \qquad \text{and} \qquad \bigplus_{a \in b} e_a = \begin{cases} 0 & \text{if } b = 0, \\ e_a +_a \left(\bigplus_{a' \in b \setminus a} e_{a'} \right) & \text{some } a \in b, \text{ otherwise.} \end{cases}$$

The generalized guarded union above is well defined, in that the order of atoms does not matter up to $\equiv_0$. See [34] for more details about the generalised guarded union.

States of GKAT-automata have the same behavior if reading the same sequence of atoms leads to the same sequence of actions, acceptance, or rejection. This happens when one state mimics the moves of the other, performing the same actions in response to the same stimuli. For instance, consider the GKAT-automaton in (1): the behavior of $p^{(b)}$ can be replicated by the behavior of $1 \cdot p^{(b)}$, in that both either consume an $a \in \bar{b}$ and terminate or consume $a \in b$ and emit p before transitioning to $1 \cdot p^{(b)}$. This can be made precise.

▶ **Definition 3.4.** *Let $R \subseteq X \times Y$ be a relation between the state spaces of* GKAT*-automata $\mathcal{X}$ and $\mathcal{Y}$. Then R is a* **bisimulation** *if for any $(x, y) \in R$ and $a \in A$,*
(1) *$x \downarrow_{\mathcal{X}} a$ if and only if $y \downarrow_{\mathcal{Y}} a$; and **(2)** $x \Rightarrow_{\mathcal{X}} a$ if and only if $y \Rightarrow_{\mathcal{Y}} a$; and*
(3) *if $x \xrightarrow{a|p}_{\mathcal{X}} x'$ and $y \xrightarrow{a|q}_{\mathcal{Y}} y'$ for some x' and y', then $p = q$ and $(x', y') \in R$.*

If a pair of states $(x, y) \in X \times Y$ is contained in a bisimulation, we say that x and y are **bisimilar**. *If a bisimulation R is the graph of a function $\varphi : X \to Y$, we write $\varphi : \mathcal{X} \to \mathcal{Y}$ and call φ a* GKAT**-automaton homomorphism** *[27].*

Indeed, bisimulations are designed to formally witness behavioral equivalence. We use the term ***behavior*** as a synonym for the phrase *bisimilarity (equivalence) class.*

4 The final GKAT-automaton

One way of assigning semantics to GKAT expressions is to find a sufficiently large GKAT-automaton $\mathcal{Z}$ that contains the behavior of every other GKAT-automaton. In this section, we provide a concrete explicit description of such a "semantic" GKAT-automaton – this is a crucial step towards being able to devise a completeness proof.

Concretely, $\mathcal{Z}$ represents the behavior of a state as a tree that holds information about acceptance, rejection, and transitions to other states (which are subtrees). Essentially, this tree is an unfolding of the transition graph from that state.

We describe these trees using partial functions. Let us write A^+ for the set of all non-empty words consisting of atoms. The state space Z of $\mathcal{Z}$ is the set of all partial functions $t : A^+ \rightharpoonup 2 + \Sigma$ with $A \subseteq \mathrm{dom}(t)$, such that the following hold for all $a \in A$ and $x \in A^+$.

$$\frac{w \in \mathrm{dom}(t) \quad t(w) \in \Sigma}{wa \in \mathrm{dom}(t)} \qquad \frac{w \in \mathrm{dom}(t) \quad t(w) \in 2}{wx \notin \mathrm{dom}(t)}$$

The transition structure of $\mathcal{Z}$ is defined by the inferences

$$\frac{t(a) = 0}{t \downarrow a} \qquad \frac{t(a) = 1}{t \Rightarrow a} \qquad \frac{t(a) = p \in \Sigma}{t \xrightarrow{a|p} \lambda w.t(aw)}$$

When $t(w) \in \Sigma$, we will write $\partial_w t$ for $\lambda u.t(wu)$. We can think of $t \in Z$ as a tree where the root has leaves for atoms $a \in A$ with $t(a) = 1$, and a subtree for every $a \in A$ with $t(a) \in \Sigma$.

▶ Remark 4.1. Trees correspond to *deterministic* (possibly *infinite*) *guarded languages* [34, 23]. More precisely, every tree can be identified with a language $L \subseteq (A \cdot \Sigma)^* \cdot A \cup (A \cdot \Sigma)^\omega$ satisfying (i) if $wap\sigma, waq\sigma' \in L$, then $p = q$; and (ii) if $wa \in L$, then $wap\sigma \notin L$ for any $p\sigma$. We forgo a description in terms of guarded languages in favor of trees because these trees have the constraint about determinism built in.

A ***node*** of t is a word $w \in A^*$ such that either $w = \epsilon$ (the empty word), or $w \in \mathrm{dom}(t)$ and $t(w) \in \Sigma$. We write $\mathrm{Node}(t)$ for the set of nodes of t. A ***subtree*** of t is a tree t' such that $t' = \partial_w t$ for some $w \in \mathrm{Node}(t)$. A ***leaf*** of t is a word $w \in \mathrm{dom}(t)$ such that $t(w) \in 2$.

Next, we specialize Definition 3.4 to $\mathcal{Z}$ (c.f. [28, Theorem 3.1]).

▶ **Lemma 4.2.** *$R \subseteq Z \times Z$ is a bisimulation on $\mathcal{Z}$ iff for any $(t, s) \in R$ and $a \in A$, (1) $t(a) = s(a)$; and (2) if either $\partial_a t$ or $\partial_a s$ is defined, then both are defined and $(\partial_a t, \partial_a s) \in R$.*

We can now prove that bisimilar trees in Z coincide.

▶ **Lemma 4.3** (Coinduction)**.** *If $s, t \in Z$ are bisimilar, then $s = t$.*

Thus, to show that two trees are equal, it suffices to demonstrate a bisimulation that relates them. This proof method is called ***coinduction***. We can also use Lemma 4.2 to define algebraic operations on Z, and such definitions are said to be ***coinductive***. Many of the results in the sequel are argued using coinduction, and many of the constructions are coinductive. With this in mind, we are now ready to prove that $\mathcal{Z}$ contains every behavior that can be represented by a GKAT-automaton, as follows.

▶ **Theorem 4.4.** *$\mathcal{Z}$ is the final GKAT-automaton. In other words, for every GKAT-automaton $\mathcal{X}$, there exists a unique GKAT-automaton homomorphism $!_{\mathcal{X}}$ from $\mathcal{X}$ to $\mathcal{Z}$.*

Given a GKAT-automaton $\mathcal{X}$, the unique map $!_{\mathcal{X}}$ assigns a tree from Z to each of its states. In particular, recalling that the syntactic GKAT-automaton $\mathcal{E}$ has Exp as its set of states, $!_{\mathcal{E}}$ is a semantics of GKAT programs in terms of trees. The following lemma states that bisimulation is sound and complete with respect to this semantics.

▶ **Lemma 4.5.** *States x and x' of a GKAT-automaton $\mathcal{X}$ are bisimilar iff $!_{\mathcal{X}}(x) = !_{\mathcal{X}}(x')$.*

5 Trees form an algebra

So far, we have seen that the behavior of a GKAT-program is naturally interpreted as a certain kind of tree, and that each such tree is the state of the final GKAT-automaton $\mathcal{Z}$. In this section, we show that the trees in Z can themselves be manipulated and combined using the programming constructs of GKAT. These operations satisfy all of the axioms that build $\equiv_0$, but fail the *early-termination axiom* S3. This gives rise to an inductive semantics of GKAT-programs $[\![-]\!] : \mathrm{Exp} \to Z$ that is sound w.r.t. $\equiv_0$. As a matter of fact, we will see that $[\![-]\!]$ coincides with the unique GKAT-automaton homomorphism $!_{\mathcal{E}} : \mathrm{Exp} \to Z$.

We begin by interpreting the tests. Given $b \subseteq A$, we define $[\![b]\!]$ as the characteristic function of b as a subset of A^+, i.e., $[\![b]\!](a) = 1$ if $a \in b$, and $[\![b]\!](a) = 0$ otherwise.

On the other hand, primitive action symbols denote programs that perform an action in one step and then terminate successfully in the next. For $p \in \Sigma$, this behavior is described by the unique tree $[\![p]\!]$ such that $[\![p]\!](a) = p$ and $\partial_a [\![p]\!] = [\![1]\!]$ for any $a \in A$. When context can disambiguate, we write b in place of $[\![b]\!]$ and p in place of $[\![p]\!]$.

Each operation is defined using a ***behavioral differential equation (BDE)*** consisting of a set of ***initial conditions*** $t(a) = \xi_a \in 2 + \Sigma$ indexed by $a \in A$ and a set of ***step equations*** $\partial_a t = s_a$ indexed by the $a \in A$ with $t(a) \in \Sigma$. This is possible because every BDE describes a unique automaton, which (by Theorem 4.4) has a unique interpretation in Z [28]. Each BDE below can be read more or less directly from Figure 2.

The first operation that we interpret in Z is sequential composition. For any $s, t \in Z$, the tree $s \cdot t$ models sequential composition of programs by replacing each non-zero leaf of s by the nodal subtree of t given by the corresponding atomic test. This can formally be defined as the unique operation satisfying the following behavioral differential equation.

$$(s \cdot t)(a) = \begin{cases} t(a) & \text{if } s(a) = 1, \\ s(a) & \text{otherwise} \end{cases} \qquad \partial_a(s \cdot t) = \begin{cases} \partial_a t & \text{if } s(a) = 1, \\ \partial_a s \cdot t & \text{otherwise.} \end{cases}$$

Here, $\partial_a s \cdot t = (\partial_a s) \cdot t$. Using this operation, we define $[\![e \cdot f]\!] = [\![e]\!] \cdot [\![f]\!]$.

To interpret the guarded union operation, define $+_b$ to be the unique operation such that

$$(s +_b t)(a) = \begin{cases} s(a) & \text{if } a \in b, \\ t(a) & \text{otherwise} \end{cases} \qquad \partial_a(s +_b t) = \begin{cases} \partial_a s & \text{if } a \in b, \\ \partial_a t & \text{otherwise.} \end{cases}$$

As before, we define $[\![e +_b f]\!] = [\![e]\!] +_b [\![f]\!]$.

Finally, we interpret the guarded exponential operation. Following Figure 2, $t^{(b)}$ can be defined as the unique tree satisfying

$$t^{(b)}(a) = \begin{cases} 1 & \text{if } a \notin b, \\ t(a) & \text{if } a \in b \text{ and } t(a) \in \Sigma, \\ 0 & \text{otherwise.} \end{cases} \qquad \partial_a(t^{(b)}) = \partial_a t \cdot t^{(b)}$$

Similar to the other operators, we set $[\![e^{(b)}]\!] = [\![e]\!]^{(b)}$. This completes our definition of the algebraic homomorphism $[\![-]\!] : \mathrm{Exp} \to Z$.

As it happens, $[\![-]\!]$ is also a GKAT automaton homomorphism from $\mathcal{E}$ to $\mathcal{Z}$. By uniqueness of such homomorphisms (Theorem 4.4), we can conclude that $[\![-]\!]$ and $!_{\mathcal{E}}$ are the same.

▶ **Proposition 5.1.** *For any $e \in \mathrm{Exp}$, $[\![e]\!] = !_{\mathcal{E}}(e)$.*

This allows us to treat the algebraic and coalgebraic semantics as synonymous. Using Lemma 4.5, we can then show soundness w.r.t. $\equiv_0$ by arguing that $\equiv_0$ is a bisimulation on $\mathcal{E}$.

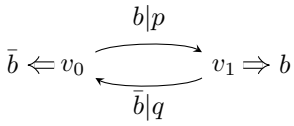

Figure 3 A GKAT-automaton without GKAT behaviors.

▶ **Theorem 5.2.** *The semantics* $[\![-]\!]$ *is sound w.r.t.* $\equiv_0$.

On the other hand, Z does not satisfy S3. For instance, $[\![p \cdot 0]\!] \neq [\![0]\!]$ for any $p \in \Sigma$. We will adapt the model to overcome this in Section 7.3.

6 Well-nested automata and nested behavior

Not all behaviors expressible in terms of finite GKAT-automata occur in $\mathcal{E}$. For example, the two-state automaton in Figure 3 fails to exhibit any behavior of the form $[\![e]\!]$, with $e \in \mathrm{Exp}$, when $b, \bar{b} \neq 0$. This is proven in the extended version [32] where we show that no branch of a GKAT behavior can accept both b and $\bar{b}$ infinitely often. For another example, see [23], where a particular three-state automaton is shown to exhibit no GKAT behavior.

Intuitively, both of the examples above fail to exhibit the behaviors of GKAT programs because GKAT lacks a **goto**-statement that allows control to transfer to an arbitrary position in the program; instead, GKAT automata corresponding to GKAT expressions are structured by branches and loops. The question then arises: can we characterize the "shapes" of automata whose behavior is **goto**-free, i.e., described by a GKAT expression?

In [34], the authors proposed the class of *well-nested* GKAT automata, consisting of automata built inductively by applying a series of operations designed to mimic the structural effects of loops. It was shown that the behavior of every GKAT expression can be described by some well-nested automaton. Moreover, they proved that the class of well-nested automata constitutes a sufficient condition: the behavior of a well-nested GKAT automaton is described by a GKAT expression. Whether this condition is also *necessary*, i.e., whether every automaton with behavior corresponding to a GKAT expression is well-nested, was left open.

