Preface

The papers in this volume were accepted for presentation at the 36th Computational Complexity Conference (CCC 2021), held between July 20–22, 2021, in a virtual online format. CCC 2021 was originally scheduled to be held in Toronto, Canada, but due to the public health measures related to Covid-19 still in place, the online format was used instead. The conference is organized by the Computational Complexity Foundation (CCF) in cooperation with the ACM Special Interest Group on Algorithms and Computation Theory (SIGACT) and the European Association for Theoretical Computer Science (EATCS).

The call for papers sought original research papers in all areas of computational complexity theory. Of the 116 submissions, the program committee selected 41 for presentation at the conference.

The program committee would like to thank everyone involved in the conference, including all those who submitted papers for consideration as well as the reviewers (listed separately) for their scientific contributions; the board of trustees of the Computational Complexity Foundation and especially its president Venkatesan Guruswami, and secretary Ashwin Nayak for their advice and assistance; Shubhangi Saraf for sharing her knowledge as prior PC chair for CCC; the Local Arrangements Committee chair Benjamin Rossman; Eric Allender for the invited talk; Meena Mahajan for her help with the submission server setup and editing of the proceedings; and Michael Wagner for coordinating the production of these proceedings.

Valentine Kabanets
Program Committee Chair, on behalf of the Program Committee
The program committee of the 36th Computational Complexity Conference is very pleased to present the **Best Student Paper Award** to Yaroslav Alekseev for his paper

**A Lower Bound for Polynomial Calculus with Extension Rule.**

Rate Amplification and Query-Efficient Distance Amplification for Linear LCC and LDC

Gil Cohen
Department of Computer Science, Tel Aviv University, Israel

Tal Yankovitz
Department of Computer Science, Tel Aviv University, Israel

Abstract

The main contribution of this work is a rate amplification procedure for LCC. Our procedure converts any $q$-query linear LCC, having rate $\rho$ and, say, constant distance to an asymptotically good LCC with $q^{\text{poly}(1/\rho)}$ queries.

Our second contribution is a distance amplification procedure for LDC that converts any linear LDC with distance $\delta$ and, say, constant rate to an asymptotically good LDC. The query complexity only suffers a multiplicative overhead that is roughly equal to the query complexity of a length $1/\delta$ asymptotically good LDC. This improves upon the poly(1/\delta) overhead obtained by the AEL distance amplification procedure [2, 1].

Our work establishes that the construction of asymptotically good LDC and LCC is reduced, with a minor overhead in query complexity, to the problem of constructing a vanishing rate linear LCC and a (rapidly) vanishing distance linear LDC, respectively.

Funding The research leading to these results has received funding from the ERC starting grant 949499, the Israel Science Foundation grant 1569/18 and from the Azrieli Faculty Fellowship.

1 Introduction

Coding theory addresses the problem of communicating over an imperfect channel. Classically, the setting is as follows. Alice wishes to communicate a message $m$ to Bob over a channel that can be tampered by an adversary. How should Alice encode $m$ so that if the amount of errors is not excessive, Bob would be able to recover $m$? To this end, error-correcting codes were first introduced [33]. Recall that a function $C : \Sigma^k \rightarrow \Sigma^n$ is an error-correcting code with distance $\delta$ if for every distinct $x, y \in \Sigma^k$, $\text{dist}(C(x), C(y)) \geq \delta$, where dist is the relative Hamming distance. The rate of the code $C$ is given by $\rho = k/n$. Using an error-correcting code, Alice can encode her message $m \in \Sigma^k$ and send the resulting codeword $C(m)$. Assuming the fraction of errors is less than $\delta/2$, Bob can decode $m$ from the received $z$ by finding the codeword closest to $z$. When there is more than one possible message length, we consider a code family, which is a family of functions in which each function is a code, and there is one code per message length $k$. A code family is asymptotically good if both the rate and distance of every code in the family are uniformly bounded below by constants $\rho > 0$ and $\delta > 0$, respectively.

1 Note that what we call here distance $\delta$ is in many cases referred to as relative distance.
1.1 Locally decodable codes and locally correctable codes

Consider the scenario in which Bob is not interested in the entire original message $m$, but rather in a specific symbol $m_i$ for some $i \in [k]$. A simple, though wasteful solution, is for Bob to decode the entire message $m$ and ignore all symbols but for $m_i$. However, it is desirable to compute $m_i$ by reading much fewer than $n$ entries of $z$. Locally decodable codes (LDC) are a class of error-correcting codes that have this very strong decoding capability. Another scenario of interest is the one in which Bob needs to know a specific symbol of the codeword $C(m)_j$ for some $j \in [n]$, while reading as few symbols as possible. Codes that allow this are called locally correctable codes (LCC). We turn to give the formal definition.

**Definition 1 (Locally decodable codes (LDC)).** A code $C: \Sigma^k \to \Sigma^n$ is $(q, \delta, \epsilon)$-locally decodable if there exists a randomized algorithm $D$, called a local decoder, that is given $i \in [k]$ as input and an oracle access to $z \in \Sigma^n$, and has the following guarantee. For every $i \in [k]$, $m \in \Sigma^k$ and $z \in \Sigma^n$ such that $\text{dist}(C(m), z) \leq \delta$ it holds that $\Pr[D^z(i) \neq m_i] \leq \epsilon$. Moreover, $D$ makes at most $q$ queries to $z$.

**Definition 2 (Locally correctable codes (LCC)).** A code $C \subseteq \Sigma^n$ is $(q, \delta, \epsilon)$-locally correctable if there exists a randomized algorithm $D$, called a local corrector, that is given $j \in [n]$ as input and an oracle access to $z \in \Sigma^n$, and has the following guarantee. For every $j \in [n]$, $c \in C$ and $z \in \Sigma^n$ such that $\text{dist}(c, z) \leq \delta$ it holds that $\Pr[D^z(j) \neq c_j] \leq \epsilon$. Moreover, $D$ makes at most $q$ queries to $z$.

We place $z$ in the upper script in our notation $D^z(i)$ to stress that the number of symbols read from $z$ by $D$ is of importance. The parameter $q$ is called the query complexity, and $\delta$ is the local error decoding radius, in the case LDC, and local error correction radius in the case of LCC. However, we also refer to $\delta$, somewhat inaccurately, as the local distance of the code. From here on, we do not make any explicit reference to the “global” distance of a code and so we refer to the local distance simply as the distance. Throughout the paper, we only consider non-adaptive LDC and LCC, defined next. Informally, these are code in which the local decoder (or corrector) samples the entries to be read before the querying step takes place. Our results only hold for non-adaptive LDCs and LCCs. For ease of discussion, throughout the introduction we ignore the error parameter $\epsilon$. More precisely, when stating our results, every LDC or LCC (both in the hypothesis as well as in the LDC or LCC guaranteed by the theorem) has constant error.

**A brief history of LDC and LCC**

Locally decodable codes were first explicitly defined by Katz and Trevisan [23]. However, codes with local guarantees have been used by complexity theorists even before (e.g., [8, 15, 16, 6]) and have been around, implicitly, in the coding theory community almost from the getting going [30]. LDC, LCC, and related notions such as locally testable codes (LTC), were intensively studied by theoretical computer scientists motivated by PCPs [3, 4, 5, 18], program checking [10, 29, 32], circuit lower bounds [12], derandomization [6, 35, 36], and private information retrieval [11] to name a few. LDC and LCC are very related notions. Clearly, an LCC with a systematic encoding\(^2\) is also an LDC and so, in particular, linear LCC induce LDC. Of note, it is not yet known in which scenarios LCC are strictly stronger objects compared to LDC.

\(^2\) An encoding from messages to codewords is called systematic if the symbols of each message are embedded in its mapped codeword.
An intensive research effort is devoted to the construction of local codes (see the excellent survey for LDC [39]). Roughly, the literature can be partitioned to two. The first research path (see e.g., [40, 25, 14, 13] and references therein) has the goal of obtaining LDC or LCC with a given, small, number of queries, and an effort is made to maximize the rate while maintaining constant distance. The second research path, which has received much attention in recent years [27, 20, 22, 26, 19], and is the focus of this paper, insists on asymptotically good codes and aims at minimizing the number of queries.

It is known [23, 38] that asymptotically good LDC require \( q = \Omega(\log n) \) queries. Whether this bound is tight is a fundamental, major open problem, regardless of explicitness. The Reed Muller code is perhaps the earliest non-trivial example of LDC and LCC. It can achieve query complexity \( n^\nu \) for any desired constant \( \nu > 0 \). However, the rate deteriorates rapidly as \( \nu \to 0 \). In fact, up until the introduction of multiplicity codes by Kopparty, Saraf and Yekhanin [27] no (non-trivial) LDC or LCC with rate higher than 1/2 were known. Guo, Kopparty and Saraf [20] introduced the notion of lifting of codes which gave a second high-rate LDC and LCC, also algebraic in nature. A combinatorial high-rate construction of an LCC was obtained by Hemenway, Ostrovsky and Wootters [22] (see also [28]).

Despite this exciting sequence of works which allowed for better rate and introduced various interesting techniques, the above constructions all have query complexity \( n^{\Theta(1)} \). The fact that three very different constructions were stuck at polynomial query complexity raised the question of whether \( n^{\Theta(1)} \)-query asymptotically good LDC or LCC exist. This question was resolved in a seminal work by Kopparty, Meir, Ron-Zewi and Saraf [26] who obtained LCC with query complexity \( q = 2^{\tilde{O}(\sqrt{\log n})} = n^{o(1)} \). To obtain their result, the authors first observed that by instantiating multiplicity codes [27] in a certain regime of parameters, one can get the stated query complexity \( q \) above albeit at the cost of having vanishing distance \( \delta = 1/(\log n)^{\Theta(1)} \). Then, in order to get codes with constant distance, the authors invoked a distance amplification procedure due to Alon et al. [2, 1]. Kopparty et al. [26] showed that the AEL distance amplification procedure, which was originally introduced in the context of linear-time erasure codes, allows one to convert, in a black-box manner, an LCC with distance \( \delta \) and query complexity \( q \) to an LCC with constant distance and query complexity \( q_{\text{new}} = q \cdot \text{poly}(1/\delta) \). This more than sufficed for [26] as, in their setting, \( q = (1/\delta)^{o(1)} \), and so the cost of the distance amplification is negligible. The LCC constructed in Kopparty et al. [26] are linear and thus yield LDC as well, and in fact in the same work the state-of-the-art LTC are constructed using the AEL distance amplification procedure.

### 1.2 Our contribution

Given the pivotal role of the AEL distance amplification procedure in the state-of-the-art constructions of LDC and LCC (as well as LTC) one is prompt to ask whether the \( \text{poly}(1/\delta) \) multiplicative cost in query complexity is inherent. If such is the case, when aiming at \( \text{poly}(\log n) \)-query complexity, a requirement for constant distance can only be relaxed to distance \( 1/\text{poly}(\log n) \) which, although proved extremely useful [26], might be restrictive for obtaining better codes.

More generally, the natural question that is raised is to what extent the construction of asymptotically good LDC/LCC can be reduced to the non-asymptotically good variants as they, in turn, may admit low query constructions. The main contribution of this work is the first rate amplification procedure for linear LCC as we elaborate on next (see Section 1.2.1). As our second contribution, we obtain a significantly improved distance amplification procedure (see Section 1.2.2).
1.2.1 Rate amplification

It is unclear to us if rate can be amplified deterministically in general, regardless of locality, in any meaningful formalization. Puncturing is a coding-theoretic technique that allows one to obtain better rates. However, it only seems to work when tailored to specific codes with certain structure or, otherwise, using a randomized encoding. Nonetheless, our main contribution is a devising a rate amplification procedure for linear non-adaptive LCC. To the best of our knowledge, all known constructions of LCC are of this kind. Among these are Reed-Muller codes (and therefore also the Hadamard code) as well as codes obtained by lifting [20], and Multiplicity codes.

▶ Theorem 3 (Main result). Assume one has a non-adaptive linear \((q, \delta = \Omega(1))-LCC\) with block-length \(n_0\) having rate \(\rho = \rho(n_0)\). Then, for every integers \(\ell, c \geq 1\) such that \(\ell^2 < c < \log n_0\), one can obtain a non-adaptive linear \((q_{new}, \delta_{new})\)-LCC with block length \(n \approx n_0\ell\), having rate \(\rho_{new}\), where

\[
q_{new} = (cq)^{\text{poly}(\ell)},
\]

\[
\delta_{new} = (cq)^{-\text{poly}(\ell)},
\]

\[
\rho_{new} = 1 - (1 - \rho)^\ell - O\left(\frac{\ell^2}{c}\right).
\]

Theorem 3, when invoked with \(\ell \approx 1/\rho\) and \(c \approx 1/\rho^2\), and combined with a distance amplification procedure, yields the following corollary.

▶ Corollary 4. Assume one has a family of constant distance non-adaptive linear LCC with rate \(\rho(n) \geq 1/\sqrt{\log n}\) and query complexity \(q(n)\). Then, for every constant \(\alpha > 0\) one can obtain asymptotically good LCC with rate \(1 - \alpha\) on block length \(n\) with query complexity \(q_{new} = (q(n)\log n)^{\text{poly}(1/\rho(n))}\).

1.2.2 Query-efficient distance amplification

The second result of this work is a significantly improved distance amplification procedure for LDC. Roughly speaking, we are able to reduce the \(\text{poly}(1/\delta)\) multiplicative factor in query complexity to the query complexity of an asymptotically good LDC on message length \(1/\delta\). More precisely,

▶ Theorem 5 (Query-efficient distance amplification; informal). Assume one has a block-length-n LDC with distance \(\delta\), constant rate, and query complexity \(q\). Assume further one has a family of asymptotically good LDC where on message length \(k\), the query complexity is \(q_k\). Then, one can obtain asymptotically good LDC with query complexity \(q_{new} = q \cdot q_{O(1/\delta)} \cdot O(\log(1/\delta) \log n)\).

\[
(1.1)
\]

Note that by using a standard error-correcting code, which has \(q_k = n = \Theta(k)\), Theorem 5 gives back the parameters of the AEL distance amplification procedure. However, one can do much better. Indeed, by using the state-of-the-art LDC [26] which has \(q_k = 2^{O(\sqrt{\log k})}\),

\[^3\] The result holds also for sub-constant \(\alpha\), and the assumption is made only for simplicity. See Theorem 46 for the formal, more general, version.

\[^4\] If the family of LDC in the hypothesis has sufficiently low error, the query complexity is even smaller \(q_{new} = q \cdot q_{O(1/\delta)}/O(\log(1/\delta))\).
one get \( q_{\text{new}} = q \cdot (1/\delta)^{o(1)} \log n \). More generally, Theorem 5 states that the lower the query complexity of the asymptotically good codes which one starts with is, the more query-efficient is the distance amplification. This “rich getting richer” type of result opens a path to recursive constructions as, indeed, several of our applications are based on. We stress that unlike the AEL distance amplification procedure, ours exploits the local decodability requirement and so it works for LDC but not for LCC. The only other technique in the literature that we are aware of that exploits the difference between decodability and correctability, and thus separates LDC from LCC in terms of techniques is matching vectors based constructions. We further remark that, for ease of discussion, Theorem 5 is stated without any reference to explicitness. Indeed, we currently lack satisfactory understanding of LDC in the more fundamental information-theoretic level. In any case, explicitness does not cost much in our reduction, and the only change in the theorem’s statement when insisting on explicit reductions is replacing Equation (1.1) by roughly \( q_{\text{new}} = q \cdot q(1/\delta)^{o(1)} \log n \) for any desired constant \( \alpha > 0 \).

We turn to draw several corollaries of Theorem 5, but first set the context. Given the Katz-Trevisan \( \Omega(\log n) \) lower bound on the query complexity of asymptotically good LDC, and reassured by [26] that \( n^{o(1)}-\)query LDC exist, the next natural goal is to try and construct, or even more fundamentally, prove the existence of LDC with poly-logarithmic (or perhaps a more modest quasi poly-logarithmic \( n^{\text{poly}(\log \log n)} \) ) number of queries. With this goal in mind, the AEL distance amplification procedure allows one to relax her effort and construct LDC with distance \( \delta = 1/\text{poly}(\log n) \) or slightly lower. Multiplicity codes are indeed a great example where such a relaxation of the distance requirement allows one to obtain much better query complexity. Using Theorem 5, we are able to obtain a reduction to LDC having exponentially lower distance \( \delta = 1/\text{poly}(n) \).

**Corollary 6 (Amplifying polynomially-small distance).** Let \( 0 < \alpha < 1 \) be an arbitrary constant. Assume there exists a family of LDC with distance \( \delta = n^{-\alpha} \), rate \( 1 - 1/(\log n)^2 \), and query complexity \( q(n) \) for block length \( n \). Then, for infinitely many \( n \)'s, there exists an asymptotically good LDC on block-length \( n \) with query complexity \( q_{\text{new}} = q(n)^{O(\log \log n)} \).

Corollary 6 implies that for constructing asymptotically good LDC with \( q = 2^{\text{poly}(\log \log n)} \) queries, it suffices to construct LDC with extremely poor distance \( \delta = 1/\text{poly}(n) \) for the same asymptotic query complexity. In fact, we can even amplify extremely small distance \( \delta = n^{-(1-\alpha(1))} \) assuming the rate is slightly larger. One instantiation is as follows.

**Corollary 7.** Let \( c \geq 1 \) be any constant. Assume there exists a family of LDC with distance \( \delta = n^{-(1-c/\log \log n)} \), rate \( \rho = 1 - \frac{1}{(\log n)^{1+c}} \), and query complexity \( q(n) \) for block-length \( n \). Then, for infinitely many \( n \)'s, there exists an asymptotically good LDC on block-length \( n \) having query complexity \( q_{\text{new}} = q(n)^{O((\log \log n)^{c+1})} \).

A third interesting application of Theorem 5 is when the distance to be amplified is larger than \( 1/\text{poly}(n) \), though still very small.

**Corollary 8.** Let \( \alpha < 1 \) be an arbitrary constant. Assume there exists a distance \( \delta = 2^{-(\log n)^\alpha} \) LDC having rate \( 1 - O(1/\log \log n) \), and query complexity \( q(n) \) for block-length \( n \). Then, for infinitely many \( n \)'s, there exists an asymptotically good LDC on block length \( n \) with query complexity \( q_{\text{new}} = q(n)^{O(\log \log \log n)} \).

We conclude this section by noting that the Katz-Trevisan bound [23] holds also for sub-constant distance. Quantitatively, the query complexity of constant rate codes with distance \( \delta = \Omega(\log(\delta n/\log n)) \). Thus, even for distance \( n^{-\alpha} \), the \( \Omega(\log n) \) lower bound holds.
2 Proof overview

In this section we give a brief and informal overview of the ideas that go into our proofs.

2.1 A characterization of non-adaptive linear LCC

To obtain our rate amplification procedure we lay a characterization of non-adaptive linear LCC. We remark that a very similar characterization was given by [23] for LDC, who defined the notion of smooth-codes.

Definition 9 (Smooth locally recoverable sets; simplified version). Let $\Sigma, P$ be arbitrary sets. We say that $C \subseteq \Sigma^P$ is $(q, \tau)$-smooth locally recoverable (SLR for short) if there exists a randomized algorithm $\text{Rec}$, called a recovering procedure, that when given as input $p \in P$ and an oracle access to $c \in C$, outputs $\text{Rec}^c(p) = c_p$ by making at most $q$ queries to $c$. Moreover, for every $c \in C$ and $p, r \in P$ (not necessarily distinct),

$$\Pr[\text{Rec}^c(p) \text{ queries } c_r] \leq \tau.$$  \hfill (2.1)

We will focus on SLR in which $\Sigma$ is a field and $C$ is a vector space over $\Sigma$. In such case we say that $C$ is linear. Of course, it is trivial to construct a $(1, 1)$-SLR. Indeed, simply query $c_p$ and output the result. The challenge is to recover $c_p$ without being able to “focus” on any particular entry. This is captured by Equation (2.1) where $\tau$—the smoothness parameter—bounds the probability a given entry is allowed to be queried. The formal definition of SLR (see Definition 21) also allows the recovering procedure to output a special “failure” symbol $\bot$ with small probability. For ease of discussion, we ignore this here. We have the following easy claim showing that SLR yield LCC. As a result, linear SLR induce LDC.

Claim 10. Let $C \subseteq \Sigma^P$ be a $(q, \tau)$-SLR. Then, $C$ is a $(q, \delta)$-LCC with $\delta = \Omega(1/(q\tau|P|))$.

For the straightforward proof, see Section 4 and, in particular, Claim 22. We also have the following (less obvious) claim, showing that, assuming linearity and non-adaptiveness, the other direction also holds, namely, LCC yield SLR.

Claim 11. Let $C \subseteq \Sigma^P$ be a non-adaptive linear $(q, \delta)$-LCC. Then, $C$ is a $(q, \tau)$-SLR with $\tau = q/(\delta|P|)$.

This claim and its proof correspond to Theorem 1 of [23] with the terminology of smooth-codes. For the more formal statement which also takes into account the error parameter and field size, see Claim 23. We remark here that for the proof of Claim 23, we construct a recovering procedure based on the local corrector of the given LCC. However, the key idea is to consider the distributions this local corrector induces while ignoring how it reconstructs the symbol after performing the queries.

Note that the lowest sensible value for $\tau$ is at about $q/|P|$. Indeed, this will be the case if each of the $q$ queries is marginally uniform over $P$, and assuming nothing about the correlations between the queries. For such $\tau$, if $C$ is linear then, By Claim 10, it yields an LCC with $\delta = \Omega(1/q^2)$. The distance can then be amplified to constant using our distance amplification procedure to yield query complexity $q^{2+o(1)}$ (or using AEL’s procedure to get poly$(q)$ queries).
2.1.1 Dual SLR and their induced SLR

By Claim 10 and Claim 11, every linear SLR is an LCC, and every linear non-adaptive LCC is a linear SLR. Our rate amplification procedure works for non-adaptive linear SLR, and thus for any non-adaptive linear LCC. In order to amplify the rate of such an SLR, we show that the dual of every non-adaptive linear SLR has a certain structure, which we use to amplify the rate.

Working with dual of codes in the context of LDC or LCC is a very natural approach, and has been explored previously (e.g., [24, 7]), but to the best of our knowledge, the definition of dual SLR as given below is new. We start by setting some notation. Let $P$ be a set, $\mathbb{F}$ a finite field, and $\mathbb{F}^P$ the set of all functions $\{f : P \to \mathbb{F}\}$. Note that $\mathbb{F}^P$ has a natural $\mathbb{F}$-vector space structure. We consider the natural inner product $\langle \cdot, \cdot \rangle : \mathbb{F}^P \times \mathbb{F}^P \to \mathbb{F}$ that is defined, for $f, g \in \mathbb{F}^P$, by $\langle f, g \rangle = \sum_{p \in P} f(p)g(p)$. For $f \in \mathbb{F}^P$ we denote $|f| = |P \setminus f^{-1}(0)|$.

For simplicity, we describe our rate amplification procedure only for $p \in P$. Consider the mapping $\Phi : \mathbb{F}^P \to \mathbb{F}^P$ defined, for $f \in \mathbb{F}^P$ and $q, \tau, \rho \in \mathbb{F}$, by $\Phi(f, f)(p) = f_f(p)$. For $p \in P$ define $S_p = \{f \in \mathbb{F}^P \mid |f(p)| = 0\}$.

The following definition captures the structural properties of the dual of an SLR, which we need for the rate amplification.

► Definition 12 (Dual SLR; simplified version). Let $P$ be a set, $\mathbb{F}$ a field. Let $D = \{D_p \mid p \in P\}$ be a collection of distributions, where for each $p \in P$, $\text{supp}(D_p) \subseteq \mathbb{F}_p$. Set $S = \bigcup_{p \in P} \text{supp}(D_p)$. The collection $D$ is said to be a $(q, \tau, \rho)$-dual SLR provided the following holds:

1. $|f| \leq q$ for all $f \in S$.
2. For every pair of distinct $p, r \in P$, it holds that
   $$\Pr_{f \sim D_p} [f(r) \neq 0] \leq \tau.$$
3. Last, $\dim \text{Span}(S) \leq (1 - \rho)|P|$.

We call $q$ the query complexity of the dual SLR, $\tau$ its smoothness and $\rho$ its rate. The linear subspace $S^\perp$ of $\mathbb{F}^P$ is called the induced SLR from $D$. As the name suggests, the induced SLR $S^\perp$ is indeed an SLR. More precisely, it is a $(q - 1, \tau)$ SLR with rate $\rho$ (see Lemma 26). It is for the class of dual-induced SLR that we are able to devise our rate amplification procedures. Let $p$ be a prime power. As an example, one can directly show that, say, the two-dimensional Reed-Muller code over $\mathbb{F}_p$ with total-degree $p - 2$ is an induced SLR from a $(q = p - 1, \tau = \frac{1}{p + 1}, \rho = \frac{1}{2} - o(1))$-dual SLR. As mentioned, any linear non-adaptive LCC is a linear SLR, and thus induces a dual SLR.

2.2 Rate amplification for dual-induced SLR

For simplicity, we describe our rate amplification procedure only for $\ell = 2$, where $\ell$ is as in the notation of Theorem 3. We briefly explain how to handle larger $\ell$’s in Section 2.2.3. Assume $D$ is a $(q, \tau, \rho)$-dual SLR on $\mathbb{F}^P$ where the rate $\rho$ is the parameter we wish to amplify. Consider the mapping $\Phi : (\mathbb{F}^P)^2 \to (\mathbb{F}^P)^2$ that maps a pair of functions $f_1, f_2 \in \mathbb{F}^P$ to the function $\Phi(f_1, f_2) : P^2 \to \mathbb{F}$ given by $\Phi(f_1, f_2)(p_1, p_2) = f_1(p_1)f_2(p_2)$. Note that this is simply the tensor product.

We now show how to convert our poor-rate dual SLR $D$ to a new dual-SLR with a better rate. Formally, consider the $(q_2, \tau_2, \rho_2)$-dual SLR $D^2 = \{D_p^2 \mid p \in P^2\}$, where for every $p = (p_1, p_2) \in P^2$, the distribution $D_p^2$ is defined as follows. To sample from $D_p^2$, sample $f_1 \sim D_{p_1}$, $f_2 \sim D_{p_2}$ independently, and return $\Phi(f_1, f_2)$. That $q_2 \leq q^2$ is straightforward, and that the new rate $\rho_2 \geq 1 - (1 - \rho)^2$ can be shown using the bilinearity of $\Phi$ (see Claim 30). As for the smoothness, we prove (see Lemma 32) that for every $p, r \in P^2$,
\[
\Pr[\Phi(f_1, f_2)(r) \neq 0] \leq \tau^{\Delta(p, r)}, \tag{2.2}
\]
where \(\Delta(p, r)\) is the non-relative Hamming distance between \(p\) and \(r\). In particular, for \(r \neq p\), we get the bound \(\tau_2 \leq \tau\).

Note that as the world is now squared, a bound on the smoothness of merely \(\tau\) is poor. However, by Equation (2.2), for most points \(r \in P^2\) we in fact have a better bound of \(\tau^2\). It is only those points of distance one from \(p\) that cause the smoothness from “squaring” and, as a result, deteriorate the distance of the induced LCC (recall Claim 10). A natural approach would be to “zero out” the problematic points. To make “zero out” formal, for a set \(S \subseteq P^2\), let \(\nu_S : P^2 \to \mathbb{F}\) be such that \(\nu_S(r) = 0\) if \(r \in S\) and \(\nu_S(r) = 1\) otherwise. Now, instead of \(\Phi(f_1, f_2)\) consider the function \(\hat{\Phi}(f_1, f_2) = \Phi(f_1, f_2) \cdot \nu_L\) where

\[
L = \{r \in P^2 \mid \Delta(p, r) = 1 \text{ and } \Phi(f_1, f_2)(r) \neq 0\}.
\]

By construction, Equation (2.2) implies that the smoothness of dual SLR defined using \(\hat{\Phi}\) is bounded by \(\tau^2\). Unfortunately, however, we can no longer guarantee anything about the rate \(\rho_2\) which, recall, is the parameter we set out to improve.

Our key idea is to construct carefully chosen functions in addition to those from \(S^2 = \bigcup_p \text{supp}(D^2_p)\) which allows us to zero out the problematic points while deteriorating the rate only slightly. To describe our solution, let \(R\) be a partition of \(P^2\), where each part has size \(c + 1\) for some parameter \(c\) to be chosen later on. We denote the part, or class, in \(R\) containing an element \(p \in P^2\) by \([p]\) and write \(p = [p] \setminus \{p\}\) for the open class of \(p\). For each \(p \in P^2\) define the function \(f_p : P^2 \to \mathbb{F}\) by \(f_p(r) = 1\) if \(r \in [p]\) and \(f_p(r) = 0\) otherwise. We adjoin all \(\frac{|P^2|}{c+1}\) functions \(L_R = \{f_p \mid p \in P^2\}\) to \(S^2\) by considering \(L_R^2 = \text{Span}(S^2) + \text{Span}(L_R)\). That is, our dual-induced SLR is redefined to be \((L_R^2)^\perp\) rather than \((S^2)^\perp\). This has some cost in rate, but a manageable one. Indeed, note that \(\dim(L_R^2) \leq (1 - \rho_2 + \frac{1}{c+1})|P^2|\). Thus, for sufficiently large \(c\), the rate loss incurred by adding the functions in \(L_R\) can be made small. The advantage we get by adjoining these functions is that we can now zero out any point \(r\) we wish by using the points in its open class (\(R\)). Indeed, for every \(f \in (L_R^2)^\perp\) and \(r \in P^2\) we have \(f(r) = -\sum_{w \in (r)} f(w)\). Note that, on top of the \(\frac{1}{c+1}\) loss in rate, we expect to pay a multiplicative \(c\) cost in query complexity as \(|\{r\}| = c\).

To be more precise, for \(p \in P^2\), we define a distribution \((D^2_R)_p\), which will avoid using the problematic points given by \(L\) above, as follows. To sample a function \(f \sim (D^2_R)_p\) proceed as follows:

1. Sample \(g \sim D^2_p\) and let \(L = \{r \in P^2 \mid \Delta(p, r) = 1 \text{ and } g(r) \neq 0\}\).
2. For every \(r \in L\) and \(w \in (r)\) sample \(h_{r, w} \sim D^2_w\).
3. Return \(f = g\nu_L + \sum_{r \in L} g(r) \sum_{w \in (r)} \frac{h_{r, w} \nu_{\{w\}}}{h_{r, w}(w)}\) \tag{2.3}\)

Observe that the first summand \(g\nu_L\) in Equation (2.3) is the attempt we started with. However, using the partition \(R\), instead of simply zeroing out \(L\) (which prevents us from arguing about the rate \(\rho_2\)), for every \(r \in L\) that was zeroed out, we go over each of the points \(w\) in its open class and add a carefully chosen linear combination of the “freshly” sampled functions \(\{h_{r, w} \sim D^2_w\}\) to \(g\nu_L\) so as to guarantee that \(f \in L_R^2\) (see Claim 41).

There is one technical issue the reader should be aware of. It might not be the case that \(f(p) \neq 0\), which is the basic requirement of dual SLR. Indeed, while \(g(p) \neq 0\) it might be the case \(h_{r, w}(p) \neq 0\) for one or more pairs \((r, w)\) as well. As a result, a cancellation may occur,
causing \( f(p) = 0 \). This is where we make use of the \( \perp \) symbol in the formal definition of dual SLR. Before outputting \( f \), we check that this cancellation has not occurred and otherwise return \( \perp \).

### 2.2.1 Axis evasive partitions

The above scheme can be implemented with any partition \( R \). However, not every partition will enable us to improve the smoothness. Informally, we would like the partition to have the property that the union of open classes taken over the set of points of distance one from a given point \( p \), is composed of points that are mostly of distance two from one another. To make this precise, we note that the set of points of distance one from a given point \( p \) is contained in the union of a horizontal and a vertical line. We refer to such lines, collectively, as axis-parallel lines. The following definition abstracts what we need from the partition so to argue about the smoothness.

**Definition 13.** Let \( P \) be a set. A partition \( R \) of \( P^2 \) is said to be \((c,s)\)-axis evasive if

1. For every \( p \in P^2 \), \(|p| = c\).
2. For every pair of axis-parallel lines \( \ell, \ell' \) (possibly equal),
   
   \[ |\ell \cap \bigcup_{\substack{p \in \ell' \\neq \ell}} (p)| \leq s. \]
3. For every \( p \in P^2 \) and every axis-parallel line \( \ell \), \(|p| \cap \ell| \leq 1\).

We show that by using a \((c,s)\)-axis evasive partition, the dual SLR defined above has smoothness \( \tau_2 = O(cs\tau^2) \) (see Claim 43). The reader should think of \( c, s \) as constants (or slightly sub-constants) and \( q \ll \tau^{-1} \), and so \( \tau_2 \approx \tau^2 \ll \tau \).

### 2.2.2 Constructing axis-evasive partitions

Assume \(|P| = m\) is an odd prime power, and let \( c \) be an even integer such that \( c + 1 \mid m + 1 \).

Under these assumptions, we are able to give an explicit algebraic construction of \((c,s)\)-axis evasive partitions of \( P^2 \) where \( s = O(c^2) \) (see Section 5.2). Intuitively, as we want to construct a partition that “breaks” axis-parallel-ness, rotation would be a natural approach. Indeed, for our construction, we identify \( P \) with the finite field \( \mathbb{F}_m \) and \( P^2 \) with \( \mathbb{F}_m^2 \). For every choice of \( \alpha \in \mathbb{F}_m^2 \setminus \mathbb{F}_m \), one can identify \( \mathbb{F}_m^2 \) with \( \mathbb{F}_m + \alpha \mathbb{F}_m \). So, informally, \( \mathbb{F}_m \) and \( \alpha \mathbb{F}_m \) are the horizontal and vertical axes, respectively. To formalize the intuition of rotation, we take an element \( \beta \) of order \( c + 1 \) in the multiplicative group of \( \mathbb{F}_m^2 \). Being a cyclic group, and since \( c + 1 \mid m + 1 \mid m^2 - 1 \), such an element exists. Multiplication by \( \beta \) can, informally, be thought of as a rotation by a \( \frac{1}{c+1} \) angle. We take the partition of \( \mathbb{F}_m^2 \setminus \{0\} \) according to the cosets of \( \langle \beta \rangle \) - the subgroup generated by \( \beta \) (and do not worry much about the origin). We show that, with this construction, properties (1) and (2) of Definition 13 are satisfied. Property (3), however, does not and so we need to make a certain modification of the construction to resolve this. We do not delve into the required alternation of the construction here.

### 2.2.3 Rate amplification for dimension higher than two

Our basic rate amplification procedure can be easily generalized to any \( \ell > 2 \). On the other hand, our distance-efficient rate amplification procedure is designed for \( \ell = 2 \). To go from \( \ell = 2 \) to higher powers, we more or less do the obvious thing, namely, apply the dual SLR construction iteratively, where in each iteration we square the size of the previously obtained set. The only technical issue is that the divisibility by \( c + 1 \) requirement is not maintained...
throughout the process. Indeed, 2 is the only nontrivial common factor of \(m+1\) and \(m^2+1\). To overcome this, we truncate the resulted set, slightly reducing its size from \(m^2\) to a prime \(m'\) that is divisible by \(c+1\). The truncation deteriorates the rate and so we would like \(m' \approx m^2\). Such prime \(m'\) is guaranteed to exist by the Siegel–Walfisz Theorem [34, 37] that refines Dirichlet’s theorem on primes in arithmetic progressions.

### 2.3 Query-efficient distance amplification

The AEL distance amplification procedure was originally based on expander graphs [2, 1]. Kopparty et al. [26] used samplers instead - a point of view that we find fruitful for our needs. Informally, an \((\varepsilon, \delta)\)-sampler is a bipartite graph on vertex set \(L \cup R\) with the following property. For every \(T \subseteq R\), having density \(\mu(T)\), all but \(\delta\)-fraction of the left vertices have \(\mu(T) \pm \varepsilon\) fraction of their neighbours in \(T\) (see Definition 14). For simplicity, we assume regularity with left-degree \(d\) and right degree \(D\).

Given a code with poor distance \(\delta\), AEL amplifies the distance to constant using an \((\varepsilon, \delta)\)-sampler where, for the reduction, \(\varepsilon\) is taken to be constant. The AEL procedure has a \(Dd\) multiplicative cost in query complexity. Prior works used either expander graphs or “balanced” samplers, namely, samplers with \(|L| = |R|\) and \(D = d\). With this choice, the lowest possible degree is \(d = \Theta(1/(\varepsilon^2\delta))\), which in turn yields a \(\Theta((1/\delta)^2)\) multiplicative cost in query complexity.

Our improved distance amplification procedure is based on two simple ideas. Our variant has a lower cost in query complexity: Instead of a \(Dd\) factor, our variant has roughly \(q_d q_d\) multiplicative cost where, recall, \(q_k\) is the query complexity of an asymptotically good LDC on message length \(k\). Our variant also makes use of samplers, and when instantiated with a balanced sampler, the cost is roughly \(q_d^2 = q_1^2/\delta\). Our second idea allows us to essentially get rid of the square (which is crucial for obtaining our corollaries). It is known that by working with unbalanced samplers, in which \(|L| \gg |R|\), one can obtain \((\varepsilon, \delta)\)-samplers with a much lower left-degree \(d = O(\log(1/\delta)/\varepsilon^2)\). We note that, for the original AEL procedure, working with unbalanced samplers cannot yield a significant improvement. Indeed, to achieve this saving in left-degree, the ratio \(|L|/|R| = \Omega(1/(\delta \log(1/\delta)))\) which in turn implies \(D = |L|d/|R| = \Omega(1/\delta)\). This then only gives a quadratic improvement over AEL. When instantiated with our variant, unbalanced samplers yield query complexity roughly \(q_1/\delta q_\Theta(1/\delta)\).

### 3 Preliminaries

#### Notations and conventions

Unless otherwise stated, all logarithms are taken to the base 2. We denote by \(\mathbb{N}\) the set of natural numbers (of course, including 0). For an integer \(c \geq 1\), we let \([c] = \{1, 2, \ldots, c\}\). For ease of readability, we avoid the use of floor and ceiling. This does not affect the stated results. For two strings \(x, y\) of equal length over a common alphabet, we denote by \(\text{dist}(x, y)\) their relative hamming distance, namely, the fraction of indices on which they disagree. Let \(A \neq \emptyset\) be an ambient (finite) set. For \(B \subseteq A\), we denote by \(\mu(B)\) the density of \(B\) in \(A\), namely, \(\mu(B) = |B|/|A|\).

Let \(G = (V, E)\) be an undirected graph with maximal degree \(D\). Assume that the neighbours of every node \(v \in V\) are labeled by distinct numbers from \(1, \ldots, \deg(v)\). We define the neighbourhood function \(\Gamma_G : V \times [D] \to (V \times [D]) \cup \{\bot\}\) as follows. For \(v \in V\) and \(i \in [\deg(v)]\) we let \(\Gamma_G(v, i) = (u, j)\) where \(u\) is the \(i\)’th neighbour of \(v\) and \(v\) is the \(j\)’th
neighbour of \( u \). For \( i \in [D \setminus \deg(v)] \) the function is defined to be \( \perp \) (though this is only for the sake of formality. We will never use such input \( i \)). If \( G \) is clear from context we sometimes omit it from the subscript. When interested only on the node \( u \) as above and not on \( j \), we make a slight abuse of notation and write \( \Gamma(v, i) \) when referring to \( u \). Last, we write \( \Gamma(v) \) for the set of all neighbours of \( v \).

### 3.1 Samplers

Our distance amplification procedure makes use of samplers. These are bipartite graphs with a certain pseudo-random property. Let \( G = (L, R, E) \) be a bipartite graph. We say \( G \) is left-regular if all nodes in \( L \) have the same degree.

**Definition 14** ([9]). Let \( 0 < \varepsilon, \delta < 1 \). A bipartite graph \( G = (L, R, E) \) is an \((\varepsilon, \delta)\)-sampler if for every subset \( T \subseteq R \), for all but \( \delta \)-fraction of vertices \( v \in L \) it holds that

\[
\frac{|\Gamma(v) \cap T|}{|\Gamma(v)|} - \mu(T) \leq \varepsilon.
\]

We will be working with “unbalanced” samplers. These are samplers with \(|L| \gg |R|\).

The state-of-the-art constructions of these samplers rely on their connection to randomness seeded extractors. We refer the interested reader to the excellent survey by Goldreich [17] for more information. When working with samplers, it is rather typical that the bipartite graph is left-regular, that is, the degree of all vertices in \( L \) is the same. A small additional technical property we need is that the degree of every vertex in \( R \) is close to the average right-degree. We make use of the following theorem which gives (non-explicit) samplers with near-optimal parameters having the above properties with respect to the degrees. We give a proof sketch for completeness.

**Theorem 15.** There exists a universal constant \( c_{\text{amp}} \geq 1 \) such that the following holds. For all integers \( \ell, r \) and all \( \varepsilon > 0 \), \( 1/2 > \delta > 0 \) for which \( \ell \geq \frac{1}{\delta \log(1/\varepsilon)} \), there exists a left-regular \((\varepsilon, \delta)\)-sampler \( G = ([\ell], [r], E) \) with left-degree \( d = c_{\text{amp}} \cdot \log(1/\delta)/\varepsilon^2 \). Moreover, provided that \( \log r < 1/(\delta \varepsilon^2) \), every right vertex has degree in \([D/2, 2D]\) where \( D = \ell d/r \) is the average right degree.

For the proof we need the following well-known lemma.

**Lemma 16.** For every integers \( 1 \leq k \leq n \) with \( \frac{k}{n} = \delta \leq \frac{1}{2} \) it holds that

\[
\sum_{i=0}^{k} \binom{n}{i} \leq 2^{H(\delta)n},
\]

where \( H(x) = -x \log(x) - (1-x) \log(1-x) \) is the binary entropy function.

**Proof sketch for Theorem 15.** The proof is via the probabilistic method, where for every left vertex we choose \( d \) neighbours independently and uniformly at random, and independently across all left vertices (note that in the above we allow for parallel edges, but if that troubles the reader, that can be avoided as well in the regime of interest \( d \ll r \) by arguing that the probability of a right neighbor to be selected more than once is small. In any case, our distance amplification procedure works just as well with parallel edges). Fix \( T \subseteq [r] \). For \( v \in [\ell] \) let \( F_v \) be the indicator random variables that is 1 if and only if \(|\Gamma(v) \cap T| = \mu(T) \). By the Chernoff bound, \( \Pr[F_v] \leq e^{-\Omega(\varepsilon^2 d \delta \ell)} \). Fix \( S \subseteq [\ell] \) with \(|S| = \frac{\delta \ell}{\ell} \). The probability that for all vertices \( v \in S \) it holds that \( F_v = 1 \) is bounded above by \( e^{-\Omega(\varepsilon \delta^2 d \delta \ell)} \). By taking the union bound over all \( S \) and \( T \), we get that except with probability

\[
2^{\left( \frac{d}{\delta \ell} \right)} e^{-\Omega(\varepsilon^2 d \delta \ell)} \leq 2^{\ell H(\delta)\ell - \varepsilon^2 \delta^2 d \ell},
\]

(3.1)
the sampled graph is an $(\varepsilon, \delta)$-sampler. Note that the last inequality follows by Lemma 16, where $c > 0$ is some constant. By taking $c_{\text{samp}} \geq 5/c$, one can verify (using that $H(x) \leq 2r \log(1/x)$ for all $x \leq 1/2$) that the right hand side in Equation (3.1) is bounded by $1/4$.

As for the moreover part, again, by the Chernoff bound, the probability that there exists a right vertex which has degree outside $[D/2, 2D]$ is bounded above by $re^{-\Omega(d/r)}$, and this is bounded by $1/4$ by our choice of parameters and by taking $c_{\text{samp}}$ large enough. 

We now turn to state the parameters of the explicit construction of samplers that we use.

\textbf{Theorem 17} ([31, 17]). \(^5\) For every constant $\Delta > 0$ there exists a constant $c = c(\Delta) \geq 1$ such that the following holds. For all $\varepsilon > 0$, $\delta > 0$ \(^6\), there exists an explicit left-regular $(\varepsilon, \delta)$-sampler $G = ([\ell], [r], E)$. The left-degree of $G$ is $d = ((1/\varepsilon) \log(1/\delta))^{c}$. Furthermore, the average right degree $D = \ell d/r$ of $G$ is in $[D', 2D']$ where

$$D'(\Delta, \varepsilon, \delta) = \frac{d}{2} \left(\frac{2}{\delta}\right)^{\Delta+1}. \quad (3.2)$$

\subsection{3.2 Codes}

We make use of “standard” error-correcting codes. In this section we gather some known results we use.

\textbf{Theorem 18} (The Gilbert-Varshamov bound). \(^7\) Let $\Sigma$ be a set of size $|\Sigma| = q$. For every $n \in \mathbb{N}$, and $0 \leq \delta \leq 1 - \frac{1}{q}$ there exists a code of block-length $n$ over $\Sigma$, with distance at least $\delta$ and rate $r \geq 1 - H_q(\delta)$. Furthermore, if $q$ is a prime power and $\Sigma = \mathbb{F}_q$, there exists a linear code over $\Sigma$ with rate $r \geq 1 - \frac{1}{q} - g(n)$, where $g(n) = O\left(\frac{1}{n}\right)$.

\textbf{Lemma 19}. There exists a constant $\beta_0 > 0$ such that the following holds. Let $n$ be an integer and $1 - \frac{1}{\log n} < \beta < \beta_0$. Let $\Sigma = \mathbb{F}_q$ for $q \geq 2$ a prime power. Then, there exists an explicit linear code of block-length $n$ over $\Sigma$ with rate $1 - \beta$ and relative distance $\beta^3$.

The existence of these codes follows from a special case of the Zyablov bound [43], but for completeness we describe a construction which attains the stated parameters. For the proof, we make use of the following easy claim whose proof is omitted.

\textbf{Claim 20}. For every $x \in (0, 1/2]$ and $q \geq 2$, $H_q(x) \leq x \log_q\left(\frac{q}{x}\right)$.

\textbf{Proof of Lemma 19}. The proof is obtained by taking the code concatenation of two codes, a Reed-Solomon code and a Gilbert-Varshamov code. Let $p$ be the least prime such that $p \geq n$. Recall that $p \leq 2n$. Set $C_{RS}$ to be the Reed-Solomon code over $\mathbb{F}_p$ of block length $n_{RS} = \frac{(1 - \beta^{1.1})n}{\log_q p}$ and message length $k_{RS} = (1 - \beta^{1.1})n_{RS}$. So, $C_{RS}$ has rate $1 - \beta^{1.1}$ and relative distance at least $\beta^{1.1}$. Now take $C_{GV}$ to be a linear code of the following parameters. The message length is $k_{GV} = \log_q p$, the block length is $\frac{1}{\beta^{1.1}}k_{GV}$ (and therefore the rate is $1 - \beta^{1.1}$), and the relative distance is at least $\beta^{1.4}$. We wish to invoke Theorem 18 so as to prove that such a code exists. To this end, we must verify that $1 - H_q(\beta^{1.4}) - g(n) \geq 1 - \beta^{1.1}$. Indeed, by Claim 20, we have that

\[^5\] The sampler in [31] has a mild requirement on $z$ which we state the theorem without, as it is explained in [17] how this requirement can be relaxed, by using a more recent extractor.

\[^6\] The sampler in [31] has a number of edges $z$ that is a power of two. We state the theorem for a general $z$ as one can take the subgraph of only part of the left vertices, and get a sampler in which $\delta$ is at most doubled.
\[ 1 - H_q(\beta^{1,4}) - g(n) \geq 1 - \beta^{1,4} \log_q \left( \frac{q^3}{\beta^{1,4}} \right) - g(n) \geq 1 - \beta^{1,1}, \]

where the last inequality holds for all sufficiently small \( \beta \geq 0 \), and since \( g(n) = O(\frac{1}{\log n}) \) and \( \beta \geq \frac{1}{\log n} \), by assumption.

Note that \( C_{GV} \) is not explicit as Theorem 18 only guarantees existence of a code with the stated parameters. However, as the block-length of \( C_{GV} \) is \( O(\log n) \), such a code can be found by an exhaustive search on generating matrices, in time \( 2^{O((\log n)^4)} \). To improve on that, we remark that the code \( C_{GV} \) can also be found by going only over a limited family of generating matrices (see [21]), and this can be done in time \( \text{poly}(n) \).

Consider the concatenated code \( C_{RS} \circ C_{GV} \). It has block length \( n_{RS} \cdot n_{GV} = n \), rate \((1 - \beta^{1,1})^2\) which is at least \( 1 - \beta \) for all small enough \( \beta > 0 \), and relative distance \( \beta^{1,2}\beta^{1,4} \geq \beta^3 \), completing the proof. \( \blacktriangleleft \)

## 4 Rate amplification for dual-induced SLR

In this section we introduce the notion of smooth locally recoverable sets (SLR) which under non-adaptive and linearity assumptions is shown to be equivalent to LCC. We consider a certain class of SLR, to which we call dual-induced SLR. These are SLR that are obtained by the dual of certain structured sets. The structure of these dual-SLR sets allows us to devise a rate amplification procedures for them. Informally, dual-SLR are sets of tuples (or linear spaces of vectors if the alphabet over which we are working is a field) in which every given entry of a tuple in the set can be recovered using only few queries and in a “smooth” manner, which is to say that the distribution of every query has high min-entropy.

\[ \text{Definition 21 (Smooth locally recoverable sets (SLR))}. \text{ Let } \Sigma, P \text{ be arbitrary non-empty sets. We say that } C \subseteq \Sigma^P \text{ is a } (q, \tau, \varepsilon)\text{-smooth locally recoverable (SLR for short) if there exists a randomized algorithm } \text{Rec}, \text{ called a recovering procedure, that is given as input } p \in P \text{ and an oracle access to } c \in C. \text{ The recovering procedure outputs either an element of } \Sigma \text{ or a symbol } \bot \text{ which is assumed not to be in } \Sigma. \text{ The algorithm } \text{Rec} \text{ has the following properties:}
\]

- For every \((c, p) \in C \times P\), \( \text{Rec}^c(p) \) makes at most \( q \) queries to \( c \).
- For every \( c \in C \) and \( p, r \in P \) it holds that \( \Pr[\text{Rec}^c(p) \text{ queries } c_r] \leq \tau. \)
- For every \((c, p) \in C \times P\), the random variable \( \text{Rec}^c(p) \in \{c_p, \bot\} \), and \( \Pr[\text{Rec}^c(p) = \bot] \leq \varepsilon \).

We assume that for every \( p \in P \) whether \( \text{Rec}^c(p) = \bot \) is independent of \( c \), and that it is never the case that \( \text{Rec}^c(p) \) queries \( c_p \). When \( \Sigma \) is a field and \( C \) is a linear subspace of \( \Sigma^P \), we say that \( C \) is linear. In this case, the rate of \( C \) is defined as \( \text{dim}(C) / |P| \). We will mostly consider non-adaptive SLR. These are SLR in which the joint distribution of queries is independent of \( c \).

We remark that the notion of SLR is very similar to the notion of smooth-codes of [23] for LDC. We now have the following easy claim showing that SLR yield LCC and, assuming linearity, LDC.

\[ \text{Claim 22}. \text{ Let } C \subseteq \Sigma^P \text{ be a } (q, \tau, \varepsilon)\text{-SLR. Then, for every } \varepsilon' > 0, C \text{ is a } (q, \delta, \varepsilon + \varepsilon')\text{-LCC with } \delta = \varepsilon' / (q\tau|P|). \text{ As a consequence, if } C \text{ is also linear then } C \text{ is a } (q, \delta, \varepsilon + \varepsilon')\text{-LDC.} \]
Proof. To show that $C$ is an LCC, we devise a local corrector for $C$. Given an oracle access to $c \in \Sigma^P$, and $p \in P$ as input, the local corrector computes $z = \text{Rec}^c(p)$. If $z = \bot$ then the local corrector returns some arbitrary element of $\Sigma$, and otherwise return $z$. To analyze this local corrector, let $c' \in \Sigma^P$ be such that $\text{dist}(c, c') \leq \delta |P|$. Denote $B = \{p \in P \mid c_p \neq c'_p\}$. Note that conditioned on $\text{Rec}^c(p) \neq \bot$, the local corrector returns $c_p$ successfully if all $q$ queries do not fall into $B$. The probability that any given query falls into $B$ is bounded above by $\tau |B|$ and so, by the union bound, the probability that some query falls into $B$ is bounded above by $\tau |B| q \leq c'$. This proves that $C$ is a $(q, \delta, \epsilon + c')$-LCC. Note that linear LCC are systematic and so every linear LCC induces an LDC.

In fact, for linear LCCs, the other direction also holds, meaning that such an LCC is an SLR, as we have in the following claim.

\begin{claim}
Let $C \subseteq \mathbb{F}^P$ be a linear non-adaptive $(q, \delta, \epsilon)$-LCC where $1 - \epsilon > 1/|\mathbb{F}|$. Then, $C$ is a $(q, \tau, c')$-SLR with $\tau = q/\delta |P|$ and $c' = 0$.
\end{claim}

Before we prove the claim, we need to state the following easy to verify fact.

\begin{fact}
Let $L \subseteq \mathbb{F}^P$ be a linear subspace, let $p \in P$, let $Q \subseteq P$ and let $x \in \mathbb{F}^{|Q|}$. Then, one of the following cases must hold.
1. There is at most one $\alpha \in \mathbb{F}$ for which there exists some $v \in L$ satisfying $v(Q) = x^7$ and $v(p) = \alpha$;
2. For every $\alpha \in \mathbb{F}$ there is an equal number of $v \in L$ for which $v(Q) = x$ and $v(p) = \alpha$.
In particular, either no function (even randomized) of $v(Q)$ can predict $v(p)$ with probability more than $1/|\mathbb{F}|$, when $v \in L$ is randomly chosen uniformly, or $v(Q)$ always determines $v(p)$.
\end{fact}

With that, we now prove Claim 23. To show that $C$ is an SLR, we devise a recovering procedure $\text{Rec}$ for it, based on the local corrector promised by it being an LCC. Let $D^0$ be such a local corrector. For every point $p \in P$, we construct a sequence of disjoint sets $Q^P_1, \ldots, Q^P_{m_p} \subseteq P$, where for every $i$, $c(Q^P_i)$ determines $c(p)$ while satisfying $|Q^P_i| \leq q$, and $m_p \geq \delta |P|/q$. On $p \in P$ and oracle access to $c \in C$, the procedure $\text{Rec}^c(p)$ acts by uniformly choosing $i \in [m_p]$, querying $c(Q^P_i)$, and using it to deduce and output $c(p)$. The correctness of the result of $\text{Rec}$ is immediate (since $\text{Rec}$ always succeeds, $c' = 0$), and indeed the number of queries is no more than $q$. Since the sets are disjoint, the probability that a point is queried is no more than $\tau = q/\delta |P|$. It only remains to show how the assumed sets can be constructed, to conclude that $C$ is a $(q, \tau, c')$-SLR, which we now turn to do.

For every $p \in P$, $Q^P_1, \ldots, Q^P_{m_p}$ are constructed as follows. Set $Q^P_0 = \emptyset$. For $i = 1, 2, \ldots$, set $S_i = Q^P_0 \cup \cdots \cup Q^P_{i-1}$. If $|S_i| > \delta |P|$, halt and set $m_p = i - 1$. Otherwise, it holds that for every $c \in C$, for every modification of the coordinates in $S_i$ to some erroneous values, the decoder $D$ correctly outputs $c(p)$ with probability at least $1 - \epsilon$. An equivalent description of this case is the following: for every $c \in C$ and $z : S_i \rightarrow \mathbb{F}$, define $c_z \in \mathbb{F}^P$ such that for $r \notin S_i$, $c_z(r) = c(r)$, and for $r \in S_i$, $c_z(r) = z(r)$; the decoder $D$ chooses a set of queries $Q \subseteq P$, $|Q| \leq q$, according to a distribution and applies a function $f_Q$ on $c_z(Q)$; with probability at least $1 - \epsilon$, $f_Q(c_z(Q)) = c(p)$. Since $Q$ is chosen in a manner independent of $c$ and $z$, one can

\begin{itemize}
\item For a set $A = \{a_1, \ldots, a_{|A|}\}$, $v(A)$ denotes the sequence $(v(a_1), \ldots, v(a_{|A|}))$.
\item This proof is inspired by the proof of [23] of their Theorem 1 and by a proof in [41] for a different claim.
\item We make the slight assumption that $D^0(p)$ never directly queries $c(p)$. If however it does, then similarly $C$ can be shown to be a $(q, \tau, c')$-SLR for $\tau = \frac{1}{(\delta |P|/q) - 1}$.
\end{itemize}
verify that this implies that there exists some fixed $Q$ for which when $c \in C$ and $z : F \to S_i$ are chosen randomly in a uniform manner, with probability at least $1 - \varepsilon$ (this time over the choice of $c$ and $z$), $f_Q(c_z(Q)) = c(p)$. Therefore, we can define another function $f_Q'$ that only gets $c(Q \setminus S_i)$, chooses $z$ at random, and outputs $f_Q(c_z(Q))$. If $c \in C$ is chosen uniformly at random, $f_Q'(Q \setminus S_i) = c(p)$ with probability at least $1 - \varepsilon > 1/|F|$. By Fact 24, this implies that $c(Q \setminus S_i)$ determines $c(p)$, for every $c \in C$. We therefore set $Q_i^p = Q \setminus S_i$, and proceed to next $i$. As this process only halts when $|S_i| > \delta|P|$, and for every $i$ $|S_i| \leq q(i - 1)$, we have that indeed $m_p \geq \delta|P|/q$. Further note that by the choice of each $Q_i^p$, the sets $Q_1^p, \ldots, Q_m^p$ are disjoint, as required.

### 4.1 Dual SLR and their induced SLR

Our construction of SLR sets will be via constructing and analyzing sets which we call dual SLR sets. The SLR will then be induced from these dual SLR. We start by setting some notation. Let $P$ be a non-empty finite set and $F$ a finite field. We make use of the standard notation $F^P$ to denote the set of all functions $\{f : P \to F\}$. Note that $F^P$ has a natural $F$-vector space structure where addition is point-wise, namely, for every $f, g \in F^P$ and $a, b \in F$ we have that $af + bg \in F^P$ is defined by $(af + bg)(p) = af(p) + bg(p)$ for all $p \in P$. We consider the natural inner product map $(\cdot, \cdot) : F^P \times F^P \to F$ that is defined, for $f, g \in F^P$, by $(f, g) = \sum_{p \in P} f(p)g(p)$. Given $f \in F^P$, we let $f^\perp = \{g \in F^P \mid (f, g) = 0\}$. Note that $f^\perp$ is a linear subspace of $F^P$. More generally, given a set $S \subseteq F^P$ we define the linear subspace $S^\perp = \bigcap_{f \in S} f^\perp$. For $f \in F^P$ we denote $|f| = |P \setminus f^{-1}(0)|$.

For the sake of readability, the field $F$ and the set $P$ will be omitted from the notation that we are about the introduce in this section. Both will be clear from context. For $p \in P$ define $F_p = \{f \in F^P \mid f(p) \neq 0\}$. Informally, a dual SLR is a collection of distributions over $F^P$, one for each point $p \in P$. The distribution $D_p$, that corresponds to $p$, outputs a function $g \in F^P$. We think of $g$ as “passing through” $p$. We also allow $D_p$ to output a special “failed symbol” $\perp$ with some small probability. A dual SLR has the guarantee that $g$ does not pass through many other points, namely, $|g|$ is bounded, and that the dimension of all functions that can be sampled, when considering all distributions $D_p$, $p \in P$, is also bounded. Perhaps most importantly is the requirement that for every other fixed $r \in P$, the sampled $g \sim D_p$ is likely to have the property that $g \notin F_r$. Formally,

**Definition 25 (Dual SLR).** Let $P$ be a set, $F$ a field. Let $\mathcal{D} = \{D_p \mid p \in P\}$ be a collection of distributions, where for each $p \in P$, $\text{supp}(D_p) \subseteq F_p \cup \{\perp\}$. Let $\mathcal{L}$ be a linear subspace of $F^P$ such that $\mathcal{L} \subseteq \mathcal{L} \cup \{\perp\}$. The pair $(\mathcal{D}, \mathcal{L})$ is said to be a $(\tau, \varepsilon, \rho)$-dual SLR on $F^P$ provided the following holds:

1. $|g| \leq q$ for all $g \in S \setminus \{\perp\}$.
2. For every pair of distinct $p, r \in P$ (not necessarily distinct), it holds that
   $$\Pr_{g \sim D_p} [g(r) \neq 0 \mid g \neq \perp] \leq \tau.$$
3. For every $p \in P$, $\Pr[D_p = \perp] \leq \varepsilon$.
4. $\dim(\mathcal{L}) \leq (1 - \rho)|P|$.

The linear subspace $\mathcal{L}^\perp$ of $F^P$ is called the induced SLR from the dual SLR $(\mathcal{D}, \mathcal{L})$. The parameter $\tau$ of a dual-SLR is referred to as its smoothness.

Let $(\mathcal{D}, \mathcal{L})$ be a dual SLR. We turn to show that, as the name suggests, the induced SLR $\mathcal{L}^\perp$ is indeed an SLR.
Lemma 26. Let \( P \) be a set, \( \mathbb{F} \) a field, and let \((D, \mathcal{L})\) be \((q, \tau, \varepsilon, \rho)\)-dual SLR on \( \mathbb{F}^P \). Then the induced SLR \( \mathcal{L}^\perp \) is a \((q − 1, \tau, \varepsilon)\)-SLR. Furthermore, \( \mathcal{L}^\perp \) is linear and has rate \( \rho \) or larger.

Proof. The moreover part readily follows since \( \mathcal{L}^\perp \) is a linear subspace of \( \mathbb{F}^P \) and since 
\[
\dim(\mathcal{L}^\perp) = |P| - \dim(\mathcal{L}) \geq \rho|P|.
\]

We describe a recovering procedure for \( \mathcal{L}^\perp \), namely, a randomized algorithm that is given an oracle access to \( f \in \mathcal{L}^\perp \) as well as a point \( p \in P \) as input. The recovering procedure proceeds as follows:

1. Sample \( g \sim D_p \). If \( g = \perp \) return \( \perp \); Otherwise,
2. Query \( f \) on all points \( Q = \{ r \in P \setminus \{p\} \mid g(r) \neq 0 \} \).
3. Return
\[
-\frac{1}{g(p)} \sum_{r \in Q} g(r)f(r).
\]

The query complexity of \( \text{Rec} \) is bounded by \( q - 1 \) as \( |Q| = |g| - 1 \leq q - 1 \). The probability that \( \perp \) is returned is at most \( \varepsilon \) by construction. We turn to prove that \( \text{Rec}^f(p) \in \{f(p), \perp\} \).

By construction, \( \text{Rec}^f(p) = \perp \) if and only if \( g = \perp \). Assume that \( g \neq \perp \), hence, \( g \in \text{supp}(D_p) \subseteq \mathcal{L} \). As \( f \in \mathcal{L}^\perp \) we have that \( 0 = \langle f, g \rangle \), and so 
\[
0 = \sum_{r \in P} g(r)f(r) = g(p)f(p) + \sum_{r \in Q} g(r)f(r).
\]
As \( g \in \text{supp}(D_p) \subseteq \mathcal{F}_p \) we have \( g(p) \neq 0 \), and so 
\[
f(p) = -\frac{1}{g(p)} \sum_{r \in Q} g(r)f(r) = \text{Rec}^f(p).
\]

To conclude the proof, we turn to analyze the smoothness of \( \text{Rec} \). First, note that, by construction, \( f \) is never queried on \( p \) itself. Consider then any \( r \in P \setminus \{p\} \). Conditioned on \( g \neq \perp \), the function \( f \) is queried on \( r \) if and only if \( g(r) \neq 0 \). Thus,
\[
\Pr[f(r) \text{ is queried}] = \Pr_{g \sim D_p}[g(r) \neq 0 \mid g \neq \perp] \leq \tau,
\]
and the proof follows.

We now show that the opposite holds as well, that any linear, non-adaptive, SLR induces a dual-SLR.

Lemma 27. Let \( P \) be a set, \( \mathbb{F} \) a field, and let \( C \subseteq \mathbb{F}^P \) be a linear non-adaptive \((q, \tau, \varepsilon)\)-SLR with rate \( \rho \). Then for some set \( D \), \((D, \mathcal{C}, \varepsilon)\) is a \((q + 1, \tau, \varepsilon, \rho)\)-dual SLR.

Proof. Let \( \text{Rec} \) be a recovering procedure promised by \( C \) being a SLR. Assume that \( \text{Rec} \) uses \( R \) random bits. For every point \( p \in P \), denote by \( E_p \) the set of choices of the random bits \( r \in \{0, 1\}^R \) for which \( \text{Rec}^c(p) = \perp \) (for any \( c \in C \)). Note that \( \mu(E_p) \subseteq \{0, 1\}^R \leq \varepsilon \).

For any \( p \in P \) and \( r \in \{0, 1\}^R \), \( r \notin E_p \), denote by \( Q_{p,r} \subseteq P \) the set of query locations which \( \text{Rec}(p) \) makes when \( r \) is the choice of randomness. Define a function \( f_{p,r} : C \rightarrow \mathbb{F} \) such that \( f(c) \) is the output of \( \text{Rec}^c(p) \) when fixing its randomness to \( r \) and note that \( f_{p,r}(c) \) only depends on \( \{c(w) \mid w \in Q_{p,r}\} \), and that \( f_{p,r}(c) = c(p) \). Since \( C \) is linear, one can easily verify that \( f_{p,r} \) is a linear map. Therefore, for some \( u_{p,r} \in \mathbb{F}^P \), \( f_{p,r}(c) = \langle u_{p,r}, c \rangle \) for every \( c \in C \), where \( u_{p,r}(w) = 0 \) if \( w \notin Q_{p,r} \). We have that \( c(p) = \langle u_{p,r}, c \rangle \) for every \( c \in C \). If we define a function \( g_{p,r} \in \mathbb{F}^P \) such that
\[
g_{p,r}(w) = \begin{cases} -1, & w = p; \\
u_{p,r}(q), & w \neq p,
\end{cases}
\]
it follows that \( g_{p,r} \in C^\perp \). Note that \( |g_{p,r}| \leq q + 1 \).
For every \( p \in P \), define \( D_p \) to be the following distribution. To sample from \( D_p \), draw \( r \in \{0,1\}^R \) uniformly at random. If \( r \in \mathcal{E}_p \), output \( \bot \); otherwise, output \( g_{p,r} \). Set \( \mathcal{D} = \{ D_p \mid p \in P \} \) and \( \mathcal{L} = C^\perp \). It follows trivially by the definitions that \( (\mathcal{D}, \mathcal{L}) \) is a \((q+1, \tau, \varepsilon, \rho)\)-dual SLR.

### 4.2 Rate amplification for dual-induced SLR

In this section we describe our first rate amplification procedure for SLR that are induced by dual SLR. Unlike the previous section, it will be more convenient to explicitly state within the notation the set \( P \) over which we are working as we will be dealing with several such sets. The field \( \mathbb{F} \), however, remains suppressed from the notation as it remains fixed in all SLR under consideration. We start by defining the following map of functions.

> **Definition 28.** Let \( P \) be a set and \( \mathbb{F} \) a field. For an integer \( \ell \geq 1 \) we define the map \( \Phi: (\mathbb{F}^P)^\ell \rightarrow \mathbb{F}^{P^\ell} \) as follows. Let \( g_1, \ldots, g_\ell \in \mathbb{F}^P \). The function \( \Phi(g_1, \ldots, g_\ell): P^\ell \rightarrow \mathbb{F} \) is defined by

\[
\Phi(g_1, \ldots, g_\ell)(p_1, \ldots, p_\ell) = \prod_{i=1}^\ell g_i(p_i)
\]

for every \((p_1, \ldots, p_\ell) \in P^\ell\).

Observe that \( \Phi \) is multi-linear. Further, when \( \ell = 2 \) and \( g_1, g_2 \) are viewed as vectors rather than functions, \( \Phi \) is the outer product of the vectors.

> **Definition 29.** Let \( P \) be a set, \( \mathbb{F} \) a field. Let \( \mathcal{L}^P \) be a linear subspace of \( \mathbb{F}^P \). For an integer \( \ell \geq 1 \), we define

\[
\mathcal{L}^{P^\ell} = \text{Span} \{ \Phi(g_1, \ldots, g_\ell) \mid g_1, \ldots, g_\ell \in \mathcal{L}^P \}.
\]

> **Claim 30.** With the notation of Definition 29,

\[
\dim(\mathcal{L}^{P^\ell}) \leq (\dim(\mathcal{L}^P))^\ell.
\]

**Proof.** Let \( B = \{ g_1, \ldots, g_b \} \) be a basis for \( \mathcal{L}^P \), where \( b = \dim(\mathcal{L}^P) \). Define

\[
B' = \{ \Phi(h_1, \ldots, h_\ell) \mid (h_1, \ldots, h_\ell) \in B^\ell \}.
\]

Observe that to prove the claim, it suffices to show that for every \( f_1, \ldots, f_\ell \in \mathcal{L}^P \) it holds that \( \Phi(f_1, \ldots, f_\ell) \in \text{Span}(B') \). As \( f_1, \ldots, f_\ell \in \mathcal{L}^P \), for every \( i \in [\ell] \) we can write \( f_i = \sum_{j=1}^b \lambda_{i,j} g_j \) with \( \lambda_{i,j} \in \mathbb{F} \). We have that

\[
\Phi(f_1, \ldots, f_\ell) = \Phi \left( \sum_{j_1=1}^b \lambda_{1,j_1} g_{j_1}, \ldots, \sum_{j_\ell=1}^b \lambda_{\ell,j_\ell} g_{j_\ell} \right)
\]

\[
= \sum_{j_1, \ldots, j_\ell \in [b]} \left( \prod_{\ell=1}^\ell \lambda_{\ell,j_\ell} \right) \Phi(g_{j_1}, \ldots, g_{j_\ell}),
\]

where the last equality follows by the multi-linearity of \( \Phi \).

> **Definition 31.** Let \( P \) be a set, \( \mathbb{F} \) a field, and let \( (\mathcal{D}^P, \mathcal{L}^P) \) be \((q, \tau, \varepsilon, \rho)\)-dual SLR. Let \( \ell \geq 1 \) be an integer. For \( p \in P^\ell \) we define the distribution \( D_p^{P^\ell} \) as follows. Write \( p = (p_1, \ldots, p_\ell) \). To sample an element from \( D_p^{P^\ell} \) proceed as follows:
1. Sample \( g_1 \sim D_{p_1}^P, \ldots, g_\ell \sim D_{p_\ell}^P \) independently.
2. If there exists \( i \in [\ell] \) such that \( g_i = \bot \), return \( \bot \); Otherwise
3. Return \( \Phi(g_1, \ldots, g_\ell) \).

The collection of distributions \( \{D_p^P \mid p \in P^\ell\} \) is denoted by \( \mathcal{D}_p^P \).

We have the following lemma.

\[ \text{Lemma 32. Let } P \text{ be a set, } F \text{ a field, and let } (D^P, L^P) \text{ be a } (q, \tau, \varepsilon, \rho)\text{-dual SLR. Let } \ell \geq 1 \text{ be an integer and } \mathcal{D}_p^P \text{ as in Definition 31. Then, for every } p, r \in P^\ell, \]

\[ \Pr_{g \sim D_p^P} [g(r) \neq 0 \mid g \neq \bot] \leq \tau^{\text{dist}(p, r)}. \]

**Proof.** Write \( p = (p_1, \ldots, p_\ell), r = (r_1, \ldots, r_\ell). \) By Definition 31, conditioned on \( g \neq \bot \) we have that \( g = \Phi(g_1, \ldots, g_\ell) \) with \( g_i \sim D_{p_i}^P \) for each \( i \in [\ell] \) independently. Thus, \( g(r) \neq 0 \) is the event

\[ \Phi(g_1, \ldots, g_\ell)(r_1, \ldots, r_\ell) = \prod_{i=1}^{\ell} g_i(r_i) \neq 0. \]

By the independence of \( g_1, \ldots, g_\ell, \) and since we are working over a field \( F \) (and so a product is nonzero if and only if each of the terms is nonzero), we get

\[ \Pr_{g \sim D_p^P}[g(r) \neq 0 \mid g \neq \bot] = \prod_{i=1}^{\ell} \Pr_{g \sim D_{p_i}^P}[g_i(r_i) \neq 0 \mid g_i \neq \bot]. \] (4.1)

Let \( T = \{i \in [\ell] \mid p_i \neq r_i\} \). As \( D^P \) is a \( (q, \tau, \varepsilon, \rho)\)-dual SLR, for each \( i \in T \) it holds that

\[ \Pr_{g \sim D_{p_i}^P}[g_i(r_i) \neq 0 \mid g_i \neq \bot] \leq \tau. \]

Substituting to Equation (4.1), we get

\[ \Pr_{g \sim D_p^P}[g(r) \neq 0 \mid g \neq \bot] \leq \tau^{|T|}, \]

which completes the proof.

\[ \text{Definition 33. Let } P \text{ be a set, } F \text{ a field, and let } (D^P, L^P) \text{ be a } (q, \tau, \varepsilon, \rho)\text{-dual SLR. For an integer } \ell \geq 1 \text{ let } L^{P^\ell}, \mathcal{D}_p^{P^\ell} \text{ as in Definition 29 and Definition 31, respectively. We denote the pair } (D^{P^\ell}, L^{P^\ell}) \text{ by } (D^P, L^P)^\ell. \]

\[ \text{Proposition 34. Let } P \text{ be a set, } F \text{ a field, and let } (D^P, L^P) \text{ be a } (q, \tau, \varepsilon, \rho)\text{-dual SLR. Then, for every integer } \ell \geq 1 \text{ we have that } (D^P, L^P)^\ell \text{ is a } (q_\ell, \tau_\ell, \varepsilon_\ell, \rho_\ell)\text{-dual SLR, where} \]

\[ q_\ell \leq q^\ell, \]

\[ \tau_\ell \leq \tau, \]

\[ \varepsilon_\ell \leq \varepsilon, \]

\[ \rho_\ell \geq 1 - (1 - \rho)^\ell. \]

**Proof.** First note that for every \( p \in P^\ell \), the distribution \( D_p^{P^\ell} \) is supported on \( F_p^{P^\ell} \cup \{\bot\} \).

Indeed, if we write \( p = (p_1, \ldots, p_\ell) \) then, conditioned on \( g \neq \bot \), we have that \( g = \Phi(g_1, \ldots, g_\ell) \) where \( g_i \in D_{p_i}^P \). Thus,

\[ g(p) = \Phi(g_1, \ldots, g_\ell)(p_1, \ldots, p_\ell) = \prod_{i=1}^{\ell} g_i(p_i) \neq 0. \]
Moreover, by Definition 29,
\[ \bigcup_{p \in P^\ell} \text{supp}(D_p^\ell) \subseteq L^\ell \cup \{\perp\}. \]

We turn to show that \( q_\ell \leq q^\ell \). Let \( p = (p_1, \ldots, p_\ell) \in P^\ell \) and consider any \( g \in \text{supp}(D_p^\ell) \). By Definition 31, if \( g \neq \perp \) then \( g = \Phi(g_1, \ldots, g_\ell) \) where \( g_i \in \text{supp}(D_{p_i}) \setminus \{\perp\} \). Now, for every \( r = (r_1, \ldots, r_\ell) \in P^\ell \) we have that
\[ g(r) \neq 0 \iff \prod_{i=1}^\ell g_i(r_i) \neq 0. \]

Since \( \mathbb{F} \) is a field, the above is equivalent to \( g_i(r_i) \neq 0 \) for all \( i \in [\ell] \). Hence there are at most \( q^\ell \) points \( r \in P^\ell \) for which \( g(r) \neq 0 \), and so \( q_\ell \leq q^\ell \).

The bound on the smoothness readily follows by Lemma 32. Indeed, consider any pair of distinct \( p, r \in \mathbb{F}^\ell \). We have that \( \text{dist}(p, r) \geq 1 \) and so, by Lemma 32,
\[ \Pr_{g \sim D_p^\ell} [g(r) \neq 0 \mid g \neq \perp] \leq \tau^{\text{dim}(p, r)} \leq \tau. \]

To bound the probability that \( \perp \) is returned, note that the event \( D_p^\ell = \perp \) holds only if for some \( i \in [\ell], g_i = \perp \). Hence, by the union bound, \( \Pr[D_p^\ell = \perp] \leq \ell \varepsilon \). We conclude the proof by bounding the dimension of \( L^\ell \). By assumption, \( \text{dim}(L^\ell) \leq (1 - \rho)|P| \). Claim 30 then implies that
\[ \text{dim}(L^\ell) \leq \left(\text{dim}(L^\ell)\right)^\ell \leq ((1 - \rho)|P|)^\ell = (1 - \rho)^\ell|P|^\ell. \]

Discussion on the smoothness \( \tau_\ell = \tau \)

The downside of the rate amplification procedure that was given in this section is that \( \tau_\ell \) does not decrease with \( \ell \) (which is bad as, recall, we wish \( \tau \) to be small as, by Claim 22, the distance \( \delta \) of the resulted LCC is proportional to \( 1/\tau \)). Indeed, with the notation of Proposition 34, \( \tau_\ell = \tau \). By examining the proof and Lemma 32 one natural idea is to consider an SLR not over the entire set \( P^\ell \) but on some subset of it which is a code with distance, say, \( d > 1 \). This will indeed guarantee that for every two points \( p, r \) we have \( \text{dist}(p, r) \geq d \) and so the bound in Equation (4.2) will be \( \tau^d \) rather than \( \tau \). While natural, this idea fails to yield better parameters as the rate-loss incurred by using a code (even an MDS) is larger than the improvement on the rate guaranteed via the rate amplification procedure.

In the next sections we give a more elaborate rate amplification procedure (that is based on the one that was given in this section) in which \( \tau \) does decrease with \( \ell \). Roughly, \( \tau_\ell = (q \cdot \log |P|)^{\text{poly}(\ell) \cdot \tau^\ell} \), and so there is a slight loss in the smoothness, which the reader should think as negligible. The query complexity \( q_\ell \) as well as the rate \( \rho_\ell \) and \( \varepsilon_\ell \) are all slightly worse than those obtained in the above rate amplification procedure and so the two techniques are incomparable.

4.3 Distance-efficient rate amplification

Let \( P \) be a set, and \( R \) a partition of \( P^2 \). We denote the part containing \( p \) by \( [p]_R \) or \( [p] \) when \( R \) is clear from context. We call \( [p] = [p] \setminus \{p\} \) the open class of \( p \). For a set \( A \subseteq P^2 \) we let \( (A) = \cup_{p \in A} \{p\} \). Given \( p \in P \) we say that \( \{p\} \times P \subseteq P^2 \) is vertical line and \( P \times \{p\} \) is a horizontal line. Horizontal and vertical lines are referred to as axis-parallel lines, and we denote the set of such lines by
\[ X = \bigcup_{p \in P} \{(p) \times P, P \times \{p\}\}. \]
For a point \( p = (p_1, p_2) \in P^2 \) we denote \( S_p = (\{p_1\} \times P) \cup (P \times \{p_2\}) \setminus \{p\} \). That is, \( S_p \) is the set of points in \( P^2 \) of distance exactly 1 from \( p \). Key to our distance-efficient rate amplification procedure is a partition of the “square” \( P^2 \) with certain properties.

**Definition 35** (Axis-evasive partitions). Let \( P \) be a set. A partition \( R \) of \( P^2 \) is said to be (\( c, s \))-axis evasive if
1. For every \( p \in P^2 \), \( |\{p\}| \leq c \).
2. For every \( \ell, \ell' \in X \) (possibly equal), \( |\ell \cap (\ell')| \leq s \).
3. For every \( p \in P^2 \) and \( \ell \in X \), \( |\{p\} \cap \ell| \leq 1 \).

In Section 5 we study such partitions. We prove their existence with certain parameters and give explicit constructions. In this section, however, we work with abstract axis-evasive partitions and analyze our rate amplification procedure with respect to the parameters \( c, s \) of the axis-evasive partition as well as the number of parts which we typically denote by \( t \).

Claim 36. Let \( p, p' \in P^2 \) (possibly equal). Then,
\[
\left|\{r \in S_p \mid (r) \cap S_{p'} \neq \emptyset\}\right| \leq 4s.
\]

Proof. Note that each of \( S_p, S_{p'} \) is a subset of the union of two axis-parallel lines. Thus, to prove the claim, it suffices to show that for every \( \ell, \ell' \in X \), not necessarily distinct,
\[
\left|\{r \in \ell \mid (r) \cap \ell' \neq \emptyset\}\right| \leq s.
\]

Let \( r_1, \ldots, r_t \in \ell \) be such that \( (r_i) \cap \ell' \neq \emptyset \). Note that for every distinct \( i, j \in [t] \) it holds that \((r_i) \cap \ell' \cap (r_j) \cap \ell' = \emptyset\). Indeed, since \( R \) is a partition, if \((r_i) \cap \ell' \cap (r_j) \cap \ell' \neq \emptyset\) then \( r_i \in [r_j] \), but this implies that \(|\ell \cap [r_j]| \geq 2\) in contradiction axis evasiveness. Thus,
\[
R = \bigcup_{i=1}^{t} ((r_i) \cap \ell')
\]
is a disjoint union of size \( t \). However, \( R \subseteq (\ell) \cap \ell' \), and so \( t \leq |R| \leq |(\ell) \cap \ell'| \leq s \).

**Definition 37.** Let \( P \) be a set, \( \mathbb{F} \) a field. Let \( R \) be a \((c, s)\)-axis evasive partition of \( P^2 \). For every \( p \in P^2 \) define the function \( g_{[p]} : P^2 \to \mathbb{F} \) as follows:
\[
g_{[p]}(r) = \begin{cases} 
1, & r \in [p]; \\
0, & \text{otherwise}.
\end{cases}
\]
We define \( \mathcal{L}_R = \{g_{[p]} \mid p \in P^2\} \).

**Definition 38.** Let \( P \) be a set, \( \mathbb{F} \) a field. For \( S \subseteq P \) define the function \( \nu_S : P \to \mathbb{F} \) by
\[
\nu_S(r) = \begin{cases} 
0, & r \in S; \\
1, & \text{otherwise}.
\end{cases}
\]
For ease of readability, when \( S \) is a singleton \( S = \{p\} \), we write \( \nu_p \) instead of \( \nu_{\{p\}} \).

With the notations and definitions above, we are ready to start developing our second rate amplification procedure. We start with the following.

**Definition 39.** Let \( P \) be a set, \( \mathbb{F} \) a field, and let \((D^P, \mathcal{L}^P)\) be a \((q, \tau, \varepsilon, \rho)\)-dual SLR. Let \( \mathcal{L}^{P^2} \) be as in Definition 29. Let \( R \) be a \((c, s)\)-axis evasive partition of \( P^2 \). We define for every \( p \in P^2 \) the distribution \((D_R^{P^2})_p\) as follows. To sample \( u \) from \((D_R^{P^2})_p\):
1. Sample $g \sim D_p^{P^2}$.
2. If $g = \perp$, return $\perp$; Otherwise, denote $L = \{r \in S_p \mid g(r) \neq 0\}$ and proceed as follows.
3. For every $r \in L$ and $w \in (r)$ sample $h_{r,w} \sim D_w^{P^2}$.
4. If there exist $r \in L$ and $w \in (r)$ such that either $h_{r,w} = \perp$ or $h_{r,w}(p) \neq 0$ return $\perp$.

Otherwise return

$$u = g \nu_L + \sum_{r \in L} g(r) \sum_{w \in (r)} \frac{h_{r,w} \nu_w}{h_{r,w}(w)},$$

(4.3)

Note that, upon reaching Step (4), $u$ is well-defined as $h_{r,w}(w) \neq 0$ for all $r \in L$ and $w \in (r)$. We denote the collection of distributions $\{D_p^{P^2}\}_{p \in P^2}$ by $D_p^{P^2}$.

We start by analyzing the function $u$ that is given by Equation (4.3) above.

\[\text{Claim 40.} \quad \text{With the notation of Definition 39, if } \perp \text{ is not returned then } u \in F_p.\]

Proof. As $\perp$ was not returned, for every $r \in L$ and $w \in (r)$ it holds that $h_{r,w} \neq \perp$ and $h_{r,w}(p) = 0$. Substituting to Equation (4.3), we get

$$u(p) = g(p) \nu_L(p) = g(p) \neq 0,$$

where the second equality holds as $p \notin L$ and the last inequality follows since $g \in \text{supp}(D_p^{P^2}) \setminus \{\perp\}$. \hfill \end{proof}

\[\text{Claim 41.} \quad \text{With the notation of Definition 39, if } \perp \text{ is not returned then } u \in L^{P^2} + L_R.\]

Proof. Take $f \in (L^{P^2} + L_R)^\perp$. To prove the claim, it suffices to show that $\langle u, f \rangle = 0$. Indeed, this would imply $u \in ((L^{P^2} + L_R)^\perp)^\perp = L^{P^2} + L_R$. As $u \neq \perp$ we have that $g \neq \perp$. Note that

$$\langle g \nu_L, f \rangle = \langle g, f \rangle - \sum_{r \in L} g(r) f(r).$$

Since $g \in \text{supp}(D_p^{P^2})$ we get that $g \in L^{P^2}$. However, $f \in (L^{P^2} + L_R)^\perp \subseteq (L^{P^2})^\perp$, implying $\langle g, f \rangle = 0$. Thus,

$$\langle g \nu_L, f \rangle = -\sum_{r \in L} g(r) f(r).$$

(4.4)

Now, fix $r \in L$ and $w \in (r)$. By Definition 39, as $u \neq \perp$ we have that $h_{r,w} \neq \perp$ and so $h_{r,w} \in L^{P^2}$. However, by the above, $f \in (L^{P^2})^\perp$ and so $\langle h_{r,w}, f \rangle = 0$. Thus,

$$\langle h_{r,w} \nu_w, f \rangle = \langle h_{r,w}, f \rangle - h_{r,w}(w) f(w) = -h_{r,w}(w) f(w).$$

Therefore, for every fixed $r \in L$ one has that

$$\left\langle \sum_{w \in (r)} h_{r,w} \nu_w, f \right\rangle = \sum_{w \in (r)} \left\langle h_{r,w} \nu_w, f \right\rangle$$

$$= \sum_{w \in (r)} \frac{1}{h_{r,w}(w)} \langle h_{r,w} \nu_w, f \rangle$$

$$= -\sum_{w \in (r)} f(w).$$

(4.5)
Now, $f \in (\mathcal{L}^{P^2} + \mathcal{L}_R)^\perp \subseteq (\mathcal{L}_R)^\perp$ whereas $g_{[r]} \in \mathcal{L}_R$, and so

$$0 = \langle f, g_{[r]} \rangle = \sum_{w \in [r]} f(w).$$

Substituting this to Equation (4.5), we get

$$\left\langle \sum_{w \in (r)} \frac{h_{r,w} \nu_w}{h_{r,w}(w)}, f \right\rangle = f(r).$$

Therefore,

$$\left\langle \sum_{r \in L} g(r) \sum_{w \in (r)} \frac{h_{r,w} \nu_w}{h_{r,w}(w)}, f \right\rangle = \sum_{r \in L} g(r) \left\langle \sum_{w \in (r)} \frac{h_{r,w} \nu_w}{h_{r,w}(w)}, f \right\rangle = \sum_{r \in L} g(r) f(r).$$

The above equation together with Equation (4.4) yield $\langle u, f \rangle = 0$. ◁

> Claim 42. With the notation of Definition 39, for every $p \in P^2$,

$$\Pr[(D_{P^2}_R)_p = \perp] \leq 18csq^2 + 2c\varepsilon.$$

Proof. First, the probability that $g = \perp$ is bounded by $\varepsilon$. Similarly, the probability that for any specific $r \in L$ and $w \in (r)$, $h_{r,w} = \perp$ is bounded by $\varepsilon$. Thus, by the union bound, and since $|L| \leq 2q - 1$ and $|(r)| \leq c$, we have that expect with probability $(1 + (2q - 1)c\varepsilon) \leq 2c\varepsilon$, the sampling process above will result in $u \neq \perp$.

To complete the analysis, we turn to bound the probability that $h_{r,w}(p) = 0$ for some $r \in L$ and $w \in (r)$. Let $L = \{r_1, \ldots, r_{|L|}\}$. While the random variables in $L$ may be dependent, marginally, it holds that for every $i \in [|L|]$ and every fixed $r \in S_p$, $\Pr[r_i = r] \leq \tau$. With this notation, by Definition 39, $(D_{P^2}_R)_p = \perp$ only if there exist $i \in [|L|]$ and $w \in (r_i)$ such that $h_{r_i,w}(p) \neq 0$.

For a fixed $r \in S_p$ define the event $\mathcal{E}_r$ in which there exists $w \in (r)$ such that $h_{r,w}(p) \neq 0$, (when conditioned on $h_{r,w} \neq \perp$). Note that this event is with respect to the randomness of sampling $h_r = \{h_{r,w} \mid w \in (r)\}$ whereas $r$ is fixed. By the union bound,

$$\Pr[\mathcal{E}_r] \leq \sum_{w \in (r)} \Pr[h_{r,w}(p) \neq 0 \mid h_{r,w} \neq \perp].$$

Observe first that $w \neq p$. Indeed, as $r \in S_p$, both $r$ and $p$ are on some common axis-parallel line $\ell \in X$. Thus, $w = p$ would imply $[r] \cap \ell \geq 2$ which stands in contradiction to the definition of axis-evasiveness. Consider $w \in (r) \setminus S_p$. As $w \neq p$ we have that $\text{dist}(w, p) = 2$. By Lemma 32, as $h_{r,w} \sim D_{P^2}_w$ we have that

$$\Pr[h_{r,w}(p) \neq 0 \mid h_{r,w} \neq \perp] \leq \tau^2.$$

If, on the other hand, $w \in (r) \cap S_p$ then $\text{dist}(w, p) = 1$, and Lemma 32 then implies that

$$\Pr[h_{r,w}(p) \neq 0 \mid h_{r,w} \neq \perp] \leq \tau.$$

As $|(r)| \leq c$ we conclude that

$$\Pr[h_r[\mathcal{E}_r] \leq c\tau^2 + \tau |(r) \cap S_p|.}
Fix $i \in [\|L\|]$ and consider the random variable $r_i$. The above equation, together with $|\{r_i\}| \leq c$, yields

$$\mathbb{P}_{r_i, h_{\nu_i}}[\mathcal{E}_r] \leq \mathbb{P}_{r_i, h_{\nu_i}}[\mathcal{E}_{r_i} \mid (r_i) \cap S_p = \emptyset] + \mathbb{P}_{r_i, h_{\nu_i}}[\mathcal{E}_{r_i} \mid (r_i) \cap S_p \neq \emptyset] \mathbb{P}_{r_i}[\{r_i\} \cap S_p \neq \emptyset]$$

$$\leq c r^2 + (c r^2 + c r) \mathbb{P}_{r_i}[\{r_i\} \cap S_p \neq \emptyset]. \quad (4.6)$$

Consider now the set $B = \{r \in S_p \mid (r) \cap S_p \neq \emptyset\}$. As $R$ is $(c, s)$-axis evasive, Claim 36 implies that $|B| \leq 4s$, and so

$$\mathbb{P}_{r_i}[\{r_i\} \cap S_p \neq \emptyset] = \mathbb{P}[r_i \in B] \leq 4s \tau.$$

Substituting to Equation (4.6), we get $\mathbb{P}[\mathcal{E}_r] \leq 9c s \tau^2$. The proof then follows by taking the union bound over all $i \in [\|L\|]$ as, indeed, $|L| = 2q - 1$.

> Claim 43. With the notation of Definition 39, for every pair of distinct $p, r \in P^2$,

$$\mathbb{P}_{u \sim (D_{P^2}^2)}[u(r) \neq 0 \mid u \neq \perp] \leq 10csq \tau^2.$$ 

Proof. By Equation (4.3), $u$ is a linear combination of the (sampled) functions $g_{\nu_r}, \{h_{r, w, \nu_r}\}$. To prove the claim, we will show that, with high probability, all these functions evaluate to 0 at the point $r$, implying $u(r) = 0$. We start by bounding $\mathbb{P}[\{g_{\nu_r}\}(r) \neq 0]$. To this end, consider two cases. First, if $r \in P^2 \setminus S_p$ then, as $L \subseteq S_p$, we have that $\nu_r(r) = 1$ and so in such case

$$\mathbb{P}[(g_{\nu_r})(r) \neq 0] = \mathbb{P}[g(r) \neq 0] \leq \tau^2, \quad (4.7)$$

where the last inequality follows by Lemma 32 and since $\text{dist}(r, p) = 2$ per our assumption $r \not\in S_p$ and since $r \neq p$. If, on the other hand, $r \in S_p$ then, by the definition of $L$,

$$g(r) \neq 0 \implies r \in L \implies \nu_r(r) = 0,$$

and so in this case $(g_{\nu_r})(r) = 0$.

Let $L = \{r_1, \ldots, r_{\|L\|}\}$. Consider a fixed $i \in [\|L\|]$ and denote $(r_i) = \{w_{i,1}, \ldots, w_{i,b}\}$, where $b \leq c$. Fix $j \in [b]$. We turn to bound $\mathbb{P}[(h_{r_i, w_j, \nu_{w_{i,j}}})(r) \neq 0]$. First note that

$$\mathbb{P}[(h_{r_i, w_j, \nu_{w_{i,j}}})(r) \neq 0 \mid (r_i) \cap S_r = \emptyset] \leq \tau^2. \quad (4.8)$$

Indeed, conditioned on the event $(r_i) \cap S_r = \emptyset$, either $w_{i,j} = r$ or $\text{dist}(w_{i,j}, r) = 2$. In the first case,

$$(h_{r_i, w_{i,j}, \nu_{w_{i,j}}})(r) = h_{r_i, r}(r)\nu_r(r) = 0.$$

In the second case, the bound follows by Lemma 32. Second, note that

$$\mathbb{P}[(h_{r_i, w_{i,j}, \nu_{w_{i,j}}})(r) \neq 0 \mid (r_i) \cap S_r = \emptyset] \leq \tau. \quad (4.9)$$

Indeed, as before, we may only consider the case $r \neq w_{i,j}$ and then observe that $\text{dist}(r, w_{i,j}) = 1$ and invoke Lemma 32. Now, let $B = \{v \in S_p \mid (v) \cap S_r = \emptyset\}$. By Claim 36, and since $R$ is $(c, s)$-axis evasive, $|B| \leq 4s$. Recall that $\mathbb{P}[r_i = v] \leq \tau$ for every fixed $v \in S_p$, and so

$$\mathbb{P}[(r_i) \cap S_r \neq \emptyset] = \mathbb{P}[r_i \in B] \leq 4s \tau. \quad (4.10)$$

By Equations (4.8), (4.9), (4.10) we get

$$\mathbb{P}[(h_{r_i, w_{i,j}, \nu_{w_{i,j}}})(r) \neq 0] \leq \tau^2 + 4s \tau^2 \leq 5s \tau^2.$$

The proof then follows by the union bound over all $i \in [\|L\|]$ and $j \in [(w_{i})]$.
Definition 44. Let \( P \) be a set, \( \mathbb{F} \) a field, and let \( (D^P, L^P) \) be a \((q, \tau, \varepsilon, \rho)\)-dual SLR. Let \( L^{P^2} \) be as in Definition 39. Let \( R \) be a \((c, s)\)-axis evasive partition of \( P^2 \) and let \( D^P_R \) be as in Definition 39. We denote by \( (D^P, L^P)_R \) the pair \((D^{P^2}_R, L^{P^2} + L_R)\).

Proposition 45. Let \( P \) be a set, \( \mathbb{F} \) a field, and let \( (D^P, L^P) \) be a \((q, \tau, \varepsilon, \rho)\)-dual SLR. Let \( R \) be a \((c, s)\)-axis evasive partition of \( P^2 \) that consists of \( t \) parts. Then, \((D^P, L^P)_R \) is a \((q_R, \tau_R, \varepsilon_R, \rho_R)\)-dual SLR with

\[
\begin{align*}
q_R &\leq 2cq^3 \\
\tau_R &\leq 10csq\tau^2 \\
\varepsilon_R &\leq 18csq\tau^2 + 2cq\varepsilon \\
\rho_R &\geq 1 - (1 - \rho)^2 - \frac{t}{|P|^2}.
\end{align*}
\]

Proof. Claim 40 implies that for every \( p \in P^2 \), \( \mathrm{supp}(D^P_R)_p \subseteq F \cup \{\perp\} \). To bound \( q_R \), note that by Equation (4.3),

\[
|u| \leq |g_{uL}| + \sum_{r \in L \in \mathbb{W}(r)} |h_{r,w}v_w|
\]

Now, \( |g_{uL}| \leq |q| \leq q^2 \) and \( |h_{r,w}v_w| \leq |h_{r,w}| \leq q^2 \). Hence, \( |u| \leq q^2 + |L|cq^2 \leq 2cq^3 \). The stated bounds on \( \tau_R \) and \( \varepsilon_R \) readily follows by Claim 43 and Claim 42, respectively. As for the rate, we have that

\[
\dim(L^{P^2} + L_R) \leq \dim(L^{P^2}) + \dim(L_R) \\
\leq (1 - \rho)^2|P|^2 + t,
\]

where the second inequality follows by Proposition 34 and since \( R \) consists of \( t \) parts, implying \( |L_R| = t \).

4.4 Proofs of Theorem 3 and Corollary 4

With the machinery developed in the previous section, and using in a black-box manner, the construction of axis-evasive partitions we obtain in Section 5, we are finally ready to prove Theorem 3 and Corollary 4. We start by giving a more formal statement of Corollary 4.

Theorem 46. There exist universal constants \( m_0, c' \geq 1 \) such that the following holds. Let \( P \) be a set of size \( m \geq m_0 \). Let \( \mathbb{F} \) be a field, and let \((D^P_{in}, L^P_{in})\) be a \((q_{in}, \tau_{in}, \varepsilon_{in}, \rho_{in})\)-dual SLR over \( \mathbb{F}^P \). Let \( 0 < \alpha < 1 \) be such that

\[
\rho_{in} \geq \frac{c'}{\sqrt{\alpha} \cdot \log m} \log \left( \frac{1}{\alpha} \right).
\]

Then, there exists a \((q_{out}, \tau_{out}, \varepsilon_{out}, \rho_{out})\)-dual SLR \((D^P_{out}, L^P_{out})\) over \( \mathbb{F}^P_{out} \), with \( m^{\ell}/2 \leq |P_{out}| \leq m^{\ell} \), where

\[
\ell = \Theta\left( \frac{1}{\rho_{in}} \log \frac{1}{\alpha} \right),
\]

having the following parameters:

\[
\begin{align*}
q_{out} &\leq q_{in}^{\text{poly}(\ell)}, \\
\tau_{out} &\leq q_{in}^{\text{poly}(\ell)}\tau_{in}^{\ell}, \\
\varepsilon_{out} &\leq q_{in}^{\text{poly}(\ell)}(\tau_{in} + \varepsilon_{in}), \\
\rho_{out} &\geq 1 - \alpha.
\end{align*}
\]
A remark regarding the error

Note that there is another implicit constraint on \( \rho_n \) and \( \alpha \) that originates from the error. Indeed, to make the result non-trivial, one must have \( \varepsilon_{\text{out}} < 1 \) which, in turn, implies some bound on \( \ell \) and then, through Equation (4.12), a constraint on \( \rho_n \) and \( \alpha \). However, if that turns out to be a problem for the regime of parameters one is interested in, the probability to output \( \bot \) can be reduced by repetition. Thus, by performing an alternating sequence of such error (or failure) reductions and rate amplifications, one can resolve this issue. Note that unlike for LDC, the error reduction has no cost in query complexity, and it certainly has no effect on the smoothness nor on the rate. It does, however, effects the running-time.

As mentioned above, our proof relies on an explicit axis-evasive partition that we construct in Section 5. Formally,

**Theorem 47.** Let \( P \) be a set of size \( q \), where \( q \) is an odd prime power. Let \( c \) be an even integer such that \( c + 1 \mid q + 1 \), and \( c \leq \sqrt{q}/10 \). Then, there exists a \((c, 4c^2)\)-axis evasive partition of \( P^2 \) with at most \( 2q^c/(c+1) \) parts.

Our proof of Theorem 46 is done by applying Proposition 45 several times, iteratively, where in each iteration we square the size of the set \( P \) obtained by the previous iterative step. Note, however, that Theorem 47 requires the set size \( |P| \) to be an odd prime power \( q \) with the property that \( c + 1 \mid q + 1 \). It is best to choose \( c \) the same in all applications of Proposition 45. However, note that if we start an iteration with a set of size \( q \) and so end the iteration with a set of size \( q^2 \) then the condition will fail to hold at the beginning of the following iteration. Indeed if \( c + 1 \mid q + 1 \) then \( q \equiv -1 \pmod{c + 1} \) and so \( q^2 \equiv 1 \pmod{c + 1} \). To overcome this technicality, we do not work with the set obtained by the previous iteration as is. Instead, we find a prime—not much smaller than \( q^2 \)—that has the desired residue \(-1 \) modulo \( c + 1 \). To this end we rely on the Siegel–Walfisz Theorem [34, 37] which refines Dirichlet’s theorem on primes in arithmetic progressions. The state the Siegel–Walfisz Theorem we set some notation. For an integer \( m \geq 1 \), we denote Euler’s totient function, that counts the positive integers up to \( m \) that are relatively prime to \( m \), by \( \phi(m) \). For integers \( n, m, r \), we denote the number of (positive) primes less than or equal to \( n \) which are congruent to \( r \) modulo \( m \) by \( \pi(n; m, r) \). The Eulerian logarithmic integral is given by

\[
\text{Li}(x) = \int_2^x \frac{dt}{\ln t}.
\]

**Theorem 48 ([34, 37]).** For every constant \( c \geq 1 \) there exists a constant \( c = c(e) \) such that the following holds. Let \( n, m, r \) be positive integers such that \( m \leq (\log n)^e \), and \( n, m, r \) coprimes. Then,

\[
\left| \pi(n; m, r) - \frac{\text{Li}(n)}{\phi(m)} \right| = O \left( n \cdot 2^{-c\sqrt{\log n}} \right).
\]

We have the following straightforward corollary.

**Corollary 49.** For every constant \( c \geq 1 \) there exist constants \( c = c(e), n_0 = n_0(e) \) such that the following holds. Let \( m, r \) be coprime integers, \( m > 0 \). Let \( n \geq n_0 \) be an integer such that \( m \leq (\log n)^e \). Then, there exists a prime \( p \in [n - \Delta, n] \), where \( \Delta = cn/\log n \), such that \( p \equiv r \pmod{m} \).

**Proof.** To prove the corollary, it suffices to show that \( \pi(n; m, r) > \pi(n - \Delta; m, r) \). By Theorem 48, there exist constants \( n_0, c' \) such that for every \( n \geq n_0 \),

\[
\left| \pi(n; m, r) - \frac{\text{Li}(n)}{\phi(m)} \right| \leq c'n \cdot 2^{-c\sqrt{\log n}}.
\]
Thus, it suffices to show that
\[
\frac{\text{Li}(n)}{\phi(m)} - c'n \cdot 2^{-c\sqrt{\log n}} > \frac{\text{Li}(n - \Delta)}{\phi(m)} + c'(n - \Delta) \cdot 2^{-c\sqrt{\log (n - \Delta)}},
\]

As we may assume that \(\Delta \leq n/2\), it suffices to prove that
\[
\text{Li}(n) - \text{Li}(n - \Delta) \geq 2c' \phi(m)n \cdot 2^{-c\sqrt{\log (n/2)}}.
\]

(4.13)

It is well-known that
\[
\text{Li}(x) = c_1 + \frac{x}{\ln x} + O\left(\frac{x}{\ln^2 x}\right),
\]

where \(c_1 = \int_{t=0}^{2} \frac{dt}{\ln t}\) is some constant. Therefore,
\[
\text{Li}(n) - \text{Li}(n - \Delta) \geq \frac{\Delta}{\ln(n/2)^2} - \frac{c'' n}{\ln^2 n},
\]

for some constant \(c''\). By our assumption on \(\Delta\) we can choose the parameter \(c\) in the definition of \(\Delta\) such that the right hand side is bounded below by \(n/\ln^2 n\). The proof then follows by Equation (4.13) and noting that \(\phi(m) \leq m \leq (\log n)^c = o(2^{-c\sqrt{\log (n/2)}}).

We turn to formally define and analyze the operation of projecting a dual SLR over \(\mathbb{R}^P\) on a (large) subset of \(P\).

Definition 50. Let \(P\) a set and \(P' \subseteq P\). Let \(p' \in P'\) and \(D\) be a distribution with \(\text{supp}(D) \subseteq F_{p'} \cup \{\bot\}\). We define the \(D|_{P'}\) as follows: To sample from \(D|_{P'}\), sample \(f \sim D\). If \(f = \bot\), output \(\bot\); if \(f \in F_{p'}\), output \(f|_{P'}\). We refer to \(D|_{P'}\) as the distribution \(D\) projected to \(P'\).

Definition 51. Let \(P\) be a set, \(F\) a field. Let \(\mathcal{D} = \{D_p \mid p \in P\}\) be a collection of distributions, where for each \(p \in P\), \(\text{supp}(D_p) \subseteq F_p \cup \{\bot\}\). Let \(P' \subseteq P\). We define \(\mathcal{D}|_{P'}\) to be the collection \(\mathcal{D}\) projected to \(P'\), that is, \(\mathcal{D}|_{P'} = \{D_{p'} \mid p' \in P'\}\).

Definition 52. Let \(P\) be a set, \(F\) a field and let \(\mathcal{L}\) be a linear subspace of \(\mathbb{R}^P\). Let \(P' \subseteq P\). We denote by \(\mathcal{L}|_{P'}\) the linear subspace \(\mathcal{L}\) projected to \(P'\), namely, \(\mathcal{L}|_{P'} = \{f|_{P'} \mid f \in \mathcal{L}\}\).

Claim 53. Let \(P\) be a set, \(F\) a field, \((\mathcal{D}, \mathcal{L})\) a \((q, \tau, \varepsilon, \rho)\)-dual SLR over \(\mathbb{R}^P\), and let \(P' \subseteq P\). Then, \((\mathcal{D}|_{P'}, \mathcal{L}|_{P'})\) is a \((q, \tau, \varepsilon, \rho')\)-dual SLR over \(\mathbb{R}^{P'}\), where \(\rho' = 1 - \frac{|P|}{|P'|} (1 - \rho)\).

Proof. That the smoothness \(\tau\), as well as \(q\) and \(\varepsilon\), all stay the same after projecting the dual SLR to \(P'\), follows immediately from the definitions. The assertion regarding the rate of the induced SLR, \(\rho'\), readily follows as we have that
\[
\dim(\mathcal{L}|_{P'}) \leq \dim(\mathcal{L}) \leq (1 - \rho)|P| = \left(1 - (1 - \frac{|P|}{|P'|} (1 - \rho))\right)|P'|.
\]

Claim 54. There exists a universal constant \(m_0\) such that the following holds. Let \(P\) be a set of size \(m \geq m_0\). Let \(F\) be a field, and let \((\mathcal{D}^P, \mathcal{L}^P)\) be a \((q_{in}, \tau_{in}, \varepsilon_{in}, \rho_{in})\)-dual SLR over \(\mathbb{F}^P\). Let \(c \leq \log m\) be an integer. Then, there exists a set \(P'\) of size
\[
|P'| \geq \left(1 - O\left(\frac{1}{\log m}\right)\right)m^2,
\]
and a \((q_{\text{out}}, \tau_{\text{out}}, \varepsilon_{\text{out}}, \rho_{\text{out}})\)-dual SLR \((D^{P'}, L^{P'})\) over \(\mathbb{F}^{P'}\), where
\[
q_{\text{out}} \leq 2c q_{\text{in}}^3,
\]
\[
\tau_{\text{out}} \leq 40c q_{\text{in}} \tau_{\text{in}}^2,
\]
\[
\varepsilon_{\text{out}} \leq 80c q_{\text{in}} (\tau_{\text{in}}^2 + \varepsilon_{\text{in}}),
\]
\[
\rho_{\text{out}} \geq 1 - (1 - \rho_{\text{in}})^2 - O\left(\frac{1}{\log m}\right).
\]

Proof. By Corollary 49 applied with \(n, m, r\) in the notation of Corollary 49 set to \(m, c + 1, -1\) in the notation of this claim, respectively, there exists some prime \(p \leq m\) such that \(m - p = O\left(\frac{m}{\log m}\right)\), and \(c + 1 \mid p + 1\). Take \(P'\) to be an arbitrary subset of \(P\) of size \(p\). By Claim 53, \((D|_{P'}, \mathcal{L}|_{P'})\) is a \((q_{\text{in}}, \tau_{\text{in}}, \varepsilon_{\text{in}}, \rho_{\text{in}})\)-dual SLR on \(P\), where
\[
\rho' = 1 - \frac{m}{p} (1 - \rho_{\text{in}}) \geq \rho_{\text{in}} - O\left(\frac{1}{\log m}\right).
\]

By Theorem 47 applied to \(P'\), which observe is indeed applicable as \(c + 1 \mid p + 1\), there exists an explicit \((c, 4c^2)\)-axis evasive partition \(R\) of \((P')^2\) with at most \(t = 2p^2/(c + 1)\) parts. With that partition, we can now apply Proposition 45 to \((D|_{P'}, \mathcal{L}|_{P'})\) and get that \((D|_{P'}, \mathcal{L}|_{P'})^R\) is a \((q_{\text{out}}, \tau_{\text{out}}, \varepsilon_{\text{out}}, \rho_{\text{out}})\)-dual SLR with the stated parameters. Note that the assertion regarding the rate follows as \(c \leq \log m\).

The following proposition is a more formal and accurate restatement of Theorem 3.

\[\text{Proposition 55. There exist universal constants } 0 < c' < 1 \text{ and } c', m', \ell' \geq 1 \text{ such that the following holds. Let } P \text{ be a set of size } m \geq m'. \text{ Let } \mathbb{F} \text{ be a field, and let } (D^P, L^P) \text{ be a } (q_{\text{in}}, \tau_{\text{in}}, \varepsilon_{\text{in}}, \rho_{\text{in}})\text{-dual SLR over } \mathbb{F}^P. \text{ Let } \ell = 2^r \text{ for an integer } r \geq 1, \text{ and assume that } \ell \geq \ell'. \text{ Let } c \text{ be an integer such that } c' \ell^2 \leq c \leq c' \log m. \text{ Then, there exists a set } P_t \text{ of size } m'^2/2 \leq |P_t| \leq m^t, \text{ and a } (q_t, \tau_t, \varepsilon_t, \rho_t)\text{-dual SLR } (D^{P_t}, L^{P_t}) \text{ over } \mathbb{F}^{P_t}, \text{ where}
\]
\[
q_t \leq (2c q_{\text{in}})^{O(q_{\text{in}}^3)},
\]
\[
\tau_t = O((c q_{\text{in}}^{2q_{\text{in}}^3})^\ell),
\]
\[
\varepsilon_t \leq O((c q_{\text{in}}^{2q_{\text{in}}^3})^\ell) \cdot (\tau_{\text{in}} + \varepsilon_{\text{in}}),
\]
\[
\rho_t \geq 1 - (1 - \rho_{\text{in}})^\ell - O\left(\frac{\ell^2}{c}\right),
\]
\]

where, recall, the log function is taken base 2.

Proof. We construct a sequence of \((q_t, \tau_t, \varepsilon_t, \rho_t)\)-dual SLR \((D^{P_t}, L^{P_t})\) for \(t = 0, 1, \ldots, r = \log \ell\), and show that the last dual-SLR in the sequence has the stated parameters. The first dual-SLR, \((D^{P_0}, L^{P_0})\), is taken to be the \((q_{\text{in}}, \tau_{\text{in}}, \varepsilon_{\text{in}}, \rho_{\text{in}})\)-dual SLR \((D^P, L^P)\) that is given by the hypothesis of the proposition. After constructing \((D^{P_t}, L^{P_t})\), we obtain \((D^{P_{t+1}}, L^{P_{t+1}})\) by applying Claim 54 to \((D^{P_t}, L^{P_t})\) with the parameter \(c\) taken to be \(c\) from the statement of this proposition. Note that, as required by the claim, \(c \leq \log m\). Note that, by taking \(m'\) to be a large enough constant, all other dual SLR in the sequence will have \(|P_t| \geq m\) as well, and so we can apply Claim 54 to them. Denote \(m_t = |P_t|\). We begin by bounding \(m_t\) from below. Indeed, by Claim 54, and using that \(1 - x \geq e^{-2x}\) for \(x \leq 1/2\), we can pick the constant \(c''\) such that
\[
m_t \geq e^{-\sum_{i=0}^{r} \rho_{t} \ell^i} m_{t-1}^2 \geq e^{-\sum_{i=0}^{r} \rho_{t} \ell^i} m_{t-1}^2,
\]
\]
where the last inequality follows as, for a large enough constant $m'$, the sequence $(m_t)$ is monotone increasing. We invoke Claim 82 with $a = e^\frac{c''}{\log m_0}$ and $b = 2$ to conclude that

$$m_t \geq m_0^2 \cdot e^{-\frac{c''}{\log m_0}} \geq \frac{1}{2} m_0^2,$$

where the last inequality follows as $t \leq r = \log \ell$ and, recall, we take $\ell \leq c' \log m$ for a sufficiently small constant $c' > 0$. In particular, $m_t \geq m'/2$ as stated.

By Claim 54, for every $t \geq 1$ we have $q_t \leq 2c\tau_{t-1}^3$. It is straightforward to prove by that

$$q_t \leq (2c\tau_{t-1})^3,$$  

(4.14)

which readily implies the assertion regarding the query complexity. We turn to analyze the rate. Denote $\beta_t = 1 - \rho_t$. Claim 54 implies that $\beta_t \leq \beta_{t-1}^2 + 4c^m/c$, for some constant $c'' > 0$. By induction on $t$, we get that $\beta_t \leq \beta_0^2 + 4c^m/c$. Indeed, the base case $t = 0$ is obvious. Now, by the induction hypothesis,

$$\beta_t \leq \beta_{t-1}^2 + 4c^m/c \leq \left( \beta_{t-1}^2 + 4t^{-1}c^m/c \right)^2 + \frac{c^m}{c}.$$

One can easily verify that the right hand side is bounded above by the desired bound $\beta_0^2 + 4c^m/c$ provided that $2c^m/c \leq 1$. As $t \leq r$ and $2r = \ell$, the latter inequality follows assuming $c^m \ell \leq c$. As we assume $c \geq c'' \ell^2$, it suffices to choose $\ell'$ from the statement of the proposition to be a constant larger than the constant $c^m/c$. We conclude that,

$$\beta_r \leq \beta_0^2 + O \left( \frac{4c}{c} \right) = \beta_0^2 + O \left( \frac{\ell^2}{c} \right),$$

which implies the assertion regarding the rate.

As for the smoothness, by Claim 54, and using Equation (4.14), we have that

$$\tau_t \leq 4c^3 \tau_{t-1}^2 \leq 4c^3 (2c\tau_{t-1})^3 \tau_{t-1}^2,$$

from which it is easy to verify that

$$\tau_t \leq (4c^3)^{4t} (2c\tau_{t-1})^{3t} \tau_{t-1}^2,$$

and the assertion regarding the smoothness readily follows. Last is the error which we leave to the reader to verify. ▲

We can now easily deduce Theorem 46

**Proof of Theorem 46.** The proof readily follows from Proposition 55 by taking $\ell$ as defined in Equation (4.12), and with $c$ in the notation of Proposition 55 taken to be $c = \Theta(\ell^2/\alpha)$. Note that this choice of parameters satisfies the hypothesis of Proposition 55 as indeed implied by Equation (4.11) and by taking $c'$ to be a sufficiently large constant. It is easy to verify that the rate is $1 - \alpha$ with our choice of $c, \ell$, and the remaining assertions readily follow by Proposition 55. ▲
5 Axis-evasive partitions

The distance-efficient rate amplification procedure that was developed in the previous section is built on axis-evasive partitions. Note that, by Proposition 45, the number of parts $t$ effects the rate, $c$ effects the query complexity and both $c,s$ the deterioration of the distance and error. It is perhaps best to consider the following goal: for a given $c$ we wish to obtain a $(c,s)$-axis evasive partition with both $s,t$ as small as possible.

We start this section by proving the existence of axis-evasive partitions with great parameters. However, our probabilistic proof does not work for every $c$ but rather, it requires $c = \Omega(\log m)$, where $m = |P|$. Unfortunately, for our distance-efficient rate amplification procedure, we are interested in $c < \log m$ (see Proposition 55). Luckily, and perhaps somewhat surprisingly, our explicit construction, described in Section 5.2, does work for every $c$ albeit it requires $c + 1 \mid m + 1$ to hold.

5.1 Existential proof

As mentioned above, while we do not use the following non-constructive proof for the existence of axis-evasive sets, as given by the following lemma, we believe the reader might benefit from reading it still, as it gives an intuition on what is it about axis-evasive partitions which is random and what requires structure.

Lemma 56. Let $P$ be a set of size $m$, and let $c$ be an integer such that $50 \log m \leq c \leq \sqrt{m}$. Then, there exists a $(c,s=c)$-axis evasive partition of $P^2$ with $t \leq 5m^2/c$ parts.

Proof. Let $k = 2m^2/c$. The proof is by a probabilistic argument. We form a partition by assigning to each point $p \in P^2$ a “color” or, more formally, a number in $[k]$. The $k$ parts are then formed by grouping together points with the same color. To this end, for every $p \in P^2$ define a random variable $C_p$ that is uniformly distributed over $[k]$, where $\{C_p \mid p \in P^2\}$ are independent. For $i \in [k]$ let $R_i$ be the number of random variables $C_p$ for which $C_p = i$. Note that $R_i$ is the size of part $i$, and that $E[R_i] = c/2$. For every fixed $i \in [k]$, by the Chernoff bound,

$$\Pr[R_i \notin \lbrack c/4,c\rbrack] \leq 2e^{-c/16}.$$ 

Thus, by the union bound over $i \in [k]$ and per our assumption $c \geq 50 \log m$, we have that except for probability $1/4$, for every $i \in [k]$, $R_i \in [c/4,c]$.

Now, we would want to claim that this partition satisfies the third condition, meaning that for every $p \in P^2$ and $\ell \in \mathcal{X}$, $|p \cap \ell| \leq 1$. However, with high probability, this property in fact does not hold. To fix this, we make a slight modification to the random partition above so that it does satisfy the requirement. The change, is simply, given a partition - whenever there is a “collision” on a line $\ell \in \mathcal{X}$, meaning that for some distinct $p,r \in \ell$, $C_p = C_r$, assign new and distinct parts to both $p$ and $r$. To analyze the number of additional parts we need, we introduce the following notation. For $\ell \in \mathcal{X}$ let

$$\nu(\ell) = \{\{p,r\} \mid p,r \in \ell \text{ and } p \neq r\}.$$ 

For $v = \{p,r\} \in \nu(\ell)$ define $\|v\|_{\ell}$ to be an indicator for the event that $C_p = C_r$. With this notation, the number of collisions is bounded by $\sum_{\ell \in \mathcal{X}} \sum_{v \in \nu(\ell)} \|v\|_{\ell}$. It holds that

$$\mathbb{E} \left[ \sum_{\ell \in \mathcal{X}} \sum_{v \in \nu(\ell)} \|v\|_{\ell} \right] = 2m \left( \begin{array}{c} m \\ 2 \end{array} \right) \frac{1}{k} \leq \frac{mc}{2}.$$
Therefore, by Markov’s inequality, with probability at least 1/2, the number of collisions is less than $mc$. In such case, we can add at most $mc$ parts to the partition and be guaranteed that for every $p \in P^2$ and $\ell \in \mathcal{X}$, $|p| \cap \ell \leq 1$. Recall that since, prior to the procedure above, every part has size at least $c/4$ the total number of parts is now bounded by

$$t \leq mc + \frac{m^2}{c/4} \leq \frac{5m^2}{c},$$

where the last inequality follows as we assume $c \leq \sqrt{m}$.

To conclude the proof, it suffices to show that, with probability larger than $7/8$, it holds that for every $\ell, \ell' \in \mathcal{X}$, $|\ell \cap \ell'| \leq c$. Note that it suffices to prove this with respect to the partition obtained prior to the procedure above since, by introducing new parts of size one each, one only decrease the intersection size we aim to bound from above. Denote by $C_\ell = \{C_p \mid p \in \ell \} \subseteq [k]$. We have that

$$|\ell \cap \ell'| = |\ell \cap \bigcup_{p \in \ell'} \{p\}| \leq 1 + |\{p \in \ell' \setminus \ell \mid C_p \in C_\ell\}|.$$

Now, by the union bound,

$$\Pr[\{C_p \mid p \in \ell\} \subseteq \mathcal{X}] \leq \frac{m}{k} = \frac{c}{2m}.$$

As $\{C_p \mid p \in \ell\}$ are chosen independently, by the Chernoff bound,

$$\Pr[|\{p \in \ell' \setminus \ell \mid C_p \in C_\ell\}| \geq c] \leq e^{-c/6} \leq \frac{1}{m^3},$$

where for the last inequality was used our assumption $c \geq 50 \log m$. The proof then follows by taking the union bound over all $\ell, \ell' \in \mathcal{X}$.

5.2 Explicit constructions

In this section we give explicit constructions of axis-evasive partitions (see Definition 35). Our constructions are based on quadratic field extensions. We identify a set $P$ of size $q$–a prime power–with the finite field $\mathbb{F}_q$ in an arbitrary manner, namely, by using an arbitrary bijection which, for ease of readability, we do not make explicit in the notation. We start by giving some basic background on finite fields.

Let $h(x) \in \mathbb{F}_q[x]$ be a degree 2 irreducible monic polynomial. It is a well-known fact that $\mathbb{F}_q[x]/(h(x))$ is a field of size $q^2$ which we denote, somewhat less informatively, by $\mathbb{F}_{q^2}$. Note that there exists $a \in \mathbb{F}_{q^2}$ such that $h(a) = 0$ (indeed, take $a = x + (h(x))$). Since $h$ is irreducible over $\mathbb{F}_q$ and has degree 2, we can write every element of $\mathbb{F}_{q^2}$ in the form $a + \alpha b$, where $a, b \in \mathbb{F}_q$, in a unique manner. That is, we can identify in the set-theoretic level, $\mathbb{F}_{q^2}$ with $\mathbb{F}_q + \alpha \mathbb{F}_q$. Using this identification, we identify $P^2$ with $\mathbb{F}_{q^2}$ in the natural way, namely, a point $(a, b) \in P^2$ is identified with $a + \alpha b$ in $\mathbb{F}_{q^2}$. Note that, with this identification, the horizontal lines in $P^2$ are of the form $bo + \mathbb{F}_q$ where $b \in \mathbb{F}_q$ can be thought of as the fixed height of the line. Similarly, the vertical lines are given by $b + \alpha \mathbb{F}_q$. Given $\delta \in \mathbb{F}_{q^2} \setminus \{0\}$, we say that $\ell_\delta = \delta \mathbb{F}_q \subseteq \mathbb{F}_{q^2}$ is the line through the origin with slope $\delta$.

Our construction of exis-evasive partitions is based on an equivalence relation that we are about to define. The partition is then obtained by considering the respective equivalence classes. We begin the construction by ignoring the “origin” $0 \in \mathbb{F}_{q^2}$ and work only with $\mathbb{F}_{q^2} \setminus \{0\}$. Note that this is the set of invertible elements of $\mathbb{F}_{q^2}$ which has a group structure under the field multiplication. When referring to this multiplicative group we write $(\mathbb{F}_{q^2})^\times$. 

Let $\beta \in (\mathbb{F}_q^\times)^\times$. Denote by $o(\beta)$ the order of $\beta$ in the multiplicative group $(\mathbb{F}_q^\times)^\times$. It will be convenient to denote $c = o(\beta) - 1$. We define an equivalence relation on $(\mathbb{F}_q^\times)^\times$, parameterized by $\beta$, as follows: For $\gamma, \delta \in (\mathbb{F}_q^\times)^\times$

$$\gamma \sim \delta \iff \gamma \delta^{-1} \in \langle \beta \rangle,$$

where $\langle \beta \rangle$ is the subgroup of $(\mathbb{F}_q^\times)^\times$ that is generated by $\beta$. Observe that this is an equivalence relation. Indeed, the classes are the different cosets, that is, the elements of the quotient group $(\mathbb{F}_q^\times)^\times / \langle \beta \rangle$. For completeness, we quickly prove that this is an equivalence relation: as $1 \in \langle \beta \rangle$, we have that $\gamma \sim \gamma$. Secondly, if $\gamma \delta^{-1} \in \langle \beta \rangle$ then $\delta \gamma^{-1} \in \langle \beta^{-1} \rangle = \langle \beta \rangle$ which establishes symmetry. As for transitivity, if $\gamma \sim \delta$ and $\delta \sim \epsilon$ then

$$\gamma \epsilon^{-1} = \gamma (\delta^{-1} \delta \epsilon^{-1}) = (\gamma \delta^{-1})(\delta \epsilon^{-1}) \in \langle \beta \rangle.$$

One can easily see that the equivalence class of an element $\gamma \in (\mathbb{F}_q^\times)^\times$ is $[\gamma] = \gamma(\beta) = \{\gamma, \beta \gamma, \ldots, \beta^c \gamma\}$. Note further that $|\gamma|| = c + 1$. Indeed, if there are $0 \leq j < i \leq c$ such that $\beta^j \gamma = \beta^i \gamma$ then $0 = (\beta^i - \beta^j) \gamma = (\beta^i - 1) \beta^j \gamma$, which is a contradiction as none of the factors in the product is zero.

In the following claim we show that, under some conditions on $\alpha, \beta$, the second property of axis-evasiveness is met by the construction above. We mention already here that the third condition in Definition 35 is not met by the construction as is (regardless of the choice of $\alpha, \beta$), and we will alter it afterwards to meet that property as well.

**Claim 57.** Assume that $\langle \beta \rangle \cap \ell_\alpha = \langle \beta \rangle \cap \ell_{\alpha-1} = \emptyset$ and that $\langle \beta \rangle \cap \mathbb{F}_q = \{1\}$. Then, for every $\ell, \ell' \in X$ (not necessarily distinct) it holds that $|\ell' \cap (\ell)| \leq c$.

**Proof.** Recall that $\langle \gamma \rangle = \{\beta \gamma, \ldots, \beta^c \gamma\}$. Thus,

$$\bigcup_{\gamma \in \ell} \langle \gamma \rangle = \bigcup_{\gamma \in \ell} \bigcup_{i=1}^c \{\beta^i \gamma\} = \bigcup_{i=1}^c \beta^i \ell.$$

Therefore,

$$\ell' \cap (\ell) = \ell' \cap \bigcup_{\gamma \in \ell} \langle \gamma \rangle = \bigcup_{i=1}^c (\ell' \cap \beta^i \ell).$$

(5.2)

Fix $i \in [c]$ and consider two cases. First, if $\ell$ is vertical, namely, $\ell = b + \alpha \mathbb{F}_q$ for some $b \in \mathbb{F}_q$, then $\beta^i \ell = b \alpha^i + \alpha \beta^i \mathbb{F}_q$. Since, by assumption, $\langle \beta \rangle \cap \mathbb{F}_q = \{1\}$ we have that $\alpha \beta^i \mathbb{F}_q \neq \alpha \mathbb{F}_q$ and so the line $\beta^i \ell$ is not vertical. As, by assumption, $\langle \beta \rangle \cap \ell_{\alpha-1} = \emptyset$, we have that $\alpha \beta^i \not\in \mathbb{F}_q$ and so the line $\beta^i \ell$ is not horizontal either.

Second, consider the case that $\ell$ is horizontal $\ell = ba + \mathbb{F}_q$ for some $b \in \mathbb{F}_q$. Then, $\beta^i \ell = ba \beta^i + \beta^i \mathbb{F}_q$. Per our assumption that $\langle \beta \rangle \cap \ell_{\alpha} = \emptyset$, we have that $\beta^i \mathbb{F}_q \neq \alpha \mathbb{F}_q$ and so the line $\beta^i \ell$ is not vertical. As we assume $\langle \beta \rangle \cap \mathbb{F}_q = \{1\}$, we have that $\beta^i \mathbb{F}_q \neq \mathbb{F}_q$, and so the line $\beta^i \ell$ cannot be horizontal either. To summarize, we have that $\beta^i \ell \not\in X$. However, $\ell' \in X$ and so $\beta^i \ell$ and $\ell'$ are two distinct lines. As such, the two lines intersect in at most one point. Equation (5.2) then yield $|\ell' \cap (\ell)| \leq c$.

Informal discussion regarding the third property

As mentioned above, the partition of $(\mathbb{F}_q^\times)^\times$ as defined above does not have the third property required for axis-evasiveness. Namely, there are $\gamma \in (\mathbb{F}_q^\times)^\times$ such that $[\gamma]$ intersects some axis-parallel line at more than one point. To get some idea on which equivalence classes
We first observe that two points \( \delta, \varepsilon \in (\mathbb{F}_q)^2 \) are on a common axis-parallel line if and only if \( \delta - \varepsilon \in \{1, \alpha\} \mathbb{F}_q \). Thus, \( \gamma \) and \( \beta \gamma \) are on the same axis-parallel line if and only if \( \gamma - \beta \gamma = (1 - \beta) \gamma \in \{1, \alpha\} \mathbb{F}_q \). This is equivalent to saying that \( \gamma \) is on one of the two lines through the origin with slopes \( \frac{1}{1-\beta}, \frac{\alpha}{1-\beta} \).

More generally, \([\gamma]\) intersects with some axis-parallel line in more than one point if and only if \( \beta^i \gamma - \beta^j \gamma \in \{1, \alpha\} \mathbb{F}_q \) for some \( 0 \leq j < i \leq c \). Equivalently, \( \gamma \) is on a line \( \ell_\delta \) with

\[
\delta \in \left\{ \frac{1}{\beta^i - \beta^j}, \frac{\alpha \beta^k}{\beta^i - \beta^j} \mid 0 \leq j < i \leq c \right\}. 
\tag{5.3}
\]

The key observation is that although there are a fair amount of “bad” points \( \gamma \), they are all contained in a small number of lines. By “small” here we mean that the number is polynomial in \( c \) and is independent of \( q \). Thus, the hope is that by redefining the partition on these few problematic lines we will not harm the previous analysis by much. Indeed, no matter how we alter the partition restricted to these lines, if we make sure none of them is axis-parallel (by requiring more properties from \( \alpha, \beta \)) then each of these lines intersect an axis-parallel line at one point. As a result, the bound obtained in Claim 57 will deteriorate proportionally to the number of lines above.

The only small technical issue is that even if \( \gamma \in \ell_\delta \) for some slope \( \delta \) as above, it is not the case that \([\gamma] \subseteq \bigcup \ell_\varepsilon \) where \( \varepsilon \) is taken from the set of slopes given by Equation (5.3). As we wish to alter the partition defined above, it would be cleaner to have all of the points in \([\gamma]\) of a problematic point \( \gamma \) contained in the set of points on which we redefine the partition. Thus, we “close” the set of slopes given by Equation (5.3) to multiplication by \( \beta \).

Ending the informal discussion and returning to the formal analysis, we consider the set of slopes.

\[
\Delta = \left\{ \frac{\beta^k}{\beta^i - \beta^j}, \frac{\alpha \beta^k}{\beta^i - \beta^j} \mid 0 \leq j < i \leq c \text{ and } 0 \leq k \leq c \right\}.
\tag{5.4}
\]

Further define the set of all points in \((\mathbb{F}_q)^2\) covered by the lines with slopes from \( \Delta \) by

\[
U = \bigcup_{\delta \in \Delta} \ell_\delta.
\]

This definition of \( \Delta \) indeed fixes the technical caveat discussed above, as the following claim states.

\[\textbf{Claim 58.} \text{ For every } \gamma \in (\mathbb{F}_q)^2 \text{ either } [\gamma] \subseteq U \text{ or } [\gamma] \cap U = \emptyset.\]

\textbf{Proof.} If an element \( \varepsilon \in U \) then \( \varepsilon \in \ell_\delta \) for some \( \delta \in \Delta \). Note that \( \beta \varepsilon \in \ell_{\beta \delta} \) and that \( \beta \delta \in \Delta \). Hence, \( \beta \varepsilon \in U \). Therefore, \( \varepsilon \in U \implies \varepsilon(\beta) \subseteq U \). Assume now that \([\gamma] \cap U \neq \emptyset \), and take \( \gamma \beta^i \in U \). By the above, \( \gamma \beta^i(\beta) \subseteq U \). The proof then follows as \( \gamma \beta^i(\beta) = \gamma(\beta) = [\gamma] \).

Define a new partition of \( \mathbb{F}_q^2 \) (including 0) which agrees with the one that is given by Equation (5.1) on \( \mathbb{F}_q^2 \setminus U \). By Claim 58, this is well-defined. The new partition, restricted to \( U \), is done as follows. Let \( \delta_0 \in \Delta \) be an arbitrary element. Note that

\[
U = \ell_{\delta_0} \cup \bigcup_{\delta \in \Delta \setminus \{\delta_0\}} (\ell_\delta \setminus \{0\})
\]

is a disjoint union. To partition \( U \), we partition \( \ell_{\delta_0} \) as well as each of \( \ell_\delta \setminus \{0\} \) where \( \delta \in \Delta \setminus \{\delta_0\} \) in an arbitrary way provided it has the least number of parts under the conditions that each part has size at most \( c + 1 \). For ease of readability, we denote by \([\gamma]\) the class with respect to the new partition.
Claim 59. Assume, on top of the assumptions of Claim 57 that for every $\delta \in \Delta$, $\ell_\delta \not\in \mathcal{X}$. Then, the new partition defined above is $(c, 4c^2)$-axis evasive.

Proof. First, observe that by construction, every class intersects any axis-parallel line in at most one point. Indeed, classes that are outside of $U$ have this property by the definition of $U$ as can be easily verified (and discussed above). Moreover, by the way we redefined the partition restricted to $U$, every class that is a subset of $U$ is also a subset of a line $\ell_\delta$ for some $\delta \in \Delta$. As $\ell_\delta \not\in \mathcal{X}$ by hypothesis, we have that the line and, as a result, the class it contains, intersects any axis-parallel line in at most one point. This establishes the third property of axis-evasiveness. The second property follows as, by construction, every part has size at most $c + 1$.

Moving on to the second property, consider $\ell, \ell' \in \mathcal{X}$, not necessarily distinct. As outside of $U$ the partition is defined as before, Claim 58 yields

$$\left| \ell' \cap \bigcup_{\gamma \in \ell \cap U} (\gamma) \right| \leq c.$$ (5.5)

Take $\gamma \in U \cap \ell$. Since, by construction $(\gamma) \subseteq \ell_\delta$ for some $\delta \in \Delta$, and since by hypothesis $\ell_\delta \not\in \mathcal{X}$ we have that $|\ell' \cap \ell_\delta| = 1$ and $(\gamma) \cap \ell' \subseteq \ell_\delta \cap \ell'$. Therefore, $|\gamma \cap \ell'| \leq 1$. Together with Equation (5.5) we get that $|\ell' \cap (\ell)| \leq c + |U \cap \ell|$. Now, since $\ell \in \mathcal{X}$ and every line $\ell_\delta$ with slope $\delta \in \Delta$ is not in $\mathcal{X}$ we have that $|\ell \cap \ell_\delta| = 1$. Thus, $|U \cap \ell| \leq |\Delta|$ which implies $|\ell' \cap (\ell)| \leq c + |\Delta|$.

To conclude the proof, we turn to bound $|\Delta|$. It is straightforward to give a bound of $O(c^3)$ though one can optimize the bound a bit. Indeed, with the notation of Equation (5.4), by multiplying by $\beta^{-\min(j, k)}$, one can rewrite

$$\Delta = \left\{ \frac{1}{\beta^j - \beta^k} \frac{\alpha}{\beta^i - \beta} \bigg| 0 < j < i \leq c \right\} \bigcup \left\{ \frac{\alpha \beta^j}{\beta^i - 1} \frac{\alpha^j}{\beta^i - 1} \bigg| 0 < i \leq c, 0 \leq j \leq c \right\}. (5.6)$$

Thus, $|\Delta| \leq 3c^2$, and the proof follows. \hfill $\triangle$

We summarize the discussion so far.

Proposition 60. Let $\mathbb{F}_q$ be finite field. Let $h(x) \in \mathbb{F}_q[x]$ be a degree 2 irreducible monic polynomial, and consider the field $\mathbb{F}_q[x]/\langle h(x) \rangle$ which we denote by $\mathbb{F}_{q^2}$. Let $\alpha, \beta \in \mathbb{F}_{q^2}$ be two elements satisfying:

1. $h(\alpha) = 0$,
2. $\langle \alpha \rangle \cap \mathbb{F}_q = \{1\}$,
3. $c + 1 = o(\beta) \leq \sqrt{q}/10$,
4. $\langle \beta \rangle \cap \ell_\alpha = \langle \beta \rangle \cap \ell_{\alpha-1} = 0$,
5. $(\langle \beta \rangle - \langle \beta \rangle) \cap \mathbb{F}_q = \{0\}$,
6. $(\langle \beta \rangle - \langle \beta \rangle) \cap \ell_\alpha = (\langle \beta \rangle - \langle \beta \rangle) \cap \ell_{\alpha-1} = \{0\}$.

Then, there exists a partition of $(\mathbb{F}_{q^2})^2$ that is $(c, 4c^2)$-axis-evasive, where $c = o(\beta) - 1$. The number of parts in the partition is bounded above by $2q^2/(c + 1)$.

To prove Proposition 60 we need the following easy claim.

Claim 61. Let $\delta \in (\mathbb{F}_{q^2})^2$ be such that $\delta \not\in \mathbb{F}_q \cup \ell_\alpha$ then, $\ell_\delta \not\in \mathcal{X}$.

Proof. Write $\delta = a + \alpha b$ with $a, b \in \mathbb{F}_q$. Then, $\ell_\delta = (a + \alpha b)\mathbb{F}_q$. Observe that if $\ell_\delta$ is vertical then $a = 0$ and so $\delta \in \ell_\alpha$. Similarly, if $\ell_\delta$ is horizontal then $b = 0$ implying $\delta \in \mathbb{F}_q$. \hfill $\triangle$
**Proof of Proposition 60.** To bound the number of parts, recall that in the original partition, each part has size $c + 1$. Moreover, in the altered partition we partition each line $\ell_\delta$ with slope $\delta \in \Delta$ (excluding the origin from all but for one of the lines $\ell_\delta$) to parts of size $c + 1$ each, except for possibly one part. As $|\Delta| \leq 3c^2$, the number of parts it bounded by

$$\frac{q^2 - 1}{c + 1} + |\Delta| \left(1 + \frac{q}{c + 1}\right) \leq \frac{q^2 - 1}{c + 1} + 6cq \leq \frac{2q^2}{c},$$

where the last inequality follows by our assumption that $o(\beta) \leq \sqrt{q}/10$.

To conclude the proof of the proposition, it suffices to show that for every $\delta \in \Delta$ it holds that $\ell_\delta \notin \mathcal{X}$. By Claim 61, it suffices to prove that $\delta \notin \mathbb{F}_q \cup \ell_a = \{1, \alpha\}\mathbb{F}_q$. There are two types of slopes $\delta \in \Delta$, according to whether they appear in the first or second set in Equation (5.6). The first kind is of the form

$$\delta = \frac{\alpha^k}{\beta^i - \beta^j},$$

with $0 < j < i \leq c$ and $k \in \{0, 1\}$. If $\delta \in \{1, \alpha\}\mathbb{F}_q$ then $\delta^{-1} \in \{1, \alpha^{-1}\}\mathbb{F}_q$ and so $\beta^i - \beta^j \in \{\alpha^k, \alpha^{k-1}\}\mathbb{F}_q$ in contradiction to our hypothesis. Consider now the other kind of slope

$$\delta = \frac{\alpha^k \beta^i}{\beta^j - 1}$$

where $0 < i \leq c$, $0 \leq j < c$ and $k \in \{0, 1\}$. If $\delta \in \{1, \alpha\}\mathbb{F}_q$ then $\delta^{-1} \in \{1, \alpha^{-1}\}\mathbb{F}_q$ and so $(\beta^i - 1)\beta^{-j} \in \{\alpha^k, \alpha^{k-1}\}\mathbb{F}_q$. Note that $(\beta^i - 1)\beta^{-j} = \beta^{-j} - \beta^{-j} \in \langle \beta \rangle - \langle \beta \rangle$ and so we again get a contradiction. $\blacktriangleleft$

We are now ready to prove Theorem 47. For the sake of readability, we repeat its statement here.

\textbf{Theorem 62.} Let $P$ be a set of size $q$, where $q$ is an odd prime power. Let $c$ be an even integer such that $c + 1 \mid q + 1$, and $c \leq \sqrt{q}/10$. Then, there exists a $(c, 4c^2)$-axis evasive partition of $P^2$ with at most $2q^2/(c + 1)$ parts.

\textbf{Proof.} As above, we identify $P^2$ with $\mathbb{F}_q^2$. It is a well-known fact that the multiplicative group $(\mathbb{F}_q)^\times$ is cyclic. A basic result in group theory states that a cyclic group has a (unique) subgroup of every given size which divides the group size. Now, $|(\mathbb{F}_q^\times)| = q^2 - 1 = (q - 1)(q + 1)$. Thus, as $c + 1 \mid q + 1$, there exists a subgroup $H$ of $(\mathbb{F}_q^\times)^\times$ of size $c + 1$. The subgroup $H$ is cyclic, being a subgroup of a cyclic group. Let $\beta$ be a generator for $H$. We first prove that $\beta$ satisfies those hypothesis of Proposition 60 that do not involve $\alpha$, namely, conditions (2) and (5).

\textbf{Claim 63.} $(\langle \beta \rangle - \langle \beta \rangle) \cap \mathbb{F}_q = \{0\}$ and $\langle \beta \rangle \cap \mathbb{F}_q = \{1\}$.

\textbf{Proof.} Assume towards a contradiction that $\beta^i - \beta^j \in \mathbb{F}_q$ for some $0 \leq j < i \leq c$. Since $x^q = x$ for every $x \in \mathbb{F}_q$, we get

$$\beta^i - \beta^j = (\beta^i - \beta^j)^q = \beta^{iq} - \beta^{jq},$$

where the last equality follows since $q$ is divisible by the characteristic of the field. Recall that $o(\beta) = c + 1 \mid q + 1$ and so $\beta^{(q+1)} = 1$, implying $\beta^q = \beta^{-i}$. Thus,

$$\beta^i - \beta^j = \frac{1}{\beta^j} - \frac{1}{\beta^j} = \frac{\beta^i}{\beta^i} = \frac{\beta^i - \beta^i}{\beta^i}.$$
As $\beta^i \neq \beta^j$ the above equation implies $\beta^{i+j} = -1$, and so $-1 \in H$. Since $q$ is odd, the characteristic of the field $\mathbb{F}_q$ is odd and so $o(-1) = 2$. Lagrange’s Theorem then implies that $2 \mid |H| = c + 1$, which stands in contradiction to $c$ being even.

To prove that $(\beta) \cap \mathbb{F}_q = \{1\}$, take $\beta^i$ with $0 < i \leq c$. If $\beta^i \in \mathbb{F}_q$ then $\beta^{2i} = \beta^i$. On the other hand, we proved above that $\beta^{2i} = -\beta^i$, and so $\beta^i = \beta^{-i}$ implying $\beta^{2i} = 1$. Therefore, $o(\beta) = c + 1 \mid 2i$, but this is impossible as $0 < i \leq c$ and, recall, $c$ is even.

We proceed with the proof of Theorem 47 by finding $\alpha \in \mathbb{F}_{q^2}$ that, together with the already chosen $\beta$, satisfies the remaining conditions in the hypothesis of Proposition 60. Since $\mathbb{F}_{q^2}$ is a quadratic field extension of $\mathbb{F}_q$, every element $\gamma \in \mathbb{F}_{q^2} \setminus \mathbb{F}_q$ has degree 2. That is, the minimal polynomial $h_\gamma$ of every such $\gamma$ over $\mathbb{F}_q$ is of degree 2 (and can be made monic by dividing by the leading coefficient, if necessary). Indeed, $\deg(h_\gamma)$ cannot equal 1 as this would imply $\gamma \in \mathbb{F}_q$. On the other hand,

$$2 = [\mathbb{F}_{q^2} : \mathbb{F}_q] = [\mathbb{F}_{q^2} : \mathbb{F}_q(\gamma)]/[\mathbb{F}_q(\gamma) : \mathbb{F}_q] = [\mathbb{F}_{q^2} : \mathbb{F}_q(\gamma)] \deg(h_\gamma),$$

which shows that if $\deg(h_\gamma) \neq 1$ then $\deg(h_\gamma) = 2$.

Thus, condition (1) in the hypothesis of Proposition 60 holds for every element in $\mathbb{F}_{q^2} \setminus \mathbb{F}_q$. Hence, to prove that all the remaining conditions in the hypothesis of Proposition 60 hold, it suffices to prove that there exists $\alpha \in \mathbb{F}_{q^2} \setminus \mathbb{F}_q$ which satisfies conditions (4) and (6). To this end, pick a set of “slopes” $\Delta' = \{\delta_1, \ldots, \delta_{q+1}\} \subseteq (\mathbb{F}_{q^2})^\times$ such that $(\mathbb{F}_{q^2})^\times$ is the disjoint union

$$(\mathbb{F}_{q^2})^\times = \bigcup_{\delta \in \Delta'} (\ell_\delta \setminus \{0\}).$$

For example, $\Delta' = \{a + \alpha \mid a \in \mathbb{F}_q\} \cup \{1\}$ will do. For $\delta \in (\mathbb{F}_{q^2})^\times$ let

$$I_{\delta} = |(\beta) \cap \ell_\delta| + |((\beta) - \langle \beta \rangle) \cap (\ell_\delta \setminus \{0\})|.$$

Since the $\ell_\delta \setminus \{0\}$ with $\delta \in \Delta'$ are disjoint, $0 \notin \langle \beta \rangle$, and since $|\langle \beta \rangle| = c + 1$ and $|\langle \beta \rangle - \langle \beta \rangle| \leq (c + 1)^2$, we have that

$$E_{\delta}[I_{\delta}] \leq \frac{(c + 1)^2 + (c + 1)}{q + 1} \leq \frac{2(c + 1)^2}{q + 1},$$

where $\delta$ is sampled uniformly from $\Delta'$. By Markov’s inequality, for at least 3/4 of the elements $\delta \in \Delta'$ it holds that

$$|I_{\delta}| \leq \frac{8(c + 1)^2}{q + 1}.$$

Note that $(\mathbb{F}_{q^2})^\times$ is also a disjoint union of $\{\ell_{\delta-1} \setminus \{0\} \mid \delta \in \Delta\}$. Thus, using the same argument as above, we get that for at least 1/2 the elements $\delta \in \Delta'$, both $|I_{\delta}|$ and $|I_{\delta-1}|$ are bounded by $8(c + 1)^2/(q + 1)$. But, as $c \leq \sqrt{q}/10$, this bound is strictly smaller than 1, implying that $I_{\delta} = I_{\delta+1-\delta} = 0$. That is, at least half the elements $\delta \in \Delta'$ satisfy conditions (4) and (6). Take $\alpha$ to be any of these elements. To conclude, we found $\alpha$ and $\beta$ for which all the conditions in the hypothesis of Proposition 60 are met, and the proof follows.
Query-efficient distance amplification

In this section we construct our query-efficient distance amplification procedure. We start by giving a somewhat more formal definition of locally decodable codes (compared to Definition 1) or, more precisely, a more formal definition of their non-adaptive counterparts. Recall that, informally, these are LDC in which the joint distribution of queries depends solely on the index one wishes to decode and is independent of the received word. By inspection, it is our understanding that the AEL distance amplification procedure also requires non-adaptivity.

Definition 64 (Locally decodable codes). Let $(C, Q, R)$ be a tuple of functions

- $C : \Sigma_{in}^k \to \Sigma_{out}^n$,
- $Q : [k] \times \{0, 1\}^r \to [n]^q$,
- $R : [k] \times \Sigma_{out}^q \times \{0, 1\}^r \to \Sigma_{in}$.

Define

$D : [k] \times \Sigma_{out}^q \times \{0, 1\}^r \to \Sigma_{in}$

as follows. For $v \in [k]$, $y \in \Sigma_{out}^q$, and $s \in \{0, 1\}^r$, let

- $Q(v, s) = (u_1, \ldots, u_q)$,
- $D(v, y, s) = R(v, y_{u_1}, \ldots, y_{u_q}, s)$.

The tuple $(C, Q, R)$ is called a $(q, \delta, \varepsilon)$-locally decodable code (or $(q, \delta, \varepsilon)$-LDC for short) if the following holds. For every $v \in [k]$, $x \in \Sigma_{in}^k$, and $y \in \Sigma_{out}^q$ for which $\text{dist}(y, C(x)) \leq \delta$, it holds that

$$\Pr_{s \sim_U} [D(v, y, s) = x_v] \geq 1 - \varepsilon.$$

We call the function $C$ the encoding function, $Q$ the querying function, and $R$ the reconstruction function. The induced function $D$ is called the decoding function. The parameters $k, n$ are referred to as the message length and the block length, respectively. The sets $\Sigma_{in}, \Sigma_{out}$ are called the input alphabet and output alphabet, respectively. We will be interested mostly in locally decodable codes in which $\Sigma_{in} = \Sigma_{out}$ in which case we refer to both as the alphabet of the code. The parameter $r$ is called the randomness complexity of the LDC. We say the LDC is explicit if all three functions $C, Q, R$ are polynomial-time computable. Note that then the decoding function $D$ is also polynomial-time computable.

6.1 The distance amplification procedure

In this section we present our query-efficient distance amplification procedure. We start by describing the building blocks we use and specify their parameters.

Building blocks

- For $i = 1, 2$ let $(C_i, Q_i, R_i)$ be a $(q_i, \delta_i, \varepsilon_i)$-LDC with message length $k_i$ and block length $n_i$ over the same alphabet $\Sigma$. We denote the rate $k_i/n_i$ of $C_i$ by $\rho_i$.
- Let $(C_3, Q_3, R_3)$ be a family of $(q_3(k_3), \delta_3(k_3), \varepsilon_3(k_3))$-LDC having rate $\rho_3(k_3)$ for message length $k_3$. The code $C_3$ is also over the alphabet $\Sigma$. We will always work with functions $q_3, \delta_3, \varepsilon_3, \rho_3$ that are monotone. More precisely, $q_3$ and $\rho_3$ are non-decreasing and $\delta_3, \varepsilon_3$...
are non-increasing. We sometimes write \( q_3, \delta_3, \varepsilon_3, \rho_3 \) without mentioning explicitly the message length, and by that refer to the largest \( k_3 \) considered in the construction for \( q_3, \delta_3 \) and the smallest \( k_3 \) when considering \( \varepsilon_3, \rho_3 \). In any case, we assume (mostly for simplicity) that \( \rho_3(k_3) \geq 1/2 \) for all \( k_3 \).

- Set \( \ell = n_1/k_2 \). Let \( G = (L, R, E) \) be a \((\delta_2/2, \delta_1)\)-sampler with \(|L| = \ell\) and \(|R| = r\).
  Assume \( G \) is left-regular with left-degree \( d = n_2 \). Assume further that every right-vertex \( v \) of \( G \) has degree \( \deg(v) \in [D/2, 2D] \), where \( D \) is the average right degree \( D = \ell d/r = n_1/(r \rho_2) \).

**How to think of the parameters?**

We think of \( C_1 \) as the code whose distance \( \delta_1 \) we wish to amplify. Typically, the code \( C_2 \) has a much shorter message length \( n_2 \ll n_1 \). In all applications in this paper we take \( \delta_2 \) to be either constant or slightly sub constant in \( n_1 \). The code \( C_3 \) has a larger block length than \( C_2 \) and, depending on the application, it has either a somewhat smaller or much smaller message length than \( n_1 \). We typically take \( \delta_3 \approx \delta_2 \). The rates of all three codes is taken to be constant and even close to one. Note that we take \( C_3 \) to be a family of codes, whereas \( C_1 \) and \( C_2 \) are codes with predetermined message lengths. The reason is that the sampler \( G \) is not necessarily right-regular, and in the construction, we associate codes from \( C_3 \) with the right vertices of \( G \). Recall, though that the ratio of largest to smallest right-degree is bounded by 4, so that is a minor technicality.

To describe the LDC that is composed of these building blocks, we need to specify the encoding function, querying function and reconstruction function. We start by describing the encoding function.

**The encoding function**

Let \( n = \sum_{v \in R} n_v \) where \( n_v \) is the block length of the code from the family \( C_3 \) having message length \( k_v = \deg(v) \). We define the function \( C : \Sigma^{k_1} \rightarrow \Sigma^n \) as follows. Let \( x \in \Sigma^{k_1} \).

1. Compute \( y = C_1(x) \in \Sigma^{n_1} \).
2. Partition \( y \) to \( y = y^{(1)} \circ \cdots \circ y^{(\ell)} \) consecutive blocks, each of length \( k_2 \). Recall that, indeed, \( n_1 = \ell k_2 \).
3. For every \( u \in [\ell] \) compute \( z^{(u)} = C_2(y^{(u)}) \in \Sigma^{n_2} \).
4. For every \( v \in [r] \) and \( j \in [\deg(v)] \) let \((u, j') = \Gamma(v, j) \in [\ell] \times [n_2] \). Define the string \( w^{(v)} \in \Sigma^{\deg(v)} \subseteq \Sigma^{k_3} \) as follows: for \( j \in [\deg(v)] \), \((w^{(v)})_j = (z^{(u)})_{j'} \).
5. For every \( v \in [r] \) compute \( t^{(v)} = C_3(w^{(v)}) \in \Sigma^{n_3} \).
6. The output of the encoding function on input \( x \) is then defined by \( C(x) = t^{(1)} \circ \cdots \circ t^{(r)} \in \Sigma^n \), where as usual we identify \( R \) with \([r] \).

By the construction of the encoding function, the message length and block length of the resulted code are \( k_1 \) and \( n \), respectively. From here on we denote \( k = k_1 \).

**The querying function**

We denote the randomness complexity of \( C_1, C_2, C_3 \) by \( r_1, r_2, r_3 \), respectively. The randomness complexity of the resulting querying function will be \( r = r_1 + r_2 + r_3 \), and the query complexity will be \( q \leq q_1 q_2 q_3 \), where \( q_3 \) is taken to be the maximum query complexity taken over all right vertices. We turn to define the querying function \( Q : [k] \times \{0, 1\}^r \rightarrow [n]^q \) as follows. On inputs \( p \in [k], s \in \{0, 1\}^r \) we proceed as follows.
1. Partition $s = s_1 \circ s_2 \circ s_3$ where $|s_1| = r_1$, $|s_2| = r_2$, $|s_3| = r_3$.
2. Compute $(a_1, \ldots, a_{q_1}) = Q_1(p, s_1) \in [n_1]^{q_1}$.
3. For $i = 1, \ldots, q_1$
   a. Set $u_i = \lfloor a_i/k_2 \rfloor$ and $b_i = 1 + ((a_i - 1) \mod k_2)$. Informally, $u_i$ is the “bucket” in which $a_i$ resides and $b_i$ is its location within the bucket. Note that we start the counting from 1 rather than 0, hence the slightly annoying addition and subtraction by 1 in the definition of $b_i$.
   b. Compute $(i_1^{(i)}, \ldots, i_{q_2}^{(i)}) = Q_2(b_i, s_2) \in [n_2]^{q_2}$.
   c. For $j = 1, \ldots, q_2$
      i. Set $(u^{(i,j)}, t_j^{(i)}) = \Gamma(u_i, t_j^{(i)}) \in [r] \times [k_{u^{(i,j)}}]$.
      ii. Compute $(e_1^{(i,j)}, \ldots, e_{q_3}^{(i,j)}) = Q_3(\tilde{t}_j^{(i)}, s_3) \in [n_{v^{(i,j)}}]^{q_3}$.
      iii. As before, we endow the right vertices of the sampler in a fixed (arbitrary) order by identifying $R$ with $[r]$. For $h = 1, \ldots, q_3$ set $e_{t_h}^{(i,j)} = e_h^{(i,j)}$ to be the absolute location of $u^{(i,j)}$ in the ordering of $R$. That is, $e_h^{(i,j)} = e_h^{(i,j)} + \sum_{v < v^{(i,j)}} n_v$.
4. The result is then given by $Q(p, s) = (e_1^{(i,j,h)})_{(i,j,h) \in [q_1] \times [q_2] \times [q_3]}$.

Note that, indeed, the query complexity $q$ of the querying function defined above is at most $q_1 q_2 q_3$ where, recall, $q_3 = q_3(2D)$. From here on we identify $[q]$ with $[q_1] \times [q_2] \times [q_3]$.

The reconstruction procedure

We define the reconstruction procedure $R : [k] \times \Sigma^q \times \{0, 1\}^r \to \Sigma$ as follows. On inputs $p \in [k], \sigma = (\sigma^{(i,j,h)})_{(i,j,h) \in [q_1] \times [q_2] \times [q_3]} \in \Sigma^q$, and $s \in \{0, 1\}^r$, we proceed as follows.

1. Partition $s = s_1 \circ s_2 \circ s_3$ where $|s_1| = r_1$, $|s_2| = r_2$, $|s_3| = r_3$ as in the querying function.
2. For $i = 1, \ldots, q_1$
   a. For $j = 1, \ldots, q_2$
      i. Denote $(z_1, \ldots, z_{q_3}) = (\sigma^{(i,j,1)}, \ldots, \sigma^{(i,j,q_3)})$.
      ii. Compute $y_j^{(i)} = R_3(\tilde{t}_j^{(i)}, z_1, \ldots, z_{q_3}, s_3)$, where $\tilde{t}_j^{(i)} = t_j^{(i)}(p, s)$ as defined in the querying function.
   b. Set $x_i = R_2(b_i, y_1^{(i)}, \ldots, y_{q_2}^{(i)}, s_2)$ where $b_i = b_i(p, s)$ as defined in the querying function.
3. The output is then given by $R(p, \sigma, s) = R_1(p, x_1, \ldots, x_{q_1}, s_1)$.

6.2 Analysis

In this section we analyze the LDC obtained above. We prove

**Proposition 65.** With the notation of the previous section, $C$ is a $(q, \delta, \varepsilon)$-LDC, where

$q \leq q_1 q_2 q_3$,

$\delta \geq \frac{\delta_2 \delta_3}{16}$,

$\varepsilon \leq \varepsilon_1 + (\varepsilon_2 + \varepsilon_3)n$.

Furthermore, $C$ has rate $\rho_1 \rho_2 \rho_3$, where $\rho_1, \rho_2$ are as defined in the building blocks paragraph, and per our convention set above, $\rho_3 = \rho_3(D/2)$.
Remark regarding the distance

Note that the distance $\delta$ of the resulted code $C$ is independent of $\delta_1$, the poor distance of $C_1$ we set out to amplify. This is the key feature of the AEL distance amplification procedure (which our variant above, of course, maintains). It is yet another instance of a general strategy in pseudo-randomness that combines objects in such a way that the resulted object enjoys the upsides of the different parts and avoid their shortcomings. The Zig-Zag product is another classic example. But, of course, $\delta_1$ has some effect on the resulted code. The effect $\delta_1$ has on the code is via the query complexity. Indeed, as the analysis will show, the smaller $\delta_1$ is (i.e., the weaker the guarantee we have on the distance of $C_1$), the larger $k_2 = k_2(\delta_1)$ and $k_3 = k_3(\delta_1)$ must be, with a far stronger effect on $k_3$. More quantitatively, roughly speaking, by taking a sufficiently good sampler (e.g., the one that is given by Theorem 15), $k_2 \approx \text{poly log}(1/\delta_1)$ and $k_3 \approx \text{poly}(1/\delta)$. This, in turn, affects the query complexities $q_2 = q_2(k_2)$ and $q_3 = q_3(k_3)$.

Proof. That the query complexity is $q \leq q_1q_2q_3$ readily follows by the querying function, where recall that per our convention $q_1 = q_1(2D)$. To analyze the rate, recall that $\rho_3$ is a non-decreasing function. Further, our convention dictates that by writing $\rho_3$ without explicitly mentioning the message length, we refer to $\rho_3$ applied with the smallest message length taken by the construction, namely, $\rho_3 = \rho_3(D/2)$. Thus,

$$n = \sum_{v \in R} n_v = \sum_{v \in R} \frac{k_v}{\rho_3(k_v)} \leq \frac{1}{\rho_3} \sum_{v \in R} k_v = \frac{\ell n_2}{\rho_3} = \frac{n_1}{\rho_2 \rho_3}.$$ 

Recall that $k = k_1 = \rho_1 n_1$ which shows that $\rho = k/n \geq \rho_1 \rho_2 \rho_3$.

We turn to analyze the distance $\delta$ and error $\varepsilon$. Let $x \in \Sigma^k$ and let $\bar{C}(x) \in \Sigma^n$ be such that $\text{dist}(\bar{C}(x), C(x)) \leq \delta$. Define the set of “errors”, namely, the disagreements between $C(x)$ and $\bar{C}(x)$ by

$$B = \{ i \in [n] \mid \bar{C}(x)_i \neq C(x)_i \}.$$ 

By assumption, $\mu(B) \leq \delta$. The error set $B$ induces errors “backwards” throughout the construction. We proceed by analyzing these induced errors. Recall that, in the encoding function, we defined for each $v \in [r]$ an element $t^{(v)} = t^{(v)}(x) \in \Sigma^{n_v}$. Partition $\bar{C}(x)$ to $r$ substrings $\bar{C}(x) = \bar{t}^{(1)} \circ \cdots \circ \bar{t}^{(r)}$, where $\bar{t}^{(v)}$ has length $n_v$, and define the set

$$B_v = \{ v \in [r] \mid \text{dist}(t^{(v)}, \bar{t}^{(v)}) \geq \delta_3 \}.$$ 

Informally, $v \in B_v$ if the adversary has introduced too many errors on the respective block to allow for correct decoding via $D_3$.

$\triangleright$ Claim 66. $\mu(B_v) \leq 8\delta/\delta_3$.

Proof. For $v \in R$ let $\epsilon_v = \text{dist}(t^{(v)}, \bar{t}^{(v)})$. We have that $\sum_{v \in R} \epsilon_v n_v \leq \delta n$. On the other hand,

$$\sum_{v \in R} \epsilon_v n_v \geq \delta_3 \sum_{v \in B_v} n_v \geq \frac{\delta_3 D|B_v|}{2}.$$ 

But, per our assumption that $\rho_3 \geq 1/2$, and since $k_v \leq 2D$ for all $v \in R$,

$$n = \sum_{v \in R} n_v \leq 2 \sum_{v \in R} k_v \leq 4Dr.$$ 

The proof follows by the above three inequalities. $\triangleright$
For convenience we also denote $B_w = B_t$. Next, we define

$$B_z = \{ u \in [\ell] \mid |\Gamma(u) \cap B_w| \geq \delta_2 n_2 \}. \tag{6.1}$$

\indent \textbf{Claim 67.} $\mu(B_z) \leq \delta_1$.

\textbf{Proof.} By Claim 66 and by our assumption on $\delta$,

$$\mu(B_w) \leq \frac{8\delta}{\delta_3} = \frac{\delta_2}{2},$$

Recall that $G$ is a $(\delta_2/2, \delta_1)$-sampler. Thus, at most $\delta_1$-fraction of the left vertices $u \in [\ell]$ satisfy $\mu(\Gamma(u) \cap B_w) \geq \mu(B_w) + \delta_2/2$. The proof then follows since $\mu(B_w) \leq \delta_2/2$. $\triangleright$

Lastly, define

$$B_y = \left\{ a \in [n_1] \mid \left\lfloor \frac{a}{k_2} \right\rfloor \in B_z \right\}.$$

For $v \in [r]$, $b \in [k_v]$ we define the function $\tilde{w}_b^{(v)} : \{0,1\}^{r_3} \to \Sigma$ as follows: on input $s_3 \in \{0,1\}^{r_3}$

$$\tilde{w}_b^{(v)}(s_3) = D_3(b, \tilde{\ell}^{(v)}, s_3).$$

\indent \textbf{Claim 68.} There exists a set $\mathcal{E}_3 \subseteq \{0,1\}^{r_3}$ with $\mu(\mathcal{E}_3) \leq \varepsilon_3 n$ such that for every $s_3 \in \{0,1\}^{r_3} \setminus \mathcal{E}_3$, $v \in [r] \setminus B_t$, and $b \in [k_3]$ it holds that $\tilde{w}_b^{(v)}(s_3) = w_b^{(v)}$.

\textbf{Proof.} Fix $v \in [r] \setminus B_t$. By the definition of $B_t$, one has that $\text{dist}(t^{(v)}, \tilde{\ell}^{(v)}) \leq \delta_3$. By the encoding function, $t^{(v)} = C_3(w^{(v)})$. Therefore, for every $b \in [k_3]$,

$$\Pr_{s_3 \sim U_{s_3}} \left[ D_3(b, \tilde{\ell}^{(v)}, s_3) \neq w_b^{(v)} \right] \leq \varepsilon_3.$$

The proof then follows by taking the union bound over all $v \in [r] \setminus B_t$ and $b \in [k_v]$ as indeed $\sum k_v \leq n$. $\triangleright$

For $(u, j) \in [\ell] \times [n_2]$ we define the function $\tilde{z}_j^{(u)} : \{0,1\}^{r_3} \to \Sigma$ as follows. For $s_3 \in \{0,1\}^{r_3}$ we have $\tilde{z}_j^{(u)}(s_3) = \tilde{w}_j^{(u)}(s_3)$, where $(v, j') = \Gamma(u, j) \in [r] \times [k_v]$. Further define the function $\tilde{z}^{(u)} : \{0,1\}^{r_3} \to \Sigma^{n_2}$ by

$$\tilde{z}^{(u)}(s_3) = \tilde{z}_1^{(u)}(s_3) \circ \cdots \circ \tilde{z}_{n_2}^{(u)}(s_3).$$

\indent \textbf{Claim 69.} For every $u \not\in B_2$ and $s_3 \in \{0,1\}^{r_3} \setminus \mathcal{E}_3$ it holds that \[\text{dist} \left( \tilde{z}^{(u)}(s_3), z^{(u)} \right) \leq \delta_2.\]

\textbf{Proof.} Fix $s_3 \in \{0,1\}^{r_3} \setminus \mathcal{E}_3$ and consider any $u \in [\ell] \setminus B_2$. By the encoding function, for every $j \in [n_2]$ it holds that $\tilde{z}_j^{(u)} = w_j^{(u)}$, where $(v, j') = \Gamma(u, j)$. As $v \not\in B_2$, at most $\delta_2 n_2$ of $j \in [n_2]$ satisfy $v \in B_w$. For every other $j$,

$$\tilde{z}_j^{(u)} = \tilde{w}_j^{(u)}(s_3) = w_j^{(u)} = z_j^{(u)},$$

proving the claim. $\triangleright$
For \( u \in [\ell], a \in [k_2] \) we define the function \( \tilde{y}^{(u)}_{a} : \{0,1\}^{r_2} \times \{0,1\}^{r_3} \rightarrow \Sigma \) as follows. On \((s_2, s_3) \in \{0,1\}^{r_2} \times \{0,1\}^{r_3}\),
\[
\tilde{y}^{(u)}_{a}(s_2, s_3) = D_2(a, \tilde{z}^{(u)}(s_3), s_2).
\]

\[\triangleright\] **Claim 70.** There exists a set \( \mathcal{E}_2 \subseteq \{0,1\}^{r_2} \) with \( \mu(\mathcal{E}_2) \leq \varepsilon_2 n \) such that for every \( u \in [\ell] \setminus B_2 \), \( a \in [k_2] \), and \((s_2, s_3) \in (\{0,1\}^{r_2} \setminus \mathcal{E}_2) \times (\{0,1\}^{r_3} \setminus \mathcal{E}_3) \) it holds that \( \tilde{y}^{(u)}_{a}(s_2, s_3) = y^{(u)}_{a} \).

Proof. Fix \( u \in [\ell] \setminus B_2 \). By the encoding function \( z^{(u)} = C_2(y^{(u)}) \). Recall that \( \tilde{y}^{(u)}_{a}(s_2, s_3) = D_2(a, \tilde{z}^{(u)}(s_3), s_2) \).

As \( s_3 \notin \mathcal{E}_2, u \notin B_2 \), Claim 69 implies \( \text{dist}(\tilde{z}^{(u)}(s_3), z^{(u)}) \leq \delta_2 \). Therefore
\[
\Pr_{s_2 \sim \{0,1\}^{r_2}} \left[ D_2(a, \tilde{z}^{(u)}(s_3), s_2) \neq y^{(u)}_{a} \right] \leq \varepsilon_2.
\]

The proof then follows by taking the union bound over all \( a \in [k_2] \) and \( u \in [\ell] \setminus B_2 \), and noting that \( k_2 \ell = n_1 \leq n \). \( \triangleright \)

\[\triangleright\] **Claim 71.** For every \((s_2, s_3) \in (\{0,1\}^{r_2} \setminus \mathcal{E}_2) \times (\{0,1\}^{r_3} \setminus \mathcal{E}_3) \), it holds that
\[
\text{dist}(\tilde{y}(s_2, s_3), y) \leq \delta_1,
\]
where \( \tilde{y}(s_2, s_3) \) is the concatenation of the \( k_2 \)-length strings \((\tilde{y}^{(u)}(s_2, s_3) | u \in [\ell])\).

Proof. Note that by Claim 70, the projection of the two strings \( \tilde{y}(s_2, s_3), y \) to a block corresponding to \( u \notin B_2 \) are in full agreement. The proof then follows by Claim 67. \( \triangleright \)

We now conclude the proof of Proposition 65. Let \( p \in [k] \), by Claim 71, for every \((s_2, s_3) \in (\{0,1\}^{r_2} \setminus \mathcal{E}_2) \times (\{0,1\}^{r_3} \setminus \mathcal{E}_3) \), we have that \( \text{dist}(\tilde{y}(s_2, s_3), y) \leq \delta_1 \). Since by the encoding function \( y = C_1(z) \), it holds
\[
\Pr_{s_1 \sim \{0,1\}^{r_1}} [ D_1(p, \tilde{y}(s_2, s_3), s_1) \neq x_p ] \leq \varepsilon_1.
\]

The proof then follows since \( \mu(\mathcal{E}_2) \leq \varepsilon_2 n \) and \( \mu(\mathcal{E}_3) \leq \varepsilon_3 n \). \( \triangleright \)

### 6.2.1 Proof of Theorem 5

In this short section we prove Theorem 5. We focus on the version that is based on non-explicit samplers, yielding non-explicit reductions. The explicit reduction, which entails a bit more technical work, is deferred to Section 6.3 and Section 6.6. We choose to focus on the non-explicit version first because we believe that understanding LDC in the information-theoretic level is, at present, a deeper and more urgent problem than the question of explicitness. Also, the parameters are easier to work with. For the information-theoretic version, we make use of the sampler that is given by Theorem 15. From here on we refer to the constant \( c_{\text{samp}} \geq 1 \) that appears in that theorem.

\[\triangleright\] **Theorem 72.** Let \( C \) be a block-length-\( n \) \((q, \delta, 1/5)\)-LDC over alphabet \( \Sigma \) having a constant rate. Let \( C' \) be a family of asymptotically good \((q_0', \delta', 1/5)\)-LDC, where \( q_0' \) is the query complexity when the code from the family is taken with block length \( n \). Then, there exists an asymptotically good LDC over \( \Sigma \), with constant error, having block length \( \Theta(n) \) and query complexity
\[
q_{\text{new}} = O \left( q \cdot q_0'(1/\delta) \log(1/\delta) \log n \right).
\]

\( (6.2) \)
Rate Amplification & Query-Efficient Distance Amplification for Linear LCC & LDC

Proof. Take $C_1$ to be the code $C$ in the hypothesis of the theorem, namely, a code with block length $n_1 = n$ and distance $d_1 = \delta$. Recall that in the distance amplification procedure from Section 6.1, we make use of a $(\delta_2/2, \delta_1)$ sampler $G = ([\ell], [\ell], E)$ with $\ell = n_1/k_2$ and left-degree $d = n_2$. For the proof, we will instantiate the distance amplification procedure with the sampler that is given by Theorem 15. We take $C_2$ to be an asymptotically good code over $\Sigma$ set with block length

$$n_2 = c_{\text{samp}} \cdot \log \left( \frac{1}{\delta_1} \right) \left( \frac{\delta_2}{2} \right)^2 = O(\log(1/\delta)),$$

where $\delta_2$ is the (constant) distance of $C_2$, having rate at least $1/2$. Note that this choice of parameters is as required by Theorem 15 from the left degree of the sampler. Clearly, $C_2$ has query complexity $O(\log(1/\delta))$ and error $\varepsilon_2 = 0$. As for the degree $D_v$ of any given right vertex $v$ of the sampler, note that the average right degree is

$$D = \frac{\ell d}{r} = \frac{d}{\delta \log(1/\delta)} = \frac{4c_{\text{samp}}}{\delta_1 \delta_2^2} = \Theta \left( \frac{1}{\delta} \right).$$

Recall that, by Theorem 15, $D_v \in [D/2, 2D]$. For every length in this range, we take a code from the family $C'$ having the required message length. We would like to take the family of codes $C_3$ to be $C'$ though we must reduce the error first. Indeed, note that the error $\varepsilon$ of the code obtained by Proposition 65 is $\varepsilon_1 + n(\varepsilon_2 + \varepsilon_3)$. As mentioned in the introduction, one can reduce the error from $1/5$ to $1/(10n)$ by applying the decoding procedure for $c \log n$ times, where $c$ is some large enough constant, and output the symbol according to plurality. This has no effect on the rate or distance of $C'$, and has a multiplicative $O(\log n)$ cost in query complexity. That is, the query complexity of $C_3$ is $O(q_{(D/1, \delta)}(\log n))$. The proof then readily follows by Proposition 65.

6.2.1.1 Improving the query complexity further given low-error LDC

We remark that, if $C'$ has error $O(1/n)$ to begin with, then one can skip the error reduction in the proof of Theorem 72, and get a slightly better query complexity. Indeed, this will save the $\log n$ factor in Equation (6.2). Moreover, observe that $C_2$ can be taken to be an LDC as well, rather than a standard code, which will reduce its deterioration on the query complexity from $O(\log(1/\delta))$ to $q_{(D/1, \delta)}(\log(1/\delta))$. However, for that, one need the error of $C_2$ to be $O(1/n)$ as well. Assuming one can obtain such low-error LDC (note that an error of $1/n$ is at least exponentially-small in the length of $C_2$ since $\delta > 1/n$), the query complexity can be improved further to

$$q_{\text{new}} \leq q \cdot q_{(D/1, \delta)}(\log(1/\delta)) \cdot q_{(\log(1/\delta))}.$$

We conclude this section by instantiating Theorem 72 with $C'$ taken to be the state-of-the-art construction of asymptotically good LDC.

Theorem 73 ([26]). Let $\Sigma$ be a finite alphabet. Then, there exist constants $\delta, \rho$ and an explicit infinite family of $(q_k, \delta, 1/5)$-LDC, $k$ being the message length, having query complexity $q_k = 2^O(\sqrt{\log(k) \log \log k})$.

Using it, one gets query complexity

$$q_{\text{new}} \leq q \log(n) \cdot 2^{O(\log(1/\delta) \log \log(1/\delta))} = q \log(n)(1/\delta)^{o(1)}.$$
6.3 Relaxing the assumption on the sampler $G$

In the distance amplification procedure described in Section 6.1, the sampler $G$ is assumed to be a left-regular $(\delta_2/2, \delta_1)$-sampler in which every right degree is in $[D/2, 2D]$. In order for the reduction to result in an explicit code, we want to be able to plug in an explicit sampler in the distance amplification procedure, for which the bounds on the right degree may not hold. We now describe how a sampler that does not satisfy this assumption can be used even so. The change to the construction is detailed as follows.

**Modified construction**

- For $i = 1, 2, 3$ let $(C_i, Q_i, R_i)$ be as in Section 6.1. Assume further that $\delta_1 \leq \delta_2/8$.
- Set $\ell = n_1/k_2$. Let $G = (L, R, E)$ be a $(\delta_2/8, \delta_1)$-sampler with $|L| = \ell$ and $|R| = r$. Assume $G$ is left-regular with left-degree $d = n_2$, and denote by $D = \ell d$ the average right degree (the right degrees may be arbitrary).
- The encoding function $C : \Sigma^{k_1} \rightarrow \Sigma^D$ is the same as in Section 6.1, but for the following change: if $v \in [r]$ has degree outside $[D/2, 2D]$ then discard it.
- The querying function is the same as in Section 6.1, but for the following change: if $v^{(i,j)}$ is a vertex with degree not in $[D/2, 2D]$, then set $(c^{(i,j,k)})_{k \in [q]}$ to be an empty tuple.
- The reconstruction procedure is the same as in Section 6.1, but for the following change: if $i, j$ are such that $v^{(i,j)}$ is a vertex with degree not in $[D/2, 2D]$, then set $y^{(i)} = \bot$ (or, if one prefers to avoid the use of $\bot$, any $\sigma \in \Sigma$ can be used).

The amendments above have the effect that when encoding the blocks corresponding to right vertices, that are either too big or too small, the encoding discards such blocks and their contents, as if they were deleted. The querying function is changed so that whenever a location was not queried on the account of it residing in a block too big or too small, some arbitrary symbol (or $\bot$) is passed on instead. To analyze the altered distance-amplification procedure we start by proving two simple statements about samplers.

- **Lemma 74.** Let $G = ([\ell], [r], E)$ be a left-regular $(\varepsilon, \delta)$-sampler with average right-degree $D$. Assume $\delta \leq 1/4$. Then, $G$ has at most $3\varepsilon r$ right vertices with degree less than $D/2$.

**Proof.** Denote by $d$ the left-degree of $G$. Define $A = \{v \in [r] \mid \deg(v) < D/2\}$. Since $G$ is an $(\varepsilon, \delta)$-sampler, at least $(1 - \delta)\varepsilon$ fraction of the left vertices have (at least) $(|A|/\varepsilon - \varepsilon)d$ neighbors in $A$. Hence, $A$ has at least $(1 - \delta)\varepsilon(1 - \varepsilon)d$ edges entering it. Therefore, it must hold that

$$\frac{(1 - \delta)\varepsilon(1 - (|A|/\varepsilon - \varepsilon)d)}{d} < \frac{D}{2}.$$ 

As the average right degree is $D = \frac{\varepsilon d}{\delta}$, and since by assumption $\delta \leq 1/4$, we conclude that the average right-degree of $A$ is at least

$$\frac{(1 - \delta)\varepsilon(1 - (|A|/\varepsilon - \varepsilon)d)}{d} = (1 - \delta)\varepsilon \left(1 - \frac{r\varepsilon}{|A|}\right) \geq \frac{3D}{4} \left(1 - \frac{r\varepsilon}{|A|}\right).$$

By the above two equation it follows that $|A| < 3\varepsilon r$. \hfill $\nabla$

- **Lemma 75.** Let $G = ([\ell], [r], E)$ be an $(\varepsilon, \delta)$-sampler, which is $d$-left-regular and has average right-degree $D$. Assume $\varepsilon \geq \delta$. Then, $G$ has at most $2\varepsilon r$ right vertices with degree larger than $2D$. 

Proof. Define $B = \{v \in [r] \mid \deg(v) > 2D\}$. At least $(1 - \delta)$-fraction of the left vertices have at least $(1 - \frac{|B|}{r} - \varepsilon)d$ neighbors in $[r] \setminus B$, so $[r] \setminus B$ has at least $(1 - \delta)(1 - \frac{|B|}{r} - \varepsilon)d$ edges going into it. We therefore have that

$$2D|B| + (1 - \delta)(1 - \frac{|B|}{r} - \varepsilon)d \leq rD.$$ 

As $rD = \ell d$, it follows that

$$|B| \leq \frac{\varepsilon + \delta - \delta\varepsilon}{1 + \delta} r \leq 2\varepsilon r.$$

We now wish to state the correctness of the changed construction.

Proposition 76. The encoding function $C$ of the modified construction is a $(q, \delta, \varepsilon)$-LDC, where

$$q \leq q_1q_2q_3,$$

$$\delta \geq \frac{\delta_2\delta_3}{32},$$

$$\varepsilon \leq \varepsilon_1 + (\varepsilon_2 + \varepsilon_3)n.$$

Furthermore, $C$ has rate $\rho_1\rho_2\rho_3$, where $\rho_1, \rho_2$ are as defined in the building blocks paragraph, and per our convention set above, $\rho_3 = \rho_3(D/2)$.

Proof. That the rate and query complexity are as stated is trivial, since the rate and query complexity can only be improved by this modification to the construction in which we discard some of the codeword symbols, and skip some of the queries. We now discuss the distance $\delta$ and error $\varepsilon$. Since the proof is almost identical to the proof of Proposition 65, we only state how to change the proof above to get a proof for the current proposition. Let

$$X = \{v \in R \mid \deg(v) \notin [D/2, 2D]\}$$

be the set of right vertices with “bad” degrees. Recall that these vertices are ignored by the modified construction. In particular, $n = \sum_{v \in R \setminus X} n_v$. The proof of Proposition 65 starts by defining the set

$$B = \{i \in [n] \mid \tilde{C}(x)_i \neq C(x)_i\},$$

which is the set of “errors”. It then goes on by defining another set, $B_t$, which is the set of “bad” right vertices, for which the adversary has introduced too many errors on the respective block. This is where we make a slight modification, ignoring the vertices in $X$. Formally, we define

$$B_t = \{v \in R \setminus X \mid \text{dist}(t^{(v)}, \tilde{t}^{(v)}) \geq \delta_3\}.$$

In the following claim we bound the density of $B_t$ with respect to the set $R$ (rather than with respect to $R \setminus X$).

Claim 77. $\mu_R(B_t) \leq \frac{\delta_3}{n}$. 

Proof. The proof is similar to the proof of Claim 66 though it takes into account our modifications as described above. For $v \in R \setminus X$ let $e_v = \text{dist}(t^{(v)}, \tilde{t}^{(v)})$. We have that

$$\sum_{v \in R \setminus X} e_v n_v \leq \delta n.$$ 

On the other hand,

$$\sum_{v \in R \setminus X} e_v n_v \geq \delta_3 \sum_{v \in B_t} n_v \geq \frac{\delta_3 D |B_t|}{2}. $$

Hence, we have

$$\frac{\delta_3 D |B_t|}{2} \leq \delta n,$$

which implies

$$\mu_R(B_t) \leq \frac{\delta_3}{n}.$$
where the last inequality follows as for every $v \in B_1 \subseteq R \setminus X$ it holds that $\deg(v) \geq D/2$. We also have, per our assumption, that $\rho_1 \geq 1/2$, and since $k_v \leq 2D$ for all $v \in R \setminus X$,

$$n = \sum_{v \in R \setminus X} n_v \leq 2 \sum_{v \in R \setminus X} k_v \leq 4Dr.$$  

The proof follows by the above three inequalities, $\triangleright$

As in Proposition 65, we also denote $B_w = B_1$. The definition of the set $B_1$ is the same as in the proof of Proposition 65 with the modification that it “treats” the vertices in $X$ as errors. Formally,

$$B_1 = \{u \in [\ell] \mid |\Gamma(u) \cap (B_w \cup X)| \geq \delta_2 n_2\}, \quad (6.3)$$

$\triangleright$ Claim 78. $\mu(B_1) \leq \delta_1$.

Proof. By Claim 77, $\mu_R(B_w) \leq \frac{8\delta}{3\delta_3}$. Now, $G$ is a $(\delta_2/8, \delta_1)$-sampler. Thus, by Lemma 74 and Lemma 75 (which are applicable as $\delta_1 \leq \delta_2/8$ per our assumption), $\mu_R(X) \leq \frac{5\delta_2}{8}$. Hence, the density of $B_w \cup X$ with respect to $R$ is

$$\mu_R(B_w \cup X) \leq \frac{8\delta}{5\delta_2} + \frac{5\delta_2}{8} \leq \frac{7\delta_2}{8},$$

where the last inequality holds per our assumption $\delta \leq \delta_2\delta_3/32$. Recall that $G$ is a $(\delta_2/8, \delta_1)$-
sampler. Thus, at most $\delta_1$-fraction of the left vertices $u \in [\ell]$ satisfy

$$\mu_R(u|\Gamma(u) \cap (B_w \cup X)) \geq \mu_R(B_w \cup X) + \frac{\delta_2}{8},$$

and the proof follows. $\triangleright$

The rest of the proof is identical to the proof of Proposition 65. $\triangleright$

### 6.4 Reduction to LDC with polynomially-small (and even smaller) distance

In this section we prove the following corollary of Proposition 65. We then deduce from it Corollary 6 and Corollary 7 from the introduction.

$\triangleright$ Corollary 79. There exists a universal constant $c'$ such that the following holds. Let $c \geq 1$ be any constant. Let $\alpha : \mathbb{N} \to (0, 1)$, $\beta : \mathbb{N} \to (0, 1)$ be two monotone non-increasing functions that satisfy

$$\alpha(n^{1.01}) \geq c' \beta(\log n) \cdot \log \log n.$$  

(6.4)

Assume further that $\alpha(n) \leq 0.009$ and that $\beta(n) \leq 0.1$ for all $n \geq 1$. Assume there exists a family of $(q_\alpha(n), n^{-(1-\alpha(n))}, 1/5)$-LDC over alphabet $\Sigma$ having rate $1 - \beta(n)$. Then, for every sufficiently large $n$ there exists a $(q, \delta, 1/5)$-LDC on block length $m \in [n, n^{1.01}]$ over $\Sigma$, where

$$q = (q_\alpha(n) \log n)^{O\left(\frac{\log \log n}{\alpha(n^{1.01})}\right)},$$

$$\rho = 1 - O\left(\frac{\beta(\log n) \log \log n}{\alpha(n^{1.01})}\right),$$

$$\delta = \beta(\log n)^{O\left(\frac{\log \log n}{\alpha(n^{1.01})}\right)}.$$  

$\triangleright$ The constant $1.01$ in the exponent, which determines the density of lengths for which we can construct the stated codes, can be replaced by any constant strictly larger than 1, and even by $1 + o(1)$ for a “sufficiently large” $o(1)$. However, for ease of presentation, we stick with this fixed choice.
To prove Corollary 79, we prove the following claim. In its statement, we refer to the constant $c_{\text{samp}} \geq 1$ that is given by Theorem 15.

**Claim 80.** Let $\beta_2 < 1/2$. Assume there exists a $(q_{\text{in}}, \delta_{\text{in}}, \epsilon_{\text{in}})$-LDC $C_{\text{in}}$ over alphabet $\Sigma$ for every message length $k_{\text{in}} \in [D/2, 2D]$ where

$$D = \frac{4c_{\text{samp}} n^{1-\alpha(n)}}{\beta_2^2},$$  

(6.5)

having rate $\rho_{\text{in}} \geq 1/2$. Then, under the hypothesis of Corollary 79, there exists a $(q_{\text{out}}, \delta_{\text{out}}, \epsilon_{\text{out}})$-LDC over $\Sigma$ with block-length $n$ having rate $\rho_{\text{out}}$, where

$$q_{\text{out}} \leq \frac{4c_{\text{samp}} \log n}{\beta_2^6} \cdot q_{\alpha}(n),$$

$$\delta_{\text{out}} \geq \frac{\beta_3}{16},$$

$$\frac{\rho_{\text{out}}}{\rho_{\text{in}}} \geq (1 - \beta_2)(1 - \beta(n)),$$

$$\epsilon_{\text{out}} \leq 1 + 5n\epsilon_{\text{in}}.$$

Proof. Let $C_1$ be the LDC from the hypothesis of Corollary 79 taken with block length $n_1 = n$. Let $C_2$ be a code set with message length $k_2 = \frac{4c_{\text{ samp}} \log n}{\beta_2^6}$, over $\Sigma$ having rate $1 - \beta_2$ and distance $\delta_2 = \beta_2^3$. A code with such parameters exists, over any alphabet, by the Gilbert-Varshamov bound.

Recall that in the distance amplification procedure (Section 6.1), we make use of a $(\delta_2/2, \delta_1)$-sampler $G = ([\ell], [r], E)$ with $\ell = n_1/k_2$ and left-degree $n_2$. For the proof of the claim, we will instantiate the distance amplification procedure with the sampler that is given by Theorem 15. To be able to use this sampler, we must verify that the left-degree is indeed large enough with respect to the parameters of the sampler. As, in our case, the left degree is $n_2$, we need to verify that

$$n_2 \geq c_{\text{ samp}} \cdot \frac{\log (1/\delta_1)}{(\delta_2/2)^2} = \frac{4c_{\text{samp}}(1 - \alpha(n)) \log n}{\beta_2^6}. $$

(6.6)

However,

$$\frac{4c_{\text{ samp}}(1 - \alpha(n)) \log n}{\beta_2^6} \leq \frac{4c_{\text{ samp}} \log n}{\beta_2^6} = k_2,$$

and so, Equation (6.6) holds.

As for the degree $D_v$ of any given right vertex $v$ of the sampler, we have by Theorem 15 that $D_v \in [D/2, 2D]$, where

$$D = \frac{\ell d}{r} = \frac{4c_{\text{ samp}} n^{1-\alpha(n)}}{\beta_3^2},$$

which equals to $D$ as defined in Equation 6.5. Thus, we may use $C_{\text{in}}$ as in the hypothesis of the claim. We are therefore in a position to apply Proposition 65. The assertions regarding the query complexity, distance and rate readily follow by Proposition 65. That the error is bounded as stated readily follows by noting that $\epsilon_2 = 0$.  

It will be more convenient to have no error loss in the reduction that is given by Claim 80. This is easily achievable by amplifying the error of the input code before applying the previous claim.
Corollary 81. Let $\beta_2 < 1/2$. Assume there exists a $(q_{\text{in}}, \delta_{\text{in}}, 1/4)$-LDC $C_{\text{in}}$ over alphabet $\Sigma$ for every message length $k_{\text{in}} \in [D/2, 2D]$, where $D$ is as in Equation (6.5), having rate $\rho_{\text{in}} \geq 1/2$. Then, under the hypothesis of Corollary 79, there exists a $(q_{\text{out}}, \delta_{\text{out}}, 1/4)$-LDC over $\Sigma$ with block-length $n$ having rate $\rho_{\text{out}}$, where

$$\begin{align*}
q_{\text{out}} < q_{\text{in}} \frac{100C_{\text{samp}} \log^2 n}{\beta_2^6} \cdot q_{\text{in}}(n),
\delta_{\text{out}} > \frac{\beta_2^3}{16},
\rho_{\text{out}} \geq (1 - \beta_2)(1 - \beta(n)).
\end{align*}$$

Proof. Let $r$ be a parameter we set later on. Define the code $C'$ to be the code $C_{\text{in}}$ though with the following decoder. To decode $C'$, apply the decoder of $C_{\text{in}}$ for $r$ times and return the symbol according to plurality. Clearly, the rate and distance remain intact. By a simple application of the Chernoff bound, one can show that the error of $C'$ is $2^{-\Omega(r)}$. The query complexity of $C'$ is then $r\rho_{\text{in}}$. Thus, by taking $r = c \log n$ for a sufficiently large constant $c$, we can get a code with error $1/n^2$. The query complexity is then increased by a multiplicative $O(\log n)$ factor. The proof then follows by applying Claim 80 to $C'$.

With Corollary 81 we are ready to prove Corollary 79.

Proof of Corollary 79. The construction of the asserted code is obtained by devising a sequence of LDC $C'_0, C'_1, C'_2, \ldots$ where $C'_0$ is taken to be a code over $\Sigma$ with block length

$$n_0 = 2 \left( \frac{16C_{\text{amp}}}{\beta(\log n)^6} \right)^{8/\alpha(n^{1.01})},$$

having rate $\rho_0 = 1 - \beta(\log n)$ and distance $\beta(\log n)^3$. A code with such parameters exists, over any alphabet, by the Gilbert-Varshamov bound. Clearly, as an LDC, this code has error $\varepsilon_0 = 0$ and query complexity $n_0$. For $t > 0$, the code $C'_t$ is obtained by applying Corollary 81 with the code $C'_{t-1}$ as $C_{\text{in}}$ in the notations of the corollary and using $\beta_2 = \beta(\log n)$. Denote the message length and block length of $C'_t$ by $k_t$ and $n_t$, respectively. By construction, for every integer $t \geq 1$ such that $n_t \leq n^{1.01}$ we have that

$$k_{t-1} \leq \frac{8C_{\text{amp}} n_t^{1-\alpha(n_t)}}{\beta(\log n)^6} \leq \frac{8C_{\text{amp}} n_t^{1-\alpha(n^{1.01})}}{\beta(\log n)^6},$$

where we used the fact that $\alpha(n)$ is non-increasing. By Corollary 81,

$$\rho_t = \frac{k_t}{n_t} \geq (1 - \beta(\log n))^2 \rho_{t-1},$$

and so

$$\rho_t \geq (1 - \beta(\log n))^{2t} \rho_0 = (1 - \beta(\log n))^{2t+1}.$$
The last inequality follows since the function \((1 - x)^{1 + \frac{1}{3\beta}}\) is bounded above by 0.1. By Equation (6.8) we have that for every \(t \leq \frac{1}{4\beta\log n}\),
\[
n_{t-1} \leq 2k_{t-1} \leq \frac{16c_{\text{samp}}h^{1-\alpha(n^{1.01})}}{\beta(\log n)^6}.
\]
Thus,
\[
n_t \geq \left(\frac{n_{t-1}(\log n)^6}{16c_{\text{samp}}}\right)^{\frac{1}{1-\alpha(n^{1.01})}}.
\]
(6.9)

One can prove the following easy claim by induction.

\(\triangleright\) Claim 82. Let \((n_t)_{t \in \mathbb{N}}\) be a sequence of positive integers such that \(n_t \geq (n_{t-1}/a)^b\) for some \(a, b > 1\). Then, for every \(t \geq 1\) we have that \(n_t \geq (n_0/a^{h(b,t)})^b\), where \(h(b, t) = \sum_{i=0}^{t-1} \frac{1}{b^i}\).

With the notation of Claim 82, we have
\[
h\left(\frac{1}{1-\alpha(n^{1.01})}, t\right) = \sum_{i=0}^{t-1} (1 - \alpha(n^{1.01}))^i \leq \frac{1}{\alpha(n^{1.01})}.
\]
By applying Claim 82 with \(a = 16c_{\text{samp}}/\beta(\log n)^6\) and \(b = \frac{1}{1-\alpha(n^{1.01})}\) we get that for every \(t\) such that \(n_t \leq n^{1.01}\) it holds
\[
n_t \geq \left(\frac{n_0}{16c_{\text{samp}}(\beta(\log n)^6)^{1/\alpha(n^{1.01})}}\right)^{\frac{1}{1-\alpha(n^{1.01})}} \geq 2^{\frac{1}{1-\alpha(n^{1.01})}},
\]
where for the last equality we used our of \(n_0\) given in Equation (6.7). We now wish to take \(t'\) to be the least integer for which the right hand side is larger or equal than \(n\). However, we must make sure that such \(t'\) exists. Indeed, the above analysis only works for \(t\) such that both \(n_t \leq n^{1.01}\) and \(t \leq \frac{1}{4\beta(\log n)}\) holds. So, one must verify that there exists a \(t' \leq \frac{1}{4\beta(\log n)}\) for which \(n \leq n_{t'} \leq n^{1.01}\). To see this, recall that \(k \in [D/2, 2D]\) where \(D\) is as given by Equation (6.5). Hence,
\[
n_{t-1} \geq k_{t-1} \geq \frac{2c_{\text{samp}}h_2^{1-\alpha(n)}}{\beta_2^n} \geq n_t^{1-\alpha(n^{1.01})},
\]
Hence, if \(n_{t-1} < n\) then
\[
n_t < n^{1-\alpha(n^{1.01})} < n^{1.01},
\]
where the last inequality follows as \(\alpha(n_t) \leq 0.009\). Thus,
\[
t' = \Theta\left(\frac{\log \log n}{\log \left(\frac{1}{1-\alpha(n^{1.01})}\right)}\right) = \Theta\left(\frac{\log \log n}{\alpha(n^{1.01})}\right),
\]
and we can thus see that \(t' \leq \frac{1}{4\beta(\log n)}\) per our assumption that is given by Equation (6.4).
It is easy to verify that the query complexity $q_{\nu}$ of and distance $\delta_{\nu}$ of $C_{\nu}$ are

$$q_{\nu} = \left( \frac{\log n}{\beta(n)} \right)^{\Theta(t')},$$

$$\delta_{\nu} = \beta(n)^{\Theta(t')}.$$

As for the rate,

$$\rho_{\nu} \geq (1 - \beta(n))^{\Theta(t')} = 1 - O\left( \frac{\beta(n) \log \log n}{\alpha(n^{1.01})} \right),$$

where the last equality follows by Equation (6.4). Finally, the error of $C_{\nu}$ can be reduced from $1/4$ to $1/5$ with no asymptotic overhead in query complexity, and so $C_{\nu}$ has all the asserted properties.

### 6.4.1 Proofs of Corollary 6 and Corollary 7

In this short section prove Corollary 6 and Corollary 7.

**Proof of Corollary 6.** With the hypothesis of the corollary, we may apply Corollary 79 with $\alpha(n)$ and $\beta(n)$ in the notation of Corollary 79 set to $\alpha(n) = \min(\alpha, 0.009)$ and $\beta(n) = \frac{1}{\log n}$ (and, in fact, taking $\beta(n) = \frac{c}{\log n}$ for sufficiently small constant $c > 0$ will do as well). Note that Equation (6.4) holds with this choice. Corollary 79 then yields a $(q_1, \delta_1, \epsilon_1 = 1/5)$-LDC, where

$$q_1 = (q_{\alpha}(n) \cdot \log n)^{O(\log \log n)},$$

$$\delta_1 = 2^{-O(\log \log(n) \log \log \log n)},$$

$$\rho_1 = 1 - O\left( \frac{1}{\log \log n} \right).$$

Recall that by the Katz-Trevisan bound [23], constant rate LDC with distance $\delta$ have query complexity $\Omega(\log(\delta n/\log n))$ (see, e.g., [42]). Thus, $q_{\alpha}(n) = \Omega(\log n)$ and so, in fact, $q_1 = q_{\alpha}(n)\log \log n$. The resulted code is obtained by amplifying the distance from $\delta_1$ to constant. Indeed, one can invoke, say, the AEL distance amplification procedure. Since $1/\delta = o(q_1)$, the proof follows.

**Proof of Corollary 7.** With the hypothesis of the corollary, we may apply Corollary 79 with $\alpha(n) = 1/\log \log n$ and $\beta(n) = 1/\log \log n$ in the notation of Corollary 79. Note that Equation (6.4) holds with this choice. Corollary 79 then yields a $(q_1, \delta_1, \epsilon_1 = 1/5)$-LDC, where

$$q_1 = (q_{\alpha}(n) \cdot \log n)^{O((\log \log n)^{c+1})},$$

$$\delta_1 = 2^{-O((\log \log n)^{c+1} \log \log \log n)},$$

$$\rho_1 = 1 - O\left( \frac{1}{\log \log n} \right).$$

By the Katz-Trevisan bound [23], $q_{\alpha}(n) = \Omega(\log n)$ and so, in fact, $q_1 = q_{\alpha}(n)\log \log n$. The resulted code is obtained by amplifying the distance from $\delta_1$ to constant. By invoking the AEL distance amplification procedure.
6.5 Proof of Corollary 8

In this section we prove Corollary 8 based on Proposition 65. We start by proving the following.

\textbf{Corollary 83.} There exists a constant $c \geq 1$ such that the following holds. Let $0 < \alpha < 1$ be an arbitrary constant, and $\beta : \mathbb{N} \to (0, 1)$ a monotone non-increasing function that satisfies
\[ 2^{-\frac{1}{2}(\log n)^\alpha} \leq \beta(n) \leq \frac{c}{\log \log n} \] (6.10)

Assume there exists a family of $(q_\alpha(n), 2^{-(\log n)^\alpha}, 1/5)$-LDC over alphabet $\Sigma$ having rate $1 - \beta(n)$. Then, for every sufficiently large $n$ there exists a $(q, \delta, 1/5)$-LDC on block length $m$ over $\Sigma$, for which $\log m \in [\log n, (\log n)^{(1-\alpha)}]$, and
\[ q = q_\alpha(n)^{O(\log \log \log n)} \]
\[ \rho = 1 - O(\beta(n) \log \log n) \]
\[ \delta = \beta(\log n)^{O(\log \log \log n)} \]

To prove Corollary 83, we prove the following claim. In its statement we refer to the constant $c_{\text{samp}} \geq 1$ that is given by Theorem 15.

\textbf{Claim 84.} Let $\beta_2 < 1/2$. Assume there exists a $(q_{\text{in}}, \delta_{\text{in}}, \epsilon_{\text{in}})$-LDC $C_{\text{in}}$ over alphabet $\Sigma$ for every message length $k_{\text{in}} \in [D/2, 2D]$ where
\[ D = \frac{4c_{\text{samp}}2(\log n)^\alpha}{\beta_2^3}, \] (6.11)

having rate $\rho_{\text{in}} \geq 1/2$. Then, under the hypothesis of Corollary 83, there exists a $(q_{\text{out}}, \delta_{\text{out}}, \epsilon_{\text{out}})$-LDC over $\Sigma$ with block length $n$ having rate $\rho_{\text{out}}$, where
\[ \frac{q_{\text{out}}}{q_{\text{in}}} \leq \frac{8c_{\text{samp}}(\log n)^\alpha}{\beta_2^3} \cdot q_\alpha(n), \]
\[ \frac{\delta_{\text{out}}}{\delta_{\text{in}}} \geq \frac{\beta_2^3}{16}, \]
\[ \frac{\rho_{\text{out}}}{\rho_{\text{in}}} \geq (1 - \beta_2)(1 - \beta(n)), \]
\[ \epsilon_{\text{out}} \leq \frac{1}{5} + n\epsilon_{\text{in}}. \]

\textbf{Proof.} Let $C_1$ be the LDC from the hypothesis of Corollary 83 taken with block length $n_1 = n$. Let $C_2$ be a code set with message length $k_2 = \frac{4c_{\text{samp}}(\log n)^\alpha}{\beta_2^3}$, over $\Sigma$ having rate $1 - \beta_2$ and distance $\delta_2 = \beta_2^3$. A code with such parameters exists, over any alphabet, by the Gilbert-Varshamov bound.

In the distance amplification procedure (Section 6.1), we make use of a $(\delta_2/2, \delta_1)$ sampler $G = ([\ell], [r], E)$ with $\ell = n_1/k_2$ and left-degree $d = n_2$. For the proof of the claim, we will instantiate the distance amplification procedure with the sampler that is given by Theorem 15, and so we must verify that the left-degree is indeed large enough with respect to the parameters of the sampler. As, in our case, the left degree is $n_2$, we need to verify that
\[ n_2 \geq c_{\text{amp}} \cdot \frac{\log (1/\delta_1)}{(\delta_2/2)^2} = \frac{4c_{\text{amp}}(\log n)^\alpha}{\beta_2^3}, \] (6.12)

which indeed holds as the right hand side equals $k_2$.  

As for the degree \( D \) of any given right vertex \( v \) of the sampler, we have by Theorem 15 that \( D \in [D/2, 2D] \), where

\[
D = \frac{\ell d}{r} = \frac{4 c_{\text{samp}} R^{1-o(n)}}{\beta_2^6},
\]

is as defined in Equation 6.11. Thus, we may use \( C_{in} \) as in the hypothesis of the claim. We are therefore in a position to apply Proposition 65, and the proof readily follows. ▷

As in the previous section, it will be convenient to have no error loss in the reduction that is given by Claim 80. This is easily achievable by amplifying the error of the input code before applying the previous claim. We state the following corollary whose proof is similar to the proof of Corollary 81 and so we omit it.

▶ Corollary 85. Let \( \beta_2 < 1/2 \). Assume there exists a \((q_{in}, \delta_{in}, 1/4)\)-LDC \( C_{in} \) over alphabet \( \Sigma \) for every message length \( k_{in} \in [D/2, 2D] \) where \( D \) is as defined in Equation (6.11), having rate \( \rho_{in} \geq 1/2 \). Then, under the hypothesis of Corollary 83, there exists a \((q_{out}, \delta_{out}, 1/4)\)-LDC over \( \Sigma \) with block length \( n \) having rate \( \rho_{out} \), where

\[
\frac{q_{out}}{q_{in}} \leq \frac{\log^2 n}{\beta_2^6}, \ q_{in}(n), \\
\frac{\delta_{out}}{\delta_{in}} \geq \frac{\beta_2^3}{16}, \\
\rho_{out} \geq (1 - \beta_2) (1 - \beta(n)).
\]

With Corollary 85 we are ready to prove Corollary 83.

Proof of Corollary 83. The construction of the asserted code starts by devising a sequence of LDC \( C'_{0}, C'_{1}, C'_{2}, \ldots \) where \( C'_{0} \) is taken to be a code over \( \Sigma \) with block length \( n_{0} = \log n \), having rate \( 1 - \beta(\log n) \) and distance \( \beta(\log n)^3 \). We obtain such code using Lemma 19. Clearly, as an LDC, this code has error \( \epsilon_{0} = 0 \) and query complexity \( n_{0} \). For \( t > 0 \), the code \( C'_{t} \) is obtained by applying Corollary 85 with the code \( C'_{t-1} \) as \( C_{in} \) in the notations of the corollary and using \( \beta_2 = \beta(\log n) \). Denote the message length and block length of \( C'_{t} \) by \( k_{t} \) and \( n_{t} \), respectively. By construction, for every integer \( t \geq 1 \) such that \( n_{t} \leq 2^{(\log n)/((t-\alpha))^1} \) we have that

\[
k_{t-1} \leq \frac{8 c_{\text{samp}} (\log n_{1})^\alpha}{\beta_2^6} \\
\]

By Corollary 81,

\[
\rho_{t} = \frac{k_{t}}{n_{t}} \geq (1 - \beta(\log n))^{2} \rho_{t-1},
\]

and so

\[
\rho_{t} \geq (1 - \beta(\log n))^{2t} \rho_{0} = (1 - \beta(\log n))^{2t+1}.
\]

In particular, for every \( t \leq \frac{1}{4\beta(\log n)} \) we get

\[
\rho_{t} \geq (1 - \beta(\log n))^{1+ \frac{1}{2\beta(\log n)}} \geq \frac{1}{2}.
\]
The last inequality follows since the function \((1 - x)^{1 + \frac{1}{4n}} \geq \frac{1}{2}\) for all \(x \leq 0.1\). Note that, indeed, by our assumption on \(\beta\) if follows that for a large enough \(n\), \(\beta(n)\) is bounded above by 0.1. Therefore,

\[
n_{t-1} \leq 2k_{t-1} \leq \frac{8c_{\text{tanh}}2^{(\log n_t)^{\alpha}}}{\beta_2^2}.
\]

Now, per our assumption that is given by Equation (6.10), we have that

\[
\beta_2 = \beta(\log n) \geq 2^{\frac{1}{\alpha} \log \log n} \geq 2^{-\frac{1}{\alpha} \log n_t}.
\]

where the last inequality follows as \(n_0 = \log n\). Thus, we get

\[
n_{t-1} \leq 8c_{\text{tanh}}2^{(\log n_t)^{\alpha}} \leq 8^{(\log n_t)^{\alpha}}.
\]

Thus, \(\log n_t \geq \left(\frac{\log n_{t-1}}{3^{\frac{1}{\alpha}}}\right)^{1/\alpha}\). By Claim 82, we get

\[
\log n_t \geq \left(\frac{\log n_0}{3^{\frac{1}{\alpha}}}\right)^{1/\alpha} \geq 2^{\frac{1}{\alpha}}.
\]

We now take \(t'\) to be the least integer for which the right hand side is larger or equal than \(\log n\). Note that \(t' = \Theta(\log \log n)\). However, the above analysis only holds only for \(t \leq \frac{1}{4\beta(\log n)}\) and so one must verify that \(t' \leq \frac{1}{4\beta(\log n)}\) which does indeed hold per our assumption that is given by Equation (6.10).

By the above, we get that \(C'_t\) is a \((q', \delta', 1/4)\)-LDC having rho \(\rho'\) where

\[
q' = (q_\alpha(n) \log n)^O(\log \log n),
\rho' = 1 - O(\beta(\log n) \log \log n),
\delta' = \beta(\log n)^O(\log \log n).
\]

By [23], \(q_\alpha(n) = \Omega(\log n)\) and so, in fact, \(q' = q_\alpha(n)^O(\log \log n)\). The final code is obtained by amplifying the distance from \(\delta'\) to constant. By invoking, say, the AEL distance amplification procedure.

### 6.6 Explicit reduction to LDC with polynomially-small distance

In this section we show a result similar to the one proven in Section 6.4, but with an explicit reduction that yields an explicit code. Throughout this section we assume \(\Sigma = \mathbb{F}_p\) for some prime power \(p\) (this is needed for the existence of explicit base codes). We prove the following corollary of Proposition 76

**Corollary 86.** Let \(\alpha > 0\) be a constant. Let \(\beta : \mathbb{N} \to (0,1)\) be a monotone non-increasing function that satisfies

\[
\frac{1}{n} \leq \beta(n) \leq \frac{\log(1/\alpha)}{24 \log n}.
\]

Assume there exists a family of explicit \((q_\alpha(n), n^{-\alpha}, 1/5)\)-LDC over alphabet \(\Sigma\) having rate \(1 - \beta(n)\) for block-length \(n\). Then, for every sufficiently large \(n\) there exists an explicit \((q, \delta, 1/5)\)-LDC over \(\Sigma\) on block length \(\text{poly}(n)\) over \(\Sigma\), where

\[
q = (q_\alpha(n) \log n)^O(\log \log n),
\rho = 1 - O(\beta(\log n) \log \log n),
\delta = \beta(\log n)^O(\log \log n).
\]
Note that the distance $\delta$ above can then be further amplified to a constant, at the expense of lowering the rate from $1 - o(1)$ to some constant, without asymptotic cost in query complexity. Indeed, in the above corollary, $1/\delta = \text{poly}(q)$ per our assumption that $\beta(\log n) \geq 1/\log n$.

To prove Corollary 86, we prove the following claim. In what follows, we refer to $c = c(\Delta)$ — the function that appears in the statement of Theorem 17.

> Claim 87. There exists a universal constant $\beta_0 \leq \frac{1}{2}$ such that the following holds. Let $n$ be an integer, and $\beta_2 \in (\frac{\log n}{\log \log n}, \beta_0)$. Assume there exists an explicit $(q_{\text{in}}, \delta_{\text{in}}, \varepsilon_{\text{in}})$-LDC $C_{\text{in}}$ over alphabet $\Sigma$ for every message length $k_{\text{in}} \in [D'/2, 4D']$ where $D' = D'(1/\sqrt{\alpha}, \delta_2/8, \delta_1)$ is as defined in Equation (3.2), having rate $\rho_{\text{in}} \geq 1/2$. Then, under the hypothesis of Corollary 86, there exists an explicit $(q_{\text{out}}, \delta_{\text{out}}, \varepsilon_{\text{out}})$-LDC over $\Sigma$ with block-length $n$ having rate $\rho_{\text{out}}$, where

\[
\frac{q_{\text{out}}}{q_{\text{in}}} \leq (\log n)^{10c(1/\sqrt{\alpha})} \cdot q_{\alpha}(n),
\]

\[
\frac{\delta_{\text{out}}}{\delta_{\text{in}}} \geq \beta_0^3 / 16,
\]

\[
\frac{\rho_{\text{out}}}{\rho_{\text{in}}} \geq (1 - \beta_2) (1 - \beta(n)),
\]

\[
\varepsilon_{\text{out}} \leq \frac{1}{5} + n \varepsilon_{\text{in}}.
\]

Proof. Let $C_1$ be the LDC from the hypothesis of Corollary 86 taken with block length $n_1 = n$. Set $\delta_2 = \beta_2^2$. By Theorem 17, invoked with $\Delta = 1/\sqrt{\alpha}$, there exists an explicit $(\delta_2/8, \delta_1)$-sampler with $z = n/(1 - \beta_2)$ edges. By Theorem 17, $G$ has left-degree

\[
d = \left( \frac{8}{\delta_2} \log \frac{1}{\delta_1} \right)^c = \left( \frac{8}{\beta_2^2} \alpha \log n \right)^c,
\]

where $c = c(\Delta) = c(1/\sqrt{\alpha})$ is the constant as defined in Theorem 17. Note that since $\beta_2 \geq 1/\log n$ we have that $d \leq (\log n)^{10c}$. We also have that the average right-degree $D$ is in $[D', 2D']$, where

\[
D' = \frac{d}{2} \left( \frac{2}{\delta_1} \right)^{\Delta+1} \leq n^{2\sqrt{\pi}},
\]

where the inequality holds for all sufficiently large $n$.

Let $C_2$ be an explicit code set with message length $k_2 = (1 - \beta_2)d$ over $\Sigma$ having rate $1 - \beta_2$ and distance $\delta_2 = \beta_2^2$. An explicit code with such parameters exists, by Lemma 19, as we can choose $\beta_0$ to be smaller than the least $\beta$ for which the lemma holds.

We now want to instantiate the distance amplification procedure with $C_1$, $C_2$, the sampler $G$, and the code family $C_{\text{in}}$ as $C_3$. Note that since the right degrees of the sampler $G$ are not necessarily bounded, we use the relaxed distance amplification of Section 6.3. Recall that it is a prerequisite of the distance amplification procedure that the sampler has $n_1/k_2$ left vertices, and that $n_2 = d$, the degree of the sampler. Both of these hold, as indeed, the block length of $C_2$ is $\frac{1}{1 - \beta_2}(1 - \beta_2)d = d$, and the number of left vertices of the sampler is $\frac{z}{3} = \frac{1}{1 - \beta_2} = n_1/k_2$. Further note that the distance amplification procedure requires that the family $C_2$ contains a code with message length $k_3$ for every $k_3 \in [D/2, 2D]$, and this is indeed satisfied by the assumption regarding the message lengths of the code family $C_{\text{in}}$, of the hypothesis of the claim.

With $C_1, C_2, G$ and $C_{\text{in}}$ at hand, we can now apply Proposition 76 of the distance amplification procedure. The assertions regarding the query complexity, distance and rate readily follow by Proposition 65. That the error is bounded as stated readily follows by noting that $\varepsilon_{\text{out}} = 0$. 

<
As in the previous sections, it will be convenient to have no error loss in the reduction that is given by Claim 87. This is easily achievable by amplifying the error of the input code before applying the previous claim. We state the following corollary whose proof is similar to the proof of Corollary 81 and so we omit it.

**Corollary 88.** There exists a universal constant \( \beta_0 \leq \frac{1}{4} \) for which the following holds. Let \( \beta \in \left( \frac{1}{\log n}, \beta_0 \right) \). Assume there exists an explicit \((q_{in}, \delta_{in}, 1/4)\)-LDC \( C_{in} \) over alphabet \( \Sigma \) for every message length \( k_{in} \in [D'/2, 4D'] \) where \( D' = D'(1/\sqrt{\epsilon}, \delta_2/8, \delta_1) \) is as defined in Equation (3.2), having rate \( \rho_{in} \geq 1/2 \). Then, under the hypothesis of Corollary 86, there exists an explicit \((q_{out}, \delta_{out}, 1/4)\)-LDC over \( \Sigma \) with block-length \( n \) having rate \( \rho_{out} \), where

\[
\begin{align*}
\frac{q_{out}}{q_{in}} &\leq \left( \log n \right)^{10c(1/\sqrt{\epsilon})} q_{in}(n), \\
\frac{\delta_{out}}{\delta_{in}} &\leq \frac{\beta_0^3}{16}, \\
\frac{\rho_{out}}{\rho_{in}} &\geq (1 - \beta_2)(1 - \beta(n)).
\end{align*}
\]

With Corollary 88 we are ready to prove Corollary 86.

**Proof of Corollary 86.** The construction of the asserted code is obtained by devising a sequence of LDC \( C'_0, C'_1, C'_2, \ldots \) where \( C'_0 \) is taken to be a code over \( \Sigma \) with block length \( n_0 = \log n \) having rate \( \rho_0 = 1 - \beta(\log n) \) and distance \( \beta(\log n)^3 \). By Lemma 19 such an explicit code exists, for every large enough \( n \) (the lemma holds for every small enough \( \beta \), and indeed by Equation (6.13), \( \beta(n) \) is decreasing). Clearly, as an LDC, this code has error \( \varepsilon_0 = 0 \) and query complexity \( n_0 \). For \( t > 0 \), the code \( C'_t \) is obtained by applying Corollary 88 with the code \( C'_{t-1} \) as \( C_{in} \) in the notations of the corollary and using \( \beta_2 = \beta(\log n) \). Note that per our assumption given by Equation (6.13), this choice satisfies \( \beta_2 \geq \frac{1}{\log n} \), and for large enough \( n \), \( \beta(n) \leq \beta_0 \), and so we can apply the corollary. Denote the message length and block length of \( C'_t \) by \( k_t \) and \( n_t \), respectively. By construction, for every integer \( t \geq 1 \) we have that

\[
k_{t-1} \leq n_t^{2\sqrt{n}} \leq n_t^{3/4}, \quad (6.14)
\]

where the last inequality holds for all large enough \( n \). By Corollary 88,

\[
\rho_t = \frac{k_t}{n_t} \geq (1 - \beta(\log n))^2 \rho_{t-1},
\]

and so

\[
\rho_t \geq (1 - \beta(\log n))^{2t} \rho_0 = (1 - \beta(\log n))^{2t+1}.
\]

In particular, for every \( t \leq \frac{1}{4\beta(\log n)} \), we get

\[
\rho_t \geq (1 - \beta(\log n))^{1 + \frac{1}{4\beta(\log n)}} \geq \frac{1}{2}.
\]

The last inequality follows since the function \( (1 - x)^{1 + \frac{1}{4\beta(\log n)}} \geq \frac{1}{2} \) for all \( x \leq 0.1 \), and for every large enough \( n \), \( \beta(n) \leq 0.1 \). By Equation (6.14) we have that for every \( t \leq \frac{1}{4\beta(\log n)} \),

\[
n_{t-1} \leq 2k_{t-1} \leq 2n_t^{3/4} \leq n_t^{1/5}.
\]
Thus,
\[ n_t \geq n_0^{\frac{1}{4\beta}}. \]  
(6.15)

It follows that by taking \( t' = \lceil \frac{6 \log \log n \log(1/\alpha)}{4\beta \log(1/\alpha)} \rceil \) for the above analysis to hold. Indeed per our assumption given by Equation (6.13), it holds that \( \frac{6 \log \log n}{\log(1/\alpha)} \leq \frac{1}{4\beta \log(1/\alpha)}. \)

It is easy to verify that the query complexity \( q_{t'} \) of and distance \( \delta_{t'} \) of \( C'_{t'} \) are
\[ q_{t'} = ((\log n)q_0(n))^{\Theta(t')}, \]
\[ \delta_{t'} = \beta(\log n)^{\Theta(t')} \]

As for the rate,
\[ \rho_{t'} \geq (1 - \beta(\log n))^{\Theta(t')} = 1 - O(\beta(\log n) \log \log n). \]

Finally, the error of \( C'_{t'} \) can be reduced from \( 1/4 \) to \( 1/5 \) with no asymptotic overhead in query complexity, and so \( C'_{t'} \) has all the asserted properties.

\[ \square \]

Abstract

In the 3-players exactly-$N$ problem the players need to decide whether $x + y + z = N$ for inputs $x, y, z$ and fixed $N$. This is the first problem considered in the multiplayer Number On the Forehead (NOF) model. Even though this is such a basic problem, no progress has been made on it throughout the years. Only recently have explicit protocols been found for the first time, yet no improvement in complexity has been achieved to date. The present paper offers the first improved protocol for the exactly-$N$ problem. This improved protocol has also interesting consequences in additive combinatorics. As we explain below, it yields a higher lower bound on the possible density of corner-free sets in $[N] \times [N]$.

1 Introduction

The multiplayer Number On the Forehead (NOF) model of communication complexity was introduced by Chandra, Furst and Lipton [9]. Given a function $f : [N]^k \rightarrow \{0, 1\}$, the $k$ players in this scenario should jointly find out $f(x_1, \ldots, x_k)$. We think of $x_i$ as being placed on player $i$’s forehead, so that each player sees the whole input bar one argument. Players communicate by writing bits on a shared blackboard according to an agreed-upon protocol. This model is intimately connected to several key problems in complexity theory. E.g., lower bounds on the size of ACC$^0$ circuits for a natural function in $P$ [23, 12], branching programs, time-space tradeoffs for Turing machines [13], and proof complexity [5]. In addition, progress in the NOF model, even for a specific problem and for $k = 3$, would have profound implications in graph theory and combinatorics [14, 3].

Much of Chandra, Furst and Lipton’s seminal paper [9] is dedicated to the exactly-$N$ function $f : [N]^k \rightarrow \{0, 1\}$, where $f(x_1, \ldots, x_k) = 1$ iff $\sum x_i = N$. They discovered a connection between the communication complexity of this function and well-known problems in additive combinatorics and Ramsey theory. They used Ramsey’s theory to prove a (rather weak) lower bound on the NOF communication complexity of this function. Using the connection to additive number theory, they showed that a $O(\sqrt{\log N})$ protocol exists, although they have not made this protocol explicit.

* Our companion paper “Larger Corner-Free Sets from Better NOF Exactly-$N$ Protocols” presents the same results, emphasizing the combinatorial perspective.
An Improved Protocol for the Exactly-\(N\) Problem

There are several reasons why it is highly significant to determine the communication complexity of the exactly-\(N\) function, aside of the very fundamental nature of the problem:

\begin{itemize}
  \item Our poor understanding of this question is manifested by the huge gap between the upper and lower bounds that we currently have on the communication complexity of this problem. This gap is double exponential for three players, and is even worse for \(k > 3\) players.
  \item Despite the significance of the NOF model, we still know very little about it. The rich web of mathematical and computational concepts surrounding the exactly-\(N\) function suggests that it may open the gate to progress in understanding numerous other NOF functions.
  \item The \(k\)-player exactly-\(N\) function is a graph function [4]. For most functions in this class the deterministic and randomized communication complexity differ substantially, but no explicit function with a significant gap is presently known.
  \item This problem is equivalent to corner theorems in additive combinatorics (e.g., [2]), and is closely related to other important problems such as constructing Ruzsa-Szemerédi graphs and the triangle removal lemma [14, 3].
\end{itemize}

Nevertheless, progress on the complexity of the NOF exactly-\(N\) problem has mostly been made on the additive combinatorics side and includes several breakthrough results such as Szemerédi’s regularity lemma [21], and its extension to hypergraphs [11, 17, 16]. Translated back to the realm of NOF communication complexity, these advances bear on lower bounds in communication complexity, yet there is essentially nothing concerning upper bounds. We believe that the more promising line of attack is for advances in communication complexity to shed light on questions in additive combinatorics by exploiting the power of new algorithmic ideas.

As mentioned, the existence of a protocol for the exactly-\(N\) problem has already been known since [9]. However, this was just an existential statement and no actual protocol was provided. This lacuna was recently remedied with two protocols [14, 3] of the exact same complexity as the one whose existence was proven in [9], namely of complexity

\[
2\sqrt{2}\sqrt{\log N} + o(\sqrt{\log N}) = 2.828\ldots\sqrt{\log N} + o(\sqrt{\log N}).
\]

Here we give the first improved protocol for the exactly-\(N\) problem, and prove

\begin{theorem}
There is an explicit protocol for NOF exactly-\(N\) of complexity

\[
2\sqrt{\log e \sqrt{\log N}} + o(\sqrt{\log N}) = 2.4022\ldots\sqrt{\log N} + o(\sqrt{\log N}).
\]
\end{theorem}

Due to the connection between NOF complexity and additive combinatorics, our improved protocol has interesting implications in that area that we briefly mention now. More details are given in Section 3. Let \(\rho_3(N)\) be the largest density of a subset of \([N]\) that contains no 3-term arithmetic progression. As Roth [18] showed, \(\rho_3(N) = o(1)\). However, we still do not know the rate at which \(\rho_3(N)\) tends to 0. The upper bounds have gradually improved over the years and the current “world record” found in 2020 by Bloom and Sisask [8] is

\[
\rho_3(N) \leq (\log N)^{-1-c} \quad \text{for some absolute constant } c > 0.
\]

\[1\] All logarithms in this paper are in base 2.

Also, unless otherwise specified, all asymptotic statements are taken with \(N \to \infty\).
Much less has happened with the lower bound. Behrend’s construction [6] yields
\[
\rho_3(N) \geq 2^{-2\sqrt{2\log N} + o(\sqrt{\log N})} = 2^{-2.828...\sqrt{\log N} + o(\sqrt{\log N})}.
\]
But in the ensuing 75 years, only the little-oh term saw an improvement (Elkin [10]).

A corner in \(\mathbb{N}^2\) is a triple of points \((x, y), (x + \delta, y), (x, y + \delta)\) for some \(\delta \neq 0\). Let \(\rho_{3}^c(N)\) be the largest density of a subset of \([N] \times [N]\) that contains no corner. Ajtai and Szemerédi’s corner theorem [2] shows that \(\rho_{3}^c(N) = o(1)\). This readily implies Roth’s theorem that \(\rho_3(N) = o(1)\).

The best previously known lower bound on \(\rho_{3}^c(N)\) again comes from Behrend’s construction:
\[
\rho_{3}^c(N) \geq 2^{-2\sqrt{2\log N} + o(\sqrt{\log N})} = 2^{-2.828...\sqrt{\log N} + o(\sqrt{\log N})}.
\]

Our work gives the first improvement in decades, showing (Theorem 3)
\[
\rho_{3}^c(N) \geq 2^{-2\sqrt{2\log e\log N} + o(\sqrt{\log N})} = 2^{-2.4022...\sqrt{\log N} + o(\sqrt{\log N})}.
\]

## 2 Proof of Theorem 1

The three players in our protocol are called \(P_x, P_y\) and \(P_z\). The inputs that they get to see are \((y, z), (x, z)\) and \((x, y)\) respectively.

Here is a similar problem in the realm of vector addition. Given integers \(q, d > 1\), define \(g = g_{q,d}(\alpha, \beta, \gamma)\) to be 1 if \(\alpha + \beta = \gamma\) and 0 otherwise. Here \(\alpha, \beta, \gamma \in [q]^d\). \(\gamma \in [2q]^d\) and addition is vector addition in \(\mathbb{R}^d\). The following one-round protocol [3] for \(g\) is correct because the inequality \(\|2\alpha - \gamma\|^2 + \|2\beta - \gamma\|^2 \geq 2\|\alpha - \beta\|^2\) holds always and is an equality iff \(\gamma = \alpha + \beta\).

> **Protocol 1.** A protocol for \(g_{q,d}\)
>
> 1. \(P_z\) computes \(\|\alpha - \beta\|^2\), and writes the result on the board.
> 2. \(P_y\) writes 1 iff \(\|\alpha - \beta\|^2 = \|2\alpha - \gamma\|^2\).
> 3. \(P_x\) writes 1 iff \(\|\alpha - \beta\|^2 = \|2\beta - \gamma\|^2\).

The cost of this protocol is \(2 + \log dq^2\).

The above is an efficient method to decide high-dimensional vector addition, but our objective is to decide the integer addition relation \(X + Y + Z = N\). We let \(x = X, y = Y\), and \(z = N - Z\), so the relation we need to consider is \(x + y = z\).

Our protocol to decide whether \(x + y = z\) builds on the protocol for \(g_{q,d}\). It is the issue of carry bits in integer addition that makes this decision problem harder. The integers \(q, d > 1\) are chosen so that
\[
2qN > q^d \geq 2N.
\]

the specific choice is made below so as to minimize the cost of the protocol.

We denote by \(w_q\) the vector that corresponds to the base \(q\) representation of the integer \(w\).

As usual, \(e_i\) is the \(d\)-dimensional vector with 1 in the \(i\)-th coordinate and zeros elsewhere. Let \(C(x, y) \in \{0, 1\}^d\) be the carry vector when \(x\) and \(y\) are added in base \(q\). The relation \(x + y = z\) among integers is equivalent to the vector relation
\[
x_q + y_q = \zeta,
\]
where the \(i\)-th coordinate of \(\zeta\) is
\[
\zeta_i = z_i + q \cdot C(x, y)_i - C(x, y)_{i-1}
\]
(Here \(C(x, y)_0 = 0\).)
An Improved Protocol for the Exactly-$N$ Problem

The protocol from [3] now suggests itself: $P_z$ posts $C(x,y)$, and Protocol 1 is used to decide the relation $x_q + y_q = \zeta$. This yields again the estimate (1).

The alternative approach that we adopt here considers instead the equivalent vector relation

$$x_q + \eta = z_q$$

where

$$\eta = (x + y)_q - x_q.$$ 

Concretely, the $i$-th coordinate of $\eta$ is:

$$\eta_i = y_i - q \cdot C(x,y)_i + C(x,y)_{i-1}.$$ 

In order to run Protocol 1, $P_z$ needs to know $\eta$ and $x_q$, which he does. The situation with $P_y$ is even simpler, since he needs to know $x_q$ and $z_q$ which are his inputs. The only difficulty is with $P_x$ who needs to know $z_q$ (which he does) and $\eta$. The latter is not part of his input and $P_z$ fills in the missing information for him.

The obvious solution is for $P_z$ to reveal $C$ to $P_x$ using $d$ bits of information. However, we can save communication by exploiting the fact that $P_x$ and $P_z$ share some information, i.e., they both know $y$ for every $y \neq 0$.

By a standard argument in this area which we detail below (Proposition 2), a protocol that works for typical pairs $x,y$ can be easily modified to work in all cases. So, let us pick $x$ and $y$ uniformly at random from among the $d$-digit numbers in base $q$ and think of $C$, the vector of carry bits as a random variable on this probability space. The number of bits that $P_z$ needs to post so that $P_x$ gets to know $C$, and therefore know $\eta$, is

$$H(C|y) = \sum_{j=1}^{r} \frac{|S_j|}{d} h\left(\frac{j}{r}\right).$$ 

Since $y$ is chosen at random, $|S_j| \leq (1 + o_r(1)) \frac{d}{r}$, and so

$$H(C|y) \leq (1 + o_r(1)) \sum_{j=1}^{r} \frac{1}{r} h\left(\frac{j}{r}\right).$$

The limit of this expression as $r \to \infty$ is

$$\lambda = \int_0^1 h(u) du = \frac{\log e}{2} = 0.721...$$
It is left to optimize on $q$ and $d$. The complexity of our protocol is
\[
\lambda d + \log dq^2 + 2,
\]
where recall that $2qN > q^d \geq 2N$. It is not hard to verify that choosing
\[
d = \sqrt{\frac{2}{\lambda} \log 2N},
\]
\[
q = 2\sqrt{\frac{\lambda}{2} \log 2N},
\]
we get a protocol with complexity
\[
2\sqrt{2\lambda \log N} + o(\sqrt{\log N}),
\]
and this is asymptotically optimal in our setting.

To sum up, here is the protocol which proves Theorem 1:

\begin{itemize}
\item \textbf{Protocol 2.} A protocol for exactly-$N$, for typical pairs $x, y$
\item For $d, q$ as in Equation (4)
\item 1. $P_z$ publishes the vector $\eta = (x + y)_q - x_q$ in a way that $P_x$ can read.
\item 2. The players run protocol 1 for $g_{q,d}$ on inputs $x_q, \eta, z_q$. That is:
\begin{itemize}
\item a. $P_z$ writes $\|\eta - x_q\|^2$ on the board
\item b. $P_y$ writes 1 iff $\|\eta - x_q\|^2 = \|2x_q - z_q\|^2$.
\item c. $P_x$ writes 1 iff $\|\eta - x_q\|^2 = \|2\eta - z_q\|^2$.
\end{itemize}
\end{itemize}

\begin{itemize}
\item \textbf{Proposition 2.} Let $P$ be an NOF protocol for the exactly-$N$ that works correctly for an $\Omega(1)$-fraction of the input pairs $x, y$ (and every $z$) with communication complexity $\Phi(N)$. Then there is an NOF protocol that works for all inputs with communication complexity $\Phi(N) + O(\log \log N)$.
\end{itemize}

\textbf{Proof.} Let $S \subseteq [N] \times [N]$ be the set of input pairs $x, y$ on which $P$ succeeds. We claim that there is a collection $F$ of $O(\log N)$ vectors $\Delta \in [N] \times [N]$ such that
\[
\bigcup_{\Delta \in F} (S + \Delta) \supseteq [N] \times [N].
\]
In the modified protocol, $P_z$ sees $x, y$ and announces the index of some $\Delta = (\Delta_1, \Delta_2) \in F$ for which $(x - \Delta_1, y - \Delta_2) \in S$. Then the players run Protocol 2 with inputs $(x - \Delta_1, y - \Delta_2, z - \Delta_1 - \Delta_2)$.

The construction of $F$ uses a standard fact about the set-cover problem. For a family of finite sets $\mathcal{X} \subseteq 2^\Omega$ we denote by $c(\mathcal{X})$ the least number of members in $\mathcal{X}$ whose union is $\Omega$. Also $c^*(\mathcal{X})$ is the minimum cost of a fractional cover. Namely,
\[
c^*(\mathcal{X}) = \min \sum_{X \in \mathcal{X}} \omega_X, \quad \text{where } \omega_X \geq 0 \text{ for every } X \in \mathcal{X} \text{ and } \sum_{x \in X} \omega_x = 1 \text{ for every } x \in \Omega.
\]
Then
\[
c(\mathcal{X}) \leq \log(|\Omega|) \cdot c^*(\mathcal{X})
\]
(e.g., Lovász [15]) and actually the greedy algorithm yields a set cover that meets this bound.

In our case $\Omega = [N] \times [N]$, and
\[
\mathcal{X} = \{ (S + \Delta) \cap ([N] \times [N]) \mid \Delta \in [-N, N] \times [-N, N] \}.
\]
It is easily verified that the weights $\omega_x = \frac{1}{N^2}$ constitute a fractional cover, so that $c^*(\mathcal{X}) \leq 40$ and hence $c(\mathcal{X}) \leq 80 \log N$, as claimed.
3 Applications in additive combinatorics

In this section we briefly explain the connections and implications in additive combinatorics. Van der Waerden’s well known theorem [22] states that for every $r, k$ and every large enough $N$, if the elements of $[N] := \{1, \ldots, N\}$ are colored by $r$ colors, then there must exist a length-$k$ monochromatic arithmetic progression. Erdős and Turán introduced the density version of this theorem. Let $\rho_k(N)$ be the largest density of a subset of $[N]$ without an arithmetic progression of length $k$. Szemerédi’s famous theorem [21] shows that $\rho_k(N) = o(1)$ for every $k \geq 3$.

Extending van der Waerden’s theorem, Gallai proved that in every finite coloring of $\mathbb{Z}^2$ some color contains arbitrarily large monochromatic square subarrays. In search of a density version of Gallai’s theorem, Erdős and Graham asked about the largest density of a subset of $[N]$ without an arithmetic progression of length $k$. Namely, for every $\epsilon > 0$ and large enough $N$, every subset of $[N] \times [N]$ of cardinality $\epsilon N^2$ must contain a corner. This theorem easily yields that $\rho_3(N) = o(1)$, namely, the $k = 3$ case of Szemerédi’s theorem (a result of Roth [18], proved two decades before Szemerédi’s theorem). Later on, Solymosi [20] showed how to derive Ajtai and Szemerédi’s corners Theorem from the Triangle Removal Lemma [19].

The quantitative aspects of all these results: Szemerédi’s theorem, the corner theorem, and the triangle removal lemma remain unfortunately poorly understood. In particular, we know very little concerning the lower bounds in these problems. Behrend [6] has famously constructed a large subset of $[N]$ without a 3-term arithmetic progression. This construction implies that

$$\rho_3(N) \geq 2^{-2\sqrt{\log N} + o(\sqrt{\log N})}.$$

Using similar tools Elkin [10] improved Behrend’s construction. However, his construction only improves the little-o term. Behrend’s construction also yields the previously best known lower bounds on $\rho_3^c(N)$, viz.

$$\rho_3^c(N) \geq 2^{-2\sqrt{\log N} + o(\sqrt{\log N})} = 2^{-2.828...\sqrt{\log N} + o(\sqrt{\log N})}. \quad (5)$$

As mentioned in the introduction, the NOF communication complexity of $f$ is closely related to corners theorems. Our Theorem 1 immediately implies,

**Theorem 3.**

$$\rho_3^c(N) \geq 2^{-2\log \epsilon \sqrt{\log N} + o(\sqrt{\log N})} = 2^{-2.4022...\sqrt{\log N} + o(\sqrt{\log N})}.$$

There is an explicit corner-free subset of $[N] \times [N]$ of size $N^2/2^2\sqrt{\log \epsilon \sqrt{\log N} + o(\sqrt{\log N})}$.

The derivation of Theorem 3 from Theorem 1 is an easy consequence of the following claim.

**Claim 4 ([9], implicit).**

1. There is an optimal one-round protocol for the addition problem.
2. Let $T = T(x, y)$ be the message that the $P_z$ sends on inputs $(x, y)$ in a one-round protocol for the addition problem. Then the set

$$S(T) = \{(x, y) : T(x, y) = T\}$$

is corner-free.
See [9, 7, 1, 14, 3] for more details about the above claim and the relation between communication complexity and additive combinatorics. The same comments and corollaries above apply also verbatim to the (6,3) Theorem (e.g., [19]) and to the quantitative version of the triangle removal lemma.

4 Discussion

The strong relation between the exactly-$N$ problem in the NOF model and questions in additive combinatorics has been discovered decades ago, in the seminal paper of Chandra, Furst and Lipton [9]. However, this subject remains under-developed. We believe that there is a lot to be done here, and many interesting avenues of research that this study can take. One obvious candidate for improvement is the addition problem. We conjecture:

$\blacktriangleright$ **Conjecture 5.** The NOF communication complexity of exactly-$N$ is $o(\sqrt{\log N})$. Possibly it is much smaller, even as small as $(\log \log N)^{O(1)}$.

In the realm of additive combinatorics these conjectures translate to:

$\blacktriangleright$ **Conjecture 6.**

$$\rho^\angle_3(N) \geq 2^{-o(\sqrt{\log N})}.$$  

and possibly even

$$\rho^\angle_3(N) \geq 2^{-(\log \log N)^{O(1)}}.$$

Abstract

A canonical communication problem Search (φ) is defined for every unsatisfiable CNF φ: an assignment to the variables of φ is partitioned among the communicating parties, they are to find a clause of φ falsified by this assignment. Lower bounds on the randomized k-party communication complexity of Search (φ) in the number-on-forehead (NOF) model imply tree-size lower bounds, rank lower bounds, and size-space tradeoffs for the formula φ in the semantic proof system \( T^{cc}(k,c) \) that operates with proof lines that can be computed by k-party randomized communication protocol using at most c bits of communication [9]. All known lower bounds on Search (φ) (e.g. [1, 9, 13]) are realized on ad-hoc formulas φ (i.e. they were introduced specifically for these lower bounds). We introduce a new communication complexity approach that allows establishing proof complexity lower bounds for natural formulas.

First, we demonstrate our approach for two-party communication and apply it to the proof system Res (⊕) that operates with disjunctions of linear equalities over \( \mathbb{F}_2 \) [14]. Let a formula \( PM_G \) encode that a graph \( G \) has a perfect matching. If \( G \) has an odd number of vertices, then \( PM_G \) has a tree-like Res (⊕)-refutation of a polynomial-size [14]. It was unknown whether this is the case for graphs with an even number of vertices. Using our approach we resolve this question and show a lower bound \( 2^{\Omega(n)} \) on size of tree-like Res (⊕)-refutations of \( PM_{K_n+2,n} \).

Then we apply our approach for k-party communication complexity in the NOF model and obtain a \( \Omega\left(\frac{2^{\Omega(n)}}{k^{2n/k-3k/2}}\right) \) lower bound on the randomized k-party communication complexity of Search \( \text{BPHP}_M^{2n} \) w.r.t. to some natural partition of the variables, where \( \text{BPHP}_M^{2n} \) is the bit pigeonhole principle and \( M = 2^n + 2^{(1-1/k)} \). In particular, our result implies that the bit pigeonhole requires exponential tree-like \( T^{cc}(k) \) proofs, where \( T^{cc}(k) \) is the semantic proof system operating with polynomial inequalities of degree at most \( k \) and \( k = O(\log^{1-\epsilon} n) \) for some \( \epsilon > 0 \). We also show that \( \text{BPHP}_M^{2n+1} \) superpolynomially separates tree-like \( T^{cc}(\log^{1-\epsilon} m) \) from tree-like \( T^{cc}(\log m) \), where \( m \) is the number of variables in the refuted formula.

1 Introduction

Propositional proof complexity studies proof systems that allow proving the unsatisfiability of Boolean CNF formulas. The main line of research in proof complexity is focused on refutation size lower bounds for different proof systems. This research activity is motivated by NP vs coNP question [3] as well as by studying properties of SAT-solvers. This paper develops the communication complexity approach to proof complexity lower bounds.

1.1 Communication complexity of search problems

In the classical communication settings, several participants collaborate to compute a function using a broadcast communication channel; each participant knows only a part of the input and the goal is to compute the function with the minimum number of transmitted bits. In the case of search problems, participants compute a relation $R \subseteq X \times Y$ instead of a function in the following sense: an input $x \in X$ is partitioned among the participants and they have to find $y \in Y$ such that $(x, y) \in R$. Analyzing the communication complexity of search problems is usually much harder than analyzing the communication complexity of functions. Unrestricted and monotone circuit depth of a Boolean function can be characterized in terms of the communication complexity of an appropriate search problem [17].

Every unsatisfiable CNF-formula $\varphi$ defines a search problem $\text{Search} (\varphi)$: the values of the variables of $\varphi$ are partitioned between the parties of the protocol in some way, the participants are to find a clause of $\varphi$ that is falsified by the values of the variables. This problem plays an important role in proof complexity.

One of the promising approaches for obtaining proof complexity lower bounds is the investigation of dag-like communication protocols [20, 33]. This approach allows proving lower bounds for proof systems operating with proof lines having small communication complexity in the appropriate communication model. Every refutation of a formula $\varphi$ of size $S$ can be translated to a dag-like communication protocol for Search ($\varphi$) of complexity $S \cdot C$, where $C$ depends on the upper bound on the communication complexity of proof lines. Thus, lower bounds on the complexity of dag-like communication protocols imply lower bounds on the size of refutations. Nontrivial lower bounds on the size of dag-like protocols are currently known only for two-party deterministic and two-party real communication models. There are two known approaches for obtaining these lower bounds. The first is based on the correspondence between dag-like protocols and monotone Boolean/real circuits [20, 33, 11]. The second approach is lifting from the resolution width [7]. The mentioned lower bounds on dag-like communication imply lower bounds for Resolution [20], OBDD-based proof systems [21] (via deterministic protocols), and Cutting Planes [28, 10, 6, 7] (via real protocols).

Proving a superpolynomial lower bound for any of the models of dag-like communication protocols listed in the left column of Table 1 seems to be a very challenging open question. Such lower bounds would imply currently unknown superpolynomial lower bounds on the corresponding proof systems in the right column of the table.

In this paper, we deal with classical (tree-like) communication protocols. A lower bound on (tree-like) communication complexity of the problem Search ($\varphi$) in the model from the left column of Table 1 implies a lower bound on the size of tree-like refutations of $\varphi$ in the corresponding proof system from the right column as well as a lower bound on the size of dag-like refutation of $\varphi$ using small space (a size-space tradeoff [9, 12]). The usual strategy for obtaining lower bounds on the proof size via communication complexity is the following: by a tree-like refutation of $\varphi$ of size $S$ (or by a realization of a dag-like refutation of $\varphi$ in size $S$ within small space), one constructs a communication protocol for Search ($\varphi$) with

</table>

Communication complexity $O(\log S \log \log S \cdot c)^1$ for an arbitrary partition of the variables of $\varphi$ between the parties, where $c$ is an upper bound for communication complexity of a proof line in the proof system in question. One then proceeds to prove a lower bound on the communication complexity of $\text{Search}(\varphi)$ for some fixed partition of variables between the parties.

Proving lower bounds for the communication complexity of $\text{Search}(\varphi)$ is not trivial since a lower bound on $\text{Search}(\varphi)$ in the two-party deterministic communication model implies a lower bound on the monotone circuit depth for the corresponding monotone Boolean function [9, 29]. However, in the tree-like case good enough lower bounds are known for all models listed in the left column of Table 1. We discuss the strongest model, $k$-party randomized communication. Typically lower bounds on the communication complexity of $\text{Search}(\varphi)$ are shown for artificial formulas $\varphi$ that are constructed as follows: take a standard formula $\psi$ and replace each of its variables with a function $g(y_1, y_2, \ldots, y_m)$ (also known as a gadget), where $y_1, y_2, \ldots, y_m$ are fresh variables; the result of this substitution is denoted by $\psi \circ g$. The variables of every gadget are partitioned among $k$ parties. Beame, Pitassi and Segerlind [1] have shown a lower bound on the randomized $k$-party communication complexity of $\text{Search}(T(G) \circ \land_k)$, where $T(G)$ is an unsatisfiable Tseitin formula based on a special expander $G$ and $\land_k$ is the conjunction of $k$ variables, and the $i$th party has the $i$th argument of each instance of $\land_k$ written on their forehead.

Huynh and Nordström [12] have introduced a method to obtain a two-party randomized communication complexity lower bound for a search problem via lifting from search problems with large critical block sensitivity. Göös and Pitassi [9] have simplified and generalized this result to multiparty communication complexity and shown that if $\text{Search}(\varphi)$ has large critical block sensitivity and a gadget $g$ has a versatile property, then $\text{Search}(\varphi \circ g)$ has large randomized communication complexity. Although the construction of versatile functions is somewhat tricky, the proof of the lower bound is much simpler than the proofs from [1, 12].

---

**Footnote:**

1 Sometimes it can be improved to $O(\log S \cdot c)$
There is an established stereotype that lower bounds on the randomized communication complexity of search problems are rather complicated and the resulting lower bounds for proof systems hold only for artificial formulas. In this paper, we break this stereotype and suggest an approach that allows obtaining lower bounds for natural families of formulas by reduction from randomized communication complexity. Moreover, our proofs are elementary.

In the first part of the paper, we demonstrate our method by proving an exponential lower bound on the size of tree-like Res(⊕)-refutations of the perfect matching principle, while the known lower bound techniques for tree-like Res(⊕) do not work for this formula. This lower bound is based on two-party communication complexity. In the second part of the paper, we apply our method to k-party communication complexity and prove a lower bound for communication complexity of Search \( \left( BPHPM_{2^k} \right) \), where BPHPM_{2^k} denotes the bit pigeonhole principle stating that there are \( M \) distinct \( n \)-bit strings \( s_1, \ldots, s_M \), every string \( s_i \) for \( i \in [M] \) is partitioned into \( k \) almost equal sequential parts and the \( j \)th part of every string is written on the forehead of the \( j \)th party. In particular, the latter result implies that the bit pigeonhole principle is hard for tree-like Th(k), so it is the first natural hard instance.

### 1.2 Search problem \( \oplus_k \text{Search} (\varphi) \)

To achieve our results we use the parity gadget, one of the simplest and the most natural gadgets. We then show how to get rid of this gadget using either properties of a proof system or properties of a family of formulas.

For an unsatisfiable CNF formula \( \varphi \) we define a \( k \)-party communication problem \( \oplus_k \text{Search} (\varphi) \) (usually denoted as Search (\( \varphi \) o \( \oplus_k \)) as follows: for every \( i \in [k] \), the \( i \)th party has an assignment \( \alpha_i \in F_2^k \) written on the forehead, where \( n \) is the number of variables of \( \varphi \). They are to find a clause of \( \varphi \) that is falsified by the assignment \( \sum_{i=1}^k \alpha_i \).

It is easy to see that the communication complexity of Search (\( \varphi \) o \( \oplus_k \)) is at least the communication complexity of \( \oplus_k \text{Search} (\varphi) \), where \( \oplus_k \) is the parity of the sum of \( k \) bits. However, the formula \( \varphi \) o \( \oplus_k \) may have exponential size if \( \varphi \) contains a wide clause.

In Section 3 we observe the following lemma.

\[ \textbf{Lemma 1.} \] If an unsatisfiable CNF-formula \( \varphi \) has a tree-like Res (PC_d) refutation of size \( S \), then there exists a bounded-error randomized communication protocol for \( \oplus_{d+1} \text{Search} (\varphi) \) that transmits \( O(d \log S) \) bits.

### 1.3 Perfect matching principle in tree-like Res(⊕)

One of the most important open questions in proof complexity is obtaining a superpolynomial lower bound for bounded-depth Frege with parity gates. Res(⊕) is a special case of this system and there are still no known superpolynomial lower bounds for its dag-like version. The first exponential lower bounds for tree-like Res(⊕) were proved by Itsykson and Sokolov [14, 15]. Itsykson and Sokolov have shown a lower bound \( 2^{\Omega(n)} \) on size of tree-like Res(⊕) refutations of Pigeonhole Principle (PHPm_n) for arbitrary \( m > n \) using generalized Prover-Delayer games. Oparin in [26] has shown a tight upper bound \( 2^{\Omega(n)} \) for such refutations. A lower bound \( 2^{\Omega(n)} \) for functional pigeonhole principle (FPHPm) for \( m = O(n) \) can be shown using a connection between the size of tree-like Res(⊕) refutations and the degree of polynomial calculus refutations (over \( F_2 \)), observed by Garlik and Kołodziejczyk (see Section 7 of [8]; this method is described in details in [27]; an alternative explanation can be found in [19]). It is also worth mentioning the result of Krajicek (Theorem 18.6.4 from [23]) that formulas encoding Hall’s theorem about matchings in bipartite graphs require exponential-size tree-like Res(⊕) refutations.
Let PM\(_G\) for a graph G encode the existence of a perfect matching in G. Itsykson and Sokolov [14, 15] have shown that for graphs with an odd number of vertices, PM\(_G\) has a polynomial-size tree-like Res(⊕) refutation. The question about graphs with an even number of vertices remained open; we resolve it in this paper.

Let K\(_{m,n}\) be the complete bipartite graphs with parts of size m and n respectively. In Section 4 we prove the following theorem.

\textbf{Theorem 2.} The size of a tree-like Res(⊕) refutation of PM\(_{K_{n+2,n}}\) is \(2^{\Omega(n)}\).

Notice that since PHP\(_n^m\) is a weakening of PM\(_{K_{n,n}}\), Oparin’s upper bound for PHP\(_n^m\) [26] implies that the obtained lower bound is tight up to a constant in the exponent.

The formula PM\(_{K_{n+2,n}}\) (however, in a different encoding) has a constant-degree derivation in Nullstellensatz over \(\mathbb{F}_2\) [2]. PM\(_{K_{n+2,n}}\) may be refuted as follows: compute the number of edges in the matching modulo 4 in two different ways, on the one hand it is \(n \mod 4\) and on the other hand it is \((n+2) \mod 4\). This yields a low-degree Nullstellensatz refutation since the function MOD\(_4\) has a representation as a polynomial of degree 3, see Lemma 8.7 of [2] for details. Thus, Theorem 2 can not be proved via the same reduction to the Polynomial Calculus degree as it can be done for FPHP\(_n^m\).

Since PM\(_{K_{n+2,n}}\) has a tree-like Cutting Planes refutation of polynomial size and with polynomial coefficients, the problem Search (PM\(_{K_{n+2,n}}\)) has communication complexity \(O(\log n)\) for any partition and thus can not yield a superpolynomial lower bound on size of tree-like Res(⊕) refutations. \textit{Therefore the methods previously used to establish tree-like Res(⊕) lower bounds fail for PM\(_{K_{n+2,n}}\).}

To establish this lower bound we employ an idea similar to the one used in [30] to show monotone circuit depth lower bound for matching.

\textbf{Proof sketch of Theorem 2.} By Lemma 1 it is sufficient to show a lower bound \(\Omega(n)\) on the two-party bounded-error randomized communication complexity of \(\oplus_2\text{Search (PM}_{K_{n+2,n}}\).\)

We show this lower bound via probabilistic reduction from the set disjointness problem. Recall that in the set disjointness problem DISJ\(_n\) Alice and Bob have strings \(x, y \in \{0, 1\}^n\) respectively and they want to verify that there are no \(i \in [n]\) such that \(x_i = y_i = 1\). It is known that two-party bounded-error randomized communication complexity of DISJ\(_n\) is \(\Omega(n)\) [16]. Let \(G_0(V, E_1)\) and \(G_1(V, E_1)\) be graphs on the same set of vertices \(V\); we define \(G_0 \oplus G_1\) as a graph on \(V\) with edges \(E_1 \oplus E_2\), where \(\oplus\) denotes the symmetric difference.

We now describe the reduction from DISJ\(_n\) to \(\oplus_2\text{Search (PM}_{K_{n+2,n}}\).\) Before starting the communication, each of the parties constructs two graphs: Alice constructs \(A(0)\) and \(A(1)\), Bob constructs \(B(0)\) and \(B(1)\) that are shown in Figure 1. These four graphs are bipartite graphs on 8 vertices, 4 vertices in each part and the parts coincide for all the graphs. These graphs have the following property: for \(a, b \in \{0, 1\}\) the graph \(A(a) \oplus B(b)\) is a perfect matching iff at least one of \(a\) and \(b\) is zero. The graph \(A(1) \oplus B(1)\) has two connected components, the first component consists of a single vertex from the first part connected with three vertices from the second part, the second connected component consists of a single vertex from the second part connected with three vertices from the first part.

For each \(i \in [n]\) Alice and Bob create new 8 vertices; Alice builds the graph \(A(x_i)\) on these vertices and Bob builds the graph \(B(y_i)\) on these vertices. Thus, Alice and Bob construct two bipartite graphs \(G_A\) and \(G_B\) with 4n vertices in each part such that \(G_A \oplus G_B\) is a perfect matching iff DISJ\(_n(x, y) = 1\). Additionally, Alice and Bob add three vertices to the first part and one vertex to the second part of \(G_A \oplus G_B\) connecting the latter with the three vertices added to the first part. Let us denote the resulting graph by \(H\). Let \(H = H_A \oplus H_B\), where \(H_A\) is known to Alice and \(H_B\) is known to Bob. An example of the
resulting graphs is shown in Figure 2. Alice and Bob shuffle the vertices in each part of their graphs according to a permutation generated using public random bits and get graphs $H_A'$ and $H_B'$. As a result, in the shuffled graph $H' = H_A' \oplus H_B'$ the violation of the perfect matching principle artificially added by Alice and Bob is indistinguishable from a violation that appears because of $\text{DISJ}_n(x, y) = 0$. After that Alice and Bob run the communication protocol for $\oplus_k \text{Search}(\text{BPHP}_{2^\ell}^{2^\ell})$. If the protocol returns a clause corresponding to the artificially added contradiction, Alice and Bob return 1; otherwise, they return 0. By repeating the whole protocol multiple times one can reduce the error probability. ▷

1.4 Bit pigeonhole principle

1.4.1 Bit pigeonhole principle with $\oplus$-gadget

In Section 5 we apply our lower bound technique for $k$-party communication in the number-on-forehead model. We consider the bit pigeonhole principle $\text{BPHP}^m_{2^\ell}$ that encodes in CNF that there are $m$ pairwise distinct strings from $\{0, 1\}^\ell$. This formula is unsatisfiable for $m > 2^\ell$.

\begin{theorem}
Let $\ell$ and $k$ be natural numbers such that $2 \leq k \leq \ell - 7$. Then the randomized communication complexity of $\oplus_k \text{Search}(\text{BPHP}_{2^\ell}^{2^\ell})$ in the $k$-party NOF model is $\Omega \left( \frac{2^{\ell/2}}{2^{(k-1)/2}} \right)$. For $k = 2$ the stronger bound $\Omega \left( 2^\ell \right)$ holds.
\end{theorem}

Proof idea. The proof follows the same plan as the communication complexity lower bound in Theorem 2. In Subsection 5.1 we consider a decision problem $\text{Distinct}_{k, \ell}$ that is similar to the search problem $\oplus_k \text{Search}(\text{BPHP}_{2^\ell}^{2^\ell})$. Let each of $k$ parties have a $2^\ell \times \ell$ matrix over $\mathbb{F}_2$ on the forehead. The goal is to determine whether the rows of the sum of these matrices are distinct. Recall that the unique disjointness $\text{UDISJ}_{k,n}$ is the promise version of the $k$-party set disjointness: the $i$th of $k$ parties has a string $x^{(i)}$ from $\{0, 1\}^n$ on the forehead, they are to verify that there is no $j \in [n]$ such that $x_j^{(i)} = 1$ for all $i \in [k]$ under the promise that there is at most one such index $j$. We describe a randomized reduction from $\text{UDISJ}_{k,2^\ell-k+1}$ to $\oplus_k \text{Search}(\text{BPHP}_{2^\ell}^{2^\ell})$ and then use the known lower bound on the communication complexity...
of the former problem [32]. First, we reduce UDISJ\(_k,2^k-1\) to the problem Distinct\(_k,ℓ\): the
ith of the parties of the UDISJ protocol generates a matrix \(D_i\) of size \(2^k × ℓ\) such that the
matrix \(\sum_{i=1}^k D_i\) contains a pair of equal rows iff UDISJ\(_k,2^k-1\) evaluates to 0. Moreover, the
matrix \(\sum_{i=1}^k D_i\) has additional properties:

- each of the \(2^ℓ-k\) bits of UDISJ correspond to a block of \(2^k\) rows of the matrix \(\sum_{i=1}^k D_i\)
  such that any two rows from different blocks are distinct;
- if the common 1-bit of the inputs of UDISJ has the index \(j \in [2^ℓ-k]\), then the block
  corresponding to the bit \(j\) contains each of its rows exactly twice (all the other blocks
  have distinct rows).

In Subsections 5.2 and 5.3 we adapt this reduction for \(⊕_k\text{Search}(\text{BPHP}_{2^ℓ}^{2^ℓ+2^k})\). We add an
additional (fake) block to each of the matrices \(D_i\) such that the matrix \(\sum_{i=1}^k D_i\) has the
following property: every row of this new block appears in it exactly twice and does not
appear anywhere else. Using randomization we make sure that the new artificially added
row collisions from the fake block are indistinguishable from the collisions coming from the
initial (genuine) blocks corresponding to the inputs of UDISJ. Finally, if UDISJ evaluates to 1
then all the collisions are artificially added; if UDISJ evaluates to 0, then with a significant
probability the protocol solving \(⊕_k\text{Search}(\text{BPHP}_{2^ℓ}^{2^ℓ+2^k})\) finds a pair of equal rows coming
from a genuine block.

Theorem 3 and Lemma 1 immediately imply the lower bound \(\exp(Ω\left(\frac{2^{2^ℓ}}{2^ℓ+\sqrt{2^ℓ}}\right))\) on the
size of tree-like Res(\(PC_{k-1}\)) refutations of \(\text{BPHP}_{2^ℓ}^{2^ℓ+2^k}\) (for \(k = 2\) the stronger lower bound
\(Ω(2^k)\)) holds.

1.4.2 Bit pigeonhole without \(⊕\)-gadget

In Section 6 we present a pretty simple and nice reduction from \(⊕_k\text{Search}(\text{BPHP}_{2^m}^{m})\) to
\(\text{Search}(\text{BPHP}_{2^n}^{2^n,2^{k+1+n}})\). Here we describe this reduction for \(k = 2\). For a larger \(k\) the
proof is essentially the same. Let us reduce \(⊕_2\text{Search}(\text{BPHP}_{2^m}^{m})\) to \(\text{Search}(\text{BPHP}_{2^n}^{2^n,m})\).
We denote the input of Alice in \(⊕_2\text{Search}(\text{BPHP}_{2^m}^{m})\) as \(a_1,\ldots,a_m \in \mathbb{F}_2^m\) and the input of
Bob as \(b_1,\ldots,b_m \in \mathbb{F}_2^m\). Their goal is to find a clause of BPHP\(_{2^n}^{m}\) falsified by the assignemnt
\(a_1 + b_1,\ldots,a_m + b_m\). Observe that given \(i ≠ j \in [m]\) such that \(a_i + b_i = a_j + b_j\) they can
find a falsified clause transmitting additional \(O(n)\) bits. For each \(i \in [m]\), Alice and Bob
generate \(2^n\) strings from \(\mathbb{F}_2^n\): Alice generates \(a_i + z\) for each \(z \in \mathbb{F}_2^n\) and Bob generates \(b_i + z\)
for each \(z \in \mathbb{F}_2^n\). For each pair of strings \(a_i + z\) and \(b_i + z\) their sum coincides with \(a_i + b_i\).
Alice and Bob run the protocol for \(\text{Search}(\text{BPHP}_{2^n}^{2^n,m})\) on an input where each line has the
form \((a_i + z, b_i + z)\) for each \(i \in [m]\) and \(z \in \mathbb{F}_2^n\). Given a falsified clause of BPHP\(_{2^n,m}\) on
this input they determine the lines \((a_i + z, b_i + z)\) and \((a_j + z', b_j + z')\) that are equal to each other.
Then \(a_i + b_i = a_j + b_j\) and \(i ≠ j\) since each pair \((i, z) \in [m] × \mathbb{F}_2^n\) is used by Alice and
Bob exactly once.

Together with Theorem 3 this yields the following theorem.

\begin{itemize}
  \item \textbf{Theorem 4.} For \(n ≥ k(k+7)\) the randomized \(k\)-party communication complexity of
  \(\text{Search}(\text{BPHP}_{2^n}^{2^n,2^{k+1+n}})\) is \(Ω\left(\frac{2^n}{2^{k+1+n/k}}\right)\), where every string of BPHP is
  partitioned into \(k\) almost equal contiguous parts such that \(j\)th party has the \(j\)th part of every string on
  its forehead. For \(k = 2\) the bound can be improved up to \(Ω(2^{n/2})\).
\end{itemize}

In particular, Theorem 4 implies the lower bound \(\exp(2^{Ω(n/k)})\) on the size of tree-like
\(T^{cc}(k, c)\) (and Th\((k-1)\)) refutations of BPHP\(_{2^n}^{2^n,2^{n+k-1(n/k)}}\).
Hrubes and Pudlák [10] proved a lower bound on the complexity of dag-like two-party real communication protocols for $\text{Search} (\text{BPHP}_m^{2^n})$ with the same variable partition, where $m > 2^\ell$ is arbitrary. Formally their and our results are incomparable. On the one hand, the result of Hrubes and Pudlák holds for dag-like protocols and arbitrary weak bit pigeonhole principle, on the other hand, we use a stronger (randomized) model and the statement holds for the multiparty communication as well.

In addition, we show an upper bound on the communication complexity of $\text{Search} (\text{BPHP}_m^{2^n})$. The gap between the upper and the lower bound for $k > 2$ is quadratic. For $k = 2$ the bounds coincide up to a logarithmic factor.

**Proposition 5.** For $M > 2^n$ and $k \in \{2, 3, \ldots, n\}$ there exists a deterministic NOF communication protocol for $\text{Search} (\text{BPHP}_m^{2^n})$ with variables partitioned as in Theorem 4 transmitting $O \left(2^{\lceil n/k \rceil} \cdot \log M \right)$ bits.

Our lower bound on the $k$-party communication complexity of $\text{Search} (\text{BPHP}_n^m)$ is non-trivial for $k \leq \log^{1-\varepsilon} n$ for $\varepsilon > 0$. This lower bound implies a superpolynomial lower bound on the size of tree-like $\text{Th}(k)$-refutations of $\text{BPHP}_n^m$ for such $k$. We show that there exists a short tree-like $\text{Th}(\log n)$ refutation:

**Proposition 6.** For $m > 2^\ell$ there exists a tree-like $\text{Th}(\ell)$ refutation of $\text{BPHP}_m^{2^n}$ of size $O(m^2 \cdot 2^\ell)$.

Proposition 6 and the result of Hrubes and Pudlák [10] imply that tree-like $\text{Th}(\log n)$ cannot be simulated by dag-like $\text{Th}(1)$. Theorem 4 and Proposition 6 imply that the bit pigeonhole principle $\text{BPHP}_2^{2^{\ell}+1}$ separates $2$ tree-like $\text{Th}(\log n)$ from tree-like $\text{Th}(k)$ for $k \leq \log^{1-\varepsilon} n$.

### 1.5 Open questions

1. Is it possible to prove lower bounds on the randomized communication complexity of $\oplus_2 \text{Search} (\text{PM}_G)$ for constant-degree graphs $G$? An $\Omega(n)$ lower bound would improve the best known $\Omega(n/\log n)$ lower bound on the two-party communication complexity of a $\text{Search} (\varphi)$ problem, where $n$ is the number of variables.

2. Is it true that our results extend to $\text{Res} (\text{PC}_d)$ over arbitrary finite fields?

3. Is our lower bound for tree-like $\text{Th}(k)$ refutation of $\text{BPHP}_n^m$ tight? Such upper bound would imply a superpolynomial separation between tree-like $\text{Th}(k)$ and dag-like cutting planes due to the lower bound by [10] as well as separations between tree-like $\text{Th}(k)$ for different values of $k$.

4. Can we show a lower bound on the communication complexity of the search problem for weaker versions of $\text{BPHP}_n^M$, for example with $M = 2^{n+1}$?

---

2 The formula $\text{BPHP}_m^{2^\ell+1}$ uses $n = (2^\ell + 1)\ell$ variables. By Proposition 6, there is a tree-like $\text{Th}(\log n)$ refutation of size $\text{poly}(n)$. By Theorem 4, the size of any tree-like $\text{Th}(\log^{1-\varepsilon} n)$ refutation is at least $\exp(\exp(\Omega(\log^3 n)))$; the latter grows superpolynomially in $n$. 

2 Preliminaries

Notations

We use the following notation: $[n] = \{1, 2, \ldots, n\}$. Let $S^{n \times m}$ denote the set of matrices of size $n \times m$ with elements from $S$. We denote by $0_{n \times m}$ the zero matrix of size $n \times m$ and by $1_{n \times m}$ the matrix of the same size containing only ones. For square matrices $A_1, \ldots, A_k$ we denote a diagonal block matrix with blocks $A_1, \ldots, A_k$ by diag($A_1, \ldots, A_k$). For $x \in \{0, 1, \ldots, 2^k - 1\}$ we denote a vector $(a_0, \ldots, a_{k-1}) \in \{0, 1\}^k$ such that $x = \sum_{i=0}^{k-1} a_i 2^i$ by bin$_k(x)$, i.e., $(a_0, \ldots, a_{k-1})$ is the reversed binary representation of $x$. For vectors $v_1, \ldots, v_n$ from a vector space over a field $F$ we denote their linear span by span$(v_1, \ldots, v_n)$. We use coordinate-wise comparison of strings from $\{0, 1\}^n$, i.e. for $x, y \in \{0, 1\}^n$ we write $x \leq y$ iff $x_i \leq y_i$ for each $i \in [n]$. We denote the set of variables of a CNF-formula $\varphi$ by vars($\varphi$).

Communication complexity

We briefly recall some notions of communication complexity. For formal definition and details we refer to [24].

In the classic two-party randomized communication protocol with public randomness, Alice and Bob cooperate to compute a relation $Q \subseteq X \times Y \times Z$: Alice has an input $x \in X$ and Bob has an input $y \in Y$, their goal is to compute $z \in Z$ such that $(x, y, z) \in Q$. We assume that Alice and Bob have access to an arbitrary large random string of bits that is common for Alice and Bob. Let for every $x \in X$ and $y \in Y$, $R^\delta_{\text{pub}}(Q, x, y)$ denote the minimal number of bits Alice and Bob need to transmit between each other so they both find a $z \in Z$ such that $(x, y, z) \in Q$ with probability at least $1 - \delta$ taken over the values of the common random string. And $R^\delta_{\text{pub}}(Q) := \max_{x \in X, y \in Y} R^\delta_{\text{pub}}(Q, x, y)$.

We also consider multiparty communication protocols in the number on forehead (NOF) model that extends two-party protocols for an arbitrary number of parties. In this setting $k$ parties cooperate to compute a relation $Q \subseteq X_1 \times X_2 \times \ldots \times X_k \times Y$. The $i$th party has $x_i \in X_i$ written on their forehead so they know all $x_j$ for $j \neq i$, their goal is to compute $y \in Y$ such that $(x_1, x_2, \ldots, x_k, y) \in Q$. The parties communicate by taking turns broadcasting messages to all other parties until all parties learn the value of $y \in Y$ such that $(x_1, \ldots, x_k, y) \in Q$. In this model we also assume that all parties have access to a common random string of bits. Let $R^\delta_{\text{pub}}(Q, x_1, \ldots, x_k)$ for $x_1 \in X_1, \ldots, x_k \in X_k$ denote the minimal total number of bits transmitted until each party learns $y \in Y$ such that $(x_1, \ldots, x_k, y) \in Q$ with probability at least $1 - \delta$ taken over the set of values of the random string of bits. Also, let $R^\delta_{\text{pub}}(Q) := \max_{x_1 \in X_1, \ldots, x_k \in X_k} R^\delta_{\text{pub}}(Q, x_1, \ldots, x_k)$.

Let $f$ be a function from $X_1 \times X_2 \times \ldots \times X_k \to Y$. Then $R^\delta_{\text{pub}}(f)$ denotes $R^\delta_{\text{pub}}(Q_f)$, where $Q_f = \{(x_1, x_2, \ldots, x_k, y) \mid f(x_1, \ldots, x_k) = y\}$.

We prove communication complexity lower bounds by reduction from different versions of the set disjointness problem. DISJ$_{k,n}$ is a function $\{0, 1\}^{k \times n} \to \{0, 1\}$ such that for every $x_1, \ldots, x_k \in \{0, 1\}^n$ the following holds: DISJ$_{k,n}(x_1, \ldots, x_k) = \bigwedge_{j=1}^n \bigvee_{i=1}^k (x_i)_j$.

Let us define the communication promise problem UDISJ$_{k,n}$ in the $k$-party NOF model. For each $i \in [k]$ the string $x_i$ is written on the forehead of the $i$th party, it is guaranteed that there exists at most one index $j \in [n]$ such that for every $i \in [k]$, $(x_i)_j = 1$. The goal is to compute DISJ$_{k,n}(x_1, \ldots, x_k)$. 

CCC 2021
Proof Complexity of Natural Formulas via Communication Arguments

Theorem 7 ([31, 32]). \( R_{\text{pub}}^{1/3}(\text{DISJ}_k,n) = \Omega \left( \frac{n^2}{2^k} \right) \).

For \( k = 2 \) we omit the first index: \( \text{DISJ}_n = \text{DISJ}_{2,n} \); in this case Theorem 7 may be improved.

Theorem 8 ([16]). \( R_{\text{pub}}^{1/3}(\text{DISJ}_n) \geq R_{\text{pub}}^{1/3}(\text{UDISJ}_2,n) = \Omega(n) \).

Proof complexity

We consider refutational proof systems for the language of unsatisfiable CNF-formulas UNSAT. A refutation of \( \varphi \in \text{UNSAT} \) in a proof system \( \Pi \) is a sequence of Boolean functions (proof lines) such that each proof line either represents a clause of \( \varphi \) or derived from previous proof lines in the sequence via some sound inference rules. The last line of the proof is identical zero function. A proof system \( \Pi \) is defined by a representation of proof lines and by a set of admissible inference rules. It is required that the inference rules are polynomially verifiable i.e. there exists an algorithm that checks whether it is legitimate to derive a line \( L_0 \) from the lines \( L_1, \ldots, L_n \).

For example, in the Resolution proof lines are represented by clauses and the only inference rule is the resolution rule that allows deriving a clause \( A \lor B \) from the clauses \( A \lor x \) and \( A \lor \neg x \).

The size of a proof is the total size of all representations of proof lines in the proof. The length of a proof is the number of proof lines in it.

A tree-like proof is such a proof that every its line can be used as a premise of a rule at most once. For each proof system, we can also consider its tree-like version where all proofs are constrained to be tree-like.

We also consider semantic refutational proof systems, where we drop the requirement for polynomial verification of inference rules i.e. we allow to derive any sound consequence from the premises. For such systems it is crucial to bound fan-in i.e. the number of the premises from which each proof line can be derived, otherwise, it would be possible to derive a contradiction from the clauses of the initial formula immediately. For example, it is well-known that Resolution is polynomially equivalent to a semantic proof system with fan-in 2 operating with clauses.

A lower bound on the proof size in a semantic proof system implies a lower bound on the proof size in its syntactic counterpart because a syntactic proof is always a semantic proof that operates with the same class of proof lines.

We define semantic Res(\( \oplus \)) as a semantic proof system with fan-in 2 that operates with linear clauses. A linear clause is a disjunction of linear equations over \( \mathbb{F}_2 \): \( \bigvee_{i=1}^k (f_i = a_i) \), where \( f_i \) is a linear form over \( \mathbb{F}_2 \) and \( a_i \in \mathbb{F}_2 \). Notice that an ordinary clause \( \bigvee_{i \in P} x_i \lor \bigvee_{j \in N} \neg x_j \) can be represented by the linear clause \( \bigvee_{i \in P} (x_i = 1) \lor \bigvee_{j \in N} (x_j = 0) \). For definition of syntactic version of Res(\( \oplus \)) we refer to [15]; it is also proved there that syntactic and semantic Res(\( \oplus \)) are polynomially equivalent.

We define semantic Res(\( \text{PC}_d \)) as a semantic proof system with fan-in 2 that operates with disjunctions of equations of type \( f = 0 \), where \( f \) is a degree-\( d \) polynomial over \( \mathbb{F}_2 \). Notice that semantic Res(\( \text{PC}_1 \)) is exactly semantic Res(\( \oplus \)). For the definition of the syntactic version of Res(\( \text{PC}_d \)) we refer to [19].

Following [1] we define Th(\( k \)) as a semantic proof system with fan-in 2 that operates with polynomial inequalities \( g \geq 0 \), where \( g \) is a polynomial of degree at most \( k \) with integer coefficients and Boolean variables. A clause \( \bigvee_{i \in P} x_i \lor \bigvee_{j \in N} \neg x_j \) can be represented by an inequality \( \sum_{i \in P} x_i + \sum_{j \in N} (1 - x_j) - 1 \geq 0 \).
Proof complexity and communication complexity

For an unsatisfiable CNF-formula \( \varphi \) we define the communication problem Search (\( \varphi \)). Search (\( \varphi \)) is the following problem: given an assignment of the variables of the unsatisfiable CNF \( \varphi \), find a clause that is falsified by this assignment. It is assumed that variables of \( \varphi \) are somehow partitioned between the parties.

Following the paper \([9]\) we consider a semantic proof system \( T^{cc}(k, c) \) that models many interesting syntactic and semantic proof systems. The proof lines in \( T^{cc}(k, c) \) can be arbitrary Boolean functions having the following property: for every proof line \( C \) and every partition of variables of \( C \) between \( k \) parties, the NOF \( k \)-party randomized communication complexity of \( C \) is at most \( c \) w.r.t. this partition. We also define a semantic proof system \( T^{cc}_{os}(k, c) \) that is a subsystem of \( T^{cc}(k, c) \) with the restriction that a communication protocol for proof lines must have a one-sided error: if the value of a proof line is zero, then the protocol should return zero with probability \( 1 \).

For example, \( T^{cc}(2, 2) \) simulates Resolution; \( T^{cc}(2, O(1)) \) simulates \( \text{Res}(\oplus) \) \([22, 15]\); \( T^{cc}(k, O(k^3 \log^2 n)) \), where \( n \) is the number of variables in a refuted formula, simulates \( \text{Th}(k - 1) \) \([9]\). In Section 3 we show that \( T^{cc}_{os}(d + 1, O(1)) \) simulates \( \text{Res}(PC_d) \).

The following connection between the communication complexity of Search (\( \varphi \)) and tree-like proof complexity of \( \varphi \) is known.

\[ \text{Lemma 9} \ (\([1, 9]\)). \] If a CNF formula \( \varphi \) has a tree-like \( T^{cc}(k, c) \) refutation of length \( \ell \) then, over any \( k \)-partition of the variables, there is a randomized bounded-error \( k \)-party NOF protocol for Search (\( \varphi \)) with communication cost \( O(c \cdot \log \ell \log \log \ell) \).

