■ Contents

Preface	
<i>Filippo Bonchi and Simon J. Puglisi</i>	0:xi
Conference Organization	
.....	0:xiii

Invited Talks

Non-Axiomatizability of the Equational Theories of Positive Relation Algebras	
<i>Amina Doumane</i>	1:1–1:1
A Deep Dive into the Weisfeiler-Leman Algorithm	
<i>Martin Grohe</i>	2:1–2:1
Holonomic Techniques, Periods, and Decision Problems	
<i>Joël Ouaknine</i>	3:1–3:1
On Dynamic Graphs	
<i>Eva Rotenberg</i>	4:1–4:1
Sublinear Algorithms for Edit Distance	
<i>Barna Saha</i>	5:1–5:1

Regular Papers

An Approximation Algorithm for the Matrix Tree Multiplication Problem	
<i>Mahmoud Abo-Khamis, Ryan Curtin, Sungjin Im, Benjamin Moseley, Hung Ngo, Kirk Pruhs, and Alireza Samadian</i>	6:1–6:14
Depth-First Search in Directed Planar Graphs, Revisited	
<i>Eric Allender, Archit Chauhan, and Samir Datta</i>	7:1–7:22
Order Reconfiguration Under Width Constraints	
<i>Emmanuel Arrighi, Henning Fernau, Mateus de Oliveira Oliveira, and Petra Wolf</i>	8:1–8:15
Universal Gauge-Invariant Cellular Automata	
<i>Pablo Arrighi, Marin Costes, and Nathanaël Eon</i>	9:1–9:14
Equivalence Testing of Weighted Automata over Partially Commutative Monoids	
<i>V. Arvind, Abhranil Chatterjee, Rajit Datta, and Partha Mukhopadhyay</i>	10:1–10:15
Finitely Tractable Promise Constraint Satisfaction Problems	
<i>Kristina Asimi and Libor Barto</i>	11:1–11:16
A Generic Strategy Improvement Method for Simple Stochastic Games	
<i>David Auger, Xavier Badin de Montjoye, and Yann Strozecki</i>	12:1–12:22
(Un)Decidability for History Preserving True Concurrent Logics	
<i>Paolo Baldan, Alberto Carraro, and Tommaso Padoan</i>	13:1–13:16

46th International Symposium on Mathematical Foundations of Computer Science (MFCS 2021).

Leibniz International Proceedings in Informatics

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Parameterized Complexity of Feature Selection for Categorical Data Clustering <i>Sayan Bandyopadhyay, Fedor V. Fomin, Petr A. Golovach, and Kirill Simonov</i> ..	14:1–14:14
Decision Questions for Probabilistic Automata on Small Alphabets <i>Paul C. Bell and Pavel Semukhin</i>	15:1–15:17
Ideal Membership Problem for Boolean Minority and Dual Discriminator <i>Arpitha P. Bharathi and Monaldo Mastrolilli</i>	16:1–16:20
Graph Traversals as Universal Constructions <i>Siddharth Bhaskar and Robin Kaarsgaard</i>	17:1–17:20
Space-Efficient Fault-Tolerant Diameter Oracles <i>Davide Bilò, Sarel Cohen, Tobias Friedrich, and Martin Schirneck</i>	18:1–18:16
ω -Forest Algebras and Temporal Logics <i>Achim Blumensath and Jakub Lédl</i>	19:1–19:21
Constructing Deterministic ω -Automata from Examples by an Extension of the RPNI Algorithm <i>León Bohn and Christof Löding</i>	20:1–20:18
Computational Complexity of Covering Multigraphs with Semi-Edges: Small Cases <i>Jan Bok, Jiří Fiala, Petr Hliněný, Nikola Jedličková, and Jan Kratochvíl</i>	21:1–21:15
Coherent Control and Distinguishability of Quantum Channels via PBS-Diagrams <i>Cyril Branciard, Alexandre Clément, Mehdi Mhalla, and Simon Perdrix</i>	22:1–22:20
Reconfiguring Independent Sets on Interval Graphs <i>Marcin Briański, Stefan Felsner, Jędrzej Hodor, and Piotr Micek</i>	23:1–23:14
Finite Convergence of μ -Calculus Fixpoints on Genuinely Infinite Structures <i>Florian Bruse, Marco Sälzer, and Martin Lange</i>	24:1–24:19
Dots & Boxes Is PSPACE-Complete <i>Kevin Buchin, Mart Hagedoorn, Irina Kostitsyna, and Max van Mulken</i>	25:1–25:18
Uncertain Curve Simplification <i>Kevin Buchin, Maarten Löffler, Aleksandr Popov, and Marcel Roeloffzen</i>	26:1–26:22
Fractional Homomorphism, Weisfeiler-Leman Invariance, and the Sherali-Adams Hierarchy for the Constraint Satisfaction Problem <i>Silvia Butti and Víctor Dalmau</i>	27:1–27:19
A Decidable Equivalence for a Turing-Complete, Distributed Model of Computation <i>Arnaldo Cesco and Roberto Gorrieri</i>	28:1–28:18
Black-Box Hypotheses and Lower Bounds <i>Brynmor K. Chapman and R. Ryan Williams</i>	29:1–29:22
Geometry of Interaction for ZX-Diagrams <i>Kostia Chardonnet, Benoît Valiron, and Renaud Vilmart</i>	30:1–30:16
Diameter Versus Certificate Complexity of Boolean Functions <i>Siddhesh Chaubal and Anna Gál</i>	31:1–31:22

Budgeted Dominating Sets in Uncertain Graphs <i>Keerti Choudhary, Avi Cohen, N. S. Narayanaswamy, David Peleg, and R. Vijayaragunathan</i>	32:1–32:22
On the Complexity of the Escape Problem for Linear Dynamical Systems over Compact Semialgebraic Sets <i>Julian D’Costa, Engel Lefaucheur, Eike Neumann, Joël Ouaknine, and James Worrell</i>	33:1–33:21
The Pseudo-Skolem Problem is Decidable <i>Julian D’Costa, Toghrul Karimov, Rupak Majumdar, Joël Ouaknine, Mahmoud Salamati, Sadegh Soudjani, and James Worrell</i>	34:1–34:21
A Recursion-Theoretic Characterization of the Probabilistic Class PP <i>Ugo Dal Lago, Reinhard Kahle, and Isabel Oitavem</i>	35:1–35:12
Parallel Polynomial Permanent Mod Powers of 2 and Shortest Disjoint Cycles <i>Samir Datta and Kishlaya Jaiswal</i>	36:1–36:22
On the Relative Power of Linear Algebraic Approximations of Graph Isomorphism <i>Anuj Dawar and Danny Vagnozzi</i>	37:1–37:16
Maximum Cut on Interval Graphs of Interval Count Four Is NP-Complete <i>Celina M. H. de Figueiredo, Alexander A. de Melo, Fabiano S. Oliveira, and Ana Silva</i>	38:1–38:15
Fuzzy Simultaneous Congruences <i>Max A. Deppert, Klaus Jansen, and Kim-Manuel Klein</i>	39:1–39:16
Pebble Transducers with Unary Output <i>Gaëtan Douéneau-Tabot</i>	40:1–40:17
Graph Characterization of the Universal Theory of Relations <i>Amina Doumane</i>	41:1–41:15
Co-Degeneracy and Co-Treewidth: Using the Complement to Solve Dense Instances <i>Gabriel L. Duarte, Mateus de Oliveira Oliveira, and Uéverton S. Souza</i>	42:1–42:17
Isometric Embeddings in Trees and Their Use in Distance Problems <i>Guillaume Ducoffe</i>	43:1–43:16
On Computing the Average Distance for Some Chordal-Like Graphs <i>Guillaume Ducoffe</i>	44:1–44:16
A Cubic Vertex-Kernel for TRIVIAALLY PERFECT EDITING <i>Maël Dumas, Anthony Perez, and Ioan Todinca</i>	45:1–45:14
Lower Bounds on Avoiding Thresholds <i>Robert Ferens, Marek Szykula, and Vojtěch Vorel</i>	46:1–46:14
HyperLTL Satisfiability Is Σ_1^1 -Complete, HyperCTL* Satisfiability Is Σ_1^2 -Complete <i>Marie Fortin, Louwe B. Kuijjer, Patrick Totzke, and Martin Zimmermann</i>	47:1–47:19
Matching Patterns with Variables Under Hamming Distance <i>Paweł Gawrychowski, Florin Manea, and Stefan Siemer</i>	48:1–48:24

Keyboards as a New Model of Computation <i>Yoan Gérard, Bastien Laboureix, Corto Mascle, and Valentin D. Richard</i>	49:1–49:20
Quantum Speedups for Dynamic Programming on n -Dimensional Lattice Graphs <i>Adam Glos, Martins Kokainis, Ryuhei Mori, and Jevgēnijs Vihrovs</i>	50:1–50:23
A Note on the Join of Varieties of Monoids with LI <i>Nathan Grosshans</i>	51:1–51:16
Optimal Regular Expressions for Palindromes of Given Length <i>Hermann Gruber and Markus Holzer</i>	52:1–52:15
A Bit of Nondeterminism Makes Pushdown Automata Expressive and Succinct <i>Shibashis Guha, Ismaël Jecker, Karoliina Lehtinen, and Martin Zimmermann</i>	53:1–53:20
Perfect Forests in Graphs and Their Extensions <i>Gregory Gutin and Anders Yeo</i>	54:1–54:13
On Deciding Linear Arithmetic Constraints Over p -adic Integers for All Primes <i>Christoph Haase and Alessio Mansutti</i>	55:1–55:20
Obstructing Classification via Projection <i>Pantea Haghighatkhah, Wouter Meulemans, Bettina Speckmann, Jérôme Urhausen, and Kevin Verbeek</i>	56:1–56:19
Online Domination: The Value of Getting to Know All Your Neighbors <i>Hovhannes A. Harutyunyan, Denis Pankratov, and Jesse Racicot</i>	57:1–57:21
A Linear-Time Nominal μ -Calculus with Name Allocation <i>Daniel Hausmann, Stefan Milius, and Lutz Schröder</i>	58:1–58:18
Test of Quantumness with Small-Depth Quantum Circuits <i>Shuichi Hirahara and François Le Gall</i>	59:1–59:15
On Search Complexity of Discrete Logarithm <i>Pavel Hubáček and Jan Václavěk</i>	60:1–60:16
A Homological Condition on Equational Unifiability <i>Mirai Ikebuchi</i>	61:1–61:16
Ordered Fragments of First-Order Logic <i>Reijo Jaakkola</i>	62:1–62:14
The Simplest Non-Regular Deterministic Context-Free Language <i>Petr Jančar and Jiří Šíma</i>	63:1–63:18
On the Hardness of Compressing Weights <i>Bart M. P. Jansen, Shivesh K. Roy, and Michał Włodarczyk</i>	64:1–64:21
Griddings of Permutations and Hardness of Pattern Matching <i>Vít Jelínek, Michal Opler, and Jakub Pekárek</i>	65:1–65:22
Sets of Linear Forms Which Are Hard to Compute <i>Michael Kaminski and Igor E. Shparlinski</i>	66:1–66:22
On Positivity and Minimality for Second-Order Holonomic Sequences <i>George Kenison, Oleksiy Klurman, Engel Lefaucheur, Florian Luca, Pieter Moree, Joël Ouaknine, Markus A. Whiteland, and James Worrell</i>	67:1–67:15

Improved Upper Bounds for the Rigidity of Kronecker Products <i>Bohdan Kivva</i>	68:1–68:18
The Power of One Clean Qubit in Communication Complexity <i>Hartmut Klauck and Debbie Lim</i>	69:1–69:23
Connecting Constructive Notions of Ordinals in Homotopy Type Theory <i>Nicolai Kraus, Fredrik Nordvall Forsberg, and Chuangjie Xu</i>	70:1–70:16
Maximum Votes Pareto-Efficient Allocations via Swaps on a Social Network <i>Fu Li and Xiong Zheng</i>	71:1–71:16
Finite Models for a Spatial Logic with Discrete and Topological Path Operators <i>Sven Linker, Fabio Papacchini, and Michele Sevegnani</i>	72:1–72:16
Recursive Backdoors for SAT <i>Nikolas Mählmann, Sebastian Siebertz, and Alexandre Vigny</i>	73:1–73:18
Parallel Algorithms for Power Circuits and the Word Problem of the Baumslag Group <i>Caroline Mattes and Armin Weiß</i>	74:1–74:24
The Complexity of Transitively Orienting Temporal Graphs <i>George B. Mertzios, Hendrik Molter, Malte Renken, Paul G. Spirakis, and Philipp Zschoche</i>	75:1–75:18
Temporal Reachability Minimization: Delaying vs. Deleting <i>Hendrik Molter, Malte Renken, and Philipp Zschoche</i>	76:1–76:15
A Timecop’s Chase Around the Table <i>Nils Morawietz and Petra Wolf</i>	77:1–77:18
Syntactic Minimization Of Nondeterministic Finite Automata <i>Robert S. R. Myers and Henning Urbat</i>	78:1–78:16
Idempotent Turing Machines <i>Keisuke Nakano</i>	79:1–79:18
Ergodic Theorems and Converses for PSPACE Functions <i>Satyadev Nandakumar and Subin Pulari</i>	80:1–80:19
On Guidable Index of Tree Automata <i>Damian Niwiński and Michał Skrzypczak</i>	81:1–81:14
Feedback Vertex Set and Even Cycle Transversal for H -Free Graphs: Finding Large Block Graphs <i>Giacomo Paesani, Daniël Paulusma, and Paweł Rzażewski</i>	82:1–82:14
Stabilization Bounds for Influence Propagation from a Random Initial State <i>Pál András Papp and Roger Wattenhofer</i>	83:1–83:15
Parameterized (Modular) Counting and Cayley Graph Expanders <i>Norbert Peyerimhoff, Marc Roth, Johannes Schmitt, Jakob Stix, and Alina Vdovina</i>	84:1–84:15
A Hierarchy of Nondeterminism <i>Bader Abu Radi, Orna Kupferman, and Ofer Leshkowitz</i>	85:1–85:21

0:x **Contents**

Boolean Automata and Atoms of Regular Languages <i>Hellis Tamm</i>	86:1–86:13
The Gödel Fibration <i>Davide Trotta, Matteo Spadetto, and Valeria de Paiva</i>	87:1–87:16
Abstract Congruence Criteria for Weak Bisimilarity <i>Stelios Tsampas, Christian Williams, Andreas Nuyts, Dominique Devriese, and Frank Piessens</i>	88:1–88:23
Quantum Multiple-Valued Decision Diagrams in Graphical Calculi <i>Renaud Vilmart</i>	89:1–89:15
Decision Problems for Origin-Close Top-Down Tree Transducers <i>Sarah Winter</i>	90:1–90:16

■ Preface

The International Symposium on Mathematical Foundations of Computer Science (MFCS conference series) is a well-established venue for presenting research results in theoretical computer science. The broad scope of the conference encourages interactions between researchers who might not meet at more specialized venues. The first MFCS conference was organized in 1972 in Jabłonna (near Warsaw, Poland). Since then, the conference traditionally moved between the Czech Republic, Slovakia, and Poland. More recently, the conference started traveling to other European countries, including Denmark, the United Kingdom, Germany. The venue for this – the 46th – edition of MFCS, is Tallinn, Estonia.

The program committee of MFCS 2021 accepted 85 papers out of 199 submissions, with the authors of the submitted papers representing over 35 countries. We would like to express our deep gratitude to all the committee members and reviewers for their extensive reports and discussions on the merits of the submissions. Due to the Covid-19 pandemic MFCS 2021 was held as a hybrid event. It featured invited talks by Amina Doumane (ENS Lyon), Martin Grohe (RWTH Aachen University), Joël Ouaknine (Max Planck Institute for Software Systems), Eva Rotenberg (Technical University of Denmark), and Barna Saha (UC Berkeley) on topics that reflected the broad scope of the conference.

MFCS proceedings have been published in the Dagstuhl/LIPIcs series since 2016. We would like to thank Michael Wagner and the LIPIcs team for all their kind help and support. We also warmly thank the organising committee of MFCS, chaired by Pawel Sobocinski, for their hard work in setting up and running the event.

Filippo Bonchi
Simon J. Puglisi

■ Conference Organization

Program Committee

Filippo Bonchi	University of Pisa, co-chair
Tiziana Calamoneri	Sapienza University of Rome
Corina Cirstea	University of Southampton

Non-Axiomatizability of the Equational Theories of Positive Relation Algebras

Amina Doumane ✉

CNRS, ENS Lyon, France

Abstract

In the literature, there are two ways to show that the equational theory of relations over a given signature is not finitely axiomatizable. The first-one is based on games and a construction called Rainbow construction. This method is very technical but it shows a strong result: the equational theory cannot be axiomatized by any finite set of *first-order formulas*. There is another method, based on a graph characterization of the equational theory of relations, which is easier to get and to understand, but proves a weaker result: the equational theory cannot be axiomatized by any finite set of *equations*.

In this presentation, I will show how to complete the second technique to get the stronger result of non-axiomatizability by first-order formulas.

2012 ACM Subject Classification Mathematics of computing → Discrete mathematics

Keywords and phrases Relation algebra, Graph homomorphism, Equational theories, First-order logic

A Deep Dive into the Weisfeiler-Leman Algorithm

Martin Grohe  

RWTH Aachen University, Germany

Abstract

The Weisfeiler-Leman algorithm is a well-known combinatorial graph isomorphism test going back to work of Weisfeiler and Leman in the late 1960s. The algorithm has a surprising number of seemingly unrelated characterisations in terms of logic, algebra, linear and semi-definite programming, and graph homomorphisms. Due to its simplicity and efficiency, it is an important subroutine of all modern graph isomorphism tools. In recent years, further applications in linear optimisation, probabilistic inference, and machine learning have surfaced.

In my talk, I will introduce the Weisfeiler-Leman algorithm and some extensions. I will discuss its expressiveness and the various characterisations, and I will speak about its applications.

2012 ACM Subject Classification Mathematics of computing → Graph theory; Theory of computation → Logic

Keywords and phrases Weisfeiler-Leman algorithm, graph isomorphism, counting homomorphisms, finite variable logics

Holonomic Techniques, Periods, and Decision Problems

Joël Ouaknine  

Max Planck Institute for Software Systems, Saarland Informatics Campus, Saarbrücken, Germany

Abstract

Holonomic techniques have deep roots going back to Wallis, Euler, and Gauss, and have evolved in modern times as an important subfield of computer algebra, thanks in large part to the work of Zeilberger and others over the past three decades (see, e.g., [3, 2]). In this talk, I give an overview of the area, and in particular present a select survey of known and original results on decision problems for holonomic sequences and functions. I also discuss some surprising connections to the theory of periods and exponential periods, which are classical objects of study in algebraic geometry and number theory; in particular, I relate the decidability of certain decision problems for holonomic sequences to deep conjectures about periods and exponential periods, notably those due to Kontsevich and Zagier.

Parts of this exposition draws upon [1].

On Dynamic Graphs

Eva Rotenberg  

Technical University of Denmark, Lyngby, Denmark

Abstract

In graph algorithms, many questions about a graph can be answered in time proportional to the size of the input, and such *linear time algorithms* are considered the epitome of efficiency. However, when the graph changes slightly, e.g. by the insertion or deletion of an edge or a vertex, it is undesirable to consider the entire input again. Rather, one would wish to keep some of the partial answers to questions about the old graph, and re-use them when computing answers to questions about the resulting graph. The art of handling such changes is studied in *dynamic graph algorithms*.

In this talk, we will see some examples of ideas and techniques for efficiently maintaining knowledge about a dynamically changing graph. We will consider classical and natural graph properties such as connectivity and planarity, and we will focus on deterministic algorithms.

Sublinear Algorithms for Edit Distance

Barna Saha ✉

University of California at Berkeley, CA, USA

Abstract

The edit distance is a way of quantifying how similar two strings are to one another by counting the minimum number of character insertions, deletions, and substitutions required to transform one string into the other. A simple dynamic programming computes the edit distance between two strings of length n in $O(n^2)$ time, and a more sophisticated algorithm runs in time $O(n + t^2)$ where t is the distance (Landau, Myers and Schmidt, SICOMP 1998). In pursuit of obtaining faster running time, the last couple of decades have seen a flurry of research on approximating edit distance, including polylogarithmic approximation in near-linear time (Andoni, Krauthgamer and Onak, FOCS 2010), and a constant-factor approximation in subquadratic time (Chakrabarty, Das, Goldenberg, Koucký and Saks, FOCS 2018). In this talk, we will discuss recent progress that goes beyond linear time, and studies sublinear time algorithms for edit distance. We will also discuss the role preprocessing might play in designing fast algorithms.

This is a joint work with Elazar Goldenberg, Tomasz Kociumaka, Robert Krauthgamer, and Aviad Rubinfeld.

Abstract

We consider the Matrix Tree Multiplication problem. This problem is a generalization of the classic Matrix Chain Multiplication problem covered in the dynamic programming chapter of many introductory algorithms textbooks. An instance of the Matrix Tree Multiplication problem consists of a rooted tree with a matrix associated with each edge. The output is, for each leaf in the tree, the product of the matrices on the chain/path from the root to that leaf. Matrix multiplications that are shared between various chains need only be computed once, potentially being shared between different root to leaf chains. Algorithms are evaluated by the number of scalar multiplications performed. Our main result is a linear time algorithm for which the number of scalar multiplications performed is at most 15 times the optimal number of scalar multiplications.

1 Introduction

An instance of the Matrix Tree Multiplication problem consists of an arborescence $T = (V, E)$. There is a positive integer dimension d_v associated with each vertex v , and a d_u by d_v matrix $M_{u,v}$ associated with each directed edge (u, v) . Let r be the root of T and L be the collection of leaves of T . The output is, for each leaf $\ell \in L$, the product of the matrices on the directed

6:2 Matrix Tree Multiplication

path from the root r to that leaf ℓ (in that order). We restrict our attention to algorithms that use the standard matrix multiplication algorithm to multiply two matrices, which uses ijk scalar multiplications to multiply an i by j matrix by a j by k matrix. We evaluate algorithms based on the aggregate number of scalar multiplications that they use. If the tree T has a single leaf, then this is the classic Matrix Chain Multiplication problem that is commonly covered in the dynamic programming chapter of introductory algorithms textbooks (e.g. [4]). However, it is important to note that a Matrix Tree Multiplication instance is not equivalent to a disjoint collection of Matrix Chain Multiplication instances, one for each leaf. This is because multiplications that are shared between various chains need only be computed once, not once for each chain.

To help the reader appreciate this difference, let us consider two instances of Matrix Tree Multiplication where T is a balanced binary tree of depth $\lg n$ with n leaves. In the first instance, depicted in Figure 1a, all dimensions are 1. Then every feasible solution for every root-to-leaf path/chain uses $\lg n - 1$ scalar multiplications. However, the aggregate number of scalar multiplications can be quite different for different feasible solutions. To see this, if u is an ancestor of v in T , let $M_{u,v}$ denote the product of the matrices between u and v in T . We now consider two feasible solutions:

- **Top-Down:** For each root-to-leaf path $r = v_1, v_2, \dots, v_k$ in T , the i^{th} matrix multiplication is $M_{v_1, v_{i+2}} = M_{v_1, v_{i+1}} M_{v_{i+1}, v_{i+2}}$ for $i \in [1, k - 2]$.
- **Bottom-Up:** For each root-to-leaf path $r = v_1, v_2, \dots, v_k$ in T , the i^{th} matrix multiplication is $M_{v_{k-i-1}, v_k} = M_{v_{k-i-1}, v_{k-i}} M_{v_{k-i}, v_k}$ for $i \in [1, k - 2]$.

For Top-Down the computation of a matrix M_{v_1, v_h} can be shared by all root-to-leaf paths with leaves in the subtree T_{v_h} of T rooted at v_h . If we charge the computation of M_{v_1, v_h} to the vertex v_h , then each vertex that is neither the root nor a child of the root is charged exactly once and this charge is one. Thus, the objective value for Top-Down is $n - 3$. In contrast, for Bottom-Up none of its matrix multiplications can be shared between different paths. Thus, the objective value for the Bottom-Up algorithm is $\Theta(n \lg n)$. Thus, conceptually the advantage of Top-Down is that it minimizes the number of matrix multiplications, and maximizes the number of root-to-leaf paths that can utilize each particular matrix multiplication.

We remark that when the dimensions higher in the tree are significantly larger than the dimensions lower in the tree Bottom-Up can be significantly cheaper than Top-Down. This is because the individual matrix multiplications can be significantly cheaper. As an example consider the instance, depicted in Figure 1b. Here the dimension of a vertex at height h is 2^{2h} . Therefore, leaves have dimension 1, and the dimensions increase geometrically by a factor of 4 as one goes up the tree, with the root ultimately having dimension n^2 . The cost of Top-Down is clearly $\Omega(n^6)$ as there are individual matrix multiplications high in the tree that have this cost. On the other hand, the cost Bottom-Up is $O(n^5)$ as its cost increases geometrically up the tree, and the last matrix multiplications cost $O(n^5)$.

One motivation for our consideration of the Matrix Tree Multiplication problem comes from Markovian models of phylogenetic trees (see for example [9, Chapter 7]). In this setting the leaves are the taxa (for example, the DNA strands for known strains of some virus such as COVID), and the internal nodes represent conjectured historic ancestors of the leaf taxa. The phylogenetic tree T is thus a conjectured explanation of the evolutionary history of the leaf taxa. The matrices represent transition probabilities for mutation of a taxon in particular state to a taxon in some other state over some period of time. Multiplying the matrices on a root-to-leaf path results in an aggregate transition probability from an initial taxon state to a final leaf taxon state. This can then be used in a variety of ways, for example to find the

■ **Figure 1** Two example trees.

initial taxon state that most likely resulted in the leaf taxa states, or for determining the likelihood that T would result in the known leaf taxa given an initial distribution of states. Such applications motivate the consideration of the Matrix Tree Multiplication problem. Additionally, we are primarily interested because we believe that the problem is an interesting and natural generalization of a known classical algorithmic problem.

Another motivation for the Matrix Tree Multiplication problem comes from automatic differentiation (AD) [5, 1], which is widely used today in machine learning [1]. In AD, we are given a differentiable multivariate function $f : \mathbb{R}^p \rightarrow \mathbb{R}^q$ for some p and q and our target is to compute the derivative of each of the q outputs with respect to each of the p inputs. Those derivatives can be arranged together in a $(q \times p)$ Jacobian matrix of f . The function f is typically represented as a computer program or a computation graph G which is a DAG where vertices and directed edges represent variables and elementary functions being applied to those variables. Now consider the special case where G has a tree structure $T = (V, E)$ where each vertex v corresponds to a set of d_v variables for some number d_v and each directed edge (u, v) corresponds to a multivariate function $f_{u,v} : \mathbb{R}^{d_u} \rightarrow \mathbb{R}^{d_v}$. Let $M_{u,v}$ be the transpose of the Jacobian matrix of $f_{u,v}$. Let r be the root of the tree and L the set of leaves. Thanks to the (multivariate) chain rule [5], the problem of computing the derivatives of the root's variables with respect to the variables of each leaf reduces to computing the multiplication of the matrices $M_{u,v}$ along each leaf-to-root path, hence to an instance of Matrix Tree Multiplication.

The standard textbook dynamic programming algorithm for the Matrix Chain Multiplication problem computes a parenthesization that results in the minimum number of scalar multiplications in time $O(n^3)$. This optimal parenthesization can be computed by a significantly more complicated algorithm that runs in time $O(n \log n)$ [7, 8]. It seems quite challenging to extend these approaches to the Matrix Tree Multiplication problem, even on very simple instances. For example, we do not know how to compute the optimal number of scalar multiplications in polynomial time even in the case that T has only 2 leaves. This is because it's not clear if there are subproblems the optimum solutions to which lead to that to the original problem.

Thus, we consider approximation algorithms. First, let us review what is known in terms of approximation algorithms for Matrix Chain Multiplication. [3] and [7] cite [2] as giving a 2-approximation algorithm for the Matrix Chain Multiplication problem.¹ A 1.25 approximation algorithm was later given in [3], and finally a 1.15 approximation algorithm was given in [6]. In each case an optimal parenthesization can be computed in linear or nearly linear time.

¹ [2] is an IBM technical report that does not seem to be available on the web, and the IBM library is closed during the COVID outbreak.

6:4 Matrix Tree Multiplication

Our main result is a linear-time 15-approximation algorithm, that we call the Cut Contraction algorithm, for the Matrix Tree Multiplication problem.

The rest of the paper is organized as follows. Section 2 gives a technical overview of the algorithm design and analysis. Section 3 introduces some additional notation and terminology that we will use. Section 4 describes the multiplications performed Cut Contraction algorithm (ignoring implementation details). Section 5 analyzes the approximation ratio for the Cut Contraction algorithm. Section 4.3 briefly discusses how to implement the Cut Contraction algorithm to get a linear-time algorithm that can output a parenthesization for each root to leaf path that has approximation ratio at most 15.

2 Technical Overview

To build some intuition, let us begin by giving a greedy 2-approximation algorithm for Matrix Chain Multiplication (which is presumably the algorithm given in [2]). Assume the vertices are $1, 2, \dots, n$. Let $m = \arg \min_i d_i$ be the index of the minimum dimension. If you think of the chain as a path graph, then d_m is the min vertex cut. Intuitively the algorithm multiplies the min-cut out to the end. So the algorithm first computes the matrix products $M_{m-i,m} = M_{m-i,m-i+1}M_{m-i+1,m}$ for $i = [2, m-1]$, $M_{m,m+i} = M_{m,m+i-1}M_{m+i-1,m+i}$ for $i = [2, n-m]$, and then finally computes $M_{1,n}$ by multiplying $M_{1,m}$ by $M_{m,n}$. This algorithm uses

$$d_1 d_n d_m + \sum_{i=1}^{m-2} d_i d_{i+1} d_m + \sum_{i=m+1}^{n-1} d_i d_{i+1} d_m$$

scalar multiplications. Observe that in any feasible solution it must be the case that for each $i \notin [m-1, m]$, the cost of the matrix multiplication that involves $M_{i,i+1}$ is at least $d_i d_{i+1} d_m$. Thus, a lower bound of the cost of optimal, that we call the edge cut lower bound, is:

$$\frac{d_1 d_n d_m + \sum_{i=1}^{m-2} d_i d_{i+1} d_m + \sum_{i=m+1}^{n-1} d_i d_{i+1} d_m}{2}$$

The factor of two comes from the fact that each matrix multiplication involves two matrices. Note that the upper bound on the cost of the algorithm is then twice this edge cut lower bound. Therefore, intuitively the edge cut lower bound assumes every edge/matrix gets multiplied by its preferred dimension, and this algorithm gives every edge its preference.

As a first step toward generalizing the algorithmic design to trees, we develop three cut based lower bounds for trees. The first lower bound is what we call the edge cut lower bound. Roughly speaking, the edge cut lower bound is

$$\sum_{(u,v) \in E} d_u d_v \alpha(u,v)/2$$

where $\alpha(u,v)$ is the minimum aggregate dimension of a cut that separates the edge (u,v) from either the root or the leaves. This edge cut lower bound assumes every edge/matrix gets multiplied by its preferred dimensions. The second lower bound is what we call the root-leaf lower bound. Roughly speaking, the root-leaf lower bound is

$$\sum_{\ell \in L} d_r d_\ell \beta(\ell)$$

where L is the set of leaves and $\beta(\ell)$ is the minimum dimension on the path from r to ℓ , excluding the endpoints. The final lower bound is what we call the vertex cut lower bound.

Roughly speaking, the vertex cut lower bound is

$$\sum_{v \in V} d_v \gamma(v)$$

where $\gamma(v)$ is the product of the min-cut separating v from the root and the aggregate dimensions of the min-cut separating v from the leaves.

With those cut lower bounds in hand, the natural path forward would be to design an algorithm in such a way that one could analyze its approximation ratio by comparing to these cut lower bounds. However, there are instances such that no matrix multiplication can be charged to the cut lower bounds (at least in a natural way). Further, there are instances where these cut lower bounds are too loose in aggregate and are more than a constant factor less than optimal. One such example is when T is a complete balanced binary tree where the dimension of the root is n , the dimension for vertices of height $h \in [0, \frac{\lg n}{2}]$ is 2^h , and the dimension of the rest of the vertices are \sqrt{n} . For this instance, all the cut lower bounds are $O(n^2)$, but the optimal solution has cost $\Theta(n^{5/2})$.

Our algorithm for Matrix Tree Multiplication first “reduces” the tree by performing all the matrix multiplications that can naturally be charged to the cut lower bounds. Roughly speaking the multiplications that can not be charged to these cut lower bounds are those in which the middle dimension d_v corresponds to a vertex v that is itself the min-cut of T_v , the subtree of T rooted at v . Thus, in the resulting reduced tree R , every node is the min-cut of its own subtree. Further it is relatively straight-forward to also ensure that the dimensions of the vertices on any root-to-leaf path in the reduced tree R form a geometrically decreasing sequence. Our algorithm then performs the multiplications on the reduced tree R in top-down order. We show that the above-mentioned properties of the reduced tree R are sufficient to allow us to use a charging argument to directly bound the cost of these top-down multiplications by a constant factor times the cost of any arbitrary feasible solution for T . Here we directly charge to the optimal and not the lower bounds.

3 Notation and Terminology

We use r to denote the root, and T_v to denote the subtree rooted at vertex v . For any vertex v and any sets of vertices A , let $\Pi_v(A)$ denote the set of vertices in A that are descendant of v . Given a set A , we denote the collective dimensions of the vertices in A by $W(A)$, that is $W(A) = \sum_{x \in A} d_x$.

We use $v \prec u$ to denote that v is a strict ancestor of u in T . We write \preceq to denote that v is an ancestor of u and also u could equal v . Given a vertex v of T , we call a collection C of vertices is a *cut* in T_v if the removal of the vertices in C leaves no remaining v to leaf path in T_v , and there are no two vertices u and v in C such that $v \prec u$. Given a vertex v of T , we call a cut C in T_v the *min-cut* of T_v if its vertices have the minimum cumulative dimensions among all cuts; that is $C = \arg \min_{C' \in \mathcal{C}} \sum_{v \in C'} d_v$.

4 The Cut Contraction Algorithm Description

Our Cut Contraction algorithm first partitions the tree T into various components. This is described in Subsection 4.1. An algorithm, which we call Reduce, then performs matrix multiplications that can be charged to the cut lower bounds. This is described in Subsection 4.2. Finally the Top-Down algorithm, described in the introduction, is applied to the resulting reduced tree R .

4.1 Classifying Vertices in the Tree

We explain how the vertices of T are classified by the algorithm before any matrix multiplications are performed. The first cut $C_1 = \mathcal{C}(r)$ is the min cut of T . To compute C_{i+1} , the algorithm iteratively considers the non-leaf vertices $u \in C_i$, and then considers all paths P from u to every leaf ℓ in T_u . Let v be the vertex with the least depth (closest to u) on P such that $d_v < d_u/2$. We call the vertex v a *checkpoint* vertex. If v does not exist then the leaf ℓ is included in C_{i+1} . If v exists then min-cut of the subtree T_v is added to C_{i+1} . Note that the min cut of T_v can be v itself.

Let D_i^v be the vertices between a non-leaf vertex $v \in C_i$ and the descendants of v in C_{i+1} including v and the descendants. That is, $D_i^v = \{u : v \preceq u \text{ and } \exists x \in C_{i+1} u \preceq x\}$. U_i^v are the vertices in D_i^v that prefer v over the cut C_{i+1} and S_i^v are the vertices that prefer C_{i+1} . Formally, $U_i^v = \{u : u \in D_i^v \text{ and } d_v \leq \sum_{w \in \Pi_u(C_{i+1})} d_w\}$ and $S_i^v = D_i^v \setminus U_i^v$. Finally $D_i = \cup_{v \in C_i} D_i^v$ are the level i intermediate vertices, $U_i = \cup_{v \in C_i} U_i^v$ are the level i upper vertices and $S_i = \cup_{v \in C_i} S_i^v$ are the level i lower vertices.

► **Observation 1.** For all vertices $v \in C_i$, the vertices in U_i^v is a connected component of T that includes v .

4.2 The Reduce Algorithm Description

Initially for every path $r = u_1, u_2, \dots, u_k$ from r to every vertex $u_k \in C_1$ of length at least two hops the algorithm computes the matrix products $M_{u_j, u_k} = M_{u_j, u_{j+1}} M_{u_{j+1}, u_k}$, for $j \in [1, k-2]$.

Next the algorithm iteratively performs matrix multiplication on matrices between C_i and C_{i+1} for $i = 1, 2, \dots$. To multiply matrices between C_i and C_{i+1} the algorithm iteratively considers vertices $v \in C_i$. The algorithm next iteratively considers vertices $u \in \Pi_v(C_{i+1})$. Let $v = u_1, u_2, \dots, u_k$ be the path from v to u . If $k \geq 3$ the algorithm then multiplies the matrices on this path in manner that we now describe (otherwise the algorithm does nothing on this path). Let m be minimum such u_{m+1} is not in U_i^v . Note that it could be that all of u_2, \dots, u_k are in S_i^v and thus $m = 1$, or all of u_1, \dots, u_k are U_i^v and thus $m = k$. If $m \geq 2$ the algorithm multiplies the matrices in U_i^v in top-down order. That is, it computes the matrix products $M_{v, u_j} = M_{v, u_{j-1}} M_{u_{j-1}, u_j}$ for $j \in [2, m]$. If $k - m \geq 2$ the algorithm multiplies the matrices in S_i^v in bottom-up order. That is, the algorithm computes the matrix products $M_{u_{k-j}, u_k} = M_{u_{k-j}, u_{k-j+1}} M_{u_{k-j+1}, u_k}$ for $j \in [2, k - m]$. Finally, if $2 \leq m \leq k - 1$ the algorithm computes the matrix product $M_{v, u_k} = M_{v, u_m} M_{u_m, u_k}$. Let the resulting tree be R .

4.3 Linear Time Implementation

Here we sketch the key steps to make the algorithm run in linear time. To find the min-cuts of *every* subtree, the algorithm can start from the leaves and make them the min-cut of their subtree. Recursively in a bottom up fashion the algorithm can find the minimum cut of all the subtrees. For each vertex, the algorithm compares its dimension with the summation of the min-cuts of its children.

Once this is known, C_1 can be found in linear time. In order to find the checkpoints and the next cuts, we only need to perform a depth first search over the tree. Similarly, finding the sets U_i^v and S_i^v can be done by a depth first search over the vertices of the tree. After this step, the multiplications are well defined.

5 Cut Contraction Approximation Analysis

In subsection 5.1 we state and prove three cut based lower bounds on optimal. In subsection 5.2 we prove some structural properties of the classification of vertices. In subsection 5.3 we analyze the Reduce algorithm. Finally in subsection 5.4 we analyze the Top-Down algorithm on the reduced tree R .

5.1 The Cut Lower Bounds

Let $\mathcal{C}(v)$ be a min-cut of the subtree T_v , and let $\mathcal{C}^-(v)$ be the minimum cut of T_v subject to the constraint that the cut does not contain v . Let $h(v)$ be the vertex x with the minimum dimension subject to the constraint that $r \preceq x \prec v$. For an edge $(u, v) \in E$ define $\alpha(u, v)$ as follows:

$$\alpha(u, v) = \begin{cases} d_{h(u)} & \text{if } u \neq r \text{ and } v \in L \\ W(\mathcal{C}^-(v)) & \text{if } u = r \text{ and } v \notin L \\ \min(d_{h(u)}, W(\mathcal{C}^-(v))) & \text{otherwise} \end{cases}$$

For a leaf $\ell \in L$ define $\beta(\ell)$ as follows:

$$\beta(\ell) = \min_{u \text{ s.t. } r \prec u \prec \ell} d_u$$

For a vertex $v \in V$ that is neither the root nor a leaf, define $\gamma(v)$ as follows

$$\gamma(v) = d_{h(v)} \cdot W(\mathcal{C}^-(v))$$

► **Lemma 2** (Edge Cut Lower Bound).

$$\sum_{(u,v) \in E} d_u d_v \alpha(u, v) \leq 2 \cdot \text{Opt}$$

Proof. Let $P_{u,v}$ be the set of all root-to-leaf paths passing an edge (u, v) . Let $A_{(u,v)}$ be the set of vertices q for which, the optimum algorithm has made a multiplication of cost $d_u d_v d_q$. That is, the algorithm has performed either the multiplication $M_{u,v} M_{v,q}$ or $M_{q,u} M_{u,v}$ and let $O_{u,v}$ be the total cost of these multiplications. That is, $O_{u,v} = \sum_{q \in A_{(u,v)}} d_u d_v d_q$.

In any feasible solution, for every path p in $P_{u,v}$, there should be one vertex in p that is in $A_{u,v}$. That is because, in order for the algorithm to find the final product of the matrices in p , at some point, it must multiply $M_{u,v}$ to some other matrix in p . Therefore, if no ancestor of u is in $A_{u,v}$, we know $A_{u,v}$ must be a cut (or its superset) in T_v that is not equal to $\{v\}$. If there exists a vertex $x \in A_{u,v}$ such that $x \prec u$, then we know $O_{u,v} \geq d_x d_u d_v \geq d_{h(u)} d_u d_v$. Otherwise, as $A_{u,v}$ is a cut in T_v , we have $W(A_{u,v}) \geq W(\mathcal{C}^-(v))$; thus, $O_{u,v} \geq W(A_{u,v}) d_u d_v \geq W(\mathcal{C}^-(v)) d_u d_v$. Therefore, in either case, $O_{u,v} \geq d_u d_v \alpha(u, v)$. Summing over all edges (u, v) , we get the following value for the total cost of the multiplications involving the matrix of an edge in T :

$$2\text{Opt} \geq \sum_{(u,v) \in E} O_{u,v} \geq \sum_{(u,v) \in E} d_u d_v \alpha(u, v)$$

We get the factor of 2 because each matrix multiplication only involves two matrices and therefore is counted at most twice. ◀

► **Lemma 3** (Root-Leaf Cut Lower Bound).

$$\sum_{\ell \in L} d_r d_\ell \beta(\ell) \leq \text{Opt}$$

Proof. Since the optimal solution is feasible, it must perform a multiplication of the form $M_{r,u}M_{u,\ell}$ for each leaf ℓ in order to compute $M_{r,\ell}$, which must cost at least $d_r d_\ell \beta(\ell)$, and cannot be shared among different leaves. ◀

► **Lemma 4** (Vertex Cut Lower Bound). *Let V' be the set of vertices in T that are neither a root nor a leaf. Then,*

$$\sum_{v \in V'} d_v \gamma(v) \leq \text{Opt}$$

Proof. Fix an edge (u, v) and consider all the root to leaf paths that pass through (u, v) . Any feasible solution needs to compute the final product of the matrices lying on all of these paths. We first prove the following claim: for any root-to-leaf path P that contains the edge (u, v) there exists a multiplication of the form $M_{a,u}M_{u,b}$ that the feasible solution computes where a and b are two vertices in P and $a \prec u \prec b$.

We can find this multiplication by the following procedure. We first consider the last multiplication that is performed on the path between r and a leaf node ℓ . Let $M_{r,w}M_{w,\ell}$, be that multiplication. If $w = u$, then we have found the multiplication. If $w \prec u$, then we recurse on the last multiplication that the algorithm has performed to calculate $M_{u,\ell}$ until we find a multiplication of the form $M_{a,u}M_{u,b}$. Lastly, if $u \prec w$, then we recurse on the last multiplication that the algorithm has performed to compute $M_{r,u}$.

Now, for an edge (u, v) , let $A_{(u,v)}$ be the set of all pairs of vertices (a, b) such that the algorithm has computed $M_{a,u}M_{u,b}$. From the above claim we can conclude that the set $B_{(u,v)} = \{b : (a, b) \in A_{(u,v)}\}$ is a cut in the subtree T_v , because for every root-to-leaf path that has the edge (u, v) , there exists a pair of (a, b) in $A_{(u,v)}$ that is on that path and $v \prec b$. Then, since these sets of multiplications are disjoint with respect to different edges (u, v) , we can get the following lower bound:

$$\text{Opt} \geq \sum_{(u,v) \in E} \sum_{(a,b) \in A_{(u,v)}} d_a d_b d_u \geq \sum_{(u,v) \in E} d_{h(u)} d_u \sum_{b \in B_{(u,v)}} d_b \geq \sum_{(u,v) \in E} d_{h(u)} d_u W(\mathcal{C}(v)).$$

Rewriting the last summation, by summing over all vertices u and then all the edges (u, v) connected to u , and the lemma follows:

$$\text{Opt} \geq \sum_{(u,v) \in E} d_{h(u)} d_u W(\mathcal{C}(v)) \geq \sum_{u \in V} d_u \gamma(u). \quad \blacktriangleleft$$

5.2 Structural Properties

Lemma 5 states that vertices between v and the cut $\mathcal{C}(v)$ inherit their min-cut from $\mathcal{C}(v)$. Lemma 6 lower bounds the size of min-cuts $\mathcal{C}(u)$ for vertices $u \in D_i$. Lemma 7 observes that the dimension of every vertex in a set C_i must be smaller than the dimension of any ancestor. Lemma 8 lower bounds the cut size for an edge $(u, w) \in D_i$. Lemma 9 observes that nodes in R are min-cuts of their subtree. Lemma 10 observes that the dimensions are geometrically decreasing on root to leaf paths in the reduced tree R .

► **Lemma 5.** *Let u be a descendant of v in T such that u also has a descendant in $\mathcal{C}(v)$. Then $\Pi_u(\mathcal{C}(v))$ is a min-cut in T_u .*

Proof. We prove the claim by contradiction. Let us assume $\Pi_u(\mathcal{C}(v))$ is not a min-cut of T_u . Note that there is no vertex $x \in \mathcal{C}(v)$ such that $x \preceq u$; because, if that was the case, we could remove any vertex in $\mathcal{C}(v)$ that is descendant of u and obtain a smaller cut. Therefore, since every v to leaf path including the ones passing through u have a vertex in $\mathcal{C}(v)$, we can conclude that $\Pi_u(\mathcal{C}(v))$ is a cut in T_u , and since we have assumed that it is not a min-cut, we can conclude $W(\mathcal{C}(u)) < W(\Pi_u(\mathcal{C}(v)))$.

Now we create a new cut in T_v by removing the vertices in $\Pi_u(\mathcal{C}(v))$ from $\mathcal{C}(v)$ and adding $\mathcal{C}(u)$. The weight of the new cut is $W(\mathcal{C}(v)) - W(\Pi_u(\mathcal{C}(v))) + W(\mathcal{C}(u))$ which is smaller than $W(\mathcal{C}(v))$ and that is a contradiction with the fact that $W(\mathcal{C}(v))$ was the min-cut of T_v . ◀

► **Lemma 6.** *For all nonleaf vertices $v \in C_i$, and for all vertices $u \in D_i^v$ it must be the case that $W(\mathcal{C}(u)) \geq \min(d_v/2, W(\Pi_u(C_{i+1})))$.*

Proof. If there is a vertex x in $\mathcal{C}(u)$ such that $d_x \geq d_v/2$ then the proof is trivial. Now we assume that for all vertices $x \in \mathcal{C}(u)$, we have $d_x < d_v/2$.

We divide the proof into two cases. In the first case assume that there is a checkpoint vertex t such that $v \prec t \preceq u$. Then by definition, $\Pi_t(C_{i+1})$ is a min-cut of T_t . Furthermore, since t is an ancestor of u , we have $\Pi_u(\Pi_t(C_{i+1})) = \Pi_u(C_{i+1})$. Then using Lemma 5, we can conclude $\Pi_u(C_{i+1})$ is a min-cut of T_u ; therefore, $W(\mathcal{C}(u)) = W(\Pi_u(C_{i+1}))$.

In the second case, assume that there is no checkpoint between v and u . Then for all the vertices $x \in \mathcal{C}(u)$, there exists a checkpoint vertex t such that $u \prec t \preceq x$; that is because $d_x \leq d_v/2$ and there is no checkpoint above v . Let T denote all such checkpoints, then T is a cut in T_u and a cut between u and $\mathcal{C}(u)$. Therefore, $\bigcup_{t \in T} \Pi_t(\mathcal{C}(u)) = \mathcal{C}(u)$, and based on the definition of C_{i+1} and the fact that T is a cut in T_u , we have $\Pi_u(C_{i+1}) = \bigcup_{t \in T} \Pi_t(C_{i+1}) = \bigcup_{t \in T} \mathcal{C}(t)$.

For any checkpoint in t , using Lemma 5, we know $\Pi_t(\mathcal{C}(u))$ is a min-cut of T_t , and as a result $W(\Pi_t(\mathcal{C}(u))) = W(\mathcal{C}(t)) = W(\Pi_t(C_{i+1}))$. Summing over all vertices in T we get $W(\mathcal{C}(u)) = W(\Pi_u(C_{i+1}))$. ◀

► **Lemma 7.** *For any nonleaf vertex $v \in C_i$ and for all ancestors u of v , it must be the case that $d_v \leq d_u$.*

Proof. We use induction on i . For the base case of $i = 1$, we know C_1 is the min-cut of T , and if there was a vertex u such that $u \prec v$ and $d_u < d_v$, we could create a smaller cut by replacing v with u in C_1 .

For $i > 1$, let q be the ancestor of v in C_{i-1} . We show that d_v is smaller than d_u for all vertices u where $q \preceq u \prec v$. Then by induction, it will be smaller than all of its ancestors because q is a non leaf vertex in C_{i-1} . Since v is not a leaf, there exists a checkpoint vertex t between v and q . Then as v is in $\mathcal{C}(t)$, for all u where $t \preceq u \preceq v$, we have $d_v \leq d_u$. Furthermore, based on the definition of a checkpoint, $d_t \leq d_q/2$ and for all vertices w where $q \preceq w \prec t$, we have $d_w > d_q/2$; therefore, $d_v \leq d_t \leq d_w$. ◀

► **Lemma 8.** *For all nonleaf vertices $v \in C_i$, and for all vertices edges (u, w) in T , with both endpoints in D_i^v we have $\alpha(u, w) \geq \min(d_v/2, W(\Pi_w(C_{i+1})))$.*

Proof. First, for every edge (u, w) with both ends in D_i^v , we prove

$$d_{h(u)} \geq \min(d_v/2, W(\Pi_w(C_{i+1}))). \quad (1)$$

6:10 Matrix Tree Multiplication

If there exists a checkpoint t such that $v \prec t \preceq u$, then for every vertex q such that $t \preceq q \preceq w$, we have $d_q \geq W(\mathcal{C}(w))$. This is because thanks to the definition of C_{i+1} and the fact that $q \preceq w$ we have $\Pi_t(C_{i+1}) = \mathcal{C}(t)$ and $\Pi_w(C_{i+1}) \subseteq \Pi_q(C_{i+1})$, and furthermore using Lemma 5, we know $\Pi_q(C_{i+1})$ is a min-cut of T_q and $\Pi_w(C_{i+1})$ is a min-cut of T_w . Therefore,

$$d_q \geq W(\mathcal{C}(q)) = W(\Pi_q(C_{i+1})) \geq W(\Pi_w(C_{i+1})) = W(\mathcal{C}(w)).$$

Moreover, for every vertex x where $v \preceq x \prec t$, we know $d_x \geq d_t$; therefore, we have $d_x \geq W(\mathcal{C}(w))$. Then, using Lemma 7, we can conclude $d_{h(u)} \geq W(\mathcal{C}(w)) = W(\Pi_w(C_{i+1}))$.

If there exists no checkpoint t between v and u , then based on the definition of a checkpoint and Lemma 7, we have $d_{h(u)} \geq d_v/2$. Thus, we have shown Eqn. (1).

Now, for every edge (u, w) with both ends in D_i^g , we prove

$$W(\mathcal{C}^-(w)) \geq \min(d_v/2, W(\Pi_u(C_{i+1}))). \quad (2)$$

First, note that $W(\mathcal{C}^-(w)) \geq W(\mathcal{C}(w))$ because $\mathcal{C}(w)$ is the minimum over all cuts including the cut $\{w\}$ whereas $\mathcal{C}^-(w) \neq \{w\}$. Furthermore, note that it is either the case that there is a checkpoint between v and every vertex in $\mathcal{C}(w)$ which implies $\mathcal{C}(w) = \Pi_w(C_{i+1})$, or $\mathcal{C}(w)$ has a vertex with dimension larger than $d_v/2$. Therefore, we have

$$W(\mathcal{C}^-(w)) \geq W(\mathcal{C}(w)) \geq \min(d_v/2, W(\Pi_w(C_{i+1}))).$$

Since $\alpha(u, w) = \min(d_{h(u)}, W(\mathcal{C}^-(w)))$, Eqn. (1) and (2) give the lemma. \blacktriangleleft

► Lemma 9. *Every vertex v in R that is not r , is the min-cut of both T_v and R_v .*

Proof. The fact that v is a min-cut of T_v follows from the definition of the cuts C_i and the definition of the Reduce algorithm. The fact that v is a min-cut of R_v follows from the fact that min-cuts of R_v are feasible cuts for T_v . \blacktriangleleft

► Lemma 10. *For every edge $(u, v) \in R$ such that $u \neq r$ and v is not a leaf, it must be the case that $d_u \geq 2d_v$.*

Proof. This is a direct consequence of the definition of the C_i 's. \blacktriangleleft

5.3 Reduce Analysis

► Lemma 11. *The cost incurred by the Reduce algorithm is at most $8 \cdot \text{Opt}$.*

Proof. We divide the multiplications into 4 categories and analyse their costs separately. We will refer to these costs as categories.

1. The multiplications that involve the matrices between the root and the vertices in C_1 .
2. The multiplications of the matrices with both ends in U_i^v for some $v \in C_i$.
3. The multiplications involving a matrix $M_{u,w}$ where (u, w) is an edge with w being in $S_i^v \cup \Pi_v(C_{i+1})$ for some $v \in C_i$.
4. The multiplications of the form $M_{v,m}M_{m,u}$ where $m \in U_i^v$ and $u \in \Pi_v(C_{i+1})$.

Note that the above categories cover all the multiplications done by the Reduce algorithm. We use the lower bound in Lemma 2, and show that the cost of each multiplication in the first three categories is a constant factor of $d_u d_v \alpha(u, v)$ for some edge (u, v) and no edge is charged more than once. Then we use the lower bound in Lemma 4 to bound the cost of the multiplications in the fourth category.

Category 1: Every matrix multiplication in this category has the form $M_{p(u)u} \cdot M_{u,v}$ where v is a vertex in C_1 and $M_{u,v}$ is the result of the product of the matrices in path between u and v for some vertex $v \in C_1$. Therefore, the cost of all multiplications in this category is

$$\sum_{(u,v) \in E_1} \sum_{x \in \Pi_v(C_1)} d_u d_v d_x,$$

where E_1 is the set of edges between the root and C_1 . This is because any matrix $M_{u,v}$ will be in one multiplication per each vertex of $\Pi_v(C_1)$. Note that since C_1 is a min-cut, for any subset B of C_1 , the value $\sum_{x \in B} d_x$ is smaller than the dimension of any of their common ancestors (otherwise, we could have got a smaller min-cut by replacing them with that ancestor). Therefore,

$$\sum_{(u,v) \in E_1} \sum_{x \in \Pi_v(C_1)} d_u d_v d_x = \sum_{(u,v) \in E_1} d_u d_v \alpha(u, v)$$

Category 2: Fix an integer i and a vertex $v \in C_i$. For every edge (u, w) with both ends in $U_i^v \setminus \{v\}$, the algorithm performs one multiplication of form $M_{v,u} M_{u,w}$ in top-down multiplication of U_i^v , and the cost for this multiplication is $d_v d_u d_w$. Using Lemma 8 and the definition of U_i^v , we know $\alpha(u, w) \geq \min(d_v/2, W(\Pi_w(C_{i+1}))) = d_v/2$. As a result the total cost of the multiplications in this category is bounded by

$$\sum_i \sum_{v \in C_i} \sum_{(u,w) \in E(U_i^v)} d_v d_u d_w \leq \sum_i \sum_{v \in C_i} \sum_{(u,w) \in E_2(v)} d_u d_w \alpha(u, w),$$

where $E_2(v)$ is the set of edges with both ends in U_i^v .

Category 3: Let u be a vertex in C_{i+1} and v be its ancestor in C_i . Then the path between u and v can be divided into two sections such that the vertices of the upper section are all in $U_i^v \cup \{v\}$ and the vertices of the lower section are in $S_i^v \cup \{u\}$. Then on the path between u and v , for every edge (w, t) on this path for which t is in $S_i^v \setminus \{u\}$, the algorithm performs the multiplication of form $M_{w,t} M_{t,u}$. Then if we sum over different vertices $u \in \Pi_t(C_{i+1})$, the total cost of the multiplications in this category that involve $M_{w,t}$ is $d_w d_t W(\Pi_t(C_{i+1}))$. Using the Lemma 8 and the definition of S_i^v , we have

$$2\alpha(w, t) \geq \min(d_v, 2W(\Pi_t(C_{i+1}))) \geq W(\Pi_t(C_{i+1})).$$

Therefore, the total cost of the multiplications in this category can be bounded by

$$\sum_i \sum_{v \in C_i} \sum_{(w,t) \in E_3(v)} d_w d_t W(\Pi_t(C_{i+1})) \leq \sum_i \sum_{v \in C_i} \sum_{(w,t) \in E_3(v)} 2d_w d_t \alpha(w, t),$$

where $E_3(v)$ is the set of edges (w, t) where t is in S_i^v .

Since the edges that are above C_1 , the edges that have both ends in $\bigcup_i \bigcup_{v \in C_i} U_i^v$, and the edges (u, w) with w being in $\bigcup_i \bigcup_{v \in C_i} S_i^v$ are disjoint, we have not double charged any edge. Therefore, using Lemma 2 we can conclude that the total cost of the multiplications in categories 1, 2, and 3 is at most 4Opt .

Category 4: Let u be a vertex in C_{i+1} and v be its ancestor in C_i . Let (q, w) be an edge on the path between v and u such that $q \in U_i^v$ and $w \in S_i^v$. The algorithm may make one multiplication of the form $M_{v,q} M_{q,u}$ for this path. Therefore, summing over all vertices $u \in \Pi_v(C_{i+1})$, we can derive the following total cost of all multiplications of this form:

6:12 Matrix Tree Multiplication

$$\sum_i \sum_{v \in C_i} \sum_{(q,w) \in E_4(v)} d_v d_q W(\Pi_w(C_{i+1}))$$

in which $E_4(v)$ is the set of edges with one end in U_v^i and one end in S_i^v .

For any edge $(q, w) \in E_4(v)$, using Lemma 6 and the fact that $w \in S_i^v$, we have

$$2W(\mathcal{C}(w)) \geq \min(d_v, 2W(\Pi_w(C_{i+1}))) \geq W(\Pi_w(C_{i+1})).$$

Furthermore, we know no checkpoint can be in U_v^i , because for any checkpoint t we have

$$W(\Pi_t(C_{i+1})) = W(\mathcal{C}(t)) \leq d_t \leq d_v/2.$$

Therefore, using Lemma 7 and the fact that no checkpoint is in U_v^i , for any edge $(q, w) \in E_4(v)$ we have $h(q) \geq d_v/2$, and we get the following upperbound on the cost of the multiplications in this category:

$$\sum_i \sum_{v \in C_i} \sum_{(q,w) \in E_4(v)} d_v d_q W(\Pi_w(C_{i+1})) \leq \sum_i \sum_{v \in C_i} \sum_{(q,w) \in E_4(v)} 4d_q d_{h(q)} W(\mathcal{C}(w)).$$

Then using Lemma 4, and taking the summation over all the edges that are not connected to the root we will get:

$$\sum_i \sum_{v \in C_i} \sum_{(q,w) \in E_4(v)} 4d_q d_{h(q)} W(\mathcal{C}(w)) \leq 4 \sum_{u \in V} d_u \gamma(u) \leq 4\text{Opt}. \quad \blacktriangleleft$$

5.4 Top-Down Analysis

Our analysis of the Top-Down algorithm on the reduced tree R is based on a charging argument. A few of the Top-Down multiplications will be charged to the root-leaf cut lower bound. However, most of the Top-Down matrix multiplications will be directly charged to various matrix multiplications in Opt. There are three different possible ways that the Top-Down matrix multiplications can be charged: leaf-charge, low-charge, and high-charge.

The charging is done independently for each root-to-leaf path P . Iteratively consider a fixed root-to-leaf path P in T ending in a leaf $\ell \in L$. Let $M_{r,u}M_{u,v}$ be a Top-Down matrix multiplication on P that has not yet leaf-charged or low-charged any multiplication in optimal. If there is no checkpoint between u and v in T , note that we must have $v = \ell$ and the root-leaf cut lower bound is charged. We call this a leaf-charge. Otherwise, assume $u \in C_i$, $v \in C_{i+1}$ and note that there must exist a checkpoint t strictly between u and v on P (and thus t can not be either the root r nor a child of the root r in T). Let $M_{r,a}M_{a,b}$ be an arbitrary matrix multiplication in the optimal solution such that $r \prec a \prec t \preceq b \preceq \ell$. We will show such a matrix multiplication must exist in the optimal solution in Lemma 12. If $b \preceq v$ then the optimal multiplication $M_{r,a}M_{a,b}$ is charged $d_r d_u d_v$, the cost of this Top-Down multiplication. Call this a low-charge. If $v \prec b$ then the optimal multiplication $M_{r,a}M_{a,b}$ is charged $d_r d_u d_b$, which is a fraction of the cost of this Top-Down multiplication. Call this a high-charge.

► **Lemma 12.** *For each root-to-leaf path P in T and for each vertex t on P that is neither the root nor a child of the root, at least one multiplication $M_{r,a}M_{a,b}$ is in the optimal solution for T such that $r \prec a \prec t \preceq b \preceq \ell$ where ℓ is the leaf in P .*

Proof. Let $x_1 \prec \dots \prec x_k = \ell$ be all the vertices in P such that the optimal solution contains a multiplication of the form $M_{r,x_i}M_{x_i,x_{i+1}}$. Note that it must be the case $k \geq 2$ since the optimal solution is feasible and it needs to compute M_{r,x_k} . The claim is there exists $j \in [1, k-1]$ such that $x_j \preceq t \preceq x_{j+1}$, and one can take $a = x_j$ and $b = x_{j+1}$.

To prove this claim, note that x_1 must be a child of root. This is because, otherwise, the optimal solution needs to perform another multiplication to compute M_{r,x_1} since it uses it in $M_{r,x_1}M_{x_1,x_2}$. Let $M_{r,x_0}M_{x_0,x_1}$ be that multiplication, then x_0 is on P which contradicts with the definition of x_1, \dots, x_k . Therefore, since t is not the root or its children, we have $x_1 \prec t$. Also we know x_k is the leaf and $t \preceq x_k$. Therefore, there exists a $j \in [1, k-1]$ such that $x_j \preceq t \preceq x_{j+1}$. ◀

► **Lemma 13.** *The aggregate amount of root-leaf cut charges is at most twice the root-leaf cut lower bound, and therefore at most $2 \cdot \text{Opt}$.*

Proof. For each leaf ℓ there can be at most one matrix multiplication, say $M_{r,u}M_{u,\ell}$ charged to it. From Lemma 7 and the fact that there is no check point between u and ℓ one can conclude that $\beta(\ell) \leq 2d_u$. ◀

► **Lemma 14.** *Every Top-Down matrix multiplication $M = M_{r,u}M_{u,v}$ charges at least $d_r d_u d_v$ to the multiplications in the optimal solution.*

Proof. If M was charged via a high charge, this is obvious. Otherwise assume M was only charged via low charges. Let $(a_1, b_1), \dots, (a_k, b_k)$ be the collection of multiplications in optimal that M was charged to via low charges. By the feasibility of the optimal solution $\{b_1, \dots, b_k\}$ must be a cut of T_v . Thus by Lemma 9 it must be the case that $\sum_{i=1}^k d_{b_i} \geq d_v$. Thus the aggregate amount of low charges is at least $d_r d_u d_v$. ◀

► **Lemma 15.** *Every matrix multiplication $M_{r,a}M_{a,b}$ in optimal is charged at most $2d_r d_a d_b$ by low charges.*

Proof. Let $M_{r,u}M_{u,v}$ with $u \in C_i$ and $v \in C_{i+1}$ be one of the multiplications of top-down that low-charges $M_{r,a}M_{a,b}$. Then we know there exists a checkpoint t in T such that $u \prec t \preceq v$ and $a \prec t \preceq b \preceq v$. Then the claim is that the only multiplications of top-down that may low-charge the multiplication $M_{r,a}M_{a,b}$ in optimal are the ones of the form $M_{r,u}M_{u,w}$ where $w \in \Pi_b(C_{i+1})$.

To see the reason for the above claim, consider any multiplication $M_{r,p}M_{p,q}$ that can low-charge $M_{r,a}M_{a,b}$. Based on the definition of low-charge, we have $p \in C_j$ is an ancestor of b , and $w \in C_{j+1}$ such that $b \preceq w$. If $j+1 \leq i$, then no vertex in C_{j+1} can be a descendent of u , and therefore, we cannot have $b \preceq w$ because that would imply $u \prec b \preceq w$. Furthermore, we cannot have $j \geq i+1$ because we already know that v is in C_{i+1} and $b \preceq v$; therefore, no vertex in C_j can be an ancestor of b , meaning we cannot have $p \prec b$; because that would mean $p \prec u$. Thus, the only possibility is $j = i$, which means $p = u$. Then the only vertices in C_{i+1} that are descendent of b are by definition $\Pi_b(C_{i+1})$.

Using this claim, we can conclude the maximum amount low-charged to a multiplication $M_{r,a}M_{a,b}$ is $d_r d_u W(\Pi_b(C_{i+1}))$. Note that $a \prec t$, therefore, $d_a > d_u/2$; that is because, all the vertices between t and u have dimensions larger than $d_u/2$, and using Lemma 7, we know the dimension of all the ancestors of u is at least d_u . Furthermore, note that $\Pi_t(C_{i+1})$ is the min-cut of T_t ; therefore, using lemma 5 and the fact that $t \preceq b \preceq v$, we can conclude $W(\Pi_b(C_{i+1})) < d_b$. Therefore, we can get the following upperbound for the total cost lower-charged to a multiplication $M_{r,a}M_{a,b}$ of optimal: $d_r d_u W(\Pi_b(C_{i+1})) \leq 2d_r d_a d_b$. ◀

► **Lemma 16.** *Every matrix multiplication $M_{r,a}M_{a,b}$ in optimal is charged at most $4d_r d_a d_b$ by high-charges.*

Proof. Consider a multiplication $M_{r,u}M_{u,v}$ in top-down that high-charges the multiplication $M_{r,a}M_{a,b}$ in optimal. We have $a \prec t \preceq v \preceq b$ where t is the checkpoint between u and v , and $M_{r,u}M_{u,v}$ high-charges the cost $d_r d_u d_b$. Note that both t and v are on the path between a and b in T . Let $(u_1, u_2), (u_2, u_3), \dots, (u_{k-1}, u_k)$ be the edges in R , for which u_2, \dots, u_k are all on the path between a and b in T , and the checkpoint between u_i, u_{i+1} for all i is also on this path. Using the definition of high-charge, the only multiplications in Top-Down that can high charge $M_{r,a}M_{a,b}$ are the multiplications of the form $M_{r,u_i}M_{u_i,u_{i+1}}$ for $i \in [1, k-1]$. Therefore, the total cost high-charged to $M_{r,a}M_{a,b}$ is at most: $d_r d_b \sum_{i=1}^k d_{u_i}$. Using Lemma 10, we know $d_{u_{i+1}} \leq d_{u_i}/2$. Furthermore, using the definition of the checkpoint and Lemma 7, we have $d_{u_1} \leq 2d_a$ because a is the ancestor of the checkpoint between u_1 and u_2 in T . Therefore, the total cost can be upper bounded as follows: $d_r d_b \sum_{i=1}^k d_{u_i} \leq d_r d_b d_{u_1} \sum_{i=0}^{\infty} 1/2^i \leq 4d_r d_b d_a$ ◀

We now can prove the main theorem.

► **Theorem 17.** *The Cut Contraction Algorithm for the Tree Matrix Multiplication problem is 15 approximate.*

Proof. Using Lemma 11, we can conclude the cost of Reduce multiplications is 8Opt, and using Lemmas 13, 14, 15, and 16, we can conclude the cost of the multiplications performed in TopDown phase is 7Opt which gives us total cost of 15Opt. ◀

6 Conclusions

In this paper we studied a natural extension of the matrix chain problem where multiples chains are overlaid forming a tree. Currently, we do not know if the problem is NP-hard although we believe so. The obvious open question is to show that the problem is indeed NP-hard. Further, we do not know how to obtain a better approximation using any polynomial time algorithms. Improving the approximation ratio would be another interesting direction. Finally, it would be very interesting to study the more general setting where the chains form an arbitrary DAG. The main challenge in such an extension seems to lie in discovering lower bounds different from what we used in this paper.

Abstract

We present an algorithm for constructing a depth-first search tree in planar digraphs; the algorithm can be implemented in the complexity class $AC^1(UL \cap co-UL)$, which is contained in AC^2 . Prior to this (for more than a quarter-century), the fastest uniform deterministic parallel algorithm for this problem was $O(\log^{10} n)$ (corresponding to the complexity class $AC^{10} \subseteq NC^{11}$).

We also consider the problem of computing depth-first search trees in other classes of graphs, and obtain additional new upper bounds.

1 Introduction

Depth-first search trees (DFS trees) constitute one of the most useful items in the algorithm designer's toolkit, and for this reason they are a standard part of the undergraduate algorithmic curriculum around the world. When attention shifted to parallel algorithms in the 1980's, the question arose of whether NC algorithms for DFS trees exist. An early negative result was that the problem of constructing the *lexicographically least* DFS tree in a given digraph is complete for P [20]. But soon thereafter significant advances were made in developing parallel algorithms for DFS trees, culminating in the RNC^7 algorithm of Aggarwal, Anderson, and Kao [1]. This remains the fastest parallel algorithm for the problem of constructing DFS trees in general graphs, in the probabilistic setting, or in the setting of nonuniform circuit complexity. It remains unknown if this problem lies in (deterministic) NC (and we do not solve that problem here).

More is known for various restricted classes of graphs. For directed acyclic graphs (DAGs), the lexicographically-least DFS tree from a given vertex can be computed in AC^1 [10]. (See also [11, 7, 13, 19, 16, 15].) For undirected planar graphs, an AC^1 algorithm for DFS trees was presented by Hagerup [14]. For more general planar directed graphs Kao and Klein presented an AC^{10} algorithm. Kao subsequently presented an AC^5 algorithm for DFS in *strongly connected* planar digraphs. In stating the complexity results for this prior work

in terms of complexity classes (such as AC^1, AC^{10} , etc.), we are ignoring an aspect that was of particular interest to the authors of this earlier work: minimizing the number of processors. This is because our focus is on classifying the complexity of constructing DFS trees in terms of complexity classes. Thus, if we reduce the complexity of a problem from AC^{10} to AC^2 , then we view this as a significant advance, even if the AC^2 algorithm uses many more processors (so long as the number of processors remains bounded by a polynomial). Indeed, our algorithms rely on the logspace algorithm for undirected reachability [21], which does not directly translate into a processor-efficient algorithm. We suspect that our approach can be modified to yield a more processor-efficient AC^3 algorithm, but we leave that for others to investigate.

1.1 Our Contributions

First, we observe that, given a DAG G , computation of a DFS tree in G logspace reduces to the problem of reachability in G . Thus, for general DAGs, computation of a DFS tree lies in NL, and for planar DAGs, the problem lies in $UL \cap \text{co-UL}$ [8, 23]. For classes of graphs where the reachability problem lies in L, so does the computation of DFS trees. One such class of graphs is planar DAGs with a single source (see [2], where this class of graphs is called SMPDs, for **S**ingle-source, **M**ultiple-sink, **P**lanar **D**AGs).

For undirected planar graphs, it was shown in [4] that the approach of Hagerup’s AC^1 DFS algorithm [14] can be adapted in order to show that construction of a DFS tree in a planar *undirected* graph logspace-reduces to computing the distance between two nodes in a planar digraph. Since this latter problem lies in $UL \cap \text{co-UL}$ [24], so does the problem of DFS for planar *undirected* graphs.

Our main contribution in the current paper is to show that a more sophisticated application of the ideas in [14] leads to an $AC^1(UL \cap \text{co-UL})$ algorithm for construction of DFS trees in planar *directed* graphs. (That is, we show DFS trees can be constructed by unbounded fan-in log-depth circuits that have oracle gates for a set in $UL \cap \text{co-UL}$.¹) Since $UL \subseteq NL \subseteq SAC^1 \subseteq AC^1$, the $AC^1(UL \cap \text{co-UL})$ algorithm can be implemented in AC^2 . Thus this is a significant improvement over the best previous parallel algorithm for this problem: the AC^{10} algorithm of [18], which has stood for 28 years.

2 Preliminaries

We assume that the reader is familiar with depth-first search trees (DFS trees).

We further assume that the reader is familiar with the standard complexity classes L, NL and P (see e.g. the text [6]). We will also make frequent reference to the logspace-uniform circuit complexity classes NC^k and AC^k . NC^k is the class of problems for which there is a logspace-uniform family of circuits $\{C_n\}$ consisting of AND, OR, and NOT gates, where the AND and OR gates have fan-in two and each circuit C_n has depth $O(\log^k n)$. (The logspace-uniformity condition implies that each C_n has only $n^{O(1)}$ gates.) AC^k is defined similarly, although the AND and OR gates are allowed unbounded fan-in. An equivalent characterization of AC^k is in terms of concurrent-read concurrent-write PRAMs with running time $O(\log^k n)$, using $n^{O(1)}$ processors. For more background on these circuit complexity classes, see, e.g., the text [26].

¹ An earlier version of this work claimed a stronger upper bound, but there was an error in one of the lemmas in that version [3].

A nondeterministic Turing machine is said to be *unambiguous* if, on every input x , there is at most one accepting computation path. If we consider logspace-bounded nondeterministic Turing machines, then unambiguous machines yield the class UL . A set A is in co-UL if and only if its complement lies in UL .

The construction of DFS trees is most naturally viewed as a *function* that takes a graph G and a vertex v as input, and produces as output an encoding of a DFS tree in G rooted at v . But the complexity classes mentioned above are all defined as sets of *languages*, instead of as sets of *functions*. Since our goal is to place DFS tree construction into the appropriate complexity classes, it is necessary to discuss how the complexity of functions fits into the framework of complexity classes.

When \mathcal{C} is one of $\{\text{L}, \text{P}\}$, it is fairly obvious what is meant by “ f is computable in \mathcal{C} ”; the classes of logspace-computable functions and polynomial-time-computable functions should be familiar to the reader. However, the reader might be less clear as to what is meant by “ f is computable in NL ”. As it turns out, essentially all of the reasonable possibilities are equivalent. Let us denote by FNL the class of functions that are computable in NL ; it is shown in [17] each of the three following conditions is equivalent to “ $f \in \text{FNL}$ ”.

1. f is computed by a logspace machine with an oracle from NL .
2. f is computed by a logspace-uniform NC^1 circuit family with oracle gates for a language in NL .
3. $f(x)$ has length bounded by a polynomial in $|x|$, and the set $\{(x, i, b) : \text{the } i^{\text{th}} \text{ bit of } f(x) \text{ is } b\}$ is in NL .

Rather than use the unfamiliar notation “ FNL ”, we will abuse notation slightly and refer to certain functions as being “computable in NL ”.

The proof of the equivalence above relies on the fact that NL is closed under complement. Thus it is far less clear what it should mean to say that a function is “computable in UL ” since it remains an open question if UL is closed under complement (although it is widely conjectured that $\text{UL} = \text{NL}$) [22, 5]). However the proof from [17] carries over immediately to the class $\text{UL} \cap \text{co-UL}$. That is, the following conditions are equivalent:

1. f is computed by a logspace machine with an oracle from $\text{UL} \cap \text{co-UL}$.
2. f is computed by a logspace-uniform NC^1 circuit family with oracle gates for a language in $\text{UL} \cap \text{co-UL}$.
3. $f(x)$ has length bounded by a polynomial in $|x|$, and the set $\{(x, i, b) : \text{the } i^{\text{th}} \text{ bit of } f(x) \text{ is } b\}$ is in $\text{UL} \cap \text{co-UL}$.

Thus, if any of those conditions hold, we will say that “ f is computable in $\text{UL} \cap \text{co-UL}$ ”.

The important fact that the composition of two logspace-computable functions is also logspace-computable (see, e.g., [6]) carries over with an identical proof to the functions computable in L^C for any oracle C . Thus the class of functions computable in $\text{UL} \cap \text{co-UL}$ is also closed under composition. We make implicit use of this fact frequently when presenting our algorithms. For example, we may say that a colored labeling of a graph G is computable in $\text{UL} \cap \text{co-UL}$, and that, given such a colored labeling, a decomposition of the graph into layers is also computable in logspace, and furthermore, that – given such a decomposition of G into layers – an additional coloring of the smaller graphs is computable in $\text{UL} \cap \text{co-UL}$, etc. The reader need not worry that a logspace-bounded machine does not have adequate space to store these intermediate representations; the fact that the final result is also computable in $\text{UL} \cap \text{co-UL}$ follows from closure under composition. In effect, the bits of these intermediate representations are re-computed each time we need to refer to them.

Finally, we will consider AC^k circuits augmented with oracle gates for an oracle in $\text{UL} \cap \text{co-UL}$, which we denote by $\text{AC}^k(\text{UL} \cap \text{co-UL})$.

3 DFS in DAGs logspace reduces to Reachability

In this section, we observe that constructing the lexicographically-least DFS tree in a DAG G can be done in logspace given an oracle for reachability in G . But first, let us define what we mean by the lexicographically-first DFS tree in G :

► **Definition 1.** *Let G be a DAG, with the neighbours of the vertices given in some order in the input. (For example, with adjacency lists, we can consider the ordering in which the neighbors are presented in the list). Then the lexicographic first DFS traversal of G is the traversal with the (very natural) condition that the children of every vertex are explored in the order given in the input. For details, see the full version [3].*

The lemma we need is the following:

► **Lemma 2.** *Construction of lexicographic least DFSs tree in DAGs logspace reduces to reachability. In particular, DFS in general DAGs, planar DAGs, and planar DAGs with single source (SMPDs) lie in classes NL, $UL \cap \text{co-UL}$, and L respectively.*

The correctness of this lemma is shown by the proof of Theorem 11 of [10] for general DAGs. The extension for the other two classes is a consequence of planar reachability in $UL \cap \text{co-UL}$ [24] and of SMPD reachability in L [2]. We defer the details to the full version [3].

4 Overview of the Algorithm

The main algorithmic insight that led us to the current algorithm was a generalization of the layering algorithm that Hagerup developed for *undirected* graphs [14]. We show that this approach can be modified to yield a useful decomposition of *directed* graphs, where the layers of the graph have a restricted structure that can be exploited. More specifically, the strongly-connected components of each layer are what we call *meshes*, which enable us easily to construct paths (which will end up being paths in the DFS trees we construct) whose removal partitions the graph into significantly smaller strongly connected components.

The high-level structure of the algorithm is thus:

1. Construct a planar embedding of G .
2. Partition the planar graph G into layers (each of which is surrounded by a directed cycle).
3. Identify one such cycle C that has properties that will allow us to partition the graph into smaller weakly connected components.
4. Depending on which properties C satisfies, create a path p from the exterior face either to a vertex on C or to one of the meshes that reside in the layer just inside C . Removal of p partitions G into weakly connected components, where each strongly-connected component therein is smaller than G by a constant factor.
5. Let the vertices on this path p be v_1, v_2, \dots, v_k . The DFS tree will start with the path p , and append DFS trees for subgraphs G_1, G_2, \dots, G_k to this path, where G_i consists of all of the vertices that are reachable from v_i that are not reachable from v_j for any $j > i$. (This is obviously a tree, and it will follow that it is a DFS tree.) Further, decompose each G_i into a DAG of strongly-connected components. Build a DFS of that DAG, and then work on building DFS trees of the remaining (smaller) strongly-connected components.
6. Each of the steps above can be accomplished in $UL \cap \text{co-UL}$, which means that there is an AC^0 circuit with oracle gates from $UL \cap \text{co-UL}$ that takes G as input and produces the list of much smaller graphs G_1, \dots, G_k , as well as the path p that forms the spine of the DFS tree. We now recursively apply this procedure (in parallel) to each of these smaller graphs. The construction is complete after $O(\log n)$ phases, yielding the desired $AC^1(UL \cap \text{co-UL})$ circuit family.

In the exposition below, we first layer the graph in terms of clockwise cycles (which we will henceforth call red cycles), and obtain a decomposition of the original graph into smaller pieces. We then apply a nested layering in terms of counterclockwise cycles (which we will henceforth call blue cycles); ultimately we decompose the graph into units that are structured as a DAG, which we can then process using the tools from the earlier sections of the paper. The more detailed presentation follows.

4.1 Degree Reduction and Expansion

► **Definition 3** (of $\mathbf{Exp}^\circ(G)$ and $\mathbf{Exp}^\circ(G)$). *Let G be a planar digraph. The “expanded” digraph $\mathbf{Exp}^\circ(G)$ (respectively, $\mathbf{Exp}^\circ(G)$) is formed by replacing each vertex v of total degree $d(v) > 3$ by a clockwise (respectively, counterclockwise) cycle C_v on $d(v)$ vertices such that the endpoint of the i -th edge incident on v is now incident on the i -th vertex of the cycle.*

$\mathbf{Exp}^\circ(G)$ and $\mathbf{Exp}^\circ(G)$ each have maximum degree bounded by 3; i.e., they are *subcubic*. Next we define the clockwise (and counterclockwise) dual for such a graph and also a notion of distance.

Recall that for an undirected plane graph H , the dual (multigraph) H^* is formed by placing, for every edge $e \in E(H)$, a dual edge e^* between the face(s) on either side of e (see Section 4.6 from [12] for more details). Faces f of H and the vertices f^* of H^* correspond to each other as do vertices v of H and faces v^* of H^* .

► **Definition 4** (of Duals G° and G°). *Let G be a plane digraph, then the clockwise dual G° (respectively, counterclockwise dual G°) is a weighted bidirected version of the undirected dual of the underlying undirected graph of G in a way so that the orientation formed by rotating the corresponding directed edge of G in a clockwise (respectively, counterclockwise) way gets a weight of 1 and the other orientation gets weight 0. We inherit the definition of dual vertices and faces from the underlying undirected dual.*

► **Definition 5.** *For a plane subcubic digraph G , let f_0 be the external face. Define the type $\mathbf{type}^\circ(f)$ (respectively, $\mathbf{type}^\circ(f)$) of a face to be the singleton set consisting of the distance at which f lies from f_0 in G° : $\{d^\circ(f_0, f)\}$ (respectively, $\{d^\circ(f_0, f)\}$). Generalise this to edges e by defining $\mathbf{type}^\circ(e)$ (respectively $\mathbf{type}^\circ(e)$) as the set consisting of the union of the \mathbf{type}° (respectively, \mathbf{type}°) of the two faces adjacent to e , and to vertices v by defining as the $\mathbf{type}^\circ(v)$ (respectively $\mathbf{type}^\circ(v)$) union of the \mathbf{type}° (respectively, \mathbf{type}°) of the faces incident on the vertex v .*

The following is a direct consequence of subcubicity and the triangle inequality:

► **Lemma 6.** *In every subcubic graph G , the cardinality $|\mathbf{type}^\circ(x)|, |\mathbf{type}^\circ(x)|$ where x is a face, edge or a vertex is at least one and at most 2 and in the latter case consists of consecutive non-negative integers.*

Further, if $v \in V(G)$ is such that $|\mathbf{type}^\circ(v)| = 2$, then there exist unique $u, w \in V(G)$, such that $(u, v), (v, w) \in E(G)$ and $|\mathbf{type}^\circ(u, v)| = |\mathbf{type}^\circ(v, w)| = 2$.

For proof, see Appendix A.1.

► **Definition 7.** *For a plane subcubic graph G as above, we refer to vertices and edges with a type of cardinality two in G° (respectively, in G°) as red (respectively, blue) while the ones with a cardinality of one as white. The resulting colored graphs are called $\mathbf{red}(G)$ and $\mathbf{blue}(G)$ respectively.*

7:6 Depth-First Search in Directed Planar Graphs, Revisited

We will see later how to apply both the duals in G to get red and blue layerings of a given input graph.

Also note that a red (respectively blue) edge must have red (respectively blue) end points, as they are adjacent to the same faces as the edge between is.

We enumerate some properties of $\mathbf{red}(G)$, $\mathbf{blue}(G)$ (G is subcubic):

► **Lemma 8.**

1. Red vertices and edges in $\mathbf{red}(G)$ form disjoint clockwise cycles.
2. No clockwise cycle in $\mathbf{red}(G)$ consists of only white edges (and hence white vertices). Similar properties hold for $\mathbf{blue}(G)$.

Proof.

1. Firstly, note that a red edge must have red end point vertices, as they are adjacent to the same faces that the edge between them is adjacent to. It is immediate from Lemma 6 that if v is a red vertex, it has exactly one red incoming edge and one red outgoing edge, proving that they form disjoint cycles. Now consider a red cycle C . The type of each edge of C must be the same, since if there are two consecutive edges in C of different types, it would make the common vertex adjacent to at least three vertices of different types contradicting lemma 6. This means that the distance in G° of each face bordering the “outside” of C from the external face is one less than the distance of each face bordering the “inside” of C . But in any *counterclockwise* cycle, the distance in G° from the external face to both sides of C are the same (by the way distances are defined in G°). Thus C is clockwise.
2. Suppose C is a clockwise cycle. Consider the shortest path in G° from the external face to a face enclosed by C . From the Jordan curve theorem (Theorem 4.1.1 [12]), it must cross the cycle C . The edge dual to the crossing must be red. ◀

The definitions above, which apply only to subcubic plane graphs, can now be extended to a general plane graph G , by considering the subcubic graphs $\mathbf{Exp}^\circ(G)$ (and $\mathbf{Exp}^\circ(G)$). But first, we must make a simple observation about $\mathbf{red}(\mathbf{Exp}^\circ(G))$ (respectively about $\mathbf{blue}(\mathbf{Exp}^\circ(G))$).

► **Lemma 9.** *Let $v \in V(G)$ be a vertex of degree more than 3. Let C_v be the corresponding expanded cycle in $\mathbf{Exp}^\circ(G)$. Suppose at least one edge of C_v is white in $\mathbf{red}(\mathbf{Exp}^\circ(G))$ then there is a unique red cycle C that shares edges with C_v .*

Proof. First we note that C_v does not contain anything inside it since it is an expanded cycle. By lemma 8 we know that C_v has at least one red edge. Suppose it shares one or more edges with a red cycle R_1 . Since both cycles are clockwise and C_v has nothing inside, the cycle R_1 must enclose C_v . Now suppose there is another red cycle R_2 that shares one or more edges with C_v . Then R_2 must also enclose C_v . But two cycles cannot enclose a cycle whilst sharing edges with it without touching each other, which contradicts the above lemma that all red cycles in a subcubic graph are vertex disjoint. ◀

The last two lemmas allow us to consistently contract the red cycles in $\mathbf{red}(\mathbf{Exp}^\circ(G))$:

► **Definition 10.** *The colored graph $\mathbf{Col}^\circ(G)$ (respectively, $\mathbf{Col}^\circ(G)$) is obtained by labeling a degree more than 3 vertex $v \in V(G)$ as red iff the cycle C_v in $\mathbf{red}(\mathbf{Exp}^\circ(G))$ has at least one red edge and at least one white edge. Else the color of v is white. All the low degree vertices and edges of G inherit their colors from $\mathbf{red}(\mathbf{Exp}^\circ(G))$. The coloring of $\mathbf{Col}^\circ(G)$ is similar.*

■ **Figure 1** An example of contracting expanded cycles. The figure on right shows the graph after contracting the expanded cycles C_1, C_2, C_3 according to definition 10.

We can now characterize the colorings in the graph $\mathbf{Col}^\circ(G)$:

► **Lemma 11.** *The following hold:*

1. A red cycle in $\mathbf{Col}^\circ(G)$ is vertex disjoint from every red cycle contained in its interior.
2. Every 2-connected component of the red subgraph of $\mathbf{Col}^\circ(G)$ is a simple clockwise cycle.

We defer the proof to Section A.1.

Although the above lemmas have been proved for the clockwise dual, they also hold for counterclockwise dual with red replaced by blue.

4.2 Layering the colored graphs

► **Definition 12.** *Let $x \in V(\mathbf{Col}^\circ(G)) \cup E(\mathbf{Col}^\circ(G))$. Let $\ell^\circ(x)$ be one more than the minimum integer that occurs in $\mathbf{type}^\circ(x')$, for each $x' \in V(\mathbf{Exp}^\circ(G)) \cup E(\mathbf{Exp}^\circ(G))$ that is contracted to x . Further let $\mathcal{L}^k(\mathbf{Col}^\circ(G)) = \{x \in V(\mathbf{Col}^\circ(G)) \cup E(\mathbf{Col}^\circ(G)) : \ell^\circ(x) = k\}$. Similarly define, $\ell^\circ(x), \mathcal{L}^k(\mathbf{Col}^\circ(G))$. We call $\mathcal{L}^k(\mathbf{Col}^\circ(G))$ the k^{th} layer of the graph.*

See Fig 11 for an example. It is easy to see the following from Lemma 11:

► **Proposition 13.** *For every $x \in V(\mathbf{Col}^\circ(G)) \cup E(\mathbf{Col}^\circ(G))$ the quantity $\ell^\circ(x)$ is one more than the number of red cycles that strictly enclose x in $\mathbf{Col}^\circ(G)$. All the vertices and edges of a red cycle of $\mathbf{Col}^\circ(G)$ lie in the same layer $\mathcal{L}^{k+1}(\mathbf{Col}^\circ(G))$ for the enclosure depth k of the cycle.*

We had already noted above that the red subgraph of G had simple clockwise cycles as its biconnected components. We note a few more lemmas about the structure of a layer of G :

► **Lemma 14.** *We have:*

1. A red cycle in a layer $\mathcal{L}^{k+1}(\mathbf{Col}^\circ(G))$ does not contain any vertex/edge of the same layer inside it.
2. Any clockwise cycle in a layer consists of only red vertices and edges.

Dually, a blue cycle in a layer does not contain any vertex or edge of the same layer inside it.

► **Remark 15.** Notice that the conclusion in the second part of the lemma fails to hold if we allow cycles spanning more than one layer.

Proof. The first part is a direct consequence of proposition 13. For the second part we mimic the proof of the second part of Lemma 8. Consider a clockwise cycle $C \subseteq \mathcal{L}^{k+1}(\mathbf{Col}^\circ(G))$ that contains a white edge e . Every face adjacent to C from the outside must have $\mathbf{type}^\circ = k$ because C is contained in layer $k + 1$. Then the \mathbf{type}° of the faces on either side of e is the same and therefore must be k . Let f be a face enclosed by C that has $\mathbf{type}^\circ(f) = k$. Thus it must be adjacent to a face of $\mathbf{type}^\circ = k - 1$. But this contradicts that every face inside and adjacent to C must have \mathbf{type}° at least k . ◀

The lemmas above show that the strongly connected components of the red subgraph of a layer consist of red cycles touching each other without nesting, in a tree like structure. This prompts the following definition:

► **Definition 16.** For a red cycle $R \subseteq \mathcal{L}^k(\mathbf{Col}^\circ(G))$ we denote by G_R , the graph induced by vertices of $\mathcal{L}^{k+1}(\mathbf{Col}^\circ(G))$ enclosed by R .

Now we combine Definitions 10 and 12:

► **Definition 17.** Each vertex or edge $x \in V(G) \cup E(G)$ gets a red layer number $k + 1$ if it belongs to $\mathcal{L}^{k+1}(\mathbf{Col}^\circ(G))$ and a blue layer number $l + 1$, if it belongs to $\mathcal{L}^{l+1}(\mathbf{Col}^\circ(G_R))$ where $R \subseteq \mathcal{L}^k(\mathbf{Col}^\circ(G))$ is the red cycle immediately enclosing x .

Moreover this defines the colored graph $\mathbf{Col}(G)$ by giving x the color red if it is red in $\mathbf{Col}^\circ(G)$ and/or blue in $\mathbf{Col}^\circ(G_R)$ (notice it could be both red and blue) and lastly white if it is white in both the graphs. In this case, we say that x belongs to sublayer $\mathcal{L}^{k+1,l+1}(\mathbf{Col}(G))$.

By Proposition 13, we can also say that a sublayer $\mathcal{L}^{k+1,l+1}(\mathbf{Col}(G))$ thus consists of edges/vertices that are strictly enclosed inside k red cycles and inside l blue cycles that are contained *inside* the first enclosing red cycle.

We'll see some observations and lemmas regarding the structure of a sublayer now.

Since every edge/vertex in $\mathcal{L}^{k+1,l+1}(\mathbf{Col}(G))$ has the same red AND blue layer number, it is clear that there can be no nesting of colored cycles. Also we have:

► **Lemma 18.** Every clockwise cycle in a sublayer $\mathcal{L}^{k+1,l+1}(\mathbf{Col}(G))$ consists of all red edges and vertices and any every counterclockwise cycle in the sublayer consists of all blue vertices and edges. (Some edges/vertices of the cycle can be both red as well as blue)

Proof. This is a direct consequence of Lemma 14 applied to the sublayer $\mathcal{L}^{k+1,l+1}(\mathbf{Col}(G))$, which is a (counterclockwise) layer in graph G_R for some red cycle R . ◀

Thus we can refer to clockwise cycles and counterclockwise cycles as red and blue cycles respectively.

► **Definition 19.** For a red or blue colored cycle C of layer $\mathcal{L}^{k,l}(\mathbf{Col}(G))$, we denote by G_C the graph induced by vertices of $\mathcal{L}^{k',l'}(\mathbf{Col}(G))$ enclosed by C , where $\{k',l'\}$ is $\{k + 1, 1\}$ or $\{k, l + 1\}$ according to whether C is a red or a blue cycle respectively.

Note that:

► **Proposition 20.** Two cycles of the same color in $\mathcal{L}^{k+1,l+1}(G)$ cannot share an edge.

This is since neither is enclosed by the other as they belong to the same layer, and as they also have the same orientation. Cycles of different colors can share edges but we note:

► **Lemma 21.** *Two cycles of a sublayer $\mathcal{L}^{k+1,l+1}(\text{Col}(G))$ can only share one contiguous segment of edges.*

Proof. Let a red cycle R and a blue cycle B in a sublayer share two vertices u, v but let the paths $R(u, v), B(u, v)$ in the two cycles be disjoint. Notice that the graph $(R \setminus R(u, v)) \cup B(u, v)$ is also a clockwise cycle that encloses the edges of $R(u, v)$ contradicting the first part of Lemma 14. ◀

We consider the strongly connected components of a sublayer and note the following lemmas regarding them:

► **Lemma 22.** *The trivial strongly connected components of a sublayer (those that consist of a single vertex) are white vertices. The non-trivial strongly connected components of a sublayer have the following properties:*

1. *Every vertex/edge in them is blue or red (possibly both).*
2. *Every face, except possibly the outer face, is a directed cycle.*
3. *Every face other than the outer face has at least one edge adjacent to the outer face.*

We defer the proof to Section A.1. The strongly connected components of a sublayer hence consist of intersecting red and blue facial cycles, with every face having at least one boundary edge adjacent to the outer face of the component.

► **Definition 23.** *We call the strongly connected components of a sublayer $\mathcal{L}(k, l)$ meshes.*

5 Mesh Properties

► **Definition 24.** *Given a subgraph H of G embedded in the plane, we define the closure of H , denoted by \tilde{H} , to be the induced graph on the vertices of H together with the vertices of G that lie in the interior of faces of H (except for the outer face of H).*

For convenience, we call a face of a graph that is not the outer face an *internal face*.

From Lemmas 18 and 22, we have a bijection: every face of a mesh, except possibly its outer face, is a directed cycle, and every directed cycle in a mesh is the boundary of a face of the mesh.

► **Definition 25.** *Let $0 < \alpha < 1$. An α separator of a digraph H that is a subgraph of a digraph G is a set of vertices of H whose removal from H separates \tilde{H} into subgraphs, where no strongly connected component has size greater than $\alpha|G|$. A path separator is a sequence of vertices $\langle v_1, \dots, v_n \rangle$ that is a separator and also is a directed path.*

► **Definition 26.** *Let G be a graph and let M be a mesh in a sublayer G . For an internal face f of M , we define $wt(f)$ to be $|V(\tilde{f})|$. Let $wt(H)$ where H is a subgraph of M be defined as $|V(\tilde{H})|$.*

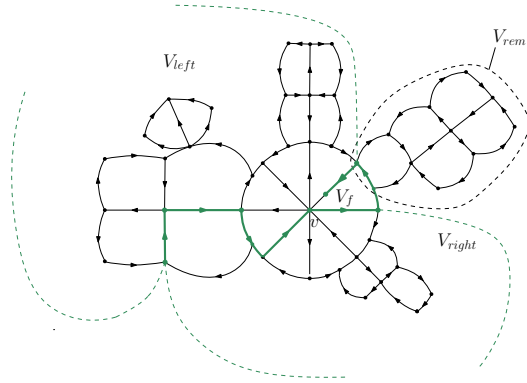

► **Definition 27.** *For a mesh M , we call a vertex that is adjacent to the outer face of M an external vertex, and a vertex that is not adjacent to the outer face an internal vertex. Also, we call vertices of degree more than two junction vertices.*

*If $p = \langle v_1, v_2, \dots, v_k \rangle$ is a directed path such that v_2, \dots, v_{k-1} are all vertices of degree two, but v_1, v_k have degree more than two, then we call p a **segment**. We call v_k the out junction neighbour of v_1 and v_1 the in junction neighbour of v_k .*

*We call a **segment** with all edges adjacent to the outer face an external **segment**, and a **segment** with no edge adjacent to the outer face an internal **segment**. If the end points of an internal **segment** are both internal vertices also, we call the segment an **i-i-segment**.*

■ **Figure 2** An example of a mesh.

■ **Figure 3** An example of a path separator. The vertex v is a central node, and the green path is a separator.

The rest of this section is devoted to a proof of the following, which asserts that we can construct a path separator in a mesh, assuming that no internal face of the mesh is too large.

► **Lemma 28.** *Suppose $wt(f) < wt(G)/12$ holds for every internal face f of a mesh M that is a subgraph of G . Then from any external vertex r of M , we can find (in $UL \cap co-UL$) an $\frac{11}{12}$ path separator of M , starting at r .*

The high level idea is that using a clique sum decomposition of 2, 3-cliques (see figure 9) we find a “central” vertex v in the mesh M , such that we can find a path from the external vertex r to v , and then extend the path around one of the faces adjacent to v to get the path separator (all faces are directed cycles by lemma 22). Because every face touches the outer face and weight of every face is small by the hypothesis of the lemma, we can always find a face adjacent to v to encircle such that removing the path leaves no large (weakly) connected component. The vertices of M with degree two (in-degree 1 and out-degree 1 because M is strongly connected) are not important since they can be seen as just “subdivision” vertices. Now we will look at the structure of a mesh around an internal junction vertex, and the way the rest of the mesh is attached to that structure. Also, we state here that we will abuse the notion of 3-connected components by ignoring the non-junction vertices for convenience.

► **Lemma 29.** *If v is an internal junction vertex of a mesh and e_1, \dots, e_k are the edges adjacent to v in the cyclic order of embedding, then the edges alternate in directions i.e. if e_1 is outgoing from v , then e_2 is incoming to v and e_3 is outgoing and so on. Consequently, v has even degree (at least 4).*

► **Definition 30.** *Let v be an internal junction vertex of degree $2d$ in a mesh M , and let its junction neighbours be $(u_1, w_1, u_2, w_2, \dots, u_d, w_d)$ in clockwise order starting from edge $\langle u_1, v \rangle$ (the w_i 's are out neighbours, and u_i 's the in neighbours, since junction neighbours alternate).*

*Every adjacent pair of edges incident to v borders a face that is not the outer face. Let $f_{u,v,w}$ denote the face bordered by v and the junction neighbours u and w of v which are adjacent in cyclic order around v . The boundary of $f_{u,v,w}$ can be written as three disjoint parts (except for endpoints), **segment** (u, v) + **segment** (v, w) + **petal** $_{w,u}$, where the third part denotes a simple path from w to u along the face boundary. We will use the notation $petal_{w,u}$ to denote the corresponding boundary for any face $f_{u,v,w}$ adjacent to v . We define **flower** (v) as $\bigcup \{ \text{vertices on boundary of faces adjacent to } v \}$ (See figure 4).*

We note the following property of petals whose proof is deferred to AppendixA.2.

► **Proposition 31.** *For all adjacent junction neighbour pairs w_i, u_j of internal vertex v , petal_{w_i, u_j} are disjoint, except possibly the end points.*

For an internal junction vertex v , the union of the petals around **flower**(v) thus form an undirected cycle around v , with at least four alternations in directions. Now we define bridges of the cycle, which roughly, are components of M we get after removing **flower**(v), leaving the points of attachment intact. We use the formal definition of bridges from [25]:

► **Definition 32.** *For a subgraph H of M , a vertex of attachment of H is a vertex of H that is incident with some edge of M not belonging to H . Let J be an undirected cycle of M . We define a **bridge** of J in M as a subgraph B of M with the following properties:*

1. *each vertex of attachment of B is a vertex of J .*
2. *B is not a subgraph of J .*
3. *no proper subgraph of B has both the above properties.*

*We denote by **2-bridge**, bridges with exactly two vertices of attachment to the specified cycle, and by **3-bridge**, bridges with three or more vertices of attachment.*

Note that for the cycle formed by petals of **flower**(v), the vertex v along with paths leading to/ coming from **flower**(v) also form a bridge, but we call that a trivial bridge and do not take it into consideration.

► **Lemma 33.**

1. *The vertices of attachment of a **2-bridge** of **flower**(v) must both lie on one **petal** of **flower**(v).*
2. *The vertices of attachment of a **3-bridge** of **flower**(P) can lie on one or, at most two adjacent petals. Moreover, in the latter case the junction neighbour of v common to both petals must be a vertex of attachment of the **3-bridge**.*
3. *For an internal vertex v , and an external vertex r of M , let $p = \langle r, \dots, u_1, v \rangle$ be a simple path from r to v , where u_1 is an in junction neighbour of v . Let the other junction neighbours of v be named as in Definition 30 in cyclic order from u_1 . For $j \in \{i, i+1\}$, consider an extended path of p , $p_{w_i, u_j} = \langle r, \dots, u_1, v, w_i \rangle + \text{petal}_{w_i, u_j} + \langle u_j, \dots, v \rangle$, excluding the last edge incident to v in the sequence. That is, p_{w_i, u_j} goes from r to v , then to an out junction neighbour w_i , and then wraps around f_{u_j, v, w_i} by taking petal_{w_i, u_j} and then the segment back towards v from u_j . If there is a bridge of **flower**(v) of which u_1 is a point of attachment and also includes the edge of p incoming to u_1 , we denote it by B_{in} . The set $V(\tilde{M}) \setminus V(p_{w_i, u_j})$ can be partitioned into four disconnected parts, say V_{left} and V_{right} , V_f , V_{rem} such that:*

$$\begin{aligned} V_{left} = & (\{\tilde{f}_{u_1, v, w_1} \cup \tilde{f}_{u_2, v, w_1} \cup \tilde{f}_{u_2, v, w_2} \dots \cup \tilde{f}_{u_i, v, w_{i-1}}\} \cup \{\tilde{f}_{u_i, v, w_i} \text{ if } j = i + 1\}) \\ & \cup \{\text{vertices in closure of bridges attached to the petals of these faces, excluding } B_{in}\} \\ & \cup \{\text{the "left" part of } B_{in}.(\text{See figure 8})\} \setminus V(p_{w_i, u_j}) \end{aligned}$$

$$\begin{aligned} V_{right} = & (\{\tilde{f}_{u_i, v, w_{i+1}} \cup \tilde{f}_{u_{i+2}, v, w_{i+1}} \dots \cup \tilde{f}_{u_d, v, w_d}\} \cup \{\tilde{f}_{u_{i+1}, v, w_i} \text{ if } j = i\}) \\ & \cup \{\text{vertices in closure of bridges attached to petals petals these faces, excluding } B_{in}\} \\ & \cup \{\text{the "right" part of } B_{in}.(\text{See figure 8})\} \setminus V(p_{w_i, u_j}) \end{aligned}$$

$$V_f = \tilde{f}_{u_j, v, w_i} \setminus V(p_{w_i, u_j})$$

$$\begin{aligned} V_{rem} = & \left(\bigcup \{\text{vertices in closure of all bridges that have vertices} \right. \\ & \left. \text{of attachment only in } \text{petal}_{w_i, u_j}\} \right) \setminus V(p_{w_i, u_j}). \end{aligned}$$

■ **Figure 4** A vertex v and $\text{flower}(v)$. B is a **bridge** with two points of attachment x, y on two different petals of $\text{flower}(v)$. On the right are drawn the **bridge** B itself, and its closed version B° . The only way the boundary of $f_{w',w,y}$ can have an external edge is if it touches B , making w a point of attachment of B also.

such that there is no undirected path between any vertex of one of these four sets to any vertex of another. The path p_{w_i, u_i} is therefore a path separator that gives these components.

We introduce another notation for an extension of a bridge:

► **Definition 34.** For a bridge B of $\text{flower}(v)$, we define B° as B along with segments of $\text{flower}(v)$ that lie between consecutive vertices of attachment of B . We call this the **closed bridge** of B .

Now we will give definitions/lemmas regarding the “internal structure” of meshes, that will be useful to define the “center” of a mesh.

► **Definition 35.** For a mesh M , we call its **internal-skeleton**, denoted by $I(M)$, the induced subgraph on the vertices of **i-i-segments** of M . (See figure 6)

► **Lemma 36.**

1. For a mesh M , the graph $I(M)$ is a forest.
2. If H is a 3-connected induced subgraph of M (ignoring subdivision vertices), then $I(H)$ is a tree.

We state a well-known proposition about a vertex separator in a tree T with weighted nodes, without the proof.

► **Proposition 37.** Suppose T is a tree with each node having a weight assigned to it. Let $wt(T')$ denote sum of weights of each node in a subgraph T' of T . Then there exists a node v_c or a pair of adjacent nodes v_{c_1}, v_{c_2} , such that after removing it (or them in case of a pair), no connected component in the remaining forest has weight more than $\frac{1}{2}wt(T)$.

We will next give a procedure to define a “center” of a mesh.

► **Definition 38.** For a mesh M , let T_M denote the tree obtained by the 1,2-clique sum decomposition of M . The nodes of T_M are of two types, clique nodes (cut vertices or separating pairs), and piece nodes, which are either 3-connected parts or cycles. Every piece node is adjacent to a clique node and vice-versa. (See [9, Section 3.1] for background about this decomposition.)

Consider the $\frac{1}{2}$ separator node of T_M as described in Proposition 37. If it is a separating pair, a cut vertex, or a face cycle, we call that subgraph the **center** of M .

■ **Figure 5** An example of a mesh.

■ **Figure 6** The internal skeleton of the mesh. One of its components is a single node.

If it is a 3-connected node P , look at its internal skeleton $I(P)$. We construct a new graph $I'(P)$ which is isomorphic to $I(P)$ but has edges directed differently. Let u, v be two adjacent internal junction vertices of M . To give direction to a **segment** (u, v) in $I'(P)$, we consider the unique **bridge** B of $\text{flower}(u)$ that contains v as a point of attachment; we denote the **closed bridge** of B by $\mathbf{B}_u^\circ(v)$. $\mathbf{B}_v^\circ(u)$ is defined analogously. We orient (u, v) in the direction of the heavier of $\mathbf{B}_u^\circ(v)$ and $\mathbf{B}_v^\circ(u)$ (breaking ties arbitrarily), where the weights of $\mathbf{B}_u^\circ(v), \mathbf{B}_v^\circ(u)$ are $|\widetilde{\mathbf{B}}_u^\circ(v)|$ and $|\widetilde{\mathbf{B}}_v^\circ(u)|$, respectively.

The **center** of M is defined to be $\text{flower}(v)$ in this case, where v is the sink node of $I'(P)$.

We show why $I'(P)$ cannot have more than one sink.

► **Lemma 39.** *The tree $I'(P)$ defined above will have exactly one sink vertex.*

► **Lemma 40.** *If the center of M is $\text{flower}(v)$, and w is an out neighbor of v , then $wt(\mathbf{B}_v^\circ(w)) \leq \frac{1}{2}(wt(\widetilde{M}) - wt(V_{rem}(u, w)))$, where u is either of the two in neighbors of v that are adjacent to w around $\text{flower}(v)$.*

Proof. Since the center is $\text{flower}(v)$, we have that $wt(\mathbf{B}_v^\circ(w)) \leq wt(\mathbf{B}_w^\circ(v))$. But $V_{rem}(u, w)$ has empty intersection with each of $\mathbf{B}_v^\circ(w)$ and $\mathbf{B}_w^\circ(v)$. Thus $wt(\mathbf{B}_v^\circ(w)) + wt(\mathbf{B}_w^\circ(v)) \leq wt(\widetilde{M}) - wt(V_{rem}(u, w))$. The lemma follows. ◀

► **Lemma 41.**

1. *If the center of M is not of the form $\text{flower}(v)$ where v is an internal node of a 3-connected component, then removing it from \widetilde{M} disconnects \widetilde{M} into weakly connected components, each with weight less than $\frac{1}{2}wt(\widetilde{M})$.*
2. *If the center of M is $\text{flower}(v)$ for an internal node v of a 3-connected component P , then on removing $\text{flower}(v)$ from \widetilde{M} , no weakly connected component has weight more than $\frac{1}{2}wt(\widetilde{M})$.*

Proof.

1. This follows from the vertex separator lemma for trees with weighted vertices.
2. This follows from the v being the sink node of $I'(P)$. ◀

► **Lemma 42.** *For every possible path p_{w_i, u_j} around v as defined in Lemma 33, V_{rem} consists of a disjoint union of weakly-connected components, each of which has weight $\leq \frac{1}{2}(wt(M))$. For a path p_{w_i, u_j} (where $j \in \{i, i+1\}$) we sometimes use the notation $V_{rem}(w_i, u_j)$ to specify the petal where the bridges of V_{rem} are attached.*

■ **Figure 7** The tree decomposition of the mesh using 1,2-clique sums. The nodes encircled red are clique separator nodes.

■ **Figure 8** An example of a path separator. The vertex v is a central node, and the green path is a separator.

5.1 Mesh Separator Algorithm

Now we give the algorithm to find an α separator in a mesh $M(G)$, assuming the hypothesis of Lemma 28.

1. Find the decomposition tree, T_M of M with 2-cliques and 1-cliques as the separating sets.
2. Find the **center** of the mesh M . It will either be a cut vertex, a separating pair, a cycle, or **flower**(v) for some internal vertex v .
3. If it is a cut vertex, we just find a path from the root r to it. If it is a separating pair (u, v) , both the vertices must lie on a same face, which is a directed cycle. In both this case, and also the case in which the **center** is a cycle, find a path from the root to any vertex of the face that touches it the first time, and then extend the path by encircling the cycle.
4. If it is **flower**(v) for some internal vertex v , find a path $p = \langle r, \dots, u_1, v \rangle$ to v . Let the junction neighbours of v in clockwise order starting from (u_1, v) , be $w_1, u_2, w_2, \dots, w_d$, with the w 's being out junction neighbours and the u 's being in junction neighbours. Starting clockwise from segment $\langle u, v \rangle$, find the first index i and $j \in \{i, i + 1\}$ s.t. after removing the extended path p_{w_i, u_j} , (defined in Lemma 33) the remaining strongly connected components are smaller than $\frac{11}{12}wt(G)$.

The algorithm above can clearly be implemented in logspace with an oracle for planar reachability, and thus it can be implemented in $UL \cap co-UL$.

It remains to show that the “first i ” mentioned in the final step actually exists. For the proof see Appendix A.3:

► **Lemma 43.** *If the center of M is **flower**(v) for some internal vertex v , then there will always exist an adjacent face f_{u_i, v, w_i} s.t. the path p_{w_i, u_i} is a $\frac{11}{12}$ -separator.*

6 Path separator in a planar digraph

Having seen how to construct a path separator in a **mesh**, we now show how to use that to construct an $\frac{11}{12}$ separator in any planar digraph.

1. Given a graph G , first embed the graph so that the root r lies on the outer face. Through the root, draw a virtual directed cycle C_0 that encloses the entire graph, and orient it, say clockwise. Find the layering described in Section 4 and output it on a transducer. Cycle C_0 will be colored red and will be in the sublayer $(0, 0)$.