Thus, a positive answer to the latter question amounts to showing that every GKAT automaton whose behavior is the same as a well-nested GKAT automaton is itself well-nested. Such a class of automata closed under behavioral equivalence is known as a ***covariety***. Covarieties have desirable structural properties. In particular, they are closed under homomorphic images [27, 12, 3]. Unfortunately, well-nested automata do not satisfy this property: we have found a well-nested automaton whose homomorphic image is not well-nested, depicted in Figure 4. In other words, there exists a non-well-nested automaton whose behavior is still described by a GKAT expression. This also closes the door on a simpler approach to completeness described in [34].

Thus, well-nested automata do not constitute a characterization of the GKAT automata that correspond to GKAT expressions. To obtain such a characterization, we take a slightly different approach: rather than describing shapes of these automata, we describe the shapes of the trees that they denote. We refer to a set of trees $\mathsf{U} \subseteq Z$ as a ***coequation***, and treat it as a predicate: a GKAT-automaton $\mathcal{X}$ ***satisfies*** U, written $\mathcal{X} \models \mathsf{U}$, if every behavior present in $\mathcal{X}$ appears in U – in other words, if $!_{\mathcal{X}}$ factors through U. We write $\mathrm{Cov}(\mathsf{U})$ to denote the class of all GKAT-automata that satisfy U. It is easily shown that $\mathrm{Cov}(\mathsf{U})$ is a covariety.

The coequation that we give to describe the covariety of automata whose behavior corresponds to a GKAT expression is driven by the intuition behind well-nested automata: the trees in this coequation are built using compositions that enforce **while**-like behavior,

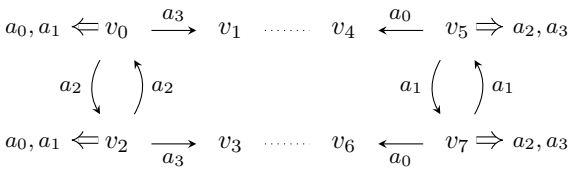

Figure 4 As depicted, this automaton is well-nested. However, identifying v_1 with v_4, and v_3 with v_6, we obtain an automaton that is not well-nested.

and do not permit the construction of **goto**-like behavior. To this end, we need to define a new *continuation* operation, as follows. Given $s, t \in Z$, the ***continuation*** $s \rhd t$ of s along t is the unique tree satisfying the behavioral differential equation

$$(s \rhd t)(a) = \begin{cases} t(a) & \text{if } s(a) = 1, \\ s(a) & \text{otherwise} \end{cases} \qquad \partial_a(s \rhd t) = \begin{cases} \partial_a t \rhd t & \text{if } s(a) = 1, \\ \partial_a s \rhd t & \text{otherwise.} \end{cases}$$

Intuitively, $s \rhd t$ is the tree that attaches infinitely many copies of t to s. This operation can be thought of as the dual to Kleene's original $*$-operation [16], which loops on its first argument some number of times before continuing in the second.

▶ **Definition 6.1.** *The* **nesting** *coequation* W *is the smallest subset of* Z *containing the* **discrete** *coequation* $\mathsf{D} := \{[\![b]\!] \mid b \subseteq A\}$ *and closed under the* **nesting** *rules below:*

$$\frac{t, s \in \mathsf{W}}{t \cdot s \in \mathsf{W}} \qquad \frac{(\forall a \in A)\ t(a) \in \Sigma \implies \partial_a t \in \mathsf{W}}{t \in \mathsf{W}} \qquad \frac{t, s \in \mathsf{W}}{t \rhd s \in \mathsf{W}}$$

The first and third nesting rules say that W is closed under composition and continuation; the second rule says that integrals over nested trees are nested.

It is not too hard to see that W is a subautomaton of $\mathcal{Z}$. In other words, if $t \in \mathsf{W}$, then the derivatives of t are in W as well. In fact, W is a subalgebra of Z in that it is closed under the operations of GKAT. This can be seen from the following observations: first, $\partial_a p = 1$ for all $a \in A$, so $p \in \mathsf{W}$ for any $p \in \Sigma$ by the second nesting rule. Second, W is closed under sequential composition by definition. Third, if $s, t \in \mathsf{W}$ and $b \subseteq A$, then every derivative of $s +_b t$ is either a derivative of s or a derivative of t. Lastly, closure under the guarded exponential is a consequence of the identity

$$t^{(b)} = 1 \rhd (\tilde{t} +_b 1), \qquad \text{where} \qquad \tilde{t} := +_{t \xrightarrow{a|p_a} t_a} p_a \cdot t_a.$$

This identity can be shown to hold for all $t \in Z$ and $b \subseteq A$ using a coinductive argument. It follows that the nesting coequation contains the image of $[\![-]\!]$. A similar argument can be used to establish the reverse containment as well, which leads to the following.

▶ **Proposition 6.2.** W *is the set of* GKAT *program behaviors, i.e,* $\mathsf{W} = \{[\![e]\!] \mid e \in \mathrm{Exp}\}$.

Proposition 6.2 characterizes W as the the set of behavioral patterns exhibited by GKAT expressions: the states of a GKAT-automaton $\mathcal{X}$ behave like GKAT programs if and only if $\mathcal{X}$ satisfies W, or, in other words, if $\mathcal{X}$ can be found in the covariety $\mathrm{Cov}(\mathsf{W})$. Since every well-nested automaton has the behavior of some GKAT expression [34], it must satisfy W.

▶ **Proposition 6.3.** *Well-nested* GKAT*-automata satisfy the nesting coequation.*

7 Completeness

This section contains two completeness theorems for GKAT . As in [34], we need to assume that W3 is generalized to arbitrary (linear) systems of equations. This *uniqueness axiom*, discussed in Section 7.1, will allow us to prove that the semantics $[\![-]\!]$ from Section 5 is free with respect to $\equiv_0$ – that is, $[\![e]\!] = [\![f]\!]$ implies $e \equiv_0 f$ – in Section 7.2. This will then provide an alternative route to completeness for GKAT in Section 7.3.

7.1 Uniqueness of solutions for Salomaa systems

In part, W3 from Figure 1 ensures that the equation $g \equiv e \cdot g +_b f$ with indeterminate g has at most one solution in $\mathrm{Exp}/\equiv_0$ for any $e, f \in \mathrm{Exp}$ under the condition that e denotes a productive program. In fact, we could have stated the axiom this way from the beginning, as W1 provides the existence of a solution to this equation (even without the restriction on productivity). As we will see, the uniqueness axiom makes a more general statement than W3 about *systems* of equations with an arbitrary number of indeterminates.

▶ **Definition 7.1.** *A* **system of (n left-affine) equations** *is a sequence of n equations of the form $x_i = e_{i1} \cdot x_1 +_{b_{i1}} \cdots +_{b_{i(n-1)}} e_{in} \cdot x_n +_{b_{in}} c_i$, indexed by $i \leqslant n$, such that (1) x_i is an indeterminate variable; (2) $(b_{ij})_{j \leqslant n}$ is a sequence of* **disjoint** *Boolean expressions, i.e. $b_{ij} \wedge b_{ik} \equiv 0$ for any $j \neq k$; (3) c_i is a Boolean expression disjoint from b_{ij} for all $j \leqslant n$; and (4) e_{ij} is a* GKAT *expression for any $j \leqslant n$.*

Given any congruence $\doteqdot$ satisfying the axioms of $\equiv_0$, a **solution in $\mathrm{Exp}/\doteqdot$** *to such a system is an n-tuple of* GKAT *expressions $(g_i)_{i \leqslant n}$ such that the equivalence $g_i \doteqdot e_{i1} \cdot g_1 +_{b_{i1}} \cdots +_{b_{i(n-1)}} e_{in} \cdot g_n +_{b_{in}} c_i$ holds for all $i \leqslant n$.*

For example, the equation in the premise of W3 is a system of one left-affine equation, and the conclusion prescribes a unique solution (in $\mathrm{Exp}/\equiv_0$) to the premise. Every finite GKAT-automaton $\mathcal{X}$ gives rise to a system of equations with variables indexed by $X = \{x_i \mid i \leqslant n\}$ and coefficients indexed by the transition map, as follows:

$$e_{ij} = \bigplus_{x_i \xrightarrow{a|p_a} x_j} p_a \qquad c_i = \{a \in A \mid x_i \Rightarrow a\} \qquad b_{ij} = \{a \in A \mid x_i \xrightarrow{a|p} x_j\}.$$

Solving this system of equations uncovers the GKAT-constructs the automaton implements.

The uniqueness axiom states that certain systems of equations, like the one in the premise of W3, admit at most one solution. Choosing which systems the axiom should apply to must be done carefully for the same reason that necessitates the side-condition on W3. Crucially, we require that the system have *productive coefficients*, i.e. $E(e_{ij}) \equiv 0$ for all $i, j \leqslant n$, to admit a unique solution. As this condition is analogous to Salomaa's *empty word property* [31], a system of equations with productive coefficients is called ***Salomaa*** [34]. The ***uniqueness axiom (for $\doteqdot$)*** states that every Salomaa system of equations has at most one solution in $\mathrm{Exp}/\doteqdot$. It is sound with respect to the semantics $[\![-]\!]$ from Section 5.

▶ **Theorem 7.2.** *For any $i, j \leqslant n$, let $s_{ij} \in Z$ satisfy $s_{ij}(a) \neq 1$ for any $a \in A$, $(b_{ij})_{j \neq n}$ be a sequence of disjoint Boolean expressions for any $i \leqslant n$, and $c_i \subseteq A$ be disjoint from b_{ij} for each $i \leqslant n$. The system of equations $x_i = s_{i1} \cdot t_1 +_{b_{i1}} \cdots +_{b_{i(n-1)}} s_{in} \cdot t_n +_{b_{in}} c_i$, indexed by $i \leqslant n$ has a unique solution in Z^n.*

7.2 Completeness with respect to $\equiv_0$

Next, we present a completeness theorem w.r.t. $\equiv_0$. We have already seen that the behavior of a program takes the form of a tree, and that the programming constructs of GKAT apply to trees in such a way that equivalence up to the axioms of $\equiv_0$ is preserved (Theorem 5.2). The completeness theorem in this section shows that up to $\equiv_0$-equivalence, GKAT programs can be identified with the trees they denote.

▶ **Theorem 7.3** (Completeness for $\equiv_0$). *Assume the uniqueness axiom for $\equiv_0$ and let $e, f \in \mathrm{Exp}$. If $[\![e]\!] = [\![f]\!]$, then $e \equiv_0 f$.*

Proof sketch. Since $[\![e]\!] = [\![f]\!]$, e and f are bisimilar as expressions. This bisimulation gives rise to a Salomaa system of equations, which can be shown to admit both the derivatives of e and f as solutions. By the unique solutions axiom, it then follows that $e \equiv_0 f$. ◀

7.3 Completeness with respect to $\equiv$

Having found a semantics that is sound and complete w.r.t. $\equiv_0$, we proceed to extend this result to find a semantics that is sound and complete w.r.t. $\equiv$. Recall that the only difference between these equivalences was S3, which equates programs that fail eventually with programs that fail immediately. To coarsen our semantics, we need an operation on labelled trees that forces early termination in case an accepting state cannot be reached.

▶ **Definition 7.4.** *We say $t \in Z$ is* **dead** *when for all $w \in \mathrm{dom}(t)$ it holds that $t(w) \neq 1$. The* **normalization** *operator is defined coinductively, as follows:*

$$t^\wedge(a) = \begin{cases} 0 & t(a) \in \Sigma \wedge \partial_a t \text{ is dead,} \\ t(a) & \text{otherwise} \end{cases} \qquad \partial_a(t^\wedge) = (\partial_a t)^\wedge.$$

▶ **Example 7.5.** Normalizing the tree $[\![p +_b p \cdot 0]\!]$ prunes the branch corresponding to $\bar{b}$, since it has no accepting leaves. This yields the tree $[\![b \cdot p]\!]$.

We can compose the normalization operator with the semantics $[\![-]\!]$ to obtain a new semantics $[\![-]\!]^\wedge$, which replaces dead subtrees with early termination. Composing normalization with the earlier semantics of GKAT, we obtain the ***normalized semantics*** $[\![-]\!]^\wedge$. This semantics is sound w.r.t. $\equiv$.

▶ **Proposition 7.6.** *If $e \equiv f$, then $[\![e]\!]^\wedge = [\![f]\!]^\wedge$.*

For the corresponding completeness property, we need a way of "normalizing" a given expression in Exp. The following observation gives us a way to do this.

▶ **Lemma 7.7.** W *is closed under normalization.*

When $e \in \mathrm{Exp}$, we have that $[\![e]\!] \in \mathsf{W}$. Moreover, by the above, $[\![e]\!]^\wedge \in \mathsf{W}$, which means that there is an $e' \in \mathrm{Exp}$ such that $[\![e']\!] = [\![e]\!]^\wedge$. We write $e^\wedge$ for this ***normalized expression***. As it turns out, we can derive the equivalence $e^\wedge \equiv e$ from the uniqueness axiom for $\equiv$. This gives an alternative proof of the completeness result of [34] that highlights the role of coequational methods in reasoning about failure modes.

▶ **Corollary 7.8** ([34]). *Assume the uniqueness axiom for $\equiv$ and $\equiv_0$. If $[\![e]\!]^\wedge = [\![f]\!]^\wedge$, then $e \equiv f$.*

Proof sketch. If $[\![e]\!]^\wedge = [\![f]\!]^\wedge$, then $[\![e^\wedge]\!] = [\![f^\wedge]\!]$. By completeness of $\equiv_0$ w.r.t. $[\![-]\!]$, we can then derive that $e \equiv e^\wedge \equiv_0 f^\wedge \equiv f$, and since $\equiv_0$ is contained in $\equiv$, also $e \equiv f$. ◀

By normalizing the trees in W, we obtain the coequation $\mathsf{W}^\wedge = \{t^\wedge \mid t \in \mathsf{W}\}$. This coequation precisely characterizes GKAT programs with forced early termination. In particular, since $\mathsf{W}^\wedge \subseteq \mathsf{W}$, neither state in Figure 3 has a semantics described by $[\![e]\!]^\wedge$ for some $e \in \mathrm{Exp}$.