In Section 3 we show that for \( T^{cc}_{os}(k, c) \) the bound can be improved, see Remark 14.

Basic formulas

A CNF formula \( \text{PHP}^m_n \) encodes the pigeonhole principle; \( \text{PHP}^m_n \) states that it is possible to put \( m \) pigeons into \( n \) holes such that every pigeon flies to at least one hole and at most one pigeon flies to each hole. \( \text{PHP}^m_n \) depends on variables \( p_{i,j} \) for \( i \in [m] \) and \( j \in [n] \) and \( p_{i,j} = 1 \) iff the \( i \)-th pigeon flies to the \( j \)-th hole. \( \text{PHP}^m_n \) is the conjunction of \( \binom{m(m-1)}{2} \) hole axioms and \( m \) pigeons axioms. For every \( i \in [m] \) \( \text{PHP}^m_n \) contains a pigeon axiom \( p_{i,1} \lor p_{i,1} \lor \cdots \lor p_{i,n} \). And for every \( j \in [n] \) and every \( k \neq \ell \in [n] \), \( \text{PHP}^m_n \) contains a hole axiom \( \neg p_{k,j} \lor \neg p_{\ell,j} \).

For an undirected graph \( G(V, E) \), the formula \( \text{PM}_G \) encodes in CNF that \( G \) has a perfect matching. The formula \( \text{PM}_G \) has \( |E| \) variables, each of them corresponds to an edge of \( G \), \( x_e \) is the variable corresponding to \( e \in E \).

\[
\text{PM}_G = \bigwedge_{v \in V} \left( \bigvee_{x_e \text{ is incident to } v} x_e \right) \land \bigwedge_{e_1 \neq e_2 \text{ are incident to } v} \left( \neg x_{e_1} \lor \neg x_{e_2} \right).
\]

\( \text{PM}_G \) is unsatisfiable iff \( G \) does not have a perfect matching.

\[ \text{Theorem 10} \ (\([26]\)). \] Let \( G \) be a graph with \( n \) vertices, which has no perfect matching. Then the formula \( \text{PM}_G \) has a tree-like \( \text{Res}(\oplus) \) refutation of size \( 2^{O(n)} \).

\[ \text{Proposition 11} \ (\([14]\)). \] Let \( G \) be a graph with an odd number of vertices. Then the formula \( \text{PM}_G \) has a tree-like \( \text{Res}(\oplus) \) refutation of size \( \text{poly}(n) \).

The binary pigeonhole principle \( \text{BPHP}^m \) states that there are \( m \) different \( \ell \)-bit binary strings \( s_1, s_2, \ldots, s_m \). \( \text{BPHP}^m \) has \( ml \) variables corresponding to the bits of \( s_i \) for \( i \in [m] \). Then \( \text{BPHP}^m = \bigwedge_{i \neq j \in [m]} s_i \neq s_j \), where the predicate \( s_i \neq s_j \) is encoded as a \( 2\ell \)-CNF formula.
of size $2^k$ as follows: $\bigwedge_{\alpha \in \{0,1\}^\ell} (s_i \neq \alpha \lor s_j \neq \alpha)$; notice that the predicate $(s_i \neq \alpha \lor s_j \neq \alpha)$ can be represented by a clause with $2\ell$ literals. If $m > 2^k$, then the formula $\text{BPHP}^m_2$ is unsatisfiable.

Let $\varphi$ be a CNF formula with $n$ variables, and $g : \{0,1\}^k \rightarrow \{0,1\}$ be a Boolean function. Then $\varphi \circ g$ denotes a CNF formula on $kn$ variables that represents $\varphi(g(x_1^k), g(x_2^k), \ldots, g(x_n^k))$, where $x_i^k$ denotes a vector of $k$ new variables. $\varphi \circ g$ is constructed by applying the substitution to every clause $C$ of $\varphi$ and converting the resulting function $C \circ g$ to CNF in some fixed way.

3 Communication protocols from tree-like $\text{Res} (\text{PC}_d)$ proofs

Let $\varphi$ be an unsatisfiable CNF formula with $n$ variables. Let us define the communication problem $\otimes_k \text{Search} (\varphi)$ with $k$ parties as follows. Assume that the $i$th party has an assignment $\alpha_i \in \{0,1\}^n$ written on the forehead. They aim to find a clause of $\varphi$ falsified by the assignment $\sum_{i=1}^k \alpha_i$ (all sums of boolean vectors are computed modulo 2).

- **Lemma 1.** Let $\varphi$ be an unsatisfiable CNF formula. If there exists a tree-like $\text{Res} (\text{PC}_d)$ proof of $\varphi$ of length $m$, then $R^{1/3}_{\text{pub}}(\otimes_{d+1} \text{Search} (\varphi)) = O(d \cdot \log m)$.

A slightly weaker version of the following lemma was implicitly proved in [15]:

- **Lemma 12** (see proof of Theorem 3.11 from [15]). Let $T$ be a binary tree with $m$ vertices such that the $i$th vertex is labeled with $a_i \in \{0,1\}$ with the hereditary property: for each inner vertex $i$ with direct descendants $c_1$ and $c_2$, if $a_i = 1$, then $a_{c_1} = 1$ or $a_{c_2} = 1$. We also assume that if $r$ is the root of $T$, then $a_r = 1$. Assume that we have a one-sided bounded error oracle access to $a_i$, i.e., if we request a value of $a_i$ and $a_i = 0$ we get 1 with probability at most $\frac{1}{2}$ and 0 with probability at least $\frac{1}{2}$; if $a_i = 1$ we get 1 with probability 1. Then there exists an algorithm $\mathcal{A}$ that with probability at least $\frac{2}{3}$ returns a leaf $\ell$ of $T$ with $a_\ell = 1$ and makes $O(\log m)$ oracle queries to $a_1, \ldots, a_m$.

**Proof.** See Appendix A.

**Proof of Lemma 1.** Let $F_1, \ldots, F_m$ be a tree-like $\text{Res} (\text{PC}_d)$-refutation of $\varphi$ with the underlying tree $T$, where vertices of $T$ are identified with $[m]$. Then the leaves of $T$ correspond to the clauses of $\varphi$ and $m$ is the root of $T$.

Let $\alpha_1, \ldots, \alpha_{d+1}$ be the assignments written on the front of the $d+1$ parties. Let $\alpha = \sum_{i=1}^{d+1} \alpha_i$. Let $\alpha = 1$ if $\alpha$ falsifies $F_i$ for $i \in [m]$. Then $a_m = 1$ since $F_m$ is identical false. For any inner node $v$ of $T$, if $a_v = 1$ then for the direct descendants of $v$, $c_1$ and $c_2$ either $a_{c_1} = 1$ or $a_{c_2} = 1$. In the next paragraphs we show that for any $i \in [m]$ there exists a $\text{NOF} (d+1)$-party protocol that computes $a_i$ given that for each $j \in [d+1]$ the $j$th party has $a_j$ written on their forehead such that

- the protocol transmits $O(d)$ bits;
- the protocol has one-sided bounded error: if $a_i = 1$ then the protocol returns 1 with probability 1 and if $a_i = 0$ the protocol returns 0 with probability at least $\frac{1}{2}$.

Then we use this protocol to compute $a_i$ as an oracle in the algorithm given by Lemma 12 and thus show that there is a $\text{NOF} (d+1)$-party protocol computing $\otimes_{d+1} \text{Search} (\varphi)$ with communication cost $O(d \log m)$.

Now we show that for every $\ell \in [m]$, $F_\ell (\alpha)$ can be computed by a $(d+1)$-party $\text{NOF}$ protocol with one-sided error using $O(d)$ bits of communication. Let $F_\ell = \bigvee_{j=1}^d (f_j = 1)$, where $f_1, \ldots, f_d$ are polynomials over $\mathbb{F}_2$ of degree at most $d$. Let $z_1, \ldots, z_n$ be the variables of $\varphi$. Let us introduce new variables $y_{i,1}, \ldots, y_{i,n}, y_{d+1,1}, \ldots, y_{d+1,n}$ and assume that for
each \( i \in [d+1] \) the \( i \)th party has the value of variables \( y_{i,1}, y_{i,2}, \ldots, y_{i,n} \) written on the forehead or in other words \( a_i \) assigns values of \( y_{i,1}, y_{i,2}, \ldots, y_{i,n} \). Let \( \bar{f}_j \) denote \( f_j \) after substitution \( z_{t} := y_{1,t} + y_{2,t} + \ldots + y_{d+1,t} \) for \( t \in [n]; \ j \in [t] \). Since for all \( j \in [t] \), \( \deg \bar{f}_j = \deg f_j \leq d \), we can represent \( \bar{f}_j = \bar{f}_{j}^{(1)} + \ldots + \bar{f}_{j}^{(d+1)} \) such that \( \bar{f}^{(s)} \) does not contain variables \( y_{s,1}, \ldots, y_{s,n} \) for each \( s \in [d+1] \). Then the \( i \)th party can compute \( \bar{f}_{j}^{(i)}(\alpha_1, \ldots, \alpha_{d+1}), \ldots, \bar{f}_{j}^{(1)}(\alpha_1, \ldots, \alpha_{d+1}) \).

Notice that \( F_\ell = -\left( \bigwedge_{j=1}^{n} (f_j = 0) \right) \).

The final step of the protocol exploits the idea used to construct a short randomized communication protocol for equality. Take a random uniformly distributed vector \( (e_1, \ldots, e_t) \in \mathbb{F}_2^t \).

Then all parties compute \( \sum_{j=1}^{d+1} e_j f_j(\alpha) = \sum_{j=1}^{d+1} \sum_{i=1}^{t} e_j \bar{f}_{j}^{(i)} \) with \( \mathcal{O}(d) \) bits of communication and the protocol halts.

To bound the error probability we use the following well-known statement:

\begin{itemize}
  \item[\textbf{Proposition 13 (Random subsum principle).}] For any \( x \in \mathbb{F}_2^k \setminus \{0^k\} \),
  \[
  \Pr_{y \in U(\mathbb{F}_2^k)} \left[ \sum_{i=1}^{k} y_i x_i = 1 \right] = \frac{1}{2}.
  \]

  \end{itemize}

If \( F_\ell(\alpha) = 1 \) then \( \Pr \left[ \sum_{j=1}^{t} e_j f_j(\alpha) \neq 0 \right] = \frac{1}{2} \) by the random subsum principle. If \( F_\ell(\alpha) = 0 \), then \( \Pr \left[ \sum_{j=1}^{t} e_j f_j(\alpha) = 0 \right] = 1. \)

\begin{itemize}
  \item[\textbf{Remark 14.}] Similarly to the proof of Lemma 1 one can prove that if an unsatisfiable CNF formula \( \varphi \) has a tree-like \( T^* \) refutation of length \( \ell \), then for any \( k \)-partition of the variables, there is a randomized bounded-error \( k \)-party NOF protocol for Search \( (\varphi) \) with communication cost \( \mathcal{O}(c \log \ell) \). Thus, the bound from Lemma 9 can be slightly improved in the case of one-sided error.
\end{itemize}

\section{Perfect matching}

In this section we prove the following theorem:

\begin{itemize}
  \item[\textbf{Theorem 2.}] The size of any tree-like semantic Res(\(\oplus\)) refutation of the formula \( \text{PM}_{K_{n+2,n}} \) is \( 2^{\Omega(n)} \).
\end{itemize}

By Lemma 1, to prove Theorem 2 it is sufficient to show that \( R^1_{\text{pub}} (\oplus \text{Search} (\text{PM}_{K_{n+2,n}})) = \Omega(n) \).

Consider the communication problem \( \oplus \text{PM}_n \) that is defined as follows: Alice and Bob have matrices \( X \) and \( Y \) over \( \mathbb{F}_2 \) respectively, each of the matrices has size \( m \times n \), where \( m \neq n \). Their goal is to find an all-zero row or column or two 1-cells in the same row or column in the matrix \( X + Y \).

\begin{itemize}
  \item[\textbf{Proposition 15.}] \( R^1_{\text{pub}} (\oplus \text{Search} (\text{PM}_{K_{n+2,n}})) \geq R^1_{\text{pub}} (\oplus \text{PM}_{n+2,n}^+). \)
\end{itemize}

\begin{proof}
A Boolean matrix of size \((n + 2) \times n\) naturally corresponds to a subset of edges of \( K_{n+2,n} \). A falsified clause encoding that a vertex must be covered by a matching corresponds to an all-zero row or column of the matrix; a falsified clause, encoding that a vertex can not be covered by a matching twice, corresponds to two ones in the same row or column.

Theorem 2 follows from Proposition 15 and the following theorem.
**Theorem 16.** $R^{1/3}_{pub}(\oplus \text{PM}_n^{n+2}) = \Omega(n)$.

**Proof.** We assume that $n = 4m + 1$, where $m$ is a non-negative integer. If the theorem is true for all $n$ with the residue 1 modulo 4, then it also holds for all other $n$. Indeed, the protocol for $\oplus \text{PM}_{n+1}^{n+3}$ can be used for $\oplus \text{PM}_n^{n+2}$ by adding to Alice’s matrix an extra column and a row with exactly one 1-cell on their intersection and to Bob’s matrix an extra column and a row with all zeros.

Let $P_0$ be a protocol for $\oplus \text{PM}_n^{n+2}$ transmitting at most $k$ bits. We are going to apply $P_0(X,Y)$ only to the instances where the matrix $X + Y$ does not contain all-zero rows or columns. Thus, we assume that with probability at least $2/3$, $P_0$ returns a tuple $(r_1, c_1, r_2, c_2) \in ([n] \times [n])^2$ such that $(X + Y)_{r_1, c_1} = (X + Y)_{r_2, c_2} = 1$ and either $r_1 = r_2$ or $c_1 \neq c_2$. With $O(1)$ bits of communication Alice and Bob can verify whether the answer of $P_0$ is correct and return ⊥ (failure) if it is not. Also, we can reduce the failure probability by the repetition of the protocol. Let $P$ be a protocol for $\oplus \text{PM}_n^{n+2}$ under the promise that $X + Y$ does not contain all-zero rows and columns that uses $O(k)$ bits of communication and returns a correct answer with probability at least $99/100$ and ⊥ otherwise.

We are going to construct a protocol for DISJ$_m$ transmitting $O(k)$ bits, where $m = \frac{n-1}{4}$. Since by Theorem 8 any protocol for DISJ$_m$ transmits $\Omega(m)$ bits, we conclude that $k = \Omega(m)$. Let Alice’s input for DISJ$_m$ be $a_1, \ldots, a_m$ and Bob’s input be $b_1, \ldots, b_m$.

**Lemma 17.** There exist matrices $A(0), A(1), B(0), B(1) \in \mathbb{F}_2^{4 \times 4}$ such that $A(x) + B(y)$ is a permutation matrix iff $x \land y$ is 0 and

$$A(1) + B(1) = \begin{pmatrix} 0 & 1 & 1 & 1 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}. \quad (1)$$

**Proof.** We simply present matrices that satisfy the conditions:

$$A(0) = \begin{pmatrix} 0 & 1 & 1 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}; \quad A(1) = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix};$$

$$B(0) = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}; \quad B(1) = \begin{pmatrix} 0 & 1 & 1 & 1 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}. \quad \blacktriangleright$$

Notice that Lemma 17 immediately allows to reduce DISJ$_m$ to the problem of checking whether the sum of Alices and Bobs matrices is a permutation matrix. In order to achieve that, Alice builds a matrix $A = \text{diag}(A(a_1), \ldots, A(a_m))$, Bob builds a matrix $B = \text{diag}(B(b_1), \ldots, B(b_m))$. It is easy to see that $A + B$ is a permutation matrix iff $\text{DISJ}_m(a,b) = 1$. 

\[\triangleright\]
Let us describe the reduction of $\text{DISJ}_m$ to $\oplus \text{PM}_n^{m+2}$. Alice and Bob first construct matrices $X_0$ and $Y_0$ of the following form:

$$X_0 = \begin{pmatrix} A & 0_{(n-1)\times 1} \\ 0_{1\times (n-1)} & 1 \\ 0_{1\times (n-1)} & 1 \\ 0_{1\times (n-1)} & 1 \end{pmatrix}; \quad Y_0 = \begin{pmatrix} B & 0_{(n-1)\times 1} \\ 0_{1\times (n-1)} & 0 \\ 0_{1\times (n-1)} & 0 \\ 0_{1\times (n-1)} & 0 \end{pmatrix},$$

then

$$X_0 + Y_0 = \begin{pmatrix} A + B & 0_{(n-1)\times 1} \\ 0_{1\times (n-1)} & 1 \\ 0_{1\times (n-1)} & 1 \\ 0_{1\times (n-1)} & 1 \end{pmatrix},$$

where $A + B$ is a permutation matrix iff $\text{DISJ}_m(a, b) = 1$. Then if $\mathcal{P}(X_0, Y_0)$ returns two cells that do not belong to the column $n$ we may conclude that $\text{DISJ}_m(a, b) = 0$. If $\mathcal{P}(X_0, Y_0)$ returns two cells from the $n$th column, then the value of $\text{DISJ}_m(a, b)$ can not be uniquely determined. Notice that for $X_0$ and $Y_0$ constructed as above the protocol always returning $(n + 1, n, n + 2, n)$ solves $\oplus \text{PM}_n^{m+2}$.

If $\text{DISJ}_m(a, b) = 0$, then the matrix $X_0 + Y_0$ contains at least two columns with three rows and these columns are indistinguishable from each other. To make use of that, we randomly shuffle rows and columns.

We are going to construct a protocol $\mathcal{T}$ for $\text{DISJ}_m$ as follows: Alice and Bob choose permutations $\pi \in S_n$, $\tau \in S_{n+2}$ and a matrix $\Delta \in \mathbb{F}_2^{(n+2)\times n}$ uniformly at random. We define matrices $X_0^\tau, \pi$ and $Y_0^\tau, \pi$ from $\mathbb{F}_2^{n+2\times n}$ such that for each $i \in [n + 2]$ and $j \in [n]$, $(X_0^\tau, \pi)_{i,j} = (X_0)_{\tau(i), \pi(j)}$ and $(Y_0^\tau, \pi)_{i,j} = (Y_0)_{\tau(i), \pi(j)}$. Alice and Bob run the protocol $\mathcal{P}$ for inputs $X = X_0^\tau, \pi + \Delta$, $Y = Y_0^\tau, \pi + \Delta$. Notice that $X + Y = X_0^\tau, \pi + Y_0^\tau, \pi$, thus $X + Y$ can be obtained from $X_0 + Y_0$ by shuffling rows and columns. If $\mathcal{P}(X, Y)$ returns two cells from the column $\pi(n)$, Alice and Bob return $1$, if $\mathcal{P}(X, Y)$ returns two cells from other column or row, Alice and Bob return $0$. If $\mathcal{P}(X, Y)$ returns $\bot$, then Alice and Bob return $\bot$.

First notice that if $\text{DISJ}_m(a, b) = 1$, then $\mathcal{T}$ returns a correct answer or $\bot$ with probability $1$ (and the probability of $\bot$ is at most $\frac{1}{320}$), since in that case $X + Y$ has exactly one column with three 1-cells, each of the other columns and rows contains exactly one 1-cell. Let us fix $a, b \in \{0, 1\}^m$ such that $\text{DISJ}_m(a, b) = 0$. We denote $p := \Pr[\mathcal{T}(a, b) = 0 \mid \bot]$, we will show that $p \geq \frac{99}{200}$. We can then increase this probability to $2/3$ by repeating the protocol twice (if $\mathcal{T}(a, b)$ returns $0$ at least once, we return $0$, if $\mathcal{T}(a, b)$ always return $\bot$, we return $\bot$, otherwise we return $1$).

Let us describe random bits $r$ by the constructed protocol $\mathcal{T}$. First, we use random bits $r$ to run the protocol $\mathcal{P}$. Second, we use random bits to generate $\pi, \tau$, and $\Delta$. Since $\text{DISJ}_m(a, b) = 0$, we can fix $i \in [m]$ such that $a_i = b_i = 1$. In that case the submatrix of $X_0 + Y_0$ formed by rows and columns with the indices $4(i - 1) + 1, 4(i - 1) + 2, 4(i - 1) + 3, 4(i - 1) + 4$ coincides with the matrix (1). Let us denote by $\text{col}(j)$ for $j \in [n]$ the set of all tuples $(x, y, j, y, j) \in ([n + 2] \times [n])^2$.

$$p = \Pr_{\pi, \tau, \Delta, r} [\mathcal{P}(X, Y) \not\in \text{col}(\pi(n))] - \Pr_{\pi, \tau, \Delta, r} [\mathcal{P}(X, Y) = \bot] = 1 - \Pr_{\pi, \tau, \Delta, r} [\mathcal{P}(X, Y) \in \text{col}(\pi(n))] - p = 1 - \sum_{\pi_0, \tau_0} \Pr_{\pi, \tau, \Delta} [\mathcal{P}(X_0^\tau, \pi_0 + \Delta, Y_0^\tau, \pi_0 + \Delta) \in \text{col}(\pi_0(n))] \Pr_{\pi, \tau} [\pi = \pi_0, \tau = \tau_0] - p$$
Observe that for fixed $\pi_0$ and $\tau_0$ the random variable $(X_0^{\pi_0,\tau_0} + \Delta, Y_0^{\pi_0,\tau_0} + \Delta)$ is uniformly distributed over the pairs of matrices with the sum $X_0^{\pi_0,\tau_0} + Y_0^{\pi_0,\tau_0}$. Let $\alpha \in S_n$ be the transposition swapping $n$ and $4(i - 1) + 1$. Let $\beta \in S_{n+2}$ be the permutation swapping $n$ and $4(i - 1) + 2$, $n + 1$ and $4(i - 1) + 3$, $n + 2$ and $4(i - 1) + 3$ (i.e. $\beta$ is a product of three transpositions). By the construction of $\alpha$ and $\beta$, $(X_0 + Y_0) = (X_0^\beta + Y_0^\beta, \alpha)$, thus $(X_0^{\tau,\pi} + Y_0^{\tau,\pi}) = (X_0^{\tau_0,\pi_0} + Y_0^{\tau_0,\pi_0})$ for every $\pi, \tau$. Thus the random variable $(X_0^{\tau_0,\pi_0} + \Delta, Y_0^{\tau_0,\pi_0} + \Delta)$ has the same distribution with $(X_0^{\pi_0,\tau_0} + \Delta, Y_0^{\pi_0,\tau_0} + \Delta)$, thus we can continue the sequence as follows:

$$p = 1 - \sum_{\pi_0,\tau_0} \Pr[\pi R(X_0^{\pi_0,\tau_0} + \Delta, Y_0^{\pi_0,\tau_0} + \Delta) \in \text{col}(\pi_0(n))] \Pr[\pi = \pi_0, \tau = \tau_0] - p_\perp$$

$$= 1 - \sum_{\pi_0,\tau_0} \Pr[\pi R(X_0^{\pi_0,\tau_0} + \Delta, Y_0^{\pi_0,\tau_0} + \Delta) \in \text{col}(\pi_0 o \alpha^{-1})(n)) \Pr[\pi = \pi_0, \tau = \tau_0] - p_\perp$$

$$= 1 - \Pr[\pi R(X,Y) \in \text{col}(\pi o \alpha^{-1})(n)] - p_\perp$$

$$\geq 1 - \Pr[\pi R(X,Y) \notin \text{col}(\pi(n))] - p_\perp = 1 - p - p_\perp$$

Thus, $p \geq 1 - p - p_\perp$ and $p \geq \frac{1-p_\perp}{2} = \frac{99}{200}$. □

5 Bit pigeonhole principle with parity gadget

In this section, we prove the following theorem.

**Theorem 3.** Let $\ell$ and $k$ be natural numbers such that $2 \leq k \leq \ell - 7$. Then

$$R_{\text{pub}}^{\ell/3} (\oplus_k \text{Search}(\text{BPHP}_{2^\ell}^{2^k+2^k})) = \Omega \left( \frac{2^\ell}{k^{2/3} \ell^{1/2}} \right).$$

For $k = 2$ the stronger bound holds:

$$R_{\text{pub}}^{1/3} (\oplus_2 \text{Search}(\text{BPHP}_{2^\ell}^{2^2+4})) = \Omega (2^\ell).$$

We consider a combinatorial analogue of the communication problem $\oplus_k \text{Search}(\text{BPHP}_{2^m}^m)$. Assume that each of $k$ parties gets $m$ binary strings from $\{0,1\}^\ell$, where $m > 2^\ell$. The $t$th party has numbers $a_{t,1}, \ldots, a_{t,m} \in \{0,1\}^\ell$ on their forehead. Based on these strings we form the following set of $m$ vectors from $\mathbb{F}_2^\ell$: $x_1, x_2, \ldots, x_m$, where $x_j = \sum_{i=1}^ka_{i,j}$. The goal of the parties is to find a pair of different indices $t, s \in [m]$ such that $x_t = x_s$. We denote this problem by $\oplus_k \text{BPHP}_{2^m}^m$. It is straightforward that $R_{\text{pub}}^{1/3} (\oplus_k \text{Search}(\text{BPHP}_{2^m}^m)) \geq R_{\text{pub}}^{1/3} (\oplus_k \text{BPHP}_{2^m}^m)$, hence it is sufficient to prove a lower bound on $R_{\text{pub}}^{1/3} (\oplus_k \text{BPHP}_{2^m}^m)$.

**Theorem 18.** Let $\ell$ and $k$ be natural numbers such that $2 \leq k \leq \ell - 7$. Then

$$R_{\text{pub}}^{1/3} (\oplus_k \text{BPHP}_{2^\ell}^{2^k+2^k}) = \Omega \left( R_{\text{pub}}^{1/3} (\text{UDISJ}_{k,2^\ell-k-1}) - \ell \right).$$

**Corollary 19.** $R_{\text{pub}}^{1/3} (\oplus_2 \text{BPHP}_{2^\ell}^{2^2+2^k}) = \Omega \left( \frac{2^{\ell/2}}{k^{3/2} \ell^{1/2}} \right)$. For $k = 2$ the stronger bound holds:

$$R_{\text{pub}}^{1/3} (\oplus_2 \text{BPHP}_{2^\ell}^{2^2+4}) = \Omega (2^{\ell}).$$

**Proof of Corollary 19.** Follows from Theorem 18 and Theorem 7; for $k = 2$ we should apply Theorem 8. □

Theorem 3 immediately follows from Corollary 19.
5.1 Warm-up example

We start with the simpler statement that, nonetheless, demonstrates the main idea of Theorem 18. Consider the following communication problem Distinct_{k,ℓ}: let each of k parties have a matrix from $\mathbb{F}_2^{2^\ell \times \ell}$ on their forehead. The goal is to determine whether all rows of the sum of all these matrices are distinct. A version of this problem without the xor-gadget is referred to as Element Distinctness (ED) in the literature [25].

\textbf{Proposition 20.} $R^{1/3}_{\text{pub}}(\text{Distinct}_{k,\ell}) \geq R^{1/3}_{\text{pub}}(\text{UDISJ}_{k,2^{\ell-k}})$. 

Let $S_k$ denote the set of matrices from $\{0,1\}^{2^\ell \times k}$ with all distinct rows. Let $K_k \in \{0,1\}^{2^\ell \times k}$ be a matrix such that its $i$th row equals bin_k(i−1−((i−1) mod 2)), i.e. the rows of $K_k$ are $\text{bin}_k(0),\text{bin}_k(1),\text{bin}_k(2),\ldots,\text{bin}_k(2^{\ell-1} - 2),\text{bin}_k(2^{\ell-1} - 2)$. Notice that every row of $K_k$ starts with zero and appears exactly twice.

In the proof of Proposition 20 as well as in the proof of Theorem 18 we will use the following combinatorial lemma that we prove in Subsection 5.4.

\textbf{Lemma 21.} There exist matrices $A_1(0), A_1(1), \ldots, A_k(0), A_k(1) \in \mathbb{F}_2^{2^\ell \times k}$ such that $\sum_{i=1}^k A_i(1) = K_k$ and for all $b_1, b_2, \ldots, b_k \in \{0, 1\}$, if $\bigwedge_{i=1}^k b_i = 0$, then $\sum_{i=1}^k A_i(b_i) \in S_k$.

\textbf{Proof of Proposition 20.} Let $(x_{1,1}, \ldots, x_{2^{\ell-k}})$ be an input of the $i$th party of the problem UDISJ_{k,2^{\ell-k}}. For all $i \in [k]$ we construct a matrix $D_i$ of size $2^k \times \ell$ and put it on the forehead of the $i$th party. Let $A_i(b)$ for $i \in [k], b \in \{0, 1\}$ be matrices of size $2^k \times k$ from Lemma 21.

Let $J$ for $t \in [1, \ldots, 2^{\ell-k}]$ be a matrix of size $2^k \times (\ell - k)$ such that all its rows are equal to bin_{\ell-k}(t-1).

Let us define

$$D_1 := \begin{pmatrix} J_1 & A_1(x_{1,1}) \\ \vdots & \vdots \\ J_j & A_1(x_{1,j}) \\ \vdots & \vdots \\ J_{2^{\ell-k}} & A_1(x_{1,2^{\ell-k}}) \end{pmatrix}; \quad D_i := \begin{pmatrix} 0_{2^k \times (\ell-k)} & A_i(x_{1,1}) \\ \vdots & \vdots \\ 0_{2^k \times (\ell-k)} & A_i(x_{1,j}) \\ \vdots & \vdots \\ 0_{2^k \times (\ell-k)} & A_i(x_{1,2^{\ell-k}}) \end{pmatrix} \text{ for } i \in \{2, \ldots, k\}.$$ 

By Lemma 21, the matrix $D_1 + D_2 + \cdots + D_k$ has the following property: for all $j \in [2^{\ell-k}]$, its submatrix formed by the rows with numbers from $[2^k \cdot (j-1) + 1, 2^k \cdot j]$ has two equal rows if and only if $x_{1,i} = x_{2,j} = \ldots = x_{k,j} = 1$. Thus, the communication complexity of UDISJ_{k,2^{\ell-k}} is at most the communication complexity of Distinct_{k,\ell}. 

5.2 Proof of Theorem 18

In order to prove Theorem 18 we modify the proof of Proposition 20 in order to reduce UDISJ_{k,2^{\ell-k}}_{-1} to $\oplus_k \text{BPHD}_{2^\ell}^{2^k + 2^k}$ by adding “fake” rows (such rows do not correspond to the input of the unique disjointness) to matrices $D_1, D_2, \ldots, D_k$. We also use some randomization in order to hide “fake” rows among other rows.

\textbf{Proof of Theorem 18.} Let $N > 2^\ell$, consider a $k$-party communication problem ROW $\oplus_k \text{BPHD}_{2^\ell}^N$, where $i$th party has a matrix $M_i \in \mathbb{F}_2^{N \times \ell}$ on their forehead and their goal is to find the value of a row of $M_1 + \cdots + M_k$ that appears in this matrix at least twice. The difference with the problem $\oplus_k \text{BPHD}_{2^\ell}^N$ is that we are looking for values of a repeated row rather than numbers of equal rows.
Claim 22. If \( R_{1/3}(\oplus_k \text{BPHP}_N^{2^k}) \leq t \), then there exists a communication protocol \( \mathcal{P} \) for ROW \( \oplus_k \text{BPHP}_N^{2^k} \) using \( O(t + \ell) \) bits of communication such that \( \mathcal{P} \) either returns the correct answer or \( \perp \) (failure) and \( \Pr[\mathcal{P}(M_1, \ldots, M_k) = \perp] \leq \frac{1}{100} \) for all input matrices \( M_i, i \in [k] \).

Proof. \( \mathcal{P} \) executes a randomized protocol for \( \oplus_k \text{BPHP}_N^{2^k} \) and verifies its answer by transferring additional \( O(\ell) \) bits. The probability of failure can be reduced by repetition.

Let us describe a protocol for the problem UDISJ\(_{k,2^{\ell-k}-1} \) that uses a protocol \( \mathcal{P} \) for ROW \( \oplus_k \text{BPHP}_N^{2^k+2^k} \) from Claim 22.

Let \( x_1, \ldots, x_k \in \{0,1\}^{2^{\ell-k}-1} \) be inputs of the communication problem UDISJ\(_{k,2^{\ell-k}-1} \). Let \( x_{i,j} \) denote the \( j \)th bit of \( x_i \) for \( i \in [k], j \in [2^{\ell-k} - 1] \). Let \( \mathfrak{F} = (x_1, x_2, \ldots, x_k) \).

### Important matrices

Let \( \gamma \) be a bijection from \([2^{\ell-k} - 1] \cup \{\ast\}\) to \([0,1]^{\ell-k} \), we define \( k \) matrices \( D_1(x_1, \gamma) \) and \( D_2(x_2), D_3(x_3), \ldots, D_k(x_k) \) of size \((2^\ell + 2^k) \times \ell\) similar to Proposition 20.

Let \( A_i(b) \) for \( i \in [k], b \in \{0,1\} \) be matrices of size \( 2^k \times k \) from Lemma 21. Let for every \( t \in [0,1]^{\ell-k}, J_t \) be a matrix of size \( 2^k \times (\ell - k) \) such that all its rows are equal to \( t \). Let \( W \) be some fixed matrix from \( S_k \).

We define

\[
D_1(x_1, \gamma) := \begin{pmatrix}
J_{\gamma(1)} & A_1(x_{1,1}) \\
\vdots & \vdots \\
J_{\gamma(j)} & A_1(x_{1,j}) \\
\vdots & \vdots \\
J_{\gamma(j)} & A_1(x_{1,2^{\ell-k}-1}) \\
J_{\gamma(\ast)} & W \\
J_{\gamma(\ast)} & W
\end{pmatrix}
\]

and for \( i \in [k] \setminus \{1\} \)

\[
D_i(x_i) := \begin{pmatrix}
0_{2^k \times (\ell-k)} & A_i(x_{i,1}) \\
\vdots & \vdots \\
0_{2^k \times (\ell-k)} & A_i(x_{i,j}) \\
\vdots & \vdots \\
0_{2^k \times (\ell-k)} & A_i(x_{i,2^{\ell-k}-1}) \\
0_{2^k \times (\ell-k)} & 0_{2^k \times k} \\
0_{2^k \times (\ell-k)} & 0_{2^k \times k}
\end{pmatrix}
\]

Notice that the submatrix of \( D_1(x_1, \gamma) \) formed by the last \( 2^k+1 \) rows of the matrix \( D_1(x_1, \gamma) \) contains every its row exactly two times.

We define \( H_{\mathfrak{F}}(\gamma) := D_1(x_1, \gamma) + D_2(x_2) + \cdots + D(x_k) \). By Lemma 21 the matrix \( H_{\mathfrak{F}}(\gamma) \) satisfies the following key property w.r.t. \((\gamma, \mathfrak{F})\) in the standard basis:

**Definition 23.** Let \( M \) be a matrix from \( \mathbb{F}_2^{(2^k+2^\ell) \times \ell} \), \( \gamma \) be a bijection from \([2^{\ell-k} - 1] \cup \{\ast\}\) to \([0,1]^{\ell-k} \) and \( e_1, e_2, \ldots, e_{\ell} \) be a basis in \( \mathbb{F}_2^\ell \).

We say that \( M \) satisfies the key property w.r.t \((\gamma, \mathfrak{F})\) in the basis \((e_1, e_2, \ldots, e_{\ell})\) if the following properties hold:
If $s$ is a row among the last $2^k+1$ rows of $M$, then
- the first $\ell - k$ coordinates of $s$ in the basis $(e_1, e_2, \ldots, e_\ell)$ are $\gamma(*)_1, \ldots, \gamma(*)_{\ell-k}$;
- $s$ appears in $M$ exactly twice.

If $s$ is a row of $M$ among the rows with numbers $[2^k(i-1) + 1; 2^k i]$ for $i \in [2^{\ell-k} - 1]$, then
- the first $\ell - k$ coordinates of $s$ in the basis $(e_1, e_2, \ldots, e_\ell)$ are $\gamma(i)_1, \ldots, \gamma(i)_{\ell-k}$;
- if $\bigwedge_{i=1}^k x_{i,j} = 0$, then $s$ appears in $M$ exactly once.
- if $\bigwedge_{i=1}^k x_{i,j} = 1$, then $s$ appears in $M$ exactly twice and $(\ell - k + 1)$th coordinate of $s$ in the basis $(e_1, e_2, \ldots, e_\ell)$ is 0.

Consider an invertible matrix $E \in \mathbb{F}_2^{\ell \times \ell}$. Let $e_1, e_2, \ldots, e_\ell$ be the rows of $E$. Since $E$ is invertible, $e_1, e_2, \ldots, e_\ell$ form a basis. Let us define $C_{\mathcal{P}}(\gamma, E) := H(\pi, \gamma)E$. Rows of $C_{\mathcal{P}}(\gamma, E)$ can be viewed as vectors with coordinates in the basis $e_1, e_2, \ldots, e_\ell$ corresponding to the rows of $H(\pi, \gamma)$. Hence, $C_{\mathcal{P}}(\gamma, E)$ satisfies the key property w.r.t. $(\gamma, \pi)$ in the basis $(e_1, e_2, \ldots, e_\ell)$.

For a bijection $\gamma$ from $[2^{\ell-k} - 1] \cup \{*\}$ to $\{0, 1\}^{\ell-k}$ and an invertible matrix $E \in \mathbb{F}_2^{\ell \times \ell}$ we define a set $\text{Fake}(\gamma, E) \subseteq \mathbb{F}_2^{\ell \times \ell}$ as a set of the last $2^k+1$ rows of the matrix $C_{\mathcal{P}}(\gamma, E)$. Notice that by the construction this set does not depend on $\pi$. By the key property rows from $\text{Fake}(\gamma, E)$ appear exactly twice in $C_{\mathcal{P}}(\gamma, E)$.

Random variables

Our protocol uses the following public random variables. In order to distinguish random variables from their values, we highlight random variables in bold.

- $\gamma$ is a random bijection from $[2^{\ell-k} - 1] \cup \{*\}$ to $\{0, 1\}^{\ell-k}$ distributed uniformly among all such bijections.
- $E$ is a random invertible matrix from $\mathbb{F}_2^{\ell \times \ell}$ distributed uniformly among all such matrices.
- $\pi$ is a random permutation of the set $\{0, 1\}^{\ell-k}$ and $M_\pi$ is a permutation matrix of size $(2^\ell + 2^k) \times (2^\ell + 2^k)$ corresponding to the permutation $\pi$ (i.e. $(M_\pi)_{i,j} = 1 \iff \pi(i) = j$).
- $\Delta_1, \Delta_2, \ldots, \Delta_k$ are random matrices from $\mathbb{F}_2^{(2^\ell + 2^k) \times \ell}$ distributed uniformly on the set of all matrices $\Delta_1, \Delta_2, \ldots, \Delta_k$ such that $\Delta_1 + \Delta_2 + \ldots + \Delta_k$ is the zero matrix.

We define random matrices $P_1, P_2, \ldots, P_k$ as follows: $P_i = M_\pi \cdot D_i(x_i) \cdot E + \Delta_i$, for $i \geq 2$ and $P_1 = M_\pi \cdot D_i(x_1, \gamma) \cdot E + \Delta_i$.

The addition of $\Delta_i$ makes $P_i$ indistinguishable from the random matrix for every $i \in [k]$.

$\sum_{i=1}^k P_i = M_\pi C_{\mathcal{P}}(\gamma, E)$ and this matrix is obtained from $C_{\mathcal{P}}(\gamma, E)$ by the permutation $\pi$ applied to its rows.

Recall that $\mathcal{P}$ is the protocol for $\text{ROW} \oplus_k \text{BPHP}^{2^\ell+2^k}$ from Claim 22. Let $N$ be a constant to be chosen later. The protocol $\mathcal{T}$ solving $\text{UDISJ}_{k, 2^{\ell-k} - 1}$ is described by Algorithm 1.

Protocol analysis

Let us analyze the protocol $\mathcal{T}$. Since it executes the protocol $\mathcal{P}$ a constant number of times, $\mathcal{T}$ transmits $O(t + \ell)$ bits. Assume that $x_1, x_2, \ldots, x_k$ is a 1-instance of $\text{UDISJ}_{k, 2^{\ell-k} + 2^k}$. Then by the key property of $C_{\mathcal{P}}(\gamma, E)$ all repeated rows of $\sum_{i=1}^k P_i$ are in $\text{Fake}(\gamma, E)$, hence the protocol $\mathcal{T}$ returns either $\perp$ or the correct answer. Since $\mathcal{P}$ is executed $N$ times independently, the probability that $Z = \{\perp\}$ is at most $\frac{1}{100N^3}$, hence $\mathcal{T}$ returns 1 with probability at least $1 - \frac{1}{100N^3}$.

The rest of the proof is devoted to the analysis of the case, where $x_1, x_2, \ldots, x_k$ is a 0-instance of $\text{UDISJ}_{k, 2^{\ell-k} + 2^k}$. This is the most technically involved part of the proof. So it is a good point to give a large scale overview of the further proof strategy. Our goal
is to show that if $x_1, x_2, \ldots, x_k$ is a 0-instance of UDISJ$_{k,2^e-1}$, then the probability that $P(P_1, \ldots, P_k)$ returns a value from Fake($\gamma, E$) is bounded by some constant less than 1. The random variable $P(P_1, \ldots, P_k)$ depends on random bits used by the protocol $P$ and on random bits needed for sampling $P_1, \ldots, P_k$. Let $R$ denote the set of all random strings used by the protocol $P$ (i.e. we assume that $P$ sample a random string from $R$ and use it as public randomness) and $S$ denote the set of all random strings used for sampling $P_1, \ldots, P_k$. We would like to construct two bijections $\alpha$ and $\beta$ on the set $S$ such that for every $s \in S$ the following two properties hold.

1. The three values of random variable $(P_1, \ldots, P_k)$ sampled using three strings $s, \alpha(s)$ and $\beta(s)$ as a random source, are the same.

2. Let $(\gamma, E), (\gamma_{\alpha}, E_{\alpha})$ and $(\gamma_{\beta}, E_{\beta})$ be values of the random variable $(\gamma, E)$ that is sampled using three strings $s, \alpha(s)$ and $\beta(s)$ as a random source. Then Fake($\gamma, E$) ∩ Fake($\gamma_{\alpha}, E_{\alpha}$) ∩ Fake($\gamma_{\beta}, E_{\beta}$) = $\varnothing$.

Consider arbitrary strings $r \in R$ and $s \in S$. The first property implies that for random variables sampled using strings $(r, s)$, $(r, \alpha(s))$ and $(r, \beta(s))$ as a random source values of $P(P_1, \ldots, P_k)$ are the same. The second property implies that for at least one of these cases this value does not belong to Fake($\gamma, E$). Then, using that $\alpha$ and $\beta$ are bijections, we get $\Pr[P(P_1, \ldots, P_k) \in \text{Fake}($$\gamma, E$)] \leq \frac{2}{3}.

Since we have many random variables, it is a tedious task to construct such $\alpha$ and $\beta$. In order to simplify this task we slightly relax the properties. We will define bijections $\alpha$ and $\beta$ not on all strings $S$ but only on the part of bits corresponding to sampling of $\gamma$ and $E$. More precisely we will define two bijections $\alpha$ and $\beta$ on the set of values of the random variable $(\gamma, E)$. We relax the first property as follows:

1'. For every $\gamma$ and $E$ the three conditional distributions of the random variable $(P_1, \ldots, P_k)$ under the following three conditions coincide:
a. \((\gamma, E) = (\gamma, E)\),
b. \((\gamma, E) = \alpha(\gamma, E)\) and
c. \((\gamma, E) = \beta(\gamma, E)\).

Unfortunately, we were not able to construct such bijections on the set of all pairs \((\gamma, E)\). Thus we take a set \(\Xi\) consisting \(1 - \delta\) fraction of all values of \((\gamma, E)\) and we will claim that \(\alpha\) and \(\beta\) are bijections on \(\Xi\). Such relaxation will weaken the bound of the probability up to \(\frac{2}{3} + \delta\). We formalize the requirements to \(\Xi, \alpha\) and \(\beta\) in Definition 24. Then we verify in Claim 25 that these requirements are sufficient to bound \(\Pr[\mathcal{P}(P_1, \ldots, P_k) \in \text{Fake}(\gamma, E)]\).

The construction of \(\Xi, \alpha\) and \(\beta\) is given in Subsection 5.3.

\textbf{Definition 24.} Let \(x_1, \ldots, x_k\) be a 0-instance of \(\text{UDISJ}_{k, 2^{\ell-k-1}}\) and \(1 > \delta \geq 0\) be an arbitrary constant. Let \(\Xi\) be a set consisting of pairs \((\gamma, E)\), where \(\gamma\) is a bijection from \([2^{\ell-k} - 1]\) to \((0, 1)^{\ell-k}\). Let \(\alpha\) and \(\beta\) be bijections from \(\Xi\) to \(\Xi\). We say that \((\Xi, \alpha, \beta)\) forms a \((1 - \delta)\)-symmetry randomness space for \(\mathcal{F}\) if the following conditions hold:

- \textbf{(Largeness)} \(\Pr[(\gamma, E) \in \Xi] \geq 1 - \delta\).
- \textbf{(Difference)} For all \((\gamma, E) \in \Xi\), \(\text{Fake}(\gamma, E) \cap \text{Fake}(\alpha(\gamma, E)) \cap \text{Fake}(\beta(\gamma, E)) = \emptyset\).
- \textbf{(Symmetry)} For all \((\gamma, E) \in \Xi\) the matrices \(C_\mathcal{F}(\gamma, E), C_\mathcal{F}(\alpha(\gamma, E))\) and \(C_\mathcal{F}(\beta(\gamma, E))\) differ only by a permutation of rows.

\textbf{Claim 25.} Assume that \(x_1, \ldots, x_k\) is a 0-instance of \(\text{UDISJ}_{k, 2^{\ell-k-1}}\), \(1 > \delta \geq 0\) is a constant. Let \((\Xi, \alpha, \beta)\) form a \((1 - \delta)\)-symmetry randomness space for \(\mathcal{F}\).

Then

\[\Pr[\mathcal{P}(P_1, P_2, \ldots, P_k) \in \text{Fake}(\gamma, E)] \leq \frac{2}{3} + \delta.\]

\textbf{Proof.}\ Let us denote \(\mathcal{P} = (P_1, P_2, \ldots, P_k), \mathcal{A} = (\Delta_1, \Delta_2, \ldots, \Delta_k)\) and \(\mathcal{D}(\mathcal{F}, \gamma) = (D_1(x_1, \gamma), D_2(x_2), \ldots, D_k(x_k))\).

\[\mathcal{P} = (\Delta_1 + M_\gamma D_1(x_1, \gamma) E, \Delta_2 + M_\gamma D_2(x_2) E, \ldots, \Delta_k + M_\gamma D_k(x_k) E),\]

for brevity we use the vector notation \(\mathcal{P} = \mathcal{A} + M_\gamma \mathcal{D}(\mathcal{F}, \gamma) E\).

Let \(p := \Pr[\mathcal{P} \in \text{Fake}(\gamma, E)]\).

Then

\[p = \sum_{(\gamma, E) \in \Xi} \Pr[\mathcal{A} + M_\gamma \mathcal{D}(\mathcal{F}, \gamma) \cdot E] \in \text{Fake}(\gamma, E) \cdot \Pr[\gamma = \gamma, E = E] \leq \sum_{(\gamma, E) \in \Xi} \Pr[\mathcal{A} + M_\gamma \cdot \mathcal{D}(\mathcal{F}, \gamma) \cdot E] \in \text{Fake}(\gamma, E) \cdot \Pr[\gamma = \gamma, E = E] + \delta \]

Notice that for fixed \(\gamma, E\) the random variable \(\mathcal{A} + M_\gamma \cdot \mathcal{D}(\mathcal{F}, \gamma) \cdot E\) is distributed uniformly on the set of tuples \((L_1, \ldots, L_k)\) of \(k\) matrices from \(F_2(2^{\ell-\ell} + 2\ell)\) such that \(\sum_{i=1}^k L_i\) differs from \(C_\mathcal{F}(\gamma, E)\) only by a permutation of rows. Let \((\gamma_{\alpha-1}, E_{\alpha-1}) = \alpha^{-1}(\gamma, E)\). By the symmetry condition, matrices \(C_\mathcal{F}(\gamma, E)\) and \(C_\mathcal{F}(\gamma_{\alpha-1}, E_{\alpha-1})\) differ only by permutation of rows. Thus, for every set \(A\) the probability \(\Pr[\mathcal{P}(\mathcal{A} + M_\gamma \cdot \mathcal{D}(\mathcal{F}, \gamma) \cdot E) \in A] = \Pr[\mathcal{P}(\mathcal{A} + M_\gamma \cdot \mathcal{D}(\mathcal{F}, \gamma_{\alpha-1}) \cdot E_{\alpha-1}) \in A]\). Hence,

\[ p \leq \sum_{(\gamma,E) \in \Xi} \Pr \left[ P \left( \bar{D} + M_\pi \cdot \left( \bar{D}(\bar{x},\gamma_{i-1}) \cdot E_{i-1} \right) \right) \in \text{Fake}(\gamma,E) \right] \cdot \Pr[\gamma = \gamma,E = E] + \delta \\
= \sum_{(\gamma,E) \in \Xi} \Pr \left[ P \left( \bar{D} + M_\pi \cdot \left( \bar{D}(\bar{x},\gamma) \cdot \gamma_{i-1} \right) \right) \in \text{Fake}(\alpha(\gamma,E)) \right] \cdot \Pr[\gamma,E = \alpha(\gamma,E)] + \delta \\
= \sum_{(\gamma,E) \in \Xi} \Pr \left[ P \left( \bar{D} + M_\pi \cdot \left( \bar{D}(\bar{x},\gamma) \cdot \gamma_{i-1} \right) \right) \in \text{Fake}(\alpha(\gamma,E)) \right] \cdot \Pr[\gamma,E = \alpha(\gamma,E)] + \delta \\
= \Pr \left[ P \left( \bar{P} \right) \in \text{Fake}(\alpha(\gamma,E)), (\gamma,E) \in \Xi \right] + \delta.
\]

Analogously, \( p \leq \Pr \left[ P \left( \bar{P} \right) \in \text{Fake}(\beta(\gamma,E)), (\gamma,E) \in \Xi \right] + \delta. \) Also the inequality \( p \leq \Pr \left[ P \left( \bar{P} \right) \in \text{Fake}(\gamma,E), (\gamma,E) \in \Xi \right] + \delta \) follows by the largeness condition. Then,

\[
3(1 - p) \geq \Pr \left[ P \left( \bar{P} \right) \notin \text{Fake}(\beta(\gamma,E)) \lor (\gamma,E) \notin \Xi \right] \\
+ \Pr \left[ P \left( \bar{P} \right) \notin \text{Fake}(\alpha(\gamma,E)) \lor (\gamma,E) \notin \Xi \right] \\
+ \Pr \left[ P \left( \bar{P} \right) \notin \text{Fake}(\gamma,E) \lor (\gamma,E) \notin \Xi \right] - 3\delta \\
\geq \Pr \left[ P \left( \bar{P} \right) \notin \text{Fake}(\gamma,E) \cap \text{Fake}(\alpha(\gamma,E)) \cap \text{Fake}(\beta(\gamma,E)) \lor (\gamma,E) \notin \Xi \right] - 3\delta \\
= 1 - 3\delta.
\]

The last equality follows by the difference condition. Hence, \( 3(1 - p) \geq 1 - 3\delta, \) thus \( p \leq \frac{2}{3} + \delta. \)

We prove the following lemma in Subsection 5.3

**Lemma 26.** Let \( x_1, \ldots, x_k \) be a 0-instance of UDISJ_{\frac{k-2}{2},k-1}. Then for some \( \delta < \frac{1}{3} - \frac{1}{100} \) there exists a \((1 - \delta)\)-symmetry randomness space for \( x \).

Lemma 26 and Claim 25 imply that there is a constant \( \varepsilon > 0 \) such that

\[ \Pr[\mathcal{P}(P_1, P_2, \ldots, P_k) \notin \text{Fake}(\gamma,E)] \geq \varepsilon + \frac{1}{100}. \]

Thus,

\[ \Pr[\mathcal{P}(P_1, P_2, \ldots, P_k) \notin \text{Fake}(\gamma,E) \cup \{\perp\}] \geq \varepsilon. \]

Then, for \( N = O \left( \log \frac{1}{\varepsilon}, T \right) \) gives a correct answer for every 0-instance with probability at least \( \frac{2}{3}. \)

### 5.3 Constructions of \( \Xi, \alpha \) and \( \beta \)

**Proof of Lemma 26.** Assume that \( x_1, \ldots, x_k \) is a 0-instance UDISJ_{\frac{k-2}{2},k-1}. Let \( i_0 \in [2^{\ell-k} - 1] \) be such that \( x_{1,i_0} = x_{2,i_0} = \ldots = x_{k,i_0} = 1. \)

Hereinafter \( \gamma \) denotes a bijection from \([2^{\ell-k} - 1] \cup \{\ast\}\) to \( \{0,1\}^{\ell-k} \), \( E \) denotes an invertible matrix from \( \mathbb{F}_2^{k \times \ell} \) and \( e_1, e_2, \ldots, e_{\ell} \) denote rows of \( E \).

Before presenting constructions of \( \Xi, \alpha, \) and \( \beta \) we explain how we are going to establish symmetry and difference properties from Definition 24.

For every \( s \in \{0,1\}^{\ell-k} \) and \( b \in \{0,1\} \) we introduce the following notation:

\[ R(s, b, E) := \left\{ (s, b, z) \cdot E \mid z \in \mathbb{F}_2^{\ell-k} \right\}. \]
Using the key property of the matrix $C_{\mathcal{F}}(\gamma, E)$ we can describe rows of $C_{\mathcal{F}}(\gamma, E)$ in terms of $R(s, b, E)$.

\textbf{Claim 27.}  
- The set of the last $2^k + 1$ rows of $C_{\mathcal{F}}(\gamma, E)$ is $R(\gamma(*), 0, E) \cup R(\gamma(*), 1, E)$ and each of this rows appears exactly twice. Recall that we already denote this set as $\text{Fake}(\gamma, E)$. Hence, $\text{Fake}(\gamma, E) = R(\gamma(*), 0, E) \cup R(\gamma(*), 1, E)$.
- The set of rows of $C_{\mathcal{F}}(\gamma, E)$ with indices from $[2^k(i - 1) + 1; 2^k i]$ for $i \in [2^{\ell - k} - 1] \setminus \{i_0\}$ is exactly $R(\gamma(i), 0, E) \cup R(\gamma(i), 1, E)$ and every such row appears exactly once.
- The set of rows of $C_{\mathcal{F}}(\gamma, E)$ with indices from $[2^k(i_0 - 1) + 1; 2^k i_0]$ is exactly $R(\gamma(i_0), 0, E)$ and every such row appears exactly twice.

\textbf{Claim 28.} $R(s, b, E)$ can be represented as a shift of the linear space $\text{Span}(e_{\ell-k+2}, \ldots, e_{\ell})$:

$$R(s, b, E) = \left(\sum_{j=1}^{\ell-k} s_j e_j + b \cdot e_{\ell-k+1}\right) + \text{Span}(e_{\ell-k+2}, \ldots, e_{\ell}).$$

\textbf{Proof.}  

$$R(s, b, E) = \{(s, b, z) \cdot E \mid z \in \mathbb{F}_2^{k-1}\} = \{(s, b, z) \cdot (e_1, e_2, \ldots, e_{\ell})^T \mid z \in \mathbb{F}_2^{k-1}\} = \left(\sum_{j=1}^{\ell-k} s_j e_j + b \cdot e_{\ell-k+1}\right) + \text{Span}(e_{\ell-k+2}, \ldots, e_{\ell}).$$

\textbf{Claim 29.} For every $s \in \{0, 1\}^{\ell-k}$ and $b \in \{0, 1\}$, $|R(s, b, E)| = 2^{k-1}$.

\textbf{Proof.} By Claim 28, $|R(s, b, E)| = \left|\left(\sum_{j=1}^{\ell-k} s_j e_j + b \cdot e_{\ell-k+1}\right) + \text{Span}(e_{\ell-k+2}, \ldots, e_{\ell})\right| = 2^{k-1}$.

\textbf{Claim 30.} Sets $R(s, b, E)$ for $s \in \{0, 1\}^{\ell-k}$ and $b \in \{0, 1\}$ are disjoint.

\textbf{Proof.} Consider two vectors $u \in R(s, b, E)$ and $v \in R(s', b', E)$ such that $(s, b) \neq (s', b')$. Then, by Claim 28, $u$ and $v$ have different coordinates in the basis $e_1, e_2, \ldots, e_{\ell}$, hence $u \neq v$.

\textbf{Claim 31.} Assume that $\gamma, \gamma'$ are bijections from $[2^{\ell-k} - 1] \cup \{\ast\}$ to $\{0, 1\}^{\ell-k}$ and $E$ and $E'$ are invertible matrices from $\mathbb{F}_2^{k \times \ell}$ such that

- $R(\gamma(i_0), 0, E) \cup R(\gamma(*), 0, E) \cup R(\gamma(*), 1, E) = R(\gamma'(i_0), 0, E') \cup R(\gamma'(\ast), 0, E') \cup R(\gamma'(\ast), 1, E')$;
- $R(\gamma(i_0), 1, E) = R(\gamma'(i_0), 1, E')$.

Then matrices $C_{\mathcal{F}}(\gamma, E)$ and $C_{\mathcal{F}}(\gamma', E')$ differ only by a permutation of rows.

\textbf{Proof.} By Claim 27, rows from $R(\gamma(i_0), 1, E)$ do not appear in $C_{\mathcal{F}}(\gamma, E)$, rows from $R(\gamma(i_0), 0, E) \cup R(\gamma(*), 0, E) \cup R(\gamma(*), 1, E)$ appear in $C_{\mathcal{F}}(\gamma, E)$ exactly twice. The matrix $C_{\mathcal{F}}(\gamma, E)$ has $2^k + 2^k$ rows. All rows of $C_{\mathcal{F}}(\gamma, E)$ that are not in $R(\gamma(i_0), 1, E) \cup R(\gamma(*), 0, E) \cup R(\gamma(*), 1, E)$, by Claim 27, appear in $C_{\mathcal{F}}(\gamma, E)$ exactly once.
By Claims 29 and 30, \(|R(\gamma(i_0), 0, E) \cup R(\gamma(\ast), 0, E) \cup R(\gamma(\ast), 1, E)| = 3 \cdot 2^{k-1}\), hence, the number of rows of \(C_{\gamma}(\gamma, E)\) that are not in \(R(\gamma(i_0), 1, E) \cup R(\gamma(\ast), 0, E) \cup R(\gamma(\ast), 1, E)\) equals \(2^\ell - 2^{k+1}\). By Claims 29 and 30, the number of \(\ell\)-bit strings not from \(R(\gamma(i_0), 1, E) \cup R(\gamma(i_0), 0, E) \cup R(\gamma(\ast), 0, E) \cup R(\gamma(\ast), 1, E)\) is also \(2^\ell - 2^{k+1}\). Hence, all rows from \(\{0, 1\}^\ell \setminus (R(\gamma(i_0), 0, E) \cup R(\gamma(\ast), 0, E) \cup R(\gamma(\ast), 1, E) \cup R(\gamma(i_0), 1, E))\) appear in \(C_{\gamma}(\gamma, E)\) exactly once. Thus, matrices \(C_{\gamma}(\gamma, E)\) and \(C_{\gamma'}(\gamma', E')\) have the same set of rows and each row appears the same number of times in each of these matrices.

For \(\alpha, \beta : \Xi \rightarrow \Xi\) we denote \(\alpha(\gamma, E) = (\gamma_\alpha, E_\alpha)\) and \(\beta(\gamma, E) = (\gamma_\beta, E_\beta)\). We are going to construct \(\alpha\) and \(\beta\) such that for all \((\gamma, E) \in \Xi\) the following equalities are satisfied.

\[
\begin{align*}
R(\gamma(i_0), 1, E) &= R(\gamma_\alpha(i_0), 1, E_\alpha) = R(\gamma_\beta(i_0), 1, E_\beta); \\
R(\gamma(i_0), 0, E) &= R(\gamma_\alpha(\ast), 0, E_\alpha) = R(\gamma_\beta(\ast), 0, E_\beta); \\
R(\gamma(\ast), 1, E) &= R(\gamma_\alpha(\ast), 1, E_\alpha) = R(\gamma_\beta(\ast), 1, E_\beta); \\
R(\gamma(\ast), 0, E) &= R(\gamma_\alpha(i_0), 0, E_\alpha) = R(\gamma_\beta(i_0), 1, E_\beta).
\end{align*}
\]

Notice that by Claim 31, equations (2) imply the symmetry property. Equations (2) also imply the difference property. Indeed,

\[
\begin{align*}
\text{Fake}(\gamma, E) &= R(\gamma(\ast), 1, E) \cup R(\gamma(\ast), 0, E); \\
\text{Fake}(\gamma_\alpha, E_\alpha) &= R(\gamma_\alpha(\ast), 1, E_\alpha) \cup R(\gamma_\alpha(\ast), 0, E_\alpha) = R(\gamma_\ast, 1, E) \cup R(\gamma(i_0), 0, E); \\
\text{Fake}(\gamma_\beta, E_\beta) &= R(\gamma_\beta(\ast), 1, E_\beta) \cup R(\gamma_\beta(\ast), 0, E_\beta) = R(\gamma(\ast), 0, E) \cup R(\gamma(i_0), 0, E).
\end{align*}
\]

Hence, by Claim 30, \(\text{Fake}(\gamma, E) \cap \text{Fake}(\gamma_\alpha, E_\alpha) \cap \text{Fake}(\gamma_\beta, E_\beta) = \emptyset\).

In order to complete the proof of the lemma we have to construct \(\Xi\) and bijections \(\alpha, \beta\) from \(\Xi\) to \(\Xi\) such that

- (Largeness) \(\Pr[(\gamma, E) \in \Xi] > \frac{2}{3} + \frac{1}{100}\);
- and for all \((\gamma, E) \in \Xi\) the equations (2) are satisfied.

**Definition of \(\Xi\).** A pair \((\gamma, E)\) is in \(\Xi\) iff there exist \(m, n \in [\ell - k]\) such that \((\gamma(\ast))_m = 1, (\gamma(i_0))_n = 0\) and \((\gamma(\ast))_m = 0, (\gamma(i_0))_n = 1\). In other words, \((\gamma(\ast))\) and \((\gamma(i_0))\) are not comparable with respect to coordinate-wise comparison.

Notice that \(\gamma(i_0)\) and \(\gamma(\ast)\) are distributed uniformly among non-equal elements of \(\{0, 1\}^{\ell - k}\). Let \(S\) and \(T\) are two independent random variables distributed uniformly on the set of all subsets of \([\ell - k]\).

Then,

\[
\Pr[(\gamma, E) \in \Xi] = 1 - \Pr[\gamma(i_0) \leq \gamma(\ast) \vee \gamma(\ast) \leq \gamma(i_0)] = 1 - 2 \Pr[\gamma(i_0) \leq \gamma(\ast)]
\]

\[
= 1 - 2 \Pr[S \subseteq T \mid S \neq T] = 1 - 2 \Pr[S \subseteq T]
\]

\[
= 1 - 2 \prod_{j=1}^{\ell - k} (1 - \Pr[j \in S \land j \not\in T]) = 1 - 2 \left(\frac{3}{4}\right)^{\ell - k} > \frac{2}{3} + \frac{1}{100}\) if \(\ell - k \geq 7\).
\]

Hence, the largeness property is satisfied.

**Construction of \(\alpha\).** Let \((\gamma, E) \in \Xi\), we define \(\alpha(\gamma, E) = (\gamma_\alpha, E_\alpha)\), where \(E_\alpha\) is a matrix with rows defined by vectors \((e_{1}, \ldots, e_{\ell}) = (e_{1}, \ldots, e_{\ell - k}, e_{\ell - k + 1} + \sum_{j=1}^{\ell - k} (\gamma(i_0))_j + \gamma(\ast))_j \epsilon_j, e_{\ell - k + 2}, \ldots, e_{\ell})\), and

\[
\gamma_\alpha(i) = \begin{cases} 
\gamma(\ast) & \text{if } i = i_0 \\
\gamma(i_0) & \text{if } i = \ast \\
\gamma(i) & \text{otherwise}
\end{cases}
\]
Thus, we can uniquely recover $\alpha$. 

Proof. Notice that rows of $E'$ form a basis since $\sum_{j=1}^{\ell-k}(\gamma(i_0)_{i_j}+\gamma(\ast)) e_j \in \text{Span}(e_1,\ldots,e_{\ell-k})$. The mapping $\gamma \mapsto \gamma_{\alpha}$ is bijective since it just swaps $\gamma(i_0)$ and $\gamma(\ast)$. Since the condition on $\gamma(i_0)$ and $\gamma(\ast)$ does not change after application of $\alpha$, we get that $\alpha(\Xi) \subseteq \Xi$. Notice that $\sum_{j=1}^{\ell-k}(\gamma(i_0)_{i_j}+\gamma(\ast)) e_j = \sum_{j=1}^{\ell-k}(\gamma_{\alpha}(i_0)_{j}+\gamma_{\alpha}(\ast)) e'_j$, hence $\alpha(\gamma_{\alpha},E_{\alpha}) = (\gamma,E)$, hence $\alpha$ is bijective. 

\begin{claim}
\begin{remark}
\alpha is a bijection from $\Xi \rightarrow \Xi$.
\end{remark}
\end{claim}

Proof. Let us denote $E_{\beta} \in \text{Span}(e_{\ell-k+2},\ldots,e_{\ell})$. 

\begin{claim}
\begin{remark}
For all $(\gamma,E) \in \Xi$ the following equalities hold
\begin{enumerate}
\item $R(\gamma_{\alpha}(i_0),1,E_{\alpha}) = R(\gamma(i_0),1,E)$;
\item $R(\gamma_{\alpha}(i_0),0,E_{\alpha}) = R(\gamma(\ast),0,E)$;
\item $R(\gamma_{\alpha}(\ast),0,E_{\alpha}) = R(\gamma(\ast),0,E)$;
\item $R(\gamma_{\alpha}(\ast),1,E_{\alpha}) = R(\gamma(\ast),1,E)$.
\end{enumerate}
\end{remark}
\end{claim}

Proof. We use Claim 28. Let us denote $S := \text{Span}(e_{\ell-k+2},\ldots,e_{\ell})$. 

\begin{construction}
\begin{remark}
For $(\gamma,E) \in \Xi$, we define $\beta(\gamma,E) = (\gamma_{\beta},E_{\beta})$, where $\gamma_{\beta} = \gamma_{\alpha}$ and $E_{\beta}$ is defined below. Let $j_{\min} = \min\{j \in [\ell-k]: (\gamma(\ast))_{j} = 1 \land (\gamma(i_0))_{j} = 0\}$; $j_{\min}$ is correctly defined since $(\gamma,E) \in \Xi$. Now we define $E_{\beta} = (e''_1,\ldots,e''_{\ell-k})$:

\begin{align*}
    e''_j &= \begin{cases} 
        e_j & \text{if } j \notin \{j_{\min},\ell-k+1\} \\
        \sum_{i=1}^{\ell-k}(\gamma(\ast))_{i} + \gamma(i_0)_i e_i & \text{if } j = \ell-k+1 \\
        e_{\min} + e_{\ell-k+1} & \text{if } j = j_{\min}
    \end{cases}.
\end{align*}
\end{remark}
\end{construction}

\begin{claim}
\begin{remark}
$\beta$ is a bijection from $\Xi \rightarrow \Xi$.
\end{remark}
\end{claim}

Proof. Let us verify that $\beta$ is injective. Given $\gamma_{\beta}$ we can easily recover $\gamma$, hence we can recover $j_{\min}$ as well. Then

\begin{align*}
\sum_{i=1}^{\ell-k}(\gamma(i_0)_{i}+\gamma(\ast)) e'_i + e''_{\ell-k+1} &= \sum_{i \in [\ell-k]\setminus\{j_{\min}\}}(\gamma(i_0)_{i}+\gamma(\ast)) e_i + e_{j_{\min}} + e_{\ell-k+1} + e''_{\ell-k+1} \\
&= e_{\ell-k+1} + \sum_{i \in [\ell-k]\setminus\{j_{\min}\}}(\gamma(i_0)_{i}+\gamma(\ast)) e_i + e_{j_{\min}} + e''_{\ell-k+1} = e_{\ell-k+1}.
\end{align*}

Thus, we can uniquely recover $e_{\ell-k+1}$ and, hence, also recover $e_{j_{\min}} = e''_{j_{\min}} + e_{\ell-k+1}$; for $j \in [\ell] \setminus \{j_{\min},\ell-k+1\}$, $e_j = e''_j$. Hence, $\beta$ is injective. Notice that since we represent $e_1,\ldots,e_\ell$ as linear combinations of $e''_1,\ldots,e''_{\ell-k}$, then $e''_1,\ldots,e''_{\ell-k}$ is a basis, hence the matrix $E_{\beta}$ is invertible. Thus, we verify that $\beta(\Xi) \subseteq \Xi$ and $\beta$ is injective, hence $\beta$ is bijective.
Claim 35. For all $(\gamma, E) \in \Xi$ the following equalities hold
1. $R(\gamma(i_0), 1, E) = R(\gamma(i_0), 1, E)$;
2. $R(\gamma(i_0), 0, E) = R(\gamma(*), 1, E)$;
3. $R(\gamma(*), 0, E) = R(\gamma(i_0), 0, E)$;
4. $R(\gamma(*), 1, E) = R(\gamma(*), 0, E)$.

Proof. We denote $S := \text{Span}(e_{-k+2}, \ldots, e_{k}) = \text{Span}(e_{-k+2}', \ldots, e_{k}')$. Recall that $\gamma(*)_{\min} = 1$ and $\gamma(i_0)_{\min} = 0$.

1. $R(\gamma(i_0), 1, E) = \sum_{i=1}^{\ell-k} \gamma(i_0)e_i + e_{-k+1} + S = \sum_{i=1}^{\ell-k} \gamma(*)e_i + e_{-k+1} + e_{-k+1} + S = R(\gamma(i_0), 1, E)$;
2. $R(\gamma(i_0), 0, E) = \sum_{i=1}^{\ell-k} \gamma(i_0)e_i + S = \sum_{i=1}^{\ell-k} \gamma(*)e_i + S = R(\gamma(i_0), 0, E)$;
3. $R(\gamma(*), 0, E) = \sum_{i=1}^{\ell-k} \gamma(*)e_i + S = \sum_{i=1}^{\ell-k} \gamma(*)e_i + e_{-k+1} + S = R(\gamma(*), 1, E)$;
4. $R(\gamma(*), 1, E) = \sum_{i=1}^{\ell-k} \gamma(*)e_i + e_{-k+1} + S = \sum_{i=1}^{\ell-k} \gamma(*)e_i + e_{-k+1} + S = R(\gamma(*), 0, E)$.

Claims 33 and 35 imply the equations 2.

5.4 Proof of Lemma 21

To prove Lemma 21 it is sufficient to prove the following:

Proposition 36. There exist matrices $T_1, \ldots, T_k \in \mathbb{F}_2^{2 \times k}$, such that

- For $\alpha_1, \ldots, \alpha_k \in \{0, 1\}$ the matrix $\sum_{i=1}^{k} \alpha_i T_i$ is zero if $\alpha_1 = \alpha_2 = \ldots = \alpha_k = 0$, i.e. $T_1, \ldots, T_k$ are linearly independent;
- For every non-zero matrix $M \in \text{Span}(T_1, \ldots, T_k)$, $M + K_k \in S_k$.

Proof of Lemma 21. Let for $i \in \{1, \ldots, k-1\}$, $A_i(0) = T_i$ and $A_i(1)$ be the zero matrix. Let $G_k(0) = K_k + T_k$, $G_k(1) = K_k$. For each $b_i, \ldots, b_k \in \{0, 1\}$, $\sum_{i=1}^{k} A_i(b_i) = \sum_{i=1}^{k} (1 - b_i)T_i + K_k$. Then $\sum_{i=1}^{k} A_i(1) = K_k$, and if for at least one $i \in [k]$, $b_i \neq 1$, then by the first condition of Proposition 36, $\sum_{i=1}^{k} (1 - b_i)T_i$ differs from zero, thus by the second condition of Proposition 36, $\sum_{i=1}^{k} A_i(b_i) \in S_k$.

Proof of Proposition 36. Let us prove the proposition by induction on $k$. We are going to prove a stronger statement: namely, we additionally require that for arbitrary non-zero matrix $M \in \text{Span}(T_1, \ldots, T_k)$ the set of even-indexed rows of $M + K_k \in S_k$ coincide with the set of odd-indexed rows of this matrix with all bits flipped.

The base case $k = 1$. $T_1 = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$, and $K_1 = \begin{pmatrix} 0 \\ 0 \end{pmatrix}$. It is easy to verify that all conditions hold.

Induction step from $k$ to $k + 1$. Notice that $K_{k+1} = \begin{pmatrix} K_k & 0_{2^k \times 1} \\ 0_{2^k \times 1} \\ 1_{2^k \times 1} \end{pmatrix}$. Let $T_1, \ldots, T_k$ be the matrices from induction hypothesis for $k$. Then define $T_i' = \begin{pmatrix} T_i & 0_{2^k \times 1} \\ 0_{2^k \times 1} \\ 1_{2^k \times 1} \end{pmatrix}$ for $i \in [k]$ and $T_{k+1}' = \begin{pmatrix} 0_{2^k \times k} & z_0 \\ 1_{2^k \times k} & z_1 \end{pmatrix}$, where $z_0 = (0, 1, 0, 1, \ldots, 0, 1)^T \in \{0, 1\}^{2^k \times 1}$, and $z_1 = (1, 0, 1, 0, 1, \ldots, 0, 1)^T \in \{0, 1\}^{2^k \times 1}$.

Let us verify that all conditions hold. First we show that the matrices $T_1', T_2', \ldots, T_{k+1}'$ are linearly independent. Matrices $T_1', T_2', \ldots, T_k'$ are linearly independent since they contain linearly independent blocks $T_1, \ldots, T_k$. The matrix $T_{k+1}'$ does not belong to $\text{Span}(T_1', \ldots, T_k')$, since the last column of $T_{k+1}'$ is non-zero, but the last columns of all $T_1', \ldots, T_k'$ are zeros.
Let us check that for any non-zero matrix $M \in \text{Span}(T_1', \ldots, T_k')$, the condition $M + K_{k+1} \in S_{k+1}$ holds and the set of even-indexed rows of $M + K_{k+1}$ coincide with the set of odd-indexed rows of this matrix with all bits flipped. Let us analyze the cases:

1. Let $M$ be a non-zero matrix from $\text{Span}(T_1', \ldots, T_k')$. Then, $M$ has form
   $$\begin{pmatrix} M' & 0_{2^k \times 1} \\ M' & 0_{2^k \times 1} \end{pmatrix},$$
   where $M'$ is a non-zero matrix from $\text{Span}(T_1, \ldots, T_k)$, thus $M' + K_k \in S_k$. Then
   $$M + K_{k+1} = \begin{pmatrix} M' + K_k & 0_{2^k \times 1} \\ M' + K_k & 1_{2^k \times 1} \end{pmatrix};$$
   it follows from the induction hypothesis that all rows of this matrix are distinct, i.e. $M + K_{k+1} \in S_{k+1}$. In order to verify that the set of even-indexed rows of this matrix coincide with the set of odd-indexed rows with all bits flipped, observe that by induction hypothesis the first $2^{k-1}$ even-indexed rows of $M + K_{k+1}$ coincide with the last $2^{k-1}$ odd-indexed rows of $M + K_{k+1}$ with all bits flipped, and the first $2^{k-1}$ odd-indexed rows of $M + K_{k+1}$ coincide with the last $2^{k-1}$ even-indexed rows of $M + K_{k+1}$ with flipped bits.

2. $M = T_k'$, then $M + K_{k+1} = \begin{pmatrix} K_k \\ 1_{2^k \times k + K_k} \end{pmatrix}$. Let us show that all rows of this matrix are distinct. The first $2^k$ rows start with 0 and are obtained by appending zeroes and ones to the rows of $K_k$ in the alternating order. Since for every pair of coinciding rows of $K_k$ they are adjacent, the first $2^k$ rows are distinct. The last $2^k$ rows start from one, so they differ from the first $2^k$ rows. The proof that they are distinct is the same as for the first $2^k$ rows. Observe that the $(2i - 1)$th row of the matrix $M + K_{k+1}$ coincide with the $(2i + 2i)$th row of $M + K_{k+1}$ with flipped bits, and the $(2i)$th row of $M + K_{k+1}$ coincide with the $(2i + 2i - 1)$th row of $M + K_{k+1}$ with flipped bits for $i \in [2^k]$.

3. $M = R + T_k'$, where $R$ is a non-zero matrix from $\text{Span}(T_1, \ldots, T_k)$. Let $R$ have the form
   $$\begin{pmatrix} R' \\ R' \end{pmatrix},$$
   where $R'$ is a non-zero matrix from $\text{Span}(T_1, \ldots, T_k)$. Then
   $$M + K_{k+1} = R + T_k' + K_{k+1} = \begin{pmatrix} R' + K_k \\ 1_{2^k \times k} + R' + K_k \end{pmatrix}.$$ By the induction hypothesis, $R' + K_k \in S_k$ and its even-indexed rows coincide with its odd-indexed rows with flipped bits. Then, all even-indexed rows of $M + K_{k+1}$ end with 0, the first $2^{k-1}$ of them are even-indexed rows of $R' + K_k$ with appended zero, and the last $2^{k-1}$ of them are even-indexed rows of $R' + K_k$ with all bits flipped and appended 0. Then, by the induction hypothesis, the set of the former rows does not intersect with the set of the latter rows, therefore they are all distinct. By the same argument, all the rows of $M + K_{k+1}$ end with 1 are distinct. Thus, $M + K_{k+1} \in S_{k+1}$.

Let us verify that the set of even-indexed rows of this matrix coincide with the set of odd-indexed rows of this matrix with all bits flipped. Observe that if the ith row of $R' + K_k$ coincides with the jth row of $R' + K_k$ with flipped bits, then the ith row of $M + K_{k+1}$ coincides with its jth row with flipped bits, and the $(2^k + j)$th row of $M + K_{k+1}$ coincides with its $(2^k + j)$th row with all bits flipped. The required property follows from the induction hypothesis.

5.5 Corollaries

**Corollary 37.** If $k + 7 \leq \ell$, then the size of any semantic Res($\text{PC}_{k-1}$) tree-like refutation of BPHP$_{2^k + 2^k}$ is at least $2^{\Omega \left( \frac{2^k}{k^{2/7}} \right)}$. For $k = 2$, the size of any tree-like semantic Res($\oplus$) refutation of BPHP$_{2^2 + 4}$ is at least $2^{\Omega(2^{\ell})}$.

**Proof.** Follows from Theorem 3 and Lemma 1.
Corollary 38. Let \( 2 \leq k \leq \ell - 7 \) and \( S \) be the minimal size of tree-like refutation of \( \varphi = \text{BPHP}^2_k \oplus_k \) in the semantic proof system \( T^{cc}(k, c) \). Then \( \log S \log \log S \geq c \cdot \Omega \left( \frac{2^{k/2}}{k^{2^{k/2-2}}} \right) \).

For \( k = 2 \), \( \log S \log \log S \geq c \cdot \Omega (2^\ell) \).

Proof. By Lemma 9, \( R^{1/3}_{pub} (\text{Search}(\varphi)) = \mathcal{O} \left( \frac{\log S \log \log S}{c} \right) \). We also know that

\[
R^{1/3}_{pub} (\text{Search} (\text{BPHP}^2_{2^\ell} \oplus_k)) \geq R^{1/3}_{pub} (\oplus_k \text{Search} (\text{BPHP}^2_{2^{\ell+2}k})).
\]

Now the statement follows from Theorem 3.

\[\square\]

6 Bit pigeonhole principle

6.1 Reduction from \( \text{BPHP} \circ \oplus_k \) to \( \text{BPHP} \)

Let \( T \subseteq X_1 \times X_2 \times \cdots \times X_k \times Y \) and \( S \subseteq Z_1 \times Z_2 \times \cdots \times Z_k \times W \) be two relations. We say that \( S \) is many-one reducible to \( T \) if there are \( k + 1 \) mappings \( f_1 : X_1 \rightarrow Z_1, f_2 : X_2 \rightarrow Z_2, \ldots, f_k : X_k \rightarrow Z_k \) and \( g : W \rightarrow Y \) such that if \( (f_1(x_1), \ldots, f_k(x_k), y) \in T \) then \( (x_1, \ldots, x_k, g(y)) \in S \).

Lemma 39. If \( S \) is many-one reducible to \( T \), then \( R^{1/3}_{pub}(S) \leq R^{1/3}_{pub}(T) \).

Proof. The \( i \)-th party computes \( f(x_j) \) for all \( j \in [k] \setminus \{i\} \) and then all parties run the optimal protocol for \( T \). As soon as all the parties learn an answer \( g(y) \) they compute \( g(y) \) without communication.

\[\square\]

Recall that \( \text{BPHP}^M_k \) encodes that there exist \( M \) different strings \( s_1, s_2, \ldots, s_M \) from \( \{0,1\}^n \). Let \( k \) be a positive integer. Let us define the partition \( \Pi_k \) of the variables of \( \text{BPHP}^M_k \) into \( k \) parts. Let \( n = \ell k + r \) where \( 0 \leq r < k \). For each \( i \in [M] \) the row \( s_i \) is partitioned into \( k \) parts \( s_i = s_i^{(1)} s_i^{(2)} \cdots s_i^{(k)} \) such that \( |s_i^{(t)}| = \ell + 1 \) if \( t < r \), and \( |s_i^{(t)}| = \ell \) if \( t > r \). The partition \( \Pi_k \) of the variables of \( \text{BPHP}^M_{2^n} \) into \( k \) parts is the following: the \( t \)-th part consists of the variables \( s_i^{(1)}, s_i^{(2)}, \ldots, s_i^{(r)} \).

We consider a search problem \( \text{SearchPair}^M_{2^n} \): given the values of the variables of \( \text{BPHP}^M_{2^n} \), that are partitioned according to \( \Pi_k \), find a pair of distinct indices \( i, j \in [M] \), such that the values of \( s_i \) and \( s_j \) coincide.

Proposition 40. The relation \( \text{SearchPair}^M_{2^n} \) is many-one reducible to \( \text{Search} (\text{BPHP}^M_{2^n}) \) with variables partitioned according to \( \Pi_k \).

Proof. The proof is straightforward.

\[\square\]

Theorem 41. \( \oplus_k \text{BPHP}^M_{2^n} \) is many-one reducible to \( \text{SearchPair}^M_{2^n} \).

Proof. Let us denote \( M = m \cdot 2^{(k-1)\ell} \). Consider a set \( Z = \left\{ (y_1, y_2, \ldots, y_k) \in (\mathbb{F}_2^r)^k \mid \sum_i y_i = 0 \right\} \). It is easy to see that \( |Z| = 2^{(k-1)\ell} \). Let \( \varphi \) be a bijection between \([M]\) and \( Z \times [m] \).

Let for \( i \in [m] \) and \( t \in [k] \), \( x_i^{(t)} \) denote the \( i \)-th string of the \( t \)-th party in the communication problem \( \oplus_k \text{BPHP}^m_{2^n} \). Let \( x_i := (x_i^{(1)}, \ldots, x_i^{(k)}) \).

For every \( t \in [k] \) we define \( f_t \) as follows: \( f_t \left( x_1^{(t)}, \ldots, x_M^{(t)} \right) \) is a sequence of rows \( r_1^{(t)}, r_2^{(t)}, \ldots, r_M^{(t)} \) such that for all \( i \in [M] \), \( r_i^{(t)} = z_t + x_i^{(t)} \), where \( (z, j) = \varphi(i) \) for all \( z \in Z \) and \( j \in [m] \) (recall that \( z \in Z \) is divided on \( k \) parts of equal lengths and \( z_t \) denotes the \( t \)-th part).

Let us construct the function \( g \) from the definition of the reduction.

Let \( q, w \in [M] \) and \( q \neq w \). Assume that \( \varphi(q) = (z, j_1) \) and \( \varphi(w) = (z, j_2) \). We define \( g(q, w) := (j_1, j_2) \).
Let us verify that \( f_1, f_2, \ldots, f_k \) and \( g \) define a reduction. Let \( q, w \in M \) be a pair of different numbers such that the assignment \( \alpha := \{ s_i \leftarrow r_i^{(1)}r_i^{(2)} \ldots r_i^{(k)} | i \in [M] \} \) satisfies \( s_q = s_w \).

Assume that \( g(q, w) = (j_1, j_2) \). We need to verify that \( j_1 \neq j_2 \) and \( \sum_{t=1}^{k} x_{j_1}^{(t)} = \sum_{t=1}^{k} x_{j_2}^{(t)} \).

Notice that under the assignment \( \alpha \) the value of \( s_q \) is \( x_{j_1} + z \) and the value of \( s_w \) is \( x_{j_2} + y \), where \( j_1, j_2 \in [m] \) and \( z, y \in Z \) such that \( (z, j_1) = \varphi(q) \) and \( (y, j_2) = \varphi(w) \). If \( j_1 = j_2 \), then \( x_{j_1} + z = x_{j_2} + y \) implies \( z = y \). Since \( \varphi \) is a bijection, we get \( q = w \). Thus, \( j_1 \neq j_2 \).

For each \( t \in [k] \), the following equality holds.

\[
z_t + x_{j_1}^{(t)} = y_t + x_{j_2}^{(t)}
\]  

(3)

If we sum up equations (3) for all \( t \in [k] \) and use that \( y_t, z \in Z \), we get \( \sum_{t=1}^{k} x_{j_1}^{(t)} = \sum_{t=1}^{k} x_{j_2}^{(t)} \). Hence, \( (j_1, j_2) \) is a correct answer for \( \oplus_k \text{BPHP}^m \).

The following proposition deals with the case, where the number of bits is not divisible by \( k \).

**Proposition 42.** Let \( n = k\ell + r \), where \( 0 \leq r < k \). Let \( M > 2^{k\ell} \). Then SearchPair\(^M\) is one-reducible to SearchPair\(^{M/2^r}\).

**Proof.** Let \( x_1, x_2, \ldots, x_M \) be the input of SearchPair\(^{M/2^r}\), let \( x_i^{(t)} \) be the \( t \)-th part of the row \( x_i \) according to the partition \( \Pi_k \). Given this input we construct an input for SearchPair\(^{M/2^r}\).

Let \( \tau \) be a bijection between \([M] \times \{0, 1\}^r\) and \([M/2^r]\).

For each \( i \in [M] \) we construct \( 2^r \) rows \( y_{\tau(i,\alpha)} \) one for each \( \alpha \in \{0, 1\}^r \). Let \( \Pi_k \) partition a row \( y_{\tau(i,\alpha)} \) into the following parts: \( y_{\tau(i,\alpha)}^{(1)}y_{\tau(i,\alpha)}^{(2)} \ldots y_{\tau(i,\alpha)}^{(k)} \).

Let 

\[
y_{\tau(i,\alpha)}^{(t)} = \begin{cases} 
x_i^{(t)} & \text{if } t > r \\
x_i^{(t)} \alpha_t & \text{if } 0 \leq t \leq r.
\end{cases}
\]

Now we can define the function \( f_t(x_1^{(t)}, \ldots, x_M^{(t)}) \) as \( y_{\tau(i,\alpha)}^{(t)} \) for each \( i \in M \) and \( \alpha \in \{0, 1\}^r \) and \( t \in [k] \). Observe that for each \( i \in [M] \) the rows \( y_{\tau(i,\alpha)} \) for \( \alpha \in \{0, 1\}^r \) are distinct. That allows us to define the function \( g \) as \( g(\tau(i_1, \alpha_1), \tau(i_2, \alpha_2)) = (i_1, i_2) \). All the required properties can be easily verified.

**Theorem 4.** Let \( M = 2^n + 2^{k+n-n[k]} \) and \( n \geq k(k + 7) \). If variables of \( \text{BPHP}^M \) are partitioned according \( \Pi_k \), then \( R_{1/3}^{\text{pub}}(\text{Search}(\text{BPHP}^M)) = \Omega \left( \frac{2^{n/2k-3k/2}}{k} \right) \).

For \( k = 2 \) a stronger bound holds: \( R_{1/3}^{\text{pub}}(\text{Search}(\text{BPHP}^M)) = \Omega(2^{n/2}) \).

**Proof.** Let \( \ell = \lfloor n/k \rfloor \) and \( r = n - \ell k \).

\[
R_{1/3}^{\text{pub}}(\text{Search}(\text{BPHP}^M)) = R_{1/3}^{\text{pub}}(\text{Search}(\text{BPHP}^{2^{k+n-k/2}}))
\]

(Proposition 40)

\[
\geq R_{1/3}^{\text{pub}}(\text{SearchPair}_{2^{k+n-k/2}}^{(2^{k+n-k/2})2^{(k-1)\ell+r}})
\]

(Proposition 42)

\[
\geq R_{1/3}^{\text{pub}}(\text{SearchPair}_{2^{k+n-k/2}}^{(2^{k+n-k/2})2^{(k-1)\ell}})
\]

(Theorem 41)

\[
\geq R_{1/3}^{\text{pub}}(\oplus_k \text{BPHP}^{2^{k+n/2}}) \quad \text{(Corollary 19)} \geq \Omega \left( \frac{2^{n/2-3k/2}}{k} \right) = \Omega \left( \frac{2^{n/2k-3k/2}}{k} \right).
\]

The case of \( k = 2 \) can be treated in the same way, the only difference is in the application of Corollary 19.
6.2 Upper bound for communication complexity of Search \((\text{BPHP}_n^m)\)

**Proposition 5.** For \(M > 2^n\) and \(k \in \{2, 3, \ldots, n\}\) there exists a deterministic NOF communication protocol for Search \((\text{BPHP}_n^M)\) w.r.t. \(\Pi_k\) transmitting \(O(2^{n/k} \cdot \log M)\) bits.

**Proof.** The protocol is going to have only two active parties: the second party, which we call Alice, and the first party, which we call Bob. We are going to use that Alice can see the variables \(s_1^{(1)}, \ldots, s_M^{(k)}\) and that Bob can see all other variables.

Let us denote \(s_0^{(1)} = s_1^{(2)} s_3^{(3)} \ldots s_k^{(k)} \in \{0, 1\}^{n-\lfloor n/k\rfloor}\) the bits Bob sees in the \(i\)th line for \(i \in [M]\). Bob finds a value \(\alpha \in \{0, 1\}^{n-\lfloor n/k\rfloor}\) such that the size of the set \(S_\alpha = \{ i \in [M] \mid s_0^{(1)} = \alpha \}\) is larger than \(2^{n/k}\). Such \(\alpha\) exists since \(M > 2^n\). Bob then picks an arbitrary subset \(S'\) of \(S_\alpha\) of size \(2^{n/k} + 1\) and sends the description of \(S'\) to Alice using \((2^{n/k} + 1) \cdot \lceil \log_2 M \rceil\) bits. Then, by the pigeonhole principle there exists \(i \neq j \in S'\) such that \(s_0^{(1)} = s_0^{(1)}\). Alice and Bob then spend \(O(\log M + n)\) bits transmitting indices \(i\) and \(j\) and all the values of the \(i\)th and \(j\)th lines to each other. Both of them then find the falsified clause of \(\text{BPHP}_n^M\) with no communication because it only depends on variables \(s_i\) and \(s_j\) and broadcast its description to all of the parties using an additional \(O(n + \log M)\) bits. \(\blacktriangleright\)

For \(k = 2\) this upper bound coincides with the lower bound given by Corollary 19 up to a logarithmic factor. For the larger value of \(k\) the upper bound and the lower bound are polynomially related. This upper bound shows that the dependence on \(k\) in the lower bound is not an artifact of the proof, but a genuine phenomenon.

6.3 Short \(\text{Th}(\log n)\) proof of \(\text{BPHP}_n^m\)

In this section we give a short tree-like \(\text{Th}(\log n)\) refutation of the bit pigeonhole principle \(\text{BPHP}_n^m\). This observation is similar to the one of [5] that converts a resolution proof of the unary encoding of the pigeonhole principle \(\text{PHP}_n^m\) to a proof of \(\text{BPHP}_n^m\) in \(\text{Res}(\log n)\).

Namely we prove the following:

**Proposition 43.** If there exists a tree-like \(\text{Th}(1)\)-refutation of \(\text{PHP}_n^m\) of size \(S\). Then there exists a tree-like \(\text{Th}(\ell)\)-refutation of \(\text{BPHP}_n^m\) of size \(O(S)\).

**Proof.** Let \(p_{i,j}\) for \(i \in [m]\) and \(j \in [2^\ell]\) be a variable of \(\text{PHP}_n^m\) indicating that the \(i\)th pigeon flies to the \(j\)th hole. Let \(s_{i,k}\) for \(i \in [m]\), \(k \in [\ell]\) be a variable of \(\text{BPHP}_n^m\) indicating the \(\ell\)th bit of the \(i\)th string \(s_i\).

Let \(Q_j(x_1, x_2, \ldots, x_\ell)\) for \(j \in [2^\ell]\) be a multilinear polynomial over reals such that for all \(a_1, a_2, \ldots, a_\ell \in \{0, 1\}^\ell\), \(Q_j(a_1, a_2, \ldots, a_\ell) = 1\) if \((a_1, a_2, \ldots, a_\ell) = \text{bin}_\ell(j - 1)\) and \(Q_j(a_1, a_2, \ldots, a_\ell) = 0\) otherwise. We may define \(Q_j\) as follows \(Q_j(x_1, \ldots, x_\ell) = \prod_{k=1}^\ell (1 - x_k + \alpha k)\) for \(i \in [m]\), \(j \in [2^\ell]\), where \(\alpha = \text{bin}_\ell(j - 1)\). By the construction \(\deg(Q_j) = \ell\).

Let \(P_{i,j} = Q_j(s_{i,1}, s_{i,2}, \ldots, s_{i,\ell})\).

Consider a tree-like \(\text{Th}(1)\)-refutation of \(\text{PHP}_n^m\) of size \(S\): \(f_1 \geq 0, f_2 \geq 0, \ldots, f_S \geq 0\), where \(f_i\) are linear real polynomials over variables \(p_{i,j}\) and \(f_S \geq 0\) is unsatisfiable on Boolean cube. For each of the inequalities on the following conditions hold:

(a) \(f_i \geq 0\) is semantically implied by \(f_j \geq 0\) and \(f_k \geq 0\) on the Boolean cube for \(j, k < i\).

(b) \(f_i\) is a linear representation of an axiom of \(\text{PHP}_n^m\);

Let \(F_\ell\) be a polynomial obtained of substitution \(p_{j,k} := P_{j,k}\) to \(f_\ell\) for all \(j \in [m]; k \in [2^\ell]\). Consider a sequence of inequalities \(F_1 \geq 0, \ldots, F_S \geq 0\). Observe that \(F_S \geq 0\) is unsatisfiable on the Boolean cube since \(P_{i,j} \in \{0, 1\}\) on the Boolean cube. Let us verify that the sequence \(F_1 \geq 0, \ldots, F_S \geq 0\) may be extended to a correct tree-like \(\text{Th}(\ell)\) refutation of \(\text{BPHP}_n^m\):
Proof.

Follows from Propositions 43 and 44.

Proposition 44 ([4]). For $m > n$ there exists a tree-like Cutting Planes (which is a subsystem of $\text{Th}(1)$) refutation of $\text{PHP}^m_n$ of size $O(m^2 n)$.

Proposition 6. For $m > 2^f$ there exists a tree-like $\text{Th}(f)$ refutation of $\text{BPHP}^m_{2^f}$ of size $O(m^2 \cdot 2^f)$.

Proof. Follows from Propositions 43 and 44.

Proof Complexity of Natural Formulas via Communication Arguments

Proof of Lemma 12

Lemma 12. Let \( T \) be a binary tree with \( m \) vertices such that the \( i \)th vertex is labeled with \( a_i \in \{0, 1\} \) with the hereditary property: for each inner vertex \( i \) with direct descendants \( c_1 \) and \( c_2 \), if \( a_i = 1 \), then \( a_{c_1} = 1 \) or \( a_{c_2} = 1 \). We also assume that if \( r \) is the root of \( T \), then \( a_r = 1 \). Assume that we have a one-sided bounded error oracle access to \( a_i \) i.e. if we request a value of \( a_i \) and \( a_i = 0 \) we get 1 with probability at most \( \frac{1}{2} \) and 0 with probability at least \( \frac{1}{2} \); if \( a_i = 1 \) we get 1 with probability 1. Then there exists an algorithm \( A \) that with probability at least \( \frac{2}{3} \) returns a leaf \( \ell \) of \( T \) with \( a_{\ell} = 1 \) and makes \( O(\log m) \) oracle queries to \( a_1, \ldots, a_m \).

Proof of Lemma 12. For a tree \( F \) we denote by \( |F| \) the number of nodes in \( F \) and for a node \( v \) of \( F \) we denote by \( \text{Subtree}(F,v) \) the subtree of \( F \) with root \( v \). Let \( \text{Oracle}(i) \) be the oracle function returning the correct value of \( a_i \) with probability at least \( \frac{C}{2} \). We can implement such a function using the majority vote of a constant number of initial oracle queries. Let \( C \) be a constant; an appropriate value of \( C \) we choose later. Consider Algorithm 2 on the following page.

We claim that at any iteration \( T_i \) has the hereditary property. This is the case in the beginning and if \( i \) decreases at some iteration, then the next \( T_i \) was considered at an earlier iteration. Otherwise, the next \( T_i \) is either a subtree of the current \( T_i \) (in that case the hereditary property is clearly maintained), or is obtained by removal a subtree with 0-labeled root (here we use that the oracle has a one-sided error) from the previous \( T_i \) (the hereditary property is also maintained in that case).

We first consider a variant of the algorithm that works infinitely long (i.e., \( C = +\infty \)) and compute the expected number of the first iteration such that \( T_i \) consists of a single 1-labeled leaf of \( T \). Notice that after the first such iteration the value of \( T_i \) stays the same for all further iterations. We show that that the expected value is at most \( C \log m \) for some constant \( C \). Then by running the algorithm for \( 3C/\log m \) iterations we obtain the required error probability by Markov’s inequality.
Algorithm 2 Search for 1-leaf.

\[
\begin{aligned}
&T_0 := T \\
i := 0 \\
&\text{for } j := 1 \text{ to } 3C[\log_{3/2} m] \text{ do} \\
&r := \text{root of } T_i \\
&\text{if } \text{Oracle}(r) = 0 \text{ then} \\
&\quad i := \max\{0, i - 1\} \quad \triangleright \text{ Backtrack since the current tree may not contain a 1-leaf} \\
&\text{else if } |T_i| \neq 1 \text{ then} \\
&\quad v := \text{a centroid node of } T_i \\
&\quad \text{if } \text{Oracle}(v) = 1 \text{ then} \\
&\qquad T_{i+1} := \text{Subtree}(T_i, v) \\
&\text{else} \\
&\qquad T_{i+1} := T_i - \text{Subtree}(T_i, v) \quad \triangleright \text{ } T_{i+1} \text{ is obtained from } T_i \text{ by the deletion of } \text{Subtree}(T_i, v) \\
&\text{return } i := i + 1 \\
\end{aligned}
\]

Let \( T(j) \) denote the value of \( T_i \) before the start of the \( j \)th iteration and \( i(j) \) denote \( i \) at the start of the \( j \)th iteration and \( r(j) \) denote the root of \( T(j) \). Notice that if \( a_r(j) = 1 \), then for every \( j' > j \), \( T(j') \) is a subtree of \( T(j) \), since the algorithm never backtracks if the true value of the roots label is 1. Hence, if \( a_r(j) = a_r(j') = 1 \) for some \( j < j' \), then \( i(j) \leq i(j') \).

Let us consider a sequence \( j_1, j_2, j_3, \ldots \), where \( j_1 = 0 \), \( j_s = \min\{j \mid a_r(j) = 1 \wedge j > j_{s-1} \wedge i(j) > i(j_{s-1})\} \), if such minimum exists.

Let us consider the iterations from \( j_s \) till \( j_{s+1} - 1 \). We consider the random variables \( Y_{j_s}, Y_{j_s+1}, \ldots, Y_{j_{s+1} - 1} \) corresponding to these iterations with the following properties:

\begin{itemize}
  \item If \( T(j) \) coincides with \( T(j_s) \), then its root is labeled with 1. Then \( Y_j = -1 \) if the second oracle query returns the correct answer and \( Y_j = 1 \) if the answer it incorrect. Notice that \( \Pr[Y_j \leq -1] \geq \frac{9}{10} \).
  \item If the root of \( T(j) \) is labeled with zero, then \( Y_j = -1 \), if the first oracle query returns the correct answer (i.e. the algorithm backtracks). Otherwise, if \( T(j) \) consists of a single node \( Y_j = 0 \). Otherwise, if the root of \( T(j + 1) \) is labeled with 0, then \( Y_j = 1 \). If it is labeled with 1, then \( Y_j = -\infty \). Notice that \( \Pr[Y_j \leq -1] \geq \frac{9}{10} \).
\end{itemize}

Notice that, \( j_{s+1} = j_s + \min\{k \mid \sum_{j=j_s}^{j_s+k-1} Y_j \leq -1\} \). In order to estimate the expected value of \( j_{s+1} - j_s \) we consider an auxiliary random variables \( X_{j_s}, X_{j_s+1}, \ldots, X_{j_{s+1} - 1} \), defined as

\[
X_j = \begin{cases} 
1, & \text{if } Y_j \geq 0 \\
-1, & \text{if } Y_j < 0
\end{cases}
\]

Notice then \( \sum_{j=j_s}^{j_s+k-1} Y_j \leq \sum_{j=j_s}^{j_s+k-1} X_j \). We can apply the following fact about random walks in a straight line to the random variables \( X_j \):

**Theorem 45 (Section XII.2 of [18]).** Let \( X_1, X_2, \ldots \) be a sequence of independent random variables that take value in \( \{-1, 1\} \). Assume that for all \( i \), \( \Pr[X_i = 1] \leq \frac{1}{10} \) and \( \Pr[X_i = -1] \geq \frac{9}{10} \). Let \( M \) be a random variable that equals the minimal natural number \( k \) such that \( \sum_{i=1}^{k} X_i = 0 \). Then the expected value of \( M \) is at most \( C \), where \( C \in \mathbb{R} \) is an absolute constant.

Fact 45 implies that \( \mathbb{E}[j_{s+1} - j_s] \leq C \). Then \( \mathbb{E}[j_s] = \mathbb{E}[j_s - j_{s-1} + (j_{s-1} - j_{s-2}) + \cdots + (j_2 - j_1) + (j_1 - j_0)] \leq C \). Thus, by Markov’s inequality \( \Pr[j_s \leq 3sC] \geq \frac{2}{3} \). Since \( |T(j)| \leq \left(\frac{3}{4}\right)^{|T(j)|} |T_{j_0}| \), the algorithm that runs for \( 3C[\log_{3/2} m] \) iterations terminates in a 1-labeled leaf with probability at least \( \frac{2}{3} \).

A Lower Bound on Determinantal Complexity

Mrinal Kumar
Department of Computer Science and Engineering, IIT Bombay, India

Ben Lee Volk
Department of Computer Science, University of Texas at Austin, TX, USA

Abstract
The determinantal complexity of a polynomial \( P \in \mathbb{F}[x_1, \ldots, x_n] \) over a field \( \mathbb{F} \) is the dimension of the smallest matrix \( M \) whose entries are affine functions in \( \mathbb{F}[x_1, \ldots, x_n] \) such that \( P = \text{Det}(M) \).

We prove that the determinantal complexity of the polynomial \( \sum_{i=1}^{n} x_i \) is at least \( 1.5n - 3 \).

For every \( n \)-variate polynomial of degree \( d \), the determinantal complexity is trivially at least \( d \), and it is a long standing open problem to prove a lower bound which is super linear in \( \max\{n, d\} \).

Our result is the first lower bound for any explicit polynomial which is bigger by a constant factor than \( \max\{n, d\} \), and improves upon the prior best bound of \( n + 1 \), proved by Alper, Bogart and Velasco [2] for the same polynomial.

1 Introduction

1.1 Computing with Determinants

The determinantal complexity of a polynomial \( f \in \mathbb{F}[x_1, \ldots, x_n] \), denoted \( \text{dc}(f) \), is the minimal integer \( m \) such that there exists an affine map \( L : \mathbb{F}^n \rightarrow \mathbb{F}^{m \times m} \) such that \( f(x) = \text{Det}(L(x)) \), where for every square matrix \( M \), \( \text{Det}(M) \) denotes the determinant of \( M \).

This notion was first implicitly defined by Valiant [24], and it is tightly related to the VP vs. VNP problem, the algebraic analog of the P vs. NP problem. The essence of the VP vs. VNP problem is showing that some explicit polynomials are hard to compute. By defining natural notions of reductions and completeness, Valiant showed that this problem is in fact equivalent to showing that, for fields of characteristic different than two, the determinantal complexity of the permanent polynomial,

\[
\text{Perm}_n(X) = \sum_{\sigma \in S_n} \prod_{i=1}^{n} x_{i, \sigma(i)},
\]

doesn’t grow like a polynomial function in \( n \).²

1 A part of this work was done while at the Center for the Mathematics of Information, California Institute of Technology, USA.

² Strictly speaking, the VP vs. VNP question is equivalent to showing that the determinantal complexity of the \( \text{Perm}_n \) is at least \( n^{\omega(\log n)} \), but we skip over this fine grained detail for now.
This fact is a consequence of the completeness property of the determinant: Valiant showed that if \( f \) has an algebraic formula of size \( s \), then the determinantal complexity of \( f \) is at most \( s \). This remains true even if \( f \) has an algebraic branching program (ABP) of size \( s \). ABPs are a natural and more powerful model of computation than formulas. We refer to [22] and [20] for more background on algebraic complexity theory and for proofs of these statements.

Thus, Valiant also established en passant the non-obvious fact that the determinantal complexity of every polynomial is finite, and it’s at most roughly \( \binom{n+d}{n} \) for every \( n \)-variate polynomial of degree \( d \). Standard counting arguments also show that this estimate is close to being tight for almost every such polynomial.

The benefit of this reformulation of the \( \text{VP} \) vs. \( \text{VNP} \) problem is that it appears to strip away altogether the notion of “computation”: indeed, this problem can be stated without even defining a computational model in any standard sense of the word, and thus it can potentially be proved without having to argue about the topology or structure of every possible arithmetic computation.

In practice, however, proving lower bounds on determinantal complexity is (unsurprisingly) difficult. Currently, for \( n \)-variate polynomials, there are no known lower bounds which are super-linear in \( n \) (see Subsection 1.2 for more details on previous work). Due to the completeness property mentioned above, a lower bound of \( s \) on the determinantal complexity of \( f \) will imply the same lower bound for algebraic formulas and even algebraic branching programs. However, super-linear lower bounds for formulas are well-known for decades [12], and super-linear lower bounds for ABPs were recently established in [7], so there doesn’t seem to be any major complexity-theoretic barrier for proving such lower bounds for determinantal complexity: the main obstacle is seemingly lack of techniques for reasoning about computations using determinants, and hence it is important to study this model and to develop techniques to understand it and to prove lower bounds, for the permanent as well as for other explicit polynomials.

Even for the purpose of separating \( \text{VP} \) and \( \text{VNP} \), one need not necessarily prove a lower bound on the determinantal complexity of the permanent; the same conclusion will hold if the lower bound on determinantal complexity is shown for any “explicit” polynomial (formally, in the class \( \text{VNP} \), which we don’t define here) in lieu of the permanent.

Before we describe the previous work concerning determinantal complexity, we provide a brief remark about the notion of a “trivial” lower bound in this context which is worth remembering when evaluating the previous results (and our result). Unlike most standard computational models, observe that for an \( n \)-variate polynomial of degree \( d \), even a lower bound of \( n \) is non-trivial for determinantal complexity. This is because every coordinate of the affine map \( L \) can depend on all \( n \) variables. Nevertheless, since the determinant of an \( m \times m \) matrix is a degree \( m \) polynomial, and thus \( \text{Det}(L(x)) \) is a polynomial of degree at most \( m \) for every affine map \( L \), the degree \( d \) is a trivial lower bound on the determinantal complexity of \( f \). Therefore, it is natural to consider polynomial families in which \( d \leq n \) or alternatively to hope to prove lower bounds stronger than \( \max\{n,d\} \).

1.2 Previous work

The early work on determinantal complexity mostly focused on proving lower bounds for the permanent. Recall that the \( n \times n \) permanent, \( \text{Perm}_n \), is a degree \( n \) polynomial, so the trivial lower bound is \( \text{dc}(\text{Perm}_n) \geq n \). Since over characteristic 2 the permanent and determinant coincide, the results described here hold for characteristic not equal to 2.

4:2 A Lower Bound on Determinantal Complexity
Already in 1913, Szegő [23], answering a question of Pólya [19], showed that there’s no way to generalize the $2 \times 2$ identity

$$\text{Perm} \begin{pmatrix} x_{1,1} & x_{1,2} \\ x_{2,1} & x_{2,2} \end{pmatrix} = \text{Det} \begin{pmatrix} x_{1,1} & x_{1,2} \\ -x_{2,1} & x_{2,2} \end{pmatrix}$$

by affixing $\pm$ signs to an $n \times n$ matrix of variables for $n \geq 3$.

Marcus and Minc [16] strengthened this result by showing that for every $n$, $dc(\text{Perm}_n) > n$. Subsequent work by von zur Gathen [25], Babai and Seress (see [25]), Cai [5] and Meshulam [17] obtained the slightly stronger lower bound $dc(\text{Perm}_n) \geq \sqrt{2n}$. Mignon and Ressayre [18] greatly improved the lower bound by proving $dc(\text{Perm}_n) \geq n^2/2$, over the complex numbers. Cai, Chen and Li [6] extended this lower bound to fields of positive characteristic different than two, and Landsberg, Manivel and Ressayre [15] extended this result to the border version of determinantal complexity, that is, they showed that the permanent is not even in the closure of polynomials with determinantal complexity less than $n^2/2$. Finally, Yabe [26] obtained an improved lower bound of $(n - 1)^2 + 1$ over the real numbers.

However, while these lower bounds are quadratic in the degree, $\text{Perm}_n$ is a polynomial with $n^2$ many variables, and notably none of these lower bounds is larger than the number of variables. In particular, these results don’t even recover a weak form of the $n^3$ formula lower bound of Kalorkoti for $\text{Perm}_n$ [12].

Landsberg and Ressayre [14] considered determinantal representations that respect certain symmetries (which they called equivariant determinantal complexity and denoted $edc$), and proved that $edc(\text{Perm}_n)$ is exponential in $n$. It’s unclear how stringent the symmetry requirement is; Landsberg and Ressayre put forward the ambitious conjecture that $edc$ and $dc$ are polynomially related, which, if true, would imply $VP \neq VNP$. To the best of our knowledge, this conjecture remains open, but it’s worth mentioning that in the context of regular determinantal complexity, another notion defined and studied by [14], it can be shown unconditionally that requiring symmetry may result in a super-polynomial blow-up [11].

The question of lower bounds for other explicit polynomial was also considered: Mignon and Ressayre [18] proved that the determinantal complexity of quadratic polynomials of rank $r$ is exactly $\ceil{(r + 1)/2}$ (this, of course, cannot give a lower bound beyond $\ceil{(n + 1)/2}$). Chen, Kayal and Wigderson [8] observed that the technique of Mignon and Ressayre implies an $n/2$ lower bound on the determinantal complexity of the elementary symmetric polynomial of degree 2, $\sum_{1 \leq i < j \leq n} x_ix_j$. Kumar [13] used a different technique to prove a similar lower bound for the power symmetric polynomials $\sum_i x_i^d$ for $d \geq 2$ over $\mathbb{C}$.

The last lower bound was improved in a recent work of Alper, Bogart and Velasco [2]; an immediate corollary of their main theorem is that $dc(\sum_i x_i^d) \geq n + 1$, for every $d \geq 2$. Note that this lower bound is (only slightly) larger than the number of variables $n$, which is the first lower bound we are aware of with this feature. The results of Alper et al. are more general, and are stated as a function of the co-dimension of the singular locus of the polynomial, a notion we use as well (see Section 3). In particular they are able to prove that $dc(\text{Perm}_3) = 7$, but their main statement can’t imply any lower bound stronger than $n + 1$ for an $n$-variate polynomial.

## 1.3 Our result

Our main result is the following theorem.

**Theorem 1.** For every natural number $n \geq 6$, the determinantal complexity of the polynomial $\sum_{i=1}^n x_i^n$ over the field of complex numbers is at least $1.5n - 3$. 
Although for simplicity we state our results for the complex numbers, all the results in this paper also hold for algebraically closed fields of positive characteristic \( p \), as long as \( p \) doesn’t divide \( n \). This assumption is not only an artifact of the proof. For example, when \( n = p^k \), and over characteristic \( p \),

\[
\sum_{i=1}^{p^k} x_i^{p^k} = \left( \sum_{i=1}^{p^k} x_i \right)^{p^k}
\]

has determinantal complexity at most \( n = p^k \); it is also a polynomial of degree \( n \), so its determinantal complexity is at least, and hence equals, \( n \).

As discussed in Subsection 1.2, this is the first non-trivial lower bound of the form \((1 + \epsilon) n\), for any \( \epsilon > 0 \) for any explicit \( n \) variate polynomial family, and improves the previous best bound of \( n + 1 \) by Alper, Bogart and Velasco [2] by a constant factor.

This result, of course, is not fully satisfactory. The best upper bound we’re aware of for \( \text{dc}(\sum_{i=1}^{n} x_i^n) \) is \( O(n^2) \), which follows from converting the natural algebraic formula or ABP computing this polynomial to a determinantal expression. We suspect that the true complexity might be \( \Omega(n^2) \) or at the very least \( \omega(n) \).

Quantitatively, the situation here is somewhat similar to the case of lower bounds on the rank of 3-dimensional tensors, where the best lower bounds are only a constant factor away from the trivial lower bound, and proving super-linear lower bounds remains a challenging open problem (cf. [1, 4, 3, 21], among others).

We now give an outline of the main ideas in our proof.

1.4 Overview of the proof

Let \( M \in F[x_1, x_2, \ldots, x_n]^{m \times m} \) matrix of affine functions such that \( \sum_{i=1}^{n} x_i^n = \text{Det}(M(x)) \). Theorem 1 shows a lower bound of \( 1.5n - 3 \) on \( m \). There are essentially three main ingredients to the proof of Theorem 1, and we now discuss them in some more detail.

Converting the matrix \( M \) into a normal form

Let \( M_0 \in F^{m \times m} \) be the constant part of the matrix \( M \), i.e. \( M_0 = M(0) \). As a first step of our proof, we show (in Lemma 5) that without loss of generality, \( M_0 \) can be assumed to be a diagonal matrix of rank equal to \( m - 1 \). We a say that a matrix \( M \) is in normal form if it has this additional structure.

It is quite easy to observe that the rank of \( M_0 \) is at most \( m - 1 \). However, for technical reasons, we actually need the lower bound on the rank as well, and this fact is a consequence of comparing the dimensions (as algebraic varieties) of the singular locus (which is just the the set of zeroes of a polynomial of multiplicity at least two) of the determinant and that of the polynomial \( \sum_{i=1}^{n} x_i^n \). Observations of this nature have been used in the context of determinantal complexity lower bounds before, and indeed, we crucially rely on a well known lemma of von zur Gathen (see Lemma 7) for the proof. The details can be found in Subsection 3.1.

---

\[^3\] This means that the degree of the polynomials is at most the number of variables.
Dedentential complexity of higher degree polynomial maps

As the key ingredient of our proof, we show that for any matrix $M(x) \in \mathbb{F}[x]^{m \times m}$ where the entries of $M$ are polynomials of degree at most $n - 1$ and $M$ is in normal form, if $\det(M(x)) = \sum_{i=1}^{n} x_i^n$, then $m \geq n/2$. Moreover, roughly the same lower bound continues to hold as long as $\det(M) = (\sum_{i=1}^{n} x_i^n)(1 + Q)$ for any polynomial $Q$, with $Q(0) = 0$.

Thus, this is a significant generalization of the $n/2$ lower bound on the standard notion of determinantal complexity (where the entries of $M$ are affine functions) of $\sum_{i=1}^{n} x_i^n$ as shown in [13]: this shows that roughly the same lower bound continues to hold even when the entries of the matrix are arbitrary polynomials of degree as high as $n - 1$ and the determinant of the matrix equals an arbitrary multiple of $\sum_{i=1}^{n} x_i^n$ with a non-zero constant term.

The proof of the lemma relies on the observation that the polynomial $\sum_{i=1}^{n} x_i^n$ does not vanish with multiplicity at least two very often. This seemingly simple observation has been previously used in the context of lower bounds on algebraic branching programs computing this polynomial [13, 7] in a crucial way. See Subsection 3.2 for further details.

Trading dimension of the matrix for degree

As the final ingredient of our proof, we use a well known property of determinants (Lemma 10) to show that if there is an $m \times m$ matrix $M$ whose entries are affine functions and $\det(M) = \sum_{i=1}^{n} x_i^n$, then there is an $(m - n + 2) \times (m - n + 2)$ matrix $N$ whose entries are polynomials of degree at most $n - 1$ and $\det(N) = (\sum_{i=1}^{n} x_i^n)(1 + Q)$ for a polynomial $Q$ which vanishes at zero. Moreover, if the matrix $M$ is in normal form, then the matrix $N$ continues to be in normal form.

Thus, we are in a setup where we can invoke the lower bound in Lemma 11 discussed earlier and we get that the dimension of $N$ which equals $m - n + 2$ must be at least $n/2 - 1$, thereby implying that $m$ is at least $1.5n - 3$. The details of this step can be found in Subsection 3.3.

2 Preliminaries

In this paper $\mathbb{F}$ always denotes an algebraically closed field. We use $x$ to denote a tuple of $n$ variables $x_1, \ldots, x_n$, where $n$ is understood from the context (or is otherwise explicitly mentioned).

We consider polynomial maps $M : \mathbb{F}^n \to \mathbb{F}^{m \times m}$ given by $m^2$ polynomials $(M_{i,j})_{i,j \in [m]}$. The same object can be thought of as a matrix of polynomials $M(x) \in \mathbb{F}[x]^{m \times m}$ and we use both points of view interchangeably. The degree of $M$ is the maximum degree of its coordinates, i.e., $\deg M = \max_{i,j} \deg M_{i,j}$.

Each $M(x) \in \mathbb{F}[x]^{m \times m}$ can be uniquely written as $M(x) = M'(x) + M_0$, where $M_0 \in \mathbb{F}^{m \times m}$ and in all $m^2$ coordinates of $M'$, the constant term is zero. We then call $M_0$ the constant part of the map. A polynomial in which the constant term is zero is called constant free, and a polynomial map is called constant free if all of its coordinates are constant free, i.e., in the above decomposition, $M_0 = 0$.

We denote the determinant polynomial by $\det$. In cases where it is important to emphasize the dimension of the matrices in question we write it in the subscript, so for example the $m \times m$ determinant polynomial is denoted by $\det_m$.

We assume knowledge of basic concepts in algebraic geometry such as affine varieties $V \subseteq \mathbb{C}^n$ and their dimension, which we denote $\dim(V)$. We encourage readers unfamiliar with those terms to consult the excellent textbook [9].
Determinantal Complexity

We now formally define the notion of determinantal complexity, which is the focus of this paper.

Definition 2 (Determinantal Complexity). The determinantal complexity of a polynomial \( P \in \mathbb{F}[x] \) is defined as the minimum \( m \in \mathbb{N} \) such that there is a \( m \times m \) matrix \( M \in \mathbb{F}[x] \) whose entries are polynomials of degree at most one such that
\[
P = \det(M).
\]

Remark 3. The above definition naturally generalizes to a family of polynomials in the following sense. A family \( \{P_n\}_{n \in \mathbb{N}} \) of polynomials is said to have determinantal complexity at most \( f(n) : \mathbb{N} \to \mathbb{N} \) if there exists an \( n_0 \in \mathbb{N} \), such that for every \( n \geq n_0 \), the determinantal complexity of \( P_n \) is at most \( f(n) \).

3 A lower bound on determinantal complexity

This section will be devoted for a proof of Theorem 1. We begin with the following lemma, which was instrumental in the recent proofs of lower bounds for algebraic formulas and algebraic branching programs.

Lemma 4 ([7, 13]). Let \( d \geq 2 \) be a natural number. Let \( P_1, P_2, \ldots, P_t, Q_1, \ldots, Q_t, L \in \mathbb{C}[x] \) be polynomials such that \( \deg(P') < d \), \( P_1, \ldots, P_t, Q_1, \ldots, Q_t \) have a common zero and
\[
\sum_{i=1}^{n} x_i^d = \sum_{j=1}^{t} P_j(x)Q_j(x) + P'.
\]
Then, \( t \geq n/2 \).

We now show that without loss of generality, the constant part of every polynomial map \( M \) such that \( \sum_{i=1}^{n} x_i^d = \det_m(M(x)) \) has a very special form: it is an \( m \times m \) diagonal matrix with 0 in the \((1,1)\) coordinate and 1 in all diagonal entries.

3.1 Reducing the matrix \( M \) to a normal form

This claim is not entirely new and very similar statements were proved, for example, in [18, 2]. For completeness, and since the exact statement we need is slightly more general, we provide a proof.

Lemma 5. Let \( d \geq 2 \) be a natural number and let \( M(x) \in \mathbb{F}[x]^{m \times m} \) be a polynomial map such that
\[
\det_m(M(x)) = \sum_{i=1}^{n} x_i^d.
\]
Then, there exists a matrix \( \tilde{M}(x) \in \mathbb{F}[x]^{m \times m} \) with \( \deg(\tilde{M}) \leq \deg(M) \),
\[
\det_m(\tilde{M}(x)) = \sum_{i=1}^{n} x_i^d,
\]
and the constant part of \( \tilde{M} \) is a diagonal \( m \times m \) matrix \( \tilde{M}_0 \) such that \( \tilde{M}_0)_{1,1} = 0 \) and \( (\tilde{M}_0)_{i,i} = 1 \), for \( 2 \leq i \leq m \).
To prove Lemma 5 we require a few preliminaries. We begin with the definition of a singular locus of a polynomial (or a hypersurface).

**Definition 6.** Let \( f \in \mathbb{F}[x] \) be a polynomial. The singular locus of \( f \), denoted \( \text{Sing}(f) \), is the variety defined by

\[
\text{Sing}(f) = \left\{ a : \frac{\partial f}{\partial x_i}(a) = 0, 1 \leq i \leq n \right\}.
\]

The singular locus of the determinant was studied by von zur Gathen, who proved the following lemma.

**Lemma 7 ([25]).** Let \( \mathbb{F} \) be an algebraically closed field and let \( \text{Det}_m \) denote the \( m \times m \) determinant polynomial. Then \( \text{Sing} (\text{Det}_m) \subseteq \mathbb{F}^{m \times m} \) is precisely the set of matrices of rank at most \( m - 2 \), and \( \dim (\text{Sing} (\text{Det}_m)) = m^2 - 4 \).

The following is a slight generalization of a lemma of von zur Gathen (cf. also [2]).

**Lemma 8.** Let \( f \in \mathbb{F}[x] \) be a polynomial, and let \( M : \mathbb{F}^n \rightarrow \mathbb{F}^{m \times m} \) be a polynomial map such that \( f(x) = \text{Det}_m (M(x)) \). Suppose further that \( \dim (\text{Sing}(f)) < n - 4 \). Then \( \text{Im}(M) \cap \text{Sing} (\text{Det}_m) = \emptyset \). Furthermore, all matrices in \( \text{Im}(M) \) have rank at least \( m - 1 \).

**Proof.** Let \( y_{i,j} \) denote the coordinates of \( \mathbb{F}^{m \times m} \) and write \( M = (M_{i,j})_{i,j \in [m]} \). Using the chain rule, we compute

\[
\frac{\partial f}{\partial x_k} = \sum_{i,j \in [m]} \frac{\partial \text{Det}_m}{\partial y_{i,j}} (M(x)) \cdot \frac{\partial M_{i,j}}{\partial x_k} (x), \quad k \in [n]. \tag{1}
\]

Suppose \( A \in \text{Im}(M) \cap \text{Sing} (\text{Det}_m) \), and let \( B \) be such that \( A = M(B) \). By definition of \( \text{Sing}(\text{Det}_m) \), \( \frac{\partial \text{Det}_m}{\partial y_{i,j}} (M(B)) = 0 \) for all \( i, j \in [m] \), and by (1) we get that \( B \in \text{Sing}(f) \). Thus \( M^{-1}(\text{Sing}(\text{Det}_m)) \subseteq \text{Sing}(f) \), and \( \dim (M^{-1}(\text{Sing}(\text{Det}_m))) \leq \dim (\text{Sing}(f)) < n - 4 \). On the other hand, using a standard lower bound on the dimension of pre-images of polynomial maps (see Theorem 17.24 of [10]), if \( \text{Im}(M) \) and \( \text{Sing}(\text{Det}_m) \) aren’t disjoint,

\[
\dim (M^{-1}(\text{Sing}(\text{Det}_m))) \geq n + (m^2 - 4) - m^2 = n - 4.
\]

This contradiction implies that \( \text{Im}(M) \cap \text{Sing}(\text{Det}_m) = \emptyset \). The “furthermore” part of the theorem follows from Lemma 7.

We will also need the following easy fact which shows that \( \sum_{i=1}^n x_i^d \) satisfies that assumption of Lemma 8.

**Lemma 9 ([13, 7]).** For every \( d \geq 2 \), \( \dim (\text{Sing}(\sum_{i=1}^n x_i^d)) = 0 \).

We are now ready to prove Lemma 5.

**Proof of Lemma 5.** Let \( f = \sum_{i=1}^n x_i^d \) and let \( M : \mathbb{F}^n \rightarrow \mathbb{F}^{m \times m} \) be a polynomial map such that \( f(x) = \text{Det}_m (M(x)) \), and write \( M = M' + M_0 \) where \( M_0 \) is the constant part of \( M \).

First, observe that

\[
0 = f(0) = \text{Det}_m (M(0)) = \text{Det}_m (M_0),
\]

which implies that \( \text{rank}(M_0) < m \). By Lemma 8 and Lemma 9, we also know that \( \text{rank}(M_0) = \text{rank}(M(0)) \geq m - 1 \), so \( \text{rank}(M_0) = m - 1 \).
4:8 A Lower Bound on Determinantal Complexity

By performing Gaussian elimination on the rows and on the columns, we can find two $m \times m$ matrices $G_1, G_2$ such that $\det(G_i) = \pm 1$ for $i = 1, 2$ and $N_0 := G_1M_0G_2$ is a diagonal matrix such that $(N_0)_{1,1} = 0$ and $(N_0)_{i,i} \neq 0$ for $2 \leq i \leq m$.

Now define a diagonal $m \times m$ matrix $\Delta$ such that $\Delta_{i,i} = 1/(N_0)_{i,i}$ for $2 \leq i \leq m$, and

$$\Delta_{1,1} = \det(G_1) \cdot \det(G_2) \cdot \prod_{i=2}^{m} (N_0)_{i,i}.$$ 

It readily follows that $\det(\Delta) = \det(G_1) \cdot \det(G_2)$, and that $\tilde{M}_0 := (G_1M_0G_2)\Delta$ is a diagonal matrix such that $(\tilde{M}_0)_{1,1} = 0$ and $(\tilde{M}_0)_{i,i} = 1$ for all $2 \leq i \leq m$.

Finally, define $\tilde{M} = G_1M_2\Delta$. We verify that indeed

$$\det(\tilde{M}(x)) = \det(G_1) \cdot \det(M(x)) \cdot \det(G_2) \cdot \det(\Delta) = \det(M(x)) \cdot (\det(G_1) \cdot \det(G_2))^2 = \det(M(x)) = f(x).$$

We also have that

$$\tilde{M} = G_1(M' + M_0)G_2\Delta = G_1M'G_2\Delta + G_1M_0G_2\Delta = G_1M'G_2\Delta + \tilde{M}_0.$$ 

Since $G_1, G_2, \Delta \in \mathbb{F}^{m \times m}$, it also holds that $\tilde{M}' := G_1M'G_2\Delta$ is a matrix of constant-free polynomials, and that $\deg \tilde{M} \leq \deg M$. ▶

We will also use the following simple and well known property of the determinant of a block matrix.

**Lemma 10.** Let $M \in \mathbb{F}^{m \times m}$ be a matrix, and let $A \in \mathbb{F}^{t \times t}$, $B \in \mathbb{F}^{t \times m-t}$, $C \in \mathbb{F}^{m-t \times t}$, $D \in \mathbb{F}^{m-t \times m-t}$ be its submatrices as follows:

$$M = \begin{pmatrix} A & B \\ C & D \end{pmatrix}$$

If $D$ is invertible, then

$$\det(M) = \det(A - BD^{-1}C) \cdot \det(D).$$

**Proof.** Follows directly from the decomposition

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} A - BD^{-1}C & BD^{-1} \\ 0 & I_{m-t} \end{pmatrix} \cdot \begin{pmatrix} I_t & 0 \\ C & D \end{pmatrix}$$

and the multiplicativity of the determinant. ▶

### 3.2 Determinantal complexity of higher degree polynomial maps

In the following lemma we prove a lower bound of $n/2$ on the determinantal complexity in a more general model than the standard model. This is a generalization with respect to two properties. First, the entries of the matrix are no longer constrained to be polynomials of degree at most 1, and can have degree as high as $d-1$, while computing the degree $d$ polynomial $\left(\sum_{i=1}^{n} x_i^d\right)$. Moreover, the determinant of the matrix $M$ does not even have to compute the candidate hard polynomial $\left(\sum_{i=1}^{n} x_i^d\right)$ exactly. It suffices if the determinant is equal to a polynomial of the form $\left(\sum_{i=1}^{n} x_i^d\right) \cdot (\beta + Q)$ where $\beta$ is a non-zero field constant and $Q$ is an arbitrary polynomial (of potentially very high degree) which is constant free, i.e. $Q(0) = 0$. 
Lemma 11. Let \( d \geq 2 \) be a natural number and let \( M(x) \in \mathbb{F}[x]^{m \times m} \) such that \( \deg(M) \leq d - 1 \), and the constant part of \( M \) is a diagonal matrix \( M_0 \) such that \( (M_0)_{1,1} = 0 \) and \( (M_0)_{1,i} = 1 \) for \( 2 \leq i \leq m \). Suppose that

\[
\text{Det}(M) = \left( \sum_{i=1}^{n} x_i^d \right) \cdot (\beta + Q),
\]

where \( \beta \in \mathbb{F} \) is non-zero and \( Q \) is a constant free polynomial. Then \( m \geq n/2 - 1 \).

Proof. Using the Laplace expansion of \( \text{Det}(M) \) along the first row, we get

\[
\text{Det}(M) = \sum_{j=1}^{m} (-1)^{(j+1)} M_{1,j} \cdot \text{Det}(N_{1,j}),
\]

where \( N_{1,j} \) is the submatrix of \( M \) obtained by deleting the \( i \)-th row and the \( j \)-th column. For every \( j \in [m], j > 1 \), we claim that \( \text{Det}(N_{1,j}) \) is a constant free polynomial, i.e.

\[
\text{Det}(N_{1,j})(0) = \text{Det}(N_{1,j}(0)) = 0.
\]

To see this, we observe that for every \( j \in [m] \setminus \{1\}, N_{1,j}(0) \) is a \((m - 1) \times (m - 1)\) matrix, which has at most \( m - 2 \) non-zero entries. This follows since \( M_0 \) has at most \( m - 1 \) non-zero entries and in obtaining \( N_{1,j} \) from \( M \), we drop the entry \( M_{1,j} \), which is one of the \((m - 1)\) entries of \( M \) with a non-zero constant term, and hence one of the \((m - 1)\) non-zero entries of \( M_0 \). However, we note that \( N_{1,1}(0) \) is the \((m - 1) \times (m - 1)\) identity matrix, so the constant term of \( \text{Det}(N_{1,1}) \) is 1, and we write \( \text{Det}(N_{1,1}) = 1 + P(x) \) where \( P \) is constant free. Therefore, we have

\[
\left( \sum_{i=1}^{n} x_i^d \right) \cdot (\beta + Q) = \text{Det}(M) = M_{1,1}(1 + P) + \sum_{j=2}^{m} (-1)^{(j+1)} M_{1,j} \cdot \text{Det}(N_{1,j})
\]

In other words,

\[
\left( \sum_{i=1}^{n} x_i^d \right) \cdot (\beta + Q) = \text{Det}(M) = M_{1,1} + M_{1,1} \cdot P + \sum_{j=2}^{m} (-1)^{(j+1)} M_{1,j} \cdot \text{Det}(N_{1,j})
\]

Slightly rearranging (and using \( \beta \neq 0 \)), we get

\[
\sum_{i=1}^{n} x_i^d = \frac{1}{\beta} \left( -\left( \sum_{i=1}^{n} x_i^d \right) \cdot Q + M_{1,1} + M_{1,1} \cdot P + \sum_{j=2}^{m} (-1)^{(j+1)} M_{1,j} \cdot \text{Det}(N_{1,j}) \right)
\]

Since, \( \deg(M_{1,1}) < d \) and \( M_{1,1}, P, M_{1,2}, \text{Det}(N_{1,2}), \ldots, M_{1,k}, \text{Det}(N_{1,k}), Q \) are all constant free (and hence share a common zero, namely \( 0 \)), we have from Lemma 4 that \( m \geq n/2 - 1 \). ▶

3.3 Completing the proof of Theorem 1

We are now ready to complete the proof of Theorem 1.

Proof of Theorem 1. Let \( M \) be an \( m \times m \) matrix with \( \deg(M) \leq 1 \) such that

\[
\sum_{i=1}^{n} x_i^n = \text{Det}(M).
\]
From Lemma 5, we can assume without loss of generality that the constant part \( M_0 \) of \( M \) is a diagonal matrix such that \((M_0)_{1,1} = 0\) and \((M_0)_{i,i} = 1\) for \( 2 \leq i \leq m \). In particular, all the off-diagonal entries of \( M \) and \( M_{1,1} \) are homogeneous linear forms or zero, and \( M_{j,j} \neq 0 \) for \( j > 1 \).

Observe that for every \( t \leq m - 1 \), the principal minor \( D_t \) of \( M \) which is obtained by deleting the first \( m - t \) rows and columns of \( M \) is invertible over the field of rational functions \( F(x) \). To see this, observe that the matrix \( D_t(0) \) is the identity matrix, which implies that \( \text{det}(D_t) \) is a non-zero polynomial. Moreover, since every entry of \( M \) has degree at most 1, and \( \text{det}(M) \) has degree \( n \), we know that \( m \geq n \). So, we conclude that the principal minor \( D := D_{(n-2)} \) of \( M \) is invertible over \( F(x) \). Thus, if \( B \) and \( C \) are respectively the submatrices of \( M \) defined as

\[
M = \begin{pmatrix} A & B \\ C & D \end{pmatrix}
\]

then by Lemma 10 we have

\[
\text{det}(M) = \text{det}(A - BD^{-1}C) \cdot \text{det}(D). \tag{2}
\]

Since \( D^{-1} = \text{adj}(D)/\text{det}(D) \), where \( \text{adj}(D) \) is the adjugate matrix of \( D \), the entries of \( D^{-1} \) can be written as a ratio of two polynomials, where the numerator has degree at most \( n - 3 \) and the denominator, which is equal to \( \text{det}(D) \), has degree at most \( n - 2 \). Moreover, as discussed earlier in the proof, the constant part of \( D \) is the identity matrix, so there is a constant free polynomial \( R \in F[x] \) such that

\[
\text{det}(D) = 1 + R.
\]

Thus, every entry of the \((m - n + 2) \times (m - n + 2)\) matrix \( A - BD^{-1}C \) can be written as a ratio of two polynomials with the numerator being a polynomial of degree at most \( n - 1 \) and the denominator being equal to \( \text{det}(D) = 1 + R \). Therefore, by clearing the denominators and using (2), we get that

\[
\text{det}(M) \cdot (1 + R)^{m-n+2} = \text{det}(N) \cdot (1 + R),
\]

where \( N \) is the matrix with polynomial entries of degree at most \( n - 1 \) obtained by multiplying every entry of \( A - BD^{-1}C \) by \( 1 + R \). Simplifying further, we get

\[
\left( \sum_{i=1}^{n} x_i^n \right) \cdot (1 + R)^{m-n+1} = \text{det}(M) \cdot (1 + R)^{m-n+1} = \text{det}(N).
\]

We are almost ready to invoke Lemma 11 to obtain a lower bound on the size of \( N \) (and hence \( M \)), but to do that we need to ensure that the constant part of \( N \), \( N_0 \), is a diagonal matrix with \((N_0)_{1,1} = 0\) and \((N_0)_{i,i} = 1\) for \( 2 \leq i \leq m - n + 2 \). We now verify that this is indeed the case.

Recall that by the structure of the constant part \( M_0 \) of \( M \), all the entries of \( B \) and \( C \) and the \((1,1)\) entry of \( A \) are constant free, and the constant term of \( A_{i,i} \) is 1 for \( 2 \leq i \leq m - n + 2 \). Thus, every entry of the matrix \( BD^{-1}C \) is a rational function with a constant free numerator, and hence all the off-diagonal entries in \( A - BD^{-1}C \) as well as its \((1,1)\) entry are rational functions with a constant free numerator. Moreover, the denominator of all the entries \((A - BD^{-1}C)\) equals \( \text{det}(D) = 1 + R \), for a constant free polynomial \( R \). So, expressing each entry of \( A - BD^{-1}C \) as a quotient of polynomials, the constant term of each numerator on
the diagonal is 1 except for the (1,1) entry, which has a constant free numerator. Finally, observe that eliminating the denominator of the entries of \((A - BD^{-1}C)\) by multiplying every entry by \((1 + R)\) gives us the matrix \(N\).

Thus the matrix \(N\) satisfies the hypothesis of Lemma 11, and hence \((m - n + 2) \geq n/2 - 1\). This gives us \(m \geq 1.5n - 3\) and completes the proof of Theorem 1.

Optimal Tiling of the Euclidean Space Using Permutation-Symmetric Bodies

Mark Braverman
Department of Computer Science, Princeton University, NJ, USA

Dor Minzer
Department of Mathematics, Massachusetts Institute of Technology, Cambridge, MA, USA

Abstract

What is the least surface area of a permutation-symmetric body $B$ whose $\mathbb{Z}^n$ translations tile $\mathbb{R}^n$? Since any such body must have volume 1, the isoperimetric inequality implies that its surface area must be at least $\Omega(\sqrt{n})$. Remarkably, Kindler et al. showed that for general bodies $B$ this is tight, i.e. that there is a tiling body of $\mathbb{R}^n$ whose surface area is $O(\sqrt{n})$.

In theoretical computer science, the tiling problem is intimately related to the study of parallel repetition theorems (which are an important component in PCPs), and more specifically in the question of whether a “strong version” of the parallel repetition theorem holds. Raz showed, using the odd cycle game, that strong parallel repetition fails in general, and subsequently these ideas were used in order to construct non-trivial tilings of $\mathbb{R}^n$.

In this paper, motivated by the study of a symmetric parallel repetition, we consider the permutation-symmetric variant of the tiling problem in $\mathbb{R}^n$. We show that any permutation-symmetric body that tiles $\mathbb{R}^n$ must have surface area at least $\Omega(n/\sqrt{\log n})$, and that this bound is tight, i.e. that there is a permutation-symmetric tiling body of $\mathbb{R}^n$ with surface area $O(n/\sqrt{\log n})$. We also give matching bounds for the value of the symmetric parallel repetition of Raz’s odd cycle game.

Our result suggests that while strong parallel repetition fails in general, there may be important special cases where it still applies.

1 Introduction

A body $D \subseteq \mathbb{R}^n$ is said to be tiling the Euclidean space $\mathbb{R}^n$, if its translations by $\mathbb{Z}^n$ cover the entire space and have disjoint interiors. The foam problem asks for the least surface area a tiling body $D$ can have. The problem had been considered by mathematicians already in the 19th century [33], and it also appears in chemistry, physics and engineering [30]. More recently, the problem had received significant attention in the theoretical computer science community due to its strong relation with the parallel repetition problem [15, 24, 2].

The simplest example for a body that tiles the Euclidean space is the solid cube, $D = [0,1]^n$, which has surface area $2n$. At first glance, one may expect the solid cube to be the best example there is, or more modestly that any tiling body would need to have surface area $\Omega(n)$. The main results of [24, 2] show that this initial intuition is completely false, and that there are far more efficient tiling bodies whose surface area is $O(\sqrt{n})$. This is surprising, since spheres – which are the minimizers of surface area among all bodies with a given,
fixed volume (in this case volume 1), have $\Theta(\sqrt{n})$ surface area and seem to be very far from forming a tiling of $\mathbb{R}^n$. As we will shortly discuss, the existence of such surprising tiling body is intimately related to the existence of another surprising object – namely non-trivial strategies for 2-prover-1-round games, repeated in parallel. The main goal of this paper is to understand the permutation-symmetric variant of the foam problem, which is closely related to the symmetric variant of parallel repetition.

### 1.1 2-Prover-1-Round Games and Parallel Repetition

**Definition 1.** A 2-Prover-1-Round Game $G = (L \cup R, E, \Phi, \Sigma_L, \Sigma_R)$ consists of a bipartite graph $(L \cup R, E)$, alphabets $\Sigma_L, \Sigma_R$, and a constraint $\Phi(u, v)$ for every edge $(u, v) \in E$. The goal is to find assignments $A_L : L \rightarrow \Sigma_L$, $A_R : R \rightarrow \Sigma_R$ that satisfy the maximum fraction of the constraints. A constraint $\Phi(u, v)$ is satisfied if $(A_L(u), A_R(v)) \in \Phi(u, v)$, where by abuse of notation, $\Phi(u, v) \subseteq \Sigma_L \times \Sigma_R$ denotes the subset of label pairs that are deemed satisfactory.

The value of a game, denoted by $\text{val}(G)$, is the maximum fraction of constraints that can be satisfied in $G$ by any pair of assignments $A_L, A_R$.

Equivalently, a 2-Prover-1-Round Game can be viewed as a “game” between two provers and a verifier. The verifier picks a constraint $(u, v)$ at random, asks the “question” $u$ to the left prover, the “question” $v$ to the right prover, receives “answers” $A_L(u), A_R(v)$ respectively from the provers; the verifier accepts if and only if $(A_L(u), A_R(v)) \in \Phi(u, v)$. It is easy to see that in this language, $\text{val}(G)$ represents the maximum probability a verifier will accept, where the maximum is taken over all of the strategies of the provers.

2-Prover-1-Round games play an important role in the study of PCPs and Hardness of approximation, and in fact an equivalent statement of the seminal PCP Theorem [14, 5, 4] can be stated in that language. It will be convenient for us to use the notation of gap problems: for $0 < s < c \leq 1$, denote by $\text{Gap2Prover1Round}(c, s)$ the promise problem in which the input is a 2-Prover-1-Round game $G$ promised to either satisfy $\text{val}(G) \geq c$ or $\text{val}(G) \leq s$, and the goal is to distinguish between these two cases. The parameters $c$ and $s$ are referred to as the completeness and soundness parameters of the problem, respectively.

**Theorem 2 (PCP Theorem, [14, 5, 4]).** There are $k \in \mathbb{N}$, $s < 1$ for which the problem $\text{Gap2Prover1Round}(1, s)$ is $\text{NP}$-hard on instances with alphabet size at most $k$.

The PCP Theorem, as stated above, can be used to establish some hardness of approximation results. However it turns out that to get strong hardness results, one must prove a variant of the theorem with small soundness, i.e. with $s$ close to 0. One way to do that is by amplifying hardness using parallel repetition.

The $t$-fold repetition of a game $G$, denoted by $G^{\otimes t}$, is the game in which the verifier picks $t$ independently chosen challenges, $(u_1, v_1), \ldots, (u_t, v_t)$ and sends them to the provers in a single bunch, i.e. $\vec{u} = (u_1, \ldots, u_t)$ to one prover and $\vec{v} = (v_1, \ldots, v_t)$ to the second one. The provers are supposed to give an answer to each one of their questions, say $A_L(\vec{u}) = (a_1, \ldots, a_t)$ and $A_R(\vec{v}) = (b_1, \ldots, b_t)$, and the verifier accepts with only if $(a_i, b_i) \in \Phi(u_i, v_i)$ for all $i = 1, \ldots, t$. What is the value of the $t$-fold repeated game, as a function of $\text{val}(G)$ and $t$?

The idea of parallel repetition was first introduced in [16], wherein it was originally suggested that $\text{val}(G^{\otimes t}) \approx \text{val}(G)^t$. Alas, in a later version of that paper it was shown to be false, leaving the question wide open. Raz [27] was the first to prove that the value of the repeated game decreases exponentially with $t$, and with many subsequent works improving the result [18, 26, 13, 10]. The most relevant version for our purposes is the result of Rao [26], which makes the following statement. First, we say a game $G$ is a projection game, if all of the constraints $\Phi(u, v)$ can be described by a projection map, i.e. there is a mapping $\pi_{u,v} : \Sigma_L \rightarrow \Sigma_R$ such that $\Phi(u, v) = \{(a, b) \mid b = \phi_{u,v}(a)\}$. 

\[ \text{val}(G^{\otimes t}) \leq \text{val}(G)^t. \]
Theorem 3. If $G$ is a projection game, and $\text{val}(G) = 1 - \varepsilon$, then $\text{val}(G^{\otimes t}) \leq (1 - \varepsilon^2)^{\Omega(t)}$.

Rao’s result seems nearly optimal, in the sense that a-priori, the best bound one can hope for is that $\text{val}(G^{\otimes t}) \leq (1 - \varepsilon)^{\Omega(t)}$. Quantitatively speaking, one may think that for all intents and purposes, Rao’s bound is just as good as the best one can hope for. However, as it turns out, there is at least one prominent problem where this quadratic gap is what makes the difference, which we describe next.

The Unique Games Conjecture and the Max-Cut Conjecture

The Unique Games problem is a specific type of projection 2-Prover-1-Round Game, in which the projection maps $\phi_{u,v}$ are also bijections. The Unique Games Conjecture of Khot [19] (abbreviated UGC henceforth) asserts that a strong PCP theorem holds for Unique-Games, and more specifically that for any $\varepsilon, \delta > 0$, the problem $\text{GapUG}(1 - \varepsilon, \delta)$ is NP-hard, when the alphabet sizes depend only on $\varepsilon, \delta$. This conjecture is now of central importance in complexity theory, and it is known to imply many, often tight inapproximability results (see [20, 34] for more details). A prominent example is the result of [21], stating that assuming UGC, the Goemans-Williamson algorithm [17] for Max-Cut is optimal. In particular, for small enough $\varepsilon > 0$, if UGC is true, then $\text{GapMaxCut}(1 - \varepsilon, 1 - \frac{2}{3}\sqrt{\varepsilon} + O(\varepsilon^{1.5}))$ is NP-hard. Does the converse hold? I.e., does the assumption that $\text{GapMaxCut}(1 - \varepsilon, 1 - \frac{2}{3}\sqrt{\varepsilon} + O(\varepsilon^{1.5}))$ is NP-hard imply UGC? If so, that would be a promising avenue of attack on the Unique-Games Conjecture.

Noting that Max-Cut is a Unique-Game and that Parallel repetition preserves uniqueness, one may hope a reduction from $\text{GapMaxCut}(1 - \varepsilon, 1 - \frac{2}{3}\sqrt{\varepsilon} + O(\varepsilon^{1.5}))$ to $\text{GapUniqueGames}(1 - \varepsilon', \delta)$ would simply follow by appealing to a parallel repetition theorem, such as Rao’s result [26]. Alas, the quadratic loss there exactly matches the quadratic gap we have in Max-Cut, thereby nullifying it completely. This possibility was discussed in [31], who among other things proposed that perhaps a stronger version of Theorem 3 should hold for Unique-Games, in which the $\varepsilon^2$ is replaced with $\varepsilon$. This conjecture was referred to as the Strong Parallel Repetition Conjecture, and unfortunately it turns out to be false.

A Strong parallel repetition theorem?

The problem of understanding parallel repetition over a very simple game, called the odd cycle game and denoted below by $C_n$, was shown to be closely related to the foam problem [15]. In this game, we have a graph $G$ which is an odd cycle of length $n$, and the provers try to convince the verifier that $G$ is a bipartite graph (while it is clearly not). To test the provers, the verifier picks a vertex $u$ from the cycle uniformly at random, and then picks $v$ as $v = u$ with probability $1/2$, and otherwise $v$ is one of the neighbours of $u$ with equal probability. The verifier sends $u$ as a question to one prover, and $v$ as a question to the other prover, and expects to receive a bit from each one $b_1, b_2$. The verifier checks that $b_1 = b_2$ in case $u = v$, or that $b_1 \neq b_2$ in case $u \neq v$.

Note that clearly, $\text{val}(C_n) = 1 - \Theta(1/n)$, and so the Strong Parallel Repetition Conjecture would predict that the value of the $t$-fold repeated game is $1 - \Theta(t/n)$ so long as $t \leq n$. Alas, this turns out to be false. First, in [15], it was shown that non-trivial solutions to the foam problem imply non-trivial strategies for the $t$-fold repeated game, and in particular the existence of a tiling body with surface area $o(n)$ would refute the Strong Parallel Repetition Conjecture. Subsequently, Raz [28] showed that the value of the $t$-fold repeated odd-cycle game is in fact at least $1 - O(\sqrt{t/n})$ so long as $t \leq n^2$, and that Theorem 3 is optimal (i.e., the quadratic gap is necessary, even for Unique-Games, and more specifically for Max-Cut).
Subsequent works were able to use these insights to solve the foam problem for the integer lattice [24, 2] and lead to better understanding of parallel repetition and its variants [6, 8]. From the point of view of UGC, these results were very discouraging since they eliminate one of the main available venues (perhaps the main one) for the proof of UGC.

Partly due to this issue, the best partial results towards UGC had to take an entirely different approach [22, 12, 11, 23, 7], and currently can only prove that GapUG(1/2, δ) is NP-hard for every δ > 0.

1.2 A symmetric variant of Parallel Repetition

One may try to revive the plan for showing the equivalence of UGC and the hardness of Max-Cut by considering variants of parallel repetition. Ideally, for that approach to work, one should come up with a variant of parallel repetition, in which (a) the value decreases exponentially with the number of repetitions, and (b) the operation preserves uniqueness. One operation that had been considered in the literature, for example, is called fortification [25, 9]. Using this operation, the value of the game indeed decreases exponentially, however this operation does not preserve uniqueness and therefore is not useful for showing the equivalence of UGC and the Max-Cut Conjecture.

More relevant to us is the symmetric variant of parallel repetition that had been previously suggested as a replacement for parallel repetition. In this variant, given a basic game $G$, the verifier chooses the challenges $(u_1, v_1), \ldots, (u_t, v_t)$, and sends the questions to the provers as unordered tuples, i.e. $U = \{u_1, \ldots, u_t\}$ and $V = \{v_1, \ldots, v_t\}$. The verifier expects to receive a label for each element in $U$ and each element in $V$, and checks that they satisfy each one of the constraints $(u_i, v_i)$. We denote this game by $G^\text{sym}$, and note that it clearly preserves uniqueness; also, we note that the arguments used to refute the strong Parallel Repetition Conjecture do not immediately apply to it. While a naive application of this variant can still be shown to fail in general, there is still a hope that it can be used in a more clever way and establish the equivalence of UGC and the Max-Cut Conjecture. Our work is partly motivated by seeking such possibilities.

We are thus led to investigate the effect on symmetric repetition on the odd cycle game, and more specifically the symmetric variant of the foam problem which again is very much related.

1.3 Our results

In this paper, our main object of study mainly are tilings of $\mathbb{R}^n$ using a permutation-symmetric body.

Definition 4. A set $D \subseteq \mathbb{R}^n$ is called permutation-symmetric if for any $\pi \in S_n$ and $x \in \mathbb{R}^n$, it holds that $x \in D$ if and only if $\pi(x) \in D$.

The main question we consider, is what is the least surface area a permutation-symmetric tiling body can have. Again, one has the trivial example of the solid cube $D = [0, 1]^n$, but inspired by the non-permutation-symmetric variant of the problem, one may expect there to be better examples. We first show that while this is possible, the savings are much milder, and can be at most a multiplicative factor of $\sqrt{\log n}$.

---

1 This can be seen by considering a graph which is the disjoint union of many odd cycles (instead of a single odd cycle), say $M$, so that one would get a canonical ordering on most subsets of $t$ vertices from this graph, so long as $t = o(\sqrt{M})$. 

---

5:4 On Symmetric Tilings of Euclidean Space
Theorem 5. Any permutation-symmetric tiling body $D$ of volume 1 with piecewise smooth surface has surface area at least $\Omega\left(\frac{n}{\sqrt{\log n}}\right)$.

Besides the quantitative result itself, we believe the argument used in the proof of Theorem 5 carries with it a lot of intuition regarding the additional challenge that the permutation-symmetric variant of the foam problem and the parallel repetition posses, and we hope that this intuition will help us to develop better understanding of symmetric parallel repetition in general. We remark that our proof actually shows a lower bound on the “noise sensitivity” parameter of the body, which is known to be smaller than the surface area of the body.

We complement Theorem 5 with a randomized construction showing that $O\left(\frac{n}{\sqrt{\log n}}\right)$ savings are indeed possible.

Theorem 6. There exists a permutation-symmetric tiling body $D$ of volume 1 with piecewise smooth surface that has surface area $O\left(\frac{n}{\sqrt{\log n}}\right)$.

Our results also imply tight bounds for the value of the $t$-fold symmetric repetition of the odd cycle game, which we discuss next.

1.4 Significance of our results for symmetric parallel repetition

Using our techniques, one may give sharp estimates to the value of the $t$-fold symmetric repetition of the odd cycle game, as follows.

Theorem 7. There is $c > 0$, such that for an odd $n$, if $t \leq cn\sqrt{\log n}$ then $\text{val}(C_n^{\text{sym}}) \leq 1 - c\frac{t}{n\sqrt{\log t}}$.

Theorem 8. For all $n,t \in \mathbb{N}$ it holds that $\text{val}(C_n^{\text{sym}}) \geq 1 - O\left(\frac{t}{n\sqrt{\log t}}\right)$.

We remark that a similar connection between the standard foam problem and the value of the $t$-fold symmetric repetition of the odd cycle game is well known. More precisely, in [15] the authors show that (1) tilings of the Euclidean space with small surface area can be used to derive good strategies for $C_n^{\text{sym}}$, and (2) the Euclidean isoperimetric inequality (which gives a lower bound of $\Theta(\sqrt{n})$ on the surface area of a tiling body) can be used to prove upper bounds on the value of $C_n^{\text{sym}}$. We remark that while (1) above is derived in a black-box way, the converse direction, i.e. (2), is done in a white-box way. That is, the authors in [15] do not actually use the Euclidean isoperimetric inequality, but rather convert one of its proofs into an upper bound of the value of the $t$-fold repeated odd cycle game.

In contrast to [15], our proof of Theorems 7, 8 follow more direct adaptations of the proofs of Theorems 5, 6. This is partly because our arguments work from scratch and are therefore more flexible. We outline these adaptations in Section 5.

We believe that Theorem 7 gives some new life to the possible equivalence between the Max-Cut Conjecture and UGC. For example, this would follow if such rate of amplification would hold for all graphs if we allow for a “mild” preprocessing phase first (i.e., preprocessing that doesn’t change the value of the instance by much). For this reason, we believe it would be interesting to investigate other graph topologies on which symmetric parallel repetition performs well, and hope that the techniques developed herein will be useful.

On the flip side, Theorem 8 asserts that even symmetric parallel repetition on the odd cycle game admits non-trivial strategies. Thus, we cannot hope to use it in order to establish the equivalence of weaker forms of the Max-Cut Conjecture and UGC. Here, by weaker
forms of the Max-Cut Conjecture, we mean the conjecture that $\text{GapMaxCut}[1 - \varepsilon, 1 - \delta(\varepsilon)]$ is NP-hard for small enough $\varepsilon$, and $\delta(\varepsilon)$ is a nearly linear function of $\varepsilon$, e.g. $\delta(\varepsilon) = 100\varepsilon$ or $\delta(\varepsilon) = \varepsilon \sqrt{\log(1/\varepsilon)}$. Given that the best known NP-hardness results for Max-Cut in this regime are only known for $\delta = (1 + \Omega(1))\varepsilon$, this means that there is still a significant road ahead to establish even the weakest version of the Max-Cut Conjecture that may be useful for UGC.

1.5 Techniques

In this section, we explain some of the intuition and idea that go into the proof of Theorems 5 and 6, focusing mostly on the former.

Let $D$ be a permutation-symmetric tiling body. To prove that the surface area of $D$ is at least $A$, it is enough to prove that $D$ is sensitive to noise rate $1/A$. I.e., that if we take a point $x$ from $D$ uniformly at random, and walk along a random Gaussian direction $u$ of expected length $1/A$, then with constant probability we escape $D$ at some point on the line $x,u(t) = x + tu$.

We begin by describing an argument showing a worse bound than the one proved in Theorem 5, which is nevertheless helpful in conveying some of the intuition. To prove that a random line $x,u(t)$ escapes $D$ with noticeable probability, we argue that for a Gaussian vector $u$ of appropriate expected length, with constant probability the line $x,u$ will contain a point in which there are two coordinates differing by a non-zero integer, say $y$ with the coordinates being $i,j$. Note that this is enough, since then if we assumed that $y \in D$, then the point $y'$ in which the value of coordinates $i,j$ is switched also lies in $D$ (by symmetry), and then the difference of $y$ and $y'$ is a non-zero lattice vector, so they must be in different cells of the tiling. Therefore we conclude that $y \notin D$.

With this plan in mind, let $x = (x_1, \ldots, x_n)$ be uniformly sampled from $D$, and consider the coordinates of $x$ modulo 1, i.e. $B = \{x_1 \mod 1, \ldots, x_n \mod 1\}$, as points in the one-dimensional torus $\mathbb{T}$. First, it can be shown without much difficulty that they are jointly distributed as uniform random points on $\mathbb{T}$, hence standard probabilistic tools tell us that any interval of length $100\log n/n$ on the torus contains at least two points from $B$. Now, regardless of how the body $D$ looks, there would be two coordinates, say $i$ and $j$, that almost differ by a non-zero integer, yet appear very close when projected on the torus, i.e. in distance at most $100\log n/n$. In this case, with constant probability the coordinates $i,j$ get even closer along a random line $x,u(t) = x + tu$, and provided the length of $u$ is long enough to cover the distance between $x_i,x_j$ on the torus (i.e. each coordinate of magnitude $\Theta(\log n/n)$), the line $x,u(t)$ would contain a point as desired.

The above argument can indeed be formalized to yield a lower bound of $\Omega\left(\frac{n}{\log n}\right)$ on the surface area of $D$, but it carries more intuition than just the bound itself. In a sense, this argument says that if we project $x$ onto the torus, we should be wary of coordinates whose projections are too close, and make sure that it would only occur if the coordinates themselves are close (as opposed to almost differing by a non-zero integer). Analyzing the event that two coordinates meet on the circle while being different is easily seen however to not yield a better bound than $\Omega(n/\log n)$, hence to prove Theorem 5 we must look at a different event. That being said, the argument does tell us that we should look at pairwise distances between coordinates of $x$ when projected on the circle, and in particular on pairs that are “relatively close” and the way they move along a line in a random direction.

It turns out that it is enough to come up with some parameter that behaves differently on the endpoints of the line, assuming the line does not escape $D$. This is because that if the escape probability from $D$ is small, then the distributions of $x$ and $x + u$ are close in
statistical distance, and in particular any parameter should behave roughly the same on $x$ and on $x + u$. Indeed, our proof utilizes an energy function (inspired by the previous argument) that considers the pairwise distances between coordinates of $x$; the contribution from a pair of coordinates that are in distance $d$ in the circle is proportional to $e^{-Z \cdot d}$, where $Z \sim n \sqrt{\log n}$.

We show that with high probability, the energy increases along a random line $\ell_{x,u}(t)$ provided it does not escape $D$, while on the other hand, if the escape probability is small, then $x$ and $x + u$ are close in statistical distance and hence $\Pr_{x,u}[\text{Energy}(x + u) > \text{Energy}(x)] \approx \frac{1}{2}$. This implies that the escape probability must be constant.

We remark that the above high-level intuition also plays a role in the proof of Theorem 5. I.e., when constructing a permutation-symmetric tiling body $D$, all we really need to care about are the pairwise distances between coordinates, and that we must make sure that somewhat far coordinates will project to far points on the torus. Indeed, given a point $x \in \mathbb{R}^n$, in order to decide which integer lattice point $y \in \mathbb{Z}^n$ we round $x$ to, we only look at this pairwise distances of $x$ on the torus. We try to find a point $z$ on the torus that is far from all the coordinates of $x$, and do the rounding according to it. One naive attempt would be to take $z$ that is furthest from all coordinates of $x$, however this point turns out to be very noise sensitive and therefore yield a body with large surface area. Instead, we consider a probability distribution that only puts significant weight on $z$’s that are somewhat far from all $x_i$’s, yet is not too concentrated around the maximizers. Coming up and analyzing a construction along these lines turns out to require considerable technical effort, and we defer a more elaborate discussion to Section 4.

**Organization of the paper**

In Section 2, we set up basic notations and preliminaries. Section 3 is devoted to the proof of Theorem 3, and Section 4 is devoted for the proof of Theorem 4. In Section 5 we prove Theorems 7, 8, and in Section 6 we state some open problems.

## 2 Preliminaries

### Notations

We write $X \lesssim Y$ or $X = O(Y)$ to say that there exists an absolute constant $C > 0$ such that $X \leq CY$, and similarly write $X \gtrsim Y$ or $X = \Omega(Y)$ to say that there exists an absolute constant $c > 0$ such that $X \geq cY$. We write $X \asymp Y$ or $X = \Theta(Y)$ to say that $Y \lesssim X \lesssim Y$.

We denote random variables by boldface letters such as $\mathbf{x}$ and $\Delta$. We denote by $\mathcal{N}(\mu, \sigma^2)$ the distribution of a standard Gaussian random variable with mean $\mu$ and variance $\sigma^2$, and by $\mathcal{N}(\bar{\mu}, \Sigma)$ the distribution of a multi-dimensional Gaussian random variable with means $\bar{\mu}$ and covariance matrix $\Sigma$.

For a measurable set $D$ of finite measure, we denote by $a \in D$ or $a \in_R D$ a uniform sample from $D$.

### Needles

**Definition 9.** Let $\delta > 0$, and let $a \in \mathbb{R}^n$. A random $\delta$-needle is a line defined as $\ell_{a,u} = \{ a + tu \mid t \in [0,1] \}$ where the direction vector $u$ is a chosen as a standard Gaussian $\mathcal{N}(0, \delta I_n)$.

Given a tiling body $D$, a random $\delta$-needle from $D$ is a random $\delta$-needle $\ell_{a,u}$ where $a \in D$ is chosen uniformly. Random needles are a useful tool to measure the surface area of a $D$, as shown in the following two lemmas. First, given a tiling body $D$ and a needle $\ell_{a,u}$, we may
think of the needle as “wrapping around” around \( D \), i.e. its points are taken modulo \( D \). We denote this “wrapped around” line by \( \tilde{\ell}_{a,u} \). We will use the following formula from [32]; the case \( n = 2 \) is formula (8.10) therein, and the extension to general \( n \) is discussed in page 274.

**Lemma 10.** There is a constant \( C_n = \Theta(1) \), such that the following holds. Let \( S \) be a piecewise smooth surface in a tiling body \( D \) of volume 1, and let \( \delta > 0 \). Then

\[
\mathbb{E}_{a \in D, u \sim \mathcal{N}(0, \delta I_n)} \left[ |\tilde{\ell}_{a,u} \cap S| \right] = C_n \cdot \sqrt{\delta} \cdot \text{area}(S).
\]

**Lemma 11.** Let \( D \) be a tiling body of volume 1, and let \( \delta > 0 \). Then

\[
\Pr_{a \in D, u \sim \mathcal{N}(0, \delta I_n)} \left[ |\tilde{\ell}_{a,u} \cap \partial D| \neq \emptyset \right] \leq \Theta(\sqrt{\delta}) \cdot \text{area}(\partial D).
\]

**Proof.** Set \( S = \partial D \), and note that whenever \( \ell_{a,\delta u} \cap \partial D \neq \emptyset \), we have that \( |\tilde{\ell}_{a,\delta u} \cap S| \geq 1 \). Hence by the previous lemma we get that

\[
\Pr_{a \in D, u \sim \mathcal{N}(0, \delta I_n)} \left[ |\tilde{\ell}_{a,u} \cap \partial D| \neq \emptyset \right] \leq \mathbb{E}_{a \in D, u \sim \mathcal{N}(0, \delta I_n)} \left[ |\tilde{\ell}_{a,u} \cap \partial D| \right] \leq \Theta(\sqrt{\delta}) \cdot \text{area}(\partial D).
\]

We will use the above lemma to prove lower bounds on the surface area of a tiling body, by finding \( \delta \) such that the probability on the left hand side of Lemma 11 is at least \( \Omega(1) \); this would imply that \( \text{area}(\partial D) \geq \Omega(1/\sqrt{\delta}) \).

### 2.2 Basic useful properties of tiling bodies

**Lemma 12.** Let \( D \subseteq \mathbb{R}^n \) be a permutation-symmetric body, such that for all \( z \in \mathbb{Z}^n \setminus \{0\} \) we have \( D \cap (D + z) = \emptyset \), and let \( x \in D \). Then for every \( 1 \leq i, j \leq n \), if \( x_i = x_j \) is a non-zero integer \( k \), and let \( S_{i,j} \in S_n \) be the permutation that maps \( i \) to \( j \), \( j \) to \( i \) and has any \( r \neq i,j \) as a fixed point. Since \( D \) is permutation-symmetric, we have that \( S_{i,j}(x) \in D \). Also, we have

\[
x - S_{i,j}(x) = (x_i - x_j)(e_i - e_j) = k(e_i - e_j),
\]

where \( e_i \) is the \( i \)th element in the standard basis. In other words, we get that \( x = S_{i,j}(x) + z \) for non-zero \( z \in \mathbb{Z}^n \), and therefore \( x \in D + z \). This contradict the fact that \( D \) and \( D + z \) are disjoint.

**Lemma 13.** Let \( D \) be a volume 1 tiling body, and choose \( a = (a_1, \ldots, a_n) \in D \) uniformly at random. Then the random variable \( (a_1 \text{mod} \, 1, \ldots, a_n \text{mod} \, 1) \) is uniform over \( [0,1)^n \).

**Proof.** Sample \( x \in [0,1)^n \), and take \( a = x \text{ (mod} \, D) \). Note that the distribution of \( a \) is uniform over \( D \). Indeed, for that we note that the map \( x \rightarrow x \text{ (mod} \, D) \) is bijection from \( [0,1)^n \) to \( D \); otherwise, there were \( x \neq x' \in [0,1)^n \) that are equal mod \( D \), and therefore differ by non-zero lattice point (which is clearly impossible). Now as the distribution of \( a \) (mod 1) is just \( x \), the claim follows.
3 The lower bound: proof of Theorem 5

In this section, we prove the lower bound on the surface area of a permutation-symmetric tiling body $D$. Throughout, we will have two parameters: $\sigma$, which is magnitude of each coordinates in the needle we consider (which will be of order $\frac{\sqrt{\log n}}{n}$), and an auxiliary parameter $Z$ (which will be of order $\frac{n}{\log n}$). Let $D$ be a permutation-symmetric tiling body containing 0. We denote by $a$ a random point in $D$, and by $u$ a Gaussian vector $\mathcal{N}(0, \sigma^2 I_n)$. We will prove that $\Pr_{a,u}[\ell_{a,u} \not\subseteq D] = \Omega(1)$, which by Lemma 11 implies that $\text{area}(\partial D) \geq \Omega(1/\sigma)$. As $\sigma = \Theta(\sqrt{\log n}/n)$, this would establish Theorem 5.

**Notations**

For $x, y \in \mathbb{R}$, define

$$d(x, y) := \min_{z \in \mathbb{Z}, z \neq 0} |(x + z) - y| \in [0, 1].$$

To gain some intuition for the definition of $d(x, y)$, suppose $x$ and $y$ are two entries of a point $a \in D$. Clearly, if $d(x, y)$ is small, then $x, y$ nearly differ by an integer $z \neq 0$, and this says that the point $a$ is somewhat close to the boundary of $D$ (in the sense that Lemma 12 could kick in if we move along a direction that decreases this distance).

Our argument will indeed inspect $d(a_i, a_j)$ for all distinct $i, j \in [n]$ and the way they change along a random direction. A key measure that we will keep track of is the energy of a point $a \in D$, defined by

$$\Psi(a) := \sum_{i<j} e^{-Z d(a_i, a_j)}.$$  

We show that for $a \in_R D$ and $u \sim \mathcal{N}(0, \sigma^2 I_n)$, if $\ell_{a,u} \not\subseteq D$ with probability close to 1, then the energy of $a$ increases along the line $\ell_{a,u}$ with high probability, and in particular that $\Psi(a + u) > \Psi(a)$. We then argue that with high probability, this should be the case for the point $a$ as well as for $a - u$, hence $\Psi(a + u) > \Psi(a - u)$ with high probability. This event however can happen with probability at most 0.5 by symmetry, hence completing the proof.

3.1 Analyzing the energy along a random line

By definition of $d(x, y)$, we either have $d(x, y) = (x + z - y)$ or $d(x, y) = -(x + z - y)$ for some $z \in \mathbb{Z} \setminus \{0\}$, and this sign determines whether $x, y$ need to move in different directions or the same direction for $d(x, y)$ to get smaller. To capture this, we denote

$$\gamma(x, y) := \begin{cases} 
+1 & \text{if } d(x, y) = x + z - y \text{ for some } z \in \mathbb{Z}, z \neq 0, \\
-1 & \text{otherwise}.
\end{cases}$$

Next, we discuss the energy of a configuration, which is the key concept used in the proof. Let $Z$ be a parameter to be chosen later (of the order $n/\log n$). As stated earlier, our goal is to analyze the behaviour of $\Psi(a)$ along a random $\sigma^2$-needle from $a$ in direction $u$. Towards this end, note that we expect (at least if $u_i, u_j$ are small) that $d(a_i + u_i, a_j + u_j) = d(a_i, a_j) + \gamma(a_i, a_j)(u_j - u_j)$, hence expect $\Psi(a + u)$ to be close to

$$\Psi(a, u) := \sum_{i<j} e^{-Z (d(a_i, a_j) + \gamma(a_i, a_j)(u_j - u_j))}.$$  

Indeed, this is the content of the following claim.
Claim 14. Suppose $|u_i| \leq 1/20$ for all $i$, and $a + [0,1] \cdot u \subset D$, then
\[
|\Psi(a+u) - \Psi(a,u)| \leq n^2 \cdot e^{-Z/4}.
\]

Proof. We consider the contribution of each pair $(i,j)$ to $\Psi(a+u)$ and $\Psi(a,u)$ separately. Without loss of generality we may only consider pairs $i,j$ that $\gamma(a_i, a_j) = 1$, and thus $d(a_i, a_j) = a_i - a_j + z$ for some $z \in \mathbb{Z}, z \neq 0$. Let
\[
d = a_i - a_j + z + (u_i - u_j) = (a_i + u_i) - (a_j + u_j) + z.
\]

First, we argue that $d \geq 0$. Otherwise, since $a_i - a_j + z \geq 0$ it follows by continuity that there is $\lambda \in [0,1]$ such that $a_i - a_j + z + \lambda(u_i - u_j) = 0$, and hence the point $a + \lambda u$ has entries that differ by an integer $z \neq 0$, and this contradicts Lemma 12 (as $a + \lambda u \in D$). We now consider two cases:

- **Case 1**: $d \in [0,0.5]$. In this case, we have $d(a_i+u_i, a_j+u_j) = d$, and thus the contribution of the pair $(i,j)$ to both sums is the same ($e^{-Zd}$).
- **Case 2**: $d > 0.5$. Since $|u_i - u_j| \leq 0.1$, it follows that $d(a_i, a_j) = d - (u_i - u_j) > 0.4$, which implies $d(a_i + u_i, a_j + u_j) > 0.3$. Therefore, the contribution to $\Psi(a,u)$ from $i,j$ is at most $e^{-0.4Z}$ and to $\Psi(a+u)$ is at most $e^{-0.3Z}$, and in particular $(i,j)$ contributes (in absolute value) at most $e^{-Z/4}$ to the difference between the sums.

Taking a sum over all pairs $(i,j)$ concludes the proof. \hfill \triangleleft

### 3.2 Analyzing the expectation and variance of $\Psi(a,u)$

Next, we consider $\Psi(a,u)$ as a random variable over the choice of $u$ and compute its expectation and variance. In both computations we will use the well-known fact that $\mathbb{E}[e^{-ZN(0,\sigma^2)}] = e^{2Z\sigma^2/2}$ for all $c > 0$.

Claim 15. For every $a \in \mathbb{R}^n$ we have $\mathbb{E}_{u \sim N(0,\sigma^2 I_n)}[\Psi(a,u)] = \Psi(a) \cdot e^{(Z/2)^2}$.

Proof. By linearity of expectation we have that
\[
\mathbb{E}_{u \sim N(0,\sigma^2 I_n)}[\Psi(a,u)] = \sum_{i<j} e^{-Zd(a_i,a_j)} \cdot \mathbb{E}_{u \sim N(0,\sigma^2 I_n)}[e^{-Z\gamma(a_i,a_j)(u_i-u_j)}].
\]

Note that the above expectation does not depend on $i,j$: for every $i,j$ the distribution of $u_i - u_j$ is $N(0,\sigma^2) - N(0,\sigma^2) \sim N(0,2\sigma^2)$, so it is symmetric around 0 and thus the sign $\gamma(a_i,a_j)$ does not affect the expectation. Hence we have
\[
\mathbb{E}_{u \sim N(0,\sigma^2 I_n)}[\Psi(a,u)] = \Psi(a) \cdot \mathbb{E}[e^{ZN(0,2\sigma^2)}] = \Psi(a) \cdot e^{2Z\sigma^2}.
\]

Next, we turn our attention into upper bounding the variance of $\Psi(a,u)$, and for that we first define the notion of good points $a \in D$ and prove two preliminary claims. We say a point $a$ is **good** if any interval of length $(10 \log n)/n$ on the torus contains at least $log n$ and at most $100 \log n$ coordinates from $a \mod 1$. Note by Lemma 13, if $a$ is chosen randomly from $D$ then $a \mod 1$ is uniform over $[0,1)^n$ and by Chernoff bound is easily shown to be good with probability $> 0.999$.

We first show that good points have high energy.

Claim 16. There exists $c_2 > 0$, such that for $Z = 0.1 \log n/n$, if $a$ is good then $\Psi(a) > c_2 \log^2 n$.

Proof. Partition the torus $[0,1)$ into $m = n/(10 \log n)$ disjoint intervals of length $1/m = (10 \log n)/n$ each. We say that $I_i$ is **unanimous**, if there is $b_i \in \mathbb{R}$ (called anchor) such that (1) $b_i \mod 1$ is the middle of $I_i$, and (2) for the majority of points $a_j \in I_i$, $|a_j - b_i| < 1/m$.

We consider two cases:
Case 1: There is an interval \(I_i\) that is not unanimous. Note that there are at least \(\log n\) coordinates \(j\) of \(a\) such that \(a_j \in I_i\). Let \(j^*\) be such coordinate, and write \(a_{j^*} = z_{j^*} + \{a_{j^*}\}\) where \(z_{j^*} \in \mathbb{Z}\) and \(\{a_{j^*}\}\) is the fractional part of \(a_{j^*}\). Consider \(b = z_{j^*} + m_i\) where \(m_i\) is the middle of \(I_i\). Then since \(I_i\) is not unanimous, \(b\) is not an anchor of it and so there are at least \(\frac{1}{2} \log n\) coordinates of \(a\), say \((a_k)_{k \in K_{i,j^*}}\) that mod 1 are in \(I_i\), and \(|a_k - b| \geq 1/m\). Writing \(a_k = z_k + \{a_k\}\), we observe that \(z_k \neq z_{j^*}\), since otherwise \(|a_k - b| = |\{a_k\} - m_i| \leq 1/(2m)|. Hence the difference \(a_k - a_{j^*}\) is \(10 \log n/m\) close to an integer \(z_k - z_{j^*} \neq 0\), and so \(d(a_k, a_{j^*}) \leq 10 \log n/m\), and the contribution of \(\Psi(a)\) is at least \(e^{-1}\). Summing we get

\[
\Psi(a) \geq \frac{1}{2} \sum_{(i,j^*) \in I_i, k \in K_{i,j^*}} e^{-Zd(a_k, a_{j^*})} \geq \frac{1}{2} \sum_{j, a_j \in I_i} e^{-1} |K_{i,j^*}| \geq \frac{1}{4e} \log^2 n.
\]

Case 2: All intervals are unanimous. Let \(b_i\) be an anchor of \(I_i\). Note that since the fractional part of two adjacent anchors, i.e. of \(b_i, b_{i+1}\), are 1/m apart, we have that either \(|b_i - b_{i+1}| \leq 1/m\) or \(|b_i - b_{i+1}| \geq 1 - 1/m\). We claim there exists \(i\) for which the latter condition holds. To see this, assume that for all \(i = 1, \ldots, m - 1\) we have that the first condition holds. Then we have \(b_i = z + i \cdot \frac{10 \log n}{n}\) for some \(z \in \mathbb{Z}\) for all \(i = 1, \ldots, m\), and hence \(|b_m - b_1| \geq 1 - 1/m\) (and the condition holds for \(i = m\)).

Thus, we fix \(i\) such that \(|b_i - b_{i+1}| \geq 1 - 1/m\), and thus \(b_i - b_{i+1} = z + \alpha\) for \(z \neq 0\) and \(|\alpha| \leq 1/m\). Let \(K_i\) be the coordinates \(j\) of \(a\) such that \(|a_j - b_j| \leq 1/m\) for \(j \in K_i\) and similarly define \(K_{i+1}\). We have that \(a_r - a_j = z + \alpha + (a_r - b_{i+1}) + (a_j - b_i)\), hence \(a_r - a_j = z + \beta\) for \(|\beta| \leq 3/m\) for all \(r \in K_{i+1}\), \(j \in K_i\). Thus \(d(a_r, a_j) \leq 3/m\), and we get

\[
\Psi(a) \geq |K_i| |K_{i+1}| e^{-Z \cdot 3/m} \geq \frac{1}{4} e^{-3} \log^2 n.
\]

Let \(C_i = \sum_{j \neq i} e^{-Zd(a_i, a_j)}\) be the contribution of \(a_i\) to \(\Psi(a)\). Note that \(\Psi(a) = \frac{1}{2} \sum_i C_i\).

\[\triangleright\text{Claim 17.}\] There exists \(c_3 > 0\), such that if \(a\) is good, then for all \(i\) we have \(C_i < c_3 \Psi(a)/\log n\).

Proof. Note that \(d(a_i, a_j) \geq |\{a_i\} - \{a_j\}|\). Since any interval of length \(10 \log n/m\) on the torus contains at most \(100 \log n\) points of \(a\), we have that the number of \(j\)'s such that \(|\{a_i\} - \{a_j\}|\) is between \(10 \log n/m \cdot k\) and \(10 \log n/m \cdot (k + 1)\) is at most \(200 \log n\) (for all \(k\)). Therefore,

\[
C_i < 200 \log n \cdot \sum_{k=0}^{\infty} e^{-Z \cdot k (10 \log n)/m} = 200 \log n \cdot \sum_{k=0}^{\infty} e^{-k} \leq 400 \log n.
\]

Using Claim 16, we may bound \(\log n \leq \frac{1}{c_2} \frac{\Psi(a)}{\log n}\), finishing the proof.

We are now ready to bound the variance of \(\Psi(a, u)\).

\[\triangleright\text{Claim 18.}\] There exists \(c_1 > 0\) such that the following holds. Let \(Z = n/10 \log n\), let \(a \in \mathbb{R}^n\) be good and let \(u \sim N(0, \sigma^2 I_n)\). Then

\[
\text{var}_u[\Psi(a, u)] \leq \frac{c_1}{\log n} \cdot (e^{4(Z \cdot \sigma^2)} - e^{2(Z \cdot \sigma^2)}) \cdot \Psi(a)^2.
\]
Proof. Using Claim 15 to compute the expectation of $\Psi(a, u)$, we have by definition that
\[
\var_u(\Psi(a, u)) = \mathbb{E}_u \left[ \left( \sum_{i < j} e^{-2Z \cdot d(a_i, a_j)} \cdot (e^{Z \cdot \gamma(a_i, a_j)} (u_i - u_j) - e^{Z \cdot \sigma}) \right)^2 \right] = \sum_{i < j} e^{-2Z \cdot d(a_i, a_j)} \mathbb{E}_u \left[ (e^{Z \cdot \gamma(a_i, a_j)} (u_i - u_j) - e^{Z \cdot \sigma})^2 \right] + \sum_{(i, j, k) \text{ distinct}} e^{-Z \cdot (d(a_i, a_j) + d(a_i, a_k))} \mathbb{E}_u \left[ (e^{Z \cdot \gamma(a_i, a_j)} (u_i - u_j) - e^{Z \cdot \sigma})(e^{Z \cdot \gamma(a_i, a_k)} (u_i - u_k) - e^{Z \cdot \sigma}) \right].
\]
Here, we used that fact that if $i, j, k, r$ are distinct then $e^{Z \cdot \gamma(a_i, a_j)} (u_i - u_j)$, $e^{Z \cdot \gamma(a_k, a_r)} (u_k - u_r)$ are independent with expectation $e^{Z \cdot \sigma}$, hence the contribution of these terms is 0. Computing, we see that
\[
\mathbb{E}_u \left[ (e^{Z \cdot \gamma(a_i, a_j)} (u_i - u_j) - e^{Z \cdot \sigma})^2 \right] = \mathbb{E}_u \left[ e^{Z \cdot N(0, \sigma^2)} \right] = e^{2Z \cdot \sigma^2} - e^{2Z \cdot \sigma^2},
\]
and
\[
\mathbb{E}_u \left[ (e^{Z \cdot \gamma(a_i, a_j)} (u_i - u_j) - e^{Z \cdot \sigma})(e^{Z \cdot \gamma(a_i, a_k)} (u_i - u_k) - e^{Z \cdot \sigma}) \right] = \mathbb{E}_u \left[ e^{(\gamma(a_i, a_j) + \gamma(a_i, a_k))Z \cdot N(0, \sigma^2)} \right] \mathbb{E}_u \left[ e^{Z \cdot N(0, \sigma^2)} \right] = e^{2Z \cdot \sigma^2} - e^{2Z \cdot \sigma^2} = e^{3Z \cdot \sigma^2} - e^{2Z \cdot \sigma^2}.
\]
Thus, we get that
\[
\var_u(\Psi(a, u)) \leq \sum_{i < j} e^{-2Z \cdot d(a_i, a_j)} \left( e^{4Z \cdot \sigma^2} - e^{2Z \cdot \sigma^2} \right) + \sum_{(i, j, k) \text{ distinct}} e^{-Z \cdot (d(a_i, a_j) + d(a_i, a_k))} \left( e^{3Z \cdot \sigma^2} - e^{2Z \cdot \sigma^2} \right) \leq \left( e^{4Z \cdot \sigma^2} - e^{2Z \cdot \sigma^2} \right) \sum_i \left( \sum_{j \neq i} e^{-2Z \cdot d(a_i, a_j)} + \sum_{j, k \neq i} e^{-Z \cdot (d(a_i, a_j) + d(a_i, a_k))} \right) = \left( e^{4Z \cdot \sigma^2} - e^{2Z \cdot \sigma^2} \right) \sum_i \left( \sum_{j \neq i} e^{-2Z \cdot d(a_i, a_j)} \right)^2 = \left( e^{4Z \cdot \sigma^2} - e^{2Z \cdot \sigma^2} \right) \cdot \sum_i C_i^2.
\]
Therefore, using Claim 17 we conclude that
\[
\var_u(\Psi(a, u)) \leq \left( e^{4Z \cdot \sigma^2} - e^{2Z \cdot \sigma^2} \right) C_3 \frac{\Psi(a)}{\log n} \sum_i C_i = \frac{2c_3}{\log n} \frac{\log n}{(e^{4Z \cdot \sigma^2} - e^{2Z \cdot \sigma^2}) \cdot \Psi(a)^2}.
\]
Setting $c_1 := 2c_3$ completes the proof.
Putting the last two claims together, we have:

\[ \Pr_u [\Psi(a, u) > \Psi(a) + \frac{(Z\sigma)^4}{2}] \geq 0.96. \]

Proof. We upper bound the probability of the complement event. Using Claim 15 (and \( e^t \geq 1 + t + t^2/2 \) for \( t \geq 0 \)), we get

\[ \mathbb{E}[\Psi(a, u)] \geq \Psi(a) \cdot \left( 1 + (Z\sigma)^2 + \frac{(Z\sigma)^4}{2} \right). \]

Hence

\[ \Pr_u \left[ \Psi(a, u) \leq \Psi(a) + \frac{(Z\sigma)^4}{2} \right] \leq \Pr_u \left[ \mathbb{E}[\Psi(a, u)] \right] \geq \Psi(a) \cdot (Z\sigma)^2. \]

We want to upper bound the probability of the last event using Chebyshev’s inequality. Since \( a \) is good, the conclusion of Claim 18 holds. Since \( Z\sigma = o(1) \), for large enough \( n \) we get

\[ \text{var}_u \Psi(a, u) \leq \frac{c_1}{\log n} \cdot (e^{4(Z\sigma)^2} - e^{2(Z\sigma)^2}) \cdot \Psi(a)^2 \leq \frac{c_1}{\log n} \cdot \Psi(a)^2 \cdot 8(Z\sigma)^2. \]

Therefore, applying Chebyshev’s inequality we see the probability in question is at most

\[ \frac{\text{var}_u \Psi(a, u)}{\Psi(a)^2 \cdot (Z\sigma)^4} \leq \frac{c_1 \cdot \Psi(a)^2 \cdot 8(Z\sigma)^2}{(\log n) \cdot (Z\sigma)^4} = \frac{8c_1}{4} \cdot \frac{4}{10^2c_1} = 0.04. \]

### 3.3 Finishing the argument

For each \( u \), denote \( \epsilon_u = \Pr_{a \in D} [I_{a, u} \notin D] \), \( \epsilon = \mathbb{E}_{u \sim N(0, \sigma^2)} [\epsilon_u] = \Pr_{a, u} [I_{a, u} \notin D] \).

\[ \Pr_{a \in D} [a \notin D] = \Pr_{a \in D} [a - u \notin D] \leq \Pr_{a \in D} [a - u \notin K] \leq \Pr_{a \in D} [a - u \notin K \cap D] = \Pr_{a \in D} [a - u \notin K \cap D] \leq \Pr_{a \in D} [a - u \notin K \cap D] \leq \epsilon_u + \epsilon_{-u}. \]

To prove (1), note that \( \Pr_{a \in D} [a \in K] = \mu(K) \) and

\[ \Pr_{a \in D} [a - u \in K] = \Pr_{a \in D} [a \in K + u] = \mu((K + u) \cap D). \]

This is at most \( \mu(K + u) = \mu(K) \) (hence the expression in (1) is non-negative) and at least \( \geq \mu(K + u) - \mu((K + u) \setminus D) = \mu(K) - \mu(K \setminus (D - u)) \). Therefore

\[ 0 \leq \Pr_{a \in D} [a \in K] - \Pr_{a \in D} [a - u \in K] \leq \mu(K \setminus (D - u)) \leq \mu(D \setminus (D - u)) = \Pr_{a \in D} [a + u \notin D] \leq \epsilon_u. \]

To prove (2), note that \( \Pr_{a \in D} [a \in K] = 0 \) (hence the expression in (2) is non-positive) and

\[ \Pr_{a \in D} [a - u \in K] \leq \Pr_{a \in D} [a - u \notin D] \leq \epsilon_{-u}. \]
5:14 On Symmetric Tilings of Euclidean Space

\(\triangleright\) Claim 21. \(\varepsilon \geq 0.1.\)

Proof. Let \(E_1\) be the event that \(a + u[0, 1] \subseteq D\), let \(E_2\) be the event that \(\Psi(a) \leq 1\), let \(E_3\) be the event that \(|u_i| > 1/20\) for some \(i\) and let \(E_4\) be the event that \(\Psi(a, u) > \Psi(a) + \frac{(Z_\varepsilon)^4}{2} \Psi(a)\). Finally, let \(E_5\) be the event that \(\Psi(a + u) > \Psi(a)\) and denote \(E(a, u) = E_1 \cap E_2 \cap \neg E_3 \cap E_4\). Note that if the event \(E\) holds for \(a, u\), then \(E_5\) also holds, since by Claim 14:

\[
\Psi(a + u) \geq \Psi(a, u) - n^2 \cdot e^{-Z/4} > \Psi(a) + \frac{(Z_\varepsilon)^4}{2} \Psi(a) - n^2 \cdot e^{-Z/4} \geq \Psi(a).
\]

By Claim 16 the probability of \(E_2\) is at most the probability of \(a\) is bad, hence it is at most 0.005. By definition, the probability of \(E_1\) is \(1 - \varepsilon\). By the union bound and Chernoff inequality, the probability of \(E_3\) is \(o(1)\). Thus, by Claim 19 we have

\[
\Pr_{a, u}[E(a, u)] \geq 0.96 - \varepsilon - 0.005 - o(1) \geq 0.95 - \varepsilon.
\]

Fix \(u\). Using Claim 20 we get that

\[
\Pr_{a}[E(a - u, u)] \geq \Pr_{a}[E(a, u)] - \mathcal{D}_{TV}[a; a - u] \geq \Pr_{a}[E(a, u)] - \varepsilon_u - \varepsilon_u.
\]

By the union bound, we now conclude that

\[
\Pr_{a}[E(a - u, u) \cap E(a, u)] \geq 1 - \Pr_{a}[E(a - u, u)] - \Pr_{a}[E(a, u)] \geq 2\Pr_{a}[E(a, u)] - 1 - \varepsilon_u - \varepsilon_u.
\]

Taking expectation over \(u\), we get that

\[
\Pr_{a, u}[E(a - u, u) \cap E(a, u)] \geq 2\Pr_{a, u}[E(a, u)] - 1 - 2\mathbb{E}[\varepsilon_u] \geq 0.9 - 4\varepsilon.
\]

Next, when both \(E(a - u, u)\) and \(E(a, u)\) hold, we have by the previous observation that \(E_5\) holds for both pairs \((a - u, u)\) and \((a, u)\), and so \(\Psi(a + u) > \Psi(a) \geq \Psi((a - u) + u) > \Psi(a - u)\). Thus, we get that \(\Pr_{a, u}[\Psi(a + u) > \Psi(a - u)] \geq 0.9 - 4\varepsilon\). On the other hand, the probability on the left hand side is at most 0.5; this follows as \(\Pr_{a, u}[\Psi(a + u) > \Psi(a - u)] = \Pr_{a, u}[\Psi(a - u) > \Psi(a + u)]\) (since the distributions of \(u\) and \(-u\) are identical) and their sum is at most 1. Combining the two inequalities we get that \(\varepsilon \geq 0.1\). \(\triangleright\)

4 The upper bound: proof of Theorem 6

In this section we prove a matching upper bound on the surface area of a permutation-symmetric foam by giving a (probabilistic) construction of a permutation-symmetric tiling body \(D\) of surface area \(O(n/\sqrt{\log n})\). The main technical result proved in this section, Lemma 23, establishes a weaker statement, and in Section B we show how to deduce Theorem 6 from it.

4.1 Reduction to constructing a rounding scheme

Suppose \(S\) is function mapping (multi-)sets of \(n\) points from \(\mathbb{R}/\mathbb{Z}\), to \(\mathbb{R}/\mathbb{Z}\). We further assume that for all (multi-)sets \(A\), it holds that \(S(A) \notin \{0\} \cup A\).

Given such \(S\), we may extend it to \(\mathbb{R}^n\) by \(S(x_1, \ldots, x_n) := S(\{\{x_1\}, \ldots, \{x_n\}\}),\) where \(\{x_i\}\) is the fractional part of \(x\). We can construct a rounding scheme \(R: \mathbb{R}^n \to \mathbb{Z}^n\) using \(S\) as follows.
On input $x = (x_1, \ldots, x_n)$, denote $z = S(x)$ and view $z$ as a number in $[0, 1)$.

For each $i \in [n]$: 
- if $\{x_i\} \in [0, z)$, set $R(x)_i = \lfloor x_i \rfloor$,
- otherwise, $\{x_i\} \in (z, 1)$, and set $R(x)_i = \lceil x_i \rceil$.

First, $R$ is well-defined since $z \notin \{0, \{x_1\}, \ldots, \{x_n\}\}$. Next, note that for any $t \in \mathbb{Z}^n$ it holds that $R(x + t) = R(x) + t$, thus $R$ induces that the body $D = \{x \mid R(x) = 0\}$ is tiling with respect to the lattice $\mathbb{Z}^n$. Last, we note that since for any $\pi \in S_n$ we have that $S(\pi(x)) = S(x)$, we also have that $R(\pi(x)) = \pi(R(x))$, and hence $D$ is permutation-symmetric.

In our proof we will define a distribution over mappings $S$, and we will want to study the noise sensitivity of the resulting body $D$ using properties of the mappings $S$. The following claim gives useful conditions to study noise sensitivity in terms of mapping $S$.

\begin{claim}
Let $x$ and $x + \Delta$ two points in $\mathbb{R}^n$. Suppose that
1. $S(x) = S(x + \Delta) = z$; and
2. for all $i$, $\{x_i + \Delta_i\} \neq z$, $\forall \lambda \in [0, 1]$.

Then the points $x, x + \Delta$ fall in the same cell in the tiling induced by $D$.
\end{claim}

\begin{proof}
Suppose towards contradiction that the conclusion of the statement does not hold, i.e. $x$ and $x + \Delta$ belong to different cells in the tiling induced by $D$. Thus, the rounding function $R$ when applied on $x$ and on $x + \Delta$ should produce different lattice points, so there is an $i$ such that $R(x)_i \neq R(x + \Delta)_i$. We fix that $i$ and assume without loss of generality that $\Delta_i \geq 0$ and that $x_i \in [0, 1)$. We now consider two cases, depending on the range $x_i$ falls into:

1. If $x_i \in [0, z)$, then by definition of $R$ we get that $R(x)_i = 0$, and $R(x + \Delta)_i = 0$ unless $x_i + \Delta_i > z$, which leads to a contradiction to the second condition ($z$ is on the interval between $x_i$ and $x_i + \Delta_i$).
2. If $x_i \in (z, 1)$, then $R(x)_i = 1$, and $R(x + \Delta)_i = 1$ unless $x_i + \Delta_i > 1 + z$, which again leads to a contradiction to the second condition ($1 + z$ is on the interval between $x_i$ and $x_i + \Delta_i$).
\end{proof}

Our main technical statement is the following lemma.

\begin{lemma}
There exists a distribution over mappings $(S_\ell)_\ell$ ($\ell$ is a vector of randomness) such that for small enough $\varepsilon > 0$, setting $\sigma = \varepsilon \sqrt{\frac{\log n}{n}}$ we have

$$
\mathbb{E}_{\ell} \left[ x, \Delta \sim \mathcal{N}(0, \sigma^2 I_n) \mid \text{Conditions of Claim 22 hold for } x \text{ and } x + \Delta \right] \geq 1 - O(\varepsilon).
$$

\end{lemma}

Deducing from Theorem 6 from Lemma 23 mostly involves measure-theoretic arguments, and we defer this deduction to Section B. We will actually need the following slightly more informative version of Lemma 23 above, using the reduction from mappings to tilings presented in the beginning of this section, and an inspection of the bodies $D_\ell$ our proof gives.

\begin{lemma}
There exists a distribution over tiling bodies $(D_\ell)_\ell$ such that

1. For small enough $\varepsilon > 0$, we have

$$
\mathbb{E}_{\ell} \left[ x, \Delta \sim \mathcal{N}(0, \varepsilon^2 I_n) \mid \text{At least one of the conditions of Claim 22 fail for } x \text{ and } x + \Delta \right] \leq \frac{n}{\sqrt{\log n}} \varepsilon.
$$

2. For each $\ell$, $D_\ell$ is a countable union of semi-algebraic sets (i.e., sets defined by finitely many polynomial inequalities).
\end{lemma}
4.2 The construction of $S_F$

4.2.1 Overview

Before jumping into the technical details, we start with some intuition. Recall that on input $x$ (a set of $n$ points from $\mathbb{R}/\mathbb{Z}$) we must output a number $z \in \mathbb{R}/\mathbb{Z}$, and our goal is to minimize the probability so that the conditions of Claim 22 fail on a short needle $\ell_{x,\Delta}$. Note that it would not be beneficial for us to choose $z$ that are close to $x_i$. For example, if we chose $z$ such that $|x_i - z| \leq \sigma$, then there is constant probability that the interval $\{x_i + \lambda \Delta_i\}_{\lambda \in [0,1]}$ would contain the point $z$, i.e. the second condition of Claim 22 would fail.

Thus, a natural candidate for the choice of $z$ would be the maximizer of $\min_{i \in [n]} |x_i - z|$. It is not hard to see that this minimum is typically of the order $\log n/n$, so intuitively the second condition of Claim 22 should hold with probability $\geq 1 - \varepsilon$. However, such choice for $z$ would not be very stable: it is typically the case that there are numerous $z_1, \ldots, z_r$ that nearly achieve this maximum, thus the maximizer among them could change when looking at $x + \Delta$ (i.e., this event would happen with probability significantly more than $\varepsilon$), leading to a failure of the first condition of Claim 22.

We must therefore assign each one of the near-maximizer $z_1, \ldots, z_r$ some weight, so that the weight of each one of them does not significantly change when moving to $x + \Delta$. A general form of construction of this type is to design a scoring function $f : [0, \infty] \rightarrow [0, 1]$, and given an input $x$ to assign the weight $w(z) = \prod_i f(|x_i - z|)$ to each $z$, and sample $z$ with probability proportional to $w(z)$.

We remark that this general recipe essentially captures our (natural) attempts so far. On the one hand, we want $f$ to penalize $z$ if it is very close to $x_i$, hence we want $f(t)$ at least mildly increasing. On the other hand, if $f$ is very sharply increasing (e.g. exponential), then one runs into the same problems as we had when we thought of picking $z$ that maximizes $\min_{i \in [n]} |x_i - z|$. We are thus led to consider “mildly increasing” scoring functions $f$, and polynomials turn out to be good choice. Indeed, our scoring function $f$ will be “trivial” if $|x_i - z|$ is too small or too large (i.e. it’ll be 0 if $|x_i - z| \leq \frac{\log n}{50n}$ and 1 if $|x_i - z| \geq \frac{\log n}{25n}$), and otherwise behaves cubically.

4.2.2 A basic scoring function

Our construction of $(S_F)_F$ uses a non-negative scoring function $f$ with the following properties.

- **Fact 25.** There exists a function $f : [0, \infty) \rightarrow [0, 1]$ that is twice differentiable with continuous second derivative with the following properties:
  1. $f(t) = 0$ if $t \leq 1$.
  2. $f(t) = 1$ if $t \geq 2$.
  3. $f(t) \approx (t-1)^3$ if $1 \leq t \leq 2$.
  4. $|f'(t)| \lesssim t^2$ and $|f''(t)| \lesssim t$ for all $t$.

Exhibiting function $f$ as in Fact 25 is not hard, and we omit the proof. The function $f$ defined by $f(t) = (t-1)^3$ if $1 \leq t \leq 2$ and $f(t) = 0$ for $t \leq 1$, $f(t) = 1$ for $t \geq 2$ is almost enough, except that it is not differentiable at $t = 1$. One can fix by convolving a smooth bump function with compact support.

Next, we wish to define the mapping $S_F$. We view the input $x$ as a multi-set, and the randomness vector $\ell_i$ as an infinite sequence of $(i, h)$ where $i$ is a uniformly random element from $[m]$ and $h$ is a uniform real-number from $[0, 1]$. 
Set $m = n^{1/3}$, partition the circle the circle $\mathbb{R}/\mathbb{Z}$ into $m$ intervals of length $1/m$ each, $I_j := [\frac{j-1}{m}, \frac{j}{m}]$, and let $z_j = \frac{j}{m}$ be the middle of $I_j$. It will be convenient for us to define $g_j(t) = f(\frac{50n}{\log n}|t - z_j|)$, and subsequently $r_j(x) := \prod_{y \in I_j \cap x} g_j(y)$. There two cases:

4.2.2.1 Case (A): $r_i(x) \neq 0$ for some $i \in [m]$

In this case, we define a probability distribution $p_i(x)$ over the $i$’s proportionally to the $r_i(x)$’s, i.e. we define $p_i(x) := \frac{r_i(x)}{\sum_{j \neq i} r_j(x)}$. We now perform correlated sampling of $i \in [m]$ according to $p_i(x)$ using the randomness vector $\vec{r}$. More precisely, we go over the randomness vector $\vec{r} = (i_1, h_1), (i_2, h_2), \ldots$ and find the smallest $j$ such that $h_j \leq p_j(x)$, in which case we choose $i = i_j$. We then define $S_{\vec{r}}(x) = z_j$.

4.2.2.2 Case (B): $r_i(x) = 0$ for all $i \in [m]$

If $1/2 \not\in x$, we define $S_{\vec{r}}(x) = 1/2$. Otherwise, we define $S_{\vec{r}}(x) = z$, where $z$ is the first element from $\{\frac{1}{3n^2}, \frac{1}{3n}, \ldots, \frac{4n-1}{4n}\}$ that is at least $\frac{1}{4n}$-away from all the entries of $x$.

4.3 Estimating $g_j$ on close points

\textbf{Fact 26.} Let $j \in [m]$ and $x_i \in [z_j - \log n \frac{-e^{0.95}}{250}, z_j + \frac{\log n + e^{0.95}}{250}], \Delta_i \in \mathbb{R}$, and denote $\alpha_i = \text{dist}(x_i, [z_j - \log n \frac{-e^{0.95}}{250}, z_j + \frac{\log n + e^{0.95}}{250}])$.

1. If $\alpha_i \geq 2|\Delta_i|$, then $|g_j(x_i + \Delta_i) - g_j(x_i)| \leq |\Delta_i| \frac{|g_j(y_i)|}{\alpha_i} g_j(x_i)$.

2. In general, $|g_j(x_i + \Delta_i) - g_j(x_i)| \leq n^3(\alpha_i^3 + |\Delta_i|^3)$.

\textbf{Proof.} Using Taylor’s approximation with remainder, there is $y_i \in [x_i, x_i + \Delta_i]$ such that $g_j(x_i + \Delta_i) = g_j(x_i) + g_j'(y_i)\Delta_i$, hence

$$|g_j(x_i + \Delta_i) - g_j(x_i)| \leq |\Delta_i| |g_j'(y_i)| \leq |\Delta_i| \frac{50n}{\log n} \left(\frac{50n}{\log n} |y_i - z_j|\right)$$

$$\leq \frac{n}{\log n} |\Delta_i| \left(\frac{50n}{\log n} |y_i - z_j| - 1\right)^2.$$ 

For the second item, since $y_i \in [x_i, x_i + \Delta_i]$, we get that $\left|\frac{50n}{\log n} |y_i - z_j| - 1\right| \leq \frac{50n}{\log n} (\alpha_i + |\Delta_i|)$, and plugging in yields

$$|g_j(x_i + \Delta_i) - g_j(x_i)| \leq n^3|\Delta_i| (\alpha_i^2 + \Delta_i^2) \leq n^3(\alpha_i^3 + |\Delta_i|^3),$$

where the last inequality holds as $ab \leq a^3 + b^3/2$ for all $a, b > 0$ (Young’s inequality). For the first item, note that since $y_i \in [x_i, x_i + \Delta_i]$ we get that $\left(\frac{50n}{\log n} |y_i - z_j| - 1\right) \geq \frac{50n}{\log n} (\alpha_i - |\Delta_i|)$, and by the lower bound on $\alpha_i$ this is $\geq \frac{25n}{\log n} \alpha_i$. Therefore we may continue as

$$|g_j(x_i + \Delta_i) - g_j(x_i)| \leq \frac{n}{\log n} |\Delta_i| \left(\frac{50n}{\log n} |y_i - z_j| - 1\right)^2 \leq \frac{|\Delta_i|}{\alpha_i} \left(\frac{50n}{\log n} |y_i - z_j| - 1\right)^3.$$ 

Also, we have that $\left(\frac{50n}{\log n} |y_i - z_j| - 1\right) \leq \frac{50n}{\log n} (\alpha_i + |\Delta_i|) \leq \frac{n}{\log n} \alpha_i$, so

$$|g_j(x_i + \Delta_i) - g_j(x_i)| \leq \frac{|\Delta_i|}{\alpha_i} \left(\frac{n}{\log n} \alpha_i\right)^3 \leq \frac{|\Delta_i|}{\alpha_i} g_j(x_i).$$

\vspace{1cm}

\textbf{CCC 2021}
4.4 Analysis of the construction

In this section we prove that Lemma 23 holds for the construction of $S_P$ from the last section, and for that we show that for small enough $\varepsilon$, the expected probability of the complement event is $O(\varepsilon)$, i.e. that

$$\mathbb{E}_{\mathbf{r}} \left[ \Pr_{\mathbf{x} \sim N(0, \sigma^2 I_n)} \left( \text{One of the conditions in Claim 22 fails for } \mathbf{x} \text{ and } \mathbf{x} + \Delta \right) \right] \lesssim \varepsilon. \quad (2)$$

We will think of $\varepsilon$ as very small (say $\varepsilon \leq 2^{-n^2}$), and analyze the contribution of $x$'s from case (A) and case (B) separately. Case (A) is the main case that occurs often, and case (B) should be thought of rare.

4.4.1 Analysis of case (B)

First, we show that the probability $x$ (or equivalently $x + \Delta$) falls into Case (B) is at most $n^{-\omega(1)}$. For this, it will be helpful for us to sample $x$, a multi-set of $n$ uniformly chosen numbers in $[0, 1]$ in the following equivalent way:

1. Sample $t_1, \ldots, t_m$ where $t_i$ is the number of $i$'s such that $x_i$'s fall into interval $I_i$.
2. Sample $t_i$ points uniformly from $I_i$, for each $i = 1, \ldots, m$.

Note that $\mathbb{E}[t_i] = n/m$, hence by Chernoff bound $\Pr[t_i \geq 2 \cdot n/m] = e^{-\Omega(n/m)} = n^{-\omega(1)}$.

Thus, by the union bound we have that

$$\Pr[\forall i \ t_i \leq 2 \cdot n/m] = 1 - n \cdot n^{-\omega(1)} = 1 - n^{-\omega(1)}.$$  

Next, we condition on $t_i = t$, and assume that indeed $t_i < 2 \cdot n/m$ for all $i$. Let $E_i$ be the event that $r_i(x) = 0$. Note that conditioned on $t_i = t$, the $E_i$'s are independent and that

$$\Pr[\neg E_i | t_1, \ldots, t_m] = \Pr_{a \in I_i} \left[ \frac{50m}{\log n} |a - z_i| \leq 1 \right]^{t_i} = \left( 1 - \frac{m \log n}{25m} \right)^{2n/m} \geq e^{-4 \log n/25} = n^{-4/25},$$

where we used the fact that $e^{-\delta} \leq 1 - \delta/2$ for small enough $\delta > 0$. Therefore,

$$\Pr[E_1 \wedge E_2 \wedge \ldots \wedge E_m | t_1, \ldots, t_m] \leq (1 - n^{-4/25})^m = (1 - n^{-4/25})^{n^{1/3}} = n^{-\omega(1)},$$

as long as the $t_i$'s satisfy the condition $t_i < 2 \cdot n/m$. Therefore, the overall probability of case (B) is $n^{-\omega(1)}$.

Next, we analyze the probability that the conditions of Claim 22 fail given we are in case (B). Note that if the conditions of Claim 22 fail to hold, then either (I) exactly one of $x$, $x + \Delta$ falls under Case (B), or (II) both $x$ and $x + \Delta$ fall under Case (B), but $1/2 \in x + \lambda \Delta$ for some $\lambda \in [0, 1]$. We'll bound these cases separately.

4.4.1.1 Case (I)

Assuming $x$ is under Case (B), we know that each of the $m$ intervals of the form $J_i := [z_i - \frac{\log n}{25m}, z_i + \frac{\log n}{25m}]$ contains at least one point from $x$. Let $x_i$ be that point (if there are multiple, pick one at random). Then $x_i$ is uniformly distributed in $J_i$. Therefore, the
probability of $x_i + \Delta_i$ is outside $J_i$, where $\Delta_i \sim N(0, \sigma^2)$ and $\sigma^2 \leq \varepsilon^2$, is $O(\varepsilon)$. Given case (B) occurs with probability $\leq n^{-\omega(1)}$, we conclude that its contribution to the conditions of Claim 22 failing is at most

$$O(m\varepsilon) \cdot n^{-\omega(1)} = O(\varepsilon).$$

4.4.1.2 Case (II)

Fix $\Delta = \Delta$, and consider $x_j$ conditioned on being in case (B). If $x_j$ is in one of the intervals $J_i$, then its distribution is uniform over $J_i$, in which case we get that the probability $1/2$ falls inside the interval $[x_j, x_j + \Delta_j]$ is at most $m |\Delta_j|$. If $x_j$ is not in one of the intervals $J_i$, then it is distributed uniformly on $[0, 1] \cup \bigcup_{i=1}^{m} J_i$, and the probability $1/2$ is in $[x_j, x_j + \Delta_j]$ is at most $2 |\Delta_j| \leq m |\Delta_j|$. Therefore by the union bound,

$$Pr_{x,\Delta} \left[ \exists j \in [n] \ 1/2 \in [x_j, x_j + \Delta_j] \mid \text{case (B)}, \Delta \right] \leq m \sum_{j=1}^{n} |\Delta_i|.
$$

Taking expectation over $\Delta \sim N(0, \sigma^2 I_n)$ and using Cauchy-Schwarz we get that

$$Pr_{x,\Delta} \left[ \exists j \in [n] \ 1/2 \in [x_j, x_j + \Delta_j] \mid \text{case (B)} \right] \leq m \sigma \sqrt{\frac{\sum_{j=1}^{n} |\Delta_i|^2}{n}} = mn \sigma.
$$

Therefore, the contribution of this case is upper bounded as

$$Pr_{x,\Delta} \left[ \text{case (B)} \land \exists j \in [n] \ 1/2 \in [x_j, x_j + \Delta_j] \right] \leq Pr_{x,\Delta} \left[ \text{case (B)} \right]mn \sigma = n^{-\omega(1)}, \sigma = O(\varepsilon).$$

4.4.2 Analysis of case (A)

We now analyze the contribution of $x$’s that fall into case (A) to the left hand side of (2).

4.4.2.1 Case (A), Condition 2

If $x$ falls under Case (A), then the distance from all $x_i$’s to $z = S(x)$ is at least $\log n / 100m$. Therefore, Condition 2 holds as long as $|\Delta_i| < \frac{\log n}{100m}$ for all $i$. Since for each $i$ we have that

$$Pr_{\Delta \sim N(0, \sigma^2 I_n)} \left[ |\Delta_i| \geq \frac{\log n}{100m} \right] = Pr_{\Delta \sim N(0, \sigma^2 I_n)} \left[ \Delta_i^2 \geq \frac{\log^2 n}{100^2 m^2} \right] \lesssim \frac{\sigma^2}{\log^2 n/m^2} \lesssim \frac{\varepsilon^2}{\log n},
$$

we get by the union bound that

$$Pr_{\Delta \sim N(0, \sigma^2 I_n)} \left[ \exists i \mid |\Delta_i| \geq \frac{\log n}{100m} \right] \lesssim n\varepsilon^2 / \log n \lesssim \varepsilon,$
$$

for a sufficiently small $\varepsilon$. 
4.5 Case (A), Condition 1

This is the main part of the proof. We show that in case (A), the probability that \( S_r(x) \neq S_r(x + \Delta) \) is at most \( O(\varepsilon) \). Note that the procedure describing \( S_r \) in this case is the correlated sampling procedure of Holenstein [18], where \( S_r(x) \) samples \( i \) according to the distribution \( p(x) = (p_1(x), \ldots, p_m(x)) \) and \( S_r(x + \Delta) \) samples \( i \) according to the distribution \( p(x + \Delta) \). Therefore, the probability they sample different \( i \)'s is at most the statistical distance between the distributions, \( \| p(x) - p(x + \Delta) \|_1 \). Therefore, we must show that

\[
\mathbb{E}_{x, x + \Delta} \| p(x) - p(x + \Delta) \|_1 | \text{case(A)} \rangle = O(\varepsilon). \tag{4}
\]

Before we turn to this task, we upper bound the contribution from several rare cases.

4.5.1 Contribution from some rare cases

First, we show that the case some \( \Delta_i \) is too large contributes at most \( O(\varepsilon) \) to the LHS of (4).

\[ \text{Claim 27. } \Pr_{\Delta \sim N(0, \sigma^2 I_n)} \left[ \| \Delta_i \| \geq \varepsilon^{0.95}/n \text{ for some } i \right] \leq \varepsilon. \]

**Proof.** For each \( i \), we have that

\[
\Pr_{\Delta \sim N(0, \sigma^2 I_n)} \left[ \| \Delta_i \| \geq \varepsilon^{0.95}/n \right] \leq 2^{-\Omega((\varepsilon^{0.95}/n)^2/\sigma^2)} = 2^{-\Omega\left( \frac{1}{\sqrt{n \log n}} \right)} \leq \frac{\varepsilon}{n},
\]

for small enough \( \varepsilon \), and the claim follows from the union bound. \(<\)

From now on, we assume that the \( \Delta_i \)'s are distributed from \( N(0, \sigma^2) | \| \Delta_i \| < \varepsilon^{0.95}/n \). In particular, we can assume that if \( t_j \) is the number of \( x \)'s that fall into interval \( I_j \), these numbers stay the same under \( x + \Delta \). Next, we handle the case in which \( p(x) \) is supported only on a single \( j \). Note that in this case, if \( p(x + \Delta) \) is also supported on this single \( j \), then the contribution of these cases to the LHS of (4) is 0. We show that the contribution from the other case is \( O(\varepsilon) \).

\[ \text{Claim 28. } \Pr_{x, \Delta} \left[ \exists j^* \text{ such that } p(x) \text{ is only supported on } j^*, \text{ the support of } p(x + \Delta) \text{ is different} \right] \leq \varepsilon. \]

**Proof.** In case (B), we have shown that the probability that \( r_j(x) = 0 \) for all \( j \) is \( n^{-\omega(1)} \), and the same argument shows that the probability \( r_j(x) = 0 \) for all but a single \( j^* \) is still \( n^{-\omega(1)} \). Denote this event by \( E \).

Let us condition on the event \( E \), on \( j^* \) and the number \( t_1, \ldots, t_m \) of \( x_i \)'s that fall into \( I_1, \ldots, I_m \). Note that for each \( j \neq j^* \), since \( r_j(x) = 0 \) there is \( i \) such that \( x_i \in J_j \). Indeed, suppose \( x_i \) is in \( I_j \) but \( x_i + \Delta_i \) is in \( I_{j+1} \). Then \( |x_i + \Delta_i - z_{j+1}| \geq |z_{j+1} - j/m| \geq |\Delta_i| \geq |x_i - j/m| \geq 1/m - 2\varepsilon^{0.95}/n \geq 1/m - \varepsilon^{0.95} \). Therefore, \( 2m^{1/2} \geq |x_i + \Delta_i - z_{j+1}| > 2 \), and so \( f(x) \nabla |x_i + \Delta_i - z_{j+1}| = 1 \).

\(^2\) Strictly speaking, \( x_i + \Delta_i \) may be in a different interval than \( x_i \), but in this case it doesn’t affects the distribution \( p(x) \). Indeed, suppose \( x_i \) is in \( I_j \) but \( x_i + \Delta_i \) is in \( I_{j+1} \). Then \( |x_i + \Delta_i - z_{j+1}| \geq |z_{j+1} - j/m| \geq |\Delta_i - x_i - j/m| \geq 1/m - 2\varepsilon^{0.95}/n \geq 1/m - \varepsilon^{0.95} \). Therefore, \( 2m^{1/2} \geq |x_i + \Delta_i - z_{j+1}| > 2 \), and so \( f(x) \nabla |x_i + \Delta_i - z_{j+1}| = 1 \).
Now note that for each $j \neq j^*$ it holds that $x_{ij} + \Delta_{ij} \in J_j$, then $r_j(x + \Delta) = 0$, so the only contribution to the probability of the event in question comes when $x_{ij} + \Delta_{ij} \notin J_j$ (or from case (B), which we have already accounted for earlier). Conditioned on $\Delta = \Delta$, the probability for that is at most

$$E_{(x_{ij})_{j \neq j^*}} \left[ \sum_{j \neq j^*} 1_{x_{ij} + \Delta_{ij} \notin J_j} \right] = \sum_{j \neq j^*} E_{x_j} \left[ 1_{x_{ij} + \Delta_{ij} \notin J_j} \right] \leq \sum_{j \neq j^*} \frac{|\Delta_j|}{\log n/(50n)},$$

therefore taking expectation over $\Delta$ and using Cauchy-Schwarz we get that

$$\Delta(\sum_{j \neq j^*} 1_{x_{ij} + \Delta_{ij} \notin J_j}) \leq \frac{n}{\log n} \sqrt{m} \sqrt{\sum_{j \neq j^*} \mathbb{E} |\Delta_j|^2} \leq \frac{n}{\log n} \sqrt{m} \sqrt{m\sigma^2} \leq n^2\sigma.$$

Therefore, we get that

$$\Pr_{x, \Delta} \left[ \sum_j r_j(x) \leq \varepsilon^{1.6} \bigg| E \right] \leq \varepsilon.$$

Let $E$ be the event that the support of $p(x)$ consists of at least two distinct $j$'s. We condition on the event $E$ in the subsequent argument. The following claim shows that conditioned on $E$, the sum of the $r_j(x)$'s is at least somewhat bounded away from 0. It will only come into play later in the proof.

> Claim 29.  \[ \Pr_x \left[ \sum_j r_j(x) \leq \varepsilon^{1.6} \bigg| E \right] \leq \varepsilon. \]

**Proof.** Since we conditioned on $E$, there are $j_1 \neq j_2$'s such that $r_{j_1}(x), r_{j_2}(x) > 0$. We condition on $j_1$ and $j_2$, and assume without loss of generality that $j_1 = 1, j_2 = 2$. We show that

$$\Pr_x \left[ r_1(x) \leq \varepsilon^{1.6} \land r_2(x) \leq \varepsilon^{1.6} \bigg| r_1(x), r_2(x) > 0 \right] \leq \varepsilon,$$

and thus the result would follow.

Let $t_1$ be the number of $i$'s such that $x_i \in I_1$, and $t_2$ be the number of $i$'s such that $x_i \in I_2$. Note that $t_1, t_2 \leq n$. In addition, conditioned on $t_1 = t_1$ and $t_2 = t_2$, the events $r_1(x) < \varepsilon^{1.6}$ and $r_2(x) < \varepsilon^{1.6}$ become independent. Therefore, to prove (5), it suffices to show for all $t_1 \leq n, t_2 \leq n$,

$$\Pr_x \left[ r_1(x) < \varepsilon^{1.6} \bigg| r_1(x) > 0, \ t_1 = t_1, \ t_2 = t_2 \right] \leq \varepsilon^{0.5}. \tag{6}$$

Note that one way to sample $r_1(x)|r_1(x) > 0, \ t_1 = t_1$ is as follows.

- Sample points $x_1, \ldots, x_{t_1}$ uniformly from $I_1$ conditioned on $|x_i - z_i| > \frac{\log n}{50n}$;
- $r_1(x) = \prod_{i=1}^{t_1} g_1(x_i)$.

Let $Y_i$ be the random variable $Y_i := g_1(x_i)^{-0.32}$, where $x_i$ is sampled as above (we need $0.32 < 1/3$). Let $E$ be the event that $|x_i - z_i| \geq \frac{\log n}{25n}$. If $E$ holds, then we get that $g_1(x_i) = 1$, and otherwise $g_1(x_i) \geq \frac{50n}{\log n} |x_i - z_i| - 1 \geq 1 - 10^{-0.96}$, so

$$\Pr[E] \leq \Pr[E] \cdot 1 + \Pr[\bar{E}] \Pr[g_1(x_i)^{-0.32} \bigg| \bar{E}] \leq 1 + \Pr \left[ \frac{50n}{\log n} |x_i - z_i| - 1 \geq 1 \bigg| \bar{E} \right] .$$

$$\Pr[Y_i] \leq \Pr[E] \cdot 1 + \Pr[\bar{E}] \Pr[g_1(x_i)^{-0.32} \bigg| \bar{E}] \leq 1 + \Pr \left[ \frac{50n}{\log n} |x_i - z_i| - 1 \geq 1 \bigg| \bar{E} \right] .$$

$$\Pr[Y_i] \leq \Pr[E] \cdot 1 + \Pr[\bar{E}] \Pr[g_1(x_i)^{-0.32} \bigg| \bar{E}] \leq 1 + \Pr \left[ \frac{50n}{\log n} |x_i - z_i| - 1 \geq 1 \bigg| \bar{E} \right] .$$
We write the last expectation as an integral, noting that \(|x_i - z_1|\) is distributed uniformly on \(\left[ \frac{\log n}{50n}, \frac{\log n}{25n} \right]\), hence

\[
\mathbb{E} \left[ \left| \frac{50n}{\log n} |x_i - z_1| - 1 \right|^{-0.96} \right] \leq \frac{n}{\log n} \int_{\frac{\log n}{50n}}^{\frac{\log n}{25n}} \left| \frac{50n}{\log n} t - 1 \right|^{-0.96} dt = \frac{1}{50} \int_0^1 y^{-0.96} dy \lesssim 1,
\]

where we made the change of variables \(y = \frac{50n}{\log n} t - 1\). Thus, \(\mathbb{E}[Y_i] \leq 1\), and so there is a constant \(B\) such that \(\mathbb{E}[Y_i] \leq B\). Therefore by independence \(\mathbb{E} \left[ \prod_{i=1}^n Y_i \right] \leq B^n \leq B^n\), and so writing \(r_1(x)\) in terms of the \(Y_i\)'s and using Markov’s inequality we get that

\[
\Pr_x \left[ r_1(x) < \varepsilon^{1.6} \mid r_1(x) > 0, t_1 = t_2 = t_2 = t_2 \right] = \Pr_\epsilon \left[ \prod_{i=1}^{t_1} Y_i > \varepsilon^{-1.6 \times 0.32} \right]
\]
\[
\leq B^n e^{-0.512 \varepsilon \log n} \lesssim \varepsilon^{-0.5}.
\]

### 4.5.2 Analyzing the typical case

To expand out \(\|p(x) - p(x + \Delta)\|_1\), we will be using the following claim. The set-up one should have in mind is that \(r_j = r_j(x)\) and \(d_j = r_j(x + \Delta)\) for some \(x\) and \(\Delta\) that are typical enough.

\(\triangleright\) Claim 30. Let \(r_j \geq 0\), \(d_j\) be real-numbers satisfying \(|d_j| \leq r_j/2\) for all \(j\). Denote \(T = \sum r_j\), \(T' = \sum (r_j + d_j)\), and let \(p_j = r_j/T\) and \(q_j = (r_j + d_j)/T\) be two distributions. Then

\[
\|p - q\|_1 \lesssim \sum_j \frac{|d_j|}{r_j} \cdot \min\left(r_j, \frac{T - r_j}{T}\right).
\]

(7)

We defer the proof of Claim 30 to Section A. Morally speaking, it says that

\[
\mathbb{E}_{x, \Delta} \left[ \|p(x) - p(x + \Delta)\|_1 \right] \lesssim \sum_{j=1}^m \mathbb{E}_{x, \Delta} \left[ \mathbb{E}_{x, \Delta} \left[ \frac{|r_j(x) - r_j(x + \Delta)|}{r_j(x)} \cdot \min\left(r_j(x), \frac{T(x) - r_j(x)}{T(x)}\right) \right] \right],
\]

(8)

where \(T(x) = \sum r_j(x)\) (this is only morally because we are assuming that the supports of \(p_j(x)\) and \(p_j(x + \Delta)\) are the same, but formally speaking they may be different). In particular, to be able to work with that we first must understand the expectation of \(|r_j(x) - r_j(x + \Delta)|\) over \(\Delta\).

\(\triangleright\) Claim 31. Let \(j \in [m], x_1, \ldots, x_k \in [z_j - \frac{\log n}{25n}, z_j + \frac{\log n}{25n} + \varepsilon^{0.95}] \setminus [z_j - \frac{\log n}{50n}, z_j + \frac{\log n}{50n}]\), and let \(r(x) = \prod_{i=1}^k g_j(x_i)\). Denote \(\alpha_i = \text{dist} \left( x_i, [z_j - \frac{\log n}{50n}, z_j + \frac{\log n}{50n}] \right)\), and let \(\Delta_i \sim N(0, \sigma^2)\) for \(\Delta_i \leq \varepsilon^{0.95}\). Then

\[
\mathbb{E}_{\Delta} \left[ |r(x + \Delta) - r(x)| \right] \lesssim \max \left( \varepsilon^{2.65}, |r(x)\cdot \sigma \cdot \sum_{i=1}^k \frac{1}{\alpha_i^2} \right).
\]

(9)
Proof. We consider two cases.

4.5.2.1 Case 1: $\alpha_i \leq \varepsilon^{0.9}$ for some $i$

In this case, we have

$$g_j(x_i) \lesssim \left( \frac{50n}{\log n \alpha_i} \right)^3 \lesssim n^3 \varepsilon^{3.09} \lesssim \varepsilon^{2.66}.$$ 

Similarly, we have $\text{dist}(x_i + \Delta_i, [z_j - \log n \frac{\log n}{50}, z_j + \log n \frac{\log n}{50}]) \leq \alpha_i + |\Delta_i| \leq 2 \alpha_i$, so $g_j(x_i + \Delta_i) \lesssim \varepsilon^{2.66}$.

We conclude that $r(x_i), r(x_i + \Delta_i) \lesssim \varepsilon^{2.66}$, hence the contribution from these cases is at most $\varepsilon^{2.65}$.

4.5.2.2 Case 2: $\alpha_i > \varepsilon^{0.9}$ for all $i$

In this case, we get that $x_i + \Delta_i$ is also not in the interval $[z_j - \log n \frac{\log n}{50}, z_j + \log n \frac{\log n}{50}]$, hence $g_j(x_i + \Delta_i) \neq 0$, so $r(x + \Delta) > 0$. Since $r(x)$ is defined using products, it would be more convenient for us to analyze $\log(r(x + \Delta)/r(x))$ as opposed to $r(x + \Delta)/r(x) - 1$, and to justify we can do that we first argue that $r(x + \Delta)/r(x) = 1 + o(1)$.

To see that, note that $|\Delta_i| \lesssim \varepsilon^{0.95} \leq \alpha_i/2$, we may use Fact 26 to conclude that

$$|g(x_i + \Delta_i) - g(x_i)| \lesssim \frac{|\Delta_i|}{\alpha_i} |g(x_i)| \lesssim \varepsilon^{0.05} |g(x_i)|.$$

In particular, we get that $\frac{g_j(x_i + \Delta_i)}{g_j(x_i)} = 1 + \mathcal{O}(\varepsilon^{0.05})$, and hence $\frac{r(x + \Delta)}{r(x)} = 1 + \mathcal{O}(k\varepsilon^{0.05})$. Writing $\frac{r(x + \Delta)}{r(x)} = 1 + \eta$, we get $\eta$ is small in absolute value, and hence $|\log(r(x + \Delta)/r(x))| \gtrsim |\eta| \gtrsim 1 + \varepsilon^{0.05}$.

Using second order Taylor’s approximation, we have that there is $\epsilon \in (x_i + \Delta_i)$ such that

$$g_j(x_i + \Delta_i) = g_j(x_i) + g_j'(x_i)\Delta_i + \frac{1}{2} g_j''(\epsilon)\Delta_i^2,$$

hence

$$\left| \frac{1}{g_j(x_i)} \mathbb{E}_\Delta \left[ g_j'(x_i)\Delta_i + \frac{1}{2} g_j''(\epsilon)\Delta_i^2 \right] \right| = \frac{1}{2g_j(x_i)} \mathbb{E}_\Delta \left[ g_j''(\epsilon)\Delta_i^2 \right].$$

Using properties of $f$, we have

$$|g_j''(\epsilon)| \leq \left( \frac{50n}{\log n} \right)^2 j'' \left( \frac{50n}{\log n} |y_i - z_j| \right) \lesssim \left( \frac{50n}{\log n} \right)^2 \left| \frac{50n}{\log n} |y_i - z_j| - 1 \right|.$$
Since \( y_i \in [x_i, x_i + \Delta_i] \), we get that \( \left( \frac{50n}{\log n} |y_i - z_j| - 1 \right) \geq \frac{50n}{\log n} \alpha_i - \varepsilon 0.95 \geq \frac{25n}{\log n} \alpha_i \), and so we may continue the previous inequality as

\[
|g''(y_i)| \lesssim \left( \frac{50n}{\log n} \right)^2 \frac{50n}{\log n} |y_i - z_j| - 1 \right)^3 \lesssim \frac{1}{\alpha_i^2} |g_j(y_i)| \approx \frac{1}{\alpha_i^2} |g_j(x_i)|,
\]

where the last inequality is by Fact 26. Plugging this into (11) we get that

\[
\left| \mathbb{E} [Z_i] \right| \lesssim \frac{1}{\alpha_i^2} \mathbb{E} \left[ \Delta_i^2 \right] = \frac{1}{\alpha_i^2} \sigma^2.
\]

In a similar fashion, we upper bound the second moment of \( Z_i \). Using Fact 26, we get that \( |Z_i| \leq \frac{\Delta_i}{\alpha_i} \), and so \( \mathbb{E}_\Delta \left[ Z_i^2 \right] \lesssim \frac{1}{\alpha_i^2} \mathbb{E}_\Delta \left[ \Delta_i^2 \right] = \frac{1}{\alpha_i^2} \sigma^2 \).

We can now upper bound the average of \( Y_i \) as follows. Recall that, \( |Z_i| = o(1) \) so by Taylor’s approximation \( Y_i = \log(1 + Z_i) = Z_i - \frac{1}{2(1 + \xi_i)} Z_i^2 \) for some \( \xi_i \in [1, 1 + Z_i] \) and hence

\[
\left| \mathbb{E}[Y_i] \right| \lesssim \left| \mathbb{E}[Z_i] \right| + \left| \mathbb{E}[Z_i^2]\right| \lesssim \frac{1}{\alpha_i^2} \sigma^2.
\]

This approximation (along with the fact that \( |Z_i| = o(1) \)) also implies \( |Y_i| \approx |Z_i| \), hence

\[
\mathbb{E}[Y_i^2] \lesssim \mathbb{E}[Z_i^2] \lesssim \frac{1}{\alpha_i^2} \sigma^2.
\]

We can now continue equation (10) to upper bound the LHS there. Denoting \( \mu_i := \mathbb{E}[Y_i] \), we have

\[
\mathbb{E}_\Delta \left[ \sum_{i=1}^k Y_i \right] \leq \sum_{i=1}^k |\mu_i| + \mathbb{E}_\Delta \left[ \sum_{i=1}^k Y_i - \mu_i \right] \leq \sum_{i=1}^k |\mu_i| + \sqrt{\mathbb{E}_\Delta \left[ \sum_{i=1}^k (Y_i - \mu_i)^2 \right]},
\]

where in the last inequality we used Cauchy-Schwarz and the fact that \( Y_i \)’s are independent. Using (12) we have that \( \sum_{i=1}^k |\mu_i| \lesssim \sigma^2 \sum_{i=1}^k \frac{1}{\alpha_i} \), and to upper bound the second term we use (13):

\[
\mathbb{E}_\Delta \left[ (Y_i - \mu_i)^2 \right] \leq \mathbb{E}_\Delta \left[ \frac{1}{\alpha_i^2} \sigma^2 \right].
\]

Together, we get that

\[
\mathbb{E}_\Delta \left[ \sum_{i=1}^k Y_i \right] \lesssim \sigma^2 \sum_{i=1}^k \frac{1}{\alpha_i^2} + \sqrt{\sigma^2 \sum_{i=1}^k \frac{1}{\alpha_i^2}} \lesssim \sigma \sqrt{\sum_{i=1}^k \frac{1}{\alpha_i^2}},
\]

where the last inequality holds since \( \sigma^2 \sum_{i=1}^k \frac{1}{\alpha_i^2} \lesssim 1 \) (as \( \sigma^2 \approx \varepsilon^2 \) and \( \alpha_i \geq \varepsilon^{0.9} \)).

Next, using the previous claim we upper bound the expectation of each summand on the RHS of (8). The following statement addresses a single term, and should be thought of as being applied after conditioning on \( x, \Delta \) being not-too untypical, and focusing only on \( x_i \)’s for which there is a chance that \( g_j(x_i + \Delta_i) \neq g_j(x_i) \).
\textbf{Claim 32.} Let $j \in [m]$, $k \leq n$, $S \geq 0$ and let $x_1, \ldots, x_k$ be chosen uniformly at random from $[z_j - \frac{\log n}{2m}, z_j + \frac{\log n}{2m}]$. Let $\Delta_i \sim N(0, \sigma^2) |_{|\Delta_i| < 0.95}$. Then

$$\mathbb{E}_{x, \Delta} \left[ \left| \frac{r_j(x + \Delta) - r_j(x)}{r_j(x)} \right| \cdot \frac{\min(r_j(x), S)}{r_j(x) + S + \epsilon^1.6} \right] \lesssim \epsilon^{1.05} + k \cdot \frac{\epsilon}{\log n} \cdot \mathbb{E}_{x} \left[ \frac{r_j(x)}{r_j(x) + S} \right].$$

\textbf{Proof.} Upper bounding $\max(a, b) \leq a + b$ for $a, b \geq 0$, by Claim 31, we have

$$\mathbb{E}_{x, \Delta} \left[ \left| \frac{r_j(x + \Delta) - r_j(x)}{r_j(x)} \right| \cdot \frac{\min(r_j(x), S)}{r_j(x) + S + \epsilon^1.6} \right] \lesssim \mathbb{E}_{x} \left[ \epsilon^{2.65} + r_j(x) \cdot \sigma \cdot \sqrt{\sum_{i=1}^{k} \frac{1}{\alpha_i^2}} \cdot \frac{\min(r_j(x), S)}{r_j(x) + S + \epsilon^1.6} \right]$$

$$\lesssim \epsilon^{1.05} + \sigma \mathbb{E}_{x} \left[ \sum_{i=1}^{k} \frac{1}{\alpha_i^2} \cdot \frac{\min(r_j(x), S)}{r_j(x) + S + \epsilon^1.6} \right],$$

and it is enough to bound the second term. Note that while we expect that each $\alpha_i$ to be of the order $\log n/n$, convexity works against us and it could still be the case that $\sum \frac{1}{\alpha_i^2}$ could be large. The point is that in this case, some $\alpha_i$ must be close to 0, in which case $g_j(x_i)$ is very small—cubically with $\alpha_i$—thereby balancing the $1/\alpha^2_i$ term. The following proposition formalizes this intuition, and the proof is deferred to Section A.

\textbf{Proposition 33.} There is an absolute constant $A > 0$ such that for any $z > 0$ and $r \leq 1$ such that $r_j(x) = r \cdot g_j(x_i)$, it holds that

$$\mathbb{E}_{x_i} \left[ \sqrt{z + \frac{1}{\alpha_i^2}} \cdot \frac{\min(r \cdot g_j(x_i), S)}{r \cdot g_j(x_i) + S + \epsilon^1.6} \right] \leq \mathbb{E}_{x_i} \left[ \sqrt{z + A \cdot \frac{n^2}{\log^2 n}} \cdot \frac{\min(r \cdot g_j(x_i), S)}{r \cdot g_j(x_i) + S + \epsilon^1.6} + A \cdot \frac{n}{\log n} \cdot \mathbb{I}_{r \cdot g_j(x_i) > S} \right].$$

Applying Proposition 33 iteratively $k$ times (once for each $i$, taking $r = \prod_{i' \neq i} g_j(x_{i'})$ and the appropriate $z$), we get that

$$\mathbb{E} \left[ \left( \sum_{i=1}^{k} \frac{1}{\alpha_i^2} \cdot \frac{\min(r_j(x), S)}{r_j(x) + S + \epsilon^1.6} \right)^2 \right] \leq \mathbb{E} \left[ \left( k \cdot A \cdot \frac{n^2}{\log^2 n} \cdot \frac{\min(r_j(x), S)}{r_j(x) + S + \epsilon^1.6} + k \cdot A \cdot \frac{n}{\log n} \cdot \mathbb{I}_{r_j(x) > S} \right)^2 \right].$$

The proof is concluded by noting that $\frac{\min(r_j(x), S)}{r_j(x) + S + \epsilon^1.6} \leq \frac{r_j(x)}{r_j(x) + S}$. 

We are now ready to finish the proof of inequality (4).
Proof of inequality (4)

Let \( E \) be the event that: (1) the support of \( p(x) \) has size at least 2. (2) \( \sum_j r_j(x) \geq \varepsilon^{1.6} \) and also for \( x + \Delta \), and (3) \( |\Delta_i| \leq \varepsilon^{0.95} \) for all \( i \in [n] \). As we argued in Claims 27, 28, 29 the contribution \( \langle x, \Delta \rangle \notin E \) to the LHS of inequality (4) is \( \ll \varepsilon \), hence it is enough to analyze the contribution of \( \langle x, \Delta \rangle \in E \).

Denote \( T(x) = \sum \limits_{j \in [m]} r_j(x) \).

\[
\mathbb{E}_{x, \Delta} \left[ \| p(x) - p(x + \Delta) \|_1 1_E \right] = \mathbb{E}_{x, \Delta} \left[ \sum \limits_{j \in [m]} \frac{r_j(x)}{T(x)} - \frac{r_j(x + \Delta)}{T(x + \Delta)} \right] 1_E \tag{I}
\]

\[
+ \mathbb{E}_{x, \Delta} \left[ \sum \limits_{j \in [m]} \frac{r_j(x)}{T(x)} - \frac{r_j(x + \Delta)}{T(x + \Delta)} \right] 1_E 1_{r_j(x) > \varepsilon^{2.7}} \tag{II}
\]

First, we show that \( (I) \ll \varepsilon \). As \( T(x) \geq \varepsilon^{1.6} \) (since \( E \) holds) and \( r_j(x) \leq \varepsilon^{2.7} \), we get that \( r_j(x)/T(x) \leq \varepsilon^{1.1} \), and next we argue that \( r_j(x + \Delta)/T(x + \Delta) \leq \varepsilon^{1.05} \). Fix \( j \) and suppose \( x_1, \ldots, x_{k_j} \) are the \( x \)'s that fall inside \( I_j \). The following easy fact will be helpful.

**Fact 34.** For all \( x, \Delta \) we have \( r_j(x + \Delta) = \sum \limits_{S \subseteq [k_j]} \prod \limits_{r \in S} g_j(x_r) \prod \limits_{r \notin S} (g_j(x_r) - g_j(x_r + \Delta_r)) \).

**Proof.** Write \( r_j(x + \Delta) = \prod \limits_{r = 1}^{k_j} g_j(x_r + \Delta_r) = \prod \limits_{r = 1}^{k_j} \left( g_j(x_r) + \left( g_j(x_r + \Delta_r) - g_j(x_r) \right) \right) \) and expand out.

Combining Fact 34 and Fact 26, we get that

\[
r_j(x + \Delta) \leq \sum \limits_{S \subseteq [k_j]} \prod \limits_{r \in S} g_j(x_r) \prod \limits_{r \notin S} \left| g_j(x_r) - g_j(x_r + \Delta_r) \right|
\]

\[
\leq \sum \limits_{S \subseteq [k_j]} \prod \limits_{r \in S} g_j(x_r) B^{[S]} n^{3|S|} \prod \limits_{r \notin S} (\alpha_r^3 + |\Delta_r|^3)
\]

\[
\leq \sum \limits_{S \subseteq [k_j]} \prod \limits_{r \in S} g_j(x_r) B^{[S]} n^{3|S|} \prod \limits_{r \notin S} \alpha_r^3
\]

\[
+ 4^n B^{[n]} n^{3n} \max_{|\Delta|} |\Delta|^3
\]

Consider the right hand side above. For the first term we use \( \alpha_r^3 \leq g_j(x_r) \) to get it is at most

\[
\sum \limits_{S \subseteq [k_j]} B^{[S]} n^{3|S|} r_j(x_r) \leq (B^n)^n n^{3n} \varepsilon^{2.7} \leq \varepsilon^{2.65}/2.
\]

For the second term we use \( |\Delta_r| \leq \varepsilon^{0.95} \) to bound it by \( \varepsilon^{2.65} / 2 \) as well. We thus get \( r_j(x + \Delta) \leq \varepsilon^{2.65} \), and so \( r_j(x + \Delta)/T(x + \Delta) \leq \varepsilon^{1.05} \). Combined, we get that

\[
(I) \leq m(\varepsilon^{1.1} + \varepsilon^{1.05}) \ll \varepsilon.
\]
Next, we handle \((II)\). Denote \(T'(x) = \sum_j r_j(x)1_{r_j(x) \geq \varepsilon^2 \tau}\), and note that \(T'(x) \geq T(x) - m \varepsilon^{2.7} (1 - m \varepsilon^{1.1}) T(x)\) and similarly for \(T'(x + \Delta)\). Thus, we may replace \(T(x), T(x + \Delta)\) with \(T'(x), T'(x + \Delta)\) and incur (by the triangle inequality) a loss of at most \(m \varepsilon^{1.1} \lesssim \varepsilon\). Thus, we want to upper bound

\[
\begin{aligned}
\mathbb{E}_{x, \Delta} \left[ \sum_{j \in [m]} r_j(x) \frac{T_j(x + \Delta)}{T'(x + \Delta)} \left| 1_{E_1} r_j(x) > \varepsilon^2 \tau \right. \right] \lesssim \varepsilon.
\end{aligned}
\]

We intend to apply Claim 30 with \(r_j = r_j(x)\) and \(d_j = r_j(x + \Delta) - r_j(x)\) for each \(x\) separately, but for that we first have to argue that \(|d_j| \leq r_j/2\). For each \(i \in [n]\) there is \(j\) such that \(x_i \in I_j\), and we denote \(\alpha_i = \text{dist} (x_i, [z_j - \log n 50n, z_j + \log n 50n])\). Note that

\[
\varepsilon^{2.7} \leq r_j(x) \leq g_j(x_i) \lesssim \left( \frac{n}{\log n} \alpha_i \right)^3,
\]

hence \(\alpha_i \geq \frac{\log n \varepsilon^{0.9}}{n}\), and for small enough \(\varepsilon\) we get that \(\alpha_i \geq \varepsilon^{0.91} \geq 2 |\Delta_i|\). Therefore, Combining Fact 34 and Fact 26 we get

\[
|d_j(x)| = |r_j(x) - r_j(x + \Delta)| \leq \sum_{S \subseteq [k_i], S \neq [k_i]} \prod_{r \in S} g_j(x_r) \prod_{r \notin S} (g_j(x_r) - g_j(x_r + \Delta_r))
\leq \sum_{S \subseteq [k_i], S \neq [k_i]} B^{|S|} r_j(x) \prod_{r \notin S} \frac{|\Delta_i|}{\alpha_i}.
\]

Bounding \(\frac{|\Delta_i|}{\alpha_i} \leq \varepsilon^{0.95}/\varepsilon^{0.91} = \varepsilon^{0.04}\) we get that

\[
|r_j(x) - r_j(x + \Delta)| \leq r_j(x) \varepsilon^{0.04} \sum_{S \subseteq [k_i], S \neq [k_i]} B^{|S|} \leq B^n \varepsilon^{0.04} r_j(x) \leq r_j(x)/2 = r_j / 2.
\]

Therefore, we may apply Claim 30 and get that

\[
(II) \lesssim \mathbb{E}_{x, \Delta} \left[ \sum_{j=1}^{m} \frac{|r_j(x) - r_j(x + \Delta)|}{r_j(x)} \min(r_j(x), T'(x)) \right] \frac{1}{\varepsilon^{2.7} \tau} \lesssim \mathbb{E}_{x, \Delta} \left[ \sum_{j=1}^{m} \frac{|r_j(x) - r_j(x + \Delta)|}{r_j(x)} \min(r_j(x), T'(x)) \right] \frac{1}{\varepsilon^{1.6} \tau} \lesssim \mathbb{E}_{x, \Delta} \left[ \sum_{j=1}^{m} \frac{|r_j(x) - r_j(x + \Delta)|}{r_j(x)} \min(r_j(x), T'(x)) \right] \frac{1}{\varepsilon^{1.6} \tau},
\]

where the last inequality holds since \(T'(x) \gtrsim \varepsilon^{1.6}\). Next, we wish to discard \(x_i\) that are very far from their closest center \(z_j\). For each \(j\), note that \([z_j - \log n 25n, z_j + \log n 25n]\) is exactly the set of \(y\)'s on which \(g_j(y) = 0\), and let \(R_j \subseteq I_j\) be \(R_j = [z_j - \log n 25n - \varepsilon^{0.95} z_j + \log n 25n + \varepsilon^{0.95}] \setminus [z_j - \log n 50n, z_j + \log n 50n]\). Note that for each \(y \in I_j \setminus R_j\), we have that either \(g_j(y) = 0\) if \(y \in [z_j - \log n 50n, z_j + \log n 50n]\), and otherwise \(g_j(y) = 1\). Furthermore, in the latter case we also have that \(g_j(y + \Delta) = 1\) since \(|\Delta_i| \leq \varepsilon^{0.95}\).
We sample $x$ in the following way. First, sample $t_1, \ldots, t_m$ the number of $x_i$’s in each interval $I_1, \ldots, I_m$, then for each $j$ sample $k_j$ to be the number of $x_i$’s inside the interval $I_j$ that fall inside $R_j$. Finally, for each $j \in [m]$ sample $k_j$ points uniformly from $R_j$, $t_j - k_j$ uniformly from $I_j \setminus R_j$, and let $x$ be the (multi-)set of all the sampled points. We condition on the $t_j$’s and $k_j$’s henceforth in (14). Furthermore, we condition on the identity of the $i$’s for which $x_i \in I_j$ for each $j$.

Since $i$’s for which $x_i \in I_j \in [z_j - \frac{\log n}{2m} - \varepsilon^{0.95}, z_j + \frac{\log n}{2m} + \varepsilon^{0.95}]$ do not affect both $r_j(x)$ and $r_j(x + \Delta)$, we may ignore them and hence take expectation only over $i$’s such $x_i \in R_j$. Call these $y$’s. Then from (14) we get

$$(III) \lesssim \mathbb{E}_{\vec{t}, \vec{k}} \left[ \mathbb{E}_{y, \Delta} \left[ \sum_{j=1}^{m} \frac{|r_j(y) - r_j(y + \Delta)|}{r_j(y)} \cdot \min(r_j(y), T'(y)) \right] \right]$$

$\leq \mathbb{E}_{\vec{t}, \vec{k}} \left[ \sum_{j=1}^{m} \mathbb{E}_{y, \Delta} \left[ \frac{|r_j(y) - r_j(y + \Delta)|}{r_j(y)} \cdot \min(r_j(y), T'(y)) \right] \right],$

where $T'(x) = \sum_{j \neq j} r_j'(x) 1_{r_j'(x) \leq \varepsilon^2 \tau}$. Note that conditioned on $\vec{t} = \vec{t}, \vec{k} = \vec{k}$, the values of $y$’s such that $y_i \in I_j$ are independent of $T'(y)$, and they are distributed uniformly over $R_j$. Therefore, using Claim 32 we have

$$(III) \lesssim \mathbb{E}_{\vec{t}, \vec{k}} \left[ \sum_{j=1}^{m} \varepsilon^{1.05} + \frac{k_j \sigma n}{\log n} \cdot \mathbb{Pr}_y \left[ r_j(y) \geq T'(y) \mid \vec{t}, \vec{k} \right] + \mathbb{E}_y \left[ \frac{\sigma n}{\log n} \sqrt{k_j} \frac{r_j(y)}{T'(y)} \right] \right].$$

$\leq m \varepsilon^{1.05} + n^2 \sigma \mathbb{Pr}_y \left[ r_j(y) \geq T'(y) \right] + \frac{\sigma n}{\log n} \mathbb{E}_{\vec{t}, \vec{k}} \left[ \max k_j \right].$

Note that if $T'(x) \leq r_j(x)$, then

$T(x) \leq T'(x) + r_j(x) + \sum_{j} r_j'(x) 1_{r_j'(x) \leq \varepsilon^2 \tau} \leq 2r_j(x) + m \cdot \varepsilon^{2.7} \leq 3,$

so we bound the sum on the right hand side by $m \mathbb{Pr}_x \left[ T(x) \leq 3 \right]$. For the expectation, we use Cauchy-Schwarz and overall we get

$$(III) \lesssim m \varepsilon^{1.05} + n^2 \sigma \mathbb{Pr}_x \left[ T(x) \leq 3 \right] + \frac{\sigma n}{\log n} \mathbb{E}_{\vec{t}, \vec{k}} \left[ \max k_j \right].$$

The first term is clearly $\lesssim \varepsilon$. For the second term, we use Claim 35 below, that asserts that $\mathbb{Pr}_x \left[ T(x) \leq 3 \right] \leq n^{-\omega(1)}$, hence by the definition of $\sigma$ the second term is also $\lesssim \varepsilon$. For the third term, note that each $k_j$ is a sum of $n$ independent Beroulli random variables with parameter $p \leq \log n/n$, therefore by Chernoff bound

$\mathbb{Pr} \left[ k_j \geq 10 \log n \right] \leq e^{-\frac{1}{2} p^2 \log n} \leq n^{-9}.$

The union bound now implies that $\mathbb{Pr} \left[ \max_j k_j \geq 10 \log n \right] \leq n^{-8}$, and hence

$\mathbb{E}_{\vec{t}, \vec{k}} \left[ \max k_j \right] \leq n^{-8} \cdot n + 10 \log n \lesssim \log n.$

Using the definition of $\sigma$, we get that the third term is also $\lesssim \varepsilon$. Combining all, we get that $(III) \lesssim \varepsilon$, and we are done.
Claim 35.

\[ \Pr_x \left[ \sum_j r_j(x) \leq 3 \right] < n^{-\omega(1)}. \] (15)

Proof. The proof is very similar to the analysis of Case (B) above. In particular, similarly to inequality (3),

\[ \Pr[r_j(x) < 1] = \left(1 - \frac{2m \log n}{25n}\right)^{t_j} \geq \left(1 - \frac{2m \log n}{25n}\right)^{2n/m} > e^{-2\log n/25} = n^{-2/25}, \]

as long as \( t_j < 2 \cdot n/m \) (which is the case except with probability \( n^{-\omega(1)} \). Since \( m > n^{2/25} \cdot n^{\Omega(1)} \), the probability of not having at least three \( r_j(x) \)'s equal to 1 is \( n^{-\omega(1)} \). ⊳

5 The value of the \( t \)-fold symmetric odd cycle game

5.1 The upper bound: Theorem 7

Suppose that \( n = 2m - 1 \) and \( A \) is a strategy for \( C_n^{\otimes m} \). We will view \( A \) as a symmetric function over ordered \( t \) tuples, i.e. as \( A: C_n^t \rightarrow \{0,1\}^t \) satisfying \( A(\pi(x)) = \pi(A(x)) \) for all permutations \( \pi \) over \( [t] \).

We identify \( C_n = \{ \frac{i}{n} | i = 0,1,\ldots,n-1 \} \), consider the lattice \( L = (C_n + \mathbb{Z})^t \) and define a rounding map \( R: L \rightarrow \mathbb{Z}^t \) on it as follows. For \( x \in C_n^t \), we define \( R(x) = A(x) + nx \) (mod 2), and then we extend \( R \) to \( L \) by \( R(x+z) = R(x)+z \) for \( x \in C_n^t \) and \( z \in \mathbb{Z}^t \).

Let \( D = R^{-1}(0^t) \). The symmetry of \( A \) implies that \( D \) is permutation-symmetric, and we also note that \( D \) is a tiling of the lattice \( L \).

Definition 36. A random \( \varepsilon \)-Bernoulli direction, denoted by \( u \sim B(\varepsilon) \), is a random variable distributed on \( \{ \pm \frac{1}{n},0 \} \), such that for each \( i \in [t] \) independently, \( \Pr[u_i = 0] = 1 - 2\varepsilon \) and \( \Pr[u_i = 1/n] = \Pr[u_i = -1/n] = \varepsilon \).

We will mostly be concerned with \( \varepsilon = 1/4 \), in which case the distribution of \( x, x+u (mod 1) \) where \( x \in_R C_n^t \) and \( u \) is an independent \( \frac{1}{4} \)-Bernoulli step, is exactly the distribution of challenges to the players. Inspecting, we see that players succeed on these challenges if and only if \( R(x) = R(x+u) \), as the following claim shows.

Claim 37. Let \( x \in C_n^t \) and \( u \in \{ \pm \frac{1}{n},0 \}^t \). Then the players succeed on challenges \( (x,x+u) \) (mod 1) if and only if \( R(x) = R(x+u) \).

Proof. Note that \( x \) and \( x+u \) are either in the same cell of \( D \) or in adjacent cells, so to prove the statement it is enough to show that the players succeed on the challenge if and only if \( R(x) = R(x+u) \) (mod 2).

Write \( x+u = d+z \) where \( d \in C_n^t \) is \( x+u \) (mod 1), and \( z \in \mathbb{Z}^t \). Note that

\[ R(x+u) = R(d)+z = A(d)+dn+z \quad (mod 2), \quad R(x) = A(x)+nx \quad (mod 2) \]

and subtracting the equations we get that

\[ R(x+u) - R(x) = A(d) - A(x) + dn + z - nx \quad (mod 2). \]

Multiplying the equality \( x+u = d+z \) by \( n \) and taking modulo 2 we get that \( nu + nx = nd + nz = nd + z \) (mod 2) where the last transition used the fact that \( n \) is odd. Thus, \( R(x+u) - R(x) = A(d) - A(x) + nu \) (mod 2). Note that the players succeed on the challenge if and only if \( A(x) = A(d) + nu \) (mod 2), and plugging that in we get that they succeed if and only if \( R(x+u) - R(x) = 0 \) (mod 2), as desired. ⊳
Claim 37 implies that the failure probability of the players is

\[ \Pr_{x \in C_n, u \sim B(1/4)} [x, x + u \text{ are in different cells of } D] . \]

Setting \( y = x \pmod D \), it is easily seen that the distribution of \( y \) is uniform over \( D \), so the probability of the above event is equal to

\[ \eta \overset{\text{def}}{=} \Pr_{y \in D, u \sim B(1/4)} [y + u \not\in D]. \]

The rest of the proof is devoted to lower bounding \( \eta \). Setting \( k = M^{\frac{n \log n}{t}} \) for large constant \( M \) to be determined later, we show:

\begin{itemize}
\item \textbf{Lemma 38.} \( \eta \geq \Omega(1/k) \).
\end{itemize}

Below, we will assume \( k \) is an integer, otherwise we may multiply it by a constant factor close to 1 and make it an integer. We then further assume \( k \) is prime, otherwise we may find a prime in \([k, 2k]\) and replace \( k \) by it. Define \( \delta = \Pr_{x \in D, u \sim B(1/4)} [x + ku \not\in D] \) and observe the following easy relation between \( \delta \) and \( \eta \).

\begin{itemize}
\item \textbf{Claim 39.} \( \delta \leq k\eta \).
\end{itemize}

**Proof.** By the union bound

\[ \delta \leq \sum_{j=0}^{k-1} \Pr_{x \in D, u} [x + ju \in D, x + (j + 1)u \not\in D] . \]

Note that for each \( j \), the distribution of \( y = x + ju \pmod D \) is uniform over \( D \), the \( j \)th term in the above sum is at most \( \Pr_{y \in D, u} [y + u \not\in D] = \eta \).

\subsection*{5.1.1 Disjoint Bernoulli steps}

We will also consider the situation after making two Bernoulli steps whose support is disjoint, and for that we make the following definition.

\begin{itemize}
\item \textbf{Definition 40.} The distribution of two disjoint \( \varepsilon \)-Bernoulli direction, denoted by \((u^1, u^2) \sim DB(\varepsilon)\), is defined as follows. For each \( i \) independently, set each one of the following options with probability \( \frac{1}{2} \): \begin{itemize}
\item \((u^1_1, u^2_1) = (1/n, 0)\), \((u^1_2, u^2_2) = (-1/n, 0)\), \((u^1_3, u^2_3) = (0, 1/n)\), \((u^1_4, u^2_4) = (0, -1/n)\);
\end{itemize}
\end{itemize}

We note that if \((u^1, u^2) \sim DB(\varepsilon)\), then \( u^1 + u^2 \) is distributed as \( B(\varepsilon) \). Therefore:

\begin{itemize}
\item \textbf{Claim 41.} It holds that:
\item \[ \Pr_{x \in D, u \sim B(1/4)} [x + ku \not\in D] \leq 2\delta; \]
\item \[ \Pr_{x \in D, u \sim B(1/4)} [x + u \not\in D] \leq 2\eta. \]
\end{itemize}

**Proof.** We prove the first item, and the second item is proved analogously. To sample \( u \sim B(1/4) \), we sample \((u^1, u^2) \sim DB(1/4)\) and take \( u = u^1 + u^2 \), so by the union bound the probability in the first item is at most

\[ \sum_{x \in D, (u^1, u^2) \sim DB(1/4)} \Pr_{x \in D, (u^1, u^2) \sim DB(1/4)} [x + ku^1 \not\in D] + \Pr_{x \in D, (u^1, u^2) \sim DB(1/4)} [x + ku^1 + ku^2 \not\in D]. \]

The first probability is \( \delta \), and we argue that the second probability is at most the first. Indeed, setting \( y = x + ku^1 \), this probability is at most the probability that \( y, y + ku^2 \) are
in different cells of $D$. Note that this occurs if and only if $y \ (\text{mod} \ D)$ and $y \ (\text{mod} \ D) + ku^2$ are in different cells of $D$; note also that for every fixing of $u^1$, the distribution of $y \ (\text{mod} \ D)$ is uniform over $D$. Thus

\[
\Pr_{x \in D, (u^1,u^2) \sim \text{DB}(1/4)} [x + ku^1 \in D, x + ku^1 + ku^2 \not\in D] \leq \Pr_{y \in D, (u^1,u^2) \sim \text{DB}(1/4)} [y + ku^2 \not\in D] = \delta.
\]

\section{Analyzing the potential function}

Our argument closely follows the argument in Section 3, and below we focus on the necessary adjustments. Set $Z = \frac{1}{10 \log 4}$. The definition of the potential function stays as is. We will have several constants floating around in the proof which are not important for the most part, however we make the distinction between the constants $c_1, \ldots, c_6$ that will be absolute (i.e. not depending on $M$), and the constants $t_0(M), t_1(M), t_2(M)$ that will depend on $M$.

The following is a variant of Claim 14, which is the main difference with the argument from Section 3.

\section{Analyzing the potential function}

\begin{definition}
Let $x \in D$ and $u$ be a direction. We say $(x,u)$ is decent if

\[
\Pr_{(u^1,u^2) \sim \text{DB}(1/4)} [x + u_1 \not\in D \lor x + u_2 \not\in D \lor x + ku_1 \not\in D \lor x + ku_2 \not\in D \mid u^1 + u^2 = u] < \frac{1}{32}.
\]

\end{definition}

\begin{claim}
Pr$_{x \in X, u \sim \text{B}(1/4)} [(x,u) \text{ is decent}] \geq 1 - 64(\eta + \delta)
\end{claim}

\begin{proof}
Denote

\[
p(x,u) = \Pr_{(u^1,u^2) \sim \text{DB}(1/4)} [x + u_1 \not\in D \lor x + u_2 \not\in D \lor x + ku_1 \not\in D \lor x + ku_2 \not\in D \mid u^1 + u^2 = u].
\]

Note that

\[
\mathbb{E}_{u \sim \text{B}(1/4)} [p(x,u)] = \Pr_{x \in D, (u^1,u^2) \sim \text{DB}(1/4)} [x + u^1 \not\in D \lor x + u^2 \not\in D \lor x + ku^1 \not\in D \lor x + ku^1 \not\in D],
\]

which is at most $2(\delta + \eta)$ by the union bound. Thus, by Markov’s inequality

\[
\Pr_{x \in D, u \sim \text{B}(1/4)} [(x,u) \text{ is not decent}] = \Pr_{x \in D, u \sim \text{B}(1/4)} [p(x,u) \geq \frac{1}{32}] \leq 64(\delta + \eta).
\]

\section{Analyzing the potential function}

\begin{claim}
If $x, x + u, x - u, x + ku, x - ku \in D$ and both $(x,u), (x,-u)$ are decent, then

\[
|\Psi(x + ku) - \Psi(x, ku)| \leq t^2 \cdot e^{-Z/4}.
\]

\end{claim}

\begin{proof}
We consider the contribution of each pair $(i,j)$ to $\Psi(x + ku)$ and $\Psi(x, ku)$ separately. Without loss of generality we may only consider pairs $i,j$ that $\gamma(x_i, x_j) = 1$, and thus $d(x_i, x_j) = x_i - x_j + z$ for some $z \in \mathbb{Z}$. Let $d = x_i - x_j + z + k(u_i - u_j)$.

\begin{proposition}
$d \geq 0$.
\end{proposition}

\begin{proof}
\end{proof}

On Symmetric Tilings of Euclidean Space

Proof. Assume otherwise. Since \( x_i - x_j + z \geq 0 \) it follows by continuity that there is \( \lambda \in [0, 1) \) such that \( x_i - x_j + z + \lambda k(u_i - u_j) = 0 \). Note that \( u_i - u_j \) can either be \( \pm \frac{1}{2} \), or \( \pm \frac{2}{n} \). If \( u_i - u_j = 0 \), we get that \( x_i - x_j + z = 0 \), and as \( x \in D \) this contradicts Lemma 12. Otherwise, multiplying by \( n \), we get that \( kn(u_i - u_j) \) is an integer. Note that \( kn(u_i - u_j) \) is either \( \pm k \) or \( \pm 2k \), and as \( k \) is prime we get that \( \lambda = \frac{1}{2}, \lambda = \frac{1}{k} \) or \( \lambda = \frac{1}{2k} \), and we analyze each case separately. If \( \lambda = \frac{1}{n} \) then we get \( x_i - x_j + u_i - u_j + z = 0 \), so \( x + u \in D \) has two coordinates differing by a non-zero integer, contradicting Lemma 12. We next consider the other two cases separately, and assume that \( u_i - u_j > 0 \) otherwise we use \( -u \) instead of \( u \) in the argument below.

If \( \lambda = \frac{1}{2} \), then necessarily \( u_i - u_j = \frac{2}{n} \) and we get that \( x_i - x_j + z + \frac{1}{n} = 0 \). Sample \((u^1, u^2) \sim DB(1/4)\) conditioned on \( u^1 + u^2 = u \). Note that the event that \( u^1 = 1/n \) and \( u^1 = 0 \) occurs with probability \( 1/32 \). Since \((x, u)\) is decent, we get that \( x + u^1 \in D \) with probability strictly greater than \( \frac{31}{32} \). Thus, the probability that \( x + u^1 \in D \) and \((u^1, u^1) = (1/n, 0)\) is positive, and in this case we get

\[
(x + u^1)_i - (x + u^1)_j = x_i - x_j + \frac{1}{n} = -z \neq 0,
\]

contradicting Lemma 12.

The case that \( \lambda = \frac{1}{k} \) is similar. We must have that \( u_i - u_j = \frac{2}{n} \), and thus we get \( x_i - x_j + \frac{2}{n} + z = 0 \). Sample \((u^1, u^2) \sim DB(1/4)\) conditioned on \( u^1 + u^2 = u \). Note that the event that \( u^1 = 1/n \) and \( u^1 = 0 \) occurs with probability \( 1/32 \). Since \((x, u)\) is decent, we get that \( x + ku^1 \in D \) with probability strictly greater than \( \frac{31}{32} \). Thus, the probability that \( x + ku^1 \in D \) and \((u^1, u^1) = (1/n, 0)\) is positive, and in this case we get

\[
(x + ku^1)_i - (x + ku^1)_j = x_i - x_j + \frac{k}{n} = -z \neq 0,
\]

contradicting Lemma 12.

We therefore get that \( d \geq 0 \), and the rest of the proof is identical to the proof of Claim 14.

\[\triangleright\]

\textbf{Claim 46.} There is an absolute constants \( c_1 > 0 \) and \( t_0(M) > 0 \), such that if \( t \geq t_0 \) then for every \( x \in D \)

\[
\Psi(x) \cdot e^{c_1 k^2 Z^2 / n^2} \leq E_{u \sim \text{B}(1/4)} [\Psi(x, ku)] \leq \Psi(x) \cdot e^{c_1' k^2 Z^2 / n^2}.
\]

Proof. By linearity of expectation we have

\[
E_{u \sim \text{B}(1/4)} [\Psi(x, ku)] = \sum_{i < j} e^{-Z_d(x_i, x_j)} \cdot E_{u' \sim \text{B}(1/4)} [e^{-Z_{\gamma(x_i, x_j)}(u_i - u_j)}].
\]

Note that the above expectation does not depend on \( i, j \); for every \( i, j \) the distribution of \( u_i - u_j \) is \( w \), where \( \Pr[w = 2/n] = \Pr[w = -2/n] = \frac{1}{4} \), \( \Pr[w = 1/n] = \Pr[w = -1/n] = \frac{1}{4} \), \( \Pr[w = 0] = \frac{1}{2} \). In particular, this distribution is symmetric around 0 and thus the sign \( \gamma(x_i, x_j) \) does not affect the expectation. Hence we have

\[
E_u [\Psi(x, u)] = \Psi(x) \cdot E_w [e^{kZw}] = \Psi(x) \cdot E_w \left[ e^{kZw + e^{-kZw}} \right].
\]

Note that \( |kZw| \leq M \frac{n \sqrt{\log t}}{t \log (1/n)} \leq 1 \) for large enough \( t \), so we have that

\[
e^{c_1 k^2 (Zw)^2} \leq e^{hZw + e^{-hZw} \frac{2}{2}} \leq e^{c_1'(kZw)^2}.
\]
Finally, the expectation of $e^{e(kZw)^2}$ is at least $e^{\epsilon k^2 Z^2/n^2}$ and at most $e^{\epsilon' k^2 Z^2/n^2}$, and the claim follows.

The proofs of the following several claims are essentially identical to their analogs in Section 3, and are therefore omitted. We say a point $x$ is good if any interval of length $\frac{10 \log t}{t}$ on the circle contains at least $\log t$ and at most $100 \log t$ coordinates from $x$ (mod 1). By Chernoff bound, a random $x \in D$ is good with probability $> 0.999$ given $t$ is large enough.

› Claim 47. There exists an absolute constant $c_2 > 0$, such that if $x$ is good then $\Psi(x) > c_2 \log^2 t$.

Proof. The proof is identical to the proof of Claim 16.

› Claim 48. There exists an absolute constant $c_3 > 0$, such that if $x$ is good, then for all $i$ we have $C_i < c_3 \frac{\Psi(x)}{\log^4}$.

Proof. The proof is identical to the proof of Claim 17.

› Claim 49. There exists an absolute constant $c_5, c_6 > 0$ and $t_1(M) > 0$, such that if $t \geq t_1$ then for all good $x \in D$ we have $\operatorname{var}_{u \sim B(1/4)}[\Psi(x, u)] \leq \frac{c_5}{\log t} \cdot \left( e^{\epsilon_6^{-1} k^2 u^2} - e^{\epsilon_6^{-1} k^2 u^2} \right) \cdot \Psi(x)^2$.

Proof. The proof is a straightforward adaptation of the proof of Claim 18.

Consequently, we have to adjust Claim 19 as follows.

› Claim 50. There is an absolute constant $M > 0$ and $t_2 > 0$ such that if $k = M \frac{n \sqrt{\log t}}{t}$ and $t \geq t_1$, then for all good $x \in D$ we have $\Pr_{u \sim B(1/4)} \left[ \Psi(x, u) > \Psi(x) + \frac{c_5^2 k_4 Z^4}{2 n^4} \Psi(x) \right] \geq 0.99$.

Proof. Let $c_1, \ldots, c_6$ be the constants from the previous claims, and choose $M = \sqrt{\frac{200 c_5}{c_6^2 c_6}}$. Then take $t_0(M), t_1(M)$ from Claims 46 49 and choose $t_2(M) = \max(t_0(M), t_1(M))$. We upper bound the probability of the complement event. Using Claim 46 (and $\epsilon' \geq 1 + t + t^2/2$), we get

$$\mathbb{E}_{u \sim B(1/4)} [\Psi(x, u)] \geq \Psi(x) \cdot \left( 1 + c_1 \frac{k^2 Z^2}{n^2} + \frac{c_5^2 k_4 Z^4}{2 n^4} \right).$$

Hence

$$\Pr_{u \sim B(1/4)} \left[ \Psi(x, u) \leq \Psi(x) + \frac{c_5^2 k_4 Z^4}{2 n^4} \Psi(x) \right] \leq \Pr_{u \sim B(1/4)} \left[ \Psi(x, u) - \mathbb{E}_{u \sim B(1/4)} [\Psi(x, u)] \geq \Psi(x) c_1 \frac{k^2 Z^2}{n^2} \right].$$

We want to upper bound the probability of the last event using Chebyshev’s inequality. Since $x$ is good, the conclusion of Claim 49 holds, and so

$$\operatorname{var}_{u \sim B(1/4)} [\Psi(x, u)] \leq \frac{c_5}{\log t} \cdot \left( e^{\epsilon_6^{-1} k^2 u^2} - e^{\epsilon_6^{-1} k^2 u^2} \right) \cdot \Psi(x)^2 \leq \frac{c_5}{\log t} \cdot \frac{2 c_6^{-1} k^2 Z^2}{n^4} \cdot \Psi(x)^2,$$

for sufficiently large $t$. Therefore, applying Chebyshev’s inequality we see the probability in question is at most

$$\operatorname{var}_{u \sim B(1/4)} [\Psi(x, u)] \leq \frac{c_5}{\Psi(x)^2} \cdot \frac{2 c_6^{-1} k^2 Z^2}{n^4} \cdot \Psi(x)^2 \leq \frac{2 c_5}{c_1^2 c_6 k^2 Z^2 \log t} = \frac{2 c_5}{c_1^2 c_6 M^2} \leq 0.01.
5.1.3 Finishing the argument

For each $u$, denote $\delta_u = \Pr_{x \in D} [x + ku \not\in D]$, and note that $\delta = \mathbb{E}_u [\delta_u]$.

$\triangleright$ Claim 51. For each $u$, $\mathcal{D}_{TV} [x; x - ku] \leq \delta_u + \delta_{-u}$.

Proof. The proof is a direct conversion of the proof of Claim 20 to the discrete setting, replacing the notion of “Borel sets” with finite sets. $\triangleright$

We can now prove Lemma 38.

Proof of Lemma 38. Take $M$ and $t_2$ from Claim 50. We may assume that $t \geq t_2$, otherwise the lemma just follows from the fact that $\eta \geq \Omega(1/n)$, which holds as the value of the $t$-fold symmetric repeated game is at most the value of the original game, which is $1 - \Theta(1/n)$.

Take $x \in_R D$, $u \sim \mathcal{B}(1/4)$. Let $E_1$ be the event that $(x, u), (x, -u)$ are descent, $E_2$ be the event that $\Psi(x) \leq c_2 \log^2 t$, $E_3$ the event that $x + ku, x - ku, x + u, x - u \in D$, and let $E_4$ be the event that $\Psi(x, u) > \Psi(x) + \frac{c_4}{4} k^4 Z^4 \Psi(x)$. Finally, let $E_5$ be the event that $\Psi(x + u) > \Psi(x)$ and denote $E(x, u) = E_1 \cap E_2 \cap E_3 \cap E_4$. Note that if the event $E$ holds for $x, u$, then $E_5$ also holds, since by Claim 44:

$$\Psi(x + u) \geq \Psi(x, u) - t^2 \cdot e^{-Z^2/4} \geq \Psi(x) + \frac{c_2}{4} k^4 Z^4 \Psi(x) - t^2 \cdot e^{-Z^2/4} > \Psi(x).$$

In the last inequality, we used the fact that if $E$ holds, then $\frac{c_2}{4} k^4 Z^4 \Psi(x) \geq \Omega(1)$, and $t^2 \cdot e^{-Z^2/4} = n^2 e^{-t^2/40 \log t} = o(1)$ for large enough $t$.

By Claim 43, $\Pr_x [E_1] \geq 1 - 128(\delta + \eta)$. By Claim 47 the probability of $E_2$ is at most the probability $x$ is bad, hence it is at most 0.005, by Claim 41 $\Pr_x [E_3] \geq 1 - 4(\delta + \eta)$, and by Claim 50, $\Pr_x [E_4] \geq 0.99$. We thus get

$$\Pr_x [E(x, u)] \geq 0.99 - 4(\delta + \eta) - 0.005 - 128(\delta + \eta) \geq 0.95 - 132(\delta + \eta). \quad (16)$$

Fix $u$. Using Claim 51 we get that

$$\Pr_x [E(x - u, u)] \geq \Pr_x [E(x, u)] - \mathcal{D}_{TV} [x; x - u] \geq \Pr_x [E(x, u)] - \delta_u - \delta_{-u}.$$ 

By the union bound, we now conclude that

$$\Pr_x [E(x - u, u) \cap E(x, u)] \geq 1 - \Pr_x [E(x - u, u)] - \Pr_x [E(x, u)] \geq 2 \Pr_x [E(x, u)] - 1 - \delta_u - \delta_{-u}.$$ 

Taking expectation over a random step $u$, we get that

$$\Pr_{x, u} [E(x - u, u) \cap E(x, u)] \geq 2 \Pr_{x, u} [E(x, u)] - 1 - 2 \mathbb{E}_u [\delta_u] \geq 0.9 - 270(\delta + \eta),$$

where we used (16). Next, when both $E(x - u, u)$ and $E(x, u)$ hold, we have by the previous observation that $E_5$ holds for both pairs $(x - u, u)$ and $(x, u)$, and so $\Psi(x + u) > \Psi(x - u) > \Psi(x - u) > \Psi(x - u)$. Thus, we get that $\Pr_{x, u} [\Psi(x + u) > \Psi(x - u)] \geq 0.9 - 270(\delta + \eta)$. On the other hand, the probability on the left hand side is at most 0.5; this follows as $\Pr_{x, u} [\Psi(x + u) > \Psi(x - u)] = \Pr_{x, u} [\Psi(x - u) > \Psi(x + u)]$, and their sum is at most 1. Combining the two inequalities we get that $\eta + \delta \geq \Omega(1)$, which using Claim 39 implies that $\eta = \Omega(1/k)$ as desired. $\triangleright$

5.2 The lower bound: proof of Theorem 8

In this section we use the permutation-symmetric body constructed in Theorem 6 in order to prove Theorem 8.
5.2.1 Tools

We need the following isoperimetric inequality.

**Fact 52.** For all \( \varepsilon > 0 \) there is \( \delta > 0 \) such that the following holds. Let \( A \subseteq [0,1]^n \) be a measurable set such that \( \varepsilon \leq \text{vol}(A) \leq 1 - \varepsilon \). Then \( \text{area}(A \cap \text{interior}([0,1]^n)) \geq \delta \).

**Proof.** This is the combination of [29, Theorem 6, Theorem 7] as we explain below. Theorem 7 therein asserts that if \( A \subseteq [0,1]^n \) has Lebesgue measure \( \alpha \) and surface area \( S \), then there is a measurable set in Gaussian space \( B \subseteq \mathbb{R}^n \) with Gaussian measure \( \alpha \) and (Gaussian) surface area at most \( S \). Now [29, Theorem 7] asserts among sets with Gaussian measure \( \alpha \), the minimizers of surface area are halfspaces of the form \( B_\beta = \{ z \in \mathbb{R}^n \mid z_1 \leq \beta \} \) where \( \beta \) is chosen so that the Gaussian measure of \( B_\beta \) is \( \alpha \), so \( S \leq \text{area}(B_\beta) \), which is bounded away from 0 if \( \alpha \) is bounded away from 0 and 1.