2. In the laminar family of red/blue cycles, find the cycle C s.t. $wt(C)$ is more than $|G|/12$, but no colored cycle C' in the interior of C has the same property. Such a cycle will clearly exist (it could be the virtual cycle C_0). Let the sublayer of C be (k, l) .
3. Find a path p from the root r to any vertex r_C of the cycle C such that no other vertex of C is in the path. As seen above in Lemma 22, the graph in the interior of C and belonging to the immediately next sublayer $((k+1, l)$ if C is clockwise and $(k, l+1)$ if C is counter-clockwise) is a DAG of meshes. There are two cases possible:
 - a. The graph \tilde{C} has no strongly connected components of weight larger than $|G|/12$. In this case we simply extend the path p from r_C by encircling the cycle C till the last vertex and stop.
 - b. The graph \tilde{C} has a strongly connected component of weight more than $|G|/12$. In this case, we extend p from r_C by encircling C till the last vertex u on C that can reach any such component M_C . Then extend the path from u to any vertex of M_C and apply the mesh separator lemma (Lemma 28) to obtain the desired separator. (Observe that M_C satisfies the hypothesis of Lemma 28.)

► **Lemma 44.** *The path p obtained by the above procedure is an $\frac{11}{12}$ separator.*

Proof. We look at the two cases:

1. In this case it is clear that the interior and exterior of cycle C are disconnected by p . The exterior of C has size $\leq \frac{11}{12}|G|$ (by definition of C), and in its interior every strongly-connected component has weight at most $|G|/12$. Thus this satisfies the definition of an $\frac{11}{12}$ separator.
2. We took the last edge in C from r_C that can reach the mesh M_C , and extended the path to M_C . Thus after removing p , one weakly-connected component consists of the exterior of G , along with (possibly) some vertices in the interior of C that cannot reach any “large” mesh in the interior. Since M_C has weight greater than $\frac{1}{12}|G|$, no strongly-connected component embedded outside of M_C can have weight more than $\frac{11}{12}|G|$. Also, after removing path p , Lemma 28 guarantees that no other strongly-connected component will have weight more than $\frac{11}{12}|G|$. Thus this is an $\frac{11}{12}$ separator.

Hence overall we can guarantee an $\frac{11}{12}$ path separator in G . ◀

7 Building a DFS tree using path separators

We give a recursive divide and conquer algorithm for DFS:

1. Given a planar drawing of G and a root vertex on the outer face r , find an $\frac{11}{12}$ path separator $p = \langle r, v_1, v_2, \dots, v_k \rangle$. Path p is included in the DFS tree.
2. Let $R(v)$ denote the set of vertices of G reachable from v . Now for every vertex v_i in p compute in parallel: $R'(v_i) = R(v) \setminus (\bigcup_{j=i+1}^k R(v_j))$. Our DFS will correspond to first traveling along p to v_k , doing DFS on $R(v_k)$, and then while backtracking on p , do DFS on $R'(v_i)$ for i from $k-1$ down to 1. Given G , the encodings of p and $R'(v_i)$ can all be computed in $\text{AC}^0(\text{UL} \cap \text{co-UL})$.
3. For any v_i , $R'(v_i)$ can be written as a DAG of SCCs (strongly connected components), where each SCC is smaller than $\frac{11}{12}|G|$. In $\text{AC}^0(\text{UL} \cap \text{co-UL})$ we can compute this DAG and we can compute an encoding of the tuple (i, M, v) where M is a SCC in $R'(v_i)$ and v is a vertex in M . Recursively, in parallel, we compute a DFS tree of M for each tuple (i, M, v) , using v as the root. Now we need to show how to sew together (some of) these trees, to form a DFS tree for G with root r .

■ **Figure 9** The tree decomposition of the mesh using 1,2-clique sums. The nodes encircled red are clique separator nodes.

■ **Figure 10** The cycle C is a cycle satisfying the property stated in step 2 of the algorithm. The mesh M in the next sublayer is heavy, so we find a path from the last vertex on C that can reach M (in this case y), and then apply the algorithm of previous section on M .

4. Given a triple (i, M, v) , let x_0, x_1, \dots, x_r be the order in which the vertices of M appear in a DFS traversal where the root $x_0 = v$. Our DFS will correspond to first following the edges from x_0 that lead to other SCCs in $R(v_i)$. (No vertex reachable in this way can reach any x_j , or else that vertex would also be in M .) And then we will move on to x_1 and repeat the process, etc. Thus let $R''_{i,M,v}(x_j) = (R'(x_j) \setminus M) \setminus (\bigcup_{k < j} R'(x_k))$. Our DFS tree is composed by computing a DFS tree T of the DAG of meshes (considering each mesh to be a vertex) using the algorithm of Section 3. A logspace machine can do a DFS traversal of T , starting with the node containing v_i as the root, and using (as auxiliary information) the DFS tree that was computed for (i, M, v_i) . If this traversal contains an edge (M, M') (where M and M' are SCCs in $R'(v_i)$), then there is exactly one j such that there is an edge from x_j in the DFS tree for (i, M, v_i) to a vertex (call it $v_{M'}$) in $M' \cap R''_{i,M,v}(x_j)$. [Namely, x_j is the first vertex in this tree that has an edge to M' .] The edge from x_j to $v_{M'}$ will be in our DFS tree, as will the DFS tree that was computed for $(i, M', v_{M'})$. We then continue the traversal of T , and process each node of the DAG in the same way. All of this can be accomplished in $\text{AC}^0(\text{UL} \cap \text{co-UL})$.
5. The final DFS tree for R_i consists of all of the edges that appear in the trees for tuples (i, M, v) that were utilized in the traversal of T . The tree for G consists of p together with the trees for each R_i .

A Appendix: Omitted details

A.1 Proofs from Section 4

We first need a simple lemma:

► **Lemma 45.** *Suppose (f_1, f_2) is a dual edge with weight 1 (and (f_2, f_1) is of weight 0) then, $d^\circ(f_0, f_1) \leq d^\circ(f_0, f_2) \leq d^\circ(f_0, f_1) + 1$.*

Proof. From the triangle inequality $d^\circ(f_0, f_1) \leq d^\circ(f_0, f_2) + d^\circ(f_2, f_1) = d^\circ(f_0, f_2)$. Similarly, $d^\circ(f_0, f_2) \leq d^\circ(f_0, f_1) + d^\circ(f_1, f_2) \leq d^\circ(f_0, f_1) + 1$. ◀

Proof of Lemma 6. Since each vertex $v \in V(G)$ of a subcubic graph is incident on at most 3 faces the only case in which $|\mathbf{type}^\circ(v)| > 2$ corresponds to three distinct faces f_1, f_2, f_3 being incident on a vertex. But here the undirected dual edges form a triangle such that in the directed dual the edges with weight 1 are oriented either as a cycle or acyclically. In the former case by three applications of the first half of Lemma 45 we get that $d^\circ(f_0, f_1) \leq d^\circ(f_0, f_2) \leq d^\circ(f_0, f_3) \leq d^\circ(f_0, f_1)$, hence all 3 distances are the same. Therefore $|\mathbf{type}^\circ(v)| = 1$.

In the latter case, suppose the edges of weight 1 are $(f_1, f_2), (f_2, f_3), (f_1, f_3)$, then by Lemma 45 we get: $d^\circ(f_0, f_1) \leq d^\circ(f_0, f_2), d^\circ(f_0, f_3) \leq d^\circ(f_0, f_1) + 1$. Thus, both $d^\circ(f_0, f_2), d^\circ(f_0, f_3)$ are sandwiched between two consecutive values $d^\circ(f_0, f_1), d^\circ(f_0, f_1) + 1$. Hence $d^\circ(f_0, f_1), d^\circ(f_0, f_2), d^\circ(f_0, f_3)$ must take at most two distinct values, and thus $|\mathbf{type}^\circ(v)| \leq 2$. Moreover either $\mathbf{type}^\circ(f_1) \neq \mathbf{type}^\circ(f_2) = \mathbf{type}^\circ(f_3)$ or $\mathbf{type}^\circ(f_1) = \mathbf{type}^\circ(f_2) \neq \mathbf{type}^\circ(f_3)$. Let e_1, e_2, e_3 be such that, $e_1^\circ = (f_2, f_3), e_2^\circ = (f_1, f_3), e_3^\circ = (f_1, f_2)$. Then the two cases correspond to $|\mathbf{type}^\circ(e_1)| = |\mathbf{type}^\circ(e_2)| = 2, |\mathbf{type}^\circ(e_3)| = 1$ and to $|\mathbf{type}^\circ(e_1)| = 1, |\mathbf{type}^\circ(e_2)| = |\mathbf{type}^\circ(e_3)| = 2$ respectively. Noticing that e_1, e_3 are both incoming or both outgoing edges of v completes the proof for the clockwise case. The proof for the counterclockwise case is formally identical. ◀

Proof of Lemma 11. For $v \in V(G)$, let $C_v \subseteq \mathbf{Exp}^\circ(G)$ be the expanded cycle. If it has a red vertex it is immediately enclosed by a unique red cycle R in $\mathbf{Exp}^\circ(G)$ by Lemma 9. Assuming C_v is not all red, it consists of alternating red subpaths and white subpaths. On contracting C_v we get a collection of clockwise red cycles outside sharing a common cut-vertex v . Notice that the new collection of red cycles consists of edges that R did not share with C_v . Also notice that (as a thought experiment) if we contracted the C_v 's that share a vertex with R , one at a time we would get an edge-disjoint set of red cycles with distinct cut vertices. Therefore, in $\mathbf{Col}^\circ(G)$, the red subgraph consists of a collection of connected components, each of which is a remnant of exactly one red cycle in $\mathbf{Exp}^\circ(G)$; these connected components consist of red cycles that touch externally at cut vertices. Hence both parts of the lemma follow. ◀

Proof of Lemma 22.

1. In a non-trivial strongly connected graph every vertex and edge lies on a cycle and therefore by Lemma 18 must be colored red or blue (or both).
2. Suppose there is a face f the boundary of which is not a directed cycle. Look at a directed dual (say clockwise) of the strongly connected component (just the component independently). This dual must be a DAG since the primal is strongly connected. The vertex f^* in the dual corresponding to face f of the strongly connected component has in degree at least one and out degree at least one since it has boundary edges of both orientations, hence the edges adjacent to f^* do not form a directed cut of the dual. Let o^* denote the dual vertex corresponding to the outer face of the SCC. In order to prove the claim, it is sufficient to show the existence of a directed cut C^* that separates f^* and o^* , since it would imply by cut cycle duality that there is a directed cycle C in the primal SCC that encloses the face f w.r.t the outer face and since the boundary of f is not a directed cycle, C must strictly enclose at least one edge of the boundary of f contradicting Lemma 14. To see the cut, consider a topological sort ordering of the dual (it is a DAG). Let the number of a dual vertex v^* in the ordering be denoted by $n(v^*)$. W.l.o.g, let $n(f^*) < n(o^*)$. Consider the partition of the dual vertices:

$$A = \{v^* \mid n(v^*) \leq n(f^*)\}, B = \{v^* \mid n(v^*) > n(f^*)\}$$

- By definition of topological sort, all edges across this partition must be directed from A to B , hence it is a directed cut, and therefore it must also contain a subset which is a minimal directed cut. But clearly the minimal cut is not the set of edges adjacent to f^* since it has both out and in degree at least one, hence proving the claim. Hence every face in the SCC of a sublayer must be a directed (hence colored) cycle (by Lemma 18).
3. Let H be an SCC of the sublayer. We observed from the proof above that no vertex in the dual of H , except possibly the vertex corresponding to the outer face of H , can have both in degree and out degree more than one. (i.e. every dual vertex, except the outer face is a source or a sink). Therefore if any dual vertex f^* has a directed path to o^* or vice versa, then the path must be an edge and we are done. Suppose there is no directed path from f^* to o^* and w.l.o.g. let f^* be a source. Consider the trivial directed cut C_1 :

$$A = \{f^*\}, B = V(H) \setminus A$$

This is a cut since there are no edges from B to A , and this cut clearly corresponds to the directed cycle which is the boundary of face f in H .

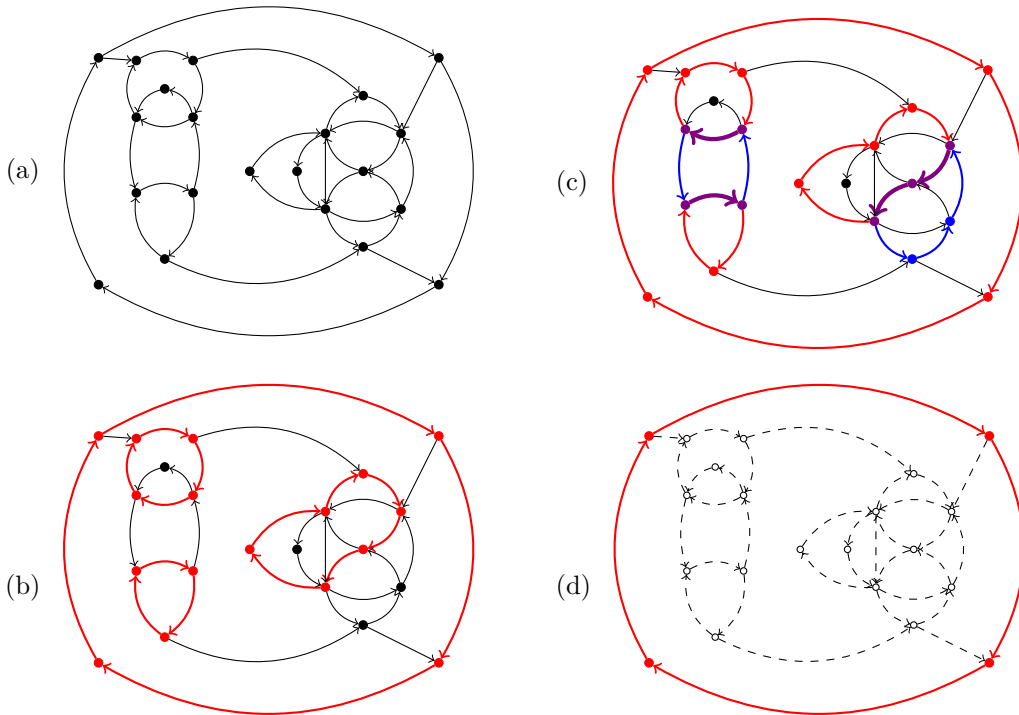

Now consider the cut C_2 :

$$A' = \{v^* \mid v^* \text{ is reachable from } f^*\}, B' = V(H) \setminus A'$$

Clearly this is a f^* - o^* cut with no edge from a vertex in A' to a vertex in B' and $o^* \in B'$. But this f^* - o^* cut is different from C_1 since f^* is a source vertex and hence A' has at least one more vertex than just f^* . Hence this corresponds to a directed cycle in H that strictly encloses at least some edge of f , and we again get a contradiction of Lemma 14. ◀

A.2 Details for Section 5

Proof. (of Lemma 29) Let e_i, e_{i+1} be two edges adjacent to v , that are also adjacent in the cyclic order of the drawing. Since they are adjacent in the drawing, they must enclose between them, a region, and hence a face, which is not the outer face. But the boundary of

■ **Figure 11** Figure (a) is a graph G . Figure (b) is the graph in (a) after labelling red edges using clockwise dual. We omit the cycle expansion and contraction procedure here.

■ **Figure 12** Figure (c) shows G after applying blue labellings to each red layer we obtained in the previous figure. The vertices and edges colored purple are those that are red as well as blue. Figure (d) represents the sublayer (1,1). The dashed edges and empty vertices are not part of the layer.

every non-outer face in a mesh is a directed cycle, hence v, e_i, e_{i+1} lie on a directed cycle, with both edges adjacent to v . Hence one of them must be an out edge from v , and the other incident towards v . ◀

Proof of Proposition 31. Petals of two faces must be internally disjoint because the corresponding faces share the vertex v and two faces cannot have a non-contiguous intersection, by Lemma 21. ◀

Proof of Lemma 33.

1. Let x, y be the two vertices of attachment of the **2-bridge** B on $\mathbf{flower}(v)$. Since bridges are connected graphs without the edges of the corresponding cycle (by 3^{rd} property of definition 32), there must be an undirected path, p in the **bridge** connecting x, y , without using any edge of $\mathbf{flower}(v)$. If x and y were *not* on the same petal, then this path along with the other petals in $\mathbf{flower}(v)$, must clearly enclose a junction neighbour of v , say w (see Figure 4). Thus w is not adjacent to the outer face. Now since w is an internal junction vertex, and two of its adjacent faces are also adjacent to v , look at another face f adjacent to w and not adjacent to v . (Internal junction vertices have at least four adjacent faces.) The boundary of this face cannot touch B since that would make it a part of B and consequently w a vertex of attachment of B to $\mathbf{flower}(v)$. Therefore the boundary of f is enclosed within the paths p and the part of $\mathbf{flower}(v)$ that is also enclosed by p . Therefore f has no external edge, contradicting Lemma 22.

■ **Figure 13** Figure (e) figure represents the sublayer (2, 1).

■ **Figure 14** Figure (f) represents the sublayer (3, 1).

2. Let x_1, x_2, \dots, x_k be the vertices of attachment of the bridge B on $\mathbf{flower}(v)$, in the cyclic order of boundary of $\mathbf{flower}(v)$. Clearly if the vertices of attachment lie on more than two petals of v , then at least one petal will be completely enclosed by B , which is not possible since every petal must have at least one external edge. Lets say they lie on two adjacent petals, and the junction neighbour common to both of them is w . By the same argument as above, w must have an edge other than those of adjacent petals of v , that connect it to B . Therefore w must be a vertex of attachment of B to $\mathbf{flower}(v)$.
3. First we note that $\mathit{petal}_{w_i, u_j}$ will have an external vertex in it since the boundary of every face has at least one external vertex (Lemma 22), and segments (u_j, v) and (v, w_i) are internal. Let z be an external vertex on $\mathit{petal}_{w_i, u_j}$. The path p starts at external vertex r , comes to u_1, v, w_i , and reaches external vertex z on its way back to v . It will clearly divide \widetilde{M} into at least two parts by Jordan Curve theorem. Since p_{w_i, u_j} is just a wrap around the face f_{u_j, v, w_i} after z , is clear that since w_1, u_2, \dots, w_{i-1} and everything connected to them after removing p lie in one region, which we call V_{left} , and $w_{i+1}, u_{i+2}, \dots, w_d$ and everything connected to them after removing p lie in another disconnected region since p wraps around $f_{u, v, w}$. ◀

Proof of Lemma 36.

1. Suppose there were an undirected cycle in M of all internal segments, then this cycle must enclose a face whose boundaries are also all internal segments. This contradicts Lemma 22 as it states that every face must have at least one external edge, and hence segment. Hence there can be no cycle (directed or undirected) consisting of all internal segments, and consequently, no cycle (directed or undirected) of all internal vertices.
2. Let H be a 3-connected induced subgraph of M . By definition, $I(H)$ is obtained from M by removing all external edges and external non-junction vertices. Suppose $I(H)$ is not a tree, and hence consists of two or more disconnected trees. Let T_1 and T_2 be any two trees in $I(H)$. Let x be a vertex in T_1 and y be a vertex in T_2 . Since H is 3-connected, there must be at least three disjoint paths(undirected) between x and y . Clearly in a planar graph, if there are three disjoint paths between two vertices, one of the paths must be strictly enclosed in the closed region formed by other two. Therefore there must a path between x and y that is strictly enclosed inside the boundary of H , and hence does not contain any edge or vertex adjacent to the outer face of H . Hence x and y cannot become disconnected after removing external edges and external non-junction vertices leading to a contradiction that $I(H)$ is disconnected. Therefore $I(H)$ must be a tree. ◀

Proof of Lemma 39. Suppose $I'(P)$ has two junction vertices x and y that are sinks. They cannot be adjacent, so consider the unique undirected path in $I'(P)$ between x and y . There must be a source z on the path. Let neighbours of z be x', y' , lying on the path from x to z and from z to y respectively.

Let $\mathbf{B}_z^\circ(x')$ and $\mathbf{B}_z^\circ(y')$ denote the **bridges of flower**(z) with points of attachments x' and y' respectively. Then by the orientations of the edges we have: $|\widetilde{\mathbf{B}_z^\circ(x')}| \geq |\widetilde{\mathbf{B}_{x'}^\circ(z)}|$ which gives $|\widetilde{\mathbf{B}_z^\circ(x')}| > |\widetilde{\mathbf{B}_z^\circ(y')}|$ since $\mathbf{B}_z^\circ(y')$ is clearly a proper subgraph of $\mathbf{B}_{x'}^\circ(z)$ and $|\widetilde{\mathbf{B}_z^\circ(y')}| \geq |\widetilde{\mathbf{B}_{y'}^\circ(z)}|$ which gives $|\widetilde{\mathbf{B}_z^\circ(y')}| > |\widetilde{\mathbf{B}_z^\circ(x')}|$ which is clearly a contradiction. \blacktriangleleft

Proof of Lemma 42. A (weakly connected) component of V_{rem} is a bridge, attached to $petal_{w_i, u_i}$ or to $petal_{w_i, u_{i+1}}$ via its vertices of attachment. In the clique sum decomposition, these vertices of attachment will always contain a 1 or 2 separating clique, since if a bridge is attached to a petal via three or more nodes, the first and the last vertices of attachment form a separating pair that separates the bridge from **flower**(v). Hence it is a branch remaining in T_M after removing the 3 – *connected* piece node that is central in T_M . Since every branch after removal of the central piece of T_M has weight $\leq \frac{1}{2}(wt(M))$, every (weakly) connected component of V_{rem} has weight $\leq \frac{1}{2}(wt(M))$. \blacktriangleleft

A.3 Mesh Separator Algorithm

Proof of Lemma 43. We have the following two cases

1. For some i and $j \in \{i, i+1\}$, p_{w_i, u_j} , $wt(V_{rem}(w_i, u_j)) \geq \frac{1}{2}wt(M)$.

Then by Lemma 42, p_{w_i, u_j} separates $V_{rem}(w_i, u_j)$ from the rest of the graph, and also every weakly connected component in $V_{rem}(w_i, u_j)$ has weight $\leq \frac{1}{2}wt(M)$. Hence every weakly connected component in M after removing p_{w_i, u_j} has weight $\leq \frac{1}{2}wt(M)$.

2. For every p_{w_i, u_j} , $wt(V_{rem}(w_i, u_j)) \leq \frac{1}{2}wt(M)$.

We know that for any index i and $j \in \{i, i+1\}$, if $f = f_{u_j, v, w_i}$, then $wt(V_f) \leq wt(G)/12$ by the hypothesis of Lemma 28. Starting clockwise from p_{u_1, w_1} , at first V_{left} is small, and on shifting from p_{w_i, u_i} to $p_{w_i, u_{i+1}}$ or from $p_{w_i, u_{i+1}}$ to $p_{w_{i+1}, u_{i+1}}$, the increase in V_{left} is bounded above by $wt(V_f) + wt(V_{rem}(w_i, u_j)) + wt(\widetilde{\mathbf{B}_v^\circ(w_i)})$. Recall that

a. $wt(V_f) \leq wt(G)/12$ (by the hypothesis of Lemma 28).

b. $wt(\widetilde{V_{rem}(w_i, u_j)}) \leq \frac{1}{2}wt(M)$ (by hypothesis for this case).

c. $wt(\widetilde{\mathbf{B}_v^\circ(w_i)}) \leq \frac{1}{2}(wt(M) - wt(V_{rem}(w_i, u_j)))$ (by Lemma 40).

Thus the addition to V_{left} in each iteration is $\leq \frac{1}{12}wt(G) + wt(V_{rem}(w_i, u_j)) + \frac{1}{2}(wt(M) - \frac{1}{2}(wt(V_{rem}(w_i, u_j))))$, which is equal to $\frac{1}{12}wt(G) + \frac{1}{2}wt(V_{rem}(w_i, u_i)) + \frac{1}{2}(wt(M)) \leq \frac{1}{12}wt(G) + \frac{3}{4}wt(M)$. Thus we can stop the first time $wt(V_{left})$ is greater than $wt(G)/12$. So, we have $wt(V_{left}) \leq \frac{2}{12}wt(G) + \frac{3}{4}wt(M) \leq \frac{11}{12}wt(G)$, and $wt(V_{right}) \leq \frac{11}{12}wt(M)$, and $wt(V_f) \leq \frac{1}{12}wt(M)$, and $wt(v_{rem}) \leq \frac{1}{2}wt(M)$. Thus we have an upper bound of $\frac{11}{12}wt(G)$ on all the disconnected components. Hence p_{x_i, w_i} is a $\frac{11}{12}$ path separator. \blacktriangleleft

Order Reconfiguration Under Width Constraints

Abstract

In this work, we consider the following order reconfiguration problem: Given a graph G together with linear orders ω and ω' of the vertices of G , can one transform ω into ω' by a sequence of swaps of adjacent elements in such a way that at each time step the resulting linear order has cutwidth (pathwidth) at most k ? We show that this problem always has an affirmative answer when the input linear orders ω and ω' have cutwidth (pathwidth) at most $k/2$. Using this result, we establish a connection between two apparently unrelated problems: the reachability problem for two-letter string rewriting systems and the graph isomorphism problem for graphs of bounded cutwidth. This opens an avenue for the study of the famous graph isomorphism problem using techniques from term rewriting theory.

1 Introduction

In the field of reconfiguration, one is interested in studying relationships among solutions of a problem instance [17, 24, 27]. Here, by reconfiguration of one solution into another, we mean a sequence of steps where each step transforms a feasible solution into another. Three fundamental questions in this context are: (1) Is it the case that any two solutions can be reconfigured into each other? (2) Can any two solutions be reconfigured into each other in a polynomial number of steps? (3) Given two feasible solutions X and Y , can one find in polynomial time a reconfiguration sequence from X to Y ?

In this work, we study the reconfiguration problem in the context of linear arrangements of the vertices of a given graph G . The space of feasible solutions is the set of all linear orders of cutwidth (pathwidth) at most k for some given $k \in \mathbb{N}$. We say that a linear order ω can be reconfigured into a linear order ω' in width k if there is a sequence $\omega_1, \dots, \omega_m$ of linear orders of width at most k such that $\omega_1 = \omega$, $\omega_m = \omega'$ and for each $i \in \{2, \dots, m\}$, ω_i is obtained from ω_{i-1} by swapping two adjacent vertices. Our main result (Theorem 3) states that if ω and ω' are linear orders of cutwidth at most k , then ω can be reconfigured into ω' in width at most $2k$. Additionally, reconfiguration in width at most $2k$ can be done using at most $\mathcal{O}(n^2)$ swaps. Finally, a reconfiguration sequence can be found in polynomial time.

Our results on reconfiguration of linear arrangements can be used to establish an interesting connection between two apparently unrelated computational problems: reachability for two-letter string rewriting and graph isomorphism.

A two-letter rewriting rule over a given alphabet Σ is a rewriting rule of the form $ab \rightarrow cd$ for letters $a, b, c, d \in \Sigma$. A two-letter string rewriting system is a collection R of two-letter string rewriting rules. The reachability problem for such a rewriting system R is the problem of determining whether a given string $x \in \Sigma^n$ can be transformed into a given string $y \in \Sigma^n$ by the application of a sequence of two-letter rewriting rules. On the other hand, in the graph isomorphism problem, we are given graphs G and G' and the goal is to determine whether there exists a bijection φ from the vertex set of G to the vertex set of G' in such a way that an edge $\{u, v\}$ belongs to G if and only if the edge $\{\varphi(u), \varphi(v)\}$ belongs to G' .

In order to describe more precisely the connections between two-letter term rewriting and graph isomorphism, we briefly discuss the notion of slices and unit decompositions. A *slice* is a graph \mathbf{S} where the vertices are partitioned into a center C and special in-frontier I and out-frontier O that can be used for composition. A slice \mathbf{S}_1 can be glued to a slice \mathbf{S}_2 if the out-frontier of \mathbf{S}_1 can be coherently matched with the in-frontier of \mathbf{S}_2 . In this case, the gluing gives rise to a bigger slice $\mathbf{S}_1 \circ \mathbf{S}_2$ which is obtained by matching the out-frontier of \mathbf{S}_1 with the in-frontier of \mathbf{S}_2 . A *unit slice* is a slice with a unique vertex in the center. Any slice \mathbf{S} can be decomposed into a sequence of unit slices. More specifically, a *unit decomposition* is a sequence $\mathbf{U} = \mathbf{S}_1 \mathbf{S}_2 \dots \mathbf{S}_n$ of unit slices with the property that for each $i \in [n - 1]$, \mathbf{S}_i can be glued to the slice \mathbf{S}_{i+1} . The result of gluing the unit slices in \mathbf{U} is a slice $\hat{\mathbf{U}}$ with n center vertices. Conversely, any slice \mathbf{S} with n center vertices can be written as a unit decomposition $\mathbf{U} = \mathbf{S}_1 \mathbf{S}_2 \dots \mathbf{S}_n$ with the property that $\hat{\mathbf{U}}$ is isomorphic to \mathbf{S} .

An important remark connecting unit decompositions and the notion of cutwidth is that if a slice \mathbf{S} has cutwidth k , then \mathbf{S} can be decomposed into a unit decomposition $\mathbf{U} = \mathbf{S}_1 \mathbf{S}_2 \dots \mathbf{S}_n$ where for each $i \in [n]$, \mathbf{S}_i has at most k vertices in each frontier. Therefore, if we let $\Sigma(k)$ denote the set of all unit slices with frontiers of size at most k , then any graph G with n vertices of cutwidth at most k can be written as a word (unit decomposition) of length n over the alphabet $\Sigma(k)$. In this work, for each $k \in \mathbb{N}$, we introduce a suitable two-letter string rewriting system $R(k)$ over the alphabet $\Sigma(k)$ with the following property: if \mathbf{U} and \mathbf{U}' are two unit decompositions over $\Sigma(k)$ and if \mathbf{U} can be transformed into \mathbf{U}' using the rewriting rules in $R(k)$, then the graphs $\hat{\mathbf{U}}$ and $\hat{\mathbf{U}}'$ are isomorphic. Our second main result is a partial converse for this property. More precisely, we show that given two unit decompositions \mathbf{U} and \mathbf{U}' over $\Sigma(k)$, if the graphs $\hat{\mathbf{U}}$ and $\hat{\mathbf{U}}'$ are isomorphic, then each of these unit decompositions can be transformed into one another by the application of rewriting rules from the string rewriting system $R(2k)$ (Theorem 11).

The proof of Theorem 11 is heavily based on Theorem 3. An important feature of this proof is that, given an isomorphism from $\hat{\mathbf{U}}$ to $\hat{\mathbf{U}}'$, one can construct a sequence of rewriting steps transforming \mathbf{U} into \mathbf{U}' . Conversely, given any such a sequence, we are able to construct an isomorphism from $\hat{\mathbf{U}}$ to $\hat{\mathbf{U}}'$. This result, together with the fact that unit decompositions of minimum cutwidth can be approximated in FPT time, implies that the graph isomorphism problem for graphs of cutwidth at most k is FPT-equivalent to the reachability problem for $R(2k)$ (Theorem 13).

Related Work. The reachability problem for a given string rewriting system R consists in determining whether a given string x can be transformed into a given string y by the application of rewriting rules from R . Reachability is a central problem in the field of string rewriting [6] and can also be studied under the light of term rewriting theory [19, 5, 1, 6].

The complexity of the reachability problem is highly dependent on the rewriting system R . For general rewriting systems, the problem becomes undecidable [6]. In the case of two-letter rewriting, reachability can be solved in PSPACE since in this case, strings never grow in size. It is also not difficult to design two-letter rewriting systems for which the reachability problem is PSPACE-complete. Nevertheless, our results imply that for each $k \in \mathbb{N}$, the $R(2 \cdot k)$ -reachability problem for unit decompositions of length n and width at most k is reducible to the graph isomorphism problem. Therefore, it can be solved in time $n^{\text{polylog}(n)}$, independently of k , using Babai's quasi-polynomial time algorithm for graph isomorphism [2]. An interesting question we leave unsolved is the complexity of $R(\alpha \cdot k)$ -reachability for unit decompositions of width at most k when α is a rational number with $1 \leq \alpha < 2$. In particular, we do not know if there is such an α for which the reachability problem becomes PSPACE-hard.

In the field of parameterized complexity theory [7, 6], a computational problem is said to be *fixed-parameter tractable (FPT)* with respect to a parameter k if it can be solved in time $f(k) \cdot n^{\mathcal{O}(1)}$ on inputs of size n . Here $f: \mathbb{N} \rightarrow \mathbb{N}$ is a computable function depending only on the parameter k , but not on the size n of the input. The GRAPH ISOMORPHISM problem (GI for short) has been shown to be solvable in time $f(k) \cdot n^{\mathcal{O}(1)}$ (that is, FPT time) whenever the parameter k stands for eigenvalue multiplicity [3], treewidth [21], feedback vertex-set number [20], or size of the largest color class [9] of the involved graphs. On the other hand, GI can be solved in time $f_1(k) \cdot n^{f_2(k)}$ (that is, in XP time), whenever the parameter k stands for genus [23], rankwidth [15], maximum degree [22], size of an excluded topological subgraph [12], or size of an excluded minor [11]. We note that, in particular, Babai's algorithm and techniques have been recently used to improve the fastest FPT algorithm for graphs of treewidth at most k from $2^{\mathcal{O}(k^5 \cdot \log k)} \cdot n^{\mathcal{O}(1)}$ [21] to $2^{\mathcal{O}(k \cdot \text{polylog}(k))} \cdot n^{\mathcal{O}(1)}$ [14], and for graphs of maximum degree d , the fastest XP-algorithm has been improved from $n^{\mathcal{O}(d/\log d)}$ [4] to $n^{\text{polylog}(d)}$ [13]. In particular, it is worth noting that graphs of cutwidth k have maximum degree at most k and treewidth $\mathcal{O}(k)$. Therefore, isomorphism of graphs of cutwidth k can be solved in time $2^{\mathcal{O}(k \cdot \text{polylog}(k))} \cdot n^{\mathcal{O}(1)}$ [14]. This implies that $R(2 \cdot k)$ -reachability can be solved in $2^{\mathcal{O}(k \cdot \text{polylog}(k))} \cdot n^{\mathcal{O}(1)}$ time when restricted to unit decompositions of width at most k . Showing that isomorphism for graphs of cutwidth k can be solved in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ is still an open problem.

Another width parameter for linear orders that has been studied in the context of graph theory is the vertex separation number of a graph [8]. This parameter may be seen as an order theoretic interpretation of the notion of pathwidth. The techniques used to prove Theorem 3 can be generalized to prove that reconfiguration of linear orders of vertex separation number k can always be achieved in width at most $2 \cdot k$ (Theorem 16). While we do not provide a string-rewriting interpretation of this result, we do state it formally in Section 5 since this result may be of independent interest in the field of reconfiguration.

2 Preliminaries

Basics. We let \mathbb{N} denote the set of natural numbers, including 0, and \mathbb{N}_+ denote the set of positive natural numbers. For each $n \in \mathbb{N}_+$, we let $[n] = \{1, \dots, n\}$. As a degenerate case, we let $[0] = \emptyset$. Given a finite set S , we let $\mathcal{P}(S)$ be the set of all subsets of S . For each $k \in \mathbb{N}$, we let $\mathcal{P}(S, k)$ and $\mathcal{P}(S, \leq k)$ be the sets of subsets of S of size exactly k and at most k , respectively.

8:4 Order Reconfiguration Under Width Constraints

Graphs. In this work, graphs are simple and undirected. Given a graph G we let $V(G)$ denote the vertex set of G and $E(G)$ denote the edge set of G . Given a subset $S \subseteq V(G)$, we let $G[S]$ be the subgraph of G induced by S . More precisely, $V(G[S]) = S$ and $E(G[S]) = E(G) \cap \mathcal{P}(S, 2)$. An *isomorphism* from a graph G to a graph G' is a bijection $\varphi : V(G) \rightarrow V(G')$ such that for each $v, u \in V(G)$, $\{v, u\} \in E(G)$ if and only if $\{\varphi(v), \varphi(u)\} \in E(G')$. If such an isomorphism exists, we say that G is *isomorphic* to G' .

Order. Let V be a set with $|V| = n$. A linear order on V is a bijection $\omega : [n] \rightarrow V$. Intuitively, for each $j \in [n]$ and $v \in V$, $\omega(j) = v$ indicates that v is the j -th element of ω . If $S \subseteq [n]$, then we let $\omega(S) = \{\omega(j) : j \in S\}$ be the image of S under ω . Given linear orders $\omega, \omega' : [n] \rightarrow V$ of V and a number $i \in [n-1]$, we write $\omega \xrightarrow{i} \omega'$ to indicate that ω' is obtained from ω by swapping the order of the vertices at positions i and $i+1$. More precisely, $\omega'(j) = \omega(j)$ for every $j \in [n] \setminus \{i, i+1\}$, $\omega'(i) = \omega(i+1)$, and $\omega'(i+1) = \omega(i)$.

Let $\omega : [n] \rightarrow V$ be a linear order on a set V . Let $S \subseteq V$. We let $\omega^S : [|S|] \rightarrow S$ be the linear order induced by ω on S . More precisely, if we write the elements of S in increasing order according to ω , then for each $i \in [|S|]$, $\omega^S(i)$ is the i -th element in this sequence.

Order Reconfiguration. We say that ω can be reconfigured into ω' in one swap, and denote this fact by $\omega \rightarrow \omega'$, if there exists some $i \in [n]$ such that $\omega \xrightarrow{i} \omega'$. We say that ω can be reconfigured into ω' in at most r swaps, and denote this fact by $\omega \rightarrow_r \omega'$, if there are numbers $r' \in [r]$, $i_1, \dots, i_{r'} \in [n]$, and linear orders $\omega_0, \dots, \omega_{r'}$ such that

$$\omega = \omega_0 \xrightarrow{i_1} \omega_1 \xrightarrow{i_2} \dots \xrightarrow{i_{r'}} \omega_{r'} = \omega'.$$

We call this sequence a *reconfiguration sequence* from ω to ω' . The mere existence of a (possibly empty) reconfiguration sequence from ω to ω' is also written as $\omega \rightarrow^* \omega'$.

Composition of Linear Orders. Let $i \in \{0, \dots, n\}$, and $\omega, \omega' : [n] \rightarrow V$. We let $\omega \oplus_i \omega' : [n] \rightarrow V$ be the linear order that orders the vertices in the subset $\omega([i]) \subseteq V$ according to ω followed by the vertices in the subset $V \setminus \omega([i])$, ordered according to ω' . More precisely, $\omega \oplus_i \omega'$ is defined as follows for each $j \in [n]$.

$$\omega \oplus_i \omega'(j) = \begin{cases} \omega(j) & \text{if } j \leq i, \\ \omega'^{V \setminus \omega([i])}(j-i) & \text{if } j > i. \end{cases} \quad (1)$$

We note that in particular, $\omega \oplus_0 \omega' = \omega'$ and $\omega \oplus_n \omega' = \omega$.

String Rewriting. A two-letter string rewriting systems is a pair (Σ, R) where Σ is a finite, non-empty set of symbols (an alphabet), and $R \subseteq \Sigma^2 \times \Sigma^2$ is a set of rewriting rules of the form $ab \rightarrow cd$. Let x and y be strings in Σ^n and $i \in [n-1]$. We say that x can be transformed into y by applying a rewriting rule $ab \rightarrow cd$ at position i if $x_i x_{i+1} = ab$, $y_i y_{i+1} = cd$ and $x_j = y_j$ for $j \notin \{i, i+1\}$. We write $x \xrightarrow{i} y$ to denote that x can be transformed into y by the application of some rewriting rule at position i . We write $x \rightarrow y$ to denote that x can be transformed into y by the application of some rewriting rule at some position $i \in [n-1]$. We say that y is reachable from x if there is a sequence of strings $x = x_0, x_1, \dots, x_m = y$ such that $x_{i-1} \rightarrow x_i$ for each $i \in [m]$. We write $x \rightarrow_* y$ to denote that y is reachable from x . We say that x and y are R -equivalent if $x \rightarrow_* y$ and $y \rightarrow_* x$.

3 Linear Order Reconfiguration

Let G be an n -vertex graph. Given sets $S, S' \subseteq V(G)$, we let $E(G, S, S') = \{\{u, v\} \in E(G) : u \in S, v \in S'\}$ be the set of edges with one endpoint in S and the other endpoint in S' . As a special case, we define $E(G, S) = E(G, S, V(G) \setminus S)$. We will often make use of the following monotonicity property without explicit mentioning: If $T \subseteq S$ and $T' \subseteq S'$, then $|E(G, T, T')| \leq |E(G, S, S')|$.

► **Definition 1** (Cutwidth). *Let G be an n -vertex undirected graph. Let $\omega : [n] \rightarrow V(G)$ be a linear order on the vertices of G . For each $p \in [n]$, we let $\text{cw}(G, \omega, p) = |E(G, \omega([p-1]))|$ be the number of edges that have one endpoint in the first $p-1$ vertices of the linear order ω and the other endpoint in the remaining vertices. The cutwidth of the linear order ω is defined as $\text{cw}(G, \omega) = \max_{p \in [n]} \text{cw}(G, \omega, p)$. The cutwidth of the graph G is defined as $\text{cw}(G) = \min_{\omega} \text{cw}(G, \omega)$, where ω ranges over all linear orders on the vertex set $V(G)$.*

For each $k \in \mathbb{N}$, and each n -vertex graph G , we let $\text{CW}(G, k) = \{\omega : [n] \rightarrow V(G) : \text{cw}(G, \omega) \leq k\}$ be the set of linear orders of $V(G)$ of cutwidth at most k . We say that ω can be *reconfigured* into ω' in cutwidth at most k if there is a *reconfiguration sequence*

$$\omega = \omega_0 \xrightarrow{i_1} \omega_1 \xrightarrow{i_2} \dots \xrightarrow{i_r} \omega_r = \omega'$$

such that for each $j \in \{0, \dots, r\}$, $\omega_j \in \text{CW}(G, k)$.

► **Problem 2** (Bounded Cutwidth Order Reconfiguration). *Let G be an n -vertex graph, $\omega, \omega' : [n] \rightarrow V(G)$ be linear orders on the vertex set of G , and $k \in \mathbb{N}$. Is it true that ω can be reconfigured into ω' in cutwidth at most k ?*

It should be clear that if k is smaller than the cutwidth of the graph G , then the answer for Problem 2 is trivially NO since in this case neither ω nor ω' are in $\text{CW}(G, k)$. On the other hand, we will show in Theorem 3 below that the answer is always YES if k is at least twice the cutwidth of the thickest input linear order.

► **Theorem 3.** *Let G be an n -vertex graph and $\omega, \omega' : [n] \rightarrow V(G)$ be linear orders of $V(G)$ of cutwidth at most k . Then, ω can be reconfigured into ω' in cutwidth at most $\text{cw}(G, \omega) + \text{cw}(G, \omega') \leq 2k$.*

To prove this theorem, we need the following three lemmas.

► **Lemma 4.** *Let G be an n -vertex graph, $S \subseteq V(G)$ and $\omega : [n] \rightarrow V(G)$ be a linear order on $V(G)$. Then, ω^S is a linear order on $V(G[S])$. Additionally, $\text{cw}(G[S], \omega^S) \leq \text{cw}(G, \omega)$.*

Proof. As $S = V(G[S])$, ω^S is a linear order on $V(G[S])$. Let $p \in [|S|]$ and let $p' \in [n]$ be the unique number such that $\omega^S(p) = \omega(p')$. Then,

$$\begin{aligned} \text{cw}(G[S], \omega^S, p) &= |E(G[S], \omega^S([p-1]))| \\ &= |E(G[S], \omega^S([p-1]), \{\omega^S(r) : r \geq p\})| \\ &= |E(G, \omega^S([p-1]), \{\omega^S(r) : r \geq p\})| \\ &\leq |E(G, \omega([p'-1]))| \\ &= \text{cw}(G, \omega, p') \\ &\leq \text{cw}(G, \omega), \end{aligned}$$

as $\omega^S([p-1]) \subseteq \omega([p'-1])$ and $\{\omega^S(r) : r \geq p\} \subseteq \{\omega(r') : r' \geq p'\} = V(G) \setminus \omega([p'-1])$. ◀

8:6 Order Reconfiguration Under Width Constraints

► **Lemma 5.** *Let G be an n -vertex graph and $\omega, \omega' : [n] \rightarrow V(G)$ be linear orders of $V(G)$ with cutwidth of at most k . Then, for each $i \in [n]$, $\omega \oplus_i \omega'$ has cutwidth at most $\text{cw}(G, \omega) + \text{cw}(G, \omega') \leq 2k$.*

Proof. Let $i, p \in [n]$. There are two cases to be analyzed. By definition, we have that

$$\text{cw}(G, \omega \oplus_i \omega', p) = |E(G, \omega \oplus_i \omega'([p-1]))| = |E(G, \omega \oplus_i \omega'([p-1]), V(G) \setminus \omega \oplus_i \omega'([p-1]))|.$$

First, if $p \leq i$, then we have

$$\text{cw}(G, \omega \oplus_i \omega', p) = |E(G, \omega([p-1]), V(G) \setminus \omega([p-1]))| = \text{cw}(G, \omega, p) \leq \text{cw}(G, \omega).$$

Secondly, if $p > i$, then we have

$$\begin{aligned} \text{cw}(G, \omega \oplus_i \omega', p) &= |E(G, \omega \oplus_i \omega'([p-1]), V(G) \setminus \omega \oplus_i \omega'([p-1]))| \\ &\stackrel{(a)}{=} |E(G, (\omega \oplus_i \omega'([p-1])) \cap \omega([i]), V(G) \setminus \omega \oplus_i \omega'([p-1]))| \\ &\quad + |E(G, (\omega \oplus_i \omega'([p-1])) \setminus \omega([i]), V(G) \setminus \omega \oplus_i \omega'([p-1]))| \\ &\stackrel{(b)}{\leq} \text{cw}(G, \omega, i+1) + \text{cw}(G[V(G) \setminus \omega([i]), \omega'^{V(G) \setminus \omega([i])}], p-i) \\ &\leq \text{cw}(G, \omega) + \text{cw}(G, \omega'). \end{aligned}$$

For Equality (a), observe that $\{(\omega \oplus_i \omega'([p-1])) \cap \omega([i]), (\omega \oplus_i \omega'([p-1])) \setminus \omega([i])\}$ is a partition of $\omega \oplus_i \omega'([p-1])$. To understand Inequality (b), we need two arguments. As $\omega([i]) \subseteq \omega \oplus_i \omega'([p-1])$,

$$E(G, (\omega \oplus_i \omega'([p-1])) \cap \omega([i]), V(G) \setminus (\omega \oplus_i \omega'([p-1]))) \subseteq E(G, \omega([i]), V(G) \setminus \omega([i])),$$

which shows that the cardinality of the first set is upper-bounded by $\text{cw}(G, \omega, i+1)$. As the edges in $E(G, (\omega \oplus_i \omega'([p-1])) \setminus \omega([i]), V(G) \setminus (\omega \oplus_i \omega'([p-1])))$ only connect vertices with positions beyond i within $\omega \oplus_i \omega'$, after an index shift, we see that only the linear order ω' really matters, which explains the inequality

$$|E(G, (\omega \oplus_i \omega'([p-1])) \setminus \omega([i]), V(G) \setminus (\omega \oplus_i \omega'([p-1])))| \leq \text{cw}(G[V(G) \setminus \omega([i]), \omega'^{V(G) \setminus \omega([i])}], p-i).$$

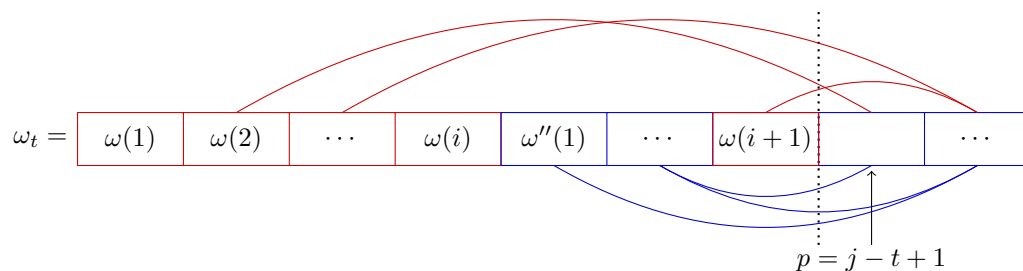

For the last inequality, apply Lemma 4 to derive $\text{cw}(G[V(G) \setminus \omega([i]), \omega'^{V(G) \setminus \omega([i])}]) \leq \text{cw}(G, \omega')$. As p is arbitrary, $\text{cw}(G, \omega \oplus_i \omega') \leq \text{cw}(G, \omega) + \text{cw}(G, \omega') \leq 2k$ follows for each $i \in [n]$. ◀

► **Lemma 6.** *Let G be an n -vertex graph, $\omega, \omega' : [n] \rightarrow V(G)$ be linear orders on $V(G)$ of cutwidth at most k and $i \in \{0, \dots, n-1\}$ be an integer. Then, $\omega \oplus_i \omega'$ can be reconfigured into $\omega \oplus_{i+1} \omega'$ in cutwidth at most $\text{cw}(G, \omega) + \text{cw}(G, \omega') \leq 2k$.*

Proof. By Lemma 5, $\omega \oplus_i \omega'$ and $\omega \oplus_{i+1} \omega'$ have cutwidth at most $\text{cw}(G, \omega) + \text{cw}(G, \omega') \leq 2k$. Let $j \in [n]$ such that $\omega \oplus_i \omega'(j) = \omega(i+1)$, i.e., j is the position of $\omega(i+1)$ in $\omega \oplus_i \omega'$. As for each $p \in [i]$, $\omega \oplus_i \omega'(p) = \omega \oplus_{i+1} \omega'(p) = \omega(p)$, we have $j > i$. Let us consider the following sequence of swaps:

$$\omega \oplus_i \omega' = \omega_0 \xrightarrow{j-1} \omega_1 \xrightarrow{j-2} \dots \xrightarrow{i+1} \omega_{j-i-1} = \omega \oplus_{i+1} \omega'.$$

If $j = i+1$, this sequence is empty and $\omega \oplus_i \omega' = \omega \oplus_{i+1} \omega'$. At each step of this sequence, we swap $\omega(i+1)$ with its left neighbor. This brings $\omega(i+1)$ from position j to position $i+1$. By doing this, we transform $\omega \oplus_i \omega'$ into $\omega \oplus_{i+1} \omega'$.

■ **Figure 1** Illustration of the key part in Lemma 6. In this figure $\omega'' = \omega^{V \setminus \omega([i+1])}$. The red part of the linear order follows the linear order ω for the first $i+1$ elements, and the blue part of the linear order follows ω' for the remaining elements. Then, the set of edges crossing the cut at position $p = j - t + 1$ can be split in two, the set of edges that start from the red part and the set of edge that start from the green part. The number of red edges is bounded by the cutwidth of ω and the number of green edges is bounded by the cutwidth of ω' .

Inductively, we show that each element ω_t in the sequence has cutwidth upper-bounded by $\text{cw}(G, \omega) + \text{cw}(G, \omega') \leq 2k$. By Lemma 5, $\text{cw}(G, \omega_0) = \text{cw}(G, \omega \oplus_i \omega') \leq \text{cw}(G, \omega) + \text{cw}(G, \omega') \leq 2k$, which proves the induction basis. Let $t \in [j-i-1]$ and $p \in [n]$ be two integers. As induction hypothesis, we have $\text{cw}(G, \omega_{t-1}) \leq \text{cw}(G, \omega) + \text{cw}(G, \omega') \leq 2k$. If $p \leq j-t$ or $p > j-t+1$, then we have $\omega_{t-1}([p-1]) = \omega_t([p-1])$, so $\text{cw}(G, \omega_t, p) = \text{cw}(G, \omega_{t-1}, p) \leq \text{cw}(G, \omega) + \text{cw}(G, \omega') \leq 2k$ by induction hypothesis. Otherwise, $p = j-t+1 \in \{i, \dots, j\}$ (Figure 1) and we have

$$\begin{aligned} \text{cw}(G, \omega_t, p) &= |E(G, \omega_t([p-1]))| \\ &= |E(G, \omega_t([p-1]), \{\omega_t(r) : r \geq p\})| \\ &= |E(G, \omega_t([i] \cup \{p-1\}), \{\omega_t(r) : r \geq p\})| \\ &\quad + |E(G, \{\omega_t(l) : i < l < p-1\}, \{\omega_t(r) : r \geq p\})|. \end{aligned}$$

By definition of ω_t and p , we have $\omega_t(p-1) = \omega_t(j-t) = \omega(i+1)$. Therefore, we have $|E(G, \omega_t([i] \cup \{p-1\}), \{\omega_t(r) : r \geq p\})| = |E(G, \omega([i+1]), \{\omega_t(r) : r \geq j-t+1\})|$. As we are swapping $\omega(i+1)$ leftwards, $\{\omega_t(r) : r \geq j-t+1\} \subseteq \{\omega(r) : r \geq i+2\} = V(G) \setminus \omega([i+1])$. Again by definition of ω_t and p , the elements in $\{\omega_t(l) : i < l < p-1\}$ are ordered according to ω' , which is also true for $\{\omega_t(r) : r \geq p\}$. More formally, $\{\omega_t(l) : i < l < p-1\} = \{\omega \oplus_i \omega'(l) : i+1 \leq l \leq p-2\} = \{\omega^{V(G) \setminus \omega([i+1])}(l') : l' \leq p-2-i\}$ and $\{\omega_t(r) : r \geq p\} = \{\omega \oplus_i \omega'(r) : r \geq p\} = \{\omega^{V(G) \setminus \omega([i+1])}(r') : r' \geq p-i-1\}$. Therefore,

$$\begin{aligned} \text{cw}(G, \omega_t, p) &\leq \text{cw}(G, \omega, i+2) + \text{cw}(G[V(G) \setminus \omega([i+1])], \omega^{V(G) \setminus \omega([i+1])}, p-i-1) \\ &\leq \text{cw}(G, \omega) + \text{cw}(G[V(G) \setminus \omega([i+1])], \omega^{V(G) \setminus \omega([i+1])}) \\ &\leq \text{cw}(G, \omega) + \text{cw}(G, \omega') \\ &\leq 2k. \end{aligned}$$

To achieve the penultimate inequality, we again apply Lemma 4. ◀

Proof of Theorem 3. Consider the following sequence: $\omega = \omega' \oplus_0 \omega \rightarrow^* \omega' \oplus_1 \omega \rightarrow^* \dots \rightarrow^* \omega' \oplus_n \omega = \omega'$. By Lemma 6, one can realize each step in cutwidth at most $\text{cw}(G, \omega) + \text{cw}(G, \omega') \leq 2k$, which then also upper-bounds the whole reconfiguration sequence. ◀

4 Slice Rewriting System

Slices. Let $\mathcal{I} = \{[a] : a \in \mathbb{N}\}$ denote the set of intervals of the form $[a] = \{1, \dots, a\}$ for $a \in \mathbb{N}$ (recall that $[0] = \emptyset$). We let $\mathcal{I}_0 = \{\{0\} \times [a] : [a] \in \mathcal{I}\}$, and $\mathcal{I}_1 = \{\{1\} \times [a] : [a] \in \mathcal{I}\}$. A *slice* $\mathbf{S} = (I, C, O, E)$ is a (multi-)graph where the vertex set $V = I \dot{\cup} C \dot{\cup} O$ is partitioned into an *in-frontier* $I \in \mathcal{I}_0$, a *center* $C \in \mathcal{I}$ and an *out-frontier* $O \in \mathcal{I}_1$, and E is a multiset of unordered pairs from $I \cup C \cup O$ in such a way that vertices of $I \cup O$ have degree exactly 1, there is no edge between any two vertices in I , and no edge between any two edges in O . We depict slices as in Figure 2. We define slices using multigraphs, as the gluing operation, defined below, can take slices which are simple graphs, and create a slice which is a multigraph (see Figure 5). Given a slice \mathbf{S} , we define $I(\mathbf{S})$ as the in-frontier of \mathbf{S} , $O(\mathbf{S})$ as the out-frontier of \mathbf{S} , and $C(\mathbf{S})$ as the center vertices of \mathbf{S} . The *width* of a slice \mathbf{S} is defined as $\mathbf{w}(\mathbf{S}) = \max(|I(\mathbf{S})|, |O(\mathbf{S})|)$.

■ **Figure 2** Slices are drawn as tiles. This figure depicts the slice $\mathbf{S} = (I, C, O, E)$ where $I = \{(0, 1), (0, 2)\}$, $C = \{1, 2, 3\}$, $O = \{(1, 1), (1, 2), (1, 3), (1, 4)\}$ and $E = \{\{(0, 1), 1\}, \{(0, 2), 3\}, \{1, 2\}, \{2, 3\}, \{1, (1, 1)\}, \{2, (1, 2)\}, \{2, (1, 3)\}, \{3, (1, 4)\}\}$. We omit the first element of the pair for frontier vertices and use the following convention. The in-frontier vertices are on the left of the tile and the out-frontier vertices are on the right of the tile. If the frontier vertices are not explicitly mentioned in the drawing, we assume that frontier vertices are ordered from top to bottom as in this drawing.

Gluing Slices. A slice $\mathbf{S}_1 = (I_1, C_1, O_1, E_1)$ can be glued to $\mathbf{S}_2 = (I_2, C_2, O_2, E_2)$ if for some interval $[a] \in \mathcal{I}$, $O_1 = \{1\} \times [a]$ and $I_2 = \{0\} \times [a]$. In this case, the gluing gives rise to the slice $\mathbf{S}_1 \circ \mathbf{S}_2 = (I_1, C_1 \cup (|C_1| \oplus C_2), O_2, E)$ where $|C_1| \oplus C_2 = \{|C_1| + 1, |C_1| + 2, \dots, |C_1| + |C_2|\}$,

$$\begin{aligned}
 E = & \{\{x, y\} \in E_1 : x, y \in I_1 \cup C_1\} \\
 & \cup \{\{x, y\} \in E_2 : x, y \in O_2\} \\
 & \cup \{\{x, y + |C_1|\} : \{x, y\} \in E_2 \wedge x \in O_2 \wedge y \in C_2\} \\
 & \cup \{\{x + |C_1|, y + |C_1|\} : \{x, y\} \in E_2 \wedge x, y \in C_2\} \\
 & \cup \{\{x, y\} : \exists i, \{x, (1, i)\} \in E_1 \wedge y \in O_2 \wedge \{(0, i), y\} \in E_2\} \\
 & \cup \{\{x, y\} : \exists i, \{x, (1, i)\} \in E_1 \wedge y \in |C_1| \oplus C_2 \wedge \{(0, i), y - |C_1|\} \in E_2\}.
 \end{aligned}$$

Note that the gluing operation is associative. Therefore, we will not write parentheses for the gluing of more than two slices. Figure 3 illustrates the gluing of two slices.

Unit Slices and Unit Decompositions. We say that a slice is a *unit slice* if it has a unique vertex in its center. A *unit decomposition* is a sequence $\mathbf{U} = \mathbf{S}_1 \mathbf{S}_2 \dots \mathbf{S}_n$, where \mathbf{S}_i are unit slices and $\mathbf{S}_i \circ \mathbf{S}_{i+1}$ is well defined for each $i \in [n - 1]$. The *slice associated to a unit decomposition* \mathbf{U} is defined as $\mathring{\mathbf{U}} = \mathbf{S}_1 \circ \mathbf{S}_2 \circ \dots \circ \mathbf{S}_n$ (Figure 4). Note that if the in-frontier of \mathbf{S}_1 and the out-frontier of \mathbf{S}_n are empty, then $\mathring{\mathbf{U}}$ is just a multigraph with vertex set $[n]$ (Figure 5). For each $k \in \mathbb{N}$, we define the alphabet $\Sigma(k)$ as the set of all unit slices of width at most k . We let $\Sigma(k)^\circledast$ denote the set of all unit decompositions over $\Sigma(k)$.

■ **Figure 3** Gluing of two slices \mathbf{S}_1 and \mathbf{S}_2 . The gluing operation is a way to merge two slices into one. In this example, the edge from the center vertex 1 from \mathbf{S}_1 to the out-frontier vertex $(1, 2)$ is stitched to the edge from the in-frontier vertex $(0, 2)$ to the center vertex 1 from \mathbf{S}_2 to form the edge between the center vertices 1 and 2 in $\mathbf{S}_1 \circ \mathbf{S}_2$. The stitching of edges is done following the order of the frontier vertices.

■ **Figure 4** Slice associated to the unit decomposition $\mathbf{U} = \mathbf{S}_1\mathbf{S}_2\mathbf{S}_3$. The gluing operation is associative, therefore parentheses are not needed.

The order of the unit slices in a unit decomposition $\mathbf{U} = \mathbf{S}_1\mathbf{S}_2 \dots \mathbf{S}_n$ induces a linear order $\omega_{\mathbf{U}}$ on the vertices of the slice $\mathring{\mathbf{U}}$. This linear order sets $\omega_{\mathbf{U}}(i) = (0, i)$ for each $(0, i) \in I(\mathbf{S}_1)$, $\omega_{\mathbf{U}}(|I(\mathbf{S}_1)| + i) = i$ for each $i \in \{1, \dots, n\}$ and $\omega_{\mathbf{U}}(|I(\mathbf{S}_1)| + n + i) = (1, i)$ for each $(1, i) \in O(\mathbf{S}_n)$.

Given a unit decomposition $\mathbf{U} = \mathbf{S}_1\mathbf{S}_2 \dots \mathbf{S}_n$ in $\Sigma(k)^\circledast$, we let $\mathbf{w}(\mathbf{U}) = \max_{i \in [n]} \mathbf{w}(\mathbf{S}_i)$.

► **Proposition 7.** *Let $k \in \mathbb{N}$, and $\mathbf{U} = \mathbf{S}_1\mathbf{S}_2 \dots \mathbf{S}_n$ be a unit decomposition in $\Sigma(k)^\circledast$, and $\omega_{\mathbf{U}}$ be the linear order induced by \mathbf{U} on $\mathring{\mathbf{U}}$. Then, $\text{cw}(\mathring{\mathbf{U}}, \omega_{\mathbf{U}}) = \mathbf{w}(\mathbf{U})$.*

Proof. This follows by noticing that for each vertex p in $\{1, \dots, |I(\mathbf{S}_1)|\}$, $\text{cw}(\mathring{\mathbf{U}}, \omega_{\mathbf{U}}, p) \leq |I(\mathbf{S}_1)|$, for each p in $\{|I(\mathbf{S}_1)| + n, \dots, |I(\mathbf{S}_1)| + n + |O(\mathbf{S}_n)|\}$, $\text{cw}(\mathring{\mathbf{U}}, \omega_{\mathbf{U}}, p) \leq O(\mathbf{S}_n)$, and for each $p \in \{|I(\mathbf{S}_1)| + 1, \dots, |I(\mathbf{S}_1)| + n\}$, $\text{cw}(\mathring{\mathbf{U}}, \omega_{\mathbf{U}}, p) \leq \mathbf{w}(\mathbf{S}_{i-|I(\mathbf{S}_1)|})$. ◀

► **Proposition 8.** *Let G be an n -vertex graph and ω be a linear order on the vertices of G of cutwidth k . Then, we can construct in time $\mathcal{O}(kn)$ a unit decomposition \mathbf{U} such that $\omega = \omega_{\mathbf{U}}$.*

Proof. We will do this construction by first drawing the graph G in the plane. G does not need to be planar for this construction to work. First, we will place the vertices of G on a straight line L isomorphic to \mathbb{R} . The i th vertex of G with respect to the linear order ω is placed at the coordinate i on the line. Then edges are drawn as curves between their endpoints. Now, we will draw $n + 1$ lines perpendicular to L at coordinates $\{-0.5, 0.5, 1.5, \dots, n - 0.5, n + 0.5\}$. We call these lines cut-lines. The cutwidth of ω is k , therefore each cut-line intersects at most k edges in the drawing of G . We put a vertex at the intersection of a cut-line and an edge. The graph between two consecutive cut-lines defines a unit slice of width at most k . Taking all those slices in the order induced by ω on the line L gives a unit decomposition \mathbf{U} of width k such that $\omega = \omega_{\mathbf{U}}$. Figure 6 illustrates this construction. ◀

Equivalence of Slices. Let $\mathbf{S}_1 = (I_1, C_1, O_1, E_1)$ and $\mathbf{S}_2 = (I_2, C_2, O_2, E_2)$ be two slices. We say that \mathbf{S}_1 is *equivalent* to \mathbf{S}_2 , denoted by $\mathbf{S}_1 \sim \mathbf{S}_2$, if and only if $I_1 = I_2$, $O_1 = O_2$, $C_1 = C_2$, and there is an isomorphism ϕ from \mathbf{S}_1 to \mathbf{S}_2 such that the restriction of ϕ to I_1 and O_1 is the identity function. In other words, \mathbf{S}_1 and \mathbf{S}_2 are equivalent if they are equal up to the renaming of the center vertices.

■ **Figure 5** Slice associated to the unit decomposition $\mathbf{U} = \mathbf{S}_1\mathbf{S}_2\mathbf{S}_3$. The resulting slice does not have any vertex in its frontier. It can therefore be seen as a multigraph on 3 vertices.

■ **Figure 6** Slicing of the graph G on the left into a unit decomposition \mathbf{U} on the right.

We let $\mathcal{R}(k) \subseteq \Sigma(k)^2 \times \Sigma(k)^2$ be the set of all rewriting rules of the form $\mathbf{S}_1\mathbf{S}_2 \rightarrow \mathbf{S}'_1\mathbf{S}'_2$ such that $\mathbf{S}_1 \circ \mathbf{S}_2 \sim \mathbf{S}'_1 \circ \mathbf{S}'_2$. Call two unit decompositions $\mathbf{U}, \mathbf{U}' \in \Sigma(k)^\otimes$ *locally $\mathcal{R}(k)$ -equivalent*, and denote this fact by $\mathbf{U} \stackrel{k}{\sim} \mathbf{U}'$, if there exist $\mathbf{W}, \mathbf{W}' \in \Sigma(k)^\otimes$ and $\mathbf{S}_1, \mathbf{S}'_1, \mathbf{S}_2, \mathbf{S}'_2 \in \Sigma(k)$ with $\mathbf{S}_1 \circ \mathbf{S}_2 \sim \mathbf{S}'_1 \circ \mathbf{S}'_2$ such that $\mathbf{U} = \mathbf{W}\mathbf{S}_1\mathbf{S}_2\mathbf{W}'$ and $\mathbf{U}' = \mathbf{W}\mathbf{S}'_1\mathbf{S}'_2\mathbf{W}'$ (Figure 7).

■ **Figure 7** Local Equivalence. $\mathbf{S}_1\mathbf{S}_2$ is (locally) $\mathcal{R}(4)$ -equivalent to $\mathbf{S}'_1\mathbf{S}'_2$.

We let $\stackrel{k}{\equiv} \subseteq \Sigma(k)^\otimes \times \Sigma(k)^\otimes$ be the equivalence relation defined on unit decompositions by taking the reflexive, symmetric and transitive closure of $\stackrel{k}{\sim}$. If $\mathbf{U} \stackrel{k}{\equiv} \mathbf{U}'$, then we say that \mathbf{U}' is $\mathcal{R}(k)$ -equivalent to \mathbf{U} . We note that there may exist unit decompositions in $\Sigma(k)^\otimes$ that are not $\mathcal{R}(k)$ -equivalent but that are $\mathcal{R}(k')$ -equivalent for some $k' > k$.

► **Lemma 9.** *Let $k \in \mathbb{N}$ and \mathbf{U} and \mathbf{U}' be unit decompositions in $\Sigma(k)^\otimes$. If \mathbf{U} is $\mathcal{R}(k)$ -equivalent to \mathbf{U}' , then $\mathring{\mathbf{U}}$ is isomorphic to $\mathring{\mathbf{U}'}$.*

Proof. It is enough to show that if \mathbf{U} can be transformed into \mathbf{U}' in one $\mathcal{R}(k)$ -rewriting step then $\mathring{\mathbf{U}}$ is isomorphic to $\mathring{\mathbf{U}'}$. Therefore, assume that $\mathbf{U} \rightarrow \mathbf{U}'$. Then there exist unit decompositions $\mathbf{W}, \mathbf{W}' \in \Sigma(k)^\otimes$ and a rewriting rule $\mathbf{S}_1\mathbf{S}_2 \rightarrow \mathbf{S}'_1\mathbf{S}'_2$ in $\mathcal{R}(k)$ such that $\mathbf{U} = \mathbf{W}\mathbf{S}_1\mathbf{S}_2\mathbf{W}'$ and $\mathbf{U}' = \mathbf{W}\mathbf{S}'_1\mathbf{S}'_2\mathbf{W}'$. Since $\mathbf{S}_1 \circ \mathbf{S}_2 \sim \mathbf{S}'_1 \circ \mathbf{S}'_2$, we have an isomorphism φ from $\mathbf{S}_1 \circ \mathbf{S}_2$ to $\mathbf{S}'_1 \circ \mathbf{S}'_2$ that acts as the identity map on frontier vertices. This implies that $\mathring{\mathbf{U}} = \mathring{\mathbf{W}} \circ \mathbf{S}_1 \circ \mathbf{S}_2 \circ \mathring{\mathbf{W}'}$ is isomorphic to $\mathring{\mathbf{U}'} = \mathring{\mathbf{W}} \circ \mathbf{S}'_1 \circ \mathbf{S}'_2 \circ \mathring{\mathbf{W}'}$. ◀

Twisting. Let $\mathbf{U} = \mathbf{S}_1\mathbf{S}_2 \cdots \mathbf{S}_n$ and $\mathbf{U}' = \mathbf{S}'_1\mathbf{S}'_2 \cdots \mathbf{S}'_n$ be two unit decompositions. We say that \mathbf{U} is a *twisting* of \mathbf{U}' if $\mathring{\mathbf{U}} = \mathring{\mathbf{U}'}$. Note that we are not equating slices up to isomorphism. In other words, we are really requiring that the slices $\mathring{\mathbf{U}}$ and $\mathring{\mathbf{U}'}$ are syntactically identical.

Let \mathbf{S}_1 and \mathbf{S}_2 be unit slices in $\Sigma(k)$ such that the out-frontier of \mathbf{S}_1 and the in-frontier of \mathbf{S}_2 have k' vertices for some $k' \leq k$. Given a permutation $\pi : [k'] \rightarrow [k']$, let \mathbf{S}_1^π be the slice obtained by renaming each vertex $(1, i)$ in the out-frontier of \mathbf{S}_1 to $(1, \pi(i))$, and let ${}^\pi\mathbf{S}_2$

Figure 8 The unit decomposition $\mathbf{U} = \mathbf{S}_1\mathbf{S}_2\mathbf{S}_3$ is a twisting of the unit decomposition $\mathbf{U}' = \mathbf{S}'_1\mathbf{S}'_2\mathbf{S}'_3$. Note that $\mathbf{S}_2 \circ \mathbf{S}_3 = \mathbf{S}'_2 \circ \mathbf{S}'_3$. Note that if we let π be the permutation that sets $\pi(1) = 2$, $\pi(2) = 3$ and $\pi(3) = 1$, then \mathbf{S}'_2 is obtained by permuting the out-frontier of \mathbf{S}_2 according to π and \mathbf{S}'_3 is obtained by permuting the in-frontier of \mathbf{S}_3 according to π .

be the slice obtained by renaming each vertex $(0, i)$ in the in-frontier of \mathbf{S}_2 to $(0, \pi(i))$. Then it should be clear that $\mathbf{S}_1 \circ \mathbf{S}_2 = \mathbf{S}'_1 \circ \pi\mathbf{S}_2$. Additionally, for each two unit slices \mathbf{S}'_1 and \mathbf{S}'_2 such that $\mathbf{S}_1 \circ \mathbf{S}_2 = \mathbf{S}'_1 \circ \mathbf{S}'_2$, it should be clear that there is some permutation π such that $\mathbf{S}'_1 = \mathbf{S}'_1 \circ \pi$ and $\mathbf{S}'_2 = \pi\mathbf{S}_2$. Note also that for each two such slices \mathbf{S}'_1 and \mathbf{S}'_2 , the rewriting rule $\mathbf{S}_1\mathbf{S}_2 \rightarrow \mathbf{S}'_1\mathbf{S}'_2$ belongs to $\mathcal{R}(k)$. This implies that if a unit decomposition $\mathbf{U} = \mathbf{S}_1\mathbf{S}_2 \dots \mathbf{S}_n$ is a twisting of a unit decomposition $\mathbf{U}' = \mathbf{S}'_1\mathbf{S}'_2 \dots \mathbf{S}'_n$, then \mathbf{U} and \mathbf{U}' are $\mathcal{R}(k)$ -equivalent and can be transformed into each other by applying a sequence of rewriting rules that “twists” for each $i \in [n - 1]$ the out-frontier of \mathbf{S}_i and the in-frontier of \mathbf{S}_{i+1} according to some permutation π_i . This process is illustrated in Figure 8.

► **Proposition 10** (Twisting). *Let $\mathbf{U} = \mathbf{S}_1\mathbf{S}_2 \dots \mathbf{S}_n$ and $\mathbf{U}' = \mathbf{S}'_1\mathbf{S}'_2 \dots \mathbf{S}'_n$ be two unit decompositions in $\Sigma(k)^\otimes$ such that \mathbf{U} is a twisting of \mathbf{U}' . Then, \mathbf{U} can be transformed into \mathbf{U}' by the application of $n - 1$ rewriting rules from $\mathcal{R}(k)$.*

An interesting question is whether, for each $k \in \mathbb{N}$, there is some $k' \in \mathbb{N}$ such that any two unit decompositions \mathbf{U} and \mathbf{U}' in $\Sigma(k)$ are $\mathcal{R}(k')$ -equivalent if and only if $\hat{\mathbf{U}}$ is isomorphic to $\hat{\mathbf{U}}'$. The answer turns out to be yes, as shown in Theorem 11 below.

► **Theorem 11.** *Let \mathbf{U} and \mathbf{U}' be unit decompositions in $\Sigma(k)^\otimes$. Then, $\hat{\mathbf{U}}$ is isomorphic to $\hat{\mathbf{U}}'$ if and only if \mathbf{U} and \mathbf{U}' are $\mathcal{R}(2k)$ -equivalent.*

Proof. Let $\mathbf{U} = \mathbf{S}_1\mathbf{S}_2 \dots \mathbf{S}_n$ and $\mathbf{U}' = \mathbf{S}'_1\mathbf{S}'_2 \dots \mathbf{S}'_n$. Suppose that \mathbf{U} and \mathbf{U}' are $\mathcal{R}(2k)$ -equivalent. Then by Lemma 9, $\hat{\mathbf{U}}$ is isomorphic to $\hat{\mathbf{U}}'$.

For the converse, suppose that $\hat{\mathbf{U}}$ is isomorphic to $\hat{\mathbf{U}}'$ and let φ be an isomorphism from $\hat{\mathbf{U}}$ to $\hat{\mathbf{U}}'$. We show that \mathbf{U} and \mathbf{U}' are $\mathcal{R}(2k)$ -equivalent.

Given a position $i \in [n - 1]$ in the unit decomposition \mathbf{U} , a *swap* between \mathbf{S}_i and \mathbf{S}_{i+1} is a rewriting rule in $\mathcal{R}(k')$ for some k' that rewrites \mathbf{U} into the unit decomposition

$$\mathbf{U}_i = \mathbf{S}_1\mathbf{S}_2 \dots \mathbf{S}_{i-1}\mathbf{S}''_i\mathbf{S}''_{i+1}\mathbf{S}_{i+2} \dots \mathbf{S}_n$$

such that, the function $\psi : [n] \rightarrow [n]$ that sets $\psi(p) = p$ for all $p \notin \{i, i + 1\}$, $\psi(i) = i + 1$ and $\psi(i + 1) = i$ is an isomorphism from $\hat{\mathbf{U}}$ to $\hat{\mathbf{U}}_i$.

Intuitively, we swap the center vertex of \mathbf{S}_i with the center vertex of \mathbf{S}_{i+1} . Note that there may be several rewriting rules corresponding to such a swap. Now, a swap in the unit decomposition \mathbf{U} corresponds to a swap in $\omega_{\mathbf{U}}$ as defined for linear orders in Section 2. The isomorphism φ defines a transformation of $\omega_{\mathbf{U}}$ into $\omega_{\mathbf{U}'}$.

By Proposition 7, $\text{cw}(\hat{\mathbf{U}}, \omega_{\mathbf{U}}) \leq k$ and $\text{cw}(\hat{\mathbf{U}}', \omega_{\mathbf{U}'}) \leq k$. Now, our result in Section 3 can be used for the slice rewriting system $\mathcal{R}(2k)$. More precisely, it follows from Theorem 3 that we can transform $\omega_{\mathbf{U}}$ into $\omega_{\mathbf{U}'}$ by a sequence of $O(n^2)$ swaps and at each step, the cutwidth is at most $2k$. By using the rewriting rules from $\mathcal{R}(2k)$, we can replicate these swaps into the unit decomposition \mathbf{U} , obtaining in this way a unit decomposition \mathbf{U}'' such that $\omega_{\mathbf{U}''} = \omega_{\mathbf{U}'}$.

8:12 Order Reconfiguration Under Width Constraints

Since $\mathring{U}'' = \mathring{U}'$, we have that U'' is a twisting of U' . Therefore, it follows from Proposition 10 that U'' can be further transformed into U' by applying a sequence of $n - 1$ rewriting rules from $\mathcal{R}(k) \subseteq \mathcal{R}(2k)$.

Hence, U can be rewritten into U'' by applying $O(n^2)$ rewriting rules from $\mathcal{R}(2k)$. ◀

Theorem 11 allows us to establish connections between the graph isomorphism problem for graphs of cutwidth at most k and the reachability problem in $\mathcal{R}(2k)$.

► **Theorem 12** ([10]). *Let G be an n -vertex graph of cutwidth k . We can compute a linear order ω of the vertices of G of width k in time $2^{\mathcal{O}(k^2)} \cdot n$.*

► **Theorem 13.** *Graph isomorphism for n -vertex graphs of cutwidth at most k can be reduced in time $2^{\mathcal{O}(k^2)} \cdot n$ to $\mathcal{R}(2k)$ -reachability.*

Proof. Given n -vertex graphs G and G' of cutwidth at most k , we first compute in time $2^{\mathcal{O}(k^2)} \cdot n$ linear orders ω and ω' of the vertex sets of G and G' , respectively, of cutwidth at most k . Then, from Proposition 8, we construct unit decompositions U and U' such that $\omega_U = \omega$, $\omega_{U'} = \omega'$, G is isomorphic to \mathring{U} and G' is isomorphic to \mathring{U}' . By Proposition 8, those decompositions belong to $\Sigma(k)^{\otimes}$. By Theorem 11, we have that \mathring{U} and \mathring{U}' are isomorphic if and only if U and U' are $\mathcal{R}(2k)$ -equivalent. ◀

5 Order Reconfiguration Parameterized by Vertex Separation Number

In this section, we show that the techniques employed in Section 3 for total orders of bounded cutwidth can be generalized to the context of orders of bounded vertex-separation number (Theorem 16). We consider that this generalization may be of independent interest in the theory of reconfiguration, since vertex separation number is a width measure for graphs that is strictly more expressive than cutwidth.

Let G be an n -vertex graph. Given sets $S, S' \subseteq V(G)$, we let $V(G, S, S') = \{u \in S : \exists v \in S' : \{u, v\} \in E(G)\}$ be the set of vertices in S that are adjacent to some vertex in S' . As a special case, we define $V(G, S) = V(G, S, V(G) \setminus S)$. We will often make use of the following monotonicity property without explicitly mentioning: If $T \subseteq S$ and $T' \subseteq S'$, then $|V(G, T, T')| \leq |V(G, S, S')|$.

► **Definition 14** (Vertex Separation Number). *Let G be an n -vertex undirected graph with vertex set $V(G)$ and edge set $E(G)$. Let $\omega : [n] \rightarrow V(G)$ be a linear order on the vertices of G . For each $p \in [n]$, we let*

$$\text{vsn}(G, \omega, p) = |V(G, \omega([p-1]))| = |\{l \in [p-1] : \exists r \geq p \text{ such that } \{\omega(l), \omega(r)\} \in E(G)\}|.$$

The vertex separation number of ω is defined as $\text{vsn}(G, \omega) = \max_{p \in [n]} \text{vsn}(G, \omega, p)$. The vertex separation number of G is defined as $\text{vsn}(G) = \min_{\omega} \text{vsn}(G, \omega)$, where ω ranges over all linear orders on the vertex set V .

For each $k \in \mathbb{N}$ and each n -vertex graph G , let $\text{VSN}(G, k) = \{\omega : [n] \rightarrow V(G) : \text{vsn}(G, \omega) \leq k\}$ be the set of linear orders of $V(G)$ of vertex separation number at most k . We say that ω can be *reconfigured* into ω' in vertex separation number at most k if there is a *reconfiguration sequence* $\omega = \omega_0 \xrightarrow{i_1} \omega_1 \xrightarrow{i_2} \dots \xrightarrow{i_r} \omega_r = \omega'$ such that for each $j \in [r]$, $\omega_j \in \text{VSN}(G, k)$.

► **Problem 15** (Bounded Vertex Separation Number Reconfiguration). *Let G be an n -vertex graph, $\omega, \omega' : [n] \rightarrow V(G)$ be linear orders on the vertex set of G , and $k \in \mathbb{N}$. Is it true that ω can be reconfigured into ω' in vertex separation number at most k ?*

The proof of Theorem 16 below is analogous to the proof of Theorem 3. More precisely, this proof follows by restating Lemma 4, Lemma 5 and Lemma 6 in terms of the vertex separation number of a graph instead of cutwidth, and then by using this last restated lemma to conclude the proof, as done in Theorem 3.

► **Theorem 16.** *Let G be an n -vertex graph and $\omega, \omega' : [n] \rightarrow V(G)$ be linear orders of $V(G)$ of vertex separation number at most k . Then, ω can be reconfigured into ω' in vertex separation number at most $\text{vsn}(G, \omega) + \text{vsn}(G, \omega') \leq 2k$.*

6 Conclusion

In this work, we have studied the order reconfiguration problem under the framework of the theory of fixed-parameter tractability. In particular, in our main technical result, we have shown that the order reconfiguration problem for orders of cutwidth at most k can always be achieved in cutwidth at most $2k$ (Theorem 3). Using this result, we have established new connections between the graph isomorphism problem and the reachability problem for a special two-letter string rewriting system operating on unit slices. In particular, we have proven that unit decompositions \mathbf{U} and \mathbf{U}' of width k are $R(2k)$ -equivalent if and only if the graphs \mathbf{U} and \mathbf{U}' are isomorphic (Theorem 11).

Theorem 11 opens up the possibility of studying the graph isomorphism problem under the perspective of term rewriting theory. The most immediate question in this direction is the complexity of deciding $R(2k)$ -reachability for unit decompositions of width k . By a reduction to isomorphism of graphs of cutwidth k , this problem can be solved in time $2^{O(k \cdot \text{polylog } k)} n^{O(1)}$ using the results from [14]. Can techniques that are intrinsic to string/term rewriting theory be used to improve this running time? Can such techniques be used to obtain algorithms running in time $f(k) \cdot n^{O(1)}$ for some computable function $f : \mathbb{N} \rightarrow \mathbb{N}$? Note that a positive answer to this question would be conceptually relevant even if the function $f(k)$ is substantially worse than the current $2^{O(k \cdot \text{polylog } k)}$, since techniques based on rewriting may carry over to contexts where group theoretic techniques do not. One interesting line of attack for this question would be to study connections between $R(2k)$ and techniques related to Knuth-Bendix completion and their generalizations [25, 26, 18, 16].

A natural question that arises in the context of reconfiguration of linear orders is the following: given two linear orders ω and ω' , what is the minimum cutwidth of a linear order ω'' occurring in a reconfiguration sequence from ω to ω' ? Is this problem NP-hard, or hard to approximate? Is it solvable in FPT-time for certain parameters? We thank one of the reviewers for bringing these interesting questions to our attention.

Abstract

Gauge symmetries play a fundamental role in Physics, as they provide a mathematical justification for the fundamental forces. Usually, one starts from a non-interactive theory which governs “matter”, and features a global symmetry. One then extends the theory so as to make the global symmetry into a local one (a.k.a. gauge-invariance). We formalise a discrete counterpart of this process, known as gauge extension, within the Computer Science framework of Cellular Automata (CA). We prove that the CA which admit a relative gauge extension are exactly the globally symmetric ones (a.k.a. the colour-blind). We prove that any CA admits a non-relative gauge extension. Both constructions yield universal gauge-invariant CA, but the latter allows for a first example where the gauge extension mediates interactions within the initial CA.

1 Introduction

Symmetries are an essential concept, whether in Computer science or in Physics. In this paper we explore the Physics concept of gauge symmetry by taking it into the rigorous, Computer Science framework of Cellular Automata (CA). Implementing gauge-symmetries within CA may prove useful in the fields of numerical analysis; quantum simulation; and digital Physics – as these are constantly looking for discrete schemes that simulate known Physics. Quite often, these discrete schemes seek to retain the symmetries of the simulated Physics; whether in order to justify the discrete scheme as legitimate or as numerically accurate (e.g. by doing the Monte Carlo-counting right [12]). More specifically, the introduction of gauge-symmetries within discrete-time lattice models has proven useful already in the field of Quantum Computation, where gauge-invariant Quantum Walks and Quantum Cellular Automata [1] provide us with concrete digital quantum simulation algorithms for particle Physics. These come to complement the already existing continuous-time lattice models of particle Physics [9, 15]. Another field where this has played a role is Quantum error correction [13, 14], where it was noticed that gauge-invariance amounts to invariance under certain local errors. This echoes the fascinating albeit unresolved question of noise resistance within Cellular Automata [7, 8, 11, 18].

In [16] the authors study G -blind cellular automata, where G is a group of permutation acting on the state space of cells. Blind cellular automata are globally symmetric under G , i.e. the global evolution commutes with the application of the same $g \in G$ at once on every cell. They show the surprising result that any CA can be simulated by such a globally symmetric CA, when G is the symbol permutations. Globally symmetric CA are therefore universal. Local symmetry, aka gauge symmetry, is way more stringent however: a different g^x can now be chosen for every cell x . Still, in this paper, we prove that any CA can be extended into a gauge-invariant CA. Gauge-invariant CA are therefore universal.

From a Physics perspective one usually motivates the demand for a certain gauge symmetry, from an already existing global symmetry. From a mathematical perspective, the gauge field that then gets introduced for that purpose is often seen as a connection between two gauge choices at neighbouring points. This raises questions however, because there is no immediate reason why a gauge symmetry should necessarily arise from an already existing global symmetry (one could ask for a certain ad hoc gauge symmetry from scratch). Nor is there an immediate reason why a gauge field should necessarily be interpretable as a connection (a gauge field could be made to hold absolute instead of relative information about gauge choices).

In this paper, we prove an original result relating these two folklore perspectives about gauge theories using purely combinatorial definitions. Namely, we prove that the CA that admit *relative* gauge extension are exactly those that have the corresponding global symmetry in the first place.

Although the gauge field was initially introduced in order to obtain gauge symmetry, it allows for new dynamics. Amongst those dynamics, one could ask for the matter field to influence the dynamics of the gauge field, as is the case in Physics. In this paper, we provide a first a Gauge-invariant CA where this is happening. This CA is obtained through a non-relative gauge extension. We leave it as an open question whether the same can be achieved through a relative gauge extension.

The present work builds upon two previous papers by a subset of the authors, which laid down the basic definitions of gauge-invariance for CA and provided a first set of examples, in both the abelian [2] and the non-abelian [3] cases. Sec. 2 first recalls these basic definitions, but it also formalises the notions of general and relative gauge extensions, which were still missing. Sec. 3 shows that CA admit a relative gauge extension if and only if they are globally symmetric. Sec. 4 shows that any CA admits a general gauge extension. Sec. 5 draws the consequences upon universality. Sec. 6 provides a first example of a gauge-extended CA whose gauge field is sourced by the matter field.

2 Definitions

2.1 Cellular Automata

A cellular automaton (CA) consist in an array of identical cells, each of which may take one in a finite number of possible states. The whole array evolves in discrete time steps by iterating a function F . Moreover this global evolution F is shift-invariant (it acts everywhere the same) and causal (information cannot be transmitted faster than some fixed number of cells per time step). Let us make this formal.

► **Definition 2.1** (Configuration). *A configuration c over an alphabet Σ and a space \mathbb{Z}^d is a function that associates a state to each point:*

$$c : \mathbb{Z}^d \longrightarrow \Sigma$$

The set of all configurations will be denoted $\Sigma^{\mathbb{Z}^d}$.

A configuration should be seen as the state of the CA at a given time. We use the short-hand notation $c_x = c(x)$ for $x \in \mathbb{Z}^d$ and $c|_I$ for the configuration c restricted to the set I , i.e. $c : I \rightarrow \Sigma$, for $I \subseteq \mathbb{Z}^d$. The association of a position and its state is called a cell.

The way to describe a global evolution F that is causal, is via the provision of a local rule. A local rule takes as input a configuration restricted to $x + \mathcal{N}$, and outputs the next value of the cell x , i.e. $f : \Sigma^{\mathcal{N}} \rightarrow \Sigma$, where \mathcal{N} is a finite subset of \mathbb{Z}^d referred to as “the neighbourhood”. Applying f at every position x simultaneously, implements F .

► **Definition 2.2** (Cellular automata). *The CA F having neighbourhood \mathcal{N} and local function $f : \Sigma^{\mathcal{N}} \rightarrow \Sigma$ is the function $F : \Sigma^{\mathbb{Z}^d} \rightarrow \Sigma^{\mathbb{Z}^d}$ such that for all $x \in \mathbb{Z}^d$,*

$$F(c)_x = f(c|_{x+\mathcal{N}}).$$

We sometimes denote by $c_{t,x}$ the value of a cell at position x and time t , where $c_{t+1} = F(c_t)$.

2.2 Global versus gauge symmetry

Global symmetry

We say that a CA is globally symmetric whenever its global evolution is invariant under the application of the same alphabet permutation at every position at once. Globally symmetric CA are also known as G -blind CA [16] with G a group of permutations over Σ .

► **Definition 2.3** (Globally symmetric). *Let $F : \Sigma^{\mathbb{Z}^n} \rightarrow \Sigma^{\mathbb{Z}^n}$ be a CA and G be a group of permutations over Σ . For all $g \in G$, let \bar{g} denote its application at every position simultaneously: $\bar{g}(c)_i = g(c_i)$. We say that F is globally G -symmetric if and only if, for any g in G , we have $F \circ \bar{g} = \bar{g} \circ F$.*

Local/gauge symmetry

We say that a CA is locally symmetric whenever its global evolution is invariant under the application of a local permutation at every position. The first difference with globally symmetric CA is the permutation is now allowed to differ from one position to the next. The second difference is that the permutation is now allowed to act on the surrounding cells. Locally symmetric CA are referred to as gauge-invariant CA [2, 3, 4].

► **Definition 2.4** (Local gauge-transformation group). *Let g be a permutation over $\Sigma^{(2s+1)^d}$, with $s \in \mathbb{N}$. We denote by $g^x : \Sigma^{\mathbb{Z}^d} \rightarrow \Sigma^{\mathbb{Z}^d}$ the function that acts as g on the cells at $\llbracket x-s, x+s \rrbracket^d$, and trivially everywhere else. A local gauge-transformation group G is a group of bijections over $\Sigma^{(2s+1)^d}$, such that for any $g, h \in G$ and any $x \neq y \in \mathbb{Z}^d$, $g^x \circ h^y = h^y \circ g^x$.*

This permutation condition makes it irrelevant to consider which local gauge-transformation gets applied first, so that the product $g^x h^y$ be defined. The condition is decidable, checking it over the $\llbracket -2s, +2s \rrbracket^d$ suffices.

► **Definition 2.5** (Gauge-transformation). *Consider G a group of local gauge-transformations. A gauge-transformation is then specified by a function $\gamma : \mathbb{Z}^d \rightarrow G$. It is interpreted as acting over $c \in \Sigma^{\mathbb{Z}^d}$ as follows:*

$$\gamma(c) = \left(\prod_{x \in \mathbb{Z}^d} \gamma^x \right)(c),$$

where γ^x is short for $\gamma(x)^x$. We denote by Γ the set of gauge-transformations.

Notice how an element $\gamma \in \Gamma$ may be thought of as a configuration over the alphabet G . Thus γ_x is an element of G which can be applied on a finite configuration, while γ^x is its natural extension which can be applied onto a full configuration.

Gauge-invariant CA are “insensitive” to gauge-transformations: performing γ before F amounts to performing some γ' after F .

► **Definition 2.6** (Gauge-invariant CA). *Let F be a CA, G be a local gauge-transformation group, and Γ be the corresponding set of gauge-transformations. F is Γ -gauge-invariant if and only if there exists a CA Z over the alphabet G , such that for all $\gamma \in \Gamma$:*

$$Z(\gamma) \circ F = F \circ \gamma.$$

The reason why γ' must result from a CA Z , instead of being left fully arbitrary, is because F is deterministic, shift-invariant and causal – from which it follows that γ' , if it exists, can be computed deterministically, homogeneously and causally from the γ applied before. Thus, the above is demanding a weakened commutation relation between the evolution F and the set of gauge-transformations Γ . In practice in Physics Z is often the identity, making gauge-invariance a commutation relation. This will be the case in our constructions.

2.3 (Relative) gauge extensions

In Physics, one usually begins with a theory that explains how matter freely propagates, i.e. in the absence of forces. This initial theory solely concerns the “matter field”, and is not gauge-invariant. For instance, the Dirac equation, which dictates how electrons propagate, is not $U(1)$ -gauge-invariant. Next, one enriches the initial theory with a second field, the so-called gauge field, so as to make the resulting theory gauge-invariant. For instance, the case of the electron, $U(1)$ -gauge-invariance is obtained thanks to the addition of the electromagnetic field. The resulting theory can still account for the free propagation of the matter field, but the presence of the gauge field also allows for richer behaviours, e.g. electromagnetism. Quite surprisingly three out of the four fundamental forces can be introduced mathematically, and thereby justified by gauge symmetry requirements, through this process of “gauge extension”.

But when is it the case that a theory is a gauge extension of another, exactly? In Physics this is left informal. One of the contributions of this paper is the provide a first rigorous definition of the notion of gauge extension, and of its relative subcase, in the discrete context of CA.

General gauge extension

A gauge extension must simulate the initial CA, extend the required gauge-transformations, and achieve gauge-invariance overall:

► **Definition 2.7** (Gauge extension). *Let F be a CA over alphabet Σ . Let Γ be a gauge-transformation group over Σ . Let Λ be a finite set which will serve as the gauge field alphabet. A gauge extension of (F, Γ) is a tuple (F', Γ') with F' a CA over alphabet $\Sigma \times \Lambda$ and Γ' a gauge-transformation group over $\Sigma \times \Lambda$, such that:*

- (Simulation) *there exists $\epsilon \in \Lambda$ such that F' simulates one step of F when the gauge field value is set ϵ everywhere. In other words for any $c \in \Sigma^{\mathbb{Z}^d}$, there exists $e' \in \Lambda^{\mathbb{Z}^d}$,*

$$F'(c, e) = (F(c), e')$$

where e is the constant gauge field configuration ($x \mapsto \epsilon$).

- (Extension) Γ' extends Γ : there exists a bijection $B : \Gamma' \rightarrow \Gamma$ such that for any $\gamma' \in \Gamma'$, there exists a CA $L_{\gamma'}$ over alphabet Λ , such that for any $c, \lambda \in \Sigma^{\mathbb{Z}^d} \times \Lambda^{\mathbb{Z}^d}$,

$$\gamma'(c, \lambda) = (\gamma(c), L_{\gamma'}(\lambda)) \tag{1}$$

where $\gamma = B(\gamma')$.

- (Gauge-invariance) F' is Γ' -gauge-invariant.

We used implicitly the canonical bijection between $(\Sigma \times \Lambda)^{\mathbb{Z}^d}$ and $\Sigma^{\mathbb{Z}^d} \times \Lambda^{\mathbb{Z}^d}$

Notice that when the gauge field does not evolve in time, we can rewrite the simulation condition as $F'(c, e) = (F(c), e)$. Then F is a sub-automaton of F' [10], whenever the gauge field is set to e .

Intuitively, the gauge field’s role is to keep track of which gauge-transformation got applied where, so as to hold enough information to insure gauge-invariance. There are different ways to do this; for instance one could indeed store the “gauge” at each point, i.e. which gauge-transformation has happened at the specific point. But one could be more parsimonious and store just the “relative gauge”, i.e. which gauge-transformation relates that which has happened at every two neighbouring points.

Relative gauge extension

The standard choice in the Physics literature is to place the gauge field between the matter cells only – i.e. on the links between two cells. This choice of layout is sometimes referred to as the “quantum link model” [6, 17]. The mathematical justification for this choice, is precisely that the gauge field may be interpreted as relative information between neighbouring matter cells. Geometrically speaking, it may be understood as a “connection” relating two closely “tangent spaces” on a manifold.

Our previous definition of general gauge extensions does allow for such relative gauge extensions as a particular case, up to a slight recoding, as shown in Fig-1, i.e. the link model is simulated by transferring the value of a gauge field on a link, to the vertex at the tip of the link.

■ **Figure 1** Capturing the link model used for relative gauge extensions with the general definition.

The following specialises the previous, mathematical notion of gauge extension, to the restricted way in which it is understood in Physics:

► **Definition 2.8** (Relative gauge extension). Given a CA F and a local gauge-transformation group Γ of radius $s = 0$, we say that a gauge extension (F', Γ') is relative when:

- (a) the gauge field is positioned on the links $(x, x + e_d)$, where e_d takes values in $\{(1\ 0\ 0\ \dots), (0\ 1\ 0\ \dots), \dots\}$.
- (b) the gauge field takes values in G and the ϵ from Definition 2.7 is the identity – i.e. $\Lambda = G$ and $\epsilon = I$

(c) for every position x a gauge-transformations $\gamma \in \Gamma'$ act both on the matter field at x according to $\gamma_x \in G$, and on the gauge field a of its links, as follows:

$$\begin{cases} \gamma^x(a)_{(x-e_d,x)} &= \gamma_x \circ a_{(x-e_d,x)} \\ \gamma^x(a)_{(x,x+e_d)} &= a_{(x,x+e_d)} \circ \gamma_x^{-1} \end{cases} \quad (2)$$

Thus relative extension keeps track of the difference of gauge between two neighbouring cells.

The above definitions were given for the \mathbb{Z}^d grid, in order to establish the notion of gauge extension in full generality. The next section, however, will be given just in one dimension ($d = 1$) for clarity. We have established it in arbitrary dimension d in a private manuscript.

3 Globally symmetric CA admit a relative gauge extension

From a Physics perspective, the gauge symmetry one seeks to impose usually comes from an already existing global symmetry. We show here that there is an equivalence between being globally G -symmetric and having a gauge extension with respect to G a subgroup of the permutations of Σ .

► **Theorem 3.1** (Global symmetry and relative gauge extension). *Let F be a CA over alphabet Σ , G a subgroup of the permutations of Σ and Γ the set of gauge-transformations defined using G as the group of local gauge-transformations. Then the following two properties are equivalent:*

- (i) F is globally G -symmetric
- (ii) (F, Γ) admits a relative gauge extension (F', Γ') with the identity for the gauge field evolution, such that F' commutes with any element of Γ' (stronger than gauge-invariance because it does not require a Z -map).

Proof.

(i \Rightarrow ii). Let f be the local rule of F with radius r . Let F' be a CA of radius r over the extended configurations – containing a gauge field in between neighboring cells – such that the gauge field evolution is the identity and the local rule f' for the evolution of the matter field is defined as follows:

$$\begin{aligned} f'(c_{-r}, a_{(-r+1, -r)}, \dots, c_0, a_{(0,1)}, \dots, c_r) = \\ f \left(\prod_{i=-1}^{-r} a_{(i, i+1)}(c_{-r}), \dots, a_{(-1,0)}(c_{-1}), c_0, a_{(0,1)}^{-1}(c_1), \dots, \prod_{i=1}^r a_{(i-1, i)}^{-1}(c_r) \right) \end{aligned} \quad (3)$$

where a is the gauge field and

$$\begin{aligned} \prod_{i=-1}^{-j} a_{(i, i+1)}(c_{-j}) &= a_{(-1,0)} \circ \dots \circ a_{(-j+1, -j+2)} \circ a_{(-j, -j+1)}(c_{-j}) \\ \prod_{i=1}^j a_{(i-1, i)}^{-1}(c_j) &= a_{(0,1)}^{-1} \circ \dots \circ a_{(j-2, j-1)}^{-1} \circ a_{(j-1, j)}^{-1}(c_j). \end{aligned}$$

f' is defined so as to apply f on a configuration that is on the same gauge basis – i.e. where relative gauge-transformations are cancelled and every cell is looked through the eyes of the gauge at position 0.

We shall now prove that (F', Γ') – with Γ' defined through Eq.(2) – is a relative gauge extension of (F, Γ) .

The fact that this extension is relative is immediate from the definition. We therefore need to prove that this extension has the 3 required properties from definition 2.7.

- *(Simulation)* The fact that F' simulates F when the gauge field is the identity is immediate from the definition of f' .
- *(Extension)* Because Γ' is defined through definition 2.8, it is also immediate that it verifies the extension property.
- *(Gauge-invariance)* For any $\gamma' \in \Gamma'$ we will check that $\gamma' \circ F' = F' \circ \gamma'$. For j between 1 and r , we apply the gauge-transformation on the inputs (c and a) – using Eq.(2) – and obtain by simple computation the following, where $\gamma = B(\gamma')$ through definition 2.7:

$$\begin{cases} \prod_{i=1}^j [\gamma_i \circ a_{(i-1,i)} \circ \gamma_{i-1}^{-1}]^{-1} \gamma_j(c_j) & = \gamma_0 \circ \left[\prod_{i=1}^j a_{(i-1,i)}^{-1}(c_j) \right] \\ \prod_{i=-1}^{-j} [\gamma_{i+1} \circ a_{(i,i+1)} \circ \gamma_i^{-1}] \gamma_j(c_j) & = \gamma_0 \circ \left[\prod_{i=-1}^{-j} a_{(i,i+1)}(c_j) \right] \end{cases}$$

where $\gamma_i \in G$. Therefore using this and Eq.(3) we have that

$$(F' \circ \gamma'(c, a))_0 = \left(f \circ \gamma_0 \begin{pmatrix} \prod_{i=-1}^{-r} a_{(i,i+1)}(c_{-r}) \\ \dots \\ a_{(-1,0)}(c_{-1}) \\ c_0 \\ a_{(0,1)}^{-1}(c_1) \\ \dots \\ \prod_{i=r}^1 a_{(i-1,i)}^{-1}(c_r) \end{pmatrix} \right)_0 \quad (4)$$

where γ_0 is here applied to every element of the tuple. Since F is globally G -symmetric, we have that $f \circ \gamma_0 = \gamma_0 \circ f$ and therefore $(F' \circ \gamma'(c, a))_0 = \gamma_0 \circ (F'(c, a))_0$ which finishes the proof that $F' \circ \gamma' = \gamma' \circ F'$ through translation invariance and because the gauge field evolution is the identity.

(ii \Rightarrow i). Suppose that (F', Γ') is a relative gauge extension of (F, Γ) , such that F' commutes with any element of Γ' , we shall prove that F is globally G -symmetric (with Γ the gauge-transformation group based on G). Let c be a configuration and e denote the empty configuration of the gauge field. For any local gauge-transformation g , we write \bar{g} the global gauge-transformation applying g everywhere – g denotes both the element of G and G' depending on the context:

$$\begin{aligned} \bar{g} \circ F'(c, e) &= \bar{g}(F(c), a) && \text{(Simulation 2.7)} \\ &= (\bar{g}(F(c)), a') && \text{(Extension 2.7)} \end{aligned}$$

where a and a' can be any gauge field configuration depending on F' and \bar{g} . And

$$\begin{aligned} F' \circ \bar{g}(c, e) &= F'(\bar{g}(c), \bar{g} \circ e \circ \bar{g}^{-1}) && \text{(Extension 2.8)} \\ &= F'(\bar{g}(c), e) \\ &= (F(\bar{g}(c)), a') && \text{(Simulation 2.7)} \end{aligned}$$

where a and a' can be any gauge field configuration depending on F' and g . The G' -gauge-invariance of F' give us $\bar{g} \circ F'(c, e) = F' \circ \bar{g}(c, e)$ and thus

$$\bar{g}(F(c)) = F(\bar{g}(c)).$$

Therefore F is globally G -symmetric. ◀

This theorem proves useful when looking for relative gauge extensions: first search for a global symmetry. The construction will be used in Sec. 5 to prove that relative gauge extensions of CA are universal.

4 Non-globally symmetric CA still admit an absolute gauge extension

We now prove that any CA can be intrinsically simulated by a gauge-invariant one, with respect to any gauge-transformation group, of any radius. The construction of this section uses non-relative gauge extensions, but it allows us to get rid of the prior requirements that there be a global symmetry or that the gauge-transformations be of radius 0.

► **Theorem 4.1** (Every CA admits a gauge extension). *For any CA F and gauge-transformation group Γ there exists for some gauge field alphabet a gauge extension (F', Γ') . Furthermore the local rule of F' acts as the identity over the gauge field.*

Proof. We give here a constructive proof for any CA over \mathbb{Z}^d .

Let F be a CA of radius s' and G be a local gauge-transformation group of radius s . We denote r the highest radius between s and s' . In the following we will consider neighbourhoods $R_x^k = [x - k \cdot r, x + k \cdot r]^d$ of each point $x \in \mathbb{Z}^d$, with $[a, b] = \{n \in \mathbb{Z} \mid a \leq n \leq b\}$.

First we choose G as gauge field alphabet and define the effect of a global gauge-transformation γ^x as $\gamma^x(a)_x = \gamma_x \circ a_x$, where a denotes a gauge field configuration. The definition is so that the gauge field simply keeps track of every gauge-transformation applied around x . For any other cell of the gauge field, γ^x has no impact. This condition along with the extension property of Definition 2.7 fully defines the new gauge-transformation group Γ' .

Next we define a new local rule f' over the neighbourhood R_x^5 . The definition below just states that the local rule applies $\prod_{i \in R_x^2} a_i^{-1}$ to undo all previous gauge-transformations, it then computes the evolution of f , and finally reapplies all the gauge-transformations, i.e.

$$f'(c|_{R_x^5}, a|_{R_x^5}) = \left(\prod_{i \in R_x^1} a_i \circ f|_{R_x^2} \left(\prod_{i \in R_x^4} a_i^{-1} (c|_{R_x^5})|_{R_x^3} \right), a_x \right)$$

where $f|_{R_x^2}$ denotes the function from R_x^3 to R_x^2 which calculates the temporal evolution of our automaton.

We can rewrite this local rule globally, using the notation a to denote either the gauge field or a gauge-transformation which applies a_x around each position x :

$$F'(c, a)_x = \left(a \circ F \circ a^{-1}(c), a \right)_x$$

Let us check that (F', Γ') is a gauge extension:

- *(Simulation)* When the gauge field is the identity f' acts the same as f over the matter field, and as the identity over the gauge field.
- *(Extension)* We used this property to define G' .
- *(Gauge-invariance)* For any $\gamma' \in \Gamma'$ – where Γ' is built from G' through definition 2.5 – we must check that $\gamma' \circ F' = F' \circ \gamma'$. We reason globally to simplify notations:

$$F' \circ \gamma'(c, a) = F'(\gamma(c), \gamma(a)) \quad (\text{Extension 2.7})$$

$$= \left(\gamma(a) \circ F \circ \gamma(a)^{-1}(\gamma(c)), \gamma(a) \right) \quad (\text{Definition of } F')$$

$$= \left(\gamma \circ a \circ F \circ a^{-1} \circ \gamma^{-1} \circ \gamma(c), \gamma(a) \right) \quad (\text{Definition 2.4})$$

$$= \left(\gamma \circ a \circ F \circ a^{-1}(c), \gamma(a) \right) \quad (\text{Definition 2.4})$$

$$\gamma' \circ F'(c, a) = \gamma' \left(a \circ F \circ a^{-1}(c), a \right) \quad (\text{Definition of } F')$$

$$= \left(\gamma \circ a \circ F \circ a^{-1}(c), \gamma(a) \right) \quad (\text{Extension 2.7})$$

5 (Relative) gauge-invariant CA are universal

Results in this section are only given for dimension 1.

In [16], the authors prove that for any alphabet Σ containing 2 symbols or more, there exists an intrinsically universal globally G -symmetric cellular automaton on $\Sigma^{\mathbb{Z}}$, where G is the group of all permutations of σ . The proof involves an extension which encodes the information in the structure of the configuration rather than the states, the idea being that a global transformation will conserve the structure – thus the information. Combining this result and Th. 3.1, we can easily prove the following corollary:

► **Corollary 5.1** (Relative gauge-invariant cellular automata are universal). *For any alphabet Σ with $|\Sigma| \geq 2$, any gauge transformation group G and any cellular automaton F on $\Sigma^{\mathbb{Z}}$, there exists a G' -gauge-invariant CA F' which intrinsically simulates F , with G' the extended gauge-transformation based on G . Moreover, F' arises as the relative gauge extension of a CA.*

Proof. Let F'' be a globally G -symmetric CA on $\Sigma^{\mathbb{Z}}$ that intrinsically simulates F using [16, Theorem 1]. From Th. 3.1, (F'', G) admits a relative gauge extension (F', G') with the evolution of the gauge field being the identity. Thus F' intrinsically simulates F'' , from which it follows that F' is a G' -gauge-invariant CA which intrinsically simulates F . ◀

Such result is interesting on two accounts: (i) it shows that universality only requires relative gauge information and does not need any absolute information stored in the gauge field; (ii) it shows that relative gauge extensions, which are the ones usually appearing in Physics, are universal. Still, the universality of gauge-invariant CA is an even more direct corollary of Th. 4.1. With that construction we can just pick any universal CA F , any local transformation group G of any radius, and gauge-extend F into F' . F' acts trivially on the gauge field in this construction, it thus intrinsically simulates F and is therefore universal.

6 Sourcing the gauge field with the matter field

In both the construction of Th. 3.1 and Th. 4.1, the evolution rule of the gauge field is the identity, meaning that it does not evolve with time. It is often the case in Physics that a further twist is then introduced, so that the matter field now influences the gauge field. We wish to do the same and find a gauge-extended CA whose gauge field influences the matter field, and whose matter field backfires on the gauge field.

We use here the general definition of a gauge extension (Definition 2.7) to search a gauge extension F' of a non gauge-invariant CA F . Without loss of generality, $F' = (F'_1, F'_2)$, where F'_1 takes (c, a) as input and returns the matter field after one time-step, and F'_2 does the same for the gauge field. We impose that the gauge (resp. matter) field be sourced by the matter (resp. gauge) field, in the strongest possible manner, i.e. we ask for F'_2 (resp. F'_1) to be injective in its first (resp. second) parameter.

We begin by choosing the alphabet $\Sigma = \{0, 1, 2\}^2$ and the space \mathbb{Z} and we denote by c_i^l and c_i^r respectively the left and the right part of the cell. In the following definitions we consider that all the additions and all the subtractions are modulo 3.

We define the initial automaton by the local rule: $F(c)_i = (c_{i-1}^l - c_i^r, c_i^l + c_{i+1}^r)$, cf. Fig.2.

We consider a local group of gauge-transformation containing three elements, namely:

$$G = \{\sigma_0, \sigma_1, \sigma_2\}$$

where σ_i is the function of radius 0 that adds i to each part of the cell.

9:10 Universal Gauge-Invariant Cellular Automata

Figure 2 The local rule of F.

We can check that F is not gauge-invariant for Γ (as defined from G), by considering a configuration c which associates $(1, 1)$ to position i and $(0, 0)$ to all other positions. Let γ be a gauge-transformation which applies σ_2 over i , $\gamma(c)$ is then the fully empty configuration e . Since F preserves emptiness we have:

$$F \circ \gamma(c) = \gamma(c) = e$$

But when we apply F to c we obtain non-empty cells in $i + 1$ and $i - 1$, this contradicts the gauge-invariance definition. This idea is illustrated in sub-Figs 3a and 3b.

