Explaining Behavioural Inequivalence Generically in Quasilinear Time

Stefan Milius Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany
Lutz Schröder Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

Abstract

We provide a generic algorithm for constructing formulae that distinguish behaviourally inequivalent states in systems of various transition types such as nondeterministic, probabilistic or weighted; genericity over the transition type is achieved by working with coalgebras for a set functor in the paradigm of universal coalgebra. For every behavioural equivalence class in a given system, we construct a formula which holds precisely at the states in that class. The algorithm instantiates to deterministic finite automata, transition systems, labelled Markov chains, and systems of many other types. The ambient logic is a modal logic featuring modalities that are generically extracted from the functor; these modalities can be systematically translated into custom sets of modalities in a postprocessing step. The new algorithm builds on an existing coalgebraic partition refinement algorithm. It runs in time $O((m + n) \log n)$ on systems with $n$ states and $m$ transitions, and the same asymptotic bound applies to the dag size of the formulae it constructs. This improves the bounds on run time and formula size compared to previous algorithms even for previously known specific instances, viz. transition systems and Markov chains; in particular, the best previous bound for transition systems was $O(mn)$.

1 Introduction

For finite transition systems, the Hennessy-Milner theorem guarantees that two states are bisimilar if and only if they satisfy the same modal formulae. This implies that whenever two states are not bisimilar, then one can find a modal formula that holds at one of the states but not at the other. Such a formula explains the difference of the two states’ behaviour and is thus usually called a distinguishing formula [13]. For example, in the transition system in Figure 1, the formula $\Box \top$ distinguishes the states $x$ and $y$ because $x$ satisfies $\Box \top$ whereas $y$ does not. Given two states in a finite transition system with $n$ states and $m$ transitions, the algorithm by Cleaveland [13] computes a distinguishing formula in time $O(mn)$. The algorithm builds on the Kanellakis-Smolka partition refinement algorithm [28, 29], which computes the bisimilarity relation on a transition system within the same time bound.
Similar logical characterizations of bisimulation exist for other system types. For instance, Desharnais et al. [16,17] characterize probabilistic bisimulation on (labelled) Markov chains, in the sense of Larsen and Skou [33] (for each label, every state has either no successors or a probability distribution on successors). In their logic, a formula $\Diamond > p \phi$ holds at states that have a transition probability of at least $p$ to states satisfying $\phi$. For example, the state $x$ in Figure 2 satisfies $\Diamond > 0.5 \Diamond \top$ but $y$ does not. Desharnais et al. provide an algorithm that computes distinguishing formulae for labelled Markov chains in run time (roughly) $O(n^4)$.

In the present work, we construct such counterexamples generically for a variety of system types. We achieve genericity over the system type by modelling state-based systems as coalgebras for a set functor in the framework of universal coalgebra [40]. Examples of coalgebras for a set functor include transition systems, deterministic automata, or weighted systems (e.g. Markov chains). Universal coalgebra provides a generic notion of behavioural equivalence that instantiates to standard notions for concrete system types, e.g. bisimilarity (transition systems), language equivalence (deterministic automata), or probabilistic bisimilarity (Markov chains). Moreover, coalgebras come equipped with a generic notion of modal logic that is parametric in a choice of modalities whose semantics is constructed so as to guarantee invariance w.r.t. behavioural equivalence; under easily checked conditions, such a coalgebraic modal logic in fact characterizes behavioural equivalence in the same sense as Hennessy-Milner logic characterizes bisimilarity [39,42]. Hence, as soon as suitable modal operators are found, coalgebraic modal formulae serve as distinguishing formulae.

In a nutshell, the contribution of the present paper is an algorithm that computes distinguishing formulae for behaviourally inequivalent states in \textit{quasilinear time}, and in fact \textit{certificates} that uniquely describe behavioural equivalence classes in a system, in coalgebraic generality. We build on an existing efficient coalgebraic partition refinement algorithm [46], thus achieving run time $O(m \log n)$ on coalgebras with $n$ states and $m$ transitions (in a suitable encoding). The dag size of formulae is also $O(m \log n)$ (for tree size, exponential lower bounds are known [22]); even for labelled transition systems, we thus improve the previous best bound $O(mn)$ [13] for both run time and formula size. We systematically extract the requisite modalities from the functor at hand, requiring binary and nullary modalities in the general case, and then give a systematic method to translate these generic modal operators into more customary ones (such as the standard operators of Hennessy-Milner logic).

We subsequently identify a notion of \textit{cancellative} functor that allows for additional optimization. E.g. functors modelling weighted systems are cancellative if and only if the weights come from a cancellative monoid, such as $\langle \mathbb{Z}, + \rangle$, or $\langle \mathbb{R}, + \rangle$ as used in probabilistic systems. For cancellative functors, much simpler distinguishing formulae can be constructed: the binary modalities can be replaced by unary ones, and only conjunction is needed in the propositional base. On labelled Markov chains, this complements the result that a logic with only conjunction and different unary modalities (mentioned above) suffices for the construction of distinguishing formulae (but not certificates) [17] (see also [19]).

\textbf{Related Work.} Cleaveland’s algorithm [13] for labelled transition systems is is based on Kanellakis and Smolka’s partition refinement algorithm [29]. The coalgebraic partition refinement algorithm we employ [46] is instead related to the more efficient Paige-Tarjan algorithm [36]. König et al. [32] extract formulae from winning strategies in a bisimulation game in coalgebraic generality; their algorithm runs in $O(n^2)$ and does not support negative
transition weights. Characteristic formulae for behavioural equivalence classes taken across all models require the use of fixpoint logics [21]. The mentioned algorithm by Desharnais et al. for distinguishing formulae on labelled Markov processes [17, Fig. 4] is based on Cleaveland’s. No complexity analysis is made but the algorithm has four nested loops, so its run time is roughly $O(n^4)$. Bernardo and Miculan [10] provide a similar algorithm for a logic with only disjunction. There are further generalizations along other axes, e.g. to behavioural preorders [12]. The TwoTowers tool set for the analysis of stochastic process algebras [8, 9] computes distinguishing formulae for inequivalent processes, using variants of Cleaveland’s algorithm. Some approaches construct alternative forms of certificates for inequivalence, such as Cranen et al.’s notion of evidence [14] or methods employed on business process models, based on model differences and event structures [5, 6, 18].

2 Preliminaries

We first recall some basic notation. We denote by $0 = \emptyset$, $1 = \{0\}$, $2 = \{0, 1\}$ and $3 = \{0, 1, 2\}$ the sets representing the natural numbers $0, 1, 2$ and $3$. For every set $X$, there is a unique map $!: X \to 1$. We write $X^Y$ for the set of functions $X \to Y$, so e.g. $X^2 \cong X \times X$. In particular, $2^X$ is the set of 2-valued predicates on $X$, which is in bijection with the powerset $\mathcal{P}X$ of $X$, i.e. the set of all subsets of $X$; in this bijection, a subset $A \in \mathcal{P}X$ corresponds to its characteristic function $\chi_A \in 2^X$, given by $\chi_A(x) = 1$ if $x \in A$, and $\chi(x) = 0$ otherwise. We generally indicate injective maps by $\hookrightarrow$. Given maps $f: Z \to X$, $g: Z \to Y$, we write $(f, g)$ for the map $Z \to X \times Y$ given by $(f, g)(z) = (f(z), g(z))$. We denote the disjoint union of sets $X, Y$ by $X + Y$, with canonical inclusion maps $i_1: X \to X + Y$ and $i_2: Y \to X + Y$. More generally, we write $\bigsqcup_{i \in I} X_i$ for the disjoint union of an $I$-indexed family of sets $(X_i)_{i \in I}$, and $i_+: X_i \to \bigsqcup_{i \in I} X_i$ for the $i$-th inclusion map. For a map $f: X \to Y$ (not necessarily surjective), we denote by $\ker(f) \subseteq X \times X$ the kernel of $f$, i.e. the equivalence relation

$$\ker(f) := \{(x, x') \in X \times X \mid f(x) = f(x')\}. \quad (1)$$

Notation 2.1 (Partitions). Given an equivalence relation $R$ on $X$, we write $[x]_R$ for the equivalence class $\{x' \in X \mid (x, x') \in R\}$ of $x \in X$. If $R$ is the kernel of a map $f$, we simply write $[x]_f$ in lieu of $[x]_{\ker(f)}$. The intersection $R \cap S$ of equivalence relations is again an equivalence relation. The partition corresponding to $R$ is denoted by $X/R = \{[x]_R \mid x \in X\}$. Note that $[\cdot]_R: X \to X/R$ is a surjective map and that $R = \ker([\cdot]_R)$.