Secondly, we need a slight strengthening of Theorem 6. Recall that in Sections 4 and B we have constructed a semi-algebraic, bounded tiling body \( D \subseteq \mathbb{R}^k \) whose surface area is \( A = O(t/\sqrt{\log t}) \), and for small enough \( \varepsilon \) we have

\[
\Pr_{x \in D, \Delta \sim N(0, \varepsilon^2 I_k)} [x + \Delta \notin D] \lesssim A \varepsilon.
\]

We note that the argument in Section 4 holds in fact for more general class of \( \Delta \) (we only used the fact it is independent of \( x \), has mean 0 and is sub-Gaussian). Thus, we consider the distribution \( \Delta_\varepsilon \in \{0, \pm \varepsilon/n\}^k \) of Bernoulli steps, namely for each \( i \) independently choosing \( (\Delta_\varepsilon)_i \), as \( \Pr [(\Delta_\varepsilon)_i = 0] = \frac{1}{2}, \Pr [(\Delta_\varepsilon)_i = -\frac{\varepsilon}{n}] = \frac{1}{4}, \Pr [(\Delta_\varepsilon)_i = \frac{\varepsilon}{n}] = \frac{1}{4} \). Thus, running the argument therein we get:

**Lemma 53.** The distribution over tiling bodies \( (D_\varepsilon)_f \) from Lemma 24 satisfies, for small enough \( \varepsilon > 0 \)

\[
\mathbb{E}_f \left[ \Pr_{x, \Delta_\varepsilon} [\text{At least one of the conditions of Claim 22 fail for } x \text{ and } x + \Delta_\varepsilon] \right] \lesssim A \frac{\varepsilon}{n}.
\]

Slightly adapting the argument from Section B, we may ensure that the chosen body \( D \) also has small noise sensitivity for Bernoulli random steps \( \Delta_\varepsilon \) for small enough \( \varepsilon \), but we will only need this to happen for a specific suitably chosen \( \varepsilon \) which can be ensured as follows. Take \( \varepsilon \) small enough for which Lemma 53 holds, and note that by Markov’s inequality we get from Lemma 53 that

\[
\Pr_f \left[ \Pr_{x, \Delta_\varepsilon} [\text{At least one of the conditions of Claim 22 fail for } x \text{ and } x + \Delta_\varepsilon] \geq C \cdot A \cdot \frac{\varepsilon}{n} \right] \leq \frac{1}{4}
\]

for an absolute constant \( C \). Thus, from Claim 50 and the union bound we get that there is \( R^* \in \bigcap_{k \geq k_0} G_k \) such that the above event holds, and the rest of the proof in Section B shows that \( D = D_{R^*} \) has surface area \( O(A) \). We summarize this discussion with the following lemma.

---

3 The proof is essentially the same, adapting the definition of \( G_k \) therein to be

\[
G_k = \left\{ f \mid \begin{array}{l}
\Pr_{x \in D_{R^*}, \Delta \sim N(0.4^{-k} I_k)} [x, x + \Delta \text{ lie in different cells of } S_{\varepsilon}] \leq 4 \cdot A 2^{-k} \\
\Pr_{x \in D_{R^*}, \Delta \sim N(0.4^{-k} I_k)} [x, x + \Delta \text{ lie in different cells of } S_{\varepsilon}] \leq 4 \cdot A 2^{-k}
\end{array} \right\}.
\]
Lemma 54. For all $t$, for small enough $\varepsilon$, there is a permutation-symmetric, bounded tiling body $D$ with surface area $A = O(t / \sqrt{\log t})$ such that
\[
\Pr_{\mathbf{x}, \Delta} \left[ \text{At least one of the conditions of Claim 22 fail for } \mathbf{x} \text{ and } \mathbf{x} + \Delta \right] \lesssim A \cdot \frac{\varepsilon}{n}.
\]

5.2.2 Decisive boxes

In this section, we use Lemma 54 to devise a symmetric strategy for the players in the $t$-fold repeated game. Take small enough $\varepsilon$ so such Lemma 54 holds and assume that $k \overset{\text{def}}{=} 1/\varepsilon$ is an integer. Let $D$ be the permutation-symmetric tiling body from Lemma 54. It will be convenient for us to think of challenges to the players as $C_t^n = \{ i^n \mid i = 0, 1, \ldots, n - 1 \}$.

Partition $[0, 1)^t$ into the boxes $B_{\vec{a}} = \prod_{i=1}^t \left[ \frac{a_i}{n}, \frac{a_i + 1}{n} \right)$ for $\vec{a} \in \{0, 1, \ldots, n - 1\}^t$; it will be convenient for us identify a challenge of a player $\mathbf{x}'$ with the box it belongs to, i.e. with $B_{\vec{a}}$ for $\vec{a} = nx'$. Consider the way $D$ further partitions the boxes $B_{\vec{a}}$.

Definition 55. We say a box $B_{\vec{a}}$ is decisive if there exists $z \in \mathbb{Z}^n$ such that $\mu(B_{\vec{a}} \cap (D + z)) \geq \frac{2}{3} \mu(B_{\vec{a}})$. Otherwise, we say $B_{\vec{a}}$ is indecisive.

We show that almost all boxes are decisive:

Lemma 56. The number of indecisive boxes is $O(A^n t - 1)$.

Proof. Define $\Phi = \sum_{z \in \mathbb{Z}^t} \sum_{\vec{a} \in \{0, 1, \ldots, n - 1\}^t} \text{area}(\partial(D + z) \cap \text{interior}(B_{\vec{a}}))$. By considering the surface area of $D$, we will show that $\Phi \leq A$, and we will lower bound $\Phi$ as a function of the number of the indecisive boxes, from which we will get the result. Let $B$ be such that $D \subseteq [-B, B]^t$, and take $m$ large enough.

5.2.2.1 The upper bound

For $\vec{a} \in \{0, 1, \ldots, mn - 1\}^t$, we define the box $B_{\vec{a}}$ as above, and define
\[
\Phi_m = \sum_{z \in \mathbb{Z}^t} \sum_{\vec{a} \in \{0, 1, \ldots, mn - 1\}^t} \text{area}(\partial(D + z) \cap \text{interior}(B_{\vec{a}})).
\]

On the one hand, we clearly have that $\Phi_m = m^t \Phi$, and we next upper bound $\Phi_m$. Since $D \subseteq [-B, B]^t$, we have that
\[
\Phi_m = \sum_{z \in \{-B, -B+1, \ldots, B+m\}^t} \sum_{\vec{a} \in \{0, 1, \ldots, mn - 1\}^t} \text{area}(\partial(D + z) \cap \text{interior}(B_{\vec{a}})) \leq \sum_{z \in \{-B, -B+1, \ldots, B+m\}^t} \text{area}(\partial(D + z)) = (m + 2B + 1)^t \text{area}(\partial D) \leq (m + 2B + 1)^t A.
\]

Combining the upper and lower bound we get $\Phi \leq (1 + \frac{2B+1}{m})^t A$, and sending $m$ to infinity gets that $\Phi \leq A$. 

5.2.2.2 The lower bound

Interchanging the order of summation, we write

\[ \Phi = \sum_{\vec{a} \in \{0,1, \ldots, n-1\}^d} \sum_{\vec{z} \in \mathbb{Z}^d} \text{area}(\partial(D + \vec{z}) \cap \text{interior}(B_{\vec{a}})), \]

and we show that if the box \( B_{\vec{a}} \) is indecisive, then the innermost sum is at least \( \Omega(1/n^{t-1}) \).

Indeed, if \( B_{\vec{a}} \) is indecisive, then \( \mu(B_{\vec{a}} \cap (D + z)) \leq \frac{2}{3} \mu(B_{\vec{a}}) \) for all \( \vec{a} \). Thus, we may find \( P \subseteq \mathbb{Z}^n \) such that for \( H = B_{\vec{a}} \cap \bigcup_{\vec{z} \in P} (D + z) \) we have that \( \frac{1}{2} \mu(B_{\vec{a}}) \leq \mu(H) \leq \frac{5}{6} \mu(B_{\vec{a}}) \). We now scale and translate \( H \), i.e. take \( H' = nH - \vec{a} \), so that the above translates to \( H' \subseteq [0,1]^n \) such that \( \frac{1}{2} \leq \mu(H') \leq \frac{5}{6} \), and hence by Fact 52 \( \text{area}(\partial H' \cap \text{interior}([0,1]^n)) \geq \Omega(1) \). Removing the scaling, we get that \( \text{area}(\partial H \cap \text{interior}(B_{\vec{a}})) \geq \Omega(n^{1-t}) \). Therefore, we get that

\[ \Phi \geq \sum_{\vec{a} \in \{0,1, \ldots, n-1\}^d \atop \vec{a} \text{ indecisive}} \Omega(n^{1-t}) = \Omega(n^{1-t} \cdot \#\{\text{indecisive boxes}\}) \]

Combining the upper and lower bound on \( \Phi \), we get that the number of indecisive boxes is at most \( O(An^{1-t}) \).

Next, we show that if \( B_{\vec{a}} \) is a typical decisive box, and \( \Delta_1 \in_R \{0, \pm 1/n\} \) is chosen randomly as above, then \( B_{\vec{a} + \Delta_1} \) is very likely to be somewhat decisive, and furthermore with the same cell of \( D \).

**Lemma 57.** It holds that

\[ \Pr_{\vec{a}} \left[ \exists \vec{z} \in \mathbb{Z}^n, \mu(B_{\vec{a}} \cap (D + z)) \geq \frac{2}{3} \mu(B_{\vec{a}}), \mu(B_{\vec{a} + \Delta_1} \cap (D + z)) > \frac{1}{2} \mu(B_{\vec{a} + \Delta_1}) \right] \geq 1 - O \left( \frac{A}{n} \right). \] (17)

**Proof.** Choose a random \( \vec{a} \), take a random \( \vec{x} \in B_{\vec{a}} \), and let \( \vec{y} = \vec{x} \pmod{D} \). Note that as the distribution of \( \vec{x} \) is uniform over \([0,1]^n\) and the distribution of \( \vec{y} \) is uniform over \( D \). Let \( E_1(\vec{a}, \vec{x}, \Delta_1) \) be the event that \( \vec{y} \) and \( \vec{y} + \Delta_1 \) are in different cells of \( D \). Then by the union bound and the choice of \( D \)

\[ \Pr_{\vec{a}, \vec{x}, \Delta_1} [E_1] = \Pr_{\vec{a}, \vec{x}, \Delta_1} [\vec{y}, \vec{y} + k\Delta_1 \text{ in different cells of } D] \]

\[ \leq \sum_{j=0}^{k-1} \Pr_{\vec{a}, \vec{x}, \Delta_1} [\vec{y} + j\Delta_1, \vec{y} + (j+1)\Delta_1 \text{ in different cells of } D] \]

\[ = \sum_{j=0}^{k-1} \Pr_{\vec{a}, \vec{x}, \Delta_1} [\vec{w}, \vec{w} + \Delta_1 \text{ in different cells of } D] \]

\[ \leq \sum_{j=0}^{k-1} C \cdot A \cdot \frac{\varepsilon}{n} = C \frac{A}{n}. \]

Let \( E_2(\vec{a}) \) be the event that \( B_{\vec{a}} \) is decisive, and if \( E_2(\vec{a}) \) holds let \( \vec{z} \in \mathbb{Z}^n \) be such that \( \mu(B_{\vec{a}} \cap (D + z)) \geq \frac{2}{3} \mu(B_{\vec{a}}) \). Then by Lemma 56 \( \Pr [E_2(\vec{a})] \geq 1 - O(A/n) \). Denote

\[ p_{\vec{a}, \Delta_1} = \Pr_{\vec{x}, \vec{a}, \Delta_1} [E_1(\vec{a}, \vec{x}, \Delta_1) \mid \vec{a} = \vec{a}, \Delta_1 = \Delta_1]. \]
The expectation of \( p_{\bar{a}, \Delta_1} \), is the probability of \( E_1(\bar{a}, x, \Delta_1) \), so

\[
\frac{\Pr_{\bar{a}, \Delta_1} \left[ E_2(\bar{a}) \land p_{\bar{a}, \Delta_1} \leq \frac{1}{10} \right]}{\Pr_{\bar{a}, \Delta_1} \left[ E_2(\bar{a}) \right]} \geq 1 - \frac{\Pr_{\bar{a}, \Delta_1} \left[ p_{\bar{a}, \Delta_1} > \frac{1}{10} \right]}{\Pr_{\bar{a}, \Delta_1} \left[ E_1(\bar{a}, x, \Delta_1) \right]} - \frac{\Pr_{\bar{a}, \Delta_1} \left[ E_2(\bar{a}) \right]}{1/10},
\]

which is at least \( 1 - O \left( \frac{\Delta}{n} \right) \). To finish the proof, we show that for every \( \bar{a}, \Delta_1 \) such that \( E_2(\bar{a}) \) holds and \( p_{\bar{a}, \Delta_1} \leq \frac{1}{10} \), we have the the event on the left hand side of (17) holds.

Indeed, fix such \( \bar{a}, \Delta_1 \). Then there is a unique \( z \in \mathbb{Z}^n \) such that \( \mu(B_{\bar{a}} \cap (D + z)) = \Pr_{x \in B_{\bar{a}} \mid x \in (D + z)} \). Note that if \( y, y + \Delta_1 \) are in the same cell of \( D \), then \( x, x + \Delta_1 \) are in the same cell of \( D \), so

\[
\frac{\mu(B_{\bar{a}} \cap (D + z))}{\mu(B_{\bar{a}} \cap \Delta_1)} = \frac{\mu(B_{\bar{a} + \Delta_1} \cap (D + z))}{\mu(B_{\bar{a}})} = \frac{\Pr_{x \in B_{\bar{a}}} [x + \Delta_1 \in (D + z)]}{\Pr_{x \in B_{\bar{a}}} [x \in D + z]} \geq \frac{\Pr_{x \in B_{\bar{a}}} [x \in (D + z), x + \Delta_1 \in (D + z)]}{\Pr_{x \in B_{\bar{a}}} [x \in (D + z) \text{ and } y, y + \Delta_1 \text{ in the same cell of } D]} \geq \frac{\Pr_{x \in B_{\bar{a}}} [y, y + \Delta_1 \text{ in the same cell of } D] - \Pr_{x \in B_{\bar{a}}} [x \notin D + z]}{1 - p_{\bar{a}, \Delta_1} - \Pr_{x \in B_{\bar{a}}} [x \notin D + z]} \geq 1 - \frac{1}{10} - \frac{1}{3} > 1 - \frac{1}{2}.
\]

\[\blacktriangleleft\]

### 5.2.3 Proof of Theorem 8

In this section, we prove Theorem 8. For that, we show that the success probability of the following players’ strategy is at least \( 1 - O(A/n) \).

1. On challenge \( x' \in C_n' \), consider the box that \( x' \) belongs to, i.e. \( B_{\bar{a}} \) for \( \bar{a} = nx' \).
2. Check if there is \( z \in \mathbb{Z}^n \) such that \( \mu(B_{\bar{a}} \cap (D + z)) > \frac{1}{2} \mu(B_{\bar{a}}) \), and note that it is unique if such point exists. If there is no such \( z \), abort. We refer to \( z \) as the chosen lattice point of the player.
3. Output \( z + nx' \) (mod 2).

First, we argue that this strategy is symmetric. Indeed, the effect of permuting the entries of \( x' \) by \( \pi \in S_t \) is that \( \bar{a}, z \) above also get permuted by \( \pi \), and therefore the output also gets permuted by \( \pi \). Next, we analyze the success probability of this strategy.

Note the following equivalent way of picking challenges \( (x', y') \): sample uniformly \( \bar{a} \in \{0, 1, \ldots, n-1\}^t \), set \( x' = \bar{a}/n \), sample \( \Delta_1 \) Bernoulli as above and set \( y' = x' + \Delta_1 \) (mod 1). Denote the box of \( x' \) by \( B_{\bar{a}(x')} \), and consider the event \( E \) defined in Lemma 57. We show that whenever the event \( E \) holds, the players are successful with the above strategy, and as the probability of \( E \) is at least \( 1 - O(A/n) \), the proof would be concluded.

Fix \( \bar{a}, \Delta_1 \) such that \( E \) holds, and let \( z \in \mathbb{Z}^n \) be the (unique) point such that \( \mu(B_{\bar{a}} \cap (D + z)) \geq \frac{1}{2} \mu(B_{\bar{a}}) \), \( \mu(B_{\bar{a} + \Delta_1} \cap (D + z)) > \frac{1}{2} \mu(B_{\bar{a} + \Delta_1}) \). The first condition implies that the \( x' \)-player does not abort and their chosen lattice point is \( z \), and we next show that the \( y' \)-player does not abort as well. Note that the box of \( y' \) is \( B_{\bar{a}(y')} \) for \( \bar{a}(y') = \bar{a} + n\Delta_1 \) (mod 1), and write \( \bar{a} + n\Delta_1 = \bar{a}(y') + w \) for \( w \in \mathbb{Z}^n \). Thus,

\[
\mu(B_{\bar{a}(y')} \cap (D + z - w)) = \mu(B_{\bar{a}(y')} + w \cap (D + z)) = \mu(B_{\bar{a} + \Delta_1} \cap (D + z)) > \frac{1}{2} \mu(B_{\bar{a} + \Delta_1}),
\]

which is equal to \( \frac{1}{2} \mu(B_{\bar{a}(y')}) \), so the \( y' \)-player also does not abort and their chosen lattice point is \( z - w \). We now analyze the answers of the players on each coordinate.
If $i$ is a coordinate such that $y'_i \neq x'_i$, then we may write $y'_i = x'_i + \Delta_1 + b$ for $b \in \{-1, 0, 1\}$ and $\Delta_1 \neq 0$. Then we get that $\vec{a}(y'_i) = \vec{a}_i + n(\Delta_1)_i + nb$, so $w_i = -nb$. Thus, the answer of the $x'$-player is $z_i + nx'_i \pmod{2}$, whereas the answer of the $y'$-player is $z_i + nx'_i + n\Delta_1 + 2nb = z_i + nx'_i + 1 \pmod{2}$, where we used $2nb = 0 \pmod{2}$, and $n\Delta_1 = 1 \pmod{2}$ (as $\Delta_1 = \pm \frac{1}{n}$). Thus, the players are consistent on the $i$th coordinate.

If $i$ is a coordinate such that $y'_i = x'_i$, then in the above notations we have $w_i = 0$, $\Delta_i = 0$ and we get that the answers of the players are the same on the $i$th coordinate, so they are consistent on $i$.

6 Open Problems

In this section, we propose several challenges for further investigation of symmetric parallel repetition.

Recall from the introduction that on general games a strong parallel repetition theorem still fails, even for symmetric repetition. A simple example is the union of many disjoint, odd cycle games. It would be interesting to understand for what instances of Max-Cut one has that a strong parallel holds with symmetric repetition, motivating the following problem.

Problem 1. For the Max-Cut problem, extend the family of graphs for which symmetric parallel repetition outperforms standard parallel repetition.

Optimistically, one may hope that if symmetric parallel repetition would work for general enough class of graphs, then one would be able to reduce any graph to a graph in that class by mild preprocessing that doesn’t affect the value of the game by much, and only then perform symmetric repetition. If possible, that would establish the equivalence of the Max-Cut Conjecture and UGC.

Secondly, there are well-known connections between parallel repetition and notions of mixing times and eigenvalues of the underlying graph; for example, a strong parallel repetition theorem is known to hold for expander graphs [31, 3], and more generally for graphs with low threshold rank [35], i.e. graphs with only constantly many eigenvalues close to 1. We expect there could be stronger relations between symmetric parallel repetition and higher order eigenvalues of $G^\otimes_{\text{sym}}^k$, the $k$-fold symmetric tensor product of $G$.

Problem 2. What is the relation between the performance of the $k$-fold symmetric parallel repetition of a given instance of Max-Cut $G$, and the first $k + 1$ eigenvalues of $G$?

Finally, we believe that solving the foam problem for special classes of bodies may be an interesting geometric question (albeit unrelated to the study of parallel repetition); a very natural class to study is the class of convex bodies.

A Deferred proofs

A.1 Proof of Claim 30

We split the proof into two cases.

Case 1: \( r_i \leq T/2 \) for all \( i \)

In this case, \( \min(r_i, T - r_i) = r_i \) for all \( i \), and the sum on the RHS of (7) is just \( (\sum_i |d_i|)/T \).

We have

\[
\|p - q\|_1 = \sum_i \frac{r_i + d_i}{T'} - \frac{r_i}{T} \leq \sum_i \frac{r_i + d_i}{T'} - \frac{r_i}{T} + \sum_i \frac{r_i + d_i}{T'} - \frac{r_i + d_i}{T} \\
= \sum_i \frac{|d_i|}{T'} + \frac{1}{T'} - \frac{1}{T} \cdot \sum_i (r_i + d_i) \\
= \sum_i \frac{|d_i|}{T'} + \frac{1}{T'} \cdot \sum_i d_i \\
\leq 2 \cdot \sum_i \frac{|d_i|}{T'}.
\]

Case 2: one of the \( r_i \)'s is greater than \( T/2 \)

Without loss of generality, \( r_1 > T/2 \). Denote by \( S := \sum_{i>1} r_i = T - r_1 \); \( S' := \sum_{i>1} (r_i + d_i) = T' - r_1 - d_1 \). In this case, the RHS of (7) is given by

\[
\frac{|d_1| \cdot S}{r_1 \cdot T} + \sum_{i>1} \frac{|d_i|}{T'}.
\]

(18)

We will estimate \( |p_1 - q_1| \) and \( \sum_{i>1} |p_i - q_i| \) separately. First, note that \( T' \geq T - \sum_j |d_j| \geq T/2 \).

For \( |p_1 - q_1| \), we have

\[
|p_1 - q_1| = \left| \frac{r_1}{T} - \frac{r_1 + d_1}{T'} \right| = \left| \frac{r_1 \cdot (S' - S) + d_1 \cdot S}{T \cdot T'} \right| \leq 2 \left| \frac{S' - S}{T} \right| + 2 \frac{|d_1| \cdot S}{T \cdot r_1 \cdot T'} \\
\leq \sum_{i>1} \frac{|d_i|}{T} + \frac{|d_1| \cdot S}{r_1 \cdot T}.
\]

In the third transition, we used the fact that \( T' \geq T/2 \geq r_1/2 \).

For \( \sum_{i>1} |p_i - q_i| \), by a similar calculation to the first case we have

\[
\sum_{i>1} |p_i - q_i| = \sum_{i>1} \left| \frac{r_i + d_i}{T'} - \frac{r_i}{T} \right| \leq \sum_{i>1} \left| \frac{r_i + d_i}{T'} - \frac{r_i}{T} \right| + \sum_{i>1} \left| \frac{r_i + d_i}{T'} - \frac{r_i + d_i}{T} \right| \\
\leq \sum_{i>1} \frac{|d_i|}{T'} + \frac{1}{T'} - \frac{1}{T} \cdot \sum_{i>1} r_i + d_i \\
= \sum_{i>1} \frac{|d_i|}{T'} + \frac{1}{T'} - \frac{1}{T} \cdot S',
\]
and it is enough to bound \( \frac{1}{T'} - \frac{1}{T} \) \( S' \) by constant times the expression in (18). We have
\[
\frac{1}{T'} - \frac{1}{T} S' = \left| \frac{S' \cdot (S' - S) + S' \cdot d_1}{T'} \right| \leq \frac{(S' + d_1) \cdot (S' - S)}{T'} + \frac{S \cdot d_1}{T'} \leq \frac{S' \cdot (S' - S)}{T'} + \frac{d_1 \cdot (S' - S)}{T'} + 2 \cdot \frac{S \cdot d_1}{T^2},
\]
where in the last transition we used \( T' \geq T/2 > 0 \). We bound each term separately. For the first term, as \( T' \geq T/2, |S'| \leq 2T \) (since \( |d_i| \leq r_i \) we get
\[
\frac{|S' \cdot (S' - S)|}{T'} \leq 4 \frac{|S' - S|}{T} \leq 4 \sum_{i \geq 2} \frac{|d_i|}{T}.
\]
For the second term, we have \( |d_1| \leq r_1 \leq T, T' \geq T/2 \) and so
\[
\frac{|d_1 \cdot (S' - S)|}{T'} \leq 2 \frac{|S' - S|}{T} \leq 2 \sum_{i \geq 2} \frac{|d_i|}{T}.
\]
For the third term, we have, as \( T \geq r_1, \frac{S \cdot d_1}{T^2} \leq \frac{|d_1|}{r_1 T} \).

### A.2 Proof of Proposition 33

We will use the fact for points \( x_i \) in our domain, \( g_j(x_i) \asymp \left( \frac{n}{\log n} \alpha_i \right)^3 \). We consider two cases, based on the values of \( S \) and \( r \).

**Case 1:** \( \Pr_{x_i} [r \cdot g_j(x_i) > S] < 1/2 \)

We claim that for a sufficiently large constant \( A > 0 \),
\[
\mathbb{E}_{x_i} \left[ \sqrt{z + \frac{1}{\alpha_i^2}} \cdot \frac{\min (r \cdot g_j(x_i), S)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}} \right] \leq \mathbb{E}_{x_i} \left[ \sqrt{z + An^2 / \log^2 n} \cdot \frac{\min (r \cdot g_j(x_i), S)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}} \right].
\]

To do that, we compare both sides to \( \mathbb{E}_{x_i} \left[ \sqrt{z + \frac{\min (r \cdot g_j(x_i), S)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}}} \right] \). For (I), we have
\[
\mathbb{E}_{x_i} \left[ \left( \sqrt{z + \frac{1}{\alpha_i^2}} - \sqrt{z} \right) \cdot \frac{\min (r \cdot g_j(x_i), S)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}} \right] \leq \mathbb{E}_{x_i} \left[ \sqrt{z + \frac{1}{\alpha_i^2}} \cdot \frac{\min (r \cdot g_j(x_i), S)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}} \right] - \mathbb{E}_{x_i} \left[ \sqrt{z + \frac{1}{\alpha_i^2}} \cdot \frac{\min (r \cdot g_j(x_i), S)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}} \right].
\]

Since \( \alpha_i \lesssim \log n/n \) always, we may further upper bound this by
\[
\leq \mathbb{E}_{x_i} \left[ \frac{1}{\sqrt{z + A / (\log n/n)^2}} \cdot \frac{\min (r \cdot g_j(x_i), S)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}} \right] \leq \mathbb{E}_{x_i} \left[ \frac{1}{\sqrt{z + A / (\log n/n)^2}} \cdot \frac{\min (r \cdot g_j(x_i), S)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}} \right] \leq \mathbb{E}_{x_i} \left[ \frac{1}{\sqrt{z + A / (\log n/n)^2}} \cdot \frac{\min (r \cdot g_j(x_i), S)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}} \right],
\]

where we used \( \min (r \cdot g_j(x_i), S) \leq r g_j(x_i) \) and the asymptotic we have for \( g_j \). Simplifying and using \( \mathbb{E}_{x_i} [\alpha_i] \lesssim \log n/n \), we get that the last expression is equal to
\[
\frac{n^2}{\log^2 n} \frac{1}{\sqrt{z + An^2 / \log^2 n}} \cdot \frac{r}{S + \varepsilon^{1.6}}.
\]
For \((II)\), we have
\[
\mathbb{E}_{x_i} \left[ \left( \frac{\sqrt{x + A n^2 / \log^2 n - \sqrt{x}}}{\sqrt{\frac{An^2 / \log^2 n}{x + A n^2 / \log^2 n} + \varepsilon}} \cdot \min \left( r \cdot g_j(x_i), S \right) \right) - \frac{r \cdot g_j(x_i) + S + \varepsilon^{1.6}}{r \cdot g_j(x_i) + S} \right] \geq \mathbb{E}_{x_i} \left[ \frac{An^2 / \log^2 n}{\sqrt{x + An^2 / \log^2 n} + \varepsilon^{1.6}} \cdot \frac{r \cdot g_j(x_i) + S + \varepsilon^{1.6}}{r \cdot g_j(x_i) + S} \right].
\]
Restricting to the event \(E\) that \(rg_j(x_i) \leq S\) (that has probability at least 1/2 by assumption), we have that the last expression is at least
\[
\mathbb{E}_{x_i} \left[ \left( \frac{\sqrt{x + 1 / \alpha_i^2 - \sqrt{x}} - \sqrt{x}}{\sqrt{\frac{An^2 / \log^2 n}{x + 1 / \alpha_i^2 - \sqrt{x}} + \varepsilon}} \cdot \min \left( \frac{r \cdot g_j(x_i)}{r \cdot g_j(x_i) + S}, S \right) \right) + \mathbb{E}_{x_i} \left[ \frac{1}{\alpha_i} \cdot \frac{\min \left( r \cdot g_j(x_i), S \right)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}} \right].
\]
where the last inequality holds since \(\mathbb{E}_{x_i} \left[ g_j(x_i) \right] \geq 1\) (this is true for any event \(E\) with constant probability in our range of interest of \(x_i\)'s). Combining the bounds for \((I), (II)\), we see that we may pick large enough \(A\) so that
\[
\mathbb{E}_{x_i} \left[ \left( \frac{\sqrt{x + 1 / \alpha_i^2 - \sqrt{x}}}{\sqrt{\frac{An^2 / \log^2 n}{x + 1 / \alpha_i^2 - \sqrt{x}}}} \cdot \min \left( \frac{r \cdot g_j(x_i)}{r \cdot g_j(x_i) + S}, S \right) \right) \right] \geq \frac{An^2 / \log^2 n}{\sqrt{x + An^2 / \log^2 n}} \cdot \frac{r}{S + \varepsilon^{1.6}}.
\]
and hence \((I) \leq (II)\). Let \(A_1\) be a large enough value of \(A\) so that this holds.

**Case 2: \(\Pr_{x_i} \left[ r \cdot g_j(x_i) > S \right] \geq 1/2\)**

Using \(\sqrt{a + b} \leq \sqrt{a} + \sqrt{b}\), we have
\[
\mathbb{E}_{x_i} \left[ \frac{1}{\sqrt{\frac{An^2 / \log^2 n}{x + A n^2 / \log^2 n} + \varepsilon}} \cdot \frac{\min \left( r \cdot g_j(x_i), S \right)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}} \right] \leq \mathbb{E}_{x_i} \left[ \sqrt{\frac{A n^2 / \log^2 n}{x + A n^2 / \log^2 n} + \varepsilon^{1.6}} \cdot \frac{\min \left( r \cdot g_j(x_i), S \right)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}} \right].
\]
Clearly, \((III) \leq \mathbb{E}_{x_i} \left[ \sqrt{\frac{A n^2 / \log^2 n}{x + A n^2 / \log^2 n} + \varepsilon^{1.6}} \cdot \frac{\min \left( r \cdot g_j(x_i), S \right)}{r \cdot g_j(x_i) + S + \varepsilon^{1.6}} \right],\) and we upper bound \((IV)\). Recall that
\[
g_j(x_i) \asymp \left( \frac{n}{\log n} \alpha_i \right)^{1/3},\]
so
\[
(IV) \leq \mathbb{E}_{x_i} \left[ \frac{1}{\alpha_i} \cdot \frac{\min \left( r \cdot g_j(x_i)/\log n, S \right)}{r \cdot g_j(x_i)/\log n + S + \varepsilon^{1.6}} \right],\]
for some absolute constant \(B > 0\). Writing the last expression as an integral, we note that \(\alpha_i\) is distributed uniformly on the interval \([0, \log n / \sqrt{\log n} + \varepsilon^{0.55}]\), so we get
\[
(IV) \lesssim \left( \frac{n}{\log n} \right) \int_0^{\log n} \frac{1}{B \cdot r(n \alpha_i / \log n)^3 + S + \varepsilon^{1.6}} dt.
\]
We break the range of integration into \(R_1 = \left[ 0, (S/r)^{1/3} \log n \right] \) and \(R_2 = \left[ (S/r)^{1/3} \log n, \log n / \sqrt{\log n} \right] \).

On \(R_1\) our expression is equal to
\[
\left( \frac{n}{\log n} \right)^2 \int_0^{(S/r)^{1/3} \log n / \sqrt{\log n}} \frac{r(n \alpha_i / \log n)^3 + S + \varepsilon^{1.6}}{B \cdot r(n \alpha_i / \log n)^3 + S + \varepsilon^{1.6}} dt \lesssim \left( \frac{n}{\log n} \right)^4 \int_0^{(S/r)^{1/3} \log n / \sqrt{\log n}} \frac{r^2}{S} dt \lesssim \frac{n}{\log n}.
\]
On $R_2$ our expression is at most
\[
\left( \frac{n}{\log n} \right) \int_{(\frac{S}{n})^{1/3} \log n}^{\frac{6}{n} \log n} \frac{S}{t} \frac{1}{B \cdot t/(nt \log n)^3} \, dt \leq \frac{S}{n} \left( \frac{\log n}{n} \right)^2 \int_{(\frac{S}{n})^{1/3} \log n}^{\frac{6}{n} \log n} \frac{1}{t^4} \, dt.
\]
Computing the integral, we see it is at most $\left( (\frac{S}{n})^{1/3} \log n \right)^{-3}$, hence the overall expression is \( \lesssim \frac{n}{\log n}, \) and since \( \mathbb{E} \left[ I_{r_j(x_i) > S} \right] \geq 1/2 \) we conclude that there is \( A_2 > 0 \) such that
\[
(IV) \leq A_2 \frac{n}{\log n} \mathbb{E} \left[ I_{r_j(x_i) > S} \right].
\]

The proposition is thus proven for \( A = \max(A_1, A_2) \).

**B. From Noise Sensitivity to Surface Area**

Let \( D_F \) be a family of tilings of \( \mathbb{R}^n \) that are constructed from Lemma 24. I.e., the family \( D_F \) satisfies that the there is \( A = O(n/\sqrt{\log n}) \) such that for sufficiently small \( \varepsilon \), we have that
\[
\mathbb{E}_F \left[ \Pr_{\vec{x} \in D_F} [\vec{x}, \vec{x} + \Delta \text{ fall in different cells of the tiling induced by } D_F] \right] \leq A \varepsilon.
\]

Let \( k_0 \) be the first integer such that this condition holds for any \( 0 < \varepsilon \leq 2^{-k_0} \). Thus, defining for each \( k \geq k_0 \) the set
\[
G_k = \left\{ \vec{r} \mid \Pr_{\vec{x} \in D_F} [\vec{x}, \vec{x} + \Delta \text{ lie in different cells of the tiling of } S_{\vec{r}}] \leq 2 \cdot A 2^{-k} \right\},
\]
we have by Markov’s inequality that \( \Pr_{\vec{r}} [\vec{r} \in G_k] \geq \frac{1}{2} \).

> **Claim 58.** The sets \( G_k \) are monotone decreasing, i.e. for each \( k, G_{k+1} \subseteq G_k \).

**Proof.** Fix \( \vec{r} \in G_{k+1} \). Let \( \Delta \sim N(0, 4^{-k-1} \cdot I_n) \), and note that \( \Delta' = 2 \cdot \Delta \sim N(0, 4^{-k} \cdot I_n) \). Thus,
\[
\Pr_{\vec{x} \in D_F} [\vec{x}, \vec{x} + \Delta' \text{ in different cells}] \leq \Pr_{\vec{x} \in D_F} [\vec{x}, \vec{x} + \Delta \text{ in different cells}] \sim N(0, A 4^{-k-1} \cdot I_n) + \Pr_{\vec{x} \in D_F} [\vec{x} + \Delta, \vec{x} + 2 \Delta \text{ in different cells}]. \tag{19}
\]

First, we argue that the second probability on the right hand side is equal to the first one. To see that, denote \( y = x + \Delta \) and observe that the points \( y, y + \Delta \) lie in different cells of the tiling induced by \( D_F \) if and only if the points \( y \) (mod \( D_F \)), \( y \) (mod \( D_F \)) + \( \Delta \) lie in different cells. Additionally, note for any fixed \( \Delta \), the distribution of \( y \) (mod \( D_F \)) when we take \( x \in_R D_F \), is uniform over \( D_F \).

Therefore, the bound we get from (19) is (using the fact that \( \vec{r} \in G_{k+1} \))
\[
2 \cdot \Pr_{\vec{x} \in D_F} [\vec{x}, \vec{x} + \Delta \text{ in different cells}] \leq 2 \cdot 2 \cdot A 2^{-(k+1)} = 2 \cdot A 2^{-k},
\]
and so \( \vec{r} \in G_k \).
▷ Claim 59. It holds that \( \Pr \left[ \vec{r} \in \bigcap_{k \geq k_0} G_k \right] \geq \frac{1}{2} \), and in particular \( \bigcap_{k \geq k_0} G_k \) is not empty.

Proof. Define the sequence of functions \( g_m(\vec{r}) = 1_{\vec{r} \in \bigcap_{k \geq k_0} G_k} \), and also \( g = 1_{\vec{r} \in \bigcap_{k \geq k_0} G_k} \).

Clearly, on each \( \vec{r} \), the sequence \( g_m(\vec{r}) \) is monotonically decreasing to \( g(\vec{r}) \), and in other words we have monotone pointwise convergence of the non-negative functions \( g_m \) to \( g \). Thus, by the monotone convergence theorem

\[
\Pr \left[ \vec{r} \in \bigcap_{k \geq 0} G_k \right] = \mathbb{E}_{\vec{r}} \left[ g(\vec{r}) \right] = \mathbb{E}_{\vec{r}} \left[ \lim_{k \to \infty} g_k(\vec{r}) \right] = \lim_{k \to \infty} \mathbb{E}_{\vec{r}} \left[ g_k(\vec{r}) \right].
\]

By the previous claim, \( g_m = 1_{G_m} \), hence \( \mathbb{E}_{\vec{r}} \left[ g_m(\vec{r}) \right] \geq \frac{1}{2} \) and in particular the limit above is at least \( \frac{1}{2} \).

Pick \( \vec{r}^* \in \bigcap_{k \geq k_0} G_k \), \( \varepsilon = 2^{-k_0} \) and denote \( D = D_{\vec{r}^*} \), for the rest of the proof. Clearly \( D \) induces a tiling of the space \( \mathbb{R}^n \), and next we will show that the surface area of \( D \) is \( O(A) = O(n/\sqrt{\log n}) \), as desired.

Towards this end, we will use Lemma 10 that tells us that the surface area of \( D \) is a constant multiple of

\[
\frac{1}{\varepsilon} \mathbb{E}_{x \in R, \Delta \sim N(0,\varepsilon I_n)} \left| (x, x + \Delta) \cap \partial D \right|
\]

and we first observe that \( (x, x + \Delta) \cap \partial D \) is almost surely countable. 4

▷ Claim 60. Let \( \varepsilon > 0 \) and sample \( x \in R, \Delta \sim N(0,\varepsilon I_n) \). Then with probability 1, \( (x, x + \Delta) \cap \partial D \) is finite or countable.

Proof. Recall that by Lemma 24, \( D \) is a countable union of semi-algebraic sets, say \( B_1, B_2, \ldots \).

Note that for each semi-algebraic set \( B_i \), the probability that \( (x, x + \Delta) \cap \partial B_i \) is infinite is 0, hence by the union bound, with probability 1 all of these sets are finite, in which case \( (x, x + \Delta) \cap \partial D \) is finite or countable.

For a parameter \( h \), a point \( x \in \mathbb{R}^n \) and a direction \( \Delta \), we say a point \( y \in (x, x + \Delta) \) is \( h \)-isolated if

1. It holds that \( y \in \partial D \).
2. The neighbourhood of radius \( h \) around \( y \) does not contain \( x, x + \Delta \) or any point from \( \partial D \) besides \( y \).

Define the quantity \( g_m(x, \Delta) \) to be the number of \( 2^{-m} \|\Delta\|_2 \)-isolated points in the interval \( [x, x + \Delta] \).

▷ Claim 61. \( g_m(x, \Delta) \) is an increasing sequence in \( m \), and for any \( x, \Delta \) for which Claim 60 holds, we have

\[
\lim_{m \to \infty} g_m(x, \Delta) = \left| (x, x + \Delta) \cap \partial D \right|.
\]

Proof. The monotonicity of \( g_m(x, \Delta) \) in \( m \), and \( g_m(x, \Delta) \leq \left| (x, x + \Delta) \cap \partial D \right| \) are clear. We set \( \ell = g_m(x, \Delta) \) and split the rest of the proof according to whether \( \ell \) is finite or not.

---

4 The diligent reader may note that here, we are only considering intersections of the surface with the open interval \( [x, x + \Delta] \) as opposed to the closed interval. This does not make any difference, since the contribution of the endpoints is proportional to the measure of \( \partial D \). Hence, if the measure of \( \partial D \) is 0 they endpoints contribute 0 to that expectation, and if the measure of \( \partial D \) is positive, then the expectation is infinite either way.
Case 1: $\ell$ is finite

In this case we argue that $g_m(x, \Delta) = |(x, x + \Delta) \cap \partial D|$ for large enough $m$. To see that, let $y_1, \ldots, y_t \in (x, x + \Delta)$ be all of the intersection points of $(x, x + \Delta)$ and $\partial D$, and take large enough $m$ so that $2^{-m}\|\Delta\|_2$ is smaller than all of the distances $\|y_i - y_j\|_2$, $\|y_i - x\|_2$, and $\|y_i - (x + \Delta)\|_2$ for all $i$ and $j$.

Case 1: $\ell$ is infinite

Consider the set $S = [x, x + \Delta] \cap \partial D$, and note that it is a closed. By Claim 60, $S$ is countable, and we argue that $S$ must have an isolated point. Otherwise, $S$ is a closed set and has no isolated point, i.e. it is a perfect set, but then it must be uncountable (e.g. see [1]). We thus conclude that $S$ has an isolated point $w_1$; we may remove it from $S$, have that the resulting set is again closed and countable, so we may again find an isolated point. Repeating this argument, for any $v \in \mathbb{N}$ we may find a collection of isolated points $w_1, \ldots, w_v \in S$ that are all different from $x$ and $x + \Delta$. As in case 1, we conclude that $g_m(x, \Delta) \geq v$ for large enough $m$, and since it holds for any $v$ we conclude that $\lim_{m \to \infty} g_m(x, \Delta) = \infty$.

By Lemma 10, we have that the surface area of $D$ is at most a constant multiple of

$$\frac{1}{\varepsilon} \mathbb{E}_{\Delta \sim N(0, \varepsilon^2 I_n)} |(x, x + \Delta) \cap \partial D| = \frac{1}{\varepsilon} \mathbb{E}_{\Delta \sim N(0, \varepsilon^2 I_n)} \left[ \lim_{m \to \infty} g_m(x, \Delta) \right] = \lim_{m \to \infty} \mathbb{E}_{\Delta \sim N(0, \varepsilon^2 I_n)} [g_m(x, \Delta)].$$

In the first transition we used Claims 61 and 60, and in the second one we used monotone convergence. Thus, if we assume that the surface area of $D$ is larger than $c \cdot A$ for a sufficiently large absolute constant $c$, then we get that $\lim_{m \to \infty} \frac{1}{\varepsilon} \mathbb{E}_{\Delta \sim N(0, \varepsilon^2 I_n)} [g_m(x, \Delta)] \geq 10A$. In the rest of the proof we will reach a contradiction and thereby show that for sufficiently large absolute constant $c$, the surface area of $D$ is at most $cA$, as required.

By properties of limits, we conclude there exists $m$ such that

$$\mathbb{E}_{\Delta \sim N(0, \varepsilon^2 I_n)} [g_m(x, \Delta)] \geq 5A \varepsilon,$$  \hfill (20)

and we fix this $m$ henceforth.

Take $0 < \delta \leq 2^{-m}$, and consider the following experiment. Take $x \in R$ uniformly at random, $\Delta \sim N(0, \varepsilon^2 I_n)$ and take a uniformly random point $y \in R [x, x + \Delta]$. We consider the event $E$ in which the points $y$ and $y + \delta \Delta$ lie in different cells in the tiling induced by $D$.

\begin{claim}
For any $x, \Delta$ we have that $\Pr_y [E \mid x, \Delta] \geq \delta g_m(x, \Delta)$.
\end{claim}

\begin{proof}
Let $\ell = g_m(x, \Delta)$, and let $z_1, \ldots, z_\ell$ be the $2^{-m}\|\Delta\|_2$-isolated points on the interval $(x, x + \Delta)$. For each $j$, let $I_j = (z_j - \delta \Delta, z_j)$, and note that as $\delta \leq 2^{-m}$ and the isolation of the points, we conclude that the intervals $I_j$ are disjoint and contained in $(x, x + \Delta)$. Also, note that if we pick $y \in I_j$, then $y$ and $y + \delta \Delta$ lie in different cells of the tiling induced by $D$; this holds since the interval between them contains exactly one point from $\partial D$ (namely, the point $z_j$). Therefore,

$$\Pr_y [E \mid x, \Delta] \geq \sum_{j=1}^\ell \Pr_y [y \in I_j \mid x, \Delta] \geq \sum_{j=1}^\ell \frac{\delta \|\Delta\|_2}{\|\Delta\|_2} = \delta \ell.$$  \hfill \qed
\end{proof}
 Claim 63. \( \Pr_{x, \Delta, y}[E] \leq 2A\delta \varepsilon \).

Proof. Consider \( x, \Delta, y \) the random variables in the definition of the event \( E \). Let \( z = y \) (mod \( D \)), and note that the points \( y \) and \( y + \delta \Delta \) fall in different cells if and only if the points \( z \) and \( z + \delta \Delta \) fall in different cells. Therefore, the probability of \( E \) is exactly the probability that \( z, z + \delta \Delta \) fall in different cells. Further, note that conditioned on \( \Delta \), the distribution of \( z \) is uniform over \( D \), so

\[
\Pr_{\Delta \sim N(0, \varepsilon^2 I_n)}[z, z + \delta \Delta \text{ lie in different cells of } D] = \Pr_{\Delta' \sim N(0, \delta^2 \varepsilon^2 I_n)}[z, z + \delta \Delta' \text{ lie in different cells of } D],
\]

which is at most \( 2A\delta \varepsilon \) by the choice of \( D \) and the fact that \( \delta \varepsilon \leq \varepsilon \leq 2^{-k_0} \). ▷

Combining the above claims we reach a contradiction:

\[
2A\delta \varepsilon \geq \Pr_{x, \Delta, y}[E] = \mathbb{E}_{x, \Delta}[\Pr_y[E \mid x, \Delta]] \geq \mathbb{E}_{x, \Delta}[\delta g_m(x, \Delta)] \geq \delta \cdot 5A\varepsilon,
\]

and contradiction. The first transition is by Claim 62, the second transition is by conditional probability formula, the third transition is by Claim 63 and the final one is by equation (20).

Abstract

The Stabbing Planes proof system [8] was introduced to model the reasoning carried out in practical mixed integer programming solvers. As a proof system, it is powerful enough to simulate Cutting Planes and to refute the Tseitin formulas – certain unsatisfiable systems of linear equations mod2 – which are canonical hard examples for many algebraic proof systems. In a recent (and surprising) result, Dadush and Tiwari [25] showed that these short refutations of the Tseitin formulas could be translated into quasi-polynomial size and depth Cutting Planes proofs, refuting a long-standing conjecture. This translation raises several interesting questions. First, whether all Stabbing Planes proofs can be efficiently simulated by Cutting Planes. This would allow for the substantial analysis done on the Cutting Planes system to be lifted to practical mixed integer programming solvers. Second, whether the quasi-polynomial depth of these proofs is inherent to Cutting Planes.

In this paper we make progress towards answering both of these questions. First, we show that any Stabbing Planes proof with bounded coefficients ($SP^*$) can be translated into Cutting Planes. As a consequence of the known lower bounds for Cutting Planes, this establishes the first exponential lower bounds on $SP^*$. Using this translation, we extend the result of Dadush and Tiwari to show that Cutting Planes has short refutations of any unsatisfiable system of linear equations over a finite field. Like the Cutting Planes proofs of Dadush and Tiwari, our refutations also incur a quasi-polynomial blow-up in depth, and we conjecture that this is inherent. As a step towards this conjecture, we develop a new geometric technique for proving lower bounds on the depth of Cutting Planes proofs. This allows us to establish the first lower bounds on the depth of Semantic Cutting Planes proofs of the Tseitin formulas.

1 Introduction

An effective method for analyzing classes of algorithms is to formalize the techniques used by the class into a formal proof system, and then analyze the formal proof system instead. By doing this, theorists are able to hide many of the practical details of implementing these algorithms, while preserving the class of methods that the algorithms can feasibly employ. Indeed, this approach has been applied to study many different families of algorithms, such as

- **Conflict-driven clause-learning** algorithms for SAT [41, 49, 61], which can be formalized using **resolution** proofs [27].
- Optimization algorithms using **semidefinite programming** [34, 51], which can often be formalized using **Sums-of-Squares proofs** [6, 38].
- The classic **cutting planes** algorithms for integer programming [18, 35], which are formalized by **cutting planes proofs** [18, 19, 23].

In the present work, we continue the study of formal proof systems corresponding to modern integer programming algorithms. Recall that in the integer programming problem, we are given a polytope \( P \subseteq \mathbb{R}^n \) and a vector \( c \in \mathbb{R}^n \), and our goal is to find a point \( x \in P \cap \mathbb{Z}^n \) maximizing \( c \cdot x \). The classic approach to solving this problem – pioneered by Gomory [35] – is to add\(^1\) **cutting planes** to \( P \). A cutting plane for \( P \) is any inequality of the form \( ax \leq \lfloor b \rfloor \), where \( a \) is an integral vector, \( b \) is rational, and every point of \( P \) is satisfied by \( ax \leq b \). By the integrality of \( a \), it follows that cutting planes preserve the integral points of \( P \), while potentially removing non-integral points from \( P \). The cutting planes algorithms then proceed by heuristically choosing “good” cutting planes to add to \( P \) to try and locate the integral hull of \( P \) as quickly as possible.

As mentioned above, these algorithms can be naturally formalized into a proof system – the **Cutting Planes proof system**, denoted \( \text{CP} \) – as follows [23]. Initially, we are given a polytope \( P \), presented as a list of integer-linear inequalities \( \{ ax \leq b \} \). From these inequalities we can then deduce new inequalities using two deduction rules:

- **Linear Combination.** From inequalities \( ax \leq b, cx \leq d \), deduce any non-negative linear combination of these two inequalities with integer coefficients.
- **Division Rule.** From an inequality \( ax \leq b \), if \( d \in \mathbb{Z} \) with \( d \geq 0 \) divides all entries of \( a \) then deduce \( (a/d)x \leq \lfloor b/d \rfloor \).

A Cutting Planes refutation of \( P \) is a proof of the trivially false inequality \( 1 \leq 0 \) from the inequalities in \( P \); clearly, such a refutation is possible only if \( P \) does not contain any integral points. While Cutting Planes has grown to be an influential proof system in propositional proof complexity, the original cutting planes algorithms suffered from numerical instabilities, as well as difficulties in finding good heuristics for the next cutting planes to add [35].

The modern algorithms in integer programming improve on the classical cutting planes method by combining them with a second technique, known as **branch-and-bound**, resulting in a family of optimization algorithms broadly referred to as **branch-and-cut algorithms**. These algorithms search for integer solutions in a polytope \( P \) by recursively repeating the following two procedures: First, \( P \) is split into smaller polytopes \( P_1, \ldots, P_k \) such that \( P \cap \mathbb{Z}^n \subseteq \bigcup_{i \in [k]} P_i \) (i.e. branching). Next, cutting planes deductions are made in order to further refine the branched polytopes (i.e. cutting). In practice, branching is usually performed by selecting a variable \( x_i \) and branching on all possible values of \( x_i \); that is, recursing on \( P \cap \{ x_i = t \} \) for each feasible integer value \( t \). More complicated branching

\(^1\) Throughout, we will say that a cutting plane, or an inequality is added to a polytope \( P \) to mean that it is added to the set of inequalities defining \( P \).
schemes have also been considered, such as branching on the hamming weight of subsets of variables [31], branching using basis-reduction techniques [1,2,45], and more general linear inequalities [42,47,50].

However, while these branch-and-cut algorithms are much more efficient in practice than the classical cutting planes methods, they are no longer naturally modelled by Cutting Planes proofs. So, in order to model these solvers as proof systems, Beame et al. [8] introduced the Stabbing Planes proof system. Given a polytope \( P \) containing no integral points, a Stabbing Planes refutation of \( P \) proceeds as follows. We begin by choosing an integral vector \( a \), an integer \( b \), and replacing \( P \) with the two polytopes \( P \cap \{ ax \leq b - 1 \} \) and \( P \cap \{ ax \geq b \} \). Then, we recurse on these two polytopes, continuing until all descendant polytopes are empty (that is, they do not even contain any real solutions). The majority of branching schemes used in practical branch-and-cut algorithms (including all of the concrete schemes mentioned above) are examples of this general branching rule.

It is now an interesting question how the two proof systems – Cutting Planes and Stabbing Planes – are related. By contrasting the two systems we see at least three major differences:

- **Top-down vs. Bottom-up.** Stabbing Planes is a top-down proof system, formed by performing queries on the polytope and recursing; while Cutting Planes is a bottom-up proof system, formed by deducing new inequalities from old ones.

- **Polytopes vs. Halfspaces.** Individual “lines” in a Stabbing Planes proof are polytopes, while individual “lines” in a Cutting Planes proof are halfspaces.

- **Tree-like vs. DAG-like.** The graphs underlying Stabbing Planes proofs are trees, while the graphs underlying Cutting Planes proofs are general DAGs: intuitively, this means that Cutting Planes proofs can “re-use” their intermediate steps, while Stabbing Planes proofs cannot.

When taken together, these facts suggest that Stabbing Planes and Cutting Planes could be incomparable in power, as polytopes are more expressive than halfspaces, while DAG-like proofs offer the power of line-reuse. Going against this natural intuition, Beame et al. proved that Stabbing Planes can actually efficiently simulate Cutting Planes [8] (see Figure 1).

Furthermore, they proved that Stabbing Planes is equivalent to the proof system \( \text{treeR}(\text{CP}) \), denoted \( \text{treeR}(\text{CP}) \), which was introduced by Krajíček [44], and whose relationship to Cutting Planes was previously unknown.

This leaves the converse problem – of whether Stabbing Planes can also be simulated by Cutting Planes – as an intriguing open question. Beame et al. conjectured that such a simulation was impossible, and furthermore that the Tseitin formulas provided a separation between these systems [8]. For any graph \( G \) and any \( \{0,1\} \)-labelling \( \ell \) of the vertices of \( G \), the Tseitin formula of \((G,\ell)\) is the following system of \( \mathbb{F}_2 \)-linear equations: for each edge \( e \) we introduce a variable \( x_e \), and for each vertex \( v \) we have an equation

\[
\bigoplus_{u:uv\in E} x_{uv} = \ell(v)
\]

asserting that the sum of the edge variables incident with \( v \) must agree with its label \( \ell(v) \) (note such a system is unsatisfiable as long as \( \sum_v \ell(v) \) is odd). On the one hand, Beame et al. proved that there are quasi-polynomial size Stabbing Planes refutations of the Tseitin formulas [8]. On the other hand, Tseitin formulas had long been conjectured to be exponentially hard for Cutting Planes [23], as they form one of the canonical families of hard examples for algebraic and semi-algebraic proof systems, including Nullstellensatz [37], Polynomial Calculus [17], and Sum-of-Squares [38,59].

In a recent breakthrough, the long-standing conjecture that Tseitin was exponentially hard for Cutting Planes was refuted by Dadush and Tiwari [25], who gave quasi-polynomial size Cutting Planes refutations of Tseitin instances. Moreover, to prove their result, Dadush...
and Tiwari showed how to translate the quasipolynomial-size Stabbing Planes refutations of Tseitin into Cutting Planes refutations. This translation result is interesting for several reasons. First, it brings up the possibility that Cutting Planes can actually simulate Stabbing Planes. If possible, such a simulation would allow the significant analysis done on the Cutting Planes system to be lifted directly to branch-and-cut solvers. In particular, this would mean that the known exponential-size lower bounds for Cutting Planes refutations would immediately imply the first exponential lower bounds for these algorithms for arbitrary branching heuristics. Second, the translation converts shallow Stabbing Planes proofs into very deep Cutting Planes proofs: the Stabbing Planes refutation of Tseitin has depth $O(\log^2 n)$ and quasi-polynomial size, while the Cutting Planes refutation has quasipolynomial size and depth. This is quite unusual since simulations between proof systems typically preserve the structure of the proofs, and thus brings up the possibility that the Tseitin formulas yield a supercritical size/depth tradeoff – formulas with short proofs, requiring superlinear depth. For contrast: another simulation from the literature which emphatically does not preserve the structure of proofs is the simulation of bounded-size resolution by bounded-width resolution by Ben-Sasson and Wigderson [10]. In this setting, it is known that this simulation is tight [14], and even that there exist formulas refutable in resolution width $w$ requiring maximal size $n^{\Omega(w)}$ [5]. Furthermore, under the additional assumption that the proofs are tree-like, Razborov [56] proved a supercritical trade-off between width and size.

### 1.1 Our Results

#### A New Characterization of Cutting Planes

Our first main result gives a characterization of Cutting Planes proofs as a natural subsystem of Stabbing Planes that we call Facelike Stabbing Planes. A Stabbing Planes query is facelike if one of the sets $P \cap \{ax \leq b - 1\}$ or $P \cap \{ax \geq b\}$ is either empty or is a face of the polytope $P$, and a Stabbing Planes proof is said to be facelike if it only uses facelike queries. Our main result is the following theorem.

▶ **Theorem 1.** The proof systems CP and Facelike SP are polynomially equivalent.

The proof of this theorem is inspired by Dadush and Tiwari’s upper bound for the Tseitin formulas. Indeed, the key tool underlying both their proof and ours is a lemma due to Schrijver [60] which allows us to simulate CP refutations of faces of a polytope, when beginning from $P$ itself.

Using this equivalence we prove the following surprising simulation (see Figure 1), stating that Stabbing Planes proofs with relatively small coefficients (quasi-polynomially bounded in magnitude) can be quasi-polynomially simulated by Cutting Planes.

▶ **Theorem 2.** Let $F$ be any unsatisfiable CNF formula on $n$ variables, and suppose that there is a SP refutation of $F$ in size $s$ and maximum coefficient size $c$. Then there is a CP refutation of $F$ in size $s (cn)^{\log s}$.

In fact, we prove a more general result (Theorem 16) which holds for arbitrary polytopes $P \in \mathbb{R}^n$, rather than only for CNF formulas, which degrades with the diameter of $P$. This should be contrasted with the work of Dadush and Tiwari [25], who show that any SP proof of size $s$ of a polytope with diameter $d$ can be assumed to have coefficients of size $(nd)^{O(n^2)}$.

As a second application of Theorem 1, we generalize Dadush and Tiwari upper bound for Tseitin to show that Cutting Planes can refute any unsatisfiable system of linear equations over a finite field. This follows by showing that, like Tseitin, we can refute such systems of linear equations in quasi-polynomial-size Facelike SP.
**Theorem 3.** Let $F$ be the CNF encoding of an unsatisfiable system of $m$ linear equations over a finite field. There is a CP refutation of $F$ of size $|F|^{O(\log m)}$.

This should be contrasted with the work of Filmus, Hrubeš, and Lauria [30], which gives several unsatisfiable systems of linear equations over $\mathbb{R}$ that require exponential size refutations in Cutting Planes (see Figure 1).

**Lower Bounds**

An important open problem is to prove superpolynomial size lower bounds for Stabbing Planes proofs. We make significant progress toward this goal by proving the first superpolynomial lower bounds on the size of low-weight Stabbing Planes proofs. Let $\text{SP}^*$ denote the family of Stabbing Planes proofs in which each coefficient has at most quasipolynomial $(n^{\log^{O(1)} n})$ magnitude.

**Theorem 4.** There exists a family of unsatisfiable CNF formulas $\{F_n\}$ such that any $\text{SP}^*$ refutation of $F$ requires size at least $2^n^{\varepsilon}$ for constant $\varepsilon > 0$.

Our proof follows in a straightforward manner from Theorem 2 together with known Cutting Planes lower bounds. We view this as a step toward proving SP lower bounds (with no restrictions on the weight). Indeed, lower bounds for $\text{CP}^*$ (low-weight Cutting Planes) [15] were first established, and led to (unrestricted) CP lower bounds [54].

Our second lower bound is a new linear depth lower bound for semantic Cutting Planes proofs. (In a semantic Cutting Planes proof the deduction rules for CP are replaced by a simple and much stronger semantic deduction rule).

**Theorem 5.** For all sufficiently large $n$ there is a graph $G$ on $n$ vertices and a labelling $\ell$ such that the Tseitin formula for $(G, \ell)$ requires $\Omega(n)$ depth to refute in Semantic Cutting Planes.

We note that depth lower bounds for Semantic Cutting Planes have already established via communication complexity arguments. However, since Tseitin formulas have short communication protocols, our depth bound for semantic Cutting Planes proofs of Tseitin is new.

Theorem 5 is established via a new technique for proving lower bounds on the depth of semantic Cutting Planes proofs. Our technique is inspired by the result of Buresh-Oppenheim et al. [16], who proved lower bounds on the depth of Cutting Planes refutations of Tseitin by studying the Chátal rank of the associated polytope $P$. Letting $P^{(d)}$ be the polytope composed of all inequalities which can be derived in depth $d$ in Cutting Planes. The Chátal rank of $P$ is the minimum $d$ such that $P^{(d)} = \emptyset$. Thus, in order to establish a depth lower bound...
On the Power and Limitations of Branch and Cut

bound of depth $d$, one would like to show the existence of a point $p \in P^{(d)}$. To do so, they give a sufficient criterion for a point $p$ to be in $P^{(i)}$ in terms of the points in $P^{(i-1)}$. This criterion relies on a careful analysis of the specific rules of Cutting Planes, and is no longer sufficient for semantic CP. Instead, we develop an analogous criterion for semantic CP by using novel geometric argument (Lemma 28) which we believe will be of independent interest.

Our main motivation behind this depth bound is as a step towards proving a supercritical tradeoff in CP for Tseitin formulas. A supercritical tradeoff for CP, roughly speaking, states that small size CP proofs must sometimes necessarily be very deep – that is, beyond the trivial depth upper bound of $O(n)$ $[11,56]$. (Observe that Dadush and Tiwari’s quasipolynomial-size CP refutations of Tseitin are quasipolynomially deep; this is preserved by our simulation of Facelike Stabbing Planes by Cutting Planes in Theorem 1.) Establishing supercritical tradeoffs is a major challenge, both because hard examples witnessing such a tradeoff are rare, and because current methods seem to fail beyond the critical regime. In fact, to date the only supercritical tradeoffs between size and depth for known proof systems are due to Razborov, under the additional assumption that the proofs have bounded width. Namely, Razborov exhibited a supercritical size-depth tradeoff for bounded width tree-like resolution $[56]$, and then extended this result to CP proofs in which each inequality has a bounded number of distinct variables $[57]$.

How could one prove a supercritical depth lower bound for Cutting Planes? All prior depth lower bounds for Cutting Planes proceed by either reducing to communication complexity, or by using so-called protection lemmas (e.g. $[16]$). Since communication complexity is always at most $n$, it will be useless for proving supercritical lower bounds directly. It therefore stands to reason that we should focus on improving the known lower bounds using protection lemmas and, indeed, our proof of Theorem 5 is a novel geometric argument which generalizes the top-down “protection lemma” approach $[16]$ for syntactic CP. At this point in time we are currently unable to use protection lemma techniques to prove size-depth tradeoffs, so, we leave this as an open problem.

▶ Conjecture 6. There exists a family of unsatisfiable formulas $\{F_n\}$ such that $F_n$ has quasipolynomial-size CP proofs, but any quasipolynomial-size proof requires superlinear depth.

1.2 Related Work

Lower Bounds on SP and treeR(CP)

Several lower bounds on subsystems of SP and treeR(CP) have already been established. Krajíček $[44]$ proved exponential lower bounds on the size of R(CP) proofs in which both the width of the clauses and the magnitude of the coefficients of each line in the proof are bounded. Concretely, let these bounds be $w$ and $c$ respectively. The lower bound that he obtains is $2^{n^{\Omega(1)}}/w^{\log^2 n}$. Kojvevnikov $[43]$ removed the dependence on the coefficient size for treeR(CP) proofs, obtaining a bound of $\exp(\Omega(\sqrt{n/w \log n}))$. Beame et al. $[8]$ provide a size-preserving simulation of Stabbing Planes by treeR(CP) which translates a depth $d$ Stabbing Planes proof into a width $d$ treeR(CP) proof, and therefore this implies lower bounds on the size of SP proofs of depth $o(n/\log n)$. Beame et al. $[8]$ exhibit a function for which there are no SP refutations of depth $o(n/\log^2 n)$ via a reduction to the communication complexity of the CNF search problem.
Supercritical Tradeoffs

Besides the work of Razborov [56], a number of supercritical tradeoffs have been observed in proof complexity. Perhaps most relevant for our work, Razborov [57] proved a supercritical tradeoff for Cutting Planes proofs under the assumption that each inequality has a bounded number of distinct variables (mimicking the bound on the width of each clause in the supercritical tradeoff of [56]).

A number of supercritical tradeoffs are also known between proof width and proof space. Beame et al. [7] and Beck et al. [9] exhibited formulas which admit polynomial size refutations in Resolution and the Polynomial Calculus respectively, and such that any refutation of sub-linear space necessitates a superpolynomial blow-up in size. Recently, Berkholz and Nordström [11] gave a supercritical trade-off between width and space for Resolution.

Depth in Cutting Planes and Stabbing Planes

It is widely known (and easy to prove) that any unsatisfiable family of CNF formulas can be refuted by exponential size and linear depth Cutting Planes. It is also known that neither Cutting Planes nor Stabbing Planes can be balanced, in the sense that a depth-\(d\) proof can always be transformed into a size \(2^{O(d)}\) proof [8,16]. This differentiates both of these proof systems from more powerful proof systems like Frege, for which it is well-known how to balance arbitrary proofs [22]. Furthermore, even though both the Tseitin principles and systems of linear equations in finite fields can be proved in both quasipolynomial-size and \(O(\log^2 n)\) depth in Facelike SP, the simulation of Facelike SP by CP cannot preserve both size and depth, as the Tseitin principles are known to require depth \(\Theta(n)\) to refute in CP [16].

We first recall the known depth lower bound techniques for Cutting Planes, semantic Cutting Planes, and Stabbing Planes proofs. In all of these proof systems, arguably the primary method for proving depth lower bounds is by reducing to real communication complexity [8,40]; however, communication complexity is always trivially upper bounded by \(n\), and it is far from clear how to use the assumption on the size of the proof to boost this to superlinear.

A second class of methods have been developed for syntactic Cutting Planes, which lower bound rank measures of a polytope, such as the Chvátal rank. In this setting, lower bounds are typically proven using so-called protection lemmas [16], which seems much more amenable to applying a small-size assumption on the proof. We also remark that for many formulas (such as the Tseitin formulas!) it is known how to achieve \(\Omega(n)\)-depth lower bounds in Cutting Planes via protection lemmas, while proving even \(\omega(\log n)\) lower bounds via communication complexity is impossible, due to a known folklore upper bound.

The first lower bound on the Chvátal rank was established by Chvátal et al. [20], who proved a linear bound for a number of polytopes in \([0,1]^n\). Much later, Pokutta and Schulz [53] characterized the polytopes \(P \subseteq [0,1]^n\) with \(P \cap \mathbb{Z}^n = \emptyset\) which have Chvátal rank exactly \(n\). However, unlike most other cutting planes procedures, the Chvátal rank is not of polytopes \(P \cap [0,1]^n\) with \(P \cap \mathbb{Z}^n = \emptyset\) is not upper bounded by \(n\). Eisenbrand and Schulz [29] showed that the Chvátal rank of any polytope \(P \subseteq [0,1]^n\) is at most \(O(n^2 \log n)\) and gave examples where it is \(\Omega(n)\); a nearly-matching quadratic lower bound was later established by Rothvoß and Sanita [58]. For CNF formulas, the Chvátal rank is (trivially) at most \(n\). Buresh-Oppenheim et al. [16] gave the first lower bounds on the Chvátal rank a number of CNF formulas, including an \(\Omega(n)\) lower bound for the Tseitin formulas.

The rank of a number of generalizations of Cutting Planes has been studied as well. However, none of these appear to capture the strength of semantic Cutting Planes. Indeed, semantic Cutting Planes is able to refute Knapsack in a single cut, and therefore is known...
not to be polynomially verifiable unless $P = \text{NP}$ [30]. Lower bounds on the rank when using split cuts and mixed integer cuts, instead of CG cuts, was established in [24]. Pokutta and Schulz [52] obtained $\Omega(n/\log n)$ rank lower bounds on the complete tautology (which includes every clause of width $n$) for the broad class of admissible cutting planes, which includes syntactic Cutting Planes, split cuts, and many of the lift-and-project operators. Bodur et al. [13] studied the relationship between rank and integrality gaps for another broad generalization of Cutting Planes known as aggregate cuts.

2 Preliminaries

We first recall the definitions of some key proof systems.

Resolution

Fix an unsatisfiable CNF formula $F$ over variables $x_1, \ldots, x_n$. A Resolution refutation $P$ of $F$ is a sequence of clauses $\{C_i\}_{i \in [s]}$ ending in the empty clause $C_s = \emptyset$ such that each $C_i$ is in $F$ or is derived from earlier clauses $C_j, C_k$ with $j, k < i$ using one of the following rules:

- Resolution. $C_i = (C_j \setminus \{\ell_k\}) \cup (C_k \setminus \{\ell_j\})$ where $\ell_k \in C_j$, $\ell_j \in C_k$ is a literal.
- Weakening. $C_i \supseteq C_j$.

The size of the resolution proof is $s$, the number of clauses. It is useful to visualize the refutation $P$ as a directed acyclic graph; with this in mind the depth of the proof (denoted $\text{depth}_{\text{Res}}(P)$) is the length of the longest path in the proof DAG. The resolution depth $\text{depth}_{\text{Res}}(F)$ of $F$ is the minimal depth of any resolution refutation of $F$.

Cutting Planes and Semantic Cutting Planes

A Cutting Planes (CP) proof of an inequality $ax \geq d$ from a system of linear inequalities $P$ is given by a sequence of inequalities

$$a_1 x \geq b_1, a_2 x \geq b_2, \ldots, a_s x \geq b_s$$

such that $a_s = c$, $b_s = d$, and each inequality $a_i x \geq b_i$ is either in $P$ or is deduced from earlier inequalities in the sequence by applying one of the two rules Linear Combination or Division Rule described at the beginning of Section 1. We will usually be interested in the case that the list of inequalities $P$ defines a polytope.

An alternative characterization of Cutting Planes uses Chvátal-Gomory cuts (or just CG cuts) [18, 23]. Let $P$ be a polytope. A hyperplane $ax = b$ is a supporting for $P$ if $b = \max \{ax : x \in P\}$, and if $ax = b$ is a supporting hyperplane then the set $P \cap \{x \in \mathbb{R}^n : ax = b\}$ is called a face of $P$. An inequality $ax \leq b$ is valid for $P$ if every point of $P$ satisfies the inequality and $ax = b$ is a supporting hyperplane of $P$.

Definition 7. Let $P \subseteq \mathbb{R}^n$ be a polytope, and let $ax \geq b$ be any valid inequality for $P$ such that all coefficients of $a$ are relatively prime integers. The halfspace $\{x \in \mathbb{R}^n : ax \geq [b]\}$ is called a CG cut for $P$. (We will sometimes abuse notation and refer to the inequality $ax \geq [b]$ also as a CG cut.)

If $ax \geq [b]$ is a CG cut for the polytope $P$, then we can derive $ax \geq [b]$ from $P$ in $O(n)$ steps of Cutting Planes by Farkas Lemma (note that the inequality $ax \geq b$ is valid for $P$ by definition, so we can deduce $ax \geq b$ as a linear combination of the inequalities of $P$ and then apply the division rule). If $P$ is a polytope and $H$ is a CG cut, then we will write $P \vdash P \cap H$, and say that $P \cap H$ is derived from $P$. 

6:8 On the Power and Limitations of Branch and Cut
Given a CNF formula $F$, we can translate $F$ into a system of linear inequalities in the following natural way. First, for each variable $x_i$ in $F$ add the inequality $0 \leq x_i \leq 1$. If $C = \bigvee_{i \in P} x_i \lor \bigvee_{i \in N} \neg x_i$ is a clause in $F$, then we add the inequality
\[
\sum_{i \in P} x_i + \sum_{i \in N} (1 - x_i) \geq 1.
\]

It is straightforward to see that the resulting system of inequalities will have no integral solutions if and only if the original formula $F$ is unsatisfiable. With this translation we consider Cutting Planes refutations (defined in the introduction) of $F$ to be refutations of the translation of $F$ to linear inequalities.

The semantic Cutting Planes proof system (denoted sCP or Semantic CP) is a strengthening of Cutting Planes proofs to allow any deduction that is sound over Boolean points [15]. Like Cutting Planes, an sCP proof is given by a sequence of halfspaces $\{a_i x \geq c_i\}_{i \in [s]}$, but now we can use the following very powerful semantic deduction rule:

- **Semantic Deduction.** From $a_j x \geq c_j$ and $a_k x \geq c_k$ deduce $a_i x \geq c_i$ if every $\{0, 1\}$ assignment satisfying both $a_j x \geq c_j$ and $a_k x \geq c_k$ also satisfies $a_i x \geq c_i$.

Filmus et al. [30] showed that sCP is extremely strong: there are instances for which any refutation in CP requires exponential size, and yet these instances admit polynomial-size refutations in semantic sCP.

The size of a Cutting Planes proof is the number of lines (it is known that for unsatisfiable CNF formulas, the CP-depth at most $O(n^2 \log n)$, and moreover there are examples requiring CP-depth more than $n$ [29]. However for unsatisfiable CNF formulas, the CP-depth is at most $n$ [12].

**Stabbing Planes**

Let $F$ be an unsatisfiable system of linear inequalities. A Stabbing Planes (SP) refutation of $F$ is a directed binary tree, $T$, where each edge is labelled with a linear integral inequality satisfying the following consistency conditions:

- **Internal Nodes.** For any internal node $u$ of $T$, if the right outgoing edge of $u$ is labelled with $ax \geq b$, then the left outgoing edge is labelled with its integer negation $ax \leq b - 1$.

- **Leaves.** Each leaf node $v$ of $T$ is labelled with a non-negative linear combination of inequalities in $F$ with inequalities along the path leading to $v$ that yields $0 \geq 1$.

For an internal node $u$ of $T$, the pair of inequalities $(ax \leq b - 1, ax \geq b)$ is called the query corresponding to the node. Every node of $T$ has a polytope $P$ associated with it, where $P$ is the polytope defined by the intersection of the inequalities in $F$ together with the inequalities labelling the path from the root to this node. We will say that the polytope $P$ corresponds to this node. The slab corresponding to the query is $\{x^* \in \mathbb{R}^n \mid b - 1 < ax^* < b\}$, which is the set of points ruled out by this query. The width of the slab is the minimum distance between $ax \leq b - 1$ and $ax \geq b$, which is $1/\|a\|_2$. The size of a refutation is the bit-length needed to encode a description of the entire proof tree, which, for CNF formulas as well as sufficiently bounded systems of inequalities, is polynomially equivalent to the number of queries in the refutation [25]. As well, the depth of the refutation is the depth of the binary tree. The proof system $SP^*$ is the subsystem of Stabbing Planes obtained by restricting all coefficients of the proofs to have magnitude at most quasi-polynomial ($n^{\log^{O(1)} n}$) in the number of input variables.
The Stabbing Planes proof system was introduced by Beame et al. [8] as a generalization of Cutting Planes that more closely modelled query algorithms and branch-and-bound solvers. Beame et al. proved that SP is equivalent to the proof system TreeR(CP) introduced by Krajíček [44] which can be thought of as a generalization of Resolution where the literals are replaced with integer-linear inequalities.

3 Translating Stabbing Planes into Cutting Planes

3.1 Equivalence of CP with Subsystems of SP

In this section we prove Theorem 1, restated below, which characterizes Cutting Planes as a non-trivial subsystem of Stabbing Planes.

▶ Theorem 8 (Theorem 1). The proof systems CP and Facelike SP are polynomially equivalent.

We begin by formally defining Facelike SP.

▶ Definition 9. A Stabbing Planes query \((ax \leq b - 1, ax \geq b)\) at a node \(P\) is facelike if one of the sets \(P \cap \{x \in \mathbb{R}^n : ax \leq b - 1\}\), \(P \cap \{x \in \mathbb{R}^n : ax \geq b\}\) is empty or a face of \(P\) (see Figure 2b). An SP refutation is facelike if every query in the refutation is facelike.

En route to proving Theorem 1, it will be convenient to introduce the following further restriction of Facelike Stabbing Planes.

▶ Definition 10. A Stabbing Planes query \((ax \leq b - 1, ax \geq b)\) at a node corresponding to a polytope \(P\) is pathlike if at least one of \(P \cap \{x \in \mathbb{R}^n : ax \leq b - 1\}\) and \(P \cap \{x \in \mathbb{R}^n : ax \geq b\}\) is empty (see Figure 2a). A Pathlike SP refutation is one in which every query is pathlike.

The name “pathlike” stems from the fact that the underlying graph of a pathlike Stabbing Planes proof is a path, since at most one child of every node has any children (see Figure 2). In fact, we have already seen (nontrivial) pathlike SP queries under another name: Chvátal-Gomory cuts.

▶ Lemma 11. Let \(P\) be a polytope and let \((ax \leq b - 1, ax \geq b)\) be a pathlike Stabbing Planes query for \(P\). Assume w.l.o.g. that \(P \cap \{x \in \mathbb{R}^n : ax \leq b - 1\} = \emptyset\) and that \(P \cap \{x \in \mathbb{R}^n : ax \geq b\}\) is a face of \(P\). Then \(ax \geq b\) is a CG cut for \(P\).

Proof. Since \(ax \geq b\) is falsified by some point in \(P\), it follows that there exists some \(0 < \varepsilon < 1\) such that \(ax \geq b - \varepsilon\) is valid for \(P\) – note that \(\varepsilon < 1\) since otherwise \(ax \leq b - 1\) would not have empty intersection with \(P\). This immediately implies that \(ax \geq b\) is a CG cut for \(P\).

With this observation we can easily prove that Pathlike SP is equivalent to CP. Throughout the remainder of the section, for readability, we will use the abbreviation \(P \cap \{ax \geq b\}\) for \(P \cap \{x \in \mathbb{R}^n : ax \geq b\}\), for any polytope \(P\) and linear inequality \(ax \geq b\).

▶ Lemma 12. Pathlike SP is polynomially equivalent to CP.

Proof. First, let \(a_1x \geq b_1, a_2x \geq b_2, \ldots, a_sx \geq b_s\) be a CP refutation of an unsatisfiable system of linear inequalities \(Ax \geq b\). Consider the sequence of polytopes \(P_0 = \{Ax \geq b\}\) and \(P_i = P_{i-1} \cap \{a_i x \geq b_i\}\). By inspecting the rules of CP, it can observed that \(P_i \cap \{a_i x \leq b_i - 1\} = \emptyset\) and thus \(P_{i+1}\) can be deduced using one pathlike SP query from \(P_i\) for all \(0 \leq i \leq s\).
Conversely, let $P$ be any polytope and let $(ax \leq b - 1, ax \geq b)$ be any pathlike SP query to $P$ (so, suppose w.l.o.g. that the halfspace defined by $ax \leq b - 1$ has empty intersection with $P$). By Lemma 11, $ax \geq b$ is a CG cut for $P$, and so can be deduced in Cutting Planes from the inequalities defining $P$ in length $O(n)$ (cf. Section 2). Applying this to each query in the Pathlike SP proof yields the theorem.

Next, we show how to simulate Facelike SP proofs by Pathlike SP proofs of comparable size. The proof of Lemma 14 is inspired by Dadush and Tiwari [25], and will use the following lemma due to Schrijver [60] (although, we use the form appearing in [23]). Recall that we write $P \vdash P'$ for polytopes $P, P'$ to mean that $P'$ can be obtained from $P$ by adding a single CG cut to $P$.

\begin{lemma}
Let $P$ be a polytope defined by a system of integer linear inequalities and let $F$ be a face of $P$. If $F \vdash F'$ then there is a polytope $P'$ such that $P \vdash P'$ and $P' \cap F \subseteq F'$.
\end{lemma}

\begin{lemma}
Facelike SP is polynomially equivalent to Pathlike SP.
\end{lemma}

\begin{proof}
That Facelike SP simulates Pathlike SP follows by the fact that any Pathlike SP query is a valid query in Facelike SP. For the other direction, consider an SP refutation $\pi$ of size $t$. We describe a recursive algorithm for generating a Pathlike SP proof from $\pi$. The next claim will enable our recursive case.
On the Power and Limitations of Branch and Cut

Claim. Let $P$ be a polytope and suppose $ax \geq b$ is valid for $P$. Assume that $P \cap \{ax = b\}$ has a Pathlike SP refutation using $s$ queries. Then $P \cap \{ax \geq b + 1\}$ can be derived from $P$ in Pathlike SP using $s + 1$ queries.

Proof of Claim. Since $ax \geq b$ is valid for $P$ it follows that $F = P \cap \{ax = b\}$ is a face of $P$ by definition. Consider the Pathlike SP refutation $F_0, F_1, \ldots, F_s = \emptyset$, where the $i$th polytope $F_i$ for $i < s$ is obtained from $F_{i-1}$ by applying a pathlike SP query and proceeding to the non-empty child. Without loss of generality we may assume that $F_i \subseteq F_{i-1}$ for all $i$, and so applying Lemma 11 we have that $F_{i-1} \vdash F_i$ for all $i$. Thus, by applying Lemma 13 repeatedly, we get a sequence of polytopes $P = P_0 \vdash P_1 \vdash \cdots \vdash P_s$ such that $P_i \cap F = P_i \cap \{ax = b\} \subseteq F_i$. This means that $P_s \cap \{ax = b\} \subseteq F_s = \emptyset$, and so $(ax \leq b, ax \geq b + 1)$ is Pathlike SP query for $P_s$. This means that $P_s \vdash P_s \cap \{ax \geq b + 1\} \subseteq P \cap \{ax \geq b + 1\}$. Since any CG cut can be implemented as a Pathlike SP query the claim follows by applying the $s$ CG cuts as pathlike queries, followed by the query $(ax \leq b, ax \geq b + 1)$.

We generate a Pathlike SP refutation by the following recursive algorithm, which performs an in-order traversal of $\pi$. At each step of the recursion (corresponding to a node in $\pi$) we maintain the current polytope $P$ we are visiting and a Pathlike SP proof $\Pi$ – initially, $P$ is the initial polytope and $\Pi = \emptyset$. We maintain the invariant that when we finish the recursive step at node $P$, the Pathlike SP refutation $\Pi$ is a refutation of $P$. The algorithm is described next:

1. Let $(ax \leq b - 1, ax \geq b)$ be the current query and suppose that $ax \geq b - 1$ is valid for $P$.
2. Recursively refute $P \cap \{ax \leq b - 1\} = P \cap \{ax = b - 1\}$, obtaining a Pathlike SP refutation $\Pi$ with $t$ queries.
3. Apply the above Claim to deduce $P \cap \{ax \geq b\}$ from $P$ in $t + 1$ queries.
4. Refute $P \cap \{ax \geq b\}$ by using the SP refutation for the right child.

Correctness follows immediately from the Claim, and also since the size of the resulting proof is the same as the size of the SP refutation.

Theorem 1 then follows by combining Lemma 12 with Lemma 14.

### 3.2 Simulating SP$^*$ by CP

In this section we prove Theorem 2, restated below for convenience.

*Theorem 15* (Theorem 2). Let $F$ be any unsatisfiable CNF formula on $n$ variables, and suppose that there is a SP refutation of $F$ in size $s$ and maximum coefficient size $c$. Then there is a CP refutation of $F$ in size $s(cn)^{\log s}$.

To prove this theorem, we will show that any low coefficient SP proof can be converted into a Facelike SP proof with only a quasi-polynomial loss. If $P$ is a polytope let $d(P)$ denote the diameter of $P$, which is the maximum Euclidean distance between any two points in $P$. Theorem 2 follows immediately from the following theorem.

*Theorem 16*. Let $P$ be a polytope and suppose there is an SP refutation of $P$ with size $s$ and maximum coefficient size $c$. Then there is a Facelike SP refutation of $P$ in size

$$s(c \cdot d(P) \sqrt{n})^{\log s}.$$

**Proof.** The theorem is by induction on $s$. Clearly, if $s = 1$ then the tree is a single leaf and the theorem is vacuously true.
We proceed to the induction step. Let $P$ be the initial polytope and $\pi$ be the SP proof. Consider the first query $(ax \leq b, ax \geq b + 1)$ made by the proof, and let $\pi_L$ be the SP proof rooted at the left child (corresponding to $ax \leq b$) and $\pi_R$ be the SP proof rooted at the right child. Let $P_L$ denote the polytope at the left child and $P_R$ denote the polytope at the right child. By induction, let $\pi'_L$ and $\pi'_R$ be the Facelike SP refutations for $P_L$ and $P_R$ guaranteed by the statement of the theorem.

Suppose w.l.o.g. that $|\pi_L| \leq |\pi|/2$. Let $b_0$ be the largest integer such that $ax \geq b_0$ is satisfied for any point in $P$. The plan is to replace the first query $(ax \leq b, ax \geq b + 1)$ with a sequence of queries $q_0, q_1, \ldots, q_{t-1}$ such that

- For each $i$, $q_i = (ax \leq b_0 + i, ax \geq b_0 + i + 1)$.
- The query $q_0$ is the root of the tree and $q_i$ is attached to the right child of $q_{i-1}$ for $i \geq 1$.

$|q_i - d|_{\infty}$

After doing this replacement, instead of having two child polytopes $P_L, P_R$ below the top query, we have $t + 1$ polytopes $P_0, P_1, \ldots, P_{t+1}$ where $P_i = P \cap \{ax = b_0 + i\}$ and $P_{i+1} = P_R$. To finish the construction, for each $i \leq t$ use the proof $\pi'_L$ to refute $P_i$ and the proof $\pi'_R$ to refute $P_{i+1}$.

We need to prove three statements: this new proof is a valid refutation of $P$, the new proof is facelike, and that the size bound is satisfied.

First, it is easy to see that this is a valid proof, since for each $i \leq t$ the polytope $P_i \subseteq P_L$ and $P_{i+1} \subseteq P_R$ – thus, the refutations $\pi'_L$ and $\pi'_R$ can be used to refute the respective polytopes.

Second, to see that the proof is facelike, first observe that all the queries in the subtrees $\pi'_L, \pi'_R$ are facelike queries by the inductive hypothesis. So, we only need to verify that the new queries at the top of the proof are facelike queries, which can easily be shown by a quick induction. First, observe that the query $q_0$ is a facelike query, since $b_0$ was chosen so that $ax \geq b_0$ is valid for the polytope $P$. By induction, the query $q_i = (ax \leq b_0 + i, ax \geq b_0 + i + 1)$ is a facelike query since the polytope $P_i$ associated with that query is $P \cap \{ax \geq b_0 + i\}$ by definition. Thus $ax \geq b_0 + i$ is valid for the polytope at the query.

Finally, we need to prove the size upper bound. Let $s$ be the size of the original proof, $s_L$ be the size of $\pi_L$, and $s_R$ be the size of $\pi_R$. Observe that the size of the new proof is given by the recurrence relation

\[ f(s) = t \cdot f(s_L) + f(s_R). \]

where $f(1) = 1$. Since the queries $q_0, q_1, \ldots, q_{t-1}$ cover the polytope $P_L$ with slabs of width $1/\|a\|_2$, it follows that

\[ t \leq d(P_L) \|a\|_2 \leq d(P) \sqrt{n} \|a\|_\infty = d(P)c\sqrt{n} \]

where we have used that the maximum coefficient size in the proof is $c$. Thus, by induction, the previous inequality, and the assumption that $s_L \leq s/2$, we can conclude that the size of the proof is

\[ f(s) \leq s_L(c \cdot d(P)\sqrt{n})^\log s_L + s_R(c \cdot d(P)\sqrt{n})^\log s_R \]

\[ \leq s_L(c \cdot d(P)\sqrt{n})^\log(s/2) + s_R(c \cdot d(P)\sqrt{n})^\log s \]

\[ \leq s_L(c \cdot d(P)\sqrt{n})^\log s + s_R(c \cdot d(P)\sqrt{n})^\log s = s(c \cdot d(P)\sqrt{n})^\log s. \]

\[ \Box \]
Theorem 2 follows immediately, since for any CNF formula $F$ the encoding of $F$ as a system of linear inequalities is contained in the $n$-dimensional cube $[0,1]^n$, which has diameter $\sqrt{n}$. We may also immediately conclude Theorem 4 by applying the known lower bounds on the size of Cutting Planes proofs $[32,33,39,54]$. As a consequence of Theorem 2 and the non-automatability of Cutting Planes $[36]$, we can conclude that $SP^*$ proofs cannot be found efficiently assuming $P \neq \text{NP}$.

\textbf{Corollary 17.} $SP^*$ is not automatable unless $P \neq \text{NP}$.

This follows by observing that the argument in $[36]$ does not require large coefficients.

## 4 Refutations of Linear Equations over a Finite Field

In this section we prove Theorem 3. To do so, we will extend the approach used by Beame et al. $[8]$ to prove quasi-polynomial upper bounds on the Tseitin formulas to work on any unsatisfiable set of linear equations over any finite field.

If $ax = b$ is a linear equation we say the \textit{width} of the equation is the number of non-zero variables occurring in it. Any width-$d$ linear equation over a finite field of size $q$, denoted $F_q$, can be represented by a CNF formula with $q^{d-1}$ width-$d$ clauses – one ruling out each falsifying assignment. For a width-$d$ system of $m$ linear equations $F$ over $F_q$, we will denote by $|F| := mq^{d-1}$ the size of the CNF formula encoding $F$.

\textbf{Theorem 18.} Let $F = \{f_1 = b_1, \ldots, f_m = b_m\}$ be a width-$d$, unsatisfiable set of linear equations over $F_q$. There is an SP refutation of (the CNF encoding of) $F$ in size $(mqd)^{(\log m)}q^d = |F|^{(\log m)}$.

First we sketch the idea for $F_2$, i.e., a system of XOR equations. In this case the SP proof corresponds to a branch decomposition procedure which is commonly used to solve SAT (see e.g. $[3,26,28,46]$). View the system $F$ as a hypergraph over $n$ vertices (corresponding to the variables) and with a $d$-edge for each equation. Partition the set of hyperedges into two sets $E = E_1 \cup E_2$ of roughly the same size, and consider the \textit{cut} of vertices that belong to both an edge in $E_1$ and in $E_2$. Using the SP rule we branch on all possible values of the sum of the cut variables in order to isolate $E_1$ and $E_2$. Once we know this sum, we are guaranteed that either $E_1$ is unsatisfiable or $E_2$ is unsatisfiable depending on the parity of the of the sum of the cut variables. This allows us to recursively continue on the side of the cut ($E_1$ or $E_2$) that is unsatisfiable. Since there are $n$ Boolean variables, each cut corresponds to at most $n + 1$ possibilities for the sum, and if we maintain that the partition of the hyper edges defining the cut is balanced, then we will recurse at most $O(\log m)$ times. This gives rise to a tree decomposition of fanout $O(n)$ and height $O(\log n)$.

Over a finite field of size $q$ the proof will proceed in much the same way. Instead of a subgraph, at each step we will maintain a subset of the equations $I \subseteq [n]$ such that $\{f_i = b_i\}_{i \in I}$ must contain a constraint that is violated by the SP queries made so far. We partition $I$ into two sets $I_1$ and $I_2$ of roughly equal size and query the values $a$ and $b$ of $\sum_{i \in I_1} f_i$ and $\sum_{i \in I_2} f_i$. Because $F$ is unsatisfiable, at least one of $a - \sum_{i \in I_1} b_i \neq 0$ or $b - \sum_{i \in I_2} b_i \neq 0$, meaning that it is unsatisfiable, and we recurse on it.

In the following, we will let $z$ stand for a vector of $F_q$-valued variables $z_i$. When we discuss any form $f := a_x$ where $a \in F_q^n$ and $z$ is a vector of $n$ variables $z_i$, we will implicitly associate it with the linear form $\sum_{i \in [n]} a_i (\sum_{j \in [\log q]} x_{i,j})$ where $x_{i,j}$ are the log $q$ many Boolean variables encoding $z_i$ in the CNF encoding of $F$. 
Proof of Theorem 18. Let $F = \{ f_1 = b_1, \ldots, f_m = b_m \}$ be a system of unsatisfiable linear equations over $\mathbb{F}_q$, where each $f_i = a_i z$ for $a_i \in \mathbb{F}_q^*$ and $b_i \in \mathbb{F}_q$. Because $F$ is unsatisfiable, there exists a $\mathbb{F}_q^*$ linear combination of the equations in $F$ witnessing this; formally, there exists $\alpha \in \mathbb{F}_q^*$ such that $\sum_{i \in \mathcal{I}} \alpha_i f_i \equiv 0 \mod q$, but $\sum_{i \in \mathcal{I}} \alpha_i b_i \not\equiv 0 \mod q$.

Stabbing Planes will implement the following binary search procedure for a violated equation; we describe the procedure first, and then describe how to implement it in Stabbing Planes. In each round we maintain a subset $I \subseteq [m]$ and an integer $k_I$ representing the value of $\sum_{i \in I} \alpha_i f_i$. Over the algorithm, we maintain the invariant that $k_I - \sum_{i \in I} b_i \not\equiv 0 \mod q$, which implies that there must be a contradiction to $F$ inside of the constraints $\{ f_i = b_i \}_{i \in I}$.

Initially, $I = [m]$ and we obtain $k_I$ by querying the value of the sum $\sum_{i \in [m]} \alpha_i f_i$. If $k_I \not\equiv 0 \mod q$ then this contradicts the fact that $\sum_{i \in I} \alpha_i f_i \equiv 0 \mod q$; thus, the invariant holds. Next, perform the following algorithm.

1. Choose a balanced partition $I = I_1 \cup I_2$ (so that $||I_1| - |I_2|| \leq 1$).
2. Query the value of $\sum_{i \in I_1 \cup \mathcal{I}} \alpha_i f_i$ and $\sum_{i \in I_2 \cup \mathcal{I}} \alpha_i f_i$; denote these values by $a$ and $b$ respectively.
3. If $a - \sum_{i \in I_1} \alpha_i b_i \not\equiv 0 \mod q$ then recurse on $I_1$ with $k_{I_1} := a$. Otherwise, if $b - \sum_{i \in I_2} \alpha_i b_i \not\equiv 0 \mod q$ then recurse on $I_2$ with $k_{I_2} := b$.
4. Otherwise (if $a - \sum_{i \in I_1} \alpha_i b_i \equiv b - \sum_{i \in I_2} \alpha_i b_i \equiv 0 \mod q$), then this contradicts the invariant:

$$0 \not\equiv k_I - \sum_{i \in I} \alpha_i b_i = \sum_{i \in I} \alpha_i f_i - b_i = \sum_{i \in I_1} \alpha_i f_i - b_i + \sum_{i \in I_2} \alpha_i f_i - b_i = (a - \sum_{i \in I_1} \alpha_i b_i) + (b - \sum_{i \in I_2} \alpha_i b_i) \equiv 0 \mod q.$$ 

This recursion stops when $|I| = 1$, at which point we have an immediate contradiction between $k_I$ and the single equation indexed by $I$.

It remains to implement this algorithm in SP. First, we need to show how to perform the queries in step 2. Querying the value of any sum $\sum_{i \in \mathcal{I}} \alpha_i f_i$ can be done in a binary tree with at most $q^2md$ leaves, one corresponding to every possible query outcome. Internally, this tree queries all possible integer values for this sum (e.g. $(\sum_{i \in \mathcal{I}} \alpha_i f_i \leq 0, \sum_{i \in \mathcal{I}} \alpha_i f_i \geq 1), (\sum_{i \in \mathcal{I}} \alpha_i f_i \leq 1, \sum_{i \in \mathcal{I}} \alpha_i f_i \geq 2), \ldots$). For the leaf where we have deduced $\sum_{i \in [m]} \alpha_i f_i \leq 0$ we use the fact that each variable is non-negative to deduce that $\sum_{i \in \mathcal{I}} \alpha_i f_i \geq 0$ as well. Note that $q^2md$ is an upper bound on this sum because there are $m$ equations, each containing at most $d$ variables, each taking value at most $(q-1)^2$. Thus, step 2 can be completed in $(q^2md)^2$ queries.

Finally, we show how to derive refinements in the following cases: (i) when we deduced that $\sum_{i \in [m]} \alpha_i f_i \not\equiv 0 \mod q$ at the beginning, (ii) in step 4, (iii) when $|I| = 1$.

(i) Suppose that we received the value $a \not\equiv 0 \mod q$ from querying $\sum_{i \in \mathcal{I}} \alpha_i f_i$. Note that every variable in $\sum_{i \in [m]} \alpha_i f_i$ is a multiple of $q$. Query

$$\left( \sum_{i \in [m]} \alpha_i f_i / q \leq [a / q] - 1, \sum_{i \in [m]} \alpha_i f_i / q \geq [a / q] \right).$$

At the leaf that deduces $\sum_{i \in [m]} \alpha_i f_i / q \leq [a / q] - 1$, we can derive $0 \geq 1$ as a non-negative linear combination of this inequality together with $\sum_{i \in [m]} \alpha_i f_i \geq a$. Similarly, at the other leaf $\sum_{i \in [m]} \alpha_i f_i / q \geq [a / q]$ can be combined with $\sum_{i \in [m]} \alpha_i f_i \leq a$ to derive $0 \geq 1$.

(ii) When $|I| = 1$ we could have queried $\sum_{i \in I} \alpha_i f_i$ (mod $q$) to decrease the number of leaves to $qmd$.\footnote{Note that instead of querying the value of $\sum_{i \in I} \alpha_i f_i$ we could have queried $\sum_{i \in I} \alpha_i f_i$ (mod $q$) to decrease the number of leaves to $qmd$.}
(ii) Suppose that \( a - \sum_{i \in L_t} \alpha_i b_i \equiv b - \sum_{i \in L_s} \alpha_i b_i \equiv 0 \mod q \). Then \( 0 \geq 1 \) is derived by summing \( \sum_{i \in L_t} \alpha_i f_i \geq a, \sum_{i \in L_s} \alpha_i f_i \geq b \) and \( \sum_{i \in L_t} \alpha_i f_i \leq k_t \), all of which have already been deduced.

(iii) When \(|I| = 1\) then we deduced that \( a_I z = k_I \) for \( k_I \neq b_I \mod q \) and we would like to derive a contradiction using the axioms encoding \( a_I z = b_I \). These axioms are presented to \( \text{SP} \) as the linear-inequality encoding of a CNF formula, and while there are no integer solutions satisfying both these axioms and \( a_I z = k_I \), there could in fact be rational solutions. To handle this, we simply force that each of the at most \( d \) variables in \( a_I z \) takes an integer value by querying the value of each variable one by one. As there are at most \( d \) variables, each taking an integer value between 0 and \( q - 1 \), this can be done in a tree with at most \( q^d \) many leaves. At each leaf of this tree we deduce \( 0 \geq 1 \) by a non-negative linear combination with the axioms, the integer-valued variables, and \( a_I z \equiv b_I \).

The recursion terminates in at most \( O(\log m) \) many rounds because the number of equations under consideration halves every time. Therefore, the size of this refutation is \((qmd)^{O(\log m)}q^d\).

Note that by making each query in a balanced tree, this refutation can be carried out in depth \( O(\log^2(mqd)) \).

Finally, we conclude Theorem 3.

**Proof of Theorem 3.** Observe that the \( \text{SP} \) refutation from Theorem 18 is facelike. Indeed, to perform step 2 we query \( (\sum_{i \in L} \alpha_i f_i \leq t - 1, \sum_{i \in L} \alpha_i f_i \geq t) \) from \( t = 1, \ldots, q^2md \). For \( t = 1 \), the halfspace \( \sum_{i \in L} \alpha_i f_i \geq 0 \) is valid for the current polytope because the polytope belongs to the \([0,1]^n\) cube. For each subsequent query, \( \sum_{i \in L} \alpha_i f_i \geq t - 1 \) is valid because the previous query deduced \( \sum_{i \in L} \alpha_i f_i \geq t - 1 \). Similar arguments show that the remaining queries are also facelike. Thus, Lemma 14 completes the proof.

We note that the \( \text{CP} \) refutations that result from Theorem 3 have a very particular structure: they are extremely long and narrow. Indeed, they have depth \( n^{O(\log m)} \). We give a rough sketch of the argument: it is enough to show that most lines \( L_i \) in the \( \text{CP} \) refutation are derived using some previous line \( L_j \) with \( j = O(i) \). This is because the final line would have depth proportional to the size of the proof. To see that the \( \text{CP} \) refutation satisfies this property, observe that for each node visited in the in-order traversal, the nodes in the right subproof \( \pi_R \) depend on the halfspace labelling the root, which in turn depends on the left subproof \( \pi_L \).

## 5 Lower Bound on the Depth of Semantic CP Refutations

Our results from Section 3 suggest an interesting interplay between depth and size of Cutting Planes proofs. In particular, we note that there is a trivial depth \( n \) and exponential size refutation of any unsatisfiable CNF formula in Cutting Planes; however, it is easy to see that the Dadush-Tiwari proofs and our own quasipolynomial size \( \text{CP} \) proofs of Tseitin are also extremely deep (in particular, they are superlinear). Even in the stronger Semantic CP it is not clear that the depth of these proofs can be decreased. However, this does not hold for \( \text{SP} \), which has quasi-polynomial size and poly-logarithmic depth refutations. This motivates Conjecture 6, regarding the existence of a “supercritical” trade-off between size and depth for Cutting Planes [11,56]. The Tseitin formulas are a natural candidate for resolving this conjecture.
In this section we develop a new method for proving depth lower bounds which we believe should be more useful for resolving this conjecture. Our method works not only for CP but also for semantic CP. Using our technique, we establish the first linear lower bounds on the depth of Semantic CP refutations of the Tseitin formulas.

Lower bounds on the depth of syntactic CP refutations of Tseitin formulas were established by Buresh-Openheim et al. [16] using a rank-based argument. Our proof is inspired by their work, and so we describe it next. Briefly, their proof proceeds by considering a sequence of polytopes $P^{(0)} \supseteq \ldots \supseteq P^{(d)}$ where $P^{(i)}$ is the polytope defined by all inequalities that can be derived in depth $i$ from the axioms in $F$. The goal is to show that $P^{(d)}$ is not empty. To do so, they show that a point $p \in P^{(i)}$ is also in $P^{(i+1)}$ if for every coordinate $j$ such that $0 < p_j < 1$, there exists points $p^{(j,0)}, p^{(j,1)} \in P^{(i)}$ such that $p^{(j,b)}_k = b$ if $k = j$ and $p^{(j,b)}_k = p_k$ otherwise. The proof of this fact is syntactic: it relies on the careful analysis of the precise rules of CP.

When dealing with Semantic CP, we can no longer analyze a finite set of syntactic rules. Furthermore, it is not difficult to see that the aforementioned criterion for membership in $P^{(i+1)}$ is no longer sufficient for Semantic CP. We develop an analogous criterion for Semantic CP given later in this section. As well, we note that the definition of $P^{(i)}$ is not well-suited to studying the depth of bounded-size CP proofs like those in Conjecture 6 – there does not appear to be a useful way to limit $P^{(i)}$ to be a polytope derived by a bounded number of halfspaces. Therefore we develop our criterion in the language of lifting, which is more amenable to supercritical tradeoffs [11,56].

Through this section we will work with the following top-down definition of Semantic CP.

**Definition 19.** Let $F$ be an $n$-variate unsatisfiable CNF formula. An sCP refutation of $F$ is a directed acyclic graph of fan-out $\leq 2$ where each node $v$ is labelled with a halfspace $H_v \subseteq \mathbb{R}^n$ (understood as a set of points satisfying a linear inequality) satisfying the following:
1. **Root.** There is a unique source node $r$ labelled with the halfspace $H_v = \mathbb{R}^n$ (corresponding to the trivially true inequality $1 \geq 0$).
2. **Internal-Nodes.** For each non-leaf node $u$ with children $v, w$, we have
   $$H_u \cap \{0,1\}^n \subseteq H_v \cup H_w.$$  
3. **Leaves.** Each sink node $u$ is labeled with a unique clause $C \in F$ such that $H_u \cap \{0,1\}^n \subseteq C^{-1}(0)$.

The above definition is obtained by taking a (standard) sCP proof and reversing all inequalities: now, a line is associated with the set of assignments falsified at that line, instead of the assignments satisfying the line.

To prove the lower bound we will need to find a long path in the proof. To find this path we will be taking a root-to-leaf walk down the proof while constructing a partial restriction $\rho \in \{0,1,*\}^n$ on the variables. For a partial restriction $\rho$, denote by $\text{free}(\rho) := \rho^{-1}(*)$ and $\text{fix}(\rho) := [n] \setminus \text{free}(\rho)$. Let the restriction of $H$ by $\rho$ be the halfspace

$$H | \rho := \{ x \in \mathbb{R}^{\text{free}(\rho)} : \exists \alpha \in H, \ \alpha_{\text{fix}(\rho)} = \rho_{\text{fix}(\rho)}, \ \alpha_{\text{free}(\rho)} = x \}.$$

It is important to note that $H | \rho$ is itself a halfspace on the free coordinates of $\rho$.

One of our key invariants needed in the proof is the following.

**Definition 20.** A halfspace $H \subseteq \mathbb{R}^n$ is good if it contains the all-$\frac{1}{2}$ vector, that is, $(\frac{1}{2})^n = (\frac{1}{2}, \frac{1}{2}, \ldots, \frac{1}{2}) \in H$. 
We will need two technical lemmas to prove the lower bounds. The first lemma shows that if a good halfspace \( H \) has its boolean points covered by halfspaces \( H_1, H_2 \), then one of the two covering halfspaces is also good modulo restricting a small set of coordinates.

**Lemma 21.** Let \( H \subseteq \mathbb{R}^n \) be any good halfspace, and suppose \( H \cap \{0, 1\}^n \subseteq H_1 \cup H_2 \) for halfspaces \( H_1, H_2 \). Then there is a restriction \( \rho \) and an \( i = 1, 2 \) such that \( |\text{fix}(\rho)| \leq 2 \) and \( H_i \upharpoonright \rho \) is good.

The second lemma shows that good halfspaces are robust, in the sense that we can restrict a good halfspace to another good halfspace while also satisfying any mod-2 equation.

**Lemma 22.** Let \( n \geq 2 \) and \( H \subseteq \mathbb{R}^n \) be a good halfspace. For any \( I \subseteq [n] \) with \( |I| \geq 2 \) and \( b \in \{0, 1\} \), there is a partial restriction \( \rho \in \{0, 1, *\}^n \) with \( \text{fix}(\rho) = I \) such that
\[
\bigoplus_{i \in I} \rho(x_i) = b \quad \text{and} \quad H \upharpoonright \rho \subseteq \mathbb{R}^{\text{free}(\rho)} \text{ is good.}
\]

With these two lemmas one can already get an idea of how to construct a long path in the proof. Suppose we start at the root of the proof; the halfspace is \( 1 \geq 0 \) (which is clearly good) and the restriction we maintain is \( \rho = *^n \). We can use the first lemma to move from the current good halfspace to a good child halfspace while increasing the number of fixed coordinates by at most 2. However, we have no control over the two coordinates which are fixed by this move, and so we may fall in danger of falsifying an initial constraint. Roughly speaking, we will use the second lemma to satisfy constraints that are in danger of being falsified.

We delay the proofs of these technical lemmas to the end of the section, and first see how to prove the depth lower bounds.

### 5.1 Lifting Decision Tree Depth to Semantic CP Depth

As a warm-up, we show how to lift lower bounds on Resolution depth to Semantic CP depth by composing with a constant-width XOR gadget. If \( F \) is a CNF formula then we can create a new formula by replacing each variable \( z_i \) with an XOR of 4 new variables \( x_{i,1}, \ldots, x_{i,4} \):

\[
z_i := \text{XOR}_4(x_{i,1}, \ldots, x_{i,4}) = x_{i,1} \oplus \cdots \oplus x_{i,4}.
\]

We call \( z_i \) the **unlifted** variable associated with the output of the XOR_4 gadget applied to the \( i \)-th block of variables. Formally, let \( \text{XOR}_4^n : \{0, 1\}^{4n} \to \{0, 1\}^n \) be the application of XOR_4 to each 4-bit block of a 4n-bit string. Let \( F \circ \text{XOR}_4^n \) denote the formula obtained by performing this substitution on \( F \) and transforming the result into a CNF formula in the obvious way.

The main result of this section is the following.

**Theorem 23.** For any unsatisfiable CNF formula \( F \),
\[
\text{depth}_{\text{ZCP}}(F \circ \text{XOR}_4^n) \geq \frac{1}{2} \text{depth}_{\text{Res}}(F).
\]

Key to our lower bound will be the following characterization of Resolution depth by Prover-Adversary games.

**Definition 24.** The Prover-Adversary game associated with an \( n \)-variate formula \( F \) is played between two competing players, Prover and Adversary. The game proceeds in rounds, where in each round the state of the game is recorded by a partial assignment \( \rho \in \{0, 1, *\}^n \) to the variables of \( F \).
Initially the state is the empty assignment $\rho = \ast^n$. Then, in each round, the Prover chooses an $i \in [n]$ with $\rho_i = \ast$, and the Adversary chooses $b \in \{0, 1\}$. The state is updated by $\rho_i \leftarrow b$ and play continues. The game ends when the state $\rho$ falsifies an axiom of $F$.

It is known [55] that $\text{depth}_{\text{Reg}}(F)$ is exactly the smallest $d$ for which there is a Prover strategy that ends the game in $d$ rounds, regardless of the strategy for the Adversary.

The proof of Theorem 23 will follow by using an optimal Adversary strategy for $F$ to construct a long path in the Semantic CP proof of $F \circ \text{XOR}_1^n$. Crucially, we need to understand how halfspaces $H$ transform under $\text{XOR}_1^n$:

$$\text{XOR}_1^n(H) := \{ z \in \{0,1\}^n : \exists x \in H \cap \{0,1\}^{4n}, \text{XOR}_1^n(x) = z \}.$$  

As we have already stated, we will maintain a partial assignment $\rho \in \{0,1,\ast\}^{4n}$ on the $4n$ lifted variables. However, in order to use the Adversary, we will need to convert $\rho$ to a partial assignment on the $n$ *unlifted* variables. To perform this conversion, for any $\rho \in \{0,1,\ast\}^{4n}$ define $\text{XOR}_1^n(\rho) \in \{0,1,\ast\}^n$ as follows: for each block $i \in [n]$, define

$$\text{XOR}_1^n(\rho)_i = \begin{cases} \text{XOR}_4(\rho(x_{i,1}), \ldots, \rho(x_{i,4})) & \text{if } (i,j) \in \text{fix}(\rho) \text{ for } j \in [4], \\ \ast & \text{otherwise.} \end{cases}$$

We are now ready to prove Theorem 23. Fix any Semantic CP refutation of $F \circ \text{XOR}_1^n$, and suppose that there is a strategy for the Adversary in the Prover-Adversary game of $F$ certifying that $F$ requires depth $d$. Throughout the walk, we maintain a partial restriction $\rho \in \{0,1,\ast\}^{4n}$ to the lifted variables satisfying the following three invariants with respect to the current visited halfspace $H$.

- **Block Closed.** In every block either all variables in the block are fixed or all variables in the block are free.
- **Good Halfspace.** $H \upharpoonright \rho$ is good.
- **Strategy Consistent.** The unlifted assignment $\text{XOR}_1^n(\rho)$ does not falsify any clause in $F$.

Initially, we set $\rho = \ast^n$ and the initial halfspace is $1 \geq 0$, so the pair $(H,\rho)$ trivially satisfy the invariants. Suppose we have reached the halfspace $H$ in our walk and $\rho$ is a restriction satisfying the invariants. We claim that $H$ cannot be a leaf. To see this, suppose that $H$ is a leaf, then by definition $H \cap \{0,1\}^{4n} \subseteq C^{-1}(0)$ for some clause $C \in F \circ \text{XOR}_1^n$. By the definition of the lifted formula, this implies that $\text{XOR}_1^n(H) \subseteq D^{-1}(0)$ for some clause $D \in F$. Since $(H,\rho)$ satisfy the invariants, the lifted assignment $\text{XOR}_1^n(\rho)$ does not falsify $D$, and so by the block-closed property it follows that there must be a variable $z_i \in D$ such that all lifted variables in the block $i$ are free under $\rho$. But then applying Lemma 22 to the block of variables $\{x_{i,1}, x_{i,2}, x_{i,3}, x_{i,4}\}$, we can extend $\rho$ to a partial assignment $\rho'$ such that $z_i = \text{XOR}_4(\rho(x_{i,1}), \rho(x_{i,2}), \rho(x_{i,3}), \rho(x_{i,4}))$ satisfies $D$. But $H \upharpoonright \rho'$ is a projection of $H \upharpoonright \rho$ and so this contradicts that $\text{XOR}_1^n(H)$ violates $D$.

It remains to show how to take a step down the proof. Suppose that we have taken $t < d/2$ steps down the Semantic CP proof, the current node is labelled with a halfspace $H$, and the partial assignment $\rho$ satisfies the invariants. If $H$ has only a single child $H_1$, then $H \cap \{0,1\}^{4n} \subseteq H_1 \cap \{0,1\}^{4n}$ and $\rho$ will still satisfy the invariants for $H_1$. Otherwise, if $H$ has two children $H_1$ and $H_2$ then applying Lemma 21 to the halfspaces $H \upharpoonright \rho, H_1 \upharpoonright \rho, H_2 \upharpoonright \rho$ we can find an $i \in \{1,2\}$ and a restriction $\tau$ such that $H_i \upharpoonright (\rho \tau)$ is good and $\tau$ restricts at most 2 extra coordinates. Let $i_1, i_2 \in [n]$ be the two blocks of variables in which $\tau$ restricts variables, and note that it could be that $i_1 = i_2$.

Finally, we must restore our invariants. We do this in the following three step process.
Query the Adversary strategy at the state \( \text{XOR}_n^2(\rho) \) on variables \( z_1, z_2 \) and let \( b_1, b_2 \in \{0, 1\} \) be the responses.

For \( i = i_1, i_2 \) let \( I_i \) be the set of variables free in the block \( i \), and note that \( |I_i| \geq 2 \). Apply Lemma 22 to \( H \upharpoonright (\rho \tau) \) and \( I_i \) to get new restrictions \( \rho_{i_1}, \rho_{i_2} \) so that blocks \( i_1 \) and \( i_2 \) both take values consistent with the Adversary responses \( b_1, b_2 \).

Upate \( \rho \leftarrow \rho \rho_{i_1} \rho_{i_2} \).

By Lemma 22 the new restriction \( \rho \) satisfies the block-closed and the good halfspace invariants. At each step we fix at most two blocks of variables, and thus the final invariant is satisfied as long as \( t < d/2 \). This completes the proof.

5.2 Semantic CP Depth Lower Bounds for Unlifted Formulas

Next we show how to prove depth lower bounds directly on unlifted families of \( \mathbb{F}_2 \)-linear equations. The strength of these lower bounds will depend directly on the expansion of the underlying constraint-variable graph of \( F \).

Throughout this section, let \( F \) denote a set of \( \mathbb{F}_2 \)-linear equations. In a Semantic CP proof, we must encode \( F \) as a CNF formula, but while proving the lower bound we will instead work with the underlying system of equations. For a set \( F \) of \( \mathbb{F}_2 \)-linear equations let \( G_F := (F \cup V, E) \) be the bipartite constraint-variable graph defined as follows. Each vertex in \( F \) corresponds to an equation in \( F \) and each vertex in \( V \) correspond to variables \( x_i \). There is an edge \((C_i, x_j) \in E \) if \( x_j \) occurs in the equation \( C_i \). For a subset of vertices \( X \subseteq F \cup V \) define the neighbourhood of \( X \) in \( G_F \) as \( \Gamma(X) := \{ v \in F \cup V : \exists u \in X, (u, v) \in E \} \).

\textbf{Definition 25.} For a bipartite graph \( G = (U \cup V, E) \) the boundary of a set \( W \subseteq U \) is

\[ \delta(W) := \{ v \in V : |\Gamma(v) \cap W| = 1 \}. \]

The boundary expansion of a set \( W \subseteq U \) is \(|\delta(W)|/|W| \). The graph \( G \) is a \((r, s)\)-boundary expander if the boundary expansion of every set \( W \subseteq U \) with \( |W| \leq r \) has boundary expansion at least \( s \).

If \( F \) is a system of linear equations then we say that \( F \) is an \((r, s)\)-boundary expander if its constraint graph \( G_F \) is. The main result of this section is the following theorem, analogous to Theorem 23.

\textbf{Theorem 26.} For any system of \( \mathbb{F}_2 \)-linear equations \( F \) that is an \((r, s + 3)\)-boundary expander,

\[ \text{depth}_{\text{CP}}(F) \geq rs/2. \]

The proof of this theorem follows the proof of Theorem 23 with some small changes. As before, we will maintain a partial assignment \( \rho \in \{0, 1, \ast\}^n \) that will guide us on a root-to-leaf walk through a given Semantic CP proof; we also require that each halfspace \( H \) that we visit is good relative to our restriction \( \rho \). Now our invariants are (somewhat) simpler: we will only require that \( F \upharpoonright \rho \) is a sufficiently good boundary expander.

We first prove an auxiliary lemma that will play the role of Lemma 22 in the proof of Theorem 26. We note that it follows immediately from Lemma 22 and boundary expansion.

\textbf{Lemma 27.} Suppose \( F \) is a system of \( \mathbb{F}_2 \)-linear equations that is an \((r, s)\)-boundary expander for \( s > 1 \), and suppose \( F' \subseteq F \) with \( |F'| \leq r \). Let \( H \) be a good halfspace. Then there exists a \( \rho \in \{0, 1, \ast\}^n \) with \( \text{fix}(\rho) = \Gamma(F') \) such that

\begin{itemize}
  \item \( F' \) is satisfied by \( \rho \), and
  \item \( H \upharpoonright \rho \) is good.
\end{itemize}
Proof. We first use expansion to find, for each constraint \( C_i \in F' \), a pair of variables \( y_{i,1}, y_{i,2} \) that are in \( C_i \)'s boundary. To do this, first observe that \( |\delta(F')| \geq s|F'| > |F'| \) by the definition of boundary expansion. The pigeonhole principle then immediately implies that there are variables \( y_{i,1}, y_{i,2} \in \delta(F') \) and a constraint \( C_i \in F' \) such that \( y_{i,1}, y_{i,2} \in C_i \). Since \( y_{i,1}, y_{i,2} \) do not occur in \( F' \setminus \{ C_i \} \), it follows that \( F' \setminus \{ C_i \} \) is still an \((r,s)\)-boundary expander. So, we update \( F' = F' \setminus \{ C_i \} \) and repeat the above process.

When the process terminates, we have for each constraint \( C_i \in F' \) a pair of variables \( y_{i,1}, y_{i,2} \) that occur only in \( C_i \). Write the halfspace \( H = \bigcup_{i \in I} \{ y_{1,1}, y_{1,2} \} \) be the set of variables occurring in \( F' \) that were not collected by the above process. We define a partial restriction \( \rho \) with \( \text{fix}(\rho) = I \) that depends on \( |I| \) as follows.

- If \(|I| = 0\) then \( \rho = *^n \).
- If \(|I| = \{ x_i \}\) then define \( \rho(x_i) = 1 \) if \( w_i \geq 0 \) and \( \rho(x_i) = 0 \) otherwise, and for all other variables set \( \rho(x) = * \).
- If \(|I| > 2\) then apply Lemma 22 to generate a partial restriction \( \rho \) with \( \text{fix}(\rho) = I \) that sets the XOR of \( I \) arbitrarily.

Observe that \( H \upharpoonright \rho \) is good. The only non-trivial case is when \(|I| = 1\), but, in this case we observe

\[
(H \upharpoonright \rho)((1/2)^{n-1}) = w_i \rho(x_i) + \sum_{j \neq i} w_j / 2 \geq \sum_{i} w_i / 2 \geq c,
\]

where we have used that \( H \) is good and the definition of \( \rho \).

Next we extend \( \rho \) as follows: for each \( i = 1, 2, \ldots, |F'| \) apply Lemma 22 to \( I_i = \{ y_{i,1}, y_{i,2} \} \) to generate a partial restriction \( \rho_i \) with \( \text{fix}(\rho_i) = I_i \) so that the constraint \( C_i \upharpoonright \rho_1 \cdots \rho_{i-1} \) is satisfied by \( \rho_i \). Observe that this is always possible since \( I_i \) is in the boundary of \( C_i \). Finally, we update \( \rho \leftarrow \rho_1 \cdots \rho_{|F'|} \). It follows by Lemma 22 that \( F' \) is satisfied by \( \rho \) and \( H \upharpoonright \rho \) is good.

We are now ready to prove Theorem 26. Fix any Semantic CP refutation of \( F \) and let \( n \) be the number of variables. We take a root-to-leaf walk through the refutation while maintaining a partial assignment \( \rho \in \{0,1,*\}^n \) and an integer valued parameter \( k \geq 0 \). Throughout the walk we maintain the following invariants with respect to the current halfspace \( H \):

- **Good Expansion.** \( F \upharpoonright \rho \) is a \((k,t)\)-boundary expander with \( t > 3 \).
- **Good Halfspace.** \( H \upharpoonright \rho \) is good.
- **Consistency.** The partial assignment \( \rho \) does not falsify any clause of \( F \).

Initially, we set \( k = r \), \( \rho = *^n \), and \( t = s + 3 \), so the invariants are clearly satisfied since \( F \) is an \((r,s+3)\)-expander. So, suppose that we have reached a halfspace \( H \) in our walk, and let \( k, \rho \) be parameters satisfying the invariants. We first observe that if \( k > 0 \) then \( H \) cannot be a sink node of the proof. To see this, it is enough to show that \( H \) contains a satisfying assignment for each equation \( C \in F \). Because \( H \upharpoonright \rho \) is non-empty (since it is good) there exists a satisfying assignment in \( H \) for every equation satisfied by \( \rho \), so, assume that \( C \) is not satisfied by \( \rho \). In this case, since \( F \upharpoonright \rho \) is a \((k,t)\)-expander for \( k > 0 \) we can apply Lemma 27 to \( \{ C \} \) and \( H \upharpoonright \rho \) and obtain a partial restriction \( \tau \) with \( \text{fix}(\tau) = \Gamma(C) \) such that \( \tau \) satisfies \( C \). It follows that \( H \) is not a leaf.

Next, we show how to take a step down the proof while maintaining the invariants. If \( H \) has only a single child \( H_1 \), then \( H \subseteq H_1 \) and we can move to \( H_1 \) without changing \( \rho \) or \( k \). Otherwise, let the children of \( H \) be \( H_1 \) and \( H_2 \). Applying Lemma 21 to \( H \upharpoonright \rho, H_1 \upharpoonright \rho, H_2 \upharpoontright \rho \) we get a partial restriction \( \tau \) and an \( i \in \{1,2\} \) such that \( H_i \upharpoonright \rho \tau \) is good and \( \text{fix}(\tau) \leq 2 \). Due to this latter fact, since \( F \upharpoonright \rho \) is a \((k,t)\)-expander it follows that \( F \upharpoonright \rho \tau \) is a \((k, t - 2)\)-expander in the worst case. Observe that since \( t > 3 \) it follows that \( F \upharpoonright \rho \tau \) still satisfies the consistency invariant. It remains to restore the expansion invariant.
To restore the expansion invariant, let $W$ be the largest subset of equations such that $|W| \leq k$ and $W$ has boundary expansion at most 3 in $F \setminus \rho r$, and note that $W$ has boundary expansion at least $t - 2 > 1$. Applying Lemma 27, we can find a restriction $\rho'$ such that $W \setminus \rho r \rho'$ is satisfied, and $H \setminus \rho r \rho'$ is a good halfspace. Since $W$ is the largest subset with expansion at most 3, it follows that $F \setminus \rho r \rho'$ is now a $(k - |W|, t')$-boundary expander with $t' > 3$. Suppose otherwise, then there exists a subset of equations $W'$ which has boundary expansion at most 3 in $F \setminus \rho r \rho'$. Then $W \cup W'$ would have had boundary expansion at most 3 in $F \setminus \rho r$, contradicting the maximality of $W$. Now update $\rho \leftarrow \rho r \rho'$ and $k \leftarrow k - |W|$. Finally, we halt the walk if $k = 0$.

We now argue that this path must have had depth at least $rs/2$ upon halting. Assume that we have taken $t$ steps down the proof. For each step $i \leq t$ let $W_i$ be the set of equations which lost boundary expansion during the $i$th cleanup step. Note that $W_i \cap W_j = \emptyset$ for every $i \neq j$. Let $W^* = \bigcup_{i=1}^{t} W_i$, note that $|W^*| = r$ because at the $i$th step we decrease $k$ by $|W_i|$. Furthermore, at the end of the walk, $W^*$ has no neighbours and therefore no boundary in $F \setminus \rho$. Before the start of the $i$th cleanup step, $W_i$ has at most $3|W_i|$ boundary variables. Therefore, at most $3|W^*| = 3r$ boundary variables were removed during the cleanup step. Since $F$ started as an $(r, s + 3)$-boundary expander, it follows that $W^*$ had at least $rs + 3$ boundary variables at the start of the walk. But, since all variables have been removed from the boundary by the end, this means that $rs$ variables must have been removed from the boundary during the move step. Thus, as each move step sets at most 2 variables, it follows that $t \geq rs/2$ before the process halted.

5.3 Proof of Lemma 21 and Lemma 22

In this section we prove our two key technical lemmas: Lemma 21 and Lemma 22. We begin by proving Lemma 22 as it is simpler.

**Proof of Lemma 22.** Let $H$ be represented by $\sum_{i \in [n]} w_i x_i \geq c$ and suppose without loss of generality that $c \geq 0$ and that $I = \{1, \ldots, k\}$. Let the weights of $\ell$ in $H$ be ordered $|w_1| \geq |w_2| \geq \ldots \geq |w_k|$. Define $\rho$ by setting $\rho(x_i) = *$ for $i \notin I$, for $i \leq k - 1$ set $\rho(x_i) = 1$ if $w_i \geq 0$ and $\rho(x_i) = 0$ otherwise, and set $\rho(x_k)$ so that $\bigoplus_{i \in I} \rho(x_i) = b$. Clearly the parity constraint is satisfied, we show that $H \setminus \rho$ is good. This follows by an easy calculation:

$$
(H \setminus \rho)((1/2)^{|n\setminus I|}) = w_{k-1} \rho(x_{k-1}) + w_k \rho(x_k) + \sum_{i \leq k-2} w_i \rho(x_i) + \sum_{i \geq k+1} w_i/2
$$

$$
\geq w_{k-1}/2 + w_k/2 + \sum_{i \leq k-2} w_i \rho(x_i) + \sum_{i \geq k+1} w_i/2
$$

$$
\geq \sum_{i \in [n]} w_i/2 \geq c
$$

where the first inequality follows by averaging since $|w_{k-1}| \geq |w_k|$, and the final inequality follows since $H$ is good. \hfill \qed

In the remainder of the section we prove Lemma 21. It will be convenient to work over $\{-1, 1\}^n$ rather than $\{0, 1\}^n$, so, we restate it over this set and note that we can move between these bases by the bijection $v \mapsto (1 - v)/2$.

**Lemma 28.** Let $H \in \mathbb{R}^n$ be a halfspace such that $0^n \in H$ and suppose that $H \cap \{-1, 1\}^n \subseteq H_1 \cup H_2$. Then one of $H_1$ or $H_2$ contains a point $y \in \{-1, 0, 1\}^n$ such that $y$ has at most two coordinates in $\{-1, 1\}$. \hfill \qed
The key ingredient in our proof of Lemma 28 is the following simple topological lemma, which will allow us to find a well-behaved point lying on a 2-face of the $[-1,1]^n$ cube

- **Definition 29 (2-face).** A 2-face of the $n$-cube with vertices $\{-1,1\}^n$ are the 2-dimensional 2-by-2 squares spanned by four vertices of the cube that agree on all but two coordinates. That is, a two face is a set $A \subseteq [-1,1]^n$ such that there exists $\rho \in \{-1,1,*\}^n$ with $|\text{free}(\rho)| = 2$ and $A = [-1,1]^n \cup \rho$.

- **Lemma 30.** Let $w_1,w_2 \in \mathbb{R}^n$ be any pair of non-zero vectors, then we can find a vector $v \in \mathbb{R}^n$ orthogonal to $w_1,w_2$, such that $v$ lies on a 2-face.

**Proof.** We will construct the vector $v$ iteratively by rounding one coordinate at a time to a $\{-1,1\}$-value until $v$ contains exactly $n-2$ coordinates fixed to $\{-1,1\}$. At each step, we will maintain that $v \in [-1,1]^n$ and that $v$ is orthogonal to $w_1$ and $w_2$. Therefore when the process halts $v$ will lie on a 2-face.

Initially, set $v = 0^n$ and observe that the invariants are satisfied. Suppose that we have constructed a vector $v$ that is orthogonal to $w_1$ and $w_2$, all of its coordinates belong to $[-1,1]$, and exactly $i < n-2$ of its coordinates belong to $\{-1,1\}$; suppose w.l.o.g. that they are the first $i$ coordinates. We will show how to “booleanize” an additional coordinate of $v$. Let $u$ be any non-zero vector that is orthogonal to $\{w_1,w_2,e_1,\ldots,e_i\}$, where $e_j$ is the $j$th standard basis vector. Begin moving from $v$ in the direction of $u$ and let $\alpha > 0$ be the smallest value such that one of the coordinates $j > i$ of $v + \alpha u$ is in $\{-1,1\}$. We verify that the following properties hold:

1. The first $i$ coordinates of $v + \alpha u$ are in $\{-1,1\}$. This follows because we moved in a direction that is orthogonal to $e_1,\ldots,e_i$.
2. $v + \alpha u$ is orthogonal to $w_1$ and $w_2$. Let $w$ be either of the vectors $w_1$ or $w_2$ and observe that $v_{[i]}w = v_{i}w + \alpha (uw) = 0$, where the final equality follows because $w$ is orthogonal to $v_i$ by induction and to $u$ by assumption.

Finally, set $v$ to be $v + \alpha u$.

**Proof of Lemma 28.** Let the children $H_1$ and $H_2$ of $H$ be given by the halfspaces $w_1x \geq b_1$ and $w_2x \geq b_2$ respectively. By Lemma 30 we can find a vector $v$ which is orthogonal to $w_1$ and $w_2$, and which lies on some 2-face $F$ of the $[-1,1]^n$ cube corresponding to some restriction $\rho \in \{0,1,*\}^n$. Then, $v$ lies in (at least) one of the four 1-by-1 quadrants of the 2-face, $[0,1]^2$, $[0,1] \times [-1,0]$, $[-1,0] \times [0,1]$, or $[-1,0]^2$; suppose that $v$ lies in the $[-1,0] \times [0,1]$ quadrant of $F$, the other cases will follow by symmetry (see Figure 3).

\[
\begin{align*}
\alpha &= (-1,1) \\
(1,1) \\
(1,1) \\
(-1,1) \\
\end{align*}
\]

**Figure 3** A 2-face of the $n$-cube together with a depiction of the booleanizing process.
Let \( a \in \mathbb{R}^n \) be the vector corresponding to the \((-1, 1)\) corner of \( F \), i.e., \( a \) is \( \rho \) extended by setting the two free bits to \(-1\) and \( 1\). By symmetry and the fact that \( H \) is good (and therefore \( 0^\rho \in H \)), we can assume that \( a \) is contained in \( H \) – otherwise, simply exchange \( a \) and \( v \) for \(-a\) and \(-v\). Since \( H \cap \{-1, 1\}^n \subseteq H_1 \cup H_2 \) and \( a \in \{-1, 1\}^\rho \), it follows that \( a \) is in one of \( H_1 \) or \( H_2 \). Assume that \( a \in H_1 \); that is, \( w_1 a \geq b_1 \). Our goal is to construct a vector \( y \in H_1 \) that satisfies the statement of the lemma. Consider the following two cases:

(i) If \( w_1(a - v) \leq 0 \), then it follows that \( y := 0^\rho \in H_1 \). Indeed, \( w_1 y = w_1 v \geq w_1 a \geq b_1 \), where first equality follows because \( w_1 \) and \( p \) are orthogonal by assumption, and the final inequality follows because \( a \in H_1 \).

(ii) Otherwise, we have that \( w_1(a - v) > 0 \). We construct a point that satisfies the statement of the lemma as follows. First, note that since \( a, v \in F \), it follows that the vector \( a - v \) has at most two non-zero coordinates. Beginning at the origin \( 0^\rho \), move in the direction \( a - v \) until a free coordinate coordinate becomes fixed to \(-1\) or \( 1\); that is, let \( \alpha > 0 \) be the minimum value such that \( \alpha(a - v) \) has at most one coordinate which is not \( \{-1, 1\}\)-valued. Since both \( a \) and \( v \) belong to the same \( 1 \times 1 \) quadrant of the \( 2\)-face, \( \|a - v\|_\infty \leq 1 \) and so \( \alpha \geq 1 \). We can then verify that \( \alpha(a - v) \in H_1 \), since

\[
w_1 \alpha(a - v) = \alpha(w_1 a) - 0 \geq w_1 a \geq b_1,\]

where we have used the fact that \( v \) is orthogonal to \( w_1 \) and \( \alpha \geq 1 \). Finally, since \( \alpha(a - v) \in H_1 \) we can round the final non-zero coordinate to \(-1 \) or \( 1 \); since \( H_1 \) is a halfspace one of the two vectors will remain in \( H_1 \).

5.4 Applications

We now use the theorems from the previous sections to obtain several concrete lower bounds. First, we give strong depth lower bounds for \( s\text{CP} \) proofs of \( \text{Tseitin} \) formulas on expander graphs.

\textbf{Theorem 31.} There exists a graph \( G \) and labelling \( \ell : V \to \{0, 1\} \) such that any \( s\text{CP} \) refutation of \( \text{Tseitin}(G, \ell) \) requires depth \( \Omega(n) \).

\textbf{Proof.} A graph \( G = (V, E) \) is a \( \gamma \)-vertex expander if

\[
\min \{|\Gamma(W)| : W \subseteq V, |W| \leq |V|/2 \} \geq \gamma |W|,
\]

where \( \Gamma(W) \) is the neighbourhood of \( W \). We claim that if \( G \) is a \( \gamma \)-vertex expander then any \( \text{Tseitin} \) formula over \( G \) is a \((n/2, \gamma)\)-boundary expander. Fix any subset \( W \) of the equations with \( |W| \leq n/2 \). By the definition of vertex expansion we have that \( |\Gamma(W)| \geq \gamma |W| \), and since each variable is contained in exactly two constraints, it follows that the boundary of \( W \) in \( \text{Tseitin}(G, \ell) \) has size at least \(|\delta(W)| \geq \gamma |W| \). The result then follows from Theorem 26 and the existence of strong vertex expanders \( G \) (e.g. \( d\)-regular Ramanujan graphs are at least \( d/4\)-vertex expanders, and exist for all \( d \) and \( n \) [48]).

Next, we give lower bounds on the depth of \( \text{Semantic CP} \) refutations of random \( k\text{-XOR} \) and random \( k\text{-CNF} \) formulas for constant \( k \).

\textbf{Definition 32.} Let \( \text{XOR}(m, n, k) \) be the distribution on random \( k\text{-XOR} \) formulas obtained by sampling \( m \) equations from the set of all mod \( 2 \) linear equations with exactly \( k \) variables.
Theorem 33. The following holds for Semantic CP:

1. For any $k \geq 6$ there exists $m = O(n)$ such that $F \sim \text{XOR}(m, n, k)$ requires refutations of depth at least $\Omega(n)$ with high probability.

2. For any $k \geq 6$ there exists $m = O(n)$ such that $F \sim \mathcal{F}(m, n, k)$ requires refutations of depth at least $\Omega(n)$ with high probability.

Proof. We first prove (1) and obtain (2) via a reduction. Fix $m = O(n)$ so that $F$ is unsatisfiable with high probability. For any constant $k, \delta$ and $m = O(n)$, $F \sim \text{XOR}(m, n, k)$ is an $(\alpha n, k - 2 - 2\delta)$-boundary expander for some $\alpha > 0$ (see e.g., [16, 21]). Thus, setting $k \geq 6$ and $\varepsilon$ to be some small constant, the boundary expansion of $G_F$ is at least 3. By Theorem 26, $F$ requires depth $\Omega(n)$ to refute in Semantic CP with high probability.

The proof of (2) is via a reduction from $\mathcal{F}(m, n, k)$ to $\text{XOR}(m, n, k)$. Every $k$-clause occurs in the clausal encoding of exactly one $k$-XOR constraint. It follows that from any $k$-CNF formula $F$ we can generate a $k$-XOR formula whose clausal expansion $F'$ contains $F$ as follows: for each clause $C \in F$, if $C$ contains an even (odd) number of positive literals then add to $F'$ every clause on the variables of $C$ which contains an even (odd) number of positive literals. The resulting $F'$ is the clausal encoding of a set of $|F|$ $k$-XOR constraints.

As there is a unique $k$-XOR consistent with the clauses of $F$, we can define the distribution $\text{XOR}(m, n, k)$ equivalently as follows:

1. Sample $F \sim \mathcal{F}(m, n, k)$.
2. Return the $k$-XOR $F'$ generated from $F$ according to the aforementioned process.

It follows that the complexity of refuting $F \sim \mathcal{F}(m, n, k)$ is at least that of refuting $F' \sim \text{XOR}(m, n, k)$ and (2) follows from (1) with the same parameters. \hfill \blacksquare

Finally, we use Theorem 26 to extend the integrality gaps from [16] to sCP by essentially the same argument. For a linear program with constraints given by a system of linear inequalities $Ax \leq b$, the $r$-round sCP relaxation adds all inequalities that can be derived from $Ax \leq b$ by a depth-$r$ sCP proof. We show that the $r$-round Semantic sCP linear program relaxation cannot well-approximate the number of satisfying assignments to a random $k$-SAT or $k$-XOR instance.

First we define our LP relaxations. Suppose that $F$ is a $k$-CNF formula with $m$ clauses $C_1, C_2, \ldots, C_m$ and $n$ variables $x_1, x_2, \ldots, x_n$. If $C_i = \bigvee_{i \in P} x_i \lor \bigwedge_{i \in N} \pi_i$, then let $E(C_i) = \sum_{i \in P} x_i + \sum_{i \in N} 1 - x_i$. We consider the following LP relaxation of $F$:

$$\begin{align*}
\max \quad & \sum_{i=1}^{m} y_i \\
\text{subject to} \quad & E(C_i) \geq y_i \quad \forall i \in [m] \\
& 0 \leq x_j \leq 1 \quad \forall j \in [n] \\
& 0 \leq y_i \leq 1 \quad \forall i \in [m]
\end{align*}$$

If $F$ is a $k$-XOR formula with $m$ constraints and $n$ variables then we consider the above LP relaxation obtained by writing $F$ as a $k$-CNF. Finally, recall that the integrality gap is the ratio between the optimal integral solution to a linear program and the optimal solution produced by the LP.

Theorem 34. For any $\varepsilon > 0$ and $k \geq 6$:

1. There is $\kappa > 0$ and $m = O(n)$ such that for $F \sim \text{XOR}(m, n, k)$ the integrality gap of the $\kappa n$-round sCP relaxation of $F$ is at least $(2 - \varepsilon)$ with high probability.

2. There is $\kappa > 0$ and $m = O(n)$ such that for $F \sim \mathcal{F}(m, n, k)$ the integrality gap of the $\kappa n$-round sCP relaxation of $F$ is at least $2^k / (2^k - 1) - \varepsilon$ with high probability.
Proof. Let $F \sim \text{XOR}(m,n,k)$ and let $Y_i$ be the event that the $i$th constraint is falsified by a uniformly random assignment. Let $\delta := \varepsilon/(2 - \varepsilon)$, then by a multiplicative Chernoff Bound, the probability that a uniformly random assignment satisfies at least a $1/(2 - \varepsilon)$-fraction of $F$ is $\Pr[\sum_{i \in [m]} Y_i \geq (1 + \delta) \frac{m}{2}] \leq 2^{-\delta m/6}$. By a union bound, the probability that there exists an assignment satisfying at least a $1/(2 - \varepsilon)$ fraction of $F$ is $2^{-\delta m/6}$ which is exponentially small when $m \geq 7n(2 - \varepsilon)/\varepsilon$.

On the other hand, consider the partial restriction to the LP relaxation of $F$ that sets $y_i = 1$ for all $i \in [m]$. Setting $m \geq 7n(2 - \varepsilon)/\varepsilon$ large enough, by Theorem 33 there some $\kappa > 0$ such that with high probability $F$ requires depth $\kappa n$. Hence, the $\kappa n$ round Semantic CP LP relaxation is non-empty, and there is a satisfying assignment $\alpha \in \mathbb{R}^n$. Thus $\alpha \cup \{y_i = 1\}$ satisfies all constraints of $\text{max}(F)$.

The second result follows by an analogous argument. ▷

6 Conclusion

We end by discussing some problems left open by this paper. The most obvious of which is a resolution to Conjecture 6. A related question is whether supercritical size-depth tradeoffs can be established for monotone circuits? Indeed, current size lower bound techniques [32,33,39,54] are via reduction to monotone circuit lower bounds. As a first step towards both of these, can one prove a supercritical size-depth tradeoff for a weaker proof system such as resolution?

The simulation results presented in Section 3 leave open several questions regarding the relationship between $\text{SP}$ and $\text{CP}$. First, the simulation of $\text{SP}^*$ by $\text{CP}$ incurs a significant blowup in the coefficient size due to Shrijver’s lemma. It would be interesting to understand whether $\text{SP}^*$ can be quasi-polynomially simulated by $\text{CP}^*$; that is, whether this blowup in the size of the coefficients is necessary.

The most obvious question left open by these simulations is whether $\text{CP}$ can polynomially simulate $\text{SP}$, or even polynomially simulate $\text{SP}^*$. Similarly, what are the relationships of both $\text{SP}$ and $\text{CP}$, to (bounded-coefficient) $\text{R}(\text{CP})$, the system which corresponds to dag-like $\text{SP}$. $\text{R}(\text{CP})$ can polynomially simulate DNF resolution, and therefore has polynomial size proofs of the Clique-Colouring formulas, for cliques of size $\Omega(\sqrt{n})$ and colourings of size $o(\log^2 n)$ [4]. Quasi-polynomial lower bounds on the size of $\text{CP}$ refutations are known for this range of parameters and this rules out a polynomial simulation by Cutting Planes; however, a quasi-polynomial simulation may be possible. A potential approach to resolving this question is to use the added expressibility of $\text{R}(\text{CP})$ over DNF resolution to extend the upper bound on Clique-Colouring to the range of parameters for which superpolynomial $\text{CP}$ lower bounds are known.

Separating ABPs and Some Structured Formulas in the Non-Commutative Setting

Prerona Chatterjee

Tata Institute of Fundamental Research, Mumbai, India

Abstract

The motivating question for this work is a long standing open problem, posed by Nisan [20], regarding the relative powers of algebraic branching programs (ABPs) and formulas in the non-commutative setting. Even though the general question remains open, we make some progress towards its resolution. To that effect, we generalise the notion of ordered polynomials in the non-commutative setting (defined by Hrubeš, Wigderson and Yehudayoff [11]) to define abecedarian polynomials and models that naturally compute them.

Our main contribution is a possible new approach towards resolving the $\text{VF}_{\text{nc}}$ vs $\text{VBP}_{\text{nc}}$ question, via lower bounds against abecedarian formulas. In particular, we show the following.

There is an explicit $n^2$-variate degree $d$ abecedarian polynomial $f_{n,d}(x)$ such that
- $f_{n,d}(x)$ can be computed by an abecedarian ABP of size $O(nd)$;
- any abecedarian formula computing $f_{n,\log n}(x)$ must have size at least $n^{O(\log \log n)}$.

We also show that a super-polynomial lower bound against abecedarian formulas for $f_{\log n,n}(x)$ would separate the powers of formulas and ABPs in the non-commutative setting.

1 Introduction

Algebraic Circuit Complexity is the study of multivariate polynomials and their classification based on how hard it is to compute them, using various computational models. The most well studied model is that of algebraic circuits. These are directed acyclic graphs that use algebraic operations like addition and multiplication over some field or ring, to compute polynomials. When the underlying graph is only allowed to be a tree, the model is that of algebraic formulas. The central question in this area is whether the class $\text{VNP}$ (algebraic analogue of the class $\text{NP}$) is contained in the class $\text{VP}$ (algebraic analogue of the class $\text{P}$). Valiant [23] has shown that the permanent polynomial is complete for $\text{VNP}$, and therefore the $\text{VP}$ vs $\text{VNP}$ question essentially boils down to asking whether the $n \times n$ permanent can be computed by a poly$(n)$-sized algebraic circuit.

In this paper, we are interested in polynomials that come from the non-commutative polynomial ring $\mathbb{F}(x_1, \ldots, x_n)$, where the indeterminates do not commute with each other (that is, $xy \neq yx$ for indeterminates $x, y$). As a consequence, any monomial in a non-commutative
polynomial \( f \in F \langle x_1, \ldots, x_n \rangle \) is essentially a string over the alphabet \( \{ x_1, \ldots, x_n \} \). This is a natural restriction and there has been a long line of work that studies non-commutative computation beginning with the seminal work of Nisan [20].

It was shown by Hrubeš, Wigderson and Yehudayoff [10] that the non-commutative permanent polynomial is complete for the class \( VNP_{nc} \) (the non-commutative version of \( VNP \)). Later Arvind, Joglekar and Raja [1] gave a natural polynomial that is complete for the class of \( n \)-variate non-commutative polynomials computable by \( \text{poly}(n) \)-sized circuits (denoted by \( VP_{nc} \)). The question of whether the classes \( VP_{nc} \) and \( VNP_{nc} \) are different is the central open problem in the non-commutative setting. Although the general question of showing lower bounds against non-commutative circuits remains open, there has been significant progress in restricted settings [17, 16, 15, 22, 8].

With respect to the general question, Hrubeš, Wigderson and Yehudayoff [11] showed that a sufficiently strong super-linear lower bound for the classical sum-of-squares problem implies a separation between \( VP_{nc} \) and \( VNP_{nc} \). In another related work, Carmosino, Impagliazzo, Lovett and Mihajlin [5] showed that proving mildly super-linear lower bounds against non-commutative circuits would imply exponential lower bounds against the same model.

One motivation for studying non-commutative computation is that it is possibly easier to prove strong lower bounds in this setting as compared to the usual commutative setting. At least intuitively, it seems harder to cancel monomials once they have been calculated when commutativity is not allowed amongst the variables.

For example, the \( n \times n \) determinant can be computed by an \( O(n^3) \) algebraic circuit, but to the best of our knowledge there is no circuit for the non-commutative determinant of size \( 2^{o(n)} \). In fact, it was shown by Arvind and Srinivasan [2] that if the non-commutative determinant had a \( \text{poly}- \)sized circuit, then \( VP_{nc} = VNP_{nc} \).

Even though a super-polynomial lower bound is not known for the non-commutative determinant against circuits, Nisan [20] gave an exponential lower bound on the number of gates in any formula computing it. In contrast, the best lower bound known against formulas in the commutative setting is quadratic\(^2\) [19, 14, 6].

A point to note about the lower bound given by Nisan however, is that the proof actually works for a computational model, called Algebraic Branching Programs (or ABPs), that is believed to be more general than algebraic formulas. In fact, Nisan [20] gave an exact characterisation for the size of any ABP computing a non-commutative polynomial. As far as we are aware, any lower bound known against general non-commutative formulas uses this characterisation and hence is essentially a lower bound against non-commutative ABPs itself.

The motivating question for this work is whether there is a separation between the powers of ABPs and formulas in the non-commutative setting. Let us denote the class of non-commutative polynomials over \( n \) variables that can be computed by \( \text{poly}(n) \)-sized ABPs by \( VBP_{nc} \). Similarly, let \( VF_{nc} \) denote the class of non-commutative polynomials over \( n \) variables that can be computed by \( \text{poly}(n) \)-sized formulas. The question is essentially whether \( VBP_{nc} \) is contained in \( VF_{nc} \) or not.

This question had been posed by Nisan [20], and the only work we are aware of that has made some progress with respect to this question is the one by Lagarde, Limaye and Srinivasan [15]. They show that certain syntactically restricted non-commutative formulas (called Unique Parse Tree formulas) cannot compute \( \text{IMM}_{n,n} \) unless they have size \( n^{\Omega(\log n)} \).

In this paper, we study restrictions of a different kind. From here on, we will only be talking about non-commutative computation unless specifically mentioned otherwise.

---

1 Hyafil [13] had considered non-commutative computation before this, but the main result in that paper is unfortunately false as shown in [20].

2 For the elementary symmetric polynomial.
1.1 Abecedarian Polynomials and Models That Compute Them

In [11], Hrubeš et al. have defined the notion of ordered polynomials. A homogeneous polynomial of degree \(d\) is said to be ordered if the set of variables it depends on can be partitioned into \(d\) buckets such that variables occurring in position \(k\) only come from the \(k\)-th bucket. We generalise this notion by making the bucket indices position independent. That is, a variables in position \(k\) need not necessarily come from the \(k\)-th bucket as long as the variables appear in non-decreasing order of their bucket indices. We call such polynomials abecedarian since, in English, an abecedarian word is one in which all of the letters are arranged in alphabetical order [18].

The difference between ordered polynomials and abecedarian ones can be explained succinctly using the notion of regular expressions from Automata Theory. For a non-commutative polynomial \(f \in \mathbb{F}\langle x_1, \ldots, x_n \rangle\), suppose the variables can been partitioned into buckets \(\{X_1, \ldots, X_m\}\). \(f\) is said to be ordered with respect to \(\{X_1, \ldots, X_m\}\) if every monomial in it is a word that can be generated using the regular expression \(X_1 \cdots X_m\). Note that this is equivalent to set-multilinear polynomials in the commutative setting. On the other hand, \(f\) is abecedarian if the monomials in it are words that can be generated using the regular expression \(X^*_1 \cdots X^*_m\). Subsection 2.1 has a formal definition.

"Getting our Hands Dirty" with Abecedarian Polynomials

Before moving ahead, let us take a look at an example of an abecedarian polynomial. Given a commutative polynomial \(f \in \mathbb{F}[x_1, \ldots, x_n]\), define its non-commutative analogue, \(f^{\text{nc}}\) as follows.

\(f\) and \(f^{\text{nc}}\) look essentially the same, except that variables in every monomial in \(f^{\text{nc}}\) are arranged in non-decreasing order of their indices.

Then, \(f^{\text{nc}}\) is abecedarian with respect to the partition \(\{X_i : X_i = \{x_i\}\}\).

Let us also look at a possibly important polynomial that is not abecedarian with respect to the partition \(\{X_i : X_i = \{x_i\}\}\). Consider the arc-full rank polynomial, \(f\), which was constructed by Dvir, Malod, Perifel and Yehudayoff [7] to give a super-polynomial separation between the powers of formulas and ABPs in the multilinear setting.

We look at \(f\) as a non-commutative polynomial, \(f'\), in the following sense. Let \(A\) be the ABP that computes \(f\) and think of \(A\) as a non-commutative ABP \(A'\). Then, \(f'\) is the polynomial computed by \(A'\).

It is not hard to see that across different monomials in \(f'\), the order in which variables are arranged is not consistent. Thus, \(f'\) is not abecedarian with respect to the given partition.

A final point to note before we move ahead is that a polynomial might be abecedarian with respect to different partitions\(^3\). In fact, even the sizes of the different partitions might be different. For example, the polynomial

\[\text{ESYM}^{\text{ord}}_{n, d} = \sum_{1 \leq i_1 < \ldots < i_d \leq n} x_1^{(i_1)} \cdots x_d^{(i_d)}\]

is abecedarian with respect to the partition \(\{X_k = \{x_i^{(k)} : i \in [n]\}\}\) which has size \(d\), as well as \(\{X_i = \{x_i^{(k)} : k \in [d]\}\}\) which has size \(n\).

\(^3\) Every polynomial \(f \in \mathbb{F}\langle x_1, \ldots, x_n \rangle\) is abecedarian with respect to the partition \(\{X\}\) for \(X = \{x_1, \ldots, x_n\}\).
Abecedarian Models of Computation

Hrubeš et al. [11] have defined ordered circuits, a model naturally suited to compute ordered polynomials. We generalise this notion to define circuits that naturally compute abecedarian polynomials. We also define abecedarian ABPs and abecedarian formulas similarly.

Suppose \( f \) is an abecedarian polynomial with respect to the partition \( \{X_1, \ldots, X_m\} \). For any \( 1 \leq a \leq b \leq m + 1 \), \( f(a, b) \) is a sub-polynomial of \( f \) defined as follows.

- For any \( 1 \leq a \leq m + 1 \), \( f(a, a) \) is the constant term in \( f \).
- For \( 1 \leq a < b \leq m + 1 \), \( f(a, b) \) contains only those monomials of \( f \) in which the first variable is from bucket \( X_a \) and the last variable is from any of the buckets in the set \( \{X_a, \ldots, X_{b-1}\} \).

A circuit is said to be abecedarian if every gate \( v \) in it can be labelled by a tuple \( (a, b) \) such that if \( f_v \) is the polynomial computed at that gate, then \( f_v = f_v[a, b] \). We call a formula abecedarian if it has a similar syntactic property at every gate. For formal definitions, see Definition 15 and Definition 17 respectively. On the other hand, an ABP is said to be abecedarian when every vertex in it can be labelled by a bucket index such that if \( f \) is the polynomial computed between vertices labelled with indices \( a \) and \( b \) respectively, then \( f = f[a, b + 1] \). Definition 16 is a formal definition.

### 1.2 Our Main Results

Our main result is a super-polynomial separation between abecedarian formulas and ABPs.

*Theorem 1 (Separating Abecedarian Formulas and Abecedarian ABPs).* Define

\[
\text{linked\_CHSYM}_{n,d}(x) = \sum_{i=1}^{n} \left( \sum_{i_0 \leq i_1 \leq \cdots \leq i_d \leq n} x_{i_0,i_1} \cdots x_{i_{d-1},i_d} \right)
\]

to be the linked complete homogeneous polynomial over \( n \)-variables of degree \( d \). This polynomial is abecedarian with respect to the partition \( \{X_i : i \in [n]\} \) if \( X_i = \{x_{i,j} : i \leq j \leq n\} \).

With respect to this partition,

1. \( \text{linked\_CHSYM}_{n,d}(x) \) has an abecedarian ABP of size \( O(nd) \);
2. any abecedarian formula computing \( \text{linked\_CHSYM}_{n/2,\log n}(x) \) has size \( n^{\Omega(\log \log n)} \).

That is, there is a super-polynomial separation between abecedarian formulas and ABPs.

Our second main result shows that in certain settings, formulas computing abecedarian polynomials can be assumed to be abecedarian without loss of generality.

*Theorem 2 (Converting Formulas into Abecedarian Formulas).* Let \( f \) be an abecedarian polynomial with respect to a partition of size \( m \), and \( F \) be a formula of size \( s \) computing \( f \).

If \( m = O(\log s) \), then there is an abecedarian formula \( F' \) computing \( f \) of size \( \text{poly}(s) \).

In other words, an \( n^{\omega(1)} \) lower bound against abecedarian formulas computing any polynomial that is abecedarian with respect to a partition of size \( O(\log n) \), would result in a super-polynomial lower bound against general non-commutative formulas. These statements suggest a new approach towards resolving the general VF vs VBP question.

### Connections to the General VF vs VBP Question

Theorem 1 gives a separation between abecedarian formulas and ABPs. On the other hand, Theorem 2 shows that if we are given a formula that computes a polynomial that is abecedarian with respect to a partition of small size, then we can assume that the formula is abecedarian.
without loss of generality. Unfortunately, the partition with respect to which our hard polynomial from Theorem 1 is abecedarian, is not small in size. Thus, the general question of whether \( \text{VBP}_{nc} \) is contained in \( \text{VF}_{nc} \) or not still remains open. However, there are two natural questions that arise at this point.

1. Can any formula computing an abecedarian polynomial be converted to an abecedarian formula without much blow-up in size, irrespective of the size of the partition?
2. Is there a polynomial \( f \) which is abecedarian with respect to a partition that has small size such that \( f \) witnesses a separation between abecedarian formulas and ABPs?

Clearly, a positive answer to either of these questions would imply that \( \text{VBP}_{nc} \neq \text{VF}_{nc} \). In particular, a super-polynomial lower bound against abecedarian formulas for a polynomial very similar to the one we used to show our separation would separate \( \text{VBP}_{nc} \) and \( \text{VF}_{nc} \).

\[ \text{Corollary 3.} \text{ Let the polynomial } \text{linked}_{\text{CHSYM}} n,d(x) \text{ be as defined in Theorem 1. An } n^{\omega(1)} \text{ lower bound against abecedarian formulas for } \text{linked}_{\text{CHSYM}} \log n, n(x) \text{ would imply a super-polynomial separation between non-commutative ABPs and formulas.} \]

In fact our proof technique also shows that a super-polynomial lower bound against homogeneous formulas for our hard polynomial would separate \( \text{VBP}_{nc} \) and \( \text{VF}_{nc} \).

\[ \text{Corollary 4.} \text{ Let } \text{linked}_{\text{CHSYM}} n,d(x) \text{ be as defined in Theorem 1. An } n^{\omega(1)} \text{ lower bound against homogeneous formulas for } \text{linked}_{\text{CHSYM}} n, \log n(x) \text{ would result in a super-polynomial separation between ABPs and formulas in the non-commutative setting.} \]

1.3 Proof Overview

We now give a proof overview of our main theorems.

**Separating Abecedarian Formulas and ABPs**

Let us first consider Theorem 1.

A small abecedarian ABP computing \( \text{linked}_{\text{CHSYM}} n,d(x) \) is essentially the following.

\[ \begin{array}{cccccccc}
 & & & s_1 & \cdots & \cdots & x_{i,i} & \cdots & \cdots \\
 & & & & & & i & & \\
 & & & & & & & & i \\
 & & & & & & & & \cdots \cdots \\
 & & & & & & & & f \\
 & & & & & & & & j \\
 & & & & & & & & \cdots \cdots \\
 & & & & & & & & \cdots \cdots \\
 & & & & & & & & \cdots \cdots \\
 & & & & & & & & t_{i} \\
 & & & & & & & & 1 \\
 & & & & & & & & k \\
 & & & & & & & & k+1 \\
 & & & & & & & & d \\
 & & & \cdots \cdots \cdots \cdots \cdots \cdots \cdots \cdots \\
1 & \cdots & \cdots & 1 \\
s_n & \cdots & \cdots & \cdots \\
0 & & & & \\
\end{array} \]

For the lower bound, assume that we have been given a small abecedarian formula computing the polynomial. We then keep modifying this formula till we get a small homogeneous multilinear formula computing the elementary symmetric polynomial of degree \( n/2 \). We then use the known lower bound against homogeneous multilinear formulas for this polynomial (shown by Hrubeš and Yehudayoff [12]), to get a contradiction.

Let us spell out the proof in some more detail.
Step 1: Suppose we are given an abecedarian formula computing linked-ChSYM_{n/2, \log n}(x) of size $O(n^{c \log \log n})$. Since the degree of the polynomial being computed is small, we can assume that there is in fact a homogeneous abecedarian formula computing linked-ChSYM_{n/2, \log n}(x) of size $O(n^{c \epsilon \log \log n})$ for some constant $c$ independent of $\epsilon$.

Step 2: Using the homogeneous abecedarian formula from Step 1, we obtain a more structured homogeneous abecedarian formula, of size $O(n^{c \epsilon \log \log n})$, that computes the same polynomial.

Step 3: We consider the complete homogeneous polynomial over $n$ variables of degree $d$

$$\text{CHSYM}_{n,d}(x) = \sum_{1 \leq i_1 \leq \ldots \leq i_d \leq n} x_{i_1} \cdots x_{i_d},$$

and show that there is a homogeneous abecedarian formula of size $\text{poly}(n)$ that computes $\text{CHSYM}_{n,\log n}(x)$.

Step 4: If the formula in Step 2 has size $s$ and that in Step 3 has $s'$, then we show that there is a homogeneous abecedarian formula of size $(s \cdot s')$ computing $\text{CHSYM}_{n/2, \log n}(x)$.

Step 5: Next, we show that Step 4 can be used repeatedly at most $O\left(\frac{n}{\epsilon \log \log n}\right)$ times, to obtain a homogeneous abecedarian formula computing $\text{CHSYM}_{n/2,n/2}(x)$ of size $O(n^{c \epsilon \log \log n})$.

Step 6: Using the formula obtained in Step 5, we get a homogeneous multilinear formula computing the elementary symmetric polynomial of degree $n/2$, of size $O(n^{c \epsilon \log \log n})$.

Step 7: Finally, we choose $\epsilon$ in such a way that Step 6 contradicts the theorem in [12]. The crucial observation that makes this proof work, is that the polynomial we are working with is structured enough for us to be able to amplify its degree in a systematic way (without blowing up the size by much). This is the 4th step in the description above.

Apart from that, the entire proof essentially boils down to the fact that when formulas are computing low degree polynomials, there are some additional tricks available to make them more structured. A complete proof of Theorem 1 can be found in Section 5.

We now elaborate a little on the first step, since the observations made to prove this step are quite general and possibly useful in various settings. These statements are known to be true in the commutative setting and their proofs in the non-commutative setting are fairly similar to the ones for their commutative counterparts. We state them here nevertheless, since to the best of our knowledge, they have not been stated formally before for the non-commutative setting.

**Homogenising Abecedarian Formulas computing Low Degree Polynomials**

Raz [21] had shown that if there is a formula computing a homogeneous polynomial of low degree in the commutative world, then it can be assumed without loss of generality that the formula is homogeneous. We show that this statement is true even in the non-commutative setting.

**Lemma 5 (Homogenising Abecedarian Formulas computing Low Degree Polynomials).** Suppose $f$ is a non-commutative homogeneous polynomial that can be computed by a fan-in 2 formula, $\mathcal{F}$, of size $s$, and has degree $d = O(\log s)$. Then there is a homogeneous formula $\mathcal{F}'$ computing $f$, that has size $\text{poly}(s)$ and whose multiplication gates have fan-in 2. Further, if $\mathcal{F}$ was abecedarian with respect to some partition, then $\mathcal{F}'$ is also abecedarian with respect to the same partition.

The only thing that needs to be checked for Raz’s proof to work in this setting is whether non-commutative formulas, and in particular abecedarian formulas can be depth-reduced to log-depth. We show that in fact they can be.
Depth Reduction for Abecedarian Formulas

Brent [4] had shown that if there is a formula of size $s$ computing a commutative polynomial $f$, then there is a formula of depth $O(\log s)$ and size $\text{poly}(s)$ that computes the same polynomial. A similar statement was shown by Hrubeš and Wigderson [9] in the non-commutative setting. We show that the statement continues to be true for abecedarian formulas. The proof is exactly along the same lines as the one by Brent [4].

Lemma 6 (Depth Reduction of Abecedarian Formulas). If there is a fan-in 2 formula $F$ of size $s$ computing a non-commutative polynomial $f$, then there is a fan-in 2 formula $F'$ of size $\text{poly}(s)$ and depth $O(\log(s))$ computing $f$. Further if $F$ is homogeneous, $F'$ is also homogeneous. Similarly, if $F$ is abecedarian with respect to some partition, then $F'$ is also abecedarian with respect to the same partition.

Converting Formulas into Abecedarian Formulas

Next we go over the proof idea of Theorem 2. In order to prove the statement, we first convert the given formula $F$ into an abecedarian circuit $C$, and then unravel $C$ in order to get an abecedarian formula $F'$ computing the same polynomial.

The first step is fairly straightforward. The proof is along the same lines as that for homogenising circuits, the only difference being that we keep track of bucket indices of the variables on either ends of the monomials being computed, instead of their degrees.

In the second step, we convert $C$ into a formula $F'$. In order to do that, we need to recompute vertices every time it is reused. Thus, to give an upper bound on the size of $F'$, we need to find an upper bound on the number of distinct paths from any vertex in $C$ to the root. This analysis is done similarly to the one by Raz [21] in his proof of the fact that formulas computing low degree polynomials can be homogenised efficiently. The requirement of the size of the partition being small also arises because of this analysis.

The only additional point that needs to be checked for the proof to go through is that similar to the commutative setting, non-commutative formulas can be depth reduced as well (Lemma 6). A complete proof of Theorem 2 can be found in Subsection 4.3.

1.4 Other Results: A Complete View of the Abecedarian World

We now go over some other results that help in completing the view of the abecedarian world. As mentioned earlier, Hrubeš et al. [11] had defined ordered circuits, a model naturally suited to compute ordered polynomials. They had then gone on to show that without loss of generality, any circuit computing an ordered polynomial can be assumed to be ordered. We show that even in the abecedarian setting, such a statement is true.

Observation 7 (Converting Circuits into Abecedarian Circuits). Let $f$ be an abecedarian polynomial with respect to a Partition of size $m$, and $C$ be a circuit of size $s$ computing $f$. Then there is an abecedarian circuit $C'$ computing $f$ of size $O(m^3 s)$.

What this implies is that an $n^{o(1)}$ lower bound against abecedarian circuits for any explicit polynomial that is abecedarian would result in a super-polynomial lower bound against general non-commutative circuits. We also show that an analogous statement is true even for abecedarian ABPs.

---

4 They in fact showed it for rational functions

5 Theorem 7.1 in [11].
Observation 8 (Converting ABPs into Abecedarian ABPs). Suppose \( f \) is an abecedarian polynomial with respect to a partition of size \( m \). If there is an ABP \( A \) of size \( s \) computing it, then there is an abecedarian ABP \( A' \) computing it of size \( O(ms) \).

Next, we define the natural classes of abecedarian polynomials. Let \( \text{abc-VP}_{nc} \) denote the class of abecedarian polynomials that can be computed by poly-sized abecedarian circuits. Similarly let \( \text{abc-VBP}_{nc} \) and \( \text{abc-VF}_{nc} \) denote the classes of abecedarian polynomials that can be computed by poly-sized abecedarian ABPs and abecedarian formulas respectively. We first note that the logical inclusions that should hold, do hold.

Observation 9 (The Usual Inclusions). Let \( \text{abc-VP}_{nc} \), \( \text{abc-VBP}_{nc} \) and \( \text{abc-VF}_{nc} \) denote the classes of abecedarian polynomials over \( n \) variables that can be computed by poly-(\( n \)) sized abecedarian circuits, abecedarian ABPs and abecedarian formulas respectively. Then,\[
\text{abc-VF}_{nc} \subseteq \text{abc-VBP}_{nc} \subseteq \text{abc-VP}_{nc}.
\]

We also observe that if a degree \( d \) polynomial has an abecedarian ABP of size \( s \), then it has an abecedarian formula of size \( O(s^{\log d}) \) via the usual divide-and-conquer algorithm.

Observation 10 (Converting Abecedarian ABPs into Abecedarian Formulas). Suppose \( f \) is an abecedarian polynomial of degree \( d \). If there is an abecedarian ABP \( A \) of size \( s \) computing it, then there is an abecedarian formula \( F \) computing \( f \) of size \( O(s^{\log d}) \).

What Theorem 1 essentially shows is that the blow-up observed in Observation 10 is tight.

Finally, it is not hard to see that Nisan’s proof can be modified to give an exponential separation between abecedarian ABPs and abecedarian circuits.

General Formula Lower Bound from Homogeneous Formula Lower Bound

We end by showing that homogeneous formula lower bounds for the iterated matrix multiplication polynomial would lead to separating \( \text{VF}_{nc} \) and \( \text{VBP}_{nc} \). This is a corollary of Lemma 5.

Corollary 11. An \( n^{\omega(1)} \) lower bound against homogeneous formulas computing the \( n \)-variate iterated matrix multiplication polynomial of degree \( \log n \), \( \text{IMM}_{n,\log n}(x) \), implies a super-polynomial separation between ABPs and formulas in the non-commutative setting.

To put the requirement of degree being \( O(\log n) \) in perspective, note the following.

Remark 12 (Analogous to Remark 5.12 in [15]). The standard divide and conquer approach for computing the iterated matrix multiplication polynomial \( \text{IMM}_{n,d}(x) \) yields a (homogeneous) formula of size \( n^{O(\log d)} \). It would be quite surprising if this standard algorithm were not optimal in terms of formula size.

Intuitively, improving on the standard divide and conquer algorithm gets harder as \( d \) gets smaller. This is because any (homogeneous) formula of size \( n^{O(\log d)} \) for computing \( \text{IMM}_{n,d} \) can be used in a straightforward manner to recursively obtain (homogeneous) formulas for \( \text{IMM}_{n,D} \) of size \( n^{O(\log D)} \) for any \( D > d \). The case of smaller \( d \), which seems harder algorithmically, is thus a natural first candidate for lower bounds.

1.5 Structure of the Paper

We begin, in Section 2, with formal definitions for abecedarian polynomials and naturally restricted version of circuits, ABPs and formulas that compute them. Then, in Section 3, we prove some structural statements, namely Lemma 6 and Lemma 5. In Section 4, we prove
Theorem 2 along with Observation 7 and Observation 8. We then prove our main result (Theorem 1), that gives a super-polynomial separation between abecedarian formulas and ABPs, in Section 5. Finally, in Section 6, we prove the remaining statements mentioned.

2 Preliminaries

Let us begin by formally defining abecedarian polynomials and the naturally restricted versions of circuits, ABPs and formulas that compute them. Throughout the write-up, we will use \([n]\) to denote the set \(\{1, \ldots, n\}\).

2.1 Abecedarian Polynomials

First, we formally define abecedarian polynomials.

▶ Definition 13 (Abecedarian Polynomials). A polynomial \(f \in \mathbb{F}\langle x_1, \ldots, x_n \rangle\) of degree \(d\) is said to be abecedarian with respect to a partition \(\{X_1, \ldots, X_m\}\) for \(\{x_1, \ldots, x_n\}\), if

\[
f = f(\emptyset) + \sum_{k=1}^{d} \left( \sum_{1 \leq i_1 \leq \cdots \leq i_k \leq m} f[X_{i_1}, \ldots, X_{i_k}] \right)
\]

where \(f(\emptyset)\) is the constant term in \(f\), and for any \(k \in [d]\), \(f[X_{i_1}, \ldots, X_{i_k}]\) is defined as follows.

For a polynomial \(f\), \(f[X_{i_1}, \ldots, X_{i_k}]\) is the homogeneous polynomial of degree \(k\) such that for every monomial \(\alpha\),

\[
\text{coeff}_\alpha(f[X_{i_1}, \ldots, X_{i_k}]) = \begin{cases} 
\text{coeff}_\alpha(f) & \text{if } \alpha = x_{i_1} \cdots x_{i_k} \text{ with } x_{i_j} \in X_{i_j} \text{ for every } j \in [k] \\
0 & \text{otherwise.}
\end{cases}
\]

In this case, we say that \(f\) is abecedarian with respect to \(\{X_1, \ldots, X_m\}\), a partition of size \(m\).

Abecedarian polynomials are essentially generalisations of ordered polynomials (defined by Hrubeš, Wigderson and Yehudayoff [11]). A homogeneous polynomial, of degree \(d\), is said to be ordered if the set of variables it depends on can be partitioned into \(d\) buckets such that variables occurring in position \(k\) only come from the \(k\)-th bucket.

It is easy to see that any ordered polynomial is also abecedarian with respect to the same partition. This is because position indices are always increasing. For example, consider the following version of the complete homogeneous symmetric polynomial.

\[
\text{CHSYM}_{n,d}^{(\text{ord})}(x) = \sum_{1 \leq i_1 \leq \cdots \leq i_d \leq n} x_{i_1}^{(1)} \cdots x_{i_d}^{(d)}.
\]

It is both ordered and abecedarian with respect to the partition \(\{X_k = \{x_i^{(k)} : i \in [n]\}\}\).

However, note that there are homogeneous polynomials that are abecedarian but not ordered. The following version of the same polynomial is an example.

\[
\text{CHSYM}_{n,d}(x) = \sum_{1 \leq i_1 \leq \cdots \leq i_d \leq n} x_{i_1} \cdots x_{i_d}
\]

is abecedarian with respect to \(\{X_i : X_i = \{x_i\}\}\), but is not ordered.

The reason is that for a polynomial to be ordered, the bucket labels have to essentially be position labels. On the other hand, for a polynomial to be abecedarian with respect to a partition, the bucket labels can be independent of position. For example, note that \(\text{CHSYM}_{n,d}^{(\text{ord})}(x)\) is abecedarian with respect to the partition \(\{X_i = \{x_i^{(k)} : k \in [d]\}\}\) along with the one mentioned earlier.

We now move on to defining algebraic models that naturally compute such polynomials.
2.2 Abecedarian Models of Computation

Homogeneous formulas have the property that any vertex can be labelled by a tuple of position indices \((a, b)\) such that all the monomials being computed at that vertex occur exactly from position \(a\) to position \(b\) in the final polynomial that is being computed by it. Hrubeš et al. [11] defined ordered circuits to be those circuits that have this property.

A circuit computing a degree \(d\) polynomial \(f \in \mathbb{F}\langle x_1, \ldots, x_n \rangle\) is said to be ordered, if \(\{X_1, \ldots, X_d\}\) forms a partition of \(\{x_1, \ldots, x_n\}\) such that

- every gate \(v\) in the circuit is labelled by a tuple of position indices \((a, b)\);
- \(f_v\) is the polynomial computed at \(v\), then
  - \(f_v\) is homogeneous and has degree \((b - a + 1)\);
  - every monomial in \(f_v\) is a product of exactly one variable from each of the buckets \(X_a, \ldots, X_b\), multiplied in increasing order of their bucket indices.

We generalise this notion to define circuits that naturally compute abecedarian polynomials. Before we can do that, we need the notion of sub-polynomials of any abecedarian polynomial.

\[\text{Definition 14 (Sub-Polynomials of an Abecedarian Polynomial). Suppose } f \text{ is an abecedarian polynomial with respect to the partition } \{X_1, \ldots, X_m\}, \text{ and has degree } d. \text{ For any } 1 \leq a \leq b \leq m + 1, f[a, b] \text{ is the sub-polynomial of } f \text{ defined as follows.}
\]

- For any \(a \in [m + 1]\), \(f[a, a] = f(\emptyset)\) is the constant term in \(f\).
- For any \(1 \leq a < b \leq m + 1\),

\[
f[a, b] = \sum_{k=1}^{d} \left( \sum_{i_1, \ldots, i_k \in [m]} f[X_{i_1}, \ldots, X_{i_k}] \right)
\]

where \(f[X_{i_1}, \ldots, X_{i_k}]\) is as defined in Definition 13.

Further, we say that a polynomial \(f\) is of type \([a, b]\) if \(f = f[a, b]\).

Let us now formally define abecedarian circuits.

\[\text{Definition 15 (Abecedarian Circuits). For any } a, b \in \mathbb{N}, \text{ let } [a, b] \text{ denote a set of the form } I = \{i : a \leq i < b\}. \text{ As a convention, } [a, a] \text{ denotes the empty set for every } a \in \mathbb{N}.
\]

A multi-output circuit \(C\) is said to be abecedarian when

- every gate \(v\) in \(C\) is associated with a set \(I_v = [a, b]\);
- if \(f_v\) is the polynomial computed at \(v\), then \(f_v = f[a, b]\);
- if \(v = v_1 + v_2\), then \(I_v = I_{v_1} = I_{v_2}\);
- if \(v = v_1 \times v_2\) with \(I_v = [a, a]\), then \(I_{v_1} = I_{v_2} = [a, a]\)
- if \(v = v_1 \times v_2\) with \(I_v = [a, b]\) and \(a < b\), then one of the following is true
  - \(I_{v_1} = [a, b]\) and \(I_{v_2} = [b, b]\);
  - \(I_{v_1} = [a, a]\) and \(I_{v_2} = [a, b]\);
  - there exists \(a \leq c < b\) such that \(I_{v_1} = [a, c + 1]\) and \(I_{v_2} = [c, b]\).

The polynomial computed by \(C\) is the sum of the polynomials computed at the output gates.

Next, we define abecedarian ABPs and abecedarian formulas as the restricted versions of ABPs and formulas respectively, that naturally compute abecedarian polynomials.
2.3 Abecedarian ABPs and Formulas

Homogeneous ABPs have the property that every vertex in it is labelled by a position index such that, polynomials computed between vertices labelled with indices \( a \) and \( b \) only contain monomials between positions \( a \) and \((b−1)\). We define abecedarian ABPs analogously except that the labels on the vertices are bucket labels instead of position labels. These restricted ABPs naturally compute abecedarian polynomials.

Definition 16 (Abecedarian ABPs). A multi-input, multi-output ABP \( A \) is said to be abecedarian when

- every vertex in it is labelled by a bucket index;
- if \( f \) is the polynomial computed between vertices labelled with indices \( a \) and \( b \) respectively, then \( f = f[a,b+1) \).

The polynomial computed by \( A \) is the sum of all the polynomials computed between the various (input, output) gate pairs.

Similarly, we define abecedarian formulas as analogues of homogeneous formulas, with the labels again referring to bucket indices instead of position indices.

Definition 17 (Abecedarian Formulas). Let sets of the form \([a,b)\), with \( a,b \in \mathbb{N} \), be as defined in Definition 15. Suppose \( F \) is a formula computing a polynomial \( f \) that is abecedarian with respect to a partition of size \( m \). Then \( F \) is said to be abecedarian if \( F = F_1 + \cdots + F_m \) for sub-formulas \( F_1, \ldots, F_{m+1} \), where for every \( i \in [m+1] \):

- \( F_i \) computes the polynomial \( f[i,m+1) \);
- every gate \( v \) in \( F_i \) is associated with a set \( I_v = [a,b) \), and in particular, the root node must be associated with the set \([i,m+1)\);
- if \( f_v \) is the polynomial computed at \( v \), then \( f_v = f_v[a,b) \);
- if \( v = v_1 + v_2 \), then \( I_v = I_{v_1} = I_{v_2} \);
- if \( v = v_1 \times v_2 \) with \( I_v = [a,a) \), then \( I_{v_1} = I_{v_2} = [a,a) \) and \( a < b \), then one of the following is true
  - \( I_{v_1} = [a,b) \) and \( I_{v_2} = [b,b) \);
  - \( I_{v_1} = [a,a) \) and \( I_{v_2} = [a,b) \);
  - there exists \( a \leq c < b \) such that \( I_{v_1} = [a,c+1) \) and \( I_{v_2} = [c,b) \).

Further, \( F \) is said to be homogeneous if each \( F_i \) is homogeneous.

With these definitions in mind, we now move to proving some structural statements.

3 Structural Statements

In this section, we prove two structural statements in the non-commutative setting that are known to be true in the commutative setting. Apart from being crucial to our proofs, they are possibly interesting observations in their own right.

3.1 Depth Reduction for Non-Commutative Formulas

Brent [4] had shown that if there is a formula of size \( s \) computing a commutative polynomial \( f \), then there is a formula of depth \( O(\log s) \) and size \( \text{poly}(s) \) that computes the same polynomial. We show that this is also true in the non-commutative setting.

The proof is essentially the same as the one by Brent [4], just analysed carefully. We give the complete proof for the sake of completeness.
Lemma 6 (Depth Reduction of Abecedarian Formulas). If there is a fan-in 2 formula \( F \) of size \( s \) computing a non-commutative polynomial \( f \), then there is a fan-in 2 formula \( F' \) of size \( \text{poly}(s) \) and depth \( O(\log(s)) \) computing \( f \). Further if \( F \) is homogeneous, \( F' \) is also homogeneous. Similarly, if \( F \) is abecedarian with respect to some partition, then \( F' \) is also abecedarian with respect to the same partition.

Proof. Suppose \( F \) is a fan-in 2 formula of size \( s \) that computes \( f \). Then, we claim the following.

\[\text{Claim 18.} \quad \text{Suppose} \quad F_0 = L \cdot F_1 \cdot R + F_2 \text{ also computes} \quad f_0; \]

- each of \( L, F_1, R, F_2 \) have size at least \((s/3)\) and at most \((2s/3)\);
- if \( F_0 \) is homogeneous, then so are \( L, F_1, R, F_2 \);
- if \( F_0 \) is abecedarian with respect to some partition, \( f_{\text{left}}, f_1, f_{\text{right}} \) are polynomials computed by \( L, F_1, R, F_2 \) respectively and \( f_0 = f_0(a, b) \) and
  - for each of \( L, F_1, R, F_2 \) are abecedarian with respect to the same partition as \( F_0 \)
  - when \( a = b \), \( f_{\text{left}} = f_{\text{left}}(a, a) \quad f_1 = f_1[a, a] \quad f_{\text{right}} = f_{\text{right}}[a, a] \);
  - when \( a < b \), there exist \( a \leq i \leq j \leq b \) such that

\[
\begin{align*}
  a = i < j = b & \implies f_{\text{left}} = f_{\text{left}}[a, i] \quad f_1 = f_1[i, j] \quad f_{\text{right}} = f_{\text{right}}[j, b]. \\
  a = i = j < b & \implies f_{\text{left}} = f_{\text{left}}[a, i] \quad f_1 = f_1[i, j] \quad f_{\text{right}} = f_{\text{right}}[j, b]. \\
  a = i < j < b & \implies f_{\text{left}} = f_{\text{left}}[a, i] \quad f_1 = f_1[i, j+1] \quad f_{\text{right}} = f_{\text{right}}[j, b]. \\
  a < i = j < b & \implies f_{\text{left}} = f_{\text{left}}[a, i+1] \quad f_1 = f_1[i+1, j] \quad f_{\text{right}} = f_{\text{right}}[j, b]. \\
  a < i < j = b & \implies f_{\text{left}} = f_{\text{left}}[a, i+1] \quad f_1 = f_1[i, j] \quad f_{\text{right}} = f_{\text{right}}[j, b]. \\
  a < i < j < b & \implies f_{\text{left}} = f_{\text{left}}[a, i+1] \quad f_1 = f_1[i, j+1] \quad f_{\text{right}} = f_{\text{right}}[j, b].
\end{align*}
\]

Before proving Claim 18, let us complete the proof of Lemma 6 using it.

By the above claim, we have a formula \( F_0' \) computing \( f_0 \) that looks like \( L \cdot F_1 \cdot R + F_2 \) where each of \( L, F_1, R, F_2 \) have size at most \((2s/3)\). Further if \( F \) is homogeneous, then so are each of \( L, F_1, R, F_2 \). Hence, \( F_0' \) is homogeneous. On the other hand, when \( F_0 \) is abecedarian, so are \( L, F_1, R, F_2 \). Further, note that \( F_0' \) is also abecedarian in this case since \( f_{\text{left}}, f_1, f_{\text{right}} \) are of the correct type due to Claim 18.

In all the cases, recursively applying this technique, on each of \( L, F_1, R, F_2 \), we get

\[
\text{depth}(s) \leq \text{depth}(2s/3) + 3 \quad \text{and} \quad \text{size}(s) \leq 4 \cdot \text{size}(2s/3) + 3.
\]

Note that in the base case, when \( s \) is constant, both \( \text{size}(s) \) and \( \text{depth}(s) \) are constants. Thus,

\[
\text{depth}(s) = O(\log s) \quad \text{and} \quad \text{size}(s) = \text{poly}(s).
\]

Pictorially, once we have Claim 18, we essentially do the following recursively.
We now complete the proof of Claim 18.

Proof of Claim 18. From the root let us traverse $F_0$ towards the leaves, always choosing the child that has a larger sub-tree under it, till we find a vertex $v$ such that the associated sub-tree has size at most $(2s/3)$. Since $F_0$ tree has fan-in 2, we also know that the size of this sub-tree must be at least $(s/3)$. Let this sub-tree be $F_1$. Additionally, in the case when $F_0$ is abecedarian, let us assume that $v$ is labelled with $[i_v,j_v]$.

Let $P$ be the path from $v$ to the root and $v_{\text{add}}$ the addition gate on $P$ which is closest to $v$. Also let the set of multiplication gates on $P$ be $\{v_1, \ldots, v_\ell\}$ for some $\ell \in \mathbb{N}$. Assume, without loss of generality, that $v_1$ is closest to $v$ and $v_\ell$ to the root. Further, for every $i \in [\ell]$, let $L_i$ be sub-formula corresponding to the left child of $v_i$ and $R_i$ the one to its right child.

Note that for every $i \in [\ell]$, exactly one of children of $v_i$ is a vertex in $P$. We can then define $L$ and $R$ as follows.

**Step 1:** Set $L = R = 1$.

**Step 2:** For $i$ from 1 to $\ell$,

$$L = \begin{cases} L_i \times L & \text{if the right child of } v_i \text{ is a vertex in } P, \\ L & \text{otherwise.} \end{cases}$$

and

$$R = \begin{cases} R & \text{if the right child of } v_i \text{ is a vertex in } P, \\ R \times R_i & \text{otherwise.} \end{cases}$$

Also define $F_2$ to be the formula we get by replacing the vertex $v$ and the sub-tree under it with 0, and then removing the redundant gates.

Clearly, by construction, $F_1$, $L$, $R$ and $F_2$ are sub-formulas of $F_0$. Further, $F_1$ is disjoint from $L$, $R$ and $F_2$. As a result, since $F_1$ has size at least $(s/3)$ and at most $(2s/3)$, it must be the case that each of $L$, $R$ and $F_2$ have size at least $(s/3)$ and at most $(2s/3)$.

Also, it is not hard to see that $F'_0 = L \cdot F_1 \cdot R + F_2$ computes $f_0$. What is left to check is that when $F_0$ is homogeneous or abecedarian, then $L, F_1, R, F_2$ have the additional properties claimed. The one line proof of this is that each parse-tree$^6$ of $F_0$ is merely restructured in the above process, without changing its value. We however go over the proof explicitly for the sake of completeness.

---

$^6$ For a definition, see for example [15].
7:14 Separating ABPs and Some Structured Formulas in the Non-Commutative Setting

When \( F_0 \) is homogeneous, since \( L, F_1, R, F_2 \) are sub-formulas, they are also homogeneous. On the other hand, suppose \( F_0 \) is abecedarian and \( f_0 = f_0(a, b) \). Recall that the vertex \( v \) was labelled by \([i_v, j_v] \). Let us set \( i = i_v \) and \( j = j_v \). Then, by definition, \( F_1 \) is labelled by \([i, j] \). Hence, if \( f_1 \) is the polynomial computed at \( v \), then \( f_1 = f_1[i, j] \). Further, \( F_1 \) is abecedarian since it is a sub-formula of \( F_0 \) and computes an abecedarian polynomial.

Now let us focus on \( F_2 \). Essentially \( F_2 \) is got by removing from \( F_0, v \) and all the multiplication gates on \( P \) between \( v \) and \( v_{\text{add}} \) along with the sub-trees under them. Thus \( F_2 \) is also abecedarian in this case, and if \( f_2 \) is the polynomial by it, then \( f_2 = f_2(a, b) \).

Finally, note that the left indices of labels on the various vertices of \( P \) change only at the gates at which multiplications to \( L \) occur. Further, note that they occur in the correct order and are of the correct type. Thus, by induction, it is easy to see that the labels on \( L \) are consistent with those on the \( L_i \)'s when the respective multiplications happen. Therefore \( L \) is abecedarian, and \( f_{\text{left}} = f_{\text{left}}[a, i] \).

For similar reasons, \( R \) is also abecedarian and \( f_{\text{right}} = f_{\text{right}}[j, b] \). This completes the proof.  

\[ \triangleleft \]

### 3.2 Homogenisation

Raz [21] had shown that if there is a formula computing a homogeneous polynomial of low degree in the commutative world, then it can be assumed without loss of generality that the formula is homogeneous. We show that his proof also works in the non-commutative setting because of Lemma 6. A complete proof is given here for the sake of completeness.

\[ \triangleright \text{Lemma 5 (Homogenising Abecedarian Formulas computing Low Degree Polynomials).} \]

Suppose \( f \) is a non-commutative homogeneous polynomial that can be computed by a fan-in 2 formula, \( F \), of size \( s \), and has degree \( d = O(\log s) \). Then there is a homogeneous formula \( F' \) computing \( f \), that has size \( \text{poly}(s) \) and whose multiplication gates have fan-in 2. Further, if \( F \) was abecedarian with respect to some partition, then \( F' \) is also abecedarian with respect to the same partition.

**Proof.** We first note that since \( s \) is the ABP complexity of \( f \), \( s' \geq s \). Further if \( F \) has depth \( r \), then by Lemma 6, we can assume without loss of generality, that \( r = O(\log s') \).

In order to construct a homogeneous formula computing \( f \), we first homogenise \( F \) to obtain a circuit \( \mathcal{C} \), and then unravel \( \mathcal{C} \) to make it into a formula \( F' \).

The first step is done in the usual manner. For every gate \( v \) in \( F \), we have \( d + 1 \) gates \((v, 0), \ldots, (v, d)\) in \( \mathcal{C} \). Intuitively if \( f_v \) is the polynomial computed at \( v \), then the polynomial computed at \((v, i)\) is the degree \( i \) homogeneous component of \( f_v \). These vertices are then connected as follows.

- If \( v = u_1 + u_2 \), then for every \( i \in \{0, \ldots, d\} \), \((v, i) = (u_1, i) + (u_2, i)\).
- If \( v = u_1 \times u_2 \), then for every \( i \in \{0, \ldots, d\} \), \((v, i) = \sum_{j=0}^{i-1} (u_1, j) \times (u_2, i-j)\).

So, we now have a homogeneous circuit \( \mathcal{C} \) that computes \( f \) and has size at most \( O(d^2 \cdot s') \). Also, the depth of this circuit is at most twice that of \( F \), and the multiplication gates have fan-in 2. To convert \( \mathcal{C} \) into a formula \( F' \), we have to recompute nodes whenever they have to be reused. That is, a particular vertex in \( \mathcal{C} \) has to be duplicated as many times as there are paths from the vertex to the root. Thus, to upper bound the size of \( F' \), we need to give an upper bound on the number of distinct paths from every vertex of \( \mathcal{C} \) to its root.

Let us arbitrarily choose a vertex \((v, i)\) in \( \mathcal{C} \), and consider the path from it to the root. Suppose the path is \((v, i) = (v_1, i_1) \rightarrow \cdots \rightarrow (v_r, i_r) = (\text{root}, d)\) where \( r \) is at most the depth of \( \mathcal{C} \). Now since \( \mathcal{C} \) comes from a formula, the only reason multiple paths can exist is because...
of the second index, and therefore it is enough to focus on that. Note that it must be the case that \( i = i_1 \leq \cdots \leq i_t = d \). Hence, if we define \( \delta_j = i_{j+1} - i_j \) for \( j \in [\ell - 1] \), then the \( \delta_j \)'s are non-negative integers such that \( \delta_1 + \cdots + \delta_{\ell-1} = (d - i) \). Thus, the number of choices we have for \((i_2, \ldots, i_t)\) such that \( i = i_1 \leq \cdots \leq i_t = d \), is the same as the number of choices we have for \((\delta_1, \ldots, \delta_{\ell-1})\) such that \( \delta_1 + \cdots + \delta_{\ell-1} = (d - i) \leq d \). This is at most \( \binom{\ell + d}{\ell} \). Note that in this process the fan-in of the gates have not changed, and hence the multiplication gates in \( \mathcal{F}' \) continue to have fan-in 2. Further, we know that the \( \mathcal{C} \) has depth 2\( r \) and hence \( \ell \leq 2r \). Therefore, the number of paths from \((v, i)\) to the root is at most \( \binom{2r + d}{2r} \). Hence, if \( \mathcal{F}' \) is the formula obtained by unravelling \( \mathcal{C} \), then \( \text{size}(\mathcal{F}') \leq s' \cdot d^2 \cdot \binom{2r + d}{2r} \). Here \( r = O(\log(s')) \), and \( s \leq s' \) implying that \( d = O(\log(s)) = O(\log(s')) \). Thus, \( \text{size}(\mathcal{F}') \leq \text{poly}(s') \).

Finally, assume that \( \mathcal{F} \) is abecedarian. Then every vertex \( v \) is labelled with a tuple of bucket indices, say \((a_v, b_v)\). In that case, we add the label \((a_v, b_v)\) to the gates \( \{(v, i)\} \) in \( \mathcal{C} \) and continue with the proof as is. Note that the final formula that we get, \( \mathcal{F}' \), is abecedarian and all the other properties that were true in the general case, continue to be true.

4 Converting Computational Models into Abecedarian Ones

In this section we show that, without loss of generality, circuits and ABPs computing abecedarian polynomials can be assumed to be abecedarian. For formulas however, we can prove such a statement only in certain cases.

4.1 Circuits

Hrubeš et al. [11] had shown that any circuit computing an ordered polynomial can be assumed to be ordered without loss of generality.

> **Theorem 19** (Theorem 7.1 in [11]). Let \( \mathcal{C} \) be a circuit of size \( s \) computing an ordered polynomial \( f \) of degree \( d \). Then, there is an ordered circuit \( \mathcal{C}' \) of size \( O(d^3 s) \) that computes \( f \).

We show that the proof of this statement can be generalised to show Observation 7. A complete proof is given for the sake of completeness.

> **Observation 7** (Converting Circuits into Abecedarian Circuits). Let \( f \) be an abecedarian polynomial with respect to a Partition of size \( m \), and \( \mathcal{C} \) be a circuit of size \( s \) computing \( f \). Then there is an abecedarian circuit \( \mathcal{C}' \) computing \( f \) of size \( O(m^3 s) \).

**Proof.** Without loss of generality, let us assume that \( \mathcal{C} \) has fan-in 2.

We have the given statement by describing how to construct \( \mathcal{C}' \) from \( \mathcal{C} \). For each gate \( v \) in \( \mathcal{C} \), we make \( O(m^2) \) copies in \( \mathcal{C}' \), \( \{(v, [a, b]) : 1 \leq a \leq b \leq m + 1\} \); and if root is the output gate in \( \mathcal{C} \), then we define the set of output gates in \( \mathcal{C}' \) to be \( \{(\text{root}, [i, m + 1])\} \).

Intuitively, if \( f_v \) is the polynomial computed at \( v \) in \( \mathcal{C} \), then the polynomial computed at \( (v, [a, b]) \) is \( f_v([a, b]) \). Thus if \( f \) was the polynomial computed at root, then the polynomial computed by \( \mathcal{C}' \) is \( \sum_{i=1}^{m+1} f[i, m + 1] \) which is indeed \( f \).

We ensure this property at every gate by adding edges as follows.

- If \( v \) is an input gate labelled by a field element \( \gamma \),
  - we set \( (v, [a, a]) = \gamma \) for every \( a \in [m + 1] \);
  - we set \( (v, [a, b]) = 0 \) for every \( 1 \leq a < b \leq m + 1 \).
- If \( v \) is an input gate labelled by a variable \( x_i \) and \( x_i \in \mathbb{X}_k \),
  - we set \( (v, [k, k + 1]) = x_i \);
  - we set \( (v, [a, b]) = 0 \) for every \( a \neq k, b \neq k + 1 \).
If \( v = v_1 + v_2 \), we set \( (v, [a, b]) = (v_1, [a, b]) + (v_2, [a, b]) \) for every \( a \leq b \leq [m + 1] \).

If \( v = v_1 \times v_2 \), we set \( (v, [a, a]) = (v_1, [a, a]) \cdot (v_2, [a, a]) \) for every \( a \in [m + 1] \); and

\[
(v, [a, b]) = (v_1, [a, a]) \cdot (v_2, [a, b]) + (v_1, [a, b]) \cdot (v_2, [b, b]) + \sum_{c=a}^{b-1} (v_1, [a, c + 1]) \times (v_2, [c, b])
\]

for every \( 1 \leq a < b \leq m + 1 \).

Finally, for every \( 1 \leq a \leq b \leq m + 1 \), we associate the gate \((v, [a, b])\) in \( \mathcal{C}' \) with the set \([a, b]\).

Using induction, one can easily show that the gates in \( \mathcal{C}' \) have the claimed properties. Hence \( \mathcal{C}' \) is indeed an abecedarian circuit computing \( f \). Further for every vertex \( v \in \mathcal{C} \), there are at most \( O(m^3) \) vertices in \( \mathcal{C}' \). Thus the size of \( \mathcal{C}' \) is \( O(m^3s) \).

### 4.2 Algebraic Branching Programs

Next, we show that a similar statement is true for ABPs as well.

**Observation 8** (Converting ABPs into Abecedarian ABPs). Suppose \( f \) is an abecedarian polynomial with respect to a partition of size \( m \). If there is an ABP \( \mathcal{A} \) of size \( s \) computing it, then there is an abecedarian ABP \( \mathcal{A}' \) computing it of size \( O(ms) \).

**Proof.** Let \( f \) have degree \( d \) and be abecedarian with respect to the buckets \( \{X_i\}_{i=1}^m \), where \( X_i = \{x_{i,j} : j \in [n_i]\} \). Without loss of generality, we can assume that \( \mathcal{A} \) is homogeneous\(^7\). If \( f \) is not homogeneous, \( \mathcal{A} \) can be thought of as a collection of homogeneous ABPs \( \mathcal{A}_1, \ldots, \mathcal{A}_d \) where \( \mathcal{A}_k \) computes the \( k \)-th homogeneous component of \( f \).

We prove the theorem by describing how to construct \( \mathcal{A}' \). For each vertex \( v \) in \( \mathcal{A} \), make \( O(m) \) copies in \( \mathcal{A}' \), namely \( \{(v, a) : 0 \leq a \leq m\} \). Intuitively, if \( g_{(u,v)} \) is the polynomial computed between \( u \) and \( v \) in \( \mathcal{A} \), then the polynomial computed between \( (u, a) \) and \( (v, b) \) in \( \mathcal{A}' \) is \( g_{(u,v)}[a,b+1] \). The way we ensure this property at every vertex is by adding edges in \( \mathcal{A}' \) as follows.

For any two vertices \( u, v \) in \( \mathcal{A} \), suppose there is an edge between them that is labelled with \( \sum_{i \in [m]} \sum_{j \in [n_i]} \gamma_{i,j} x_{i,j} \). Then, for every \( a, b \in [m] \) with \( a \leq b \), add an edge from \((u,a)\) to \((v,b)\) with label \( \sum_{i=a}^{b} \left( \sum_{j \in [n_i]} \gamma_{i,j} x_{i,j} \right) \).

Also, associate the bucket index \( a \) with the gate \((v,a)\) in \( \mathcal{A}' \).

By induction, one can easily show that the gates in \( \mathcal{A}' \) have the claimed property. Hence \( \mathcal{A}' \) is indeed an abecedarian ABP computing \( f \). Further, every vertex \( v \) in \( \mathcal{A} \), there are at most \( O(m) \) vertices in \( \mathcal{A}' \). Therefore, the size of \( \mathcal{A}' \) is \( O(ms) \).

### 4.3 Formulas

Finally we show that in the case of formulas, we can prove a similar statement only when the polynomial is abecedarian with respect to a partition of small size. The proof is very similar to that of Lemma 5.

**Theorem 2** (Converting Formulas into Abecedarian Formulas). Let \( f \) be an abecedarian polynomial with respect to a partition of size \( m \), and \( \mathcal{F} \) be a formula of size \( s \) computing \( f \). If \( m = O(\log s) \), then there is an abecedarian formula \( \mathcal{F}' \) computing \( f \) of size \( \text{poly}(s) \).

---

\(^7\) Every edge is labelled by a homogeneous form.
Proof. Let us assume additionally that \( F \) has depth \( r \). Now Lemma 6 implies that \( r = \log(s) \) without loss of generality. By Observation 7, there is an abecedarian circuit \( C \) that computes \( f \) and has size at most \( s' = O(s \cdot m^3) \). Further its proof implies that the depth of \( C \) is at most \( 2r \).

To convert \( C \) into an abecedarian formula \( F' \), we have to recompute a node each time it has to be reused. That is, a particular vertex in \( C \) has to be duplicated as many times as there are paths from the vertex to the root. Thus to upper bound the size of \( F' \), we need to give an upper bound on the number of distinct paths from every vertex in \( C \) to its root.

Let us arbitrarily choose a vertex \((v, [a, b])\) in \( C \), and consider the path from it to the root. Suppose the path is \((v, [a, b]) = (v_1, [a_1, b_1]) \rightarrow \cdots \rightarrow (v_{\ell}, [a_\ell, b_\ell]) = (\text{root}, [i, m + 1])\) for some \( \ell \) that is at most the depth of \( C \). Note that it must be the case that
\[
i \leq a_\ell \leq \cdots \leq a_1 \leq a \leq b \leq b_1 \leq b_\ell \leq m + 1.
\]

Let us define \( \delta_j = a_j - a_{j+1} \) and \( \delta'_j = b_{j+1} - b_j \) for \( j \in [\ell - 1] \). Then, the number of choices we have for \((a_1, \ldots, a_\ell)\) and \((b_1, \ldots, b_\ell)\) such that
\[
i = a_\ell \leq \cdots \leq a_1 \leq a \leq b \leq b_1 \leq \cdots \leq b_\ell = m + 1
\]
is the same as the number of choices we have for \((\delta_1, \ldots, \delta_{\ell-1}, \delta'_1, \ldots, \delta'_{\ell-1})\) such that
\[
\delta_1 + \cdots + \delta_{\ell-1} + \delta'_1 + \cdots + \delta'_{\ell-1} = (m + 1) - (b - a) - i \leq m.
\]
This is clearly at most \((2^{\ell+m})\).

Further, we know that the \( C \) has depth \( 2r \) and hence \( \ell \leq 2r \). Therefore, the number of paths from \((v, i)\) to the root is at most \((4^{2r+m})\). Hence if \( F' \) is the formula obtained by unravelling \( C \), then \( \text{size}(F') \leq s' \cdot m^2 \cdot (4^{2r+m}) \). Here \( s' = O(m^3 \cdot s) \), \( r = O(\log(s)) \) and \( m = O(\log(s)) \). Thus, \( \text{size}(F') \leq \text{poly}(s) \). \(\square\)

5 Separating Abecedarian ABPs and Abecedarian Formulas

In this section, we prove our main theorem: a super-polynomial separatum between the powers of abecedarian formulas and ABPs. Before proceeding to the proof however, we first go over some observations that will help us with the proof.

5.1 Some Simple Observations

The two main polynomials we will be working with are linked\_CHSYM\(_{n,d}\) and CHSYM\(_{n,d}\). Let us recall their definitions.

\[
\text{linked\_CHSYM}_{n,d}(x) = \sum_{i_0=1}^{n} \left( \sum_{i_0 \leq i_1 \leq \ldots \leq i_d \leq n} x_{i_0, i_1} \cdot x_{i_1, i_2} \cdots x_{i_d-1, i_d} \right),
\]
is abecedarian with respect to the partition \( \{X_1, \ldots, X_n\} \) where \( X_i = \{x_{i,j} : j \in [n]\} \), and

\[
\text{CHSYM}_{n,d}(x) = \sum_{1 \leq i_0 \leq \ldots \leq i_d \leq n} x_{i_1} \cdots x_{i_d}.
\]
is abecedarian with respect to the partition \( \{X_i : X_i = \{x_i\}\} \).

We begin with the notion of a linked abecedarian formula computing \(\text{linked\_CHSYM}_{n,d}(x)\).
Definition 20. An abecedarian formula computing \text{linked}_\text{CHSYM}_{n,d} is said to be linked if at every gate, all the monomials occurring in the polynomial computed at that gate have the following property.

\[ x_{ij} \text{ appears right before } x_{i',j'} \text{ in the monomial } \implies j = i'. \]

The first observation shows that any abecedarian formula computing \text{linked}_\text{CHSYM}_{n,d}(x) can be assumed to be linked without loss of generality.

Observation 21. Let \( F \) be a homogeneous abecedarian formula of size \( s \) that computes \text{linked}_\text{CHSYM}_{n,d}(x), and let the multiplication gates of \( F \) have fan-in 2. Then there is a homogeneous linked abecedarian formula \( F' \) computing the same polynomial of size \( O(s) \).

Proof. For any leaf \( \ell \) in \( F \) labelled by a variable, say \( x_{i,j} \), suppose \( P \) is the path from \( \ell \) to the root. Consider the set of multiplication gates on \( P \) whose left child is part of \( P \), and let \( v \) be the one that is closest to \( \ell \). Since \( F \) is abecedarian, the right child of \( v \) must be associated with a set, say \([a,b]\). If \( j \neq a \), we set the label of \( \ell \) to zero; otherwise we let it be \( x_{i,j} \).

Note that this operation does not kill any valid monomial. Let \( F' \) be the formula we get by performing the above operation on every leaf of \( F \) that is labelled by a variable. \( F' \) is clearly homogeneous and abecedarian. We show that \( F' \) is also linked.

Suppose that is not the case. Then there is must be a problematic vertex in \( F' \). Let \( v \) be such a vertex of minimal height. That is, there is a monomial in the polynomial computed at \( v \) in which, say, \( x_{i,j} \) appears right before \( x_{i',j'} \), but \( j \neq i' \). Further, the sub-formulas corresponding to the children of \( v \) are linked. Note that \( v \) must be a multiplication gate; not a leaf or an addition gate.

Let \( f_{\text{left}} \) and \( f_{\text{right}} \) be the polynomials computed at the left and right children of \( v \) respectively. Also, let \([a,b]\) be the set associated with the right child of \( v \). Then, it must be the case that the first variable in any monomial in \( f_{\text{right}} \) looks like \( x_{a,j'} \) for some \( j' \). Further, there must be a monomial in \( f_{\text{left}} \) in which the last variable looks like \( x_{i,j} \) for \( j \neq a \).

Look at the leaf corresponding to this variable. Let this leaf be \( \ell \) and let \( P \) be the path from \( \ell \) to the root. Since \( x_{i,j} \) is the right most variable in \( f_{\text{left}} \), it must be the case that \( v \) is the multiplication gate that is closest to \( \ell \), whose left child is on \( P \). But then, we should have set \( x_{i,j} \) to zero since \( j \neq a \). Hence, such a monomial can not appear in \( f_{\text{left}} \).

This shows that \( F' \) is indeed a homogeneous linked abecedarian formula of size at most that of \( F \) that computes \text{linked}_\text{CHSYM}_{n,d}(x).

The next observation shows that there is a poly-sized homogeneous abecedarian formula that computes \text{CHSYM}_{n/2}\log(n)(x).

Observation 22. \text{CHSYM}_{n/2}\log(n)(x) can be computed by a homogeneous abecedarian formula of size \text{poly}(n).

Proof. Consider the following polynomial over variables \( \{t,x_1,\ldots,x_n\} \), where we think of \( t \) as a commuting variable and \( x_1,\ldots,x_n \) as non-commuting variables.

\[
f_{n,d}(x) = \prod_{i=1}^{n} \left( 1 + \sum_{j=1}^{d} t^j \cdot x_i^j \right)\]

Note that the coefficient of \( t^d \) in \( f_{n,d}(x) \) is exactly \text{CHSYM}_{n,d}(x). Further, it is not hard to see that \( f_{n/2}\log(n)(x) \) is abecedarian in terms of \( x \) with respect to the partition \( \{X_1 : X_i = \{x_i\}\} \), and that the given expression results in an abecedarian formula of size \( O(n(\log n)^2) \).
Since \( t \) is a commuting variable, we can use the usual interpolation techniques [3], to get an abecedarian formula computing CHSYM\(_{n/2, \log n}(x)\) of size \( O(n \log n \cdot n(\log n)^2) = O(n^2(\log n)^3) = \text{poly}(n) \). Since the degree of CHSYM\(_{n/2, \log n}(x)\) is \( O(\log n) \), by Lemma 5, there is a homogeneous abecedarian formula computing CHSYM\(_{n/2, \log n}(x)\) of size \( \text{poly}(n) \). ▶

Another simple observation is that if we are given a homogeneous abecedarian formula for an abecedarian polynomial, then we almost immediately have one for its various sub-polynomials.

▶ Observation 23. Suppose there is a homogeneous abecedarian formula \( F \) computing a polynomial \( f \) that is abecedarian with respect to a partition of size \( m \). Then, for any \( a, b \in [m + 1] \), there is a homogeneous abecedarian formula \( F_{a,b} \) of size \( s \) that computes \( f[a, b] \).

Proof. Recall that if \( F \) is a homogeneous abecedarian formula computing \( f \), then \( F \) is in fact a set of formulas \( \{ F_i : F_i \text{ computes } f[i, m + 1] \} \). Consider the formula \( F_a \) and set all variables that belong to buckets \( \{ X_a, \ldots, X_m \} \) to zero in \( F_a \). This operation clearly kills exactly the monomials in \( f[a, m + 1] \) that are not in \( f[a, b] \). Thus if we call this new formula \( F_{a,b} \), then \( F_{a,b} \) is homogeneous, abecedarian and computes \( f[a, b] \). ▶

The next observation is extremely crucial, since it allows us to amplify the degree of CHSYM\(_{n,d}\).

▶ Lemma 24. Suppose there is a homogeneous abecedarian formula computing CHSYM\(_{n,d}(x)\) of size \( s \), and a homogeneous linked abecedarian formula computing linked-CHSYM\(_{n,d}(x)\) of size \( s' \). Then, there is a homogeneous abecedarian formula computing CHSYM\(_{n,(d,d')}(x)\) of size \( (s \cdot s') \).

Proof. Let \( F \) be the homogeneous abecedarian formula computing CHSYM\(_{n,d}(x)\) of size \( s \), and \( F' \) be the homogeneous linked abecedarian formula computing linked-CHSYM\(_{n,d}(x)\) of size \( s' \). We think of the variable \( x_{a,b} \) in linked-CHSYM\(_{n,d}(x)\) as a placeholder for the sub-polynomial CHSYM\(_{n,d}(a, b + 1)(x)\)\(^8\) of CHSYM\(_{n,d}(x)\). Note that there is a bijection between monomials in CHSYM\(_{n,(d,d')}(x)\) and those in the polynomial we get by substituting \( x_{a,b} \) in linked-CHSYM\(_{n,d}(x)\) with CHSYM\(_{n,d}(a, b + 1)(x)\).

By Observation 23, there is homogeneous abecedarian formula \( F_{a,b} \), of size \( O(s) \) computing CHSYM\(_{n,d}(a, b + 1)(x)\) for every \( a, b \in [n + 1] \). Thus, if we replace every leaf of \( F' \) labelled by \( x_{a,b} \) with \( F_{a,b} \), then the resulting formula is a homogeneous abecedarian formula computing CHSYM\(_{n,(d,d')}(x)\) of size \( (s \cdot s') \).

Finally, we observe that if we are given a homogeneous abecedarian formula computing the polynomial CHSYM\(_{(n-d+1),d}(x)\), then we get a homogeneous multilinear formula computing the non-commutative version of ESYM\(_{n,d}(x)\).

▶ Observation 25. Consider the elementary symmetric polynomial

\[
\text{ESYM}_{n,d}(x) = \sum_{1 \leq i_1 < \ldots < i_d \leq n} x_{i_1} \cdots x_{i_d}.
\]

If there is a homogeneous abecedarian formula computing CHSYM\(_{(n-d+1),d}(x)\) of size \( s \), then there is a homogeneous multilinear formula computing ESYM\(_{n,d}(x)\) of size \( s \).

---

\(^8\) Sum of monomials in CHSYM\(_{n,d}(x)\) whose first variable is \( a \) and last variable is one of \( \{x_a, \ldots, x_b\} \).
Suppose \( F \) is a homogeneous abecedarian formula computing \( \text{CHSYM}_{(n-d+1),d}(x) \) of size \( s \). Since \( F \) is homogeneous, every leaf labelled by a variable can be associated with a position index. If a leaf labelled \( x_i \) has position \( k \) associated with it, then replace the label of that leaf with \( x_{i+k-1} \). Call this formula \( F' \). Then clearly \( F' \) is a homogeneous formula of size \( s \) computing \( \text{ESYM}_{n,d}(x) \). Further note that since \( F \) was abecedarian, \( F' \) is multilinear. ▶

### 5.2 Proof of the Separation

We now prove Theorem 1. Let us first recall the statement.

**Theorem 1** (Separating Abecedarian Formulas and Abecedarian ABPs). Define

\[
\text{linked}_{-\text{CHSYM}}_{n,d}(x) = \sum_{i,j=1}^{n} \sum_{0 \leq i_1 \leq \ldots \leq i_d \leq n} x_{i_0,i_1} \cdot x_{i_1,i_2} \cdots x_{i_{d-1},i_d}
\]

This polynomial is abecedarian with respect to the partition \( \{ X_i : i \in [n] \} \) if \( X_i = \{ x_i,j : i \leq j \leq n \} \).

With respect to this partition,
1. \( \text{linked}_{-\text{CHSYM}}_{n,d}(x) \) has an abecedarian ABP of size \( O(nd) \);
2. any abecedarian formula computing \( \text{linked}_{-\text{CHSYM}}_{n/2,\log n}(x) \) has size \( n^{\Omega(\log \log n)} \).

That is, there is a super-polynomial separation between abecedarian formulas and ABPs.

That \( \text{linked}_{-\text{CHSYM}}_{n,d}(x) \) has a small abecedarian ABP is not very hard to see. For the lower bound, we assume that we have been given an abecedarian formula \( F \), computing the polynomial \( \text{linked}_{-\text{CHSYM}}_{n,d}(x) \), of size \( \text{poly}(n) \). We then keep making changes to this formula till we get a homogeneous multilinear formula computing \( \text{ESYM}_{n,d/2}(x) \) of size \( \text{poly}(n) \). Finally, we use the following theorem of Hrubeš and Yehudayoff [12] to get a contradiction.

**Theorem 26** (Theorem 1, [12]). Any homogeneous multilinear formula that computes \( \text{ESYM}_{n,d}(x) \), for \( d \leq n/2 \), must have size \( n \times d^{\Omega(\log d)} \).

Let us now complete the proof of our main theorem.

**Proof of Theorem 1.** An abecedarian ABP of size \( O(nd) \) computing \( \text{linked}_{-\text{CHSYM}}_{n,d}(x) \) is the following.

```
\[ s_1 \quad \cdots \quad x_{i,j} \quad \cdots \quad t_1 \]
\[ \vdots \quad \cdots \quad \vdots \quad \vdots \quad \vdots \]
\[ \vdots \quad \cdots \quad x_{i,j} \quad \cdots \quad \vdots \]
\[ \vdots \quad \cdots \quad \vdots \quad \vdots \quad \vdots \]
\[ s_n \quad \cdots \quad \cdots \quad \cdots \quad \cdots \quad t_n \]
```

The ABP has \( d+1 \) layers, labelled 0 through \( d \), each with \( n \) nodes. Between any consecutive layers \( k-1 \) and \( k \), where \( 1 \leq k \leq d \), there is an edge from the \( i \)-th node in layer \( k-1 \) to the \( j \)-th node in layer \( k \) layer if \( i \leq j \). The label on this edge is \( x_{i,j} \). All the nodes in the first layer are start nodes, and all the ones in the last layer are terminal nodes.
It is easy to check, by induction, that the polynomial computed between \( s_a \) and the \( b \)-th vertex in layer \( k \) computes \( \text{CHSYM}_{n,k}[a,b+1](x) \). Thus the polynomial computed by the abecedarian ABP constructed above is indeed \( \text{CHSYM}_{n,d}(x) \), and its size is clearly \( O(nd) \).

Let us now move on to proving the lower bound against abecedarian formulas. We show that there is a fixed constant \( \epsilon_0 \) such that any abecedarian formula that computes the polynomial \( \text{linked\_CHSYM}_{n/2,\log n}(x) \) must have size at least \( \Omega(n^{\epsilon_0 \log \log n}) \). Suppose this is not the case. Then for every \( \epsilon > 0 \), there is an abecedarian formula \( F'(\epsilon) \) of size \( O(n^{\epsilon \log \log n}) \) that computes \( \text{linked\_CHSYM}_{n/2,\log n}(x) \).

Without loss of generality, we can assume that \( F'(\epsilon) \) has fan-in 2. Further, by Lemma 6, we can reduce the depth of \( F'(\epsilon) \) to \( \log \log n \). That is, we get an abecedarian formula \( F'_1(\epsilon) \) computing \( \text{linked\_CHSYM}_{n/2,\log n}(x) \) of depth \( O(\epsilon \log n \log \log n) \) and size \( O(n^{c_1 \epsilon \log \log n}) \), where \( c_1 \) is a fixed constant independent of \( \epsilon \).

Next, since the degree of the polynomial being computed is small, Lemma 5 implies that \( F'_1(\epsilon) \) can in fact be homogenised without much blow-up in size. In other words, there is a homogeneous abecedarian formula computing \( \text{linked\_CHSYM}_{n/2,\log n}(x) \) of size \( O(n^{c_1 \epsilon \log \log n}) \), where \( c_2 \) is again a fixed constant independent of \( \epsilon \). Let this formula be \( F'_2(\epsilon) \).

By Observation 21, we can then use \( F'_2(\epsilon) \) to get a homogeneous linked abecedarian formula \( F'_3(\epsilon) \) of size \( O(n^{c_1 \epsilon \log \log n}) \) that computes the same polynomial. Further, because of Observation 22, we know that there is a homogeneous abecedarian formula, say \( F' \), of size \( \text{poly}(n) = O(n^{c_1 \epsilon \log \log n}) \) that computes \( \text{CHSYM}_{n/2,\log n}(x) \).

With \( F \) and \( F'_3(\epsilon) \) in hand, we get a homogeneous abecedarian formula \( \text{CHSYM}_{n/2,2\log^2 n}(x) \) because of Lemma 24. To get such a formula for \( \text{CHSYM}_{n/2,2}(x) \), we need to use Lemma 24 at most \( k \) times where

\[
(n \log n) = \frac{n}{2} \implies k = O \left( \frac{\log n}{\log \log n} \right).
\]

Thus, using Lemma 24 repeatedly at most \( O(\log n / \log \log n) \) times, we get that there is a homogeneous abecedarian formula, \( F(\epsilon) \), computing \( \text{CHSYM}_{n/2,2}(x) \) of size

\[
O(n^{c_1 \epsilon \log \log n}) \cdot \left( \frac{\log n}{\log \log n} \right) = O(n^{c_1 \epsilon \log \log n}).
\]

By Observation 25, we know that \( F(\epsilon) \) can be used to get a homogeneous multilinear formula, \( F_1(\epsilon) \), computing \( \text{ESYM}_{n-1,n/2}(x) \) of size \( O(n^{c_1 \epsilon \log \log n}) \). Finally, Theorem 26 tells us that there is a constant \( \delta \) such that any homogeneous multilinear formula computing \( \text{ESYM}_{n-1,n/2}(x) \) must have size at least \( n^{\delta \log n} \). For \( \epsilon = \delta / 2 c_1 \), this contradicts the existence of \( F_1(\epsilon) \) and hence \( F(\epsilon) \). Thus, it must be the case that any abecedarian formula computing \( \text{linked\_CHSYM}_{n/2,\log n}(x) \) has size at least \( n^{\Omega(\log \log n)} \). This completes the proof.  

### 6 Proofs of the Remaining Statements

In this section we give proof ideas of the remaining statements mentioned in the introduction.

#### 6.1 Formula Lower Bounds from Structured Formula Lower Bounds

\[\textbf{Corollary 3.}\] Let the polynomial \( \text{linked\_CHSYM}_{n,d}(x) \) be as defined in Theorem 1. An \( n^{\omega(1)} \) lower bound against abecedarian formulas for \( \text{linked\_CHSYM}_{\log n,n}(x) \) would imply a super-polynomial separation between non-commutative ABPs and formulas.
7:22 Separating ABPs and Some Structured Formulas in the Non-Commutative Setting

**Proof.** By Theorem 1, we know that the ABP complexity of $\text{linked}_\text{CHSYM}_{n,n}(x)$ is $\text{poly}(n)$. Therefore any formula computing the polynomial must have size at least $n^{\Omega(1)}$. Further, note that the polynomial is abecedarian with respect to a partition of size $O(\log n)$. Therefore, by Theorem 2, if there is a formula $F$ computing $\text{linked}_\text{CHSYM}_{n,n}(x)$ of size $s$, then there is an abecedarian formula computing it of size $\text{poly}(s)$. This immediately implies the given statement.

**Corollary 4.** Let $\text{linked}_\text{CHSYM}_{n,d}(x)$ be as defined in Theorem 1. An $n^{\omega(1)}$ lower bound against homogeneous formulas for $\text{linked}_\text{CHSYM}_{n,\log n}(x)$ would result in a super-polynomial separation between ABPs and formulas in the non-commutative setting.

**Proof.** By Theorem 1, we know that the ABP complexity of $\text{linked}_\text{CHSYM}_{n,\log n}(x)$ is $\text{poly}(n)$. Further, the degree of the polynomial is $O(\log n)$. Thus, by Lemma 5, if there is a formula computing $\text{linked}_\text{CHSYM}_{n,\log n}(x)$ of size $s$, then there is a homogeneous formula computing it of size $\text{poly}(s)$. This immediately implies the given statement.

**Corollary 11.** An $n^{\omega(1)}$ lower bound against homogeneous formulas computing the $n$-variate iterated matrix multiplication polynomial of degree $\log n$, $\text{IMM}_{n,\log n}(x)$, implies a super-polynomial separation between ABPs and formulas in the non-commutative setting.

**Proof.** Clearly, the ABP complexity of $\text{IMM}_{n,\log n}(x)$ is $\text{poly}(n)$. Thus, by Lemma 5, if there is a formula computing $\text{IMM}_{n,\log n}(x)$ of size $s$, then there is a homogeneous formula computing it of size $\text{poly}(s)$. This immediately implies the given statement.

6.2 Known Relations in the Non-Commutative Setting that Continue to Hold with the Abecedarian Restriction

**Observation 9 (The Usual Inclusions).** Let $abc - \text{VP}_{nc}$, $abc - \text{VBP}_{nc}$ and $abc - \text{VF}_{nc}$ denote the classes of abecedarian polynomials over $n$ variables that can be computed by $\text{poly}(n)$ sized abecedarian circuits, abecedarian ABPs and abecedarian formulas respectively. Then,

$$abc - \text{VF}_{nc} \subseteq abc - \text{VBP}_{nc} \subseteq abc - \text{VP}_{nc}.$$ 

**Proof.** Suppose $f \in abc - \text{VF}_{nc}$. Then $f$ is abecedarian, and in particular $f \in \text{VF}_{nc}$. But we know that $\text{VF}_{nc} \subseteq \text{VBP}_{nc}$, and so $f \in \text{VBP}_{nc}$. By Observation 8, this implies that $f \in abc - \text{VBP}_{nc}$.

Similarly, suppose $f \in abc - \text{VBP}_{nc}$. Then $f$ is abecedarian, and $f \in \text{VBP}_{nc}$. But $\text{VBP}_{nc} \subseteq \text{VP}_{nc}$, and so $f \in \text{VP}_{nc}$. By Observation 7, this implies that $f \in abc - \text{VP}_{nc}$.

**Observation 10 (Converting Abecedarian ABPs into Abecedarian Formulas).** Suppose $f$ is an abecedarian polynomial of degree $d$. If there is an abecedarian ABP $A$ of size $s$ computing it, then there is an abecedarian formula $F$ computing $f$ of size $O(s^{\log d})$.

**Proof.** The formula we get using the usual divide-and-conquer algorithm has the property that polynomials computed at any of its gate is a polynomial computed between two vertices in the ABP. Thus by definition of abecedarian ABPs, the statement follows via the usual algorithm.

The (Generalized) Orthogonality Dimension of (Generalized) Kneser Graphs: Bounds and Applications

Alexander Golovnev  
Georgetown University, Washington, DC, USA

Ishay Haviv  
School of Computer Science, The Academic College of Tel Aviv-Yaffo, Israel

Abstract

The orthogonality dimension of a graph $G = (V, E)$ over a field $F$ is the smallest integer $t$ for which there exists an assignment of a vector $u_v \in F^t$ with $\langle u_v, u_{v'} \rangle \neq 0$ to every vertex $v \in V$, such that $\langle u_v, u_{v'} \rangle = 0$ whenever $v$ and $v'$ are adjacent vertices in $G$. The study of the orthogonality dimension of graphs is motivated by various applications in information theory and in theoretical computer science. The contribution of the present work is two-fold.

First, we prove that there exists a constant $c$ such that for every sufficiently large integer $t$, it is NP-hard to decide whether the orthogonality dimension of an input graph over $\mathbb{R}$ is at most $t$ or at least $3t/2 - c$. At the heart of the proof lies a geometric result, which might be of independent interest, on a generalization of the orthogonality dimension parameter for the family of Kneser graphs, analogously to a long-standing conjecture of Stahl (J. Comb. Theo. Ser. B, 1976).

Second, we study the smallest possible orthogonality dimension over finite fields of the complement of graphs that do not contain certain fixed subgraphs. In particular, we provide an explicit construction of triangle-free $n$-vertex graphs whose complement has orthogonality dimension over the binary field at most $n^{1-\delta}$ for some constant $\delta > 0$. Our results involve constructions from the family of generalized Kneser graphs and they are motivated by the rigidity approach to circuit lower bounds. We use them to answer a couple of questions raised by Codenotti, Pudlák, and Resta (Theor. Comput. Sci., 2000), and in particular, to disprove their Odd Alternating Cycle Conjecture over every finite field.

1 Introduction

A $t$-dimensional orthogonal representation of a graph $G = (V, E)$ over a field $F$ is an assignment of a vector $u_v \in F^t$ with $\langle u_v, u_{v'} \rangle \neq 0$ to every vertex $v \in V$, such that $\langle u_v, u_{v'} \rangle = 0$ whenever $v$ and $v'$ are adjacent vertices in $G$. The orthogonality dimension of a graph $G$ over $F$, denoted by $\xi(G, F)$, is the smallest integer $t$ for which there exists a $t$-dimensional orthogonal representation of $G$ over $F$. The orthogonality dimension parameter is closely related to...
several other well-studied graph parameters. In particular, for every graph $G$ and every field $F$, $\xi(G, F)$ is sandwiched between the clique number and the chromatic number of $G$, that is, $\omega(G) \leq \xi(G, F) \leq \chi(G)$.\footnote{Orthogonal representations of graphs are sometimes defined in the literature as orthogonal representations of the complement, namely, the definition requires vectors associated with non-adjacent vertices to be orthogonal. We have decided to use here the other definition, but one may view the notation $\xi(G, F)$ as standing for $\xi(\overline{G}, F)$.}

Orthogonal representations of graphs have been found useful over the years for various applications in information theory and in theoretical computer science. They were originally introduced over the real field in a seminal work of Lovász [32], where they were used to define the influential Lovász $\vartheta$-function. The latter was used in [32] to determine the Shannon capacity, a notoriously difficult information-theoretic graph parameter, of the cycle on five vertices, and in the last decades it was successfully applied in algorithmic and combinatorial results (see, e.g., [28, 17, 3]). The orthogonality dimension of graphs plays an important role in several areas of computational complexity. Over finite fields, the orthogonality dimension and its extension due to Haemers [21] to a graph parameter called minrank have attracted a significant attention in circuit complexity, and more specifically, in the study of Valiant’s rigidity approach to circuit lower bounds [43] (see, e.g., [11, 37, 20]). Over the complex field, the orthogonality dimension was used in a characterization of the quantum communication complexity of promise equality problems [12, 4, 5] and in the study of the quantum chromatic number [8, 39]. The orthogonality dimension parameter was also investigated in the contexts of hardness of approximation [36, 29], integrality gaps for linear programming [26, 25], and algorithms based on semi-definite programming [9, 23].

The present work studies two aspects of the orthogonality dimension of graphs. First, we prove an $\text{NP}$-hardness result for approximating the orthogonality dimension of graphs over the real field $\mathbb{R}$. At the heart of the proof lies a geometric result, which might be of independent interest, on a generalization of the orthogonality dimension parameter for the family of Kneser graphs, analogously to a long-standing graph-theoretic conjecture due to Stahl [40]. The second aspect of the orthogonality dimension parameter considered in this work, motivated by the area of circuit complexity, is that of determining the smallest possible orthogonality dimension over finite fields of the complement of graphs that do not contain certain fixed subgraphs. In this context, we prove a new bound on the minrank parameter over finite fields for the family of generalized Kneser graphs. The bound is used to settle a couple of questions raised by Codenotti, Pudlák, and Resta in [11] and to disprove their Odd Alternating Cycle Conjecture over every finite field.

1.1 Our Contribution

1.1.1 The Generalized Orthogonality Dimension of Kneser Graphs

We start by considering the computational hardness of determining the orthogonality dimension of graphs over the real field $\mathbb{R}$. The challenge of understanding the hardness of this parameter was posed already in the late eighties by Lovász, Saks, and Schrijver [34] (see also [33, Chapter 10]), and yet, the problem is far from being well-understood. It is easy to see that deciding whether an input graph $G$ satisfies $\xi(G, \mathbb{R}) \leq t$ can be solved in polynomial running-time for $t \in \{1, 2\}$, and Peeters [36] has shown that it is $\text{NP}$-hard for $t \geq 3$. His result is known to imply that for every $t \geq 6$ it is $\text{NP}$-hard to decide whether an input graph $G$ satisfies $\xi(G, \mathbb{R}) \leq t$ or $\xi(G, \mathbb{R}) \geq \lceil 4t/3 \rceil$ (see [23]). In the current work, we improve on the $4/3$ multiplicative gap and prove the following.
Theorem 1. There exists a constant $c$ such that for every sufficiently large integer $t$, it is NP-hard to decide whether an input graph $G$ satisfies $\xi(G, \mathbb{R}) \leq t$ or $\xi(G, \mathbb{R}) \geq 3t/2 - c$.

It is worth noting that in order to obtain hardness results for the orthogonality dimension parameter, it is natural to employ known hardness results regarding the closely related chromatic number of graphs. Indeed, it is easy to verify (see, e.g., [23]) that every graph $G$ satisfies

$$\log_3 \chi(G) \leq \xi(G, \mathbb{R}) \leq \chi(G),$$

hence hardness of deciding whether an input graph $G$ satisfies $\chi(G) \leq t_1$ or $\chi(G) \geq t_2$ immediately implies the hardness of deciding whether it satisfies $\xi(G, \mathbb{R}) \leq t_1$ or $\xi(G, \mathbb{R}) \geq \log_3 t_2$. In particular, a result of Dinur, Mossel, and Regev [14] on the hardness of the chromatic number implies that assuming a certain variant of the unique games conjecture, deciding whether a given graph $G$ satisfies $\xi(G, \mathbb{R}) \leq 3$ or $\xi(G, \mathbb{R}) \geq t$ is NP-hard for every $t \geq 4$. However, if one is interested in standard NP-hardness for the orthogonality dimension, the state of the art for the hardness of the chromatic number does not seem to imply any hardness results, despite some remarkable recent progress [7, 44]. Moreover, most hardness proofs for the chromatic number crucially use the fact that an upper bound on the independence number of a graph implies a stronger lower bound on its chromatic number (namely, $\chi(G) \geq \frac{|V(G)|}{\alpha(G)}$), whereas an analogue of such a statement for the orthogonality dimension does not hold in general (see, e.g., [23, Proposition 2.2]).

One technique for proving hardness results for the chromatic number that can be applied for the orthogonality dimension is that of Garey and Johnson [18], who have related hardness of graph coloring to the multichromatic numbers of Kneser graphs. The $k$th multichromatic number of a graph $G$, denoted by $\chi_k(G)$, is the smallest number of colors needed in order to assign to every vertex of $G$ a set of $k$ colors so that adjacent vertices are assigned to disjoint sets. Notice that $\chi_1(G)$ is simply the standard chromatic number $\chi(G)$. The family of Kneser graphs is defined as follows.

Definition 2 (Kneser Graphs). For integers $d \geq 2s$, the Kneser graph $K(d, s)$ is the graph whose vertices are all the $s$-subsets of $[d] = \{1, \ldots, d\}$, where two sets are adjacent if they are disjoint.

Note that the multichromatic numbers can be defined in terms of Kneser graphs, namely, $\chi_k(G)$ is the smallest integer $d$ for which there exists a homomorphism from $G$ to $K(d, k)$.

In the seventies, Stahl [40] has made the following conjecture.

Conjecture 3 (Stahl’s Conjecture [40]). For all integers $k$ and $d \geq 2s$,

$$\chi_k(K(d, s)) = \left\lfloor \frac{k}{s} \right\rfloor \cdot (d - 2s) + 2k.$$

Stahl’s conjecture has received a significant attention in the literature over the years. Even very recently, it was related to the well-known recently disproved Hedetniemi’s conjecture [42]. Nevertheless, more than forty years since it was proposed, Stahl’s conjecture is still open. It is known that the right-hand side in Conjecture 3 forms an upper bound on $\chi_k(K(d, s))$, and that this bound is tight up to an additive constant that depends solely on $s$ [10, 41].

The precise statement of the conjecture was confirmed only for a few special cases. This includes the case of $k = 1$ proved by Lovász [31], the cases of $s \leq 2$, $k \leq s$, $d = 2s + 1$, and $k$ divisible by $s$ proved by Stahl [40, 41], and the case of $s = 3$ and $k = 4$ proved by Garey and Johnson [18] (extended to $s = 3$ with any $k$ in [41]). The result of [18] was combined there with a simple reduction to show that for every $t \geq 6$, it is NP-hard to decide whether a given graph $G$ satisfies $\chi(G) \leq t$ or $\chi(G) \geq 2t - 4$. 
The recent work [23] has suggested to borrow the reduction of [18] to prove hardness results for the orthogonality dimension parameter. This approach requires the following generalization of orthogonal representations of graphs over the reals.

**Definition 4 (Orthogonal Subspace Representation).** A $t$-dimensional orthogonal $k$-subspace representation of a graph $G = (V, E)$ is an assignment of a subspace $U_v \subseteq \mathbb{R}^t$ with $\dim(U_v) = k$ to every vertex $v \in V$, such that the subspaces $U_v$ and $U_{v'}$ are orthogonal whenever $v$ and $v'$ are adjacent in $G$. For a graph $G$, let $\bar{\xi}_k(G, \mathbb{R})$ denote the smallest integer $t$ for which there exists a $t$-dimensional orthogonal $k$-subspace representation of $G$.\footnote{Over the complex field, the definition is equivalent to the notion of a projective representation from [35, Definition 6.1].}

Note that for $k = 1$, Definition 4 coincides with the orthogonality dimension over the reals, and that for every graph $G$ and every $k$ it holds that $\bar{\xi}_k(G, \mathbb{R}) \leq \chi_k(G)$.

A combination of the hardness result of Peeters [36] and the reduction of [18] implies the following.

**Proposition 5 ([23, Theorem 1.3]).** For every graph $F$, it is NP-hard to decide whether an input graph $G$ satisfies $\bar{\xi}(G, \mathbb{R}) \leq \bar{\xi}_3(F, \mathbb{R})$ or $\bar{\xi}(G, \mathbb{R}) \geq \bar{\xi}_4(F, \mathbb{R})$.

With Proposition 5 in hand, it is of interest to find graphs $F$ with a large gap between $\bar{\xi}_3(F, \mathbb{R})$ and $\bar{\xi}_4(F, \mathbb{R})$. In light of Conjecture 3, it is natural to consider the generalized orthogonality dimension parameters for the family of Kneser graphs. For $k = 1$, it was shown in [25] that the standard chromatic number and the standard orthogonality dimension over $\mathbb{R}$ coincide on all Kneser graphs. In addition, a result of Bukh and Cox [6, Proposition 23] implies that for every $d \geq 2s$ and every $k$, $\bar{\xi}_k(K(d, s), \mathbb{R}) \geq kd/s$. This implies that the $k$th chromatic number and the $k$th orthogonality dimension over $\mathbb{R}$ coincide on $K(d, s)$ whenever $k$ is divisible by $s$.

In this work we initiate a systematic study of the generalized orthogonality dimension parameters of Kneser graphs, analogously to Conjecture 3. Let us already mention that the arguments applied in the study of Stahl’s conjecture do not seem to extend to our question. The main reason is that the proofs in [40, 18, 10, 41] use Hilton-Milner-type theorems to characterize the possible structures of the independent sets induced by generalized colorings of Kneser graphs, whereas in our setting, orthogonal subspace representations do not naturally induce large independent sets and the problem seems to require a more geometric approach.

The first non-trivial case is that of Kneser graphs $K(d, s)$ with $s = 2$, for which we show that the generalized orthogonality dimension parameters are equal to the multichromatic numbers.

**Theorem 6.** For all integers $k \geq 1$ and $d \geq 4$, $\bar{\xi}_k(K(d, 2), \mathbb{R}) = \left\lceil \frac{k}{2} \right\rceil \cdot (d - 4) + 2k$.

We proceed by considering a general $s \geq 3$ and prove the following lower bound.

**Theorem 7.** For every integers $k \geq s \geq 3$ there exists $c = c(s, k)$ such that for all integers $d \geq 2s$,

$$\bar{\xi}_k(K(d, s), \mathbb{R}) \geq k - \left\lceil \frac{k+1}{s-1} \right\rceil \cdot d - c.$$ 

Note that for $k = \ell \cdot s - 1$ where $\ell$ is an integer, the bound provided by Theorem 7 is tight up to the additive constant $c$. Indeed, in this case we get that there exists a constant $c$ such that for all integers $d \geq 2s$ it holds that

$$\ell \cdot d - c \leq \bar{\xi}_{\ell \cdot s - 1}(K(d, s), \mathbb{R}) \leq \chi_{\ell \cdot s - 1}(K(d, s)) \leq \ell \cdot d - 2.$$
The definition is naturally extended to (undirected) graphs by replacing every undirected edge contains an alternating cycle of length $\ell$ with two oppositely directed edges.

We next consider the orthogonality dimension over finite fields of the complement of graphs rigidity. Theorem 1. Indeed, given a $t$-dimensional orthogonal representation of an $n$-vertex graph $G$ over a field $F$, consider the matrix $B \in F^{n \times t}$ whose rows contain the vectors associated with the vertices of $G$. Then, the $n$ by $n$ matrix $B \cdot B^T$ represents $\bar{G}$ and has rank at most $t$ over $F$, hence $\text{minrk}_F(\bar{G}) \leq t$.

1.1.2 The Orthogonality Dimension of Generalized Kneser Graphs

We consider here the question of whether there are graphs with no short odd cycles and yet low minrank over finite fields. This question is motivated by the area of circuit complexity, and more specifically, by Valiant’s approach to circuit lower bounds [43], as described next.

Theorem 7, as it is easy to see that every graph $F$ satisfies $\overline{\xi}_4(F, \mathbb{R}) \leq \overline{\xi}(F, \mathbb{R}) + \overline{\xi}_3(F, \mathbb{R}) \leq 2 \cdot \overline{\xi}_3(F, \mathbb{R})$.

Note further that for the special case of $k = 4$ and $s = 3$, Theorem 7 implies that there exists a constant $c$ such that $\overline{\xi}_4(K(d, 3, \mathbb{R})) \geq 3d/2 - c$ for every sufficiently large integer $d$. This, combined with Proposition 5 and the fact that $\overline{\xi}_3(K(d, 3, \mathbb{R})) = d$, yields our hardness result Theorem 1.

It will be interesting to figure out if the bounds given in Theorem 7 can be tightened to the quantity given in the right-hand side of Conjecture 3, at least up to an additive term independent of $d$. In particular, it will be nice to decide whether for all integers $d \geq 6$ it holds that $\overline{\xi}_4(K(d, 3, \mathbb{R})) = 2d - 4$. A positive answer would imply that for every $t \geq 6$, it is NP-hard to decide whether an input graph $G$ satisfies $\overline{\xi}(G) \leq t$ or $\overline{\xi}(G) \geq 2t - 4$. We remark, however, that the approach suggested by Proposition 5 for the hardness of the orthogonality dimension cannot yield a multiplicative hardness gap larger than 2, as it is easy to see that every graph $F$ satisfies $\overline{\xi}_4(F, \mathbb{R}) \leq \overline{\xi}(F, \mathbb{R}) + \overline{\xi}_3(F, \mathbb{R}) \leq 2 \cdot \overline{\xi}_3(F, \mathbb{R})$.

Definition 8 (Minrank). Let $G = (V, E)$ be a directed graph on the vertex set $V = [n]$ and let $F$ be a field. We say that an $n$ by $n$ matrix $M$ over $F$ represents $G$ if $M_{i,j} \neq 0$ for every $i \in V$, and $M_{i,j} = 0$ for every distinct $i, j \in V$ such that $(i, j) \notin E$. The minrank of $G$ over $F$ is defined as

$$\text{minrk}_F(G) = \min \{ \text{rank}_F(M) \mid M \text{ represents } G \text{ over } F \}.$$ 

The definition is naturally extended to (undirected) graphs by replacing every undirected edge with two oppositely directed edges.

Note that for every graph $G$ and every field $F$, $\text{minrk}_F(\bar{G}) \leq \overline{\xi}(G, F)$.\(^3\)

We consider here the question of whether there are graphs with no short odd cycles and yet low minrank over finite fields. This question is motivated by the area of circuit complexity, and more specifically, by Valiant’s approach to circuit lower bounds [43], as described next. The rigidity of an $n$ by $n$ matrix $M$ over a field $F$ with respect to a given parameter $r$ is the smallest number of entries that one has to change in $M$ in order to reduce its rank over $F$ to below $r$. Roughly speaking, it was shown in [43] that $n$ by $n$ matrices with large rigidity for $r = \epsilon \cdot n$ where $\epsilon > 0$ is a constant can be used to obtain superlinear lower bounds on the size of logarithmic depth arithmetic circuits computing linear transformations. In 2000, Codenotti, Pudlák, and Resta [11] have proposed the Odd Alternating Cycle Conjecture, stated below. By an alternating odd cycle we refer to a directed graph which forms an odd cycle when the orientation of the edges is ignored, and such that the orientation of the edges alternates with one exception.

Conjecture 9 (The Odd Alternating Cycle Conjecture [11]). For every field $F$ there exist $\epsilon > 0$ and an odd integer $\ell$ such that every $n$-vertex directed graph $G$ with $\text{minrk}_F(G) \leq \epsilon \cdot n$ contains an alternating cycle of length $\ell$.

Theorem 1.
It was proved in [11] that Conjecture 9 implies, if true, that certain explicit circulant matrices have superlinear rigidity. In contrast, for \( \ell = 3 \) it was shown in [11] that there are \( n \)-vertex (undirected) triangle-free graphs \( G \) satisfying \( \minrk_{\mathbb{F}}(G) \leq O(n^{3/4}) \) for every field \( \mathbb{F} \), and it was left open whether the statement of Conjecture 9 may hold for larger values of \( \ell \). In the recent work [24] the conjecture was disproved over the real field, but remained open for finite fields which are of special interest in circuit complexity. For the orthogonality dimension over the binary field \( \mathbb{F}_2 \), it was shown in [11] that there exist triangle-free \( n \)-vertex graphs \( G \) satisfying \( \xi(G, \mathbb{F}_2) = n/4 + 2 \). It was asked there whether every \( n \)-vertex graph \( G \) satisfying \( \xi(G, \mathbb{F}_2) \leq n/4 + 1 \) must contain a triangle.

In the current work we prove a new upper bound on the minrank parameter over finite fields of generalized Kneser graphs. In these graphs the vertices are all the \( s \)-subsets of a universe \([d]\), where two sets are adjacent if their intersection size is smaller than some integer \( m \). Note that for \( m = 1 \) we get the standard family of Kneser graphs (see Definition 2). In the proof we modify and extend an argument of [24], which is based on linear spaces of multivariate polynomials, building on a previous work of Alon [2]. For the precise statement, see Theorem 18. We turn to describe several applications of our bound.

As a first application, we establish an explicit construction of graphs that do not contain short odd cycles and yet have low minrank over every finite field.

**Theorem 10.** For every odd integer \( \ell \geq 3 \) there exists \( \delta = \delta(\ell) > 0 \) such that for every sufficiently large integer \( n \), there exists an \( n \)-vertex graph \( G \) with no odd cycle of length at most \( \ell \) such that for every finite field \( \mathbb{F} \), \( \minrk_{\mathbb{F}}(G) \leq n^{1-\delta} \).

Theorem 10 immediately implies that the Odd Alternating Cycle Conjecture is false over every finite field, even for undirected graphs. This rules out the approach suggested in [11] for lower bounds on the rigidity of certain circulant matrices and thus falls into the recent line of non-rigidity results based on the polynomial method (see, e.g., [1, 15, 16]). We note, however, that the general upper bound of [16] on the rigidity of \( n \times n \) circulant matrices does not apply to the setting of parameters considered in [11] (because in [16] the upper bound is \( n^{1+\varepsilon} \) for a constant \( \varepsilon > 0 \), whereas in [11] the rigidity is only claimed to be \( \Omega(n \cdot \log^5 n) \) for a constant \( \varepsilon > 0 \).

We next consider the behavior of the orthogonality dimension over the binary field of the complement of triangle-free graphs. It is relevant to mention here that in the proof of Theorem 10, the matrices that imply the stated bound on the minrank are symmetric (see Remark 20). For the binary field, this can be combined with a matrix decomposition result due to Lempel [30] to obtain the following theorem, which answers a question of [11] negatively.

**Theorem 11.** There exists a constant \( \delta > 0 \) such that for every sufficiently large integer \( n \) there exists a triangle-free \( n \)-vertex graph \( G \) such that \( \xi(G, \mathbb{F}_2) \leq n^{1-\delta} \).

The above result can also be stated in terms of nearly orthogonal systems. For a field \( \mathbb{F} \), a system of vectors in \( \mathbb{R}^m \) is said to be nearly orthogonal if every vector of the system is not self-orthogonal and any set of three of them contains an orthogonal pair. For the real field, it was proved by Rosenfeld [38] that every nearly orthogonal system in \( \mathbb{R}^m \) has size at most \( 2m \). Theorem 11 shows that the situation is quite different over the binary field. Namely, it implies that there exists a constant \( \delta > 0 \) such that for infinitely many integers \( m \) there exists a nearly orthogonal system in \( \mathbb{F}_2^m \) of size at least \( m^{1+\delta} \).

We finally mention that our bound on the minrank parameter of generalized Kneser graphs can be used to obtain graphs with a constant vector chromatic number \( \chi_v \) (see Definition 24) whose complement has a polynomially large minrank over every finite field.
Theorem 12. There exists a constant $\delta > 0$ such that for infinitely many integers $n$ there exists an $n$-vertex graph $G$ such that $\chi_v(G) \leq 3$ and yet $\minrk_F(G) \geq n^\delta$ for every finite field $F$.

The interest in such graphs comes from the semidefinite programming algorithmic approach applied in [9] for approximating the minrank parameter. As explained in [22], such graphs imply a limitation on this approach, which is based on the constant vector chromatic number of the complement of the instances. Theorem 12 improves on [22, Theorem 1.3] where the bound on the minrank is shown only for sufficiently large finite fields.

1.2 Outline

The rest of the paper is organized as follows. In Section 2, we prove our bounds on the generalized orthogonality dimension parameters of Kneser graphs (Theorems 6 and 7) and derive our hardness result (Theorem 1). In Section 3, we prove our bound on the minrank parameter over finite fields of generalized Kneser graphs and deduce Theorems 10, 11, and 12.

2 The Generalized Orthogonality Dimension of Kneser Graphs

In this section we study the generalized orthogonality dimension parameters of Kneser graphs, namely, the quantities $\bar{\xi}_k(K(d, s))$ (recall Definitions 2 and 4), and prove Theorems 6 and 7. We start with a linear algebra lemma that will be useful in our proofs.

2.1 Linear Algebra Lemma

Lemma 13. Let $U$ be a subspace of $\mathbb{R}^t$ with $\dim(U) = \ell$, let $\mathcal{W}$ be a finite collection of subspaces of $\mathbb{R}^t$, and let $\ell' \leq \ell$ be an integer satisfying $\dim(U \cap W) \leq \ell'$ for every $W \in \mathcal{W}$. Then, there exists a subspace $U'$ of $U$ with $\dim(U') = \ell - \ell'$ such that $\dim(U' \cap W) = 0$ for every $W \in \mathcal{W}$.

Intuitively, given a subspace $U$ and a collection $\mathcal{W}$ as in the lemma, a “random-like” subspace $U'$ of $U$ with dimension $\ell - \ell'$ is expected to have a trivial intersection with each of the subspaces of $\mathcal{W}$, and thus to satisfy the assertion of the lemma. The formal proof can be found in [19].

2.2 The case $s = 2$

We turn to prove Theorem 6 which determines the generalized orthogonality dimension parameters of Kneser graphs $K(d, s)$ for $s = 2$.

Proof of Theorem 6. Fix an integer $k \geq 1$. For the upper bound, recall that for all integers $d \geq 4$ we have

$$\bar{\xi}_k(K(d, 2), \mathbb{R}) \leq \chi_k(K(d, 2)) = \left\lceil \frac{k}{2} \right\rceil \cdot (d - 4) + 2k.$$ 

For the lower bound, we consider the induced subgraph of $K(d, 2)$, denoted by $K^-(d, 2)$, obtained from $K(d, 2)$ by removing one of its vertices, say, the vertex $\{1, 2\}$. We turn to prove that for all integers $d \geq 4$ it holds that

$$\bar{\xi}_k(K^-(d, 2), \mathbb{R}) \geq \left\lceil \frac{k}{2} \right\rceil \cdot (d - 4) + 2k,$$ (1)
The (Generalized) Orthogonality Dimension of (Generalized) Kneser Graphs

which immediately implies the required lower bound on $\bar{\xi}_k(K(d, 2), \mathbb{R})$ as well. To this end, we apply an induction on $d$. For $d = 4$, the graph $K(d, 2)$ is a perfect matching on 6 vertices, hence its subgraph $K^-(d, 2)$ clearly contains an edge. Since every orthogonal $k$-subspace representation of this graph assigns to the vertices of this edge orthogonal $k$-subspaces it follows that $\bar{\xi}_k(K^-(4, 2), \mathbb{R}) \geq 2k$, as desired. Now, fix some $d > 4$. Assuming that (1) holds for $d - 1$, we turn to prove it for $d$.

Recall that the vertex set $V$ of $K^-(d, 2)$ consists of all the 2-subsets of $[d]$ except $\{1, 2\}$. Let $(U_A)_{A \in V}$ be a $t$-dimensional orthogonal $k$-subspace representation of $K^-(d, 2)$. We proceed by considering the following two cases.

Assume first that there exists some $i \geq 4$ for which

$$\dim(U_{\{1,3\}} \cap U_{\{1,i\}}) \geq \left\lceil \frac{k}{2} \right\rceil. \tag{2}$$

In this case, consider the induced subgraph of $K^-(d, 2)$ on the vertex set $V'$ obtained from $V$ by removing the vertex $[3, i]$ and all the vertices that include the element 1. Notice that this subgraph is isomorphic to $K^-(d - 1, 2)$ and that every vertex of $V'$ is disjoint from either $\{1, 3\}$ or from $\{1, i\}$ (or both). This implies that the restriction $(U_A)_{A \in V'}$ of the given assignment to the vertices of $V'$ forms an orthogonal $k$-subspace representation of $K^-(d - 1, 2)$, all of whose subspaces lie in the subspace of $\mathbb{R}^t$ that is orthogonal to $U = U_{\{1,3\}} \cap U_{\{1,i\}}$. By applying an orthogonal linear transformation from this subspace to $\mathbb{R}^{t-\dim(U)}$, we obtain that

$$\bar{\xi}_k(K^-(d - 1, 2), \mathbb{R}) \leq t - \dim(U) \leq t - \left\lceil \frac{k}{2} \right\rceil,$$

where in the second inequality we have used (2). Using the induction hypothesis, this implies that

$$t \geq \bar{\xi}_k(K^-(d - 1, 2), \mathbb{R}) + \left\lceil \frac{k}{2} \right\rceil \geq \left\lceil \frac{k}{2} \right\rceil \cdot (d - 5) + 2k + \left\lceil \frac{k}{2} \right\rceil = \left\lceil \frac{k}{2} \right\rceil \cdot (d - 4) + 2k,$$

and we are done.

We are left with the case where for every $i \geq 4$ it holds that $\dim(U_{\{1,3\}} \cap U_{\{1,i\}}) \leq \left\lceil \frac{k}{2} \right\rceil - 1$. Apply Lemma 13 to the $k$-subspace $U_{\{1,3\}}$ and the collection $\{U_{\{1,i\}} \mid 4 \leq i \leq d\}$. It follows that there exists a subspace $U$ of $U_{\{1,3\}}$ with $\dim(U) = k - \left(\left\lceil \frac{k}{2} \right\rceil - 1\right) \geq \left\lceil \frac{k}{2} \right\rceil$ such that for every $i \geq 4$ it holds that $\dim(U \cap U_{\{1,i\}}) = 0$. Consider the induced subgraph of $K^-(d, 2)$ on the vertex set $V'$ obtained from $V$ by removing the vertex $\{2, 3\}$ and all the vertices that include the element 1. As before, this subgraph is isomorphic to the graph $K^-(d - 1, 2)$.

We define an orthogonal $k$-subspace representation of this graph as follows. Let $B$ be a set in $V'$. If $3 \notin B$ we define $\bar{U}_B = U_B$. Otherwise we have $B = \{3, i\}$ for some $i \geq 4$, and we let $\bar{U}_{\{3,i\}}$ be the projection of $U_{\{1,i\}}$ to the subspace of $\mathbb{R}^t$ that is orthogonal to $U$. Note that the fact that $\dim(U \cap U_{\{1,i\}}) = 0$ guarantees that $\dim(\bar{U}_{\{3,i\}}) = \dim(U_{\{1,i\}}) = k$.

To prove that the assignment $(\bar{U}_B)_{B \in V'}$ forms an orthogonal $k$-subspace representation of the graph, let $B_1$ and $B_2$ be disjoint sets in $V'$. If $3 \notin B_1 \cup B_2$ then we have $\bar{U}_{B_1} = U_{B_1}$ and $\bar{U}_{B_2} = U_{B_2}$, so it is clear that $\bar{U}_{B_1}$ and $\bar{U}_{B_2}$ are orthogonal. Otherwise, assume without loss of generality that $B_1 = \{3, i\}$ for some $i \geq 4$ and that $3 \notin B_2$. In this case we have $\bar{U}_{B_2} = U_{B_2}$, and since $B_2$ is disjoint from $B_1$ it is also disjoint from $\{1,i\}$ and from $\{1,3\}$, hence $\bar{U}_{B_2}$ is orthogonal to both $U_{\{1,i\}}$ and $U_{\{1,3\}}$ as well as to the projection $\bar{U}_{B_1}$ of $U_{\{1,3\}}$ to the subspace orthogonal to $U \subseteq U_{\{1,3\}}$. We get that $\bar{U}_{B_1}$ and $\bar{U}_{B_2}$ are orthogonal, as required.

Finally, observe that all the subspaces $\bar{U}_B$ lie in the subspace of $\mathbb{R}^t$ that is orthogonal to $U$. Indeed, for sets $B$ with $3 \in B$ this follows from the definition of $\bar{U}_B$, and for the other sets this holds because they are disjoint from $\{1,3\}$. By applying an orthogonal linear transformation
from this subspace to $\mathbb{R}^{t-\dim(U)}$, we obtain that $\xi_k(K^-(d-1,2),\mathbb{R}) \leq t - \dim(U) \leq t - \lceil \frac{d}{2} \rceil$, and as in the previous case, by the induction hypothesis it follows that $t \geq \lceil \frac{d}{2} \rceil \cdot (d - 4) + 2k$, completing the proof.

2.3 General $s$

We now prove Theorem 7 which provides a lower bound on the generalized orthogonality dimension parameters of Kneser graphs $K(d,s)$ for $s \geq 3$.

**Proof of Theorem 7.** Fix integers $k \geq s \geq 3$ and denote $m = \lceil \frac{k+1}{s} \rceil$. Let $d_0 = d_0(s,k)$ be a sufficiently large integer to be determined later. We apply an induction on $d$. To do so, we define $c = c(s,k)$ to be sufficiently large, say, $c = \frac{k-m+1}{s+1} \cdot (d_0 + s - 2)$, so that the statement of the theorem trivially holds for all integers $d \leq d_0 + s - 2$, and turn to prove the statement for $d \geq d_0$ assuming that it holds for $d - (s - 1)$.

Let $(U_A)_{A \in \mathcal{V}}$ be a $t$-dimensional orthogonal $k$-subspace representation of $K(d,s)$. We start with some notation. For an $s$-subset $A$ of $[d]$, an element $i \in A$, and an $s$-subset $B$ of $[d]$ satisfying $A \cap B = \{i\}$, we let $\mathcal{G}_{A,i}(B)$ denote the collection that consists of the set $B$ and all the sets obtained from $B$ by replacing $i$ with some element from $A \setminus \{i\}$. Note that $|\mathcal{G}_{A,i}(B)| = s$. We say that a vertex $A$ of $K(d,s)$ is good (with respect to the given orthogonal subspace representation) if there exists an $i \in A$ such that for every vertex $B$ satisfying $A \cap B = \{i\}$ it holds that $\dim(U_A \cap U_C) \leq m - 1$ for some $C \in \mathcal{G}_{A,i}(B)$.

Assume first that there exists a good vertex $A$ in $K(d,s)$ associated with an element $i \in A$. Applying Lemma 13, we get that there exists a $(k - m + 1)$-subspace $U$ of $U_A$ such that for every vertex $B$ satisfying $A \cap B = \{i\}$ it holds that $\dim(U \cap U_C) = 0$ for some $C \in \mathcal{G}_{A,i}(B)$. We define an orthogonal $k$-subspace representation of the graph $K(d - (s - 1),s)$ on the ground set $[d] \setminus (A \setminus \{i\})$ as follows. Let $B$ be an $s$-subset of $[d] \setminus (A \setminus \{i\})$. If $i \notin B$ we define $\bar{U}_B = U_B$. Otherwise, we have $A \cap B = \{i\}$, and we let $\bar{U}_B$ be the projection of $U_C$ to the subspace of $\mathbb{R}^t$ orthogonal to $U$, where $C \in \mathcal{G}_{A,i}(B)$ is a set satisfying $\dim(U \cap U_C) = 0$. Note that this condition guarantees that $\dim(\bar{U}_B) = \dim(U_C) = k$.

We claim that the subspaces $\bar{U}_B$ form an orthogonal $k$-subspace representation of the graph $K(d - (s - 1),s)$. To see this, let $B_1$ and $B_2$ be disjoint $s$-subsets of $[d] \setminus (A \setminus \{i\})$. If $i \notin B_1 \cup B_2$ then we have $\bar{U}_{B_1} = U_{B_1}$ and $\bar{U}_{B_2} = U_{B_2}$, so it is clear that $\bar{U}_{B_1}$ and $\bar{U}_{B_2}$ are orthogonal. Otherwise, assume without loss of generality that $i \in B_1$ and $i \notin B_2$. In this case, $\bar{U}_{B_1} = U_{B_1}$, and $\bar{U}_{B_2}$ is the projection of $U_C$ to the subspace of $\mathbb{R}^t$ orthogonal to $U$ for some $C \in \mathcal{G}_{A,i}(B_1)$. Since $B_2$ is disjoint from $A$, it follows that the subspace $\bar{U}_{B_2}$ is orthogonal to $U_A$ as well as to its subspace $U$. It also follows that $B_2$ is disjoint from every set in $\mathcal{G}_{A,i}(B_1)$, hence the subspace $\bar{U}_{B_2}$ is orthogonal to $U_C$. We get that $\bar{U}_{B_2}$ is orthogonal to $\bar{U}_{B_1}$, as required.

Now, observe that the above orthogonal $k$-subspace representation of $K(d - (s - 1),s)$ lies in the subspace of $\mathbb{R}^t$ that is orthogonal to the $(k - m + 1)$-subspace $U$. Indeed, for sets $B$ with $i \in B$ this follows from the definition of $\bar{U}_B$, and for the other sets this holds because they are disjoint from $A$. By applying an orthogonal linear transformation from this subspace to $\mathbb{R}^{t-\dim(U)}$, it follows that

$$\xi_k(K(d - (s - 1),s),\mathbb{R}) \leq t - \dim(U) = t - (k - m + 1).$$

Using the induction hypothesis, this implies that

$$t \geq \frac{k - m + 1}{s - 1} \cdot (d - (s - 1)) - c + (k - m + 1) = \frac{k - m + 1}{s - 1} \cdot d - c,$$

and we are done.
We are left with the case where no vertex of $K(d, s)$ is good, for which we need the following lemma. Its proof can be found in [19].

**Lemma 14.** If a vertex $A$ of $K(d, s)$ is not good then there exists a nonzero vector $u_A \in U_A$ such that the number of vertices $D$ of $K(d, s)$ for which $U_D$ is not orthogonal to $u_A$ is at most $\left(\frac{2^s - 1}{2}\right) \cdot \left(\frac{d - 2}{s - 2}\right)$.

We finally show how Lemma 14 completes the proof of the theorem. Assume that no vertex of $K(d, s)$ is good, and consider the following process: We start with the entire vertex set of $K(d, s)$, and in every iteration we choose an arbitrary vertex $A$ associated with its nonzero vector $u_A \in U_A$ from Lemma 14 and eliminate all vertices whose subspaces are not orthogonal to $u_A$. The nonzero vectors associated with the chosen vertices are clearly pairwise orthogonal, and their number, just like the number of iterations in the process, is at least $\left(\frac{d}{s}\right) \cdot \left(\frac{(d - 2)}{s - 2}\right) \geq k - m + 1 \cdot d - c$,

where the inequality holds for every $d \geq d_0$ assuming that $d_0 = d_0(s, k)$ is sufficiently large (because the left-hand side of the inequality is quadratic in $d$ whereas the right-hand side is linear in $d$). However, the size of the obtained orthogonal set cannot exceed the dimension $t$, hence $t \geq \frac{k - m + 1}{s - 1} \cdot d - c,$

and we are done.

As immediate corollaries of Theorem 7, we obtain the following.

**Corollary 15.** For every integers $s \geq 3$ and $\ell \geq 2$ there exists $c = c(s, \ell)$ such that for all integers $d \geq 2s$,

$$\bar{\xi}_{\ell,s-1}(K(d, s), \mathbb{R}) \geq \ell \cdot d - c.$$ 

As mentioned before, the bound given in Corollary 15 is tight up to the additive constant $c$.

**Corollary 16.** There exists a constant $c$ such that for all integers $d \geq 6$, $\bar{\xi}_4(K(d, 3), \mathbb{R}) \geq 3d/2 - c$.

Equipped with Corollary 16, we are ready to deduce Theorem 1.

**Proof of Theorem 1.** Let $t$ be a sufficiently large integer. Recall that a result of [6] implies that $\bar{\xi}_3(K(t, 3), \mathbb{R}) = t$, whereas Corollary 16 implies that $\bar{\xi}_4(K(t, 3), \mathbb{R}) \geq 3t/2 - c$ for an absolute constant $c$. Applying Proposition 5 with $F = K(t, 3)$, it follows that it is NP-hard to decide whether an input graph $G$ satisfies $\bar{\xi}(G, \mathbb{R}) \leq t$ or $\bar{\xi}(G, \mathbb{R}) \geq 3t/2 - c$, as desired.

## 3 The Minrank of Generalized Kneser Graphs

In this section we consider a generalization of the family of Kneser graphs, defined as follows.

**Definition 17 (Generalized Kneser Graphs).** For integers $m \leq s \leq d$, the generalized Kneser graph $K^{<}(d, s, m)$ is the graph whose vertices are all the $s$-subsets of $[d]$, where two sets $A, B$ are adjacent if $|A \cap B| < m$. 

For this family of graphs, we prove the following upper bound on the minrank parameter over finite fields (recall Definition 8).

**Theorem 18.** For all integers \( m \leq s \leq d \) and for every finite field \( \mathbb{F} \),
\[
\text{minrk}_\mathbb{F}(K^<(d, s, m)) \leq \sum_{i=0}^{s-m} \binom{d}{i}.
\]
Moreover, the bound on the minrank can be achieved by a symmetric matrix.

As in the previous section, we start with a simple linear algebra lemma, whose proof can be found in [19].

**Lemma 19.** For a graph \( G \) on the vertex set \([n]\), let \( M \in \mathbb{Z}^{n \times n} \) be an integer matrix such that \( M_{i,i} = 1 \) for every \( i \in [n] \), and \( M_{i,j} = 0 \) for every distinct non-adjacent vertices \( i \) and \( j \) in \( G \). Then, for every finite field \( \mathbb{F} \), \( \text{minrk}_\mathbb{F}(G) \leq \text{rank}_\mathbb{Z}(M) \).

**Proof of Theorem 18.** Consider the polynomial \( q \in \mathbb{R}[x] \) defined by
\[
q(x) = \binom{x-m}{s-m} = \frac{1}{(s-m)!} (x-m)(x-(m+1)) \cdots (x-(s-1)).
\]
Notice that \( q \) is an integer-valued polynomial of degree \( s - m \). Let \( f : \{0,1\}^d \times \{0,1\}^d \to \mathbb{R} \) be the function defined by
\[
f(x,y) = q \left( \sum_{i=1}^{d} x_i y_i \right)
\]
for every \( x, y \in \{0,1\}^d \). Expanding \( f \) as a linear combination of monomials, the relation \( z^2 = z \) for \( z \in \{0,1\} \) implies that one can reduce to 1 the exponent of each variable occurring in a monomial. It follows that \( f \) can be represented as a multilinear polynomial in the \( 2d \) variables of \( x \) and \( y \). By combining terms involving the same monomial in the variables of \( x \), one can write \( f \) as
\[
f(x,y) = \sum_{i=1}^{R} g_i(x)h_i(y)
\]
for an integer \( R \) and functions \( g_i, h_i : \{0,1\}^d \to \mathbb{R} \), \( i \in [R] \), such that the \( g_i \)'s are distinct multilinear monomials of total degree at most \( s - m \) in \( d \) variables. It follows that \( R \leq \sum_{s=0}^{s-m} \binom{d}{i} \).

Now, let \( M_1 \) and \( M_2 \) be the \( 2^d \times R \) matrices whose rows are indexed by \( \{0,1\}^d \) and whose columns are indexed by \( [R] \), defined by \((M_1)_{x,i} = g_i(x)\) and \((M_2)_{x,i} = h_i(x)\). Then, the rank over \( \mathbb{R} \) of the matrix \( M = M_1 \cdot M_2^T \) is at most \( R \) and for every \( x, y \in \{0,1\}^d \) it holds that \( M_{x,y} = f(x,y) \). By the definition of \( f \) the matrix \( M \) is symmetric, and since \( q \) is an integer-valued polynomial, all of its entries are integer.

Finally, let \( V \) be the vertex set of \( K^<(d, s, m) \), that is, the collection of all \( s \)-subsets of \([d]\), and identify every vertex \( A \in V \) with an indicator vector \( e_A \in \{0,1\}^d \) in the natural way. Observe that for every \( A, B \in V \) we have
\[
M_{e_A,e_B} = f(e_A, e_B) = q(|A \cap B|).
\]
Hence, for every \( A \in V \) we have \( |A| = s \) and therefore \( M_{e_A,e_A} = q(s) = 1 \), whereas for every distinct non-adjacent \( A, B \in V \) we have \( m \leq |A \cap B| \leq s - 1 \) and thus \( M_{e_A,e_B} = q(|A \cap B|) = 0 \). Since the restriction of \( M \) to \( V \times V \) is symmetric and has rank at most \( R \) over the reals, Lemma 19 implies that \( \text{minrk}_\mathbb{F}(K^<(d, s, m)) \leq R \) for every finite field \( \mathbb{F} \) and that the bound can be achieved by a symmetric matrix, as desired. ▶
Remark 20. Theorem 18 guarantees that the bound on the minrank can be achieved by a symmetric matrix. This will be crucial for one of our applications, namely, for a construction of triangle-free graphs whose complement has low orthogonality dimension over the binary field \( \mathbb{F}_2 \) (see Section 3.1.2). We remark, however, that for undirected graphs and for fields of characteristic different from 2, attaining the bound on the minrank by a symmetric matrix can be achieved easily with a factor of 2 worse bound on the minrank. Indeed, if a matrix \( M \) represents a graph \( G \) over a field \( \mathbb{F} \) of characteristic different from 2 and satisfies \( \text{rank}_\mathbb{F}(M) = r \) then the matrix \( M + M^T \) also represents \( G \) and has rank at most \( 2r \) over \( \mathbb{F} \). This argument does not hold over fields of characteristic 2, since in this case the diagonal entries of \( M + M^T \) are all zeros.

3.1 Applications

We gather below several applications of Theorem 18.

3.1.1 The Odd Alternating Cycle Conjecture over Finite Fields

We turn to disprove Conjecture 9 over every finite field. We will use the simple fact that generalized Kneser graphs do not contain short odd cycles, as stated below (see, e.g., [13, 24]).

Lemma 21. Let \( \ell \geq 3 \) be an odd integer. For every even integer \( d \) and an integer \( m \leq \frac{d}{2} \), the graph \( K^<(d, \frac{d}{2}, m) \) contains no odd cycle of length at most \( \ell \).

We prove the following theorem, confirming Theorem 10.

Theorem 22. For every odd integer \( \ell \geq 3 \) there exists \( \delta = \delta(\ell) > 0 \) such that for every sufficiently large integer \( n \), there exists an \( n \)-vertex graph \( G \) with no odd cycle of length at most \( \ell \) such that for every finite field \( \mathbb{F} \),

\[ \text{minrk}_\mathbb{F}(G) \leq n^{1-\delta}. \]

Moreover, the bound on the minrank can be achieved by a symmetric matrix.

Proof. Fix an odd integer \( \ell \geq 3 \). For an integer \( d \) divisible by \( 2\ell \), consider the graph \( G = K^<(d, \frac{d}{2}, m) \) where \( m = \frac{d}{2} \). By Lemma 21, \( G \) contains no odd cycle of length at most \( \ell \). As for the minrank parameter, Theorem 18 implies that for every finite field \( \mathbb{F} \),

\[ \text{minrk}_\mathbb{F}(G) \leq \sum_{i=0}^{d/2-m} \binom{d}{i} 2^{H\left(\frac{i}{2} - \frac{m}{2}\right) \cdot \frac{d}{2}} = 2^{H\left(\frac{1}{2} - \frac{m}{d}\right) \cdot d}, \]

where \( H \) stands for the binary entropy function. Since \( G \) has \( |V| = \binom{d/2}{d/2} = 2^{(1-o(1)) \cdot d} \) vertices, for any \( \delta > 0 \) such that \( H\left(\frac{1}{2} - \frac{m}{d}\right) < 1 - \delta \) we have \( \text{minrk}_\mathbb{F}(G) \leq |V|^{1-\delta} \) for every sufficiently large integer \( d \). The proof is completed by considering, for every sufficiently large integer \( n \), some \( n \)-vertex subgraph of the graph defined above, where \( d \) is the smallest integer divisible by \( 2\ell \) such that \( n \leq \binom{d}{d/2} \). ▷

3.1.2 Triangle-free Graphs and the Orthogonality Dimension over the Binary Field

We turn to prove Theorem 11. Its proof adopts the following special case of a result due to Lempel [30].
Lemma 23 ([30]). Let M be an n by n symmetric matrix over the binary field \( \mathbb{F}_2 \) with at least one nonzero diagonal entry and rank r. Then, there exists an n by r matrix B over \( \mathbb{F}_2 \) satisfying \( M = B \cdot B^T \).

Proof of Theorem 11. Apply Theorem 22 with \( \ell = 3 \) to obtain some \( \delta > 0 \) such that for every sufficiently large integer \( n \), there exist a triangle-free \( n \)-vertex graph \( G \) and an \( n \) by \( n \) symmetric matrix \( M \) over \( \mathbb{F}_2 \) of rank \( r = \text{rank}_{\mathbb{F}_2}(M) \leq n^{1-\delta} \) that represents \( G \). By Lemma 23, there exists an \( n \) by \( r \) matrix \( B \) over \( \mathbb{F}_2 \) satisfying \( M = B \cdot B^T \). By assigning the \( i \)th row of \( B \) to the \( i \)th vertex of \( G \) we get an \( r \)-dimensional orthogonal representation of \( \overline{G} \) over \( \mathbb{F}_2 \), hence \( \xi(G, \mathbb{F}_2) \leq r \leq n^{1-\delta} \). ▶

### 3.1.3 The Vector Chromatic Number vs. Minrank

The vector chromatic number of graphs, introduced by Karger, Motwani, and Sudan in [27], is defined as follows.

**Definition 24 (Vector Chromatic Number).** For a graph \( G = (V, E) \) the vector chromatic number of \( G \), denoted by \( \chi_v(G) \), is the minimal real value of \( \kappa > 1 \) such that there exists an assignment of a unit vector \( w_v \) to every vertex \( v \in V \) satisfying the inequality \( \langle w_v, w_{v'} \rangle \leq -\frac{1}{\kappa-1} \) whenever \( v \) and \( v' \) are adjacent in \( G \).

To prove Theorem 12, we need the following simple fact that relates the minrank of a graph to the minrank of its complement (see, e.g., [36, Remark 2.2]).

**Fact 25.** For every field \( \mathbb{F} \) and an \( n \)-vertex graph \( G \), \( \text{minrk}_{\mathbb{F}}(G) \cdot \text{minrk}_{\mathbb{F}}(\overline{G}) \geq n \).

Proof of Theorem 12. For an integer \( d \) divisible by 8, consider the graph \( G = K^{<}(d, \frac{d}{4}, m) \) where \( m = \frac{d}{8} \). We first claim that \( \chi_v(G) \leq 3 \). To see this, assign to every vertex \( A \) of \( G \), representing a \( \frac{d}{2} \)-subset of \( [d] \), the unit vector \( w_A \in \mathbb{R}^d \) defined by \( (w_A)_i = \frac{1}{\sqrt{d}} \) if \( i \in A \) and \( (w_A)_i = -\frac{1}{\sqrt{d}} \) otherwise. Observe that every two distinct vertices \( A \) and \( B \) that are adjacent in \( G \) satisfy \( |A \cap B| < \frac{d}{8} \) and thus \( |A \triangle B| > \frac{3d}{4} \), implying that \( \langle w_A, w_B \rangle = \frac{d-|A\triangle B|}{d} < -\frac{1}{2} \). This implies that \( \chi_v(G) \leq 3 \), as claimed. As for the minrank parameter, Theorem 18 implies that for every finite field \( \mathbb{F} \),

\[
\text{minrk}_{\mathbb{F}}(G) \leq \sum_{i=0}^{d/2-m} \binom{d}{i} \leq 2^H\left(\frac{1}{2} - \frac{3}{8}\right) \cdot d = 2^{H(3/8)} \cdot d,
\]

where \( H \) stands for the binary entropy function. Since \( G \) has \( n = \binom{d}{d/2} = 2^{(1-o(1)) \cdot d} \) vertices, for any \( \delta < 1 - H(3/8) \) we have \( \text{minrk}_{\mathbb{F}}(G) \leq n^{1-\delta} \) assuming that \( d \) is sufficiently large. By Fact 25, this implies that \( \text{minrk}_{\mathbb{F}}(\overline{G}) \geq n^{\delta} \), and we are done. ▶

Abstract

We define the shadow complexity of a polytope $P$ as the maximum number of vertices in a linear projection of $P$ to the plane. We describe connections to algebraic complexity and to parametrized optimization. We also provide several basic examples and constructions, and develop tools for bounding shadow complexity.

Acknowledgements

We thank Michael Forbes for pointing out the connection between shadow complexity and Conjecture 47.

1 Introduction

A polytope is the convex hull of a finite set of points in Euclidean space. Equivalently, it is a compact set that is defined by finitely many linear inequalities. Polytopes are central in convex geometry and linear optimization algorithms.

Our goal is to understand

how many vertices can a shadow of a polytope have?

A shadow of a polytope $P \subseteq \mathbb{R}^n$ is a set of the form $L(P)$, where $L : \mathbb{R}^n \to \mathbb{R}^2$ is a linear map. The shadows of $P$ are two-dimensional polygons, and hence typically much simpler than $P$. The shadow complexity of $P$ is

$$\sigma(P) = \max_L |\text{vert}(L(P))|,$$

where $L$ is a linear map and $\text{vert}(Q)$ is the vertex set of the polytope $Q$.