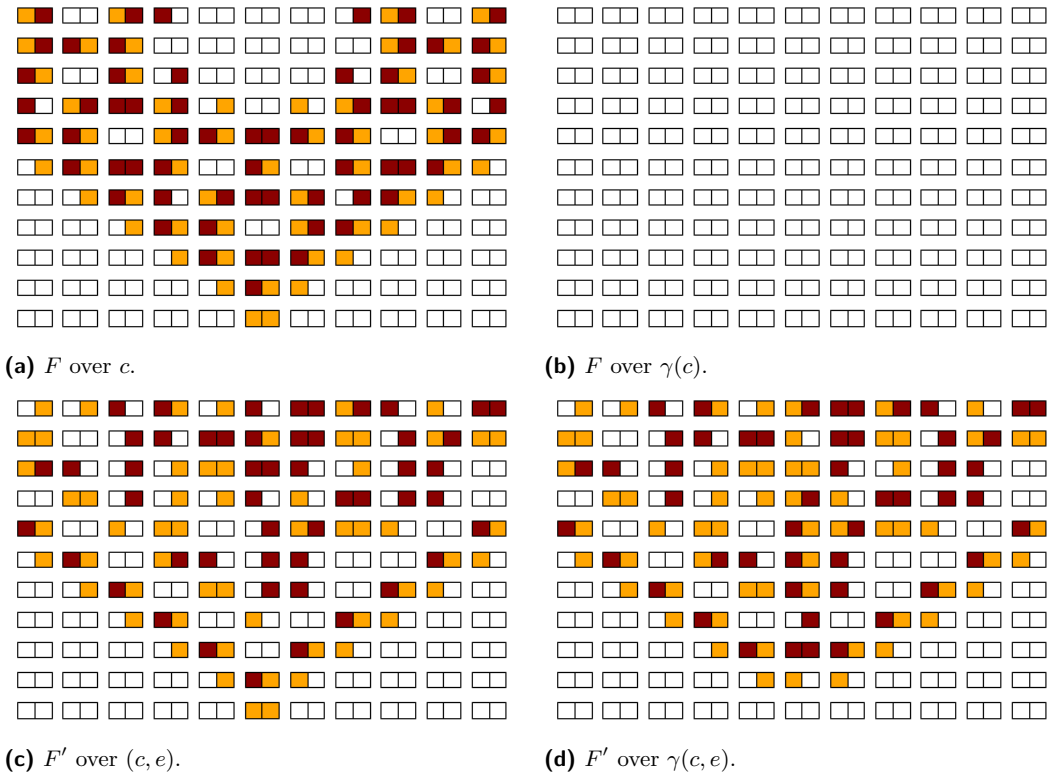

Figure 3 Space-time representation of F and F' over the same initial configurations c and $\gamma(c)$, where c is the configuration at the bottom line of 3a 3c. The values 1 and 2 are respectively represented by orange and red, while 0 is just an empty cell. Only the matter field is represented here.

We now provide a gauge extension for (F, Γ) . We begin by choosing the gauge field alphabet $\Lambda = \Sigma$ and placing the gauge field between each cell.

Next we engineer the injective influence of the gauge field over the matter field in the simplest possible way. We simply add, to each sub-cell of the matter field, the value of the nearest sub-cell of the gauge field during each evolution. See Fig. 4b.

Finally we extend gauge-transformations to the gauge field (Fig. 4a) and choose the evolution of the gauge field (green cells of Fig. 4b) to make sure that F' is a reversible gauge-invariant dynamics. Notice that the figures were chosen so that all cases are given. The proof of gauge-invariance for this example is given in appendix-A, and can be visually seen from Figs. 3c and 3d where a gauge-transformation does not impact the overall dynamics.

Figure 4 Description of the gauge extension (F', Γ') . Green circles represent the gauge field and black rectangles the matter field.

Overall, starting from a CA F we have defined a gauge extension F' which features a strong interaction between the gauge and the matter field. In the world of CA this is the first example of the kind [5, 3]. Building this example required the choice of a very specific extension of the gauge-transformation over the gauge field (cf Fig.4a) so as to obtain gauge-invariance whilst preserving reversibility and injectivity. Under a relative gauge extension this extension of the gauge-transformation is forced upon us, it seems hard to find such an example.

Notice that since the gauge field is sourced by the matter field it typically does not remain empty during the evolution. Thus F' can only simulate F for one time step. This may seem strange from a mathematical point of view, as we may expect from an extension that it preserves the original dynamics over several steps, too. But in Physics the initial non gauge-invariant theory is indeed used to inspire a more complex dynamics, which enriches and ultimately diverges from the original one. Fig.5 shows how starting from the same configuration, one obtains very different evolutions.

7 Conclusion

In order to obtain a gauge-invariant theory, starting from a non-gauge-invariant one, the usual route is to extend the theory by means of a gauge field. As discussed in the introduction, the gauge field usually turns out to be a connection between gauge choices at neighbouring points, but there is no immediate reason why this should be the case. In the first part, we formalised, in the framework of Cellular Automata (CA), the notions of gauge extension and relative gauge extension. The latter forces the gauge field to act as a connection.

(a) Evolution of F .(b) Evolution of F' .

■ **Figure 5** Evolution of F and its gauge extension F' over 9000 temporal step.

Again in Physics one usually starts from a theory featuring a global symmetry, before “making it local” through the gauge extension. Again there is no immediate reason why this should be the case. In our framework, we were able to establish a logical relation between global symmetry and relative gauge-invariance. Namely we proved that the CA that admit a relative gauge extension are exactly those that have the corresponding global symmetry. To the best of our knowledge, no continuous equivalent of that theorem exists in the literature; perhaps the discrete offers better opportunities for formalisation.

We also proved that any CA can be extended into a gauge-invariant one. Thus, gauge-invariant CA are universal. Two different constructions were provided. One construction uses the gauge field to store, at each location, the value of the gauge-transformation which the matter field has undergone at that location, thereby allowing for the action of the transformation to be counteracted. This path uses a non-relative gauge extension. Another construction puts together the fact that any CA can be made globally-symmetric [16], with the fact that any globally-symmetric CA admits a relative gauge extension. Thus, relative gauge-extended CA are universal.

Whilst the introduction of the gauge field is initially motivated by the gauge symmetry requirement, the gauge field ends up triggering new, richer behaviours as it influences the matter field. However, in order for it to mediate the interactions within the matter field, as is the case in Physics, it should be the case that the matter field also influences the gauge field – and back. In this paper, we provided a first example of a gauge-extended CA whose matter field injectively influences gauge field, whilst preserving reversibility. This was done through a general gauge extension, we leave it open whether this can be achieved through a relative gauge extension. The difficulty here is that relative gauge extensions seem to store just the minimal amount of information required for gauge-invariance, and any further influence upon the gauge field runs the risk of jeopardising that.

This difficulty can be circumvented in the quantum setting: the Quantum Cellular Automaton of [1] arises from a relative gauge extension, and yet features a gauge field which is “sourced” by the matter field. The construction directly yields a quantum simulation algorithm for one-dimensional quantum electrodynamics. This should serve us a reminder that whilst this work is theoretical, it is not merely of theoretical interest. Gauge extensions is exactly what one needs to do in order to capture physical interactions within discrete quantum models. This may lead for instance to digital quantum simulation algorithms, with improved numerical accuracy, as fundamental symmetries are preserved throughout the computation.

A Proof of gauge-invariance for Sec. 6

In order to prove that the example illustrated in Fig. 4 is gauge-invariant, we will show that $\gamma' \circ F' = F' \circ \gamma'$ for any $\gamma' \in \Gamma'$. It is sufficient to prove this locally, we do so using the notations of the figure and we denote by f' and g' the local application of the evolution and a gauge-transformation:

$$\begin{aligned} f' \circ g'(c_1^l, a_1, a_2, c_2^r) &= \begin{pmatrix} c_1^l + c_2^r + a_1 + k_1, \\ a_2 + c_1^l - k_2, \\ a_1 + a_2 + c_2^r - k_1 - k_2, \\ c_1^l - c_2^r + a_2 + k_2 \end{pmatrix} \\ &= g' \circ f'(c_1^l, a_1, a_2, c_2^r) \end{aligned}$$

Therefore F' is Γ' -gauge-invariant.

Equivalence Testing of Weighted Automata over Partially Commutative Monoids*

Abstract

Motivated by equivalence testing of k -tape automata, we study the *equivalence* testing of weighted automata in the more general setting, over partially commutative monoids (in short, pc monoids), and show efficient algorithms in some special cases, exploiting the structure of the underlying non-commutation graph of the monoid.

Specifically, if the edge clique cover number of the non-commutation graph of the pc monoid is a constant, we obtain a deterministic quasi-polynomial time algorithm for equivalence testing. As a corollary, we obtain the first deterministic quasi-polynomial time algorithms for equivalence testing of k -tape weighted automata and for equivalence testing of deterministic k -tape automata for constant k . Prior to this, the best complexity upper bound for these k -tape automata problems were randomized polynomial-time, shown by Worrell [24]. Finding a polynomial-time deterministic algorithm for equivalence testing of deterministic k -tape automata for constant k has been open for several years [13] and our results make progress.

We also consider pc monoids for which the non-commutation graphs have an edge cover consisting of at most k cliques and star graphs for any constant k . We obtain a randomized polynomial-time algorithm for equivalence testing of weighted automata over such monoids.

Our results are obtained by designing efficient zero-testing algorithms for weighted automata over such pc monoids.

1 Introduction

Testing the equivalence of two multi-tape finite automata is a fundamental problem in automata theory. For a k -tape automaton, we denote the mutually disjoint alphabets for the k tapes by $\Sigma_1, \dots, \Sigma_k$. The automaton accepts a subset of the product monoid $\Sigma_1^* \times \dots \times \Sigma_k^*$. Two multi-tape automata are *equivalent* if they accept the same subset.

* A preliminary version of this work was presented at HIGHLIGHTS of Logic, Games and Automata 2020.

Equivalence testing of multi-tape *non-deterministic* automata is undecidable [14]. The problem was shown to be decidable for 2-tape *deterministic* automata independently by Bird [5] and Valiant [22]. Subsequently, an exponential upper bound was shown for it [3]. Eventually, a polynomial-time algorithm was obtained by Friedman and Greibach [13] and the authors conjectured that equivalence testing of deterministic k -tape automata for any constant k is in polynomial time.

A closely related problem is testing the *multiplicity equivalence* of non-deterministic multi-tape automata. The multiplicity equivalence testing problem is to decide whether for each tuple in the product monoid $\Sigma_1^* \times \dots \times \Sigma_k^*$, the number of accepting paths in the two input automata is the same. Since a deterministic automaton has at most one accepting path for each input word, the equivalence of deterministic k -tape automata coincides with multiplicity equivalence. More generally, equivalence testing for *weighted automata* (over the underlying field or ring of coefficients) is to decide if the coefficient of each word (i.e. the total sum of weights of each accepting path) is the same for the two given automata. For the weighted case, equivalence testing is in deterministic polynomial time for one-tape automata [19, 21]. Equivalence testing of k -tape weighted automata was shown *decidable* by Harju and Karhumäki [15] using the theory of free groups¹. An improved complexity-theoretic upper bound remained elusive for k -tape multiplicity equivalence testing, until recently Worrell [24] obtained a *randomized* polynomial-time algorithm for testing the equivalence of k -tape weighted automata (and equivalence testing of deterministic k -tape automata) for any constant k . Worrell takes a different approach via Polynomial Identity Testing (PIT). In [24], Worrell asked if the equivalence testing problem for k -tape weighted automata can be solved in *deterministic* polynomial time, for constant k .

This Paper. Building on Worrell’s results [24] and exploiting further the connections between weighted automata equivalence and polynomial identity testing, we show that equivalence testing of two k -tape weighted automata is in *deterministic* quasi-polynomial time. This immediately yields the first deterministic quasi-polynomial time algorithm for equivalence testing of deterministic k -tape automata.

Our approach solves a more general problem in the setting of *partially commutative monoids*. To motivate this, let us consider k -tape weighted automata in this setting. The *product monoid* $M = \Sigma_1^* \times \dots \times \Sigma_k^*$ associated with k -tape automata is a *partially commutative monoid* (henceforth, *pc monoid*), in the sense that any two variables $x \in \Sigma_i, y \in \Sigma_j, i \neq j$ commute with each other². Variables in the same tape alphabet Σ_i are mutually non-commuting. We associate a *non-commutation graph* G_M with M to describe the non-commutation relations: (x, y) is an edge if and only if x and y do not commute. If there is no edge (x, y) in G_M , the words xy and yx are equivalent as the variables x and y commute. The words over any pc monoid are defined with respect to the equivalence relation induced by the non-commutation graph of the pc monoid. The notion of words and their equivalence over a pc monoid is formally explained in Section 3. For the k -tape case, the non-commutation graph G_M is a union of k disjoint cliques: its vertex set is $\Sigma_1 \cup \dots \cup \Sigma_k$ and G_M is the union of k disjoint cliques, induced by each Σ_i .

More generally, we obtain an equivalence testing algorithm for weighted automata over any pc monoid whose non-commutation graph has a constant-size edge clique cover (*not necessarily* disjoint) with a constant number of isolated vertices. Recall that the edge clique

¹ This also shows the decidability of equivalence problem for deterministic multi-tape automata.

² These are sometimes also called as free partially commutative monoids.

cover of a graph is a collection of subgraphs where each subgraph is a clique and each edge of the graph is contained in at least one of the subgraphs. The size of the edge clique cover is the number of cliques in it.

The isolated vertices can be thought of as a part of the edge clique cover by adding a new vertex (variable) for each isolated vertex and introducing a matching edge between them. Henceforth, we will not worry about the isolated vertices separately and consider them as part of the edge clique cover. We call such monoids as *k-clique monoids* where the edge clique cover size is bounded by k .

► **Remark 1.1.** Since two weighted automata, A and B are equivalent if and only if their difference $C = A - B$ is a weighted automaton equivalent to zero (formally explained in Section 2), we can describe the results in terms of zero-testing of a weighted automaton.³

In this paper, the field \mathbb{F} from which the weights of automata are taken is an infinite field. For computational implementation, we assume that the field arithmetic can be performed efficiently (for example, \mathbb{F} could be the field of rational numbers). Also, throughout the paper the size of an automaton refers to the number of states.

► **Theorem 1.2.** *Let A be an input \mathbb{F} -weighted automaton of size s over a pc monoid M such that its non-commutation graph G_M has an edge clique cover of size k . Then, the zero-testing of A has a deterministic $(nks)^{O(k^2 \log ns)}$ time algorithm. Here n is the size of the alphabet of M , and the edge clique cover is given as part of the input.*

It is interesting to note that the decidability of the equivalence problem over partially commutative monoids is already studied [23]. As an immediate corollary, the above theorem yields a deterministic quasi-polynomial time algorithm for equivalence testing of k -tape weighted automata (also for equivalence testing of deterministic k -tape automata). Notice that, for the k -tape case, the edge clique cover of size k is also part of the input since for each $1 \leq i \leq k$, the i^{th} tape alphabet Σ_i is explicitly given and it induces a clique.

► **Corollary 1.3.** *The equivalence testing problem for k -tape weighted automata and deterministic k -tape automata can be solved in deterministic quasi-polynomial time for constant k .*

Next, we consider equivalence testing over more general pc monoids M .

Given a graph $G = (X, E)$, a collection of k graphs $\{G_i = (X_i, E_i)\}_{i=1}^k$ such that $X = \cup_{i=1}^k X_i$ and $E = \cup_{i=1}^k E_i$ is called a *k-covering* of G . It seems natural to investigate whether there are covers other than just edge clique cover for which one can obtain efficient equivalence test.

We say M is a *k-monoid* if its non-commutation graph G_M has a 2-covering $\{G_1, G_2\}$ such that, for some $k' \leq k$, G_1 has an edge clique cover of size at most k' and G_2 has a vertex cover of size at most $k - k'$ (hence the edges of G_2 can be covered by $k - k'$ many star graphs). We show that equivalence testing over k -monoids has a randomized polynomial-time algorithm for constant k . This result can be seen as a generalization of Worrell's result [24].

► **Theorem 1.4.** *Let A be an input \mathbb{F} -weighted automaton of size s over a k -monoid M . Then the zero-testing of A can be decided in randomized $(ns)^{O(k)}$ time. Here n is the size of the alphabet of M .*

³ The difference C of two weighted automata A and B means the weight of each word w in C is the difference between the weights of w in A and B .

10:4 Equivalence Testing of Weighted Automata

► **Remark 1.5.** What is the complexity of equivalence testing for weighted automata over an arbitrary pc monoid? The non-commutation graph G_M of any pc monoid M over the alphabet X trivially has an edge clique cover of size bounded by $\binom{|X|}{2}$. Hence, the above results would only give an exponential-time algorithm. Note that if G_M has an *induced matching*⁴ of size more than k then M is not a k -monoid. Call M a *matching monoid* if G_M is a perfect matching. It follows from Lemma 3.3, shown in Section 3, that equivalence testing over arbitrary pc monoids is deterministic polynomial-time reducible to equivalence testing over matching monoids. Thus, the complexity of zero-testing of \mathbb{F} -weighted automata over matching monoids is essentially the most general case. We also note that Worrell has shown that the evaluation problem for multi-tape automata is $\#P$ -complete if the number of tapes is not fixed [24, Proposition 3].

Various automata-theoretic problems have been studied in the setting of pc monoids. For example, pc monoids have found applications in modeling the behavior of concurrent systems [16]. Droste and Gastin [10] have studied the relation between recognizability and rationality over pc monoids.

Proofs Overview. Our proof is inspired by Worrell’s key insight [24] that the k -tape automata equivalence problem can be reduced to a suitable instance of polynomial identity testing problem over partially commuting variables. Worrell’s algorithm is randomized. In contrast, since we are considering automata over general pc monoids and we aim to design efficient deterministic algorithms, we require additional ideas. First, we suitably apply a classical algebraic framework to transfer the zero-testing problem over general pc monoids to pc monoids whose non-commutation graphs are a disjoint union of cliques [6, 8]. This allows us to generalize a zero-testing criteria for weighted automata over standard noncommutative setting [11, Cor. 8.3] to the setting of *general pc monoids*. The generalization states that any nonzero weighted automata of size s over any pc monoid must have a non-zero word within the length $\text{poly}(s, n)$ where n is the alphabet size. This allows us to reduce zero-testing of weighted automata to an instance of polynomial identity testing over pc monoids, where these polynomials are computable by small algebraic branching programs (ABPs) over pc monoids. Over noncommutative variables, ABPs are well-studied in arithmetic circuit complexity [17]. It turns out that we can solve the identity testing problem for ABPs over k -clique monoids in deterministic quasi-polynomial time by suitably adapting a black-box polynomial identity test for noncommutative algebraic branching programs based on a quasi-polynomial size hitting set construction [12]. Our algorithm recursively builds on this construction, ensuring that the resulting hitting set remains of quasi-polynomial size.

The proof of Theorem 1.4 is along similar lines. First, we obtain a randomized polynomial-time identity testing algorithm over pc monoids whose non-commutation graph has a k -vertex cover for constant k . This algorithm itself uses ideas from automata theory. Then a composition lemma yields an identity testing algorithm over k -monoids.

The paper is organized as follows. In Section 2, we provide the necessary background. We prove a zero testing criteria for automata over pc monoids in Section 3. Theorem 1.2 is presented in Section 4, and Theorem 1.4 in Section 5. Some proof details are in the appendix.

⁴ An induced matching is a matching that includes every edge connecting any two vertices in the subset as an induced subgraph.

2 Preliminaries

We recall basic definitions and results, mainly from automata theory and arithmetic circuit complexity, and define notations used in the paper.

Notation. Let \mathbb{F} be an infinite field. $\text{Mat}_t(\mathbb{F})$ denotes the ring of $t \times t$ matrices over \mathbb{F} . For matrices A and B of sizes $m \times n$ and $p \times q$ respectively, their tensor (Kronecker) product $A \otimes B$ is defined as the block matrix $(a_{ij}B)_{1 \leq i \leq m, 1 \leq j \leq n}$, and the dimension of $A \otimes B$ is $pm \times qn$. Given bases $\{v_i\}_{1 \leq i \leq \dim(V)}$ and $\{w_j\}_{1 \leq j \leq \dim(W)}$ for the vector spaces V and W , the vector space $V \otimes W$ is the tensor product space with a basis $\{v_i \otimes w_j\}_{1 \leq i \leq \dim(V), 1 \leq j \leq \dim(W)}$.

For a series (resp. polynomial) S and a word (resp. monomial) w , let $[w]S$ denote the coefficient of w in the series S (resp. polynomial). In this paper, we consider weighted automata over a field \mathbb{F} and alphabet (or variables) $X = \{x_1, \dots, x_n\}$.

Arithmetic Circuit Complexity. An *algebraic branching program* (ABP) is a layered directed acyclic graph with one in-degree-0 vertex called *source*, and one out-degree-0 vertex called *sink*. Its vertex set is partitioned into layers $0, 1, \dots, d$, with directed edges only between adjacent layers (i to $i + 1$). The source and the sink are in layers zero and d , respectively. Each edge is labeled by a linear form over \mathbb{F} in variables $X = \{x_1, \dots, x_n\}$. The polynomial computed by the ABP is the sum over all source-to-sink directed paths of the product of linear forms that label the edges of the path. The maximum number of nodes in any layer is called the width of the algebraic branching program. The size of the branching program is taken to be the total number of nodes.

Equivalently, the computation of an algebraic branching program can be defined via the iterated matrix product $\lambda^T M_1 M_2 \cdots M_d \mu$, where λ, μ are vectors in \mathbb{F}^w and each M_i is a $w \times w$ matrix whose entries are affine linear forms over X . Here w corresponds to the ABP width and $d + 1$ corresponds to the number of layers in the ABP.

If X is a set of non-commuting variables then the ABP is a noncommutative algebraic branching program (e.g., see [17]).

Let $S \subset \mathbb{F}\langle X \rangle$ be a subset of polynomials in the noncommutative polynomial ring $\mathbb{F}\langle X \rangle$. A mapping $\mathbf{v} : X \rightarrow \text{Mat}_t(\mathbb{F})$ from variables to $t \times t$ matrices, it defines an *evaluation map* defined for any polynomial $f \in \mathbb{F}\langle X \rangle$ as $\mathbf{v}(f) = f(\mathbf{v}(x_1), \dots, \mathbf{v}(x_n))$. A collection H of such evaluation maps is a *hitting set* for S , if for every nonzero f in S , there is an evaluation $\mathbf{v} \in H$ such that $\mathbf{v}(f) \neq 0$.

Let $S_{n,d,s}$ denote the set of noncommutative polynomials in $\mathbb{F}\langle X \rangle$ (where $n = |X|$) that have algebraic branching programs of size s and d layers. Forbes and Shpilka [12] have given a quasi-polynomial size hitting set $H_{n,d,s}$ computable in quasi-polynomial time for $S_{n,d,s}$ that can. Moreover, the matrix tuples in $H_{n,d,s}$ are $d + 1$ dimensional.

► **Theorem 2.1** ([12, Theorem 1.8]). *For all $s, d, n \in \mathbb{N}$, if $|\mathbb{F}| \geq \text{poly}(d, n, s)$ then there is a hitting set $H_{n,d,s}$ for $S_{n,d,s}$. Further $|H_{n,d,s}| \leq (sdn)^{O(\log d)}$ and $H_{n,d,s}$ is computable in deterministic time $(sdn)^{O(\log d)}$.*

Automata Theory. We recall some basic algebraic automata theory from the Berstel-Reutenauer book [4].

Let \mathbb{F} be a field⁵ and X be an alphabet. A \mathbb{F} -weighted automaton⁶ A over X has a finite set of states Q . There is a weight function $E : Q \times X \times Q \rightarrow \mathbb{F}$ that assigns a weight to each transition. The number of states, $|Q|$ is the *size* of the automaton. A path is a sequence

⁵ In general \mathbb{F} can be a semiring, but for our purpose it suffices to consider fields.

⁶ Sometime called nondeterministic weighted automata in the literature.

10:6 Equivalence Testing of Weighted Automata

of edges: $(q_0, x_1, q_1)(q_1, x_2, q_2) \cdots (q_{t-1}, x_t, q_t)$. The weight of the path is the product of the weights of the edges. For each word $w = x_1 x_2 \cdots x_t \in X^*$, the coefficient of w , $[w]S$ is the total contribution of all the paths between a start and accepting state for the word w , which is an element of \mathbb{F} . This defines a formal series $S = \sum_{w \in X^*} [w]S \cdot w$ which is an element of the *formal power series ring* $\mathbb{F}\langle\langle X \rangle\rangle$. We say that S is the formal series *recognized* by the (weighted) automaton A .

Multi-tape automata. Next, we briefly explain weighted multi-tape automata defined in terms of pc monoids. Let M be the pc monoid over variables $X = X_1 \cup \cdots \cup X_k$ defined as follows: the variables in each X_i are non-commuting, but for all $i \neq j$ and any $x \in X_i, y \in X_j$ we have $xy = yx$. As defined already, the transition function E is a mapping $Q \times X \times Q \rightarrow \mathbb{F}$. A path is a sequence of edges: $(q_0, x_1, q_1)(q_1, x_2, q_2) \cdots (q_{t-1}, x_t, q_t)$ where each $x_i \in X_j$ for some j . The label of the run is $m = x_1 x_2 \cdots x_t$ in the pc monoid M , and $[m]A$ is the total contribution of all the runs between start and accepting states having the label equivalent to m .

An automaton is *deterministic* if the set of states can be partitioned as $Q = Q^{(1)} \sqcup \cdots \sqcup Q^{(k)}$, where states in $Q^{(i)}$ read input only from the i^{th} tape alphabet X_i , and each state has a single transition for every input variable. Thus, a deterministic automaton has at most one accepting path for each input $m \in M$.

Now we explain how equivalence testing of weighted automata is polynomial-time reducible to zero testing of weighted automata. Let A and B be \mathbb{F} -weighted automata over the alphabet X . The transition matrices N_A and N_B are defined as follows: $N_A[i, j] = \sum_{x \in X} E_A(q_i, x, q_j) \cdot x$. (N_B is defined similarly)⁷. Let the series computed by A and B be $\lambda_A^T \cdot \sum_{i \geq 0} N_A^i \cdot \mu_A$ and $\lambda_B^T \cdot \sum_{i \geq 0} N_B^i \cdot \mu_B$, respectively. Here $\lambda_A, \mu_A, \lambda_B, \mu_B$ are column scalar vectors. Define the weighted automaton C with transition matrix N_C and the scalar vectors λ_C, μ_C as follows:

$$\lambda_C = \begin{bmatrix} \lambda_A \\ \lambda_B \end{bmatrix}, \quad N_C = \begin{bmatrix} N_A & 0 \\ 0 & N_B \end{bmatrix}, \quad \mu_C = \begin{bmatrix} \mu_A \\ -\mu_B \end{bmatrix}.$$

We state an easy fact also used in [24].

► **Fact 1.** *A and B are equivalent if and only if C is a zero automaton.*

3 A Zero Testing Criteria Over Partially Commutative Monoids

A basic result in algebraic automata theory, says that an \mathbb{F} -weighted automaton A of size s represents a nonzero series in $\mathbb{F}\langle\langle X \rangle\rangle$ if and only if there is a word $w \in X^*$ of length at most $s - 1$, such that $[w]S$ is nonzero. It has a simple linear algebraic proof [11, Corollary 8.3, Page 145]⁸.

In this section, we prove a theorem similar in spirit over general pc monoids.

Pc monoids and partitioned pc monoids. Let X be a finite alphabet (equivalently, variable set). Formally, a pc monoid M over X is a pair $M = (X^*, I)$ where $I \subseteq X \times X$ be such that $(x_1, x_2) \in I$ if and only if $x_1 x_2 = x_2 x_1$. I is reflexive and symmetric. Let \tilde{I} be the *congruence* generated from I by transitive closure. The monoid elements are defined as the congruence classes \tilde{m} for $m \in X^*$. In other words, M is a factor monoid of X^* generated by \tilde{I} . The *non-commutation graph* $G_M = (X, E)$ of M is a simple undirected graph such that $(x_1, x_2) \in E$ if and only if $(x_1, x_2) \notin I$.

⁷ Here q_1, q_2, \dots be the enumeration of the states of A (and similarly for B).

⁸ This result is generally attributed to Schützenberger.

A pc monoid M over alphabet (i.e. variable set) X is a k -partitioned pc monoid if its non-commutation graph G_M has a k -covering $\{G_i\}_{i=1}^k$ such that the subgraphs G_i are pairwise vertex disjoint. Given any pc monoid M with a k -covering, we can associate a k -partitioned pc monoid M' with it, such that M is isomorphic to a submonoid of M' , as follows.

Suppose $G_M = (X, E)$ has a k -covering $\{G_i\}_{i=1}^k$, where $G_i = (X_i, E_i)$. Let $\hat{X} = \{x_{ti} \mid 1 \leq t \leq n, 1 \leq i \leq k\}$ be kn new variables. Here $|X| = n$ and $X = x_1, \dots, x_n$. Let $G'_i = (X'_i, E'_i)$ be a copy of G_i obtained by replacing the vertex $x_t \in X_i$ by its i^{th} copy x_{ti} , such that (x_{ti}, x_{si}) is an edge in G'_i if and only if (x_t, x_s) is an edge in G_i . Let G' denote the disjoint union graph $G' = G'_1 \sqcup G'_2 \sqcup \dots \sqcup G'_k$, and M' be the pc monoid whose non-commutation graph is $G' = (X', E')$. Clearly, M' is a k -partitioned pc monoid, defined by M and its given k -covering.

As an \mathbb{F} -algebra, we note that $\mathbb{F}\langle M' \rangle$ is isomorphic to the tensor product of the \mathbb{F} -algebras $\mathbb{F}\langle M'_1 \rangle \otimes \dots \otimes \mathbb{F}\langle M'_k \rangle$ where M'_i is the pc monoid defined by G'_i .

The following simple observation, which shows that the pc monoid M is isomorphic to a submonoid of M' , is well-known [6, 8, 9].

► **Lemma 3.1.** *Let $\psi : \mathbb{F}\langle M \rangle \rightarrow \mathbb{F}\langle M' \rangle$ be the map such that $\psi(m) = m_1 \otimes m_2 \otimes \dots \otimes m_k$ for any monomial m in M and extend by linearity. Here, for $1 \leq i \leq k$, the monomial m_i is obtained from m (by dropping the letters of m not in X_i) and replacing each occurrence $x_t \in X_i$ by the variable x_{ti} , $1 \leq t \leq n$. Then, ψ is an injective homomorphism.*

► **Remark 3.2.** We include a self-contained proof in the appendix for completeness, in our notation.

By Lemma 3.1, zero testing for weighted automata over pc monoids is reducible to zero-testing of weighted automata over partitioned pc monoids in deterministic polynomial time. More formally, we show the following.

► **Lemma 3.3.** *Let A be the given \mathbb{F} -weighted automaton of size s over a pc monoid M for which the non-commutation graph G_M has k -covering $\{G_i = (X_i, E_i)\}_{i=1}^k$. Then zero testing of A is reducible to the zero testing of another \mathbb{F} -weighted automaton B over the associated k -partitioned pc monoid M' in deterministic polynomial time. Moreover, the size of the automaton B is $O(ns^2k)$.*

Proof. The automaton B is simply obtained by applying the map ψ on the variables in M . For a variable x_t , let $J_t \subseteq \{1, 2, \dots, k\}$ be the set of indices such that, $i \in J_t$ if and only if $x_t \in X_i$. Then $\psi(x_t) = \eta_{i_1} \otimes \dots \otimes \eta_{i_{|J_t|}}$ where $i_1 < i_2 < \dots < i_{|J_t|}$ and for each j , $i_j \in J_t$, $\eta_{i_j} = x_{ti_j}$. Now for each $q_0, q_k \in Q$ such that $(q_0, x_t, q_k) \in E$ ⁹ and $wt(q_0, x_t, q_k) = \alpha \in \mathbb{F}$, we introduce new states $q_1, \dots, q_{|J_t|-1}$ and for each $j \leq |J_t| - 1$, add the edge $e_j = (q_{j-1}, \eta_{i_j}, q_j)$ in E and $wt(e_1) = \alpha$ and for other newly added edges the weight is 1. Since the number of edges in A is $O(ns^2)$, it is easy to see the number of nodes in B is $O(ns^2k)$. The fact that A computes the zero series if and only if B computes the zero series, follows from Lemma 3.1 and in particular from the fact that ψ is injective on the set of monomials. ◀

Worrell has already proved that the zero-testing of weighted automata over partitioned monoids whose non-commutation graphs are union of disjoint cliques, can be reduced to the identity testing of noncommutative ABPs [24]. We restate a proposition from Worrell's paper in our framework.

⁹ Here for simplicity of notation, we have used q_0, q_k to represent an arbitrary pair such that there is a transition between them, and q_0 is not necessarily the initial state.

► **Proposition 3.4** (Adaptation of Proposition 5 of [24]). *Let A be a given \mathbb{F} -weighted automaton of size s over a partitioned pc monoid M computing a series S . Moreover the non-commutation graph G_M is the disjoint union of k cliques. Let N be the transition matrix of A . Then S is the zero series if and only if the ABPs $\lambda^T N^\ell \mu = 0$ for each $0 \leq \ell \leq s - 1$, where λ, μ are vectors in \mathbb{F}^s .*

Combining Lemma 3.3 and Proposition 3.4, we obtain the following generalization of [11, Corollary 8.3] over arbitrary pc monoids which may be of independent interest.

► **Theorem 3.5.** *Let A be a given \mathbb{F} -weighted automaton of size s over any pc monoid M representing a series S . Then S is a nonzero series if and only if there exists a word $w \in X^*$ such that $[w]S$ is nonzero where the length of w is bounded by $O(n^3 s^2)$.*

Proof. Observe that the non-commutation graph G_M has a trivial edge clique cover of size $\leq n^2$ where n is the size of the alphabet. Then we apply Lemma 3.3 to conclude that S is a zero series if and only if the series S' computed by the \mathbb{F} -weighted automaton B over the associated partitioned pc monoid (whose non-commutation graph is a disjoint union of cliques) is zero. The size s' of B is bounded by $O(n^3 s^2)$. Now we use Proposition 3.4 to see that S' is identically zero if and only if the ABPs $\lambda^T N^\ell \mu = 0$ for each $0 \leq \ell \leq s' - 1$ are identically zero where N is the transition matrix of B . Now notice that under the image of ψ map, the length of any word can only increase. In other words, for any word $w : |\psi(w)| \geq |w|$. It follows that $(S' = \psi(S))^{\leq s'-1}$ is a nonzero polynomial where S' is the part of $\psi(S)$ of degree at most $s' - 1$. Since ψ is injective, it must be the case that $S^{\leq s'-1}$ is also a nonzero polynomial, and the theorem follows. ◀

4 Deterministic Zero Testing of Weighted Automata Over k -Clique Monoids

In this section, we show that zero testing for weighted automata over k -clique monoids for constant k is in deterministic quasi-polynomial time. In fact, by Lemma 3.3 and Proposition 3.4, the zero testing problem reduces to the polynomial identity testing of ABPs over partitioned pc monoids whose non-commutation graph is a disjoint union of k cliques. Thus, in order to prove Theorem 1.2 it suffices to design an efficient identity testing algorithm for ABPs computing polynomials in $\mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$, where k is a constant and the variable sets $X_j = \{x_{ij}\}_{1 \leq i \leq n}$ are of size n each and pairwise disjoint.

Evaluation over algebras. For a polynomial $f \in \mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$ and a k -tuple of \mathbb{F} -algebras $\mathbf{A} = (A_1, \dots, A_k)$, an *evaluation* of f in \mathbf{A} is given by a k -tuple of maps $\mathbf{v} = (v_1, v_2, \dots, v_k)$, where $v_i : X_i \rightarrow A_i$. We can extend it to the map $\mathbf{v} : \mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle \rightarrow A_1 \otimes \cdots \otimes A_k$ as follows: For any monomial $m = m_1 \otimes \cdots \otimes m_k$ where $m_i \in X_i^*$, let $\mathbf{v}(m) = v_1(m_1) \otimes \cdots \otimes v_k(m_k)$. In particular, for each $x \in X_j$ let $\mathbf{v}(x) = 1_1 \otimes \cdots \otimes v_j(x) \otimes \cdots \otimes 1_k$ where 1_j is the multiplicative identity of A_j . We can now extend \mathbf{v} by linearity to all polynomials in the domain $\mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$.

Next, we define a *partial evaluation* of $f \in \mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$ in \mathbf{A} . Let $k' < k$ and $\hat{\mathbf{A}} = (A_1, \dots, A_{k'})$ be a k' -tuple of \mathbb{F} -algebras. A partial evaluation of $\mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$ in $\hat{\mathbf{A}}$ is given by a k' -tuple of maps $\hat{\mathbf{v}} = (v_1, \dots, v_{k'})$, where $v_i : X_i \rightarrow A_i$. Now, we can define $\hat{\mathbf{v}} : \mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle \rightarrow A_1 \otimes \cdots \otimes A_{k'} \otimes \mathbb{F}\langle X_{k'+1} \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$ as follows. For a monomial $m = (m_1 \otimes \cdots \otimes m_k)$, $m_i \in X_i^*$, we let $\hat{\mathbf{v}}(m) = v_1(m_1) \otimes \cdots \otimes v_{k'}(m_{k'}) \otimes m_{k'+1} \otimes \cdots \otimes m_k$. By linearity, the partial evaluation $\hat{\mathbf{v}}$ is defined for any $f \in \mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$ where $\hat{\mathbf{v}}$ takes values in $A_1 \otimes \cdots \otimes A_{k'} \otimes \mathbb{F}\langle X_{k'+1} \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$.

Although it is implicit, we formally recall that when we consider ABPs over $\mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$ the linear forms are defined over tensors of the form $1 \otimes \cdots \otimes x_{ij} \otimes \cdots \otimes 1$. These tensors play the role of an individual variable in the tensor product structure.

Some more notation. Let $S_{k,n,d,s}$ denote the set of all polynomials in $\mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$ computed by ABPs of size s and layers $0, 1, \dots, d$, and $n = |X_i|$ for each $1 \leq i \leq k$. Following the notation in Theorem 2.1, we will denote by $\mathcal{H}_{k,n,d,s}$ the hitting set that we will construct for $S_{k,n,d,s}$. That is, $\mathcal{H}_{k,n,d,s}$ is a collection of evaluations in the ring of square matrices $\mathbf{v} = (v_1, \dots, v_k)$, such that for any nonzero polynomial $f \in S_{k,n,d,s}$ there is an evaluation $\mathbf{v} = (v_1, \dots, v_k) \in \mathcal{H}_{k,n,d,s}$ such that $\mathbf{v}(f)$ is a nonzero matrix. Recall from Theorem 2.1 that a quasi-polynomial size hitting set $\mathcal{H}_{1,n,d,s}$ for $S_{1,n,d,s}$ can be explicitly constructed. In the next lemma we describe an efficient bootstrapped construction of the hitting set $\mathcal{H}_{k,n,d,s}$ for the set $S_{k,n,d,s}$ of polynomials, from the hitting set $\mathcal{H}_{1,n,d,s}$.

► **Lemma 4.1.** *There is a set of evaluation maps $\mathcal{H}_{k,n,d,s} = \{(v_1, \dots, v_k) : v_i \in \mathcal{H}_{1,n,d,s_k}\}$ where $s_k = s(d+1)^{(k-1)}$ such that, for $i \in [k]$, we have $v_i : X_i \rightarrow \mathcal{M}_{d+1}(\mathbb{F})$, and $\mathcal{H}_{k,n,d,s}$ is a hitting set for the class of polynomials $S_{k,n,d,s}$. Moreover, the size of the set is at most $(nskd)^{O(k^2 \log d)}$, and it can be constructed in deterministic $(nskd)^{O(k^2 \log d)}$ time.*

The above lemma yields the identity test: we only need to evaluate the input polynomial on each point of the hitting set and check whether it is nonzero.

Before presenting the proof, we discuss two important ingredients. A polynomial f in $\mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$ can be written as $f = \sum_{m \in X_k^*} f_m \otimes m$ where each m is a monomial over variables X_k and $f_m \in \mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_{k-1} \rangle$. Given that f has a small ABP, we first show that each polynomial f_m also has a small ABP.

► **Lemma 4.2.** *For each $f \in S_{k,n,d,s}$ and $m \in X_k^*$, the polynomial $f_m \in \mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_{k-1} \rangle$ has an ABP of size $s(d+1)$ and $d+1$ layers.*

Proof. Suppose $f \in \mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$ has an ABP B of size s and d layers, and the monomial $m = x_{i_1 k} x_{i_2 k} \cdots x_{i_\ell k}$ where some of the indices could be repeated. We will construct an ABP of size $s(d+1)$ for the polynomial f_m . First, we identify each variable $1 \otimes \cdots \otimes x_{ij} \otimes \cdots \otimes 1$ as x_{ij} and construct the following ABP B' from B :

For every node u in the ABP B , we have nodes $(u, i), 0 \leq i \leq \ell$ in the ABP B' . We now describe the edges of B' and the edge labels. In the ABP B , let (u, v) be an edge, where u is in layer j and v is in layer $j+1$, for some $j \leq d-1$. We can write the linear form labeling (u, v) as a sum $L_1 + L_2$, where L_1 is an affine linear form in variables from $X \setminus X_k$, and L_2 is a homogeneous linear form in variables from X_k .

For $0 \leq r \leq \ell-1$: we put an edge from (u, r) to (v, r) with label L_1 . For $0 \leq r \leq \ell-1$: we put an edge from (u, r) to $(v, r+1)$ with edge label $\alpha \cdot x_{i_{r+1} k}$ if the coefficient of $x_{i_{r+1} k}$ in L_2 is $\alpha \neq 0$. If s and t are the source and sink nodes of the ABP B , we designate $(s, 0)$ and (t, ℓ) as the source and sink nodes of the ABP B' .

It is evident from the construction that the ABP B' has at most $s(d+1)$ many nodes. Furthermore, the only nonzero monomials in the polynomial computed by B' are of the form $m' \otimes m$, where m' is a monomial over the letters $X \setminus X_k$, and the coefficient of $m' \otimes m$ is the same as its coefficient in polynomial f . It follows, that B' computes the polynomial $f_m \otimes m$, and we can obtain an ABP for f_m by setting to 1 all the variables occurring in m . This completes the proof. ◀

For a polynomial f in $\mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_k \rangle$, consider a partial evaluation $\mathbf{v} = (v_1, \dots, v_{k-1})$ such that each $v_i : X_i \rightarrow \mathcal{M}_{t_i}(\mathbb{F})$. The evaluation $\mathbf{v}(f)$ is a $T \times T$ matrix with entries from $\mathbb{F}\langle X_k \rangle$, where $T = t_1 t_2 \cdots t_{k-1}$.

10:10 Equivalence Testing of Weighted Automata

► **Lemma 4.3.** *For each $p, q \in [T]$ and $f \in S_{k,n,d,s}$, the $(p, q)^{th}$ entry of $\mathbf{v}(f)$ can be computed by an ABP of size sT and $d + 1$ layers.*

The proof is routine and given in the appendix. Now we are ready to prove Lemma 4.1.

Proof of Lemma 4.1. The proof is by induction on k . For the base case $k = 1$ the hitting set $\mathcal{H}_{1,n,d,s}$ of Theorem 2.1 suffices. We can write each nonzero $f \in S_{k,n,d,s}$ as $f = \sum_{m \in X_k^*} f_m \otimes m$, where $m \in X_k^*$ and $f_m \in \mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_{k-1} \rangle$. Since $f \neq 0$ we have $f_m \neq 0$ for some $m \in X_k^*$. By Lemma 4.2, for each $m \in X_k^*$ the polynomial $f_m \in \mathbb{F}\langle X_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle X_{k-1} \rangle$ has an ABP of size $s(d + 1)$. Let $s' = s(d + 1)$.

By induction hypothesis, f_m is nonzero on some point in the set $\{(v_1, v_2, \dots, v_{k-1}) \mid v_i \in \mathcal{H}_{1,n,d,s'_{k-1}}\}$ where $s'_{k-1} = s'(d + 1)^{k-2} = s(d + 1)^{k-1}$. Hence, there is an evaluation $\mathbf{v}' \in \mathcal{H}_{k-1,n,d,s'}$ such that $\mathbf{v}'(f_m)$ is a nonzero matrix of dimension $(d + 1)^{k-1}$. Interpreting \mathbf{v}' as a *partial evaluation* for f , we observe that $\mathbf{v}'(f)$ is a $(d + 1)^{k-1} \times (d + 1)^{k-1}$ matrix with entries from $\mathbb{F}\langle X_k \rangle$. Since $\mathbf{v}'(f_m) \neq 0$, it follows that some $(p, q)^{th}$ entry of $\mathbf{v}'(f)$ is a nonzero polynomial $g \in \mathbb{F}\langle X_k \rangle$. By Lemma 4.3, each entry of $\mathbf{v}'(f)$ has an ABP of size $s(d + 1)^{k-1}$. In particular, $g \in S_{1,n,d,s(d+1)^{k-1}}$ and it follows from Theorem 2.1 that there is an evaluation \mathbf{v}'' in $\mathcal{H}_{1,n,d,s(d+1)^{k-1}}$ such that $\mathbf{v}''(g)$ is a nonzero matrix of dimension $(d + 1) \times (d + 1)$.

Thus, for the combined evaluation map $\mathbf{v} = (\mathbf{v}', \mathbf{v}'')$, $\mathbf{v}(f)$ is a nonzero matrix of dimension $(d + 1)^k \times (d + 1)^k$. Define $\mathcal{H}_{k,n,d,s} = \{(v_1, \dots, v_k) : v_i \in \mathcal{H}_{1,n,d,s_k}\}$, where $s_k = s(d + 1)^{k-1}$. However, by induction hypothesis, we have $\mathbf{v}' = (v_1, \dots, v_{k-1}) \in \mathcal{H}_{k-1,n,d,s(d+1)}$ where each $v_i \in \mathcal{H}_{1,n,d,s(d+1)^{k-1}}$. Therefore, $\mathbf{v} = (\mathbf{v}', \mathbf{v}'') \in \mathcal{H}_{k,n,d,s}$ and $\mathcal{H}_{k,n,d,s}$ is a hitting set for the class of polynomials $S_{k,n,d,s}$.

Finally, note that $|\mathcal{H}_{k,n,d,s}| = |\mathcal{H}_{1,n,d,s_k}|^k$. Since $|\mathcal{H}_{1,n,d,s_k}| \leq (nds_k)^{O(\log d)}$, it follows that $|\mathcal{H}_{k,n,d,s}| \leq (nsk d)^{O(k^2 \log d)}$, and the hitting set $\mathcal{H}_{k,n,d,s}$ can be constructed in the claimed running time¹⁰. For zero testing, we need to evaluate the input ABP on the matrices of the hitting set, and this can be done in time polynomial in the input size and the size of the hitting set by matrix additions and multiplications. ◀

5 Randomized Zero Testing of Weighted Automata Over k -Monoids

We now consider pc monoids more general than k -clique monoids. A k -monoid is a pc monoid M whose non-commutation graph G_M has a 2-covering $\{G_1, G_2\}$ such that G_1 has an edge clique cover of size k' and G_2 has a vertex cover of size $k - k'$, for some k' . It follows that G_M has a k -covering of cliques and star graphs. We assume that this k -covering of G_M is given as part of the input. Let $\mathbb{F}\langle M \rangle$ denote the \mathbb{F} -algebra generated by the monoid M .

► **Lemma 5.1.** *Let $\{M_i\}_{i=1}^k$ be pc monoids defined over disjoint variable sets $\{X_i\}_{i=1}^k$, respectively. For each i , suppose \mathcal{A}_i is a randomized procedure that outputs an evaluation $v_i : \mathbb{F}\langle M_i \rangle \rightarrow \mathcal{M}_{t_i(d)}(\mathbb{F})$ such that for any polynomial g_i in $\mathbb{F}\langle M_i \rangle$ of degree at most d , g_i is nonzero if and only if $v_i(g_i)$ is a nonzero matrix with probability at least $1 - \frac{1}{2k}$.*

Then, for the evaluation $\mathbf{v} : \mathbb{F}\langle M_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle M_k \rangle \rightarrow \mathcal{M}_{t_1(d)}(\mathbb{F}) \otimes \cdots \otimes \mathcal{M}_{t_k(d)}(\mathbb{F})$ such that $\mathbf{v} = (v_1, \dots, v_k)$ and any nonzero polynomial $f \in \mathbb{F}\langle M_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle M_k \rangle$ of degree at most d , the matrix $\mathbf{v}(f)$ is nonzero with probability at least $1/2$.

¹⁰Independent to the context of the current paper, bootstrapping hitting sets has found other interesting applications in arithmetic circuit complexity [1].

Proof. The proof is by induction on k . For the base case $k = 1$, it is trivial. Let us fix an $f \in \mathbb{F}\langle M_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle M_k \rangle$ of degree at most d such that $f \neq 0$. The polynomial f can be written as $f = \sum_{m \in M_k} f_m \otimes m$ where m are the words over the pc monoid M_k and $f_m \in \mathbb{F}\langle M_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle M_{k-1} \rangle$. Since $f \neq 0$ we must have $f_m \neq 0$ for some $m \in M_k$.

Now, inductively we have the evaluation $\mathbf{v}' = (v_1, \dots, v_{k-1})$ for the class of polynomials in $\mathbb{F}\langle M_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle M_{k-1} \rangle$ of degree at most d . Since $f_m \neq 0$, with high probability $\mathbf{v}'(f_m)$ is a nonzero matrix of dimension $\prod_{i=1}^{k-1} t_i(d)$. By induction the failure probability is bounded by $\frac{k-1}{2k}$.

As \mathbf{v}' is a *partial evaluation* for f , we observe that $\mathbf{v}'(f)$ is a matrix of dimension $\prod_{i=1}^{k-1} t_i(d)$ whose entries are polynomials in $\mathbb{F}\langle M_k \rangle$. Since $\mathbf{v}'(f_m) \neq 0$ we conclude that some $(p, q)^{th}$ entry of $\mathbf{v}'(f)$ contains a nonzero polynomial $g \in \mathbb{F}\langle M_k \rangle$ of degree at most d . Choose the evaluation $v_k \in S_k$ which is the output of the randomized procedure \mathcal{A}_k , such that $v_k(g)$ is a nonzero matrix of dimension $t_k(d)$. Hence, for the combined evaluation $\mathbf{v} = (\mathbf{v}', v_k)$, $\mathbf{v}(f)$ is a nonzero matrix of dimension $\prod_{i=1}^k t_i(d)$. A union bound shows that the failure probability is at most $1/2$. ◀

For the proof of Theorem 1.4, we first give a randomized polynomial-time identity testing algorithm for polynomials over pc monoids whose non-commutation graph is a star graph.

▶ **Lemma 5.2.** *Let $M = ((X \cup y)^*, I)$ be a monoid whose non-commutation graph G_M is a star graph with center y . Then for any constant k , there is a randomized procedure that outputs an evaluation $\mathbf{v} : X \cup \{y\} \rightarrow \text{Mat}_{t(d)}(\mathbb{F})$ where $t(d)$ is at most d , such that for any polynomial $f \in \mathbb{F}\langle M \rangle$ of degree at most d , the polynomial f is nonzero if and only if $\mathbf{v}(f)$ is a nonzero matrix. The success probability of the algorithm is at least $1 - \frac{1}{2k}$.*

Proof. If f is nonzero, then there exists a monomial m in M with nonzero coefficient. The idea is to isolate all monomials in $\{X \cup y\}^*$ that are equivalent to m in M . Let the degree of y in monomial m be $\ell \leq d$. Then m can be written as $m = m_1 y m_2 \cdots m_\ell y m_{\ell+1}$ where each m_i is a word in X^* . As X is a commuting set of variables, any permutation of m_i produces a monomial equivalent to m in M . Now consider the automaton in Figure 1.

■ **Figure 1** The transition diagram of the automaton.

Let m as $m = m_1 y m_2 \cdots m_\ell y m_{\ell+1}$, where each m_i is a maximal substring of m in X^* . We refer to the m_i as blocks. The above automaton keeps count of blocks as it scans the monomial m . As it scans m , if the automaton is in the j^{th} block, it substitutes each variable $x_i \in X$ read by a corresponding commuting variable x_{ij} where the index j encodes the block number. The y variable is renamed by a commutative variable y_c . The transition matrices N_{x_i} and N_y of dimension $d + 1$. The transition matrices are explicitly given below.

$$N_{x_i} = \begin{bmatrix} x_{i1} & 0 & 0 & \dots & 0 \\ 0 & x_{i2} & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & x_{id} & 0 \\ 0 & 0 & \dots & 0 & x_{i(d+1)} \end{bmatrix}, \quad N_y = \begin{bmatrix} 0 & y_c & 0 & \dots & 0 \\ 0 & 0 & y_c & \dots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 0 & y_c \\ 0 & 0 & \dots & 0 & 0 \end{bmatrix}.$$

10:12 Equivalence Testing of Weighted Automata

Now we explain this matrix substitution. Let $f = \sum_m \alpha_m m$, where $\alpha_m \in \mathbb{F}$. We write $f = \sum_{\ell=1}^d f_\ell$, where $f_\ell = \sum_{m: \deg_y(m)=\ell} \alpha_m m$. That is, f_ℓ is the part of f consisting of monomials m with y -degree $\deg_y(m) = \ell$.

From the description of the automaton, we can see that for each $\ell \in [d]$, the $(0, \ell)^{th}$ entry of the output matrix is the commutative polynomial $f_\ell^c \in \mathbb{F}[\{x_{i,j}\}_{1 \leq i \leq n, 1 \leq j \leq d+1}, y_c]$. The construction ensures the following: For each $0 \leq \ell \leq d$, $f_\ell = 0$ if and only if $f_\ell^c = 0$.

The randomized identity test is by substituting random scalar values for the commuting variables x_{ij} and y_c from a set $S \subseteq \mathbb{F}$ of size at least $2kd$, such that the output matrix becomes nonzero. The bound on the success probability follows from Polynomial Identity Lemma [25, 20, 7]. ◀

Now we are ready to prove Theorem 1.4.

Proof of Theorem 1.4. Let M' be a pc monoid whose non-commutation graph $G_{M'}$ is a clique. Let $g \in \mathbb{F}\langle M' \rangle$ be a nonzero polynomial of degree at most d . By the Amitsur-Levitzki Theorem [2], if we substitute variables $x_i \in M'$ by generic matrix of size d over the variables $\{x_{u,v}^{(i)}\}_{1 \leq u,v \leq d}$, the output matrix is nonzero¹¹. Moreover, the entries of the output matrix are commutative polynomials of degree at most d in the variables $\{x_{u,v}^{(i)}\}_{1 \leq i \leq n, 1 \leq u,v \leq d}$. It suffices to randomly substitute for each $x_{u,v}^{(i)}$ variable from a set $S \subseteq \mathbb{F}$ of size at least $2kd$. This defines the evaluation map $v : \mathbb{F}\langle M' \rangle \rightarrow \mathbb{M}_d(\mathbb{F})$. The resulting identity test succeeds with probability at least $1 - \frac{1}{2k}$. For the star graphs, the evaluation map is already defined in Lemma 5.2.

Given a \mathbb{F} -weighted automaton A of size s over a k -monoid $M = (X^*, I)$, by Theorem 3.5, the zero testing of A reduces to identity testing of a collection of ABPs of the form : $f = \lambda^T N^d \mu$ over $\mathbb{F}\langle M \rangle$, where N is the transition matrix of A and d is bounded by $O(ns^2k)$. Now, to test identity of f where M is a k -monoid, it suffices to test identity of $\psi(f)$ where ψ is the injective homomorphism from Lemma 3.1. Now $\psi(f)$ in $\mathbb{F}\langle M'_1 \rangle \otimes \cdots \otimes \mathbb{F}\langle M'_k \rangle$, where for each $i \in [k]$ the non-commutation graph of M'_i is either a clique or a star.

By Lemma 5.1, we can construct the evaluation map $\mathbf{v} = v_1 \otimes v_2 \otimes \cdots \otimes v_k$ where for each $i \in [k]$, v_i is an evaluation map for either a clique or a star graph depending on M'_i . The range of \mathbf{v} is matrices of dimension at most d^k , which is bounded by $(sn)^{O(k)}$ as d is bounded by $O(ns^2k)$. This completes the proof of Theorem 1.4. ◀

Concluding Remarks

The bootstrapped construction presented in Section 4 designs a quasi-polynomial time algorithm for the k -clique monoid problem which uses evaluation over a suitable matrix algebra. However, to design a polynomial-time algorithm, one may try to exploit finer structures in the problem than evaluating it over a matrix algebra. The obvious natural idea is to generalize the white-box polynomial-time identity testing algorithm for noncommutative ABPs [18] in the pc monoid setting. However, it is unclear whether such a generalization is possible.

¹¹ In fact the Amitsur-Levitzki theorem guarantees that generic matrices of size $\lceil \frac{d}{2} \rceil + 1$ suffice [2].

A The Proof of Lemma 3.1

Proof. It is straightforward to check that ψ is a ring homomorphism. To show the injectivity, it is enough to show that $\psi(m) = \psi(m')$ implies $m = m'$ in M for any words $m, m' \in M$. We prove the claim by induction on the length of words in M . Suppose that for words $m \in M$ of length at most ℓ , if m' is not \tilde{I} -equivalent to m then $\psi(m) \neq \psi(m')$. The base case, for $\ell = 0$ clearly holds.

Now, suppose $m = x \cdot m_1 \in X^{\ell+1}$ for $x \in X$ and $\psi(m) = \psi(m')$.

▷ **Claim A.1.** For some $m_2 \in M$, $m' = x \cdot m_2$ in M .

Proof. Assume, to the contrary, that there is no $m_2 \in M$ such that $m' = x \cdot m_2$. Let $J = \{j \in [k] \mid x \in X_j\}$. If the variable x does not occur in m' then $m|_{X_j} \neq m'|_{X_j}$ for each $j \in J$. This implies that $\psi(m) \neq \psi(m')$ which is a contradiction.

On other hand, suppose x occurs in m' and it cannot be moved to the leftmost position in m' applying the commutation relations in I . Then we must have $m' = ayxb$ for some $y \in X_j$ and $j \in J$, where $a, b \in X^*$, for the leftmost occurrence of x in m' . Hence $m|_{X_j} \neq m'|_{X_j}$, because x is the first variable in $m|_{X_j}$ and x comes after y in $m'|_{X_j}$. Therefore, $\psi(m) \neq \psi(m')$ which is a contradiction. ◁

Now, $\psi(x \cdot m_1) = \psi(x \cdot m_2)$ implies that $\psi(m_1) = \psi(m_2)$. Both m_1 and m_2 are of length ℓ . By induction hypothesis it follows that $m_1 = m_2$, and hence $m = m'$. ◀

B The Proof of Lemma 4.3

Proof. In effect the edges of the input branching program B are now labelled by matrices of dimension T with entries are linear forms over the variables X'_k . To show that each entry of the final $T \times T$ matrix can be computed by an ABP of size sT , let us fix some (i, j) such that $1 \leq i, j \leq T$ and construct an ABP B'_{ij} computing the polynomial in the $(i, j)^{th}$ entry.

The construction of B'_{ij} is as follows. We make T copies of each node p (except the source and sink node) of B and label it as (p, k) for each $k \in [T]$. Let us fix two nodes p and q from B such that there is a $T \times T$ matrix M_{pq} labelling the edge (p, q) after the substitution. Then, for each $j_1, j_2 \in [T]$, add an edge between (p, j_1) and (q, j_2) in B'_{ij} and label it by the $(j_1, j_2)^{th}$ entry of M_{pq} . When p is the source node, for each $j_2 \in T$, add an edge between the

source node and (q, j_2) in B'_{ij} and label it by the $(i, j_2)^{th}$ entry of M_{pq} . Similarly, when q is the sink node, for each $j_1 \in T$, add an edge between (p, j_1) and the sink node in B'_{ij} and label it by the $(j_1, j)^{th}$ entry of M_{pq} .

We just need to argue that the intermediate edge connections simulate matrix multiplications correctly. This is simple to observe, since for each path

$$\mathcal{P} = \{(s, p_1), (p_1, p_2), \dots, (p_{\ell-1}, t)\}$$

in B (where s, t are the source and sink nodes respectively) and each $(j_1, \dots, j_{\ell-1})$ such that $1 \leq j_1, \dots, j_{\ell-1} \leq T$, there is a path $(s, (p_1, j_1)), ((p_1, j_1), (p_2, j_2)), \dots, ((p_{\ell-1}, j_{\ell-1}), t)$ in B'_{ij} that computes $M_{(s, p_1)}[i, j_1]M_{(p_1, p_2)}[j_1, j_2] \cdots M_{(p_{\ell-1}, t)}[j_{\ell-1}, j]$ where $M_{(p, q)}$ is the $T \times T$ matrix labelling the edge (p, q) in B . The size of B'_{ij} is sT , and the number of layers is $d + 1$. ◀

Finitely Tractable Promise Constraint Satisfaction Problems

Kristina Asimi ✉

Abstract

The Promise Constraint Satisfaction Problem (PCSP) is a generalization of the Constraint Satisfaction Problem (CSP) that includes approximation variants of satisfiability and graph coloring problems. Barto [LICS '19] has shown that a specific PCSP, the problem to find a valid Not-All-Equal solution to a 1-in-3-SAT instance, is not finitely tractable in that it can be solved by a trivial reduction to a tractable CSP, but such a CSP is necessarily over an infinite domain (unless $P=NP$). We initiate a systematic study of this phenomenon by giving a general necessary condition for finite tractability and characterizing finite tractability within a class of templates – the “basic” tractable cases in the dichotomy theorem for symmetric Boolean PCSPs allowing negations by Brakensiek and Guruswami [SODA'18].

1 Introduction

Many computational problems, including various versions of logical satisfiability, graph coloring, and systems of equations can be phrased as Constraint Satisfaction Problems (CSPs) over fixed templates (see [5]). One of the possible formulations of the CSP is via homomorphisms of relational structures: a *template* \mathbb{A} is a relational structure with finitely many relations and the CSP over \mathbb{A} , written $\text{CSP}(\mathbb{A})$, is the problem to decide whether a given finite relational structure \mathbb{X} (similar to \mathbb{A}) admits a homomorphism to \mathbb{A} .

The complexity of CSPs over finite templates (i.e., those templates whose domain is a finite set) is now completely classified by a celebrated dichotomy theorem independently obtained by Bulatov [10] and Zhuk [19, 20]: every $\text{CSP}(\mathbb{A})$ is either tractable (that is, solvable in polynomial-time) or NP-complete. The landmark results leading to the complete classification include Schaefer’s dichotomy theorem [18] for CSPs over Boolean structures (i.e., structures with a two-element domain), Hell and Nešetřil’s dichotomy theorem [15] for CSPs over graphs, and Feder and Vardi’s thorough study [13] through Datalog and group theory. The latter paper also inspired the development of a mathematical theory of finite-template CSPs [16, 9, 6], the so called *algebraic approach*, that provided guidance and tools for the general dichotomy theorem by Bulatov and Zhuk.

The algebraic approach has been successfully applied in many variants and generalizations of the CSP such as the infinite-template CSP [7] or valued CSP [17]. This paper concerns a recent vast generalization of the basic CSP framework, the Promise CSP (PCSP).

A *template* for the PCSP is a pair (\mathbb{A}, \mathbb{B}) of similar structures such that \mathbb{A} has a homomorphism to \mathbb{B} , and the PCSP over (\mathbb{A}, \mathbb{B}) , written $\text{PCSP}(\mathbb{A}, \mathbb{B})$, is the problem to distinguish between the case that a given finite structure \mathbb{X} admits a homomorphism to \mathbb{A} and the case that \mathbb{X} does not have a homomorphism to \mathbb{B} (the promise is that one of the cases takes place). This framework generalizes that of CSP (take $\mathbb{A} = \mathbb{B}$) and additionally includes important problems in approximation, e.g., if $\mathbb{A} = \mathbb{K}_k$ (the clique on k vertices) and $\mathbb{B} = \mathbb{K}_l$, $k \leq l$, then $\text{PCSP}(\mathbb{A}, \mathbb{B})$ is a version of the approximate graph coloring problem, namely, the problem to distinguish graphs that are k -colorable from those that are not l -colorable, a problem whose complexity is open after more than 40 years of research. On the other hand, the basics of the algebraic approach to CSPs can be generalized to PCSPs [1, 8, 11, 3].

The approximate graph coloring problem shows that a full classification of the complexity of PCSPs over graph templates is still open and so is the analogue of Schaefer’s Boolean CSP, PCSPs over pairs of Boolean structures. However, strong partial results have already been obtained. Brakensiek and Guruswami [8] proved a dichotomy theorem for all symmetric Boolean templates allowing negations, i.e., templates (\mathbb{A}, \mathbb{B}) such that $\mathbb{A} = (\{0, 1\}; R_0, R_1, \dots)$, $\mathbb{B} = (\{0, 1\}; S_0, S_1, \dots)$, each relation R_i, S_i is invariant under permutations of coordinates, and $R_0 = S_0$ is the binary disequality relation \neq . Fıcak, Kozik, Olřák, and Stankiewicz [14] later generalized this result to all symmetric Boolean templates. These templates play a central role in this paper.

To prove tractability or hardness results for PCSPs, a very simple but useful reduction is often applied: If (\mathbb{A}, \mathbb{B}) and $(\mathbb{A}', \mathbb{B}')$ are similar PCSP templates and there exist homomorphisms $\mathbb{A}' \rightarrow \mathbb{A}$ and $\mathbb{B} \rightarrow \mathbb{B}'$, then the trivial reduction (which does not change the instance) reduces $\text{PCSP}(\mathbb{A}', \mathbb{B}')$ to $\text{PCSP}(\mathbb{A}, \mathbb{B})$; we say that $(\mathbb{A}', \mathbb{B}')$ is a *homomorphic relaxation* of (\mathbb{A}, \mathbb{B}) . In fact, all the tractable symmetric Boolean PCSPs can be reduced in this way to a tractable CSP over a structure with a *possibly infinite domain*.

An interesting example of a PCSP that can be naturally reduced to a tractable CSP over an infinite domain is the following problem. An instance is a list of triples of variables and the problem is to distinguish instances that are satisfiable as positive 1-in-3-SAT instances from those that are not even satisfiable as Not-All-Equal-3-SAT instances. This computational problem is essentially the same as $\text{PCSP}(\mathbb{A}, \mathbb{B})$ where \mathbb{A} consists of the ternary 1-in-3 relation over $\{0, 1\}$ and \mathbb{B} consists of the ternary not-all-equal relation over $\{0, 1\}$. It is easy to see that $\mathbb{A} \rightarrow \mathbb{C} \rightarrow \mathbb{B}$ where \mathbb{C} is the relation “ $x + y + z = 1$ ” over the set of all integers. Therefore $\text{PCSP}(\mathbb{A}, \mathbb{B})$ is reducible (by means of the trivial reduction) to $\text{PCSP}(\mathbb{C}, \mathbb{C}) = \text{CSP}(\mathbb{C})$ which is a tractable problem. The main result of [2] is that no finite structure can be used in place of \mathbb{C} for this particular template – this PCSP is not finitely tractable in the sense of the following definition.

► **Definition 1.** *We say that $\text{PCSP}(\mathbb{A}, \mathbb{B})$ is finitely tractable if there exists a finite relational structure \mathbb{C} such that $\mathbb{A} \rightarrow \mathbb{C} \rightarrow \mathbb{B}$ and $\text{CSP}(\mathbb{C})$ is tractable. Otherwise we call $\text{PCSP}(\mathbb{A}, \mathbb{B})$ not finitely tractable. (We assume $P \neq NP$ throughout the paper.)*

In this paper, we initiate a systematic study of this phenomenon. As the main technical contribution, we determine which of the “basic tractable cases” in Brakensiek and Guruswami’s classification [8] are finitely tractable. It turns out that finite tractability is quite rare, so the infinite nature of the 1-in-3 versus Not-All-Equal problem is not exceptional at all.

1.1 Symmetric Boolean PCSPs allowing negations

We now discuss the classification of symmetric Boolean templates allowing negations from [8]. It will be convenient to describe these templates by listing the corresponding relation pairs, that is, instead of $(\mathbb{A} = (\{0, 1\}; R_1, \dots, R_n), \mathbb{B} = (\{0, 1\}; S_1, \dots, S_n))$ we describe this

template by the list $(R_1, S_1), \dots, (R_n, S_n)$. Recall that the template is *symmetric* if all the involved relations are symmetric, i.e., invariant under any permutation of coordinates, and the template *allows negations* if (\neq, \neq) is among the relation pairs, where $\neq = \{(0, 1), (1, 0)\}$ is the disequality relation.

It may be also helpful to think of an instance of $\text{PCSP}(\mathbb{A}, \mathbb{B})$ as a list of constraints of the form $R_i(\text{variables})$ and the problem is to distinguish between instances where each constraint is satisfiable and those which are not satisfiable even when we replace each R_i by the corresponding “relaxed version” S_i . Allowing negations then means that we can use constraints $x \neq y$ – we can effectively negate variables.

The following relations are important for the classification.

- odd-in- $s = \{\mathbf{x} \in \{0, 1\}^s : \sum_{i=1}^s x_i \text{ is odd}\}$, even-in- $s = \{\mathbf{x} \in \{0, 1\}^s : \sum_{i=1}^s x_i \text{ is even}\}$
- r -in- $s = \{\mathbf{x} \in \{0, 1\}^s : \sum_{i=1}^s x_i = r\}$
- $\leq r$ -in- $s = \{\mathbf{x} \in \{0, 1\}^s : \sum_{i=1}^s x_i \leq r\}$, $\geq r$ -in- $s = \{\mathbf{x} \in \{0, 1\}^s : \sum_{i=1}^s x_i \geq r\}$
- not-all-equal- $s = \{\mathbf{x} \in \{0, 1\}^s : \sum_{i=1}^s x_i \notin \{0, s\}\}$

The next theorem lists some of the tractable cases of the classification, which are “basic” in the sense explained below.

► **Theorem 2** ([8]). $\text{PCSP}((P, Q), (\neq, \neq))$ is tractable if (P, Q) is equal to

- (a) (odd-in- s , odd-in- s), or (even-in- s , even-in- s), or
- (b) ($\leq r$ -in- s , $\leq (2r - 1)$ -in- s) and $r \leq s/2$, or
($\geq r$ -in- s , $\geq (2r - s + 1)$ -in- s) and $r \geq s/2$, or
- (c) (r -in- s , not-all-equal- s)

for some positive integers r, s .

It follows from the results in [8] (namely Theorem 2.1 and a simple analysis of compatible relations) that every tractable symmetric Boolean PCSP allowing negations can be obtained by

- taking any number of (\neq, \neq) and any number of relation pairs from a fixed item in Theorem 2,
- adding any number of “trivial” relation pairs (P, Q) such that $P \subseteq Q$, and Q is the full relation or P contains only constant tuples, and
- taking a homomorphic relaxation of the obtained template.

In this sense, Theorem 2 provides building blocks for all tractable templates.

1.2 Contributions

Some of the cases in Theorem 2 are finitely tractable: templates in item (a) are tractable CSPs (they can be decided by solving systems of linear equations of the two-element field), templates in item (c) for r odd and s even are homomorphic relaxations of (odd-in- s , odd-in- s), and templates in item (b) for $r = 1$ or $r = s - 1$ as well as all templates with $s \leq 2$ are tractable CSPs (reducible to 2-SAT) [18, 5]. Our main theorem proves that all the remaining cases are not finitely tractable. In fact, we prove this property even for some relaxations of these templates:

► **Theorem 3.** *The PCSP over any of the following templates is not finitely tractable.*

- (1) (r -in- s , $\leq (2r - 1)$ -in- s), (\neq, \neq) where $1 < r < s/2$,
(r -in- s , $\geq (2r - s + 1)$ -in- s), (\neq, \neq) where $s/2 < r < s - 1$
- (2) ($\leq r$ -in- s , $\leq (2r - 1)$ -in- s), (\neq, \neq) where s is even, $1 < r = s/2$
($\geq r$ -in- s , $\geq (2r - s + 1)$ -in- s), (\neq, \neq) where s is even, $1 < r = s/2$

- (3) (r -in- s , $\leq(2r - 1)$ -in- s), (\neq, \neq) where s is even, $1 < r = s/2$, and r is even
 $(r$ -in- s , $\geq(2r - s + 1)$ -in- s), (\neq, \neq) where s is even, $1 < r = s/2$, and r is even
- (4) (r -in- s , not-all-equal- s) where $s > r$, $s > 2$, and r is even or s is odd

Note that the templates in the last item do not contain the disequality pair; the special case with $r = 1$ and $s = 3$ is the main result of [2]. Disequalities in the other items are necessary, since otherwise the templates are homomorphic relaxations of CSPs over one-element structures.

In Theorem 18 we provide a general necessary condition for finite tractability of an arbitrary finite-template PCSP in terms of so called h1 identities. Showing that templates in Theorem 3 do not satisfy this necessary condition forms the bulk of the paper.

The necessary condition in Theorem 18 seems very unlikely to be sufficient for finite tractability. Nevertheless, we observe in Theorem 12 that finite tractability *does* depend only on h1 identities, just like standard tractability [11], see Theorem 10 and the discussion following the theorem.

2 Preliminaries

2.1 PCSP

We use the notation $[n] = \{1, 2, \dots, n\}$ throughout the paper.

A *relational structure* (of finite signature) is a tuple $\mathbb{A} = (A; R_1, R_2, \dots, R_n)$ where A is a set, called the *domain*, and each R_i is a relation on A of arity $\text{ar}(R_i) \geq 1$, that is, $R_i \subseteq A^{\text{ar}(R_i)}$. The structure \mathbb{A} is finite if A is finite. Two relational structures $\mathbb{A} = (A; R_1, R_2, \dots, R_n)$ and $\mathbb{B} = (B; S_1, S_2, \dots, S_n)$ are *similar* if they have the same number of relations and $\text{ar}(R_i) = \text{ar}(S_i)$ for each $i \in [n]$. In this case, a *homomorphism* from \mathbb{A} to \mathbb{B} is a mapping $f : A \rightarrow B$ such that $(f(a_1), f(a_2), \dots, f(a_k)) \in S_i$ whenever $i \in [n]$ and $(a_1, a_2, \dots, a_k) \in R_i$ where $k = \text{ar}(R_i)$. If there exists a homomorphism from \mathbb{A} to \mathbb{B} , we write $\mathbb{A} \rightarrow \mathbb{B}$, and if there is none, we write $\mathbb{A} \not\rightarrow \mathbb{B}$.

► **Definition 4.** A PCSP template is a pair (\mathbb{A}, \mathbb{B}) of similar relational structures such that $\mathbb{A} \rightarrow \mathbb{B}$.

The PCSP over (\mathbb{A}, \mathbb{B}) , written $\text{PCSP}(\mathbb{A}, \mathbb{B})$, is the following problem. Given a finite relational structure \mathbb{X} similar to \mathbb{A} (and \mathbb{B}), output “Yes.” if $\mathbb{X} \rightarrow \mathbb{A}$ and output “No.” if $\mathbb{X} \not\rightarrow \mathbb{B}$.

We define $\text{CSP}(\mathbb{A}) = \text{PCSP}(\mathbb{A}, \mathbb{A})$.

► **Definition 5.** Let (\mathbb{A}, \mathbb{B}) and $(\mathbb{A}', \mathbb{B}')$ be similar PCSP templates. We say that $(\mathbb{A}', \mathbb{B}')$ is a homomorphic relaxation of (\mathbb{A}, \mathbb{B}) if $\mathbb{A}' \rightarrow \mathbb{A}$ and $\mathbb{B} \rightarrow \mathbb{B}'$.

Recall that if $(\mathbb{A}', \mathbb{B}')$ is a homomorphic relaxation of (\mathbb{A}, \mathbb{B}) , then the trivial reduction, which does not change the input structure \mathbb{X} , reduces $\text{PCSP}(\mathbb{A}', \mathbb{B}')$ to $\text{PCSP}(\mathbb{A}, \mathbb{B})$.

2.2 Polymorphisms

A crucial concept for the algebraic approach to (P)CSP is a polymorphism.

► **Definition 6.** Let $\mathbb{A} = (A; R_1, \dots, R_m)$ and $\mathbb{B} = (B; S_1, \dots, S_m)$ be two similar relational structures. A function $c : A^n \rightarrow B$ is a polymorphism from \mathbb{A} to \mathbb{B} if for each relation R_i in \mathbb{A} with $k_i = \text{arity}(R_i)$

$$\begin{pmatrix} a_{11} \\ a_{21} \\ \vdots \\ a_{k_i1} \end{pmatrix} \in R_i, \begin{pmatrix} a_{12} \\ a_{22} \\ \vdots \\ a_{k_i2} \end{pmatrix} \in R_i \dots, \begin{pmatrix} a_{1n} \\ a_{2n} \\ \vdots \\ a_{k_in} \end{pmatrix} \in R_i \Rightarrow \begin{pmatrix} c(a_{11}, a_{12}, \dots, a_{1n}) \\ c(a_{21}, a_{22}, \dots, a_{2n}) \\ \vdots \\ c(a_{k_i1}, a_{k_i2}, \dots, a_{k_in}) \end{pmatrix} \in S_i.$$

We denote the set of all polymorphisms from \mathbb{A} to \mathbb{B} by $\text{Pol}(\mathbb{A}, \mathbb{B})$ and define $\text{Pol}(\mathbb{C}) = \text{Pol}(\mathbb{C}, \mathbb{C})$.

The computational complexity of a PCSP depends only on the set of polymorphisms of its template [8]. We note that tractability of the PCSPs in Theorem 2 stems from nice polymorphisms: parities (item (a)), majorities (item (b)), and alternating thresholds (item (c)).

The set of polymorphisms is an algebraic object named minion in [11], which we define in Definition 8 below.

► **Definition 7.** An n -ary function $f^\pi : A^n \rightarrow B$ is called a minor of an m -ary function $f : A^m \rightarrow B$ given by a map $\pi : [m] \rightarrow [n]$ if

$$f^\pi(x_1, \dots, x_n) = f(x_{\pi(1)}, \dots, x_{\pi(m)})$$

for all $x_1, \dots, x_n \in A$.

► **Definition 8.** Let $\mathcal{O}(A, B) = \{f : A^n \rightarrow B : n \geq 1\}$. A minion on (A, B) is a non-empty subset \mathcal{M} of $\mathcal{O}(A, B)$ that is closed under taking minors. For fixed $n \geq 1$, let $\mathcal{M}^{(n)}$ denote the set of n -ary functions from \mathcal{M} .

As mentioned, $\mathcal{M} = \text{Pol}(\mathbb{A}, \mathbb{B})$ is always a minion and the complexity of $\text{PCSP}(\mathbb{A}, \mathbb{B})$ depends only on \mathcal{M} . This result was strengthened in [11, 3] (generalizing the same result for CSPs [6]) as follows.

► **Definition 9.** Let \mathcal{M} and \mathcal{N} be two minions. A mapping $\xi : \mathcal{M} \rightarrow \mathcal{N}$ is called a minion homomorphism if it preserves arities and preserves taking minors, i.e., $\xi(f^\pi) = (\xi(f))^\pi$ for every $f \in \mathcal{M}^{(m)}$ and every $\pi : [m] \rightarrow [n]$.

► **Theorem 10.** Let (\mathbb{A}, \mathbb{B}) and $(\mathbb{A}', \mathbb{B}')$ be PCSP templates. If there exists a minion homomorphism $\text{Pol}(\mathbb{A}', \mathbb{B}') \rightarrow \text{Pol}(\mathbb{A}, \mathbb{B})$, then $\text{PCSP}(\mathbb{A}, \mathbb{B})$ is log-space reducible to $\text{PCSP}(\mathbb{A}', \mathbb{B}')$.

An *h1 identity* (h1 stands for height one) is a meaningful expression of the form $\text{function}(\text{variables}) \approx \text{function}(\text{variables})$, e.g., if $f : A^3 \rightarrow B$ and $g : A^4 \rightarrow B$, then $f(x, y, x) \approx g(y, x, x, z)$ is an h1 identity. Such an h1 identity is *satisfied* if the corresponding equation holds universally, e.g., $f(x, y, x) \approx g(y, x, x, z)$ is satisfied if and only if $f(x, y, x) = g(y, x, x, z)$ for every $x, y, z \in A$.

Every minion homomorphism $\xi : \mathcal{M} \rightarrow \mathcal{N}$ preserves h1 identities in the sense that if functions $f, g \in \mathcal{M}$ satisfy an h1 identity, then so do their ξ -images $\xi(f), \xi(g) \in \mathcal{N}$. In fact, an arity-preserving ξ between minions is a minion homomorphism if and only if it preserves h1 identities (see [6] for details). In this sense, Theorem 10 shows that the complexity of a PCSP depends only on h1 identities satisfied by polymorphisms.

2.3 Notation for tuples

Repeated entries in tuples will be indicated by \times , e.g. $(2 \times a, 3 \times b)$ stands for the tuple (a, a, b, b, b) .

The i -th *cyclic shift* of a tuple (x_1, \dots, x_m) is the tuple $(x_{(m-i \bmod m)+1}, \dots, x_m, x_1, \dots, x_{(m-i-1 \bmod m)+1})$. A *cyclic shift* is the i -th cyclic shift for some i . We will use cyclic shifts both for tuples of zeros and ones and tuples of variables.

We will often use special p -tuples and $n = p^2$ -tuples of zeros and ones as arguments for Boolean functions, where p will be a fixed prime number. For $0 \leq k \leq p$, $0 \leq l \leq p^2$, and $0 \leq k^1, \dots, k^p \leq p$ we write

$$\langle k \rangle_p = (k \times 1, (p - k) \times 0) = (\underbrace{1, 1, \dots, 1}_k, \underbrace{0, 0, \dots, 0}_{p-k}), \quad \langle l \rangle_n = (\underbrace{1, 1, \dots, 1}_l, \underbrace{0, 0, \dots, 0}_{n-l})$$

and

$$\langle k^1, \dots, k^p \rangle_p = \langle k^1 \rangle_p \langle k^2 \rangle_p \dots \langle k^p \rangle_p$$

for the concatenation of $\langle k^1 \rangle_p, \dots, \langle k^p \rangle_p$. (Note here that the “ i ” in k^i is an index, not an exponent.) The subscripts p and n in $\langle \rangle_p$ and $\langle \rangle_n$ will be usually clear from the context and we omit them. We will sometimes need to shift n -ary tuples $\langle k^1, \dots, k^p \rangle$ blockwise, e.g., to $\langle k^2, \dots, k^p, k^1 \rangle$. In such a situation we talk about a *p-ary cyclic shift* to avoid confusion.

It will be often convenient to think of an n -tuple $\mathbf{k} = \langle k^1, \dots, k^p \rangle$ as a $p \times p$ zero-one matrix with columns $\langle k^1 \rangle, \dots, \langle k^p \rangle$. For example, the ones in $\langle p \times 5 \rangle$ form a $5 \times p$ “rectangle” and $\langle (p-2) \times 5, 2 \times 4 \rangle$ is “almost” a $5 \times p$ rectangle – the bottom right 1×2 corner is removed. A p -ary cyclic shift of \mathbf{k} corresponds to cyclic permutation of columns.

The area of a zero-one n -tuple \mathbf{k} is defined as the fraction of ones and is denoted $\lambda(\mathbf{k})$.

$$\lambda(\mathbf{k}) = \left(\sum_{i=1}^n k_i \right) / p^2$$

The area of $\langle k^1, \dots, k^p \rangle$ is thus $(k^1 + \dots + k^p) / p^2$.

If t is a p -ary function we simply write $t\langle k \rangle$ instead of $t(\langle k \rangle)$. Similar shorthand is used for n -ary functions and tuples $\langle k^1, \dots, k^p \rangle_p$.

3 Finitely tractable PCSPs

3.1 Finite tractability depends only on h1 identities

We start by observing that finite tractability also depends only on h1 identities satisfied by polymorphisms, just like standard tractability (recall the discussion about h1 identities and minion homomorphisms below Theorem 10). This result, Theorem 12, is an immediate consequence of the following lemma and Theorem 10.

- **Lemma 11.** *Let (\mathbb{A}, \mathbb{B}) be a PCSP template. Then the following are equivalent.*
- PCSP (\mathbb{A}, \mathbb{B}) is finitely tractable.
 - There exists a finite relational structure \mathbb{C} such that CSP (\mathbb{C}) is solvable in polynomial time and there exists a minion homomorphism $\text{Pol}(\mathbb{C}) \rightarrow \text{Pol}(\mathbb{A}, \mathbb{B})$.

Proof. This lemma is a consequence of known results and we only sketch the argument here. In Section II.B of [2] it is argued that the first item is equivalent to the claim that a finite tractable template (\mathbb{C}, \mathbb{C}) pp-constructs (\mathbb{A}, \mathbb{B}) . The latter claim is equivalent to the second item by Theorem 4.12 in [3]. ◀

► **Theorem 12.** *Let (\mathbb{A}, \mathbb{B}) and $(\mathbb{A}', \mathbb{B}')$ be PCSP templates. If there exists a minion homomorphism $\text{Pol}(\mathbb{A}', \mathbb{B}') \rightarrow \text{Pol}(\mathbb{A}, \mathbb{B})$ and $\text{PCSP}(\mathbb{A}', \mathbb{B}')$ is finitely tractable, then so is $\text{PCSP}(\mathbb{A}, \mathbb{B})$.*

3.2 Necessary condition for finite tractability

In this subsection, we derive the necessary condition for finite tractability that will be used to prove Theorem 3. A cyclic polymorphism is a starting point for the condition.

► **Definition 13.** *A function $c : A^p \rightarrow B$ is called cyclic if it satisfies the h1 identity*

$$c(x_1, x_2, \dots, x_p) \approx c(x_2, \dots, x_p, x_1).$$

Cyclic polymorphisms can be used [4] to characterize the borderline between tractable and NP-complete CSPs proposed in [9] and confirmed in [10, 19, 20]. We only state the direction needed in this paper.

► **Theorem 14 ([4]).** *Let \mathbb{C} be a CSP template over a finite domain C . If $\text{CSP}(\mathbb{C})$ is not NP-complete, then \mathbb{C} has a cyclic polymorphism of arity p for every prime number $p > |C|$.*

Polymorphism minions of CSP templates are closed under arbitrary composition (cf. [5]). In particular, if $\text{CSP}(\mathbb{C})$ is not NP-complete, then $\text{Pol}(\mathbb{C})$ contains the function

$$\begin{aligned} t(x_{11}, x_{21}, \dots, x_{p1}, x_{12}, x_{22}, \dots, x_{p2}, \dots, x_{1p}, x_{2p}, \dots, x_{pp}) \\ = c(c(x_{11}, x_{21}, \dots, x_{p1}), c(x_{12}, x_{22}, \dots, x_{p2}), \dots, c(x_{1p}, x_{2p}, \dots, x_{pp})), \end{aligned} \quad (1)$$

where c is a p -ary cyclic function and $p > |C|$. Such a function satisfies strong h1 identities which are not satisfied by the templates in Theorem 3. We now (in two steps) describe one such collection of strong enough identities.

► **Definition 15.** *A function $t : A^{p^2} \rightarrow B$ is doubly cyclic if it satisfies every identity of the form $t(\mathbf{x}_1, \dots, \mathbf{x}_p) \approx t(\mathbf{y}_1, \dots, \mathbf{y}_p)$, where \mathbf{x}_i is a p -tuple of variables and \mathbf{y}_i is a cyclic shift of \mathbf{x}_i for every $i \in [p]$, and every identity of the form $t(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_p) \approx t(\mathbf{x}_2, \dots, \mathbf{x}_p, \mathbf{x}_1)$, where each \mathbf{x}_i is a p -tuple of variables.*

Observe that t from Equation (1) is doubly cyclic – the first type of identities come from the cyclicity of the inner c while the second type from the outer c . It will be also useful for us to observe in Lemma 22 that, after rearranging the arguments (we read them row-wise), t is a cyclic function of arity p^2 . From the finiteness of the domain C we get one more property of function t . In the next definition, by an x/y -tuple we mean a tuple containing only variables x and y .

► **Definition 16.** *A doubly cyclic function $t : A^{p^2} \rightarrow B$ is b -bounded if there exists an equivalence relation \sim on the set of all p -ary x/y -tuples with at most b equivalence classes such that t satisfies every identity of the form $t(\mathbf{u}_1, \dots, \mathbf{u}_p) \approx t(\mathbf{v}_1, \dots, \mathbf{v}_p)$ where \mathbf{u}_i and \mathbf{v}_i are x/y -tuples such that $\mathbf{u}_i \sim \mathbf{v}_i$ for every $i \in [p]$.*

► **Lemma 17.** *Let $c : C^p \rightarrow C$ be a cyclic function. Then the function t defined by Equation (1) is a b -bounded doubly cyclic function for $b = |C|^{|C|^2}$.*

Proof. We define \sim by declaring two p -ary x/y -tuples \mathbf{u} and \mathbf{v} \sim -equivalent if $c(\mathbf{u}) \approx c(\mathbf{v})$. As there are $b = |C|^{|C|^2}$ binary functions $C^2 \rightarrow C$, this equivalence has at most b equivalence classes. By definitions, t is then b -bounded and doubly cyclic. ◀

The promised necessary condition for finite tractability is now a simple consequence:

► **Theorem 18.** *Let (\mathbb{A}, \mathbb{B}) be a finite PCSP template that is finitely tractable. Then there exists b such that (\mathbb{A}, \mathbb{B}) has a p^2 -ary b -bounded doubly cyclic polymorphism for every sufficiently large prime p .*

Proof. If (\mathbb{A}, \mathbb{B}) is finitely tractable, then, by Lemma 11, there exists a minion homomorphism $\xi : \text{Pol}(\mathbb{C}) \rightarrow \text{Pol}(\mathbb{A}, \mathbb{B})$, where \mathbb{C} is finite and $\text{CSP}(\mathbb{C})$ is tractable. By Theorem 14, \mathbb{C} has a p -ary cyclic polymorphism for every sufficiently large prime. Then, by Lemma 17, the polymorphism t of \mathbb{C} defined by Equation (1) is a b -bounded and doubly cyclic (with the appropriate b). As ξ preserves h1 identities, $\xi(t)$ is a b -bounded doubly cyclic polymorphism of (\mathbb{A}, \mathbb{B}) . ◀

3.3 Proof of Theorem 3

Finally, we are ready to start proving Theorem 3. Without loss of generality, we consider only templates on the first lines of Cases (1)–(3) of Theorem 3 (in particular, $r \leq s/2$) and assume that $r \leq s/2$ in Case (4) (the remaining templates can be obtained by swapping zero and one in the domains). We fix such a template (\mathbb{A}, \mathbb{B}) .

Striving for a contradiction, suppose that $\text{PCSP}(\mathbb{A}, \mathbb{B})$ is finitely tractable. By Theorem 18 there exists b such that (\mathbb{A}, \mathbb{B}) has a p^2 -ary b -bounded doubly cyclic polymorphism t for every sufficiently large arity p^2 . We fix such a b and t , where p is fixed to a sufficiently large prime p congruent to 1 modulo s (which is possible by the Dirichlet prime number theorem). How large must p be will be seen in due course. We denote $n = p^2$ and observe that $n \equiv 1 \pmod{s}$ as well.

Using the cyclicity in Section 4 and double cyclicity in Section 5 we will show that certain evaluations $t(\mathbf{z})$ of t are tame in that $t(\mathbf{z}) = t\langle 0 \rangle$ (recall here the notation in Subsection 2.3) if the area of \mathbf{z} is below a threshold θ . The *threshold* is defined as $\theta = 1/2$ for all the templates but the $(r$ -in- s , not-all-equal- s) template in Case (4), where we set $\theta = r/s$ (observe that $\theta = r/s$ also in Case (2) and (3)). We restate the definition of tameness for convenience.

► **Definition 19.** *A tuple $\mathbf{z} \in \{0, 1\}^n$ is tame if*

$$t(\mathbf{z}) = \begin{cases} t\langle 0 \rangle_n & \text{if } \lambda(\mathbf{z}) < \theta \\ 1 - t\langle 0 \rangle_n & \text{if } \lambda(\mathbf{z}) > \theta \end{cases}$$

(Note here that $\lambda(\mathbf{z})$ is never equal to θ since n is odd and $n \equiv 1 \pmod{s}$.)

The evaluations that we use are called near-threshold almost rectangles defined as follows.

► **Definition 20.** *A tuple $\mathbf{z} \in \{0, 1\}^n$ is an almost rectangle if it is a p -ary cyclic shift of a tuple of the form $\langle z^1, \dots, z^1, z^2, \dots, z^2 \rangle_p$, where $0 \leq z^1, z^2 \leq p$, the number of z^1 's is arbitrary, and $|z^1 - z^2| < 5b$. The quantity $\Delta z = |z^1 - z^2|$ is referred to as the step size. We say that \mathbf{z} is near-threshold if $|\lambda(\mathbf{z}) - \theta| < 1/s^{\Delta z+3}$.*

The proof can now be finished by using the tameness of near-threshold almost rectangles (that will be established in Lemma 25) together with the b -boundedness of t as follows.

Let $m = (p-1)/2$ and choose positive integers $z^{2,1}$ and $z^{2,2}$ so that $\theta p - 2b < z^{2,1} < z^{2,2} < \theta p$ and the x/y -tuples $(z^{2,1} \times x, (p - z^{2,1}) \times y)$ and $(z^{2,2} \times x, (p - z^{2,2}) \times y)$ are \sim -equivalent (see Definition 16 of boundedness). This is possible by the pigeonhole principle since there are more than b integers in the interval and \sim has at most b classes.

By the choice of $z^{2,1}$ and $z^{2,2}$, for any meaningful choice of z^1 , we have $t(\mathbf{z}_1) = t(\mathbf{z}_2)$ where $\mathbf{z}_i = \langle m \times z^1, (p - m) \times z^{2,i} \rangle_p$, $i = 1, 2$. We choose z^1 as the maximum number such that $\lambda(\mathbf{z}_1) < \theta$. (Note here that for $z^1 = p$ the area of \mathbf{z}_1 can be made arbitrarily close to

$(1 + \theta)/2 > \theta$ by choosing a sufficiently large p , so we may assume $z^1 < p$.) From $m < p/2$ it follows that increasing $z^{2,1}$ by one makes the area of \mathbf{z}_1 greater than increasing z^1 by one, therefore $\lambda(\mathbf{z}_2) > \theta$.

Note that $z^1 > p\theta$ since otherwise the area of \mathbf{z}_2 is less than θ . On the other hand, $z^1 < p\theta + 3b$, otherwise the area of \mathbf{z}_1 is greater (assuming $p > 5$):

$$\lambda(\mathbf{z}_1) = \frac{mz^1 + (p - m)z^{2,1}}{p^2} \geq \frac{\frac{p-1}{2}(p\theta + 3b) + \frac{p+1}{2}(p\theta - 2b)}{p^2} = \frac{p^2\theta + \frac{b(p-5)}{2}}{p^2} > \theta.$$

It follows that the step size of both \mathbf{z}_1 and \mathbf{z}_2 is less than $5b$, so both \mathbf{z}_i are almost rectangles. By choosing a sufficiently large p , the difference $\lambda(\mathbf{z}_2) - \lambda(\mathbf{z}_1)$ can be made arbitrarily small, and since $\lambda(\mathbf{z}_1) < \theta < \lambda(\mathbf{z}_2)$ both \mathbf{z}_i are then near-threshold.

Now the tameness of near-threshold almost rectangles (Lemma 25) gives us $t(\mathbf{z}_1) = t\langle 0 \rangle_n \neq 1 - t\langle 0 \rangle_n = t(\mathbf{z}_2)$. On the other hand, we also have $t(\mathbf{z}_1) = t(\mathbf{z}_2)$, a contradiction.

4 Step size at most one

In this section we prove the following lemma.

► **Lemma 21.** *Every near-threshold almost rectangle of step size at most one is tame.*

We will use the cyclicity of an operation obtained from t by an appropriate rearrangement of its arguments, stated in the following lemma. Its proof is in Appendix A.

► **Lemma 22.** *Let $t : A^{p^2} \rightarrow B$ be a doubly cyclic function. Then the function t^σ defined by*

$$t^\sigma \left(\begin{array}{cccc} x_{11} & x_{12} & \cdots & x_{1p} \\ x_{21} & x_{22} & \cdots & x_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ x_{p1} & x_{p2} & \cdots & x_{pp} \end{array} \right) = t \left(\begin{array}{cccc} x_{11} & x_{21} & \cdots & x_{p1} \\ x_{12} & x_{22} & \cdots & x_{p2} \\ \vdots & \vdots & \ddots & \vdots \\ x_{1p} & x_{2p} & \cdots & x_{pp} \end{array} \right)$$

is a cyclic function.

Observe that an almost rectangle $\mathbf{z} = \langle z^2 + 1, \dots, z^2 + 1, z^2, \dots, z^2 \rangle_p$ regarded as a $p \times p$ matrix is, when read row-wise, equal to a sequence of consecutive ones, followed by zeros. In other words, using the notation t^σ from Lemma 22, we have $t(\mathbf{z}) = t^\sigma \langle k \rangle_n$ for some k . Also note that every almost rectangle of step size at most one has a p -ary cyclic shift of this form. Finally, notice that if \mathbf{z} is near-threshold, then $k \leq 2\lfloor \theta n \rfloor$. In order to prove Lemma 21, it is therefore enough to verify the following lemma.

► **Lemma 23.** *Denote $a = \lfloor \theta n \rfloor$. For every $0 \leq k \leq 2a$, we have*

$$t^\sigma \langle k \rangle_n = \begin{cases} t^\sigma \langle 0 \rangle_n & \text{if } 0 \leq k \leq a \\ 1 - t^\sigma \langle 0 \rangle_n & \text{if } 1 + a \leq k \leq 2a \end{cases}$$

The rest of this section is devoted to proving this lemma. We require an additional definition. We say that an s -tuple of evaluations $\langle k_1 \rangle_n, \dots, \langle k_s \rangle_n$, where $0 \leq k_i \leq n$, is *plausible* if $\sum_{i=1}^s k_i = rn$ in Cases (1), (3), (4) and $\sum_{i=1}^s k_i \leq rn$ in Case (2). The following lemma is a consequence of the fact that t^σ is a polymorphism (as t is) which is, additionally, cyclic by Lemma 22. No other properties of t are needed in this section.

► **Lemma 24.** *If an s -tuple $\langle k_1 \rangle_n, \dots, \langle k_s \rangle_n$ is plausible, then $(t^\sigma \langle k_1 \rangle_n, \dots, t^\sigma \langle k_s \rangle_n) \in Q$ (recall here that (P, Q) is introduced in the statement of Theorem 3).*

Moreover, in Cases (1), (2), and (3), we have $t^\sigma \langle n - k \rangle_n = 1 - t^\sigma \langle k \rangle_n$ for every $0 \leq k \leq n$.

11:10 Finitely Tractable Promise Constraint Satisfaction Problems

Proof. For the first part, let $\langle k_1 \rangle, \dots, \langle k_s \rangle$ be plausible. Form an $s \times rn$ matrix M whose first row is $\langle k_1 \rangle_{rn}$ and the j -th row is the $(\sum_{l=1}^{j-1} k_l)$ -th cyclic shift of $\langle k_j \rangle_{rn}$ for $j \in \{2, \dots, s\}$. Note that each of the first $\sum k_i$ columns of M contains exactly 1 one and the remaining columns are all zero (the latter only applies in Case (2)). Split this matrix into r -many $s \times n$ blocks M^1, M^2, \dots, M^r . Their sum $X = \sum_{j=1}^r M^j$ is an $s \times n$ zero-one matrix whose each column contains exactly r ones in Cases (1), (3), and (4), and at most r ones in Case (2). Moreover, for all $j \in [s]$, the j -th row of X is a cyclic shift of $\langle k_j \rangle$, therefore its t^σ -image is $t^\sigma \langle k_j \rangle$ by cyclicity of t^σ . Each column belongs to the relation P , therefore, as t^σ is a polymorphism, we get that t^σ applied to the rows gives a tuple in Q . This implies the first claim.

For the second part, we take $\langle k \rangle$ together with the k -th cyclic shift of $\langle n - k \rangle$ and use the fact that t^σ preserves the disequality relation pair. ◀

We now consider Cases (1)–(4) separately. Case (2) is the simplest. If $0 \leq k \leq a$ then $\langle k \rangle, \langle k \rangle, \dots, \langle k \rangle$ is a plausible tuple. By Lemma 24, the tuple $(t^\sigma \langle k \rangle, t^\sigma \langle k \rangle, \dots, t^\sigma \langle k \rangle)$ is in Q ; therefore $t^\sigma \langle k \rangle = 0$. For the remaining values $2a \geq k \geq a + 1$ we apply the second part of this lemma and get $t^\sigma \langle k \rangle = 1$.

For Case (1) we prove $t^\sigma \langle k \rangle = 0$ and $t^\sigma \langle n - k \rangle = 1$ for any $0 \leq k \leq a$ by induction on $i = a - k$, $i = 0, 1, \dots, a$. For the first step, $k = (n - 1)/2$, we apply Lemma 24 to the plausible s -tuple $2r \times \langle k \rangle, \langle r \rangle, (s - 2r - 1) \times \langle 0 \rangle$. Since Q contains no p -tuple with more than $(2r - 1)$ ones, we get $t^\sigma \langle k \rangle = 0$. Then also $t^\sigma \langle n - k \rangle = 1$ by the second part of the lemma. For the induction step, we use the tuple

$$r \times \langle k \rangle, r \times \langle n - k - 1 \rangle, \langle r \rangle, (s - 2r - 1) \times \langle 0 \rangle$$

in a similar way, additionally using that $t^\sigma \langle n - k - 1 \rangle = 1$ by the induction hypothesis.

We proceed to Case (4). We will prove, starting from the left, the following chain of disequalities.

$$t^\sigma \langle a \rangle \neq t^\sigma \langle a + 1 \rangle \neq t^\sigma \langle a - 1 \rangle \neq t^\sigma \langle a + 2 \rangle \neq t^\sigma \langle a - 2 \rangle \neq \dots \neq t^\sigma \langle 2a \rangle \neq t^\sigma \langle 0 \rangle$$

This will imply $t^\sigma \langle a \rangle = t^\sigma \langle a - 1 \rangle = \dots = t^\sigma \langle 0 \rangle \neq t^\sigma \langle a + 1 \rangle = t^\sigma \langle a + 2 \rangle = \dots = t^\sigma \langle 2a \rangle$. We start with the first disequality $t^\sigma \langle a \rangle \neq t^\sigma \langle a + 1 \rangle$. The sequence of arguments

$$(s - r) \times \langle a \rangle, r \times \langle a + 1 \rangle$$

has length s and is plausible as $(s - r)a + r(a + 1) = sa + r$ and $sa + r$ is equal to rn . (Indeed, $n \equiv 1 \pmod{s}$, so $n = ms + 1$ for some integer m ; then $a = mr$ and $sa + r = smr + r = (n - 1)r + r = rn$.) By Lemma 24, $t^\sigma \langle a \rangle \neq t^\sigma \langle a + 1 \rangle$ since Q does not contain all-equal tuples in Case (4). The remaining disequalities are proved in Appendix B.

Case (3) can be done similarly as Case (4) with an additional reasoning that we now explain. Consider, e.g., the proof that $t^\sigma \langle a \rangle \neq t^\sigma \langle a + 1 \rangle$ using the sequence $(s - r) \times \langle a \rangle, r \times \langle a + 1 \rangle$. We cannot directly conclude that $t^\sigma \langle a \rangle \neq t^\sigma \langle a + 1 \rangle$ since relation Q contains the all-zero tuple – we can only conclude that $t^\sigma \langle a \rangle$ and $t^\sigma \langle a + 1 \rangle$ are not both ones. However, we can also prove in the same way that $t^\sigma \langle n - a \rangle$ and $t^\sigma \langle n - (a + 1) \rangle$ are not both ones by using the “complementary” tuple $(s - r) \times \langle n - a \rangle, r \times \langle n - (a + 1) \rangle$. The claim $t^\sigma \langle a \rangle \neq t^\sigma \langle a + 1 \rangle$ then follows from the second part of Lemma 24.

The proof of Lemma 23 is concluded.

5 Arbitrary step size

The entire section is devoted to the proof of the following lemma.

► **Lemma 25.** *Every near-threshold almost rectangle is tame.*

We start by redefining plausibility.

We say that an m -tuple of evaluations $\mathbf{k}_1 = \langle k_1^1, \dots, k_1^p \rangle, \dots, \mathbf{k}_m = \langle k_m^1, \dots, k_m^p \rangle$, where $m \in [s]$, is *plausible* if $\sum_{j=1}^m k_j^i = rp$ for all $i \in [p]$ (note that we do not make exception for Case (2) here). In other words, by arranging the integers defining $\mathbf{k}_1, \mathbf{k}_2, \dots, \mathbf{k}_m$ as rows of an $m \times p$ matrix, we get a matrix whose every column sums up to rp . Note that the sum of the areas of the evaluations is then equal to r .

The following lemma is a “2-dimensional analogue” of Lemma 24. The proof applies the first type of doubly cyclic identities from Definition 15, it is given in Appendix C.

► **Lemma 26.** *If a tuple $\mathbf{k}_1, \dots, \mathbf{k}_s$ is plausible, then $(t(\mathbf{k}_1), \dots, t(\mathbf{k}_s)) \in Q$.*

Moreover, in Cases (1), (2), and (3), we have $t(p - k^1, \dots, p - k^p) = 1 - t(k^1, \dots, k^p)$ for any evaluation $\langle k^1, \dots, k^p \rangle$.

The next lemma will be applied to produce plausible sequence of evaluations. The proof uses the other type of doubly cyclic identities. It is given in Appendix D, here we provide a brief sketch. (In the statement, note that $r/\theta = s$ except for Case (1) where $r/\theta = 2r$.)

► **Lemma 27.** *Let \mathbf{z} be an almost rectangle of step size $\Delta z \geq 2$ with $|\lambda(\mathbf{z}) - \theta| \leq 1/s^3$ and let p be sufficiently large. Then*

- *there exists a plausible r/θ -tuple $\mathbf{k}_1, \mathbf{k}_2, \dots, \mathbf{k}_{r/\theta-1}, \mathbf{l}$ of almost rectangles such that $t(\mathbf{z}) = t(\mathbf{k}_1) = t(\mathbf{k}_2) = \dots = t(\mathbf{k}_{r/\theta-1}), \lambda(\mathbf{z}) = \lambda(\mathbf{k}_1) = \dots = \lambda(\mathbf{k}_{r/\theta-1})$, and \mathbf{l} has the same step size Δz as \mathbf{z} ;*
- *there exists a plausible r/θ -tuple $\mathbf{k}_1, \mathbf{k}_2, \dots, \mathbf{k}_{r/\theta-2}, \mathbf{l}_1, \mathbf{l}_2$ of almost rectangles such that $t(\mathbf{z}) = t(\mathbf{k}_1) = t(\mathbf{k}_2) = \dots = t(\mathbf{k}_{r/\theta-2}), \lambda(\mathbf{z}) = \lambda(\mathbf{k}_1) = \dots = \lambda(\mathbf{k}_{r/\theta-2})$, both \mathbf{l}_1 and \mathbf{l}_2 have step size strictly smaller than Δz , and $|\lambda(\mathbf{l}_1) - \lambda(\mathbf{l}_2)| \leq 1/p$.*

Proof sketch. We can assume that $\mathbf{z} = \langle c \times z^1, d \times z^2 \rangle$ for some c, d, z^1, z^2 . For the first item, we consider the $(r/\theta - 1) \times p$ matrix X whose first row is \mathbf{z} and the i -th row is the c -th cyclic shift of the $(i - 1)$ -st row for each $i \in \{2, \dots, r/\theta - 1\}$. Let Y be the $r/\theta \times p$ matrix obtained from X by adding a row (l^1, \dots, l^p) so that each column sums up to rp and we define $\mathbf{k}_1, \dots, \mathbf{k}_m, \mathbf{l}$ as the n -tuples determined by the rows of Y via $\langle \rangle$, e.g., $\mathbf{l} = \langle l^1, \dots, l^p \rangle$. The inequality $|\lambda(\mathbf{z}) - \theta| \leq 1/s^3$ (and p being sufficiently large) ensures that \mathbf{l} is correctly defined (i.e., all the l^i are between 0 and p), the construction gives that \mathbf{l} is an almost rectangle with step size Δz and that \mathbf{z} and \mathbf{k}_i have equal areas, and the double cyclicity of t implies $t(\mathbf{z}) = t(\mathbf{k}_i)$. For the second item we additionally split the l row in two roughly equal rows. This will guarantee the two properties of \mathbf{l}_1 and \mathbf{l}_2 . ◀

Equipped with these lemmata we are ready to prove Lemma 25. The proof is by induction on the step size. Step sizes zero and one are dealt with in Lemma 21, so we assume that \mathbf{z} is a near-threshold almost rectangle of step size $2 \leq \Delta z < 5b$.

We will consider Case (4) in detail and discuss the adjustments for the other cases afterwards. Assume first that $\lambda(\mathbf{z})$ is not *too close to* θ , say, $|\lambda(\mathbf{z}) - \theta| \geq 1/s^{5b+4}$. We apply the second item in Lemma 27 and get a plausible s -tuple $\mathbf{k}_1, \dots, \mathbf{k}_{s-2}, \mathbf{l}_1, \mathbf{l}_2$ such that $\mathbf{z}, \mathbf{k}_1, \dots, \mathbf{k}_{s-2}$ all have the same t -images and areas, and \mathbf{l}_1 and \mathbf{l}_2 are almost rectangles with step sizes strictly smaller than Δz , whose areas differ by at most $1/p$.

11:12 Finitely Tractable Promise Constraint Satisfaction Problems

The average area of almost rectangles $\mathbf{k}_1, \dots, \mathbf{k}_{s-2}, \mathbf{l}_1, \mathbf{l}_2$ is $r/s = \theta$, the first $s - 2$ of them have the same area as \mathbf{z} , bounded away from θ by a constant (namely $1/s^{5b+4}$), and the last two have almost the same area (the difference is at most $1/p$). By choosing a large enough p we get $\text{sgn}(\lambda(\mathbf{l}_1) - \theta) = \text{sgn}(\lambda(\mathbf{l}_2) - \theta) \neq \text{sgn}(\lambda(\mathbf{z}) - \theta)$ and $|\lambda(\mathbf{l}_i) - \theta| \leq s \cdot |\lambda(\mathbf{z}) - \theta|$; in particular, both \mathbf{l}_i are near-threshold since $s \cdot |\lambda(\mathbf{z}) - \theta| \leq 1/s^{\Delta z+3-1} \leq 1/s^{\Delta l_i+3}$. By the induction hypothesis, both \mathbf{l}_i are tame. By Lemma 26, the values $t(\mathbf{k}_1), \dots, t(\mathbf{k}_{s-2}), t(\mathbf{l}_1)$, and $t(\mathbf{l}_2)$ are not all equal. But $t(\mathbf{z}) = t(\mathbf{k}_1) = \dots = t(\mathbf{k}_{s-2}), t(\mathbf{l}_1) = t(\mathbf{l}_2)$, and $\text{sgn}(\lambda(\mathbf{z}) - \theta) \neq \text{sgn}(\lambda(\mathbf{l}_1) - \theta)$ so it follows that \mathbf{z} is tame, as required.

It remains to deal with the case that $\lambda(\mathbf{z})$ is too close to θ . In this case we will find an almost rectangle \mathbf{l} with the same step size as \mathbf{z} such that $t(\mathbf{l}) = 1 - t(\mathbf{z})$ and $\lambda(\mathbf{l}) - \theta = -s'(\lambda(\mathbf{z}) - \theta)$, where s' is such that $2 \leq s' \leq s$. If $\lambda(\mathbf{l})$ is already not too close to the threshold θ , then we observe that \mathbf{l} is near-threshold (indeed, $|\lambda(\mathbf{l}) - \theta| \leq s|\lambda(\mathbf{z}) - \theta| \leq s/s^{5b+4} \leq 1/s^{\Delta z+3}$) and apply to \mathbf{l} the first part of the proof, thus obtaining that \mathbf{l} is tame and, consequently, \mathbf{z} is tame as well. If $\lambda(\mathbf{l})$ is still too close to θ , then we simply repeat the process until we get a rectangle that is not too close.

To find such an almost rectangle \mathbf{l} we apply the first item of Lemma 27 and get a plausible s -tuple $\mathbf{k}_1, \dots, \mathbf{k}_{s-1}, \mathbf{l}$ such that $t(\mathbf{z}) = t(\mathbf{k}_1) = \dots = t(\mathbf{k}_{s-1})$ and \mathbf{l} is an almost rectangle of the same step size as \mathbf{z} . Since the area of each \mathbf{k}_i is equal to $\lambda(\mathbf{z})$ and the average area in the plausible s -tuple is θ , we get that $\lambda(\mathbf{l}) - \theta = -(s - 1)(\lambda(\mathbf{z}) - \theta)$. By Lemma 26, $t(\mathbf{l})$ and $t(\mathbf{z})$ are not equal. This concludes the construction of \mathbf{l} and the proof of Lemma 25 for Case (4).