A signature is a set $\Sigma$, whose elements are called operation symbols, equipped with a function $a: \Sigma \to \mathbb{N}$ assigning to each operation symbol its arity. We write $\sigma/n \in \Sigma$ for $\sigma \in \Sigma$ with $a(\sigma) = n$. We will apply the same terminology and notation to collections of modal operators.

2.1 Coalgebra

Universal coalgebra [40] provides a generic framework for the modelling and analysis of state-based systems. Its key abstraction is to parametrize notions and results over the transition type of systems, encapsulated as an endofunction on a given base category. Instances cover, for example, deterministic automata, labelled (weighted) transition systems, and Markov chains.

Definition 2.2. A set functor $F: \text{Set} \to \text{Set}$ assigns to every set $X$ a set $FX$ and to every map $f: X \to Y$ a map $Ff: FX \to FY$ such that identity maps and composition are preserved: $F(id_X) = id_{FX}$ and $F(g \cdot f) = Fg \cdot Ff$. An $F$-coalgebra is a pair $(C, c)$ consisting of a set $C$ (the carrier) and a map $c: C \to FC$ (the structure). When $F$ is clear from the context, we simply speak of a coalgebra.
In a coalgebra \( c: C \rightarrow FC \), we understand the carrier set \( C \) as consisting of states, and the structure \( c \) as assigning to each state \( x \in C \) a structured collection of successor states, with the structure of collections determined by \( F \). In this way, the notion of coalgebra subsumes numerous types of state-based systems, as illustrated next.

**Example 2.3.**
1. The powerset functor \( \mathcal{P} \) sends a set \( X \) to its powerset \( \mathcal{P}X \) and a map \( f: X \rightarrow Y \) to the map \( \mathcal{P}f = f[-]: \mathcal{P}X \rightarrow \mathcal{P}Y \) taking direct images. A \( \mathcal{P} \)-coalgebra \( c: C \rightarrow \mathcal{P}C \) is precisely a transition system: It assigns to every state \( x \in C \) a set \( c(x) \in \mathcal{P}C \) of successor states, inducing a transition relation \( \rightarrow \) given by \( x \rightarrow y \) iff \( y \in c(x) \). Similarly, coalgebras for the finite powerset functor \( \mathcal{P}_f \) (with \( \mathcal{P}_fX \) being the set of finite subsets of \( X \)) are finitely branching transition systems.
2. Coalgebras for the functor \( FX = 2 \times X^A \), where \( A \) is a fixed input alphabet, are deterministic automata (without an explicit initial state). Indeed, a coalgebra structure \( F \times A \rightarrow C \) in curried form \( t: C \rightarrow C^A \).
3. Every signature \( \Sigma \) defines a signature functor that maps a set \( X \) to the set
\[
T_\Sigma X = \bigsqcup_{\sigma \in \Sigma} X^n,
\]
whose elements we may understand as flat \( \Sigma \)-terms \( \sigma(x_1, \ldots, x_n) \) with variables from \( X \). The action of \( T_\Sigma \) on maps \( f: X \rightarrow Y \) is then given by \((T_\Sigma f)(\sigma(x_1, \ldots, x_n)) = \sigma(f(x_1), \ldots, f(x_n))\). For simplicity, we write \( \sigma \) (instead of \( \sigma_n \)) for the coproduct injections, and \( \Sigma \) in lieu of \( T_\Sigma \) for the signature functor. States in \( \Sigma \)-coalgebras describe possibly infinite \( \Sigma \)-trees.
4. For a commutative monoid \((M, +, 0)\), the monoid-valued functor \( M(-) \) [25] is given by
\[
M^X := \{ \mu: X \rightarrow M \mid \mu(x) = 0 \text{ for all but finitely many } x \in X \}
\]
on sets \( X \); for a map \( f: X \rightarrow Y \), the map \( M^X \rightarrow M^Y \) is defined by
\[
(M^f)(\mu)(y) = \sum_{x \in X : f(x) = y} \mu(x).
\]
A coalgebra \( c: C \rightarrow M^C \) is a finitely branching weighted transition system, where \( c(x)(x') \in M \) is the transition weight from \( x \) to \( x' \). For the Boolean monoid \( B = (2, \lor, 0) \), we recover \( \mathcal{P}_f = \mathcal{P}_B \). Coalgebras for \( \mathbb{R}(-) \), with \( \mathbb{R} \) understood as the additive monoid of the reals, are \( \mathbb{R} \)-weighted transition systems. The functor
\[
\mathcal{D}X = \{ \mu \in \mathbb{R}_\geq(X) \mid \sum_{x \in X} \mu(x) = 1 \},
\]
which assigns to a set \( X \) the set of all finite probability distributions on \( X \) (represented as finitely supported probability mass functions), is a subfunctor of \( \mathbb{R}(-) \).
5. Functors can be composed; for instance, given a set \( A \) of labels, the composite of \( \mathcal{P} \) and the functor \( A \times (-) \) (whose action on sets maps a set \( X \) to the set \( A \times X \)) is the functor \( \mathcal{P}(A \times X) \), whose coalgebras are \( A \)-labelled transition systems. Coalgebras for \( (\mathcal{D}(-) + 1)^A \) have been termed probabilistic transition systems [33] or labelled Markov chains [17], and coalgebras for \( (\mathcal{D}((\mathcal{D}(-) + 1)^A \) are partial labelled Markov chains [17]. Coalgebras for \( SX = \mathcal{P}_f(A \times DX) \) are variously known as simple Segala systems or Markov decision processes.

We have a canonical notion of behaviour on \( F \)-coalgebras:
Definition 2.4. An $F$-coalgebra morphism $h : (C,c) \to (D,d)$ is a map $h : C \to D$ such that $d \cdot h = Fh \cdot c$. States $x,y$ in an $F$-coalgebra $(C,c)$ are behaviourally equivalent ($x \sim y$) if there exists a coalgebra morphism $h$ such that $h(x) = h(y)$.

Thus, we effectively define the behaviour of a state as those of its properties that are preserved by coalgebra morphisms. The notion of behavioural equivalence subsumes standard branching-time equivalences:

Example 2.5.
1. For $F \in \{P,P_f\}$, behavioural equivalence on $F$-coalgebras, i.e. on transition systems, is bisimilarity in the usual sense.
2. For deterministic automata as coalgebras for $FX = 2 \times XA$, two states are behaviourally equivalent iff they accept the same formal language.
3. For a signature functor $\Sigma$, two states of a $\Sigma$-coalgebra are behaviourally equivalent iff they describe the same $\Sigma$-tree.
4. For labelled transition systems as coalgebras for $FX = P(A \times X)$, coalgebraic behavioural equivalence precisely captures Milner’s strong bisimilarity [1].
5. For weighted and probabilistic systems, coalgebraic behavioural equivalence instantiates to weighted and probabilistic bisimilarity, respectively [41, Cor. 4.7], [7, Thm. 4.2].