The shadow problem is interesting already in three-dimensional space. Moser’s shadow problem asks about the shadow complexity of three-dimensional polytopes [35]. Specifically, the question is what is the minimum of $\sigma(P)$ over all three dimensional polytopes $P$ with $n$ vertices. The solution is $\Theta(\log n / \log \log n)$; see [9, 33]. In other words, every $n$-vertex polytope in $\mathbb{R}^3$ has a projection to $\mathbb{R}^2$ with at least $\Omega(\log n / \log \log n)$ vertices, and there are polytopes where this is tight. The latter is quite surprising; in such a polytope, most vertices must disappear when projected to the plane.

Our main motivation comes from algebraic complexity theory. This is the study of computations of polynomials over a field. The connection between between polynomials and polytopes is via the notion of Newton polytope. Let $\mathbb{F}$ be a field. For a list of variables $x = (x_1, \ldots, x_n)$ and $\alpha \in \mathbb{N}^n$, let $x^\alpha$ be the monomial $\prod_{i=1}^n x_i^{\alpha_i}$. A polynomial $f \in \mathbb{F}[x_1, \ldots, x_n]$ is a formal sum of the form $\sum_{\alpha \in \mathbb{N}^n} a_\alpha x^\alpha$ where $\text{supp}(f) := \{ \alpha \in \mathbb{N}^n : a_\alpha \neq 0 \}$ is finite. The Newton polytope of $f$ is

$$\text{Newt}(f) := \text{conv}(\text{supp}(f)),$$

where $\text{conv}(\cdot)$ denotes the convex hull.
Koiran et al. [30] made a bold conjecture relating the complexity of \( \text{Newt}(f) \) with the computational complexity of \( f \). The \( \tau \)-conjecture for Newton polygons asserts, roughly speaking, that if a bi-variate polynomial \( f \) is easy to compute then \( \text{Newt}(f) \) has a small number of vertices. This conjecture has serious consequences. It implies that the permanent polynomial requires arithmetic circuit of exponential size. This is a central and long-standing open problem in algebraic complexity.

The Newton polytope of the permanent polynomial is the the Birkhoff polytope \( DS_n \subseteq \mathbb{R}^{n \times n} \); namely, the set of \( n \times n \) doubly stochastic matrices. The vertices of \( DS_n \) are all \( n \times n \) permutation matrices. This perspective leads us to the following question.

▶ **Problem 1.** What is \( \sigma(DS_n) \)?

The Birkhoff polytope has the curious property that it is both the Newton polytope of the determinant and of the permanent polynomial. This creates friction in the context of the \( \tau \)-conjecture. Determinant is easy to compute whereas permanent is largely believed to be hard. More specifically, it can be shown that the \( \tau \)-conjecture implies \( \sigma(DS_n) \leq 2^{O(\sqrt{n \log^2 n})} \). Proving that \( \sigma(DS_n) = 2^{\Omega(n)} \) refutes this \( \tau \)-conjecture.  

Any non-trivial connection between the arithmetic complexity of \( f \) and some geometric complexity measure of \( \text{Newt}(f) \), such as shadow complexity, will be an exciting development.

We exhibit such a connection in the case of monotone computations. A monotone arithmetic circuit uses the operations \( +, \times \) and only non-negative numbers so that no cancellations can occur in the course of a computation (for definitions see Section 5). They have been considered in the seminal papers of Valiant [45] and of Jerrum and Snir [23], and many others including a less known line of research by Kasim-Zade, Kuznetsev, Gashkov and Sergeev [26, 32, 17, 18]. We show that shadow complexity allows to prove hardness results for monotone computation.

▶ **Theorem 1.** Every monotone formula computing \( f \) contains at least \( \sigma(\text{Newt}(f)) \) leaves.

What we are really interested in is understanding algebraic circuits, not formulas. We show that in some cases shadow complexity allows to lower bound monotone circuit complexity. A polynomial \( f \) is transparent if \( |\text{supp}(f)| = \sigma(\text{Newt}(f)) \). In other words, there is a linear map \( L : \mathbb{R}^n \to \mathbb{R}^2 \) which maps \( \text{supp}(f) \) to distinct convexly independent points in \( \mathbb{R}^2 \).

▶ **Theorem 2.** If \( f \) is transparent then every monotone circuit computing \( f \) has size at least \( \Omega(\sigma(\text{Newt}(f))) \).

Theorem 2 can be used to explicitly find a monotone multilinear polynomial in \( n \) variables which requires an arithmetic circuit of size \( \Omega(2^{n/3}) \); see Corollary 40. This surpasses the classical bounds from [45, 23] which are of the form \( 2^{\Omega(n^{1/2})} \), and matches the bounds from [26, 18] and [39] up to the constant in the exponent. The combinatorial essence of our argument resembles the arguments of Gashkov and Sergeev [18].

▶ **Remark 3.** The transparency assumption is unavoidable. There exists a bivariate polynomial \( f \) with a monotone circuit of size \( O(n) \) such that \( \text{Newt}(f) \) has \( 2^n \) vertices (see Theorem 30).

Shadow complexity has an algorithmic perspective as well. A polytope naturally defines a linear optimization problem \( \Phi(w) = \max_{x \in P} \langle x, w \rangle \), where \( \langle x, w \rangle \) is the standard inner product. The maximizers of this optimization problem are vertices of \( P \). The Birkhoff

---

1 This observation came from Michael Forbes in a private conversation.
polytope, e.g., corresponds to the maximum weight bipartite perfect matching problem. Some additional examples of linear optimization problems include the shortest path problem or the maximum cut problem.

In parametrized complexity, one considers weights that come from a one dimensional space \( w(t) = w_0 + tw_1 \) parametrized by \( t \in \mathbb{R} \). The map \( t \mapsto \Phi(w(t)) \) is a convex and piecewise linear function. A natural complexity measure for such a map is the number \( \beta(P, w(t)) \) of the breakpoints in \( \Phi(w(t)) \). The parametrized complexity of \( P \) now becomes

\[
\beta(P) = \max_{w_0, w_1} \beta(P, w(t)).
\]

The quantity \( \beta(P) \) has been studied by Carstensen [7, 8], Mulmuley and Shah [36, 37], and many others. Carstensen [8] and later [37] showed that the shortest path problem in an \( n \)-vertex graph can have \( 2^{\Omega(\log^3 n)} \) breakpoints, and that the maximum cut problem can have \( 2^{\Omega(n)} \) breakpoints. In Section 3.4, we give an example of a polytope that corresponds to a linear optimization problem on \( n \) variables with \( 2^{\Omega(n)} \) breakpoints; the previous constructions gave only \( 2^{\Omega(\sqrt{n})} \) breakpoints.

We observe a fundamental connection between shadow complexity and parametrized complexity.

\begin{itemize}
  \item [\textbf{Theorem 4.}] If \(|\text{vert}(P)| > 1\) then \( \sigma(P) \geq \beta(P) \geq \sigma(P) - 1 \).
\end{itemize}

This means that results from parametrized complexity translate to the language of shadows, and vice versa. Carstensen’s lower bound for example implies that

\[
\sigma(DS_n) \geq 2^{\Omega(\log^2 n)}.
\]

This is the best lower bound on \( \sigma(DS_n) \) we are aware of. The best upper bound we know is \( \sigma(DS_n) \leq 2^{\Omega(n)} \). This is not entirely obvious and we shall explain this later on (see Proposition 23).

The connection between shadow and parametrized complexities leads to interesting conclusions. The idea, in a nutshell, is that if optimization over \( P \) is easy then \( \beta(P) \) is low. For example, if we can optimize over \( P \) by a greedy algorithm then \( \beta(P) \) is at most quadratic. We do not want to dive into the theory of greedy algorithms, or a formal definition for that matter. Edmonds and Rado [12, 15] proved that if \( R \subseteq \{0, 1\}^n \) is a matroid then the optimization problem over \( R \) can be solved by a greedy algorithm. Many generalizations of this theorem have been considered (see [46] and references within).

For our purposes, the following simple definition is sufficient. Let \( P \subseteq \mathbb{R}^n \) be a polytope and \( w \in \mathbb{R}^n \). We denote by \( \text{Opt}_P(w) \) the set of vertices \( v \) of \( P \) such that \( \langle v, w \rangle = \max_{x \in P} \langle x, w \rangle \). Given \( w, w' \in \mathbb{R}^n \), we say that they are order-equivalent if for every \( i, j \in [n] \), we have \( w_i \leq w_j \) iff \( w'_i \leq w'_j \). The polytope \( P \) is greedy-like, if for every order-equivalent \( w \) and \( w' \), we have \( \text{Opt}_P(w) = \text{Opt}_P(w') \). In other words, \( P \) is greedy-like if for every weight function \( w \), where the maximum for \( w \) is achieved on \( P \) depends only on the order induced by \( w \).

\begin{itemize}
  \item [\textbf{Lemma 5.}] If \( P \subseteq \mathbb{R}^n \) is a greedy-like polytope then \( \beta(P) \leq \binom{n}{2} \) and \( \sigma(P) \leq n(n - 1) \).
\end{itemize}

A more general link was established by Mulmuley [36]. He considers a model of computation called \textit{PRAM model without bit operations} intended to solve decision problems or optimization problems. This model allows to use basic arithmetic operations such as +, \times as well as =, \leq, but does not allow access to the individual bits of the inputs. Mulmuley showed\(^2\) that a fast parallel algorithm for optimizing over \( P \) gives a small \( \beta(P) \). This leads to several interesting lower bounds in this model.

\(^2\) There is a technical issue of bit-lengths which we avoid.
The above can be further linked to our discussion concerning monotone arithmetic circuits. A monotone arithmetic formula can be interpreted as a computation over the semiring \((\mathbb{R}, \min, +, \infty, 0)\) which solves the optimization problem over \(\text{Newt}(f)\); see Section 5.1 for more details. This a particular instance of the PRAM model.

Are there general non trivial bounds on shadow complexity? Let \(M_\sigma(n)\) be the maximum \(\sigma(P)\) over all polytopes \(P \subseteq \mathbb{R}^n\) with vertices in \(\{0, 1\}^n\). In [31], Kortenkamp et al. have shown the following:

\[ \text{Proposition 6 ([31]). There exist constants } 0 < c_1 < c_2 < 1 \text{ such that for every } n \text{ sufficiently large } 2^{c_1 n} \leq M_\sigma(n) \leq 2^{c_2 n}. \]

An explicit construction yields \(c_1 \geq 1/3\); see Remark 20.

\subsection{Why the plane?}

Why do we study projections of polytopes to two dimensions?

First, our results rely on the fact that in two dimensions Minkowski sum (defined in Section 2.3) is well-behaved with respect to the number of vertices. In \(\mathbb{R}^2\), we have \(|\text{vert}(P + Q)| \leq |\text{vert}(P)| + |\text{vert}(Q)|\). Already in \(\mathbb{R}^3\), only the trivial upper bound \(|\text{vert}(P + Q)| \leq |\text{vert}(P)| \cdot |\text{vert}(Q)|\) holds.

Second, there exists a polytope in \(\mathbb{R}^3\) with \(k\) vertices such that every projection to \(\mathbb{R}^2\) has only \(O(\log k / \log \log k)\) vertices. Hence it may happen that a polytope in \(\mathbb{R}^n\) has exponentially many vertices when projected to \(\mathbb{R}^3\) but only polynomially many when projected to \(\mathbb{R}^2\).

That said, there are non-trivial upper bounds on the number of vertices of \(P_1 + \cdots + P_r\) in \(\mathbb{R}^d\) if \(r\) is large. For the sake of simplicity, we discuss the case of \(d = 3\). It follows from a result of Gritzman and Sturmfels [19] that, given polytopes \(P_1, \ldots, P_r\) with \(n_1, \ldots, n_r\) vertices in \(\mathbb{R}^3\),

\[ |\text{vert}(P_1 + \cdots + P_r)| \leq O((n_1 + \cdots + n_r)^2). \]

This beats the trivial bound \(n_1 n_2 n_3\) already for \(r = 3\). The improved bound could be used to derive non-trivial bounds on monotone computations of a bounded depth (see Remark 51).

\subsection{Extension complexity}

As a final remark, we briefly discuss a different possible connection between polytopes and algebraic complexity. The extension complexity of \(P\), denoted \(\text{xc}(P)\), as the smallest \(r\) such that \(P\) is a linear projection of a polytope \(Q \subseteq \mathbb{R}^m\) where \(Q\) can be defined using \(r\) inequalities and an arbitrary number of equalities; see [47, 40, 13] and references within. It is related to communication complexity and algorithms (see, e.g., [38]).

We observe that, like shadow complexity, extension complexity also allows to prove lower bounds on monotone computation. Namely, if \(f\) has monotone formula of size \(s\) then \(\text{xc}(\text{Newt}(f)) \leq O(s)\). This uses simple properties of extension complexity together with a result of Balas [2].

Extension complexity, however, can not yield general lower bounds in the non-monotone setting. There exists a polynomial with a polynomial size arithmetic circuit, but whose Newton polytope has an exponential extension complexity. See Section 5.4 for more details.
2 Tools

We start by presenting several tools for bounding shadow complexity, including some elementary facts about Newton polytopes.

2.1 Parametrized complexity

Some of the bounds on shadow complexity we describe come from the algorithmic viewpoint. So, we first prove the connection between shadow complexity and parametrized complexity.

Proof of Theorem 4. It is convenient to argue about

\[ B^*(P, w(t)) := \beta(P, w(t)) + 1, \]

which counts to the number of pieces of \( \Phi(w(t)) \). Given \( w(t) = w_0 + tw_1 \), define \( L : \mathbb{R}^n \to \mathbb{R}^2 \) by

\[ L(x) = (\langle w_0, x \rangle, \langle w_1, x \rangle). \]

Because \( \langle w(t), x \rangle = \langle (1, t), L(x) \rangle \), we see that

\[ \max_{x \in P} \langle x, w(t) \rangle = \max_{y \in L(P)} \langle y, (1, t) \rangle. \]

Since the maximum is always achieved at a vertex of \( L(P) \), we obtain \( B^*(P, w(t)) \leq \sigma(P) \).

To prove the other inequality, we first show that \( B^*(Q) \geq k/2 + 1 \) for every polytope \( Q \) in \( \mathbb{R}^2 \) with \( k \geq 2 \) vertices. Take non-parallel \( w_0, w_1 \in \mathbb{R}^2 \) so that \( \langle v, w_i \rangle \) are distinct for distinct vertices \( v \) of \( Q \). Let \( w(t) = w_0 + tw_1 \) and \( \bar{w}(t) = -w_0 + tw_1 \). Each vertex \( v \) of \( Q \) can be separated from the other vertices by a hyperplane (in two dimensions, a line), and a small perturbation of the hyperplane is still separating. Hence, there exists a non-empty open interval \( I \) such that either \( \max_{x \in Q} \langle x, w(t) \rangle \) or \( \max_{x \in Q} \langle x, \bar{w}(t) \rangle \) is achieved at \( x = v \) on \( t \in I \). (And \( v \) is the only such vertex.) Let \( v_1 \) be the vertex for which \( \langle x, w_1 \rangle \) is the largest, and \( v_2 \) the one where it is smallest. When \( t \to \infty \), both \( \max_{x \in Q} \langle x, w(t) \rangle \) and \( \max_{x \in Q} \langle x, \bar{w}(t) \rangle \) is achieved at \( v_1 \); similarly for \( v_2 \) and \( t \to -\infty \). It follows that \( B^*(Q, w(t)) + B^*(Q, \bar{w}(t)) \geq k/2 + 1 \) and so \( B^*(Q) \geq k/2 + 1 \).

Now, given \( P \subseteq \mathbb{R}^n \), let \( L : \mathbb{R}^n \to \mathbb{R}^2 \) be a linear map so that \( L(P) \) has \( \sigma(P) \) vertices. By the above, there exists \( w(t) \) in \( \mathbb{R}^2 \) so that \( \max_{x \in L(P)} \langle x, w(t) \rangle \) has at least \( \sigma(P)/2 \) breakpoints. Maximizing \( \langle x, w(t) \rangle \) on \( L(P) \) is equivalent to maximizing some \( w'(t) \) on \( P \) and so \( \beta(P) \geq \sigma(P)/2 \).

2.2 Greedy polytopes

Our goal here is to prove that \( \sigma(P) \) is small whenever \( P \) is greedy-like (Lemma 5).

Proof of Lemma 5. Let \( w(t) \) be a line in \( \mathbb{R}^n \). For a given \( t \), the weight vector \( w(t) \) defines a preorder on \([n]\) by \( i \leq_t j \) iff \( w(t)_i \leq w(t)_j \). Since \( P \) is greedy-like, every breakpoint of \( \Phi(w(t)) = \max_{x \in P} \langle x, w(t) \rangle \) occurs at a time where the order \( \leq_t \) changes. Hence there exist \( i \neq j \) such that the linear function \( w(t)_i - w(t)_j \) changes sign. There are \( \binom{n}{2} \) pairs, and a linear function can change sign at most once. So, \( \Phi(w(t)) \) has at most \( \binom{n}{2} \) breakpoints. This means \( \beta(P) \leq \binom{n}{2} \) and \( \sigma(P) \leq o(n - 1) \).
Lemma 7. Let $P \subseteq \mathbb{R}^n$ be a polytope. Assume that for every order-equivalent $w, w' \in \mathbb{R}^n$, the equality $\text{Opt}_P(w) = \text{Opt}_P(w')$ holds whenever $|\text{Opt}_P(w)| = 1$. Then $P$ is greedy-like.

Proof. Let $P$ be as in the assumption. Assume that $w, w' \in \mathbb{R}^n$ are order-equivalent with $|\text{Opt}_P(w)| \geq 1$. We want to show that $\text{Opt}_P(w) = \text{Opt}_P(w')$. Given $v \in \text{Opt}_P(w)$, we can find $z \in \mathbb{R}^n$ such that $\text{Opt}_P(z) = \{v\}$. Hence for every $\epsilon > 0$ we have $\text{Opt}_P(w + \epsilon z) = \{v\}$. For $\epsilon > 0$ small enough, we also have that $w + \epsilon z$ and $w' + \epsilon z$ are order-equivalent. It follows that $v \in \text{Opt}_P(w' + \epsilon z)$. Letting $\epsilon$ tend to zero, we can conclude $v \in \text{Opt}_P(w')$.

We have shown $\text{Opt}_P(w) \subseteq \text{Opt}_P(w')$. By symmetry, we also have $\text{Opt}_P(w') \subseteq \text{Opt}_P(w)$. ▲

2.3 Operations on polytopes

Given $A, B \subseteq \mathbb{R}^n$, their Minkowski sum is defined as

$$A + B := \{a + b : a \in A, b \in B\}.$$ 

If $P$ and $Q$ are polytopes then $P + Q$ is also a polytope. In two-dimensions, Minkowski sum has nice properties. Let $P$ be a polytope in $\mathbb{R}^2$ with vertices $v_1, \ldots, v_k$ where $k > 1$. We can assume they are ordered so that $P$ lies in the left closed half plane determined by the line going from $v_1$ to $v_{i+1}$ for $i < k$, and similarly for $v_k$ and $v_1$. Let $E(P)$ be the collection of unit vectors in the direction of these $k$ edges. That is, vectors of the form $(v_{i+1} - v_i)/\|v_{i+1} - v_i\|$ for $i < k$, and $(v_1 - v_k)/\|v_1 - v_k\|$. If $|\text{vert}(P)| \leq 1$ then $E(P) := \emptyset$.

Lemma 8. Let $P_1, \ldots, P_r$ be non-empty polytopes in $\mathbb{R}^2$. Then $E(P_1 + \cdots + P_r) = \bigcup_{i=1}^r E(P_i)$. Consequently, $|\text{vert}(P_1 + \cdots + P_r)| \leq \sum_{i=1}^r |\text{vert}(P_i)|$. The latter holds for empty $P_i$’s as well.

The lemma is folklore. It can be inferred from Chapter 13.3 in [11], and we give only an outline of proof.

Proof sketch of Lemma 8. Given a non-empty polytope $P$ and $w \in \mathbb{R}^2$, let $P^w := \{x \in P : \langle x, w \rangle = \max_{z \in P} \langle z, w \rangle\}$ be the set of extreme points of $P$ in the direction $w$. It is either a vertex or an edge of $P$. For a pair of polytopes we have $(P_1 + P_2)^w = P_1^w + P_2^w$. Every edge of $P_1$ yields an edge of $P_1 + P_2$ with the same direction. Conversely, every edge of $P_1 + P_2$ comes from one of $P_1$ or $P_2$. ▲

The second operation we use is

$$A \cup B := \text{conv}(A \cup B).$$

If $P$ and $Q$ are polytopes then $P \cup Q$ is also a polytope.

Lemma 9. Let $L : \mathbb{R}^n \to \mathbb{R}^m$ be a linear map. Given polytopes $P, Q \subseteq \mathbb{R}^n$, $L(P + Q) = L(P) + L(Q)$ and $L(P \cup Q) = L(P) \cup L(Q)$.

Proof. The first equality holds by linearity. The second one can be proved by

$$L(P \cup Q) = L(\text{conv}(P \cup Q)) = \text{conv}(L(P \cup Q))$$

$$= \text{conv}(L(P)) \cup \text{conv}(L(Q)) = L(P) \cup L(Q).$$ ▲

We next relate the shadow complexity of $P$ with the shadow complexity of its faces. A face of a polytope $P$ is the intersection of $P$ with a hyperplane $H$ such that $P$ is completely contained in one of the two closed halfspaces determined by $H$. We stipulate that both $\emptyset$ and $P$ are faces of $P$. 
Lemma 10. Let $F$ be a face of a polytope $P$. Then $\beta(F) \leq \beta(P)$ and $\sigma(F) \leq 2\sigma(P)$.

For example, this implies $\beta(DS_{n_2}) \leq \beta(DS_{n_2})$ whenever $n_1 \leq n_2$. This reflects the fact that finding a maximum perfect matching is harder for larger graphs.

Proof. Without loss of generality, assume that $P \subset \mathbb{R}^n$ is contained in the halfspace \( \{ x \in \mathbb{R}^n : x_1 \geq 0 \} \) and that $F \not\in \{ \emptyset, P \}$ is the intersection with the hyperplane $x_1 = 0$.

Let $w(t)$ be a line in $\mathbb{R}^n$ so that $\beta(F, w(t)) = \beta(F) = k$ with $w(t)_1 = 0$. Let $t_1 < t_2$ be such that the breakpoints of $\max_{x \in F} \langle x, w(t) \rangle$ are contained in the open interval $(t_1, t_2)$. Let $V := \text{vert}(P) \setminus \text{vert}(F)$. Define

$$\mu_F := \min_{x \in F, t \in [t_1, t_2]} \langle x, w(t) \rangle$$

and

$$\mu_P := \max_{v \in V, t \in [t_1, t_2]} \langle v, w(t) \rangle.$$

Take $\lambda \in \mathbb{R}$ sufficiently small so that for every $v \in V$, we have $\lambda v_1 + \mu_P < \mu_F$. Define $\bar{w}(t)$ by changing the first coordinate of $w(t)$ to $\lambda + 0 \cdot t$. This means that

$$\max_{x \in F} \langle x, w(t) \rangle = \max_{x \in P} \langle x, \bar{w}(t) \rangle$$

holds on $[t_1, t_2]$. So, $\beta(P, \bar{w}(t)) = k$ and $\beta(P) \geq \beta(F)$.

If $|\text{vert}(F)| \leq 2$, then $\sigma(F) \leq 2\sigma(P)$ holds trivially. Otherwise, $\sigma(F) \leq 2\sigma(P)$ follows from Theorem 4.

2.4 Laurent polynomials

It is convenient to work with Laurent polynomials instead of polynomials. In a Laurent polynomial, variables are allowed to have negative integer exponents. The notions of $\text{supp}(f)$ and Newton polytope of $f$ are defined in the obvious manner. A Laurent polynomial over $\mathbb{R}$ is monotone, if all of its coefficients are non-negative.

Lemma 11. Let $f, g$ be Laurent polynomials over $\mathbb{F}$.

(i) Then $\text{Newt}(fg) = \text{Newt}(f) \cap \text{Newt}(g)$.

(ii) $\text{Newt}(f + g) = \text{Newt}(f) \cup \text{Newt}(g)$, provided $\mathbb{F} = \mathbb{R}$ and both $f$ and $g$ are monotone.

Proof. Part (i) can be found in [16] for polynomials; it extends to Laurent polynomials. Part (ii) is straightforward to verify.

An application is that the shadow complexity of $\text{Newt}(g)$ is at least the shadow complexity of any of its factors.

Lemma 12. Let $g$ be a non-zero polynomial (over an arbitrary field). If $f$ divides $g$ then $\sigma(\text{Newt}(f)) \leq \sigma(\text{Newt}(g))$.

Proof. Let $L$ be such that $L(\text{Newt}(f)) \subseteq \mathbb{R}^2$ has $\sigma(\text{Newt}(f))$ vertices. By the assumption, we have $g = fh$ for some non-zero polynomial $h$ and so $\text{Newt}(g) = \text{Newt}(f) + \text{Newt}(h)$ by Lemma 11. By Lemma 9, we have $L(\text{Newt}(g)) = L(\text{Newt}(f)) + L(\text{Newt}(h))$ and so $|\text{vert}(L(\text{Newt}(g)))| \geq |\text{vert}(L(\text{Newt}(f)))|$ by Lemma 8.
3 Examples

We now describe some examples, and analyze the shadow complexity of several natural polytopes. We start with polytopes with small $\sigma$, continue with polytopes with large $\sigma$, and then discuss our favorites, the ones where we do not yet know.

3.1 The hypercube

Optimizing over the discrete cube $\{0, 1\}^n \subset \mathbb{R}^n$ leads to the polytope $Q_n = [0, 1]^n$. The solid cube $Q_n$ has $2^n$ vertices, but its shadow complexity is small.

Proposition 13. $\sigma(Q_n) = 2n$ and $\beta(Q_n) = n$.

The proposition shows that the factor of two in Theorem 4 is necessary. The lower bound on $\sigma$ also follows from a more general theorem of Klee [27].

Proof. Let $\ell_i \subseteq \mathbb{R}^n$ be the line segment joining the origin and the $i$-th unit vector for $i \in [n]$. The solid cube $Q_n$ is the Minkowski sum of $\ell_1, \ldots, \ell_n$. Given $L : \mathbb{R}^n \to \mathbb{R}^2$, the image $L(Q_n)$ is the Minkowski sum of $L(\ell_1), \ldots, L(\ell_n)$ by Lemma 9. Since $|\text{vert}(L(\ell_i))| \leq 2$, Lemma 8 gives that $|\text{vert}(L(Q_n))| \leq 2n$. The bound $\sigma(Q_n) \geq 2n$ is achieved by the same lemma. It is enough to take $L$ so that $L(\ell_i)$ are not parallel to get $|\text{vert}(L(Q_n))| = 2n$.

The above and Theorem 4 imply that $\beta(Q_n) \geq n$. It remains to prove $\beta(Q_n) \leq n$. For every $w \in \mathbb{R}^n$, the maximum $\max_{x \in Q_n} \langle x, w \rangle$ equals the sum of the positive entries in $w$, or zero if all entries are non-positive. A breakpoint of $\max_{x \in Q_n} \langle x, w(t) \rangle$ can therefore occur only when some coordinate of $w(t)$ changes sign. A linear function can change sign at most once and there are $n$ linear functions.

Remark 14. The solid cube $Q_n$ is not greedy-like as defined above. This is because in the optimization algorithm, we must distinguish which entries are non-negative. Shifting all coordinates of $w$ by $\lambda$ does not change their order but may change where the maximum is achieved.

3.2 Permutahedra

Given $z = (z_1, \ldots, z_n) \in \mathbb{R}^n$, let

$$P(z) := \text{conv}\{ (z_{\pi(1)}, \ldots, z_{\pi(n)}) : \pi \in S_n \},$$

where $S_n$ is the family of permutations of $[n]$. The permutahedron is usually defined using the point $z = (0, 1, \ldots, n-1)$. However, we do not insist $z$ to have distinct coordinates. Setting $z$ to be a zero-one vector with $k$ ones, $P(z)$ becomes the convex hull of Boolean vectors of Hamming weight $k$. For every $z$, the polytope $P(z)$ is a linear projection of $DS_n$. The polytope $P(z)$ typically has $n!$ vertices, but its shadow complexity is always small.

Proposition 15. For every $z \in \mathbb{R}^n$, $\sigma(P(z)) \leq n(n-1)$. The bound is attained for $z = (0, 1, \ldots, n-1)$.

Proof. Let $z := (0, 1, \ldots, n-1)$. Let $e_i \in \mathbb{R}^n$ be the $i$-th unit vector. Let $\ell_{i,j}$ be the line segment joining $e_i$ and $e_j$ for $i \neq j$. We claim that the polytope $P(z)$ can be written as the following Minkowski sum

$$P(z) = \bigoplus_{i<j} \ell_{i,j}.$$  \hfill (1)
Indeed, let $X$ be the $n \times n$ matrix such that $X_{i,j} = x_i^{z_j}$. Observe that

$$P(z) = \text{Newt}(\det(X)).$$

The matrix $X$ is a Vandermonde matrix whose determinant, over any field, factorizes as $\det(X) = \prod_{i \neq j} (x_i - x_j)$. Lemma 11 implies (1).

Now, given $L : \mathbb{R}^n \to \mathbb{R}^2$, we thus have $L(P(z)) = \bigoplus_{i \leq j} L(i,j)$. By Lemma 8, if we choose $L$ so that the lines $L(i,j)$ are non-parallel, the number of vertices of $L(P)$ is $2 \cdot \binom{n}{2} = n(n-1)$.

The general upper bound is an application of Lemma 5. We claim that $P(z)$ is greedy-like. Permuting the entries of $z$ does not changes $\sigma$. So, we can assume that $z_1 \leq z_2 \leq \ldots z_n$. Given $w \in \mathbb{R}^n$, 

$$\max_{x \in P(z)} \langle x, w \rangle = \max_{\pi \in S_n} \langle z, w_{\pi} \rangle,$$

where $w_{\pi} := (w_{\pi(1)}, \ldots, w_{\pi(n)})$. The maximum is achieved iff $w_{\pi(1)} \leq w_{\pi(2)} \cdots \leq w_{\pi(n)}$. This means that $\text{Opt}_w(P(z)) = \text{Opt}_{w'}(P(z))$ whenever $w$ and $w'$ are order-equivalent.

\textbf{Remark 16.} Here we provide an additional algebraic proof. Consider $z = (z_1, \ldots, z_n)$ with $z_i = 2^{i-1}$. The matrix $X$ defined by $X_{i,j} = x_i^{z_j}$ is a Moore matrix [34]. Over $F = GF(2)$, the polynomial $\det(X(z))$ factorizes as

$$\det(X(z)) = \prod_{A \subseteq [n]} \sum_{i \in A} x_i.$$

The number of factors is exponential but we can still get a quadratic upper bound. We have $P(z) = \bigoplus_{A \subseteq [n]} R_A$ where $R_A = \text{conv}\{e_i : i \in A\}$. Given a projection $L : \mathbb{R}^n \to \mathbb{R}^2$, we have $L(P(z)) = \bigoplus_{A \subseteq [n]} L(R_A)$. The polytopes $L(R_A)$ contain at most $\binom{n}{2}$ non-parallel edges and hence $L(P(z))$ has again at most $n(n-1)$ vertices.

### 3.3 Spanning trees

Every $\alpha \in \{0,1\}^{\binom{n}{2}}$ can be interpreted as the incidence vector of an undirected graph on $n$ vertices. Namely, $\alpha_{i,j} = 1$, if $i,j$ are adjacent, and $\alpha_{i,j} = 0$ otherwise. The polytope $\text{TREE}_n$ is defined as the convex hull of spanning trees of the complete $n$-vertex graph.

\textbf{Proposition 17.} $\sigma(\text{TREE}_n) \leq n^4$.

\textbf{Proof.} By Lemma 5, it is enough to show that $P = \text{TREE}_n$ is greedy-like. Indeed, Kruskal’s algorithm for finding a minimum weight spanning tree takes into account only the ordering of weights on the edges. That is, if $w$, $w'$ are order-equivalent and $\text{Opt}_P(w)$ is a singleton then $\text{Opt}_P(w) = \text{Opt}_P(w')$. Hence $\text{TREE}_n$ is greedy-like by Lemma 7. \hfill \qed

\textbf{Remark 18.} This is interesting when contrasted with algebraic complexity. Consider the unique polynomial $\text{Tree}_n$ with zero-one coefficients so that $\text{Newt}(\text{Tree}_n) = \text{TREE}_n$. It is a homogeneous multilinear polynomial of degree $n-1$. Proposition 17 shows that the shadow complexity of its Newton polytope is polynomial. On the other hand, Jerrum and Snir showed that $\text{Tree}_n$ requires exponential monotone arithmetic circuit [23]. They also pointed out that it has a non-monotone circuit of polynomial size. More surprisingly, $\text{Tree}_n$ has a monotone circuit with division of polynomial size [14].
3.4 Cliques

The correlation polytope $\text{COR}_n \subseteq \mathbb{R}^{n \times n}$ is the convex hull of all symmetric rank-one Boolean matrices:

$$\text{COR}_n = \text{conv}\{bb^t : b \in \{0, 1\}^n\}.$$

**Proposition 19.** $\sigma(\text{COR}_n) = 2^n$.

**Proof.** Let $e_{i,j}$ be the $n \times n$ matrix whose $(i,j)$ entry is one and every other entry is zero. The vertices of $\text{COR}_n$ are of the form $v_A = \sum_{i,j \in A} e_{i,j}$ with $A \subseteq [n]$. Define

$$L(e_{i,j}) := \begin{cases} (2^i, 2^{2i}) & i = j, \\ (0, 2^{i+j}) & i \neq j, \end{cases}$$

and extend it linearly to $\mathbb{R}^{n \times n}$. Setting $n_A := \sum_{i \in A} 2^i$, this guarantees

$$L(v_A) = \left( \sum_{i \in A} 2^i, \sum_{i,j \in A} 2^{i+j} \right) = (n_A, n_A^2).$$

These $2^n$ points are convexly independent. ◀

**Remark 20.** The polytope $\text{COR}_n$ lives in dimension $N = n^2$, and so $\sigma(\text{COR}) = 2^\sqrt{N}$. The polytope $\text{ART}_n \subseteq \mathbb{R}^{3n}$, which we define next, has truly exponential shadow complexity. It is defined as the convex hull of

$$\left\{(a_0, \ldots, a_{n-1}, b_0, \ldots, b_{2n-1}) \in \{0, 1\}^{3n} : \sum_{i=0}^{2n-1} b_i 2^i = \left( \sum_{i=0}^{n-1} a_i 2^i \right)^2 \right\}.$$

In words, $b$ is the binary representation of the square of the number represented by $a$. It follows that $\sigma(\text{ART}_n) = 2^n$.

**Remark 21.** The polynomial that corresponds to $\text{COR}_n$ is

$$\text{Clique}_n = \sum\limits_{A \subseteq [n]} \prod_{i,j \in A} x_{i,j}.$$

It has $n^2$ variables and $\text{Newt}(\text{Clique}_n) = \text{COR}_n$. We can interpret the polynomial as counting cliques of all sizes in a directed graph with loops, hence the name.

3.5 More graph-based polytopes

Consider a layered directed graph $G_n$ as follows. The vertex-set of $G_n$ is partitioned into layers $V_0, \ldots, V_n$. The first and the last layer consist of a single vertex $s$ and $t$. Every other layer has $n$ vertices. The edges are all pairs from $V_i \times V_{i+1}$ directed from layer $i$ to $i + 1$. Overall, $G_n$ has $n(n-1) + 2$ vertices and $N := (n-2)n^2 + 2n$ edges. Let $\text{CONN}_n \subseteq \mathbb{R}^N$ be the convex hull of incidence vectors of directed paths from $s$ to $t$ in $G_n$. The following proposition can be found in [8, 37], where the results are stated in terms of the parametrized complexity $\beta$, which is equivalent to the shadow complexity by Theorem 4.

**Proposition 22.** $\sigma(\text{CONN}_n) = 2^{\Theta(\log^2 n)}$.

We now deduce the best bound we are aware of for the Birkhoff polytope.

**Proposition 23.** $2^{\Omega(\log^2 n)} \leq \sigma(\text{DS}_n) \leq 2^{O(n)}$. 
Proof. As pointed by Mulmuley and Shah in [37], the lower bound for $\text{CONN}_n$ translates to $DS_n$. For the upper bound, we claim that
\[ \sigma(DS_{2n}) \leq 2^{\left(\frac{2n}{n}\right)}\sigma(DS_n). \] (2)
By induction, this indeed implies $\sigma(DS_n) \leq 2^{O(n)}$.

Let us prove (2). Given $A \subseteq [2n]$ with $|A| = n$, let $\Pi_A$ be the set of permutation matrices which, when viewed as a permutation on $[2n]$, map $\{1, \ldots, n\}$ to $A$. The set of all $2n \times 2n$ permutation matrices is the union of all $\Pi_A$ with $|A| = n$. Hence,
\[ DS_{2n} = \text{conv}\left( \bigcup_{A: |A|=n} \Pi_A \right). \]
We can view $\text{conv}(\Pi_A)$ as the Minkowski sum of two copies of $DS_n$ embedded into $\mathbb{R}^{2n \times 2n}$. Given $L : \mathbb{R}^{2n \times 2n} \to \mathbb{R}^2$ this gives, by Lemma 8, $|\text{vert}(L(\text{conv}(\Pi(A))))| \leq 2|\text{vert}(L(DS_n))|$. The bound in (2) follows.

Remark 24. The upper bound on $DS_n$ is more exactly of the form $2^{(2-o(1))n}$. In the proof, we implicitly construct a monotone arithmetic formula for $\text{perm}_n$ of this size. This matches the lower bound from [43]. Curiously, $\text{perm}_n$ has a monotone circuit of size $O(n2^n)$ [23] and a (non-monotone) formula of size $O(n^22^n)$ [42].

Remark 25. Let $\text{Mat}_n := (X_0 \cdot X_1 \cdots X_n)_{1,1}$, where $X_0, \ldots, X_n$ are $n \times n$ matrices whose entries are distinct variables. Then $\text{Newt}(\text{Mat}_n) = \text{CONN}_n$.

Remark 26. The perfect matching polytope $\text{MATCH}_n$ is the the convex hull of incidence vectors of perfect matchings in the complete (non-bipartite) graph on $2n$ vertices. A similar argument to the proof of Proposition 23 gives
\[ \sigma(DS_n) \leq \sigma(\text{MATCH}_n) \leq 2^{\left(\frac{2n}{n}\right)}\sigma(DS_n) \leq 2^{O(n)}. \]

4 Projections
We now discuss some connection between algebraic projections of polynomials and linear projections of Newton polytopes. The results here shall also be used later on.

A high power projection (h.p.-projection for short) is a homomorphism
\[ \pi : F[x_1, \ldots, x_n] \to F[y_1, \ldots, y_m, y_1^{-1}, \ldots, y_m^{-1}] \]
such that $\pi(x_i) = a_i y^{\alpha_i}$ for every $x_i$, where $a_i \in F$ and $\alpha_i \in \mathbb{Z}^m$, and for every $f \in F[x_1, \ldots, x_n], \pi(f(x_1, \ldots, x_n)) = f(\pi(x_1), \ldots, \pi(x_n))$.

The constants $a_i$ are called the coefficients of $\pi$ and $\alpha_i$ its exponents. If $F = \mathbb{R}$ and $\pi$ has non-negative coefficients, then $\pi$ is called monotone.

An h.p.-projection $\pi$ induces a linear map $L_\pi : \mathbb{R}^n \to \mathbb{R}^m$ by setting $L_\pi(e_i) = \alpha_i$ and extending it linearly to $\mathbb{R}^n$. It follows that $\text{supp}(\pi(f)) \subseteq L_\pi(\text{supp}(f))$. The inclusion may be strict, as some monomials of $f$ can cancel out in the projection. If no cancellations occur, we indeed have $\text{Newt}(\pi(f)) = L_\pi(\text{Newt}(f))$. This is satisfied, e.g., if $f$ is monotone and the coefficients of $\pi$ are positive, or if the coefficients are algebraically independent.
In the other direction, take \( L : \mathbb{R}^n \to \mathbb{R}^m \) a linear map defined by \( m \times n \) matrix with integer coefficients. Consider a h.p.-projection \( \pi_L \) of the form \( \pi(x_i) = a_i x_i^{L(c_i)} \). If we choose the coefficients \( a_i \) to be sufficiently independent, we again obtain \( L(\text{Newt}(f)) = \text{Newt}(\pi_L(f)) \).

The following we do not really need, but it puts things into perspective. A similar fact has been noted by Grochow [20].

\[ \text{Proposition 27. Let } f \text{ be a monotone polynomial. Assume that a Laurent polynomial } g \text{ is a monotone h.p.-projection of } f \text{. Then } \text{Newt}(g) \text{ is a linear projection of some face of } \text{Newt}(f). \text{ Hence } \sigma(\text{Newt}(g)) \leq 2\sigma(\text{Newt}(f)). \]

**Proof.** Assume \( g = \pi(f) \) with \( \pi \) an h.p.-projection. Let \( A \subseteq [n] \) be the set of \( i \in [n] \) with \( a_i = 0 \). Let \( f^* \) be the polynomial obtained by substituting 0 for \( x_i \) for every \( i \in A \). The polytope \( \text{Newt}(f^*) \) is a face of \( \text{Newt}(f) \). Indeed, since \( f \) has non-negative exponents, \( \text{Newt}(f^*) = \text{Newt}(f) \cap H \) where \( H \) is the hyperplane defined by \( \sum_{i \in A} z_i = 0 \), and \( \text{Newt}(f) \) lies in the halfspace \( \sum_{i \in A} z_i \geq 0 \).

We can now write \( \pi(f) = \pi^*(f^*) \) where \( \pi^* \) has positive coefficients. This means that \( \text{supp}(\pi(f)) = L_{\pi^*}(\text{supp}(f^*)) \) and hence \( \text{Newt}(\pi(f)) = L_{\pi^*}(\text{Newt}(f^*)) \). The bound on \( \sigma \) follows from Lemma 10.

The following we do need:

\[ \text{Lemma 28. Let } f \text{ be a polynomial over an infinite field } \mathbb{F}. \text{ Assume that } \sigma(\text{Newt}(f)) = k. \text{ Then there exists a bivariate Laurent polynomial } g \in \mathbb{F}(y_1, y_2, y_1^{-1}, y_2^{-1}) \text{ which is an h.p.-projection of } f \text{ so that } \text{Newt}(g) \text{ has } k \text{ vertices. Moreover, if } f \text{ is a homogeneous polynomial then } g \text{ is a polynomial. If } \mathbb{F} = \mathbb{R}, \text{ then the coefficients in the projection can be assumed positive.} \]

**Proof.** Let \( L(z) = Az \) with \( A \in \mathbb{R}^{2 \times n} \) be a linear map so that

\[ |\text{vert}(L(\text{Newt}(f)))| = k. \]

We can assume that the entries of \( A \) are rational, because a small perturbation of \( A \) cannot decrease \( |\text{vert}(L(\text{Newt}(f)))| \). Now, we can assume that the entries of \( A \) are integers, because we can multiply \( A \) by a suitable integer.

Moreover, when \( f \) is homogeneous of degree \( d \), increasing all entries of \( A \) by \( \lambda \) corresponds to shifting \( L(\text{Newt}(f)) \) by \( (\lambda d, \lambda d) \), which does not change the number of vertices. Hence, in this case, \( A \) can be taken with non-negative integer entries.

Let us now consider a h.p.-projection \( \pi \) with \( \pi(x_i) = a_i y_i^{L(c_i)} \). It follows that \( \text{supp}(\pi(f)) \subseteq L(\text{supp}(f)) \). Now, we claim that we can choose the coefficients \( a_i \) so that equality holds. This can be seen as follows. Given \( \alpha \in \text{supp}(f) \), the coefficient of \( y_i^{L(c_i)} \) in \( \pi(f) \) is a non-zero polynomial \( h_\alpha \) in the coefficients of \( \pi \). Hence, if \( \mathbb{F} \) is infinite, there exist non-zero coefficients for which \( h_\alpha \) is non zero for every \( \alpha \in \text{supp}(f) \). If \( \mathbb{F} = \mathbb{R} \), they can be taken positive.

\[ \text{Remark 29. We emphasize the difference between linear projections of polytopes and algebraic projections of polynomials. Since the permanent polynomial is VNP-complete, } \text{Clique}_n \text{ from Remark 21 is a projection (in the common sense) of } \text{perm}_m \text{ with } m \text{ polynomial in } n. \text{ However, } \text{Newt}(\text{Clique}_n) \text{ is not a linear projection of } \text{Newt}(\text{perm}_m), \text{ neither of any of its faces, unless } m \text{ is exponentially large [20]. The idea is that } DS_m \text{ has } O(m^2) \text{ facets whereas } \text{Newt}(\text{Clique}_n) \text{ is not a projection of any polytope with few facets. It follows that } \text{Clique}_n \text{ is not a monotone projection of } \text{perm}_m. \]
Monotone computation

As the standard model of computation of polynomials we take the arithmetic circuit model. It is a (finite) directed acyclic graph whose every node has in-degree zero or two. Nodes of in-degree zero (input nodes) are labelled with a constant or a variable. Nodes of in-degree two are labelled with operations $+$ or $\times$. Every node of the circuit computes a polynomial in $\mathbb{F}$ in the natural way. As the size of the circuit, we take the number of nodes. A circuit is called a formula if its underlying graph is a tree. For more background and motivation, see [44] and references within.

Our focus is mainly on monotone computation. A polynomial over $\mathbb{R}$ is monotone if all of its coefficients are non-negative. Similarly, a monotone arithmetic circuit can use only non-negative constants.

5.1 Optimization problems

We start with a somewhat surprising connection between monotone computation and Newton polytopes. A monotone circuit over $\mathbb{R}$ computing $f$ can be interpreted as a computation over the semi-ring $M = (\mathbb{R} \cup \{\infty\}, \min, +, \infty, 0)$. That is, replace "$+$" by "$\min$", replace "$\times$" by "$+$", replace "0" by "$\infty$", and replace every positive constant "$a$" by "0". A circuit with operations from $M$ has also been called a tropical circuit [24]. The resulting circuit computes the function $f^* : \mathbb{R}^n \to \mathbb{R}$ which turns out to be precisely

$$f^*(w) = \min_{x \in \text{Newt}(f)} \langle x, w \rangle.$$ 

For example, any monotone circuit for the permanent polynomial can also be viewed as a tropical circuit for the minimum weight perfect matching in a bipartite graph. Computations over general semi-rings have been considered in [23, 24], where the reader can find more details.

5.2 Shadows and monotone computations

We explore some connections between the structure of the Newton polytope of $f$ and monotone arithmetic computations. We prove that shadow complexity allows to prove lower bounds on monotone complexity (Theorems 1 and 2). We also show that in general Theorem 1 does not hold for circuits instead of formulas and so the assumption of transparency in Theorem 2 cannot be removed.

Theorem 30. For every $n$, there exists a monotone bivariate polynomial $f_n$ such that $f_n$ has a monotone arithmetic circuit of size $O(n)$ and $\text{Newt}(f)$ has $2^n$ vertices.

Theorem 30 is proved in Section 8. The construction is reminiscent of that in [3] of a univariate polynomial with circuit of size $s$ and $2^{\Omega(s)}$ real roots (cf. Chapter 12 of [6]). A weaker bound can also be deduced as follows:

Remark 31. Recall the polynomial $\text{Mat}_n$ from Remark 25. Then $\text{Mat}_n$ has a monotone circuit of size $O(n^4)$ whereas $\sigma(\text{Newt}(\text{Mat}_n)) = 2^{\Omega(\log^2 n)}$.

Remark 32. When a monotone arithmetic formula is interpreted as a tropical formula (cf. Section 5.1), it becomes an instance of parallel computation in the PRAM model without bit operations of Mulmuley [36]. Hence Theorem 1 can be seen as special case\(^3\) of Theorem 3.3 from [36].

\(^3\) This is not a “black box” reduction. Mulmuley’s result has an additional parameter representing bit size of the input, whereas we have no such thing.
5.3 Monotone formulas

Here we show that shadow complexity allows to lower bound monotone formula complexity.

A high powered circuit (h.p.-circuit for short) is an arithmetic circuit in which every input node is labelled by a term $ax_1^{k_1} \cdots x_n^{k_n}$ with $a \in \mathbb{F}$ and $k_1, \ldots, k_n \in \mathbb{Z}$. The size of the circuit is the number of its nodes.

In other words, we have given the circuit a power to compute every term $ax^\alpha$ at a unit cost. This is especially important in the case of h.p.-formula. An arithmetic formula of size $s$ can compute a polynomial of degree at most $s$, whereas there is no such restriction in an h.p.-formula. Furthermore, we have allowed the variables to have negative exponents and hence an h.p.-circuit computes a Laurent polynomial instead of a polynomial. But this is only a cosmetic detail.

**Theorem 33.** Let $f$ be a monotone bivariate Laurent polynomial such that $\text{Newt}(f)$ has $k$ vertices. Then every monotone h.p.-formula computing $f$ has at least $k$ leaves.

**Proof.** Straightforward induction using Lemma 11 and 8.

We can now prove that every monotone formula computing $f$ contains at least $\sigma(\text{Newt}(f))$ leaves.

**Proof of Theorem 1.** By Lemma 28 there exists a bivariate $g$ which is a monotone h.p.-projection of $f$ so that $\text{Newt}(g)$ has $k$ vertices. The projection also transforms a monotone formula for $f$ to a monotone h.p.-formula for $g$.

5.4 Lower bounds from extension complexity

As mentioned in Section 1.2, one can obtain monotone formula lower bounds also from extensions complexity of Newton polytopes. The main ingredient is the following lemma.

**Lemma 34.** For polytopes $P, Q \subseteq \mathbb{R}^n$ we have

$$\text{xc}(P + Q) \leq \text{xc}(P) + \text{xc}(Q) \quad \text{and} \quad \text{xc}(P \sqcup Q) \leq \text{xc}(P) + \text{xc}(Q) + 2.$$ 

**Proof.** The first inequality is rather obvious. The second follows from a theorem of Balas [2], see also [10].

The lower bound is now proved by a straightforward induction.

**Theorem 35.** Assume that $f$ has a monotone formula of size $s$. Then $\text{xc}(\text{Newt}(f)) \leq O(s)$.

**Remark 36.** The Pfaffian $\text{Pf}_n$ is the polynomial so that $\text{Pf}_n^2 = \det(X)$, where $X$ is the $2n \times 2n$ antisymmetric matrix with $X_{i,i} = 0$ and $X_{i,j} = -X_{j,i} = x_{i,j}$ if $i < j$. The Pfaffian has an arithmetic circuit of size polynomial in $n$, and a formula of size $2^{O(\log^2 n)}$; see [45]. The Newton polytope $\text{Newt}(\text{Pf}_n)$ is the perfect matching polytope $\text{MATCH}_n$, as described in Remark 26. By a result of Rothvoss [41], $\text{MATCH}_n$ has extension complexity $2^{\Theta(n)}$.

5.5 Monotone circuits

We move to proving the circuit lower bound stated in Theorem 2. We first observe that Minkowski sum typically can not avoid convex independence.

**Lemma 37.** Let $A, B \subseteq \mathbb{R}^2$ be non-empty sets such that $A + B$ is a convexly independent set with $|A| \geq |B|$. Then either $|A| \leq 2$ or $|B| \leq 1$. 

Proof. For the sake of contradiction, assume that $A + B$ is convexly independent, $|A| \geq 3$ and $|B| \geq 2$. By Lemma 8, the convex hull of $A + B$ has at most $|A| + |B|$ vertices. By the size assumption, there exist $a_1 \neq a_2 \in A$ and $b_1 \neq b_2 \in B$ with $a_1 + b_1 = a_2 + b_2$. The point $a_1 + b_1$ is the average of $a_1 + b_2$ and $a_2 + b_1$ and it is distinct from them, a contradiction. ▷

Theorem 38. Let $f$ be a monotone bivariate Laurent polynomial such that $\text{supp}(f)$ is convexly independent and $|\text{supp}(f)| = k$. Then $f$ requires monotone h.p.-circuit with $k/4$ gates.

Theorem 38 implies Theorem 2 via Lemma 28.

Proof. The lower bound is proved using the following "progress" measure. Given $A \subseteq \mathbb{R}^2$ and $\epsilon \in \{0, 1\}$, let $A' := A$ if $\epsilon = 1$ and $A' := \emptyset$ if $\epsilon = 0$. Given $v \in \mathbb{R}^2$, let $v + A := \{v\} + A$. Let $\mathcal{A}$ be a finite set of finite subsets of $\mathbb{R}^2$. For functions $\epsilon : \mathcal{A} \to \{0, 1\}$ and $v : \mathcal{A} \to \mathbb{R}^2$, let

$$\mathcal{A}_{\epsilon,v} = \bigcup_{\mathcal{A} \in \mathcal{A}} (v(A) + A)^{\epsilon(A)}.$$

Let

$$\mu(\mathcal{A}) = \max_{\epsilon,v}|\mathcal{A}_{\epsilon,v}| : \mathcal{A}_{\epsilon,v} \text{ is convexly independent}|.$$

Claim. Let $\mathcal{A}' = \mathcal{A} \cup \{B\}$ and $A_1, A_2 \in \mathcal{A}$. Then

$$\begin{align*}
\mu(\mathcal{A}') \leq & \mu(\mathcal{A}) + |B|, & (3) \\
\mu(\mathcal{A}') \leq & \mu(\mathcal{A}) + 2, \text{ if } B = u + A_1 \text{ for some } u \in \mathbb{R}^2, & (4) \\
\mu(\mathcal{A}') \leq & \mu(\mathcal{A}) + 4, \text{ if } B = A_1 \cup A_2, & (5) \\
\mu(\mathcal{A}') \leq & \mu(\mathcal{A}) + 4, \text{ if } B = A_1 + A_2. & (6)
\end{align*}$$

Proof of Claim. Inequality (3) is straightforward.

To prove (4), suppose that $\epsilon, v$ are such that $\mathcal{A}_{\epsilon,v}$ is convexly independent. Suppose $\epsilon(A_1) = \epsilon(B) = 1$ and $v(A_1) + A_1 \neq v(B) + B$; otherwise we have $|\mathcal{A}_{\epsilon,v}| \leq \mu(\mathcal{A})$. Then $(v(A_1) + A_1) \cup (v(B) + B) = \{v(A_1), v(B) + u\} + A_1$ is convexly independent. Since $|\{(v(A_1), v(B) + u)\}| = 2$, by Lemma 37, $A_1$ has size at most 2. This means $\mu(\mathcal{A}') \leq \mu(\mathcal{A}) + 2$ by (3).

For (5), observe that $\mu(\mathcal{A}') \leq \mu(\mathcal{A} \cup \{u_1 + A_1, u_2 + A_2\})$ whenever $u_1, u_2 \neq 0$ are distinct and apply (4) twice.

Finally, we prove (6). If $B = A_1 + A_2$ is not convexly dependent, it contributes nothing to $\mu$. Assume that $B$ is convexly independent and $|A_1| \geq |A_2| > 0$. By Lemma 37, either $|A_1 + A_2| \leq 4$ or $|A_2| = 1$. In the former case, $\mu(\mathcal{A}') \leq \mu(\mathcal{A}) + 4$ by (3). In the latter, $A_2 = \{u\}$ for some $u$ and $\mathcal{A}' = \mathcal{A} \cup \{u + A_1\}$ and we can apply (4). ▷

Let us call a h.p.-circuit transparent, if every gate in the circuit computes a polynomial with convexly independent support. Given a circuit $\Psi$ and a node $u$, let $\text{supp}(u)$ be the support of the Laurent polynomial computed by $u$. Let $\mathcal{A}_\Psi$ be the set $\{\text{supp}(u) : u \in \Psi\}$.

Using the Claim, we can show that whenever a transparent and monotone $\Psi$ has $s$ gates then $\mu(\mathcal{A}_\Psi) \leq 4s$. The proof is by induction. The induction base $s = 1$ trivially holds. It remains to verify the induction step. Let $u$ be an output gate of $\Psi$. If $u$ is also an input gate, apply (3). If $u = u_1 + u_2$ then $\text{supp}(u) = \text{supp}(u_1) \cup \text{supp}(u_2)$ and (5) completes the proof. If $u = u_1 \times u_2$ then $\text{supp}(u) = \text{supp}(u_1) + \text{supp}(u_2)$ and (6) completes the proof.
Finally, consider a monotone circuit $\Psi$ for $f$ of minimal size $s$. No gate in the circuit computes the zero polynomial (unless $f$ itself the zero polynomial). The circuit is transparent because a monotone computation does not cancel monomials unless multiplying by zero, and because $+, \times$ can not “undo” convex dependence. This means that $\mu(A_\Psi) \leq 4s$.

On the other hand, since $\text{supp}(f)$ consists of $k$ convexly independent points, we have $\mu(A_\Psi) \geq |\text{supp}(f)| = k$.

Other illustrative consequences are the following:

- **Corollary 39.** $\sum_{k=0}^{n} x^k y^{k^2}$ requires monotone h.p.-arithmetic circuit of size $\Omega(n)$.

Recall the $\text{Clique}_n$ polynomial from Remark 21 and the polytope $\text{ART}_n$ from Remark 20. Let $\text{Art}_n$ be the unique polynomial with zero-one coefficients so that $\text{Newt}(\text{Art}_n) = \text{ART}_n$.

- **Corollary 40.** Both $\text{Clique}_n$ and $\text{Art}_n$ require monotone arithmetic circuits of size $\Omega(2^n)$.

**Proof.** Proposition 19 and Remark 20 show that $\text{Clique}_n$ and $\text{Art}_n$ are transparent with shadow complexity $2^n$.

**5.6 Generalizations**

The results of this section can be strengthened in several ways. First, one could extend the notion of monotone computation to any field. A monotone circuit would be such that for every sum gate $f_1 + f_2$, no monomial can vanish:

$$\text{supp}(f_1 + f_2) = \text{supp}(f_1) \cup \text{supp}(f_2).$$

Then Theorem 1 goes through.

Second, one may consider circuits with high-power gates. This would be an arithmetic circuit which, apart from the $+, \times$ gates, can use also unary gates of the form $(\cdot)^k$ which raises its input to a power of $k \in \mathbb{N}$. A similar notion has appeared in the context of additive complexity of a polynomial and counting real roots of univariate polynomials (see Section 12.3 of [6] and references within). Our lower bounds hold also in this setting. This is because $\text{Newt}(f^k)$ with $k > 0$ is merely a scaling of $\text{Newt}(f)$.

Finally, our results extend to other semi-rings as well. For definitions of polynomials over semi-rings and their computations see, e.g., [23, 24]. Let $\mathbb{B} = \{0, 1\} \cup \{\lor, \land\}$ be the Boolean semi-ring.

- **Proposition 41.** Theorems 1 and 2 hold also over $\mathbb{B}$.

**Proof.** Given a circuit over $\mathbb{B}$ computing $f$, we can interpret it as a computation over $\mathbb{R}$ by replacing $\land$ by $\times$ and replacing $\lor$ by $\pm$. The circuit then computes a polynomial $f^*$ over $\mathbb{R}$ with $\text{supp}(f^*) = \text{supp}(f)$. Since the two theorems take into account only $\text{supp}(f^*)$, they hold over $\mathbb{B}$ as well.

**6 Divisions**

The model of monotone circuits can be extended to include division gates. We may allow the circuit to use an extra gate computing $f/g$. A monotone circuit with divisions can compute a non-monotone polynomial; e.g., $x^2 - x + 1 = \frac{x^3 + 1}{x+1}$.

Monotone circuits with divisions were extensively studied by Fomin et al. [14]. They proved, among other nice things, a separation between monotone circuits and monotone circuits with division. The $\text{Spanning Tree}$ polynomial (see Section 3.3) has a polynomial size.

---

4 Monomials can however vanish on a product as in $(x + y)(x - y) = x^2 - y^2$. 

monotone circuit with divisions but requires an exponential size monotone circuit by [23]. This is in sharp contrast with the result of Strassen that division gates cannot help in the general arithmetic setting\(^5\).

Super-polynomial lower bounds on monotone circuits with division computing a monotone polynomial \(f\) are not known. In [14], strong lower bounds were given for a non-monotone \(f\). The non-monotonicity, however, is more than a subtlety. Their proof hinges on the fact that \((x−1)^2 + 2^{-2^{n+1}}\) can be written as \(f/g\) with \(f, g\) monotone, whereas they require degrees \(2^2n\).

This question can be phrased more generally. If \(f\) can be computed by a monotone circuit with divisions of size \(s\) then we can find non-zero \(h\) and \(g\) with monotone circuit size \(O(s)\) such that \(fh = g\). In other words, \(f\) divides \(g\).

**Problem 2.** Find an explicit monotone \(f_n\) (with polynomially many variables and of a polynomial degree) such that \(g\) requires superpolynomial monotone circuit whenever \(g \neq 0\) and \(f_n\) divides \(g\).

A seminal result of Kaltofen [25], see also [5], states the following: if \(f\) of degree \(d\) can be computed by a circuit of size \(s\), we can compute each factor of \(f\) by a (non-monotone) circuit of size polynomial in \(s\) and \(d\). We believe that in fact \(d\) can be replaced by the degree of the factor. This means that in the non-monotone setting, Problem 2 is equivalent to proving lower bound on \(f_n\).

Shadow complexity gives a partial solution to Problem 2.

**Theorem 42.** Let \(f\) be a (not necessarily monotone) real polynomial such that \(\sigma(\text{Newt}(f)) = k\). Assume that \(g \neq 0\) is a monotone polynomial such that \(f\) divides \(g\). Then every monotone formula computing \(g\) contains at least \(k\) leaves.

**Proof.** Lemma 12 gives \(\sigma(\text{Newt}(g)) \geq \sigma(\text{Newt}(f))\), and we can apply Theorem 1. \(\blacklozenge\)

Shadow complexity also provides lower bounds on monotone circuit complexity provided the degree is not too large. This is another partial solution to Problem 2.

**Proposition 43.** Let \(f\) be either \(\text{Clique}_n\) or \(\text{Art}_n\). Let \(g \neq 0\) be a monotone polynomial such that \(f\) divides \(g\).

1. \(g\) requires monotone formula with \(2^n\) leaves.
2. If \(g\) has degree \(d \leq 2^{o(n^{1/2})}\), then \(g\) requires monotone circuit of size \(2^\Omega(n^{1/2})\).
3. If \(g = \alpha f\) with \(\alpha\) a monomial of an arbitrary degree, then \(g\) requires monotone arithmetic circuit of size \(\Omega(2^n)\).

**Proof.** 1 follows from Theorem 42 and the fact that \(f\) is transparent (see Proposition 19 and Remark 20). Similarly, \(\text{Newt}(\alpha f)\) is merely a shift of \(\text{Newt}(f)\) and hence it remains transparent, which gives 3.

For 2 we use a result of Hyafil [22]: If \(g\) has a monotone circuit of size \(s\), then it has a monotone formula of size \(2^{O(\log s \log d + \log^2 d)}\). Part 1 completes the proof. \(\blacklozenge\)

The degree assumption in 2 is rather artificial. A monotone circuit with divisions can result in \(g\) with an exponential degree, as is the case in the circuit from [14] computing the spanning tree polynomial. Nevertheless, this yields lower bounds at least for monotone formulas with division.

\(^5\) This holds for polynomials of low degree; the spanning tree polynomial indeed has this property.
Theorem 44. The polynomials $\text{Clique}_n$ and $\text{Art}_n$ require monotone formula with division of size $2^{\Omega(n)}$.

Proof. Brent’s [4] argument that formulas with division can be balanced implies that if $f$ has monotone formula with divisions of size $s$, then $f = g/h$ where both $g$ and $h$ have monotone formulas of size polynomial in $s$. Proposition 43 part 1 completes the proof.

Remark 45. Transparency is fragile. If $f$ is transparent then $f^2$ is not necessarily so. In fact, if $f$ is monotone then $f^2$ is never transparent unless $|\text{supp}(f)| \leq 1$. Hence, the techniques from Proposition 43 do not give anything when $g = f^m$ and $m$ is exponentially large.

Remark 46. A different partial solution to Problem 2 can be inferred from monotone Boolean lower bounds. Let $\text{Clique}_{k,n}$ be the polynomial $\sum A \prod_{i,j \in A} x_{i,j}$, where $A$ ranges over $k$-element subsets of $[n]$. For $k := \lceil (n/\log n)^{2/3} / 4 \rceil$, and for every $m$, the polynomial $(\text{Clique}_{k,n})^m$ requires a monotone arithmetic circuit of size $2^{n\Omega(1)}$.

Indeed, a monotone arithmetic can be interpreted as a monotone Boolean circuit (cf. Section 5.1). Hence, a monotone arithmetic circuit for $(\text{Clique}_{k,n})^m$ translates to a monotone Boolean circuit deciding whether a graph has a $k$-clique. This requires an exponential circuit by a result of Alon and Boppana [1].

7 \tau-Conjecture for Newton polygons

Koiran et al. made the following conjecture [30].

Conjecture 47 ([30]). Let $F$ be a field. Let $f \in F[x_1, x_2]$ be a bivariate polynomial which can be written as

$$f = \sum_{i=1}^{p} \prod_{j=1}^{q} f_{i,j}, \text{ where } |\text{supp}(f_{i,j})| \leq r,$$

then $\text{Newt}(f)$ has at most $O((pqr)^c)$ vertices (for some absolute constant $c$).

The authors of [30] have shown that Conjecture 47 implies VP$\neq$VNP over the field in question. The conjecture is related to a similar conjecture by Koiran from [28] about the number of real roots of univariate polynomials. In [21], it was shown that the conjecture from [28] in fact implies Conjecture 47. Theorem 33 validates the conjecture in the monotone setting:

Remark 48. Let $f$ be as in (7) with $f_{i,j}$ monotone. Then $\text{Newt}(f)$ has at most $pqr$ vertices.

The conjecture can be used to upper-bound the shadow complexity.

Proposition 49. Let $F$ be an infinite field. Assume Conjecture 47 holds over $F$. Assume that a polynomial $f$ of degree $d$ has an arithmetic circuit of size $s$. Then $\sigma(\text{Newt}(f)) \leq s^{O(\sqrt{d} \log d)}$.

Proof. First, observe that if Conjecture 47 is true, it is also true when $f$ and $f_{i,j}$ in (7) are allowed to be Laurent polynomials.

Now, if $f$ has a circuit of size $s$, then $f$ has a depth-four circuit of size $s^{O(\sqrt{d} \log d)}$; see [29] and references within. This means that we can write

$$f = \sum_{i=1}^{p} \prod_{j=1}^{q} f_{i,j}, \text{ where } |\text{supp}(f_{i,j})| \leq r,$$

with $pqr \leq s^{O(\sqrt{d} \log d)}$. 
Suppose that $\sigma(\text{Newt}(f)) = k$. By Lemma 28, there is a h.p.-projection $\pi$ so that the Newton polytope of the bivariate Laurent polynomial $\pi(f)$ has $k$ vertices. Hence $\sigma(f) = \sum_{i=1}^{\dim \pi} \prod_{j=1}^{\dim \pi} \pi(f_{i,j})$. Since $|\text{supp}(\pi(f_{i,j}))| \leq r$, Conjecture 47 implies $k \leq O((pqr)^r)$ and hence $k \leq s^{O(\sqrt{d \log d})}$.

This gives quantitative bounds for some specific polytopes, mainly the Birkhoff polytope and the Matching polytope from Remark 26:

\begin{itemize}
  \item [*Corollary 50.] Assume that Conjecture 47 holds over some infinite field. Then both $\sigma(\text{DS}_n)$ and $\sigma(\text{MATCH}_n)$ are at most $2^{O(\sqrt{\log n})}$.
\end{itemize}

\begin{proof}
$\text{DS}_n$ is the Newton polytope of the determinant polynomial which has an arithmetic circuit of size $s = n^{O(1)}$. For $\text{MATCH}_n$, the same holds by Remark 36.
\end{proof}

We do not know whether these conclusions hold or not. Another implication of Conjecture 47 is that $\sigma(Q_{k,n}) \leq n^{O(1)}$, where $Q_{k,n}$ is the convex hull of vectors in $\{0,1\}^n$ of Hamming weight $k$. It follows from Proposition 15 that this is actually true: $\sigma(Q_{k,n}) \leq n^2$.

\begin{itemize}
  \item [*Remark 51.] Results of Gritzman and Sturmfels [19] (cf. Section 1.1) imply the following monotone three-dimensional version. Let $f$ be as in (7), where $f_{ij} \in \mathbb{R}[x_1,x_2,x_3]$ are monotone. Then $\text{Newt}(f) \subseteq \mathbb{R}^3$ has at most $O(p^{r+2})$ vertices.
\end{itemize}

### 8 An easy polynomial with many vertices

Here we construct a bivariate polynomial with a monotone arithmetic circuit of linear size, but whose Newton polytope has exponentially many vertices. This proves Theorem 30.

We use the following notation. Given $(a, b) \in \mathbb{R}^2$,

$$(a, b) \cdot P := \{(ax, by) : (x, y) \in P\}.$$ 

Given $a \in \mathbb{R}$,

$$aP := (a, a) \cdot P.$$ 

\begin{itemize}
  \item [*Observation 52.] For a bivariate polynomial $f(x, y)$,
    $$\text{Newt}(f(x^a, y^b)) = (a, b) \cdot \text{Newt}(f(x, y)) \text{ and } \text{Newt}(f^a) = a \cdot \text{Newt}(f).$$
\end{itemize}

The building block of the polynomial are the following two polytopes. Let $P_n$ be the polytope with vertices $\{(k, k^2) : 0 \leq k \leq n - 1\}$. Let $Q_n$ be the polytope with vertices $\{(k, k^2 + k) : 0 \leq k \leq n - 1\}$. These polytopes can be constructed inductively as follows.

\begin{itemize}
  \item [*Lemma 53.] For every $n \geq 1$,
    \begin{align*}
    P_{2n} &= \{2, 4\} \cdot P_n \cup \{(1, 1) + (2, 4) \cdot Q_n\} \\
    Q_{2n} &= (1, 2) \cdot (P_n + Q_n) \cup \{(2n - 1, 2n(2n - 1))\}.
    \end{align*}
\end{itemize}

\begin{proof}
Part (8). Let $0 \leq k \leq 2n - 1$. If $k = 2r$ is even then $r \leq n - 1$ and

$$(k, k^2) = (2, 4)(r, r^2)$$ 

with $(r, r^2)$ a vertex of $P_n$. If $k = 2r + 1$ is odd then $r \leq n - 1$ and

$$(k, k^2) = (2r + 1, 4r^2 + 4r + 1) = (1, 1) + (2, 4) \cdot (r, r^2 + r),$$ 

\end{proof}
where \((r, r^2 + r)\) is a vertex of \(Q_n\). This shows the containment \(\subseteq\) in (8). The other direction holds since \(P_n \cup Q_n\) can have at most \(2n\) vertices.

Part (9). We first describe the vertices of \((1, 2)(P_n + Q_n)\). We claim that
\[
\text{vert}((1, 2)(P_n + Q_n)) = \{v_0, v_1, \ldots, v_{2n-2}, u\},
\]
where \(v_k := (k, k^2 + k), u := (n - 1, 2n(n - 1))\).

Given \(0 \leq k \leq 2n - 2\), let us show that \(v_k\) is a vertex of \((1, 2)(P_n + Q_n)\). If \(k = 2r\) is even, we have \(r \leq n - 1\) and
\[(k, k^2 + k) = (2r, 4r^2 + 2r) = (1, 2)(r, r^2) + (1, 2)(r, r^2 + r).
\]
If \(k = 2r + 1\) is odd, we have \(r \leq n - 2\) and
\[(k, k^2 + k) = (2r + 1, 4r^2 + 6r + 2) = (1, 2)(r + 1, (r + 1)^2) + (1, 2)(r, r^2 + r).
\]
This means that \(v_k \in (1, 2)(P_n + Q_n)\). Now, every \((z_1, z_2) \in (1, 2)(P_n + Q_n)\) satisfies
\[z_2 \geq z_1^2 + z_1,\]
because
\[2r_1^2 + 2(r_2^2 + r_2) - (r_1 + r_2)^2 - (r_1 + r_2) = (r_1 - r_2)^2 - (r_1 - r_2) \geq 0.\]
Since \(v_k\) lies on the curve \(z_2 = z_1^2 + z_1\), and the curve is strictly convex, \(v_k\) cannot be convex combination of other points in \((1, 2)(P_n + Q_n)\). So, \(v_k\) is indeed a vertex. To show that \(u\) is a vertex, note that both \((1, 2)P_n\) and \((1, 2)Q_n\) are contained in the halfplane \(\{(z_1, z_2) \in \mathbb{R}^2 : z_2 \leq 2n z_1\}\). On the boundary \(z_2 = 2n z_1\), \((1, 2)Q_n\) has vertices \((0, 0)\) and \(u\), and \((1, 2)P_n\) only the vertex \((0, 0)\). This implies \(u\) is a vertex of \((1, 2)(P_n + Q_n)\). This proves the containment \(\subseteq\) in (10). Equality holds since \(P_n + Q_n\) can have at most \(2n\) vertices.

To infer (9) from (10), note that \(u\) lies on the line connecting the origin and \(v_{2n-1} = (2n - 1, 2n(2n - 1))\).

**Proof of Theorem 30.** Inductively define a sequence of bivariate polynomials. The base case is
\[p_0 = 1\] and \(q_0 = 1\).

The inductive step is
\[p_{n+1} = p_n(x^2, y^4)^2 + x^N y^N q_n(x^2, y^4)^2\]
and
\[q_{n+1} = p_n(x^2, y^4)q_n(x^2, y^4) + x^{N(N-1)} y^{N^2(N-1)}\]
where \(N = 2^{n+1}\).

We claim that for every \(n \geq 0\),
\[\text{Newt}(p_n) = 2^n P_{2^n} \text{ and } \text{Newt}(q_n) = 2^n Q_{2^n} .\]

For \(n = 0\), this follows from \(\text{Newt}(p_0) = \text{Newt}(q_0) = \{(0, 0)\} = P_1 = Q_1\). The induction step uses Lemma 11 and Observation 52. Assume that (11) holds for a given \(n \geq 0\). Then
\[\text{Newt}(p_n(x^2, y^4)) = 2^n (2, 4) P_{2^n} \text{ and } \text{Newt}(q_n(x^2, y^4)) = 2^n (2, 4) Q_{2^n} .\]
Using (8),
\[
\text{Newt}(p_{n+1}) = 2 \cdot 2^n (2, 4) P_{2^n} \sqcup ((N, N) + 2 \cdot 2^n (2, 4) Q_{2^n})
\]
\[
= 2^{n+1} ((2, 4) P_{2^n} \sqcup ((1, 1) + (2, 4) Q_{2^n}))
\]
\[
= 2^{n+1} P_{2^{n+1}}.
\]
Similarly, part (9) gives
\[
\text{Newt}(q_{n+1}) = 2^n (2, 4) (P_{2^n} + Q_{2^n}) \sqcup \{(N(N - 1), N^2(N - 1))\}
\]
\[
= 2^{n+1} ((1, 2) (P_{2^n} + Q_{2^n}) \sqcup \{(N - 1, N(N - 1))\})
\]
\[
= 2^{n+1} Q_{2^{n+1}}.
\]
This proves (11).

To compute \(p_n, q_n\), first construct a circuit of size \(O(n)\) that simultaneously computes
\(x^M, x^{M(M-1)}, y^M, y^{M(M-1)}\) for every \(M = 2^m\) with \(m \leq n\). Now, construct a circuit for
\(p_n\) and \(q_n\) inductively. Given a circuit for \(p_n\) and \(q_n\), we can construct a new one computing
\(p_{n+1}, q_{n+1}\) by introducing a constant number of extra gates.

9 Open problems

We conclude with the main open problems of this paper.

- **Open Problem 1.** Is \(\sigma(\text{DS}_n)\) or \(\sigma(\text{MATCH}_n)\) exponential in \(n\)?

- **Open Problem 2.** Is Conjecture 47 true? If not, is it true when \(f\) in (7) is required to
  have convexly independent support?

- **Open Problem 3.** Find an explicit monotone \(f_n\) (with polynomially many variables and
  of a polynomial degree) such that \(g\) requires superpolynomial monotone arithmetic circuit
  whenever \(g \neq 0\) and \(f_n\) divides \(g\).

Abstract

We prove new results on the polarizing random walk framework introduced in recent works of Chattopadhyay et al. [4, 6] that exploit $L_1$ Fourier tail bounds for classes of Boolean functions to construct pseudorandom generators (PRGs). We show that given a bound on the $k$-th level of the Fourier spectrum, one can construct a PRG with a seed length whose quality scales with $k$. This interpolates previous works, which either require Fourier bounds on all levels [4], or have polynomial dependence on the error parameter in the seed length [6], and thus answers an open question in [6]. As an example, we show that for polynomial error, Fourier bounds on the first $O(\log n)$ levels is sufficient to recover the seed length in [4], which requires bounds on the entire tail.

We obtain our results by an alternate analysis of fractional PRGs using Taylor’s theorem and bounding the degree-$k$ Lagrange remainder term using multilinearity and random restrictions. Interestingly, our analysis relies only on the level-$k$ unsigned Fourier sum, which is potentially a much smaller quantity than the $L_1$ notion in previous works. By generalizing a connection established in [5], we give a new reduction from constructing PRGs to proving correlation bounds. Finally, using these improvements we show how to obtain a PRG for $\mathbb{F}_2$ polynomials with seed length close to the state-of-the-art construction due to Viola [26].

1 Introduction

A central pursuit in complexity theory is to understand the need of randomness in efficient computation. Indeed there are important conjectures (such as $P = BPP$) in complexity theory which state that one can completely remove the use of randomness without losing much in efficiency. While we are quite far from proving such results, a rich line of work has focused on derandomizing simpler models of computation (see [25] for a survey of prior work on derandomization). A key tool for proving such derandomization results is through the notion of a pseudorandom generator defined as follows.

**Definition 1.** Let $F$ be a class of $n$-variate Boolean functions. A pseudorandom generator (PRG) for $F$ with error $\varepsilon > 0$ is a random variable $X \in \{-1, 1\}^n$ such that for all $f \in F$,

$$|E_X[f(X)] - E_{U_n}[f(U_n)]| \leq \varepsilon,$$

where $U_n$ is the uniform distribution on $\{-1, 1\}^n$. We also say that $X$ fools $F$ with error $\varepsilon$. If $X = G(U_s)$ for some explicit function $G : \{-1, 1\}^s \to \{-1, 1\}^n$, then $X$ has seed length $s$.

There is a long line of research on explicit constructions of PRGs for various classes of Boolean functions in the literature and it is well beyond our scope to survey prior work here. We focus on a recent line of works initiated by Chattopadhyay et al. [4, 6] that provide a framework for constructing pseudorandom generators for any Boolean function classes that exhibit Fourier tail bounds (we will define and discuss this in more details in the next subsection; see Section 2.1 for a brief introduction to Fourier analysis of Boolean functions). This provides a unified PRG for several well-studied function classes such as small-depth circuits, low-sensitivity functions, and read-once branching programs that exhibit such Fourier tails.

We now briefly discuss this new framework, and then in Section 1.2 we present our new results, which significantly generalize this approach.

1.1 The Polarizing Random Walk Framework

The polarizing random walk framework was introduced by Chattopadhyay, Hatami, Hosseini, and Lovett [4]. The authors showed that for any class of $n$-variate Boolean functions that is closed under restrictions, one can flexibly construct pseudorandom generators via the following local-to-global principle: it suffices to construct fractional pseudorandom generators (fractional PRGs), a notion that generalizes PRGs to allow the random variable $X$ (in Definition 1) to be supported on the solid cube $[-1, 1]^n$ instead of $\{-1, 1\}^n$, while still requiring that $X$ fools (the multilinear extension) of each Boolean function in the class. Ideally, the variance of each coordinate of $X$ should be as large as possible. Towards this, we define a fractional PRG $X$ to be $p$-noticeable if the variance in each of its coordinates is least $p$ (See Definition 13 for a formal definition of a fractional PRG).

To obtain a genuine pseudorandom generator from a fractional PRG, the authors give a random walk gadget that composes together independent copies of the fractional PRG in a random walk that polarizes $X$ quickly to take values from the Boolean hypercube $\{-1, 1\}^n$. The analysis for how the error accumulates in this process relies on interpreting the intermediate points of $X$ in this random walk as an average of random restrictions of the original Boolean function. As the fractional PRG locally fools the class by definition, this analysis shows that the random walk does not incur much additional error at each intermediate step and the rapid polarization shows that it does not take too many steps. Taken together, these two facts imply that the final random variable (supported on $\{-1, 1\}^n$) successfully fools the class.
Through this construction, the design of pseudorandom generators reduces to the easier task of designing fractional pseudorandom generators. It is easier as such random variables need not be Boolean-valued. The authors further construct such fractional pseudorandom generators for any class of functions satisfying Fourier tail bounds, that is, every function in the class is such that the $L_1$ Fourier mass at each level $1 \leq k \leq n$ is at most $b^k$ for some fixed $b \geq 1$. For error $\varepsilon$, their fractional pseudorandom generators have seed length $O(\log \log n + \log(1/\varepsilon))$ and variance $\Theta(b^{-2})$ in each coordinate. Combining this fractional pseudorandom generator with their random walk gadget yields a pseudorandom generator with seed length $b^2 \cdot \text{polylog}(n/\varepsilon)$ for any class with such Fourier tail bounds.

As a result, if one can show that a function class admits nontrivial Fourier tail bounds (and is closed under restriction), then the construction in [4] immediately implies a pseudorandom generator for this class. Some examples of Boolean functions that exhibit such tail bounds include AC$^0$ circuits with the parameter $b = \text{poly}(\log n)$ [13, 23], constant width read-once branching programs with $b = \text{poly}(\log n)$ [7], $s$-sensitive functions with $b = O(s)$ [11, 10], and product tests [12]. Using these tail bounds, [4] immediately gave PRGs for these function classes. It was also conjectured in [4] that the class of $n$-variate degree-$d$ polynomials over $\mathbb{F}_2$ satisfy such tail bounds. We discuss this in more detail in Section 1.2.

A natural question is whether the complete control on the entire Fourier tail of a class is necessary to obtain a PRG in this framework. In the subsequent work by Chattopadhyay, Hatami, Lovett, and Tal [6], the authors show how to construct fractional pseudorandom generators using different pseudorandom primitives whose seed length depends on just the second Fourier level of the class. They construct their fractional PRGs by derandomizing the celebrated work of Raz and Tal [18], which establishes an oracle separation of BQP and PH. Raz and Tal show that classes of multilinear functions with small level-two Fourier mass cannot significantly distinguish between a suitable variant of the Forrelation distribution and the uniform distribution. However, this construction incurs exponentially worse dependence on the error parameter in each fractional step to sample sufficiently good approximations to Gaussian random variables. The final seed length given by this construction has the form $O((b^2/\varepsilon)^2 + \text{polylog}(n))$, where $b^2$ is the level-two Fourier mass of the class. This yields exponentially worse dependence on the error compared to the generator of [4], as well as quadratically worse dependence on the level-two mass (though without assumptions on the rest of the Fourier levels).

### 1.2 Our Contribution

In this paper, we address several open questions in this framework by leveraging a novel connection between polarizing random walk and the classical theory of polynomial approximation. Given these prior works, a very natural question (also explicitly asked in [6]) is whether it is possible to interpolate between these previous constructions by assuming Fourier bounds on an intermediate level. Concretely, can this framework still succeed if one has Fourier control at just level $k$? If the class further has such Fourier bounds up to and including level $k$, can one interpolate between the seed lengths of [4] and [6]? Given Fourier bounds from level 1 up to level $k$, what range of error $\varepsilon > 0$ can the resulting PRG tolerate while maintaining polylogarithmic dependence on $1/\varepsilon$ in the seed length (or equivalently, given a desired error $\varepsilon > 0$, how many levels of Fourier bounds are sufficient to ensure that the seed length remains polylogarithmic in $1/\varepsilon$)?

---

1 It turns out that this fact can be interpreted via Itô’s Lemma, which shows that the local behavior of a smooth function of Brownian motion is essentially determined by the first two derivatives [28].
Moreover, it was previously not known whether $L_1$ control of Fourier tails is really necessary for this framework to yield effective PRGs, or whether weaker Fourier quantities would suffice. To this end, define

$$L_{1,k}(f) \triangleq \sum_{S \subseteq \llbracket n \rrbracket : |S| = k} |\hat{f}(S)|$$

to be the level-$k$ $L_1$ Fourier mass of $f$, and

$$M_k(f) \triangleq \max_{x \in \{-1,1\}^n} \left| \sum_{S \subseteq \llbracket n \rrbracket : |S| = k} \hat{f}(S)x^S \right| = \max_{x \in \{-1,1\}^n} \left| \sum_{S \subseteq \llbracket n \rrbracket : |S| = k} \hat{f}(S)x^S \right|.$$ 

to be the level-$k$ absolute Fourier sum of $f$. For a function class $\mathcal{F}$, we define $L_{1,k}(\mathcal{F})$ and $M_k(\mathcal{F})$ as the maximum of $L_{1,k}(f)$ and $M_k(f)$ taken over $f \in \mathcal{F}$. The recent work by Chattopadhyay, Hatami, Hosseini, Lovett, and Zuckerman [5] considers the weaker quantity of the level-two unsigned Fourier sum, defined as the absolute value of the sum of the Fourier coefficients rather than the sum of their absolute values that is considered in [4, 6]. The authors show that the problem of bounding the level-two unsigned Fourier sum corresponds to the problem of bounding the covariance of the function class and the XOR of shifted majority functions. For a class that is closed under negations of the variables, the level-two unsigned Fourier sum is precisely the quantity $M_2(\mathcal{F})$. In particular, using this connection to this weaker object, the authors explicitly ask whether bounding the weaker Fourier quantity $M_2(\mathcal{F})$ (or more generally, $M_k(\mathcal{F})$) yields pseudorandom generators.

In this work, we positively resolve all of these questions. To do so, we establish novel connections between the polarizing random walk framework and the classical theory of polynomial approximations of Boolean functions. We show that the seed length of a fractional PRG for a given class of functions $\mathcal{F}$ is intimately connected to the uniform error of low-degree approximations of functions on subcubes of the form $[-c, c]^n$ for some $c < 1$.

Our main technical result provides an upper bound on this quantity in terms of $M_k(\mathcal{F})$ for every function $f$ in a class $\mathcal{F}$ that is closed under restrictions. For any multilinear polynomial $f : \{-1,1\}^n \to \mathbb{R}$, define $f_{\geq k}$ to be component of $f$ with monomials of degree at least $k$. Then our main result asserts the following bound:

**Theorem 2.** Let $f \in \mathcal{F}$ with $\mathcal{F}$ closed under restrictions. Then for all $c \in (0, 1)$, we have

$$\max_{x \in [-c, c]^n} |f_{\geq k}(x)| \leq \left( \frac{c}{1 - c} \right)^k M_k(\mathcal{F}).$$

For intuition, recall that by Parseval’s identity in Fourier analysis the low-degree Fourier expansion of any Boolean function $f$ is provably the best $\ell_2$-approximator on $\{-1,1\}^n$. Conversely, from elementary analysis, one can show that the best uniform (i.e. $\ell_\infty$) low-degree approximators of $f$ converge, coefficient-by-coefficient, to the low-degree expansion of $f$ as the domain converges to 0. Our main result shows that one can strongly quantify the $\ell_\infty$ error of the low-degree approximator of Boolean functions on subcubes so long as $c$ is not too close to 1 (compare this bound to when $f$ has degree exactly $k$).

We complement this result with a corresponding lower bound on the best attainable uniform error for any low-degree approximation on these subcubes that will be comparable for sufficiently small values of $c$ (see Theorem 23). These results combined together imply that the low-order expansion of a Boolean function is a reasonable uniform approximation for small domains. Note that the properties of low-degree approximations on subcubes with $c \ll 1$ can be quite different than for $c = 1$; for instance the PARITY function on $n$ bits is well-known to be inapproximable on $\{-1,1\}^n$ to constant error unless the approximating polynomial has degree $\Omega(n)$, but is trivially approximable for any $c$ bounded away from 1.
From this main result, we can positively resolve the above open questions in the polarizing random walk framework as a nearly immediate corollary. To do so, we provide a new analysis of the fractional pseudorandom generator of [4] that views fractional pseudorandom generators as fooling a low-degree part of a function on \([-c, 1]^n\) for some \(c < 1\), where the high-degree part has small \(\ell_\infty\) norm on \([-c, 1]^n\). Recall that the seed length of the final generator depends on the variance of the constituent fractional generator; the connection to the above result is that for a given error \(\varepsilon\), the largest subcube on which the above approximation holds can be lower-bounded using just the weaker \(M_k(F)\) quantity. Leveraging this insight, our main result in the polarizing random walk framework is the following analysis of a fractional pseudorandom generator:

**Theorem 3.** Let \(F\) be any class of \(n\)-variate Boolean functions that is closed under restrictions. Suppose \(M_k(F) \leq b^k\) for some \(b \geq 1\) and \(k \geq 1\). Then for any \(\varepsilon > 0\), there exists an explicit \(\Omega(\varepsilon^{2k}/b^k)\)-noticeable fractional PRG for \(F\) with error \(\varepsilon\) and seed length \(O(k \cdot \log n)\).

Further, if it holds that \(L_{1, i}(F) \leq b^i\) for all \(1 \leq i < k\), then the seed length can be improved to \(O(\log \log n + \log k + (1/\varepsilon))\).

Using the fractional pseudorandom generator from Theorem 3, we obtain the following consequences almost immediately from the random walk gadget of [4] (see Theorem 14):

1. **Pseudorandom Generators from Fourier Bounds at Level \(k\):** From our fractional pseudorandom generator, we show that the random walk framework yields nontrivial pseudorandom generators assuming Fourier bounds just at level \(k\) of the associated class, with improvements if we assume bounds from level 1 up to level \(k\). The informal statement is the following:

   **Theorem 4.** Let \(F\) be any class of \(n\)-variate Boolean functions that is closed under restrictions. Suppose that \(F\) satisfies \(M_k(F) \leq b^k\) for some \(b \geq 1\) and \(k \geq 3\). Then there exists an explicit pseudorandom generator for \(F\) for error \(\varepsilon\) with seed length \(k \cdot b^{2+4/(k-2)} \cdot \polylog(n/\varepsilon)/\varepsilon^{2/(k-2)}\). The seed length can be improved if \(L_{1, i}(F) \leq b^i\) for all levels \(i \leq k\).

   See Theorem 27 for the precise statement. One immediate consequence is that if one has a non-trivial bound on \(M_3(F)\), then the seed length of our PRG has the same dependence on the error \(\varepsilon\) as the one in [6]. Further, given \(M_2(F) \leq b^2\), one obtains better seed length than [6]; in particular it has quadratically better dependence on \(1/\varepsilon\) in the seed length (as well as polylogarithmic factors in \(n/\varepsilon\)). More generally, given an appropriate Fourier bound of \(b^k\) on just some level \(k \leq \polylog(n)\), one obtains a pseudorandom generator with error \(\varepsilon\) with seed length \(O(b^{2+4/(k-2)} \cdot \polylog(n/\varepsilon)/\varepsilon^{2/(k-2)})\).

We note that the fractional PRG from Theorem 3 cannot be converted into a PRG for \(k = 1, 2\). Informally, this is because of the following reason: the number of steps one needs to take in the random walk gadget of [4] (with each step using an independent copy of the fractional PRG) scales roughly with the variance of the fractional PRG, and the error adds up in each step. As is clear from Theorem 3, for the variance of the fractional PRG to scale sublinearly with the error, one requires \(k > 2\). See Remark 28 for more discussion.

---

\(^2\) We remark that at this level of generality, this linear dependence on \(k\) is essentially necessary. Indeed, any Boolean function on \(n\)-variables has \(L_{1, 1}\) level-\(n\) mass at most 1, but one cannot hope to generically fool all Boolean functions simultaneously without using \(n\) bits.
2. Pseudorandom Generators with Polylogarithmic Error Dependence from Up-to-level-k Bounds: A simple corollary of our fractional pseudorandom generator is that one can recover the polylogarithmic dependence on $1/\varepsilon$ from [4] if $\varepsilon \geq b \cdot \log n \cdot 2^{-O(k)}$ and we have Fourier bounds up to level $k$.

▶ Corollary 5. Let $\mathcal{F}$ be any class of $n$-variate Boolean functions that is closed under restrictions. Suppose that for some level $k \geq 3$ and $b \geq 1$, we have $M_k(\mathcal{F}) \leq b^k$ and $L_{1,i}(\mathcal{F}) \leq b^i$ for $i < k$. Then, for any $\varepsilon \geq b \cdot \log n \cdot 2^{-O(k)}$, there exists an explicit pseudorandom generator for $\mathcal{F}$ with error $\varepsilon$ and seed length $O(b^2 \log(n/\varepsilon))$.

This actually subsumes the analysis of [4] without requiring anything on the full Fourier tail, and addresses an open question of [6] asking how many levels of Fourier bounds one needs control of to regain polylogarithmic dependence on $\varepsilon$. In particular, if one requires error $\varepsilon = 1/\text{poly}(n)$, then it suffices to have Fourier bounds up to level $\Theta(\log n)$ to get the same dependence.

We view this work as a proof of concept that it is indeed possible to interpolate between the two extremes of [4, 6] in the polarizing random walk framework and obtain better results using weakened Fourier assumptions. We prove Theorem 3 in Section 4, from which Theorem 4 and Corollary 5 follow without much difficulty using the existing random walk gadget of [4].

Note that for some Boolean classes of great interest such as the class of low-degree $\mathbb{F}_2$-polynomials, Fourier tail bounds as required by [4] are not yet known and thus Theorem 3 allows us to leverage potentially much weaker bounds proved in [4] to construct a PRG with polylogarithmic dependence on $n/\varepsilon$ in the seed length (see Theorem 6). This almost matches the best known PRG due to Viola [26]. In particular, we show the following:

▶ Theorem 6. Let $\mathcal{F}$ be the class of degree-$d$ polynomials over $\mathbb{F}_2$ on $n$ variables. Then there exists an explicit pseudorandom generator for $\mathcal{F}$ with error $\varepsilon$ and seed length $2^{O(d)} \cdot \text{polylog}(n/\varepsilon)$.

We present the proof of Theorem 6 in Section 5. While this result does not quite match the current state-of-the-art PRG for this class due to Viola [26] (and therefore fails to give anything nontrivial for $d = \Omega(\log n)$), we view this as a conceptual contribution that the random walk framework can yield an explicit pseudorandom generator with seed length that is polylogarithmic in $n/\varepsilon$, which was not known from previous works [4, 6]. As we discuss below, the results in [4, 6] do not give a PRG for the class of $\mathbb{F}_2$-polynomials with polylogarithmic error dependence using known Fourier tail bounds.

As a concrete application of this approach which would dramatically improve the state-of-the-art PRGs for $\mathbb{F}_2$-polynomials, both [4] and [6] conjecture Fourier bounds on the $L_1$ mass of the class of degree-$d$ $\mathbb{F}_2$ polynomials. The former conjectures that this class satisfies a tail bound of the form $c_d^k$ for some constant $c_d$ at all levels $1 \leq k \leq n$ (so as to apply their approach), while the latter conjectures just that the level-two $L_1$ mass is $O(d^2)$. While neither conjecture seems close to being resolved, our work shows that one can instead prove bounds for the smaller quantities $M_k(\mathcal{F})$ for any $k \geq 3$. If one could prove such bounds of the form $(\text{poly}(d, \log n))^k$ for some level $k = \Omega(1)$, or even more optimistically, for some $k = \Omega(\log(n))$, this would immediately imply a breakthrough pseudorandom generator for $\text{AC}^0[\mathbb{F}_2]$ using the results of Razborov [19] and Smolensky [21, 22] (see the discussion in [6]).

To our knowledge, our application of $M_k(\mathcal{F})$ bounds is new to the pseudorandomness literature. There are several advantages to proving $M_k(\mathcal{F})$ bounds over $L_{1,k}(\mathcal{F})$ bounds. For one, from the definition we clearly have $M_k(\mathcal{F}) \leq L_{1,k}(\mathcal{F})$ for any class $\mathcal{F}$. This improvement alone potentially gives smaller seed length for any class. From an analytical perspective, we believe that the quantity $M_k(\mathcal{F})$ is easier to estimate. Specifically, for a class $\mathcal{F}$ that is closed under negation of input variables, $M_k(\mathcal{F})$ is precisely an unsigned Fourier sum and...
can be bounded via the recent connections established by Chattopadhyay et al. [5], which reduces $M_2(F)$ bounds to proving correlation bounds against certain resilient functions. We straightforwardly generalize their reduction to $M_k(F)$ bounds in Section 6.

1.3 Overview of Our Approach

To prove Theorem 2, we rely on Taylor’s theorem, as well as multilinearity and the random restriction trick of [4]. Recall that Taylor’s theorem, when applied to a sufficiently smooth function $h : [-1,1] \to \mathbb{R}$, asserts that the Taylor expansion at 0 can be expressed in terms of its first $(k-1)$-th order derivatives at 0 along with a Lagrange error term that depends on its $k$-th order derivatives at some intermediate point in our domain. In doing so, the higher-order components of the function “collapse” down to the $k$-th order term. While Taylor’s theorem has been extensively applied in the construction of pseudorandom generators, often in tandem with invariance principles, we somewhat counterintuitively apply it to the multilinear expansion of the Boolean functions themselves.

To apply Taylor’s theorem here, we consider one-dimensional restrictions of (the multilinear extension) of a Boolean function $f : \{-1,1\}^n \to \{-1,1\}$. While the full Taylor expansion of a polynomial is trivially the same polynomial, the Lagrange error term eliminates the dependence on the high order Fourier coefficients (corresponding to the terms of degree $> k$). Moreover, the low-order terms of the Taylor expansion of $f$ at 0 are precisely the original low-degree part of its Fourier expansion. However, the Lagrange error term requires the derivatives to be evaluated at a point away from 0. While the derivatives of $f$ at a nonzero point are related to the biased Fourier coefficients of $f$, it is not clear how to estimate these quantities. To overcome this difficulty, recall that we are interested in bounds on $|f_{\geq k}(x)|$ for $x \in \{-c,c\}^n$ where $c < 1$. In Lemma 22, we show that by “recentering” $x$ using the random restriction technique of [4], we can write the error term as an average of the $k$-th order derivatives at 0 of some random restrictions of our original function $f$, up to a multiplicative factor depending on $c$.

We can then apply multilinearity to bound these error terms using $M_k(F)$ to obtain Theorem 17.

While Theorem 17 shows that the low-order Taylor expansion of a Boolean function is a decent uniform approximator on subcubes $[-c,c]^n$ for some sufficiently small $c$ that depends on the class $F$, it is natural to wonder if one can obtain a better low-order approximation. Using our upper bound along with Chebyshev polynomials on the univariate restrictions, we give a lower bound showing that no low-order approximator can give significantly smaller error over $[-c,c]^n$ for any $c$ less than some quantity depending on the ratio $M_k(F)/M_{k+1}(F)$ for some $k$. This quantifies the intuition that the low-degree Fourier expansion is a near optimal uniform approximator of $f$ over small enough neighborhoods of 0. These arguments are formally carried out in Section 3.

To prove our results in the polarizing random walk framework, we rely on an alternate, simple analysis of fractional pseudorandom generators. The original analysis in [4] assumes control of $L_{1,k}(F)$ at all levels of the Fourier spectrum. We now explain how these assumptions can be weakened using Theorem 17. Consider a candidate fractional PRG $X \in [-1,1]^n$. We first decompose the multilinear (Fourier) expansion of $f \in F$ in the same manner as [4]:

\[
|\mathbb{E}_X[f(X)] - \mathbb{E}_U[f(U)]| \leq \sum_{i=1}^{k-1} \sum_{S \subseteq [n] : |S| = i} |\hat{f}(S)| |\mathbb{E}_X[X^S]| + |\mathbb{E}_X[f_{\geq k}(X)]|. \tag{1}
\]

\[\text{low-order terms} \quad \text{high-order term}\]

---

3 We note that similar ideas for the $k = 1$ case also appeared in [1] (attributed to Avishay Tal).
[4] requires bounding $L_{1,\ell}(F)$ for all $\ell \geq k$ to give a uniform bound on the high-order term. Using Theorem 17, we can obtain small error in the high-order term so long as we choose $X \in [-c,c]^n$ for sufficiently small $c$ depending on $\varepsilon$ and $M_k(F)$. To handle the low-order terms, we consider two cases: if we further have $L_{1,\ell}(F)$ bounds for $\ell < k$, then we may choose $X$ to be a scaled $(k-1)$-wise $\delta$-biased distribution to nearly fool each of the low-order terms as in [4]. Otherwise, we may choose $X$ to be a scaled $(k-1)$-wise independent distribution to incur zero error from the low-order terms. Note that the latter pseudorandom primitives are more expensive in terms of seed length. Finally, to obtain pseudorandom generators, we then simply apply the random walk gadget of [4] to our fractional PRGs as a blackbox. We refer the reader to Section 4 for formal proofs of the ideas in this section.

We immediately leverage this newfound flexibility to construct new pseudorandom generators for $F_2$-polynomials of degree $d = O(\log n)$. We do this using known $L_{1,k}(F)$ bounds derived in [4]. Previously these bounds were not sufficient to give PRGs with polylogarithmic error dependence as their analysis of fractional PRGs either required control of the entire Fourier tail or could not leverage higher Fourier levels, but they can be employed here due to our more flexible analysis. This result is given in Section 5. Finally, we show how $M_k(F)$ bounds can be obtained using correlation bounds with shifted majority functions in Section 6. This is done by straightforwardly generalizing the analysis of [5], which shows how such correlation bounds can be used to bound the bulk of the terms in the definition of $M_k(F)$.

1.4 Other Related Work

To our knowledge, our use of $M_k(F)$ bounds is new to the derandomization literature. As mentioned earlier, the stronger and better-known $L_{1,k}(F)$ notion has been extensively studied in recent years. In addition to derandomization, a recent line of work [24, 3, 20] has used $L_{1,k}$ bounds for decision trees to obtain an optimal separation of quantum and classical query complexity. Among these works, the work of Bansal and Sinha [3] generalizes the results of Raz and Tal [18] by considering a $k$-generalization of their Forrelation distribution and bounding the distinguishing advantage of any function with small $L_{1,\ell}$ bounds for $\ell = 1, \ldots, k$. Much as how the results of Chattopadhyay et al. [6] derandomize the result of Raz and Tal, we believe that their construction can be derandomized for pseudorandomness purposes, but appears to give significantly worse seed length, nor obtains bounds in terms of $M_k(F)$. A related work by Girish, Raz, and Zhan [9] establishes a similar result with a different generalization of the Forrelation distribution, but we do not know how to use their construction for pseudorandom generators.

The relationship between $M_k(F)$ and $L_{1,k}(F)$ has been of intense study in the mathematics literature due to renewed interest in Bohnenblust–Hille inequalities (see, for instance, the breakthrough work of Defant, Frerick, Ortega–Cerdà, Ounaïes, and Seip [8]). The optimal constant $C_{n,k}$ satisfying $L_{1,k}(f) \leq C_{n,k}M_k(f)$ for any polynomial $f : \mathbb{C}^n \rightarrow \mathbb{C}$ is known as the Sidon constant. It is known that $C_{n,k}$ is, up to small exponential factors in $k$, proportional to roughly $n^{1-k}$, and its tightness is witnessed by a random function with high probability. The quantity $M_k(F)$ also has applications in other areas in theoretical computer science, such as quantum information theory (see for instance the survey of Montanaro [14]) and Boolean function analysis [2].

Subsequent to our work, Viola [27] observed that $M_k(F)$ bounds imply correlation bounds between $F$ and an explicit function.
2 Preliminaries

As in [4] and [6], we study PRGs for classes \( \mathcal{F} \) of \( n \)-variate Boolean functions that are closed under restriction (that is, fixing any subset of the input variables of a function in the class yields a function that remains in the class).

2.1 Fourier Analysis

We briefly recall basic Fourier analysis: any Boolean function \( f: \{-1, 1\}^n \to \{-1, 1\} \) admits a unique multilinear expansion, also known as the Fourier expansion, given by

\[
f(x) = \sum_{S \subseteq [n]} \hat{f}(S)x^S,
\]

(2)

where we write \( x^S \triangleq \prod_{i \in S} x_i \). The Fourier coefficient \( \hat{f}(S) \) is given by

\[
\hat{f}(S) = \mathbb{E}_{x \sim \{-1, 1\}^n} [f(x)x^S].
\]

For more on Fourier analysis of Boolean functions, see the excellent book by O’Donnell [16]. One may thus extend the domain of \( f \) to \( [-1, 1]^n \), where \( f(x) \) for arbitrary \( x \) is evaluated according to the expression in Equation (2). Note that in this case, \( f(0) = \hat{f}(\emptyset) = \mathbb{E}_{U_n}[f(U_n)] \).

One of the main parameters of interest from the Fourier expansion for this framework is the following:

\begin{definition}
The level-\( k \) mass of a Boolean function \( f \) is
\[ L_{1,k}(f) \triangleq \sum_{S \subseteq [n]:|S|=k} |\hat{f}(S)|, \]

and the level-\( k \) mass of a class \( \mathcal{F} \) is \( L_{1,k}(\mathcal{F}) \triangleq \max_{f \in \mathcal{F}} L_{1,k}(f) \).
\end{definition}

In this work, we will show how to construct PRGs whose seed length depends on the following, smaller quantity:

\begin{definition}
For any multilinear polynomial \( f: \mathbb{R}^n \to \mathbb{R} \) given by \( f(x) = \sum_{S \subseteq [n]} \hat{f}(S)x^S \), define the level-\( k \) part by
\[ f_k(x) \triangleq \sum_{S \subseteq [n]:|S|=k} \hat{f}(S)x^S, \]

and further define \( f_{<k}(x) \triangleq \sum_{i=0}^{k-1} f_i(x) \) and \( f_{\geq k}(x) \triangleq \sum_{i=k}^{n} f_i(x) \). Then we define the level-\( k \) absolute Fourier sum of \( f \) by
\[ M_k(f) \triangleq \max_{x \in \{-1, 1\}^n} \left| \sum_{S \subseteq [n]:|S|=k} \hat{f}(S)x^S \right| = \max_{x \in \{-1, 1\}^n} \left| \sum_{S \subseteq [n]:|S|=k} \hat{f}(S)x^S \right| \]

and analogously define \( M_k(\mathcal{F}) \triangleq \max_{f \in \mathcal{F}} M_k(f) \) for a class \( \mathcal{F} \).
\end{definition}

Note that the equality arises by multilinearity, and clearly we have \( M_k(f) \leq L_{1,k}(f) \) by the triangle inequality. Without loss of generality, we may further assume that our class is closed under flipping the image, i.e. we may suppose that \( f \in \mathcal{F} \) if and only if \( -f \in \mathcal{F} \); this transformation does not change either \( L_{1,k}(f) \) or \( M_k(f) \), and therefore the same bound on the class still holds when completing it to include all such functions. If this is the case, we get the more striking identity:
Lemma 9. Suppose that \( \mathcal{F} \) is closed under negation of variables and that \( f \in \mathcal{F} \) implies \(-f \in \mathcal{F}\). Then

\[
M_k(\mathcal{F}) = \max_{f \in \mathcal{F}} \sum_{S \subseteq [n]: |S| = k} \hat{f}(S) = \max_{f \in \mathcal{F}} f_k(1).
\]

To see why this holds, simply note that if \((f, z) \in \mathcal{F} \times \{-1, 1\}^n\) is a maximizer in the definition of \(M_k(\mathcal{F})\) (where we may now assume that the sign is positive), then by replacing the function \(f(x)\) with \(g(x) = f(x \circ z)\), where \(\circ\) denotes componentwise multiplication, we have

\[
M_k(\mathcal{F}) = \left| \sum_{S \subseteq [n]: |S| = k} \hat{f}(S)z^S \right| = \max_{h \in \mathcal{F}} \sum_{S \subseteq [n]: |S| = k} \hat{h}(S).
\]

In particular, it suffices to bound the \textit{unsigned level-}k \textit{Fourier sum} of such a class.

Lastly, we require the following notion:

Definition 10. Let \( \mathcal{F} \) be a class of \( n \)-variate multilinear polynomials that is closed under restrictions. Define \( \text{conv}(\mathcal{F}) \) as the convex closure of \( \mathcal{F} \),

\[
\text{conv}(\mathcal{F}) \triangleq \left\{ \sum_{f \in \mathcal{F}} \lambda_f f \mid \sum_{f \in \mathcal{F}} \lambda_f = 1, \lambda_f \geq 0 \ \forall f \in \mathcal{F} \right\}.
\]

We briefly note the following two elementary facts: first, by the assumption that \( \mathcal{F} \) is closed under restrictions, the same is true of \( \text{conv}(\mathcal{F}) \). The second is the following simple claim:

Lemma 11. For any class \( \mathcal{F} \) of Boolean functions, \( M_k(\mathcal{F}) = M_k(\text{conv}(\mathcal{F})) \).

Proof. One direction is obvious: as \( \mathcal{F} \subseteq \text{conv}\mathcal{F} \), clearly \( M_k(\mathcal{F}) \leq M_k(\text{conv}(\mathcal{F})) \). In the other direction, let \( g = \sum_{f \in \mathcal{F}} \lambda_f f \) be an arbitrary element of \( \text{conv}(\mathcal{F}) \), where \( \lambda_f \geq 0 \) and \( \sum_{f \in \mathcal{F}} \lambda_f = 1 \). Then

\[
M_k(g) = \max_{x \in \{-1, 1\}^n} \left| \sum_{S \subseteq [n]: |S| = k} \hat{g}(S)x^S \right| = \max_{x \in \{-1, 1\}^n} \left| \sum_{S \subseteq [n]: |S| = k} \left( \sum_{f \in \mathcal{F}} \lambda_f \hat{f}(S) \right)x^S \right| \\
\leq \sum_{f \in \mathcal{F}} \lambda_f \max_{x \in \{-1, 1\}^n} \left| \sum_{S \subseteq [n]: |S| = k} \hat{f}(S)x^S \right| = \max_{f \in \mathcal{F}} M_k(f).
\]

The reverse inequality immediately follows.

2.2 (Fractional) Pseudorandom Generators

We now recall the (well-known) definition of a pseudorandom generator, as well as the generalization of a fractional pseudorandom generator as introduced by [4]:

Definition 12. Let \( \mathcal{F} \) be a class of \( n \)-variate Boolean functions. Then a pseudorandom generator (PRG) for \( \mathcal{F} \) with error \( \epsilon > 0 \) is a random variable \( X \in \{-1, 1\}^n \) such that for all \( f \in \mathcal{F} \),

\[
|\mathbb{E}_X[f(X)] - \mathbb{E}_{U_n}[f(U_n)]| \leq \epsilon,
\]

where \( U_n \) is the uniform distribution on \( \{-1, 1\}^n \). If \( X = G(U_s) \) for some explicit function \( G : \{-1, 1\}^s \rightarrow \{-1, 1\}^n \), then \( X \) has seed length \( s \).
Definition 13. A fractional pseudorandom generator (fractional PRG) for $F$ with error $\varepsilon > 0$ is a random variable $X \in [-1,1]^n$ such that for all $f \in F$ (identifying $f$ with its multilinear expansion)

$$|E_X[f(X)] - f(0)| \leq \varepsilon,$$

where the definition of seed length is the same. A fractional PRG is $p$-noticeable if for each $i \in [n]$, $E[X_i^2] \geq p$.

We now state the main results of [4] and [6] that show how to construct PRGs from suitably combining noticeable fractional PRGs. This is done by the following amplification theorem, which roughly composes fractional random variables into a random walk inside the Boolean hypercube:

Theorem 14. Suppose $F$ is class of $n$-variate Boolean functions that is closed under restrictions, and that $X$ is an explicit $p$-noticeable fractional PRG with error $\varepsilon$ and seed length $s$. Then there exists an explicit PRG for $F$ with seed length $O(s \log(n/\varepsilon)/p)$ and error $O(\varepsilon \log(n/\varepsilon)/p)$.

Using this result, [4] proved the following theorem that exploits strong $L_1$ control of each Fourier level:

Theorem 15. Let $F$ be any class of $n$-variate Boolean functions that is closed under restrictions. Suppose that $L_{1,k}(F) \leq b^k$ for some $b \geq 1$ and all $1 \leq k \leq n$. Then for any $\varepsilon > 0$, there exists an explicit PRG for $F$ with error $\varepsilon$ and seed length $b^2 \cdot \text{polylog}(n/\varepsilon)$.

This is achieved by constructing a fractional PRG that is a scaled version of a log(1/\varepsilon)-wise nearly unbiased distribution. As we will be analyzing a similar fractional PRG, we defer the details to next section. To lessen the requisite assumptions on the Fourier spectrum, Chattopadhyay et al. [6] derandomize a construction of Raz and Tal [18] to prove the following result that requires only level-two control, albeit at a cost of exponentially worse dependence on the error $\varepsilon$, and quadratically worse dependence on the level-two mass:

Theorem 16. Let $F$ be any class of $n$-variate Boolean functions that is closed under restrictions. Suppose that $L_{1,2}(F) \leq b^2$ for some $b \geq 1$. Then for any $\varepsilon > 0$, there exists an explicit PRG for $F$ with error $\varepsilon$ and seed length $O((b^2/\varepsilon)^{2+o(1)} \text{polylog}(n))$.

### 3 Low-Degree Polynomial Approximations on Subcubes

Throughout this section, we assume that $F$ is a class of $n$-variate Boolean functions closed under restrictions. As mentioned above, the main result from which we derive our improvements in constructing pseudorandom generators is essentially a statement about low-degree polynomial approximations on subcubes $[-c, c]^n$ for $c < 1$. We remark that this setting is equivalent to approximating noisy versions $T_{\rho}f$ on $[-1,1]^n$, where $T_{\rho}$ is the $\rho$-noise operator. This is because for any $y \in [-c, c]^n$, we can write $y = cx$ for some $x \in [-1,1]^n$ and

$$f(y) = f(cx) = \sum_{S \subseteq [n]} \hat{f}(S)(cx)^S = \sum_{S \subseteq [n]} c^{|S|}\hat{f}(S)x^S = T_{c}f(x).$$

In general, given any $k \leq n$, $c \geq 0$, and any $f \in F$, let $\varepsilon_{c,k}(f)$ be defined by

$$\varepsilon_{c,k}(f) \triangleq \inf_{g : \deg(g) < k} \max_{x \in [-c,c]^n} |f(x) - g(x)|,$$

(3)
and extend the definition to function classes by
\[ \varepsilon_{c,k}(\mathcal{F}) \triangleq \max_{f \in \mathcal{F}} \varepsilon_{c,k}(f). \]

Now, given \( \varepsilon > 0 \), \( k \leq n \), and the class \( \mathcal{F} \), define \( c_k(\varepsilon, \mathcal{F}) \) by
\[ c_k(\varepsilon, \mathcal{F}) \triangleq \max\{c \geq 0 : \varepsilon_{c,k}(\mathcal{F}) \leq \varepsilon\}. \]

In words, \( c_k(\varepsilon, \mathcal{F}) \) measures how small a hypercube we must take to ensure that for every function in our class, there exists a degree-\((k-1)\) approximating polynomial that agrees with \( f \) up to a uniform \( \varepsilon \) error on the subcube \([-c,c]^n\); by multilinearity, it actually suffices that this holds at the extreme points \([-c,c]^n\). Note that Equation (3) can be formulated as a linear program and its optimal solution is the best low-degree \( \ell_\infty \)-approximation to \( f \).

The main technical claim in this section is that we bound \( c_k(\varepsilon, \mathcal{F}) \) in terms of \( M_k(\mathcal{F}) \).

Specifically, we show that for any class \( \mathcal{F} \) that is closed under restrictions, truncating the Fourier expansion of a function \( f \in \mathcal{F} \) to its first \( (k-1) \) levels serves as a good approximation to \( f \) on a sufficiently small hypercube around the origin.

\begin{itemize}
  \item **Theorem 17.** Let \( f \in \mathcal{F} \) that is closed under restrictions. Then for all \( c \in (0,1) \), we have
    \[ \max_{x \in [-c,c]^n} |f_{\geq k}(x)| \leq \left( \frac{c}{1-c} \right)^k M_k(\mathcal{F}). \]
    In particular, it follows that
    \[ \varepsilon_{c,k}(\mathcal{F}) \leq \left( \frac{c}{1-c} \right)^k M_k(\mathcal{F}). \]

From Theorem 17, one immediately obtains a lower bound on \( c_k(\varepsilon, \mathcal{F}) \):

\begin{itemize}
  \item **Corollary 18.** For any class \( \mathcal{F} \) that is closed under restrictions, and any \( \varepsilon > 0 \) and \( k \leq n \),
    \[ c_k(\varepsilon, \mathcal{F}) = \Omega \left( \left( \frac{\varepsilon}{M_k(\mathcal{F})} \right)^{1/k} \right) \]
    \[ \text{Proof.} \text{ Observe that by setting } c = \Omega \left( \left( \frac{\varepsilon}{M_k(\mathcal{F})} \right)^{1/k} \right) \text{ in Theorem 17, the right side is bounded by } \varepsilon. \text{ Because } f_{\geq k} = f - f_{<k} \text{ and } f_{<k} \text{ has degree strictly less than } k, \text{ it follows immediately from the definition of } c_k(\varepsilon, \mathcal{F}) \text{ that } c_k(\varepsilon, \mathcal{F}) \text{ is at least } c. \]
\end{itemize}

We now return to the proof of Theorem 17. To prove this result, we require the following intermediate claims. The first simply shows that we may always bound the contribution of the level-\( k \) part of any function in \( \mathcal{F} \) by simply rescaling the argument:

\begin{itemize}
  \item **Lemma 19.** Let \( f \in \text{conv}(\mathcal{F}) \). Then, for all \( c \in (0,1) \) and \( x \in [-c,c]^n \), we have
    \[ |f_k(x)| \leq c^k M_k(\mathcal{F}). \]
    \[ \text{Proof.} \text{ Observe that } c^{-1}x \in [-1,1]^n \text{ by assumption, and by homogeneity of } f_k \text{ as a polynomial, we have}
    \[ |f_k(x)| = c^k |f_k(c^{-1}x)| \leq c^k M_k(\text{conv}(\mathcal{F})) = c^k M_k(\mathcal{F}). \]
\end{itemize}
The next simple yet powerful claim shows that one can “recenter” functions in \( \mathcal{F} \) and they remain in \( \text{conv}(\mathcal{F}) \) (and therefore, enjoy the same Fourier bounds). This random restriction technique is a key tool in [4].

**Lemma 20.** Let \( f \in \text{conv}(\mathcal{F}) \), \( \mathbf{a} \in [-1,1]^n \) and \( \mathbf{b} \in [0,1] \) such that \( |a_i| + b_i \leq 1 \) for all \( i \in [n] \). Define \( \tilde{f} \) by \( \tilde{f}(\mathbf{x}) = f(\mathbf{a} + \mathbf{b} \circ \mathbf{x}) \), where \( \circ \) denotes componentwise multiplication. Then, \( \tilde{f} \in \text{conv}(\mathcal{F}) \).

**Proof.** Given \( \mathbf{a} \) and \( \mathbf{b} \), define a distribution \( D_i \) on \( Z_i = \{-1,1,x_i\} \) where \( x_i \) is treated as formal variable, such that \( \mathbb{E}_{y_i \sim D_i}[y_i] = a_i + b_i x_i \); note that this is possibly by the assumption that \( |a_i| + b_i \leq 1 \). Let \( D = \prod_i D_i \) be the product distribution of the \( D_i \). For any \( \mathbf{z} \in \prod_i Z_i \), define \( f_\mathbf{z}(\mathbf{x}) \) as the function obtained by setting \( x_i = z_i \) for each \( i \); in particular, each variable gets set to \( \pm 1 \) or remains a formal variable. By our assumption on the closure of \( \mathcal{F} \), we clearly have \( f_\mathbf{z} \in \mathcal{F} \) for any \( \mathbf{z} \). By multilinearity and independence of the product distribution, we have \( f(\mathbf{a} + \mathbf{b} \circ \mathbf{x}) = \mathbb{E}_{\mathbf{z} \sim D}[f_\mathbf{z}(\mathbf{x})] \). Thus \( \tilde{f} \in \text{conv}(\mathcal{F}) \). ▶

As mentioned before, our approach will be to bound the higher-order terms of the Fourier expansion at the fractional points of the fractional PRG via the error term that arises in Taylor’s theorem. Denote by \( h^{(k)} \) the \( k \)-th derivative of any \( \mathcal{C}^k \) function \( h : \mathbb{R} \to \mathbb{R} \). We then have the following claim:

**Lemma 21.** Let \( f : \mathbb{R}^n \to \mathbb{R} \) be multilinear and let \( \mathbf{x} \in \mathbb{R}^n \). Define \( g : \mathbb{R} \to \mathbb{R} \) by \( g(t) = f(t\mathbf{x}) \). Then,

\[
g^{(k)}(0) = k! \cdot f_k(\mathbf{x}).
\]

**Proof.** From the definition, it follows that

\[
g(t) = \sum_{S \subseteq [n]} t^{|S|} \hat{f}(S) \mathbf{x}^S.
\]

Differentiating \( g \) with respect to \( t \), we get

\[
g^{(k)}(t) = \sum_{S \subseteq [n],|S| \geq k} \left( \prod_{i=0}^{k-1} (|S| - i) \right) t^{|S|-k} \hat{f}(S) \mathbf{x}^S.
\]

Setting \( t = 0 \) eliminates all of the monomials with \( |S| > k \), giving us the required bound. ▶

The last intermediate result we require connects the function defined in the previous part with our assumed Fourier bounds:

**Lemma 22.** Let \( f \in \text{conv}(\mathcal{F}) \), \( c \in (0,1) \) and \( \mathbf{x} \in [-c,c]^n \). Define \( g \) as in Lemma 21. Then,

\[
\max_{s \in [0,1]} |g^{(k)}(s)| \leq \left( \frac{c}{1-c} \right)^k \cdot k! \cdot M_k(\mathcal{F})
\]

**Proof.** Fix \( s \in [0,1] \) and let \( \lambda = 1 - c \in [0,1] \). Define the auxiliary function \( \tilde{f}(\mathbf{y}) = f(s\mathbf{x} + \lambda \mathbf{y}) \).

Writing \( \mathbf{a} = s\mathbf{x} \) and \( \mathbf{b} = (\lambda, \ldots, \lambda) \), we clearly have \( s|\mathbf{x}| + \lambda \leq 1 \), so we may apply Lemma 20 to see that \( \tilde{f} \in \text{conv}(\mathcal{F}) \). Now writing \( \tilde{g}(t) = \tilde{f}(t\mathbf{x}) = f(s\mathbf{x} + \lambda t \mathbf{x}) \), we also have \( \tilde{g}(t) = g(s + t\lambda) \).

By the chain rule, differentiating both sides \( k \) times and then setting \( t = 0 \), we have

\[
\lambda^k \tilde{g}^{(k)}(s) = \tilde{g}^{(k)}(0).
\]
On the other hand, by Lemma 21, we have $\tilde{g}^{(k)}(0) = k! \cdot \tilde{f}_k(x)$, and as $\tilde{f} \in \text{conv}(\mathcal{F})$ by Lemma 20, we conclude using Lemma 19 that

$$|g^{(k)}(s)| = \left| \frac{\tilde{g}^{(k)}(0)}{\lambda^k} \right| \leq \left( \frac{c}{1-c} \right)^k \cdot k! \cdot M_k(\mathcal{F}).$$

With these intermediate claims taken care of, we may now put them together to obtain Theorem 17.

**Proof of Theorem 17.** The second statement follows immediately from the first by setting $g = f_{<k}$ for any given $f$, and noticing that $f - g = f_{\geq k}$. Therefore, we focus on the first statement.

Let $f \in \mathcal{F}, x \in [-c,c]^n$ and define $g(t) = f(tx)$. Then, by Taylor expanding $g$ about $t = 0$ and evaluating $g$ at $t = 1$, we have

$$g(1) = \sum_{i<k} \frac{g^{(i)}(0)}{i!} + R_k,$$

where $R_k$ is the error term and is given in Lagrange form by

$$R_k = \frac{g^{(k)}(s)}{k!}$$

for some $s \in (0,1)$. By Lemma 21, we easily see that the first term in the right hand side of Equation (4) is precisely $f_{<k}(x)$, and as $g(1) = f(x)$, we clearly then must have $R_k = f_{\geq k}(x)$. Therefore, by Lemma 22, we obtain

$$|f_{\geq k}(x)| = \left| \frac{g^{(k)}(s)}{k!} \right| \leq \left( \frac{c}{1-c} \right)^k M_k(\mathcal{F}),$$

as desired.

**3.1 Lower Bounds via Chebyshev Polynomials**

In this subsection, we show that our bounds on the uniform error of any low-degree polynomial approximator are essentially tight for a reasonable range of $c < 1$. Recall that Theorem 17 shows that the low-degree Fourier expansion is an excellent approximator to the original function for $c$ small enough; we now show that this bound cannot be significantly improved for a reasonable range of $c$ using any approximator. Our main result of this section is the following converse:

**Theorem 23.** Let $\mathcal{F}$ be any class of $n$-variate multilinear functions that are closed under restrictions. Then for any $c \leq \min \left( \frac{1}{3}, 3^{-k} \frac{M_k(\mathcal{F})}{M_{k+1}(\mathcal{F})} \right)$, we have

$$\epsilon_{c,k}(\mathcal{F}) \geq \left( \frac{C}{2} \right)^k M_k(\mathcal{F}).$$

Recall that on the interval $[-1,1]$, the Chebyshev polynomials give the minimum $\ell_{\infty}$ norm among all polynomials with same leading coefficient in magnitude:

**Fact 24 (Theorem 1.5.4 of [17]).** If a polynomial $f : \mathbb{R} \to \mathbb{R}$ is monic of degree $n$, then $\max_{x \in [-1,1]} |f(x)| \geq 2^{-n+1}$, with equality if and only if $f = T_n$, the normalized $n$-th Chebyshev polynomial.
Therefore, we obtain

$$M_k(F) = \left| \sum_{S \subseteq \{0,1\}^n : |S| = k} \hat{f}(S)x^S \right|.$$  

First, note that the claim is trivial if every function in $\mathcal{F}$ is of degree at most $k$, because then $f_{\geq k}$ is a homogeneous polynomial of degree $k$ and this lower bound is trivial. Under this assumption, $M_{k+1}(\mathcal{F}) > 0$. Fix $c \in (0,1)$ and let $p : [-1,1]^n \to \mathbb{R}$ be any multilinear polynomial of degree strictly less than $k$. Define the univariate function $g : [-1,1] \to \mathbb{R}$ by

$$g(t) = f(tc) - p(tc).$$

By taking the Fourier expansion of $f$, it is easy to see that the coefficient of $t^\ell$ for $\ell \geq k$ is precisely

$$c^\ell \sum_{S \subseteq \{0,1\}^n : |S| = \ell} \hat{f}(S)x^S,$$

so that the coefficient of $t^k$ is equal to $c^k M_k(\mathcal{F})$ in magnitude. We then have

$$\sup_{z \in [-c,c]^n} |f(z) - p(z)| \geq \max_{z \in [-c,c]^n} |f(z) - p(z)| = \sup_{t \in [-1,1]} |g(t)| \geq \sup_{t \in [-1,1]} |g_{\leq k}(t)| - \sup_{t \in [-1,1]} |g_{> k}(t)|.$$

By Fact 24, the first term is at least $c^k M_k(\mathcal{F}) / 2^{k-1}$. On the other hand, the second term can be bounded using Theorem 17 by

$$\sup_{t \in [-1,1]} |g_{> k}(t)| \leq \left( \frac{c}{1-c} \right)^{k+1} M_{k+1}(\mathcal{F}).$$

Therefore, we obtain

$$\sup_{z \in [-c,c]^n} |f(z) - p(z)| \geq 2 \left( \frac{c}{2} \right)^k M_k(\mathcal{F}) - \left( \frac{c}{1-c} \right)^{k+1} M_{k+1}(\mathcal{F}).$$

It is straightforward to verify that for $c \leq \min \left( 1/3, 3^{-k} M_k(\mathcal{F}) / M_{k+1}(\mathcal{F}) \right)$, the second term is bounded by half of the first. Because $p$ was an arbitrary low-degree multilinear polynomial, the claim follows.

4 From Polynomial Approximations to PRGs

4.1 From Polynomial Approximations to Fractional PRGs

From Theorem 17, we now show how the construction of fractional PRGs from level-$k$ bounds reduces to efficient polynomial approximation on “large” subcubes.

**Theorem 25.** Let $\mathcal{F}$ be closed under restrictions. Then there exists a fractional PRG for $\mathcal{F}$ with error $\epsilon$ and seed length $O(k \log n)$ that is $(c_k(\epsilon/2, \mathcal{F}))^2$-noticeable. In particular, if $M_k(\mathcal{F}) = b^k$, there exists such a fractional PRG that is $\Omega \left( \frac{2^k}{b^k} \right)$-noticeable with seed length $O(k \log n)$.  

**Proof of Theorem 23.** Let $(f, \mathbf{x})$ attain the maximum in the definition of $M_k(\mathcal{F})$, namely

$$M_k(\mathcal{F}) = \left| \sum_{S \subseteq \{0,1\}^n : |S| = k} \hat{f}(S)x^S \right|.$$
We first deal with the second term on the right hand side. By Theorem 17 we have

$$\sum_{i=1}^{k-1} \epsilon \sum_{S \subseteq \{n\}; |S| = i} \hat{f}(S) X^S \leq \epsilon^2.$$  

Therefore, we have the Fourier expansion of $f$.

$$\sum_{i=1}^{k-1} \epsilon \sum_{S \subseteq \{n\}; |S| = i} \hat{f}(S) X^S \leq \epsilon^2.$$  

The first inequality applies Equation (5) at the point $x = 0$, and the second uses the fact that $X$ is $(k-1)$-wise independent and $\hat{f}$ has degree at most $k-1$. The final inequality holds because of (5) and the fact that $X \in [-c, c]$.

### Proof.

The second statement follows immediately from the first using Corollary 18, so we focus on the first statement.

Fix $f \in F$, $\epsilon > 0$, and let $X$ be a $(k-1)$-wise independent random variable over $\{-1, 1\}^n$ such that $|X_i| = c \leq 1/2$ for all $i \in [n]$ for some $c > 0$ we specify momentarily. It is well-known that $X$ can be sampled efficiently with seed length $O(k \log n)$ [25]. By definition of $c := c_k(\epsilon/2, F)$, there exists a degree-$(k-1)$ multilinear polynomial $\hat{f}$ which $\epsilon$-approximates $f$ on the subcube $[-c, c]^n$, i.e.

$$\max_{y \in [-c, c]^n} |f(y) - \hat{f}(y)| \leq \epsilon/2. \tag{5}$$

Then we have, via the Fourier expansion of $f$,

$$\left| \mathbb{E}_X [f(X)] - f(0) \right| \leq \frac{\epsilon}{2} + \left| \mathbb{E}_X [f(X) - \hat{f}(X)] \right|$$

$$\leq \frac{\epsilon}{2} + \mathbb{E}_X \left[ |f(X) - \hat{f}(X)| \right]$$

$$\leq \epsilon.$$

Although it does not fit so neatly in this approximation framework, one can essentially recover the improved seed length of [4] (which we recall assumes $L_{1,i}(F)$ bounds for $i = 1, \ldots, n$) if one further has $L_{1,i}(F)$ bounds just up to level $k-1$:

**Theorem 26.** Let $F$ be closed under restrictions, and suppose that $M_k(F) \leq b^k$ for some $b \geq 1$, $k \geq 2$. If it further holds that $L_{1,i}(F) \leq b^i$ for all $1 \leq i < k$, then there exists a $\Theta(\epsilon^{2/k}/b^2)$-noticeable fractional pseudorandom generator for $F$ with error $\epsilon$ and seed length $O(\log \log n + \log k + \log(1/\epsilon))$.

**Proof.** Fix $f \in F$, and let $X$ be a random variable such that $|X_i| = c$ for all $i \in [n]$ for some $c > 0$ we specify momentarily. Then we have, via the Fourier expansion of $f$,

$$\left| \mathbb{E}_X [f(X)] - f(0) \right| = \left| \mathbb{E}_X \left[ \sum_{S \subseteq \{n\}; |S| \leq k-1} \hat{f}(S) X^S \right] \right| + \left| \mathbb{E}_X [f_{\geq k}(X)] \right|.$$  

We first deal with the second term on the right hand side. By Theorem 17 we have

$$\left| \mathbb{E}_X [f_{\geq k}(X)] \right| \leq \left( \frac{c}{1-c} \right)^k M_k(F).$$

By assumption, $M_k(F) \leq b^k$ for some $b \geq 1$; therefore, by taking $c = \Theta(\epsilon^{1/k}/b)$, this term is at most $\epsilon/2$. To deal with the first term, we take the same approach as [4]. Under the assumption $L_{1,i}(F) \leq b^i$ for all $i < k$, one may apply their analysis by letting $X = c \cdot Y'$, where $Y'$ is an $(k-1)$-wise $(\epsilon/2)$-biased independent random variable over $\{-1, 1\}^n$. It is clear that $X$ is $c^2 = \Theta(\epsilon^{2/k}/b^2)$-noticeable. Moreover, exactly as in [4], we have

$$\left| \mathbb{E}_X \left[ \sum_{S \subseteq \{n\}; |S| \leq k-1} \hat{f}(S) X^S \right] \right| \leq \sum_{i=1}^{k-1} c^i \sum_{S \subseteq \{n\}; |S| = i} \left| \hat{f}(S) \right| \mathbb{E} \left[ Y'^S \right] \leq \left( \frac{\epsilon}{2} \right) \sum_{i=1}^{k-1} (bc)^i \leq \epsilon/2,$$
because by our choice of $c$ we have $bc \leq 1/2$. By standard constructions, $Y'$ can be efficiently sampled with seed length $O(\log \log n + \log k + \log(1/\varepsilon))$ [15]. Combining these two errors proves the theorem. ▷

### 4.2 From Fractional PRGs to PRGs

Using Theorem 25 and Theorem 26 in tandem with Theorem 14, it is fairly immediate to obtain PRGs that rely only on a bound on some $k$-th Fourier level. Similarly, bounds on levels up to $k$ can be leveraged to get an improved seed length.

▶ **Theorem 27** (Theorem 4, restated). Let $F$ be any class of $n$-variate Boolean functions that is closed under restrictions. Suppose that $M_k(F) \leq b^k$ for some $b \geq 1$ and $k \geq 3$. Then for any $\varepsilon > 0$, there exists an explicit PRG for $F$ with error $\varepsilon$ with seed length

$$O\left(\frac{b^2 + \frac{4}{\varepsilon} \cdot \log \log n + \log k + \log(b/\varepsilon) \cdot \log \frac{1}{\varepsilon} \cdot (n/\varepsilon)}{\varepsilon}\right).$$

If it further holds that $L_{1,i}(F) \leq b^i$ for all $1 \leq i < k$, then the seed length can be improved to

$$O\left(\frac{b^2 + \frac{4}{\varepsilon} \cdot \log \log n + \log k + \log(b/\varepsilon) \cdot \log \frac{1}{\varepsilon} \cdot (n/\varepsilon)}{\varepsilon}\right).$$

**Proof.** By Theorem 14, given an explicit $p$-noticeable fractional PRG for $F$ with error $\delta$ and seed length $s$, one immediately obtains an explicit PRG for $F$ with error $O(\delta \log(n/\delta)/p)$ and seed length $O(s \log(n/\delta)/p)$.

For the first statement, by our assumption and using the fractional PRG guaranteed by Theorem 25, for any $\delta > 0$, we immediately obtain an explicit PRG for $F$ with error $O(b^2 \delta^{1-2/k} \log(n/\delta))$ and seed length $O(b^2 k \log(n/\delta)/\delta^{2/\varepsilon})$. To get the error below $\varepsilon$, we set

$$\delta = \Theta\left(\frac{\varepsilon}{b^2 \log(n/\delta)^{1/2}}\right)$$

(the astute reader may notice we implicitly use $b \leq n$ here). This yields a PRG with error $\varepsilon$ and seed length

$$O\left(\frac{b^2 + \frac{4}{\varepsilon} \cdot \log \log n + \log k + \log(b/\varepsilon) \cdot \log \frac{1}{\varepsilon} \cdot (n/\varepsilon)}{\varepsilon}\right).$$

The second statement follows in an identical manner from the improved seed length given in the second part of Theorem 26 in the case that one has control on the $L_1$ Fourier mass on the lower levels.

Corollary 5 is now an immediate consequence of Theorem 27; for any desired $\varepsilon > b \cdot \log(n) \cdot 2^{-O(k)}$, one can simply apply Theorem 27 using level $k = \Theta(\log(b \log(n)/\varepsilon))$ to obtain a PRG for $F$ with error at most $\varepsilon$ with seed length

$$O(b^2 \cdot \log(b \log(n)/\varepsilon) \cdot \log(n/\varepsilon)).$$

Note that for error $\varepsilon = 1/\text{poly}(n)$, one needs bounds only up to level $\Theta(\log n)$ (again, using the fact that $b \leq n$). This also partially answers an open question of [6], which asks how many levels of Fourier bounds suffice to recover polylogarithmic dependence in $1/\varepsilon$. ▷
Remark 28. Note that this Taylor’s theorem approach does not yield anything nontrivial given bounds just on the second level, unlike the fractional PRG in [6]. This is actually a necessary byproduct of combining this approach with the random walk gadget of [4]. Given only level-two bounds, this approach attempts to use $j$-wise independence for $j < k = 2$ and smallness to deal with errors on the high degree terms ($k \geq 2$). However, the trivial random variable that is $\pm 1$ with equal probability is trivially $1$-wise independent, as each component is a uniform random bit, albeit completely correlated. No matter how we scale them, one can show that composing arbitrarily many independent copies of this random variable via the random walk gadget must necessarily polarize to $\pm 1$ at termination, which clearly cannot fool any nontrivial functions.

5 Low-degree Polynomials over $\mathbb{F}_2$

Our analysis recovers all the existing applications of [4] (among them, $\text{AC}^{0}$ circuits, low-sensitivity functions, and read-once branching programs); indeed, all the classes considered there satisfy $L_1$ Fourier bounds on the entire tail. To our knowledge, our new analysis does not immediately improve the seed lengths obtained there, though it shows that (i) the seed lengths there can potentially be improved using stronger bounds on $M_k$, and (ii) the PRGs there would still have fooled those classes had these Fourier bounds been known only up to some level $k$.

However, the generality afforded to us by this new analysis allows us to obtain a new PRG for low-degree polynomials over $\mathbb{F}_2$, which addresses an open question of [4] by showing that this framework can handle this class. Indeed, let $\mathcal{F}$ be the set of $n$-variate, degree-$d$ polynomials over $\mathbb{F}_2$. As a preliminary step towards deriving Fourier tail bounds that would imply a nontrivial PRG for this class using their framework, [4] proves the following Fourier bounds:

Proposition 29 (Theorem 6.1 of [4]). Let $p : \mathbb{F}_2^n \to \mathbb{F}_2$ be a degree-$d$ polynomial, and let $f(x) = (-1)^{p(x)}$. Then $L_{1,k}(f) \leq (k \cdot 2^{3d})^k$.

Note that this result cannot be applied to their original analysis, for they require a nontrivial bound at all levels, while this bound is trivial for $k = \Omega(\sqrt{n})$ and any $d$. While Theorem 16 can yield a nontrivial PRG by just applying the level-two bound, the dependence on $1/\varepsilon$ is at least quadratic. However, using our new, more flexible analysis, one can obtain a nontrivial PRG with polylogarithmic dependence on the error parameter. Our formal result is the following:

Theorem 30. Let $\mathcal{F}$ be the class of degree-$d$ polynomials over $\mathbb{F}_2$ on $n$ variables. Then there exists an explicit pseudorandom generator for $\mathcal{F}$ with error $\varepsilon$ and seed length

$$2^{O(d)} \cdot \log^3 \left( \frac{\log(n)}{\varepsilon} \right) \cdot \log(n/\varepsilon).$$

Proof. Fix $\varepsilon > 0$ and let $k = \Theta(\log((\log(n))/\varepsilon))$. By Proposition 29, we have that for all $j \leq k$,

$$L_{1,j}(\mathcal{F}) \leq \Theta \left( \log((\log(n))/\varepsilon) \cdot 2^{3d} \right)^j.$$

4 By applying this Fourier bound at level-two, one can use the fractional PRG of [6] to obtain seed length $2^{O(d)} \cdot \log(n) \cdot |\varepsilon|^{2+o(1)}$ using the random walks framework. This gives exponentially worse error dependence compared to our approach.
By setting $b = \Theta(\log(\log(n)/\varepsilon) \cdot 2^{\Theta(d)})$, we may apply Theorem 27 for $F$ and error $\varepsilon$. Note that $\varepsilon^{\Theta(1/\log(1/\varepsilon))} = O(1)$, so plugging in this value of $b$, we immediately obtain the desired pseudorandom generator.

For comparison, the best known construction by Viola [26], obtained by summing $d$ independent copies of a sufficiently good small-bias space, attains seed length $d \cdot \log n + O(d \cdot 2^{d^2} \log(1/\varepsilon))$, which for constant $\varepsilon$ and $d$ is within a constant factor of the optimal seed length. The generator implied by our analysis recovers this polylogarithmic dependence in $n/\varepsilon$, although with slightly worse dependence on $\log n$ and polynomially worse dependence in $\log(1/\varepsilon)$. Neither generator can handle superlogarithmic degree. While this result clearly falls short of the state-of-the-art, we emphasize that this generator is conceptually distinct from the existing constructions, and yet belongs to this generic random walk framework.

Our analysis allows us to exploit known Fourier bounds that are too weak for the existing analyses to obtain polylogarithmic error dependence. In particular, to get a nontrivial pseudorandom generator for polynomials of superlogarithmic degree with nontrivial seed length, our work shows that the following weaker conjecture would suffice to break the logarithmic degree barrier and still achieve polylogarithmic (in $n$) seed length for $\varepsilon = 1/poly(n)$:

\begin{definition}{Conjecture 31.}
Let $F$ be the class of degree-$d$ polynomials over $\mathbb{F}_2$ on $n$ variables. Then
\[ M_k(F) \leq (\text{poly}(k, \log n) \cdot 2^{O(d)})^k \]
for $k \leq O(\log n)$.
\end{definition}

In fact, we observe that to break the logarithmic degree barrier, it actually suffices that this holds just at level $k = 3$, though with poor dependence on $\varepsilon$. Note that this is a significantly weaker conjecture than positing that the same bounds hold for $L_{1,\varepsilon}(F)$. Moreover, as we explain in the next section, $M_k(F)$ can be controlled using correlation bounds, which are much better studied than $L_1$ Fourier bounds.

6 Bounds on $M_k(F)$ via Correlation with Shifted Majorities

As we have seen, our new analysis lets one construct PRGs from the weaker quantity $M_k(F)$. In this section, we extend the argument of Chattopadhyay, Hatami, Hosseini, Lovett, and Zuckerman [5] to show how bounds on $M_k(F)$ follow from covariance bounds with certain resilient functions (in particular, shifted majorities). In their paper, they deal with the case of $k = 2$; we rather straightforwardly generalize this argument, but stress that the approach is the same as in Section 6 of their paper. To that end, for convenience and consistency with their argument, we adopt their conventions and requisite definitions just for this section. We will now consider Boolean functions written as $f : \{0,1\}^n \to \{0,1\}$. Translating to this notation, for any such Boolean function $f$, let $e(f)(x) \triangleq (-1)^f(x)$. Then, letting $F = e(f)$, we now have $\hat{F}(S) = \mathbb{E}_x[F(x)e(\sum_{i \in S} x_i)]$.

\begin{definition}{Definition 32.}
The covariance between $f$ and $g$, where $f, g$ are Boolean is
\[ \text{cov}(f, g) \triangleq |\mathbb{E}[e(f(x))e(g(x))] - \mathbb{E}[e(f(x))][\mathbb{E}[e(g(x))]]|. \]
The covariance between a function $f$ and a class $G$ is defined as $\text{cov}(f, G) \triangleq \max_{g \in G} \text{cov}(f, g)$.
\end{definition}
For any $x \in \{0,1\}^n$, we write $|x|$ for its Hamming weight, i.e. $\sum_{i=1}^n x_i$. For any $a \in \{0,1,\ldots,n\}$, [5] defines $\text{Maj}_a$ by

$$\text{Maj}_a(x) \triangleq \begin{cases} 1 & \text{if } |x| > a \\ 0 & \text{otherwise}, \end{cases}$$

as well as the following associated functions for any $\theta \in [n/2]$:

$$\text{Thr}_\theta(x) \triangleq \begin{cases} (-1)^{\text{Maj}_{n/2}(x)} & \text{if } |x| - n/2 > \theta \\ 0 & \text{otherwise}. \end{cases}$$

We now prove the following lemma relating $M_k(\mathcal{F})$ with covariance bounds against the $k$-XORs of these functions:

**Lemma 33** (Lemma 6.1 of [5], adapted). Let $\mathcal{F}$ be any family of $(kn)$-variate Boolean functions that is closed under relabeling and negation of input variables. Suppose that for any $a_1, \ldots, a_k$ such that $|a_i - n/2| = O(\sqrt{kn \log n})$ for all $i \in [k]$, and all $f \in \mathcal{F}$, we have for some $t \geq 1$

$$\text{cov}(f, \oplus_{i=1}^k \text{Maj}_{a_i}) \leq \left(\frac{t}{n}\right)^k,$$

where $\oplus$ denotes the XOR function. Then,

$$M_k(\mathcal{F}) \leq O\left(\sqrt{k \log n}\right)^k.$$

To prove this lemma, [5] uses the following sequence of claims.

**Fact 34** (Claim 6.2 in [5]). For any $f \in \mathcal{F}$, let $F(x_1, \ldots, x_k) = e(f(x_1, \ldots, x_k))$. Under the hypotheses of Lemma 33, for any $1 \leq a_1, \ldots, a_k \leq O(\sqrt{kn \log n})$,\n
$$\left|\mathbb{E}_{x_1, \ldots, x_k} \left[ (F(x_1, \ldots, x_k) - \mathbb{E}[F]) \prod_{i=1}^k \text{Thr}_{a_i}(x_i) \right]\right| \leq \left(\frac{T}{n}\right)^k.$$

**Fact 35** (Claim 6.3 of [5]). For any $x \in \{0,1\}^n$, $\sum_{i=1}^n e(x_i) = 2 \sum_{1 \leq a \leq n/2} \text{Thr}_a(x)$.

**Fact 36** (Claim 6.4 of [5], adapted). For any Boolean function $f : \{0,1\}^{kn} \to \{0,1\}$, there exists a $k$-equipartition of $[kn]$ into disjoint sets $S_1, \ldots, S_k$ such that

$$\left| \sum_{S \subseteq [kn] : |S| = k} \hat{f}(S) \right| \leq C^k \sum_{i_1 \in S_1 \land i_2 \in S_2} \hat{f}(\{i_1, \ldots, i_k\})$$

for some absolute constant $C > 0$.

As this fact is not quite identical to that in [5], we give an argument here:

**Proof.** We use the probabilistic method: let $\mathcal{P}$ be the set of $k$-equipartitions of $[kn]$. Let $T \subseteq [kn]$ of size $k$ be arbitrary; without loss of generality, suppose $T = [k]$. Consider a uniformly random $k$-equipartition $P = S_1 \cup \cdots \cup S_k \in \mathcal{P}$. The probability that each $i \in T$ belongs to a distinct $S_i$ is easily seen to be

$$\prod_{i=1}^{k-1} \frac{(k-i) \cdot n - i}{kn - i} \geq \frac{(k-1)! \cdot n^{k-1}}{(kn)^{k-1}} = \frac{(k-1)!}{k^{k-1}} = e^{-O(k)},$$
where the last equality uses Stirling’s approximation. By symmetry, let \( \alpha \in \mathbb{N} \) be the number of \( k \)-equipartitions that any arbitrary subset \( T \) is in. Then we have

\[
\begin{align*}
\alpha \left| \sum_{S \subseteq [kn]: |S| = k} \hat{f}(S) \right| &= \sum_{P \in \mathcal{P}} \sum_{i_j \in S_j, \forall j \in [k]} \hat{f}(\{i_1, \ldots, i_k\}) \\
&\leq \sum_{P \in \mathcal{P}} \sum_{i_j \in S_j, \forall j \in [k]} \hat{f}(\{i_1, \ldots, i_k\}) \\
&\leq |\mathcal{P}| \max_{P \in \mathcal{P}} \sum_{i_j \in S_j, \forall j \in [k]} \hat{f}(\{i_1, \ldots, i_k\}).
\end{align*}
\]

The first line follows from simple counting, while the second is the triangle inequality. Rearranging, we deduce that (writing \( T \) as a generic subset of size \( k \))

\[
\begin{align*}
\left| \sum_{S \subseteq [kn]: |S| = k} \hat{f}(S) \right| &\leq \frac{|\mathcal{P}| \alpha}{\alpha} \max_{P \in \mathcal{P}} \sum_{i_j \in S_j, \forall j \in [k]} \hat{f}(\{i_1, \ldots, i_k\}) \\
&= \Pr_{P \sim \mathcal{P}} (T \in P)^{-1} \max_{P \in \mathcal{P}} \sum_{i_j \in S_j, \forall j \in [k]} \hat{f}(\{i_1, \ldots, i_k\}) \\
&\leq e^{O(k)} \max_{P \in \mathcal{P}} \sum_{i_j \in S_j, \forall j \in [k]} \hat{f}(\{i_1, \ldots, i_k\})
\end{align*}
\]

The last fact that is needed can be deduced from the Chernoff bound:

\[\textbf{Fact 37} \text{ (Claim 6.5 of [5], adapted).} \text{ For any } a \geq \Omega(\sqrt{kn \log n}), \text{ } \mathbb{E}[\text{Thr}_a] \leq O(1/n^k).\]

With these facts, we can now prove Lemma 33 in an entirely analogous fashion to [5]:

**Proof of Lemma 33.** Fix \( f \in \mathcal{F} \), and again write \( F(x_1, \ldots, x_k) = e(f(x_1, \ldots, x_k)) \). Let \( F' = F - \mathbb{E}[F] \). Let \( U_j = \{ i : (j - 1)n + 1 \leq i \leq jn \} \). Then, possibly after relabelling variables, we have by Fact 36 that

\[
\begin{align*}
\left| \sum_{S \subseteq [kn]: |S| = k} \hat{f}(S) \right| &\leq C^k \sum_{i_j \in U_j, \forall j \in [k]} \hat{f}(\{i_1, \ldots, i_k\}),
\end{align*}
\]

so we may turn to bounding this latter term. We have

\[
\begin{align*}
\left| \sum_{i_j \in U_j, \forall j \in [k]} \hat{f}(\{i_1, \ldots, i_k\}) \right| &= \left| \sum_{i_j \in U_j, \forall j \in [k]} \mathbb{E}[F'(x_1, \ldots, x_k) \prod_{j=1}^k e^f(x_j)_{i_j}] \right| \\
&= \left| \mathbb{E}[F'(x_1, \ldots, x_k) \prod_{j=1}^k e^f(x_j)_{i_j}] \right| \\
&\leq 2^k \sum_{1 \leq a \leq n/2, \forall j \in [k]} \left| \mathbb{E}[F'(x_1, \ldots, x_k) \prod_{i=1}^k \text{Thr}_{a_i}(x_i)] \right| \\
&\leq 2^k \left( \sum_{1 \leq a \leq O(\sqrt{kn \log n}), \forall j \in [k]} \left| \mathbb{E}[F'(x_1, \ldots, x_k) \prod_{i=1}^k \text{Thr}_{a_i}(x_i)] \right| + O(1) \right) \\
&\leq 2^k \cdot O(\sqrt{kn \log n})^k \cdot \left( \frac{T}{n} \right)^k \\
&= O(\sqrt{1k \log n})^k.
\end{align*}
\]
The first inequality follows from Fact 35, the second from Fact 37, and the last from Fact 34. Because we assumed that \( \mathcal{F} \) is closed under negations of input variables and \( f \in \mathcal{F} \) was arbitrary, we obtain the desired claim from Lemma 9 after absorbing the constant \( C \) above into the implicit constant in this bound.

7 Discussion and Open Questions

In this work, we have given a nearly complete interpolation between the previous PRGs obtained in the polarizing random walk framework by exploiting level-\( k \) bounds on the class of functions, thus answering an open question from [6]. We do so by exploiting an alternate Fourier analysis via Taylor’s theorem and utilizing multilinearity and random restrictions. This new analysis enables us to construct PRGs from bounds on the potentially much smaller and better-understood Fourier quantity \( M_k(\mathcal{F}) \), for any \( k \geq 3 \). By generalizing the connection established in [5], this reduces the problem of constructing PRGs in this framework to proving correlation bounds. Further, we show how to get a PRG with an improved seed length if we have bounds on \( L_{1,i}(\mathcal{F}) \), for all \( i \leq k \), where \( k \geq 3 \). A natural open question along these lines is to obtain the improved seed length using bounds on \( M_i(\mathcal{F}) \) (instead of \( L_{1,i}(\mathcal{F}) \)) for all \( i \leq k \). Another natural question is to construct a PRG using bounds on just \( M_2 \) (recall that [6] gives such a construction using bounds on \( L_{1,2}(\mathcal{F}) \) and our analysis only gives a non-trivial PRG from bounds on \( M_k(\mathcal{F}) \) when \( k \geq 3 \)).

Finally, exploiting known level-\( k \) bounds for \( \mathbb{F}_2 \) polynomials, our approach shows that the polarizing random walk framework can yield pseudorandom generators for the class of \( \mathbb{F}_2 \) polynomials that is competitive with the state of the art. As mentioned, we hope this paper gives evidence that stronger Fourier control (perhaps via proving the required correlation bounds) can give better PRGs using this framework, and can also handle classes that were previously not known to be possible. In particular, we emphasize that proving Conjecture 31 even for the case of \( k = 3 \) will lead to PRGs for \( \mathbb{F}_2 \)-polynomials with degree \( \omega((\log n)) \), a longstanding problem in complexity theory.

Abstract

Polynomial Identity Testing (PIT) is a fundamental computational problem. The famous depth-4 reduction (Agrawal & Vinay, FOCS’08) has made PIT for depth-4 circuits, an enticing pursuit. The largely open special-cases of sum-product-of-sum-of-univariates ($\Sigma^k[\Pi\Sigma\wedge]$) and sum-product-of-constant-degree-polynomials ($\Sigma^k[\Pi\Sigma^\delta]$), for constants $k, \delta$, have been a source of many great ideas in the last two decades. For eg. depth-3 ideas (Dvir & Shpilka, STOC’05; Kayal & Saxena, CCC’06; Saxena & Seshadhri, FOCS’10, STOC’11); depth-4 ideas (Beecken, Mittmann & Saxena, ICALP’11; Saha, Saxena & Saptharishi, Comput.Compl.’13; Forbes, FOCS’15; Kumar & Saraf, CCC’16); geometric Sylvester-Gallai ideas (Kayal & Saraf, FOCS’09; Shpilka, STOC’19; Peleg & Shpilka, CCC’20, STOC’21). We solve two of the basic underlying open problems in this work.

We give the \textit{first} polynomial-time PIT for $\Sigma^k[\Pi\Sigma\wedge]$. Further, we give the \textit{first} quasipolynomial time blackbox PIT for both $\Sigma^k[\Pi\Sigma\wedge]$ and $\Sigma^k[\Pi\Sigma^\delta]$. No subexponential time algorithm was known prior to this work (even if $k = \delta = 3$). A key technical ingredient in all the three algorithms is how the logarithmic derivative, and its power-series, modify the top $\Pi$-gate to $\wedge$.

1 Introduction: PIT & beyond

Algebraic circuits are natural algebraic analog of boolean circuits, with the logical operations being replaced by $+$ and $\times$ operations over the underlying field. The study of algebraic circuits comprise the large study of algebraic complexity, mainly pioneered (and formalized) by Valiant [87]. A central problem in algebraic complexity is an algorithmic design problem, known as Polynomial Identity Testing (PIT): given an algebraic circuit $C$ over a field $\mathbb{F}$ and input variables $x_1, \ldots, x_n$, determine whether $C$ computes the identically zero polynomial. PIT has found numerous applications and connections to other algorithmic problems. Among the examples are algorithms for finding perfect matchings in graphs [59, 62, 24], primality testing [4], polynomial factoring [52, 19], polynomial equivalence [21], reconstruction algorithms [48, 83, 44] and the existence of algebraic natural proofs [16, 53]. Moreover, efficient design of PIT algorithms is intrinsically connected to proving strong lower bounds [39, 1, 42, 23, 29, 17, 20]. Interestingly, PIT also emerges in
many fundamental results in complexity theory such as \( \text{IP} = \text{PSPACE} \) [82, 60], the PCP theorem [10, 11], and the overarching Geometric Complexity Theory (GCT) program towards \( \text{P} \neq \text{NP} \) [64, 63, 32, 41].

There are broadly two settings in which the PIT question can be framed. In the \textit{whitebox} setup, we are allowed to look inside the wirings of the circuit, while in the \textit{blackbox} setting we can only evaluate the circuit at some points from the given domain. There is a very simple randomized algorithm for this problem - evaluate the polynomial at a random point from a large enough domain. With very high probability, a nonzero polynomial will have a nonzero evaluation; this is famously known as the Polynomial Identity Lemma [66, 18, 89, 81]. It has been a long standing open question to derandomize this algorithm.

For many years, blackbox identity tests were only known for depth-2 circuits (equivalently sparse polynomials) [13, 49]. In a surprising result, Agrawal and Vinay [7] showed that a complete derandomization of blackbox identity testing for just depth-4 algebraic circuits (\( \Sigma \Pi \Sigma \Pi \)) already implies a near complete derandomization for the general PIT problem. More recent depth reduction results [50, 36], and the bootstrapping phenomenon [2, 55, 34, 9] show that even PIT for very restricted classes of depth-4 circuits (\( \text{even depth-3} \)) would have very interesting consequences for PIT of general circuits. These results make the identity testing regime for depth-4 circuits, a very meaningful pursuit.

Three PITs in one-shot. Following the same spirit, here we solve three important (and open) PIT questions. We give the \textit{first} deterministic polynomial-time whitebox PIT algorithm for the bounded sum-of-product-of-sum-of-univariates circuits (\( \Sigma^k \Pi \Sigma \Lambda \)) [71, Open Prob. 2]; polynomials computed by these circuits are of the form \( \Sigma_{i \in [k]} \Pi_j (g_{ij1}(x_1) + \cdots + g_{ijn}(x_n)) \) (Theorem 1). In fact, we also design the \textit{first} quasipolynomial-time blackbox PIT algorithm for the same model (Theorem 2a). To the best of our knowledge, no subexponential time algorithm was known prior to this work. A similar technique also gives a quasipolynomial-time blackbox PIT algorithm for the bounded top and bottom fanin circuits \( \Sigma^{[k]} \Pi \Sigma \Pi^{[\delta]} \) (where \( k \) and \( \delta \) are constants), see Theorem 2b. These circuits compute polynomials of the form \( \Sigma_{i \in [k]} \Pi_j g_{ij}(x) \), where \( \deg(g_{ij}) \leq \delta \). Even \( \delta = 2 \) was a challenging open problem [56, Open Prob. 2].

Prior works on the related models. In the last two decades, there has been a surge of results on identity testing for restricted classes of bounded depth algebraic circuits (eg. “locally” bounded independence, bounded read/occur, bounded variables). There have been numerous results on PIT for depth-3 circuits with bounded top fanin (known as \( \Sigma^{[k]} \Pi \Sigma \)-circuits). Divir and Shpilka [22] gave the first quasipolynomial-time deterministic whitebox algorithm for \( k = O(1) \), using rank based methods, which finally lead Karnin and Shpilka [45] to design algorithm of same complexity in the blackbox setting. Kayal and Saxena [47] gave the first polynomial-time algorithm of the same. Later, a series of works in [78, 79, 80, 5] generalized the model and gave \( n^{O(k)} \)-time algorithm when the algebraic rank of the product polynomials are bounded.

There has also been some progress on PIT for restricted classes of depth-4 circuits. A quasipolynomial-time blackbox PIT algorithm for \textit{multilinear} \( \Sigma^{[k]} \Pi \Sigma \Pi \)-circuits was designed in [43], which was further improved to a \( n^{O(k^2)} \)-time deterministic algorithm in [74]. A quasipolynomial blackbox PIT was given in [12, 56] when algebraic rank of the irreducible factors in each multiplication gate as well as the bottom fanin are bounded. Further interesting restrictions like sum of product of fewer variables, and more structural restrictions have been exploited, see [28, 6, 25, 61, 57]. Some progress has also been made for bounded top-fanin and bottom-fanin depth-4 circuits via incidence geometry [35, 84, 68]. In fact, very recently, [69] gave a polynomial-time blackbox PIT for \( \Sigma^{[3]} \Pi \Sigma \Pi^{[2]} \)-circuits.
P. Dutta, P. Dwivedi, and N. Saxena

Why were the problems open? As mentioned above, people have studied depth-4 PIT only with extra restrictions, mostly due to the limited applicability of the existing techniques: they were tailor-made for the specific models and do not generalize. Eg. the previous methods handle $\delta = 1$ (i.e. linear polynomials at the bottom) or $k = 2$ (via factoring, [71]). While $k = 2$ to 3, or $\delta = 1$ to 2 (i.e. “linear” to “quadratic”) already demands a qualitatively different approach.

Whitebox $\Sigma[k] \Pi \Sigma \Lambda$ model generalizes the famous bounded-top-fanin-depth-3 $\Sigma[k] \Pi \Sigma$ of [47]; but their Chinese Remaindering (CR) method, loses applicability and thus fails to solve even a slightly more general model. The blackbox setting involved similar “certifying path” ideas [79] which could be thought of as general CR. It comes up with an ideal $I$ such that $f \neq 0 \mod I$ and finally preserves it under a constant-variate linear map. The preservation gets harder (for both $\Sigma[k] \Pi \Sigma \Lambda$ and $\Sigma[k] \Pi \Sigma \Pi[\delta]$) due to the increased non-linearity of the ideal $I$ generators. Intuitively, larger $\delta$, via ideal-based routes, brings us to the Gröbner basis method (which is doubly-exponential-time in $n$) [88]. We know that ideals even with 3-generators (analogously $k = 4$) already capture the whole ideal-membership problem [73].

The algebraic-geometric approach to $\Sigma[k] \Pi \Sigma \Pi[\delta]$ has been explored in [12, 35, 61, 33]. The families which satisfy a certain Sylvester–Gallai configuration (called SG-circuits) is the harder case which is conjectured to have constant transcendence degree [35, Conj. 1]. Non-SG circuits is the case where the nonzeroness-certifying-path question reduces to radical-ideal non-membership questions [30]. This is really a variety question where one could use algebraic-geometry tools to design a poly-time blackbox PIT. In fact, very recently, Guo [33] gave a $s^3 \cdot$-time PIT by constructing explicit variety evasive subspace families. Unfortunately, this is not the case in the ideal non-membership; this scenario makes it much harder to solve $\Sigma[k] \Pi \Sigma \Pi[\delta]$. From this viewpoint, radical-ideal-membership explains well why the intuitive $\Sigma[k] \Pi \Sigma$ methods do not extend to $\Sigma[k] \Pi \Sigma \Pi[\delta]$.

Interestingly, Forbes [25] found a quasipolynomial-time PIT for $\Sigma \Lambda \Sigma \Pi[\delta]$ using shifted-partial derivative techniques; but it naively fails when one replaces the $\Lambda$-gate by $\Pi$ (the “measure” becomes too large). The “duality trick” [75] completely solves whitebox PIT for $\Sigma \Lambda \Sigma \Lambda$, by transforming it to a read-once oblivious ABP (ROABP); but it is inapplicable to our models with the top $\Pi$-gate (due to large waring rank and ROABP-width). A priori, our models are incomparable to ROABP, and thus, the famous PIT algorithms for ROABP [28, 27, 37] are not expected to help either.

Similarly, a naive application of the “Jacobian” + “certifying path” technique [5] fails for our models because it is difficult to come up with a faithful map (for constant-variate reduction). Kumar and Saraf [56] crucially used that the computed polynomial has low individual degree (such that [23] can be invoked), while in [57] they exploits the low algebraic rank of the polynomials computed below the top $\Pi$-gate. Neither of them hold, in general, for our models. Very recently, Peleg and Shpilka [69] gave a poly-time blackbox PIT for $\Sigma[3] \Pi \Sigma \Pi[2]$, via incidence geometry (eg. Edelstein-Kelly theorem involving “quadratic” polynomials), by solving [35, Conj. 1] for $k = 3, \delta = 2$. The method seems very strenuous to generalize even to “cubic” polynomials ($\delta = 3 = k$).

PIT for other models. Blackbox PIT algorithms for many restricted models are known. Egs. ROABP related models [70, 40, 3, 37, 38, 27, 8], log-variate circuits [26, 14], certain non-commutative models [31, 58]. We refer to [85, 76, 64, 77, 54, 72] for detailed surveys on PIT and related topics.
11.4 Bounded Depth-4 Identity Testing Paradigms

1.1 Our results: An analytic detour to three PITs

Though some attempts have been made to solve PIT for \(\Sigma^k[3] \Pi \Sigma \Lambda\), no subexponential time PIT for \(k \geq 3\) even in the whitebox settings is known, see [71, Open Prob. 2]. Our first result exactly addresses this problem and designs a polynomial-time algorithm (Algorithm 1). The technique (we call it DiDi-paradigm, Sec. 1.2) used is very analytic (k “non-ideal” based). Throughout the paper, we will work with \(F = \mathbb{Q}\), though all the results hold for field of large characteristic.

▶ Theorem 1 (Whitebox \(\Sigma \Pi \Sigma \Lambda\) PIT). There is a deterministic, whitebox \(s^{O(k \cdot k^3)}\)-time PIT algorithm for \(\Sigma^k[3] \Pi \Sigma \Lambda\) circuits of size \(s\), over \(F[x]\). (See Algorithm 1.)

▶ Remark.
1. Case \(k \leq 2\) can be solved by invoking [71, Thm.5.2]; but \(k \geq 3\) was open.
2. Our technique necessarily blows up the exponent exponentially in \(k\). In particular, it would be interesting to design a subexponential time algorithm when \(k = \Theta(\log s)\).
3. It is not clear if the current technique gives PIT for \(\Sigma^k[3] \Pi \Sigma \Lambda[2]\) circuits, i.e. sum of bivariate polynomials computed and fed into the top product gate.

Next, we go to the blackbox setting and address two models of interest, namely - \(\Sigma^k[3] \Pi \Sigma \Lambda\) and \(\Sigma^k[3] \Pi \Sigma \Pi \Lambda[6]\), where \(k, \delta\) are constants. The prior best algorithms were exponential-time in \(s\). Our work builds on previous ideas for unbounded top fanin – (1) Jacobian [5], (2) the known blackbox PIT for \(\Sigma \Lambda \Sigma \Lambda\) and \(\Sigma \Lambda \Sigma \Pi \Lambda[6]\) [37, 25] – maneuvering with an analytic approach, via power-series, which unexpectedly reduces the top \(\Pi\)-gate to a \(\wedge\)-gate.

▶ Theorem 2 (Blackbox PIT for depth-4).
(a) There is a deterministic \(s^{O(k \log \log s)}\)-time blackbox PIT algorithm for \(\Sigma^k[3] \Pi \Sigma \Lambda\) circuits of size \(s\), over \(F[x]\).
(b) There is a \(s^{O(\delta^2 k \log s)}\)-time blackbox PIT algorithm for \(\Sigma^k[3] \Pi \Sigma \Pi \Lambda[6]\) circuits of size \(s\), over \(F[x]\).

▶ Remark.
1. Thm. 2 has a better dependence on \(k\), but worse on \(s\), than Thm. 1. Our results are quasipoly-time even up to \(k, \delta = \text{poly}(\log s)\).
2. Thm. 2a is better than Thm. 2b, because \(\Sigma \Lambda \Sigma \Lambda\) has a faster algorithm than \(\Sigma \Lambda \Sigma \Pi \Lambda[6]\).
3. Even for \(\Sigma^3[3] \Pi \Sigma \Lambda\) and \(\Sigma^3[3] \Pi \Sigma \Pi \Lambda[3]\) models, we leave the poly-time blackbox question open.

1.2 Proof ideas: A technical synopsis

In this section, we overview the proof of Theorems 1-2. Both the proofs are analytic, i.e. they use logarithmic derivative, and its power-series expansion; greatly transforming the respective models. The first proof is inductive, while the second is a one-shot proof. We remark that in both the cases, we essentially reduce to the well-known “wedge” models, that have unbounded top fanin, yet for which PITs are known. This reduction is unforeseeable and quite “power”ful.

The analytic tool that we use, appears in algebra (and complexity theory) through the formal power series ring \(R[[x_1, \ldots, x_n]]\) (in short \(R[[x]]\)), see [65, 86, 19]. The advantages of the ring \(R[[x]]\) are many. They usually emerge because of the inverse: \((1 - x_1)^{-1} = \sum_{i \geq 0} x_1^i\), which does not make sense in \(R[x]\), but valid in \(R[[x]]\). Other analytic tools used are inspired from Wronskian (aka linear dependence) [51, Thm.7] [46], jacobian (aka algebraic dependence) [12, 5, 67], and logarithmic derivative operator \(\text{dlog}_z(f) = (\partial_z f)/f\).
Moreover, we will be working with the division operator (eg. $\mathbb{R}(z_1)$, over a certain ring $\mathbb{R}$). The divisions do not come for “free” – they require invertibility with respect to $z_1$ throughout (again landing us in $\mathbb{R}[[z_1]]$, see Lem. 18). We define class $\mathcal{C}/\mathcal{D} := \{ f/g \mid f \in \mathcal{C}, \mathcal{D} \ni g \neq 0 \}$, for circuit classes $\mathcal{C}, \mathcal{D}$, (similarly $\mathcal{C} \cdot \mathcal{D}$ denotes the class taking respective products).

**The DiDI-technique [Idea of Theorem 1].** The proof of Thm. 1 is recursive and uses a novel technique that we introduce in this work, called DiDI (Di = Divide, D = Derive, I = Induct).

We illustrate it in $k = 3$, which generalizes to any $k$.

Before going into the technicalities, we want to convey that $k = 3$ is perhaps the first non-trivial case-study. While $k = 1$ is the simplest case (follows directly using sparse-PIT hitting set [49]), $k = 2$ invokes a strong irreducibility property [71, Thm. 5.2]; and neither of them work for $k \geq 3$.

The case $k = 3$ asks to check whether $T_1 + T_2 + T_3 \neq 0$, where $T_i \in \Pi \Sigma \land$ of deg $< d$. We apply a homomorphism $\Phi : \mathbb{F}[x] \rightarrow \mathbb{F}[z_1, z_2]$ such that $x_i \mapsto z_1 \cdot x_i + \Psi(x_i)$ where $\Psi$ is another homomorphism. The map $\Psi : \mathbb{F}[x] \rightarrow \mathbb{F}[z_2]$ is a sparse-PIT map s.t. $\Psi(T_i) \neq 0$ for non-zero $T_i$, using [49], which ensures that the degree of $z_2$ is polynomially bounded (Theorem 11). Think of the variable $z_1$ as a degree-counter which also helps later to derive (the second “D” of DiDI). Observe that $\Phi$ is a nonzeroness preserving $1$-1 map:

$$T_1 + T_2 + T_3 \neq 0 \iff \Phi(T_1) + \Phi(T_2) + \Phi(T_3) \neq 0.$$  

Denote $R := \mathbb{F}(z_2)[z_1] / (z_1^d)$. We divide (first “D” of DiDI), by $\Phi(T_3)$, and derive, wrt $z_1$, to conclude that $T_1 + T_2 + T_3 = f$ over $\mathbb{F}[x]$ implies

$$\frac{\partial}{\partial z_1} \left( \frac{\Phi(T_1) + \Phi(T_2)}{\Phi(T_3)} \right) = \frac{\partial z_1}{\partial z_1} \left( \frac{\Phi(f)}{\Phi(T_3)} \right) \quad \text{over} \, R(x).$$

Denote $\tilde{T}_1 := \partial z_1 (\Phi(T_1)/\Phi(T_3))$ and $\tilde{T}_2 := \partial z_1 (\Phi(T_2)/\Phi(T_3))$. Moreover, $\partial z_1 (\Phi(f)/\Phi(T_3)) = 0$, over $R(x)$, if and only if either (1) $\Phi(f)/\Phi(T_3)$ is $z_1$-free, in which case it is an element of $\mathbb{F}(z_2)$, which can be easily argued by substituting $z_1 = 0$ in the map $\Phi$; or (2) $\text{val}_{z_1}(\partial z_1 (\Phi(f)/\Phi(T_3))) \geq d$, which is a contradiction since it implies $\text{val}_{z_1}(\Phi(f)) \geq d + 1$. Here, $\text{val}_{z_1}(\cdot)$ denotes the valuation i.e. the maximum power of $z_1$ dividing it (which easily extends to fractions via $\text{val}_{z_1}(p/q) := \text{val}_{z_1}(p) - \text{val}_{z_1}(q)$). Whenever we talk about val, think of working over $\mathbb{F}(z_2, x)(z_1)$; which is a ring notion that helps us computationally, and we track the degree of $z$. This discussion summarizes a crucial fact:

$$T_1 + T_2 + T_3 \neq 0 \iff \tilde{T}_1 + \tilde{T}_2 \neq 0 \quad \text{over} \ R(x), \text{ or } \left. \frac{\Phi(f)}{\Phi(T_3)} \right|_{z_1=0} \in \mathbb{F}(z_2) \setminus \{0\}. $$

We remark that the $z_1 = 0$ substitution is a natural condition as the derivation forgets the (mod $z_1$)-part. At the core, the idea is really “primal”: if a polynomial $g(x) \neq 0$, then either its derivative $g'(x) \neq 0$, or its constant-term $g(0) \neq 0$ (note: $g(0) \equiv g \mod x$).

Note that, the $z_1 = 0$ substitution part is easy by poly-degree restriction on $z_2$. If it is already $\neq 0$, we are done, otherwise we need to check $\tilde{T}_1 + \tilde{T}_2 \neq 0$. Rewrite $\tilde{T}_i$ as $\Phi(T_i)/\Phi(T_3)$.

$d\log_{z_1}(\Phi(T_i)/\Phi(T_3))$, where $d\log$ denotes the logarithmic-derivative, i.e., $d\log_{z_1}(\cdot) = \partial z_1(\cdot)/\cdot$.

**Convert top II to $\land$: version 1.** The map $\Psi$ ensures that $\Phi(T_3)$ is a unit over $\mathbb{R}$. A calculation shows that the action $d\log(\Sigma \land)$ is in $\Sigma \land / \Sigma \land \in \Sigma \land \Sigma \land$, over $R[x]$ (Claim 4). This crucially uses the inverse identity:

$$\frac{1}{1 - a \cdot z_1} = 1 + a \cdot z_1 + \ldots + a^{d-1} \cdot z_1^{d-1} \quad \text{over} \, R[x], \quad (1)$$

P. Dutta, P. Dwivedi, and N. Saxena 11:5

**CCC 2021**
11.6 Bounded Depth-4 Identity Testing Paradigms

for \( a \in \mathbb{R}[x] \). Since, dlog is additive over a product (Sec. 2), the action puts \( \text{dlog}(\Pi \Sigma \wedge / \Pi \Sigma \wedge) \) in \( \sum \text{dlog}(\Sigma \wedge) \), so in \( \Sigma \wedge \Sigma \wedge \). Thus, both \( \tilde{T}_1 \) and \( \tilde{T}_2 \) are of the bloated form \( (\Pi \Sigma \wedge / \Pi \Sigma \wedge) \cdot (\Sigma \wedge \Sigma \wedge) \), over \( \mathbb{R}(x) \).

Invertibility. The crucial point is that the \( \Pi \Sigma \wedge \) -circuits are still invertible over \( \mathbb{R}(x) \) as: dlog newly introduces only \( \Sigma \wedge \Sigma \wedge \), while the \( \Pi \Sigma \wedge \) -parts get multiplied by the \( \Pi \Sigma \wedge \) within \( T_i \)'s, which are invertible by \( \Psi \). Thus, such \( (\Pi \Sigma \wedge)|_{z_1=0} \in \mathbb{F}(z_2)\setminus\{0\} \) which will be useful later.

Bloated \( k = 2 \) model. Is the newly “reduced” model similar to \( k = 2 \) base-case? It is a more general expression \( (\Pi \Sigma \wedge / \Pi \Sigma \wedge) \cdot (\Sigma \wedge \Sigma \wedge) + (\Pi \Sigma \wedge / \Pi \Sigma \wedge) \cdot (\Sigma \wedge \Sigma \wedge) \). Let \( \tilde{T}_1 + \tilde{T}_2 =: f_1 \), over \( \mathbb{R}(x) \). We know that \( f_1 \neq 0 \) (by hypothesis). We again apply “Divide and Derive” of DiDi; here we divide with the \( \tilde{T}_1 \) where \( \text{val}_{z_1} \) is minimal. Wlog, \( \text{val}_{z_1}(\tilde{T}_2) =: v \), is the minimal valuation. Of course, \( 0 \leq v < d \) (strict because of \( \Psi \)). Let us define \( R := \mathbb{F}(z_2)[z_1]/(z_1^{d-v-1}) \).

Then, \( (\tilde{T}_1/\tilde{T}_2) + 1 = f_1/\tilde{T}_2 \) over \( R(x) \). This is well-defined as the division is being done by the minimum valuation (Lemma 18); thus after derivation, the modulus goes from \( z_1^d \) to \( z_1^{d-v-1} \) which is well-defined over \( R'(x) \). However, if we derive: \( \partial_{z_1}(f_1/\tilde{T}_2) =: f_2 \) may become \( 0 \) over \( R'(x) \). That could happen if and only if:

1. Either, \( f_1/\tilde{T}_2 \) is \( z_1 \)-free; in that case

\[
\left. \frac{f_1}{\tilde{T}_2} \right|_{z_1=0} = \left. \left( \frac{\tilde{T}_1}{\tilde{T}_2} + 1 \right) \right|_{z_1=0} \in \mathbb{F}(z_2) \cdot \frac{\Sigma \wedge \Sigma \wedge}{\Sigma \wedge \Sigma \wedge} + 1.
\]

This is easy to test using \( \Sigma \wedge \Sigma \wedge \) whitebox PIT (Lemma 19) (we keep track of the circuit-size respectively the degree of \( z_2 \) and ensure them polynomially bounded),

2. Or, \( \text{val}_{z_1}(f_2) \geq d-v-1 \implies \partial_{z_1}(f_1/\tilde{T}_2) = z_1^{d-v-1} \cdot p \), for some \( p \in R'(x) \) s.t. \( \text{val}_{z_1}(p) \geq 0 \); this further implies \( p \in \mathbb{F}(z_2,x)[[z_1]] \) (Lemma 18). Thus \( \text{val}_{z_1}(f_1/\tilde{T}_2) \geq d-v \implies f_1 = 0 \), over \( \mathbb{R}(x) \), a contradiction.

Thus, we check the easy condition (1). If the \( z_1 = 0 \) substitution outputs \( 0 \), we need to check whether other monomials of \( z_1 \) in \( f_2 \) survive. This suffices to conclude \( f \neq 0 \). Thankfully \( f_2 = \partial_{z_1}(\tilde{T}_1/\tilde{T}_2) \) is now a \( (\Pi \Sigma \wedge / \Pi \Sigma \wedge) \cdot (\Sigma \wedge \Sigma \wedge / \Sigma \wedge \Sigma \wedge) \) circuit over \( R'(x) \). This is the same analysis as above that converts top \( \Pi \) to \( \wedge \). Except, we may not be able to remove \( \Sigma \wedge \Sigma \Sigma \) from the denominator; so we work with this fractional bloated model. (Note: the reciprocal may not be in the polynomial ring \( R'[x] \), but only in the ring \( R'(x) \).)

Finally, identity testing of \( (\Pi \Sigma \wedge / \Pi \Sigma \wedge) \cdot (\Sigma \wedge \Sigma \wedge / \Sigma \wedge \Sigma \wedge) \), over \( R'(x) \) is easy: (1) \( \Sigma \wedge \Sigma \wedge \) is closed under coefficient extraction with respect to \( z_1 \) (Lemma 14), (2) whitebox identity testing is in \( \mathbb{P} \) for both \( \Pi \Sigma \wedge \) (Theorem 11) and \( \Sigma \wedge \Sigma \wedge \) (convert it to an ROABP using [75] and invoke [70], see Lemma 19), (3) the degree of \( z_1, z_2 \) respectively circuit-size remain polynomially bounded.

For general induction, our bloated model is \( \Sigma^k(\Pi \Sigma \wedge / \Pi \Sigma \wedge) \cdot (\Sigma \wedge \Sigma \wedge / \Sigma \wedge \Sigma \wedge) \). More work shows that it is closed under DiDi-technique. This is primarily what makes our polynomial-time algorithm possible. For details, refer to Section 3.1 and Algorithm 1

Jacobian hits again [Idea of Theorem 2]. Suppose we want to test \( T_1 + \ldots + T_k = 0 \), where \( T_i \in \Pi \Sigma \Pi^d \) (respec. \( \Pi \Sigma \wedge \)). We associate a famous polynomial – the Jacobian \( J(T_1, \ldots, T_r) \) (see Sec. 2). It captures the algebraic independence of \( T_1, \ldots, T_r \) assuming this to be a transcendence basis of the \( T_i \)’s (see Fact 23). If we could find an \( r \)-variate

\footnote{This is a special case of \( \Sigma^k(\Pi \Sigma \wedge \Sigma \wedge \) circuits; which is really depth-6.}
linear map \( \Phi \), that keeps \( T_1, \ldots, T_r \) algebraically independent, then \( \Phi(T_1), \ldots, \Phi(T_r) \) are again algebraically independent and it can be shown that for any \( C: C(T_1, \ldots, T_k) = 0 \iff C(\Phi(T_1), \ldots, \Phi(T_k)) = 0 \) (Fact 22). Such a map is called “faithful” [5].

The overall idea is to find an explicit homomorphism \( \Psi: \mathbb{F}[x] \rightarrow \mathbb{F}[x, z_1, z_2] \), and then fix \( x \) by a hitting-set \( H' \) to get a composed map \( \Psi' \) s.t. \( \text{rk}_{\mathbb{F}(x)} J_\Psi(T) = \text{rk}_{\mathbb{F}(x)} \Psi\left(J_x(T)\right) \) [here \( J \) is the jacobian matrix and \( T = (T_1, \ldots, T_r) \)]. Next, extend this map to \( \Phi: \mathbb{F}[z, y, t] \rightarrow \mathbb{F}[x, z_1, z_2] \) s.t. \( x_i \mapsto (\sum_{j=1}^k y_j t^{i,j}) + \Psi'(x_i) \), which is faithful. The construction of the map \( \Psi' \) is crucial. We efficiently construct it by reducing \( \Psi(J_x(T)) \) to \( \Sigma \land \Sigma \land \) circuits, which have quasipoly size hitting sets [25] (respec. Lemma 19).

**Jacobian works.** A priori, Jacobian is a difficult determinant to work with, and so is finding a faithful \( \Phi \). However, for the special models (in this paper) we are able to design \( \Phi \), mainly because of two reasons – (1) Jacobian being defined via partial derivatives, has a polynomially bounded. The idea behind the map is similar to that of Thm. 1. Next, we sketch why \( \Psi(J_x(T)) \rightarrow \Sigma \land \Sigma \land \) this again follows from the inverse identity Equation 1. We keep track of the degree of \( T \). Define, \( \Psi: x_i \mapsto z_i x_i + \Psi_1(x_i), \) where \( \Psi_1(.) \) is a sparse-PIT map s.t. \( \Phi_1: \mathbb{F}[x] \rightarrow \mathbb{F}[z_2] \) s.t. \( \Psi_1(T_i) \neq 0 \). Under the \( \Psi, T_i \) is a unit over ring \( R := F(z_2)[z_1]/\langle z_2^D \rangle \), where \( D \) is polynomially bounded. The idea behind the map is similar to that of Thm. 1. Next, we sketch why \( \Psi(J_x(T)) \) has a \( \Sigma \land \Sigma \land \) circuit (respec. \( \Sigma \land \Sigma \land \) of size \( s^{O(k)} \) over \( R[x] \).

**Convert top II to \( \land \): version 2.** The critical point is to show that \( 1/\Psi(g_1 \cdots g_k), \) over \( R[x] \), where \( g_i \in \Sigma \land \Sigma \land \) has \( s^{O(k)} \) size \( \Sigma \land \Sigma \land \) circuit (respec. \( \Sigma \land \Sigma \land \) circuit (see Lem. 10): this again follows from the inverse identity Equation 1. We keep track of the degree of \( z \) throughout, which eventually is bounded by \( s^{O(k)} \). Thus, the \( H' \) can be efficiently constructed from the hitting set of the respective models (of quasipolynomial size), see Thm. 27 and 19. The map \( \Phi \) ultimately provides a hitting set for \( T_1 + \cdots + T_k \), as we reduce to a PIT of a polynomial over “few” (roughly equal to \( k \)) variables, yielding a QP-time algorithm.

It is important to note that there was no power series in [5]; this really empowers the Jacobian technique as it now manifests new reduced models, for which a hitting-set is known. This technique is also inherently map-based. So, it requires a hitting-set and fails to give a poly-time whitebox PIT for the respective models. For the detailed proof, see Section 3.2.

## 2 Preliminaries

Before proving the results, we describe some of the assumptions and notations used throughout the paper. \( \mathbf{x} \) denotes \( (x_1, \ldots, x_n) \). \([n]\) denotes \( \{1, \ldots, n\} \).

**Logarithmic derivative.** Over a ring \( R \) and a variable \( y \), the logarithmic derivative \( d\log_y : R[y] \rightarrow R(y) \) is defined as \( d\log_y(f) := \partial(y f)/f \); here \( \partial_y \) denotes the partial derivative with respect to variable \( y \). One important property of \( \text{dlog} \) is that it is additive over a product as

\[
d\log_y(f \cdot g) = \frac{\partial_y(f \cdot g)}{f \cdot g} = \frac{f \cdot \partial_y g + g \cdot \partial_y f}{f \cdot g} = \text{dlog}_y(f) + \text{dlog}_y(g).
\]

We refer this effect as **linearization of product**.
11:8  Bounded Depth-4 Identity Testing Paradigms

Circuit size. Sparsity sp(·) refers to the number of nonzero monomials. In this paper, it is a parameter of the circuit size. In particular, size\((g_1 \cdots g_s) = \sum_{i \in [s]} \text{sp}(g_i) + \text{deg}(g_i)\), for \(g_i \in \Sigma \land \) (respec. \(\Sigma \Pi \Sigma \)). In whitebox settings, we also include the bit-complexity of the circuit (i.e. bit-complexity of the constants used in the wires) in the size parameter. Some of the complexity parameters of a circuit are depth (number of layers), syntactic degree (the maximum degree polynomial computed by any node), fanin (maximum number of inputs to a node).

Hitting set. A set of points \(H \subseteq \mathbb{F}^n\) is called a hitting-set for a class \(C\) of \(n\)-variate polynomials if for any nonzero polynomial \(f \in C\), there exists a point in \(H\) where \(f\) evaluates to a nonzero value. A \(T(n)\)-time hitting-set would mean that the hitting-set can be generated in time \(T(n)\), for input size \(n\).

Valuation. Valuation is a map \(\text{val}_y : \mathbb{R}[y] \to \mathbb{Z}_{\geq 0}\), over a ring \(\mathbb{R}\), such that \(\text{val}_y(\cdot)\) is defined to be the maximum power of \(y\) dividing the element. It can be easily extended to fraction field \(\mathbb{R}(y)\), by defining \(\text{val}_y(p/q) := \text{val}_y(p) - \text{val}_y(q)\); where it can be negative.

Field. We denote the underlying field as \(\mathbb{F}\) and assume that it is of characteristic 0. All our results hold for other fields (eg. \(\mathbb{Q}_p, \mathbb{F}_p\)) of large characteristic (see Remarks in Section 3.1–3.2).

Jacobian. The Jacobian of a set of polynomials \(\mathbf{f} = \{f_1, \ldots, f_m\}\) in \(\mathbb{F}[\mathbf{x}]\) is defined to be the matrix \(J_{\mathbf{f}}(\mathbf{x}) := (\partial f_i(\mathbf{x}))_{m \times n}\). Let \(S \subseteq \mathbf{x} = \{x_1, \ldots, x_n\}\) and \(|S| = m\). Then, polynomial \(J_S(\mathbf{f})\) denotes the minor (i.e. determinant of the submatrix) of \(J_{\mathbf{f}}(\mathbf{x})\), formed by the columns corresponding to the variables in \(S\). For its useful properties, see Appendix C.

3  Proof of the main theorems

This section proves Theorems 1-2. The proofs are self contained and we assume for the sake of simplicity that the underlying field \(\mathbb{F}\) has characteristic 0. When this is not the case, we discuss the corresponding required characteristic as remarks after the respective proofs.

3.1  Proof of Theorem 1

As seen in Section 1.2, we will induct over the bloated model which naturally generalizes \(\Sigma \Pi \Sigma \land\) circuits and works ideally under the DiDi-techniques. Formally, we define it below.

Definition 3. We call a circuit \(C \in \text{Gen}(k, s)\), over \(\mathbb{R}(\mathbf{x})\), for any ring \(\mathbb{R}\), with parameter \(k\) and size-\(s\), if \(C \in \Sigma^{[k]}(\Pi \Sigma \land /\Pi \Sigma \land \cdot (\Sigma \land \Sigma \land /\Sigma \land \Sigma \land))\). It computes \(f \in \mathbb{R}(\mathbf{x})\), if \(f = \sum_{i=1}^{k} T_i\), where

1. \(T_i := (U_i/V_i) \cdot (P_i/Q_i)\), for \(U_i, V_i \in \Pi \Sigma \land\) and \(P_i, Q_i \in \Sigma \land \Sigma \land\).
2. \(\text{size}(T_i) = \text{size}(U_i) + \text{size}(V_i) + \text{size}(P_i) + \text{size}(Q_i)\), and \(\text{size}(f) = \sum_{i \in [k]} \text{size}(T_i)\).

Eg. Size-\(s\) \(\Sigma^{[k]}\Pi \Sigma \land\)-circuit \(\in \text{Gen}(k, s)\). We will design a recursive algorithm.

Proof of Theorem 1. Begin with \(T_{i_0} := T_i\) and \(f_0 := f\) where \(T_{i_0} \in \Pi \Sigma \land; \sum_{i} T_{i_0} = f_0\), and \(f_0\) has size \(\leq s\). Assume \(\deg(f) < d \leq s\); we keep the parameter \(d\) separately, to help optimize the complexity later. In every recursive call we work with \(\text{Gen}(\cdot, \cdot)\) circuits. As the input case, define \(U_{i_0} := T_{i_0}\) and \(V_{i_0} := P_{i_0} := Q_{i_0} := 1\). Further define a 1-1 homomorphism \(\Phi : \mathbb{F}[\mathbf{x}] \to \mathbb{F}[\mathbf{x}, z_1, z_2]\) such that \(x_i \mapsto z_1 x_i + \Psi(x_i)\). Here, \(\Psi : \mathbb{F}[\mathbf{x}] \to \mathbb{F}[\mathbf{z}]\) is a sparse-PIT map [49] s.t. \(\Psi(U_{i_0}) \neq 0\), \(\forall i \in [k]\) (Theorem 11). Invertibility implies that
\( f_0 = 0 \iff \Phi(f_0) = 0 \). Further, the degree bound of \( z_2 \) on \( \Phi(T_{i,0}) \) is \( \text{poly}(s) \). The algorithm is recursive, and first reduces the identity testing from top-fanin \( k \) to \( k - 1 \). Note: \( k = 1 \) is trivial.

**0-th step. Efficient reduction from \( k \) to \( k - 1 \).** By assumption, \( \sum_{i=1}^{k} T_{i,0} = f_0 \) and \( T_{k,0} \neq 0 \). Apply \( \Phi \) both sides. Then divide and derive:

\[
\sum_{i \in [k]} T_{i,0} = f_0 \iff \sum_{i \in [k]} \Phi(T_{i,0}) = \Phi(f_0)
\]

\[
\iff \sum_{i \in [k-1]} \frac{\Phi(T_{i,0})}{\Phi(T_{k,0})} + 1 = \frac{\Phi(f_0)}{\Phi(T_{k,0})}
\]

\[
\iff \sum_{i \in [k-1]} \partial_{z_1} \left( \frac{\Phi(T_{i,0})}{\Phi(T_{k,0})} \right) = \partial_{z_1} \left( \frac{\Phi(f_0)}{\Phi(T_{k,0})} \right)
\]

\[
\iff \sum_{i=1}^{k-1} \Phi(T_{i,0}) \cdot \text{dlog} \left( \frac{\Phi(T_{i,0})}{\Phi(T_{k,0})} \right) = \partial_{z_1} \left( \frac{\Phi(f_0)}{\Phi(T_{k,0})} \right). \quad (2)
\]

Define the following:

- \( R_1 := \mathbb{F}(z_2)[z_1]/(z_1^d) \). Note that, Eqn. (2) holds over \( R_1(x) \).

- \( \tilde{T}_{i,1} := \Phi(T_{i,0})/\Phi(T_{k,0}) \cdot \text{dlog}(\Phi(T_{i,0})/\Phi(T_{k,0})) \), \( \forall \, i \in [k - 1] \).

- \( f_1 := \partial_{z_1}(\Phi(f_0)/\Phi(T_{k,0})) \), over \( R_1(x) \).

**Definability of \( T_{i,1} \) and \( f_1 \).** It is easy to see that these are well-defined terms. Here, we emphasize that we do not exactly compute/store \( \tilde{T}_{i,1} \) as a fraction where the degree in \( z_1 \) is \( < d \); instead it is computed/stored as an element in \( \mathbb{F}(z_2)(z_1, x) \), where \( z_1 \) is a formal variable. Formally, we compute \( T_{i,1} \in \mathbb{F}(z_2)(z_1, x) \), such that \( \tilde{T}_{i,1} = T_{i,1} \), over \( R_1(x) \). We keep track of the degree of \( z_1 \) and \( z_2 \) in \( T_{i,1} \). Thus, \( \sum_{i \in [k-1]} T_{i,1} = f_1 \), over \( R_1(x) \).

The “iff” condition. Equality in Eqn. (2) over \( R_1(x) \) is one-sided; however we want a \( \iff \) condition to efficiently reduce the identity testing. Note that \( f_1 \neq 0 \) implies \( \text{val}_{z_1}(f_1) < d := d_1 \). By assumption, \( \Phi(T_{k,0}) \) is invertible over \( R_1(x) \). Further, \( f_1 = 0 \), over \( R_1(x) \), implies –

1. Either, \( \Phi(f_0)/\Phi(T_{k,0}) \) is \( z_1 \)-free. This implies \( \Phi(f_0)/\Phi(T_{k,0}) \in \mathbb{F}(z_2)(x) \), which further implies it is in \( \mathbb{F}(z_2) \), because of the map \( \Phi \) (\( z_1 \)-free implies \( x \)-free, by substituting \( z_1 = 0 \)). Also, note that \( f_0, T_{k,0} \neq 0 \) implies \( \Phi(f_0)/\Phi(T_{k,0}) \) is a nonzero element in \( \mathbb{F}(z_2) \). Thus, it suffices to check whether \( \Phi(f_0)|_{z_1=0} = \Psi(f_0) \) is non-zero or not. Further, the degree of \( z_2 \) in \( \Psi(f_0) \) is polynomially bounded.

2. Or, \( \partial_{z_1}(\Phi(f_0)/\Phi(T_{k,0})) = z_1^{d_1} \cdot p \) where \( p \in \mathbb{F}(z_2)(z_1, x) \) s.t. \( \text{val}_{z_1}(p) \geq 0 \). By simple power series expansion, one can conclude that \( p \in \mathbb{F}(z_2, x)[[z_1]] \) (Lemma 18). Hence, \( \Phi(f_0)/\Phi(T_{k,0}) = z_1^{d_1+1} \cdot q \) where \( q \in F(z_2, x)[[z_1]] \), i.e.

\[
\Phi(f_0)/\Phi(T_{k,0}) \in (z_1^{d_1+1})_{F(z_2, x)[[z_1]]} \implies \text{val}_{z_1}(\Phi(f_0)) \geq d + 1,
\]

a contradiction.
Conversely, it is obvious that \( f_0 = 0 \) implies \( f_1 = 0 \). Thus, we have proved the following

\[
\sum_{i \leq k} T_{i,0} \neq 0 \quad \text{over } \mathbb{F}[x] \iff \sum_{i \leq k-1} T_{i,1} \neq 0 \quad \text{over } \mathbb{R}_1(x), \quad \text{or } \quad 0 \neq \Phi(f_0)|_{z_1=0} \in \mathbb{F}(z_2). 
\]

Eventually, we show that \( T_{i,1} \in (\Pi \Sigma \land/\Pi \Sigma \land \cdot (\Sigma \land \Sigma \land \Sigma \land \Sigma \land)), \) over \( \mathbb{R}_1(x) \), with polynomial blowup in size (Claim 4). So, the above circuit is in \( \text{Gen}(k-1, \cdot) \), over \( \mathbb{R}_1(x) \), which we recur on to finally give the identity testing. The 1-th step is a bit more tricky:

**Induction step.** Assume that we are in the \( j \)-th step (\( j \geq 1 \)). Our induction hypothesis assumes –

1. \( \sum_{i \leq k-j} T_{i,j} = f_j \), over \( \mathbb{R}_j(x) \), where \( \mathbb{R}_j := \mathbb{F}(z_2)[z_1]/(z_1^{d_j+1}) \), and \( T_{i,j} \neq 0 \).
2. Here, \( T_{i,j} := (U_{i,j}/V_{i,j}) \cdot (P_{i,j}/Q_{i,j}) \), where \( U_{i,j}, V_{i,j} \in \Pi \Sigma \land \Sigma \land \Sigma \land \Sigma \land \Sigma \land \) each in \( \mathbb{R}_j(x) \). Think of them being computed as \( \mathbb{F}(z_2)(z_1, x) \), with the degrees being tracked.
3. Wlog, assume that \( \text{val}_{z_1}(T_{i,j}) \geq 0, \forall i \in [k-j] \). Moreover, \( U_{i,j}|_{z_1=0} \in \mathbb{F}(z_2)\{0\} \) (similarly \( V_{i,j} \)).
4. \( f \neq 0 \), over \( \mathbb{F}[x] \iff f_j \neq 0 \), over \( \mathbb{R}_j(x) \), or, \( \forall j=0 \) \( \left((f_j/T_{k-1,j})|_{z_1=0} \neq 0, \right. \) over \( \mathbb{F}(z_2)(x) \).

We follow the 0-th step, without applying any further homomorphism. Note that the “or condition” in the last hypothesis is similar to the \( j = 0 \) case except that there is no \( \Phi \); this is because \( \Phi(f_0)|_{z_1=0} \neq 0 \iff \Phi(f_0/T_{k,0})|_{z_1=0} \neq 0 \). This condition just separates the derivative from the constant-term (as pointed in Section 1.2).

Let \( \text{val}_{z_1}(P_{i,j}/Q_{i,j}) := v_{i,j}, \) for \( i \in [k-j] \). Note that

\[
\min_i \text{val}_{z_1}(T_{i,j}) = \min_i \text{val}_{z_1}(P_{i,j}/Q_{i,j}) = v_{k-j,j}
\]

since \( \text{val}_{z_1}(U_{i,j}) = \text{val}_{z_1}(V_{i,j}) = 0 \) (else we reorder). We remark that \( 0 \leq v_{i,j} < d_j \) for all \( i \)'s in \( j \)-th step; upper-bound is strict, since otherwise \( T_{i,j} = 0 \) over \( \mathbb{R}_j(x) \).

**Min val computation is easy.** Finding this min val is easy, as we can compute \( \text{val}_{z_1}(P_{i,j}) \) and \( \text{val}_{z_1}(Q_{i,j}) \), \( \forall i \in [k-j] \). To compute \( \text{val} \), note that \( \text{coeff}_{z_1}(P_{i,j}) \) and \( \text{coeff}_{z_1}(Q_{i,j}) \) are in \( \Sigma \land \Sigma \land \Sigma \land \) as well, over \( \mathbb{F}(z_2)(x) \) (Lemma 14). We can keep track of \( z_1 \) degree and thus interpolate to find the minimum \( e < d_j \) such that it is \( \neq 0 \) (implying it to be the respective val).

**Efficient reduction from \( k-j \) to \( k-j-1 \).** Similar to the 0-th step, we divide and derive:

\[
\sum_{i \leq k-j} T_{i,j} = f_j \iff \sum_{i \leq k-j-1} T_{i,j} = f_j / T_{k-j,j} + 1 = f_j / T_{k-j,j}
\]

\[
\iff \sum_{i \leq k-j-1} \partial z_1(T_{i,j}/T_{k-j,j}) = \partial z_1(f_j/T_{k-j,j})
\]

\[
\iff \sum_{i=1}^{k-j-1} T_{i,j}/T_{k-j,j} \cdot \text{dlog}(T_{i,j}/T_{k-j,j}) = \partial z_1(f_j/T_{k-j,j}) \quad (3)
\]

Define the following:

- \( R_{j+1} := \mathbb{F}(z_2)[z_1]/(z_1^{d_{j+1}}) \), where \( d_{j+1} := d_j - v_{k-j,j} - 1 \).
- \( \bar{T}_{i,j+1} := T_{i,j}/T_{k-j,j} \cdot \text{dlog}(T_{i,j}/T_{k-j,j}), \forall i \in [k-j-1] \).
- \( f_{j+1} := \partial z_1(f_j/T_{k-j,j}), \) over \( \mathbb{R}_{j+1}(x) \).
Definability of $T_{i,j+1}$ and $f_{j+1}$. By the minimal valuation assumption, it follows that $\text{val}(f_j) \geq v_k - j, j$, and thus $\hat{T}_{i,j+1}$ and $f_{j+1}$ are all well-defined over $R_{j+1}(x)$. Note that, Eqn. (3) holds over $R_{j+1}(x)$ as $d_{j+1} < d_j$ (because, whatever identity holds true mod $z^d_j$ must hold mod $z^{d_{j+1}}$ as well). Hence, we must have $\sum_{i=1}^{k-j-1} \hat{T}_{i,j+1} = f_{j+1}$, over $R_{j+1}(x)$ [proving induction hypothesis (1)].

Similarly, we emphasize on the fact that we do not exactly compute $\hat{T}_{i,j+1}$ mod $z^{d_{j+1}}$; instead it is computed as a fraction in $F(z_2)(z_1, x)$, with formal $z_1$. Formally, we compute/store $T_{i,j+1} \in F(z_2)(z_1, x)$, such that $\hat{T}_{i,j+1} = T_{i,j+1}$, over $R_{j+1}(x)$. We keep track of the degree of $z_1$ and $z_2$ in $T_{i,j+1}$. Also, by definition, $\text{val}_{z_1}(T_{i,j+1}) \geq 0$ (as we divide by the min val) [proving induction hypothesis (3), first part]. Of course, we have $\sum_{i \in [k-j-1]} T_{i,j+1} = f_{j+1}$, over $R_{j+1}(x)$.

The “iff” condition. The above Eqn. (3) pioneers to reduce from $k - j$-summands to $k - j - 1$. But we want a $\iff$ condition to efficiently reduce the identity testing. If $f_{j+1} \neq 0$, then $\text{val}_1(f_{j+1}) < d_{j+1}$. Further, $f_{j+1} = 0$, over $R_{j+1}(x)$ implies:

1. Either, $f_j/T_{k-j,j}$ is $z_1$-free. This implies it is in $F(z_2)[x]$. Now, if indeed $f_0 \neq 0$, then the computed $T_{i,j}$ as well as $f_j$ must be non-zero over $F(z_2)(z_1, x)$, by induction hypothesis (as they are non-zero over $R_j(x)$). However,

$$\left( \frac{T_{i,j}}{T_{k-j,j}} \right) \bigg|_{z_1 = 0} = \left( U_{i,j} \cdot V_{k-j,j} \bigg| \frac{P_{i,j} \cdot Q_{k-j,j}}{P_{k-j,j} \cdot Q_{i,j}} \right) \bigg|_{z_1 = 0} \in F(z_2) \cdot \left( \frac{z \cdot \Sigma \cdot \Sigma}{\Sigma \cdot \Sigma} \right).$$

Thus,

$$f_j \in T_{k-j,j} \in \sum F(z_2) \cdot \left( \frac{\Sigma \cdot \Sigma}{\Sigma \cdot \Sigma} \right) \in \left( \frac{\Sigma \cdot \Sigma}{\Sigma \cdot \Sigma} \right).$$

Here we crucially use that $\Sigma \cdot \Sigma$ is closed under multiplication (Lemma 16). We show that the degree of $z_2$ (in denominator and numerator) in each $T_{i,j} / T_{k,j}$ is poly-bounded. Thus, this identity testing can be done in poly-time (Lemma 19). For, detailed time-complexity and calculations, see Claim 4 and its subsequent paragraph.

2. Or, $\partial_{z_1}(\frac{f_j}{T_{k-j,j}}) = \frac{d_{j+1}}{z_1} \cdot p$, where $p \in F(z_2)(z_1, x)$ s.t. $\text{val}_{z_1}(p) \geq 0$. By a simple power series expansion, one concludes that $p \in F(z_2)(x)[[z_1]]$ (Lemma 18). Hence, one concludes that

$$\frac{f_j}{T_{k-j,j}} \in \left( z_1^{d_{j+1}+1} \right)_{F(z_2)(x)[[z_1]]} \implies \text{val}_{z_1}(f_j) \geq d_j,$$

i.e. $f_j = 0$, over $R_j(x)$.

Conversely, $f_j = 0$, over $R_j(x)$, implies

$$\text{val}_{z_1}(f_j) \geq d_j \implies \text{val}_{z_1} \left( \partial_{z_1} \left( \frac{f_j}{T_{k-j,j}} \right) \right) \geq d_j - v_{k-j,j} - 1 \implies f_{j+1} = 0$, over $R_{j+1}(x)$.

Thus, we have proved that $\sum_{i \in [k-j]} T_{i,j} \neq 0$, over $R_{j+1}(x)$ iff

$$\sum_{i \in [k-j-1]} T_{i,j+1} \neq 0$, over $R_{j+1}(x)$, or, $0 \neq \left( \frac{f_j}{T_{k-j,j}} \right) \bigg|_{z_1 = 0} \in F(z_2)(x).$$

Therefore induction hypothesis (4) holds. All we need to show is hypothesis (2) and second part of (3). This part is involved in the size-analysis and dlog-computation, discussed below.
Invertibility of $\Pi\Sigma\land$-circuits. Before going into the size analysis, we want to remark that the dlog computation plays a crucial role here. The action $\text{dlog}(\Sigma\land\Sigma\land) \in \Sigma\land\Sigma\land / \Sigma\land\Sigma\land$, is of poly-size (Lemma 17). What is the action on $\Pi\Sigma\land$? dlog distributes the product additively, so it suffices to work with $\text{dlog}(\Sigma\land)$; and we show that $\text{dlog}(\Sigma\land) \in \Sigma\land\Sigma\land$ of poly-size.

Assuming these, we simplify

$$\frac{T_{i,j}}{T_{k,j,j}} = \frac{U_{i,j} \cdot V_{k-j,j}}{V_{i,j} \cdot U_{k-j,j}} \cdot \frac{P_{i,j} \cdot Q_{k-j,j}}{Q_{i,j} \cdot P_{k-j,j}},$$

and its dlog. Thus, using Eq. (3), $U_{i,(j+1)}$ grows to $U_{i,j} \cdot V_{k-j,j}$ (and similarly $V_{i,(j+1)}$). This also means: $U_{i,(j+1)}|_{z_1=0} \in F(z_2) \setminus \{0\}$ (proving hypothesis (3), second part).

Size analysis. We will show that $T_{i,j+1} \in (\Pi\Sigma / \Pi\Sigma\land) \cdot (\Sigma\land\Sigma\land / \Sigma\land\Sigma\land)$, over $R_{j+1}(x)$, with only polynomial blowup in size. Let size($T_{i,j}$) $\leq s_j$, for $i \in [k-j]$ and $j \in [k]$. Note that, by assumption, $s_0 \leq s$.

$\triangleright$ Claim 4 (Final size). $T_{1,k-1} \in (\Pi\Sigma / \Pi\Sigma\land) \cdot (\Sigma\land\Sigma\land / \Sigma\land\Sigma\land)$ of size $s^{O(k^2)}$, over $R_k(x)$.

Proof. Steps $j = 0$ and $j > 0$ are slightly different because of the $\Phi$. However the main idea of using power-series is the same which eventually shows that $\text{dlog}(\Sigma\land) \in \Sigma\land\Sigma\land$.

We first deal with $j = 0$. Let $A \cdot z_2^1 \cdot B = \Phi(g) \in \Sigma\land$, for some $A \in F(z_2)$ and $B \in R_1[x]$. Note that $A \neq 0$ because of the map $\Phi$. Further, size($B$) $\leq O(d \cdot \text{size}(g))$, as a single monomial of the form $x^c$ can produce $d+1$-many monomials. Over $R_1(x)$,

$$\text{dlog}(\Phi(g)) = -\frac{\partial_{z_2}(B \cdot z_2)}{A(1 - \frac{B}{A} \cdot z_2)} = -\frac{\partial_{z_2}(B \cdot z_2)}{A} \cdot \sum_{i=0}^{d-1} \left( \frac{B}{A} \right)^i \cdot z_1.$$  

Equation (4)

$B^i$ has a trivial $\land\Sigma\land$-circuit of size $O(d \cdot \text{size}(g))$. Also, $\partial_{z_2}(B \cdot z_2)$ has a $\land\Sigma\land$-circuit of size at most $O(d \cdot \text{size}(g))$. Using Waring identity (Lemma 15), we get that each $\partial_{z_2}(B : z_2) \cdot (B/A)^i \cdot z_1^i$ has size $O(i \cdot d \cdot \text{size}(g))$, over $R_1(x)$. Summing over $i \in [d_i - 1]$, the overall size is at most $O(d_i^2 \cdot d \cdot \text{size}(g))) = O(d^3 \cdot \text{size}(g))$, as $d_0 = d_1 = d$.

For the $j$-th step, we emphasize that the degree could be larger than $d$. Assume that syntactic degree of denominator and numerator of $T_{i,j}$ (each in $F[x, z]$) are bounded by $D_j$ (it is not $d_j$ as seen above; this is to save on the trouble of mod-computation at each step). Of course, $D_0 < d \leq s$.

For $j > 0$, the above summation in Equation 4 is over $R_j(x)$. However the degree could be $D_j$ (possibly more than $d_j$) of the corresponding $A$ and $B$. Thus, the overall size after the power-series expansion would be $O(D_j^2 \cdot d \cdot \text{size}(g))$.

Using Lemma 17, we can show that $\text{dlog}(P_{i,j}) \in \Sigma\land\Sigma\land / \Sigma\land\Sigma\land$ (similarly for $Q_{i,j}$), of size $O(D_j^2 \cdot s_j)$. Also $\text{dlog}(U_{i,j} \cdot V_{k-j,j}) \in \Sigma\land\Sigma\land$, i.e. sum of action of dlog on $\Sigma\land$ (since dlog linearizes product); and it can be computed by the above formulation. Thus, $\text{dlog}(T_{i,j} / T_{k-j,j})$ is a sum of 4-many $\Sigma\land\Sigma\land / \Sigma\land\Sigma\land$ of size at most $O(D_j^2 s_j)$ and 1-many $\Sigma\land\Sigma\land$ of size $O(D_j^2 d_j s_j)$ (from the above power-series computation) [Note: we summed up the $\Sigma\land\Sigma\land$-expressions from $\text{dlog}(\Sigma\land\Sigma\land)$ together]. Additionally the syntactic degree of each denominator and numerator (of the $\Sigma\land\Sigma\land / \Sigma\land\Sigma\land$) is $O(D_j)$. We rewrite the 4 expressions (each of $\Sigma\land\Sigma\land / \Sigma\land\Sigma\land$) and express it as a single $\Sigma\land\Sigma\land / \Sigma\land\Sigma\land$ using Waring identity (Lemma 16), with the size blowup of $O(D_j^2 s_j^2)$; here the syntactic degree blowup to $O(D_j)$. Finally we add the remaining $\Sigma\land\Sigma\land$ circuit (of size $O(D_j^2 s_j)$ and degree $O(d D_j)$) to get $O(s_j^2 D_j^{16} d)$.

To bound this, we need to understand the degree bound $D_j$. 

11:12 Bounded Depth-4 Identity Testing Paradigms
Finally we need to multiply $T_{i,j}/T_{k-j,j} \in (\Pi\Sigma \land /\Pi\Sigma\land \cdot (\Sigma\land\Sigma\land /\Sigma\land\Sigma\land)$ where each $\Sigma\land\Sigma\land$ is a product of two $\Sigma\land\Sigma\land$ expression of size $s_j$ and syntactic degree $D_j$; clubbed together owing a blowup of $O(D_j \cdot s_j^2)$. Hence multiplying it with $\Sigma\land\Sigma\land /\Sigma\land\Sigma\land$ expression obtained from dlog computation above gives size blowup of $s_{j+1} = s_j^7 \cdot D_{O(1)}^1 \cdot d $.

Computing $T_{i,j}/T_{k-j,j}$ increases the syntactic degree “slowly”; which is much less than the size blowup. As mentioned before, the deg-blowup in dlog-computation is $O(dD_j)$ and in the clearing of four expressions, it is just $O(D_j)$. Thus, $D_{j+1} = O(dD_j) \implies D_j = d^{O(j)}$.

The recursion on the size is $s_{j+1} = s_j^7 \cdot d^{O(j)}$. Using $d \leq s$ we deduce, $s_j = (sd)^{O(j-7)}$. In particular, $s_{k-1}$, size after $k-1$ steps is $s^{O(k-7)}$. This computation quantitatively establishes induction hypothesis (2).

Final time complexity. The above proof actually shows that $T_{1,k-1}$ has a “bloated” circuit of size $s^{O(k-7)}$ over $R_{k-1}(x)$; and that the degree bound on $s_2$ and $z_1$ (over $F(z_2)[z_1,x]$, keeping denominator and numerator “in place”) is $D_{k-1} = d^{O(k)}$. We note that whitebox PIT for both $\Pi\Sigma\land$ and $\Sigma\land\Sigma\land$ is in poly-time (using Thm. 11 & Lem. 19 respectively), and the proof above is constructive: we calculate $U_{i,j+1}$ (and other terms) from $U_{i,j}$ explicitly. Thus, this part can be done in $s^{O(k^2)}$ time.

What remains is to test the $z_1 = 0$-part of induction hypothesis (4); it could short-circuit the recursion much before $j = k - 1$. As we mentioned before, in this case, we need to do a PIT on $\Sigma\land\Sigma\land$ only. At the $j$-th step, when we substitute $z_1 = 0$, the size of each $T_{i,j}$ can be at most $s_j$ (by definition). We need to do PIT on a simpler model: $\sum_{[k-j]}^j F_{(z_2)}(\Sigma\land\Sigma\land /\Sigma\land\Sigma\land)$. We can clear out and express this as a single $\Sigma\land\Sigma\land /\Sigma\land\Sigma\land$ expression; with a size blowup of $s_{j}^{O(k-j)} \leq (sd)^{O((k-j)^7)}$. Further, use the fact that $\max_{j \in [k-1]} j(k-j)7^j = (k-1)^7 - 1$ (see Lemma 20). The degree bound on $s_{z_2}$ remains as before. Finally, use Lemma 19 for the base-case whitebox PIT. Thus, the final time complexity is $s^{O(k^2)}$.

Here we also remark that in $z_1 = 0$ substitution $\Sigma\land\Sigma\land /\Sigma\land\Sigma\land$ may be undefined. However, we keep track of $z_1$ degree of numerator and denominator, which will be polynomially bounded as seen in the discussion above. We can easily interpolate and cancel the $z_1$ power to make it work.

Bit complexity. It is routine to show that the bit-complexity is really what we claim. Initially, the given circuit has bit-complexity $s$. The main blowup happens due to the dlog-computation which is a poly-size blowup. We also remark that while using Lemma 16 (using Lemma 15), we may need to go to a field extension of at most $s^{O(k)}$ (because of the $\varepsilon(i)$ and correspondingly the constants $\gamma_{\varepsilon(2)},...\varepsilon(k)$, but they still are $s^{O(k)}$-bits). Also, Theorem 11 and Lemma 19 computations blowup bit-complexity polynomially. This concludes the proof.

Remark.
1. The above method does not give whitebox PIT (in poly-time) for $\Sigma^k\Pi\Sigma\Pi[6]$, as we do not know poly-time whitebox PIT for $\Sigma^k\Pi\Sigma\Pi[6]$. However, the above methods do show that whitebox-PIT for $\Sigma^k\Pi\Sigma\Pi[6]$ polynomially reduces to whitebox-PIT for $\Sigma^k\Pi\Sigma\Pi[6]$.
2. DiDiI-technique can be used to give whitebox PIT for the general bloated model Gen$(k,s)$.
3. The above proof works when the characteristic is $\geq d$. This is because the nonzeroness remains preserved after derivation wrt $z_1$. 
3.2 Proof of Theorem 2

Here we prove Theorem 2b only. The proof technique of part (a) has analogous calculations (using bottom Σ∧ instead of ΣΠ[δ]); see Appendix D. The main idea is to use the Jacobian [5]. In fact, it solves a more general model than Σ[δ]ΠΣΠ[δ].

Transcendence basis. Polynomials \( T_1, \ldots, T_m \) are called algebraically dependent if there exists a nonzero annihilator \( A \) s.t. \( A(T_1, \ldots, T_m) = 0 \). Transcendence degree is the size of the largest subset \( S \subseteq \{T_1, \ldots, T_m\} \) that is algebraically independent. Then \( S \) is called a transcendence basis.

\[ \text{Problem 5.} \quad \text{Let } \{T_i \mid i \in [m]\} \text{ be } \Pi \Sigma \Pi[\delta] \text{ circuits of (syntactic) degree at most } d \text{ and size } s. \text{ Let the transcendence degree of } T_i \text{'s, } \text{trdeg}(T_1, \ldots, T_m) = k < s. \text{ Further, } C(x_1, \ldots, x_m) \text{ be a circuit of (size + deg) } < s'. \text{ Design a black-box-PIT algorithm for } C(T_1, \ldots, T_m). \]

Trivially, \( \Sigma[k] \Pi \Sigma \Pi[\delta] \) is a very special case of the above setting. Let \( T := \{T_1, \ldots, T_m\} \). Let \( T_k := \{T_1, \ldots, T_k\} \) be a transcendence basis. For \( T_i = \prod_j g_{ij} \), we denote the set \( L(T_i) := \{g_{ij} \mid j\} \).

We want to find an explicit homomorphism \( \Psi : \mathbb{F}[x] \rightarrow \mathbb{F}[z_1, z_2] \) s.t. \( \Psi(J_{x_k}(T)) \) is of a “nice” form. In the image we fix \( x \) suitably, to get a composed map \( \Psi' : \mathbb{F}[x] \rightarrow \mathbb{F}[z_1, z_2] \) s.t. \( \text{rk}_\mathbb{F}(x)J_{x_k}(T) = \text{rk}_\mathbb{F}(x)\Psi(J_{x_k}(T)) \). Then, we can extend this map to \( \Phi : \mathbb{F}[x] \rightarrow \mathbb{F}[z, y, t] \) s.t. \( x_i \mapsto (\sum_{j=1}^k y_{ij}^{\Psi}(x_i)) + \Psi'(x_i) \), which is faithful [5, Lemma 2.7]; see Lemma 24. We show that the map \( \Phi \) can be efficiently constructed using a scaling and shifting map \( (\Phi) \) which is eventually fixed by the hitting set \( (H' \text{ defining } \Psi') \) of a \( \Sigma \land \Sigma \Pi[\delta] \) circuit. Overall, \( \Phi(f) \) is a \( k+3 \)-variate polynomial for which a trivial hitting set exists.

\[ \text{Wlog, } J_{x_k}(T) \text{ is full rank with respect to the variable set } x_k = (x_1, \ldots, x_k). \text{ Thus, by assumption, } J_{x_k}(T) \neq 0 \text{ (for notation, see Section 2). We want to construct a } \Psi \text{ s.t. } \Psi(J_{x_k}(T)) \text{ has an “easier” PIT. We have the following identity } [5, \text{ Eqn. 3.1}], \text{ from the linearity of the determinant, and the simple observation that } \partial_x(T_i) = T_i \cdot \left(\sum_j \partial_x(g_{ij})/g_{ij}\right), \text{ where } T_i = \prod_j g_{ij}: \]

\[ J_{x_k}(T_k) = \sum_{g_{1, \ldots, g_k} \in L(T_k)} \left(\frac{T_1 \cdots T_k}{g_1 \cdots g_k}\right) \cdot J_{x_k}(g_1, \ldots, g_k). \tag{5} \]

The homomorphism \( \Psi \). Define \( \Psi : \mathbb{F}[x] \rightarrow \mathbb{F}[z_1, z_2] \) as \( x_i \mapsto z_1 \cdot x_i + \Psi_1(x_i) \), where \( \Psi_1 : \mathbb{F}[x] \rightarrow \mathbb{F}[z_2] \), is a sparse-PIT map. The importance of \( \Psi_1 \) is to ensure that \( \Psi_1(g) \neq 0 \), \( \forall g \in \bigcup_i L(T_i) \). As \( \text{deg}(g) \leq \delta \), \( \text{sp}(g) \leq \bigl(\frac{n+\delta}{\delta}\bigr). \text{ Thus, } [49] \text{ (Theorem 11) gives the upper bound: } \]

\[ \text{deg}_{z_2}(\Psi(g)) \leq \delta \cdot \left(\frac{n+\delta}{\delta}\right) \cdot n \cdot \log \delta \leq 1. \]

Denote the ring \( \mathbb{R}[x] \) where \( \mathbb{R} := \mathbb{F}[z_2]/(z_2^p) \), and \( D := \text{deg}(d - 1) + 1 \). Being 1-1, \( \Psi \) is clearly a non-zero preserving map. Moreover,

\[ \text{Claim 6. } J_{x_k}(T_k) = 0 \iff \Psi(J_{x_k}(T_k)) = 0, \text{ over } \mathbb{R}[x]. \]

Proof. As \( \text{deg}(T_i) \leq d \), each entry of the matrix can be of degree at most \( d - 1 \); therefore \( \text{deg}(J_{x_k}(T_k)) \leq k(d - 1) = D - 1 \). Thus, \( \text{deg}_{z_2}(\Psi(J_{x_k}(T_k))) < D \). Hence, the conclusion. <\
Eqn. (5) implies that
\[
\Psi(J_{x_k}(T_k)) = \Psi(T_1 \cdots T_k) \cdot \sum_{g_1 \in L(T_1), \ldots, g_k \in L(T_k)} \frac{\Psi(J_{x_k}(g_1, \ldots, g_k))}{\Psi(g_1 \cdots g_k)}.
\] (6)

As \( T_i \) has product fanin \( s \), the top-fanin in the sum in Eqn. (6) can be at most \( s^k \). Then define,
\[
\tilde{F} := \sum_{g_1 \in L(T_1), \ldots, g_k \in L(T_k)} \frac{\Psi(J_{x_k}(g_1, \ldots, g_k))}{\Psi(g_1 \cdots g_k)} \text{, over } R[x].
\] (7)

**Well-definability of \( \tilde{F} \).** Note that,
\[
\Psi(g_i) \equiv \Psi_1(g_i) \mod z_1 \neq 0 \implies 1/\Psi(g_1 \cdots g_k) \in F(z_2)[[x, z_1]].
\]

Thus, RHS is an element in \( F(z_2)[[x, z_1]] \) and taking mod \( z_1^{D_1} \) it is in \( R[x] \). We remark that instead of minimally reducing mod \( z_1^{D_1} \), we will work with an \( F \in F(z_2)[z_1, x] \) such that \( F = \tilde{F} \) over \( R[x] \). Further, we ensure that the degree of \( z \) is polynomially bounded.

▷ Claim 7. Over \( R[x] \), \( \Psi(J_{x_k}(T_k)) = 0 \iff F = 0 \).

Proof sketch. This follows from the invertibility of \( \Psi(T_1 \cdots T_k) \) in \( R[x] \).

**The hitting set \( H' \).** By \( J_{x_k}(T_k) \neq 0 \), and Claims 6-7, we have \( F \neq 0 \) over \( R[x] \). We want to find \( H' \subseteq F^n \), s.t. \( \Psi(J_{x_k}(T_k))|_{x=\alpha} \neq 0 \), for some \( \alpha \in H' \) (which will ensure the rank-preservation). Towards this, we will show (below) that \( F \) has \( s^{O(D_k)} \)-size \( \Sigma \land \Sigma \Pi^{[\delta]} \)-circuit over \( R[x] \). Next, Theorem 27 provides the hitting set \( H' \) in time \( s^{O(D_k \log s)} \).

▷ Claim 8 (Main size bound). \( F \in R[x] \) has \( \Sigma \land \Sigma \Pi^{[\delta]} \)-circuit of size \( s^{3^\delta} O(k) \).

The proof studies the two parts of Eqn. (7).

1. The numerator \( \Psi(J_{x_k}(g_1, \ldots, g_k)) \) has \( O(3^\delta 2^k k! \cdot s) \)-size \( \Sigma \land \Sigma \Pi^{[\delta-1]} \)-circuit (see Lemma 9), and
2. \( 1/\Psi(g_1 \cdots g_k) \), for \( g_i \in L(T_i) \) has \( s^{3^\delta} O(k) \)-size \( \Sigma \land \Sigma \Pi^{[\delta]} \)-circuit; both over \( R[x] \) (see Lemma 10).

▷ **Lemma 9 (Numerator size).** \( \Psi(J_{x_k}(g_1, \ldots, g_k)) \in \Sigma \land \Sigma \Pi^{[\delta-1]} \) of size \( O(3^\delta 2^k k! \cdot s) =: s_2 \).

**Proof sketch.** One can show that \( J_{x_k}(g_1, \ldots, g_k) \in \Sigma^{[k]} \Pi^{[k]} \Sigma^{[\delta-1]} \) of size \( O(k! s) \), where \( g_i \in L(T_i) \) (Claim 25): this basically follows from the determinant expansion which has fanin \( k \) and the degree at the bottom is \( \leq \delta - 1 \) because of the derivative. Moreover, for a \( g \in \Sigma^{[\delta-1]} \), we have \( \Psi(g) \in \Sigma \Pi^{[\delta-1]} \) of size at most \( 3^\delta \cdot \text{size}(g) \), over \( R[x] \) (Claim 26): this follows from the fact that \( x^\delta \) (where \( |e|_0 \leq \delta \)), after shift, can produce at most \( \prod(e_i + 1) \leq e^\delta \) many monomials (for large \( n \)). Combining these, one concludes \( \Psi(J_{x_k}(g_1, \ldots, g_k)) \in \Sigma^{[k]} \Pi^{[k]} \Sigma^{[\delta-1]} \), of size \( O(3^\delta k! \cdot s) \). We convert the \( \Pi \)-gate to \( \land \) gate using waring identity (Lemma 15) which blows up the size by a multiple of \( 2^{k-1} \). Thus, \( \Psi(J_{x_k}(g_1, \ldots, g_k)) \in \Sigma \land \Sigma \Pi^{[\delta-1]} \) of size \( O(3^\delta 2^k k! \cdot s) \).

By power series expansion of expressions like \( 1/(1 - a \cdot z_1) \), one can conclude that \( 1/\Psi(g) \) has a small \( \Sigma \land \Sigma \Pi^{[\delta]} \)-circuit, which would further imply the same for \( 1/\Psi(g_1 \cdots g_k) \) (see below).
Lemma 10 (Denominator size). Let $g_i \in L(T_i)$. Then, \(1/\Psi(g_1 \cdots g_k)\) can be computed by a \(\Sigma \land \Sigma \Pi[\delta]^{-}\)-circuit of size \(s_1 := (s3^\delta)^{O(k)},\) over \(R[x]\).

Proof. Let \(g \in L(T_i)\) for some \(i\). Assume, \(\Psi(g) = A - z_i \cdot B,\) for some \(A \in \mathbb{F}[z_2]\) and \(B \in R[x]\) of degree \(\delta\), with \(\deg(B) \leq 3^\delta \cdot s\), from Claim 26. Note that, over \(R[x]\),

\[
1/\Psi(g) = \frac{1}{A(1 - \frac{B}{A} \cdot z_i)} = \frac{1}{A} \cdot \sum_{i=0}^{D-1} \left(\frac{B}{A}\right)^i \cdot z_i.
\]

As, size\((B^i)\) has a trivial \(\land \Sigma \Pi[\delta]^{-}\)-circuit (over \(R[x]\)) of size \(\leq 3^\delta \cdot s + i\); summing over \(i \in [D-1]\), the overall size is at most \(D \cdot 3^\delta \cdot s + O(D^2)\). As \(D < k \cdot d\), we conclude that \(1/\Psi(g)\) has \(\Sigma \land \Sigma \Pi[\delta]^{-}\)-size \(\mathrm{poly}(s \cdot k \cdot d3^\delta)\), over \(R[x]\). Multiplying \(k\)-many such products directly gives an upper bound of \((s \cdot 3^\delta)^{O(k)}\), using Lemma 16 (basically, waring identity).

Proof of Claim 8. Combining Lemmas 9-10, observe that \(\Psi(J_{x_k}(g_1, \ldots, g_k))/\Psi(g_1 \cdots g_k)\) has \(\Sigma \land \Sigma \Pi[\delta]^{-}\)-circuit of size at most \((s_1 \cdot s_2)^2 = (s \cdot 3^\delta)^{O(k)},\) over \(R[x]\), using Lemma 16. Summing up at most \(s^k\) many terms (by defn. of \(F\)), the size still remains \((s \cdot 3^\delta)^{O(k)}\).

Degree bound. As, syntactic degree of \(T_i\) are bounded by \(d\), and \(\Psi\) maintain \(\deg_x = \deg_{z_1}\), we must have \(\deg_{z_1}(\Psi(J_{x_k}(g_1, \ldots, g_k))) = \deg_{z_1}(J_{x_k}(g_1, \ldots, g_k)) \leq D - 1\). Similarly, by assumption \(\deg_{z_2}(\Psi(g_1)) \leq D_1 := \mathrm{poly}(n^\delta)\), and thus \(\deg_{z_2}(\Psi(J_{x_k}(g_1, \ldots, g_k))) \leq D_1 \cdot k\). Note that, Lemma 9 actually works over \(F[x, z]\) and thus there is no additional degree blowup (in \(z\)). However, there is some degree blowup in Lemma 10, due to Eqn. (8).

Note that Eqn. (8) shows that over \(R[x]\),

\[
1/\Psi(g) = \left(\frac{1}{A^D}\right) \cdot \sum_{i=0}^{D-1} A^{D-1-i} z_i \cdot B^i =: \frac{p(x, z)}{q(z_2)},
\]

where \(q(z_2) = A^D\). We think of \(p \in \mathbb{F}[x, z]\) and \(q \in \mathbb{F}[z_2]\). It follows that \(\deg_{z_2}(q) \leq D_1 \cdot D\). Also, \(\deg_{z_1}(\Psi(g)) \leq \delta\) implies \(\deg_{z_1}(p) \leq \deg_{z_1}((B \cdot z_1)^{D-1}) \leq \delta \cdot (D - 1)\). Since, \(\deg_{z_1}(\Psi(g)) \leq D_1\), by assumption, \(\deg_{z_1}(p) \leq \max\deg_{z_2}(A^{D-1-i}) \cdot B^i \leq D_1 \cdot (D - 1)\).

Finally, denote \(1/\Psi(g_1 \cdots g_k) := P_{g_1 \cdots g_k} / Q_{g_1 \cdots g_k}\), over \(R[x]\). This is just multiplying \(k\)-many \((p/q)\)'s; implying a degree blowup by a multiple of \(k\). In particular,

\[
\begin{align*}
\deg_{z_2}(P_{\emptyset}) &\leq \delta \cdot k \cdot (D - 1), \\
\deg_{z_2}(P_{\{1\}}) &\leq D_1 \cdot (D - 1) \cdot k, \\
\deg_{z_2}(Q_{\emptyset}) &\leq D_1 \cdot D \cdot k.
\end{align*}
\]

Thus, in Eqn. (7), summing up \(s^k\)-many terms gives an expression (over \(R[x]\)):

\[
F = \sum_{g_i \in L(T_i), g_k \in L(T_k)} \Psi(J_{x_k}(g_1, \ldots, g_k)) \cdot \left(\frac{P_{g_1, \ldots, g_k}}{Q_{g_1, \ldots, g_k}}\right) =: \frac{P(x, z)}{Q(z_2)}.
\]

Verify that \(Q \in \mathbb{F}[z_2]\) is of degree at most \(s^k \cdot D_1 \cdot D \cdot k = s^{O(k)} \cdot \mathrm{poly}(n^\delta)\) (since \(k, d < s\)). A similar bound also holds for \(\deg_{z_2}(P)\). The degree of \(z_1\) also remains bounded by

\[
\max_{g_i \in L(T_i), i \in [k]} \deg_{z_1}(P_{g_1 \cdots g_k}) + \delta k \leq \mathrm{poly}(s).
\]

Using the degree bounds, we finally have \(P \in \mathbb{F}[x, z]\) as a \(\Sigma \land \Sigma \Pi[\delta]^{-}\)-circuit (over \(F(z)\)) of size \(s^{O(\delta)} (s3^\delta)^{O(k)} = 3^{O(sk)}s^{O(k+\delta)} =: s_3\).
We want to construct a set $H' \subseteq F^n$ such that the action $P(H', z) \neq 0$. Using (Theorem 27), we conclude that it has $s^{O(\delta \log s)} = s^{O(\delta k \log s)}$ size hitting set which is constructible in a similar time. Hence, the construction of $\Phi$ follows, making $\Phi(f)$ a $k + 3$ variate polynomial. Finally, by the obvious degree bounds of $y, z, t$ from the definition of $\Phi$, we get the blackbox PIT algorithm with time-complexity $s^{O(\delta k \log s)}$; finishing Theorem 2b.

We could also give the final hitting set for the general problem.

Solution to Problem 5. We know that $C(T_1, \ldots, T_m) = 0 \iff E := \Phi(C(T_1, \ldots, T_m)) = 0$. Since, $H'$ can be constructed in $s^{O(\delta k \log s)}$-time, it is trivial to find hitting set for $E|_{H'}$ (which is just a $k + 3$-variate polynomial with the aforementioned degree bounds). The final hitting set for $E$ can be constructed in $s^{O(k) \cdot s^{O(\delta k \log s)}}$-time.

Remark.
1. As Jacobian Criterion (Fact 23) holds when the characteristic is $> d \text{trdeg}$, it is easy to conclude that our theorem holds for all fields of char $> d^k$.

2. The above proof gives an efficient reduction from blackbox PIT for $\Sigma[k] \Pi \Sigma \Pi \delta$ circuits to $\Sigma \Lambda \Sigma \Pi \delta$ circuits. In particular, a poly-time hitting set for $\Sigma \Lambda \Sigma \Pi \delta$ circuits would put PIT for $\Sigma[k] \Pi \Sigma \Pi \delta$ in $P$.

3. Also, DiDI-technique (of Theorem 1) directly gives a blackbox algorithm, but the complexity is exponentially worse (in terms of $k$ in the exponent) for its recursive blowups.

4 Conclusion

This work introduces the powerful DiDI-technique and solves three open problems in PIT for depth-4 circuits, namely $\Sigma[k] \Pi \Sigma \Pi \delta$ (blackbox) and $\Sigma[k] \Pi \Sigma \Lambda$ (both whitebox and blackbox). Here are some immediate questions of interest which require rigorous investigation.

1. Can the exponent in Theorem 1 be improved to $O(k)$? Currently, it is exponential in $k$.
2. Can we improve Theorem 2b to $s^{O(\log \log s)}$ (like in Theorem 2a)?
3. Can we design a polynomial-time PIT for $\Sigma[k] \Pi \Sigma \Pi \delta$?
4. Design a poly-time PIT for $\Sigma \Lambda \Sigma \Pi \delta$ circuits (i.e. unbounded top-fanin)?
5. Can we solve PIT for $\Sigma[k] \Pi \Sigma \Lambda [2]$ in subexponential-time?
6. Can we design a subexponential-time PIT for rational functions of the form $\Sigma (1/\Sigma \Lambda) \Sigma$ or $\Sigma (1/\Sigma \Pi)$ (for unbounded top-fanin)?

11:22 Bounded Depth-4 Identity Testing Paradigms

There have been a lot of work on sparse-PIT, for details see [13, 49] and references therein.

**Theorem 11** ([49]). Let $p(x) \in \mathbb{F}[x]$ with individual degree at most $d$ and sparsity at most $m$. Then, there exists $1 \leq r \leq (md \log d)^2$, such that $p(y, y^d, \ldots, y^{d^{r-1}}) \not\equiv 0 \mod y^r - 1$.

An ABP is a layered directed acyclic graph with $q+1$ many layers of vertices $\{V_0, \ldots, V_q\}$ and a source $a$ and a sink $b$ such that all the edges in the graph only go from $a$ to $V_0$, $V_{i-1}$ to $V_i$ for any $i \in [q]$, and $V_q$ to $b$. The edges have univariate polynomials as their weights. The ABP is said to compute the polynomial

$$f(x) = \sum_{p \in \text{paths}(a, b)} \prod_{e \in p} W(e),$$

where $W(e)$ is the weight of the edge $e$. The ABP has width-$w$ if $|V_i| \leq w, \forall i \in \{0, \ldots, q\}$. Formally, it computes polynomials of the form $A^T(\prod_{i \in [q]} D_i)B$, where $A, B \in \mathbb{F}^{w \times 1}[x]$, and $D_i \in \mathbb{F}^{w \times w}[x]$, where entries are univariate polynomials.

**Definition 12** (Read-once oblivious ABP (ROABP)). An ABP is called a read-once oblivious ABP (ROABP) if the edge weights are univariate polynomials in distinct variables across layers. Formally, there is a permutation $\pi$ on the set $[q]$ such that the entries in the $i$-th matrix $D_i$ are univariate polynomials over the variable $x_{\pi(i)}$, i.e., they come from the polynomial ring $\mathbb{F}[x_{\pi(i)}]$.

A polynomial $f(x)$ is said to be computed by width-$w$ ROABPs in any order, if for every permutation $\sigma$ of the variables, there exists a width-$w$ ROABP in the variable order $s$ that computes the polynomial $f(x)$. There have been quite a few results on blackbox PIT for ROABPs [28, 27, 37] and the current best known algorithm works in quasipolynomial time.

**Theorem 13** ([37]). For $n$-variate, individual-degree-$d$ polynomials computed by width-$w$ ROABPs in any order, a hitting set of size $(ndw)^{O(\log \log w)}$ can be constructed.
B Details for Section 3.1

Here is an important lemma which shows that coefficient of $y^e$ of a polynomial $f(x, y) \in \mathbb{F}[x, y]$, computed by a $\Sigma \wedge \Sigma \wedge$ circuit, can be computed by a small $\Sigma \wedge \Sigma \wedge$ circuit.

**Lemma 14 (Coefficient extraction).** Let $f(x, y) \in \mathbb{F}[y][x]$ be computed by a $\Sigma \wedge \Sigma \wedge$ circuit of size $s$ and degree $d$. Then, $\text{coef}_y(f) \in \mathbb{F}[x]$ can be computed by a small $\Sigma \wedge \Sigma \wedge$ circuit of size $O(sd)$, over $\mathbb{F}[x]$.

**Proof sketch.** Let, $f = \sum_i a_i \cdot y^{e_i}$. Of course, $e_i \leq s$ and $\deg_y(f) \leq d$. Thus, write $f = \sum_{i=0}^d f_i \cdot y^{e}$, where $f_i \in \mathbb{F}[x]$. We can interpolate on $d+1$-many distinct points $y \in \mathbb{F}$ and conclude that $f_i$ has a $\Sigma \wedge \Sigma \wedge$ circuit of size at most $O(sd)$.

The next identity gives us a way to write a product of a few powers as a sum of powers, using simple interpolation. For a more algebraic proof, see [15, Proposition 4.3].

**Lemma 15 (Waring Identity for a monomial).** Let $M = x_1^{b_1} \cdots x_k^{b_k}$, where $1 \leq b_1 \leq \ldots \leq b_k$, and roots of unity $\mathcal{Z}(i) := \{ z \in \mathbb{C} : z^{b_i+1} = 1 \}$. Then,

$$M = \sum_{\varepsilon(i) \in \mathcal{Z}(i): i=1, \ldots, k} \gamma_{\varepsilon(2), \ldots, \varepsilon(k)} \cdot (x_1^{\varepsilon(2)} x_2 \cdots + \varepsilon(k)x_k)^d,$$

where $d := \deg(M) = b_1 + \ldots + b_k$, and $\gamma_{\varepsilon(2), \ldots, \varepsilon(k)}$ are scalars ($\rho_k(M) := \prod_{i=2}^k (b_i + 1)$ many).

**Remark.** We actually need not work with $\mathbb{F} = \mathbb{C}$. We can go to a small extension (at most $d^k$), for a monomial of degree $d$, to make sure that $\varepsilon(i)$ exists.

The next lemma shows that $\Sigma \wedge \Sigma \wedge$ is closed under multiplication.

**Lemma 16.** Let $f_i(x, y) \in \mathbb{F}[y][x]$, of syntactic degree $\leq d_i$, be computed by a $\Sigma \wedge \Sigma \wedge$ circuit of size $s_i$, for $i \in [k]$ (wrt $x$). Then, $f_1 \cdots f_k$ has $\Sigma \wedge \Sigma \wedge$ circuit of size $O((d_2 + 1) \cdots (d_k + 1) \cdot s_1 \cdots s_k)$.

**Proof.** Let $f_i = \sum_{j} f_{ij}^{e_{ij}}$; by assumption $e_{ij} \leq d_i$ (by assumption). Using Lemma 15, $f_{1j_1} \cdots f_{kj_k}$ has size at most $(d_2 + 1) \cdots (d_k + 1) \cdot \left( \sum_{i=1}^k \text{size}(f_{ij_i}) \right)$, for indices $j_1, \ldots, j_k$. Summing up for all $s_1 \cdots s_k$ many products (atmost) gives the upper bound.

The next lemma shows that $\Sigma \wedge \Sigma \wedge$ is closed under differentiation.

**Lemma 17 (Differentiation).** Let $f(x, y) \in \mathbb{F}[y][x]$ be computed by a $\Sigma \wedge \Sigma \wedge$ circuit of size $s$ and degree $d$. Then, $\partial_y(f)$ can be computed by a small $\Sigma \wedge \Sigma \wedge$ circuit of size $O(sd^2)$, over $\mathbb{F}[y][x]$.

**Proof sketch.** Lemma 14 shows that each $f_e$ has $O(sd)$ size circuit where $f = \sum_e f_e y^e$. Doing this for each $e \in [0, d]$ gives a blowup of $O(sd^2)$.

The next lemma shows that non-negative valuation corresponds to a power-series.

**Lemma 18 (Valuation).** Consider a polynomial $f \in \mathbb{F}(x, y)$ such that $\text{val}_y(f) \geq 0$. Then, $f \in \mathbb{F}(x)[[y]] \cap \mathbb{F}(x, y)$.
Proof sketch. Let \( f = g/h, \) where \( g, h \in \mathbb{F}[x, y]. \) Now, \( \text{val}_g(f) \geq 0 \) implies \( \text{val}_h(g) \geq \text{val}_h(h). \)
Let \( \text{val}_h(g) = d_1 \) and \( \text{val}_h(h) = d_2, \) where \( d_1 \geq d_2 \geq 0. \) Write \( g = y^{d_1} \cdot \tilde{g} \) and \( h = y^{d_2} \cdot \tilde{h}. \)
Write, \( \tilde{h} = h_0 + h_1 y + h_2 y^2 + \ldots + h_d y^d, \) for some \( d. \) Note that \( h_0 \neq 0. \) Thus,
\[
f = y^{d_1-d_2} \cdot \tilde{g} / (h_0 + h_1 y + \ldots + h_d y^d) = y^{d_1-d_2} \cdot (\tilde{g}/h_0) \cdot (1 + (h_1/h_0) y + \ldots + (h_d/h_0) y^d)^{-1} \in \mathbb{F}(x[[y]]) .
\]
The last conclusion follows by the inverse identity in the power-series ring.

Using duality trick \[75\] and PIT results from \[70, 37\], one can design efficient PIT algorithm for \( \Sigma \land \Sigma \land \) circuits:

**Lemma 19** (PIT for \( \Sigma \land \Sigma \land \)-circuits). Let \( P \in \Sigma \land \Sigma \land \) of size \( s. \) Then, there exists a \( \text{poly}(s) \) (resp. \( s^{\Omega(\log \log s)} \)) time whitebox (resp. blackbox) PIT for the same.

**Proof sketch.** We show that any \( g(x)^c = (g_1(x_1) + \ldots + g_n(x_n))^c, \) where \( \deg(g_i) \leq s \) can be written as \( \sum_j h_{ij}(x_1) \cdots h_{ijs}(x_n), \) for some \( h_{ij} \) of degree at most \( es. \) Define, \( G := (g + g_1) \cdots (y + g_n) - y^n. \) In its \( e \)-th power, notice that the leading-coefficient is \( \text{coef}_{x(n-1)}(G^e) = g^e. \) So, interpolate on \( e(n-1) + 1 \) many points \((y = \beta_i \in \mathbb{F})\) to get
\[
\text{coef}_{y(n-1)}(G^e) = \sum_{i=1}^{e(n-1)+1} \alpha_i G^e(\beta_i).
\]

Now, expand \( G^e(\beta_i) = ((\beta_i + g_1) \cdots (\beta_i + g_n) - \beta_i^n)^e, \) by binomial expansion (without expanding the inner \( n \)-fold product). The top-fanin can be atmost \( s \cdot (e + 1) \cdot (e(n-1) + 1) = O(se^2n). \)
The individual degrees of the intermediate univariates can be at most \( es. \) Thus, it can be computed by an ROABP (of any order) of size at most \( O(s^2e^3n). \)

Now, if \( f = \sum_{j \in [s]} f_j(x) \) is computed by a \( \Sigma \land \Sigma \land \) circuit of size \( s, \) then clearly, \( f \) can also be computed by an ROABP (of any order) of size at most \( O(s^3). \) So, the whitebox PIT follows from \[70\], while the blackbox PIT follows from Theorem 13.

For the time-complexity bound, we need optimization of the following function:

**Lemma 20.** Let \( k \in \mathbb{N}, \) and \( h(x) := x(k-x)7^x. \) Then, \( \max_{i \in [k-1]} h(i) = h(k-1). \)

**Proof sketch.** Differentiate to get \( h'(x) = (k-x)7^x - x7^x + x(k-x)(\log 7)7^x = 7^x \cdot [x^2(-\log 7) + x(k \log 7 - 2) + k]. \) It vanishes at \( x = \left( \frac{k}{7} - \frac{1}{\log 7} \right) + \sqrt{\left( \frac{k}{7} - \frac{1}{\log 7} \right)^2 - \frac{k}{\log 7}}. \)
Thus, \( h \) is maximized at the integer \( x = k - 1. \)

### C Details for Section 3.2

**Definition 21** (Faithful hom). \( \Phi : \mathbb{F}[x] \longrightarrow \mathbb{F}[y] \) is faithful for \( T \) if \( \text{trdeg}_y(T) = \text{trdeg}_y(\Phi(T)). \)

The following fact about faithful maps is from \[5, \text{Thm. 2.4}.\]

**Fact 22** (Faithful is useful). For any \( C \in \mathbb{F}[y_1, \ldots, y_m], \) \( C(T) = 0 \iff C(\Phi(T)) = 0. \)

Here is an important criterion about the jacobian matrix which basically shows that it preserves algebraic independence.

**Fact 23** (Jacobian criterion). Let \( f \subset \mathbb{F}[x] \) be a finite set of polynomials of degree at most \( d, \) and \( \text{trdeg}_y(f) \leq r. \) If \( \text{char}(\mathbb{F}) = 0, \) or \( \text{char}(\mathbb{F}) > d^r, \) then \( \text{trdeg}_y(f) = \text{rk}_{\mathbb{F}(x)} J_x(f). \)
The following lemma (& the proof) is similar to [5, Lem. 2.7]. It is a recipe to “drastically” reduce variables, if \( \text{trdeg} \) is small.

\textbf{Lemma 24 (Recipe for faithful maps).} Let \( T \in \mathbb{F}[x] \) be be a finite set of polynomials of degree at most \( d \) and \( \text{trdeg}_{xy}(T) \leq r \), and \( \text{char}(F) = 0 \) or \( \geq d' \). Let \( \Psi: \mathbb{F}[x] \rightarrow \mathbb{F}[z_1, z_2] \) such that \( \text{rk}_{xy} J_x(T) = \text{rk}_{yz} \Psi'(J_x(T)) \).

Then, the map \( \Phi: \mathbb{F}[x] \rightarrow \mathbb{F}[z, t, y] \), such that \( x_i \mapsto (\sum_j y_j t^j) + \Psi'(x_i) \), is a faithful homomorphism for \( T \).

\section*{C.1 Technical Details for Theorem 2b}

\textbf{Claim 25.} Let \( g_i \in L(T_i) \), where \( T_i \in \Pi \Sigma \Pi^{[d]} \) of size atmost \( s \), then \( J_{\text{rst}}(g_1, \ldots, g_k) \in \Sigma^{[k]} \Pi^{[k]} \Sigma^{[\delta-1]} \) of size \( O(k! \cdot s) \).

Proof sketch. Each entry of the matrix has degree at most \( \delta - 1 \). Trivial expansion gives \( k! \) top-fanin where each product (of fanin \( k \)) has size \( \sum_i \text{size}(g_i) \). As, \( \text{size}(T_i) \leq s \), trivially each size(\( g_i \)) \( \leq s \). Therefore, the total size is \( k! \cdot \sum_i \text{size}(g_i) = O(k! \cdot s) \).

\textbf{Claim 26.} Let \( g \in \Sigma^{[\delta]} \), then \( \Psi(g) \in \Sigma^{[\delta]} \) of size \( 3^\delta \cdot \text{size}(g) \) (for \( n \gg \delta \)).

Proof sketch. Each monomial \( x^e \) of degree \( \delta \), can produce \( \prod_i (e_i + 1) \leq (\sum_i e_i + n)/n \leq (\delta/n + 1)^n \)-many monomials, by AM-GM inequality as \( \sum_i e_i \leq \delta \). As \( \delta/n \rightarrow 0 \), we have \( (1 + \delta/n)^n \rightarrow e^\delta \). As \( e < 3 \), the upper bound follows.

[25, Prop. 4.18] gave the first nontrivial PIT for \( \Sigma \land \Sigma \Pi^{[d]} \) circuits:

\textbf{Theorem 27 ([25]).} There is a \( \text{poly}(n, d, \delta \log s) \)-explicit hitting set of size \( (nd)^{O(\delta \log s)} \) for the class of \( n \)-variate, degree-(\( \leq d \)) polynomials \( f(x) \), computed by \( \Sigma \land \Sigma \Pi^{[d]} \)-circuit of size \( s \).

\section*{D Proof sketch of Theorem 2a: Similar to Section 3.2}

Similar to Theorem 2b, we generalize this theorem and prove for a much bigger class of polynomials.

\textbf{Problem 28.} Let \( \{T_i \mid i \in [m]\} \) be \( \Pi \Sigma \land \) circuits of (syntactic) degree at most \( d \) and size \( s \). Let the transcendence degree of \( T_i \)'s, \( \text{trdeg}_{xy}(T_1, \ldots, T_m) =: k \ll s \). Further, \( C(x_1, \ldots, x_m) \) be a circuit of size \( + \) degree \( < s' \). Design a blackbox-PIT algorithm for \( C(T_1, \ldots, T_m) \).

It is trivial to see that \( \Sigma^{[k]} \Pi \Sigma \land \) is a very special case of the above settings. We will use the same idea (\& notation) as in Theorem 2b, using the Jacobian technique. The main idea is to come up with \( \Phi \) map, and correspondingly the hitting set \( H' \). If \( g \in L(T_i) \), then \( \text{size}(g) \leq O(dn) \). We also note that \( D_1 \), which is an upper bound on \( \text{deg}_{x_2} \Psi(g) \) is \( \text{poly}(n, d) \) (Lemma 11). The \( D \) (and hence \( R[x] \)) remains as before. Claims 6-7 hold similarly. We will construct the hitting set \( H' \) by showing that \( F \) has a small \( \Sigma \land \Sigma \land \) circuit over \( R[x] \).

Note that, Claim 25 remains the same for \( \Sigma \land \Sigma \land \) (implying the same size blowup). However, Claim 26, the size blowup is \( O(d \text{size}(g)) \), because each monomial \( x^e \) can only produce \( d + 1 \) many monomials. Therefore, similar to Lemma 10, one can show that \( \Psi(J_{\text{rst}}(g_1, \ldots, g_k)) \in \Sigma \land \Sigma \land \), of size \( O(2^k k! d s) \). Similarly, the size in Lemma 9 can be replaced by \( O(k!) \). Therefore, we get (similar to Claim 8):

\textbf{Claim 29.} \( F \in R[x] \) has \( \Sigma \land \Sigma \land \)-circuit of size \( s^{O(k)} \).
Next, the degree bound also remains the same (except the parameter \(D_1\) which is now \(\text{poly}(nd)\)). Following the same footsteps, it is not hard to see that the degree bound of \(z_2\) on \(P\) and \(Q\), where \(F = P(x, z)/Q(z_2)\), is \(s^{O(k)}\text{poly}(nd)\), while degree bound on \(z_1\) remains \(\text{poly}(k`s)\). Therefore, \(P \in \mathbb{F}[x, z]\) has \(\Sigma^k\langle \Sigma^\Lambda\rangle\) -circuit of size \(s^{O(k)}\).

We want to construct a set \(H' \subseteq \mathbb{F}^n\) such that the action \(P(H', z) \neq 0\). By Theorem 19, we conclude that it has \(s^{O(k \log \log s)}\) size hitting set which is constructible in a similar time. Hence, the construction of map \(\Phi\) and the theorem follows (from \(s\)-degree bound).

Solution to Problem 28. We know that \(C(T_1, \ldots, T_m) = 0 \iff E := \Phi(C(T_1, \ldots, T_m)) = 0\). Since, \(H'\) can be constructed in \(s^{O(k \log \log s)}\) time, it is trivial to find hitting set for \(E|_{H'}\) (which is just a \(k + 3\)-variate polynomial with the aforementioned degree bounds). The final hitting set for \(E\) can be constructed in \(s^{O(k)} \cdot s^{O(k \log \log s)}\) time.

\section{Algorithm for Theorem 1}

The whitebox PIT for Theorem 1, that is discussed in Section 3.1, appears (below) as Algorithm 1.

\textbf{Algorithm 1} Whitebox PIT Algorithm for \(\Sigma^k\langle \Pi^\Lambda\rangle\)-circuits.

\begin{algorithm}
\caption{Whitebox PIT Algorithm for \(\Sigma^k\langle \Pi^\Lambda\rangle\)-circuits.}
\begin{algorithmic}[1]
\Require \(f = f_1 + \cdots + f_s \in \Sigma^k\langle \Pi^\Lambda\rangle\), a whitebox circuit of size \(s\) over \(\mathbb{F}[x]\).
\Ensure \(0\) if \(f \equiv 0\) and \(1\) if \(f\) is non-zero.
\State Let \(\Psi : \mathbb{F}[x] \rightarrow \mathbb{F}[z_2]\), be a sparse-PIT map, using \cite{[49]} (Theorem 11). Apply it on \(f\) and check whether \(\Psi(f) = 0\). If non-zero, output \(1\) otherwise, apply \(\Phi : x_i \mapsto z_1 \cdot x_i + \Psi(x_i)\) on \(f\). Check \(\sum_{i \in [k-1]} \partial_{x_i} (\Phi(T_i) / \Phi(T_j)) \equiv 0 \mod \{d_1 := s\}\) as follows:
\State Consider each \(T_{i,j} := \partial_{x_i} (\Phi(T_i) / \Phi(T_j))\) over \(\mathbb{F}[z_2]\), where \(R_i := \mathbb{F}(z_2)[z_1]/(z_1^{d_i})\). Use dlog computation (Claim 4), to write each \(T_{i,j}\) in a “bloated” form as \(\langle \Pi^\Lambda / \Pi^\Lambda \rangle \cdot \langle \Sigma^\Lambda / \Sigma^\Lambda \rangle \cdot \langle \Sigma^\Lambda / \Sigma^\Lambda \rangle\).
\State for \(j \leftarrow 1\) to \(k - 1\) do
\State Reduce the top-fan-in at each step using “\textit{Divide \\& Derive}” technique. Assume that at \(j\)-th step, we have to check the identity:
\State \(\sum_{i \in [k-j]} T_{i,j} \equiv 0 \mod R_j(x)\), where \(R_j := \mathbb{F}(z_2)[z_1]/(z_1^{d_j})\), each \(T_{i,j}\) has a \((\Pi^\Lambda / \Pi^\Lambda) \cdot (\Sigma^\Lambda / \Sigma^\Lambda)\) representation and therein each \(\Pi^\Lambda, \Sigma^\Lambda \in \mathbb{F}(z_2)\) \(\setminus \{0\}\).
\State 1. Compute \(v_{k-j,j} := \min \{v_i(x_j)\}\); by reordering it is for \(i = k - j\). To compute \(v_{k-j,j}\), use coefficient extraction (Lemma 14) and \(\Sigma^\Lambda / \Sigma^\Lambda\)-circuit PIT (Lemma 19).
\State 2. “\textit{Divide}” by \(T_{k-j,j}\) and check whether \(\sum_{i \in [k-j]} (T_{i,j} / T_{k-j,j}) + 1 \mod z_1 = 0\). Note: this expression is in \((\Sigma^\Lambda / \Sigma^\Lambda)\) under multiplication. Finally, do PIT on this by Lemma 19.
\State 3. If it is non-zero, output \(1\) otherwise “\textit{Derive}” wrt \(z_1\) and “\textit{Induct}” on \(\sum_{i \in [k-j]} \partial_{x_i} (T_{i,j} / T_{k-j,j}) \equiv 0 \mod R_{j+1}(x)\), where \(R_{j+1} := \mathbb{F}(z_2)[z_1]/(z_1^{d_j - v_{k-j,j} - 1})\).
\State 4. Again using dlog (Claim 4), show that \(T_{i,j+1} := \partial_{x_i} (T_{i,j} / T_{k-j,j})\) has small \((\Pi^\Lambda / \Pi^\Lambda) \cdot (\Sigma^\Lambda / \Sigma^\Lambda)\) circuit over \(R_{j+1}(x)\). So call the algorithm on \(\sum_{i \in [k-j]} T_{i,j+1} = 0\).
\State end
\State at the end, \(j \leftarrow k - 1\). Do PIT (Lemma 19) on the single \((\Pi^\Lambda / \Pi^\Lambda) \cdot (\Sigma^\Lambda / \Sigma^\Lambda)\) circuit, over \(R_{k-1}(x)\). If it is zero, output \(0\) otherwise output \(1\).
\end{algorithmic}
\end{algorithm}

\textbf{Words of caution:} Throughout the algorithm there are intermediate expressions to be stored compactly. Think of them as “special” circuits in \(x\), but over the \textit{function-field} \(\mathbb{F}(z)\). Keep track of their degrees wrt \(z_1, z_2\); and that of the sizes of their fractions represented in “bloated” circuit form.
Robustly Self-Ordered Graphs: Constructions and Applications to Property Testing

Oded Goldreich
Faculty of Mathematics and Computer Science, Weizmann Institute of Science, Rehovot, Israel

Avi Wigderson
School of Mathematics, Institute for Advanced Study, Princeton, USA

Abstract

A graph \( G \) is called self-ordered (a.k.a asymmetric) if the identity permutation is its only automorphism. Equivalently, there is a unique isomorphism from \( G \) to any graph that is isomorphic to \( G \). We say that \( G = (V, E) \) is robustly self-ordered if the size of the symmetric difference between \( E \) and the edge-set of the graph obtained by permuting \( V \) using any permutation \( \pi : V \to V \) is proportional to the number of non-fixed-points of \( \pi \). In this work, we initiate the study of the structure, construction and utility of robustly self-ordered graphs.

We show that robustly self-ordered bounded-degree graphs exist (in abundance), and that they can be constructed efficiently, in a strong sense. Specifically, given the index of a vertex in such a graph, it is possible to find all its neighbors in polynomial-time (i.e., in time that is poly-logarithmic in the size of the graph).

We provide two very different constructions, in tools and structure. The first, a direct construction, is based on proving a sufficient condition for robust self-ordering, which requires that an auxiliary graph is expanding. The second construction is iterative, boosting the property of robust self-ordering from smaller to larger graphs. Structurally, the first construction always yields expanding graphs, while the second construction may produce graphs that have many tiny (sub-logarithmic) connected components.

We also consider graphs of unbounded degree, seeking correspondingly unbounded robustness parameters. We again demonstrate that such graphs (of linear degree) exist (in abundance), and that they can be constructed efficiently, in a strong sense. This turns out to require very different tools. Specifically, we show that the construction of such graphs reduces to the construction of non-malleable two-source extractors (with very weak parameters but with some additional natural features).

We demonstrate that robustly self-ordered bounded-degree graphs are useful towards obtaining lower bounds on the query complexity of testing graph properties both in the bounded-degree and the dense graph models. Indeed, their robustness offers efficient, local and distance preserving reductions from testing problems on ordered structures (like sequences) to the unordered (effectively unlabeled) graphs. One of the results that we obtain, via such a reduction, is a subexponential separation between the query complexities of testing and tolerant testing of graph properties in the bounded-degree graph model.

Acknowledgements We are grateful to Eshan Chattopadhyay for discussions regarding non-malleable two-source extractors, and to Dana Ron for discussions regarding tolerant testing. We are deeply indebted to Jyun-Jie Liao for pointing out an error in the proof of [23, Lem. 9.7].
1 Introduction

For a (labeled) graph $G = (V, E)$, and a bijection $\phi : V \to V'$, we denote by $\phi(G)$ the graph $G' = (V', E')$ such that $E' = \{\{\phi(u), \phi(v)\} : \{u, v\} \in E\}$, and say that $G'$ is isomorphic to $G$. The set of automorphisms of the graph $G = (V, E)$, denoted $\text{aut}(G)$, is the set of permutations that preserve the graph $G$; that is, $\pi \in \text{aut}(G)$ if and only if $\pi(G) = G$. We say that a graph is asymmetric (equiv., self-ordered) if its set of automorphisms is a singleton, which consists of the trivial automorphism (i.e., the identity permutation). We actually prefer the term self-ordered, because we take the perspective that is offered by the following equivalent definition.

**Definition 1.1 (self-ordered (a.k.a asymmetric) graphs).** The graph $G = ([n], E)$ is self-ordered if for every graph $G' = (V', E')$ that is isomorphic to $G$ there exists a unique bijection $\phi : V' \to [n]$ such that $\phi(G') = G$.

In other words, given an isomorphic copy $G' = (V', E')$ of a fixed graph $G = ([n], E)$, there is a unique bijection $\phi : V' \to [n]$ that orders the vertices of $G'$ such that the resulting graph (i.e., $\phi(G')$) is identical to $G$. Indeed, if $G' = G$, then this unique bijection is the identity permutation.\(^1\)

In this work, we consider a feature, which we call robust self-ordering, that is a quantitative version self-ordering. Loosely speaking, a graph $G = ([n], E)$ is robustly self-ordered if, for every permutation $\pi : [n] \to [n]$, the size of the symmetric difference between $G$ and $\pi(G)$ is proportional to the number of non-fixed-points under $\pi$; that is, $|E \triangle \{\{\pi(u), \pi(v)\} : \{u, v\} \in E\}|$ is proportional to $|\{i \in [n] : \pi(i) \neq i\}|$. (In contrast, self-ordering only means that the size of the symmetric difference is positive if the number of non-fixed-points is positive.)

**Definition 1.2 (robustly self-ordered graphs).** A graph $G = (V, E)$ is said to be $\gamma$-robustly self-ordered if for every permutation $\pi : V \to V$ it holds that

$$|E \triangle \{\{\pi(u), \pi(v)\} : \{u, v\} \in E\}| \geq \gamma \cdot |\{i \in [n] : \pi(i) \neq i\}|,$$

where $\triangle$ denotes the symmetric difference operation. An infinite family of graphs $\{G_n = ([n], E_n)\}_{n \in \mathbb{N}}$ (such that each $G_n$ has maximum degree $d$) is called robustly self-ordered if there exists a constant $\gamma > 0$, called the robustness parameter, such that for every $n$ the graph $G_n$ is $\gamma$-robustly self-ordered.

Note that $|E_n \triangle \{\{\pi(u), \pi(v)\} : \{u, v\} \in E_n\}| \leq 2d \cdot |\{i \in [n] : \pi(i) \neq i\}|$ always holds (for families of maximum degree $d$). The term “robust” is inspired by the property testing literature (cf. [31]), where it indicates that some “parametrized violation” is reflected proportionally in some “detection parameter”.

The second part of Definition 1.2 is tailored for bounded-degree graphs, which will be our focus in Section 2–6. Nevertheless, in Sections 7–10 we consider graphs of unbounded degree and unbounded robustness parameters. In this case, for a function $\rho : \mathbb{N} \to \mathbb{R}$, we say that an infinite family of graphs $\{G_n = ([n], E_n)\}_{n \in \mathbb{N}}$ is $\rho$-robustly self-ordered if for every $n$ the graph $G_n$ is $\rho(n)$-robustly self-ordered. Naturally, in this case, the graphs must have $\Omega(\rho(n) \cdot n)$ edges.\(^2\) In Sections 7–9 we consider the case of $\rho(n) = \Omega(n)$.

---

1 Naturally, we are interested in efficient algorithms that find this unique ordering, whenever it exists; such algorithms are known when the degree of the graph is bounded [29].

2 Actually, all but at most one vertex must have degree at least $\rho(n)/2$. 

1.1 Robustly self-ordered bounded-degree graphs

The first part of this paper (i.e., Section 2–6) focuses on the study of robustly self-ordered bounded-degree graphs.

1.1.1 Our main results and motivation

We show that robustly self-ordered (n-vertex) graphs of bounded-degree not only exist (for all \( n \in \mathbb{N} \)), but can be efficiently constructed in a strong (or local) sense. Specifically, we prove the following result.

**Theorem 1.3** (constructing robustly self-ordered bounded-degree graphs). For all sufficiently large \( d \in \mathbb{N} \), there exist an infinite family of \( d \)-regular robustly self-ordered graphs \( \{G_n\}_{n \in \mathbb{N}} \) and a polynomial-time algorithm that, given \( n \in \mathbb{N} \) and a vertex \( v \in [n] \) in the \( n \)-vertex graph \( G_n \), finds all neighbors of \( v \) (in \( G_n \)).

We stress that the algorithm runs in time that is polynomial in the description of the vertex; that is, the algorithm runs in time that is polylogarithmic in the size of the graph. Theorem 1.3 holds both for graphs that consists of connected components of logarithmic size and for “strongly connected” graphs (i.e., expanders).

Recall that given an isomorphic copy \( G' \) of such a graph \( G_n \), the original graph \( G_n \) (i.e., along with its unique ordering) can be found in polynomial-time [29]. Furthermore, we show that the pre-image of each vertex of \( G' \) in the graph \( G_n \) (i.e., its index in the aforementioned ordering) can be found in time that is polylogarithmic in the size of the graph (see discussion in Section 4.4, culminating in Theorem 4.7).

We present two proofs of Theorem 1.3. Loosely speaking, the first proof reduces to proving that a \( 2d \)-regular \( n \)-vertex graph representing the action of \( d \) permutations on \([n]\) is robustly self-ordered if the \( n(n-1) \)-vertex graph representing the action of these permutations on vertex-pairs is an expander. The graphs constructed in this proof are expanders, whereas the graphs constructed via by the second proof can be either expanders or consist of connected components of logarithmic size. More importantly, the graphs constructed in the second proof are couple with local self-ordering and local reversed self-ordering algorithms (see Section 4.4). The second proof proceeds in three steps, starting from the mere existence of robustly self-ordered bounded-degree \( \ell \)-vertex graphs, which yields a construction that runs in \( \text{poly}(\ell\ell) \)-time. Next, a \( \text{poly}(n) \)-time construction of \( n \)-vertex graphs is obtained by using the former graphs as small subgraphs (of \( o(\log n) \)-size). Lastly, strong (a.k.a local) constructability is obtained in an analogous manner. For more details, see Section 1.1.2.

We demonstrate that robustly self-ordered bounded-degree graphs are useful towards obtaining lower bounds on the query complexity of testing graph properties in the bounded-degree graph model. Specifically, we use these graphs as a key ingredient in a general methodology of transporting lower bounds regarding testing binary strings to lower bounds regarding testing graph properties in the bounded-degree graph model. In particular, using the methodology, we prove the following two results.

---

3 The algorithm asserted above is said to perform local self-ordering of \( G' \) according to \( G_n \). For \( \phi(G') = G_n \), given a vertex \( v \) in \( G' \), this algorithm returns \( \phi(v) \) in poly(\( \log n \))-time. In contrast, a local reversed self-ordering algorithm is given a vertex \( i \in [n] \) of \( G_n \) and returns \( \phi^{-1}(i) \). The second algorithm is also presented in Section 4.4 (see Theorem 4.9).
Robustly Self-Ordered Graphs

1. A subexponential separation between the complexities of testing and tolerant testing of graph properties in the bounded-degree graph model; that is, for some constant $c > 0$, the query complexity of tolerant testing is at least $\exp(q^c)$, where $q$ is the query complexity of standard testing.

   This result, which appears as Theorem 5.5, is obtained by transporting an analogous result that was known for testing binary strings [15].

2. A linear query complexity lower bound for testing an efficiently recognizable graph property in the bounded-degree graph model, where the lower bound holds even if the tested graph is restricted to consist of connected components of logarithmic size (see Theorem 5.2).

   As discussed in Section 5, an analogous result was known in the general case (i.e., without the restriction on the size of the connected components), and we consider it interesting that the result holds also in the special case of graphs with small connected components. To get a feeling of why robustly self-ordered graphs are relevant to such transportation, recall that strings are ordered objects, whereas graphs properties are effectively sets of unlabeled graphs, which are unordered objects. Hence, we need to make the graphs (in the property) ordered, and furthermore make this ordering robust in the very sense that is reflected in Definition 1.2. Furthermore, local self-ordering algorithms are used for transporting lower bounds (and local reversed self-ordering algorithms are used for transporting upper bounds). We comment that the theme of reducing ordered structures to unordered structures occur often in the theory of computation and in logic, and is often coupled with analogous of query complexity.

   Lastly, in Section 6, we prove that random $2d$-regular graphs are robustly self-ordered; see Theorem 6.1. This extends work in probabilistic graph theory, which proves a similar result for the weaker notion of self-ordering [5, 4].

1.1.2 Techniques

As stated above, we present two different constructions that establish Theorem 1.3: A direct construction and a three-step construction. Both constructions utilize a variant of the notion of robust self-ordering that refers to edge-colored graphs, which we review first.

1.1.2.1 The edge-coloring methodology

At several different points, we found it useful to start by demonstrating the robust self-ordering feature in a relaxed model in which edges are assigned a constant number of colors, and the symmetric difference between graphs accounts also for edges that have different colors in the two graphs (see Definition 2.1). This allows us to analyze different sets of edges separately.

   For example, we actually analyze the direct construction in the edge-colored model, since this allows for identifying each of the underlying permutations with a different color. Another example, which arises in the three-step construction, occurs when we super-impose a robustly self-ordered graph with an expander graph in order to make the robustly self-ordered graph expanding (as needed for the second and third step of the aforementioned three-step construction). In this case, assigning the edges of each of the two graphs a different color, allows for easily retaining the robust self-ordering feature (of the first graph).

   We obtain robustly self-ordered graphs (in the original sense) by replacing all edges that are assigned a specific color with copies of a constant-sized (asymmetric) gadget, where different (and in fact non-isomorphic) gadgets are used for different edge colors. The soundness of this transformation is proved in Theorem 2.4.
1.1.2.2 The direct construction

For any \(d\) permutations, \(\pi_1, \ldots, \pi_d : [n] \to [n]\), we consider the Schreier graph (see [25, Sec. 11.1.2]) defined by the action of these permutation on \([n]\); that is, the edge-set of this graph is \(\{(v, \pi_i(v)) : v \in [n] \& i \in [d]\}\). Loosely speaking, we prove that this 2\(d\)-regular \(n\)-vertex graph is robustly self-ordered if another Schreier graph is an expander. The second Schreier graph represents the action of the same permutations on pairs of vertices (in \([n]\)); that is, this graph consisting of the vertex-set \(\{(u, v) : u, v \in [n]\}\) and the edge-set \(\{\{(u, v), (\pi_i(u), \pi_i(v))\} : u, v \in [n] \& i \in [d]\}\).

The argument is actually made with respect to edge-colored directed graphs (i.e., the edge-set of the first graph is \(\{(v, \pi_i(v)) : v \in [n] \& i \in [d]\}\) and the directed edge \((v, \pi_i(v))\) is assigned the color \(i\)). Hence, we also present a transformation of robustly self-ordered edge-colored directed graphs to analogous undirected graphs. Specifically, we replace the directed edge \((u, v)\) colored \(j\) by a 2-path with a designated auxiliary vertex \(a_{u,v,j}\), while coloring the edge \(\{u, a_{u,v,j}\}\) by \(2j - 1\) and the edge \(\{a_{u,v,j}, v\}\) by \(2j\).

We comment that permutations satisfying the foregoing condition can be efficiently constructed; for example, any set of expanding generators for \(\text{SL}_2(p)\) (e.g., the one used by [28]) yield such permutations on \([n] \equiv \{(1, i) : i \in \text{GF}(p)\} \cup \{(0, 1)\}\) (see Proposition 3.3).

1.1.2.3 The three-step construction

Our alternative construction of robustly self-ordered (bounded-degree) \(n\)-vertex graphs proceeds in three steps.

1. First, we prove the existence of bounded-degree \(n\)-vertex graphs that are robustly self-ordered (see Theorem 4.1), while observing that this yields a \(\exp(O(n \log n))\)-time algorithm for constructing them.

2. Next (see Theorem 4.2), we use the latter algorithm to construct robustly self-ordered \(n\)-vertex bounded-degree graphs that consist of \(2\ell\)-sized connected components, where \(\ell = O(\log n)\). These connected components are far from being isomorphic to one another, and are constructed using robustly self-ordered \(\ell\)-vertex graphs as a building block. This yields an algorithm that constructs the \(n\)-vertex graph in \(\text{poly}(n)\)-time, since \(\exp(\ell \log \ell) = \text{poly}(n)\).

3. Lastly, we derive Theorem 1.3 (restated as Theorem 4.5) by repeating the same strategy as in Step 2, but using the construction of Theorem 4.2 for the construction of the small connected components (and setting \(\ell = O(\log n)\)). This yields an algorithm that finds the neighbors of a vertex in the \(n\)-vertex graph in \(\text{poly}(\log n)\)-time, since \(\text{poly}(\ell) = \text{poly}(\log n)\).

The foregoing description of Steps 2 and 3 yields graphs that consists of small connected components. We obtain analogous results for “strongly connected” graphs (i.e., expanders) by superimposing these graphs with expander graphs (while distinguishing the two types of edges by using colors (see the foregoing discussion)). In fact, it is essential to perform this transformation (on the result of Step 2) before taking Step 3; the transformation itself appears in the proof of Theorem 2.6.

---

4 Equivalently, we consider only pairs of distinct vertices; that is, the vertex-set \(\{(u, v) : u, v \in [n] \& u \neq v\}\).

5 In this case, the primary Schreier graph represents the natural action of the group on the 1-dimensional subspaces of \(\text{GF}(p)^2\).
1.1.2.4 Using large collections of pairwise far apart permutations

One ingredient in the foregoing three-step construction is the use of a single \( \ell \)-vertex robustly self-ordered (bounded-degree) graph towards obtaining a large collection of \( 2\ell \)-vertex (bounded-degree) graphs such that every two graphs are far from being isomorphic to one another, where “large” means \( \exp(\Omega(\ell \log \ell)) \) in one case (i.e., in the proof of Theorem 4.2) and \( \exp(\Omega(\ell)) \) in another case (i.e., in the proof of Theorem 4.5). Essentially, this is done by constructing a large collection of permutations of \( [\ell] \) that are pairwise far-apart, and letting the \( i \)th graph consists of two copies of the \( \ell \)-vertex graph that are matched according to the \( i \)th permutation (see the aforementioned proofs). (Actually, we use two robustly self-ordered \( \ell \)-vertex graphs that are far from being isomorphic (e.g., have different degree).)