The remaining cases (1), (2), and (3) require a modification that is similar to the modification for Case (3) in the proof of Lemma 23. Consider the situation that $\lambda(\mathbf{z})$ is not too close to θ . In Cases (2) and (3) Lemma 27 is applied not only to $\mathbf{k}_1, \dots, \mathbf{k}_{2r-2}, \mathbf{l}_1, \mathbf{l}_2$ but also to the tuple formed by “complementary” almost rectangles, which have different t -images by the second part of Lemma 26. In Case (1) we additionally complete the two $2r$ tuples to s -tuples by adding $s - 2r$ zeros. The other situation, that $\lambda(\mathbf{z})$ is too close, is adjusted in an analogous fashion.

6 Conclusion

We have characterized finite tractability among the basic tractable cases in the Brakensiek–Guruswami classification [8] of symmetric Boolean PCSPs allowing negations. A natural direction for future research is an extension to all the tractable cases (not just the basic ones), or even to all symmetric Boolean PCSPs [14], not only those allowing negations. An obstacle, where our efforts have failed so far, is already in relaxations of the basic templates (P, Q) with disequalities. For example, which (P, Q) , (\neq, \neq) , with P a subset of $\leq r$ -in- s and Q a superset of $\leq (2r - 1)$ -in- s , give rise to finitely tractable PCSPs?

Another natural direction is to better understand the “level of tractability.” For the finitely tractable templates (\mathbb{A}, \mathbb{B}) considered in this paper, it is always possible to find a tractable CSP (\mathbb{C}) with $\mathbb{A} \rightarrow \mathbb{C} \rightarrow \mathbb{B}$ and such that \mathbb{C} is two-element. Is it so for all symmetric Boolean templates? For general Boolean templates, the answer is “No”: [12] presents an example that requires a three-element \mathbb{C} . However, it is unclear whether there is an upper bound on the size of \mathbb{C} for finitely tractable (Boolean) PCSPs, and if there is, how it could be computed. There are also natural concepts beyond finite tractability, still stronger than standard tractability. We refer to [2] for some questions in this direction.

A

 Doubly cyclic functions are cyclic

In this appendix we prove Lemma 22, which we restate here for convenience.

► **Lemma 22.** *Let $t : A^{p^2} \rightarrow B$ be a doubly cyclic function. Then the function t^σ defined by*

$$t^\sigma \left(\begin{array}{cccc} x_{11} & x_{12} & \cdots & x_{1p} \\ x_{21} & x_{22} & \cdots & x_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ x_{p1} & x_{p2} & \cdots & x_{pp} \end{array} \right) = t \left(\begin{array}{cccc} x_{11} & x_{21} & \cdots & x_{p1} \\ x_{12} & x_{22} & \cdots & x_{p2} \\ \vdots & \vdots & \ddots & \vdots \\ x_{1p} & x_{2p} & \cdots & x_{pp} \end{array} \right)$$

is a cyclic function.

Proof. By cyclically shifting the arguments we get the same result:

$$\begin{aligned} & t^\sigma(x_{21}, x_{31}, \dots, x_{p1}, x_{12}, x_{22}, x_{32}, \dots, x_{p2}, x_{13}, \dots, x_{2p}, x_{3p}, \dots, x_{pp}, x_{11}) \\ &= t^\sigma \left(\begin{array}{cccc} x_{21} & \cdots & x_{2,p-1} & x_{2p} \\ \vdots & \ddots & \vdots & \vdots \\ x_{p1} & \cdots & x_{p,p-1} & x_{pp} \\ x_{12} & \cdots & x_{1p} & x_{11} \end{array} \right) = t \left(\begin{array}{cccc} x_{21} & \cdots & x_{p1} & x_{12} \\ \vdots & \ddots & \vdots & \vdots \\ x_{2,p-1} & \cdots & x_{p,p-1} & x_{1p} \\ x_{2p} & \cdots & x_{pp} & x_{11} \end{array} \right) \\ &= t \left(\begin{array}{cccc} x_{21} & \cdots & x_{p1} & x_{11} \\ \vdots & \ddots & \vdots & \vdots \\ x_{2,p-1} & \cdots & x_{p,p-1} & x_{1,p-1} \\ x_{2p} & \cdots & x_{pp} & x_{1p} \end{array} \right) = t \left(\begin{array}{cccc} x_{11} & x_{21} & \cdots & x_{p1} \\ x_{12} & x_{22} & \cdots & x_{p2} \\ \vdots & \vdots & \ddots & \vdots \\ x_{1p} & x_{2p} & \cdots & x_{pp} \end{array} \right) \\ &= t^\sigma \left(\begin{array}{cccc} x_{11} & x_{12} & \cdots & x_{1p} \\ x_{21} & x_{22} & \cdots & x_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ x_{p1} & x_{p2} & \cdots & x_{pp} \end{array} \right) \\ &= t^\sigma(x_{11}, x_{21}, \dots, x_{p1}, x_{12}, x_{22}, \dots, x_{p2}, \dots, x_{1p}, x_{2p}, \dots, x_{pp}). \quad \blacktriangleleft \end{aligned}$$

B

 Step size one, Case (4)

In this section we finish the proof of Lemma 23 for Case (4). We state the lemma for convenience.

► **Lemma 23.** *Denote $a = \lfloor \theta n \rfloor$. For every $0 \leq k \leq 2a$, we have*

$$t^\sigma \langle k \rangle_n = \begin{cases} t^\sigma \langle 0 \rangle_n & \text{if } 0 \leq k \leq a \\ 1 - t^\sigma \langle 0 \rangle_n & \text{if } 1 + a \leq k \leq 2a \end{cases}$$

Recall that we want to prove, starting from the left, the chain of disequalities

$$t^\sigma \langle a \rangle \neq t^\sigma \langle a+1 \rangle \neq t^\sigma \langle a-1 \rangle \neq t^\sigma \langle a+2 \rangle \neq t^\sigma \langle a-2 \rangle \neq \dots \neq t^\sigma \langle 2a \rangle \neq t^\sigma \langle 0 \rangle$$

and that we have already verified the first one.

For the second disequality $t^\sigma \langle a+1 \rangle \neq t^\sigma \langle a-1 \rangle$, as well as for the further disequalities we need to distinguish two cases: Case (4a) r and s have the same parity and Case (4b) r is even and s is odd. In Case (4a) we directly use the sequence

$$(s-r)/2 \times \langle a-1 \rangle, (s+r)/2 \times \langle a+1 \rangle$$

and derive $t^\sigma \langle a+1 \rangle \neq t^\sigma \langle a-1 \rangle$ using Lemma 24 as before. In Case (4b) we first use

$$(s-1) \times \langle a \rangle, \langle a+r \rangle$$

to deduce $t^\sigma \langle a+r \rangle \neq t^\sigma \langle a \rangle$ (so $t^\sigma \langle a+1 \rangle = t^\sigma \langle a+r \rangle$) and then

$$(s-1)/2 \times \langle a-1 \rangle, (s-1)/2 \times \langle a+1 \rangle, \langle a+r \rangle$$

to deduce $t^\sigma \langle a-1 \rangle \neq t^\sigma \langle a+1 \rangle$.

To prove $t^\sigma \langle a-i+1 \rangle \neq t^\sigma \langle a+i \rangle$ for $i \in \{2, 3, \dots, a\}$, we observe that, by the already established disequalities, we have $t^\sigma \langle a-i+1 \rangle = \dots = t^\sigma \langle a \rangle$, and then use

- $(s+r)/4 \times \langle a+i \rangle, (s-r)/2 \times \langle a-1 \rangle, (s+r)/4 \times \langle a-i+2 \rangle$ in Case (4a) and $(s+r)/2$ is even;
- $(s+r+2)/4 \times \langle a+i \rangle, (s-r-2)/2 \times \langle a-1 \rangle, 2 \times \langle a-i+1 \rangle, (s+r-6)/4 \times \langle a-i+2 \rangle$ in Case (4a) and $(s+r)/2$ is odd;
- $r/2 \times \langle a+i \rangle, (s-r) \times \langle a \rangle, r/2 \times \langle a-i+2 \rangle$ in Case (4b).

Finally, for proving $t^\sigma \langle a+i \rangle \neq t^\sigma \langle a-i \rangle$ we use

- $(s-r)/2 \times \langle a-i \rangle, (s-r)/2 \times \langle a+i \rangle, r \times \langle a+1 \rangle$ in Case (4a) and
- $(s-1)/2 \times \langle a-i \rangle, (s-1)/2 \times \langle a+i \rangle, 1 \times \langle a+r \rangle$ in Case (4b).

This completes the proof for Case (4).

C Proof of Lemma 26

► **Lemma 26.** *If a tuple $\mathbf{k}_1, \dots, \mathbf{k}_s$ is plausible, then $(t(\mathbf{k}_1), \dots, t(\mathbf{k}_s)) \in Q$.*

Moreover, in Cases (1), (2), and (3), we have $t(p-k^1, \dots, p-k^p) = 1 - t(k^1, \dots, k^p)$ for any evaluation $\langle k^1, \dots, k^p \rangle$.

Proof. Let $\mathbf{k}_1, \dots, \mathbf{k}_s$ be a plausible tuple. Fix, for a while, an arbitrary $i \in [p]$. Form a $s \times rp$ matrix M_i whose first row is $\langle k_1^i \rangle_{rp}$ and j -th row is the $(\sum_{l=1}^{j-1} k_l^i)$ -th cyclic shift of $\langle k_j^i \rangle_{rp}$ for $j \in \{2, \dots, s\}$. Split this matrix into r -many $s \times p$ blocks $M_i^1, M_i^2, \dots, M_i^r$. Their sum $X_i = \sum_{j=1}^r M_i^j$ is an $s \times p$ matrix whose each column contains exactly r ones. Moreover, for all $j \in [s]$, the j -th row of the matrix X_i is a cyclic shift of $\langle k_j^i \rangle_p$. Put the matrices X_1, \dots, X_p aside to form an $s \times n$ matrix Y . Its rows have the same t -images as $\mathbf{k}_1, \dots, \mathbf{k}_s$, respectively, because t is doubly cyclic. Each column belongs to the relation P , therefore, as t is a polymorphism, we get that t applied to the rows gives a tuple in Q . This tuple is equal to $(t(\mathbf{k}_1), \dots, t(\mathbf{k}_s))$.

The second part can be proved in a similar way as the second part of Lemma 24 using the disequality relation pair. ◀

D Proof of Lemma 27

► **Lemma 27.** *Let \mathbf{z} be an almost rectangle of step size $\Delta z \geq 2$ with $|\lambda(\mathbf{z}) - \theta| \leq 1/s^3$ and let p be sufficiently large. Then*

- *there exists a plausible r/θ -tuple $\mathbf{k}_1, \mathbf{k}_2, \dots, \mathbf{k}_{r/\theta-1}, \mathbf{l}$ of almost rectangles such that $t(\mathbf{z}) = t(\mathbf{k}_1) = t(\mathbf{k}_2) = \dots = t(\mathbf{k}_{r/\theta-1}), \lambda(\mathbf{z}) = \lambda(\mathbf{k}_1) = \dots = \lambda(\mathbf{k}_{r/\theta-1}),$ and \mathbf{l} has the same step size Δz as \mathbf{z} ;*
- *there exists a plausible r/θ -tuple $\mathbf{k}_1, \mathbf{k}_2, \dots, \mathbf{k}_{r/\theta-2}, \mathbf{l}_1, \mathbf{l}_2$ of almost rectangles such that $t(\mathbf{z}) = t(\mathbf{k}_1) = t(\mathbf{k}_2) = \dots = t(\mathbf{k}_{r/\theta-2}), \lambda(\mathbf{z}) = \lambda(\mathbf{k}_1) = \dots = \lambda(\mathbf{k}_{r/\theta-2}),$ both \mathbf{l}_1 and \mathbf{l}_2 have step size strictly smaller than $\Delta z,$ and $|\lambda(\mathbf{l}_1) - \lambda(\mathbf{l}_2)| \leq 1/p.$*

Proof. Without loss of generality we can assume that $\mathbf{z} = \langle c \times z^1, d \times z^2 \rangle$ for some c, d and $z^1 > z^2$. Let $m = r/\theta - 1$ for the first item and $m = r/\theta - 2$ for the second one. We define an integer $m \times p$ matrix X so that the first row is $(c \times z^1, d \times z^2)$ and the i -th row is the c -th cyclic shift of the $(i - 1)$ -st row for each $i \in \{2, \dots, m\}$. Let Y be the $(m + 1) \times p$ matrix obtained from X by adding a row (l^1, \dots, l^p) so that each column sums up to rp . It is easily seen by induction on $i \leq m$ that the sum of the first i rows is a cyclic shift of a tuple of the form $(e, \dots, e, e', \dots, e')$, where $|e - e'| = \Delta z$ and the “step down” is at position $ci \pmod p$ (when columns are indexed from 0). It follows that (l^1, \dots, l^p) is also a cyclic shift of a tuple of the form $(e, \dots, e, e', \dots, e')$ where e and e' differ by Δz .

Next we observe that each $l^i > 0$ if p is sufficiently large. Indeed, note that since $|z^1 - z^2|/p$ can be made arbitrarily small (recall $|z^1 - z^2| < 5b$), we have $p(\lambda(\mathbf{z}) - \epsilon) < z^1, z^2 < p(\lambda(\mathbf{z}) + \epsilon)$, where $\epsilon > 0$ can be made arbitrarily small. We then have $l^i > rp - mp(\lambda(\mathbf{z}) + \epsilon) \geq rp - (r/\theta - 1)p(\theta + 1/s^3 + \epsilon) = p(\theta - (r/\theta - 1)(1/s^3 + \epsilon)) > p(\theta - r/\theta(1/s^3 + \epsilon))$, which is, for a sufficiently small ϵ , greater than 0 since $r/\theta s^3 \leq 1/s^2 < \theta$. Similarly, each $l^i < 2\theta \leq p$ if $m = r/\theta - 1$ and $l^i < 3\theta$ if $m = r/\theta - 2$.

Now we can finish the proof of the first item. We set $\mathbf{k}_1, \dots, \mathbf{k}_m, \mathbf{l}$ to be the n -tuples determined by the rows of Y via $\langle \rangle$, e.g., $\mathbf{l} = \langle l^1, \dots, l^p \rangle$. The inequalities $0 \leq l^i \leq p$ guarantee that \mathbf{l} is correctly defined and we see, using also the double cyclicity of t (for $t(\mathbf{z}) = t(\mathbf{k}_1) = \dots$), that these n -tuples have all the required properties.

To finish the proof of the second item, we define the \mathbf{k}_i as above and set $\mathbf{l}_1 = \langle \lfloor l^1/2 \rfloor, \dots, \lfloor l^p/2 \rfloor \rangle, \mathbf{l}_2 = \langle \lceil l^1/2 \rceil, \dots, \lceil l^p/2 \rceil \rangle$. Since $0 \leq l^i \leq 3\theta/2 < p$, these tuples are correctly defined almost rectangles. Their areas clearly differ by at most $1/p$. As $\Delta z \geq 2$, their step sizes are strictly smaller than Δz , and we are done in this case as well. ◀

A Generic Strategy Improvement Method for Simple Stochastic Games

Abstract

We present a generic strategy improvement algorithm (GSIA) to find an optimal strategy of simple stochastic games (SSG). We prove the correctness of GSIA, and derive a general complexity bound, which implies and improves on the results of several articles. First, we remove the assumption that the SSG is stopping, which is usually obtained by a polynomial blowup of the game. Second, we prove a tight bound on the denominator of the values associated to a strategy, and use it to prove that all strategy improvement algorithms are in fact fixed parameter tractable in the number r of random vertices. All known strategy improvement algorithms can be seen as instances of GSIA, which allows to analyze the complexity of converge from below by Condon [14] and to propose a class of algorithms generalising Gimbert and Horn’s algorithm [16, 17]. These algorithms terminate in at most $r!$ iterations, and for binary SSGs, they do less iterations than the current best deterministic algorithm given by Ibsen-Jensen and Miltersen [18].

1 Introduction

A *simple stochastic game*, or SSG, is a two-player turn-based zero-sum game with perfect information introduced by Condon [13]. It is a simpler version of *stochastic games*, previously defined by Shapley [23]. An SSG is played by two players MAX and MIN moving a pebble on a graph. Vertices are divided into MIN vertices, MAX vertices, random vertices and a target vertex for MAX. When the pebble reaches a MIN or MAX vertex, corresponding players move the pebble to a neighbouring vertex of their choice. If it reaches a random vertex, the next vertex is chosen at random following some probability law. Finally, when the pebble reaches the target vertex, MIN pays 1 to MAX. The goal of MIN is to minimise the probability to reach the target vertex while MAX must maximise this probability.

We study the algorithmic problem of *solving* an SSG, i.e. finding a pair of optimal strategies in an SSG, or equivalently the optimal value vector of the optimal probabilities for MAX to reach the sink from each vertex. There are always optimal strategies for both players that are positional [13], i.e. stationary and deterministic, but the number of positional strategies is exponential in the size of the game. Consequently, finding a pair of optimal strategies is a problem not known to be in FP, but it is in PPAD [20], a class included in FNP.

Simple Stochastic Games can be used to simulate many classical games such as parity games, mean or discounted payoff games [2, 9]. Moreover, stochastic versions of these games are equivalent to SSGs [2], which underlines that SSGs are an important model to study. SSGs have applications in different domains such as model checking of modal μ -calculus [24], or modelling autonomous urban driving [11].

There are roughly three known methods to solve SSGs: strategy improvement, value iteration and quadratic programming. A strategy improvement algorithm (SIA) starts with a strategy for one player and improves it until it is optimal, whereas value iteration algorithms (VIA) update a value vector by elementary operations, which converges to the optimal value vector of the game. Implementations of those algorithms have been written and compared in [21].

Denote by n be the number of MAX vertices and r be the number of random vertices in an SSG. For SSGs with MAX vertices of outdegree 2, the best known deterministic algorithm is an SIA which makes at worst $O(2^n/n)$ iterations (see [25]), and the best known randomised algorithm is a SIA described by Ludwig in [22], which runs in $2^{O(\sqrt{n})}$.

Gimbert and Horn give an SIA in [16], running in $O^*(r!)$ iterations, namely a superpolynomial dependency in r only (O^* omits polynomial factors in r and n). For SSGs where random vertices have a probability distribution $(1/2, 1/2)$ (coin toss), Ibsen-Jensen and Miltersen present a VIA of complexity in $O^*(2^r)$ [18]. It turns out that all SIA runs in $O^*(2^r)$ on SSGs with probability distribution $(1/2, 1/2)$, as we prove in this article. The same complexity of $O^*(2^r)$ is obtained for general SSGs with a more involved randomised algorithm in [5].

Most of the aforementioned algorithms rely on the game being stopping, meaning that it structurally ends in a sink with probability 1. This condition is not restrictive since any SSG can be transformed into a stopping SSG while keeping the same optimal strategies. However, this transformation incurs a quadratic blow-up of the game and cannot be used in real life application. In this paper we give bounds in $O(2^r \text{Poly}(n))$ computational time for some kinds of algorithm. Using the stopping transformation would have induced a $O(2^{nr^2} \text{Poly}(n))$ complexity. The stopping restriction has been lifted for quadratic programming in [21] and before that for SIA and VIA in [10, 8].

Contributions

We introduce GSIA, a new meta-algorithm to solve SSGs in Sec. 3. This algorithm proves simultaneously the correctness of multiple algorithms ([14, 16, 15, 25, 18, 5]). In Sec. 4, we give a general complexity bound that matches or improves on previous bounds obtained by ad-hoc methods. We show that all these algorithms are fixed-parameter tractable in the number of random vertices. Moreover, we do not rely on the fact that the game is stopping, which was commonly used in the aforementioned papers. The proof of correctness relies on a notion of concatenation for strategies and an analysis of absorbing sets in the game, while the complexity bound is derived from a new and tight characterisation of the values of an SSG. Finally, in Sec. 5, we show how GSIA can be used to derive new algorithms, generalising classical ones. In particular, we exhibit a class of algorithms which generalise Gimbert and Horn's algorithm and use less iterations than Ibsen-Jensen and Miltersen's algorithm.

We emphasise that our goal here is not to define a new algorithm that would have a better –but still exponential– complexity bound than the state of the art (a sub-exponential algorithm for SSGs, like the ones found for parity games [6, 12], would already be a significant improvement), but rather to wrap-up a lot of previous research by showing that all known

SIA for SSGs, despite having emerged in different contexts and having ad-hoc proofs of convergence, are in fact instances of a general pattern that can be further expanded, and actually share the best known complexity bounds.

2 Simple Properties of Simple Stochastic Games

Some proofs are missing from this extended abstract for space reason, but they can be found in the appendices or in a long version [3].

2.1 Simple Stochastic Games

We give a generalised definition of *Simple Stochastic Game*, a two-player zero-sum game with turn-based moves and perfect information introduced by Anne Condon [14].

► **Definition 1.** *A Simple Stochastic Game (SSG) is a directed graph G , together with:*

1. *A partition of the vertex set V in four parts V_{MAX} , V_{MIN} , V_R and V_S (all possibly empty, except V_S), satisfying the following conditions:

 - a. *every vertex of V_{MAX} , V_{MIN} or V_R has at least one outgoing arc;*
 - b. *every vertex of V_S has exactly one outgoing arc which is a loop on itself.**
2. *For every $x \in V_R$, a probability distribution $p_x(\cdot)$ with rational values, on the outneighbourhood of x .*
3. *For every $x \in V_S$, a value $\text{Val}(x)$ which is a rational number in the closed interval $[0, 1]$.*

In the article, we denote $|V_{\text{MAX}}|$ by n and $|V_R|$ by r . Vertices from V_{MAX} , V_{MIN} , V_R and V_S are respectively called MAX vertices, MIN vertices, random vertices and sinks. For $x \in V$, we denote by $N^+(x)$ the set of outneighbours of x . We assume that for every $x \in V_R$ and $y \in V$, $y \in N^+(x)$ if and only if $p_x(y) > 0$.

The game is played as follows. The two players are named MAX and MIN. A token is positioned on a starting vertex x . If x is in V_{MAX} (resp. V_{MIN}) the MAX player (resp. the MIN player) chooses one of the outneighbours of x to move the token to. If x is in V_R , the token is randomly moved to one of the outneighbours of x according to the probability distribution $p_x(\cdot)$, independently of everything else. This process continues until the token reaches a sink s and then, player MIN has to pay $\text{Val}(s)$ to player MAX and the game stops. The problem we study is to *find the best possible strategies* for MIN and MAX, and the expected value that MIN has to pay to MAX while following those strategies.

We consider a slightly restricted class of SSGs where the probability distribution on each random vertex has a given precision and the value of the sinks are 0 and 1.

► **Definition 2.** *For q a positive integer, we say that an SSG is a q -SSG if there are only two sinks of value 0 and 1, and for all $x \in V_R$, there is an integer $q_x \leq q$ such that the probability distribution $p_x(\cdot)$ can be written as $p_x(x') = \frac{\ell_{x,x'}}{q_x}$ for all x' where $\ell_{x,x'}$ is a natural number.*

As an example, let x be a random vertex of a 2-SSG, and let $u \in N^+(x)$, then $p_x(u)$ can be equal to 0, $1/2$ or 1. The case $p_x(u) = 0$ is forbidden by definition, and if $p_x(u) = 1$, then x is of degree one and can be removed (by redirecting arcs entering x directly to u), without changing anything about the outcome of the game. Hence, we suppose without loss of generality that each random vertex of a 2-SSG has degree 2 and has probability distribution $(1/2, 1/2)$. This definition matches the one of a *binary SSG*, given by Condon and used in most articles on SSGs, except that we allow here MAX and MIN vertices to have an outdegree larger than 2.

2.2 Play, History and Strategies

► **Definition 3.** A **play** in G is an infinite sequence of vertices $X = (x_0, x_1, x_2, \dots)$ such that for all $t \geq 0$, (x_t, x_{t+1}) is an arc of G .

If for a play $X = (x_t)$ there is some $t \geq 0$ with $x_t = s \in V_S$, then all subsequent vertices in the play are also equal to s . In this case, we say that the play **reaches** sink vertex s and we define the **value of the play** $\text{Val}(X)$ as $\text{Val}(s)$. If the play reaches no sink, then we set $\text{Val}(X) = 0$.

A **history** of G is a finite directed path $h = (x_0, x_1, \dots, x_k)$. If the last vertex x_k is a MAX vertex (resp. MIN vertex), we say that h is a MAX history (resp. MIN history).

► **Definition 4.** A **general MAX strategy** (resp. **general MIN strategy**) is a map σ assigning to every MAX history (resp. MIN history) $h = (x_0, x_1, \dots, x_k)$ a vertex $\sigma(h)$ which is an outneighbour of x_k . The set of these strategies is denoted by Σ_{gen}^{MAX} (resp. Σ_{gen}^{MIN}).

For $\sigma \in \Sigma_{gen}^{MAX}$ and $\tau \in \Sigma_{gen}^{MIN}$, given a starting vertex x_0 , we recursively define a random play $X = (X_0, X_1, \dots)$ of G in the following way. At $t = 0$ let $X_0 = x_0$, and for $t \geq 0$:

- if $X_t \in V_{MAX}$, define $X_{t+1} = \sigma(X_0, X_1, \dots, X_t)$;
- if $X_t \in V_{MIN}$, define $X_{t+1} = \tau(X_0, X_1, \dots, X_t)$;
- if $X_t \in V_R$, then X_{t+1} is an outneighbour of X_t chosen following the probability distribution $p_{X_t}(\cdot)$, independently of everything else;
- if $X_t \in V_S$, define $X_{t+1} = X_t$.

This defines a distribution on plays which we denote by $\mathbb{P}_{\sigma, \tau}^{x_0}(\cdot)$, or simply $\mathbb{P}(\cdot)$ if strategies and starting vertex are clear from context. The corresponding expected value and conditional expected values are denoted by $\mathbb{E}_{\sigma, \tau}^{x_0}(\cdot|\cdot)$, or simply $\mathbb{E}(\cdot|\cdot)$.

We now define **positional strategies** which only depend on the last vertex in the history:

► **Definition 5.** A **general MAX strategy** σ (resp. **MIN strategy**) is said to be **positional** if for any MAX vertex x (resp. MIN vertex) and any history $h = (x_0, \dots, x)$, we have $\sigma(h) = \sigma((x))$ where (x) is the history containing only x as a start vertex. The set of positional MAX strategies (resp. MIN strategies) is denoted Σ^{MAX} (resp. Σ^{MIN}).

2.3 Values in an SSG

► **Definition 6.** Let G be an SSG and let (σ, τ) be a pair of MAX and MIN strategies, the **value vector** $v_{\sigma, \tau}^G$ is the real vector of dimension $|V|$ defined by, for any $x_0 \in V$,

$$v_{\sigma, \tau}^G(x_0) = \mathbb{E}_{\sigma, \tau}^{x_0}(\text{Val}(X)).$$

This value represents the expected gains for player MAX if both players plays according to (σ, τ) and the game starts in vertex x_0 .

As before, the superscript G can be omitted when the context is clear.

To compare value vectors, we use the pointwise order: we say that $v \geq v'$ if for all vertices $x \in V$ we have $v(x) \geq v'(x)$. Moreover, we say that $v > v'$ if $v \geq v'$ and there is some x such that $v(x) > v'(x)$. Given a MAX strategy σ , a **best response** to σ is a MIN strategy τ such that $v_{\sigma, \tau} \leq v_{\sigma, \tau'}$ for all MIN strategies τ' .

► **Proposition 7** ([14]). A positional strategy admits a positional best response, which can be found in polynomial time using linear programming.

The set of positional best responses to σ is denoted by $BR(\sigma)$. Similarly, for a MIN strategy τ , we define the notion of best response to τ and the corresponding set is denoted by $BR(\tau)$. Except explicitly stated otherwise (in Sec. 3.3), all considered strategies are positional.

We denote by $\tau(\sigma)$ a positional best response to σ . For a MAX strategy σ and $\tau \in BR(\sigma)$, we write v_σ for $v_{\sigma,\tau}$. For a MIN strategy τ and $\sigma \in BR(\tau)$, we write v_τ for $v_{\sigma,\tau}$. The vector v_σ is called the value vector of strategy σ , and is used to compare strategies by writing $\sigma' \underset{G}{>} \sigma$ if and only if $v_{\sigma'}^G > v_\sigma^G$.

It is well known (see [14, 25]) that there is a pair of deterministic positional strategies (σ^*, τ^*) called optimal strategies, that satisfies for all x , $v^* = v_{\sigma^*, \tau^*} = v_{\sigma^*} = v_{\tau^*}$ since σ^* and τ^* are best responses to each other.

2.4 Optimality Conditions

The next two lemmas give characterisations of (optimal) value vectors under a pair of strategies. They are fundamental to all algorithms finding optimal strategies. Proofs of similar results can be found in [13]; we add here a fifth condition to make the characterisation hold when the game is not stopping.

For any SSG, the vertices with value 0 under optimal strategies can be found in linear time by a simple graph traversal computing its complementary, the set of MAX vertices which can access a sink of positive value, regardless of the choice of the MIN player. Let K^G be the set of vertices with value 0 under optimal strategies. For a MAX strategy σ of G and a MIN strategy τ , we call $K_{\sigma,\tau}^G$ the set of vertices with value zero under the pair of strategies σ, τ , and K_σ^G the set of vertices with value zero under σ, τ when τ is a best response to σ .

► **Lemma 8.** *Given positional strategies (σ, τ) and a real $|V|$ -dimensional vector v , one has equality between v and $v_{\sigma,\tau}$ if and only if the following conditions are met:*

- (i) For $s \in V_S$, $v(s) = \text{Val}(s)$
- (ii) For $r \in V_R$, $v(r) = \sum_{y \in N^+(r)} p_r(y)v(y)$
- (iii) For $x \in V_{\text{MIN}}$, $v(x) = v(\tau(x))$
- (iv) For $x \in V_{\text{MAX}}$, $v(x) = v(\sigma(x))$
- (v) For any $x \in V$, $v(x) = 0$, if and only if $x \in K_{\sigma,\tau}^G$

Moreover, $\tau \in BR(\sigma)$ if and only if for any x in V_{MIN} , $v(x) = \min_{y \in N^+(x)} v(y) = v(\tau(x))$ and the last condition is modified into $v(x) = 0$ if and only if $x \in K_\sigma^G$.

► **Lemma 9 (Optimality conditions).** *Given positional strategies (σ, τ) and denoting $v = v_{\sigma,\tau}$, (σ, τ) are optimal strategies if and only if:*

- (i) For $s \in V_S$, $v(s) = \text{Val}(s)$
- (ii) For $r \in V_R$, $v(r) = \sum_{y \in N^+(r)} p_r(y)v(y)$
- (iii) For $x \in V_{\text{MIN}}$, $v(x) = \min_{y \in N^+(x)} v(y)$
- (iv) For $x \in V_{\text{MAX}}$, $v(x) = \max_{y \in N^+(x)} v(y)$
- (v) For any $x \in V$, $v(x) = 0$, if and only if $x \in K^G$

The conditions of Lemma 9 imply that (σ, τ) is a certificate of optimality that can be checked in polynomial time: compute $v_{\sigma,\tau}$ by solving the linear system of Lemma 8, compute K^G in linear time, then check in linear time if conditions are met.

■ **Figure 1** Transformation of the graph G in $G[\{(x_2, x_3)\}, f]$ where $f((x_2, x_3)) = 0.3$.

3 Generic Strategy Improvement Algorithm

3.1 Game Transformation

We present a simple transformation of an SSG, where some arcs of the game are rerouted to new sinks with appropriate values.

► **Definition 10.** Let G be an SSG, A be a subset of the arcs of G and f be a function from A to the set of rational numbers. Let $G[A, f]$ be the SSG obtained from a copy of G with the following modifications: each arc $e = (x, y) \in A$ is removed and replaced in $G[A, f]$ by $e' = (x, s_e)$ where s_e is a new sink vertex with value $f(e)$. These new sinks of $G[A, f]$ are called A -sinks, and A is called the set of fixed arcs.

Note that in the previous definition, the end vertex y of an arc $(x, y) \in A$ is not removed from the game. Its incoming arcs which are in A are simply redirected to sinks, see Fig. 1.

The function f is usually given by the values of a strategy: we denote by $G[A, \sigma]$ the game $G[A, f]$, where f is defined on every arc $e = (x, y)$ of A by $f(e) = v_\sigma(y)$. Comparing G and $G[A, \sigma]$, the only differences are that arcs of A have their endpoints changed to new sinks. Therefore, a strategy defined in G can be interpreted as a strategy of $G[A, \sigma]$ and vice versa, and we identify strategies in G and $G[A, \sigma]$. However, when we compare the values of a strategy in both games (as in Lemma 12 below), it makes sense to compare only the values on vertices in G and not on A -sinks (and anyway values of A -sinks are fixed).

► **Lemma 11.** For an SSG G , a subset of arcs A , and a MAX strategy σ , $K_\sigma^G = K_\sigma^{G[A, \sigma]}$.

Proof. Fix a min strategy τ and define $R_{\sigma, \tau}^G(x)$ as the set of vertices that can be reached from x in G , following only arcs corresponding to σ and τ after MAX and MIN vertices, and any arc out of random vertices. We repeatedly use the easy fact that the three following assertions are equivalent:

- (i) $v_{\sigma, \tau}^G(x) = 0$;
- (ii) $v_{\sigma, \tau}^G(y) = 0$ for all $y \in R_{\sigma, \tau}^G(x)$;
- (iii) $\text{Val}^G(s) = 0$ for all $s \in V_S^G \cap R_{\sigma, \tau}^G(x)$.

The same equivalence is true in $G[A, \sigma]$, where we define $R_{\sigma, \tau}^{G[A, \sigma]}$ likewise. Denote by $R_A^G(x)$ vertices of $R_{\sigma, \tau}^G(x)$ that are endpoints of arcs in A , and let $S_A(x)$ be the corresponding A -sinks in $G[A, \sigma]$.

Suppose that $v_{\sigma, \tau}^G(x) = 0$ and consider a sink s in $V_S^{G[A, \sigma]} \cap R^{G[A, \sigma]}(x)$: either it belongs to V_S^G hence also to $R^G(x)$ and satisfies $\text{Val}^G(s) = 0$ by (iii), or it belongs to $S_A(x)$ and then by definition

$$\text{Val}^{G[A, \sigma]}(s) = v_\sigma^G(s) \leq v_{\sigma, \tau}^G(s) = 0.$$

Thus, by (iii) once again we have $v_{\sigma, \tau}^{G[A, \sigma]}(x) = 0$.

Conversely, suppose that $v_{\sigma,\tau}^{G[A,\sigma]}(x) = 0$ and let $s \in V_S^G \cap R_{\sigma,\tau}^G(x)$. Then, either $s \in R_{\sigma,\tau}^{G[A,\sigma]}$, hence by (iii)

$$\text{Val}^G(s) = \text{Val}^{G[A,\sigma]}(s) = 0,$$

or there is a $y \in R_A^G(x)$ such that $s \in R_{\sigma,\tau}^G(y)$. In this case we have $v_{\sigma,\tau}^G(y) = 0$ by (ii), hence $\text{Val}^G(s) = 0$ by (iii) applied to y , and we see that $v_{\sigma,\tau}^G(x) = 0$.

Since we have $v_{\sigma,\tau}^G(x) = 0$ if and only if $v_{\sigma,\tau}^{G[A,\sigma]}(x) = 0$, regardless of τ , the result follows. \blacktriangleleft

► **Lemma 12.** For an SSG G , a subset of arcs A , and a MAX strategy σ , $v_\sigma^G = v_\sigma^{G[A,\sigma]}$.

Proof. This is a direct consequence of Lemma 8 and Lemma 11, since the vector v_σ^G satisfies the best-response conditions in $G[A,\sigma]$ and vice versa. \blacktriangleleft

3.2 The Algorithm

An SSG is **stopping** if under every pair of strategies, a play eventually reaches a sink with probability 1. Most algorithms in the literature depend on the game being stopping. It is usually not seen as a limitation since it is possible to transform every SSG into a stopping SSG, but the transformation makes the game polynomially larger by adding $O(nr)$ random vertices, which is bad from a complexity point of view, especially for algorithm with parametrized complexity in the number of random vertices. We strengthen the classical order on strategies, to get rid of the stopping condition in the generic strategy improvement algorithm presented in this section.

► **Definition 13.** Let σ and σ' be two MAX strategies, then $\sigma' \succ_G \sigma$ if $\sigma' \succ_G \sigma$ and for every MAX vertex x , if $v_{\sigma'}^G(x) = v_\sigma^G(x)$, then $\sigma'(x) = \sigma(x)$.

Algorithm 1 is a classical strategy improvement algorithm with two twists: the improvement is for *the stricter order* \succ and it is guaranteed in *the transformed game* rather than in the original game. We call Algorithm 1 the Generic Strategy Improvement Algorithm, or GSIA.

■ **Algorithm 1** GSIA.

Data: G a stopping SSG
Result: $(\sigma, \tau(\sigma))$ a pair of optimal strategies

```

1 begin
2   select an initial MAX strategy  $\sigma$ 
3   while  $(\sigma, \tau(\sigma))$  are not optimal strategies of  $G$  do
4     choose a subset  $A$  of arcs of  $G$ 
5     find  $\sigma'$  such that  $\sigma' \succ_{G[A,\sigma]} \sigma$ .
6      $\sigma \leftarrow \sigma'$ 
7   return  $(\sigma, \tau(\sigma))$ 

```

Algorithm 1 is a generic algorithm (or meta-algorithm) because neither the selection of an initial strategy σ at line 2, nor the way of choosing A at line 4, nor the way of finding σ' at line 5, are specified. A choice of implementation for these three parts is an **instance** of GSIA, that is a concrete strategy improvement algorithm.

Note that if $\sigma' \succ_{G[A,\sigma]} \sigma$ is found, it is easy to find σ'' with $\sigma'' \succ_{G[A,\sigma]} \sigma$: define σ'' as equal to σ' , except for MAX vertices x such that $v_{\sigma'}^G(x) = v_{\sigma}^G(x)$ and $\sigma'(x) \neq \sigma(x)$ where $\sigma''(x)$ is defined as $\sigma(x)$.

When we prove some property of GSIA in this article, it means that the property is true for all instances of GSIA, that is regardless of the selection of the initial strategy, the set A and the method for selecting σ' .

In order to prove the correctness of GSIA, we need to prove two points:

1. If σ is not optimal in G , then σ is not optimal in $G[A, \sigma]$.
2. If $\sigma' \succ_{G[A,\sigma]} \sigma$ then $\sigma' \succ_G \sigma$.

The first point is proved in the following lemma, while the second one is harder to obtain and is the subject of the next two subsections.

► **Lemma 14.** *For an SSG G and a subset of arcs A , a MAX strategy σ is optimal in G if and only if it is optimal in $G[A, \sigma]$.*

Proof. Except on A -sinks, the value vectors of σ in G and $G[A, \sigma]$ are equal by Lemma 12. Furthermore, by Lemma 11, $K_{\sigma}^G = K_{\sigma}^{G[A,\sigma]}$; hence σ satisfies the optimality conditions of Lemma 9 in G if and only if it satisfies them in $G[A, \sigma]$. ◀

3.3 Concatenation of Strategies

As a tool for proving the correctness of Algorithm 1, we introduce the notion of concatenation of strategies which produces non-positional strategies even if both concatenated strategies are positional. The idea of using a sequence of concatenated strategies to interpolate between two strategies has been introduced in [17].

► **Definition 15.** *For two MAX strategies σ, σ' and a subset of arcs A , we call $\sigma'|_A\sigma$ the non-positional strategy that plays like σ' until an arc of A is crossed, and then plays like σ until the end of the game. We let $\sigma'|_A^0\sigma = \sigma$ and for all $i \geq 0$, $\sigma'|_A^{i+1}\sigma = \sigma'|_A(\sigma'|_A^i\sigma)$.*

When A is clear from the context, we omit it and write $\sigma'|^i\sigma$. Strategy $\sigma'|_A^i\sigma$ is the strategy that plays like σ' until i arcs from A have been crossed, and then plays like σ . Hence, we can relate the strategy $\sigma'|_A\sigma$ to a positional strategy in $G[A, \sigma]$ as shown in the next lemma.

► **Lemma 16.** *For two MAX strategies σ, σ' and a subset of arcs A , we have: $v_{\sigma'|_A\sigma}^G = v_{\sigma'}^{G[A,\sigma]}$*

Proof. In G , after crossing an arc from A , by definition of $\sigma'|_A\sigma$, MAX plays according to σ . The game being memoryless, from this point, the best response for MIN is to play like $\tau(\sigma) \in BR(\sigma)$. Thus, there is a best response to $\sigma'|_A\sigma$ of the form $\tau'|\tau(\sigma)$ with τ' a MIN strategy not necessarily positional. Let us consider a play following $(\sigma'|_A\sigma, \tau|\tau(\sigma))$ with τ any MIN strategy. If the play does not cross an arc of A , then there is no difference between this play and a play following (σ', τ) in $G[A, \sigma]$. If an arc of A is used, then by Lemma 12 there is no difference between stopping with the value of $G[A, \sigma]$ or continuing in G while following (σ, τ) . Thus we have: $v_{\sigma'|_A\sigma, \tau|\tau(\sigma)}^G = v_{\sigma', \tau}^{G[A,\sigma]}$.

Thus, if τ' is a best response to σ' in $G[A, \sigma]$, then $\tau'|\tau(\sigma)$ is a best response to $\sigma'|_A\sigma$ in G . This implies that $v_{\sigma'|_A\sigma}^G = v_{\sigma'}^{G[A,\sigma]}$. ◀

We now prove the fact that increasing the values of sinks can only increase the value of the game (a similar lemma is proved in [4]).

► **Lemma 17.** *Let G and G' be two identical SSGs except the values of their sinks $s \in V_S$, denoted respectively by $Val(s)$ and $Val'(s)$. If for every $s \in V_S$, $Val'(s) \geq Val(s)$, then for every MAX strategy σ we have $v_{\sigma}^{G'} \geq v_{\sigma}^G$.*

Proof. For $s \in V_S$, let $\mathbb{P}_{\sigma,\tau}^x(\rightarrow s)$ be the probability that the play ends in sink s while starting from vertex x , following strategies (σ, τ) . For any vertex x we have:

$$v_{\sigma,\tau}^{G'}(x) = \sum_{s \in V_S'} \mathbb{P}_{\sigma,\tau}^x(\rightarrow s) Val'(s) \geq \sum_{s \in V_S'} \mathbb{P}_{\sigma,\tau}^x(\rightarrow s) Val(s) = v_{\sigma,\tau}^G(x)$$

This is true for any MIN strategy τ , thus $v_{\sigma}^{G'} \geq v_{\sigma}^G$. ◀

The following proposition is the core idea of GSIA: a strategy which improves on σ in the transformed game also improves on σ in the original game. The proof relies on a precise analysis of the set of vertices which cannot reach a sink, to deal with the fact that the game is not stopping. We prove that, if $\sigma' \succ_{G[A,\sigma]} \sigma$ the limit of $v_{\sigma'|^i \sigma}^G$ is $v_{\sigma'}^G$ and the two previous lemmas imply $\sigma'|^i \sigma \geq \sigma'|^{i-1} \sigma > \sigma$, which yields the following proposition.

► **Proposition 18.** *Let G be an SSG, A a subset of arcs of G and σ, σ' two MAX strategies. If $\sigma' \succ_{G[A,\sigma]} \sigma$ then $\sigma' \succ_G \sigma$.*

In order to avoid requiring the game to be stopping, it is necessary to pay particular attention to the set of vertices where the play can loop infinitely and yield value zero, which is a subset of the set of vertices of value 0. We now prove that a step of GSIA can only reduce this set, which is then used to prove Proposition 18.

► **Definition 19.** *For an SSG G and two strategies (σ, τ) , an absorbing set Z is a subset of $V \setminus V_S$ such that starting from any vertex of Z and playing according to (σ, τ) , there is a probability zero of reaching a vertex of $V \setminus Z$.*

For σ and τ two strategies, $Z(\sigma, \tau)$ is the set of all vertices in some absorbing set under (σ, τ) . Hence, $Z(\sigma, \tau)$ is also an absorbing set. By definition, a play remains stuck in an absorbing set and can never reach a sink, hence all vertices of an absorbing set have *value zero* under (σ, τ) . The next lemma proves the existence of the inclusion-wise maximum over τ of $Z(\sigma, \tau)$ that we denote by $Z(\sigma)$. An example is given Fig. 2.

► **Lemma 20.** *For every MAX strategy σ , there is $\tau \in BR(\sigma)$ such that for every MIN strategy τ' , we have $Z(\sigma, \tau') \subseteq Z(\sigma, \tau)$.*

Proof. For τ in $BR(\sigma)$ and τ' such that $Z(\sigma, \tau') \not\subseteq Z(\sigma, \tau)$, then we define $\tilde{\tau}$ as $\tilde{\tau}(x) = \tau'(x)$ for x in $Z(\sigma, \tau')$ and $\tilde{\tau}(x) = \tau(x)$ otherwise. We now prove that $\tilde{\tau} \in BR(\sigma)$ and $Z(\sigma, \tilde{\tau}) \supseteq Z(\sigma, \tau) \cup Z(\sigma, \tau')$.

Since τ is a best response to σ , we have $v_{\sigma,\tau}(x) \leq v_{\sigma,\tau'}(x)$. Moreover, for $x \in Z(\sigma, \tau')$, $v_{\sigma,\tau'}(x) = 0$ thus $v_{\sigma,\tau}(x) = 0$. From this, we deduce that the two systems of linear equations given by Lemma 8, characterising respectively vectors $v_{\sigma,\tau}$ and $v_{\sigma,\tilde{\tau}}$, are exactly the same: for the only vertices where $\tilde{\tau}(x)$ and $\tau(x)$ differ satisfy $v_{\sigma,\tau}(\tau(x)) = v_{\sigma,\tau}(\tilde{\tau}(x)) = 0$. Hence, we have $v_{\sigma,\tau} = v_{\sigma,\tilde{\tau}}$ and $\tilde{\tau} \in BR(\sigma)$.

For any play under strategies $(\sigma, \tilde{\tau})$ starting in $x \in Z(\sigma, \tau')$, the MIN vertices of the play are all in $Z(\sigma, \tau')$ because $\tilde{\tau}$ plays as τ' on these vertices. Thus, we have $Z(\sigma, \tau') \subseteq Z(\sigma, \tilde{\tau})$. For a play starting in $x \in Z(\sigma, \tau)$, either the play reaches a vertex of $Z(\sigma, \tau')$ and then stays in $Z(\sigma, \tau')$ or it plays like τ and stays in $Z(\sigma, \tau)$. Hence, we have $Z(\sigma, \tau) \subseteq Z(\sigma, \tilde{\tau})$. ◀

■ **Figure 2** Example of an SSG where the x , n and r vertices are respectively from V_{MAX} , V_{MIN} and V_R . The pair of strategy (σ, τ) is displayed as plain arrows. Here $Z(\sigma, \tau) = Z(\sigma) = \{n_1, x_1, x_2\}$.

From this we deduce the following result on the improvement step for GSIA (where absorbing sets are understood in G):

► **Proposition 21** (Proof in Appendix A). *Let G be an SSG, A a set of arcs of G , σ and σ' two MAX strategies such that $\sigma' \succ_{G[A, \sigma]} \sigma$, then $Z(\sigma') \subseteq Z(\sigma)$.*

We now prove Proposition 18.

Proof. We introduce a sequence of non-positional strategies $(\sigma_i)_{i \geq 0}$ defined by $\sigma_i = \sigma'|^i \sigma$ for $i \geq 1$. By hypothesis $\sigma' \succ_{G[A, \sigma]} \sigma$, and by Lemma 16 $v_{\sigma'|_A \sigma}^G = v_{\sigma'}^{G[A, \sigma]}$, then we have

$$v_{\sigma_1}^G = v_{\sigma'|_A \sigma}^G = v_{\sigma'}^{G[A, \sigma]} > v_{\sigma}^{G[A, \sigma]} = v_{\sigma}^G.$$

Hence, by definition, sinks of $G[A, \sigma_1]$ will have at least the values of the corresponding sinks in $G[A, \sigma]$. Applying Lemma 17, we obtain that $v_{\sigma_1}^{G[A, \sigma_1]} \geq v_{\sigma}^{G[A, \sigma]}$, which can also be written as $v_{\sigma_2}^G \geq v_{\sigma_1}^G$. More generally, we have:

$$\forall i \geq 1, v_{\sigma_{i+1}}^G \geq v_{\sigma_i}^G \geq v_{\sigma_1}^G > v_{\sigma}^G.$$

We now prove that $v_{\sigma_i}^G \geq v_{\sigma_1}^G$ to conclude the proof.

From now on, we only consider the game G . Fix a vertex x and a MIN strategy $\tau \in BR(\sigma')$ such that $Z(\sigma') = Z(\sigma', \tau)$. From Proposition 21 we know that, $Z(\sigma') \subseteq Z(\sigma)$. It implies that for every $z \in Z(\sigma')$, $v_{\sigma}^G(z) = v_{\sigma'}^G(z) = 0$ which implies that $v_{\sigma'}^{G[A, \sigma]}(z) = 0$. Thus, $\sigma'(z) = \sigma(z)$. It implies that $Z(\sigma') \subseteq Z(\sigma, \tau)$.

We now only consider G' the game G where we replace every vertex in $Z(\sigma', \tau)$ by a sink of value 0. Lemma 12 directly implies that $v_{\sigma}^G = v_{\sigma'}^{G'}$ and $v_{\sigma'}^G = v_{\sigma'}^{G'}$. Moreover, when playing following σ_i when a vertex of $Z(\sigma')$ is reached, for all possible history, the play will stay in the absorbing set. Thus, $v_{\sigma_i}^G = v_{\sigma_i}^{G'}$.

Recall that $\mathbb{P}_{\sigma', \tau}^x(\rightarrow s)$ is the probability to reach a sink s in G' while starting in x and following (σ', τ) . Let $T^{\sigma', \tau}$ be a random variable defined as the time at which a sink is reached. Note that $T^{\sigma', \tau}$ may be equal to $+\infty$.

For every $i \geq 1$, we use Bayes rule to express the value of $v_{\sigma',\tau}(x)$ while conditioning on finishing the game before i steps.

$$\begin{aligned} v_{\sigma',\tau}(x) = & \mathbb{P}(T^{\sigma',\tau} < i) \sum_{s \in V_S} \mathbb{P}_{\sigma',\tau}^x(\rightarrow s \mid T^{\sigma',\tau} < i) \text{Val}(s) \\ & + \mathbb{P}(i \leq T^{\sigma',\tau} < +\infty) \sum_{s \in V_S} \mathbb{P}_{\sigma',\tau}^x(\rightarrow s \mid +\infty > T^{\sigma',\tau} \geq i) \text{Val}(s) \end{aligned}$$

If $T^{\sigma_i,\tau} < i$, only i arcs have been crossed, thus at most i arcs from A have been crossed when the sink is reached. Hence σ_i acts like σ' during the whole play, which yields:

$$\begin{aligned} v_{\sigma',\tau}(x) = & \mathbb{P}(T^{\sigma_i,\tau} < i) \sum_{s \in V_S} \mathbb{P}_{\sigma_i,\tau}^x(\rightarrow s \mid T^{\sigma_i,\tau} < i) \text{Val}(s) \\ & + \mathbb{P}(i \leq T^{\sigma_i,\tau} < +\infty) \sum_{s \in V_S} \mathbb{P}_{\sigma_i,\tau}^x(\rightarrow s \mid +\infty > T^{\sigma_i,\tau} \geq i) \text{Val}(s) \end{aligned}$$

We use Bayes rule in the same way for $v_{\sigma_i,\tau}(x)$

$$\begin{aligned} v_{\sigma_i,\tau}(x) = & \mathbb{P}(T^{\sigma_i,\tau} < i) \sum_{s \in V_S} \mathbb{P}_{\sigma_i,\tau}^x(\rightarrow s \mid T^{\sigma_i,\tau} < i) \text{Val}(s) \\ & + \mathbb{P}(i \leq T^{\sigma_i,\tau} < +\infty) \sum_{s \in V_S} \mathbb{P}_{\sigma_i,\tau}^x(\rightarrow s \mid T^{\sigma_i,\tau} \geq i) \text{Val}(s) \end{aligned}$$

Since every absorbing vertex in G associated with σ' has been turned into a sink, in G' $\mathbb{P}(T^{\sigma',\tau} < i) = \mathbb{P}(T^{\sigma_i,\tau} < i)$ converges to 1 when i grows. Hence, both $\mathbb{P}(i \leq T^{\sigma',\tau} < +\infty)$ and $\mathbb{P}(i \leq T^{\sigma_i,\tau} < +\infty)$ go to 0 and

$$\lim_{i \rightarrow +\infty} |v_{\sigma',\tau}(x) - v_{\sigma_i,\tau}(x)| = 0.$$

Hence, if there was x such that $v_{\sigma'}(x) < v_{\sigma_1}(x)$, we denote $\epsilon = v_{\sigma_1}(x) - v_{\sigma'}(x)$. For some rank I for all $i \geq I$ we have $|v_{\sigma',\tau} - v_{\sigma_i,\tau}| < \epsilon/2$. Which implies $v_{\sigma_i,\tau}(x) < v_{\sigma_1}(x)$. We recall that $v_{\sigma_1}(x) \leq v_{\sigma_i}(x)$. This means that $v_{\sigma_i,\tau} < v_{\sigma_i}(x)$, which contradicts the notion of optimal response against σ_i . Therefore, we have shown that $\sigma' \underset{G}{\geq} \sigma_1 \underset{G}{\geq} \sigma$. ◀

As a consequence of all previous lemmas, we obtain the correction of GSIA.

► **Theorem 22.** *GSIA terminates and returns a pair of optimal strategies.*

Proof. We denote by σ_i the MAX strategy σ at the end of the i -th loop in Algorithm 1. By induction, we prove that the sequence σ_i is of increasing value. Indeed, Line 5 of Algorithm 1 guarantees that $\sigma' \underset{G[A,\sigma]}{\succ} \sigma$, thus Prop. 18 implies that $\sigma' \underset{G}{\succ} \sigma$, that is $\sigma_{i+1} > \sigma_i$.

The strategies produced by the algorithm are positional, hence there is only a finite number of them. Since the sequence is strictly increasing, it stops at some point. The algorithm only stops when Line 5 of Algorithm 1 fails to find $\sigma' \underset{G[A,\sigma]}{\succ} \sigma$. In other words, σ is optimal in $G[A,\sigma]$. By Lemma 14, σ is also optimal in G . ◀

4 Complexity of GSIA

We analyse the algorithmic complexity of GSIA, by lower bounding the values of the sequence of strategies it produces. We obtain a bound on the number of iterations of GSIA depending on the number of random vertices, rather than on the number of MAX or MIN vertices. Then, we can derive the complexity of any instance of GSIA, by evaluating the cost of computing σ' from σ in $G[A, \sigma]$.

4.1 Values of q -SSGs

To prove a complexity bound using the values of a strategy, we need to precisely characterise the form of these values. In a 2-SSG, there is a function $f(r)$ such that, for every pair of positional strategies (σ, τ) , there is $t \leq f(r)$, such that for every vertex x , there is an integer p_x , such that $v_{\sigma, \tau}(x) = \frac{p_x}{t}$.

Condon proved in [13] that $f(r) \leq 4^r$. Then Auger, Coucheney and Strozecki improved this to $f(r) \leq 6^{r/2}$ in [4]. We show that $f(r) = q^r$ for q -SSGs, which gives the improved bound of $f(r) \leq 2^r$ for 2-SSGs.

► **Theorem 23** (Proof in Appendix B). *Let $q \geq 1$ and G a q -SSG with r random vertices, then for any pair of strategies (σ, τ) there is $t \leq q^r$ such that, for every vertex x , there is an integer s_x such that, $v_{\sigma, \tau} = \frac{s_x}{t}$.*

Proof of Th. 23 relies on the matrix tree theorem applied to a directed multigraph representing the game under a pair of strategies. Let us show that q^r is a tight bound for $f(r)$. Consider a Markov chain (an SSG with no MAX nor MIN vertices) with $r + 2$ vertices: two sinks 0 and 1 and r random vertices x_1, \dots, x_r . Vertex x_1 goes to 1 with probability $1/q$ and to 0 with probability $(q - 1)/q$. For $r \geq i \geq 2$, x_i goes to 0 with probability $(q - 1)/q$ and to x_{r-1} with probability $1/q$. Then, the value of x_r is q^{-r} .

4.2 Bounding the Number of Iterations of GSIA

GSIA produces a sequence of strictly increasing positional MAX strategies. The number of positional MAX strategies is bounded by $|\Sigma^{\text{MAX}}| = \prod_{x \in V_{\text{MAX}}} \text{deg}(x)$, hence the number of iterations of GSIA is bounded by this value. If we consider the case of a binary SSG (all vertices of outdegree 2), we have the classical bound of $|\Sigma^{\text{MAX}}| = 2^n$ iterations. The best known bound for a deterministic algorithm is $2^n/n$ iterations obtained for Hoffman-Karp algorithm [25], which is not far from the trivial bound of 2^n iterations.

We give a bound for q -SSG, which depends on q and r the number of random vertices. The difference of two values written as a/b and c/d , with a and b less than q^{-r} is more than q^{-2r} . Hence, if a value increases in GSIA, it increases at least by q^{-2r} . Using the classical notion of switch and anti-switch [25], recalled in Appendix C, we can prove that all vertices which have their value increased by a step of GSIA, are increased by at least q^{-r} .

► **Theorem 24** (Proof in Appendix C). *For G a q -SSG with r random vertices and n MAX vertices, the number of iterations of GSIA is at most nq^r .*

The complexity of GSIA is the number of iterations given by Th. 24, multiplied by the complexity of an iteration. In an iteration, there are two sources of complexity: constructing the game $G[A, \sigma]$ and finding an improving strategy σ' in $G[A, \sigma]$. To construct the game, v_σ is computed by solving a linear program of size m up to precision $p = q^r$. Let $C_1(m, p)$ be the

complexity of computing v_σ , then the best bound is currently in $O(m^\omega \log(p))$ [19], with ω the current best bound on the matrix multiplication exponent. Let $C_2(n, r, q)$ be the complexity of computing σ' , the complexity of an iteration is in $O(nq^r(C_1(n+r, q^r) + C_2(n, r, q)))$.

We obtain a better complexity, when $C_2(n, r, q) = O(C_1(n, q^r)r/n)$, which is the case for most instances of GSIA mentioned in this article. The number of iterations is only rq^r if we can guarantee that a random vertex increases its value at each step. When no random vertex is improved, the cost of computing $G[A, \sigma]$ can be made smaller, which yields the following theorem.

► **Theorem 25** (Proof in Appendix D). *Let G be a q -SSG with r random vertices and n MAX vertices. If $C_2(n, r, q) = O(C_1(n, q^r)r/n)$, then the complexity of GSIA is in $O(rq^r C_1(n, q^r))$.*

5 Two Instances of GSIA

As previously mentioned, all known strategy improvement algorithms can be viewed as particular instances of GSIA. This includes e.g. switch-based algorithms, like Hoffman-Karp algorithm [14, 25] or Ludwig's recursive algorithm [22]. With the help of GSIA it also becomes very easy to derive new algorithms, by transforming the game into polynomial time solvable instances, such as almost acyclic games [4]. We detail all these old and new algorithms in Sec. 6.

In this section, we focus instead on two particular instances (or family of instances) of GSIA, for which we obtain new complexity bounds using the results of the previous sections.

5.1 GSIA and f -strategies

The strategy improvement algorithm proposed by Gimbert and Horn in [16] (denoted by GHA) can be viewed as an instance of GSIA where the set A of fixed arcs is the set R of all arcs going out of random vertices, and the improvement step in the subgame $G[R, \sigma]$ consists in taking an optimal strategy. In this case, the subgame $G[R, \sigma]$ is deterministic (random vertices are connected to sinks only and can be replaced by sinks), hence optimal values in $G[R, \sigma]$ depend only on the relative ordering of the values $v_\sigma(x)$ for sink and random vertices x of G . These values can be computed in $O(r \log(r) + n)$ time [1]. In the original paper [16], the algorithm is proposed in a context where the number of sinks is two, but we generalise their definitions to our context.

Consider a total ordering f on $V_R \cup V_S$, $f : x_1 < x_2 < \dots < x_{r+s}$, where s is the number of sinks. An f -strategy corresponding to this ordering is an optimal MAX strategy in the game where the $s + r$ vertices above are replaced by sinks with new values satisfying $\text{Val}(x_1) < \text{Val}(x_2) < \dots < \text{Val}(x_{r+s})$. Clearly, this strategy does not depend on the actual values given but only on f . Note that if several f -strategies exist for a given f , they share the same values on all vertices.

Algorithm GHA produces an improving sequence of f -strategies, and the two sinks of value zero and one are always first and last in the order, hence its number of iterations is bounded by $r!$, the total number of possible orderings of the random vertices. We extend this result to a large class of instances of GSIA: let us call Optimal-GSIA (Opt-GSIA), the meta algorithm obtained from Algorithm 1 with two additional constraints:

- the set A of fixed arcs is the same at each step of Algorithm 1;
- at line 5, the improving strategy σ' is the optimal strategy in $G[A, \sigma]$.

All classical algorithms captured by GSIA, or new ones presented in this article are in fact instances of Opt-GSIA. We now show that Opt-GSIA has an iteration number similar to GHA. Since we have proved a bound of nq^r iterations, by Th. 24, Opt-GSIA has essentially the best known number of iterations, for q small and large (the latter being interesting in the case of random vertices with large degree and arbitrary probability distributions).

► **Theorem 26.** *Consider an SSG G and a set of arcs A containing k arcs out of MAX or MIN vertices. Then Algorithm Opt-GSIA runs in at most $\min((r+k)q^r, (r+k)!) iterations.$*

Proof. Let σ be one of the iterated MAX strategies obtained by an instance of Opt-GSIA, and σ' be an optimal strategy in $G[A, \sigma]$. Then σ' is consequently an f -strategy in $G[A, \sigma]$, where f is the ordering on $V_R \cup V_A$ (where V_A is the set of A -sinks) which is induced by the value vector $v_{\sigma'}^{G[A, \sigma]}$ (if vertices have the same value, just arbitrarily decide their relative ordering in f).

Since strategies produced by the algorithm strictly increase in values by Prop. 18, they must be all distinct. Hence, the order f must be distinct at each step of the algorithm, which proves that Opt-GSIA does at most $(r+k)!$ iterations.

Moreover, at every step the value in G of at least one vertex in $V_R \cup V_A$ must improve, by at least q^{-r} because of Th. 23. Since the value of these vertices is bounded by 1, the number of iterations of Opt-GSIA is bounded by $(r+k)q^r$. ◀

Those results can be used to generalize Gimbert and Horn's Algorithm [16] and to compare it with Ibsen-Jensen and Miltersen's algorithm [18]. It is possible to create an instance of GSIA with less iterations than Ibsen-Jensen and Miltersen's algorithm and which terminates exponentially faster on some input. Due to a lack of space this is detailed in a long version of this paper [3].

5.2 Condon's Converge From Below Algorithm

In [14], Condon first presents a faulty algorithm (the Naive Converge From Below Algorithm) and then a correct modified version, the Converge From Below (CFB) Algorithm. This algorithm proceeds by improving a value vector iteratively, but we show here that is in fact a disguised strategy improvement algorithm, that can be seen as an instance of Opt-GSIA. This gives us a proof of convergence of the CFB algorithm in the general, non-stopping case (whereas Condon has the assumption that the game is stopping in her proof), and also bounds on the number of iterations (none are given in the original paper) by Theorem 24 and Theorem 26.

The CFB algorithm is restated with some clarifications on listing 2 (we omit the details of the linear program, see [14]). The algorithm uses two properties of a vector, that we now define. First, vector v is *feasible* if

- (i) For $s \in V_S$, $v(s) = \text{Val}(s)$
- (ii) For $r \in V_R$, $v(r) = \sum_{x \in N_r} p_r(x)v(x)$
- (iii) For $x \in V_{\text{MIN}}$, $v(x) \leq \min_{y \in N^+(x)} v(y)$
- (iv) For $x \in V_{\text{MAX}}$, $v(x) \geq \max_{y \in N^+(x)} v(y)$.

A feasible vector is *stable* at x a MIN vertex (resp. MAX vertex) if satisfies condition (iii) (resp. condition (iv)) of feasibility for x with an equality.

We now show by induction that the CFB algorithm is equivalent to the instance of Opt-GSIA where all MIN vertices are fixed, i.e. A is the set of arcs entering MIN vertices. Let A_{MIN} denote this set.

To see this, suppose that at the beginning of line 5 of CFB, Vector v_r is the value vector of a MAX-strategy σ in G . Then:

- at Line 5, we “update v as the feasible vector where all MIN vertices x have value $v_r(x)$ and all MAX vertices are stable”. This amounts to finding a MAX-strategy σ' which satisfies optimality conditions in $G[A_{\text{MIN}}, \sigma]$, i.e. an optimal strategy for MAX in this subgame. This is exactly the subgame improvement step of Opt-GSIA. At the end of this step, v is the optimal value vector in $G[A_{\text{MIN}}, \sigma]$;
- in the next loop, at Line 4 of CFB, we “compute the value vector v_r of an optimal response to the MAX strategy that plays greedily according to v ”, i.e. v_r is updated to the value vector $v_{\sigma'}^G$. This is precisely Line 6 of GSIA when we update values in the subgame.

Hence, we see that except for the initialisation where v_r may not correspond to a MAX-strategy, it will be the case as soon as we reach Line 5 of the first loop, and from this point on CFB will correspond exactly to the instance of Opt-GSIA described above.

■ **Algorithm 2** Converge From Below Algorithm.

Data: G an SSG

Result: The optimal value vector v^* of G

```

1 begin
2   · let  $v$  be a feasible vector in which all MIN vertices have value 0 and all MAX
   vertices are stable
3   while  $v$  is not an optimal value vector do
4     · use linear programming to compute the value vector  $v_r$  of an optimal
     response to the MAX strategy that plays greedily according to  $v$ 
5     · update  $v$  as the feasible vector where all MIN vertices  $x$  have value  $v_r(x)$  and
     all MAX vertices are stable
6   return  $v$ 

```

6 Algorithms Derived from GSIA

We show that all known strategy improvement algorithms can be expressed as instances of GSIA and we also propose several new algorithms, derived from choices of A which make the transformed game polynomial time solvable. The only algorithms which are not instances of GSIA are based on values rather than strategies: value propagation [10, 14, 18], quadratic programming [14, 21] and dichotomy [4].

6.1 Hoffman-Karp Algorithms

The most classical method to solve an SSG, called the Hoffman-Karp algorithm, repeatedly applies switches to the strategy until finding the optimal one. It is also a generic algorithm, since the choice of the set of vertices to switch at each step is not specified nor the choice of the initial strategy. Many details on these algorithms can be found in [14] or [25].

Hoffman-Karp algorithms are instances of GSIA, where A is the set of all arcs of the SSG. Indeed, as proved in Lemma 30, a switch σ' of σ satisfies $\sigma \succ_{G[A, \sigma]} \sigma'$. Interpreting

Hoffman-Karp algorithms as instances of GSIA proves that they work on non-stopping games, while in most article the stopping condition is required. Moreover, it shows that their number of iterations is $O(nq^r)$ on q -SSGs, a complexity exponential in r only, which was known only for algorithms specially designed for this purpose [17, 15, 18, 5].

Ludwig’s Algorithm [22], which is the best randomised algorithm to solve SSGs, can be seen as an Hoffman-Karp algorithm using Bland’s rule as shown in [5]: a random order on the vertices is drawn, and at each step, the first switchable vertex in the order is switched. Two other Hoffman-Karp algorithms are presented in [25]: switching all switchable vertices at each step or switching a random subset. Seeing these three algorithms as instances of GSIA yields $O(nq^r)$ as a deterministic bound on their number of iterations, which was unknown. However, the analysis of [22, 25] is required to obtain a good complexity in n for these algorithms.

6.2 Selection of the Initial Strategy

In [15], Dai and Ge give a randomised improvement of GHA simply by choosing a better initial strategy. To do so, they choose randomly $\sqrt{r!} \log(r!)$ strategies and choose the one with the highest value. This ensures, with high probability, that at most $\sqrt{r!}$ iterations will be done in GHA. Thus, their algorithm runs in $O(\sqrt{r!})$ iterations. This algorithm is also captured by GSIA by selecting the initial strategy in the same way, however it seems hard to combine the gain made by the random selection of the strategy and the bound in $O(q^r)$ of GSIA, since even a strategy close to the optimal one may have values far from it. Remark that it is trivial to extend this method to any instance of Opt-GSIA to improve on the complexity of Th. 26.

6.3 New Algorithms

We can use GSIA to design many strategy improvement algorithms. We present three of them, all based on a choice of A which makes $G[A, \sigma]$ solvable in polynomial time. The initial strategy can be anything and σ' is always chosen to be the optimal strategy in $G[A, \sigma]$. Most of them can be seen as generalisations of known algorithms.

1. Let A be a feedback arc set of G , then $G[A, \sigma]$ is acyclic and it can be solved in linear time. It seems intuitively appealing to think that this algorithm will be faster if the feedback arc set is small but we have no proof to sustain such a proposition.
2. A MAX acyclic SSG is an SSG such that every MAX vertex has at most one outgoing arc in a cycle. MAX acyclic SSG can be solved in polynomial time, see [4]. If we let A be a set of arc that contains all but one outgoing arcs of each MAX vertex, then $G[A, \sigma]$ is MAX acyclic and can be solved in polynomial time. Moreover, such a game can be solved by strategy improvement in at most n iterations. This can be seen as a generalisation of Hoffman-Karp algorithm, in which A contains *all* outgoing arcs of MAX vertices.
3. As an intermediate between acyclic games and MAX acyclic games, we may consider almost acyclic games, where all vertices have at most one outgoing arc in a cycle. Almost acyclic SSGs can be solved in linear time [4].

A Proof of the decreasing absorbing set

Here we prove Prop. 21

Proof. Suppose that $Z(\sigma')$ is not a subset of $Z(\sigma)$. From Lemma 20 there is $\tau \in BR(\sigma)$ such that $Z(\sigma, \tau) = Z(\sigma)$ and $\tau' \in BR(\sigma')$ such that $Z(\sigma', \tau') = Z(\sigma')$. We write $Z = Z(\sigma')$

Let X be the set of MAX vertices x in $Z(\sigma') \setminus Z(\sigma)$ such that $\sigma(x) \neq \sigma'(x)$; it is nonempty otherwise $Z(\sigma')$ would be an absorbing set for (σ, τ') . If x is in X , since $\sigma' \succ_{G[A, \sigma]} \sigma$, we have

$$v_{\sigma'}^{G[A, \sigma]}(x) > v_{\sigma}^{G[A, \sigma]}(x) \geq 0$$

Thus, a sink is reached in $G[A, \sigma]$ starting from x under the strategies (σ', τ') . Since Z is an absorbing set in G under the same strategies, it implies that all the accessible sinks in $G[A, \sigma]$ are A -sinks. Hence, there is at least one arc $e = (y, z) \in A$ with both ends in Z and such that $v_{\sigma}(z) > 0$. We define the vertex s of Z as:

$$s = \arg \max_{z \in Z} \{v_{\sigma}(z) \mid \exists y \in V, (y, z) \in A\}$$

and we let $v = v_{\sigma}(s)$. The value of each vertex in Z is bounded by v . Similarly than for x , in G under strategies (σ, τ) the value of s is bounded by the value of the vertex leaving Z . Such vertices exist since Z is not a subset of $Z(\sigma)$. We now want to show that those vertices all have value strictly lesser than v , thus proving a contradiction.

First, since Z is an absorbing set for (σ', τ') , all arcs leaving a random vertex in $Z(\sigma')$ remain in $Z(\sigma')$ in G ; this is not dependent on the strategies considered.

Let $E_X \subseteq X$ the set of MAX vertices x of X such that $\sigma(x) \notin Z$ and let $E_N \subseteq Z \cap V_{\text{MIN}}$ the set of MIN vertices x of Z such that $\tau(x) \notin Z$.

On the one hand, for a MIN vertex $x \in E_N$:

$$\begin{aligned} v_{\sigma}^G(\tau(x)) &\leq v_{\sigma}^G(\tau'(x)) && \text{Since } \tau = \tau(\sigma) \\ v_{\sigma}^G(\tau'(x)) &= v_{\sigma}^{G[A, \sigma]}(\tau'(x)) \\ v_{\sigma}^{G[A, \sigma]}(\tau'(x)) &\leq v_{\sigma'}^{G[A, \sigma]}(\tau'(x)) && \text{Since } \sigma' \succ_{G[A, \sigma]} \sigma \\ v_{\sigma'}^{G[A, \sigma]}(\tau'(x)) &\leq v && \text{Since } \tau'(x) \in Z \end{aligned}$$

Thus, $v_{\sigma}^G(\tau(x)) \leq v$. In case of equality, we have $v = v_{\sigma}^G(\tau'(x)) = v_{\sigma}^G(\tau(x))$; hence we can replace τ by $\bar{\tau}(x)$, which is identical to τ except that $\bar{\tau}(x) = \tau'(x)$. We have $v_{\sigma, \tau} = v_{\sigma, \bar{\tau}}$ and $Z(\sigma, \tau) = Z(\sigma, \bar{\tau})$. Indeed, according to Lemma 8 the only situation that could occur would be to violate the condition (v) by creating an absorbing set. However this would contradict the definition of τ . Thus, we can suppose that for any x in E_N , $v_{\sigma}(\tau(x)) < v$.

On the other hand, since $\sigma' \succ_{G[A, \sigma]} \sigma$ we know that for any x in E_X :

$$v_{\sigma}^G(\sigma(x)) < v_{\sigma'}^{G[A, \sigma]}(x) \leq v$$

Now, for any vertex x of $E = E_X \cup E_N$, let p_x be the probability of x being the first vertex of E reached starting from s following strategies (σ, τ) . By conditional expectation:

$$v_{\sigma}(s) = \sum_{x \in E_X} p_x v_{\sigma}(\sigma(x)) + \sum_{x \in E_N} p_x v_{\sigma}(\tau(x))$$

Thus, $v_{\sigma}(s) < v$ which contradicts the definition of v , and proves that $Z(\sigma') \subseteq Z(\sigma)$. ◀

B Proof of the value of a q -SSG

Here, we prove Th. 23.

Let us remark that a q -SSG can be assumed to have all its probability transition of the form p/q . The idea here is to notice that it is possible to loop with a certain probability on the same random vertices.

► **Lemma 27.** *Let G be a q -SSG, then there is G' a q -SSG with the same vertices which defines the same expectation $\mathbb{E}_{\sigma, \tau}^{x_0}(\cdot)$ and such that for all $x \in V_R$ and all $x' \in N^+(x)$ then there is an integer $p_{x,x'}$ such that $p_x(x') = p_{x,x'}/q$.*

Proof. For a a random vertex in G , and $q_a < q$ such that for every other vertex x in G there is $p_x \in \mathbb{N}$ and a probability p_x/q_a to go directly from a to x , we change those probabilities to p_x/q and we add a probability p/q to stay in a , where:

$$p = q - \sum_{x \in V} p_x. \quad \blacktriangleleft$$

Now, we state the classical matrix-tree theorem that we use in our proof (see e.g. [7]). Let G be a directed multigraph with n vertices, then the *Laplacian matrix* of \mathcal{G} is a $n \times n$ matrix $L(\mathcal{G}) = (l_{i,j})_{i,j \leq n}$ defined by:

- (i) $l_{i,j}$ equals $-m$ where m is the number of arcs from i to j .
- (ii) $l_{i,i}$ is the number of arcs going to i , excluding the self-loops.

► **Theorem 28** (Matrix tree theorem for directed multigraphs). *For $G = (V, E)$ a directed multigraph with vertices $V = \{v_1, \dots, v_k\}$ and L its Laplacian matrix, the number of spanning trees rooted at v_i is $\det(\hat{L}_{i,i})$ where $\hat{L}_{i,i}$ is the matrix obtained by deleting the i -th row and column from L .*

We can now prove Th. 23.

Proof of Th. 23. The beginning of the proof is the same as in [14] and [4]. We start by transforming the game with fixed strategies in a Markov Chain with equivalent values. Then, we show that the value of each vertex can be written $\frac{\det B_i}{\det q(I - A)}$ using Cramer rule, for B_i and A two matrix which will be carefully defined. To conclude, we will show that $\det q(I - A) < q^r$ by creating a graph obtain from our initial game and using Th. 28.

We consider a q -SSG G and two positional strategies σ and τ . Without loss of generality, we can restrict ourselves to the computation of non-zero, non-sink values. Thus, each vertex has a non-zero probability to reach the 1-sink. To compute the values $v_{\sigma, \tau}$, we can consider G_A an SSG with vertices $V_R \cup V_S$: the random vertices and the sinks of V . The value of the sinks is not changed and the probability distribution p'_x is defined as follows. For $x \in V_R$ and x' in G_A , we call $M_{x,x'}$ the set of MAX and MIN vertex y in $N^+(x)$ such that there is a path following only arcs of σ and τ from y to x' . We then have

$$p'_x(x') = \sum_{y \in M_{x,x'}} p_x(y)$$

The graph G_A has $r + 2$ vertices that we denote by $a_1, \dots, a_{r+1}, a_{r+2}$ where a_{r+1} is the 0-sink and a_{r+2} is the 1-sink. Let b be the r -dimensional column vector with $b_i = p'_{a_i}(a_{r+2})$. We define A the $r \times r$ matrix, with $A_{i,j} = p'_{a_i}(a_j)$.

12:20 A Generic Strategy Improvement Method for Simple Stochastic Games

The values of the random vertices are defined by the vector z that satisfies the following equation:

$$z = Az + b$$

Let I be the identity matrix, $(I - A)$ is invertible because each random vertex has access to a sink and every eigenvalue of A is strictly less than 1. We refer to [14] for details. Hence, the equation has a unique solution and z is also solution of:

$$q(I - A)z = qb$$

Hence, under the strategies σ, τ , the value z_i of a random vertex a_i given by the Cramer rule is

$$z_i = \frac{\det B_i}{\det q(I - A)}$$

where B_i is the matrix $q(I - A)$ where the i -th column has been replaced by qb . The value $\det B_i$ is an integer. See [4] for more details. Our goal is now to bound $\det q(I - A)$.

From the graph G_A , we construct the graph G' by inverting all arcs, and duplicating an arc of probability p/q into p arcs of probability $1/q$. We also add an arc coming from the 1-sink to the 0-sink and one from the 0-sink towards the 1-sink. Figure 3 shows an example of the transformation from G to G' . The Laplacian L of G' is thus the following matrix.

$$L = \left(\begin{array}{c|cc} q(I - A)^T & B & \\ \hline 0 & 1 & 1 \\ & 1 & 1 \end{array} \right)$$

Indeed, every random vertex has indegree q minus the number of loops. Thus the number of spanning trees of G' rooted in the 1-sink is equal by Th. 28 to $\det \hat{L}_{r+2, r+2}$ where we have

$$\hat{L}_{r+2, r+2} = \left(\begin{array}{c|c} q(I - A)^T & B' \\ \hline 0 & 1 \end{array} \right).$$

In other words, the number of spanning trees of G' is equal to $\det q(I - A)$. Furthermore, each spanning tree contains exactly one incoming arcs for every random vertices, and the arc (a_{r+2}, a_{r+1}) has to be used. Thus, there is at most q^r spanning trees rooted in G' and $\det q(I - A) \leq q^r$. ◀

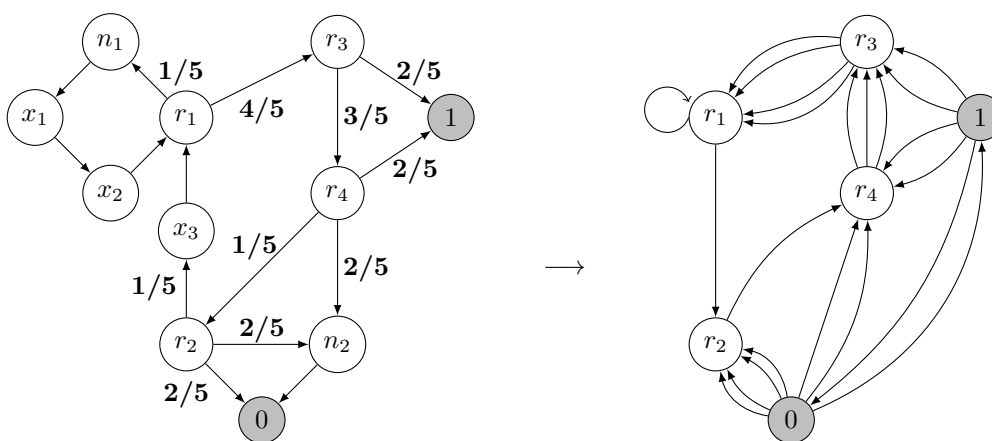

C Bounding the Number of Iterations of GSIA

We introduce the notion of switch and anti-switch, to prove that the improvement is at least q^{-r} rather than q^{-2r} .

► **Definition 29.** A *switch* (resp. an *anti-switch*) of a MAX strategy σ with switched set $S \subseteq V_{\text{MAX}}$ is a strategy σ_S defined by $\sigma_S(x) = \sigma(x)$ for $x \notin S$, and satisfying $v_\sigma(\sigma(x)) < v_\sigma(\sigma_S(x))$ (resp. $v_\sigma(\sigma(x)) > v_\sigma(\sigma_S(x))$) for $x \in S$ (hence $\sigma_S(x) \neq \sigma(x)$).

A common tool to solve SSGs is the fact that a switch increases the value of a strategy, while an anti-switch decreases it. Within our framework of transformed game, it is extremely simple to prove.

► **Lemma 30.** If σ_S is a switch of σ , then $\sigma_S > \sigma$. If σ_S is an anti-switch of σ , then $\sigma_S < \sigma$.

■ **Figure 3** Example of a transformation of a graph G into a graph G' .

Proof. Consider $G[A, \sigma]$ the game obtained from G , where A is the set of all arcs of G . Let us consider x a vertex switched in σ' , that is with $v_\sigma^G(\sigma(x)) < v_{\sigma'}^G(\sigma'(x))$. Then, because all arcs are in A , we have $v_\sigma^{G[A, \sigma]}(x) = v_\sigma^G(\sigma(x))$ and $v_{\sigma'}^{G[A, \sigma]}(x) = v_{\sigma'}^G(\sigma'(x))$. Hence, $v_\sigma^{G[A, \sigma]}(x) < v_{\sigma'}^{G[A, \sigma]}(x)$ and for $v_\sigma^G(\sigma(x)) \geq v_{\sigma'}^G(\sigma'(x))$, $\sigma(x) = \sigma'(x)$, which implies $\sigma' \succ_{G[A, \sigma]} \sigma$.

Prop. 18 proves $\sigma' \succ_G \sigma$.

The proof is the same for an anti-switch, since $\sigma \succ_{G[A, \sigma]} \sigma' \Rightarrow \sigma \succ_G \sigma'$ (which can be proved similarly as Prop. 18, while keeping in mind that in the decreasing case, creating absorbing set lowers the value). ◀

We use the previous lemma to prove Th. 24.

Proof. Let us consider σ the strategy computed at some point by GSIA and σ' the next strategy. By Prop. 18, $\sigma < \sigma'$. Hence, by Lemma 30, σ' cannot be an anti-switch of σ . Thus, there is a MAX vertex x such that $v_\sigma(\sigma(x)) < v_{\sigma'}(\sigma'(x))$. We recall that $\sigma'(x)$ denotes the successor of x under strategy σ' .

Since $\sigma < \sigma'$, we have $v_\sigma(x) = v_\sigma(\sigma(x)) < v_\sigma(\sigma'(x)) \leq v_{\sigma'}(\sigma'(x)) = v_{\sigma'}(x)$. We now evaluate $v_{\sigma'}(\sigma'(x)) - v_\sigma(\sigma(x))$. In the game G , under the strategies $\sigma, \tau(\sigma)$, Th. 23 implies that for some $t \leq q^r$, $v_\sigma(\sigma(x)) = p/t$ and $v_\sigma(\sigma'(x)) = p'/t$. We have $p/t < p'/t$, thus $p'/t - p/t \geq 1/t \geq 1/q^r$. Hence, the value of some MAX vertex increases by $1/q^r$ in each iteration of GSIA. Since there are n MAX vertices and their values are bounded by 1, there are at most nq^r iterations. ◀

D Amortised Complexity of GSIA

Here, we prove Th. 25.

Proof. We assume that $r < n$, otherwise the theorem is trivial. Let σ' be the strategy computed by GSIA at some point, improving on the strategy σ . GSIA must compute $G[A, \sigma']$, and thus $v_{\sigma'}$ and we explain a method to do so efficiently.

We assume that the order of the values (in G) of the random vertices is the same for σ and σ' . Then, knowing this order and σ' , it is easy to compute $\tau(\sigma')$ a best response to σ' in $O(r \log(r) + n)$ time [1]. Then, we can compute the values $v_{\sigma', \tau(\sigma')}$ in time $O(C_1(r, q^r))$, since it is done by solving a linear system of dimension r with precision q^r , a task which

12:22 A Generic Strategy Improvement Method for Simple Stochastic Games

is simpler than solving a linear program. Since $C_1(r, q^r)$ is at least quadratic in r , then $C_1(r, q^r) < C_1(n, q^r)r/n$ and by hypothesis $C_2(n, r, q) = O(C_1(n, q^r)r/n)$, hence a step is of complexity at most $O(C_1(n, q^r)r/n)$. There are at most nq^r such steps, for a total complexity of $O(rq^r C_1(n, q^r))$.

We need to detect when the assumption that the values of the random vertices are the same for σ and σ' is false. If $v_{\sigma', \tau(\sigma')}$ satisfies the optimality conditions at the MIN vertices, then $\tau(\sigma')$ is a best response. Otherwise, we compute the best response by solving a linear program in time $C(n, q^r)$. In that case, the order of the random vertices has changed: there are two vertices x_1 and x_2 such that $v_\sigma(x_1) < v_\sigma(x_2)$ and $v_{\sigma'}(x_1) > v_{\sigma'}(x_2)$. Hence, $v_{\sigma'}(x_1) > v_\sigma(x_2)$, which implies that $v_{\sigma'}(x_1) - v_\sigma(x_1) > v_\sigma(x_2) - v_\sigma(x_1) > q^{-r}$.

We have proved that when the random order changes, the value of some random vertex increases by at least q^{-r} , hence there are at most nq^r such steps. The complexity from these steps is bounded by $O(rq^r C_1(n, q^r))$, which proves the theorem. ◀

(Un)Decidability for History Preserving True Concurrent Logics

Abstract

We investigate the satisfiability problem for a logic for true concurrency, whose formulae predicate about events in computations and their causal (in)dependencies. Variants of such logics have been studied, with different expressiveness, corresponding to a number of true concurrent behavioural equivalences. Here we focus on a mu-calculus style logic that represents the counterpart of history-preserving (hp-)bisimilarity, a typical equivalence in the true concurrent spectrum of bisimilarities.

It is known that one can decide whether or not two 1-safe Petri nets (and in general finite asynchronous transition systems) are hp-bisimilar. Moreover, for the logic that captures hp-bisimilarity the model-checking problem is decidable with respect to prime event structures satisfying suitable regularity conditions. To the best of our knowledge, the problem of satisfiability has been scarcely investigated in the realm of true concurrent logics.

We show that satisfiability for the logic for hp-bisimilarity is undecidable via a reduction from domino tilings. The fragment of the logic without fixpoints, instead, turns out to be decidable. We consider these results a first step towards a more complete investigation of the satisfiability problem for true concurrent logics, which we believe to have notable solvable cases.

1 Introduction

When dealing with concurrent and distributed systems, the so-called true concurrent models are used to provide a precise account of the computational steps and of their dependencies, like causality and concurrency. An early and widely used foundational model in this class is given by Winskel's event structures [41]. They describe the behaviour of a system in terms of events in computations and two dependency relations: a partial order modelling causality and an additional relation representing conflict. A survey on the applications of such causal models can be found in [42]. Recently they have been used in the study of concurrency in weak memory models [31, 20], for process mining and differencing [14], in the study of atomicity [15] and information flow [2] properties.

In the true concurrent approach numerous behavioural equivalences have been defined ranging from hereditary history-preserving bisimilarity to the coarser pomset and step equivalences (see, e.g., [37]). Correspondingly, behavioural logics have been proposed including operators that allow one to express causal properties of computations (see, e.g., [12, 7, 32, 29, 25, 11, 33] just to mention a few).

In particular, event-based logics have been introduced [3, 30], interpreted over event structures, expressive enough to provide a logical characterization of the main behavioural equivalences in the true concurrent spectrum [37], from hereditary history-preserving (hhp-)bisimilarity [7] to the coarser equivalences. Formulae of such logics include variables which can be bound to events in computations and describe their dependencies.

The relation between operational models, behavioural equivalences, and true concurrent logics has been widely studied and the model-checking problem has been investigated for various logics describing true concurrency properties (see, e.g., [1, 18, 16, 17, 23, 6, 27]). The decidability of true concurrent equivalences has also been settled in various papers.

A natural problem that, to the best of our knowledge, has been scarcely investigated for true concurrent logics is satisfiability, which has been historically referred to as the *classical decision problem* [10] in the context of first-order logic. The satisfiability problem for true concurrent logics is the quest for an algorithm that, given as input any formula φ , determines whether or not there exists an event structure that satisfies φ . From this point of view, formulae are intended as abstract specifications of desired properties and event structures are abstractions of actual systems that, if implemented, should have those properties. An algorithm for satisfiability is therefore a sort of oracle that can tell system designers whether or not their desires can be realized. Obviously, checking satisfiability allows one also to verify whether two requirements, despite being syntactically different, are equivalent.

In this paper we tackle the satisfiability problem for the logic proposed in [3], referred to as \mathcal{L}_{hp} , corresponding to history-preserving (hp-)bisimilarity [9, 34, 13], a classical equivalence in the spectrum. The logic is endowed with least and greatest fixpoint operators, in mu-calculus style, in order to express interesting properties of infinite computations. For the propositional mu-calculus, corresponding to ordinary interleaving bisimilarity, satisfiability is decidable and every satisfiable formula has a finite model. For \mathcal{L}_{hp} instead the finite model property fails, essentially because of the presence of an interpreted transitive relation (causality).

Still, hp-bisimilarity and the related logic has been shown to have good decidability properties. The equivalence itself is known to be decidable for finite safe Petri nets [38, 19, 24] (while hhp-bisimilarity is undecidable [21]). Additionally, the model-checking problem has been proved decidable for \mathcal{L}_{hp} over event structures satisfying a suitable regularity property [5].

Here we show that satisfiability for \mathcal{L}_{hp} is undecidable via a reduction from a well-known undecidable tiling problem [8], similarly to what was done for some two-variable logics [26]. Despite the first-order features of \mathcal{L}_{hp} , the reduction is not trivial since quantifications can be used in a quite restricted way: formulae can refer only to events enabled in the current configuration and execute them, inspecting their relations with (a limited number) of past events. In particular, it is impossible to relate events which are not consistent (in conflict). The “local” nature of quantifications makes it hard to constrain the event structure model to have a “grid shape”. Still, we can show that, given a domino system, it is possible to construct a formula which is satisfied only by event structures embedding an event-based representation of a valid tiling for such domino. Consequently, the formula is satisfiable if and only if the domino system admits a tiling, whence the undecidability of satisfiability.

We show that, instead, for \mathcal{L}_{hp}^f , the fragment of \mathcal{L}_{hp} without fixpoints, satisfiability is decidable. The result relies on the fact that \mathcal{L}_{hp}^f can be encoded into first-order logic and the fact that it enjoys the finite model property.

We foresee that our results can be of help for settling the decidability status of other similar logics for true concurrency, like other fragments of the logic in [3], or the event identifier logic of [30] and the mu-calculi for true concurrency in [18, 16, 17], for which satisfiability has not yet been investigated.

■ **Figure 1** A simple PES \mathcal{E} and (part of) its set of configurations.

2 Event Structures

We recap the basics of prime event structures [41], a widely known model of concurrency. Throughout the paper \mathbb{E} is a fixed countable set of events from which all events are taken, Λ a set of labels ranged over by a, b, c, \dots , and $\lambda : \mathbb{E} \rightarrow \Lambda$ a labelling function.

► **Definition 1** (prime event structure). A (Λ -labelled) prime event structure (PES) is a tuple $\mathcal{E} = \langle E, \leq, \# \rangle$, where $E \subseteq \mathbb{E}$ is the set of events and $\leq, \#$ are binary relations on E , called causality and conflict respectively, such that:

1. \leq is a partial order and $[e] = \{e' \in E \mid e' \leq e\}$ is finite for all $e \in E$;
2. $\#$ is irreflexive, symmetric and for all $e, e', e'' \in E$, if $e \# e' \leq e''$ then $e \# e''$.

Hereafter, we will assume that the components of a PES \mathcal{E} are named as in the definition above, possibly with subscripts. Concurrency is a derived relation, defined as follows.

► **Definition 2** (consistency, concurrency). Let \mathcal{E} be a PES. We say that $e, e' \in E$ are consistent, written $e \sim e'$, if $\neg(e \# e')$. A subset $X \subseteq E$ is called consistent if $e \sim e'$ for all $e, e' \in X$. We say that e and e' are concurrent, written $e \parallel e'$, if $e \sim e'$ and $\neg(e \leq e'), \neg(e' \leq e)$.

Causality and concurrency will be sometimes used on set of events. Given $X \subseteq E$ and $e \in E$, by $X < e$ we mean that for all $e' \in X, e' < e$. Similarly $X \parallel e$, resp. $X \sim e$, means that for all $e' \in X, e' \parallel e$, resp. $e' \sim e$.

A simple PES is depicted in Fig. 1(left). Graphically, curly lines represent immediate conflicts and the causal partial order proceeds along the arrows. Events are denoted by their labels, possibly with superscripts. For instance, in \mathcal{E} , the events a^1 and b^1 , labelled by a and b , respectively, are in conflict. Event a^0 causes the event b^0 which, in turn, is concurrent with each a^i and b^i (for $i \geq 1$).

A state of a system modelled as a PES is represented as the set of events executed to reach the state. It is formalised by the notion of configuration.

► **Definition 3** (configuration). Let \mathcal{E} be a PES. A configuration in \mathcal{E} is a finite consistent subset of events $C \subseteq E$ closed w.r.t. causality (i.e., $[e] \subseteq C$ for all $e \in C$). The set of finite configurations of \mathcal{E} is denoted by $\mathcal{C}(\mathcal{E})$.

In words, a configuration cannot contain events in conflict and it must be closed with respect to causality. The empty set of events \emptyset is always a configuration, which can be interpreted as the initial state of the computation. The evolution of a system can be represented by a transition system where configurations are states.

13:4 (Un)Decidability for History Preserving True Concurrent Logics

► **Definition 4** (transition system). *Let \mathcal{E} be a PES and let $C \in \mathcal{C}(\mathcal{E})$. Given $e \in E \setminus C$ such that $C \cup \{e\} \in \mathcal{C}(\mathcal{E})$, and $X, Y \subseteq C$ with $X < e$, $Y \parallel e$ we write $C \xrightarrow{X, \bar{Y} < e}_{\lambda(e)} C \cup \{e\}$, possibly omitting X , Y or the label $\lambda(e)$.*

Transitions are labelled by the executed event e . In addition, they can report its label $\lambda(e)$, a subset of causes X and a set of events $Y \subseteq C$ concurrent with e . When X or Y are empty they are normally omitted, e.g., we write $C \xrightarrow{X < e}_{\lambda(e)} C'$ for $C \xrightarrow{X, \emptyset < e}_{\lambda(e)} C'$ and $C \xrightarrow{e}_{\lambda(e)} C'$ for $C \xrightarrow{\emptyset, \emptyset < e}_{\lambda(e)} C'$. Some configurations of the PES \mathcal{E} in Fig. 1 (left) can be found in the same figure, on the right. Examples of transitions are $\{a^0, b^0\} \xrightarrow{a^0, \bar{b}^0 < b^1}_a \{a^0, b^0, b^1\}$ and $\{a^0, b^0\} \xrightarrow{a^0 < a^1}_a \{a^0, b^0, a^1\}$.

A PES is called image-finite when every configuration enables a finite number of events for each fixed label. In the rest of the paper all PESs will be assumed to be image-finite. This assumption, as it commonly happens for modal logics, is crucial to have a logical characterisation of bisimilarity in terms of a finitary logic.

► **Definition 5** (image-finiteness). *A PES \mathcal{E} is called image-finite when, for every configuration $C \in \mathcal{C}(E)$ and label $a \in \Lambda$, the set $\{C' \in \mathcal{C}(\mathcal{E}) \mid \exists e \in E. C \xrightarrow{e}_a C'\}$ is finite.*

3 A Logic for True Concurrency

We review the logic for concurrency of interest in the paper, a Hennessy-Milner style logic, originally introduced in [3], which corresponds to history-preserving bisimilarity. Its formulae predicate over executability of events in computations and their mutual relations (causality and concurrency).

Syntax

In order to specify dependencies between events in computation, formulae include event variables, from a fixed denumerable set Var , denoted by x, y, \dots . Tuples of variables like x_1, \dots, x_n will be denoted by the corresponding boldface letter \mathbf{x} and, abusing the notation, tuples will be often used as sets. The logic, besides standard propositional connectives, includes a diamond modality (and, dually, a box modality). The formula $\langle \mathbf{x}, \bar{\mathbf{y}} < \mathbf{a} z \rangle \varphi$ holds when in the current configuration an \mathbf{a} -labelled event e is enabled which causally depends on the events bound to the variables in \mathbf{x} and is concurrent with those in \mathbf{y} . Event e is executed and bound to variable z , and then the formula φ must hold in the resulting configuration.

Fixpoint operators refer to propositional variables. In order to let them interact correctly with event variables, whose values can be passed from an iteration to the next one in the recursion, we use abstract propositions. For dealing with fixpoint operators we fix a denumerable set \mathcal{X}^a of *abstract propositions*, ranged over by X, Y, \dots . Each abstract proposition X has an arity $ar(X)$ and it represents a formula with $ar(X)$ (unnamed) free event variables. Then, for \mathbf{x} such that $|\mathbf{x}| = ar(X)$, we write $X(\mathbf{x})$ to indicate the abstract proposition X whose free event variables are named \mathbf{x} .

► **Definition 6** (hp-logic). *The syntax of \mathcal{L}_{hp} over the sets of event variables Var , abstract propositions \mathcal{X}^a and labels Λ is defined as follows:*

$$\begin{aligned} \varphi ::= & \top \mid \varphi \wedge \varphi \mid \langle \mathbf{x}, \bar{\mathbf{y}} < \mathbf{a} z \rangle \varphi \mid (\mu Z(\mathbf{x}).\varphi)(\mathbf{y}) \mid Z(\mathbf{x}) \mid \\ & \text{F} \mid \varphi \vee \varphi \mid \llbracket \mathbf{x}, \bar{\mathbf{y}} < \mathbf{a} z \rrbracket \varphi \mid (\nu Z(\mathbf{x}).\varphi)(\mathbf{y}) \end{aligned}$$

The free event variables of a formula φ are denoted $fv(\varphi)$ and defined in the obvious way. Just note that the modalities act as binders for the variable representing the event executed, hence $fv(\langle \mathbf{x}, \bar{\mathbf{y}} < \mathbf{a} z \rangle \varphi) = fv(\llbracket \mathbf{x}, \bar{\mathbf{y}} < \mathbf{a} z \rrbracket \varphi) = (fv(\varphi) \setminus \{z\}) \cup \mathbf{x} \cup \mathbf{y}$. The free propositions

in φ , i.e., the propositions not bound by μ , are denoted by $fp(\varphi)$. In fixpoint formulae, like $(\mu X(\mathbf{x}).\varphi)(\mathbf{y})$, we require that the tuple \mathbf{x} does not include multiple occurrences of the same variable and correspond exactly to the free event variables of the inner formula φ , i.e., $fv(\varphi) = \mathbf{x}$. Intuitively, the fixpoint part $\mu X(\mathbf{x}).\varphi$ defines a recursive formula $X(\mathbf{x})$ whose free variables are then instantiated with \mathbf{y} . The formula $(\mu X(\mathbf{x}).\varphi)(\mathbf{x})$ will be abbreviated as $\mu X(\mathbf{x}).\varphi$. When both $fv(\varphi)$ and $fp(\varphi)$ are empty we say that φ is *closed*. When \mathbf{x} or \mathbf{y} are empty they are often omitted, e.g., we write $\langle \mathbf{a} z \rangle \varphi$ for $\langle \emptyset, \bar{\emptyset} < \mathbf{a} z \rangle \varphi$.

Given a formula φ and variables $x, y \in Var$, we denote by $\varphi[y/x]$ the formula obtained from φ via a (capture avoiding) substitution of the free occurrences of x in φ by y . Similarly, given a proposition $Z(\mathbf{x}) \in \mathcal{X}$ and a formula ψ such that $fv(\psi) \subseteq \mathbf{x}$, we denote by $\varphi[Z(\mathbf{x}) := \psi]$ the formula obtained from φ by replacing free occurrences of $Z(\mathbf{y})$ by $\psi[\mathbf{y}/\mathbf{x}]$.

In the logic we can easily represent the possibility of performing concurrent events. Borrowing the notation from [3], we write $(\langle \mathbf{a} z \rangle \otimes \langle \mathbf{b} z' \rangle) \varphi$ for the formula $\langle \mathbf{a} z \rangle \langle \bar{z} < \mathbf{b} z' \rangle \varphi$ that declares the existence of two concurrent events labelled by \mathbf{a} and \mathbf{b} , respectively, such that if we execute such events and bind them to z and z' , respectively, then φ holds.

Consider again the PES in Fig. 1. Let $\psi_{2b} = (\langle \mathbf{b} x \rangle \otimes \langle \mathbf{b} y \rangle) \top$ be the formula stating that two concurrent \mathbf{b} -events can be executed. Then \mathcal{E} satisfies the formula $\langle \mathbf{a} z \rangle \psi_{2b}$, which states that after executing an \mathbf{a} -labelled event one can execute two concurrent \mathbf{b} -labelled events. It satisfies also the formula $\llbracket \mathbf{a} x \rrbracket (\nu X(x).(\psi_{2b} \wedge \llbracket x < \mathbf{a} z \rrbracket X(z)))$ stating that after any causal chain of \mathbf{a} -labelled events ψ_{2b} holds. Instead the formula $\mu X.(\llbracket \mathbf{a} x \rrbracket \otimes \llbracket \mathbf{a} y \rrbracket) \top \vee \langle \mathbf{a} z \rangle X$ that asks for the reachability of a state where two concurrent \mathbf{a} -labelled events can be executed, is false in \mathcal{E} . As a final example, the formula $\langle \mathbf{a} x \rangle (\nu X(x) \langle x < \mathbf{a} y \rangle X(y))$ asks for the existence of an infinite causal chain of \mathbf{a} -labelled events and it is satisfied by \mathcal{E} .

Semantics

Since the logic \mathcal{L}_{hp} is interpreted over PESs, the satisfaction of a formula is defined with respect to a configuration C , representing the state of the computation and an *environment* $\eta : Var \rightarrow E$, that binds free variables in the formula to events in C . Namely, if $Env_{\mathcal{E}}$ denotes the set of environments, the semantics of a formula will be a set of pairs in $\mathcal{C}(\mathcal{E}) \times Env_{\mathcal{E}}$. Given a set of pairs $S \subseteq \mathcal{C}(\mathcal{E}) \times Env_{\mathcal{E}}$ and two tuples of variables \mathbf{x} and \mathbf{y} , with $|\mathbf{x}| = |\mathbf{y}|$, we define $S[\mathbf{y}/\mathbf{x}] = \{(C, \eta') \mid \exists (C, \eta) \in S \wedge \eta(\mathbf{x}) = \eta'(\mathbf{y})\}$. The semantics of \mathcal{L}_{hp} also depends on a proposition environment providing a semantic interpretation for propositions.

► **Definition 7** (proposition environment). *Let \mathcal{E} be a PES. A proposition environment is a function $\pi : \mathcal{X} \rightarrow 2^{\mathcal{C}(\mathcal{E}) \times Env_{\mathcal{E}}}$ such that for all abstract propositions X and tuples of variables \mathbf{x}, \mathbf{y} with $|\mathbf{x}| = |\mathbf{y}| = ar(X)$ it holds $\pi(X(\mathbf{y})) = \pi(X(\mathbf{x}))[\mathbf{y}/\mathbf{x}]$. The set of proposition environments, ranged by π , is denoted $PEnv_{\mathcal{E}}$.*

The condition posed on proposition environments ensures that the semantics of a formula only depends on the events that the environment associates with its free variables and that it does not depend on the naming of the variables.

We can now give the semantics of the logic \mathcal{L}_{hp} . Given an event environment η and an event e we write $\eta[x \mapsto e]$ to indicate the updated environment which maps x to e . Similarly, for a proposition environment π and $S \subseteq \mathcal{C}(\mathcal{E}) \times Env_{\mathcal{E}}$, we write $\pi[Z(\mathbf{x}) \mapsto S]$ for the corresponding update. For a pair $(C, \eta) \in \mathcal{C}(\mathcal{E}) \times Env_{\mathcal{E}}$ and variables $\mathbf{x}, \mathbf{y}, z$, we define the $(\mathbf{x}, \bar{\mathbf{y}} < \mathbf{a} z)$ -successors of (C, η) , as

$$\text{Succ}_{\mathcal{E}}^{\mathbf{x}, \bar{\mathbf{y}} < \mathbf{a} z}(C, \eta) = \{(C', \eta[z \mapsto e]) \mid C \xrightarrow{\eta(\mathbf{x}), \overline{\eta(\mathbf{y})} < e}_{\mathbf{a}} C'\}.$$

13:6 (Un)Decidability for History Preserving True Concurrent Logics

In words $\text{Succ}_{\mathcal{E}}^{\mathbf{x}, \bar{\mathbf{y}} < \mathbf{a}z}(C, \eta)$ consists of the pairs (C', η') where C' is a configuration reachable from C , by executing an event e satisfying the requirement expressed by $\mathbf{x}, \bar{\mathbf{y}} < \mathbf{a}z$, namely events in $\eta(\mathbf{x})$ are causes of e and events in $\eta(\mathbf{y})$ are concurrent with e . The environment η' is the update of η where event e has been bound to variable z .

► **Definition 8 (semantics).** *Let \mathcal{E} be a PES. The denotation of a formula in \mathcal{L}_{hp} is given by the function $\{\cdot\}_{\pi}^{\mathcal{E}} : \mathcal{L}_{hp} \rightarrow PEnv_{\mathcal{E}} \rightarrow 2^{\mathcal{C}(\mathcal{E}) \times Env_{\mathcal{E}}}$ defined inductively as follows, where we write $\{\varphi\}_{\pi}^{\mathcal{E}}$ instead of $\{\varphi\}_{\pi}^{\mathcal{E}}(\pi)$:*

$$\begin{aligned} \{\top\}_{\pi}^{\mathcal{E}} &= \mathcal{C}(\mathcal{E}) \times Env_{\mathcal{E}} & \{\text{F}\}_{\pi}^{\mathcal{E}} &= \emptyset & \{Z(\mathbf{y})\}_{\pi}^{\mathcal{E}} &= \pi(Z(\mathbf{y})) \\ \{\varphi_1 \wedge \varphi_2\}_{\pi}^{\mathcal{E}} &= \{\varphi_1\}_{\pi}^{\mathcal{E}} \cap \{\varphi_2\}_{\pi}^{\mathcal{E}} & \{\varphi_1 \vee \varphi_2\}_{\pi}^{\mathcal{E}} &= \{\varphi_1\}_{\pi}^{\mathcal{E}} \cup \{\varphi_2\}_{\pi}^{\mathcal{E}} \\ \{\langle \mathbf{x}, \bar{\mathbf{y}} < \mathbf{a}z \rangle \varphi\}_{\pi}^{\mathcal{E}} &= \{(C, \eta) \in \mathcal{C}(\mathcal{E}) \times Env_{\mathcal{E}} \mid \text{Succ}_{\mathcal{E}}^{\mathbf{x}, \bar{\mathbf{y}} < \mathbf{a}z}(C, \eta) \cap \{\varphi\}_{\pi}^{\mathcal{E}} \neq \emptyset\} \\ \{\llbracket \mathbf{x}, \bar{\mathbf{y}} < \mathbf{a}z \rrbracket \varphi\}_{\pi}^{\mathcal{E}} &= \{(C, \eta) \in \mathcal{C}(\mathcal{E}) \times Env_{\mathcal{E}} \mid \text{Succ}_{\mathcal{E}}^{\mathbf{x}, \bar{\mathbf{y}} < \mathbf{a}z}(C, \eta) \subseteq \{\varphi\}_{\pi}^{\mathcal{E}}\} \\ \{\nu Z(\mathbf{x}).\varphi\}_{\pi}^{\mathcal{E}} &= \nu(f_{\varphi, Z(\mathbf{x}), \pi}) & \{\mu Z(\mathbf{x}).\varphi\}_{\pi}^{\mathcal{E}} &= \mu(f_{\varphi, Z(\mathbf{x}), \pi}) \end{aligned}$$

where $f_{\varphi, Z(\mathbf{x}), \pi} : 2^{\mathcal{C}(\mathcal{E}) \times Env_{\mathcal{E}}} \rightarrow 2^{\mathcal{C}(\mathcal{E}) \times Env_{\mathcal{E}}}$ is the function defined by $f_{\varphi, Z(\mathbf{x}), \pi}(S) = \{\varphi\}_{\pi[Z(\mathbf{x}) \mapsto S]}^{\mathcal{E}}$, that we refer to as the semantic function of φ , $Z(\mathbf{x})$, π . Moreover, $\alpha(f_{\varphi, Z(\mathbf{x}), \pi})$, for $\alpha \in \{\mu, \nu\}$, denotes the corresponding (least or greatest) fixpoint. When $(C, \eta) \in \{\varphi\}_{\pi}^{\mathcal{E}}$ we say that the PES \mathcal{E} satisfies the formula φ in the configuration C and environments η, π .

The semantics of boolean connectives is standard. The formula $\langle \mathbf{x}, \bar{\mathbf{y}} < \mathbf{a}z \rangle \varphi$ holds in (C, η) when configuration C enables an \mathbf{a} -labelled event e that is causally dependent on (at least) the events bound to the variables in \mathbf{x} and concurrent with (at least) those bound to the variables in \mathbf{y} and can be executed producing a new configuration $C' = C \cup \{e\}$ which, paired with the environment $\eta' = \eta[z \mapsto e]$, satisfies φ . The semantics of $\llbracket \mathbf{x}, \bar{\mathbf{y}} < \mathbf{a}z \rrbracket \varphi$ is dual. When φ is closed (so that the environments η, π are irrelevant) and \mathcal{E} satisfies the formula φ in the empty configuration, we simply say that \mathcal{E} satisfies φ .

4 Undecidability of \mathcal{L}_{hp}

In this section we study the satisfiability problem for the logic \mathcal{L}_{hp} , i.e., the problem of determining whether a closed formula in \mathcal{L}_{hp} is satisfied by some (image-finite) PES. We prove it to be undecidable by reduction from domino tilings.

Domino systems

Tiling problems are a simple and general form of combinatorial problems introduced in [39, 40] for proving the unsolvability of the $\forall\exists\forall$ -prefix class in the pure predicate calculus. Along the years they revealed to be a powerful tool for proving undecidability results for fragments of first-order logic and for decision problems in mathematical theories (see, e.g., [10]).

► **Definition 9 (dominoes).** *A domino system is a tuple $\mathcal{D} = (D, H, V)$ where D is a finite set and $H, V \subseteq D^2$ are binary relations.*

The elements of D should be thought of as square tiles (called domino pieces, or *Wang tiles*) with a color on each side and a fixed orientation. Hence for $d, e \in D$ read $(d, e) \in V$, or dVe , as “ e can stand immediately above d ” because the upper color of d and the lower color of e are the same. Similarly $(d, e) \in H$, or dHe , should be read as “the left side of e can be attached to the right side of d ”. A tiling is thus a covering of $\mathbb{N} \times \mathbb{N}$ thought as an infinite board on which each point is a spot to be occupied by a domino.

The plane $\mathbb{N} \times \mathbb{N}$ together with the binary relations $H = \{(p, q), (p+1, q) : p, q \in \mathbb{N}\}$ and $V = \{(p, q), (p, q+1) : p, q \in \mathbb{N}\}$ can be seen as domino system referred to as the *grid* $\mathfrak{S}_{\mathbb{N}}$. Given two domino systems $\mathcal{D} = (D, H, V)$ and $\mathcal{D}' = (D', H', V')$ a homomorphism $f : \mathcal{D} \rightarrow \mathcal{D}'$ is a function $f : D \rightarrow D'$ such that for all $(d_1, d_2) \in H$ it holds that $(f(d_1), f(d_2)) \in H'$ and, similarly, for all $(d_1, d_2) \in V$ it holds that $(f(d_1), f(d_2)) \in V'$. Tilings can be then formalised relying on the notion of homomorphism.