8 Related work

This paper builds on [34], where GKAT was proposed together with a language semantics based on guarded strings [15] and an axiomatization closely related to Salomaa's axiomatization of regular expressions based on unique fixpoints [31]. Note that the language of *propositional while programs* from [23, 20] is closely related to GKAT in terms of semantics, although the compact syntax and axiomatization were only introduced in [34].

Some GKAT-automata have behavior that does not correspond to any GKAT expression, such as the example in [23]. The upshot is that the Böhm-Jacopini theorem [6, 13], which states that every deterministic flowchart corresponds to a WHILE program, does not hold propositionally, i.e., when we abstract from the meaning of individual actions and tests [23].

In contrast with [34, 23], our work provides a precise characterization of the behaviors denoted by GKAT programs using trees. In other words, we characterize the image of the semantic map inside the space of all behaviors. This explicit characterization was essential for proving completeness of the full theory of GKAT, including the early termination axiom. KAT equivalence without early termination has been investigated by Mamouras [24].

Brzozowski derivatives [7] appear in the completeness proof of KA [18, 21, 14]. We were more directly inspired by Silva's coalgebraic analogues of Brzozowski derivatives used in the context of completeness [33]. Rutten [28] and Pavlovic and Escardo [26] document the connection between the differential calculus of analysis and coalgebraic derivatives.

Coequations have appeared in the coalgebra literature in a variety of contexts, e.g. [3, 1, 5, 29, 30], and notably in the proof of generalized Eilenberg theorems [36, 2]. The use of coequations in completeness proofs is, as far as we are aware, new.

9 Discussion

GKAT was introduced in [23] under the name *propositional while programs* and extensively studied in [34] as an algebraic framework to reason about simple imperative programs. We presented a new perspective on the theory of GKAT, which allowed us to isolate a fragment of the original axiomatization that captures the purely behavioral properties of GKAT programs. We solved an open problem from [34], providing a proof that well-nested automata are not closed under homomorphisms, thereby making it unlikely that these automata can be used in a completeness proof that does not rely on uniqueness axioms. Finally, we proved completeness for the full theory, respecting the early-termination property, in which programs that fail immediately are equated with programs that fail eventually.

There are several directions for future work that are worth investigating. First, it was conjectured in [34] that the uniqueness axiom follows from the other axioms of GKAT. This remains open, but at the time of writing we think this conjecture might be false. Secondly, the technique we use, based on coequations, can serve as basis for a general approach to completeness proofs. We plan to investigate other difficult problems where our technique might apply. Of particular interest is an open problem posed by Milner in [25], which consists of showing that a certain set of axioms are complete w.r.t. bisimulation equivalence for regular expressions. Recently, Grabmeyer and Fokkink [11] provided a partial solution. We believe our technique can simplify their proofs and shed further light on Milner's problem.

We have chosen to adopt the axiomatization from [34], which can be described as a Salomaa-style axiomatization – the loop is a unique fixpoint satisfying a side condition on termination. We would like to generalize the results of the present paper to an axiomatization in which the loop is a least fixpoint w.r.t. an order. The challenge is that there is no natural order in the language because the $+$ of Kleene Algebra has been replaced by $+_b$. However, we hope to devise an order $\leqslant$ directly on expressions and extend the characterizations that we have to the new setting. This new axiomatization would have the advantage of being algebraic (that is, sound under arbitrary substitution), which makes it more suitable for verification purposes as the number of models of the language would increase.

Abstract

Differential lambda-calculus was first introduced by Thomas Ehrhard and Laurent Regnier in 2003. Despite more than 15 years of history, little work has been done on a differential calculus with integration. In this paper, we shall propose a differential calculus with integration from a programming point of view. We show its good correspondence with mathematics, which is manifested by how we construct these reduction rules and how we preserve important mathematical theorems in our calculus. Moreover, we highlight applications of the calculus in incremental computation, automatic differentiation, and computation approximation.

1 Introduction

Differential calculus has more than 15 years of history in computer science since the pioneer work by Thomas Ehrhard and Laurent Regnier [9]. It is, however, not well-studied from the perspective of programming languages; we would expect the profound connection of differential calculus with important fields such as incremental computation, automatic differentiation and self-adjusting computation just like how mathematical analysis connects with mathematics. We want to understand what is the semantics of the derivative of a program and how we can use these derivatives to write a program. That is, we wish to have a clear description of derivatives and introduce integration to compute from operational derivatives to the program.

The two main lines of the related work are the differential lambda-calculus [9, 8] and the change theory [7, 4, 5]. On one hand, the differential lambda-calculus uses linear substitution to represent the derivative of a term. For example, given a term $x * x$ (i.e., x^2), with the differential lambda-calculus, we may use the term $\frac{\partial x * x}{\partial x} \cdot 1$ to denote its derivative at 1. As there are two alternatives to substitute 1 for x in the term $x * x$, it gives $(1 * x) + (x * 1)$ (i.e., $2x$) as the derivative (where $+$ denotes "choice").

Despite that the differential lambda-calculus provides a concise way to analyze the alternatives of linear substitution on a lambda term, there is a gap between analysis on terms and computation on terms. For instance, let $+'$ denote our usual addition operator, and $+$ denote the choice of linear substitution. Then we have that $\frac{\partial x +' x}{\partial x} \cdot 1 = (1 +' x) + (x +' 1)$, which is far away from the expected $1 +' 1$. Moreover, it offers no method to integrate over a derivative, say $\frac{\partial t}{\partial x} \cdot y$.

On the other hand, the change theory gives a systematic way to define and propagate (transfer) changes. The main idea is to define the change of function f as *Derive* f, satisfying

$$f(x \oplus \Delta x) = f(x) \oplus (\textit{Derive } f)\ x\ \Delta x.$$

where $\oplus$ denotes an updating operation. It reads that the change over the input x by Δx results in the change over the result of $f(x)$ by (*Derive* f) x Δx. While change theory provides a general way to describe changes, the changes it described are differences (deltas) instead of derivatives. It is worth noting that derivative is not the same as delta. For example, by change theory, we can deduce that $f(x)$ will be of the form of $x * x + C$ if we know (*Derive* f) x $\Delta x = 2 * x * \Delta x + \Delta x * \Delta x$, but we cannot deduce this form if we just know that its derivative is $2 * x$, because change theory has no concept of integration or limits.

Although a bunch of work has been done on derivatives [9, 8, 7, 4, 19, 16, 21, 10, 1], there is unfortunately, as far as we are aware, little work on integration. It may be natural to ask what a derivative really means if we cannot integrate it. If there is only a mapping from a term to its derivative without its corresponding integration, how can we operate on derivatives with a clear understanding of what we actually have done?

In this paper[1], we aim at a new differential framework, having dual mapping between derivatives and integrations. With this framework, we can manifest the power of this dual mapping by proving, among others, three important theorems, namely the Newton-Leibniz formula, the Chain Rule and the Taylor's theorem.

Our key idea can be illustrated by a simple example. Suppose we have a function f mapping from an n-dimensional space to an m-dimensional space. Then, let x be $(x_1, x_2, ..., x_n)^T$, and $f(x)$ be $(f_1(x), f_2(x), ..., f_m(x))^T$. Mathematically, we can use a Jacobian matrix A to represent its derivative, which satisfies the equation

$$f(x + \Delta x) - f(x) = A\Delta x + o(\Delta x),\ \text{where } A\ = \begin{pmatrix} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \cdots & \frac{\partial f_1}{\partial x_n} \\ \frac{\partial f_2}{\partial x_1} & \frac{\partial f_2}{\partial x_2} & \cdots & \frac{\partial f_2}{\partial x_n} \\ \cdots & \cdots & \cdots & \cdots \\ \frac{\partial f_m}{\partial x_1} & \frac{\partial f_m}{\partial x_2} & \cdots & \frac{\partial f_m}{\partial x_n} \end{pmatrix}$$

However, computer programs usually describe computation over data of some structure, rather than just scalar data or matrix. In this paper, we extend the idea and propose a new calculus that enables us to perform differentiation and integration on data structures. Our main contributions are summarized as follows.

- To our knowledge, we have made the first attempt of designing a calculus that provides both derivative and integral. It is an extension of the lambda-calculus with five new operators including derivatives and integrations. We give clear semantics and typing rules, and prove that it is sound and strongly normalizing. (Section 2)
- We prove three important theorems and highlight their practical application for incremental computation, automatic differentiation, and computation approximation.
  - We prove the Newton-Leibniz formula: $\int_{t_1}^{t_2} \frac{\partial t}{\partial y}|_x dx = t[t_2/y] \ominus t[t_1/y]$, which is also known as Second Fundamental Theorem of Calculus. It shows the duality between derivatives and integrations, and can be used for incremental computation. (Section 3)
  - We prove the Chain Rule: $\frac{\partial f(g\ x)}{\partial x}|_{t_1} * t = \frac{\partial f\ y}{\partial y}|_{g\ t_1} * (\frac{\partial g\ z}{\partial z}|_{t_1} * t)$. It says $\forall x, \forall x_0, (f(g(x)))' * x_0 = f'(g(x)) * g'(x) * x_0$, and can be used for incremental computation and automatic differentiation. (Section 4)

Figure 1 Calculus Syntax.

- We prove the Taylor's Theorem: $f\ t = \sum_{k=0}^{\infty} \frac{1}{k!}(f^{(k)}\ t_0) * (t \ominus t_0)^k$. Different from that one of the differential lambda-calculus [9], this Taylor's theorem manifests results of computation instead of analysis on occurrence of terms. It can be used for approximation of a function computation. (Section 5)

2 Calculus

In this section, we shall give a clear definition of our calculus with both derivatives and integration. We explain important insights in our design, and prove some useful properties and theorems that will be used later.

2.1 Syntax

Our calculus, as defined in Figure 1, is an extension of the simply-typed lambda calculus [20]. Besides the usual constant, variable, lambda abstraction, function application, and tuple, it introduces five new operations: addition $\oplus$, subtraction $\ominus$, multiplication $*$, derivative $\frac{\partial t}{\partial x}|_t$ and integration $\int_t^t t\ dx$. The three binary operations, namely $\oplus$, $\ominus$, and $*$, are generalizations of those from our mathematics. Intuitively, $x \oplus \Delta$ is for updating x with change Δ, $\ominus$ for canceling updates, and * for distributing updates. We build up terms from terms of base types (such as $\mathbb{R}$, $\mathbb{C}$), and on each base type we require these operations satisfy the following properties:

$$\frac{c : T \in \Gamma}{\Gamma \vdash c : T}\ (\textsc{TCon}) \qquad \frac{x : T \in \Gamma}{\Gamma \vdash x : T}\ (\textsc{TVar})$$

$$\frac{\Gamma \vdash t : T_1}{\Gamma \vdash inl\ t : T_1 + T_2}\ (\textsc{TInl}) \qquad \frac{\Gamma \vdash t : T_2}{\Gamma \vdash inr\ t : T_1 + T_2}\ (\textsc{TInr})$$

$$\frac{\Gamma \vdash t_1 : T^* \quad \Gamma \vdash t_2 : T^*}{\Gamma \vdash t_1 \oplus t_2 : T^*}\ (\textsc{TAdd}) \qquad \frac{\Gamma \vdash t_1 : T^* \quad \Gamma \vdash t_2 : T^*}{\Gamma \vdash t_1 \ominus t_2 : T^*}\ (\textsc{TSub})$$

$$\frac{\Gamma, x : T_1 \vdash t : T_2}{\Gamma \vdash \lambda x : T_1 . t : T_1 \to T_2}\ (\textsc{TAbs}) \qquad \frac{\Gamma \vdash t_1 : T_1 \to T_2 \quad \Gamma \vdash t_2 : T_1}{\Gamma \vdash t_1\ t_2 : T_2}\ (\textsc{TApp})$$

$$\frac{\Gamma \vdash t : T \to T}{\Gamma \vdash fix\ t : T}\ (\textsc{TFix}) \qquad \frac{\Gamma \vdash t_1 : T_1 \quad \Gamma, x : T_1 \vdash t_2 : T_2}{\Gamma \vdash \frac{\partial t_2}{\partial x}|_{t_1} : \frac{\partial T_2}{\partial T_1}}\ (\textsc{TDer})$$

$$\frac{\forall j \in [1,n], \Gamma \vdash t_j : T_j}{\Gamma \vdash (t_1, t_2, ..., t_n) : (T_1, T_2, ..., T_n)}\ (\textsc{TPair}) \qquad \frac{\forall j \in [1,n], \Gamma \vdash t : (T_1, T_2, ..., T_n)}{\Gamma \vdash \pi_j\ t : T_j}\ (\textsc{TProj})$$

$$\frac{\Gamma \vdash t_1 : \frac{\partial T^*}{\partial T} \quad \Gamma \vdash t_2 : T}{\Gamma \vdash t_1 * t_2 : T^*}\ (\textsc{TMul})$$

$$\frac{\Gamma \vdash t_1 : T \quad \Gamma \vdash t_2 : T \quad \Gamma, x : T \vdash t : \frac{\partial T^*}{\partial T}}{\Gamma \vdash \int_{t_1}^{t_2} t\ dx : T^*}\ (\textsc{TInt})$$

$$\frac{\Gamma, x_1 : T_1 \vdash t_1 : T \quad \Gamma, x_2 : T_2 \vdash t_2 : T \quad \Gamma \vdash t : T_1 + T_2}{\Gamma \vdash case\ t\ of\ inl\ x_1 \Rightarrow t_1 \mid inr\ x_2 \Rightarrow t_2 : T}\ (\textsc{TCase})$$

Figure 2 Typing Rules.