Remark 2.6.
1. The notion of behavioural equivalence extends straightforwardly to states in different coalgebras, as one can canonically define the disjoint union of coalgebras.
2. We may assume without loss of generality that a set functor $F$ preserves injective maps [43] (see also [2, 8.1.12–17]), that is, $Ff$ is injective whenever $f$ is.

2.2 Coalgebraic Logics

We briefly review basic concepts of coalgebraic modal logic [38,42]. Coalgebraic modal logics are parametric in a functor $F$ determining the type of systems underlying the semantics, and additionally in a choice of modalities interpreted in terms of predicate liftings. For now, we use $F = P$ as a basic example, deferring further examples to Section 5.

Syntax. The syntax of coalgebraic modal logic is parametrized over the choice of signature $\Lambda$ of modal operators (with assigned arities). Then, formulae $\phi$ are generated by the grammar

$$\phi_1, \ldots, \phi_n ::= \top | \neg \phi_1 | \phi_1 \land \phi_2 | \bigcirc(\phi_1, \ldots, \phi_n) \quad (\bigcirc/n \in \Lambda).$$

Example 2.7. For $F = P$, one often takes $\Lambda = \{\bigcirc/1\}$; the induced syntax is that of (single-action) Hennessy-Milner logic. As usual, we write $\Box \phi \equiv \neg \bigcirc \neg \phi$.

Semantics. We interpret formulae as sets of states in $F$-coalgebras. This interpretation arises by assigning to each modal operator $\bigcirc/n \in \Lambda$ an $n$-ary predicate lifting $[\bigcirc]$ [38,42], i.e. a family of maps $[\bigcirc]_X : (2^X)^n \to 2^{FX}$, one for every set $X$, such that the naturality condition

$$Ff^{-1}[\bigcirc]_Y(P_1, \ldots, P_n) = [\bigcirc]_X(f^{-1}[P_1], \ldots, f^{-1}[P_n])$$ (3)
Explaining Behavioural Inequivalence Generically in Quasilinear Time

for all \( f : X \to Y \) and all \( P_1, \ldots, P_n \in 2^X \) (for categorically-minded readers, \( \llbracket \circ \rrbracket \) is a natural transformation \( (2^{\text{op}})^n \to 2^{P^{\text{op}}} \)); the idea being to lift given predicates on states to predicates on structured collections of states. Given these data, the extension of a formula \( \phi \) in an \( F \)-coalgebra \( (C, c) \) is a predicate \( \llbracket \phi \rrbracket_{(C, c)} \), or just \( \llbracket \phi \rrbracket \), on \( C \), recursively defined by

\[
\llbracket \top \rrbracket_{(C, c)} = C \quad \llbracket \phi \land \psi \rrbracket_{(C, c)} = \llbracket \phi \rrbracket_{(C, c)} \cap \llbracket \psi \rrbracket_{(C, c)} \quad \llbracket \lnot \phi \rrbracket_{(C, c)} = C \setminus \llbracket \phi \rrbracket_{(C, c)} \\
\llbracket \diamond \phi_1, \ldots, \phi_n \rrbracket_{(C, c)} = c^{-1}(\llbracket \diamond \rrbracket_C(\llbracket \phi_1 \rrbracket_{(C, c)}, \ldots, \llbracket \phi_n \rrbracket_{(C, c)})) \quad (\forall n \in \Lambda)
\]

(where we apply set operations to predicates with the evident meaning). We say that a state \( x \in C \) satisfies \( \phi \) if \( \llbracket \phi \rrbracket(x) = 1 \). Notice how the clause for modalities says that \( x \) satisfies \( \diamond(\phi_1, \ldots, \phi_n) \) iff \( c(x) \) satisfies the predicate obtained by lifting the predicates \( \llbracket \phi_1 \rrbracket, \ldots, \llbracket \phi_n \rrbracket \) on \( C \) to a predicate on \( FC \) according to \( \llbracket \circ \rrbracket \).

**Example 2.8.** Over \( F = \mathcal{P} \), we interpret \( \diamond \) by the predicate lifting

\[
\llbracket \circ \rrbracket_X : 2^X \to 2^{2^X} \quad P \mapsto \{ K \subseteq X \mid \exists x \in K : x \in P \} = \{ K \subseteq X \mid K \cap P \neq \emptyset \},
\]

The arising notion of satisfaction over \( \mathcal{P} \)-coalgebras \( (C, c) \) is precisely the standard one: \( x \in [\llbracket \phi \rrbracket_{(C, c)} \iff y \in [\llbracket \phi \rrbracket]_{(C, c)} \) for some transition \( x \to y \).

The naturality condition (3) of predicate liftings guarantees invariance of the logic under coalgebra morphisms, and hence under behavioural equivalence:

**Proposition 2.9 (Adequacy [38, 42]).** Behaviourally equivalent states satisfy the same formulae: \( x \sim y \) implies that for all formulae \( \phi \), we have \( x \in [\llbracket \phi \rrbracket] \) iff \( y \in [\llbracket \phi \rrbracket] \).

In our running example \( F = \mathcal{P} \), this instantiates to the well-known fact that modal formulae are bisimulation-invariant, that is, bisimilar states in transition systems satisfy the same formulae of Hennessy-Milner logic.

### 3 Constructing Distinguishing Formulae

A proof method certifying behavioural equivalence of states \( x, y \) in a coalgebra is immediate by definition: One simply needs to exhibit a coalgebra morphism \( h \) such that \( h(x) = h(y) \). In fact, for many system types, it suffices to relate \( x \) and \( y \) by a coalgebraic bisimulation in a suitable sense (e.g. [1, 24, 34, 40]), generalizing the Park-Milner bisimulation principle [35, 37]. It is less obvious how to certify behavioural inequivalence \( x \not\sim y \), showing that such a morphism \( h \) does not exist. By Proposition 2.9, one option is to exhibit a (coalgebraic) modal formula \( \phi \) that is satisfied by \( x \) but not by \( y \). In the case of (image-finite) transition systems, such a formula is guaranteed to exist by the Hennessy-Milner theorem, which moreover is known to generalize to coalgebras [39, 42]. More generally, we consider separation of sets of states by formulae, following Cleaveland [13, Def. 2.4]:

**Definition 3.1.** Let \( (C, c) \) be an \( F \)-coalgebra. A formula \( \phi \) **distinguishes** a set \( X \subseteq C \) from a set \( Y \subseteq C \) if \( X \subseteq [\llbracket \phi \rrbracket] \) and \( Y \cap [\llbracket \phi \rrbracket] = \emptyset \). In case \( X = \{ x \} \) and \( Y = \{ y \} \), we just say that \( \phi \) **distinguishes** \( x \) from \( y \). We say that \( \phi \) is a **certificate** of \( X \) if \( \phi \) distinguishes \( X \) from \( C \setminus X \), that is if \( [\llbracket \phi \rrbracket] = X \).

Note that \( \phi \) distinguishes \( X \) from \( Y \) iff \( \lnot \phi \) distinguishes \( Y \) from \( X \). Certificates have also been referred to as **descriptions** [22]. If \( \phi \) is a certificate of a behavioural equivalence class \( [x]_\sim \), then by definition \( \phi \) distinguishes \( x \) from \( y \) whenever \( x \not\sim y \). To obtain distinguishing formulae for behaviourally inequivalent states in a coalgebra, it thus suffices to construct certificates
for all behavioural equivalence classes, and our algorithm does just that. Of course, every certificate must be at least as large as a smallest distinguishing formula. However, already on transition systems, distinguishing formulae and certificates have the same asymptotic worst-case size (cf. Section 6).

A natural approach to computing certificates for behavioural equivalence classes is to extend algorithms that compute these equivalence classes. In particular, partition refinement algorithms compute a sequence \( C/R_0, C/R_1, \ldots \) of consecutively finer partitions (i.e. \( R_{i+1} \subseteq R_i \)) on the state space, where every block \( B \in C/R_i \) is a union of behavioural equivalence classes, and the final partition is precisely \( C/\sim \). Indeed, Cleaveland’s algorithm for computing certificates on labelled transition systems [13] correspondingly extends Kanellakis and Smolka’s partition refinement algorithm [28,29], which runs in \( O(mn) \) on systems with \( n = |C| \) states and \( m \) transitions. Our generic algorithm will be based on a more efficient partition refinement algorithm.