► **Definition 10** (tiling). *A tiling of a domino system \mathcal{D} is a homomorphism $T : \mathfrak{S}_{\mathbb{N}} \rightarrow \mathcal{D}$.*

Given a tiling $T : \mathfrak{S}_{\mathbb{N}} \rightarrow \mathcal{D}$, intuitively $T(p, q) = d$ means that the point (p, q) is filled with a copy of the piece d . Our undecidability proof relies on the following well-known result about domino tilings.

► **Theorem 11** (undecidability of tiling [8]). *The problem of establishing the existence of a tiling for a given domino system is undecidable.*

Reduction from Domino Tiling

In order to show that \mathcal{L}_{hp} is undecidable, we associate with each domino system a formula of \mathcal{L}_{hp} such that the formula is satisfiable if and only if the domino system admits a tiling.

For various fragments of first-order logic (even with only two variables), the approach consists in using suitable unary predicates to establish a correspondence between elements of the model and domino pieces, and binary predicates to represent adjacency. For example, undecidability results for two-variables logics are obtained in [26, 22] using in a crucial way the transitivity of some predicates in the chosen relational vocabulary. A suitable interplay between existential and universal quantifications allows to build formulae whose models are *grid-like*, i.e., such that $\mathfrak{S}_{\mathbb{N}}$ can be embedded into these models.

Similarly, the idea here is to embed the grid inside a PES. Events are associated, via their label, with pieces of the domino and adjacency is suitably represented with arrangements of causality and concurrency between events. This is far from trivial since formulae of the logic can refer only to events enabled in the current configuration and execute them, checking their relations with (a limited number) of past events. As a consequence, quantification has a “local” nature and only the relations between consistent events can be inspected. This is quite a subtle point, since similar restrictions upon quantifications can yield decidable logics, like the guarded fragment with transitive guards studied in [35].

Greatest fixpoints like $(\nu X(\mathbf{x}).\varphi)(\mathbf{y})$ can be used to ensure that what is being predicated by $\varphi(\mathbf{x})$ holds repeatedly throughout an unbounded number of reachable configurations. For a given domino system, we define formulae that verify the proper adjacency of pieces by exploring the events along diagonal slices of the grid, starting from the bottom row and ending at the leftmost column. All slices are finite causal chains but overall they grow unboundedly in length. The formula for a domino system is quite complex and not immediate to read, but the underlying intuition will be explained in detail after the definition.

► **Definition 12** (formula for a domino). *Let \mathcal{D} be a domino system with $D = \{d_1, \dots, d_n\}$. Define the set of $6n$ labels $A = \{b_k^s \mid b \in \{a, i, j\} \wedge k \in \{1, \dots, n\} \wedge s \in \{0, 1\}\}$. For $s \in \{0, 1\}$ we let \bar{s} abbreviate $1 - s$. Consider the following formulae (1)–(4).*

$$\bigvee_{\substack{d_k \text{ H } d_h \\ d_k \text{ V } d_v}} \langle i_k^0 x \rangle \langle x < i_h^1 y \rangle \langle y < j_v^1 z \rangle \top \quad (1)$$

$$\begin{aligned}
 & \bigwedge_{\substack{b \in \{a, j\} \\ d_k, d_l \in D \\ s \in \{0, 1\}}} \llbracket i_k^s x \rrbracket \llbracket x < b_l^s y \rrbracket (\nu X(x, y, z)). \\
 & \bigvee_{d_k H d_h} \langle x, \bar{y} < i_h^{\bar{s}} u \rangle \top \wedge \bigwedge_{\substack{c \in \{a, j\} \\ d_m \in D}} \llbracket z < c_m^s v \rrbracket X(x, y, v))(x, y, y)
 \end{aligned} \tag{2}$$

$$\begin{aligned}
 & \bigwedge_{\substack{b \in \{a, i\} \\ c \in \{a, j\} \\ d_l, d_m \in D \\ d_k H d_h \\ s \in \{0, 1\}}} \llbracket b_k^s x \rrbracket \llbracket x < a_l^s y \rrbracket \llbracket y < c_m^s z \rrbracket \llbracket x, \bar{y} < b_h^{\bar{s}} w \rrbracket (\nu X(y, z, w, u)). \\
 & \bigvee_{\substack{d_k V d_p \\ d_l H d_p}} \langle y, w, \bar{z} < a_p^{\bar{s}} r \rangle \top \wedge \bigwedge_{\substack{e \in \{a, j\} \\ d_q \in D}} \llbracket u, \bar{w} < e_q^s v \rrbracket X(y, z, w, v))(y, z, w, z)
 \end{aligned} \tag{3}$$

$$\begin{aligned}
 & \bigwedge_{\substack{b \in \{a, i\} \\ d_l \in D \\ d_k H d_h \\ s \in \{0, 1\}}} \llbracket b_k^s x \rrbracket \llbracket x < j_l^s y \rrbracket \llbracket x, \bar{y} < b_h^{\bar{s}} z \rrbracket \bigvee_{\substack{d_k V d_p \\ d_l H d_p \\ d_l V d_q}} \langle y, z < a_p^{\bar{s}} v \rangle \langle v < j_q^{\bar{s}} w \rangle \top
 \end{aligned} \tag{4}$$

Calling ψ_i the corresponding formula (i) above, we denote the formula for the domino system \mathcal{D} by $\varphi_{\mathcal{D}} = \psi_1 \wedge \nu Z.(\psi_2 \wedge \psi_3 \wedge \psi_4 \wedge \llbracket A z \rrbracket Z)$, where we write $\llbracket A z \rrbracket Z$ for $\bigwedge_{b_k^s \in A} \llbracket b_k^s z \rrbracket Z$.

Intuitively, the formula $\varphi_{\mathcal{D}}$ requires a model to contain a grid of consistent events, as depicted in Fig. 2. The formula also arranges causal dependencies that constrain the order of exploration, i.e., of execution, of the grid as an ever growing right-angled triangle. This allows to build the grid one diagonal at a time, starting from the leftmost smallest diagonal which consists of a single event at coordinates (0, 0) in Fig. 2. Every diagonal, except the first, is delimited by two events with special labels: the first at the bottom of the diagonal is labelled i , the last at the top is labelled j . Inner events are, instead, all labelled a . Actually, labels include also a subscript and a superscript. Subscripts $k \in \{1, \dots, n\}$ represent the associated domino piece d_k . Superscripts $s \in \{0, 1\}$, instead, are used to distinguish events in a diagonal from those in the next and previous ones. So the superscript for all the events in a diagonal starting at coordinates $(t, 0)$ is simply $s = t \bmod 2$, as shown in the figure.

To explain how the formula works we first comment on how the satisfaction of the formula implies the existence of a grid in the model. For this, the superscripts on labels play no role and can be safely ignored. They will become relevant later for the converse implication.

The first two diagonals are determined by the first subformula ψ_1 (1). This formula simply requires the existence of three events, executable from the initial state, such that each one causes the next. Such events represent the first three domino pieces in the tiling. So, they are required to be labelled i_k, i_h, j_v , in a way that the adjacency constraints are respected, i.e., $d_k H d_h$ and $d_k V d_v$. Each diagonal beyond the first two is, instead, jointly defined by the other three subformulae ψ_2, ψ_3, ψ_4 , which are guaranteed to be checked on every reachable state of the computation via the outermost greatest fixpoint of $\varphi_{\mathcal{D}}$.

In Fig. 3 we give a graphical representation of such three subformulae. In each sub-figure, greyed out events represent the configuration to which the subformula is intended to apply. Events highlighted in red are universally quantified by box operators in the formula, while events highlighted in blue are existentially quantified by diamond operators. The picture also reports, close to events, the variables to which such events are bound in the formula.

The subformula ψ_2 (2) starts a new diagonal. The first event in the new diagonal must be labelled i_p , for some domino piece d_p horizontally compatible with the one corresponding to the first event in the previous diagonal, labelled i_l in the figure. Moreover, the new event i_p must be caused by i_l and concurrent with the second event in the previous diagonal, labelled a_m in the figure. In addition, using a fixpoint subformula, we ask that the new event is executed after (hence consistent with) the whole red diagonal. This implies that i_p is necessarily concurrent with all the events in the red diagonal, although not explicitly required. In fact, since it is consistent and executed after the diagonal, the only alternative would be that i_p were caused by some event in the diagonal. But this would mean that also a_m causes i_p , while we know that they are concurrent.

The subformula ψ_3 (3) continues the “construction” of the new diagonal starting from the second event and, with each successive application, up to the third-to-last event of the new diagonal. Basically, it builds the a -labelled part of the new diagonal, except the last a -labelled event. In particular, a single application of ψ_3 ensures the executability of an event labelled a_q , for some domino piece d_q vertically compatible with the one corresponding to the event just below in the grid, which is necessarily part of the previous diagonal, labelled i_l in the figure, and horizontally compatible with the one just after the latter in the previous diagonal, that is a_m in the example. The new event a_q must be caused by the one just before it in the new diagonal, i_p in this case. Furthermore, as in the previous property, the new event must be caused by the event a_m at the same height in the previous diagonal, and concurrent with the events coming after it in such diagonal.

Finally, the subformula ψ_4 (4) concludes the construction of the new diagonal, requiring the executability of the last two events labelled a_s and j_t , respectively. As before, the corresponding domino pieces d_s and d_t must be compatible with those of the adjacent events below and on the left, all of which belonging to the previous diagonal. Moreover, the new event a_s must be caused by the one just before it in the new diagonal and by the last event of the previous diagonal. Instead, j_t is just required to be caused by a_s , which, however, by transitivity of the causality relation, means that j_t is caused by every other event in the new diagonal and all those in the previous diagonals.

■ **Figure 2** Grid of events for the domino tiling (with simplified event labels).

13:10 (Un)Decidability for History Preserving True Concurrent Logics

■ **Figure 3** Graphical representation of the properties, from left to right, (2), (3) and (4).

Note that the subformulae ψ_2 and ψ_3 use a (greatest) fixpoint in order to fully explore a diagonal, which is unbounded. This ensures the consistency of each newly added event with the previous diagonal and thus with the whole right-angled triangle up to such diagonal.

Relying on the intuitions described above we can prove the desired result: given a domino system \mathcal{D} , the formula $\varphi_{\mathcal{D}}$ is satisfiable if and only if \mathcal{D} admits a tiling. We next present a sketch of the proof.

For proving the first implication we show how, given a PES which satisfies the formula $\varphi_{\mathcal{D}}$, one can build a tiling for the domino system \mathcal{D} . Recall that a tiling of \mathcal{D} is a function $T : \mathbb{N} \times \mathbb{N} \rightarrow D$ complying with the adjacency relations H and V of \mathcal{D} . Proceeding, as mentioned before, by diagonals, we can inductively define an infinite chain of functions f_i , for all $i \in \mathbb{N}^+$, whose domain is the right-angled triangle up to the $(i + 1)$ -th diagonal, i.e. $\{(x, y) \in \mathbb{N} \times \mathbb{N} \mid x + y \leq i\}$. The first function f_1 is obtained directly from the events guaranteed to exist by the satisfaction of the subformula ψ_1 of $\varphi_{\mathcal{D}}$. Every other function f_i is defined extending f_{i-1} and using the events whose existence is required by the other subformulae of $\varphi_{\mathcal{D}}$. The join of the f_i 's is defined on the whole grid and provides a tiling.

► **Theorem 13** (satisfiability implies tiling). *Let \mathcal{D} be a domino system with $D = \{d_1, \dots, d_n\}$, if the corresponding formula $\varphi_{\mathcal{D}}$ is satisfiable, then \mathcal{D} admits a tiling.*

For the converse implication, we need to show how to transform a tiling T of \mathcal{D} into a PES which satisfies the property $\varphi_{\mathcal{D}}$. From the grid of domino pieces corresponding to the tiling T we define a PES \mathcal{E} whose events are $E = \mathbb{N} \times \mathbb{N}$. Events are labelled i_k^s if they belong to the bottom row, j_k^s if in the left-most column, except $(0, 0)$, or a_k^s otherwise, where k is the subscript of the corresponding domino piece d_k occupying the same position, and s is the index corresponding to the diagonal to which the event belongs. Explicitly, if the coordinates of the event are (x, y) , then the index is $s = (x + y) \bmod 2$, hence it is the same for all the events in a same diagonal. The PES has empty conflict relation, while causality is defined as in Fig. 4. In this way, every event

- is caused exactly by those at lower or equal height in the smallest right-angled triangle containing the event,
- causes those at higher or equal height outside of such triangle or above the event along its diagonal,
- is concurrent with all the others.

For instance, consider the event at position $(4, 2)$ in Fig. 4, labelled a_k^0 . It is caused by the events highlighted in red, it causes those highlighted in green, and it is concurrent with those highlighted in blue. It is easy to see that \mathcal{E} is well-defined, i.e. it is a PES, in fact, the set of causes of each event is clearly finite. Moreover, \mathcal{E} is image-finite since every configuration enables a finite number of events (bounded by 1 plus half the size of the configuration).

■ **Figure 4** PES for the canonical grid of the domino tiling (with simplified event labels).

Formalising the ideas outlined above, one can prove that $\varphi_{\mathcal{D}}$ holds in the initial state of \mathcal{E} . In particular, the formulae ψ_2 , ψ_3 and ψ_4 , inside the outermost fixpoint, can be shown to hold in every reachable state, sometimes vacuously. For example, consider the configuration C consisting of all the events appearing in Fig. 4 except those highlighted in green. Let us focus on the subformula ψ_3 (3) and argue that it holds in configuration C . Observe that the initial three box modalities in ψ_3 require a specific structure to be executable, in absence of which the formula holds vacuously. Such structure consists of a causal chain of three events, labelled with some combination of letters i, a, j but all with the same superscript s . Inspecting the structure in the figure, it occurs that there are only two possible causal chains of three events executable from C : both starting with $(4, 2)$, and then going either along its diagonal up to $(2, 4)$, or along its row up to $(6, 2)$. However, since the three events must be labelled with the same superscript s , only the chain along the diagonal is actually considered by the formula (along rows events alternate superscripts instead). Then, exploiting the similarities with the graphical representation of ψ_3 in Fig. 3b, it is possible to see that after binding those events the rest of the property holds.

► **Theorem 14** (tiling implies satisfiability). *Let \mathcal{D} be a domino system with $D = \{d_1, \dots, d_n\}$, if \mathcal{D} admits a tiling, then the formula $\varphi_{\mathcal{D}}$ is satisfiable.*

By the theorems above and the undecidability of the domino problem we conclude.

► **Corollary 15** (undecidability of \mathcal{L}_{hp}). *The satisfiability problem for \mathcal{L}_{hp} is undecidable.*

5 Decidability without fixpoints

In this section we show that, in absence of fixpoint operators, the logic \mathcal{L}_{hp} has the finite model property. Moreover, we provide an encoding of formulae into first-order logic preserving their (un)satisfiability. As a consequence we deduce tha satisfiability for the logic without fixpoints becomes decidable.

In the following we will denote by \mathcal{L}_{hp}^f the fragment of the logic \mathcal{L}_{hp} without fixpoint operators (and propositions). Consequently, the semantics of formulae in \mathcal{L}_{hp}^f can be defined without proposition environments π , since there are no propositions to interpret.

13:12 (Un)Decidability for History Preserving True Concurrent Logics

In order to prove the finite model property the idea consists in showing that every model of a formula can be reduced to a finite one by restricting to a suitable chosen subset of events. To this aim, we introduce a way to truncate PESs by keeping only events up to a certain causal level and with a specific subset of labels. The causal level of an event e is inductively defined as $lev(e) = \max\{lev(e') + 1 \mid e' \in E \wedge e' < e\}$, where it is intended that $\max \emptyset = 0$.

► **Definition 16** (prefix of a PES). *Let E be a PES. For $k \in \mathbb{N}$ and $A \subseteq \Lambda$, consider the set of events $E^{(A,k)} = \{e \in E \mid lev(e) \leq k \wedge \forall e' \in [e]. \lambda(e') \in A\}$. Then, the A -labelled k -prefix of \mathcal{E} is the PES defined as $\mathcal{E}^{(A,k)} = \langle E^{(A,k)}, <|_{E^{(A,k)}}, \#|_{E^{(A,k)}} \rangle$.*

Note that, by the very definition of causal level, $lev(e') < lev(e)$ for all $e' < e$; hence, the (A -labelled) k -prefix $\mathcal{E}^{(A,k)}$ of a PES \mathcal{E} is a causally closed subset of \mathcal{E} . From this observation, it immediately follows that $\mathcal{E}^{(A,k)}$ is indeed a PES, i.e., the definition is well-given.

Notably, when a PES is image-finite, the same holds for all its prefixes. Hence, for every $k \in \mathbb{N}$ and finite A , the A -labelled k -prefix $\mathcal{E}^{(A,k)}$ can be shown to be finite.

► **Lemma 17** (finiteness of prefixes). *Let \mathcal{E} be a image-finite PES. For all $k \in \mathbb{N}$ and $A \subseteq \Lambda$, if A is finite, then $\mathcal{E}^{(A,k)}$ is finite.*

Now, in order to prove the finite model property of \mathcal{L}_{hp}^f it is enough to show that the satisfaction of formulae of \mathcal{L}_{hp}^f is preserved when truncating a PES up to a suitable level k and set of labels A . Both k and A can be obtained directly from the formula. Let the *modal depth* of a formula φ , denoted by $d(\varphi)$, be defined as usual. If φ is \top or F , its modal depth is 0. If it is a conjunction or disjunction, the modal depth is the maximum of those of the conjuncts, resp. disjuncts. Otherwise, when φ consists of a modality followed by a subformula ψ , the modal depth is $d(\varphi) = 1 + d(\psi)$. Let $A(\varphi)$ be the (finite) set of labels appearing in the formula φ . Then, whenever a formula φ is satisfied by a PES \mathcal{E} , it is also satisfied by the $A(\varphi)$ -labelled $d(\varphi)$ -prefix of \mathcal{E} , which, by the previous lemma, is finite.

► **Theorem 18** (finite model property of \mathcal{L}_{hp}^f). *Let φ be a closed formula of \mathcal{L}_{hp}^f . If φ is satisfiable, then there exists a finite PES satisfying φ .*

The result above implies that satisfiability for \mathcal{L}_{hp}^f is semi-decidable. In fact, finite PESs are denumerable and checking whether a finite PES satisfies a formula is decidable. Then, to conclude it is sufficient to observe that the axioms of PESs are expressible as first-order formulae and \mathcal{L}_{hp}^f , as it happens for many modal logics, can be encoded into first-order logic, hence also unsatisfiability is semi-decidable.

First, as mentioned, for a fixed formula in \mathcal{L}_{hp}^f the set of labels appearing in it is finite. Once the finite set of labels A is fixed, the theory of prime event structures, apart from the axiom of finite causes, is expressible as a finite set of first-order axioms.

► **Definition 19** (first-order theory of PESs). *Let $A \subseteq \Lambda$ be a finite set of labels. The first order theory of theory of PESs over A , consists of the following axioms with $<$ and $\#$ as binary predicates and labels as unary predicates.*

1. $\forall x, y, z. (x < y) \wedge (y < z) \rightarrow (x < z)$
2. $\forall x. \neg(x < x)$
3. $\forall x. \neg(x \# x)$
4. $\forall x, y. (x \# y) \rightarrow (y \# x)$
5. $\forall x, y, z. (x < y) \wedge (x \# z) \rightarrow (y \# z)$
6. $\forall x. \left(\bigvee_{a \in A} a(x) \wedge \bigwedge_{a, b \in A, a \neq b} \neg(a(x) \wedge b(x)) \right)$

We denote by $T_{PES}(A)$ the conjunction of the above axioms.

Axioms (1) and (2) state that $<$ is a (strict) partial order. Axioms (3) and (4) ask conflict $\#$ to be irreflexive and symmetric, while (5) requires conflict to be inherited along causality. Finally (6) asks that each event has exactly one label.

Now, given a set of variables $X \subseteq \text{Var}$ and a variable $y \in \text{Var}$, let us write $y \in X$ as an abbreviation for $\bigvee_{x \in X} (x = y)$. Then we can express the property of being a configuration as:

$$\begin{aligned} \text{conf}(X) \equiv & \forall x, y. ((x \in X) \wedge (y < x) \rightarrow (y \in X)) \wedge \\ & \forall x, y. ((x \# y) \rightarrow \neg((x \in X) \wedge (y \in X))) \end{aligned}$$

We can finally provide the translation of \mathcal{L}_{hp}^f into first-order formulae.

► **Definition 20** (compiling \mathcal{L}_{hp}^f to first-order logic). *Let X be a finite set of variables and let φ be a formula of \mathcal{L}_{hp}^f . We denote by $(\varphi)_X$ the first-order formula inductively defined as follows:*

- $(\top)_X = \top$ and $(\text{F})_X = \text{F}$
- $(\varphi \wedge \psi)_X = (\varphi)_X \wedge (\psi)_X$ and $(\varphi \vee \psi)_X = (\varphi)_X \vee (\psi)_X$
- $(\langle \mathbf{x}, \bar{\mathbf{y}} < \mathbf{a} z \rangle \varphi)_X = \exists z. \bigwedge_{x \in \mathbf{x}} (x < z) \wedge \bigwedge_{y \in \bar{\mathbf{y}}} \neg(y < z) \wedge \mathbf{a}(z) \wedge \neg(z \in X) \wedge \text{conf}(X \cup \{z\}) \wedge (\varphi)_{X \cup \{z\}}$
- $(\llbracket \mathbf{x}, \bar{\mathbf{y}} < \mathbf{a} z \rrbracket \varphi)_X = \forall z. (\bigwedge_{x \in \mathbf{x}} (x < z) \wedge \bigwedge_{y \in \bar{\mathbf{y}}} \neg(y < z) \wedge \mathbf{a}(z) \wedge \neg(z \in X) \wedge \text{conf}(X \cup \{z\})) \rightarrow (\varphi)_{X \cup \{z\}}$

Then, given a closed formula φ of the logic \mathcal{L}_{hp}^f we can obtain an equisatisfiable first-order formula by taking the conjunction of the first order theory of PESs and the encoding of φ defined above.

► **Proposition 21.** *Let φ be a closed formula of \mathcal{L}_{hp}^f and let A be the set of labels occurring in φ . It holds that φ is satisfiable iff the first-order formula $T_{PES}(A) \wedge (\varphi)_\emptyset$ is satisfiable.*

The proof is straightforwardly based on the observation that a PES \mathcal{E} satisfying φ can be seen as a first-order structure satisfying $T_{PES}(A) \wedge (\varphi)_\emptyset$, and vice versa. The only delicate aspects is the absence of the axiom of finite causes in $T_{PES}(A)$. Hence, it could happen that $T_{PES}(A) \wedge (\varphi)_\emptyset$ is satisfiable by a structure which, seen as a PES \mathcal{E} , includes events with infinitely many causes. However, in this case, since these events would never be executable, it is clear that also the PES \mathcal{E}' obtained from \mathcal{E} by removing all events with infinitely many causes is a model for φ .

We can finally deduce that the satisfiability for \mathcal{L}_{hp}^f is decidable.

► **Corollary 22** (decidability of \mathcal{L}_{hp}^f). *The satisfiability problem for the logic fragment \mathcal{L}_{hp}^f is decidable and every satisfiable formula has a finite model.*

The proof combines the results proved above. First, by Theorem 18, when a formula φ in \mathcal{L}_{hp}^f is satisfiable it has a finite model labelled over the finite set A of labels occurring in φ . Since the finite PESs labelled over a finite alphabet are denumerable and checking whether a finite PES satisfies a formula is decidable, we can semi-decide satisfiability of a formula φ by enumerating the finite PESs labelled over A and checking whether each of the generated PES satisfies φ . Moreover, by Proposition 21, unsatisfiability of a formula φ in \mathcal{L}_{hp}^f is reducible to unsatisfiability of the first-order formula $T_{PES}(A) \wedge (\varphi)_\emptyset$, and thus it is semi-decidable. We conclude that satisfiability for \mathcal{L}_{hp}^f is decidable.

6 Conclusions and Perspectives

The logic \mathcal{L}_{hp} investigated in this paper is one of a number of fragments of a logic introduced in [3]. Other fragments \mathcal{L}_p and \mathcal{L}_s can be obtained by syntactical restrictions, characterising coarser true concurrent notions of bisimilarity, namely pomset and step bisimilarity. The full logic, instead, corresponds to hereditary hp-bisimilarity, the finest behavioural equivalence in the true concurrent spectrum of [37], finer than hp-bisimilarity. Each logic fragment admits a variant with fixpoints and a variant without fixpoints. However, the induced logical equivalences for image-finite PESs are the same with or without fixpoints. We proved that the satisfiability problem for \mathcal{L}_{hp} is undecidable, and thus the same holds also for the logic for hereditary hp-bisimilarity in [3]. On the other hand, satisfiability is decidable for \mathcal{L}_{hp}^f , the fragment of \mathcal{L}_{hp} without fixpoints.

Some preliminary investigations suggest that the step logic \mathcal{L}_s (with fixpoints) is decidable via a reduction to the propositional μ -calculus. The same technique appears to be promising for the pomset logic \mathcal{L}_p (with fixpoints) but this case is more complex and unresolved to this day. Similar logics for true concurrent properties are event identifier logic of [30] and the mu-calculi for true concurrency in [18, 16, 17]. Also in this case, to the best of our knowledge satisfiability has not yet been investigated. This offers a range of open questions that, when answered, would draw an interesting picture of problems across the decidability border.

In a sense there are “two dimensions” to the satisfiability problem: one is the syntax and the other the semantics, so that there are also many interesting variants and facets of the satisfiability question when the restrictions are imposed on the model side. For example a notable semantics is that of *regular* models in the sense of [36]. Investigating whether restricting the semantics with the constraint of regularity affects decidability is an intriguing direction of future work.

A formalisation of the semantics of the logics in terms of suitable (parity) games is often a source of inspiration for facing complexity and decidability issues for modal logics. Currently, there is no established game-theoretical characterisation of the semantics of the logic in [3], of which \mathcal{L}_{hp} is a fragment. However, such a development could be naturally guided by the approach in [16, 17] and by the relation between fixpoint games [4] and logics for concurrency, hinted at in [28]. This also appears as an interesting route to explore.

Abstract

We develop new algorithmic methods with provable guarantees for feature selection in regard to categorical data clustering. While feature selection is one of the most common approaches to reduce dimensionality in practice, most of the known feature selection methods are heuristics. We study the following mathematical model. We assume that there are some inadvertent (or undesirable) features of the input data that unnecessarily increase the cost of clustering. Consequently, we want to select a subset of the original features from the data such that there is a small-cost clustering on the selected features. More precisely, for given integers ℓ (the number of irrelevant features) and k (the number of clusters), budget B , and a set of n categorical data points (represented by m -dimensional vectors whose elements belong to a finite set of values Σ), we want to select $m - \ell$ relevant features such that the cost of any optimal k -clustering on these features does not exceed B . Here the cost of a cluster is the sum of Hamming distances (ℓ_0 -distances) between the selected features of the elements of the cluster and its center. The clustering cost is the total sum of the costs of the clusters.

We use the framework of parameterized complexity to identify how the complexity of the problem depends on parameters k , B , and $|\Sigma|$. Our main result is an algorithm that solves the Feature Selection problem in time $f(k, B, |\Sigma|) \cdot m^{g(k, |\Sigma|)} \cdot n^2$ for some functions f and g . In other words, the problem is fixed-parameter tractable parameterized by B when $|\Sigma|$ and k are constants. Our algorithm for Feature Selection is based on a solution to a more general problem, Constrained Clustering with Outliers. In this problem, we want to delete a certain number of outliers such that the remaining points could be clustered around centers satisfying specific constraints. One interesting fact about Constrained Clustering with Outliers is that besides Feature Selection, it encompasses many other fundamental problems regarding categorical data such as Robust Clustering, Binary and Boolean Low-rank Matrix Approximation with Outliers, and Binary Robust Projective Clustering. Thus as a byproduct of our theorem, we obtain algorithms for all these problems. We also complement our algorithmic findings with complexity lower bounds.

1 Introduction

Clustering is one of the most fundamental concepts in data mining and machine learning. A considerable challenge to the clustering approaches is the high dimensionality of modern datasets. When the data contains many irrelevant features (or attributes), an application of cluster analysis with a complete set of features could significantly decrease the solution's quality. The typical approach to overcome this challenge in practice is *feature selection*. The method is based on selecting a small subset of relevant features from the data and applying the clustering algorithm only on the selected features. The survey of [1] provides a comprehensive overview on methods for feature selection in clustering. Due to the significance of feature selection, there is a multitude of heuristic methods addressing the problem. However, very few provably correct methods are known [6, 7, 11].

Kim et al. [20] introduced a model of feature selection in the context of k -means clustering. We use their motivating example here. Decision-making based on market surveys is a pragmatic marketing strategy used by manufacturers to increase customer satisfaction. The respondents of a survey are segmented into similar-interest groups so that each group of customers can be treated in a similar way. Consider such a market survey data that typically contains responses of customers to a set of questions regarding their demographic and psychographic information, shopping experience, attitude towards new products and expectations from the business. The standard practice used by market managers to segment customers is to apply clustering techniques w.r.t. the whole set of features. However, depending on the application, responses corresponding to some of the features might not be relevant to find the target set of market segments. Also, some of the responses might contain incomplete or spurious information. To address this issue, Kim et al. [20] considered several quality criteria to return *Pareto* optimal (or non-dominated) solutions that optimize one or more criteria. One such solution removes a suitable subset of features and cluster the data w.r.t. the remaining features.

The main objective of this work is to study clustering problems on *categorical* data. In statistics, a categorical variable is a variable that can admit a fixed number of possible values. For example, it could be a gender, blood type, political orientation, etc. A prominent example of categorical data is binary data where the points are vectors each of whose coordinates can take value either 0 or 1. Binary data arise in several important applications. In electronic commerce, each transaction can be modeled as a binary vector (known as market basket data) each of whose coordinates denotes whether a particular item is purchased or not [32, 22]. The most common similarity (or dissimilarity) measure for categorical data objects is the Hamming distance, which is basically the number of mismatched attributes of the objects.

2 Our results

In this paper, we introduce a new model of feature selection w.r.t. categorical data clustering, which is motivated by the work of Kim et al. [20]. We assume that there are some inadvertent features of the input data that unnecessarily increase the cost of clustering. Consequently, in our model, we define the best subset of features (of a given size) as the subset that minimizes the corresponding cost of clustering. The goal is to compute such a subset and the respective clusters. We provide the first parameterized algorithmic and complexity results for feature selection in regard to categorical data clustering.

Let Σ be a finite set of non-negative integers. We refer to Σ as the alphabet and we denote the m -dimensional space over Σ by Σ^m . Given two m -dimensional vectors $\mathbf{x}, \mathbf{y} \in \Sigma^m$, the *Hamming distance* (or ℓ_0 -distance) $d_H(\mathbf{x}, \mathbf{y})$ is the number of different coordinates in \mathbf{x} and

\mathbf{y} , that is $d_H(\mathbf{x}, \mathbf{y}) = |\{i \in \{1, \dots, m\} : \mathbf{x}[i] \neq \mathbf{y}[i]\}|$. For a set of indices $S \subset \{1, 2, \dots, m\}$ and an $m \times n$ matrix \mathbf{A} , let \mathbf{A}^{-S} be the matrix obtained from \mathbf{A} by removing the rows with indices in S . We denote the columns of \mathbf{A}^{-S} by \mathbf{a}_{-S}^j for $1 \leq j \leq n$. We consider the following mathematical model of feature selection.

FEATURE SELECTION

Input: An alphabet Σ , an $m \times n$ matrix \mathbf{A} with columns $\mathbf{a}^1, \mathbf{a}^2, \dots, \mathbf{a}^n$ such that $\mathbf{a}^j \in \Sigma^m$ for all $1 \leq j \leq n$, a positive integer k , non-negative integers B and ℓ .

Task: Decide whether there is a subset $O \subset \{1, 2, \dots, m\}$ of size at most ℓ , a partition $\{I_1, I_2, \dots, I_k\}$ of $\{1, 2, \dots, n\}$, and vectors $\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_k \in \Sigma^{m-|O|}$ such that

$$\sum_{i=1}^k \sum_{j \in I_i} d_H(\mathbf{a}_{-O}^j, \mathbf{c}_i) \leq B.$$

In the above definition and all subsequent problem definitions, without loss of generality, we assume that each cluster is non-empty, i.e., $I_i \neq \emptyset$ for each $1 \leq i \leq k$. Note that, otherwise, one could probe different values $k' < k$ for the actual number of non-empty clusters. The problem is defined as a decision problem, however if the instance is a yes-instance we would also like to find such a clustering. For $\ell = 0$, FEATURE SELECTION is the popular BINARY k -CLUSTERING problem, which is known to be NP-hard for every $k \geq 2$ [13]. This makes it natural to investigate the parameterized complexity of FEATURE SELECTION.

Our main result is the following theorem.

► **Theorem 1.** *FEATURE SELECTION is solvable in time $f(k, B, |\Sigma|) \cdot m^{g(k, |\Sigma|)} \cdot n^2$, where f and g are computable functions.*

In particular, this implies that for fixed k and $|\Sigma|$, the problem is fixed-parameter tractable (FPT¹) parameterized by B . Note that in any study concerning the parameterized complexity of a problem, the value of the parameter is implicitly assumed to be sufficiently small compared to the input size. Although the parameter B seems to be a natural choice from the problem definition, in general B can be fairly large. Hence, Theorem 1 is mostly applicable in the scenario when for the selected features the cost of clustering B is small and thus the points are well-clustered on the selected features. Even in this case the problem is far from being trivial. One can think of our problem as a problem from the broader class of editing problems, where the goal is to check whether a given instance is close to a “structured” one. In particular, our problem can be seen as the problem of editing the input matrix after removing at most ℓ rows such that the resulting matrix contains at most k distinct columns and the number of edits does not exceed the budget B . In this sense, our work is in line with the work of [18] on matrix completion and [15] on clustering. Note that in many applications it is reasonable to assume that k and $|\Sigma|$ are bounded, as the alphabet size and the number of clusters are small in practice. Indeed, for binary data, $|\Sigma| = 2$.

Another interesting property of our algorithm is that the running time does not depend on the number of irrelevant features ℓ . In particular, for fixed k , B , and $|\Sigma|$, it runs in polynomial time even when $\ell = \Omega(m)$. Also, the theorem could be used to identify the minimum number of irrelevant features ℓ such that the cost of k -clustering on the remaining features does not exceed B . Note that our time complexity also exponentially depends on the

¹ A problem is FPT or fixed-parameter tractable parameterized by a set of parameters if it can be solved by algorithms that are exponential only in the values of the parameters while polynomial in the size of the input.

14:4 Parameterized Complexity of Feature Selection for Categorical Data Clustering

number of clusters k . In this regard, one can compare our result with the result in [15] that shows that the binary version of the problem with $\ell = 0$ (BINARY k -CLUSTERING) is FPT parameterized by B only. However, in the presence of irrelevant features, the dependence on k is unavoidable as we state in our next theorem.

► **Theorem 2.** *FEATURE SELECTION is $W[1]$ -hard parameterized by*

- *either $k + (m - \ell)$*
- *or ℓ*

even when $B = 0$ and $\Sigma = \{0, 1\}$. Moreover, assuming the Exponential Time Hypothesis (ETH), the problem cannot be solved in time $f(k) \cdot m^{o(k)} \cdot n^{O(1)}$ for any function f , even when $B = 0$ and the alphabet Σ is binary.

Note that when $B = 0$ and $\Sigma = \{0, 1\}$, from Theorem 1 it follows that FEATURE SELECTION can be solved in time $f(k) \cdot m^{g(k)} \cdot n^2$. Theorem 2 shows that the dependence of such a function g on k is inevitable, unless $W[1] = \text{FPT}$, and $g(k)$ is unlikely to be sublinear up to ETH.

In order to prove Theorem 1, we prove a more general theorem about CONSTRAINED CLUSTERING WITH OUTLIERS. In this problem, one seeks a clustering with centers of clusters satisfying the property imposed by a set of relations. Constrained clustering [14] was introduced as the tool in the design of approximation algorithms for binary low-rank approximation problems. The CONSTRAINED CLUSTERING WITH OUTLIERS problem is basically the robust variant of this problem. As we will see, by the reduction given in Lemma 5, Theorem 4 proves Theorem 1. Besides FEATURE SELECTION, CONSTRAINED CLUSTERING WITH OUTLIERS encompasses a number of well-studied problems around robust clustering, low-rank matrix approximation, and dimensionality reduction. Our algorithm for constrained clustering implies fixed-parameter tractability for all these problems.

To define constrained clustering, we need a few definitions. A p -ary relation on Σ is a collection of p -tuples whose elements are in Σ .

► **Definition 3** (Vectors satisfying \mathcal{R}). *An ordered set $C = \{\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_p\}$ of m -dimensional vectors in Σ^m is said to satisfy a set $\mathcal{R} = \{R_1, R_2, \dots, R_m\}$ of p -ary relations on Σ if for all $1 \leq i \leq m$, the p -tuple formed by the i -th coordinates of vectors from C , that is $(\mathbf{c}_1[i], \mathbf{c}_2[i], \dots, \mathbf{c}_p[i])$, belongs to R_i .*

We define the following constrained variant of robust categorical clustering.

CONSTRAINED CLUSTERING WITH OUTLIERS

Input: An alphabet Σ , an $m \times n$ matrix \mathbf{A} with columns $\mathbf{a}^1, \mathbf{a}^2, \dots, \mathbf{a}^n$ such that $\mathbf{a}^j \in \Sigma^m$ for all $1 \leq j \leq n$, a positive integer k , non-negative integers B and ℓ , a set $\mathcal{R} = \{R_1, R_2, \dots, R_m\}$ of k -ary relations on Σ .

Task: Decide whether there is a subset $O \subset \{1, 2, \dots, n\}$ of size at most ℓ , a partition $\mathcal{I} = \{I_1, I_2, \dots, I_k\}$ of $\{1, 2, \dots, n\} \setminus O$, and a set $C = \{\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_k\}$ of m -dimensional vectors in Σ^m such that C satisfies \mathcal{R} and

$$\sum_{i=1}^k \sum_{j \in I_i} d_H(\mathbf{a}^j, \mathbf{c}_i) \leq B.$$

Thus in CONSTRAINED CLUSTERING WITH OUTLIERS we want to identify a set of outliers $\mathbf{a}^i, i \in O$, such that the remaining $n - \ell$ vectors could be partitioned into k clusters $\{I_1, I_2, \dots, I_k\}$. Each cluster I_j could be identified by its center $\mathbf{c}_j \in \Sigma^m$ as the set of vectors that are closer to $\mathbf{c}_j \in \Sigma^m$ than to any other center (ties are broken arbitrarily). Then the

cost of each cluster I_j is the sum of the Hamming distances between its vectors and the corresponding center $\mathbf{c}_j \in \Sigma^m$. However, there is an additional condition that the set of cluster centers $C = \{\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_k\}$ must satisfy the set of k -ary relations \mathcal{R} . And, the total sum of costs of all clusters must not exceed B . We prove the following theorem.

► **Theorem 4.** *CONSTRAINED CLUSTERING WITH OUTLIERS is solvable in time*

$$(kB)^{O(kB)} |\Sigma|^{kB} \cdot n^{O(k)} \cdot m^2.$$

The connection between CONSTRAINED CLUSTERING WITH OUTLIERS and FEATURE SELECTION is established in the following lemma.

► **Lemma 5.** *For any instance (\mathbf{D}, k, B, ℓ) of FEATURE SELECTION, one can construct in time $\mathcal{O}(mn + k \cdot |\Sigma|^k)$ an equivalent instance $(\mathbf{A}, k', B', \ell', \mathcal{R})$ of CONSTRAINED CLUSTERING WITH OUTLIERS such that \mathbf{A} is the transpose of \mathbf{D} , $k' = |\Sigma|^k$, $B' = B$ and $\ell' = \ell$.*

Theorem 1 follows from Theorem 4 and Lemma 5. Connections of constrained clustering with several other clustering and low-rank matrix approximation problems have been established in the literature [14]. Similarly, Theorem 4 allows to design parameterized algorithms for robust variants of these problems.

Robust low-rank matrix approximation. Here we discuss two problems where for a given matrix of categorical data, we seek to remove ℓ columns such that the remaining columns are well approximated by a matrix of small rank. The vanilla case of the ℓ_0 -LOW RANK APPROXIMATION problem is the following. Given an $m \times n$ matrix \mathbf{A} over $\text{GF}(p)$ (a finite field of order p), the task is to find an $m \times n$ matrix \mathbf{B} over $\text{GF}(p)$ of $\text{GF}(p)$ -rank at most r which is closest to \mathbf{A} in the ℓ_0 -norm, i.e., the goal is to minimize $\|\mathbf{A} - \mathbf{B}\|_0$, the number of different entries in \mathbf{A} and \mathbf{B} . In the robust version of this problem, some of the columns of \mathbf{A} could be outliers, which brings us to the following problem.

ROBUST ℓ_0 -LOW RANK APPROXIMATION

Input: An $m \times n$ matrix \mathbf{A} over $\text{GF}(p)$, a positive integer r , non-negative integers B and ℓ .

Task: Decide whether there is a matrix \mathbf{B} of $\text{GF}(p)$ -rank at most r , and a matrix \mathbf{C} over $\text{GF}(p)$ with at most ℓ non-zero columns such that $\|\mathbf{A} - \mathbf{B} - \mathbf{C}\|_0 \leq B$.

Note that in this definition the non-zero columns of \mathbf{C} can take any values. However, it is easy to see that the problem would be equivalent if the columns of \mathbf{C} were constrained to be either zero columns or the respective columns of \mathbf{A} . This holds since if \mathbf{C} contains a non-zero column, it could be replaced by the respective column of \mathbf{A} , and the respective column of \mathbf{B} can be replaced by a zero column. This does not increase the cost nor the rank of \mathbf{B} . Thus any of the two formulations allows to restore the column outliers in \mathbf{A} from \mathbf{C} .

By a reduction [14, Lemma 1] similar to Lemma 5, we can show that Theorem 4 yields the following theorem.

► **Theorem 6.** *ROBUST ℓ_0 -LOW RANK APPROXIMATION is FPT parameterized by B when p and r are constants.*

Another popular variant of low-rank matrix approximation is the case when the approximation matrix \mathbf{B} is of low Boolean rank. More precisely, let \mathbf{A} be a binary $m \times n$ matrix. Now we consider the elements of \mathbf{A} to be *Boolean* variables. The *Boolean rank* of \mathbf{A} is the minimum r such that $\mathbf{A} = \mathbf{U} \wedge \mathbf{V}$ for a Boolean $m \times r$ matrix \mathbf{U} and a Boolean $r \times n$ matrix

\vee , where the product is Boolean, that is, the logical \wedge plays the role of multiplication and \vee the role of sum. The variant of the low Boolean-rank matrix approximation is the following problem.

ROBUST LOW BOOLEAN-RANK APPROXIMATION

Input: A binary $m \times n$ matrix \mathbf{A} , a positive integer r , non-negative integers B and ℓ .
Task: Decide whether there is a binary matrix \mathbf{B} of Boolean rank $\leq r$, and a binary matrix \mathbf{C} with at most ℓ non-zero columns such that $\|\mathbf{A} - \mathbf{B} - \mathbf{C}\|_0 \leq B$.

By Theorem 4 and reduction from constrained clustering to Boolean-rank matrix approximation identical to [14, Lemma 2], we have the following.

► **Theorem 7.** *ROBUST LOW BOOLEAN-RANK APPROXIMATION is FPT parameterized by B when r is a constant.*

Finally, we consider clustering with outliers. This problem looks very similar to feature selection. The only difference is that instead of features (the rows of the matrix \mathbf{A}), we seek to remove some columns of \mathbf{A} . More precisely, we consider the following problem.

k -CLUSTERING WITH COLUMN OUTLIERS

Input: An alphabet Σ , an $m \times n$ matrix \mathbf{A} with columns $\mathbf{a}^1, \mathbf{a}^2, \dots, \mathbf{a}^n$ such that $\mathbf{a}^j \in \Sigma^m$ for all $1 \leq j \leq n$, a positive integer k , non-negative integers B and ℓ .
Task: Decide whether there is a subset $O \subset \{1, 2, \dots, n\}$ of size at most ℓ , a partition of $\{1, 2, \dots, n\} \setminus O$ into k sets $\{I_1, I_2, \dots, I_k\}$ called clusters, and vectors $\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_k \in \Sigma^m$ such that the cost of clustering

$$\sum_{i=1}^k \sum_{j \in I_i} d_H(\mathbf{a}^j, \mathbf{c}_i) \leq B.$$

Note that k -CLUSTERING WITH COLUMN OUTLIERS is also a special case of CONSTRAINED CLUSTERING WITH OUTLIERS when every relation $R_i \in \mathcal{R}$ contains all possible k -tuples over Σ , that is, there are no constraints on the centers. Hence, by Theorem 4, we readily obtain the same result for this problem. However, in this special case we show that it is possible to obtain an improved result.

► **Theorem 8.** *k -CLUSTERING WITH COLUMN OUTLIERS is solvable in time $2^{O(B \log B)} |\Sigma|^B \cdot (nm)^{O(1)}$.*

In particular, the theorem implies that the problem is FPT parameterized by B and $|\Sigma|$. We note that the running time of Theorem 8 matches the running time in [15] obtained for the BINARY k -CLUSTERING problem without outliers on binary data. The interesting feature of the theorem is that the running time of the algorithm does not depend on the number of outliers ℓ , matching the bound of the problem without outliers. Most of the clustering procedures in robust statistics, data mining and machine learning perform well only for small number of outliers. Our theorem implies that if all of the inlier points could be naturally partitioned into k distinct clusters with small cost, then such a clustering could be efficiently recovered even after arbitrarily many outliers are added.

Related Work. CONSTRAINED CLUSTERING (without outliers) was introduced in [14] as a tool for designing EPTAS for LOW BOOLEAN-RANK APPROXIMATION. ROBUST ℓ_0 -LOW RANK APPROXIMATION is a variant of robust PCA for categorical data. The study of robust

PCA, where one seeks for a PCA when the input data is noisy or corrupted, is the large class of extensively studied problems, see the books [30, 8]. There are many models of robustness in the literature, most relevant to our work is the approach that became popular after the work of [9]. The variant of robust PCA where one seeks for identifying a set of outliers, also known as PCA with outliers, were studied in [4, 10, 31, 29].

For the vanilla variant, ℓ_0 -LOW RANK APPROXIMATION, a number of parameterized and approximation algorithms were developed [3, 14, 15, 21].

LOW BOOLEAN-RANK APPROXIMATION has attracted much attention, especially in the data mining and knowledge discovery communities. In data mining, matrix decompositions are often used to produce concise representations of data. Since much of the real data is binary or even Boolean in nature, Boolean low-rank approximation could provide a deeper insight into the semantics associated with the original matrix. There is a big body of work done on LOW BOOLEAN-RANK APPROXIMATION. We refer to [23, 25, 27, 26] for further references on this interesting problem. Parameterized algorithms for LOW BOOLEAN-RANK APPROXIMATION (without outliers) were studied in [15].

There are several approximations and parameterized algorithms known for BINARY k -CLUSTERING, which is the vanilla (without outliers) case of k -CLUSTERING WITH COLUMN OUTLIERS and with $\Sigma = \{0, 1\}$ [28, 14, 3, 16]. Most relevant to our work is the parameterized algorithm for BINARY k -CLUSTERING from [15]. Theorem 8 extends the result from [15] to clustering with outliers.

Paper Outline. In the remaining part of this extended abstract we focus on our algorithmic results. We briefly outline our techniques in Section 3. Then, in Section 4 we describe our main result, the FPT algorithm for CONSTRAINED CLUSTERING WITH OUTLIERS. Finally, in Section 5, we conclude with some open problems. Due to space constraints, the detailed presentation of the remaining results appears in the attached full version of the paper.

3 Our Techniques

Both of our algorithmic results, Theorems 4 and 8, have at their core the subhypergraph enumeration technique introduced by Marx [24]. This is fairly natural, since our algorithms solve generalized versions of the vanilla binary clustering problem, and the only known FPT algorithm [15] for the latter problem parameterized by B relies on the hypergraph enumeration as well. In fact, our algorithm for k -CLUSTERING WITH COLUMN OUTLIERS closely follows this established approach of applying the hypergraph construction to clustering problems ([16], and partly [15]). However, for the CONSTRAINED CLUSTERING WITH OUTLIERS problem the existing techniques do not work immediately. To deal with this, we generalize the previously used hypergraph construction. In what follows, we present the key ideas of both algorithms. We begin with the simpler case of k -CLUSTERING WITH COLUMN OUTLIERS, even though our main results are for FEATURE SELECTION and CONSTRAINED CLUSTERING WITH OUTLIERS.

For the presentation of our algorithms, we recall standard hypergraph notations and the notion of a fractional cover of a hypergraph. A hypergraph $G(V_G, E_G)$ consists of a set V_G of vertices and a set E_G of edges, where each edge is a subset of V_G . Consider two hypergraphs $H(V_H, E_H)$ and $G(V_G, E_G)$. We say that H appears in G at $V' \subseteq V_G$ as a partial hypergraph if there is a bijection π between V_H and V' such that for any edge $e \in E_H$, $\pi(e) \in E_G$, where $\pi(e) = \cup_{v \in e} \pi(v)$. H is said to appear in G at $V' \subseteq V_G$ as a subhypergraph if there is a bijection π between V' and V_H such that for any edge $e \in E_H$, there is an edge $e' \in E_G$ such that $\pi(e) = e' \cap V'$.

A fractional edge cover of H is an assignment $\phi : E_H \rightarrow [0, 1]$ such that for every vertex $v \in V_H$, the sum of the values assigned to the edges that contain v is at least 1, i.e., $\sum_{e \ni v} \phi(e) \geq 1$. The fractional cover number $\rho^*(H)$ of H is the minimum value $\sum_{e \in E} \phi(e)$ over all fractional edge covers ϕ of H . The following theorem is required for our algorithm.

► **Theorem 9** ([24]). *Let $H(V_H, E_H)$ be a hypergraph with fractional cover number $\rho^*(H)$, and let $G(V_G, E_G)$ be a hypergraph where each edge has size at most L . There is an algorithm that enumerates, in time $|V_H|^{O(|V_H|)} \cdot L^{|V_H| \rho^*(H) + 1} \cdot |E_G|^{\rho^*(H) + 1} \cdot |V_G|^2$, every subset $V \subseteq V_G$ where H appears in G as a subhypergraph.*

3.1 The Algorithm for k -Clustering with Column Outliers

Given an instance (\mathbf{A}, k, B, ℓ) of k -CLUSTERING WITH COLUMN OUTLIERS, we note that at most $2B$ distinct columns can belong to “nontrivial” clusters (with at least 2 distinct columns), exactly like in the case without the outliers. So we employ a color-coding scheme [2] to partition the columns in a way so that every column belonging to a nontrivial cluster of a fixed feasible solution is colored with its own color. Thus we reduce to multiple instances of the problem we call Restricted Clustering. In Restricted Clustering, we are given sets of columns U_1, U_2, \dots, U_p and a parameter B . The goal is to select p columns $\mathbf{b}_1, \mathbf{b}_2, \dots, \mathbf{b}_p$ and a cluster center \mathbf{s} such that $\mathbf{b}_t \in U_t$ for $1 \leq t \leq p$ and $\sum_{i=1}^p d_H(\mathbf{b}_i, \mathbf{s}) \leq B$.

Restricted Clustering is similar to the Cluster Selection problem of [16] and [15], and the hypergraph-based algorithm to solve it is essentially the same as in [16]. However, next we briefly sketch the details, as this construction serves as the base for our more general CONSTRAINED CLUSTERING WITH OUTLIERS algorithm. First, guess $\mathbf{b}_1 \in U_1$ in the optimal solution to the instance of Restricted Clustering. If the cost of the optimal solution is at most B , then $d_H(\mathbf{b}_1, \mathbf{s})$ is at most B as well. If we know the set of at most B positions P where \mathbf{b}_1 and \mathbf{s} differ, we can easily identify \mathbf{s} by trying all possible $|\Sigma|^B$ options at these positions. For each option, we can find the closest \mathbf{b}_i from each U_i and check whether the total cost is at most B .

To show that we can enumerate all potential sets of deviating positions in FPT time, we identify the instance with the following hypergraph $H(V, E)$. The vertices V are the positions $\{1, \dots, m\}$. With each column \mathbf{x} in $\bigcup_{i=1}^p U_i$, we identify a hyperedge containing exactly the positions where \mathbf{x} is different from \mathbf{b}_1 . Now the optimal set of positions P and the optimal columns $\{\mathbf{b}_i\}_{i=1}^p$ induce a subhypergraph $H_0(V_0, E_0)$ of H such that $|V_0| \leq B$ and the fractional cover number of H_0 is at most two. The latter holds simply because wherever \mathbf{s} is different from \mathbf{x} , at least half of the chosen columns must also be different from \mathbf{x} , otherwise modifying \mathbf{s} to match \mathbf{x} decreases the cost. If we enumerate all possible subhypergraphs H_0 and all possible locations in H where they occur, we can surely find the optimal set of locations P . Since $|V_0| \leq B$, enumerating all choices for H_0 is clearly in FPT time. For a fixed H_0 , finding all occurrences in H is in FPT time by Theorem 9. Note that applying Theorem 9 results in FPT time only when the fractional cover number of H_0 is bounded by a constant. Also, by a sampling argument one can show that it suffices to consider only those H_0 with $O(\log B)$ hyperedges. It follows that the number of distinct hypergraphs that we have to consider for enumeration is bounded by only $2^{O(B \log B)}$. Thus it is possible to bound the dependence on B in the running time by $2^{O(B \log B)}$.

3.2 The Algorithm for Feature Selection

For FEATURE SELECTION, the above-mentioned approach is not applicable, for several reasons. Most crucially, it does not seem that one can partition the problem into k independent instances of a simpler single-center selection problem, in a way that we reduce k -CLUSTERING

WITH COLUMN OUTLIERS to k instances of Restricted Clustering (for a fixed coloring). Intuitively, the possibility to remove a subset of features does not allow such a partition as all the clusters depend simultaneously on the choice of those features. Moreover, our hardness result shows that for FEATURE SELECTION the running time cannot match with k -CLUSTERING WITH COLUMN OUTLIERS, as no $n^{o(k)}$ time algorithm is possible for constant B , assuming ETH.

By Lemma 5, for solving FEATURE SELECTION, it suffices to solve CONSTRAINED CLUSTERING WITH OUTLIERS. For the same reasons as with FEATURE SELECTION, the approach used for k -CLUSTERING WITH COLUMN OUTLIERS fails, as the constraints on the centers do not allow to form clusters independently. Instead, we generalize the hypergraph construction used for Restricted Clustering to handle the choice of all k centers simultaneously, as opposed to just one center at a time. This is the most technical part of the paper. The main idea is to base the hypergraph on k -tuples of columns instead of just single columns. In the next section, we formalize this intuitive discussion, presenting the proof in full detail.

4 The Algorithm for Constrained Clustering with Outliers

In this section we prove Theorem 4 by giving an algorithm for CONSTRAINED CLUSTERING WITH OUTLIERS that runs in $(kB)^{O(kB)} n^{O(k)} m^2 |\Sigma|^{kB}$ time. First, we prove a structural lemma that will be useful for analysis of the algorithm.

4.1 Structural Lemma

Here we show that an optimal set of centers corresponds to a “good” subhypergraph in a certain hypergraph. Consider a feasible clustering $\mathcal{I} = \{I_1, I_2, \dots, I_k\}$ having the minimum cost. Let $\{\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_k\}$ be a fixed set of centers corresponding to \mathcal{I} . Also, let T be the set of all tuples of the form $(\mathbf{a}^{i_1}, \mathbf{a}^{i_2}, \dots, \mathbf{a}^{i_k})$ such that $i_j \in I_j$ for all j . Note that we do not actually need to know the set T – we just introduce the notation for the sake of analysis. For a k -tuple $x = (\mathbf{x}_1, \dots, \mathbf{x}_k)$, we denote the tuple $(\mathbf{x}_1[j], \mathbf{x}_2[j], \dots, \mathbf{x}_k[j])$ by $x[j]$. Two k -tuples x and y are said to differ from each other at location j if $x[j] \neq y[j]$.

Let C be the k -tuple such that $C = (\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_k)$. Suppose $x = (\mathbf{x}_1, \dots, \mathbf{x}_k)$ is such that there are at most B positions h where $x[h] \neq C[h]$, and for each $1 \leq j \leq m$, $x[j] \in R_j$. Consider the hypergraph H defined in the following way with respect to x . The labels of the vertices of H are in $\{1, 2, \dots, m\}$. For each k -tuple $y = (\mathbf{y}_1, \dots, \mathbf{y}_k)$ of T , we add an edge $S \subseteq \{1, 2, \dots, m\}$ such that $h \in S$ if $x[h] \neq y[h]$.

In the following lemma, we show that the hypergraph H has a “good” subhypergraph.

► **Lemma 10 (Structural Lemma).** *Suppose the input is a yes-instance. Consider a k -tuple $x = (\mathbf{x}_1, \dots, \mathbf{x}_k)$ such that there are at most B positions h where $x[h] \neq C[h]$ and for each $1 \leq j \leq m$, $x[j] \in R_j$. Also, consider the hypergraph H defined in the above with respect to x . There exists a subhypergraph $H^*(V^*, E^*)$ of H with the following properties.*

1. $|V^*| \leq B$.
2. $|E^*| \leq 200 \ln B$.
3. *The indices in V^* are the exact positions h such that $x[h] \neq C[h]$.*
4. *The fractional cover number of H^* is at most 4.*

To prove the above lemma, first, we show the existence of a subhypergraph that satisfies all the properties except the second one. Let P be the set of positions h such that $x[h] \neq C[h]$. Let $H_0(V_0, E_0)$ be the subhypergraph of H induced by P . By definition of x , P contains at most B indices. Thus, the first property follows immediately. The third property also follows, as $V_0 = P$, is exactly the set of positions $h \in \{1, 2, \dots, m\}$, where $x[h] \neq C[h]$. Next, we show that the fourth property holds for H_0 . In fact, we show a stronger bound.

► **Lemma 11.** *The fractional cover number of H_0 is at most 2.*

Proof. Note that the total number of edges of H_0 is $\tau = |T|$. We claim that each vertex of H_0 is contained in at least $\tau/2$ edges.

Consider any vertex h of H_0 . Suppose there is a $1 \leq j \leq k$, such that for at least $\lceil |I_j|/2 \rceil$ columns in I_j the value at location h is not $\mathbf{x}_j[h]$. Note that each such column contributes to $\prod_{t^1=1}^{j-1} |I_{t^1}| \cdot \prod_{t^2=j+1}^k |I_{t^2}| = \tau/|I_j|$ tuples $(\mathbf{y}_1, \dots, \mathbf{y}_k)$ of T such that $\mathbf{y}_j[h] \neq \mathbf{x}_j[h]$. Thus, the edge corresponding to each such tuple contains h . It follows that, at least $\lceil |I_j|/2 \rceil \cdot (\tau/|I_j|) \geq \tau/2$ edges in E_0 contain h .

In the other case, for all $1 \leq j \leq k$ and less than $\lceil |I_j|/2 \rceil$ columns in I_j , the value at location h is not $\mathbf{x}_j[h]$. We prove that this case does not occur. Note that there is a k -tuple z in R_h such that $z = x[h]$. Consider replacing $C[h]$ by z at position h of C . Next, we analyze the change in cost of the clustering \mathcal{I} . Note that the cost corresponding to positions other than h remains same. For a $1 \leq j \leq k$, if previously $\mathbf{c}_j[h] = \mathbf{x}_j[h]$, the cost remains same. Otherwise, $\mathbf{c}_j[h] \neq \mathbf{x}_j[h]$. Note that for more than $\lceil |I_j|/2 \rceil$ columns in I_j , the value at location h is $\mathbf{x}_j[h]$. Thus, by replacing $\mathbf{c}_j[h]$ by $\mathbf{x}_j[h]$, the cost decrement corresponding to the index j and location h is at least 1. As $x[h] \neq C[h]$, there is an index j such that $\mathbf{c}_j[h] \neq \mathbf{x}_j[h]$. It follows that the overall cost decrement is at least 1, which contradicts the optimality of the previously chosen centers. Hence, this case cannot occur. This completes the proof of the lemma. ◀

So far we have proved the existence of a subhypergraph that satisfies all the properties except the second. Next, we show the existence of a subhypergraph that satisfies all the properties. The following lemma completes the proof of Lemma 10. Its proof follows a standard sampling argument, and is presented in the full version.

► **Lemma 12.** *Let $B \geq 2$. Consider the subhypergraph H_0 that satisfies all the properties of Lemma 10 except (2). It is possible to select at most $200 \ln B$ edges from H_0 such that the subhypergraph H_0^* obtained by removing all the other edges from H_0 satisfies all the properties of Lemma 10.*

4.2 The Algorithm for Constrained Clustering

In this section, we describe our algorithm. The algorithm outputs a feasible clustering of minimum cost if there is a feasible clustering of the given instance. Otherwise, the algorithm returns “NO”.

The Algorithm. First, we consider all k -tuples $x = (\mathbf{x}_1, \dots, \mathbf{x}_k)$ such that \mathbf{x}_j is a column of \mathbf{A} for $1 \leq j \leq k$, and apply the following refinement process on each of them. Here, a k -tuple x of columns of \mathbf{A} is said to differ from \mathcal{R} at a position j for $1 \leq j \leq m$ if $x[j] \notin R_j$.

- Let $P \subseteq \{1, 2, \dots, m\}$ be the set of positions where x differs from \mathcal{R} .
- If $|P| > B$, probe the next k -tuple x .
- For each position $h \in P$, replace $x[h]$ by any element of R_h .

Next, for each refined k -tuple $x = (\mathbf{x}_1, \dots, \mathbf{x}_k)$, we construct a hypergraph G whose vertices are in $\{1, 2, \dots, m\}$. For each k -tuple $y = (\mathbf{y}_1, \dots, \mathbf{y}_k)$ of columns of \mathbf{A} , we add an edge $S \subseteq \{1, 2, \dots, m\}$ such that $h \in S$ if $x[h] \neq y[h]$. For all hypergraphs H_0^* having at most B vertices and at most $200 \ln B$ edges, we check if each vertex of H_0^* is contained in at least $1/4$ fraction of the edges. If that is the case, we use the algorithm of Theorem 9 to find every place P' where H_0^* appears in G as subhypergraph. For each such set P' , we perform

all possible $B' \leq B \cdot k$ edits of the tuple x at the locations in P' . In particular, for each B' , the editing is done in the following way. For each possible B' entries $(a_1, \dots, a_{B'})$ in $(\mathbf{x}_1, \dots, \mathbf{x}_k)$ at the locations in P' and each set of B' symbols $(s_1, \dots, s_{B'})$ from Σ , we put s_j at the entry a_j for all j . After each such edit, we retrieve the edited tuple $(\mathbf{x}_1, \dots, \mathbf{x}_k)$ and perform a sanity check on this tuple to ensure that it is a valid k -tuple center. In particular, for each index $1 \leq h \leq m$, if there is a $z \in R_h$ such that $z = x[h]$, we tag x as a valid tuple. Lastly, we output all such valid k -tuples as candidate centers if the corresponding cost of clustering is at most B . If no k -tuple is output as a candidate center, we return “NO”.

Note that, given a k -tuple candidate center $z = (z_1, \dots, z_k)$, one can compute a minimum cost clustering in the following greedy way, which implies that we can correctly compute the cost of clustering in the above. At each step i , we assign a new column of \mathbf{A} to a center. In particular, we add a column \mathbf{a}^j of \mathbf{A} to a cluster I'_t such that \mathbf{a}^j incurs the minimum cost over all unassigned columns if it is assigned to a center, i.e, it minimizes the quantity $\min_{t'=1}^k d(\mathbf{a}^j, z_{t'})$, and $z_{t'}$ is a corresponding center nearest to \mathbf{a}^j . As we are allowed to exclude ℓ outliers, we assign $n - \ell$ columns. The clustering $\{I'_1, \dots, I'_k\}$ obtained at the end of this process is the output. This finishes the description of our algorithm.

4.3 Analysis

Again consider the feasible clustering with partition $\mathcal{I} = \{I_1, I_2, \dots, I_k\}$ and the corresponding center tuple $C = (\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_k)$ having the minimum cost. First, we have the following observation.

► **Observation 13.** *Suppose for a k -tuple x , x differs from C at B_1 positions. Then, after refinement, there is at most B_1 positions h such that $x[h] \neq C[h]$. Moreover, after refinement, $d_H(x, C) \leq B_1 \cdot k$.*

The first part is true for the following reason. If x was different from \mathcal{R} at a position h , then $x[h] \neq C[h]$ as well. Thus, refinement is applied for a position h where $x[h]$ already differs from $C[h]$. Hence, refinement does not affect a position h where $x[h] = C[h]$. The moreover part follows trivially from the first part as x is a k -tuple. Now, it is sufficient to prove the following lemma.

► **Lemma 14.** *Suppose there is a feasible clustering with partition $\mathcal{I} = \{I_1, I_2, \dots, I_k\}$ as defined above. The above algorithm successfully outputs the k -tuple $(\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_k)$.*

Proof. Consider a k -tuple $x = (\mathbf{x}_1, \dots, \mathbf{x}_k)$ such that the column \mathbf{x}_j is in cluster I_j . As the algorithm considers all possible k -tuples of columns in \mathbf{A} , it must consider x . By Observation 13, after refinement, there are at most B positions h where $x[h] \neq C[h]$. Also, for each $1 \leq j \leq m$, $x[j] \in R_j$. Let G be the hypergraph constructed by the algorithm corresponding to this refined x . Note that the hypergraph H defined in Lemma 10 is a partial subhypergraph of G . Thus, the subhypergraph H^* of H is also a subhypergraph of G . As we enumerate all hypergraphs having at most B vertices, at most $200 \ln B$ edges and at most 4 fractional covering number, H^* must be considered by the algorithm. Let P' be the place in G where H^* appears. By the third property of Lemma 10, the locations in P' are the exact positions h such that $x[h] \neq C[h]$. It follows that an edit corresponding to P' generates the tuple $C = (\mathbf{c}_1, \dots, \mathbf{c}_k)$, as $d_H(x, C) \leq B \cdot k$. It is easy to see that C also passes the sanity check. Hence, C must be an output of the algorithm. ◀

Given the tuple center $C = (\mathbf{c}_1, \dots, \mathbf{c}_k)$, we use the greedy assignment scheme (described in the algorithm) to find the underlying clustering. Note that given any k -tuple candidate center $z = (z_1, \dots, z_k)$, this greedy scheme computes a minimum cost clustering with

z_1, \dots, z_k being the cluster centers. Thus, the cost of the clustering computed by the algorithm is at most B . Hence, the algorithm successfully outputs C as a candidate center. We summarize our findings in the following lemma.

► **Lemma 15.** *Suppose the input instance is a no-instance, then the algorithm successfully outputs “NO”. If the input instance is a yes-instance, the algorithm correctly computes a feasible clustering.*

4.4 Time Complexity

Next, we discuss the time complexity of our algorithm. The number of choices of x is $n^{O(k)}$. For each choice of x , the hypergraph G can be constructed in $n^{O(k)}$ time. The number of distinct hypergraphs H_0^* with at most B vertices and at most $200 \ln B$ edges is $2^{B \cdot 200 \ln B} = B^{O(B)}$, since there are 2^B possibilities for each edge. Now we analyze the time needed for locating a particular H_0^* in G . For any tuple $y \in T$, $d_H(y, C) \leq B$. By triangle inequality, $d_H(x, y) \leq 2B$. Thus, the size of any edge in H is at most $2B$, and we can remove any edge of G of size more than $2B$. From Theorem 9, it follows that every occurrence of H_0^* in G can be found in $B^{O(B)} \cdot (2B)^{4B+1} \cdot n^{4k+k} \cdot m^2 = B^{O(B)} \cdot n^{O(k)} m^2$ time. If H_0^* appears at some place in G , it would take $O((kB|\Sigma|)^{kB})$ time to edit x . Hence, in total the algorithm takes $(kB)^{O(kB)} |\Sigma|^B \cdot n^{O(k)} m^2$ time. By the above discussion, we have Theorem 4.

5 Conclusion

We initiated the systematic study of parameterized complexity of robust categorical data clustering problems. In particular, for k -CLUSTERING WITH COLUMN OUTLIERS, we proved that the problem can be solved in $2^{O(B \log B)} |\Sigma|^B \cdot (nm)^{O(1)}$ time. Further, we considered the case of row outliers and proved that FEATURE SELECTION is solvable in time $f(k, B, |\Sigma|) \cdot m^{g(k, |\Sigma|)} n^2$. We also proved that we cannot avoid the dependence on k in the degree of the polynomial of the input size in the running time unless $W[1] = \text{FPT}$, and the problem cannot be solved in $m^{o(k)} \cdot n^{O(1)}$ time, unless ETH is false. To deal with row outliers, we introduced the CONSTRAINED CLUSTERING WITH OUTLIERS problem and obtained the algorithm with running time $(kB)^{O(kB)} |\Sigma|^{kB} \cdot m^2 n^{O(k)}$. This problem is very general, and the algorithm for it not only allowed us to get the result for FEATURE SELECTION, but also led to the algorithms for the robust low rank approximation problems. In particular, we obtained that ROBUST ℓ_0 -LOW RANK APPROXIMATION is FPT if k and p are constants when the problem is parameterized by B . However, even if the low rank approximation problems are closely related to the matrix clustering problems, there are structural differences. For instance, we show that the complexity of clustering with column outliers is different from row outliers, however, low-rank approximation problems are symmetric. This leads to the question whether ROBUST ℓ_0 -LOW RANK APPROXIMATION, ROBUST LOW BOOLEAN-RANK APPROXIMATION and ROBUST PROJECTIVE CLUSTERING could be solved by better algorithms specially tailored for these problems. It is unlikely that potential improvements would considerably change the general qualitative picture. For example, ROBUST ℓ_0 -LOW RANK APPROXIMATION for $p = 2$ and $\ell = 0$ is NP-complete if $k = 2$ [12, 19] and W[1]-hard when parameterized by B [17]. It is also easy to observe that ROBUST ℓ_0 -LOW RANK APPROXIMATION for $p = 2$, $B = 0$ and $k = n - \ell - 1$ is equivalent to asking whether the input matrix A has $n - \ell$ linearly dependent columns. This immediately implies that ROBUST ℓ_0 -LOW RANK APPROXIMATION for $p = 2$ and $B = 0$ is W[1]-hard when parameterized by k or $n - \ell$ by the recent results about the EVEN SET problem [5]. The most interesting open question, by our opinion, is whether

the exponential dependence on k in the degree of the polynomial of the input size in the running time produced by our reduction of ROBUST ℓ_0 -LOW RANK APPROXIMATION to CONSTRAINED CLUSTERING WITH OUTLIERS could be avoided, even if p is a constant. Can the dependence of k be made polynomial (or even linear)?

Decision Questions for Probabilistic Automata on Small Alphabets

Department of Computer Science, University of Oxford, UK

Abstract

We study the emptiness and λ -reachability problems for unary and binary Probabilistic Finite Automata (PFA) and characterise the complexity of these problems in terms of the degree of ambiguity of the automaton and the size of its alphabet. Our main result is that emptiness and λ -reachability are solvable in EXPTIME for polynomially ambiguous unary PFA and if, in addition, the transition matrix is over $\{0, 1\}$, we show they are in NP. In contrast to the Skolem-hardness of the λ -reachability and emptiness problems for exponentially ambiguous unary PFA, we show that these problems are NP-hard even for finitely ambiguous unary PFA. For binary polynomially ambiguous PFA with commuting transition matrices, we prove NP-hardness of the λ -reachability (dimension 9), nonstrict emptiness (dimension 37) and strict emptiness (dimension 40) problems.

1 Introduction

There are many possible extensions of the fundamental notion of a nondeterministic finite automaton. One such notion is that of a Probabilistic Finite Automata (PFA) which was first introduced by Rabin [19]. In a PFA \mathcal{P} over a (finite) input alphabet Σ the outgoing transitions from a state, for each input letter of Σ , form a probability distribution, as does the initial state vector. Thus, a word $w \in \Sigma^*$ is accepted with a certain probability, which we denote $\mathcal{P}(w)$.

There are a variety of interesting questions that one may ask about a PFA \mathcal{P} over an alphabet Σ . In this article we focus on two decision questions, that of λ -reachability and emptiness. The λ -reachability problem is stated thus: given a probability $\lambda \in [0, 1]$, does there exist some word $w \in \Sigma^*$ such that $\mathcal{P}(w) = \lambda$? In the (strict) emptiness problem, we ask if there exists *any* word $w \in \Sigma^*$ such that $\mathcal{P}(w) \geq \lambda$ (resp. $\mathcal{P}(w) > \lambda$). We also mention the related *cutpoint isolation* problem – to determine if for each $\epsilon > 0$, there exists a word $w \in \Sigma$ such that $|\mathcal{P}(w) - \lambda| < \epsilon$.

In general, the emptiness problem is undecidable for PFA [18], even over a binary alphabet when the automaton has 25 states [12]. The cutpoint isolation problem is undecidable [4] even for PFA with 420 states over a binary alphabet [5]. The problem is especially interesting given the seminal result of Rabin that if a cutpoint λ is isolated, then the cutpoint language associated with λ is necessarily regular [19].

We may ask which restrictions of PFA may lead to decidability of the previous problems. In this paper we are interested in PFA of *bounded ambiguity*, where the ambiguity of a word denotes the number of accepting runs of that word in the PFA. A PFA \mathcal{P} is f -ambiguous,

for a function $f : \mathbb{N} \rightarrow \mathbb{N}$, if every word of length n has at most $f(n)$ accepting runs. A run is *accepting* if the probability of that run ending in a final state is strictly positive. The degree of ambiguity is thus a property of the NFA underlying a PFA (i.e. the NFA produced by setting all nonzero transition probabilities to 1). We may consider the notions of finite, polynomial or exponential ambiguity of \mathcal{P} based on whether f is bounded by a constant, is a polynomial or else is exponential, respectively. Characterisations of the degree of ambiguity of NFA are given by Weber and Seidel [23].

The authors of [8] show that emptiness for PFA remains undecidable even for polynomially ambiguous automata (quadratic ambiguity), show PSPACE-hardness results for finitely ambiguous PFA and that emptiness is in NP for the class of k -ambiguous PFA for every $k > 0$. The emptiness problem for PFA was later shown to be undecidable for linearly ambiguous automata [7].

Another restriction is to constrain input words of the PFA to come from a given language \mathcal{L} . If \mathcal{L} is a *letter-bounded* language, then the emptiness and λ -reachability problems remain undecidable for polynomially ambiguous PFA, even when all transition matrices commute [2]. In contrast, the *cutpoint-isolation* problem is decidable even for exponentially ambiguous PFA when inputs are constrained to come from a given letter-bounded context-free language, although it is NP-hard for 3-state PFA on letter-bounded inputs [3].

Our main results are as follows. We show that the λ -reachability and emptiness problems for probabilistic finite automata are:

- In EXPTIME for the class of polynomially ambiguous unary PFA and are NP-complete if, in addition, the transition matrix is over $\{0, 1\}$ [Theorem 4 and Corollary 11].
- NP-hard for polynomially ambiguous PFA over a binary alphabet with *fixed* and *commuting* transition matrices of dimension 40 (strict emptiness problem), 37 (nonstrict emptiness problem) and 9 (λ -reachability problem) [Theorem 12].

We also show NP-hardness for the class of finitely ambiguous unary PFA with $\{0, 1\}$ transition matrix [Theorem 10]. Our hardness results rely on the NP-hardness of solving binary quadratic equations and the universality problem for unary regular expressions. An interesting question, that is left open, is to find out the exact computational complexity of the above problems in the case of polynomially ambiguous unary PFA, i.e. to close the gap between the EXPTIME upper bound and NP lower bound.

2 Probabilistic Finite Automata and Notation

We denote by $\mathbb{Q}^{n \times n}$ the set of all $n \times n$ matrices over \mathbb{Q} . Given two column vectors $u \in \mathbb{Q}^n$ and $v \in \mathbb{Q}^m$, we denote by $[u|v]$ the column vector $(u_1, \dots, u_n, v_1, \dots, v_m)^T \in \mathbb{Q}^{n+m}$. For a sequence of vectors u_1, u_2, \dots, u_k , we write $[u_1|u_2|\dots|u_k]$ for the column vector which stacks the vectors on top of each other.

Given $A = (a_{ij}) \in \mathbb{Q}^{m \times m}$ and $B \in \mathbb{Q}^{n \times n}$, we define the direct sum $A \oplus B$ and Kronecker product $A \otimes B$ of A and B by:

$$A \oplus B = \left[\begin{array}{c|c} A & \mathbf{0}_{m,n} \\ \hline \mathbf{0}_{n,m} & B \end{array} \right], \quad A \otimes B = \begin{bmatrix} a_{11}B & a_{12}B & \cdots & a_{1m}B \\ a_{21}B & a_{22}B & \cdots & a_{2m}B \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1}B & a_{m2}B & \cdots & a_{mm}B \end{bmatrix},$$

where $\mathbf{0}_{i,j}$ denotes the zero matrix of dimension $i \times j$. Note that neither \oplus nor \otimes are commutative in general. The following useful properties of \oplus and \otimes are well known.

► **Lemma 1.** *Let $A, B, C, D \in \mathbb{Q}^{n \times n}$. Then we have:*

- *Associativity: $(A \otimes B) \otimes C = A \otimes (B \otimes C)$ and $(A \oplus B) \oplus C = A \oplus (B \oplus C)$, thus $A \otimes B \otimes C$ and $A \oplus B \oplus C$ are unambiguous.*
- *Mixed product properties: $(A \otimes B)(C \otimes D) = (AC \otimes BD)$ and $(A \oplus B)(C \oplus D) = (AC \oplus BD)$.*
- *If A and B are stochastic matrices, then so are $A \oplus B$ and $A \otimes B$.*
- *If $A, B \in \mathbb{Q}^{n \times n}$ are both upper-triangular, then so are $A \oplus B$ and $A \otimes B$.*

See [13] for proofs of the first three properties of Lemma 1. The fourth property follows directly from the definition of the direct sum and Kronecker product and is not difficult to prove.

A Probabilistic Finite Automaton (PFA) \mathcal{P} with n states over an alphabet Σ is defined as $\mathcal{P} = (u, \{M_a | a \in \Sigma\}, v)$ where $u \in \mathbb{Q}^n$ is the *initial probability distribution*; $v \in \{0, 1\}^n$ is the *final state vector* and each $M_a \in \mathbb{Q}^{n \times n}$ is a (row) stochastic matrix. We will primarily be interested in *unary* and *binary* PFA, for which $|\Sigma| = 1$ and $|\Sigma| = 2$ respectively. For a word $w = a_1 a_2 \cdots a_k \in \Sigma^*$, we define the acceptance probability $\mathcal{P}(w) : \Sigma^* \rightarrow \mathbb{Q}$ of \mathcal{P} as:

$$\mathcal{P}(w) = u^T M_{a_1} M_{a_2} \cdots M_{a_k} v \in [0, 1],$$

which denotes the acceptance probability of w .¹

For a given cutpoint $\lambda \in [0, 1]$, we define the following languages: $L_{\geq \lambda}(\mathcal{P}) = \{w \in \Sigma^* \mid \mathcal{P}(w) \geq \lambda\}$, a nonstrict cutpoint language, and $L_{> \lambda}(\mathcal{P}) = \{w \in \Sigma^* \mid \mathcal{P}(w) > \lambda\}$, a strict cutpoint language. The (strict) emptiness problem for a cutpoint language is to determine if $L_{\geq \lambda}(\mathcal{P}) = \emptyset$ (resp. $L_{> \lambda}(\mathcal{P}) = \emptyset$). We are also interested in the λ -*reachability* problem, for which we ask if there exists a word $w \in \Sigma^*$ such that $\mathcal{P}(w) = \lambda$.

2.1 PFA Ambiguity

The degree of ambiguity of a finite automaton is a structural parameter, roughly indicating the number of accepting runs for a given input word. See [23] for a thorough discussion of ambiguity for nondeterministic automata and [2, 3, 7, 8] for connections to PFA.

Let $w \in \Sigma^*$ be an input word of an NFA $\mathcal{N} = (Q, \Sigma, \delta, Q_I, Q_F)$, with Q the set of states, Σ the input alphabet, $\delta \subset Q \times \Sigma \times Q$ the transition function, Q_I the set of initial states and Q_F the set of final states. For each $(p, w, q) \in Q \times \Sigma^* \times Q$, define $\text{da}_{\mathcal{N}}(p, w, q)$ as the number of paths for w in \mathcal{N} leading from state p to q . The *degree of ambiguity* of w in \mathcal{N} , denoted $\text{da}_{\mathcal{N}}(w)$, is defined as the number of all *accepting paths* for w (starting from an initial and ending in a final state). The *degree of ambiguity* of \mathcal{N} , denoted $\text{da}(\mathcal{N})$, is the supremum of the set $\{\text{da}_{\mathcal{N}}(w) \mid w \in \Sigma^*\}$. \mathcal{N} is called *infinitely ambiguous* if $\text{da}(\mathcal{N}) = \infty$, *finitely ambiguous* if $\text{da}(\mathcal{N}) < \infty$, and *unambiguous* if $\text{da}(\mathcal{N}) \leq 1$. The *degree of growth* of the ambiguity of \mathcal{N} , denoted $\text{deg}(\mathcal{N})$, is defined as the minimum degree of a univariate polynomial h with positive integral coefficients such that for all $w \in \Sigma^*$, $\text{da}_{\mathcal{N}}(w) \leq h(|w|)$ (if such a polynomial exists, in which case \mathcal{N} is called *polynomially ambiguous*, otherwise the degree of growth is infinite and \mathcal{N} is called *exponentially ambiguous*).

The above notions relate to NFA. We may derive an analogous notion of ambiguity for PFA by considering an embedding of a PFA \mathcal{P} to an NFA \mathcal{N} in such a way that for each letter $a \in \Sigma$, if the probability of transitioning from a state i to state j is nonzero under \mathcal{P} , then there is an edge from state i to j under \mathcal{N} for letter a . The initial states of \mathcal{N} are those of \mathcal{P} having nonzero initial probability and the final states of \mathcal{N} and \mathcal{P} coincide. We then say that \mathcal{P} is *finitely/polynomially/exponentially ambiguous* if \mathcal{N} is (respectively).

¹ Some authors interchange the order of u and v and use column stochastic matrices, although the two definitions are trivially equivalent.

15:4 Decision Questions for Probabilistic Automata on Small Alphabets

A state $q \in Q$ in an NFA (resp. PFA) is called *useful* if there exists an accepting path which visits q (resp. an accepting path of nonzero probability which visits q). We can characterise whether an NFA \mathcal{A} (and thus a PFA by the above embedding) has finite, polynomial or exponential ambiguity using the following properties:

EDA – There is a useful state $q \in Q$ such that, for some word $v \in \Sigma^*$, $da_{\mathcal{A}}(q, v, q) \geq 2$.

IDA_d – There are useful states $r_1, s_1, \dots, r_d, s_d \in Q$ and words $v_1, u_2, v_2, \dots, u_d, v_d \in \Sigma^*$ such that for all $1 \leq i \leq d$, r_i and s_i are distinct and $(r_i, v_i, r_i), (r_i, v_i, s_i), (s_i, v_i, s_i) \in \delta$ and for all $2 \leq i \leq d$, $(s_{i-1}, u_i, r_i) \in \delta$.

► **Theorem 2** ([14, 20, 23]). *An NFA (or PFA) \mathcal{A} having the EDA property is equivalent to it being exponentially ambiguous. For any $d \in \mathbb{N}$, an NFA (or PFA) \mathcal{A} having property IDA_d is equivalent to $\text{deg}(\mathcal{A}) \geq d$.*

Clearly, if \mathcal{N} agrees with IDA_d for some $d > 0$, then it also agrees with IDA₁, \dots , IDA_{d-1}. An NFA (or PFA) is thus finitely ambiguous if it does not possess property IDA₁.

3 Unary PFA

Our main focus is on unary automata. We begin by giving a simple folklore proof that the λ -reachability and emptiness problems are as computationally difficult as the famous Skolem problem, which is only known to be decidable for instances of depth 4 [22]. See also [1] for connections to reachability problems for Markov chains.

► **Theorem 3.** *The λ -reachability and emptiness problems for unary exponentially ambiguous Probabilistic Finite Automata are Skolem-hard.*

Proof. (*Folklore*). The λ -reachability problem for unary exponentially ambiguous PFA can be shown Skolem-hard based on the well known matrix formulation of Skolem's problem [11] and Turakainen's technique showing the equivalence of (strict) cutpoint language acceptance of generalised automata and exponentially ambiguous probabilistic automata [21].

The emptiness problem can be shown Skolem-hard by encoding the positivity problem which is known to be Skolem-hard, see [17] for example. ◀

We now move to prove our main result, specifically that the emptiness and λ -reachability problems for polynomially ambiguous unary probabilistic finite automata are in EXPTIME. Note again that without the restriction of polynomial ambiguity the problem is Skolem-hard by Theorem 3 and thus not even known to be decidable.

► **Theorem 4.** *The λ -reachability and (strict) emptiness problems for unary polynomially ambiguous Probabilistic Finite Automata are decidable in EXPTIME.*

In order to establish Theorem 4, we need to prove a series of lemmas.

The next lemma states that we may consider a unary polynomially ambiguous PFA whose transition matrix is upper-triangular. This will prove useful since in that case the eigenvalues of the transition matrix are rational nonnegative. In general, a polynomially ambiguous unary PFA may have a transition matrix with complex eigenvalues. The proof of the lemma relies on the analysis of strongly connected components (SCCs) of the underlying transition graph of a PFA.

► **Lemma 5.** Let $\mathcal{P} = (u, A, v)$ be a polynomially ambiguous unary Probabilistic Finite Automaton with acceptance function $\mathcal{P}(a^k) = u^T A^k v$. Then we can compute in EXPTIME a set of d polynomially ambiguous unary PFAs $\{\mathcal{P}_s = (u_s, U, v') \mid 0 \leq s \leq d-1\}$ such that U is rational upper-triangular and $\mathcal{P}(a^k) = \mathcal{P}_s(a^r) = u_s^T U^r v'$, where $k = rd + s$ with $0 \leq s \leq d-1$.

Proof. We will identify \mathcal{P} and its underlying graph in which an edge (p, q) exists iff $A_{p,q} \neq 0$. Two states p, q of a PFA are said to be *connected* if there exists a path from p to q and from q to p . We partition the set of states into Strongly Connected Components (SCC) denoted S_1, S_2, \dots, S_ℓ so that for any SCC S_j , either $|S_j| = 1$, or else any two states in S_j are connected. These SCCs can be computed in linear time.

A polynomially ambiguous PFA does not have the EDA property (see Sec. 2.1). This implies that every S_j , with $|S_j| > 1$, consists of a single directed cycle, possibly with transitions to other SCCs. To see this, suppose there are two different directed cycles inside S_j of lengths m and n and a common vertex p . Then one can construct two different paths of length mn from p to p by going m times along the first cycle and n time along the second cycle, respectively, contradicting the assumption that \mathcal{P} does not have the EDA property.

Note that if there exists a path from a state $p \in S_{j_1}$ to some $q \in S_{j_2}$, then there does not exist any path from any state in S_{j_2} to a state in S_{j_1} , otherwise S_{j_1} and S_{j_2} would merge to a single SCC (since all vertices are then connected). This implies that the connected components S_1, S_2, \dots, S_ℓ can be reordered in such a way that there are no transitions from S_j to S_i for $i < j$. Hence there exists a permutation matrix P such that the following matrix is stochastic block upper-triangular:

$$B = PAP^{-1} = \begin{pmatrix} B_1 & * & \cdots & * \\ 0 & B_2 & \ddots & * \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & B_\ell \end{pmatrix},$$

such that each $B_j \in \mathbb{Q}^{d_j \times d_j}$, where d_j is the size of S_j , and $B_j \preceq P_j$, where $P_j \in \mathbb{N}^{d_j \times d_j}$ is a permutation matrix, and the entries $*$ are arbitrary. Here $M \preceq N$ means that M is entrywise less than N , i.e. $M_{i,j} \leq N_{i,j}$.

Let $d = \text{lcm}\{d_j \mid 1 \leq j \leq \ell\}$ (in fact, we can simply take $d = \prod_{j=1}^{\ell} d_j$). We then see that:

$$U := B^d = PA^d P^{-1} = \begin{pmatrix} B_1^d & * & \cdots & * \\ 0 & B_2^d & \ddots & * \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & B_\ell^d \end{pmatrix}.$$

Note that each $B_j^d \preceq P_j^d = I_j$, where $I_j \in \mathbb{N}^{d_j \times d_j}$ is the identity matrix, and the entries $*$ are arbitrary. Therefore, each B_j^d is diagonal, and so U is clearly upper-triangular.

We then define $\mathcal{P}_s = (u_s, U, v')$, for $0 \leq s \leq d-1$, with $u_s^T = u^T A^s P^{-1}$ and $v' = Pv$ noting that Pv is a binary vector as required of a final state vector. We now see that:

$$\mathcal{P}(a^k) = u^T A^k v = u^T A^s A^{rd} v = u^T A^s P^{-1} (PA^{rd} P^{-1}) Pv = u_s^T U^r v' = \mathcal{P}_s(a^r)$$

for $k = rd + s$ with $0 \leq s \leq d-1$ as required. Here we used the identity $U^r = PA^{rd} P^{-1}$.

Finally, note that d can be exponential in the number of states of \mathcal{P} , which in turn is bounded by the input size. Hence computing U and all u_s , for $0 \leq s \leq d-1$, takes exponential time. ◀

15:6 Decision Questions for Probabilistic Automata on Small Alphabets

The next lemma gives us an efficient method to compute an explicit formula for the acceptance probability function of a unary PFA with upper-triangular transition matrix.

► **Lemma 6.** *Let $\mathcal{P} = (u, A, v)$ be a unary probabilistic finite automaton such that A is rational upper-triangular, and let $\lambda_0 = 1 > \lambda_1 > \dots > \lambda_m \geq 0$ be distinct eigenvalues of A . Then there exist a constant $c \in \mathbb{Q}$ and univariate polynomials p_1, \dots, p_m over \mathbb{Q} , all of which can be computed in polynomial time, such that*

$$\mathcal{P}(a^k) = c + \sum_{i=1}^m p_i(k) \lambda_i^k.$$

Proof. First, we write A in *Jordan normal form* $A = S^{-1}JS$, where S is a nonsingular ($\det(S) \neq 0$) matrix consisting of the generalised eigenvectors of A . Recall that A is a rational upper-triangular matrix. It follows that J and S must have rational entries. Moreover, to compute J and S , we need to solve systems of linear equations over \mathbb{Q} , which can be done in polynomial time. Computing S^{-1} also requires polynomial time. Matrix J has the form $J = \bigoplus_{i=0}^m \bigoplus_{j=1}^{n_i} J_{\ell_{i,j}}(\lambda_i)$, where $J_{\ell_{i,j}}(\lambda_i)$ is a $\ell_{i,j} \times \ell_{i,j}$ *Jordan block* and n_i is the geometric multiplicity of λ_i (hence $\sum_{j=1}^{n_i} \ell_{i,j}$ is the algebraic multiplicity of λ_i). Recall that a Jordan block $J_\ell(\lambda)$ of size $\ell \times \ell$ that corresponds to an eigenvalue λ has the form:

$$J_\ell(\lambda) = \begin{pmatrix} \lambda & 1 & 0 & \dots & 0 \\ 0 & \lambda & 1 & \dots & 0 \\ 0 & 0 & \lambda & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & \lambda \end{pmatrix} \in \mathbb{Q}^{\ell \times \ell}.$$

Noting that $\binom{x}{y} = 0$ if $y > x$, we see that

$$J_\ell(\lambda)^k = \begin{pmatrix} \lambda^k & \binom{k}{1} \lambda^{k-1} & \binom{k}{2} \lambda^{k-2} & \dots & \binom{k}{\ell-1} \lambda^{k-(\ell-1)} \\ 0 & \lambda^k & \binom{k}{1} \lambda^{k-1} & \dots & \binom{k}{\ell-2} \lambda^{k-(\ell-2)} \\ 0 & 0 & \lambda^k & \dots & \binom{k}{\ell-3} \lambda^{k-(\ell-3)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & \lambda^k \end{pmatrix}. \quad (1)$$

Note that the entries of $J_\ell(\lambda)^k$ have the form $q_{i,j}(k) \lambda^k$, where $q_{i,j}(k)$ are polynomials over \mathbb{Q} that can be computed in polynomial time. Namely, $q_{i,i+p}(k) = \binom{k}{p} \lambda^{-p}$ for $0 \leq p \leq \ell - i$, and $q_{i,j}(k) = 0$ for $i > j$. Note that even though p appears in the exponent of λ^{-p} and as $p!$ in $\binom{k}{p}$, these values are still computable in PTIME from the input data because p is bounded by the dimension of the matrix, which in turn is bounded by the input size.

Next, we note that $J^k = \bigoplus_{i=0}^m \bigoplus_{j=1}^{n_i} J_{\ell_{i,j}}(\lambda_i)^k$. Hence the entries of J^k have the form $p_{s,t}(k) \lambda_i^k$, where $p_{s,t}(k)$ are polynomials over \mathbb{Q} . So we can write the function $\mathcal{P}(a^k)$ as follows:

$$\mathcal{P}(a^k) = u^T A^k v = (u^T S^{-1}) J^k (Sv).$$

Note that in the above equation, $u^T S^{-1}$ and Sv are rational vectors. It follows that

$$\mathcal{P}(a^k) = \sum_{i=0}^m p_i(k) \lambda_i^k$$

for some polynomials $p_i(k)$ over \mathbb{Q} . In fact, these polynomials are rational linear combinations of those $p_{s,t}(k)$ that multiply λ_i^k in the expression for J^k , and so they can be computed in polynomial time.

Finally, recall that $\lambda_0 = 1$ and note that the Jordan blocks that correspond to the dominant eigenvalues of a stochastic matrix have size 1×1 (for the proof of this fact see, e.g. [9, Theorem 6.5.3]). It follows from (1) that the terms λ_0^k in the formula for J^k are multiplied by constant polynomials $p_{s,t}(k) = 1$. Hence $p_0(k) = c$ for some constant $c \in \mathbb{Q}$. ◀

The next technical lemma is crucial in our later analysis of the running time of the algorithms for the emptiness and λ -reachability problems presented in Lemmas 8 and 9.

► **Lemma 7.** *Let $D \in \mathbb{R}$ be such that $\ln D > 2$. Then for all $x > 3D \ln D$, we have $D \ln x < x$.*

Proof. Our goal is to find $x_0 > 0$ such that every $x > x_0$ satisfies $D \ln x < x$. First, let us make a substitution $x = Dt$, where $t > 1$. Then we can rewrite $D \ln x < x$ as follows

$$\begin{aligned} D \ln(Dt) &< Dt, \\ \ln t + \ln D &< t. \end{aligned}$$

We want to find $t_0 > 1$ such that every $t > t_0$ satisfies $\ln t + \ln D < t$. Let us make another substitution $t = \ln D + u \ln \ln D$, where $u > 0$. Then we can write the previous inequality as

$$\begin{aligned} \ln(\ln D + u \ln \ln D) + \ln D &< \ln D + u \ln \ln D, \\ \ln \left(\ln D \left(1 + u \frac{\ln \ln D}{\ln D} \right) \right) &< u \ln \ln D, \\ \ln \ln D + \ln \left(1 + u \frac{\ln \ln D}{\ln D} \right) &< u \ln \ln D. \end{aligned} \tag{2}$$

So we need to find $u_0 > 0$ such that for all $u > u_0$, the inequality (2) holds. In order to do this, we can replace the left-hand side of (2) with a larger value using $\ln \left(1 + u \frac{\ln \ln R}{\ln R} \right) < u \frac{\ln \ln R}{\ln R}$. Thus we obtain

$$\begin{aligned} \ln \ln D + u \frac{\ln \ln D}{\ln D} &< u \ln \ln D, \\ 1 + \frac{u}{\ln D} &< u, \quad \ln D + u < u \ln D, \quad \frac{\ln D}{\ln D - 1} < u. \end{aligned}$$

Recall that by our assumption $\ln D > 2$. In this case, $\frac{\ln D}{\ln D - 1} < 2$, and hence we can choose $u_0 = 2$. This gives us the values $t_0 = \ln D + u_0 \ln \ln D = \ln D + 2 \ln \ln D$ and $x_0 = Dt_0 = D(\ln D + 2 \ln \ln D)$. Since $\ln \ln D < \ln D$, we can choose x_0 to be $x_0 = 3D \ln D$. ◀

We now proceed to the proof of our main result. We split the analysis into two cases depending on whether or not the cutpoint λ coincides with the limit $\lim_{k \rightarrow \infty} \mathcal{P}(a^k)$, which is unique by Lemma 6.

► **Lemma 8.** *Let $\mathcal{P} = (u, A, v)$ be a unary probabilistic finite automaton such that A is rational upper-triangular, and let $\lambda \in [0, 1] \cap \mathbb{Q}$ be a cutpoint. Assuming that $\lambda \neq \lim_{k \rightarrow \infty} \mathcal{P}(a^k)$, the (strict) emptiness and λ -reachability problems for \mathcal{P} and λ are decidable in EXPTIME.*

Proof. By Lemma 6, we can write $\mathcal{P}(a^k) = c + \sum_{i=1}^m p_i(k) \lambda_i^k$, where $1 > \lambda_1 > \dots > \lambda_m$ are the eigenvalues of A and c and the coefficients of p_i are rational numbers that can be computed in polynomial time. By assumption, $\lim_{k \rightarrow \infty} \mathcal{P}(a^k) = c \neq \lambda$. Let $\epsilon = \frac{|c-\lambda|}{2}$. We now determine a natural number $k_0 > 0$ such that $\mathcal{P}(a^k) \in (c - \epsilon, c + \epsilon)$ for all $k > k_0$.

15:8 Decision Questions for Probabilistic Automata on Small Alphabets

Let each $p_i(k)$ have the form $p_i(k) = a_{i,s}k^s + a_{i,s-1}k^{s-1} + \dots + a_{i,0}$, where $s \leq n$ is the size of the largest Jordan block in the Jordan normal form of A (we do not assume here that $a_{i,s} \neq 0$). Then for all $k > 0$ we have

$$\left| \sum_{i=1}^m p_i(k) \lambda_i^k \right| \leq \lambda_1^k \sum_{i=1}^m |p_i(k)| \leq \lambda_1^k k^s \sum_{i=1}^m \sum_{j=0}^s |a_{i,j}| = d k^s \lambda_1^k,$$

where $d = \sum_{i=1}^m \sum_{j=0}^s |a_{i,j}| \in \mathbb{Q}$ can be computed in polynomial time by Lemma 6.

Let $k_1 > 0$ be a number to be defined later such that for all $k > k_1$,

$$k^s < \left(\frac{1}{\sqrt{\lambda_1}} \right)^k = \lambda_1^{-\frac{k}{2}}.$$

Then for all $k > k_1$, we have $d k^s \lambda_1^k < d \lambda_1^{\frac{k}{2}}$. Thus we need to find $k_0 \geq k_1$ such that for all $k > k_0$, we have $\lambda_1^{\frac{k}{2}} < \epsilon/d$. Note that if $\epsilon/d \geq 1$, then we can take $k_0 = k_1$. Hence we assume that $\epsilon/d < 1$.

The inequality $\lambda_1^{\frac{k}{2}} < \epsilon/d$ is equivalent to $k \ln \lambda_1 < 2 \ln(\epsilon/d)$. Since $\ln \lambda_1 < 0$, the previous inequality is equivalent to

$$k > \frac{2 \ln(\epsilon/d)}{\ln \lambda_1} = \frac{2 \ln(d/\epsilon)}{-\ln \lambda_1}. \quad (3)$$

To determine k_0 , we need an upper bound on the right-hand side of (3). We will use the fact that for any rational $r > 1$, $\ln r < \log_2 r \leq \log_2 \lceil r \rceil < \text{bins}(\lceil r \rceil)$, where $\text{bins}(n)$ is the size of the binary representation of n . Thus $\text{bins}(\lceil r \rceil)$ gives a polynomially computable integer upper bound for $\ln r$.

Next, using the fact that $\ln(1+x) < x$ for $x \neq 0$, we obtain

$$\ln \lambda_1 = \ln(1 + (\lambda_1 - 1)) < \lambda_1 - 1,$$

which gives $-\ln \lambda_1 > 1 - \lambda_1$. Hence a polynomially computable upper bound on the right-hand side of (3) is

$$\frac{2 \ln(d/\epsilon)}{-\ln \lambda_1} < \frac{2 \text{bins}(\lceil d/\epsilon \rceil)}{1 - \lambda_1}. \quad (4)$$

Next we compute a value k_1 such that for all $k > k_1$:

$$k^s < \lambda_1^{-\frac{k}{2}} \quad \text{or, equivalently,} \quad C \ln k < k, \quad (5)$$

where $C = \frac{2s}{-\ln \lambda_1}$. Using the fact that $\ln(1+x) < x$ for $x \neq 0$, we obtain $C < \frac{2s}{1 - \lambda_1}$.

Hence in order to find k_1 , we can replace C in (5) with $D = \frac{2s}{1 - \lambda_1}$. In addition, we can assume that $\ln D > 2$, since otherwise we can replace D with a larger value that satisfies this condition, e.g. with $D = 9$. Now, Lemma 7 implies that every $k > 3D \ln D$ satisfies $D \ln k < k$. To make this value polynomially computable, we can choose it to be

$$k_1 = 3 \lceil D \rceil \text{bins}(\lceil D \rceil), \quad \text{where } D = \max \left\{ \frac{2s}{1 - \lambda_1}, 9 \right\}.$$

Finally, combining the right-hand side of (4) with the above formula, we can define

$$k_0 = \max \left\{ \frac{2 \text{bins}(\lceil d/\epsilon \rceil)}{1 - \lambda_1}, 3 \lceil D \rceil \text{bins}(\lceil D \rceil) \right\}.$$

Note that all the values that appear in the above formula, e.g. ϵ , d and D , can be computed in polynomial time from the input data.

At this point we have derived a polynomially computable k_0 such that $\mathcal{P}(a^k) = u^T A^k v \in (c - \epsilon, c + \epsilon)$ and, in particular, $\mathcal{P}(a^k) \neq \lambda$ for all $k > k_0$. Now, to decide the λ -reachability problem, we need to check for each integer $k \in [0, k_0]$ whether $u^T A^k v = \lambda$. Note that the number of integers in $[0, k_0]$ is equal to $2^{\text{bins}(k_0)}$, which is exponential in the instance size. Also, computing A^k for a given $k \in [0, k_0]$ takes exponential time because $\text{bins}(A^k) = \mathcal{O}(2^{\text{bins}(k_0)} \text{bins}(A))$. So, the overall algorithm is in EXPTIME.

In a similar way, we can decide the (strict) emptiness problem in EXPTIME. For instance, suppose $\lambda > c$. Then for all $k > k_0$, we have $\mathcal{P}(a^k) < c + \epsilon < \lambda$. Thus deciding whether there exists k such that $\mathcal{P}(a^k) < \lambda$ is trivial. Suppose we want to know if there exists k such that $\mathcal{P}(a^k) \geq \lambda$. In this case, we need to check for each integer $k \in [0, k_0]$ whether $u^T A^k v \geq \lambda$. By the same argument as before, this can be done in EXPTIME. \blacktriangleleft

► Lemma 9. *Let $\mathcal{P} = (u, A, v)$ be a unary polynomially ambiguous probabilistic finite automaton such that A is upper-triangular and let $\lambda \in [0, 1] \cap \mathbb{Q}$ be a cutpoint. Assuming that $\lambda = \lim_{k \rightarrow \infty} \mathcal{P}(a^k)$, the (strict) emptiness and λ -reachability problems for \mathcal{P} and λ are decidable in EXPTIME.*

Proof. Recall that by Lemma 6, we can write $\mathcal{P}(a^k) = c + \sum_{i=1}^m p_i(k) \lambda_i^k$, where $1 > \lambda_1 > \dots > \lambda_m$ are the eigenvalues of A and c and the coefficients of p_i are rational numbers computable in polynomial time. By our assumption, $\lambda = \lim_{k \rightarrow \infty} \mathcal{P}(a^k) = c$. As before, let each $p_i(k)$ have the form $p_i(k) = a_{i,s} k^s + a_{i,s-1} k^{s-1} + \dots + a_{i,0}$, where $s \leq n$ (we do not assume here that $a_{i,s} \neq 0$).

In addition, assume that the leading coefficient of $p_1(k)$ is $a_{1,t}$, for some $t \leq s$. Without loss of generality, suppose $a_{1,t} > 0$; the case when $a_{1,t} < 0$ is similar. First, we compute k_0 such that $p_1(k) > \frac{1}{2} a_{1,t} k^t$ for all $k > k_0$. To do this, we will use the following inequalities:

$$a_{1,t} k^t + a_{1,t-1} k^{t-1} + \dots + a_{1,0} > \frac{1}{2} a_{1,t} k^t \iff \frac{1}{2} a_{1,t} k^t + a_{1,t-1} k^{t-1} + \dots + a_{1,0} > 0$$

$$\text{and } |a_{1,t-1} k^{t-1} + \dots + a_{1,0}| \leq k^{t-1} (|a_{1,t-1}| + \dots + |a_{1,0}|) = k^{t-1} \sum_{j=0}^{t-1} |a_{1,j}| \quad \text{if } k \geq 1.$$

So, the inequality $p_1(k) > \frac{1}{2} a_{1,t} k^t$ follows from $\frac{1}{2} a_{1,t} k^t > k^{t-1} \sum_{j=0}^{t-1} |a_{1,j}|$, which is equivalent to $k > \frac{2}{a_{1,t}} \sum_{j=0}^{t-1} |a_{1,j}|$. Therefore, we conclude that

$$p_1(k) > \frac{1}{2} a_{1,t} k^t \quad \text{for all } k \text{ such that } k > k_0 := \max \left\{ 1, \frac{2}{a_{1,t}} \sum_{j=0}^{t-1} |a_{1,j}| \right\}. \quad (6)$$

Now we want to find $k_1 \geq k_0$ such that for all $k > k_1$, we have

$$\lambda_1^k p_1(k) + \lambda_2^k p_2(k) + \dots + \lambda_m^k p_m(k) > 0. \quad (7)$$

Note that

$$|\lambda_2^k p_2(k) + \dots + \lambda_m^k p_m(k)| \leq \lambda_2^k (|p_2(k)| + \dots + |p_m(k)|) \leq d k^s \lambda_2^k, \quad (8)$$

where $d = \sum_{i=2}^m \sum_{j=0}^s |a_{i,j}|$. Using (6) and (8), we see that (7) holds whenever $k > k_0$ and $d k^s \lambda_2^k < \frac{1}{2} a_{1,t} k^t \lambda_1^k$, which is equivalent to

15:10 Decision Questions for Probabilistic Automata on Small Alphabets

$$\frac{2dk^{s-t}}{a_{1,t}} < \left(\frac{\lambda_1}{\lambda_2}\right)^k \quad \text{or} \quad \ln \frac{2d}{a_{1,t}} + (s-t) \ln k < k \ln \frac{\lambda_1}{\lambda_2}$$

$$\frac{1}{\ln \lambda_1/\lambda_2} \left(\ln \frac{2d}{a_{1,t}} + (s-t) \ln k \right) < k. \quad (9)$$

We will use the following inequality

$$\ln \frac{\lambda_1}{\lambda_2} = -\ln \frac{\lambda_2}{\lambda_1} = -\ln \left(1 + \frac{\lambda_2 - \lambda_1}{\lambda_1} \right) > -\frac{\lambda_2 - \lambda_1}{\lambda_1} > \lambda_1 - \lambda_2.$$

Then we can replace (9) with a stronger inequality

$$\frac{1}{\lambda_1 - \lambda_2} \left(\ln \frac{2d}{a_{1,t}} + (s-t) \ln k \right) < k. \quad (10)$$

In the following, we will assume $t < s$ since otherwise (10) simplifies to $\frac{1}{\lambda_1 - \lambda_2} \ln \frac{2d}{a_{1,t}} < k$.

Let us make the substitution $k = t \left(\frac{2d}{a_{1,t}} \right)^{-\frac{1}{s-t}}$, where $t > 0$. Then (10) can be written as

$$\frac{1}{\lambda_1 - \lambda_2} \left(\ln \frac{2d}{a_{1,t}} + (s-t) \ln t + (s-t) \frac{-1}{s-t} \ln \frac{2d}{a_{1,t}} \right) < t \left(\frac{2d}{a_{1,t}} \right)^{-\frac{1}{s-t}}$$

$$\left(\frac{2d}{a_{1,t}} \right)^{\frac{1}{s-t}} \frac{s-t}{\lambda_1 - \lambda_2} \ln t < t.$$

Let $D = \max \left\{ 9, \left(\frac{2d}{a_{1,t}} \right)^{\frac{1}{s-t}} \frac{s-t}{\lambda_1 - \lambda_2} \right\}$. Here 9 is needed to satisfy the requirement $\ln D > 2$ in Lemma 7. Then by Lemma 7, the above inequality holds when $t > 3D \ln D$. Therefore, (10) and hence (9) holds when $k > 3 \left(\frac{2d}{a_{1,t}} \right)^{-\frac{1}{s-t}} D \ln D$. To make this bound polynomially computable, we can simplify it as follows. Suppose that $2d \geq a_{1,t}$. Then (9) holds when

$$k > k_1 := 3 \lceil E \rceil \text{bins}(\lceil E \rceil), \quad \text{where } E = \max \left\{ 9, \frac{2d}{a_{1,t}} \cdot \frac{s-t}{\lambda_1 - \lambda_2} \right\}$$

because in this case $\left(\frac{2d}{a_{1,t}} \right)^{\frac{1}{s-t}} \leq \frac{2d}{a_{1,t}}$ and $\left(\frac{2d}{a_{1,t}} \right)^{-\frac{1}{s-t}} \leq 1$. On the other hand, if $2d < a_{1,t}$, then (9) holds when

$$k > k_1 := 3 \left\lceil \frac{a_{1,t}}{2d} E \right\rceil \text{bins}(\lceil E \rceil), \quad \text{where } E = \max \left\{ 9, \frac{s-t}{\lambda_1 - \lambda_2} \right\}$$

because in this case $\left(\frac{2d}{a_{1,t}} \right)^{-\frac{1}{s-t}} < \left(\frac{2d}{a_{1,t}} \right)^{-1}$ and $\left(\frac{2d}{a_{1,t}} \right)^{\frac{1}{s-t}} < 1$.

Finally, we conclude that (7) holds for all $k > k_2 := \max\{k_0, k_1\}$, where both k_0 and k_1 are computable in PTIME. In other words, we obtained a polynomially computable value k_2 such that $\mathcal{P}(a^k) > c = \lambda$ for all $k > k_2$. Using the same argument as at the end of the proof of Lemma 8, we can show that the (strict) emptiness and λ -reachability problems are decidable in EXPTIME. \blacktriangleleft

We are now ready to give a proof of Theorem 4.

Proof of Theorem 4. Let $\mathcal{P} = (u, A, v)$ be a polynomially ambiguous unary PFA. By Lemma 5, we can compute in EXPTIME a set of d polynomially ambiguous unary PFAs $\{\mathcal{P}_s = (u_s, U, v') \mid 0 \leq s \leq d-1\}$ such that U is rational upper-triangular and

$$\mathcal{P}(a^{rd+s}) = \mathcal{P}_s(a^r) = u_s^T U^r v',$$

where $0 \leq s \leq d-1$.

Suppose λ is a given cutpoint. If we want to decide whether there exists k such that $\mathcal{P}(a^k) = \lambda$ (or $\mathcal{P}(a^k) \geq \lambda$), we can check for every s from 0 to $d-1$ whether there exists r such that $\mathcal{P}_s(a^r) = \lambda$ (or $\mathcal{P}_s(a^r) \geq \lambda$, respectively), which can be done in EXPTIME using Lemmas 8 and 9. Namely, we will use Lemma 8 if $\lambda \neq c_s$ and Lemma 9 if $\lambda = c_s$ for the current values of $s \in [0, d-1]$. Finally, we note that even though the value of d can be exponential in the input size, the whole procedure can still be done in EXPTIME. ◀

Skolem's problem is at least NP-hard [6] implying that the λ -reachability and emptiness problems are also NP-hard, at least for PFA of exponential ambiguity. Our next result shows that NP-hardness can be established even for unary PFAs of *finite ambiguity*.