- The addition and multiplication are associative and commutative, i.e., $(a \oplus b) \oplus c = a \oplus (b \oplus c)$, $a \oplus b = b \oplus a$, $(a * b) * c = a * (b * c)$, $a * b = b * a$.
- The addition and the subtraction are cancellable, i.e., $(a \oplus b) \ominus b = a$ and $(a \ominus b) \oplus b = a$.
- The multiplication is distributive over addition, i.e., $a * (b \oplus c) = a * b \oplus a * c$.

▶ **Example 1** (Basic Operations on Real Numbers). For real numbers $r_1, r_2 \in \mathbb{R}$, we have the following definitions.

$$\begin{aligned} r_1 \oplus r_2 &= r_1 + r_2 \\ r_1 \ominus r_2 &= r_1 - r_2 \\ r_1 * r_2 &= r_1\ r_2 \end{aligned}$$

We use $\frac{\partial t_1}{\partial x}|_{t_2}$ to denote derivative of t_1 over x at point t_2, and $\int_{t_1}^{t_2} t\ dx$ to denote integration of t over x from t_1 to t_2.

2.2 Typing

As defined in Figure 1, we have base types (denoted by B), tuple types, function types, and sum type. To make our later typing rules easy to understand, we introduce the following type notations.

$$\begin{array}{llll} \text{Type} & T^* ::= & B & \text{base type} \\ & \mid & (T^*, T^*, ..., T^*) & \text{product type} \\ & \mid & T \to T^* & \text{arrow type} \end{array}$$

T^* means the types that are addable (i.e., updatable through $\oplus$). We view the addition between functions, tuples and base type terms as valid, which will be showed by our reduction rules later. But here, we forbid the addition and subtraction between sum types because we view updates such as $inl\ 0 \oplus inr\ 1$ as invalid. If we want to update the change to a term of sum types anyway, we may do case analysis such as $case\ t\ of\ inl\ x_1 \Rightarrow inl\ (x_1 \oplus ...) \mid inr\ x_2 \Rightarrow (x_2 \oplus ...)$.

Next, we introduce two notations for derivatives on types:

$$\frac{\partial T}{\partial \mathsf{B}} = T,$$

$$\frac{\partial T}{\partial (T_1, T_2, ..., T_n)} = (\frac{\partial T}{\partial T_1}, \frac{\partial T}{\partial T_2}, ..., \frac{\partial T}{\partial T_n}).$$

The first notation says that with the assumption that differences (subtraction) of values of base types are of base types, the derivative over base types has no effect on the result type. And, the second notation resembles partial differentiation. Note that we do not consider derivatives on functions because even for functions on real numbers, there is no good mathematical definition for them yet. Therefore, we do not have a type notation for $\frac{\partial T}{\partial (T_1 \to T_2)}$. Besides, because we forbid the addition and subtraction between the sum types, we will iew the differentiation of the sum types as invalid, so we do not have notations for $\frac{\partial T}{\partial (T_1 + T_2)}$ either.

Figure 2 shows the typing rules for the calculus. The typing rules for constant, variable, lambda abstraction, function application, tuple, and projection are nothing special. The typing rules for addition and subtraction are natural, but the rest three kinds of rules are more interesting. Rule TMul the typing rule for $t_1 * t_2$. If t_1 is a derivative of T_1 over T_2, and t_2 is of type T_2, then multiplication will produce a term of type T_1. This may be informally understood from our familiar equation $\frac{\triangle Y}{\triangle X} * \triangle X = \triangle Y$. Rule TDer shows introduction of the derivative type through a derivative operation, while Rule TInt cancellation of the derivative type through an integration operation.

2.3 Semantics

We will give a two-stage semantics for the calculus. At the first stage, we assume that all the constants (values and functions) over the base types are *interpretable* in the sense there is a default well-defined interpreter to evaluate them. At the second stage, the important part of this paper, we define a set of reduction rules and use the full reduction strategy to compute their normal form, which enjoys good properties of soundness, confluence, and strong normalization.

More specifically, after the full reduction of a term in our calculus, every subterm (now in a normal form of interpretable types) outside the lambda function body will be interpretable on base types, which will be proved in the full version. In other words, our calculus helps to reduce a term to a normal form which is interpretable on base types, and leave the remaining evaluations to interpretation on base types. We will not give reduction rules to the operations on base types because we do not want to touch on implementations of primitive functions on base types.

For simplicity, in this paper we will assume that the important properties such as the Newton-Leibniz formula, the Chain Rule, and the Taylor's theorem, are satisfied by all the primitive functions and their closures through addition, subtraction, multiplication, derivative and integration. This assumption may seem too strong, since not all primitive functions on base types meet this assumption. However, it would make sense to start with the primitive functions meeting these requirements to build our system, and extend it later with other primitive functions.

$$\frac{t_0 : \mathsf{B}}{\frac{\partial(t_1,t_2,...,t_n)}{\partial x}|_{t_0} \rightarrow (\frac{\partial t_1}{\partial x}|_{t_0}, \frac{\partial t_2}{\partial x}|_{t_0}, ..., \frac{\partial t_n}{\partial x}|_{t_0})} \quad \text{(EAppDer1)}$$

$$\frac{t_0 : \mathsf{B}}{\frac{\partial inl/inr\ t}{\partial x}|_{t_0} \rightarrow inl/inr\ \frac{\partial t}{\partial x}|_{t_0}} \quad \text{(EAppDer2)}$$

$$\frac{t_0 : \mathsf{B}}{\frac{\partial(\lambda y{:}T.t)}{\partial x}|_{t_0} \rightarrow \lambda y : T.\frac{\partial t}{\partial x}|_{t_0}} \quad \text{(EAppDer3)}$$

$$\frac{\forall i \in [1,n],\ t_{i*} = (t_1, t_2..., t_{i-1}, x_i, t_{i+1}..., t_n)}{\frac{\partial t}{\partial x}|_{(t_1,t_2,...,t_n)} \rightarrow (\frac{\partial t[t_{1*}/x]}{\partial x_1}|_{t_1}, \frac{\partial t[t_{2*}/x]}{\partial x_2}|_{t_2}, ..., \frac{\partial t[t_{n*}/x]}{\partial x_n}|_{t_n})} \quad \text{(EAppDer4)}$$

$$\frac{t_1, t_2 : \mathsf{B}}{\int_{t_1}^{t_2}(t_{11}, t_{12}, ...t_{1n})dx \rightarrow (\int_{t_1}^{t_2} t_{11}dx, \int_{t_1}^{t_2} t_{12}dx, ..., \int_{t_1}^{t_2} t_{1n}dx)} \quad \text{(EAppInt1)}$$

$$\frac{t_1, t_2 : \mathsf{B}}{\int_{t_1}^{t_2} inl/inr\ t\ dx \rightarrow inl/inr\ \int_{t_1}^{t_2} t\ dx} \quad \text{(EAppInt2)}$$

$$\frac{t_1, t_2 : \mathsf{B}}{\int_{t_1}^{t_2} \lambda y : T_2.tdx \rightarrow \lambda y : T_2.\int_{t_1}^{t_2} tdx} \quad \text{(EAppInt3)}$$

$$\frac{\forall i \in [1,n], t_{i*} = (t_{21}..., t_{2i-1}, x_i, t_{1i+1}..., t_{1n})}{\int_{(t_{11},t_{12},...t_{1n})}^{(t_{21},t_{22},...,t_{2n})} tdx \rightarrow \int_{t_{11}}^{t_{21}} \pi_1(t[t_{1*}/x])dx_1 \oplus ... \oplus \int_{t_{1n}}^{t_{2n}} \pi_n(t[t_{n*}/x])dx_n} \quad \text{(EAppInt4)}$$

Figure 3 Reduction Rules for Derivative and Integration.

2.4 Reduction Rules

Our calculus is an extension of simply-typed lambda-calculus. Our lambda abstraction and application are nothing different from the simply-typed lambda calculus, and we have the reduction rule:

$$(\lambda x : T.\, t)t_1 \rightarrow t[t_1/x].$$

We use an n-tuple to model structured data and projection π_j to extract j-th component from a tuple, and we have the following reduction rule:

$$\pi_j(t_1, t_2, ...t_n) \rightarrow t_j.$$

Similarly, we have reduction rules for the case analysis:

$$case\ (inl\ t)\ of\ inl\ x_1 \Rightarrow t_1 \mid inr\ x_2 \Rightarrow t_2 \rightarrow t_1[t/x_1]$$

$$case\ (inr\ t)\ of\ inl\ x_1 \Rightarrow t_1 \mid inr\ x_2 \Rightarrow t_2 \rightarrow t_2[t/x_2]$$

Besides, we introduce fix-point operator to deal with recursion:

$$fix\ f \rightarrow f\ (fix\ f)$$

It is worth noting that tuples, having a good correspondence in mathematics, should be understood as structured data instead of high-dimensional vectors because there are some operations that are different from those in mathematics. As will be seen later, there is difference between our multiplication and matrix multiplication, and derivative and integration on tuples of tuples has no correspondence to mathematical objects.

The core reduction rules in our calculus are summarized in Figure 3, which define three basic cases for both reducing derivative terms and integration terms. For derivative, we use $\frac{\partial t}{\partial x}|_{t_0}$ to denote the derivative of t over x at point t_0, and we have four reduction rules:

- Rule EAppDer1 is to distribute point $t_0 : \mathsf{B}$ into a tuple. This resembles the case in mathematics; if we have a function f defined by $f(x) = (f_1(x), f_2(x), \ldots, f_m(x))^T$, its derivative will be $(\frac{\partial f_1}{\partial x}, \frac{\partial f_2}{\partial x}, \ldots, \frac{\partial f_m}{\partial x})^T$. For example, if we have a function $f : \mathbb{R} \to (\mathbb{R}, \mathbb{R})$ defined by $f(x) = (x, x * x)$, then its derivative will be $(1, 2 * x)$.
- Rule EAppDer2 is similar to Rule EAppDer1.
- Rule EAppDer3 is to distribute point $t_0 : \mathsf{B}$ into a lambda abstraction. Again this is very natural in mathematics. For example, for function $f(x) = \lambda y : B.\, x * y$, then we would have its derivative on x as $\lambda y : B.y$.
- Rule EAppDer4 is to deal with partial differentiation, similar to the Jacobian matrix in mathematics (as shown in the introduction). For example, if we have a function that maps a pair (x, y) to $(x * x, x * y \oplus y)$, which may be written as $\lambda z : (\mathsf{B}, \mathsf{B}).\, (\pi_1 z * \pi_1 z, (\pi_1 z * \pi_2 z \oplus \pi_2 z))$ then we would have its derivative $\frac{\partial (f\ z)}{\partial z}|_{(x,y)}$ as $((2 * x, y), (0, x \oplus 1))$.

Similarly, we can define four reduction rules for integration. Rules EAppInt1,EAppInt2 and EAppInt3 are simple. Rule EAppInt4 is worth more explanation. It is designed to establish the Newton-Leibniz formula

$$\int_{t_1}^{t_2} \frac{\partial t}{\partial y}|_x dx = t[t_2/y] \ominus t[t_1/y]$$

when t_1 and t_2 are tuples:

$$\int_{(t_{11}, t_{12}, \ldots, t_{1n})}^{(t_{21}, t_{22}, \ldots, t_{2n})} \frac{\partial t}{\partial y}|_x dx = t[(t_{21}, t_{22}, ..., t_{2n})/y] \ominus t[(t_{11}, t_{12}, ..., t_{1n})/y].$$

So we design the rule to have

$$\int_{t_{1j}}^{t_{2j}} \frac{\partial t[(t_{21}, ..., t_{2(j-1)}, x'_j, t_{1(j+1)}, ..., t_{1n})/y]}{\partial x'_j}|_{x_j} dx_j = \int_{(t_{21}, \ldots, t_{2(j-1)}, t_{1j}, t_{1(j+1)}, \ldots, t_{1n})}^{(t_{21}, \ldots, t_{2(j-1)}, t_{2j}, t_{1(j+1)}, \ldots, t_{1n})} \frac{\partial t}{\partial y}|_x dx.$$

Notice that under our evaluation rules on derivative, $\pi_j(\frac{\partial t}{\partial x}|_{x=(x_1, x_2, \ldots, x_n)})$ will be equal to the derivative of t to its j-th parameter x_j, so the integration will lead us to the original t.