3.1 Paige-Tarjan with Certificates

Before we turn to constructing certificates in coalgebraic generality, we informally recall and extend the Paige-Tarjan algorithm [36], which computes the partition modulo bisimilarity of a given transition system with \( n \) states and \( m \) transitions in time \( O((m + n) \log n) \). We fix a given finite transition system, viewed as a \( \mathcal{P}\)-coalgebra \( c: C \rightarrow \mathcal{P}C \).

The algorithm computes two sequences \( (C/P_i)_{i \in \mathbb{N}} \) and \( (C/Q_i)_{i \in \mathbb{N}} \) of partitions of \( C \) (with \( Q_i, P_i \) equivalence relations), where only the most recent partition is held in memory and \( i \) indexes the iterations of the main loop. Throughout the execution, \( C/P_i \) finer than \( C/Q_i \) (that is, \( P_i \subseteq Q_i \) for all \( i \)), and the algorithm terminates when \( P_i = Q_i \). Intuitively, \( P_i \) is “one transition ahead” of \( Q_i \): if \( Q_i \) distinguishes states \( x \) and \( y \), then \( P_i \) is based on distinguishing transitions to \( x \) from transitions to \( y \).

Initially, \( C/Q_0 := \{C\} \) consists of only one block and \( C/P_0 \) of two blocks: the live states and the deadlocks (i.e. states with no outgoing transitions). If \( P_i \nsubseteq Q_i \), then there is a block \( B \in C/Q_i \) that is the union of at least two blocks in \( C/P_i \). In such a situation, the algorithm chooses \( S \subseteq B \) in \( C/P_i \) to have at most half the size of \( B \) and then splits the block \( B \) into \( S \) and \( B \setminus S \) in the partition \( C/Q_{i+1} \):

\[
C/Q_{i+1} = (C/Q_i \setminus \{B\}) \cup \{S, B \setminus S\}.
\]

This is correct because every state in \( S \) is already known to be behaviourally inequivalent to every state in \( B \setminus S \). By the definition of bisimilarity, this implies that every block \( T \in C/P_i \) with some transition to \( B \) may contain behaviourally inequivalent states as illustrated in Figure 3; that is, \( T \) may need to be split into smaller blocks, as follows:

- **(C1)** states in \( T \) with successors in \( S \) but not in \( B \setminus S \) (e.g. \( x_1 \) in Figure 3),
- **(C2)** states in \( T \) with successors in \( S \) and \( B \setminus S \) (e.g. \( x_2 \)), and
- **(C3)** states in \( T \) with successors \( B \setminus S \) but not in \( S \) (e.g. \( x_3 \)).

The partition \( C/P_{i+1} \) arises from \( C/P_i \) by splitting all such predecessor blocks \( T \) of \( B \) accordingly. If no such \( T \) is properly split, then \( P_{i+1} = Q_{i+1} \), and the algorithm terminates.

It is straightforward to construct certificates for the blocks arising during the execution:

- The certificate for the only block \( C \in C/Q_0 \) is \( \top \), and the blocks for live states and deadlocks in \( C/P_i \) have certificates \( \diamond \top \) and \( \neg \diamond \top \), respectively.
- In the refinement step, suppose that \( \delta, \beta \) are certificates of \( S \in C/P_i \) and \( B \in C/Q_i \), respectively, where \( S \nsubseteq B \). For every predecessor block \( T \) of \( B \), the three blocks obtained by splitting \( T \) are distinguished (see Definition 3.1) as follows:

\[
\begin{align*}
(C1) \quad & \neg \diamond (\beta \land \neg \delta), \\
(C2) \quad & \diamond (\delta) \land \diamond (\beta \land \neg \delta), \\
(C3) \quad & \neg \diamond \delta.
\end{align*}
\]
3.2 Generic Partition Refinement

The Paige-Tarjan algorithm has been adapted to other system types, e.g. weighted systems [44], and it has recently been generalized to coalgebras [20,46]. A crucial step in this generalization is to rephrase the case distinction \((C1)-(C3)\) in terms of the functor \(P\): Given a predecessor block \(T\) in \(C/P_i\) for \(S \subseteq B \in C/Q_i\), the three cases distinguish between the equivalence classes \([x]_\sim^{P}B\) for \(x \in T\), where the map \(\chi_B^S : C \rightarrow 3\) in the composite \(P\chi_B^S \cdot c : C \rightarrow 3\) is defined by

\[
\chi_B^S : C \rightarrow 3, \quad \chi_B^S(x) = \begin{cases} 
2 & \text{if } x \in S, \\
1 & \text{if } x \in B \setminus S, \\
0 & \text{if } x \in C \setminus B,
\end{cases} \quad \text{for sets } S \subseteq B \subseteq C. \tag{5}
\]

Every case is a possible value of \(t := P\chi_B^S(c(x)) \in 3:\) \((C1)\) \(2 \in t \neq 1, (C2)\) \(2 \in t \ni 1,\) and \((C3)\) \(2 \notin t \ni 1\). Since \(T\) is a predecessor block of \(B\), the “fourth case” \(2 \notin t \ni 1\) is not possible. There is a transition from \(x\) to some state outside of \(B\) iff \(0 \in t\). However, because of the previous refinement steps performed by the algorithm, either all or no states states of \(T\) have an edge to \(C \setminus B\) (a property called stability [36]), hence no distinction on \(0 \in t\) is necessary.

It is now easy to generalize from transition systems to coalgebras by simply replacing the functor \(P\) with \(F\) in the refinement step. We recall the algorithm:

\[\textbf{Algorithm 3.2} \ [46, Alg. 4.9, (5.1)].\] Given a coalgebra \(c : C \rightarrow FC\), put

\[C/Q_0 := \{C\} \quad \text{and} \quad P_0 := \ker(C \xrightarrow{\sim} FC \xrightarrow{\Phi_1} F1).\]

Starting at iteration \(i = 0\), repeat the following while \(P_i \neq Q_i:\)

(A1) Pick \(S \in C/P_i\) and \(B \in C/Q_i\) such that \(S \subseteq B\) and \(2 \cdot |S| \leq |B|\)

(A2) \(C/Q_{i+1} := (C/Q_i \setminus \{B\}) \cup \{S, B \setminus S\}\)

(A3) \(P_{i+1} := P_i \cap \ker(C \xrightarrow{\sim} FC \xrightarrow{\Phi_2} F3)\)
This algorithm formalizes the intuitive steps from Section 3.1. Again, two sequences of partitions \( P_i, Q_i \) are constructed, and \( P_i = Q_i \) upon termination. Initially, \( Q_0 \) identifies all states and \( P_0 \) distinguishes states by only their output behaviour; e.g. for \( F = \mathcal{P} \) and \( x \in C \), the value \( \mathcal{P}!/(c(x)) \in \mathcal{T} \) is 0 if \( x \) is a deadlock, and \( \{1\} \) if \( x \) is a live state, and for \( FX = 2 \times X^A \), the value \( F1/(c(x)) \in F1 = 2 \times 1^A \cong 2 \) indicates whether \( x \) is a final or non-final state.