► **Theorem 10.** *The λ -reachability and emptiness problems for unary finitely ambiguous Probabilistic Finite Automata $\mathcal{P} = (u, A, v)$ with $\{0, 1\}$ -matrix A are NP-hard.*

Proof. The NP-hardness of Skolem's problem was established in [6]. Specifically, Corollary 1.3 of [6] states that the problem of determining, for a given matrix $A \in \{0, 1\}^{n \times n}$ and row vectors $b, c \in \{0, 1\}^n$, if $b^T A^k c = 0$ for some $k \geq 0$ is NP-hard. Examination of the proof of this corollary shows that in fact \mathcal{P} is finitely ambiguous as we shall show.

The proof of Theorem 1.1 of [6] shows a reduction of 3SAT on m clauses with n letters to a unary rational expression E of the form:

$$E = \bigcup_{j=0}^k a^{z_j} (a^{r_j})^*,$$

where $k = \mathcal{O}(n^3 m)$ and $z_j, r_j = \mathcal{O}(n^6)$ as is not difficult to see from the proof in [6]. Notice then that each z_j, r_j represented in unary has a polynomial size in terms of the 3SAT instance and thus E also has a polynomial representation size.

We may then invoke Kleene's theorem [15] to state that the language recognised by E is also recognised by an NFA $\mathcal{P} = (b, \{A\}, c)$ which thus allows the derivation of Corollary 1.3 of [6]. Note that E is simply the union of rational expressions of the form $E_j = a^{z_j} (a^{r_j})^*$. Each E_j can be transformed to an NFA \mathcal{N}_j with $z_j + r_j + 1$ states $S_j = n_{0,j}, \dots, n_{z_j,j}, n_{z_j+1,j}, \dots, n_{z_j+r_j,j}$ with initial state $n_{0,j}$, final state $n_{z_j+1,j}$ and transition function $\delta : S_j \times \{a\} \rightarrow S_j$ given by $\delta(n_{i,j}, a) = n_{i+1,j}$ for $0 \leq i \leq z_j + r_j - 1$ and $\delta(n_{z_j+r_j,j}, a) = n_{z_j+1,j}$.

We may then form an NFA \mathcal{N} by $\mathcal{N} = \bigcup_{j=0}^k \mathcal{N}_j$ with the usual construction. In this case, \mathcal{N} has set of initial states $\{n_{0,j} \mid 1 \leq j \leq k\}$, set of final states $\{n_{z_j+1,j} \mid 1 \leq j \leq k\}$ and states in disjoint subsets S_j and $S_{j'}$ with $j \neq j'$ are not connected. This implies by the IDA property of [23] that \mathcal{N} is finitely ambiguous since there does not exist any state with two outgoing transitions (by which reasoning we also know that each row of \mathcal{N} 's transition matrix has exactly one entry 1 with all others 0). In fact one may see that \mathcal{N} is k -ambiguous with $k = \mathcal{O}(n^3 m)$. The number of states of \mathcal{N} is $d = \sum_{j=0}^k z_j + r_j + 1 = \mathcal{O}(n^9 m)$ which is polynomial in the 3SAT instance representation size.

We note that actually \mathcal{N} is already close to a PFA. Since each row is zero except for exactly one entry 1, matrix A is stochastic. We thus consider Probabilistic Finite Automaton $\mathcal{P} = (u, \{A\}, c)$ where $u = \frac{b}{|b|}$ is the initial (stochastic) vector. \mathcal{P} has polynomial ambiguity

15:12 Decision Questions for Probabilistic Automata on Small Alphabets

since \mathcal{N} does. Therefore, deciding if there exists $k \geq 0$ such that $\mathcal{P}(a^k) = 0$ or $\mathcal{P}(a^k) \leq 0$ is NP-hard to determine, proving NP-hardness of the λ -reachability and emptiness problems. Since we did not modify \mathcal{N} to derive \mathcal{P} other than to scale the initial vector, the degree of ambiguity is retained. \blacktriangleleft

► **Corollary 11.** *The λ -reachability and emptiness problems for unary polynomially ambiguous PFA $\mathcal{P} = (u, A, v)$ with $\{0, 1\}$ -matrix A are NP-complete.*

Proof. NP-hardness follows from Theorem 10 since finite ambiguity is a stronger property than polynomially ambiguity. To prove the NP upper bound, we will show that the algorithm in the proof of Theorem 4 can be done in NP. We again use Lemmas 5, 6, 8 and 9. Note that the value d from Lemma 5 can be exponential. However, its binary presentation has polynomial size. So, instead of cycling through all s from 0 to $d-1$, we can nondeterministically guess in polynomial time a value $s \in [0, d-1]$.

Next, we note that the values of k_0 in Lemma 8 and k_2 in Lemma 9 also have binary representations of polynomial size. Again, instead of checking every k in $[0, k_0]$ or $[0, k_2]$, we can nondeterministically guess k in polynomial time.

Finally, in the verification step of our algorithm we need to compute the matrices A^d , A^s and $(A^d)^k$. This can be done in polynomial time using exponentiation by squaring. Indeed, the exponentiation by squaring requires polynomially many steps. Also, any power of a stochastic $\{0, 1\}$ -matrix is also a stochastic $\{0, 1\}$ -matrix, so the entries of the power matrices do not grow in size. \blacktriangleleft

4 Binary PFA

The following theorem shows that the λ -reachability and emptiness problems are NP-hard for binary PFA of *polynomial ambiguity* with *commuting* transition matrices (and the matrices can be assumed fixed in the case of λ -reachability and nonstrict emptiness). The emptiness problem for non-commutative binary PFA over 25 states is known to be undecidable, at least over exponentially ambiguous PFA [12]. Emptiness is also undecidable for exponentially ambiguous commutative PFA, although with many more states and a larger alphabet [2].

► **Theorem 12.** *The λ -reachability and emptiness problems are NP-hard for binary probabilistic finite automata of polynomial ambiguity with commuting matrices of dimension 9 for λ -reachability, 37 for nonstrict emptiness, and 40 for strict emptiness. Moreover, the matrices can be assumed fixed for the λ -reachability and nonstrict emptiness problems.*

Proof. We use a reduction from the solvability of binary quadratic Diophantine equations. Namely, given an equation of the form $ax^2 + by - c = 0$, where $a, b, c \in \mathbb{N}$, it is NP-hard to determine if there exists $x, y \in \mathbb{N}$ satisfying the equation [16]. We begin with the λ -reachability problem before considering the emptiness problem.

λ -Reachability reduction. Let $A = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ and note that $A^k = \begin{pmatrix} 1 & k \\ 0 & 1 \end{pmatrix}$ and that $(A \otimes A)^k_{1,4} = (A^k \otimes A^k)_{1,4} = k^2$. We form a weighted automaton² W_1 on binary alphabet $\Sigma = \{h, g\}$ in the following way to encode $ax^2 + by$ (we will deal with c later). Let $W_1 = (u_1, \phi, v_1)$ where $u_1, v_1 \in \mathbb{N}^7$ and $\phi : \Sigma^* \rightarrow \mathbb{N}^{7 \times 7}$. We define $u_1 = (a, 0, 0, 0, b, 0, 0)^T$, $v_1 = (0, 0, 0, 1, 0, 1, 0)^T$ and $\phi(\ell) = \frac{1}{4}\phi'(\ell)$ for $\ell \in \{h, g\}$ with

² For our purposes here, by a *weighted automaton* we simply mean an automaton whose initial vector, final vector, and transition matrices are over nonnegative integers.

$$\phi'(h) = \left(\frac{(A \otimes A) \oplus I_2}{\mathbf{0}^6} \middle| \frac{t_1}{4} \right), \quad \phi'(g) = \left(\frac{I_4 \oplus A}{\mathbf{0}^6} \middle| \frac{t_2}{4} \right),$$

with $\mathbf{0}^k = (0, 0, \dots, 0) \in \mathbb{N}^k$, $t_1 = (0, 2, 2, 3, 3, 3)^T$ and $t_2 = (3, 3, 3, 3, 2, 3)^T$. We see then that each row of $\phi'(\ell)$ is nonnegative and sums to 4, thus $\phi(\ell)$ is stochastic for $\ell \in \{g, h\}$. Furthermore, by the mixed product property of the Kronecker product, we see that $((A \otimes A) \oplus I_2)^x = (A^x \otimes A^x) \oplus I_2$ and $(I_4 \oplus A)^y = I_4 \oplus A^y$ for $x, y \in \mathbb{N}$ and thus by the block upper triangular structure of $\phi'(h), \phi'(g)$, we see that

$$\phi'(h^x g^y) = \left(\frac{(A^x \otimes A^x) \oplus A^y}{\mathbf{0}^6} \middle| \frac{t_{xy}}{4^{x+y}} \right),$$

where t_{xy} is a nonnegative vector maintaining the row sum at 4^{x+y} . We now see that

$$u_1^T \phi(h^x g^y) v_1 = \frac{ax^2 + by}{4^{x+y}} \quad (11)$$

We define a second weighted automaton $W_2 = (u_2, \psi, v_2)$ with $u_2 = (c, 0)^T$, $v_2 = (0, 1)^T$ and $\psi : \Sigma^* \rightarrow \mathbb{N}^{2 \times 2}$ with $\psi(\ell) = \frac{1}{4} \psi'(\ell)$ for $\ell \in \{h, g\}$ defined thus: $\psi'(h) = \psi'(g) = \begin{pmatrix} 1 & 3 \\ 0 & 4 \end{pmatrix}$.

We therefore see that

$$u_2^T \psi(h^x g^y) v_2 = \frac{c(4^{x+y} - 1)}{4^{x+y}} = c \left(1 - \frac{1}{4^{x+y}}\right) \quad (12)$$

We now join W_1 and W_2 into a 9-state PFA $\mathcal{P} = (u, \gamma, v)$ where $u = \frac{1}{a+b+c}[u_1 | u_2]$, $v = [v_1 | v_2]$ and $\gamma(\ell) = \phi(\ell) \oplus \psi(\ell)$. Combining Eqns (11) and (12) we see that

$$\begin{aligned} u^T \gamma(h^x g^y) v &= \frac{1}{a+b+c} \left(\frac{ax^2 + by}{4^{x+y}} + c \left(1 - \frac{1}{4^{x+y}}\right) \right) \\ &= \frac{1}{a+b+c} \left(c + \frac{ax^2 + by - c}{4^{x+y}} \right) \end{aligned} \quad (13)$$

which equals $\frac{c}{a+b+c}$ if and only if $ax^2 + by - c = 0$. Note that $\gamma(h)$ and $\gamma(g)$ commute by their structure since clearly $(A \otimes A) \oplus I$ and $I_4 \oplus A$ commute, giving $(A \otimes A) \oplus A$ in both cases (as a consequence of the mixed product properties of Lemma 1) and the rightmost vector of the matrix simply retains the row sum at 1 for such a product since the matrices are stochastic. Both $\gamma(h)$ and $\gamma(g)$ are upper-triangular thus \mathcal{P} is polynomially ambiguous.

Nonstrict Emptiness reduction. We now show the proof of the emptiness problem. We showed that the λ -reachability problem is NP-hard by deriving a PFA \mathcal{P} over the binary alphabet $\{h, g\}$ such that $\mathcal{P}(h^x g^y)$ is given by Eqn. 13. We note however that a non solution to $ax^2 + by - c = 0$ can be positive or negative and thus we may be above or below the threshold $\frac{c}{a+b+c}$. This encoding thus cannot be used to show the NP-hardness of the *emptiness* problem.

Instead, we can use a similar encoding of the quartic polynomial given by $(ax^2 + by - c)^2 = a^2x^4 + 2abx^2y + b^2y^2 + c^2 - 2acx^2 - 2bcy$ with $a, b, c \in \mathbb{N}$. Note that we arranged the four positive terms first, followed by the two negative terms. Clearly $(ax^2 + by - c)^2$ is nonnegative and equals zero if and only if $ax^2 + by - c = 0$. We will derive a PFA \mathcal{P}_2 such that

$$\mathcal{P}_2(h^x g^y) = \frac{1}{z} \left((2ac + 2bc) + \frac{1}{16^{x+y}} (ax^2 + by + c)^2 \right),$$

15:14 Decision Questions for Probabilistic Automata on Small Alphabets

where $z = a^2 + 2ab + b^2 + c^2 + 2ac + 2bc$, with the property that $\mathcal{P}_2(h^x g^y) \geq \frac{2ac+2bc}{z}$ with equality if and only if $(ax^2 + by - c)^2 = 0$ which is NP-hard to determine. To this end, we compute the following four matrices $\{H_+, G_+, H_-, G_-\}$, the idea being that H_+ and G_+ will be used to compute the positive four terms and H_- and G_- will compute the negative terms:

$$\begin{aligned} H_+ &= \underbrace{(A \otimes A \otimes A \otimes A)}_{x^4} \oplus \underbrace{(A \otimes A \otimes I_2)}_{x^2 y} \oplus \underbrace{(I_2 \otimes I_2)}_{y^2} \oplus \underbrace{1}_1 \\ G_+ &= \underbrace{(I_2 \otimes I_2 \otimes I_2 \otimes I_2)}_{x^4} \oplus \underbrace{(I_2 \otimes I_2 \otimes A)}_{x^2 y} \oplus \underbrace{(A \otimes A)}_{y^2} \oplus \underbrace{1}_1 \\ H_- &= \underbrace{(A \otimes A)}_{x^2} \oplus \underbrace{I_2}_y \\ G_- &= \underbrace{(I_2 \otimes I_2)}_{x^2} \oplus \underbrace{A}_y \end{aligned}$$

and by the mixed product property of Kronecker products of Lemma 1),

$$\begin{aligned} H_+^x G_+^y &= (A^x \otimes A^x \otimes A^x \otimes A^x) \oplus (A^x \otimes A^x \otimes A^y) \oplus (A^y \otimes A^y) \oplus 1 \\ H_-^x G_-^y &= (A^x \otimes A^x) \oplus A^y \end{aligned}$$

Note that $H_+^x G_+^y$ and $H_-^x G_-^y$ each contain the positive and negative (respectively) term of $(ax^2 + by - c)^2$, excluding the coefficients, e.g. $(H_+^x G_+^y)_{1,16} = x^4$ and $(H_+^x G_+^y)_{17,24} = x^2 y$ etc. Note also that $H_+ G_+ = G_+ H_+$ and $H_- G_- = G_- H_-$ which also follows from the mixed product properties and thus matrices $\{H_+, G_+\}$ and $\{H_-, G_-\}$ commute.

As before, we may now increase the dimension of each matrix $\{H_+, H_-, G_+, G_-\}$ by 1 to ensure a common row sum (of 16 in this case) by adding a new column on the right hand side of each matrix, and then divide each matrix by this common value to give $\{H'_+, H'_-, G'_+, G'_-\}$ so that each of these matrices is row stochastic. Matrices $\{H'_+, G'_+\}$ and $\{H'_-, G'_-\}$ still commute since this change only has an effect on the final column of the matrix.

We now show how to handle each term of $(ax^2 + by - c)^2$. We first handle the positive terms. We define $u_1 = (a^2, 0, \dots, 0)^T \in \mathbb{Q}^{16}$, $u_2 = (2ab, 0, \dots, 0)^T \in \mathbb{Q}^8$, $u_3 = (b^2, 0, 0, 0)^T \in \mathbb{Q}^4$ and $u_4 = c^2$ and then let $u_+ = [u_1 | u_2 | u_3 | u_4 | 0] \in \mathbb{Q}^{30}$. We let $v_1 = (0, \dots, 0, 1)^T \in \mathbb{Q}^{16}$, $v_2 = (0, \dots, 0, 1)^T \in \mathbb{Q}^8$, $v_3 = (0, 0, 0, 1)^T \in \mathbb{Q}^4$ and $v_4 = 1$, and let $v_+ = [v_1 | v_2 | v_3 | v_4 | 0] \in \mathbb{Q}^{30}$. We then see that

$$\begin{aligned} & u_+^T (H'_+)^x (G'_+)^y v_+ \\ &= \frac{1}{16^{x+y}} (u_1^T (A^x \otimes A^x \otimes A^x \otimes A^x) v_1 + u_2^T (A^x \otimes A^x \otimes A^y) v_2 + u_3^T (A^y \otimes A^y) v_3 + u_4^T v_4) \\ &= \frac{1}{16^{x+y}} (a^2 x^4 + 2abx^2 y + b^2 y^2 + c^2) \end{aligned} \quad (14)$$

We next handle the negative terms, which is essentially accomplished by switching final and non-final states in the final state vectors to follow. Define $u_5 = (2ac, 0, 0, 0)^T \in \mathbb{Q}^4$ and $u_6 = (2bc, 0)^T \in \mathbb{Q}^2$ and let $u_- = [u_5 | u_6 | 0] \in \mathbb{Q}^7$. We let $v_5 = (0, 0, 0, 1)^T \in \mathbb{Q}^4$ and $v_6 = (0, 1)^T \in \mathbb{Q}^2$. Define $v_- = [v_5 | v_6 | 0] \in \mathbb{Q}^7$. We then see that

$$\begin{aligned} & u_-^T (H'_-)^x (G'_-)^y (\mathbf{1} - v_-) \\ &= (2ac + 2bc) - \frac{1}{16^{x+y}} (u_5^T (A^x \otimes A^x) v_5 + u_6^T A^y v_6 + 0) \\ &= (2ac + 2bc) - \frac{1}{16^{x+y}} (2acx^2 + 2bcy), \end{aligned} \quad (15)$$

where $\mathbf{1} = (1, 1, \dots, 1)^T \in \mathbb{Q}^7$. We used here the fact that $X\mathbf{1} = \mathbf{1}$ for a row stochastic matrix X . We finally define that $H = H'_+ \oplus H'_- \in \mathbb{Q}^{37 \times 37}$ and $G = G'_+ \oplus G'_- \in \mathbb{Q}^{37 \times 37}$, both of which are row stochastic and commute, and let $u_\star = \frac{[u_+ | u_-]}{z} \in \mathbb{Q}^{37}$ and $v_\star = [v_+ | (\mathbf{1} - v_-)] \in \mathbb{Q}^{37}$,

with $z = a^2 + 2ab + b^2 + c^2 + 2ac + 2bc$ to normalise vector u_* . We see then that u_* is a stochastic vector as required. We define the PFA $\mathcal{P}_2 = (u_*, \{H, G\}, v_*)$ and we can now compute that

$$\begin{aligned}
\mathcal{P}_2(h^x g^y) &= u_*^T H^x G^y v_* \\
&= u_*^T (H'_+ G'^y \oplus H'_- G'^y) v_* \\
&= \frac{1}{16^{x+y}} \left(\frac{[u_+ | u_-]^T}{z} \left(\begin{array}{c|c} \frac{H'_+ G'^y}{\mathbf{0}} & \begin{array}{c} * \\ 16^{x+y} \end{array} \\ \hline \mathbf{0} & \frac{H'_- G'^y}{\mathbf{0}} \begin{array}{c} * \\ 16^{x+y} \end{array} \end{array} \right) [v_+ | (\mathbf{1} - v_-)] \right) \\
&= \frac{1}{z 16^{x+y}} (u_+^T H'_+ G'^y v_+ + u_-^T H'_- G'^y (\mathbf{1} - v_-)) \\
&= \frac{1}{z} (u_+^T (H'_+)^x (G'_+)^y v_+ + u_-^T (H'_-)^x (G'_-)^y (\mathbf{1} - v_-)) \\
&= \frac{1}{z} \left((2ac + 2bc) + \frac{1}{16^{x+y}} (a^2 x^4 + 2abx^2 y + b^2 y^2 + c^2) - \frac{1}{16^{x+y}} (2acx^2 + 2bcy) \right) \\
&= \frac{1}{z} \left((2ac + 2bc) + \frac{1}{16^{x+y}} (ax^2 + by - c)^2 \right) \tag{16}
\end{aligned}$$

where $*$ denote the column vectors used to ensure row sums of 16^{x+y} and $\mathbf{0}$ denotes zero matrices of appropriate sizes. We also used Eqns (14) and (15).

Since $(ax^2 + by - c)^2$ is nonnegative, we see that $u_*^T H^x G^y v_* \geq \frac{2ac+2bc}{z}$ with equality if and only if $(ax^2 + by - c)^2 = 0$, which is NP-hard to determine. Therefore using cutpoint $\lambda = \frac{2ac+2bc}{z} \in \mathbb{Q} \cap [0, 1]$ means the (nonstrict) emptiness problem is NP-hard (i.e. does there exist $x, y \in \mathbb{N}$ such that $u_*^T H^x G^y v_* \leq \lambda$ is NP-hard). As before, matrices H and G are upper-triangular and commute by their structure, and therefore the result holds.

Strict Emptiness reduction. Finally we show how to handle the strict emptiness problem. We proceed with a technique inspired by [10]. By (16), if $\mathcal{P}_2(h^x g^y) = u_*^T H^x G^y v_* \neq \frac{1}{z}(2ac + 2bc)$, then $u_*^T H^x G^y v_* \geq \frac{1}{z} \left((2ac + 2bc) + \frac{1}{16^{x+y}} \right)$ therefore $\mathcal{P}_2(h^x g^y) \leq \frac{1}{z}(2ac + 2bc)$ if and only if $\mathcal{P}_2(h^x g^y) < \frac{1}{z} \left((2ac + 2bc) + \frac{1}{16^{x+y}} \right)$.

Let us adapt \mathcal{P}_2 in the following way to create a new PFA \mathcal{P}_3 . Note that \mathcal{P}_2 has 6 initial states (by u_*). We add three new states to \mathcal{P}_3 , denoted q_0, q_F and q_* . State q_0 is a new initial state of \mathcal{P}_3 which, for any input letter, has probability $\frac{1}{2 \cdot 6}$ of moving to each of the 6 initial states of \mathcal{P}_2 and probability $\frac{1}{2}$ to move to new state q_F . State q_F is a new final state that remains in q_F for any input letter with probability $1 - \frac{1}{16z}$ and moves to a new non-accepting absorbing sink state q_* with probability $\frac{1}{16z}$. We now see that for any $a \in \{h, g\}$:

$$\mathcal{P}_3(aw) = \frac{1}{2} \mathcal{P}_2(w) + \frac{1}{2} \left(1 - \frac{1}{16^{|w|} z^{|w|}} \right)$$

If there exists $w_1 = h^x g^y$ with $x, y \geq 0$ such that $\mathcal{P}_2(w_1) \leq \frac{1}{z}(2ac + 2bc)$ then $\mathcal{P}_2(w_1) = \frac{1}{z}(2ac + 2bc)$ and thus:

$$\mathcal{P}_3(aw_1) = \frac{1}{2} \left(\frac{1}{z}(2ac + 2bc) \right) + \frac{1}{2} \left(1 - \frac{1}{16^{|w_1|} z^{|w_1|}} \right) < \frac{1}{2} \left(\frac{1}{z}(2ac + 2bc) + 1 \right).$$

For any $w_2 = h^x g^y$ with $x, y \geq 0$ such that $\mathcal{P}_2(w_2) > \frac{1}{z}(2ac + 2bc)$ then $\mathcal{P}_2(w_2) \geq \frac{1}{z}(2ac + 2bc) + \frac{1}{16^{x+y}}$ by (16). Thus:

$$\mathcal{P}_3(aw_2) \geq \frac{1}{2} \left(\frac{1}{z}(2ac + 2bc) + \frac{1}{16^{|w_2|}} \right) + \frac{1}{2} \left(1 - \frac{1}{16^{|w_2|} z^{|w_2|}} \right) > \frac{1}{2} \left(\frac{1}{z}(2ac + 2bc) + 1 \right).$$

Thus determining if there exists $w = h^x g^y$ such that $\mathcal{P}_3(w) < \frac{1}{2} \left(\frac{1}{z}(2ac + 2bc) + 1 \right)$, i.e. the strict emptiness problem for \mathcal{P}_3 on cutpoint $\frac{1}{2} \left(\frac{1}{z}(2ac + 2bc) + 1 \right)$, is NP-hard. The modifications to \mathcal{P}_2 retain polynomial ambiguity since q_0 and q_F have no incoming (non self looping) edges and q_* has no outgoing edges, therefore property EDA does not hold. Commutativity of the PFA is unaffected since \mathcal{P}_3 is identical to \mathcal{P}_2 except for adding three new states, behaving identically for both input letters. Note that \mathcal{P}_3 has $37 + 3 = 40$ states. ◀

Ideal Membership Problem for Boolean Minority and Dual Discriminator

Arpitha P. Bharathi ✉

IDSIA-SUPSI, Lugano, Switzerland

Abstract

The polynomial Ideal Membership Problem (IMP) tests if an input polynomial $f \in \mathbb{F}[x_1, \dots, x_n]$ with coefficients from a field \mathbb{F} belongs to a given ideal $I \subseteq \mathbb{F}[x_1, \dots, x_n]$. It is a well-known fundamental problem with many important applications, though notoriously intractable in the general case. In this paper we consider the IMP for polynomial ideals encoding combinatorial problems and where the input polynomial f has degree at most $d = O(1)$ (we call this problem IMP_d).

A dichotomy result between “hard” (NP-hard) and “easy” (polynomial time) IMPs was achieved for Constraint Satisfaction Problems over finite domains [6, 34] (this is equivalent to IMP_0) and IMP_d for the Boolean domain [23], both based on the classification of the IMP through functions called polymorphisms. For the latter result, there are only six polymorphisms to be studied in order to achieve a full dichotomy result for the IMP_d . The complexity of the IMP_d for five of these polymorphisms has been solved in [23] whereas for the ternary minority polymorphism it was incorrectly declared in [23] to have been resolved by a previous result. In this paper we provide the missing link by proving that the IMP_d for Boolean combinatorial ideals whose constraints are closed under the minority polymorphism can be solved in polynomial time. This completes the identification of the precise borderline of tractability for the IMP_d for constrained problems over the Boolean domain. We also prove that the proof of membership for the IMP_d for problems constrained by the dual discriminator polymorphism over any finite domain can also be found in polynomial time. Bulatov and Rafiey [8] recently proved that the IMP_d for this polymorphism is decidable in polynomial time, without needing a proof of membership. Our result gives a proof of membership and can be used in applications such as Nullstellensatz and Sum-of-Squares proofs.

1 Introduction

The study of polynomial ideals and related algorithmic problems goes back to David Hilbert [17]. The methods developed in this area to date find a wide range of applications in mathematics and computer science. In this paper we consider the polynomial Ideal Membership Problem, where we want to decide if a given polynomial belongs to a given ideal. This problem is a fundamental algorithmic problem with important applications in solving polynomial systems (see e.g. [12]), polynomial identity testing [12, 30] and underlies proof systems such as Nullstellensatz and Polynomial Calculus (see e.g. [2, 9, 15]).

16:2 Ideal Membership Problem for Boolean Minority and Dual Discriminator

To introduce the problem formally, let $\mathbb{F}[x_1, \dots, x_n]$ be the ring of polynomials over a field \mathbb{F} with indeterminates x_1, \dots, x_n . A polynomial *ideal* I is a subset of the polynomial ring $\mathbb{F}[x_1, \dots, x_n]$ with two properties: for any two polynomials f, g in I , $f + g$ also belongs to I and so does hf for any polynomial h . By the Hilbert Basis Theorem [16] every ideal I has a finite generating set $F = \{f_1, \dots, f_r\} \subset I$ such that for every $f \in \mathbb{F}[x_1, \dots, x_n]$, we have $f \in I$ if and only if there is an “ideal membership proof”, namely a set of polynomials $\{h_1, \dots, h_r\} \subset \mathbb{F}[x_1, \dots, x_n]$ such that $f = h_1 f_1 + \dots + h_r f_r$. The polynomial IDEAL MEMBERSHIP PROBLEM (IMP) is to find out if a polynomial f belongs to an ideal I or not, given a set F of generators of the ideal (we use IMP_d to denote IMP when the input polynomial f has degree at most $d = O(1)$). The IMP is, in general, notoriously intractable. The results of Mayr and Meyer show that it is EXPSPACE-complete [24, 25].

Semidefinite programming (SDP) relaxations have been a powerful technique for approximation algorithm design ever since Goemans and Williamson celebrated result of Max-Cut [14]. With the aim to construct stronger and stronger SDP relaxations, the Sum-of-Squares (SOS) hierarchy has emerged as the most promising set of relaxations (see e.g. [20]). However, we still do not know the answer to even very basic questions about its power. For example, we do not even know when SOS is guaranteed to run in polynomial time! As recently observed by O’Donnell [26], bounded degree SOS proof does not necessarily imply its low bit complexity, showing that the often repeated claim, that for any fixed degree SOS runs in polynomial time, is far from true. O’Donnell raised the open problem to establish useful conditions under which “small” SOS proof can be guaranteed. With this aim, a first elegant sufficient condition is due to Raghavendra and Weitz [27, 33]. For each instance \mathcal{C} of a combinatorial problem, the set of polynomials that vanish at every point of the set of solutions of \mathcal{C} is called the *combinatorial ideal* of \mathcal{C} and denoted by $I_{\mathcal{C}}$. To satisfy Raghavendra and Weitz’s criterion, it is necessary (but also sufficient) that the ideal membership problem IMP_d for each $I_{\mathcal{C}}$ is polynomial time solvable and that ideal membership proofs can be efficiently found too.¹ So the tractability of the ideal membership proof ensures that SOS runs in polynomial time for combinatorial problems. This is currently the only known general result that addresses the SOS bit complexity issue. However, the IMP_d tractability criterion of Raghavendra and Weitz suffers from a severe limitation, namely it is not clear which restrictions on combinatorial problems can guarantee an efficient computation of the IMP_d proofs for combinatorial ideals.

The Constraint Satisfaction Problem (CSP) provides a general framework for a wide range of combinatorial problems, where we are given a set of variables and a set of constraints, and we have to decide whether the variables can be assigned values that satisfy the constraints. There are useful connections between IMP_d and the CSP: for example a CSP instance \mathcal{C} is unsatisfiable if and only if $1 \in I_{\mathcal{C}}$. It follows that CSP is just the special case of IMP_d with $d = 0$ (see Appendix A.1 for more details on Ideal-CSP correspondence). Restrictions on CSPs, called $\text{CSP}(\Gamma)$, in which the type of constraints is limited to relations from a set Γ , have been successfully applied to study the computational complexity classification (and other algorithmic properties) of CSPs (see [7] for an excellent survey).

Motivated by the aforementioned issue of Raghavendra and Weitz criterion, Mastrolilli [23] initiated a systematic study of the IMP_d tractability for combinatorial ideals of the form $\text{IMP}_d(\Gamma)$ arising from combinatorial problems from $\text{CSP}(\Gamma)$ for a set of relations Γ over the Boolean domain. The classic dichotomy result of Schaefer [29] gives the complexity of $\text{CSP}(\Gamma)$ (and therefore of $\text{IMP}_0(\Gamma)$) for the Boolean domain: $\text{CSP}(\Gamma)$ is solvable in polynomial time

¹ Note that answering whether a polynomial belongs to a certain ideal does not necessarily mean finding an ideal membership proof of that.

if all constraints are closed under one of six polymorphisms (majority, minority, MIN, MAX, constant 0 and constant 1), else it is NP-complete. Mastrolilli [23] claimed a dichotomy result for the $\text{IMP}_d(\Gamma)$ for the Boolean domain: for any constant $d \geq 1$, the $\text{IMP}_d(\Gamma)$ of Boolean combinatorial ideals is solvable in polynomial time if all constraints are closed under one of four polymorphisms (majority, minority, MIN, MAX), else it is coNP-complete. In [23], for three polymorphisms (majority, MIN, MAX), it is shown that $\text{IMP}_d(\Gamma)$ is polynomial time solvable, and moreover ideal membership proofs can be efficiently found, too. Whereas for the ternary minority polymorphism it was incorrectly declared to have been resolved by a previous result². As a matter of fact the complexity of the $\text{IMP}_d(\Gamma)$ for the ternary minority polymorphism is open. It was mistakenly assumed in [23] that computing the (mod 2) Gröbner basis in lexicographic order was sufficient to solve the IMP_d problem in polynomial time, but the issue is that we require polynomials to be over \mathbb{R} and not $\text{GF}(2)$.

We address these issues in this paper and therefore establish the full dichotomy result claimed in [23] (see [22] for an updated version of the paper). To ensure efficiency of the $\text{IMP}_d(\Gamma)$ for the ternary minority polymorphism, it is sufficient to compute a d -truncated Gröbner basis in the graded lexicographic order (see Definition 8 and Appendix A for more details). This is achieved by first showing that we can easily find a Gröbner basis in the lexicographic order for the combinatorial ideal. Since polynomials in this Gröbner basis can have degrees up to n and coefficients of exponential size, we show how this basis can be converted to a d -truncated Gröbner basis in the graded lexicographic order in polynomial time, whose polynomials have degrees up to d and coefficients of constant size. This efficiently solves the $\text{IMP}_d(\Gamma)$ for combinatorial ideals whose constraints are over a language Γ closed under the minority polymorphism. Together with the results in [23, 22], our result allows to complete the answer of the aforementioned question by allowing to identify the precise borderline of tractability of the Boolean $\text{IMP}_d(\Gamma)$. Thus the following summarizes our first result of this paper:

► **Theorem 1.** *Let Γ be a constraint language over the Boolean domain that is closed under the minority polymorphism. For each instance \mathcal{C} of $\text{CSP}(\Gamma)$, the d -truncated reduced Gröbner basis in the graded lexicographic monomial ordering of the combinatorial ideal $I_{\mathcal{C}}$ can be computed in $n^{O(d)}$ time.*

► **Corollary 2.** *If Γ is closed under the minority polymorphism, then the ideal membership proofs of $\text{IMP}_d(\Gamma)$ over the Boolean domain can be computed in polynomial time for $d = O(1)$.*

After the appearance of a preliminary version of this paper [4], Bulatov and Rafiey [8] have recently obtained exciting new results. For a finite domain $D = \{0, 1, \dots, p-1\}$ with prime p elements, they consider the affine polymorphism $\otimes : D^3 \rightarrow D$ defined as $\otimes(a, b, c) = a - b + c \pmod{p}$ (it is easy to see that this is the minority polymorphism for the Boolean domain). By building on our approach, they prove that a d -truncated Gröbner basis can be computed in time $n^{O(d)}$ for any fixed prime p .

In [3], we began the generalization of $\text{CSP}(\Gamma)$ (viz. $\text{IMP}_0(\Gamma)$) by working on the corresponding $\text{IMP}_d(\Gamma)$ for any $d = O(1)$ in the ternary domain, which expands the known set of tractable IMP_d cases by providing a suitable class of combinatorial problems. We considered problems constrained under the dual discriminator polymorphism and prove that we can find the reduced Gröbner basis of the corresponding combinatorial ideal in polynomial time. This ensures that we can check if any degree d polynomial belongs to the combinatorial ideal or not in polynomial time, and provide proof of membership if it does. Among the very interesting results obtained in [8], the authors show that the IMP_d is solvable in polynomial

² This was pointed out by Andrei Bulatov, Akbar Rafiey and Stanislav Živný.

time for *any* finite domain for problems constrained under the dual discriminator. This was done by eliminating permutation constraints in some sense through a pre-processing step and converting an instance $\mathcal{C} = (X, D, C)$ to an instance $\mathcal{C}' = (X', D, C')$ where $X' \subseteq X$ and $C' \subseteq C$. Moreover, a polynomial $f(X)$ was converted to a polynomial $f'(X')$ such that $f \in I_{\mathcal{C}}$ if and only if $f' \in I_{\mathcal{C}'}$. They calculated a Gröbner basis of $I_{\mathcal{C}'}$, in polynomial time, which reflected the remaining constraints. This gives a proof of membership of f' in $I_{\mathcal{C}'}$ if it does belong to the ideal, but it is not yet known as to how to recover the proof of membership for f in $I_{\mathcal{C}}$. Meanwhile our results in [3] gives proof of membership, but is only constrained to a 3-element domain.

In this paper, we compute a Gröbner basis for the entire combinatorial ideal over a finite domain by showing that a Gröbner basis of the ideal associated with permutation constraints can also be calculated in polynomial time. We forego the pre-processing step of [8], include the permutation constraints and directly calculate a Gröbner basis of $I_{\mathcal{C}}$. The set of polynomials that the elements of the Gröbner basis can come from is polynomial in size and hence we show that a proof of membership can also be calculated in polynomial time as required in [28]. The following summarizes the second result of this paper:

► **Theorem 3.** *Let Γ be a constraint language over a finite domain D that is closed under the dual discriminator polymorphism. For each instance \mathcal{C} of $\text{CSP}(\Gamma)$, a Gröbner basis in the graded lexicographic monomial ordering of the combinatorial ideal $I_{\mathcal{C}}$ can be computed in time polynomial in the number of variables. The polynomials in this basis have degree at most $|D|$.*

► **Corollary 4.** *If Γ is closed under the dual discriminator polymorphism, then membership proofs for $\text{IMP}(\Gamma)$, over a finite domain, can be computed in polynomial time.*

The study of CSP-related IMPs is in its early stages. The results obtained in this paper are steps towards the long term and challenging goal of extending the celebrated dichotomy results of $\text{CSP}(\Gamma)$ for finite domain [6, 34] to $\text{IMP}(\Gamma)$. This would provide a complete CSP-related characterization of when the IMP tractability criterion is applicable.

Due to space limitations, we provide a sketch for some of the proofs, and the complete proofs will be updated in [4]. To make the paper more self-contained, some essential background and standard (according to the book [12]) Gröbner basis notations can be found in Appendix A.

2 Preliminaries

Let D denote a finite set (*domain*). By a k -ary **relation** R on a domain D we mean a subset of the k -th cartesian power D^k ; k is said to be the *arity* of the relation. We often use relations and (affine) varieties interchangeably since both essentially represent a set of solutions. A **constraint language** Γ over D is a set of relations over D . A constraint language is **finite** if it contains finitely many relations, and is **Boolean** if it is over the 2-element domain $\{0, 1\}$. A **constraint** over a constraint language Γ is an expression of the form $R(x_1, \dots, x_k)$ where R is a relation of arity k contained in Γ , and the x_i are variables. A constraint is satisfied by a mapping ϕ defined on the x_i if $(\phi(x_1), \dots, \phi(x_k)) \in R$.

► **Definition 5.** *The (nonuniform) CONSTRAINT SATISFACTION PROBLEM (CSP) associated with language Γ over D is the problem $\text{CSP}(\Gamma)$ in which: an instance is a triple $\mathcal{C} = (X, D, C)$ where $X = \{x_1, \dots, x_n\}$ is a set of n variables and C is a set of constraints over Γ with variables from X . The goal is to decide whether or not there exists a solution, i.e. a mapping $\phi : X \rightarrow D$ satisfying all of the constraints. We will use $\text{Sol}(\mathcal{C})$ to denote the set of solutions of \mathcal{C} .*

Moreover, we follow the algebraic approach to Schaefer's dichotomy result [29] formulated by Jeavons [18] where each class of CSPs that are polynomial time solvable is associated with a polymorphism.

► **Definition 6.** An operation $f : D^m \rightarrow D$ is a **polymorphism** of a relation $R \subseteq D^k$ if for any choice of m tuples from R (allowing repetitions), it holds that the tuple obtained from these m tuples by applying f coordinate-wise is in R . If this is the case we also say that f preserves R , or that R is invariant or closed with respect to f . A polymorphism of a constraint language Γ is an operation that is a polymorphism of every $R \in \Gamma$.

For a given instance \mathcal{C} of $\text{CSP}(\Gamma)$, the vanishing ideal of its solution set, $\mathbf{I}(\text{Sol}(\mathcal{C}))$, is called its **combinatorial ideal** and is denoted by $I_{\mathcal{C}}$ (see Definition 20 in Appendix A). We call polynomials of the form $\prod_{a \in D} (x_i - a)$ **domain polynomials**, denoted by $\text{dom}(x_i)$. They describe the fact that $\text{Sol}(\mathcal{C}) \subseteq D^n$. For a more detailed Ideal-CSP correspondence we refer to Appendix A.1.

► **Definition 7.** The IDEAL MEMBERSHIP PROBLEM associated with language Γ is the problem $\text{IMP}(\Gamma)$ in which the input consists of a polynomial $f \in \mathbb{F}[X]$ and a $\text{CSP}(\Gamma)$ instance $\mathcal{C} = (X, D, C)$. The goal is to decide whether f lies in the combinatorial ideal $I_{\mathcal{C}}$. We use $\text{IMP}_d(\Gamma)$ to denote $\text{IMP}(\Gamma)$ when the input polynomial f has degree at most d .

The Gröbner basis G of an ideal is a set of generators such that $f \in \langle G \rangle \iff f|_G = 0$, where $f|_G$ denotes the remainder of f divided by G (see [12] or Appendix A.2 for more details and notations).

► **Definition 8.** If G is a Gröbner basis of an ideal in $\mathbb{F}[x_1, \dots, x_n]$, the **d -truncated Gröbner basis** G' of G is defined as

$$G' = G \cap \mathbb{F}[x_1, \dots, x_n]_d,$$

where $\mathbb{F}[x_1, \dots, x_n]_d$ is the set of polynomials of degree less than or equal to d .

It is not necessary to compute a Gröbner basis of $I_{\mathcal{C}}$ in its entirety to solve the IMP_d . Since the input polynomial f has degree $d = O(1)$, the only polynomials from G that can possibly divide f in the graded lexicographic order (see Definition 26 in Appendix A.2), are those that are in G' . The remainders of such divisions are also in $\mathbb{F}[x_1, \dots, x_n]_d$. Therefore, by Proposition 32 and Corollary 33, the membership test can be computed by using only polynomials from G' and therefore we have

$$f \in I_{\mathcal{C}} \cap \mathbb{F}[x_1, \dots, x_n]_d \iff f|_{G'} = 0.$$

From the previous observations it follows that if we can compute G' in $n^{O(d)}$ time then this yields an algorithm that runs in $n^{O(d)}$ time for the IMP_d (note that the size of the input polynomial f is bounded by $n^{O(d)}$).

3 Boolean Minority

The Boolean Minority polymorphism is an affine polymorphism defined as follows. Note that there is only one such polymorphism for the Boolean domain.

► **Definition 9.** For a finite domain D , a ternary operation \otimes is called a **minority polymorphism** if $\otimes(a, a, b) = \otimes(a, b, a) = \otimes(b, a, a) = b$ for all $a, b \in D$.

3.1 Gröbner bases in lex order

Consider an instance $\mathcal{C} = (X = \{x_1, \dots, x_n\}, D = \{0, 1\}, C)$ of $\text{CSP}(\Gamma)$ where Γ is \otimes -closed. Any constraint of \mathcal{C} can be written as a system of linear equations over $\text{GF}(2)$ (see e.g. [10]). These linear systems with variables x_1, \dots, x_n can be solved by Gaussian elimination. If there is no solution, then we have from Hilbert's Weak Nullstellensatz (Theorem 25) that $1 \in I_{\mathcal{C}} \iff \text{Sol}(\mathcal{C}) = \emptyset \iff I_{\mathcal{C}} = \mathbb{R}[\mathbf{x}]$. If $1 \in I_{\mathcal{C}}$ the reduced Gröbner basis is $\{1\}$. We proceed only if $\text{Sol}(\mathcal{C}) \neq \emptyset$. In this section, we assume the lex order $>_{\text{lex}}$ with $x_1 >_{\text{lex}} x_2 >_{\text{lex}} \dots >_{\text{lex}} x_n$. We also assume that the linear system has $r \leq n$ equations and is already in its reduced row echelon form with x_i as the leading monomial of the i -th equation. Let $\text{Supp}_i \subset [n]$ such that $\{x_j : j \in \text{Supp}_i\}$ is the set of variables appearing in the i -th equation of the linear system except for x_i . Let the i -th equation be $R_i = 0 \pmod{2}$ where

$$R_i := x_i \oplus f_i, \quad (1)$$

with $i \in [r]$ and f_i is the Boolean function $(\bigoplus_{j \in \text{Supp}_i} x_j) \oplus \alpha_i$ and $\alpha_i = 0/1$.

3.2 From (mod 2) to regular arithmetic Gröbner basis

In this section, we show how to transform R_i 's into polynomials in regular arithmetic. The idea is to map R_i to a polynomial R'_i over $\mathbb{R}[x_1, \dots, x_n]$ such that $a \in \{0, 1\}^n$ satisfies $R_i = 0$ if and only if a satisfies $R'_i = 0$. Moreover, R'_i is such that it has the same leading term as R_i . We produce a set of polynomials G_1 and prove that G_1 is the reduced Gröbner basis of $I_{\mathcal{C}}$ over $\mathbb{R}[x_1, \dots, x_n]$ in the lex ordering. We define R'_i as

$$R'_i := x_i - M(f_i) \quad (2)$$

where

$$M(f_i) = \begin{cases} \sum_{k=1}^{|\text{Supp}_i|} \left((-1)^{k-1} \cdot 2^{k-1} \sum_{\{x_{j_1}, \dots, x_{j_k}\} \subseteq \text{Supp}_i} x_{j_1} x_{j_2} \dots x_{j_k} \right) & \text{when } \alpha_i = 0 \\ 1 + \sum_{k=1}^{|\text{Supp}_i|} \left((-1)^k \cdot 2^{k-1} \sum_{\{x_{j_1}, \dots, x_{j_k}\} \subseteq \text{Supp}_i} x_{j_1} x_{j_2} \dots x_{j_k} \right) & \text{when } \alpha_i = 1 \end{cases} \quad (3)$$

► **Lemma 10.** *Consider the following set of polynomials:*

$$G_1 = \{R'_1, \dots, R'_r, x_{r+1}^2 - x_{r+1}, \dots, x_n^2 - x_n\}, \quad (4)$$

where R'_i is from Equation (2). G_1 is the reduced Gröbner basis of $I_{\mathcal{C}}$ in the lexicographic order $x_1 >_{\text{lex}} x_2 >_{\text{lex}} \dots >_{\text{lex}} x_n$.

Proof. For any two Boolean variables x and y ,

$$x \oplus y = x + y - 2xy. \quad (5)$$

By repeatedly using Equation (5) to obtain the equivalent expression for f_i , we see that $R_i = 0 \pmod{2}$ and $R'_i = 0$ have the same set of 0/1 solutions. Therefore $\mathbf{V}(\langle G_1 \rangle)$ is equal to $\text{Sol}(\mathcal{C})$. This implies that $\langle G_1 \rangle \subseteq I_{\mathcal{C}}$. Moreover, $\text{LM}(R_i) = \text{LM}(R'_i) = x_i$, by construction. For every pair of polynomials in G_1 the reduced S -polynomial is zero as the leading monomials of any two polynomials in G_1 are relatively prime. By Buchberger's Criterion (see Theorem 36) it follows that G_1 is a Gröbner basis of $\langle G_1 \rangle$ over $\mathbb{R}[x_1, \dots, x_n]$ (according to the lex order).

In fact, it can be seen by inspection that G_1 is the *reduced* Gröbner basis of $\langle G_1 \rangle$. To prove that $I_{\mathcal{C}} = \langle G_1 \rangle$, we need to prove that any $p \in I_{\mathcal{C}} \implies p \in \langle G_1 \rangle$. It is enough to prove that $p|_{G_1} = 0$ as this implies $p \in \langle G_1 \rangle$. We have that $p|_{G_1}$ cannot contain variable x_i for all $1 \leq i \leq r$. Hence $p|_{G_1}$ is multilinear in $x_{r+1}, x_{r+2}, \dots, x_n$. Each tuple of D^{n-r} extends to exactly that n -tuple in $Sol(\mathcal{C})$ whose coordinate associated with x_i ($1 \leq i \leq r$) is the unique value x_i takes to satisfy $x_i \oplus f_i = 0$ (see Equation (1) and Equation (2)). As $p|_{G_1}$ is multilinear in $x_{r+1}, x_{r+2}, \dots, x_n$, there are at most 2^{n-r} coefficients. Since every point of D^{n-r} is a solution of $p|_{G_1}$, we see that every coefficient of $p|_{G_1}$ is zero and hence $p|_{G_1}$ is the zero polynomial. Hence G_1 is the reduced Gröbner basis of $I_{\mathcal{C}}$. ◀

Note that the reduced Gröbner basis in Equation (4) can be “efficiently” computed by exploiting the high degree of symmetry in each $M(f_i)$ and using elementary symmetric polynomials with variables from $Supp_i$.

3.3 Computing a truncated Gröbner basis

Now that we have the reduced Gröbner basis in lex order, we show how to obtain the d -truncated reduced Gröbner basis in \mathbf{glex} order in polynomial time for any fixed $d = O(1)$. Before we describe our conversion algorithm, we show how to expand a product of Boolean functions. This expansion will play a crucial step in our algorithm.

3.3.1 Expansion of a product of Boolean functions

In this section, we show a relation between a product of Boolean functions and (mod 2) sums of the Boolean functions, which is heavily used in our conversion algorithm in Section 3.3.2. We have already seen from Equation (5) that if f, g are two Boolean functions,³ then

$$2 \cdot f \cdot g = f + g - (f \oplus g).$$

Hence it can be proved by repeated use of the above equation that the following holds for Boolean functions f_1, f_2, \dots, f_m :

$$f_1 \cdot f_2 \cdots f_m = \frac{1}{2^{m-1}} \left[\sum_{i \in [m]} f_i - \sum_{\{i,j\} \subset [m]} (f_i \oplus f_j) + \sum_{\{i,j,k\} \subset [m]} (f_i \oplus f_j \oplus f_k) + \cdots + (-1)^{m-1} (f_1 \oplus f_2 \oplus \cdots \oplus f_m) \right]. \quad (6)$$

We call each Boolean function of the form $(f_{i_1} \oplus \cdots \oplus f_{i_k})$ in Equation (6) as a **Boolean term**. We call the Boolean term $(f_1 \oplus f_2 \oplus \cdots \oplus f_m)$ as the **longest Boolean term** of the expansion. Thus, a product of Boolean functions can be expressed as a linear combination of Boolean terms. Note that Equation (6) is *symmetric* with respect to f_1, f_2, \dots, f_m as any f_i interchanged with f_j produces the same expression. It is no coincidence that we chose the letter f in the above equation: we later apply this identity using f_j from $R_j := x_j \oplus f_j$ (see Section 3.1). When we use Equation (6) in the conversion algorithm, we will have to evaluate a product of at most d functions, i.e. $m \leq d = O(1)$. We now see in the right hand side of Equation (6) that the coefficient $1/2^{m-1}$ is of constant size and there are $O(1)$ many Boolean terms.

³ We earlier considered Boolean variables, but the same holds for Boolean functions.

3.3.2 Our conversion algorithm

The FGLM [13] conversion algorithm is well known in computer algebra for converting a given reduced Gröbner basis of a zero dimensional ideal in some ordering to the reduced Gröbner basis in any other ordering. However, it does so with $O(nD(\langle G_1 \rangle)^3)$ many arithmetic operations, where $D(\langle G_1 \rangle)$ is the dimension of the \mathbb{R} -vector space $\mathbb{R}[x_1, \dots, x_n]/\langle G_1 \rangle$ (see Proposition 4.1 in [13]). $D(\langle G_1 \rangle)$ is also equal to the number of common zeros (with multiplicity) of the polynomials from $\langle G_1 \rangle$, which would imply that for the combinatorial ideals considered in this paper, $D(\langle G_1 \rangle) = O(2^{n-r})$. This exponential running time is avoided in our conversion algorithm, which is a variant the FGLM algorithm, by exploiting the symmetries in Equation (3) and by truncating the computation up to degree d .

Some notations necessary for the algorithm are as follows: G_1 and G_2 are the reduced Gröbner basis of $\langle G_1 \rangle$ in `lex` and `grlex` ordering respectively. $\text{LM}(G_i)$ is the set of leading monomials of polynomials in G_i for $i \in \{1, 2\}$. Since we know G_1 , we know $\text{LM}(G_1)$, whereas G_2 and $\text{LM}(G_2)$ are constructed by the algorithm. $B(G_1)$ is the set of monomials that cannot be divided (considering the `lex` order) by any monomial of $\text{LM}(G_1)$. Therefore, $B(G_1)$ is the set of all multilinear monomials in variables x_{r+1}, \dots, x_n . Similarly, $B(G_2)$ is the set of monomials that cannot be divided (considering the `grlex` order) by any monomial of $\text{LM}(G_2)$. Recall the definition of f_i for $i \leq r$ from Section 3.1. For $i > r$, for notational purposes, we define the Boolean function $f_i := x_i$.

► **Lemma 11.** *Consider a monomial q such that $\deg(q) \leq d$. Then $q|_{G_1}$ can be expressed as a linear combination of Boolean terms.*

Proof. Consider $q = x_{i_1}x_{i_2} \cdots x_{i_k}$ where $k \leq d$. Then from Equations (1) and (2), $q|_{G_1} = f_{i_1}f_{i_2} \cdots f_{i_k}$ and the lemma holds using Equation (6). ◀

Let elements b_i of $B(G_2)$ be arranged in increasing `grlex` order. We construct a set A in our algorithm such that its elements a_i are defined as $a_i = b_i|_{G_1}$ written as linear combinations of Boolean terms using Lemma 11. We say that a Boolean term f of a_i “appears in a_j ” for some $j < i$ if the longest Boolean term of a_j is $f \oplus \alpha$ where $\alpha = 0/1$.

Let Q be the set of all monomials m such that $1 <_{\text{grlex}} \deg(m) \leq_{\text{grlex}} d$. We recommend the reader to refer to the example in [4] for an intuitive working of the algorithm. The conversion is described in full in Algorithm 1 (we assume $1 \notin I_C$, else $G_1 = \{1\} = G_2$ and we are done).

► **Lemma 12.** *The set A is such that every a_i is a linear combination of existing $b_j|_{G_1}$ ’s ($j < i$) and the longest Boolean term of $b_i|_{G_1}$.*

Proof. By definition, element a_i is added to A when a monomial q is added to $B(G_2)$ where $b_i = q$ and $a_i = b_i|_{G_1}$ expressed in Boolean terms (see Algorithm 1). This means that q is not divisible by any monomial in $\text{LM}(G_2)$. We prove the lemma by induction on the degree of q . Note that $b_1 = 1$ and hence $a_1 = b_1|_{G_1} = 1$.

If $\deg(q) = 1$, then q is some x_i and $x_i|_{G_1}$ is one of $0, 1$ or f_i . If $x_i|_{G_1}$ is either 0 or 1 , then it appears in a_1 . We are now in the “else” condition of Algorithm 1, so q should be added to $\text{LM}(G_2)$ and not $B(G_2)$. Hence $x_i|_{G_1}$ can be neither 0 nor 1 and the lemma holds for $\deg(q) = 1$ as f_i is the longest Boolean term.

Let us assume the statement holds true for all monomials with degree less than m . Consider q such that $\deg(q) = m$ and $q = x_{i_1}x_{i_2} \cdots x_{i_m}$ where i_j ’s need not be distinct, and the lemma holds for every monomial $<_{\text{grlex}} q$. Then $q|_{G_1} = f_{i_1} \cdot f_{i_2} \cdots f_{i_m}$. Let $(f_{j_1} \oplus \cdots \oplus f_{j_k})$ be a Boolean term in the expansion of $q|_{G_1}$ (by using Equation (6)), that

■ **Algorithm 1** Computing the d -truncated reduced Gröbner basis.

Input: Degree d , G_1 , Q .
Output: d -Truncated versions of G_2 , $B(G_2)$.
Initialization: $G_2 = \emptyset$, $B(G_2) = \{b_1 = 1\}$, $A = \{a_1 = 1\}$.

- 1 **while** $Q \neq \emptyset$ **do**
- 2 Let q be the smallest (according to grlex order) monomial in Q .
- 3 Find $q|_{G_1}$, by which we simply replace any occurrence of x_i by the Boolean functions f_i .
- 4 Expand $q|_{G_1}$ by using Equation (6).
- 5 **if** the longest Boolean term of $q|_{G_1}$ does not appear in any $a \in A$ **then**
- 6 Write $q|_{G_1}$ as a linear combination of $b_i|_{G_1}$ and its longest Boolean term (see Lemma 12).
- 7 Add this polynomial to A and add q to $B(G_2)$.
- 8 **else**
- 9 Every Boolean term of $q|_{G_1}$ can be written as linear combinations of $b_j|_{G_1}$'s. Note that if the longest Boolean term f appears in a as $f \oplus 1$, then we use $f \oplus 1 = 1 - (f)$ (see Equation (5)). Thus we have $q|_{G_1} = \sum_j k_j b_j|_{G_1} \implies q - \sum_j k_j b_j \in \langle G_1 \rangle$.
- 10 Add the polynomial $q - \sum_j k_j b_j$ to G_2 and q to $\text{LM}(G_2)$.
- 11 Delete any monomial in Q that q can divide.
- 12 Delete q from Q .
- 13 G_2 is the d -truncated reduced Gröbner basis.

is not the longest Boolean term, so $\{j_1, \dots, j_k\} \subset \{i_1, \dots, i_m\}$ and $k < m$. Consider the monomial $x_{j_1} x_{j_2} \dots x_{j_k}$. We will now prove that $x_{j_1} x_{j_2} \dots x_{j_k}$ is in fact some $b_l \in B(G_2)$ and there exists $a_l \in A$ which is a linear combination of $b_i|_{G_1}$'s and $(f_{j_1} \oplus \dots \oplus f_{j_k})$. The monomial $x_{j_1} x_{j_2} \dots x_{j_k}$ either belongs to $\text{LM}(G_2)$ or $B(G_2)$. If $x_{j_1} x_{j_2} \dots x_{j_k} \in \text{LM}(G_2)$ then it divides q , a contradiction to our choice of q . Therefore, $x_{j_1} x_{j_2} \dots x_{j_k} = b_l \in B(G_2)$. Clearly $b_l <_{\text{grlex}} q$ and the induction hypothesis applies, so there exists $a_l \in A$ such that

$$b_l|_{G_1} = a_l = \sum_{i < l} c_i b_i|_{G_1} + c_0 (f_{j_1} \oplus \dots \oplus f_{j_k})$$

where c_i 's are constants. Then we simply use the above equation to substitute for the Boolean term $f_{j_1} \oplus \dots \oplus f_{j_k}$ in $q|_{G_1}$ as a linear combination of $b_i|_{G_1}$ where $i \leq l$. We can do this for every Boolean term of $q|_{G_1}$ except the longest one. Hence the lemma holds. ◀

► **Theorem 13.** *The conversion algorithm terminates for every input G_1 and correctly computes a d -truncated reduced Gröbner basis, with the grlex ordering, of the ideal $\langle G_1 \rangle$ in polynomial time.*

Proof. Algorithm 1 runs at most $|Q| = O(n^d)$ times. Evaluation of any $q|_{G_1}$ can be done in $O(n)$ steps (see Equation (6)), checking if previous a_i 's appear (and replacing every Boolean term appropriately if it does) takes at most $O(n^d)$ steps since there are at most $|Q|$ many elements in A . Hence the running time of the algorithm is $O(n^{2d})$.

Suppose the set of polynomials $\{g_1, g_2, \dots, g_k\}$ is the output of the algorithm for some input G_1 . Clearly, $\deg(g_i) \leq d$ for all $i \in [k]$. We now prove by contradiction that the output is the d -truncated Gröbner basis of the ideal $\langle G_1 \rangle$ with the grlex ordering. Suppose g is a

16:10 Ideal Membership Problem for Boolean Minority and Dual Discriminator

polynomial of the ideal with $\deg(g) \leq d$, but no $\text{LM}(g_i)$ can divide $\text{LM}(g)$. In fact, since every $g_i \in \langle G_1 \rangle$ we can replace g by $g|_{\{g_1, g_2, \dots, g_k\}}$ (g generalises the reduced S -polynomial). The fact that $g \in \langle G_1 \rangle$ and $g|_{G_1} = 0$ implies that $\text{LM}(g)$ is a linear combination of monomials that are less than $\text{LM}(g)$ (in the grlex order) and hence must be in $B(G_2)$, i.e

$$g|_{G_1} = 0 \implies \text{LM}(g)|_{G_1} = \sum_i k_i b_i|_{G_1}$$

where every $b_i \in B(G_2)$ and $b_i <_{\text{grlex}} \text{LM}(g)$. When the algorithm runs for $q = \text{LM}(g)$, since q was not added to $\text{LM}(G_2)$,

$$\text{LM}(g)|_{G_1} = \sum_j k_j b_j|_{G_1} + f$$

where f is the longest Boolean term of $\text{LM}(g)|_{G_1}$ which does not appear in any previous element of A . But the two equations above imply that $\sum_i k_i b_i|_{G_1} = \sum_j k_j b_j|_{G_1} + f$, which proves that there exists some $b_l \in B(G_2)$ such that a_l has f as its longest Boolean term, so f should have appeared in a_l , a contradiction. Therefore the output is a d -truncated Gröbner basis. Although unnecessary for the IMP_d , we also prove that the output is reduced: every non leading monomial of every polynomial in the output comes from $B(G_2)$ and no leading monomial is a multiple of another by construction. ◀

Thus we have proof of Theorem 1 and Corollary 2.

4 Dual discriminator

We assume in this section that the solution set is non-empty, $D \subset \mathbb{F}$ is any finite domain and the polymorphism in question is the dual discriminator ∇ . The dual discriminator is a majority polymorphism [19, 1] and is often used as a starting point in many CSP-related classifications [1]. For a finite domain D , a ternary operation f is called a majority polymorphism if $f(a, a, b) = f(a, b, a) = f(b, a, a) = a$ for all $a, b \in D$.

► **Definition 14.** *The dual discriminator, denoted by ∇ , is a majority polymorphism such that $\nabla(a, b, c) = a$ for pairwise distinct $a, b, c \in D$.*

The constraints for ∇ -closed problems can be assumed to be binary [19] and are of three types: permutation constraints, complete constraints and two-fan constraints [31, 11]. Bulatov and Rafiey [8] recently proved that the $\text{IMP}(\Gamma)$ over a finite domain is decidable in polynomial time, without showing a proof of membership. They did so by cleverly eliminating the permutation constraints, but were unable to recover a proof for the original problem. We show that a Gröbner basis of the ideal restricted to the permutation constraints can be computed in polynomial time in Section 4.1. We then show in Section 4.2 that the Gröbner basis of constraints that are complete and two-fan constraints can come from a fixed set (see Definition 17). We prove in Section 4.3 that the Gröbner basis of the entire ideal can be found in polynomial time. This Gröbner basis is independent of degree d of the input polynomial: it only contains polynomials with degree less than or equal to $|D|$. Due to space constraints, we give a gist of the proofs as the full proofs will be updated in [4].

4.1 Permutation constraints

A permutation constraint is of the form $R(x_i, x_j)$ where $R = \{(a, \pi_{ij}(a)) \mid a \in D_{ij}\}$ for some $D_{ij} \subseteq D$ and some bijection $\pi_{ij} : D_{ij} \rightarrow D'_{ij}$, where $D'_{ij} \subseteq D$. Let \mathcal{P} be the set of input permutation constraints. We can assume that there exists at most one permutation

constraint over every pair of variables: if there are two on the same set of variables, then their intersection is a permutation constraint. Let $R_{ij}(x_i, x_j)$ represent the unique permutation constraint on variables x_i, x_j , if one exists.

Informally, the goal is to make larger constraints called *chained permutation constraints* (CPC's). Permutation constraints on overlapping variables can be linked to form a larger constraint by using bijections. For example, if there exists $R_{ij}(x_i, x_j), R_{jk}(x_j, x_k) \in \mathcal{P}$, we form a new constraint on x_i, x_j, x_k by using π_{ij} and π_{jk} : the chained permutation constraint is $R(x_i, x_j, x_k)$ where

$$R = \{(\pi_{ij}^{-1}(a), a, \pi_{jk}(a)) \mid a \in D'_{ij} \cap D_{jk}\}.$$

The number of tuples in any CPC is always less than or equal to the domain size, since there is always a bijection between any two variables of a CPC. The constructing of CPC's can be carried out by the arc consistency algorithm described in [21]. A brief working of the algorithm tailored to our application is as follows: let $J \subset [n]$ be an index set for the CPC's (it becomes clear later why there can be at most $\lfloor n/2 \rfloor$ of them but we use n for convenience). We initialise $J = \emptyset$. A general chained permutation constraint CPC_i is defined as $R_i(X_i)$ where R_i is a relation and $X_i \subseteq X$ is a variable set. We keep track of the values that each variable is allowed to take, i.e., S_a is the set of solutions of x_a that satisfies CPC_i for all $x_a \in X_i$. The sets S_a and X_i are updated as CPC_i grows. We define $\sigma_{ab} : S_a \rightarrow S_b$ to be the bijection between any two pairs of variables $x_a, x_b \in X_i$. Hence $\sigma_{ba} = \sigma_{ab}^{-1}$. Let σ_{aa} denote the identity function for all $a \in [n]$. For any permutation constraint R_{pq} in \mathcal{P} , one of the four is true:

- neither x_p nor x_q belong to $\cup_{j \in J} X_j$: in which case we create a CPC. We define $\text{CPC}_i = R_{pq}(x_p, x_q)$ and $X_i = \{x_p, x_q\}$ where $i \in [n] \setminus J$.
- $x_p \in X_i$ and $x_q \notin \cup_{j \in J} X_j$, in which case we expand CPC_i to include R_{pq} and x_q is included in X_i .
- $x_p \in X_i, x_q \in X_j$ and $i \neq j$, in which case CPC_i and CPC_j have a permutation constraint linking two of their variables, so we combine the two CPC's into one. The set $X_i \cup X_j$ is the new X_i and j is deleted from J .
- both $x_p, x_q \in X_i$, in which case we update CPC_i to retain only the common solutions between CPC_i and R_{pq} .

As $R_{pq}(x_p, x_q)$ is now accounted for in some CPC, it is deleted from \mathcal{P} . The algorithm runs until \mathcal{P} is empty. Once \mathcal{P} is empty, CPC_i is defined as

$$\text{CPC}_i := R_i(X_i = \{x_{i_1}, x_{i_2}, \dots, x_{i_r}\}) \text{ where } R_i = \{(a, \sigma_{i_1 i_2}(a), \dots, \sigma_{i_1 i_r}(a)) \mid a \in S_{i_1}\}$$

for each $i \in J$.

► **Remark 15.** For $i \neq j$, $X_i \cap X_j = \emptyset$.

► **Lemma 16.** Let I_{CPC_i} be the combinatorial ideal associated with CPC_i . A Gröbner basis of $\sum_i I_{\text{CPC}_i}$ can be calculated in polynomial time.

The main idea behind the proof is as follows: suppose we see a relation as a matrix where each tuple is a row. Then the arity is equal to the number of columns. The relation R_i in $\text{CPC}_i = R_i(X_i)$ is such that it has at most $|D|!$ pairwise distinct columns, as there exists a bijection between every pair of variables in X_i . If the columns corresponding to x_j and x_k are the same, then the polynomial $x_j - x_k \in I_{\text{CPC}_i}$. We can separate these linear polynomials, and the problem reduces to finding a Gröbner basis of the ideal associated with a constraint that has at most $|D|!$ variables and $|D|$ tuples. This implies that a Gröbner basis can be

computed where the polynomials have degree at most $|D|$. We in fact do not need to find the Gröbner basis of I_{CPC_i} yet. We show in the Section 4.3 as to how we can compute the rest of the polynomials in the Gröbner basis of I_C by using the relations R_i , the sets S_j , the bijections σ_{kl} and polynomials that define complete and two-fan constraints.

4.2 Complete and two-fan constraints

A complete constraint is of the form $R(x_i, x_j)$ where $R = D_i \times D_j$ for some $D_i, D_j \subseteq D$. The polynomials that can represent these constraints are $\prod_{a \in D_i} (x_i - a)$ and $\prod_{b \in D_j} (x_j - b)$. We call these polynomials *partial domain polynomials*. If no such input explicitly exists for a variable, the domain polynomial in that variable itself is the partial domain polynomial. A two-fan constraint is of the form $R(x_i, x_j)$ where $R = (\{a\} \times D_j) \cup (D_i \times \{b\})$ for some $D_i, D_j \subseteq D$ with $a \in D_i, b \in D_j$. This constraint can be represented by the set of polynomials $\{(x_i - a)(x_j - b), \prod_{c \in D_i} (x_i - c), \prod_{d \in D_j} (x_j - d)\}$.

► **Definition 17.** *The set of polynomials \mathcal{D} , \mathcal{F} and \mathcal{L} is defined as follows:*

$$\begin{aligned} \mathcal{D} &= \{\prod_{a \in A} (x_i - a) \mid i \in [n], A \subseteq D\}, \\ \mathcal{F} &= \{(x_i - a)(x_j - b) \mid i, j \in [n], i \neq j\}, \\ \mathcal{L} &= \{x_i - \alpha_2 - (x_j - \beta_2)(\alpha_1 - \alpha_2)/(\beta_1 - \beta_2) \mid i, j \in [n], i \neq j\}, \end{aligned}$$

for all $a, b, \alpha_1, \alpha_2, \beta_1, \beta_2 \in D$ where $\alpha_1 \neq \alpha_2$ and $\beta_1 \neq \beta_2$.

In other words $\mathcal{D} \cup \mathcal{F}$ is the set of all complete constraints and two-fan constraints and \mathcal{L} is the set of polynomials in two variables that pass through two points $(\alpha_1, \beta_1), (\alpha_2, \beta_2) \in D^2$ where $\alpha_1 \neq \alpha_2$ and $\beta_1 \neq \beta_2$. Let $G \subset \mathcal{D} \cup \mathcal{F}$ be the set of polynomials that describes the input complete constraints and two-fan constraints of an instance of $\text{IMP}_d(\Gamma)$. Let $I_{\text{CF}} = \langle G \rangle$ (combinatorial ideal for the Complete and two-Fan constraints). Then

$$I_C = \sum_{i \in J} I_{\text{CPC}_i} + I_{\text{CF}} = \sum_{i \in J} I_{\text{CPC}_i} + \langle G \rangle.$$

► **Lemma 18.** *The reduced Gröbner basis of I_{CF} can be calculated in polynomial time and is a subset of $\mathcal{D} \cup \mathcal{F} \cup \mathcal{L}$.*

Proof sketch. For any pair $f, g \in G$, we show that there are polynomials $H \in \langle G \rangle$ such that $H \in \mathcal{D} \cup \mathcal{F} \cup \mathcal{L}$ and $S(f, g)|_H = 0$. We then include these polynomials in G , i.e. $G := G \cup H$. The cases already considered in Lemma 5.16 of [8] are when:

- $f, g \in \mathcal{F}$ where $f = (x_i - a)(x_j - b)$, $g = (x_i - c)(x_k - d)$ for $a = c$ and $a \neq c$,
- $f \in \mathcal{D}, g \in \mathcal{F}$ where $f = \prod_{a \in D_i} (x_i - a)$, $g = (x_i - c)(x_j - b)$ and $c \in D_i$.

Of the remaining cases, the case that deserves most attention is when $f, g \in \mathcal{F}$ produces a permutation constraint (i.e., when $f = (x_i - a)(x_j - b)$ and $g = (x_i - c)(x_j - d)$ where $a \neq c$ and $b \neq d$).

Hence, the S -polynomial for every two polynomials in G is such that there are polynomials in I_{CF} that belong in $\mathcal{D} \cup \mathcal{F} \cup \mathcal{L}$ which reduce the S -polynomial to zero. In fact, it is not difficult to see that the reduced Gröbner basis is also a subset of $\mathcal{D} \cup \mathcal{F} \cup \mathcal{L}$. Since $|\mathcal{D} \cup \mathcal{F} \cup \mathcal{L}| = O(n^2)$, the reduced Gröbner basis of I_{CF} can be calculated in polynomial time. ◀

■ **Algorithm 2** Calculating Gröbner basis.

Input: G, CPC_i .

Output: Gröbner basis of I_C .

- 1 Compute and replace G by the reduced Gröbner basis of I_{CF} .
- 2 **for** every $g = \prod_{a \in D_p} (x_p - a) \in G \cap \mathcal{D}$ **do**
- 3 **if** $D_p \neq S_p$ **then**
- 4 $S_p := S_p \cap D_p$. Suppose $x_p \in X_i$.
- 5 $S_k := \{\sigma_{pk}(a) \mid a \in S_p\}$ for every $x_k \in X_i \setminus \{x_p\}$.
- 6 Replace g by $\prod_{a \in S_p} (x_p - a)$ in G . Go to Line 1.
- 7 Let $C = G \cap \mathcal{F}$.
- 8 **while** $C \neq \emptyset$ **do**
- 9 Choose $g = (x_p - a)(x_q - b) \in C$. Suppose $x_p \in X_i$.
- 10 **if** $a \notin S_p$ **then**
- 11 Add $x_q - b$ to G if $a \notin S_q$ else add $x_p - a$ to G . Go to Line 1.
- 12 /* At this point $a \in S_p$ and $b \in S_q$. */
- 13 **if** $x_q \in X_j$ for some $i \neq j$ **then**
- 14 **if** $b \notin S_q$ **then**
- 15 Add $x_p - a$ to G . Go to Line 1.
- 16 /* At this point $a \in S_p$ and $b \in S_q$. */
- 17 Let $B := \{(x_k - \sigma_{pk}(a))(x_l - \sigma_{ql}(b)) \mid x_k \in X_i, x_l \in X_j\} \setminus \{g\}$.
- 18 **if** $\exists h \in B$ such that $h|_G \neq 0$ **then**
- 19 $G := G \cup B$. Go to Line 1.
- 20 **if** $x_q \notin \cup_{j \in J} X_j$ **then**
- 21 Let $B := \{(x_k - \sigma_{pk}(a))(x_q - b) \mid x_k \in X_i\}$.
- 22 **if** $\exists h \in B$ such that $h|_G \neq 0$ **then**
- 23 $G := G \cup B$. Go to Line 1.
- 24 Delete g from C .
- 25 Calculate \mathcal{G}_i for every i .
- 26 A Gröbner basis of I_C is $\cup_i \mathcal{G}_i \cup G$.

4.3 Computing a Gröbner basis

► **Theorem 19.** A Gröbner basis of the combinatorial ideal I_C can be calculated in polynomial time.

Proof sketch. Let G be the reduced Gröbner basis of I_{CF} . Then,

$$I_C = \sum_{i \in J} I_{\text{CPC}_i} + I_{\text{CF}} = \sum_{i \in J} \langle \mathcal{G}_i \rangle + \langle G \rangle.$$

For two polynomials $f, g \in \cup_i \mathcal{G}_i \cup G$, we see what the reduced S -polynomial can imply. The straightforward cases are when

- $f, g \in \mathcal{G}_i$: here $S(f, g)|_{\mathcal{G}_i} = 0$ since \mathcal{G}_i is the reduced Gröbner basis of I_{CPC_i} ,
- $f \in \mathcal{G}_i, g \in \mathcal{G}_j$ where $i \neq j$: as f and g don't share any variable in common (see Remark 15), the leading monomials are relatively prime, hence $S(f, g)|_{\{f, g\}} = 0$,
- $f, g \in \mathcal{D} \cup \mathcal{F} \cup \mathcal{L}$: here $S(f, g)|_G = 0$ because of Lemma 18.

The only cases to examine is when $f \in \mathcal{G}_i$ and $g \in G \subset \mathcal{D} \cup \mathcal{F} \cap \mathcal{L}$. In each case, polynomials from $\cup_i \mathcal{G}_i$ and $\mathcal{D} \cup \mathcal{F} \cup \mathcal{L}$ reduce $S(f, g)$ to zero.

Clearly, this Gröbner basis is independent of degree d of the input polynomial. Hence, we have proof of Theorem 3 and Corollary 4. ◀

5 Conclusion

The IMP_d tractability for combinatorial ideals has useful practical applications as it implies bounded coefficients in Sum-of-Squares proofs. A dichotomy result between “hard” (NP-hard) and “easy” (polynomial time) IMPs was achieved for the IMP_0 [6, 34] over the finite domain nearly thirty years after that over the Boolean domain [29]. The IMP_d for $d = O(1)$ over the Boolean domain was tackled by Mastrolilli [23] based on the classification of the IMP through polymorphisms, where the complexity of the IMP_d for five of six polymorphisms was solved. We solve the remaining problem, i.e. the complexity of the $\text{IMP}_d(\Gamma)$ when Γ is closed under the ternary minority polymorphism. This is achieved by showing that the d -truncated reduced Gröbner basis can be computed in polynomial time, thus completing the missing link in the dichotomy result of [23]. We also show that a proof of membership can be found in polynomial time regarding the $\text{IMP}(\Gamma)$ for which constraints are closed under the dual discriminator polymorphism. We believe that generalizing the dichotomy results of solvability of the IMP_d for a finite domain is an interesting and challenging goal that we leave as an open problem.

A Ideals, Varieties and Constraints

Let \mathbb{F} denote an arbitrary field (for the applications of this paper $\mathbb{F} = \mathbb{R}$). Let $\mathbb{F}[x_1, \dots, x_n]$ be the ring of polynomials over a field \mathbb{F} and indeterminates x_1, \dots, x_n . Let $\mathbb{F}[x_1, \dots, x_n]_d$ denote the subspace of polynomials of degree at most d .

► **Definition 20.** *The ideal (of $\mathbb{F}[x_1, \dots, x_n]$) generated by a finite set of polynomials $\{f_1, \dots, f_m\}$ in $\mathbb{F}[x_1, \dots, x_n]$ is defined as*

$$\mathbf{I}(f_1, \dots, f_m) \stackrel{\text{def}}{=} \left\{ \sum_{i=1}^m t_i f_i \mid t_1, \dots, t_m \in \mathbb{F}[x_1, \dots, x_n] \right\}.$$

The set of polynomials that vanish in a given set $S \subseteq \mathbb{F}^n$ is called the **vanishing ideal** of S and denoted: $\mathbf{I}(S) \stackrel{\text{def}}{=} \{f \in \mathbb{F}[x_1, \dots, x_n] : f(a_1, \dots, a_n) = 0 \forall (a_1, \dots, a_n) \in S\}$.

► **Definition 21.** *An ideal \mathbf{I} is **radical** if $f^m \in \mathbf{I}$ for some integer $m \geq 1$ implies that $f \in \mathbf{I}$.*

Another common way to denote $\mathbf{I}(f_1, \dots, f_m)$ is by $\langle f_1, \dots, f_m \rangle$ and we will use both notations interchangeably.

► **Definition 22.** *Let $\{f_1, \dots, f_m\}$ be a finite set of polynomials in $\mathbb{F}[x_1, \dots, x_n]$. We call $\mathbf{V}(f_1, \dots, f_m) \stackrel{\text{def}}{=} \{(a_1, \dots, a_n) \in \mathbb{F}^n \mid f_i(a_1, \dots, a_n) = 0 \quad 1 \leq i \leq m\}$ the **affine variety** defined by f_1, \dots, f_m .*

► **Definition 23.** *Let $\mathbf{I} \subseteq \mathbb{F}[x_1, \dots, x_n]$ be an ideal. We will denote by $\mathbf{V}(\mathbf{I})$ the set $\mathbf{V}(\mathbf{I}) = \{(a_1, \dots, a_n) \in \mathbb{F}^n \mid f(a_1, \dots, a_n) = 0 \quad \forall f \in \mathbf{I}\}$.*

► **Theorem 24** ([12], Th.15, p.196). *If \mathbf{I} and \mathbf{J} are ideals in $\mathbb{F}[x_1, \dots, x_n]$, then $\mathbf{V}(\mathbf{I} \cap \mathbf{J}) = \mathbf{V}(\mathbf{I}) \cup \mathbf{V}(\mathbf{J})$.*

A.1 The Ideal-CSP Correspondence

Indeed, let $\mathcal{C} = (X, D, C)$ be an instance of the CSP(Γ) (see Definition 5). Without loss of generality, we shall assume that $D \subset \mathbb{N}$ and $D \subseteq \mathbb{F}$.

Let $Sol(\mathcal{C})$ be the (possibly empty) set of all feasible solutions of \mathcal{C} . In the following, we map $Sol(\mathcal{C})$ to an ideal $I_{\mathcal{C}} \subseteq \mathbb{F}[X]$ such that $Sol(\mathcal{C}) = \mathbf{V}(I_{\mathcal{C}})$.

Let $Y = (x_{i_1}, \dots, x_{i_k})$ be a k -tuple of variables from X and let $R(Y)$ be a non empty constraint from C . In the following, we map $R(Y)$ to a generating system of an ideal such that the projection of the variety of this ideal onto Y is equal to $R(Y)$ (see [32] for more details).

Every $v = (v_1, \dots, v_k) \in R(Y)$ corresponds to some point $v \in \mathbb{F}^k$. It is easy to check [12] that $\mathbf{I}(\{v\}) = \langle x_{i_1} - v_1, \dots, x_{i_k} - v_k \rangle$, where $\langle x_{i_1} - v_1, \dots, x_{i_k} - v_k \rangle \subseteq \mathbb{F}[Y]$ is radical. By Theorem 24, we have

$$R(Y) = \bigcup_{v \in R(Y)} \mathbf{V}(\mathbf{I}(\{v\})) = \mathbf{V}(I_{R(Y)}), \text{ where } I_{R(Y)} = \bigcap_{v \in R(Y)} \mathbf{I}(\{v\}), \quad (7)$$

where $I_{R(Y)} \subseteq \mathbb{F}[Y]$ is zero-dimensional and radical ideal since it is the intersection of radical ideals (see [12], Proposition 16, p.197). Equation (7) states that constraint $R(Y)$ is a variety of \mathbb{F}^k . It is easy to find a generating system for $I_{R(Y)}$:

$$I_{R(Y)} = \langle \prod_{v \in R} (1 - \prod_{j=1}^k \delta_{v_j}(x_{i_j})), \prod_{j \in D} (x_{i_1} - j), \dots, \prod_{j \in D} (x_{i_k} - j) \rangle, \quad (8)$$

where $\delta_{v_j}(x_{i_j})$ are indicator polynomials, i.e. equal to one when $x_{i_j} = v_j$ and zero when $x_{i_j} \in D \setminus \{v_j\}$; polynomials $\prod_{j \in D} (x_{i_k} - j)$ force variables to take values in D and will be denoted as *domain polynomials*.

The smallest ideal (with respect to inclusion) of $\mathbb{F}[X]$ containing $I_{R(Y)} \subseteq \mathbb{F}[\mathbf{x}]$ will be denoted $I_{R(Y)}^{\mathbb{F}[X]}$ and it is called the $\mathbb{F}[X]$ -module of I . The set $Sol(\mathcal{C}) \subset \mathbb{F}^n$ of solutions of $\mathcal{C} = (X, D, C)$ is the intersection of the varieties of the constraints:

$$Sol(\mathcal{C}) = \bigcap_{R(Y) \in C} \mathbf{V}(I_{R(Y)}^{\mathbb{F}[X]}) = \mathbf{V}(I_{\mathcal{C}}), \text{ where } I_{\mathcal{C}} = \sum_{R(Y) \in C} I_{R(Y)}^{\mathbb{F}[X]}. \quad (9)$$

The following properties follow from Hilbert's Nullstellensatz.

► **Theorem 25.** *Let \mathcal{C} be an instance of the CSP(Γ) and $I_{\mathcal{C}}$ defined as in (9). Then*

$$(Weak Nullstellensatz) \quad \mathbf{V}(I_{\mathcal{C}}) = \emptyset \Leftrightarrow 1 \in I_{\mathcal{C}} \Leftrightarrow I_{\mathcal{C}} = \mathbb{F}[X], \quad (10)$$

$$(Strong Nullstellensatz) \quad \mathbf{I}(\mathbf{V}(I_{\mathcal{C}})) = \sqrt{I_{\mathcal{C}}}, \quad (11)$$

$$(Radical Ideal) \quad \sqrt{I_{\mathcal{C}}} = I_{\mathcal{C}}. \quad (12)$$

Theorem 25 follows from a simple application of the celebrated and basic result in algebraic geometry known as Hilbert's Nullstellensatz. In the general version of Nullstellensatz it is necessary to work in an algebraically closed field and take a radical of the ideal of polynomials. In our special case it is not needed due to the presence of domain polynomials. Indeed, the latter implies that we know a priori that the solutions must be in \mathbb{F} (note that we are assuming $D \subseteq \mathbb{F}$).

A.2 Gröbner bases

In this section we suppose a fixed monomial ordering $>$ on $\mathbb{F}[x_1, \dots, x_n]$ (see [12], Definition 1, p.55), which will not be defined explicitly. We can reconstruct the monomial $x^\alpha = x_1^{\alpha_1} \cdots x_n^{\alpha_n}$ from the n -tuple of exponents $\alpha = (\alpha_1, \dots, \alpha_n) \in \mathbb{Z}_{\geq 0}^n$. This establishes a one-to-one correspondence between the monomials in $\mathbb{F}[x_1, \dots, x_n]$ and $\mathbb{Z}_{\geq 0}^n$. Any ordering $>$ we establish on the space $\mathbb{Z}_{\geq 0}^n$ will give us an ordering on monomials: if $\alpha > \beta$ according to this ordering, we will also say that $x^\alpha > x^\beta$. The two monomial orderings that we use in this paper are the lexicographic order $>_{\text{lex}}$ and the graded lexicographic ordering $>_{\text{grlex}}$.

► **Definition 26.** Let $\alpha = (\alpha_1, \dots, \alpha_n), \beta = (\beta_1, \dots, \beta_n) \in \mathbb{Z}_{\geq 0}^n$ and $|\alpha| = \sum_{i=1}^n \alpha_i, |\beta| = \sum_{i=1}^n \beta_i$.

- (i) We say $\alpha >_{\text{lex}} \beta$ if, in the vector difference $\alpha - \beta \in \mathbb{Z}^n$, the left most nonzero entry is positive. We will write $x^\alpha >_{\text{lex}} x^\beta$ if $\alpha >_{\text{lex}} \beta$.
- (ii) We say $\alpha >_{\text{grlex}} \beta$ if $|\alpha| > |\beta|$, or $|\alpha| = |\beta|$ and $\alpha >_{\text{lex}} \beta$.

► **Definition 27.** For any $\alpha = (\alpha_1, \dots, \alpha_n) \in \mathbb{Z}_{\geq 0}^n$ let $x^\alpha \stackrel{\text{def}}{=} \prod_{i=1}^n x_i^{\alpha_i}$. Let $f = \sum_{\alpha} a_{\alpha} x^{\alpha}$ be a nonzero polynomial in $\mathbb{F}[x_1, \dots, x_n]$ and let $>$ be a monomial order.

- (i) The **multidegree** of f is $\text{multideg}(f) \stackrel{\text{def}}{=} \max(\alpha \in \mathbb{Z}_{\geq 0}^n : a_{\alpha} \neq 0)$.
- (ii) The **degree** of f is $\text{deg}(f) = |\text{multideg}(f)|$. In this paper, this is always according to grlex order.
- (iii) The **leading coefficient** of f is $\text{LC}(f) \stackrel{\text{def}}{=} a_{\text{multideg}(f)} \in \mathbb{F}$.
- (iv) The **leading monomial** of f is $\text{LM}(f) \stackrel{\text{def}}{=} x^{\text{multideg}(f)}$ (with coefficient 1).
- (v) The **leading term** of f is $\text{LT}(f) \stackrel{\text{def}}{=} \text{LC}(f) \cdot \text{LM}(f)$.

The concept of *reduction*, also called *multivariate division* or *normal form computation*, is central to Gröbner basis theory. It is a multivariate generalization of the Euclidean division of univariate polynomials.

► **Definition 28.** Fix a monomial order and let $G = \{g_1, \dots, g_t\} \subset \mathbb{F}[x_1, \dots, x_n]$. Given $f \in \mathbb{F}[x_1, \dots, x_n]$, we say that **f reduces to r modulo G** , written $f \rightarrow_G r$, if f can be written in the form $f = A_1 g_1 + \cdots + A_t g_t + r$ for some $A_1, \dots, A_t, r \in \mathbb{F}[x_1, \dots, x_n]$, such that:

- (i) No term of r is divisible by any of $\text{LT}(g_1), \dots, \text{LT}(g_t)$.
- (ii) Whenever $A_i g_i \neq 0$, we have $\text{multideg}(f) \geq \text{multideg}(A_i g_i)$.

The polynomial remainder r is called a **normal form of f by G** and will be denoted by $f|_G$.

A normal form of f by G , i.e. $f|_G$, can be obtained by repeatedly performing the following until it cannot be further applied: choose any $g \in G$ such that $\text{LT}(g)$ divides some term t of f and replace f with $f - \frac{t}{\text{LT}(g)}g$. Note that the order we choose the polynomials g in the division process is not specified.

In general a normal form $f|_G$ is not uniquely defined. Even when f belongs to the ideal generated by G , i.e. $f \in \mathbf{I}(G)$, it is not always true that $f|_G = 0$.

► **Example 29.** Let $f = xy^2 - y^3$ and $G = \{g_1, g_2\}$, where $g_1 = xy - 1$ and $g_2 = y^2 - 1$. Consider the graded lexicographic order (with $x > y$) and note that $f = y \cdot g_1 - y \cdot g_2 + 0$ and $f = 0 \cdot g_1 + (x - y) \cdot g_2 + x - y$.

This non-uniqueness is the starting point of Gröbner basis theory.

► **Definition 30.** Fix a monomial order on the polynomial ring $\mathbb{F}[x_1, \dots, x_n]$. A finite subset $G = \{g_1, \dots, g_t\}$ of an ideal $I \subseteq \mathbb{F}[x_1, \dots, x_n]$ different from $\{0\}$ is said to be a **Gröbner basis** (or **standard basis**) if $\langle \text{LT}(g_1), \dots, \text{LT}(g_t) \rangle = \langle \text{LT}(I) \rangle$, where we denote by $\langle \text{LT}(I) \rangle$ the ideal generated by the elements of the set $\text{LT}(I)$ of leading terms of nonzero elements of I .

► **Definition 31.** A **reduced Gröbner basis** for a polynomial ideal I is a Gröbner basis G for I such that:

- (i) $\text{LC}(g) = 1$ for all $g \in G$.
- (ii) For all $g \in G$, g cannot reduce any other polynomial from G , i.e. $f|_g = f$ for every $f \in G \setminus \{g\}$.

It is known (see [12], Theorem 5, p.93) that for a given monomial ordering, a polynomial ideal $I \neq \{0\}$ has a reduced Gröbner basis (see Definition 31), and the reduced Gröbner basis is unique.

► **Proposition 32** ([12], Proposition 1, p.83). Let $I \subset \mathbb{F}[x_1, \dots, x_n]$ be an ideal and let $G = \{g_1, \dots, g_t\}$ be a Gröbner basis for I . Then given $f \in \mathbb{F}[x_1, \dots, x_n]$, f can be written in the form $f = A_1g_1 + \dots + A_tg_t + r$ for some $A_1, \dots, A_t, r \in \mathbb{F}[x_1, \dots, x_n]$, such that:

- (i) No term of r is divisible by any of $\text{LT}(g_1), \dots, \text{LT}(g_t)$.
- (ii) Whenever $A_i g_i \neq 0$, we have $\text{multideg}(f) \geq \text{multideg}(A_i g_i)$.
- (iii) There is a unique $r \in \mathbb{F}[x_1, \dots, x_n]$.

In particular, r is the remainder on division of f by G no matter how the elements of G are listed when using the division algorithm.

► **Corollary 33** ([12], Corollary 2, p.84). Let $G = \{g_1, \dots, g_t\}$ be a Gröbner basis for $I \subseteq \mathbb{F}[x_1, \dots, x_n]$ and let $f \in \mathbb{F}[x_1, \dots, x_n]$. Then $f \in I$ if and only if the remainder on division of f by G is zero.

► **Definition 34.** We will write $f|_F$ for the remainder of f by the ordered s -tuple $F = (f_1, \dots, f_s)$. If F is a Gröbner basis for $\langle f_1, \dots, f_s \rangle$, then we can regard F as a set (without any particular order) by Proposition 32.

The “obstruction” to $\{g_1, \dots, g_t\}$ being a Gröbner basis is the possible occurrence of polynomial combinations of the g_i whose leading terms are not in the ideal generated by the $\text{LT}(g_i)$. One way (actually the only way) this can occur is if the leading terms in a suitable combination cancel, leaving only smaller terms. The latter is fully captured by the so called S -polynomials that play a fundamental role in Gröbner basis theory.

► **Definition 35.** Let $f, g \in \mathbb{F}[x_1, \dots, x_n]$ be nonzero polynomials. If $\text{multideg}(f) = \alpha$ and $\text{multideg}(g) = \beta$, then let $\gamma = (\gamma_1, \dots, \gamma_n)$, where $\gamma_i = \max(\alpha_i, \beta_i)$ for each i . We call x^γ the **least common multiple** of $\text{LM}(f)$ and $\text{LM}(g)$, written $x^\gamma = \text{lcm}(\text{LM}(f), \text{LM}(g))$. The **S -polynomial** of f and g is the combination $S(f, g) = \frac{x^\gamma}{\text{LT}(f)} \cdot f - \frac{x^\gamma}{\text{LT}(g)} \cdot g$.

The use of S -polynomials to eliminate leading terms of multivariate polynomials generalizes the row reduction algorithm for systems of linear equations. If we take a system of homogeneous linear equations (i.e.: the constant coefficient equals zero), then it is not hard to see that bringing the system in triangular form yields a Gröbner basis for the system.

► **Theorem 36 (Buchberger’s Criterion).** (See e.g. [12], Theorem 3, p.105) A basis $G = \{g_1, \dots, g_t\}$ for an ideal I is a Gröbner basis if and only if $S(g_i, g_j) \rightarrow_G 0$ for all $i \neq j$.

By Theorem 36 it is easy to show whether a given basis is a Gröbner basis. Indeed, if G is a Gröbner basis then given $f \in \mathbb{F}[x_1, \dots, x_n]$, $f|_G$ is unique and it is the remainder on division of f by G , no matter how the elements of G are listed when using the division algorithm.

■ **Algorithm 3** Buchberger's Algorithm.

```

1: Input: A finite set  $F = \{f_1, \dots, f_s\}$  of polynomials
2: Output: A finite Gröbner basis  $G$  for  $\langle f_1, \dots, f_s \rangle$ 
3:  $G := F$ 
4:  $C := G \times G$ 
5: while  $C \neq \emptyset$  do
6:   Choose a pair  $(f, g) \in C$ 
7:    $C := C \setminus \{(f, g)\}$ 
8:    $h := S(f, g)|_G$ 
9:   if  $h \neq 0$  then
10:     $C := C \cup (G \times \{h\})$ 
11:     $G := G \cup \{h\}$ 
12:   end if
13: end while
14: Return  $G$ 

```

Furthermore, Theorem 36 leads naturally to an algorithm for computing Gröbner bases for a given ideal $I = \langle f_1, \dots, f_s \rangle$: start with a basis $G = \{f_1, \dots, f_s\}$ and for any pair $f, g \in G$ with $S(f, g)|_G \neq 0$ add $S(f, g)|_G$ to G . This is known as Buchberger's algorithm [5] (for more details see Algorithm 3 in Section A.2.1).

Note that Algorithm 3 is non-deterministic and the resulting Gröbner basis is not uniquely determined by the input. This is because the normal form $S(f, g)|_G$ (see Algorithm 3, line 8) is not unique as already remarked. We observe that one simple way to obtain a deterministic algorithm (see [12], Theorem 2, p. 91) is to replace $h := S(f, g)|_G$ in line 8 with $h := S(f, g)|_G$ (see Definition 34), where in the latter G is an ordered tuple. However, this is potentially dangerous and inefficient. Indeed, there are simple cases where the combinatorial growth of set G in Algorithm 3 is out of control very soon.

A.2.1 Construction of Gröbner Bases

Buchberger's algorithm [5] can be formulated as in Algorithm 3. The pairs that get placed in the set C are often referred to as *critical pairs*. Every newly added reduced S -polynomial enlarges the set C . If we use $h := S(f, g)|_G$ in line 8 then there are simple cases where the situation is out of control. This combinatorial growth can be controlled to some extent by eliminating unnecessary critical pairs.

Graph Traversals as Universal Constructions

Siddharth Bhaskar  

Department of Computer Science, University of Copenhagen, Denmark

Robin Kaarsgaard   

School of Informatics, University of Edinburgh, UK

Abstract

We exploit a decomposition of graph traversals to give a novel characterization of depth-first and breadth-first traversals by means of universal constructions. Specifically, we introduce functors from two different categories of *edge-ordered* directed graphs into two different categories of transitively closed edge-ordered graphs; one defines the lexicographic depth-first traversal and the other the lexicographic breadth-first traversal. We show that each functor factors as a composition of universal constructions, and that the usual presentation of traversals as linear orders on vertices can be recovered with the addition of an inclusion functor. Finally, we raise the question of to what extent we can recover search algorithms from the categorical description of the traversal they compute.

Acknowledgements We would like to thank Steve Lindell and Scott Weinstein for inspiring us to study traversals in terms of their predecessor functions, as well as suggesting the characterization of breadth-first traversals in Corollary 27. We also thank Jade Master for discussions relating to this work. We are indebted to the anonymous reviewers for their thorough and detailed comments.

1 Introduction

Graph searches are algorithms for visiting the vertices in a connected graph from a prescribed source. Both graph searches and their resulting vertex orders, or *traversals*, are absolutely fundamental in the theory of graph algorithms, and have important applications in other areas of theoretical computer science such as computational complexity theory.

We start from the premise that a concept as natural as a traversal should be obtainable canonically from the original graph. For example, let us consider the graph G in Figure 1, and fix a as a source. Of the six vertex orderings of G starting with a , two are not traversals: (a, d, b, c) and (a, d, c, b) . This is because while searching a graph, each vertex added must be in the boundary of previously visited vertices, but d is not in the boundary of $\{a\}$.

Of the four remaining vertex orders, two are breadth-first traversals $((a, b, c, d)$ and $(a, c, b, d))$ and two are depth-first traversals $((a, b, d, c)$ and $(a, c, d, b))$. This can easily be checked by hand: in a breadth-first search, we go level-by-level, and must visit both b and c before we visit d . In a depth-first search, we prioritize the neighbor of the most recently visited vertex, so we visit d before the latter of $\{b, c\}$.

■ **Figure 1** A 4-cycle.

However, notice that there is no way of canonically distinguishing between the two breadth-first or the two depth-first traversals. Concretely, once we visit a , there is no canonical way to choose between b and c . A natural fix is to linearly order each neighborhood and visit lesser neighbors first. We call the resulting traversals *lexicographic*. For example, if we say that $b < c$, then the lexicographic breadth-first traversal is (a, b, c, d) and the lexicographic depth-first traversal is (a, b, d, c) . If we say that $c < b$, we get (a, c, b, d) and (a, c, d, b) respectively. We call a graph whose neighborhoods are linearly ordered an *edge-ordered* graph.

In the present paper, we show that both the lexicographic breadth-first traversal and lexicographic depth-first traversal are canonically obtainable from a given edge-ordered graph with a distinguished source. Specifically, we equip edge-ordered graphs with two different kinds of morphisms, and obtain lexicographic breadth- and depth-first traversals by applying a functor out of each category of edge-ordered graphs into the category of linear orders. We furthermore factor each functor as a composition of a forgetful functor and a sequence of *universal* (free and cofree) constructions on edge-ordered graphs.

At a first approximation, each lexicographic traversal can be expressed as the composition of a least-path tree and a transitive closure (see Figure 2). This decomposition was first observed in [7] – not in the context of category theory – where it was used to derive efficient parallel algorithms; see also [3, 6]. The main technical contribution of our paper is in identifying precisely the right notions of edge-ordered graphs and homomorphisms that allow us to formulate least-path trees and transitive closures as universal constructions.

To the best of our knowledge, equipping algorithmic problems with a categorical structure is a relatively recent idea. While graphs have been studied extensively from a categorical point of view, the focus has been on topics such as graph rewriting and string diagrams [8, 10] and relationships with properads [9] rather than graph algorithms. Closer to our approach, a surprisingly simple and elegant characterization of reachability in all *coalgebras* (i.e., including graphs) is studied in [2, 14]. A categorical treatment of the open algebraic path problem is given in [11], and a compositional algorithm for reachability in Petri nets is described in [12].

In [1], Abramsky describes a “great divide” between those areas of theoretical computer science focused on *structure* (semantics and type theory), and those focused on *power* (computability and complexity theory); they have “almost disjoint communities” with “no common technical language or tools.” He proposes a high-level “theory-building” program of integrating these approaches with the intent of solving hard problems, akin to Grothendieck’s program in algebraic geometry. We envision developing a theory of *compositional graph algorithms through universal properties* as a step along this way. A long-term goal of such a project would be to see whether one could recover *algorithms* from *problem statements*, if the latter are suitably formulated.

■ **Figure 2** The construction of the lexicographic depth-first traversal starting from a on a given edge-ordered graph. First we extract the least-path tree, transitively close it, then isolate the ordered neighborhood of a . Numerals indicate the edge ordering. Each transformation is universal, except for a “silent” (forgetful) transformation fixing the transitive graph but forgetting some structure on morphisms.

This paper is structured as follows: We describe the necessary background on graphs and (lexicographic) traversals in Section 2, and present an alternate formulation of traversals in Section 3 that the remaining work will build on. We go on to describe the categories of edge-ordered graphs on which our work is founded in Section 4, and present the two categories of least path trees and universal constructions associated with lexicographic breadth-first and depth-first traversals respectively in Section 5 and Section 6. The categories of transitively closed least path trees and their universal constructions are presented in Section 7 and Section 8. Finally, we summarise our categorical construction of lexicographic breadth-first and depth-first traversals by universal means in Section 9, and end with some concluding remarks in Section 10.

Note that in the interests of space, we omit proofs in the pre-categorical development (Sections 2 and 3), and we relegate the category-theoretic proofs from Sections 4 through Section 9 to the Appendix. The omitted proofs may be found in [4].

2 Background and Preliminaries

Our objective is to give a categorical formulation of the canonical breadth-first and depth-first traversals of directed edge-ordered graphs. But first, in Sections 2 and 3, we give a “pre-categorical” account of these traversals in terms of extremal-path trees, which motivates the subsequent categorical treatment in Sections 4 through 8. The main results of Sections 2 and 3 can be found in [7], but we provide our own presentation.

► **Definition 1.** A (directed) graph is a pair (V, \rightarrow) where V is the set of vertices and $\rightarrow \subseteq V \times V$ is the edge relation.

► **Definition 2.** The neighborhood of a vertex $v \in V$, denoted $N(v)$, is the set of outgoing edges of v ; that is, $N(v) = \rightarrow \cap \{(v, x) \mid x \in V\}$. A graph with a distinguished vertex is pointed.

► **Definition 3.** A path in a graph is a finite sequence of vertices $v_1 \rightarrow v_2 \rightarrow \dots \rightarrow v_n$; say that v_1 is the source of the path, and v_n the target. We will write $u \rightsquigarrow v$ to say that there is a path from u to v , and $u \xrightarrow{\pi} v$ about a specific such path named π . We say that a path is proper when no vertex occurs more than once in the path, i.e., when $v_i = v_j$ implies $i = j$ for all $i, j \in I$. We use ε to denote the unique empty (proper) path in each neighborhood.

► **Remark 4.** Notice that $u \rightsquigarrow v$ iff there exists a proper path from u to v , as repetitions in a path can always be deleted.

► **Definition 5.** Two paths are co-initial in case they share a source, and co-final in case they share a target. If the source of σ agrees with the target of π , we can compose them to obtain $\pi\sigma$. For two co-initial paths π and σ , we say $\pi \sqsubset \sigma$ (read: σ extends π) in case π is a proper initial subsequence (i.e., a proper prefix) of σ .

► **Definition 6.** A pointed graph (G, v_0) is connected if for every vertex v , there exists a path $v_0 \rightsquigarrow v$.

2.1 Graph searching and traversals

By a *graph search*, we mean an algorithm for visiting all the vertices in a connected graph, starting at a given source. Two of the most important types of graph search are *depth-first* and *breadth-first*:

► **Definition 7 (Depth-first search).** Given as input a finite connected graph $G = (V, E)$, initialize a list $L = ()$, and a stack $S = (v_0)$ for some vertex v_0 . While S is nonempty, pop the first element v from S . If v is already contained in L , go back to the start of the loop. Otherwise, let $L = (L, v)$, and push every vertex in ∂v onto S , where $\partial v = N(v) \setminus L$.

► **Definition 8 (Breadth-first search).** Given as input a finite connected graph $G = (V, E)$, initialize a list $L = ()$, and a queue $Q = (v_0)$ for some vertex v_0 . While S is nonempty, dequeue the front element v from Q . If v is already contained in L , go back to the start of the loop. Otherwise, let $L = (L, v)$, and enqueue every vertex in ∂v to the back of Q , where $\partial v = N(v) \setminus L$.

Note that depth-first and breadth-first search are nondeterministic, in the sense that we do not specify which order to add vertices from ∂v in. Moreover, vertices may occur more than once in S or Q , as the same vertex may be added as a neighbor multiple times. However, vertices may not occur more than once in L ; when depth-first or breadth-first search is complete, L lists all the vertices in G .

As we vary over all the nondeterministic traces of depth-first search or breadth-first search over a graph G , the resulting orderings are depth-first or breadth-first traversals.

► **Definition 9.** A linear ordering $<$ of the vertices of a graph G is a depth-first traversal, respectively breadth-first traversal of G if there exists some computation of depth-first search, respectively breadth-first search, on G according to which vertices are added to L in exactly the order $<$.

Both depth- and breadth-first traversals have important characterizations in the first-order language of ordered graphs; these are due to Corneil and Krueger [5], who state them in the special case of undirected graphs. Here, we only need to know that they are necessary.

► **Lemma 10.** Suppose G is a finite, connected graph and $\cdot < \cdot$ is a depth-first traversal of G . Then for any vertices $u < v < w$ such that $u \rightarrow w$, there exists some v' such that $u \leq v' < v$ and $v' \rightarrow v$.

► **Lemma 11.** Suppose G is a finite, connected graph and $\cdot < \cdot$ is a breadth-first traversal of G . Then for any vertices $u < v < w$ such that $u \rightarrow w$, there exists some v' such that $v' \leq u < v$ and $v' \rightarrow v$.

These characterizations motivate the following definitions.

► **Definition 12.** Let G be a finite connected graph and $\cdot < \cdot$ be a depth-first traversal of G . Then for any vertex v , define the depth-first predecessor $dfp(v)$ to be the greatest $u < v$ such that $u \rightarrow v$, if v is not the minimal vertex. For the minimal vertex v , let $dfp(v) = v$.

► **Definition 13.** Let G be a finite connected graph and $\cdot < \cdot$ be a breadth-first traversal of G . Then for any vertex v , define the breadth-first predecessor $bfp(v)$ to be the least $u < v$ such that $u \rightarrow v$, if v is not the minimal vertex. For the minimal vertex v , let $bfp(v) = v$.

Depth- and breadth-first predecessors allow for elegant restatements of Lemmata 10 and 11: if $\cdot < \cdot$ is a depth-first traversal of G , then for any $v < w$, if $dfp(w) < v$, then $dfp(w) \leq dfp(v)$. Similarly, if $\cdot < \cdot$ is a breadth-first traversal of G then for any $v < w$, if $bfp(w) < v$, then $bfp(v) \leq bfp(w)$. In fact the second condition is equivalent to saying that bfp is weakly monotone, viz., $v \leq w \implies bfp(v) \leq bfp(w)$.

For the next definition, notice that the orbits $\{v, dfp(v), dfp^2(v), \dots\}$ and $\{v, bfp(v), bfp^2(v), \dots\}$ of any vertex v are finite, and their *reversals* are paths from the least vertex v_0 to v .

► **Definition 14.** Let G be a finite connected graph, $\cdot < \cdot$ be a depth-first traversal of G , and v_0 be the $<$ -least vertex. Then the canonical df-path from v_0 to any vertex v is the path $v_0 \rightarrow v_1 \rightarrow \dots \rightarrow v_{\ell-1}$ such that $v_{\ell-1} = v$, and for every $0 \leq i < \ell - 1$, $dfp(v_{i+1}) = v_i$.

Analogously, the canonical bf-path from v_0 to any vertex v is the path $v_0 \rightarrow v_1 \rightarrow \dots \rightarrow v_{\ell-1}$ such that $v_{\ell-1} = v$, and for every $0 \leq i < \ell - 1$, $bfp(v_{i+1}) = v_i$.

2.2 Lexicographic searching

The objective of this paper is to show that the depth-first and breadth-first traversals of a graph is *canonical* in some precise categorical sense. Of course, this cannot be true at face value: in a complete graph, every ordering of the vertices is both a breadth-first and a depth-first traversal, and none of them is canonical.

As we remarked in the introduction, an edge-ordering is precisely the amount of additional structure we need. Over such graphs, we can make searching deterministic, as we now show.

► **Definition 15.** A finite edge-ordered graph is a finite graph where each neighborhood is equipped with a (strict) linear order $\triangleleft \cdot$.

► **Definition 16** (Lexicographic depth-first search). Let G be a finite, pointed, connected, edge-ordered graph with distinguished vertex v_0 . Initialize a list $L = ()$ and a stack $S = (v_0)$. While S is nonempty, pop the first element v from S . If v is already contained in L , go back to the start of the loop. Otherwise, let $L = (L, v)$, and push every vertex in ∂v onto S in reverse \triangleleft -order, where ∂v is the set of neighbors of v not in L .

► **Remark 17.** We push vertices from ∂v onto S in reverse \triangleleft -order, so that the least vertices from ∂v end up on top of S .

► **Definition 18** (Lexicographic breadth-first search). Let G be a finite, pointed, connected, edge-ordered graph with distinguished vertex v_0 . Initialize a list $L = ()$ and a queue $Q = (v_0)$. While Q is nonempty, dequeue first element v from S . If v is already contained in L , go back to the start of the loop. Otherwise, let $L = (L, v)$, and enqueue every vertex from ∂v onto Q in \triangleleft -order, where ∂v is the set of neighbors of v not in L .

► **Definition 19.** The depth-first traversal computed by lexicographic depth-first search on a finite, pointed, connected, edge-ordered graph G , is its lexicographic depth-first traversal. Similarly, the breadth-first traversal computed by lexicographic breadth-first search is its lexicographic breadth-first traversal.

► Remark 20. The usage of *lexicographic (depth, breadth)-first (search, traversal)* is ambiguous in the literature. Here, we use it in the same way as Delatorre and Kruskal [7, 6]; however, the *lexicographic breadth-first search* of Rose and Tarjan [13] and the analogous *depth-first* version of Corneil and Krueger [5] are different. The latter are further refinements of breadth-first search and depth-first search over graphs, not a “determinization” by an edge-ordering.

3 Orders on paths

In this section, we give different characterizations of the lexicographic depth-first and breadth-first traversals, independent of any graph search, which suggest the category-theoretic treatment that occupies us for the rest of the paper.

► **Definition 21.** Fix an edge-ordered graph G . Define the lexicographic path relation $\cdot \prec \cdot$ on any proper co-initial paths π and σ in G as follows:

- (i) if $\pi \sqsubset \sigma$, then $\pi \prec \sigma$, similarly if $\sigma \sqsubset \pi$, then $\sigma \prec \pi$; otherwise,
- (ii) let ζ be the longest common prefix of π and σ , let u be the target of ζ , and let v_1 and v_2 be the first vertices immediately following ζ in π and σ respectively. Order $\pi \prec \sigma \iff u \rightarrow v_1 \triangleleft u \rightarrow v_2$.

► Remark 22. The following properties hold of \prec :

1. The empty path (v) is least among all paths from v .
2. If $\pi \prec \sigma$ and $\pi \not\sqsubseteq \sigma$, then for any α and β , $\pi\alpha \prec \sigma\beta$.
3. If $\pi \prec \sigma$, then $\alpha\pi \prec \alpha\sigma$.
4. If $\alpha\pi \prec \alpha\sigma$, then $\pi \prec \sigma$.

Since the set of proper paths is finite, any subset has a \prec -least element, which justifies the next definitions.

► **Definition 23.** For vertices u, v in a finite edge-ordered graph, let $\min(u \rightsquigarrow v)$ be the lexicographically least proper path from u to v .

► **Definition 24.** For vertices u, v in a finite edge-ordered graph, let $\min^s(u \rightsquigarrow v)$ be the lexicographically least shortest path from u to v .

In fact, it will be convenient to define the following relation, the *shortlex* order:

► **Definition 25.** Let $\pi \prec^s \sigma$ mean that either $|\pi| < |\sigma|$, or $|\pi| = |\sigma|$ and $\pi \prec \sigma$.

In this case, $\min^s(u \rightsquigarrow v)$ is simply, the \prec^s -least path $u \rightsquigarrow v$.

In the remainder of this section, we fix a finite, pointed, connected, edge-ordered graph G with distinguished element v_0 . Reserve the symbol $\cdot \triangleleft \cdot$ for the given ordering on co-initial edges and $\cdot \prec \cdot$ for the induced lexicographic ordering on co-initial paths. Let $\cdot <_D \cdot$ and $\cdot <_B \cdot$ denote the lexicographic depth-first and breadth-first traversals respectively. Let $\mathfrak{P}v$ and $\mathfrak{Q}v$ denote the canonical df- and bf-paths from v_0 to v with respect to $\cdot <_D \cdot$ and $\cdot <_B \cdot$ respectively.