A collection of \( L = \exp(\Omega(\ell \log \ell)) \) pairwise far-apart permutations over \( [\ell] \) can be constructed in \( \text{poly}(L) \)-time by selecting the permutations one by one, while relying on the existence of a permutation that augments the current sequence (while preserving the distance condition, see the proof of Theorem 4.2). A collection of \( L = \exp(\Omega(\ell)) \) pairwise far-apart permutations over \( [\ell] \) can be locally constructed such that the \( i \)th permutation is constructed in \( \text{poly}(\ell) \)-time by using sequences of disjoint transpositions determined via a good error correcting code (see the proof of Theorem 4.5).

The foregoing discussion begs the challenge of obtaining a construction of a collection of \( L = \exp(\Omega(\ell \log \ell)) \) permutations over \( [\ell] \) that are pairwise far-apart along with a polynomial-time algorithm that, on input \( i \in [L] \), returns a description of the \( i \)th permutation (i.e., the algorithm should run in \( \text{poly}(\log L) \)-time). We meet this challenge in [21]. Note that such a collection constitutes a an asymptotically good code over the alphabet \( [\ell] \), where the permutations are the codewords (being far-apart corresponds to constant relative distance and \( \log L = \Omega(\log(\ell)) \) corresponds to constant rate).

1.1.2.5 On the failure of some natural approaches

We mention that natural candidates for robustly self-ordered bounded-degree graphs fail. In particular, there exist expander graphs that are not robustly self-ordered. In fact, any Cayley graph is symmetric (i.e., has non-trivial automorphisms).\(^6\)

In light of the above, it is interesting that expansion can serve as a sufficient condition for robust self-ordering (as explained in the foregoing review of the direct construction); recall, however, that this works for Schreier graphs, and expansion needs to hold for the action on vertex-pairs.

1.1.2.6 On optimization

We made no attempt to minimize the degree bound and maximize the robustness parameter. Note that we can obtain 3-regular robustly self-ordered graphs by applying degree reduction; that is, given a \( d \)-regular graph, we replace each vertex by a \( d \)-cycle and use each of these vertices to “hook” one original edge. To facilitate the analysis, we may use one color for the edges of the \( d \)-cycles and another color for the other (i.e., original) edges.\(^7\) Hence, the issue at hand is actually one of maximizing the robustness parameter of the resulting 3-regular graphs.

\(^6\) Specifically, multiplying the vertex labels (say, on the right) by any non-zero group element yields a non-trivial automorphism (assuming that edges are defined by multiplying with a generator on the left). Such automorphisms cannot be constructed in general for Schreier graphs, and some Schreier graphs have no automorphisms (e.g., the ones we construct here).

\(^7\) Needless to say, we later replace all colored edges by copies of adequate constant-sized gadgets.
1.1.2.7 Caveat (tedious)

Whenever we assert a $d$-regular $n$-vertex graph, we assume that the trivial conditions hold; specifically, we assume that $n > d$ and that $nd$ is even (or, alternatively, allow for one exceptional vertex of degree $d - 1$).

1.2 Robustly self-ordered dense graphs

In the second part of this paper (i.e., Sections 7–10) we consider graphs of unbounded degree, seeking correspondingly unbounded robustness parameters. In particular, we are interested in $n$-vertex graphs that are $\Omega(n)$-robustly self-ordered, which means that they must have $\Omega(n^2)$ edges.

The construction of $\Omega(n)$-robustly self-ordered graphs offers yet another alternative approach towards the construction of bounded-degree graphs that are $\Omega(1)$-robustly self-ordered. Specifically, we show that $n$-vertex graphs that are $\Omega(n)$-robustly self-ordered can be efficiently transformed into $O(n^2)$-vertex bounded-degree graphs that are $\Omega(1)$-robustly self-ordered; see Proposition 7.2, which is essentially proved by the “degree reduction via expanders” technique, while using a different color for the expanders’ edges, and then using gadgets to replace colored edges (see Theorem 2.4).

1.2.1 Our main results

It is quite easy to show that random $n$-vertex graphs are $\Omega(n)$-robustly self-ordered (see Proposition 7.1); in fact, the proof is easier than the proof of the analogous result for bounded-degree graphs (Theorem 6.1). Unfortunately, constructing $n$-vertex graphs that are $\Omega(n)$-robustly self-ordered seems to be no easier constructing robustly self-ordered bounded-degree graphs. In particular, it seems to require completely different techniques and tools.

▶ Theorem 1.4 (constructing $\Omega(n)$-robustly self-ordered graphs). There exist an infinite family of dense $\Omega(n)$-robustly self-ordered graphs $\{G_n\}_{n \in \mathbb{N}}$ and a polynomial-time algorithm that, given $n \in \mathbb{N}$ and a pair of vertices $u, v \in [n]$ in the $n$-vertex graph $G_n$, determines whether or not $u$ is adjacent to $v$ in $G_n$.

Unlike in the case of bounded-degree graphs, in general, we cannot rely on an efficient isomorphism test for finding the original ordering of $G_n$, when given an isomorphic copy of it. However, we can obtain dense $\Omega(n)$-robustly self-ordered graphs for which this ordering can be found efficiently (see Theorem 8.10).

Our proof of Theorem 1.4 is by a reduction to the construction of non-malleable two-source extractors, where a suitable construction of the latter was provided by Chattopadhyay, Goyal, and Li [7]. We actually present two different reductions (Theorems 8.3 and 8.7), one simpler than the other but yielding a less efficient construction when combined with the known constructions of extractors. We mention that the first reduction (Theorem 8.3) is partially reversible (see Proposition 8.5, which reverses a special case captured in Remark 8.4).

We show that $\Omega(n)$-robustly self-ordered $n$-vertex graphs can be used to transport lower bounds regarding testing binary strings to lower bounds regarding testing graph properties in the dense graph model. This general methodology, presented in Section 9, is analogous to the methodology for the bounded-degree graph model, which is presented in Section 5.

We mention that in a follow-up work [22], we employed this methodology in order to resolve several open problems regarding the relation between adaptive and non-adaptive testers in the dense graph model. In particular, we proved that there exist graph properties...
for which any non-adaptive tester must have query complexity that is almost quadratic in
the query complexity of the best general (i.e., adaptive) tester, whereas it has been known for
a couple of decades that the query complexity of non-adaptive testers is at most quadratic in
the query complexity of adaptive testers.

The case of intermediate degree bounds

Lastly, in Section 10, we consider $n$-vertex graphs of degree bound $d(n)$, for every $d : \mathbb{N} \to \mathbb{N}$
such that $d(n) \in [\Omega(1), n]$. Indeed, the bounded-degree case (studied in Section 2–6) and the
dense graph case (studied in Sections 7–9) are special cases (which correspond to $d(n) = O(1)$
and $d(n) = n$). Using results from these two special cases, we show how to construct
$\Omega(d(n))$-robustly self-ordered $n$-vertex graphs of maximum degree $d(n)$, for all $d : \mathbb{N} \to \mathbb{N}$.

1.2.2 Techniques

As evident from the foregoing description, we reduce the construction of $\Omega(n)$-robustly
self-ordered $n$-vertex graphs to the construction of non-malleable two-source extractors.

Non-malleable two-source extractors were introduced in [8], as a variant on seeded (one-
source) non-malleable extractors, which were introduced in [12]. Loosely speaking, we say that
$\text{nmE}: \{0,1\}^\ell \times \{0,1\}^\ell \to \{0,1\}^m$ is a non-malleable two-source extractor for a class of sources $\mathcal{C}$
if for every two independent sources in $\mathcal{C}$, denoted $X$ ands $Y$, and for every two functions
$f, g : \{0,1\}^\ell \to \{0,1\}^\ell$ that have no fixed-point it holds that $\langle \text{nmE}(X, Y), \text{nmE}(f(X), g(Y)) \rangle$ is
close to $\langle U_m, \text{nmE}(f(X), g(Y)) \rangle$, where $U_m$ denotes the uniform distribution over $\{0,1\}^m$. We
show that a non-malleable two-source extractor for the class of $\ell$-bit sources of min-entropy
$\ell - O(1)$, with a single output bit (i.e., $m = 1$) and constant error, suffices for constructing
$\Omega(n)$-robustly self-ordered $n$-vertex graphs. Recall that constructions with much stronger
parameters (e.g., min-entropy $\ell - \ell^{\Omega(1)}$, negligible error, and $m = \ell^{\Omega(1)}$) were provided
by Chattopadhyay, Goyal, and Li [7, Thm. 1]. (These constructions are quite complex.
Interestingly, we are not aware of a simpler way of obtaining the weaker parameters that we
need.)

Actually, we show two reductions of the construction of $\Omega(n)$-robustly self-ordered $n$-
vertex graphs to the construction of non-malleable two-source extractors. In both cases we
use extractors that operate on pairs of sources of length $\ell = \log_2 n - O(1)$ that have
min-entropy $k = \ell - O(1)$, hereafter called $(\ell, k)$-sources. The extractor is used to define
a bipartite graph with $2^\ell$ vertices on each side, and a clique is placed on the vertices of
one side so that a permutation that maps vertices from one side to the other side yields a
proportional symmetric difference (between the original graph and the resulting graph).

The first reduction, presented in Theorem 8.3, requires the extractor to be quasi-orthogonal,
which means that the residual functions obtained by any two different fixings of one of the
extractor’s two arguments are almost unbiased and uncorrelated. Using the fact that non-
malleable two-source extractors for $(\ell, k)$-sources can we made quasi-orthogonal in $\exp(\ell)$-time,
we obtain an explicit construction of $\Omega(n)$-robustly self-ordered $n$-vertex graphs (i.e., the
$n$-vertex graph is constructed in $\text{poly}(n)$-time).

The second reduction, presented in Theorem 8.7, yields a strongly explicit construction
as asserted in Theorem 1.4 (i.e., the adjacency predicate of the $n$-vertex graph is computable
in $\text{poly}(\log n)$-time). This reduction uses an arbitrary non-malleable two-source extractor,
and shifts the quasi-orthogonality condition to two auxiliary bipartite graphs.

Both reductions are based on the observation that if the number of non-fixed-points (of
the permutation) is very large, then the non-malleability condition implies a large symmetric
difference (between the original graph and the resulting graph). This holds as long as there
are at least $\Omega(2^\ell)$ non-fixed-points on each of the two sides of the corresponding bipartite graph (which corresponds to the extractor). The complementary case is handled by the quasi-orthogonality condition, and this is where the two reductions differ.

The simpler case, presented in the first construction (i.e., Theorem 8.3), is that the extractor itself is quasi-orthogonal. In this case we consider the non-fixed-points on the side that has more of them. The quasi-orthogonality condition gives us a contribution of approximately $0.5 \cdot 2^\ell$ units per each non-fixed-point, whereas the upper-bound on the number of non-fixed-points on the other side implies that most of these contributions actually count in the symmetric difference (between the original graph and the resulting graph).

In the second construction (i.e., Theorem 8.7), we augment the foregoing $2^\ell$-by-$2^\ell$ bipartite graph, which is now determined by any non-malleable extractor, with an additional $4 \cdot 2^\ell$-vertex clique that is connected to the two original $2^\ell$-vertex sets by a bipartite graph that is merely quasi-orthogonal. The analysis is analogous to the one used in the proof of Theorem 8.3, but is slightly more complex because we are dealing with a slightly more complex graph.

**Errata regarding the original posting**

We retract the claims made in our initial posting [23] regarding the construction of non-malleable two-source extractors (which are quasi-orthogonal) as well as the claims about the construction of relocation-detecting codes (see Theorems 1.5 and 1.6 in the original version).\(^8\) The source of trouble is a fundamental flaw in the proof of [23, Lem. 9.7], which may as well be wrong.

### 1.3 Perspective

Asymmetric graphs were famously studied by Erdos and Renyi [14], who considered the (absolute) distance of asymmetric graphs from being symmetric (i.e., the number of edges that should be removed or added to a graph to make it symmetric), calling this quantity the degree of asymmetry. They studied the extremal question of determining the largest possible degree of asymmetry of $n$-vertex graphs (as a function of $n$). We avoided the term “robust asymmetry” because it could be confused with the degree of asymmetry, which is a very different notion. In particular, the degree of asymmetry cannot exceed twice the degree of the graph (e.g., by disconnecting two vertices), whereas our focus is on robustly self-ordered graphs of bounded-degree.

We mention that Bollobas proved that, *for every constant $d \geq 3$, almost all $d$-regular graphs are asymmetric* [5, 4]. This result was extended to varying $d \in [3, n - 4]$ by Kim, Sudakov, and Vu [26]. We also mention that their proof of [26, Thm. 3.1] implies that a random $n$-vertex Erdos–Renyi graph with edge probability $p$ is $2p(1 - p)n$-robustly self-ordered.

### 1.4 Roadmaps

This work consists of two parts. The first part (Sections 2–6) refers to bounded-degree graphs, and the second part (Sections 7–10) refers to dense graphs. These parts are practically independent of one another, except that Theorem 10.3 builds upon Section 6. Even when focusing on one of these two parts, its contents may attract attention from diverse perspectives. Each such perspective may benefit from a different roadmap.

---

\(^8\) In [23] quasi-orthogonality is called niceness; we prefer the current term, which is less generic.
Efficient combinatorial constructions

As mentioned above, in the regime of bounded-degree graphs we present two different constructions that establish Theorem 1.3. Both constructions make use of the edge-colored model and the transformations presented in Section 2. The direct construction is presented in Section 3, and the three-step construction appears in Section 4. The three-step construction is augmented by local self-ordering and local reversed self-ordering algorithms (see Section 4.4).\footnote{For a locally constructable $G_n$, and $G' = \phi^{-1}(G_n)$, a local self-ordering algorithm is given a vertex $v$ in $G'$, and returns $\phi(v)$. In contrast, a local reversed self-ordering algorithm is given a vertex $i \in [n]$ of $G_n$ and returns $\phi^{-1}(i)$. Both algorithms run in poly(log $n$)-time.}

In the regime of dense graphs, Sections 7 and 8 refer to the constructability of a couple of combinatorial objects; see roadmap “for the dense case” below.

Potential applications to property testing

In Section 5 we demonstrate applications of Theorem 1.3 to proving lower bounds (on the query complexity) for the bounded-degree graph testing model. Specifically, we present a methodology of transporting bounds regarding testing properties of strings to bounds regarding testing properties of bounded-degree graphs. The specific applications presented in Section 5 rely on Section 4. For the first application (Theorem 5.2) the construction presented in Section 4.2 suffices; for the second application (i.e., Theorem 5.5, which establishes a separation between testing and tolerant testing in the bounded-degree graph model), the local computation tasks studied in Section 4.4 are needed. An analogous methodology for the dense graph testing model is presented in Section 9.

Properties of random graphs

As stated above, it turns out that random $O(1)$-regular graphs are robustly self-ordered. This result is presented in Section 6, and this section can be read independently of any other section. (In addition, Section 7 presents a proof that random (dense) $n$-vertex graphs are $O(n)$-robustly self-ordered.)

The dense case and non-malleable two-source extractors

The regime of dense graphs is studied in Sections 7–9, where the construction of such graphs is undertaken in Section 8. In Section 7, we show that $\Omega(n)$-robustly self-ordered $n$-vertex graphs provide yet another way of obtaining $\Omega(1)$-robustly self-ordered bounded-degree graphs. In Section 8, we reduce the construction of $O(n)$-robustly self-ordered $n$-vertex graphs to the construction of non-malleable two-source extractors. As outlined in Section 1.2.2, we actually present two different reductions, where a key issue is the quasi-orthogonality condition.

Lastly, in Section 10, for every $d : \mathbb{N} \to \mathbb{N}$ such that $d(n) \in [\Omega(1), n]$, we show how to construct $n$-vertex graphs of maximum degree $d(n)$ that are $\Omega(d(n))$-robustly self-ordered. Some of the results and techniques presented in this section are also relevant to the setting of bounded-degree graphs.
Part I

The Case of Bounded-Degree Graphs

As stated in Section 1.1.2, a notion of robust self-ordering of edge-colored graphs plays a pivotal role in our study of robustly self-ordered bounded-degree graphs. This notion as well as a transformation from it to the uncolored version (of Definition 1.2) is presented in Section 2.

In Section 3, we present a direct construction of $O(1)$-regular robustly self-ordered edge-colored graphs; applying the foregoing transformation, this provides our first proof of Theorem 1.3. Our second proof of Theorem 1.3 is presented in Section 4, and consists of a three-step process (as outlined in Section 1.1.2). Sections 3 and 4 can be read independently of one another, but both rely on Section 2.

In Section 5 we demonstrate the applicability of robustly self-ordered bounded-degree graphs to property testing; specifically, to proving lower bounds (on the query complexity) for the bounded-degree graph testing model. For these applications, the global notion of constructability, established in Section 4.2, suffices. This construction should be preferred over the direct construction presented in Section 3, because it yields graphs with small connected components. More importantly, the subexponential separation between the complexities of testing and tolerant testing of graph properties (i.e., Theorem 5.5) relies on the construction of Section 4 and specifically on the local computation tasks studied in Section 4.4.

Lastly, in Section 6, we prove that random $O(1)$-regular graphs are robustly self-ordered. This section may be read independently of any other section.

2 The Edge-Colored Variant

Many of our arguments are easier to make in a model of (bounded-degree) graphs in which edges are colored (by a bounded number of colors), and where one counts the number of mismatches between colored edges. Namely, an edge that appears in one (edge-colored) graph contributes to the count if it either does not appear in the other (edge-colored) graph or appears in it under a different color. Hence, we define a notion of robust self-ordering for edge-colored graphs. We shall then transform robustly self-ordered edge-colored graphs to robustly self-ordered ordinary (uncolored) graphs, while preserving the degree, the asymptotic number of vertices, and other features such as expansion and degree-regularity. Specifically, the transformation consists of replacing the colored edges by copies of different connected, asymmetric (constant-sized) gadgets such that different colors are reflected by different gadgets.

We start by providing the definition of the edge-colored model. Actually, for greater flexibility, we will consider multi-graphs; that is, graphs with possible parallel edges and self-loops. Hence, we shall consider multi-graphs $G = (V, E)$ coupled with an edge-coloring function $\chi : E \to \mathbb{N}$, where $E$ is a multi-set containing both pairs of vertices and singletons (representing self-loops). Actually, it will be more convenient to represent self-loops as 2-element multi-sets containing two copies of the same vertex.

Definition 2.1 (robust self-ordering of edge-colored multi-graphs). Let $G = (V, E)$ be a multi-graph with colored edges, where $\chi : E \to \mathbb{N}$ denotes this coloring, and let $E_i$ denote the multi-set of edges colored $i$ (i.e., $E_i = \{e \in E : \chi(e) = i\}$). We say that $(G, \chi)$ is $\gamma$-robustly self-ordered if for every permutation $\mu : V \to V$ it holds that

$$\sum_{i \in \mathbb{N}} |E_i \Delta \{\mu(u), \mu(v) : \{u, v\} \in E_i\}| \geq \gamma \cdot |\{i \in V : \mu(i) \neq i\}|,$$

(2)
where \( A \Delta B \) denotes the symmetric difference between the multi-sets \( A \) and \( B \); that is \( A \Delta B \) contains \( t \) occurrences of \( e \) if the absolute difference between the number of occurrences of \( e \) in \( A \) and \( B \) equals \( t \).

(Definition 1.2 is obtained as a special case when the multi-graph is actually a graph and all edges are assigned the same color.)

We stress that whenever we consider “edge-colored graphs” we actually refer to edge-colored multi-graphs (i.e., we explicitly allow parallel edges and self-loops).\(^{10}\) In contrast, whenever we consider (uncolored) graph, we refer to simple graphs (with no parallel edges and no self-loops).

Our transformation of robustly self-ordered edge-colored multi-graphs to robustly self-ordered ordinary graphs depends on the number of colors used by the multi-graph. In particular, \( \gamma \)-robustness of edge-colored multi-graph that uses \( c \) colors gets translated to \((\gamma / f(c))\)-robustness of the resulting graph, where \( f : \mathbb{N} \to \mathbb{N} \) is an unbounded function. Hence, we focus on coloring functions that use a constant number of colors, denoted \( c \). That is, fixing a constant \( c \in \mathbb{N} \), we shall consider multi-graphs \( G = (V, E) \) coupled with an edge-coloring function \( \chi : E \to [c] \).

### 2.1 Transformation to standard (uncolored) version

As a preliminary step for the transformation, we add self-loops to all vertices and make sure that parallel edges are assigned different colors. The self-loops make it easy to distinguish the original vertices from auxiliary vertices that are parts of gadgets introduced in the main transformation. Different colors assigned to parallel edges are essential to the mere asymmetry of the resulting graph, since we are going to replace edges of the same color by copies of the same gadget.

**Construction 2.2** (preliminary step towards Construction 2.3). For a fixed \( d \geq 3 \), given a multi-graph \( G = (V, E) \) of maximum degree \( d \) and an edge-coloring function \( \chi : E \to [c] \), we define a multi-graph \( G' = (V, E') \) and an edge-coloring function \( \chi' : E' \to [d \cdot c + 1] \) as follows.

1. For every pair of vertices \( u \) and \( v \) that are connected by few parallel edges, denoted \( e^{(1)}_{u,v}, \ldots, e^{(d)}_{u,v} \), we change the color of \( e^{(i)}_{u,v} \) to \( \chi' (e^{(i)}_{u,v}) \leftarrow (i - 1) \cdot d + \chi(e^{(i)}_{u,v}) \). This includes also the case \( u = v \).
2. We augment the multi-graph with self-loops colored \( d \cdot c + 1 \); that is, \( E' \) is the multi-set \( E \cup \{ e_v : v \in V \} \), where \( e_v \) is a self-loop added to \( v \), and \( \chi' (e_v) = dc + 1 \).

(Other edges \( e \in E \) maintain their color; that is, \( \chi' (e) = \chi(e) \) holds).

(For simplicity, we re-color all parallel edges, save the first one, rather than re-coloring only parallel edges of the same color.) Note that refining the coloring may only increase the robustness parameter of a multi-graph. Clearly, \( G' \) preserves many features of \( G \). In particular, it preserves \( \gamma \)-robust self-ordering, expansion, degree-regularity, and the number of vertices.

\(^{10}\) We comment that a seemingly more appealing definition can be used for edge-colored (simple) graphs. Specifically, in that case (i.e., \( E \subseteq \binom{V}{2} \)), we can extend \( \chi : E \to \mathbb{N} \) to non-edges by defining \( \chi(\{u, v\}) = 0 \) if \( \{u, v\} \notin E \), and say that \((G, \chi)\) is \( \gamma \)-robustly self-ordered if for every permutation \( \mu : V \to V \) it holds that

\[
\left| \left\{ \{u, v\} \in \binom{V}{2} : \chi(\{\mu(u), \mu(v)\}) \neq \chi(\{u, v\}) \right\} \right| \geq \gamma \cdot |\{i \in V : \mu(i) \neq i\}|.
\]

As stated above, our transformation of edge-colored multi-graphs to ordinary graphs uses gadgets, which are constant-size graphs. Specifically, when handling a multi-graph of maximum degree \(d\) with edges that are colored by \(c\) colors, we shall use \(c\) different connected and asymmetric graphs. Furthermore, in order to maintain \(d\)-regularity, we shall use \(d\)-regular graphs as gadgets; and in order to have better control on the number of vertices in the resulting graph, each of these gadgets will contain \(k = k(d, c)\) vertices. The existence of such \((d\text{-regular})\) asymmetric (and connected) graphs is well-known, let alone that it is known that a random \((d\text{-regular})\) \(k\)-vertex graph is asymmetric (for any constant \(d \geq 3\)) [5, 4].

We stress that the different gadgets are each connected and asymmetric, and it follows that they are not isomorphic to one another. We designate in each gadget an edge \(\{p, q\}\), called the designated edge, such that omitting this edge does not disconnect the gadget. The endpoint of this edge will be used to connect two vertices of the original multi-graph.

The endpoint of this edge will be used to connect two vertices of the original multi-graph. Specifically, we replace each edge \(\{u, v\}\) (of the original multi-graph) that is colored \(i\) by a copy of the \(i^{th}\) gadget, while omitting one its designated edge \(\{p, q\}\) and connecting \(u\) to \(p\) and \(v\) to \(q\). The construction is spelled out below.

We say that a (non-simple) multi-graph \(G = (V, E)\) coupled with an edge-coloring \(\chi\) is eligible if each of its vertices contains a self-loop, and parallel edges are assigned different colors. Recall that eligible comes almost for free (by applying Construction 2.2). We shall apply the following construction only to eligible edge-colored multi-graphs.

**Construction 2.3 (the main transformation).** For a fixed \(d \geq 3\) and \(c\), let \(k = k(d, c)\) and \(G_1, \ldots, G_k\) be different asymmetric and connected \(d\)-regular graphs over the vertex-set \([k]\). Given a multi-graph \(G = (V, E)\) of maximum degree \(d\) and an edge-coloring function \(\chi: E \to [c]\), we construct a graph \(G' = (V', E')\) as follows.

Suppose that the multi-set \(E\) has size \(m\). Then, for each \(j \in [m]\), if the \(j^{th}\) edge of \(E\) connects vertices \(u\) and \(v\), and is colored \(i\), then we replace it by a copy of \(G_i\), while omitting its designated edge and connecting one of its endpoints to \(u\) and the other to \(v\).

Specifically, assuming that \(V = [n]\) and recalling that \(j\) is the index of the edge (colored \(i\)) that connects \(u\) and \(v\), let \(G_i^{u,v}\) be an isomorphic copy of \(G_i\) that uses the vertex set \(\{n + (j-1) \cdot k + i : i \in [k]\}\). Let \(\{p, q\}\) be the designated edge in \(G_i^{u,v}\), and \(\tilde{G}_i^{u,v}\) be the graph that results from \(G_i^{u,v}\) by omitting \(\{p, q\}\). Then, we replace the edge \(\{u, v\}\) by \(\tilde{G}_i^{u,v}\), and add the edges \(\{u, p\}\) and \(\{v, q\}\).

Hence, \(V' = [n + m \cdot k]\) and \(E'\) consists of the edges of all \(\tilde{G}_i^{u,v}\)'s as well as the edges connecting the endpoint of the corresponding designated edges to the corresponding vertices \(u\) and \(v\).

We stress that, although \(G\) may have parallel edges and self-loops, the graph \(G'\) has neither parallel edges nor self-loops. Also note that \(G'\) preserve various properties of \(G\) such as degree-regularity, number of connected components, and expansion (up to a constant factor).

Showing that the resulting graph \(G' = (V', E')\) is robustly self-ordered relies on a correspondence between the colored edges of \(G = (V, E)\) and the gadgets in \(G'\). For starters, suppose that the permutation \(\mu' : V' \to V'\) maps \(V\) to \(V\) (i.e., \(\mu'(V) = V\)), and gadgets to the corresponding gadgets; that is, if \(\mu'\) maps the vertex-pair \((u, v)\) \(\in V^2\) to \((\mu'(u), \mu'(v))\) \(\in V^2\), then \(\mu'\) maps the vertices in the possible gadget that connects \(u\) and \(v\) to the vertices in the gadget that connects \(\mu'(u)\) and \(\mu'(v)\). In such a case, letting \(\mu\) be the restriction of \(\mu'\) to \(V\), a difference of \(D\) colored edges between \(G\) and \(\mu(G)\) translates to a difference of at least \(D\) edges between \(G'\) and \(\mu'(G')\), due to the difference between the gadgets that replace...
the corresponding edges of $G'$, whereas the number of non-fixed-point vertices in $\mu'$ is $k$ times larger than the number of non-fixed-point vertices in $\mu$, which is at most $D/\gamma$ (by the $\gamma$-robust self-ordering of $G$). Hence, in this case we have

$$\frac{|G' \triangle \mu'(G')|}{|\{v \in V' : \mu'(v) \neq v\}|} = \frac{D}{k \cdot |\{v \in V : \mu(v) \neq v\}|} \geq \frac{D}{k \cdot D/\gamma}$$

which equals $\gamma/k$. However, in general, $\mu'$ needs to satisfy the foregoing condition. Nevertheless, if $\mu'$ splits some gadget or maps some gadget in a manner that is inconsistent with the vertices of $V$ connected by it, then this gadget contributes at least one unit to the difference between $G'$ and $\mu'(G')$, whereas the number of non-fixed-point vertices in this gadget is at most $k$. Lastly, if $\mu'$ maps vertices of a gadget to other vertices in the same gadget, then we get a contribution of at least one unit due to the asymmetry of the gadget.

The foregoing is made rigorous in the proof of the following theorem.

**Theorem 2.4 (from edge-colored robustness to standard robustness).** For constant $d \geq 3$ and $c$, suppose that the multi-graph $G = (V, E)$ coupled with $\chi : E \to [c]$ is eligible and $\gamma$-robustly self-ordered. Then, the graph $G' = (V', E')$ resulting from Construction 2.3 is $(\gamma/3k)$-robustly self-ordered, where $k = k(d, c)$ is the number of vertices in a gadget (as determined above).

**Proof.** As a warm-up, let us verify that $G'$ is asymmetric. We first observe that the vertices of $G$ are uniquely identified (in $G'$), since they are the only vertices that are incident at copies of the gadget that replaces the self-loops.\(^{11}\) Hence, any automorphism of $G'$ must map $V$ to $V$. Consequently, for any $i$, such an automorphism $\mu'$ must map each copy of $G_i$ to a copy of $G_i$, which induces a unique coloring of the edges of $G$. By the “colored asymmetry” of $G$, this implies that $\mu'$ maps each $v \in V$ to itself, and consequently each copy of $G_i$ must be mapped (by $\mu'$) to itself. Finally, using the asymmetry of the $G_i$'s, it follows that each vertex of each copy of $G_i$ is mapped to itself.

We now turn to proving that $G'$ is actually robustly self-ordered. Considering an arbitrary permutation $\mu' : V' \to V'$, we lower-bound the distance between $G'$ and $\mu'(G')$ as a function of the number of non-fixed-points under $\mu'$ (i.e., of $v \in V'$ such that $\mu'(v') \neq v'$). We do so by considering the contribution of each non-fixed-point to the distance between $G'$ and $\mu'(G')$.

We first recall the fact that the vertices of $V$ (resp., of gadgets) are uniquely identified in $\mu'(G')$ by virtue of the gadgets that replace self-loops (see the foregoing warm-up).

**Case 1:** Vertices of some copy of $G_i$ that are not mapped by $\mu'$ to a single copy of $G_i$; that is, vertices in some $G_{i,v}^u$ that are not mapped by $\mu'$ to some $G_{i,v}^{u',v'}$. (This includes the case of vertices $w'$ and $w''$ of some $G_{i,v}^u$ such that $\mu'(w')$ is in $G_{i,v}^{u,v}$ and $\mu'(w'')$ is in $G_{i,v}^{u,v'}$, but $(i', u', v') \neq (i'', u'', v'')$. It also includes the case of a copy of $G_i$ that is mapped by $\mu'$ to a copy of $G_j$ for $j \neq i$, and the case that a vertex $w$ in some $G_{i,v}^u$ that is mapped by $\mu'$ to a vertex in $V$.)

The set of vertices $S_{i,v}^{u,v}$ of each such copy (i.e., $G_{i,v}^{u,v}$) contribute at least one unit to the difference between $G'$ and $\mu'(G')$, since $\mu'(S_{i,v}^{u,v})$ induces a copy of $\tilde{G}_i$ in $\mu(G)$ but not in $G'$, where here we also use the fact that the $\tilde{G}_i$'s are connected (and not isomorphic for the case of $i' = i'' \neq i$). Note that the total contribution of all vertices of the current case equals at least the number of gadgets in which they reside. Hence, if the current case contains $n_1$ vertices, then their contribution to the distance between $G'$ and $\mu'(G')$ is at least $n_1/k$.

\(^{11}\) Note that this gadget cannot appear as part of any other gadget, since all gadgets have the same number of vertices.
Ditto for vertices that do not belong to a single copy of $G_i$ and are mapped by $\mu'$ to a single copy of $G_i$. (This also includes $v \in V$ being mapped to some copy of some $G_i$.)

**Case 2:** Vertices of some copy of $G_i$ that are mapped by $\mu'$ to a single copy of $G_i$, while not preserving their indices inside $G_i$.

(This refers to vertices of some $G_i^{u,v}$ that are mapped by $\mu$ to vertices of $G_i^{u',v'}$, where $(u', v')$ may but need not equal $(u, v)$, such that for some $j \in [k]$ the $j^{th}$ vertex of $G_i^{u,v}$ is not mapped by $\mu$ to the $j^{th}$ vertex of $G_i^{u',v'}$.)

By the fact that $G_i$ is asymmetric, it follows that each such copy contributes at least one unit to the difference between $G'$ and $\mu'(G')$, and so (again) the total contribution of all these vertices is proportional to their number; that is, if the number of vertices in this case is $n_2$, then their contribution is at least $n_2/k$.

**Case 3:** Vertices $v \in V$ such that $\mu'(v) \neq v$ (equiv., $\mu'(v) \in V \setminus \{v\}$).

(This is the main case, where we use the hypothesis that the edge-colored $G$ is robustly self-ordered.

By the hypothesis that the edge-colored $G$ is robustly self-ordered, it follows that such vertices contribute proportionally to the difference between the colored versions of the multi-graphs $G$ and $\mu(G)$, where $\mu$ is the restriction of $\mu'$ to $V$. Specifically, the number of tuples $\{(u, v), i\}$ such that $\{u, v\}$ is colored $i$ in exactly one of these multi-graphs (i.e., either in $G$ or in $\mu(G)$ but not in both) is at least $\gamma \cdot |\{v \in V : \mu(v) \neq v\}|$.

Assume, without loss of generality that $\chi((u, v)) = i$ but either $\{\mu^{-1}(u), \mu^{-1}(v)\} \notin E$ or $\chi((\mu^{-1}(u), \mu^{-1}(v))) = j \neq i$. Either way, it follows that some vertices that do not belong to a copy of $G_i$ are mapped by $\mu'$ to $G_i^{u',v'}$, which means that Case 1 applies for each such a tuple. Hence, if the number of vertices in the current case is $n_3$, then $n_3 \geq \gamma \cdot n_3$, and we get a contribution of at least $\gamma \cdot n_3/k$ via Case 1.

**Case 4:** Vertices of some copy of $G_i$ that are mapped by $\mu'$ to a different copy of $G_i$.

This refers to the case that $\mu'$ maps $G_i^{u,v}$ to $G_i^{u',v'}$ such that $(u', v') \neq (u, v)$, which corresponds to mapping the gadget to a gadget connecting a different pair of vertices (but by an edge of the same color).

For $u, v, u', v'$ and $i$ as above, if $\mu'(u) = u'$ and $\mu'(v) = v'$, then a gadget that connects $u$ and $v$ in $G'$ is mapped to a gadget that does not connects them in $\mu'(G')$ (but rather connects the vertices $u'$ and $v'$, whereas either $u' \neq u$ or $v' \neq v$). So we get a contribution of at least one unit to the difference between $G'$ and $\mu'(G')$ (i.e., the gadget-edge incident at either $u$ or $v$), whereas the number of vertices in this gadget is $k$. Hence, the contribution is proportional to the number of non-fixed-points of the current type. Otherwise (i.e., $(\mu'(u), \mu'(v)) \neq (u', v')$), we get a vertex as in Case 3, and get a proportional contribution again.

Hence, the contribution of each of these cases to the difference between $G'$ and $\mu'(G')$ is proportional to the number of vertices involved. Specifically, if there are $n_i$ vertices in Case $i$, then we get a contribution-count of at least $\gamma \cdot \sum_{i \in [k]} n_i/k$, where some of these contributions were possibly counted thrice. The claim follows.

$\blacktriangleright$ *Remark 2.5 (fitting any desired number of vertices).* Assuming that the hypothesis of Theorem 2.4 can be met for any sufficiently large $n \in S \subseteq N$, Construction 2.3 yields robustly self-ordered $n'$-vertex graphs for any $n' \in \{k \cdot n : n \in S\}$. To obtain such graphs also for $n'$ that is not a multiple of $k$, we may use two gadgets with a different number of vertices for replacing at least one of the sets of colored edges.

---

$^{12}$Recall that $G_i^{u,v}$ and $G_i^{u',v'}$ are both copies of the $k$-vertex graph $G_i$, which is an asymmetric graph, and so the notion of the $j^{th}$ vertex in them is well-defined. Formally, the $j^{th}$ vertex of $G_i^{u,v}$ is $\phi^{-1}(j)$ such that $\phi$ is the (unique) bijection satisfying $\phi(G_i^{u,v}) = G_i$. 

---

**CCC 2021**
2.2 Application: Making the graph regular and expanding

We view the edge-colored model as an intermediate locus in a two-step methodology for constructing robustly self-ordered graphs of bounded-degree. First, one constructs edge-colored multi-graphs that are robustly self-ordered in the sense of Definition 2.1, and then converts them to ordinary robustly self-ordered graphs (in the sense of Definition 1.2), by using Construction 2.3 (while relying on Theorem 2.4).

We demonstrate the useful of this methodology by showing that it yields a simple way of making robustly self-ordered graphs be also expanding as well as regular, while maintaining a bounded degree. We just augment the original graph by super-imposing an expander (on the same vertex set), while using one color for the edges of the original graph and another color for the edges of the expander. Note that we do not have to worry about the possibility of creating parallel edges (since they are assigned different colors). The same method applies in order to make the graph regular. We combine both transformations in the following result, which we shall use in the sequel.

Theorem 2.6 (making the graph regular and expanding). For constant $d \geq 3$ and $\gamma$, there exists an efficient algorithm that given a $\gamma$-robustly self-ordered graph $G = (V, E)$ of maximum degree $d$, returns a $(d + O(1))$-regular multi-graph coupled with a 2-coloring of its edges such that the edge-colored graph is $\gamma$-robustly self-ordered (in the sense of Definition 2.1).

The same idea can be applied to edge-colored multi-graphs; in this case, we use one color more than given. We could have avoided the creation of parallel edges with the same color by using more colors, but preferred to relegate this task to Construction 2.2, while recalling that it preserves both the expansion and the degree-regularity. Either way, applying Theorem 2.4 to the resulting edge-colored multi-graph, we obtain robustly self-ordered (uncolored) graphs.

Proof. For any $d'' \geq d + d'$, given a graph $G = (V, E)$ of maximum degree $d$ that is $\gamma$-robustly self-ordered and a $d'$-regular expander graph $G' = (V', E')$, we construct the desired $d''$-regular multi-graph $G''$ by super-imposing the two graphs on the same vertex set, while assigning the edges of each of these graphs a different color. In addition, we add edges to make the graph regular, and color them using the same color as used for the expander.\(^\text{13}\) Details follow.

- We superimpose $G$ and $G'$ (i.e., create a multi-graph $(V, E \cup E')$), while coloring the edges of $G$ (resp., $G'$) with color 1 (resp., color 2). Note that this may create parallel edges, but with different colors.
- Let $d_v \leq d + d'$ denote the degree of vertex $v$ in the resulting multi-graph. Then, we add edges to this multi-graph so that each vertex has degree $d''$. These edges will also be colored 2.
  (Here, unless we are a bit careful, we may introduce parallel edges that are assigned the same color. This can be avoided by using more colors for these added edges, but in light of Construction 2.2 (which does essentially the same) there is no reason to worry about this aspect.)

(Recall that the resulting edge-colored multi-graph is denoted $G''$.)

\(^{13}\)We assume for simplicity that $|V'|$ is even. Alternatively, assuming that $G$ contains no isolated vertex, we first augment it with an isolated vertex and apply the transformation on the resulting graph. Yet another alternative is to consider only even $d''$. 

The crucial observation is that, since the edges of $G$ are given a distinct color in $G''$, the added edges do not harm the robust self-ordering feature of $G$. Hence, for any permutation $\mu : V \to V$, any vertex-pair that contributes to the symmetric difference between $G$ and $\mu(G)$, also contributes to an inequality between colored edges of $G''$ and $\mu(G'')$ (by virtue of the edges colored 1).

2.3 Local computability of the transformations

In this subsection, we merely point out that the transformation presented in Constructions 2.2 and 2.3 as well as the one underlying the proof of Theorem 2.6 preserve efficient local computability (e.g., one can determine the neighborhood of a vertex in the resulting multigraph by making a polylogarithmic number of neighbor-queries to the original multigraph). Actually, this holds provided that we augment the (local) representation of graphs, in a natural manner.

Recall that the standard representation of bounded-degree graphs is by their incidence functions. Specifically, a graph $G = ([n], E)$ of maximum degree $d$ is represented by the incident function $g : [n] \times [d] \to [n] \cup \{0\}$ such that $g(v, i) = u \in [n]$ if $u$ is the $i$th neighbor of $v$, and $g(v, i) = 0$ if $v$ has less than $i$ neighbors. This does not allow us to determine the identity of the $j$th edge in $G$, nor even to determine the number of edges in $G$, by making a polylogarithmic number of queries to $g$. Nevertheless, efficient local computability is preserved if we use the following local representation (presented for edge-colored multigraphs).

**Definition 2.7** (local representation). For $d, c \in \mathbb{N}$, a local representation of a multi-graph $G = ([n], E)$ of maximum degree $d$ that is coupled with a coloring $\chi : E \to [c]$ is provided by the following three functions:

1. An incidence function $g_1 : [n] \times [d] \to \mathbb{N} \cup \{0\}$ such that $g_1(v, i) = j \in \mathbb{N}$ if $j$ is the index of the $i$th edge that incident at vertex $v$, and $g_1(v, i) = 0$ if $v$ has less than $i$ incident edges.
2. An edge enumeration function $g_2 : \mathbb{N} \to ([n]^2 \times [c]) \cup \{0\}$ such that $g_2(j) = (u, v, \chi(e_j))$ if the $j$th edge, denoted $e_j$, connects the vertices $u$ and $v$, and $g_2(j) = 0$ if the multi-graph has less than $j$ edges.
3. An vertex enumeration (by degree) function $g_3 : [d] \to ([n] \to [n]) \cup \{0\}$ such that $g_3(i, j) = v \in [n]$ if $v$ is the $i$th vertex of degree $j$ in the multi-graph, and $g_3(i, j) = 0$ if the multi-graph has less than $j$ vertices of degree $i$.

Needless to say, the function $g_3$ is redundant in the case that we are guaranteed that the multi-graph is regular. One may augment the above representation by providing also the total number of edges, but this number can be determined by binary search.

**Theorem 2.8** (the foregoing transformations preserve local computability). The local representation of the multi-graph that result from Construction 2.2 can be computed by making a polylogarithmic number of queries to the given multi-graph. The same holds for Construction 2.3 and for the transformation underlying the proof of Theorem 2.6.

**Proof.** For Construction 2.2, we mostly need to enumerate all parallel edges that connect $u$ and $v$. This can be done easily by querying the incidence function on $(u, 1), \ldots, (u, d)$ and querying the edge enumeration function on the non-zero answers. (In addition, when adding a self-loop on vertex $v \in [n]$, we need to determine the degree of $v$ as well as the number of edges in the multi-graph (in order to know how to index the self-loop in the incidence and edge enumeration functions, respectively). For Construction 2.3, we merely need to determine the color of the $j$th edge and its index in the incidence list of each of its endpoints (in order to replace it by edges that lead to the gadget).
For the transformation underlying the proof of Theorem 2.6, adding edges to make the multi-graph regular requires determining the index of a vertex in the list of all vertices of the same degree (in order to properly index the added edges). Here is where we use the vertex enumeration (by degree) function. (We also need to select a fixed procedure for transforming an sorted \( n \)-long sequence \((d_1, ..., d_n) \in [d''']\) into an all-\( d''' \) sequence by making pairs of increments; that is, given \( j \in [D] \) such that \( D = (d'''n - \sum_{i \in [n]} d_i)/2 \), we should determine a pair \((u_j, v_j)\) such that for every \( i \in [n] \) it holds that \( d_i + |\{j : u_j = i\}| + |\{j : v_j = i\}| = d''' \). ▶

# 3 The Direct Construction

We shall make use of the edge-colored variant presented in Section 2, while relying on the fact that robustly self-ordered colored multi-graphs can be efficiently transformed into robustly self-ordered (uncolored) graphs. Actually, it will be easier to present the construction as a directed edge-colored multi-graph. Hence, we first define a variant of robust self-ordering for directed edge-colored multi-graph (see Definition 3.1), then show how to construct such multi-graphs (see Section 3.2), and finally show how to transform the directed variant into an undirected one (see Section 3.1).

The construction is based on \( d \) permutations, denoted \( \pi_1, ..., \pi_d : [n] \rightarrow [n] \), and consists of the directed edge-colored multi-graph that is naturally defined by them. Specifically, for every \( v \in [n] \) and \( i \in [d] \), this multi-graph contains a directed edge, denoted \((v, \pi_i(v))\), that goes from vertex \( v \) to vertex \( \pi_i(v) \), and is colored \( i \).

We prove that a sufficient condition for this edge-colored directed multi-graph, denoted \( G_1 \), to be robustly self-ordered is that a related multi-graph is an expander. Specifically, we refer to the multi-graph \( G_2 = (V_2, E_2) \) that represents the actions of the permutation of pairs of vertices of \( G_1 \); that is, \( V_2 = \{(u, v) \in [n]^2 : u \neq v\} \) and \( E_2 = \{\{(u, v), (\pi_i(u), \pi_i(v))\} : (u, v) \in V_2 \& i \in [d]\} \).

The foregoing requires extending the notion of robustly self-ordered (edge-colored) multi-graphs to the directed case. The extension is straightforward and is spelled-out next, for sake of good order.

▶ **Definition 3.1** (robust self-ordering of edge-colored directed multi-graphs). Let \( G = (V, E) \) be a directed multi-graph with colored edges, where \( \chi : E \rightarrow \mathbb{N} \) denotes this coloring, and let \( E_i \) denote the multi-set of edges colored \( i \). We say that \((G, \chi)\) is \( \gamma \)-robustly self-ordered if for every permutation \( \mu : V \rightarrow V \) it holds that

\[
\sum_{i \in \mathbb{N}} |E_i \triangle \{(\mu(u), \mu(v)) : (u, v) \in E_i\}| \geq \gamma \cdot |\{i \in V : \mu(i) \neq i\}|, \tag{3}
\]

where \( A \triangle B \) denotes the symmetric difference between the multi-sets \( A \) and \( B \) (as in Definition 2.1).

(The only difference between Definition 3.1 and Definition 2.1 is that (3) refers to the directed edges of the directed multi-graph, whereas (2) refers to the undirected edges of the undirected multi-graph.)

In Section 3.1 we present a construction of a directed edge-colored \( O(1) \)-regular multi-graph that is \( \Omega(1) \)-robustly self-ordered. We shall actually present a sufficient condition and a specific instantiation that satisfies it. In Section 3.2 we show how to transform any directed edge-colored multi-graph into an undirected one while preserving all relevant features; that is, bounded robustness, bounded degree, regularity, expansion, and local computability.
3.1 A sufficient condition for robust self-ordering of directed colored graphs

For any $d$ permutations, $\pi_1, \ldots, \pi_d : [n] \rightarrow [n]$, we consider two multi-graphs.

1. The primary directed multi-graph (of $\pi_1, \ldots, \pi_d$) is a directed multi-graph, denoted $G_1 = ([n], E_1)$, such that $E_1 = \{(v, \pi_i(v)) : v \in [n] \& i \in [d]\}$. This directed multi-graph is coupled with an edge-coloring in which the directed edge from $v$ to $\pi_i(v)$ is colored $i$.

2. The secondary multi-graph (of $\pi_1, \ldots, \pi_d$) is an undirected multi-graph, denoted $G_2 = (V_2, E_2)$, such that $V_2 = \{(u, v) \in [n]^2 : u \neq v\}$ and $E_2 = \{(u, v), (\pi_i(u), \pi_i(v)) : (u, v) \in V_2 \& i \in [d]\}$.

We note that each of these multi-graphs is a Schreier graph that correspond to the action of the permutation $\pi_1, \ldots, \pi_d$ on the corresponding vertex sets (i.e., $[n]$ and $V_2$, respectively). For a wider perspective see the (paragraph at the) end of this subsection.

We now state the main result of this section, which asserts that the primary multi-graph $G_1$ is robustly self-ordered if the secondary multi-graph $G_2$ is an expander. We use the combinatorial definition of expansion: A multi-graph $G = (V, E)$ is $\gamma$-expanding if, for every subset $S$ of size at most $\lfloor V/2 \rfloor$, there are at least $\gamma \cdot |S|$ vertices in $V \setminus S$ that neighbor some vertex in $S$.

**Theorem 3.2** (expansion of $G_2$ implies robust self-ordering of $G_1$). For any $d \geq 2$ permutations, $\pi_1, \ldots, \pi_d : [n] \rightarrow [n]$, if the secondary multi-graph $G_2$ of $\pi_1, \ldots, \pi_d$ is $\gamma$-expanding, then the primary directed multi-graph $G_1$ of $\pi_1, \ldots, \pi_d$ coupled with the foregoing edge-coloring is $\gamma$-robustly self-ordered. Furthermore, $G_1$ (or rather the undirected multi-graph underlying $G_1$) is min$(0.25, \gamma/3)$-expanding.

**Proof.** Let $\mu : [n] \rightarrow [n]$ be an arbitrary permutation, and let $T = \{v \in [n] : \mu(v) \neq v\}$ be its set of non-fixed-points. Then, the size of the symmetric difference between $G_1$ and $\mu(G_1)$ equals $2 \cdot \sum_{i \in [d]} |D_i|$ such that $v \in D_i$ if $(\mu(v), \mu(\pi_i(v)))$ is either not an edge in $G_1$ or is not colored $i$ in it, whereas $(v, \pi_i(v))$ is an edge colored $i$ in $G_1$. Note that if $(\mu(v), \mu(\pi_i(v)))$ is not an $i$-colored edge in $G_1$, then $\pi_i(\mu(v)) \neq \mu(\pi_i(v))$. Hence, $D_i = \{v \in [n] : \mu(\pi_i(v)) \neq \pi_i(\mu(v))\}$.

The key observation (proved next) is that if $v \in T \setminus D_1$, then $(\pi_i(v), \pi_i(\mu(v))) \in T_2$, where $T_2 = \{(v, \mu(v)) : v \in T\}$ represents the sets of replacements performed by $\mu$. This fact implies that if $\sum_{i \in [d]} |D_i|$ is small in comparison to $|T|$, then the set $T_2$ (which is a set of vertices in $G_2$) does not expand much, in contradiction to the hypothesis. Details follow.

**Observation 3.2.1 (key observation).** For $T$, $D_1$, and $T_2$ as defined above, if $v \in T \setminus D_1$, then $(\pi_i(v), \pi_i(\mu(v))) \in T_2$.

Recall that $v \in T$ implies $(v, \mu(v)) \in T_2$. Observation 3.2.1 asserts that if (in addition to $v \in T$) it holds that $v \notin D_1$, then $(\pi_i(v), \pi_i(\mu(v)))$ is also in $T_2$. This means that the edges colored $i$ incident at $(\pi_i(v), \pi_i(\mu(v))) : v \in T \setminus D_1$ do not contribute to the expansion of the set $T_2$ in $G_2$.

**Proof.** Since $v \notin D_1$, we have $\pi_i(\mu(v)) = \mu(\pi_i(v))$, and $\mu(\pi_i(v)) \neq \pi_i(v)$ follows, because otherwise $\pi_i(\mu(v)) = \pi_i(v)$, which implies $\mu(v) = v$ in contradiction to $v \in T$. However, $\mu(\pi_i(v)) \neq \pi_i(v)$ means that $\pi_i(v) \in T$, and $(\pi_i(v), \pi_i(\mu(v))) = (\pi_i(v), \mu(\pi_i(v))) \in T_2$ follows.

\[\square\]
Conclusion. Recall that Observation 3.2.1 implies that \( \{(\pi_i(v), \pi_i(\mu(v))) : v \in T \setminus D_i\} \subseteq T_2 \), whereas \( \bigcup_{i \in [d]} \{(\pi_i(v), \pi_i(\mu(v))) : v \in T\} \) is the neighborhood of \( T_2 \) in the multi-graph \( G_2 \) (since \( \{(\pi_i(v), \pi_i(\mu(v))) : i \in [d]\} \) the neighbor-set of \( (v, \mu(v)) \) in \( G_2 \)). Using the \( \gamma \)-expansion of \( G_2 \) (and \( |T_2| \leq n < |V_2|/2 \)), it follows that \( \sum_{i \in [d]} |D_i| \geq \gamma \cdot |T| \). The main claim follows.

The expansion of \( G_1 \) is shown by relating sets of vertices of \( G_1 \) to the corresponding sets of pairs in \( G_2 \). Specifically, for and \( S \subseteq [n] \) of size at most \( n/2 \), we consider the set \( T = \{(u, v) \in V_2 : u, v \in S\} \), which has size \( |S| \cdot (|S| - 1) \leq \frac{n^2}{4} \cdot \left( \frac{n}{2} - 1 \right) < \frac{|V_2|^2}{4} \). Letting \( T' \) denote the set of neighbors of \( T \) in \( G_2 \), and \( |S'| \) denote the set of neighbors of \( S \) in \( G_1 \), we have \( |T' \setminus T| \geq \gamma \cdot |T| \), on the one hand (by expansion of \( G_2 \)), and \( |T' \setminus T| \leq 2 \cdot |S| \cdot |S' \setminus S| + |S' \setminus S| \cdot (|S' \setminus S| - 1) \) on the other hand. This implies \( |S' \setminus S| \geq (\gamma/3) \cdot |S| \) (unless \( |S| < 5 \), which can be handled by using \( |S' \setminus S| \geq 1 \)).

Primary and secondary multi-graphs based on \( SL_2(p) \)

Recall that \( SL_2(p) \) is the group of 2-by-2 matrices over \( GF(p) \) that have determinant 1. There are several different explicit constructions of constant-size expanding generating sets for \( SL_2(p) \), namely making the associated Cayley graph an expander (see, e.g., [28], [27], Thm. 4.4.2(i)), and [6]). We use any such generating set to define a directed (edge-colored) multi-graph \( G_1 \) on \( p + 1 \) vertices, and show that the associated multi-graph on pairs, \( G_2 \), is an expander.

\begin{itemize}
  \item \textbf{Proposition 3.3} (expanding generators for \( SL_2(p) \) yield an expanding secondary multi-graph). For any prime \( p > 2 \), let \( V = \{(1, i)^\top : i \in GF(p)\} \cup \{(0, 1)^\top\} \), and \( M_1, \ldots, M_4 \in SL_2(p) \). For every \( i \in [d] \), define \( \pi_i : V \to \text{V such that } \pi_i(u) = v \text{ if } v \in V \text{ is a non-zero multiple of } M_i \).
  \begin{enumerate}
    \item Each \( \pi_i \) is a bijection.
    \item If the Cayley multi-graph \( C = C(SL_2(p), [M_1, \ldots, M_4]) = (SL_2(p), \{M, M_i M\} : M \in SL_2(p) \& i \in [d]\}) \) is an expander, then the (Schreier) multi-graph \( G_2 \) with vertex-set \( P = \{(v, v') : v \in V \& v' \in V \setminus \{v\}\} \) and edge-set \( \{\{(v, v'), (\pi_i(v), \pi_i(v')) : (v, v') \in P\} \) is an expander.
  \end{enumerate}
\end{itemize}

Part 1 implies that these permutations yield a primary directed edge-colored multi-graph on the vertex-set \( V \), whereas Part 2 asserts that the corresponding secondary graph is an expander (if the corresponding Cayley graph is expanding). Note that \( |V| = p + 1 \) and \( |P| = (p + 1)p \), whereas \( |SL_2(p)| = p^3 - p = (p - 1) \cdot |P| \).

\begin{proof}
  Part 1 follows by observing that for every \( M \in SL_2(p) \) and every vector \( v \in GF(p)^2 \) and scalar \( \alpha \in GF(p) \) it holds that \( M \alpha v = \alpha M v \). Consequently, if for some non-zero \( \alpha, \alpha' \in GF(p) \) it holds that \( \alpha M v = \alpha' M v' \), then \( M v = M \alpha' v' \) for \( \alpha' = \alpha' / \alpha \), which implies \( v = \alpha' v' \) (since \( M \) is invertible). Hence, \( \pi_i(v) = \pi_i(v') \), for \( v, v' \in V \), implies \( v = v' \).

  Part 2 follows by observing that the vertices of \( G_2 \) correspond to equivalence classes of the vertices of \( C \) that are preserved by \( SL_2(p) \), where \( A, B \in SL_2(p) \) are equivalent if the columns of \( A \) are non-zero multiples of the corresponding columns of \( B \). That is, we consider an equivalence relation, denoted \( \equiv \), such that \( A = [A_1 | A_2] \) and \( B = [B_1 | B_2] \) in \( SL_2(p) \) it holds that \( A \equiv B \) if \( A_i = \alpha_i B_i \) for both \( i \in \{1, 2\} \), where \( \alpha_1, \alpha_2 \in [p - 1] \) (and, in fact, \( \alpha_2 = 1 / \alpha_1 \)). By saying that these equivalence classes are preserved by \( SL_2(p) \), we mean that, for every \( A, B, M \in SL_2(p) \), if \( A \equiv B \), then \( MA \equiv MB \). Hence, the (combinatorial)

\footnotesize
\begin{itemize}
  \item Recall that \( \det(A) = 1 = \det(B) \), whereas \( \det([\alpha_1 B_1 | \alpha_2 B_2]) = \alpha_1 \alpha_2 \cdot \det(B) \). Note that each equivalence class contains a single element of \( P \).
\end{itemize}

expansion of $G_2$ follows from the expansion of $C$, because the neighbors of a vertex-set $S \subseteq P$ in $G_2$ are the vertices of $G_2$ that are equivalent to $T'$ such that $T'$ is the set of vertices of $\mathcal{C}^{(t)}$ that neighbor (in $\mathcal{C}^{(t)}$) vertices that are equivalent to vertices in $S$.\footnote{Specifically, let $S$ have density at most half in $P$, and let $T$ be the set of vertices of $C$ that are equivalent to $S$. Note that $|T| = (p - 1) \cdot |S|$, since each equivalence class contains a single element of $P$. By the foregoing, the set of neighbors of $T$ in $C$, denoted $T'$, is a collection of equivalence classes of vertices of $G_2$, and $|T' \setminus T| = \Omega(|T|)$ by the expansion of $C$. It follows that the set of neighbors of $S$ in $G_2$, denoted $S'$, is the set of vertices that are equivalent to $T'$, which implies that $|S' \setminus S| = \frac{|T' \setminus T|}{p-1} = \Omega(|S|)$.
}

A simple construction

Combining Theorem 3.2 with Proposition 3.3, while using a simple pair of expanding generators (which does not yield a Ramanujan graph), we get

\begin{corollary} \label{cor:expander}
(a simple robustly self-ordered primary multi-graph). For any prime $p > 2$, let $V = \{(1, i)^T : i \in \text{GF}(p)\} \cup \{(0, 1)^T\}$, and consider the matrices

\[ M_1 \overset{\text{def}}{=} \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \quad \text{and} \quad M_2 \overset{\text{def}}{=} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \quad \text{(4)} \]

Then, for $\pi_1$ and $\pi_2$ defined as in Proposition 3.3, the corresponding primary (directed edge-colored) multi-graph is robustly self-ordered.

This follows from the fact that the corresponding Cayley graph $\mathcal{C}(\text{SL}_2(p), \{M_1, M_2\})$ is an expander [27, Thm. 4.4.2(i)].

Perspective

The foregoing construction using the group $\text{SL}_2(p)$ is a simple case of a much more general family of constructions, and the elements of the proof of Proposition 3.3 follow an established theory (explained, e.g., in [25, Sec. 11.1.2]), which we briefly describe.

Let $H$ be any finite group, and $S$ an expanding generating set of $H$ (i.e., the Cayley graph $\mathcal{C}(H, S)$ is an expander). Assume that $H$ acts on a finite set $V$ (i.e., each $h \in H$ is associated with a permutation on $V$, and $h' h(v) = h'(h(v))$ for every $h, h' \in H$ and $v \in V$). Then, the primary (directed edge-colored) multi-graph $G_1$ on vertices $V$ can be constructed from the permutations defined by members of $S$. The secondary multi-graph $G_2$ is naturally defined by the action of $S$ on pairs of elements in $V$. Finally, the expansion of $\mathcal{C}(H, S)$ implies that every connected component of $G_2$ is an expander.\footnote{Indeed, this was easy to demonstrate directly in the case of Proposition 3.3.} Thus, whenever this (Schreier) graph $G_2$ is connected (as it is in Proposition 3.3), one may conclude that $G_1$ is a directed edge-colored robustly self-ordered multi-graph.

3.2 From the directed variant to the undirected one

In this section we show how to transform directed (edge-colored) multi-graphs, of the type constructed in Section 3.1, into undirected ones, while preserving all relevant features (i.e., bounded robustness, bounded degree, regularity, expansion, and local computability). The transformation is extremely simple and natural: We replace the directed edge $(u, v)$ colored $j$ by a 2-path with a designated auxiliary vertex $a_{u,v,j}$, while coloring the edge $\{u, a_{u,v,j}\}$ by $2j - 1$ and the edge $\{a_{u,v,j}, v\}$ by $2j$. Evidently, this colored 2-path encodes the direction of the original edge (as well as the original color).
Note that the foregoing transformation works well provided that there are no parallel edges that are colored with the same color, a condition which is satisfied by the construction presented in Section 3.1. Furthermore, since the latter construction has no vertices of (in+out) degree less that 2d ≥ 4, there is no need to mark the original vertices by self-loops. Hence, a preliminary step akin to Construction 2.2 in unnecessary here, although it can be performed in general.

**Proposition 3.5** (from directed robust self-ordering to undirected robust self-ordering). For constants \( d \geq 3 \) and \( c \), let \( G = (V, E) \) be a directed multi-graph in which each vertex has between three and \( d \) incident edges (in both directions), and that \( G \) is coupled with an edge-coloring function \( \chi : E \to [c] \) such that no parallel edges (in same the direction) are assigned the same color. Letting \( E_i = \{ e \in E : \chi(e) = i \} \) denote the set of edges colored \( i \) in \( G \), consider the undirected multi-graph \( G' = (V', E') \) such that \( V' = V \cup \{ \langle a_{u,v}, i \rangle : (u,v) \in E_i \} \) and \( E' = \bigcup_{j \in [2c]} E_j' \) where

\[
E_{2i-1}' = \{ \{u, a_{u,v,i}\} : (u,v) \in E_i \}, \\
E_{2i}' = \{ \{a_{u,v,i}, v\} : (u,v) \in E_i \},
\]

and the edge-coloring function \( \chi : E' \to [2c] \) that assigns the edges of \( E_i' \) the color \( j \) (i.e., \( \chi(e) = j \) for every \( e \in E_i' \). Then, if \( (G, \chi) \) is \( \gamma \)-robustly self-ordered (in the sense of Definition 3.1), then \( (G', \chi') \) is \((\gamma/2)\)-robustly self-ordered (in the sense of Definition 2.1).

We comment that the transformation of \( (G, \chi) \) to \( (G', \chi') \) preserves bounded robustness, bounded degree, regularity, expansion, and local computability (cf. Theorem 2.8).

**Proof.** The proof is analogous to the proof of Theorem 2.4, but it is much simpler because the gadgets used in the current transformation (i.e., the auxiliary vertices \( a_{u,v,i} \)) are much simpler.

Considering an arbitrary permutation \( \mu' : V' \to V' \), we lower-bound the distance between \( G' \) and \( \mu'(G') \) as a function of the number of non-fixed-points under \( \mu' \). We do so by considering the contribution of each non-fixed-point to the distance between \( G' \) and \( \mu'(G') \).

We first recall the fact that the vertices of \( V' \) (resp., the auxiliary vertices) are uniquely identified in \( \mu'(G') \) by virtue of their degree, since each vertex of \( V \) has degree at least three (in \( G' \)) whereas the auxiliary vertices have degree 2.

**Case 1:** Auxiliary vertices of the form \( a_{u,v,i} \) that are not mapped by \( \mu' \) to auxiliary vertices of the form \( a_{u',v',i} \); that is, \( \mu'(a_{u,v,i}) \notin (V \cup \bigcup_{j \neq i} \{ a_{u',v',j} : (u',v') \in E_j \}) \).

Each such vertex \( a_{u,v,i} \) contributes at least one unit to the difference between \( G' \) and \( \mu'(G') \), since the two edges incident at \( a_{u,v,i} \) in \( G' \) are colored \( 2i - 1 \) and \( 2i \) respectively, whereas \( \mu(a_{u,v,i}) \) has either more than two edges (in \( G' \)) or its two edges are colored \( 2j - 1 \) and \( 2j \) respectively, where for \( j \neq i \). Hence, if the current case contains \( n_1 \) vertices, then their contribution to the distance between \( G' \) and \( \mu'(G') \) is at least \( n_1 \).

Ditto for vertices of \( V \) that are mapped by \( \mu' \) to an auxiliary vertex.

**Case 2:** Vertices \( v \in V \) such that \( \mu'(v) \notin V \setminus \{ v \} \).

By the hypothesis that the edge-colored directed \( G \) is robustly self-ordered, it follows that such vertices contribute proportionally to the difference between the colored versions of the directed multi-graphs \( G \) and \( \mu(G) \), where \( \mu \) is the restriction of \( \mu' \) to \( V \). Specifically, the number of tuples \( \langle (u,v), i \rangle \) such that \( (u,v) \) is colored \( i \) in exactly one of these multi-graph (i.e., either in \( G \) or in \( \mu(G) \) but not in both) is at least \( \gamma : |\{ v \in V : \mu(v) \neq v \}| \).

Assume, without loss of generality that \( (u,v) \in E_i \) but either \( (\mu^{-1}(u), \mu^{-1}(v)) \notin E \) or \( (\mu^{-1}(u), \mu^{-1}(v)) \in E_j \) for \( j \neq i \). Either way, it follows that a vertex not in \( \{ a_{u',v',i} : \)
(u', v') ∈ E_i \}$ is mapped by μ' to $a_{u,v,i}$, which means that Case 1 applies for each such a tuple. Hence, if the number of vertices in the current case is $n_2$, then $n_1 ≥ γ \cdot n_2$, and we get a contribution of at least $γ \cdot n_2$ via Case 1.

**Case 3:** Auxiliary vertices of the form $a_{u,v,i}$ that are mapped by μ’ to auxiliary vertices of the form $a_{u',v',i}$, for $(u', v') ≠ (u, v)$; that is, $μ'(a_{u,v,i}) ∈ \{a_{u',v',i} : (u', v') ∈ E_i \setminus \{(u, v)\}\}$. For $u, v, u', v'$ and $i$ as above, if $μ'(u) = u'$ and $μ'(v) = v'$, then an auxiliary vertex that connects $u$ and $v$ in $G'$ is mapped to an auxiliary vertex that does not connect them in $μ'(G')$ (but rather connects the vertices $u'$ and $v'$, whereas either $u' ≠ u$ or $v' ≠ v$). So we get a contribution of at least one unit to the difference between $G'$ and $μ'(G')$ (i.e., the edge incident at either $u$ or $v$). Hence, the contribution is proportional to the number of non-fixed-points of the current type. Otherwise (i.e., $(μ'(u), μ'(v)) ≠ (u', v')$), we get a vertex as in either Case 1 or Case 2, and get a proportional contribution again.

Hence, the contribution of each of these cases to the difference between $G'$ and $μ'(G')$ is proportional to the number of vertices involved. Specifically, if there are $n_i$ vertices in Case $i$, then we get a contribution-count of at least $γ \cdot \sum_{i ∈ [3]} n_i$, where some of these contributions were possibly counted twice. The claim follows.

## 4 The Three-Step Construction

In this section we present a different construction of bounded-degree graphs that are robustly self-ordered. It uses totally different techniques than the ones utilized in the construction presented in Section 3. Furthermore, the current construction offers the flexibility of obtaining either graphs that have small connected components (i.e., of logarithmic size) or graphs that are highly connected (i.e., are expanders). Actually, one can obtain anything in-between (i.e., $n$-vertex graphs that consist of $s(n)$-sized connected components that are each an expander, for any $s(n) = Ω((\log n)/\log \log n)$). We mention that robustly self-ordered bounded-degree graphs with small connected components are used in the proof of Theorem 5.2.

As stated in Section 1.1.2, the current construction proceeds in three steps. First, in Section 4.1, we prove the existence of robustly self-ordered bounded-degree graphs, and observe that such $ℓ$-vertex graphs can actually be found in $\text{poly}(ℓ)$-time [sic]. Next, setting $ℓ = Ω((\log n)/\log \log n)$, we use these graphs as part of $2ℓ$-vertex connected components in an $n$-vertex (robustly self-ordered bounded-degree) graph that is constructed in $\text{poly}(n)$-time (see Section 4.2). Lastly, in Section 4.3, we repeat this strategy using the graphs constructed in Section 4.2, and obtain exponentially larger graphs that are locally constructible.

In addition, in Section 4.4, we show that the foregoing graphs can be locally self-ordered. That is, given a vertex $v$ in any graph $G' = (V', E')$ that is isomorphic to the foregoing $n$-vertex graph and oracle access to the incidence function of $G'$, we can find the vertex to which this unique isomorphism maps $v$ in $\text{poly}(\log n)$-time.

### 4.1 Existence

As stated above, we start with establishing the mere existence of bounded-degree graphs that are robustly self-ordered.

**Theorem 4.1** (robustly self-ordered graphs exist). For any sufficiently large constant $d$, there exists a family $\{G_n\}_{n ∈ \mathbb{N}}$ of robustly self-ordered $d$-regular graphs. Furthermore, these graphs are expanders.
Actually, it turns out that random \( d \)-regular graphs are robustly self-ordered; see Theorem 6.1. Either way, given the existence of such \( n \)-vertex graphs, they can actually be found in \( \text{poly}(n!) \)-time, by an exhaustive search. Specifically, for each of the possible \( n^{dn/2} \) graphs, we check the robust self-ordering condition by checking all \( n!-1 \) relevant permutations. (The expansion condition can be checked similarly, by trying all \((0.5 + o(1)) \cdot 2^n\) relevant subsets of \([n]\).)

The proof of Theorem 4.1 utilizes a simpler probabilistic argument than the one used in the proof of Theorem 6.1. This argument (captured by Claim 4.1.1) refers to the auxiliary model of edge-colored multi-graphs (see Defintion 2.1) and is combined with a transformation of this model to the original model of uncolored graphs (provided in Construction 2.3 and analyzed in Theorem 2.4). Indeed, the relative simplicity of Claim 4.1.1 is mainly due to using the edge-colored model (see digest at the end of Section 6).

**Proof.** To facilitate the proof, we present the construction while referring to the edge-colored model presented in Section 2. We shall then apply Theorem 2.4 and obtain a result for the original model (of uncolored simple graphs).

For \( m = n/O(1) \), we shall consider \( 2m \)-vertex multi-graphs that consists of two \( m \)-vertex cycles, using a different color for the edges of each cycle, that are connected by \( d' = O(1) \) random perfect matching, which are also each assigned a different color. (Hence, we use \( 2 + d' \) colors in total.) We shall show that (w.h.p.) a random multi-graph constructed in this way is robustly self-ordered (in the colored sense). (Note that parallel edges, if they exist, will be assigned different colors.) Specifically, we consider a generic \( 2m \)-vertex multi-graph that is determined by \( d' \) perfect matchings of \([m]\) with \( \{m + 1, \ldots, 2m\} \). Denoting this sequence of perfect matchings by \( \mathcal{M} = (M_1, \ldots, M_{d'}) \), we consider the (edge-colored) multi-graph \( G_{\mathcal{M}}([2m], E_{\mathcal{M}}) \) given by

\[
E_{\mathcal{M}} = C_1 \cup C_2 \cup \bigcup_{j \in [d']} M_j
\]

where \( C_1 = \{(i, i+1) : i \in [m-1]\} \cup \{\{m, 1\}\} \)

and \( C_2 = \{\{m + i, m + i + 1\} : i \in [m-1]\} \cup \{\{2m, m + 1\}\} \)

and a coloring \( \chi \) in which the edges of \( C_j \) are colored \( j \) and the edges of \( M_j \) are colored \( j + 2 \). (That is, for \( i \in \{1, 2\} \), the set \( C_i \) forms a cycle of the form \(((i-1)m + 1, (i-1)m + 2, \ldots, (i - 1)m + m, (i - 1)m + 1)\) and its edges are colored \( i \).) Note that the \( d' + 1 \) edges incident at each vertex are assigned \( d' + 1 \) different colors.

▷ Claim 4.1.1 (w.h.p., \( G_{\mathcal{M}} \) is robustly self-ordered). For some constant \( \gamma > 0 \), with high probability over the choice of \( \mathcal{M} \), the edge-colored multi-graph \( G_{\mathcal{M}} \) is \( \gamma \)-robustly self-ordered. Furthermore, it is also an expander.

Proof. Consider an arbitrary permutation \( \mu : [2m] \rightarrow [2m] \), and let \( t = \|\{i \in [2m] : \mu(i) \neq i\}\| \). We shall show that, with probability \( 1 - \exp(-\Omega(dt \log m)) \) over the choice of \( \mathcal{M} \), the difference between the colored versions of \( G_{\mathcal{M}} \) and \( \mu(G_{\mathcal{M}}) \) is \( \Omega(t) \). Towards this end, we consider two cases.

**Case 1:** \( \|\{i \in [m] : \mu(i) \notin [m]\}\| > t/4 \). Equivalently, \( \|\{i \in [2m] : [\mu(i)/m] \neq [i/m]\}\| > t/2 \).

The vertices in the set \( \{i \in [m] : \mu(i) \notin [m]\} \) are mapped from the first cycle to the second cycle, and so rather than having two incident edges that are colored 1 they have two incident edges colored 2. Hence, each such vertex contributes two units to the difference (between the colored versions of \( G_{\mathcal{M}} \) and \( \mu(G_{\mathcal{M}}) \)), and the total contribution is greater than \( 2 \cdot (t/4) \cdot 2 \), where the first factor of 2 accounts also for vertices that are mapped from \( C_2 \) to \( C_1 \).
Case 2: $|\{i \in [m] : \mu(i) \notin [m]\}| \leq t/4$. Equivalently, $|\{i \in [2m] : [\mu(i)/m] \neq [i/m]\}| \leq t/2$. We focus on the non-fixed-points of $\mu$ that stay on their original cycle (i.e., those not considered in Case 1). Let $A \overset{\text{def}}{=} \{i \in [m] : \mu(i) \neq i \wedge \mu(i) \in [m]\}$ and $B \overset{\text{def}}{=} \{i \in \{m+1, \ldots, 2m\} : \mu(i) \neq i \wedge \mu(i) \in \{m+1, \ldots, 2m\}\}$. By the case hypothesis, $|A| + |B| \geq t/2$, and we may assume (without loss of generality) that $|A| \geq t/4$. As a warm-up, we first show that each element of $A$ contributes a non-zero number of units to the difference (between the colored versions of $G_{\mathcal{M}}$ and $\mu(G_{\mathcal{M}})$) with probability $1 - O(1/m)^{d'}$, over the choice of $\mathcal{M}$.

To see this, let $\pi_j : [m] \rightarrow \{m+1, \ldots, 2m\}$ be the mapping used in the $j$th matching; that is, $M_j = \{i, \pi_j(i) : i \in [m]\}$, which means that $\pi_j(i)$ is the $j$th match of $i$ in $G_{\mathcal{M}}$ (i.e., the vertex matched to $i$ by $M_j$). Then, we consider the event that for some $j \in [d']$, the $j$th match of $i \in [m]$ in $\mu(G_{\mathcal{M}})$ is different from the $j$th match of $i$ in $G_{\mathcal{M}}$, and note that when this event occurs $i$ contributes to the difference (between the colored versions of $G_{\mathcal{M}}$ and $\mu(G_{\mathcal{M}})$). Note that $x$ is the $j$th match of $i$ in $\mu(G_{\mathcal{M}})$ if and only if $\mu^{-1}(x)$ is the $j$th match of $\mu^{-1}(i)$ in $G_{\mathcal{M}}$, which holds if and only if $\mu^{-1}(x) = \mu_j(\mu^{-1}(i))$ (equiv., $x = \mu_j(\mu^{-1}(i))$). Hence, $i \in [m]$ contributes to the difference if and only if for some $j$ it holds that $\pi_j(i) \neq \mu_j(\mu^{-1}(i))$, because $\pi_j(i) \neq \mu_j(\mu^{-1}(i))$ means that the edge $\{i, \pi_j(i)\}$ is colored $j+2$ in $G_{\mathcal{M}}$ but is not colored $j+2$ in $\mu(G_{\mathcal{M}})$ (since a different edge incident at $i$ in $\mu(G_{\mathcal{M}})$ is colored $j+2$). Letting $\pi = (\pi_1, \ldots, \pi_{d'})$, the probability of the complementary event (i.e., $i$ does not contribute to the difference) is given by

$$P_{\pi}([\forall j \in [d'] \] \pi_j(i) = \mu(\pi_j(\mu^{-1}(i)))] \leq (m-1)^{-d'},$$

where the inequality uses the hypothesis that $\mu(i) \neq i$ and $\mu(i) \in [m]$; specifically, fixing the value of $\pi_j(\mu^{-1}(i))$, leaves $\pi_j(i)$ uniformly distributed in $S \overset{\text{def}}{=} \{m+1, \ldots, 2m\} \setminus \{\pi_j(\mu^{-1}(i))\}$, which means that $P_{\pi_j}[\pi_j(i) = \mu(v) | v = \pi_j(\mu^{-1}(i))] \leq 1/|S|$ (where equality holds if $\mu(v) \in S$).

The same argument generalises to any set $I \subseteq A$ such that $I \cap \mu(I) = \emptyset$. In such a case, letting $I = \{i_1, \ldots, i_{d'}\}$, we get

$$P_{\pi}([\forall i \in I \forall j \in [d'] \] \pi_j(i) = \mu(\pi_j(\mu^{-1}(i)))]$$

$$= \prod_{k \in [r]} \prod_{j \in [d']} \text{Pr}_{\pi_j}([\pi_j(i_k) = \mu(\pi_j(\mu^{-1}(i_k)))) \mid ([\forall k' \in [k-1]] \pi_j(i_{k'}) = \mu(\pi_j(\mu^{-1}(i_{k'}))))]$$

$$\leq (m-2t' + 1)^{-t'd'},$$

where the inequality uses the hypothesis that $I \cap \mu(I) = \emptyset$; specifically, for each $k \in [t']$, we use the fact that $i_k \notin \{i_1, \ldots, i_k-1, \mu^{-1}(i_1), \ldots, \mu^{-1}(i_k)\}$. Hence, fixing the values of $\pi_j(i_k')$ for all $k' \in [k-1]$ and the values of $\pi_j(\mu^{-1}(i_k))$ for all $k \in [k]$, and denoting these values by $u_1, \ldots, u_{k-1}$ and $v_1, \ldots, v_k$ respectively, leaves $\pi_j(i_k)$ uniformly distributed in $S \overset{\text{def}}{=} \{m+1, \ldots, 2m\} \setminus \{u_1, \ldots, u_{k-1}, v_1, \ldots, v_k\}$, which means that $P_{\pi_j}[\pi_j(i) = \mu(v_k) \mid \text{foiging fixing}] \leq 1/|S|$ (where equality holds if $\mu(v_k) \in S$).

Recalling that $|A| \geq t/4$ and $t \leq 2m$, we have an upper-bound the probability (over the choice of $\mathcal{M}$) that $A$ contains a $t/4$-subset $A'$ such that $([\forall i \in A' \forall j \in [d'] \] \pi_j(i) = \mu(\pi_j(\mu^{-1}(i)))$, by taking a union bound over all possible $A'$ and using for each such $A'$ a subset $I \subset A'$ such that $I \cap \mu(I) = \emptyset$. (So we actually take a union bound over the $I$'s and derive a conclusion regarding the $t/4$-subsets $A'$.) Observing that $|I| \geq |A'|/2 \geq t/16$, we conclude that, with probability at most $\left(\frac{t}{16}\right)^{d'} \cdot (m/2)^{d't/16} = \exp(-\Omega(d't \log m))$ over the choice of $\mathcal{M}$, the set $A$ contains no $t/4$-subset $A'$ as above. This means that, with probability at most $\exp(-\Omega(d't \log m))$, less than $t/8$ of the indices $i \in A$ contribute a non-zero number of units to the difference (between the colored versions of $G_{\mathcal{M}}$ and $\mu(G_{\mathcal{M}})$).
Hence, we have shown that, for every permutations \( \mu : [2m] \to [2m] \), the probability (over the choice of \( M \)) that the size of the symmetric difference between the colored versions of \( G_{M} \) and \( \mu(G_{M}) \) is smaller than \( t/8 \) is \( \exp(-\Omega((d'-O(1)) \cdot \log m)) \), where \( t \) is the number of non-fixed-points of \( \mu \). Letting \( \gamma = 1/8 \) and taking a union bound over all (non-trivial) permutations \( \mu : [2m] \to [2m] \), we conclude that the probability, over the choice of \( M \), that \( G_{M} \) is not \( \gamma \)-robustly self-ordered is at most
\[
\sum_{t \in [2m]} \left( \begin{array}{c} 2m \\ t \end{array} \right) \cdot \exp(-\Omega(d' \cdot \log m)) = \sum_{t \in [2m]} \exp(-\Omega((d'-O(1)) \cdot \log m)) = \exp(-\Omega((d'-O(1)) \cdot \log m)),
\]
and the claim follows (for any sufficiently large \( d' \)), while observing that, with very high probability, these multi-graphs are expanders. 

Back to the non-colored version. We now convert the edge-colored multi-graphs \( G = G_{M} \) that are \( \gamma \)-robustly self-ordered into standard graphs \( G' \) that are robustly self-ordered in the original sense. This is done by using Construction 2.3 (while relying on Theorem 2.4). Recall that this transformation also preserves expansion. Actually, before invoking Construction 2.3, we augment the multi-graph \( G \) by adding a self-loop to each vertex, and color all these self-loops using a special color. Combining Claim 4.1.1 and Theorem 2.4, the current theorem follows.

\[\triangleright\]

### 4.2 Constructions

Having established the existence of bounded-degree graphs that are robustly self-ordered, we now turn to actually construct them. We shall use the fact that the proof of existence yields a construction that runs in time that is polynomial in the number of possible graphs. Specifically, for \( \ell = \Theta(\log n) \), we shall construct \( \ell \)-vertex graphs in \( \text{poly}(\ell^{\ell}) \)-time and use them in our construction of \( n \)-vertex graphs, while noting that \( \text{poly}(\ell^{\ell}) = \text{poly}(n) \).

\[\triangleright\text{Theorem 4.2 (constructing robustly self-ordered graphs).} \text{ For any sufficiently large constant } d, \text{ there exists an efficiently constructable family } \{G_n\}_{n \in \mathbb{N}} \text{ of robustly self-ordered graphs of maximum degree } d. \text{ That is, there exists a polynomial-time algorithm that on input } n^n \text{ outputs the } n \text{-vertex graph } G_n = ([n], E_n). \text{ Furthermore, } G_n \text{ consists of connected components of size } O(\log n) = o(\log n).\]

Note that the connected components of \( G_n \) cannot be any smaller (than \( O(\log n) \)). This is the case because an asymmetric \( n \)-vertex bounded-degree graph, let alone a robustly self-ordered one, cannot have connected components of size \( o(\log n) \) (because the number of \( t \)-vertex graphs of bounded-degree is \( t^{O(1)} \)).

\[\triangleright\text{Proof.} \text{ The proof proceeds in two steps. We first use the existence of } \ell \text{-vertex } (d' \text{-regular}) \text{ expanders graphs that are robustly self-ordered towards constructing a sequence of } m = \text{exp}(\Omega(\ell \log \ell)) \text{ bounded-degree } 2\ell \text{-vertex graphs that are robustly self-ordered, expanding, and far from being isomorphic to one another. We construct this sequence of } 2\ell \text{-vertex graphs in } \text{poly}(m) \text{-time, using the fact that } (\ell!)^{O(1)} = \text{poly}(m). \text{ In the second step, we show that the}\]

- \( m \) is the number of non-fixed-points of \( \mu \).
- \( \gamma = 1/8 \) is the probability threshold.
- \( \log \) is the logarithm function.
- \( \text{poly}(n) \) is the polynomial function in \( n \).
- \( \Omega \) is the big Omega notation.
- \( O \) is the big O notation.
- \( \Theta \) is the big Theta notation.
- \( \gamma \)-robustly self-ordered means that the size of the symmetric difference between the colored versions of the graph and its permutation is small.
- Construction 2.3 is a method to convert edge-colored graphs into standard graphs.
- Theorem 2.4 is a theorem about the properties of the constructed graphs.
- \( n^n \) is the input size.
- \( G_n \) is the constructed graph.
- \( G_{M} \) is the multi-graph.
- \( (\ell!)^{O(1)} = \text{poly}(m) \) is an equality between an exponential function and a polynomial function.
- \( t^{O(1)} \) is an exponential function with a small constant.
(m \cdot 2\ell)-vertex graph that consists of these 2\ell-vertex graphs (as its connected components) is robustly self-ordered. Note that this graph is constructed in time that is polynomial in its size, since its size is \(\Omega(m)\), whereas it is constructed in \(\text{poly}(m)\)-time.\(^{17}\)

Given a generic \(n\), let \(\ell = \frac{G(n)}{\log \log n}\), which implies that \(\ell^2 = \text{poly}(n)\). By Theorem 4.1, for all sufficiently large \(d'\), there exist \(\ell\)-vertex \(d'\)-regular expander graphs that are robustly self-ordered (with respect to the robustness parameter \(c'\)). Furthermore, we can find such a graph, denoted \(G'_\ell\), in time \(\text{poly}(\ell^2) = \text{poly}(n)\), by scanning all \(\ell\)-vertex \(d'\)-regular graphs and checking both the expansion and the robustness (w.r.t parameter \(c'\)) conditions for each of them. Actually, for \(d'' = d' + 1\), we shall also find an \(\ell\)-vertex \(d''\)-regular expander, denoted \(G''_\ell\), that is robustly self-ordered.

**The construction of \(G_n\).** Using \(G'_\ell\) and \(G''_\ell\), we construct an \(n\)-vertex robustly self-ordered graph, denoted \(G_n\), that consists of \(n/2\ell\) connected components that are pairwise far from being isomorphic to one another. This is done by picking \(m = n/2\ell\) permutations, denoted \(\pi_1, \ldots, \pi_m : [\ell] \rightarrow [\ell]\), that are pairwise far-apart and constructing \(2\ell\)-vertex graphs such that the \(i\)th such graph consist of a copy of \(G'_\ell\) and a copy of \(G''_\ell\) that are connected by a matching as determined by the permutation \(\pi_i\). Specifically, for \(G'_\ell = ([\ell], E'_\ell)\) and \(G''_\ell = ([\ell], E''_\ell)\), the \(i\)th connected component is isomorphic to a graph with the vertex set \([2\ell]\) and the edge set

\[
E'_\ell \cup \{\{u, v\} : \{u, v\} \in E''_\ell\} \cup \{\{u, v + 1\} : u, v \in [\ell]\}.
\]

(The first two sets correspond to the copies of \(G'_\ell\) and \(G''_\ell\), and the third set corresponds to the matching between these copies. Note that the vertices in \([\ell]\) have degree \(d' + 1\), whereas vertices in \([\ell + 1, \ldots, 2\ell]\) have degree \(d'' + 1 = d' + 1\).)

To see that this construction can be carried out in \(\text{poly}(n)\)-time, we need to show that the sequence of \(m\) pairwise far-apart permutations can be determined in \(\text{poly}(n)\)-time, let alone that such a sequence exists. This is the case, because we can pick the permutation sequentially (one after the other) by scanning the symmetric group on \([\ell]\) and relying on the fact that for \((i < n\) and\) any fixed sequence of permutations \(\pi_1, \ldots, \pi_{i-1} : [\ell] \rightarrow [\ell]\) it holds that a random permutation \(\pi_i\) is far-apart from each of the fixed \(i - 1\) permutations; that is, \(\Pr_{\pi}[\{|v \in [\ell] : \pi_i(v) \neq \pi_j(v)\} = \Omega(\ell)] = 1 - o(1/n)\) for every \(j \in [i - 1]\).\(^{18}\)

Towards proving that \(G_n\) is robustly self-ordered. We now prove that the resulting graph \(G_n\), which consists of these \(m\) connected components, is \(c\)-robustly self-ordered, where \(c\) is a universal constant (which is independent of the generic \(n\)). For starters, let’s verify that \(G_n\) is self-ordered. We first note that any automorphism of \(G_n\) must map the vertices of copies of \(G'_\ell\) (resp., \(G''_\ell\)) to vertices of copies of \(G'_\ell\) (resp., \(G''_\ell\)), since these are the only vertices of degree \(d' + 1\). The connectivity of these copies implies that the automorphism must map each connected component to some connected component, which determines the \(m\) connected

\(^{17}\)We mention that a slightly different construction can be based on the fact that random \(\ell\)-vertex \((d'\)-regular) graphs are robustly self-ordered expanders (see Theorem 6.1). In this alternative construction we find a sequence of \(m\) such graphs that are pairwise far from being isomorphic to one another. As further detailed in Remark 6.2, the analysis of the alternative construction is somewhat easier than the analysis of the construction presented below, but we need the current construction for the proof of Theorem 4.5.

\(^{18}\)Specifically, for some \(\ell' = \Omega(\ell)\), we upper-bound \(\Pr_{\pi}[\{|v \in [\ell] : \pi(v) = v\} \geq \ell - \ell']\), where \(\pi : [\ell] \rightarrow [\ell]\) is a random permutation. We do so by observing that the number of permutations that have at least \(\ell - \ell'\) fixed-points is at most \((\ell')! \cdot (\ell'! = \frac{\ell'}{1 - \ell'!}, \text{ whereas } (\ell - \ell'!)! = \exp(\Omega(\ell \log \ell)) = \omega(n)\) for any \(\ell'\) such that \(\ell - \ell' = \Omega(\ell)\).
components. The self-ordered feature of \( G'_\ell \) and \( G''_\ell \) determines a unique ordering on each copy, whereas the fact the permutations (i.e., \( \pi_i \)'s) are different imposes that each connected component is mapped to itself (i.e., the order of the connected components is preserved). Hence, the automorphism must be trivial (and it follows that \( G_n \) is self-ordered).

An analogous argument establishes the robust self-ordering of \( G_n \), where we use the hypothesis that \( G'_\ell \) and \( G''_\ell \) are expanders (rather than merely connected), the choice of the \( \pi_i \)'s as being far-apart (rather than merely different), and the robust self-ordering of \( G'_\ell \) and \( G''_\ell \) (rather than their mere self-ordering) in order to establish the robust self-ordering of \( G_n \). Considering an arbitrary permutation \( \mu : [n] \to [n] \), these stronger features are used to establish a lower bound on the size of the symmetric difference between \( G_n \) and \( \mu(G_n) \) as follows:

- The fact that \( G'_\ell \) is an expander implies that if \( \mu \) splits the vertices of a copy of \( G'_\ell \) such that \( \ell' \) vertices are mapped to copies that are different than the other \( \ell - \ell' \geq \ell' \) vertices, then this contributes \( \Omega(\ell') \) units to the difference between \( G_n \) and \( \mu(G_n) \). Ditto for \( G''_\ell \), whereas mapping a copy of \( G'_\ell \) to a copy of \( G''_\ell \) contributes \( \Omega(\ell) \) units (per the difference in the degrees).

- The robust self-ordering of \( G'_\ell \) and \( G''_\ell \) implies that if \( \mu \) changes the index of vertices inside a component, then this yields a proportional difference between \( G_n \) and \( \mu(G_n) \).

- The distance between the \( \pi_i \)'s (along with the aforementioned robustness) implies that if \( \mu \) changes the indices of the connected components, then each such change contributes \( \Omega(\ell) \) units to the difference between \( G_n \) and \( \mu(G_n) \).

The actual implementation of this sketch requires a careful accounting of the various contributions. As a first step in this direction we provide a more explicit description of \( G_n \). We denote the set of vertices of the copy of \( G'_\ell \) (resp., \( G''_\ell \)) in the \( i \)th connected component of \( G_n \) by \( F_i = \{2(i-1)\ell + j : j \in [\ell]\} \) (resp., \( S_i = \{2(i-1)\ell + \ell + j : j \in [\ell]\} \)). Recall that \( F_i \) and \( S_i \) are connected by the edge-set

\[
\{\{2(i-1)\ell + j, 2(i-1)\ell + \ell + \pi_i(j)\} : j \in [\ell]\}
\]

whereas the subgraph of \( G_n \) induced by \( F_i \) (resp., \( S_i \)) has the edge-set \( \{\{2(i-1)\ell + u, 2(i-1) + v\} : \{u, v\} \in E'_\ell\} \) (resp., \( \{\{2(i-1)\ell + \ell + u, 2(i-1) + \ell + v\} : \{u, v\} \in E''_\ell\} \)). In addition, let \( F = \bigcup_{i \in [n]} F_i \) (resp., \( S = \bigcup_{i \in [n]} S_i \)).

### The actual proof (that \( G_n \) is robustly self-ordered).

Considering an arbitrary permutation \( \mu : [n] \to [n] \), we lower-bound the distance (i.e., size of the symmetric difference) between \( G_n \) and \( \mu(G_n) \) as a function of the number of non-fixed-points under \( \mu \) (i.e., the number of \( v \in [n] \) such that \( \mu(v) \neq v \)). We do so by considering the (average) contribution of every non-fixed-point to the distance between \( G_n \) and \( \mu(G_n) \) (i.e., number of pairs of vertices that form an edge in one graph but not in the other). We may include the same contribution in few of the following (seven) cases, but this only means that we are double-counting the contribution by a constant factor.

**Case 1: Vertices \( v \in F \) such that \( \mu^{-1}(v) \in S \).** Ditto for \( v \in S \) such that \( \mu^{-1}(v) \in F \).

Each such vertex contributes at least one unit to the distance (between \( G_n \) and \( \mu(G) \)) by virtue of \( v \) having degree \( d' + 1 \) in \( G_n \) and strictly higher degree in \( \mu(G_n) \), since vertices in \( F \) have degree \( d' + 1 \) (in \( G_n \)) whereas vertices in \( S \) have higher degree (in \( G_n \)).

\[\text{Note that } v \text{ neighbors } u \text{ in } \mu(G_n) \text{ if and only if } \mu^{-1}(v) \text{ neighbors } \mu^{-1}(u) \text{ in } G_n.\]
In light of Case 1, we may focus on vertices whose “type” is preserved by \( \mu^{-1} \). Actually, it will be more convenient to consider the set of vertices whose “type” is preserved by \( \mu \); that is, the set \( \{v \in F : \mu(v) \in F_j\} \cup \{v \in S : \mu(v) \in S\} \). Next, for each \( i \in [m] \), we define \( \mu^*(i) \) to be the index of the connected component that takes the plurality of \( \mu(F_i) \); that is, \( \mu^*(i) \equiv j \) if \(|\{v \in F_i : \mu(v) \in F_j\}\| \geq |\{v \in F_i : \mu(v) \in F_k\}| \) for all \( k \in [m] \) (breaking ties arbitrarily).

**Case 2:** Vertices \( v \in F_i \) such that \( \mu(v) \in F \setminus F_{\mu^*(i)} \).

For starters, suppose that \(|\{v \in F_i : \mu(v) \notin F_{\mu^*(i)}\}| \geq \ell/2 \); that is, a majority of the vertices of \( F_i \) are mapped by \( \mu \) to \( F_{\mu^*(i)} \). In this case, by the expansion of \( G_i \), we get a contribution that is proportional to the size of the set \( F_i^* \equiv \{v \in F_i : \mu(v) \notin F_{\mu^*(i)}\} \), because there are \( \Omega(|F_i^*|) \) edges between \( F_i^* \) and the rest of \( F_i \) but there are no edges between \( F_i^* \) and \( F_i \setminus F_i^* \) in \( \mu(G_n) \). In the general case, we have to be more careful since expansion is guaranteed only for sets that have size at most \( \ell/2 \). In such a case we use an adequate subset of \( F_i^* \).

Details follow. Let \( J \subseteq [m] \setminus \{\mu^*(i)\} \) be maximal such that \( \sum_{j \in J} |\{v \in F_i : \mu(v) \in F_j\}| \leq \ell/2 \), and note that \( F_i^* \equiv \bigcup_{j \in J} \{v \in F_i : \mu(v) \in F_j\} \) occupies at least one third of \( \{v \in F_i : \mu(v) \in F \setminus F_{\mu^*(i)}\} \). Recall that the subgraph of \( G_n \) induced by \( F_i \) is an expander, and consider the edges in \( G_n \) that cross the cut between \( F_i^* \) and the rest of \( F_i \). Then, this cut has \( \Omega(|F_i^*|) \) edges in \( G_n \), but there are no edges between \( F_i^* \) and \( F_i \setminus F_i^* \) in \( \mu(G_n) \), because \( \mu^{-1}(F_i) \subseteq \bigcup_{j \notin J} F_i \) and \( \mu^{-1}(F_i \setminus F_i^*) \subseteq \bigcup_{j \notin J} F_i \) are not connected in \( G_n \). Hence, the total contribution of the vertices in \( \{v \in F_i : \mu(v) \in F \setminus F_{\mu^*(i)}\} \) to the distance (between \( G_n \) and \( \mu(G) \)) is \( \Omega(|F_i^*|) \), which is proportional to their number (i.e., is \( \Omega(|\{v \in F_i : \mu(v) \in F \setminus F_{\mu^*(i)}\}|) \)).

Defining \( \mu^*(i) \) in an analogous manner with respect to \( \mu(S_i) \), we get an analogous contribution by the expander induced by \( S_i \). Specifically, for each \( i \in [m] \), we define \( \mu^*(i) \) to be the index of the connected component that takes the plurality of \( \mu(S_i) \); that is, \( \mu^*(i) \equiv j \) if \(|\{v \in S_i : \mu(v) \in S_j\}| \geq |\{v \in S_i : \mu(v) \in S_k\}| \) for all \( k \in [m] \) (breaking ties arbitrarily).

**Case 3:** Vertices \( v \in S_i \) such that \( \mu(v) \in S \setminus S_{\mu^*(i)} \).

Here we get a contribution of \( \Omega(|\{v \in S_i : \mu(v) \in S \setminus S_{\mu^*(i)}\}|) \), where the analysis is analogous to Case 2. Recall that if \( v \in F_i \) then it holds that \( v = 2(i - 1)\ell + j \) for some \( j \in [\ell] \), and that (in \( G_n \)) vertex \( v \) has a unique neighbor in \( S \), which is \( 2(i - 1)\ell + \pi_i(j) \in S \). It will be convenient to denote this neighbor by \( \phi_i(v) \); that is, for \( v \in F_i \) such that \( v = 2(i - 1)\ell + j \), we have \( \phi_i(v) = 2(i - 1)\ell + \ell + \pi_i(j) \in S \). The next two cases refer to vertices that are mapped by \( \mu \) according to the plurality vote (e.g., \( v \in F_i \) is mapped to \( \mu(v) \in F_{\mu^*(i)} \)), but their match is not mapped accordingly (i.e., \( \phi_i(v) \in S \) is not mapped to \( S_{\mu^*(i)} \)).

**Case 4:** Vertices \( v \in F_i \) such that \( \mu(v) \in F_{\mu^*(i)} \) but \( \mu(\phi_i(v)) \notin S_{\mu^*(i)} \).

(Note that the condition \( v \in F_i \) and \( \mu(v) \in F_{\mu^*(i)} \) means that vertex \( v \) is not covered in Case 2. If \( \mu^*(i) = \mu(i) \) then \( \mu(\phi_i(v)) \notin S_i \) means that \( v \) is covered in Case 3, since \( \phi_i(v) \in S_i \). Hence, the current case is of interest only when \( \mu^*(i) \neq \mu(i) \). In particular, it is of interest when referring to vertices in the \( i^{th} \) connected component of \( G_n \) that reside in the copies of \( G_n' \) and \( G_n'' \) and are mapped according to the plurality votes of these copies, whereas these two plurality votes are inconsistent.)

We focus on the case that a vast majority of the vertices in both \( F_i \) and \( S_i \) are mapped according to the plurality votes (i.e., \( \mu(i) \) and \( \mu^*(i) \)), since the complementary cases are covered by Cases 2 and 3, respectively. Specifically, if either \(|\{v \in F_i : \mu(v) \in [n] \setminus F_{\mu^*(i)}\}| > \ell/3 \) or \(|\{u \in S_i : \mu(u) \in [n] \setminus S_{\mu^*(i)}\}| > \ell/3 \), then we get a contribution of \( \Omega(\ell) \) either by Cases 1&2 or by Cases 1&3. Otherwise, it follows that
\[
|\{v \in F_i : \mu(v) \in F_{\mu^*(i)} \land \mu(\phi_i(v)) \in S_{\mu^*(i)}\}| \geq \ell - 2 \cdot \ell/3
\]
which implies that, if \( \mu'(i) \neq \mu''(i) \), then the \( i \)th connected component of \( G_n \) contributes \( \ell/3 \) units to the difference (between \( G_n \) and \( \mu(G_n) \)), since \( v \) and \( \phi_i(v) \) are connected in \( G_n \), but \( \mu(v) \in F_{\mu'(i)} \) and \( \mu(\phi_i(v)) \in S_{\mu''(i)} \) reside in different connected components of \( \mu(G_n) \). (That is, the contribution is due to vertices \( v \) of \( F_i \) that are mapped by \( \mu \) to \( F_{\mu'(i)} \), while the corresponding vertices \( \phi_i(v) \) of \( S_i \) (which are connected to them in \( G_n \)) are mapped by \( \mu \) to \( S_{\mu''(i)} \subset S \setminus S_{\mu'(i)} \), whereas \( F_{\mu'(i)} \) and \( S_{\mu''(i)} \) are not connected in \( G_n \), assuming \( \mu'(i) \neq \mu''(i) \).)

To conclude: The contribution of the vertices of Case 4 (to the difference between \( G_n \) and \( \mu(G_n) \)) is proportional to the number of these vertices (where this contribution might have been counted already in Cases 1, 2 and 3).

Case 5: Vertices \( v \in F_i \) such that \( \mu(v) \notin F_{\mu'(i)} \) but \( \mu(\phi_i(v)) \in S_{\mu'(i)} \).

(Equiv., vertices \( v \in S_i \) such that \( \mu(v) \in S_{\mu'(i)} \) but \( \mu(\phi_i^{-1}(v)) \notin F_{\mu'(i)} \).)

Analogously to Case 4, the contribution of these vertices is proportional to their number.

In light of Cases 2–5, we may focus on indices \( i \in [m] \) such that \( \mu'(i) = \mu''(i) \) and on vertices in \( i \)th connected component that are mapped by \( \mu \) to the \( i \)th connected component (and the same "type" per Case 1). The following case refers to such vertices that do not maintain their position in this connected component.

Case 6: Vertices \( v = 2(i-1)\ell + j \in F_i \) such that \( \mu(v) \in F_{\mu'(i)} \setminus \{2(\mu'(i) - 1)\ell + j\} \).

Ditto for \( v = 2(i-1)\ell + j \in S_i \) such that \( \mu(v) \in S_{\mu'(i)} \setminus \{2(\mu'(i) - 1)\ell + j\} \).

(This case refers to vertices in \( F_i \) that are mapped to \( F_{\mu'(i)} \) but do not maintain their index in the relevant copy of \( G_i' \); indeed, \( v = 2(i-1)\ell + j \) is the \( j \)th vertex of \( F_i \), but it is mapped by \( \mu \) to the \( k \)th vertex of \( F_{\mu'(i)} \) (i.e., \( \mu(v) = 2(\mu'(i) - 1)\ell + k \)) such that \( k \neq j \).)

Fixing \( i \), let \( C \triangleq \{v = 2(i-1)\ell + j \in F_i : \mu(v) \in F_{\mu'(i)} \setminus \{2(\mu'(i) - 1)\ell + j\}\} \) denote the set of vertices considered in this case, and \( D = \{v \in F_i : \mu(v) \notin F_{\mu'(i)}\} \) denote the set of vertices that we are going to discount for. As a warm-up, consider first the case that \( D = \emptyset \). In this case, by the robust self-ordering of \( G_i' \), the contribution of the vertices in \( C \) to the difference between \( G_n \) and \( \mu(G_n) \) is \( \Omega(|C|) \).

In the general case (i.e., where \( D \) may not be empty), we get a contribution of \( \Omega(|C| - d' \cdot |D|) \), where the second term compensates for the fact that the vertices of \( D \) were moved outside of this copy of \( G_i' \) and replaced by different vertices that may have different incidences. Letting \( c' \) be the constant hidden in the \( \Omega \)-notation, we get a contribution of at least \( c' \cdot |D| - d' \cdot |D| \), which is at least \( c' \cdot |C|/2 \) if \( |D| \leq c' \cdot |C|/2d' \). On the other hand, if \( |D| > c' \cdot |C|/2d' \), then we get a contribution of \( \Omega(|D|) = \Omega(|C|) \) by Cases 1–2. Hence, in both sub-cases we have a contribution of \( \Omega(|C|) \) to the difference between \( G_n \) and \( \mu(G_n) \).

The same analysis applies to \( \{v = 2(i-1)\ell + j \in S_i : \mu(v) \in S_{\mu'(i)} \setminus \{2(\mu'(i) - 1)\ell + j\}\} \), where we use the robust self-ordering of \( G_i' \) and Cases 1&3.

Lastly, we consider vertices that do not fall into any of the prior cases. Such vertices maintain their type, are mapped with the plurality vote of their connected component, which is consistent among its two parts (i.e., \( \mu' \) and \( \mu'' \)), and maintain their position in that component. Hence, the hypothesis that they are not fixed-points of \( \mu \) can only be attributed to the fact that these vertices are mapped to a connected component with a different index.

Case 7: Vertices \( v \in F_i \) such that both \( \mu(v) \in F_{\mu'(i)} \setminus F_i \) and \( \mu(\phi_i(v)) \in S_{\mu''(i)} \setminus S_i \) hold.

(We may assume that \( \mu'(i) \neq i \) and \( \mu''(i) \neq i \), since otherwise this set is empty. We may also assume that \( \mu'(i) = \mu''(i) \), since the complementary case was covered by Cases 4 and 5. Hence, we focus on pairs of vertices that are matched in the \( i \)th connected component of \( G_n \) and are mapped by \( \mu \) to the \( k \)th component of \( G_n \) such that \( k \neq i \).)
The construction presented in the proof of Theorem 4.2 utilizes a collection of \((\ell!)^{\Omega(1)}\) permutations over \([\ell]\) that are pairwise far-apart (i.e., every two permutations differ on \(\Omega(\ell)\) inputs). Such a collection is constructed in \(O(\ell^2)\)-time by an iterative exhaust
search, where the permutations are selected iteratively such that in each iteration we find a permutation that is far from permutations that were included in previous iterations. We mention that in Section 4.3 we shall use a collection of $\exp(\Omega(\ell))$ such permutations that is locally computable (i.e., given the index of a permutation we find its explicit description in polynomial time). We also mention that, in follow-up work [21], we provided a locally computable collection of $(\ell!)^{\Omega(1)}$ that are pairwise far-apart.

**Digest: Combining two robustly self-ordered graphs**

One ingredient in the proof of Theorem 4.2 is forming connected components that consist of two robustly self-ordered graphs that have different vertex degrees and are connected by a bounded-degree bipartite graph. Implicit in the proof is the fact that such the resulting graph is robustly self-ordered graph.

▷ **Claim 4.3 (combining two $\Omega(1)$-robustly self-ordered graphs).** For $i \in \{1, 2\}$ and constant $\gamma > 0$, let $G_i = (V_i, E_i)$ be an $\gamma$-robustly self-ordered graph, and consider a graph $G = (V_1 \cup V_2, E_1 \cup E_2 \cup E)$ of maximum degree $d$ such that $E$ contain edges with a single vertex in each $V_i$; that is, $G$ consists of $G_1$ and $G_2$ and an arbitrary bipartite graph that connects them. If the maximum degree in $G$ of each vertex in $V_1$ is strictly smaller than the minimum degree of each vertex in $V_2$, then $G$ is $\gamma/(2d + 3)$-robustly self-ordered.

**Proof Sketch.** For an arbitrary permutation $\mu : V \to V$, let $T$ denote the set of its non-fixed points, and consider the following two cases.

**Case 1:** More than $t = \gamma' |T|$ vertices are mapped by $\mu$ from $G_1$ to $G_2$, where $\gamma' = \gamma/(2d+3)$.
In this case, we get a contribution of at least one unit per each such vertex, due to the difference in the degrees between $V_1$ and $V_2$.

**Case 2:** at most $t$ vertices are mapped by $\mu$ from $G_1$ to $G_2$.
In this case, letting $T_i$ denote the set of non-fixed vertices in $G_i$ that are mapped by $\mu$ to $G_1$, we get a contribution of at least $\sum_{i=1,2} (\gamma \cdot |T_i| - d \cdot t)$ units, where the negative term is due to possible change in the incidence with vertices in $T \setminus T_i$. Hence, the total contribution in this case is at least $\gamma \cdot (|T| - 2t) - 2d \cdot t = \gamma' \cdot |T|$. The claim follows.

**Regaining regularity and expansion**

While Theorem 4.2 achieves our main objective, it useful towards some applications (see, e.g., the proof of Theorem 4.5) to obtain this objective with graphs that are both regular and expanding. This is achieved by applying Theorem 2.6. Hence, we have.

▷ **Theorem 4.4 (Theorem 4.2, revised).** For any sufficiently large constant $d$, there exists an efficiently constructable family $\{G_n\}_{n\in\mathbb{N}}$ of robustly self-ordered $d$-regular expander graphs. That is, there exists a polynomial-time algorithm that on input $1^n$ outputs the $n$-vertex graph $G_n$.

**4.3 Strong (i.e., local) constructions**

While Theorem 4.4 provides an efficient construction of robustly self-ordered $d$-regular expander graphs, we seek a stronger notion of constructability. Specifically, rather than requiring that the graph be constructed in time that is polynomial in its size, we require that the neighbors of any given vertex can be found in time that is polynomial in the vertex’s name (i.e., time that is polylogarithmic in the size of the graph). We call such graphs **locally constructable** (and comment that the term “strongly explicit” is often used in the literature).
Theorem 4.5 (locally constructing robustly self-ordered graphs). For any sufficiently large constant $d$, there exists a locally constructable family $\{G_n = ([n], E_n)\}_{n \in \mathbb{N}}$ of robustly self-ordered $d$-regular graphs. That is, there exists a polynomial-time algorithm that on input $n$ and $v \in [n]$ outputs the list of neighbours of vertex $v$ in $G_n$. Furthermore, the graphs are either expanders or consist of connected components of logarithmic size.

(Indeed, this establishes Theorem 1.3.) We comment that using the result of [21], we can also get connected components of sub-logarithmic size, as in Theorem 4.2.\footnote{Specifically, the result of [21] provides a construction of a collection of $L = \exp(\Omega(\ell \log \ell))$ permutations over $[\ell]$ that are pairwise far-apart along with a polynomial-time algorithm that, on input $i \in [\ell]$, returns a description of the $i^{th}$ permutation (i.e., the algorithm should run in $\text{poly}(\log L)$-time). Using this algorithm, we can afford to set $\ell = \frac{O(\log n)}{\log \log n}$ as in Theorem 4.2.}

Proof. We employ the idea that underlies the proof of Theorem 4.2, while starting with an efficiently constructable family of robustly self-ordered graphs (as provided by Theorem 4.4) rather than with the mere existence of a family of such graphs (equiv., with $\ell$-vertex graphs that can be constructed in $\text{poly}(\ell)$-time). We use a slightly larger setting of $\ell$, which allows us to use a collection of $\exp(\Omega(\ell))$ pairwise-far-apart permutations (rather than a collection of $\exp(\Omega(\ell \log \ell))$ such permutations). Lastly, we apply the same transformation as in the proof of Theorem 4.4 (so to regain regularity and expansion). Details follow.

Given a generic $n$, let $\ell = O(\log n)$, which implies that $\exp(\ell) = \text{poly}(n)$. By Theorem 4.4, for all sufficiently large $d'$, we can construct $\ell$-vertex $d'$-regular expander graphs that are robustly self-ordered (with respect to the robustness parameter $c$) in $\text{poly}(\ell)$-time. Again, we shall use two such graphs: a $d'$-regular graph, denoted $G'_\ell = ([\ell], E'_\ell)$, and a $d''$-regular graph, denoted $G''_\ell = ([\ell], E''_\ell)$, where $d'' = d' + 1$.

Using $G'_\ell$ and $G''_\ell$, we construct an $n$-vertex robustly self-ordered graph, denoted $G_n$, that consists of $n/2\ell$ connected components that are pairwise far from being isomorphic to one another. This is done by picking $m = n/2\ell$ permutations, denoted $\pi_1, ..., \pi_m : [\ell] \to [\ell]$, that are pairwise far-apart, and constructing $2\ell$-vertex graphs such that the $i^{th}$ such graph consist of a copy of $G'_\ell$ and a copy of $G''_\ell$ that are connected by a matching as determined by the permutation $\pi_i$. (As detailed in (7)).

Using the fact that $m < 2^\ell$ (rather that $m = \exp(\Theta(\ell \log \ell))$), we can construct each of these permutations in $\text{poly}(\ell)$-time by using sequences of disjoint transpositions determined via a good error correcting code. Specifically, for $k = \log_2 m < \log_2 n$, we use an error correcting code $C : \{0,1\}^k \to \{0,1\}^\ell$ of constant rate (i.e., $\ell = O(k)$) and linear distance (i.e., the codewords are $\Omega(\ell)$ bits apart from each other), and let $\pi_i(2j - 1) = 2j - 1 + C(i)_j$ and $\pi_i(2j) = 2j - C(i)_j$, where $i \in [m] = [2^k] \equiv \{0,1\}^k$ and $j \in [\ell/2]$. (That is, the $i^{th}$ permutation switches the pair $(2j - 1, 2j) \in [\ell]^2$ if and only if the $j^{th}$ bit in the $i^{th}$ codeword is 1, where $C(i)$ is considered the $i^{th}$ codeword.)

Like in the proof of Theorem 4.2, the $i^{th}$ connected component of $G_n$ is isomorphic to a graph with the vertex set $[2\ell]$ and the edge set

$$E'_\ell \cup \{\ell + u, \ell + v\} : \{u, v\} \in E''_\ell \cup \{\{v, \ell + \pi_i(v)\} : v \in [\ell]\}. \quad (7)$$

The key observation is that, for every $i \in [m]$ and $j \in [\ell]$, the neighborhood of the $j^{th}$ (resp., $(\ell + j)^{th}$) vertex in the $i^{th}$ connected component of the $n$-vertex graph $G_n$ is determined by $G'_\ell$ and $\pi_i(j)$ (resp., by $G''_\ell$ and $\pi_i^{-1}(j)$), which means that it can be found in $\text{poly}(\ell)$-time. This implies local constructability, since $\ell = O(\log n)$.\footnote{Specifically, the result of [21] provides a construction of a collection of $L = \exp(\Omega(\ell \log \ell))$ permutations over $[\ell]$ that are pairwise far-apart along with a polynomial-time algorithm that, on input $i \in [\ell]$, returns a description of the $i^{th}$ permutation (i.e., the algorithm should run in $\text{poly}(\log L)$-time). Using this algorithm, we can afford to set $\ell = \frac{O(\log n)}{\log \log n}$ as in Theorem 4.2.}
The fact that $G_n$ is robustly self-ordered was already established in the proof of Theorem 4.2, which is oblivious of the permutations used as long as any pair of permutations disagrees on $\Omega(\ell)$ points. Lastly, we may obtain regularity and expansion by applying Theorem 2.6.

### 4.4 Local self-ordering

Recall that by Definition 1.1 a graph $G = ([n], E)$ is called self-ordered if for every graph $G' = (V', E')$ that is isomorphic to $G$ there exists a unique bijection $\phi : V' \rightarrow [n]$ such that $\phi(G') = G$. One reason for our preferring the term "self-ordered" over the classical term "asymmetric" is that we envision being given such an isomorphic copy $G' = (V', E')$ and asked to find its unique isomorphism to $G$, which may be viewed as ordering the vertices of $G'$ according to (their name in) $G$. The task of finding this unique isomorphism will be called self-ordering $G'$ according to $G$ or self-ordering $G'$ (when $G$ is clear from the context).

Evidently, the task of self-ordering a given graph $G'$ according to a self-ordered graph $G$ that can be efficiently constructed reduces to testing isomorphism. When the graphs have bounded-degree the latter task can be performed in polynomial-time [29]. These are general facts that do apply also to the robustly self-ordered graph $G_n$ constructed in the proof of Theorem 4.5. However, in light of the fact that the graph $G_n$ is locally constructable, we can hope for more. Specifically, it is natural to ask if we can perform self-ordering of a graph $G'$ that is isomorphic to $G_n$ in a local manner; that is, given a vertex in $G'$ (and oracle access to the incidence function of $G'$), can we find the corresponding vertex in $G_n$ in $\text{poly}(\log n)$-time? Let us define this notion formally.

▶ Definition 4.6 (locally self-ordering a self-ordered graph). We say that a self-ordered graph $G = ([n], E)$ is locally self-ordered if there exists a polynomial-time algorithm that, given a vertex $v$ in any graph $G' = (V', E')$ that is isomorphic to $G$ and oracle access to the incidence function of $G'$, finds $\phi(v) \in [n]$ for the unique bijection $\phi : V' \rightarrow [n]$ such that $\phi(G') = G$ (i.e., the unique isomorphism of $G'$ to $G$).

Indeed, the isomorphism $\phi$ orders the vertices of $G'$ in accordance with the original (or target) graph $G$. We stress that the foregoing algorithm works in time that is polynomial in the description of a vertex (i.e., $\text{poly}(\log n)$-time), which is polylogarithmic in the size of the graph (i.e., $n$). We show that such algorithms exist for the graphs constructed in the proof of Theorem 4.5.

▶ Theorem 4.7 (locally self-ordering the graphs of Theorem 4.5). For any sufficiently large constant $d$, there exists a locally constructable family $\{G_n = ([n], E_n)\}_{n \in \mathbb{N}}$ of robustly self-ordered $d$-regular graphs that are locally self-ordered. Furthermore, the graphs are either expanders or consist of connected components of logarithmic size.

As in Theorem 4.5, we can obtain connected components of sub-logarithmic size by using [21].

**Proof.** We first consider the version that yields $n$-vertex graphs that consist of connected components of logarithmic size. The basic idea is that it we can afford reconstructing the connected component in which the input vertex reside, and this allows us both to determine the index of the vertex in this connected component as well as the index of the component in the graph. Specifically, on input a vertex $v$ in a graph $G'$ that is isomorphic to $G_n$, we proceed as follows.
1. Using queries to the incidence function of $G'$, we explore and retrieve the entire $2\ell$-vertex connected component in which $v$ resides, where $\ell = \log_2 n$.

Recall that this connected component consists of (copies of) two $\ell$-vertex regular graphs, denoted $G'_v$ and $G''_v$, that are connected by a matching. Furthermore, these graphs have different degrees and are each (robustly) self-ordered.

2. Relying on the different degrees, we identify the foregoing partition of this $2\ell$-vertex component into two $\ell$-vertex (self-ordered) graphs, denoted $A_v$ and $B_v$, where $A_v$ (resp., $B_v$) is isomorphic to $G'_v$ (resp., $G''_v$).

3. Relying on the self-ordering of $G'_v$ (resp., $G''_v$), we order the vertices of $A_v$ (resp., $G''_v$). This is done by constructing $G'_v$ (resp., $G''_v$), and using an isomorphism tester. The order of the vertices in $A_v$ and $B_v$ also determines the permutation that defines the matching between the two graphs.

4. Relying on the correspondence between the permutations used in the construction and codewords of a good error-correcting code, we decode the relevant codeword (i.e., this is decoding without error). This yields the index of the permutation in the collection, which equals the index of the connected component.

Note that this refers to the basic construction that was presented in the proof of Theorem 4.5, before it was transformed to a regular graph and to an expander. Recall that both transformations are performed by augmenting the graph with auxiliary edges that are assigned a different color than the original edges, and that edges with different colors are later replaced by copies of different (constant-size) gadgets. These transformations do not hinder the local self-ordering procedure described above, since it may identify the original graph (and ignore the gadgets that replace other edges). The claim follows.

Local reversed self-ordering

While local self-ordering a (self-ordered) graph seems the natural local version of self-ordering the graph, an alternative notion called local reversed self-ordering will be defined and studied next (and used in Section 5). Both notions refer to a self-ordered graph, denoted $G = ([n], E)$, and to an isomorphic copy of it, denoted $G' = (V', E')$; that is, $G = \phi(G')$ for a (unique) bijection $\phi : V' \rightarrow [n]$. While local self-ordering is the task of finding the index of a given vertex of $G'$ according to $G$ (i.e., given $v \in V'$, find $\phi(v) \in [n]$), local reversed self-ordering is the task of finding the vertex of $G'$ that has a given index in $G$ (i.e., given $i \in [n]$, find $\phi^{-1}(i) \in V'$). In both cases, the graph $G$ is locally constructible and we are given oracle access to the incidence function of $G'$. In addition, in the reversed task, we assume that the algorithm is given an arbitrary vertex in $G'$, since otherwise there is no hope to hit any element of $V'$.

Definition 4.8 (locally reversed self-ordering). We say that a self-ordered graph $G = ([n], E)$ is locally reversed self-ordered if there exists a polynomial-time algorithm that, given $i \in [n]$ and oracle access to the incidence function of a graph $G' = (V', E')$ that is isomorphic to $G$ and an arbitrary vertex $s \in V'$, finds $\phi^{-1}(i) \in V'$ for the unique bijection $\phi : V' \rightarrow [n]$ such that $\phi(G') = G$ (i.e., the unique isomorphism of $G'$ to $G$).

We stress that the foregoing algorithm works in time that is polynomial in the description of a vertex (i.e., $\text{poly}(\log n)$-time), which is polylogarithmic in the size of the graph (i.e., $n$). We show that such algorithms exist for variants of the graphs constructed in the proof of Theorem 4.5. In fact, we show a more general result that refers to any graph that is locally self-ordered and for which short paths can be locally found between any given pair of vertices.

---

22 Needless to say, this is not needed in case $V' = [n]$, which is the case that is used in Section 5.
Theorem 4.9 (sufficient conditions for locally reversed self-ordering of graphs). Suppose that \( \{G_n = ([n], E_n)\}_{n \in \mathbb{N}} \) is a family of bounded degree graphs that is locally self-ordered. Further suppose that given \( v, u \in [n] \), one can find in polynomial-time a path from \( u \) to \( v \) in \( G_n \). Then, \( \{G_n = ([n], E_n)\}_{n \in \mathbb{N}} \) is locally reversed self-ordered.

We mention that a family of robustly self-ordered graphs that is locally self-ordered can be transformed into one that also supports locally finding short paths. This is done by superimposing the graphs of this family with graphs that supports locally finding short paths, while using different colors for the edges of the two graphs and later replacing these colored edges by gadgets (as done in Section 2.1). We also mention that applying degree reduction to the hyper-cube (i.e., replacing the original vertices with simple cycles) yields a graph that supports locally finding short paths.\(^{23}\)

Proof. On input \( i \in [n] \) and \( s \in V' \), and oracle access to the incidence function of a graph \( G' = (V', E') \) that is isomorphic to \( G_n \), we proceed as follows.

1. Using the local self-ordering algorithm, we find \( i_0 = \phi(s) \), where \( \phi : V' \to [n] \) is the unique bijection satisfying \( \phi(G') = G \).

2. Using the path-finding algorithm for \( G \), we find a poly(\( \log n \))-long path from \( i_0 \) to \( i \) in \( G \).

   Let \( \ell \) denote the length of the path, and denote its intermediate vertices by \( i_1, \ldots, i_{\ell-1} \); that is, the full path is \( i_0, i_1, \ldots, i_{\ell-1}, i_\ell = i \).

3. For \( j = 1, \ldots, \ell \), we find \( v_j \) as follows. First, using queries to the incidence function of \( G' \), we find all neighbors (in \( G' \)) of \( v_{j-1} \), where \( v_0 \) is \( s \) (and, indeed, \( v_0 = \phi^{-1}(i_0) \)). Next, using the local self-ordering algorithm, we find the indices of all these vertices in \( G \); that is, for every vertex \( v \) that neighbors \( v_{j-1} \), we find \( \phi(v) \). Last, we set \( v_j \) to be the neighbor that has index \( i_j \) in \( G \); that is, \( v_j \) satisfies \( \phi(v_j) = i_j \).

Hence, \( v_\ell \) is the desired vertex; that is, \( v_\ell \) satisfies \( \phi(v_\ell) = i_\ell = i \).

Assuming that the local self-ordering algorithm has query complexity \( q(n) \), that the paths found in \( G \) have length at most \( \ell(n) \), and that \( d \) is the degree bound, the query complexity of our reversed self-ordering algorithm is \( (1 + \ell(n) \cdot d) \cdot (q(n) + 1) \), where we count both our direct queries to the incidence function of \( G \) and the queries performed by the local self-ordering algorithm. Similar considerations apply to its time complexity.

Corollary 4.10 (a version of Theorem 4.7 supporting local reversed self-ordering). For any sufficiently large constant \( d \), there exists a locally constructable family \( \{G_n = ([n], E_n)\}_{n \in \mathbb{N}} \) of robustly self-ordered graphs of maximum degree \( d \) that are both locally self-ordered and locally reversed self-ordered.

The corollary follows by combining Theorem 4.7 with Theorem 4.9, while using the augmentation outlined following the statement of Theorem 4.9. We mention that Corollary 4.10 will be used in Section 5.

\(^{23}\) For any \( \ell \in \mathbb{N} \), the resulting graph consists of the vertex-set \( \{\langle x, i \rangle : x \in \{0, 1\}^\ell \land i \in [\ell] \} \) and edges that connect \( \langle x, i \rangle \) to \( \langle x \oplus 0^\ell, i \rangle \) and to \( \langle x, i + 1 \rangle \), where \( \ell + 1 \) stands for 1. For simplicity of exposition, we also add self-loops on all vertices. Then, given \( \langle x, i \rangle \) and \( \langle y, j \rangle \), we can combine the 2\( \ell \)-path that goes from \( \langle x, i \rangle \) to \( \langle y, i \rangle \) with the \( j - i \)-path that goes from \( \langle y, i \rangle \) to \( \langle y, j \rangle \), where the odd steps on the first path move from \( \langle z, k \rangle \) to \( \langle z \oplus 0^{\ell - 1}10^{\ell - 1}, k \rangle \) (or stay in place) and the even steps (on this path) move from \( \langle z, k \rangle \) to \( \langle z, k + 1 \rangle \).
Application to Testing Bounded-Degree Graph Properties

Our interest in efficiently constructable bounded-degree graphs that are robustly self-ordered was triggered by an application to property testing. Specifically, we observed that such constructions can be used for proving a linear lower bound on the query complexity of testing an efficiently recognizable graph property in the bounded-degree graph model.

It is well known that 3-Colorability has such a lower bound [3], but this set is NP-complete. On the other hand, linear lower bounds on the query complexity of testing efficiently recognizable properties of functions (equiv., sequences) are well known (see [18, Sec. 10.2.3]). So the idea was to transport the latter lower bounds from the domain of functions to the domain of bounded-degree graphs, and this is where efficient constructions of robustly self-ordered bounded-degree graphs come into play. (We mention that an alternative way of obtaining the desired lower bound was outlined in [17, Sec. 1], see details below.)

More generally, the foregoing transportation demonstrates a general methodology of transporting lower bounds that refer to testing binary strings to lower bounds regarding testing graph properties in the bounded-degree graph model. The point is that strings are ordered objects, whereas graphs properties are effectively sets of unlabeled graphs, which are unordered objects. Hence, we need to make the graphs (in the property) ordered, and furthermore make this ordering robust in the very sense that is reflected in Definition 1.2. Essentially, we provide a reduction of testing a property of strings to testing a (related) property of graphs.

We apply this methodology to obtain a subexponential separation between the complexities of testing and tolerant testing of graph properties in the bounded-degree graph model. This result is obtained by transporting an analogous result that was known for testing binary strings [15]. In addition to using a reduction from tolerantly testing a property of strings to tolerantly testing a property of graphs, this trasportation also uses a reduction in the opposite direction, which relies on the local computation features asserted in Corollary 4.10.

Organization of this section

We start with a brief review of the bounded-degree graph model for testing graph properties. Next, we prove the aforementioned linear lower bound on the query complexity of testing an efficiently recognizable property, and later we abstract the reduction that underlies this proof. Observing that this reduction applies also to tolerant testing, and presenting a reduction in the opposite direction, we derive the aforementioned separation between testing and tolerant testing.

Background

Property testing refers to algorithms of sublinear query complexity for approximate decision; that is, given oracle access to an object, these algorithms (called testers) distinguish objects that have a predetermined property from objects that are far from the property. Different models of property testing arise from different query access and different distance measures.

In the last couple of decades, the area of property testing has attracted significant attention (see, e.g., [16]). Much of this attention was devoted to testing graph properties in a variety of models including the dense graph model [18], and the bounded-degree graph model [20] (surveyed in [16, Chap. 8] and [16, Chap. 9], resp.). In this section, we refer to the bounded-degree graph model, in which graphs are represented by their incidence function and distances are measured as the ratio of the number of differing incidences to the maximal number of edges.
Specifically, for a degree bound \( d \in \mathbb{N} \), we represent a graph \( G = ([n], E) \) of maximum degree \( d \) by the incidence function \( g : [n] \times [d] \to [n] \cup \{0\} \) such that \( g(v, i) = 0 \) indicates the \( i \)th neighbor of \( v \) (where \( g(v, i) = 0 \) indicates that \( v \) has less than \( i \) neighbors). The distance between the graphs \( G = ([n], E) \) and \( G' = ([n], E') \) is defined as the size of the symmetric difference between \( E \) and \( E' \) over \( dn/2 \).

A tester for a property \( \Pi \) is given oracle access to the tested object, where here oracle access to a graph means oracle access to its incidence function. In addition, such a tester is given a size parameter \( n \) (i.e., the number of vertices in the graph), and a proximity parameter, denoted \( \epsilon > 0 \). Tolerant testers, introduced in [30] (and briefly surveyed in [16, Sec. 12.1]), are given an additional parameter, \( \eta < \epsilon \), which is called the tolerance parameter.

**Definition 5.1** (testing and tolerant testing graph properties in the bounded-degree graph model). For a fixed degree bound \( d \), a tester for a graph property \( \Pi \) is a probabilistic oracle machine that, on input parameters \( n \) and \( \epsilon \), and oracle access to an \( n \)-vertex graph \( G = ([n], E) \) of maximum degree \( d \), outputs a binary verdict that satisfies the following two conditions.

1. If \( G \in \Pi \), then the tester accepts with probability at least \( 2/3 \).
2. If \( G \) is \( \epsilon \)-far from \( \Pi \), then the tester accepts with probability at most \( 1/3 \), where \( G \) is \( \epsilon \)-far from \( \Pi \) if for every \( n \)-vertex graph \( G' = ([n], E') \in \Pi \) of maximum degree \( d \) it holds that the size of the symmetric difference between \( E \) and \( E' \) has cardinality that is greater than \( \epsilon \cdot dn/2 \).

A tolerant tester is also given a tolerance parameter \( \eta \), and is required to accept with probability at least \( 2/3 \) any graph that is \( \eta \)-close to \( \Pi \) (i.e., not \( \eta \)-far from \( \Pi \)).

We stress that a graph property is defined as a property that is preserved under isomorphism; that is, if \( G = ([n], E) \) is in the graph property \( \Pi \), then all its isomorphic copies are in the property (i.e., \( \pi(G) \in \Pi \) for every permutation \( \pi : [n] \to [n] \)). The fact that we deal with graph properties (rather than with properties of functions) is the source of the difficulty (of transporting results from the domain of functions to the domain of graphs) and the reason that robust self-ordering is relevant.

The query complexity of a tester for \( \Pi \) is a function (of the parameters \( d, n \) and \( \epsilon \)) that represents the number of queries made by the tester on the worst-case \( n \)-vertex graph of maximum degree \( d \), when given the proximity parameter \( \epsilon \). Fixing \( d \), we typically ignore its effect on the complexity (equiv., treat \( d \) as a hidden constant). Also, when stating that the query complexity is \( \Omega(q(n)) \), we mean that this bound holds for all sufficiently small \( \epsilon > 0 \); that is, there exists a constant \( c_0 > 0 \) such that distinguishing between \( n \)-vertex graphs in \( \Pi \) and \( n \)-vertex graphs that are \( \epsilon_0 \)-far from \( \Pi \) requires \( \Omega(q(n)) \) queries.

**Our first result**

With the foregoing preliminaries in place, we state the first result of this section, which is proved using Theorem 4.2.

**Theorem 5.2** (linear query complexity lower bound for testing an efficiently recognizable graph property in the bounded-degree graph model). For any sufficiently large constant \( d \), there exists an efficiently recognizable graph property \( \Pi \) such that testing \( \Pi \) in the bounded-degree graph model (with degree bound \( d \)) has query complexity \( \Omega(n) \). Furthermore, each \( n \)-vertex graph in \( \Pi \) consists of connected components of size \( o(\log n) \).

---

24 Of course, a tolerant tester is also required to reject with probability at least \( 2/3 \) any graph that is \( \epsilon \)-far from \( \Pi \).

25 As noted in Section 1.1.1, this is a special case of the general phenomenon pivoted at the difference between ordered and unordered structures, which arises in many contexts (in complexity and logic).
The main part of the theorem was known before: As observed in [17, Sec. 1], there exists graph properties that are recognizable in polynomial-time and yet are extremely hard to test in the bounded-degree graph model. This follows from the fact that the local reduction from testing $3\text{LIN (mod 2)}$ to testing 3-Colorability used by Bogdanov, Obata, and Trevisan [3] is invertible in polynomial-time (which is a common feature of reductions used in the context of NP-completeness proofs).\textsuperscript{26} Indeed, their reduction actually demonstrates that the set of (3-colorable) graphs that are obtained by applying this reduction to satisfiable 3LIN (mod 2) instances is hard to test (i.e., requires linear query complexity in the bounded-degree graph properties that are recognizable in polynomial-time and yet are extremely hard to test in the bounded-degree graph model).\textsuperscript{27} We note that the resulting property contains only connected graphs, which means that Theorem 5.2 has some added value: The fact that it applies to graphs with tiny connected components is interesting, since testing properties of such graphs may seem easy (or at least not extremely hard) at first thought.

Proof. Our starting point is a property $\Phi$ of (binary) strings (equiv., Boolean functions) that is recognizable in polynomial-time but has a linear query complexity lower bound (see, e.g., [19, Sec. 7]). This refers to a model in which one makes queries to bits of the tested string, and the distance between strings is the (relative) Hamming distance. Such lower bounds were transported to the dense graph model in [18, 10.2.3] (see also [19]), but to the best of own knowledge – no such transportation were performed before in the context of the bounded-degree graph model. Using robustly self-ordered graphs of bounded degree, we present such a transportation.

\textit{Construction 5.2.1 (from properties of strings to properties of bounded-degree graphs).}

Suppose that $\{G_n = ([n], E_n)\}_{n \in \mathbb{N}}$ is a family of robustly self-ordered graphs of maximum degree $d - 2$.

- For every $n \in \mathbb{N}$ and $s \in \{0, 1\}^n$, we define the graph $G_n' = ([n], E_n')$ such that
  \[ E_n' = E_n \cup \{i, n + i, n + 2i : i \in [n]\} \cup \{n + i, 2n + i : i \in [n] \land s_i = 1\} \] (8)
  That is, $G_n'$ consists of a copy of $G_n$ augmented by $2n$ vertices such that vertex $i \in [n]$ forms a triangle with $n + i$ and $2n + i$ is $s_i = 1$, and forms a wedge with $n + i$ and $2n + i$ otherwise.

- For a set of strings $\Phi$, we define $\Pi = \bigcup_{n \in \mathbb{N}} \Pi_n$ as the set of all graphs that are isomorphic to some graph $G_n'$ such that $s \in \Phi$; that is,
  \[ \Pi_n = \{\pi(G_n') : s \in (\Phi \cap \{0, 1\}^n) \land \pi \in \text{Sym}_{3n}\} \] (9)

where $\text{Sym}_{3n}$ denote the set of all permutations over $[3n]$.

We may assume, without loss of generality, that $G_n$ has no isolated vertices. Hence, given a graph of the form $\pi(G_n')$, the vertices of $G_n$ are easily identifiable as having degree at least three (since vertices outside $G_n$ have degree at most two). The foregoing construction yields a local reduction of $\Phi$ to $\Pi$, where locality means that each query to $G_n'$ can be answered by making a constant number of queries to $s$, and the (standard) validity of the reduction is based on the fact that $G_n$ is asymmetric.\textsuperscript{28}

\textsuperscript{26}Of course, 3LIN (i.e., the satisfiability of linear equations with three variables each) over GF(2) is easily solvable in polynomial-time. Nevertheless, Bogdanov et al. [3] use a reduction of 3LIN to 3-Colorability (via 3SAT) that originates in the theory of NP-completeness in order to reduce between the testing problems.

\textsuperscript{27}Like almost all reductions of this type, the analysis of the reduction actually refers to the promise problem induced by the image of the reduction (i.e., the image of both the yes- and no-instances).

\textsuperscript{28}Standard validity means that $s \in \Phi$ if and only if $G_n' \in \Pi$. Evidently, $s \in \Phi$ is mapped to $G_n' \in \Pi$; the asymmetry of $G_n$ is used to show that $s \notin \Phi$ is mapped to $G_n' \notin \Pi$, since $G_n'$ can not be isomorphic to any graph $G_w'$ such that $w \neq s$. This, by itself, does not mean that if $s$ is far from $\Phi$ then $G_n'$ is far from $\Pi$. 

\vspace{2cm} 

\textit{CCC 2021}
In order to be useful towards proving lower bounds on the query complexity of testing \( \Pi \), we need to show that the foregoing reduction is “distance preserving” (i.e., strings that are far from \( \Phi \) are transformed into graphs that are far from \( \Pi \)). The hypothesis that \( G_n \) is robustly self-ordered is pivotal to showing that if the string \( s \) is far from \( \Phi \), then the graph \( G'_n \) is far from \( \Pi \).

\[ \triangleright \text{Claim 5.2.2 (preserving distances).} \quad \text{If } s \in \{0, 1\}^n \text{ is } \epsilon \text{-far from } \Phi, \text{ then the } 3n \text{-vertex graphs } G'_n \text{(as defined in Construction 5.2.1)} \text{ is } \Omega(\epsilon) \text{-far from } \Pi. \]

Proof. We prove the contrapositive. Suppose that \( G'_n \) is \( \delta \)-close to \( \Pi \). Then, for some \( r \in \Phi \) and a permutation \( \pi : [3n] \to [3n] \), it holds that \( G'_n \) is \( \delta \)-close to \( \pi(G'_n) \). (The possible use of a non-trivial permutation arises from the fact that \( \Pi \) is closed under isomorphism.) If \( \pi(i) = i \) for every \( i \in [n] \), then \( s \) must be \((3d\delta/2)\)-close to \( r \), where \( d \) is the degree bound (of the model), since \( s_i = 1 \) (resp., \( r_i = 1 \)) if and only if \( i \) forms a triangle with \( n + i \) and \( 2n + i \) in \( G_n \) (resp., in \( \pi(G'_n) = G'_n \)). Unfortunately, the foregoing condition (i.e., \( \pi(i) = i \) for every \( i \in [n] \)) need not hold in general.

In general, the hypothesis that \( \pi(G'_n) \) is \( \delta \)-close to \( G'_n \) implies that \( \pi \) maps at most \( 3d\delta n/2 \) vertices of \( [n] \) to \( \{n + 1, \ldots, 3n\} \). This is the case since each vertex of \( [n] \) has degree at least \( 3 \) in \( G'_n \), whereas the other vertices have degree at most two in \( G'_n \) (or in any other graph \( G'_n \)). Hence, if \( t = \left| \{i \in [n] : \pi(i) \in [n + 1, \ldots, 3n]\} \right| \), then \( \pi(G'_n) \) and \( G'_n \) differ on at least \( t \) edges, whereas the hypothesis is that the difference is at most \( \delta \cdot 3dn/2 \).

Turning to the vertices \( i \in [n] \) that \( \pi \) maps to \( [n] \setminus \{i\} \), we upper-bound their number by \( O(\delta d^2 n) \), since the difference between \( \pi(G'_n) \) and \( G'_n \) is at most \( \delta \cdot 3dn/2 \), whereas the hypothesis that \( G_n \) is \( \epsilon \)-robustly self-ordered implies that the difference between \( \pi(G'_n) \) and \( G'_n \) (or any other graph \( G'_n \)) is at least

\[ \Delta = c \cdot \left| \{i \in [n] : \pi(i) \neq i\} \right| - d \cdot \left| \{i \in [n] : \pi(i) \notin [n]\} \right|. \]

(Compare Case 6 in the proof of Theorem 4.2.)

Letting \( I = \{i \in [n] : \pi(i) = i\} \), observe that \( D \stackrel{\text{def}}{=} \left| \{i \in I : r_i \neq s_i\} \right| \leq 3dn/2 \), since \( r_i \neq s_i \) implies that, for every \( i \in I \), the subgraph induced by \( \{i, n + i, 2n + 1\} \) is different in \( \pi(G'_n) \) and \( G'_n \) (i.e., it is a triangle in one graph and contains two edges in the other), whereas by the hypothesis \( \pi(G'_n) \) and \( G'_n \) differ on at most \( \delta \cdot 3dn/2 \) edges. Recalling that \( |I| = n - O(\delta d^2 n) \), it follows that \( \left| \{i \in [n] : r_i \neq s_i\} \right| \leq (n - |I|) + D = O(\delta d^2 n) \). Recalling that \( d \) is a constant, we infer that \( s \) is \( O(\delta) \)-close to \( r \in \Phi \), and the claims follows. \( \triangleright \)

Conclusion. Starting with Theorem 4.2 (i.e., an efficient construction of robustly self-ordered graphs of bounded degree), using Construction 5.2.1, and applying Claim 5.2.2, the theorem follows. Specifically, we need to verify the following facts.

\[ \begin{align*}
29 \text{Hence, } G'_n \text{ is } \delta \text{-close to } G'_n \text{ implies that } \left| \{i \in [n] : s_i \neq r_i\} \right| \leq \delta \cdot 3dn/2, \text{ which means that } s \text{ is } \frac{3\delta dn/2}{n} \text{-close to } r. \\
30 \text{Hence, } \Delta \leq \delta \cdot 3dn/2 \text{ implies that } \\
\left| \{i \in [n] : \pi(i) \neq i\} \right| = \Delta + d \cdot \left| \{i \in [n] : \pi(i) \notin [n]\} \right| \\
\leq \frac{\Delta + d \cdot \left| \{i \in [n] : \pi(i) \notin [n]\} \right|}{c} \\
\leq \frac{3\delta dn/2 + d \cdot 3\delta dn/2}{c} \\
\text{which is } O(\delta d^2 n). 
\end{align*} \]
The set \( \Pi \) is polynomial-time recognizable. Given an \( 3n \)-vertex graph \( G' \), an adequate algorithm first tries to identify and order the vertices of the corresponding graph \( G_n \), which means that it finds \( s \in \{0, 1\}^n \) such that \( G' \) is isomorphic to \( G'_s \) (or determines that no such \( s \) exists). (Note that once the vertices of \( G_n \) are identified, their unique ordering, whenever it exists, can be found in polynomial time by running an isomorphism tester on the subgraph induced by them (while relying on the fact that the degree of the graph is bounded [29]).) Having found \( s \), the algorithm accepts if and only if \( s \in \Phi_n \), where \( \Phi \) is polynomial-time recognizable by our starting hypothesis.

Testing \( \Pi \) requires linear query complexity. This is shown by reducing testing \( \Phi \) to testing \( \Pi \), while recalling that testing \( \Phi \) requires linear query complexity. Given (proximity parameter \( \epsilon \) and) oracle access to a string \( s \in \{0, 1\}^n \), we invoke the tester for \( \Pi \) (with proximity parameter \( \Omega(\epsilon) \)) while emulating oracle access to \( G'_s \) in a straightforward manner (i.e., each query to \( G'_s \) is answered by making at most one query to \( s \)). Recall that \( s \in \Phi \) implies \( G'_s \in \Pi \), whereas by Claim 5.2.2 if \( s \) is \( \epsilon \)-far from \( \Phi \) then \( G'_s \) is \( \Omega(\epsilon) \)-far from \( \Pi \).

This completes the proof, since the \( n \)-vertex graphs of Theorem 4.2 have connected components of size \( o(\log n) \).

Digest: Reducing testing properties of strings to testing graph properties

We wish to highlight the fact that the proof of Theorem 5.2 is based on a general reduction of testing any property \( \Phi \) of strings to testing a corresponding (bounded-degree) graph property \( \Pi \). This reduction is described in Construction 5.2.1 and its validity is proved in Claim 5.2.2. Recall that, for any \( n \), the graph property \( \Pi \) consists of \( 3n \)-vertex graphs (of bounded-degree) that encode the different \( n \)-bit long strings in \( \Phi \). This reduction is local and preserves distances:

- **Locality**: Each string \( s \in \{0, 1\}^n \) is encoded by a graph \( G'_s \) such that each query to \( G'_s \) can be answered by making at most one query to \( s \).

- **Preserving distances**: If \( s \in \Phi \) then \( G'_s \in \Pi \), whereas if \( s \) is \( \epsilon \)-far from \( \Phi \) then \( G'_s \) is \( \Omega(\epsilon) \)-far from \( \Pi \).

Recall that \( G'_s \) consists of a fixed robustly self-ordered \( n \)-vertex graph \( G_n \) augmented by \( (n \text{-vertex}) \) gadgets that encode \( s \). Let us spell out the effect of this reduction.

\[ \text{Corollary 5.3 (implicit in the proof of Theorem 5.2).} \text{ For } \Phi \text{ and } \Pi \text{ as in Construction 5.2.1, let } Q_\Phi \text{ and } Q_\Pi \text{ denote the query complexities of testing } \Phi \text{ and } \Pi \text{, respectively. Then, } Q_\Phi(n, \epsilon) \leq Q_\Pi(3n, \Omega(\epsilon)). \text{ Likewise, letting } Q'_\Phi \text{ (resp., } Q'_\Pi) \text{ denote the query complexity of tolerant testing } \Phi \text{ (resp., } \Pi) \text{, it holds that } Q'_\Phi(n, \eta, \epsilon) \leq Q'_\Pi(3n, \eta/3, \Omega(\epsilon)). \]

The tolerant testing part requires an additional justification. Specifically, we observe that strings \( s \) that are \( \eta \)-close to \( \Phi \) yield graphs \( G'_s \) that are \( \eta/3 \)-close to \( \Pi \). This is the case because, if the \( n \)-bit long strings \( s \) and \( r \) differ on \( k \) bits, then the \( 3n \)-vertex graphs \( G'_s \) and \( G'_r \) differ on \( k \) vertex pairs. In preparation to proving the separation between the complexities of testing and tolerant testing, we show a reduction in the opposite direction. This reduction holds provided that the robustly self-ordered graphs used in the definition of \( \Pi \) are locally reversed self-ordered (see Definition 4.8).
Proposition 5.4 (reducing testing \( \Pi \) to testing \( \Phi \)). Suppose that the graphs used in Construction 5.2.1 are locally self-ordered and locally reversed self-ordered, and let \( \Phi, \Pi \) and \( Q_\Phi, Q_\Pi \) be as in Corollary 5.3. Then, \( Q_\Pi(3n, \epsilon) \leq \text{poly}(\log n) \cdot (Q_\Phi(n, 2\epsilon) + O(1/\epsilon)) \). Furthermore, one-sided error probability is preserved.\(^{31}\)

Recall that the hypothesis can be met by using Corollary 4.10.

Proof. Given oracle access to a graph \( G' = ([3n], E') \), we first test that \( G' \) is isomorphic to \( G'_s \), for some \( s \in \{0, 1\}^n \), and then invoke the tester for \( \Phi \) while providing it with oracle access to \( s \). Specifically, when the latter tester queries the bit \( i \), we use the local reversed self-ordering algorithm in order to locate the \( i \)th vertex of \( G'_s \) in \( G' \), and then determine the bit \( s_i \), accordingly. Details follow.

Let \( V \) denote the set of vertices of the graph \( G' = ([3n], E') \) that have degree greater than 2 and neighbor two vertices that have degree at most 2 and neighbor each other if they have degree 2. Evidently, the vertices of \( V \) are easy to identify by querying \( G' \) for their neighbors and their neighbors’ neighbors. Furthermore, \(|V| \leq n\), since each vertex in \( V \) has two neighbors that are not connected to any other vertex in \( V \), and equality holds in case \( G' \in \Pi \). We try to find a ("pivot") vertex \( p \in V \) by picking an arbitrary vertex in \( G' \) and checking it and its neighbors. If none of these is in \( V \), then we reject. Otherwise, we continue; we shall be using \( p \) as an auxiliary input in all (future) invocations of the local reversed self-ordering algorithm, denoted \( A \).

Using the foregoing algorithm \( A \) and the pivot \( p \in V \), we define \( A'(i) = A(p, i) \) if \( A(p, i) \in V \) and invoking the local self-ordering algorithm on input \( A(p, i) \) yields \( i \). Otherwise \( A'(i) \) is undefined. Hence, evaluating \( A' \) amounts to evaluating \( A \) as well as evaluating the local self-ordering algorithm. Letting \( I' \subseteq [n] \) denote the set of "indices" (i.e., vertices of \( G_n \)) on which \( A' \) is defined, we note that \( A' \) is a bijection from \( I' \) to \( V' \) defined \( A'(i) : i \in I' \), and that \( I' = [n] \) if \( G' \in \Pi \). Hence, our first test is testing whether \( I' = [n] \), which is done by selecting at random \( O(1/\epsilon) \) elements of \([n]\), and rejecting if \( A' \) is undefined on any of them. Otherwise, we proceed, while assuming that \(|I'| \geq (1 - 0.1\epsilon) \cdot n\).

Next, we test whether the subgraph of \( G_n \) induced by \( I' \) is isomorphic to the subgraph of \( G' \) induced by \( V' \), where the isomorphism is provided by \( A' \) (which maps \( I' \) to \( V' \)). This can be done by sampling \( O(1/\epsilon) \) vertices of \( G_n \) and comparing their neighbors to the neighbors of the corresponding vertices in \( G' \), which are found by \( A' \). Specifically, for every sampled vertex \( i \in [n] \), we determine its set of neighbors \( S_i \) in \( G_n \), obtain both \( A'(i) \) and \( A'(S_i) = \{ A'(j) : j \in S_i \} \), which are supposedly the corresponding vertices in \( G' \), and check whether \( A'(S_i) \) is the set of neighbors of \( A'(i) \) in \( G' \). We reject if \( A' \) is undefined on any of these vertices (i.e., on sampled vertices or their neighbors in \( G_n \)). Needless to say, we also reject if any of the foregoing neighborhood checks fails.

Assuming that we did not reject so far, we may assume that \( G' \) is \( \epsilon/2 \)-close to being isomorphic to some \( G'_s \), where the isomorphism is consistent with the inverse of \( A' \). At this point, we invoke the tester for \( \Phi \), denoted \( T \), in order to test whether \( s \in \Phi \). This is done by providing \( T \) with oracle access to \( s \) as follows. When \( T \) makes a query \( i \in [n] \), we determine \( A'(i) \), and use our query access to \( G' \) in order to determine the two neighbors of \( A'(i) \) that have degree at most 2. If this fails, we reject. Otherwise, we answer 1 if and only if these two neighbors are connected in \( G' \).

---

\(^{31}\) A tester is said to have one-sided error probability if it always accepts objects that have the property.
To summarize, we employ three tests to $G'$: An initial test of the size $I'$ (which also includes finding a pivot $p \in V$), an isomorphism test between the subgraph of $G'$ induced by $I'$ and the subgraph of $G_n$ induced by $V'$, and an emulation of the testing of $\Phi$. (In all tests, if we encounter an index in $[n] \setminus I'$, we suspend the execution and reject.) For simplicity and without loss of generality, we may assume that $T$ is correct with high (constant) probability.

Note that if $G' \in \Pi$, then it holds that $G' = \pi(G'_s)$ for some $s \in \Phi$ and some permutation $\pi \in \text{Sym}_{3n}$. In this case, it holds that $|I'| = n$ and we always find a pivot $p \in V$. Furthermore, $A'$ equals the restriction of $\pi$ to $[n]$, the isomorphism test always succeeds, and the emulation of oracle access to $s$ is perfect. Hence, we accept with high probability (or always, if $T$ has one-sided error probability).

On the other hand, suppose that $G'$ is $\epsilon$-far from $\Pi$. If either $|I'| < (1 - 0.1\epsilon) \cdot n$ or the subgraph of $G'$ induced by $V'$ is $0.1\epsilon$-far from $A'(G_{I'})$, where $G_I$ denotes the subgraph of $G_n$ induced by $I'$, then we reject with high probability due to one of the first two tests. Otherwise, letting $\pi$ be an arbitrary bijection of $[3n]$ to $[3n]$ that extends $A'$, it follows that for some $s \in \{0, 1\}^n$ the graph $G'$ is $0.2\epsilon$-close to $\pi(G'_s)$, since we may obtain $\pi(G'_s)$ from $G'$ by modifying the neighborhood of $0.1n$ vertices in $I'$ as well as of the vertices in $[n] \setminus I'$. Furthermore, for every $i \in [n]$ on which $A'$ is defined, it holds that $s_i = 1$ if and only if the two neighbors of $A'(i)$ that have degree at most 2 are connected. By the hypothesis regarding $G'$, the string $s$ must be $2.4\epsilon$-far from $\Phi$, and $A'(i) = \pi(i)$ whenever $A'$ is defined on $i \in [n]$. It follows that either the emulation of $T$ was abruptly terminated (leading to rejection) or the answers provided to $T$ are according to $s$. Hence, we reject with high probability. ◀

Separating tolerant testing from testing

Using Corollary 5.3 and Proposition 5.4, we transport the separation of tolerant testing from testing, which has been established in [15], from the domain of testing strings to the domain of testing graph properties in the bounded-degree graph model.

**Theorem 5.5** (in the bounded-degree graph model, tolerant testing is harder than testing).

For any sufficiently large constant $d$ and any constant $c \in (0, 1)$, there exists a graph property $\Pi$ such that testing $\Pi$ in the bounded-degree graph model (with degree bound $d$) has query complexity $O(\text{poly}(\log n) / \epsilon)$, but tolerantly testing $\Pi$ has query complexity $\Omega(n^{\Omega(1-c)})$, provided that the tolerance parameter is not smaller than $n^{-c}$. Furthermore, $\Pi$ is efficiently recognizable.

**Proof.** A small variant on the proof of [15, Thm. 1.3] yields an efficiently recognizable set of strings $\Phi$ that is testable in $O(1/\epsilon)$ queries but tolerantly testing it requires $\Omega(n^{\Omega(1-c)})$ queries. Using Construction 5.2.1 with graphs that are locally self-ordered and locally reversed self-ordered (as provided by Corollary 4.10), we obtain the desired graph property $\Pi$. By Corollary 5.3 tolerantly testing $\Pi$ requires $\Omega(n^{\Omega(1)})$ queries, whereas by Proposition 5.4 (non-tolerant) testing $\Pi$ has query complexity $\text{poly}(\log n) \cdot O(1/\epsilon)$. The claim follows. ◀

---

32 Basically, the construction of [15] consists of repeating some $m$-bit long string $\text{poly}(m)$ times and augmenting it with a PCP of Proximity (PCPP) [2, 11] of membership in some polynomial-time recognizable set that is hard to test. Essentially, the PCPP helps the tester, but it may be totally useless (when corrupted) in the tolerant testing setting. While [15] lets the PCPP occupy an $o(1/\log \log n)$ fraction of the final $n$-bit string, we let it occupy just a $n^{-c}$ fraction (and use $m = n^{\Omega(1-c)}$). This requires using a different PCPP than the one used in [15], e.g., using a strong PCPP with linear detection probability [10, Def. 2.2] will do, and such a PCPP is available [10, Thm. 3.3].

CCC 2021
Digest: Tightly reducing testing properties of strings to testing graph properties

In continuation to (the main part of) Corollary 5.3, we highlight the fact that Construction 5.2.1 not only reduces testing the string property $\Phi$ to testing the graph property $\Pi$, but rather does so in a rather tight manner. Specifically, for $\Phi, \Pi$ and $Q_{\Phi}, Q_{\Pi}$ as in Corollary 5.3, it holds that $Q_{\Phi}(n, e)$ and $Q_{\Pi}(\Theta(n), \Theta(e))$ agree up to a poly$(\log n)$ factor. In other words, for any property of strings $\Phi$, there exists a property of bounded-degree graphs $\Pi$ such that the (query and time) complexity of testing $\Phi$ is reflected in the (query and time) complexity of testing $\Pi$, where our notion of reflection allows for a polylogarithmic slackness. Recall that the transformation of strings in $\Phi$ to graphs in $\Pi$ is (strongly/locally) efficient.

6 Random Regular Graphs are Robustly Self-Ordered

While Theorem 4.1 only asserts the existence of robustly self-ordered $d$-regular graphs, we next show that almost all $d$-regular graphs are robustly self-ordered. This extends work in probabilistic graph theory, which proves a similar result for the weaker notion of self-ordered (a.k.a asymmetric) graphs [5, 4].

**Theorem 6.1** (random $d$-regular graphs are robustly self-ordered). For any sufficiently large constant $d$, a random 2d-regular $n$-vertex graph is robustly self-ordered with probability $1 - o(1)$.

Recall that, with very high probability, these graphs are expanders. We mention that the proof of Theorem 4.1 actually established that $n$-vertex graphs drawn from a weird distribution (which has min-entropy $\Omega(n)$) are robustly self-ordered with probability $1 - o(1)$. However, this is established by using the edge-coloring variant, and requires employing the transformation presented in Section 2.1. In contrast, the following proof works directly with the original (uncolored) variant, and is completely self-contained.

**Proof.** The proof is quite similar to the proof Claim 4.1.1, but it faces complications that were avoided in the prior proof by using edge-colors and implicitly directed edges. Specifically, for candidate permutations $\pi_1, \ldots, \pi_d : [n] \to [n]$ (to be used in the construction) and all (non-trivial) permutations $\mu : [n] \to [n]$, the proof of Claim 4.1.1 considered events of the form ($\forall j \in [d]$) $\pi_j(i) = \mu(\pi_j(\mu^{-1}(i)))$, whereas here we shall consider events of the form $\{\pi_j^{(i)} : j \in [d] \& b \in \{\pm 1\}\} = \{\mu(\pi_j^{(i)}) : j \in [d] \& b \in \{\pm 1\}\}$. These multi-set equalities will be reduced to equalities among sequences by considering all possible ordering of these multi-sets. This amounts to taking a union bound over all possible ordering and results in a more complicated analysis (due to the $\pi_j^{-1}$'s) and much more cumbersome notation.

To facilitate the proof, we use the standard methodology (cf. [13, Apdx. 2]) of first proving the result in the random permutation model, then transporting it to the configuration model (by using a general result of [24]), and finally conditioning on the event that the generated graph is simple (which occurs with positive constant probability). Indeed, both models generate multi-graphs that are not necessarily simple graphs (i.e., these multi-graphs may have self-loops and parallel edges). We also use the fact that the simple graphs that are generated by the configuration model (for degree $d'$) are uniformly distributed among all $d'$-regular graphs.

Recall that in the random permutation model a 2d-regular $n$-vertex multi-graph is generated by selecting uniformly and independently $d$ permutations $\pi_1, \ldots, \pi_d : [n] \to [n]$. The multi-graph, denoted $G_{(\pi_1, \ldots, \pi_d)}$, consists of the edge multi-set $\bigcup_{i \in [d]} \{\{i, \pi_j(i)\} : i \in [n]\}$, where the $2j^{th}$ (resp., $(2j - 1)^{st}$) neighbor of vertex $i$ is $\pi_j(i)$ (resp., $\pi_j^{-1}(i)$). Note that this multi-graph
may have self-loops (due to $\pi_j(i) = i$), which contributed two units to the degree of a vertex, as well as parallel edges (due to $\pi_j(i) = \pi_k(i)$ for $j \neq k$ and $\pi_j(i) = \pi_k^{-1}(i)$ for any $j, k$.

We denote the $j^{th}$ neighbor of vertex $i$ by $g_j(i)$; that is, $g_j(i) = \pi_{j/2}(i)$ if $j$ is even, and $g_j(i) = \pi_{(j+1)/2}(i)$ otherwise.

Consider an arbitrary permutation $\mu : [n] \to [n]$, and let $T = \{i \in [n] : \mu(i) \neq i\}$ be its set of non-fixed-point. We shall show that, with probability $1 - \exp(-\Omega(d \cdot |T| \cdot \log n))$ over the choice of $\mu = (\pi_1, \ldots, \pi_d)$, the size of the symmetric difference between $G_{\pi}$ and $\mu(G_{\pi})$ is $\Omega(|T|)$. Note that this difference is (half) the sum over $i \in [n]$ of the size of the symmetric difference between the multi-set of neighbors of vertex $i$ in $G_{\pi}$ and the multi-set of neighbors of vertex $i$ in $\mu(G_{\pi})$. We refer to the latter difference by the phrase the contribution of vertex $i$ to the difference between $G_{\pi}$ and $\mu(G_{\pi})$.

As a warm-up, we first show that each element of $T$ contributes a non-zero number of units to the difference (between $G_{\pi}$ and $\mu(G_{\pi})$) with probability $1 - O(\text{poly}(d/n)^{d/3})$ over the choice of $\pi$. Consider the event that for some $j, k \in [2d]$, the $j^{th}$ neighbor of $i \in [n]$ in $\mu(G_{\pi})$ is different from the $k^{th}$ neighbor of $i$ in $G_{\pi}$. Note that $x$ is the $j^{th}$ neighbor of $i$ in $\mu(G_{\pi})$ if and only if $\mu^{-1}(x)$ is the $k^{th}$ neighbor of $\mu^{-1}(i)$ in $G_{\pi}$, which holds if and only if $\mu^{-1}(x) = g_k(\mu^{-1}(i))$ (equiv., $x = \mu(g_k(\mu^{-1}(i)))$). Recalling that $i \in T$ contributes to the difference (between $G_{\pi}$ and $\mu(G_{\pi})$) if the multi-sets of its neighbors in $G_{\pi}$ and $\mu(G_{\pi})$ differ, it follows that $i \in T$ contributes to the difference if and only if for every permutation $\sigma : [2d] \to [2d]$ there exists $j \in [2d]$ such that $g_j(i) \neq \mu(g_{\sigma(j)}(\mu^{-1}(i)))$. Thus, the probability of the complementary event (i.e., $i$ does not contribute to the difference) is given by

$$
\Pr_{\pi} \left[ \exists \sigma \in \text{Sym}_{2d} \left( \forall j \in [2d] \right) \ g_j(i) = \mu(g_{\sigma(j)}(\mu^{-1}(i))) \right] = \frac{d!}{2d} \cdot \max_{\sigma \in \text{Sym}_{2d}} \left\{ \Pr_{\pi} \left[ \left( \forall j \in [2d] \right) \ g_j(i) = \mu(g_{\sigma(j)}(\mu^{-1}(i))) \right] \right\}. \tag{10}
$$

Fixing $\sigma$ that maximizes the probability, and denoting it $\sigma$, consider any $J_i \subseteq [d]$ such that for the $j$’s in $J_i$ the multi-sets $\{j, [\sigma_{i}(2j)/2]\}$’s are disjoint (i.e., $\{j, [\sigma_{i}(2j)/2]\} \cap \{k, [\sigma_{i}(2k)/2]\} = \emptyset$ for any $j \neq k \in J_i$). Note that we may select $J_i$ such that $|J_i| \geq d/3$, since taking $j$ to $J_i$ only rules out taking (to $J_i$) any $k$ such that $[\sigma_{i}(2k)/2] = v_{\sigma_{i}(2j)/2}$ (equiv., $k$ such that $\sigma_{i}(2k) \in \{2v-1, 2v\}$). Using this property of $J_i$, we prove

$\triangleright$ Claim 6.1.1 (warm-up). \text{33}  $\tag{10}$ is upper-bounded by $(2d)^{2d} \cdot (2/n)^{|J_i|}$.

Proof. We upper-bound (10) by

$$
(2d)! \cdot \max_{\sigma \in \text{Sym}_{2d}} \left\{ \Pr_{\pi} \left[ \left( \forall j \in J_i \right) \ g_j(i) = \mu(g_{\sigma(j)}(\mu^{-1}(i))) \right] \right\} = (2d)! \cdot \prod_{j \in J_i} \Pr_{\pi, \pi_{[\sigma_{i}(2j)/2]}} \left[ g_j(i) = \mu(g_{\sigma(j)}(\mu^{-1}(i))) \right] \tag{11}
$$

where the equality uses the disjointness of the multi-sets $\{j, [\sigma_{i}(2j)/2]\}$ for the $j$’s in $J_i$.

Next, we upper-bound (11) by

$$
(2d)! \cdot \prod_{j \in J_i} \Pr_{\pi_{[\sigma_{i}(2j)/2]}} \left[ \pi_j(i) = \mu(\pi_{[\sigma_{i}(2j)/2]}^{-1}(\mu^{-1}(i))) \right] < (2d)^{2d} \cdot (2/n)^{|J_i|}, \tag{12}
$$

where $\Pr_{\pi_{[\sigma_{i}]}}[\cdot]$ stands for $\Pr_{\pi_{[\sigma_{i}]}}[\cdot]$ and $\pi^1$ stands for $\pi$, while the inequality is justified by considering the following three cases (w.r.t each $j \in J_i$).

\[\text{33} \text{One may obtain a better bound of } O(d/n)^{2d} \text{ by analyzing (10) directly, by considering all the } 2d \text{ events and accounting for their small dependency. On the other hand, we can obtain higher robustness parameter by considering smaller sets } J_i \text{'s (say of size } d/4), \text{ which suffice for counting vertices that contribute (say) } d/4 \text{ units to the difference between } G_{\pi} \text{ and } \mu(G_{\pi}).\]
1. If \( k \stackrel{\text{def}}{=} [\sigma_i(2j)/2] \neq j \), then, letting \( b = (-1)^{\sigma_i(2j)} \mod 2 \), the corresponding factor in the l.h.s of (12) is
\[
\Pr_{\pi, \pi_k} \left[ \pi_j(i) = \mu(\pi_k^b(\mu^{-1}(i))) \right]
\]
which equals \( 1/n \) by fixing \( \pi_k \), letting \( v = \mu(\pi_k^b(\mu^{-1}(i))) \), and using \( \Pr_{\pi_j}[\pi_j(i) = v] = 1/n \).

2. If \( \sigma_i(2j) = 2j \), then the corresponding factor in the l.h.s of (12) is
\[
\Pr_{\pi, \pi_j} \left[ \pi_j(i) = \mu(\pi_j^{2j}((\mu^{-1}(i))) \right]
\]
which is at most \( 1/(n - 1) \) since \( \mu(i) \neq i \); specifically, fixing the value of \( \pi_j(\mu^{-1}(i)) \), and denoting this value by \( v \), leaves \( \pi_j(i) \) uniformly distributed in \([n] \setminus \{v\} \), which means that \( \Pr_{\pi_j}[\pi_j(i) = \mu(v)|v = \pi_j(\mu^{-1}(i))] \leq 1/(n - 1) \) (where equality holds if \( \mu(v) \neq v \)).

3. If \( \sigma_i(2j) = 2j - 1 \), then the corresponding factor in the l.h.s of (12) is
\[
\Pr_{\pi, \pi_j} \left[ \pi_j(i) = \mu(\pi_j^{2j-1}(\mu^{-1}(i))) \right]
\]
which is less than \( 2/n \). In this case, we consider two sub-cases depending on whether or not \( \pi_j(i) = \mu^{-1}(i) \), while noting that the first case occurs with probability \( 1/n \) whereas
\[
\Pr_{\pi, \pi_j} \left[ \pi_j(i) = \mu(\pi_j^{2j-1}(\mu^{-1}(i)))|\pi_j(i) \neq \mu^{-1}(i) \right] \leq 1/(n - 1).
\]
Hence, each of the factors in the l.h.s of (12) is upper-bounded by \( 2/n \), and the claim follows.

\[\triangleright\]

The general case. The same argument generalizes to a set \( I \subseteq T \) such that \( I \cap \mu(I) = \emptyset \). In such a case we get
\[
\Pr_{\pi} \left[ \left( \forall i \in I \right) \left( \exists \sigma_i \in \text{Sym}_{2d} \left( \forall j \in [2d] \right) g_j(i) = \mu(g_{\sigma,ij}(\mu^{-1}(i))) \right) \right] = \left( 2d \right)!^{-|I|} \cdot \max_{\sigma_1,\ldots,\sigma_n} \left\{ \Pr_{\pi} \left( \left( \forall i \in I \right) \left( \forall j \in [2d] \right) g_j(i) = \mu(g_{\sigma,ij}(\mu^{-1}(i))) \right) \right\}
\]
(13)

\[\triangleright\] Claim 6.1.2 (actual analysis). (13) is upper-bounded by
\[
\left( 2d \right)!^{-|I|} \cdot \left( 2/(n - 2(|I| - 1)) \right)^{|I| - d/3}.
\]
(14)

Proof. For every \( i \in I = \{i_1,\ldots,i_m\} \), we fixed a set \( J_i \) of size at least \( d/3 \) such that the multi-sets \{\( j_i, [\sigma_i(2j)/2] \)\}’s are disjoint, and upper-bound (13) by
\[
\left( 2d \right)!^{-m} \cdot \prod_{k \in [m]} \prod_{j \in J_k} \Pr_{\pi_1,\ldots,\pi_{2d}} \left[ g_{2j}(i_k) = \mu(\sigma_{i_k^{(2j)}}(\mu^{-1}(i_k))) | E_{j,k}(\pi_1,\ldots,\pi_{2d}) \right] = \left( 2d \right)!^{-m} \cdot \prod_{k \in [m]} \prod_{j \in J_k} \Pr_{\pi_1,\ldots,\pi_{2d}} \left[ \pi_j(i_k) = \mu(\sigma_{i_k^{(2j)}}(\mu^{-1}(i_k))) | E_{j,k}(\pi_1,\ldots,\pi_{2d}) \right]
\]
(15)

where \( \sigma_{i}^{(2j)} \stackrel{\text{def}}{=} [\sigma_i(2j)/2] \), and \( \sigma_{i}^{(2j)} \stackrel{\text{def}}{=} (-1)^{\sigma_i^{(2j)} \mod 2} \), whereas \( E_{j,k}(\pi_1,\ldots,\pi_{2d}) \) is an event that depends only on the value of \( \pi_j \) and \( \pi_{i_k^{(2j)}} \) on the points \( i_1, \ldots, i_{k-1} \) and \( \mu^{-1}(i_1), \ldots, \mu^{-1}(i_{k-1}) \), respectively. Specifically, \( E_{j,k}(\pi_1,\ldots,\pi_{2d}) \) is the event
\[
(\forall k' \in [k - 1]) \ g_{2j}(i_{k'}) = \mu(g_{\sigma_{i_{k'}^{(2j)}}(\mu^{-1}(i_{k'})))
\]
which can be written as
\[
(\forall k' \in [k - 1]) \ \pi_j(i_{k'}) = \mu(\sigma_{i_{k'}^{(2j)}}(\mu^{-1}(i_{k'}))).
\]
The proof of Theorem 6.1 is quite similar to the proof Claim 4.1.1, but it faces two complications that were avoided in the prior proof (by using edge-colors and implicitly directed edges). Most importantly, the current proof has to handle equality between multi-sets instead of equality between sequences. This is done by considering all possible ordering of these

Recall that (14) refers to a fixed set \( I \subseteq T \) such that \( I \cap \mu(I) = \emptyset \), and that it constitutes an upper bound on the probability (over the choice of \( \pi \)) that, for each \( i \in I \) there exists a permutation \( \sigma_i : [2d] \to [2d] \) such that \( g_j(i) = \mu(g_{\sigma_i(j)}(\mu^{-1}(i))) \) holds for all \( j \in [2d] \). This upper bound (i.e., \( (2d)^{2d|I|} \cdot (2/|I| \cdot n^3/n^3)^{|\partial(I)|/d^3} \)) simplifies to \( (2d)^{2d|I|} \cdot (6/n)^{|\partial(I)|/d^3} \), provided that \(|I| \leq n/3\).

Recalling that \( t \stackrel{\text{def}}{=} |T| \in [n] \), we shall upper-bound the probability (over the choice of \( \pi \)) that \( T \) contains a \([t/2]\)-subset \( T' \) such that for each \( i \in T' \) there exists a permutation \( \sigma_i : [2d] \to [2d] \) such that \( g_j(i) = \mu(g_{\sigma_i(j)}(\mu^{-1}(i))) \) holds for all \( j \in [2d] \). We do so by taking a union bound over all \([t/6]\)-subsets \( I \) such that \( I \cap \mu(I) = \emptyset \) and for each \( i \in I \) there exists a permutation \( \sigma_i : [2d] \to [2d] \) such that \( g_j(i) = \mu(g_{\sigma_i(j)}(\mu^{-1}(i))) \) holds for all \( j \in [2d] \). (Note that such a \([t/6]\)-subset \( I \) exists in each \([t/2]\)-subset \( T' \), and that \([t/6]\) < \( n/3 \)). Using the aforementioned simplified form of (14), we conclude that, with probability at most

\[
\left( \frac{t}{t/6} \right) \cdot (2d)^{2d|t/6|} \cdot (6/n)^{|t/6|/d^3} < 2^t \cdot (6 \cdot (2d)^6/n)^{|t/6|/d^3} = \exp(-\Omega(dt \log n))
\]

The proof of Theorem 6.1 is quite similar to the proof Claim 4.1.1, but it faces two complications that were avoided in the prior proof (by using edge-colors and implicitly directed edges). Most importantly, the current proof has to handle equality between multi-sets instead of equality between sequences. This is done by considering all possible ordering of these
multi-sets, which amounts to taking a union bound over all possible ordering and results in more complicated analysis and notation. (Specifically, see the introduction of $\sigma_i$’s and $J_i$’s and the three cases analyzed in the warm-up.) In addition, since edges are defined by permutations over the vertex-set rather than by perfect matching, we have to consider both the forward and backward direction of each permutation, which results in further complicating the analysis and the notation. (Specifically, see the introduction of $\sigma_i''$’s and $\sigma_i'''$’s and the three cases analyzed in the warm-up.)

**An alternative proof of Theorem 4.2**

We mention that combining an extension of Theorem 6.1 with some of the ideas underlying the proof of Theorem 4.2 yields an alternative proof of Theorem 4.2 (i.e., an alternative construction of robustly self-ordered bounded-degree graphs).

**Remark 6.2 (an alternative construction of $d$-regular robustly self-ordered graphs).** On input $1^n$, we set $\ell = \frac{O(\log n)}{\log \log n}$, and proceeds in three steps.

1. Extending the proof of Theorem 6.1, we show that for all sufficiently large constant $d$, for any set $G$ of $t = t(\ell) < n = \ell^{\Omega(\ell)}$ $(2d$-regular) $\ell$-vertex graphs, with probability $1 - o(1)$, a random $2d$-regular $\ell$-vertex graph is both robustly self-ordered and far from being isomorphic to any graph in $G$. Note that, with probability $1 - o(1)$, such a graph is also expanding.
   
   Here two $\ell$-vertex graphs are said to be far apart if they disagree on $\Omega(\ell)$ vertex-pairs. The proof of Theorem 6.1 is extended by considering, for a random graph, the event that it is either not robustly self-ordered or is not far from an isomorphic copy of one of the $t$ (fixed) graphs. The later event (i.e., being close to isomorphic to one of these graphs) occurs with probability $o(t/n)$.

2. Relying on Step 1, we find a sequence of $n/\ell$ robustly self-ordered $2d$-regular $\ell$-vertex graphs that are expanding and pairwise far from being isomorphic to one another. This is done by iteratively finding robustly self-ordered $2d$-regular $\ell$-vertex expanding graphs that are far from being isomorphic to all prior ones, where scanning all possible graphs and checking the condition can be done in time $n \cdot \ell^{\ell/2} \cdot (\ell!) = \text{poly}(n)$.

3. Using the sequence of $n/\ell$ graphs found in Step 2, we consider the $n$-vertex graph that consists of these $\ell$-vertex graphs as its connected components, and use parts of the proof of Theorem 4.2 to show that this graph is robustly self-ordered. Specifically, we only need to consider cases that are analogous to Cases 2, 6 and 7. The treatment of the analogous cases is slightly simpler than in the proof of Theorem 4.2, since the graphs are somewhat simpler.

Note that the resulting graphs are not locally constructable.
Part II
The Case of Dense Graphs

Recall that when considering graphs of unbounded degree, we ask whether we can obtain unbounded robustness parameters. In particular, we are interested in $n$-vertex graphs that are $\Omega(n)$-robustly self-ordered, which means that they must have $\Omega(n^2)$ edges.

In Section 7 we prove the existence of $\Omega(n)$-robustly self-ordered $n$-vertex graphs, and show that they imply $\Omega(1)$-robustly self-ordered bounded-degree $O(n^2)$-vertex graphs. In Section 8, we reduce the construction of the former (dense) $n$-vertex graphs to the construction of non-malleable two-source extractors (with very mild parameters). We actually show two reductions: The first reduction (presented in Section 8.1) requires the extractors to have an additional natural feature, called quasi-orthogonality, and yields a construction of such $n$-vertex graphs that runs in $\text{poly}(n)$-time. The second reduction (presented in Section 8.2) does not make this requirement, and yields an algorithm that computes the adjacency predicate of such $n$-vertex graphs in $\text{poly}(\log n)$-time.

In Section 9 we demonstrate the applicability of $\Omega(n)$-robustly self-ordered $n$-vertex graphs to property testing; specifically, to proving lower bounds (on the query complexity) for the dense graph testing model. Lastly, in Section 10, we consider the construction of $\Omega(d(n))$-robustly self-ordered $n$-vertex graphs of maximum degree $d(n)$, for every $d : \mathbb{N} \to \mathbb{N}$ such that $d(n) \in [\Omega(1), n]$.

7 Existence and Transformation to Bounded-Degree Graphs

It seems easier to prove that random $n$-vertex graphs are $\Omega(n)$-robustly self-ordered (see Proposition 7.1) than to prove that random bounded-degree graphs are $\Omega(1)$-robustly self-ordered (or even just prove that such bounded-degree graphs exist). In contrast, it seems harder to construct $\Omega(n)$-robustly self-ordered $n$-vertex graphs than to construct $\Omega(1)$-robustly self-ordered bounded-degree graphs. In particular, we show that $\Omega(n)$-robustly self-ordered $n$-vertex graphs can be easily transformed into $O(n^2)$-vertex bounded-degree graphs that are $\Omega(1)$-robustly self-ordered (see Proposition 7.2). We stress that the construction of robustly self-ordered bounded-degree graphs that is obtained by combining the foregoing transformation with Theorem 1.4 is entirely different from the constructions presented in the first part of the paper.

Random graphs are robustly self-ordered

We first show that, with very high probability, a random $n$-vertex graph $G_n = ([n], E_n)$, where $E_n$ is a uniformly distributed subset of $\binom{[n]}{2}$, is $\Omega(n)$-robustly self-ordered.

▶ Proposition 7.1 (robustness analysis of a random graph). A random $n$-vertex graph $G_n = ([n], E_n)$ is $\Omega(n)$-robustly self-ordered with probability $1 - \exp(-\Omega(n))$.

As stated above, the following proof is significantly easier than the proof provided for the bounded-degree analogue (i.e., Theorem 6.1).

Proof. For each (non-trivial) permutation $\mu : [n] \to [n]$, letting $T \overset{\text{def}}{=} \{i \in [n] : \mu(i) \neq i\}$ denote its (non-empty) set of non-fixed-points, we show that, with probability $1 - \exp(-\Omega(n \cdot |T|))$, the size of the symmetric different between a random $n$-vertex graph $G_n = ([n], E_n)$ and $\mu(G_n)$ is $\Omega(n \cdot |T|)$.
For every $u, v \in [n]$ such that $u < v$, let $\chi_{u,v}^\mu = \chi_{u,v}^\mu(G_n)$ represent the event that the pair $(\mu(u), \mu(v))$ contributes to the symmetric difference between $G_n$ and $\mu(G_n)$; that is, $\chi_{u,v}^\mu = 1$ if exactly one of the edges $(\mu(u), \mu(v))$ and $(u, v)$ is in $G_n$, since $(u, v)$ is an edge of $G_n$ if and only if $(\mu(u), \mu(v))$ is an edge of $\mu(G_n)$. We shall prove that

$$\Pr_{G_n} \left[ \sum_{u < v \in [n]} \chi_{u,v}^\mu(G_n) < \frac{n \cdot |T|}{20} \right] = \exp(-\Omega(n \cdot |T|)). \tag{16}$$

We prove (16) by using a $|[T]/3$-subset $I \subseteq T$ such that $T \cap \mu(I) = \emptyset$. Let $T' = T \setminus (I \cup \mu^{-1}(I))$, which implies $T' \cap I = \emptyset$ and $\mu(T') \cap I = \emptyset$. Let $J = ([n] \setminus T) \cup T'$, and note that $|J| = n - |T| + (|T| - 2 \cdot |[T]/3|) \geq n - (2|T|/3) - 2 \geq (n/3) - 2$. Observe that, for every $(u, v) \in J \times I$, it holds that $u \neq v$ and $\Pr[\chi_{u,v} = 1] = 1/2$, where the equality is due to $\{u, v\} \neq \{\mu(u), \mu(v)\}$, which holds since $(u, v) \in J \times I$ but $\mu(u), \mu(v) \in [n] \setminus I$. Furthermore, the events the correspond to the pairs in $J \times I$ are independent, because the sets $\{\{u, v\} : (u, v) \in J \times I\}$ and $\{\{\mu(u), \mu(v)\} : (u, v) \in J \times I\}$ are disjoint; that is, $(u, v) \in J \times I$ implies $(\mu(u), \mu(v)) \in ([n] \setminus I) \times ([n] \setminus I)$. Hence (using $n \leq 3(|J| + 2)$ and $|T| \leq 3|I|$) as well as $3(|J| + 2) \cdot 3|I| < 9.9 \cdot |J| \cdot |I|$), the l.h.s. of (16) is upper-bounded by

$$\Pr_{G_n} \left[ \sum_{(u,v) \in J \times I} \chi_{u,v}^\mu(G_n) < \frac{3|J| + 2}{20} \cdot 3|I| \right] \leq \Pr_{G_n} \left[ \sum_{(u,v) \in J \times I} \chi_{u,v}^\mu(G_n) < \frac{0.99 \cdot |J| \cdot |I|}{2} \right] = \exp(-\Omega(|J| \cdot |I|))$$

which is $\exp(-\Omega(n \cdot |T|))$. Having established (16), the claim follows by a union bound (over all non-trivial permutations $\mu : [n] \to [n]$); specifically, denoting the set of non-trivial permutations by $P_n$, we upper-bound the probability that $G_n$ is not $\frac{n}{2\mu}$-robust by

$$\sum_{\mu \in P_n} \Pr_{G_n}[\mu \text{ violates the condition in (16)}] \leq \sum_{t \in [n]} \binom{n}{t} \cdot (t!) \cdot \exp(-\Omega(n \cdot t)) < n \cdot \max_{t \in [n]} \{t! \cdot \exp(-\Omega(n \cdot t))\} = \exp(-\Omega(n))$$

where $t$ represents the size of the set of non-fixed-points (w.r.t $\mu$).

\[\square\]

**Obtaining bounded-degree robustly self-ordered graphs**

We next show how to transform $\Omega(n)$-robustly self-ordered $n$-vertex graphs to $O(n^2)$-vertex bounded-degree graphs that are $\Omega(1)$-robustly self-ordered. Essentially, we show that the standard “degree reduction via expanders” technique works (when using a different color for the expanders’ edges, and then using gadgets to replace colored edges). Specifically, we replace each vertex in $G_n = ([n], E_n)$ by an $(n - 1)$-vertex expander graph and connect each of these vertices to at most one vertex in a different expander, while coloring the edges of the expanders with 1, and coloring the other edges by 2. Actually, the vertex $v$ is replaced by the vertex-set $C_v = \{v, w : u \in [n] \setminus \{v\}\}$ and in addition to the edges of the expander, colored 1, we connect each vertex $\langle v, u \rangle \in C_v$ to the vertex $\langle u, v \rangle \in C_u$ and color this edge 2 if
\{u, v\} \in E_n \) and 0 otherwise.\(^{34}\) This yields an \(n \cdot (n - 1)\)-vertex \(O(1)\)-regular graph, denoted \(G'_n\), coupled with an edge-coloring, denoted \(\chi'\), which uses three colors. Using the hypothesis that \(G_n\) is \(\Omega(n)\)-robustly self-ordered, we prove that \((G'_n, \chi')\) is \(\Omega(1)\)-robustly self-ordered (in the colored sense).

\textbf{Proposition 7.2 (robustness analysis of the degree reduction).} If \(G_n\) is \(\Omega(n)\)-robustly self-ordered, then \((G'_n, \chi')\) is \(\Omega(1)\)-robustly self-ordered (in the colored sense of Definition 2.1).

Using Theorem 2.4 (after adding self-loops), we obtain a \(O(1)\)-regular \(O(n^2)\)-vertex graph that is \(\Omega(1)\)-robustly self-ordered (in the standard sense).

\textbf{Proof.} Denoting the vertex-set of \(G'_n\) by \(V = \bigcup_{v \in [n]} C_v\), we consider an arbitrary (non-trivial) permutation \(\mu' : V \to V\), and the corresponding set of non-fixed-points \(T'\). Intuitively, if \(\mu'\) maps vertices of \(C_v\) to several \(C_w\)'s, then we get a proportional contribution to the difference between \(G_n\) and \(\mu'(G'_n)\) by the \(1\)-colored edges of the expander. Otherwise, \(\mu'\) induces a permutation \(\mu\) over the vertices of \(G_n\), and we get a corresponding contribution via the \(2\)-colored edges of \(G_n\). Lastly, non-identity mapping inside the individual \(C_v\)'s are charged using the \(0\)-colored and \(2\)-colored edges that connect different \(C_v\)'s. Details follow.

For a permutation \(\mu' : V \to V\) as above, let \(\mu : [n] \to [n]\) be a permutation that maximizes the \(\text{average over } v \in [n]\) of the number of vertices in \(C_v\) that are mapped by \(\mu'\) to vertices in \(C_{\mu(v)}\); that is, for every permutation \(\nu : [n] \to [n]\), it holds that
\[
\left|\left\{ (v, u) \in V : \mu'((v, u)) \in C_{\nu(v)} \right\}\right| \geq \left|\left\{ (v, u) \in V : \mu'((v, u)) \in C_{\nu(v)} \right\}\right|. \tag{17}
\]
We consider the following three cases.

\textbf{Case 1:} \(\sum_{v \in [n]} |B_v| = \Omega(|T'|)\), where \(B_v \overset{\text{def}}{=} \{ (v, u) \in C_v : \mu'(\langle v, u \rangle) \notin C_{\mu(v)} \}\).

(This refers to the case that many vertices are mapped by \(\mu'\) to an expander that is different from the one designated by \(\mu\), which represents the best possible mapping of whole expanders.)

Letting \(C_{v, w} \overset{\text{def}}{=} \{ \langle v, u \rangle : \mu'(\langle v, u \rangle) \in C_w \}\), we first observe that for every \(v\) it holds that \(\max_{v \neq \mu(v)} |C_{v, w}| \leq \frac{2}{3} \cdot (n - 1)\), because otherwise we reach a contradiction to the maximality of \(\mu\) by defining \(\nu(v) = w\) and \(\nu(\mu^{-1}(w)) = \mu(v)\), where \(w\) is the element obtaining the maximum, and \(\nu(x) = \mu(x)\) otherwise.

Next, observe that there exists \(W_v \subseteq [n] \setminus \{ \mu(v) \}\) such that \(B'_v = \bigcup_{w \in W_v} C_{v, w}\) satisfies both \(|B'_v| \leq \frac{2}{3} \cdot (n - 1)\) and \(|B'_v| \geq |B_v|/3\). Now, consider the sets \(B'_v\) and \(C_v \setminus B'_v\).

On the one hand, in \(\mu'(G'_n)\) there are \(\Omega(|B'_v|)\) \(1\)-colored edges connecting \(\mu'(B'_v)\) and \(\mu'(C_v \setminus B'_v)\), due to the subgraph of \(\mu'(G'_n)\) induced by \(\mu'(C_v)\) which equals subgraph of \(G'_n\) induced by \(C_v\) (which, in turn, is an expander). On the other hand, in \(G'_n\) there are no \(1\)-colored edges between \(\mu'(B'_v)\) and \(\mu'(C_v \setminus B'_v)\), since \(\mu'(B'_v) \subseteq \bigcup_{w \in W_v} C_w\) and \(\mu'(C_v \setminus B'_v) \subseteq \bigcup_{w \in [n] \setminus W_v} C_w\).

We conclude that, in this case, the difference between \(G'_n\) and \(\mu'(G'_n)\) is \(\sum_v \Omega(|B'_v|) = \sum_v \Omega(|B_v|) = \Omega(|T'|)\).

\textbf{Case 2:} \(\sum_{v \in [n], \mu(v) \neq \mu'(v)} |C'_v| = \Omega(|T'|)\), where \(C'_v \overset{\text{def}}{=} \{ (v, u) \in C_v : \mu'(\langle v, u \rangle) \in C_{\mu(v)} \}\).

(This refers to the case that many vertices are mapped by \(\mu'\) to an expander that is designated by \(\mu\), but this expander is not the one in which they reside (i.e., \(\mu\) has many non-fixed-points).)

\(^{34}\)This is equivalent to first converting \(G_n\) into a \(n\)-vertex clique while coloring an edge 2 if and only if it is in \(E_n\).
Letting $\gamma > 0$ be a constant such that $G_n$ is $\gamma \cdot n$-robustly self-ordered, we may assume that $\sum_{v \in [n] : \mu(v) \neq v} |C'_v| \geq (1 - 0.5 \cdot \gamma) \cdot \sum_{v \in [n] : \mu(v) \neq v} |C_v|$, since otherwise we are done by Case 1.

By the $\gamma n$-robust self-ordering of $G_n$, the difference between $G_n$ and $\mu(G_n)$ is at least $\Delta \overset{\text{def}}{=} \gamma n \cdot |\{ v \in [n] : \mu(v) \neq v \}|$. Assuming, for a moment, that $\mu'(C_v) = C_v$ for every $v$ such that $\mu(v) \neq v$, the difference between $G_n'$ and $\mu'(G_n')$ is $\Delta$, where the difference is due to edges colored 2 (i.e., the edges inherited from $G_n$). This amount is prorotional to the number of vertices in the current case, since

$$\Delta = \frac{\gamma n}{n - 1} \cdot \sum_{v \in [n] : \mu(v) \neq v} |C_v| > \gamma \cdot \sum_{v \in [n] : \mu(v) \neq v} |C_v|.$$ 

In general, $\mu'(C_v)$ may not hold for some $v$, and in this case we may lose the contribution of the 2-colored edges incident at vertices in $\bigcup_{v \in [n]} \mu(v) \neq v (C_v \setminus C'_v)$. Recalling that (by our hypothesis) the size of this set is at most $0.5 \cdot \gamma \cdot \sum_{v \in [n] : \mu(v) \neq v} |C_v|$, we are left with a contribution of at least $0.5 \gamma \cdot \sum_{v \in [n] : \mu(v) \neq v} |C'_v|$.

We conclude that, in this case, the difference between $G_n'$ and $\mu'(G_n')$ is $\Omega(\sum_{v \in [n] : \mu(v) \neq v} |C'_v|) = \Omega(\lvert T' \rvert)$.

Case 3: $\sum_{v \in [n]} |C''_v| = \Omega(\lvert T' \rvert)$, where $C''_v \overset{\text{def}}{=} \{ \langle v, u \rangle \in C_v : \mu'(\langle v, u \rangle) \notin C'_v \}$.

(This refers to the case that many vertices are mapped by $\mu'$ to a different vertex in the same expander in which they reside.)

This case would have been easy to handle if the expanders used on the $C_v$’s were robustly self-ordered. Needless to say, we want to avoid such an assumption. Instead, we rely on the fact that in $G_n'$ different vertices in $C_v$ are connected to different $C_v$’s.

We may assume that $\sum_{v \in [n]} |C''_v| \geq 2 \cdot \sum_{v \in [n]} |\{ \langle v, u \rangle \in C_v : \mu'(\langle v, u \rangle) \notin C'_v \}|$, since otherwise we are done by either Case 1 or Case 2. Now, consider a generic $\langle v, u \rangle \in C''_v$, and let $w \neq u$ be such that $\mu'(\langle v, u \rangle) = \langle v, w \rangle$. Then, in $\mu'(G_n')$, an edge colored either 0 or 2 connects $\langle v, w \rangle = \mu'(\langle v, u \rangle)$ to $\mu'(\langle u, v \rangle)$, since $\langle v, u \rangle$ and $\langle u, v \rangle$ are so connected in $G_n'$, whereas in $G_n'$ an (even-colored) edge connects $\langle v, w \rangle$ to $\langle w, v \rangle \in C_w$. We consider two sub-cases.

- If $\mu'(\langle u, v \rangle) \in C_u$, then $\langle v, w \rangle$ contributes to the difference between $\mu'(G_n')$ and $G_n'$, because in $\mu'(G_n')$ vertex $\langle v, w \rangle$ is connected (by its even-colored edge) to a vertex in $C_u$ whereas in $G_n'$ vertex $\langle v, w \rangle$ is connected (by its even-colored edge) to a vertex in $C_w$.

(Recall that $w$ is uniquely determined by $\langle v, u \rangle \in C''_v$, since $\mu'(\langle v, u \rangle) = \langle v, w \rangle$, and so this contribution can be charged to $\langle v, u \rangle$.)

- If $\mu'(\langle u, v \rangle) \notin C_u$, then $\langle u, v \rangle$ contributes to the set $\bigcup_{v \in [n]} \{ \langle x, y \rangle \in C_x : \mu'(\langle x, y \rangle) \notin C'_x \}$, which (by the hypothesis) has size at most $0.5 \cdot \sum_{v \in [n]} |C''_v|$

Hence, at least half of $\sum_{v \in [n]} |C''_v|$ appears in the first sub-case, which implies that, in this case, the difference between $G_n'$ and $\mu'(G_n')$ is at least $\frac{1}{2} \cdot \sum_{v \in [n]} |C''_v| = \Omega(\lvert T' \rvert)$.

Hence, the difference between $G_n'$ and $\mu'(G_n')$ is $\Omega(\lvert T' \rvert)$.

\[\□\]

---

35 Note that if $\langle v, u \rangle \in C_v$ is not mapped by $\mu'$ to $C_v$, then either $\mu'(\langle v, u \rangle) \notin C_{\mu(v)}$ holds (i.e., Case 1) or $\mu'(\langle v, u \rangle) \in C_{\mu(v)}$ such that $\mu(v) \neq v$ (i.e., Case 2). Hence, if $(u, v) \in T'$ is not counted in Cases 1 and 2, then it must be counted in Case 3.
8 Relation to Non-Malleable Two-Source Extractors

For \( n = 2^k \), we reduce the construction of \( \Omega(n) \) robustly self-ordered (dense) \( n \)-vertex graphs to the construction of non-malleable two-source extractors for \((\ell, \ell - O(1))\)-sources. Recall that a random variable \( X \) is called an \((\ell, k)\)-source if \( X \) is distributed over \( [2^\ell] \) and has min-entropy at least \( k \) (i.e., \( \Pr[X = i] \leq 2^{-k} \) for every \( i \in [2^\ell] \)).\(^{36}\) A function \( E : [2^\ell] \times [2^\ell] \rightarrow \{0, 1\}^m \) is called a (standard) two-source \((k, \epsilon)\)-extractor if, for every two independent \((\ell, k)\)-sources \( X \) and \( Y \), it holds that \( E(X, Y) \) is \( \epsilon \)-close to the uniform distribution over \( \{0, 1\}^m \), denoted \( U_m \).

Our notion of a non-malleable two-source extractor, presented next, is a restricted case of the notions considered in \([8, 7]\).\(^{37}\)

Definition 8.1 (non-malleable two-source extractors). A function \( nmE : [2^\ell] \times [2^\ell] \rightarrow \{0, 1\}^m \) is called a non-malleable two-source \((k, \epsilon)\)-extractor if, for every two independent \((\ell, k)\)-sources \( X \) and \( Y \), and for every two functions \( f, g : [2^\ell] \rightarrow [2^\ell] \) that have no fixed-point (i.e., \( f(z) \neq z \) and \( g(z) \neq z \) for every \( z \in [2^\ell] \)), it holds that \( (nmE(X, Y), nmE(f(X), g(Y))) \) is \( \epsilon \)-close to \( (U_m, nmE(f(X), g(Y))) \): that is,

\[
\frac{1}{2} \sum_{\alpha, \beta} |\Pr[(nmE(X, Y), nmE(f(X), g(Y))) = (\alpha, \beta)] - 2^{-m} \cdot \Pr[nmE(f(X), g(Y)) = \beta]| \leq \epsilon. \quad (18)
\]

The parameter \( \epsilon \) is called the error of the extractor.

We shall be interested in the special case in which \( f \) and \( g \) are permutations. In this case, the foregoing condition (i.e., (18)) can be replaced by requiring that \( (nmE(X, Y), nmE(f(X), g(Y))) \) is \( 2\epsilon \)-close to the uniform distribution over \( \{0, 1\}^{m+m} \).\(^{38}\) Furthermore, we shall focus on non-malleable two-source \((k, \epsilon)\)-extractors that output a single bit (i.e., \( m = 1 \)), and in this case non-triviality mandates \( \epsilon < 0.5 \). In general, we view \( \epsilon \) as a constant, but view \( \ell \) and \( k \) as varying (or generic) parameters, and focus on the case of \( k = \ell - O(1) \).

Recall that constructions of non-malleable two-source \((k, \epsilon)\)-extractors with much better parameters are known \([7, \text{Thm. 1}]\). In particular, these constructions support \( k = \ell - \ell^{O(1)} \), negligible error (i.e., \( \epsilon = \exp(-\ell^{O(1)}) \)), and \( m = \ell^{O(1)} \). We stress that, as is the norm in the context of randomness extraction, the extracting function is computable in polynomial-time (i.e., in \( \text{poly}(\ell) \)-time).

We shall show that any non-malleable two-source \((\ell - O(1), 0.49)\)-extractor (for sources over \([2^\ell] \)) yields \( \Omega(2^\ell) \)-robustly self-ordered \( O(2^\ell) \)-vertex graphs. Actually, we shall show two such constructions: The first construction runs in \( \text{poly}(2^\ell) \)-time, and the second construction provides strong constructability (a.k.a local computability) as claimed in Theorem 1.4. Both constructions use a similar underlying logic, which is more transparent in the first construction.

8.1 The first construction

For the first construction, we need the extractor to satisfy the following natural (and quite minimal) requirement, which we call quasi-orthogonality. We say that an extractor \( nmE : [2^\ell] \times [2^\ell] \rightarrow \{0, 1\} \) is quasi-orthogonal (with error \( \epsilon \)) if the following conditions hold:

\(^{36}\) Indeed, for the sake of simplicity (of our arguments), we do not require that \( \ell \in \mathbb{N} \), but rather only that \( 2^\ell \in \mathbb{N} \); consequently, we consider distributions over \([2^\ell] \) rather than over \([0, 1]^\ell \).

\(^{37}\) In particular, in \([8, 7]\) it is only required that one of the two functions \( f, g : [2^\ell] \rightarrow [2^\ell] \) has no fixed-points.

\(^{38}\) There seems to be no concrete reason to prefer one of these three variants over the others. We mention that Definition 8.1 is strictly weaker than the definition of \([8]\) (even in its simplified form \([7, \text{Def. 1.3}]\); see Appendix).

\(^{38}\) In this case, \( f(X) \) and \( g(Y) \) have min-entropy at least \( k \), which implies that \( nmE(f(X), g(Y)) \) is \( \epsilon \)-close to the uniform distribution over \( \{0, 1\}^m \).
1. The residual function obtained from \( \text{nmE} \) by any fixing of one of its two arguments is almost unbiased: For every \( x \in [2^\ell] \) and every \( \sigma \in \{0, 1\} \) it holds that \( |\{y \in [2^\ell] : \text{nmE}(x, y) = \sigma\}| \leq (0.5 + \varepsilon) \cdot 2^\ell \); ditto for every \( y \in [2^\ell] \) and the corresponding set \( \{x \in [2^\ell] : \text{nmE}(x, y) = \sigma\} \).

2. The residual functions obtained from \( \text{nmE} \) by any two different fixings of one of its two arguments are almost uncorrelated: For every \( \{x, x'\} \in \binom{[2^\ell]}{2} \) it holds that \( |\{y \in [2^\ell] : \text{nmE}(x, y) \neq \text{nmE}(x', y)\}| \geq (0.5 - \varepsilon) \cdot 2^\ell \); ditto for every \( \{y, y'\} \in \binom{[2^\ell]}{2} \) and the corresponding set \( \{x \in [2^\ell] : \text{nmE}(x, y) \neq \text{nmE}(x, y')\} \).

As shown in Proposition 8.2, any non-malleable two-source \((k, \varepsilon)\)-extractor can be transformed (in poly(2\(^\ell\))-time) into a quasi-orthogonal one at a small degradation in the parameters (i.e., \( \varepsilon \) increases by an additive term of \( O(2^{-\ell - k}) \) and \( 2^\ell \) decreases by an additive term of \( O(2^k) \)).

Note that poly(2\(^\ell\))-time is acceptable when one aims at constructing \( O(2^k) \)-vertex graphs; however, aiming at strong/local constructability (as in Theorem 1.4), we shall avoid such a transformation in the second construction (presented in Section 8.2).

\[\text{Proposition 8.2} \text{ (transforming non-malleable two-source extractors into ones that are quasi-orthogonal). For every } k \leq \ell - 3, \text{ there exists a poly}(2^\ell)\text{-time transformation that gives a non-malleable two-source } (k, \varepsilon)\text{-extractor } \text{nmE} : [2^\ell] \times [2^\ell] \rightarrow \{0, 1\}, \text{ returns a non-malleable two-source } (k', \varepsilon')\text{-extractor } \text{nmE}' : [n'] \times [n'] \rightarrow \{0, 1\} \text{ such that } n' \geq 2^k - O(2^k) \text{ and } \text{nmE}' \text{ is quasi-orthogonal with error } \varepsilon' = \varepsilon + O(2^k/n').\]

\[\text{Proof.} \text{ Essentially, } \text{nmE}' \text{ is obtained from } \text{nmE} \text{ by simply discarding inputs that violate the quasi-orthogonality conditions. Letting } n = 2^k, \text{ first note that the number of } x's \text{ that violate the first condition is at most } 2^{k+1}, \text{ because otherwise we obtain a contradiction to the hypothesis that } \text{nmE} \text{ is a two-source } (k, \varepsilon)\text{-extractor (by letting } X \text{ be uniform on the } x's \text{ that satisfy } \{y \in [n] : \text{nmE}(x, y) = \sigma\} > (0.5 + \varepsilon) \cdot n \text{ for either } \sigma = 0 \text{ or } \sigma = 1, \text{ and } Y \text{ be uniform on } \{0, 1\}^n\). \text{ Next, consider the residual } (k, \varepsilon)\text{-extractor } \text{nmE}_1 : [n_1] \times [n_1] \rightarrow \{0, 1\}, \text{ where } n_1 \geq n - 2^{k+1}, \text{ obtained by omitting the exceptional } x's. \text{ Note that } \text{nmE}_1 \text{ satisfies the first quasi-orthogonality condition with respect to the first argument with error } \varepsilon. \text{ Doing the same for the second argument yields a residual } (k, \varepsilon)\text{-extractor } \text{nmE}_2 : [n_2] \times [n_2] \rightarrow \{0, 1\}, \text{ where } n_2 \geq n_1 - 2^{k+1} \text{ and } \text{nmE}_2 \text{ satisfies the first quasi-orthogonality condition (for both arguments) with error } \varepsilon + \frac{2^{k+1}}{n_1}. \text{ Likewise, we claim that there are at most } 2^k \text{ disjoint pairs } \{x, x'\}'s \text{ that violate the second condition (i.e., } \{y \in [n_2] : \text{nmE}_2(x, y) \neq \text{nmE}_2(x', y)\} > (0.5 - \varepsilon) \cdot n_2, \text{ because otherwise we obtain a contradiction to the hypothesis that } \text{nmE}_2 \text{ is a non-malleable two-source } (k, \varepsilon)\text{-extractor (by using a function that maps each such } x \text{ to its matched } x'. \text{ And, again, we consider a residual extractor obtained by omitting the exceptional pairs. Doing the same for the } y's, \text{ we obtained the desired extractor.}}\]

Recall that non-malleable two-source extractors with much stronger parameters than we need (i.e., min-entropy \( \ell - \ell^{R(1)} \), negligible error, and \( \ell^{R(1)} \) bits of output), were constructed in [7, Thm. 1], but these extractors are not quasi-orthogonal. Employing Proposition 8.2, we obtain a quasi-orthogonal non-malleable two-source \((\ell - 4, 0.1)\)-extractor that can be used in the construction of Theorem 8.3. Essentially, the construction consists of a bipartite graph, with \( 2^\ell \) vertices on each side, such that the edges between the two sides are determined by the extractor. In addition, we add a clique on one of the two sides so that the two sides are (robustly) distinguishable (see Figure 1). We stress that the resulting \( 2^{k+1} \)-vertex graph is \( \Omega(2^k) \)-robustly self-ordered as long as the non-malleable extractor is quasi-orthogonal and works for very mild parameters; that is, we only require error that is bounded away from 1/2 with respect to min-entropy \( \ell - O(1) \).
Figure 1 Illustrating the construction of Theorem 8.3.

Theorem 8.3 (using a quasi-orthogonal non-malleable two-source extractor to obtain a $\Omega(2^\ell)$-robustly self-ordered $O(2^\ell)$-vertex graph). For a constant $\epsilon \in (0,0.5)$ varying $\ell \geq k$ such that $k \leq \ell - 2 + \log_2(0.5 - \epsilon) = \ell - O(1)$, suppose that $\text{nmE} : [2^\ell] \times [2^\ell] \rightarrow \{0,1\}$ is a quasi-orthogonal (with error $\epsilon$) non-malleable two-source $(k,\epsilon)$-extractor. Then, the $2^{\ell+1}$-vertex graph $G = (V_1 \cup V_0, E)$ such that $V_\sigma = \{\langle \sigma,i \rangle : i \in [2^\ell]\}$ and

$$E = \{\{1,i\}, (0,j) : \text{nmE}(i,j) = 1\} \cup \binom{V_1}{2}$$

is $\Omega(|V_1 \cup V_0|)$-robustly self-ordered. Furthermore, the claim holds even if the non-malleability condition (i.e., (18)) holds only for permutations $f$ and $g$.

Indeed, the first set of edges, denoted $E'$, corresponds to a bipartite graph between $V_1$ and $V_0$ that is determined by $\text{nmE}$, and the second set corresponds to a $2^\ell$-vertex clique. Note that the extraction parameters are extremely weak; that is, the min-entropy may be very high (i.e., $k = \ell - O(1)$), the error may be an arbitrary non-trivial constant (i.e., $\epsilon < 1/2$), and we only extract one bit (i.e., $m = 1$).

Proof. Let $V = V_1 \cup V_0$, and consider an arbitrary (non-trivial) permutation $\mu : V \rightarrow V$. Intuitively, if $\mu$ maps a vertex of $V_1$ to $V_0$, then the difference in degrees of vertices in the two sets (caused by the clique edges) contributes at least $((2^\ell - 1) - 2\epsilon \cdot 2^\ell)/2$ units to the symmetric difference between $G$ and $\mu(G)$, where here we use the first quasi-orthogonality condition. On the other hand, if $\mu$ maps $\langle 1,i \rangle \in V_1$ to $V_1 \setminus \{\langle 1,i \rangle\}$, then the difference in the neighborhoods caused by the bipartite graph contributes at least $(0.5 - \epsilon) \cdot 2^\ell/2$ units to the symmetric difference between $G$ and $\mu(G)$. To prove this, we distinguish between the case that $\mu$ has relatively few non-fixed-points (in either $V_0$ or $V_1$), which is analyzed using the second quasi-orthogonality condition, and the case that $\mu$ has relatively many non-fixed-points (in both $V_0$ and $V_1$), which is analyzed using the non-malleability condition. Details follow.

Let $T = \{v \in V : \mu(v) \neq v\}$ denote the set of non-fixed-points of $\mu$. Then, we consider two types of vertices: Those that belong to the set $T' = \bigcup_{\sigma \in \{0,1\}} \{v \in V_\sigma : \mu(v) \notin V_\sigma\} \subseteq T$ and those that belong to $T \setminus T'$. The threshold for distinguishing these cases is set to $K = (0.5 - \epsilon) \cdot 2^{\ell-2} = \Omega(|V|)$.
Case 1: $|T'| \geq K$.
(This refers to the case that many vertices are mapped by $\mu$ to the opposite side of the bipartite graph $(V, E')$, where “many” means $\Omega(|V'|).$)
Each vertex in $T'$ contributes $(1 - 2\epsilon) \cdot 2^\ell - 1$ units to the symmetric difference between $G$ and $\mu(G)$, because the degree of each vertex in $V_1$ is at least $(2^\ell - 1) + (0.5 - \epsilon) \cdot 2^\ell$, whereas the degree of each vertex in $V_0$ is at most $(0.5 + \epsilon) \cdot 2^\ell$, where we use the first quasi-orthogonality condition, which implies that the number of bipartite edges incident at each vertex is at least $(0.5 - \epsilon) \cdot 2^\ell$ and at most $(0.5 + \epsilon) \cdot 2^\ell$.
Hence, the symmetric difference between $G$ and $\mu(G)$ is at least $(1 - 2\epsilon) \cdot 2^\ell - 1 \cdot |T'| = \Omega(|V|) \cdot |T'|$, since $2^\ell = \Omega(|V|)$. Using the case’s hypothesis, we have $|T'| = \Omega(|V|) = \Omega(|T|)$, which means that in this case the difference between $G$ and $\mu(G)$ is $\Omega(|V|) \cdot |T|$. We stress that the difference between $G$ and $\mu(G)$ is at least $\Omega(|V|) \cdot |T'|$ also if the case hypothesis does not hold.

Case 2: $|T'| < K$.
(This refers to the case that few vertices are mapped by $\mu$ to the opposite side of the bipartite graph $(V, E')$, where “few” means less than $K \leq |V|/20$ (assuming $\epsilon \leq 0.1.$)
For every $\sigma \in \{0, 1\}$, let $V'_\sigma = V_\sigma \cap \mu(V_\sigma)$ and $T_\sigma = V'_\sigma \cap T$. Indeed, $(T', T_0, T_1)$ is a three-way partition of $T$. Note that the size of the symmetric difference between $G$ and $\mu(G)$ is lower-bounded by
\begin{equation}
|\{(v, u) \in V'_1 \times V'_0 : \text{nmE}(\mu(v), \mu(u)) \neq \text{nmE}(v, u)\}|, \tag{20}
\end{equation}
since, for any $(v, u) \in V'_1 \times V'_0$, it holds that $\mu(v)$ neighbors $\mu(u)$ in $G$ if and only if $\text{nmE}(\mu(v), \mu(u)) = 1$, whereas $\mu(v)$ neighbors $\mu(u)$ in $\mu(G)$ if and only if $v$ neighbors $u$ in $G$ which holds if and only if $\text{nmE}(v, u) = 1$.
We consider two sub-cases according to whether or not $\min(|T_0|, |T_1|)$ is relatively large. The threshold for distinguishing these sub-cases is also set to $K = (0.5 - \epsilon) \cdot 2^{\ell - 2}$; note that $K = \Omega(|V|)$ and $K \geq 2^k$.

Case 2.1: $\min(|T_0|, |T_1|) < K$.
In this case we shall use the (second condition of) quasi-orthogonality of $\text{nmE}$.
Suppose, without loss of generality, that $|T_0| \leq |T_1|$, which implies $|T_0| < K$. Then, the contribution of each vertex $v \in T_1$ to (20) equals
\begin{align*}
|\{u \in V'_0 : \text{nmE}(\mu(v), \mu(u)) \neq \text{nmE}(v, u)\}| \\
&\geq |\{u \in V'_0 : \text{nmE}(\mu(v), u) \neq \text{nmE}(v, u)\}| - |T_0| \\
&\geq |\{u \in V'_0 : \text{nmE}(\mu(v), u) \neq \text{nmE}(v, u)\}| - |T'| - |T_0| \\
&\geq (0.5 - \epsilon) \cdot 2^\ell - 2 \cdot K \\
&= (0.5 - \epsilon) \cdot 2^{\ell - 1}
\end{align*}
where the first inequality uses $\mu(u) = u$ for $u \in V'_0 \setminus T_0$, the second inequality uses $|V'_0| \geq |V_0| - |T'|$, the third inequality uses $\mu(v) \neq v$ along with the (second condition of) quasi-orthogonality of $\text{nmE}$ (and the hypotheses regarding $|T'|$ and $|T_0|$), and the equality is due to $K = (0.5 - \epsilon) \cdot 2^{\ell - 2}$.
Hence, in this case, the total contribution to (20) is $(0.5 - \epsilon) \cdot 2^{\ell - 1} \cdot |T_1|$, which is $\Omega(|V|) \cdot (|T| - |T'|)$, since $|T_1| \geq (|T| - |T'|)/2$.

Case 2.2: $\min(|T_0|, |T_1|) \geq K$.
In this case we shall use the non-malleable feature of $\text{nmE}$.
Specifically, for each $\sigma \in \{0, 1\}$, let $\mu_\sigma$ denote the restriction of $\mu$ to $T_\sigma$. Essentially, using $K \geq 2^k$, the non-malleability condition of the $(k, \epsilon)$-extractor $\text{nmE}$ implies
\begin{equation}
|\{(i, j) \in T_0 \times T_1 : \text{nmE}(\mu(i), \mu_1(j)) \neq \text{nmE}(\mu_0(i), \mu_1(j))\}| \geq (0.5 - \epsilon) \cdot |T_0| \cdot |T_1|.
\end{equation}
This can be seen by letting $X$ and $Y$ be uniform over $T_0$ and $T_1$, respectively, and combining the fact that $\Pr[\text{nmE}(\mu_0(X), \mu_1(Y)) \neq U_1] = 0.5$ with the non-malleability condition (while noting that $\mu_0 : T_0 \rightarrow \mu(T_0)$ and $\mu_1 : T_1 \rightarrow \mu(T_1)$ have no fixed-points).\(^{39}\)

Hence, in this case, the total contribution to (20) is $(0.5 - \epsilon) \cdot |T_0| \cdot |T_1| = \Omega(|V|) \cdot ((|T| - |T'|))$, where we use $\min(|T_0|, |T_1|) = \Omega(|V|)$.

Hence, in both sub-cases, the difference between $G$ and $\mu(G)$ is $\Omega(|V|) \cdot (|T| - |T'|)$. Recall that (by the last comment at Case 1) the difference between $G$ and $\mu(G)$ is $\Omega(|V|) \cdot |T'|$. Combining this lower-bound with the conclusion of Case 2, the difference between $G$ and $\mu(G)$ is $\Omega(|V|) \cdot |T|$.

**Digest**

Note that the quasi-orthogonality of $\text{nmE}$ was used in Cases 1 and 2.1, whereas the non-malleability of $\text{nmE}$ (w.r.t derangements) was used in Case 2.2. In particular, Case 1 only uses the first condition of quasi-orthogonality, and does so in order to infer that the degrees of all vertices in the bipartite graph are approximately equal. In Case 2.1 the second quasi-orthogonality condition is used in order to assert that the neighborhoods of two different vertices in $V_{1 - \sigma}$ is relatively small. When the number of non-fixed-points is large but no vertex is mapped to the other side (i.e., $T' = \emptyset$), we only use Case 2.2, which does not refer to quasi-orthogonality at all. Hence, we have the following –

**Remark 8.4 (a special case of Theorem 8.3).** For bipartite graphs $G = (V, E)$ such that $V = V_0 \cup V_1$ and $E \subseteq V_0 \times V_1$, we consider the special case of robust self-ordering that refers only to permutations $\mu : V \rightarrow V$ that are derangements that preserve the bipartition of $V$ (i.e., $\mu$ has no fixed-points and $\mu(V_0) = V_0$).\(^{40}\) In this case, assuming (only) that $\text{nmE}$ is a non-malleable two-source $(\ell, \epsilon)$-extractor (i.e., the case of $k = \ell$), implies that, for any such $\mu$, the size of the symmetric difference between $G$ and $\mu(G)$ is $(0.5 + \epsilon) \cdot |V_0| \cdot |V_1|$. In particular, the quasi-orthogonality condition is not necessary, the proof of Theorem 8.3 simplifies, since $T' = \emptyset$ and $T_\sigma = V_\sigma = V_\sigma'$ hold, and the size of the symmetric difference between $G$ and $\mu(G)$ equal the quantity in (20).

Interestingly, the special case of Theorem 8.3 asserted in Remark 8.4 can be reversed in the sense that a bipartite graph that is robustly self-ordered in the foregoing restricted sense is actually a non-malleable two-source $(\ell, 0.5 - \Omega(1))$-extractor.

**Proposition 8.5 (a reversal of the special case of Theorem 8.3 (i.e., of Remark 8.4)).** Let $G = (V_0 \cup V_1, E)$ be a bipartite graph such that $|V_0| = |V_1|$ and $E \subseteq V_0 \times V_1$. Let $V = V_0 \cup V_1$, and suppose that for every derangement $\mu : V \rightarrow V$ such that $\mu(V_0) = V_0$ it holds that the size of the symmetric difference between $G$ and $\mu(G)$ is $(0.5 \pm \epsilon) \cdot |V_0| \cdot |V_1|$. Then, $F : V_0 \times V_1 \rightarrow \{0, 1\}$ such that $F(x, y) = 1$ if and only if $\{x, y\} \in E$ is a non-malleable two-source $(\ell, \epsilon + \sqrt{2\epsilon} + o(1))$-extractor.

Needless to say, the claim holds also if $G$ is augmented by complete graph on the vertex-set $V_1$. Note that we lose a $\sqrt{2\epsilon} + o(1)$ term in the reversal.

---

\(^{39}\)Formally, we should extend $\mu_0$ and $\mu_1$ to (arbitrary) derangements $f$ and $g$, respectively. (Note that we may assume, w.l.o.g., that $|T_\sigma \cup \mu(T_\sigma)| \leq |V_\sigma| - 2$.) Lastly, note that (18) implies that $\Pr[\text{nmE}(X, Y) \neq \text{nmE}(f(X), g(Y))] \geq \Pr(\mu_1 \neq \text{nmE}(f(X), g(Y))) - \epsilon = 0.5 - \epsilon$.

\(^{40}\)That is, the requirement regarding the symmetric difference between $G$ and $\mu(G)$ is made only for permutations $\mu$ that have no fixed-points and satisfy $\mu(V_0) = V_0$. 

Proof. Let \((f,g)\) and \((X,Y)\) be as in Definition 8.1, and note that in this case \(X\) and \(Y\) are independent distributions that are each uniformly distributed on \([2^2]\). Define \(\mu : V \to V\) such that \(\mu(z) = f(z)\) if \(z \in V_0\) and \(\mu(z) = g(z)\) otherwise, and note that \(\mu\) is a derangement that preserves the partition of \(V\). Recall that \((\mu(x), \mu(y))\) contributes to the symmetric difference between \(G\) and \(\mu(G)\) if and only if \(F(\mu(x), \mu(y)) \neq F(x, y)\), since \(\mu(x)\) is connected to \(\mu(y)\) in \(\mu(G)\) if and only if \(x\) is connected to \(y\) in \(G\). Hence, by the hypothesis, we have

\[
\Pr[F(X, Y) \neq F(\mu(X), \mu(Y))] = 0.5 \pm \epsilon. \tag{21}
\]

Letting \(p_{\sigma, \tau}^\mu \overset{\text{def}}{=} \Pr[(F(X, Y), F(\mu(X), \mu(Y))) = (\sigma, \tau)]\), we have \(p_{0, 1}^\mu + p_{1, 0}^\mu = 0.5 \pm \epsilon\), and using the fact that \((X, Y)\) and \((\mu(X), \mu(Y))\) are identically distributed we have \(p_{1, 0}^\mu = p_{0, 1}^\mu\) (since \(p_{1, 1}^\mu + p_{0, 0}^\mu = p_{0, 1}^\mu + p_{0, 0}^\mu\)). Hence, \(p_{0, 1}^\mu = 0.25 \pm 0.5\epsilon\). Lastly, we show that \(p_{1, 1}^\mu + p_{0, 0}^\mu = 0.5 \pm \sqrt{\epsilon/2} + o(1)\), and conclude that \(p_{1, 1}^\mu = 0.25 \pm (0.5\epsilon + \sqrt{\epsilon/2} + o(1))\); it follows that \(F\) is a non-malleable (two-source) \((\ell, \epsilon + \sqrt{\epsilon/2} + o(1))\)-extractor.

To show that \(p_{1, 1}^\mu + p_{0, 0}^\mu = 0.5 \pm \sqrt{\epsilon/2} + o(1)\), we first note that \(p \overset{\text{def}}{=} p_{1, 1}^\mu + p_{0, 0}^\mu = \Pr[F(X, Y) = 1]\) is actually oblivious of \(\mu\). Hence, by considering a random derangement \(\mu\) that preserves \(V_0\) (i.e., \(\mu(V_0) = V_0\)), we observe that, with overwhelmingly high probability (over the choice of \(\mu\)), it holds that \(\{(x, y) \in V_0 \times V_1 : F(x, y) \neq F(\mu(x), \mu(y))\}\) has size \((2p(1-p)\pm o(1))/|V_0|\cdot|V_1|\). Confronting this with (21), we infer that \(p = 0.5\pm(\sqrt{\epsilon/2}+o(1))\). 

Corollary

Combining Theorem 8.3 with the non-malleable two-source extractors of [7, Thm. 1], while using Proposition 8.2, we obtain an efficient construction of \(\Omega(n)\)-robustly self-ordered graphs (at least a strongly explicit (aka locally computable) one).

**Theorem 8.6** (constructing \(\Omega(n)\)-robustly self-ordered \(n\)-vertex graphs). There exist an algorithm that, on input \(n\), works in \(\text{poly}(n)\)-time and outputs an explicit description of an \(\Omega(n)\)-robustly self-ordered \(O(n)\)-vertex graph. Furthermore, each vertex in this graph has degree at least \(0.24 \cdot n\) and at most \(0.76 \cdot n\).

The degree bounds follow by observing that the vertices in the graph described in Theorem 8.3 have degree at least \((0.5 - \epsilon) \cdot n/2\) and at most \((1.5 + \epsilon) \cdot n/2\), whereas [7, Thm. 1] provides for \(\epsilon = o(1)\).

### 8.2 The second construction

Combining Theorem 8.3 with the non-malleable two-source extractors of [7, Thm. 1], while using Proposition 8.2, we obtained an efficient construction of \(\Omega(n)\)-robustly self-ordered \(n\)-vertex graphs (see Theorem 8.6). However, this construction is not locally computable (as postulated in Theorem 1.4), because the non-malleable two-source extractors of [7, Thm. 1] are not quasi-orthogonal and the transformation of Proposition 8.2 runs in time that is polynomial in the size of the resulting graph.

To avoid the foregoing transformation and prove Theorem 1.4, we employ a variant on the construction presented in Theorem 8.3. Rather than connecting two sets of vertices using a bipartite graph that corresponds to a *quasi-orthogonal* non-malleable two-source extractor, we connect three sets of vertices such that one pair of vertex-sets is connected by a (not necessarily quasi-orthogonal) non-malleable two-source extractor, whereas the other two pairs are connected by bipartite graphs that are merely quasi-orthogonal. In analogy to
the definition of a quasi-orthogonal (two-source) extractor, we say that a bipartite graph on the vertex-set \( X \cup Y \) is quasi-orthogonal (with error \( \epsilon \)) if the following two conditions hold regarding its adjacency predicate \( B : X \times Y \to \{0, 1\} \):

1. The degree of each vertex is approximately half the number of the vertices on the other side. For each \( x \in X \) (resp., \( y \in Y \)), it holds that \(|\{y \in Y : B(x, y) = 1\}| = (0.5 \pm \epsilon) \cdot |Y|\) (resp., \(|\{x \in X : B(x, y) = 1\}| = (0.5 \pm \epsilon) \cdot |X|\)).

2. Each pair of vertices on one side neighbors approximately a quarter of the vertices on the other side: For every \( x \neq x' \in X \), it holds that \(|\{y \in Y : B(x, y) \neq B(x', y)\}| = (0.5 \pm \epsilon) \cdot |Y|\).

Similarly, for \( y \neq y' \in Y \).

We note that the inner-product (mod 2) extractor \( [9] \), denoted \( E_2 : \{0, 1\}^\ell \times \{0, 1\}^\ell \to \{0, 1\} \), corresponds to a quasi-orthogonal bipartite graph for the case \( X = Y = \{0, 1\}^\ell \setminus \{0^\ell\} \). We will however need quasi-orthogonal bipartite graphs with different-sized sides, which can be obtained by a simple variant. Specifically, for the case of \( X = \{0, 1\}^\ell \setminus \{0^\ell\} \) and \( Y = \{0, 1\}^{\ell+2} \setminus \{0^\ell\} \), we use the function \( B(x, y) = E_2(G(x), y) \), where \( G : \{0, 1\}^\ell \to \{0, 1\}^{\ell+2} \) is a small-bias generator that satisfies \( G(x) \neq 0^{\ell+2} \) and \( G(x) \neq 0^{\ell+2} \) for every \( x \neq 0^\ell \) and \( x' \neq x \) (see Proposition 8.8, and note that \( G(a, b, c, d) = (a, b, c, d, E_2(a, b), E_2(c, d)) \) will do).

We stress that the foregoing construction is strongly explicit (i.e., locally computable).

We shall also assume that the (bipartite graph corresponding to the) non-malleable extractor \( \text{nmE} : [2^\ell - 1] \times [2^\ell - 1] \to \{0, 1\} \) has linear degrees in the sense that for every \( x \) it holds that \(|\{y \in [2^\ell - 1] : \text{nmE}(x, y) = 1\}| \geq \epsilon' \cdot 2^\ell \) for some constant \( \epsilon' > 0 \). This can be enforced by starting with an arbitrary non-malleable two-source \((k, \epsilon')\)-extractor (e.g., the one of [7, Thm. 1]) and resetting pairs in \( m = \epsilon' \cdot 2^\ell \) fixed perfect matchings to 1 (i.e., for each \((x, y)\) in one of these matching, we reset \( \text{nmE}(x, y) = 1 \)).

This increases the error of the extractor by an additive term of \( m/2^k = \epsilon' \cdot 2^\ell \), which we can afford (e.g., \( \epsilon' = 0.01 \) and \( k = \ell - 4 \), yields extraction error \( \epsilon < 0.2 \)). We stress that this transformation preserves polynomial-time computability of the extracting function.

Theorem 8.7 (using a non-malleable two-source extractor with linear degrees to obtain a \( \Omega(2^\ell) \)-robustly self-ordered \( O(2^\ell) \)-vertex graph).

For any constants \( \epsilon, \epsilon' \in (0, 0.5) \) and varying \( k \leq \ell - 4 \), where \( \ell \in \mathbb{N} \), suppose that \( \text{nmE} : [2^\ell - 1] \times [2^\ell - 1] \to \{0, 1\} \) is a non-malleable two-source \((k, \epsilon)\)-extractor such that for every \( x \) it holds that \(|\{y \in [2^\ell - 1] : \text{nmE}(x, y) = 1\}| \geq \epsilon' \cdot 2^\ell \).

Further suppose that \( B : [2^\ell - 1] \times [2^\ell - 1] \to \{0, 1\} \) is quasi-orthogonal with error \( 0.1 \cdot \epsilon' \).

Then, the \( (6 \cdot 2^\ell - 3) \)-vertex graph \( G = (V_0 \cup V_1 \cup V_2, E) \) such that \( V_0 = \{(\sigma, i) : i \in [2^\ell - 1]\} \), where \( \ell_0 = \ell_1 = \ell \) and \( \ell_2 = \ell + 2 \), and

\[
E = \{(1, i, (0, j)) : \text{nmE}(i, j) = 1\} \cup \{(\sigma, i, (2, j)) : B(i, j) = 1, \sigma \in \{0, 1\}\} \cup \frac{V_1}{2} \cup \frac{V_2}{2}
\]

is \( \Omega(|V|) \)-robustly self-ordered, where \( V = V_0 \cup V_1 \cup V_2 \). Furthermore, each vertex in this graph has degree at least \( 0.3 \cdot |V| \) and at most \( 0.9 \cdot |V| \).

Using the foregoing ingredients (including the non-malleable extractor of [7, Thm. 1]), Theorem 1.4 follows (see also Remark 8.9). Looking at (22), note that the first set of edges corresponds to a bipartite graph on \( V_1 \) and \( V_0 \) that is determined by \( \text{nmE} \), the second set corresponds the bipartite graphs between \( V_0 \) (for \( \sigma \in \{0, 1\}\)) and \( V_2 \) that are determined by \( B \), and the other two sets correspond to cliques on \( V_1 \) and on \( V_2 \). (See Figure 2.)

---

For example, we may use the matchings \( \{(z, z + i) : z \in [2^\ell - 1]\} \) for \( i \in [m] \), where addition is mod \( 2^\ell - 1 \).

In addition, starting from an extractor that is defined over \( \ell \)-bit strings, we may omit one of these strings (and obtain an extractor defined over \( [2^\ell - 1] \)).
Figure 2 Illustrating the construction of Theorem 8.7.

Proof. Recall that $V = V_0 \cup V_1 \cup V_2$, and consider an arbitrary (non-trivial) permutation $\mu : V \to V$. Intuitively, if $\mu$ maps a vertex of $V_0$ (or $V_1$) to $V_2$, then the difference in degrees of vertices in the two sets (caused by the $|V_2|$-clique edges) contributes $\Omega(|V|)$ units to the symmetric difference between $G$ and $\mu(G)$, where here we use the first quasi-orthogonality condition of $B$. A similar argument, which uses the $V_1$-clique edges and relies on the linear degrees of $nmE$, applies to a vertex of $V_\sigma$ mapped to $V_{\sigma-\sigma}$ for any $\sigma \in \{0, 1\}$. On the other hand, if for some $\sigma \in \{0, 1, 2\}$ the bijection $\mu$ maps $\langle \sigma, i \rangle \in V_\sigma$ to $V_\sigma \setminus \{\langle \sigma, i \rangle\}$, then the difference in the neighborhoods caused by one of the two relevant bipartite graphs contributes $\Omega(|V|)$ units to the symmetric difference between $G$ and $\mu(G)$. Here, we distinguishes between the case that $\mu$ has relatively few non-fixed-points in either $V_0$ or $V_1$, which is analyzed using the second quasi-orthogonality condition of $B$, and the case that $\mu$ has relatively many non-fixed-points in both $V_0$ and $V_1$, which is analyzed using the non-malleability condition of $nmE$. Indeed, the structure of the proof is similar to the one of Theorem 8.3, but the details are different in many aspects, and so we provide them below.

Let $T = \{v \in V : \mu(v) \neq v\}$ denote the set of non-fixed-points of $\mu$. Then, we consider two types of vertices: Those that belong to the set $T' = \bigcup_{\sigma \in \{0, 1, 2\}} \{v \in V_\sigma : \mu(v) \not\in V_\sigma\} \subseteq T$ and those that belong to $T \setminus T'$. The threshold for distinguishing these cases is set to $K = (0.5 - 0.1 \cdot \epsilon') \cdot |V_0|/4 = \Omega(|V|)$.$^{42}$ Recall that $\epsilon$ denotes the extraction error of $nmE$, whereas $\epsilon'$ is the fractional degree bound associated with its linear degrees feature, and $0.1 \cdot \epsilon'$ is the quasi-orthogonality error of $B$.

Case 1: $|T'| \geq K$.

(This refers to the case that many vertices are mapped by $\mu$ to a different part of the three-way partition $(V_0, V_1, V_2)$ of $V$, where “many” means $\Omega(|V|)$.)

Each vertex in $T'$ contributes $\Omega(|V|)$ units to the symmetric difference between $G$ and $\mu(G)$, because of the differences in the degrees of vertices in the three parts. Specifically:

$^{42}$The threshold is set depending on the quasi-orthogonality error of $B$. In the proof of Theorem 8.3, the threshold was set depending on the quasi-orthogonality error of $nmE$ (which equaled its extraction error).
Case 2:

We consider two sub-cases according to whether or not 

\[ |\{v \in V : \deg(v) \geq \epsilon \cdot |V|\}| \leq |\{v \in V : \deg(v) \leq \epsilon \cdot |V|\}|. \]

The threshold for distinguishing these sub-cases is also set to 

\[ \min(|T_0|, |T_1|) \leq K. \]

Vertices in \( V_2 \) have degree at least 

\[ (|V_2| - 1) + (0.5 - 0.1\epsilon') \cdot (|V_0| + |V_1|) > (5 - 0.2\epsilon') \cdot |V_0| - O(1), \]

where the first term is due to the clique edges and the second term is due to the bipartite graphs connecting \( V_2 \) to \( V_0 \) and \( V_1 \) (and relies on the first quasi-orthogonality condition of \( B \)).

Vertices in \( V_0 \) have degree at most 

\[ |V_1| + (0.5 + 0.1\epsilon') \cdot |V_2| < (3 + 0.4\epsilon') \cdot |V_0| + O(1), \]

where the first term is due to the edges (determined by \( \text{nmE} \)) connecting \( V_0 \) to \( V_1 \) and the second term is due to the bipartite graph connecting \( V_0 \) to \( V_2 \).

Vertices in \( V_1 \) have degree at least 

\[ (|V_1| - 1) + \epsilon' \cdot |V_0| + (0.5 - 0.1\epsilon') \cdot |V_2| > (3 + 0.6\epsilon') \cdot |V_0| - O(1) \]

and at most 

\[ (|V_1| - 1) + |V_0| + (0.5 + 0.1\epsilon') \cdot |V_2| < (4 + 0.4\epsilon') \cdot |V_0|. \]

In both cases, the first term is due to clique edges, the second term is due to the edges connecting \( V_1 \) to \( V_0 \) (as determined by \( \text{nmE} \)), and the third term is due to the edges connecting \( V_1 \) to \( V_2 \) (as determined by \( B \)). The crucial fact is that the linear degrees of \( \text{nmE} \) provides a non-trivial lower bound (of \( \epsilon' \cdot |V_0| \)) on the second term.

Hence, the difference in the degrees of vertices in the different parts is at least 

\[ 0.2\epsilon' \cdot |V_0| - O(1), \]

where the first term is due to the difference between the degrees of vertices in \( V_1 \) and the degrees of vertices in \( V_0 \).

It follows that the symmetric difference between \( G \) and \( \mu(G) \) is at least 

\[ (0.2\epsilon' \cdot |V_0| - O(1)) \cdot |T'| = \Omega(|V|) \cdot |T'|, \]

since, for any \( \sigma \in \{0, 1, 2\}, \) let \( V'_\sigma = V_\sigma \cap \mu(V_\sigma) \) and \( T_\sigma = V'_\sigma \cap T. \) Indeed, \( (T', T_0, T_1, T_2) \) is a four-way partition of \( T. \) Note that the size of the symmetric difference between \( G \) and \( \mu(G) \) is lower-bounded by

\[
|\{(v, u) \in V'_1 \times V'_2 : \text{nmE}(\mu(v), \mu(u)) \neq \text{nmE}(v, u)\}| \\
+ |\{(v, u) \in V'_1 \times V'_2 : B(\mu(v), \mu(u)) \neq B(v, u)\}| \\
+ |\{(v, u) \in V_0' \times V_2' : B(\mu(v), \mu(u)) \neq B(v, u)\}|,
\]

(23)

since, for any \( (v, u) \in V'_1 \times V'_2, \) it holds that \( \mu(v) \) neighbors \( \mu(u) \) in \( G \) if and only if \( \text{nmE}(\mu(v), \mu(u)) = 1 \), whereas \( \mu(v) \) neighbors \( \mu(u) \) in \( \mu(G) \) if and only if \( v \) neighbors \( u \) in \( G \) which holds if and only if \( \text{nmE}(v, u) = 1 \). Ditto for the other two cases.

We consider two sub-cases according to whether or not \( \min(|T_0|, |T_1|) \) is relatively large. The threshold for distinguishing these sub-cases is also set to 

\[ K = (0.5 - 0.1 \cdot \epsilon') \cdot |V_0|/4; \]

note that 

\[ K = \Omega(|V|) \]

and 

\[ K > 0.1 \cdot |V_0| > 2^{\epsilon'-4} \geq 2^k. \]

Case 2.1: \( \min(|T_0|, |T_1|) < K. \)

In this case we shall use the quasi-orthogonality of \( B. \)

Suppose, without loss of generality, that 

\[ |T_0| \leq |T_1|, \]

which implies 

\[ |T_0| < K. \]

Depending on the relative sizes of \( T_1 \) and \( T_2, \) we shall use either the quasi-orthogonal bipartite graph between \( V_1 \) and \( V_2 \) or the quasi-orthogonal bipartite graph between \( V_2 \) and \( V_0. \)
Formally, we should extend that we may assume, w.l.o.g., that \( \Pr[\min(\text{Case 2.1})] \geq |T_1| - |T_2| \). Hence, in both sub-cases, the difference between \( |V_0| \geq |V_0| - |T'| \) and the hypothesis \( |T_2| < |T_1| \), the third inequality uses \( \mu(v) \neq v \) along with the (second condition of) quasi-orthogonality of \( B \) and the hypotheses \( |T'| < K \) and the fact that \( |T_1| \leq |V_1| = |V_0| \), and the fourth inequality uses \( \epsilon' < 0.5 \) and \( |V_0| > 4 \cdot |V_0| \). So the total contribution in this sub-case is \( |T_1| \cdot \Omega(|V|) \geq (|T| - |T'|) \cdot \Omega(|V|) \), since \(|T_1| \geq \max(|T_0|,|T_2|) \) and \(|T_0| + |T_1| + |T_2| = |T| - |T'| \).

2. On the other hand, if \( |T_1| \leq |T_2| \), then we consider the quasi-orthogonal bipartite graph between \( V_2 \) and \( V_0 \). The contribution of each vertex \( v \in T_2 \) to (23) equals

\[
\begin{align*}
\Pr[\{u \in V_2 : B(\mu(v), \mu(u)) \neq B(v, u)\}] & \geq \Pr[\{u \in V_2 : B(\mu(v), u) \neq B(v, u)\}] - |T_2| \\geq \{(u \in V_2 : B(\mu(v), u) \neq B(v, u))\} - |T'| - |T_0| \\geq (0.5 - 0.1 \cdot \epsilon') \cdot |V_0| - 2 \cdot K \\geq 0.5 \cdot \epsilon' \cdot |V_0|/2
\end{align*}
\]

where the first inequality uses \( \mu(u) = u \) for \( u \in V_2 \), the second inequality uses \( |V_0| \geq |V_0| - |T'| \), and the hypothesis \( |T_2| < |T_1| \), the third inequality uses \( \mu(v) \neq v \) along with the (second condition of) quasi-orthogonality of \( B \) (and the hypotheses regarding \( |T'| \) and \(|T_0| \)), and the equality is due to \( K = (0.5 - 0.1 \cdot \epsilon') \cdot |V_0|/2 \). So the total contribution in this sub-case is \( |T_2| \cdot \Omega(|V|) \geq (|T| - |T'|) \cdot \Omega(|V|) \), since \(|T_2| \geq |T_1| \geq |T_0| \).

Hence, the total contribution (of Case 2.1) to (23) is \( \Omega(|V|) \cdot (|T| - |T'|) \).

**Case 2.2:** \( \min(|T_0|,|T_1|) \geq K \).

In this case we shall use the non-malleable feature of \( \text{nmE} \).

Specifically, for each \( \sigma \in \{0, 1\} \), let \( \mu_{\sigma} \) denote the restriction of \( \mu \) to \( T_{\sigma} \). Essentially, using \( K \geq 2^K \), the non-malleability condition of the \((k, \epsilon)\)-extractor \( \text{nmE} \) implies

\[
|\{(i, j) \in T_0 \times T_1 : \text{nmE}(i, j) \neq \text{nmE}(\mu_0(i), \mu_1(j))\}| \geq (0.5 - \epsilon) \cdot |T_0| \cdot |T_1|.
\]

This can be seen by letting \( X \) and \( Y \) be uniform over \( T_0 \) and \( T_1 \), respectively, and combining the fact that \( \Pr[\text{nmE}(\mu_0(X), \mu_1(Y)) \neq U_1] = 0.5 \) with the non-malleability condition (while noting that \( \mu_0 : T_0 \rightarrow \mu(T_0) \) and \( \mu_1 : T_1 \rightarrow \mu(T_1) \) have no fixed-points).\(^{43}\)

Hence, in this case, the total contribution to (23) is \((0.5 - \epsilon) \cdot |T_0| \cdot |T_1| = \Omega(|V|^2)\), where we use \( \min(|T_0|,|T_1|) = \Omega(|V|) \).

Hence, in both sub-cases, the difference between \( G \) and \( \mu(G) \) is \( \Omega(|V|) \cdot (|T| - |T'|) \).

\(^{43}\) Formally, we should extend \( \mu_0 \) and \( \mu_1 \) to (arbitrary) derangements \( f \) and \( g \), respectively. (Note that we may assume, w.l.o.g., that \( |T_2| \cup \mu(T_2) \leq |V_0| - 2 \).) Lastly, note that (18) implies that

\[
\Pr[\text{nmE}(X, Y) \neq \text{nmE}(f(X), g(Y))] \geq \Pr[U_1 \neq \text{nmE}(f(X), g(Y))] - \epsilon = 0.5 - \epsilon.
\]
Recall that (by the last comment at Case 1) the difference between $G$ and $\mu(G)$ is $\Omega(|V|) \cdot |T|$. Combining this lower-bound with the conclusion of Case 2, the difference between $G$ and $\mu(G)$ is $\Omega(|V|) \cdot |T|$. As for the degree bounds, note that each vertex has degree at most $(|V_2| - 1) + (0.5 - 0.1\epsilon') \cdot (|V_0| + |V_1|) = (5 + 0.2\epsilon') \cdot |V_0| + O(1)$, and at least $(0.5 - 0.1\epsilon') \cdot |V_2| < (2 - 0.4\epsilon') \cdot |V_0| - O(1)$, where maximum (resp., minimum) is obtained by vertices in $V_2$ (resp., $V_0$).

**Digest**

Compared to the construction used in Theorem 8.3, the construction in Theorem 8.7 decouples the non-malleable feature from the quasi-orthogonality feature, using non-malleable extractors for connecting one pair of vertex-sets and quasi-orthogonal functions to connect the other two pairs. The current analysis is slightly more complex because it has to handle the fact that these features hold for different pairs. Specifically, the quasi-orthogonality of $B$ is used in Cases 1 and 2.1, whereas the non-malleability of $\mE$ is used in Case 2.2. In particular, Case 1 only uses the first condition of quasi-orthogonality, and does so in order to infer that the degrees of all vertices in the bipartite graph determined by $B$ are approximately equal. In Case 2.1 the second quasi-orthogonality condition is used in order to assert that the neighborhoods of two different vertices in $V_\epsilon$ (for every $\sigma \in \{0, 1, 2\}$) are significantly different. This is useful only when the number of non-fixed-points in the other side of the graph $B$ is relatively small.

In light of the key role that quasi-orthogonal unbalanced bipartite graphs play in Theorem 8.7 and given their natural appeal, it feel adequate to provide a general construction of these graphs, which generalizes the construction outlined before Theorem 8.7 (for the case of $\ell' = \ell + 2$).

> **Proposition 8.8** (quasi-orthogonal unbalanced bipartite graphs). For $S_N \triangleq \{0, 1\}^N \setminus \{0^N\}$ let $G : S_N \rightarrow S_{\ell'}$ be small-bias generator with bias $\epsilon$ such that $G(s) \neq G(s')$ for every $s \neq s'$, and let $E_\ell$ denote the inner-product mod 2 function. Then, the bipartite graph described by the adjacency predicate $B : S_N \times S_{\ell'} \rightarrow \{0, 1\}$ such that $B(x, y) = E_\ell(G(x), y)$ is quasi-orthogonal with error $\epsilon$.

(Note that the hypothesis implies $\epsilon > 1/|S_{\ell'}|$. The definition of quasi-orthogonal bipartite graphs appears before Theorem 8.7.)

**Proof Sketch.** Our starting point is the fact that $E_\ell : S_N \times S_{\ell'} \rightarrow \{0, 1\}$ is quasi-orthogonal with error $1/|S_{\ell'}|$. The quasi-orthogonality feature of the first argument of $B$ follows as a special case of the corresponding feature of $E_\ell$. Turning to fixings of the second argument of $E_\ell$ and letting $X$ be uniform over $S_N$, we observe that, for every $y \in S_{\ell'}$, the bit $B(G(X), y)$ is a linear combination of the bits of $G(X)$, and hence $\Pr[B(G(X), y) = 1] = 0.5 \pm \epsilon$. Similarly, for $y \neq y'$, it holds that $B(G(X), y) \oplus B(G(X), y') = B(G(X), y \oplus y')$ is linear combination of the bits of $G(X)$.

> **Remark 8.9** (obtaining $\Omega(n)$-robustly self-ordered $n$-vertex graphs, for every $n$). Theorem 8.7 provides a construction of $\Omega(n)$-robustly self-ordered $n$-vertex graphs, for every $n$ of the form $6 \cdot 2^\ell - 3$, where $\ell \in \mathbb{N}$. A construction for every $n \in \mathbb{N}$ can be obtained by using a few minor modifications.

- Rather than using $|V_2| = 2^{\ell^2} - 1 = 4 \cdot (|V_0| + 1) - 3$, we may use $|V_2| = n - 2 \cdot |V_0|$ such that $|V_0| = \Omega(n)$. Specifically, we still use $|V_0| = 2^\ell - 1$, for $\ell = \log_2 n - \Theta(1)$, along with $|V_2| \in [4 \cdot |V_0|, 10 \cdot |V_0|]$. Doing so requires decreasing the quasi-orthogonality error of $B$ to $0.04\epsilon'$ so that $0.04\epsilon' \cdot |V_2| \leq 0.4 \cdot |V_0|$ still holds.
More importantly, we need a construction of a quasi-orthogonal bipartite graph with an adjacency predicate $B: [2^t - 1] \times [n'] \to \{0, 1\}$ such that $n' = n - 2 \cdot (2^t - 1) \geq 2n/3$. The solution is to associated $[n']$ with an easily enumerable small-bias space $S \subseteq \{0, 1\}^{t+4} \setminus \{0^{t+4}\}$ and use $B(x, y) = E_\phi(G(x), y)$, where $E_\phi$ and $G$ are as in Proposition 8.8. Specifically, for $t = \log_2 \log_2 \ell$ and $D = [n' \cdot 2^t / 2^{t+4}]$, we let $S$ contain the $n'$ lexicographically first strings in $S' \times \{0, 1\}^{t+4-t}$, where $S'$ is a small-bias sample space of size $D$ over $\{0, 1\}^{t}$ that is found by exhaustive search.\footnote{Note that for every $z = (z', z'') \in \{0, 1\}^{t+4} \setminus \{0^{t+4}\}$ and $Y = (Y', Y'')$ that is uniformly distributed over $S$ such that $|z'| = |Y'| = t$ it holds that 

$$E[(-1)^{E_\phi(z, Y)}] = E[(-1)^{E_\phi(z', Y')} \cdot E[(-1)^{E_\phi(z'', Y'')}]]$$

where the absolute value of each of the factors is $o(1)$ if the corresponding fixed string (i.e., $z'$ or $z''$) is non-zero. Specifically, note that $Y'$ (resp., $Y''$) is $o(1)$-close to being uniformly distributed over $S'$ (resp., $\{0, 1\}^{t+4-t}$).

}\footnote{Note that for every $z = (z', z'') \in \{0, 1\}^{t+4} \setminus \{0^{t+4}\}$ and $Y = (Y', Y'')$ that is uniformly distributed over $S$ such that $|z'| = |Y'| = t$ it holds that 

$$E[(-1)^{E_\phi(z, Y)}] = E[(-1)^{E_\phi(z', Y')} \cdot E[(-1)^{E_\phi(z'', Y'')}]]$$

where the absolute value of each of the factors is $o(1)$ if the corresponding fixed string (i.e., $z'$ or $z''$) is non-zero. Specifically, note that $Y'$ (resp., $Y''$) is $o(1)$-close to being uniformly distributed over $S'$ (resp., $\{0, 1\}^{t+4-t}$).}

### 8.3 Obtaining efficient self-ordering

We say that a self-ordered graph $G = ([n], E)$ is efficiently self-ordered if there exists a polynomial-time algorithm that, given any graph $G' = (V', E')$ that is isomorphic to $G$, finds the unique bijection $\phi: V' \to [n]$ such that $\phi(G') = G$ (i.e., the unique isomorphism of $G'$ and $G$). Indeed, this isomorphism orders the vertices of $G'$ in accordance with the original (or target) graph $G$.

Recall that in the case of bounded-degree graphs, we relied on the existence of a polynomial-time isomorphism test (see \cite{29}) for efficiently self-ordering the robustly self-ordered graphs that we constructed. We cannot do so in the dense graph case, since a general polynomial-time isomorphism test is not known (see \cite{1}). Instead, we augment the construction asserted in Theorem 1.4 so to obtain dense $\Omega(n)$-robustly self-ordered graphs that are efficiently self-ordered.\footnote{Unlike in the bounded degree case (see Section 4.4), we do not know how to construct $\Omega(n)$-robustly self-ordered graphs with information-theoretically local self-ordering do exist [22].}

\begin{thm}[strengthening Theorem 1.4] \label{thm:8.10}
There exist an infinite family of dense $\Omega(n)$-robustly self-ordered graphs $\{G_n\}_{n \in \mathbb{N}}$ and a polynomial-time algorithm that, given $n \in \mathbb{N}$ and a pair of vertices $u, v \in [n]$ in the $n$-vertex graph $G_n$, determines whether or not $u$ is adjacent to $v$ in $G_n$. Furthermore, these graphs are efficiently self-ordered, and the degrees of vertices in $G_n$ reside in $[0.06n, 0.73n]$.
\end{thm}

**Proof.** Our starting point is the construction of $m$-vertex graphs that are $\Omega(m)$-robustly self-ordered (see Theorem 1.4, which uses Theorem 8.7). Recall that the vertices in these graphs have degree that ranges between $\Omega(n)$ and $\Omega(n)$ (see \cite{29}). The idea is to use two such graphs, $G_1$ and $G_2$, one with $m$ vertices and the other with $4 \cdot m$ vertices, where $m = n/5$, and connect them in a way that assists finding the ordering of vertices in each of these two graphs. Specifically, we designate a set, denoted $S_1$, of $s \defeq 2 \sqrt{\log_2 n}$ vertices in $G_1 = ([m], E_1)$, and a set, denoted $S_2$, of $\ell \defeq \binom{m}{2} \in [\log_2 n, 2 \log_2 n]$ vertices in $G_2 = ([m + 1, \ldots, 5m], E_2)$, and use them as follows:

- Connect each vertex in $S_2$ to two different vertices in $S_1$, while noting that each vertex in $S_1$ is connected to $2\ell/s = o(\ell)$ vertices of $S_2$.
- Connect each vertex in $R_1 \defeq [m] \setminus S_1$ to a different set of neighbors in $S_2$ such that each vertex in $R_1$ has at least $\ell/2$ neighbors in $S_2$. 

Connect each vertex in $R_2 \overset{\text{def}}{=} \{m + 1, \ldots, 5m\} \setminus S_2$ to a different set of neighbors in $R_1$ such that each vertex in $R_2$ has two neighbors in $R_1$ and each vertex in $R_1$ has at most eight neighbors in $R_2$.

(See Figure 3.) Denote the resulting graph by $G = ([n], E)$, and note that the vertices of $G_1$ have degree at most $0.9 \cdot m + \ell$, whereas the vertices of $G_2$ have degree at least $0.3 \cdot 4m$.

Given an isomorphic copy of the $G$, we can find the unique isomorphism (i.e., its ordering) as follows:

1. Identify the vertices that belong to $G_1$ by virtue of their lower degree.
2. Identify the set $S_1$ as the set of vertices that belong to $G_1$ and have $2\ell/s = o(\ell)$ neighbors in $G_2$.
   (Recall that each vertex in $R_1$ has at least $\ell/2$ neighbors in $S_2$.)
3. Identify the set $S_2$ as the set of vertices that belong to $G_2$ and have (two) neighbors in $S_1$.
4. For each possible ordering of $S_1$, order the vertices of $S_2$ by their neighborhood in $S_1$, and order the vertices of $R_1$ according to their neighborhood in $S_2$.
   If the resulting ordering (of $S_1 \cup R_1$) yields an isomorphism to $G_1$, then continue. Otherwise, try the next ordering of $S_1$.
5. Order the vertices of $R_2$ according to their neighborhood in $R_1$.

Note that by the asymmetry of $G_1$, there exists a unique ordering of its vertices, and a unique ordering of $S_1$ that fits it and leads the procedure to successful termination. One the other hand, the number of possible ordering of $S_1$ is $s! = n^{o(1)}$, which means that the procedure is efficient.

It is left to show that the graph $G$ is $\Omega(n)$-robustly self-ordered. Let $\gamma \in (0, 1]$ be a constant such that that $G_1$ (resp., $G_2$) is $\gamma \cdot m$-robustly self-ordered (resp., $\gamma \cdot 4m$-robustly self-ordered). Then, fixing an arbitrary permutation $\mu : [n] \to [n]$, and letting $T = \{v \in [n] : \mu(v) \neq v\}$, we consider the following cases.

**Case 1:** $|\{v \in [m] : \mu(v) \in [m]\}| > \gamma \cdot |T|/10$.

In this case, we get a contribution of at least $\Omega(m \cdot |T|)$ units to the symmetric difference between $G$ and $\mu(G)$, because of the difference in degree between vertices in $[m]$ and outside $[m]$. (Recall that the former have degree at most $0.9 \cdot m + \ell < m$, whereas the latter have degree at least $0.3 \cdot 4m = 1.2 \cdot m$.)

**Case 2:** $t \overset{\text{def}}{=} |\{v \in [m] : \mu(v) \in [m]\}| \leq \gamma \cdot |T|/10$.

In this case, at least $(1 - 0.1\gamma) \cdot |T|$ vertices in $T$ are mapped by $\mu$ to the side in which they belong (i.e., each of these vertices $v$ satisfies $v \in [m]$ if and only if $\mu(v) \in [m]$).

Let $T_1 \overset{\text{def}}{=} \{v \in T \cap [m] : \mu(v) \in [m]\}$ and $T_2 \overset{\text{def}}{=} \{v \in T \setminus [m] : \mu(v) \not\in [m]\}$. Then, the
vertices in $T_1$ contribute at least $|T_1| \cdot \gamma \cdot m - t \cdot m$ units to the symmetric difference between $G$ and $\mu(G)$, where the negative term is due to possible change in the incidence with vertices that did not maintain their side. Similarly, the vertices in $T_2$ contribute at least $|T_2| \cdot \gamma \cdot 4m - t \cdot 4m$ units to the symmetric difference. Hence, it total, we get a contribution of at least $(|T| - 2t) \cdot \gamma \cdot m - t \cdot 5m = \Omega(m \cdot |T|)$.

The claims follows.\(^{46}\)

**Digest**

The $n$-vertex graph constructed in the proof of Theorem 8.10 is proved to be $\Omega(n)$-robustly self-ordered by implicitly using the following claim.

\textit{\textbf{Claim 8.11 (combining two $\Omega(n)$-robustly self-ordered graphs).}} For $i \in \{1, 2\}$, let $G_i = (V_i, E_i)$ be an $\Omega(n)$-robustly self-ordered graph, and consider a graph $G = (V_1 \cup V_2, E_1 \cup E_2 \cup E)$ such that $E$ contain edges with a single vertex in each $V_i$; that is, $G$ consists of $G_1$ and $G_2$ and an arbitrary bipartite graph that connects them. If the maximum degree in $G$ of each vertex in $V_1$ is smaller by an $\Omega(n)$ term from the minimum degree of each vertex in $V_2$, then $G$ is $\Omega(n)$-robustly self-ordered.

Indeed, Claim 8.11 is analogous to Claim 4.3 (which refers to bounded-degree graphs). We also comment that $\Omega(n)$-robustly self-ordered graph maintain this feature also when $o(n)$ edges are added (and/or removed) from the incidence of each vertex.

## 9 Application to Testing Dense Graph Properties

In Section 5, we demonstrated the applicability of robustly self-ordered bounded-degree graphs to the study of testing graph properties in the bounded-degree graph model. In the current section, we provide a corresponding demonstration for the regime of dense graphs. Hence, we refer to testing graph properties in the dense graph model, which was introduced in [18] and is surveyed in [16, Chap. 8]. In this model, graphs are represented by their adjacency predicate, and distances are measured as the ratio of the number of differing incidences to the maximal number of edges.

**Background**

We represent a graph $G = ([n], E)$, by the adjacency predicate $g : [n] \times [n] \to \{0, 1\}$ such that $g(u, v) = 1$ if and only if $\{u, v\} \in E$, and oracle access to a graph means oracle access to its adjacency predicate (equiv., adjacency matrix). The distance between the graphs $G = ([n], E)$ and $G' = ([n], E')$ is defined as the fraction of entries (in the adjacency matrix) on which the two graphs disagree.

\textit{\textbf{Definition 9.1 (testing graph properties in the dense graph model).}} A tester for a graph property $\Pi$ is a probabilistic oracle machine that, on input parameters $n$ and $\epsilon$, and oracle access to an $n$-vertex graph $G = ([n], E)$ outputs a binary verdict that satisfies the following two conditions.

1. If $G \in \Pi$, then the tester accepts with probability at least $2/3$.
2. If $G$ is $\epsilon$-far from $\Pi$, then the tester accepts with probability at most $1/3$, where $G$ is $\epsilon$-far from $\Pi$ if for every $n$-vertex graph $G' = ([n], E') \in \Pi$ the adjacency matrices of $G$ and $G'$ disagree on at least $\epsilon \cdot n^2$ entries.

\(^{46}\)Note that the degree of each vertex in $G_1$ is at least $0.3m = 0.06n$, whereas the degree of each vertex in $G_2$ is at most $0.9 \cdot 4m + s < 0.75n$. 
The *query complexity* of a tester for \( \Pi \) is a function (of the parameters \( n \) and \( \ell \)) that represents the number of queries made by the tester on the worst-case \( n \)-vertex graph, when given the proximity parameter \( \ell \).

**Our result**

We present a general reduction of testing any property \( \Phi \) of (bit) strings to testing a corresponding graph property \( \Pi \). Loosely speaking, \( n \)-bit long strings will be encoded as part of an \( O(\sqrt{n}) \)-vertex graph, which is constructed using \( \Omega(\sqrt{n}) \)-robustly self-ordered \( \Theta(\sqrt{n}) \)-vertex graphs. This reduction is described in Construction 9.2 and its validity is proved in Lemma 9.3. Denoting the query complexities of \( \Phi \) and \( \Pi \) by \( Q_\Phi \) and \( Q_\Pi \), respectively, we get

\[
Q_\Phi(n, \ell) \leq Q_\Pi(O(n^{1/2}), \Omega(\ell)).
\]

Thus, lower bounds on the query complexity of testing \( \Phi \), which is a property of “ordered objects” (i.e., bit strings), imply lower bounds on the query complexity of testing \( \Pi \), which is a property of “unordered objects” (i.e., graphs).

Our starting point is the construction of \( m \)-vertex graphs that are \( \Omega(m) \)-robustly self-ordered. Actually, wishing to preserve the computational complexity of \( \Phi \), we use a construction of graphs that are efficiently self-ordered, as provided by Theorem 8.10. Recall that the vertices in these graphs have degree that ranges between \( 0.06 \cdot m \) and \( 0.73 \cdot m \).

The idea is to use two such graphs, \( G_1 \) and \( G_2 \), one with \( m \) vertices and the other with \( 49 \cdot m \) vertices, where \( m = \sqrt{n} \), and encode an \( n \)-bit string in the connection between them. Specifically, we view the latter string as a \( m \)-by-\( m \) matrix, denoted \( (s_{i,j})_{i,j \in [m]} \), and connect the \( i \)th vertex of \( G_1 \) to the \( j \)th vertex of \( G_2 \) if and only if \( s_{i,j} = 1 \).

**Construction 9.2** (from properties of strings to properties of dense graphs). Suppose that \( \{G_m = ([m], E_m)\}_{m \in \mathbb{N}} \) is a family of \( \Omega(n) \)-robustly self-ordered graphs. For every \( n \in \mathbb{N} \), we let \( m = \sqrt{n} \), and proceed as follows.

- For every \( s \in \{0,1\}^n \) views as \( (s_{i,j})_{i,j \in [m]} \in \{0,1\}^{m \times m} \), we define the graph \( G'_s = ([50m], E'_s) \) such that

  \[
  E'_s = E_m \cup \{\{m+i, m+j\} : i, j \in [50m] \} \cup \{\{i, m+j\} : i, j \in [m] \land s_{i,j} = 1\} \quad (24)
  \]

  That is, \( G'_s \) consists of a copy of \( G_m \) and a copy of \( G_{49m} \) that are connected by a bipartite graph that is determined by \( s \).

- For a set of strings \( \Phi \), we define \( \Pi = \bigcup_{n \in \mathbb{N}} \Pi_n \) as the set of all graphs that are isomorphic to some graph \( G'_s \) such that \( s \in \Phi \); that is,

  \[
  \Pi_n = \{\pi(G'_s) : s \in (\Phi \cap \{0,1\}^n) \land \pi \in \text{Sym}_{50m}\} \quad (25)
  \]

where \( \text{Sym}_{50m} \) denote the set of all permutations over \([50m]\).

Note that, given a graph of the form \( \pi(G'_s) \), the vertices of \( G_m \) are easily identifiable (as having degree at most \( 0.73m^2 + m < 1.8m \)). The foregoing construction yields a local reduction of \( \Phi \) to \( \Pi \), where locality means that each query to \( G'_s \) can be answered by making a constant number of queries to \( s \). The (standard) validity of the reduction (i.e., \( s \in \Phi \) if and only if \( G'_s \in \Pi \)) is based on the fact that \( G_m \) and \( G_{49m} \) are asymmetric.

In order to be useful towards proving lower bounds on the query complexity of testing \( \Pi \), we need to show that the foregoing reduction is “distance preserving” (i.e., strings that are far from \( \Phi \) are transformed into graphs that are far from \( \Pi \)). The hypothesis that \( G_m \) and \( G_{49m} \) are \( \Omega(m) \)-robustly self-ordered is pivotal to showing that if the string \( s \) is far from \( \Phi \), then the graph \( G'_s \) is far from \( \Pi \).

\[47\] In contrast, the vertices of \( G_{49m} \) have degree at least \( 0.06 \cdot 49m > 2.9m \).
Lemma 9.3 (preserving distances). If \( s \in \{0, 1\}^n \) is \( \epsilon \)-far from \( \Phi \), then the 50m-vertex graph \( G'_s \) (as defined in Construction 9.2) is \( \Omega(\epsilon) \)-far from \( \Pi \).

Proof. We prove the contraposition. Suppose that \( G'_s \) is \( \delta \)-close to \( \Pi \). Then, for some \( r \in \Phi \) and a permutation \( \pi : [50m] \to [50m] \), it holds that \( G'_s \) is \( \delta \)-close to \( \pi(G'_r) \), which means that these two graphs differ on at most \( \delta \cdot (50m)^2 \) vertex pairs. If \( \pi(i) = i \) for every \( i \in [2m] \), then \( s \) must be \( O(\delta) \)-close to \( r \), since \( s_{ij} = 1 \) (resp., \( r_{ij} = 1 \)) if and only if \( i \) is connected to \( m + j \) in \( G' \) (resp., in \( \pi(G'_r) = G'_r \)).\(^{48}\) Unfortunately, the foregoing condition (i.e., \( \pi(i) = i \) for every \( i \in [2m] \)) need not hold in general.

In general, the hypothesis that \( \pi(G'_r) \) is \( \delta \)-close to \( G'_s \) implies that \( \pi \) maps at most \( O(\delta m) \) vertices of \( [m] \) to \( \{m + 1, \ldots, 2m\} \), and maps to \( [m] \) at most \( O(\delta m) \) vertices that are outside it. This is the case because each vertex of \( [m] \) has degree smaller than \( 0.73m + m < 1.8m \), whereas the other vertices have degree at least \( 0.06 \cdot 49m > 2.9m \).

Turning to the vertices \( i \in [m] \) that \( \pi \) maps to \( [m] \setminus \{i\} \), we upper-bound their number by \( O(\delta m) \), since the difference between \( \pi(G'_r) \) and \( G'_s \) is at most \( \delta \cdot (50m)^2 \), whereas the hypothesis that \( G_m \) is \( c \cdot m \)-robustly self-ordered implies that the difference between \( \pi(G'_r) \) and \( G'_s \) (or any other graph \( G'_w \)) is at least

\[
\Delta = c \cdot m \cdot \left| \left\{ i \in [m] : \pi(i) \neq i \right\} \right| - m \cdot \left| \left\{ i \in [m] : \pi(i) \notin [n] \right\} \right|.
\]

(Hence, \( \left| \left\{ i \in [m] : \pi(i) \neq i \right\} \right| \leq \frac{\Delta + m \cdot O(\delta m)}{cm} = O(\delta m) \). The same considerations apply to the vertices \( i \in \{m + 1, \ldots, 2m\} \) that \( \pi \) maps to \( \{m + 1, \ldots, 2m\} \setminus \{i\} \); their number is also upper-bounded by \( O(\delta m) \).

For every \( k \in \{1, 2\} \), letting \( I_k = \{i \in [m] : \pi((k - 1) \cdot m + i) = (k - 1) \cdot m + i \} \), observe that \( D \stackrel{\text{def}}{=} \left| \left\{ (i, j) \in I_0 \times I_1 : r_{ij} \neq s_{ij} \right\} \right| \leq \delta \cdot (50m)^2 \), since \( r_{ij} \neq s_{ij} \) implies that \( \pi(G'_r) \) and \( G'_s \) differ on the vertex-pair \( (i, m + j) \). Recalling that \( m - |I_k| = O(\delta m) \), it follows that

\[
\left| \left\{ (i, j) \in [m] : r_{ij} \neq s_{ij} \right\} \right| \leq (m - |I_1|) - (m - |I_2|) \cdot m + D = O(\delta m^2).
\]

Hence, \( s \) is \( O(\delta) \)-close to \( r \), and the claims follows. \( \blacktriangleleft \)

## 10 The Case of Intermediate Degree Bounds

While Section 2–6 study bounded-degree graphs and Sections 7–9 study dense graphs (i.e., constant edge density), in this section we shall consider graphs of intermediate degree bounds. That is, for every \( d : \mathbb{N} \to \mathbb{N} \) such that \( d(n) \in \Omega(1) \), we consider \( n \)-vertex graphs of degree bound \( d(n) \). In this case, the best robustness we can hope for is \( \Omega(d(n)) \), and we shall actually achieve it for all functions \( d \).

Theorem 10.1 (robustly self-ordered graphs for intermediate degree bounds). For every \( d : \mathbb{N} \to \mathbb{N} \) such that \( d(n) \) is computable in \( \text{poly}(n) \)-time, there exists an efficiently constructable family of graphs \( \{G_n\}_{n \in \mathbb{N}} \) such that \( G_n \) has maximal degree \( d(n) \) and is \( \Omega(d(n)) \)-robustly self-ordered.

We prove Theorem 10.1 in three parts, each covering a different regime of degree-bounds (i.e., \( d(n)'s \)). Most of the range (i.e., \( d(n) = \Omega(\log n)^{0.5} \)) is covered by Theorem 10.2, whereas Theorem 10.3 handles small degree-bounds (i.e., \( d(n) = O(\log n)^0.499 \)) and Theorem 10.5

\(^{48}\) Hence, \( G'_s \) is \( \delta \)-close to \( G'_r \) implies that \( \left| \left\{ i, j \in [n] : s_{ij} \neq r_{ij} \right\} \right| \leq \delta \cdot (50m)^2 \), which means that \( s \) is \( \frac{(50m)^2 \delta}{n} \)-close to \( r \). (Recall that \( m = \sqrt{n} \).)
handles the degree-bounds that are in-between. One ingredient in the proof of Theorem 10.5 is a transformation of graphs that makes them expanding, while preserving their degree and robustness parameters up to a constant factor. This transformation, which is a special case of Theorem 10.4, is of independent interest.

**Theorem 10.2** (robustly self-ordered graphs for large degree bounds). For every $d : \mathbb{N} \to \mathbb{N}$ such that $d(n) \geq O(\sqrt{\log n})$ is computable in $\text{poly}(n)$-time, there exists an efficiently constructable family of graphs $\{G_n\}_{n \in \mathbb{N}}$ such that $G_n$ has maximal degree $d(n)$ and is $\Omega(d(n))$-robustly self-ordered.

The graphs will consist of connected components of size $d(n)$, and in this case $d(n) = \Omega(\sqrt{\log n})$ is necessary, since these components must be different.

**Proof Sketch.** We combine ideas from Construction 9.2 with elements of the proof of Theorem 4.2. Specifically, as in Construction 9.2, we shall use constructions of $m$-vertex and $9m$-vertex graphs that are $\Omega(m)$-robustly self-ordered, but here we set $m = d(n)/10$ and use $n/d(n)$ different $d(n)$-vertex graphs that are based on the foregoing two graphs. As in the proof of Theorem 4.2, these (10$m$-vertex) graphs will be far from being isomorphic to one another and will form the connected components of the final $n$-vertex graph.

Our starting point is the construction of $m$-vertex graphs that are $\Omega(m)$-robustly self-ordered. Specifically, we may use Theorem 8.6 and note that in this case the vertices in these $m$-vertex graph have degree that ranges between $0.24 \cdot m$ and $0.76 \cdot m$. Furthermore, these graphs have extremely high conductance; that is, in each of these graphs, the number of edges crossing each cut (in the graph) is at least $\Omega(m)$ times the number of vertices in the smaller side (of the cut).

The idea is to use two such graphs, $G_1$ and $G_2$, one with $m \stackrel{\text{def}}{=} 0.1 \cdot d(n)$ vertices and the other with $0.9 \cdot d(n) = 9 \cdot m$ vertices, and connect them in various ways as done in Section 4.2. Specifically, using an error correcting code with constant rate and constant relative distance and weight, denoted $C : [2^k] \to \{0,1\}^{m^2}$, we obtain a collection of $2^k \geq n/d(n)$ strongly connected $d(n)$-vertex graphs such that the $i$th graph consists of copies of $G_1$ and $G_2$ that are connected according to the codeword $C(i)$; more specifically, we use the codeword $C(i)$ (viewed as an $m$-by-$m$ matrix) in order to determine the connections between the vertices of $G_1$ and the first $0.1 \cdot d(n)$ vertices of $G_2$. The final $n$-vertex graph, denoted $G$, consists of $n/d(n)$ connected components that are the first $n/d(n)$ graphs in this collection.\(^{49}\)

The analysis adapts the analysis of the construction presented in the proof of Theorem 4.2. Towards this analysis, we let $G_1^{(i)}$ denote the $i$th copy of $G_j$; that is, the copy of $G_j$ that is part of the $i$th connected component of $G$. Hence, for each $i \in [n/d(n)]$, the $i$th connected component of $G$ is isomorphic to a graph that consists of copies of $G_1 = ([m], E_1)$ and $G_2 = ([m+1, \ldots, 10m], E_2)$ such that for every $u,v \in [m]$ the vertex $u$ (of $G_1^{(i)}$) is connected to the vertex $m+v$ (of $G_1^{(j)}$) if and only if $C(i)_{u,v} = 1$. Loosely speaking, considering an arbitrary permutation $\mu : [n] \to [n]$, we proceed as follows.\(^{50}\)

- The discrepancy between the degrees of vertices in copies of $G_1$ and $G_2$ (i.e., degree smaller than $0.76m + m$ versus degree at least $0.24 \cdot 9m$) implies that each vertex that resides in a copy of $G_1$ and is mapped by $\mu$ to a copy of $G_2$ yields a contribution of $\Omega(d(n))$ units to the symmetric difference between $G$ and $\mu(G)$.

\(^{49}\)Note that we used $2^k \geq n/d(n)$ and $m^2 = O(k)$, where $m = 0.1 \cdot d(n) > \sqrt{k}$. This setting allows for handling any $d(n) \geq O(\sqrt{\log n})$.

\(^{50}\)These cases are analogous to the cases treated in the proof of Theorem 4.2, with the difference that we merged Cases 2&3 (resp., Cases 4&5) into our second (resp., third) case.
Let \( \mu'(i) \) (resp., \( \mu''(i) \)) denote the index of the connected component to which \( \mu \) maps a plurality of the vertices that reside in \( G_1(i) \) (resp., of \( G_2(i) \)). Then, the extremely high conductance of \( G_1 \) (resp., \( G_2 \)) implies that the vertices that resides in \( G_1(i) \) (resp., of \( G_2(i) \)) and are mapped by \( \mu \) to a connected component different from \( \mu'(i) \) (resp., \( \mu''(i) \)) yields an average contribution of \( \Omega(d(n)) \) units per each of these vertices.

- The lower bound on the number of edges between \( G_1(i) \) and \( G_2(i) \) implies that every \( i \) such that \( \mu'(i) \neq \mu''(i) \) yields a contribution of \( \Omega(d(n)^2) \) units, where we assume that few vertices fell to the previous case (i.e., are mapped by \( \mu \) in disagreement with the relevant plurality vote). (Analogously to the proof of Theorem 4.2, each of these few exceptional vertices reduces the contribution by at most \( d(n) \) units.)

- The \( \Omega(d(n))- \)robust self-ordering of \( G_1 \) (resp., \( G_2 \)) implies that each vertex that reside in \( G_1(i) \) (resp., of \( G_2(i) \)) and is mapped by \( \mu \) to a different location in \( G_1(\mu'(i)) \) (resp., in \( G_2(\mu''(i)) \)) yields a contribution of \( \Omega(d(n)) \) units. Again, this assumes that few vertices fell to the penultimate case, whereas each of these few vertices reduces the contribution by one unit (per each vertex in the current case).

- The distance between the codewords of \( C \) implies that every \( i \) such that \( \mu'(i) = \mu''(i) \neq i \) yields a contribution of \( \Omega(d(n)^2) \), where we assume that few vertices fell to the previous cases.

As in the proof of Theorem 4.2, there may be a double counting across the different cases, but this only means that we overestimate the contribution by a constant factor. Overall the size of the symmetric difference is \( \Omega(d(n)) \) times the number of non-fixed-points of \( \mu \).

**Handling smaller degree bounds**

Theorem 10.2 is applicable only for degree bounds that are at least \( O(\log n)^{0.5} \). A different construction allows handling degree bounds up to \( O(\log n)^{0.49} \), which leaves a small gap (which we shall close in Theorem 10.5).

**Theorem 10.3 (robustly self-ordered graphs for small degree bounds).** For every every constant \( \epsilon > 0 \), and every \( d : \mathbb{N} \to \mathbb{N} \) such that \( d(n) = \Omega(\log n)^{0.5-\epsilon} \) is computable in poly\((n)\)-time, there exists an efficiently constructable family of graphs \( \{G_n\}_{n \in \mathbb{N}} \) such that \( G_n \) has maximal degree \( d(n) \) and is \( \Omega(d(n))- \)robustly self-ordered.