In the main loop, blocks \( S \in C/P_i \) and \( B \in C/Q_i \) witnessing \( P_i \nsubseteq Q_i \) are picked, and \( B \) is split into \( S \) and \( B \setminus S \), like in the Paige-Tarjan algorithm. Note that step (A2) is equivalent to directly defining the equivalence relation \( Q_{i+1} \) as

\[
Q_{i+1} := Q_i \cap \ker \chi_S^B.
\]

A similar intersection of equivalence relations is performed in step (A3). The intersection splits every block \( T \in C/P_i \) into smaller blocks such that \( x, x' \in T \) end up in the same block iff \( F\chi_S^B/(c(x)) = F\chi_S^B/(c(x')) \), i.e. \( T \) is replaced by \( \{[x]_F\chi_S^B(c(x)) \mid x \in T\} \). Again, this corresponds to the distinction of the three cases (C1)–(C3). For example, for \( FX = 2 \times X^A \), there are \( |F3| = 2 \cdot 3^{|A|} \) cases to be distinguished, and so every \( T \in C/P_i \) is split into at most that many blocks.

The following property of \( F \) is needed for correctness [46, Ex. 5.11].

\textbf{Definition 3.3} [46]. A functor \( F \) is \textit{zippable} if map

\[
(F(A+1), F(1+B)) : F(A + B) \rightarrow F(A + 1) \times F(1 + B)
\]

is injective for all sets \( A, B \).

Intuitively, \( t \in F(A + B) \) is a term in variables from \( A \) and \( B \). If \( F \) is zippable, then \( t \) is uniquely determined by the two elements in \( F(A + 1) \) and \( F(1 + B) \) obtained by identifying all \( B \)- and all \( A \)-variables with \( 0 \in 1 \), respectively. E.g. \( FX = X^2 \) is zippable: \( t = (in_1(a), in_2(b)) \in (A + B)^2 \) is uniquely determined by \( (in_1(a), in_2(0)) \in (A + 1)^2 \) and \( (in_1(0), in_2(b)) \in (1 + B)^2 \), and similarly for the three other cases of \( t \). In fact, all signature functors as well as \( \mathcal{P} \) and all monoid-valued functors are zippable. Moreover, the class of zippable functors is closed under products, coproducts, and subfunctors but not under composition, e.g. \( \mathcal{P}\mathcal{P} \) is not zippable [46].

\textbf{Remark 3.4}. To apply the algorithm to coalgebras for composites \( FG \) of zippable functors, e.g. \( \mathcal{P}(A \times (-)) \), there is a reduction [46, Section 8] that embeds every \( FG \)-coalgebra into a coalgebra for the zippable functor \( (F + G)(X) := FX + GX \). This reduction preserves and reflects behavioural equivalence, but introduces an intermediate state for every transition.

\textbf{Theorem 3.5} [46, Thm 4.20, 5.20]. On a finite coalgebra \((C,c)\) for a zippable functor, Algorithm 3.2 terminates after \( i \leq |C| \) loop iterations, and the resulting partition identifies precisely the behaviourally equivalent states \((P_i = \sim)\).

### 3.3 Generic Modal Operators

The extended Paige-Tarjan algorithm (Section 3.1) constructs a distinguishing formula according to the three cases (C1)–(C3). In the coalgebraic Algorithm 3.2, these cases correspond to elements of \( F3 \), which determine in which block an element of a predecessor block \( T \) ends up. Indeed, the elements of \( F3 \) will also serve as generic modalities in characteristic formulae for blocks of states, essentially by the known equivalence between \( n \)-ary predicate liftings and (in this case, singleton) subsets of \( F(2^n) \) [42] (termed \textit{tests} by Klin [30]):
Definition 3.6. The signature of $F3$-modalities for a functor $F$ is
\[
\Lambda = \{ t^\top \mid t \in F3 \};
\]
that is, we write $t^\top$ for the syntactic representation of a binary modality for every $t \in F3$. The interpretation of $t^\top$ for $F3$ is given by the predicate lifting
\[
\llbracket t^\top \rrbracket : (2^X)^2 \rightarrow 2^{FX}, \quad \llbracket t^\top \rrbracket(S,B) = \{ t' \in FX \mid FX_{B \cap S}^B(t') = t \}.
\]
The intended use of $t^\top$ is as follows: Suppose a block $B$ is split into subblocks $S \subseteq B$ and $B \setminus S$ with certificates $\delta$ and $\beta$, respectively: $[\delta] = S$ and $[\beta] = B$. As in Algorithm 3.2, we then split every predecessor block $T$ of $B$ into smaller parts, each of which is uniquely characterized by the formula $t^\top(\delta,\beta)$ for some $t \in F3$.

Example 3.7. For $F = P$, $t^\top(\delta,\beta)$ is equivalent to $\Diamond \neg \beta \land \neg \Diamond (\beta \land \neg \delta) \land \Diamond (\delta \land \beta)$.

Lemma 3.8. Given an $F$-coalgebra $(C,c)$, $x \in C$, and formulae $\delta$ and $\beta$ such that $[\delta] \subseteq [\beta] \subseteq C$, we have $x \in \llbracket t^\top(\delta,\beta) \rrbracket$ if and only if $FX^{[\beta]}_{[\delta]}(c(x)) = t$.

In the initial partition $C/P_0$ on a transition system $(C,c)$, we used the formulae $\Diamond T$ and $\neg \Diamond T$ to distinguish live states and deadlocks. In general, we can similarly describe the initial partition using modalities induced by elements of $F1$.

Notation 3.9. Define the injective map $j_1 : 1 \rightarrow 3$ by $j_1(0) = 2$. Then the injection $Fj_1 : F1 \rightarrow F3$ provides a way to interpret elements $t \in F1$ as nullary modalities $t^\top$:
\[
t^\top := t^\top j_1(t)(\top, \top) \quad \text{for } t \in F1.
\]
(Alternatively, we could introduce $t^\top$ directly as a nullary modality.)

Lemma 3.10. For $x \in C$, $c : C \rightarrow FC$, and $t \in F1$, we have $x \in \llbracket t^\top \rrbracket$ if and only if $F1(c(x)) = t$.

3.4 Algorithmic Construction of Certificates

The $F3$-modalities introduced above (Definition 3.6) induce an instance of coalgebraic modal logic (Section 2.2). We refer to coalgebraic modal formulae employing the $F3$-modalities as $F3$-modal formulae, and write $\mathcal{M}$ for the set of $F3$-modal formulae. As in the extended Paige-Tarjan algorithm (Section 3.1), we annotate every block arising during the execution of Algorithm 3.2 with a certificate in the shape of an $F3$-modal formula. Annotating blocks with formulae means that we construct maps
\[
\beta_i : C/Q_i \rightarrow \mathcal{M} \quad \text{and} \quad \delta_i : C/P_i \rightarrow \mathcal{M} \quad \text{for } i \in \mathbb{N}.
\]
As in Algorithm 3.2, $i$ indexes the loop iterations. For blocks $B, S$ in the respective partition, $\beta_i(B)$, $\delta_i(S)$ denote corresponding certificates: we will have
\[
\forall B \in X/Q_i : [\beta_i(B)] = B \quad \text{and} \quad \forall S \in X/P_i : [\delta_i(S)] = S.
\]
We construct $\beta_i(B)$ and $\delta_i(S)$ iteratively, using certificates for the blocks $S \subseteq B$ at every iteration.

Algorithm 3.11. We extend Algorithm 3.2 by the following. Initially, put
\[
\beta_0(\{C\}) := \top \quad \text{and} \quad \delta_0([x]_{P_0}) := t^\top F1(c(x)) \quad \text{for every } x \in C.
\]
In the $i$-th iteration, extend steps (A2) and (A3) by the following assignments:
\[(A'2) \quad \beta_{i+1}(D) = \begin{cases} 
\delta_i(S) & \text{if } D = S \\
\beta_i(B) \land \neg \delta_i(S) & \text{if } D = B \setminus S \\
\beta_i(D) & \text{if } D \in C/Q_i
\end{cases}\]

\[(A'3) \quad \delta_{i+1}([x]_{P_{i+1}}) = \begin{cases} 
\delta_i([x]_{P_i}) & \text{if } [x]_{P_{i+1}} = [x]_{P_i} \\
\delta_i([x]_{P_i}) \land \neg \mathcal{F}X^{3}F(c(x))^\gamma(\delta_i(S), \beta_i(B)) & \text{otherwise.}
\end{cases}\]

Upon termination, return \(\delta_i\).