Our goal is to prove that $<_D$ and $<_B$ satisfy the following properties,

$$u <_D v \iff \mathfrak{P}u \prec \mathfrak{P}v$$

$$u <_B v \iff \mathfrak{Q}u \prec^s \mathfrak{Q}v,$$

which then in turn yield the following alternate characterizations:

$$u <_D v \iff \min(v_0 \rightsquigarrow v) \prec \min(v_0 \rightsquigarrow u)$$

$$u <_B v \iff \min^s(v_0 \rightsquigarrow v) \prec \min^s(v_0 \rightsquigarrow u).$$

► **Lemma 26.** If $u \leq_B v$, then for any path $\pi : v_0 \rightsquigarrow v$, $|\mathfrak{Q}u| \leq |\pi|$. In addition, if $|\mathfrak{Q}u| = |\pi|$, then $\mathfrak{Q}u \preceq \pi$.

► **Corollary 27.** *The following are all true of the operator Ω :*

1. *For any vertex v of G , $\Omega v = \min^s(v_0 \rightsquigarrow v)$.*
2. *$u \leq_B v$ iff $\Omega u \preceq^s \Omega v$.*

Corollary 27 yields $u <_B v \iff \min^s(v_0 \rightsquigarrow v) < \min^s(v_0 \rightsquigarrow u)$, as desired.

► **Definition 28.** *Define $v <_D w$ in case $\min(v_0 \rightsquigarrow v) < \min(v_0 \rightsquigarrow w)$.*

► **Lemma 29.** *For any vertex v of G , $\mathfrak{F}v = \min(v_0 \rightsquigarrow v)$.*

► **Theorem 30.** *The order $\cdot <_D \cdot$ is exactly the lexicographic depth-first traversal $\cdot <_D \cdot$ of G .*

4 Categories of graphs

We now work towards a categorical formulation of the above material. This means we need to categorify, i.e., equip with morphisms, all the objects we defined in Section 2, as well as introduce some new objects.

Continuing the convention established above, we use the symbol $<$ and variations thereof to refer to orderings of co-initial paths, and the symbol \triangleleft to refer to neighborhood orders, i.e., orderings of co-initial edges. We reserve the symbol $<$ for vertex orders, but these will not reappear until Section 9.

► **Definition 31.** *A homomorphism of graphs $G \xrightarrow{h} H$ is a function from G -vertices to H -vertices which preserves edge connectivity: For all G -vertices u, v , $u \rightarrow v$ in G implies $h(u) \rightarrow h(v)$ in H . A homomorphism of pointed graphs $G \xrightarrow{h} H$ must additionally map the distinguished vertex of G , and only that vertex, to the distinguished vertex of H .*

► **Definition 32.** *If $h : G \rightarrow H$ is a graph homomorphism and π is the path $v_1 \rightarrow v_2 \rightarrow \dots \rightarrow v_n$ in G , then $h(\pi)$ is defined to be the path $h(v_1) \rightarrow h(v_2) \rightarrow \dots \rightarrow h(v_n)$ in H .*

► **Remark 33.** The following hold of any homomorphism $h : G \rightarrow H$;

1. $h(\varepsilon) = \varepsilon$, $h(\pi\sigma) = h(\pi)h(\sigma)$, and if $\pi \sqsubset \sigma$, then $h(\pi) \sqsubset h(\sigma)$.
2. If h is injective on vertices and π is a proper path, then $h(\pi)$ is a proper path.
3. If h is injective on vertices, then h preserves longest common prefixes.

We now define homomorphisms of edge-ordered graphs (cf. Definition 15). In addition to the “straightforward” property of being monotone on neighborhoods, we also want to consider homomorphisms that preserve lexicographically least paths. This gives us two refinements of the notion of homomorphism, depending on whether we want to preserve lexicographically ($<$) least paths or short-lex ($<^s$) least paths.

► **Definition 34.** *A homomorphism of finite, pointed, edge-ordered graphs $G \xrightarrow{h} H$ is a homomorphism of pointed graphs that is monotone on neighborhoods; explicitly,*

- (i) $u \rightarrow v$ in G implies $h(u) \rightarrow h(v)$ in H ,
- (ii) v_G is the unique vertex such that $h(v_G) = v_H$, where v_G and v_H are the distinguished points of G and H respectively, and
- (iii) $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ implies $h(u) \rightarrow h(v_1) \triangleleft h(u) \rightarrow h(v_2)$.

In addition, a lex-homomorphism must preserve least paths:

- (iv) $h(\min(u \rightsquigarrow v)) = \min(h(u) \rightsquigarrow h(v))$,

and a short-lex homomorphism must preserve least shortest paths:

- (v) $h(\min^s(u \rightsquigarrow v)) = \min^s(h(u) \rightsquigarrow h(v))$.

► **Lemma 35.** *If $h : G \rightarrow H$ is a homomorphism of edge-ordered graphs then h preserves $\cdot < \cdot$ as well as $\cdot <^s \cdot$.*

■ **Table 1** Categories of edge-ordered graphs and their morphisms.

Category	Objects	Morphisms
$\mathbf{FinGraph}_x^<$	finite, pointed, connected edge-ordered graphs	pointed, edge-ordered graph homomorphisms
$\mathbf{FinGraph}_x^l$	finite, pointed, connected edge-ordered graphs	lex-homomorphisms (<i>pointed, edge-ordered graph homomorphisms that preserve least paths</i>)
$\mathbf{FinGraph}_x^s$	finite, pointed, connected edge-ordered graphs	short-lex homomorphisms (<i>pointed, edge-ordered graph homomorphisms that preserve least shortest paths</i>)
$\mathbf{LexGraph}$	lex-graphs (<i>finite, pointed, connected, and edge-ordered by definition</i>)	lex-homomorphisms
$\mathbf{FinArb}_x^<$	finite, pointed, edge-ordered arborescences	pointed, edge-ordered graph homomorphisms
$\mathbf{TLexGraph}$	transitive lex-graphs	lex-homomorphisms

An important special case of edge-ordered graphs are those where the edge order agrees with the path order in each neighborhood.

► **Definition 36.** A lex-graph is a finite, pointed, connected, edge-ordered graph such that the edge order is compatible with the lexicographic path order; explicitly, it is a finite directed graph equipped with

- (i) a distinguished vertex v_0 , and
- (ii) a linear order \triangleleft on each neighbourhood $N(u)$ such that for every $v_1, v_2 \in N(u)$, $\min(u \rightsquigarrow v_1) \prec \min(u \rightsquigarrow v_2) \iff u \rightarrow v_1 \triangleleft u \rightarrow v_2$.

► **Remark 37.** We might be tempted to define, analogously, a *short-lex graph* by demanding that $v_1, v_2 \in N(u)$, $\min^s(u \rightsquigarrow v_1) \prec^s \min^s(u \rightsquigarrow v_2) \iff u \rightarrow v_1 \triangleleft u \rightarrow v_2$. However notice that this condition simply holds automatically for any edge-ordered graph: if there is an edge $u \rightarrow v$, that edge is the lexicographically least shortest path.

Finally, we isolate two extremal special cases of lex-graphs, one with very few edges, and one with very many.

► **Definition 38.** An arborescence is a pointed directed graph $G = (V, \rightarrow, v_0)$ such that for every vertex u , there is a unique path $v_0 \rightsquigarrow u$ in G .

► **Remark 39.** If (V, \rightarrow, v_0) is an arborescence, its underlying undirected graph (V, E) is connected and acyclic (where $E(u, v)$ iff $(u \rightarrow v)$ or $(v \rightarrow u)$), and every edge $u \rightarrow v$ is oriented away from v_0 , meaning that the distance from v_0 to u is less than the distance from v_0 to v . If G is a finite edge-ordered graph that is also an arborescence, then it is already lex-graph, since the only path between u and $v \in N(u)$ is the edge $u \rightarrow v$. Moreover, if S and T are arborescences and if $h : S \rightarrow T$ is a pointed, edge-ordered graph homomorphism, then it is already both a lex-homomorphism and a short-lex homomorphism.

► **Definition 40.** A graph is transitive if its edge relation is; i.e., if $u \rightarrow v$ and $v \rightarrow w$ implies $u \rightarrow w$. A transitive lex-graph is a lex-graph with a transitive edge relation.

It follows readily that this zoo of graph variations each form a category, summarized in Table 1. Diagrammatically, we show the relationships between these categories in Figure 3, where each arrow indicates inclusion as a subcategory.

There is one additional category that will be introduced in Section 8, and that is \mathbf{TArb} (Definition 51) whose objects are transitive closures of arborescences with a particular edge order depending on the underlying arborescence. Curiously, their morphisms preserve *longest* paths instead of shortest paths.

■ **Figure 3** Categories of edge-ordered graphs and their relationships.

5 Least path trees

Given a finite, pointed, connected, edge-ordered graph, we can delete all edges which are not on some lexicographically least path starting from the distinguished vertex v_0 . We get a finite, edge-ordered arborescence. In this section, we show that this construction (denoted Θ) is cofree, indeed coreflective: it is right adjoint to the inclusion functor I .

► **Definition 41** (The functor Θ). *Given a finite, pointed, connected, edge-ordered graph G , with distinguished vertex v_0 , the graph $\Theta(G)$ is defined as follows:*

- *the vertices of $\Theta(G)$ are the vertices of G , and*
- *any edge $u \rightarrow v$ appears in $\Theta(G)$ iff $u \rightarrow v$ is contained in $\min(v_0 \rightsquigarrow v)$.*
- *Order co-initial edges $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in $\Theta(G)$ iff the same relation holds in G .*

For a lex-homomorphism $h : G \rightarrow H$ define $\Theta(h) : \Theta(G) \rightarrow \Theta(H)$ by $\Theta(h)(v) = h(v)$ for any vertex $v \in \Theta(G)$.

The proof that Θ is a well-defined functor into the indicated category is in the appendix (Lemma 61). Next we define I , which is simply inclusion of categories.

► **Definition 42** (The functor I). *Given a finite, edge-ordered arborescence T , the object $I(T)$ is simply identified with T . Given a pointed, edge-ordered homomorphism $h : S \rightarrow T$, the homomorphism $I(h) : I(S) \rightarrow I(T)$ is simply identified with h .*

Since every finite, edge-ordered arborescence is a finite, pointed, connected, edge-ordered graph, and since morphisms in $\mathbf{FinArb}_*^<$ are defined to be morphisms of pointed, edge-ordered graphs, I is well-defined.

► **Theorem 43.** *There is an adjunction* $\mathbf{FinGraph}_*^l \begin{array}{c} \xrightarrow{\Theta} \\ \top \\ \xleftarrow{I} \end{array} \mathbf{FinArb}_*^<$.

Something for free

Since the image of I is always a lex-graph, and since $\mathbf{LexGraph}$ is a full subcategory of $\mathbf{FinGraph}_*^l$, we actually get the following adjunction for free:

$$\mathbf{LexGraph} \begin{array}{c} \xrightarrow{\Theta'} \\ \top \\ \xleftarrow{I'} \end{array} \mathbf{FinArb}_*^<$$

where I' is the functor I but with target category $\mathbf{LexGraph}$, and Θ' is Θ restricted to $\mathbf{LexGraph}$. The proof is in the appendix (Lemma 62).

■ **Figure 4** The lexicographic-transitive closure of lex-graphs specializes the transitive closure of finite graphs.

6 Least shortest-path trees

Our objective in this section is to establish a shortest-paths analogue of the previous section, i.e., to define a lexicographically least *shortest-path* tree functor $\mathbf{FinGraph}_*^s \xrightarrow{S} \mathbf{FinArb}_*^{<}$ and an inclusion functor $\mathbf{FinArb}_*^{<} \xrightarrow{I} \mathbf{FinGraph}_*^s$. (It is not, of course, the same I as in the previous section, the source category being different.)

► **Definition 44** (The functor S). *Given a finite, pointed, connected, edge-ordered graph G , with distinguished vertex v_0 , the graph $S(G)$ is defined as follows:*

- *the vertices of $S(G)$ are identified with the vertices of G , and*
- *any edge $u \rightarrow v$ appears in $S(G)$ iff $u \rightarrow v$ is contained in $\min^s(v_0 \rightsquigarrow v)$.*
- *Order co-initial edges $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in $S(G)$ iff the same relation holds in G .*

If $h : G \rightarrow H$ is a homomorphism, define $S(h) : S(G) \rightarrow S(H)$ by $S(h)(v) = h(v)$, for any vertex $v \in S(G)$.

To show that S is functorial, it suffices to check that $S(G)$ is always an arborescence. We prove this in the appendix (Lemma 63).

► **Theorem 45.** *There is an adjunction* $\mathbf{FinGraph}_*^s \begin{array}{c} \xrightarrow{S} \\ \top \\ \xleftarrow{I} \end{array} \mathbf{FinArb}_*^{<}$.

7 Transitive closure of lex-graphs

There is a well-known adjunction between the category of graphs and the category \mathbf{TGraph} of transitive graphs, where the functor in one direction transitively closes the edge relation, and in the other direction is simply inclusion [11]. Here, we refine this to an adjunction between $\mathbf{LexGraph}$ and $\mathbf{TLexGraph}$. Indeed, the usual transitive closure appears when forgetting the order as in Figure 4 (where the functors $(\mathbf{T})\mathbf{LexGraph} \rightarrow (\mathbf{T})\mathbf{Graph}$ simply forget the edge order).

While it is immediately clear that there is a forgetful (inclusion) functor $\mathbf{TLexGraph} \xrightarrow{U} \mathbf{LexGraph}$, we must construct the free functor in the other direction.

► **Definition 46** (The functor F). *Given a lex-graph G , define the transitive lex-graph $F(G)$ as follows:*

- *the vertices of $F(G)$ are the vertices of G ,*
- *the distinguished point of $F(G)$ is the distinguished point of G ,*
- *The edge relation of $F(G)$ is the transitive closure of the edge relation of G , and finally*

- for any vertices v_1, v_2 in a common neighborhood $N(u)$, let $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in $F(G)$ iff $\min(u \rightsquigarrow v_1) \prec \min(u \rightsquigarrow v_2)$ in G .

On morphisms, given $G \xrightarrow{h} H$ we define $F(G) \xrightarrow{F(h)} F(H)$ by $F(h)(v) = h(v)$.

We must show that F is a well-defined functor, but before doing so, we state several important relationships between the lex-graph G and the edge-ordered graph $F(G)$:

- **Lemma 47.** For any lex-graph G ,
 - The neighborhood order of $F(G)$ extends that of G
 - The lexicographic path order of $F(G)$ extends that of G .
 - Least paths in G and $F(G)$ coincide.

- **Lemma 48.** The map $\mathbf{LexGraph} \xrightarrow{F} \mathbf{TLexGraph}$ is well-defined and functorial.

► **Remark 50.** In the title of this paper, we promise universal constructions – and while such do arise from adjunctions (from the unit and counit), it seems fitting that we make this explicit at least once. As a consequence of Theorem 49, for any lex-graph G in with lexicographic-transitive closure $U(F(G))$, given any other transitive lex-graph $U(G')$ and $G \xrightarrow{h} U(G')$ there is a *unique* homomorphism of transitive lex-graphs $F(G) \xrightarrow{\hat{h}} G'$ such that the diagram below commutes in $\mathbf{LexGraph}$:

$$\begin{array}{ccc} G & \xrightarrow{\quad} & U(F(G)) \\ & \searrow h & \downarrow U(\hat{h}) \\ & & U(G') \end{array}$$

The reader is invited to extract similar universal mapping properties from other adjunctions in this paper.

8 Transitive closure of least shortest path trees

We now establish the final adjunction of our paper, and the second adjunction needed to characterize breadth-first traversals. Analogously to the depth-first case, this adjunction relates $\mathbf{FinArb}_*^{\prec}$ and a category of transitively closed graphs:

► **Definition 51** (The category \mathbf{TArb}). A finite, pointed, connected, edge-ordered graph G is an object of \mathbf{TArb} iff there exists a finite, pointed, connected, edge-ordered arborescence T and an identification of the vertices of G with the vertices of T such that

- the distinguished points of each are identical,
- the edge relation of G is the transitive closure of the edge relation of T , and
- $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in G iff $v_0 \rightsquigarrow v_1 \prec^s v_0 \rightsquigarrow v_2$ in T , where $v_0 \rightsquigarrow v$ is the unique path from v_0 to v in T .

A map $G_1 \xrightarrow{h} G_2$ is a morphism in \mathbf{TArb} if it is a homomorphism of edge-ordered graphs ((i)–(iii) of Definition 34) and in addition it preserves longest paths.

This last property only makes sense if longest paths are unique. Luckily, longest paths in the transitive closure of an arborescence are exactly the edges of the original tree.

17:12 Graph Traversals as Universal Constructions

► **Lemma 52.** *If T is an arborescence (not necessarily edge-ordered) with root v_0 , and G is its transitive closure, then an edge $u \rightarrow v$ of G is an edge of T iff $u \rightarrow v$ appears on a longest path $v_0 \rightsquigarrow v$ in G . Moreover, the longest path $u \rightsquigarrow v$ in G is unique.*

► **Remark 53.** As a consequence of Lemma 52, for any graph $G \in \mathbf{TArb}$, $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in G iff $v_0 \rightsquigarrow v_1 \prec^s v_0 \rightsquigarrow v_2$ in G , where $v_0 \rightsquigarrow v$ is the unique longest path from v_0 to v in G .

While the presentation of depth- and breadth-first traversals has thus far been similar even at a rather small scale, this adjunction diverges from the previous one in several ways: it does not decompose into an inclusion and a functor which lifts the ordinary transitive closure, and the curious preservation of longest paths by morphisms is not suggested by the pre-categorical treatment of breadth-first traversals. This category arises somewhat mysteriously, and we have no justification for introducing it other than it works.

We now define the two functors of the adjunction. The proofs that they are functorial are Lemmas 64 and 65 in the appendix.

► **Definition 54.** *Define the functor $\mathbf{FinArb}_*^{\leq} \xrightarrow{\Gamma} \mathbf{TArb}$ by $\Gamma(V, v_0, \rightarrow) = (V, v_0, \xrightarrow{\text{trans}})$, and for any vertices (u, v_1, v_2) such that $u \rightarrow v_1$ and $u \rightarrow v_2$ in $\Gamma(T)$, define $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ iff $v_0 \rightsquigarrow v_1 \prec^s v_0 \rightsquigarrow v_2$ in T . For morphisms $T \xrightarrow{h} T'$, define $\Gamma(h) : \Gamma(T) \rightarrow \Gamma(T')$ by $\Gamma(h)(v) = h(v)$.*

► **Definition 55.** *Define the functor $\mathbf{TArb} \xrightarrow{L} \mathbf{FinArb}_*^{\leq}$ by identifying the set of vertices of $L(G)$ with the vertices of G , and including an edge $u \rightarrow v$ in $L(G)$ iff it lies on the longest path $v_0 \rightsquigarrow v$ in G . The neighborhood order in $L(G)$ is inherited from G , and for morphisms $G \xrightarrow{h} H$, define $L(h) : L(G) \rightarrow L(H)$ by $L(h)(v) = h(v)$.*

► **Theorem 56.** *There is an adjunction $\mathbf{FinArb}_*^{\leq} \begin{array}{c} \xrightarrow{\Gamma} \\ \perp \\ \xleftarrow{L} \end{array} \mathbf{TArb}$.*

9 Putting it all together

Combining the adjunctions from Sections 5 and 7, we get a chain of adjunctions

$$\mathbf{FinGraph}_*^{\leq} \begin{array}{c} \xrightarrow{\Theta} \\ \top \\ \xleftarrow{I} \end{array} \mathbf{FinArb}_*^{\leq} \begin{array}{c} \xrightarrow{I'} \\ \perp \\ \xleftarrow{\Theta'} \end{array} \mathbf{LexGraph} \begin{array}{c} \xrightarrow{F} \\ \perp \\ \xleftarrow{U} \end{array} \mathbf{TLexGraph}$$

Since adjunctions of the same handedness compose, we can rewrite this as

$$\mathbf{FinGraph}_*^{\leq} \begin{array}{c} \xrightarrow{\Theta} \\ \top \\ \xleftarrow{I} \end{array} \mathbf{FinArb}_*^{\leq} \begin{array}{c} \xrightarrow{I' \circ F} \\ \top \\ \xleftarrow{\Theta' \circ U} \end{array} \mathbf{TLexGraph}$$

Similarly, by combining the adjunctions of Sections 6 and 8 we get

$$\mathbf{FinGraph}_*^s \begin{array}{c} \xrightarrow{S} \\ \top \\ \xleftarrow{I} \end{array} \mathbf{FinArb}_*^{\leq} \begin{array}{c} \xrightarrow{\Gamma} \\ \top \\ \xleftarrow{L} \end{array} \mathbf{TArb}$$

Suppose we fix a finite, pointed, edge-ordered graph, locate it in either $\mathbf{FinGraph}_*^l$ or $\mathbf{FinGraph}_*^s$, then apply the appropriate least-path tree and the transitive closure functors. Then the edge ordering of the distinguished vertex in the result is the lexicographic depth-first or breadth-first traversal respectively.

► **Lemma 57.** *Given any $G \in \mathbf{FinGraph}_*^l$, let $T = (F \circ I' \circ \Theta)(G)$. Then the neighborhood ordering \triangleleft on the distinguished point in T is the lexicographic depth-first traversal of G .*

► **Lemma 58.** *Given any $G \in \mathbf{FinGraph}_*^s$, let $T = (\Gamma \circ S)(G)$. Then the neighborhood ordering \triangleleft on the distinguished point in T is the lexicographic breadth-first traversal of G .*

Finally, we show that these traversals can be extracted as vertex orders rather than edge orders, by defining a functor that takes an edge-ordered graph into the ordered neighborhood of its distinguished point. Let $\mathbf{FinLoSet}$ denote the category of finite linearly ordered sets with monotone functions.

► **Lemma 59.** *There is a functor $E : \mathbf{FinGraph}_*^< \rightarrow \mathbf{FinLoSet}$ that linearly orders the vertices in a given graph according to the ordering on $N(v_0)$.*

Since there are inclusions $\mathbf{TLexGraph} \rightarrow \mathbf{FinGraph}_*^<$ and $\mathbf{TArb} \rightarrow \mathbf{FinGraph}_*^<$, we get

► **Corollary 60.** *There are functors $\mathbf{FinGraph}_*^l \rightarrow \mathbf{FinLoSet}$ and $\mathbf{FinGraph}_*^s \rightarrow \mathbf{FinLoSet}$ which compute the lexicographic depth-first and breadth-first traversals respectively.*

Note that parts of this final step $\mathbf{FinGraph}_*^< \rightarrow \mathbf{FinLoSet}$ can also be made universal, but since we still have to accept the presence of inclusion functors without adjoints, we only sketch this construction: The functor E from Lemma 59 restricts to a functor from the category of *transitive* finite, pointed, edge-ordered graphs and their homomorphisms, and into the category of finite *nonempty* linearly ordered sets with monotone functions *which additionally preserve the least element*. This restricted functor has a left adjoint given by mapping a finite linearly ordered set $(V, <)$ to the graph with vertices V , distinguished vertex the least element v_0 of V (guaranteed to exist when V is finite), and edge relation given by $v_0 \rightarrow v$ for all $v \in V$ with $v \neq v_0$. This specializes to neither $\mathbf{TLexGraph}$ nor \mathbf{TArb} , however, since the counit of this adjunction need not preserve either least or longest paths.

10 Discussion and open questions

We have described a construction of depth-first traversals from a category of finite edge-ordered graphs whose morphisms preserve least paths as a series of universal constructions, and in analogous fashion, a construction of breadth-first traversals from a category of finite edge-ordered graphs whose morphisms preserve least shortest paths. A diagram summarizing the various adjunctions involved is shown in Figure 5. The prevalence of coreflections in our work is nicely aligned with previous work on reachability in coalgebras [2, 14], where well-pointed and reachable coalgebras respectively turn out to form coreflective subcategories.

This begs the question of whether there is way of generalizing these two constructions using a general notion of extremal path. Such a method is suggested by Delatorre and Kruskal [7] using the machinery of a closed semiring system, which provides a general setting for several lexicographic algebraic path problems; not only breadth-first and depth-first search, but *lexicographic topological search* as well.

The deeper question raised by our work is how, if at all, the categorification of a problem informs the algorithms which solve it. For example, it seems natural that problems which can be expressed by a *single* (free or cofree) universal construction would be amenable to a

■ **Figure 5** Categories of edge-ordered graphs and adjunctions between them.

solution by a greedy algorithm. Intuitively, if an object is free, then it can be built up *over here* without affecting what happens *over there*, and can thus be constructed by making local choices – exactly what a greedy algorithm does.

What if a problem can be expressed by a composition of two adjunctions of opposite handedness, as we show here? Is there an algorithmic strategy for such problems? More generally, is there a robust hierarchy of problems on graphs which classifies them by the number of free-cofree alternations, and can we unite problems in the same level of the hierarchy with a common algorithmic template?

Speculatively, we envision a world in which properties of algorithms could be inferred from the appropriate categorical formulation of the problems they solve. In such a world, a statement like *problem X can be solved using two sequential applications of depth-first search, but no fewer* would have a precise meaning. The semantics functor that transforms an algorithm into a problem that it solves could be decomposed in several meaningful ways, which would give different pieces of information about the algorithm. (Perhaps, for example, one decomposition would give upper bounds on the sequential complexity of solving the problem, and another on the parallel complexity.)

This is a long-term goal. In the medium term, there are still many compelling questions we might hope to answer. For example, the common sequential algorithm implementing depth-first search uses stacks, and the analogous algorithm for breadth-first search uses queues. Can we somehow infer “stacks” and “queues” from a common categorical formulation of depth-first and breadth-first traversals? Can we recover the parallel complexities of these problems proven in [6]?

Positive answers to these or similar questions would be strong evidence that the “categorical structure theory of algorithms” mentioned in the introduction is actually a viable program; that it can not only describe problems, but suggest ways to solve them – in the elegant characterization of [1], to *lead* rather than to *follow*.

A Appendix: Proofs from Sections 4 through 9

Proof of Lemma 35. It suffices to show that h preserves $\cdot \prec \cdot$; the second statement follows from the observation that graph homomorphisms preserve path length, i.e., $|\pi| = |h(\pi)|$ for every path π .

Suppose that π and σ are co-initial paths in G such that $\pi \prec \sigma$. If $\pi \sqsubset \sigma$, then $h(\pi) \sqsubset h(\sigma)$ and we're done. Otherwise, let $u \rightarrow v_1$ and $u \rightarrow v_2$ be the first edges in π and σ respectively following their longest common prefix ζ . Since $\pi \prec \sigma$, $u \rightarrow v_1 \triangleleft u \rightarrow v_2$, so $h(u) \rightarrow h(v_1) \triangleleft h(u) \rightarrow h(v_2)$.

Notice that $h(\zeta)$ is a common prefix of $h(\pi)$ and $h(\sigma)$, and since $h(u) \rightarrow h(v_1) \triangleleft h(u) \rightarrow h(v_2)$, it must be the longest one. Moreover, since $h(u) \rightarrow h(v_1) \triangleleft h(u) \rightarrow h(v_2)$, $h(\pi) \prec h(\sigma)$, which is what we wanted to show. \blacktriangleleft

► **Lemma 61.** *The functor Θ is well-defined.*

Proof. We first have to check that $\Theta(G)$ is a finite, edge-ordered arborescence. It is trivially finite and edge-ordered. Notice that $\Theta(G)$ is connected: for every vertex u , every edge on the path $\min(v_0 \rightsquigarrow u)$ is contained in $\Theta(G)$. On the other hand, the in-degree of each vertex is at most 1: there cannot be two distinct edges $u \rightarrow v$ and $u' \rightarrow v$ in $\min(v_0 \rightsquigarrow v)$.

Next we have to check that for any homomorphism h , $\Theta(h)$ is in fact a homomorphism of pointed, edge-ordered graphs. First notice that $\Theta(h)$ actually maps into $\Theta(H)$: if $u \rightarrow v$ is included in $\Theta(G)$, then it must be contained in $\min(v_0 \rightsquigarrow v)$ in G , whose h -image is $\min(h(v_0) \rightsquigarrow h(v))$ by property (iv) of Definition 34; therefore, $h(u \rightarrow v)$ is contained in a least path and so included in $\Theta(H)$.

Moreover, $\Theta(h)$ clearly fixes the distinguished vertex, and visibly inherits monotonicity on co-initial edges from h . Hence, $\Theta(h)$ is a pointed, edge-ordered graph homomorphism. \blacktriangleleft

Proof of Theorem 43. First, given $I(T) \xrightarrow{h^\uparrow} G$ in $\mathbf{FinGraph}_*^l$, we describe how to obtain $T \xrightarrow{h_\downarrow} \Theta(G)$ in $\mathbf{FinArb}_*^<$. Define $h_\downarrow(v) = h^\uparrow(v)$, for $v \in T$ (which, remember is the same as $I(T)$). To check that h_\downarrow is well-defined, we must show that if $u \rightarrow v$ is an edge of T , then

17:16 Graph Traversals as Universal Constructions

$h^\uparrow(u \rightarrow v)$ is contained in $\Theta(G)$. But since T is an arborescence, $u \rightarrow v$ is trivially contained in $\min(v_0 \rightsquigarrow v)$, so $h^\uparrow(u \rightarrow v)$ is contained in $\min(h(v_0) \rightsquigarrow h(v))$, and hence included in $\Theta(G)$.

Moreover, the fact that h_\downarrow maps edges to edges, preserves the distinguished point, and is monotone on co-initial edges, is immediately inherited from h^\uparrow .

Next, given $T \xrightarrow{h^\downarrow} \Theta(G)$ in $\mathbf{FinArb}_*^<$, define $I(T) \xrightarrow{h^\uparrow} G$ in $\mathbf{FinGraph}_*^l$ by $h^\uparrow(v) = h_\downarrow(v)$, for $v \in I(T)$. In this case, we do not need to check that h^\uparrow is well-defined, and the properties of mapping edges to edges, preserving the distinguished point, and monotonicity on neighborhoods, are inherited immediately from h_\downarrow . The fact that h^\uparrow maps least paths to least paths is easily justified by observing that h^\uparrow maps into $\Theta(G)$, the tree of least paths in G .

To check that this correspondence is bijective, notice that starting from either h^\uparrow or h_\downarrow , passing to the other one, and passing back again, gives us the same morphism we started with. Naturality follows straightforwardly by observing that both functors are the identity on morphisms, so naturality squares trivially commute. \blacktriangleleft

► **Lemma 62.** *There is an adjunction*

$$\mathbf{LexGraph} \quad \begin{array}{c} \xrightarrow{\Theta'} \\ \top \\ \xleftarrow{I'} \end{array} \quad \mathbf{FinArb}_*^<$$

Proof. The adjunction from Theorem 43 factors as

$$\begin{array}{ccc} \mathbf{LexGraph} & \xrightarrow{J} & \mathbf{FinGraph}_*^l \\ & \searrow^{I'} & \uparrow \left(\begin{array}{c} \dashv \\ \ominus \end{array} \right) \\ & & \mathbf{FinArb}_*^< \end{array}$$

where J is the fully faithful identity-on-objects functor witnessing the inclusion of $\mathbf{LexGraph}$ in $\mathbf{FinGraph}_*^l$, and $\Theta' = \Theta \circ J$. The natural isomorphism

$$\begin{aligned} \mathbf{LexGraph}(I'(G), H) &\cong \mathbf{FinGraph}_*^l(J(I'(G)), J(H)) \\ &= \mathbf{FinGraph}_*^l(I(G), J(H)) \\ &\cong \mathbf{FinArb}_*^<(G, \Theta(J(H))) \\ &= \mathbf{FinArb}_*^<(G, \Theta'(H)) \end{aligned}$$

establishes this adjunction. \blacktriangleleft

► **Lemma 63.** *For any finite, pointed, connected, edge-ordered graph G , $S(G)$ is an arborescence.*

Proof. To verify that $S(G)$ is a well-defined arborescence, it suffices to observe that $S(G)$ is connected (as it preserves least shortest paths), and that there is a unique path $v_0 \rightsquigarrow v$: two distinct edges $u \rightarrow v$ and $u' \rightarrow v$ cannot both occur in $\min^s(v_0 \rightsquigarrow v)$.

To check that $S(G \xrightarrow{h} H)$ is well defined, we have to verify for $u \rightarrow v \in S(G)$, $h(u) \rightarrow h(v) \in S(H)$. But such morphisms h preserve least shortest paths by Definition 34 (v). \blacktriangleleft

Proof of Theorem 45. The proof is obtained by literally copying the proof of Theorem 43 and replacing $\mathbf{FinGraph}_*^l$ by $\mathbf{FinGraph}_*^s$, Θ by S , and \min by \min^s throughout.

Given $I(T) \xrightarrow{h^\uparrow} G$ in $\mathbf{FinGraph}_*^s$, we describe how to obtain $T \xrightarrow{h_\downarrow} T(G)$ in $\mathbf{FinArb}_*^<$. Define $h_\downarrow(v) = h^\uparrow(v)$, for $v \in T$ (which we identified with $I(T)$). To check that h_\downarrow is well-defined, we must show that if $u \rightarrow v$ is an edge of T , then $h^\uparrow(u \rightarrow v)$ is contained in $S(G)$. But since T is an arborescence, $u \rightarrow v$ is trivially contained in $\min^s(v_0 \rightsquigarrow v)$, so $h^\uparrow(u \rightarrow v)$ is contained in $\min^s(h(v_0) \rightsquigarrow h(v))$, and hence included in $S(G)$.

Moreover, the fact that h_\downarrow maps edges to edges, preserves the distinguished point, and is monotone on co-initial edges, is immediately inherited from h^\uparrow .

Next, given $T \xrightarrow{h_\downarrow} S(G)$ in $\mathbf{FinArb}_*^<$, define $I(T) \xrightarrow{h^\uparrow} G$ in $\mathbf{FinGraph}_*^s$ by $h^\uparrow(v) = h_\downarrow(v)$, for $v \in I(T)$ (which we identified with T). In this case, we do not need to check that h^\uparrow is well-defined, and the properties of mapping edges to edges, preserving the distinguished point, and monotonicity on neighborhoods, are inherited immediately from h_\downarrow . The fact that h^\uparrow maps least shortest paths to least shortest paths is easily justified by observing that h^\uparrow maps into $S(G)$, the tree of least shortest paths in G .

To check that this correspondence is bijective, notice that starting from either h^\uparrow or h_\downarrow , passing to the other one, and passing back again, gives us the same morphism we started with. Naturality follows straightforwardly by observing that both functors are the identity on morphisms, so naturality squares trivially commute. \blacktriangleleft

Proof of Lemma 47. (i): If there are edges $u \rightarrow v_1$ and $u \rightarrow v_2$ of G , then $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in G iff $\min(u \rightsquigarrow v_1) \prec \min(u \rightsquigarrow v_2)$ in G (since G is a lex-graph) iff $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in $F(G)$ (by definition of F).

(ii): Suppose σ and π are co-initial paths from G . We may assume that σ and π share no nontrivial prefix; then either σ or π is empty (and the claim is trivial), or σ and π differ on their first edge, and the claim follows from (i).

(iii): Work in $F(G)$. It suffices to show that least paths in $F(G)$ consist of only edges in G ; by the above remark, if two paths consist of G -edges, it does not matter whether we compare them in G or in $F(G)$.

Towards which, it suffices to show that every edge $u \rightarrow v$ not in G is greater than the least path $\min_G(u \rightsquigarrow v)$ between u and v in G . Then any path with non-edges in G can be lessened; in particular least paths in $F(G)$ cannot contain any non-edges of G .

Let $v_1 \neq v$ be the second vertex in $\min_G(u \rightsquigarrow v)$. Since least paths are closed under taking prefixes, $u \rightarrow v_1 = \min_G(u \rightsquigarrow v_1)$, in both G and $F(G)$. Since $\min_G(u \rightsquigarrow v_1) \prec \min_G(u \rightsquigarrow v)$, $u \rightarrow v_1 \triangleleft u \rightarrow v$ in $F(G)$. But then $\min_G(u \rightsquigarrow v) \prec u \rightarrow v$, which is what we wanted to show. \blacktriangleleft

Proof of Lemma 48. Given any lex-graph G , $F(G)$ is clearly a transitive edge-ordered graph, but we must check that it satisfies the lex-graph property (Definition 36-(ii)). But for any v_1 and v_2 in the neighborhood of a common u in $F(G)$, $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in $F(G)$ iff $\min(u \rightsquigarrow v_1) \prec \min(u \rightsquigarrow v_2)$ in G (by definition of F) iff $\min(u \rightsquigarrow v_1) \prec \min(u \rightsquigarrow v_2)$ in $F(G)$ (by Lemma 47 plus the preceding remark).

By definition, F immediately preserves identities and compositions of homomorphisms, and it remains to check that for any lex-homomorphism $G \xrightarrow{h} H$ of lex-graphs, $F(h)$ is a lex-homomorphism $F(G) \rightarrow F(H)$. We check each of the conditions in Definition 34:

- (i) If $u \rightarrow v$ in $F(G)$, then there is a path $u \rightsquigarrow v$ in G , so there is a path $h(u) \rightsquigarrow h(v)$ in H , and hence an edge $h(u) \rightarrow h(v)$ in $F(H)$.
- (ii) Since h preserves the distinguished point, so does $F(h)$.
- (iii) If $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in G , $\min(u \rightsquigarrow v_1) \prec \min(u \rightsquigarrow v_2)$, as G is a lex-graph. Since h is a lex-homomorphism, $\min_H(h(u) \rightsquigarrow h(v_i)) = h(\min_G(u \rightsquigarrow v_i))$, so $\min(h(u) \rightsquigarrow h(v_1)) \prec \min(h(u) \rightsquigarrow h(v_2))$ in H . By definition of F , $h(u) \rightarrow h(v_1) \triangleleft h(u) \rightarrow h(v_2)$ in $F(H)$.

17:18 Graph Traversals as Universal Constructions

- (iv) As the least path $\min(u \rightsquigarrow v)$ in $F(G)$ is also least in G , as shown above, and as h preserves least paths, $h(\min(u \rightsquigarrow v))$ is $\min(h(u) \rightsquigarrow h(v))$ in H , and this in turn is also the least path in $F(H)$. ◀

Proof of Theorem 49. Let $F(G) \xrightarrow{h^\uparrow} H$ be a homomorphism of **TLexGraph**. Since $F(G)$ has the same vertices as G , we may define $G \xrightarrow{h_\downarrow} U(H)$ by $h_\downarrow(v) = h^\uparrow(v)$ (since H and $U(H)$ are exactly identical).

We check that h_\downarrow is a lex-homomorphism by checking Definition 34 (i)-(iv). We write, e.g., $h(v)$ to refer unambiguously to the vertex $h^\uparrow(v) = h_\downarrow(v)$.

- (i) If $u \rightarrow v$ is an edge of G , it is an edge of $F(G)$, so $h(u) \rightarrow h(v)$ is an edge of H , and hence an edge of $U(H)$.
- (ii) h_\downarrow directly inherits preservation of the distinguished point from h^\uparrow
- (iii) If $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in G , then $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in $F(G)$ (Lemma 47), so $h(u) \rightarrow h(v_1) \triangleleft h(u) \rightarrow h(v_2)$ in H (monotonicity of h^\uparrow), and hence the same holds in $U(H)$.
- (iv) If π is the least path $u \rightsquigarrow v$ in G , then it's least in $F(G)$ (Lemma 47), so $h(\pi)$ is least in H (since h^\uparrow is a lex-homomorphism), and hence also in $U(H)$.

In the other direction, we suppose that we are given some homomorphism of lex-graphs $G \xrightarrow{h_\downarrow} U(H)$ in **LexGraph**. Define $F(G) \xrightarrow{h^\uparrow} H$ by $h^\uparrow(v) = h_\downarrow(v)$. Again, we check (i)-(iv) of Definition 34.

- (i) If $u \rightarrow v$ is an edge of $F(G)$, then there is a path $u \rightsquigarrow v$ in G , and hence a path $h(u) \rightsquigarrow h(v)$ in $U(H)$, and (since H is transitive), and edge $h(u) \rightarrow h(v)$.
- (ii) h^\uparrow directly inherits preservation of the distinguished point from h_\downarrow
- (iii) If $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in $F(G)$, then $\min(u \rightsquigarrow v_1) \prec \min(u \rightsquigarrow v_2)$ in G ; hence (since h_\downarrow is a lex-homomorphism) $\min(h(u) \rightsquigarrow h(v_1)) \prec \min(h(u) \rightsquigarrow h(v_2))$ in $U(H)$, hence in H . Since H is a lex-graph, $h(u) \rightarrow h(v_1) \triangleleft h(u) \rightarrow h(v_2)$.
- (iv) If π is the least path $u \rightsquigarrow v$ in $F(G)$, then it's the least path in G (Lemma 47), so $h(\pi)$ is least in $U(H)$ (since h_\downarrow is a lex-homomorphism), and hence in H .

We need only now to check that this correspondence is bijective and natural. Bijectivity follows readily from the fact that we always have $h^\uparrow = h_\downarrow$, so going from $G \xrightarrow{h_\downarrow} U(H)$ to $F(G) \xrightarrow{h^\uparrow} H$ and back has no effect, and similarly in the other direction. Similarly, naturality follows straightforwardly by noting that $U(h)(v) = F(h)(v) = h(v)$ for all h and v , so naturality squares trivially commute. ◀

Proof of Lemma 52. Notice that distances between vertices are never increased in G compared to T , only decreased, meaning that if there is a path $u \rightsquigarrow v$ in G , there is a path $u \rightsquigarrow v$ in T that is no shorter. Therefore, longest paths in G must consist entirely of edges in T , and are therefore unique.

Conversely, if $u \rightarrow v$ is an edge of T , then it appears on the unique path $v_0 \rightsquigarrow v$ in T . As just observed, the longest path $v_0 \rightsquigarrow v$ in G is also a path in T ; hence, it is the unique path $v_0 \rightsquigarrow v$ in T , and thus contains $u \rightarrow v$. ◀

► **Lemma 64.** Γ is a well-defined functor.

Proof. Clearly Γ preserves identities and composition. We must check that for any morphism h of $\mathbf{FinArb}_*^<$, $\Gamma(h)$ satisfies Definition 34 (i)-(iii) and preserves longest paths:

- (i) If $u \rightarrow v$ in $\Gamma(T)$, then $u \rightsquigarrow v$ in T , so $h(u) \rightsquigarrow h(v)$ in T' , so $h(u) \rightarrow h(v)$ in $\Gamma(T')$.
- (ii) Since h maps the distinguished point, and only that point, of T to the distinguished point of T' , Γ does the same from $\Gamma(T)$ to $\Gamma(T')$.

- (iii) If $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in $\Gamma(T)$, then $v_0 \rightsquigarrow v_1 \prec^s v_0 \rightsquigarrow v_2$ in T . By Lemma 35, $h(v_0 \rightsquigarrow v_1) \prec^s h(v_0 \rightsquigarrow v_2)$ in T' , and since paths in arborescences are unique, $h(u) \rightsquigarrow h(v_1) \prec^s h(u) \rightsquigarrow h(v_2)$ in T' . Hence $h(u) \rightarrow h(v_1) \triangleleft h(u) \rightarrow h(v_2)$ in $\Gamma(T')$.
- Finally, if $u \rightsquigarrow v$ is the longest path in $\Gamma(T)$, then it is a path in T by Lemma 52, and therefore, $h(u \rightsquigarrow v) = h(u) \rightsquigarrow h(v)$ is a path in T' . Again by Lemma 52, $h(u \rightsquigarrow v)$ is the longest path in $\Gamma(T')$. ◀

► **Lemma 65.** L is a well-defined functor $\mathbf{TArb} \rightarrow \mathbf{FinArb}_*^{\leq}$.

Proof. In each graph $G \in \mathbf{TArb}$, the unique longest paths are closed under taking prefixes. Therefore, the union of all least longest paths forms an arborescence.

To check that L is a functor, note that for any morphism $h \in \mathbf{TArb}$, $L(h)$ clearly preserves the distinguished point and is monotone on neighborhoods. We only need to show that if $u \rightarrow v$ is an edge in $L(G)$ and $h : G \rightarrow H$ is a morphism in \mathbf{TArb} , then $h(u) \rightarrow h(v)$ is an edge of $L(H)$. But, this is guaranteed by the fact that h preserves longest paths.

Finally, note that L preserves the identity morphism and respects composition. ◀

Proof of Theorem 56. Fix a pointed, connected, edge-ordered arborescence T and a pointed, connected, transitive, edge-ordered graph G .

Given $\Gamma(T) \xrightarrow{h^\uparrow} G$ in \mathbf{TArb} , we define $T \xrightarrow{h_\downarrow} L(G)$ by $h_\downarrow(v) = h^\uparrow(v)$. This is well-defined, because if $u \rightarrow v$ is an edge in T , then by Lemma 52, it appears on the unique longest path $v_0 \rightsquigarrow v$ in $\Gamma(T)$. Since h^\uparrow preserves least longest paths, the edge $u \rightarrow v$ maps into $L(G)$. Moreover, h_\downarrow preserves the distinguished point and inherits monotonicity in neighborhoods from h^\uparrow , so satisfies the conditions of Definition 34 and is a morphism in \mathbf{FinArb}_*^{\leq} .

In the other direction, given $T \xrightarrow{h_\downarrow} L(G)$ in \mathbf{FinArb}_*^{\leq} , we define $\Gamma(T) \xrightarrow{h^\uparrow} G$ by $h^\uparrow(v) = h_\downarrow(v)$; let us unambiguously write $h(v)$ for brevity. If $u \rightarrow v$ is an edge of $\Gamma(T)$, then there is a path $u \rightsquigarrow v$ in T , hence a path $h(u) \rightsquigarrow h(v)$ in $L(G)$, and therefore an edge $h(u) \rightarrow h(v)$ in G . Moreover, if $u \rightarrow v_1 \triangleleft u \rightarrow v_2$ in $\Gamma(T)$, then $v_0 \rightsquigarrow v_1 \prec^s v_0 \rightsquigarrow v_2$ in T , so $h(u) \rightsquigarrow h(v_1) \prec^s h(u) \rightsquigarrow h(v_2)$ in $L(G)$, by Lemma 35. By the remark succeeding Lemma 52, $h(u) \rightarrow h(v_1) \triangleleft h(u) \rightarrow h(v_2)$ in G . Finally, if $u \rightsquigarrow v$ is the longest path from u to v in $\Gamma(T)$, then each of its edges lies in T by Lemma 52, hence its h -image lies in $L(G)$, which means it is a longest path of G . Therefore, h^\uparrow is a morphism of \mathbf{TArb} .

It remains to show that the maps relating h^\uparrow and h_\downarrow are bijective and natural. As in the proof of Theorem 49, this is immediate from the definition of each map; the only thing to show is that they were well-defined. ◀

Proof of Lemma 57. Fix $u, v \neq v_0$. By definition of F , $v_0 \rightarrow u \triangleleft v_0 \rightarrow v$ in T iff $\min(v_0 \rightsquigarrow u) \prec \min(v_0 \rightsquigarrow v)$ in $(I' \circ \Theta)(G)$. Since I' is an inclusion functor, this is equivalent to $\min(v_0 \rightsquigarrow u) \prec \min(v_0 \rightsquigarrow v)$ in $\Theta(G)$; indeed, the *unique* path $v_0 \rightsquigarrow u$ is less than the *unique* path $v_0 \rightsquigarrow v$ in $\Theta(G)$.

But the unique paths $v_0 \rightsquigarrow u$ and $v_0 \rightsquigarrow v$ in $\Theta(G)$ are exactly $\min(v_0 \rightsquigarrow u)$ and $\min(v_0 \rightsquigarrow v)$ in G respectively; moreover, the relative order on the latter two paths in G is inherited from the relative order on the former two in $\Theta(G)$.

Therefore, $v_0 \rightarrow u \triangleleft v_0 \rightarrow v$ in T iff $\min(v_0 \rightsquigarrow u) \prec \min(v_0 \rightsquigarrow v)$ in G , but this is exactly the relation $<_D$ of Definition 28, which is the lexicographic depth-first traversal of G by Theorem 30. ◀

Proof of 58. Fix $u, v \neq v_0$. By definition of Γ , $v_0 \rightarrow u \triangleleft v_0 \rightarrow v$ in T iff $v_0 \rightsquigarrow u \prec^s v_0 \rightsquigarrow v$ in $S(G)$ (where paths from v_0 are unique). By definition of S , this is equivalent to $\min^s(v_0 \rightsquigarrow u) \prec^s \min^s(v_0 \rightsquigarrow v)$ in G . By Corollary 27, this is equivalent to $u <_B v$. ◀

17:20 Graph Traversals as Universal Constructions

Proof of Lemma 59. For a finite, edge-ordered graph G , we define $E(G)$ to be the order $(\{v_0\} \cup N(v_0), <)$, where for $u, v \neq v_0$, $u < v \iff v_0 \rightarrow u \triangleleft v_0 \rightarrow v$, and for $u \neq v_0$, $v_0 < u$.

On morphisms, given a homomorphism of edge-ordered graphs $G \xrightarrow{h} H$, we define $E(G) \xrightarrow{E(h)} E(H)$ by $E(h)(v) = h(v)$. Notice that E is well-defined, since it maps the distinguished point v_0 of G to the distinguished point w_0 of H , and also maps $N_G(v_0)$ into $N_H(w_0)$. By definition, it is clear that E preserves both identities and compositions, so we have only left to show that $E(h)$ is monotone.

Since h maps only v_0 to w_0 , it suffices to show that if $u, v \in N_G(v_0)$ and $v_0 \rightarrow u \triangleleft v_0 \rightarrow v$ in G , then $w_0 \rightarrow h(u) \triangleleft w_0 \rightarrow h(v)$ in H . But this follows from monotonicity of h (Definition 34-(iii)) ◀

Space-Efficient Fault-Tolerant Diameter Oracles

Abstract

We design f -edge fault-tolerant diameter oracles (f -FDO, or simply FDO if $f = 1$). For a given directed or undirected and possibly edge-weighted graph G with n vertices and m edges and a positive integer f , we preprocess the graph and construct a data structure that, when queried with a set F of edges, where $|F| \leq f$, returns the diameter of $G - F$. An f -FDO has stretch $\sigma \geq 1$ if the returned value \hat{D} satisfies $\text{diam}(G - F) \leq \hat{D} \leq \sigma \text{diam}(G - F)$.

For the case of a single edge failure ($f = 1$) in an unweighted directed graph, there exists an approximate FDO by Henzinger et al. [ITCS 2017] with stretch $(1 + \varepsilon)$, constant query time, space $O(m)$, and a combinatorial preprocessing time of $\tilde{O}(mn + n^{1.5} \sqrt{Dm/\varepsilon})$, where D is the diameter.

We present an FDO for directed graphs with the same stretch, query time, and space. It has a preprocessing time of $\tilde{O}(mn + n^2/\varepsilon)$, which is better for constant $\varepsilon > 0$. The preprocessing time nearly matches a conditional lower bound for combinatorial algorithms, also by Henzinger et al. With fast matrix multiplication, we achieve a preprocessing time of $\tilde{O}(n^{2.5794} + n^2/\varepsilon)$. We further prove an information-theoretic lower bound showing that any FDO with stretch better than $3/2$ requires $\Omega(m)$ bits of space. Thus, for constant $0 < \varepsilon < 3/2$, our combinatorial $(1 + \varepsilon)$ -approximate FDO is near-optimal in all parameters.

In the case of multiple edge failures ($f > 1$) in undirected graphs with non-negative edge weights, we give an f -FDO with stretch $(f + 2)$, query time $O(f^2 \log^2 n)$, $\tilde{O}(fn)$ space, and preprocessing time $\tilde{O}(fm)$. We complement this with a lower bound excluding any finite stretch in $o(fn)$ space.

Many real-world networks have polylogarithmic diameter. We show that for those graphs and up to $f = o(\log n / \log \log n)$ failures one can swap approximation for query time and space. We present an exact combinatorial f -FDO with preprocessing time $mn^{1+o(1)}$, query time $n^{o(1)}$, and space $n^{2+o(1)}$. When using fast matrix multiplication instead, the preprocessing time can be improved to $n^{\omega+o(1)}$, where $\omega < 2.373$ is the matrix multiplication exponent.

1 Introduction

The diameter is one of the most fundamental graph parameters. It plays a particular significant role in the analysis of communication networks as the time to transmit a message to all nodes is strongly related with the diameter. Several lines of work have recently attacked the problem of computing the diameter in different settings. For example, Choudhary and Gold [16] constructed diameter spanners, which are subgraphs that approximately preserve the diameter of the original graph, Ancona et al. [6] developed algorithms for computing the diameter in dynamic scenarios and proved matching conditional lower bounds, and Bonnet [10] proved that, for any constant $\varepsilon > 0$, computing a $(7/4 - \varepsilon)$ -approximation of the diameter of a sparse graph n vertices and $m = n^{1+o(1)}$ edges requires $m^{4/3-o(1)}$ time, unless the Strong Exponential Time Hypothesis fails.

In this paper, we approach the diameter from the perspective of fault tolerance. A communication network may be subject to a small number of transient failures, and we want to quickly find out the new diameter without recomputing it from scratch. Therefore, we study the problem of constructing space-efficient data structures that can quickly report the diameter even if up to f edges fail in the graph. We refer to them as *f-edge fault-tolerant diameter oracles* (f -FDO, or simply FDO if $f = 1$). More precisely, given an undirected or directed and possibly edge-weighted graph G and a positive integer f , we want to construct an f -FDO that, when queried on a set F of up to f edges of G , returns a value \widehat{D} that is always at least as large the diameter of $G - F$, denoted by $\text{diam}(G - F)$. We say that an f -FDO has a *stretch* of $\sigma \geq 1$ (or that it is σ -approximate) if the value \widehat{D} returned by the oracle additionally satisfies $\text{diam}(G - F) \leq \widehat{D} \leq \sigma \text{diam}(G - F)$.

When designing f -FDOs one must find a good compromise between the following parameters: the stretch, the time needed to query the oracle, the size of the data structure, and the preprocessing time needed to build it. We focus particularly on space-optimal solutions, while keeping the query and preprocessing times low. For the case of a single edge failure in undirected edge-weighted graphs, there are two folklore FDOs known. One reports the exact diameter and has size $O(m)$, while the other takes $O(n)$ space, but guarantees only a stretch of 2. (more details are given in Section 2.1.) In a sense they mark the extreme points of a spectrum. It is natural to ask whether there are more trade-offs possible between the stretch and size of an FDO. More precisely, we pose the following question.

Question 1 – space vs. approximation trade-off. What is the minimum achievable size of an FDO for a given stretch σ ? To answer the question, we prove an information-theoretic lower bound. It shows that for undirected unweighted graphs and every (even non-constant) $1 \leq \sigma < 3/2$, every σ -approximate diameter oracle requires $\Omega(m)$ bits of space. The space lower bound also holds for the harder case of directed graphs. The size of the exact folklore FDO is thus optimal up to the size of a machine word. Moreover, we prove that the stretch 2 of the approximate FDO cannot be improved on weighted graphs while keeping $O(n)$ space.

► **Theorem 1.** *Any FDO with stretch $\sigma = \sigma(m) < 3/2$ must take $\Omega(m)$ bits of space on undirected graphs with m edges. The bound increases to $\sigma < 2$ if the graphs are edge-weighted.*

When we focus our attention on the preprocessing time, the exact FDO can be constructed in $\widetilde{O}(n^3)$ time¹ using the distance sensitivity oracle (DSO) of Bernstein and Karger [8]. Henzinger et al. [30] proved an essentially matching conditional lower bound for combinatorial²

¹ For a positive function $g(n, m, f)$, we use $\widetilde{O}(g)$ to denote $O(g \cdot \text{polylog}(n))$.

² The term “combinatorial algorithm” is not well-defined, and is often interpreted as not using any matrix multiplication. Arguably, combinatorial algorithms can be considered efficient in practice as the constants hidden in the matrix multiplication bounds are rather high.

algorithms. They assumed that any combinatorial algorithm requires $n^{3-o(1)}$ time to multiply two Boolean $n \times n$ matrices, known as the BMM conjecture. The restriction to combinatorial algorithms is crucial as the task is reducible to integer matrices and one can use fast matrix multiplication to solve it in $O(n^\omega)$ time, where $\omega < 2.37286$ is the matrix multiplication exponent [2]. Under the BMM conjecture, Henzinger et al. [30] showed that, for $0 < \varepsilon < 1/3$, any combinatorial preprocessing algorithm requires $n^{3-o(1)}$ time to build an FDO of stretch $(1 + \varepsilon)$, even if we allow $O(n^{2-\delta})$ query time for any constant $\delta > 0$.

They match this bound with an FDO with stretch $(1 + \varepsilon)$ and $O(1)$ query time that can be constructed in time $\tilde{O}(mn + n^{1.5} \sqrt{\text{diam}(G)} \cdot m/\varepsilon)$. Their oracle also reports the radius and vertex eccentricities in the presence of a single edge failure. Even on sparse graphs with $m = \tilde{O}(n)$ edges and constant diameter, the preprocessing time is $\tilde{O}(n^{2.5}/\sqrt{\varepsilon})$. For constant $\varepsilon > 0$, this is by a factor \sqrt{n} larger than the $\tilde{O}(mn)$ time needed to build the DSO of Bernstein and Karger [8]. It is interesting whether one can close the gap.

Question 2 – fast preprocessing time. Does there exist a combinatorial algorithm that constructs in $\tilde{O}(mn)$ time an FDO with stretch $(1 + \varepsilon)$ and constant query time? In addition, can one bypass the combinatorial lower bound by using fast matrix multiplication? We answer these questions affirmatively for the diameter case with the following theorem. The proof of the algebraic part uses the DSO presented very recently by Gu and Ren [28].

► **Theorem 2.** *For every unweighted directed graph and $\varepsilon > 0$, there exists a randomized combinatorial $(1 + \varepsilon)$ -approximate FDO that takes $O(m)$ space and has $\tilde{O}(mn + n^2/\varepsilon)$ preprocessing time and $O(1)$ query time. The returned values are correct w.h.p.³ Using fast matrix multiplication instead, one can construct the FDO in time $\tilde{O}(n^{2.5794} + n^2/\varepsilon)$.*

Note that, for any constant $0 < \varepsilon < 1/3$, our combinatorial $(1 + \varepsilon)$ -approximate combinatorial FDO from Theorem 2 is near-optimal with respect to all parameters. The $\Theta(m)$ space is near-optimal by Theorem 1, the query time is $\tilde{O}(1)$, and the $\tilde{O}(mn)$ preprocessing time comes within sub-polynomial factors of the conditional lower bound by Henzinger et al. [30]. Furthermore, when fast matrix multiplication is permitted, our algebraic preprocessing algorithm is even faster on dense graphs. However, our FDO is randomized.

Question 3 – derandomization. Can the construction of Theorem 2 be derandomized in the same asymptotic running time? We answer this question partially in that we derandomize the approximation part of our algorithm. When combined with the DSO of Bernstein and Karger [8] this gives a deterministic combinatorial FDO. For the derandomization, we adapt the framework of Alon, Chechik, and Cohen [3]. We identify a set of $O(n^{3/2})$ critical paths one needs to hit, and show how to compute them in $O(mn)$ time. It is then enough to let the folklore greedy algorithm compute a hitting set in $\tilde{O}(n^2)$ time.

It remains an open problem whether one can derandomize the algebraic approach, whose randomization stems solely from the DSO by Gu and Ren [28].

► **Theorem 3.** *For every unweighted directed graph and $\varepsilon > 0$, there exists a deterministic combinatorial $(1 + \varepsilon)$ -approximate FDO that takes $O(m)$ space and has $\tilde{O}(mn + n^2/\varepsilon)$ preprocessing time and $O(1)$ query time.*

³ An event occurs *with high probability* (w.h.p.) if it has probability at least $1 - n^{-c}$ for some $c > 0$.

Question 4 – space vs. approximation trade-off for multiple failures. Finally, we consider the case of multiple edge failures and examine similar questions. What is the minimum size for an exact, respectively, approximate, diameter oracle in the presence of up to f edge failures? We again prove an information-theoretic lower bound and show that for arbitrary finite stretch σ , any σ -approximation diameter oracle requires $\Omega(fn)$ bits of space, at least if the oracle can be queried also with sets F that contain non-edges.

► **Theorem 4.** *Suppose $f < n$. Any f -FDO with finite stretch that can be queried also for non-edges must take $\Omega(fn)$ bits of space on graphs with n vertices.*

We develop an efficient f -FDO whose space requirement almost matches the lower bound. Our result adapts and improves a construction by Bilò et al. [9]. Note that we use the \tilde{O} -notation to suppress polylogarithmic factors in n .

► **Theorem 5.** *For every undirected graph with non-negative edge weights, there exists a deterministic combinatorial $(f + 2)$ -approximate f -FDO that takes $\tilde{O}(fn)$ space and has $\tilde{O}(fm)$ preprocessing time and $\tilde{O}(f^2)$ query time.*

Real-world networks are often described as having a small diameter, dubbed as the “small world property” [35]. Many graph models used to analyze social and communication networks have provable polylogarithmic guarantees on the diameter, e.g. Chung-Lu graphs [17], hyperbolic random graphs [24], or the preferential attachment model [31]. We show that on graphs with low diameter one can swap approximation for query time even for multiple failures, while still retaining efficient preprocessing time and a low space requirement. To achieve this, we combine fault-tolerant trees that were introduced by Chechik et al. [13] with the random graphs of Weimann and Yuster [43].

► **Theorem 6.** *Let f be a positive integer and $\delta = \delta(n, m) > 0$ a real number. For every undirected unweighted graph with diameter at most $n^{\delta/f}/(f+1)$, there exists a randomized combinatorial f -FDO that takes $O(n^{2+\delta})$ space, has $O(2^f)$ query time, and with high probability $\tilde{O}(fmn^{1+\delta} + fn^{2+(2-1/f)\delta})$ preprocessing time. Using fast matrix multiplication instead, one can construct the FDO w.h.p. in time $\tilde{O}(fn^{\omega+\delta} + fn^{2+(2-1/f)\delta})$.*

If the diameter is in fact polylogarithmic and the number of failures is bounded by $f = o(\log n / \log \log n)$, we obtain the following corollary.

► **Corollary 7.** *Let $f = o(\log n / \log \log n)$. For every undirected graph with polylogarithmic diameter, there is an f -FDO that takes $n^{2+o(1)}$ space and has $n^{o(1)}$ query time. It can be preprocessed in time $mn^{1+o(1)}$, or algebraically in time $n^{\omega+o(1)}$. If f is constant, the preprocessing times are $\tilde{O}(mn)$, resp. $\tilde{O}(n^\omega)$, with $\tilde{O}(n^2)$ space and $\tilde{O}(1)$ query time.*

1.1 Related Work

We briefly review previous work on distance sensitivity oracles and diameter computation.

Distance sensitivity oracles. Distance oracles for all-pairs distances were introduced in a seminal paper by Thorup and Zwick [42]. Demetrescu et al. [19] extended the notion of distance oracles to the fault-tolerant setting in which either an edge or a vertex of a graph can fail (i.e., distance sensitivity oracles or DSOs). They showed that it is possible to preprocess a directed weighted graph in $\tilde{O}(mn^2)$ time to compute a data-structure of size $O(n^2 \log n)$ capable of answering distance queries in constant time. Bernstein and Karger [8] improved the preprocessing time to $\tilde{O}(mn)$ and Duan and Zhang [23] reduced the space to $O(n^2)$, which is asymptotically optimal.

Duan and Pettie [22] considered the more involved case of two failures and presented an oracle with $O(n^2 \log^3 n)$ size, $O(\log n)$ query time and polynomial construction time. Chechik et al. [13] presented a DSO of size $O(n^{2+o(1)})$ that supports up to $o(\log n / \log \log n)$ edge failures and guarantees a stretch of $(1 + \epsilon)$, for every constant $\epsilon > 0$. The approach has been recently extended to also handle vertex failures by Duan, Gu, and Ren [21].

The construction of DSOs have also been considered in the approximate regime [13]. Algebraic algorithms are known to improve the preprocessing times, if one is willing to employ fast matrix multiplication (for e.g., see [28, 12] and the references therein).

Diameter computation. The fastest known combinatorial algorithms (up to polylogarithmic factor) for both solving the all-pairs shortest paths (APSP) problem and the diameter problem, are the trivial ones with $\tilde{O}(mn)$ running time. There is extensive research on developing faster approximate APSP algorithms [7, 18, 33], as well as faster approximation algorithms for the diameter [14, 40]. For special classes of graphs, for example planar graphs, efficient exact algorithms for computing the diameter are known [25].

2 Preliminaries

We let $G = (V, E)$ denote the (possibly directed) base graph on n vertices and m edges. We tacitly assume that G is (strongly) connected, i.e., $m = \Omega(n)$. For a graph H , we denote by $V(H)$ the set of its vertices, and by $E(H)$ its edges. The (*closed*) *neighborhood* of a vertex $v \in V(H)$ is the set $N[v] = \{u \in V(H) \mid \{v, u\} \in E(H)\} \cup \{v\}$. Let P be a path in H , its *length* $|P|$ is the number of its edges. For any two vertices $x, y \in V(P)$, $P[x..y]$ is the subpath of P from x to y . For $s, t \in V(H)$, the *distance* $d_H(s, t)$ is the minimum length of an s - t -paths in H ; if s and t are disconnected, we set $d_H(s, t) = +\infty$. We drop the subscript when talking about the base graph G . The *eccentricity* of s is $\text{ecc}(s, H) = \max_{t \in V(H)} d_H(s, t)$ and the *diameter* is $\text{diam}(H) = \max_{s \in V(H)} \text{ecc}(s, H)$. Any graph distance can be stored in a single machine word on $O(\log n)$ bits. Unless explicitly stated otherwise, we measure the space complexity in the number of words. For a collection $F \subseteq \binom{V(H)}{2}$ of 2-sets of vertices (edges or non-edges), let $H - F$ be the graph obtained from H by removing all edges in F (graph H is not altered if $F \cap E(H) = \emptyset$). A *replacement path* $P_H(s, t, F)$ is a shortest path from s to t in $H - F$. Its length $d_H(s, t, F) = |P_H(s, t, F)|$ is the *replacement distance*. The *fault-tolerant diameter* of H with respect to F is the diameter of $H - F$.

For a positive integer f , an f -*fault-tolerant diameter oracle* (f -FDO) for the graph G is a data structure that reports, upon query F with $|F| \leq f$, the value $\text{diam}(G - F)$. For any $\sigma = \sigma(n, m, f) \geq 1$, such an oracle is σ -*approximate*, or has *stretch* σ , if it answers a query F with a value \hat{D} such that $\text{diam}(G - F) \leq \hat{D} \leq \sigma \cdot \text{diam}(G - F)$. In case of a single failure, we write FDO for 1-FDO and abbreviate $F = \{e\}$ to e . An f -*distance sensitivity oracle* (f -DSO) reports, upon query (s, t, F) with $|F| \leq f$, the replacement distance $d(s, t, F)$.

2.1 (Mostly) Known FDOs for Single Edge Failures

The first folklore FDO handles single edge failures in unweighted (directed or undirected) graphs. It has also been observed in [30]. The DSO of Bernstein and Karger [8] constructible in $\tilde{O}(mn)$ time and is able to report in constant time the exact distance of any pair of vertices in the presence of a single edge failure. With this one can construct the FDO by explicitly computing all the eccentricities $\text{ecc}(v, G - e)$, for every vertex v and every edge e of G , in $O(n^3)$ time. For a fixed vertex v , the m values $\text{ecc}(v, G - e)$ can be obtained in $O(n^2)$ time as follows. First compute a shortest paths tree T_v of G rooted at v . For each edge e that

is not in T_v , we have that $\text{ecc}(v, G - e) = \text{ecc}(v, G)$. For the tree-edges e in T_v , we use the DSO to compute $\text{ecc}(v, G - e)$ which is the maximum distance from v to any other vertex in $G - e$. Therefore, $\text{ecc}(v, G - e)$ can be computed by performing $n - 1$ queries, as there are $n - 1$ edges in T_v , we need $O(n^2)$ time. The fault-tolerant diameter $\text{diam}(G - e)$ is the maximum of the $\text{ecc}(v, G - e)$, it can be stored in $O(m)$ space with one entry for each edge e .

The second folklore FDO can only be used for undirected edge-weighted graphs. The FDO has stretch 2 and uses the fact that the diameter of the graph is intimately related to the eccentricity of *any* vertex. For an arbitrary v , we have that $\text{ecc}(v, G) \leq \text{diam}(G) \leq 2 \text{ecc}(v, G)$ as, by the triangle inequality, we can bound the distance between any two vertices $u, u' \in V$ by $d_G(u, u') \leq d_G(u, v) + d_G(v, u') \leq 2 \text{ecc}(v, G)$. The FDO again computes a shortest paths tree T rooted at a fixed source v and stores an array of length $n - 1$, corresponding to the edges of T . For every such edge e , one computes and stores $2 \text{ecc}(s, G - e)$. When queried with edge e , the FDO returns the stored value or, if e is not in the tree, the value $2 \text{ecc}(s, G)$. The size of this FDO is $O(n)$.

A maybe lesser-known way of building FDOs is via spanners. For any $\sigma > 0$, we say that a subgraph H of G is a *spanner* of stretch σ if, for every two vertices s, t of G , we have $d_H(s, t) \leq \sigma d_G(s, t)$. For every positive integer k , it is known how to construct a spanner H of G such that (a) H has a stretch of $2k - 1$ and (b) the size of H is $O(n^{1+1/k})$ [5]. Observe that for every edge $e = \{u, v\}$ that is in G but not in H , we have $d(u, v, e) \leq 2k - 1$. We now describe how spanners can be used to construct another easy oracle for undirected unweighted graphs whose stretch guarantee depends on both k and the inverse of $\text{diam}(G)$. This implies that the oracle already performs quite well for large-diameter graphs.

We construct such a spanner oracle with parameter k by first computing a spanner that satisfies (a) and (b). Then, we associate the value $\text{diam}(G - e)$ to each edge e in the spanner H and build a dictionary in which we store information about the edges of the spanner together with the corresponding associated values. Consider a query of edge e . If $e \in E(H)$ then we return the value associated with e ; otherwise, we return $\text{diam}(G) + 2(k - 1)$. The proof of the next lemma is deferred to the full version.

► **Lemma 8.** *For every positive integer k , the spanner oracle with parameter k has $O(n^{1+1/k})$ size, a constant query time, and a stretch of $1 + 2(k - 1)/\text{diam}(G)$.*

The result of Lemma 8 already implies the existence of sparse FDOs of $o(m)$ size and of stretch $\sigma < 3/2$ for sufficiently dense graphs with diameter strictly larger than 4. This does not contradict the lower bound of Theorem 1, but allows us to conclude that strong lower bounds on the size of FDOs for unweighted undirected graphs can only hold when the diameter of the input graph is bounded by a small constant.

3 Single Edge Failures

First, we treat single edge failures, $f = 1$. In this section, we assume the base graph G to be directed and present an $(1 + \varepsilon)$ -approximate fault-tolerant diameter oracle with space $O(m)$ and $O(1)$ query time. We give two variants, one is deterministic and combinatorial, the other randomized and algebraic. We then show that the space requirement is optimal up to the size of the machine word.

3.1 An $(1 + \varepsilon)$ -approximate FDO for Single Failures

We construct here the approximate FDO, thereby proving Theorem 2. Suppose we know for each $s, t \in V$ some shortest path $P(s, t)$ in G and additionally have access to a distance sensitivity oracle that, for any edge e , reports in constant time the replacement distances

$d(s, t, e)$ whenever needed. Clearly, $d(s, t, e)$ differs from the original graph distance only if e is on $P(s, t)$. To determine the diameters of *all* the graphs $G - e$, it is thus enough to query the DSO only for the edges on the shortest paths, which can be done in time $O(n^2 \cdot \text{diam}(G))$. We use approximation to avoid the cubic running time in case of a large diameter. For this, we randomly sample a small set B of so-called *pivots* and prove that it is enough to compute the replacement distances only between pairs from $B \times V$, instead of all pairs of vertices. Subsequently, we derandomize the pivot selection.

We fill in the details starting with the APSP computation in G and the preprocessing of the DSO. The combinatorial version uses a breath-first search from every vertex and the DSO of Bernstein and Karger [8], taking total time $\tilde{O}(mn)$. Alternatively, compute APSP algebraically and use the randomized DSO by Gu and Ren [28].⁴ APSP is computable in time $O(n^{2.575})$ on unweighted directed graphs with a variant of Zwick's algorithm [44, Corollary 4.5], this is in turn dominated by the $O(n^{2.5794})$ preprocessing time of the DSO [28]. After these computation, the distances $d(s, t)$, shortest paths $P(s, t)$ in G , and the replacement distances $d(s, t, e)$ are available to us (w.h.p., in the randomized case) with a constant query time per distance/path edge.

From here on out, the process for both variants is the same. Our fault-tolerant diameter oracle also allows non-edges to be queried, for which we return the original diameter $\text{diam}(G)$. To account for this, we store all edges in a static dictionary of size $O(m)$ that allows for worst-case constant look-up times after an $\tilde{O}(m)$ preprocessing [4, 29].⁵

Now fix a parameter $\varepsilon > 0$ for the approximation, possibly even depending on m, n . We initialize an array D indexed by the edges of G , all its cells hold the value $\text{diam}(G)$. Assume first that $\varepsilon \cdot \text{diam}(G) = O(\log n)$. For any two vertices s, t and edge e on the shortest path $P(s, t)$, we update $D[e]$ to the maximum of the previous value and $d(s, t, e)$. This takes $O(n^2 \text{diam}(G)) = \tilde{O}(n^2/\varepsilon)$ time. After all updates, the entry $D[e]$ stores the *exact* fault-tolerant diameter $\text{diam}(G - e)$ (possibly w.h.p.). For $\varepsilon \cdot \text{diam}(G) = \omega(\log n)$, we first give a randomized $(1+\varepsilon)$ -approximation and later derandomize it in Section 3.2. This yields the deterministic combinatorial algorithm of Theorem 3. The remaining use of randomness in the algebraic variant is due to the DSO by Gu and Ren [28].

To guard for the case that the failure of e disconnects the graph, we compute all *strong bridges* of G , that is, edges whose removal increases the number of strongly connected components, in time $O(m)$ with the algorithm by Italiano, Laura, and Santaroni [32]. For each strong bridge e , we set $D[e] = \infty$. To compute the other entries, we construct the set $B \subseteq V$ of pivots by randomly sampling every vertex independently with probability $C(\log n)/(\varepsilon \text{diam}(G))$ for a sufficiently large constant $C > 0$. A simple calculation using Chernoff bounds shows that $|B| = \tilde{O}(n/(\varepsilon \text{diam}(G)))$ w.h.p. Moreover, with high probability for all $s, t \in V$ and $e \in E$ such that $\varepsilon \text{diam}(G) < d(s, t, e) < \infty$, there exists a replacement path from s to t that avoids e and additionally contains a pivot from B . See [27, 41] for details. We update the entries of D in the same fashion as above, but now only use the (directed) distance $d(x, t, e)$ for all pivots $x \in B$ and vertices $t \in V$. In the end, we add $\varepsilon \text{diam}(G)$ to the value in $D[e]$. The array D is computable in time $O(m + n|B| \text{diam}(G)) = \tilde{O}(n^2/\varepsilon)$.

⁴ The DSO by Gu and Ren [28] is not path-reporting; if it were, we would not have to compute APSP. The fastest path-reporting algebraic DSO was given by Ren [38, 39] and can be constructed in time $O(n^{2.7233})$ on directed graphs, respectively in time $O(n^{2.6865})$ on undirected graphs.

⁵ The weak non-uniformity mentioned in [29], i.e., the need of compile-time constants depending on the word size, only holds if this size is $\omega(\log n)$, which is not the case for us.

We verify that $D[e]$ is an $(1+\varepsilon)$ -approximation of the fault-tolerant diameter $\text{diam}(G - e)$.

► **Lemma 9.** *We have $\text{diam}(G - e) \leq D[e] \leq (1+\varepsilon) \text{diam}(G - e)$ w.h.p.*

Proof. We can assume that $G - e$ is strongly connected as otherwise $D[e] = \infty = \text{diam}(G - e)$. The upper bound follows from $D[e] = \max_{x \in B, t \in V} d(x, t, e) + \varepsilon \text{diam}(G) \leq (1+\varepsilon) \text{diam}(G - e)$.

The main part consists of showing the lower bound $D[e] \geq \text{diam}(G - e)$. The idea is to prove the existence of a pivot $x \in B$ and vertex $t \in V$ whose replacement distance underestimates the fault-tolerant diameter by at most an additive term $\varepsilon \text{diam}(G)$, which we offset when computing $D[e]$. If $\text{diam}(G - e) \leq \varepsilon \text{diam}(G)$ (which can only happen for $\varepsilon \geq 1$), the lower bound holds vacuously as we have $D[e] \geq \varepsilon \text{diam}(G)$.

Let thus vertices $s, t \in V$ be such that $d(s, t, e) = \text{diam}(G - e) > \varepsilon \text{diam}(G)$. Since $G - e$ is strongly connected the diameter is finite and realized by some replacement path $P(s, t, e)$. In particular, we have $|P(s, t, e)| > \varepsilon \text{diam}(G)$. Let y be the unique vertex on $P(s, t, e)$ with $d(s, y, e) = \varepsilon \text{diam}(G)$. Recall that w.h.p. the set B hits *some* shortest path P' from s to y that avoids e . The path P' is not necessarily equal to the subpath $P(s, t, e)[s..y]$, but they have the same length $d(s, y, e)$. Substituting P' for $P(s, t, e)[s..y]$ therefore guarantees a replacement path from s to t that (w.h.p.) has a pivot $x \in B$ on its prefix of length $\varepsilon \text{diam}(G)$. For notational convenience, we use $P(s, t, e)$ to also denote this particular path.

The replacement distance from pivot x to target t satisfies $d(x, t, e) = |P(s, t, e)[x..t]| = |P(s, t, e)| - |P(s, t, e)[s..x]| \geq d(s, t, e) - \varepsilon \text{diam}(G)$. The entry $D[e]$ is also updated using the pivot x , whence $D[e] \geq d(x, t, e) + \varepsilon \text{diam}(G) \geq d(s, t, e) = \text{diam}(G - e)$. ◀

3.2 Derandomization

For the randomized combinatorial FDO, we had a preprocessing time of $\tilde{O}(mn + n^2/\varepsilon)$. The underlying APSP computation and the DSO are deterministic. We now derandomize the approximation part in the same asymptotic running time, proving Theorem 3. In Lemma 9, we used that the set B intersects at least one long replacement path from s to t exactly. We argue that it is in fact enough to hit the set of all vertices with distance at most $\varepsilon \text{diam}(G)$ from s in each strongly connected $G - e$. The pivot x does not need to be on any replacement path. The only assertion of Lemma 9 that is possibly in doubt is the lower bound $D[e] \geq \text{diam}(G - e)$. Let again s and t be such that $d(s, t, e) = \text{diam}(G - e)$ and let $x \in B$ be a pivot with $d(s, x, e) = d_{G - e}(s, x) \leq \varepsilon \text{diam}(G)$. Whenever $G - e$ is strongly connected, a replacement path $P(x, t, e)$ exists and, by the triangle inequality, we have $d(x, t, e) \geq d(s, t, e) - d(s, x, e) \geq d(s, t, e) - \varepsilon \text{diam}(G)$. The claim follows.

For the derandomization, we adopt the framework of Alon, Chechik and Cohen [3]. This involves efficiently finding a small set of critical paths such that hitting them ensures to hit each $(\varepsilon \text{diam}(G))$ -ball in the strongly connected $G - e$. If the critical paths are both short enough and few in numbers, it is then enough to compute the hitting set via the folklore greedy algorithm. In [3], it was sufficient to give a single set of critical paths. We generalize this to multiple sets, where the later-defined sets depend on the paths in the former.

Set $\ell = \min\{\varepsilon \text{diam}(G), \sqrt{n}\}$ and let r be an arbitrary vertex in G . We compute the in-tree $T_{\text{in}}(r)$, containing the shortest paths in G leading to r , with breath-first search. In the set \mathcal{P} , we collect, for each vertex s with $d(s, r) > \ell$, the path of $T_{\text{in}}(r)$ starting in s and having length ℓ . Let $P \in \mathcal{P}$ be a path with start vertex s and let $e \in E(P)$ be such that it is not a strong bridge. We compute the in-tree $T_{\text{in},e}(r)$ in $G - e$ rooted in r . Note that s has distance $d(s, r, e) \geq d(s, r) > \ell$ from the root in the tree. We add the corresponding path to the set \mathcal{P}_e . The original in-tree $T_{\text{in}}(r)$ contains only $n - 1$ edges, so all

trees can be computed in total time⁶ $O(mn)$. Moreover, there are at most $\ell + 1$ paths with starting vertex s . In total, we thus have $O(n\ell)$ paths each of length ℓ . A greedy algorithm computes a hitting set B for all paths in the \mathcal{P} and \mathcal{P}_e . It iteratively selects the vertex that is contained in the most yet unhit paths, it terminates in time $\tilde{O}(n\ell^2) = \tilde{O}(n^2)$ and produces a set of $|B| = \tilde{O}(n/\ell) = \tilde{O}(n/(\varepsilon \text{diam}(G)))$ pivots, see [3, 34]. We used the definition $\ell = \min\{\varepsilon \text{diam}(G), \sqrt{n}\}$ for both estimates. Finally, we add the root r to the set B to cover all paths in the trees that are shorter than ℓ .

► **Lemma 10.** *For each vertex $s \in V$ and edge e such that $G - e$ is strongly connected, there exists a pivot $x \in B$ with $d(s, x, e) \leq \varepsilon \text{diam}(G)$.*

Proof. If $d(s, r) \leq \varepsilon \text{diam}(G)$, we are done. Otherwise, let P be the prefix of length ℓ of the path from s to r in the tree $T_{\text{in}}(r)$, whence $P \in \mathcal{P}$. If P does not contain the edge e , it also exists in $G - e$ and the corresponding pivot $x \in B \cap V(P)$ satisfies $d(s, x, e) = d(s, x) \leq \ell \leq \varepsilon \text{diam}(G)$. If P contains e , then let instead $P' \in \mathcal{P}_e$ be the length- ℓ prefix of the path from s to r in $T_{\text{in},e}(r)$. Again, $x \in B \cap V(P')$ implies $d(s, x, e) \leq \varepsilon \text{diam}(G)$. ◀

3.3 Space Lower Bounds

Finally, we prove Theorem 1 thus showing that the space requirement of the FDOs in Theorems 2 and 3 is near-optimal provided that the stretch is $\sigma = \sigma(m, n) < 3/2$, that is, $\varepsilon < 1/2$. This even holds for the simpler task of computing the diameter in undirected graphs. For better exposition, we first show that any diameter oracle with such a stretch requires $\Omega(n^2)$ space on at least one n -vertex graph, which is, however, only tight for dense graphs. We then sparsify the construction to for an $\Omega(m)$ bound for graphs with m edges. Any σ -approximate FDO solves the promise problem of distinguishing, for each edge e , whether $G - e$ has diameter 2 or 3.

► **Lemma 11.** *There is a graph G on n vertices such that $G - e$ has diameter 2 or 3 for any $e \in E$. Any data structure that decides which one is the case must take $\Omega(n^2)$ bits of space.*

Proof. We give an incompressibility argument by encoding any binary $(n/4) \times (n/4)$ matrix X in the fault-tolerant diameters of G . No data structure can store this in $o(n^2)$ bits. The construction is illustrated in Figure 1a.

Without losing generality, n is divisible by 4, we can add up to three dummy vertices if needed. Split the vertex set equally into four groups A, B, C, D and let $a_1, \dots, a_{n/4}$ be an arbitrary numbering of the elements of A , same with the other groups. All groups are made into cliques and, for all $i \in [n/4]$, we make a_i, b_i , and c_i into a triangle. This results in matchings for the pairs (A, B) , (B, C) , and (A, C) , respectively. We further add edges so as to make (B, D) into a biclique. To encode the matrix X , we introduce the edge $\{c_i, d_j\}$ if and only if $X_{i,j} = 1$.

The graph G indeed has diameter 2 (even if X is the all-zeros matrix). Vertices a_i and b_j are joined by the path (a_i, a_j, b_j) —which by symmetry also holds for the other pairs of groups among A, B , or C —and the vertices a_i or c_i are connected to d_j via the paths (a_i, b_i, d_j) or (c_i, b_i, d_j) , respectively. Removing any edge increases the diameter by at most 1 since for any $e = \{u, v\}$ there exists a common neighbor in $w \in N[u] \cap N[v]$. This is clear inside the (bi-)cliques. For the matching edges, say $e = \{a_i, b_i\}$, we have $w = a_j, j \neq i$. Finally, for $e = \{c_i, d_j\}$ (if it exists), we have $w = b_i$.

⁶ For a single source, there are *randomized* algorithms known that compute the trees faster [11, 15, 26].

■ **Figure 1** Illustration of Lemma 11 **(a)** and of Lemma 12 **(b)**. The full ellipses A, B, C, D are cliques on the respective number of vertices, the dashed ellipse R is an independent set. The three parallel lines stand for matchings, the two crossed lines for a biclique. Edges encoding the binary matrix X run between C and D . Every vertex $r \in R$ is connected to $a_1 \in A$, $b_1 \in B$, and $c_1 \in C$.

We now prove that the graph $G - \{b_i, d_j\}$ has diameter 3 if and only if the edge $\{c_i, d_j\}$ is *not* present in G , that is, iff $X_{i,j} = 0$. When arguing the diameter above, edge $\{b_i, d_j\}$ was only needed for the paths (a_i, b_i, d_j) and (c_i, b_i, d_j) . Consider the neighborhoods of the three vertices in $G - \{b_i, d_j\}$, $N[a_i] = A \cup \{c_i, d_i\}$, $N[c_i] = C \cup \{a_i, b_i\} \cup \{d_k \mid X_{i,k} = 1\}$, and $N[d_j] = D \cup (B \setminus \{b_i\}) \cup \{c_k \mid X_{k,j} = 1\}$. If $X_{i,j} = 1$, then the neighborhoods intersect, namely in c_i , keeping the diameter at 2. If, however, $X_{i,j} = 0$, then $N[a_i] \cap N[d_j] = \emptyset$ and the diameter increases to 3. ◀

We now refine the result to give a better bound for sparse graphs. Note that a logarithmic gap remains between Lemma 12 and Theorem 2 since we lower bound the space at $\Omega(m)$ bits while the FDO takes this many words.

► **Lemma 12.** *There is a graph G with m edges such that $G - e$ has diameter 2 or 3 for any edge $e \in E$. A data structure that decides which one is the case must take $\Omega(m)$ bits of space.*

Proof. The main weakness of the construction in Lemma 11 is that it requires $\Omega(n^2)$ edges inside the cliques. As it turns out, this is not necessary and we can sparsify the graph G as long as we keep its diameter at 2. Figure 1b shows the idea of the sparsification.

Let m' be a parameter to be fixed later. We now store a binary $\sqrt{m'} \times \sqrt{m'}$ matrix X . Split the vertices into five groups, where A, B, C, D each contain $\sqrt{m'}$ vertices and R the remaining $n - 4\sqrt{m'}$. The edges among vertices in A through D are the same as in Lemma 11. Each vertex in R has degree 3 and is connected to a_1, b_1 , and c_1 . The graph G has $4\binom{\sqrt{m'}}{2} + 3\sqrt{m'} + m' + |\{(i, j) \mid X_{i,j} = 1\}| + 3(n - 4\sqrt{m'}) = O(m')$ edges. We fix the parameter m' such that the total number of edges is m . If needed, we introduce additional edges among vertices in R without affecting the result.

Note that the eccentricity of any vertex in $r \in R$ is 2 (even if R is not an independent set). Vertex a_i is reached via the path (r, a_1, a_i) , similar for the vertices in B and C , the ones in D are reached via b_1 . Moreover, for any edge involving r , say $\{r, a_1\}$, we have $b_1 \in N[r] \cap N[a_1]$. Therefore, the proof that G has diameter 2, $G - e$ has diameter 2 or 3, and $G - \{b_i, d_j\}$ has diameter 3 iff $X_{i,j} = 0$ is almost exactly as in Lemma 11. The sole difference is the case in which the edge $\{b_1, d_j\}$ fails since this may also increase the eccentricity of r . This is settled by observing that the neighborhood $N[r] = \{r, a_1, b_1, c_1\}$ in $G - \{b_1, d_j\}$ intersects $N[d_j]$ iff $X_{1,j} = 1$. To accommodate all possible matrices X , we require $\Omega(m') = \Omega(m)$ bits. ◀

The same construction shows that for edge-weighted graphs there is no $(2-\varepsilon)$ -approximate FDO, for any $\varepsilon = \varepsilon(m) > 0$, with space $o(m)$. In more detail, we choose an $\varepsilon' > 0$ small enough so that $\varepsilon' < 2\varepsilon/(1-\varepsilon)$ and give weight ε' to all matching edges as well as the edges incident to vertices in R , all other edges are weighted 2. One can verify that $\text{diam}(G) = 2 + \varepsilon'$ and the fault-tolerant diameter $\text{diam}(G - \{b_i, d_j\})$ remains at that value iff $\{c_i, d_j\}$ is present, it raises to $4 + \varepsilon'$ otherwise. The bound on the stretch cannot be improved as shown by the trivial FDO discussed in the introduction, which gives a 2-approximation in $O(n)$ space.

4 Multiple Edge Failures

We now turn to multiple edge failures. Recall that in the fault-tolerant setting the maximum number f of failures is known in advance, and stretch, space, preprocessing, and query time usually depend on f . In this section, we first prove the following lemma. Let $\alpha = \alpha(m, n)$ denote the inverse Ackermann function.

► **Lemma 13** (Theorem 5 with explicit logarithmic factors). *For every undirected graph with non-negative edge weights, there exists a deterministic combinatorial $(f+2)$ -approximate f -FDO that takes $O(fn \log^2 n)$ space and has $O(fm\alpha + fn \log^3 n)$ preprocessing time and $O(f^2 \log^2 n)$ query time. For $f = 1$, the size of the oracle is $O(n)$, the preprocessing time $O(m\alpha + n \log n)$, and the query time is constant.*

Bilò et al. [9] designed an $(2f+1)$ -approximate single-source f -DSO. That means, the oracle processes an undirected graph G with non-negative edge weights and a distinguished source s , and, upon query (t, F) with $|F| \leq f$, it returns $d(s, t, F)$. The oracle can be built in $O(fm\alpha + fn \log^3 n)$ time, has size $O(fn \log^2 n)$, and answers queries in $O(f^2 \log^2 n)$ time. In principle we can modify the oracle so as, when queried with the set F , it returns twice the eccentricity of s in the graph $G - F$. This would clearly allow us to construct an f -FDO of stretch $2 \cdot (2f+1)$. We show that the same oracle construction, but with a better query algorithm, allows us to develop an f -FDO of stretch $f+2$.

We let $w(e)$ denote the weight of the edge $e \in E$. The length of a path is now defined as the sum of its edge weights; the definitions of distance and diameter are adjusted accordingly. The oracle in [9] first computes a shortest path tree T of G rooted at the source s and uses it to re-weight all the edges of G . The new weight function w' assigns weight of 0 to each edge of T and weight $w'(e) = d(s, x) + w(e) + d(y, s)$ to any other edge $e = \{x, y\}$. When queried with (t, F) , the oracle computes a spanning forest T_F of $G - F$ w.r.t. the new weight function w' in $O(f^2 \log^2 n)$ time. Let $k = |F \cap E(T)|$. The oracle replaces the k failing edges in $F \cap E(T)$ with a minimum-weight set of edges in $G - F$ w.r.t. to w' , say E_F , whose addition to $T - F$ forms a spanning forest of $G - F$.⁷ The obtained forest T_F is then used to estimate the distance from s to t in $G - F$. We reuse a nice property proven in [9].

► **Lemma 14** (Bilò et al. [9]). *T_F is a minimum spanning forest of $G - F$ w.r.t. w' .*

Our query algorithm works as follows. Let tree T be rooted at s and $F \cap E(T) = \{f_1, \dots, f_k\}$ with $k \leq f$ the edges in T that are also in F . Let T_0, \dots, T_k denote the $k+1$ subtrees of $T - F$, and r_i the root of the subtree T_i . W.l.o.g., we assume $r_0 = s$. We use

⁷ This is done by computing, for each unordered pair $\phi = (T', T'')$ of connected components of $T - F$, the minimum-weight edge w.r.t. w' , say e_ϕ , that has one endpoint in T' and the other endpoint in T'' . Then, the set E_F is computed in $O(f^2)$ time using any time-efficient algorithm for computing a minimum spanning tree of an auxiliary graph in which each of the connected components of $T - F$ is modelled by a vertex and the edge between the unordered pair $\phi = (T', T'')$ of $T - F$ has a weight equal to $w'(e_\phi)$. The authors of [9] design a data structure that is able to retrieve, for each pair $\phi = (T', T'')$ of connected components of $T - F$, the edge e_ϕ in $O(\log^2 n)$ time.

f_1, \dots, f_k to compute the roots r_1, \dots, r_k in $O(k)$ time. We then build a forest T' on $k+1$ new vertices v_0, \dots, v_k , where v_i represents T_i . The forest T' contains an edge $\{v_i, v_j\}$ iff E_F contains an edge e with one end point in $V(T_i)$ and the other in $V(T_j)$. Obviously, if T' is not connected, then we can simply certify that $\text{diam}(G-F) = \infty$. So, we assume that T' is a tree. We root T' at v_0 and denote by e_i the edge that joins v_i with its parent $p(v_i)$. We compute the value $\Delta = \max_{1 \leq i \leq k} w'(e_i) - d(s, r_i)$ and output $\widehat{D} = f\Delta + 2 \cdot \max_{t \in V} d(s, t)$. The time needed for the query algorithm is dominated by the computation of T in time $O(f^2 \log^2 n)$ as all the new operations can be performed in $O(f^2)$ time. Observe that $\max_{t \in V} d(s, t)$ is independent of F and can be precomputed in time $O(n)$.

For a single failure, $f = 1$, the query time can be reduced to $O(1)$. In fact, for each edge e of T , it is enough to precompute the minimum weight edge of $E(G) \setminus E(T)$, w.r.t. weight function w' , that crosses the cut induced by $T - e$. This, a.k.a. the sensitivity analysis problem of a minimum spanning tree, can be solved in $O(m \log \alpha)$ time on a graph with m edges [37]. We show in the remainder that \widehat{D} is an $(f+2)$ -approximation of $\text{diam}(G-F)$. The proof of the following lemma can be found in the full version.

► **Lemma 15.** *We have that $\text{diam}(G-F) \geq \Delta$.*

We now prove the approximation with the help of Lemma 15.

► **Lemma 16.** *The value \widehat{D} satisfies $\text{diam}(G-F) \leq \widehat{D} \leq (f+2) \text{diam}(G-F)$.*

Proof. Again, we only need to prove anything if T' is connected, which implies that T_F is connected. By Lemma 15, we have that $\text{diam}(G-F) \geq \Delta$. Moreover, $\text{diam}(G-F) \geq \text{diam}(G) \geq \max_{t \in V} d(s, t)$. The value \widehat{D} returned by the query algorithm satisfies $\widehat{D} \leq f\Delta + 2 \max_{t \in V} d(s, t) \leq (f+2) \text{diam}(G-F)$. It remains to show that $\widehat{D} \geq \text{diam}(G-F)$. We prove the latter by verifying that, for any two vertices x and y , $\widehat{D} \geq d(x, y, F)$ holds.

Let r_x and r_y be the roots of the subtrees of $T-F$ that contain x and y , respectively. It is possible that $r_x = r_y$. Let $r_{p(i)}$ denote the root of the tree of $T-F$ that corresponds to the parent vertex $p(v_i)$ in T' . Consider the subgraph of T_F consisting of the edges of the paths in T_F between the following pairs of vertices: (a) $r_{p(i)}$ and r_i for every i , (b) x and r_x , (c) y and r_y . The subgraph contains a path from x to y since T_F is connected. Therefore, the replacement distance $d(x, y, F)$ is upper bounded by the total weight of the subgraph. The path in T_F between r_x and x has length at most $\max_{t \in V} d(s, t)$ as r_x is an ancestor of x in the shortest path tree T rooted at s ; same for r_y and y . Finally, for any $i > 0$, let $e_i = \{x_i, y_i\}$ be the edge in E_F that caused the addition of the edge $(v_i, p(v_i))$ in T' . W.l.o.g., we assume that x_i (resp., y_i) is a vertex of the tree of $T-F$ represented by v_i (resp., $p(v_i)$) in T' . The path from r_i to $r_{p(i)}$ in $G-F$ has length at most $d(r_i, x_i) + w(e_i) + d(y_i, r_{p(i)}) \leq d(r_i, x_i) + w(e_i) + d(y_i, s) + d(s, r_i) - d(s, r_i) = w'(e_i) - d(s, r_i) \leq \Delta$. Therefore, $d(x, y, F) \leq k\Delta + 2 \max_{t \in V} d(s, t) \leq f\Delta + 2 \max_{t \in V} d(s, t) = \widehat{D}$. ◀

4.1 Exact f -FDO for Low Diameter

We show that one can swap approximation for query time in low-diameter graphs, namely, with diameter at most $n^{\delta/f}/(f+1)$ for arbitrary $\delta = \delta(m, n) > 0$. This is summarized in Theorem 6. The case $f=1$ is solved like in Section 3.1 only that there is no need for approximation here as the diameter is small enough to process all pairs of vertices in time $O(n^{2+\delta})$. We thus assume $f \geq 2$. We adapt a space-saving technique introduced by Chechik et al. [13]. In a bird's-eye view, we construct a recursion tree $T(s, t)$ of size $O(n^\delta)$ for each pair of vertices s and t . It contains all *relevant* replacement distances $d(s, t, F)$ for sets F with up to f failures. We then show how we can simulate the search for $\text{diam}(G-F)$ in the $O(n^2)$ trees in total time $O(2^f)$.

Afek et al. [1, Theorem 1] showed that if G is undirected, then any shortest path in $G - F$, with $|F|$, is a concatenation of at most $|F| + 1$ shortest paths in G . The condition on the diameter and $|F| \leq f$ ensure that every path below has length at most $(f+1) \cdot \text{diam}(G) \leq n^{\delta/f}$.

Assume we have access to a path-reporting f -DSO. That means, upon query (s, t, F) , the oracle either certifies that $d(s, t, F) = \infty$, i.e., s and t are disconnected in $G - F$, or reports the replacement distance and a shortest s - t -path in $G - F$. The preprocessing time of the combinatorial version is assumed to be $\tilde{O}(f m n^{1+\delta})$ with a $\tilde{O}(f n^{(1-1/f)\delta} + |P|) = \tilde{O}(f n^{(1-1/f)\delta})$ query time w.h.p. reporting path P . Here, we used the assumption $f \geq 2$, whence $|P| \leq n^{\delta/f} = \tilde{O}(f n^{(1-1/f)\delta})$. Alternatively, we have algebraic preprocessing in time $\tilde{O}(f n^{\omega+\delta})$. We show how to obtain the oracle in the full version, using an idea of Weimann and Yuster [43] with a more refined analysis of the query time.

Fix two vertices s and t . We construct the tree $T(s, t)$ recursively. Each node in the tree is associated with a set $F' \subseteq \binom{V}{2}$ containing $f' = |F'| \leq f$ possible failures. We have $F' = \emptyset$ in the root. Upon creation, the node queries the assumed oracle with (s, t, F') and holds the returned path $P(s, t, F')$, if any. If $f' = f$ or s and t are disconnected in $G - F'$, the node is a leaf. Otherwise, it has $d(s, t, F')$ many children, one for each edge of $e \in E(P(s, t, F'))$ of the path. The respective child is associated with the set $F' \cup \{e\}$.

The tree indeed has at least one node for every distinct replacement distance $d(s, t, F)$ with $|F| \leq f$. To see this, let F', F be two sets with $F' \subseteq F \subseteq \binom{V}{2}$. Clearly, we have $d(s, t, F') \leq d(s, t, F)$, but $d(s, t, F') < d(s, t, F)$ can only hold if $F \setminus F'$ contains an edge of the path $P(s, t, F')$ in the node associated with F' . The fan-out of each node is at most $n^{\delta/f}$, the height of the tree is f . For all $s, t \in V$, the trees thus have $O(n^{2+\delta})$ nodes in total and can be constructed with that many queries to the f -DSO in time $\tilde{O}(f n^{2+(2-1/f)\delta})$.

Consider the following naive algorithm to handle a query to the f -FDO for the fault-tolerant diameter $\text{diam}(G - F)$. Each tree $T(s, t)$ is searched individually starting in the root. The processing of a node depends on the associated set F' . If it is a leaf or the set $F \setminus F'$ is disjoint from the replacement path $P(s, t, F')$, then we return the length $d(s, t, F')$ of the path; otherwise, we recurse on all children associated with $F' \cup \{e\}$ for all edges $e \in (F \setminus F') \cap E(P(s, t, F'))$. By the argument as above, the maximum over all reported distances is indeed $\max_{s, t \in V; F' \subseteq F} d(s, t, F') = \text{diam}(G - F)$. This approach can be improved significantly by aggregating the values $\{d(s, t, F')\}_{s, t \in V}$ already at construction.

Observe that we never query the underlying f -DSO with a set F' that contains non-edges. We prepare a hash table H whose entries are indexed by subsets of E of size at most f . For every query (s, t, F') we compare the returned replacement distance with the value $H[F']$. If no such entry exists, we initialize it with $d(s, t, F')$; else, we update it to $\max\{H[F'], d(s, t, F')\}$. The final table has size $O(n^{2+\delta})$ and we discard the trees. The table H is constructible w.h.p. in time $O(n^{2+\delta})$, guaranteeing constant query time [20, 36]. However, to simulate the naive algorithm for the query F to the f -FDO, we have to check $H[F']$ for all $O(2^f)$ subsets $F' \subseteq F$ as we do not know which ones were used during construction.

4.2 Space Lower Bound

We conclude with the space lower bound of Theorem 4. It rules out any finite stretch in $o(fn)$ space for an arbitrary number f of failures. We use the fact that an f -FDO with finite stretch is able to decide whether the edges in F are a cut-set of the graph.

Assume for now that f is even. Let k be the largest integer such that $fk + 1 \leq n$. We construct a graph G as follows. It has vertices c, v_1, \dots, v_{fk} as well as $n - fk - 1$ auxiliary vertices. Define $E_i = \{\{v_i, v_j\} \mid 1 \leq |i - j| \leq f/2\}$. The edge set of G is $\bigcup_{i=1}^{fk} E_i$ together with all possible edges $\{c, u\}$, including to the auxiliaries. In other words, G consists of a star

centered at c with $n - 1$ leaves, and leaves v_i, v_j are joined by an edge iff their indices have difference at most $f/2$. Let set \mathcal{G} contain all spanning subgraphs of G that retain at least all star edges incident to c . Since $|E_i| = f$, there are $|\mathcal{G}| = 2^{(f-1)f/2} = 2^{\Omega(fn)}$ such subgraphs.

Let H be any subgraph in \mathcal{G} . For $i \neq j$ with $|i - j| \leq f/2$, define the set $F_{i,j} = (E_i \setminus \{v_i, v_j\}) \cup \{c, v_i\}$. Note that $F_{i,j}$ may contain non-edges. We have $|F_{i,j}| = f$ and evidently $\{v_i, v_j\}$ is present in H iff $H - F_{i,j}$ is connected. Any two f -FDOs for graphs in \mathcal{G} thus differ in at least one bit. For odd values $f \geq 3$, we emulate this using $f - 1$ failures.

For the remaining case $f = 1$, we use a different construction. W.l.o.g., n is even, connecting a single excess vertex to some other vertex in the graph is immaterial. The graph G contains two parallel paths P_1 and P_2 , each on $n/2$ vertices, respectively numbered from 1 to $n/2$. The graph also contains a matching M in which the i -th vertex of P_1 is matched with the i -th vertex of P_2 . Let \mathcal{G} be the set of all spanning subgraphs that have at least all the edges of P_1 and M . We have $|\mathcal{G}| = 2^{(n/2)-1} = 2^{\Omega(n)}$. Let $H \in \mathcal{G}$ and define e_i , with $i < n/2$, be the edge of P_1 between the i -th and $(i+1)$ -th vertices. The corresponding edge of P_2 is present in H if and only if $H - e_i$ is connected.

Abstract

We use the algebraic framework for languages of infinite trees introduced in [4] to derive effective characterisations of various temporal logics, in particular the logic EF (a fragment of CTL) and its counting variant cEF.

1 Introduction

Among the many different approaches to language theory, the algebraic one seems to be particularly convenient when studying questions of expressive power. While algebraic language theories for word languages (both finite and infinite) were already fully developed a long time ago, the corresponding picture for languages of trees, in particular infinite ones, is much less complete. Seminal results contributing to such an algebraic framework for languages of infinite trees were provided by the group of Bojańczyk [7, 8] with one article considering languages of *regular* trees only, and one considering languages of *thin* trees. The first complete framework that could deal with arbitrary infinite trees was provided in [2, 3]. Unfortunately, it turned out to be too complicated and technical for applications. Recently, two new general frameworks have been introduced [1, 4] which seem to be more satisfactory: one is based on the notion of a *branch-continuous tree algebra*, while the other uses *regular tree algebras*. The first one seems to be more satisfactory from a theoretical point of view, while the second one is more useful for applications, in particular for characterisation results.

In this article we concentrate on the approach based on regular tree algebras from [4] which seems to be emerging as the standard. The goal is to apply the framework to a few test cases and to see how well it performs for its intended purpose. While the definition of a regular tree algebra (given in Section 2 below) is a bit naïve and seems circular at first sight, it turns out that it is sufficient to guarantee the properties we need for applications: one can show that (i) the class of regular tree algebras forms a pseudo-variety and that (ii) every regular tree language has a syntactic algebra, which is in fact a regular tree algebra. By general category-theoretic results, such as those from [6] or [5], this implies that there exists a Reiterman type theorem for such algebras, i.e., the existence of equational characterisations for sub-pseudo-varieties. This is precisely what is needed for a characterisation theorem.

Unfortunately progress on an algebraic theory of infinite trees has been rather slow since matters have turned out to be significantly more complicated than the case of words or finite trees. Hence, every step of progress is very welcome. For instance, the recent paper [11] characterises the languages of infinite trees that are recognised by algebras of bounded growth. The applications we are looking at in the present paper concern certain temporal logics,

in particular, the logic EF and its counting variant cEF, and we aim to derive decidable algebraic characterisations for them using our algebraic framework. Note that Bojańczyk and Idziaszek have already provided a decidable characterisation for EF in [7], but their result is only partially algebraic. They prove that a regular language is definable in EF if, and only if, the language is bisimulation-invariant and its syntactic algebra satisfies a certain equation, but they were not able to provide an algebraic characterisation of bisimulation invariance. Due to our more general algebraic framework we are able to fill this gap below.

We start in the next section with a short overview of the algebraic framework from [4]. We have to slightly modify this material since it was originally formulated in the setting of ranked trees while, when looking at temporal logics, it is more natural to consider unranked trees and forests. The remainder of the article contains our various characterisation results. In Section 3 we derive an algebraic characterisation of bisimulation-invariance, the result missing in [7]. Then, in Section 4, we turn to our main result and present characterisations for the logic cEF and some of its fragments, including a new and complete characterisation of the logic EF.

2 Forest algebras

The main topic of this article are languages of (possibly infinite) forests and the logics defining them. Before introducing the algebras we will use to recognise such languages, let us start by fixing some notation and conventions. Although our main interest is in unranked forests, we will use a more general version that combines the ranked and the unranked cases. As we will see below (cf. Theorem 3.1), the ability to use ranks will increase the expressive power of equations for our algebras considerably. Thus, we will work with *ranked sets*, i.e., sets where every element a is assigned an *arity* $\text{ar}(a)$. Formally, we consider such sets as families $A = (A_m)_{m < \omega}$, where A_m is the set of all elements of A of arity m . Functions between ranked sets then take the form $f = (f_m)_{m < \omega}$ with $f_m : A_m \rightarrow B_m$.

We will consider (unranked, finitely branching, possibly infinite) forests where each vertex is labelled by an element of a given ranked set A and each edge is labelled by a natural number with the restriction that, if a vertex is labelled by an element of arity m , the numbers labelling the outgoing edges must be less than m . If an edge $u \rightarrow v$ is labelled by the number k , we will call v a *k-successor* of u . Note that a vertex may have several k -successors, or none at all. We assume that the roots of a forest are ordered from left to right, as are all the k -successors of a given vertex v , while we impose no ordering between a k -successor and an l -successor, for $k \neq l$. We write $\mathbb{F}_0 A$ for the set of all such A -labelled forests. (We shall explain the index 0 further below.) We write $\text{dom}(s)$ for the set of vertices of a forest $s \in \mathbb{F}_0 A$, and we will usually identify s with the function $s : \text{dom}(s) \rightarrow A$ that maps vertices to their labels. We denote the empty forest by 0 and the disjoint union of two forests s and t by $s + t$ (where the roots of t are added after those of s). We will frequently use term notation to denote forests such as

$$a(b + c, 0, b) + b,$$

which denotes a forest with two components: the first one consisting of a root labelled by an element a of arity 3 which has two 0-successors labelled b and c , no 1-successor, and one 2-successor; the second component consists of a singleton with label b .

We use the symbol \preceq for the forest ordering where the roots are the minimal elements and the leaves the maximal ones. For a forest s , we denote by $s|_v$ the subtree of s attached to the vertex v . The *successor forest* of v in s is the forest obtained from $s|_v$ by removing the root v .

For a natural number n , set $[n] := \{0, \dots, n-1\}$. An *alphabet* is a finite (unranked) set Σ of symbols. If we use an alphabet in a situation such as $\mathbb{F}_0\Sigma$ where a ranked set is expected, we will consider each symbol in Σ as having arity 1. Thus, for us a *forest language over an alphabet* Σ will be a set $L \subseteq \mathbb{F}_0\Sigma$ consisting of the usual unranked forests. (The power to have elements of various arities is useful when writing down algebraic equations, but it is rather unnatural when considering languages defined by temporal logics.) We denote by Σ^* the set of all finite words over Σ , by Σ^ω the set of infinite words, and $\Sigma^\infty := \Sigma^* \cup \Sigma^\omega$. A *family of (word, forest, ...) languages* is a function \mathcal{K} mapping each alphabet Σ to a class $\mathcal{K}[\Sigma]$ of (word, forest, ...) languages over Σ .

Our algebraic framework to study forest languages is built on the notion of an Eilenberg–Moore algebra for a monad. To keep category-theoretical prerequisites at a minimum we will give an elementary, self-contained definition. The basic idea is that, in the same way we can view the product of a semigroup as an operation turning a sequence of semigroup elements into a single element, we view the product of a forest algebra as an operation turning a given forest that is labelled with elements of the algebra into a single element. The material in this section is taken from [4] with minor adaptations to accommodate the fact that we are dealing with unranked forests instead of ranked trees. Proofs can also be found in [5], although in a much more general setting. We start by defining which forests we allow in this process.

► **Definition 2.1.**

- (a) We denote by \mathbb{F} the functor mapping a ranked set A to the ranked set $\mathbb{F}A = (\mathbb{F}_m A)_m$ where $\mathbb{F}_m A$ consists of all $(A \cup \{x_0, \dots, x_{m-1}\})$ -labelled forests such that
- the new labels x_0, \dots, x_{m-1} have arity 0,
 - each label x_i appears at least once, but only finitely many times, and
 - no root is labelled by an x_i .
- (b) The *singleton function* $\text{sing} : A \rightarrow \mathbb{F}A$ maps a label a of arity m to the forest $a(x_0, \dots, x_{m-1})$.
- (c) The *flattening function* $\text{flat} : \mathbb{F}\mathbb{F}A \rightarrow \mathbb{F}A$ takes a forest $s \in \mathbb{F}\mathbb{F}A$ and maps it to the forest $\text{flat}(s)$ obtained by assembling all forests $s(v)$, for $v \in \text{dom}(s)$, into a single large forest. This is done as follows. For every vertex of $s(v)$ that is labelled by a variable x_k , we take the disjoint union of all forests labelling the k -successors of v and substitute them for x_k . This is done simultaneously for all $v \in \text{dom}(s)$ and all variables in $s(v)$ (see Figure 1 for an example.) ┘

Now we can define a forest algebra to be a set A equipped with a product $\mathbb{F}A \rightarrow A$.

► **Definition 2.2.**

- (a) An ω -forest algebra $\mathfrak{A} = \langle A, \pi \rangle$ consists of a ranked set A and a function $\pi : \mathbb{F}A \rightarrow A$ satisfying the following two axioms:

$$\text{the associative law } \pi \circ \mathbb{F}\pi = \pi \circ \text{flat} \quad \text{and} \quad \text{the unit law } \pi \circ \text{sing} = \text{id}.$$

We will denote forest algebras by fraktur letters \mathfrak{A} and their universes by the corresponding roman letter A . We will usually use the letter π for the product, even if several algebras are involved.