In this case, the graphs will consist of connected components of size \( \frac{\Theta(\log n)}{d(n) \cdot \log \log n} > d(n) \).

**Proof Sketch.** Setting \( m(n) \overset{\text{def}}{=} \frac{\Theta(\log n)}{d(n) \cdot \log \log n} > d(n) \cdot (\log n)^\epsilon \), we proceed in three steps.

1. We first tighten the proof of Theorem 6.1 such that it establishes that, with probability at least \( 1 - \exp(-\Omega(d(n) \cdot \log m(n))) = 1 - o(1) \), a \( d(n)- \)regular \( m(n) \)-vertex multi-graph generated by the random permutation model is \( \Omega(d(n)) \)-robustly self-ordered and expanding. The fact that the proof extends to a varying degree bound is implicit in the proof of Theorem 6.1, and the higher robustness is obtained by using smaller sets \( J_s \)'s (see Footnote 33).

Then, we extend the argument (as done in Step 1 of Remark 6.2) and show that, for any set \( \mathcal{G} \) of \( t < n \) multi-graphs (which is each \( d(n) \)-regular and has \( m(n) \) vertices), with probability at least \( 1 - t \cdot \exp(-\Omega(d(n) \cdot \log m(n))) = 1 - o(1) \), a random \( d(n) \)-regular \( m(n) \)-vertex multi-graph (as generated above) is both \( \Omega(d(n)) \)-robustly self-ordered and expanding and far from being isomorphic to any multi-graph in \( \mathcal{G} \). Here two \( d(n) \)-regular \( m(n) \)-vertex multi-graphs are said to be far apart if they disagree on \( \Omega(d(n) \cdot m(n)) \) vertex-pairs. (Note that the probability that such a random multi-graph is close to being
isomorphic to a fixed multi-graph is at most $\exp(-\Omega(d(n) \cdot m(n) \log(m(n)/d(n)))) = o(1/n^2)$, where the last inequality is due to the setting of $m(n)$.)\(^{51}\)

Note that this multi-graph may have parallel edges and self-loops, but their number can be upper-bounded with high probability. Specifically, for $t = 1/\epsilon$, with probability at least $1 - O(d(n)^t/m(n)^{t-1})$, no vertex has $t$ (or more) self-loops and no vertex is incident to $t + 1$ (or more) parallel edges. Hence, omitting all self-loops and all parallel edges leaves us with a simple graph that is both $\Omega(d(n))$-robustly self-ordered (and expanding) and far from being isomorphic to any graph in $G$.

2. Next, using Step 1, we show that one can construct in $\text{poly}(n)$-time a collection of $n/m(n)$ graphs such that each graph is $d(n)$-regular, has $m(n)$ vertices, is $\Omega(d(n))$-robustly self-ordered and expanding, and the graphs are pairwise far from being isomorphic to one another.

As in Step 2 of Remark 6.2, this is done by iteratively finding robustly self-ordered $d(n)$-regular $m(n)$-vertex expanding graphs that are far from being isomorphic to all prior ones, while relying on the fact that $m(n)^{d(n) \cdot m(n)} = \text{poly}(n)$ (by the setting of $m(n)$).

3. Lastly, we use the graphs constructed in Step 2 as connected components of an $n$-vertex graph, and obtain the desired graph.

Note that we have used $m(n) > (\log n)^\epsilon \cdot d(n)$ and $d(n) \cdot m(n) \cdot \log m(n) = \Theta(\log n)$, which is possible if (and only if) $d(n) \leq (\log n)^{0.5-\Theta(\epsilon)}$.

### Obtaining strongly connected graphs

The graphs constructed in the proofs of Theorems 10.2 and 10.3 consists of many small connected components; specifically, we obtain $n$-vertex graphs of maximum degree $d(n)$ with connected components of size $\max(O(d(n)), o(\log n))$ that are $\Omega(d(n))$-robustly self-ordered. We point out that the latter graphs can be transformed into ones with asymptotically maximal expansion (under any reasonable definition of this term), while preserving their maximal degree and robustness parameter (up to a constant factor). This is a consequence of the following general transformation.

> **Theorem 10.4** (the effect of super-imposing two graphs). For every $d, d' : \mathbb{N} \to \mathbb{N}$ and $\rho : \mathbb{N} \to \mathbb{R}$, let $G$ and $G'$ be $n$-vertex graphs such that $G$ is $\rho(n)$-robustly self-ordered and has maximum degree $d(n)$, and $G'$ has maximum degree $d(n)$. Then, the graph obtained by super-imposing $G$ and $G'$ is $(\rho(n) - d'(n))$-robustly self-ordered and has maximum degree $d(n) + d'(n)$.

Note that Theorem 10.4 is not applicable to the constructions of bounded-degree graphs obtained in the first part of this paper, because their robustness parameter was a constant smaller than 1. (This is due mostly to Construction 2.3, but also occurs in the proof of Theorem 4.2.)\(^{52}\) A typical application of Theorem 10.4 may use $d'(n) = \rho(n)/2 \geq 3$. (Recall that $\rho(n) \leq d(n)$ always holds.)

---

\(^{51}\) For starters, the probability that an edge that appears in the fixed multi-graph appears in the random graph is $d(n)/m(n)$. Intuitively, these events are sufficiently independent so to prove the claim; for example, we may consider the neighborhoods of the first $m(n)/2$ vertices in the random graph, and an iterative process in which they are determined at random conditioned on all prior choices.

\(^{52}\) In contrast, the construction of Theorem 10.3, which builds upon the proof of Theorem 6.1, does yield $\Omega(d)$-robustly self-ordered graphs of maximum degree $d$, for sufficiently large constant $d$. 
Proof. Fixing any permutation $\mu$ of the vertex set, note that the contribution of each non-fixed-point of $\mu$ to the symmetric difference between $G \cup G'$ and $\mu(G \cup G')$ may decrease by at most $d'(n)$ units due to $G'$.

Closing the gap between Theorems 10.2 and 10.3

Recall that these theorems left few bounding functions untreated; essentially, these were functions $d : \mathbb{N} \to \mathbb{N}$ such that $d(n) \in [(\log n)^{0.499}, O((\log n)^{0.5})$. We close this gap now.

\textbf{Theorem 10.5} (robustly self-ordered graphs for the remaining degree bounds). For every $d : \mathbb{N} \to \mathbb{N}$ such that $d(n) \in [(\log n)^{1/3}, (\log n)^{2/3}]$ is computable in poly$(n)$-time, there exists an efficiently constructable family of graphs $\{G_n\}_{n \in \mathbb{N}}$ such that $G_n$ has maximal degree $d(n)$ and is $\Omega(d(n))$-robustly self-ordered.

In this case, the graphs will consist of connected components of size $2 \log n$.

\textbf{Proof Sketch.} We apply the proof strategy of Theorem 10.2, while using the graphs obtained by combining Theorems 10.2 and 10.4. Specifically, setting $\ell = \log n$, while noting that $d(n) \geq \ell^{1/3} \gg O(\log \ell)^{1/2}$, we use the construction of $\ell$-vertex $\Omega(d(n))$-robustly self-ordered graphs of degree at most $d(n)/2$ that are expanding, which is obtained by combining the latter two results. Furthermore, we shall use the fact that these graphs have degree at least $d(n)/200$, and will also use the same construction with degree bound $d(n)/300$. Using these two graphs, we shall construct $n/2\ell$ different $\ell$-vertex graphs that are far from being isomorphic to one another, and these will form the connected components of the final $n$-vertex graph.

Our starting point is the construction of $\ell$-vertex graphs that, for some constant $\gamma \in (0, 1)$, are $\gamma \cdot d(n)$-robustly self-ordered and have maximum degree $d(n)/4$ and minimum degree $d(n)/100$. Such graphs are obtained by Theorem 10.2, while setting $m = d(n)/40$. Using Theorem 10.4 (with $d'(n) = \gamma \cdot d(n)/4$), we transform these graphs to ones of maximum degree $d(n)/2$ and asymptotically maximal conductance (i.e., in each of these graphs, the number of edges crossing each cut (in the graph) is at least $\Omega(d(n))$ times the number of vertices in the smaller side (of the cut)). We denote the resulting graph $G_1$, and apply the same process while setting $m = d(n)/600$ so to obtain a graph of maximum degree $d(n)/300$, denoted $G_2$.

Next, we connect $G_1$ and $G_2$ in various ways so to obtain $n/2\ell$ graphs that are far from being isomorphic to one another. This is done by a small variation on the proof of Theorem 10.2. Specifically, we fix $d(n)/2$ disjoint perfect matchings between the vertices of $G_1$ and the vertices $G_2$, and use the error correcting code to determine which of these $\ell \cdot d(n)/2 = \omega(\log n)$ edges to include in the code. More specifically, using an error correcting code with constant rate and constant relative distance and weight, denoted $C : [2^k] \to \{0, 1\}^{\ell \cdot d(n)/2}$, we obtain a collection of $n/2\ell < 2^k$ strongly connected $2\ell$-vertex graphs such that the $r$th graph consists of copies of $G_1$ and $G_2$ that are connected according to the codeword $C(i)$; that is, the $(r, c)$th bit of the codeword $C(i)$ (viewed as an $d(n)/2$-by-$\ell$ matrix) determines whether the $c$th edge of the $r$th matching is included in the $i$th graph. The final $n$-vertex graph, denoted $G$, consists of these $n/2\ell$ graphs as its connected components.

The analysis is almost identical to the analysis provided in the proof of Theorem 10.2, since the key facts used there hold here too (although the construction is somewhat different). The key facts are that the degrees of vertices in $G_1$ and $G_2$ differ in $\Omega(d(n))$ units, that the relative conductance of the connected components is $\Omega(d(n))$, that $G_1$ and $G_2$ are both $\Omega(d(n))$-robustly self-ordered, and that the bipartite graphs (used in the different connected components) are far away from one another.

Appendix: On Definitions of Non-Malleable Two-Source Extractor

Recall that Definition 8.1 differs from [7, Def. 1.3] only in the scope of the “tampering functions” $f$ and $g$. Whereas Definition 8.1 requires both $f$ and $g$ to have no fixed-point, in [7, Def. 1.3] it is only required that either $f$ or $g$ has no fixed-point. In both cases, the extraction condition is captured by (18) and is applied to the eligible functions $f$ and $g$ (and to random variables $X$ and $Y$ of sufficiently high min-entropy).

We show that Definition 8.1 is strictly weaker than [7, Def. 1.3]. To see this, let $E : \{0,1\}^{n-1} \times \{0,1\}^n \rightarrow \{0,1\}^m$ be a non-malleable extractor under [7, Def. 1.3] (say, for constant error and constant deficiency). Actually, we will only use the hypothesis that (18) holds for $f$ and $g$ such that $g$ has no fixed-point (i.e., we make no requirement of $f$). Now, let $E'(bx', y) = E(x', y)$, where $b \in \{0, 1\}$.

1. Clearly, $E'$ violates (18) for $g(y) = y$ and $f(bx') = \bar{b}x'$, where $\bar{b} = 1 - b$, since $E'(f(bx'), g(y)) = E(x', y) = E'(bx', y)$. Hence, $E'$ does not satisfy [7, Def. 1.3].

2. To see that $E''$ satisfies Definition 8.1, consider any $f$ and $g$ that have no fixed-points, and distributions $X = (B, X')$ and $Y$ of low deficiency. Define a random process $F : \{0,1\}^{n-1} \rightarrow \{0,1\}^n$ such that $F(x') = f(bx')$, where $b$ is selected according to the residual distribution of $B$ conditioned on $X' = x'$ (i.e., $\Pr[F(x') = z] = \Pr[f(X) = z|X' = x']$). Then, letting $f'(x)$ (resp., $F'(x')$) be the $(n - 1)$-bit suffix of $f(x)$ (resp., of $F(x')$), we have

$$(E'(X, Y), E'(f(X), g(Y))) = (E'(X', Y), E'(B X', g(Y))) = (E(X', Y), E(F'(X'), g(Y))),$$

which is close to $(U_m, E(F(X'), g(Y)))$, by the hypothesis regrading $E$ (since $g$ has no fixed-point), while also using a convexity argument (for $F'$). Using $(U_m, E(F'(X'), g(Y))) = (U_m, E'(F(X'), g(Y))) = (U_m, E'(F(X), g(Y)))$, we conclude that $(E'(X, Y), E'(f(X), g(Y)))$ is close to $(U_m, E'(f(X), g(Y)))$. 

References:

We study a class of optimization problems including matrix scaling, matrix balancing, multidimensional array scaling, operator scaling, and tensor scaling that arise frequently in theory and in practice. Some of these problems, such as matrix and array scaling, are convex in the Euclidean sense, but others such as operator scaling and tensor scaling are geodesically convex on a different Riemannian manifold. Trust region methods, which include box-constrained Newton’s method, are known to produce high precision solutions very quickly for matrix scaling and matrix balancing (Cohen et. al., FOCS 2017, Allen-Zhu et. al. FOCS 2017), and result in polynomial time algorithms for some geodesically convex problems like operator scaling (Garg et. al. STOC 2018, Bürgisser et. al. FOCS 2019). One is led to ask whether these guarantees also hold for multidimensional array scaling and tensor scaling.

We show that this is not the case by exhibiting instances with exponential diameter bound: we construct polynomial-size instances of 3-dimensional array scaling and 3-tensor scaling whose approximate solutions all have doubly exponential condition number. Moreover, we study convex-geometric notions of complexity known as margin and gap, which are used to bound the running times of all existing optimization algorithms for such problems. We show that margin and gap are exponentially small for several problems including array scaling, tensor scaling and polynomial scaling. Our results suggest that it is impossible to prove polynomial running time bounds for tensor scaling based on diameter bounds alone. Therefore, our work motivates the search for analogues of more sophisticated algorithms, such as interior point methods, for geodesically convex optimization that do not rely on polynomial diameter bounds.
The **commutative setting**, in which the underlying group is Abelian, captures matrix scaling, matrix balancing and array scaling, which arise in scientific computing and optimal transport [17, 46]. Such problems fall into the framework of unconstrained geometric programming. Though these problems are convex, there are at least two reasons to study them further. Firstly, they are of such practical importance that speed matters. Naively applying powerful algorithms like ellipsoid and interior point methods can be impractically slow. Hence, it is important to understand when faster methods can succeed. Matrix scaling and balancing, in particular, have enjoyed some success stories - there are fast algorithms to obtain high precision solutions [16, 3], and there are more general upper bounds [14]. Secondly, the algorithms developed for the commutative setting are candidates for generalization to our second setting, which takes place in the less well-understood arena of geodesically convex optimization.

The second context, which we call the **noncommutative setting**, arises when the underlying group is non-Abelian. The noncommutative setting captures problems like operator and tensor scaling [25, 13], the quantum marginal problem [11] and statistical estimators such as Tyler’s M estimator [23] and maximum likelihood estimates for matrix and tensor normal models [6]. Deciding whether the value of the optimization problem is zero or not is equivalent to deciding a central polynomial identity testing (P.I.T.) problem in invariant theory known as the **null cone** problem. It is hoped that efficient optimization algorithms will result in efficient algorithms for the null-cone problem. One approach to complexity lower bounds, geometric complexity theory, suggests that these P.I.T. problems should be in P [43, 26], and the optimization approach has resulted in polynomial time algorithms in some cases [25, 2]. The optimization problems that arise in the noncommutative setting are not convex in the Euclidean sense, but rather **geodesically convex**, a notion of convexity on a Riemannian manifold. Currently, the only implementable algorithms for geodesically convex optimization are analogues of gradient descent and trust region methods [1, 53, 2]. There are, as of yet, no efficiently implementable geodesically convex counterparts to the interior point or cutting plane methods.

In both the commutative and noncommutative settings, algorithms are typically analysed using two quantities. One is **diameter**, or how far approximate minimizers can be from the origin. The other is a geometric measure of well-conditionedness known as **margin** (or gap in the noncommutative case), which has several variants in the literature and appears in two primary ways. Firstly, the smaller the margin, the higher the degree of precision required to decide if the value of the optimization problem is zero or not [12, 30]. Secondly, the larger the margin, the smaller the diameter [48, 50, 12, 14]. In this paper we show the following:

i) In the commutative setting, and in particular for array scaling, approximate minimizers for the functions we study can have doubly exponential condition number. That is, the problems have exponential diameter. As a consequence, popular classes of algorithms such as gradient descent and trust region methods cannot produce high-precision solutions in polynomial time in general. This result applies in the noncommutative setting as well, which provides evidence that even cutting plane methods are unlikely to produce high-precision solutions in polynomial time. This shows it is necessary to develop powerful methods like the interior point method in the geodesically convex setting.

ii) In the commutative and noncommutative settings, we study the margin and gap, respectively, which appear in running time bounds for all existing algorithms. We prove that these measures can be exponentially small in the input size for several problems including array scaling and tensor scaling. In the commutative case, this gives
evidence that existing algorithms for array scaling do not run in near-linear time. In
the noncommutative case, our results show that margin-based analyses like [12] cannot
prove polynomial time guarantees for deciding the null cone problem for tensor scaling
using trust region methods.

We use the remainder of the introduction to describe both settings in more detail, state
our main results precisely, and discuss previous work. For both the commutative and
noncommutative settings, we proceed in the following order. We start with an introduction
and motivation of the setting, continue with diameter bounds and afterwards treat bounds
on the margin and gap, respectively. We end each setting with a short discussion of the main
proof techniques.

1.1 The commutative setting: matrix scaling and its relatives
Matrix scaling and array scaling
Consider the matrix scaling problem: given a nonnegative matrix $A$, find nonnegative diagonal
matrices $X, Y$ such that $XAY$ is doubly stochastic (i.e. has row and column sums equal to
one). The matrices, if they exist, can be found by the exceedingly simple and fast alternating
minimization method known as Sinkhorn’s algorithm. It is frequently used in practice, e.g.
for quickly approximating the solution to optimal transport problems [17].

Like all other algorithms for matrix scaling, Sinkhorn’s algorithm is typically analyzed
through optimization. One finds that $X$ and $Y$ are $e^{\text{diag}(x), e^{\text{diag}(y)}}$, where $x, y \in \mathbb{R}^n$ are solutions to the following optimization problem:

\[
\inf_{x,y \in \mathbb{R}^n} \sum A_{ij}e^{x_i+y_j-\bar{x}-\bar{y}}
\tag{1}
\]

for $\bar{x} := \frac{1}{n} \sum z_i$ (c.f. [35]). Moreover, the infimum is greater than zero if and only if $A$ is
approximately scalable, i.e. the row and column sums of $XAY$ can be made arbitrarily close
to one for $X, Y$ nonnegative, diagonal.

More generally, given a finite set $\Omega \subseteq \mathbb{R}^m$ and a nonnegative function $p: \Omega \to \mathbb{R}_{\geq 0}$, define the capacity $[30]$ as the value of the unconstrained geometric program

\[
\text{cap}(p) := \inf_{x \in \mathbb{R}^m} f_p(x) := \inf_{x \in \mathbb{R}^m} \sum_{\omega \in \Omega} p_\omega e^{\omega \cdot x}.
\tag{2}
\]

The capacity is positive if and only if zero is in the Newton polytope $\text{conv}(\text{supp } p)$. Matrix
scaling arises when $m = n$ and $\Omega = \{(\epsilon_i, \epsilon_j) : i, j \in [n]\}$ for $\epsilon_k := e_k - \frac{1}{n} 1_n$, where $e_k \in \mathbb{R}^n$ is the $k^{th}$ canonical unit vector and $1_n \in \mathbb{R}^n$ denotes the all-ones vector. In this case
Equation (2) reduces to precisely Equation (1), and $|\nabla \log f_p(x)|$ measures the deviation of
$p$ from doubly stochastic.

Matrix balancing, in which we instead wish to find a scaling for which the $i^{th}$ row and
column sum match, arises when $m = n$ and $\Omega = \{\epsilon_i - \epsilon_j : i \neq j \in [n]\}$. When $m = 3n$ and
$\Omega = \{(\epsilon_i, \epsilon_j, \epsilon_k) : i, j, k \in [n]\}$ we obtain the 3-dimensional array scaling problem. In analogy
to matrix scaling, in array scaling one has an array $p$ of numbers in $(\mathbb{R}^{n\times n\times n})^{3d}$ and seeks positive vectors $X, Y, Z \in \mathbb{R}^{n\times n\times n}$ so that the array $q$ with entries $q_{ijk} = p_{ijk}X_{iy}Y_{jy}Z_{ky}$ is tristochastic. That
is, the sum over every slice is equal to one, i.e. $\sum_{j,k} q_{i0,j,k} = \sum_{i,k} q_{i0,j,k} = \sum_{i,j} q_{i,j,0,k} = 1$ for all
$i_0, j_0, k_0 \in [n]$. If it is possible to satisfy these equations to arbitrary precision we say $p$
is approximately scalable. As for matrix scaling, $p$ is approximately scalable if and only if
cap($p$) > 0. In the same manner, we obtain $d$-dimensional array scaling for $m = dn$ and

\[
\Omega = \Omega_{n,d} := \{\epsilon_i : i \in [n]\}^d \subseteq (\mathbb{R}^n)^d.
\tag{3}
\]
We can think of subsets of $\Omega_{n,d}$ as $d$-uniform, $d$-partite hypergraphs. Up to an additive shift by $-\frac{1}{n}n_0$, the elements of $\Omega_{n,d}$ are indicator vectors of the edges in such hypergraphs. For $d = 2$, the matrix $p$ is scalable if and only if the bipartite graph corresponding to $\text{supp } p$ contains a perfect matching, but this is not the case for $d \geq 3$ (indeed, $d$-partite hypergraph matching is $\text{NP}$-hard).

**Algorithms for array scaling**

Array scaling serves the same role for speeding up multimarginal transport as matrix scaling for optimal transport, and yet again there is a simple and fast alternating minimization algorithm that produces $\varepsilon$-tristochastic scalings in time $O(1/\varepsilon^2)$ [5, 39]. Moreover, algorithms to approximate the capacity arise in varied settings including radial isotropic position [33], entropy maximization [50], and approximate counting [7].

It is natural to ask if there are high-precision algorithms for array scaling with $\log(1/\varepsilon)$ dependence on the error and linear or mild dependence on the number of nonzero entries. For matrix scaling and matrix balancing, several works have shown that trust regions and interior point methods can obtain such guarantees [16, 3]. Our work is concerned with whether the performance of such algorithms carries over to array scaling and the computation of the capacity in general.

### 1.1.1 Diameter lower bounds

Guarantees for many iterative algorithms in convex optimization require diameter bounds, or bounds on the distance $R$ from the starting point to an $\varepsilon$-approximate solution. Trust region methods, also called box-constrained Newton’s method, are iterative algorithms that, at each step, move to the best solution within a typically small distance $D$ of the previous solution. By their nature, trust region methods take at least $R/D$ steps to produce an $\varepsilon$-approximate solution. Gradient descent for Lipschitz functions also depends quadratically on a diameter bound, and cutting plane methods typically use diameter bounds to control the volume of a starting region.

**Known diameter upper and lower bounds**

For matrix scaling and matrix balancing, it has been shown in [16] that one may take $R = O(n\log(w_A/\varepsilon))$, where $w_A$ is the ratio between the sum of the entries of the matrix and the least nonzero entry. For 3-dimensional array scaling, the best upper bound of which we are aware is $R = O(n^{1.2}2^{m_0}\log(1/\varepsilon))$, which follows from the general upper bound of [50] on diameter bounds for unconstrained geometric programming. There is also a diameter bound for array scaling in the multimarginal transport context that is polynomial in the input size assuming the tensor has no nonzero entries [39].

Regarding diameter lower bounds, in the context of computing maximum entropy distributions it was shown that there is some bounded set $\Omega \subset \mathbb{Z}^m$ in a poly($m$) size ball such that there are no $\varepsilon$-approximate minimizers of norm poly($m$, log 1/\varepsilon) for $f_p$ as in Equation (2) [50].

**Main theorem**

Where do the polynomial diameter bounds for matrix scaling (i.e. 2-dimensional array scaling) transition to the superpolynomial diameter bounds for general $\Omega$? We show that this transition takes place in the next simplest problem, the 3-dimensional array scaling problem.
Theorem 1.1. There is an absolute constant $C > 0$ and an array $p_{ijk} \in (\mathbb{R}_{\geq 0}^n)^{\otimes 3}$ with $O(n)$ nonzero entries, each of bit-complexity $O(n)$, that satisfies the following property. For all $0 < \varepsilon \leq \exp(-Cn^2 \log n)$ and $(x, y, z) \in \mathbb{R}^{3n}$, if

$$f_p(x, y, z) \leq \text{cap}(p) + \varepsilon$$

then $\| (x, y, z) \|_2 = \Omega \left( 2^{n/3} \log(1/\varepsilon) \right)$.

To emphasize that the difficulties do not lie in an additive vs multiplicative approximation, we remark that our array $p$ has unit sum and $\text{cap}(p) = 1/2$. By a simple duplication trick, the same bound holds for $d$-dimensional array scaling with $d \geq 3$; see Corollary 3.7.

Implications of Theorem 1.1 and relation to the literature

Theorem 1.1 shows that trust region methods for array scaling with polynomial step size cannot provide high-precision solutions in $\text{poly}(n, \log(1/\varepsilon))$ time for $d \geq 3$. Moreover, gradient descent on the Lipschitz convex function $\log f_p$ has a bounded step size, and so also cannot provide high precision solutions in polynomial time.

In [50, Section 2.1] the authors ask whether there is $\Omega$ whose elements are Boolean (up to an additive shift) with a superpolynomial diameter lower bound. As subsets of $\Omega_{n,d}$ are automatically of this form, we answer their open problem in the affirmative. Our lower bound on $\log R$ is tight up to constant factors by the diameter upper bound from [50] mentioned above; moreover the logarithmic dependence on $\varepsilon$ is best possible. Determining the correct constant in the exponent is an interesting open direction. We believe that that the requirement that $\varepsilon$ is very small is an artifact of our specific construction and proof strategy, and thus can probably be relaxed significantly.

Lastly, we remark that [14] bounds the diameter for $f_p$ by a polynomial in the facet gap, i.e. the minimum distance between an element of $\text{supp} p$ and an affine hull of a facet of the Newton polytope. The construction in Theorem 1.1 has exponentially small facet gap; see Corollary 3.6.

1.1.2 Margins: the geometry of scaling problems

Many computational aspects of the capacity rely on the convex geometry of the finite set $\Omega \subseteq \mathbb{R}^m$. Consider the following quantity, which we call the margin of $\Omega$. The margin is the minimum positive distance from a convex hull of a subset of $\Omega$ to the origin. Formally,

**Definition 1.2 (Margin).** For a finite set $\Omega \subseteq \mathbb{R}^m$, define the margin $\gamma(\Omega)$ by

$$\gamma(\Omega) := \min \{ \text{dist}(0, \text{conv}(S)) \mid S \subseteq \Omega, \ 0 \notin \text{conv}(S) \}.$$  

We point out that for all considered capacity problems in this paper, the margin is actually the weight margin (c.f. [12] and our Definition 4.3) of a certain group representation. For example, the margin for array scaling is the weight margin for tensor scaling. We now discuss how the margin enters in decision problems and diameter bounds.

Margin as a precision parameter for the decision problem

To illustrate how the margin enters the decision problem of whether $\text{cap}(p) > 0$, consider matrix scaling. To certify that the capacity of a matrix is nonzero, we compute $\varepsilon$-doubly stochastic scalings for some $\varepsilon$ smaller than the distance to doubly stochastic attained by any matrix that is not approximately scalable. This turns out to be precisely $\gamma(\Omega_{n,2})$. More
generally, it is a classical fact that for $p$ with support contained in $\Omega$, the gradient $\nabla \log f_p(x)$ can take any value in the Newton polytope of $p$. Thus, $\text{cap}(p) > 0$ if and only if there is some $x$ with $|\nabla \log f_p(x)| \leq \gamma(\Omega)$.

For matrix scaling and matrix balancing, it is known that $\gamma(\Omega)$ is on the order of $n^{-3/2}$, despite the exponential number of subsets $S \subseteq \Omega!$. This luck can be attributed to the extraordinary geometry of $\Omega$ in these cases, whose elements form the rows of a totally unimodular matrix (up to a shift). On the other hand, for $d$-dimensional array scaling for $n = 2$, the margin $\gamma(\Omega_{2,d})$ is on the order of the margin of the $d$-dimensional hypercube $\{-1,1\}^d$, which satisfies $\gamma(\{-1,1\}^d) = d^{-\frac{d}{2(1+o(1))}}$ by [4]. However, between the extreme cases $\Omega_{n,2}$ (matrix scaling) and $\Omega_{2,d}$ (the hypercube), very little is known.

**Margin and related quantities for diameter bounds**

In addition to their role in the decision problem, margins and related quantities can be used to prove diameter bounds for Equation (2). The work [12] proves the diameter bound $\text{poly}(\gamma(\Omega)^{-1}, \log(1/\epsilon))$. In [50] it is shown that the diameter is polynomial in the logarithm of the minimum nonzero $p_{ij}$, and a quantity called the **unary facet complexity**. The latter is defined as the maximal length of an integer normal vector of a face of the Newton polytope $\text{conv}(\text{supp } p)$. In the case of $d$-dimensional arrays, one can use Cramer’s rule to crudely bound the unary facet complexity by $(d+1)^{dn}$. In the case when $0$ is in the relative interior of the Newton polytope, [48] has shown that there is a minimizer with Euclidean norm $O(\log |\text{supp } p|/\eta)$, where $\eta$ is the distance from $0$ to the boundary of the Newton polytope. The diameter bounds in [48, 50] were used to design ellipsoid methods that are tractable even for $|\text{supp } p|$ very large, and in [14] they were used to bound the running time of interior point methods.

**Main theorem**

One is led to ask if the margin remains large for array scaling when $d \geq 3$. We show that this is not the case. In fact, the margin becomes exponentially small in $nd$ for $d \geq 3$. What follows is stated in more detail later in Theorem 2.1.

**Theorem 1.3.** Let $d \geq 3$ and $n \geq 2$. Let $\Omega_{n,d} = \{ \varepsilon_i : i \in [n] \}^d \subseteq (\mathbb{R}^n)^d$, where $\varepsilon_i := e_j - \frac{1}{n} \mathbb{1}_n$. There exists a constant $C > 0$, independent of $n$ and $d$, such that $\gamma(\Omega_{n,d}) \leq 2^{-Cnd}$.

That is, there are $d$-dimensional arrays $p \in (\mathbb{R}_{\geq 0}^n)^{\otimes d}$ such that the $d$-tuple of marginals of $p$ is at distance at most $2^{-Cnd}$ from $\frac{1}{n}(\mathbb{1}_n, \ldots, \mathbb{1}_n)$, yet the support of $p$ does not admit an array with uniform marginals, i.e. $\text{cap}(p) = 0$. We note that the support of the array $p$ we construct has $O(nd)$ elements.

**Implications of Theorem 1.3 and relation to the literature**

We remark that the construction yields a tensor whose Newton polytope has a facet exponentially close to the origin. Therefore, the bound proved in [14] on the number of iterations for interior point methods on 3-tensors is $\Omega(k^{3/2} + k^{1/2} \log(1/\epsilon))$ for tensors with $O(k)$ nonzero entries.

Theorem 1.3 aligns with existing results showing that the $d > 2$ array case is more complex than the matrix case. Indeed, it is known that the polytope of arrays with uniform marginals, known as the **$d$-index axial assignment polytope**, has many more vertices when $d \geq 3$ and that the vertices can have exponential entries [40]. In contrast, for $d = 2$ this polytope (known as the Birkhoff-von Neumann polytope) has integral vertices by the Birkhoff-von Neumann theorem.
The exponential rate of decay in Theorem 1.3 is tight up to log factors: [12, Theorem 6.10 Item 3] shows that the margin for \( d \)-dimensional array scaling is at least \( (n\sqrt{d} - d^{n-1}) \). It is interesting to ask whether the true bound is \( 2^{-\Theta(nd)} \) as in our upper bound or \( 2^{-\Theta(nd\log(n + \log d))} \) as in the lower bound. [4] shows that the latter is correct in the case \( n = 2 \).

### 1.1.3 Proof techniques for the commutative setting

We first discuss the techniques for proving our margin bounds. Theorem 1.3 is proven by explicit construction of witness sets \( \Gamma_{n,d} \subseteq \Omega_{n,d} := \{ \varepsilon_i : i \in [n] \}^{d} \), i.e. \( 0 \notin \text{conv}(\Gamma_{n,d}) \) but zero is exponentially close to \( \text{conv}(\Gamma_{n,d}) \). This is done by using that \( \sum_{i} n^{-1} \varepsilon_{i} \) is the unique way to express zero as a convex combination of the \( \varepsilon_{i} \), compare Lemma 2.2, and by heavily exploiting the combinatorics of \( \Omega_{n,d} \). For example, in the case \( d = 3 \) and \( n \geq 3 \) the key combinatorial idea builds on a construction by Kravtsov in [38]. Kravtsov’s motivation is to characterize the non-integer vertices of the 3-index axial assignment polytope. He explicitly constructs a certain non-integer vertex with maximal support [38, Theorem 1 with \( k = 0 \)] which has an exponentially small entry.

By definition of the 3-index axial assignment polytope, the support of this vertex corresponds to a subset \( S \subseteq \Omega_{n,3} \) with \( 0 \in \text{conv}(S) \). Removing the element of \( S \) corresponding to the small entry in Kravtsov’s vertex yields our witness set \( \Gamma_{n,3} \) with a convex hull very close to zero. In fact, the whole idea generalizes (in a technical way) whenever \( d = 6r - 3, r \geq 1 \) and \( n \geq 3 \), see section 2.3. For \( n = 2 \) and \( d \geq 3 \), the bound follows from the existing work [4], as mentioned before. While the construction in that work via \( \{-1,1\} \) matrices yields a stronger bound, we provide a different construction of \( \{-1,1\} \) matrices\(^1\), which has the additional property of freeness. The latter will prove useful when we adapt Theorem 1.3 to the noncommutative case.

We now discuss the proof of the diameter lower bound, Theorem 1.1. The high level idea is as follows. We first construct a subset \( \Omega_{0} \subseteq \Omega_{n,3} \) with \( 0 \in \text{conv}(\Omega_{0}) \) such that there is another element \( \omega \in \Omega_{n,3} \) exponentially close to \( \text{conv}(\Omega_{0}) \), much like our construction of the witness set for small margin discussed above. We then choose an appropriate array \( p \) supported on \( \Omega_{0} \cup \omega \). This suggests that the only approximate minimizers of \( f_{p} \) have a very large component in the direction \( x \) from \( \omega \) to \( \text{conv}(\Omega_{0}) \), because as \( y \in \mathbb{R}^{n} \) tends to a minimizer of \( f_{p} \) the term \( e^{y^\omega} \) should vanish compared to the others. This reasoning requires that \( y \) is approximately a multiple of \( x \); to enforce this we also ensure that zero is far into the relative interior of \( \text{conv}(\Omega_{0}) \).

The structure of this argument bears some similarity to that in [50], which uses the construction of [4]. The main difference is that the set \( \Omega_{n,3} \) in the 3-dimensional array scaling problem consists of vectors of very specific structure: up to an additive shift of \( -\frac{1}{n} 1_{3n} \), they are Boolean vectors in \( \mathbb{R}^{3n} \) with exactly one nonzero entry among indices in the intervals \( [1,n],[n+1,2n],[2n+1,3n] \). Thus, our construction of \( \Omega_{0} \) must consist of vectors of this special form and not simply bounded integral vectors as in [50]. This is the main additional technical contribution of our construction.

---

\(^1\) The \( \{-1,1\} \) matrices from our construction are obtained by replacing all two’s in the entries of \( A_{2r} \) (6) with \(-1\).
13:8 Barriers in Geodesic Optimization

1.2 The noncommutative setting

In the noncommutative setting, we consider a group $G$ acting on $\mathbb{C}^n$. The optimization problem we investigate is given by the capacity of a vector $v \in \mathbb{C}^n$ (c.f. [12]):

$$\text{cap}(v) := \inf_{g \in G} f_v(g) := \inf_{g \in G} \|g \cdot v\|^2.$$  \hspace{1cm} (4)

For the majority of this paper we work with the tensor scaling action, in which $G = \text{SL}(n, \mathbb{C})^d$, the group of $d$-tuples of complex matrices with determinant one, acts on $v \in (\mathbb{C}^n)^{\otimes d}$ by $(g_1, \ldots, g_d) \cdot v = (g_1 \otimes \cdots \otimes g_d)v$. The corresponding representation is always denoted by $\pi_{n,d}$. Sometimes we also consider the operator scaling action, in which $\text{SL}(n)^2$ acts on $v \in (\mathbb{C}^n)^{\otimes 2} \otimes \mathbb{C}^k$ by $(g_1, g_2) \cdot v = (g_1 \otimes g_2 \otimes I_k)v$.

Though Equation (4) looks quite different from Equation (2), one can show that restricting Equation (4) to a certain Abelian subgroup of $G$ (a torus) and making a change of variables yields an instance of Equation (2) (c.f. [12]). For example, restricting the tensor scaling action to the diagonal matrices in $G$ amounts precisely to the array scaling problem from the previous subsection. Likewise, restricting to diagonal matrices in the operator scaling action yields an instance of matrix scaling.

Relation to null cone problem and Geometric Complexity Theory

We study Equation (4) because it is deeply connected to invariant theory through a well-known connection between group orbits and invariant polynomials: zero is in the closure of an orbit of a vector $v$ if and only if every non-constant homogeneous $G$-invariant polynomial vanishes on $v$, i.e. if $v$ is in the null-cone. Null-cone membership is a well-studied polynomial identity testing (P.I.T.) problem. One approach to complexity lower bounds, geometric complexity theory, suggests that null-cone membership should be in $\mathbb{P}$ [43, 26].

Solving Equation (4) directly allows one to study the null-cone problem through optimization: one notes that $\text{cap}(v) = 0$ if and only if $v$ is in the null cone. In fact, Equation (4) is a geodesically convex optimization problem over a certain Riemannian manifold. Algebraic and optimization-based algorithms have, independently and nearly concurrently, resulted in polynomial time algorithms for nearly the same set of P.I.T. problems arising in invariant theory [22, 43, 25, 34, 20, 2], including the null-cone problem for the operator scaling and simultaneous conjugation action. However, neither approach has succeeded in solving the null-cone problem for the 3-tensor action. Recent degree lower bounds for invariant polynomials for the 3-tensor action pose significant challenges for the algebraic approach [21]. It is natural to ask whether the optimization approach can overcome these challenges.

Algorithms for computing the capacity

A nonzero tensor $w = g \cdot v$ attains the capacity when $w$ has all quantum marginals equal to $I_n/n$. The quantum marginals of a tensor $w$, analogous to the sums along slices of an array, are the three $n \times n$ matrices $M_1M_1^t, M_2M_2^t, M_3M_3^t$ for the $n \times n^2$ matrices $M_1, M_2, M_3$ known as flattenings of $w/\|w\|$. For operator scaling, the capacity is attained when the first two quantum marginals are $I_n/n$. To compute the capacity, existing algorithms attempt to find $g$ such that the quantum marginals of $g \cdot v$ are all close to $I_n/n$. There are alternating minimization algorithms that can attain distance $\varepsilon$ in time $\text{poly}(n, 1/\varepsilon)$ [25, 13], and for the

---

2 Technically we require that $G$ is a reductive group over $\mathbb{C}$ which acts rationally on $\mathbb{C}^n$. All the group actions in this paper satisfy this assumption.
operator scaling this is possible in \(\text{poly}(n, \log(1/\varepsilon))\) time [2]. However, for 3-tensor scaling, running time \(\text{poly}(1/\varepsilon)\) is not sufficient to efficiently decide null-cone membership, and the only algorithms with \(\log(1/\varepsilon)\) dependence on \(\varepsilon\) have an exponential dependence on \(n\) [12].

To explain the increased complexity, we discuss a noncommutative analogue of the Newton polytope known as the moment polytope, denoted \(\Delta_G(v)\). In particular, \(0 \notin \Delta_G(v)\) if and only if \(v\) is in the null-cone (i.e. \(\text{cap}(v) = 0\)).

For tensor scaling, the moment polytope is the set of tuples of spectra of the quantum marginals as \(w\) ranges over \(G \cdot \tau\), shifted by \(-\frac{1}{n}(1_n, 1_n, 1_n)\). The gap of the action of \(G\), i.e. the minimum positive distance from \(0\) to a moment polytope \(\Delta_G(v)\), is a noncommutative generalization of the margin. Whereas the operator scaling and simultaneous conjugation actions have polynomially large gaps, we show that the gap for the tensor scaling action is exponentially small. Scaling algorithms amount to outer \(\varepsilon\)-approximation algorithms for \(\Delta_G(v)\), which is why \(\text{poly}(1/\varepsilon)\)-time algorithms do not suffice to decide null-cone membership. Like for the margin, the smaller gap corresponds to a larger diameter, which is why so far no algorithm has had running time \(\text{poly}(n, \log(1/\varepsilon))\).

### 1.2.1 Diameter lower bound for noncommutative scaling

Here we describe how diameter bounds cause the state-of-the-art algorithms to be slow for the tensor scaling action. We begin by discussing geodesically convex optimization. In general Equation (4) is not convex, but rather geodesically convex. That is, \(G\) can be viewed as a manifold in such a way that the function \(g \mapsto \|g \cdot v\|^2\) is convex along “geodesics” of the form \(\gamma(t) = e^{tH}g\) for \(H\) Hermitian. The manifold we consider is not exactly \(G\) but rather a quotient \(P\) of it; we will make this more precise later in Section 4.5. For \(G = \text{SL}(n)^d\), the manifold \(P\) is the set of tuples of positive-definite matrices with determinant one. \(P\) is equipped with the geometry on positive-definite matrices known in statistics as the Fisher-Rao metric, and studied in depth in e.g. [9]. Though we do not need many details of this geometry here, one can think of the distance between \(g, h \in G\) as a bound on the logarithms of the singular values of \(g^{-1}h\). In particular, the geodesic “ball” of radius \(R\) about the identity in \(G\) is the intersection of \(G\) with the set \(\{U \exp(A) : A\text{ Hermitian}, \|A\|_F \leq R, U\text{ unitary}\}\). Note that the ball of radius \(\sqrt{n}R\) includes all elements of \(G\) whose singular values are in \([e^{-R}, e^R]\).

The existing algorithms to compute Equation (4) adapt simple first order methods, such as gradient descent, and second order methods, such as trust regions, to the geodesically convex setting [53, 2, 12]. As in the commutative case, to run in polynomial time such algorithms require that an \(\varepsilon\)-approximate solution is contained in a geodesic ball of radius \(\text{poly}(n^d, \log(1/\varepsilon))\). However, for 3-tensors we have the following diameter lower bound.

**Theorem 1.4 (Noncommutative diameter lower bound).** There is a constant \(C > 0\) such that the following holds. For all \(\varepsilon \leq \exp(-Cn^2 \log n)\), there is a tensor \(v = v(\varepsilon) \in (\mathbb{C}^n)^\otimes 3\) with \(O(n)\) nonzero entries of bit complexity \(O(\log n + \log(1/\varepsilon))\), and a geodesic ball \(B = B(\varepsilon)\) of radius \(\Omega(2^{n/3} \log(1/\varepsilon))\) about the identity in \(\text{SL}(n)^3\), such that

\[
\inf_{g \in B} \|g \cdot v\|^2 \geq \text{cap}(v) + \varepsilon.
\]

To emphasize that the difficulties are not caused by requiring additive approximation, we remark that the vector \(v\) satisfies \(1/4 \leq \text{cap}(v) \leq 1\) and \(1/2 \leq \|v\| \leq 1\). A duplication trick analogous to Corollary 3.7 yields the same diameter bound for \(d \geq 3\), but for the action of \(G\) simultaneously on a tuple of tensors rather than on a single one. See Corollary 4.24.

---

3 Moment polytope membership is an interesting problem in and of itself; for \(d = 3\), for generic \(v \in (\mathbb{C}^n)^\otimes 3\), \(\Delta_G(v)\) is the Kronecker polytope arising in representation theory and quantum information theory. Deciding membership in this polytope is known to be in \(\text{NP} \cap \text{coNP}\) but not known to be in \(\text{P}\) [10].

4 We define exponentials, Hermitian-ness, and Frobenius norm on tuples by treating them as block diagonal matrices.
Implications of Theorem 1.4 and relation to the literature

Theorem 1.4 shows that trust region methods with constant step size cannot \( \varepsilon \)-approximate the capacity in \( \text{poly}(n, 1/\varepsilon) \) time for 3-tensors. It also shows that cutting plane methods are unlikely to do so. Cutting plane methods, such as ellipsoid, require an exponential bound on the volume of a known region containing an approximate optimizer. This is the case for Rusciano’s non-constructive query upper bound for cutting plane methods on manifolds of non-positive curvature [47], which is essentially tight [32]. The volume of a ball in the manifold we consider grows exponentially in the radius (see Section 4.5), so this query bound will be exponential. Regarding tightness, the best upper bound known to the authors for the diameter bound in the noncommutative case is \( O(n(\sqrt{3}n)^{3+3\varepsilon} \log(1/\varepsilon)) \), which can be deduced from the diameter and margin bounds [12, Proposition 5.6, Theorem 6.10]. This matches our lower bound up to logarithmic factors in the exponent. As with Theorem 1.1, Theorem 1.4 holds only values of \( \varepsilon \) that are very small (though still of polynomial bit-complexity). It would be very interesting to prove a version of Theorem 1.1 for \( \varepsilon \) larger than the gap, which is \( \exp(-O(n)) \). This would imply that trust region methods cannot solve the null-cone problem for the 3-tensor action in polynomial time.

1.2.2 Gaps: the geometry of noncommutative scaling problems

In analogy to the commutative case, one typically attempts to certify \( \text{cap}(v) > 0 \), i.e. \( 0 \in \Delta_G(v) \), by finding a tensor \( g \cdot v \) such that all the quantum marginals are close to \( \frac{1}{n} I_n \). In order to certify \( \text{cap}(v) > 0 \) their distance to \( \frac{1}{n} (I_n, I_n, \ldots, I_n) \) must be at most a certain quantity, which we call the gap.

**Definition 1.5 (Gap).** The gap\(^6\) for the \( d \)-tensor scaling problem is

\[
\gamma_G(\pi_{n,d}) := \min \{ \text{dist} \ (0, \Delta_G(v)) \mid v \in (\mathbb{C}^n)^{\otimes d}, \ v \neq 0, \ 0 \notin \Delta_G(v) \}.
\]

If the gap is exponentially small, high-precision algorithms will be necessary to decide if \( \text{cap}(v) > 0 \). In operator scaling, the gap is known to be \( \Omega(n^{-3/2}) \) [29], which explains why we do not need high-precision algorithms for the decision problem in that case. In addition to its role in the decision problem, the inverse of the gap\(^7\) is used to control the diameter bound [12]. In that sense, the presence of a small gap can explain both the need for high precision algorithms and the slowness of existing high-precision algorithms. We show that, indeed, the tensor scaling action has an exponentially small gap for \( d \geq 3 \).

**Theorem 1.6.** There is a constant \( C > 0 \) such that for all \( d \geq 3 \) and \( n \geq 2 \), there are non-zero tensors \( v \in (\mathbb{C}^n)^{\otimes d} \) such that \( 0 \notin \Delta_G(v) \) but \( \text{dist}(0, \Delta_G(v)) \leq 2^{-Cdn} \). That is, the gap for \( d \)-tensor scaling satisfies

\[
\gamma_G(\pi_{n,d}) \leq 2^{-Cdn}.
\]

A detailed statement on bounds for the gap can be found in Theorem 4.11, and we show in Appendix C how to fill in the missing values of \( n, d \) to obtain Theorem 1.6. Since the gap is larger than the margin (c.f. Proposition 4.6), Theorem 1.6 is at least as tight as Theorem 1.3, i.e. the exponent \( Cnd \) is tight up to an \( O(\log n + \log d) \) factor.

---

\( ^6 \) [32] applies to the hyperbolic plane, which is a totally geodesic submanifold of the manifold \( P \) we consider.

\( ^7 \) This notion can be defined similarly for any rational representation \( \pi \) of a reductive group \( G \), see Definition 4.3. This definition of the gap is already described in [12].

actually, a smaller quantity known as weight margin.
Interestingly, for local dimension $n = 2$ [42, Main result] shows that $\text{dist}(0, \Delta_G(v))^2$ for some moment polytope $\Delta_G(v) \neq 0$ tends for $d \to \infty$ to the Gamma distribution $\Gamma(1/2, 2d)$, where $2d$ is the rate parameter. Therefore, the witnesses of the exponential behaviour in Theorem 4.11(a) are quite rare. Moreover, the authors numerically found several tensors of format $(\mathbb{C}^2)^{\otimes d}$ with $\text{dist}(0, \Delta_G(v))$ at most $\exp(-d)$; Theorem 1.6 confirms that this exponential behavior is the case for all $n$ and $d$.

**Margin and gap results for other group actions**

In addition to the tensor scaling action, we also consider some other actions of groups $G$ of interest in computational invariant theory. The first is the action of the special linear group on the space of homogeneous $d$-forms $\mathbb{C}[x_1, \ldots, x_n]_d$, in which $G = \text{SL}(n)$ acts by $g \cdot p(x) = p(g^{-1}x)$ for $p \in \mathbb{C}[x_1, \ldots, x_n]_d$. Homogeneous $d$-forms were among the objects studied earliest in computational invariant theory, and much of the theory was developed to catalogue invariants of the $\text{SL}(n)$ action on forms [52]. Still, deciding null-cone membership for $d = 3$ seems challenging. After extending the definition of the gap to other group actions in Section 4, we explain the difficulty by showing that the gap for this action is also inverse exponential in $n$ as soon as $d \geq 3$, see Theorem 4.17. This shows that the diameter bound in [12] becomes exponentially large in $n$.

The other group action we consider is the action of $\text{SL}(n)^d$ on *quivers* with $d$ vertices. A quiver is a directed multigraph, and a quiver representation is a labelling of the vertex set $Q_0$ of the quiver with finite-dimensional vector spaces and the edge set $Q_1$ with a linear map from the vector space at the tail of the edge to the vector space at the head of the edge. Given a quiver representation $A$ with vertices labeled by $\mathbb{C}^{n_A}$ for $x \in Q_0$ and edges $e : x \to y$ labeled with matrices $A_e$, the group $G = \prod_{x \in Q_0} \text{SL}(n_x)$ acts on $A$ by $(g \cdot A)_e = g_y A g_x^{-1}$. Quiver representations include the operator scaling action, and an action used to bound the Brascamp-Lieb constant in analysis. In Section 4.6 we show that the (weight) margin can become exponentially small as the number of vertices grows. For this, we exhibit a quiver with $d - 1$ arrows, $d$ vertices of dimension $n$ and weight margin $O(n^{-d})$, see Theorem 4.25. This bound shows that the diameter bound computed in [12] can become exponentially large in $d$. Furthermore, when allowing $n$ copies of each arrow in the constructed quiver, i.e. $n(d - 1)$ arrows in total, we can ensure the same bound for the gap, Theorem 4.25.

### 1.2.3 Proof technique in the noncommutative case: Freeness

Regarding the idea of the proof, we may transfer both the diameter lower bound and the gap upper bound to the commutative case by virtue of the tensors we construct having free support.

A tensor has free support if any two distinct $(d - 1)$-dimensional slices of the tensor have disjoint support. This condition ensures that, even after being acted on by any diagonal group elements, the tensor’s quantum marginals are all diagonal. This allows us to restrict to the action of the diagonal matrices and thereby reduce to the commutative (array scaling) case. Thus, we may obtain the same bounds on the tensor gap as for the array margin. However, this requires additional care to ensure freeness of our constructions. This is why we cannot naively use the construction of [4] for $d$-tensors with $n = 2$. Regarding the noncommutative diameter bound, we show that for tensors with free support the diameter bound matches that of the commutative problem obtained by restricting to the diagonal. To do this, we project the group elements to the set of diagonal elements, and use the properties of spaces of non-positive curvature to show that this projection moves the point nearer to the origin and decreases the function value.
The idea and the concept of freeness generalize to rational representations of reductive groups \[24\]. The key statement is given in full generality in Proposition 4.8. This proposition is needed to prove bounds on the gap for the action on homogeneous polynomials and for the action on quivers. Interestingly, in [21] the concept of freeness is used in a similar way to prove exponential lower bounds on the degree of invariants for actions on cubic forms and 3-tensors. There, free is called uncramped and it is used crucially to prove closedness of certain orbits.

Freeness also played a role in the numerical results by Sawicki and Maciążek, which were obtained by applying the algorithm of [41] to several free tensors of local dimension two.

1.3 Organization of the paper

We begin with the commutative case, which is split into the study of the margin in Section 2 and diameter bounds in Section 3. Then we move to the noncommutative case in Section 4. The appendix contains some representation-theoretic background and proofs of technical lemmas, as well as a glossary of notation.

2 The geometry of commutative scaling problems

The purpose of this section is to show the following theorem on the margin of \(\Omega_{n,d}\)-dimensional array scaling. Recall that the latter arises for \(\Omega_{n,d}\):

\[
\begin{align*}
\Omega_{n,d} & := \{ \epsilon_i : i \in [n] \}^d \subseteq (\mathbb{R}^n)^d. \\
\end{align*}
\]

\(\textbf{Theorem 2.1 (Margin for array scaling).} \) The margin of \(\Omega_{n,d} \subseteq (\mathbb{R}^n)^d\) is bounded as follows.

(a) If \(n = 2\) and \(d \geq 3\), then \(\gamma(\Omega_{2,d}) \leq 2^{-\frac{d}{2}+1}\).

(b) If \(n \geq 3\) and \(d = 3\), then \(\gamma(\Omega_{n,3}) \leq 2^{-n+1}\).

(c) If \(n \geq 3\) and \(d = 6r - 3\) for some integer \(r \geq 2\), then

\[
\gamma(\Omega_{n,d}) \leq \frac{\sqrt{6}}{(n - 1)\sqrt{2}} 2^{-r(n-1)+1} \leq 2^{-r(n-1)+1} = 2^{-\frac{(d+3)(n-1)}{6}+1}. 
\]

By “padding” the tensors appropriately, one sees that a bound for \(\gamma(\Omega_{n,d})\) also applies to \(\gamma(\Omega_{n,d+1})\) (see Proposition C.1). Combining this result with Theorem 2.1 above implies Theorem 1.3 from the introduction. The next three subsections each prove one of the parts of Theorem 2.1; the construction for part (a) with \(n = 2\) is slightly different and the construction for part (c), \(d > 3\) builds on the one for part (b), \(d = 3\).

To prove the results, we will frequently use the following simple lemma. Recall that an \textit{affine linear combination} of \(v_1, \ldots, v_k \in \mathbb{R}^n\) is \(\lambda_1 v_1 + \cdots + \lambda_k v_k\) for \(\lambda_i \geq 0, \sum_{i=1}^{k} \lambda_i = 1\). The affine hull \(\text{Aff}(S)\) of a set \(S \subset \mathbb{R}^n\) is the set of all affine linear combinations of finite subsets of \(S\), or equivalently the affine space (i.e. translate of a subspace) of lowest dimension containing \(S\).

\(\textbf{Lemma 2.2.} \) In \(\mathbb{R}^n\) we have

\[
\sum_{i=1}^{n} \frac{1}{n} \epsilon_i = 0_n 
\]

and this is the only affine linear combination of \(\epsilon_1, \ldots, \epsilon_n\) giving zero.

---

\(8\) This concept is also implicitly contained in [49, Lemma 7.1] and can at least be traced back to [18] as strong orthogonality.

\(9\) Indeed, [21, Theorem 6.5] is used to show the vanishing of the moment map at a vector. First, freeness is used as in Proposition 4.8 to ensure that one can restrict to the moment map for the maximal torus. Second, condition (2) of [21, Theorem 6.5] just states that the moment map for the torus action vanishes at the vector.
where will correspond to an element of \( \Gamma A \) of \( p \). In the following we construct a subset of exponentially small in \( p \).

In this subsection we prove part (a) of Theorem 2.1 by showing that the margin of 2.1 Local dimension two: the hypercube

Proof. One calculates directly that \( \sum_{i} \frac{1}{n} \varepsilon_i = 0 \). To show uniqueness of this affine combination, we note that the vectors \( e_2, \ldots, e_n, \mathbb{1}_n \) are linearly independent. Thus, \( \varepsilon_2, \ldots, \varepsilon_n \) are linearly independent. On the other hand, \( \varepsilon_1, \ldots, \varepsilon_n \) are linearly dependent. Therefore \( (\lambda_1, \ldots, \lambda_n) \in \mathbb{R}^n \mid \sum \lambda_i \varepsilon_i = 0 \) is a one-dimensional subspace of \( \mathbb{R}^n \), which yields the uniqueness of the affine linear combination.

\[ \Omega_{2,d} = \{ (\varepsilon_1, \ldots, \varepsilon_i) \mid i_1, \ldots, i_d \in [2] \} \subseteq (\mathbb{R}^2)^d. \]

In the following we construct a subset of \( \Omega_{2,d} \), which witnesses the exponentially small margin. For this, we construct a matrix with entries in \( [2] \), and each row of the matrix will correspond to an element of \( \Omega_{2,d} \). For example, the row \((1, 2, 2)\) would correspond to \((\varepsilon_1, \varepsilon_2, \varepsilon_2) \in \Omega_{2,3} \). To do so, we begin with the matrices

\[ A_2 := \begin{pmatrix} 1 & 1 \\ 2 & 1 \end{pmatrix}, B_1 := \begin{pmatrix} 1 & 1 \\ 2 & 2 \end{pmatrix}, B_2 := \begin{pmatrix} 1 & 2 \\ 2 & 2 \end{pmatrix}, B_3 := \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}, \]

and define recursively

\[ A_{2r+2} := \begin{pmatrix} A_2 & B_1 \\ \vdots & \vdots \\ B_2 & B_3 \\ A_{2r} \\ B_1 \\ B_2 & B_3 \end{pmatrix}, \]

for \( r \geq 1 \). Figure 1 is supplied as a visualization aid.

We remark that the entry of \( A_{2r} \) at position \((i, j)\) is independent of \( r \) and denote it by \( a(i,j) \). We set for \( r \geq 1 \)

\[ \Gamma_{2,2r} := \{ (\varepsilon_{a(i,1)}, \varepsilon_{a(i,2)}, \ldots, \varepsilon_{a(i,2r)}) \mid i \in [2r] \} \subseteq \Omega(\pi_{2,2r}) \subseteq (\mathbb{R}^2)^{2r}, \]

\[ \Gamma_{2,2r+1} := \{ (\varepsilon_{a(i,1)}, \varepsilon_{a(i,2)}, \ldots, \varepsilon_{a(i,2r)}, \varepsilon_{\chi(i)}) \mid i \in [2r] \} \subseteq \Omega(\pi_{2,2r+1}) \subseteq (\mathbb{R}^2)^{2r+1}, \]

where \( \chi : \mathbb{N} \rightarrow \{1, 2\}, i \mapsto i \mod 2 \). That is, \( \Gamma_{2,2r} \) is the subset of \( \Omega_{2,2r} \) induced by the rows of \( A_{2r} \), and \( \Gamma_{2,2r+1} \) is obtained by alternatingly appending \( \varepsilon_1 \) or \( \varepsilon_2 \) to the \( 2r \)-many elements of \( \Gamma_{2,2r} \).
Lemma 2.3. For \( r \geq 1 \) it holds that \( 0 \notin \operatorname{Aff}(\Gamma_{2,2r}) \) and \( 0 \notin \operatorname{Aff}(\Gamma_{2,2r+1}) \).

Proof. By construction, \( 0 \in \operatorname{Aff}(\Gamma_{2,2r+1}) \) implies \( 0 \in \operatorname{Aff}(\Gamma_{2,2r}) \), so it suffices to prove \( 0 \notin \operatorname{Aff}(\Gamma_{2,2r}) \). We proceed by induction on \( r \geq 1 \). For \( r = 1 \), it is clear that \( 0 \notin \operatorname{Aff}(\Gamma_{2,2}) \subseteq \mathbb{R}^2 \times \{1\} \). Now assume that \( 0 \notin \operatorname{Aff}(\Gamma_{2,2r}) \). For the sake of contradiction, let

\[
\sum_{i=2}^{2r+2} \lambda_i (\varepsilon_{a(i,1)}, \varepsilon_{a(i,2)}, \ldots, \varepsilon_{a(i,2r+2)}) = 0 \in (\mathbb{R}^2)^{2r+2} \tag{7}
\]

be an affine linear combination of \( \Gamma_{2,2r+2} \). Then equation (7) gives in each of the \((2r+2)\)-many \( \mathbb{R}^2 \)-components the affine linear combination \( 2^{-1}(\varepsilon_1 + \varepsilon_2) = 0 \), by Lemma 2.2. Considering the scalar factor of \( \varepsilon_1 \) in the first, the penultimate and the last \( \mathbb{R}^2 \)-component respectively, we conclude

\[
\begin{align*}
\sum_{j=1}^{r+1} \lambda_{2j-1} &= \frac{1}{2} = \lambda_{2r+2} + \sum_{j=1}^{r} \lambda_{2j-1} = \frac{1}{2} = \lambda_{2r+2} + \sum_{j=1}^{r+1} \lambda_{2j-1} \\
&= \text{first} = \text{penultimate} = \text{last}
\end{align*}
\]

by construction of \( A_{2r+2} \). Hence, \( \lambda_{2r+2} = 0 \) using the first and last component. Furthermore, the first and penultimate column give \( \lambda_{2r+1} = \lambda_{2r+2} = 0 \). Therefore, the first \( 2r \)-many components in Equation (7) show \( 0 \in \operatorname{Aff}(\Gamma_{2,2r}) \), which contradicts our induction hypothesis.

Lemma 2.4. For \( r \geq 1 \) it holds that \( \operatorname{dist}(0, \operatorname{conv}(\Gamma_{2,2r})) \leq 2^{-r+\frac{1}{2}} \) and

\[
\operatorname{dist}(0, \operatorname{conv}(\Gamma_{2,2r+1})) \leq 2^{-r+\frac{1}{2}}.
\]

Proof. We first prove the inequality for \( \operatorname{conv}(\Gamma_{2,2r}) \). For \( i \in [2r] \) let \( \omega_i := (\varepsilon_{a(i,1)}, \ldots, \varepsilon_{a(i,2r)}) \in (\mathbb{R}^2)^{2r} \) be the weight in \( \Gamma_{2,2r} \) that corresponds to the \( i \)-th row of \( A_{2r} \). Consider the convex combination

\[
(x_1, \ldots, x_{2r}) := 2^{-r}(\omega_{r-1} + \omega_{r}) + \sum_{l=1}^{r-1} 2^{-l-1}(\omega_{2l-1} + \omega_{2l}) \in (\mathbb{R}^2)^{2r}. \tag{8}
\]

Note that \( x_i \in \mathbb{R}^2 \). We will argue that \( (x_1, \ldots, x_{2r}) = 2^{-r+1}(0_2, \ldots, 0_2, \varepsilon_1) \). Since \( x \) is a convex combination of the elements in \( \Gamma_{2,2r} \), the statement then follows from \( \|\varepsilon_1\| = \sqrt{2}^{-1} \).

We consider \( A_{2r} \), like in its construction (6) as a \( r \times r \) block matrix with block entries being \( 2 \times 2 \) matrices. For \( m \in [r] \) the two weights \( \omega_{2m-1} \) and \( \omega_{2m} \) correspond to the \( m \)-th block row of \( A_{2r} \) and have the same scalar factor in (8). Hence, whenever for \( i \in [2r] \) the \( i \)-th component of the \( m \)-th block row of \( A_{2r} \) contains exactly one entry equal to one (and so the other entry equals two), then the contribution of \( \omega_{2m-1} \) and \( \omega_{2m} \) to \( x_i \) cancels due to \( \varepsilon_1 + \varepsilon_2 = 0_2 \). In particular, in (8) all contributions of block entries equal to \( B_1 \) cancel. Therefore the last column of \( A_{2r} \) gives

\[
x_{2r} = 2^{-r}(\varepsilon_1 + \varepsilon_1) = 2^{-r+1}\varepsilon_1.
\]

Furthermore, \( x_1 = x_3 = \ldots = x_{2r-1} = 0_2 \) using that also the first columns of \( A_2 \), of \( B_2 \) and of \( B_3 \) contain exactly one entry equal to one. For \( r = 1 \) we are done. If \( r \geq 2 \), then reading off the second column of \( A_{2r} \), we find

\[
x_2 = 2^{-2}(\varepsilon_1 + \varepsilon_1) + 2^{-r}(\varepsilon_2 + \varepsilon_2) + \sum_{l=2}^{r-1} 2^{-l-1}(\varepsilon_2 + \varepsilon_2) = 2^{-2}(\varepsilon_1 + \varepsilon_2) = 0_2.
\]

\[\text{first block row} \quad \text{last block row} \quad \text{middle rows}\]
Analogously, as $B_1$ does not contribute we compute for $j = 2, 3, \ldots, r - 1$ that
\[
x_{2j} = 2^{-j-1}(\varepsilon_1 + \varepsilon_1) + 2^{-r}(\varepsilon_2 + \varepsilon_2) + \sum_{t=j+1}^{r-1} 2^{-t-1}(\varepsilon_2 + \varepsilon_2) = 2^{-j}(\varepsilon_1 + \varepsilon_2) = 0_2,
\]
because the second columns of $B_2$ and $B_3$ are, respectively, $(2, 2)^T$ and $(1, 1)^T$. This proves the inequality in the case $\Gamma_{2, 2r}$.

By construction, for $\Gamma_{2, 2r+1}$ the same convex combination works, because the last $\mathbb{R}^2$-component does not contribute as the entries of the weights alternate between $\varepsilon_1$ and $\varepsilon_2$. ◀

Finally, Lemma 2.3 and Lemma 2.4 together yield Theorem 2.1(a), noting that for odd $d = 2r + 1$ one has $-r + 1/2 = -(d/2) + 1$.

### 2.2 3-tensors

The main goal of this section is to show that the margin of $\Omega_{n,3}$ is exponentially small in $n$, i.e. to show Theorem 2.1(b). To do so, we set
\[
\mathcal{M}_n := \bigcup_{s=2}^{n} \{(s, 1, s), (s, s, 1), (s - 1, s, s)\} \subseteq [n] \times [n] \times [n]
\]
and consider the corresponding subset
\[
\Gamma_{n,3} := \{(\varepsilon_i, \varepsilon_j, \varepsilon_k) \mid (i, j, k) \in \mathcal{M}_n\} \subseteq \Omega_{n,3}.
\]  
The key combinatorial idea, which is presented in the following lemma, is due to [38, Theorem 1 with $k = 0$]. According to [38] the special case $k = 0$ is already contained in [37, Theorem 9].

**Lemma 2.5.** Let $n \geq 3$. For $(i, j, k) \in [n]^3 \setminus (\mathcal{M}_n \cup \{(1, 1, 1)\})$ set $\lambda_{i,j,k} := 0$. Moreover, define
\[
\lambda_{1,1,1} := 2^{-n+1}, \quad \lambda_{1,2,2} := 1 - 2^{-n+1}, \quad \lambda_{n,1,n} = \lambda_{n,n,1} := 2^{-1}
\]
and for $s = 2, 3, \ldots, n - 1$
\[
\lambda_{s,1,s} = \lambda_{s,s,1} := 2^{-n+s-1}, \quad \lambda_{s,s+1,s+1} := 1 - 2^{-n+s}.
\]

Then the following equations hold:
\[
\left( \forall i \in [n] : \sum_{j,k=1}^{n} \lambda_{i,j,k} = 1 \right), \quad \left( \forall j \in [n] : \sum_{i,k=1}^{n} \lambda_{i,j,k} = 1 \right), \quad \left( \forall k \in [n] : \sum_{i,j=1}^{n} \lambda_{i,j,k} = 1 \right).
\]
In particular, $\sum_{i,j,k} \lambda_{i,j,k} = n$.

**Proof.** This is [38, Theorem 1 with $k = 0$]. Alternatively, the statement can be checked by straightforward computation. ◀
Example 2.6. To visualize Lemma 2.5 it is helpful to consider the slices $\Lambda_i$ given by $(\Lambda_i)_{j,k} = \lambda_{i,j,k}$. For $n = 4$ one has

$$\Lambda_1 = \frac{1}{8} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 7 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad \Lambda_2 = \frac{1}{8} \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

$$\Lambda_3 = \frac{1}{8} \begin{pmatrix} 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 0 \\ 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 4 \end{pmatrix}, \quad \Lambda_4 = \frac{1}{8} \begin{pmatrix} 0 & 0 & 0 & 4 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 4 & 0 & 0 & 0 \end{pmatrix}.$$

For $n = 5$ one has

$$\Lambda_1 = \frac{1}{16} \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 15 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}, \quad \Lambda_2 = \frac{1}{16} \begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix},$$

$$\Lambda_3 = \frac{1}{16} \begin{pmatrix} 0 & 0 & 2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 2 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 12 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}, \quad \Lambda_4 = \frac{1}{16} \begin{pmatrix} 0 & 0 & 0 & 4 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 4 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 8 \end{pmatrix}, \quad \Lambda_5 = \frac{1}{16} \begin{pmatrix} 0 & 0 & 0 & 0 & 8 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 8 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

Lemma 2.7. For $n \geq 3$, it holds that $\text{dist} \left(0, \text{conv}(\Gamma_{n,3})\right) \leq 2^{-n+1}$.

Proof. Define $\lambda_{i,j,k} \geq 0$ for all $i,j,k \in [n]$ as in Lemma 2.5. Note that $\sum_{i=1}^{n} \xi_i = 0$; thus Lemma 2.5 implies

$$\sum_{i,j,k} \lambda_{i,j,k}(\xi_i, \xi_j, \xi_k) = 0_{3n}, \quad \text{equivalently} \quad -2^{-n+1}(\xi_1, \xi_1, \xi_1) = \sum_{(i,j,k) \in 2^n} \lambda_{i,j,k}(\xi_i, \xi_j, \xi_k).$$

Normalizing the latter equation we obtain

$$x := -\frac{1}{c 2^{n-1}}(\xi_1, \xi_1, \xi_1) \in \text{conv}(\Gamma_{n,3}), \quad \text{where} \quad c := \sum_{(i,j,k) \in 2^n} \lambda_{i,j,k} = n - 2^{-n+1} \geq \sqrt{3}.$$

Finally, $\|\xi_1\|^2 \leq 1$ implies $\|x\| \leq c^{-1}2^{-n+1}\sqrt{3} \leq 2^{-n+1}$.

To finish the proof of Theorem 2.1(b) we are left to show $0 \not\in \text{conv}(\Gamma_{n,3})$. We actually prove the stronger statement $0 \not\in \text{Aff}(\Gamma_{n,3}).$

Lemma 2.8. The zero vector is not contained in the affine hull of $\Gamma_{n,3}$.

Proof. For a proof by contradiction we assume $0 \in \text{Aff}(\Gamma_{n,3})$. Then there exist $a_s, b_s, c_s \in \mathbb{R}$ for $s = 2, 3, \ldots, n$ such that $\sum a_s + b_s + c_s = 1$ and

$$\sum_{s=2}^{n} \left( a_s(\xi_s, \xi_s, \xi_s) + b_s(\xi_s, \xi_s, \xi_1) + c_s(\xi_{s-1}, \xi_s, \xi_s) \right) = (0_n, 0_n, 0_n) \in (\mathbb{R}^n)^3.$$

In each of the three $\mathbb{R}^n$-components we obtain $0_n$ as an affine linear combination of $\xi_1, \ldots, \xi_n$. Applying Lemma 2.2 to the coefficient of $\xi_{s-1}$ in the first component, respectively to the coefficient of $\xi_s$ in the second and third component yields

$$a_{s-1} + b_{s-1} + c_s = \frac{1}{n} \quad \text{for} \quad s = 2, 3, \ldots, n \quad (12)$$

respectively

$$b_s + c_s = a_s + c_s = \frac{1}{n} \quad \text{for} \quad s = 2, 3, \ldots, n \quad (13)$$
where we necessarily set \( a_1 = b_1 = 0 \). Equation (12) for \( s = 2 \) is \( c_2 = n^{-1} \) and hence \( a_2 = b_2 = 0 \) by (13) for \( s = 2 \). But now (12) for \( s = 3 \) gives \( c_3 = n^{-1} \) and we can proceed inductively to conclude \( c_s = n^{-1} \) and \( a_s = b_s = 0 \) for all \( s = 2, 3, \ldots, n \). This gives the contradiction \( 1 = \sum_{s=2}^{n}(a_s + b_s + c_s) = \frac{n-1}{n} \), so we must have \( 0 \notin \text{Aff}(\Gamma_{n,3}) \). Another contradiction arises when one applies Lemma 2.2 to the coefficient \( \varepsilon_n \) in the first component, which yields \( a_n + b_n = n^{-1} \).

2.3 \( d \)-tensors

In this subsection we show that the margin of \( \Omega_{n,d} \) is inverse exponential in \( nd \) for \( n, d \geq 3 \), proving part (c) of Theorem 2.1.

Let us give some intuition for our construction. The main idea is to recycle the construction from the previous subsection for some multiple of \( n \), i.e. considering \( \mathbb{M}_m \) for \( r \geq 2 \). Thereby, the main challenge is to ensure that the constructed subset of \( \Omega_{n,d} \) does not contain zero in its convex hull. We can try to extend the elements of \( \Omega_{n,3} \) to elements of \( \Omega_{n,d} \). One natural idea is duplicate each component \( d/3 \) times, i.e. when \( d = 6 \) the vector \((\varepsilon_i, \varepsilon_j, \varepsilon_k) \in \Omega_{n,3} \) becomes \((\varepsilon_i, \varepsilon_i, \varepsilon_j, \varepsilon_j, \varepsilon_k, \varepsilon_k) \in \Omega_{n,6} \). However, we need a subset of \( \Omega_{n,d} \) with \( rn \) many elements to imitate the construction from the previous subsection. We still extend the elements of \( \Omega_{n,3} \) in this way, but will additionally “shift” and “twist” by some functions \( \sigma_1, \ldots, \sigma_{2r-1} : [rn] \to [n], \) so that the elements of our set will look like

\[
\left( \varepsilon_{\sigma_1(i)}, \ldots, \varepsilon_{\sigma_{d/3}(i)} \right) \in [n]
\]

for \( d/3 = 2r - 1 \) and \((i, j, k) \in \mathbb{M}_m \). We now set about choosing the functions \( \sigma_k \). For this, let \( n \geq 3 \) and fix a natural number \( r \geq 2 \). It is convenient to use an adjusted modulo \( n \) function \( \mathcal{M} \) that takes values in \([n]\), i.e. instead of zero it outputs \( n \). For \( i \in [r] \) we consider

\[
\sigma_i : [rn] \to [n], \quad j \mapsto \left[ \frac{j + (i - 1)}{r} \right] \quad \mathcal{M}
\]

\[
\sigma_{r+1} := \sigma_1 \circ (r - i + 1) \circ (r + 1) : [rn] \to [n]
\]

where \((r - i + 1) \circ (r + 1) \) denotes the corresponding transposition in the symmetric group of \([rn]\).\(^{11}\) We only need the first \( 2r - 1 \) of these functions and combine them to obtain

\[
\sigma : [rn] \to [n]^{2r-1}, \quad j \mapsto (\sigma_1(j), \sigma_2(j), \ldots, \sigma_{2r-1}(j)).
\]

\[\text{Example 2.9. For } r = 3 \text{ the functions } \sigma_1, \sigma_2, \ldots, \sigma_6 \text{ are sketched by the following table.}\]

\[
\begin{array}{|c|c|c|c|c|c|c|c|c|c|c|}
\hline
j & 1 & 2 & 3 & 4 & 5 & 6 & \cdots & 3n-5 & 3n-4 & 3n-3 & 3n-2 & 3n-1 & 3n \\
\hline
\sigma_1 & 1 & 1 & 1 & 2 & 2 & 2 & \cdots & n-1 & n-1 & n-1 & n & n & n \\
\sigma_2 & 1 & 1 & 2 & 2 & 2 & 3 & \cdots & n-1 & n-1 & n & n & n & 1 \\
\sigma_3 & 1 & 2 & 2 & 2 & 2 & 3 & 3 & \cdots & n-1 & n & n & n & 1 & 1 \\
\sigma_4 & 1 & 1 & 2 & 1 & 2 & 2 & \cdots & n-1 & n-1 & n-1 & n & n & n \\
\sigma_5 & 1 & 2 & 1 & 1 & 2 & 2 & \cdots & n-1 & n-1 & n-1 & n & n & n \\
\sigma_6 & 2 & 1 & 1 & 1 & 2 & 2 & \cdots & n-1 & n-1 & n-1 & n & n & n \\
\hline
\end{array}
\]

For \( r = 3 \) and \( n = 5 \) the functions \( \sigma_1, \sigma_2, \ldots, \sigma_6 \) are given by the following table.

\[\text{We stress that we always take } \sigma_1 \text{ (and not } \sigma_i \text{) to define } \sigma_{r+1}.\]

\[^{11}\text{We stress that we always take } \sigma_1 \text{ (and not } \sigma_i \text{) to define } \sigma_{r+1}.\]
### Remark 2.10.
By construction, each element of $[n]$ is attained exactly $r$-times by $\sigma_k$, $k \in [2r - 1]$. Moreover, the definition of $\sigma_1, \ldots, \sigma_r$ yields that $\sigma$ is injective.

For $i, j, k \in [rn]$ we introduce the short-hand

$$
\epsilon_{\sigma(i), \sigma(j), \sigma(k)} := (\epsilon_{\sigma_1(i), \epsilon_{\sigma_2(i)}, \ldots, \epsilon_{\sigma_{2r-1}(i)}) \in (\mathbb{R}^n)^{2r-1}.
$$

and we set

$$
\Omega_{n,6r-3} := \{ (s,1,s), (s,s,1) \mid s = 2, 3, \ldots, r \} \subseteq \mathbb{Z}.
$$

In the following we show that the convex hull of the set

$$
\Gamma_{n,6r-3} = \{ \epsilon_{\sigma(i), \sigma(j), \sigma(k)} \mid (i,j,k) \in \mathcal{M}_{rn} \backslash \Omega \} \subseteq \mathbb{R}^{n,6r-3} \subseteq \left( \mathbb{R}^n \right)^{2r-1} \right)^3
$$

does not contain the zero vector, but is very close to it.

### Lemma 2.11.
For $n \geq 3$ and $r \geq 2$ it holds that $0 \notin \text{Aff} \left( \Gamma_{n,6r-3} \right)$.

Below we give the proof in the special case $r = 3$, in which all main ideas of the general proof become apparent and visible. The proof for the general statement is given in Appendix D and certainly looks technical at a first encounter. Therefore, we strongly suggest that the reader first reads the proof for $r = 3$ below.

#### Proof of Lemma 2.11 for $r = 3$.
For the sake of contradiction assume that $0 \in \text{Aff}(\Gamma_{n,15})$. Then there are coefficients $a_s, b_s, c_s \in \mathbb{R}$, where $2 \leq s \leq 3n$, such that $a_2 = a_3 = b_2 = b_3 = 0$, $\sum_s (a_s + b_s + c_s) = 1$ and

$$
\sum_{s=2}^{3n} \left( a_s \epsilon_{\sigma(s), \sigma(1), \sigma(s)} + b_s \epsilon_{\sigma(s), \sigma(s), \sigma(1)} + c_s \epsilon_{\sigma(s-1), \sigma(s), \sigma(s)} \right) = 0 \in \mathbb{R}^{n,15}.
$$

The bulk of our work will consist of proving the equations

$$
b_2 + c_2 = b_3 + c_3 = \ldots = b_{3n} + c_{3n} \quad (15)
$$

$$
a_2 + c_2 = a_3 + c_3 = \ldots = a_{3n} + c_{3n} \quad (16).
$$

\[12\] One could suggest to consider the set $\{ \epsilon_{\sigma(i), \sigma(j), \sigma(k)} \mid (i,j,k) \in \mathcal{M}_{rn} \}$, but this still won’t ensure that zero is not in the convex hull. The intuition behind is, that $\Gamma_{n,3}$ from the last section is “nearly at the limit”, i.e. $0 \notin \text{conv}(\Gamma_{n,3})$ but $0 \in \text{conv}(\Gamma_{n,3} \cup \{ (\sigma_2, \sigma_1, \sigma_1) \})$. Now the function $\sigma$ “introduces $2r - 2$ additional linear relations” as $\epsilon_{\sigma(i)} \in (\mathbb{R}^n)^{2r-1}$, since the orthogonal complement $\mathbb{R}^n \perp \Gamma_{n,3}$ has codimension one while $\mathbb{R}^{n,2r-1} \subseteq (\mathbb{R}^n)^{2r-1}$ has codimension $2r - 1$. Thus, it is reasonable to remove $2r - 2$ many elements from $\mathcal{M}_{rn}$.\n

</table>
From here we will derive a contradiction. We now set about proving Equations (15) and (16).

Rewrite the left-hand-side of Equation (14) as the collection for \( k \in [5] \) of the following affine linear combinations of \( \varepsilon_1, \ldots, \varepsilon_n \) in \( \mathbb{R}^n \):

\[
\sum_{s=2}^{3n} \left( a_s \varepsilon_{s_k(s)} + b_s \varepsilon_{s_k(s-1)} + c_s \varepsilon_{s_k(s-1)} \right) = 0 \quad (17)
\]

\[
\sum_{s=2}^{3n} \left( a_s \varepsilon_{s_k(1)} + b_s \varepsilon_{s_k(s)} + c_s \varepsilon_{s_k(s)} \right) = 0 \quad (18)
\]

\[
\sum_{s=2}^{3n} \left( a_s \varepsilon_{s_k(s)} + b_s \varepsilon_{s_k(1)} + c_s \varepsilon_{s_k(s)} \right) = 0. \quad (19)
\]

If we expand each expression as an affine linear combination of the \( \varepsilon_l \), then by Lemma 2.2 the coefficient of \( \varepsilon_l \) must be \( n^{-1} \) for all \( l \in [n] \). Translating this for equation (17) with \( k = 2, l = 2, \ldots, n \) and using Example 2.9 we obtain

\[
(a_{m-3} + a_{m-2} + a_{m-1}) + (b_{m-3} + b_{m-2} + b_{m-1}) + (c_{m-3} + c_{m-1} + c_m) = \frac{1}{n} \quad (20)
\]

for \( m = 6, 9, 12, \ldots, 3n \). A similar calculation for \( k = 1, 3 \) and \( l = 2, \ldots, n \) shows Equation (20) holds for all \( 5 \leq m \leq 3n + 1 \), where we set \( c_{3n+1} := 0 \).

Similarly for Equation (18) with \( l = 2, \ldots, n \) and \( k = 1, 2, 3 \) we obtain for \( 4 \leq m \leq 3n \) that

\[
(b_{m-2} + c_{m-2}) + (b_{m-1} + c_{m-1}) + (b_m + c_m) = \frac{1}{n} \quad (21)
\]

and the same equations with “\( b \)” replaced by “\( a \)” when considering Equation (19).

In the following we prove Equation (15). Subtracting (21) from (21) with values of \( m \) differing by one, we deduce that

\[
\begin{align*}
\frac{1}{n} + b_2 + c_2 &= b_5 + c_5 = \ldots = b_{3n-1} + c_{3n-1} \\
\frac{1}{n} + b_3 + c_3 &= b_6 + c_6 = \ldots = b_{3n} + c_{3n}, \quad \text{and} \\
\frac{1}{n} + b_4 + c_4 &= b_7 + c_7 = \ldots = b_{3n-2} + c_{3n-2}.
\end{align*}
\]

Next we deduce Equation (15) by showing \( b_2 + c_2 = b_3 + c_3 = b_4 + c_4 \).

To do so, we apply Lemma 2.2 to (18) for the coefficient of \( \varepsilon_2 \) using Example 2.9, which yields for \( k = 4, 5 \) the equations

\[
(b_3 + c_3) + (b_5 + c_5) + (b_6 + c_6) = \frac{1}{n} \quad (22)
\]

\[
(b_2 + c_2) + (b_5 + c_5) + (b_6 + c_6) = \frac{1}{n} \quad (23)
\]

respectively. Subtracting the two shows \( b_2 + c_2 = b_3 + c_3 \), and we have \( b_3 + c_3 = b_4 + c_4 \) via subtracting (22) from (21) for \( m = 6 \). This completes the proof of Equation (15); using Equation (19) we similarly deduce Equation (16).

To get a contradiction we show that \( a_s = b_s = c_s = 0 \) for all \( s = 2, 3, \ldots, 3n \). For this, we set \( a := \sum_s a_s \) and \( b := \sum_s b_s \), and recall that we have defined \( a_2 = a_3 = b_2 = b_3 = 0 \).

This time we use Lemma 2.2 applied to the coefficient of \( \varepsilon_1 \) in (17), (18) and (19) respectively for \( k = 1 \) to get

\[
c_2 + c_3 + c_4 = \frac{1}{n}, \quad \frac{1}{n} + a + c_2 + c_3 = \frac{1}{n} \quad \text{and} \quad \frac{1}{n} + b + c_2 + c_3 = \frac{1}{n} \quad (24)
\]
respectively. We deduce from these three equations that \( a = b = c_4 \). Furthermore, \( b_2 = b_3 = 0 \) shows that (21) for \( m = 4 \) is \( b_4 + (c_2 + c_3 + c_4) = n^{-1} \). Subtracting from the latter the left-hand equation in (24) yields \( b_4 = 0 \). Similarly, \( a_4 = 0 \) follows from \( a_2 = a_3 = 0 \) and the analogous equation of (21) with \( a \)'s replaced by \( b \)'s.

Now, (20) for \( m = 5 \) simplifies to \( c_3 + c_4 + c_5 = n^{-1} \). Thus, \( c_2 = c_5 \) with (24) and therefore \( a_5 = b_5 = 0 \) by (15), (16) and \( a_2 = b_2 = 0 \). This simplifies (20) for \( m = 6 \) to \( c_4 + c_5 + c_6 = n^{-1} \). Hence, \( c_3 = c_6 \) as we also have \( c_3 + c_4 + c_5 = n^{-1} \) and we get via (15) and (16) that \( a_6 = b_6 = 0 \). The latter in turn shows that (20) for \( m = 7 \) becomes \( c_5 + c_6 + c_7 = n^{-1} \), so \( c_4 = c_7 \) and \( a_7 = b_7 = 0 \) by, again, (15) and (16).

It should have become apparent that we can proceed inductively in the same manner with (20) for \( m = 5, \ldots, 3n + 1 \); thereby using (15) and (16) to deduce \( a_s = b_s = 0 \) for all \( s = 2, 3, \ldots, 3n \). In particular, \( a = b = c_4 = 0 \). Finally, Equation (15) implies \( c_4 = c_s \) for all \( s = 2, 3, \ldots, 3n \), which gives the desired contradiction.

We finish the proof of part (c) of Theorem 2.1 by showing the following Lemma.

**Lemma 2.12.** Let \( n \geq 3 \) and \( r \geq 2 \). Then

\[
\text{dist}(0, \text{conv}(\Gamma_{n,6r-3})) \leq \frac{\sqrt{6}}{(n-1)^2} 2^{-r(n-1)+1} \leq 2^{-r(n-1)+1}.
\]

**Proof.** We set \( N := rn \) and for \( i, j, k \in [N] \) we set \( \lambda_{i,j,k} \) as in Lemma 2.5 applied for the dimension \( N \). Then Equation (11) of Lemma 2.5 yields

\[
\sum_{i,j,k=1}^{N} \lambda_{i,j,k} \left( \varepsilon_{\sigma(i)}, \varepsilon_{\sigma(j)}, \varepsilon_{\sigma(k)} \right) = \sum_{i,j,k=1}^{N} \lambda_{i,j,k} \left( \varepsilon_{\sigma(i)}, 0, 0 \right) + \sum_{i,j,k=1}^{N} \lambda_{i,j,k} \left( 0, \varepsilon_{\sigma(j)}, 0 \right) + \sum_{i,j,k=1}^{N} \lambda_{i,j,k} \left( 0, 0, \varepsilon_{\sigma(k)} \right) = \sum_{i=1}^{N} \varepsilon_{\sigma(i)} \varepsilon_{\sigma(i)}, \varepsilon_{\sigma(i)} = 0 \in (\mathbb{R}^n)^{6r-3},
\]

where we used in the last step equation (5) and Remark 2.10, i.e. that each element of \([n]\) is attained exactly \( r \)-many times by all \( \sigma_k : [rn] \to [n] \), \( k \in [2r-1] \). Because \( W_N \) contains the support of \( \lambda \) apart from the element (1, 1, 1), we have

\[
\sum_{(i,j,k) \in W_N \setminus \{1,1,1\}} \lambda_{i,j,k} \varepsilon_{\sigma(i)}, \varepsilon_{\sigma(j)}, \varepsilon_{\sigma(k)} = -\lambda_{1,1,1} \varepsilon_{\sigma(1)}, \varepsilon_{\sigma(1)}, \varepsilon_{\sigma(1)} - \sum_{(i,j,k) \in \mathcal{J}_r} \lambda_{i,j,k} \varepsilon_{\sigma(i)}, \varepsilon_{\sigma(j)}, \varepsilon_{\sigma(k)} = \colon x \in (\mathbb{R}^n)^{6r-3},
\]

which is an element in the positive cone of \( \Gamma_{n,6r-3} = \{ \varepsilon_{\sigma(i)}, \varepsilon_{\sigma(j)}, \varepsilon_{\sigma(k)} \mid (i,j,k) \in W_N \setminus \mathcal{J}_r \} \). Normalizing the latter equation with

\[
\rho := \sum_{(i,j,k) \in W_N \setminus \mathcal{J}_r} \lambda_{i,j,k} = \sum_{i,j,k=1}^{N} \lambda_{i,j,k} - \left( \lambda_{1,1,1} + \sum_{(i,j,k) \in \mathcal{J}_r} \lambda_{i,j,k} \right) \geq N - 1
\]

shows \( \rho x \in \text{conv}(\Gamma_{n,6r-3}) \). To bound the norm of \( \rho x \) we compute

\[
\lambda_{1,1,1} + \sum_{(i,j,k) \in \mathcal{J}_r} \lambda_{i,j,k} = 2^{-N+1} + \sum_{s=2}^{r} \left( \lambda_{s,1,s} + \lambda_{s,s,1} \right)
\]

\[
= 2^{-N+1} + \sum_{s=2}^{r} \left( 2^{-N+s-1} + 2^{-N+s-1} \right) = \sum_{s=1}^{r} 2^{-N+s} < 2^{-N+r+1}.
\]
Finally, using $|\varepsilon_{i_1,i_2,\ldots,i_{6r-3}}| \leq \sqrt{6r-3}$ for any $i_1,i_2,\ldots,i_{6r-3} \in [n]$ together with the triangle inequality on Equation (26) implies

$$|c^{-1}x| \leq \sqrt{6r-3} \frac{2^{-N+r+1}}{N-1} \leq \frac{\sqrt{6}}{(n-1)\sqrt{r}} 2^{-N+r+1} \leq 2^{-r(n-1)+1},$$

where we used $n \geq 3$ and $r \geq 2$ for $\sqrt{6} \leq (n-1)\sqrt{r}$.

### 2.4 Polynomial scaling

A simple example of Equation (2) is the minimization of an $n$-variate homogeneous polynomial of degree $d$ with nonnegative coefficients over the set $x_1,\ldots,x_n > 0$, $\prod x_i = 1$, as studied in [30]. In this case the sets conv($S$) for $S \subseteq \Omega$ are Newton polytopes of homogeneous polynomials, and the minimum of a polynomial is bounded below if and only if the Newton polytope contains $\underline{1}_n$. If the polynomials are hyperbolic of degree $n$, as in [30], their Newton polytope either contains $\underline{1}_n$ or is at least $1/\sqrt{n}$ away from it. However, we show that for general homogeneous polynomials the margin can get exponentially small in $n$ even for $d = 3$.

Minimizing a degree $d$ homogeneous polynomial $\sum_{a \in \mathbb{Z}_{\geq 0}^n} p_a x^a$ with nonnegative coefficients over the set $x_1,\ldots,x_n > 0$, $\prod x_i = 1$ is the same as computing Equation (2) for

$$\gamma(\Omega') := \left\{-\alpha + \frac{d}{n} \underline{1}_n \mid \alpha \in (\mathbb{Z}_{\geq 0})^n \text{ with } |\alpha| = d \right\}. \tag{27}$$

If $n = dm$ for some integer $m \geq 1$, then we have $-\Omega_{m,d} \subseteq \Omega'$. Therefore, Theorem 2.1(b) and (c) and the padding from Appendix C directly yield the following.

#### Corollary 2.13 (Margin for Polynomial scaling).

Fix some $d \geq 3$ and assume $n = dm$ for some $m \geq 3$. Let $\Omega'$ be as in Equation (27). Then

$$\gamma(\Omega') \leq \gamma(\Omega_{m,d}) \leq 2^{-m+1} = 2^{-\frac{n}{2}+1}.$$  

and for $d \geq 9$ we even have

$$\gamma(\Omega') \leq \gamma(\Omega_{m,d}) \leq 2^{-\frac{\left(m-1\right)(d+2)}{6}+1} \approx 2^{-\frac{n}{2}}.$$  

Thus, for fixed $d \geq 3$ and $n \to \infty$ the margin of $\Omega'$ can be exponentially small in $n$. In terms of polynomials, this states that the Newton polytope of a degree $d \geq 3$ homogeneous polynomial can be exponentially close to the origin without containing it.

### 3 Diameter bounds in the commutative case

In this section we describe an array such that all approximate scalings are very ill conditioned, proving Theorem 1.1. Let us define the diameter bound.

#### Definition 3.1.

Let $\varepsilon \to 0$ and $f : \mathbb{R}^n \to \mathbb{R}$. The diameter bound $D_f(\varepsilon)$ is defined as the infimum over $R > 0$ such that

$$\inf_{\|x\| \leq R} f(x) \leq \varepsilon + \inf_{x \in \mathbb{R}^n} f(x).$$

Thus, Theorem 1.1 is equivalent to the statement that $D_f(\varepsilon) = \Omega(2^{n/3} \log(1/\varepsilon))$ for $\varepsilon \leq e^{-Cn^2 \log n}$. We now give a proof outline for Theorem 1.1.
3.1 Proof outline

The high-level intuition applies not only to array scaling but to the capacity in general. Recall that the array scaling capacity is

$$\inf_{x \in \mathbb{R}^{3n}} \sum_{\omega \in \Omega} p_{\omega} e^{\omega \cdot x}$$

for $\Omega = \Omega_{n,3} = \{e_i - \frac{1}{n} 1_n : i \in [n]\} \subseteq \mathbb{R}^{3n}$. We build both the support $\Omega' \subseteq \Omega_{n,3}$ and the entries $p$ in the following way. We construct a set $\Omega_0 \subseteq \Omega_{n,3}$, another element $\omega \in \Omega_{n,3}$, and an array $q$ with the following properties.

1. The set $\Omega_0 \subseteq \Omega_{n,3}$ should be the support of a tristochastic array $q$.
2. The affine hull of $\Omega_0$, should have codimension one\(^\text{13}\) in $\mathbb{R}^{3n}$.
3. The origin is in the relative interior of $\text{conv}(\Omega_0)$. Note that the origin is already in $\text{conv}(\Omega_0)$ by the tristochasticity of $q$.
4. The vector $\omega \in \Omega_{n,3}$ should be at a very small, but positive, distance $\eta$ from $\text{Aff}(\Omega_0)$.

   Note that this already implies that the facet gap of $\Omega_0 \cup \omega$ is small.

Finally, we define the entries of $p$ by $p|_{\Omega_0} = \frac{1}{2} q$, $p_{\omega} = \frac{1}{2}$, and $p_{\omega} = 0$ elsewhere. Assuming we have found $p$ according to this process, we now give intuition for the diameter bound.

Let $v$ be the projection of $\omega$ to the orthogonal complement of $\text{Aff}(\Omega_0)$. Intuitively, the capacity is only approximately attained by vectors very far in the $-v$ direction. Indeed, first note that $\text{cap}(p) = 1/2$, because $\text{cap}(q) = 1$ by tristochasticity, $\text{cap}(p) \geq \frac{1}{2} \text{cap}(q) = \frac{1}{2}$, and $f_p(-tv/\|v\|) = \frac{1}{2} + e^{-\eta t}$ so $f_p(-tv/\|v\|)$ tends to $\frac{1}{2}$. However, $f_p(-tv/\|v\|)$ tends to $\frac{1}{2}$ slowly if $\eta$ is small. Indeed, $f_p(-tv/\|v\|) \leq \frac{1}{2} (1 + \varepsilon)$ only if $t \geq \frac{1}{2} \log(1/\varepsilon)$.

To conclude rigorously that the capacity is only approached by vectors very far in the $-v$ direction, we must rule out directions with nonzero components in $\text{Aff}(\Omega_0)$. For this, we must use the assumption that 0 is rather deep in the relative interior of $\text{conv}(\Omega_0)$. If this is the case, then any $\varepsilon$-approximate minimizer must have a bounded component in $\text{Aff}(\Omega_0)$, for otherwise the contribution to $f_p$ from the elements of $\Omega_0$ alone will be larger than $\frac{1}{2} + \varepsilon$.

The remainder of the section will be concerned with the construction of a subset $\Omega_0$, an array $q$, and an element $\omega$ with these properties.

3.2 The construction

We construct the subset $\Omega_0$ from a directed graph $D$ on $[n]$, which we will determine later. If $i, j$ is an edge in $D$, then $\Omega_0$ includes the elements $(\varepsilon_i, \varepsilon_i, \varepsilon_j)$ as well as the three cyclic permutations of it. That is,

$$\Omega_0 = \{(\varepsilon_j, \varepsilon_i, \varepsilon_i), (\varepsilon_i, \varepsilon_j, \varepsilon_i), (\varepsilon_i, \varepsilon_i, \varepsilon_j) :ij \in E(D)\}.$$ 

We now describe the graph, as seen in Figure 2.

\(^{13}\)This will not quite apply in our setting, because $\text{Aff}(\Omega_{n,3})$ is not full-dimensional. Instead, $\text{Aff}(\Omega_0)$ will be codimension one in $\text{Aff}(\Omega_{n,3})$.  

The graph $D_l$ from Definition 3.2 with the edge labels proportional to the edge labeling $q$ in Item 1 of Lemma 3.3 (the constant factor 1/6n is omitted for readability). We have also omitted the directions, which are all towards the root $r$.

Definition 3.2. The graph $D_l = (W, E)$ is a directed tree with $l + 1$ levels, where the root is on the 0th level and the leaves are on the $l$th level. The tree is constructed as follows.

- All the edges are directed toward the root and are between adjacent levels.
- The root has three children, and on the $l - 1$ levels below the root every node has one child.
- Additionally, one of the vertices on level $l - 2$ has an additional child which has its own child.

Explicitly, the vertices $W$ and edges $E$ are given by

$$W = \{u_i, v_i, w_i : i \in [l]\} \cup \{w_0 := u_0 := v_0 := r, \bar{w}_{l-1}, \bar{w}_l\}.$$  
$$E = \{u_i u_{i-1}, v_i v_{i-1}, w_i w_{i-1} : i \in [l]\} \cup \{\bar{w}_{l-1} w_{l-2}, \bar{w}_l \bar{w}_{l-1}\}.$$ 

Note that $D_l$ has $3(l + 1)$ vertices so we set $n = 3(l + 1)$. Thus $D_l$ has $3l + 2$ edges and so $|\Omega_0| = 3(3l + 2) = 3n - 3$. It is helpful to construct the matrix $M$ whose set of rows is $\Omega_0$. To make the matrix sparser, first replace $\varepsilon_i$ by $e_i$ by restricting the minimization to the
A directed graph $D_0$ has the matrix $M$ with blocks of size $3$. As such the dimensions of the five column groups, from left, are $3\cdot 2$, $3(l-1)$, $3(l-1)$, $3(l-1)$, $3\cdot 2$. $A$ is as in Equation (28) and $I$ is the $3 \times 3$ identity matrix.

Figure 4 If $v$ is a vertex of $D_0$ with edges weighted $q_1$ and $q_2$ incident to it, then the column $v,i$ of $M$ for $i \in [3]$ sums to $q_1 + 2q_2$. That is, the incoming edge contributes its weight and the outgoing edge contributes twice its weight.

subspace $\sum x_i = \sum y_i = \sum z_i = 0$, which is without loss of generality. We define $\Omega_0' \subseteq \mathbb{R}^3n$ to be $\Omega_0$ but with each $(\varepsilon_i, \varepsilon_j, \varepsilon_k)$ replaced by $(\varepsilon_i, \varepsilon_j, \varepsilon_k)$; define $\Omega_{n,3}'$ similarly and define $P_{(\varepsilon_i, \varepsilon_j, \varepsilon_k)} := P_{(\varepsilon_i, \varepsilon_j, \varepsilon_k)}$. Then

$$\inf_{x \in \mathbb{R}^3n} \sum_{\omega \in \Omega_{n,3}} p_{\omega} e^{(\varepsilon_i, \varepsilon_j, \varepsilon_k)}(x) = \inf_{x, y, z \in \mathbb{R}^n} \sum_{\sum \varepsilon_i = \sum \varepsilon_j = \sum \varepsilon_k = 0} p_{\omega} e^{(\varepsilon_i, \varepsilon_j, \varepsilon_k)}(x,y,z).$$

Moreover, when we write the matrix $M$, it is easier to write the vector $(x, y, z)$ in the order $(x_1, y_1, z_1, x_2, y_2, z_2, \ldots)$ instead of the order $(x_1, \ldots, x_n, y_1, \ldots, y_n, z_1, \ldots, z_n)$. With this ordering, the matrix $M$ with rows in $\Omega_0'$ is a block matrix $M$ with blocks of size 3, with $n - 1$ block rows, and with $n$ block columns. Each block row corresponds to an edge in the directed graph $D_1 = (W, E)$ on $n = 3(l + 1)$ vertices. If $e \in E$ is an edge from $i \to j$, then the $e^{th}$ row of $M$ has the matrix
\[
A = \begin{bmatrix}
0 & 1 & 1 \\
1 & 0 & 1 \\
1 & 1 & 0
\end{bmatrix}
\]

in the \(i^{th}\) block entry and
\[
I = \begin{bmatrix}
1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 0 & 1
\end{bmatrix}
\]
in the \(j^{th}\) block entry and zeroes elsewhere. See Figure 3 for a portrayal of the whole matrix \(M\).

The first three properties for \(\Omega_0\) in the proof plan translate to the following three claims about \(M\). The first relates to the stochasticity of \(q\), the second to the codimension of \(\text{Aff}(\Omega_0)\) in the subspace \((1_{\frac{1}{n}})^3\), and the third to the depth of the point \(\frac{1}{n}1_{3n}\) in \(\text{conv}(\Omega_0)\).

\begin{lemma}
Let \(n = 3(l + 1)\).
\begin{enumerate}
\item The probability distribution \(q\) on \(E \times [3]\) defined (for \(i \in [3]\)) by
\[
q_{u_1v_1,i} = q_{v_1v_1-1,i} = \frac{1}{6n} \left(2 + (-2)^{(l-j)}\right)
\]
for \(j \in [l]\),
\[
q_{w_1w_1-2,i} = q_{w_1w_1-2,i} = \frac{1}{2} q_{w_1w_1-1,i} = \frac{1}{2} q_{w_1w_1-1,i} = \frac{1}{6n} \left(\frac{3}{2}\right)
\]
on the rows of \(M\) has expectation \(\frac{n}{6}1_{3n}\). That is, if the rows of \(M\) are scaled by the values of \(q\), each column sums to \(1/n\). Note that the entries of \(q\) are \(\Theta(\frac{1}{n})\). Ignoring the index \(i\) in \(q_{uv,i}\) allows us to view \(q\) as a labeling of the edges of the graph \(D_l\); see Figures 2 and 4.
\item \(\ker M = \text{span}(\Omega_0)^\perp\) is spanned by the 2-dimensional space \(S \subseteq \mathbb{R}^{W \times [3]}\) given by
\[
S = \{s : s(v,1) = \alpha, s(v,2) = \beta, s(v,3) = \gamma\ \text{for all } v \in W, \alpha + \beta + \gamma = 0\}
\]
and the function \(f \in \mathbb{R}^{W \times [3]}\) which for all \(i \in [3]\) assigns
\[
f(u_j,i) = f(v_j,i) = f(w_j,i) = (-2)^{-j} \text{ for } j \in [l] \cup \{0\}
\]
and \(f(w_{l-k},i) = f(w_{l-k},i)\) for \(k \in \{0,1\}\).
\item Apart from the three zero singular values, all singular values of \(M\) are \(\Omega(1/n)\).
\end{enumerate}
\end{lemma}

Given the lemma, let us prove that the diameter bound holds according to the proof outline at the beginning of the section.

**Proof of Theorem 1.1.** We first show the claim for \(n\) of the form \(n = 3(l + 1)\); the bound follows for \(3(l + 1) < n < 3(l + 2)\) by applying Proposition 3.5 with \(t = 3(l + 1)\), using that the array we construct has capacity \(1/2\) and \(t/n \geq 2/3\).

We now show the diameter lower bound for \(n = 3(l + 1)\). It is enough to exhibit a constant \(C > 0\), and a probability distribution \(p\) on \(\Omega_{n,3} = \{e_i : i \in [n]\}\) such that for for all \(N \geq Cn^2 \log n\) and all \(x, y, z \in 1_{\frac{1}{n}}\),
\[
\sum_{\omega \in \Omega_{n,d}^\perp} p_{x,y,z} e^{\omega(x,y,z)} \leq e^{-N} + \inf_{x',y',z' \in 1_{\frac{1}{n}}} \sum_{\omega \in \Omega_{n,d}^\perp} p_{x,y,z} e^{\omega(x,y,z)}
\]
only if \(|(x, y, z)|_2 = \Omega(2^{n/3} N)|. Note that the space \((\mathbb{1}_n^+)\) over which we are minimizing is a subspace of \(S\), where \(S\) is as in Lemma 3.3, and that \(\Omega_{n,N} \subseteq \Omega_{n,d}^+\). The proof will follow the outline in Section 3.1; namely, we will consider a subset \(\Omega_0^\prime \subseteq \Omega_{n,d}^\prime\) and an element \(\omega' \in \Omega_{n,d}^\prime\) very close to, but outside of, \(\text{Aff}(\Omega_0^\prime)\).

Consider the set \(\Omega_0^\prime \subseteq \Omega_{n,d}^\prime\) of rows of \(M\) in Lemma 3.3 and the probability distribution \(q\) on \(\Omega_0^\prime\) from Lemma 3.3. Let \(\omega' = (e_{u_1}, e_{v_1}, e_{w_1})\) for the vertices \(u_1, v_1, w_1 \in D_1\). Let \(\Omega = \Omega_0 \cup \{\omega'\}\), and define the probability distribution \(p\) on \(\Omega\) by \(p_{\omega'} = \frac{1}{2}\) and \(p_{\omega} = \frac{1}{2}q_\omega\) for \(\omega \in \Omega_0^\prime\). Recall from Lemma 3.3 the orthogonal decomposition \(\text{span}(\Omega_0^\prime) = S \oplus \text{span} f\). As \(\mathbb{R}^m = \text{span}(\Omega_0^\prime) \oplus \text{span}(\Omega_0^\prime)\), we have the orthogonal decomposition \(S = \text{span}(\Omega_0^\prime) \oplus \text{span} f\). Observe that \(\omega' \notin \text{span}(\Omega_0^\prime)\), because by Lemma 3.3 we have \(\text{span}(\Omega_0^\prime) = \ker M = S + \text{span} f\) and clearly \(f \cdot \omega' \neq 0\).

By Item 1 of Lemma 3.3 we have \(\sum_{\omega \in \Omega_0^\prime} q_{\omega} \omega = \frac{1}{n}(\mathbb{1}_n, \mathbb{1}_n, \mathbb{1}_n)\) and thus \(\text{cap}(q) = 1\). Therefore, \(\omega' \notin \text{span}(\Omega_0^\prime)\) implies that the infimum is \(1/2\) for this choice of \(\Omega\) and \(p\). We claim that the infimum can only be approximately attained by \(h \in (\mathbb{1}_n^+)\) with a very large component in the one-dimensional space \(\text{span} f = \text{span}(\Omega_0^\prime) \cap (\mathbb{1}_n^+)\). As in the proof outline, we must bound the components in \(\text{span}(\Omega_0^\prime)\) of the approximate minimizer \(h\). For \(h \in (\mathbb{1}_n^+)\) write \(h = h_0 + af\) and \(\omega_0 = \omega + bf\) where \(h_0, \omega_0 \in \text{span} \Omega_0^\prime\). Note that \(|h| = \|h_0 + af\|_1 = O(2^{-1}) = O(2^{-n/3})\) and that \(h_0 \in (\mathbb{1}_n^+)\), because \(n\) and \(f\) are.

\[
\sum_{\omega \in \Omega_0^\prime} p_\omega e^{\omega \cdot h_0} \leq \frac{1}{2} e^{-N} + \frac{1}{2}.
\]

Equivalently,

\[
\sum_{\omega \in \Omega_0^\prime} q_\omega e^{\omega \cdot h_0} + e^{h_0 \cdot \omega_0 + ab} \|f\|^2 \leq e^{-N} + 1.
\]

Suppose \(|h_0|\) is bounded by \(L\). If \(e^{h_0 \cdot \omega_0 + ab} \|f\|^2 \leq e^{-N}\), then \(|ab| = \Omega((N - L))\). In particular, \(|h| \geq |af| = |ab| \|f\| / |b| \approx 2^n / \Omega((N - L)^n/3)\) because of the previous bounds on \(|ab|, |b|\), and the fact that \(|f| = \Theta(1)|. It remains to prove a bound \(L\) for \(|h_0|\). We will do this by showing that if \(|h_0|\) were too large, then the first term of the left-hand side of Equation (30) would be too large. This amounts to \(1/2 \mathbb{1}_n\), being in the relative interior of \(\text{conv}(\Omega_0^\prime)\), but will be proved using lower bounds on the singular values of \(M\).

Let \(\alpha\) denote the least nonzero singular value of \(M\); by Item 3 of Lemma 3.3 \(\alpha = \Omega(1/n)|. As h_0 \in \text{span}(\Omega_0^\prime) = \text{rowspan}(M), we have \|Mh_0\| \geq \alpha \|h_0\|\) by the singular value bound. We claim that there is some \(\omega \in \Omega_0^\prime\) satisfying \(\omega \cdot h_0 = \Omega(\alpha \|h_0\|/n)|. The claim follows from Lemma 3.4 below applied to the sequence \((\omega', h_0 \in \Omega_0^\prime)\).

Because \(q_\omega = \Theta(1/n)|, we must have that \(\omega \cdot h_0 = O(\log n)\) for all \(\omega \in \Omega_0^\prime\). Else, the contribution from the term \(q_\omega e^{\omega \cdot h_0}| alone is larger than 1, in which case \(x\) cannot be an \(e^{-N}\)-approximate minimizer. Finally, \(|h_0| = O(n(\log n)/\alpha) = O(n^2 \log n)|, and so we may take \(L = O(n^2 \log n)\) and \(N \geq 2L|.

In the above proof, we used the following simple lemma.

**Lemma 3.4.** Let \(0 < \beta < \gamma\). Suppose \(z \in \mathbb{R}^m\) is such that \(\sum_{i=1}^m q_i z_i = 0\) for \(q_i \in (\beta/m, \gamma/m)\). Then there exists \(i \in [m]\) such that \(z_i \geq \frac{\beta}{2\gamma m} \|z\|_2\).

**Proof.** Because \(\sum q_i z_i = 0\),

\[
\sum_{i : z_i \leq 0} q_i |z_i| = \sum_{i : z_i \geq 0} q_i z_i.
\]
and
\[ \sum_{i: z_i < 0} q_i z_i + \sum_{i: z_i > 0} q_i z_i \geq (\beta/m) \|z\|_1 \geq (\beta/m) \|z\|_2. \]

Thus \( \sum_{i: z_i > 0} q_i |z_i| \geq \frac{\beta}{2m} \|z\|_2 \), so there is some \( i \) such that \( q_i z_i > \frac{1}{m} \frac{\beta}{2m} \|z\|_2 \). Thus \( z_i > \frac{\beta}{2ym} \|z\|_2 \).

To show that our diameter lower bound holds for all values of \( n \), we need the following proposition, which is proved in Appendix E. The idea is to prove diameter bounds for larger arrays from diameter bounds for smaller ones by embedding the smaller array in a “corner” of the larger array.

\[ \textbf{Proposition 3.5.} \text{ Suppose } 1 \leq t \leq n. \text{ Let } p \text{ be a } d \text{-dimensional array in } (\mathbb{R}^{t \geq 0})^{\otimes d} \text{ with unit sum; in particular } \text{cap}(p) \leq 1. \text{ Let } q \text{ be the } d \text{-dimensional array in } (\mathbb{R}^n_{\geq 0})^{\otimes d} \text{ array such that } q_{i_1, \ldots, i_d} = \frac{1}{n} p_{i_1, \ldots, i_d} \text{ for } i_1, \ldots, i_d \in [t], \ q_{ii} = 1/n \text{ for } t + 1 \leq i \leq n, \text{ and } q_{i_1, \ldots, i_d} = 0 \text{ otherwise. For } \varepsilon \leq 1 - \text{cap}(p),
\]
\[ D_{f_q}(\varepsilon) \geq D_{f_p} \left( \frac{1 - \text{cap}(p)}{1 - \text{cap}(p)^{1/n}} \varepsilon \right). \]

In particular, the norm of any \( \varepsilon \)-approximate minimizer of \( f_q \) is at least the norm of some \((1 - \text{cap}(p))\varepsilon\)-approximate minimizer of \( f_p \).

As a corollary of the proof of Theorem 1.1, we have a bound on the facet gap of [14].

The facet gap of a finite set \( \Omega \) is defined to be the least distance of an element of \( \Omega \) to the affine hull of a facet of \( \text{conv}(\Omega) \). We have shown that the distance between \( \text{Aff}(\Omega^0) \) and \( \omega' \) is \( O(2^{-t}) \), or \( O(2^{-n/3}) \).

\[ \textbf{Corollary 3.6 (Facet gap of array scaling).} \text{ There is a subset } \Omega_1 \subseteq \Omega_{n,3} \text{ with facet gap } O(2^{-n/3}). \]

Analogously to what is done for the margin in Proposition C.1, we may also embed this array inside a larger array to obtain a diameter bound for \( d \geq 3 \). For \( d \geq 3 \), take \( q(i, j, k, l, t, \ldots, t) = \frac{1}{n} p_{ijk} \) for all \( i, j, k, l \in [n] \). Then for \( (x_1, \ldots, x_d) \in (1/n)^d \) we have
\[ f_q(x_1, \ldots, x_d) = \frac{1}{n} f_p(x_1, x_2, x_3) \sum_{i=1}^n e^{|x_i^d - 4(x_i)|}. \]

For fixed \( x_1, x_2, x_3 \), by Jensen’s inequality \( f_q \) is minimized when \( x_j = 0 \) for \( j \geq 4 \) and takes value \( f_p(x_1, x_2, x_3) \), and thus \( f_q \) has the same diameter bound as \( f_p \).

\[ \textbf{Corollary 3.7 (Diameter bound for } d \geq 3). \text{ There is an absolute constant } C > 0 \text{ such that the following holds. For all } d \geq 3, \text{ there is a family of arrays } q \in (\mathbb{R}_{\geq 0}^n)^{\otimes d} \text{ with } O(n^2) \text{ nonzero entries, each of bit-complexity } O(n), \text{ that satisfies the following property. For all } 0 < \varepsilon \leq \exp(-Cn^2 \log n) \text{ and } x \in \mathbb{R}^dn, \text{ if}
\]
\[ f_q(x) \leq \text{cap}(p) + \varepsilon \]
\[ \text{then } \|x\|_2 = \Omega \left( 2^{n/3} \log(1/\varepsilon) \right). \]
3.3 Proof of the properties of the construction

We now prove Lemma 3.3.

Proof of Lemma 3.3. It is first helpful to change basis on each copy of $\mathbb{R}^3$ so that the $A$ blocks are diagonalized. Let $U \in \text{Mat}(3)$ be an orthogonal matrix such that

$$U^t AU = \begin{bmatrix} 2 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{bmatrix}.$$ 

This is possible because $2,-1,-1$ are the eigenvalues of the symmetric matrix $A$. In particular, the first column of $U$ is $(1,1,\sqrt{3})$, and the second two columns span the space of vectors with sum zero. Then $M' = (U^{\otimes n})^t M U^{\otimes n}$ is of the form $P \otimes L \otimes L$ where $P_{e,v} = M'_{e,1}(v,1)$ for $e,v \in E \times V$ and $L_{e,v} = M'_{e,2}(v,2)$. Note that $L$ is the edge-vertex incidence matrix of the directed graph $D_1$, the row corresponding to the edge $(u,v)$ of $D_1$ has $-1$ in the column indexed by the vertex $u$ and $+1$ in the column indexed by $v$. Moreover, $P$ is the matrix obtained from $L$ by replacing every $-1$ entry by a $2$.

To prove Item 2, observe that $\ker M = (U^{\otimes n})^t \ker M' = (U^{\otimes n})^t \ker P \otimes \ker L \otimes \ker L$. Because $D_1$ is connected, $\ker L = \text{span} \mathbb{1}_n$. As the second two columns of $U$ span the subspace of $\mathbb{R}^3$ of vectors with sum 0, the two-dimensional space $S$ is given by $(U^{\otimes n})^t 0 \oplus \text{span} \mathbb{1}_n \oplus (U^{\otimes n})^t \ker L \oplus \ker L$. We next reason for $\ker P$, the other summand of the orthogonal decomposition of $\ker M'$. The graph $D_1$ is a connected tree, so $\ker P$ is one dimensional. This is because every choice of $g(w_0) \in \mathbb{R}$ determines a unique function $g : V \rightarrow \mathbb{R}$ in $\ker P$. We claim that the function $g(v) = f(v,1)$ for $f$ as in Equation (29) is in $\ker P$, and hence spans it. To check this, one must check that for every edge $(v,w) \in E$ we have $2g(v) + g(w) = 0$. It is instructive to look at Figure 2. Observe that this property holds for the edges $u_k,k-1$ if the sequence $g(w_k)$ obeys the recurrence relation $g(w_{k-1}) = -2g(w_k)$ for $k \in [I]$, which is indeed true by the definition of $f$. Checking the condition for $v$ and $w$ is similar. As the first column of $U$ is proportional to $\mathbb{1}_3$, $(U^{\otimes n})^t \ker P \otimes 0 \otimes 0$ is spanned by the function $f$. This proves Item 2.

To show Item 3, it is enough to argue that the singular values of $P,L,L$ obey the desired bound. For $L$ this follows straightforwardly from the fact that $L$ is an incidence matrix of a connected, directed tree and so is totally unimodular with linearly independent rows. The singular value bound follows by Lemma 3.8. Rather than arguing spectrally for $P$, we make an ad-hoc argument using the structure of $D_1$. We first show that $\|x^t P\|_x = \Omega(\|x\|_x)$ for all $x \in \mathbb{R}^{n-1}$, which suffices because $\|x^t P\|_2 \geq \|x^t P\|_x$ and $\|x\|_x \geq \frac{1}{\sqrt{n}} \|x\|_2$.

Let $x \in \mathbb{R}^{n-1}\{0\}$ and $e$ be an edge in $D_1$ such that $|x(e)| = \|x\|_x$. If $e = u_iu_{i-1}$ for $i \in [I]$, then $|x^t P(u_i)| \geq \|x\|_x$ because either $i < l$ in which case

$$|x^t P(u_i)| = |2x(u_i u_{i-1}) + x(u_{i+1} u_i)| \geq 2\|x\|_x - \|x(u_{i+1} u_i)\| \geq \|x\|_x$$

or $i = l$ and so $|x^t P(u_i)| = |2x(e)| = 2\|x\|_x$. The same argument applies to all other edges except $e = w_l w_{l-1}$. In the latter case we are done if $x^t P(w_{l-2}) \geq 1/3 \|x\|_x$. Otherwise we necessarily have $|x(w_{l-2} w_{l-1})| + |x(\bar{w}_{l-1} w_{l-2})| \geq 5/3 |x|_x$, since $x^t P(w_{l-2}) = 2x(e) + x(w_{l-1} w_{l-2}) + x(\bar{w}_{l-1} w_{l-2})$. It follows that $|x(w_{l-2} w_{l-1})| \geq 5/3 |x|_x - |x(\bar{w}_{l-1} w_{l-2})| \geq 5/3 |x|_x - \frac{1}{3} |x|_x \geq 2/3 |x|_x$. As $|x^t P(w_{l-1})| = 2x(w_l w_{l-1}) + x(w_l w_{l-1})$, we have

$$|x^t P(w_{l-1})| \geq 2|x(w_{l-2} w_{l-1})| - |x(w_l w_{l-1})| \geq \frac{4}{3} |x|_x - |x|_x \geq \frac{1}{3} |x|_x.$$ 

In any case, there is some value of $x^t P$ with absolute value greater or equal $1/3 \|x\|_x$. 

Finally, for Item 1 we note that the probability distribution \( q \) on the rows of \( M \) has expectation equal to the all 1/\( n \) function if and only if the probability distribution \( q' \) defined by \( q' = 3q + 1 \) on the rows of \( P \) has expectation equal to the all 3/\( n \) function on the vertices of \( D_t \). Recall that \( P \) is obtained from the edge-vertex incidence matrix of \( D_t \) by replacing every \(-1\) with a \( 2 \). Thus the expectation of the rows under \( q' \) at a vertex \( v \) is \( \sum_{w:(v,w) \in D_t} q'(v,w) + \sum_{w:(w,v) \in D_t} 2q'(v,w) \) see Figure 4. We now check that this is equal to \( 3/n \) for each vertex of \( D_t \); it is helpful to look at Figure 2. The leaves \( u_t, v_t, w_t \), and \( w_t \) all have outdegree one and indegree zero, and \( q' \) takes the value \( 3 \cdot 3/6n = 3/2n \) on the outgoing edges. The expectation under \( q' \) thus takes value \( 3/n \) on these vertices. On vertices of indegree one and outdegree one, \( q' \) takes the value \( \frac{1}{2n} (2 + (-2)^{-k}) \) on the incoming edge and \( \frac{1}{2n} (2 + (-2)^{-k}) + \frac{1}{2n} (4 - (-2)^{-k}) = 3/n \). The remaining vertices to check, those of total degree three, are \( r \) and \( u_{t-2} \). For \( r \), which has only incoming edges, the expectation under \( q' \) is \( 2 \cdot \frac{1}{2n} (2 + (-2)^{-i(t-1)}) + \frac{1}{2n} (2 + (-2)^{-i(t-2)}) \), which is again \( 3/n \). For \( w \) the expectation is \( 2 \cdot \frac{1}{2n} (2 - \frac{1}{2}) + \frac{1}{2n} (2 - \frac{1}{2}) = 3/n \). This completes the proof.

Lemma 3.8. If \( A \) is an \( n \times k \) totally unimodular matrix with linearly independent columns, then the eigenvalues of \( A^T A \) are all at least \( 1/n^2 \).

Proof. First note that \( k < n \) by the linear independence of the columns of \( A \). The least eigenvalue of \( A^T A \) is \( \min_{x \in \mathbb{R}^k \setminus \{0\}} (x^T A^T A x) / \|x\|^2 = \min_{x \in \mathbb{R}^k \setminus \{0\}} \|A x\|^2 / \|x\|^2 = \), so it suffices to show that for all \( x \in \mathbb{R}^k \), \( A x \) has norm at least \( \|x\|/n \). Indeed, if \( A x = y \), then there is some invertible \( k \times k \) submatrix \( A' \) of \( A \) and \( k \times 1 \) submatrix \( y' \) of \( y \) such that \( A' x = y' \). By Cramer’s rule and unimodularity of \( A' \) we have that, for \( i \in [k] \),

\[
x_i = \frac{\det(B_i)}{\det(A')} = \pm \det(B_i)
\]

where \( B_i \) is simply the matrix that one obtains by replacing the \( i \)th column of \( A' \) with the vector \( y' \). By performing the Laplace expansion with respect to the \( i \)th column, and by unimodularity of the minors, we have that \( x_i \leq \|y\|_1 \), and so \( \|x\|_2 \leq \sqrt{k} \|y\|_1 \leq n \|A x\|_2 \) (using \( k \leq n \)).

The noncommutative case

In this section we extend the results from the commutative to the noncommutative case. For this, we recall in the first subsection necessary concepts such as moment maps and moment polytopes, and we define the weight margin and the gap of a representation. The second subsection introduces the key concept of a free subset of weights, see [24]. This concept dates at least back to [18, Proposition 1.2], where it is called strong orthogonality. Freeness will be used to transfer results from the commutative to the noncommutative case. The latter is done in the following three subsections, where we prove bounds on the tensor gap, on the gap for homogeneous polynomials and on the diameter for the natural \( SL(n)^d \) action on 3-tensors. Finally, we show a bound for the weight margin of certain quiver representations. This provides an example, where the constructed set of weights is not free, compare Remark 4.28. Still, after adding enough arrows to the considered quiver, we are able to ensure the same bound for the gap.

\[14\] Actually all presented concepts in the first two subsections work in the very general setting of reductive groups and their rational representations. For the sake of clarity and concreteness we stick to the special case needed in this paper, i.e. the reductive group \( SL(n)^d := SL(n) \times \cdots \times SL(n) \) with \( d \geq 1 \) many copies of \( SL(n) \).
4.1 Moment maps and moment polytopes

In the following we introduce the null-cone problem and its dual characterization via moment maps and moment polytopes. This allows us to rigorously introduce the weight margin and the gap of a rational representation. Thereby we establish precise meaning and interpretation of our results regarding these two notions (in view of the null-cone problem). We stick to the notation of [12], where the gap (implicitly) and the weight margin have been introduced. A reader unfamiliar with representation theory is referred to Appendix B.

Let $G = \text{SL}(n)^d$, $K = \text{SU}(n)^d$, $T = \text{ST}(n)^d$ and $T_K = K \cap T$ be matrix Lie subgroups of $\text{GL}(dn)$ via block-diagonal embedding. Then we can think of their Lie algebras $\text{Lie}(G)$ etc. as being block diagonally embedded into $\mathbb{C}^{dn \times dn}$. For a rational representation $\pi: G \rightarrow \text{GL}(V)$ we write $g \cdot v := \pi(g)v$ for the induced action, where $g \in G$ and $v \in V$. Moreover, we denote the set of weights of $\pi$ by $\Omega(\pi) \subseteq i\text{Lie}(T_K)$ and the induced representation on Lie algebras by $\Pi: \text{Lie}(G) \rightarrow \text{End}(V)$. We remark that we usually identify $i\text{Lie}(T_K) \cong (\mathbb{I}_n^+)^d \subseteq (\mathbb{R}^n)^d$, where $\mathbb{I}_n^+$ denotes the orthogonal complement of the all-ones vector $\mathbb{I}_n$ in $\mathbb{R}^n$.

The orbit of $v \in V$ is $G \cdot v := \{g \cdot v \mid g \in G\}$ and we denote its closure\(^\text{15}\) by $\overline{G \cdot v}$. A vector $v$ is called $G$-unstable, if $0 \in \overline{G \cdot v}$, and otherwise $v$ is $G$-semistable. Equivalently, a vector $v \in V$ is $G$-unstable if and only if its capacity $\text{cap}_G(v) := \inf_{g \in G} \|g \cdot v\|^2$ equals zero. The $G$-unstable vectors form an affine subvariety of $V$ - the null-cone (with respect to $G$). Orbit, stability, and capacity can also be defined for $T$ by replacing $G$ by $T$ in the definitions.

As discussed in Section 1.2, the null-cone problem has many applications in different fields of computer science, mathematics and physics.

Next, we introduce the moment map. Given a rational representation $\pi: G \rightarrow \text{GL}(V)$ there exists an Hermitian inner product $\langle \cdot, \cdot \rangle$ on $V$, by convention linear in the second argument, such that $\langle k \cdot v, k \cdot w \rangle = \langle v, w \rangle$ holds for all $k \in K$ and all $v, w \in V$.\(^\text{16}\)

\[ \text{Definition 4.1.} \text{ For } v \in V \backslash \{0\} \text{ we define } \mu_G(v) \in i\text{Lie}(K) \text{ as the unique element of the real vector space } i\text{Lie}(K), \text{ which satisfies for all } A \in i\text{Lie}(K) \]

\[ \text{tr} \left( \mu_G(v)A \right) = \frac{\langle v, A(v) \rangle}{\langle v, v \rangle}. \]

This defines the moment map $\mu_G: V \backslash \{0\} \rightarrow i\text{Lie}(T)$ of $G$. Replacing $G$ by $T$ and $K$ by $T_K$ we derive the moment map $\mu_T: V \backslash \{0\} \rightarrow i\text{Lie}(T_K)$ of $T$.

The maps $\mu_G$ and $\mu_T$ are indeed moment maps in the sense of symplectic geometry; namely for the induced action of $K$ and, respectively, $T_K$ on the projective space $\mathbb{P}(V)$. Recall $i\text{Lie}(K) \subseteq \mathbb{C}^{dn \times dn}$ so we can consider $\|\mu_G(v)\|_F$ and $\|\mu_T(v)\|_F$.

An important application of these moment maps is due to the Kempf-Ness theorem [36], which provides a duality for the null-cone membership problem:

\[ \text{cap}_G(v) = 0 \iff 0 < \inf_{g \in G} \|\mu_G(g \cdot v)\|_F = \min_{0 \neq w \in G \cdot v} \|\mu_G(w)\|_F \]  \quad (31)

and similarly for $T$, replacing $G$ by $T$ in the above equation. The two moment maps are related as follows.

\(^{15}\)The Euclidean- and the Zariski-closure of $G \cdot v$ coincide.

\(^{16}\)In our concrete representations later on this will be the standard inner product.
Proposition 4.2. Let \( p : i \operatorname{Lie}(K) \to i \operatorname{Lie}(T_K) \) be the orthogonal projection. Then \( \mu_T = p \circ \mu_G \) and \( \|\mu_T(v)\|_F \leq \|\mu_G(v)\|_F \) for all \( v \in V \setminus \{0\} \).

Proof. Since \( i \operatorname{Lie}(T_K) \subseteq i \operatorname{Lie}(K) \) the definition of the moment maps gives \( \operatorname{tr}[\mu_T(v)H] = \operatorname{tr}[\mu_G(v)H] \) for all \( H \in i \operatorname{Lie}(T_K) \). But \( \mu_T(v) \in i \operatorname{Lie}(T_K) \) is the unique element with this property, hence \( p(\mu_G(v)) = \mu_T(v) \). The inequality \( \|\mu_T(v)\|_F \leq \|\mu_G(v)\|_F \) follows directly from the first part.

Now, we explain how the moment maps induce certain polytopes, which can also be used to express the duality in (31). Moreover, the combinatorics of these polytopes captures the important complexity measures (weight) margin and gap. Indeed, one of our main contributions is to analyze parts of this combinatorics, thereby deducing complexity barriers for certain computational problems.

Since the action of \( T \) via \( \pi \) is completely determined by the weight space decomposition \( V = \bigoplus_{\omega \in \Omega(\pi)} V_\omega \) of \( V \), one can compute \( \mu_T(v) \) in terms of this decomposition. For this, write \( v = \sum_\omega v_\omega \) with \( v_\omega \in V_\omega \) and define the support of \( v \) with respect to \( \pi \) as

\[
\operatorname{supp}(v) := \{ \omega \in \Omega(\pi) \mid v_\omega \neq 0 \}.
\]

Using that distinct weight spaces are orthogonal, one computes

\[
\mu_T(v) = \sum_\omega \langle v_\omega, v_\omega \rangle \omega,
\]

which is a convex combination of the weights in \( \operatorname{supp}(v) \). Noting that \( \operatorname{supp}(v) = \operatorname{supp}(t \cdot v) \) for \( t \in T \) also \( \mu_T(t \cdot v) \in \Delta_T(v) := \operatorname{conv}\{\omega \mid \omega \in \operatorname{supp}(v)\} \). In fact,

\[
\Delta_T(v) = \{ \mu_T(t \cdot v) \mid t \in T \} = \{ \mu_T(w) \mid w \in T \cdot v, w \neq 0 \} \subseteq i \operatorname{Lie}(T_K)
\]

and \( \Delta_T(v) \) is called the weight polytope of \( v \).

It is an astonishing result that for fixed \( v \in V \setminus \{0\} \), the set \( \{ \mu_G(g \cdot v) : g \in G \} \) gives rise to a polytope as follows. Let \( \operatorname{spec} : \operatorname{Herm}(n) \to \mathbb{R}^n \) be the function sending a Hermitian matrix to its eigenvalues in decreasing order. Recalling that \( i \operatorname{Lie}(K) \subseteq \operatorname{Herm}(n)^d \) is block-diagonally embedded in \( \mathbb{C}^{dn \times dn} \), we set

\[
s : i \operatorname{Lie}(K) \to (\mathbb{R}^n)^d, \quad \operatorname{diag}(A_1, \ldots, A_d) \mapsto (\operatorname{spec}(A_1), \ldots, \operatorname{spec}(A_d)).
\]

Then for \( v \in V \setminus \{0\} \) the set

\[
\Delta_G(v) := \{ s(\mu_G(w)) \mid w \in T \cdot v, w \neq 0 \}
\]

is a rational convex polytope, see e.g. [28] or [45, Appendix] by Mumford. We call \( \Delta_G(v) \) the moment polytope of \( v \). Noting that \( \|A\|_F = \|\operatorname{spec}(A)\|_2 \) for any \( A \in \operatorname{Herm}(n) \) we have \( \|\mu_G(v)\|_F = \|s(\mu_G(v))\|_2 \) for all \( v \in V \setminus \{0\} \). Thus, we can formulate the duality from (31) also as follows:

\[
\operatorname{cap}_G(v) = 0 \iff \operatorname{dist}(0, \Delta_G(v)) > 0 \iff 0 \notin \Delta_G(v),
\]

and similarly for \( T \). This motivates the following two definitions.
Therefore, the weight margin of $\pi$ as

$$\gamma_G(\pi) := \min \{ \| \mu_G(v) \|_F \mid v \neq 0 \text{ is } G\text{-unstable} \} = \min \{ \text{dist} (0, \Delta_G(v)) \mid v \neq 0 \text{ is } G\text{-unstable} \},$$

and the weight margin of $\pi$ as

$$\gamma_T(\pi) := \min \{ \| \mu_T(v) \|_F \mid v \neq 0 \text{ is } T\text{-unstable} \} = \min \{ \text{dist} (0, \Delta_T(v)) \mid v \neq 0 \text{ is } T\text{-unstable} \}.$$  

Equivalently, $\gamma_T(\pi)$ is the margin of the set of weights $\Omega(\pi)$, i.e. $\gamma_T(\pi) = \gamma(\Omega(\pi))$.

Thus, the gap $\gamma_G(\pi)$ is the largest constant $C > 0$ with the following property: If $\| \mu_G(v) \|_F < C$ for some vector $v \in V$, then $v$ is $G$-semistable. The same statement holds for the weight margin $\gamma_T(\pi)$ replacing $G$ by $T$. Therefore, these notions capture how small $\mu_G(g \cdot v)$ (respectively $\mu_T(t \cdot v)$) must be to certify null-cone non-membership. The next remark connects the gap to the classical notion of instability due to Mumford [44].

**Remark 4.4.** The gap is twice the minimum value of all positive instabilities. Indeed, let $M(v)$ denote the instability of a non-zero vector $v$, see e.g. [45, eq. (9)]. Then $\text{dist}(0, \Delta_G(v)) \geq 2M(v)$ and [45, Theorem 6.1] implies

$$\gamma_G(\pi) = \inf \{ 2M(v) : v \neq 0, v \text{ is } G\text{-unstable} \}.$$

**Example 4.5.** Recall the tensor scaling action, in which the group $G = \text{SL}(n)^d$ acts on $(\mathbb{C}^n)^{\otimes d}$ via the representation

$$\pi_{n,d}: \text{SL}(n)^d \to \text{GL}((\mathbb{C}^n)^{\otimes d}), \quad (g_1, \ldots, g_d) \mapsto g_1 \otimes \cdots \otimes g_d.$$  

Similar computations to those in Example B.2 show that the set of weights of $\pi_{n,d}$ is

$$\Omega(\pi_{n,d}) = \Omega_{n,d} = \{ \epsilon_i \mid i \in [n] \}^d \subseteq (\mathbb{R}^n)^d.$$  

Therefore, the weight margin $\gamma_T(\pi_{n,d})$ is the margin $\gamma(\Omega_{n,d})$ for the array scaling problem from Theorem 1.3 and Theorem 2.1. Moreover, the moment map $\mu_G$ for $\pi_{n,d}$ can be computed in terms of the quantum marginals as described in the introduction, i.e. $\gamma_G(\pi_{n,d})$ is indeed the tensor gap.

The weight margin and the gap satisfy the following inequality.

**Proposition 4.6.** It holds that $\gamma_T(\pi) \leq \gamma_G(\pi)$.

**Proof.** Let $v \neq 0$ be $G$-unstable. Then there exists $k \in K$ such that $k \cdot v$ is $T$-unstable; see [51, Theorem 3.25]. By Proposition 4.2 we obtain

$$\| \mu_G(v) \|_F = \| \mu_G(k \cdot v) \|_F \geq \| \mu_T(k \cdot v) \|_F \geq \gamma_T(\pi)$$

where we used in the first equality that $\mu_G(k \cdot v) = k \mu_G(v)k^\dagger$. Therefore $\gamma_G(\pi) \geq \gamma_T(\pi)$.  

This inequality motivates the next subsection.

---

17 Gap and weight margin are well-defined, i.e. the minimum is attained. Indeed, the moment maps give rise to continuous maps on $\text{P}(V)$ and the non-zero $G$-unstable (respectively non-zero $T$-unstable) vectors form a projective subvariety of $\text{P}(V)$; in particular they form a compact set.
4.2 Free sets of weights

Proposition 4.6 from the preceding subsection shows us that an upper bound for the weight margin $\gamma_T(\pi)$ need not necessarily apply to the gap $\gamma_G(\pi)$. Still, many of our bounds in the commutative case (weight margin and diameter) transfer to the noncommutative case (gap and diameter). We use crucially the notion of a free subset of weights (or [24]). Freeness is also known as strong orthogonality [18].

**Definition 4.7.** Let $\pi: G \to \text{GL}(V)$ be a rational representation with set of weights $\Omega(\pi)$. A subset $\Gamma \subseteq \Omega(\pi)$ is called free if no two distinct elements of $\Gamma$ differ by a root of $G$. In other words, $\Gamma \cap (\Gamma + \alpha) = \emptyset$ holds for all roots $\alpha$ of $G$.

Furthermore, a vector $v \in V \setminus \{0\}$ is called free if its support $\text{supp}(v) \subseteq \Omega(\pi)$ is free.

We transfer the results from the commutative to the noncommutative case with the upcoming Proposition 4.8. It is known that for vectors $v$ with free support one has $\mu_G(v) = \mu_T(v)$. This appears implicitly in [49, Lemma 7.1] and [24, Proposition 2.2], but we prove it below for completeness. We thank Visu Makam for pointing out to us that this equality still holds under a weaker condition on $v$, when the representation decomposes into orthogonal subrepresentations. This can be used to turn our weight margin upper bound for quivers into a gap upper bound (Theorem 4.25). This weaker condition also appears in [21, Theorem 6.5].

**Proposition 4.8.** Let $\pi: G \to \text{GL}(V)$ be a rational representation and suppose $V = \bigoplus_{i=1}^k V_i$ is an orthogonal decomposition into $G$-subrepresentations with respect to the $K$-invariant inner product, that is used to define $\mu_T$ and $\mu_G$. Let $v = (v_1, \ldots, v_k) \in V \setminus \{0\}$, $v_i \in V_i$ be such that all supports $\Gamma_i := \text{supp}(v_i) \subseteq \Omega(\pi)$ are free. Then for all $t \in T$ it holds that $\mu_G(t \cdot v) \in i\text{Lie}(T_K)$ and $\mu_G(t \cdot v) = \mu_T(t \cdot v)$.

If additionally $0 \notin \Delta_T(v) = \text{conv}(\Gamma)$, where $\Gamma = \bigcup_i \Gamma_i$, then the upper bound $\text{dist}(0, \text{conv}(\Gamma))$ for the weight margin $\gamma_T(\pi)$ also applies to the gap, i.e. $\gamma_G(\pi) \leq \text{dist}(0, \text{conv}(\Gamma))$.

**Proof.** The action of $T$ preserves the supports $\Gamma_i$, and in particular preserves their freeness. Hence, it suffices to show $\mu_G(v) \in i\text{Lie}(T_K)$, which immediately yields $\mu_G(v) = \mu_T(v)$ by Proposition 4.2. Moreover, the orthogonality with respect to the $K$-invariant inner product shows $\mu_G(v) = H_1 \oplus \cdots \oplus H_k$, where $H_i = \mu_G^{(i)}(v_i)$ is given by the moment map $\mu_G^{(i)}$ of the $G$-module $V_i$ if $v_i \neq 0$ and otherwise $H_i = 0$. The latter holds similarly for $\mu_T$.

Therefore, we may assume $k = 1$, i.e. $v \neq 0$ has free support $\Gamma$. We write $v = \sum_{\omega \in \Gamma} v_\omega$ for $v_\omega \in V_\omega$. Then, for any root $\alpha$ of $G$ and all $A \in i\text{Lie}(K) \cap \text{Lie}(G)_\alpha$ we have $\Pi(A)v_\omega = 0$ by $\Gamma \cap (\Gamma + \alpha) = \emptyset$ (i.e., freeness) and Proposition B.4. Thus, $\Pi(A)v = 0$ and tr $(\mu_G(v)A) = 0$ for all roots $\alpha$ and all $A \in i\text{Lie}(K) \cap \text{Lie}(G)_\alpha$. With the root space decomposition $\text{Lie}(G) = \text{Lie}(T) \oplus \bigoplus_\alpha \text{Lie}(G)_\alpha$ (see also Example B.3) we conclude $\mu_G(v) \in i\text{Lie}(T_K)$. The first statement is proven.

For the second claim we note that indeed $\bigcup_i \Gamma_i = \text{supp}(v)$. If additionally $0 \notin \text{conv}(\Gamma) = \Delta_T(v)$, then $v$ is $T$-unstable. In particular, $v$ is $G$-unstable and thus $\gamma_G(\pi) \leq \text{dist}(0, \Delta_G(v))$.

On the other hand, we have

$$\text{dist}(0, \Delta_G(v)) = \inf_{g \in G} |\mu_G(g \cdot v)|_F \leq \inf_{t \in T} |\mu_G(t \cdot v)|_F \overset{(*)}{=} \text{dist}(0, \text{conv}(\Gamma)),$$

where we used $\mu_G(t \cdot v) = \mu_T(t \cdot v)$ in $(*)$. We conclude by combining the two inequalities. ▶
13:34  Barriers in Geodesic Optimization

Remark 4.9. It is well-known that any rational representation \( \pi : G \to GL(V) \) can be decomposed into \( G \)-irreducible subrepresentations that are pairwise orthogonal with respect to the fixed \( K \)-invariant inner product. Proposition 4.8 shows that ensuring freeness on the irreducible subrepresentations suffices.

We end the section with an interesting connection between the weight margin and the gap.

Proposition 4.10. Let \( \pi : G \to GL(V) \) be a rational representation and denote its \( m \)-fold direct sum by \( \pi^m \).
\begin{enumerate}
\item The weight margin satisfies \( \gamma_T(\pi) = \gamma_T(\pi^m) \) for all \( m \geq 1 \).
\item The gap satisfies \( \gamma_G(\pi^m) \geq \gamma_G(\pi^{m+1}) \) for all \( m \geq 1 \).
\item There exists some \( m \leq \dim(V) \) such that \( \gamma_G(\pi^m) = \gamma_T(\pi^m) = \gamma_T(\pi) \).
\end{enumerate}

Proof. We note that \( \pi^m \) is given by the action \( g \cdot (v_1, \ldots, v_m) = (g \cdot v_1, \ldots, g \cdot v_m) \) on \( V^m \). Furthermore, the \( K \)-invariant inner product \( \langle \cdot, \cdot \rangle \) of \( V \) induces naturally a \( K \)-invariant product on \( V^m \) by
\[ \langle (v_1, \ldots, v_m), (w_1, \ldots, w_m) \rangle_{V^m} := \sum_{i=1}^m \langle v_i, w_i \rangle. \]

For the first claim just note that the weight space decomposition for \( \pi^m \) is \( V^m = \bigoplus_{\omega \in \Omega(\pi)} V^m_{\omega} \) and hence \( \Omega(\pi^m) = \Omega(\pi) \).

For the second claim, let \( (v_1, \ldots, v_m) \in V^m \setminus \{0\} \) be \( G \)-unstable such that \( \|\mu_G(v_1, \ldots, v_m)\|_{F} = \gamma_G(\pi^m) \). Then \( (v_1, \ldots, v_m, 0) \in V^{m+1} \setminus \{0\} \) is \( G \)-unstable as well, so \( \|\mu_G(v_1, \ldots, v_m, 0)\|_{F} \geq \gamma_G(\pi^{m+1}) \). Moreover, under the inner product \( \langle \cdot, \cdot \rangle_{V^{m+1}} \) the first \( m \) copies of \( V \) are orthogonal to the last copy. Thus, \( \mu_G(v_1, \ldots, v_m, 0) \) is the \( 2 \times 2 \) block-diagonal matrix \( \text{diag}(\mu_G(v_1, \ldots, v_m)) \) and hence \( \|\mu_G(v_1, \ldots, v_m, 0)\|_{F} = \|\mu_G(v_1, \ldots, v_m)\|_{F} = \gamma_G(\pi^m) \).

Finally, let \( \Gamma = \{\omega_1, \ldots, \omega_m\} \subseteq \Omega(\pi) \) be such that \( 0 \not\in \text{conv}(\Gamma) \) and \( \text{dist}(0, \text{conv}(\Gamma)) = \gamma_T(\pi) \). We have \( m \leq |\Omega(\pi)| \leq \dim(V) \) by the weight space decomposition \( V = \bigoplus_{\omega \in \Omega(\pi)} V_{\omega} \). Now, for each \( \omega_i \in \Gamma \) fix some weight vector \( v_i \in V_{\omega_i} \setminus \{0\} \). Then \( v := (v_1, \ldots, v_m) \in V^m \) satisfies the assumptions of Proposition 4.8, because \( \Gamma_i = \{\omega_i\} \) is free and the distinct copies of \( V \) are orthogonal under \( \langle \cdot, \cdot \rangle_{V^m} \). Thus, we obtain
\[ \gamma_G(\pi^m) \leq \text{dist}(0, \text{conv}(\Gamma)) \leq \gamma_T(\pi) = \gamma_T(\pi^m), \]
but on the other hand \( \gamma_G(\pi^m) \geq \gamma_T(\pi^m) \) by Proposition 4.6.

4.3 Freeness for tensors

We recall from Example 4.5 that \( \pi_{n,d} \) denotes the natural representation of \( G = \text{SL}(n)^d \) on \( (\mathbb{C}^n)^{\otimes d} \) and that the weight margin \( \gamma_T(\pi_{n,d}) \) is the margin \( \gamma(\Omega_{n,d}) \) for the array scaling problem from Theorem 1.3 and Theorem 2.1. The purpose of this subsection is to prove the bounds for \( \gamma_T(\pi_{n,d}) \) from Theorem 2.1 also for the gap \( \gamma_G(\pi_{n,d}) \).

Theorem 4.11. Let \( \pi_{n,d} \) be the representation induced by the natural action of \( G := \text{SL}(n)^d \) on \( (\mathbb{C}^n)^{\otimes d} \). Then the weight margin \( \gamma_T(\pi_{n,d}) \) and the gap \( \gamma_G(\pi_{n,d}) \) can be bounded as follows:
\begin{enumerate}
\item If \( n = 2 \) and \( d \geq 3 \), then \( \gamma_T(\pi_{2,d}) \leq \gamma_G(\pi_{2,d}) \leq 2^{-\frac{d}{2}+1}. \)
\item If \( n \geq 3 \) and \( d = 3 \), then \( \gamma_T(\pi_{n,3}) \leq \gamma_G(\pi_{n,3}) \leq 2^{-n+1}. \)
\item If \( n \geq 3 \) and \( d = 6r - 3 \) for some integer \( r \geq 2 \), then
\[ \gamma_T(\pi_{n,d}) \leq \gamma_G(\pi_{n,d}) \leq \frac{\sqrt{6}}{(n-1)^{\frac{r}{2}}} \leq 2^{-r(n-1)+1} = 2^{-\frac{(d+3)(n-1)}{6}+1}. \]
\end{enumerate}
Though the above theorem only applies to certain $d$, we can “pad” the tensors to obtain similar results for all $d \geq 3$. This is because bounds for $\gamma_G(\pi_{n,d})$ via free subsets of weights also hold for $\gamma_G(\pi_{n,d+2})$ and $\gamma_G(\pi_{n,d+4})$, see Proposition C.1. The missing case $n \geq 3$ and $d = 4$ is treated in Proposition C.2. Therefore, we can conclude Theorem 1.6 from the above Theorem 4.11.

Our main method for transferring the bounds from the commutative case (Theorem 2.1) to the noncommutative case is to use the concept of freeness in conjunction with Proposition 4.8. The following definition will be convenient for proving freeness of tensors.

Definition 4.12 (Free sets). A set $M \subseteq [n]^d$ is called free, if $i = (i_1, \ldots, i_d), j = (j_1, \ldots, j_d) \in M$ with $i \neq j$ always implies $|\{i_l \neq j_l | l = 1, \ldots, d\}| \geq 2$.

Proposition 4.13. Let $M \subseteq [n]^d$ and denote the induced subset of weights by

$$\Gamma_M := \{(\epsilon_{i_1}, \ldots, \epsilon_{i_d}) | (i_1, \ldots, i_d) \in M\} \subseteq (\mathbb{R}^n)^d.$$ 

Then $M$ is a free set if and only if the set of weights $\Gamma_M \subseteq \Omega(\pi_{n,d})$ is free as in Definition 4.7.

Proof. We recall that $\Gamma_M$ is free if and only if no two distinct elements of $\Gamma_M$ differ by a root of $G = \text{SL}(n)^d$, see Definition 4.7. Furthermore, remember that the roots of $G$ are

$$(e_i - e_j, 0_n, \ldots, 0_n), (0_n, e_i - e_j, 0_n, \ldots, 0_n), \ldots, (0_n, \ldots, 0_n, e_i - e_j) \in (\mathbb{R}^n)^d$$

for $i, j \in [n]$ with $i \neq j$; see also Example B.3. Now, if $M \subseteq [n]^d$ is not free, then there exist $i = (i_1, \ldots, i_d), j = (j_1, \ldots, j_d) \in M$ with $i \neq j$ such that they exactly differ one component. Without loss of generality we assume $i_1 \neq j_1$ and $i_l = j_l$ for $l = 2, \ldots, n$. But then

$$(\epsilon_{i_1}, \ldots, \epsilon_{i_d}) = (\epsilon_{j_1}, \ldots, \epsilon_{j_d}) + (\epsilon_{i_1} - \epsilon_{j_1}, 0_n, \ldots, 0_n),$$

and hence $\Gamma_M$ is not free. Clearly, the argument can be inverted to show that if $\Gamma_M$ is not free, then $M$ is not free. △

The above proposition shows how the equality $\mu_G(t \cdot v) = \mu_T(t \cdot v)$ of Proposition 4.8 can be verified directly for tensors. For tensors, the moment map components are the quantum marginals, and the equality $\mu_G(t \cdot v) = \mu_T(t \cdot v)$ simply says that the quantum marginals are diagonal. Each off-diagonal entry of a quantum marginal is the inner product between distinct $d - 1$-dimensional slices of a tensor, and if the support of the tensor is free then the supports of such slices are entirely disjoint - thus the quantum marginals are diagonal.

In the following two Propositions we show, that the subsets of weights, which witness the upper bounds for the (weight) margin in Theorem 2.1, are all free. Thereby, we will implicitly use Proposition 4.13.

Proposition 4.14. For $r \geq 2$ the rows of $A_{2r}$ form a free subset of $[2]^{2r}$, i.e. $\Gamma_{2,2r}$ is free. Moreover, for $r \geq 1$ the set of weights $\Gamma_{2,2r+1}$ is free.

Proof. Clearly, $\Gamma_{2,3} = \{\epsilon_{1,1,1}, \epsilon_{2,1,2}\}$ is free. Recall the constructions of $\Gamma_{2,2r}$ and $\Gamma_{2,2r+1}$ from Section 2.1. If $\Gamma_{2,2r}$ is free, then $\Gamma_{2,2r+1}$ is clearly also free. Thus, we are left to prove the former.

Consider $A_{2r}$ as defined in Equation (6). We must show that distinct rows of $A_{2r}$ differ in at least two entries for all $r \geq 2$. The claim is proven by induction on $r \geq 3$. For $r = 3$, we verify the claim by inspection of $A_6$. Let $a_i$ be the $i^{th}$ row of $A_6$; its definition is recalled in the left-hand table below. The right-hand table lists for each pair $a_i$, $a_j$ with $i < j$ two distinct entries in which $a_i$ and $a_j$ differ, which shows the claim for $r = 3$. 
13:36 Barriers in Geodesic Optimization

\[
\begin{array}{cccccc}
\text{entry} & 1 & 2 & 3 & 4 & 5 & 6 \\
\hline
a_1 & 1 & 1 & 1 & 1 & 1 & 1 \\
a_2 & 2 & 1 & 2 & 2 & 2 & 2 \\
a_3 & 2 & 2 & 1 & 1 & 2 & 2 \\
a_4 & 2 & 2 & 2 & 2 & 2 & 2 \\
a_5 & 1 & 1 & 1 & 1 & 1 & 1 \\
a_6 & 2 & 2 & 2 & 2 & 2 & 2 \\
\end{array}
\]
\[
\begin{array}{cccccc}
\text{entry} & 1 & 2 & 3 & 4 & 5 & 6 \\
\hline
a_1 & 1 & 3 & 2 & 3 & 1,2 & 4,2 \\
a_2 & 2 & 1 & 2 & 2 & 2 & 2 \\
a_3 & 1,3 & 2,3 & 1,2 & 4,2 & 5,6 \\
a_4 & 1,3 & 3,4 & 1,4 & 4,2 & 3,4 \\
a_5 & 1,3 & 1,4 & 3,4 & 4,2 & 1,3 \\
a_6 & 1,2 & 2,3 & 1,2 & 5,6 & 1,2 \\
\end{array}
\]

In fact, the table also proves the claim for \( r = 2 \), since \( a_1, \ldots, a_4 \) already pairwise differ in at least two of the first four entries.

Now assume that the claim holds for some fixed \( r \geq 3 \). Let \( a_i, a_j \) be distinct rows of \( A_{2r+2} \); we will show they differ in at least two entries. If \( 1 \leq i < j \leq 2r \), then by our inductive hypothesis there is nothing to prove because the first \( 2r \) rows of \( A_{2r+2} \) contain \( A_2 \) as a submatrix.

To complete the proof, it is enough to show that the \( 4 \times (2r + 2) \) submatrix formed by restricting to the \( m^{\text{th}} \) block row, \( m \in [r] \), and the last block row of \( A_{2r+2} \) satisfies the hypothesis, i.e. any two distinct rows of this submatrix differ in at least two entries. This is the case as restricting to its \( 1^\text{st} \), \( m^{\text{th}} \) and last block columns yields a \( 4 \times 6 \) submatrix of \( A_6 \) if \( m \neq 1 \), namely

\[
\begin{pmatrix}
B_2 & B_3 & B_1 \\
B_2 & B_2 & B_3
\end{pmatrix},
\]

and a \( 4 \times 4 \) submatrix equal to \( A_4 \) if \( m = 1 \). ▶

**Proposition 4.15.** For \( n \geq 3 \) the set \( W_n \subseteq \mathbb{R}^3 \) is free, i.e. \( \Gamma_{n,3} \subseteq \Omega(\pi_{n,3}) \) is free. Furthermore, for \( n \geq 3 \) and \( r \geq 2 \) the set of weights \( \Gamma_{n,6r-3} \subseteq \Omega(\pi_{n,6r-3}) \) is free.

**Proof.** We remind the reader that

\[
W_n = \{(s,1,s),(s,s,1),(s-1,s,s) \mid s = 2,3,\ldots,n\}.
\]

Let \( x = (x_1,x_2,x_3), y = (y_1,y_2,y_3) \in W_n \) be such that \( x \neq y \). We prove by a distinction of cases that \( x \) and \( y \) differ in at least two entries. First, we assume \( x_1 = y_1 \). Then \( a := x_1 = y_1 \geq 2 \), otherwise \( x = (1,2,2) = y \) contradicts \( x \neq y \). Thus, \( x,y \in \{(a,1,a),(a,1,1),(a,a+1,a+1)\} \) and we conclude that \( x \) and \( y \) differ in at least two entries as \( x \neq y \). Second, we assume \( x_1 \neq y_1 \). There is nothing to show if \( x_2 \neq y_2 \), so we additionally assume \( b := x_2 = y_2 \). If \( b = 1 \), then we are done by \( x = (x_1,1,x_1) \) and \( y = (y_1,1,y_1) \). On the other hand, \( b \geq 2 \) yields \( x,y \in \{(b,b,1),(b-1,b,b)\} \) and as \( x \neq y \) they differ in the first and third entry. This proves the first statement.

For the second claim, recall that

\[
\Gamma_{n,6r-3} = \{ e_{\sigma(1),\sigma(j),\sigma(k)} \mid (i,j,k) \in W_{rn} \setminus J_r \},
\]

where \( \sigma \colon [rn] \to [n]^{2r-1} \) is injective, compare Remark 2.10. By the first part \( W_n \) is free and so is its subset \( W_{rn} \setminus J_r \). Hence \( \Gamma_{n,6r-3} \) is free as \( \sigma \) is injective. ▶

We are now ready to deduce Theorem 4.11.

**Proof of Theorem 4.11.** Recall that all the bounds in Theorem 4.11 hold for the weight margin \( \gamma_T(x) \) by Theorem 2.1. This was proven by exhibiting witness sets \( \Gamma_{n,d} \subseteq \Omega(\pi_{n,d}) \) such that \( 0 \notin \text{conv}(\Gamma_{n,d}) \), which gives the bound \( \gamma_T(\pi_{n,d}) \leq \text{dist}(0,\text{conv}(\Gamma_{n,d})) \). But if \( \Gamma_{n,d} \) is free, then we even have

\[
\gamma_G(\pi_{n,d}) \leq \text{dist}(0,\text{conv}(\Gamma_{n,d}))
\]
by Proposition 4.8. By Proposition 4.14 the witness sets $\Gamma_{2,3}$ and $\Gamma_{2,2r}$, $\Gamma_{2,2r+1}$, $r \geq 2$ for Theorem 2.1(a) are free, which proves Theorem 4.11(a). Similarly, we conclude parts (b) and (c) with Proposition 4.15, which shows that for $n \geq 3$ and $r \geq 2$ the witness sets $\Gamma_{n,3}$ and $\Gamma_{n,6r-3}$ are free.

### 4.4 Freeness for homogeneous polynomials

In the following we transfer the result from $d$-tensors to the natural $\text{SL}(n)$ action on homogeneous $d$-forms in $n$ variables. This representation is given by

$$\varrho_{n,d} : \text{SL}(n) \rightarrow \text{GL}(\mathbb{C}[x_1, \ldots, x_n]_d), \quad g \mapsto (p(x) \mapsto p(g^{-1}x)).$$

Each monomial $x^\alpha = x_1^{\alpha_1} \cdots x_n^{\alpha_n}$, given by a multi-index $\alpha = (\alpha_1, \ldots, \alpha_n) \in (\mathbb{Z}_{\geq 0})^n$ with $|\alpha| := \sum \alpha_i = d$, is a weight vector for $\varrho_{n,d}$ with weight $-\alpha + \frac{d}{n} 1_n$. Therefore

$$\Omega(\varrho_{n,d}) = \left\{ -\alpha + \frac{d}{n} 1_n \, | \, \alpha \in (\mathbb{Z}_{\geq 0})^n \text{ with } |\alpha| = d \right\},$$

i.e. $\Omega(\varrho_{n,d}) = \Omega'$ from Equation (27) and the bounds from Corollary 2.13 apply to $\gamma_{ST(n)}(\varrho_{n,d}) = \gamma(\Omega')$. If $n = dm$ for some integer $m \geq 1$, then we have $-\Omega(\pi_{m,d}) \subseteq \Omega(\varrho_{n,d})$.

**Proposition 4.16.** Let $n = dm$ for some integer $m \geq 1$. If $\Gamma \subseteq \Omega(\pi_{m,d})$ is free, then $-\Gamma \subseteq \Omega(\varrho_{n,d})$ is free.

**Proof.** We prove the statement by contraposition. Assume that $-\Gamma \subseteq \Omega(\varrho_{n,d})$ is not free. Then there exists a root $\alpha = e_i - e_j \in \mathbb{R}^n$ of $\text{SL}(n)$, where $i, j \in [n]$ with $i \neq j$, and two different weights $\omega, \omega' \in -\Gamma$ such that $\omega = \omega' + e_i - e_j$, equivalently $-\omega = -\omega' - e_i + e_j$. The latter equation enforces $-\alpha$ to be of the form

$$(0, m, \ldots, 0, e_k - e_l, 0, \ldots, 0, m) \in (\mathbb{R}^m)^d \cong \mathbb{R}^n$$

for some $k, l \in [m]$ with $k \neq l$, because $-\omega, -\omega' \in \Omega(\pi_{m,d})$. Thus, $-\alpha$ is a root of $\text{SL}(m)^d$ and hence $\Gamma \subseteq \Omega(\pi_{m,d})$ is not free.

As a consequence of the preceding Proposition we obtain bounds for the gap $\gamma_{\text{SL}(n)}(\varrho_{n,d})$.

**Theorem 4.17 (Gap for Polynomial scaling).** Let $d \geq 3$ and let $n = dm$ for some integer $m \geq 2$. Then there exists a constant $C > 0$, independent of $n$ and $d$ such that

$$\gamma_{\text{SL}(n)}(\varrho_{n,d}) \leq 2^{-Cdn} = 2^{-Cn}.$$

More concretely, for $d = 3$ and $m \geq 3$ it holds that

$$\gamma_{\text{SL}(n)}(\varrho_{n,d}) \leq \text{dist} (0, \Gamma_{m,3}) \leq 2^{-m+1} = 2^{-\frac{d}{3} + 1},$$

and if $m \geq 3$ and $d = 6r - 3$ for some $r \geq 2$, we have

$$\gamma_{\text{SL}(n)}(\varrho_{n,d}) \leq \text{dist} (0, \Gamma_{m,6r-3}) \leq 2^{-(m-1)+1} = 2^{-(d+3)(m-1)+1} \approx 2^{-\frac{d}{3}}.$$

**Proof.** We recall that Theorem 1.6 was proven by padding the results from Theorem 4.11. Thus, for each $m \geq 2$ and $d \geq 3$ the bound $\gamma_{\text{SL}(m)^d}(\pi_{m,d}) \leq 2^{-Cnm}$ from Theorem 1.6 is witnessed by a free set of weights $\Gamma_{m,d} \subseteq \Omega(\pi_{m,d})$, i.e. $0 < \text{dist}(0, \text{conv}(\Gamma_{m,d})) \leq 2^{-Cdn}$. But then $0 \notin \text{conv}(-\Gamma_{m,d})$ and $-\Gamma_{m,d} \subseteq \Omega(\varrho_{n,d})$ is free by Proposition 4.16. Therefore, Proposition 4.8 yields

$$\gamma_{\text{SL}(n)}(\varrho_{n,d}) \leq \text{dist} (0, \text{conv}(-\Gamma_{m,d})) = \text{dist} (0, \text{conv}(\Gamma_{m,d})) \leq 2^{-Cdn}.$$

Similarly, we get the other bounds by using freeness of $\Gamma_{m,3}$ and, respectively, $\Gamma_{m,6r-3}$ (see Proposition 4.15) combined with the distance bounds Lemma 2.7 and Lemma 2.12, respectively.
4.5 Freeness and diameter bound

In this section we show that the diameter lower bound of Theorem 1.1 generalizes to diameter bounds for the capacity Equation (4) over the noncommutative group $G = \text{SL}(n)^d$. Many algorithms for computing the capacity have resorted to geodesically convex optimization - $G$ can be viewed as a manifold on which $g \mapsto \|g \cdot v\|^2$ is geodesically convex. The distance between an element of $g$ and the identity in this geometry is closely related to the condition number of the matrix $g$. The diameter bound question is the following: given an input $v$ and $\varepsilon > 0$, how large a ball in $G$ about the identity must we optimize over to find an approximate minimizer $g \in G$ such that $\|g \cdot v\|^2 - \text{cap}(v) \leq \varepsilon$? In other words, how well-conditioned can we expect approximate minimizers to Equation (4) to be? This matters because all the algorithms we know start at the origin and take small steps in the manifold, and if all the high-precision solutions are far from the origin then such algorithms cannot reach any of them quickly.

Before tackling this question we must make our notions of distance more precise. The manifold we use is actually not $G$ but rather the manifold $P$ of Hermitian, positive-definite matrices in $G$. Indeed, we can write

$$\inf_{g \in G} \|g \cdot v\|^2 = \inf_{g \in G} \langle v, g^\dagger g \cdot v \rangle = \inf_{x \in P} \langle v, x \cdot v \rangle.$$ 

Thus we may instead optimize the function $f_v : g \mapsto \langle v, g \cdot v \rangle$ over $P$. The manifold $P$ is a prototypical example of a Hadamard manifold, a complete, simply connected Riemannian manifold of non-positive sectional curvature [8]. For us, $G = \text{SL}(n)^d$ for some $d$, and so $P$ is just the set of $d$-tuples of positive-definite matrices of determinant 1. Even for $d = 1$, $P$ contains a totally geodesic submanifold isometric to the hyperbolic plane; as such the volumes of balls grow exponentially in their radius.\(^{18}\)

The function $f_v : g \mapsto \|g \cdot v\|^2$ is convex along geodesics in this manifold [12]\(^{19}\). The geodesics through a point $X \in P$ are given by $\gamma(t) = \sqrt{X} e^{\varepsilon t} \sqrt{X}$ for Hermitian $H$. The Riemannian gradient $\nabla \log f_v$ of $f_v$ at $g \in P$ is given by the moment map $\mu_G(g \cdot v)$. The geodesic ball of radius $R$ in $P$ about the identity is given by

$$B_R := \{ e^A : A \text{ traceless, Hermitian, } \|A\|_F \leq R \} \subseteq P.$$ 

In a slight abuse of notation, we define the geodesic ball in $G$ (rather than $P$) to be $KB_R$, as in the introduction. The values taken by $f_v$ over $B_{2R}$ are the same as the values taken by $g \mapsto \|g \cdot v\|^2$ on $KB_R$. We now define diameter bounds.

**Definition 4.18.** The diameter bound $D_f(\varepsilon)$ for a function $f$ on $P$ and a real number $\varepsilon > 0$ is defined as the infimum over $R > 0$ such that

$$\inf_{g \in B_R} f(g) \leq \varepsilon + \inf_{g \in P} f(g).$$

We will show that the diameter bound for the norm-squared function can grow faster than $\text{poly}(n, \log(1/\varepsilon))$ for $d = 3$. Firstly, we need to review how diameter bounds for tensors in $(\mathbb{R}^n)^d$ like that in Theorem 1.1 relate to diameter bounds for tensors in $(\mathbb{C}^n)^d$ over $\text{SL}(n)^d$.

---

\(^{18}\) The volume of a ball can be computed exactly [27], but the very crude bound of volume $\Omega(e^{2\Theta(r)} - O(n^{\log n})$ for the geodesic ball of radius $r$ can be proved elementarily. The manifold $\text{PD}(n) \cap \text{SL}(n)$ contains the hyperbolic plane as a totally geodesic submanifold, in which the ball of radius $r$ has area $e^{\Theta(r)}$ [15]. This shows the ball of radius $r$ in $\text{PD}(n) \cap \text{SL}(n)$ contains $\Omega(e^{\Theta(r)})$ balls of radius 1, which themselves have volume at least $e^{-O(n^{\log n})}$ by comparison with the Euclidean ball.

\(^{19}\) This was implicitly shown much earlier in [36].
and $\text{ST}(n)^d$. Minimizing $f_v(g)$ over the subset $P \cap \text{ST}(n)^d \subseteq P$, or the tuples of positive-definite diagonal matrices within $\text{SL}(n)^d$, results in a program of the form Equation (2). For $d = 3$, for example,

$$\inf_{g \in P \cap \text{ST}(n)^3} \langle v, g \cdot v \rangle = \inf_{x \in (\mathbb{R}^n)^3} \sum_{\omega \in \Omega_{n,3}} p_{\omega} e^{\omega \cdot x} = \inf_{x \in (1^+)^3} \sum_{\omega \in \Omega_{n,3}} p_{\omega} e^{\omega \cdot x}$$

(32)

where $\Omega_{n,3} = \{(\epsilon_i, \epsilon_j, \epsilon_k) : i, j, k \in [n]\}$ and $p_{(\epsilon_i, \epsilon_j, \epsilon_k)} = |v_{ijk}|^2$. The correspondence is exactly $g = e^{\text{diag}(x)}$ for $x \in (1^+)^3$, which implies the following.

**Lemma 4.19.** For all $\varepsilon > 0$, the diameter bound $D_f(\varepsilon)$ for the function $f_v : g \mapsto \langle v, g \cdot v \rangle$ on $\text{ST}(n)^d$ is equal to the diameter bound $D_h(\varepsilon)$ of the function $f_p$ where $p_{ijk} = |v_{ijk}|^2$, or

$$f_p : (\mathbb{R}^n)^d \rightarrow \mathbb{R}, \quad x \mapsto \sum_{i,j,k \in [n]} |v_{ijk}|^2 e^{(\epsilon_i, \epsilon_j, \epsilon_k) \cdot x}.$$ 

Of course, there’s nothing special about $d = 3$ here, and the lemma generalizes straightforwardly to other $d$. For instance, applying Lemma 4.19 for $d = 2$ shows that restricting operator scaling to diagonal matrices yields an instance of matrix scaling. We have shown how diameter bounds over $\text{ST}(n)^d$ relate to those over $\text{SL}(n)^d$. Now complete the chain by showing how to relate diameter bounds over $\text{SL}(n)^d$ to those over $\text{ST}(n)^d$. We will show that tensors with free support (defined in Definition 4.12) have the same diameter bound over $\text{SL}(n)^d$ as they do over $\text{ST}(n)^d$, which by Theorem 1.1 and Lemma 4.19 we have shown can be superpolynomial. We then show that the construction from Section 3.2 is free.

**Theorem 4.20.** Let $G$ denote $\text{SL}(n)^d$, and let $T$ denote $\text{ST}(n)^d$. Suppose $\mu_T(t \cdot v) = \mu_G(t \cdot v)$ for all $t \in T$ (which holds if $v$ has free support). Then for any $R > 0$ we have

$$\inf_{g \in B_R} f_v(g) = \inf_{g \in T \cap B_R} f_v(g),$$

where $B_R$ denotes the geodesic ball of radius $R$ about the identity in $G$.

**Proof.** Define $B := B_R$ and recall that $P$ denotes the positive-definite matrices in $G$. Let $f : P \rightarrow \mathbb{R}$ be given by $f : g \mapsto \langle v, g \cdot v \rangle$. Clearly $\inf_{g \in B} f(g) \leq \inf_{g \in T \cap B} f(g)$. We must show the converse inequality. Let $g^* := \arg\min_{g \in B} f(g)$. Recall that $P$ is a Hadamard manifold. Define $T_+ := T \cap B$. Let $\pi g^*$ denote the projection of $g^*$ to $T_+$, that is, the closest point in $T_+$ to $g^*$. As $T_+$ is a geodesically convex set, projections to $T_+$ are unique and distances decrease under the projection [8, Theorem 2.1.12]. Thus, $\pi g^* \in B$. If we can show that $f(\pi g^*) \leq f(g^*)$ then the proof is complete.

Let $g^* = \exp_{x \cdot g^*}(x)$ for some $x$ in the tangent space $T_{\pi g^*}P$ to $P$ at $\pi g^*$. That is, $\gamma : [0, 1] \rightarrow P, t \mapsto \exp_{\pi g^*}(tx)$ is the geodesic between $\pi g^*$ and $g^*$. Then, in the local inner product $\langle \cdot, \cdot \rangle_{\pi g^*}$ at $\pi g^*$, $x$ is orthogonal to the tangent space $T_{\pi g^*}T_+ \subseteq T_{\pi g^*}P$ of $T_+$ at $\pi g^*$, because $\pi g^*$ is a local minimum of the geodesically convex function $d(g^*, \cdot)^2$ on $T_+$ and $x$ is proportional to the gradient of $d(g^*, \cdot)^2$ at $\pi g^*$.

The function $f$ is geodesically convex, and its gradient $\nabla f(\pi g^*)$ is proportional to the moment map $\mu_G(\pi g^* \cdot v)$. By the assumption that $\mu_T(t \cdot v) = \mu_G(t \cdot v)$ for all $t \in T$, $\mu_G(\pi g^* \cdot v)$ is in $\mathfrak{t} \mathfrak{L}(T_K)$, which is precisely the tangent space of $T_+$ at $\pi g^*$. Thus

$$f(g^*) = f(\exp_{x \cdot g^*}(x)) \geq f(\pi g^*) + \langle x, \nabla f(\pi g^*) \rangle_{\pi g^*} = f(\pi g^*),$$

which completes the proof.

**Lemma 4.21.** The support of the tensor $p$ from Theorem 1.1 is free.
13:40 Barriers in Geodesic Optimization

Proof. Recall that a tensor in \((\mathbb{C}^n)^{\otimes 3}\) is free if and only if the supports of distinct rows of its weight matrix intersect in at most one element. The construction in Proposition 3.5 preserves freeness, so we can consider the case \(n = 3(l + 1)\) treated in the proof of Theorem 1.1. Recall that, in this case, the support of \(p\) is \(\Omega'_0 \cup \omega'\) where \(\Omega'_0\) is the rows of a matrix \(M\) defined from the directed graph \(D_l\). Each row in the matrix \(M\) corresponds to some edge \(D_l\). Let us first verify that \(\Omega'_0\) is free. Assuming the rows correspond to the same edge, they can be verified to have intersection in at most one element, because the nonzero entries of the three rows corresponding to an edge are contained in a \(3 \times 6\) submatrix with the following form:

\[
[A \ I] = \begin{bmatrix}
0 & 1 & 1 & 1 & 0 & 0 \\
1 & 0 & 1 & 0 & 1 & 0 \\
1 & 1 & 0 & 0 & 1 & 1
\end{bmatrix}
\]

Here the cells containing 1 are colored for readability. Now consider the case that the rows belong to two different edges. If the two edges share no vertices, then clearly the corresponding edges do not intersect. Because the graph is a directed tree, edges may only share a vertex which is the sink of at least one of the edges. If the vertex is a sink for both edges, then the nonzero entries in the 6 rows belonging to either edge (after permutation) take the form:

\[
\begin{bmatrix}
0 & A & I \\
A & 0 & I
\end{bmatrix} = \begin{bmatrix}
0 & 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\
0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 1 \\
0 & 1 & 1 & 0 & 0 & 0 & 1 & 0 & 0 \\
1 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 \\
1 & 1 & 0 & 0 & 0 & 0 & 0 & 1 & 1
\end{bmatrix}
\]

If the shared vertex is a sink for only one edge, then the rows are:

\[
\begin{bmatrix}
0 & A & I \\
A & 0 & I
\end{bmatrix} = \begin{bmatrix}
0 & 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\
0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 1 \\
0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 0 & 1 & 0 & 1 & 0 & 0 & 0 & 0 \\
1 & 1 & 0 & 0 & 0 & 1 & 1 & 0 & 0
\end{bmatrix}
\]

In all these cases it can be verified that supports of distinct rows intersect in at most one element. Lastly, we need to make sure that the intersection of the support of \(\omega'\) with the support of any element of \(\Omega'_0\) is at most one. Recall that \(\omega'\) is defined to have entry one in each block corresponding to the leaves \(u_l, v_l, w_l\) in \(D_l\). However, there are no edges between the leaves, so the support of no row can intersect that of \(\omega'\) in more than one element. ▶

We are now nearly ready to prove Theorem 1.4. We would simply use the array \(p\) from the proof of Theorem 1.1, but setting \(|v_{ijk}| = p_{ijk}\) would not be solvable over the rationals. Therefore we must round \(\sqrt{p_{ijk}}\), which requires some additional technical lemmas proven in Appendix E.

Lemma 4.22 (Rounding and diameter bounds). Let \(p, q : \Omega \rightarrow \mathbb{R}_{\geq 0}\) be positive functions on a finite set \(\Omega \subseteq \mathbb{R}^m\). Suppose there is a set \(B\) such that

\[
\inf_{x \in B} f_p(x) \geq (1 + \varepsilon) \operatorname{cap} p,
\]

and let \(M = \max\{1/q_\omega, 1/p_\omega : \omega \in \Omega\}\). Then

\[
\inf_{x \in B} f_q(x) \geq (1 + \varepsilon)(1 - M\|p - q\|_\infty) - M\|p - q\|_1 \operatorname{cap} q.
\]
Lemma 4.23 (Rounding and capacity). Let $\Omega \subseteq \mathbb{R}^m$ be finite and let $p, q : \Omega \to \mathbb{R}_{\geq 0}$ be positive functions on $\Omega$. Let $M_0 = \max_{x \in \Omega} 1/q_x$. Then

$$\log \text{cap } q \geq \log \text{cap } p - M_0\|p - q\|_x.$$

Proof of Theorem 1.4. First recall that the values taken by $g \mapsto \|g \cdot v\|^2$ on the geodesic ball $KB_R$ in $G$ are the same as the values taken by $f_v : g \mapsto \langle v, g \cdot v \rangle$ on $B_{2R}$ in $P$. Thus it is enough to show that $f := f_v$ has diameter bound $D_f(\varepsilon) = \Omega(2^{n/3} \log(1/\varepsilon))$ for $\varepsilon \leq e^{-Cn^2 \log n}$.

We will apply Lemma 4.22 with $p$ as in the proof of Theorem 1.1 and $q_{ijk} = |v_{ijk}|^2$, with $v_{ijk}$ chosen so that $v$ has the same support as $p$ and $p_{ijk} - \delta < |v_{ijk}|^2 \leq p_{ijk}$ for $\delta$ small. Because $v$ is free, by Theorem 4.20 the diameter bound for $f_v$ is the same as the diameter bound for $f_q$. It remains to show that $D_{f_q}(\varepsilon) = \Omega(2^{n/3} \log(1/\varepsilon))$. We will do this by relating $D_{f_q}(\varepsilon)$ to $D_{f_p}(\varepsilon)$; in particular we will show $D_{f_p}(\Omega(\varepsilon)) \geq D_{f_q}(\varepsilon)$.

Let $R = D_{f_p}(\varepsilon)$. We have $\inf_{x \in \{p \neq 0\}, |x| \leq R} f_p(x) \geq \text{cap}(p) + \varepsilon = (1 + 2\varepsilon)\text{cap}(p)$, recalling that $\text{cap}(p) = 1/2$. By Lemma 4.22,

$$\inf_{x \in \{p \neq 0\}, |x| \leq R} f_q(x) \geq ((1 + 2\varepsilon)(1 - M\|p - q\|_x) - M\|p - q\|_1)\text{cap}(q).$$

As $\text{cap } q \leq 1/2$, if $M\|p - q\|_x \leq M\|p - q\|_1 \leq c\varepsilon$ for $c$ a small enough constant, then we have $((1 + 2\varepsilon)(1 - M\|p - q\|_x) - M\|p - q\|_1)\text{cap } q = \text{cap } q + \Omega(\varepsilon)$, so

$$\inf_{x \in \{p \neq 0\}, |x| \leq R} f_q(x) \geq \text{cap } q + \Omega(\varepsilon).$$

Thus $D_{f_q}(\Omega(\varepsilon)) \geq D_{f_p}(\varepsilon)$ assuming $M\|p - q\|_1 \leq c\varepsilon$. To ensure that this constraint is satisfied, choose $v$ of bit complexity $O(\log n + \log(1/\varepsilon))$ such that $\|p - q\|_1 = \frac{\varepsilon}{2}$. Because $p_{ijk} = \Omega(1/n)$ for $i, j, k$ in the support of $p$ by construction, we have $q_{ijk} = \Omega(1/n)$ for $i, j, k$ in the support of $q$ and hence $M = O(n)$. Thus $M\|p - q\|_1 \leq c\varepsilon$. Applying Lemma 4.23 together with our assumptions about the size of $p - q$ and the fact that $\text{cap } q = \text{cap } v$ implies the final claim that $\text{cap } v \geq 1/4$ and that $1 \geq \|v\|_1 \geq 1/2$.

Finally, we remark that the same diameter bound holds for $d \geq 3$ for tuples of tensors. We note that if $v \in (C^n)^{\otimes d}$ has free support, then so does the tensor $v \otimes e_1 \otimes \ldots \otimes e_l \subseteq (C^n)^{\otimes d}$ for $d \geq 3$. By Proposition 4.8, the tuple $w \in ((C^n)^{\otimes d})^n$ given by

$$w_t = \frac{1}{n} v \otimes e_t \otimes \ldots \otimes e_t$$

has $\mu_T(t \cdot v) = \mu_G(t \cdot v)$ for all $t \in \text{ST}(n)^d$. The commutative problem obtained by restricting to $\text{SL}(n)^d$ as in Lemma 4.19 is precisely $f_q$ as in Corollary 3.7. As in the proof of Theorem 1.4, by Theorem 4.20, Lemma 4.19 and Corollary 3.7, we have the following.

Corollary 4.24. There is a constant $C > 0$ such that the following holds for all $d \geq 3$.

For all $\varepsilon \leq \exp(-Cu^2 \log n)$, there is a tuple of tensors $w = w(\varepsilon) \in ((C^n)^{\otimes d})^n$ with $O(n^2)$ nonzero entries of bit complexity $O(\log n + \log(1/\varepsilon))$, and a geodesic ball $B = B(\varepsilon)$ of radius $\Omega(2^{n/3} \log(1/\varepsilon))$ about the identity in $\text{SL}(n)^d$, such that

$$\inf_{g \in B} \|g \cdot w\|^2 \geq \text{cap } (v) + \varepsilon.$$

Moreover, it holds that $1/4 \leq \text{cap } (w) \leq 1$ and $1/2 \leq \|w\| \leq 1$. 

CCC 2021
4.6 A bound on weight margin and gap for quivers

For \( d \geq 2 \) let \( Q_d \) be the quiver
\[
\begin{array}{cccccccc}
1 & \longrightarrow & 2 & \longrightarrow & 3 & \text{........} & d-2 & \longrightarrow & d-1 & \longrightarrow & d \\
1 & \longrightarrow & 2 & \longleftrightarrow & 3 & \text{........} & d-2 & \longrightarrow & d-1 & \longleftrightarrow & d
\end{array}
\]
if \( d \) even
\[
\begin{array}{cccccccc}
1 & \longrightarrow & 2 & \longrightarrow & 3 & \text{........} & d-2 & \longrightarrow & d-1 \\
1 & \longrightarrow & 2 & \longleftrightarrow & 3 & \text{........} & d-2 & \longrightarrow & d-1
\end{array}
\]
if \( d \) odd.

and let \( Q_d^{(k)} \) be the quiver one obtains from \( Q_d \) by adding \( k-1 \) additional copies of each arrow in \( Q_d \). As before, let \( G = \text{SL}(n)^d \) and \( T = \text{ST}(n)^d \). Then \( G \) acts on the quiver \( Q_d \) with dimension vector \((n, \ldots, n)\) as described in the introduction. We denote the corresponding representation by \( \pi_d \). Note that the action of \( G \) on \( Q_d^{(k)} \) with dimension vector \((n, \ldots, n)\) is given by \( \pi_d^k \).

In this subsection we prove a bound on the weight margin of \( \pi_d \) and on the gap of \( \pi_d^k \). The bound on \( \gamma_G(\pi_d^k) \) is thanks to the refinement of freeness in Proposition 4.8 pointed out by Visu Makam.

\begin{theorem}
Let \( n, d \geq 2 \) and denote the natural action of \( G = \text{SL}(n)^d \) on the quiver \( Q_d \) with dimension vector \((n, \ldots, n)\) by \( \pi_d \): \( \text{SL}(n)^d \to \text{GL}(V_d) \), where \( V_d = (\mathbb{C}^{n \times n})^{d-1} \). The representation \( \pi_d^k \) corresponds to the \( G \)-action on the quiver \( Q_d^{(n)} \) with dimension vector \((n, \ldots, n)\). It holds that
\[
\gamma_T(\pi_d) \leq (n-1)^{-d+1} \quad \text{and} \quad \gamma_G(\pi_d^k) \leq (n-1)^{-d+1}.
\]
\end{theorem}

\begin{remark}
Before proving the theorem, we point out a few consequences.
\end{remark}

1. **Theorem 4.25** shows that \( \gamma_T(\pi_d)^{-1} \) and \( \gamma_G(\pi_d^k)^{-1} \) are not polynomially bounded with respect to \( \dim V_d = (d-1)n^2 \) and \( \dim \text{SL}(n)^d = d(n^2 - 1) \). Instead we see for fixed \( n \) and \( d \to \infty \) an exponential behaviour in the number of vertices \( d \). Thus, our bound shows that the exponential behaviour in \( d \) cannot be avoided in general lower bounds for quiver actions like [12, Theorem 6.21 Item 4]. The latter applied to \( \pi_d \) shows \( \gamma_T(\pi_d) \geq n^{-d-(3/2)d}(dn + 1)^{-d} \).

2. The proof of Theorem 4.25 below shows that for the bound on the gap it is enough to consider the quiver \( Q_d^{(n-1)} \) with an additional \( n^{th} \) arrow from \( d \) to \( d-1 \).

3. The ideas presented below can be adjusted to prove similar bounds for other dimension vectors. For example, one can show that the gap for the \( \text{SL} \)-action on \( Q_d^{(2)} \) with dimension vector \((1, 3, 3, \ldots, 3, 2)\) is inverse exponential in \( d \). This aligns with an algebraic barrier for this action; the invariants that cut out the null cone for this action have exponential degree [19, Proposition 1.5].

4. The quiver \( Q_d \) is of finite representation type and has no oriented cycles. Therefore, the null-cone membership problem for \( \pi_d \) can be solved in polynomial-time by algebraic algorithms. This means \( Q_d \) is an example where the weight margin is very small but there still exist efficient algorithms. Can the existence of efficient algorithms still be explained by a large gap in this case? This leads to the following interesting open question.

\begin{problem}
Is the gap \( \gamma_G(\pi_d) \) inverse polynomial in \( n \) and \( d \)?
\end{problem}

A positive answer would provide an interesting example, since in this case the weight margin of \( \pi_d \) would be significantly smaller than the gap of \( \pi_d \).

We now introduce several lemmas needed to prove Theorem 4.25. Note that the set of weights of \( \pi_d \) viewed as a subset of \( (\mathbb{R}^n)^d \) is
\[
\{(e_1, e_2, \ldots, e_n, 0, \ldots, 0), (0, e_1, e_2, \ldots, e_n, 0, \ldots, 0), \ldots, (0, \ldots, 0, e_i, -e_j) \mid i, j \in [n] \}.
\]

\[20\] Personal communication with Visu Makam. There does not seem to be an explicit reference in the literature.
We define recursively the subsets of weights
\[ \Gamma_2 := \{(\varepsilon_i, -\varepsilon_j) \mid i \in [n-1], j \in [n]\} \subseteq \Omega(\pi_2) \subseteq \mathbb{R}^{2n} \]
for \( d > 3 \), \( \Gamma_d := \left \{ ((-1)^d \varepsilon_i, (-1)^{d-1} \varepsilon_n, 0, \ldots, 0) \mid i \in [n-1] \right \} \cup \left \{ (0_n) \times \Gamma_{d-1} \right \} \subseteq \Omega(\pi_d) \subseteq \mathbb{R}^{dn} \).

**Remark 4.28.** We note that for \( d \geq 2 \), \( \Gamma_d \) is not free. For instance, we can always write
\[ (0_n, \ldots, 0_n, \varepsilon_1, - \varepsilon_1) = (0_n, \ldots, 0_n, \varepsilon_1, - \varepsilon_2) + (0_n, \ldots, 0_n, \varepsilon_2 - \varepsilon_1), \]
i.e. the weights \((0_n, \ldots, 0_n, \varepsilon_1, - \varepsilon_1), (0_n, \ldots, 0_n, \varepsilon_1, - \varepsilon_2) \in \Gamma_d \) differ by the root \((0_n, \ldots, 0_n, \varepsilon_2 - \varepsilon_1) \) of \( \text{SL}(n)^d \). Therefore, we cannot deduce a bound on the gap \( \gamma_G(\pi_d) \) via Proposition 4.8. However, the latter allows us to deduce at least a bound on the gap of \( \pi_d^\dagger \).

In the next two lemmas we show that \( \Gamma_d \) witnesses the bound on \( \gamma_T(\pi_d) \) and afterwards we use Proposition 4.8 to transfer this bound to \( \gamma_G(\pi_d^\dagger) \).

**Lemma 4.29.** For all \( d \geq 2 \) it holds that \( 0 \notin \text{conv}(\Gamma_d) \).

**Proof.** We prove the statement by induction on \( d \geq 2 \). For \( d = 2 \), just note that any element in \( \text{conv}(\Gamma_2) \subseteq \mathbb{R}^{2n} \) has value \(-1/n\) in the \( n\)-th entry. In particular, \( 0 \notin \text{conv}(\Gamma_2) \). For \( d \geq 3 \) let
\[ x = \sum_{\omega \in \Gamma_d} \lambda_\omega \omega , \quad \lambda_\omega \geq 0 \]
be a convex combination of the elements in \( \Gamma_d \). Assume there is an \( i \in [n-1] \) such that for
\[ \omega_i := ((-1)^d \varepsilon_i, (-1)^{d-1} \varepsilon_n, 0, \ldots, 0_n) \]
one has \( \lambda_{\omega_i} > 0 \). Then the \( n\)-th entry of \( x \) is non-zero, since \( \omega_i \) has \( n\)-th entry \((-1)^{d+1}/n\) and all (other) \( \omega \in \Gamma_d \) have \((-1)^{d+1}/n\) or zero as \( n\)-th entry. On the other hand, if \( \lambda_{\omega_i} = 0 \) for all \( i \in [n-1] \), then \( x \in \{0_n\} \times \text{conv}(\Gamma_{d-1}) \). By induction hypothesis on \( d-1 \) we necessarily have \( x \neq 0 \). ▶

**Lemma 4.30.** For \( d \geq 2 \) it holds that \( x_d := \lambda_d((-1)^{d-1} \varepsilon_n, 0_n, \ldots, 0_n) \in \text{conv}(\Gamma_d) \), where
\[ \lambda_d := \left( \sum_{i=1}^{d-1} (n-1)^i \right)^{-1} . \]
In particular, \( \|x_d\|_2 < |\lambda_d| \leq (n-1)^{-d+1} \).

**Proof.** We proceed by induction on \( d \geq 2 \). In the case \( d = 2 \), consider the convex combination
\[ \sum_{i=1}^{n-1} \sum_{j=1}^{n} \frac{1}{(n-1)n} (\varepsilon_i, -\varepsilon_j) = \frac{1}{n-1} (-\varepsilon_n, 0_n) = x_2 , \]
where we used (5). Now assume the claim is proven for some \( d \geq 2 \), hence
\[ \lambda_d(0_n, (-1)^{d-1} \varepsilon_n, 0_n, \ldots, 0_n) \in \{0_n\} \times \text{conv}(\Gamma_d) \subseteq \text{conv}(\Gamma_{d+1}) . \tag{33} \]
Setting \( \mu := (n-1)\lambda_{d+1} \lambda_d^{-1} \) we have \( \mu \lambda_d = (n-1)\lambda_{d+1} \) and \( \mu + (n-1)\lambda_{d+1} = 1 \). Together with (5) and (33) we deduce \( x_{d+1} \in \text{conv}(\Gamma_{d+1}) \) via
\[ \mu \lambda_d(0_n, (-1)^{d-1} \varepsilon_n, 0_n, \ldots, 0_n) + \lambda_{d+1} \sum_{i=1}^{n-1} ((-1)^{d+1} \varepsilon_i, (-1)^d \varepsilon_n, 0_n, \ldots, 0_n) = x_{d+1} . \]
This ends the induction. Finally, \( \|x_d\|_2 < |\lambda_d| \) follows from \( \|\varepsilon_n\|_2 < 1 \). ▶
Proof of Theorem 4.25. By Lemma 4.29 and Lemma 4.30 we have

\[ \gamma_T(\pi_d) \leq (n-1)^{-d+1}. \]

With the fact \( \Omega(\pi_d) = \Omega(\pi_d^n) \) and with Proposition 4.8 we transfer this bound to the gap of \( \pi_d^n \). To do so, we note that the natural inner product on \( V_d^n = (\mathbb{C}^{n \times n})^n(d-1) \), given by the trace inner product on each \( \mathbb{C}^{n \times n} \) copy, is invariant under the action of \( K = \text{SU}(n)^d \). Clearly, distinct \( \mathbb{C}^{n \times n} \) copies are orthogonal under this inner product. Thus, to be able to apply Proposition 4.8 it is enough to assign to each \( \mathbb{C}^{n \times n} \) copy, i.e. to each arrow of \( Q_d^n \), a matrix \( M_i \) such that supp(\( M_i \)) is free and \( \Gamma_d = \bigcup_i \text{supp} (M_i) \).

For this, we consider the \( n \times n \) matrices

\[ M := \begin{pmatrix} I_{n-1} & 0 \\ 0 & 0 \end{pmatrix} \quad \text{and} \quad P := \begin{pmatrix} 0 & I_{n-1} \\ 1 & 0 \end{pmatrix}, \]

and \( E_{i,j} \) is the matrix with \((i,j)\)-entry one and all other entries zero. Then \( E_{i,i}P = E_{i,i,\sigma(i)} \), where \( \sigma : [n] \to [n] \) is the cycle \((1 \ 2 \ \ldots \ n)\). Therefore, for \( k \in [n] \) we have

\[ \text{supp} \left( MP^{k-1} \right) = \left\{ 0_{n(d-2)}, \varepsilon_{i_1},-\varepsilon_{\sigma^{-1}(i_1)} \mid i \in [n-1] \right\} \quad \text{and} \quad [0_{n(d-2)}] \times \Gamma_2 = \bigcup_{k \in [n]} \text{supp} \left( MP^{k-1} \right). \]

For fixed \( k \), \( i_1 \neq i_2 \) implies \( \sigma^{k-1}(i_1) \neq \sigma^{k-1}(i_2) \), so any distinct elements of \( \text{supp}(MP^{k-1}) \) differ in the last two \( \mathbb{R}^n \)-components. Hence, each \( \text{supp}(MP^{k-1}) \) is free and we assign \( M, MP, \ldots, MP^{n-1} \) to the \( n \) arrows that go from vertex \( d \) to vertex \( d-1 \). For \( l \in [d-2] \), we assign to the \( n \) arrows between the vertices \( l \) and \( l+1 \) each of the matrices \( E_{1,n}, E_{2,n}, \ldots, E_{n-1,n} \) at least once. (Exactly one of the latter matrices is assigned to two of these arrows.) Clearly, the support of \( E_{i,n}, i \in [n-1] \) is free as it contains just one weight. By construction, this assignment does the job. Moreover, the argument shows that \( n-1 \) arrows between the vertices \( l \) and \( l+1, l \in [d-2], \) suffice.

B Representation theory background

In this section we briefly recall some representation theory. All the concepts we present here actually work in the very general setting of reductive groups and their rational representations, see e.g. [12, section 2]. For the sake of clarity and concreteness we stick to the special case needed in this paper, i.e. the reductive group \( \text{SL}(n)^d := \text{SL}(n) \times \cdots \times \text{SL}(n) \) with \( d \geq 1 \) many copies of \( \text{SL}(n) \).

We call a Euclidean-closed subgroup \( H \subseteq \text{GL}(n) \) a matrix Lie group. Indeed, such an \( H \) is naturally a Lie group (c.f. [31, Theorem 1.19]) with real Lie algebra

\[ \text{Lie}(H) := \{ A \in \mathbb{C}^{n \times n} : \forall t \in \mathbb{R} : e^{tA} \in H \} \]
The Lie bracket for \( \text{Lie}(H) \) is the commutator \([A, B] := AB - BA\). Moreover, for \( d \geq 1 \) the product \( H^d := H \times \cdots \times H \) becomes a matrix Lie group via block-diagonal embedding into \( \text{GL}(dn) \), i.e.

\[
H^d \hookrightarrow \text{GL}(dn), \quad (h_1, \ldots, h_d) \mapsto \begin{pmatrix} h_1 & & \\ & \ddots & \\ & & h_d \end{pmatrix}
\]

Then the Lie algebra of \( H^d \) is \( \text{Lie}(H)^d = \text{Lie}(H) \times \cdots \times \text{Lie}(H) \) block-diagonally embedded into \( \mathbb{C}^{dn \times dn} \). If \( G \subseteq \text{GL}(n) \) is another matrix Lie group, then \( G \cap H \) is again a matrix Lie group with Lie algebra \( \text{Lie}(G \cap H) = \text{Lie}(G) \cap \text{Lie}(H) \).

**Example B.1.** The groups \( \text{GL}(n) \), \( \text{SL}(n) \), \( \text{U}(n) \) and \( \text{GT}(n) \) are matrix Lie groups with Lie algebras

\[
\text{Lie}(\text{GL}(n)) = \mathbb{C}^{n \times n} \quad \text{Lie}(\text{U}(n)) = \{ A \in \mathbb{C}^{n \times n} \mid A^\dagger = -A \} = i \text{Herm}(n)
\]

\[
\text{Lie}(\text{SL}(n)) = \{ A \in \mathbb{C}^{n \times n} \mid \text{tr}(A) = 0 \} \quad \text{Lie}(\text{GT}(n)) = \{ A \in \mathbb{C}^{n \times n} \mid A \text{ diagonal matrix} \}
\]

Therefore, also \( \text{SU}(n) \), \( \text{ST}(n) \) and \( \text{U}(n) \cap \text{ST}(n) \) are matrix Lie groups and their Lie algebras are obtained by corresponding intersections of the above Lie algebras. In particular, we have

\[
\text{Lie}(\text{U}(n) \cap \text{ST}(n)) = \{ i \text{diag}(x_1, \ldots, x_n) \mid x_j \in \mathbb{R}, x_1 + \ldots + x_n = 0 \}.
\]

Thus, we can identify \( i \text{Lie}(\text{U}(n) \cap \text{ST}(n)) \) with the orthogonal complement \((\mathbb{I}_n)^\perp \subseteq \mathbb{R}^n\) of the all-ones vector \( \mathbb{I}_n \).

In the following, let \( G := \text{SL}(n)^d \) for some \( d \geq 1 \). Then \( K := \text{SU}(n)^d \) is a maximal compact subgroup of \( G \), and \( T := \text{ST}(n)^d \) and \( T_K := K \cap T \) are maximal tori of \( G \) and \( K \), respectively. As explained above, we think of all these groups as matrix Lie subgroups of \( \text{GL}(dn) \), and hence of their Lie algebras as subsets of \( \mathbb{C}^{dn \times dn} \).

A rational representation of \( G = \text{SL}(n)^d \) is a group morphism \( \pi : G \rightarrow \text{GL}(V) \), such that in some basis of \( V \) the matrix entries of \( \pi(g) \in \text{GL}(V) \) are polynomials in the matrix entries of \( g \).

Such a rational representation of \( G \) induces a representation of the Lie algebras by

\[
\Pi : \text{Lie}(G) \rightarrow \text{End}(V), \quad A \mapsto \frac{d}{dt}_{|_{t=0}} \pi(e^{tA})
\]

with the property \( \pi(e^A) = e^{\Pi(A)} \) for all \( A \in \text{Lie}(G) \). Restricting \( \pi \) to the commutative subgroup \( T \) induces a so-called weight space decomposition of \( V \). That is, there is some finite set \( \Omega(\pi) \subseteq i \text{Lie}(T_K) \) and a decomposition \( V = \bigoplus_{\omega \in \Omega(\pi)} V_\omega \) into non-zero subspaces such that each \( \omega \in \Omega(\pi) \) and any \( v_\omega \in V_\omega \) satisfy

\[
\forall A \in \text{Lie}(T) : \quad \pi(e^A) v_\omega = e^{\text{tr}(A\omega)} v_\omega
\]

or, equivalently,

\[
\forall A \in \text{Lie}(T) : \quad \Pi(A) v_\omega = \text{tr}(A\omega) v_\omega.
\]

The elements \( \omega \in \Omega(\pi) \) are called weights of \( \pi \) and the \( v_\omega \in V_\omega \) are called weight vectors. Considering Example B.1 we frequently use the identification \( i \text{Lie}(T_K) \cong (\mathbb{I}_n^\perp)^d \), where \( \mathbb{I}_n^\perp \) is the orthogonal complement of \( \mathbb{I}_n \) in \( \mathbb{R}^n \). We note that for \( \omega \in i \text{Lie}(T_K) \subseteq \mathbb{C}^{dn \times dn} \) the Frobenius norm \( \|\omega\|_F \) becomes under this identification the 2-norm \( |\omega|_2 \) in \( (\mathbb{R}^n)^d \).

---

21 In other words, \( \pi \) is a morphism of affine algebraic groups.
Example B.2. Let \( d = 1 \). The group \( G = \text{SL}(n) \) acts on \( \mathbb{C}^n \) by left-multiplication, which induces the rational representation \( \pi : \text{SL}(n) \to \text{GL}(n), g \mapsto g \) with corresponding Lie algebra representation \( \Pi : \text{Lie} (\text{SL}(n)) \to \mathbb{C}^{n \times n}, A \mapsto A \). For \( i \in [n] \) we set
\[
e_i := e_i - \frac{1}{n} 1_n \in \mathbb{R}_n \subseteq \mathbb{R}^n.
\]
For all \( A = \text{diag}(a_1, \ldots, a_n) \in \text{Lie} (T) \) and all \( i \in [n] \)
\[
\pi (e^A) e_i = \text{diag}(e^{a_1}, \ldots, e^{a_n}) e_i = e^{a_i} e_i = e^{\text{tr} (A \text{diag} (e_i))} e_i
\]
where we used \( a_1 + \ldots + a_n = 0 \) in \((\ast)\). Thus, \( e_i \in \mathbb{R}_n \cong i \text{Lie} (T_K) \) is a weight of \( \pi \) with weight vector \( e_i \). Since \( \mathbb{C}^n = \bigoplus_i \mathbb{C} e_i \), we deduce \( \Omega (\pi) = \{ e_i \mid i \in [n] \} \).

Example B.3. Of particular importance in representation theory is the adjoint representation. That is, \( G = \text{SL}(n)^d \) acts on its Lie algebra by conjugation \( \text{Ad} : G \to \text{GL} (\text{Lie} (G)), g \mapsto (A \mapsto g A g^{-1}) \), which induces the representation of Lie algebras \( \text{ad} : \text{Lie} (G) \to \text{End} (\text{Lie} (G)) \), \( A \mapsto (B \mapsto [A, B]) \). The non-zero weights \( \alpha \in \Omega (\text{Ad}) \) are called roots of \( G \) and the weight spaces \( \text{Lie} (G)_\alpha \) are called root spaces.

Let \( d = 1 \) and for \( i, j \in [n] \) denote by \( E_{i,j} \) the matrix with entry one at position \( i, j \) and all other entries being zero. Then for \( i, j \in [n] \) with \( i \neq j \) and for all \( A = \text{diag}(a_1, \ldots, a_n) \), \( B \in \text{Lie} (T) \) we compute
\[
\text{ad} (A) E_{i,j} = [A, E_{i,j}] = (a_i - a_j) E_{i,j} = \text{tr} \left ( A \text{diag} (e_i - e_j) \right ) E_{i,j},
\]
\[
\text{ad} (A) (B) = [A, B] = 0.
\]
Since \( 0_n, e_i - e_j \in \mathbb{R}_n \cong i \text{Lie} (T_K) \), we deduce \( e_i - e_j \in \Omega (\text{Ad}) \) with weight vector \( E_{i,j} \) and \( 0_n \in \Omega (\text{Ad}) \) with weight vector \( B \in \text{Lie} (T) \). Therefore, the set of roots of \( \text{SL}(n) \) is \( \{ e_i - e_j \mid i, j \in [n], i \neq j \} \), because \( \text{Lie} (G) = \text{Lie} (T) \bigoplus \bigoplus_{i \neq j} \mathbb{C} E_{i,j} \).

More generally, one can deduce that the roots of \( G = \text{SL}(n)^d \) are the
\[
(e_i - e_j, 0_n, \ldots, 0_n), (0_n, e_i - e_j, 0_n, \ldots, 0_n), \ldots, (0_n, \ldots, 0_n, e_i - e_j) \in (\mathbb{R}^n)^d
\]
for \( i, j \in [n] \) with \( i \neq j \) and that \( \text{Lie} (G) = \text{Lie} (T) \bigoplus \bigoplus_\alpha \text{Lie} (G)_\alpha \).

We need the following property of roots, see e.g. [31, Lemma 7.11].

Proposition B.4. Let \( \alpha \) be a root of \( G = \text{SL}(n)^d \) and let \( \pi : G \to \text{GL} (V) \) be a rational representation of \( G \). If \( V_{\omega} \) is the weight space of some weight \( \omega \in \Omega (\pi) \), then
\[
\Pi (\text{Lie} (G)_\alpha) (V_{\omega}) \subseteq V_{\omega + \alpha},
\]
where \( V_{\omega + \alpha} := \{ 0 \} \), if \( \omega + \alpha \notin \Omega (\pi) \).

C Padding for tensor margin and tensor gap

The Theorems 2.1 and 4.11 only give for all \( n \geq 2 \) bounds for certain sub-families of \( \{(n, d) \mid d \geq 3\} \). Still, we can deduce Theorems 1.3 and 1.6 via some padding on the number of tensor factors \( d \) that padding is provided in Proposition C.1 below. Recall the representation for tensor scaling
\[
\pi_{n,d} : \text{SL}(n)^d \to \text{GL} \left ( (\mathbb{C}^n)^{\otimes d} \right ) , \ (g_1, \ldots, g_d) \mapsto g_1 \otimes \cdots \otimes g_d,
\]
which set of weights is \( \Omega (\pi_{n,d}) = \Omega_{n,d} = \{ e_i \mid i \in [n] \}^{d} \subseteq (\mathbb{R}^n)^d \).
Proposition C.1. Let $G := \text{SL}(n)^d$ and $n, d \geq 1$. Consider a set of weights $\Gamma_{n,d} \subseteq \Omega_{n,d}$ such that $0 \notin \text{conv}(\Gamma_{n,d})$, i.e., $\Gamma_{n,d}$ witnesses the inequality $\gamma(\Omega_{n,d}) = \gamma_T(\pi_{n,d}) \leq \text{dist}(0, \text{conv}(\Gamma_{n,d}))$.

1. Then $\gamma(\Omega_{n,d+1}) \leq \text{dist}(0, \text{conv}(\Gamma_{n,d}))$. Consequently, $\gamma(\Omega_{n,d+1}) \leq \gamma(\Omega_{n,d})$.
2. If additionally $\Gamma_{n,d}$ is free, then $\gamma_G(\pi_{n,d+r}) \leq \text{dist}(0, \text{conv}(\Gamma_{n,d}))$ for all $r \geq 2$.

Proof. To prove the statement we set for $r \geq 1$

$\Delta_r := \{\{\varepsilon_i, \ldots, \varepsilon_i\} | i \in [n]\} \subseteq (\mathbb{R}^n)^r$ and $\Gamma_{n,d+r} := \Gamma_{n,d} \times \Delta_r \subseteq \Omega(\pi_{n,d+r})$.

By Equation (5) we have $\text{dist}(\text{conv}(\Gamma_{n,d+r}), \text{conv}(\Gamma_{n,\text{aff}})) \leq \text{dist}(0, \text{conv}(\Gamma_{n,d+r}))$.

Clearly, $0 \in \text{conv}(\Gamma_{n,d+r})$ implies $0 \in \text{conv}(\Gamma_{n,d})$ or, by contraposition, the assumption $0 \notin \text{conv}(\Gamma_{n,d})$ yields $0 \notin \text{conv}(\Gamma_{n,d+r})$. The latter for $r = 1$ shows $\gamma_T(\pi_{n,d+1}) \leq \text{dist}(0, \text{conv}(\Gamma_{n,d+1}))$ and we conclude the first assertion with Equation (34).

Assume in addition that $\Gamma_{n,d}$ is free and let $r \geq 2$. Considering Definition 4.12 and Proposition 4.13 we prove that also $\Gamma_{n,d+r}$ is free. For this, let $M \subseteq [n]^r$ be such that $\Gamma_M \Gamma_{n,d}$ and consider $(x, i, \ldots, i), (y, j, \ldots, j) \in M \times [n]^r$ with $(x, i, \ldots, i) \neq (y, j, \ldots, j)$. If $x \neq y$, then $x$ and $y$ differ in at least two components by freeness of $M$. If $x = y$, then we have $i \neq j$ and so $(x, i, \ldots, i)$ and $(y, j, \ldots, j)$ differ in at least two components, using $r \geq 2$. This shows that $\Gamma_{n,d+r}$ is free for $r \geq 2$. Since also $0 \notin \text{conv}(\Gamma_{n,d+r})$ we obtain with Proposition 4.8 that $\gamma_G(\pi_{n,d+r}) \leq \text{dist}(0, \text{conv}(\Gamma_{n,d+r}))$ holds for all $r \geq 2$. Finally, we deduce the second statement using Equation (34).

Proposition C.2. For $n \geq 3$ it holds that $\gamma_T(\pi_{n,4}) \leq \gamma_G(\pi_{n,4}) \leq 2^{-n+1}$.

Proof. This result can be obtained by imitating the proof of Theorem 2.1(b) in subsection 2.2 by using

$\Gamma_{n,4} := \{(\varepsilon_i, \varepsilon_j, \varepsilon_k, \varepsilon_i) | (i, j, k) \in \{0, 1\} \subseteq \Omega(\pi_{n,4})\}$.

Clearly, $0 \notin \text{conv}(\Gamma_{n,4})$ as $0 \notin \text{conv}(\Gamma_{n,3})$ by Lemma 2.8. Moreover, one can show with Lemma 2.5 (similar to the proof of Lemma 2.7) that

$x := -\frac{1}{c^{n-1}}(\varepsilon_1, \varepsilon_1, \varepsilon_1, \varepsilon_1) \in \text{conv}(\Gamma_{n,4}), \text{ where } c = n - 2^{-n+1} \geq 2$.

Thus, $\|\varepsilon_1, \varepsilon_1, \varepsilon_1\| \leq \sqrt{4} \text{ implies } \|x\| \leq e^{-2^{-n+1}} \sqrt{4} \leq 2^{-n+1}$. This proves $\gamma_T(\pi_{n,4}) \leq 2^{-n+1}$.

Since $\mathfrak{M}_n$ is free by Proposition 4.13, the set $\{(i, j, k) | (i, j, k) \in \mathfrak{M}_n\}$ is free. Hence, we conclude $\gamma_G(\pi_{n,4}) \leq 2^{-n+1}$ with Proposition 4.13 and Proposition 4.8.

Proof of Lemma 2.11

Proof. For the sake of contradiction assume that $0 \notin \text{Aff}(\Gamma_{n,6r-3})$. Then there are coefficients $a_s, b_s, c_s \in \mathbb{R}$, where $2 \leq s \leq rn$, such that $a_2 = \ldots = a_r = b_2 = \ldots = b_r = 0$, $\sum_a (a_s + b_s + c_s) = 1$ and

\[
\sum_{s=2}^{rn} \left(a_s \varepsilon_{\sigma(s), \sigma(1), \sigma(2)} + b_s \varepsilon_{\sigma(s), \sigma(3), \sigma(1)} + c_s \varepsilon_{\sigma(s-1), \sigma(3), \sigma(1)}\right) = 0 \in (\mathbb{R}^n)^{6r-3}.
\] (35)
The bulk of our work will consist of proving the equations
\[ \begin{align*}
  b_2 + c_2 &= b_3 + c_3 = \ldots = b_{rn} + c_{rn} \\
  a_2 + c_2 &= a_3 + c_3 = \ldots = a_{rn} + c_{rn}.
\end{align*} \tag{36} \tag{37} \]

From here we will derive a contradiction. We now set about proving Equations (36) and (37). Rewrite the left-hand-side of Equation (35) as the collection for \( k \in [2r - 1] \) of the following affine linear combinations of \( \varepsilon_1, \ldots, \varepsilon_n \) in \( \mathbb{R}^n \):
\[ \begin{align*}
  \sum_{s=2}^{rn} \left( a_s \varepsilon_{\sigma_k(s)} + b_s \varepsilon_{\sigma_k(s)} + c_s \varepsilon_{\sigma_k(s-1)} \right) &= 0 \tag{38} \\
  \sum_{s=2}^{rn} \left( a_s \varepsilon_{\sigma_k(1)} + b_s \varepsilon_{\sigma_k(s)} + c_s \varepsilon_{\sigma_k(s)} \right) &= 0 \tag{39} \\
  \sum_{s=2}^{rn} \left( a_s \varepsilon_{\sigma_k(s)} + b_s \varepsilon_{\sigma_k(1)} + c_s \varepsilon_{\sigma_k(s)} \right) &= 0. \tag{40}
\end{align*} \]

If we expand this expressions as affine linear combinations of the \( \varepsilon_l \), then by Lemma 2.2 the coefficient of \( \varepsilon_l \) must be \( n^{-1} \) for all \( l \in [n] \). Translating this for equations (38), (39) and (40) respectively with \( 2 \leq l \leq n \) and \( k \in [r] \), and using for \( j \in [r] \) that
\[ \sigma_k(r(l - 1) + j - k + 1) = \left( \frac{r(l - 1) + j - k + 1 + (k - 1)}{r} \right) = l \tag{41} \]
we get
\[ \begin{align*}
  \forall k \in [r], l \in \{2, 3, \ldots, n\} : \sum_{j=1}^{r} \left( a_{r(l-1)+j-k+1} + b_{r(l-1)+j-k+1} + c_{r(l-1)+j-k+2} \right) &= \frac{1}{n} \tag{42} \\
  \forall k \in [r], l \in \{2, 3, \ldots, n\} : \sum_{j=1}^{r} \left( b_{r(l-1)+j-k+1} + c_{r(l-1)+j-k+1} \right) &= \frac{1}{n} \tag{43} \\
  \forall k \in [r], l \in \{2, 3, \ldots, n\} : \sum_{j=1}^{r} \left( a_{r(l-1)+j-k+1} + c_{r(l-1)+j-k+1} \right) &= \frac{1}{n} \tag{44}
\end{align*} \]
respectively, where we set \( c_{rn+1} := 0 \). Fixing some \( l \geq 2 \) and subtracting Equation (43) with \( k = 1 \) from Equation (44) for \( k = 2 \), we find a telescoping sum that reduces to
\[ b_{r(l-1)} + c_{r(l-1)} = b_{rl} + c_{rl}. \]
Indeed, subtracting the two yields
\[ \begin{align*}
  0 &= \sum_{j=1}^{r} \left( b_{r(l-1)+j-k+1} + c_{r(l-1)+j-k+1} \right) - \sum_{j=1}^{r} \left( b_{r(l-1)+j} + c_{r(l-1)+j} \right) \\
  &= \sum_{j=0}^{r-1} \left( b_{r(l-1)+j} + c_{r(l-1)+j} \right) - \sum_{j=1}^{r} \left( b_{r(l-1)+j} + c_{r(l-1)+j} \right) \\
  &= (b_{r(l-1)} + c_{r(l-1)}) - (b_{rl} + c_{rl}).
\end{align*} \]

More generally, for \( k \in [r-1] \) combining (43) for \( k \) and \( k \leftrightarrow k+1 \), implies \( b_{rl-k+1} + c_{rl-k+1} = b_{rl-(k+1)} + c_{rl-(k+1)} \) for all \( 2, \ldots, n \), i.e. for every \( k \in [r-1] \) we have
\[ c_{r-k+1} = b_{r-k+1} + c_{r-k+1} = b_{2r-k+1} + c_{2r-k+1} = \ldots = b_{rn-k+1} + c_{rn-k+1}. \tag{45} \]
We are still missing the value $k = 0$, or the equations
\[ b_{r+1} + c_{r+1} = b_{2r+1} + c_{2r+1} = \ldots = b_{r(n-1)+1} + c_{r(n-1)+1}. \]  
(46)

We obtain this by subtracting, for $l = 2, \ldots, n$, (43) for $k = 1$ and $l$ from (43) with $k = r$ and $l = l + 1$. Indeed,
\[
0 = \sum_{j=1}^{r} (b_{rl+j-r+1} + c_{rl+j-r+1}) - \sum_{j=1}^{r} (b_{rl-1+j} + c_{rl-1+j}) \\
= \sum_{j=2}^{r+1} (b_{rl-1+j} + c_{rl-1+j}) - \sum_{j=1}^{r} (b_{rl-1+j} + c_{rl-1+j}) \\
= (b_{rl+1} + c_{rl+1}) - (b_{rl-1+j} + c_{rl-1+j}).
\]

Lastly, we are missing the equations $b_2 + c_2 = b_3 + c_3 = \ldots = b_{r+1} + c_{r+1}$ for Equation (36). We have not yet used in Equation (39) the values $k = r + m$ with $m \in [r - 1]$. For this we note that
\[
\sigma_{r+m}(j) = 2 \quad \text{for} \quad j \in \{r - m + 1 \cup \{r + 2, r + 3, \ldots, 2r\}.
\]

We use this equation to apply Lemma 2.2 to (39) for $\varepsilon_2$ and $k = r + m$ with $m \in [r - 1]$ to obtain
\[ b_{r-m+1} + c_{r-m+1} + \sum_{j=2}^{r} (b_{r+j} + c_{r+j}) = \frac{1}{n}. \]

We need one more equation to eliminate the right-hand term, so we use the following. Lemma 2.2 applied to equation (43) for $k = 1$ and $l = 2$ yields
\[ \sum_{j=1}^{r} (b_{r+j} + c_{r+j}) = \frac{1}{n}. \]

Subtracting this equation from the previous one yields, $b_{r-m+1} + c_{r-m+1} = b_{r+1} + c_{r+1}$ for all $m = 1, \ldots, r - 1$. Together with the equations (45) and (46) we conclude Equation (36). Analogously, (40) and (44) can be used to obtain Equation (37).

To get a contradiction we show that $a_s = b_s = c_s = 0$ for all $s = 2, 3, \ldots, rn$. For this, we set $a := \sum_s a_s$ and $b := \sum_s b_s$. Equation (41) still applies for $l = 1, k = 1$, so Lemma 2.2 applied to the coefficient of $\varepsilon_1$ in (38), in (39) and in (40) respectively for $k = 1$ gives
\[ \sum_{j=1}^{r} c_{j+1} = \frac{1}{n}, \quad a + \sum_{j=1}^{r} c_{j+1} = \frac{1}{n} \quad \text{and} \quad b + \sum_{j=1}^{r} c_{j+1} = \frac{1}{n} \]
respectively. Subtracting the second equation from the first gives $a = c_{r+1}$, and reasoning analogously for the third yields $a = b = c_{r+1}$. Moreover, (43) with $k = r$ and $l = 2$ is $\sum_{j=1}^{r} (b_{j+1} + c_{j+1}) = n^{-1}$. Using the latter together with $b_2 = \ldots = b_r = 0$ and $\sum_{j=1}^{r} c_{j+1} = n^{-1}$ yields $b_{r+1} = 0$ and similarly $a_{r+1} = 0$ via (44) with $k = r$ and $l = 2$.

Since now also $a_{r+1} = b_{r+1} = 0$, the equation (42) with $k = r$ and $l = 2$ simplifies to $\sum_{j=1}^{r} c_{j+2} = n^{-1}$. In conjunction with $\sum_{j=1}^{r} c_{j+1} = n^{-1}$ we deduce $c_2 = c_{r+2}$ and hence $b_{r+2} = 0 = c_{r+2}$ by (36) and (37). But now (42) with $k = r - 1$ and $l = 2$ is $\sum_{j=1}^{r} c_{j+3} = n^{-1}$ and together with $\sum_{j=1}^{r} c_{j+2} = n^{-1}$ we get $c_3 = c_{r+3}$. Continuing inductively we obtain
\[
\forall j \in [r]: \quad c_{j+1} = c_{r+j+1} \quad \text{and} \quad a_{r+j+1} = b_{r+j+1} = 0
\]
via (42) with \( l = 2, k \in [r] \) and via (36), (37). Then (42) with \( k = r \) and \( l = 3 \) simplifies to 

\[ \sum_{j=1}^{r-1} c_{r+j} = n^{-1} \] 

and together with \( n^{-1} = \sum_{j=1}^{r} c_{r+j+1} = \sum_{j=1}^{r} c_{r+j+1} \) we have \( c_{r+2} = c_{2r+2} \). Hence, \( b_{2r+2} = 0 \) via (36) respectively (37). Continuing inductively in the outlined manner with equation (42) for \( k \in [r], l = 3, \ldots, n \) and with the equations (36) and (37) we conclude \( a_s = b_s = 0 \) for all \( s = 2, 3, \ldots, r_n \), so \( a = b = 0 \). Finally, (36) implies \( c_{r+1} = c_s \) for all \( s = 2, \ldots, r_n \), but \( c_{r+1} = b = 0 \) giving the desired contradiction. \( \blacksquare \)

### E Padding and rounding for diameter bounds

We begin with the proof of Proposition 3.5. We prove it only for \( d = 3 \), but the proof goes through mutatis mutandis for all \( d \geq 1 \).

**Proof of Proposition 3.5.** Recall that \( q \) is the \( n \times n \times n \) array such that \( q_{ijk} = \frac{i}{n} p_{ijk} \) for \( i, j, k \in [t], q_{ii} = 1/n \) for \( t + 1 \leq i \leq n \), and \( q_{ijk} = 0 \) otherwise. We may split the inputs \( x, y, z \in \mathbb{R}^n \) into

\[
x = \left( x' + \alpha_1 \mathbb{1}_t, x'' - \frac{t}{n-t} \alpha_1 \mathbb{1}_{n-t} \right),
\]

\[
y = \left( y' + \alpha_2 \mathbb{1}_t, y'' - \frac{t}{n-t} \alpha_2 \mathbb{1}_{n-t} \right),
\]

\[
z = \left( z' + \alpha_3 \mathbb{1}_t, z'' - \frac{t}{n-t} \alpha_3 \mathbb{1}_{n-t} \right)
\]

where \( x', y', z' \in \mathbb{R}^n, x'', y'', z'' \in \mathbb{R}^{n-t} \) each sum to zero; write \( w = (x', y', z') \). As \( \| (x, y, z) \|_2 \geq \| w \|_2 \), it is enough to prove that \( \| w \|_2 \) is large for any approximate minimizer. By optimizing over \( \alpha_i \) and \( x'', y'', z'' \) for fixed \( w \), one computes that the optimum value for \( f_q \) for any fixed \( w \) is \( f_p(w)^{1/n} \). To see this, write

\[
f_q(x, y, z) = \frac{te^{\alpha_1 + \alpha_2 + \alpha_3}}{n} f_p(w) + \frac{e^{-\frac{t}{n-t}(\alpha_1 + \alpha_2 + \alpha_3)}}{n} \sum_{t=1}^{n} e^{x''_t + y''_t + z''_t}.
\]

First note that for fixed \( \alpha_i \)’s, the second term is minimized at \( x'' = y'' = z'' = 0 \) by Jensen’s inequality. Furthermore, the value only depends on \( \alpha := \alpha_1 + \alpha_2 + \alpha_3 \). With \( x'', y'', z'' = 0 \), we have

\[
f_q(x, y, z) = g(w, \alpha) := \frac{te^{\alpha}}{n} f_p(w) + \left( \frac{n-t}{n} \right) e^{-\frac{\alpha}{n-t}}.
\]

Taking the derivative in \( \alpha \), we see that this is minimized when \( f_p(w) e^\alpha = e^{-\frac{\alpha}{n-t}} \), or \( e^\alpha = f_p(w)^{-1/(1+\frac{\alpha}{n-t})} = f_p(w)^{-\frac{n-t}{\alpha}} \). Plugging this value in proves that the optimum is \( f_p(w)^{1/n} \). By concavity of \( x'^{1/n} \), provided \( f_p(w) \leq 1 \) we have

\[
f_p(w)^{1/n} - \text{cap}(p)^{1/n} \geq \frac{1 - \text{cap}(p)^{1/n}}{1 - \text{cap}(p)} (f_p(w) - \text{cap}(p)).
\]

The first factor in the second term is the slope of the line from \((\text{cap}(p), \text{cap}(p)^{1/n})\) to \((1, 1)\). Thus for any \( \varepsilon \ll 1 - \text{cap}(p) \), any \( \varepsilon \)-approximate minimizer for \( f_q \) has norm at least that of some \( \left( \frac{1 - \text{cap}(p)}{1 - \text{cap}(p)^{1/n}} \right) \varepsilon \)-approximate minimizer for \( f_p \). \( \blacksquare \)

**Proof of Lemma 4.23.** We use the dual expression: \( \log \text{cap} q = -\inf_{r, \omega = 0} D_{KL}(r||q) \) where \( r \) ranges over probability distributions on \( \Omega \). In particular,

\[
\log \text{cap} q \geq -D_{KL}(r||q)
\]
for any distribution \( r \) on \( \Omega \) with \( \mathbb{E}_r \omega = 0 \). Let \( r \) be a probability distribution; calculate
\[
\log \text{cap} q \geq -D_{KL}(r \| q) = -D_{KL}(r \| p) + D_{KL}(r \| p) - D_{KL}(r \| q) \\
= -D_{KL}(r \| p) + \sum_{\omega \in \Omega} r_\omega \log(r_\omega / p_\omega) - \sum_{\omega \in \Omega} r_\omega \log(r_\omega / q_\omega) \\
= -D_{KL}(r \| p) + \sum_{\omega \in \Omega} r_\omega (\log q_\omega - \log p_\omega).
\]
We lower bound \( \log q_\omega - \log p_\omega \geq \frac{1}{q_\omega}(q_\omega - p_\omega) \) by applying the inequality \( \log x \leq x - 1 \) to \( x = p_\omega / q_\omega \). Hence
\[
\log \text{cap} q \geq -D_{KL}(r \| p) + \sum_{\omega \in \Omega} r_\omega \frac{1}{q_\omega}(q_\omega - p_\omega) \\
\geq -D_{KL}(r \| p) - M_0 \| p - q \|_\infty.
\]
Allowing \(-D_{KL}(r \| p)\) to tend to \( \log \text{cap} p \) completes the proof. \( \blacksquare \)

**Proof of Lemma 4.22.** Applying Lemma 4.23 with the roles of \( p \) and \( q \) switched yields
\[
\log \text{cap} p \geq \log \text{cap} q - M \| p - q \|_\infty.
\]
Exponentiating both sides and applying the inequality \( e^x \geq 1 + x \) yields \( \log p \geq (1 - M \| p - q \|_\infty) \log q \). Thus
\[
\inf_{x \in B} f_q(x) = \inf_{x \in S} f_q(x) \geq -\sup_{x \in S} \left| f_q(x) - f_p(x) \right| + \inf_{x \in S} f_p(x).
\]
Note that the minimizer for \( f_q \) over \( B \) lies in the set \( S := B \cap \{ x : \forall \omega, q_\omega e^{x_\omega} \leq f_q(0) = \| q \|_1 \} \). For all \( x \in S \), we have \( e^{x_\omega} \leq \text{cap} q / p_\omega \) for all \( \omega \in \Omega \), so
\[
f_q(x) - f_p(x) \leq \sum_{\omega \in \Omega} \left| p_\omega - q_\omega \right| e^{x_\omega} \\
\leq \sum_{\omega \in \Omega} \left| p_\omega - q_\omega \right| q_\omega / q_\omega \\
\leq \| p - q \|_1 M \| q \|_1.
\]
Combining the above inequality with the lower bound for \( \text{cap}(p) \),
\[
\inf_{x \in B} f_q(x) \geq -M \| q \|_1 \| p - q \|_1 + (1 + \varepsilon) \text{cap} p \\
\geq (1 + \varepsilon)(1 - M \| p - q \|_\infty) \text{cap} q - M \| p - q \|_1 \| q \|_1. \quad \blacksquare

Abstract
Starting with the two standard model of randomized communication complexity, we study the communication complexity of functions when the protocol has access to a defective source of randomness. Specifically, we consider both the public-randomness and private-randomness cases, while replacing the commonly postulated perfect randomness with distributions over $\ell$ bit strings that have min-entropy at least $k \leq \ell$. We present general upper and lower bounds on the communication complexity in these cases, where the bounds are typically linear in $\ell - k$ and also depend on the size of the fooling set for the function being computed and on its standard randomized complexity.

1 Introduction
While communication complexity is typically viewed as a tool for establishing lower bound on other models of computation, one may also view it as a study of (two-party) collaborations that can be carried out using a small amount of communication. The (two) parties participating in such a typical collaboration have a common goal, which is modeled as the computation of a function of their private inputs, and they wish to achieve it efficiently, which means using a small amount of communication (i.e., much smaller than required for communicating their entire input).

Given this perspective, one can ask whether randomness is helpful, and it is well-known that it is extremely helpful. For example, computing the equality function requires deterministic protocols that use a linear amount of communication (i.e., are not significantly better than the straightforward one), but can be performed by randomized protocols that use a constant amount of communication. The question addressed in this work is what happens when the parties have at their disposal only defective sources of randomness?
14:2 Communication Complexity with Defective Randomness

1.1 The Models

Our starting point is the two standard models of randomized communication complexity, which are closely related in the standard setting but may not be so in the current setting. In the standard public randomness model, one postulates that the parties have access to a common (i.e., public) source of perfect randomness, whereas in the standard private randomness model, one postulates that each party has access to a private source of perfect randomness (which is uncorrelated to the other party’s source). Indeed, in the standard setting, the public randomness model can easily emulate the private randomness model, and the opposite emulation is also possible at a very moderate cost [9].

We consider variants of these two models in which the postulated sources of perfect randomness are replaced by defective sources of randomness. In particular, we consider sources that output \( \ell \)-bit long strings such that no string appears with probability exceeding \( 2^{-k} \); that is, we consider sources of min-entropy \( k \), with a focus on the case that \( k \in [\Omega(\log \ell), \ell) \). A special case of interest is when the min-entropy rate (i.e., \( k/\ell \)) is a constant smaller than 1 and the actual inputs are of length related to \( \ell \); yet, we shall consider the problem in almost full generality.

1.2 Our Results

We show that if the random sources available to the two parties are moderately defective in the sense that their min-entropy rate is a constant smaller than 1, then computing the equality function on strings of length comparable to the length of the random sources requires a linear amount of communication, just as in the case that one uses no randomness at all. More generally, we show that, when using defective sources of randomness, no improvement can be obtained over the lower bound on the communication complexity of deterministic protocol that follows by a “fooling set” argument (see Definition 2.2). The foregoing assertions refers to the case that \( \min(m, \ell) = \Omega(n) \) and \( k < (1 - \Omega(1)) \cdot \ell \).

**Theorem 1.1** (general lower bounds). Suppose that \( f : \{0,1\}^n \times \{0,1\}^n \rightarrow \{0,1\} \) has a fooling set of size \( 2^n \), and let \( k \leq \ell \).

- (public randomness version): If \( f \) is computed by a protocol whose only source of randomness is a public random string of length \( \ell \) that has min-entropy \( k \), then the protocol uses at least \( \min(m - 1, \ell - k - 1)/2 \) bits of communication.

- (private randomness version): If \( f \) is computed by a protocol in which the only source of randomness is provided by two independent random strings of length \( \ell \), each seen by one of the parties and having min-entropy \( k \), then the protocol uses at least \( \min(m - 1, \ell - k - 1)/2 \) bits of communication.

We stress that, in the current context, the two models (i.e., public-randomness and private-randomness) are not easily reducible to one another.\(^1\) Recall that lower-bounding the size of a fooling set is one of the King’s Roads for proving lower bounds on the deterministic communication complexity of functions.\(^2\) In particular, equality has a fooling set of size \( 2^n \). In general, the logarithm of the size of the fooling set seems a reasonable proxy for the deterministic communication complexity, but it is indeed interesting to ask whether a result as Theorem 1.1 holds with \( m \) replaced by the deterministic communication complexity of \( f \).

---

\(^1\) In particular, the fact that a random source of logarithmic length suffices does not apply here: we are given defective random sources of certain length, and cannot easily transform them to significantly shorter length.

\(^2\) However, as shown by Dietzfelbinger, Hromkovic, and Schnitger [4], the deterministic complexity may be exponentially larger than the lower bound provided by any fooling set.
While Theorem 1.1 asserts that using a moderately defective random sources of length that is comparable to the input is useless, it does not rule out the benefit of sources that are either less defective or are shorter (i.e., have shorter length). It turns out that it is possible to benefit from the use of such sources.

Theorem 1.2 (generic upper bounds). For \( f : \{0,1\}^n \times \{0,1\}^n \rightarrow \{0,1\} \) and \( k \geq 2 \log_2 n + O(1) \), the following holds.

- (public randomness version): Suppose that the randomized communication complexity of \( f \) in the standard public-randomness model is \( C \). Then, \( f \) can be computed by a protocol whose sole source of randomness is a public random string of length \( \ell \) that has min-entropy \( k \) using \( O(\ell - k + 1) \cdot C \) bits of communication.

- (private randomness version): Suppose that the randomized communication complexity of \( f \) in the standard private-randomness model is \( C \). Then, \( f \) can be computed by a protocol whose sole source of randomness is provided by two independent random strings of length \( \ell \), each seen by one of the parties and having min-entropy \( k \), using \( 2(\ell - k) + 3 \log_2 n + O(C) \) bits of communication.

The protocols use suitable methods of randomness extraction. Specifically, in the public-randomness case the two parties apply a seeded extractor to the only random string available to them, while using all possible seeds (of length \( \log_2(\ell - k) + O(1) \)). In the private-randomness case the parties apply a two-source extractor to the \( 2 \cdot (\ell - k + \log_2 n + O(1)) \)-bit long prefix of their sources, which requires them to only communicate this prefix.

Recall that in the case of perfect randomness, a common random source (i.e., public randomness) is preferable to private randomness, since the public randomness is known to both parties whereas uncorrelated private randomness require coordination (or communication). In contrast, in the context of defective randomness, two independent sources (even when each is only seen by one party) seem preferable to a single source of (defective) public randomness. We stress that our results only suggest that the communication complexity in the private (defective-randomness) case may be lower than in the public (defective-randomness) case, and establishing such a separation is left as an open problem. We mention that for some functions such separation does not exist (see Proposition 3.5).

We focus on the case of min-entropy that is at least logarithmic in the length of the input to the protocol (i.e., \( k \geq \log_2 n \)), because this is the minimal amount of perfect randomness that is required for constant-communication protocols for equality.\(^3\) Still, one may study the case of sub-logarithmic min-entropy (and possibly integrate our results with those of [1]).

### 1.3 Remotely Related Works

Goldwasser, Sudan, and Vaikuntanathan [6] raised the general question of which distributed computing tasks that require randomness can be performed also when having access to defective sources of randomness.\(^4\) Specifically, they showed that (Byzantine) agreement tasks fall into this category; that is, they can be performed quite well also in the case that each

---

3 See [1, Thm. 3], which shows that computing the equality function when having access only to \( k \) bits of perfect public randomness requires communication complexity \( \Omega(n/2^k) \).

4 In a somewhat related vein, a body of work has investigated whether defective randomness suffices for cryptographic security in a variety of settings. McInnes and Pinkas [8] initiated this line of work by showing that information theoretic symmetric key cryptography is impossible without pure randomness. Dodis et al. [5] later extended this result to rule out the feasibility of a variety of cryptographic tasks from defective randomness, including computationally-secure symmetric key cryptography.
party has access to a (single) defective source of randomness. We stress that since the parties do not trust each other, the fact that their sources are independent of one another does not mean that they can extract almost perfect randomness by using some adequate extractor.

The following works that refer to different models of communication complexity are more related to the current study.

- Canonne et al. [2] considered a model that lies between the standard public and private randomness models (when the amount of randomness is sublogarithmic in the length of the inputs). Specifically, they considered two parties that are each given access to a private source of perfect randomness such that the two sources are tightly correlated (i.e., for a parameter \( \rho \in [\pm 1] \), for each \( i \), the \( i^{th} \) bit in the first source is \( \rho \)-correlated with the \( i^{th} \) bit in the second source). We mention that their motivation is not to study the usefulness of defective sources of randomness but rather to study the effect on uncertainty (about “contents”) in communication complexity.

- Canetti and Goldreich [1] studied trade-offs between randomness and communication complexity. In particular, they showed that a logarithm amount of (perfect) randomness is sufficient for any communication protocol and that in some cases this upper bound is tight.

- Chor and Goldreich [3] studied the “distributional communication complexity” of functions when the protocol is only required to be correct with a specified probability \( p > 1/2 \), where the probability is taken over input pairs that are each chosen according to some distribution of specified min-entropy bound (i.e., min-entropy at least \( k \)). We stress that their study is fundamentally different from ours; they study the average-case (on inputs) behavior of protocols, where the inputs are drawn from a defective source of randomness, whereas we study the worst-case (on inputs) behavior of protocols that employ defective sources of randomness.

2 Preliminaries

We consider two-party randomized protocols for computing functions of the form \( f : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\} \), while using a defective source of randomness. Specifically, we consider sources of randomness that produce \( \ell \)-bit long strings having min-entropy at least \( k \); that is, each outcome occurs with probability at most \( 2^{-k} \). Such sources are called \((\ell, k)\)-sources.

We consider both the public-randomness model in which the parties have access to common (public) randomness, and the private-randomness model in which each party has its private source of randomness, which is independent of the randomness of the other party. In our context (of defective random sources) it is important to stress that the postulated sources of randomness are the only ones available to the parties.

The results hold not only for “alternating protocols” (in which the parties alternatively exchange single bits), but directly for any protocol in which the sender of the next bit is determined by the communication so far; that is, no need to lose a factor of two in translation (from such general protocols to “alternating” ones).

2.1 Specific Background About Communication Complexity

We shall use the following basic result that refers to deterministic communication protocols.

▷ Claim 2.1 (the “corners lemma” (cf., e.g., [7, Prop. 1.13–1.14] or [10, Lem. 1.3–1.4])). Let \( \Pi' \) be a deterministic communication protocol and suppose that \( \gamma \overset{\text{def}}{=} \Pi'(x_1, x_2) = \Pi'(y_1, y_2) \). Then, \( \Pi'(x_1, y_2) = \Pi'(y_1, x_2) = \gamma \).
In addition, a basic notion of communication complexity that underlies many of its lower bound proofs is that of a fooling set, defined as follows.

Definition 2.2 (fooling set (cf., e.g., [7, Sec. 1.3] or [10, Chap. 1])). We say that $S \subseteq \{0,1\}^{n+n}$ is a fooling set for $f : \{0,1\}^{n+n} \to \{0,1\}$ if every $f$-monochromatic rectangle contains at most one point in $S$, where an $f$-monochromatic rectangle is a set $X \times Y$ such that $X,Y \subseteq \{0,1\}^n$ and $f$ is constant on $X \times Y$ (i.e., $f(x,y) = f(x',y')$ for every $(x,y), (x',y') \in X \times Y$).

Note that a fooling set cannot contain two pre-images of $f^{-1}(0)$ (resp., $f^{-1}(1)$) that differ only on one coordinate; that is, if $(x,y)$ and $(x',y')$ are in a fooling set for $f$ and $f(x,y) = f(x',y')$, then $x \neq x'$ and $y \neq y'$ (because two points that differ on a single coordinate constitute an $f$-monochromatic rectangle).

2.2 Specific Background About Randomness Extraction

As stated above, an $(\ell,k)$-source is a distribution over $\ell$-bit long strings having min-entropy at least $k$, where the min-entropy of a random variable $X$ is $\min_{v \in \text{Supp}(X)} \{ \log_2(1/\Pr[X=v]) \}$. That is, $X$ has min-entropy $k$ if and only if for every $v$ it holds that $\Pr[X=v] \leq 2^{-k}$.

We say that $\text{EXT} : \{0,1\}^{d} \times \{0,1\}^{\ell} \to \{0,1\}^{m}$ is a (seeded) $(k,\epsilon)$-extractor if for every random variable $X$ of min-entropy $k$ the total variation distance between $\text{EXT}(U_d,X)$ and $U_m$ is at most $\epsilon$, where $U_m$ denotes the uniform distribution on $\{0,1\}^{m}$. In this case $\epsilon$ is called the error of $\text{EXT}$, and $d$ is its seed length.

We say that $\text{EXT} : \{0,1\}^{d} \times \{0,1\}^{\ell} \to \{0,1\}^{m}$ is a two-source extractor for independent $(\ell,k)$-sources if for every two independent random variables $X$ and $Y$ of min-entropy $k$ the total variation distance between $\text{EXT}(X,Y)$ and $U_m$ is at most $\epsilon$, called its error. This definition is readily extended to independent sources of parameters $(\ell_1,k_1)$ and $(\ell_2,k_2)$ respectively.

3 The Public-Randomness Model

For a protocol $\Pi$ in the public-randomness model, we denote by $\Pi(x,y;r)$ the transcript of the communication on input $(x,y) \in \{0,1\}^{n+n}$ and randomness $r \in \{0,1\}^{\ell}$. The output of such a protocol is determined by its transcript (e.g., it may be its last bit), and is denoted $\Pi(x,y;r)$.

Definition 3.1 (communication complexity with a weak public source). An $(\ell,k)$-public-randomness protocol for computing a function $f : \{0,1\}^{n} \times \{0,1\}^{n} \to \{0,1\}$ is a protocol that satisfies $\Pr[\Pi(x,y;\Xi) = f(x,y)] \geq 2/3$, for every $(x,y) \in \{0,1\}^{n+n}$ and every $(\ell,k)$-source $\Xi$.

Theorem 3.2 (a general lower bound). Suppose that $f : \{0,1\}^{n+n} \to \{0,1\}$ has a fooling set of size $2^m$. Then, any $(\ell,k)$-public-randomness protocol for computing $f$ has communication complexity at least $\min(m-1,\ell-k-1)/2$.

Proof. Suppose that $f$ has a $(\ell,k)$-public-randomness protocol, denoted $\Pi$, of communication complexity $t \leq (n-1)/2$. We first observe that there exists a dense set of possible source-outcomes $R$ and two input pairs $(x_1,y_1)$ and $(x_2,y_2)$ that reside in the fooling set such that $\Pi$ in constant on all triples $(x_i,y_i,r)$, where $r \in R$ and $i \in \{1,2\}$. The theorem will follow by using the standard “corners lemma” (in a non-standard way) and defining a source that is uniform over $R$. Details follow.
The following technical claim has nothing to do with communication complexity; it holds for any function $F : [2^m] \times \{0, 1\}^t \rightarrow \{0, 1\}^t$, where in the current case $[2^m]$ represents the indices of the strings in the fooling set (for $f$), $\{0, 1\}^t$ represents possible outcomes of the public source, and $\{0, 1\}^t$ represents possible transcripts of $\Pi$.

Claim 3.2.1 (a simple combinatorial claim). Let $F : [2^m] \times \{0, 1\}^t \rightarrow \{0, 1\}^t$. Then, for any $S = \{(x_1, y_1), \ldots, (x_{2^m}, y_{2^m})\}$ and $t \leq (m - 1)/2$, there exist distinct $i, j \in [2^m]$, a string $\gamma \in \{0, 1\}^t$ and a set $R \subseteq \{0, 1\}^t$ of density at least $2^{-2t-1}$ such that for every $r \in R$ it holds that $F(i, r) = F(j, r) = \gamma$.

We will apply Claim 3.2.1 to the hitting set $S$ and to the function $F(i, r) \overset{\text{def}}{=} \Pi(x_i, y_i; r)$. But let us prove the claim first.

Proof. A simple counting implies that, for every $i \in [2^m]$, there exist $\gamma_i \in \{0, 1\}^t$ and a set $R_i \subseteq \{0, 1\}^t$ of density $2^{-t}$ such that for every $r \in R_i$ it holds that $F(i, r) = \gamma_i$. Similarly, there exist $\gamma \in \{0, 1\}^t$ and $\gamma \in \{0, 1\}^t$ of density $2^{-t}$ such that $\gamma_i = \gamma$ for every $i \in G$.

The key observation is that if $t \leq (m - 1)/2$, then there exist distinct $i, j \in G$ such that $|R_i \cap R_j| \geq 2^{t-2t-1}$. This is shown by fixing an arbitrary $G' \subseteq G$ of size $2^{t+1}$, which is possible since $2^{t+1} \leq 2^{n-t}$, and assuming towards the contradiction that, for every distinct $i, j \in G'$, it holds that $|R_i \cap R_j| < 2^{t-2t-1}$. Then, we get

$$\left| \sum_{i \in G'} R_i \right| \geq \sum_{i \in G'} |R_i| - \sum_{i \neq j \in G'} |R_i \cap R_j|$$

$$\geq 2^{t+1} \cdot 2^{t-t} \cdot \left(\frac{2^{t+1}}{2}\right) \cdot 2^{t-2t-1}$$

$$\geq 2^{t+1} - 2^{2t+1} \cdot 2^{t-2t-1}$$

$$= 2^t$$

which is impossible. The claim follows by fixing $i \neq j$ such that $|R_i \cap R_j| \geq 2^{t-2t-1}$, and defining $R = R_i \cap R_j$.

Applying Claim 3.2.1 to the hitting set $S = \{(x_1, y_1), \ldots, (x_{2^m}, y_{2^m})\}$ of the hypothesis, while letting $F(i, r) \overset{\text{def}}{=} \Pi(x_i, y_i; r)$ and using $t \leq (m - 1)/2$, we infer that the fooling set contains two points $(x_i, y_i)$ and $(x_j, y_j)$ such that $\Pi(x_i, y_i; r) = \Pi(x_j, y_j; r) = \gamma$ holds for any $r \in R$, where $R \subseteq \{0, 1\}^t$ has density at least $2^{-2t-1}$.

Next, applying the “corners lemma” (i.e., Claim 2.1), we infer that $\Pi(x_i, y_i; r) = \Pi(x_i, y_i; r) = \Pi(x_j, y_j; r)$ for every $r \in R$. Note that this application of the “corners lemma” refers to the residual deterministic protocols $\Pi'_i(x, y) = \Pi(x, y; r)$, for all $r \in R$, and it implies that $\Pi'_i(x_i, y_j) = \Pi'_i(x_j, y) = \gamma$ for each $r \in R$.

Lastly, picking an $(\ell, \ell - 2t - 1)$-source that is uniform on $R$, we infer that, when fed with randomness from this source, the execution of $\Pi$ does not distinguish these four input-pairs (i.e., $(x_i, y_i)$, $(x_j, y_i)$, $(x_j, y_j)$ and $(x_j, y_j)$). On the other hand, by hypothesis that $(x_i, y_i)$ and $(x_j, y_j)$ belong to a fooling set, these four input-pairs cannot have the same $f$-value (i.e., it cannot be that $f(x_i, y_i) = f(x_i, y_j) = f(x_j, y_i) = f(x_j, y_j)$, since this would mean that $(x_i, y_i)$ and $(x_j, y_j)$ reside in the $f$-monochromatic rectangle $\{x_i, x_j\} \times \{y_i, y_j\}$. Hence, the hypothesis that $\Pi$ is an $(\ell, k)$-public-randomness protocol for $f$ implies that the foregoing source has min-entropy below $k$: that is, $\ell - 2t - 1 < k$. The theorem follows, since we established $t > (\ell - k - 1)/2$, under the hypothesis $t \leq (m - 1)/2$. 

\[\blacksquare\]
An archetypical corollary

Recalling that equality has a fooling set of size $2^n$ and applying Theorem 3.2, we get

**Corollary 3.3** (lower bound for equality). Any $(\ell, k)$-public-randomness protocol for computing equality of $n$-bit strings has communication complexity at least $\min(n - 1, \ell - k - 1)/2$.

This lower bound is tight up to a constant factor, since equality has a constant communication protocol in the standard public-randomness model and the following generic result definitely applies to it.

**Theorem 3.4** (a generic upper bound). Suppose that $f : \{0, 1\}^{n+m} \rightarrow \{0, 1\}$ has communication complexity $C_{\text{pub}}(f)$ in the standard public-randomness model. Then, for every $k \leq \ell$ such that $k > \log_2 n + O(1)$, there exists an $(\ell, k)$-public-randomness protocol for computing $f$ with communication complexity $O(\ell - k) \cdot C_{\text{pub}}(f)$.

Recall that equality has constant communication complexity in the standard public-randomness model.

**Proof.** Recall that the randomness complexity of any protocol for computing $f$ can be reduced to $m \overset{\text{def}}{=} \log_2 n + O(1)$ (while possibly increasing its communication complexity by a constant factor). The key observation is that the parties can emulate the extraction of $m$ almost-random bits from the public $(\ell, k)$-source, by trying all possible seeds for an adequate randomness extractor, and use the extracted bit to emulate the original randomized protocol. Specifically, for $k \geq m$, such extraction is possible using a (perfectly random) seed of length $d \overset{\text{def}}{=} \log(\ell - k) + O(1)$ (see, e.g., [11, Sec. 3.1]). Hence, the parties can emulate the randomized protocol by invoking it $2^d$ times using as randomness the “extracted outputs” under all possible seeds. Details follow.

Let $\text{EXT}(s, r)$ denote the output of the extractor $\text{EXT} : \{0, 1\}^d \times \{0, 1\}^\ell \rightarrow \{0, 1\}^m$ on seed $s$ and source outcome $r$. Then, given (defective) public-randomness $r \in \{0, 1\}^\ell$, the parties emulate $2^d$ invocations of the standard randomized protocol such that in the $i$th invocation they use public-randomness $\text{EXT}(i, r)$, where $i \in [2^d] \equiv \{0, 1\}^d$, and rule by majority. Actually, we use a randomized protocol for the standard model that has error probability at most 0.1 (rather than at most 1/3), which can be obtained by a constant number of repetitions.

We claim that if $\text{EXT}$ has error 0.05 on any $(\ell, k)$-source $R$, then, for every fixed input pair, with probability at least 2/3 over the outcome of $R$, the majority of the extracted values (over all possible seeds) yield protocol executions with the correct output. This is the case because otherwise the statistical difference between $\text{EXT}(U_d, R)$ and $U_m$ is at least $\frac{1}{2} \cdot \frac{1}{2} - 0.1 > 0.05$, where the first (resp., second) term represents a lower bound (resp., upper bound) on the probability that the protocol yields a wrong answer when run with randomness $\text{EXT}(U_d, R)$ (resp., $U_m$). This yields an $(\ell, k)$-public-randomness protocol of communication complexity $2^d \cdot O(C_{\text{pub}}(f)) = O(\ell - k) \cdot C_{\text{pub}}(f)$.

---

5 See, e.g., [1, Thm. 5] and [9]. The basic argument leaves the communication complexity intact, but increases the error probability by an arbitrary small constant, where this constant effects the additive constant in $m$. To regain the original error bound, three repetitions suffice.
On the gap between the lower and upper bound

The bounds provided by Theorems 3.3 and 3.4 leave a gap of a factor \(\Theta(C^{\text{pub}}(f))\) in the non-trivial case (i.e., \(\Omega(\ell - k)\)) versus \(O(\ell - k) \cdot C^{\text{pub}}(f)\)). The following example implies that the gap cannot be closed by increasing the lower bound.

\[\textbf{Proposition 3.5} \text{ (improved upper bound). For every } m < n, \text{ there exists a function } f : \{0,1\}^{n+m} \rightarrow \{0,1\} \text{ that satisfies the following two conditions:} \]

1. \(\text{The function } f \text{ has communication complexity } C^{\text{pub}}(f) = \Theta(m) \text{ in the standard public-randomness model;} \)

2. \(\text{For every } k \leq \ell \text{ such that } k > \log_2 n + O(1), \text{ there exists an } (\ell,k)\text{-public-randomness protocol for computing } f \text{ with communication complexity } O(\ell - k) + O(C^{\text{pub}}(f)). \)

Proof. Consider the function \(f(x',x'',y',y'') = EQ(x',y') \oplus IP_2(x'',y'')\), where \(|x''| = m = n - |x'|\). \(EQ\) denotes the equality function, and \(IP_2\) denotes inner-product mod 2. Then, \(C^{\text{pub}}(f) \geq C^{\text{pub}}(IP_2) = \Omega(m)\), where the first inequality follows by a straightforward reduction and the lower bound is proved in [3]. We obtain an \((\ell,k)\text{-public-randomness protocol for computing } f \text{ with communication complexity } O(\ell - k) \cdot C^{\text{pub}}(EQ) + m + 1 = O(\ell - k) + O(C^{\text{pub}}(f)), \)

by combining the generic protocol for \(EQ\) (see Theorem 3.4) with the straightforward deterministic protocol for \(IP_2\).

\[\blacktriangleleft\]

4 The Private-Randomness Model

For a protocol \(\Pi\) in the private-randomness model, we denote by \(\Pi((x,r),(y,s))\) the transcript of the communication on input \((x,y) \in \{0,1\}^{n+m}\) with private randomness \(r, s \in \{0,1\}^t\); that is, the first (resp., second) party gets input \(x\) (resp., \(y\)) and private randomness \(r\) (resp., \(s\)). The output of such a protocol is determined by its transcript (e.g., it may be its last bit), and is denoted \(\Pi((x,r),(y,s))\).

\[\textbf{Definition 4.1} \text{ (communication complexity with weak private sources). An } (\ell,k)\text{-private-randomness protocol for computing a function } f : \{0,1\}^n \times \{0,1\}^n \rightarrow \{0,1\} \text{ is a protocol that satisfies } \Pr[\Pi((x,\Xi),(y,\Xi')) = f(x,y)] \geq 2/3, \text{ for every } (x,y) \in \{0,1\}^{n+m} \text{ and every pair of independent } (\ell,k)\text{-sources } \Xi' \text{ and } \Xi''. \]

\[\textbf{Theorem 4.2} \text{ (a general lower bound). Suppose that } f : \{0,1\}^{n+m} \rightarrow \{0,1\} \text{ has a fooling set of size } 2^m. \text{ Then, any } (\ell,k)\text{-private-randomness protocol for computing } f \text{ has communication complexity at least } \min(m - 1, \ell - k - 1)/2. \]

Proof. The proof is analogous to the proof of Theorem 3.2. We start with a hypothetical \((\ell,k)\text{-private-randomness protocol, denoted } \Pi, \text{ that computes } f \text{ with communication complexity } t \leq (n-1)/2. \text{ Then, we apply Claim 3.2.1 to the (somewhat less natural) function } F : [2^n] \times \{0,1\}^t \rightarrow \{0,1\}^t \text{ defined by } F(i,r) = \Pi((x_i,y_i),r), \text{ where } S = \{(x_1,y_1),..., (x_{2^m},y_{2^m})\} \text{ is a fooling set for } f, \text{ Hence, we infer that there exist distinct } i,j \in [2^n], \text{ a string } \gamma \in \{0,1\}^t, \text{ and a set } R \subseteq \{0,1\}^t \text{ of density } 2^{t-1} \text{ such that for every } r \in R \text{ it holds that } \Pi((x_i,r),(y_j,r)) = \Pi((x_j,r),(y_i,r)) = \gamma. \]

Now, applying Claim 2.1 thrice, we infer that \(\Pi((x_a,r),(y_b,s)) = \gamma \text{ for every } r,s \in R \text{ and } a,b \in \{i,j\}. \text{ Specifically, for both } a \in \{i,j\} \text{ and every } r,s \in R, \text{ considering the residual protocol } \Pi_{r,s}((x_a,r),(y_a,s)) = \Pi((x_a,r),(y_a,s)) \text{ and using } \Pi((x_a,r),(y_a,r)) = \Pi((x_a,s),(y_a,s)) = \gamma, \text{ we infer that } \Pi((x_a,r),(y_a,s)) = \gamma. \text{ Hence, } \Pi((x_i,r),(y_j,s)) = \gamma = \Pi((x_j,r),(y_i,s)). \text{ Now, considering the residual protocol } \Pi_{x,y}((x,y)) = \Pi((x,r),(y,s)) \text{ and using } \Pi((x_i,r),(y_j,s)) = \Pi((x_j,r),(y_i,s)), \text{ we get that } \Pi((x_i,r),(y_j,s)) = \gamma = \Pi((x_j,r),(y_i,s)). \)
Picking a pair of independent \((\ell, \ell - 2t - 1)\)-sources that are each uniform on \(R\), we infer that the execution of \(\Pi\) does not distinguish the four input-pairs \((x_i, y_j), (x_i, y_j), (x_i, y_j)\) and \((x_j, y_j)\). On the other hand, by hypothesis that \((x_i, y_j)\) and \((x_j, y_j)\) belong to a fooling set, and so these four input-pairs cannot have the same \(f\)-value. Hence, the hypothesis that \(\Pi\) is a \((\ell, k)\)-private-randomness protocol for \(f\) implies that \(\ell - 2t - 1 < k\). The theorem follows, since we established \(t > (\ell - k - 1)/2\), under the hypothesis \(t \leq (m - 1)/2\). □

**Theorem 4.3** (a generic upper bound). Suppose that \(f : \{0, 1\}^{n+n} \to \{0, 1\}\) has communication complexity \(C_{\text{PRIV}}(f)\) in the standard private-randomness model. Then, for every \(k \leq \ell\) such that \(k > 2\log_2 n + 2\log_2 \ell + O(1)\), there exists an \((\ell, k)\)-private-randomness protocol for computing \(f\) with communication complexity \(\min(2(\ell - k) + 3\log_2 n + O(C_{\text{PRIV}}(f)), \ell + \log_2 n + O(C_{\text{PRIV}}(f)))\).

**Proof.** The bounds follow by having one party send a \(\min(2(\ell - k) + 3\log_2 n + O(1)), \ell\)-bit long prefix of its private randomness to the second party, who extracts almost perfect randomness from the two outcomes (using a two-source extractor), sends one half of it back, and then both parties execute the standard protocol. Details follow.

First, recall that the randomness complexity of any protocol for computing \(f\) can be reduced to \(m \overset{\text{def}}{=} \log_2 n + O(1)\) (while possibly increasing its communication complexity by a constant factor). Second, recall that a seedless (two-source) randomness extractor can extract \(2m\) almost random bits from an \((\ell, k)\)-source and an independent \((\ell', k')\)-source, provided that \(2m \leq k + k' - \max(\ell, \ell') - O(1)\) (see [3, Thm. 7(2)]). Now, if \(\ell' \overset{\text{def}}{=} 2(\ell - k) + \log_2 n + O(1) \leq \ell\), then an \(\ell'\)-bit prefix of an \((\ell, k)\)-source has min-entropy \(k' \overset{\text{def}}{=} \ell' - (\ell - k) = (\ell - k) + 2\log_2 n + O(1)\), and so \(k + k' - \max(\ell, \ell') - O(1) = 2\log_2 n + O(1)\). Hence, sending the prefix of the first source sent to the second party, allows it to extract \(2\log_2 n + O(1)\) bits that are almost random. Sending half of these bits to the first party allows the two parties to emulate the original protocol. The communication complexity of the proposed protocol is at most \(\ell' + \log_2 n + O(1) + O(C_{\text{PRIV}}(f))\), which equals \(2(\ell - k) + 3\log_2 n + O(C_{\text{PRIV}}(f))\).

As for the case of \(\ell' > \ell\), recall that a seedless (two-source) randomness extractor can extract \(2m\) almost random bits from a pair of independent \((\ell, k)\)-source, provided that \(2m \leq k - 2\log_2 \ell - O(1)\) (see [3, Thm. 7(1)]). In this case, sending the outcome of the first source to the second party allows for the foregoing emulation, at a total communication cost of \(\ell + \log_2 n + O(C_{\text{PRIV}}(f))\).

\[ □ \]

Abstract

Let $G = (V, w)$ be a weighted undirected graph with $m$ edges. The cut dimension of $G$ is the dimension of the span of the characteristic vectors of the minimum cuts of $G$, viewed as vectors in $\{0, 1\}^m$. For every $n \geq 2$ we show that the cut dimension of an $n$-vertex graph is at most $2n - 3$, and construct graphs realizing this bound.

The cut dimension was recently defined by Graur et al. [13], who show that the maximum cut dimension of an $n$-vertex graph is a lower bound on the number of cut queries needed by a deterministic algorithm to solve the minimum cut problem on $n$-vertex graphs. For every $n \geq 2$, Graur et al. exhibit a graph on $n$ vertices with cut dimension at least $3n/2 - 2$, giving the first lower bound larger than $n$ on the deterministic cut query complexity of computing mincut. We observe that the cut dimension is even a lower bound on the number of linear queries needed by a deterministic algorithm to solve mincut, where a linear query can ask any vector $x \in \mathbb{R}^{(\binom{n}{2})}$ and receives the answer $w^T x$. Our results thus show a lower bound of $2n - 3$ on the number of linear queries needed by a deterministic algorithm to compute minimum cut on $n$-vertex graphs, and imply that one cannot show a lower bound larger than this via the cut dimension.

We further introduce a generalization of the cut dimension which we call the $\ell_1$-approximate cut dimension. The $\ell_1$-approximate cut dimension is also a lower bound on the number of linear queries needed by a deterministic algorithm to compute minimum cut. It is always at least as large as the cut dimension, and we construct an infinite family of graphs on $n = 3k + 1$ vertices with $\ell_1$-approximate cut dimension $2n - 2$, showing that it can be strictly larger than the cut dimension.

1 Introduction

Let $G = (V, w)$ be a weighted undirected $n$-vertex graph where $w$ is an $\binom{n}{2}$-dimensional nonnegative real vector assigning a (possibly zero) weight to each edge slot. For a nontrivial subset $\emptyset \neq X \subseteq V$, let $\Delta(X)$ be the set of edges of $G$ with one endpoint in $X$ and one endpoint in $X^{c} = V \setminus X$. A cut $S$ in $G$ is a subset of edges of the form $\Delta(X)$ for a nontrivial set $X$. The sets $X$ and $X^{c}$ are called the shores of the cut. For a cut $S$, its weight is the sum of the weights of the edges in $S$, denoted $w(S)$. The minimum cut problem is to find the minimum of $w(S)$ over all cuts $S$. The study of algorithms for the minimum cut problem in theoretical computer science goes back at least to the 1960’s and has given rise to a vast and beautiful literature. Minimum cut is also a problem of great practical importance with applications to, for example, clustering algorithms and evaluating network reliability. Randomized algorithms can solve the minimum cut problem in nearly linear time: in 1996 Karger gave an algorithm with running time $O(m \log^{2}(n))$ to compute the minimum cut of a weighted graph with $m$ edges [20]. This was the best known bound until very recently when two independent works improved on it. Gawrychowski, Mozes, and Weimann [8] gave a randomized algorithm with running time $O(m \log^{2}(n))$ [8] and Mukhopadhyay and Nanongkai [24] gave a randomized algorithm with time complexity $O(m \log^{2}(n) \frac{\log \log n}{\log \log m} + n \log^{6}(n))$. Gawrychowski, Mozes, and Weimann [9] later improved the running time of the Mukhopadhyay and Nanongkai algorithm to $O(m \log^{2}(n) \frac{\log \log n}{\log \log m} + n \log^{3+\epsilon}(n))$.

For simple graphs $G$, randomized algorithms are known with running times $O(m \log(n))$ and $O(m + n \log^{3}(n))$ [10]. For simple graphs even nearly linear time deterministic algorithms are known. Kawarabayashi and Thorup gave an $O(m \log^{12}(n))$ time algorithm [21], which was subsequently improved to $O(m (\log(n) \log \log n)^{2})$ by Henzinger, Rao, and Wang [16].

Our work spans two aspects of the study of the minimum cut problem. The first is to query complexity lower bounds on minimum cut. A natural model in which to study the query complexity of minimum cut is for algorithms allowed to make cut queries. A cut query algorithm can query any subset $\emptyset \neq X \subseteq V$ and receives the answer $w(\Delta(X))$. One motivation to study cut query algorithms comes from submodular function minimization. The cut function $f(X) = w(\Delta(X))$ is a submodular function, and finding the minimum cut value is equivalent to finding the minimum value of $f$ over all nontrivial sets $X$. The problem of minimizing a submodular function is often studied with respect to an evaluation oracle, which in the case of the cut function is exactly a cut query.

Harvey [15] observed that results on the deterministic communication complexity of deciding graph connectivity [14] imply that any deterministic cut query algorithm to compute minimum cut, or even to decide if the graph is connected or not, must make at least $cn$ cut queries, for a constant $c < 1$. Analogous results on the randomized communication complexity of connectivity [2] imply an $\Omega(n/\log(n))$ lower bound on the number of cut queries needed by a randomized algorithm to compute minimum cut (or even connectivity).

On the algorithms side, Rubinstein, Shramm, and Weinberg [26] gave a randomized algorithm computing the minimum cut of a simple graph with $O(n)$ many cut queries. Recently, Mukhopadhyay and Nanongkai [24] used a different approach based on Karger’s 2-respecting tree algorithm [20] to also give a randomized $O(n)$ cut query algorithm to compute minimum cut in a general undirected weighted graph.

For deterministic cut query algorithms, there remains a large gap between the best upper and lower bounds. We are not aware of any deterministic algorithm for minimum cut better than learning the entire graph, which can take $\Omega(n^2/\log(n))$ cut queries in the worst case. On the lower bound side, Graur, Pollner, Ramaswamy, and Weinberg [13] recently introduced a
very interesting lower bound technique called the cut dimension, which we now describe. Let \( G = (V, w) \) be a weighted undirected graph with \( n \) vertices and \( m \) edges, and let \( \mathcal{M}(G) \) be the set of minimum cuts of \( G \). For a cut \( S \in \mathcal{M}(G) \), let \( \chi(S) \in \{0, 1\}^m \) be the characteristic vector of \( S \) amongst the \( m \) edges of \( G \). Let \( \mathcal{M}(G) = \{ \chi(S) : S \in \mathcal{M}(G) \} \). The cut dimension of \( G \), denoted \( cdim(G) \), is the dimension of \( \text{span}(\mathcal{M}(G)) \). It is shown in [13] that for any \( n \)-vertex graph \( G \), the cut dimension \( cdim(G) \) is a lower bound on the deterministic cut query complexity of computing minimum cut on weighted \( n \)-vertex graphs. Moreover, for every \( n \geq 2 \) they construct an \( n \)-vertex graph \( G \) with cut dimension \( 3n/2 - 2 \).

Besides showing lower bounds on cut query complexity, the cut dimension is a natural measure of the complexity of mincuts in a graph. There is a rich literature on the possible structure of mincuts in a graph. Perhaps the first result of this kind is the cactus representation of mincuts by [6]. A cactus for a graph \( G \) is a sparse weighted graph \( C \) that represents all the mincuts of \( G \). One consequence of the cactus representation is that the number of possible mincuts in an \( n \)-vertex weighted graph is at most \( \binom{n}{2} \). This upper bound was later given an algorithmic proof via Karger’s famous contraction algorithm ([19], Theorem 6.1). The \( n \)-vertex cycle graph has \( \binom{n}{2} \) many minimum cuts and shows that this bound can be tight.

While the cycle has \( \binom{n}{2} \) many mincuts, these cuts live in an \( n \)-dimensional space as the \( n \)-vertex cycle only has \( n \) edges. Is it possible to construct graphs with many cuts that also have high cut dimension? We show that this is not possible, and in fact the cut dimension of an \( n \)-vertex graph is at most \( 2n - 3 \).

- **Theorem 1 (Main Upper Bound).** For any weighted undirected graph \( G \) on \( n \geq 2 \) vertices it holds that \( cdim(G) \leq 2n - 3 \).

Like the cactus representation, this shows another aspect in which the mincuts of a graph are constrained to have a relatively simple structure. We further show that this bound is tight by constructing graphs with cut dimension \( 2n - 3 \) for every \( n \geq 2 \).

- **Theorem 2 (Main Lower Bound).** For every \( n \geq 2 \) there exists an \( n \)-vertex weighted undirected graph \( G \) with \( cdim(G) = 2n - 3 \).

In addition to shedding further light on the structure of minimum cuts, this improves the best known lower bound on the deterministic cut query complexity of the minimum cut problem to \( 2n - 3 \). We additionally show that the cut dimension is even a lower bound on a stronger query model called the linear query model, recently studied in [1]. In the linear query model, the algorithm can query any vector \( x \in \mathbb{R}^{\binom{n}{2}} \) and receives the answer \( \langle w, x \rangle \), the inner product of \( w \) and \( x \). Linear queries can be much more powerful than cut queries as one can completely learn an unweighted graph with a single linear query. By an information theoretic argument learning an unweighted graph can require \( \Omega(n^2 / \log(n)) \) many cut queries since each cut query reveals at most \( O(\log(n)) \) bits.

We further introduce a lower bound technique which is a generalization of the cut dimension that we call the \( \ell_1 \)-approximate cut dimension. This technique looks not just at mincuts in the graph, but all cuts. We again look at the span of the dimension of these cuts with an additional twist. Suppose the weight of a minimum cut in \( G \) is \( \lambda \) and cut \( S \) has \( w(S) = \lambda + \delta \). Abusing notation we will let \( S \) represent both a set of edges and the characteristic vector \( S \in \{0, 1\}^{\binom{n}{2}} \) of \( S \) among all edge slots. The vector \( S \) can be perturbed to \( S - u \) for any vector \( u \geq 0 \) with \( \|u\|_1 \leq \delta \). Here \( \|u\|_{1,w} = \sum_{i} |w(i) \cdot u(i)| \) is the \( \ell_1 \) norm of \( u \) weighted by the edge weights of the graph. The \( \ell_1 \)-approximate cut dimension of \( G \) is then the minimum over all valid perturbations of the dimension of the span of the perturbed cut vectors.
On the Cut Dimension of a Graph

The minimization over all perturbations makes the $\ell_1$-approximate cut dimension a difficult quantity to lower bound. We are able to show, however, that the $\ell_1$-approximate cut dimension can be strictly larger than the cut dimension. For every $k \in \mathbb{N}$ and $n = 3k + 1$, we construct an unweighted $n$-vertex graph $G$ whose $\ell_1$-approximate cut dimension is $2n - 2$. This has the following application.

**Theorem 3.** Any deterministic linear query algorithm that correctly computes the minimum cut of all $n$-vertex weighted undirected graphs must make at least $2n - 2$ queries in the worst case.

Computing the minimum cut of a graph with cut queries is a special case of finding the nontrivial minimum of a symmetric submodular function $f : 2^V \rightarrow \mathbb{R}$ with evaluation queries. That is, to find $\min_{X \neq \emptyset, X \subseteq V} f(S)$ for a submodular $f$ that satisfies $f(X) = f(V \setminus X)$ for all $X \subseteq V$. As linear queries are more powerful than cut queries, Theorem 3 also implies a $2n - 2$ evaluation query lower bound for a deterministic algorithm finding a nontrivial minimum of a symmetric submodular function, which is currently the best known.

### 1.1 Techniques

We give two different proofs of the $2n - 3$ upper bound on the cut dimension and two different techniques to create graphs with cut dimension $2n - 3$. The first proof is direct and uses the combinatorial uncrossing technique, and in particular a key lemma of Jain [18] in his factor of 2 approximation algorithm for the survivable network design problem. The second proof is by induction and follows a framework for constructing a cactus representation of the mincuts of a graph [6, 7]. The second proof uses very few properties of mincuts and seems better suited to also upper bound the $\ell_1$-approximate cut dimension, one of our main open questions.

Key to both proofs is the concept of when cuts cross each other. Two cuts $\Delta(X), \Delta(Y)$ are said to cross if all four of the intersections $X \cap Y, X \cap Y, X \cap Y, X \cap Y$ are non-empty. Note that in the definition of crossing it does not matter which shore we take to define the cut, thus crossing is a property of the cuts themselves. A family $L$ of cuts is called cross-free if for all cuts $S, T \in L$ it holds that $S$ and $T$ do not cross.

**First upper and lower bound proof.** In the first upper bound proof, we first show that any cross-free family of cuts has cardinality at most $2n - 3$ (see Section 4.1). We then use Jain’s lemma [18] (stated in Lemma 19) to conclude that for a maximal cross-free subset $L \subseteq \mathcal{M}(G)$ it holds that $\tilde{L} = \{\chi(S) : S \in L\}$ spans the set $\tilde{\mathcal{M}}(G)$. This shows that the cut dimension of a graph is at most $2n - 3$.

In the first lower bound proof we use a tree-representation of a cross-free family of cuts to show that in a complete graph the cut vectors of a cross-free family of cuts are linearly independent (Lemma 27). Thus the lower bound reduces to constructing a graph whose minimum cuts are a cross-free family of cuts of size $2n - 3$. Such a construction has already been given by Chandra and Ram [5]. We go a step further, however. For any $L$ which is a cross-free family of cuts from a complete $n$-vertex graph with $|L| = 2n - 3$, in Theorem 31 we explicitly give the edge weights of a complete weighted graph $G$ such that $\mathcal{M}(G) = L$ and therefore $\text{cdim}(G) = 2n - 3$. This task is made easier by Lemma 29, which states that if $L$ is a cross-free family of cuts of size $2n - 3$ that all have the same weight, then this must be the weight of a minimum cut of the graph. This lemma is again shown by the combinatorial uncrossing technique. This reduces the construction problem to solving the linear program of finding a positive vector $w$ that makes all cuts in $L$ have the same weight. We explicitly give a solution to this linear program by viewing it as a flow problem on the tree-representation of $L$. 

Second upper and lower bound proof. The second upper bound proof is by induction and follows methods to construct a cactus representation of mincuts [6, 7]. In the base case $n = 2$ it is easy to see that the cut dimension is at most $2n - 3 = 1$. For the inductive step, when $G$ is an $n > 2$ vertex graph, there are 3 cases to consider. We call a cut of the form $\Delta(\{v\})$ a star cut, and we will refer to all other cuts as non-star cuts. The first case is where all cuts in $\mathcal{M}(G)$ are star cuts. As the graph has $n$ vertices there are at most $n$ star cuts and so in this case the cut dimension is at most $n \leq 2n - 3$. The second case is where for every non-star cut $S \in \mathcal{M}(G)$ there is a cut $T \in \mathcal{M}(G)$ which crosses $S$. In this case [6] show that the graph must be a cycle and the cut dimension is again at most $n \leq 2n - 3$.

The interesting case is where there is a non-star cut $\Delta(V_0) \in \mathcal{M}(G)$ which is not crossed by any other cut in $\mathcal{M}(G)$. Let $V_1 = V_0$. In this case we use a decomposition of $G$ along the cut $\Delta(V_0)$, that we call the separation of $G$, into two smaller graphs $G_b$, for $b \in \{0, 1\}$. The graph $G_b$ is formed from $G$ by contracting $V_{1-b}$ into a single new vertex $v_{1-b}$. We show that $\text{cdim}(G) \leq \text{cdim}(G_0) + \text{cdim}(G_1) - 1$ which implies immediately the upper bound. Indeed, let $k = |V_0| \geq 2$. Then $G_0$ is a graph on $k + 1$ vertices and $G_1$ is a graph on $n - k + 1$, both of which are less than $n$. The inductive hypothesis therefore gives $\text{cdim}(G) \leq 2(k + 1) - 3 + 2(n - k + 1) - 3 = 2n - 3$.

For the second lower bound proof we use the merge operation which creates from two graphs $G_b$, for $b \in \{0, 1\}$, and a specified vertex $v_{1-b}$ from each, a composed graph $G$ where the vertices $v_0, v_1$ are not present but the cut $\Delta(V_0)$ reflects the structure of the star cuts at $v_0$ and $v_1$ in the original graphs. The operations separation and merge are inverses in the sense that if we apply merge to $\{G_0, G_1\}$ followed by separation on the resulting graph $G$, we receive back $\{G_0, G_1\}$. We also show that the inequality $\text{cdim}(G) \leq \text{cdim}(G_0) + \text{cdim}(G_1) - 1$ holds with equality if $\Delta(V_0)$ is a connected graph. This enables us to construct inductively a sequence of graphs $G^{(n)}$ on $n$ vertices whose cut dimension is $2n - 3$. In the base case $G^{(3)}$ is defined as the complete graph on 3 vertices where all the edges have the same weight. Then $G^{(n)}$ is defined as the merge of $G^{(3)}$ and $G^{(n-1)}$ where the specified vertices can be chosen arbitrarily. Since the separation of $G^{(n)}$ along the newly constructed complete cut gives back $G^{(3)}$ and $G^{(n-1)}$, from the inductive hypothesis we conclude that $\text{cdim}(G) = \text{cdim}(G_0) + \text{cdim}(G_1) - 1 = 2n - 3$.