Like in Section 3.1, the only block of \(C/Q_0\) has \(\beta_0(\{C\}) = \top\) as a certificate. Since the partition \(C/P_0\) distinguishes by the “output” (e.g. final vs. non-final states), the certificate of \([x]_{P_0}\) specifies what \(F!c(x)\) ∈ \(F1\) is (Lemma 3.10).

In the \(i\)-th iteration of the main loop, we have certificates \(\delta_i(S)\) and \(\beta_i(B)\) for \(S \subseteq B\) in step (A1) satisfying (6) available from the previous iterations. In (A2), the Boolean connectives describe how \(B\) is split into \(S\) and \(B\setminus S\). In (A3), new certificates are constructed for every predecessor block \(T \in C/P_i\) that is refined. If \(T\) does not change, then neither does its certificate. Otherwise, the block \(T = [x]_{P_i}\) is split into the blocks \([x]_{F\chi^3F(c(x))}\) for \(x \in T\) in step (A3), which is reflected by the \(F3\) modality \(\mathcal{F}X^{3}F(c(x))^\gamma\) as per Lemma 3.8.

- **Remark 3.12.** In step (A2), \(\beta_{i+1}(D)\) can be simplified to be no larger than \(\delta_i(S)\). To see this, note that for \(S \subseteq B \subseteq C\), \(S \in X/P_i\), and \(B \in X/Q_i\), every conjunct of \(\beta_i(B)\) is also a conjunct of \(\delta_i(S)\). In \(\beta_i(B) \land \neg \delta_i(S)\), one can hence remove all conjuncts of \(\beta_i(B)\) from \(\delta_i(S)\), obtaining a formula \(\delta'\), and then equivalently use \(\beta_i(B) \land \neg \delta'\) in the definition of \(\beta_{i+1}(D)\).

- **Theorem 3.13.** For zippable \(F\), Algorithm 3.11 is correct, i.e. (6) holds for all \(i\). Thus, upon termination \(\delta_i\) assigns certificates to each block of \(C/\sim = C/P_i\).

- **Corollary 3.14 (Hennessy-Milner).** For zippable \(F\), states \(x, y\) in a finite \(F\)-coalgebra are behaviourally equivalent iff they agree on all \(F3\)-modal formulae.

- **Remark 3.15.** A smaller formula distinguishing a state \(x\) from a state \(y\) can be extracted from the certificates in time \(O(|C|)\). It is the leftmost conjunct that is different in the respective certificates of \(x\) and \(y\). This is the subformula starting at the modal operator introduced in \(\delta_i\) for the least \(i\) with \((x, y) \notin P_i\); hence, \(x\) satisfies \(\mathcal{F}t'(\delta, \beta)\) but \(y\) satisfies \(\mathcal{F}t''(\delta, \beta)\) for some \(t' \neq t\) in \(F3\).

### 3.5 Complexity Analysis

The operations introduced by Algorithm 3.11 can be implemented with only constant run time overhead. To this end, one implements \(\beta\) and \(\delta\) as arrays of formulae of length \(|C|\) (note that at any point, there are at most \(|C|\)-many blocks). In the refinable-partition data structure [45], every block has an index (a natural number) and there is an array of length \(|C|\) mapping every state \(x \in C\) to the block it is contained in. Hence, for both partitions \(C/P\) and \(C/Q\), one can look up a state’s block and a block’s certificate in constant time.

It is very likely that the certificates contain a particular subformula multiple times and that certificates of different blocks share common subformulae. For example, every certificate of a block refined in the \(i\)-th iteration using \(S \subseteq B\) contains the subformulas \(\delta_i(S)\) and \(\beta_i(B)\). Therefore, it is advantageous to represent all certificates constructed as one directed acyclic graph (dag) with nodes labelled by modal operators and conjunction and having precisely two outgoing edges. Moreover, edges have a binary flag indicating whether they represent negation \(\neg\). Initially, there is only one node representing \(\top\), and the operations of Algorithm 3.11 allocate new nodes and update the arrays for \(\beta\) and \(\delta\) to point
to the right nodes. For example, if the predecessor block \( T \in C/P_i \) is refined in step (A3), yielding a new block \([x]_{P_{i+1}}\), then a new node labelled \( \wedge \) is allocated with edges to the nodes \( \delta_i(T) \) and to another new node labelled \( F_X \{ (c(x)) \} \) with edges to the nodes \( \delta_i(S) \) and \( \delta_i(B) \).

For purposes of estimating the size of formulae generated by the algorithm, we use a notion of transition in coalgebras, inspired by the notion of canonical graph [26].

- **Definition 3.16.** For states \( x, y \) in an \( F \)-coalgebra \((C, c)\), we say that there is a transition \( x \to y \) if \( c(x) \in FC \) is not in the image \( Fi[F(C \setminus \{ y \})] \subseteq FC \), where \( i : C \setminus \{ y \} \to C \) is the inclusion map.

- **Theorem 3.17.** For a coalgebra with \( n \) states and \( m \) transitions, the formula dag constructed by Algorithm 3.11 has size \( \mathcal{O}(m \cdot \log n + n) \) and height at most \( n + 1 \).

- **Theorem 3.18.** Algorithm 3.11 adds only constant run time overhead, thus it has the same run time as Algorithm 3.2 (regardless of the optimization from Remark 3.12).

For a tighter run time analysis of the underlying partition refinement algorithm, one additionally requires that \( F \) is equipped with a refinement interface [46, Def. 6.4], which is based on a given encoding of \( F \)-coalgebras in terms of edges between states (encodings serve only as data structures and have no direct semantic meaning, in particular do not entail a semantic reduction to relational structures). This notion of edge yields the same numbers (in \( \mathcal{O} \)-notation) as Definition 3.16 for all functors considered. All zippable functors we consider here have refinement interfaces [15, 46]. In presence of a refinement interface, step (A3) can be implemented efficiently, with resulting overall run time \( \mathcal{O}((m + n) \cdot \log n \cdot p(c)) \) where \( n = |C| \), \( m \) is the number of edges in the encoding of the input coalgebra \((C, c)\), and the run-time factor \( p(c) \) is associated with the refinement interface. In most instances, e.g. for \( P \), \( \mathbb{R}^{(-)} \), one has \( p(c) = 1 \); in particular, the generic algorithm recovers the run time of the Paige-Tarjan algorithm.

- **Remark 3.19.** The claimed run time relies on close attention to a number of implementation details. This includes use of an efficient data structure for the partition \( C/P_i \) [31, 45]; the other partition \( C/Q_i \) is only represented implicitly in terms of a queue of blocks \( S \subseteq B \) witnessing \( P_i \subseteq Q_i \), requiring additional care when splitting blocks in the queue [44, Fig. 3]. Moreover, grouping the elements of a block by \( F3 \) involves the consideration of a possible majority candidate [44].

- **Theorem 3.20.** On a coalgebra with \( n \) states and \( m \) transitions for a zippable set functor with a refinement interface with factor \( p(c) \), Algorithm 3.11 runs in time \( \mathcal{O}((m+n) \cdot \log n \cdot p(c)) \).