Finally, we discuss the reduction rules for the three new binary operations, as summarized in Figure 4. The addition $\oplus$ is introduced to support the reduction rule of integration. It is also useful in proving the theorem and constructing the formula. We can understand the two reduction rules for addition as the addition of high-dimension vectors and functions respectively. Similarly, we can have two reduction rules for subtraction $\ominus$. The operator $*$ was introduced as a powerful tool for constructing the Chain Rule and the Taylor's theorem. The first two reduction rules can be understood as multiplications of a scalar with a function and a high-dimension vector respectively, while the last one can be understood as the multiplication on matrix. For example, we have

$$((1, 4), (2, 5), (3, 6)) * (7, 8, 9) = (50, 122)$$

which corresponds to the following matrix multiplication.

$$\begin{pmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{pmatrix} \begin{pmatrix} 7 \\ 8 \\ 9 \end{pmatrix} = \begin{pmatrix} 50 \\ 122 \end{pmatrix}$$

$$(t_{11},...,t_{1n}) \oplus (t_{21},...,t_{2n}) \ \to \ (t_{11} \oplus t_{21},...,t_{1n} \oplus t_{2n}) \quad \text{(EAppAdd1)}$$

$$(\lambda x : T.\, t_1) \oplus (\lambda y : T.\, t_2) \ \to \ \lambda x : T.\, (t_1 \oplus t_2[y/x]) \quad \text{(EAppAdd2)}$$

$$(t_{11},...,t_{1n}) \ominus (t_{21},...,t_{2n}) \ \to \ (t_{11} \ominus t_{21},...,t_{1n} \ominus t_{2n}) \quad \text{(EAppSub1)}$$

$$(\lambda x : T.\, t_1) \ominus (\lambda y : T.\, t_2) \ \to \ \lambda x : T.\, (t_1 \ominus t_2[y/x]) \quad \text{(EAppSub2)}$$

$$\frac{t_0 : \mathsf{B}}{(t_1, t_2, ..., t_n) * t_0 \ \to \ (t_1 * t_0, t_2 * t_0, ..., t_n * t_0)} \quad \text{(EAppMul1)}$$

$$\frac{t_0 : \mathsf{B}}{(\lambda x : T.t) * t_0 \ \to \ \lambda x : T.(t * t_0)} \quad \text{(EAppMul2)}$$

$$\frac{t_0 : \mathsf{B}}{(inl/inr\ t) * t_0 \ \to \ inl/inr\ (t * t_0)} \quad \text{(EAppMul3)}$$

$$\frac{t_1 : (t_{11}, t_{12}, ...t_{1n}), t_2 : (t_{21}, t_{22}, ...t_{2n})}{t_1 * t_2 \ \to \ (t_{11} * t_{21}) \oplus (t_{12} * t_{22}) \oplus ... \oplus (t_{1n} * t_{2n})} \quad \text{(EAppMul4)}$$

Figure 4 Reduction Rules for Addition, Subtraction and Multiplication.

It is worth noting that while they are similar, $*$ is different from the matrix multiplication operation. For example, we cannot write x as an m-dimensional vector (or $m * 1$ matrix) in Taylor's theorem because no matrix A is well-performed under $A * x * x$, but we can write Taylor's Theorem easily under our framework. In the matrix representation, the number of rows of the first matrix and the number of columns of the second matrix must be equal so that we can perform multiplication on them. This means, we can only write case $m = 1$'s Taylor's theorem in matrices, while our version can perform for any tuples.

2.5 Properties

Next, we prove some properties of our calculus. The proof is rather routine with some small variations.

▶ **Lemma 2** (Properties)**.** This calculus has the properties of progress, preservation and confluence. Moreover, if a term t does not contain subterms $fix\ t'$, then t is strong normalizable.

Proof. Full proof is in the full version, which is adapted from the standard proof. ◀

2.6 Term Equality

We need to talk a bit more on equality because we do not consider reduction or calculation on primitive functions. This notion of equality has little to do with our evaluation but has a lot to do with the equality of primitive functions. Using this notion of equality, we can compute the result from completely different calculations. This will be used in our later proof of the three theorems.

Since we have proved the confluence property, we know that every term has at most one normal form after reduction. Thus, we can define our equality based on their normal forms; the equality between unnormalizable terms is undefined.

▶ **Definition 3** (Term Equality). An open term t_1 is said to be equal to a term t_2, if and only if for all free variables $x_1, x_2, ..., x_n$ in t_1 and t_2, for all closed and weak-normalizable term u_i whose type is the same as that of x_i, we have $t_1[u_1/x_1, ..., u_n/x_n] = t_2[u_1/x_1, ..., u_n/x_n]$.

A closed-term $t_1 = t_2$, if their normal forms n_1 and n_2 have the relation that $n_1 = n_2$, where a normal form n_1 is said to be equal to another normal form n_2, if they satisfy one of the following rules:

- (1) n_1 is a of type iB (Type iB is used to capture terms with base type constants and functions, being defined by $iB = iB \to iB \mid B$). A normal form of type iB is interpretable by the base type interpreter. Detailed proof is in the full version), then n_2 has to be of the same type, and under the base type interpretation, n_1 is equal to n_2;
- (2) n_1 is $(t_1, t_2, ..., t_n)$, then n_2 has to be $(t'_1, t'_2, ..., t'_n)$, and $\forall j \in [1, n], t_j$ is equal to t'_j;
- (3) n_1 is $\lambda x : T.t$, then n_2 has to be $\lambda y : T.t'$ (y can be x), and $n_1\ x$ is equal to $n_2\ x$.
- (4) n_1 is $inl\ t'_1$, then n_2 has to be $inl\ t'_2$, and t'_1 is equal to t'_2.
- (5) n_1 is $inr\ t'_1$, then n_2 has to be $inr\ t'_2$, and t'_1 is equal to t'_2.

▶ **Lemma 4.** The equality is reflexive, transitive and symmetric for weak-normalizable terms.

Proof. Based on the equality of terms of base types, we can prove it by induction. ◀

▶ **Lemma 5.** The equality is consistent, e.g., we can not prove equality between arbitrary two terms.

Proof. Notice that except for the equality introduced by the base type interpreter, other equality inferences all preserve the type. So for arbitrary t_1 of type (B, B) and t_2 of type B, we can not prove equality between them. ◀

Next we give some lemmas that will be used later in our proof. It is relatively unimportant to the mainline of our calculus, so we put their proofs in the full version.

▶ **Lemma 6.** If $t_1 \rho^* t'_1, t_2 \rho^* t'_2$, then $t_1[t_2/x]\rho^* t'_1[t'_2/x]$.

▶ **Lemma 7.** If $t_1 = t'_1$, $t_2 = t'_2$, then $t_1 \oplus t_2 = t'_1 \oplus t'_2$.

▶ **Lemma 8.** For a term t, for any subterm s, if the term s'=s, then t[s'/s]=t. (We only substitute the subterm s, but not other subterms same as s)

▶ **Lemma 9.** If $t_1 * (t_2 \oplus t_3)$ and $(t_1 * t_2) \oplus (t_1 * t_3)$ are weak-normalizable, then $t_1 * (t_2 \oplus t_3) = (t_1 * t_2) \oplus (t_1 * t_3)$.

▶ **Lemma 10.** If $(t_1 \ominus t_2) \oplus (t_2 \ominus t_3)$ and $t_1 \ominus t_3$ are weak-normalizable, then $(t_1 \ominus t_2) \oplus (t_2 \ominus t_3) = t_1 \ominus t_3$.

3 Newton-Leibniz's Formula

The first important theorem we will give is the Newton-Leibniz's formula, which ensures the duality between derivatives and integration. This theorem lays a solid basis for our calculus.

▶ **Theorem 11** (Newton-Leibniz). Let t contain no free occurrence of x, and both $\int_{t_1}^{t_2} \frac{\partial t}{\partial y}|_x dx$ and $t[t_2/y] \ominus t[t_1/y]$ are well-typed and weak-normalizable. Then we have

$$\int_{t_1}^{t_2} \frac{\partial t}{\partial y}|_x dx = t[t_2/y] \ominus t[t_1/y].$$

Proof. If t_1, t_2 or t is not closed, then we need to prove $\forall u_1, ..., u_n$, we have

$$(\int_{t_1}^{t_2} \frac{\partial t}{\partial y}|_x dx)[u_1/x_1, ..., u_n/x_n] = (t[t_2/y] \ominus t[t_1/y])[u_1/x_1, ..., u_n/x_n].$$

By freezing $u_1, ..., u_n$, we can apply the substitution $[u_1/x_1, ..., u_n/x_n]$ to make every term closed. So, for simplicity, we will assume t, t_1 and t_2 to be closed.

We prove this by induction on types.

- Case: t_1,t_2 and t are of base types. By the confluence lemma, we know there exists the normal form t', t'_1 and t'_2 of the term t, t_1 and t_2. Also, we know $\int_{t_1}^{t_2} \frac{\partial t}{\partial y}|_x dx = \int_{t'_1}^{t'_2} \frac{\partial t'}{\partial y}|_x dx$ and $t[t_2/y] \ominus t[t_1/y] = t'[t'_2/y] \ominus t'[t'_1/y]$. Since on base types we have $\int_{t'_1}^{t'_2} \frac{\partial t'}{\partial y}|_x dx = t'[t'_2/y] \ominus t'[t'_1/y]$, we have $\int_{t_1}^{t_2} \frac{\partial t}{\partial y}|_x dx = t[t_2/y] \ominus t[t_1/y]$.
- Case: t_1,t_2 are of base types, t is of type $(T_1, T_2, ..., T_n)$. By the confluence lemmas, there exist a normal form $(t'_{11}, t'_{12}, ..., t'_{1n})$ for t. Using Rules (EAppInt1) and (EAppDer1), we know

$$\begin{array}{rcl} \int_{t_1}^{t_2} \frac{\partial t}{\partial y}|_x dx & = & \int_{t_1}^{t_2} \frac{\partial (t'_{11}, t'_{12}, ..., t'_{1n})}{\partial y}|_x dx \\ & = & \int_{t_1}^{t_2} (\frac{\partial t'_{11}}{\partial y}|_x, \frac{\partial t'_{12}}{\partial y}|_x, ..., \frac{\partial t'_{1n}}{\partial y}|_x) dx \\ & = & (\int_{t_1}^{t_2} \frac{\partial t'_{11}}{\partial y}|_x dx, \int_{t_1}^{t_2} \frac{\partial t'_{12}}{\partial y}|_x dx, ..., \int_{t_1}^{t_2} \frac{\partial t'_{1n}}{\partial y}|_x dx) \end{array}$$

  On the other hand, we have

$$\begin{array}{l} t[t_2/y] \ominus t[t_1/y] \\ \quad = (t'_{11}[t_2/y], t'_{12}[t_2/y], ..., t'_{1n}[t_2/y]) \ominus (t'_{11}[t_1/y], t'_{12}[t_1/y], ..., t'_{1n}[t_1/y]) \\ \quad = (t'_{11}[t_2/y] \ominus t'_{11}[t_1/y], t'_{12}[t_2/y] \ominus t'_{12}[t_1/y], ..., t'_{1n}[t_2/y] \ominus t'_{1n}[t_1/y]) \end{array}$$

  By induction, we have $\forall j \in [1, n], \int_{t_1}^{t_2} \frac{\partial t'_{1j}}{\partial y}|_x dx = t'_{1j}[t_2/y] \ominus t'_{1j}[t_1/y]$, so we have proven the case.
- Case: t_1,t_2 are of base types, t is of type $A \to B$. By Lemma 8, we can use $\lambda z : A.t\ z$ (for simiplicity, we use $\lambda z : A.t'$ where $t' = t\ z$) to substitute for t, where z is a fresh variable. Now, we have for any u,

$$\begin{array}{rcl} (\int_{t_1}^{t_2} \frac{\partial t}{\partial y}|_x dx)\ u & = & (\int_{t_1}^{t_2} \frac{\partial \lambda z:A.t'}{\partial y}|_x dx)\ u \\ & = & \lambda z : A.(\int_{t_1}^{t_2} \frac{\partial t'}{\partial y}|_x dx)\ u \\ & = & \int_{t_1}^{t_2} \frac{\partial t'[u/z]}{\partial y}|_x dx \end{array}$$

  and on the other hand, since z is free in t_1 and t_2, we have

$$\begin{array}{rcl} (t[t_2/y] \ominus t[t_1/y])\ u & = & ((\lambda z : A.t')[t_1/y] \ominus (\lambda z : A.t')[t_2/y])\ u \\ & = & \lambda z : A.(t'[t_2/y] \ominus t'[t_1/y])\ u \\ & = & (t'[t_2/y] \ominus t'[t_1/y])[u/z] \\ & = & (t'[u/z])[t_2/y] \ominus (t'[u/z])[t_1/y] \end{array}$$

  By induction (on B), we know $\int_{t_1}^{t_2} \frac{\partial t'[u/z]}{\partial y}|_x dx = (t'[u/z])[t_2/y] \ominus (t'[u/z])[t_1/y]$, thus we have proven the case.
- Case: t_1,t_2 are of base types, t is of type $T_1 + T_2$. This case is impossible because the righthand term is not well-typed.