$L_1$-approximate cut dimension. As the cut dimension is at most $2n - 3$, we have to look to other methods in order to show larger lower bounds, if possible. We propose a generalization of the cut dimension which we call the $L_1$-approximate cut dimension. In order to motivate this, we quickly explain why the cut dimension is a lower bound on the linear query complexity of mincut. The main idea behind the cut dimension lower bound and query complexity is to answer all queries of the algorithm according to an $n$-vertex graph $G = (V, w)$. Supposing the algorithm makes $k$ queries, we package these into a $k$-by-$\binom{n}{2}$ matrix $A$ whose rows are the query vectors. If there is a cut $S \in M(G)$ which is not in the rowspace of $A$, then by the Fredholm alternative there is a vector $z$ such that $Az = 0$, where $0$ is the all-zero vector, but $(S, z) > 0$ and furthermore $z(i) = 0$ whenever $w(i) = 0$. Thus for a sufficiently small $\varepsilon > 0$ we have that $w - \varepsilon z \geq 0$ and so $G' = (V, w - \varepsilon z)$ defines a valid non-negatively weighted graph that has all the same answers to the queries of the algorithm as $G$. On the other hand, the weight of a minimum cut in $G'$ is strictly smaller than that of $G$ and thus as the algorithm cannot distinguish $G$ and $G'$ it cannot correctly compute the weight of a minimum cut in all $n$-vertex graphs.

The $L_1$-approximate cut dimension extends this adversary argument to include all the cuts of $G$ instead of just the mincuts. If the minimum cut weight of $G$ is $\lambda$ and $S$ is a cut with weight $\lambda + \delta$, then the algorithm will still fail if there is a $z$ such that
1. \( w - z \geq 0 \)
2. \( A \mathbf{z} = 0 \)
3. \( \langle S, \mathbf{z} \rangle > \delta \).

The reason is the same: the graph \( G' = (V, w - z) \) has all the same answers to the queries made by the algorithm as \( G \) yet has a cut with weight strictly smaller than \( \lambda \).

Taking the dual of the corresponding linear program shows that such a vector \( \mathbf{z} \) will not exist iff \( S - u \) is in the rowspace of \( A \) for a vector \( u \geq 0 \) with \( \| u \|_{1, w} \leq \delta \). This leads us to define the \((w, c)\) one-sided row-by-row \( \ell_1 \) approximate rank of a matrix. For a matrix \( Y \in \mathbb{R}^{M \times N} \) this is defined by a weight vector \( w \in \mathbb{R}^N \) and a cost vector \( c \in \mathbb{R}^M \) with \( c \geq 0 \). It is the minimum rank of a matrix \( \tilde{Y} \) such that \( \tilde{Y} \leq Y \) and \( \| Y(i, :) - \tilde{Y}(i, :) \|_{1, w} \leq c(i) \) for every row \( i \), where \( Y(i, :) \) denotes the \( i^{th} \) row of \( Y \). Let \( G = (V, w) \) be a graph and the weight of a minimum cut in \( G \) be \( \lambda \). The \( \ell_1 \)-approximate cut dimension of a graph \( G = (V, w) \), denoted \( \text{cdim}(G) \), is the \((w, c)\) one-sided row-by-row \( \ell_1 \)-approximate rank of the matrix \( Y \) whose rows are the vectors \( S \in \{0, 1\}^{\binom{n}{2}} \) for every cut \( S \) of \( G \), and where \( c = Yw - \lambda \mathbf{1} \), and \( \mathbf{1} \) is the all-one vector.

Lower bounding the rank under such an \( \ell_1 \) perturbation is a difficult task. However, we are able to show an infinite family of graphs whose \( \ell_1 \)-approximate cut dimension is \( 2n - 2 \), thereby showing the \( \ell_1 \)-approximate cut dimension can be strictly larger than the cut dimension. This lower bound is of a “direct sum” type. We show that the \( \ell_1 \)-approximate cut dimension of \( K_4 \), the complete graph on 4 vertices, is 6, giving a tight lower bound of 6 on the number of linear queries needed to compute minimum cut on a 4 vertex graph. We then show that the direct union (see Definition 6) of \( k \) copies of \( K_4 \) has \( \ell_1 \)-approximate cut dimension \( 6k \). The proof is tailored to the specific properties of the cut vectors of \( K_4 \), and makes use of Gaussian elimination and properties of diagonally dominant matrices.

**Near-mincuts.** Related to the \( \ell_1 \)-approximate cut dimension is the question of the cut dimension of near-mincuts. For \( \alpha \geq 1 \) call a cut \( S \) of a graph \( G \) an \( \alpha \)-near-mincut if its weight is at most \( \alpha \) times the weight of a minimum cut of \( G \). Let \( \mathcal{M}_\alpha(G) = \{ S : S \text{ is an } \alpha \text{-near-mincut of } G \} \). It is known that \( |\mathcal{M}_\alpha(G)| \leq \binom{n}{2} \) for \( \alpha < 4/3 \) [25] (see also the beautiful proof given in Theorem 15 of [12]). Even for \( \alpha < 3/2 \) the number of \( \alpha \)-near-mincuts is \( O(n^2) \) [17], which is a sharp threshold as there exist graphs with \( \Omega(n^3) \) many 3/2-mincuts. There is also a generalization of the cactus representation of mincuts in terms of a tree of deformable polygons that applies to \( \alpha \)-near-mincuts for \( \alpha < 6/5 \) [3]. In Section 8 we show that if \( G \) is a simple graph then \( \text{dim}(\text{span}(\mathcal{M}_\alpha(G))) = O(n) \) for any \( \alpha < 2 \) (Theorem 41). This bound is tight as for \( \alpha = 2 \) the unweighted complete graph \( K_n \) witnesses \( \text{dim}(\text{span}(\tilde{\mathcal{M}}_2(K_n))) = \binom{n}{2} \). For weighted graphs, on the other hand, we show that for any \( \alpha > 1 \) there exists an \( n \)-vertex weighted graph \( G \) with \( \text{dim}(\text{span}(\tilde{\mathcal{M}}_\alpha(G))) = \binom{n}{2} \).

### 1.2 Open Problems

Several interesting open problems remain from this work.

- There is still a large gap between the known upper and lower bounds on the deterministic cut/linear query complexity of minimum cut. What is the right answer? We conjecture there is a deterministic cut query algorithm for minimum cut making \( O(n^{2-\varepsilon}) \) many queries for some \( \varepsilon > 0 \).
- Is the \( \ell_1 \)-approximate cut dimension \( O(n) \) for any \( n \)-vertex graph? Also can one show a general direct sum theorem for the \( \ell_1 \)-approximate cut dimension?
1.3 Organization

The rest of the paper is organized as follows. We review necessary backgrounds about graphs, operations on graphs, and query models in Section 2. In Section 3, we show that the cut dimension is a lower bound on the deterministic linear query complexity of computing minimum cut. We then prove that the cut dimension is at most $2n - 3$ in Section 4, and give an explicit construction of graphs with cut dimension $2n - 3$ in Section 5. In Section 6, we give another proof for both the upper and lower bounds on $2n - 3$ using graph operations. In Section 7 we show a $2n - 2$ lower bound on $\ell_1$-approximate cut dimension which implies Theorem 3. Finally, in Section 8 we show that for a simple graph $G$ and $1 \leq \alpha < 2$ it holds that $\dim(\text{span}(\mathcal{M}_\alpha(G))) = O(n)$.

2 Preliminaries

For every natural number $n$, we denote by $[n]$ the set $\{1, 2, \ldots, n\}$. For a vector $z \in \mathbb{R}^n$ we write $z \geq 0$ if every coordinate of the vector is at least 0, and similarly we write $z = 0$ if $z$ is the all-zero vector. We denote the scalar product of two vectors $z, z' \in \mathbb{R}^n$ by $\langle z, z' \rangle$. For any matrix, denote the rank of $A$ by $\text{rk}(A)$. We denote the disjoint union of sets $X$ and $Y$ by $X \sqcup Y$.

2.1 Graphs, cuts, sets

An undirected weighted graph on $n$ vertices is a couple $G = (V, w)$, where $V$ is the set of vertices with $|V| = n$, the set of edge slots $V^{(2)}$ is the set of subsets of $V$ with cardinality 2, and the weight function $w : V^{(2)} \to \mathbb{R}$ is non-negative. We refer to the vertex set of $G$ as $V(G)$. The set of edges of $G$ is defined as $E = \{e \in V^{(2)} : w(e) > 0\}$. When in a graph $G = (V, w)$ the weight of every edge is 1, we say that the graph is unweighted, and we refer to it also as $G = (V, E)$; such graph is also called a simple graph. For an edge $e = \{u, v\}$, we say that $u$ and $v$ are the endpoints of $e$. For a subset $X \subseteq V$ of the vertices, we denote by $E(X)$ the set of edges in $E$ which have both endpoints in $X$, and for disjoint subsets $X, Y \subseteq V$, we denote by $E(X, Y)$ the set of edges with exactly one endpoint in each of the two sets. We extend the weight function $w$ to any subset $E'$ of the edges by $w(E') = \sum_{e \in E'} w(e)$. We will deal only with graphs which have at least 2 vertices.

We fix an ordering $v_1 < v_2 < \cdots < v_n$ of the vertices which induces also an ordering \{v_1, v_2\}, \{v_1, v_3\}, \ldots, \{v_{n-1}, v_n\} of the edge slots as well as an ordering $e_1 < e_2 < \cdots < e_m$ of the $m = |E|$ edges. We view $w \in \mathbb{R}^{(2)}$ as a vector whose $i^{th}$ coordinate gives the (possibly zero) weight of the $i^{th}$ edge slot according to this ordering, and we define $\bar{w} \in \mathbb{R}^m$ as the restriction of $w$ to the edges. With some slight abuse of notation, for a set of edges $S \subseteq E$, we use the same symbol $S$ to also denote the characteristic vector in $\{0, 1\}^m$ of $S$ among all edge slots. We further need the characteristic vector of $S \subseteq E$ among the $m$ edges $E$, for which we use the notation $\chi(S) \in \{0, 1\}^m$. For a family $\mathcal{F}$ of subsets of the edges, we use the notation $\bar{\mathcal{F}} = \{\chi(S) \in \{0, 1\}^m : S \in \mathcal{F}\}$.

For $X \subseteq V$, we denote by $\bar{X}$ the set $V \setminus X$. A cut $S$ is a set $E(X, \bar{X})$ for some $\emptyset \neq X \subseteq V$. We call $X$ and $\bar{X}$ the shores of $S$, and we denote the cut by $\Delta(X)$. A cut is a star cut if one of its shores is a singleton, otherwise it is non-star cut. If the singleton shore of a star cut $S$ is \{v\}, then we say that $S$ is a star cut at $v$. The weight of a cut is the sum of the weights of its edges. For a cut $S$ we define the graph of the cut $S$ as the unweighted graph $G(S) = (V', E')$ where $V'$ is the set of vertices in $V$ that are endpoints of at least one edge in $S$, and $E' = S$. We say that a cut $S$ is connected if $G(S)$ is a connected graph. A cut is a minimum cut, or mincut, for short, if no other cut has smaller weight. We denote by $\mathcal{M}(G)$ be the set of minimum cuts of $G$. The cut dimension of $G$ is $\text{cdim}(G) = \dim(\text{span}(\mathcal{M}(G)))$. 
Let $V$ be a set of size $n$. Two sets $X, Y \subseteq V$ are said to overlap if $X \cap Y \neq \emptyset, X \cap \bar{Y} \neq \emptyset$. A family $\mathcal{G}$ of subsets of $V$ is said to be laminar if for all $X, Y \in \mathcal{G}$ it holds that $X$ and $Y$ do not overlap. A set family $\mathcal{G} \subseteq 2^V$ is said to be closed under overlaps if for every $X, Y \in \mathcal{G}$ that overlap it holds that $X \cap Y, X \cup Y \in \mathcal{G}$. A laminar subset $\mathcal{L} \subseteq \mathcal{G}$ is said to be maximal in $\mathcal{G}$ if for every $X \in \mathcal{G} - \mathcal{L}$ there is a $Y \in \mathcal{L}$ such that $X, Y$ overlap. We say a laminar subset $\mathcal{L}$ is maximal if it is maximal in $2^V$.

The sets $X, Y \subseteq V$ cross if they overlap and additionally $\bar{X} \cap \bar{Y} \neq \emptyset$. Note that if $X, Y$ cross then so do $X, Y$. A set family $\mathcal{G} \subseteq 2^V$ is said to be cross-free if for all $X, Y \in \mathcal{G}$ it holds that $X$ and $Y$ do not cross. Observe that if $X$ and $Y$ do not cross then either $Y$ or $\bar{Y}$ is a subset of $X$ or $\bar{X}$. Let $G = (V, w)$ be a graph with $n$ vertices. Two cuts $\Delta(X)$ and $\Delta(Y)$ of $G$ are crossing if $X$ and $Y$ are crossing. Let $\mathcal{F} = \{\Delta(X_1), \ldots, \Delta(X_k)\}$ be a set of cuts of $G$. We say that $\mathcal{F}$ is cross-free family of cuts if $\mathcal{G} = \{X_1, \ldots, X_k\}$ is cross-free. Note that it does not matter which shore we take to be in $\mathcal{G}$.

There is a close relationship between cross-free families of cuts and laminar sets. Let $\mathcal{F} = \{\Delta(X_1), \ldots, \Delta(X_k)\}$ be a cross-free family of cuts where each $X_i \subseteq V$, and let $X'_i = X_i$ if $v_1 \notin X_i$, and $X'_i = \bar{X}_i$ otherwise. The beach of $\mathcal{F}$ is the set $\mathcal{G} = \{X'_1, \ldots, X'_k\}$. For a family of sets $\mathcal{G} \subseteq 2^V$ we say that it is proper if $\emptyset, V \notin \mathcal{G}$, and we say that it is complement free if it does not contain $X, Y$ with $Y = \bar{X}$.

\begin{itemize}
  \item \textbf{Claim 4.} Let $\mathcal{F}$ be a cross-free family of distinct cuts and $\mathcal{G}$ its beach. Then $\mathcal{G}$ is proper, complement free and laminar.
  \end{itemize}

\textbf{Proof.} First, $\mathcal{G}$ does not contain $\emptyset$ or $V$ because these are not shores of cuts. It is complement free because $\mathcal{F}$ contains distinct cuts, and its beach contains exactly one representative shore from each cut. Finally, we show that it is laminar. Let $X_1, X_2 \in \mathcal{G}$. By definition of a beach, neither of these sets contain $v_1$, thus $X_1 \cap \bar{X}_2 = \emptyset$. Therefore if $X_1, X_2$ overlapped they would also cross, in contradiction to $\mathcal{F}$ being a cross-free family of cuts.

A mincut is crossless if no other mincut crosses it. Observe that a star mincut is always crossless. Also, if a mincut $\Delta(X)$ is crossless then for every mincut $\Delta(Y)$, either $Y$ or $\bar{Y}$ is a subset of $X$ or $\bar{X}$. Crossing mincuts have a nice structural property which was already observed by [6].

\begin{itemize}
  \item \textbf{Claim 5.} Let $G = (V, w)$ be a weighted graph. If $\Delta(X), \Delta(Y) \in \mathcal{M}(G)$ cross then $\Delta(X \cap Y), \Delta(X \cup Y) \in \mathcal{M}(G)$.
  \end{itemize}

\textbf{Proof.} We have $\Delta(X \cap Y) \neq \emptyset$ and $\Delta(X \cup Y) \neq V$ because $\Delta(X)$ and $\Delta(Y)$ cross. The cut function is submodular therefore we have

$$w(\Delta(X \cap Y)) + w(\Delta(X \cup Y)) \leq w(\Delta(X)) + w(\Delta(Y)).$$

Let $c$ be the weight of a minimum cut in $G$. Then the right hand side of the above inequality is equal to $2c$, while its left hand side is at least $2c$. Therefore $w(\Delta(X \cap Y)) + w(\Delta(X \cup Y)) = 2c$ from which the statement follows.

\section{Operations on Graphs}

We will use several operations on graphs. The first of these is the \textit{direct union}. 

\begin{itemize}
  \item \textbf{Definition 6 (direct union).} For two graphs $G_0 = (V_0, w_0), G_1 = (V_1, w_1)$ with disjoint vertex sets, and for vertices $v_0 \in V_0$ and $v_1 \in V_1$, the direct union of $G_0$ and $G_1$ at vertices $v_0, v_1$ is the fusion of the two by identifying $v_0$ and $v_1$. Formally, the direct union is $G_0^{v_0} \oplus G_1^{v_1} = (V, w)$ where $V = (V_0 \cup V_1 \cup \{v\}) \setminus \{v_0, v_1\}$, for a new vertex $v \notin V_0 \cup V_1$. The weight function of $G_0^{v_0} \oplus G_1^{v_1}$ is defined by
The cut dimension of a direct union is a simple function of the cut dimensions of its components.

\[ w(\{x, y\}) = \begin{cases} w_b(\{x, y\}) & \text{if } x, y \in V_b \setminus \{v_b\}, b \in \{0, 1\}, \\ w_b(\{x, v_b\}) & \text{if } x \in V_b \setminus \{v_b\}, y = v, b \in \{0, 1\}, \\ 0 & \text{otherwise.} \end{cases} \]

The cut dimension of a direct union is a simple function of the cut dimensions of its components.

\[ \text{Claim 7.} \quad \text{Let } G = G_0^b \oplus G_1^b \text{ be the direct union of } G_0 \text{ and } G_1 \text{ at vertices } v_0, v_1. \text{ Let } c_b \text{ be the weight of a minimum cut in } G_b, \text{ for } b = 0, 1. \text{ Then } \text{cdim}(G) = \text{cdim}(G_0) + \text{cdim}(G_1) \text{ if } c_0 = c_1, \text{ and } \text{cdim}(G) = \text{cdim}(G_b) \text{ if } c_b < c_{1-b}. \]

\[ \text{Proof.} \quad \text{Let } \Delta(X) \text{ be an arbitrary cut of } G \text{ where } v \notin X. \text{ If } X \subseteq V_b, \text{ for } b \in \{0, 1\}, \text{ then the weight of the cut } \Delta(X) \text{ is at least } c_0 + c_1, \text{ and therefore it is not a minimum cut. If } X \subseteq V_b, \text{ for some } b \in \{0, 1\} \text{ then the weight of } \Delta(X) \text{ in } G \text{ is the same as the weight of } \Delta(X) \text{ in } G_b. \text{ Therefore if } c_0 = c_1 \text{ then every mincut in } G_0 \text{ and every mincut of } G_1 \text{ is a mincut of } G, \text{ and these are the only mincuts. Since their supports are disjoint, we have } \text{cdim}(G) = \text{cdim}(G_0) + \text{cdim}(G_1). \text{ If } c_b < c_{1-b} \text{ then only the mincuts of } G_b \text{ are mincuts of } G, \text{ and therefore } \text{cdim}(G) = \text{cdim}(G_b). \]

The next two operations, which are inverses of each other, give a decomposition of a graph along a cut into two smaller graphs, and a composition of two graphs into a bigger one by unfolding a star cut in each components. The decomposition operation was essentially defined in [7]. Let \( G = (V, w) \) be a weighted graph and let \( Z \) be a cut in \( G \) with shores \( X_0 = V \setminus X_0 \) and \( X_1 = V \setminus X_1 \). The separation of \( G \) along the cut \( Z \), denoted by \( \text{sep}(G, Z) \), is the set of two graphs \( \{G_0 = (V_0, w_b), G_1 = (V_1, w_1)\} \), where \( V_b = X_b \cup \{v_{1-b}\} \), for \( b = 0, 1 \) with new vertices \( v_0, v_1 \). The respective weight functions are defined by \( w_b(\{x, y\}) = w_b(\{x, y\}) \) for any \( x, y \in V_0 \), and \( w_b(\{x, v_{1-b}\}) = \sum_{y \in V_{1-b}} w_b(\{x, y\}) \) for any \( x \in V_b \).

Let \( G_0 = (V_0, w_0), G_1 = (V_1, w_1) \) be two graphs on disjoint vertex sets, and let \( v_b \in V_{1-b} \) be arbitrary vertices for \( b \in \{0, 1\} \). The merge of \( G_0 \) and \( G_1 \) along the vertices \( v_0, v_1 \) denoted by \( \text{mer}(\{(G_0, v_0), (G_1, v_1)\}) \), is the graph \( G = (V, w) \), where \( V = (V_0 \cup V_1) \setminus \{v_0, v_1\} \). The weight function in \( G \) is defined by \( w(\{x, y\}) = w_b(\{x, y\}) \) if \( x, y \in V_b \), for \( b \in \{0, 1\} \), and \( w(\{x, v_1\}) = w_b(\{x, v_1\})w_1(\{v_0, y\}) \), if \( x \in V_0 \) and \( y \in V_1 \).

It follows from the definitions sep is the left inverse of mer if the star cut at \( v_1 \) in \( V_0 \) and the star cut at \( v_0 \) in \( V_1 \) both have weight one, and sep is the right inverse of mer if the weight of the cut \( Z \) is one. We formally state the former property.

\[ \text{Claim 8.} \quad \text{Let } G_0 = (V_0, w_0) \text{ and } G_1 = (V_1, w_1) \text{ have disjoint vertex sets, and let } v_b \in V_{1-b} \text{ such that } w_b(\{v_{1-b}\}) = 1, \text{ for } b = 0, 1. \text{ Let } Z \text{ be the cut in mer}(\{(G_0, v_1), (G_1, v_0)\}) \text{ whose shores are } V_0 \setminus \{v_1\} \text{ and } V_1 \setminus \{v_0\}. \text{ Then } w(Z) = 1 \text{ and } \text{sep}(\text{mer}(\{(G_0, v_1), (G_1, v_0)\}), Z) = (G_0, G_1). \]

### 2.3 Query models

\[ \text{Definition 9 (MINCUT}_n). \quad \text{The input in the MINCUT}_n \text{ problem is an } n \text{-vertex weighted undirected graph } G = (V, w). \text{ The required output on } G \text{ is the weight of a minimum cut in } G. \]
A deterministic algorithm correctly solves the MINCUT$_n$ problem if it outputs the correct mincut weight for every $n$-vertex input graph $G$. We consider algorithms given two models of query access to the input graph $G = (V, w)$, linear queries and cut queries. A linear query for $G$ is a vector $x \in \mathbb{R}^{\binom{n}{2}}$, and the query is answered by $\langle x, w \rangle$. A cut query is a vector $x \in \{0, 1\}^{\binom{n}{2}}$ which is the characteristic vector of a cut in the complete $n$-vertex graph. The answer to a cut query is again $\langle x, w \rangle$. Clearly any cut query algorithm can be simulated by a linear query algorithm.

We use $D_{\text{cut}}(\text{MINCUT}_n)$ to denote the minimum, over all deterministic query algorithms $A$ that correctly solve MINCUT$_n$, of the maximum over all $n$-vertex input graphs $G = (V, w)$ of the number of cut queries made by $A$ on $G$. $D_{\text{lin}}(\text{MINCUT}_n)$ is defined analogously for linear queries.

Some authors instead define the output of the minimum cut problem to be a cut $S$ that achieves the minimum weight, rather than the weight itself. Over $n$-vertex weighted graphs let us denote this problem as ARGMINCUT$_n$. For linear and cut queries, an algorithm that finds a minimum cut $S$ can also return the weight of $S$ with one additional query. Thus $D_{\text{lin, cut}}(\text{ARGMINCUT}_n) \geq D_{\text{lin, cut}}(\text{MINCUT}_n) - 1$, and the lower bounds we prove for MINCUT$_n$ can be applied, minus 1, to ARGMINCUT$_n$ as well.

### 3 Lower bounds on the linear query complexity of MINCUT

Graur et al. [13] introduce the cut dimension as a means to show lower bounds on the deterministic cut query complexity of computing minimum cut.

> Theorem 10 ([13]). If there is an $n$-vertex weighted graph $G = (V, w)$ with $\text{cdim}(G) = k$ then $D_{\text{cut}}(\text{MINCUT}_n) \geq k$.

We show that this theorem even holds with respect to a stronger computational model where the algorithm is able to make linear queries. We also give a generalization of the cut dimension to a quantity which is at least as large, and can be strictly larger, that we call the $\ell_1$-approximate cut dimension. We now give an overview of the Graur et al. [13] argument in the context of linear queries and how we can extend it.

The proof of Theorem 10 is based on an adversary argument. Suppose a deterministic algorithm makes $k$ linear queries and consider the execution of the algorithm on a fixed $n$-vertex graph $G = (V, w)$ whose set of minimum cuts is $\mathcal{M}(G)$. Make a $k$-by-$\binom{n}{2}$ matrix $A$ whose rows are the query vectors asked by the algorithm. Suppose we can find a vector $z \in \mathbb{R}^{\binom{n}{2}}$ such that

1. $w - z \geq 0$,
2. $Az = 0$,
3. There is a cut $S \in \mathcal{M}(G)$ such that $\langle S, z \rangle > 0$.

The existence of such a vector $z$ means the algorithm cannot correctly compute minimum cut weight on all weighted $n$-vertex graphs. The reason is that $G' = (V, w - z)$ is a valid non-negatively weighted graph by (1), has the same answers on all queries asked by the algorithm by (2), and by (3) has minimum cut weight at most $\langle S, w - z \rangle = \langle S, w \rangle - \langle S, z \rangle < \langle S, w \rangle$, which is strictly less than the minimum cut weight of $G$. As with $k$ queries the algorithm cannot distinguish whether the input is $G$ or $G'$, it cannot correctly output the minimum cut weight for all $n$-vertex weighted graphs.

A weaker condition than (3) suffices for this argument to work. Suppose that the minimum cut weight in $G$ is $c^*$. Then the argument still goes through with the condition
3’. There is a cut $S$ such that $\langle S, z \rangle > \langle S, w \rangle - c^*$. This is because the algorithm cannot distinguish the graph $G$ with minimum cut weight $c^*$ from the graph $G' = (V, w - z)$ which has minimum cut weight at most $\langle S, w - z \rangle < c^*$.

In order to understand what kind of bound this argument gives, for fixed $w, A, S$ we define the quantity $\alpha(w, A, S)$ which is given by the following linear program.

$$\alpha(w, A, S) = \maximize_z \langle S, z \rangle$$

subject to

$$w - z \geq 0$$

$$Az = 0$$

Taking the dual of this program gives

$$\alpha(w, A, S) = \minimize_v \langle S - ATv, w \rangle$$

subject to

$$S - ATv \geq 0$$

The dual tells us that a vector $z$ having large overlap with $S$ and satisfying items (1), (2) above exists if the vector $S$ is far away from the rowspace of $A$. The notion of far away here is a one-sided $\ell_1$ distance weighted by $w$. It is one-sided because the condition $S - ATv \geq 0$ tells us we are looking to approximate $S$ by vectors in the rowspace of $A$ that are entrywise at most $S$. As $S - ATv \geq 0$ and $w \geq 0$ this means $\langle S - ATv, w \rangle = \sum_i |w(i) - (S(i) - ATv(i))| = \|S - ATv\|_{1,w}$, where $\|v\|_{1,w}$ is defined to be $\sum_i |w(i)v(i)|$. Thus the value of the dual can be interpreted as the one-sided $\|\cdot\|_{1,w}$ distance between $S$ and the rowspace of $A$.

This leads us to define an $\ell_1$ approximate version of the cut dimension. The notion we need is given by the following definitions.

**Definition 11** (one-sided row-by-row $\ell_1$-approximate rank). Let $Y \in \mathbb{R}^{M \times N}$ be a matrix, $w \in \mathbb{R}^N$ a weight vector and $c \in \mathbb{R}^M$ a cost vector. We define the $(w, c)$ one-sided row-by-row $\ell_1$-approximate rank of $Y$ to be the minimum rank of a matrix $\tilde{Y}$ such that $\tilde{Y} \leq Y$ and $\|Y(i, :) - \tilde{Y}(i, :\|_{1,w} \leq c(i)$, for all $1 \leq i \leq M$.

**Definition 12** ($\ell_1$-approximate cut dimension). Let $G = (V, w)$ be an $n$-vertex weighted undirected graph with minimum cut weight $c^*$. Let $M$ be a $(2^n - 1) \times \binom{n}{2}$ matrix whose rows are $S \in \{0, 1\}^{\binom{n}{2}}$ for all cuts $S$ of $G$. Let $c = Mw - c^*1$, where $1$ is the all one vector. Then the $\ell_1$-approximate cut dimension of $G$, denoted $\widetilde{\text{cdim}}(G)$, is the $(w, c)$ one-sided row-by-row $\ell_1$-approximate rank of $M$.

**Theorem 13.** If there is an $n$-vertex graph weighted graph $G = (V, w)$ with $\tilde{\text{cdim}}(G) = k$ then $\text{D}_{\text{lin}}(\text{MINCUT}_n) \geq k$.

**Proof.** Let $G = (V, w)$ be a graph with $\tilde{\text{cdim}}(G) = k$ and let $c^*$ be the minimum cut weight of $G$. Suppose for contradiction there is a deterministic $k - 1$ linear query algorithm that correctly computes the minimum cut of any $n$-vertex graph. Run this algorithm answering queries according to $G$ and package the queries into a $(k - 1) \times \binom{n}{2}$ matrix $A$.

As the algorithm is correct, for every cut $S$ of $G$ it must be the case that $\alpha(w, A, S) \leq \langle S, w \rangle - c^*$. If not, the graph $G' = (V, w - z)$, where $z$ is an optimal solution to the primal of $\alpha(w, A, S)$, has minimum cut weight strictly smaller than $c^*$, yet $G'$ cannot be distinguished from $G$ by the algorithm. Thus by the dual formulation of $\alpha(w, A, S)$, this means that for every cut $S$ of $G$ there is a vector $\tilde{S} = ATv$ in the rowspace of $A$ such that $\tilde{S} \leq S$ and $\|S - \tilde{S}\|_{1,w} \leq (S, w) - c^*$. The matrix $M$ whose rows are $\tilde{S}$ for all cuts $S$ therefore witnesses that $\text{cdim}(G) \leq \text{rk}(A) \leq k - 1$, a contradiction.
15:12 On the Cut Dimension of a Graph

Lemma 14. For any weighted graph \( G = (V, w) \) we have \( cdim(G) \leq \tilde{cdim}(G) \).

Proof. Suppose that \( G = (V, w) \) has minimum cut weight \( c^* \), and let \( \mathcal{M}(G) \) be the set of minimum cuts of \( G \). Let \( M \) be the \((2^{n-1} - 1) \times \binom{n}{2}\) matrix whose rows are \( S \in \{0, 1\}^{\binom{n}{2}} \) for all cuts \( S \) of \( G \) and let \( c = Mw - c^* \).

Let \( Y \) be the submatrix of \( M \) where rows are restricted to cuts in \( \mathcal{M}(G) \) and columns are restricted to the edge slots \( e \) where \( w(e) > 0 \). Thus the rows of \( Y \) are exactly the vectors \( \chi(S) \) for \( S \in \mathcal{M}(G) \), and the rank of \( Y \) is \( cdim(G) \). Any matrix \( \tilde{M} \) which satisfies \( \tilde{M} \leq M \) and \( \|M(i,:) - \tilde{M}(i,:}\|_1, w \leq c(i) \) for all \( i \) must contain \( Y \) as a submatrix, as \( c(i) = 0 \) for rows \( i \) that correspond to minimum cuts and \( w \) is positive on the edge slots labeling the columns of \( Y \). Thus \( \text{rk}(\tilde{M}) \geq \text{rk}(Y) \) for any \((w, c)\) one-sided row-by-row \( \ell_1 \) approximation \( \tilde{M} \) of \( M \), giving the lemma.

In Section 7 we will see that \( \tilde{cdim}(G) \) can be strictly larger than \( cdim(G) \). From Theorem 13 and Lemma 14 we obtain the following corollary.

Corollary 15. If there is an \( n \)-vertex weighted graph \( G = (V, w) \) with \( cdim(G) = k \) then \( D_{\text{lin}}(\text{MINCUT}_n) \geq k \).

4 The cut dimension is at most \( 2n - 3 \)

In this section we prove Theorem 1 that \( cdim(G) \leq 2n - 3 \) for any undirected weighted graph \( G \) on \( n \geq 2 \) vertices. This will follow from two facts:

1. For \( n \geq 2 \) a cross-free family of cuts in an \( n \)-vertex graph has cardinality at most \( 2n - 3 \).
2. If \( \mathcal{L} \subseteq \mathcal{M}(G) \) is a maximal cross-free subset of the mincuts of \( G \) then \( \text{span}(\tilde{L}) = \text{span}(\mathcal{M}(G)) \).

We remind the reader that \( \tilde{L} = \{\chi(S) : S \in \mathcal{L}\} \) where \( \chi(S) \in \{0, 1\}^{\mid E\} \) is the characteristic vector of the cut \( S \) amongst the edges of \( G \).

These two facts are presented in the next two subsections.

4.1 Cardinality of a cross-free family of cuts

Recall from Claim 4 that if \( \mathcal{L} \) is a cross-free family of cuts then the beach \( \mathcal{G} \) of \( \mathcal{L} \) is a laminar family of sets. A standard inductive proof shows that a laminar family of subsets of a universe of cardinality \( n \) that contains no singletons has size at most \( n - 1 \), and thus a laminar family in general has size at most \( 2n - 1 \). A beach has the additional properties of being proper and complement free which allows one to prove an upper bound of \( 2n - 3 \). This is mentioned by Goemans [11] in the paragraph after Theorem 4 under the heading “Size of a Laminar Family”, who observes that the standard inductive proof also implies the bound is attained only if the family includes the universe and at least one set and its complement. See also Corollary 2.15 of [22], where it is shown that a proper laminar family has cardinality at most \( 2n - 2 \).

Lemma 16. Let \( n \geq 2, V \) a set of cardinality \( n \), and \( \mathcal{G} \subseteq 2^V \) be a family of sets which is proper and laminar. Then \( \mid \mathcal{G} \mid \leq 2n - 2 \). If \( \mathcal{G} \) is proper, laminar, and complement free then \( \mid \mathcal{G} \mid \leq 2n - 3 \).

Proof. First we show the \( 2n - 2 \) upper bound. We prove by induction. Consider first the base case where \( n = 2 \) and \( V = \{v_1, v_2\} \). As \( \emptyset, V \not\in \mathcal{G} \) the only possible elements to include in \( \mathcal{G} \) are \( \{v_1\}, \{v_2\} \) and \( \mid \mathcal{G} \mid \leq 2 = 2n - 2 \).
Now we assume the statement is true for families of sets on a universe of \( n - 1 \) elements and show it holds for families of sets on a universe of size \( n \). Let \( G \subseteq 2^V \) be a proper laminar family. We say that \( X \in G \) is maximal if there is no set \( Y \in G \) with \( X \subset Y \). Let \( X_1, \ldots, X_m \) be the maximal sets in \( G \). Note that we must have \( X_i \cap X_j = \emptyset \) for all \( i \neq j \in [m] \). This is because for distinct maximal sets \( X_i, X_j, X_j - X_i \neq \emptyset \) thus if \( X_i \cap X_j \neq \emptyset \) they would be overlapping. If \( \cup_{i=1}^m X_i \subseteq V \) then the result already holds by the induction hypothesis. Thus we may assume \( m \geq 2 \) and \( X_1, \ldots, X_m \) form a partition of \( V \). The family \( F_1 = \{Y : Y \subseteq X_1\} \) is a laminar family on the universe \( X_1 \) which does not contain \( X_1 \). Hence by the induction hypothesis it has at most \( 2|X_1| - 2 \) many sets. This holds for all \( i = 1, \ldots, m \), thus including \( X_1, \ldots, X_m \) the total number of sets is \( \sum_{i=1}^m 2|X_i| - m \leq 2n - 2 \).

Now we show the \( 2n - 3 \) upper bound additionally assuming the family is complement free. We show this result directly using the upper bound of \( 2n - 2 \) we have just shown on the size of proper laminar families. Let \( G \subseteq 2^V \) be proper, laminar, and complement free, and let \( X_1, \ldots, X_m \) be the maximal sets in \( G \), which again must be disjoint. The number of subsets strictly contained in \( X_1 \) is at most \( 2|X_1| - 2 \) by the previous result. Thus, including \( X_1, \ldots, X_m \) we can upper bound the size of \( G \) by \( \sum_{i=1}^m 2|X_i| - m \). If \( m > 2 \) then the upper bound of \( 2n - 3 \) already holds. If \( m = 1 \) then as \( G \) is a proper family we must have \( |X_1| \leq n - 1 \) in which case the upper bound of \( 2n - 3 \) holds as well. Finally, consider the case \( m = 2 \). In this case, if \( |X_1 \cup X_2| < n \) then the bound already holds. If \( X_1 \cup X_2 = V \) then \( X_2 = \bar{X}_1 \) and we must exclude one of these sets, giving a bound of \( 2n - 2 - 1 = 2n - 3 \).

\begin{remark}
From the proof in the proper, laminar, complement-free case we can observe for what maximal sets equality in the upper bound can hold. The first is the case where there are three maximal sets \( X_1, X_2, X_3 \) that form a partition of \([n]\). With \( V = [6] \) an example of this type saturating the bound is \( G = \{\{1\}, \ldots, \{6\}, \{1, 2\}, \{3, 4\}, \{5, 6\}\} \). The second is the case where there are two maximal sets \( X_1, X_2 \) that form a partition of \([n]\) and exactly one of \( X_1, X_2 \) is not included. The latter includes the case where there is a single maximal set \( X_1 \) of size \( |X_1| = n - 1 \). For \( V = [6] \), an example of this type is \( G = \{\{2\}, \ldots, \{6\}, \{2, 3\}, \{2, 3, 4\}, \{2, 3, 4, 5\}, \{2, 3, 4, 5, 6\}\} \).

Chandran and Ram (Lemma 2.13 in [5]) show that if the set \( \mathcal{M}(G) \) of minimum cuts of a graph \( G \) is cross-free, then \( |\mathcal{M}(G)| \leq \) \( 2n - 3 \). This is an easy corollary of Lemma 16, which gives something more general.

\begin{corollary}
Let \( G = (V, w) \) be a graph on \( n \geq 2 \) vertices. Let \( \mathcal{L} \subseteq \mathcal{M}(G) \) be a subset of minimum cuts that is cross-free. Then \( |\mathcal{L}| \leq \) \( 2n - 3 \).
\end{corollary}

4.2 Spanning

Let \( \mathcal{L} \subseteq \mathcal{M}(G) \) be a maximal cross-free subset of \( \mathcal{M}(G) \). Here maximal means that for any cut \( S \in \mathcal{M}(G) \setminus \mathcal{L} \) there is a cut \( T \in \mathcal{L} \) that crosses \( S \). The fact that \( \text{span}(\mathcal{L}) = \text{span}(\mathcal{M}(G)) \) essentially follows from a key lemma of Jain in his factor of 2 approximation algorithm for the survivable network design problem (Lemma 4.2 in [18]). Another application of a similar lemma can be found in Goeman’s approximation algorithm for the bounded-degree minimum spanning tree problem [11].

The context of Jain’s lemma is slightly different than ours, as we now explain. Instead of mincuts, Jain considers the set of cuts \( \mathcal{T} \) which saturate the inequalities of a particular linear program. He shows that the set \( \mathcal{T} \) has the property that if \( \Delta(X), \Delta(Y) \in \mathcal{T} \) cross then either

1. \( \Delta(X \cap Y), \Delta(X \cup Y) \in \mathcal{T} \) and \( \chi(\Delta(X)) + \chi(\Delta(Y)) = \chi(\Delta(X \cap Y)) + \chi(\Delta(X \cup Y)) \), or
2. \( X \setminus Y, Y \setminus X \in \mathcal{T} \) and \( \chi(\Delta(X)) + \chi(\Delta(Y)) = \chi(\Delta(X \setminus Y)) + \chi(\Delta(Y \setminus X)) \).
As shown by Dinitz, Karzanov, and Lomonosov [6], for crossing mincuts \( \Delta(X), \Delta(Y) \) both items (1), (2) hold (see Proposition 45 for a proof). Thus Jain’s lemma applies to \( \mathcal{M}(G) \) as well.

Lemma 19 ([18]). Let \( G = (V, w) \) be a graph and \( \mathcal{L} \subseteq \mathcal{M}(G) \) be a maximal cross-free family of mincuts. Then \( \text{span}(\mathcal{L}) = \text{span}(\mathcal{M}(G)) \).

For completeness, we include a full proof of Lemma 19 in Appendix A.

We now can give the first proof of our main upper bound that for any \( n \geq 2 \) an \( n \)-vertex graph \( G = (V, w) \) has \( \text{cdim}(G) \leq 2n-3 \).

Proof of Theorem 1. Follows from Corollary 18 and Lemma 19.

5 Explicit construction of graphs with cut dimension \( 2n - 3 \)

In this section we prove Theorem 2 by giving a general technique to explicitly construct graphs of cut dimension \( 2n - 3 \). We focus on constructing graphs \( G = (V, w) \) where \( w \) is strictly positive, i.e. where \( G \) is a complete weighted graph. The main lemma of this section, Lemma 27, shows that, in a complete weighted graph, for any cross-free family of cuts \( \mathcal{L} \) the vectors in \( \mathcal{L} \) are linearly independent.

Thus to construct a graph with cut dimension \( 2n - 3 \) it suffices to construct a complete weighted graph whose set of mincuts is a cross-free family of cuts of cardinality \( 2n - 3 \). Such a graph is constructed for every \( n \geq 2 \) in Theorem 5.2 of [5]. Combining this construction with our linear independence result Lemma 27 gives a proof of our main lower bound Theorem 2.

In Section 5.3 we go further and show for any maximal cross-free family \( \mathcal{F} \subseteq [n]^{\mathcal{P}} \) there is a complete weighted graph \( G = ([n], w) \) with \( \mathcal{M}(G) = \{ \Delta(X) : X \in \mathcal{F} \} \). Moreover, we give an explicit formula for the weight vector \( w \). Part of this construction is a lemma, Lemma 29, which may be of independent interest: it says that if \( \mathcal{L} \) is a maximal family of cross-free cuts in a graph \( G \), and all cuts in \( \mathcal{L} \) have the same weight \( c \), then \( c \) is the weight of the minimum cut in \( G \).

A key tool for showing the linear independence of cuts from a cross-free family is the tree representation of a laminar family, which we go over next.

5.1 Tree representation

Definition 20. For an unweighted directed graph \( G = (V, E) \) we let \( \delta^+(X) = \{(x, y) \in E : x \in X, y \in V - X \} \). For a singleton \( v \in V \) we write \( \delta^+(v) \) instead of \( \delta^+([v]) \).

Definition 21 (Arborescence). An arborescence is a directed rooted tree where all edges point away from the root. A vertex of an arborescence which is not the root or a leaf we call an internal vertex.

Definition 22 (Tree representation). Let \( T \) be a directed graph whose underlying undirected graph is a tree. Let \( U \) be a finite set and \( \phi : U \to V(T) \). For \( e = (x, y) \in E(T) \) define \( S_e \) as

\[ S_e = \{ s \in U : \phi(s) \text{ is in the same connected component of } T - e \text{ as } y \} \, . \]

Then \( (T, \phi) \) defines a set family \( \mathcal{F} = \mathcal{F}(T, \phi) \) where \( \mathcal{F} = \{ S_e : e \in E(T) \} \). We say that \( (T, \phi) \) is a tree representation of \( (U, \mathcal{F}) \). We call \( (T, \phi) \) a faithful tree representation if \( |E(T)| = |\mathcal{F}| \). For \( v \in V(T) \), if there is a \( u \in U \) such that \( \phi(u) = v \) then we say that \( v \) has a label.
We will need the fact that a laminar set family has a faithful tree representation by an arborescence. A textbook proof of this fact can be found in Korte and Vygen Proposition 2.14 [22]. While they do not explicitly say the tree representation they construct is faithful, this is clear from the proof.

\textbf{Proposition 23.} Let \((U, F)\) be laminar family. Then there is a faithful tree representation \((T, \phi)\) of \((U, F)\) where \(T\) is an arborescence.

Recall from Claim 4 that if \(\mathcal{L}\) is a cross-free family of cuts then its beach \(\mathcal{G}\) is laminar, and thus has a tree representation.

\textbf{Lemma 24 (Tree structure of maximal cross-free families).} Let \(\mathcal{L}\) be a maximal family of cross-free cuts of a graph \(G = ([n], w)\) and \(\mathcal{G} \subseteq 2^{[n]}\) its beach. Then in a faithful tree representation \((T, \phi)\) of \(\mathcal{G}\) it holds that

1. The root \(v\) is labeled by 1 and has \(|\delta^+(v)| = 1\)
2. There are \(n - 1\) leaves of \(T\) each with a distinct label in \(\{2, \ldots, n\}\).
3. Every internal vertex \(v\) has \(|\delta^+(v)| = 2\).

\textbf{Proof.} As by the definition of a beach, sets do not contain 1, this means that 1 must be the label of the root. As star cuts do not cross any other cut, if \(\mathcal{L}\) is maximal it must contain all the star cuts. This means that \(\mathcal{G}\) contains the sets \(\{2\}, \ldots, \{n\}, \{2, \ldots, n\}\). Thus the outdegree of the root must be 1, as this outgoing edge represents the set \(\{2, \ldots, n\}\). Further there must be \(n - 1\) leaves which are labeled by \(2, \ldots, n\). We have now accounted for all the labels, thus no internal vertex has a label. Further, if there was a leaf \(v\) with parent \(u\) such that \(v\) did not have a label, then \((u, v)\) would represent the empty set, which by definition is not in \(\mathcal{G}\). Thus there are exactly \(n - 1\) leaves.

It remains to show that every internal vertex \(v\) of \(T\) which is not the root has \(|\delta^+(v)| = 2\). Let \(v\) be an internal vertex, and as \(v\) is not the root, let \(u\) be its parent, and as \(v\) is not a leaf let \(w\) be a child of \(v\). If \(|\delta^+(v)| = 1\) then the edges \((u, v), (v, w)\) would represent the same set, as \(v\) is not labeled. This contradicts the fact that \((T, \phi)\) is a faithful tree representation. Now suppose \(|\delta^+(v)| > 2\) and let \(w, x, y\) be three of its children. Consider the sets \(X_1, X_2, X_3 \in \mathcal{G}\) represented by the edges \((v, w), (v, x), (v, y)\). Further the edge \((u, v)\) represents a set \(A \in \mathcal{G}\) with \(X_1 \cup X_2 \cup X_3 \subseteq A\). We claim that in this case \(\mathcal{L}\) is not maximal because the cut \(\Delta(X_1 \cup X_2)\) does not cross any cut in \(\mathcal{L}\). Indeed, \(X_1 \cup X_2\) is contained in all the sets represented by edges on the path from \(v\) to the root, and is disjoint from the sets represented by any other edge of \(T\). Thus we have a contradiction.

\textbf{Corollary 25.} Let \(\mathcal{L}\) be a maximal family of cross-free cuts of a graph \(G = ([n], w)\). Then 
\(|\mathcal{L}| = 2n - 3\).

\textbf{Proof.} Let \(\mathcal{G}\) be the beach of \(\mathcal{L}\) and \((T, \phi)\) a faithful tree representation of \(\mathcal{G}\). As \((T, \phi)\) is faithful \(|E(T)| = |\mathcal{L}|\). Let \(T'\) be the undirected graph underlying \(T\). Clearly \(|E(T')| = |E(T)|\).

We use Lemma 24 to count \(|E(T')|\). Let \(i\) be the number of internal vertices of \(T'\), each of which has degree 3. There are also \(n\) non-internal vertices each of which has degree 1. Thus \(|E(T')| = (3i + n)/2\). Also as \(T'\) is a tree \(|E(T')| = |V(T')| = 1 = n + i - 1\). Hence \(i = n - 2\) and \(|\mathcal{L}| = |E(T)| = |E(T')| = 2n - 3\).

\section{Linear independence}

We now show the main theorem of this section that in a complete weighted graph any set \(\mathcal{L}\) of cut vectors of a cross-free family of cuts \(\mathcal{L}\) is linearly independent. We will use the tree representation \((T, \phi)\) of the beach \(\mathcal{G}\) of \(\mathcal{L}\) to do this via the following lemma.
Lemma 26. Let \( T \) be an arborescence with root \( r \) and \( \psi : E(T) \to \mathbb{R} \). Let \( U \) be a finite set and \( \phi : U \to V(T) \). Suppose that \( T, \phi, \psi \) have the property that

1. The root \( r \) is labeled and has \( |\delta^+(r)| = 1 \).
2. Every internal vertex \( v \) is unlabeled and has \( |\delta^+(v)| = 2 \).
3. Every leaf of \( T \) has a label.
4. For every \( s, t \in U \) it holds that \( \sum_{e \in \phi(s) - \phi(t)} \psi(e) = 0 \), where \( \phi(s) - \phi(t) \) is the set of edges on the undirected path from \( \phi(s) \) to \( \phi(t) \).

Then \( \psi \) is identically 0.

Proof. We will prove by induction on the depth of the arborescence. We need a slightly different statement for the inductive hypothesis since when considering a sub-arborescence \( T' \) of \( T \) we do not know that the root of \( T' \) has property (1).

Inductive hypothesis. Let \( T \) be an arborescence with root \( r \) that is unlabeled and has \( |\delta^+(r)| = 2 \), and further suppose \( T, \phi, \psi \) satisfy conditions (2)-(4) of the proposition. Then letting \( u, v \) be the children of \( r \) it holds that \( \psi((r, u)) = -\psi((r, v)) \) and for any other edge \( e \in E(T) \), \( e \neq (r, u), (r, v) \) it holds that \( \psi(e) = 0 \).

For the base case consider a tree of depth 1, with root \( r \) and two children \( u, v \) which are leaves. As they are leaves, \( u, v \) are labeled which, considering the path from \( u \) to \( v \), means \( \psi((r, u)) + \psi((r, v)) = 0 \). This concludes the base case.

Now we prove the inductive step. Let \( r \) be the root of a tree with children \( u, v \). We consider two cases:

Case 1: one of \( u, v \) is a leaf. Suppose without loss of generality that \( u \) is a leaf and \( v \) is an internal node with children \( v_1, v_2 \). By the inductive hypothesis \( \psi((v, v_1)) + \psi((v, v_2)) = 0 \) and \( \psi \) is identically 0 on the sub-trees rooted at \( v_1, v_2 \). Let \( y_1, y_2 \) be leaves that are descendants of \( v_1, v_2 \) respectively (and can possibly be \( y_1, y_2 \) themselves). Considering the path from \( u \) to \( y_1 \) and \( y_2 \) we have the equations

\[
\psi((r, u)) + \psi((r, v)) + \psi((v, v_1)) = 0
\]

\[
\psi((r, u)) + \psi((r, v)) + \psi((v, v_2)) = 0
\]

As \( \psi((v, v_1)) + \psi((v, v_2)) = 0 \), adding these equations shows that \( \psi((r, u)) + \psi((r, v)) = 0 \), as desired. Substituting this back into the equations further implies that \( \psi((v, v_1)) = \psi((v, v_2)) = 0 \) so \( \psi \) is identically 0 on the sub-tree rooted at \( v \) completing this case.

Case 2: both \( u, v \) are internal vertices. Let the children of \( u \) be \( u_1, u_2 \) and the children of \( v \) be \( v_1, v_2 \). By the inductive hypothesis, \( \psi(\cdot) \) is identically zero on the sub-trees rooted at \( u_1, u_2, v_1, v_2 \) and we have \( \psi((u, u_1)) + \psi((u, u_2)) = \psi((v, v_1)) + \psi((v, v_2)) = 0 \). We must show that \( \psi((u, u_1)) = \psi((u, u_2)) = \psi((v, v_1)) = \psi((v, v_2)) = 0 \) and that \( \psi((r, u)) + \psi((r, v)) = 0 \).

Let \( x_1, x_2 \) be a leaves that are descendants of \( u_1, u_2 \), respectively, and similarly let \( y_1, y_2 \) be leaves that are descendants of \( v_1, v_2 \), respectively. By assumption all of these leaves are labeled. Considering the paths from \( x_b - y_{b'} \) for \( b, b' \in \{0, 1\} \) we obtain the following four constraints on \( \psi \):

\[
\psi((u, u_1)) + \psi((r, u)) + \psi((r, v)) + \psi((v, v_1)) = 0
\]

\[
\psi((u, u_1)) + \psi((r, u)) + \psi((r, v)) + \psi((v, v_2)) = 0
\]

\[
\psi((u, u_2)) + \psi((r, u)) + \psi((r, v)) + \psi((v, v_1)) = 0
\]

\[
\psi((u, u_2)) + \psi((r, u)) + \psi((r, v)) + \psi((v, v_2)) = 0
\]
Adding all four equations and using \( \psi((u, u_1)) + \psi((u, u_2)) = \psi((v, v_1)) + \psi((v, v_2)) = 0 \) shows that \( \psi((r, u)) + \psi((r, v)) = 0 \). Taking this into account, adding the first two equations then shows \( \psi((u, u_1)) = 0 \), and adding the last two equations shows \( \psi((u, u_2)) = 0 \). This then also means \( \psi((v, v_1)) = \psi((v, v_2)) = 0 \).

We have now shown the inductive statement holds. It remains to see why this implies the lemma. Let \( r \) be the root of the tree, let \( u \) be the child of \( r \), and let \( u_1, u_2 \) be the children of \( u \). By the inductive statement we have that \( \psi((u, u_1)) + \psi((u, u_2)) = 0 \) and \( \psi \) is identically zero on the subtree rooted at \( u_1 \) and the subtree rooted at \( u_2 \). Let \( x_1, x_2 \) be leaves which are descendants of \( u_1, u_2 \), respectively. As the root has a label, considering the path from \( r \) to \( u_1 \) implies that \( \psi((r, u)) + \psi((u, u_1)) = 0 \) and considering the path from \( r \) to \( u_2 \) implies \( \psi((r, u)) + \psi((u, u_2)) = 0 \). Adding these equations implies that \( \psi((r, u)) = 0 \), from which it then follows that \( \psi((u, u_1)) = \psi((u, u_2)) = 0 \).

\[ \text{Lemma 27.} \quad \text{Let} \ G = ([n], w) \text{ be a complete weighted graph and let} L \text{ be a cross-free family of cuts. Then} \tilde{L} = \{\chi(S) : S \in L\} \text{ form a linearly independent set of vectors.} \]

\[ \text{Proof.} \quad \text{We may assume that} L \text{ is a maximal cross-free family, as showing that a superset of} \tilde{L} \text{ is linearly independent implies that} \tilde{L} \text{ is as well. Thus suppose} L \text{ is a maximal cross-free family and let} G \text{ be its beach. Let} (T, \phi) \text{ be a faithful tree representation of} G. \text{ By Lemma 24 we have that} (T, \phi) \text{ satisfy conditions (1)-3 of Lemma 26.} \]

\[ \text{Now we ask the question: for an edge} \{i, j\} \in E(G) \text{ which sets} S \in L \text{ contain it? This has a very nice description in terms of the tree decomposition. Let} u, v \in V(T) \text{ be the vertices with} \phi(i) = u, \phi(j) = v. \text{ Then the sets containing} i \text{ are the sets represented by edges from the root to} u; \text{ the sets containing} j \text{ are the sets represented by the edges on the path from the root to} v. \text{ Therefore the sets which contain} i \text{ but not} j \text{ or} j \text{ but not} i, \text{ are exactly those represented by the edges on the path from} u \text{ to} v \text{ in the undirected tree underlying} T. \text{ Thus the cuts which contain the edge} \{i, j\} \text{ are exactly those with a shore which is represented by an edge on the path from} u \text{ to} v \text{ in undirected graph underlying} T. \]

\[ \text{Consider a linear combination} \sum_{S \in L} \alpha_S \chi(S) = 0 \text{ which is equal to the all zero vector. The} \{i, j\} \text{ coordinate of this equation says that} \sum_{S \in L, \{i, j\} \subset S} \alpha_S \chi(S)(\{i, j\}) = 0. \text{ This sum is exactly over the sets represented by edges on the path from} \phi(i) \text{ to} \phi(j). \text{ As this sum must be zero for every edge} \{i, j\}, \text{ this says that if we let} \psi(e) = \alpha_S \text{ where the edge} e \text{ represents a shore of} S \text{ then for any two labeled vertices} u, v \in V(T) \text{ the sum of} \psi(e) \text{ over the edges on the path from} u \text{ to} v \text{ is zero. Thus also condition (4) of Lemma 26 is satisfied. Hence all of the conditions of Lemma 26 hold which implies that} \psi \text{ must be identically zero and therefore all coefficients} \alpha_S = 0. \text{ This shows that} \{\chi(S) : S \in L\} \text{ is a linearly independent set.} \]

\[ \text{We can now give the first proof of our main lower bound result on the cut dimension Theorem 2, which says that for every integer} n \geq 2 \text{ there is an} n\text{-vertex weighted graph} G = (V, w) \text{ with} \text{edim}(G) \geq 2n - 3. \]

\[ \text{Proof of Theorem 2.} \quad \text{For every integer} n \geq 2, \text{ Theorem 5.2 of [5] constructs a complete weighted graph} G = (V, w) \text{ on} n \text{ vertices such that} \mathcal{M}(G) \text{ is a cross-free family of size} |\mathcal{M}(G)| = 2n - 3. \text{ By Lemma 27 the vectors in} \mathcal{M} \text{ form a linearly independent set, thus} \text{edim}(G) \geq 2n - 3. \]

### 5.3 Constructing graphs with a cross-free set of mincuts

In this subsection we explicitly construct, for any maximal cross-free family \( \mathcal{F} \subseteq 2^{[n]} \), a complete weighted graph \( G = ([n], w) \) with \( \mathcal{M}(G) = \{\Delta(X) : X \in \mathcal{F}\} \). This task is made easier by the next lemma. We first need a definition.
On the Cut Dimension of a Graph

- **Definition 28.** Let $F \subseteq 2^V$. For a subset $X \subseteq V$, let $\text{overlap}_F(X) = \{Y \in F : X, Y \text{ overlap}\}$.

- **Lemma 29.** Let $G = (V, w)$ be a graph and $L$ be a maximal cross-free family of cuts. Suppose that for all $S \in L$ it holds that $w(S) = c$. Then the weight of a minimum cut in $G$ is $c$.

**Proof.** Let $G$ be the beach of $L$. Suppose for a contradiction that the weight of a minimum cut of $G$ is $< c$. Let $T = \{Z : \emptyset \neq Z \subseteq V, v_1 \notin Z, Z \notin G, w(\Delta(Z)) < c\}$ and

$$X = \arg\min_{z} \{\text{overlap}_G(z) : Z \in T\}.$$ 

In the following we always use $\text{overlap}(\cdot)$ with respect to $G$ and drop the subscript. As $|\text{overlap}(X)| \geq 1$, let $Y \in \text{overlap}(X)$. As shown in Appendix A Lemma 46, both $|\text{overlap}(X \cap Y)|$ and $|\text{overlap}(X \cup Y)|$ are strictly smaller than $|\text{overlap}(X)|$. Thus it must be the case that $X \cap Y, X \cup Y \notin T$. Let us take the case of $X \cap Y$. It does not contain $v_1$, as neither $X$ nor $Y$ do, and it is a nonempty set by the definition of overlap. Thus it must be the case that either $w(\Delta(X \cap Y)) \geq c$ or that $X \cap Y \in G$, which implies $w(\Delta(X \cap Y)) = c$. The same argument holds for $X \cup Y$, thus both $w(\Delta(X \cap Y)), w(\Delta(X \cup Y)) \geq c$.

However by submodularity of the cut function we have $w(\Delta(X \cap Y)) + w(\Delta(X \cup Y)) \leq w(\Delta(X)) + w(\Delta(Y))$, which implies that at least one of $\Delta(X \cap Y), \Delta(X \cup Y)$ must have weight $< c$. Hence we have a contradiction and the lemma holds.

- **Theorem 30 ([5]).** Let $G = (V, w)$ be a complete weighted graph. Then $\mathcal{M}(G)$ is a cross-free family of cuts.

- **Theorem 31.** Let $n \geq 2$ and $L$ be a maximal cross-free family of cuts in the $n$-vertex complete graph. Let $A$ be an $|L|$-by-$\binom{n}{2}$ matrix whose rows are the vectors $\chi(S)$ for $S \in L$ and let $z = A^T 1$. Define $w(e) = 2^{-z(e)} + 1$ for $e \in [n]^{(2)}$. Then $G = ([n], w)$ is a complete weighted graph with $\text{cdim}(G) = 2n - 3$ and $\mathcal{M}(G) = L$.

**Proof.** It is clear from the definition that $w > 0$ and so defines a complete weighted graph. We will show that $Aw = 1$. By Lemma 29 this shows that the minimum cut weight of $G$ is 1 and so the set of minimum cuts includes $L$. As $w$ defines a complete weighted graph, by Theorem 30 the set of minimum cuts in $G$ is cross-free and therefore must be exactly $\mathcal{M}(G) = L$, since $L$ is maximal. Further, $|L| = 2n - 3$ by Corollary 25 and the vectors in $\vec{L}$ are linearly independent by Lemma 27, thus $\text{cdim}(G) = 2n - 3$.

It remains to show $Aw = 1$. We do this using an alternative way of viewing the assignment of edge weights. Let $G \subseteq 2^{[n]}$ be the beach of $L$, and $(T, \phi)$ be a faithful tree representation of $G$. For vertices $u, v \in V(T)$ let $d(u, v)$ be the length of the shortest path between $u, v$ in the undirected graph underlying $T$. Now let $\{i, j\} \in [n]^{(2)}$ and suppose $\phi(i) = u, \phi(j) = v$. We claim that $w(\{i, j\}) = 2^{-d(u, v)} + 1$. The sets of $G$ containing $i$ are the sets represented by edges from the root to $w$; the sets of $G$ containing $j$ are the sets represented by the edges on the path from the root to $v$. Therefore the sets which contain $i$ but not $j$ or $j$ but not $i$, are exactly those represented by the edges on the path from $u$ to $v$ in the undirected tree underlying $T$. As $(T, \phi)$ is faithful, each of these edges represents a different set, and therefore the number of edges on the path from $u$ to $v$ is exactly the number of sets of $L$ which contain $\{i, j\}$.

We now continue with the proof that $Aw = 1$ using this interpretation of the weights. For any cut $S \in L$ with shore $X \in G$, take the edge $(u, v) \in E(T)$ representing $X$. Now imagine we remove the edge $(u, v)$ from $T$ which disconnects $T$ into two components. Let $T_u$ be the
component containing \( u \) and \( T_u \) the component containing \( v \). From \( T_u \), which contains the root \( r \) of \( T \), we create a graph \( T'_u \) whose underlying undirected graph is the same as \( T_u \), but for which all edges are directed away from \( u \). Thus in \( T'_u \), vertex \( u \) becomes the root and \( r \) becomes a leaf. Now by item (2) of Lemma 24, every non-leaf vertex in \( T_v \) and \( T'_u \) has out-degree 2. We inject a unit of flow into \( u \) in the graph \( T'_u \) and let it propagate according to the rule that at every non-leaf vertex half of the flow is routed along each outgoing edge. We similarly inject a unit of flow into \( v \) in the graph \( T_v \) and let it propagate according to the same rule. Thus in the tree \( T_v \), each leaf \( a \) gets \( f(a) = 2^{-d(a,v)} \) amount of flow, where \( d(a,v) \) is the number of edges along the path from \( v \) to \( a \) in \( T_v \). Similarly, if \( b \) is a leaf in the tree \( T'_u \), the amount of flow arriving at \( b \) is \( f(b) = 2^{-d(b,u)} \). Now let \( \{i,j\} \in [n]^{(2)} \) with \( i \in \mathcal{X}, j \in \bar{X} \) and observe that the way we defined \( w(\{i,j\}) \) satisfies

\[
w(\{i,j\}) = 2^{-d(\phi(i),\phi(j))} = 2^{-d(\phi(i),v) - d(\phi(j),u)} = f(\phi(i)) \cdot f(\phi(j)).
\]

Thus the weight of the cut \( S \) is

\[
\sum_{i \in \mathcal{X}, j \in \mathcal{X}} w(\{i,j\}) = \sum_{i \in \mathcal{X}, j \in \mathcal{X}} f(\phi(i)) \cdot f(\phi(j)) = \left( \sum_{i \in \mathcal{X}} f(\phi(i)) \right) \left( \sum_{j \in \mathcal{X}} f(\phi(j)) \right) = 1 \cdot 1 = 1.
\]

6 Another proof using graph operations

In this section we give another proof of our main theorems: we prove that the cut dimension of any \( n \)-vertex graph is at most \( 2n - 3 \) and we also prove that this upper bound is tight. An important role will be played by the following lemma, giving an explicit characterization of graphs having at least one non-star mincut, where none of these mincuts is crossless. This characterization has originally appeared in [4, 6]. More modern presentations can be found in Lemma 2.9 of [5] or Lemma 2 of [7].

\textbf{Lemma 32.} Suppose that \( G = (V,w) \) is a graph which has a non-star mincut, and every non-star mincut is crossed by a non-star mincut. Then \( G \) is a cycle where all edges have the same weight.

Let us denote by \( C_n \) the cycle on the \( n \) vertex set \( V = \{v_1, \ldots, v_n\} \) and with edge set \( E = \{\{v_1, v_2\}, \ldots, \{v_{n-1}, v_n\}, \{v_n, v_1\}\} \), where the weight of every edge is the same. We also need that the cut dimension of \( C_n \) is at most \( n \). In fact, it is easy to prove that the its cut dimension is exactly \( n \) when \( n \geq 3 \).

\textbf{Lemma 33.} The cut dimension of \( C_2 \) is 1, and \( \text{cdim}(C_n) = n \), for \( n \geq 3 \).

\textbf{Proof.} The statement for \( n = 2 \) is obvious. For \( n \geq 3 \) we have \( \text{cdim}(C_n) \leq n \) as the graph only has \( n \) edges and thus the cut vectors are elements of \( \mathbb{R}^n \) which has dimension \( n \).

For the lower bound we construct a set of \( n \) linearly independent minimum cut vectors in \( C_n \). Label the coordinates of the vectors by the edges \( \{v_1, v_2\}, \ldots, \{v_{n-1}, v_n\}, \{v_n, v_1\} \). We define the sets \( X_1 = \{v_1, v_2\} \) and \( X_k = \{v_2, \ldots, v_k\} \), for \( 2 \leq k \leq n \).

We claim that the cut vectors \( \xi_k = \chi(\Delta(X_k)) \), for \( 1 \leq k \leq n \), are linearly independent. Let \( e_i \) be the \( i^{th} \) standard basis vector in \( \mathbb{R}^n \). Then we see that \( \xi_1 = e_2 + e_n \) and \( \xi_k = e_1 + e_k \), for \( 2 \leq k \leq n \). Thus \( \xi_2 = \xi_k - \xi_1 = 2e_1 \), so \( e_1 \) is in the span of these vectors. Also \( e_k = \xi_k - e_1 \) is in the span for \( 2 \leq k \leq n \). Hence these \( n \) vectors span all of \( \mathbb{R}^n \) and therefore must be linearly independent. ▶
6.1 Two lemmas on graph operations

The main technical part of the second proof of our main theorems is played by the two lemmas in this section. The second lemma gives an upper bound on the cut dimension of a graph \( G \) in function of the cut dimension of the smaller graphs obtained when \( G \) is separated along a crossless non-star minimum cut \( Z \). Moreover, this upper bound becomes an equality when in addition the cut \( Z \) is connected. Our upper and lower bounds for the cut dimension are respectively almost immediate consequences of these results.

\[\boxed{\text{Lemma 34.}}\]

Let \( G = (V,w) \) be a weighted graph and let \( Z \subseteq \mathcal{M}(G) \) be a crossless non-star minimum cut defined by shores \( X_0, X_1 = V \setminus X_0 \). For \( b \in \{0,1\} \), let \( \mathcal{M}_b = \{S \in \mathcal{M}(G) : S \subseteq Z \cup E(X_b)\} \). Let \( \text{sep}(G,Z) = \{G_0 = (V_0,w_0), G_1 = (V_1,w_1)\} \) as defined in Section 2, where \( V_b = X_b \cup \{v_1 - b\} \), for \( b \in \{0,1\} \), with \( v_0, v_1 \notin X_0 \cup X_1 \). Then \( \dim(\text{span}(\mathcal{M}_b)) = \text{cdim}(G_b) \), for \( b \in \{0,1\} \).

\[\text{Proof.}\] We prove the statement for \( b = 0 \), the other case follows in exactly the same manner.

Let \( m = |E| \) and partition \( E \) into three disjoint sets \( E = E(X_0) \cup Z \cup E(X_1) \). Call a vertex \( x \in X_0 \) friendly if it has a neighbor in \( X_1 \), that is there exists an edge \( \{x,y\} \in Z \) for some \( y \in X_1 \). The edges in \( Z \) can then be partitioned into the disjoint union of sets \( Z_x \), over all friendly \( x \), where \( Z_x = \{e \in Z : x \in e\} \).

Let \( \mathcal{M}(G_0) \) be the set of all minimum cuts of \( G_0 \). The set \( \overline{\mathcal{M}}(G_0) \) is composed of \( m_0 \) dimensional vectors where \( m_0 = \dim(\text{span}(\mathcal{M}_b)) + \deg(v_1) \). Observe that \( \deg(v_1) \) is the number of friendly vertices in \( X_0 \). We can partition the edges of \( G_0 \) into two sets \( E(X_0) \cup Z_1 \) where \( Z_1 = \{\{x,v_1\} : x \text{ is friendly}\} \).

We define a natural bijection \( \psi : \mathcal{M}_0 \rightarrow \mathcal{M}(G_0) \) as follows. Let \( S \) be a mincut in \( \mathcal{M}_0 \) with shores \( X' \) and \( V \setminus X' \), where \( X' \subseteq X_0 \). Note that we can assume this because \( Z \) is crossless. Then \( \psi(S) \) is the mincut in \( \mathcal{M}(G_0) \) whose shores are \( X' \) and \( (X_0 \setminus X') \cup \{v_1\} \). Let \( k = |\mathcal{M}_0| = |\mathcal{M}(G_0)| \).

We now consider two matrices \( C \) and \( D \), where \( C \) is a \( k \)-by-\( m \) matrix and \( D \) is a \( k \)-by-\( m_0 \) matrix. Fix an ordering \( S_1, \ldots, S_k \) of \( \mathcal{M}_0 \) and let the \( i^{th} \) row of \( C \) be \( \chi(S_i) \), the characteristic vector of the cut \( S_i \). Likewise the \( i^{th} \) row of \( D \) is \( \chi(\psi(S_i)) \). We have \( \text{rk}(C) = \dim(\text{span}(\mathcal{M}_0)) \) and \( \text{rk}(D) = \text{cdim}(G_0) \).

The columns of \( C, D \) are labeled by edges. For \( C \), we label the edges according to the partition \( E = E(X_0) \cup Z \cup E(X_1) \), with edges in \( E(X_0) \) coming first, then edges from \( Z \), then edges from \( E(X_1) \). For \( D \), we label the edges according to the partition \( E(X_0) \cup Z_1 \), again with edges from \( E(X_0) \) coming first and then those from \( Z_1 \). We observe the following facts:

- The edges in \( E(X_0) \) are common in \( G \) and \( G_1 \), and \( \chi(\psi(S_i))(e) = \chi(S_i)(e) \), for every \( S_i \in \mathcal{M}_0 \) and edge \( e \in E(X_0) \). This means that columns of \( C \) and \( D \) labeled by an edge \( e \in E(X_0) \) are identical.
- For an edge \( e \in E(X_1) \), we have that \( \chi(S_i)(e) = 0 \), for every \( S_i \in \mathcal{M}_0 \). Thus columns of \( C \) labeled by an edge \( e \in E(X_1) \) are all zero.
- Finally, for a friendly \( x \in X_0 \) consider any edge \( e = \{x,y\} \in Z_x \) and the edge \( f = \{x,v_1\} \in Z_1 \). Then the \( e^{th} \) column of \( C \) and the \( f^{th} \) column of \( D \) are identical because for every \( S_i \in \mathcal{M}_0 \) we have \( \chi(S_i)(e) = 1 \) iff \( x \in X' \) iff \( \chi(\psi(S_i))(f) = 1 \).

These points together imply that \( D \) is actually a submatrix of \( C \), which can be obtained by taking the columns labeled by edges in \( E(X_0) \) and then taking \( |Z_1| \) more columns of \( C \) by choosing one \( e \in Z_x \) for every friendly \( x \in X_0 \). Therefore \( \text{rk}(C) \leq \text{rk}(D) \). We can also see that \( \text{rk}(C) \leq \text{rk}(D) \) as \( C \) can be obtained from \( D \) by repeating columns labeled by edges in \( Z_1 \) several times and adding all zero columns, and neither of these operations increase the rank.

\[\boxed{\text{\textup{\textendash}}}\]
Lemma 35. Let $G, Z, G_0, G_1$ as in Lemma 34. Then \( \text{cdim}(G) \leq \text{cdim}(G_0) + \text{cdim}(G_1) - 1 \), and if $Z$ is connected then the equality holds.

Proof. We first prove that \( \text{cdim}(G) \leq \text{cdim}(G_0) + \text{cdim}(G_1) - 1 \). The important fact is that \( \mathcal{M}(G) \subseteq \mathcal{M}_0 \cup \mathcal{M}_1 \) because $Z$ is a crossless mincut. Also since $\mathcal{M}_0, \mathcal{M}_1 \subseteq \mathcal{M}(G)$ we in fact have $\mathcal{M}(G) = \mathcal{M}_0 \cup \mathcal{M}_1$. Therefore

\[
\text{cdim}(G) = \dim(\text{span}(\tilde{\mathcal{M}}(G))) = \dim(\text{span}(\tilde{\mathcal{M}}_0 \cup \tilde{\mathcal{M}}_1)) = \dim(\text{span}(\text{span}(\tilde{\mathcal{M}}_0) \cup \text{span}(\tilde{\mathcal{M}}_1))) = \dim(\text{span}(\tilde{\mathcal{M}}_0)) + \dim(\text{span}(\tilde{\mathcal{M}}_1)) - \dim(\text{span}(\tilde{\mathcal{M}}_0) \cap \text{span}(\tilde{\mathcal{M}}_1)) = \text{cdim}(G_0) + \text{cdim}(G_1) - \dim(\text{span}(\tilde{\mathcal{M}}_0) \cap \text{span}(\tilde{\mathcal{M}}_1)).
\]

We use Lemma 34 to obtain the last equality. Notice that $Z \in \mathcal{M}_0 \cap \mathcal{M}_1$, which implies that \( \dim(\text{span}(\tilde{\mathcal{M}}_0) \cap \text{span}(\tilde{\mathcal{M}}_1)) \geq 1 \), and thus \( \text{cdim}(G) \leq \text{cdim}(G_0) + \text{cdim}(G_1) - 1 \).

We now prove the inequality in the reverse direction, when $Z$ is connected. Let $d_b = \text{cdim}(G_b) - 1$, for $b = 0, 1$. Let $Z_b$ be the star cut at $v_{1-b}$ in $G_b$. Since these are mincuts, we can extend them to a basis in the respective graphs. Therefore there exist $A_1, \ldots, A_{d_0} \subseteq X_0$ and $B_1, \ldots, B_{d_1} \subseteq X_1$ such that the family \( \{\chi(\Delta(A_1)), \ldots, \chi(\Delta(A_{d_0}))\}, \chi(Z_0) \} \) is independent in $\text{span}(\tilde{\mathcal{M}}(G_0))$ and the family \( \{\chi(\Delta(B_1)), \ldots, \chi(\Delta(B_{d_1}))\}, \chi(Z_1) \} \) is independent in $\text{span}(\tilde{\mathcal{M}}(G_1))$. We claim that in $\text{span}(\tilde{\mathcal{M}}(G))$ the set

\[
\{\chi(\Delta(A_1)), \ldots, \chi(\Delta(A_{d_0})), \chi(\Delta(B_1)), \ldots, \chi(\Delta(B_{d_1})), \chi(Z)\}
\]

of size $d_0 + d_1 + 1$ is independent.

Let us suppose on the contrary that a non-trivial linear combination of these $d_0 + d_1 + 1$ vectors gives $0$. Then there exist non all zero real numbers $a_1, \ldots, a_{d_0}, b_1, \ldots, b_{d_1}$ and $\varepsilon \in \{0,1\}$ such that

\[
\sum_{i=1}^{d_0} a_i \chi(\Delta(A_i)) + \sum_{j=1}^{d_1} b_j \chi(\Delta(B_j)) = \varepsilon \chi(Z).
\]  

We define the function $S : V \to \mathbb{R}$ by

\[
S(x) = \begin{cases} 
\sum_{i \in A_i} a_i & \text{if } x \in X_0, \\
\sum_{j \in B_j} b_j & \text{if } x \in X_1. 
\end{cases}
\]

If $x \in X_0$ and $y \in X_1$ are arbitrary elements and $\{x,y\} \in Z$, then $\chi(\Delta(A_i))(\{x,y\}) = 1$ iff $x \in A_i$ and $\chi(\Delta(B_j))(\{x,y\}) = 1$ iff $y \in B_j$. Therefore for every $\{x,y\} \in Z$, the coordinate $\{x,y\}$ of Equation (1) gives

\[
S(x) + S(y) = \varepsilon. 
\]  

From Equation (1) we can also deduce that for every $\{x,x'\} \in E(X_0)$ we have

\[
\sum_{i=1}^{d_0} a_i \chi(\Delta(A_i))(\{x,x'\}) = 0, 
\]

and for every $\{y,y'\} \in E(X_1)$ we have

\[
\sum_{j=1}^{d_1} b_j \chi(\Delta(B_j))(\{y,y'\}) = 0. 
\]
Let \( \{x_0, y_0\} \) be an arbitrary edge in \( Z \), where \( x_0 \in X_0 \) and \( y_0 \in X_1 \). We set \( s_0 = S(x_0) \) and \( s_1 = S(y_0) \). We know from Equation (2) that
\[
s_0 + s_1 = \varepsilon.
\]

We claim that for every \( \{x, y\} \in Z \), where \( x \in X_0 \) and \( y \in X_1 \), we have \( S(x) = s_0 \) and \( S(y) = s_1 \). For this consider an arbitrary breadth first search tree with root \( x_0 \). Since the graph of the cut \( Z \), the graph \( G(Z) = (V', Z) \), is a connected bipartite graph, every vertex in \( V' \cap X_0 \) will be at some even depth of the tree, and every vertex in \( V' \cap X_1 \) at some odd depth of the tree. Going through all the vertices depth by depth starting with \( x_0 \) at depth 0, Equation (2) gives the claim.

We now distinguish two cases. In the first case at least one of \( s_0 \) and \( s_1 \) is non-zero, say without loss of generality that \( s_0 \neq 0 \). For \( i = 1, \ldots, d_0 \), we define
\[
a'_i = a_i / s_0.
\]

Then Equation (3) implies that in \( G_0 \), for every \( \{x, x'\} \in E(X_0) \), we have
\[
\sum_{i=1}^{d_0} a'_i \chi(\Delta(A_i))\{x, x'\} = 0.
\]  \( \tag{5} \)

Also in \( G_0 \), if \( x \in X_0 \) then \( \chi(\Delta(A_i))\{x, v_1\} = 1 \) iff \( x \in A_i \). Therefore
\[
\sum_{i=1}^{d_0} a'_i \chi(\Delta(A_i))\{x, v_1\} = s_0/s_0 = 1.
\]  \( \tag{6} \)

Therefore Equations (5) and (6) imply that
\[
\sum_{i=1}^{d_0} a'_i \chi(\Delta(A_i)) = \chi(Z_0),
\]  \( \tag{7} \)

which contradicts the linear independence of \( \{\chi(\Delta(A_1)), \ldots, \chi(\Delta(A_{d_0})), \chi(Z_0)\} \).

In the second case \( s_0 = s_1 = 0 \), and thus for all \( \{x, y\} \in Z \), with \( x \in X_0 \) and \( y \in X_1 \), we have \( S(x) = S(y) = 0 \). Therefore in \( G_0 \), for every edge \( \{x, v_1\} \),
\[
\sum_{i=1}^{d_0} a_i \chi(\Delta(A_i))\{x, v_1\} = 0,
\]  \( \tag{8} \)

and similarly in \( G_1 \), for every edge \( \{y, v_0\} \),
\[
\sum_{j=1}^{d_1} b_j \chi(\Delta(B_j))\{y, v_0\} = 0.
\]  \( \tag{9} \)

Since \( a_1, \ldots, a_{d_0}, b_1, \ldots, b_{d_1} \) are not all zero, either \( a_1, \ldots, a_{d_0} \) is not all zero or \( b_1, \ldots, b_{d_1} \) is not all zero. If \( a_1, \ldots, a_{d_0} \) is not all zero then from Equations (3) and (8) it follows that the family \( \{\chi(\Delta(A_1)), \ldots, \chi(\Delta(A_{d_0}))\} \) is dependent in \( \text{span}(\tilde{M}(G_0)) \). If \( b_1, \ldots, b_{d_1} \) is not all zero then similarly from Equations (4) and (9) it follows that the family \( \{\chi(\Delta(B_1)), \ldots, \chi(\Delta(B_{d_1}))\} \) is dependent in \( \text{span}(\tilde{M}(G_1)) \). In either case, we reach a contradiction. \( \Box \)
6.2 The upper bound

We now can give our second proof of the upper bound on the cut dimension Theorem 1.

Proof of Theorem 1. The proof is by induction. For the base case $n = 2$, the only graph to be considered consists of a single edge and the cut dimension is $1 = 2n - 3$.

Now let $n \geq 3$, and we assume the inductive hypothesis holds for all graphs on at most $n - 1$ vertices. We consider 3 cases.

Case 1: The graph $G$ has only star mincuts, say at vertices $v_1, \ldots v_k$, for some $1 \leq k \leq n$. As there are only $k$ mincuts here we have $\text{cdim}(G) \leq k \leq n \leq 2n - 3$ for $n \geq 3$.

Case 2: There is a non-star mincut in $G$, and every non-star mincut is crossed by a non-star mincut. Then by Lemma 32, the graph $G$ is a cycle where the edges have all the same weight. In this case by Lemma 33, we have $\text{cdim}(G) = \text{cdim}(G_0) = n \leq 2n - 3$ for $n \geq 3$.

Case 3 is where we use the induction hypothesis: Suppose that $G$ has a non-star crossless mincut $Z$ with shores $X_0 \cup X_1 = V \setminus X_0$. Let $|X_0| = k$. Then by Lemma 35 there are graphs $G_0, G_1$ such that $\text{cdim}(G) \leq \text{cdim}(G_0) + \text{cdim}(G_1) - 1$, where $G_0$ is a graph on $k + 1$ vertices, and $G_1$ is a graph on $n - k + 1$ vertices. Therefore by the inductive hypothesis

$$\text{cdim}(G) \leq 2(k + 1) - 3 + 2(n - k + 1) - 3 - 1 = 2n - 3.$$ ▶

6.3 The lower bound

We now give our second proof of Theorem 2 that for every $n \geq 2$ there exist graphs $G$ with $\text{cdim}(G) = 2n - 3$. We need a slightly more detailed statement for the inductive hypothesis which is given in the following theorem.

Theorem 36. For every integer $n \geq 2$, there is a complete weighted graph $G = (V, w)$ on $n$ vertices with cut dimension $2n - 3$ and minimum cut weight 1, and where for every $v \in V$, the star cut $\Delta(\{v\})$ is a minimum cut.

Proof. For $n = 2$ the statement is satisfied by the graph consisting of a single edge of weight one which has cut dimension one and where the two star cuts are minimum cuts. For $n = 3$ we may take the complete graph $G^{(3)} = (V^{(3)}, w^{(3)})$ with all weights $1/2$, which has cut dimension 3.

Now assume that there exists a graph $G^{(n-1)} = (V^{(n-1)}, w^{(n-1)})$ on $n - 1$ vertices satisfying the inductive hypothesis. Let us consider a copy of $G^{(3)} = (V^{(3)}, w^{(3)})$ where $V^{(3)} = \{t, u, v_0\}$ and $V^{(n-1)} \cap V^{(3)} = \emptyset$. We choose $v_1 \in V^{(n-1)}$ arbitrarily. We claim that the $n$-vertex graph $G_n = (V^{(n)}, w^{(n)})$ defined as $\text{mer}((G^{(n-1)}, v_1), (G^{(3)}, v_0))$ satisfies the statement. It follows from the definition of the merge operation that $G_n$ is a complete weighted graph and that its star cuts are of weight one. In addition Claim 8 asserts that if $Z$ is the cut in $G_n$ whose shores are $V^{(n-1)} \setminus \{v_1\}$ and $V^{(3)} \setminus \{v_0\}$ then $w(Z) = 1$.

We now claim that the weight of a minimum cut of $G_n$ is one and that the mincut $Z$ is crossless. Consider a non-star cut $\Delta(X)$. If both vertices $t, u$ are on the same shore then the weight of $\Delta(X)$ is the same as the analogous cut in $G^{(n-1)}$ and therefore is at least one. If $\Delta(X)$ crosses $Z$, then we suppose without loss of generality that $t \in X, u \in X$. We show that the weight of $\Delta(X)$ is greater than one, which then implies both claims. The cut contains the edge $\{t, u\}$ which has weight $1/2$. For every $y \in V^{(n-1)} \setminus \{v_1\}$, the cut either contains the edge $\{t, y\}$ or the edge $\{u, y\}$, and these edges have the same weight. Thus the total weight of such edges is half of the weight of $Z$, that is $1/2$. In addition, the cut contains also at least one edge from $G^{(n-1)}$, therefore its total weight is greater than one.
15:24 On the Cut Dimension of a Graph

- Figure 1 Example graph $G$ showing the necessity of the connected condition in Lemma 34. Red edges have weight 2 and black edges have weight 1. The minimum cut weight is 4 and the cuts achieving this are all the star cuts and $\Delta(\{1, 2\}), \Delta(\{3, 4\}), \Delta(\{5, 6\}), \Delta(\{7, 8\}), \Delta(\{1, 2, 3, 4\})$.

- Figure 2 The graph $G_0$. Red edges have weight 2 and black edges have weight 1. The minimum cut weight is 4 and the cuts achieving this are all the star cuts and $\Delta(\{1, 2\}), \Delta(\{3, 4\})$. The cut dimension is 7.

Finally Claim 8 says that $\text{sep}(G(n), Z) = \{G(n-1), G(3)\}$. Since $Z$ is a crossless non-star minimum cut that is also connected, Lemma 35 implies that $\text{cdim}(G(n)) = \text{cdim}(G(n-1)) + \text{cdim}(G(3)) - 1$, which is $2n - 3$ by the inductive hypothesis.

6.4 On the tightness of Lemma 35

One can wonder whether the connectedness of $Z$ is a necessary hypothesis in Lemma 35. In fact it is, when $Z \in \mathcal{M}(G)$ is not connected then we can have $\text{cdim}(G) < \text{cdim}(G_0) + \text{cdim}(G_1) - 1$. An example is given in Figure 1. The mincuts in this graph are all the star cuts and $\Delta(\{1, 2\}), \Delta(\{3, 4\}), \Delta(\{5, 6\}), \Delta(\{7, 8\}), \Delta(\{1, 2, 3, 4\})$.

Thus no mincuts cross each other. Also none of the non-star mincuts are connected.

Consider the case where $Z = \Delta(\{1, 2, 3, 4\})$. When we separate $G$ along this cut we see that $G_0 = G_1$ and they are equal to the graph in Figure 2. The mincuts in $G_0$ are all star cuts and $\Delta(\{1, 2\}), \Delta(\{3, 4\})$. All non-star mincuts in $G_0$ are connected so one can use Lemma 34 to compute that $\text{cdim}(G_0) = 7$, i.e. all these mincut vectors are linearly independent. However, the cut dimension of $G$ is clearly at most 12 as it only has 12 edges. Direct computation shows that in fact $\text{cdim}(G) = 11$.
In this section, we use the $\ell_1$-approximate cut dimension method to show Theorem 3 that for any $k \in \mathbb{N}$ and $n = 3k + 1$, it holds that $D_{lin}(\text{MINCUT}_n) \geq 2n - 2$.

Let $K_4$ be the complete graph on 4 vertices with all edge weights equal to 1. The theorem will follow from showing that the $\ell_1$-approximate cut dimension of the direct union of $k$ copies of $K_4$ has $\ell_1$-approximate cut dimension $6k$. We start with the base case $k = 1$ to build up the notation and intuition that will be needed for the general case. The following definition and fact will be useful.

**Definition 37 (Strictly diagonally dominant).** Let $A \in \mathbb{R}^{n \times n}$ be a matrix. We say that the $i$th row of $A$ is strictly diagonally dominant if $|A(i, i)| > \sum_{j \neq i} |A(i, j)|$. We say that $A$ is strictly diagonally dominant iff all of its rows are.

It is well known that a strictly diagonally dominant matrix has full rank. One way to prove this is via the following fact, which we will make use of in the proof of Theorem 3.

**Fact 38.** Let $A \in \mathbb{R}^{n \times n}$ be a matrix whose $i$th row is strictly diagonally dominant. If $Au = 0$ for a vector $u \neq 0$ then $|u_i| < \|u\|_\infty$.

**Proof.** Suppose for a contradiction that for some $u \neq 0$ it holds that $Au = 0$ and $|u_i| = \|u\|_\infty$ where the $i$th row of $A$ is strictly diagonally dominant. By normalizing and flipping the sign of $u$ if necessary we may assume $\|u\|_\infty = 1$ and $A(i, i)u_i = |A(i, i)|$. Thus

$$\sum_j A(i, j)u_j = |A(i, i)| + \sum_{j \neq i} A(i, j)u_j \geq |A(i, i)| - \sum_{j \neq i} |A(i, j)| > 0,$$

a contradiction.

### 7.1 $\ell_1$-approximate cut dimension of $K_4$

![Figure 3](image-url) The complete graph on 4 vertices with all edge weights equal to 1. The labels on edges indicate the ordering of edges used to represent cut vectors in the proof.

We label the vertices of $K_4$ by $a, b, c, v$, and use the ordering of edges indicated in Figure 3. Let $X$ be the 7-by-6 matrix whose rows correspond to the cut vectors of all the nontrivial cuts.
The cut vectors in $X$ are given in the order
\[ \Delta(\{a\}), \Delta(\{b\}), \Delta(\{c\}), \Delta(\{a,b\}), \Delta(\{a,c\}), \Delta(\{b,c\}) \] .

The first 4 rows correspond to star cuts which are minimum cuts of weight 3 in $K_4$. The last three rows correspond to cuts which have weight 4 in $K_4$. Thus to show a lower bound of 6 on the number of linear queries needed to compute the minimum cut of a 4 vertex graph, we need to show that the $w = (1, 1, 1, 1, 1, 1)$, $c = (0, 0, 0, 1, 1, 1)$ one-sided $\ell_1$ approximate rank of $X$ is 6.

\[ \text{Claim 39.} \text{ Let } w = 1 \in \mathbb{R}^6, \text{ and } c = (0, 0, 0, 1, 1, 1). \text{ The } (w, c) \text{ one-sided } \ell_1 \text{ approximate rank of } X \text{ is 6.} \]

\[ \text{Proof.} \text{ The rank of } X \text{ at most 6 as this is the number of columns, which takes care of the upper bound.} \]

\[ \text{Now consider the lower bound. To do this we need to lower bound the rank of the matrix} \]

\[ Z = X - \begin{bmatrix} 0_{4,2} & 0_{4,2} & 0_{4,2} \\ A_1 & A_2 & A_3 \end{bmatrix} \]

\[ \text{where each of } A_1, A_2, A_3 \geq 0 \text{ are 3-by-2 matrices and every row of } A_1 + A_2 + A_3 \text{ sums to at most 1. As the first 4 rows of } X \text{ correspond to vectors of minimum cuts, no error is allowed on the first 4 rows.} \]

\[ \text{The first 4 rows of } Z \text{ are equal to the first 4 rows of } X, \text{ as there is no perturbation allowed on these rows. By doing elementary row operations on the first four rows, which do not change the rank, we can transform the first four rows of } Z \text{ into the reduced row echelon form of } X(1:4,:) \text{. Thus we arrive at the following matrix.} \]

\[ \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & -1 \\ 0 & 1 & 0 & 0 & -1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 \\ 0 & 1 & 1 & 1 & 1 & 0 \\ 1 & 0 & 1 & 1 & 0 & 1 \\ 1 & 1 & 0 & 0 & 1 & 1 \end{bmatrix} - \begin{bmatrix} 0_{4,2} & 0_{4,2} & 0_{4,2} \\ A_1 & A_2 & A_3 \end{bmatrix} . \]

Now we do column operations to zero out the entries in the first four rows and last two columns. For a $m$-by-2 matrix $A$ we will use the notation $A^\circ$ to denote the matrix $A$ with the order of the columns swapped. We arrive at
$$\begin{bmatrix}
1 & 0 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 0 \\
0 & 1 & 1 & 1 & 0 & -2 \\
1 & 0 & 1 & 1 & -2 & 0 \\
1 & 1 & 0 & 0 & 2 & 2
\end{bmatrix} - \begin{bmatrix}
0_{4,2} & 0_{4,2} \\
A_1 & A_2 & A_1^2 - A_2 - A_2^2 + A_3
\end{bmatrix}.$$

Finally, we can do row operations to zero out the first four columns in the last three rows.

$$\begin{bmatrix}
1 & 0 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & -2 \\
0 & 0 & 0 & 0 & -2 & 0 \\
0 & 0 & 0 & 0 & 2 & 2
\end{bmatrix} - \begin{bmatrix}
0_{4,2} & 0_{4,2} \\
0_{3,2} & 0_{3,2} & A_1^2 - A_2 - A_2^2 + A_3
\end{bmatrix}.$$

The task has now reduced to showing the matrix

$$Z' = \begin{bmatrix} 2 & 0 \\ 0 & 2 \\ -2 & -2 \end{bmatrix} + A_1 - A_2 - A_2^2 + A_3^2$$

has rank 2 for any $A_1, A_2, A_3$ satisfying the constraints. Let us simplify the matrix $A_1 - A_2 - A_2^2 + A_3^2$. First, let $A_1^2 = A_1 + A_3$. Next, note that $D = A_2 + A_3^2$ has the property that $D(i, 1) = D(i, 2)$ for $i \in [3]$. In the sequel we call this the partner property.

As the row sum of $A_1 + A_2$ is at most 1, unless $A_1(1:2, 1:2) = 0_{2,2}$ and at least one row sum of $A_2(1:2, 1:2)$ is equal to 1 the first two rows of $Z'$ will be strictly diagonally dominant. If the first two rows of $Z'$ are strictly diagonally dominant then the rank of $Z'$ must be 2, thus we now handle the “unless” case.

First, suppose exactly one row sum of $A_2(1:2, 1:2)$ is equal to 1. Say without loss of generality it is the second one, thus the first row of $Z'$ will be strictly diagonally dominant. If for a sufficiently small $\epsilon$ we can multiply the first column by $1 - \epsilon$ so that the first row remains strictly diagonally dominant and the second row becomes strictly diagonally dominant as well. This does not increase the rank and thus shows again that the rank of $Z'$ is 2.

The remaining case is where both rows of $A_2(1:2, 1:2)$ sum to one. In this case by the partner property we have

$$Z'(1:2, 1:2) = \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}.$$

On the other hand, the last row of $Z'$ must have both entries $\leq -1$. Thus the determinant of the submatrix formed by the first row and the third is strictly negative and so $Z'$ has rank 2.
Figure 4 Example of the direct union of two copies of \( K_4 \). With the ordering of the edges given by the edge labels, the matrix of cut vectors of the cuts \( \Delta\{a^{(i)}\}, \Delta\{b^{(i)}\}, \Delta\{c^{(i)}\} \), \( \Delta\{a^{(i)}, b^{(i)}, c^{(i)}\} \), \( \Delta\{a^{(i)}, b^{(i)}\}, \Delta\{a^{(i)}, c^{(i)}\} \), \( \Delta\{b^{(i)}, c^{(i)}\} \) for \( i \in [2] \) becomes the matrix \( X^{(2)} \) on the right.

7.2 Direct union of \( K_4 \) with itself

Now we prove the general case. The key to the proof is the following lemma.

Lemma 40. Let \( k \in \mathbb{N} \) and \( B \) be the 3k-by-2k matrix

\[
B = \begin{bmatrix}
2I_{2k} \\
-2I_k \otimes [1,1]
\end{bmatrix}.
\]

For any matrices 3k-by-2k matrices \( A_1, A_2 \) satisfying the conditions

1. \( A_1, A_2 \geq 0 \)
2. (partner property) For all \( i \in [3k] \) and \( j \in [k] \) it holds that \( A_2(i, 2j - 1) = A_2(i, 2j) \).
3. Every row of \( A_1 + A_2/2 \) sums to at most 1

it holds that \( B + A_1 - A_2 \) has rank \( 2k \).

Proof. The rank is at most \( 2k \) as that is the number of columns; we focus on showing the columns are linearly independent.

Let \( Z = B + A_1 - A_2 \). We call the first \( 2k \) rows of \( Z \) rows of type I, and the last \( k \) rows of type II. If a type I row is not strictly diagonally dominant, we call it full. Notice that a type I row \( i \) is full if and only if the \( i^{th} \) row of \( A_1 \) is zero and the \( i^{th} \) row of \( A_2 \) sums to 2. In this case, \( Z(i,j) \leq 0 \) for every \( j \neq i \) and it holds that \( Z(i,i) = -\sum_{j \neq i} Z(i,j) \). For \( i \in [k] \) we call \( 2i - 1 \) and \( 2i \) partners.

Suppose for contradiction there is a vector \( \vec{u} \neq 0 \) such that \( A\vec{u} = 0 \). As \( \vec{u} \neq 0 \) by normalizing and multiplying by \( -1 \) as needed we may assume that \( \|\vec{u}\|_{\infty} = 1 \) and \( i \) is a coordinate with \( \vec{u}(i) = 1 \). By Fact 38 the \( i^{th} \) row of \( Z \), which is a type I row, cannot be strictly diagonally dominant. Thus the \( i^{th} \) row must be full. Therefore for \( Z(i,:)\vec{u} = 0 \) to hold it must be the case that \( \vec{u}(j) = 1 \) for every \( j \) where \( A_2(i,j) > 0 \). Such a \( j \) must exist as the \( i^{th} \) row of \( A_2 \) sums to 2. So let \( j \) be a coordinate with \( A_2(i,j) > 0 \) and let \( j' \) be the partner of \( j \). By the partner property we also have \( A_2(i,j') > 0 \) and therefore \( \vec{u}(j) = \vec{u}(j') = 1 \).
Now consider the type II row $\ell$ for which $B(\ell,j) = B(\ell,j') = -2$. As $B(\ell,t) = 0$ for $t \notin \{j,j'\}$ this means
\[
Z(\ell,:)\vec{u} = Z(\ell,j) + Z(\ell,j') + \sum_{t \notin \{j,j'\}} Z(\ell,t)\vec{u}(t) \\
\leq B(\ell,j) + A_1(\ell,j) + B(\ell,j') + A_1(\ell,j') + \|\vec{u}\|_\infty \sum_{t \notin \{j,j'\}} |Z(\ell,t)| \\
\leq -4 + \sum_{t} A_1(\ell,t) + A_2(\ell,t) \\
\leq -2 ,
\]
and we have arrived at a contradiction.  

With Lemma 40 in hand we are now ready to prove Theorem 3.

**Proof of Theorem 3.** Let $G^{(1)}, \ldots, G^{(k)}$ be $k$ copies of $K_4$ where the vertices in $G^{(i)}$ are labeled by $a^{(i)}, b^{(i)}, c^{(i)}, v^{(i)}$ for $i \in [k]$. The graph $G$ is formed by taking the direct union of $G^{(1)}, \ldots, G^{(k)}$ at the vertices $v^{(1)}, \ldots, v^{(k)}$. That is, the vertices $v^{(1)}, \ldots, v^{(k)}$ are all identified by a common vertex denoted $v$. See Figure 4 for an illustration of the graph for $k = 2$.

In order to make reference to the base case, we need to use the matrix $A = I_k \otimes X$, where $X$ is the matrix from Equation (10). In every nonzero block of $X^{(k)}$ the first four rows are minimum cuts with weight 3 and the last 3 rows are cuts with weight 4. Let $c' = (0,0,0,1,1,1)$. The theorem will follow from Theorem 13 by showing that the $w = 1_{6k}, c = 1_k \otimes c'$ one-sided $\ell_1$ approximate rank of $X^{(k)}$ is $6k$.

To do this, we must show that $X^{(k)} - A$ has rank $6k$ for any matrix $A \geq 0$ which is all zero on any row of $I_k \otimes X$ corresponding to a minimum cut, and where the row sum of $A$ is at most 1 on any row of $I_k \otimes X$ corresponding to a cut of weight 4. In order to make reference to the base case, it will be useful to partition the columns into $k$ blocks of 6 columns, where the $i^{th}$ block is further partitioned into blocks of size 2 represented by the $7k$-by-2 matrices $A_1^{(i)}, A_2^{(i)}, A_3^{(i)}$. In other words, we view $A$ as follows
\[
A = \begin{bmatrix} A_1^{(1)} & A_2^{(1)} & A_3^{(1)} & \cdots & A_1^{(k)} & A_2^{(k)} & A_3^{(k)} \end{bmatrix}
\]
where each $A_{j}^{(i)}$ for $j \in [3], i \in [k]$ is a $7k$-by-2 matrix.

As in the base case, we begin by doing Gauss-Jordan elimination on the rows corresponding to mincuts of each $X$ block in $X^{(k)}$. These operations only touch rows corresponding to mincuts where $A$ is zero, thus they do not change $A$. After these operations we arrive at the matrix $I_k \otimes X' - A$ where
\[
X' = \begin{bmatrix} 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & -1 \\ 0 & 1 & 0 & 0 & -1 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 & 0 & 1 & 1 & 0 \\ 1 & 0 & 1 & 1 & 1 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 0 \end{bmatrix}
\]
Next, as in the base case, we do column operations to zero out the last two columns in the first four rows of each block of $X'$. This gives us the matrix $I_k \otimes X'' - A'$ where

$$X'' = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 1 & 0 & -2 \\ 1 & 0 & 1 & 1 & 0 & -2 \\ 1 & 1 & 0 & 0 & 2 & 2 \end{bmatrix}$$

and the $i^{th}$ block of $A'$ looks like

$$[A_1^{(i)} \mid A_2^{(i)} \mid A_1^{(i)} - A_2^{(i)} - A_3^{(i)} + A_4^{(i)}].$$

Here $A_1^{(i)}$ denotes the matrix $A_1^{(i)}$ with the order of the columns swapped. Finally, we use $X''(1:4, 1:4)$ to zero out all other entries of $I_k \otimes X'' - A'$ in the first 4 columns of each block. This brings us to the matrix $I_k \otimes X''' - A''$ where

$$X''' = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -2 \\ 0 & 0 & 0 & 0 & 0 & -2 \\ 0 & 0 & 0 & 0 & 2 & 2 \end{bmatrix}$$

and the $i^{th}$ block of $A''$ is

$$[0_{7k,2} \mid 0_{7k,2} \mid A_1^{(i)} - A_2^{(i)} - A_3^{(i)}].$$

Again, each of $A_1^{(i)}, A_2^{(i)}, A_3^{(i)}$ is zero on rows corresponding to minimum cuts. Thus by multiplying the last two columns of each block by $-1$ and permuting rows and columns we can transform $I_k \otimes X''' - A''$ into the form

$$\begin{bmatrix} I_{4k} & 0_{4k,2k} \\ 0_{8k,4k} & B + A_1 - A_2 \end{bmatrix}$$

where $B, A_1, A_2$ satisfy the conditions of Lemma 40. Thus a rank lower bound of $6k$ follows from the lower bound of $2k$ on the rank of $B + A_1 - A_2$ given in Lemma 40.

8 The dimension of approximate mincuts

Let $G$ be a weighted graph and $\lambda$ the weight of a minimum cut in $G$. For $\alpha \geq 1$ define an $\alpha$-near-mincut of $G$ to be a cut $S$ whose weight is at most $\alpha \lambda$. Let $\mathcal{M}_\alpha(G)$ be the set of all $\alpha$-near-mincuts of $G$ and $\overline{\mathcal{M}}_\alpha(G) = \{ \chi(S) : S \in \mathcal{M}_\alpha(G) \}$. In this section, we look at $\text{cdim}_\alpha(G) = \dim(\text{span}(\overline{\mathcal{M}}_\alpha(G)))$.

The first observation is that if $\alpha = 2$ then the unweighted complete graph $K_n$ satisfies $\text{cdim}_\alpha(K_n) = \binom{n}{2}$. For simple graphs we can show $\alpha = 2$ is a sharp threshold.

\begin{tcolorbox}
\textbf{Theorem 41.} Let $1 \leq \alpha < 2$ be a constant and $G$ be a simple $n$-vertex graph. Then $\text{cdim}_\alpha(G) = O(n)$.
\end{tcolorbox}
The key to this theorem is the following lemma of Rubinstein, Schramm, and Weinberg [26].

**Lemma 42** (Lemma 2.6 [26]). Let $G$ be a simple graph with minimum degree $d_{\text{min}}$ and minimum cut value $\lambda$. For constant $0 \leq \varepsilon < 1$ let $T$ be the set of non-star cuts of $G$ whose weight is at most $\lambda + \varepsilon d_{\text{min}}$. Then $|\bigcup_{T \in T} T| = O(n)$.

**Proof of Theorem 41.** Let $G$ be a simple graph. To prove the theorem we create a set of $O(n)$ vectors that span $\tilde{M}_n(G)$. Let $M_n(G) = T \cup S$, where $T$ is the set of non-star cuts of $M_n(G)$ and $S$ is the set of star cuts of $M_n(G)$. Let $E' = \bigcup_{T \in T} T$ be the set of edges involved in the cuts in $T$. Let $\tilde{E} = \{e_i : i \in E\}$. Note that from the definition of $d_{\text{min}}$, there is a star cut with cut value $d_{\text{min}}$, which implies that $\lambda \leq d_{\text{min}}$. As a result, every $\alpha$-near-mincut has cut value at most $\alpha \lambda \leq \lambda + (\alpha - 1)d_{\text{min}}$, and hence by Lemma 42 we have $|\tilde{E}| = O(n)$. Also span($\tilde{E}$) $\subseteq$ span($\tilde{E}$). Thus span($M_n(G)$) $\subseteq$ span($\tilde{E} \cup S$). As $|S| \leq n$ this is a spanning set of size $O(n)$.

In a previous version of this work we conjectured that for an $n$-vertex weighted graph $G$ it holds that $cdim_n(G) = O(n)$ for any $\alpha < 4/3$. This turns out to be false, however. The reason is that, on the one hand, in a graph $G = (V, w)$ the characteristic vector of a cut $\chi(S)$ depends only on the set of edges, but not the weight of these edges. On the other hand, $w(S)$ does of course depend on the weight of the edges. We can utilize this difference to construct an example as follows. Let us start with a cycle $C_n$ with all edge weights being 1. While $C_n$ has $(n - 2)$ mincuts with weight 2, these mincuts live in an $n$-dimensional space as $C_n$ only has $n$ edges. We can then turn $C_n$ into a complete weighted graph $G$ by adding a tiny weight $\varepsilon = (n - 1)/\binom{n}{2}$ edge to all pairs of vertices that are not adjacent in the cycle. As adding edges cannot decrease the minimum cut weight, the weight of a minimum cut in $G$ is at least 2. Further, if $X$ is the shore of a minimum cut in $C_n$ then in the graph $G$ we have $w(\Delta(X)) \leq 2 + (\binom{n}{2}) \varepsilon = 2$, as the weight is at most its weight in $C_n$ plus the weight of all added edges. Thus $\Delta(X)$ is an $\alpha$-near-mincut in $G$. Further, the characteristic vectors $\chi(\Delta(X)) \in \{0, 1\}^{\binom{n}{2}}$ of these cuts in $G$ now live in an $\binom{n}{2}$-dimensional space and become linearly independent. This example demonstrates that a reasonable extension of the cut dimension to near-mincuts should take into account the magnitude of the edge weights, as the $\ell_1$-approximate cut dimension does.

We now give the formal proof that the graph $G$ mentioned above has the correct properties.

**Lemma 43.** Let $n \in \mathbb{N}$. Let $C_n$ be the cycle on $n$ vertices and $G$ the beach of $M(C_n)$. Let $K_n$ be the complete graph on $n$ vertices. Let $T = \{\Delta(X) : X \in G\}$, where here $\Delta(X) \in \{0, 1\}^{\binom{n}{2}}$ is the cut in $K_n$ with shore $X$. Then $\dim(\text{span}(\tilde{T})) = \binom{n}{2}$.

**Proof.** For this proof we assume the vertices are labeled by $0, \ldots, n - 1$ and use addition modulo $n$. We will show that all of the standard basis vectors $e_{i,j}$ are in span($\tilde{T}$). For concreteness, we show how to construct the vectors $e_{i,j}$; by symmetry the same argument can then be used for any $e_{i,j}$.

We will actually construct the vectors $E_j = \sum_{k=1}^{j} e_{0,k}$. This suffices as $e_{0,j} = E_j - E_{j-1}$. First note that $e_{0,j} = \frac{1}{2}(\chi(\Delta([0])) + \chi(\Delta([1])) - \chi(\Delta([0, 1])))$, and thus is in span($\tilde{T}$) as all the vectors on the right hand side are in $\tilde{T}$.

Now let $j > 1$ and $X = \{1, \ldots, j\}, X' = X \cup \{0\}$. Then

$$\chi(\Delta(X))(e) - \chi(\Delta(X'))(e) = \begin{cases} 1 & \text{if } e = [0,k], k \in X \\ -1 & \text{if } e = [0,k], k \in X' \\ 0 & \text{otherwise} \end{cases}$$

Thus $E_j = \frac{1}{2}(\Delta([0]) + \chi(\Delta(X)) - \chi(\Delta(X')))$.\hfill\&
Theorem 44. Let $n \in \mathbb{N}$. For any $\alpha > 1$ there exists a graph $G = ([0, \ldots, n-1], w)$ such that $\text{cdim}_n(G) = \binom{n}{2}$.

Proof. We again use addition modulo $n$ on the labels of the vertices. Let $\varepsilon = 2(\alpha - 1)/\binom{n}{2}$. Define $w(\{i, i+1\}) = 1$ for $i \in [0, \ldots, n-1]$ and for any other $i, j$ let $w(\{i, j\}) = \varepsilon$. Let $G = ([0, \ldots, n-1], w)$. Thus $G$ is the graph of the cycle $C_n$ with edges of weight $\varepsilon$ added between all pairs of vertices that are not adjacent in the cycle. The weight of a minimum cut of $G$ is at least that of $C_n$, which is 2, as adding edges cannot decrease the weight of a cut. Further, if $X$ is the shore of a minimum cut in $C_n$ then in the graph $G$ we have $w(\Delta(X)) \leq 2 + \binom{\alpha}{2}\varepsilon = 2\alpha$, as the weight is at most its weight in $C_n$ plus the weight of all added edges. Thus $\Delta(X)$ is an $\alpha$-near-mincut in $G$ and $\text{cdim}_n(G)$ is at least $\binom{n}{2}$ by Lemma 43. It also clearly cannot be larger than $\binom{n}{2}$ and so the theorem is proved.

References

A Jain’s spanning lemma

In this appendix we prove Lemma 19. The proof uses the following key property of mincuts which goes back at least to work of Dinitz, Karzanov, and Lomonosov [6].

\textbf{Proposition 45 ([6] “Lemma on a quadrangle”).} Let $G = (V, w)$ be a graph. For any crossing mincuts $\Delta(X), \Delta(Y)$ of $G$ it holds that

$$\chi(\Delta(X)) + \chi(\Delta(Y)) = \chi(\Delta(X \cap Y)) + \chi(\Delta(X \cup Y)).$$

\textbf{Proof.} If $\Delta(X), \Delta(Y)$ cross then $\Delta(X \cap Y), \Delta(X \cup Y)$ are mincuts of $G$ by Claim 5. Further, by counting the number of times an edge appears on each side it can be seen (eg. Ex. 6.48 in [23]) that

$$\chi(\Delta(X)) + \chi(\Delta(Y)) = \chi(\Delta(X \cap Y)) + \chi(\Delta(X \cup Y)) + 2\chi(E(X - Y, Y - X)).$$  (11)
Let the minimum cut value of $G$ be $\lambda$. Let $m$ be the number of edges in $G$ and $\vec{w} \in \mathbb{R}^m$ be the positive vector resulting from restricting $w$ to the edges of $G$. The inner product of $\vec{w}$ with the left hand side of Equation (11) is $2\lambda$, and with the right hand side is $2\lambda + 2\langle \vec{w}, \chi(E(X - Y, Y - X)) \rangle$. Thus $\langle \vec{w}, \chi(E(X - Y, Y - X)) \rangle = 0$, which implies $\chi(E(X - Y, Y - X)) = 0$ since $\vec{w}$ is positive and $\chi(E(X - Y, Y - X))$ is nonnegative.

Jain’s proof uses the technique of combinatorial uncrossing. Recall the definition of $\text{overlap}_G(X)$ from Definition 28. A key to the proof is the following simple lemma about $\text{overlap}_G(X)$.

Lemma 46 ([18]). Let $\mathcal{F} \subseteq 2^V$ be a set family closed under overlaps and $\mathcal{G} \subseteq \mathcal{F}$ be a maximal laminar subset of $\mathcal{F}$. Then for any $X \in \mathcal{F} - \mathcal{G}$ and $Y \in \text{overlap}_G(X)$

\begin{align}
\text{overlap}_G(X \cap Y) &\subseteq \text{overlap}_G(X) \\
\text{overlap}_G(X \cup Y) &\subseteq \text{overlap}_G(X).
\end{align}

Proof. In the following we always refer to $\text{overlap}(X)$ with respect to $\mathcal{G}$ and drop the subscript. We first show Equation (12). First note that $Y \in \text{overlap}(X) - \text{overlap}(X \cap Y)$. Thus to show Equation (12) it suffices to show $\text{overlap}(X \cap Y) \subseteq \text{overlap}(X)$. Let $W \in \text{overlap}(X \cap Y)$. We want to show that $W \in \text{overlap}(X)$, i.e. that it cannot be the case that $W \subseteq X, X \subseteq W$, or $X \cap W = \emptyset$. We know that the last one cannot hold because $W \in \text{overlap}(X \cap Y)$ implies $W \cap (X \cap Y) \neq \emptyset$.

Also as $W, Y \in \mathcal{G}$ they do not overlap and thus either $Y \subseteq W, W \subseteq Y$, or $Y \cap W = \emptyset$. Again the last one cannot hold as $W \cap (X \cap Y) \neq \emptyset$. The following table shows that assuming $W \notin \text{overlap}(X)$ leads to a contradiction in all 4 remaining cases.

<table>
<thead>
<tr>
<th>$W \subseteq X$</th>
<th>$Y \subseteq X$</th>
<th>$W \subseteq X \cap Y$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$Y \notin \text{overlap}(X)$</td>
<td>$W \notin \text{overlap}(X \cap Y)$</td>
<td></td>
</tr>
<tr>
<td>$X \subseteq W$</td>
<td>$X \cap Y \subseteq W$</td>
<td>$X \subseteq Y$</td>
</tr>
<tr>
<td>$W \notin \text{overlap}(X \cap Y)$</td>
<td>$Y \notin \text{overlap}(X)$</td>
<td></td>
</tr>
</tbody>
</table>

We now show Equation (13), which follows similarly. Again $Y \in \text{overlap}(X) - \text{overlap}(X \cup Y)$ thus it suffices to show $\text{overlap}(X \cup Y) \subseteq \text{overlap}(X)$. Let $W \in \text{overlap}(X \cup Y)$. We want to show that $W \in \text{overlap}(X)$, i.e. that is not the case that either $W \cap X = \emptyset, X \subseteq W$, or $W \subseteq X$. We cannot have $W \subseteq X$ because this means $W \subseteq X \cup Y$ which contradicts $W \in \text{overlap}(X \cup Y)$. As $W, Y \in \mathcal{G}$ they do not overlap, so we also know either $Y \subseteq W, W \cap Y = \emptyset$, or $W \subseteq Y$. The last one again cannot hold as it implies $W \subseteq X \cup Y$. The following table shows that assuming $W \notin \text{overlap}(X)$ leads to a contradiction in the remaining 4 cases.

<table>
<thead>
<tr>
<th>$X \subseteq W$</th>
<th>$Y \subseteq W$</th>
<th>$W \cap Y = \emptyset$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$X \cup Y \subseteq W$</td>
<td>$X \cap Y = \emptyset$</td>
<td>$Y \notin \text{overlap}(X)$</td>
</tr>
<tr>
<td>$W \notin \text{overlap}(X \cup Y)$</td>
<td>$W \cap (X \cup Y) = \emptyset$</td>
<td></td>
</tr>
</tbody>
</table>

We are now ready to show the key lemma of Jain.

Lemma 19 ([18]). Let $G = (V, w)$ be a graph and $\mathcal{L} \subseteq \mathcal{M}(G)$ be a maximal cross-free family of mincuts. Then $\text{span}(\mathcal{L}) = \text{span}(\mathcal{M}(G))$. 
Proof. It is clear that $\text{span}(\vec{L}) \subseteq \text{span}(\vec{M}(G))$ so we focus on the other direction.

Let $\mathcal{F}$ be the beach of $\mathcal{M}(G)$. By Claim 5 $\mathcal{F}$ is closed under overlaps. Let $\mathcal{G} \subseteq \mathcal{F}$ be the beach of $\mathcal{L}$. As $\mathcal{L}$ is a maximal cross-free subset of $\mathcal{M}(G)$ it follows that $\mathcal{G}$ is a maximal laminar subset of $\mathcal{F}$. Thus $|\text{overlap}_G(X)| \geq 1$ for all $X \in \mathcal{F} - \mathcal{G}$. In the following we will always refer to $\text{overlap}(X)$ with respect to $\mathcal{G}$ and drop the subscript.

Suppose for a contradiction that $\text{span}(\vec{L})$ is a strict subset of $\text{span}(\vec{M}(G))$. Let

$$X = \arg\min_{Z \in \mathcal{F} - \mathcal{G}} \{|\text{overlap}(Z)| : \chi(\Delta(Z)) \notin \text{span}(\vec{L})\}.$$ 

As $\text{overlap}(X) \geq 1$, let $Y \in \text{overlap}(X)$. By Lemma 46

$$|\text{overlap}(X \cap Y)| < |\text{overlap}(X)| \quad (14)$$

$$|\text{overlap}(X \cup Y)| < |\text{overlap}(X)|. \quad (15)$$

By the definition of $X$, and as $\mathcal{F}$ is closed under overlaps, we must have $\chi(\Delta(X \cap Y)), \chi(\Delta(X \cup Y)) \in \text{span}(\vec{L})$. Also as $Y \in \mathcal{G}$ we have $\chi(\Delta(Y)) \in \vec{L}$ which implies by Proposition 45 that

$$\chi(\Delta(X)) = \chi(\Delta(X \cap Y)) + \chi(\Delta(X \cup Y)) - \chi(\Delta(Y)).$$

This implies $\chi(\Delta(X)) \in \text{span}(\vec{L})$, a contradiction. ▶
On $p$-Group Isomorphism: Search-To-Decision, Counting-To-Decision, and Nilpotency Class Reductions via Tensors

Joshua A. Grochow

Abstract

In this paper we study some classical complexity-theoretic questions regarding Group Isomorphism ($\text{GpI}$). We focus on $p$-groups (groups of prime power order) with odd $p$, which are believed to be a bottleneck case for $\text{GpI}$, and work in the model of matrix groups over finite fields. Our main results are as follows.

- Although search-to-decision and counting-to-decision reductions have been known for over four decades for Graph Isomorphism ($\text{GI}$), they had remained open for $\text{GpI}$, explicitly asked by Arvind & Torán (Bull. EATCS, 2005). Extending methods from Tensor Isomorphism (Grochow & Qiao, ITCS 2021), we show moderately exponential-time such reductions within $p$-groups of class 2 and exponent $p$.

- Despite the widely held belief that $p$-groups of class 2 and exponent $p$ are the hardest cases of $\text{GpI}$, there was no reduction to these groups from any larger class of groups. Again using methods from Tensor Isomorphism (ibid.), we show the first such reduction, namely from isomorphism testing of $p$-groups of “small” class and exponent $p$ to those of class two and exponent $p$.

For the first results, our main innovation is to develop linear-algebraic analogues of classical graph coloring gadgets, a key technique in studying the structural complexity of $\text{GI}$. Unlike the graph coloring gadgets, which support restricting to various subgroups of the symmetric group, the problems we study require restricting to various subgroups of the general linear group, which entails significantly different and more complicated gadgets. The analysis of one of our gadgets relies on a classical result from group theory regarding random generation of classical groups (Kantor & Lubotzky, Geom. Dedicata, 1990). For the nilpotency class reduction, we combine a runtime analysis of the Lazard Correspondence with Tensor Isomorphism-completeness results (Grochow & Qiao, ibid.).

Acknowledgements The authors would like to thank James B. Wilson for related discussions, and Ryan Williams for pointing out the problem of distinguishing between ETH and $\#\text{ETH}$. J. A. G. would like to thank V. Futorny and V. V. Sergeichuk for their collaboration on the related work [28].

Ideas leading to this work originated from the 2015 workshop “Wildness in computer science, physics, and mathematics” at the Santa Fe Institute.
1 Introduction

In this paper, we study the algorithmic problem of deciding whether two finite groups are isomorphic, known as the Group Isomorphism problem (GpI). Different variants of the GpI problem arise, with correspondingly different complexities, when the groups are given in different ways, e.g. by a generating set of permutations, a generating set of matrices, a full multiplication table, or a black box oracle. In its various incarnations, GpI is a fundamental problem in computational algebra and computational complexity. The generator-enumerator algorithm solves isomorphism in $|G|^\log|G| + O(1)$-time [26,58], and even the current state of the art for general groups – in any of the aforementioned input models – is still $|G|^{\Theta(\log|G|)}$ [9,10,17,25,49,66,70]. Nonetheless, over the past 15 years there has been significant progress on efficient isomorphism tests in various classes of groups: here is an incomplete list of references [4–6,12,13,15,30,31,47,48,63,65,66].

When given by multiplication tables, GpI reduces to GI [44], and in the other, more realistic (for computer algebra systems) and more succinct models, we get a reduction in the other direction [32,34,52,57]. As a result, the techniques and complexity of GpI are closely bound up with GI. However, since the techniques used in GpI are often independent of the input model, we are free to focus on the abstract structure of the groups in question, and the choice of input model is then essentially just a choice of how we measure and report the running time. For example, if GI is in $\mathsf{P}$, then GpI can be solved in $\text{poly}(|G|)$ time; if GpI for groups given by a generating set of $m$ matrices of size $n \times n$ over $F_p$ can be solved in $p^{O(n+m)}$ time, then GI is in $\mathsf{P}$.

For GI, a wide variety of algorithmic and structural complexity results are known (see, e.g., [3,33,44]). In particular, there are polynomial-time search-to-decision and counting-to-decision reductions [54], so search, counting, and decision are all equivalent for GI. (This was an early piece of evidence that GI was not likely to be $\mathsf{NP}$-complete, since for $\mathsf{NP}$-complete problems, their counting variants are typically $\#\mathsf{P}$-complete, hence at least as hard as all of $\mathsf{PH}$ [68].) For GpI, no such reductions are known, even in restricted classes of groups; Arvind and Torán [2, Problem 16] explicitly asked for such reductions. Additionally, for GI, there are many classes of graphs for which the isomorphism problem remains GI-complete – such as graphs of diameter 2 and radius 1, directed acyclic graphs, regular graphs, line graphs, polytopal graphs [74] – but no such analogous results are known for GpI.

In this paper, we make progress on all three of these questions, within the class of groups widely believed to be hardest cases of GpI, namely the $p$-groups of nilpotency class 2 and exponent $p$; these are groups of order a power of the prime $p$, such that $G$ modulo its center is abelian, and such that $g^p = 1$ for all $g \in G$. (Throughout most of this paper we assume $p$ is an odd prime.) For each of our three main results, we now give further motivation before stating it formally.

1.1 Main results

Search-to-decision reductions. The “decision versus search” question is a classical one in complexity theory, having attracted the attention of researchers since the introduction of $\mathsf{NP}$. Efficient search-to-decision reductions for SAT and GI are now standard. Valiant first showed the existence of an $\mathsf{NP}$ relation for which search does not reduce to decision in polynomial time [69]. A celebrated result of Bellare and Goldwasser shows that, assuming

1 Miller [58] attributes this algorithm to Tarjan.
DTIME($2^{O(n)}$) ≠ NTIME($2^{O(n)}$), there exists an NP language for which search does not reduce to decision in polynomial time [8]. However, as usual for such statements based on complexity-theoretic assumptions, the problems constructed by such a proof are considered somewhat unnatural, and natural problems for which search seems not reducible to decision are rare. The most famous candidate may be FACTORING (with the decision version being PRIMALITY)\(^2\) and Nash Equilibrium [18] (the decision version is trivial).

Let \(p\) be an odd prime, and let GP\(_{p,2}\) denote the isomorphism problem for \(p\)-groups of class 2 and exponent \(p\) in the model of matrix groups over \(\mathbb{F}_p\). For groups of order \(p^n\), there is a search-to-decision reduction for GP\(_{p,2}\) running in time \(p^{O(n)} = \text{poly}(|G|)\).

Remark 1. This runtime is really only square-root (moderately) exponential: The running time of the best-known algorithm for GP\(_{p,2}\) is essentially \(p^{\Theta(n^2)}\), and the best-known witness size, if we think in terms of nondeterministic algorithms, is \(\Theta(n^2)\) [50]. So our search-to-decision reduction in time \(p^{O(n)}\) is akin to having such a reduction running in time \(2^{\Theta(\sqrt{N})}\) for a problem that is solvable in \(2^{\Theta(N)}\) time (resp., has witness size \(\Theta(N)\)).

We note that that GP\(_{p,2}\) seems different from all the problems listed above in terms of search-to-decision reductions, in the following ways. First, unlike SAT and GI, a polynomial-time search-to-decision reduction has been open for decades, whereas those for SAT and GI are straightforward. Note that a polynomial-time reduction would need to run in time \(\text{poly}(n, \log p)\), and we find it unlikely that the time complexity of our reduction can be brought down this far with current techniques. Second, unlike FACTORING and Nash Equilibrium, whose decision versions are computationally easy, its decision version also seems to require deeper techniques. Indeed, it is a long-standing open problem to test isomorphism of \(p\)-groups of class 2 and exponent \(p\) in time polynomial in the group order, which already can be exponential in the input size if the input is given by a generating set of matrices.

Counting-to-decision reductions. Counting-to-decision reductions are also of great interest in complexity theory. An efficient counting-to-decision reduction for GI is also a well-known result [54]. In contrast, for SAT, a polynomial-time counting-to-decision reduction would imply that PH collapses [68].

Theorem B. For \(p\) an odd prime, \(p \geq n^{O(1)}\), there is a randomized counting-to-decision reduction for GP\(_{p,2}\) for groups of order \(p^n\), running in time \(p^{O(n)} = \text{poly}(|G|)\).

As with Theorem A, the runtime here is only moderately exponential, see Remark 1.

Also as in the case of search-to-decision, GP\(_{p,2}\) seems different from the problems listed above in terms of reducing counting to decision. First, a polynomial-time counting-to-decision reduction for GP\(_{p,2}\) remains open after 40 years, whereas the reduction for GI was found within the first decade of the rise of computational complexity theory. Second, unlike SAT, for which there have been no non-trivial algorithms to reduce exact counting to decision, we show a moderately exponential-time algorithm for GP\(_{p,2}\). As Ryan Williams pointed out to us, asking for the existence of subexponential-time counting-to-decision reduction for SAT seems to lead to asking for the relation between the decision [35] and the counting [22] versions of the Exponential Time Hypothesis.

\(^2\) Here we are thinking of FACTORING as the search problem corresponding to the relation \(\{(n, d) : d \text{ is a proper divisor of } n\} \subseteq \mathbb{N} \times \mathbb{N}\), so that the existence problem is then precisely PRIMALITY.
Nilpotency class reduction. Unlike the case of Graph Isomorphism, for GpI essentially the only class of groups for which isomorphism is known to be as hard as the general case are those which are directly indecomposable, that is, they cannot be written as a direct product $A \times B$ with both $A, B$ nontrivial [42,72,73]. However, this result is the group analogue of saying that isomorphism of connected graphs is GI-complete, so although useful (and much less trivial than in the case of graphs vs connected graphs), from a structural perspective it is more like a zero-th step.

For a variety of reasons (e.g., [29]), $p$-groups of nilpotency class 2 and exponent $p$ are widely believed to be the hardest cases of GpI, but to date there is no known reduction from isomorphism in any larger class of groups to this class. The Tensor Isomorphism-completeness of testing isomorphism in this class of groups (when given by generating matrices over $\mathbb{F}_p$) suggests an additional reason for hardness [32] (see also Section 6.1). Here, we leverage that completeness result to give a reduction within GpI itself. While it falls short of being GpI-complete (equivalent to GpI), this is the first such reduction that we are aware of.

To state our result, we need to first recall the definition of nilpotency class. We will give an inductive definition: a group $G$ is nilpotent of class 1 if it is abelian, and nilpotent of class $c > 1$ if $G/Z(G)$ ($G$ modulo its center) is nilpotent of class $c - 1$. Recall that a finite group is nilpotent iff it is the direct product of its Sylow $p$-subgroups, so from the comment above, isomorphism of nilpotent groups is polynomial-time equivalent to isomorphism of $p$-groups (for varying $p$).

**Theorem P.** Let $p$ be an odd prime. For groups given by generating sets of $m$ matrices of size $n \times n$ over $\mathbb{F}_{p^e}$, Group Isomorphism for $p$-groups of exponent $p$ and class $c < p$ reduces to Group Isomorphism for $p$-groups of exponent $p$ and class 2 in time $\text{poly}(n, m, e\log p)$.

In fact, because the Lazard Correspondence works whenever all subgroups generated by 3 elements have nilpotency class $< p$, our reduction also works in this more general setting. For example, as a consequence of Theorem P, testing isomorphism of $5$-groups in which every 3-generated subgroup has class 4 (the groups themselves may have larger class) reduces to testing isomorphism of $5$-groups of class 2 in the matrix group model over fields of characteristic 5.

**Remark 2.** Two additional results would suffice to get the analogous result in the Cayley table model. The first is to compute the Lazard Correspondence in the Cayley table model in time $\text{poly}(|G|)$; we thank an anonymous ITCS reviewer for pointing out that this can be achieved by applying the matrix Lazard Correspondence (see Proposition 26) to the left regular representation of the group on itself. The second is to improve the blow-up in the reduction from (Lie) Algebra Isomorphism to 3TI from [28]. Currently this reduction increases the dimension quadratically, which means the size of the group becomes $|G|^{O(\log |G|)}$ after the reduction; instead, we would need a reduction that increases the dimension only linearly.

**Remark 3.** One may also ask whether our theorems can be combined, in order to get search-to-decision and counting-to-decision reductions for $p$-groups of class $c < p$ instead of only class 2. We believe this should be approachable, but again the quadratic increase in dimension in reductions, mentioned in the previous remark, gets in the way. The quadratic increase makes the square-root exponential reductions into ordinary exponential reductions, negating any gains.
1.2 Main techniques and proof strategies

All our results are based on the connection with TENSOR ISOMORPHISM (TI) [32]. Let \( \Lambda(n, \mathbb{F}) \) denote the space of \( n \times n \) skew-symmetric (alternating) matrices over \( \mathbb{F} \). Then the Baer Correspondence [7] gives an equivalence between

\[
\begin{align*}
\left\{ \text{p-groups of class 2, exponent } p, G/Z(G) \cong \mathbb{Z}_p, \dim A = m \right\} & \leftrightarrow \left\{ \text{nilpotent } \mathbb{F}_p\text{-Lie algebras } L, L/Z(L) \cong \mathbb{F}_p^n \right\}
\end{align*}
\]

in such a way that two such groups are isomorphic iff the corresponding matrix algebras are isomorphic iff the corresponding matrix spaces are isometric. Here, we say that two such linear subspaces are **isometric** if there is an invertible matrix \( L \in \text{GL}(n, \mathbb{F}_p) \) such that \( B = L^t A L := \{ L^t B L : B \in \mathcal{A}\} \). The corresponding computational problem is:

\textbf{Definition 4} (The Alternating Matrix Space Isometry problem). 
Input: \( A_1, \ldots, A_m \) and \( B_1, \ldots, B_m, n \times n \) alternating matrices over a field \( \mathbb{F} \),

**Decide:** Is there a \( L \in \text{GL}(n, \mathbb{F}) \), such that the linear span of \( \{ A_i : i \in [m] \} \) is equal to the linear span of \( \{ L^t B_i L : i \in [m] \} \)?

Our search- and counting-to-decision reductions (Theorems A and B) actually follow from analogous results on Alternating Matrix Space Isometry (Theorems A′ and B′), using a constructive version of the Baer Correspondence communicated to us by James B. Wilson (Lemma 24). The viewpoint of alternating matrix spaces made the constructions much easier to find and reason about.

Our nilpotency class reduction uses a constructive version of the Lazard Correspondence (Proposition 26), which generalizes the Baer Correspondence to nilpotency class \( c < p \); the \( \mathcal{C} \)-completeness of Lie Algebra Isomorphism for nilpotent Lie algebras of class 2 (a combination of reductions from [28] and [32]); and finally the aforementioned constructive Baer Correspondence to go back to \( p \)-groups of class 2.

In the remainder of this section we give more details of the techniques involved.

1.2.1 Linear algebraic coloring gadgets

Our most novel technique is to devise linear algebraic analogues for Alternating Matrix Space Isometry of the graph coloring gadget, a key technique in the structural complexity study of Graph Isomorphism (see, e.g., [44]). This technique is crucial in the following theorems, used to prove Theorems A and B, respectively.

\textbf{Theorem A′.} Let \( q \) be a prime power. There is a search-to-decision reduction for Alternating Matrix Space Isometry which, given \( n \times n \) alternating matrix spaces \( \mathcal{A}, \mathcal{B} \) over \( \mathbb{F}_q \) of dimension \( m \), computes an isometry between them if they are isometric, in time \( q^{O(n)} \) or in time \( q^{O(n+m)} \). The reduction queries the decision oracle with inputs of dimension at most \( O(n^2) \).

---

3 For bilinear maps – which are another way of viewing matrix spaces – the corresponding notion is often called “pseudo-isometry”, with “isometry” of bilinear maps being a more restrictive notion. We chose our nomenclature by analogy with individual matrices: just as we call two matrix spaces \( \mathcal{A}, \mathcal{B} \) “conjugate” when \( L A L^{-1} = \mathcal{B} \), or “equivalent” when \( L A M = \mathcal{B} \), we call two matrix spaces “isometric” when there is an isometry-transformation that sends one such space to another. We are careful to use “pseudo-isometry” when we refer to the corresponding notions for matrix tuples or for bilinear maps.

4 An \( n \times n \) matrix \( A \) over \( \mathbb{F} \) is alternating if for every \( v \in \mathbb{F}^n \), \( v^t A v = 0 \). When \( \mathbb{F} \) is not of characteristic 2, this is equivalent to being skew-symmetric \( A^t = -A \).
Theorem B'. For a prime power with \( q = n^{O(1)} \), there is a randomized counting-to-decision reduction for Alternating Matrix Space Isometry which, given \( n \times n \) alternating matrix spaces \( A, B \) over \( \mathbb{F}_q \) of dimension \( m \), computes the number of isometries from \( A \) to \( B \) in time \( q^{O(n)} \). The reduction queries the decision oracle with inputs of dimension at most \( O(n^2) \).

Let us first briefly review the graph coloring gadgets. Suppose we have a graph \( G = (V, E) \) with the vertices colored, i.e., there is a map \( f : V \to \{1, \ldots, c\} =: [c] \), where we view \([c]\) as the set of colors. Let \( n = |V| \). Suppose we want to construct an uncolored graph \( \tilde{G} \), in which the color information carried by \( f \) is encoded. One way to achieve this is the following. (See \[44\] for other more efficient constructions.) For every \( v \in V \), if \( v \in V \) is assigned color \( k \in [c] \), then attach a “star” of size \( kn \) to \( v \), that is add \( kn \) new vertices to \( G \) and attach them all to \( v \). We then get a graph \( \tilde{G} \) with \( O(cn^2) \) vertices, and we see that an automorphism of \( \tilde{G} \), when restricting to \( V \), has to map \( v \in V \) to another \( v' \in V \) of the same color, as degrees need to be preserved under automorphisms.

Such an idea can be carried out in the 3-tensor context as in \[28\], but with a significant loss of efficiency which prevents its use for search- and counting-to-decision reductions and indicates the needs for new techniques. To illustrate the situation, we consider a toy problem. To ease the presentation, we adopt a perspective on 3-tensors that we hope is clear on its own; the analogy with the graph case is fairly close, but not immediately obvious, and we present it in full detail in Section 3. Note that by slicing a 3-tensor along one direction, we get a tuple of matrices (see also Section 2); in the following of this subsection we shall mostly work with matrix tuples.

Let \( A = (A_1, \ldots, A_m) \in M(n, \mathbb{F})^m \) be a tuple of matrices, where \( A_i \)'s are linearly independent. There are two natural actions on \( A \). The first action is \( S = (s_{i,j}) \in GL(m, \mathbb{F}) \) on \( A \) by sending \( A_j \) to \( \sum_{i \in [m]} s_{i,j}A_i \). Denote the resulting matrix tuple by \( A^S \). The second action is \( (L, R) \in GL(n, \mathbb{F}) \times GL(m, \mathbb{F}) \) on \( A \) by sending \( A_j \) to \( LA_jR^T \) for \( j = 1, \ldots, m \). Denote the resulting matrix tuple by \( LA^R \). For two tuples \( A, B \), and for the purposes of this illustration, let us define the set of isomorphisms as \( \text{Iso}(A, B) = \{ S \in GL(m, \mathbb{F}) : \exists L, R \in GL(n, \mathbb{F}), LA^R = B^S \} \).

In the counting-to-decision reduction we will need to test isomorphism of such tuples under the action by diagonal matrices. Let \( \text{diag}(n, \mathbb{F}) \) denote the subgroup of \( GL(n, \mathbb{F}) \) consisting of diagonal matrices. Our goal then is to construct \( \tilde{A} = (\tilde{A}_1, \tilde{A}_2, \tilde{A}_3) \in M(N, \mathbb{F})^3 \) and \( \tilde{B} \), such that \( \text{Iso}(\tilde{A}, \tilde{B}) = \text{Iso}(A, B) \cap \text{diag}(3, \mathbb{F}) \). The construction we use, from \[28\], is as follows. Let \( N = 2^k \cdot n = 8n \), and let

\[
\tilde{A}_1 = \begin{bmatrix} A_1 & 0 & 0 & 0 \\ 0 & I_n & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad \tilde{A}_2 = \begin{bmatrix} A_2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & I_{2n} & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad \tilde{A}_3 = \begin{bmatrix} A_3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & I_{4n} \end{bmatrix},
\]

where \( I_s \) denotes the identity matrix of size \( s \), and \( 0 \)'s denote all-zero matrices of appropriate sizes, and define \( \tilde{B} \) similarly. By \[28, \text{Lemma 2.2}\], we have \( \text{Iso}(\tilde{A}, \tilde{B}) = \text{Iso}(A, B) \cap \text{diag}(3, \mathbb{F}) \). The proof, while not difficult, relies on certain algebraic machineries like the Krull–Schmidt Theorem for quiver representations. For our purpose, we only point out that a key in the proof is that \( \text{Iso}(\tilde{A}, \tilde{B}) \subseteq \text{diag}(3, \mathbb{F}) \), which can be easily checked by comparing the ranks of the \( A_i, B_i \). (We note that, because \( L \) and \( R \) act independently on the rows and columns of the \( \tilde{A}_i \), for individual slices rank is essentially the only invariant we have.)
The preceding gadget construction can be generalized to handle subgroups of \( GL(n, \mathbb{F}) \) of the form
\[
\left\{ \begin{bmatrix}
S_1 & 0 & \cdots & 0 \\
0 & S_2 & \cdots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
0 & 0 & \cdots & S_c
\end{bmatrix} : S_i \in GL(n_i, \mathbb{F}) \right\},
\]

where \( c = O(\log n) \). We shall refer to this gadget as the Futorny–Grochow–Sergeichuk gadget, or FGS gadget for short.

However, the FGS gadget cannot be used for search- and counting-to-decision reductions in Theorems A and B. The key bottleneck is the restriction that \( c = O(\log n) \). To check why this is so reveals an interesting distinction between the combinatorial and the linear algebraic worlds. Recall that in the graph setting, if there are \( c \) colors, we need stars of size at most \( cn \). While in the linear algebraic setting, if there are \( c \) components, the biggest identity matrix needs to be of size \( 2^c \cdot n \times 2^c \cdot n \). The reason is that we can do non-trivial linear combinations of the matrices \( \tilde{A}_i \), so several matrices of small ranks might be combined to get a matrix of large rank. Indeed, in Eq. 1, if \( \tilde{A}_3 \) was accompanied with \( I_{4n} \) instead of \( I_{3n} \), then a non-trivial linear combination of \( \tilde{A}_1 \) and \( \tilde{A}_2 \) could be of rank the same as \( \tilde{A}_3 \), and the argument that \( \text{Iso}(\tilde{A}, \tilde{B}) \subseteq \text{diag}(m, \mathbb{F}) \) would not go through. That’s why we need such exponential growth as the number of components grow.

To address this challenge, we devise two new gadgets, which restrict to the monomial group and the diagonal group, respectively.

The monomial group of \( GL(n, \mathbb{F}) \), denoted as \( \text{Mon}(n, \mathbb{F}) \), consists of monomial matrices, i.e. a matrix with exactly one non-zero entry in each row and each column. We design a gadget that restricts to \( \text{Mon}(n, \mathbb{F}) \), which is the key in the search-to-decision reduction (Theorem A').

In the case of \( \mathbb{F} = \mathbb{F}_q \) and \( q = n^{O(1)} \), we design a gadget that restricts to \( \text{diag}(n, q) \), which is the key in the counting-to-decision reduction (Theorem B'). The gadget for restricting to monomial groups cannot be used in the counting-to-decision reduction. Its construction is already delicate, and the analysis is involved, relying on a celebrated result of Kantor and Lubotzky regarding random generation of classical groups [41].

### 1.2.2 Constructive Lazard Correspondence

In light of the \( \text{TI} \)-completeness of isomorphism of class 2 \( p \)-groups given by matrices over finite fields of characteristic \( p \) [32], the key idea here is how to reduce isomorphism for other classes of groups to some tensor problem. For groups in general it is unclear how to do this, as tensors are multilinear and groups are not. But for \( p \)-groups of nilpotency class \( < p \), the Lazard Correspondence gives an equivalence between the category of such groups and a corresponding category of Lie algebras (over the same field, nilpotent of the same class). If this correspondence were computationally efficient, we would then be in the fortunate setting in which \( \text{LIE ALGEBRA ISOMORPHISM} \) is multilinear, and is in \( \text{TI} \) [28], so we can then reduce back to isomorphism of class 2 \( p \)-groups. We observe (Proposition 26) that when the groups are given by matrices in characteristic \( p \), the Lazard Correspondence can be efficiently computed using the usual matrix logarithm and exponential.

The restriction to groups of nilpotency class \( c < p \) comes entirely from the Lazard Correspondence, which is also known only to work under this same assumption (see [60] for details, and what can be said when \( c = p \), but unfortunately already when \( c = p \) one no longer gets an equivalence up to isomorphism). Despite this restriction, we note that we know of no prior reductions from any class of groups to \( p \)-groups of class 2.
In Remark 2 we discuss the ingredients necessary to get the same result for GI in the Cayley table model, which seems approachable.

1.3 Organization of the paper

In Section 2 we present preliminaries and notation. In Section 3 we present more details of the analogy with individualizing vertices in graphs by attaching stars, using the example of reducing Monomial Code Equivalence to Tensor Isomorphism. In Section 4 we present our gadget to restrict to the monomial subgroup, an example use of this to reduce GI to Alternating Matrix Space Isometry, and Theorem A’. In Section 5 we prove Theorem B’. In Section 6 we present the constructive Baer and Lazard Correspondences, and use them to derive Theorems A and B from Theorems A’ and B’, respectively, as well as proving Theorem P. Finally, in Section 7 we conclude with open questions and discuss the relationship between this work and the authors’ line of work on Tensor Isomorphism.

**Vector spaces.** Let \(\mathbb{F}\) be a field. In this paper we only consider finite-dimensional vector spaces over \(\mathbb{F}\). We use \(\mathbb{F}^n\) to denote the vector space of length-\(n\) column vectors. The \(i\)th standard basis vector of \(\mathbb{F}^n\) is denoted \(\vec{e}_i\). Depending on the context, 0 may denote the zero vector space, a zero vector, or an all-zero matrix. For \(S\) a set of vectors, we use \(\langle S \rangle\) to denote the subspace spanned by elements in \(S\).

**Some groups.** The general linear group of degree \(n\) over a field \(\mathbb{F}\) is denoted by \(\text{GL}(n, \mathbb{F})\). The symmetric group of degree \(n\) is denoted by \(S_n\). The natural embedding of \(S_n\) into \(\text{GL}(n, \mathbb{F})\) is to represent permutations by permutation matrices. The subgroup of \(\text{GL}(n, \mathbb{F})\) consisting of diagonal matrices is called the diagonal subgroup, denoted by \(\text{diag}(n, \mathbb{F})\). A monomial matrix is a product of a diagonal and a permutation matrix; equivalently, each row and each column has exactly one non-zero entry. The collection of monomial matrices forms a subgroup of \(\text{GL}(n, \mathbb{F})\), which we call the monomial subgroup and denote by \(\text{Mon}(n, \mathbb{F})\). It is the semi-direct product \(\text{diag}(n, \mathbb{F}) \rtimes S_n \cong (\mathbb{F}^*)^n \rtimes S_n\).

**Nilpotent groups.** If \(A, B\) are two subsets of a group \(G\), then \([A, B]\) denotes the subgroup generated by all elements of the form \(ab^{-1}a^{-1}\), for \(a \in A, b \in B\). The lower central series of a group \(G\) is defined as follows: \(\gamma_1(G) = G, \gamma_{k+1}(G) = [\gamma_k(G), G]\). A group is nilpotent if there is some \(c\) such that \(\gamma_{c+1}(G) = 1\); the smallest such \(c\) is called the nilpotency class of \(G\), or sometimes just “class” when it is understood from context. A finite group is nilpotent if and only if it is the product of its Sylow subgroups; in particular, all groups of prime power order are nilpotent.
Matrices. Let $M(\ell \times n, F)$ be the linear space of $\ell \times n$ matrices over $F$, and $M(n, F) := M(n \times n, F)$. Given $A \in M(\ell \times n, F)$, $A^t$ denotes the transpose of $A$.

A matrix $A \in M(n, F)$ is alternating, if for any $u \in F^n$, $u^t A u = 0$. That is, $A$ represents an alternating bilinear form. Note that in characteristic $\neq 2$, alternating is the same as skew-symmetric, but in characteristic 2 they differ (in characteristic 2, skew-symmetric=symmetric). The linear space of $n \times n$ alternating matrices over $F$ is denoted by $\Lambda(n, F)$.

The $n \times n \times n$ identity matrix is denoted by $I_n$, and when $n$ is clear from the context, we may just write $I$. The elementary matrix $E_{i,j}$ is the matrix with the $(i,j)$th entry being 1, and other entries being 0. The $(i,j)$-th elementary alternating matrix is the matrix $E_{i,j} - E_{j,i}$.

Matrix tuples. We use $M(\ell \times n, F)^m$ to denote the linear space of $m$-tuples of $\ell \times n$ matrices. Boldface letters like $A$ and $B$ denote matrix tuples. Let $A = (A_1, \ldots, A_m), B = (B_1, \ldots, B_m) \in M(\ell \times n, F)^m$. Given $P \in M(\ell, F)$ and $Q \in M(n, F)$, $PAQ := (PA_1Q, \ldots, PA_mQ) \in M(\ell \times n, F)$. Given $R = (r_{i,j})_{i,j \in [m]} \in M(m, F)$, $A^R := (A_1^R, \ldots, A_m^R) \in M(m, F)$ where $A_i^R = \sum_{j \in [m]} r_{ij} A_j$.

Remark 5. In particular, note that the coefficients in the formula of defining $A_i^R$ correspond to the entries in the $i$th column of $R$. While this choice is immaterial (we could have chosen the opposite convention), all of our later calculations are consistent with this convention.

Given $A, B \in M(\ell \times n, F)^m$, we say that $A$ and $B$ are isometric, if there exists $P \in \text{GL}(n, F)$, such that $P^t A P = B$. Finally, $A$ and $B$ are pseudo-isometric if there exist $P \in \text{GL}(n, F)$ and $R \in \text{GL}(m, F)$, such that $P^t A P = B^R$.

Matrix spaces. Linear subspaces of $M(\ell \times n, F)$ are called matrix spaces. Calligraphic letters like $\mathcal{A}$ and $\mathcal{B}$ denote matrix spaces. By a slight abuse of notation, for $A \in M(\ell \times n, F)^m$, we use $\langle A \rangle$ to denote the subspace spanned by those matrices in $A$. For $A, B \in M(n, F)^m$, we say that the spaces $\langle A \rangle, \langle B \rangle$ are isometric iff the tuples $A, B$ are pseudo-isometric.

3-way arrays. Let $T(\ell \times n \times m, F)$ be the linear space of $\ell \times n \times m$ 3-way arrays over $F$. We use the fixed-width teletype font for 3-way arrays, like $\mathcal{A}$, $\mathcal{B}$, etc.. Given $\mathcal{A} \in T(\ell \times n \times m, F)$, we can think of $\mathcal{A}$ as a 3-dimensional table, where the $(i, j, k)$th entry is denoted as $\mathcal{A}(i,j,k) \in F$. We can slice $\mathcal{A}$ along one direction and obtain several matrices, which are then called slices. For example, slicing along the first coordinate, we obtain the horizontal slices, namely $\ell$ matrices $A_1, \ldots, A_\ell \in M(n \times m, F)$, where $A_i(j, k) = \mathcal{A}(i,j,k)$. Similarly, we also obtain the lateral slices by slicing along the second coordinate, and the frontal slices by slicing along the third coordinate.

We will often represent a 3-way array as a matrix whose entries are vectors. That is, given $\mathcal{A} \in T(\ell \times n \times m, F)$, we can write

$$
\mathcal{A} = \\
\begin{bmatrix}
  w_{1,1} & w_{1,2} & \ldots & w_{1,n} \\
  w_{2,1} & w_{2,2} & \ldots & w_{2,n} \\
  \vdots & \ddots & \ddots & \vdots \\
  w_{l,1} & w_{l,2} & \ldots & w_{l,n}
\end{bmatrix},
$$

where $w_{i,j} \in F^m$, so that $w_{i,j}(k) = \mathcal{A}(i,j,k)$. Note that, while $w_{i,j} \in F^m$ are column vectors, in the above representation of $\mathcal{A}$, we should think of them as along the direction “orthogonal to the paper.” Following [45], we call $w_{i,j}$ the tube fibers of $\mathcal{A}$. Similarly, we can have the row fibers $v_{i,k} \in F^n$ such that $v_{i,k}(j) = \mathcal{A}(i,j,k)$, and the column fibers $u_{j,k} \in F^\ell$ such that $u_{j,k}(i) = \mathcal{A}(i,j,k)$.
Given $P \in M(\ell, \mathbb{F})$ and $Q \in M(n, \mathbb{F})$, let $PAQ$ be the $\ell \times n \times m$ 3-way array whose $k$th frontal slice is $PA_kQ$. For $R = (r_{i,j}) \in GL(m, \mathbb{F})$, let $A^R$ be the $\ell \times n \times m$ 3-way array whose $4$th frontal slice is $\sum_{k' \in [m]} r_{k,k'}A_k'$. Note that these notations are consistent with the notations for matrix tuples above, when we consider the matrix tuple $A = (A_1, \ldots, A_k)$ of frontal slices of $A$.

### 3 Warm up: reducing Monomial Code Equivalence to Tensor Isomorphism

The purpose of this section is to present a concrete example that illustrates what we mean by a gadget restricting to monomial subgroups. We also explain why the gadget would be viewed as a linear algebraic analogue of attaching stars in the graph setting as mentioned in Section 1.2.1.

We will give a reduction here to the Tensor Isomorphism (TI) problem, so we begin by recalling its definition:

**Definition 6 (The $d$-Tensor Isomorphism problem).** $d$-Tensor Isomorphism over a field $\mathbb{F}$ is the problem: given two $d$-way arrays $A = (a_{i_1, \ldots, i_d})$ and $B = (b_{i_1, \ldots, i_d})$, where $i_k \in [n_k]$ for $k \in [d]$, and $a_{i_1, \ldots, i_d}, b_{i_1, \ldots, i_d} \in \mathbb{F}$, decide whether there is $P_k \in GL(n_k, \mathbb{F})$ for $k \in [d]$, such that for all $i_1, \ldots, i_d$,

$$a_{i_1, \ldots, i_d} = \sum_{j_1, \ldots, j_d} b_{j_1, \ldots, j_d}(P_1)_{i_1,j_1}(P_2)_{i_2,j_2} \cdots (P_d)_{i_d,j_d}.$$

Let $A$ be an $\ell \times n \times m$ 3-way array, with lateral slices $L_1, L_2, \ldots, L_n$ (each an $\ell \times m$ matrix). For any vector $v \in \mathbb{F}^n$, we get an associated lateral matrix $L_v$, which is a linear combination of the lateral slices as given, namely $L_v := \sum_{j=1}^n v_j L_j$ (note that when $v = e_j^T$ is the $j$-th standard basis vector, the associated lateral matrix is indeed $L_j$). By analogy with adjacency matrices of graphs, $L_v$ is a natural analogue of the neighborhood of a vertex in a graph. Correspondingly, we get a notion of “degree,” which we may define as

$$\text{deg}_A(v) := \text{rk}(L_v) = \text{rk}(\sum_{j=1}^n v_j L_j) = \dim \text{span}\{L_v w : w \in \mathbb{F}^m\} = \dim \text{span}\{u^T L_v : u \in \mathbb{F}^\ell\}.$$

The last two characterizations are analogous to the fact that the degree of a vertex $v$ in a graph $G$ may be defined as the number of “in-neighbors” (nonzero entries the corresponding row of the adjacency matrix) or the number of “out-neighbors” (nonzero entries in the corresponding column).

To “individualize” $v$, we can enlarge $A$ with a gadget to increase $\text{deg}_A(v)$, as in the graph case. Note that $\text{deg}_A(v) \leq \min\{\ell, m\}$ because the lateral matrices are all of size $\ell \times m$. For notational simplicity, let us individualize $v = e_1^T = (1, 0, \ldots, 0)^T$. To individualize $v$, we will increase its degree by $d = \min\{\ell, m\} + 1 > \max_{v \in \mathbb{F}^n} \text{deg}_A(v)$. Extend $A$ to a new 3-way array $A_v$ of size $(\ell + d) \times n \times (m + d)$; in the “first” $\ell \times n \times m$ “corner”, we will have the original array $A$, and then we will append to it an identity matrix in one slice to increase $\text{deg}(v)$. More specifically, the lateral slices of $A_v$ will be

$$L'_1 = \begin{bmatrix} L_1 & 0 \\ 0 & I_d \end{bmatrix} \quad \text{and} \quad L'_j = \begin{bmatrix} L_j & 0 \\ 0 & 0 \end{bmatrix} \quad \text{(for } j > 1).$$

Now we have that $\text{deg}_A(v) \geq d$. This almost does what we want, but now note that any vector $w = (w_1, \ldots, w_d)$ with $w_i \neq 0$ has $\text{deg}_A(w) = \text{rk}(w_1 L'_1 + \sum_{j \geq 2} w_j L'_j) \geq d$. We can nonetheless consider this a sort of linear-algebraic individualization.
Leveraging this trick, we can then individualize an entire basis of $\mathbb{F}^n$ simultaneously, so that $d \leq \deg(v) < 2d$ for any vector $v$ in our basis, and $\deg(v') \geq 2d$ for any nonzero $v'$ outside the basis (not a scalar multiple of one of the basis vectors), as we do in the following result. This is also a 3-dimensional analogue of the reduction from GI to CODEQ [52,59,62] (where they use Hamming weight instead of rank).

We now come to the concrete result. Given two $d \times n$ matrices $A, B$ over $\mathbb{F}$ of rank $d$, the Monomial Code Equivalence problem is to decide whether there exist $Q \in \text{GL}(d,\mathbb{F})$ and a monomial matrix $P \in \text{Mon}(n,\mathbb{F}) \leq \text{GL}(n,\mathbb{F})$ (product of a diagonal matrix and a permutation matrix) such that $QAP = B$. Monomial equivalence of linear codes is a basic notion in coding theory [11], and Monomial Code Equivalence was recently studied in the context of post-quantum cryptography [67].

\textbf{Proposition 7. Monomial Code Equivalence reduces to 3-Tensor Isomorphism.}

\textbf{Proof.} Without loss of generality we assume $d > 1$, as the problem is easily solvable when $d = 1$. We treat a $d \times n$ matrix $A$ as a 3-way array of size $d \times n \times 1$, and then follow the outline proposed above, of individualizing the entire standard basis $e_1, \ldots, e_n$. Since the third direction only has length 1, the maximum degree of any column is 1, so it suffices to use gadgets of rank 2. More specifically, (see Figure 1) we build a $(d + 2)n \times n \times (1 + 2n)$ 3-way array $A$ whose lateral slices are

$$L_j = \begin{bmatrix} a_{1,j} & 0_{1 \times 2} & 0_{1 \times 2} & \cdots & 0_{1 \times 2} & \cdots & 0_{1 \times 2} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ a_{d,j} & 0_{1 \times 2} & 0_{1 \times 2} & \cdots & 0_{1 \times 2} & \cdots & 0_{1 \times 2} \\ 0_{2 \times 1} & 0_{2 \times 2} & 0_{2 \times 2} & \cdots & 0_{2 \times 2} & \cdots & 0_{2 \times 2} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 0_{2 \times 1} & 0_{2 \times 2} & 0_{2 \times 2} & \cdots & I_2 & \cdots & 0_{2 \times 2} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 0_{2 \times 1} & 0_{2 \times 2} & 0_{2 \times 2} & \cdots & 0_{2 \times 2} & \cdots & 0_{2 \times 2} \end{bmatrix}$$

where the $I_2$ block is in the $j$-th block of size 2 (that is, rows $d + 2(j - 1) + \{1,2\}$ and columns $2(j - 1) + \{1,2,3\}$).

It will also be useful to visualize the frontal slices of $A$, as follows. Here each entry of the “matrix” below is actually a $(1 + 2n)$-dimensional vector, “coming out of the page”:

$$A_j = \begin{bmatrix} \tilde{a}_{1,1} & \tilde{a}_{1,2} & \cdots & \tilde{a}_{1,n} \\ \vdots & \vdots & \ddots & \vdots \\ \tilde{a}_{d,1} & \tilde{a}_{d,2} & \cdots & \tilde{a}_{d,n} \\ e_{1,1} & 0 & \cdots & 0 \\ e_{1,2} & 0 & \cdots & 0 \\ 0 & e_{2,1} & \cdots & 0 \\ 0 & e_{2,2} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & e_{n,1} \\ 0 & 0 & \cdots & e_{n,2} \end{bmatrix}$$

where

$$\tilde{a}_{i,j} = \begin{bmatrix} a_{i,j} \\ 0_{2n \times 1} \end{bmatrix} \in \mathbb{F}^{1+2n}$$

and the frontal slices are

$$A_1 = \begin{bmatrix} A \\ 0_{2n \times n} \end{bmatrix}$$

$$A_{i+2(i-1)+j} = E_{d+2(i-1)+j,i} \quad \text{for } i \in [n], j \in [2]$$

(In $A$ we turn the vectors $\tilde{a}_{i,j}$ and $e_{i,j}$ “on their side” so they become perpendicular to the page.)
We claim that $A$ and $B$ are monomially equivalent as codes if and only if $A$ and $B$ are isomorphic as $3$-tensors.

$(\Rightarrow)$ Suppose $QADP = B$ where $Q \in \text{GL}(d,F)$, $D \in \text{diag}(n,F)$ and $P \in S_n \leq \text{GL}(n,F)$. Then by examining the frontal slices it is not hard to see that for $Q' = \begin{bmatrix} Q & 0 \\ 0 & (DP)^{-1} \otimes I_2 \end{bmatrix}$ (where $(DP)^{-1} \otimes I_2$ denotes a $2n \times 2n$ block matrix, where the pattern of the nonzero blocks and the scalars are governed by $(DP)^{-1}$, and each $2 \times 2$ block is either zero or a scalar multiple of $I_2$) we have $Q'A_1DP = B_1$ and $Q'A_{1+2(j-1)+i}DP = B_{1+2(\pi(j-1)+i)}$, where $\pi$ is the permutation corresponding to $P$. Thus $A$ and $B$ are isomorphic tensors, via the isomorphism $(Q',DP,\text{diag}(I_1,P))$.

$(\Leftarrow)$ Suppose there exist $Q \in \text{GL}(d+2n,F)$, $P \in \text{GL}(n,F)$, and $R \in \text{GL}(1+2n,F)$, such that $QAP = BR$. First, note that every lateral slice of $A$ is of rank either 2 or 3, and the actions of $Q$ and $R$ do not change the ranks of the lateral slices. Furthermore, any non-trivial linear combination of more than 1 lateral slice results in a lateral matrix of rank $\geq 4$. It follows that $P$ cannot take nontrivial linear combinations of the lateral slices, hence it must be monomial.

Now consider the frontal slices. Note that, as we assume $d > 1$, every frontal slice of $QAP$, except the first one, is of rank 1. Therefore, $R$ must be of the form $\begin{bmatrix} r_{1,1} & 0_{1 \times (n-1)} \\ r' & R' \end{bmatrix}$ where $R'$ is $(n-1) \times (n-1)$. Since $R$ is invertible, we must have $r_{1,1} \neq 0$, and the first frontal slice of $B^R$ contains all the rows of $B$ scaled by $r_{1,1}$ in its first $d$ rows. The first frontal slice of $QAP$ is a matrix that generates, by definition (and since we've shown $P$ is monomial), a code monomially equivalent to $A$. Since the first frontal slices of $QAP$ and $B^R$ are equal, and the latter is just a scalar multiple of $B_1$, we have that $A$ and $B$ are monomially equivalent as codes as well.
4 Search-to-decision reduction by restricting to monomial groups

4.1 The gadget restricting to the monomial group

In this section, we present the gadget that restricts to the monomial group in the setting of Alternating Matrix Space Isometry. To show this, we will need the concept of monomial isometry; see Some Groups above. Recall that a matrix is monomial if, equivalently, it can be written as $DP$ where $D$ is a nonsingular diagonal matrix and $P$ is a permutation matrix. We say two matrix spaces $A, B$ are monomially isometric if there is some $M \in \text{Mon}(n, \mathbb{F})$ such that $M^tAM = B$.

\begin{lemma}
Alternating Matrix Space Monomial Isometry reduces to Alternating Matrix Space Isometry.
\end{lemma}

More specifically, there is a $\text{poly}(n, m)$-time algorithm $r$ taking alternating matrix tuples to alternating matrix tuples, such that for $A, B \in \Lambda(n, \mathbb{F})^m$, the matrix spaces $A = (A_i)$ and $B = (B_i)$ are monomially isometric if and only if the matrix spaces $(r(A))$ and $(r(B))$ are isometric.

The gadget used in Lemma 8 is essentially to apply the gadget in Proposition 7 “in two directions.” Still, to prove the correctness requires some work.

\begin{proof}
For $A = (A_1, \ldots, A_m) \in \Lambda(n, \mathbb{F})^m$, define $r(A)$ to be the alternating matrix tuple $A = (A_1, \ldots, A_{m+n}) \in \Lambda(n+n^2, \mathbb{F})^{m+n^2}$, where

1. For $k = 1, \ldots, m$, $A_k = \begin{bmatrix} A_k & 0 \\ 0 & 0 \end{bmatrix}$.
2. For $k = m + (i-1)n + j$, $i \in [n]$, $j \in [n]$, $A_k$ is the elementary alternating matrix $E_{i,m+j} - E_{m+i,j}$.

At this point, some readers may wish to look at the large matrix in Equation 2 and/or at Figure 2.

It is clear that $r$ can be computed in time $\tilde{O}((m+n^2)(n^2+n)) = \text{poly}(n, m)$. Given alternating matrix tuples $A, B$, let $A, B$ be the corresponding matrix spaces they span, and let $A = (r(A))$ and $B = (r(B))$. We claim that $A$ and $B$ are monomially isometric if and only if $A$ and $B$ are isometric.

To prove this, it will help to think of our matrix tuples $A, \tilde{A}, \mathcal{A}$, etc. as (corresponding to) 3-way arrays, and to view these 3-way arrays from two different directions. Towards this end, write the 3-way array corresponding to $A$ as

$$A = \begin{bmatrix}
0 & a_{1,2} & a_{1,3} & \cdots & a_{1,n} \\
-a_{1,2} & 0 & a_{2,3} & \cdots & a_{2,n} \\
-a_{1,3} & -a_{2,3} & 0 & \cdots & a_{3,n} \\
\vdots & \ddots & \ddots & \ddots & \vdots \\
-a_{1,n} & -a_{2,n} & -a_{3,n} & \cdots & 0
\end{bmatrix},$$

where $a_{i,j}$ are vectors in $\mathbb{F}^m$ (“coming out of the page”), namely $a_{i,j}(k) = A_k(i,j)$. The frontal slices of this array are precisely the matrices $A_1, \ldots, A_m$.

The 3-way array corresponding to $\tilde{A} = r(A)$ is then the $(n+1)n \times (n+1)n \times (m+n^2)$ array:
where $\tilde{a}_{i,j} = \begin{bmatrix} a_{i,j} & 0 \end{bmatrix} \in \mathbb{F}^{m+n^2}$ (here think of the vector $a_{i,j}$ as a column vector, _not_ coming out of the page; in the above array we then lay the column vector $\tilde{a}_{i,j}$ “on its side” so that it is coming out of the page), and $e_{i,j} := e_{m+(i-1)n+j} \in \mathbb{F}^{m+n^2}$, which we can equivalently write as $\begin{bmatrix} 0_m \otimes e_j \end{bmatrix}$, where we think of $e_i \otimes e_j$ here as a vector of length $n^2$. Note that all the nonzero blocks besides upper-left “$A$” block only have nonzero entries that are strictly behind the nonzero entries in the upper-left block.

![Figure 2](image-url) Pictorial representation of the reduction for Lemma 8.
The second viewpoint, which we will also use below, is to consider the lateral slices of $A$, or equivalently, to view $A$ from the side. When viewing $A$ from the side, we see the $(n+1)n \times (m+n^2) \times (n+1)n$ 3-way array:

$$
\tilde{A}^{lat} = \begin{bmatrix}
\ell_{1,1} & \ell_{1,2} & \ldots & \ell_{1,m} & e_{n+1} & \ldots & e_{2n} & \ldots & 0 & \ldots & 0 \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\
\ell_{n,1} & \ell_{n,2} & \ldots & \ell_{n,m} & 0 & \ldots & 0 & \ldots & \ldots & \ldots & \ldots \\
0 & 0 & \ldots & 0 & e_1 & \ldots & 0 & \ldots & \ldots & \ldots & \ldots \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots & \vdots & \ddots & \ddots & \ddots \\
0 & 0 & \ldots & 0 & 0 & \ldots & 0 & \ldots & \ldots & \ldots & \ldots \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots & \vdots & \ddots & \ddots & \ddots \\
0 & 0 & \ldots & 0 & 0 & \ldots & 0 & \ldots & \ldots & \ldots & \ldots \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots & \vdots & \ddots & \ddots & \ddots \\
0 & 0 & \ldots & 0 & 0 & \ldots & 0 & \ldots & \ldots & \ldots & \ldots \\
\end{bmatrix},
$$

(3)

where every $\ell_{i,k} \in \mathbb{F}^{n^2+n}$ has only the first $n$ components being possibly non-zero, namely, $\ell_{i,k}(j) = A_k(i,j)$ for $i \in [n], j \in [n], k \in [m]$ and $\ell_{i,k}(j) = 0$ for any $j > n$.

For the only if direction. Suppose there exist $P \in \text{Mon}(n, \mathbb{F})$ and $Q \in \text{GL}(m, \mathbb{F})$, such that $P^t A P = B^Q$. We can construct $\tilde{P} \in \text{Mon}(n+n^2, \mathbb{F})$ and $\tilde{Q} \in \text{GL}(m+n^2, \mathbb{F})$ such that $\tilde{P}^t \tilde{A} \tilde{P} = \tilde{B}^\tilde{Q}$. In fact, we will show that we can take $\tilde{P} = \begin{bmatrix} P & 0 \\ 0 & P' \end{bmatrix}$ where $P' \in \text{Mon}(n^2, \mathbb{F})$,

and $\tilde{Q} = \begin{bmatrix} Q & 0 \\ 0 & Q' \end{bmatrix}$ where $Q' \in \text{Mon}(n^2, \mathbb{F})$. It is not hard to see that this form already ensures that the first $m$ matrices in the vector $\tilde{P}^t \tilde{A} \tilde{P}$ and those of $\tilde{B}^\tilde{Q}$ are the same, since when $P, Q$ are of this form, those first $m$ matrices are controlled entirely by the $P$ (resp., $Q$) in the upper-left block of $\tilde{P}$ (resp., $\tilde{Q}$).

The remaining question is then how to design appropriate $P'$ and $Q'$ to take care of the last $n^2$ matrices in these tuples. This actually boils down to applying the following simple identity, but “in 3 dimensions:” Let $P$ be the permutation matrix corresponding to $\sigma \in S_n$, so that $P e_i = e_{\sigma(i)}$, and $e_i^t P = e^t_{\sigma^{-1}(i)}$. Let $D = \text{diag}(\alpha_1, \ldots, \alpha_n)$ be a diagonal matrix. Then

$$
P^t D P = \text{diag}(\alpha_{\sigma^{-1}(1)}, \ldots, \alpha_{\sigma^{-1}(n)}).
$$

(4)

To see how Equation 4 helps in our setting, it is easier to focus attention on the lower right $n^2 \times n^2$ sub-array of $\tilde{A}^{lat}$, which can be represented as a symbolic matrix

$$
M = \begin{bmatrix}
x_1 I_n & 0 & \ldots & 0 \\
0 & x_2 I_n & \ldots & 0 \\
\vdots & \ddots & \ddots & \vdots \\
0 & 0 & \ldots & x_n I_n \\
\end{bmatrix}.
$$

Here we think of the $x_i$’s as independent variables, whose indices correspond to “how far into the page” they are. That is, $x_i$ corresponds to the vector $\tilde{e}_i$ in $\tilde{A}^{lat}$, which is coming out of the page and has its only nonzero entry $i$ slices back from the page.
Then the action of $P$ permutes the $x_i$'s and multiplies them by some scalars, the action of $P'$ is on the left-hand side, and the action of $Q'$ is on the right-hand side. Let $\sigma$ be the permutation supporting $P$. Then $P$ sends $M$ to

$$M^P = \begin{bmatrix}
\alpha_{1}x_{\sigma(1)}I_n & 0 & \cdots & 0 \\
0 & \alpha_{2}x_{\sigma(2)}I_n & \cdots & 0 \\
\vdots & \ddots & \ddots & \vdots \\
0 & 0 & \cdots & \alpha_{n}x_{\sigma(n)}I_n
\end{bmatrix}.$$ 

So setting $P' = \sigma \odot I_n$, $Q'$ the monomial matrix supported by $\sigma \odot I_n$ with scalars being $1/\alpha_i$'s, we have $P'^nM^PQ' = M$ by Equation 4.

For the if direction. Suppose there exist $\tilde{P} \in \GL(n + n^2, \mathbb{F})$ and $\tilde{Q} \in \GL(m + n^2, \mathbb{F})$, such that $\tilde{P}\tilde{A}\tilde{P} = \tilde{B}^Q$. The key feature of these gadgets now comes into play: consider the lateral slices of $\tilde{A}$, which are the frontal slices of $A^{lat}$ (which may be easier to visualize by looking at Equation 3 and Figure 2). The first $n$ lateral slices of $\tilde{A}$ and $\tilde{B}$ are of rank $\geq n$ and $< 2n$, while the other lateral slices are of rank $< n$ (in fact, they are of rank 1; note that without loss of generality we may assume $n > 1$, for the only $1 \times 1$ alternating matrix space is the zero space). Furthermore, left multiplying a lateral slice by $\tilde{P}^t$ and right multiplying it by $\tilde{Q}$ does not change its rank. However, the action of $\tilde{P}$ here is by $\tilde{P}^t\tilde{A}\tilde{P}$, and while the $\tilde{P}^t$ here corresponds to left multiplication on the lateral slices ($=$frontal slices of $A^{lat}$), the $\tilde{P}$ on the right here corresponds to taking linear combinations of the lateral slices. In other words, just as $A^{lat}$ is the “side view” of $\hat{A}$, $(\tilde{P}^tA^{lat}\tilde{Q})^P$ is the side view of $(\tilde{P}^t\hat{A}\tilde{P})^Q$. Taking linear combinations of the lateral slices could, in principle, alter their rank; we will use the latter possibility to show that $\tilde{P}$ must be of a constrained form.

Write $\tilde{P} = \begin{bmatrix} P_{1,1} & P_{1,2} \\ P_{2,1} & P_{2,2} \end{bmatrix}$ where $P_{1,1}$ is of size $n \times n$. We first claim that $P_{1,2} = 0$. For if not, then in $(A^{lat})^P$ (the side view), one of the last $n^2$ frontal slices receives a nonzero contribution from one of the first $n$ frontal slices of $A^{lat}$. Looking at the form of these slices from Equation 3, we see that any such nonzero combination will have rank $\geq n$, but this is a contradiction since the corresponding slice in $B^{lat}$ has rank 1. Thus $P_{1,2} = 0$, and therefore $P_{1,1}$ must be invertible, since $\tilde{P}$ is.

Finally, we claim that $P_{1,1}$ has to be a monomial matrix. If not, then some frontal slice of $(A^{lat})^P$ among the first $n$ would have a contribution from more than one of these $n$ slices. Considering the lower-right $n^2 \times n^2$ sub-matrix of such a slice, we see that it would have rank exactly $kn$ for some $k \geq 2$, which is again a contradiction since the first $n$ slices of $B^{lat}$ all have rank $< 2n$. It follows that $P_{1,1}^tA_iP_{1,1}$, $i \in [m]$, are in $B$, and thus $A$ and $B$ are monomially isometric via $P_{1,1}$.

4.1.1 Application: reducing Graph Isomorphism to Alternating Matrix Space Isometry

An application of the monomial-restricting gadget is to give an immediate reduction from Graph Isomorphism to Alternating Matrix Space Isometry. While a reduction between these two problems is already known (cf. [32] for details), we choose to present it as an illustration of using this gadget.

\textbf{Proposition 9.} Graph Isomorphism reduces to Alternating Matrix Space Isometry.
Proof. For a graph \( G = ([n], E) \), let \( A_G \) be the alternating matrix tuple \( A_G = (A_1, \ldots, A_{|E|}) \) with \( A_e = E_{i,j} - E_{j,i} \) where \( e = \{i, j\} \in E \), and let \( A_H = (A_H) \) be the alternating matrix space spanned by that tuple. If \( P \) is a permutation matrix giving an isomorphism between two graphs \( G \) and \( H \), then it is easy to see that \( P^t A_G P = A_H \), and thus the corresponding matrix spaces are isometric. The converse direction is not clear, though it is recently shown to be true in [34] with a rather intricate proof. Instead, we will provide a conceptually simpler proof, by showing that this construction gives a reduction to a monomial isometry, and then using Lemma 8 to reduce to ordinary Alternating Matrix Space Isometry.

Let us thus establish that the preceding construction gives a reduction from GI to Alternating Matrix Space Monomial Isometry. We will show that \( G \cong H \) if and only if \( A_G \) and \( A_H \) are monomialially isometric. The forward direction was handled above. For the converse, suppose \( P^t D^t A_G D P = A_H \) where \( D \) is diagonal and \( P \) is a permutation matrix. We claim that in this case, \( P \) in fact gives an isomorphism from \( G \) to \( H \). First let us establish that \( P \) alone gives an isometry between \( A_G \) and \( A_H \). Note that for any diagonal matrix \( D = \text{diag}(\alpha_1, \ldots, \alpha_n) \) and any elementary alternating matrix \( E_{i,j} - E_{j,i} \), we have\( \text{det}(D) = (\alpha_i - \alpha_j)^2 \). Since \( A_G \) has a basis of elementary alternating matrices, the action of \( D \) on this basis is just to re-scale each basis element, and thus \( D^t A_G D = A_G \).

Finally, note that \( P^t (E_{i,j} - E_{j,i}) P = E_{\pi(i), \pi(j)} - E_{\pi(j), \pi(i)} = A_{\pi(e)} \), where \( \pi \in S_n \) is the permutation corresponding to \( P \), and by abuse of notation we write \( \pi(e) = \pi(\{i, j\}) = (\pi(i), \pi(j)) \) as well. Since the elementary alternating matrices are linearly independent, and \( A_H \) has a basis of elementary alternating matrices, the only way for \( A_{\pi(e)} \) to be in \( A_H \) is for it to be equal to one of the basis elements (one of the matrices in \( A_H \)). In other words, \( \pi(e) \) must be an edge of \( H \). As \( P \) is invertible, we thus have that \( P \) gives an isomorphism \( G \cong H \). \( \blacksquare \)

4.2 Search-to-decision reduction for Alternating Matrix Space Isometry

\textbf{Theorem A}. Given an oracle deciding Alternating Matrix Space Isometry, the task of finding an isometry between two alternating matrix spaces \( A, B \in \Lambda(n, \mathbb{F}_q) \), if it exists, can be solved using at most \( q^{O(n)} \) oracle queries each of size at most \( O(n^2) \), and in time either \( q^{O(n)} \cdot n! \) or \( q^{O(n+m)} \).

\textbf{Proof.} We first present the gadget construction. Then based on this gadget, we present the search-to-decision reduction.

\textbf{Gadget construction.} Let \( A = (A_1, \ldots, A_m) \) be an ordered linear basis of \( \mathcal{A} \), and let \( A \in T(n \times n \times m, \mathbb{F}_q) \) be the 3-way array constructed from \( A \), so we can write

\[
A = \begin{bmatrix}
0 & a_{1,2} & a_{1,3} & \ldots & a_{1,n} \\
-a_{1,2} & 0 & a_{2,3} & \ldots & a_{2,n} \\
-a_{1,3} & -a_{2,3} & 0 & \ldots & a_{3,n} \\
\vdots & \ddots & \ddots & \ddots & \vdots \\
-a_{1,n} & -a_{2,n} & -a_{3,n} & \ldots & 0
\end{bmatrix},
\]

where \( a_{i,j} \in \mathbb{F}_q \), \( 1 \leq i < j \leq n \) thought of as a vector coming out of the page.
We first consider a 3-way array $\tilde{A}_i$ constructed from $A$, for any $1 \leq i \leq n - 1$, as $\tilde{A}_i = \begin{bmatrix} e_{i,1} & 0 & \cdots & 0 \\ -e_{i,1} & e_{i,2} & \cdots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ -e_{i,n-1} & -e_{i,n} & \cdots & e_{i,1} \end{bmatrix}$, where $e_{j,k}$ is the $(m + 2n(j - 1) + k)$th standard basis vector, and $f_{j,k}$ is the $(m + 2ni + n(j - 1) + k)$th standard basis vector. A pictorial description can be seen by combining Figure 2 (for the $e_{j,k}$) and [32, Figure 3] (for the $f_{j,k}$).

We claim the following.

> **Claim 10.** If there exist invertible matrices $P$ and $Q$ to satisfy $P^t \tilde{A}_i P = B_i^Q$, then $P$ must be in the form $\begin{bmatrix} P_{1,1} & 0 & 0 \\ 0 & P_{2,2} & 0 \\ P_{3,1} & P_{3,2} & P_{3,3} \end{bmatrix}$, where $P_{1,1}$ is a monomial matrix of size $i \times i$, $P_{2,2}$ is of size $(n - i) \times (n - i)$, and $P_{3,3}$ is of size $(2ni + n) \times (2ni + n)$.

Furthermore, there exist such $P$ and $Q$ if and only if $A$ and $B$ are isometric by a matrix of the form $\begin{bmatrix} P_{1,1} & 0 \\ 0 & P_{2,2} \end{bmatrix}$ where $P_{1,1}$ is a monomial matrix of size $i \times i$.

**Proof.** This claim is immediate by combining the arguments for the FGS gadget [28] as used in [32], and the monomial-restricting gadget introduced in Section 4.1. We only outline the argument and point out some subtle issues here.

First, observe that for the lateral slices of $A_i$:

- The first $i$ lateral slices have rank in $[2n, 3n)$. Note that the rank is strictly less than $3n$ because some tube fibers (coming out of the page) are 0 in the upper-left $n \times n$ sub-array.
- The next $n - i$ lateral slices have rank in $[n, 2n)$.
- The remaining $2ni + n$ lateral slices have rank in $[1, n)$ (since $i \geq 1$).

Because of the above, for $P$ and $Q$ to satisfy $P^t \tilde{A}_i P = B_i^Q$, $P$ must be in the required form.

It is the furthermore statement that requires certain care. The only if direction is straightforward: after observing that $P$ has to be of the above form, we can easily verify that $\begin{bmatrix} P_{1,1} & 0 \\ 0 & P_{2,2} \end{bmatrix}$ is an isometry from $A$ to $B$. For the if direction, starting from $\begin{bmatrix} P_{1,1} & 0 \\ 0 & P_{2,2} \end{bmatrix}$ and $Q_{1,1} \in \text{GL}(m, \mathbb{F})$, we need to design $P_{3,3} \in \text{GL}(2ni + n, \mathbb{F})$ and $Q_{2,2} \in \text{GL}(2ni + n(n - i), \mathbb{F})$ such that letting $P = \begin{bmatrix} P_{1,1} & 0 & 0 \\ 0 & P_{2,2} & 0 \\ 0 & 0 & P_{3,3} \end{bmatrix}$ and $Q = \begin{bmatrix} Q_{1,1} & 0 \\ 0 & Q_{2,2} \end{bmatrix}$, we have $P^t \tilde{A}_i P = B_i^Q$.

This can be achieved by combining the arguments for the only if directions in the proofs of Lemma 8 and [32, Proposition 3.3].

<!>
The search-to-decision reduction. Given these preparations, we now present the search-to-decision reduction for Alternating Matrix Space Isometry. Recall that this requires us to use the decision oracle $O$ to compute an explicit isometry transformation $P \in \text{GL}(n, q)$, if $\mathcal{A}$ and $\mathcal{B}$ are indeed isometric. Think of $P$ as sending the standard basis $(\vec{e}_1, \ldots, \vec{e}_n)$ to another basis $(v_1, \ldots, v_n)$, where $\vec{e}_1$ and $v_1$ are in $\mathbb{F}_q^n$.

In the first step, we guess $v_1$, the image of $\vec{e}_1$, and a complement subspace of $\langle v_1 \rangle$, at the cost of $q^{O(n)}$. For each such guess, let $P_1$ be the matrix which sends $\vec{e}_1 \mapsto v_1$ and sends $\langle \vec{e}_2, \ldots, \vec{e}_n \rangle$ to the chosen complementary subspace arbitrarily. We apply $P_1$ to $\vec{a}$, and still call the resulting 3-way array $\vec{a}$ in the following. Then construct $\tilde{\mathcal{A}}_1$ and $\tilde{\mathcal{B}}_1$, and feed these two instances to the oracle $O$. Note that, since $P_{1,1}$ (using notation as above) must be monomial, any equivalence between $\tilde{\mathcal{A}}_1$ and $\tilde{\mathcal{B}}_1$ must preserve our choice of $v_1$ up to scale. Thus, clearly, if $\mathcal{A}$ and $\mathcal{B}$ are indeed isometric and we guess the correct image of $\vec{e}_1$, then the oracle $O$ will return yes (and conversely).

In the second step, we guess $v_2$, the image of $\vec{e}_2$, and a complement subspace of $\langle v_2 \rangle$ within $\langle \vec{e}_2, \ldots, \vec{e}_n \rangle$, at the cost of $q^{O(n)}$. Note here that the previous step guarantees that there is an isometry respecting the direct sum decomposition $\langle v_1 \rangle \oplus \langle \vec{e}_2, \ldots, \vec{e}_n \rangle$, so we need only search for a complement of $v_2$ within $\langle \vec{e}_2, \ldots, \vec{e}_n \rangle$, and not a more general complement of $(v_1, v_2)$ in all of $\mathbb{F}_q^n$. This is crucial for the runtime, as at the $n/2$ step, the latter strategy would result in searching through $q^{O(n^2)}$ possibilities.

For each such guess, we apply the corresponding transformation to $\vec{a}$ (and again call the resulting 3-way array $\vec{a}$). Then construct $\tilde{\mathcal{A}}_2$ and $\tilde{\mathcal{B}}_2$, and feed these two instances to the oracle $O$. Clearly, if $\mathcal{A}$ and $\mathcal{B}$ are indeed isometric and we guess the correct image of $\vec{e}_2$ (and $\vec{e}_1$ from the previous step), then the oracle $O$ will return yes. However, there is a small caveat here, namely we may guess some image of $e_2$, such that $\mathcal{A}$ and $\mathcal{B}$ are actually isometric by some matrix $P$ of the form

$$
P = \begin{bmatrix}
P_{1,1} & 0 \\
0 & P_{2,2}
\end{bmatrix}
$$

where $P_{1,1}$ is a monomial matrix of size 2 (instead of the more desired diagonal matrix). But this is fine, as it still ensures $P_{1,1}$ to be monomial, which is the key property to keep. This means that our choices of $(v_1, v_2)$ is correct as a set up yes (and conversely).

In general, in the $i$th step, we maintain the property that $\mathcal{A}$ and $\mathcal{B}$ are isometric by some $P = \begin{bmatrix}
P_{1,1} & 0 \\
0 & P_{2,2}
\end{bmatrix}$ where $P_{1,1}$ is a monomial matrix of size $(i - 1) \times (i - 1)$. We guess $v_i$, the image of $\vec{e}_i$ in $(\vec{e}_1, \ldots, \vec{e}_n)$, and a complement subspace of $\langle v_i \rangle$ within $\langle \vec{e}_1, \ldots, \vec{e}_n \rangle$. This cost is $q^{O(n)}$. For each such guess, we apply the corresponding transformation to $\vec{a}$ (and call the resulting 3-way array $\vec{a}$). Then construct $\tilde{\mathcal{A}}_i$ and $\tilde{\mathcal{B}}_i$, and feed these two instances to the oracle $O$. Once we guess correctly, we ensure that $\mathcal{A}$ and $\mathcal{B}$ are isometric by $P = \begin{bmatrix}
P_{1,1} & 0 \\
0 & P_{2,2}
\end{bmatrix}$ where $P_{1,1}$ is a monomial matrix of size $i \times i$.

So after the $(n - 1)$th step, we know that $\mathcal{A}$ and $\mathcal{B}$ are isometric by a monomial transformation. As the number of all monomial transformations is $(q-1)^n \cdot n! \leq q^n \cdot 2^n \log n = q^{O(n)}$, we can enumerate all monomial transformations and check correspondingly. This gives an algorithm in time $q^{O(n)}$. By resorting to Proposition 11 which solves Alternating Matrix Space Monomial Isometry in time $q^{O(n + m)}$, we have an algorithm in time $q^{O(n + m)}$.

Note that all the instances we feed into the oracle $O$ are of size $O(n^2)$. This concludes the proof.
4.3 A simply-exponential algorithm for monomial isometry of alternating matrix spaces

We now state the algorithm for monomial isometry used in Theorem A'.

Proposition 11. Let \( A, B \leq \Lambda(n, q) \) be \( m \)-dimensional. Then there exists a \( q^{O(n+m)} \)-time algorithm that decides whether \( A \) and \( B \) are monomially isometric, and if so, computes an explicit monomial isometry.

Proof. Let \( A, B \leq \Lambda(n, q) \) be two \( m \)-dimensional alternating matrix spaces. Clearly, by incurring a multiplicative factor of \( q^n \), we can reduce to the problem of testing whether \( A \) and \( B \) are permutation isometric, i.e., whether there exists a permutation matrix \( T \in \text{GL}(n, q) \), such that \( T \cdot A T = B \). We will solve this problem in time \( 2^{O(n)} \cdot q^{O(m)} \). This would give an algorithm with total running time \( q^n \cdot 2^{O(n)} \cdot q^{O(m)} = q^{O(n+m)} \). The basic idea of the algorithm comes from Luks’s dynamic programming technique for HYPERGRAPH ISOMORPHISM [53].

Reducing to a generalized linear code equivalence problem. Suppose \( A = \langle A_1, \ldots, A_m \rangle \), and \( B = \langle B_1, \ldots, B_m \rangle \). Let \( A \) and \( B \) be the \( n \times n \times m \) 3-way arrays formed by the given bases of \( A \) and \( B \). For \( S \subseteq [n] \) of size \( s \), let \( A_i \) be the submatrix of \( A_i \) with row and column indices in \( S \). Then let \( A_S \) be the \( s \times s \times m \) 3-way array formed by \( \langle (A_1)_S, \ldots, (A_m)_S \rangle \). Similarly we can define \( B_S \) for \( S \subseteq [n] \).

For each \( S \subseteq [n] \) of size \( s \), let \( \text{Iso}(A_{[s]}, B_S) \) be the coset in \( S_n \times \text{GL}(m, q) \), such that \( (A, B) \in S_n \times \text{GL}(m, q) \) if and only if the natural action of \( (A, B) \) sends \( A_{[s]} \) to \( B_S \). Since all the matrices are alternating, their diagonal entries are zero, and thus \( A_{[i]} \) and \( B_{(i)} \) are both the \( 1 \times 1 \times m \) zero vector for any \( i \). It follows that if \( s = 1 \) and \( S = \{i\} \), \( \text{Iso}(A_{[1]}, B_S) = G \times \text{GL}(m, q) \), where \( G \) is the coset of \( S_n \) consisting of permutations sending \( 1 \) to \( i \).

Suppose we have computed \( \text{Iso}(A_{[s]}, B_S) \) for all \( s < t \). Fix \( T \subseteq [n] \), \( |T| = t \), and let us compute \( \text{Iso}(A_{[t]}, B_T) \). For any \( (A, B) \in \text{Iso}(A_{[t]}, B_T) \), \( A \) sends \( t-1 \) to some \( T' \subseteq T \) of size \( t-1 \). So in this case, \( (A, B) \in \text{Iso}(A_{[t-1]}, B_{T'}) \), which has been computed. Let \( T \setminus T' = \{t'\} \).

On the other hand, for \( (A, B) \in \text{Iso}(A_{[t-1]}, B_{T'}) \) to be in \( \text{Iso}(A_{[t]}, B_T) \), \( (A, B) \) needs to send the \( t \)th horizontal slice of \( A_{[t]} \) to the \( t' \)th horizontal slice of \( B_{T'} \). We first identify \( T' \) with \( [t-1] \). We then note that every horizontal slice of \( A_{[1]} \) has a row of zeros. So the problem now becomes: given two \( (t-1) \times m \) matrices \( P \) and \( Q \) over \( F_q \), decide whether \( P \) and \( Q \) are the same under \( G \leq S_{t-1} \times \text{GL}(m, q) \). (Note that \( G = \text{Iso}(A_{[t-1]}, B_{T'}) \) from above.) Clearly, this is a generalization of the LINEAR CODE EQUIVALENCE problem. Furthermore, if we could solve this problem in time \( 2^{O(n)} \cdot q^{O(m)} \), we would have achieved our original goal.

Solving the generalized linear code equivalence problem. We solve the above problem again by a dynamic programming scheme as follows. For \( R \subseteq [t-1] \) of size \( r \), \( P_R \) denotes the \( r \times m \) submatrix of \( P \) with row indices from \( R \). Let \( \text{Iso}'(P_{[r]}, Q_R) \) be the coset in \( S_{t-1} \times \text{GL}(m, q) \), such that \( (C, D) \in \text{Iso}'(P_{[r]}, Q_R) \) if and only if the natural action of \( (C, D) \) sends \( P_{[r]} \) to \( Q_R \). If \( r = 0 \), then \( \text{Iso}'(P_0, Q_0) = G \) where \( G \leq S_{t-1} \times \text{GL}(m, q) \) is given as an input.

Suppose we have computed \( \text{Iso}'(P_{[r]}, Q_R) \) for any \( r < u \). Fix \( U \subseteq [t-1] \), \( |U| = u \), and let us compute \( \text{Iso}'(P_{[u]}, Q_U) \). For any \( (C, D) \in \text{Iso}'(P_{[u]}, Q_U) \), \( C \) sends \( [u-1] \) to some \( U' \subseteq U \) of size \( u-1 \). So in this case, \( (A, B) \in \text{Iso}(P_{[u-1]}, Q_{U'}) \), which has been computed. Let \( U \setminus U' = \{u'\} \). On the other hand, for \( (C, D) \in \text{Iso}(P_{[u-1]}, Q_{U'}) \) to be in \( \text{Iso}(P_{[u]}, Q_U) \), \( D \)
needs to send the $u'$th row of $P_{[u]}$ to the $u'$th row of $Q_{V'}$. This subcoset of $\text{Iso}(P_{[u-1]}, Q_{V'})$ can be computed in time $q^{O(m)}$, by treating $\text{GL}(m, q)$ as a permutation group on $\mathbb{F}_q^m$. We then take a union over size-$(u - 1)$ subsets $U'$ to obtain a generating set for $\text{Iso}(P_{[u]}, Q_{V})$. If necessary, we can reduce the generating set size by applying the standard permutation group machinery, as our time bound is $2^{O(n)} \cdot q^{O(m)}$, which is quite generous.

5 Counting-to-decision reduction by restricting to diagonal groups

In this section, we devise a gadget to achieve the restriction to the group of diagonal matrices, and use it to do the counting to decision reduction for Alternating Matrix Space Isometry.

5.1 Preliminaries

Some preparations are in order.

Observation 12. Let $n \geq 23$. Then any permutation $\sigma \in S_n$ either fixes a set of 6 points $P \subseteq [n]$, or moves a set of 6 points $P \subseteq [n]$ to another set of 6 points $Q \subseteq [n]$ such that these two sets are disjoint.

Proof. Suppose $\sigma$ fixes at most 5 points. Then there are at least 18 points that are not fixed by $\sigma$. Suppose $\sigma$ has $t$ non-trivial cycles of length $l_1, \ldots, l_t$, such that $\sum_i l_i \geq 18$. For a cycle $(p_1, \ldots, p_s)$, we can choose $p_1, p_3, \ldots, p_{2\lfloor s/2 \rfloor}$ and put them in $P$, and $p_2, p_4, \ldots, p_{2\lfloor s/2 \rfloor}$ in $Q$. Do this for every cycle, we obtain the desired $P$ and $Q$. The worst case is when every cycle is of length 3. Since there are at least 18 points not fixed by $\sigma$, $P$ is of size $\geq 6$.

We shall make repeated uses of the following facts.

Fact 13.
1. Given $a_i \in \mathbb{R}, 0 \leq a_i \leq 1, i \in [m], \prod_{i \in [m]} (1 - a_i) \geq 1 - \sum_{i \in [m]} a_i$.
2. Let $m, N \in \mathbb{N}$ and $1 \leq m \leq N$. A random matrix $A \in M(N \times m, q)$ is of rank $m$ with probability $\geq 1 - 2/q^{N-m+1}$.
3. For $n \in \mathbb{N}, 0 \leq d \leq n$, the number of dimension-$d$ subspaces of $\mathbb{F}_q^n$ is equal to the Gaussian binomial coefficient
   \[ \binom{n}{d}_q := \frac{(q^n-1) \cdot (q^n-q) \cdot \cdots \cdot (q^n-q^{d-1})}{(q^d-1) \cdot (q^d-q) \cdot \cdots \cdot (q^d-q^{d-1})} \]
4. The Gaussian binomial coefficient satisfies:
   \[ q^{(n-d)d} \leq \binom{n}{d}_q \leq q^{(n-d)d+d} \]
5. For $d \in \mathbb{N}$, the number of complement subspaces of a fixed dimension-$d$ subspace of $\mathbb{F}_q^n$ is $q^{d(n-d)}$.

Proof. For (2), $\Pr[\text{rk}(A) = m] = (1 - \frac{1}{q^m}) \cdot (1 - \frac{2}{q^m}) \cdot \cdots \cdot (1 - \frac{m-1}{q^{m-1}})$. By (1), we have $\Pr[\text{rk}(A) = m] \geq 1 - \sum_{i=N-m+1}^{N} \frac{1}{q^i} \geq 1 - \frac{1}{q^{N-m+1}} - \sum_{i=N-m+2}^{N} \frac{1}{q^i} \geq 1 - \frac{q^{N-m+1}}{q^{N-m+1}}$.

5.2 Describing the gadget

Let $\mathcal{A} \leq \Lambda(n, q)$ be an alternating matrix space, and let $\mathbf{A} = (A_1, \ldots, A_m) \in \Lambda(n, q)^m$ be an ordered linear basis of $\mathcal{A}$. Let $\mathbf{A} \in T(n \times n \times m, \mathbb{F}_q)$ be the 3-way array constructed from $\mathbf{A}$, i.e. the $i$th frontal slice of $\mathbf{A}$ is $A_i$.

We shall assume $n = \Omega(1)$, and $q = n^{\Omega(1)}$ throughout the remainder of this section.
The form of the gadget. To describe the gadget, it is easier to view \( \mathcal{A} \) from the lateral viewpoint. That is, for \( i \in [n] \), let \( C_i = [A_1 e_i, \ldots, A_m e_i] \in M(n \times m, q) \). Let \( C = (C_1, \ldots, C_n) \in M(n \times n, q)^n \). Then construct \( C' = (C'_1, \ldots, C'_n) \), where \( C'_i \) is of size \( 6n \times 4n \). For \( i \in [n] \), \( G_i = [0 \ldots 0 \ H_i \ 0 \ldots 0] \), where \( H_i \) is of size \( 6n \times 4n \) in the \( i \)th block, and \( 0 \) denotes an all-zero matrix of size \( 6n \times 4n \). The \( H_i \) will be described below.

Note that from the frontal viewpoint of looking at \( \mathcal{A} \), \( G_i \)’s are inserted, vertically, below and behind \( \mathcal{A} \). So to preserve the alternating structure, \( -G_i \)’s also need to be inserted, horizontally, on the right and behind \( \mathcal{A} \). We therefore get \( \tilde{\mathcal{A}} \), which is of size \( 7n \times 7n \times (m + 4n^2) \).

Conditions imposed on the \( H_i \)'s. Of course, the key to the construction above lies in the properties of the \( H_i \)'s. Let \( V_i \leq F_q^{6n} \) be the subspace spanned by the columns of \( H_i \). We shall impose the following conditions on \( H_i \).

1. For any \( i \in [n] \), \( \text{rk}(H_i) = \dim(V_i) = 4n \).
2. For any \( i, j \in [n], i \neq j \), \( \text{rk}([H_i, H_j]) = \dim(V_i \cup V_j) = 6n \).
3. For any \( (i_1, i_2, i_3, i_4, i_5, i_6) \in [n]^6 \) and \( (j_1, j_2, j_3, j_4, j_5, j_6) \in [n]^6 \), such that \( \{|i_1, \ldots, i_6\} \cup \{j_1, \ldots, j_6\} = 12 \), i.e. \( i_k \) and \( j_k \) all different, the coset \( C = \{T \in \text{GL}(6n, q) : \forall k \in [6], T(V_{i_k}) = V_{j_k}\} \) is empty. Note that for any \( i \in [n] \), \( T(V_i) \) is spanned by the columns of \( TH_i \).
4. For any \( (i_1, i_2, i_3, i_4, i_5, i_6) \in [n]^6 \), \( i_k \) all different, the group \( S = \{T \in \text{GL}(6n, q) : \forall k \in [6], T(V_{i_k}) = V_{i_k}'\} \) consists of only of scalar matrices.

\[\text{Remark 14. Given } H_1, \ldots, H_n \in M(6n \times 4n, q), \text{ whether they satisfy the four conditions can be verified in polynomial time.}\]

Conditions (1) and (2) are easily verified in deterministic polynomial time.

For condition (3), it can be formulated as a linear algebraic problem as follows. Let \( X \) be a \( 6n \times 6n \) variable matrix. Let \( Y_k, k \in [6] \), be \( 4n \times 4n \) variable matrices. Set up the equations \( XH_{i_k} = H_{j_k}Y_k \), and solve the linear equations to get a subspace of \( F_q^{6(6n)^2+6(4n)^2} \). The question is then whether this subspace contains \( (T, R_1, \ldots, R_6) \) where \( T \in \text{GL}(6n, q) \) and \( R_i \in \text{GL}(4n, q) \). This is an instance of the symbolic determinant identity testing (SDIT) problem, so it admits a randomized efficient algorithm when \( q = n^{\Omega(1)} \).

In fact, this instance of SDIT problem can be solved in deterministic polynomial time. For this let us also check out condition (4). Here, let \( X \) and \( Y_i \) be from above, and set up the equations \( XH_{i_k} = H_{i_k}Y_k \). Solve the linear equations to get a subspace of \( F_q^{6(6n)^2+6(4n)^2} \). This subspace turns out to be an algebra under the natural multiplications. Indeed, if \( AH_{i_k} = H_{i_k}B_k \) and \( A'H_{i_k} = H_{i_k}B'_k \), then \( A'A'H_{i_k} = H_{i_k}B_kB'_k \). To compute the unit group in a matrix algebra can be solved by a polynomial-time Las Vegas algorithm by [16].

Given the unit group, whether it consists of only scalar matrices can be verified easily in deterministic polynomial time.

Then the linear space in condition (3) is a module over the algebra defined in the last paragraph. Because of this structure, the SDIT problem for such instances can be solved in deterministic polynomial time [14,19,37].

5.3 Construction and properties of the gadget

The following three propositions reveal the construction and functions of the gadget described above.

First about the construction. Instead of constructing the above \( H_i \)'s explicitly in a deterministic way, we shall show that random choices suffice.
Proposition 15. Let $H_i \in M(6n \times 4n, q), i \in [n]$, be random matrices. Then $H_i$’s satisfy the four conditions in Section 5.2 with probability $\geq 1 - \frac{n^{O(1)}}{\Omega(n^2)}$.

Second about the functionality. The following proposition formally explains this.

Proposition 16. Suppose $\mathbf{A}$ and $\mathbf{B}$ are two 3-tensors constructed from ordered bases of $m$-dimensional alternating matrix spaces $\mathcal{A}, \mathcal{B} \leq \Lambda(n, q)$. Let $\mathbf{A}$ and $\mathbf{B}$ be constructed as above, and let $\tilde{\mathcal{A}}$ and $\tilde{\mathcal{B}}$ be the alternating matrix spaces spanned by the frontal slices of $\mathbf{A}$ and $\mathbf{B}$, respectively. Then $\mathcal{A}$ and $\mathcal{B}$ are isometric via a diagonal matrix if and only if $\tilde{\mathcal{A}}$ and $\tilde{\mathcal{B}}$ are isometric.

Finally we shall use this gadget to achieve a counting-to-decision reduction for Alternating Matrix Space Isometry. Formally, we have the following.

Proposition 17. Suppose we are given $\mathcal{A}, \mathcal{B} \leq \Lambda(n, q)$ and a decision oracle for Alternating Matrix Space Isometry. Then there exists a Las Vegas randomized algorithm that computes the number of isometries from $\mathcal{A}$ to $\mathcal{B}$ in time $q^{O(n)}$.

The next three subsections are devoted to the proofs of Propositions 15 (Section 5.3.3), 16 (Section 5.3.1), and 17 (Section 5.3.2). Note that, because the proof of Proposition 15 is more complicated compared to the other two, we postpone it to the last.

Remark 18. In fact, we expect that this construction works even for small finite fields. The bottleneck lies in Proposition 15. If the probability $\frac{n^{O(1)}}{\Omega(n^2)}$ could be improved to $\frac{n^{O(1)}}{\Omega(n)}$, then we would be done. We believe it possible to utilize the structure of invariant subspaces under matrix actions over $F_q$ to achieve this. However, we expect that the calculations will be tedious and heavy, so we hope to leave this to a future work.

5.3.1 Restricting to the diagonal group

Briefly speaking, conditions 1 and 2 ensure that we first restrict to monomial matrices. Conditions 3 and 4 prevent non-trivial permutations due to the following. As we assume $n = \Omega(1)$, by Observation 12, $\sigma \in S_n$ either fixes 6 elements in $[n]$, or moves a set of 6 elements to another, disjoint, set of 6 elements. Condition 3 ensures that the second case could not happen. Condition 4 ensures that in the first case, the only possible invertible matrices that “preserves” the matrices $G_i$ for $i \in P$ when multiplying from the left are scalar matrices.

We now prove Proposition 16.

Proof of Proposition 16. Recall that we construct such $\mathbf{A}$ and $\mathbf{B}$ from $\mathcal{A}$ and $\mathcal{B}$, respectively, using the method in Section 5.2. Let $\tilde{\mathcal{A}}$ and $\tilde{\mathcal{B}}$ be alternating matrix spaces in $\Lambda(7n, q)$, spanned by the frontal slices of $\mathbf{A}$ and $\mathbf{B}$, respectively.

We want to show that $\tilde{\mathcal{A}}$ and $\tilde{\mathcal{B}}$ are isometric if and only if $\mathcal{A}$ and $\mathcal{B}$ are isometric via diagonal matrices. The if direction is straightforward. Suppose there exist $P = \text{diag}(\alpha_1, \ldots, \alpha_n) \in \text{diag}(n, q)$ and $Q \in \text{GL}(m, q)$ such that $P^t \mathbf{A} P = B Q$. Let $\tilde{P} = \begin{bmatrix} P & 0 \\ 0 & I_{6n} \end{bmatrix} \in \text{GL}(7n, q)$. Let $\tilde{Q} = \begin{bmatrix} Q \\ 0 \end{bmatrix} \in \text{GL}(m + 4n^2)$, where $Q' = \text{diag}(\alpha_1 I_{4n}, \ldots, \alpha_n I_{4n})$. Then it is easy to verify that $\tilde{P}^t \tilde{A} \tilde{P} = \tilde{B} \tilde{Q}$.

Now we turn to the only if direction. If $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{B}}$ are isometric, then there exists $\tilde{P} \in \text{GL}(7n, q)$ and $\tilde{Q} \in \text{GL}(m + 4n^2, q)$, such that $\tilde{P}^t \tilde{A} \tilde{P} = \tilde{B} \tilde{Q}$. Let $\tilde{P} = \begin{bmatrix} P_{1,1} & P_{1,2} \\ P_{2,1} & P_{2,2} \end{bmatrix}$, where $P_{1,1}$ is of size $n \times n$. It can be checked easily, from the lateral viewpoint, that $P_{1,2} = 0$. As
We then have shown that which contradicts that the corresponding lateral slice of \(\bB^Q\) is of rank \(\leq n\). It follows that \(P_{1,1} \in \GL(n,q)\) and \(P_{2,2} \in \GL(6n,q)\).

We first claim that \(P_{1,1}\) has to be a monomial matrix. If not, then one of the first \(n\) lateral slice of \(\tilde{\bP}\) has two distinct \(H_i\) and \(H_j\). By condition (2), this slice is of rank \(\geq 6n\), which contradicts that the corresponding lateral slice of \(\tilde{\bB}^Q\) is of rank \(\leq 5n\).

We further claim that \(P_{1,1}\) has to be a diagonal matrix. If not, then suppose the non-trivial permutation underlying \(P_{1,1}\) is \(\sigma \in S_n\). Since we assumed \(n = \Omega(1)\), by Observation 12, one of the following two cases has to happen.

\[\exists \{i_1, \ldots, i_6\} \subseteq [n], \{j_1, \ldots, j_6\} \subseteq [n], \{i_1, \ldots, i_6\} \cup \{j_1, \ldots, j_6\} = 12, \text{ such that } \sigma(i_k) = j_k \text{ for } k \in [6].\]

We then claim the following.

▷ Claim 19. For \(\hat{\bP}_t \hat{\bP} = \hat{\bB}^Q\) to hold, a necessary condition is that \(\forall k \in [6], P_{2,2} H_{i_k} \text{ and } H_{i_k}\) have the same linear span.

Proof. To see this, note that the \(i_k\)th lateral slice of \(\hat{\bP}_t \hat{\bP}\) is the \(j_k\)th lateral slice of \(\hat{\bP}_t \hat{\bP}\) (up to a scalar multiple). It is equal to the \(i_k\)th lateral slice of \(\tilde{\bB}^Q\). Then \(\hat{\bP}_t\) acts on the left on the \(j_k\)th lateral slice of \(\hat{\bP}\). Noting that \(P^t = \begin{bmatrix} P_{1,1}^t & P_{2,1}^t \\ 0 & P_{2,2}^t \end{bmatrix}\) and the \(j_k\)th lateral slice of \(\hat{\bP}\) is \(\hat{C}_{i_k} = \begin{bmatrix} C_{i_k} & 0 \\ 0 & G_{j_k} \end{bmatrix}\), we see that \(P^t C_{i_k} = \begin{bmatrix} * & * \\ 0 & P_{2,2}^t G_{j_k} \end{bmatrix}\). (Here, \(C_i\) and \(G_i\) are defined in Section 5.2.) On the other hand, we see that the \(i_k\)th lateral slice of \(\hat{\bB}^Q\) is the \(i_k\)th lateral slice multiplied from the right by \(\hat{Q}\). Our claim follows then by comparing the last \(6n\) rows.

But the condition (3) excludes the existence of such \(P_{2,2}\), so this cannot happen.

\[\exists \{i_1, \ldots, i_6\} \subseteq [n], i_k \text{ all different, such that } \sigma(i_k) = i_k.\] In this case, for \(\hat{\bP}_t \hat{\bP} = \hat{\bB}^Q\) to hold, by the same argument as in the proof of Claim 19, a necessary condition is that \(P_{2,2} H_{i_k} \text{ and } H_{i_k}\) have the same linear span. Then the condition (4) ensures that \(P_{2,2} = \lambda I_{6n}\) for some \(\lambda \neq 0 \in F\) in this setting. Then because \(\sigma\) is non-trivial, \(\sigma\) moves some \(i \in [n]\) to \(j \in [n], i \neq j\). By comparing the \(j\)th lateral slice of \(\hat{\bP}_t \hat{\bP}\) and the \(i\)th lateral slice of \(\hat{\bB}^Q\), \(P_{2,2} H_i = \lambda H_i\) and \(H_j\) have the same linear span, which is not possible because the condition (2) ensures that \(H_i\) and \(H_j\) span different subspaces.

We have then shown that \(P_{1,1}\) must be a diagonal matrix. By comparing the top-left-front sub-tensors of size \(n \times n \times m\) of \(\hat{\bP}_t \hat{\bP}\) and \(\tilde{\bB}^Q\), we arrive at the desired conclusion that \(\bA\) and \(\bB\) are isometric via the diagonal matrix \(P_{1,1}\).

5.3.2 Using the gadget for counting-to-decision reduction

The strategy follows closely the counting to decision reduction for graph isomorphism.

We first review the strategy for counting to decision reduction for graph isomorphism [54]. Suppose we are given two graphs with the vertex set being \([n]\), i.e. \(G,H \subseteq \binom{[n]}{2}\). We first use the decision oracle to decide whether \(G\) and \(H\) are isomorphic. If not, the number of isomorphisms is 0. If so, we turn to compute the order of \(\text{Aut}(G)\). Let \(A = \text{Aut}(G)\). For \(i \in [n]\), let \(A_i = \{\sigma \in A : \forall 1 \leq j \leq i, \sigma(j) = j\}\). Set \(A_0 = A\). We then have the tower of subgroups \(A_0 \supseteq A_1 \supseteq \cdots \supseteq A_n = \{id\}\). The order of \(A_0\) is then the product of \([A_i : A_{i+1}]\), the index of \(A_{i+1}\) in \(A_i\), for \(i = 0, 1, \ldots, n - 1\). Let \(G_i\) be the graph with the first \(i\) vertices in \(G\) individualized. Then \(\text{Aut}(G_i) \cong A_i\). To compute \([A_i : A_{i+1}]\), we note that it is equal to the size of the orbit of the vertex \(i + 1\) under \(A_i\). For each \(j \geq i + 1\), construct from \(G_i\) two
graphs \(G_i'\) and \(G_i''\) as follows. In \(G_i'\), individualize \(i+1\), and in \(G_i''\), individualize \(j\). Then \(j\) is in the orbit of \(i+1\) under \(A_i\) if and only if \(G_i'\) and \(G_i''\) are isomorphic. Enumerating over \(j \geq i+1\) gives us the size of the orbit of \(i+1\) under \(A_i\). This finishes an overview of the idea for counting to decision reduction for graph isomorphism.

We then apply the above strategy to get a counting to decision reduction for alternating matrix space isometry to prove Proposition 17.

**Proof of Proposition 17.** Our goal is to compute the number of isomorphisms from \(A\) to \(B\), where \(A, B \leq \Lambda(n, q)\) are of dimension \(m\). First, we use the decision oracle first to decide whether \(A\) and \(B\) are isometric. If not, the number of isometries is 0. If so, we need to calculate the order of the autometry group of \(A, \text{Aut}(A)\). To do that, we first randomly sample \(n \times 4n\) matrices \(H_1, \ldots, H_n\) over \(F_q\), and verify whether they satisfy the four conditions in Section 5.2 using Remark 14. Note that this is where the algorithm needs to be a Las Vegas algorithm.

Let \(A = \text{Aut}(A)\). Recall that \(e_i\) denotes the \(i\)th standard basis vector in \(F_q^n\). For \(i \in [n]\), let \(A_i = \{ T \in A : \forall 1 \leq j \leq i, T(e_j) = \lambda e_j, \lambda_i \neq 0 \in F_q \} \). Note that \(A_n = A \cap \text{diag}(n, q)\). We can calculate the order of \(A_i\) in time \(q^{O(n)}\) by brute-force, i.e., enumerating all invertible diagonal matrices. Set \(A_0 = A\). We then have the tower of subgroups \(A_0 \supset A_1 \supset \cdots \supset A_n\).

To compute the order of \(A_0\), it is enough to compute \([A_i : A_{i+1}]\). Note that for \(T, T' \in A_i\), \(T A_{i+1} = T' A_{i+1}\) as left cosets in \(A_i\) if and only if \(T(e_{i+1}) = \lambda T'(e_{i+1})\) for some \(\lambda \neq 0 \in F_q\). So \([A_i : A_{i+1}]\) is equal to the size of the orbit of \(e_{i+1}\) under \(A_i\) in the projective space. Let \(v \in F_q^n\). To test whether \(v\) is in the orbit of \(e_{i+1}\) under \(A_i\) in the projective space, we transform \(A\) by \(P' \cdot P\), where \(P \in \text{GL}(n, q)\) sends \(e_{i+1}\) to \(v\) and \(e_j\) to \(e_j\) for \(j \neq i+1\), to get \(A'\). We then add the diagonal restriction gadget to the first \(i+1\) lateral slices and the first \(i+1\) horizontal slices of \(A\) and \(A'\), to obtain \(A\) and \(A'\) respectively. Then feed \(A\) and \(A'\) to the decision oracle. By the functionality of the diagonal restriction gadget, \(v\) is in the orbit of \(e_{i+1}\) in the projective space if and only if \(A\) and \(A'\) are isometric. Enumerating \(v \in F_q^n\) up to scalar multiples gives us the size of the orbit of \(e_{i+1}\) under \(A_i\) in the projective space. This finishes the description of the algorithm.

A small caveat in the above is that our gadget requires \(n = \Omega(1)\), so we cannot start from \(A_0\) at the beginning. This issue can be resolved by noting that the order of \(A_c\), for any constant \(c\), can be computed in time \(q^{O(n)}\), by enumerating all possible images of \(e_1, \ldots, e_c\) in time \(q^{O(n)}\), adding the diagonal restriction gadget, and utilizing the decision oracle.

### 5.3.3 Random \(H_i\)'s satisfy the requirements when \(q = n^{\Omega(1)}\)

In the following we will encounter random matrices over \(F_q\) as well as random subspaces in \(F_q^n\). There is a subtle point which we want to clarify now. Let \(m \leq n\). Note that there are \(\binom{n}{m}\) subspaces of \(F_q^n\), and there are \(N_1 = \binom{n}{m} \cdot \cdots \cdot \binom{n}{m}\) rank-\(m\) matrices of size \(n \times m\). It can be seen easily that each \(m\)-dimensional subspace \(V\) of \(F_q^n\) has \(N_2 = \binom{n}{m} \cdot \cdots \cdot \binom{n}{m-1}\) many representations as rank-\(m\) matrices of size \(n \times m\), i.e., the columns of the matrix span \(V\). It follows that we can work with random rank-\(m\) matrices of size \(n \times m\) as if we are working with random \(m\)-dimensional subspaces of \(F_q^n\). Such correspondences will be used implicitly for other structures, including direct sum decompositions.

Now let us get back to our question. We shall show that a random choice of \(H_i, i \in [n]\), would satisfy the four conditions we imposed on \(H_i\)’s. We will prove that for conditions

\[
\text{Pr}[\text{random } H_i \text{ not satisfy condition } k] \leq \frac{n^{O(1)}}{q^{\Omega(n)}}.
\]

---

\[\text{CCC 2021}\]
Once these hold, by a union bound, we have
\[
\Pr[\exists i \in [3], \text{random } H_i \not\text{ satisfy condition } i] \leq n^{O(1)} \frac{q^{2n+1}}{q^{12n+1}}
\]
For condition (4), we will prove that
\[
\Pr[\text{random } H_i \not\text{ satisfy condition } 4 \mid H_i \text{ satisfy conditions } 1, 2, 3] \leq n^{O(1)} \frac{q^{2n+1}}{q^{12n+1}}
\]
This then would allow us to conclude that when \( q = n^{O(1)} \), random \( H_i \)'s satisfy all the four conditions.

We examine the first three conditions one by one.
1. For condition (1), by Fact 13 (2), we have \( \Pr[\exists i \not\in [n], \rk(H_i) < 4n] \leq n \cdot \Pr[\rk(H_i) < 4n] \leq \frac{2n}{q^{2n+1}}. \)
2. For condition (2), noting that the block matrix \( (H_i, H_j) \) is a random \( 6n \times 8n \) matrix over \( \mathbb{F}_q \), by Fact 13 (2), we have \( \Pr[\exists i \not\in [n], \rk((H_i, H_j)) < 6n] \leq (\frac{n}{2}) \frac{2}{q^{2n+1}} \leq \frac{n^2}{q^{2n+1}}. \)
3. For condition (3), let \( I = (H_i_1, \ldots, H_i_k) \), and \( J = (H_{j_1}, \ldots, H_{j_k}) \). We see that \( C \) is non-empty if and only if there exists \( L \in \GL(6n, q) \) and \( R_k \in \GL(4n, q) \), \( k \in [6] \), such that \( LH_i R_k = H_{j_k} \). Note that the orbit of \( I \) under this group action is of size at most \( q^{(6n)^2 + 6(4n)^2} = q^{12n^2} \). Since \( i_k \) and \( j_k \) are all different, the probability of \( J \) belonging to this orbit is \( \frac{q^{12n^2}}{q^{12n^2}} = \frac{1}{q^{12n^2}} \). We then have \( \Pr[\exists i_k, j_k \in [n], k \in [6], i_k, j_k \text{ all different}, C = 0] \leq (\frac{n}{12}) \frac{2}{q^{12n^2}} \leq \frac{n^2}{q^{12n^2}}. \)

We now focus on condition (4). For condition (4), we first assume that the conditions (1) and (2) as above hold. Then \( V_i \)'s are random \( 4n \)-dimensional subspaces of \( \mathbb{F}_q^{6n} \). Note that
\[
\Pr[\exists i \in [n], k \in [6], i_k \text{ all different}, S \text{ non-scalar}] \leq n^6 \cdot \Pr[S \text{ non-scalar for } V_1, \ldots, V_6].
\]
So we turn to study \( \Pr[S \text{ non-scalar for } V_1, \ldots, V_6] \), and will show that it is \( \leq \frac{1}{q^{2n+1}}. \)

Let \( U_1 = V_1 \cap V_2, U_2 = V_2 \cap V_3, \) and \( U_3 = V_1 \cap V_3. \) Let \( W_1 = V_4 \cap V_5, W_2 = V_5 \cap V_6, \) and \( W_3 = V_4 \cap V_6. \) Since conditions (1) and (2) hold, we have \( \dim(U_i) = \dim(W_i) = 2n. \) We claim that with probability \( \geq 1 - 2/q \), \( \mathbb{F}_q^{6n} = U_1 \oplus U_2 \oplus U_3, \) i.e., \( U_1 \cup U_2 \cup U_3 \) span \( \mathbb{F}_q^{6n} \). This can be seen as follows. Since we assumed conditions (1) and (2), this happens if and only if \( V_1 \cap V_2 \) and \( V_3 \) together span \( \mathbb{F}_q^{6n} \). Therefore we calculate, using Fact 13 (1), (3), and (5), that
\[
\Pr[V_3 \text{ is a complement subspace of } V_1 \cap V_2]
\geq \frac{(q^{6n} - q^{2n})(q^{6n} - q^{2n+1}) \ldots (q^{6n} - q^{6n-1})}{(q^{6n} - 1)(q^{6n} - q) \ldots (q^{6n} - q^{4n-1})}
\geq \frac{(q^{6n} - q^{2n})(q^{6n} - q^{2n+1}) \ldots (q^{6n} - q^{6n-1})}{q^{6n} \cdot q^{6n} \ldots q^{6n}} = (1 - 1/q^{4n})(1 - 1/q^{4n-1}) \ldots (1 - 1/q)
\geq 1 - \sum_{i=1}^{4n} 1/q^i \geq 1 - 2/q.
\]
It follows that with probability \( \geq 1 - 4/q \), we can assume in addition that \( W_i \) form a direct sum decomposition of \( \mathbb{F}_q^{6n} \).

Therefore, we turn to bound the probability that there exists a non-scalar invertible matrix stabilizing these two direct sum decompositions of \( \mathbb{F}_q^{6n} \). Since \( i_k \) are all different, the two direct sum decompositions \( U_1 \oplus U_2 \oplus U_3 \) and \( W_1 \oplus W_2 \oplus W_3 \) are independent.
So we can assume that $U_i$ is spanned by those standard basis vectors $e_{2n(i-1)+1}, \ldots, e_{2ni}$, $i = 1, 2, 3$. The group that stabilizes this direct sum decomposition $U_1 \oplus U_2 \oplus U_3$ consists of 
\[
\begin{bmatrix} D_1 & 0 & 0 \\ 0 & D_2 & 0 \\ 0 & 0 & D_3 \end{bmatrix} \in \text{GL}(6n, \mathbb{F}_q) \quad \text{where } D_i \text{ is of size } 2n \times 2n.
\]

The question then becomes to bound the probability for a random $W_1 \oplus W_2 \oplus W_3$ to be stabilized by a non-scalar matrix of the above form. This can be formulated as the following linear algebraic problem. (Recall the correspondence between random $m$-dimensional subspaces and random rank-$m$ matrices as discussed at the beginning of the subsection.) Let $W = \begin{bmatrix} W_{11} & W_{12} & W_{13} \\ W_{21} & W_{22} & W_{23} \\ W_{31} & W_{32} & W_{33} \end{bmatrix} \in \text{GL}(6n, q)$ be a block matrix where $W_{ij}$ is of size $2n \times 2n$. Suppose the columns of $W_{ij}$ span $W_i$. Then $D = \text{diag}(D_1, D_2, D_3)$ stabilizes $W_1 \oplus W_2 \oplus W_3$ if and only if there exists a block diagonal matrix $E = \text{diag}(E_1, E_2, E_3)$, $E_i \in \text{GL}(2n, q)$, such that
\[
\begin{bmatrix} D_1 & 0 & 0 \\ 0 & D_2 & 0 \\ 0 & 0 & D_3 \end{bmatrix} \begin{bmatrix} W_{11} & W_{12} & W_{13} \\ W_{21} & W_{22} & W_{23} \\ W_{31} & W_{32} & W_{33} \end{bmatrix} = \begin{bmatrix} W_{11} & W_{12} & W_{13} \\ W_{21} & W_{22} & W_{23} \\ W_{31} & W_{32} & W_{33} \end{bmatrix} \begin{bmatrix} E_1 & 0 & 0 \\ 0 & E_2 & 0 \\ 0 & 0 & E_3 \end{bmatrix}. \tag{5}
\]

Note that each direct sum decomposition $W_1 \oplus W_2 \oplus W_3$, $\dim(W_i) = 2n$, has $6 \cdot |\text{GL}(2n, q)|^3$ such matrix representations. (The factor 6 takes care of the orders of the three summands.) So the question becomes to bound the probability for a random invertible matrix to have a non-scalar $D$ and $E$ satisfying Equation 5.

First, note that Equation 5 holds if and only if $D_iW_{i,j} = W_{i,j}E_j$ for $i, j \in [3]$.

\textbf{Claim 20.} When $q = \Omega(1)$, we have $\Pr[\forall i, j \in [3], \text{rk}(W_{i,j}) = 2n] \geq 1 - \frac{20}{q}$.

\textbf{Proof.} Let us work in the setting when $W$ is a random matrix, not necessarily the one above. Then $\Pr[\text{rk}(W) = 6n] \geq 1 - \frac{2}{q}$. For any $i, j \in [3]$, $\Pr[\text{rk}(W_{i,j}) < 2n] \leq \frac{2}{q}$, so $\Pr[\exists i, j \in [3], \text{rk}(W_{i,j}) < 2n] \leq \frac{18}{q^2}$.

It follows that $\Pr[\exists i, j \in [3], \text{rk}(W_{i,j}) < 2n \land \text{rk}(W) = 6n] = \Pr[\exists i, j \in [3], \text{rk}(W_{i,j}) < 2n \land \text{rk}(W) = 6n]/\Pr[\text{rk}(W) = 6n] \leq \frac{18}{q^2}/\frac{2}{q} = \frac{9}{q} \leq \frac{20}{q}$, where the last inequality uses that $q = \Omega(1)$.

So we assume that $\text{rk}(W_{i,j}) = 2n$ for all $i, j \in [3]$ in the following, with a loss of probability $\leq \frac{20}{q}$.

For $i \in [3]$, by $D_iW_{ii} = W_{ii}E_i$, we have $D_i = W_{ii}E_iW_{ii}^{-1}$. For $i \neq j$, by $(W_{jj}E_jW_{jj}^{-1})W_{jj} = D_jW_{jj} = W_{jj}E_j$, we have $E_j = W_{jj}^{-1}W_{jj}E_jW_{jj}^{-1}W_{jj}$. Again for $i \neq j$, we have $W_{ii}E_iW_{ii}^{-1}W_{ij} = D_iW_{ij} = W_{ij}E_j = W_{ij}W_{jj}^{-1}W_{jj}E_jW_{jj}^{-1}W_{jj}$. It follows that
\[
\forall i, j \in [3], i \neq j, E_iW_{ii}^{-1}W_{ij}W_{jj}^{-1}W_{jj} = W_{ii}^{-1}W_{ij}W_{jj}^{-1}W_{jj}E_i.
\]

In particular, $E_3$ commutes with $X = W_{33}^{-1}W_{32}W_{22}^{-1}W_{23}$ and $Y = W_{33}^{-1}W_{31}W_{11}^{-1}W_{13}$. Since $W_{ij}$ are independent random invertible matrices, $X$ and $Y$ are independent random invertible matrices. We now resort to the following classical result.

\textbf{Theorem 21 (}[41], cf. also [23, 40]). Let $X$ and $Y$ be two random matrices in $\text{SL}(n, q)$. Then the probability of $X$ and $Y$ not generating $\text{SL}(n, q)$ is $\leq \frac{1}{q^{n(n+1)}}$.}
Back to our setting, the above theorem implies that the group $G$ generated by random $X$ and $Y$ from $GL(2n, q)$ contains $SL(2n, q)$ with probability $\geq 1 - \frac{1}{q^{\Omega(n)}}$. It follows that $E_3$ belongs to the centralizer of $G$, so $E_3$ must be a scalar matrix. Then note that $D_i$’s and other $E_i$’s are all conjugates of $E_3$. So we have $\forall i \in [3], D_i = E_i = \lambda I_{2n}$ for some $\lambda \neq 0 \in \mathbb{F}_q$.

Summarizing the above, we have

$$\Pr[S \text{ non-scalar for } V_1, \ldots, V_6] \leq \Pr[S \text{ non-scalar for } V_i \wedge \mathbb{P}^{6n}_q = U_1 \oplus U_2 \oplus U_3 = W_1 \oplus W_2 \oplus W_3] + \frac{4}{q}$$

$$\leq \Pr[D \text{ non-scalar for } W \wedge \forall i, j \in [3], \text{rk}(W_{ij}) = 2n] + \frac{20}{q} + \frac{4}{q}$$

$$\leq \Pr[D \text{ non-scalar for } W | \forall i, j \in [3], \text{rk}(W_{ij}) = 2n] + \frac{24}{q}$$

$$\leq \frac{1}{q^{d(\pi)}} + \frac{24}{q}$$

$$\leq \frac{1}{q^{d(\Omega(1))}}$$

when $q = n^{\Omega(1)}$. This concludes the proof of Proposition 15.

6 Application to $p$-GROUP ISOMORPHISM, using constructive Baer and Lazard Correspondences

The applications to $p$-GROUP ISOMORPHISM rely on the following well-known connections between alternating bilinear maps and Lie algebras on the one hand, and $p$-groups of “small” class on the other. We present these connections here, partly for audiences not from computational group theory, and partly because we will need to address some computational aspects of these procedures. We begin with some preliminaries.

6.1 Preliminaries

TI-completeness. As the proof of Theorem P in Section 6.3.1 uses a result on TI-completeness from [32], here we recall the definition of TI; see Definition 6 for the $d$-TENSOR ISOMORPHISM problem.

▶ Definition 22 (dT1, TI). For any field $\mathbb{F}$, $dT_1^F$ denotes the class of problems that are polynomial-time Turing (Cook) reducible to $d$-TENSOR ISOMORPHISM over $\mathbb{F}$. Also let $T_1^F = \bigcup_{d \geq 1} dT_1^F$.

The relationship between TI over different fields remains an intriguing open question [32], but here we will only need TI over $\mathbb{F}_p$. One of the the main results of [32] is that $TI = dTI$ for any fixed $d \geq 3$.

Algebras and their algorithmic representations. A Lie algebra $A$ consists of a vector space $V$ and a bilinear map $[,] : V \times V \to V$ that is alternating ($[v, v] = 0$ for all $v \in V$; this is equivalent to skew-symmetry $[u, v] = -[v, u]$ in characteristic not 2) and satisfies the Jacobi identity $[x, [y, z]] + [z, [x, y]] + [y, [z, x]] = 0$. The Jacobi identity is essentially the “derivative” of associativity.
After choosing an ordered basis \((b_1, \ldots, b_n)\) where \(b_i \in \mathbb{F}^n\) of \(V \cong \mathbb{F}^n\), this bilinear map \([,]\) can be represented by an \(n \times n \times n\) 3-way array \(A\), such that \([b_i, b_j] = \sum_{k=1}^{n} A(i, j, k) b_k\). This is the structure constant representation of \(A\). Algorithms for Lie algebras have been studied intensively in this model, e.g., [21,38].

It is also natural to consider matrix spaces that are closed under commutator. More specifically, let \(A \subseteq M(n, \mathbb{F})\) be a matrix space. If \(A\) is closed under commutator, that is, for any \(A, B \in A\), \([A, B] = AB - BA \in A\), then \(A\) is a matrix Lie algebra with the product being the commutator. (Protip: one way to remember the Jacobi identity is to derive it as the natural identity among nested commutators of three matrices.) Algorithms for matrix Lie algebras have also been studied, e.g., [24,36,38].

6.2 Constructive Baer Correspondence and Theorems A and B

Let us review Baer’s Correspondence [7], which connects alternating bilinear maps with \(p\)-groups of class 2 and exponent \(p\). Let \(P\) be a \(p\)-group of class 2 and exponent \(p > 2\). Suppose the commutator subgroup \([P, P] \cong \mathbb{Z}_p^m\) and \(P/[P, P] \cong \mathbb{Z}_p^n\). Then the commutator map \([,] : P/[P, P] \times P/[P, P] \to [P, P]\) is an alternating bilinear map. Conversely, let \(\phi : \mathbb{Z}_p^n \times \mathbb{Z}_p^n \to \mathbb{Z}_p^n\) be an alternating bilinear map. Then a \(p\)-group of class 2 and exponent \(p\), denoted as \(P_\phi\), can be defined as follows. The group elements are from \(\mathbb{Z}_p^n \times \mathbb{Z}_p^n\), and the group product \(\cdot\) is defined as

\[(u, v) \cdot (u', v') = (u + u', v + v' + \frac{1}{2} \phi(u, u')).\]

We say that \((A, B) \in \text{GL}(n, p) \times \text{GL}(m, p)\) is a pseudo-automorphism of \(\phi\), if \(\phi = B \circ \phi \circ A\). Wilson [71] elucidated the structure of \(\text{Aut}(P_\phi)\) in terms of the pseudo-automorph group of \(\phi\), that we denote \(\Psi\text{Aut}(\phi)\). Here we recall the consequence of Wilson’s result that we need for counting group isomorphisms.

\begin{itemize}
  \item \textbf{Proposition 23} (Wilson [71, Prop. 3.8], see [15, Prop. 2.4] for notation closer to ours). For \(\phi : \mathbb{Z}_p^n \times \mathbb{Z}_p^n \to \mathbb{Z}_p^n\) an alternating bilinear map,

  \(|\text{Aut}(P_\phi)| = |\Psi\text{Aut}(\phi)|p^{mn},\)

  where \(\Psi\text{Aut}(\phi)\) denotes the pseudo-automorphism group of \(\phi\).
\end{itemize}

We then state a lemma which can be viewed as a constructive version of Baer’s Correspondence, communicated to us by James B. Wilson.

\begin{itemize}
  \item \textbf{Lemma 24} (Constructive version of Baer’s Correspondence for matrix groups). Let \(p\) be an odd prime. Over the finite field \(\mathbb{F} = \mathbb{F}_p\), \textsc{Alternating Matrix Space Isometry} is equivalent to \textsc{Group Isomorphism} for matrix groups over \(\mathbb{F}\) that are \(p\)-groups of class 2 and exponent \(p\). More precisely, there are functions computable in time \(\text{poly}(n, m, \log |\mathbb{F}|)\):

  \begin{itemize}
    \item \(G : \Lambda(n, \mathbb{F})^m \to M(n + m + 1, \mathbb{F})^{n + m}\) and
    \item \(\text{Alt} : M(n, \mathbb{F})^m \to \Lambda(m, \mathbb{F})^{(m^2)}\)
  \end{itemize}

  such that: (1) for an alternating bilinear map \(A\), the group generated by \(G(A)\) is the Baer group corresponding to \(A\), (2) \(G\) and \(\text{Alt}\) are mutually inverse, in the sense that the group generated by \(G(\text{Alt}(M_1, \ldots, M_m))\) is isomorphic to the group generated by \(M_1, \ldots, M_m\), and conversely \(\text{Alt}(G(A))\) is pseudo-isometric to \(A\).
\end{itemize}

\begin{itemize}
  \item \textbf{Proof.} First, let \(G\) be a \(p\)-group of class 2 and exponent \(p\) given by \(m\) generating matrices of size \(n \times n\) over \(\mathbb{F}\). Then from the generating matrices of \(G\), we first compute a generating set of \([G, G]\), by just computing all the commutators of the given generators. We can then
\end{itemize}
remove those redundant elements from this generating set in time poly(\(\log |G, G|, \log |F|\)), using Lukić's result on computing with solvable matrix groups \([51]\). We then compute a set of representatives of a non-redundant generating set of \(G/[G, G]\), again using Lukić's aforementioned result. From these data we can compute an alternating bilinear map representing the commutator map of \(G\) in time poly(\(n, m, \log |F|\)).

Conversely, let an alternating bilinear map be given by \(A = (A_1, \ldots, A_m) \in \Lambda(n, F)^m\). From \(A\), for \(i \in [n]\), construct \(B_i = [A_1e_i, \ldots, A_me_i] \in M(n \times m, F)\), where \(e_i\) is the \(i\)th standard basis vector of \(F^m\). That is, the \(j\)th column of \(B_i\) is the \(i\)th column of \(A_j\). Then for \(i \in [n]\), construct

\[
\tilde{B}_i = \begin{bmatrix} 1 & e_i^t & 0 \\ 0 & I_n & B_i \\ 0 & 0 & I_m \end{bmatrix} \in \text{GL}(1 + n + m, F),
\]

where \(e_i \in F^n\), and for \(j \in [m]\), construct

\[
\tilde{C}_j = \begin{bmatrix} 1 & 0 & e_j^t \\ 0 & I_n & 0 \\ 0 & 0 & I_m \end{bmatrix} \in \text{GL}(1 + n + m, F),
\]

where \(e_j \in F^m\). Let \(G(A)\) be the matrix group generated by \(\tilde{B}_i\) and \(\tilde{C}_j\). Then it can be verified easily that, \(G(A)\) is isomorphic to the Baer group corresponding to the alternating bilinear map defined by \(A\). In particular, \([G, G] \cong F^m \cong Z_p^m\) (isomorphism of abelian groups), and \(G/[G, G] \cong F^m \cong Z_p^m\). This construction can be done in time poly(\(n, m, \log |F|\)).

Given the above lemma, we can present search- and counting-to-decision reductions for testing isomorphism of a class of \(p\)-groups, proving Theorems A and B.

**Proof of Theorem A.** The search-to-decision reduction follows from Theorem \(A'\), using the \(q^{O(n + m)}\)-time algorithm, with the constructive version of Baer’s Correspondence in the model of matrix groups over finite fields (Lemma 24).

In more detail, given Lemma 24 we can follow the procedure in the proof of Theorem \(A'\). For the given \(p\)-groups, we compute their commutator maps. Then whenever we need to feed the decision oracle, we transform from the alternating bilinear map to a generating set of a \(p\)-group of class 2 and exponent \(p\) with this bilinear map as the commutator map. After getting the desired pseudo-isometry for the alternating bilinear maps, we can easily recover an isomorphism between the originally given \(p\)-groups.

**Proof of Theorem B.** For the counting-to-decision reduction, we basically follow the above routine, but with a twist, because of the minor distinction between alternating matrix space isometry, and alternating bilinear map pseudo-isometry. Let us briefly explain this issue. Suppose from an alternating bilinear map \(\phi: Z_p^n \times Z_p^n \rightarrow Z_p^{nm}\) we constructed the \(p\)-group \(P_\phi\) of class 2 and exponent \(p\); by Proposition 23 \(|\text{Aut}(P_\phi)| = p^{nm}|\Psi \text{Aut}(\phi)|\), so by multiplying the result by \(p^{nm}\), it is necessary and sufficient to count the pseudo-autometries of \(\phi\).

Towards that end, let \((C_1, \ldots, C_m) \in \Lambda(n, p)\) be a matrix representation of \(\phi\). If \(C_i\)’s are linearly independent, then for a pseudo-autometry \((A, B) \in \text{GL}(n, p) \times \text{GL}(m, p)\), given \(A\) there exists a unique \(B\) that makes \((A, B)\) a pseudo-autometry. If \(C_i\)’s are not linearly independent, say the linear span of \(C_i\)’s is of dimension \(m'\), then the number of \(B\) such that \((A, B)\) is a pseudo-autometry (assuming there are any) is \(|M((m - m') \times m', p)||\text{GL}(m - m', p)| = p^{m(m-m')}|\text{GL}(m - m', p)|\). To see this, suppose that we have taken linear combinations of the \(C_i\) so that \(C_1, \ldots, C_{m'}\) are linearly independent and \(C_{m'+1}, C_{m'+2}, \ldots, C_m\) are zero. Then
without changing the $C_i$, we may take any invertible linear combination among $C_{m+1}, \ldots, C_m$ (a copy of $GL(m - m', p)$), and we may add any linear combination of the last $m - m'$ matrices to the first $m'$ matrices (a copy of $M((m - m') \times m', p)$). The counting to decision reduction for Alternating Matrix Space Isometry computes the number of $A \in GL(n, p)$ so that there exists some $B \in GL(m, p)$ such that $(A, B)$ is a pseudo-autometry. So it needs to be multiplied by a factor of $p^{m'(m-m')}/|GL(m - m', p)|$.

6.3 Constructive Lazard’s Correspondence and Theorem P

The Lazard Correspondence [46] is a correspondence between certain classes of groups and Lie algebras, which extends the usual correspondence between Lie groups and Lie algebras (say, over $\mathbb{R}$) to some groups and Lie algebras in positive characteristic. Here we state just enough to give a sense of it; for further details and exposition we refer to Khukhro’s book [43] and Naik’s thesis [60]. While Naik’s thesis is quite long, it also includes a reader’s guide, and collects many results scattered across the literature or well-known to the experts in one place, building the theory from the ground up and with many examples.

Recall that a Lie ring is an abelian group $L$ equipped with a bilinear map $[,]$, called the Lie bracket, which is (1) alternating ($[x, x] = 0$ for all $x \in L$) and (2) satisfies the Jacobi identity $[x, [y, z]] + [y, [z, x]] + [z, [x, y]] = 0$ for all $x, y, z \in L$ (in some sense the “derivative” of the associativity equation). Let $L^1 = L$, and $L^{i+1} = [L, L^i]$, which is the subgroup (of the underlying additive group) generated by all elements of the form $[x, y]$ for $x \in L, y \in L^i$. Then $L$ is nilpotent if $L^{c+1} = 0$ for some finite $c$; the smallest such $c$ is the nilpotency class. (Lie algebras are just Lie rings over a field.)

The correspondence between Lie algebras and Lie groups over $\mathbb{R}$ uses the Baker–Campbell–Hausdorff (BCH) formula to convert between a Lie algebra and a Lie group, so we start there. The BCH formula is the solution to the problem that for non-commuting matrices $X, Y$, $e^X e^Y \neq e^{X+Y}$ in general (where the matrix exponential here is defined using the power series for $e^t$). Rather, using commutators $[A, B] = AB - BA$, we have

$$\exp(X) \exp(Y) = \exp \left( X + Y + \frac{1}{2} [X, Y] + \frac{1}{12} ([X, [X, Y]] - [Y, [X, Y]]) + \cdots \right),$$

where the remaining terms are iterated commutators that all involve at least 4 $X$s and $Y$s, and successive terms involve more and more. Applying the exponential function to a Lie algebra in characteristic zero yields a Lie group. The BCH formula can be inverted, giving the correspondence in the other direction.

In a nilpotent Lie algebra, the BCH formula has only finitely many nonzero terms, so issues of convergence disappear and we may consider applying the correspondence over finite fields or rings; the only remaining obstacle is that the denominators appearing in the formula must be units in the ring. It turns out that the correspondence continues to work in characteristic $p$ so long as one does not need to use the $p$-th term of the BCH formula (which includes division by $p$), and the latter is avoided whenever a nilpotent group has class strictly less than $p$, or even when all subgroups generated by at most 3 elements have class strictly less than $p$. While the correspondence does apply more generally, here we only state the version for finite groups. For any fixed nilpotency class $c$, computing the Lazard Correspondence is efficient in theory; for how to compute it in practice when the groups are given by polycyclic presentations, see [20].

Let $\text{Grp}_{p,n,c}$ denote the set of finite groups of order $p^n$ and class $c$, and let $\text{Lie}_{p,n,c}$ denote the set of Lie rings of order $p^n$ and class $c$. We note that for nilpotency class 2, the Baer Correspondence is the same as the Lazard Correspondence.
Theorem 25 (Lazard Correspondence for finite groups [46], see, e.g., [43, Ch. 9 & 10] or [60, Ch. 6]). For any prime \( p \) and any \( 1 \leq c < p \), there are functions \( \log: \text{Grp}_{p,n,c} \leftrightarrow \text{Lie}_{p,n,c} : \exp \) such that (1) \( \log \) and \( \exp \) are inverses of one another, (2) two groups \( G, H \in \text{Grp}_{p,n,c} \) are isomorphic if and only if \( \log(G) \) and \( \log(H) \) are isomorphic, and (3) if \( G \) has exponent \( p \), then the underlying abelian group of \( \log(G) \) has exponent \( p \). More strongly, \( \log \) is an isomorphism of categories \( \text{Grp}_{p,n,c} \cong \text{Lie}_{p,n,c} \).

Part (3) can be found as a special case of [60, Lemma 6.1.2].

For \( p \)-groups given by \( d \times d \) matrices over the finite field \( \mathbb{F}_p \), we will need one additional fact about the correspondence, namely that it also results in a Lie algebra of \( d \times d \) matrices. (Being able to bound the dimension of the Lie algebra and work with it in a simple linear-algebraic way seems crucial for our reduction to work efficiently.) In fact, the BCH Correspondence is easier to see for matrix groups using the matrix exponential and matrix logarithm; most of the work for BCH and Lazard is to get the correspondence to work even without the matrices. In some sense, this is thus the “original” setting of this correspondence. Though it is surely not new, we could not find a convenient reference for this fact about matrix groups over finite fields, so we state it formally here.

Proposition 26 (cf. [43, Exercise 10.6]). Let \( G \leq \text{GL}(d, \mathbb{F}_p^e) \) be a finite \( p \)-subgroup of exponent \( p \), consisting of \( d \times d \) matrices over a finite field of characteristic \( p \). Then \( \log(G) \) (from the Lazard Correspondence) can be realized as a finite Lie subalgebra of \( d \times d \) matrices over \( \mathbb{F}_p \). Given a generating set for \( G \) of \( m \) matrices, a generating set for \( \log(G) \) can be constructed in \( \text{poly}(d, n, e \log p) \) time.

Khukhro [43] gives the characteristic zero analogue of this result (minus the straightforward complexity analysis) for the full group of upper unitriangular matrices as Exercise 10.6. One way to see Proposition 26 is to use the characteristic zero result, apply the fact that these isomorphisms are in fact equivalence of categories (and thus hold for subgroups/subalgebras as well), and note that the same formulae in characteristic zero apply in characteristic \( p \) so long as one never needs to divide by \( p \). We now sketch the argument.

Proof sketch. First we use the standard embedding of \( \text{GL}(d, \mathbb{F}_p^e) \) into \( \text{GL}(de, \mathbb{F}_p) \) (replace each element by an \( e \times e \) block which is the left regular representation of \( \mathbb{F}_p^e \) acting on itself as an \( e \)-dimensional \( \mathbb{F}_p^e \)-vector space), to realize \( G \) as a subgroup of \( \text{GL}(de, \mathbb{F}_p) \). \( G \) is conjugate in \( \text{GL}(de, \mathbb{F}_p) \) to a group of upper unitriangular matrices (upper triangular with all 1s on the diagonal); this is a standard fact that can be seen in several ways, for example, by noting that the group \( U \) of all upper unitriangular matrices in \( \text{GL}(de, \mathbb{F}_p) \) is a Sylow \( p \)-subgroup, and applying Sylow’s Theorem. (Note that we do not need to do this conjugation algorithmically, though it is possible to do so [27,36,64]; this is only for the proof.) Thus we may write every \( g \in G \) as \( 1 + n \), where the sum here is the ordinary sum of matrices, \( 1 \) denotes the identity matrix, and \( n \) is strictly upper triangular. To see that we can truncate the Taylor series for logarithm before the \( p \)-th term (thus avoiding needing to divide by \( p \)), note that \( (1+n)^p = 1 \) since \( G \) is exponent \( p \). We have \((1+n)^p = 1^n + \binom{p}{1} n + \binom{p}{2} n^2 + \cdots + \binom{p}{i-1} n^{i-1} + n^p \). Since these are matrices over a field of characteristic \( p \), and \( p \) for all \( 1 \leq i \leq p-1 \), all the intermediate terms vanish and we have that \((1+n)^p = 1^n + n^p \). Thus \( 1 = (1+n)^p = 1 + n^p \), so we get that \( n^p = 0 \). Thus, in the the Taylor series for the logarithm

\[
\log(1+n) = -\frac{n^2}{2} + \frac{n^3}{3} - \cdots
\]

the last nonzero term is \( n^{p-1}/(p-1) \), so we may use this Taylor series even over \( \mathbb{F}_p^e \).
The main things to check are that the set \( \log(G) := \{ \log(1 + n) : 1 + n \in G \} \) is closed under scalar multiplication, matrix addition, and matrix commutator \([X, Y] = XY - YX\).

Suppose \( g_1, g_2 \) are matrices in \( G \), and write them as \( g_i = 1 + n_i \) \((i = 1, 2)\), as above. We recall that, because \( n_i^p = 0 \) from above, the power series for both \( \log \) and \( \exp \) work to compute the matrix logarithm and exponential over \( \mathbb{F}_p \), respectively, and that the usual rules of logarithms are satisfied for a single matrix \( A \): whenever \( A \in M_{de}(\mathbb{F}_p) \) satisfies \( A^p = 0 \), we have \( \log \exp A = A \), \( \log \exp(1 + A) = 1 + A \), \( \exp(nA) = (\exp A)^n \) for \( n \in \mathbb{Z} \), and \( \log((1 + A)^n) = n \log(1 + A) \).

- **Scalar multiplication:** For \( \alpha \in \mathbb{F}_p \), we show that \( \alpha \log(1 + n_1) \) is in \( \log(G) \). This is easy to show, as it follows directly from the rules of logarithms just mentioned: \( \alpha \log(1 + n_1) = \log((1 + n_1)^\alpha) \) where on the right-hand side we treat \( \alpha \) as an integer in the range \([0, p - 1]\). (This is the only point where we are using that we are working over \( \mathbb{F}_p \) now rather than \( \mathbb{F}_{p^r} \).)

- **Addition:** Let \( x_i = \log(1 + n_i) \) for \( i = 1, 2 \). We want to show that \( x_1 + x_2 \) is in \( \log(G) \), or equivalently that \( \exp(x_1 + x_2) \in G \). This follows from the first inverse BCH formula \( h_1 \), which satisfies \( \exp(x_1 + x_2) = h_1(\exp(x_1), \exp(x_2)) \) for \( \hat{x}_i \) in the free nilpotent-of-class-\( c \) \( \mathbb{F}_p \)-Lie algebra, and then we may apply the homomorphism from the latter algebra to the subalgebra of \( M_n(\mathbb{F}_p) \) generated by the \( n_i \) to see that the same formula works. (We note, because a reviewer asked, that here we do not need this entire subalgebra to be in \( \{ g - 1 : g \in G \} \); the use of that subalgebra is just convenient for talking about algebra homomorphisms in the proof. Rather, it suffices that the preceding equation holds for these particular elements \( n_i \), which are by definition of the form \( g_i - 1 \) for some matrices \( g_i \in G \).)

- **Commutator:** \( \log([1 + n_1], [1 + n_2]) \). A similar argument as in the previous case works, using the second inverse BCH formula \( h_2 \), which satisfies \( \exp([\hat{x}_1, \hat{x}_2]) = h_2(\exp(\hat{x}_1), \exp(\hat{x}_2)) \).

Equivalently, we may note that the derivation of the inverse BCH formulas in [43] uses a free nilpotent associative algebra as an ambient setting in which both the group (or rather, \( n \) such that \( 1 + n \) is in the group) and the corresponding Lie algebra live; in our case, we may replace the ambient free nilpotent associative algebra with the algebra of \( de \times de \) strictly upper-triangular matrices over \( \mathbb{F}_p \), and all the derivations remain the same, *mutatis mutandis*. See, for example, [43, p. 105, “Another remark...”].

### 6.3.1 Class reduction in \( p \)-group isomorphism testing

Proposition 26 now allows us to prove Theorem P.

**Proof of Theorem P.** By the Lazard Correspondence (reproduced as Theorem 25) two \( p \)-groups of exponent \( p \) and class \( c < p \) are isomorphic if and only if their corresponding \( \mathbb{F}_p \)-Lie algebras are. By Proposition 26, we can construct a generating set for the corresponding \( \mathbb{F}_p \)-Lie algebra by applying the power series for logarithm to the generating matrices of \( G \).

This Lie algebra is thus a subalgebra of \( ne \times ne \) matrices over \( \mathbb{F}_p \), so we can generate a basis for the entire Lie algebra (using the linear-algebra version of breadth-first search; its dimension is \( \leq (ne)^2 \)) and compute its structure constants in time polynomial in \( n, m \), and \( e \log p \). Then use [28] to reduce isomorphism of Lie algebras to 3-TENSOR ISOMORPHISM, and then use the fact that isomorphism of \( p \)-groups of exponent \( p \) and class 2 given by a matrix generating set over \( \mathbb{F}_p \) is \( \text{T1-complete} \) [32] to reduce to the latter problem. ▶
Conclusion

In this paper, we gave first-of-their-kind results around search-to-decision, counting-to-decision, and reductions to hard instances in the context of Group Isomorphism. We focused on $p$-groups of class 2 (or more generally small class) and exponent $p$, as these are widely believed to be the hardest cases of GPI. They also have the closest connection with tensors.

We view this paper as the second in a planned series, focusing on isomorphism problems for tensors, groups, polynomials, and related structures. Although Graph Isomorphism (GI) is perhaps the most well-studied isomorphism problem in computational complexity – even going back to Cook’s and Levin’s initial investigations into NP (see [1, Sec. 1]) – it has long been considered to be solvable in practice [55,56], and Babai’s recent quasi-polynomial-time breakthrough is one of the theoretical gems of the last several decades [3]. However, several isomorphism problems for tensors, groups, and polynomials seem to be much harder to solve, both in practice – they’ve been suggested as difficult enough to support cryptography [39,61] – and in theory: the best known worst-case upper bounds are barely improved from brute force (e.g., [49,66]). As these problems arise in a variety of areas, from multivariate cryptography and machine learning, to quantum information and computational algebra, getting a better understanding of their complexity is an important goal with many potential applications.

In the first paper in this series [32], we showed that numerous such isomorphism problems from many research areas are equivalent under polynomial-time reductions, creating bridges between different disciplines. The Tensor Isomorphism (TI) problem turns out to occupy a central position among these problems, leading us to define the complexity class TI, consisting of those problems polynomial-time reducible to the Tensor Isomorphism problem. The gadgets and TI-completeness result from that first paper in some cases opened the door, and in other cases are used as subroutines, in the main results of the current paper.

Finally, we list here some additional questions that we find interesting and approachable. One question is whether our tensor-based methods here can be extended or combined with other methods to get analogous results in wider classes of groups; for isomorphism algorithms, something along these lines was proposed by Brooksbank, Grochow, Li, Wilson, & Qiao [12], but there are many interesting open questions in this direction.

Getting the results of this paper to work in the Cayley table model would also be interesting from the complexity-theoretic perspective; the necessary ingredients are discussed in Remark 2.

Lastly, we mention that extending the results of the present paper, [28], and [32] to rings beyond fields would be very interesting. In particular, working with tensors over $\mathbb{Z}/p^k\mathbb{Z}$ is an important step towards extending the results of this paper to $p$-groups of class 2 without restricting them to exponent $p$. (This is particularly important when $p = 2$, as groups of exponent 2 are abelian, so the hardest instances of 2-groups, rather than “$p$-groups of class 2 and exponent $p$” with $p = 2$, are often taken to be 2-groups of class 2 and exponent four.)

It seems conceivable that many of our arguments could extend to tensors over local rings – those with a unique maximal ideal – as many of our arguments are rank-based, and rank still has nice properties over local rings (e.g. Nakayama’s Lemma). In particular, if $R$ is a ring and $m$ a maximal ideal, then $R/m$ is a field; in a local ring, there is a unique maximal ideal, so the field $R/m$ is canonically associated to $R$, and one can talk cleanly about rank and dimension of $R$-modules considered over the field $R/m$. Besides $\mathbb{Z}/p^k\mathbb{Z}$, another local ring of interest is the ring $\mathbb{F}[[t]]$ of power series in one variable over a field $\mathbb{F}$; a tensor over $\mathbb{F}[[t]]$ is essentially a 1-parameter family of tensors over $\mathbb{F}$, so studying tensor problems over $\mathbb{F}[[t]]$ could have applications to border rank and geometric complexity theory.

Abstract
Restricted branching programs capture various complexity measures like space in Turing machines or
length of proofs in proof systems. In this paper, we focus on the application in the proof complexity
that was discovered by Lovasz et al. [14] who showed the equivalence between regular Resolution and
read-once branching programs for “unsatisfied clause search problem” (Search). This connection is
widely used, in particular, in the recent breakthrough result about the Clique problem in regular
Resolution by Atserias et al. [5].

We study the branching programs with bounded repetitions, so-called (1, +k)-BPs (Sieling [21])
in application to the Search problem. On the one hand, it is a natural generalization of read-once
branching programs. On the other hand, this model gives a powerful proof system that can efficiently
certify the unsatisfiability of a wide class of formulas that is hard for Resolution (Knop [13]).

We deal with Search that is “relatively easy” compared to all known hard examples for
the (1, +k)-BPs. We introduce the first technique for proving exponential lower bounds for the
(1, +k)-BPs on Search. To do it we combine a well-known technique for proving lower bounds on
the size of branching programs [12,21,22] with the modification of the “closure” technique [1,3].
In contrast with most Resolution lower bounds, our technique uses not only “local” properties of
the formula, but also a “global” structure. Our hard examples are based on the Flow formulas
introduced in [3].

1 Introduction

Branching program is a computational model that generalizes decision tree in the most
natural way: the underlying graph of computation can be an arbitrary directed acyclic graph.
This is one of the most fundamental models in theoretical computer science: it captures the
space complexity of many versions of restricted and unrestricted Turing machines, various
proof systems may be described in terms of this model, etc.
A Shannon’s style counting argument says that there is a boolean function such that any branching program that computes this function requires an exponential size. However for an explicit function, we are still far from a superpolynomial lower bound, and the best known result is $n^2 \log^2 n$ due to Nechiporuk [16].

For some applications, it is enough to deal with the restricted models of branching programs and many such models were considered. One of the most popular restrictions is the read-once model of branching programs [15] where any input bit may be queried at most once during each computation. This model corresponds to the eraser Turing machines. Exponential lower bounds for this model were proven in [24,26]. For capturing more general machines some natural generalization of read-once branching programs were studied. And one of the most important models among these generalizations is the model with bounded repetitions aka $(1, k)$-BP that was described in [21]. In this model, we allow our branching programs to requery variables, but on each computation only $k$ input bits may be queried more than one time. There are two natural points of view on this model:

- syntactic: if we apply the restriction on every path;
- semantic: if we apply the restriction on consistent paths

(for formal definition see section 2.1). The semantic version is more powerful and may capture strong Turing machine models (for details see [12]).

Exponential lower bounds on $(1, k)$-BP were shown in [12,20–22] for various parameters $k$. Lower bounds from [12] hold for $k = \Omega \left( \frac{n \log n}{\log \log n} \right)$ and the lower bound from [10] holds even for $k = \Omega(n)$, where $n$ is the number of input bits. We refer the reader to the books [11,25] with the detailed description of results related to branching programs.

Lower bounds for $(1, k)$-BP described above are given for “complicated” functions (usually it is characteristic functions of an error-correcting code with additional properties). In particular, these functions are complicated in terms of the certificate complexity. Unfortunately, for some applications, it is not enough. Following [14], we have a connection between proof systems and branching programs in application to the “unsatisfied clause search problem”. Hence for the lower bounds in proof complexity we want to deal with this search problem, which is an “easy” problem. Namely, it can be described by a small collection of certificates. In this paper we introduce a technique for proving such lower bounds on the semantic $(1, k)$-BP where $k = O \left( \log n / \log \log n \right)$ where $n$ is the number of variables.

### 1.1 Search Problem and Proof Systems

Consider a search problem, defined by a relation $S \subseteq \mathcal{I} \times \mathcal{O}$ for some finite sets $\mathcal{I}$ and $\mathcal{O}$. On input $x \in \mathcal{I}$ the search problem is to find some output in $S(x) := \{ o \in \mathcal{O} \mid (x,o) \in S \}$.

In this paper we study the “unsatisfied clause search problem” for a CNF formula.

**Definition 1.** A unsatisfied search problem $\text{Search}_\varphi$ for an unsatisfiable CNF formula $\varphi := \bigwedge_{i \in I} C_i$ on $n$ variables is defined as follows:

- input: an $n$-variable assignment $z \in \{0,1\}^n$;
- output: an element $i \in I$ such that clause $C_i$ of $\varphi$ is falsified by $z$.

Informally speaking, we may think that if we can solve the $\text{Search}_\varphi$ problem in some computational model $\mathcal{C}$, then the description of $C \in \mathcal{C}$ that solves $\text{Search}_\varphi$ is a “certificate of unsatisfiability” of a formula $\varphi$. So we may think of this model as a proof system. We do not want to formalize this statement for a general computational model, but we prove the formal statement for the branching programs (see section 5).
The proof system that is defined by the read-once branching programs is equivalent to regular Resolution [14]. This connection is widely used in proof complexity. As an example, we can consider first lower bounds on the regular Resolution and Resolution proofs of the Weak Pigeonhole Principle [17,18], recent breakthrough result: a lower bound on the regular Resolution proofs of the Clique formulas [5].

The connection between regular Resolution and branching programs makes it interesting to consider some less restricted models of branching programs in application to the Search problems. Some of these models were considered in [13]. In this paper we focus on (1, +k)-BP’s. Despite the success in proving lower bounds on the Resolution (and hence read-once programs) the lower bounds for (1, +k)-BP on the Search are an open question even for k = 1.

Previous Techniques

The behaviour of branching programs on functions differs from the behaviour on the Search problem. For example, the unrestricted programs may solve Search for any φ in linear size (we can implement a simple algorithm that checks clauses of φ step by step). Informally speaking, as we said above, the lower bounds for functions on (1, +k)-BP [12,20–22] heavily used the fact that there is no efficient description of these functions in terms of certificates. However Search is defined by a small set of certificates. Considering this difference, it is unclear how to use the classical techniques for our problem.

Another issue is that (1, +k)-BP is much stronger than general Resolution on some classes of formulas [13] even for small constant k and syntactic model. This is a crucial observation and it means that we cannot directly apply general techniques for proving lower bounds in proof complexity like [3,6] etc., since these techniques cannot distinguish between considered classes of formulas and other hard examples for Resolution. Hence if we want to prove lower bound for (1, +k)-BP on Search we need some additional arguments in comparison to Resolution lower bounds.

1.2 Our Results

The main result is an exponential lower bound on the size of (1, +k)-BPs in application to Search for k = O \left( \frac{\log n}{\log \log n} \right).

\textbf{Theorem 2.} For n \in \mathbb{N} and k_0 := k_0(n) there is an unsatisfiable formula \varphi on n variables of size n^{O(k_0)} such that any semantic (1, +k_0)-BP solving Search requires size \exp \left[ \Omega \left( \frac{n}{(\log n)^{1.7}} \right) \right].

We also show that (1, +k)-BPs define a proof system in terms of Cook–Reckhow definition [7] (1, +k)-BP-PS (see section 5). That is a generalization of the result from [13], where it was shown only for \ell-CNFS where \ell is an absolute constant.

\textbf{Theorem 3.} A syntactic (1, +k)-BP-PS is a proof system in terms of Cook–Reckhow definition for any constant k \in \mathbb{N}.

1.3 Technique

The key ingredients for the lower bound are:

- garlands: aka (s, ℓ)-chains, that is a standard technique for proving lower bounds on the branching programs [11,12,20–22];
- closure: a technique that allows to make large partial restriction and keep the search problem hard for branching programs (and proof systems) [1,3];
amplification: a trick from [2] that makes formula hard for regular Resolution (and
read-once branching programs) and help us to force the branching program to use the
repetitions in a very structured way;

Flow-Cut: the famous Theorem [8] that shows the duality between the maximum flow
and the minimum cut, that we use to extend partial assignments to total assignments
with good properties.

Let us introduce a general sketch of the proof. In section 4.1 we define an unsatisfiable
formula $\text{Flow}_G$ [3] that states: in graph $G$ we have a source of a flow but there is no sink.
We require graph $G$ to be an algebraic expander, but, in fact, we need two properties:

- $G$ is a combinatorial expander; namely, each set of vertices of size at most $r = \Omega \left( \frac{n \log n}{\log \log n} \right)$
  has a lot of neighbours (this is a “local” property, since we care only about small enough
  sets);
- max-balanced-cut of the graph $G$ is large enough (this is a “global” property of the graph
  $G$), where “balanced” means that each piece has size at least $\Omega(r)$.

It is not clear how to show the lower bound for this formula itself and we amplify $\text{Flow}_G$
formulas by using the trick from [2]. Denote the result of amplification by $\varphi$.

1. For the sake of contradiction we assume that we have a small $(1, +k)$-BP solving $\text{Search}_\varphi$.
   We generate a big family of paths and, using the upper bound on the size of our program,
   we find some paths in the program that form a “garland” structure (see section 4). This
   idea is similar to the idea from [12].
2. These paths correspond to some assignments and we keep our formula “hard” under
   these assignments. To do it we use a modification of the “closure” technique [3] (an
   easier version of this iterative modification was used in [23]). Here we use a combinatorial
   expansion of the graph $G$.
3. By using the fact that we deal with an amplified version of $\text{Flow}_G$ we show that from the
   end point of paths that form the garland we cannot reach any leaf that is marked by one
   of the clauses from some set $T \subseteq \varphi$. Here we use the fact that $k$ is small enough.
4. To conclude the proof, we use the Max-Flow Min-Cut Theorem (and global properties of
   our graph) to show that there should be some path from the garland to some clause from
   the set $T$.

See section 4 for more details.

2 Preliminaries

Let $X$ be a set of boolean variables. For a variable $x \in X$ we denote $x^1 := x$ and $x^0 := \neg x$.
We say that $\alpha: X \to \{0, 1, *, ?\}$ is a generalized partial assignment and $\alpha$ assigns
or touches $x \in X$ iff $\alpha(x) \in \{0, 1, ?\}$. And an assignment $\gamma$ is an instance of $\alpha$ iff:

- $\alpha(x) \in \{0, 1, *\}$ implies $\gamma(x) = \alpha(x)$;
- $\alpha(x) = ?$ implies $\gamma(x) \in \{0, 1\}$.

If $\alpha$ and $\beta$ are two partial assignments to variables from the set $X$, we say that a
generalized partial assignment $\alpha \cup \beta: X \to \{0, 1, *, ?\}$ is a joint assignment iff:

- if $\alpha(x) = a$ and $\beta(x) \in \{a, *, ?\}$, then $\alpha \cup \beta(x) = a$;
- if $\beta(x) = a$ and $\alpha(x) \in \{a, *, ?\}$, then $\alpha \cup \beta(x) = a$;
- if $\alpha(x) = a$ and $\beta(x) = 1 - a$, then $\alpha \cup \beta(x) = ?$;
- if $\alpha(x) = \beta(x) = *$, then $\alpha \cup \beta(x) = *$,
where $a \in \{0, 1\}$.

We will also use the famous Max-Flow Min-Cut Theorem.
Theorem 4 (Max-Flow Min-Cut [8]). Let $G := (V, E)$. For any $s, t \in V$ the maximum value of an $s$-$t$ flow is equal to the minimum capacity over all $s$-$t$ cuts.

2.1 Branching Programs

Let $X := \{x_1, \ldots, x_n\}$ be a set of propositional variables and $O$ be a finite set. A branching program is a directed acyclic graph with one source. Every vertex of the graph is labeled by a variable from $X$, or by an element of the set $O$ with respect to the following properties:

- if a vertex is labeled by $o \in O$, then it is a sink;
- if a vertex is labeled by a variable, then it has exactly two outgoing edges: one edge is labeled by $0$ and the other one is labeled by $1$.

Every branching program $B$ defines a function $f_B : \{0, 1\}^n \rightarrow O$. We assume that every input $z \in \{0, 1\}^n$ induces a path from source to sink in a natural way. If this path ends in a vertex with a label $o \in O$ then we define $f_B(z) := o$.

We say that $B$ is a branching program for the relation $S \subseteq \{0, 1\} \times O$ iff $f_B$ is consistent with $S$: namely if $f_B(z) = o$ then $(z, o) \in S$.

Let $D$ be a branching program and $v$ is a node in it. The subprogram of $D$ with the root $v$ we denote by $D(v)$ and define as the subgraph of $D$ that is reachable from $v$. Also for a partial assignment $\rho$ we define a branching program $D|\rho$ as the following transformation applied to $D$:

- for each variable $y$ to which $\rho$ assigns a value $a$, contract edges $y = a$ and delete edges $y = \neg a$;
- delete all vertices that are unreachable from the root.

These operations only decrease the size of the program.

If $p$ is a consistent path in a branching program, we denote a partial assignment that corresponds to this path by $\tau_p$.

Let us also define some classical restrictions of the general branching programs.

Definition 5. Let $B$ be a branching program. We say that $B$ is a (syntactic) read-once branching program or 1-BP iff on every path from the source to a sink we can see each variable at most once.

We say that $B$ is a $(1, +k)$-BP iff on every path $p$ from the source to a sink there is a set of variables $X_p$ of size at most $k$ such that all other variables appear in $p$ at most once. And we can twist this definition a little bit and say that $B$ is a semantic $(1, +k)$-BP iff on every consistent path from source to sink there is a set of variables $X_p$ of size at most $k$ such that all other variables appear in $p$ at most once.

If a branching program $B$ computes a boolean function, we say that it is satisfiable iff $f_B$ is not identically zero.

Theorem 6 (Savický [19]). There is an algorithm to check a satisfiability of a syntactic $(1, +k)$-BP in time $O \left[ \left( \frac{4n}{k+1} \right)^k sn \right]$.

The following algorithm also will be useful for us.

Theorem 7 (Savický [19]). The test whether an input branching program is a syntactic $(1, +k)$-BP can be done in time $O \left[ \left( \frac{3n}{k+1} \right)^{k+1} s \right]$.

The next observation is natural and extremely useful for proving lower bounds.
17:6 Branching Programs with Bounded Repetitions and Flow Formulas

Lemma 8. Let $D$ be a $(1, +k)$-BP for $\text{Search}_2$, $p$ be a consistent path from the root to some node $v$. If $p$ has a variable $x$ queried more than one time on it then $D(v)|_{r_p}$ is a $(1, +(k-1))$-BP for the $\text{Search}_{2|r_p}$. The result holds for both: semantic and syntactic models.

Proof. A program $D(v)|_{r_p}$ is a program for the $\text{Search}_{2|r_p}$ by the correctness of the program $D$. Consider a path $s$ in $D$ from $v$ to some leaf. Let $X_s$ be a set of variables that are queried more than one time on $s$. If $|X_s| = k$ and $x \notin X_s$, the path $ps$ has at least $k + 1$ variables that are queried more that one time. This is a contradiction. If $|X_s| = k$ and $x \in X_s$, note that in $D(v)|_{r_p}$ we contract all edges that correspond to the $x$ variable and hence we transform this path into a path with at most $k - 1$ repetitions.

3 Expanders

We are given a graph $G = (V, E)$. For two subsets of vertices $A, B$ we write $E(A, B)$ to denote the set of pairs $(v, e)$ where $v \in A$, $e$ is an edge that is incident to $v$ and $e$ connects $v$ with some vertex in $B$. We will think about it as about set of edges between $A$ and $B$, but if $A$ and $B$ intersect we count edges within intersection twice. We also use a shortcut notations $E(S) := E(S, V)$ and $\overline{S} := V \setminus S$. If the graph we consider is unclear from the context we specify it as a subscript: $E_G(A, B)$.

Remark 9. Assuming that $G$ is $\Delta$-regular graph this definition allows us to use natural equalities:

$|E(S)| = \Delta |S|$;
$|E(A, \overline{A})| = \Delta |A| - |E(A, A)|$.

We write $N_G(v)$ to denote the set of neighbours of $v$ in the graph $G$. We extend this notion to sets and denote by $N_G(S) := \{v \mid \exists u \in S, (u, v) \in E\}$ the neighbourhood of a set of vertices $S \subseteq V$.

A graph $G := (V, E)$ is an $(n, \Delta, \alpha)$-algebraic expander (or just expander), if:

$|V| = n$;
the degree of any vertex $v \in V$ equals $\Delta$;
the absolute value of the second largest eigenvalue of the adjacency matrix of $G$ is at most $\alpha \Delta$.

Lemma 10 (Mixing Lemma [4]). Let $G := (V, E)$ be an $(n, \Delta, \alpha)$-expander. For any two subsets $A, B \subseteq V$ the following holds:

$$\left| |E(A, B)| - \frac{|A||B|}{n} \right| \leq \alpha \Delta \sqrt{|A||B|}.$$

We also need combinatorial edge expansion. We say that $G := (V, E)$ satisfies $(r, \beta)$-(edge) expansion property for some $r, \beta > 0$, if for all $S \subseteq V$ of size at most $r$ holds $E(S, \overline{S}) \geq \beta \Delta |S|$. The Mixing Lemma says that any expander graph satisfies expansion property for suitable parameters.

Corollary 11. If $G := (V, E)$ is an $(n, \Delta, \alpha)$-expander, then for any $0 < \beta < 1 - \alpha$ the graph $G$ satisfy $((1 - \alpha - \beta)n, \beta)$-expansion property.

Proof. Consider some $A \subseteq V$ of size at most $(1 - \alpha - \beta)n$. Note that $|E(A, \overline{A})| = \Delta |A| - |E(A, A)|$. By Mixing Lemma:

$$|E(A, A)| \leq \frac{|A|^2}{n} + \alpha \Delta |A| = \Delta |A| \left( \frac{|A|}{n} + \alpha \right) \leq \Delta |A|(1 - \beta).$$

Hence $|E(A, \overline{A})| \geq \beta \Delta |A|$ by Remark 9.
The “vertex analog” of the next proposition is well known in the literature (for example [9]). We turn it into edge version.

**Proposition 12.** Let $G := (V,E)$ be a graph of degree $\Delta$. If $G$ satisfies $(r, \beta)$-expansion property then for any set $S \subseteq V$ of size $k \leq r$ there is an enumeration $v_1, v_2, \ldots, v_k \in S$ and a sequence $R_1, \ldots, R_k \subseteq E(S)$ such that:

- $R_i = E(\{v_i\}, V \setminus \{v_1, v_2, \ldots, v_{i-1}\})$;
- $|R_i| \geq \beta \Delta$.

**Proof.** We create this sequence in reversed order. Since $|S| \leq r$, it holds that $|E(S, S)| \geq \beta \Delta |S|$ and there is a vertex $v_k \in S$ such that $|E(\{v_k\}, S)| \geq \beta \Delta$. Let $R_k := |E(\{v_k\}, S)|$, and repeat the process for $S \setminus \{v_k\}$.

4 Lower Bounds for $(1, +k)$-BP

In this section, we will prove the following theorem:

**Theorem 13 (2).** For $n \in \mathbb{N}$ and $k_0 := k_0(n)$ there is an unsatisfiable formula $\varphi$ on $n$ variables of size $n^{O(k_0)}$ such that any semantic $(1, +k_0)$-BP solving $\text{Search}_\varphi$ requires size $\exp[\Omega(n^{2 O(k_0)})]$.

Let us describe the main ideas used in the proof. To prove this Theorem we would like to construct an exponentially big set of paths, which cannot be compactly “glued” together in $(1, +k)$-BP, correctly solving $\text{Search}_\varphi$.

To give a detailed plan we need an auxiliary definition.