### 4 Cancellative Functors

Our use of binary modalities relates to the fact that, as observed already by Paige and Tarjan, when splitting a block according to an existing partition of a block \( B \) into \( S \subseteq B \) and \( B \setminus S \), it is not in general sufficient to look only at the successors in \( S \). However, this does suffice for some transition types; e.g. Hopcroft’s algorithm for deterministic automata [27] and Valmari and Franceschini’s algorithm for weighted systems (e.g. Markov chains) [44] both split only with respect to \( S \). In the following, we exhibit a criterion on the level of functors that captures that splitting w.r.t. only \( S \) is sufficient:

- **Definition 4.1.** A functor \( F \) is cancellative if the map
  \[
  \langle F_X(1, 2), F_X(2) \rangle : F3 \to F2 \times F2
  \]
  is injective.
To understand the role of the above map, recall the function \( \chi^B_S : C \rightarrow 3 \) from (5) and note that \( \chi_{\{1,2\}} \cdot \chi^B_S = \chi_B \) and \( \chi_{\{2\}} \cdot \chi^B_S = \chi_S \), so the composite \( \langle F\chi_{\{1,2\}}, F\chi_{\{2\}} \rangle \cdot F\chi^B_S \) yields information about the accumulated transition weights into \( B \) and \( S \) but not about the one into \( B \setminus S \); the injectivity condition means that for cancellative functors, this information suffices in the splitting step for \( S \subseteq B \subseteq C \). The term `cancellative' stems from the respective property on monoids; recall that a monoid \( M \) is cancellative if \( s + b_1 = s + b_2 \) implies \( b_1 = b_2 \) for all \( s, b_1, b_2 \in M \).

- Proposition 4.2. The monoid-valued functor \( M(-) \) for a commutative monoid \( M \) is cancellative if and only if \( M \) is a cancellative monoid.

Hence, \( \mathbb{R}(-) \) is cancellative, but \( \mathcal{P}(t) \) is not. Moreover, all signature functors are cancellative:

- Proposition 4.3. The class of cancellative functors contains the all constant functors as well as the identity functor, and it is closed under subfunctors, products, and coproducts.

For example, \( \mathcal{D} \) is cancellative, but \( \mathcal{P} \) is not because of its subfunctor \( \mathcal{P}(t) \).

- Remark 4.4. Cancellative functors are neither closed under quotients nor under composition. Zippability and cancellativity are independent properties. Zippability in conjunction with cancellativity implies \( m \)-zippability for all \( m \in \mathbb{N} \), the \( m \)-ary variant [32] of zippability.

- Theorem 4.5. If \( F \) is a cancellative functor, \( F^{\chi^B_S}(c(x))^{\top}(\delta_i(S), \beta_i(B)) \) in Algorithm 3.11 can be replaced with \( F^{\chi^B_S}(c(x))^{\top}(\delta_i(S), \top) \). Then, the algorithm still correctly computes certificates in the given \( F \)-coalgebra \((C, c)\).

Note that in this optimized algorithm, the computation of \( \beta \) can be omitted because it is not used anymore. Hence, the resulting formulae only involve \( \wedge, \top \), and modalities from the set \( F^3 \) (with the second parameter fixed to \( \top \)). These modalities are equivalently unary modalities induced by elements of \( F^2 \), which we term \( F^2 \)-modalities; hence, the corresponding Hennessy-Milner Theorem (Corollary 3.14) adapts to \( F^2 \) for cancellative functors, as follows:

- Corollary 4.6. For zippable and cancellative \( F \), states in an \( F \)-coalgebra are behaviourally equivalent iff they agree on modal formulae built using \( \top, \wedge, \) and unary \( F^2 \)-modalities.

5 Domain-Specific Certificates

On a given specific system type, one is typically interested in certificates and distinguishing formulae expressed via modalities whose use is established in the respective domain, e.g. \( \Box \) and \( \Diamond \) for transition systems. We next describe how the generic \( F^3 \) modalities can be rewritten to domain-specific ones in a postprocessing step. The domain-specific modalities will not in general be equivalent to \( F^3 \)-modalities, but still yield certificates.

- Definition 5.1. The Boolean closure \( \bar{\Lambda} \) of a modal signature \( \Lambda \) has as \( n \)-ary modalities propositional combinations of atoms of the form \( \Diamond(i_1, \ldots, i_k) \), for \( \Diamond/k \in \Lambda \), where \( i_1, \ldots, i_k \) are propositional combinations of elements of \( \{1, \ldots, n\} \). Such a modality \( \lambda/n \) is interpreted by predicate liftings \( \llbracket \lambda \rrbracket_X : (2^X)^n \rightarrow FX \) defined inductively in the obvious way.

For example, the boolean closure of \( \Lambda = \{\Diamond/1\} \) contains the unary modality \( \Box = \neg\Diamond\neg \).

- Definition 5.2. Given a modal signature \( \Lambda \) for a functor \( F \), a domain-specific interpretation consists of functions \( \tau : F^1 \rightarrow \bar{\Lambda} \) and \( \lambda : F^3 \rightarrow \bar{\Lambda} \) assigning to each \( o \in F^1 \) a nullary modality \( \tau_o \) and to each \( t \in F^3 \) a binary modality \( \lambda_t \) such that the predicate liftings \( \llbracket \tau_o \rrbracket_X \in 2^{FX} \) and \( \llbracket \lambda_t \rrbracket_X : (2^X)^2 \rightarrow 2^{FX} \) satisfy
\[
\llbracket \tau_o \rrbracket_X = \{o\} \quad \text{(in } 2^{F^1}) \quad \text{and} \quad \llbracket t \rrbracket_{\chi_{\{1,2\}}} \cap \llbracket \lambda_t \rrbracket_{\Lambda^{\chi_{\{2\}}}({\{2\}, {1}})} = \{t\} \quad \text{(in } 2^{F^3}).
\]
(Recall that \(\chi_{(1,2)} : 3 \rightarrow 2\) is the characteristic function of \(\{1,2\} \subseteq 3\), and \(\{t\}F_{\chi_{(1,2)}} \subseteq F3\) denotes the equivalence class of \(t\) w.r.t. \(F_{\chi_{(1,2)}} : F3 \rightarrow F2\).

Thus, \(\tau_0\) holds precisely at states with output behaviour \(o \in F1\). Intuitively, \(\lambda_t(\delta, \rho)\) describes the refinement step of a predecessor block \(T\) when splitting \(B := [\delta] \cup [\rho]\) into \(S := [\delta]\) and \(B \setminus S := [\rho]\) (Figure 3), which translates into the arguments \(\{2\}\) and \(\{1\}\) of \([\lambda_t]\). In the refinement step, we know from previous iterations that all elements have the same behaviour w.r.t. \(B\). This is reflected in the intersection with \([t]F_{\chi_{(1,2)}}\). The axiom guarantees that \(\lambda_t\) characterizes \(t \in F3\) uniquely, but only within the equivalence class representing a predecessor block. Thus, \(\lambda_t\) can be much smaller than equivalents of \(\langle T \rangle\) (cf. Example 3.7):

\[\Box\hspace{1em}\text{Example 5.3.}\]

1. For \(F = P\), we have a domain-specific interpretation over the modal signature \(\Lambda = \{\varnothing/1\}\).

   For \(\emptyset, \{0\} \in P1\), take \(\tau_{\{0\}} = \emptyset \top\) and \(\tau_{\emptyset} = \top\ \emptyset\). For \(t \in P_{\emptyset}\), we put

   \[\lambda_{\max}(\delta, \rho) = -\emptyset \rho\text{ if }2 \in t \not\ni 1\]

   \[\lambda_{\max}(\delta, \rho) = -\emptyset \delta \cup \emptyset \rho\text{ if }2 \in t \ni 1\]

   The certificates obtained via this translation are precisely the ones generated in the example using the Paige-Tarjan algorithm, cf. (4), with \(\rho\) in lieu of \(\beta \land -\delta\).