- Case: t_1,t_2 are of type $(T_1, T_2, ..., T_n)$, t is of any type T. By using the confluence lemma, we know there exist the normal forms $(t'_{11}, t'_{12}, ..., t'_{1n})$ and $(t'_{21}, t'_{22}, ..., t'_{2n})$ for t_1 and t_2 respectively.
  Applying Rules (EAppDer3) and (EAppInt3), we have

$$\begin{aligned}\int_{t_1}^{t_2} \tfrac{\partial t}{\partial y}|_x dx &= \int_{(t'_{11},t'_{12},...,t'_{1n})}^{(t'_{21},t'_{22},...,t'_{2n})} \tfrac{\partial t}{\partial y}|_x dx \\ &= \int_{t'_{11}}^{t'_{21}} \pi_1(\tfrac{\partial t}{\partial y}|_x[(x_1, t'_{12}, ...t'_{1n})/x])dx_1 \oplus \cdots \oplus \\ &\quad \int_{t'_{1n}}^{t'_{2n}} \pi_n(\tfrac{\partial t}{\partial y}|_x[(t'_{21}, t'_{22}, ..., x_n)/x])dx_n\end{aligned}$$

  Notice that there is no occurrence of x in t, so we have

$$\begin{aligned}&\int_{t'_{1j}}^{t'_{2j}} \pi_j(\tfrac{\partial t}{\partial y}|_x[(t'_{21}, t'_{22}, ..., t'_{2(j-1)}, x_j, t'_{1(j+1)}, ..., t'_{1n})/x])dx_j \\ &= \int_{t'_{1j}}^{t'_{2j}} \pi_j(\tfrac{\partial t}{\partial y}|_{(t'_{21},t'_{22},...,t'_{2(j-1)},x_j,t'_{1(j+1)},...,t'_{1n})})dx_j \\ &= \int_{t'_{1j}}^{t'_{2j}} \pi_j(\tfrac{\partial t[t_{1*}/y]}{\partial x_1}|_{t'_{21}}, \tfrac{\partial t[t_{2*}/y]}{\partial x_2}|_{t'_{22}}, ..., \tfrac{\partial t[t_{(j-1)*}/y]}{\partial x_{j-1}}|_{t'_{2(j-1)}}, \\ &\qquad \tfrac{\partial t[t_{j*}/y]}{\partial x'_j}|_{x_j}, \tfrac{\partial t[t_{(j+1)*}/y]}{\partial x_{j+1}}|_{t'_{1(j+1)}}, ..., \tfrac{\partial t[t_{n*}/y]}{\partial x_n}|_{t'_{1n}})dx_j \\ &= \int_{t'_{1j}}^{t'_{2j}} \tfrac{\partial t[(t'_{21},t'_{22},...,t'_{2(j-1)},x'_j,t'_{1(j+1)},...,t'_{1n})/y]}{\partial x'_j}|_{x_j} dx_j\end{aligned}$$

  By induction (on the case where t_1, t_2 are of type T_j, t is of type T), we have

$$\begin{aligned}&\int_{t'_{1j}}^{t'_{2j}} \tfrac{\partial t[(t'_{21},t'_{22},...,t'_{2(j-1)},x'_j,t'_{1(j+1)},...,t'_{1n})/y]}{\partial x'_j}|_{x_j} dx_j \\ &= (t[(t'_{21}, t'_{22}, ..., t'_{2(j-1)}, x'_j, t'_{1(j+1)}, ..., t'_{1n})/y])[t'_{2j}/x'_j] \ominus \\ &\qquad (t[(t'_{21}, t'_{22}, ..., t'_{2(j-1)}, x'_j, t'_{1(j+1)}, ..., t'_{1n})/y])[t'_{1j}/x'_j] \\ &= (t[(t'_{21}, t'_{22}, ..., t'_{2(j-1)}, t'_{2j}, t'_{1(j+1)}, ..., t'_{1n})/y]) \ominus \\ &\qquad (t[(t'_{21}, t'_{22}, ..., t'_{2(j-1)}, t'_{1j}, t'_{1(j+1)}, ..., t'_{1n})/y])\end{aligned}$$

  Note that the last equation holds because x'_j is a fresh variable and t has no occurrence of x'_j.
  Now we have the following calculation.

$$\begin{aligned}&\int_{t_1}^{t_2} \tfrac{\partial t}{\partial y}|_x dx \\ =\ & \{ \text{ all the above } \} \\ & ((t[(t'_{21}, t'_{12}, ..., t'_{1n})/y]) \ominus (t[(t'_{11}, t'_{12}, ..., t'_{1n})/y])) \oplus \\ & \quad ((t[(t'_{21}, t'_{22}, ..., t'_{1n})/y]) \ominus (t[(t'_{21}, t'_{12}, ..., t'_{1n})/y])) \oplus \cdots \oplus \\ & \quad\quad ((t[(t'_{21}, t'_{22}, ..., t'_{2n})/y]) \ominus (t[(t'_{21}, t'_{22}, ..., t'_{1n})/y])) \\ =\ & \{ \text{ Lemma 10 } \} \\ & (t[(t'_{21}, t'_{22}, ..., t'_{2n})/y]) \ominus (t[(t'_{11}, t'_{12}, ..., t'_{1n})/y]) \\ =\ & \{ \text{ Lemma 6 } \} \\ & t[t_2/y] \ominus t[t_1/y]\end{aligned}$$

  Thus we have proven the theorem. ◀

Application: Incremental Computation

A direct application is incrementalization [17, 7, 11]. Given a function $f(x)$, if the input x is changed by Δ, then we can obtain its incremental version of $f(x)$ by $f'(x, \Delta)$.

$$f(x \oplus \Delta) = f(x) \oplus f'(x, \Delta)$$

where f' satisfies that

$$f'(x,\Delta) = \int_x^{x\oplus\Delta} \frac{\partial f(x)}{\partial x}|_x \; dx.$$

▶ **Example 12** (Averaging a Pair of Real numbers)**.** As a simple example, consider the average of a pair of real numbers

$$\begin{array}{lcl} average & :: & (\mathbb{R},\mathbb{R}) \to \mathbb{R} \\ average & = & \lambda x.(\pi_1(x)+\pi_2(x))/2 \end{array}$$

Suppose that we want to get an incremental computation of *average* at $x = (x_1, x_2)$ when the first element x_1 is changed to $x_1 + d$ while the second component x_2 is kept the same. The incremental computation is defined by

$$inc(x,d) = average(x,(d,0)) = \int_x^{x\oplus(d,0)} \frac{\partial average(x)}{\partial x}|_x \; dx = \frac{d}{2}$$

which is efficient.

4 Chain Rule

The Chain Rule is another important theorem of the relation between function composition and derivatives. This Chain Rule in our calculus has many important applications in automatic differentiation and incremental computation.

▶ **Theorem 13** (Chain Rule)**.** Let $f : T_1 \to T$, $g : T_2 \to T_1$. If both $\frac{\partial f(g\ x)}{\partial x}|_{t_1} * t$ and $\frac{\partial f\ y}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ z}{\partial z}|_{t_1} * t)$ are well-typed and weak-normalizable. Then for any $t, t_1 : T_2$, we have

$$\frac{\partial f(g\ x)}{\partial x}|_{t_1} * t = \frac{\partial f\ y}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ z}{\partial z}|_{t_1} * t).$$

Proof. Like in the proof of Theorem 11, for simplicity, we assume that f, g, t and t_1 are closed. Furthermore, we assume that t and t_1 are in normal form. We prove this by induction on types.

- Case T, T_2 are base types, and T_1 is any type. To be well-typed, T_1 must contain no $\to$ or $+$ type. So for simplicity, we suppose T_1 to be $(B, B, B, ..., B)$ of n-tuples, but the technique below can be applied to any T_1 type (such as tuples of tuples) that makes the term well-typed.
  First we notice that

$$\begin{array}{lcl} g\ z & = & (\pi_1(g\ z), \pi_2(g\ z), ..., \pi_n(g\ z)) \\ & = & ((\lambda b' : B.\pi_1(g\ b'))\ z, (\lambda b' : B.\pi_2(g\ b'))\ z, ..., (\lambda b' : B.\pi_n(g\ b'))\ z) \end{array}$$

  and for any j, we notice that $\pi_j(g\ b')$ has only one free variable of base type, so it can be reduced to a normal form, say E_j, of base type. Let g_j be $\lambda b' : B.E_j$, then we have $g\ z = (g_1\ z, g_2\ z, ..., g_n\ z)$.
  Next, we deal with the term f:

$$\begin{array}{lcl} f & = & \lambda a : T_1.(f\ a) \\ & = & \lambda a : T_1.((\lambda y_1 : B.\, \lambda y_2 : B., ... \lambda y_n : B.\, (f\ (y_1, y_2, ..., y_n)))\ \pi_1(a)\ \pi_2(a) ...\ \pi_n(a)) \end{array}$$

and we know that $(f\ (y_1, y_2, ..., y_n))$ only contains base type free variables, so it can be reduced to a base type normal form, say N, so we have

$$f = \lambda a : T.\ ((\lambda y_1 : B.\lambda y_2 : B., ...\lambda y_n : B.\ N)\ \pi_1(a)\ \pi_2(a)...\ \pi_n(a)).$$

Now, we can calculate as follows:

$$\begin{aligned}
&\tfrac{\partial f\ (g\ x)}{\partial x}|_{t_1} * t \\
&\quad = \tfrac{\partial (\lambda a{:}T.(\lambda y_1{:}B.\lambda y_2{:}B.,...\lambda y_n{:}B.N)\ \pi_1(a)\ \pi_2(a)...\ \pi_n(a))\ (g_1\ x, g_2\ x, ..., g_n\ x)}{\partial x}|_{t_1} * t \\
&\quad = \tfrac{\partial (\lambda y_1{:}B.\lambda y_2{:}B.,...\lambda y_n{:}B.N)\ (g_1\ x)\ (g_2\ x)...\ (g_n\ x)}{\partial x}|_{t_1} * t \\
&\quad = \tfrac{\partial N[(g_1\ x)/y_1, (g_2\ x)/y_2, ...(g_n\ x)/y_n]}{\partial x}|_{t_1} * t
\end{aligned}$$

$$\begin{aligned}
&\tfrac{\partial f\ y}{\partial y}|_{(g\ t_1)} * (\tfrac{\partial g\ z}{\partial z}|_{t_1} * t) \\
&\quad = \tfrac{\partial f\ y}{\partial y}|_{(g_1\ t_1, g_2\ t_1, ..., g_n\ t_1)} * (\tfrac{\partial (g_1\ z, g_2\ z, ..., g_n\ z)}{\partial z}|_{t_1} * t) \\
&\quad = \tfrac{\partial f\ y}{\partial y}|_{(g_1\ t_1, g_2\ t_1, ..., g_n\ t_1)} * (\tfrac{\partial g_1\ z}{\partial z}|_{t_1} * t, \tfrac{\partial g_2\ z}{\partial z}|_{t_1} * t, ..., \tfrac{\partial g_n\ z}{\partial z}|_{t_1} * t) \\
&\quad = \tfrac{\partial (\lambda y_1{:}B.\lambda y_2{:}B.,...\lambda y_n{:}B.N)\ \pi_1(y)\ \pi_2(y)...\ \pi_n(y)}{\partial y}|_{(g_1\ t_1, g_2\ t_1, ..., g_n\ t_1)} * \\
&\qquad\qquad (\tfrac{\partial g_1\ z}{\partial z}|_{t_1} * t, \tfrac{\partial g_2\ z}{\partial z}|_{t_1} * t, ..., \tfrac{\partial g_n\ z}{\partial z}|_{t_1} * t) \\
&\quad = (\tfrac{\partial N[y_1'/y_1, g_2\ t_1/y_2, ..., g_n\ t_1/y_n]}{\partial y_1'}|_{g_1\ t_1}, ..., \tfrac{\partial N[g_1\ t_1/y_1, g_2\ t_1/y_2, ..., y_n'/y_n]}{\partial y_n'}|_{g_n\ t_1}) * \\
&\qquad\qquad (\tfrac{\partial g_1\ z}{\partial z}|_{t_1} * t, \tfrac{\partial g_2\ z}{\partial z}|_{t_1} * t, ..., \tfrac{\partial g_n\ z}{\partial z}|_{t_1} * t) \\
&\quad = (\tfrac{\partial N[y_1'/y_1, g_2\ t_1/y_2, ..., g_n\ t_1/y_n]}{\partial y_1'}|_{g_1\ t_1} * (\tfrac{\partial g_1\ z}{\partial z}|_{t_1} * t)) \oplus ... \oplus \\
&\qquad\qquad (\tfrac{\partial N[g_1\ t_1/y_1, g_2\ t_1/y_2, ..., y_n'/y_n]}{\partial y_n'}|_{g_n\ t_1} * (\tfrac{\partial g_n\ z}{\partial z}|_{t_1} * t))
\end{aligned}$$

Notice that by the base type interpretation, $f(g_1(x), g_2(x), ..., g_n(x)) = f_1'(g_1(x), g_2(x), ..., g_n(x)) * g_1'(x) + f_2'(g_1(x), g_2(x), ..., g_n(x)) * g_2'(x) + ... + f_n'(g_1(x), g_2(x), ..., g_n(x)) * g_n'(x)$ where f_j' means the derivative of f to its j-th parameter, so we get the following and prove the case.

$$\begin{aligned}
&\tfrac{\partial N[(g_1\ x)/y_1, (g_2\ x)/y_2, ...(g_n\ x)/y_n]}{\partial x}|_{t_1} * t \\
&\quad = (\tfrac{\partial N[y_1'/y_1, g_2\ t_1/y_2, ..., g_n\ t_1/y_n]}{\partial y_1'}|_{g_1\ t_1} * (\tfrac{\partial g_1\ z}{\partial z}|_{t_1} * t)) \oplus ... \oplus \\
&\qquad (\tfrac{\partial N[g_1\ t_1/y_1, g_2\ t_1/y_2, ..., y_n'/y_n]}{\partial y_n'}|_{g_n\ t_1} * (\tfrac{\partial g_n\ z}{\partial z}|_{t_1} * t))
\end{aligned}$$