**Definition 14.** A $\ell$-garland in a branching program is a pair of paths $(a, b)$ from the root such that $a := v_0a_1v_1a_2v_2a_3 \ldots a_{\ell}v_{\ell}$ and $b := v_0b_1v_1b_2v_2b_3 \ldots b_{\ell}v_{\ell}$ where $a_i, b_i$ are possibly empty paths and paths $v_ja_{j+1}v_{j+1}$ and $v_jb_{j+1}v_{j+1}$ are different for all $0 \leq j < \ell$ (see Fig. 1).

![Figure 1](image-url) 2-garland.

Let us consider the detailed plan.

1. By induction on $k$ we want to show that $\text{Search}_{\varphi|\rho}$ is hard for $(1, +k)$-BP even after some “good” restriction $\rho$.
2. For the sake of contradiction we assume that we have a small $(1, +k)$-BP solving $\text{Search}_{\varphi|\rho}$.
   In the section 4.2.1 we generate a family of paths starting from the root of the program and find in this family a $(k+1)$-garland (see Fig. 1). This idea is similar to [12].
3. To argue that we can find a garland we generate exponentially many paths by walking from root (section 4.2). During this process, we have to make sure that on these paths our branching program cannot determine an answer (that would mean that we cannot walk anymore). To avoid it we use the “closure” technique that is motivated by technique from [1,3] and avoid “local contradictions”. And hence we have to choose the formula $\varphi$ very carefully, but we still have some freedom.
If we found a repetition while constructing a garland, we use Lemma 8 and apply induction hypothesis. This is a place where we use that formula \( \varphi \) is still hard even after the restriction.

In the section 4.2.2 we combine different parts of garland and argue about the reachability of certain leaves. We have to make sure that the paths we consider are consistent and that when we reach the endpoint of the garland, formula \( \varphi \) remains hard. We achieve it by using the following properties.

We have already removed repetitions from the garland by using Lemma 8 and induction hypothesis.

To show that combinations of different parts of the garland give us consistent paths we equip the closure technique by the notion of “strongly satisfied” (see Section 4.1.1) constraints. This is the second place that requires specific properties of the formula \( \varphi \).

At the end of this section, we will have a set of clauses \( C \subseteq \varphi \) such that leaves marked by elements of this set should be unreachable from the endpoint of the garland.

For the last part (section 4.2.3) we consider an arbitrary path \( r \) in our garland and note that \( \varphi \setminus C \) is a satisfiable formula even under the restriction \( \tau_r \). It is hard to show this property for the formulas that encode natural combinatorial principles. We use the trick from [2] to change the formula \( \varphi \) to make sure that \( C \) is large enough.

Here we use the global structure of our formula \( \varphi \) (in our case we use the Max-Flow Min-Cut Theorem) to satisfy all clauses in \( \varphi \setminus C \).

We start with defining the hard formulas on a suitable expander graph.

### 4.1 Hard Formulas

Let \( G := (V, E) \) be a directed graph. Each edge \( e \in E \) has the corresponding variable \( x_e \), where \( x_e = 1 \) indicates that a flow of size 1 is going through an edge \( e \). Let \( u \) be an arbitrary, but fixed vertex of the graph.

The formula \( \text{Flow}_{G,u} \) consists of the following constraints written in CNF for all \( v \in V \):

\[
\sum_{e \in E: \text{st}(e) = v} x_e - \sum_{e \in E: \text{en}(e) = v} x_e \geq c(v),
\]

where \( c = (\text{st}(e), \text{en}(e)) \) and \( c: V \to \{0, 1\} \) is a labeling function:

- \( c(v) = 0 \), for all \( v \in V \setminus \{u\} \);
- \( c(u) = 1 \).

This formulas states: for all vertices in the graph the flow is non-negative, and at least for one vertex it is strictly positive. It is easy to see that \( \text{Flow}_{G,u} \) is unsatisfiable. We omit index \( u \) since in our applications it is an arbitrary vertex.

We use the most naive CNF encoding of these constraints. We represent each constraint separately. Consider a vertex \( v \in V \) and a set of edges \( E_v := \{e_1, e_2, \ldots, e_s\} \subseteq E \) that are incident to \( v \). Let \( \rho_v : E_v \to \{0, 1\} \) be an assignment that violates the constraint in \( v \). In this case we add to the formula a clause \( C \):

\[
x_{e_1}^{1-\rho(x_{e_1})} \lor x_{e_2}^{1-\rho(x_{e_2})} \lor \cdots \lor x_{e_s}^{1-\rho(x_{e_s})},
\]

and we also say that this assignment has a gap:

\[
g(\rho_v) := c(v) - \sum_{e \in E: \text{st}(e) = v} \rho_v(x_e) + \sum_{e \in E: \text{en}(e) = v} \rho_v(x_e).
\]
For our purpose we consider $\text{Flow}_G$ based on expanders. To be precise, we start with a graph $G$ that is an $(n, \Delta, \alpha)$-expander, where $\Delta = \Theta(\log n)$ and $\alpha$ is some fixed constant, and replace each undirected edge by two directed edges (we say that these edges are dual). The exact value of $\Delta$ depends on a value of $k$.

**Remark 15.** We consider only proper partial assignments $\rho$ that satisfy the following property for all pairs of dual edges $(e, e')$:
- $\rho(x_e) \in \{0, 1\}$ iff $\rho(x_{e'}) \in \{0, 1\}$;
- if $\rho(x_e) = 1$ then $\rho(x_{e'}) = 0$.
We also identify supp($\rho$) with an undirected set of edges that are assigned by $\rho$.

To make the formula somewhat “confusing” for $(1, +k)$-BP, we would like to add more variables to clauses. These variables do not really affect the physical meaning of the formula, but make it hard for $(1, +k)$-BP to extract additional information from repetitions on paths. This transformation is sensitive to the exact CNF encoding of the constraints that is written above.

**Definition 16.** Let $G := (V, E)$ be an undirected graph and $C_v$ be a subset of clauses corresponding to vertex $v$ in $\text{Flow}_G$. Let $\eta^k_v : C_v \rightarrow \binom{(E)}{k}$ be a mapping, and $\eta^k := \{\eta^k_v | v \in V\}$ be a family of such mappings. We define $\text{Flow}^k_G$ the following way:
- for each $v \in V$ we consider each $C \in C_v$;
- we take $\eta^k(C) = \{e_1, \ldots, e_k\}$, which is a set of $k$ edges;
- we replace $C$ by $2^{2k}$ clauses of the form:

$$C \lor \bigvee_{i} x_{s_i}^{a_i} \lor x_{s'_i}^{a'_i}$$

enumerated by $a_i, a'_i \in \{0, 1\}$, where $i \in [k]$ and $s_i, s'_i$ are directed copies of the edge $e_i$.

As described in the plan, at some point in the proof we would like to construct an assignment that leaves certain clauses (to which a certain set of variables was added) unsatisfied. For our purpose, we would like those clauses to “strongly unsatisfy” the condition in their vertices.

Let us describe the construction of $\eta^k$. Assume that $\Delta \geq 50 \cdot k \log n$. For each $v \in V$ we define $\eta_v$ independently. We will be interested in adding variables to clauses which correspond to large incoming flow.

1. Let us consider a set of clauses $C$ that corresponds to $v$ and a proper partial assignment on edges incident to $v$ with gap equal to $\frac{\Delta}{4} + 1$.
2. Note that $|C| \geq \binom{n^\Delta}{\Delta/4} \geq 4^{n^\Delta/4} \geq n^{1k}$. The first inequality holds since we can choose arbitrary $\Delta/4 + 1$ incoming edges to obtain the desired gap and set all other incident edges to zero.
3. There are at most $\binom{n^\Delta}{k} \leq \left(\frac{n\Delta}{k}\right)^k \leq n^{2k}$ different sets of $k$ edges. Hence we can choose a subset of $B \subseteq C$ and define $\eta^k_B$ to be a bijection between $B$ and all possible choices of sets of $k$ edges.

Note that the existence of $(1, +k)$-BP of size $S$ solving $\text{Search}_{\text{Flow}^k_G}$ (for any $\eta^k$) implies the existence of $(1, +k)$-BP of size $S$ solving $\text{Search}_{\text{Flow}_G}$.

### 4.1.1 Locally Consistent Assignments

We need a notion of “good assignments”, i.e. assignments that reduce $\text{Flow}_G$ formulas to smaller, but “equally hard” instances.
Let $G := (V, E)$ be a graph. A proper assignment $\rho$ $\delta$-satisfies a set of vertices $U \subseteq V$ iff for all $v \in U$ the following holds:

- $\rho$ assigns all edges that are incident to $v$;
- $\rho$ satisfies the constraint for $v$;
- $\sum_{e \in E : \operatorname{st}(e) = v} \rho(x_e) \geq \delta \cdot \Delta$.

We also say that a proper assignment $\rho$ is $(r, \delta, \beta)$-locally consistent iff there is a set of vertices $V_{\rho}$ of size at most $r$ such that:

- $\rho$ $\delta$-satisfies $V_{\rho}$;
- $(V \setminus V_{\rho}, E \setminus \operatorname{supp}(\rho))$ satisfies $(r, \beta)$-expansion property.

\[\Box\]

**Remark 17.** If $\rho$ is an $(r, \delta, \beta)$-locally consistent assignment for some $\beta > 0$, then $V_{\rho}$ is uniquely defined.

**Proof.** For the sake of contradiction assume that there are two candidates $A, B$. Wlog $A \setminus B \neq \emptyset$. Pick an arbitrary vertex $v \in A \setminus B$. Since $A$ satisfies the required properties, $\rho$ assigns all edges that are incident to $v$, which contradicts the fact that $(V \setminus B, E \setminus \operatorname{supp}(\rho))$ satisfies $(r, \beta)$-expansion property. \[\Box\]

### 4.2 Proof of Theorem 2

Let $G$ be an $(n, \Delta, \alpha)$-expander and $\phi^{k_0+1}$ be a mapping defined in section 4.1. In this section we prove an exponential lower bound on $\text{Search}_{\text{Flow}_{G}^{n, k_0+1}}(1, +k_0)$-BP. We assume that $n$ is large enough.

Let us fix some parameters:

- $\Delta := 100k_0 \log n$ and $\Delta > 200$;
- $\alpha := 0.01$ is the second eigenvalue of the normalized adjacency matrix of $G$;
- $r := \frac{\alpha}{\Delta}$ and $\beta := 0.96$ is the “combinatorial expansion” of the graph $G$;
- $\beta' := 0.95$ is an expansion parameter that we try to maintain after removing some vertices and edges from $G$;
- $\nu_k := \left(\frac{1}{4}(\beta - \beta')\right)^{k+3}$ is a scaling factor that indicates the fraction of edges that we want to assign in our partial assignment.

Note that $r \ll (1 - \beta - \alpha)n = 0.03 \cdot n$ and hence by Corollary 11 $G$ satisfies $(r, \beta)$-expansion property, hence we can use all combinatorial expansion properties and tools.

To formulate the induction hypothesis we need one more definition. Let $M \subseteq E$ and $\rho$ is a proper assignment. We say that $\rho$ is $\gamma$-minimal local consistent extension or (mlce) on $M$ iff:

- $\rho$ is $(r, 0.6, \gamma)$-locally consistent assignment;
- $\operatorname{supp}(\rho) = M \cup E(V_{\rho})$;
- $|E(V_{\rho}, V_{\rho}) \setminus M| < \gamma \Delta |V_{\rho}|$.

Informally we may think about it in the following way: after we assign edges from $M$ somehow, $\rho$ should assign also $V_{\rho}$ as a “minimal” set of vertices to take care of in order to be locally consistent.

Let $\varphi := \text{Flow}_{G}^{n, k_0+1}$. By induction on $k \leq k_0$ we show the following statement. For all sets of edges $M \subseteq E$ of size at most $\nu_k \Delta r$ and all $\beta'$-mlce $\rho$ on $M$ any $(1, +k)$-BP for $\text{Search}_{\varphi|M}$ has size at least $2^{\frac{\nu_k}{2^{k+1}} \Delta r}$. Fix some $M$, $\rho$, $0 \leq k \leq k_0$ and for the sake of contradiction assume that we have a $(1, +k)$-BP $D$ of size $2^{\frac{\nu_k}{2^{k+1}} \Delta r}$ for $\text{Search}_{\varphi|M}$.
4.2.1 Construction of the Garland

To fulfill our plan of the proof, described at the beginning of the section, we start constructing the garland by obtaining an exponentially big set of paths with the corresponding assignments. Let us remind that $|M| \leq \nu_k \Delta r$ and $\rho$ is $\beta'$-mlce on $M$.

We say that triple $(p, U_p, \sigma_p)$ is $\gamma$-good iff:

- $p$ is a path from the root of the branching program;
- $U$ is a subset of edges such that corresponding variables are queried on $p$, so-called “branching variables”;
- $\sigma_p$ is a partial assignment such that:
  a. $\sigma_p$ extends $\rho \cup \tau_p$;
  b. $\sigma_p$ is a $\gamma$-mlce on $M \cup U_p$;
  c. $\sigma_p$ 0.8-satisfies $V_{\sigma_p} \setminus V_{\rho}$,
  where $\tau_p$ is an assignment that corresponds to $p$.

We maintain the set of $\beta'$-good triples $P$ and an auxiliary set $S$ of triples that appear in the set $P$ at some moment during the process. In the beginning of our construction $P := \{(\emptyset, \emptyset, \rho)\}$ and $S := P$.

We repeat the following process while we have at least one triple $(p, U_p, \sigma_p) \in P$ such that $|U_p| \leq \nu_k \Delta r$.

Consider the triple described above. Let $v$ be the end of $p$ and $x_v$ be the variable asked in $v$.

1. If $x_v$ was queried on $p$ we stop the process. In this case we return “Repetition” and we remember the path $p$.
2. Erase the triple $(p, U_p, \sigma_p)$ from $P$.
3. If $\sigma_p(x_v) \in \{0, 1\}$, then we continue along the edge $x_e = \sigma_p(x_v)$. Consider a path $p'$ that is the extension of $p$ along this edge, $U_{p'} := U_p$ and $\sigma_{p'} := \sigma_p$. Put $(p', U_{p'}, \sigma_{p'})$ into $P$ and $S$ and repeat the process from the beginning.
4. If $\sigma_p(x_v) = \gamma$, then it is a “branching node”, and we call this step a branching step.
   a. Let $p'$ be a path obtained by continuing $p$ along the edge $x_e = 0$, and $p''$ be a path obtained by continuing $p$ along the edge $x_e = 1$.
   b. $U_{p'} := U_p \cup e$, $U_{p''} := U_p \cup e$.
   c. $\tau' := \sigma_p \cup \{x_e = 0, x_{e'} = 0\}$, $\tau'' := \sigma_p \cup \{x_e = 1, x_{e'} = 0\}$, where $x_{e'}$ is a dual edge.
   d. $(p', U_{p'}, \tau')$ is $(\beta' - 0.01)$-good triple. We extend an assignment $\tau'$ to make this triple $\beta'$-good. For the formal statement see Lemma 18. Here we describe an idea. Let $B \subseteq \delta E$ be a set of edges that are unassigned by $\tau'$ (or $\tau''$), and $B \subseteq V \setminus V_{\sigma_p}$ be the maximal set of vertices that satisfies:
      - $|B| \leq \gamma$
      - $|E(B,\overline{B}) \cap R| \leq \beta' \Delta |B|$.

Let $\kappa$ be an assignment on variables that correspond to edges in the set $E(B) \setminus \text{supp}(\tau')$ such that $\tau' \cup \kappa$ 0.8-satisfies the constraints for all $v \in B$. This assignment $\kappa$ always exists (and moreover it is independent of the value of $x_e$, but we do not use this fact).

We denote $\sigma_{p'} := \tau' \cup \kappa$, $\sigma_{p''} := \tau'' \cup \kappa$ and put $(p', U_{p'}, \sigma_{p'})$ and $(p'', U_{p''}, \sigma_{p''})$ into $P$ and into $S$.

To conclude the construction we want to show the following claims.

- **Repetition case.** In the first case of the proof (if we have a repetition) we can reduce the problem to a lower bound on $(1, +(k - 1))$-BP.
- **Correctness.** The branching step can be done and triples $(p', U_{p'}, \sigma_{p'})$ and $(p'', U_{p''}, \sigma_{p''})$ satisfy the required properties.
- **Garland extraction.** Among these paths we can find an $k$-garland $(a, b)$ and a locally consistent extension of $\rho$.
4.2.1.1 Correctness

We show that if we have a triple \((p, U_p, \tau_p)\) which is \(\beta\)'-good then after processing it with our algorithm we also put in our sets \(\beta\)'-good triples. Let us formulate the general Lemma that helps us with it.

\[\text{Lemma 18.} \text{ Let } (p, U_p, \sigma_p) \text{ and } (q, U_q, \sigma_q) \text{ be } 0.9\text{-good triples. Then there is an assignment } \kappa \text{ such that:}
\]

\[\sqrt{\text{ for any } \gamma \text{ that is an instance of } \sigma_p \cup \sigma_q \text{ an assignment } \gamma \cup \kappa \text{ is a } \beta\text{-mlce on supp}(\sigma_p) \cup \text{ supp}(\sigma_q);}\]

\[|\text{ supp}(\gamma \cup \kappa)| \leq \nu_{k-1} \Delta r.\]

Moreover if \(p = q\) then triple \((p, U_p, \sigma_p \cup \kappa)\) is \(\beta\)'-good.

\[\text{Proof.} \text{ The proof was motivated by the closure technique developed in [1,3]. For the full version of the proof see Appendix A.}\]

If the branching step was not done, then we do not change \(U\) and \(\tau\), and we extend the path \(p\) according to the assignment \(\tau\) hence the triple remains \(\beta\)'-good. We are left with the branching step. Note that \((p', U_{p'}, \tau')\) is 0.9-good and we apply Lemma 18 to a pair composed of two identical triples \((p', U_{p'}, \tau')\) and obtain \(\kappa\) that satisfies the required properties.

4.2.1.2 Repetition case

First let us note that if there is a repetition, then \(k > 0\). Suppose we found a repetition while considering a triple \((p, U_p, \sigma_p)\). The size of \(M \cup U_p\) is at most \(2\nu_k \Delta r\) and \(\sigma_p\) is \(\beta\)'-mlce on \(M \cup U_p\). Let \(v\) be an end node of \(p\). The program \(D(v)|_{\sigma_p}\) is a \((1, +(k - 1))\)-BP for Search Flow \(U_{\sigma_p}|_p\) by Lemma 8. Thus by induction hypothesis we have a lower bound of

\[2^{\frac{\nu_k-1}{2k+1} \Delta r} \geq \frac{2^{\frac{\nu_k}{16} \nu_k \Delta r}}{2^{4(k+1)^2} \Delta r} \text{ on the size of } D(v)|_{\sigma_p}\text{ and in this case we are done.}\]

4.2.1.3 Garland extraction

The following Lemma gives us a pair of triples \((p, U_p, \sigma_p),(q, U_q, \sigma_q) \in P\) such that \((p, q)\) forms a \((k + 1)\)-garland.

\[\text{Lemma 19. There are } (p, U_p, \sigma_p),(q, U_q, \sigma_q) \in S\text{ such that } (p, q)\text{ forms a } (k + 1)\text{-garland.}\]

\[\text{Proof.} \text{ For the proof see Appendix B.}\]

To continue the proof we need some additional property that we can “avoid repetitions” in this garland. We say that there is a **repetition in a garland** \(p = v_0q_1v_1q_2v_2q_3\ldots q_{k_0+1}v_{k_0+1}\) and \(q = v_0q_1v_1q_2v_2q_3\ldots q_{k_0+1}v_{k_0+1}\) if there is a path \(r\) of the form \(v_0r_1v_1r_2v_2r_3\ldots r_{k_0+1}v_{k_0+1}\), such that some variable is queried more than one time on it, where \(r_i \in \{p_i, q_i\}\).

Consider a path \(r\) in our garland \((p, q)\) that contains a repetition and \(r' \subseteq r\) the largest initial segment of \(r\) without repetitions. Let \(v\) be its end node. We apply Lemma 18 to triples \((p, U_p, \sigma_p),(q, U_q, \sigma_q)\), which gives us assignment \(\kappa\), and choose a instance \(\gamma\) of \(\sigma_p \cup \sigma_q\) that is consistent with \(\tau_r\). Moreover, \(|\text{ supp}(\gamma \cup \kappa)| \leq \nu_{k-1} \Delta r\), and \(\gamma \cup \kappa\) is a \(\beta\)-mlce on \(\text{ supp}(\sigma_p) \cup \text{ supp}(\sigma_q)\). Hence by Lemma 8 we can use the induction hypothesis for \((1, +k - 1)\)-BP \(D(v)|_{\tau_r}\) and formula \(\varphi|_{\gamma \cup \kappa}\). The size of \(D(v)|_{\tau_r}\) is at least

\[2^{\frac{\nu_k-1}{2k+1} \Delta r} \geq 2^{\frac{\nu_k}{16} \nu_k \Delta r}\]

For the rest of the proof we can assume that on any path \(r\) of the form described above there are no repetitions.
4.2.2 Unreachable Leaves

Let us summarize what we have from the previous section. We created a pair of triples: 
\((p, U_p, \sigma_p)\) and \((q, U_q, \sigma_q)\) such that:

\[ \begin{align*}
(0, q) & \text{ forms } (k_0 + 1)\text{-garland:} \\
& = (p, U_p, \sigma_p) \text{ and } (q, U_q, \sigma_q) \text{ are } \beta'\text{-good;} \\
& \text{ there are no repetitions on any path in the garland } (p, q).
\end{align*} \]

We use Lemma 18 for \((p, U_p, \sigma_p)\) and \((q, U_q, \sigma_q)\) and get an assignment \(\kappa\). Let us fix an assignment \(\gamma\) that is an instance of \(\sigma_p \cup \sigma_q\) consistent with:

\[ \begin{align*}
& \tau_p; \\
& \text{ values in } \sigma_q \text{ that do not contradict } \tau_p \\
& \text{ and denote } \zeta := \gamma \cup \kappa. \text{ Note that, by construction:} \\
& |\zeta| \leq v_{k-1}\Delta r; \\
& |\zeta| \text{ is } (r, 0.6, \beta')\text{-locally consistent.}
\end{align*} \]

In this section we describe a set of clauses that should be unreachable from the vertex \(v_{k_0+1}\). Note that on each segment of a garland \((v_i p_1 v_i p_2 v_i p_3 \ldots v_i p_{k_0+1})\) we query at least one variable in both assignments \(\tau_p\) and \(\tau_q\) and get the different values. Denote any variable that satisfies this property by \(x_i\).

We remind that \(\varphi := \text{Flow}_{k_0+1}^\eta\). Let \(D, C\) be the subsets of clauses:

\[ D := \{ D \in \text{Flow}_G \mid \text{ for every } e \text{ that corresponds to some } x_i : e \in \eta^{k_0+1}(D) \}. \]

and

\[ C := \{ C \in \varphi \mid C \text{ is obtained from some } D \in D \text{ by the amplification trick} \}. \]

For the sake of contradiction suppose that there is a path \(s\) from \(v_{k_0+1}\) such that:

\[ \begin{align*}
& s \text{ is a consistent path and } \tau_s \text{ is consistent with } \zeta \text{ and hence } ps \text{ is also consistent;} \\
& s \text{ ends in a clause } C \in C.
\end{align*} \]

Consider a family of paths \(r_i := v_{i0} p_1 v_{i1} p_2 v_{i3} \ldots p_{i-1} v_{i2} p_{i1} v_{i0+1} q_{i1} p_{i2} \ldots p_{i0+1} v_{i0+1} v_{i1+1}\), where \(i \in [k_0 + 1]\). All paths \(r_i\) are consistent since there are no repetitions in the garland \((p, q)\). Hence if \(r_i\) is inconsistent with \(s\) then on \(s\) we requery some variable \(x_i\) from the segment \(v_{i-1} q_{i}, v_{i}\), and get an inconsistent value.

By construction, \(\tau_s\) is consistent with \(\zeta\), and \(\zeta := \gamma \cup \kappa\), where \(\gamma\) is an instance of \(\sigma_p \cup \sigma_q\). If \(x_i\) appeared in \(v_{i-1} q_{i} v_{i}\), but not in \(v_{i-1} p_{i} v_{i}\) (note that it cannot appear in any other segment of the garland, since there are no repetitions on the garland), then \((\sigma_p \cup \sigma_q)(x_i) \notin \{ \sigma_q(x_i), ? \}\) and \(\tau_s(x_i) = \ast\) thus \(\gamma(x_i) = \sigma_q(x_i)\) by the choice of \(\gamma\). It follows that \(\zeta(x_i) = \sigma_q(x_i)\) as well, and since \(\tau_s\) is consistent with \(\zeta\), we cannot obtain an inconsistent with \(\tau_q\) value for \(x_i\) while requerying it. Hence \(x_i\) had appeared in \(v_{i-1} p_{i} v_{i}\) as well, and on \(s\) we requeryed a variable from \(v_{i-1} p_{i} v_{i}\) in consistent way. Moreover if all paths from some set \(\{r_i\}_{i \in L}\) where \(L \subseteq [k_0 + 1]\) are inconsistent with \(s\) we requery at least \(|L|\) variables from the path \(p\) on the path \(s\). Hence at least one of the paths \(r_{i_0}\) is consistent with \(s\), where \(i_0 \in [k_0 + 1]\) (or on the path \(ps\) we requery at least \(k_0 + 1\) variables).

\[ \text{Remark 20. This is the only place there we use the property that there are no repetitions on the garland.} \]
Consider two paths $p_s$ and $r_s$:
- these paths are consistent;
- $\tau_{p_s}(x_{i_0}) \neq \tau_{r_s}(x_{i_0})$.

These properties imply that clause $C$ is not a legal answer for at least one of these paths, and we have a contradiction with the assumption that there is a consistent path from $v_{k_0+1}$ to this clause. That gives us the desired description of leaves that should be unreachable for $v_{k_0+1}$.

To conclude the proof it remains to show that there should be a path from $v_{k_0+1}$ to at least one leaf marked by a clause $C \in \mathcal{C}$. We do it in the next section.

4.2.3 Directing the Flow

Let us remind that we deal with $\varphi := \text{Flow}_G^{k_0+1}$. To show that there is a path consistent with $\zeta$ from $v_{k_0+1}$ to a leaf with a label $C \in \mathcal{C}$ we show that $(\varphi \setminus \mathcal{C})|_{\zeta}$ is satisfiable and hence there should be an extension of $\zeta$ that violates only clauses from $\mathcal{C}$.

**Remark 21.** If we do not care about assignment $\zeta$, the statement is trivial, since $\varphi$ is so-called minimally unsatisfiable formula (that becomes satisfiable after removing any clause).

Note that by construction of $\eta^{k_0+1}$ for each $v \in V$ there exists a clause $D \in \mathcal{D}$ that had originated from the constraint for $v$. For each $v$, we pick any such clause and denote it by $D_v$. We divide the rest of the proof into two parts.

1. **“Local part”**. We find a carefully chosen large enough set of vertices $U \subseteq V$ and an assignment $\tau \supseteq \zeta$ such that there is a set $V_\tau \supseteq (U \cup V_\zeta)$:
   - $(V \setminus V_\tau, E \setminus \text{supp(}\tau))$ satisfies $(r, \beta')$-expansion property;
   - for all $v \in U$ the assignment $\tau$ violates $D_v$ and hence $\tau$ assigns all edges incident to $v$;
   - for all $v \in V_\tau \setminus U$ the assignment $\tau$ satisfies constraint for $v$.
   For this part we use the simplified version of technique used for the garland creation.

2. **“Global part”**. By using Max-Flow Min-Cut Theorem we show that $\tau$ can be extended to total assignment that satisfies constraints for vertices whose constraints are neither satisfied nor falsified by $\tau$ yet.

Since we satisfy all the constraints of $(\text{Flow}_G \setminus \mathcal{D})|_\zeta$ this assignment also satisfies all constraints in $(\varphi \setminus \mathcal{C})|_\zeta$ by the construction of the formula $\varphi$ (clauses of $\varphi$ are the weakened versions of the clauses $\text{Flow}_G$).

Before we proceed with the proof let us define the “overflow”.

**Definition 22.** The overflow introduced by a locally consistent assignment $\sigma$ is:

$$\text{of}_\sigma := 1 + \sum_{v \in V_\sigma} \left( \sum_{e \in E: \text{stat}(e) = v} x_e - \sum_{e \in E: \text{en}(e) = v} x_e - c(v) \right).$$

Note that $\text{of}_\zeta \leq |\zeta| + 1 \leq \nu_{k-1}\Delta r + 1$.

4.2.3.1 Local part

We start with the local part of the proof. In the beginning of our construction $U_0 := \emptyset$, $\tau_0 := \zeta$, $V_{r_0} := V_\zeta$ and $i := 0$. 
We repeat the following process while of\(r_i > 0\).
1. Choose a vertex \(u_i\) that is untouched by \(\tau_i\).
2. Let \(\rho_{u_i}\) be an assignment to edges that are incident to \(u_i\) such that \(D_{u_i}\) is unsatisfied by \(\rho_{u_i}\).
3. \(\tau' := \tau_i \cup \rho_{u_i}\). Since \(u_i\) is untouched by \(\tau_i\) there is no intersection between \(\rho_{u_i}\) and \(\tau_i\).
4. Let \(H_i \subseteq V \setminus V_{\tau_i}\) be the maximal set of vertices that satisfies:
   - \(|H_i| \leq r_i\);
   - \(|E(H_i, \overline{H_i} \setminus \{u_i\}) \setminus \text{supp}(\tau_i)| \leq \beta|H_i|\).
     Let \(\kappa_i\) be an assignment on variables that correspond to edges in the set \(E(H) \setminus \text{supp}(\tau')\) such that for all \(v \in H_i\):
     \[
     \sum_{e \in E_{\text{st}(e) = v}} (\tau' \cup \kappa_i)(x_e) - \sum_{e \in E_{\text{en}(e) = v}} (\tau' \cup \kappa_i)(x_e) = c(v).
     \]
5. \(U_{i+1} := U_i \cup \{u_i\}\), \(\tau_{i+1} := \tau' \cup \kappa_i\) and \(V_{\tau_{i+1}} := V_{\tau_i} \cup H_i \cup \{u_i\}\).
6. \(i := i + 1\).

Let \(\ell\) be a number of iterations in this process. Let \(U := U_\ell\) and \(\tau := \tau_\ell\).

At first we give an upper bound on \(\ell\). Since for all \(i\) an assignment \(\kappa_i\) exactly satisfies vertices in \(H_i\), inclusion of \(H_i\) into \(V_{\tau_i}\) does not change the overflow. Assignment \(\rho_{u_i}\) violates \(D_{u_i} \in \mathcal{D}\) and by definition of \(\eta^{k+1}\):
\[
-\frac{\Delta}{4} - 1 \leq \sum_{e \in E_{\text{st}(e) = u_i}} \rho_{u_i}(x_e) - \sum_{e \in E_{\text{en}(e) = u_i}} \rho_{u_i}(x_e) \leq -\frac{\Delta}{4}.
\]

Hence on each iteration of \(\tau_{i+1} \leq \text{of}_{\tau_i} - \frac{\Delta}{4}\) and \(|\{U_{i+1}\}| \leq \frac{|\{U_i\}|}{\Delta} + \frac{\Delta}{4} - 1 \leq \text{of}\), \(\leq 0\).

\begin{itemize}
  \item \textbf{Lemma 23.} For all \(i \leq \ell\):
    \begin{itemize}
      \item \(\kappa_i\) exists;
      \item \(|V_{\tau_i}| \leq \frac{1}{(\beta - \beta') \Delta} (\text{supp}(\zeta) + \Delta |U_i|)\) and hence \(|\tau_i| \leq \frac{2}{(\beta - \beta') |\text{supp}(\zeta)| + \Delta |U_i|}\);
      \item \((V \setminus V_{\tau_i}, E \setminus \text{supp}(\tau_i))\) satisfies \((r, \beta')\)-expansion property.
    \end{itemize}
\end{itemize}

\textbf{Proof.} This Lemma may be considered as simplified version of Lemma 18. For the proof see Appendix A.

To conclude the construction note that \(\tau_i \leq \frac{10}{4} \nu_k - 2 \Delta \leq \frac{3}{2} r\) for all \(i \leq \ell\) and we always can find the vertex untouched by \(\tau_i\).

\begin{itemize}
  \item \textbf{Remark 24.} This is the only place where we use that \(r \leq \frac{\Delta}{2}\).
\end{itemize}

\subsection{Global part}

Let \(B := V_r \setminus V_{\tau}\). For the vertex \(v \in V\) the \textit{overflow} of \(v\) is defined in the following way:
\[
\text{of}(v) := -\sum_{e \in \text{supp}(\tau) \setminus \text{st}(e) = u} \tau(x_e) + \sum_{e \in \text{supp}(\tau) \setminus \text{en}(e) = u} \tau(x_e) + c(v).
\]

We want to create an auxiliary graph. Let \(F^+ := \{v \in V \setminus V_r \mid \text{of}(v) > 0\}\) and \(F^- := \{v \in V \setminus V_r \mid \text{of}(v) < 0\}\). See Fig. 2.

We define a graph \(G' := (V', E')\) on vertices \(V' := (V \setminus V_r) \cup \{s\} \cup \{t\}\), where \(s\) is a source and \(t\) is a sink. Edges \(E'\) include four groups:
Let \( f := \deg(s) \). To conclude the proof we want to show that there is an \( s-t \) flow in \( G' \) of size \( f \) (assuming that capacity of each edge is 1) and that if this flow exists, then we have an extension of \( \tau \) that satisfies \( \text{Flow}_{G'} \setminus \mathcal{D} \). As we mention above together these facts imply that \( (\text{Flow}_{G'} \setminus \mathcal{D})|_\tau \) is satisfiable hence \( (\text{Flow}_{G'} \setminus \mathcal{D})|_\xi \) is satisfiable and \( (\varphi \setminus \mathcal{E})|_\xi \) is also satisfiable hence there is a path from \( v_{k_0+1} \) to a leaf marked by some \( C \in \mathcal{C} \) which is a contradiction with an existence of a garland and an assumption about size of the branching program.

We start with the second part. Suppose that we have a flow of size \( f \). Fix the flow that achieves this value. We define a total proper assignment \( \sigma \supseteq \tau \) in the natural way. Consider an edge \( e \in E' \cup E \) and \( a = (u, v), a' = (v, u) \) its directed copies. If there is a flow on the edge \( e \):

- from \( u \) to \( v \) then \( x_a = 1 \) and \( x_{a'} = 0 \);
- from \( v \) to \( u \) then \( x_a = 0 \) and \( x_{a'} = 1 \).

otherwise we set \( x_a = 0 \) and \( x_{a'} = 0 \).

Note that \( f = \deg(s) \) hence we use all edges that connect \( s \) with other vertices to push the flow. That implies for all \( v \in V \setminus V' \):

\[
\sum_{e \in \text{supp}(\sigma) \setminus \text{supp}(\tau)} \sigma(x_e) + \sum_{e \in \text{supp}(\sigma) \setminus \text{supp}(\tau)} \sigma(x_e) = |E(s, v)| = \text{of}(v)
\]

and hence

\[
\sum_{e \in E : \text{st}(e) = v} \sigma(x_e) + \sum_{e \in E : \text{en}(e) = v} \sigma(x_e) = c(v).
\]

and constraints for all vertices in \( V \setminus V' \) are satisfied, but \( \tau \) itself satisfied all constraints in \( \text{Flow}_{G'} \setminus \mathcal{D} \) that correspond to vertices in \( V' \). Altogether it says that \( \sigma \) satisfies all constraints in \( \text{Flow}_{G'} \setminus \mathcal{D} \) as desired.
It remains to show that we have an $s$-$t$ flow of size $f$ in $G'$. To do it we use the Max-Flow Min-Cut Theorem and show that minimal $s$-$t$ cut has size $f$. Consider such a cut $(S,T)$, where $S,T$ are disjoint subsets of $V'$ such that $s \in S$ and $t \in T$. We consider two cases:

- either $S$ or $T$ is small enough, then we use the $(r,\beta')$-expansion property that we have after removing $\text{supp}(\tau)$ and $V_\tau$ from $G$;
- $S$ and $T$ are large enough, then we use the Mixing Lemma to show that even removing $\text{supp}(\tau)$ from $G$ cannot destroy balanced cuts.

Consider the following cases.

1. If $0 < |J| \leq r$ or $0 < |K| \leq r$. Wlog assume that $|J| \leq r$. Note that:

$$E_{G'}(S,T) = E_{G'}(\{s\},K) + E_{G'}(\{t\},J) + E_{G'}(J,K).$$

$E_{G'}(\{s\},K) = \sum_{v \in F^+ \cap K} \text{of}(v)$, so by Remark 25 to give a lower bound on the size of cut it is enough to show that $E_{G'}(J,K) \geq \frac{\Delta}{4} + 1 + \sum_{v \in F^+ \cap J} \text{of}(v)$. But $(V \setminus V_\tau, E \setminus \text{supp}(\tau))$ satisfies $(r,\beta')$-expansion property. Hence

- for all $v \in V \setminus V_\tau$: $|\text{of}(v)| \leq 0.1 \cdot \Delta$;
- $|E_{G'}(J,K)| \geq 0.9 \cdot \Delta |J|$, that implies that $|E_{G'}(J,K)| - \frac{\Delta}{4} - 1 \geq 2 \sum_{v \in F^+ \cap J} \text{of}(v)$.

2. $|J| > r, |K| > r$. Wlog assume that $|J| \leq |K|$. By Mixing Lemma:

$$|E_G(J,\overline{J})| = \Delta |J| - E_G(J,J) \geq \Delta |J| - \frac{\Delta}{n} |J|^2 - \alpha \Delta |J| \geq \Delta |J| - |J| - \alpha \Delta |J| \geq 0.9 \cdot \Delta r,$$

and

$$|E_{G'}(J,K)| \geq |E_G(J,\overline{J})| - |\text{supp}(\tau)| \geq 0.6 \cdot \Delta r.$$

On the other hand:

$$f = \sum_{v \in F^+} \text{of}(v) =\sum_{v \in F^+} \left( - \sum_{e \in \text{supp}(\tau), \text{st}(e) = u} \tau(x_e) + \sum_{e \in \text{supp}(\tau), \text{en}(e) = u} \tau(x_e) + e(v) \right) \leq \Delta r,$$

so by Remark 25 to give a lower bound on the size of cut.

Figure 4: Graph $s$-$t$ cut.

Consider an arbitrary $s$-$t$ cut $S \cup T$. Let $J := S \setminus \{s\}$ and $K := T \setminus \{t\}$ (see Fig. 4). Consider the following cases.

1. If $J = \emptyset$ or $K = \emptyset$ then size of $(S,T)$ cut equals $\deg(s)$ or $\deg(t)$ respectively and we are done.

2. $0 < |J| \leq r$ or $0 < |K| \leq r$. Wlog assume that $|J| \leq r$. Note that:

$$E_{G'}(S,T) = E_{G'}(\{s\},K) + E_{G'}(\{t\},J) + E_{G'}(J,K).$$

$E_{G'}(\{s\},K) = \sum_{v \in F^+ \cap K} \text{of}(v)$, so by Remark 25 to give a lower bound on the size of cut it is enough to show that $E_{G'}(J,K) \geq \frac{\Delta}{4} + 1 + \sum_{v \in F^+ \cap J} \text{of}(v)$. But $(V \setminus V_\tau, E \setminus \text{supp}(\tau))$ satisfies $(r,\beta')$-expansion property. Hence

- for all $v \in V \setminus V_\tau$: $|\text{of}(v)| \leq 0.1 \cdot \Delta$;
- $|E_{G'}(J,K)| \geq 0.9 \cdot \Delta |J|$, that implies that $|E_{G'}(J,K)| - \frac{\Delta}{4} - 1 \geq 2 \sum_{v \in F^+ \cap J} \text{of}(v)$.

3. $|J| > r, |K| > r$. Wlog assume that $|J| \leq |K|$. By Mixing Lemma:

$$|E_G(J,\overline{J})| = \Delta |J| - E_G(J,J) \geq \Delta |J| - \frac{\Delta}{n} |J|^2 - \alpha \Delta |J| \geq \Delta |J| - |J| - \alpha \Delta |J| \geq 0.9 \cdot \Delta r,$$

and

$$|E_{G'}(J,K)| \geq |E_G(J,\overline{J})| - |\text{supp}(\tau)| \geq 0.6 \cdot \Delta r.$$
Hence in all cases \((S, T)\) has size at least \(f\) which by Max-Flow Min-Cut Theorem implies the existence of flow in \(G'\) of size at least \(f\). That as mentioned above implies the desired lower bound on the size of branching program.

5 Cook–Reckhow Proof Systems

In this section we illustrate that syntactic \((1, +k)\)-BP give us a proof system in terms of Cook–Reckhow. This result is a generalization of the same result for formulas of bounded width [13]. We start with the most general definition of a proof system for a language of unsatisfiable formulas.

▶ Definition 26 (Cook, Reckhow [7]). A proof system is a polynomial-time algorithm \(\Pi(\varphi, w)\) that satisfies two properties:

- correctness: if there is some \(w \in \{0, 1\}^*\) such that \(\Pi(\varphi, w) = 1\) then \(\varphi\) is unsatisfiable;
- soundness: if \(\varphi\) is an unsatisfiable boolean formula then there is a string \(w \in \{0, 1\}^*\) such that \(\Pi(\varphi, w) = 1\).

We say that \(w\) is a witness of unsatisfiability of \(\varphi\).

\((1, +k)\)-BP can be used to define a natural proof system. We assume that the witness of unsatisfiability of a CNF formula \(\varphi\) is a description of a \((1, +k)\)-BP that solves \(\text{Search}_\varphi\) problem; denote it by \((1, +k)\)-BP-PS. This definition is equivalent to the definition of \((1, +k)\)-BP-PS from [13] but we erase some technicalities.

For our purpose we need to show that there is a polynomial-time algorithm that checks whether a given description is a \((1, +k)\)-BP and that it solves \(\text{Search}_\varphi\).

▶ Lemma 27. There is an algorithm that for given syntactic \((1, +k)\)-BP of size \(s\) and boolean CNF formula \(\varphi := \bigvee_{i=1}^{m} C_i\) with \(m\) clauses and \(n\) variables checks whether this program solves \(\text{Search}_\varphi\) in time \(O\left(\left(\frac{4n}{k}\right)^k s n^2 m\right)\).

We defer the proof of this Lemma to section 5.1.

▶ Theorem 5.1 (3). A syntactic \((1, +k)\)-BP-PS is a proof system in terms of Cook–Reckhow definition for any constant \(k \in \mathbb{N}\).

Proof. Given a description of a branching program \(B\) we can use an algorithm from Theorem 7 to check whether it is \((1, +k)\)-BP. After that we can use an algorithm from Lemma 27 to check whether this program solves \(\text{Search}_\varphi\) problem. If \(k\) is an absolute constant both algorithms work in time \(\text{poly}(|\varphi|, |B|)\). ◀

5.1 Proof of Lemma 27

Fix some syntactic \((1, +k)\)-BP \(B\) and some CNF formula \(\varphi := \bigvee_{i=1}^{m} C_i\). Leaves of \(B\) are marked by clauses of \(\varphi\). We construct an auxiliary branching programs \(B_i\) that are obtained by replacing the labels \(C_i\) of sinks by 1 and other labels by 0.

The clause \(C\) is a solution of the \(\text{Search}_\varphi\) problem for an assignment \(z\) iff \(C(z) = 0\). Hence \(B\) makes a mistake on the assignment \(z\) iff the path that corresponds to \(z\) ends in sink marked by \(C\) and \(C(z) = 1\). But it means that \(B\) makes a mistake iff there is a variable \(x_i\) such that an assignment \(x_i \leftarrow z_i\) satisfies \(C\) and there is a path in \(B\) from source to sink labeled by \(C\) consistent with an assignment \(x_i \leftarrow z_i\).
The last observation gives useful criteria of correctness. We have path in $B$ from source to sink that is labeled by $C_i$ consistent with some assignment $x_j \leftarrow a$ iff $B_i|_{x_j \leftarrow a}$ is satisfiable. We are ready to describe an algorithm:

1. enumerate all clauses $C_i \in \varphi$;
2. enumerate variables $x_j \in C_i$ and consider a constant $a$ such that $C_i|_{x_j \leftarrow a} = 1$;
3. check whether $B_i|_{x_j \leftarrow a}$ is satisfiable, if yes return “NO”;
4. if $B$ passes all tests then return “$B$ is correct”.

The correctness of this algorithm follows from previous observation. And we run satisfiability algorithm at most $nm$ times hence the running time is at most $O \left( \left( \frac{4en}{k} \right)^k \cdot s \cdot n^2 \cdot m \right)$.

6. Open Problems

In conclusion we want to mention some open problems. We start with the obvious ones.

1. Find a formula that is hard for $(1, +k)$-BP where $k := n^\varepsilon$.
2. Find a formula that is hard for read-twice branching programs (programs that on any path may read each variable at most twice).

Another problems are more technical, but in our opinion the solution of these problems may lead to new techniques for proving lower bounds.

1. Find a “natural” formula that is hard for $(1, +k)$-BP for any $k > 0$. The main problem with the current bound is that we amplify our formula by an $\eta$ function. This is an artificial trick that prevents generalization of our main Theorem.
2. More difficult question: can we prove a lower bound on random $\Delta$-CNF formulas? This is a canonical example of the hard formulas. Typically, only the “local” structure is used for proving lower bounds on these formulas, which is one of the important barriers for proving lower bounds on these formulas in $\mathbf{AC}_0$-Frege proof system.

References

A. Sofronova and D. Sokolov

At first we prove an auxiliary Lemma.

Lemma 18. Let \((p, U_p, \sigma_p)\) and \((q, U_q, \sigma_q)\) be 0.9-good triples. Then there is an assignment \(\kappa\) such that:

- for any \(\gamma\) that is an instance of \(\sigma_p \cup \sigma_q\) an assignment \(\gamma \cup \kappa\) is a \(\beta'\)-mlce on \(\text{supp}(\sigma_p) \cup \text{supp}(\sigma_q)\);
- \(|\text{supp}(\gamma \cup \kappa)| \leq \nu_{k-1} r\).

Moreover if \(p = q\) then triple \((p, U_p, \sigma_p \cup \kappa)\) is \(\beta'\)-good.

Proof. Let \(S := V_{\sigma_p} \cup V_{\sigma_q}\), \(E_{\sigma} := \text{supp}(\sigma_p) \cup \text{supp}(\sigma_q)\) and \(B \subseteq V \setminus S\) be the maximal set of vertices that satisfies:

- \(|B| \leq r\);
- \(|E(B, B) \setminus E_{\sigma}| \leq \beta' \Delta |B|\).

At first we give an upper bound on the size of set \(B\).

Partial assignment \(\sigma_p\) is 0.9-mlce on \(M \cup U_p\). \(\beta' \Delta |V_{\sigma_p}| \geq |E(V_{\sigma_p}, V_{\sigma_p}) \setminus (M \cup U_p)|\) and by Lemma 28

\[
|V_{\sigma_p}| \leq \frac{|M \cup U_p|}{(\beta - \beta') \Delta} \leq 2 \frac{\nu_k}{(\beta - \beta') r} \leq \frac{1}{2} \nu_{k-1} r.
\]

By analogy the same holds for \(V_{\sigma_q}\).

The equality \(E(B, B) \cap E_{\sigma} = E(B, S) \cup (E(B) \cap |M \cup U_p \cup U_q|)\) together with \(|E(B, B) \setminus E_{\sigma}| \leq \beta' \Delta |B|\) implies:

\[
(1 - \beta') \Delta |B| - |M \cup U_p \cup U_q| \leq |E(B, S)|
\]

By Mixing Lemma:

\[
|E(B, S)| \leq \frac{\Delta}{n} |B||S| + \alpha \Delta \sqrt{|S||B|}.
\]

For the sake of contradiction assume that \(|B| \geq |S|\) thus:

\[
|E(B, S)| \leq \frac{\Delta}{n} |B||S| + \alpha \Delta |B|.
\]
Altogether:

\[(1 - \beta')\Delta |B| \leq \frac{\Delta r}{n} \nu_{k-1}|B| + \alpha \Delta |B| + 3\nu_{k-1} \Delta r \leq 2\alpha \Delta |B|,\]

that contradicts the choice of \(\alpha\) and \(\beta'\), hence \(|B| \leq |S| \leq \nu_{k-1} r\).

At first we show that \((V \setminus (S \cup B), E \setminus (E_\sigma \cup E(B)))\) satisfies \((r, \beta')\)-expansion property.

By contradiction, suppose that there is a set \(B' \subseteq V \setminus (S \cup B)\) of size at most \(r\) such that \(|E(B', B') \setminus (E_\sigma \cup E(B))| < \beta' \Delta |B'|\).

Again by Lemma 28 we conclude that:

\[|B'| \leq \frac{|M \cup U_p \cup U_q| + \Delta |S \cup B|}{(\beta - \beta') \Delta} \leq \nu_{k-1} r + \frac{1}{2} r \leq \frac{3}{4} r.\]

But it implies that \(|B \cup B'| \leq r\), moreover:

\[|E(B \cup B', B' \cup B') \setminus E_\sigma| \leq \beta' \Delta |B| + \beta' \Delta |B'| = \beta' \Delta |B \cup B'|.\]

That contradicts the choice of \(B\).

Now we find a proper assignment \(\kappa\) on the \(E(B) \setminus E_\sigma\) such that for all \(v \in B\):

\[\sum_{e \in E^{\text{sat}(e)=v}} x_e \geq 0.8 \cdot \Delta.\]

Since \(\sigma_p\) is an \((r, 0.6, 0.9)\)-locally consistent assignment, then \((V \setminus V_{\sigma_p}, E \setminus \text{supp}(\sigma_p))\) satisfies \((r, 0.9)\)-expansion property. By analogy we have the same property for \(\sigma_q\) that implies: \((V \setminus S, E \setminus E_\sigma)\) satisfies \((r, 0.8)\)-expansion property. Indeed, consider a set \(C \subseteq V \setminus S\) of size at most \(r\):

\[|E(C, C) \setminus E_\sigma| = |E(C, C)| - |E(C, C) \cap E_\sigma| \geq |E(C, C)| - |E(C, C) \cap \text{supp}(\sigma_p)| - |E(C, C) \cap \text{supp}(\sigma_q)| = |E(C, C) \setminus \text{supp}(\sigma_p)| - 0.1 \cdot \Delta |C| \geq 0.8 \cdot \Delta |C|.\]

By Proposition 12 there is an enumeration of vertices in \(B\): \(v_1, v_2, \ldots, v_{|B|} \in B\) and a sequence \(R_1, \ldots, R_{|B|} \subseteq (E(B) \setminus E_\sigma)\) such that:

- \(R_i = E(\{v_i\}, V \setminus \{v_1, v_2, \ldots, v_i\}) \setminus E_\sigma;\)
- \(|R_i| \geq 0.8 \Delta.\)

We define \(\kappa\) in the following way:

- for an \(e \in R_i\) we assign corresponding variables to direct the flow outside of the vertex \(v_i\) (i.e. if \(e'\) is a directed copy of \(e\) that goes outside of \(v_i\) we set \(x_{e'}\) to 1 and set the dual edge to 0);
- for all loops inside the set \(B\) we assign corresponding variables to 0.

Let \(\gamma\) be an instance of \(\sigma_p \cup \sigma_q\), \(\zeta \equiv \gamma \cup \kappa\) and \(V_\zeta \equiv S \cup B\). We have already shown that the graph \((V \setminus V_\zeta, E \setminus \text{supp}(\zeta))\) satisfies \((r, \beta')\)-expansion property. We want to show that vertices in \(V_\zeta\) are 0.6-satisfied by \(\zeta\). Consider four cases.

1. \(v \in V_p\). Both assignments \(\sigma_p\) and \(\sigma_q\) extend an assignment \(\rho\) hence \(\gamma\) agreed with both assignments on edges incident to \(V_p\). Thus \(\gamma\) 0.6-satisfies \(v\).
2. \( v \in V_{\sigma_p} \setminus V_p \). Let \( E_v \) be a set of edges that are incident to \( v \). At least \( 0.8 \cdot \Delta \) of those edges carry outgoing flow from \( v \) in \( \sigma_p \). Denote those edges as \( E_{\sigma_p} \).

If \( v \not\in V_{\sigma_p} \) then \( \sigma_q \) may assign at most \( 0.1 \cdot \Delta \) edges in \( E_v \). That means that in \( \gamma \) at least \( 0.7 \cdot \Delta \) edges from \( E_{\sigma_p} \) still carry outgoing flow from \( v \).

If \( v \in V_{\sigma_q} \) then \( \sigma_p \) and \( \sigma_q \) both \( 0.8 \)-satisfy \( v \). Let \( E_{\sigma_q} \subseteq E_v \) be the set of edges that carry outgoing flow from \( v \) in \( \sigma_q \). Then \( E_{\sigma_p} \cap E_{\sigma_q} \geq 0.6 \cdot \Delta \), and all those edges carry outgoing flow from \( v \) in \( \gamma \).

Note that if \( \sigma_p = \sigma_q \), then we \( 0.8 \)-satisfy \( v \).

3. \( v \in V_{\sigma_p} \setminus V_p \). By analogy with the previous case.

4. \( v \in B \). We direct the flow on at least \( 0.8 \cdot \Delta \) edges from \( E_v \) outside of \( v \) hence \( \kappa \) \( 0.8 \)-satisfies \( v \).

By construction \( V_\zeta := V_{\sigma_p} \cup V_{\sigma_q} \cup B \) hence \( |V_\zeta| \leq \nu_{k-1} r \) and \( |\text{supp}(\zeta)| \leq \nu_{k-1} r \). In order to check that \( \zeta \) is \( \beta' \)-mlce note that:

\[ |E(B, B) \setminus E_{\sigma}| \leq \beta' \Delta|B| \leq \beta' \Delta|V_\zeta|, \]

but

\[ |E(B, B) \setminus E_{\sigma}| = |E(V_\zeta, \overline{V_\zeta}) \setminus E_{\sigma}| \]

since \( \sigma_p \) and \( \sigma_q \) together assign all edges that are incident to \( V_{\sigma_p} \cup V_{\sigma_q} \). Thus:

\[ |E(V_\zeta, \overline{V_\zeta}) \setminus E_{\sigma}| \leq \beta' \Delta|V_\zeta| \]

that concludes the proof.

In case of \( (p, U_p, \sigma_p) = (q, U_q, \sigma_q) \) it remains to show that \( \zeta \) is \( \beta' \)-mlce on \( M \cup U_p \). Again we note that:

\[ |E(B, B) \setminus E_{\sigma}| \leq \beta' \Delta|B|, \]

and also

\[ |E(V_{\sigma_p}, \overline{V_{\sigma_p}}) \setminus E_{\sigma}| \leq \beta' \Delta|V_{\sigma_p}|, \]

hence

\[ |E(V_{\sigma_p} \cup B, \overline{V_{\sigma_p} \cup B}) \setminus E_{\sigma}| \leq \beta' \Delta(|V_{\sigma_p}| + |B|) \leq \beta' \Delta|V_{\sigma_p} \cup B|, \]

where the last inequality holds since \( B \) and \( V_{\sigma_p} \) are disjoint, that concludes the proof.

**A.2 Lemma 23**

**Lemma A.2** (23). For all \( i \leq \ell \):

- \( \kappa_i \) exists;
- \( |V_{\tau_i}| \leq \frac{1}{(\beta - \beta') \Delta} \left( |\text{supp}(\zeta)| + \Delta|U_i| \right) \) and hence \( |\tau_i| \leq \frac{2}{(\beta - \beta') \Delta} \left( |\text{supp}(\zeta)| + \Delta|U_i| \right) \);
- \( (V \setminus V_{\tau_i}, E \setminus \text{supp}(\tau_i)) \) satisfies \( (r, \beta') \)-expansion property.

**Proof.** We show by induction on \( i \) that:

- \( (V \setminus V_{\tau_i}, E \setminus \text{supp}(\tau_i)) \) satisfies \( (r, \beta') \)-expansion property;
- \( |E(V_{\tau_i}, \overline{V_{\tau_i}}) \setminus (\text{supp}(\zeta) \cup E(U_i))| < \beta' \Delta|V_{\tau_i}|; \)
- \( |V_{\tau_i}| \leq \frac{1}{(\beta - \beta') \Delta} \left( |\text{supp}(\zeta)| + \Delta|U_i| \right) \) and hence \( |\tau_i| \leq \frac{2}{(\beta - \beta') \Delta} \left( |\text{supp}(\zeta)| + \Delta|U_i| \right). \)
Assignment $\tau_0$ is $\zeta$ and $\zeta$ is $(r, 0.6, \beta')$-locally consistent, in particular, $(V \setminus \mathcal{V}_\zeta, E \setminus \text{supp}(\zeta))$ satisfies $(r, \beta')$-expansion property and $E(V_\zeta, \mathcal{V}_\zeta \setminus \text{supp}(\zeta)) = \emptyset$.

By definition of $H_i$:

$$\beta' \Delta |H_i| > |E(H_i, \overline{H}_i \setminus \{u_i\}) \setminus \text{supp}(\tau_i)| \geq |E(H_i, \overline{H}_i) \setminus (\text{supp}(\tau_i) \cup E(H_i, \{u_i\}))|$$

and by Lemma 28

$$|H_i| \leq \frac{|\text{supp}(\tau_i) \cup E(H_i, u_i)|}{(\beta - \beta') \Delta} \leq \frac{|\text{supp}(\tau_i) \cup E(H_i, u_i)|}{(\beta - \beta') \Delta} \leq \frac{1}{2} \nu_{k-2}(r + 1).$$

Hence $|H_i \cup V_{\tau_i} \cup \{u_i\}| \leq r$ that together with:

$$|E(H_i \cup V_{\tau_i} \cup \{u_i\}, \overline{H}_i \cup V_{\tau_i} \cup \{u_i\}) \setminus (\text{supp}(\zeta) \cup E(U_{i+1}))| \leq |E(V_{\tau_i}, \overline{H}_i \cup V_{\tau_i}) \setminus (\text{supp}(\zeta) \cup E(U_{i+1}))| + |E(H_i, \overline{H}_i) \setminus (\text{supp}(\zeta) \cup E(U_{i+1}) \cup E(V_{\tau_i}))| \leq \beta' \Delta |V_{\tau_i}| + \beta' \Delta |H_i| \leq \beta' \Delta |H_i \cup V_{\tau_i} \cup \{u_i\}|$$

implies $|V_{\tau_{i+1}}| = |H_i \cup V_{\tau_i} \cup \{u_i\}| \leq \frac{1}{(\beta - \beta') \Delta} |\text{supp}(\zeta) + \Delta |U_{i+1}| \cup \{u_i\}|$ by Lemma 28. Also $|\tau_{i+1}| \leq \frac{2}{(\beta - \beta') \Delta} |\text{supp}(\zeta) + \Delta |U_{i+1}| \cup \{u_i\}|$ since by construction $\tau_{i+1}$ assigns only edges in $\text{supp}(\zeta) \cup E(U_{i+1}) \cup V_{\tau_{i+1}}$.

Now we show that a graph $(V \setminus V_{\tau_i+1}, E \setminus \text{supp}(\tau_{i+1}))$ satisfies $(r, \beta')$-expansion property. For the sake of contradiction assume that there is a set $S \subseteq V \setminus V_{\tau_i+1}$ of size at most $r$ such that: $E(S, \overline{S}) \setminus \text{supp}(\tau_{i+1}) \leq \beta' \Delta |B|$. By Lemma 28 $|S| \leq \frac{|\text{supp}(\tau_{i+1})|}{(\beta - \beta') \Delta} \leq \frac{1}{2} \nu_{k-2}(r + 1)$. Hence $|H_i \cup S| \leq r$ that together with:

$$E(H_i \cup S, \overline{H}_i \cup S \setminus \{u_i\}) \setminus \text{supp}(\tau_i)) \leq E(H_i, \overline{H}_i \cup S \setminus \{u_i\}) \setminus \text{supp}(\tau_i) \cup E(S, \overline{H}_i \cup S \setminus \{u_i\}) \setminus \text{supp}(\tau_i) \leq \beta' \Delta |H_i| + \beta' \Delta |S| = \beta' \Delta |H_i \cup S|$$

contradicts the choice of $H_i$.

To conclude the proof we have to show the existence of $\kappa_i$. Note that $(V \setminus V_{\tau_i}, E \setminus \text{supp}(\tau_i))$ satisfies $(r, \beta')$-expansion property. Consider an arbitrary set $B \subseteq V \setminus (V_{\tau_i} \cup \{u_i\})$ of size at most $r$:

$$|E(B, \overline{B}) \setminus (\text{supp}(\tau_i) \cup E(\{u_i\}))| \geq \beta' \Delta |B| - E(B, \{u_i\}).$$

By Mixing Lemma:

$$|E(B, \{u_i\})| \leq \frac{\Delta}{n} |B| + \alpha \Delta \sqrt{B} \leq 0.05 \cdot \Delta |B|,$$

and hence

$$|E(B, \overline{B}) \setminus (\text{supp}(\tau_i) \cup E(\{u_i\}))| \geq 0.9 \cdot \Delta |B|$$

and graph $(V \setminus V_{\tau_i} \setminus \{u_i\}, E \setminus \text{supp}(\tau_i))$ satisfies $(r, 0.9)$-expansion property.

By Proposition 12 there is an enumeration of vertices in $H_i$: $v_1, v_2, \ldots, v_{|H_i|} \in H_i$ and a sequence $R_1, \ldots, R_{|H_i|} \subseteq E(H_i) \setminus (\text{supp}(\tau_i) \cup E(\{u_i\}))$ such that:
\[ R_k = E(\{v_k\}, V \setminus \{v_1, v_2, \ldots, v_k\}) \setminus (\text{supp}(\tau_i) \cup E(\{u_i\})); \]

\[ |R_i| \geq 0.9 \cdot \Delta. \]

We define \( \kappa_i \) for vertices \( v_1, \ldots, v_H \) step by step, such that \( \kappa_i \) on \( E(v_k) \) satisfies the constraint:

\[
\sum_{e \in E:\text{st}(e) = v_k} (\tau' \cup \kappa_i)(x_e) - \sum_{e \in E:\text{en}(e) = v_k} (\tau' \cup \kappa_i)(x_e) = c(v_k).
\]

Since we have access to the 0.9 \cdot \Delta edges and others are already assigned, we can always choose the right values (loops are always assigned to zero).

\[ \Box \]

\section*{Garland in the Paths}

\begin{lemma}[19] \label{lem:garland}
There are \((p, U_p, \sigma_p), (q, U_q, \sigma_q) \in S\) such that \((p, q)\) forms a \((k + 1)\)-garland.
\end{lemma}

\begin{proof}
Note that we can describe elements in \( \mathcal{P} \) by a sequence of bits of size \( s := \nu_k \Delta r \).

Each bit of this sequence describes an assignment for an edge \( e \) that we choose on “branching step”. From the construction it follows that different sequences generate different paths in the branching program and hence different elements of \( \mathcal{P} \).

Let \( s_k = \lfloor \frac{1}{k+1} \rfloor \). We construct our garland by the iterative algorithm. After \( i \)-th iteration we have a set \( S_i \) of sequences of size \( is_k \) such that any two of the corresponding paths form \( i \)-garland and all paths end in the same node. The size of \( S_i \) will be at least \( \exp \left[ s_k - \frac{i}{2}s_k \right] \) for all \( 1 \leq i \leq k + 1 \).

1. For \( i = 1 \) consider all possible strings of length \( s_k \) and paths that correspond to them.

   The branching program has size at most \( 2^\frac{sk}{sk} \), hence there exists a node such that at least \( 2^{-\frac{sk}{sk}+1} \) paths end there. The set \( S_1 \) consists of all corresponding sequences.

2. For the step \( i, 2 \leq i \leq k + 1 \), we consider all sequences in \( S_{i-1} \). Let \( v \) be the end node of all paths corresponding to sequences in the set. To each sequence \( s \in S_{i-1} \) we append a string \( u_s \) of \( s_k \) bits in such a way that for any pair \( r, r' \in S_{i-1} \) paths that corresponds to \( ru_r \) and \( ru_{r'} \) differ at some node after \( v \). Since \( 2^{sk} \geq |S_{i-1}| \), it is possible to do this.

   For the resulting sequences, we consider the set of the corresponding paths. The set of paths has size at least \( 2^{-\frac{s_k}{sk+1}} \), and the size of the program is at most \( 2^\frac{sk}{sk} \). Hence there exists a node such that \( 2^{\frac{s_k}{ski+1}} \) paths end there. Let \( S_i \) be the set of sequences corresponding to those paths.

After \( k + 1 \) steps we have a set \( S_{k+1} \), \(|S_{k+1}| \geq 2\), such that any two sequences in it correspond to a \((k + 1)\)-garland.
\[ \Box \]
A Majority Lemma for Randomised Query Complexity

Mika Göös
School of Computer and Communication Sciences, EPFL, Lausanne, Switzerland
Gilbert Maystre
School of Computer and Communication Sciences, EPFL, Lausanne, Switzerland

Abstract

We show that computing the majority of $n$ copies of a boolean function $g$ has randomised query complexity $R(Maj \circ g^n) = \Theta(n \cdot R_{1/n}(g))$. In fact, we show that to obtain a similar result for any composed function $f \circ g^n$, it suffices to prove a sufficiently strong form of the result only in the special case $g = GapOr$.

1 Introduction

In boolean function complexity theory, a typical direct sum problem asks: For a given boolean function $g : \{0,1\}^m \rightarrow \{0,1\}$, how much harder is it to compute $g$ on $n$ separate inputs, that is, computing $g^n(x^1, \ldots, x^n) := (g(x^1), \ldots, g(x^n))$, compared to computing $g$ on a single input? For randomised query complexity, a complete answer was recently obtained by Blais and Brody [7] (improving on [17, 6]). They showed that the most obvious way to compute $g^n$ is optimal: Evaluate each copy of $g$ separately with a “reduced” error probability $\ll 1/n$ so that, by a union bound, the $n$-bit output will be correct with high probability. More precisely, their result states (we assume $n \geq 3$ for simplicity of notation throughout the paper)

$$\forall g : R(g^n) = \Theta(n \cdot R_{1/n}(g)). \quad \text{(Direct sum)}$$

Here we used standard notation: $R(g) := R_{1/3}(g)$ where $R_{\epsilon}(g)$ denotes the $\epsilon$-error query complexity of $g$, that is, the least number of queries a randomised algorithm (decision tree) must make to the input bits $x_i \in \{0,1\}$ of an unknown input $x \in \{0,1\}^m$ in order to output $g(x)$ with probability at least $1 - \epsilon$ (where the probability is over the internal randomness of the algorithm). Similarly, $R_{\epsilon}(g)$ denotes the $\epsilon$-error expected query complexity of $g$ where we measure the expected (rather than worst-case) number of queries made by the algorithm. See Section 2 for precise definitions.

How far can we push the direct sum result? What if, instead of all the $n$ output bits of $g^n$, we only wanted to compute their parity? In other words, what is the randomised query complexity of the composed function $Xor \circ g^n$? Do we still have to compute each $g$ with reduced error? Brody et al. [8] provided an affirmative answer:

$$\forall g : R(Xor \circ g^n) = \Theta(n \cdot R_{1/n}(g)). \quad \text{(Xor Lemma)}$$

More generally, we can ask the following question.

Problem 1. For which $n$-bit outer functions $f$ (assume $R(f) = \Theta(n)$ for simplicity) and inner functions $g$ does the composed function $f \circ g^n$ necessitate error reduction?
There is no conjectured characterisation for when error reduction is necessary. To showcase the subtlety of this question, we mention that \( f = \text{Or} \), despite having a highly “sensitive” input \( x = 0^n \), never necessitates error reduction. By now, there are many proofs \([12, 20, 22, 15, 5]\) showing that \( R(\text{Or} \circ g^n) = O(n \cdot R(g)) \) for every \( g \).

Our goal in this paper is to make further progress on Problem 1.

### 1.1 Our results

Our main result is to prove tight bounds for composing with the \( n \)-bit majority function \( \text{Maj} \). This in particular confirms a conjecture made in \([7, 5]\).

\[ \text{Theorem 2 (Maj lemma). } R(\text{Maj} \circ g^n) = \Theta(n \cdot R_{1/n}(g)) \text{ for every partial function } g. \]

Previously, Ben-David et al. \([5]\) proved Theorem 2 in the special case \( g = \text{GapOr} \) where \( \text{GapOr}_m \) is the \( m \)-bit partial function defined by \( \text{GapOr}(x) = \text{Or}(x) \) on inputs of Hamming weight \( |x| \in \{0, m/2\} \) and is undefined otherwise. This is a particularly clean example of a function whose query complexity behaves as (assuming \( m \geq \log(1/\epsilon) \))

\[ R_{\epsilon}(\text{GapOr}) = \Theta(\log(1/\epsilon)). \]

We prove Theorem 2 by a direct reduction to this previous result! Our more general result says, informally, that error reduction is necessary for any composed function \( f \circ g^n \) if it is necessary in the special case \( g = \text{GapOr} \). Our key conceptual insight is to formulate a sense in which every \( g \) can be “simulated” by \( \text{GapOr} \). There is, however, a slight technical caveat. For the reduction to work, we need to assume that the lower bound for \( f \circ \text{GapOr}^n \) holds not only against randomised decision trees but also against a more powerful model called \( \epsilon \)-approximate nonnegative degree \( \deg_{\epsilon}^+ \) (aka conical junta degree, partition bound), which we will recall in Section 2.

\[ \text{Theorem 3 (Reduction to GapOr). } \text{If a function } f \text{ satisfies } \deg_{\epsilon}^+(f \circ h^n) \geq \Omega(n \log n) \text{ for some constant } \epsilon > 0 \text{ and for both } h \in \{\text{GapOr}_{\log n}, \neg\text{GapOr}_{\log n}\}, \text{ then} \]

\[ \forall g : \ R(f \circ g^n) = \Omega(n \cdot R_{1/n}(g)). \]

Theorem 2 follows immediately by combining Theorem 3 with \([5, \text{Theorem 4}]\), which proved the required nonnegative degree lower bound for \( \text{Maj} \circ \text{GapOr}^n \) (we only note that their proof works equally well for \( \neg\text{GapOr} \) in place of \( \text{GapOr} \)). In fact, the nonnegative degree lower bound holds more generally for any \((2n+1)\)-bit outer function that agrees with \( \text{Maj} \) on inputs of weight \( n \) and \( n+1 \). For example, \( \text{Xor} \) is such a function, and hence the \( \text{Xor} \) lemma of Brody et al. \([8]\) can be recovered using Theorem 3. However, the original proof in \([8]\) is much simpler than ours, and moreover, the result of \([8]\) actually characterises \( \overline{R}_\epsilon(\text{Xor} \circ g^n) \) for all \( \epsilon > 0 \) while we focus on the bounded-error case \( \epsilon = 1/3 \).

Our goal for the rest of the paper is to prove Theorem 3.

**Optimality?** We note that our choice of \( \text{GapOr} \) in Theorem 3 is optimal at least in the sense that it cannot be replaced with the more symmetric alternative \( \text{GapMaj} \), which is defined by \( \text{GapMaj}_m(x) = \text{Maj}_m(x) \) on inputs of weight \( |x| \in \{m/3, 2m/3\} \) and undefined otherwise. There are known examples of partial \( f \) (but no known total ones) for which \( \text{GapOr} \) does not need error reduction while \( \text{GapMaj} \) does \([5, \text{Section 4}]\). We suspect however that other aspects of Theorem 3 can be improved; see Subsection 1.4 for open problems.
1.2 Techniques: Leaf Lemma

Our main technical contribution, which might be of independent interest, is what we call Leaf Lemma. It states that every boolean function \( g \) admits a balanced input distribution \( \mu = \frac{1}{2}(\mu_0 + \mu_1) \), where \( \mu_i \) is a distribution supported on \( g^{-1}(i) \), and a “hard side” \( b \in \{0, 1\} \) satisfying the following: If we run a decision tree of shallow depth \( \ll R(g) \) on a random input \( x \sim \mu \) then we will typically reach a leaf \( \ell \) making one-sided error, that is, if the leaf \( \ell \) is reached by \( x \sim \mu^b \) with probability \( p \), then \( \ell \) is also reached by \( x \sim \mu^{1-b} \) with probability at least \( \epsilon \cdot p \). Interestingly, this property is inherently one-sided and the choice of the hard side \( b \) depends on the function \( g \). For example, \( \text{GapOr} \) and \( \neg \text{GapOr} \) have distinct hard sides. See our proof overview in Section 3 for more details.

1.3 Other related work

Complexity of composition. A major theme in boolean function complexity theory is to understand the complexity of the composition \( f \circ g^n \) in terms of the complexities of its two constituent functions. It has been long known that many well-studied complexity measures behave multiplicatively under composition. For example, deterministic query complexity satisfies \( D(f \circ g^n) = D(f)D(g) \) [24], quantum query complexity satisfies \( Q(f \circ g^n) = \Theta(Q(f)Q(g)) \) [23, 21], and yet more examples (degree, certificate complexity, sensitivity) are discussed in [25]. An interesting exception to this rule is randomised query complexity, where we can have two types of counter-examples.

- Super-multiplicative: There are functions \( f \) and \( g \) such that \( R(f \circ g^n) \geq \omega(R(f)R(g)) \).
  - For example, this happens whenever \( f \) necessitates error reduction for \( g = \text{GapOr} \).
- Sub-multiplicative: Recent work [13, 3] has found surprising examples of partial \( f \) and \( g \) such that \( R(f \circ g^n) \leq o(R(f)R(g)) \).

It is still open to quantify the extent to which multiplicativity can fail. For example, it has not been ruled out that \( R(f \circ g^n) \geq R(f)R(g)/\text{poly}(\log n) \) for all partial functions. It is also possible that a strict multiplicative lower bound holds for all total functions. This latter question is known as the randomised composition conjecture (for total functions) and it has been studied in a long line of work [6, 1, 13, 2, 3, 4].

Noisy decision trees. Necessity of error reduction is closely related to the model of “noisy decision trees” [12, 11, 10, 15]. In this model, the goal is to compute a boolean function \( f \) given noisy query access to its input bits. A single query to an input variable \( x_i \) returns its correct value with probability \( 2/3 \) (say) and the opposite value \( 1 - x_i \) with probability \( 1/3 \). This model is effectively equivalent to computing \( f \circ \text{GapMaj}^n \) in the standard query model. With this interpretation, one of the results of [12] states that \( R(\text{Maj} \circ \text{GapMaj}^n) = \Theta(n \log n) \). We note that this is weaker (in two respects) than the result \( \text{deg}_+^e(\text{Maj} \circ \text{GapOr}^n) = \Theta(n \log n) \) from [5], which we used to derive our main result (although see Problem 4 below).

1.4 Open problems

How optimal is Theorem 3? We suspect that our assumption about nonnegative degree is an artifact of our proof and can be relaxed as follows.

- Problem 4. Show that the hypothesis in Theorem 3 can be weakened to \( R(f \circ h^n) \geq \Omega(n \log n) \).
Whether we need to assume hardness for both $\text{GapOR}$ and its negation, we do not know.

\textbf{Problem 5.} Are there examples of $f$ with $R(f \circ \text{GapOR}^n) \geq \omega(R(f \circ \neg \text{GapOR}^n))$?

Theorem 3 could be useful in showing tight composition results for yet more outer functions. For example, consider the well-studied partial function $\text{SqrtGapMaj}_n$ (often called simply the gap majority function) defined as $\text{Maj}_n$ but restricted to inputs of Hamming weight $|x| \notin n/2 \pm \sqrt{n}$.

\textbf{Problem 6.} Show $R(\text{SqrtGapMaj} \circ g^n) = \Theta(n \cdot R_{1/n}(g))$ for every $g$.

## 2 Query complexity basics

We study partial boolean functions $f : \{0, 1\}^n \to \{0, 1, *\}$. The domain of the function is $\text{dom}(f) := f^{-1}(\{0, 1\})$ and the inputs $f^{-1}(*)$ are undefined. We say $f$ is total if $\text{dom}(f) = \{0, 1\}^n$. For partial functions $f$ and $g$, their composition $f \circ g^n$ is defined by $(f \circ g^n)(x^1, \ldots, x^n) := f(g(x^1), \ldots, g(x^n))$ if $x^i \in \text{dom}(g)$ for all $i \in [n]$; otherwise $(f \circ g^n)(x^1, \ldots, x^n) := *$. Standard references for boolean function complexity are [9, 18].

\textbf{Decision trees.} A (deterministic) decision tree $t$ is an algorithm for computing a boolean function on an unknown input $x \in \{0, 1\}^n$. The algorithm repeatedly queries the input variables $x_i \in \{0, 1\}$ in some order (which can depend on outcomes of queries made so far) until eventually producing an output $t(x)$. Such an algorithm can be represented as a binary tree, with internal nodes labelled with variables $x_i$, outgoing edges of the internal nodes labelled with query outcomes ($x_i = 0$ and $x_i = 1$), and leaves labelled with output values. Each input $x$ determines a unique root-to-leaf path, obtained by following the query outcomes consistent with $x$. The most important cost measure of $t$ is its depth, denoted $\text{depth}(t)$, which is the longest root-to-leaf path in the tree and equals $\max_x q(t, x)$ where $q(t, x)$ denotes the number of queries made by $t$ on input $x$.

A randomised decision tree $T$ is a distribution over deterministic decision trees $t \sim T$. We say $T$ computes $f : \{0, 1\}^n \to \{0, 1, *\}$ with error $\epsilon$ if for every $x \in \text{dom}(f)$ we have $\Pr_{t \sim T}[t(x) = f(x)] \geq 1 - \epsilon$. There are two cost measures for $T$: the (worst-case) depth is the maximum depth of any decision tree in the support of $T$; the expected depth is $\max_x \mathbb{E}_{t \sim T}[q(t, x)]$. The $\epsilon$-error query complexity of $f$, denoted $R_\epsilon(f)$, is the least depth of a randomised decision tree that computes $f$ with error $\epsilon$. The $\epsilon$-error expected query complexity, denoted $\overline{R}_\epsilon(f)$, is defined analogously.

\textbf{Error reduction.} It is well known that the error probability of an algorithm (computing a boolean-valued function) can be reduced from any constant $1/2 - \delta$, where $\delta > 0$, to any other constant $\epsilon > 0$ by repeating the algorithm constantly many times (in fact, $O(\log(1/\epsilon)/\delta)$ many) and outputting the majority answer. Hence we often set $\epsilon := 1/3$ and omit $\epsilon$ from notation. In this bounded-error regime, we have $\overline{R}_\epsilon(f) \leq R(f) \leq O(\overline{R}_\epsilon(f))$ where the second inequality follows by truncating executions that query many more bits than the expectation. For vanishing $\epsilon = o(1)$ (as $n \to \infty$), it is possible that $\overline{R}_\epsilon(f) \leq o(R_\epsilon(f))$. For example, consider the partial $2n$-bit function $f$ where the task is to distinguish inputs of the form $x0^n$ from inputs of the form $0^n x$ with the promise that $|x| = n/2$. We have $\overline{R}_{1/n}(f) = O(1)$ while $R_{1/n}(f) = \Theta(\log n)$. In this small-error regime, the following fine-grained error reduction calculation will be useful.

\textbf{Claim 7.} $\overline{R}_{\epsilon,k}(f) \leq 4k \cdot \overline{R}_\epsilon(f)$ for every $k \geq 1$ and $\epsilon \leq 1/16$. 

Proof. Suppose $T$ computes $f$ with error $\epsilon$ and consider the algorithm $T'$ that runs $T$ $4k-1$ times and outputs the majority answer. Then $T'$ errs iff at least $2k$ of the runs err. This happens with probability at most $\sum_{i=2k}^{4k-1} (4k-1)^i \epsilon^i (1-\epsilon)^{4k-1-i} \leq 2^{4k-2k} \leq \epsilon^k$. \hfill \diamondsuit

**Leaf indicators.** Let $t$ be a decision tree with $n$-bit inputs. We denote by $L(t)$ the set of its leaves and by $\ell_x^t \in L(t)$ the unique leaf reached on input $x$. We often identify a leaf $\ell \in L(t)$ with its associated leaf indicator function $\ell_x : \{0,1\}^n \rightarrow \{0,1\}$ defined by $\ell(x) := 1$ iff input $x$ reaches leaf $\ell$. Thus each $\ell$ is simply a conjunction of at most $\text{depth}(t)$ literals $(x_i \lor \bar{x}_i)$ determined by the unique root-to-$\ell$ path in $t$. If $t$ outputs boolean values, we let $A(t) \subseteq L(t)$ denote the set of accepting leaves, that is, those that output 1. Since the leaf indicators have pairwise disjoint supports, we can write the function computed by $t$ as

$$t(x) = \sum_{\ell \in A(t)} \ell(x). \quad (1)$$

**Nonnegative degree.** Let $p : \{0,1\}^n \rightarrow \mathbb{R}_{\geq 0}$ be a nonnegative function. We say $p$ is a nonnegative $d$-junta if it depends on at most $d$ of its variables. For example, if $t$ is a depth-$d$ decision tree, then each $\ell \in L(t)$ is a nonnegative $d$-junta. More generally, we say that $p$ is a conical junta of degree $d$ if it can be written as a conical combination of nonnegative $d$-juntas, that is, $p(x) = \sum_t a_t q_t(x)$ where $a_t \geq 0$ are nonnegative scalars and the $q_t$ are nonnegative $d$-juntas. For example, the function computed by $t$ is a degree-$d$ conical junta, as given by the expression $(1)$. The nonnegative degree of $p$, denoted $\deg^+(p)$, is the least $d$ such that $p$ is a degree-$d$ conical junta.

Let $f : \{0,1\}^n \rightarrow \{0,1,*\}$ be a partial function. We say that $p$ $\epsilon$-approximates $f$ if $p(x) \in f(x) \pm \epsilon$ for every $x \in \text{dom}(f)$. The $\epsilon$-approximate nonnegative degree of $f$, denoted $\deg^+(f)$, is the least degree of a conical junta that $\epsilon$-approximates $f$. For example, if $T$ is a depth-$d$ randomised $\epsilon$-error decision tree for $f$, then there exists a degree-$d$ conical junta $p_T$ that $\epsilon$-approximates $f$, namely,

$$p_T(x) := \mathbb{E}_{t \sim T} [t(x)] \in f(x) \pm \epsilon.$$  

This shows that $\deg^+_d(f) \leq R_s(f)$. The gap between $\deg^+_d(f)$ and $R(f)$ can be huge for partial functions. For example, consider the $n$-bit UNIQUE-OR defined by $\text{UNIQUE-OR}(x) = \text{Or}(x)$ for inputs of weight $|x| \in \{0,1\}$ and undefined otherwise. Then $\deg^+_d(\text{UNIQUE-OR}) = 1$ (computed by $\sum x_i$) while $R(\text{UNIQUE-OR}) = \Theta(n)$. For total functions, the gap is at most polynomial [9].

Nonnegative degree has been studied under many names: (one-sided) partition bound [16], WAPP query complexity [14, 5], and query complexity “in expectation” [19].

3 Proof overview

Here we outline the proof of Theorem 3. We phrase the proof in the contrapositive: Supposing that $T$ is a randomised decision tree computing $f \circ g^n$ of shallow depth $\ll n \cdot R_{1/n}(g)$ we construct an approximate conical junta for $f \circ \text{GAP-OR}^n$ (or $f \circ \neg\text{GAP-OR}^n$) of degree $\ll n \log n$.

Our overview is in two parts.  

(§3.1) We first formulate our main technical lemma called Leaf Lemma and its generalisation Multileaf Lemma. They describe what typical leaves of $T$ look like: they are noisy, meaning that they make noticeable errors in predicting the outputs of many copies of $g$. The proofs of these lemmas will occupy the remaining sections of this paper.

---

**CCC 2021**
Then we use Multileaf Lemma to prove Theorem 3. A notable component of this part of the proof is showing how the acceptance probabilities of noisy leaves can be “simulated” by low-degree conical juntas in the domain of \( f \circ \text{GapOr}^n \).

### 3.1 Statement of Leaf Lemma

**Example.** We build up to the statement of Leaf Lemma by first considering the prototypical example \( g = \text{GapOr}_m \). Define two distributions \( \mu^0 \) and \( \mu^1 \) so that \( \mu^1 \) is uniform over \( \text{GapOr}_m \). Namely, \( \mu^0 \) places probability 1 on the input \( 0^m \) and \( \mu^1 \) is uniform over \( x \) of weight \( |x| = m/2 \). Suppose \( t \) is a deterministic decision tree of shallow depth \( d \leq m \) trying to compute \( \text{GapOr}_m \). For a leaf \( \ell \in \mathcal{L}(t) \) and any input distribution \( \mu \) we write for short

\[
\ell(\mu) := \mathbb{E}_{x \sim \mu}[\ell(x)] = \mathbb{P}_{x \sim \mu}[\ell(x) = 1].
\]

What do the typical leaves look like when we run \( t \) on a random input \( x \sim \mu^i \) for \( i \in \{0,1\} \)?

- **Easy side** \( i = 1 \). The tree will query a 1-bit after about 2 queries in expectation. Such leaves \( \ell \) are safe to output 1 as they know \( \text{GapOr}(x) = 1 \) for certain: \( \ell(\mu^0) = 0 \) and \( \ell(\mu^1) > 0 \).

- **Hard side** \( i = 0 \). Here every query returns 0 and we reach a leaf \( \ell \) reading \( d \) many 0s. Although the leaf \( \ell \) can be quite confident that the input \( x \) was sampled from \( \mu^0 \) rather than \( \mu^1 \), some uncertainty remains: \( \ell(\mu^0) = 1 \) and \( \ell(\mu^1) \geq \epsilon \), for \( \epsilon := 2^{-\Omega(d)} \).

In both cases, we have \( \ell(\mu^1) \geq \epsilon \cdot \ell(\mu^0) \) and we say that \( \ell \) is (one-sidedly) noisy. We now formalise how every \( g \) gives rise to such noisy leaves.

**General case.** Fix a partial function \( g : \{0,1\}^m \to \{0,1,\ast\} \). Let \( \mu = \frac{1}{2}(\mu^0 + \mu^1) \) be a balanced distribution where \( \mu^i \) is supported on \( g^{-1}(i) \). For a leaf \( \ell \) over \( m \) bits, a “hard side” \( b \in \{0,1\} \), and an error parameter \( \epsilon \geq 0 \), we define

\[
\ell \text{ is } (\epsilon,\mu,b)-\text{noisy} \overset{\text{def}}{=} \ell(\mu^{1-b}) \geq \epsilon \cdot \ell(\mu^b).
\]

Our Leaf Lemma says that every partial function \( g \) admits a hard distribution \( \mu = \frac{1}{2}(\mu^0 + \mu^1) \) such that if we run a shallow decision tree \( t \) on a random input \( x \sim \mu \), the leaf reached \( \ell^t \) will typically be noisy. For simplicity of notation, for small quantities \( a, b \in [0,1] \), we write \( a \ll b \) (resp. \( a \ll \ll b \)) to mean \( a \leq c b \) (resp. \( a^{\epsilon} \leq b \)) for a sufficiently small constant \( c > 0 \).

**Leaf Lemma.** For every partial \( g \) and \( 0 < \epsilon \ll \ll \delta \ll 1 \), there exists a distribution \( \mu = \frac{1}{2}(\mu^0 + \mu^1) \) over \( \text{dom}(g) \) and a hard side \( b \in \{0,1\} \) such that for every deterministic tree \( t \) and \( i \in \{0,1\} \):

\[
\mathbb{P}_{x \sim \mu^i}[g(t, x)] \ll \delta \implies \mathbb{P}_{x \sim \mu^i}[\ell^t_x \text{ is } (\epsilon,\mu,b)-\text{noisy}] \geq 1 - \delta.
\]

Leaf Lemma is our main technical contribution. The proof appears in Section 4. To whet the reader’s appetite, we highlight two interesting challenges that make the lemma non-trivial.

**C1** Which side is hard? We need to somehow tease out a hard side for an arbitrary \( g \) and this can even depend on the choice of \( \mu \). For example, consider \( g(b, x) := b \oplus \text{GapOr}(x) \) where \( b \in \{0,1\} \). Rather than \( \mu \) assigning \( b \) at random, the distribution can fix \( b \) to either 0 or 1, which reduces \( g \) to either \( \text{GapOr} \) or \( \neg\text{GapOr} \) (two functions with distinct hard sides).
(C2) Behaviour of typical leaves. The existence of $\mu$ is often proved using various minimax theorems (we use one due to Blais and Brody [7]). These theorems typically guarantee that any shallow decision tree incurs error at least $\epsilon$ on average relative to $\mu$. This does not rule out the following bad scenario: the tree could make error $1/2$ on $2\epsilon$ fraction of the leaves reached and no error on $1-2\epsilon$ fraction of the leaves – here the typical leaves are not noisy!

In order to use Leaf Lemma in the context of composed functions, we generalise it to the direct sum setting where the inputs come from $\text{dom}(g^n) := \text{dom}(g)^n$. Let $\ell$ be a leaf over $nm$ bits and write $\ell(x) = \prod_{i \in [n]} \ell_i(x^i)$ where $x^i \in \{0,1\}^m$ and each $\ell_i$ is over $m$ bits. We define

$$\ell \text{ is } (\delta, \epsilon, \mu, b)\text{-noisy } \iff \ell_i \text{ is } (\epsilon, \mu, b)\text{-noisy for at least } (1-\delta)n \text{ many } i \in [n].$$

Our generalised lemma says that we will typically reach a noisy leaf if we run a shallow decision tree on a random input from the product distribution $\mu^y := \mu^{y_1} \times \cdots \times \mu^{y_n}$ where $y \in \{0,1\}^n$.

▶ Multileaf Lemma. For every partial $g$ and $0 < \epsilon \ll \delta \ll 1$, there exists a distribution $\mu = \frac{1}{2}(\mu^0 + \mu^1)$ over $\text{dom}(g)$ and a hard side $b \in \{0,1\}$ such that for every deterministic tree $t$ taking inputs from $\text{dom}(g^n)$ and having depth($t$)/$(n\overline{R}_c(g)) \ll \delta$,

$$\forall y \in \{0,1\}^n : \quad \mathbb{P}_{x \sim \mu^y} [\ell^*_x \text{ is } (\delta, \epsilon, \mu, b)\text{-noisy}] \geq 1-\delta.$$

Given Leaf Lemma the proof of the generalisation is not difficult: we can use linearity of expectation to see that the expected number of queries $t$ makes to most copies of $g$ is low, and hence we can apply Leaf Lemma for those copies. The details appear in Section 5.

### 3.2 Proof of Theorem 3

We conclude this overview section with a proof of Theorem 3 using Multileaf Lemma. We start with a lemma that shows how the noisy leaves in the domain of $g^n$ can be “simulated” by low-degree conical juntas in the domain of $\text{GapOr}^n$. For simplicity, we state the lemma assuming a hard side $b = 0$; an analogous lemma holds for $b = 1$ by replacing $\text{GapOr}$ with $\sim\text{GapOr}$.

▶ Simulation Lemma. Let $\ell$ be a $(\delta, \epsilon, \mu, 0)$-noisy leaf over the variables of $g^n$. There exists a conical junta $p_{\ell'} : (\{0,1\}^m)^n \rightarrow \mathbb{R}_{\geq 0}$ of degree at most $n \cdot [\delta \log n + \log(1/\epsilon)]$ such that

$$\forall x \in \text{dom}(\text{GapOr}^n_{\text{log } n}) : \quad p_{\ell'}(x) = \ell(\mu^\text{GapOr}^n_{\text{log } n}(x)).$$

**Proof.** We start by defining three conical juntas in the domain of $\text{GapOr}_m$ for $m := \log n$. Let $S^m_k$ be the distribution over multisets obtained by picking $k$ random elements from $[m]$ with replacement.

$$
\begin{align*}
q_1(x) &:= \frac{1}{m} \sum_{i \in [m]} x_i & \text{of degree } 1, \\
q_2(x) &:= \prod_{i \in [m]} \bar{x}_i & \text{of degree } m = \log n, \\
q_3(x) &:= \mathbb{E}_{S \sim S^m_k} \prod_{i \in S} \bar{x}_i & \text{of degree } k := \log(1/\epsilon).
\end{align*}
$$

Note the following output values:

$$
\begin{align*}
\forall x \in (\text{GapOr}_m)^{-1}(0) : & \quad q_1(x) = 0, \quad q_2(x) = 1, \quad q_3(x) = 1, \\
\forall x \in (\text{GapOr}_m)^{-1}(1) : & \quad q_1(x) = 1, \quad q_2(x) = 0, \quad q_3(x) = 2^{-k} = \epsilon.
\end{align*}
$$
Let $y = (y^1, \ldots, y^n)$ be the input variables of $g^n$. We write $\ell(y) = \prod \ell_i(y^i)$ so that $\ell(\mu^{\text{GapOr}_{\log n}^n}(x)) = \prod \ell_i(\mu^{\text{GapOr}_{\log n}^n}(x^i))$. We simulate each factor in this product separately. For $i \in [n]$ consider the function $p_i : \{0, 1\}^m \rightarrow \mathbb{R}_{\geq 0}$ defined by

$$p_i(x) := \ell_i(\mu^{\text{GapOr}_{\log n}^n}(x)),$$

First note that $p_i$ can always be written as a conical combination of $q_1$ and $q_2$ in degree $\log n$. Moreover, if $\ell_i$ is $(\epsilon, \mu, 0)$-noisy, meaning $\ell_i(\mu^1) \geq \epsilon \cdot \ell_i(\mu^0)$, then we can do better and write $p_i$ as a conical combination of $q_1$ and $q_3$ in degree $\log(1/\epsilon)$. We now define $p_T := \prod p_i$. The claimed bound on the degree of $p_T$ follows because at most $\delta$ fraction of the $\ell_i$ are non-noisy. ▶

We are now ready to prove Theorem 3 using Multileaf Lemma and Simulation Lemma.

**Proof of Theorem 3.** Suppose for contradiction that $T$ is a randomised decision tree for $f \circ g^n$ having error $1/3$ and depth $\gamma n \mathbb{R}_{1/n}(g)$ where $\gamma = o(1)$ as $n \rightarrow \infty$. Our goal is to construct an $o(n \log n)$-degree $(1)$-approximate conical junta for $f \circ \text{GapOr}_{\log n}$ (or $f \circ \neg \text{GapOr}_{\log n}$).

We make two simplifying assumptions wlog.

1. The randomised tree $T$ has error $o(1)$. To ensure this, we may reduce $T$’s error by running it $1/\sqrt{n} = \omega(1)$ times. This will yield an $o(1)$-error tree of depth $\gamma n \mathbb{R}_{1/n}(g) = o(n \mathbb{R}_{1/n}(g))$.

2. There is some $\epsilon := 1/n^{\Omega(1)}$ such that $T$ has depth $o(n \mathbb{R}_{1/n}(g))$. To ensure this, we may apply Claim 7 to see that $\gamma n \mathbb{R}_{1/n}(f) \leq \sqrt{\gamma n \mathbb{R}_{1/n}(f)} \leq o(n \mathbb{R}_{1/n}(f))$ where $\epsilon := 1/n^{4\sqrt{n}}$.

We invoke Multileaf Lemma with the above $\epsilon \leq o(1)$ and $\delta := \max\{\gamma^c, \epsilon^c\} \leq o(1)$ for small enough constant $c > 0$. We get a hard distribution $\mu$ and a hard side $b$, say $b = 0$ (case $b = 1$ is similar, but using $\neg \text{GapOr}$), such that the following holds: For every $t$ in the support of $T$ if we run $t$ on a random input $x \sim \mu^y$, where $y \in \{0, 1\}^n$, then the leaf reached $\ell^t_x$ will be $(\delta, \epsilon, \mu, 0)$-noisy with probability $1 - o(1)$. This allows us to effectively ignore non-noisy leaves: denoting by $\mathcal{N}(t) \subseteq \mathcal{A}(t)$ the set of accepting leaves that are $(\delta, \epsilon, \mu, 0)$-noisy, we have

$$\forall y \in \{0, 1\}^n : \quad \mathbb{E}_{x \sim \mu^y}[\ell(x)] = \mathbb{E}_{x \sim \mu^y}[\sum_{\ell \in \mathcal{A}(t)} \ell(x)]$$

(Using (1))

(2)

We now define the approximating conical junta by

$$p(x) := \mathbb{E}_{t \sim T} \left[ \sum_{\ell \in \mathcal{N}(t)} p_t(x) \right],$$

where the $p_t$ are given by Simulation Lemma. Hence $p$ has degree at most

$$n \cdot [\delta \log n + \log(1/\epsilon)] = n \cdot [o(1) \log n + \log n^{\Theta(1)}] = o(n \log n).$$

We finish the proof of Theorem 3 by verifying that $p$ indeed $o(1)$-approximates $f \circ \text{GapOr}_{\log n}^n$.

$$\forall x : \quad p(x) = \mathbb{E}_{t \sim T} \left[ \sum_{\ell \in \mathcal{N}(t)} p_t(x) \right]$$

$$= \mathbb{E}_{t \sim T} \left[ \sum_{\ell \in \mathcal{N}(t)} \ell(\mu^y) \right]$$

$$= \mathbb{E}_{t \sim T} \left[ \sum_{\ell \in \mathcal{N}(t)} \mathbb{E}_{x \sim \mu^y}[\ell(x')] \right]$$

$$= \mathbb{E}_{t \sim T} \left[ \mathbb{E}_{x \sim \mu^y} [\sum_{\ell \in \mathcal{N}(t)} \ell(x')] \right]$$

$$\in \mathbb{E}_{t \sim T} \left[ \mathbb{E}_{x \sim \mu^y} [\ell(x')] \right] \pm o(1)$$

(Using (2))
When searching for the hard side of a partial function
we formulate a distributional version of
the Leaf Lemma in three subsections.

A (deterministic) abort-tree $t$ is a decision tree that outputs either a boolean value (0 or 1) or
the abort symbol $\perp$. When an abort-tree is trying to compute a boolean function $g$, we
do not consider the output $\perp$ as an “error”; the tree simply gives up on the computation.
Indeed, we say that $t(x)$ errs iff $t(x) = 1 - g(x)$, that is, $t(x) \neq \perp$ and $t(x) \neq g(x)$. As before,
a randomised abort-tree is a probability distribution over deterministic abort-trees. For
$\gamma \in (0, 1)$ and $\epsilon \in [0, 1/2]$ we define $R_{\gamma, \epsilon}(g)$ as the least (worst-case) depth of a randomised
abort-tree $T$ such that for all $x \in \text{dom}(g)$:

$$
\Pr_{t \sim T}[t(x) = \perp] \leq \gamma \quad \text{and} \quad \Pr_{t \sim T}[t(x) \text{ errs}] \leq \epsilon.
$$

We formulate a distributional version of $R_{\gamma, \epsilon}(g)$ as follows. For a distribution $\mu$ over $\text{dom}(g)$,
we define $D_{\gamma, \epsilon}^\mu(g)$ as the least depth of a deterministic abort-tree $t$ such that

$$
\Pr_{x \sim \mu}[t(x) = \perp] \leq \gamma \quad \text{and} \quad \Pr_{x \sim \mu}[t(x) \text{ errs}] \leq \epsilon.
$$

The following two lemmas from [7, §3.1] connect abort-trees and $R_{\gamma}(g)$.

**Lemma 8** (Abort vs. expected depth). For every $\epsilon \in [0, 1/2)$ and $\gamma \in (0, 1)$,

$$
\gamma \cdot R_{\gamma, \epsilon}(g) \leq R_{\epsilon}(g) \leq \frac{1}{1 - \gamma} \cdot R_{\gamma, (1-\gamma)\epsilon}(g).
$$

**Lemma 9** (Minimax). For every $\epsilon \in [0, 1/2)$, $\gamma \in (0, 1)$, and $\alpha, \beta \in (0, 1)$ with $\alpha + \beta \leq 1$,

$$
\max_\mu D_{\gamma/\alpha, \epsilon/\beta}^\mu(g) \leq R_{\gamma, \epsilon}(g) \leq \max_\mu D_{\alpha\gamma, \beta\epsilon}(g).
$$

### 4.1 Distributional characterisation of $R_\epsilon$ due to Blais–Brody

A (deterministic) abort-tree $t$ is a decision tree that outputs either a boolean value (0 or 1) or
the abort symbol $\perp$. When an abort-tree is trying to compute a boolean function $g$, we
do not consider the output $\perp$ as an “error”; the tree simply gives up on the computation.
Indeed, we say that $t(x)$ errs iff $t(x) = 1 - g(x)$, that is, $t(x) \neq \perp$ and $t(x) \neq g(x)$. As before,
a randomised abort-tree is a probability distribution over deterministic abort-trees. For
$\gamma \in (0, 1)$ and $\epsilon \in [0, 1/2]$ we define $R_{\gamma, \epsilon}(g)$ as the least (worst-case) depth of a randomised
abort-tree $T$ such that for all $x \in \text{dom}(g)$:

$$
\Pr_{t \sim T}[t(x) = \perp] \leq \gamma \quad \text{and} \quad \Pr_{t \sim T}[t(x) \text{ errs}] \leq \epsilon.
$$

We formulate a distributional version of $R_{\gamma, \epsilon}(g)$ as follows. For a distribution $\mu$ over $\text{dom}(g)$,
we define $D_{\gamma, \epsilon}^\mu(g)$ as the least depth of a deterministic abort-tree $t$ such that

$$
\Pr_{x \sim \mu}[t(x) = \perp] \leq \gamma \quad \text{and} \quad \Pr_{x \sim \mu}[t(x) \text{ errs}] \leq \epsilon.
$$

The following two lemmas from [7, §3.1] connect abort-trees and $R_{\gamma}(g)$.

**Lemma 8** ( Abort vs. expected depth). For every $\epsilon \in [0, 1/2)$ and $\gamma \in (0, 1)$,

$$
\gamma \cdot R_{\gamma, \epsilon}(g) \leq R_{\epsilon}(g) \leq \frac{1}{1 - \gamma} \cdot R_{\gamma, (1-\gamma)\epsilon}(g).
$$

**Lemma 9** ( Minimax). For every $\epsilon \in [0, 1/2)$, $\gamma \in (0, 1)$, and $\alpha, \beta \in (0, 1)$ with $\alpha + \beta \leq 1$,

$$
\max_\mu D_{\gamma/\alpha, \epsilon/\beta}^\mu(g) \leq R_{\gamma, \epsilon}(g) \leq \max_\mu D_{\alpha\gamma, \beta\epsilon}(g).
$$

### 4.2 Statement of Hard Side Lemma

When searching for the hard side of a partial function $g$ under a distribution $\mu = \frac{1}{2}(\mu^0 + \mu^1)$,
it is convenient to study a more symmetric notion of noisiness than the one-sided variant
defined earlier. For a leaf $\ell \in \mathcal{L}(t)$ of an abort-tree $t$, we define the relative error $\text{re}(\ell, \mu)$ so
that if $\ell$ is an aborting leaf, then $\text{re}(\ell, \mu) = 0$; otherwise

$$
\text{re}(\ell, \mu) := \frac{\min\{\ell(\mu^0), \ell(\mu^1)\}}{\ell(\mu^0) + \ell(\mu^1)} \in [0, 1/2].
$$
This definition captures the best achievable error of a leaf in an abort-tree. Namely, let us say that \( t \) is \( \mu \)-smart if every non-abort leaf \( \ell \in \mathcal{L}(t) \) outputs a boolean value \( i \in \{ 0, 1 \} \) that maximises \( \ell(\mu^t) \). Then for every leaf \( \ell \) in a \( \mu \)-smart \( t \) we have \( \mathbb{P}_{x \sim \mu^t}[t(x) \text{ errs } | \ell^t_x = \ell] = \mathbb{R}(\ell, \mu) \). An easy calculation gives the following claim, which we record for future use.

\[ \mathbb{P}_{x \sim \mu^t}[t(x) \text{ errs } | \ell^t_x = \ell] = \mathbb{R}(\ell, \mu). \]

\[ \mathbb{R}(\ell, \mu) = \begin{cases} 1, & \text{if } \ell^t_x = \ell \text{ and } \mathbb{E}[\ell(\mu^t)] = 1 \text{ (with dotted parameters).} \\ 0, & \text{else} \end{cases} \]

Another easy calculation shows that relative error implies noisiness.

\[ \text{Relative error implies noisiness} \]

\[ \mathbb{E}_{x \sim \mu^t}[\mathbb{R}(\ell, \mu)] = \mathbb{R}(\ell, \mu). \]

\[ \mathbb{R}(\ell, \mu) = \begin{cases} 1, & \text{if } \ell^t_x = \ell \text{ and } \mathbb{E}[\ell(\mu^t)] = 1 \text{ (with dotted parameters).} \\ 0, & \text{else} \end{cases} \]

\[ \text{We invoke Hard Side Lemma with parameters } \mathbb{R}(\ell, \mu) \text{ and } \mathbb{R}(\ell, \mu) \text{ to show that typical leaves are noisy.} \]

\[ \mathbb{R}(\ell, \mu) = \begin{cases} 1, & \text{if } \ell^t_x = \ell \text{ and } \mathbb{E}[\ell(\mu^t)] = 1 \text{ (with dotted parameters).} \\ 0, & \text{else} \end{cases} \]

\[ \text{We defer the proof until Subsection 4.3. We first use the lemma to prove Leaf Lemma, and here is where we address challenge 3.1: we exploit the high abort probability (namely, } 1 - \delta \text{) guaranteed by Hard Side Lemma to show that typical leaves are noisy.} \]

\[ \text{Leaf Lemma (rephrased). For every partial function } g \text{ and } 0 < \epsilon \ll \delta \ll 1, \text{ there exists a distribution } \mu = \frac{1}{2}(\mu^0 + \mu^1) \text{ over } \text{dom}(g) \text{ and a hard side } b \in \{ 0, 1 \} \text{ such that for every deterministic abort-tree } t \text{ and } i \in \{ 0, 1 \}:} \]

\[ \mathbb{E}_{x \sim \mu^t}[g(t, x)] \ll \delta \implies \mathbb{P}_{x \sim \mu^t}[\ell^t_x \text{ is } (\epsilon, \mu, b)\text{-noisy}] \geq 1 - \delta. \]

**Proof.** We observe first that regardless of \( \mu, b \), or even the expected depth of \( t \), the lemma holds for the easy side \( i = 1 - b \). Indeed, if we let \( \mathcal{B} \subseteq \mathcal{L}(t) \) denote the set of non-\( (\epsilon, \mu, b)\)-noisy leaves,

\[ \mathbb{P}_{x \sim \mu^t}[\ell^t_x \in \mathcal{B}] = \sum_{\ell \in \mathcal{B}} \ell(\mu^{1-b}) < \epsilon \mathbb{E}\sum_{\ell \in \mathcal{B}} \ell(\mu^b) \leq \epsilon \sum_{\ell \in \mathcal{L}(t)} \ell(\mu^b) = \epsilon \leq \delta. \]

Let us then focus on the interesting case \( i = b \) where the careful choice of \( \mu \) and \( b \) is essential. We invoke Hard Side Lemma with parameters \( \epsilon \) and \( \delta := \delta^2 \) (assuming suitably \( 0 < \epsilon \ll \delta \ll 1 \)) to obtain \( \mu \) and \( b \) such that for every abort-tree \( \ell \) with depth\( (\ell) \leq \delta^2 \mathbb{R}(\ell, \mu) \) the property (3) holds (with dotted parameters). Let \( x \sim \mu^b \) henceforth and write \( \mathbb{E}(\ell) := \mathbb{E}[\mathbb{R}(\ell, \mu)] \) for short. Suppose \( t \) satisfies \( \mathbb{E}[g(t, x)] \leq \delta^{c+2} \mathbb{R}(\ell, \mu) \) (where we chose \( 2(c+2) \) as the exponent hidden by \( \ll \)). Recalling from Claim 11 that relative error implies noisiness, our goal is to show

\[ \mathbb{P}_{x}[\mathbb{R}(\ell^t_x) \geq \epsilon] \geq 1 - \delta. \]

We convert \( t \) into an abort-tree by letting \( t' \) be a modification of \( t \) that aborts whenever more than \( \delta^2 \mathbb{R}(\ell, \mu) \) queries are made. Using Markov’s inequality and the low expected depth of \( t \),

\[ \mathbb{P}_{x}[t'(x) = \bot] \leq \mathbb{P}_{x}[g(t, x) > \delta^{c+2} \mathbb{R}(\ell, \mu)] \leq \mathbb{E}[g(t, x)] \leq \delta^2. \]
We also have $\mathbb{P}_x[\text{re}(\ell_x^t) \geq \epsilon] \geq \mathbb{P}_x[\text{re}(\ell_x^t) \geq \epsilon]$ since we only made more executions abort. To prove (4), suppose for contradiction that $\mathbb{P}_x[\text{re}(\ell_x^t) \geq \epsilon] < 1 - \delta$. Let $t$ be a further modification of $t'$ that aborts any leaf $\ell \in \mathcal{L}(t')$ with $\text{re}(\ell) \geq \epsilon$. Note that

$$\mathbb{P}_x[t(x) = \perp] \leq \mathbb{P}_x[t'(x) = \perp] + \mathbb{P}_x[\text{re}(\ell_x^t) \geq \epsilon] \leq \delta^2 + 1 - \delta \leq 1 - \delta.$$

Hence we get from (dotted) property (3) that $\mathbb{E}_x[\text{re}(\ell_x^t)] > \epsilon$. But this contradicts the fact that $\text{re}(\ell) < \epsilon$ for all $\ell \in \mathcal{L}(t)$ by construction. This verifies (4) and concludes the proof. 

4.3 Proof of Hard Side Lemma

Let $\nu$ be a distribution that witnesses $D := \max_{\nu'} D'_{1-\delta, \epsilon/3}(g)$ so that every abort-tree $t$ with depth $(t) < D$ fails to satisfy at least one of the following:

- $\mathbb{P}_{\nu}[t(x) = \perp] \leq 1 - \delta$ \hspace{1cm} (5)
- $\mathbb{P}_{\nu}[t(x) \text{ errs }] \leq \epsilon^{1/3}$. \hspace{1cm} (6)

As a minor technicality, we re-balance $\nu$. We can write $\nu = \lambda \mu^0 + (1 - \lambda) \mu^1$ where $\lambda \in (0, 1)$ and $\mu^i$ is a distribution supported on $g^{-1}(i)$. We define $\mu := \frac{1}{2} (\mu^0 + \mu^1)$ as our balanced distribution.

Assume towards a contradiction that there does not exist a hard side for $\mu$, that is, the claim of the lemma fails for both $b \in \{0, 1\}$. This means there exists two abort-trees $t_0$ and $t_1$ of depth at most $\delta^3 \mathcal{R}_c(g)$ (where we chose 3 as the exponent hidden by $\ll$) such that for both $b \in \{0, 1\}$:

- $\mathbb{P}_{\nu}[t_b(x) = \perp] \leq 1 - \delta$ \hspace{1cm} (7)
- $\mathbb{E}_{\nu}[\text{re}(\ell_x^t, \mu)] \leq \epsilon$. \hspace{1cm} (8)

We will use $t_0$ and $t_1$ to construct a third tree $t$ that computes $g$ too well relative to $\nu$ contradicting our choice of $\nu$. We may assume wlog that $t_0$ and $t_1$ are $\mu$-smart, since the properties (7)–(8) do not depend on the boolean leaf-labels (only whether a leaf aborts or not). We now define $t$ as follows: On input $x$ we run both $t_0(x)$ and $t_1(x)$; if $t_0(x) \neq \perp$, we output $t_0(x)$; otherwise we output $t_1(x)$. We will show that $t$ has depth$(t) < D$ and satisfies (5)–(6), which will contradict our choice of $\nu$.

**Tree $t$ is shallow.** We have the following chain of inequalities

$$\text{depth}(t) \leq 2\delta^3 \mathcal{R}_c(g) \leq 32\delta^3 \mathcal{R}_{\epsilon/4}(g) \leq \delta^2 \mathcal{R}_{\epsilon/4}(g) \leq \mathcal{R}_{1-\delta^2, \epsilon/4}(g) \leq \max_{\nu'} D'_{1-\delta^2, \epsilon/4}(g) =: D.$$

The first inequality uses the definition of $t$. Second uses error reduction (Claim 7 with $k := 4$). Third uses $\delta \ll 1$. Fourth uses Lemma 8 (with $\gamma := 1 - \delta^2$). Fifth uses the minimax lemma (Lemma 9 with $\alpha := 1 - \delta^2$, $\beta := \delta^2$). The final inequality uses $\epsilon \ll \delta \ll 1$.

**Tree $t$ has bounded abort.** We verify property (5) by

$$\mathbb{P}_{\nu}[t(x) = \perp] = \mathbb{P}_{\nu}[t_0(x) = \perp \land t_1(x) = \perp] = \lambda \mathbb{P}_{\nu}[t_0(x) = \perp \land t_1(x) = \perp] + (1 - \lambda) \mathbb{P}_{\nu}[t_0(x) = \perp \land t_1(x) = \perp] \leq \lambda \mathbb{P}_{\nu}[t_0(x) = \perp] + (1 - \lambda) \mathbb{P}_{\nu}[t_1(x) = \perp] \leq 1 - \delta.$$

(Using (7))
We now verify property (6), which concludes the proof of Hard Side Lemma. We prove the claim for $\epsilon$.\hfill \Box

\begin{proof}

We prove the claim for $b = 0$ as the other case is analogous. Since $t'$ and $\mu$ are fixed, we drop them from notation writing $\text{re}(\ell) := \text{re}(\ell, \mu)$, $\ell_x := \ell^0_x$, $\mathcal{L} := \mathcal{L}(t')$. We argue that relative error on one side of the distribution must spill over to the other side:

$$\mathbb{E}_{x \sim \mu^b}[\text{re}(\ell_x)] = \sum_{\ell \in \mathcal{L}} \ell(\mu^0) \text{re}(\ell)$
$$

Here the first inequality used $\ell(\mu^0) \geq \ell(\mu^1)$ (from Claim 11) and the second inequality used Jensen’s inequality. It follows that $\mathbb{E}_{x \sim \mu^b}[\text{re}(\ell_x)] \leq \mathbb{E}_{x \sim \mu^b}[\text{re}(\ell_x)]^{1/2} \leq \epsilon^{1/2}$ and therefore $\mathbb{E}_{x \sim \mu}[\text{re}(\ell_x)] \leq \epsilon^{1/2}$. The claim then follows from Claim 10. \hfill \Box

We now verify property (6), which concludes the proof of Hard Side Lemma.

$$\mathbb{P}_{x \sim \mu}[t(x) \text{ errs}] \leq \mathbb{P}_{x \sim \mu}[t_0(x) \text{ errs } \lor t_1(x) \text{ errs}]
= \sum_{b \in \{0, 1\}} \mathbb{P}_{x \sim \mu}[t_b(x) \text{ errs}]
= \sum_{b \in \{0, 1\}} \lambda \mathbb{P}_{x \sim \mu}[t_b(x) \text{ errs}] + (1 - \lambda) \mathbb{P}_{x \sim \mu}[t_b(x) \text{ errs}]
\leq \sum_{b \in \{0, 1\}} 2 \mathbb{P}_{x \sim \mu}[t_b(x) \text{ errs}]
\leq \sum_{b \in \{0, 1\}} 2 \epsilon^{1/2}
= 4\epsilon^{1/2}
\leq \epsilon^{1/3}. \quad (\epsilon \ll 1)
$$

\section{Proof of Multileaf Lemma}

\begin{itemize}
\item \textbf{Multileaf Lemma (referred).} For every partial $g$ and $0 < \epsilon \ll \delta \ll 1$, there exists a distribution $\mu = \frac{1}{2}(\mu^0 + \mu^1)$ over $\text{dom}(g)$ and a hard side $b \in \{0, 1\}$ such that for every deterministic tree $t$ taking inputs from $\text{dom}(g^n)$ and having $\text{depth}(t)/(n \text{Re}(g)) \ll \delta$,

$$\forall y \in \{0, 1\}^n : \mathbb{P}_{x \sim \mu^n}[\ell_y^{t'} \text{ is } (\delta, \epsilon, \mu, b)\text{-noisy}] \geq 1 - \delta.$$  
\end{itemize}
We have that

\[ 1 - \delta \]

To show this, we compute as follows (using Claim 13 that is proved below)

\[
\text{variables, we define}
\]

\[
\text{depth at most}
\]

Here is the plan for our proof. An input \( x \in \text{dom}(g^n) \) can be seen as inducing several subtrees of \( t \) corresponding to distinct coordinates \( i \in [n] \). Indeed, define \( t^{x,i} \) as the tree over inputs from \( \text{dom}(g) \) that is obtained from \( t \) by substituting \( x \) as its input variables except retaining \( x^i \) as free variables. If we can show that \( t^{x,i} \) has shallow depth in expectation over an input \( z \sim \mu^b \) then we can hope to use and argue that the reached leaf \( \ell_z \in \mathcal{L}(t^{x,i}) \) (which is one of the \( n \) components of a leaf of \( t \)) is typically \((\epsilon, \mu, b)\)-noisy.

Let us formalise this plan. Let \( x \sim \mu^b \) henceforth. For \( i \in [n] \) we define two events

\[
i \text{-th tree is shallow: } S_i(x) \iff E_{z \sim \nu_i}[g(t^{x^i}, z)] \leq \delta \mathcal{R}_e(g).
\]

\[
i \text{-th leaf is noisy: } N_i(x) \iff \ell_{x^i} \in \mathcal{L}(t^{x^i}) \text{ is } (\epsilon, \mu, b) \text{-noisy).
\]

Note that Leaf Lemma states \( \Pr_x[S_i | S_i] \geq 1 - \delta. \) Thinking of \( S_i \) and \( N_i \) as indicator variables, we define \( S := \frac{1}{n} \sum_i S_i \) and \( N := \frac{1}{n} \sum_i N_i \). With this notation, Multileaf Lemma becomes equivalent to

\[
\Pr_x[N \geq 1 - \delta] \geq 1 - \delta.
\]

(9)

To show this, we compute as follows (using Claim 13 that is proved below)

\[
E_x[N] = \frac{1}{n} \sum_i \Pr_x[N_i] \\
\geq \frac{1}{n} \sum_i (1 - \delta) \Pr_x[S_i] \\
= (1 - \delta) E_x[S] \\
\geq (1 - \delta)(1 - \delta) \tag{Claim 13} \\
\geq 1 - \delta^2. \tag{\( \delta := \delta^3 \ll 1 \)}
\]

Hence (9) follows by applying Markov’s inequality to the nonnegative random variable \( 1 - N \geq 0 \). This completes the proof apart from the following claim. ▲

\[\triangleright \textbf{Claim 13. } E_x[S] \geq 1 - \delta. \]

Proof. Let \( q_i(t, x) \) denote the number of queries made by \( t \) to the \( i \)-th component of \( x \). Define \( x^{i \leftarrow z} \) as a copy of \( x \) but where \( z \) is inserted at the \( i \)-th component. Note that \( q_i(t, x^{i \leftarrow z}) = g(t^{x^i}, z) \). Linearity of expectation gives

\[
\sum_{i \in [n]} E_x[q_i(t, x)] \leq \text{depth}(t) \leq \delta^{c+4} n \mathcal{R}_e(g). \tag{10}
\]

Define \( I \subseteq [n] \) as the set of coordinates \( i \) satisfying

\[
E_x[q_i(t, x)] \leq \delta^{c+2} \mathcal{R}_e(g). \tag{11}
\]

We have that \( |I| \geq (1 - \delta^2)n \) as otherwise more than \( \delta^2 n \) terms in the sum (10) are larger than \( \delta^{c+2} \mathcal{R}_e(g) \) contradicting the upper bound on \( \text{depth}(t) \). Fix \( i \in I \). Sampling \( x \sim \mu^b \) is equivalent to first taking \( x \sim \mu^b \), then sampling independently \( z \sim \mu^v \), and finally outputting \( x^{i \leftarrow z} \). Hence

\[
E_x E_{z \sim \nu_i}[q_i(t, x^{i \leftarrow z})] = E_x[q_i(t, x)] \leq \delta^{c+2} \mathcal{R}_e(g).
\]
We get from Markov’s inequality and the above that
\[ P_x[\neg S_i] = P_x \left[ \mathbb{E}_{z \sim \mu} \left[ q_i(t, x, z_t) \right] > \delta \mathbb{R}_c(g) \right] \leq \delta^2. \] (12)

In conclusion,
\[ \mathbb{E}_x[S] \geq \frac{1}{n} \sum_{i \in I} P_x[S_i] \geq \frac{1}{n} |I| \cdot (1 - \delta^2) \geq (1 - \delta^2)^2 \geq 1 - \delta. \]

Abstract

In this paper we study polynomials in $\text{VP}_e$ (polynomial-sized formulas) and in $\Sigma\Pi\Sigma$ (polynomial-size depth-3 circuits) whose orbits, under the action of the affine group $\text{GL}_n^{\text{aff}}(F)$ (the action of $(A,b) \in \text{GL}_n^{\text{aff}}(F)$ on a polynomial $f \in F[x]$ is defined as $(A,b) \circ f = f(A^T x + b)$), are dense in their ambient class. We construct hitting sets and interpolating sets for these orbits as well as give reconstruction algorithms. Specifically, we obtain the following results:

1. For $C_n (\ell_1(x),\ldots,\ell_n(x)) \triangleq \text{Trace} \left( \begin{pmatrix} \ell_1(x) & 1 \\ 1 & 0 \end{pmatrix} \cdots \begin{pmatrix} \ell_n(x) & 1 \\ 1 & 0 \end{pmatrix} \right)$, where the $\ell_i$'s are linearly independent linear functions, we construct a polynomial-sized interpolating set, and give a polynomial-time reconstruction algorithm. By a result of Bringmann, Ikenmeyer and Zuiddam, the set of all such polynomials is dense in $\text{VP}_e$ [14], thus our construction gives the first polynomial-size interpolating set for a dense subclass of $\text{VP}_e$.

2. For polynomials of the form $\text{ANF}_{\Delta} (\ell_1(x),\ldots,\ell_{\Delta}(x))$, where $\text{ANF}_{\Delta}(x)$ is the canonical read-once formula in alternating normal form, of depth $2\Delta$, and the $\ell_i$'s are linearly independent linear functions, we provide a quasipolynomial-size interpolating set. We also observe that the reconstruction algorithm of [35] works for every polynomial in this class. This class is also dense in $\text{VP}_e$.

3. Similarly, we give a quasipolynomial-sized hitting set for read-once formulas (not necessarily in alternating normal form) composed with a set of linearly independent linear functions. This gives another dense class in $\text{VP}_e$.

4. We give a quasipolynomial-sized hitting set for polynomials of the form $f (\ell_1(x),\ldots,\ell_m(x))$, where $f$ is an $m$-variate $s$-sparse polynomial, and the $\ell_i$'s are linearly independent linear functions in $n \geq m$ variables. This class is dense in $\Sigma\Pi\Sigma$.

5. For polynomials of the form $\sum_{i=1}^s \prod_{j=1}^k \ell_{i,j}(x)$, where the $\ell_{i,j}$'s are linearly independent linear functions, we construct a polynomial-sized interpolating set. We also observe that the reconstruction algorithm of [45] works for every polynomial in the class. This class is dense in $\Sigma\Pi\Sigma$.

As $\text{VP} = \text{VNC}^2$, our results for $\text{VP}_e$ translate immediately to $\text{VP}$ with a quasipolynomial blow up in parameters. If any of our hitting or interpolating sets could be made robust then this would immediately yield a hitting set for the superclass in which the relevant class is dense, and as a consequence also a lower bound for the superclass. Unfortunately, we also prove that the kind of constructions that we have found (which are defined in terms of $k$-independent polynomial maps) do not necessarily yield robust hitting sets.

1 Introduction

Proving lower bounds on the size of algebraic circuits (also called arithmetic circuits), is an outstanding open problem in algebraic complexity. In spite of much effort, only a handful of lower bounds are known (a detailed account of most known lower bounds can be found in the excellent survey of Saptharishi [61]). One common theme of most known lower bounds is that they are proved using algebraic arguments. That is, if a proof of a lower bound for a class of circuits $\mathcal{C}$, usually has the following structure: one comes up with a set of (nonzero) polynomials $F_1, \ldots, F_m$, in $N = \binom{n+d}{d}$ many variables, such that the coefficient vector of every $n$-variate, degree-$d$ polynomial that can be computed in $\mathcal{C}$, is a common zero of all the $F_i$s (such $F_i$s are called separating polynomials). Then, one exhibits a polynomial $f$ whose coefficient vector is not a common zero, thus proving $f \not\in \mathcal{C}$. As an example one can immediately see that the well known partial derivative technique, and its successor, shifted partial derivative technique, are algebraic. Grochow [29] demonstrated this for most of the known lower bound proofs. As the set of common zeros of a set of polynomials is closed,\(^1\) this immediately implies that if we prove that $f \not\in \mathcal{C}$ using an algebraic argument, then the same argument also implies that $f \not\in \mathcal{C}$, the closure of $\mathcal{C}$. Recall that, in characteristic zero, the closure of a class $\mathcal{C}$ is the set of all polynomials that are limit points of sequences of polynomials from $\mathcal{C}$, where convergence is coefficient-wise (see Definition 9 for a general definition over arbitrary characteristic). As most known techniques are algebraic, we see that for proving a lower bound for a class $\mathcal{C}$ one actually has to consider the larger, and less structured class, $\overline{\mathcal{C}}$.

Geometric Complexity Theory (GCT for short), which was initiated by Mulmuley and Sohoni [55, 56], approaches the lower bound question from a different angle. GCT also looks for an algebraic lower bound proof, but rather than exhibiting an algebraic argument, it aims to prove the existence of a separating polynomial. Specifically, GCT attempts to prove Valiant’s hypothesis, that $\text{VP} \neq \text{VNP}$, over $\mathbb{C}$, via representation theory. Valiant’s hypothesis is, more or less, equivalent to showing that the permanent of a symbolic $m \times m$ matrix is not a projection of the symbolic $m \times m$ determinant for any $m = m(n)$ polynomial in $n$.\(^2\) Recall that a projection of a polynomial is a restriction of the polynomial to an affine subspace of its inputs. Observe that a restriction of an $n$-variate polynomial $f(x)$ to a subspace of its inputs, is equivalent to considering the polynomial $f(Ax + b)$, where $A$ is an $n \times n$ matrix and $b \in \mathbb{C}^n$. As any matrix is a limit point of a sequence of invertible matrices, an algebraic proof that the permanent is not a projection of the $m \times m$ determinant, over $\mathbb{C}$, is equivalent to an algebraic proof showing that the permanent is not in the closure of the set of polynomials $\{\text{Det}(AX + b) \mid A \in \text{GL}_m(\mathbb{C}), \ B \in \mathbb{C}^{m^2}\}$, where $\text{GL}_m(\mathbb{C})$ is the group of invertible $m \times m$ matrices (this is true for every field of characteristic $\neq 2$). The set $\{\text{Det}(AX + b) \mid A \in \text{GL}_m(\mathbb{C}), \ B \in \mathbb{C}^{m^2}\}$ is called the orbit of the determinant under the action of the affine group (we denote the affine group over $\mathbb{C}^m$ with $\text{GL}_m^{\text{aff}}(\mathbb{C})$). GCT considers the linear space of polynomials that vanish on every coefficient vector in the orbit of the determinant, and similarly the linear space of polynomials that vanish on every coefficient vector in the orbit of the permanent. There is a natural action of $\text{GL}_m^{\text{aff}}(\mathbb{C})$ on those linear spaces, thus defining two representations of $\text{GL}_m^{\text{aff}}(\mathbb{C})$. GCT wishes

---

\(^1\) It is closed in the Zariski topology. Over $\mathbb{R}$ or $\mathbb{C}$ this is the same as being closed in the Euclidean topology.

\(^2\) A super-quasipolynomial lower bound would imply that $\text{VP} \neq \text{VNP}$ whereas a super-polynomial lower bound would imply that permanent does not have polynomial-size algebraic formulas or algebraic branching programs.
to find a separating polynomial by showing that some irreducible representation of $\text{GL}_{\text{aff}}^m(C)$ has strictly larger multiplicity when considering the representation corresponding to the determinant. This approach bypasses the barrier given in [28, 30] as it does not exhibit any efficiently computable separating polynomial but rather just proves the existence of one. However, the representation theory questions arising in this program are quite difficult, even when considering the analog questions for restricted classes. For an introduction to GCT see the lecture notes of Bläser and Ikenmeyer [13].

Another possible approach for proving lower bounds against a class of polynomials $C$, is via the construction of a hitting set for $C$. Recall that a hitting set $H$ for a class $C$ is a set of points such that for any nonzero polynomial $f$, that can be computed by a circuit from $C$, there is $v \in H$ such that $f(v) \neq 0$. In [37] Heintz and Schnorr observed that if we have such a hitting set $H$ then any nonzero polynomial $g$ that vanishes on $H$ cannot be computed in $C$. It is also not hard to see that this way of obtaining lower bounds also bypasses the natural proof barrier of [28, 30]. The problem is that in most cases we obtained a hitting set for a class only after proving a lower bound for it.

In [26] Forbes and Shpilka defined the notion of a robust hitting set for a circuit class $C$. Over fields of characteristic zero, a hitting set $H$ for a class $C$ is $c$-robust if it also satisfies that for every $f \in C$ there is $v \in H$ such that $|f(v)| \geq c \cdot \|f\|$, where $\|\|$ is some fixed norm on $\mathbb{C}[x]$ (see Definition 13 for a definition over arbitrary fields). It is not hard to see that if $H$ is a robust hitting set for a class $C$ then it also hits the closure of $C$.

In this work we focus on depth-3 algebraic circuits, known as $\Sigma\Pi\Sigma$, and on $\text{VP}_e$, the class of algebraic formulas, two classes for which we lack strong lower bounds, and in particular we do not have hitting sets for them. For $\Sigma\Pi\Sigma$ circuits the best lower bound is the near cubic lower bound of Kayal, Saha and Tavenas [46], and for $\text{VP}_e$ the best lower bound is the quadratic lower bound of Kalarkoti [39]. Recall that by the result of Valiant et al. [71], a super-quasipolynomial lower bound against $\text{VP}_e$ implies a super-polynomial lower bound against $\text{VP}$. Similarly, a hitting set for $\text{VP}_e$ implies a hitting set for $\text{VP}$. We also note that by a result of Gupta et al. [33], a strong enough lower bound or a hitting set for $\Sigma\Pi\Sigma$ imply both a lower bound for general circuits and a hitting set for them. This result also implies that a polynomial-time reconstruction algorithm for $\Sigma\Pi\Sigma$ circuits would give rise to a sub-exponential time reconstruction algorithm for general circuits. Recall that a reconstruction algorithm for a class $C$ is an algorithm that, given black-box access to a circuit from $C$, outputs a circuit in $C$ that computes the same polynomial.

Instead of viewing robust hitting sets as a way to obtain hitting sets for the closure of circuit classes, we suggest to find subclasses of interesting classes, $\tilde{C} \subset C$, such that $C$ is contained in the closure of $\tilde{C}$, and aim to construct a robust hitting set for the subclass $\tilde{C}$. This offers a new approach for constructing hitting sets for known classes and for obtaining lower bounds. Specifically, we consider subclasses of $\Sigma\Pi\Sigma$ and $\text{VP}_e$ that are dense in their superclasses. Each of these subclasses is the orbit of some simple polynomial under the group of invertible affine transformations.

For $\text{VP}_e$, we first consider a subclass that was defined by Bringmann, Ikenmeyer and Zuiddam [14]—the orbit of the so called continuant polynomial (see Definition 27). We give a polynomial-sized interpolating set for this subclass as well as a polynomial-time

---

3 Recall that an interpolating set for a class $C$ of polynomials in $n$ variables, over a field $F$, is a set of points $H \subset F^n$ such that for every $f \in C$, the list of values $f(H)$ uniquely determines $f$. See Definition 15.
Deterministic reconstruction algorithm that uses as oracle a root-finding algorithm\(^4\) in particular, this implies a polynomial-time randomized reconstruction algorithm, and, in some cases, a polynomial-time deterministic algorithm.

In addition, we exhibit two other subclasses that are dense in \(\text{VP}_e\). The first class is defined as the orbit of read-once formulas (ROF for short, see Definition 5) and the second as the orbit of read-once formulas in alternating normal form (ROANF for short, see Definition 7). We obtain hitting sets for both classes and an interpolating set for the second. We also observe that the reconstruction algorithm of [35] works for the polynomials in the orbit of ROANFs. Although the results that we obtain for the subclass defined by the continuant polynomial are stronger, we think that every such dense subclass can shed more light on \(\text{VP}_e\), and may eventually be used in order to obtain new lower bounds.

For \(\Sigma\Pi\Sigma\) we consider two subclasses. One is based on orbits of sparse polynomials (polynomials having polynomially many monomials) and the other on orbits of diagonal tensors (see Definition 40). We give a hitting set for the first, an interpolation set for the second, and we also observe that a slight modification of the randomized reconstruction algorithm of [43] applies for the second class.

In particular, our results give the first dense subclasses inside \(\text{VP}_e\) and \(\Sigma\Pi\Sigma\) for which a polynomial-size interpolating set is known as well as a polynomial-time reconstruction algorithm. By [71] our result immediately translate to \(\text{VP}\), giving a dense subclass of for which a quasipolynomial-sized interpolating set is known as well as a quasipolynomial-time reconstruction algorithm.

If we could transform the interpolating sets that we have found to robust hitting sets for the orbits, then this will immediately give hitting sets for the closure of the orbits, i.e. for \(\Sigma\Pi\Sigma\) and \(\text{VP}_e\), which, by [37] gives a lower bound for the class. Thus, our work raises an intriguing problem:

**Problem 1.** Given an interpolating set for a class \(C\) construct a robust hitting set for \(\tilde{C}\).

We stress that by our results, solving this problem would lead to hitting sets, and lower bounds, for \(\text{VP}_e\) and \(\text{VP}\).

Another advantage for having small interpolating sets for dense subclasses is the following: One approach for searching for separating polynomials for a class, is by considering the map from circuits in the class to the coefficient vectors of the polynomials that they compute. That is, once we fix a computation graph, an assignment to the constants appearing in the circuit determines the output polynomial. Each coefficient is a polynomial in those constants, and as there are “few” constants (polynomially many for polynomially sized circuits), and there are exponentially many coefficients, there should be many polynomials vanishing on the closure of the image of this map. If we could get a good understanding of this map then perhaps we could use it to construct a polynomial that vanishes on all such coefficient vectors. This polynomial will vanish on all coefficient vectors of the superclass in which the subclass is dense. A different approach is to find a coefficient vector that is not in the closure of the image of this map (this is the approach of Raz in [57]). Now, assume that \(H\) is an interpolating set for a dense subclass \(\tilde{C} \subset C\). We know that the map \(f \mapsto f|_H\) is one-to-one on \(\tilde{C}\). Thus, the list of values \(f|_H\) can be viewed as an efficient encoding that is given in terms of values of the computed polynomial. This provides a different encoding of a circuit – instead of the constants in it, use the evaluations on \(H\). Thus, by studying the closure of

\(^4\) A root-finding algorithm, over a field \(F\), when given black-box access to a univariate polynomial, outputs a root of that polynomial in \(F\), if such a root exists.
The size of a formula is the number of wires in it. The depth of a formula is the length of the longest simple leaf-root path in it. The formula size of a polynomial depends on its label. The output of the formula is the polynomial computed at its root.

An algebraic formula computes a polynomial in the natural way. Each leaf computes the rooted tree whose leaves are labeled with either variable or scalars from internal nodes (called gates) are labeled with either “+” (addition) or “×” (multiplication). An algebraic formula computes a polynomial in the natural way. Each leaf computes the polynomial that labels it, and each gate computes either the sum or product of its children, depending on its label. The output of the formula is the polynomial computed at its root.

The size of a formula is the number of wires in it. The depth of a formula is the length of the longest simple leaf-root path in it. The formula size of a polynomial depends on its label. The output of the formula is the polynomial computed at its root.

To formally state our results we need some definitions that we give next.

### 1.1 Basic definitions

#### 1.1.1 Notation

For $k \in \mathbb{N}$, we denote $[k] \triangleq \{1, 2, 3, \ldots, k\}$ and $[k]_0 \triangleq \{0, 1, 2, \ldots, k - 1\}$. We use boldface lowercase letters to denote tuples of variables or vectors, as in $\mathbf{x} = (x_1, \ldots, x_n)$, $\mathbf{a} = (a_1, \ldots, a_m)$, when the dimension is clear from the context. For any two elements $i, j$ coming from some set $S$ (usually $i$ and $j$ will be numbers), $\delta_{i,j}$ equals 1 when $i = j$ and 0 otherwise.

The individual degree of a variable $x_i$ in $f(\mathbf{x})$ is the degree of $f$ as a polynomial in $x_i$. A polynomial $f \in \mathbb{F}[\mathbf{x}]$ of $\deg(f) \leq 1$ is called a linear function, and if $f$ is homogeneous then it is called a linear form. For a polynomial $f \in \mathbb{F}[\mathbf{x}]$ and an integer $k \in \mathbb{N}$ we denote by $f^{[k]}$ the degree-$k$ homogeneous part of $f(\mathbf{x})$, i.e. the sum of all monomials of $f$ of degree exactly $k$. In particular,

$$f(\mathbf{x}) = f^{[0]}(\mathbf{x}) + f^{[1]}(\mathbf{x}) + \ldots + f^{[\deg(f)]}(\mathbf{x}).$$

Note that for a linear function $f$, $f^{[1]}$ is a linear form. We say that a polynomial $f$ is homogeneous of degree $k$ or that $f$ is $k$-homogeneous if $f = f^{[k]}$. We say a set of linear functions $\{\ell_1(\mathbf{x}), \ldots, \ell_n(\mathbf{x})\} \subset \mathbb{F}[\mathbf{x}]$ is linearly independent if the set $\{\ell_1^{[1]}\}$ is linearly independent. Given a polynomial $f(\mathbf{x})$, a subset of variables $\mathbf{y} \subseteq \{x_1, \ldots, x_n\}$ and an assignment to those variables $\mathbf{a} \in \mathbb{F}^{[n]}$, we denote by $f\big|_{\mathbf{y} = \mathbf{a}} \in \mathbb{F}[\mathbf{x} \setminus \mathbf{y}]$ the polynomial resulting from assigning the values of $\mathbf{a}$ to the variables of $\mathbf{y}$ in $f(\mathbf{x})$. We sometimes abuse notation and write $\mathbf{y} \subseteq [n]$ to indicate the indices of the assigned variables instead of the variables themselves.

#### 1.1.2 Circuit classes

**Definition 2.** An algebraic formula (also called arithmetic formula) over a field $\mathbb{F}$, is a rooted tree whose leaves are labeled with either variable or scalars from $\mathbb{F}$, and whose root and internal nodes (called gates) are labeled with either “+” (addition) or “×” (multiplication). An algebraic formula computes a polynomial in the natural way. Each leaf computes the polynomial that labels it, and each gate computes either the sum or product of its children, depending on its label. The output of the formula is the polynomial computed at its root.

The size of a formula is the number of wires in it. The depth of a formula is the length of the longest simple leaf-root path in it. The formula size of a polynomial $f$ is defined as the smallest size of a formula that outputs $f$.

---

5 Note that by our definition, $x$ and $x + 1$ are linearly dependent.
A sequence $m(n)$ of natural numbers is called polynomially bounded if there exists a univariate polynomial $q$ such that $m(n) \leq q(n)$ for all $n$.

The complexity class $\text{VP}_e$ is defined as the set of all families of polynomials $(f_n)_n$, with $f_n \in \mathbb{F}[x_1, \ldots, x_n]$, whose formula size is polynomially bounded.

\textbf{Definition 3.} An arithmetic circuit $\Phi$ is a $\Sigma^i[\Pi^d]$ circuit if it is a layered graph of depth-2, has a top gate labeled $+$ with fan-in $\leq s$ and its second layer is comprised entirely of $\times$ gates with fan-in $\leq d$. In other words, $\Sigma^i[\Pi^d]$ compute polynomials of degree $d$ with at most $s$ monomials.

\textbf{Definition 4.} An arithmetic circuit $\Phi$ in $n$ variables is a $\Sigma^i[\Pi^d][\Sigma]$ circuit if it is a layered graph of depth-3, has a top gate labeled $+$ with fan-in $\leq s$, its second layer is comprised entirely of $\times$ gates with fan-in $\leq d$, and its bottom layer is comprised of linear functions in $x_1, \ldots, x_n$. In other words, $\Sigma^i[\Pi^d][\Sigma]$ circuit compute polynomials of the form

$$f(x) = \sum_{i=1}^{s} \prod_{j=1}^{d}(\alpha_{i,j,0} + \sum_{k=1}^{n} \alpha_{i,j,k}x_k).$$

Given a family of circuits $C$, we will sometime denote it as $C(\mathbb{F})$ to stress that we allow coefficients to come from the field $\mathbb{F}$. Observe that the definitions of the classes above do not depend on the field and so we can define them over any field of our choice.

\textbf{Definition 5.} An arithmetic read-once formula (ROF for short) $\Phi$ over a field $\mathbb{F}$ in the variables $\mathbf{x} = (x_1, \ldots, x_n)$ is a binary tree $T$ whose leaves are labeled with input variables and a pairs of field elements $(\alpha, \beta) \in \mathbb{F}^2$, and whose internal nodes are labeled with the arithmetic operations $\{+, \times\}$ and a field element $\alpha \in \mathbb{F}$. Each input variable can label at most one leaf. The computation is performed in the following way: A leaf labeled with the variable $x_i$ and with $(\alpha, \beta)$, computes the polynomial $\alpha x_i + \beta$. If a node $v$ is labeled with the operation $* \in \{+, \times\}$ and with $\alpha \in \mathbb{F}$, and its children compute the polynomials $\Phi_{v_1}$ and $\Phi_{v_2}$, then the polynomial computed at $v$ is $\Phi_v = \Phi_{v_1} \times \Phi_{v_2} + \alpha$. A polynomial $f(\mathbf{x})$ is called a read-once polynomial (ROF for short) if $f(\mathbf{x})$ can be computed by a ROF.

\textbf{Observation 6.} Read-once polynomials are always multilinear polynomials.

We next define formulas in alternating normal form, as was first defined in [35].

\textbf{Definition 7} (Section 3.2 in [35]). We say that an arithmetic formula $\Phi$, over $\mathbb{F}$, is in alternating normal form ($\Phi$ is called an ANF for short) if:

1. The underlying tree of $\Phi$ is a complete rooted binary tree (the root node is called the output node). In particular, size($\Phi$) = $2^{\text{depth}(\Phi)+1} - 1$, where size($\Phi$) is the number of nodes in the tree of $\Phi$ and $\text{depth}(\Phi)$ is the maximum distance of a leaf node from the output node of $\Phi$.

2. The internal nodes consist of alternating layers of $+$ and $\times$ gates. In particular, the label of an internal node at distance $d$ from the closest leaf node is $+$ if $d$ is even and $\times$ otherwise. So if the root node is a $+$ node, its children are all $\times$ nodes, its grandchildren are all $+$ etc.

3. The leaves of the tree are labeled with linear functions. That is, each leaf is labeled with $\ell(\mathbf{x}) = a_0 + \sum_{i=1}^{n} a_i x_i$, where each $a_i \in \mathbb{F}$ is a scalar. 

The product depth $\Delta$ of $\Phi$ is the number of layers of product gates. The number of leaves of $\Phi$ is therefore always $4^\Delta$ if the top gate is $+$, and $\frac{1}{2} \cdot 4^\Delta$ if the top gate is $\times$. 

Hitting Sets and Reconstruction for Dense Orbits in $\text{VP}_e$ and $\Sigma\Pi\Sigma$ Circuits
The class ANF\(^{GL,m}(F)\) mentioned in Section 1.2.2 is defined in terms of the following canonical read-once ANF formula (ROANF for short):

**Definition 8** (Notation from Fact 3.4 of [35]). We denote the canonical ROANF polynomial, of product depth \(\Delta\) on \(4^\Delta\) variables, as ANF\(_{\Delta}(x)\). It is defined recursively as follows:

\[
\begin{align*}
ANF_0(x) &= x_1 \\
ANF_{\Delta+1}(x) &= ANF_\Delta(x^{(1)}) ANF_\Delta(x^{(2)}) + ANF_\Delta(x^{(3)}) ANF_\Delta(x^{(4)}) ,
\end{align*}
\]

where \(x^{(i)}\) is the \(4^\Delta\)-tuple of variables \(\{x^{(1)}, x^{(2)}, x^{(3)}, x^{(4)}\}\).

For example, ANF\(_{1}(x) = x_1 x_2 + x_3 x_4\).

Observe that any polynomial in ANF\(_{\Delta}^{GL,m}(F)\) is an ANF according to Definition 7, but not vice versa.

### 1.1.3 Approximate complexity

The following definition gives sense to the notion of approximation over arbitrary fields. In what follows we let \(\varepsilon\) be a new formal variable.\(^6\) For a field \(F\) we denote with \(F[\varepsilon]\) the field of polynomial expressions in \(\varepsilon\) over \(F\), and with \(F(\varepsilon)\) the fraction field of \(F[\varepsilon]\), i.e. the field of rational expressions in \(\varepsilon\).

**Definition 9.** Let \(C(F)\) be a circuit class over a field \(F\). The closure of \(C\), denoted \(\overline{C(F)}\), is defined as follows: A family of functions \((f_n)_n\), where \(f_n \in F[x_1, \ldots, x_n]\), is in \(\overline{C(F)}\) if there is a polynomially bounded function \(m : \mathbb{N} \to \mathbb{N}\), and a family of functions \((g_{m(n)})_n \in C(F(\varepsilon))\), with \(g_{m(n)} \in F[\varepsilon][x_1, \ldots, x_{m(n)}]\), such that for all \(n \in \mathbb{N}\),

\[
g_{m(n)}(x_1, \ldots, x_{m(n)}) = f_n(x_1, \ldots, x_n) + \varepsilon \cdot g_{n,0}(x_1, \ldots, x_{m(n)}) ,
\]

for some polynomial \(g_{n,0} \in F(\varepsilon)[x_1, \ldots, x_{m(n)}]\). Whenever an equality as in (1) holds we say that

\[
g_{m(n)} = f_n + O(\varepsilon) \quad \text{or} \quad f_n = g_{m(n)} + O(\varepsilon) .
\]

In that case we think of \(g_{m(n)}\) as an “approximation” of \(f_n\), and we say that the family \((g_{m(n)})_n\) approximates the family \((f_n)_n\).

Alder [3] have shown that over \(C\) it holds that \((f_n) \in \overline{C(C)}\), in the sense of Definition 9, if and only if it is in the closure of \(C(C)\) in the usual sense. That is, if for every \(n\) there exists a sequence of polynomials \(g_{n,k} \in C(C)\) such that \(\lim_{k \to \infty} g_{n,k} = f_n\), where convergence is taken coefficient wise. This result holds over \(\mathbb{R}\) as well, see [52, 17].

Finally, we note that every matrix is approximable (in the sense of Definition 9) by a non-singular matrix (which is equivalent to being a limit of a sequence of non-singular matrices, in characteristic zero).

**Observation 10.** For every \(A \in F^{n \times n}\) there exists a non-singular matrix \(B \in F(\varepsilon)^{n \times n}\) such that \(A = B + O(\varepsilon)\).

---

\(^6\) Intuitively, one should think of \(\varepsilon\) as an infinitesimal quantity.
1.1.4 Hitting and interpolating sets

Definition 11. A set of points $\mathcal{H} \subseteq \mathbb{F}^n$ is called a hitting set for a circuit class $\mathcal{C}$ (we also say that $\mathcal{H}$ hits $\mathcal{C}$) if for every circuit $\Phi \in \mathcal{C}$, computing a non-zero polynomial, there exists some $a \in \mathcal{H}$ such that $\Phi(a) \neq 0$.

We next give the definition of a robust hitting set, a notion first defined in [26]. Here we extend the definition for arbitrary characteristic. We start by giving the definition of [26], over characteristic zero (and focus on $\mathbb{C}$) and then the more general definition.

Definition 12 (Following Definition 5.1 of [26]). Let $\| \cdot \|$ be some norm on $\mathbb{C}[x]$. A hitting set $\mathcal{H}$ for a circuit class $\mathcal{C} \subseteq \mathbb{C}[x]$ is called robust if there exists some constant $c > 0$ such that, for every $0 \neq f \in \mathcal{C}$, there exists some $a \in \mathcal{H}$ such that $|f(a)| \geq c \cdot \|f\|$.

For arbitrary characteristic we use the same approach as in Definition 9.

Definition 13. Let $\mathbb{F}$ be a field of arbitrary characteristic. A hitting set $\mathcal{H} \subset \mathbb{F}^n$ for a circuit class $\mathcal{C}([\mathbb{F}])$ is called robust if for every circuit $\Phi \in \mathcal{C}([\mathbb{F}(\varepsilon)])$ computing a polynomial $f(x) = h(x) + \varepsilon \cdot g(x)$, where $h(x) \in \mathbb{F}[x]$ and $g(x) \in \mathbb{F}[\varepsilon][x]$, there exists some $a \in \mathcal{H}$ such that $f(a) \notin \varepsilon \cdot \mathbb{F}[\varepsilon]$.

It is not hard to prove using the result of [3] that for $\mathbb{F} = \mathbb{C}$, Definitions 12 and 13 are equivalent.

Observation 14. If $\mathcal{H}$ is a finite robust hitting set for $\mathcal{C}(\mathbb{F})$, then $\mathcal{H}$ hits $\overline{\mathcal{C}(\mathbb{F})}$ as well.

Proof. Consider $0 \neq f \in \overline{\mathcal{C}(\mathbb{F})}$. By Definition 9 there is $g \in \mathcal{C}(\mathbb{F}(\varepsilon))$, such that $f = g + O(\varepsilon)$. Clearly $g \neq 0$. Let $a \in \mathcal{H}$ be such that $g(a) \notin \varepsilon \cdot \mathbb{F}[\varepsilon]$. It follows that $f(a) \notin \varepsilon \cdot \mathbb{F}[\varepsilon]$. In particular, $f(a) \neq 0$. □

We next define the notion of an interpolating set.

Definition 15. Let $\mathcal{C}$ be a class of $n$-variate polynomials. A set $\mathcal{H} \subseteq \mathbb{F}^n$ is called an interpolating set for $\mathcal{C}$ if, for every $f \in \mathcal{C}$, the evaluations of $f$ on $\mathcal{H}$ uniquely determine $f$.

Observation 16. If $\mathcal{H}$ is a hitting set for $\mathcal{C}(\mathbb{F}) + \mathcal{C}(\mathbb{F}) \triangleq \{ \alpha f + \beta g : f, g \in \mathcal{C}, \alpha, \beta \in \mathbb{F} \}$, then $\mathcal{H}$ is an interpolating set for $\mathcal{C}$.

A common method for designing hitting and interpolating sets is via hitting set generators.

Definition 17. A polynomial mapping $\mathcal{G} : \mathbb{F}^k \rightarrow \mathbb{F}^n$ is called a hitting set generator (or simply a generator) for a circuit class $\mathcal{C}(\mathbb{F})$ if for any non-zero $n$-variate polynomial $f \in \mathcal{C}$, the $k$-variate polynomial $f \circ \mathcal{G}$ is non-zero.

Similarly, we call $\mathcal{G} : \mathbb{F}^k \rightarrow \mathbb{F}^n$ an interpolating set generator for a circuit class $\mathcal{C}(\mathbb{F})$ if for any two different $n$-variate polynomials $f_1, f_2 \in \mathcal{C}$, the $k$-variate polynomial $(f_1 - f_2) \circ \mathcal{G}$ is non-zero.

Generators immediately give rise to hitting sets.

Observation 18. Let $\mathcal{G} : \mathbb{F}^k \rightarrow \mathbb{F}^n$ be a generator for $\mathcal{C}(\mathbb{F})$ such that the individual degree of each coordinate of $\mathcal{G}$ is at most $r$. Let $W \subset \mathbb{F}$ be any set of size $|W| = d \cdot r + 1$. Let $\mathcal{H} = \mathcal{G}(W^k)$. Then $\mathcal{H}$ hits every $n$-variate polynomial $f \in \mathcal{C}$ of degree at most $d$.

Proof. As $\mathcal{G}$ is a generator, the $k$-variate polynomial $f \circ \mathcal{G}$ is nonzero. As its individual degrees are bounded by $d \cdot r$ it follows that at least one of the values in $(f \circ \mathcal{G})(W^k) = f(\mathcal{H})$ is not zero. □

---

7 We abuse notation and write $f \in \mathcal{C}$ when $f$ is the output of some circuit from $\mathcal{C}$. 

---
1.1.5 \textbf{$k$-independent maps}

Our constructions rely on polynomial mappings $\mathcal{G}_k$, parameterized by some integer $k \leq n$, with the property that the image of $f \circ \mathcal{G}_k$ contains all projections of $f$ to $k$ variables. We call such a map a $k$-independent map.

\begin{definition}
We call a polynomial mapping $\mathcal{G}(y_1, \ldots, y_t) : \mathbb{F}^{t+1} \to \mathbb{F}^n$ a 1-independent polynomial map if for every index $i \in [n]$ there exists an assignment $a_i \in \mathbb{F}^t$ to $y_1, \ldots, y_t$ such that the $i$th coordinate of $\mathcal{G}(a_i, z_i)$ is $z_i$, and the rest of the coordinates are 0. For $k > 1$, a polynomial mapping $\mathcal{G}(y_1, \ldots, y_{tk}, z_1, \ldots, z_k) : \mathbb{F}^{k(t+1)} \to \mathbb{F}^n$ is called a $k$-independent polynomial map (or a $k$-independent map) if $\mathcal{G}$ is a sum of $k$ variable-disjoint 1-independent polynomial maps. We denote $k$-independent polynomial maps as $\mathcal{G}(y, z)$ when $k, t$ are implicit. The $y$ variables are called control variables.

A $k$-independent polynomial map $\mathcal{G}$ is called uniform if all $n$ coordinates of $\mathcal{G}$ are homogeneous polynomials of the same degree.
\end{definition}

We discuss $k$-independent maps in more detail in Section 2.

1.1.6 \textbf{Subgroups of the linear and affine groups and their actions}

Given a matrix $A \in \mathbb{F}^{n \times n}$ and a tuple of variables $x = (x_1, \ldots, x_n)$, we denote

$$Ax = \left( \sum_{i=1}^{n} A_{1,i}x_i, \sum_{i=1}^{n} A_{2,i}x_i, \ldots, \sum_{i=1}^{n} A_{n,i}x_i \right).$$

Let $n \geq m \in \mathbb{N}$. For an $m$-variate polynomial $f(x_1, \ldots, x_m) \in \mathbb{F}[x_1, \ldots, x_m]$, a matrix $A = (A_{i,j})_{i,j=1}^{n} \in \mathbb{F}^{n \times n}$ and a vector $b = (b_1, \ldots, b_n) \in \mathbb{F}^n$, we define the $n$-variate polynomial $f(Ax + b)$ to be

$$f(Ax + b) = f\left( \sum_{i=1}^{n} A_{1,i}x_i + b_1, \sum_{i=1}^{n} A_{2,i}x_i + b_2, \ldots, \sum_{i=1}^{n} A_{n,i}x_i + b_n \right). \quad (2)$$

Note that we ignored the last $n - m$ coordinates of $Ax + b$.

We denote with $\text{GL}_n(\mathbb{F})$ the group of invertible $n \times n$ matrices over $\mathbb{F}$, and with $\text{GL}_n^\text{aff}(\mathbb{F})$ the group of invertible affine transformation, i.e. all the maps $x \to Ax + b$, where $A \in \text{GL}_n(\mathbb{F})$ and $b \in \mathbb{F}^n$.

For an $m$-variate polynomial $f$ over $\mathbb{F}$, and $n \geq m$ we denote with $f^{\text{GL}_n^\text{aff}(\mathbb{F})}$ the orbit of $f$ under the natural action of $\text{GL}_n^\text{aff}(\mathbb{F})$:\footnote{To be precise, the action is $(A, b) \circ f)(x) = f(A^\top x + b)$. This is required in order to make the action a homomorphism, however, for the groups that we consider it does not change the orbit.}

$$f^{\text{GL}_n^\text{aff}(\mathbb{F})} = \{ f(Ax + b) \mid A \in \text{GL}_n(\mathbb{F}), b \in \mathbb{F}^n \}.$$

We similarly define $f^{\text{GL}_n(\mathbb{F})}$. More generally, for a class of $m$-variate polynomials $\mathcal{C}(\mathbb{F})$, we denote the orbit of $\mathcal{C}$ under $\text{GL}_n^\text{aff}(\mathbb{F})$ by

$$\mathcal{C}^{\text{GL}_n^\text{aff}(\mathbb{F})} = \{ f(Ax + b) \mid f \in \mathcal{C}, A \in \text{GL}_n(\mathbb{F}), b \in \mathbb{F}^n \}.$$

We similarly define $\mathcal{C}^{\text{GL}_n(\mathbb{F})}$. When we want to speak about orbits of families of polynomials from $\mathcal{C}(\mathbb{F})$, with arbitrary number of variables, we use the notation $\mathcal{C}^{\text{GL}(\mathbb{F})}$ or $\mathcal{C}^{\text{GL}^\text{aff}(\mathbb{F})}$. 
19:10  Hitting Sets and Reconstruction for Dense Orbits in $\text{VP}_e$ and $\Sigma\Pi\Sigma$ Circuits

- **Observation 20.** For any $m$ variate polynomial $f(x_1, \ldots, x_m)$ and $n \geq m$:
  - For any $A \in \text{GL}_n(F)$ and $d \in \mathbb{N}$, $f^{[d]}(Ax)$ is the $d$-homogeneous part of $f(Ax)$.
  - For any $A \in \text{GL}_n^\text{aff}(F)$, $f(x)$ is irreducible if and only if $f(Ax)$ is irreducible.
  - The set of matrices $A$ for which $f(x) = f(Ax)$ forms a multiplicative subgroup of $\text{GL}_n^\text{aff}(F)$ and a similar claim holds for $\text{GL}_n^\text{aff}(F)$.

We next define some special groups that serve as group of symmetries of some of the models that we consider. We first define the group of symmetries of $\text{ANF}_\Delta(x)$. We denote with $I_k$ the $k \times k$ identity matrix.

- **Definition 21.** For $m, \Delta \in \mathbb{N}$ such that $m = 2^\Delta$, the tree-symmetry group $T_{R_m}(F)$ denotes the automorphisms of a rooted complete binary tree of depth $\Delta$. It is defined recursively as follows.
  - For $m = 1$, $T_{R_1}(F)$ consists only of the identity matrix.
  - For $m > 0$, $T_{R_m}(F)$ is generated by matrices of the form
    \[
    \begin{pmatrix}
    A & 0 \\
    0 & B
    \end{pmatrix}
    \quad \text{and} \quad
    \begin{pmatrix}
    0 & I_{\frac{m}{2}} \\
    I_{\frac{m}{2}} & 0
    \end{pmatrix}
    \]
    where $A, B \in T_{R_{\frac{m}{2}}}(F)$.

- **Definition 22.** For any $m = 4^\Delta$, the tree-scale group $T_{S_m}(F)$ is the group generated by elements of $T_{R_m}(F)$ and matrices of the form
  \[
  \begin{pmatrix}
  \alpha I_{\frac{m}{2}} & 0 & 0 & 0 \\
  0 & \alpha^{-1} I_{\frac{m}{2}} & 0 & 0 \\
  0 & 0 & \beta I_{\frac{m}{2}} & 0 \\
  0 & 0 & 0 & \beta^{-1} I_{\frac{m}{2}}
  \end{pmatrix}
  \]
  where $0 \neq \alpha, \beta \in F$.

The importance of the group $T_{S_m}(F)$ stems from the fact that it is the symmetry group of $\text{ANF}_\Delta$. To intuitively see why this is the case, notice that in any representation of an ANF one may swap children of any node without changing the output polynomial. We call such symmetries “tree-symmetries” and they are captured by the group $T_{R_n}(F)$. A second source of ambiguity comes from the fact that we can rescale the formula. Recall that the output polynomial is of the form $f_1 \cdot f_2 + f_3 \cdot f_4$ (Definition 7). Clearly, the output does not change if we replace $f_1$ by, say, $2f_1$ and $f_2$ by $f_2/2$. Such rescaling symmetries are captured by the group $T_{S_m}(F)$. Finally, another source for ambiguity comes from the fact that the quadratic polynomials computed at the bottom two layers of the ANF may have different representations. For example,

\[4xy + 4wz = (x + y + w - z) \cdot (x + y + w + z) + (w + z + x - y) \cdot (w + z - x + y)\,.

As there is an infinite number of representations for each quadratic polynomial (over infinite fields), we can expect to characterize the symmetries in term of the quadratics computed at the bottom two layers of the ANF.

- **Fact 23** (Special case of Theorem 5.43(iii) of [35]). Let $m, \Delta, n \in \mathbb{N}$ such that $m = 4^\Delta - 1 \leq n/4$. Let $f = \text{ANF}_\Delta(\ell_1, \ldots, \ell_{4n}) \in \text{ANF}^\text{GL}_n^\text{aff}(F)$. Let $Q = (q_1, \ldots, q_m)$ be the list of quadratic polynomials that are computed at the bottom two layers of the formula $\text{ANF}_\Delta(\ell_1, \ldots, \ell_{4n})$. In particular, $f = \text{ANF}_\Delta(q_1, \ldots, q_m)$. If $Q' = (q'_1, \ldots, q'_m)$ is any other $m$-tuple of quadratic polynomials for which $f = \text{ANF}_\Delta(q'_1, \ldots, q'_m)$ then $Q$ is $T_{S_m}(F)$-equivalent to $Q'$. 

Next, we define the group of symmetries of $T_{s,d}(x)$.

**Definition 24.** For any $n \in \mathbb{N}$ the permutation-scale group, denoted $PS_n(\mathbb{F})$, is the set of all matrices $A \in GL_n(\mathbb{F})$ which are row-permutations of non-singular diagonal matrices with determinant one.

For example, $\begin{pmatrix} 0 & -2 & 0 \\ 0 & 0 & -1 \\ 1/2 & 0 & 0 \end{pmatrix} \in PS_3(\mathbb{C})$.

**Definition 25.** Let $s,d,n \in \mathbb{N}$ such that $n = s \cdot d$. A matrix $A \in GL_n(\mathbb{F})$ is a member of the tensor permutation-scale group, denoted $TPS_{s,d}(\mathbb{F})$, if $A = (P \otimes I_d) \cdot B$, where $P$ is an $s \times s$ permutation matrix and $B = \begin{pmatrix} B_1 & 0 & \ldots & 0 \\ 0 & B_2 & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \ldots & 0 & B_d \end{pmatrix}$ is a block diagonal matrix such that each block $B_i$ of $B$ satisfies $B_i \in PS_d(\mathbb{F})$.

For example, for $s = d = 2$ the matrix $A = \begin{pmatrix} 0 & 0 & 0 & 2 \\ 0 & 0 & 1/2 & 0 \\ -1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{pmatrix}$ is in $TPS_{2,2}(\mathbb{C})$, as for $P = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ and $B = \begin{pmatrix} -1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 2 \\ 0 & 0 & 1/2 & 0 \end{pmatrix}$, we have $A = (P \otimes I_2) \cdot B$, and clearly each block of $B$ is in $PS_2(\mathbb{C})$.

Another way of defining the group is as follows: index rows and columns of $A$ with pairs $(i,j) \in [s] \times [d]$. Then, $A \in TPS_{s,d}(\mathbb{F})$ if and only if there exists a permutation $\pi : [s] \to [s]$, and for all $i \in [s]$ permutations $\theta_i : [d] \to [d]$ and constants $\alpha_i,j$ satisfying $\prod_{j=1}^d \alpha_i,j = 1$, such that $A_{(i,j), (i',j')} = \delta_{\pi(i),i'} \cdot \delta_{\theta_i(j),j'} \cdot \alpha_i,j$ for all $i,j$.

We next prove that $TPS_{s,d}(\mathbb{F})$ is the group of symmetries of $T_{s,d}(x)$. In other words, we show that $T_{s,d}(x) = T_{s,d}(Ax)$ if and only if $A \in TPS_{s,d}(\mathbb{F})$. Intuitively, $T_{s,d}$ admits no symmetries other than the trivial ones: permutations on the product gates, and internal permutation-scale of each product gate such that the product of the scale coefficients is 1. This is exactly captured by the group $TPS_{s,d}(\mathbb{F})$, which is therefore contained in the group of symmetries of $T_{s,d}(x)$.

**Lemma 26.** Let $s,d,n \in \mathbb{N}$, such that $d > 2$ and $n = s \cdot d$. If $A \in GL_n(\mathbb{F})$ satisfies $T_{s,d}(x) = T_{s,d}(Ax)$, then $A \in TPS_{s,d}(\mathbb{F})$.

### 1.2 Our results

We first give our results for the class $VP_c$ and then for the class of depth-$3$ circuits, for which it may be easier to obtain a robust hitting set, or prove super-polynomial lower bounds.

#### 1.2.1 The continuant polynomial

Bringmann, Ikenmeyer and Zuiddam [14] defined the following polynomial (in Remark 3.14 of their paper), which they called the continuant polynomial:
Definition 27. The continuant polynomial on $n$ variables, $C_n(x_1, \ldots, x_n)$, is defined as the trace of the following matrix product:

$$
C_n(x_1, \ldots, x_n) \triangleq \text{Trace} \left( \begin{pmatrix} x_1 & 1 \\ 1 & 0 \end{pmatrix} \cdot \begin{pmatrix} x_2 & 1 \\ 1 & 0 \end{pmatrix} \cdot \ldots \cdot \begin{pmatrix} x_n & 1 \\ 1 & 0 \end{pmatrix} \right) .
$$

(3)

We denote with $C_{\text{GL}^{\text{aff}}}(F)$ the class of families of polynomials $(f_n)_n$ such that $f_n \in F[x_1, \ldots, x_n]$ and for some $m \leq n$, $f_n \in C_{m \text{aff}}^{\text{GL}^{\text{aff}}}(F)$.

A result of Allender and Wang implies that the polynomial $x_1 \cdot y_1 + \cdots + x_8 \cdot y_8$ is not in $C_{\text{GL}^{\text{aff}}}(F)$ [4]. Thus, as a computational class it is very weak. However, Theorem 3.12 of [14] states that for every field $F$ of characteristic different than 2, it holds that

$$
\overline{C_{\text{GL}^{\text{aff}}}(F)} = \text{VP}_e .
$$

(4)

We give a polynomial-size interpolating set for the class $C_{\text{GL}^{\text{aff}}}(F)$ as well as a polynomial-time reconstruction algorithm for it. We first state a simple result that gives a hitting set for the class.

Theorem 28. Let $f(x_1, \ldots, x_n) \in C^{\text{GL}^{\text{aff}}}(F)_m$, for $m \leq n$, and arbitrary $F$. Then, for any uniform 1-independent polynomial map $\mathcal{G}$ over $F$, $f \circ \mathcal{G} \neq 0$.

As immediate corollary we get a hitting set for the class.

Corollary 29. For every field $F$, there is an explicit hitting set $\mathcal{H} \subset F^n$, of size $|\mathcal{H}| = O \left( n^6 \right)$, that hits every $0 \neq f \in C^{\text{GL}^{\text{aff}}}(F)_m$. If $|F| < n^2$ then $\mathcal{H}$ is defined over a polynomial-sized extension field of $F$, $K$, such that $|K| \geq n^2$.

Theorem 30. For every field $F$, there is an explicit interpolating set $\mathcal{H} \subset F^n$, of size $|\mathcal{H}| = O \left( n^{10} \right)$, for $\bigcup_{m=1}^{n} C^{\text{GL}^{\text{aff}}}(F)_m$. If $|F| < n^2$ then $\mathcal{H}$ is defined over a polynomial-sized extension field of $F$, $K$, such that $|K| \geq n^2$.

Theorem 31. There is a deterministic algorithm that given $F$, an integer $n$, oracle access to a root-finding algorithm over $F$, and black-box access to a polynomial $f(x_1, \ldots, x_n) \in C^{\text{GL}^{\text{aff}}}(F)_m$ (for any $m \leq n$), runs in polynomial-time and outputs linear functions $(\ell_1(x_1, \ldots, x_n), \ldots, \ell_m(x_1, \ldots, x_n))$ such that

$$
f(x_1, \ldots, x_n) = C_m \left( \ell_1(x), \ldots, \ell_m(x) \right) .
$$

If $|F| < n^3$ then the algorithm will make queries from a polynomial-sized extension field of $F$, $K$, such that $|K| \geq n^3$, and it also requires oracle access to a root-finding algorithm over $K$.

1.2.2 Orbits of read-once formulas

We denote with $\text{ROF}_{\text{GL}^{\text{aff}}}(F)$ the class of families of polynomials $(f_n)_n$, such that for every $n$ there exists a ROF $\Phi$, on $m \leq n$ variables, such that $f_n(x_1, \ldots, x_n) \in \Phi^{\text{GL}^{\text{aff}}}(F)$. Similarly, we denote with $\text{ANF}_{\text{GL}^{\text{aff}}}(F)$ the class of families of polynomials $(f_n)_n$, such that for every $n$ there exists $\Delta$ such that $4^{\Delta} \leq n$ and $f_n(x_1, \ldots, x_n) \in \text{ANF}_{\Delta}^{\text{GL}^{\text{aff}}}(F)$.

We first make the following simple observation.

Theorem 32. For every field $F$, it holds that

$$
\text{ANF}_{\text{GL}^{\text{aff}}}(F) \subseteq \text{ROF}_{\text{GL}^{\text{aff}}}(F) \subseteq \text{VP}_e(F) .
$$

(5)

However, when taking closures we get

$$
\overline{\text{ANF}_{\text{GL}^{\text{aff}}}(F)} = \overline{\text{ROF}_{\text{GL}^{\text{aff}}}(F)} = \overline{\text{VP}_e(F)} .
$$

(6)
Our main results for ROFs and ROANFs are a construction of a hitting set for the orbit of ROFs, and an interpolating set for the orbit of ROANFs. Both constructions are obtained using independent polynomial maps (Definition 19).

**Theorem 33.** Let \( 0 \neq f \in \text{ROF}_{d}(\mathbb{F}) \) where the underlying ROF depends on \( 2^{d} \) variables, for \( 2^{d} \leq n \). Then, for any \((t+1)\)-independent polynomial map \( \mathcal{G} \), over \( \mathbb{F} \), \( f \circ \mathcal{G} \neq 0 \).

**Corollary 34.** For every field \( \mathbb{F} \), there is a hitting set \( \mathcal{H} \subset \mathbb{F}^{n} \), of size \( |\mathcal{H}| = n^{O(\log n)} \), that hits every \( 0 \neq f \in \text{ROF}_{d}(\mathbb{F}) \). If \( |\mathbb{F}| < n^{2} \) then \( \mathcal{H} \) is defined over a polynomial-sized extension field of \( \mathbb{F} \), \( \mathbb{K} \) such that \( |\mathbb{K}| \geq n^{2} \).

Since a hitting set for all polynomials of the form \( g - h \) where \( g, h \in \mathcal{C} \) is the same as an interpolating set for \( \mathcal{C} \), the following theorem gives an interpolating set for the orbit of ROANFs.

**Theorem 35.** Let \( f_{1} = \text{ANF}_{\Delta_{1}}(A_{1}x + b_{1}), f_{2} = \text{ANF}_{\Delta_{2}}(A_{2}x + b_{2}) \in \text{ANF}_{d}(\mathbb{F}) \) and \( f = f_{1} - f_{2} \). Set \( k = 2 \max \{\Delta_{1}, \Delta_{2}\} + 7 \) and let \( \mathcal{G} \) be any uniform \( k \)-independent polynomial map over \( \mathbb{F} \). If \( f \neq 0 \) then \( f \circ \mathcal{G} \neq 0 \).

**Corollary 36.** For any field \( \mathbb{F} \), the class \( \text{ANF}_{d}(\mathbb{F}) \), for \( 4^{\Delta} \leq n \), admits an interpolating set \( \mathcal{H} \subset \mathbb{F}^{n} \), of size \( |\mathcal{H}| = n^{O(\Delta)} \). If \( |\mathbb{F}| < n^{2} \) then \( \mathcal{H} \) is defined over a polynomial-sized extension field of \( \mathbb{F} \), \( \mathbb{K} \), such that \( |\mathbb{K}| \geq n^{2} \).

Finally, we observe that the randomized algorithm of Gupta, Kayal And Qiao [35], for reconstructing random algebraic formula (for a natural definition of a random formula), yields a randomized reconstruction algorithm for \( \text{ANF}_{d}(\mathbb{C}) \). Naturally, the reconstruction is up to the symmetry group of ROANFs.

**Theorem 37 (A special case of Theorem 1.1 of [35]).** Let \( T \) be a finite subset of \( \mathbb{C} \). Let \( n, \Delta \geq 1 \) be integers such that \( s \leq 4^{\Delta} \leq n \). Given black-box access to the output \( f \) of a circuit \( \Phi \in \text{ANF}_{d}(\mathbb{C}) \), with probability at least \( 1 - \frac{\|\Phi\|_{\text{aff}}}{|T|} \) (on internal randomness), Algorithm 6.9 of [35] successfully computes a tuple of \( s \) linearly independent linear functions \( L = (\ell_{1}, \ldots, \ell_{s}) \in \mathbb{C}[x]^{s} \) such that \( f = \text{ANF}_{\Delta}(\ell_{1}, \ldots, \ell_{s}) \), and the \( \ell_{i} \)s are identical to the labels of the leaves of \( \Phi \) up to \( \text{TS}_{n}(\mathbb{C}) \)-equivalence (see Definition 22). Moreover, the running time of the algorithm is \( \text{poly}(n, s, \log(|T|)) \).

**Remark 38.** Theorem 1.1 of [35] is stated only for characteristic zero fields. However, in Remark 6.10 they explain how to make the algorithm work over any characteristic, for a large enough field. Thus, Theorem 37 also holds over large enough fields in arbitrary characteristic.

**Remark 39.** As a direct implication of Theorem 35, the reconstruction algorithm of Theorem 37 can be converted into a zero-error algorithm, with expected quasipolynomial running time: Given black-box access to some \( f_{1} \in \text{ANF}_{d}(\mathbb{F}) \), we define \( f_{2} \) to be the output of the algorithm of Theorem 37 on input \( f_{1} \), and then verify \( f_{1} = f_{2} \) using Corollary 36.

### 1.2.3 Dense subclasses of \( \Sigma\Pi\Sigma \)

We start by defining the canonical diagonal tensor of degree \( d \) and rank \( s \), \( T_{s,d} \in \mathbb{F}[x_{1}, \ldots, x_{s,d}] \), and the resulting class of polynomials \( T_{d}(\mathbb{F}) \).

**Definition 40.** Let \( T_{s,d} = \sum_{i=1}^{s} \prod_{j=1}^{d} x_{i,j} \). I.e., it is a sum of \( s \) variable-disjoint monomials. For \( n \geq s \cdot d \), we denote with \( T_{d}(\mathbb{F}) \) the orbit of \( T_{s,d} \) over \( \mathbb{F} \), under the action of the affine group. Finally, we denote with \( T_{d}(\mathbb{F}) \) the class of families of polynomials \( (f_{n})_{n} \), such that for every \( n \) there exist \( s \) and \( d \) such that \( n \geq s \cdot d \) and \( f_{n}(x_{1}, \ldots, x_{n}) \in T_{d}(\mathbb{F}) \).
Clearly, $T_{s,d}^{GL_n^m(\mathbb{F})} \subset \Sigma[s]\Pi[d]\Sigma$. We next define the class consisting of orbits of sparse polynomials.

**Definition 41.** Let $\Sigma\Pi^{GL_n^m(\mathbb{F})}$ denote the class of families of polynomials that are computed by orbits of depth-2 circuits, of polynomially bounded size, over $\mathbb{F}$. I.e., it is all families $(f_n)_{n \geq 1}$, of polynomially bounded degree, such that for some polynomially bounded $m(n)$, there exist $\Sigma[m(n)]\Pi[\deg(f_n)]$ circuits $\Phi_m$, in $k \leq n$, many variables, such that $f_n \in \Phi_m^{GL_n^m(\mathbb{F})}$.

As before we first give the basic observation connecting all three classes.

**Theorem 42.** For every field $\mathbb{F}$ it holds that

$$T^{GL_n^m(\mathbb{F})} \subseteq \Sigma\Pi^{GL_n^m(\mathbb{F})} \subseteq \Sigma\Pi\Sigma(\mathbb{F}),$$

and for fields of size $|\mathbb{F}| \geq n + 1$

$$\Sigma\Pi^{GL_n^m(\mathbb{F})} \subseteq \Sigma\Pi\Sigma(\mathbb{F}).$$

In addition,

$$T^{GL_n^m(\mathbb{F})} = \Sigma\Pi^{GL_n^m(\mathbb{F})} = \Sigma\Pi\Sigma(\mathbb{F}).$$

Our main results for this section are a quasipolynomial-size hitting set for the class $\Sigma\Pi^{GL_n^m(\mathbb{F})}$, and a polynomial-size interpolating set for $T^{GL_n^m(\mathbb{F})}$.

**Theorem 43.** Let $0 \neq g \in \mathbb{F}[x]$ have sparsity $\leq 2^t$. Let $(A, b) \in GL_n^m(\mathbb{F})$, and $f(x) = g(Ax + b)$. Then, for any $(t + 1)$-independent polynomial map $G$, $f \circ G \neq 0$.

**Corollary 44.** For any integers $s,d,n$, there exists an explicit hitting set $H \subseteq \mathbb{F}^n$, of size $|H| = (nd)^{O(\log s)}$, such that $H$ hits every nonzero polynomial $f \in (\Sigma[s]\Pi[d])^{GL_n^m(\mathbb{F})}$. If $|\mathbb{F}| \leq n \cdot d$ then we let $H$ be defined over an extension field $K$ of $\mathbb{F}$ of size $|K| > n \cdot d$.

We next state our result concerning an interpolating set for $T^{GL_n^m(\mathbb{F})}$.

**Theorem 45.** Let $n,s_1,s_2,d_1,d_2 \in \mathbb{N}$ be such that $n \geq s_1 \cdot d_1, s_2 \cdot d_2$. For $i \in \{1,2\}$ let $f_i \in T_{s_i,d_i}^{GL_n^m(\mathbb{F})}$, and let $f = f_1 - f_2$. If $f \neq 0$, then any uniform $6$-independent polynomial map $G$ satisfies $f \circ G \neq 0$.

Finally we note that the randomized reconstruction algorithm of Kayal and Saha [45], which works for (as it is termed in their paper) “non-degenerate” homogeneous depth-3 circuits, works for $T^{GL_n^m(\mathbb{F})}$. This follows from the observation that $T^{GL_n^m(\mathbb{F})}$ circuits are always non-degenerate.

**Theorem 46** (special case of Theorem 1 of [45]). Let $n,d,s \in \mathbb{N}$, $n \geq (3d)^2$ and $s \leq (\frac{n}{3d})^2$. Let $\mathbb{F}$ be a field of characteristic zero or greater than $ds^2$. There is a randomized poly$(n,d,s) = poly(n,s)$ time algorithm which takes as input black-box access to a polynomial $f$ that is computable by a $T_{s,d}^{GL_n^m(\mathbb{F})}$ circuit, and outputs a $T_{s,d}^{GL_n^m(\mathbb{F})}$ circuit $\Phi$ computing $f$ with high probability. Furthermore, $\Phi$ is unique up to TPS$_{s,d}(\mathbb{F})$-equivalence (see Definition 25).

**Remark 47.** As in Remark 39, Theorem 45 enables us to convert the reconstruction algorithm of Theorem 46 to a zero-error algorithm, with expected polynomial running time. Given black-box access to some $f_1 \in T^{GL_n^m(\mathbb{F})}$, we define $f_2$ to be the output of the algorithm of Theorem 46 on input $f_1$, and then verify $f_1 \equiv f_2$ by applying Theorem 45 to $f = f_1 - f_2$. 

1.2.4 Robust hitting sets?

As we showed in Observation 14, if a hitting set \( \mathcal{H} \) for a circuit class \( \mathcal{C} \) is robust, then \( \mathcal{H} \) hits \( \mathcal{C} \) as well. It is thus natural to ask whether our interpolating sets are already robust. Our next result shows that the property of being a \( t \)-independent map, which was sufficient for the constructions in Theorems 28, 30, 33, 35, 43, and 45 (for the appropriate values of \( t \)), by itself is not sufficient for obtaining robust hitting sets. We prove this by constructing an independent polynomial map which gives rise to a provably non-robust hitting set. Our construction is the same as the one given by Forbes et al. [27] (Construction 6.3 in the full version).

**Theorem 48.** Let \( \mathbb{F} \) be of characteristic zero. For every \( t \), there exists a uniform \( t \)-independent polynomial map \( G \) and a nonzero polynomial \( f \) such that \( f \circ G \equiv 0 \), and \( f \) can be computed by a \( \Sigma \Pi \Sigma \) formula of size \( tO(\sqrt{t}) \). If \( \mathbb{F} \) has a positive characteristic then \( f \) can be computed by a \( \Sigma \Pi \Sigma \) formula of size \( t^t \), or by a general formula of size \( t^{O(\log t)} \). Furthermore, for a certain arrangement of the variables in a \( \sqrt{n} \times \sqrt{n} \) matrix, \( f \) can be taken to be the determinant of any \( (t + 1) \times (t + 1) \) minor.

1.3 Polynomial Identity Testing

So far we discussed our work from the perspective of dense subclasses of classes for which no strong lower bounds are known. Here we put our work in the context of the polynomial identity testing problem.

Polynomial Identity Testing (PIT for short) is the problem of designing efficient deterministic algorithms for deciding whether a given arithmetic circuit computes the identically zero polynomial. PIT has many applications, e.g. deciding primality [1], finding a perfect matching in parallel [23, 69] etc., and strong connection to circuit lower bounds [38, 22, 19, 32]. See [67, 62, 63] for surveys on PIT and [50] for a survey of algebraic hardness-randomness tradeoffs.

PIT is considered both in the white-box model, in which we get access to the graph of computation of the circuit, and in the black-box model in which we only get query access to the polynomial computed by the circuit. Clearly, a deterministic PIT algorithm in the black-box model is equivalent to a hitting set for the circuit class. In this work we only focus on the black-box model.

**The continuant polynomial and algebraic branching programs**

The continuant polynomial is trivially computed by width-2 *Algebraic Branching Programs* (ABPs). Recall that an ABP of depth-\( d \) and width-\( w \) computes polynomials of the form \( \text{Trace}(M_1(x) \cdot \ldots \cdot M_d(x)) \), where each \( M_i \) is a \( w \times w \) matrix whose entries contain variables or field elements. Ben-Or and Cleve proved that every polynomial in \( \text{VP}^{e} \) can be computed by a width-3 ABP of polynomial-size [8].

Raz and Shpilka gave the first polynomial-time white-box PIT algorithm for read-once ABPs (ABPs in which every variable can appear in at most one matrix) [58]. Forbes, Saptharishi and Shpilka gave the first quasipolynomial-sized hitting set for read-once ABPs (ROABPs) [25]. This result was slightly improved in [31] for the case where the width of the ROABP is small. Anderson et al. gave a subexponential hitting set for read-\( k \) ABPs [5]. We note that none of these models is strong enough to contain the orbit \( C^{\text{GL}_{n}^{w}(\mathbb{F})} \). For ABPs that are not constant-read we do not have sub-exponential time PIT algorithms. Thus, the following is an interesting open problem (recall that by the result of Ben-Or and Cleve a PIT algorithm for width-3 ABPs works for \( \text{VP}^{e} \) as well).
Problem 49. Give a sub-exponential time PIT algorithm for ABPs of width-2.

It is interesting to note that by a result of Saha, Saptharishi and Saxena [59], PIT for ABPs of width-2 would yield PIT for ΣΠΣ circuits.

Although we do not have a PIT algorithm for general branching programs, in [44] Kayal et al. gave an average-case reconstruction algorithm for low width ABPs. Kayal, Nair and Saha obtained a significantly better algorithm in [43]. Their algorithm succeeds w.h.p., provided the ABP satisfies four non-degeneracy conditions (these conditions are defined in Section 4.3 of [43]). However, the ABP computing the continuant polynomial does not satisfy the non-degeneracy conditions that are required for their algorithm to work. Thus, Theorem 31 does not follow from [43].

To the best of our knowledge, CGL-aff(𝔽) is the first natural⁹ computational class that is dense in VP_e for which a polynomial (or even sub-exponential)-sized interpolating set (or a hitting set) is known.

Read-Once formulas

Hitting sets for read-once formulas were first constructed by Volkovich and Shpilka [66], who gave quasipolynomial-sized hitting set for the model, as well as a deterministic reconstruction algorithm of the same running time (earlier randomized reconstruction algorithms were known [16, 15]). Minahan and Volkovich obtained a polynomial-sized hitting set for the class, which led to a similar improvement in the running time of the reconstruction algorithm [54]. Anderson, van Melkebeek and Volkovich constructed a hitting set of size $n^{O(k)} + O(k \log n)$ for read-k formulas [6]. All these results work in a slightly stronger model in which we allow to label leaves with univariate polynomials, of polynomial degree, such that every variable appears in at most one polynomial, or with sparse polynomials on disjoint sets of variables.

The read-once models that we consider here, ANF^{GL-aff}(𝔽) and ROF^{GL}(𝔽), can be viewed as read-once formulas composed with a layer of addition gates with the restriction that the bottom layer of additions computes linearly independent linear functions. We note that these models do not fall into any of the previously studied models, as a variable can appear in all the linear functions.

As is the case with C^{GL-aff}(𝔽), our hitting sets for ANF^{GL-aff}(𝔽) and ROF^{GL}(𝔽) are the first sub-exponential-sized hitting sets for natural dense subclasses of VP_c.

Small depth circuits

The class of ΣΠ circuits was considered in many works, see e.g. [9, 48] and polynomial-sized hitting sets were constructed. The class of ΣΠΣ circuits also received a lot of attention but with lesser success. Devir and Shpilka [21] and Karnin and Shpilka [40] gave the first quasipolynomial-time white-box and black-box PIT algorithms for Σ[k]Π[d]Σ circuits, respectively. Currently, the best result is by Saxena and Seshadhri who gave a hitting set of size $(nd)^{O(k)}$ for such circuits [64]. In [20] a subexponential-size hitting set for multilinear ΣΠΣ circuits was given. In [2], Agrawal et al. gave a hitting set of size $n^{O(1)} \cdot (kd)^{O(r)}$ for Σ[k]Π[d]Σ circuits, where $r$ is an upper bound on the algebraic rank of the multiplication gates in the circuit. Thus, known quasipolynomial-size hitting sets for subclasses of ΣΠΣ circuits are known when the fan-in of the top gate is poly-logarithmic, or when the algebraic rank of

⁹ It is hard to define what a natural class means, but, for example the set of all polynomials in VP_e with a nonzero free term has a trivial hitting set, but is not a “computational” subclass.
the set of multiplication gates is poly-logarithmic. In contrast, polynomials in $T^{GL_{n}}(F)$ and $\Sigma \Pi^{GL_{n}}(F)$, when viewed as $\Sigma \Pi \Sigma$ circuits, can have polynomially many multiplication gates and their algebraic rank can be $n$. On the other hand, the corresponding $\Sigma \Pi \Sigma$ circuits are such that the different linear functions that are computed at their bottom layer are linearly independent (when we view linear functions that are a constant multiple of each other as the same function). Thus, our Corollary 44 provides a hitting set for a new subclass of $\Sigma \Pi \Sigma$ circuits.

To the best of our knowledge, our results for $T^{GL_{n}}(F)$ and $\Sigma \Pi^{GL_{n}}(F)$ give the first sub-exponential size hitting sets for natural subclasses that are dense in $\Sigma \Pi \Sigma$.

1.4 More related work

Approximations in algebraic complexity were first studied by Bini et al. in the context of algorithms for matrix multiplication [12]. For more on the history of border rank in the context of matrix multiplication see notes of chapter 15 in [18]. More recently, influenced by the GCT program, a lot of research was invested in trying to find polynomials characterizing tensors of small rank. See [51] for a discussion on this approach. More recently, Kumar proved that every polynomial over $\mathbb{C}$ can be approximated by a $\Sigma^{2} \Pi \Sigma$ circuit (of exponential degree) [49].

Very little is known about the closure of circuit classes. Forbes observed that the class of ROABPs is closed [24]. I.e. $\text{ROABP} = \overline{\text{ROABP}}$. We are not aware of other collapses or separation between general “natural” classes and their closures.

Beside the reconstruction algorithms mentioned earlier, reconstruction algorithms are known for $\Sigma \Pi$ circuits [9, 48]; for random depth three powering circuits [42]; for set-multilinear $\Sigma \Pi \Sigma$ and ROABPs [7, 47]; for $\Sigma \Pi \Sigma$ circuits with bounded top fan-in [65, 41, 68]; and for multilinear depth-4 circuits with a constant top fan-in [34, 11].

In general, we do not expect the reconstruction problem to be solvable efficiently, as the problem of finding the minimal circuit computing a given polynomial is a notoriously hard problem. A detailed discussion on the hardness of reconstruction can be found in [43].

Independently and concurrently with our work Saha and Thankey gave PIT algorithms for orbits of different models of read-once oblivious algebraic branching programs (ROABPs) and for constant-depth, constant-occur formulas [60]. Their results concerning ROABPs were recently improved by Bhargava and Ghosh [10]. Interestingly, both [60, 10] use $k$-wise independent maps in their construction. We note that the only model that is studied in this paper and in [60, 10] is that of (orbits of) sparse polynomials. For orbits of sparse polynomials are hitting set is potentially much smaller than those constructed in [60, 10] as it does not depend on the individual degrees appearing in the sparse polynomial.

Simultaneously and independently, Saha and Thankey [60] studied PIT for orbits of related computational models. Specifically, they obtained quasi-polynomial sized hitting sets for: Low-individual-degree polynomials computable by commutative ROABP; Multilinear polynomials computable by constant-width ROABP; Polynomials computable by constant-depth, constant-occur formulas with low-individual-degree sparse polynomials at the leaves; and Polynomials computable by occur-once formulas with low-individual-degree sparse polynomials at the leaves. We refer the reader for their paper for definitions of these models. The results of [60] are mostly disjoint from ours, except for the model of sparse polynomials that is captured by commutative ABPs. In this case our result is superior to theirs as their hitting set has an exponential dependence in the individual degrees, while ours work for any polynomial degree sparse polynomial. It is interesting to note that the hitting set constructions of [60] are also based on $k$-independent maps.
1.5 Proof technique

Our proofs are based on the following simple yet important, and as far as we know novel, observations concerning \(k\)-independent polynomial maps. Specifically, our proofs are based on the following two claims:

1. If we have a hitting-set generator \(H\) for nonzero polynomials of the form \(\frac{\partial f}{\partial x_1}\), for \(f \in \mathcal{C}\), and if \(G\) is a 1-independent map then \(H + G\) hits every nonzero \(f \in \mathcal{C}\). This is proved in Lemma 61.

2. Similarly, we prove that if we have a hitting-set generator \(H\) for nonzero polynomials of the form \(f\big|_{x_1=0}(Ax+b)\), for \(f \in \mathcal{C}\), a linear function \(\ell\), and an invertible affine transformation \((A,b)\), and if \(G\) is a 1-independent map then \(H + G\) hits every nonzero \(f \in \mathcal{C}\). This follows from Lemma 62.

By applying these claims \(k+r\) times we get that composition with a \((k+r)\)-independent map allows to reduce the problem of hitting a class \(\mathcal{C}\) to hitting polynomials of the form \(\frac{\partial f}{\partial x_1 \partial x_2 \cdots \partial x_k}|_{\ell_1=\ldots=\ell_r=0}\). Thus, if we could prove that for a class \(\mathcal{C}\), there is such a sequence of derivatives and restrictions that simplifies the polynomials in it to a degree that they can be easily hit by some map \(H\), then we conclude that \(H + \mathcal{G}_{k+r}\), for a \((k+r)\)-independent map \(\mathcal{G}_{k+r}\), is a hitting set generator for \(\mathcal{C}\).

It seems that all that is left to do is prove that for each of the orbits that we consider in Section 1.2 that is such small \(k\) and \(r\). However, a potential problem is that a partial derivative of the polynomial \(g(x) = f(Ax+b)\) gives \(\frac{\partial g}{\partial x_1} = \sum_{i=1}^n \frac{\partial f}{\partial x_i} \cdot \ell_i\), where \(\ell_i\) is the \(i\)th coordinate of \(Ax+b\). Thus, it is no longer a derivative composed with an affine transformation but rather a sum of such derivatives, which could lead to polynomials outside of our class. For example, it is not hard to prove that if we compose the ROF \(y_1 \cdot y_2 \cdot y_3\) with \((x_1, x_1 + x_2, x_1 + x_3)\) and then take a derivative according to \(x_1\), then the resulting polynomial, \(\frac{\partial g}{\partial x_1}(x_1 + x_2)(x_1 + x_3)) = 3x_1^2 + 2x_1 \cdot (x_2 + x_3) + x_2 \cdot x_3\), is not in the orbit of any ROF. The solution to this problem is to take a directional derivative in a direction coming from a dual basis. For example if \(\ell_i(v_1) = \delta_{i,1}\) then \(\frac{\partial g}{\partial x_1} = \frac{\partial f}{\partial x_1}(Ax + b)\) (see Lemma 60). Now, comes another important observation: If \(H\) is a hitting-set generator for nonzero polynomials of the form \(\frac{\partial f}{\partial x_1}\), for \(f \in \mathcal{C}\) and a direction \(v\), and if \(G\) is a 1-independent map then \(H + G\) hits every nonzero \(f \in \mathcal{C}\). The point is that if \(\frac{\partial f}{\partial x_1} \circ H \neq 0\) then for some \(i\), \(\frac{\partial f}{\partial x_i} \circ H \neq 0\) and the claim follows from the first claim above. Thus, composition with \((k+r)\)-independent maps allows us to reduce the problem of hitting a class \(\mathcal{C}\) to finding a generator for polynomials that are obtained as a restriction to a subspace of co-dimension \(r\) of a directional partial derivative of order \(k\) of polynomials in \(\mathcal{C}\).

Let us demonstrate this idea for the case of orbits of sparse polynomials. I.e. to polynomials of the form \(g(x) = f(Ax+b)\), where the number of monomials in \(f\) is at most \(2^t\). It is not hard to see that there is a variable \(x_i\) such that if we consider \(f|x_i=0\) and \(\frac{\partial f}{\partial x_i}\), then one of these polynomials has at most \(2^{t-1}\) monomials.\(^{10}\) Thus, after a sequence of at most \(t\) partial derivatives and restrictions, we get to a polynomial with only one monomial that we can easily hit. Hence after at most \(t\) directional derivatives and restrictions to a subspace, we get that \(g\) is a product of linear forms, which we can easily hit. This proves that any \((t+1)\)-independent map hits such nonzero polynomials \(g\).

\(^{10}\) This is not exactly accurate – it only holds if \(f\) is not divisible by some variable \(x_i\). However, the case where there is a monomial dividing \(f\) is also quite easy to handle as it is enough to hit the polynomial obtained after dividing by that monomial (since a composition with a 1-independent map keeps any nonzero linear function nonzero).
To obtain interpolating sets for our classes (and also a reconstruction algorithm for the orbit of the continuant polynomial), we prove that if two polynomials in the orbit, of any of the classes that we consider, are different, then there is a sequence of a few (directional) partial derivatives and restrictions that makes one of them zero while keeping the other nonzero. Using this and the ideas from above we construct our interpolating sets.

**Remark 50.** In this version of the paper we only give proofs of the main properties of \( k \)-wise independent maps (outlined above), as these are the main tool that we used in all our proofs. The full version can be found at [53].

### 1.6 Discussion

As Theorem 48 shows, our hitting sets are not necessarily robust. It is thus an outstanding open problem to find a way to convert a hitting set to a robust one (recall Problem 1).

The following toy example demonstrates that converting a hitting set for a class \( \mathcal{C} \) to a robust hitting set for \( \mathcal{C} \), cannot be done in a black-box manner and one has to use information about \( \mathcal{C} \) for that: let \( \mathcal{C}(F) \) be the class of all polynomials with non-zero free term. A trivial hitting set for \( \mathcal{C} \) would simply be the singleton set \( \mathcal{H} = \{0\} \). On the other hand, it is clear that \( \mathcal{C} = F[x] \), so making \( \mathcal{H} \) robust would yield a hitting set for all polynomials. Note, however, that this is not a “computational class.”

Another potential approach for obtaining robust hitting sets follows from the observation that the set of queries made by a non-adaptive deterministic black-box reconstruction algorithm, \( \mathcal{A} \), for \( \mathcal{C} \), which is continuous at 0 (i.e. at the identically zero polynomial) is a robust hitting set for \( \mathcal{C} \). The reason is, that if \( 0 \neq f \in \mathcal{C} \) and \( \{f_k\}_{k=1}^\infty \subseteq \mathcal{C} \) converges to \( f \), then for large enough \( k \): \( \|f_k\|_2 \geq \frac{1}{2} \|f\|_2 > 0 \). As the \( f_k \) sequence converges and polynomial evaluation is continuous (and their evaluation vectors are bounded), the sequence \( v_k = f_k|_H \subseteq \mathbb{C}^{|H|} \) must also converge to some vector \( v = f|_H \in \mathbb{C}^{|H|} \). If \( v = 0 \) then the continuity of \( \mathcal{A} \) at 0 implies the coefficients of the polynomials \( f_k(x) \) must also converge to zero, as \( \mathcal{A}(0) = 0 \). This would contradict \( \|f_k\|_2 \geq \frac{1}{2} \|f\|_2 > 0 \) for large enough \( k \), so \( v \neq 0 \) and thus \( H \) hits \( \mathcal{C} \).

Thus, an interesting challenge is to derandomize the reconstruction algorithms given in Theorems 31, 37, and 46, hoping that the resulting algorithms are continuous at 0. We note however, that currently we do not even have efficient deterministic root-finding algorithms over \( \mathbb{C} \). It is also known that in general, finding the minimal circuit for a polynomial can be very difficult. E.g., in [36, 70] it was shown that the question of computing, or even approximating, tensor rank, for degree 3 tensors, is NP hard, over any field.

**Remark 51.** In Theorem 45, we have seen that any uniform \( O(\log(sn)) \)-independent polynomial map \( \mathcal{G} \) is an interpolating set generator for \( \mathcal{C}^{GL,n}(C) \); i.e, \( \mathcal{G} \) induces an interpolating set \( \mathcal{H} \) for \( \mathcal{C}^{GL,n}(C) \). On the other hand, in Theorem 48, we constructed such a map \( \mathcal{G} \), with the additional property that \( \mathcal{G} \) is not a hitting set generator for \( \Sigma\Pi\Sigma \) circuits. In particular, this implies that the induced (non-efficient) reconstruction map \( \mathcal{A} \) (that takes \( f(\mathcal{H}) \)) and returns a circuit computing \( f \) is not continuous at 0.

We conclude this section with a somewhat vague question.

**Problem 52.** Find a “computational” class of polynomials \( \mathcal{C} \) with a known hitting set \( \mathcal{H} \), such that \( \mathcal{C} \neq \mathcal{C} \), and convert \( \mathcal{H} \) to a robust hitting set.

We note that the closure of \( \Sigma \Lambda \Sigma \) circuits (i.e. circuits computing polynomials of the form \( \sum \ell_i(x)^d \), for linear functions \( \ell_i \)) is contained in the class of commutative read-once algebraic branching programs (see [25]). Thus, the hitting set for the latter class gives a robust hitting set for the former [25]. However, we seek an example in which there is an “interesting” conversion of a hitting set to a robust one.
2 \hspace{1cm} k\text{-independent polynomial maps and their properties}

\textbf{Observation 53.} It holds that
1. If \( G(y, z) \) is a \((k+1)\)-independent polynomial map, then there exists a subset of variables \( S \) and an assignment \( \alpha \in \mathbb{F}^{\mid S \mid} \) such that \( G\big|_{S=\alpha} \) is a \( k \)-independent polynomial map.
2. For any \( k \geq 1 \), the \( n \) coordinates of any \( k \)-independent polynomial map are \( \mathbb{F} \)-linearly independent.
3. Let \( \ell_1(x) \) and \( \ell_2(x) \) be linearly independent linear functions in \( \mathbb{F}[x] \). Let \( G(y, z_1, z_2) \) be any \( 2 \)-independent polynomial map. Consider \( \ell_1 \circ G \) and \( \ell_2 \circ G \) as polynomials in \( z_1, z_2 \) over \( \mathbb{F}(y) \). Then, \((\ell_1 \circ G)^{[1]}\) and \((\ell_2 \circ G)^{[1]}\) are linearly independent, as linear forms in \( z_1, z_2 \) over \( \mathbb{F}(y) \).

We next give the construction of [66] of a \( k \)-independent polynomial map (denoted \( G_k \) in [66]).

\textbf{Definition 54.} Fix \( n \) and a set of \( n \) distinct field elements \( A = \{\alpha_1, \ldots, \alpha_n\} \subseteq \mathbb{F} \).\footnote{If \( \mid \mathbb{F} \mid < n \) then we take these elements from an appropriate extension field of \( \mathbb{F} \).} For every \( i \in [n] \) let \( L_i(w) : \mathbb{F} \to \mathbb{F} \) be the \( i \)th Lagrange Interpolation polynomial for the set \( A \). That is, each \( L_i(w) \) is polynomial of degree \( n - 1 \) that satisfies \( L_i(\alpha_j) = \delta_{i,j} \). We define \( G_1^{SV}(y_1, z_1) : \mathbb{F}^2 \to \mathbb{F}^n \) as:
\[
G_1^{SV}(y_1, z_1) \triangleq (L_1(y_1) \cdot z_1, L_2(y_1) \cdot z_1, \ldots, L_n(y_1) \cdot z_1),
\]
and for any \( k \geq 1 \), we define \( G_k^{SV} : \mathbb{F}^{2k} \to \mathbb{F}^n \) as:
\[
G_k^{SV}(y, z) \triangleq G_1^{SV}(y_1, z_1) + y_2^{SV}(y_2, z_2) + \ldots + G_k^{SV}(y_k, z_k)
\]
\[
= \left( \sum_{j=1}^{k} L_1(y_j) \cdot z_j, \sum_{j=1}^{k} L_2(y_j) \cdot z_j, \ldots, \sum_{j=1}^{k} L_n(y_j) \cdot z_j \right).
\]

\textbf{Observation 55.} \( G_k^{SV} \) is a \( k \)-independent polynomial map, in which each variable has degree at most \( n - 1 \).

The generator \( G_k^{SV} \) can be converted to a uniform \( k \)-independent polynomial map by adding another \( k \) control variables \( y_{k+1}, \ldots, y_{2k} \), and swapping out the \( L_i(y_j) \)s for their homogenizations \( y_j^{n-1}L_i \left( \frac{y_j}{y_{j+k}} \right) \):

\textbf{Definition 56.} With the notation used in Definition 54, define the uniform SV-generator with \( k \) independence \( G_k^{SV-hom} : \mathbb{F}^{3k} \to \mathbb{F}^n \) as:
\[
G_k^{SV-hom}(y_1, \ldots, y_{2k}, z_1, \ldots, z_k)
\]
\[
= y_1^{n-1} \cdot G_1^{SV} \left( \frac{y_1}{y_{1+k}}, z_1 \right) + y_2^{n-1} \cdot G_1^{SV} \left( \frac{y_2}{y_{2+k}}, z_2 \right) + \ldots + y_{2k}^{n-1} \cdot G_1^{SV} \left( \frac{y_{2k}}{y_{2k+k}}, z_k \right)
\]
\[
= \left( \sum_{j=1}^{k} y_j^{n-1} L_1 \left( \frac{y_j}{y_{j+k}} \right) \cdot z_j, \sum_{j=1}^{k} y_j^{n-1} L_2 \left( \frac{y_j}{y_{j+k}} \right) \cdot z_j, \ldots, \sum_{j=1}^{k} y_j^{n-1} L_n \left( \frac{y_j}{y_{j+k}} \right) \cdot z_j \right).
\]

\textbf{Observation 57.} \( G_k^{SV-hom} \) is a uniform \( k \)-independent polynomial map, with individual degrees at most \( n - 1 \).
We next show how we can use \( k \)-independent polynomial maps in order to, roughly, simulate a \( k \)th order directional derivative or, project a polynomial to a subspace of co-dimension \( k \). We first need to define the notion of a directional derivative.

**Definition 58.** For an \( n \)-variate polynomial \( f \in \mathbb{F}[x] \) and \( v = (v_1, \ldots, v_n) \in \mathbb{F}^n \), the derivative of \( f(x) \) in the direction \( v \) is defined as:

\[
\frac{\partial f}{\partial v} = \sum_{i=1}^{n} v_i \cdot \frac{\partial f}{\partial x_i}.
\]

If \( \mathbb{F} \) has positive characteristic then by \( \frac{\partial g}{\partial x} \), we refer to the formal derivative (which in the case of fields of characteristic zero is equal to the analytical definition). Observe that we still have that

\[
\frac{\partial^2 f}{\partial y \partial x} = \frac{\partial f}{\partial x} \cdot \frac{\partial (fg)}{\partial y} = \frac{\partial f}{\partial x} \cdot g + \frac{\partial g}{\partial x} \cdot f
\]

and

\[
\frac{\partial f}{\partial x_k}(g_1(x), \ldots, g_m(x)) = \sum_{i=1}^{m} \frac{\partial f}{\partial y_i}(g_1(x), \ldots, g_m(x)) \cdot \frac{\partial g_i}{\partial x_k},
\]

where in the last expression \( f \) is an \( m \) variate polynomial, and \( g_1, \ldots, g_m \) are \( n \) variate polynomials.

We shall often take derivatives according to a dual set to a set of linearly independent linear functions:

**Definition 59.** A dual set for \( m \) linearly independent linear functions (recall that we say that linear functions are linearly independent if and only if their degree-1 homogeneous parts are linearly independent) in \( n \geq m \) variables, \( \ell_1(x), \ldots, \ell_m(x) \) is a set of \( m \) vectors \( \{v_i\} \subset \mathbb{F}^n \) such that \( \ell^{[1]}_i(v_j) = \delta_{i,j} \).

**Lemma 60.** Let \( \ell_1, \ldots, \ell_m \in \mathbb{F}[x_1, \ldots, x_n] \), for \( n \geq m \), be linearly independent linear functions. Let \( \{v_i\} \subset \mathbb{F}^n \) be a dual set. Let \( g \in \mathbb{F}[y_1, \ldots, y_m] \) be a polynomial. Then, for \( f(x) = g(\ell_1(x), \ldots, \ell_m(x)) \) it holds that

\[
\frac{\partial f}{\partial v_i}(x) = \frac{\partial g}{\partial y_i}(\ell_1(x), \ldots, \ell_m(x)) .
\]

**Proof.**

\[
\frac{\partial f}{\partial v_i}(x) = \sum_j v_{i,j} \cdot \frac{\partial f}{\partial x_j}(x) = \sum_j v_{i,j} \cdot \frac{\partial \ell_k}{\partial x_j} \cdot \frac{\partial g}{\partial y_k}(\ell_1(x), \ldots, \ell_m(x))
\]

\[
= \sum_k \ell^{[1]}_k(v_i) \cdot \frac{\partial g}{\partial y_k}(\ell_1(x), \ldots, \ell_m(x)) = \frac{\partial g}{\partial y_i}(\ell_1(x), \ldots, \ell_m(x)) .
\]

**Lemma 61.** Let \( f \in \mathbb{F}[x] \) where \( x = (x_1, \ldots, x_n) \). Let \( H(w) : \mathbb{F}^t \rightarrow \mathbb{F}^n \) be a polynomial map in variables \( w \), and let \( G(y, z) \) be a \( k \)-independent polynomial map such that \( \text{var}(H) \cap \text{var}(G) = \emptyset \). Then, for any \( v_1, \ldots, v_k \in \mathbb{F}^n \):

\[
\frac{\partial^k f}{\partial v_1 \partial v_2 \cdots v_k} \circ H \neq 0 \quad \Rightarrow \quad f \circ (G + H) \neq 0 .
\]
Proof. By definition of $k$-independent polynomial maps, $G = G_1(y_1, z_1) + \ldots + G_k(y_k, z_k)$ for some variable-disjoint 1-independent polynomial maps $G_1, \ldots, G_k$. It is therefore enough to prove the lemma for $k = 1$, as we can replace $f$ with $\frac{\partial f}{\partial y_1}$, $H$ with $H + G_2 + \ldots + G_k$ and $G$ with $G_1$; by iterative application of the result for $k = 1$, we will get the general result for an arbitrary $k \in \mathbb{N}$.

Denote $H = (H_1, H_2, \ldots, H_n)$. By Definition 58, the condition $\frac{\partial f}{\partial y_1} \circ H \neq 0$ implies that there exists some $i \in [n]$ such that $\frac{\partial f}{\partial y_i} \circ H \neq 0$. Assume, WLOG, $\frac{\partial L}{\partial y_i} \circ H \neq 0$. As $G$ is a 1-independent polynomial map, there exists some $\alpha \in \mathbb{F}[y_1]$ such that $f \circ (G + H)|_{y_1=\alpha} = f(z_1 + H_1, H_2, \ldots, H_n)$; denote $g \triangleq f \circ (G + H)|_{y_1=\alpha}$. As no coordinate of $H$ depends on $z_1$:

\[
\frac{\partial g}{\partial z_1} = \frac{\partial (z_1 + H_1)}{\partial z_1} \cdot \frac{\partial f}{\partial x_1} (z_1 + H_1, H_2, \ldots, H_n) = 1 \cdot \left( \frac{\partial f}{\partial x_1} \right) (z_1 + H_1, H_2, \ldots, H_n)
\]

and therefore:

\[
\frac{\partial g}{\partial z_1} \bigg|_{z_1=0} = 1 \cdot \left( \frac{\partial f}{\partial x_1} \right) (0 + H_1, H_2, \ldots, H_n) = \left( \frac{\partial f}{\partial x_1} \right) \circ H \neq 0.
\]

As $g$ is a projection of $f \circ (G + H)$, it follows that $f \circ (G + H) \neq 0$. ◀

The next lemma shows how to use $k$-independent maps in order to project a polynomial to a subset of its coordinates.

Lemma 62. Let $m \leq n \in \mathbb{N}$ and $g(w) \in \mathbb{F}[w_1, \ldots, w_m]$. Let $f(x) = g(\ell_1(x), \ldots, \ell_m(x))$ for linearly independent linear functions $\ell_1(x), \ldots, \ell_m(x)$. Let $G(y, z)$ be a $k$-independent polynomial map. For a set $S \subseteq [n]$ of size $k$ denote by $\tilde{g}(x_1 : i \in [m] \setminus S) = g|_{S=0}$ the projection of $g$ to the variables outside of $S$. Then, there exist linearly independent linear functions $\{ \tilde{\ell}_i(x) : i \in [m] \setminus S \}$, additional linear functions $L(x) = (L_1(x), \ldots, L_k(x))$ and an assignment $\alpha \in \mathbb{F}[y]$ such that:

\[
f(x + G(\alpha, L(x))) = \tilde{g}(\tilde{\ell}_1(x) : i \in [m] \setminus S).
\]

Proof. It is enough to prove the lemma for the case $k = 1$, as we may then define $\tilde{f}(x) \triangleq f(x + G(\alpha, L_1(x))) = \tilde{g}(\tilde{\ell}_1(x), \ldots, \tilde{\ell}_{m-1}(x))$ and apply the result iteratively. Thus, assume $k = 1$, and WLOG assume $S = \{x_1\}$ (thus, $\tilde{g}(w_2, \ldots, w_m) = g(0, w_2, \ldots, w_m)$).

Let $x_1$ be some variable with a non-zero coefficient in $\ell_1(x)$. Such a variable exists as the $\ell_j$s are linearly independent. For $j \in [m]$, denote $\beta_j = \frac{\partial \ell_j}{\partial x_1}$, i.e. $\beta_j$ is the coefficient of $x_1$ in $\ell_j$. By our choice of $i, \beta_j \neq 0$. Choose some $\alpha \in \mathbb{F}[y]$ such that $G(\alpha, z_1)$ has $z_1$ in the $i$th coordinate, and 0 in all other coordinates. Define $L(x) \triangleq -\frac{\ell_1(x)}{\beta_1}$, so we get:

\[
f(x + G(\alpha, L(x))) = f\left(x_1, x_2, \ldots, x_{i-1}, x_1 - \frac{\ell_1(x)}{\beta_1}, x_{i+1}, \ldots, x_n\right).
\]

Observe that for every $i$,

\[
\ell_i(x + G(\alpha, L(x))) = \ell_i\left(x_1, x_2, \ldots, x_{i-1}, x_1 - \frac{\ell_1(x)}{\beta_1}, x_{i+1}, \ldots, x_n\right) = \ell_i(x) - \frac{\beta_i}{\beta_1} \cdot \ell_1(x).
\]

In particular, $\ell_1 (x + G(\alpha, L(x)) = 0$. For $i = 2, \ldots, m$, define:

\[
\tilde{\ell}_i(x) \triangleq \ell_i(x) - \frac{\beta_i}{\beta_1} \cdot \ell_1(x).
\]

As $\ell_1, \ldots, \ell_m$ are linearly independent, it follows that $\tilde{\ell}_2, \ldots, \tilde{\ell}_m$ are also linearly independent. We get that

\[
f(x + G(\alpha, L(x))) = g(0, \tilde{\ell}_2(x), \ldots, \tilde{\ell}_m(x)) = \tilde{g}(\tilde{\ell}_2(x), \ldots, \tilde{\ell}_m(x)).
\]

\[
\begin{cases} 
\end{cases}
\]

\[
\begin{cases} 
\end{cases}
\]
2.1 Proof of Theorem 48

We next prove that there are $k$-independent maps that are provably not robust. The proof is by giving a different construction of such maps that, for an appropriate arrangement of the $n$ variables in a matrix, is guaranteed to output matrices of rank at most $k$. Thus, a determinant of any $(k+1) \times (k+1)$ minor, a polynomial that has small formulas for small values of $k$, vanishes on the output of any such map.

The fact that such a construction exists was already noticed in [27] (Construction 6.3 of the full version of the paper). For completeness we repeat the construction here.

Proof. (of Theorem 48) Fix the number of variables $n$ and assume WLOG $n$ is a perfect square, i.e., $n = m^2$. We index the variables as $x_{i,j}$ for $i, j \in [m]$. We let $f = \text{Det}_{t+1}$. By [33], over fields of characteristic zero, $f$ has a $t^{O(\sqrt{t})} = O(n)$ sized $\Sigma\Pi\Sigma$ formula, which is polynomial in $n$ for $t = O\left((\log n/\log\log n)^2\right)$. Over fields of positive characteristic the formula size is quasipolynomial in $t$, and the $\Sigma\Pi\Sigma$ complexity is at most $t!$, which is polynomial in $n$ for $t = O(\log n/\log\log n)$.

Denote by $M$ the $(t+1) \times (t+1)$ symbolic matrix of variables $M_{i,j} = x_{i,j}$. We first construct a uniform 1-independent polynomial map $G_1$ such that $M \circ G_1$ is of rank 1, and define $G$ to be a sum of $t$ variable-disjoint copies of $G_1$. As $\text{rank}(M \circ G_1) = 1$, we have $\text{rank}(M \circ G) \leq t$ so $\text{Det}_{t+1}(M \circ G) = 0$, as required. We now focus on $G_1$.

Fix $n$ distinct field elements $(\alpha_{i,j})_{i,j=1}^m \subseteq F$ and let $w, y, z$ be new variables. Define two vectors of polynomials of degree $n - 1$, $R = (R_1, \ldots, R_m), C = (C_1, \ldots, C_m) \in F[y]^m$, such that for every $k \in [m]$ $R_k$ and $C_k$ satisfy

$$R_k(\alpha_{i,j}) = \delta_{i,k} \quad \text{and} \quad C_k(\alpha_{i,j}) = \delta_{j,k}.$$

Define $G_1(w, y, z)$ as the $m \times m$ matrix $z \cdot (w^{2n-2} R(x^T) \cdot C(y^T))$ (the $(i,j)$ entry of $G_1$ is $z \cdot w^{2n-2} \cdot R_i(C_j(x^T)))$. As every coordinate of $G_1$ is a homogeneous polynomial of degree $2n - 1$, $G_1$ is a uniform polynomial map. For any $i, j \in [m]$ we have that

$$G_1(1, \alpha_{i,j}, z) = z \cdot (R_{i'}(\alpha_{i,j}) \cdot C_{j'}(\alpha_{i,j}))_{i', j' \in [m]} = z \cdot (\delta_{i,i'} \delta_{j,j'})_{i', j' \in [m]}.$$

The above matrix has $z$ in entry $(i,j)$ and $0$ everywhere else, so $G_1$ is a uniform 1-independent polynomial map. The resulting matrix $M \circ G_1$ is of rank 1 since it is a product of vectors $R \cdot C$, so the variable-disjoint sum $G = \sum_1 G_1(w_i, y_i, z_i)$ is a uniform $t$-independent polynomial map satisfying $f \circ G = 0$.

Variety Evasive Subspace Families

Zeyu Guo

Department of Computer Science, University of Haifa, Israel

Abstract

We introduce the problem of constructing explicit variety evasive subspace families. Given a family $\mathcal{F}$ of subvarieties of a projective or affine space, a collection $\mathcal{H}$ of projective or affine $k$-subspaces is $(\mathcal{F}, \epsilon)$-evasive if for every $V \in \mathcal{F}$, all but at most $\epsilon$-fraction of $W \in \mathcal{H}$ intersect every irreducible component of $V$ with (at most) the expected dimension. The problem of constructing such an explicit subspace family generalizes both deterministic black-box polynomial identity testing (PIT) and the problem of constructing explicit (weak) lossless rank condensers.

Using Chow forms, we construct explicit $k$-subspace families of polynomial size that are evasive for all varieties of bounded degree in a projective or affine $n$-space. As one application, we obtain a complete derandomization of Noether’s normalization lemma for varieties of bounded degree in a projective or affine $n$-space. In another application, we obtain a simple polynomial-time black-box PIT algorithm for depth-4 arithmetic circuits with bounded top fan-in and bottom fan-in that are not in the Sylvester–Gallai configuration, improving and simplifying a result of Gupta (ECCC TR 14-130).

As a complement of our explicit construction, we prove a lower bound for the size of $k$-subspace families that are evasive for degree-$d$ varieties in a projective $n$-space. When $n - k = n^{\Omega(1)}$, the lower bound is superpolynomial unless $d$ is bounded. The proof uses a dimension-counting argument on Chow varieties that parametrize projective subvarieties.

1 Introduction

Polynomial identity testing (PIT) is a fundamental problem in the areas of derandomization and algebraic complexity theory. The problem asks whether a multivariate polynomial, computed by an arithmetic circuit, formula, or other algebraic computational models, is identically zero. For example, the polynomial $(X + Y)(X - Y) - X^2 - Y^2$ is identically zero while $(X + Y)^2 - X^2$ is not.

It is easy to solve PIT in randomized polynomial time, as we may simply evaluate the input polynomial at a random point and check if the evaluation is zero. On the other hand, finding a deterministic polynomial-time PIT algorithm for general arithmetic circuits is a long-standing open problem. Such algorithms are known for some special cases, and we refer the readers to the surveys [67, 68, 73] for details.

Black-box PIT algorithms are a special kind of PIT algorithm. A (deterministic) black-box PIT algorithm tests if a polynomial in a family $\mathcal{F}$ is zero by constructing a hitting set for $\mathcal{F}$, which is a finite collection $\mathcal{H}$ of evaluation points with the following property: for any nonzero $Q \in \mathcal{F}$, there exists $p \in \mathcal{H}$ such that the evaluation of $Q$ at $p$ is nonzero. After constructing
such a hitting set $H$, the algorithm simply checks if the evaluation of the given polynomial at every point in $H$ is zero. The problem of designing a deterministic black-box PIT algorithm is thus equivalent to constructing a hitting set. To make the algorithm efficient, such a hitting set should be small and efficiently computable.

From a geometric perspective, an $n$-variate nonzero polynomial $Q$ over an algebraically-closed field $\mathbb{F}$ defines a hypersurface $V(Q) := \{ \alpha \in \mathbb{F}^n : Q(\alpha) = 0 \}$ of $\mathbb{F}^n$. A hitting set $H$ for $\mathcal{F}$ has the property that for every nonzero $Q \in \mathcal{F}$, there exists a point $p \in H$ that is disjoint from the hypersurface $V(Q)$, or we say $p$ evades $V(Q)$. It is natural to consider the generalization of this property to higher dimensions/codimensions. Namely, we want to construct a finite collection $H$ of affine $k$-subspaces (i.e., affine subspaces of dimension $k$) such that for every variety $V \subseteq \mathbb{F}^n$ (i.e., solution set of a set of polynomial equations) from a certain family, some (or most) $W \in H$ evade $V$, in the sense that the dimension of the intersection $V \cap W$ is bounded by the expected dimension achieved by $W$ in general position. A similar property can be defined for projective $k$-spaces, to be defined below. We call such a collection $H$ of projective or affine $k$-subspaces a variety evasive subspace family. The formal definition is given below.

### 1.1 Variety Evasive Subspace Families

Let $\mathbb{F}$ be an algebraically closed field. An affine $n$-space $\mathbb{A}^n$, as a set, is simply defined to be the vector space $\mathbb{F}^n$. We also need the notion of a projective $n$-space, denoted by $\mathbb{P}^n$, which is (intuitively) the set of lines passing through the origin $0$ of $\mathbb{A}^{n+1}$. Formally, it is defined to be the quotient set $(\mathbb{A}^{n+1} \setminus \{0\})/\sim$, where $\sim$ is the equivalence relation defined by scaling, i.e., $u \sim v$ if $u = cv$ for some nonzero scalar $c \in \mathbb{F}$.

An (affine) subvariety $V \subseteq \mathbb{A}^n$ is the set of common zeros of a set of $n$-variate polynomials over $\mathbb{F}$. Similarly, a (projective) subvariety $V \subseteq \mathbb{P}^n$ is the set of common zeros of a set of homogeneous $(n + 1)$-variate polynomials over $\mathbb{F}$, where we represent each element of $\mathbb{P}^n$ as an $(n + 1)$-tuple in $\mathbb{A}^{n+1}$. In this paper, a variety refers to a subvariety of a projective or affine space, and is said to be irreducible if it cannot be written as a union of finitely many proper subvarieties.

The dimension of a variety $V$, denoted by $\dim(V)$, is intuitively the “degree of freedom” of picking a point in the variety. See Subsection 2.3 for its formal definition. For a linear subspace $V \subseteq \mathbb{A}^n$, the linear-algebraic dimension of $V$ is the same as its dimension as a variety.

For two irreducible subvarieties $V_1$ and $V_2$ of $\mathbb{P}^n$ or $\mathbb{A}^n$ in general position, we expect the dimension of $V_1 \cap V_2$ to be $\dim(V_1) + \dim(V_2) - n$ (unless $\dim(V_1) + \dim(V_2) < n$, in which case we expect $V_1 \cap V_2 = \emptyset$). The following definition captures the condition that $\dim(V_1 \cap V_2)$ is bounded by the expected dimension.

**Definition 1 (Evading).** Let $V_1$ and $V_2$ be irreducible subvarieties of $\mathbb{P}^n$ or $\mathbb{A}^n$. We say $V_1$ evades $V_2$ if

$$\dim(V_1 \cap V_2) \leq \dim(V_1) + \dim(V_2) - n,$$

where the dimension of an empty set is assumed to be $-\infty$. In particular, if $\dim(V_1) + \dim(V_2) < n$, then $V_1$ evades $V_2$ iff $V_1 \cap V_2 = \emptyset$.

More generally, suppose $V_1$ is irreducible but $V_2$ is possibly reducible. We say $V_1$ evades $V_2$ if it evades every irreducible component of $V_2$.

---

1 Varieties in this paper are not necessarily irreducible and are often called algebraic sets in literature.
Next, we define *subspace families* and *variety evasive subspace families*.

- **Definition 2 (Subspace family).** For $0 \leq k \leq n$, a finite collection$^2$ of $k$-subspaces of $\mathbb{P}^n$ is called a (projective) $k$-subspace family on $\mathbb{P}^n$. Similarly, a finite collection of affine $k$-subspaces of $\mathbb{A}^n$ is called an affine $k$-subspace family on $\mathbb{A}^n$.

- **Definition 3 (Variety evasive subspace family).** Let $\mathcal{F}$ be a family of subvarieties of $\mathbb{P}^n$ (resp. $\mathbb{A}^n$). Let $\mathcal{H}$ be a $k$-subspace family on $\mathbb{P}^n$ (resp. affine $k$-subspace family on $\mathbb{A}^n$) where $0 \leq k \leq n$. Then:
  - We say $\mathcal{H}$ is $\mathcal{F}$-evasive if for every $V \in \mathcal{F}$, there exists $W \in \mathcal{H}$ that evades $V$.
  - We say $\mathcal{H}$ is $(\mathcal{F}, \epsilon)$-evasive if for every $V \in \mathcal{F}$, a random element $W \in \mathcal{H}$ evades $V$ with probability at least $1 - \epsilon$.

**Connection with hitting sets.** Definition 3 naturally generalizes the notions of hitting sets in the context of PIT. For example, a collection of points in $\mathbb{P}^n$ is a hitting set for a family $\mathcal{F}$ of homogeneous polynomials in $\mathbb{F}[X_1, \ldots, X_{n+1}]$ if it is an $\mathcal{F}'$-evasive 0-subspace family, where $\mathcal{F}' = \{ V(P) : P \in \mathcal{F} \}$ is the family of hypersurfaces defined by the polynomials in $\mathcal{F}$. In other words, hitting sets may be viewed as 0-subspace families that are evasive for varieties of codimension one.

**Connection with lossless rank condensers.** Other than the case of codimension one, we may also consider the special case of degree one, and this leads to another important family of pseudorandom objects, called (weak) lossless rank condensers $\{33, 29, 28, 27\}$. These objects were used by Gabizon and Raz [33] to construct affine extractors. They also play a crucial role in polynomial identity testing $\{51, 69, 29, 28\}$.

A lossless rank condenser is defined as follows: Let $r \leq t \leq n$ be positive integers. A finite collection $\mathcal{H}$ of matrices $E \in \mathbb{F}^{t \times n}$ is called an $(r, L)$-lossless rank condenser if for every matrix $M \in \mathbb{F}^{n \times t}$ of rank $r$, the number of $E \in \mathcal{H}$ satisfying $\text{rank}(EM) < r$ is at most $L$.

The connection between lossless rank condensers and variety evasive subspace families can be seen as follows: Let us assume every matrix $E \in \mathcal{H}$ has full rank $t$. Such a matrix $E$ corresponds to a linear $t$-subspace $W$ of $\mathbb{F}^n$. On the other hand, a matrix $M \subseteq \mathbb{F}^{n \times r}$ of rank $r$ corresponds to a linear $(n-r)$-subspaces of $\mathbb{F}^n$ via $M \mapsto \ker(M)$, where $\ker(M) = \{ u \in \mathbb{F}^n : uM = 0 \}$ denotes the left kernel of $M$. It is easy to see that the condition $\text{rank}(EM) = r$ is equivalent to $\text{dim}(W \cap \ker(M)) = t - r$. Passing from $\mathbb{F}^n$ to $\mathbb{P}^{n-1}$ by taking the quotient modulo scalars, this condition is also equivalent to the condition that the two projective subspaces $\mathbb{P}W$ and $\mathbb{P}(\ker(M))$ evade each other.

Every projective $(n-r-1)$-subspace of $\mathbb{P}^{n-1}$ can be realized as $\mathbb{P}(\ker(M))$ for some rank-$r$ matrix $M$. Therefore, $\mathcal{H}$ is an $(r, L)$-lossless rank condenser if it is an $(\mathcal{F}, \epsilon)$-evasive $(t-1)$-subspace family on $\mathbb{P}^{n-1}$, where $\epsilon = L/|\mathcal{H}|$ and $\mathcal{F}$ is the family of all $(n-r-1)$-subspaces of $\mathbb{P}^{n-1}$.

Rank condensers are central objects in the theory of “linear-algebraic pseudorandomness” coined by Guruswami and Forbes $\{27\}$. Our study of variety evasive subspace families may be seen as one step of extending the theory to a nonlinear setting.

Explicit lossless rank condensers were used to construct explicit (deterministic) affine extractors $\{33\}$ and more generally, extractors for varieties $\{18\}$. Similar ideas were used to construct explicit deterministic extractors (and rank extractors) for polynomial sources $\{19\}$.

---

$^2$ In this paper, a *collection* is a multiset, i.e., its elements are allowed to appear more than once.
which also generalize affine extractors. It is an interesting question to us whether explicit variety-evasive subspace families and the related derandomized Noether’s normalization lemma (see below) can be similarly useful in this area.

### 1.2 Our Results

We have seen that variety evasive subspace families generalize some important and well-studied pseudorandom objects. This leads to the following natural question: For which interesting families $F$ of subvarieties can we construct explicit $F$-evasive or $(F,\epsilon)$-evasive subspace families?

In this paper, we focus on the families of subvarieties of bounded degree. First, we recall the definition of the degree of a variety.

#### Definition 4 (degree). The degree of an irreducible variety $V$ in $\mathbb{P}^n$ (resp. $\mathbb{A}^n$) is the number of intersections of $V$ with a general projective (resp. affine) subspace of codimension $\dim(V)$. Following [46], we define the degree of a (possibly reducible) variety to be the sum of the degrees of its irreducible components.

For convenience, we introduce the following definition.

#### Definition 5. We say a projective (resp. affine) $k$-subspace family $H$ on $\mathbb{P}^n$ (resp. $\mathbb{A}^n$) is $(n,d)$-evasive if it is $F$-evasive, where $F$ is chosen to be the family of all subvarieties of $\mathbb{P}^n$ (resp. $\mathbb{A}^n$) of degree at most $d$. Similarly, we say $H$ is $(n,d,\epsilon)$-evasive if it is $(F,\epsilon)$-evasive.

#### Remark. In Definition 5, we do not make any assumption about the dimension of the varieties in $F$ or their irreducible components. We will see in Subsection 3.1 that in fact, it suffices to consider the subfamily of equidimensional varieties or even irreducible varieties of dimension $n - k - 1$ when constructing variety evasive $k$-subspace families.

For $n, d \in \mathbb{N}^+$ and $k \in \{0,1,\ldots,n\}$, define $N(k,d,n)$ by

$$N(k,d,n) := \min \left\{ \frac{(k+1)(n+1+d)}{(k+1)d}, \frac{(n-k)(n+1+d)}{(n-k)d}, \frac{(d-1)(n+1+d)}{(d-1)d} \right\}.$$ 

Our main theorem then states as follows.

#### Theorem 6 (Main Theorem). For $n, d \in \mathbb{N}^+$, $k \in \{0,1,\ldots,n\}$, and $\epsilon \in (0,1)$, there exists an $(n,d,\epsilon)$-evasive $k$-subspace family (resp. affine $k$-subspace family) $H$ on $\mathbb{P}^n$ (resp. $\mathbb{A}^n$) of size $\text{poly}(N(k,d,n), n, 1/\epsilon)$, which is $\text{poly}(n^{\min\{k+1,n-k,d\}}d, 1/\epsilon)$ when $d = o(n)$. Moreover, the total time complexity of computing the linear equations defining the projective or affine subspaces in $H$ is polynomial in $|H|$ (and $\log p$, if the characteristic of the base field $\mathbb{F}$ is $p > 0$). In particular, $H$ can be constructed in polynomial time when $d$ is bounded.

#### Remark (Boundedness of coefficients). For simplicity, the base field $\mathbb{F}$ in this paper is assumed to be an algebraically closed field. Nevertheless, we choose the coefficients of the linear equations defining the subspaces in $H$ so that they live in either $\mathbb{Q}$ (if $\text{char}(\mathbb{F}) = 0$) or a finite extension of $\mathbb{F}_p$ (if $\text{char}(\mathbb{F}) = p > 0$). Moreover, when $\text{char}(\mathbb{F}) = 0$, the bit-length of the numerators and denominators of these coefficients are bounded by $|H|^{O(1)}$. And when $\text{char}(\mathbb{F}) = p > 0$, the finite field that contains these coefficients has size $\max\{|H|^{O(1)}, p\}$. This can be readily checked from our construction. Similar properties hold for all constructions presented in this paper.
Lower bound. As a complement of the above result, we establish the following lower bound for projective $k$-subspace families. It implies that when $n - k = \Omega(1)$, the assumption of $d$ being bounded is necessary for a projective $(n,d)$-evasive $k$-subspace family to have polynomial size.

**Theorem 7.** Let $n,d \in \mathbb{N}^+$ and $k \in \{0, 1, \ldots, n-1\}$. Let $\mathcal{F}$ be the family of equidimensional projective subvarieties of $\mathbb{P}^n$ of dimension $n - k - 1$ and degree at most $d$. Suppose $\mathcal{H}$ is an $\mathcal{F}$-evasive $k$-subspace family on $\mathbb{P}^n$. Then

$$|\mathcal{H}| \geq \begin{cases} (n - k)(k + 1) + 1 & \text{if } d = 1, \\ \max \left\{d(n - k)(k + 1) + 1, \binom{d + n - k}{d} + (n - k + 1)k \right\} & \text{if } d > 1. \end{cases}$$

In particular, $|\mathcal{H}|$ is superpolynomial in $n$ when $n - k = \Omega(n)$ and $d = \omega(1)$.

When $d = 1$, the lower bound $|\mathcal{H}| \geq (n - k)(k + 1) + 1$ in Theorem 7 is achieved by known explicit lossless rank condensers [29, 28, 26] (see Subsection 2.2). For general $d$, the lower bound in Theorem 7 is also tight and matched by non-explicit constructions. See Section 4 for a discussion.

Next, we list two applications of our Main Theorem (Theorem 6): derandomizing Noether’s normalization lemma for varieties of bounded degree, and polynomial identity testing for a special family of depth-4 arithmetic circuits.

### 1.2.1 Derandomizing Noether’s Normalization Lemma

**Noether’s normalization lemma**, introduced by Noether [64], is an important result in commutative algebra and algebraic geometry with many applications. For example, it is used in the development of dimension theory and can be used to prove Grothendieck’s generic freeness lemma [23]. It also has applications in computational algebraic geometry, e.g., computing the dimension of a projective variety [36, 35].

The usual geometric formulation of Noether’s normalization lemma states that for any affine variety $V \subseteq \mathbb{A}^n$ of dimension $r$, there exists a surjective finite morphism $\pi : V \to \mathbb{A}^r$. (See Subsection 2.3 for the definition of finite morphisms.) Moreover, $\pi$ may be chosen to be the restriction of a linear map $\mathbb{A}^n \to \mathbb{A}^r$. There is also a related projective or graded version of the lemma, which states that for any projective variety $V$ of dimension $r$, there exists a surjective finite morphism $\pi : V \to \mathbb{P}^r$. A special form of this lemma goes back to Hilbert [48].

In these versions of Noether’s normalization lemma, it can be shown that with high probability, a random linear map yields a valid finite morphism $\pi$, where “random” means the coefficients of the linear map are chosen randomly from a sufficiently large finite set $S \subseteq \mathbb{F}$. It is thus a natural question to derandomize the lemma.

Mulmuley [62] studied a form of Noether’s normalization lemma and proved that derandomizing it is equivalent to a strengthened form of the black-box derandomization of PIT. There, the ambient projective space has exponential dimension and the problem is
constructing a finite morphism \( \pi : V \to \mathbb{P}^k \) with a succinct specification in deterministic polynomial time, where \( k = \text{poly}(\dim(V)) \) and \( V \) is an explicit variety [62]. This problem was later shown to be in PSPACE [31, 38]. The special case for the ring of matrix invariants under simultaneous conjugation was solved in quasipolynomial time by Forbes and Shpilka [30].

We consider Noether’s normalization lemma in its original context and completely derandomize it for projective/affine varieties of bounded degree. The following two theorems summarize our results.

**Theorem 8.** Let \( n, d \in \mathbb{N}^+ \), \( r \in \{0, 1, \ldots, n\} \), and \( \epsilon \in (0, 1) \). There exists an explicit collection \( \mathcal{L} \) of linear maps \( \mathbb{A}^{n+1} \to \mathbb{A}^{r+1} \) of size \( \text{poly}(N(k, d, n), n, 1/\epsilon) \) such that for every subvariety \( V \subseteq \mathbb{P}^n \) of dimension \( r \) and degree at most \( d \), all but at most \( \epsilon \)-fraction of \( \pi \in \mathcal{L} \) induce a surjective finite morphism from \( V \) to \( \mathbb{P}^r \). Moreover, \( \mathcal{L} \) can be computed in time polynomial in \( |\mathcal{L}| \) (and \( \log p \), if \( \text{char}(\mathbb{F}) = p > 0 \)).

**Theorem 9.** Let \( n, d \in \mathbb{N}^+ \) and \( r \in \{0, 1, \ldots, n\} \), and \( \epsilon \in (0, 1) \). There exists an explicit collection \( \mathcal{L} \) of linear maps \( \mathbb{A}^n \to \mathbb{A}^r \) of size \( \text{poly}(N(k, d, n), n, 1/\epsilon) \) such that for every subvariety \( V \subseteq \mathbb{A}^n \) of dimension \( r \) and degree at most \( d \), all but at most \( \epsilon \)-fraction of \( \pi \in \mathcal{L} \) restrict to a surjective finite morphism from \( V \) to \( \mathbb{A}^r \). Moreover, \( \mathcal{L} \) can be computed in time polynomial in \( |\mathcal{L}| \) (and \( \log p \), if \( \text{char}(\mathbb{F}) = p > 0 \)).

Theorem 8 is proved by derandomizing a standard proof of Noether’s normalization lemma that has a geometric flavor [71]. Namely, we consider a projection \( \pi : \mathbb{P}^n \setminus W \to \mathbb{P}^r \) sending \( x \) to \( (\ell_1(x), \ldots, \ell_{r+1}(x)) \), where \( \ell_1, \ldots, \ell_r \) are linear forms and \( W \) is the \((n-r-1)\)-subspace where these linear forms simultaneously vanish. It is known that \( \pi \) restricts to a finite morphism \( V \to \mathbb{P}^r \) iff \( W \cap V = \emptyset \). So the problem reduces to choosing a family of \((n-r-1)\)-subspaces of \( \mathbb{P}^n \) such that most of them are disjoint from \( V \). This is exactly the property satisfied by our explicit variety evasive subspace families.

Theorem 9 is proved similarly. Here \( \mathbb{A}^n \) is viewed as an open subset of \( \mathbb{P}^n \) whose complement is the “hyperplane at infinity” \( H_\infty \). Then we first construct a projection \( \pi : \mathbb{P}^n \setminus W \to \mathbb{P}^r \) such that \( W \) is a subspace of \( H_\infty \) and is disjoint from the projective closure of \( V \). Then restrict \( \pi \) to \( \mathbb{A}^n \). By carefully choosing \( \pi \), we can make sure that the restriction is a linear map \( \mathbb{A}^n \to \mathbb{A}^r \) and is a surjective finite morphism.

**Dimension-preserving morphisms vs. finite morphisms.** Our construction of finite linear morphisms preserve the dimension of a variety of low degree while reducing the dimension of the ambient space. This generalizes the property of lossless rank condensers. However, for the dimension-preserving property, better constructions are known. For example, it follows implicitly from the proof in [18] that most of the linear maps \( \mathbb{A}^n \to \mathbb{A}^1 \) from a lossless rank condenser \( H \subseteq \mathbb{P}^{t \times n} \) already preserve the dimension of a variety \( V \subseteq \mathbb{A}^n \). This was used by Dvir [18] in his explicit constructions of extractors for varieties, which generalize affine extractors [33].

On the other hand, the morphisms we construct are finite morphisms, which are strictly stronger than morphisms that are dimension-preserving. In particular, a finite morphism \( \pi \) always maps a closed set onto a closed set in the Zariski topology. Moreover, the preimage \( \pi^{-1}(p) \) of every point \( p \) in the image of \( \pi \) is a finite set. Neither of these two properties is necessarily satisfied by morphisms that are only dimension-preserving.

---

4 The intuition here is that \( V \) can be locally approximated at a nonsingular point \( p \in V \) by its tangent space at \( p \). So any linear map that preserves the dimension of this tangent space also preserves the dimension of \( V \).
These properties of finite morphisms may be useful in extractor theory or other areas. For example, in Theorem 9, the cardinality of \( \pi^{-1}(p) \) is bounded by the degree of \( \mathcal{V} \) for every \( p \in \pi(\mathcal{V}) \), which translates into a lower bound for the min-entropy of the output of \( \pi \) when the input random source is distributed over the variety \( \mathcal{V} \).

### 1.2.2 Depth-4 Polynomial Identity Testing

Depth-4 arithmetic circuits, also known as \( \Sigma \Pi \Sigma \Pi \) circuits, play a very important role in polynomial identity testing. In a surprising result, Agrawal and Vinay [3] proved that a complete derandomization of black-box PIT for depth-4 circuits implies an \( n^{O(\log n)} \)-time derandomization of PIT for general circuits of poly\((n)\) degree.

Dvir and Shpilka [22] initialized the approach of applying Sylvester–Gallai type theorems in geometry to PIT for depth-3 (\( \Sigma \Pi \Sigma \)) circuits. Extending this approach, Gupta [39] formulated a conjecture of Sylvester–Gallai type and proved that his conjecture implies a complete derandomization of black-box PIT for depth-4 circuits with bounded top fan-in and bottom fan-in (also called \( \Sigma \Pi \Sigma \Pi(k, r) \) circuits, where \( k, r = O(1) \)). In a recent breakthrough (built on [72, 65]), Peleg and Shpilka [66] proved that this conjecture holds for \( k = 3 \) and \( r = 2 \), and used it to give a polynomial-time black-box PIT algorithm for \( \Sigma \Pi \Sigma \Pi(3, 2) \) circuits.

In [39], Gupta divided \( \Sigma \Pi \Sigma \Pi(k, r) \) into two families: those in a certain Sylvester–Gallai configuration and those that are not. His conjecture states that the circuits in the first family always have bounded transcendence degree, depending only on \( k \) and \( r \). If the conjecture is true, then the results in [6, 2] imply a complete derandomization of the black-box PIT for this family. For the second family of circuits, which we call non-SG circuits, he proved that the black-box PIT can also be derandomized completely.

#### Theorem 10 ([39]).
There exists a deterministic black-box PIT algorithm with time complexity \( (dnk)^{\text{poly}(r^2+k)} \) for non-SG \( \Sigma \Pi \Sigma \Pi(k, r) \) circuits of degree at most \( d \) in \( X_1, \ldots, X_n \) over \( \mathbb{F} \). In particular, the algorithm runs in polynomial time when \( k \) and \( r \) are bounded.

Gupta’s proof of Theorem 10 is quite complex and used tools from computational algebraic geometry, including an effective version of Bertini irreducibility theorem [47] and radical membership testing (which in turn depends on effective Nullstellensatz [53, 17]).

We observe that what is needed here is simply an explicit construction of subspaces intersecting certain varieties with (at most) the expected dimension. Plugging in our explicit construction of variety evasive subspace families, we obtain an improved black-box PIT algorithm with a simple proof.

#### Theorem 11.
There exists a deterministic black-box PIT algorithm with time complexity polynomial in \( d \cdot (k(n+1)^{r^2+k}) \cdot (k-1+d) \leq \text{poly}(d^k, n^k, r^2, r^k) \) (and \( \log p \), if \( \text{char}(\mathbb{F}) = p > 0 \)) for non-SG \( \Sigma \Pi \Sigma \Pi(k, r) \) circuits of degree at most \( d \) in \( X_1, \ldots, X_n \) over an algebraically closed field \( \mathbb{F} \).

In particular, Theorem 11 improves the exponent of \( n \) in the time complexity from \( \text{poly}(r^{k^2} + k) \) to \( O(r^k) \), and the exponent of \( d \) from \( \text{poly}(r^{k^2} + k) \) to \( O(k) \). Moreover, our proof is more direct and conceptually simpler than the proof in [39].

#### Remark. In [61], Mukhopadhyay gave a deterministic polynomial-time black-box PIT algorithm for \( \Sigma \Pi \Pi(k, r) \) circuits satisfying a variant of the non-SG assumption. (Its time complexity is similar to the time complexity in Theorem 10.) It appears to us that his assumption in fact implies the non-SG assumption. The main tool used there is the multivariate resultant, which may be related to our approach based on Chow forms (see Subsection 1.3). Indeed, it is known that a multivariate resultant is the Chow form of a Veronese variety [34, Chapter 3, Example 2.4].
1.3 Proof Overview

We present an overview of our proof of Theorem 6 and that of Theorem 7.

Overview of the proof of Theorem 6

In the proof of Theorem 6, we focus on constructing a \( k \)-subspace family on \( \mathbb{P}^n \). The case of \( \mathbb{A}^n \) can be easily derived from it by viewing \( \mathbb{A}^n \) as an open subset of \( \mathbb{P}^n \) and restricting to this subset.

Consider a variety \( V \subseteq \mathbb{P}^n \) of degree at most \( d \). We want to construct a \( k \)-subspace family \( \mathcal{H} \) on \( \mathbb{P}^n \), independent of \( V \), such that all but at most \( \epsilon \)-fraction of \( W \in \mathcal{H} \) evade \( V \). Our key ideas can be summarized as follows.

Reducing to the equidimensional/irreducible case of dimension \( n - k - 1 \). As a first step, we reduce the problem to the special case that \( V \) is an equidimensional (or even irreducible) variety of \( \mathbb{P}^n \) of dimension \( n - k - 1 \), which means every irreducible component of \( V \) has dimension exactly \( n - k - 1 \). This step is explained in Subsection 3.1.

Hitting the Chow form of \( V \). Denote by \( G(k, n) \) the Grassmannian consisting of all \( k \)-subspaces of \( \mathbb{P}^n \). As \( \text{codim}(V) = n - (n - k - 1) > k \), a general \( k \)-subspace \( W \in G(k, n) \) is disjoint from \( V \), but we want to find such \( W \) explicitly.

One remarkable fact in algebraic geometry is that there is a single polynomial \( \tilde{R}_V \) on the Grassmannian \( G(k, n) \) that defines precisely the subset of \( k \)-subspaces that intersect \( V \). This polynomial \( \tilde{R}_V \) is called the Chow form of \( V \) (in Stiefel coordinates). Chow forms are also known as Cayley forms or Cayley–van der Waerden–Chow forms in literature. They were introduced by Cayley [11] to represent curves in \( \mathbb{P}^3 \) and later generalized by Chow and van der Waerden [13]. See [15] for an introduction to Chow forms and [34] for an exposition in the context of elimination theory.

To be more specific, for a \( k \)-subspace \( W \in G(k, n) \), we choose a \( (k + 1) \times (n + 1) \) matrix \( A \) that represents \( W \). The Chow form \( \tilde{R}_V \) is a polynomial of degree \( (k + 1)\deg(V) \) in \( (k + 1)(n + 1) \) variables with the following property: \( \tilde{R}_V \) vanishes at the matrix \( A \) (viewed as a list of \( (k + 1)(n + 1) \) coordinates) if and only if \( V \cap W \neq \emptyset \). Thus, \( \tilde{R}_V \) defines precisely the subset of “bad” \( k \)-subspaces that we want to avoid.

Therefore, the problem becomes finding a collection of \( (k + 1) \times (n + 1) \) matrices of full rank that “hit” the polynomial \( \tilde{R}_V \) of degree \( (k + 1)\deg(V) \leq (k + 1)d \). Using black-box PIT for low degree polynomials (see Subsection 2.1), we are able to construct an \((n, d, \epsilon)\)-evasive \( k \)-subspace family of size polynomial in \( \binom{(k+1)(n+1+d)}{(k+1)d} \) and \( 1/\epsilon \), which is \( \text{poly}(n, 1/\epsilon) \) when \( k \) and \( d \) are both bounded. A similar “dual” construction yields a \( k \)-subspace family of size polynomial in \( \binom{(n-k)(n+1+d)}{(n-k)d} \) and \( 1/\epsilon \), which is \( \text{poly}(n, 1/\epsilon) \) when both \( n - k \) and \( d \) are bounded. For applications where \( d \) is small and either \( k \) or \( n - k \) is small (e.g., Theorem 11), these constructions are good enough. However, when \( k \) and \( n - k \) are both linear in \( n \), the resulting \( k \)-subspace families have exponential size in \( n \), even if \( d \) is bounded.

A two-step construction. To obtain a good construction for arbitrary dimension \( k \), we use a standard fact from algebraic geometry, which states that the codimension of an irreducible subvariety \( V \subseteq \mathbb{P}^n \) in \( \text{span}(V) \) is at most \( \deg(V) - 1 \), where \( \text{span}(V) \) denotes the smallest projective subspace containing \( V \) (see Lemma 32). Therefore, for irreducible \( V \) of degree at most \( d \), there exists a projective subspace \( \Lambda \) of dimension (at most) \( \dim(V) + d - 1 \) that contains \( V \).
Our idea is to use a two-step construction. Namely, we first construct subspaces of dimension \( n - \dim \Lambda - 1 \) that evade \( \Delta \), and then extend these subspaces to \( k \)-subspaces that evade \( \mathcal{V} \). The first step is just the problem of constructing lossless rank condensers, which has an optimal solution [29, 28] (see Subsection 2.2). The second step is equivalent to extending a \( ((k + 1) - (d - 1)) \times (n + 1) \) matrix \( B \) to a \( (k + 1) \times (n + 1) \) matrix \( (a) \) such that the polynomial \( \tilde{R}_V \) does not vanish at \( (a) \). The polynomial \( \tilde{R}_V((a)) \) has degree \( (d - 1) \deg(V) \leq (d - 1)d \), as there are only \( d - 1 \) rows of free variables. Using black-box PIT for low degree polynomials, we obtain a construction of size polynomial in \( \binom{(d-1)(n+1+d)}{(d-1)d} \) and \( 1/\epsilon \), which is poly\((n, 1/\epsilon)\) for any bounded \( d \).

**Overview of the proof of Theorem 7**

Our lower bound (Theorem 7) follows from a dimension counting argument. Let \( C(r, d, n) \) be the set of all varieties \( \mathcal{V} \subseteq \mathbb{P}^n \) of dimension \( r := n - k - 1 \) and degree \( d \), which is the space of varieties that we want to evade.

Roughly speaking, the idea is to show that (1) \( C(r, d, n) \) itself can be realized as a subvariety of some projective space \( \mathbb{P}^N \), and (2) for every \( k \)-subspace \( W \), the subset of \( \mathcal{V} \subseteq C(r, d, n) \) that \( W \) fails to evade is the intersection of \( C(r, d, n) \) with some hyperplane \( H_W \) of \( \mathbb{P}^N \).

To see how (1) and (2) above lead to a lower bound, suppose \( \mathcal{H} \) is a \( C(r, d, n) \)-evasive \( k \)-subspace family, i.e., for any \( \mathcal{V} \subseteq C(r, d, n) \), there exists \( W \in \mathcal{H} \) that is disjoint from \( \mathcal{V} \). Then the intersection \( C(r, d, n) \cap \bigcap_{W \in H} H_W \) must be empty. On the other hand, taking the intersection with each hyperplane \( H_W \) reduces the dimension of a projective variety by at most one. So we have a lower bound \( |\mathcal{H}| \geq \dim(C(r, d, n)) + 1 \).

How do we realize \( C(r, d, n) \) as a subvariety of \( \mathbb{P}^N \)? It turns out that this is a classical problem in the study of moduli spaces and a solution was given by Cayley [11] and Chow–van der Waerden [13] using the Chow embedding: The Chow embedding \( C(r, d, n) \to \mathbb{P}^N \) simply sends a variety \( \mathcal{V} \) to its Chow form \( \tilde{R}_V \), where \( \tilde{R}_V \) is viewed as a point in the projective space \( \mathbb{P}^N \) whose homogeneous coordinates are given by the coefficients of \( \tilde{R}_V \).

A technical issue here is that the image of \( C(r, d, n) \) under the Chow embedding is generally not closed in the Zariski topology. To fix this issue, the definition of \( C(r, d, n) \) needs to be modified so that it contains not only subvarieties of \( \mathbb{P}^n \), but also (effective) algebraic cycles on \( \mathbb{P}^n \), which are a generalization of subvarieties. A theorem of Chow and van der Waerden [13] then states that the Chow embedding does embed \( C(r, d, n) \) in a projective subspace \( \mathbb{P}^N \) as a subvariety, known as a Chow variety.

Finally, we also need a lower bound for the dimension of the Chow variety \( C(r, d, n) \). In fact, the exact value of \( \dim(C(r, d, n)) \) was determined by Azcué [5] and independently by Lehmann [59]. Plugging in the value of \( \dim(C(r, d, n)) \) proves Theorem 7.

### 1.4 Other Related Work

In [20], Dvir, and Kollár, and Lovett constructed explicit variety evasive sets, which are large subsets of \( \mathbb{F}_q^n \) over a finite field \( \mathbb{F}_q \) that have small intersection with affine varieties of fixed dimension and bounded degree. It generalizes an earlier construction of subspace evasive sets of Dvir and Lovett [21]. The definition of evasiveness there is different from ours, but they are related, since a key step in the proofs of [21, 20] is proving the intersection of two

---

5 The actual Chow embedding we use has a slightly different form, which is essentially equivalent to the one described here.
varieties has dimension zero. We also note that a subspace/variety evasive set is a single set, defined in a highly nonlinear way, whereas we define a variety evasive subspace family to be a collection of projective or affine subspaces. Finally, the results in [21, 20] hold only for affine subspaces/subvarieties, whereas we give our construction first in the projective setting and then derive the affine counterpart from it.

Guruswami and Xing in [43] introduced a related notion called subspace designs. A subspace design is a collection \( H \) of large subspaces of \( \mathbb{F}^n \) such that for any small subspace \( V \subseteq \mathbb{F}^n \), the number of \( W \in H \) satisfying \( \dim(W \cap V) > 0 \) is small (or even the sum \( \sum_{W \in H} \dim(W \cap V) \) is small). An equivalence between subspace designs and lossless rank condensers was proved in [27]. Explicit subspace designs were constructed by Guruswami and Kopparty [40] and also by Guruswami, Xing, and Yuan [44]. They have applications to constructing explicit list-decodable codes with small list size [43, 42, 55, 37] and explicit dimension expanders [27, 41]. Subspace designs were also used to prove lower bounds in communication complexity [12].

Jeronimo, Krick, Sabia, and Sombra [49] gave a randomized algorithm, in the Blum-Shub-Smale model over fields of characteristic zero, that computes the Chow forms of varieties defined by input polynomials. The (expected) time complexity of their algorithm is polynomial in the sizes of the arithmetic circuits encoding the input polynomials and the geometric degree of the polynomial system. See also the survey by Krick [56].

Chow varieties of effective zero-cycles and their higher secant varieties are related to lower bounds for depth-3 arithmetic circuits. They have received a considerable amount of attention in Geometric Complexity Theory [57, 58].

**Organization of the paper.** Preliminaries and notations are given in Section 2. We prove the Main Theorem (Theorem 6) in Section 3. The lower bound (Theorem 7) is proved in Section 4. The applications to the derandomization of Noether’s normalization lemma and PIT for depth-4 circuits are explained in Section 5. Finally, we list some open problems and future directions in Section 6.

2 Preliminaries and Notations

Define \( \mathbb{N} := \{0, 1, 2, \ldots\} \) and \( \mathbb{N}^+ := \{1, 2, \ldots\} \). Let \( [n] := \{1, 2, \ldots, n\} \) for \( n \in \mathbb{N} \). For a set \( S \) and \( k \in \mathbb{N} \), denote by \( \binom{S}{k} \) the set of all subsets of \( S \) of cardinality \( k \).

Denote by \( \mathbb{F} \) an algebraically closed field throughout this paper. We use notations like \( \mathbb{F}[X_{i,j} : i \in [n], j \in [m]] \) to denote the polynomial ring over \( \mathbb{F} \) in a finite set of variables (in this case, in the set of variables \( \{X_{i,j} : i \in [n], j \in [m]\} \)). The vector space of \( n \times m \) matrices over \( \mathbb{F} \) is denoted by \( \mathbb{F}^{n \times m} \).

For an \( n \times m \) matrix \( A \) and subsets \( S \subseteq [n], T \subseteq [m] \), denote by \( A_{S,T} \) the submatrix of \( A \) whose rows and columns are selected by \( S \) and \( T \) respectively, where the orderings of rows and columns are preserved.

2.1 Black-Box PIT for Low Degree Polynomials

For convenience, we strengthen the definition of hitting sets as follows.

▶ **Definition 12** (\( \epsilon \)-hitting set). Let \( \mathcal{F} \) be a family of polynomials in \( \mathbb{F}[X_1, \ldots, X_n] \) and \( \epsilon \in (0, 1) \). We say a finite collections of points \( \mathcal{H} \subseteq \mathbb{F}^n \) is an \( \epsilon \)-hitting set for \( \mathcal{F} \) if for any nonzero \( Q \in \mathcal{F} \), the evaluation \( Q(\alpha) \) is nonzero for all but at most \( \epsilon \)-fraction of \( \alpha \in \mathcal{H} \).
We need an explicit construction of $c$-hitting sets for low degree polynomials. This problem has been well studied [16, 74, 70, 52, 8, 60, 14, 10, 7]. For completeness, we present a construction based on sparse polynomial identity testing.

Recall that a polynomial is $s$-sparse if it has at most $s$ monomials. We need the following lemma from [1].

Lemma 13 ([1, Lemma 4, restated]). For $n, s, d \in \mathbb{N}^+$ and $\epsilon_0 \in (0, 1)$, there exist maps $w_1, w_2, \ldots, w_N : [n] \rightarrow [N \log N]$, where $N = \text{poly}(n, s, \log d, \epsilon_0^{-1})$, such that for any nonzero $s$-sparse polynomial $f \in \mathbb{F}[X_1, \ldots, X_n]$ of individual degree at most $d$, all but at most $\epsilon_0$-fraction of $w_i$ among $w_1, w_2, \ldots, w_N$ satisfies $f(w_i^{w_1(1)}, \ldots, w_i^{w_n(n)}) \neq 0$. Moreover, the time complexity of computing $w_1, w_2, \ldots, w_N$ is polynomial in $N$.

Given $n, d \in \mathbb{N}^+$ and $\epsilon \in (0, 1)$, we construct an $\epsilon$-hitting set for $n$-variate polynomials of degree at most $d$ as follows:

1. Let $s = \left(\binom{n+d}{d}\right)$, $\epsilon_0 = \epsilon/2$, and $M = \lceil \epsilon^{-1}dN \log N \rceil$, where $N$ is as in Lemma 13.
2. Let $w_1, \ldots, w_N$ be as in Lemma 13, which can be computed in time $\text{poly}(N)$.
3. If $\text{char}(\mathbb{F}) = 0$, let $S = [M] \subseteq \mathbb{Z} \subseteq \mathbb{F}$. If $\text{char}(\mathbb{F}) = p > 0$, choose a finite extension $\mathbb{F}_p$ of $\mathbb{F}$ such that $M \leq q = \text{poly}(M, p)$, and choose $S$ to be a subset of $\mathbb{F}_p \subseteq \mathbb{F}$ of cardinality $M$.
4. Finally, construct the following collection of points in $\mathbb{F}^n$ of size $MN$

$$T = \{(\alpha^{w_i(1)}, \ldots, \alpha^{w_i(n)}) : \alpha \in S, i \in [N]\} \subseteq \mathbb{F}^n.$$  

Lemma 14. For any nonzero polynomial $f \in \mathbb{F}[X_1, \ldots, X_n]$ of degree at most $d$, we have $f(u) \neq 0$ for all but at most $\epsilon$-fraction of $u \in T$. The collection $T$ has cardinality $\text{poly} \left(\left(\binom{n+d}{d}\right), 1/\epsilon\right)$ and can be computed in time $\text{poly}(|T|)$.

Proof. Let $f \in \mathbb{F}[X_1, \ldots, X_n]$ be a nonzero polynomial of degree at most $d$. Note that $f$ is trivially $s$-sparse, where $s = \left(\binom{n+d}{d}\right)$. So by Lemma 13, for all but at most $\epsilon_0$-fraction of $i \in [N]$, we have $\tilde{f}_i := f(Y_i^{w_i(1)}, \ldots, Y_i^{w_i(n)}) \neq 0$. Consider $i \in [N]$ such that $\tilde{f}_i \neq 0$. Note that $\tilde{f}_i$ is a univariate polynomial of degree at most $\lceil dN \log N \rceil$. So it has at most $dN \log N \leq \epsilon_0M$ zeros. Therefore, by the choice of $M$, we have $f(\alpha^{w_i(1)}, \ldots, \alpha^{w_i(n)}) = \tilde{f}_i(\alpha) \neq 0$ for all but at most $\epsilon_0$-fraction of $\alpha \in S$. It follows that $f(u) \neq 0$ holds for all but at most $\epsilon$-fraction of $u \in T$, as claimed. The rest of the lemma follows easily from the construction.

Note that the seed length required to choose a random element in $T$ is $\log |T| = O(\log \left(\binom{n+d}{d}\right) + \log(1/\epsilon))$, which is optimal up to a constant factor. We have made no effort to optimize the constant hidden in $O(\cdot)$. Interested readers may find the state-of-the-art result in [7], which achieves the optimal constant, at least for $d = o(n)$.

2.2 Explicit Lossless Rank Condensers

We need the following lemma in the context of lossless rank condensers. The construction in the lemma was given by Forbes and Shpilka [29] and the lemma itself follows implicitly from the analysis of Forbes, Saptharishi, and Shpilka in [28]. It was also stated explicitly in [26, Theorem 5.4.3].

Lemma 15 ([28, 26]). Let $n \in \mathbb{N}^+$ and $r \in [n]$. Let $\omega \in \mathbb{F}^\times$ such that the multiplicative order of $\omega$ is at least $n$. Define the $r \times n$ matrix $W = (w_{i,j})_{i \in [r], j \in [n]}$ over $\mathbb{F}[X]$ by

$$w_{i,j} = (\omega^{i-1}X)^{j-1}.$$  

Then for every $r \times r$ matrix $M$ over $\mathbb{F}$ of rank $r$, the polynomial $\det(WM) \in \mathbb{F}[X]$ is nonzero and has degree at most $r(n-r)$ after dividing out powers of $X$. 

CCC 2021
20:12 Variety Evasive Subspace Families

**Corollary 16.** Let $n,r,W$ be as in Lemma 15 and $\epsilon \in (0,1)$. Let $S \subseteq \mathbb{F}^n$ be a finite set of cardinality at least $r(n-r)/\epsilon$. For every $n \times r$ matrix $M$ over $\mathbb{F}$ of rank $r$, we have rank$(W(\alpha)M) = r$ for all but at most $\epsilon$-fraction of $\alpha \in S$, where $W(\alpha)$ denotes the matrix $(w_{i,j}(\alpha))_{i \in [r], j \in [n]}$ over $\mathbb{F}$.

Corollary 16 states that the collection $\{W(\alpha) : \alpha \in S\}$ of matrices is a (weak) $(r,\epsilon|S|)$-lossless rank condenser, as defined in [27]. Note that for each $\alpha \in S$, we have rank$(W(\alpha)) = r$ and hence $W(\alpha)$ correspond to an $(r-1)$-subspace $U_{W(\alpha)}$ of $\mathbb{F}^{n-1}$. As explained in the introduction, the collection $H = \{U_{W(\alpha)} : \alpha \in S\}$ is an $(F,\epsilon)$-evasive $(r-1)$-subspace family on $\mathbb{P}^{n-1}$, where $F$ is the family of $(n-r-1)$-subspaces of $\mathbb{P}^{n-1}$. Choosing $S$ of size $r(n-r)+1$ and $\epsilon = \frac{1}{r(n-r)+1}$ shows that the lower bound in Theorem 7 is achieved when $d = 1$.

2.3 Preliminaries on Algebraic Geometry

We list basic preliminaries and notations on algebraic geometry used in this paper. One can also refer to a standard text, e.g., [71, 45].

**Affine and projective spaces.** For $n \in \mathbb{N}$, write $\mathbb{A}^n$ for the affine $n$-space over $\mathbb{F}$. It is defined to be the set $\mathbb{F}^n$ equipped with the Zariski topology, defined as follows: A subset $S \subseteq \mathbb{A}^n$ is (Zariski-)closed if it is the set of common zeros of a set of polynomials in $\mathbb{F}[X_1, \ldots, X_n]$. The complement of a closed set is an open set. The origin of an affine space is denoted by $0$.

Write $\mathbb{P}^n$ for the (projective) $n$-space over $\mathbb{F}$, defined to be the quotient set $(\mathbb{A}^{n+1} \setminus \{0\})/\sim$, where $\sim$ is the equivalence relation defined by scaling, i.e., $u \sim v$ if $u = cv$ for some $c \in \mathbb{F}^\times$. The set $\mathbb{P}^n$ is again equipped with the Zariski topology, where a subset is closed if it is the set of common zeros of a set of homogeneous polynomials in $\mathbb{F}[X_1, \ldots, X_{n+1}]$. We use $(n+1)$-tuples $(x_1, \ldots, x_{n+1})$ to represent points in $\mathbb{P}^n$, called homogeneous coordinates.

For a vector space $V$ over $\mathbb{F}$ of dimension $n+1$, where $n \in \mathbb{N}$, define the projective space $\mathbb{P}V = (V \setminus \{0\})/\sim$, where $\sim$ is again the equivalence relation defined by scaling. By fixing a coordinate system of $V$ and identifying it with $\mathbb{A}^{n+1}$, we may identify $\mathbb{P}V$ with $\mathbb{P}^n$.

**Varieties.** Varieties in this paper refer to either projective or affine varieties. A projective (resp. affine) variety is simply a closed subset of a projective (resp. affine) subspace. If $\mathcal{V}_1$ and $\mathcal{V}_2$ are closed subsets of a projective or affine space and $\mathcal{V}_1 \subseteq \mathcal{V}_2$, we say $\mathcal{V}_1$ is a subvariety of $\mathcal{V}_2$.

A variety is reducible if it is the union of finitely many proper subvarieties, and otherwise irreducible. Affine and projective spaces are irreducible. A variety $\mathcal{V}$ can be uniquely written as the union of finitely many irreducible varieties, which are called the irreducible components of $\mathcal{V}$.

A projective or affine variety is called a hypersurface (resp. hyperplane) if it is definable by a single polynomial (resp. single linear polynomial).

**Hilbert’s Nullstellensatz.** An ideal $I$ of a commutative ring $R$ is radical if $a^m \in I$ implies $a \in I$ for every $a \in R$ and $m \in \mathbb{N}^+$. For an ideal $I$ of $\mathbb{F}[X_1, \ldots, X_n]$, denote by $\mathcal{V}(I)$ the subvariety of $\mathbb{A}^n$ defined by the polynomial in $I$. Define $\mathcal{V}(f_1, \ldots, f_k) = \mathcal{V}(\langle f_1, \ldots, f_k \rangle)$ for $f_1, \ldots, f_k \in \mathbb{F}[X_1, \ldots, X_n]$. For a subvariety $\mathcal{V}$ of $\mathbb{A}^n$, denote by $I(\mathcal{V})$ the ideal of $\mathbb{F}[X_1, \ldots, X_n]$ consisting of all the polynomials vanishing on $\mathcal{V}$. **Hilbert’s Nullstellensatz** states that the map $\mathcal{V} \mapsto I(\mathcal{V})$ is an inclusion-reversing one-to-one correspondence between the subvarieties of $\mathbb{A}^n$ and the radical ideals of $\mathbb{F}[X_1, \ldots, X_n]$, with the inverse map $I \mapsto \mathcal{V}(I)$.  

For a subvariety \( V \) of \( \mathbb{A}^n \), define \( \mathbb{F}[V] := \mathbb{F}[X_1, \ldots, X_n]/I(V) \), called the \textit{coordinate ring} of \( V \).

**Projective Nullstellensatz.** Consider the polynomial ring \( R = \mathbb{F}[X_1, \ldots, X_{n+1}] \). It can be written as a direct sum \( R = \bigoplus_{d=0}^{\infty} R_d \) where each \( R_d \) denotes the space of degree-\( d \) homogeneous polynomials, called the \textit{homogeneous part} of degree \( d \) of \( R \) or simply the degree-\( d \) part of \( R \). For an ideal \( I \) of \( R \) and \( d \in \mathbb{N} \), let \( I_d := I \cap R_d \), called the degree-\( d \) part of \( I \). We say \( I \) is a \textit{homogeneous ideal} if \( I = \bigoplus_{d=0}^{\infty} I_d \). For a homogeneous ideal \( I \) of \( R \), we have \( R/I = \bigoplus_{d=0}^{\infty}(R/I_d) \) where \( (R/I)_d := R_d/I_d \).

For a homogeneous ideal \( I \) of \( R \), denote by \( \mathcal{V}(I) \) the subvariety of \( \mathbb{P}^n \) defined by the homogeneous polynomials in \( I \). Define \( \mathcal{V}(f_1, \ldots, f_k) = \mathcal{V}((f_1, \ldots, f_k)) \) for homogeneous polynomials \( f_1, \ldots, f_k \in R \). For a subvariety \( V \) of \( \mathbb{P}^n \), denote by \( I(V) \) the ideal generated by the homogeneous polynomials vanishing on \( V \), which is a homogeneous ideal. The \textit{projective Nullstellensatz} states that the map \( \mathcal{V} \rightarrow I(V) \) is an inclusion-reversing one-to-one correspondence between the nonempty subvarieties of \( \mathbb{P}^n \) and the radical homogeneous ideals of \( R \) properly contained in \( \langle X_1, \ldots, X_{n+1} \rangle \), with the inverse map \( I \rightarrow \mathcal{V}(I) \).

For a subvariety \( V \subseteq \mathbb{P}^n \) and the corresponding homogeneous ideal \( I = I(V) \), we say \( R/I \) is the \textit{homogeneous coordinate ring} of \( V \).

**Morphisms.** Let \( V_1 \subseteq \mathbb{A}^n \) and \( V_2 \subseteq \mathbb{A}^m \) be affine varieties. A \textit{morphism} from \( V_1 \) to \( V_2 \) is a map \( f : V_1 \rightarrow V_2 \) that is a restriction of a polynomial map \( \mathbb{A}^n \rightarrow \mathbb{A}^m \). Such a morphism \( f \) is associated with a ring homomorphism \( f^* : \mathbb{F}[V_2] \rightarrow \mathbb{F}[V_1] \), making \( \mathbb{F}[V_1] \) an algebra over \( \mathbb{F}[V_2] \). We say \( f \) is finite if \( \mathbb{F}[V_1] \) is finitely generated as an \( \mathbb{F}[V_2] \)-module.

Let \( f : V_1 \rightarrow V_2 \) be a map between projective varieties \( V_1 \) and \( V_2 \). We say \( f \) is a morphism from \( V_1 \) to \( V_2 \) if there exists a collection of open subsets \( \{U_i \}_{i \in I} \) of \( V_2 \) such that \( V_2 = \bigcup_{i \in I} U_i \) (i.e., \( \{U_i \}_{i \in I} \) is an open cover of \( V_2 \)) and for each \( i \in I \), the restriction \( f|_{f^{-1}(U_i)} : f^{-1}(U_i) \rightarrow U_i \) is a morphism between affine varieties. Furthermore, if each \( f|_{f^{-1}(U_i)} \) is finite, then we say \( f \) is finite. Finiteness does not depend on the choice of the affine open cover. Namely, if \( f : V_1 \rightarrow V_2 \) is a finite morphism between projective varieties \( V_1 \) and \( V_2 \), and \( U \) is an open subset of \( V_2 \) such that \( f|_{f^{-1}(U)} : f^{-1}(U) \rightarrow U \) is a morphism between affine varieties, then \( f|_{f^{-1}(U)} \) is also finite.

The image of a morphism \( f : V_1 \rightarrow V_2 \) is denoted by \( \text{Im}(f) \) or \( f(V_1) \). The image of a closed set under a finite morphism is still closed.

**Dimension.** The \textit{dimension} of an irreducible variety \( V \), denoted by \( \dim(V) \), is the largest integer \( m \) such that there exists a chain of irreducible varieties \( \emptyset \subsetneq V_0 \subsetneq V_1 \subsetneq \cdots \subsetneq V_m = V \). More generally, the dimension of a nonempty variety is the maximal dimension of its irreducible components. We define the dimension of an empty set to be \( -\infty \). A variety is \textit{equidimensional} if its irreducible components have the same dimension.

If \( \pi : V \rightarrow V' \) is a finite morphism, then \( \dim(V) = \dim(\pi(V)) \).

**Degree.** The \textit{degree} of an irreducible subvariety \( V \) of \( \mathbb{P}^n \) (resp. \( \mathbb{A}^n \)), denoted by \( \deg(V) \), is the number of intersections of \( V \) with a projective (resp. affine) subspace of codimension \( \dim(V) \) in general position. More generally, we define the degree of a subvariety of \( \mathbb{P}^n \) or \( \mathbb{A}^n \) to be the sum of the degrees of its irreducible components.
Variety Evasive Subspace Families

Projective closure. The affine $n$-space $A^n$ may be regarded as an open subset of $P^n$ via the map $(x_1, …, x_n) \mapsto (x_1, …, x_n, 1)$. The complement $H_\infty := P^n \setminus A^n$ is a hyperplane of $P^n$ defined by $X_{n+1} = 0$, called the hyperplane at infinity. For an affine subvariety $V$ of $A^n \subseteq P^n$, the smallest projective subvariety of $P^n$ containing $V$ is the projective closure of $V$, which we denote by $V_{cl}$. It is known that $V_{cl} \cap A^n = V$, $\dim(V_{cl}) = \dim(V)$, and $\deg(V_{cl}) = \deg(V)$.

Joins of disjoint projective varieties. For two distinct points $p, q \in P^n$, denote by $\overline{pq}$ the unique projective line passing through them. For two disjoint projective subvarieties $V_1, V_2 \subseteq P^n$, define the join $J(V_1, V_2)$ of $V_1$ and $V_2$ as

$J(V_1, V_2) := \bigcup_{p \in V_1, q \in V_2} \overline{pq}$.

▶ Lemma 17 ([45, Examples 6.17, 11.36, and 18.17]). $J(V_1, V_2)$ is a subvariety of $P^n$ of dimension $\dim(V_1) + \dim(V_2) + 1$ and degree at most $\deg(V_1) \cdot \deg(V_2)$.

We also need the following lemmas.

▶ Lemma 18. Let $V$ be a nonempty subvariety of $P^n$ of dimension $r < n$. Let $W \subseteq P^n$ be a $k$-subspace disjoint from $V$. Let $k'$ be an integer satisfying $k \leq k' \leq n - r - 1$. Then there exists a $k'$-subspace $W' \subseteq P^n$ such that $W \subseteq W'$ and $W'$ is disjoint from $V$. In particular, choosing $W$ to be a point not in $V$ shows that there exists an $(n - r - 1)$-subspace disjoint from $V$.

Proof. We prove the lemma for the special case $k' = k + 1 \leq n - r - 1$ and the general case follows from iteration. By Lemma 17, $J(V, W)$ has dimension $r + k + 1 \leq n - 1$. Pick a point $p \in P^n \setminus J(V, W)$ and let $W' = J(p, W)$. Then $W'$ is a $(k + 1)$-subspace and $W \subseteq W'$. To prove $W'$ is disjoint from $V$, assume to the contrary that there exists a point $q \in W' \cap V$. By definition, $q \in \overline{pq}'$ for some $q' \in W$. As $W$ is disjoint from $V$, we have $q' \neq q$. Then $p \in \overline{pq'} = \overline{qq'} \in J(V, W)$, contradicting the choice of $p$.

▶ Lemma 19 ([45, Exercise 11.6 and Corollary 18.5]). Let $V$ be a nonempty equidimensional subvariety of $P^n$ and $H$ a hypersurface of $P^n$ not containing an irreducible component of $V$. Then $V \cap H$ is an equidimensional subvariety of dimension $\dim(V) - 1$ and degree at most $\deg(V) \cdot \deg(H)$ (or an empty set if $\dim(V) = 0$).

▶ Lemma 20 ([71, Section I.6.2, Theorem 6]). Suppose $V_1$ and $V_2$ are subvarieties of $P^n$ and $\dim(V_1) + \dim(V_2) \geq n$. Then $V_1 \cap V_2 \neq \emptyset$ and $\dim(V_1 \cap V_2) \geq \dim(V_1) + \dim(V_2) - n$.

3 Proof of the Main Theorem