2. For a signature (functor) \(\Sigma\), take \(\Lambda = \{\sigma/0 \mid \sigma|_n \in \Sigma\} \cup \{\langle w/1 \mid I \in P_{\emptyset}(\mathbb{N})\}\). We interpret \(\Lambda\) by the predicate liftings

   \[\llbracket \sigma \rrbracket_X = \{\sigma(x_1, \ldots, x_n) \mid x_1, \ldots, x_n \in X\} \subseteq \Sigma X,\]

   \[\llbracket \langle w \rangle \rrbracket(S) = \{\sigma(x_1, \ldots, x_n) \in \Sigma X \mid \forall i \in \mathbb{N} : i \leftrightarrow (1 \leq i \leq n \land x_i \in S)\}.\]

   Intuitively, \(\llbracket \langle w \rangle \rrbracket\) states that the \(i\)th successor satisfies \(\phi\) if \(i \in I\). We then have a domain-specific interpretation \((\tau, \lambda)\) given by \(\tau_{\emptyset} := \sigma\) for \(\sigma = (0, \ldots, 0) \in \Sigma 1\) and \(\lambda_{\max}(\delta, \rho) := \langle w \rangle \delta\) for \(t = \sigma(x_1, \ldots, x_n) \in \Sigma 3\) and \(I = \{i \in \{1, \ldots, n\} \mid x_i = 2\}\).

3. For a monoid-valued functor \(M(-)\), take \(\Lambda = \{\langle w \rangle/1 \mid m \in M\}\), interpreted by the predicate liftings \(\llbracket \langle w \rangle \rrbracket_X : 2^X \rightarrow 2^{M^{(X)}}\) given by

   \[\llbracket \langle w \rangle \rrbracket_X(S) = \{m \in M^{(X)} \mid m = \sum_{x \in S} \mu(x)\}.\]

   A formula \(\langle w \rangle\delta\) thus states that the accumulated weight of the successors satisfying \(\delta\) is exactly \(m\). A domain-specific interpretation \((\tau, \lambda)\) is then given by \(\tau_{\emptyset} := \langle w \rangle\top\) and \(\lambda_{\max}(\delta, \rho) := \langle w(2i) \rangle \delta \land \langle w(1i) \rangle \rho\) for \(t \in M^{(3)}\). In case \(M\) is cancellative, we can also simply put \(\lambda_{\max}(\delta, \rho) := \langle w(2i) \rangle \delta\).

4. For labelled Markov chains, i.e. \(FX = (DX + 1)^A\), let \(\Lambda = \{(a)p/1 \mid a \in A, p \in [0,1]\}\), where \(\langle a \rangle_p\phi\) denotes that on input \(a\), the next state will satisfy \(\phi\) with probability at least \(p\), as in cited work by Desharnais et al. [17]. This gives rise to the interpretation:

   \[\tau_{\emptyset} = \bigwedge_{a \in A} \langle a \rangle_1 \top \land \bigwedge_{a \in A} \langle a \rangle_1 \top\]

   \[\lambda_{\max}(\delta, \rho) = \bigwedge_{a \in A} \bigwedge_{t(a) \in D_a} (\langle a \rangle_{t(a)(2i)} \delta \land \langle a \rangle_{t(a)(1i)} \rho)\]

Given a domain-specific interpretation \((\tau, \lambda)\) for a modal signature \(\Lambda\) for the functor \(F\), we can postprocess certificates \(\phi\) produced by Algorithm 3.11 by replacing the modalities \(\langle T \rangle\) for \(t \in F3\) according to the translation \(T\) recursively defined by the following clauses for modalities and by commutation with propositional operators:

\[T(\langle T \rangle(\top \land \top)) = T(\langle T \rangle(\top \land \top)) = T(\langle T \rangle(\top \land \top)) = \lambda_{\max}(T(\delta), T(\beta) \land T(\delta)).\]

Note that one can replace \(T(\beta) \land \neg T(\delta)\) with \(T(\beta) \land \neg T(\delta')\) for the optimized \(\delta'\) from Remark 3.12; the latter conjunction has essentially the same size as \(T(\delta)\).
Proposition 5.4. For every certificate $\phi$ of a behavioural equivalence class of a given coalgebra produced by either Algorithm 3.11 or its optimization (Theorem 4.5), $T(\phi)$ is also a certificate for that class.

Thus, the domain-specific modal signatures also inherit a Hennessy-Milner Theorem.

Example 5.5. For labelled Markov chains $(FX = (DX + 1)^A)$ and the interpretation via the modalities $\langle a \rangle_p$ (Example 5.3.4), this yields certificates (thus in particular distinguishing formulae) in run time $O(|A| \cdot m \cdot \log n)$, with the same bound on formula size. Desharnais et al. describe an algorithm [17, Fig. 4] that computes distinguishing formulae in the negation-free fragment of the same logic (they note also that this fragment does not suffice for certificates). They do not provide a run-time analysis, but the nested loop structure indicates that the asymptotic complexity is roughly $|A| \cdot n^4$.

6 Worst Case Tree Size of Certificates

In the complexity analysis (Section 3.5), we have seen that certificates – and thus also distinguishing formulae – have dag size $O(m \cdot \log n + n)$ on input coalgebras with $n$ states and $m$ transitions. However, when formulae are written in the usual linear way, multiple occurrences of the same subformula lead to an exponential blow up of the formula size in this sense, which for emphasis we refer to as the tree size.

Figueira and Gorín [22] show that exponential tree size is inevitable even for distinguishing formulae. The proof is based on winning strategies in bisimulation games, a technique that is also applied in other results on lower bounds on formula size [3,4,23].

Open Problem 6.1. Do states in $R^{(-)}$-coalgebras generally have certificates of subexponential tree size in the number of states? If yes, can small certificates be computed efficiently?

We note that for another cancellative functor, the answer is well-known: On deterministic automata, i.e. coalgebras for $FX = 2 \times X^A$, the standard minimization algorithm constructs distinguishing words of linear length.

Remark 6.2. Cleaveland [13, p. 368] also mentions that minimal distinguishing formulae may be exponential in size, however for a slightly different notion of minimality: a formula $\phi$ distinguishing $x$ from $y$ is minimal if no $\phi$ obtained by replacing a non-trivial subformula of $\phi$ with the formula $\top$ distinguishes $x$ from $y$. This is weaker than demanding that the formula size of $\phi$ is as small as possible. For example, in the transition system

\[
\begin{array}{cccccc}
\cdot & \bullet & \bullet & \bullet & \cdots & \bullet \\
x & & & & & y \\
\end{array}
\]

for $n \in \mathbb{N}$,

the formula $\phi = \Diamond^{n+2} \top$ distinguishes $x$ from $y$ and is minimal in the above sense. However, $x$ can in fact be distinguished from $y$ in size $O(1)$, by the formula $\Diamond \neg \Diamond \top$.

7 Conclusions and Further Work

We have presented a generic algorithm that computes distinguishing formulae for behaviourally inequivalent states in state-based systems of various types, cast as coalgebras for a functor capturing the system type. Our algorithm is based on coalgebraic partition refinement [46], and like that algorithm runs in time $O((m + n) \cdot \log n \cdot p(c))$, with a functor-specific factor $p(c)$ that is 1 in many cases of interest. Independently of this factor, the distinguishing formulae constructed by the algorithm have dag size $O(m \cdot \log n + n)$; they live in a dedicated instance
of coalgebraic modal logic [39, 42], with binary modalities extracted from the type functor in a systematic way. We have shown that for cancellative functors, the construction of formulae and, more importantly, the logic can be simplified, requiring only unary modalities and conjunction. We have also discussed how distinguishing formulae can be translated into a more familiar domain-specific syntax (e.g. Hennessy-Milner logic for transition systems).

There is an open source implementation of the underlying partition refinement algorithm [15], which may serve as a basis for a future implementation.

In partition refinement, blocks are successively refined in a top-down manner, and this is reflected by the use of conjunction in distinguishing formulae. Alternatively, bisimilarity may be computed bottom-up, as in a recent partition aggregation algorithm [11]. It is an interesting point for future investigation whether this algorithm can be extended to compute distinguishing formulae, which would likely be of a rather different shape than those computed via partition refinement.