- Case T_2 is base type, T_1 is any type, T is $A \to B$. We prove that for any u of type A, we have $(\tfrac{\partial f\ (g\ x)}{\partial x}|_{t_1} * t)\ u = (\tfrac{\partial f\ y}{\partial y}|_{(g\ t_1)} * (\tfrac{\partial g\ z}{\partial z}|_{t_1} * t))\ u$.
  First, let $f' = \lambda x : T_1.(f\ x)\ u$, $g' = g$, then by induction we have

  $$\tfrac{\partial f'(g'\ x)}{\partial x}|_{t_1} * t = \tfrac{\partial f'\ y}{\partial y}|_{(g'\ t_1)} * (\tfrac{\partial g'\ z}{\partial z}|_{t_1} * t)$$

  that is, we have

  $$(\tfrac{\partial f\ (g\ x)\ u}{\partial x}|_{t_1} * t) = (\tfrac{\partial f\ y\ u}{\partial y}|_{(g\ t_1)} * (\tfrac{\partial g\ z}{\partial z}|_{t_1} * t))$$

  Then, we prove $(\tfrac{\partial f\ (g\ x)\ u}{\partial x}|_{t_1} * t) = (\tfrac{\partial f\ (g\ x)}{\partial x}|_{t_1} * t)\ u$ by the following calculation.

  $$\begin{aligned}
  (\tfrac{\partial f\ (g\ x)}{\partial x}|_{t_1} * t)\ u &= (\tfrac{\partial \lambda a{:}A.(f\ (g\ x))\ a}{\partial x}|_{t_1} * t)\ u \\
  &= (\lambda a : A.(\tfrac{\partial (f\ (g\ x))\ a}{\partial x}|_{t_1} * t))\ u \\
  &= (\tfrac{\partial f\ (g\ x)\ u}{\partial x}|_{t_1} * t)
  \end{aligned}$$

Next, we prove $(\frac{\partial f\ y}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ z}{\partial z}|_{t_1} * t))\ u = \frac{\partial f\ y\ u}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ z}{\partial z}|_{t_1} * t)$. For simplicity, we assume T_1 to be $(B, B, B, ..., B)$ of n-tuples (the technique below can be applied to any T_1 type which makes the term well-typed).
On one hand, by substituting $(g_1\ z, g_2\ z, ..., g_n\ z)$ for $g\ z$, we have

$$\begin{aligned}
&(\frac{\partial f\ y}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ z}{\partial z}|_{t_1} * t))\ u \\
&\quad = \frac{\partial f\ y}{\partial y}|_{(g_1\ t_1, g_2\ t_1, ..., g_n\ t_1)} * (\frac{\partial (g_1\ z, g_2\ z, ..., g_n\ z)}{\partial z}|_{t_1} * t)\ u \\
&\quad = (\frac{\partial f(y_1, g_2\ t_1, ..., g_n\ t_1)}{\partial y_1'}|_{g_1\ t_1} * (\frac{\partial g_1\ z}{\partial z}|_{t_1} * t) \oplus ... \oplus \\
&\qquad\qquad \frac{\partial f(g_1\ t_1, g_2\ t_1, ..., y_n)}{\partial y_n'}|_{g_n\ t_1} * (\frac{\partial g_n\ z}{\partial z}|_{t_1} * t))\ u
\end{aligned}$$

Since

$$\begin{aligned}
&f(g_1\ t_1, g_2\ t_1, ..., g_{j-1}\ t_1, y_j, g_{j+1}\ t_1, ..., g_n\ t_1) \\
&\quad = \lambda a : A. f\ (g_1\ t_1, g_2\ t_1, ..., g_{j-1}\ t_1, y_j, g_{j+1}\ t_1, ..., g_n\ t_1)\ a
\end{aligned}$$

which will be denoted as $\lambda a : A.t_j^*$, we continue the calculation as follows.

$$\begin{aligned}
&(\frac{\partial f\ y}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ z}{\partial z}|_{t_1} * t))\ u \\
&\quad = (\frac{\partial \lambda a : A.t_1^*}{\partial y_1}|_{g_1\ t_1} * (\frac{\partial g_1\ z}{\partial z}|_{t_1} * t) \oplus ... \oplus \frac{\partial \lambda a : A.t_n^*}{\partial y_n}|_{g_n\ t_1} * (\frac{\partial g_n\ z}{\partial z}|_{t_1} * t))\ u \\
&\quad = \lambda a : A.(\frac{\partial t_1^*}{\partial y_1}|_{g_1\ t_1} * (\frac{\partial g_1\ z}{\partial z}|_{t_1} * t)) \oplus ... \oplus (\frac{\partial t_n^*}{\partial y_n}|_{g_n\ t_1} * (\frac{\partial g_n\ z}{\partial z}|_{t_1} * t))\ u \\
&\quad = \frac{\partial t_1^*[u/a]}{\partial y_1}|_{g_1\ t_1} * (\frac{\partial g_1\ z}{\partial z}|_{t_1} * t) \oplus ... \oplus \frac{\partial t_n^*[u/a]}{\partial y_n}|_{g_n\ t_1} * (\frac{\partial g_n\ z}{\partial z}|_{t_1} * t)
\end{aligned}$$

On the other hand, we have

$$\begin{aligned}
&(\frac{\partial f\ y\ u}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ z}{\partial z}|_{t_1} * t)) \\
&\quad = \frac{\partial f\ y\ u}{\partial y}|_{(g_1\ t_1, g_2\ t_1, ..., g_n\ t_1)} * (\frac{\partial (g_1\ z, g_2\ z, ..., g_n\ z)}{\partial z}|_{t_1} * t) \\
&\quad = \frac{\partial f\ (y_1, g_2\ t_1, ..., g_n\ t_1)\ u}{\partial y_1}|_{g_1\ t_1} * (\frac{\partial g_1\ z}{\partial z}|_{t_1} * t) \oplus ... \oplus \\
&\qquad\qquad \frac{\partial f\ (g_1\ t_1, g_2\ t_1, ..., y_n)\ u}{\partial y_n}|_{g_n\ t_1} * (\frac{\partial g_n\ z}{\partial z}|_{t_1} * t) \\
&\quad = \frac{\partial (\lambda a : A.t_1^*)\ u}{\partial y_1}|_{g_1\ t_1} * (\frac{\partial g_1\ z}{\partial z}|_{t_1} * t) \oplus ... \oplus \frac{\partial (\lambda a : A.t_n^*)\ u}{\partial y_n}|_{g_n\ t_1} * (\frac{\partial g_n\ z}{\partial z}|_{t_1} * t) \\
&\quad = (\frac{\partial t_1^*[u/a]}{\partial y_1}|_{g_1\ t_1} * (\frac{\partial g_1\ z}{\partial z}|_{t_1} * t)) \oplus ... \oplus (\frac{\partial t_n^*[u/a]}{\partial y_n}|_{g_n\ t_1} * (\frac{\partial g_n\ z}{\partial z}|_{t_1} * t))
\end{aligned}$$

Therefore, we have proven the case.

- Case T_2 is base type, T_1 is any type, T is $(T_1, T_2, ..., T_n)$. We need to prove that for all j, we have $\pi_j(\frac{\partial f(g\ x)}{\partial x}|_{t_1} * t) = \pi_j(\frac{\partial f\ y}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ z}{\partial z}|_{t_1} * t))$. We may follow the proof for the case when T has type $A \to B$. Let $f' = \lambda x : T_1.\pi_j(f\ x), g' = g$, by induction, we have

$$\frac{\partial \pi_j(f(g\ x))}{\partial x}|_{t_1} * t = \frac{\partial \pi_j(f\ y)}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ z}{\partial z}|_{t_1} * t)$$

  The rest of the proof is similar to that for the case when $T = A \to B$.
- Case T_2 is base type, T_1 is any type, T is $T_1 + T_2$. Notice that T_1 has to be base type to be well-typed. But either the case, the proof is similar to the case when $T = A \to B$.
- Case T_2 , T_1 and T are any type. Notice that T_2 does not contain no $\to$ or $+$ to be well-typed (i.e., no derivative over function types). We have proved the case when T_2 is base type, and we assume that T_2 has type $(T_1, T_2, ..., T_n)$. Suppose the normal form of t_1 is $(t_{11}', t_{12}', ..., t_{1n}')$ and the normal form of t is $(t_{21}', t_{22}', ..., t_{2n}')$, Then

$$\begin{aligned}
&\frac{\partial f(g\ x)}{\partial x}|_{t_1} * t \\
&\quad = \frac{\partial f(g\ x)}{\partial x}|_{(t_{11}', t_{12}', ..., t_{1n}')} * (t_{21}', t_{22}', ..., t_{2n}') \\
&\quad = (\frac{\partial f(g\ (x_1, t_{12}', ..., t_{1n}'))}{\partial x_1}|_{t_{11}'}, ..., \frac{\partial f(g\ (t_{11}', t_{12}', ..., x_n))}{\partial x_n}|_{t_{1n}'}) * (t_{21}', ..., t_{2n}') \\
&\quad = (\frac{\partial f(g\ (x_1, t_{12}', ..., t_{1n}'))}{\partial x_1}|_{t_{11}'} * t_{21}') \oplus ... \oplus (\frac{\partial f(g\ (t_{11}', t_{12}', ..., x_n))}{\partial x_n}|_{t_{1n}'} * t_{2n}')
\end{aligned}$$

On the other hand, we can use Lemma 9 (i.e., $t_1 * (t_2 \oplus t_3) = (t_1 * t_2) \oplus (t_1 * t_3)$) to do the following calculation.

$$\begin{aligned}
&\frac{\partial f\ y}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ z}{\partial z}|_{t_1} * t) \\
&\quad = \frac{\partial f\ y}{\partial y}|_{(g\ t_1)} * ((\frac{\partial g\ (x_1, t'_{12}, \ldots, t'_{1n})}{\partial x_1}|_{t'_{11}} * t'_{21}) \oplus \ldots \oplus (\frac{\partial g\ (t'_{11}, t'_{12}, \ldots, x_n)}{\partial x_n}|_{t'_{1n}} * t'_{2n})) \\
&\quad = \frac{\partial f\ y}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ (x_1, t'_{12}, \ldots, t'_{1n})}{\partial x_1}|_{t'_{11}} * t'_{21}) \oplus \ldots \oplus \\
&\qquad\quad \frac{\partial f\ y}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ (t'_{11}, t'_{12}, \ldots, x_n)}{\partial x_n}|_{t'_{1n}} * t'_{2n})
\end{aligned}$$

Now by induction using $f' = f, g' = \lambda x : T_j.g\ (t'_{11}, t'_{12}, ..., t'_{1(j-1)}, x, t'_{1(j+1)}, ..., t'_{1n})$, we have

$$\begin{aligned}
&\frac{\partial f(g\ (t'_{11}, t'_{12}, \ldots, t'_{1(j-1)}, x_j, t'_{1(j+1)} \cdots, t'_{1n})}{\partial x_j}|_{t'_{1j}} * t'_{2j} \\
&\quad = \frac{\partial f\ y}{\partial y}|_{(g'\ t'_{1j})} * (\frac{\partial g\ (t'_{11}, t'_{12}, \ldots, t'_{1(j-1)}, x_j, t'_{1(j+1)} \cdots, t'_{1n})}{\partial x_j}|_{t'_{1j}} * t'_{2j}) \\
&\quad = \frac{\partial f\ y}{\partial y}|_{(g\ t_1)} * (\frac{\partial g\ (t'_{11}, t'_{12}, \ldots, t'_{1(j-1)}, x_j, t'_{1(j+1)} \cdots, t'_{1n})}{\partial x_j}|_{t'_{1j}} * t'_{2j})
\end{aligned}$$

Therefore by Lemma 7, we have proven the case.
Thus we have proven the theorem. ◀

Application: Automatic Differentiation

The Chain Rule provides another way to compute the derivatives. There are many applications of the chain rule, and here we give an example of how to associate it with the automatic differentiation [10].

▶ **Example 14** (AD). This is an example from [10]. Let *sqr* and *magSqr* be defined as follows.

$$\begin{aligned}
&sqr && :: && \mathbb{R} \to \mathbb{R} \\
&sqr\ a && = && a * a \\
&magSqr && :: && (\mathbb{R}, \mathbb{R}) \to \mathbb{R} \\
&magSqr\ (a, b) && = && sqr\ a \oplus sqr\ b
\end{aligned}$$

First of all, let t_1 and t_2 two pairs, then it is easy to prove that $\frac{\partial (t_1 \oplus t_2)}{\partial x}|_{t_3} = \frac{\partial t_1}{\partial x}|_{t_3} \oplus \frac{\partial t_2}{\partial x}|_{t_3}$. Next, we can perform automatic differentiation on *magSqr* by the following calculation.

$$\begin{aligned}
&\frac{\partial (magSqr\ x)}{\partial x}|_{(a,b)} * t \\
&\quad = \frac{\partial (sqr(\pi_1 x) \oplus sqr(\pi_2 x))}{\partial x}|_{(a,b)} * t \\
&\quad = \frac{\partial (sqr\ y)}{\partial y}|_{\pi_1(a,b)} * (\frac{\partial (\pi_1 x)}{\partial x}|_{(a,b)} * t) \oplus \frac{\partial (sqr\ y)}{\partial y}|_{\pi_2(a,b)} * (\frac{\partial (\pi_2 x)}{\partial x}|_{(a,b)} * t) \\
&\quad = 2 * a * ((1, 0) * t) \oplus 2 * b * ((0, 1) * t)
\end{aligned}$$

Now, because the theorem applies for any t of pair type, we use $(1, 0)$ and $(0, 1)$ to substitute for t respectively, and we will get $\frac{\partial (magSqr\ x)}{\partial x}|_{(a,b)} = (2 * a, 2 * b)$, which means its derivative to a is $2 * a$ and its derivative to b is $2 * b$.

5 Taylor's Theorem

In this section, we discuss Taylor's Theorem, which is useful to give an approximation of a k-order differentiable function around a given point by a polynomial of degree k. In programming, it is important and has many applications in approximation and incremental computation.

First of all, we introduce some high-order notations.

$$\begin{array}{lcllcl} \frac{\partial^0 t_1}{\partial x^0}|_{t_2} & = & t_1 & \frac{\partial^n t_1}{\partial x^n}|_{t_2} & = & \frac{\partial \frac{\partial^{n-1} t_1}{\partial x^{n-1}}|_x}{\partial x}|_{t_2} \\ t * t_1^0 & = & t & t * t_1^n & = & (t * t_1) * t_1^{n-1} \\ f^0 & = & f & f^n & = & (f')^{n-1} \\ (\lambda x : T.\, t)' & = & \lambda x : T.\, \frac{\partial t}{\partial x}|_x & & & \end{array}$$

Now our Taylor's Theorem can be expressed as follows.

▶ **Theorem 15** (Taylor's Theorem). If both $f\ t$ and $\sum_{k=0}^{\infty} \frac{1}{k!}(f^{(k)}\ t_0) * (t \ominus t_0)^k$ are weak-normalizable, then

$$f\ t = \sum_{k=0}^{\infty} \frac{1}{k!}(f^{(k)}\ t_0) * (t \ominus t_0)^k.$$

Proof. Like in the proof of Theorem 11, for simplicity, we assume that f, g, t and t_1 are closed. Furthermore, we assume that t and t_1 are in normal form. We prove it by induction on the type of $f : T \to T'$.

- Case T' is a base type. T must contain no $\to$ by our typing, so for simplicity, we suppose T to be $(B, B, ..., B)$. Using the same technique in Theorem 13, we assume f to be

$$f = \lambda x : T.\, (\lambda x_1 : B.\, \lambda x_2 : B., ...\lambda x_n : B.\, N)\ \pi_1(x)\ \pi_2(x)...\ \pi_n(x)$$

(denoted by $f = \lambda x : T.\, t_2$ later), t to be $(t_{11}, t_{12}, ..., t_{1n})$, and t_0 to be $(t_{21}, t_{22}, ..., t_{2n})$, where each t_{ij} is a normal form of base type. Then we have

$$\begin{aligned} &(f^{(n)}\ t_0) * (t \ominus t_0)^n \\ &\quad = \frac{\partial^n t_2}{\partial x^n}|_{t_0} * (t \ominus t_0)^n \\ &\quad = (\frac{\partial \frac{\partial^{n-1} t_2}{\partial x^{n-1}}|_{(x_1, t_{22}, ..., t_{2n})}}{\partial x_1}|_{t_{21}}, ..., \frac{\partial \frac{\partial^{n-1} t_2}{\partial x^{n-1}}|_{(t_{21}, t_{22}, ..., x_n)}}{\partial x_n}|_{t_{2n}}) * (t \ominus t_0)^n \\ &\quad = (\frac{\partial \frac{\partial^{n-1} t_2}{\partial x^{n-1}}|_{(x_1, t_{22}, ..., t_{2n})}}{\partial x_1}|_{t_{21}} * (t_{11} \ominus t_{21}) \oplus ... \oplus \frac{\partial \frac{\partial^{n-1} t_2}{\partial x^{n-1}}|_{(t_{21}, t_{22}, ..., x_n)}}{\partial x_n}|_{t_{2n}} \\ &\qquad\qquad * (t_{1n} \ominus t_{2n})) * (t \ominus t_0)^{n-1} \\ &\quad = ((\frac{\partial (\frac{\partial \frac{\partial^{n-2} t_2}{\partial x^{n-2}}|_{(x_1, t_{22}, ..., t_{2n})}}{\partial x_1}|_{x_1}, ..., \frac{\partial \frac{\partial^{n-2} t_2}{\partial x^{n-2}}|_{(x_1, t_{22}, ..., x_n)}}{\partial x_n}|_{t_{2n}})}{\partial x_1}|_{t_{21}}) * (t_{11} \ominus t_{21}) \oplus ... \oplus \\ &\qquad\qquad (\frac{\partial (\frac{\partial \frac{\partial^{n-2} t_2}{\partial x^{n-2}}|_{(x_1, t_{22}, ..., x_n)}}{\partial x_1}|_{t_{21}}, ..., \frac{\partial \frac{\partial^{n-2} t_2}{\partial x^{n-2}}|_{(t_{21}, t_{22}, ..., x_n)}}{\partial x_n}|_{x_n})}{\partial x_n}|_{t_{2n}}) \\ &\qquad\qquad * (t_{1n} \ominus t_{2n})) * (t \ominus t_0)^{n-1} \\ &\quad = ((\frac{\partial \frac{\partial \frac{\partial^{n-2} t_2}{\partial x^{n-2}}|_{(x_1, t_{22}, ..., t_{2n})}}{\partial x_1}|_{x_1}}{\partial x_1}|_{t_{21}}) * (t_{11} \ominus t_{21})^2 \oplus ... \oplus \\ &\qquad\qquad ((\frac{\partial \frac{\partial \frac{\partial^{n-2} t_2}{\partial x^{n-2}}|_{(x_1, t_{22}, ..., x_n)}}{\partial x_1}|_{t_{21}}}{\partial x_n}|_{t_{2n}}) * (t_{1n} \ominus t_{2n})) * (t_{11} \ominus t_{21}), \end{aligned}$$

$$
\begin{aligned}
&((\frac{\partial \frac{\partial^{n-2} t_2}{\partial x^{n-2}}|_{(x_1,x_2,\ldots,t_{2n})}}{\partial x_2}|_{t_{22}}}{\partial x_1}|_{t_{21}}) * (t_{11} \ominus t_{21})) * (t_{12} \ominus t_{22}) \oplus ... \oplus \\
&\qquad ((\frac{\partial \frac{\partial^{n-2} t_2}{\partial x^{n-2}}|_{(t_{11},x_2,\ldots,x_n)}}{\partial x_2}|_{t_{22}}}{\partial x_n}|_{t_{2n}}) * (t_{1n} \ominus t_{2n})) * (t_{12} \ominus t_{22}), \\
&... \\
&((\frac{\partial \frac{\partial^{n-2} t_2}{\partial x^{n-2}}|_{(x_1,t_{22},\ldots,x_n)}}{\partial x_n}|_{t_{2n}}}{\partial x_1}|_{t_{21}}) * (t_{11} \ominus t_{21})) * (t_{1n} \ominus t_{2n}) \oplus ... \oplus \\
&\qquad (\frac{\partial \frac{\partial^{n-2} t_2}{\partial x^{n-2}}|_{(t_{11},t_{22},\ldots,x_n)}}{\partial x_n}|_{x_n}}{\partial x_n}|_{t_{2n}}) * (t_{1n} \ominus t_{2n})^2) * (t \ominus t_0)^{n-2} \\
&= ...
\end{aligned}
$$

As seen in the above, every time we decompose a $\frac{\partial}{\partial x_i}|_{(...)}$, apply Rule EAppDer1, and then make reduction with Rule EAppMul3 to lower down the exponent of $(t \ominus t_0)^n$. Finally, we will decompose the last derivative and get the term t_2 in the form of $t_2[t'_{21}/x_1, t'_{22}/x_2, ..., t'_{2n}/x_n]$ where $\forall j \in [1, n], t'_{2j}$ is either t_{2j} or x_j.
Note that on base type we assume that we have Taylor's Theorem:

$$f(x_0 + h) = f(x_0) + \sum_{k=1}^{\infty} \frac{1}{k!} (\sum_{i=1}^{n} h_i \frac{\partial}{\partial x_i})^k f(x_0)$$

where x_0 and h is an n-dimensional vector, and x_j, h_j is its projection to its j-th dimension.
So we have $(f^{(k)}\ t_0) * (t \ominus t_0)^k$ corresponds to the k-th addend $\frac{1}{k!}(\sum_{i=1}^{n} h_i \frac{\partial}{\partial x_i})^k f(x_0)$.

- Case: T' is function type $A \to B$. Similar to the proof in Theorem 13, for all u of type A, we define $f^* = \lambda x : T.\, f\ x\ u$, and by using the inductive result on type B, we can prove the case simiarly as that in Theorem 13.
- Case: T' is a tuple type $(T_1, T_2, T_3, ...)$. Just define $f^* = \lambda x : T.\, \pi_j(f\ x)$ to use inductive result. The rest is simple.
- Case: T' is a tuple type $T_1 + T_2$. This case is impossible because the righthand is not well-typed.

Thus we have proven the theorem. ◀

Application: Polynomial Approximation

Taylor's Theorem has many applications. Here we give an example of using Taylor's Theorem for approximation. Suppose there is a point $(1, 0)$ in the polar coordinate system, and we want to know where the point will be if we slightly change the radius r and the angle θ. Since it is extremely costive to compute functions such as sin() and cos(), Taylor's Theorem enables us to make a fast polynomial approximation.

▶ **Example 16.** Let function *polar2catesian* be defined by

$$
\begin{array}{lcl}
\mathit{polar2cartesian} & :: & (\mathbb{R}, \mathbb{R}) \to (\mathbb{R}, \mathbb{R}) \\
\mathit{polar2cartesian}(r, \theta) & = & (r * \cos(\theta), r * \sin(\theta))
\end{array}
$$

We show how to expand $\mathit{polar2cartesian}(r, \theta)$ at $(1, 0)$ up to 2nd-order derivative. Since

$$\begin{aligned}\frac{\partial(\mathit{polar2cartesian}(x))}{\partial x}|_{(1,0)} &= \frac{\partial(\pi_1 x * \mathit{cos}(\pi_2 x), \pi_1 x * \mathit{sin}(\pi_2 x)}{\partial x}|_{(1,0)} \\ &= (\frac{\partial(x_1 * \cos(0), x_1 * \sin(0))}{\partial x_1}|_1, \frac{\partial(1 * \cos(x_2), 1 * \sin(x_2))}{\partial x_2}|_0) \\ &= ((1, 0), (0, 1))\end{aligned}$$

we have

$$\frac{\partial(\mathit{polar2cartesian}(x))}{\partial x}|_{(1,0)} * (\Delta r, \Delta\theta) = (\Delta r, \Delta\theta).$$

Again, we have

$$\begin{aligned}\frac{1}{2}\frac{\partial^2(\mathit{polar2cartesian}(x))}{\partial x^2}|_{(1,0)} * (\Delta r, \Delta\theta)^2 &= (((0, 0), (0, 1)), ((0, 1), (-1, 0))) * (\Delta r, \Delta\theta)^2 \\ &= (-\frac{1}{2}\Delta\theta^2, \Delta r * \Delta\theta).\end{aligned}$$

Combining the above, we can use $(1 \oplus \Delta r \ominus \frac{1}{2}\Delta\theta^2, \Delta\theta \oplus \Delta r * \Delta\theta)$ to make an approximation to $\mathit{polar2cartesian}(1 + \Delta r, \Delta\theta)$.

6 Related Work

Differential Calculus and The Change Theory. The differential lambda-calculus [9, 8] has been studied for computing derivatives of arbitrary higher-order programs. In the differential lambda-calculus, derivatives are guaranteed to be linear in its argument, where the incremental lambda-calculus does not have this restriction. Instead, it requires that the function should be differentiable. The big difference between our calculus and differential lambda calculus is that we perform computation on terms instead of analysis on terms.

The idea of performing incremental computation using derivatives has been studied by Cai et al. [7], who give an account using change structures. They use this to provide a framework for incrementally evaluating lambda calculus programs. It is shown that the work can be enriched with recursion and fix-point computation [4]. The main difference between our work and change theory is that we describe changes as mathematical derivatives while the change theory describe changes as (discrete) deltas.

Incremental/Self-Adaptive Computation. Paige and Koenig [19] present derivatives for a first-order language with a fixed set of primitives for incremental computation. Blakeley et al. [16] apply these ideas to a class of relational queries. Koch [14] guarantees asymptotic speedups with a compositional query transformation and delivers huge speedups in realistic benchmarks, though still for a first-order database language. We have proved Taylor's theorem in our framework, which provides us with another way to perform finite difference on the computation.

Self-adjusting computation [2] or adaptive function programming [3] provides a dynamic approach to incrementalization. In this approach, programs execute on the original input in an enhanced runtime environment that tracks the dependencies between values in a dynamic dependence graph; intermediate results are memoized. Later, changes to the input propagate through dependency graphs from changed inputs to results, updating both intermediate and final results; this processing is often more efficient than recomputation. Mathematically, self-adjusting computations corresponds to differential equations (The derivative of a function can be represented by the computational result of function), which may be a future work of our calculus.

Automatic Differentiation. Automatic differentiation [12] is a technique that allows for efficiently computing the derivative of arbitrary programs, and can be applied to probabilistic modeling [15] and machine learning [6]. This technique has been successfully applied to some higher-order languages [21, 10]. As pointed out in [4], while some approaches have been suggested [18, 13], a general theoretical framework for this technique is still a matter of open research. We prove the chain rule inside our framework, which lays a foundation for our calculus to perform automatic differentiation. And with more theorems in our calculus, we expect more profound applications in differential calculus.

7 Conclusion

In this paper, we propose an analytical differential calculus which is equipped with integration. This calculus, as far as we are aware, is the first one that has well-defined integration, which has not appeared in both differential lambda calculus and the change theory. Our calculus enjoys many nice properties such as soundness and strong normalizing, and has three important theorems, which have profound applications in computer science. Also, our calculus is highly extendable, it would be easy for users to add new features and prove more theorems inside our calculus.