- (b) A *morphism* of ω -forest algebras is a function $\varphi : \mathfrak{A} \rightarrow \mathfrak{B}$ that commutes with the products in the sense that $\pi \circ \mathbb{F}\varphi = \varphi \circ \pi$. ┘

► **Remark.**

- (a) In the following we will simplify terminology by dropping the ω and simply speaking of *forest algebras*. But note that, strictly speaking, this name belongs to the kind of algebras introduced by Bojańczyk and Walukiewicz in [10].

■ **Figure 1** The flattening operation.

- (b) One can show that the functor \mathbb{F} together with the two natural transformations flat and sing forms what is called a *monad* in category theory. In this terminology, we can define forest algebras as *Eilenberg-Moore algebras* for this monad.
- (c) Note that a forest algebra $\mathfrak{A} = \langle A, \pi \rangle$ contains a monoid $\langle A_0, +, 0 \rangle$ (called the *horizontal monoid*) and an ω -semigroup $\langle A_1, A_0, \cdot \rangle$ (the *vertical ω -semigroup*), whose operations are derived from the product π . For instance, the vertical product $a \cdot b$, for $a, b \in A_1$, is formed as the product $\pi(s)$, where s consists of a root labelled a , an internal vertex labelled b , and a leaf labelled by the variable x_0 .
- (d) The reason why we do not allow forests where some root is labelled by a variable x_k is that an infinite product of such forests is not always defined. For instance, multiplying an infinite sequence of forests of the form $x_0 + a$ would create a forest with infinitely many components, which is not allowed.

Sets of the form $\mathbb{F}A$ can be equipped with a canonical forest algebra structure by using the flattening operation $\text{flat} : \mathbb{F}\mathbb{F}A \rightarrow \mathbb{F}A$ for the product. By general category-theoretical considerations it follows that algebras of this form are exactly the *free* forest algebras (generated by A). In this article we consider *forest languages* over an alphabet Σ as subsets $L \subseteq \mathbb{F}_0\Sigma$. Such a language is *recognised* by a morphism $\eta : \mathbb{F}\Sigma \rightarrow \mathfrak{A}$ of forest algebras if $L = \eta^{-1}[P]$ for some $P \subseteq A_0$.

Example. Let $\Sigma := \{a, b\}$. We can recognise the language $L \subseteq \mathbb{F}_0\Sigma$ of all forests s containing at least one occurrence of the letter a as follows. Let \mathfrak{A} be the algebra consisting of two elements 0_m and 1_m , for each arity m , where the product π maps a forest $s \in \mathbb{F}_m A$ to 1_n if at least one vertex is labelled by 1_n , for some n . Otherwise, s is mapped to 0_m . Then $L = \varphi^{-1}(1_0)$ where the morphism $\varphi : \mathbb{F}_0\Sigma \rightarrow \mathfrak{A}$ is defined by $\varphi(a) := 1_1$ and $\varphi(b) := 0_1$. (As $\mathbb{F}\Sigma$ is freely generated by the set $\{a, b\}$, this determines φ for all inputs.)

In analogy to the situation with word languages we would like to have a theorem stating that a forest language is regular if, and only if, it is recognised by a morphism into some finite forest algebra. But this statement is wrong for two reasons. The first one is that every forest algebra with at least one element of positive arity has elements of every arity and, thus, is infinite. (For instance, given $a \in A_1$, we obtain an element $a(x_0 + \dots + x_{n-1}) \in A_n$ of arity n). To fix this, we have to replace the property of being finite by that of having only finitely many elements of each arity. We call such algebras *finitary*.

But even if we modify the statement in this way it still fails since one can find finitary forest algebras recognising non-regular languages. (An example for tree languages is given by Bojańczyk and Klin in [9].) Therefore we have to restrict our class of algebras. A simple way to do so is given by the class of (locally) regular algebras introduced in [4] where all of the following results are taken from (again in the case of trees instead of forests).

► **Definition 2.3.** Let \mathfrak{A} be a forest algebra.

- (a) A subset $C \subseteq A$ is *regularly embedded* if, for every element $a \in A$, the preimage $\pi^{-1}(a) \cap \mathbb{F}C$ is a regular (i.e., automaton recognisable) language over C .
- (b) \mathfrak{A} is *locally regular* if every finite subset is regularly embedded.
- (c) \mathfrak{A} is *regular* if it is finitary, finitely generated, and locally regular. ┘

The definition of a regular forest algebra is not very enlightening. We refer the interested reader to [4] for a purely algebraic (but much more complicated) characterisation.

► **Theorem 2.4.** Let $L \subseteq \mathbb{F}_0\Sigma$ be a forest language. The following statements are equivalent.

- (1) L is regular (i.e., automaton recognisable).
- (2) L is recognised by a morphism into a locally regular forest algebra.
- (3) L is recognised by a morphism into a regular forest algebra.

(The reason why we introduce two classes is that locally regular algebras enjoy better closure properties, while the regular ones are more natural as recognisers of languages.) One can show (see [4]) that the (locally) regular algebras form a pseudo-variety in the sense that locally regular algebras are closed under quotients, subalgebras, finite products, and directed colimits, while regular algebras are closed under quotients, finitely generated subalgebras, finitely generated subalgebras of finite products, and so-called “rank-limits”. More important for our current purposes is the existence of syntactic algebras and the fact that these are always regular.

► **Definition 2.5.** Let $L \subseteq \mathbb{F}\Sigma$ be a forest language.

- (a) The *syntactic congruence* of L is the relation

$$s \sim_L t \quad \text{:iff} \quad p[s] \in L \Leftrightarrow p[t] \in L, \quad \text{for every context } p,$$

where a *context* is a $(\Sigma \cup \{\square\})$ -labelled forest (where \square is a new symbol of the same arity as s and t) and $p[s]$ is the forest obtained from p by replacing each vertex labelled by \square by the forest s .

- (b) The *syntactic algebra* of L is the quotient $\mathfrak{S}(L) := \mathbb{F}\Sigma / \sim_L$. ┘

► **Theorem 2.6.** The syntactic algebra $\mathfrak{S}(L)$ of a regular forest language L exists, it is regular, and it is the smallest forest algebra recognising L . Furthermore, $\mathfrak{S}(L)$ can be computed given an automaton for L .

Regarding the last statement of this theorem, we should explain what we mean by computing a forest algebra. Since forest algebras have infinitely many elements, we cannot simply compute the full multiplication table. Instead, we say that a regular forest algebra \mathfrak{A} is computable if, given a number $n < \omega$, we can compute a list $\langle \mathcal{A}_a \rangle_{a \in A_n}$ of automata such that \mathcal{A}_a recognises the set $\pi^{-1}(a) \cap \mathbb{F}C$, for some fixed set C of generators.

3 Bisimulation

To illustrate the use of syntactic algebras let us start with a simple warm-up exercise: we derive an algebraic characterisation of bisimulation invariance. This example also explains why algebras with elements of higher arities are needed (this is the reason Bojańczyk and Idziaszek [7], whose framework supported only arity 1, had to leave such a characterisation as an open problem).

Recall that a *bisimulation* between two forests s and t is a binary relation $Z \subseteq \text{dom}(s) \times \text{dom}(t)$ such that $\langle u, v \rangle \in Z$ implies that

- $s(u) = t(v)$ and,
- for every k -successor u' of u , there is some k -successor v' of v with $\langle u', v' \rangle \in Z$ and vice versa.

Two trees are *bisimilar* if there exists a bisimulation between them that relates their roots. More generally, two forests are bisimilar if every component of one is bisimilar to some component of the other. A language L of forests is *bisimulation-invariant* if $s \in L$ implies $t \in L$, for every forest t bisimilar to s .

► **Theorem 3.1.** *A forest language $L \subseteq \mathbb{F}_0\Sigma$ is bisimulation-invariant if, and only if, the syntactic algebra $\mathfrak{S}(L)$ satisfies the following equations:*

$$\begin{aligned} c + c &= c, & a(x_0 + x_0) &= a(x_0), \\ c + d &= d + c, & a(x_0 + x_1 + x_2 + x_3) &= a(x_0 + x_2 + x_1 + x_3), \end{aligned}$$

for all $a \in S_1(L)$ and $c, d \in S_0(L)$.

Proof. Let $\eta : \mathbb{F}\Sigma \rightarrow \mathfrak{S}(L)$ be the syntactic morphism mapping a forest to its \sim_L -class.

(\Rightarrow) Given elements $c, d \in S_0(L)$, we fix forests $s \in \eta^{-1}(c)$ and $t \in \eta^{-1}(d)$. If L is bisimulation-invariant, we have

$$p[s] \in L \quad \text{iff} \quad p[s + s] \in L \quad \text{and} \quad p[s + t] \in L \quad \text{iff} \quad p[t + s] \in L,$$

for every context p . Consequently, $s \sim_L s + s$ and $s + t \sim_L t + s$, which implies that $c = c + c$ and $c + d = d + c$.

The remaining two equations are proved similarly. Fix $a \in S_1(L)$ and $s \in \eta^{-1}(a)$. Setting $s' := s(x_0 + x_0)$, bisimulation-invariance of L implies that

$$p[s] \in L \quad \text{iff} \quad p[s'] \in L, \quad \text{for every context } p.$$

Consequently $s \sim_L s'$ and $a(x_0) = \eta(s) = \eta(s') = a(x_0 + x_0)$.

Similarly, for $t := s(x_0 + x_1 + x_2 + x_3)$ and $t' := s(x_0 + x_2 + x_1 + x_3)$, we have

$$p[t] \in L \quad \text{iff} \quad p[t'] \in L, \quad \text{for every context } p.$$

Hence, $t \sim_L t'$ and $a(x_0 + x_1 + x_2 + x_3) = a(x_0 + x_2 + x_1 + x_3)$.

(\Leftarrow) Suppose that $\mathfrak{S}(L)$ satisfies the four equations above and let s and s' be bisimilar forests. We claim that $\eta(s) = \eta(s')$, which implies that $s \in L \Leftrightarrow s' \in L$.

Fix a bisimulation relation $Z \subseteq \text{dom}(s) \times \text{dom}(s')$. W.l.o.g. we may assume that Z only relates vertices on the same level of the respective forests and that it only relates vertices whose predecessors are also related. (If not, we can always remove the pairs not satisfying this condition without destroying the fact that Z is a bisimulation.) Let \approx be the equivalence relation on $\text{dom}(s) \cup \text{dom}(s')$ generated by Z .

We will transform the forests s and s' in several steps while preserving their value under η until both forests are equal. (Note that each of these steps necessarily modifies the given forest at every vertex.) An example of this process can be found in Figure 2. The first step consists in translating the problem into the algebra $\mathfrak{S}(L)$. We define two new forests $t_0, t'_0 \in \mathbb{F}_0S(L)$ with the same domains as, respectively, s and s' and the following labelling. If $v \in \text{dom}(s)$ has the 0-successors u_0, \dots, u_{n-1} , we set

$$t_0(v) := \eta(s(v))(x_0 + \dots + x_{n-1})$$

and we make u_i an i -successor of v in t_0 . We obtain t'_0 from s' in the same way. By associativity it follows that $\pi(t_0) = \eta(s)$ and $\pi(t'_0) = \eta(s')$.

■ **Figure 2** Transforming bisimilar forests.

Next we make the shapes of the forests t_0 and t'_0 the same. Let t_1 and t'_1 be the forests with the same domains as t_0 and t'_0 and the following labelling. For every vertex v of t_0 with successors u_0, \dots, u_{n-1} and labelling

$$t_0(v) = a(x_0 + \dots + x_{n-1}),$$

we set

$$t_1(v) := a(x_0 + \dots + x_0 + \dots + x_{n-1} + \dots + x_{n-1}),$$

where each variable x_i is repeated m_i times and the numbers m_i are determined as follows. Let M be some number such that, for every $i < n$, no vertex $v' \approx v$ has at more than M successors u' with $u' \approx u_i$. (Note that there are only finitely many such vertices.) We choose the constants m_i such that

$$\sum_{k \in U_i} m_k = M, \quad \text{where } U_i := \{k < n \mid u_k \approx u_i\}.$$

We obtain the forest t'_1 in the same way from t'_0 . By the top right equation in the statement of the theorem, the value of the product is not affected by this modification. Hence, $\pi(t_1) = \pi(t_0)$ and $\pi(t'_1) = \pi(t'_0)$.

Finally, let t_2 and t'_2 be the unravelling of, respectively, t_1 and t'_1 , i.e., the forest where for every vertex v with successors u_0, \dots, u_{n-1} and label

$$t_1(v) = a(x_0 + \dots + x_0 + \dots + x_{n-1} + \dots + x_{n-1}),$$

we set

$$t_2(v) := a(x_0 + \dots + x_k + \dots + x_l + \dots + x_m)$$

(where we number the variables from left-to-right, e.g., $a(x_0 + x_0 + x_1 + x_2 + x_2)$ becomes $a(x_0 + x_1 + x_2 + x_3 + x_4)$), and we duplicate each attached subforest a corresponding number of times such that the value of the product does not change. We do the same for t'_2 .

We have arrived at a situation where, for each component r of the forests t_2 , there is some component r' of t'_2 that differs only in the ordering of successors, but not in their number. Consequently, there exists a bijection $\sigma : \text{dom}(t) \rightarrow \text{dom}(r')$ such that, for a vertex v of r with successors u_0, \dots, u_{n-1} ,

$$r'(v) = r(v)(x_{\sigma_v(0)} + \dots + x_{\sigma_v(n-1)}),$$

where the function $\sigma_v : [n] \rightarrow [n]$ is chosen such that $\sigma(u_i)$ is the $\sigma_v(i)$ -successor of $\sigma(v)$.

Let \hat{r} be the tree obtained from r as follows. For a vertex v with successors u_0, \dots, u_{n-1} and labelling

$$r(v) = a(x_0 + \dots + x_{n-1}),$$

we set

$$\hat{r}(v) := a(x_{\sigma_v(0)} + \dots + x_{\sigma_v(n-1)}),$$

and we reorder the attached subtrees accordingly. By associativity and the bottom right equation, this does not change the value of the product. It follows that $\hat{r} = r'$. Consequently, $\pi(r) = \pi(r')$.

We have shown that, for every component of t_0 there is some component of t'_0 with the same product. Therefore, we can write

$$\pi(t_0) = a_0 + \dots + a_{m-1} \quad \text{and} \quad \pi(t'_0) = b_0 + \dots + b_{n-1}$$

where the sets $\{a_0, \dots, a_{m-1}\}$ and $\{b_0, \dots, b_{n-1}\}$ coincide. Using the equations $c + c = c$ and $c + d = d + c$ we can therefore transform $\pi(t_0)$ into $\pi(t'_0)$. Consequently,

$$\eta(s) = \pi(t_0) = \pi(t'_0) = \eta(s').$$

As η recognises L it follows that $s \in L \Leftrightarrow s' \in L$, as desired. \blacktriangleleft

Note that we immediately obtain a decision procedure for bisimulation-invariance from this theorem, since we can compute the syntactic algebra and check whether it satisfies the given set of equations.

► **Corollary 3.2.** *It is decidable whether a given regular language L is bisimulation-invariant.*

4 The Logic cEF

Let us now proceed to the main result of this article: a characterisation of the temporal logic cEF. For simplicity, the following definition of its semantics only considers forests instead of arbitrary transition systems.

► **Definition 4.1.**

(a) *Counting* EF, cEF for short, has two kinds of formulae: *tree formulae* and *forest formulae*, which are inductively defined as follows.

- Every forest formula is a finite boolean combination of formulae of the form $E_k \varphi$ where k is a positive integer and φ a tree formula.
- Every tree formula is a finite boolean combination of (i) forest formulae and (ii) formulae of the form P_a , for $a \in \Sigma$.

To define the semantics we introduce a satisfaction relation \models_f for forest formulae and one \models_t for tree formulae. In both cases boolean combinations are defined in the usual way. For a tree t , we define

$$\begin{aligned} t \models_t P_a & \quad \text{: iff} \quad \text{the root of } t \text{ has label } a, \\ t \models_t \varphi & \quad \text{: iff} \quad t' \models_f \varphi, \quad \text{for a forest formula } \varphi, \text{ where } t' \text{ denotes the successor} \\ & \quad \quad \quad \text{forest of the root of } t. \end{aligned}$$

For a forest s , we define

$$\begin{aligned} s \models_f E_k \varphi & \quad \text{: iff} \quad \text{there exist at least } k \text{ vertices } v, \text{ distinct from the roots, such that} \\ & \quad \quad \quad s|_v \models \varphi. \end{aligned}$$

- (b) For $k, m < \omega$, we denote by cEF_k the fragment of cEF that uses only operators E_l where $l \leq k$, and cEF_k^m is the fragment of cEF_k where the nesting depth of the operators E_l is restricted to m . For $k = 1$, we set $\text{EF} := \text{cEF}_1$ and $\text{EF}^m := \text{cEF}_1^m$. \square

The following is our main theorem. Before giving the statement a few technical remarks are in order. In the equations below we make use of the ω -power a^ω of an element $a \in A_1$ (which is the infinite vertical product $aaa\dots$), and the *idempotent power* a^π (which is the defined as $a^\pi = a^n$ for the minimal number n with $a^n a^n = a^n$). For the horizontal semigroup we use multiplicative notation instead: $n \times a$ for $a + \dots + a$ and $\pi \times a$ for $n \times a$ with n as above.

When writing an ω -power of an element of arity greater than one, we need to specify with respect to which variable we take the power. We use the notation a^{ω_i} to indicate that the variable x_i should be used. Note that, when using several ω -powers like in $(a(x_0, (b(x_0, x_1))^{\omega_1}))^{\omega_0}$, the intermediate term after resolving the inner power can be a forest with infinitely many occurrences of the variable x_0 . But after resolving the outer ω -power, we obtain a forest without variables, i.e., a proper element of $\mathbb{F}_0 A$. Consequently, the equations below are all well-defined. Finally, to keep notation light we will frequently write x instead of x_0 , if this is the only variable present.

► **Theorem 4.2.** *A forest language $L \subseteq \mathbb{F}_0 \Sigma$ is definable in the logic cEF_k if, and only if, the syntactic algebra $\mathfrak{S}(L)$ satisfies the following equations:*

$$\begin{array}{ll}
c + d = d + c & (a(x) + b(x))^\omega = (ab(x))^\omega \\
(ab)^\pi = b(ab)^\pi & (a(x) + c)^\omega = (a(x + c))^\omega \\
a^\omega + a^\omega = a^\omega & (a(x + c + c))^\omega = (a(x + c))^\omega \\
(abb')^\omega = (ab'b)^\omega & [a(b(x_0, x_1))^{\omega_1}]^{\omega_0} = [ab(x_0, x_0)]^{\omega_0} \\
(aab)^\omega = (ab)^\omega & [a(x + bc + c)]^\omega = [a(x + bc)]^\omega \\
\\
a_n(c, \dots, c) + (k - n) \times c = a_n(c, \dots, c) + (k - n + 1) \times c, \\
[a(x + (a(k \times x))^\pi(c))]^\omega = k \times (a(k \times x))^\pi(c)
\end{array}$$

for all $a, b, b' \in S_1(L)$, $c, d \in S_0(L)$, $a_n \in S_n(L)$, and $n \leq k$.

No attempt was made to simplify the above axioms. While having a simpler description would of course be nice, the importance of this result lies in the facts that (i) an equational axiomatisation exists; that (ii) the equations can be checked algorithmically; and (iii) that our framework was sufficient to derive them.

We defer the proof to the appendix. Let us here concentrate on some of the consequences instead.

► **Corollary 4.3.** *For fixed k , it is decidable whether a given regular language L is cEF_k -definable.*

For the logic cEF , where the value of k is not bounded, a similar result can now be derived as a simple corollary. The basic argument is contained in the following lemma.

► **Lemma 4.4.** *Given a forest algebra \mathfrak{A} that is generated by $A_0 \cup A_1$, we can compute a number K such that, if \mathfrak{A} satisfies the equations of Theorem 4.2 for some value of k , it satisfies them for $k = K$.*

Proof. Set $K := m_0^{2m_1} + m_0$ where $m_0 := |A_0|$ and $m_1 := |A_1|$. By assumption there is some number k for which \mathfrak{A} satisfies the equations of Theorem 4.2. W.l.o.g. we may assume that $k \geq K$. The only two equations depending on k are

19:10 ω -Forest Algebras and Temporal Logics

$$(1)_k \quad a_n(c, \dots, c) + (k - n) \times c = a_n(c, \dots, c) + (k - n + 1) \times c$$

$$(2)_k \quad [a(x + (a(k \times x))^\pi(c))]^\omega = k \times (a(k \times x))^\pi(c)$$

We have to show that \mathfrak{A} also satisfies $(1)_K$ and $(2)_K$.

For $(2)_K$, note that $k \geq K \geq |A_0|$ implies that $K \times c = \pi \times c = k \times c$, for all $c \in A_0$. Consequently,

$$a(K \times x)(c) = a(k \times x)(c) \quad \text{and, therefore,} \quad (a(K \times x))^\pi(c) = (a(k \times x))^\pi(c).$$

This implies the claim.

For $(1)_K$, fix $a \in A_n$ and $c \in A_0$. If $n \leq K - m_0$, then $K - n \geq m_0 = |A_0|$ implies that $(K - n) \times c = \pi \times c$. Consequently,

$$a(c, \dots, c) + (K - n) \times c = a(c, \dots, c) + \pi \times c = a(c, \dots, c) + \pi \times c + c$$

and we are done. Thus, we may assume that $n > K - m_0 = m_0^{2m_1}$. As \mathfrak{A} is generated by $A_0 \cup A_1$, there exists some forest $s \in \mathbb{F}_i(A_0 \cup A_1)$ with $\pi(s) = a$. We distinguish several cases.

If some of the variables x_0, \dots, x_{n-1} does not appear in s , we can use $(1)_k$ to show that

$$\begin{aligned} a(c, \dots, c, \dots, c) + (K - n) \times c &= a(c, \dots, c + \dots + c, \dots, c) + (K - n) \times c \\ &= a(c, \dots, k \times c, \dots, c) + (K - n) \times c \\ &= a(c, \dots, k \times c, \dots, c) + (K - n) \times c + c. \end{aligned}$$

Next, suppose that s is highly branching in the sense that it has the form

$$s = r(t_0 + \dots + t_{m_0^2-1})$$

where each subterm t_i contains some variable. Then there are indices $i_0 < \dots < i_{m_0-1}$ such that $\pi(t_{i_0}(\bar{c})) = \dots = \pi(t_{i_{m_0-1}}(\bar{c}))$ (where \bar{c} denotes as many copies of c as appear in the respective term). Hence, $(1)_k$ again implies that

$$\begin{aligned} a(\bar{c}) + (K - n) \times c &= \pi(s(\bar{c})) + (K - n) \times c \\ &= \pi(r(t_0(\bar{c}) + \dots + t_{m_0^2-1}(\bar{c}))) + (K - n) \times c \\ &= \pi(r(t_0(\bar{c}) + \dots + t_{m_0^2-1}(\bar{c}) + k \times t_{i_0}(\bar{c}))) + (K - n) \times c \\ &= a(\bar{c}) + (K - n) \times c + c. \end{aligned}$$

Note that a tree of height $h := m_1$ where every vertex has at most $d := m_0^2$ successors has at most $d^h = m_0^{2m_1}$ leaves. Hence, if s is not highly branching in the sense above, the fact that it contains $n > m_0^{2m_1}$ variables implies that there must be a chain $v_0 \prec \dots \prec v_{m_1}$ of vertices such that, for every $i < m_1$, there is some leaf u labelled by a variable with $v_{i-1} \prec u$ and $v_i \not\prec u$. (For $i = 0$, we omit the first condition.) Hence, we can decompose s as

$$s(\bar{c}) = r_0(\bar{c}, r_1(\bar{c}, \dots, r_{m_1}(\bar{c}))),$$

and there are two indices $i < j$ such that

$$\pi(r_0(\bar{c}, \dots, r_i(\bar{c}, x))) = \pi(r_0(\bar{c}, \dots, r_j(\bar{c}, x))).$$

Consequently, we can use pumping to obtain a term

$$\pi(s(\bar{c})) = \pi(r_0(\bar{c}, \dots, r_i(\bar{c}, x)) [r_{i+1}(\bar{c}, \dots, r_j(\bar{c}, x))]^k r_{j+1}(\bar{c}, \dots, r_{m_1}(\bar{c})))$$

which contains at least k occurrences of c , and the claim follows again by $(1)_k$. \blacktriangleleft

According to this lemma, we can check for cEF-definability of a language L , by computing its syntactic algebra $\mathfrak{S}(L)$, the associated constant K , and then checking the equations for $k = K$.

► **Corollary 4.5.** *It is decidable whether a given regular language L is cEF-definable.*

When taking the special case of $k = 1$ in Theorem 4.2, we obtain the following characterisation of EF-definability.

► **Theorem 4.6.** *A forest language $L \subseteq \mathbb{F}_0\Sigma$ is definable in the logic EF if, and only if, the syntactic algebra $\mathfrak{S}(L)$ satisfies the following equations:*

$$\begin{array}{ll}
 c + d = d + c & (a(x) + b(x))^\omega = (ab(x))^\omega \\
 (ab)^\pi = b(ab)^\pi & (a(x) + c)^\omega = (a(x + c))^\omega \\
 (abb')^\omega = (ab'b)^\omega & (a(x + c + c))^\omega = (a(x + c))^\omega \\
 (aab)^\omega = (ab)^\omega & [a(b(x_0, x_1))^{\omega_1}]^{\omega_0} = [ab(x_0, x_0)]^{\omega_0} \\
 ac = ac + c \quad c = c + c & [a(x + a^\pi c)]^\omega = a^\pi c,
 \end{array}$$

for all $a, b, b' \in S_1(L)$ and $c, d \in S_0(L)$.

► **Corollary 4.7.** *It is decidable whether a given regular language L is EF-definable.*

A

 The proof of Theorem 4.2

For the proof of Theorem 4.2, we need to set up a bit of machinery. We start by defining the suitable notion of bisimulation for cEF_k . The difference to the standard notion is that we use reachability instead of the edge relation and that we also have to preserve the number of reachable positions.

► **Definition A.1.** Let $m, k < \omega$.

(a) For trees $s, t \in \mathbb{F}\Sigma$, we define

$$\begin{aligned}
 s \approx_k^0 t & \quad \text{: iff} \quad \text{the roots of } s \text{ and } t \text{ have the same label} \\
 s \approx_k^{m+1} t & \quad \text{: iff} \quad \text{the roots of } s \text{ and } t \text{ have the same label,} \\
 & \quad \text{for every } k\text{-tuple } \bar{x} \text{ in } \text{dom}(s) \text{ not containing the root, there is} \\
 & \quad \text{some } k\text{-tuple } \bar{y} \text{ in } \text{dom}(t) \text{ not containing the root such that} \\
 & \quad s|_{x_i} \approx_k^m t|_{y_i} \quad \text{for all } i < k \text{ and,} \\
 & \quad \text{for every } k\text{-tuple } \bar{y} \text{ in } \text{dom}(t) \text{ not containing the root, there is} \\
 & \quad \text{some } k\text{-tuple } \bar{x} \text{ in } \text{dom}(s) \text{ not containing the root such that} \\
 & \quad s|_{x_i} \approx_k^m t|_{y_i} \quad \text{for all } i < k.
 \end{aligned}$$

To simplify notation, we will frequently write $x \approx_k^m y$ for vertices x and y instead of the more cumbersome $s|_x \approx_k^m t|_y$.

(b) For forests $s, t \in \mathbb{F}\Sigma$ with possibly several components, we set

$$\begin{aligned}
 s \sim_k^{m+1} t & \quad \text{: iff} \quad \text{for every } k\text{-tuple } \bar{x} \text{ in } s \text{ there is some } k\text{-tuple } \bar{y} \text{ in } t \text{ such that} \\
 & \quad s|_{x_i} \approx_k^m t|_{y_i} \quad \text{for all } i < k \text{ and,} \\
 & \quad \text{for every } k\text{-tuple } \bar{y} \text{ in } t \text{ there is some } k\text{-tuple } \bar{x} \text{ in } s \text{ such that} \\
 & \quad s|_{x_i} \approx_k^m t|_{y_i} \quad \text{for all } i < k. \quad \lrcorner
 \end{aligned}$$

Let us show that this notion of bisimulation captures the expressive power of cEF . The proof is mostly standard. We start by introducing the following notion of a type.

► **Definition A.2.**

(a) We define the *type* $\text{tp}_k^m(s)$ of a tree $s \in \mathbb{F}\Sigma$ by

$$\text{tp}_k^0(s) := s(\langle \rangle) \quad \text{and} \quad \text{tp}_k^{m+1}(s) := \langle s(\langle \rangle), \theta_s \rangle$$

where $\langle \rangle$ denotes the root of s and

$$\begin{aligned}
 \theta_s := \{ \langle l, \sigma \rangle \mid l \leq k, x_0, \dots, x_{l-1} \in \text{dom}(s) \text{ distinct, not equal to the root,} \\
 \sigma = \text{tp}_k^m(s|_{x_0}) = \dots = \text{tp}_k^m(s|_{x_{l-1}}) \}.
 \end{aligned}$$

(b) For an arbitrary forest $s \in \mathbb{F}\Sigma$, we set $\text{Tp}_k^{m+1}(s) := \theta_s$, where

$$\begin{aligned}
 \theta_s := \{ \langle l, \sigma \rangle \mid l \leq k, x_0, \dots, x_{l-1} \in \text{dom}(s) \text{ distinct,} \\
 \sigma = \text{tp}_k^m(s|_{x_0}) = \dots = \text{tp}_k^m(s|_{x_{l-1}}) \}. \quad \lrcorner
 \end{aligned}$$

As standard proof establishes the following equivalences.

► **Lemma A.3.** *Let $k, m < \omega$.*

(a) *For trees $s, t \in \mathbb{F}_0\Sigma$, the following statements are equivalent.*

- (1) $s \approx_k^m t$
- (2) $\text{tp}_k^m(s) = \text{tp}_k^m(t)$
- (3) $s \models \varphi \Leftrightarrow t \models \varphi$, for all $\varphi \in \text{cEF}_k^m$.

(b) *For arbitrary forests $s, t \in \mathbb{F}_0\Sigma$, the following statements are equivalent.*

- (1) $s \sim_k^m t$
- (2) $\text{Tp}_k^m(s) = \text{Tp}_k^m(t)$
- (3) $s \models \varphi \Leftrightarrow t \models \varphi$, for all $\varphi \in \text{cEF}_k^m$.

► **Corollary A.4.** *A language $L \subseteq \mathbb{F}\Sigma$ is cEF_k^m -definable if, and only if, it is regular and satisfies*

$$s \sim_k^m t \text{ implies } s \in L \Leftrightarrow t \in L, \text{ for all regular forests } s, t \in \mathbb{F}_0\Sigma.$$

Proof. (\Rightarrow) follows by the implication (1) \Rightarrow (3) of Lemma A.3.

(\Leftarrow) Set

$$\varphi := \bigvee \{ \chi_\tau \mid \tau = \text{Tp}_k^m(s) \text{ for some regular forest } s \in L \},$$

where χ_τ are the formulae from the proof of Lemma A.3. For a regular forest $t \in \mathbb{F}_0\Sigma$, it follows that

$$\begin{aligned} t \models \varphi & \text{ iff } \text{Tp}_k^m(t) = \text{Tp}_k^m(s), \text{ for some regular forest } s \in L, \\ & \text{ iff } t \sim_k^m s, \text{ for some regular forest } s \in L, \\ & \text{ iff } t \in L. \end{aligned}$$

Let K be the language defined by φ . Since L and K are both regular languages that contain the same regular forests, it follows that $L = K$. Thus, L is cEF_k^m -definable. ◀

We want to show that an algebra recognises cEF_k -definable languages if, and only if, it satisfies the following equations.

► **Definition A.5.**

(a) A forest algebra \mathfrak{A} is an *algebra for cEF_k* if it is finitary, generated by $A_0 \cup A_1$, and satisfies the following equations.

$$\text{(G1)}_k \quad a_n(c, \dots, c) + (k - n) \times c = a_n(c, \dots, c) + (k - n + 1) \times c$$

$$\text{(G1)} \quad (ab)^\pi = b(ab)^\pi$$

$$\text{(G2)} \quad a^\omega + a^\omega = a^\omega$$

$$\text{(G3)} \quad c + d = d + c$$

$$\text{(G4)} \quad (a(x) + b(x))^\omega = (ab(x))^\omega$$

$$\text{(G5)} \quad (a(x) + c)^\omega = (a(x + c))^\omega$$

$$\text{(G6)} \quad (a(x + c + c))^\omega = (a(x + c))^\omega$$

$$\text{(G7)} \quad [a(b(x_0, x_1))^\omega]^\omega = [ab(x_0, x_0)]^\omega$$

$$\text{(G8)} \quad (abb')^\omega = (ab'b)^\omega$$

$$\text{(G9)} \quad (aab)^\omega = (ab)^\omega$$

$$\text{(G10)} \quad [a(x + bc + c)]^\omega = [a(x + bc)]^\omega$$

$$\text{(G12)}_k \quad [a(x + (a(k \times x))^\pi(c))]^\omega = k \times (a(k \times x))^\pi(c)$$

where $a, b, b' \in A_1$, $c, d \in A_0$, $a_n \in A_n$, and $n \leq k$.

(b) A forest algebra \mathfrak{A} is an *algebra for cEF* if it is an algebra for cEF_k , for some $k \geq 1$. ◻

■ **Figure 3** A forest s with a convex set U (in bold) that has three close U -ends (on the left) and five far ones (on the right). The height is $h(s, U) = 2$.

In the proof that algebras for cEF recognise exactly the cEF-definable languages, we use one of the Green's relations (suitably modified for forest algebras).

► **Definition A.6.** Let \mathfrak{A} be a forest algebra. For $a, b \in A_0$, we define

$$a \leq_L b \quad \text{iff} \quad a = c(b) \quad \text{or} \quad a = b + d, \quad \text{for some } c \in A_1, d \in A_0. \quad \lrcorner$$

► **Lemma A.7.** Let \mathfrak{A} be an algebra for cEF_k .

- (a) The relation \leq_L is antisymmetric.
 (b) For $a \in A_1$, $c \in A_0$, we have

$$\begin{aligned} c = c + c & \quad \text{implies} \quad ac = ac + c, \\ c = a(c, c) & \quad \text{implies} \quad c = c + c. \end{aligned}$$

Proof.

- (a) For a contradiction, suppose that there are elements $a \neq b$ with $a \leq_L b \leq_L a$. By definition, we can find elements c and d such that (1) $a = c(b)$ or (2) $a = b + c$, and (i) $b = d(a)$ or (ii) $b = a + d$. We have thus to consider four cases. In each of them we obtain a contradiction via $(G1)_k$ or $(G2)$.

$$\begin{aligned} (1, i) \quad a = cb = cda = (cd)^\pi(a) = d(cd)^\pi(a) = da = b. \\ (1, ii) \quad a = cb = c(a + d) = (c(x + d))^\pi(a) = (c(x + d))^\pi(a) + d = a + d = b. \\ (2, i) \quad b = da = d(b + c) = (d(x + c))^\pi(b) = (d(x + c))^\pi(b) + c = b + c = a. \\ (2, ii) \quad a = b + c = a + d + c = a + k \times (d + c) = a + k \times (d + c) + d = a + d = b. \end{aligned}$$

- (b) By $(G1)_k$ we have

$$\begin{aligned} c = c + c & \quad \text{implies} \quad ac = a(c + c) = a(k \times c) = a(k \times c) + c = ac + c, \\ c = a(c, c) & \quad \text{implies} \quad c = a(c, c) = (a(x, c))^\pi(c) = (a(x, c))^\pi(c) + c = c + c. \quad \blacktriangleleft \end{aligned}$$

Let us take a look at the following situation (see Figure 3). Let s be a forest and U a set of vertices. We assume that U is *convex* in the sense that $u \preceq v \preceq w$ and $u, w \in U$ implies $v \in U$ (where \preceq denotes the forest order). We call the maximal elements (w.r.t. \preceq) of U the *U-ends*. An U -end u is *close* if $u' \in U$, for all $u' \preceq u$. Otherwise, it is *far*. We would like to know how many of the U -ends are close.

► **Lemma A.8.** Let $m \geq 0$ and $k \geq 1$, let $s \sim_k^{m+k+2} t$ be two forests, $U \subseteq \text{dom}(s)$ a convex set that is closed under \approx_k^m , and set

$$V := \{v \in \text{dom}(t) \mid u \approx_k^m v \text{ for some } u \in U\}.$$

- (a) V is convex and closed under \approx_k^m .
- (b) The numbers of ends of U and V are the same, or both numbers are at least k .
- (c) If U has less than k ends, then U is finite if, and only if, V is finite.
- (d) If U is finite and has less than k ends, then U and V have the same numbers of close ends and of far ends.

Proof.

- (a) If V is not convex, there are vertices $v \prec v' \prec v''$ of t with $v, v'' \in V$ and $v' \notin V$. Fix vertices $u \prec u' \prec u''$ with $u \approx_k^{m+2} v$, $u' \approx_k^{m+1} v'$, and $u'' \approx_k^m v''$. By definition of V , we have $u, u'' \in U$ and $u' \notin U$. This contradicts the fact that U is convex.
To see that V is closed under \approx_k^m , suppose that $v \in V$ and $v \approx_k^m v'$. By definition of V , there is some $u \in U$ with $u \approx_k^m v$. Hence, $u \approx_k^m v \approx_k^m v'$. As \approx_k^m is transitive, this implies that $v' \in V$.
- (b) For a contradiction, suppose that U has $n < k$ ends while V has more than n ends. (The other case follows by symmetry.) Choose $n + 1$ ends $v_0, \dots, v_n \in V$. Since $s \approx_k^{m+2} t$, there are vertices u_0, \dots, u_n in s with $u_i \approx_k^{m+1} v_i$. By definition of V , we have $u_i \in U$. By assumption, there is some index j such that u_j is not an end. Hence, we can find a vertex $u' \succ u_j$ with $u' \in U$. Fix a vertex $v' \succ v_j$ of t with $u' \approx_k^m v'$. Then $v' \in V$ and v_j is not an end. A contradiction.
- (c) For a contradiction, suppose that U is finite, but V is not. (The other case follows by symmetry.) By (b), V has only finitely many ends. Hence, there is some element $v \in V$ such that $v \not\leq v'$ for every end v' of V . Since $s \approx_k^{m+3} t$, we can find a vertex u of s with $u \approx_k^{m+2} v$. This implies that $u \in U$. As U is finite, we can find some end u' of U with $u \leq u'$. Fix some $v' \geq v$ with $u' \approx_k^{m+1} v'$. Then $u' \in U$ implies $v' \in V$. By choice of v , there is some $v'' \succ v'$ with $v'' \in V$. Choose $u'' \succ u'$ with $u'' \approx_k^m v''$. By choice of u' , we have $u'' \notin U$. This contradicts the fact that $v'' \in V$.
- (d) By (b), we only need to prove that the number of close ends is the same. Let \hat{U} and \hat{V} be the sets of U -ends and V -ends, respectively. We denote by $N(s, U)$ the number of close U -ends and by $F(s, U)$ the set of all proper subforests s' of s that are attached to some vertex v that does not belong to U but where at least one root belongs to U . (A forest s' is a *proper subforest* of s attached at v if s' can be obtained from the subtree $s|_v$ by removing the root v .) We define the following equivalence relation.

$$\begin{aligned} \langle s, U \rangle \asymp_0 \langle t, V \rangle & \quad \text{: iff } N(s, U) = N(t, V), \\ \langle s, U \rangle \asymp_{i+1} \langle t, V \rangle & \quad \text{: iff } N(s, U) = N(t, V) \text{ and} \\ & \quad \#_\tau(s, U) = \#_\tau(t, V), \text{ for every } \asymp_i\text{-class } \tau, \end{aligned}$$

where $\#_\tau(s, U)$ denotes the number of subforests $s' \in F(s, U)$ that belong to the class τ . We define the U -height of s by

$$h(s, U) := \begin{cases} 0 & \text{if } F(s, U) = \emptyset \\ 1 + \max \{ h(s', U) \mid s' \in F(s, U) \} & \text{otherwise.} \end{cases}$$

By induction on l , we will prove the following claim:

$$(*) \quad s \sim_k^{m+l+2} t \quad \text{and} \quad h(s, U) \leq l \quad \text{implies} \quad h(s, U) = h(t, V) \quad \text{and} \quad \langle s, U \rangle \asymp_l \langle t, V \rangle.$$

As $h(s, U) \leq |\hat{U}| < k$, it then follows that $\langle s, U \rangle \asymp_k \langle t, V \rangle$. In particular, $N(s, U) = N(t, V)$, as desired.

It thus remains to prove (*). First, consider the case where $l = 0$. If $h(t, V) > 0$, there is some V -end v that is not close. Fix some vertex $v' \prec v$ with $v' \notin V$. Since $s \sim_k^{m+2} t$, we can find vertices $u' \prec u$ of s with $u' \approx_k^{m+1} v'$ and $u \approx_k^m v$. By definition of V , it follows that $u' \notin U$ and $u \in U$. As U is finite, we can find some U -end $w \succeq u$. But $u' \prec u \preceq w$ implies that w is not close. Hence, $h(s, U) > 0$. A contradiction.

For the second part, suppose that $\langle s, U \rangle \not\approx_0 \langle t, V \rangle$, that is, $N(s, U) \neq N(t, V)$. By symmetry, we may assume that $m := N(s, U) < N(t, v)$. Pick $m + 1$ distinct close V -ends v_0, \dots, v_m . Since $m + 1 \leq k$ and $s \sim_k^{m+2} t$, there are elements $u_0, \dots, u_m \in \text{dom}(s)$ with $u_i \approx_k^{m+1} v_i$. There must be some index j such that u_j is not a close U -end. As U is closed under \approx_k^m and $u_j \approx_k^m v_j \approx_k^m u$, for some $u \in U$, it follows that $u_j \in U$. Furthermore, $u_j \approx_k^{m+1} v_j$ and the fact that v_j is a V -end implies that $u' \notin U$, for all $u' \succ u_j$. Thus, u_j is a U -end. But $h(s, U) = 0$ implies that all U -ends of s are close. A contradiction.

For the inductive step, suppose that $s \sim_k^{m+(l+1)+2} t$ holds but we have $h(s, U) \neq h(t, V)$ or $\langle s, U \rangle \not\approx_{l+1} \langle t, V \rangle$. We distinguish several cases.

- (i) Suppose that $h(s, U) > h(t, V)$. By definition of h , there is a subforest $s' \in F(s, U)$ with $h(s', U) = h(s, U) - 1$. Then there is some subforest t' of t with $s' \sim_k^{m+l+2} t'$. By inductive hypothesis it follows that

$$h(s, U) = h(s', U) + 1 = h(t', V) + 1 < h(t, V) + 1 \leq h(s, U).$$

A contradiction.

- (ii) Suppose that $h(s, U) < h(t, V)$. By definition of h , there is a subforest $t' \in F(t, V)$ with $h(t', V) = h(t, V) - 1$. Fix a subforest s' of s with $s' \sim_k^{m+l+2} t'$. By inductive hypothesis, it follows that

$$h(s, U) > h(s', U) = h(t', V) = h(t, V) - 1 \geq h(s, U).$$

A contradiction.

- (iii) Suppose that $N(s, U) \neq N(t, v)$ and there is no \approx_l -class τ with $\#_\tau(s, U) \neq \#_\tau(t, V)$. Then we have $|\hat{U}| - N(s, U) = |\hat{V}| - N(t, V)$. Since $|\hat{U}| = |\hat{V}|$ it follows that $N(s, U) = N(t, V)$. A contradiction.

- (iv) Finally, suppose that there is some \approx_l -class τ with $\#_\tau(s, U) \neq \#_\tau(t, V)$. By symmetry, we may assume that $m := \#_\tau(s, U) < \#_\tau(t, V)$. We choose $m + 1$ vertices v_0, \dots, v_m of t such that the attached subforests have class τ . Since $s \sim_k^{m+(l+1)+2} t$ and $m + 1 \leq k$, there are vertices u_0, \dots, u_m of s such that $u_i \sim_k^{m+l+2} v_i$, for all $i \leq m$. Let s_i be the subforest of s attached to u_i , and t_i the subforest of t attached to v_i . By inductive hypothesis, it follows that $s_i \approx_l t_i$, for $i \leq m$. Thus, s has at least $m + 1$ different subforest in the class τ . A contradiction. \blacktriangleleft

► **Proposition A.9.** *Let \mathfrak{A} be an algebra for cEF_k . Then*

$$s \approx_k^{(k+3)(|A_0|+1)} t \text{ implies } \pi(s) = \pi(t), \text{ for all regular trees } s, t \in \mathbb{F}_0(A_0 \cup A_1).$$

Proof. Let m be the number of L -classes above $b := \pi(s)$ (including that of b itself). We will prove by induction on m that

$$s \approx_k^{f(m)} t \text{ implies } \pi(t) = b,$$

where $f(m) := (m + 1)(k + 3)$. Set

$$S := \{x \in \text{dom}(s) \mid \pi(s|_x) = b\},$$

$$T := \{y \in \text{dom}(t) \mid x \approx^{f(m-1)} y \text{ for some } x \in S\}.$$

As t is regular it is the unravelling of some finite graph G . For each $y \in T$, we will prove that $\pi(t|_y) = b$ by induction on the number of strongly connected components of G that are contained in T and that are reachable from y . Hence, fix $y \in T$, let C be the strongly connected component of G containing y , and choose some $x \in S$ with $x \approx_k^{f(m)-1} y$. We distinguish two cases.

(a) Let us begin our induction with the case where C is trivial, i.e., it consists of the single vertex y without self-loop. Then

$$t|_y = a(t_0 + \cdots + t_{n-1} + t'_0 + \cdots + t'_{q-1})$$

where $a := t(y)$ and the subtrees t_i lie outside of T while the t'_i contain vertices in T . Set $d_i := \pi(t_i)$. By our two inductive hypotheses, we already know that $\pi(t'_i) = b$ and that $b <_{\mathbb{L}} d_i$. Hence,

$$\pi(t|_y) = a(d_0 + \cdots + d_{n-1} + q \times b).$$

We have to show that this value is equal to b . Suppose that

$$s|x = a(s_0 + \cdots + s_{l-1} + s'_0 + \cdots + s'_{p-1}),$$

where again the trees s_i lie outside of S , while the s'_i contain vertices of S . Setting $c_i := \pi(s_i)$ it follows that

$$\pi(s|x) = a(c_0 + \cdots + c_{l-1} + p \times b).$$

Since $x \in S$, we already know that this value is equal to b . Hence, it remains to show that

$$a(c_0 + \cdots + c_{l-1} + p \times b) = a(d_0 + \cdots + d_{n-1} + q \times b).$$

We start by proving that

$$c_0 + \cdots + c_{l-1} = d_0 + \cdots + d_{n-1}.$$

By (G4) it is sufficient to prove that, for every $c \in A_0$, the number of occurrences of the value c in the sum on the left-hand side is either the same as that on the right-hand side, or that we can add an arbitrary number of c on both sides without changing the respective values. Hence, consider some element $c \in A_0$ where these numbers are different. Let U be the set of all vertices $u \succ x$ such that $\pi(s|_u) = c$ and let V be the set of vertices $v \succ y$ with $\pi(t|_v) = c$. As $\leq_{\mathbb{L}}$ is antisymmetric, these two sets are convex. Furthermore, by inductive hypothesis on m , they are also closed under $\approx_k^{f(m-1)}$. Since $f(m) - 1 = f(m-1) + k + 2$, we can therefore apply Lemma A.8 and we obtain one of the following cases.

(i) U and V both have at least k ends. Then we can write $s_0 + \cdots + s_{l-1}$ as $r(s'_0, \dots, s'_{k-1})$ with $\pi(s'_i) = c$. Hence, it follows by (G1) $_k$ that

$$\begin{aligned} c_0 + \cdots + c_{l-1} &= \pi(r)(c, \dots, c) = \pi(r)(c, \dots, c) + \pi \times c \\ &= c_0 + \cdots + c_{l-1} + \pi \times c. \end{aligned}$$

For t it follows in the same way that

$$d_0 + \cdots + d_{n-1} = d_0 + \cdots + d_{n-1} + \pi \times c.$$

Consequently, we can add an arbitrary number of terms c to both sides of the above equation and thereby make their numbers equal.

- (ii) Both U and V are infinite, but each has less than k ends. Thus, U contains an infinite path and we can use Ramsey's Theorem (or the fact that s is regular) to write $\pi(s_0 + \cdots + s_{l-1})$ as $a'e^\omega$ where $ec = c = e^\omega$. By (G3) and (G1) $_k$ it follows that

$$\begin{aligned} c_0 + \cdots + c_{l-1} &= a'e^\omega = a'(e^\omega + \cdots + e^\omega) = a'(c + \cdots + c) \\ &= a'(c + \cdots + c) + \pi \times c \\ &= c_0 + \cdots + c_{l-1} + \pi \times c. \end{aligned}$$

For $t|_y$, we similarly obtain

$$d_0 + \cdots + d_{n-1} = d_0 + \cdots + d_{n-1} + \pi \times c,$$

and we can equalise the number of c as in Case (i).

- (iii) The last remaining case is where both U and V are finite and they have the same number of close ends. Then the sums $c_0 + \cdots + c_{l-1}$ and $d_0 + \cdots + d_{n-1}$ contain the same number of terms with value c and there is nothing to prove.

We have thus shown that

$$c_0 + \cdots + c_{l-1} = d_0 + \cdots + d_{n-1}.$$

If $p = q$, we are done. Hence, we may assume that $p \neq q$. To conclude the proof, we set

$$U := \{u \in S \mid x \prec u\} \quad \text{and} \quad V := \{v \in T \mid y \prec v\}.$$

If $p > 0$, then $x \approx_k^{f(m)-1} y$ and $U \neq \emptyset$ implies $V \neq \emptyset$. Hence, $q > 0$. In the same way, $q > 0$ implies $p > 0$. Consequently, we have $p, q > 0$. We consider several cases.

- (i) If $b + b = b$, then

$$\begin{aligned} a(d_0 + \cdots + d_{n-1} + q \times b) &= a(c_0 + \cdots + c_{l-1} + q \times b) \\ &= a(c_0 + \cdots + c_{l-1} + p \times b) = b, \end{aligned}$$

as desired.

- (ii) If U is not a chain, we obtain $b = a'(b, b)$, for some a' , and Lemma A.7 implies that we are in Case (i).
- (iii) If U contains an infinite chain, we can use Ramsey's Theorem (or the fact that s is regular), to obtain a factorisation $b = e^\omega$, which implies that $b + b = b$ by (G3). Hence, we are in Case (i) again.
- (iv) If U is a finite chain, then so is V , by Lemma A.8. Hence, $p = 1 = q$ and we are done.

- (b) It remains to consider the case where C is not trivial. Then we can factorise

$$t|_y = r(t_0, \dots, t_{n-1}, t'_0, \dots, t'_{q-1}),$$

where $r \in \mathbb{F}A$ is the unravelling of C , the subtrees t_i lie outside of T , while the subtrees t'_i contain vertices in T . Setting $d_i := \pi(t_i)$, it follows by the two inductive hypotheses that $d_i >_{\perp} b$ and $\pi(t'_i) = b$. Consequently,

$$\pi(t|_y) = \pi(r)(d_0, \dots, d_{n-1}, b, \dots, b).$$

Let us simplify the term r . Introducing one variable x_v , for every vertex $v \in C$, we can write r as a system of equations

$$x_v = a_v(x_{u_0} + \cdots + x_{u_{l-1}} + c_0 + \cdots + c_{q-1}), \quad \text{for } v \in C,$$

where u_0, \dots, u_{l-1} are the successors of v that belong to C and c_0, \dots, c_{q-1} are constants from $\{d_0, \dots, d_{n-1}, b\}$ that correspond to successors outside of C . Solving this system of equations, we obtain a finite term r_0 built up from elements of $A_0 \cup A_1$ using as operations the horizontal product, the vertical product, and the ω -power operation, such that

$$\pi(t|_y) = \pi(r_0)(d_0, \dots, d_{n-1}, b).$$

With the help of the equations (G5)–(G10), we can transform r_0 in several steps (while preserving its product) until it assumes the form

$$\begin{aligned} & [a_0 \cdots a_{j-1}(x + d_0 + \cdots + d_{n-1} + b)]^\omega \\ \text{or } & [a_0 \cdots a_{j-1}(x + d_0 + \cdots + d_{n-1})]^\omega \end{aligned}$$

where a_0, \dots, a_{j-1} are the labels of the vertices in C .

We distinguish two cases. First suppose that there is no term with value b in the above sum. This means that every subtree attached to C lies entirely outside of the set T . Then $x \approx_k^{f(m)-1} y$ implies that we can factorise $s|_x$ as

$$s|_x = r'(s_0, \dots, s_{l-1})$$

where

- $\{\pi(s_0), \dots, \pi(s_{l-1})\} = \{d_0, \dots, d_{n-1}\}$,
- all labels of r' are among a_0, \dots, a_{j-1} ,
- every vertex of r' has, for every $i < k$, some descendant labelled a_i .

As above we can transform $s|_x$ into

$$[a_0 \cdots a_{j-1}(x + c_0 + \cdots + c_{l-1})]^\omega$$

where $c_i := \pi(s_i)$. Since $\{c_0, \dots, c_{l-1}\} = \{d_0, \dots, d_{n-1}\}$ it follows that

$$\begin{aligned} \pi(t|_y) &= (a_0 \cdots a_{j-1}(x + d_0 + \cdots + d_{n-1}))^\omega \\ &= (a_0 \cdots a_{j-1}(x + c_0 + \cdots + c_{l-1}))^\omega = \pi(s|_x) = b. \end{aligned}$$

It thus remains to consider the case where some term has value b . Using (G7) and (G11) and the fact that $b <_{\mathbb{L}} d_i$, it then follows that

$$\pi(t|_y) = [a_0 \cdots a_{j-1}(x + d_0 + \cdots + d_{n-1} + b)]^\omega = [a_0 \cdots a_{j-1}(x + b)]^\omega.$$

For every $i < j$, we fix some $z_i \in S$ with label a_i such that $x \prec z_i$ and some successor of z_i also belongs to S . Then

$$\pi(s|_{z_i}) = a_i(c_0^i + \cdots + c_{i-1}^i + b + \cdots + b),$$

for some $c_0^i, \dots, c_{i-1}^i >_{\mathbb{L}} b$. Since

$$b = \pi(s|_{z_i}) = a_i(c_0^i + \cdots + c_{i-1}^i + b + \cdots + b) \leq_{\mathbb{L}} c_0^i + \cdots + c_{i-1}^i + b + \cdots + b \leq_{\mathbb{L}} b$$

it follows by asymmetry of \leq_L that

$$c_0^i + \cdots + c_{i+1}^i + b + \cdots + b = b \quad \text{and} \quad a_i(b) = a_i(c_0^i + \cdots + c_{i+1}^i + b + \cdots + b) = b.$$

Consequently, $a_0 \cdots a_{j-1} b = b$, which implies that $a^\pi b = b$ where $a := a_0 \cdots a_{j-1}$. We claim that $b + b = b$. It then follows that

$$b = a(b) = a(k \times x)(b) = (a(k \times x))^\pi(b),$$

which, by $(G12)_k$, implies that

$$\pi(t|_y) = [a(x + b)]^\omega = [a(x + a(k \times x)^\pi(b))]^\omega = k \times a(k \times x)^\pi(b) = k \times b = b,$$

as desired.

Hence, it remains to prove our claim that $b + b = b$. By our assumption on y and C , there is some vertex $u \in C$ that has some successor $v \notin C$ with $v \in T$. Since $s|_x \approx_k^{f(m)-1} t|_y$ and $f(m) \geq f(m-1) + k + 1$, there are vertices $x \preceq u_0 < \cdots < u_{k-1}$ each of which has some successor $v_i \in S$ with $v_i \not\preceq u_{i+1}$. Consequently, we can write

$$\pi(s|_x) = a' a''(b, \dots, b) \quad \text{and} \quad \pi(s|_{u_0}) = a''(b, \dots, b),$$

where $a' \in A_1$ and $a'' \in A_k$. Hence, it follows by $(G1)_k$ that

$$b + b = \pi(s|_{u_0}) + b = a''(b, \dots, b) + b = a''(b, \dots, b) = \pi(s|_{u_0}) = b. \quad \blacktriangleleft$$

► **Theorem A.10.** *A regular forest algebra \mathfrak{A} is an algebra for cEF_k if, and only if, there exists a number $m < \omega$ such that*

$$s \sim_k^m t \quad \text{implies} \quad \pi(s) = \pi(t), \quad \text{for all regular forests } s, t \in \mathbb{F}(A_0 \cup A_1).$$

Proof. (\Leftarrow) In each of the equations $(G1)_k$ – $(G12)_k$, the two terms on both sides are \sim_k^m -equivalent.

(\Rightarrow) By Proposition A.9, there is some number m such that

$$s \approx_k^m t \quad \text{implies} \quad \pi(s) = \pi(t), \quad \text{for regular trees } s, t \in \mathbb{F}(A_0 \cup A_1).$$

Let $s, t \in \mathbb{F}(A_0 \cup A_1)$ be regular forests. We claim that

$$s \sim_k^{m+k+2} t \quad \text{implies} \quad \pi(s) = \pi(t).$$

Suppose that $s = s_0 + \cdots + s_{l-1}$ and $t = t_0 + \cdots + t_{n-1}$, for trees s_i and t_i , and set $c_i := \pi(s_i)$ and $d_i := \pi(t_i)$. Analogous to Part (a) of the proof of Proposition A.9, we can use Lemma A.8 to show that

$$\pi(s) = c_0 + \cdots + c_{l-1} = d_0 + \cdots + d_{n-1} = \pi(t). \quad \blacktriangleleft$$

We complete the proof of Theorem 4.2 as follows.

► **Theorem A.11.** *A regular language $L \subseteq \mathbb{F}_0 \Sigma$ is cEF_k -definable if, and only if, its syntactic algebra $\mathfrak{S}(L)$ is an algebra for cEF_k .*

Proof. (\Leftarrow) Suppose that $\mathfrak{S}(L)$ is an algebra for cEF_k . By Theorem A.10, every language recognised by $\mathfrak{S}(L)$ is invariant under \sim_k^m , for some m (when considering regular forests only). Consequently, the claim follows by Corollary A.4.

(\Rightarrow) If L is cEF_k -definable, it follows by Corollary A.4 that L is \sim_k^m -invariant, for some m . Thus \sim_k^m is contained in the syntactic congruence of L , which means that the syntactic morphism $\eta : \mathbb{F}\Sigma \rightarrow \mathfrak{S}(L)$ maps \sim_k^m -equivalent forests to the same value. Given forests $s, t \in \mathbb{F}(S_0 \cup S_1)$ with $s \sim_k^m t$, we can choose forests $s', t' \in \mathbb{F}\Sigma$ with $s' \sim_k^m t'$ and $s(v) = \eta(s'(v))$ and $t(v) = \eta(t'(v))$. Thus,

$$s \sim_k^m t \quad \text{implies} \quad \pi(s) = \eta(s') = \eta(t') = \pi(t).$$

By Theorem A.10, it follows that $\mathfrak{S}(L)$ is an algebra for cEF_k . ◀

Constructing Deterministic ω -Automata from Examples by an Extension of the RPNI Algorithm

León Bohn  

RWTH Aachen University, Germany

Christof Löding 

RWTH Aachen University, Germany

Abstract

The RPNI algorithm (Oncina, Garcia 1992) constructs deterministic finite automata from finite sets of negative and positive example words. We propose and analyze an extension of this algorithm to deterministic ω -automata with different types of acceptance conditions. In order to obtain this generalization of RPNI, we develop algorithms for the standard acceptance conditions of ω -automata that check for a given set of example words and a deterministic transition system, whether these example words can be accepted in the transition system with a corresponding acceptance condition. Based on these algorithms, we can define the extension of RPNI to infinite words. We prove that it can learn all deterministic ω -automata with an informative right congruence in the limit with polynomial time and data. We also show that the algorithm, while it can learn some automata that do not have an informative right congruence, cannot learn deterministic ω -automata for all regular ω -languages in the limit. Finally, we also prove that active learning with membership and equivalence queries is not easier for automata with an informative right congruence than for general deterministic ω -automata.

1 Introduction

In this paper we consider learning problems for automata on infinite words, also referred to as ω -automata, which have been studied since the early 1960s as a tool for solving decision problems in logic [7] (see also [26]), and are nowadays used in procedures for formal verification and synthesis of reactive systems (see, e.g., [5, 27, 18] for surveys and recent work). Syntactically ω -automata are very similar to NFA resp. DFA (standard nondeterministic resp. deterministic finite automata on finite words), and they also share many closure and algorithmic properties. However, many algorithms and constructions are much more involved for ω -automata, one prominent such example being determinization [23, 22, 24, 15], and another one the minimization of deterministic ω -automata [25], which is hard for most of the acceptance conditions of ω -automata. The underlying reason is that regular languages of finite words have a simple characterization in terms of the Myhill/Nerode congruence, and the unique minimal DFA for a regular language can be constructed by merging language equivalent states (see [13]). In contrast, deterministic ω -automata need, in general, different language equivalent states for accepting a given regular ω -language.

The characterization of minimal DFA in terms of the Myhill/Nerode congruence is also an important property that is used by learning algorithms for DFA. In automaton learning one usually distinguishes the two settings of passive and active learning. We are mainly concerned with passive learning in this paper, where the task is to construct an automaton

from a sample, a given finite set of words together with a classification if they are in the language or not. The RPNI algorithm [21] is a passive learning algorithm that constructs a DFA from a given sample of positive and negative examples (words that are in the language and words that are not in the language, respectively). It starts with the prefix tree acceptor, a tree shaped DFA that accepts precisely the positive examples and subsequently it tries to merge pairs of states in the canonical order of words (each state is associated with the word reaching it in the prefix tree acceptor). If a merge results in a DFA that accepts a negative example, the merge is discarded. Otherwise the merge is kept and the algorithm continues with this DFA. RPNI can learn the minimal DFA for each regular language in the limit with polynomial time and data. This means that RPNI runs in polynomial time in the size of the given sample, and for each regular language L there is a characteristic sample S_L of polynomial size, such that RPNI produces the minimal DFA for L for each sample that is consistent with L and contains S_L [21]. The RPNI algorithm is a simple algorithm that also produces useful results if the sample does not include the characteristic sample of any language L . Therefore its principle of state merging has been used for other automaton models, e.g., probabilistic automata [8, 17] and sequential transducers [20].

In this paper we propose and analyze an extension of RPNI to ω -automata. In the setting of infinite words, one uses ultimately periodic words of the form uv^ω for finite words u, v . These are infinite words with a finite representation, and each regular ω -language is uniquely determined by the set of ultimately periodic words that it contains (see [26]). There are two main obstacles that one has to overcome for a generalization of RPNI. First, it is not clear how to generalize the prefix tree acceptor to infinite words, since a tree shaped acceptor for a set of infinite words necessarily needs to be infinite. We therefore propose a formulation of the algorithm that inserts transitions instead of merging states, and creates new states in case none of the existing states can be used as a target of the transition. In the setting of finite words, this method of inserting transitions produces the same result as RPNI, and it can easily be used for infinite words as well. Because this algorithm produces growing transition system, we call it **Sprout**.

The second problem arises in the test whether a merge (in our formulation an inserted transition) should be kept or discarded. In the case of finite words, one can simply check whether there are a positive and a negative example that reach the same state, which obviously is not possible in a DFA that is consistent with the sample. For ω -automata the situation is a bit more involved, because acceptance of a word is not determined by a single state, but rather the set of states that is reached infinitely often. And furthermore, there are various acceptance conditions using different ways of classifying these infinity sets into accepting and rejecting. To solve this problem, we propose polynomial time algorithms for checking whether a deterministic transition system admits an acceptance condition of a given type (Büchi, generalized Büchi, parity, or Rabin) that turns the transition system into a deterministic ω -automaton that is consistent with the sample. These consistency algorithms are then used in **Sprout** in order to check whether a merge (inserted transition) produces a transition system that can still be consistent with the sample (for the acceptance condition under consideration). However, we believe that these consistency algorithms are of interest on their own and might also be useful in other contexts. We also show that bounding the size of the acceptance condition can make the problem hard: consistency with a Rabin condition with three pairs or generalized Büchi condition with three sets is NP-hard.

Our analysis of **Sprout** reveals that it can learn every ω -regular language with an informative right congruence (IRC) in the limit from polynomial time and data. A deterministic ω -automaton has an informative right congruence if it has only one state for each My-

hill/Nerode equivalence class of the language that it defines [3]. Recently, another algorithm that can learn every ω -regular language with an IRC in the limit from polynomial time and data has been proposed [4]. This algorithm is an extension of the approach from [12] from finite to infinite words. However, the algorithm from [4] has explicitly been developed for automata with an IRC, and it can only produce such automata (it defaults to an automaton accepting precisely the positive examples in case the sample does not completely characterize the target automaton). In contrast, **Sprout** is not specifically designed for IRC languages, it can also construct automata that do not have an IRC. But on the negative side we also show that **Sprout** cannot learn a deterministic ω -automaton for every regular ω -language.

The positive results for passive learning of IRC languages raise the question whether this class is also simpler for active learning than general deterministic ω -automata. The standard model for active learning of automata uses membership and equivalence queries, and DFA can be learned in polynomial time in this model [1]. This approach has been extended to the class of weak deterministic Büchi automata [16], whose minimal automata can also be defined using the standard right congruence. For general regular ω -languages, the only known algorithms either learn a different representation based on DFA [2], or add another query about the loop structure of the target automaton [19]. Since the characterization of the minimal automata by a right congruence is a crucial point in many active learning algorithms, it is tempting to believe that the algorithms can be extended to the classes of languages with an IRC. We prove that this is not the case by showing that a polynomial time active learning algorithm for deterministic ω -automata with an IRC can be turned into a polynomial time learning algorithm for general deterministic ω -automata.

Finally, we also make the observation that polynomial time active learning (with membership and equivalence queries) is at least as hard as learning in the limit with polynomial time and data.

The paper is structured as follows. In Section 2 we give basic definitions. In Section 3 we present the consistency algorithms, and in Section 4 we describe our extension of RPNI to ω -automata. In Section 5 we show that the property of an IRC does not help for polynomial time active learning, and in Section 6 we conclude.

2 Preliminaries

For a finite alphabet Σ we use Σ^* and Σ^ω to refer to the set of finite and infinite words respectively. The empty word is denoted by ε , and $\Sigma^+ = \Sigma^* \setminus \{\varepsilon\}$. A deterministic transition system (TS) is defined by a tuple $\mathcal{T} = (Q, \Sigma, q_0, \delta)$ where Q is a finite set of states, Σ a finite alphabet, $q_0 \in Q$ the initial state and $\delta : Q \times \Sigma \rightarrow Q$ is the transition function. We use $\delta(q, a) = \perp$ to indicate that a transition $(q, a) \in Q \times \Sigma$ is not defined in \mathcal{T} . Further we extend δ to $\delta^* : Q \times \Sigma^* \rightarrow Q$ defined as $\delta^*(q, \varepsilon) = q$ and $\delta^*(q, aw) = \delta^*(\delta(q, a), w)$ for $q \in Q, a \in \Sigma$ and $w \in \Sigma^*$. Unless otherwise specified \mathcal{T} will be used to refer to a transition system with components as above. The unique run of \mathcal{T} on $w \in \Sigma^\omega$ is a sequence of transitions $\rho = q_0 w_0 q_1 w_1 \dots$ with $q_{i+1} = \delta(q_i, w_i)$. For an infinite run ρ we denote by $\text{inf}(\rho)$ the *infinity set* of ρ , consisting of all state-symbol pairs that occur infinitely often in ρ . A set of states $\emptyset \neq C \subseteq Q$ is called *strongly connected* if for all $p, q \in C$ we have $\delta^*(p, w) = q$ for some $w \in \Sigma^+$. The \subseteq -maximal strongly connected sets of \mathcal{T} are called strongly connected components (SCCs) and for a set R we use $\text{SCC}(R)$ to refer to the set of all SCCs $S \subseteq R$.

Augmenting a transition system \mathcal{T} with an acceptance condition \mathcal{C} yields an ω -automaton $\langle \mathcal{T}, \mathcal{C} \rangle = (Q, \Sigma, q_0, \delta, \mathcal{C})$. We now introduce different types of acceptance conditions (based on the survey [26]), give a notion of their size $|\mathcal{C}|$ and define which sets $X \subseteq Q \times \Sigma$ satisfy

them. Note that while acceptance is often defined based on *states* that occur infinitely often, we opt for transition-based acceptance due to its succinctness (state-based acceptance can be turned into transition-based acceptance without changing the transition system, while the transformation in the other direction requires a blow-up of the transition system depending on the acceptance condition).

A *Büchi condition* $F \subseteq Q \times \Sigma$ is satisfied if $X \cap F \neq \emptyset$, whereas a *generalized Büchi condition* $\mathcal{B} = \{F_1, \dots, F_k\}$ with $F_i \subseteq Q \times \Sigma$ is satisfied if $X \cap F_i \neq \emptyset$ for all $i \in [1, k] \subseteq \mathbb{N}$. The set X satisfies a *parity condition* $\kappa : (Q \times \Sigma) \rightarrow C$ for a finite $C \subseteq \mathbb{N}$ if $\min(\kappa(X))$ is even where $\kappa(X) = \{\kappa(q, a) : (q, a) \in X\}$. We call $\mathcal{R} = \{(E_1, F_1), \dots, (E_k, F_k)\}$ with $E_i, F_i \subseteq (Q \times \Sigma)$ a *Rabin condition* and it is satisfied if $E_i \cap X = \emptyset$ and $F_i \cap X \neq \emptyset$ for some $i \in [1, k] \subseteq \mathbb{N}$. Finally a *Muller condition* $\mathcal{F} \subseteq 2^{Q \times \Sigma}$ is satisfied if $X \in \mathcal{F}$. For an acceptance condition \mathcal{C} of type $\Omega \in \{\text{Parity, generalized Büchi, Rabin}\}$ we use $|\mathcal{C}|$ to refer to the number of priorities/recurring sets/Rabin pairs respectively. We use abbreviations (g)DBA, DPA, DRA to refer to deterministic (generalized) Büchi, Parity and Rabin automata and introduce a set Acc containing these acceptance types. An automaton $\mathcal{A} = \langle \mathcal{T}, \mathcal{C} \rangle$ accepts $w \in \Sigma^\omega$ if $\text{inf}(\rho)$ satisfies \mathcal{C} , where ρ refers to the unique run of \mathcal{T} on w . The set of all words that are accepted by \mathcal{A} is the language accepted by \mathcal{A} , denoted by $L(\mathcal{A})$.

Let \sim be an equivalence relation over Σ^* . We refer to the equivalence class of x under \sim as $[x]_\sim = \{y \in \Sigma^* : x \sim y\}$ and call \sim a (right) *congruence* if $u \sim v$ implies $ua \sim va$ for all $a \in \Sigma$. A regular language $L \subseteq \Sigma^\omega$ induces the *canonical right congruence* \sim_L in which $u \sim_L v$ holds if and only if $u^{-1}L = v^{-1}L$ with $u^{-1}L = \{w \in \Sigma^\omega : uw \in L\}$. Using the terminology of [3], we say that an automaton \mathcal{A} has an *informative right congruence* (IRC) if $u \sim_{L(\mathcal{A})} v$ implies that \mathcal{A} reaches the same state from q_0 when reading u or v . A language L has an Ω -IRC for $\Omega \in \text{Acc}$ if an Ω -automaton with an IRC which recognizes L exists and we denote by $\text{ind}(L)$ the number of equivalence classes of \sim_L .

A word $w \in \Sigma^\omega$ is called *ultimately periodic* if $w = uv^\omega$ with $u \in \Sigma^*, v \in \Sigma^+$. We denote by UP_Σ the set of all ultimately periodic words in Σ^ω and note that two regular languages $K, L \subseteq \Sigma^\omega$ are equal if and only if $K \cap \text{UP}_\Sigma = L \cap \text{UP}_\Sigma$ [7]. Note that there always exists a reduced form $w = uv^\omega$ in which u and v are as short as possible. We call a pair $S = (S_+, S_-)$ with $S_+, S_- \subseteq \text{UP}_\Sigma$ and $S_+ \cap S_- = \emptyset$ a *sample* and say that S is *in reduced form* if each $uv^\omega \in S$ is in a reduced form where $w \in S$ is used as a shorthand for $w \in S_+ \cup S_-$. For $L \subseteq \Sigma^\omega$ we say that S is consistent with L if $S_+ \subseteq L$ and $S_- \cap L = \emptyset$. Similarly an automaton \mathcal{A} is consistent with S if $S_+ \subseteq L(\mathcal{A})$ and $S_- \cap L(\mathcal{A}) = \emptyset$.

For $\Omega \in \text{Acc}$ we call a function f that maps a sample to an Ω -automaton a *passive learner*. f is called *consistent* if for any sample S the constructed automaton $f(S)$ is consistent with S . A sample S_L is *characteristic* for L and f if for any sample S that is consistent with L and that contains S_L , the learner produces an automaton $f(S)$ recognizing L . For a class of representations of languages \mathbb{C} (in our case deterministic ω -automata) we use $\mathcal{L}(\mathbb{C})$ to refer to the represented languages and define the size of $L \in \mathcal{L}(\mathbb{C})$ to be the size of the minimal representation of L in \mathbb{C} . Based on the definition in [10] we say \mathbb{C} is *learnable in the limit using polynomial time and data* if there exists a learner f that runs in polynomial time for any input sample, and for each $L \in \mathcal{L}(\mathbb{C})$ there exists a characteristic sample whose size is polynomial in the size of L .

We call $w \in \Sigma^\omega$ *escaping* from $p \in Q$ with $a \in \Sigma$ in \mathcal{T} if there exists a decomposition $w = uav$ with $v \in \Sigma^\omega$ such that $\delta^*(q_0, u) = p$ and $\delta(p, a) = \perp$. We refer to ua as the *escape-prefix* and call av the *exit string* of w . Two escaping words w_1, w_2 are *indistinguishable* if they escape \mathcal{T} from the same state and their exit strings coincide. We call \mathcal{T} Ω -*consistent* with a sample S if there exists an Ω -acceptance condition \mathcal{C} such that $\{w \in S_+ : w \text{ not escaping in } \mathcal{T}\} \subseteq$

$L(\mathcal{T}, \mathcal{C}), S_- \cap L(\mathcal{T}, \mathcal{C}) = \emptyset$ and no pair of sample words from $S_+ \times S_-$ is indistinguishable. Note that Ω -consistency with a transition system does not require all words from S_+ to have an infinite run in the transition system. It just means that \mathcal{T} does not produce any conflicts between words in S_+ and in S_- . In contrast, for an automaton to be considered consistent with S it is required that all words from S_+ are accepted.

3 Consistency Algorithms

The algorithm for learning ω -automata that we describe in Section 4 constructs a transition system and then tests whether an acceptance condition can be found such that all sample words are accepted and rejected accordingly. In this section we develop algorithms for this test, so we assume that a transition system $\mathcal{T} = (Q, \Sigma, q_0, \delta)$ is given. We do not work with the sample directly in this section, and rather work with the infinity sets induced by the sample words. This leads to the notion of a partial condition, which we define below. Then we investigate how different types of acceptance conditions that are consistent with such a partial condition can be constructed.

Recall that a Muller condition $\mathcal{F} \subseteq 2^{Q \times \Sigma}$ is satisfied by an infinity set $X \subseteq Q \times \Sigma$ if and only if $X \in \mathcal{F}$. Instead of specifying such a Muller condition based solely on the infinity sets that satisfy it, we can also define it as a partition $\mathcal{F} = (\mathcal{F}_0, \mathcal{F}_1)$ of $2^{Q \times \Sigma}$ into accepting and rejecting sets, in the following also referred to as positive and negative sets respectively. In other words such a condition assigns to each possible set $X \subseteq Q \times \Sigma$ a *classification* $\sigma \in \{0, 1\}$, which we denote as $\mathcal{F}(X) = \sigma$ for $X \in \mathcal{F}_\sigma$. Note that any acceptance condition \mathcal{C} can be viewed as a Muller condition $(\mathcal{F}_0^{\mathcal{C}}, \mathcal{F}_1^{\mathcal{C}})$ by assigning to $\mathcal{F}_0^{\mathcal{C}}$ exactly those sets $X \subseteq Q \times \Sigma$ that satisfy \mathcal{C} and defining $\mathcal{F}_1^{\mathcal{C}}$ to contain all others.

To incorporate the fact that the infinity sets induced by sample words might not classify all subsets of $Q \times \Sigma$, we introduce the concept of a *partial condition* $\mathcal{H} = (\mathcal{H}_0, \mathcal{H}_1)$ with $\mathcal{H}_0, \mathcal{H}_1 \subseteq 2^{Q \times \Sigma}$ in which only a subset of all elements $X \subseteq Q \times \Sigma$ receives a classification $\mathcal{H}(X) \in \{0, 1\}$. We use $X \in \mathcal{H}$ to denote $X \in \mathcal{H}_0 \cup \mathcal{H}_1$ and call a partial condition $\mathcal{H} = (\mathcal{H}_0, \mathcal{H}_1)$ *consistent* if $\mathcal{H}_0 \cap \mathcal{H}_1 = \emptyset$. A component \mathcal{H}_σ of a partial condition is called *union-closed* if for any finite collection $X_1, \dots, X_n \in \mathcal{H}_\sigma$ we have $X_1 \cup \dots \cup X_n \notin \mathcal{H}_{1-\sigma}$ or in other words the union of positive sets is not negative and vice versa. We call an acceptance condition \mathcal{C} *consistent with* a partial condition $\mathcal{H} = (\mathcal{H}_0, \mathcal{H}_1)$ if $\mathcal{H}_0 \subseteq \mathcal{F}_0^{\mathcal{C}}$ and $\mathcal{H}_1 \subseteq \mathcal{F}_1^{\mathcal{C}}$.

For each $\Omega \in \text{Acc}$ we can now define the decision problem Ω -CONSISTENCY: Given a transition system $\mathcal{T} = (Q, \Sigma, q_0, \delta)$ and a partial condition $\mathcal{H} = (\mathcal{H}_0, \mathcal{H}_1)$ with $\mathcal{H}_0, \mathcal{H}_1 \subseteq 2^{Q \times \Sigma}$, the question is whether there exists an acceptance condition \mathcal{C} of type Ω over $Q \times \Sigma$ that is consistent with \mathcal{H} . In the following we provide algorithms that decide Ω -CONSISTENCY for the various acceptance types we introduced and investigate their complexity.

Büchi and generalized Büchi conditions. For a Büchi condition $F \subseteq Q \times \Sigma$ we know that every superset of some $X \subseteq Q \times \Sigma$ with $X \cap F \neq \emptyset$ clearly has a non-empty intersection with F . Based on this observation we can define an algorithm that computes for a given partial condition $\mathcal{H} = (\mathcal{H}_0, \mathcal{H}_1)$ a Büchi condition F which is consistent with \mathcal{H} . We forego a formal definition of the algorithm itself and instead define the partial function it computes, where a result of \perp is used to indicate that no Büchi condition exists that is consistent with \mathcal{H} .

$$\text{BuchiCons}(\mathcal{H}_0, \mathcal{H}_1) = \begin{cases} \text{return } \perp & \text{if } P \in \mathcal{H}_0 \text{ exists with } P \subseteq \bigcup \mathcal{H}_1 \\ \text{return } (Q \times \Sigma) \setminus \bigcup \mathcal{H}_1 & \text{otherwise} \end{cases}$$

It is easily verified that BuchiCons is computable in polynomial time and a formal proof for the correctness of this algorithm can be found in the full version of this paper.

With generalized Büchi conditions it is no longer guaranteed that the union of two negative sets $N, N' \in \mathcal{H}_1$ is also negative. Consider a generalized Büchi condition $\mathcal{B} = \{F, F'\}$ such that N has a non-empty intersection with F but not with F' , whereas $N' \cap F = \emptyset$ and $N' \cap F' \neq \emptyset$. Then their union $F \cup F'$ has a non-empty intersection with both F and F' and hence satisfies \mathcal{B} . Therefore we first isolate the \subseteq -maximal sets N_1, \dots, N_k in \mathcal{H}_1 . As before we give a function

$$\text{genBuchiCons}(\mathcal{H}_0, \mathcal{H}_1) = \begin{cases} \text{return } \perp & \text{if } P \in \mathcal{H}_0 \text{ with } P \subseteq N_i \text{ exists} \\ \text{return } \{(Q \times \Sigma) \setminus N_i : i \leq k\} & \text{otherwise} \end{cases}$$

which maps a partial condition to a generalized Büchi condition that is consistent with \mathcal{H} or \perp if no such condition exists. It is again not difficult to see that an algorithm can compute genBuchiCons in polynomial time. A formal proof of the correctness of genBuchiCons can be found in the full version of this paper.

► **Theorem 1.** *The algorithm (*gen*)BuchiCons decides the (generalized) Büchi-CONSISTENCY problem in polynomial time and returns a corresponding acceptance condition if one exists.*

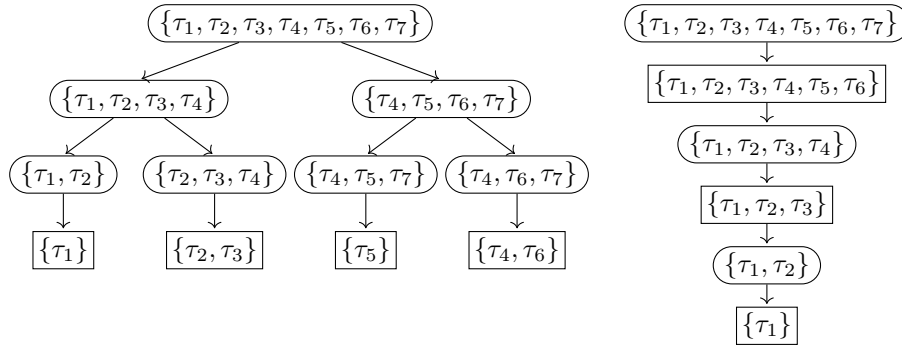

Parity Conditions. It is a well-known observation that for a given Muller condition $(\mathcal{F}_0, \mathcal{F}_1)$ there exists an equivalent parity condition κ if and only if \mathcal{F}_0 and \mathcal{F}_1 are union-closed [28]. We show an analogous statement for partial conditions, starting with the following lemma which establishes that if the union of positive and negative elements coincide, then no equivalent parity condition can be found.

► **Lemma 2.** *Let $\mathcal{H} = (\mathcal{H}_0, \mathcal{H}_1)$ be a consistent partial condition. If we have $P = N$ for $P = P_1 \cup \dots \cup P_k$ and $N = N_1 \cup \dots \cup N_l$ with $P_i \in \mathcal{H}_0$ and $N_j \in \mathcal{H}_1$ then there exists no parity condition that is consistent with \mathcal{H}*

It turns out that the opposite direction also holds, meaning if no such unions of positive and negative sets can be found, then an equivalent parity condition must exist. This implication arises as a consequence of the ParityCons algorithm we present later together with the proofs of its correctness. For a given partial condition ParityCons (see Algorithm 1) attempts to construct a chain of sets of transitions $Z_0 \supseteq Z_1 \supseteq \dots \supseteq Z_{n-1}$ with alternating classifications $\sigma_i \in \{0, 1\}$, i.e., $\sigma_{i+1} = 1 - \sigma_i$ for $i < n - 1$. We refer to this as a *Zielonka path* because it corresponds to the Split or Zielonka tree representation of a parity condition [28, 11].

From such a Zielonka path one obtains a parity condition κ where $\kappa(q, a) = \sigma_0 + i$ for the maximal i such that $(q, a) \in Z_i$. On the other hand every parity condition κ with priorities C determines a chain $Z_0 \supseteq Z_1 \supseteq \dots \supseteq Z_{|C|-1}$ and alternating classifications σ_i where $\sigma_0 = \min(C) \bmod 2$, $\sigma_{i+1} = 1 - \sigma_i$ and Z_i contains all state-symbol pairs whose color is greater or equal to $\sigma_0 + i$. To guarantee the existence of such an alternating chain, we assume that κ is optimal and contains no gaps, which can be ensured in polynomial time [9].

► **Example 3.** As an example consider a partial condition $\mathcal{H} = (\mathcal{H}_0, \mathcal{H}_1)$ with set inclusion diagram as shown on the left of Figure 1, where \mathcal{H}_0 contains the transition sets drawn with rounded border, and \mathcal{H}_1 those with rectangular border (the leaves of the tree, in this example). We assume an underlying transition system in which the transition sets in \mathcal{H} are strongly connected. It is easily verified that \mathcal{H} does not satisfy the condition of Lemma 2. Since we claimed the converse of Lemma 2 to be true, a parity condition that is consistent with \mathcal{H} should exist. It turns out that such a parity condition requires 6 distinct priorities (the corresponding Zielonka path is shown on the right of Figure 1) even though there is at most one alternation between positive and negative sets along inclusion chains in \mathcal{H} . This is due to the fact that more alternations are introduced by unions of positive and negative sets.

■ **Figure 1** On the left an inclusion graph for the partial condition \mathcal{H} from Example 3 can be seen in which positive elements are depicted with rounded and negative ones with rectangular borders. The path depicted on the right corresponds to a priority function κ with domain $\{0, 1, 2, 3, 4, 5\}$ such that $\tau_7 \mapsto 0, \tau_6 \mapsto 1, \tau_5 \mapsto 1, \tau_4 \mapsto 2, \tau_3 \mapsto 3, \tau_2 \mapsto 4, \tau_1 \mapsto 5$ which is the minimal parity condition that is consistent with \mathcal{H} .

We now present an algorithm that given a consistent partial condition \mathcal{H} over $Q \times \Sigma$ constructs an equivalent parity condition with the least number of distinct priorities if one exists. As a simplification we assume that the set $Q \times \Sigma$ of all transitions is classified by \mathcal{H} , which enables us to use $Q \times \Sigma$ as the first set Z_0 of the chain that is constructed. We describe later how partial conditions that do not satisfy this assumption can be dealt with.

■ **Algorithm 1** ParityCons.

Input: A consistent partial condition $\mathcal{H} = (\mathcal{H}_0, \mathcal{H}_1)$ with $Q \times \Sigma \in \mathcal{H}$

Output: A Zielonka path $(Z_0, \sigma_0), (Z_1, \sigma_1), \dots, (Z_{n-1}, \sigma_{n-1})$

$Z_0 \leftarrow Q \times \Sigma, \sigma_0 \leftarrow \mathcal{H}(Q \times \Sigma), i \leftarrow 0$

repeat

$i \leftarrow i + 1$

$Z \leftarrow \bigcup \{X \subseteq Z_{i-1} : \mathcal{H}(X) = 1 - \sigma_{i-1}\}$

if $Z = Z_{i-1}$ **then**

return *No consistent parity condition exists.*

$Z_i \leftarrow Z, \sigma_i \leftarrow 1 - \sigma_{i-1}$

until $Z = \emptyset$

return $(Z_0, \sigma_0), \dots, (Z_{i-1}, \sigma_{i-1})$

After Z_0 and its corresponding classification $\sigma_0 = \mathcal{H}(Z_0)$ have been determined, the algorithm computes Z_1 as the union of all $1 - \sigma_0$ subsets of Z_0 . If this union coincides with Z_0 then the conditions for Lemma 2 are met and the algorithm terminates prematurely as no equivalent parity condition can exist. Otherwise this construction ensures that every strict superset of Z_1 receives the same classification as Z_0 from the constructed parity condition. This process is then repeated for Z_1 with $\sigma_1 = 1 - \sigma_0$, Z_2 with $\sigma_2 = 1 - \sigma_1$ and so on until no subsets of opposite classification remain. At this point the algorithm terminates and returns the constructed chain of sets of transitions together with their corresponding classification.

Proving the correctness of this approach forms the opposite direction of Lemma 2 as it entails that if no union of positive and negative sets as in Lemma 2 is found, an equivalent parity condition can be constructed. One restriction on the partial conditions that can be passed to ParityCons is that the set of all transitions, $Q \times \Sigma$, must be present in either \mathcal{H}_0 or \mathcal{H}_1 . As these partial conditions arise from the infinity sets that words from a finite sample

induce, however, it is easily conceivable that there are many scenarios - for example when the automaton that we want to learn is made up of multiple SCCs - in which no word inducing $Q \times \Sigma$ exists. In this case we can simply define two extended partial conditions \mathcal{H}^p and \mathcal{H}^n in which $Q \times \Sigma$ is added as a positive or negative set respectively and execute `ParityCons` separately for each of them. If only one computation results in a Zielonka path we are done, otherwise the two resulting paths are compared with regard to their length and the longer one is discarded.

► **Theorem 4.** *ParityCons decides Parity-CONSISTENCY in polynomial time and returns a corresponding parity condition with a minimal number of priorities if one exists.*

Proof (sketch). We proceed in two steps and first show that the classification obtained by the Zielonka path computed by `ParityCons` are indeed consistent with the original partial condition. Subsequently one shows that if the computation exits prematurely, then there exist positive and negative sets whose unions coincide, which by Lemma 2 means that no equivalent parity condition exists. ◀

Rabin Conditions. We now turn towards computing an equivalent Rabin condition based on a given partial condition, for which we again utilize an observation about union-closedness. Specifically, a Muller condition is equivalent to a Rabin condition if and only if \mathcal{F}_1 is union-closed [28]. The algorithm `RabinCons` (see Algorithm 2) computes for each positive set P in \mathcal{H} a separate Rabin pair (E_P, F_P) in which each transition that is not part of P belongs to E_P and every transition which does not occur in a negative subloop of P belongs to F_P . In case a positive loop is equal to the union of its maximal negative subloops, no equivalent Rabin condition can be found as the condition on union-closedness outlined above is violated.

■ **Algorithm 2** `RabinCons`.

Input: A consistent partial condition $\mathcal{H} = (\mathcal{H}_0, \mathcal{H}_1)$
Output: A Rabin condition \mathcal{R} consistent with \mathcal{H}
 $\mathcal{R} \leftarrow \emptyset$
foreach $P \in \mathcal{H}_0$ **do**
 $N_1, \dots, N_k \leftarrow$ maximal sets in $\mathcal{P}(P) \cap \mathcal{H}_1$
 $E_P \leftarrow (Q \times \Sigma) \setminus P$
 $F_P \leftarrow P \setminus (N_1 \cup \dots \cup N_k)$
 if $F_P = \emptyset$ **then**
 | **return** *No consistent Rabin condition exists*
 $\mathcal{R} \leftarrow \mathcal{R} \cup \{(E_P, F_P)\}$
return \mathcal{R}

► **Theorem 5.** *The algorithm RabinCons decides Rabin-CONSISTENCY in polynomial time and returns a corresponding Rabin condition if one exists.*

A Rabin condition produced by `RabinCons` has $|\mathcal{H}_0|$ pairs and is not guaranteed to have the minimal number of pairs. Even though it is possible to find optimizations which might make use of the underlying structure with regard to strongly connected components and subset relations between positive and negative loops, we now illustrate why the computation of an optimal Rabin condition (with a minimal number of pairs) is NP-hard.

■ **Figure 2** This figure contains a depiction of the transition system $\mathcal{T}_{\mathcal{G}}$, which can be used to show NP-completeness of k -generalized Büchi-CONSISTENCY and k -Rabin-CONSISTENCY.

Fixed-size consistency. For each acceptance type $\Omega \in \{\text{generalized Büchi, Parity, Rabin}\}$ and every natural number $k \in \mathbb{N}$ we define the decision problem k - Ω -CONSISTENCY: Given a transition system \mathcal{T} and a consistent partial condition \mathcal{H} the question is whether there is an acceptance condition \mathcal{C} of type Ω in \mathcal{T} which is consistent with \mathcal{H} such that $|\mathcal{C}| \leq k$. The algorithm `ParityCons` we provided earlier decides k -Parity-CONSISTENCY in polynomial time, however finding a Rabin or generalized Büchi condition of bounded size turns out to be much more difficult.

Intuitively, the difficulty in finding an optimal generalized Büchi condition with at most k components arises from the fact that the union of two negative sets is not necessarily guaranteed to also be negative. As there are in general exponentially many possible ways of partitioning the transitions into k sets, a procedure for constructing an optimal generalized Büchi condition would need to consider all of them. In the following we establish that the fixed-size consistency problem for generalized Büchi conditions is already NP-complete when $k = 3$. This is done by giving a reduction from 3-Coloring for directed graphs, which is known to be NP-complete [14].

► **Lemma 6.** *3-generalized Büchi-CONSISTENCY is NP-complete.*

Proof. Let $\mathcal{G} = (V, E)$ be a finite directed graph with $V = \{v_1, v_2, \dots, v_n\}$. We define the deterministic partial transition system

$$\mathcal{T}_{\mathcal{G}} = (\{0, 1, 2, \dots, n\}, \{1, 2, \dots, n\}, 0, \delta) \text{ with } \delta(q, a) = \begin{cases} a & \text{if } q = 0 \\ 0 & \text{if } q = a \\ \perp & \text{otherwise} \end{cases}$$

which is depicted in Figure 2. Note that it is possible to construct an equivalent transition system over a binary alphabet $\Sigma' = \{a, b\}$ by encoding $i \in \Sigma$ as $a^i b$. Thus our choice of Σ depending on the size of the graph merely serves to simplify notation in the following. We define a sample $S_{\mathcal{G}} = (P_{\mathcal{G}}, N_{\mathcal{G}})$ with

$$P_{\mathcal{G}} = \{p_{ij} : (v_i, v_j) \in E\} \text{ and } N_{\mathcal{G}} = \{n_i : 0 < i \leq n\} \text{ where } p_{ij} = (iij)^\omega, n_i = i^\omega$$

In the following we use \bar{p}_{ij} and \bar{n}_i to refer to the infinity set of the unique run of $\mathcal{T}_{\mathcal{G}}$ on p_{ij} and n_i respectively. Let $c : V \rightarrow \{1, 2, 3\}$ be a 3-coloring for V such that $c(v_i) \neq c(v_j)$ for all $(v_i, v_j) \in E$. We construct a generalized Büchi condition $\mathcal{B}_{\mathcal{G}} = (F_1, F_2, F_3)$ with $F_k = \{i : c(v_i) \neq k\}$, witnessing membership in 3-generalized Büchi-CONSISTENCY. For all $i \leq n$ we have for $k = c(v_i)$ that $\bar{n}_i \cap F_k = \{0, i\} \cap F_k = \emptyset$ and thus $n_i \notin L(\mathcal{T}, \mathcal{B}_{\mathcal{G}})$. On the other hand $\bar{p}_{ij} \cap F_k = \{0, i, j\} \cap F_k \neq \emptyset$ for all k as $c(v_i) \neq c(v_j)$ is guaranteed for all $(v_i, v_j) \in E$ by the coloring function c . Hence $p_{ij} \in L(\mathcal{T}, \mathcal{B}_{\mathcal{G}})$ and the constructed condition is indeed consistent with the sample.

20:10 Constructing Deterministic ω -Automata from Examples

For the other direction assume that there exists a generalized Büchi condition $\mathcal{B} = (F_1, F_2, F_3)$ such that $\langle \mathcal{T}, \mathcal{B} \rangle$ is consistent with S . Clearly it must hold that $F_1 \cap F_2 \cap F_3 = \emptyset$ as otherwise there would exist some word $n_i \in N_{\mathcal{G}}$ with $\bar{n}_i \cap F_k = \{0, i\} \cap F_k \neq \emptyset$ for all k , which would contradict consistency with S . We can now define a coloring $c : V \rightarrow \{1, 2, 3\}$ with $c(v_i) = \min\{k : i \notin F_k\}$. For any $v_i, v_j \in V$ with $c(v_i) = c(v_j) = k$ we have $(v_i, v_j) \notin E$. If not then there would exist a word $p_{ij} \in P_{\mathcal{G}}$ for which consistency guarantees that $\bar{p}_{ij} \cap F_k = \{0, i, j\} \cap F_k \neq \emptyset$, which can only hold if v_i and v_j are assigned different colors. Thus c is indeed a valid 3-coloring, which concludes the reduction proof.

Membership in NP holds as it is possible to verify for a guessed generalized Büchi condition \mathcal{B} of size 3 whether $\langle \mathcal{T}, \mathcal{B} \rangle$ is consistent with S in polynomial time by iterating over all $w \in P_{\mathcal{G}} \cup N_{\mathcal{G}}$ and verifying adequate acceptance/rejection by $\langle \mathcal{T}, \mathcal{B} \rangle$. ◀

A similar reduction can be used to show the NP-hardness of k -Rabin-CONSISTENCY as well. This leads to the following theorem, which establishes the complexity of all fixed-size consistency decision problems we defined above.

► **Theorem 7.** *k -Parity-CONSISTENCY is solvable in polynomial time. For $k > 2$ both k -generalized Büchi-CONSISTENCY and k -Rabin-CONSISTENCY are NP-complete.*

4 Passive learning

Our procedure for the construction of a deterministic partial transition system is inspired by the well known regular positive negative inference (RPNI) algorithm through which deterministic finite automata can be constructed [21]. RPNI first constructs a prefix tree automaton which accepts precisely the positive sample words from S_+ and subsequently attempts to merge states of this automaton in canonical order. If a merge introduces an inconsistency with the sample (i.e. the resulting automaton accepts a word in S_-) it is reverted. Otherwise the algorithm continues with the resulting automaton until no further merges are possible at which point it terminates.

When attempting to transfer this principle to infinite words, it is difficult to find a suitable counterpart for the prefix tree automaton. If we simply attached disjoint loops to the prefix tree at a certain depth, the resulting transition system could certainly be equipped with an acceptance condition such that it accepts precisely S_+ . However, through the introduction of loops with a fixed length that cannot be resolved during the execution, we already determine parts of the structure of the resulting automaton. Instead, we start with a transition system consisting of a single initial state and attempt to introduce new transitions in a specific order (which is reminiscent of the algorithm presented in [6]).

The resulting algorithm **Sprout** is shown in Algorithm 3. In each iteration we begin by computing $\text{Escapes}(S_+, \mathcal{T})$, the set of all prefixes of words in S_+ which are escaping in \mathcal{T} . From this set we now determine the word with the minimal escape-prefix ua in length-lexicographic order. The existing states are then tested as a target for the missing transition in canonical order and if the resulting transition system is Ω -consistent with the sample, we continue with the next escaping word. Checking for consistency is done by using the results from Section 3 and ensuring that no pair of indistinguishable words in $S_+ \times S_-$ exists, both of which are possible in polynomial time. If no suitable target can be found, a new state is introduced instead. See Figure 3 for an illustration. Note that the order in which states are checked as a potential transition target coincides with the order in which merges are attempted in RPNI.

■ **Algorithm 3** Sprout.

Input: A Sample $S = (S_+, S_-)$ over the alphabet Σ and an acceptance type $\Omega \in \text{Acc}$
Output: The deterministic Ω -automaton $\mathcal{A} = (Q, \Sigma, q_0, \delta, \mathcal{C})$ consistent with S
 $Q \leftarrow \{\varepsilon\}$, $\delta \leftarrow \emptyset$, $\mathcal{T} \leftarrow (Q, \Sigma, \varepsilon, \delta)$
while $\text{Escapes}(S_+, \mathcal{T}) \neq \emptyset$ **do**
 $ua \leftarrow$ length-lexicographic minimal escape-prefix of a word in S_+
 if $|u| > \text{Thres}(S, \mathcal{T})$ **then**

 forall $q \in Q$ *in canonical order* **do**
 | $\delta' \leftarrow \delta \cup \{\hat{u} \xrightarrow{a} q\}$ for the $\hat{u} \in Q$ with $\delta^*(\varepsilon, u) = \hat{u}$
 | **if** $(Q, \Sigma, \varepsilon, \delta')$ *is Ω -consistent with S* **then**
 | $\delta \leftarrow \delta'$ and **continue** with the next escaping word
 $Q \leftarrow Q \cup \{\hat{u}a\}$, $\delta \leftarrow \delta \cup \{\hat{u} \xrightarrow{a} \hat{u}a\}$ for the $\hat{u} \in Q$ with $\delta^*(\varepsilon, u) = \hat{u}$
return $\text{Aut}(\mathcal{T}, S, \Omega)$

Unfortunately there exist samples for which this approach of introducing transitions does not terminate. When executed on $S = (\{(baa)^\omega\}, \{(ab)^\omega, (ba)^\omega, (babaa)^\omega\})$ for example, the algorithm would not terminate and instead construct an infinite b -chain with a -loops on each state. We therefore introduce a threshold on the maximal length of escape-prefixes that are considered in the algorithm. Once this threshold is exceeded, the algorithm terminates. We have chosen the threshold such that we can show completeness for IRC, which works for $\text{Thres}(S, \mathcal{T}) = l_b + l_e^2 + 1$, where l_e and l_b denote the maximal length of u and v for any sample word $uv^\omega \in S$. Intuitively, this value is sufficient to obtain completeness for IRC as any two sample words must have already differed in at least one position once it is exceeded.

If the threshold is exceeded before a transition system is found that is consistent with the sample and has no escaping words from S_+ , the transition system is extended with disjoint loops that guarantee acceptance of the remaining words in S_+ through the function Extend , which we describe in the following. Assume that the algorithm has constructed a transition system $\mathcal{T} = (Q, \Sigma, \varepsilon, \delta)$ for which it then encounters an escape-prefix exceeding the defined threshold. For each state $q \in Q$ we collect all exit strings that leave \mathcal{T} from q in a set E_q . Note that since the shortest escape-prefix in \mathcal{T} exceeded the threshold, each word in E_q must be of the form u^ω for some $u \in \Sigma^+$ and we can write $E_q = \{u_1^\omega, \dots, u_k^\omega\}$.

For each state q such that $E_q \neq \emptyset$ we now construct the transition system $\mathcal{T}_{E_q}^\circ$ in which exactly those words that belong to E_q induce loops. To prevent any unintended words from being accepted, we additionally ensure that the initial state of $\mathcal{T}_{E_q}^\circ$ is transient (meaning it cannot be reached from any state within $\mathcal{T}_{E_q}^\circ$). In the following we use $\text{Prf}(u)$ for a word $u \in \Sigma^*$ to denote the set of all prefixes of u . Formally we define $\mathcal{T}_{E_q}^\circ = (Q_{E_q}^\circ, \Sigma, q_0, \delta_{E_q}^\circ)$ with

$$Q_{E_q}^\circ = \{q_0\} \cup \bigcup_{u^\omega \in E_q} \text{Prf}(u)$$

$$\delta_{E_q}^\circ(w, a) = \begin{cases} a & \text{if } w = q_0 \text{ and } a \in \Sigma \cap Q_{E_q}^\circ \\ \varepsilon & \text{if } (wa)^\omega \in E_q \\ wa & \text{if } wa \in Q_{E_q}^\circ \text{ and } (wa)^\omega \notin E_q \\ \perp & \text{otherwise} \end{cases}$$

It is easy to see that q_0 is indeed transient in $\mathcal{T}_{E_q}^\circ$ and we can clearly find a Büchi (and thus also a generalized Büchi, Rabin and Parity) condition such that every word in E_q induces an accepting run in $\mathcal{T}_{E_q}^\circ$. By attaching the corresponding $\mathcal{T}_{E_q}^\circ$ to each state q for which E_q is non-empty, we obtain a transition system in which no word from S_+ is escaping.

20:12 Constructing Deterministic ω -Automata from Examples

■ **Figure 3** In this figure three transition systems that arise during the execution of `Sprout` on the sample $S = (S_+, S_-)$ are depicted. The dashed transition cannot lead to ε as otherwise the union of the infinity sets of $(ba)^\omega$ and $(bba)^\omega$ would coincide with that of $(bbbabbaba)^\omega$ and thus no consistent parity condition exists. Similarly a self-loop on b would mean that the infinity sets induced by $(babb)^\omega$ and $(bba)^\omega$ would coincide. Thus the b -transition must lead to a new state bb . On the right we can see the DPA obtained by augmenting \mathcal{T}_3 with the parity function computed by `ParityCons` on the partial condition induced by S .

Once the main loop terminates, the function `Aut` is called, which uses the results from Section 3 to compute an automaton that is Ω -consistent with S , which is then returned.

► **Proposition 8.** *For a given sample S and an acceptance type $\Omega \in \text{Acc}$ the algorithm `Sprout` computes in polynomial time an automaton of type Ω that is consistent with S .*

While `Sprout` cannot learn all regular ω -languages in the limit (see Proposition 10), we can show completeness for languages with an IRC.

► **Theorem 9.** *The algorithm `Sprout` learns every Ω -IRC language L for $\Omega \in \text{Acc}$ in the limit with polynomial time and data.*

Proof (sketch). We describe the properties that a sample $S = (S_+, S_-)$ has to satisfy in order to be *characteristic* for an Ω -IRC language L :

- The set of prefixes of S_+ has to contain for each \sim_L equivalence class the minimal word in length-lexicographic order on which it is reached.
- Further the sample needs to contain words with which all pairs of equivalence classes can be separated.
- Finally S needs to contain sufficient information about the acceptance condition of an automaton recognizing L .

The first two requirements can be satisfied in a similar way as for the original RPNI algorithm [21]. For parity conditions this has already been investigated in [4]. Below we give a description for Rabin conditions. Detailed definitions for the remaining types of acceptance conditions we introduced can be found in the full version of this paper.

A sample $S_{\mathcal{R}} = (S_+, S_-)$ capturing a Rabin condition \mathcal{R} can be obtained as follows: For each pair (E_i, F_i) we remove all transitions in E_i from the transition system that \mathcal{R} is defined in, decompose the result into its SCCs C_1, \dots, C_k and compute sets K_i consisting of all transitions in C_i . If the set of all transitions K_i in such an SCC satisfies \mathcal{R} we add a word w_i inducing K_i to S_+ , otherwise w_i is added to S_- . For each accepting K_i we then remove all transitions in an F_j for which $K_i \cap E_j = \emptyset$, and decompose the resulting transition system into its SCCs D_1, \dots, D_l . These are the maximal negative subloops of K_i and for each D_j a word visiting all transitions in D_j is added to S_- . ◀

While every Ω -IRC language can be learned through a characteristic sample, the same does not hold for arbitrary ω -regular languages as the following proposition establishes.

■ **Figure 4** In this figure an excerpt of the transition system for the proof of Proposition 10 is depicted. The transition from q_n to q_j forms a closed loop and words $w_1 \in L_\vee, w_2 \notin L_\vee$ which induce the same infinity set can be found. Based on the existence of these words we can conclude that **Sprout** constructs a chain with self-loops on each state when attempting to learn an automaton recognizing L_\vee .

► **Proposition 10.** *The language $L_\vee = \{w \in \{a, b\}^\omega : aaaa \text{ occurs infinitely often in } w \text{ or } bbbb \text{ occurs infinitely often in } w\}$ cannot be learned by **Sprout**.*

Proof. To simplify notation, we exchange the alphabet and use $\Sigma = \{0, 1\}$ instead, as it allows arithmetic on the symbols in Σ . We prove this claim by showing through induction that the transition system constructed by **Sprout** must be a chain with loops on each state. Specifically we show that every intermediate transition system $\mathcal{T} = (Q, \Sigma, q_0, \delta)$ with $Q = \{q_0, q_1, \dots, q_n\}$ created by **Sprout** before the threshold is exceeded is either not Ω -consistent with L_\vee for any $\Omega \in \text{Acc}$ or the following holds:

- for each $i < n$ there exists a symbol $\sigma \in \Sigma$ such that $\delta(q_i, \sigma) = q_i$ and $\delta(q_i, 1 - \sigma) = q_{i+1}$
- if q_n has an outgoing transition on some $\sigma \in \Sigma$ then $\delta(q_n, \sigma) = q_n$ and $\delta(q_n, 1 - \sigma) = \perp$

The initial transition system is clearly Ω -consistent with L_\vee for all $\Omega \in \text{Acc}$. Further it trivially satisfies the two outlined conditions as it has only one state, for which no outgoing transitions exist. For the induction step assume that **Sprout** has constructed a transition system $\mathcal{T} = (Q, \Sigma, q_0, \delta)$ with $Q = \{q_0, q_1, \dots, q_n\}$ for which the claim holds. We now show that the next inserted transition either introduces an inconsistency with L_\vee or it leads to a transition system that also satisfies the two conditions.

If a transition from q_n to some q_j with $j < n$ were inserted, then a closed cycle is formed. As q_j is reachable there must exist some word $u \in \Sigma^*$ such that $\delta^*(q_0, u) = q_j$. Consider now the word $v \in \Sigma^*$ such that $\delta^*(q_j, v) = q_j$ and the letters in v are such that they alternate between taking the self-loop and moving to the next state along the cycle. If the loop on q_n does not exist, then v just transitions back to q_j at this point. As can be seen in Figure 4, no alphabet symbol can occur more than once in a row in v if the dashed self-loop on q_n is present. Otherwise at most three consecutive occurrences of the same symbol can appear in v and we clearly have that $w_1 = uv^\omega \notin L_\vee$. Consider now a word w_2 which takes each self-loop on the cycle four times before moving to the next state. This means $w_2 \in L_\vee$ but because the infinity sets induced by w_1 and w_2 coincide (as both words take all possible transitions infinitely often), an automaton containing such a closed cycle cannot be consistent with L_\vee .

We have thus shown that no transition can lead from q_n back to a state q_j with $j < n$. If q_n has no outgoing transitions, then a self-loop on the currently escaping symbol is inserted as it clearly does not introduce an inconsistency. On the other hand if q_n already has a self-loop on some symbol $\sigma \in \Sigma$, then the transition on $1 - \sigma$ must lead to a new state q_{n+1} as otherwise $(ab)^\omega \notin L_\vee$ and $(aabb)^\omega \in L_\vee$ would induce the same infinity set. Thus the **Sprout** algorithm indeed constructs a chain with self-loops until it eventually exceeds the threshold. Once this happens, the transition system is extended such that it accepts precisely the positive sample words. As the sample is finite, the resulting automaton cannot recognize L_\vee since there will always be some word $w \in L_\vee$ that is not present in the sample. ◀

However on the other hand **Sprout** is not limited to learning automata for languages with IRC of some type. In the following proposition we give an infinite family of languages which are not in Ω -IRC for any $\Omega \in \text{Acc}$, and have polynomial size characteristic samples for **Sprout**.

► **Proposition 11.** *For $i > 1$, consider $L_i = (\Sigma^*b^i)^\omega$ and the sample $S^i = (S_+^i, S_-^i)$ with $S_+^i = \{b^\omega, (b^i a b^{i-1} a \dots b^2 a b^1 a)^\omega\} \cup \{(b^j a b^k)^\omega : j + k = i\}$ and $S_-^i = \{(b^j a)^\omega : j < i\}$. Then S^i is a characteristic sample for L_i and the learner **Sprout** with parity as target condition. (The sample for $i = 3$ is used in the example in Figure 3.)*

Proof. In the following we show that **Sprout** constructs a DPA for the language L_i from the characteristic sample S^i . Note first that the exit-strings of any two sample words are distinct for every transition system constructed by **Sprout**, since all words in S^i consist of only a periodic part. Further in every word $v^\omega \in S_+^i$ the infix b^i occurs, which means that an infinite run on any positive sample word is only possible in a transition system that permits i consecutive transitions on the symbol b .

Initially, the algorithm inserts a self-loop on a as no sample words prevent this. Subsequently the b -transition cannot be a self-loop as otherwise the infinity sets induced by positive and negative sample words would coincide. Thus a new state is added to which the b -transition from ε leads. We now proceed inductively to show that a b -chain of length $i - 1$ with a -transitions leading back to the initial state is created. We will identify each state on this chain with the minimal word of the form b^j that reaches it.

Formally such a chain satisfies that for all $j < i$ we have $\delta^*(\varepsilon, b^j) = b^j$ and $\delta^*(\varepsilon, b^k a) = \varepsilon$ for all $k < j$. The base case for $j = 1$ has already been described above so assume now that the statement holds for $j - 1$ and consider the two transitions that **Sprout** inserts for the state b^{j-1} . We see that inserting an a -transition from b^{j-1} to ε does not introduce an inconsistency. This is because as outlined above no positive sample word induces an infinite run and the exit string of any two sample words must be distinct.

It remains to be shown that the b -transition from b^{j-1} must lead to a new state b^j . To see this assume to the contrary that the introduction of a b -transition from b^{j-1} to some b^l with $l < j$ leads to a transition system \mathcal{T}' which is Parity-consistent with S^i . It is not hard to see that the infinity set P induced by the positive sample word $(b^i a b^{i-1} \dots b^1 a)^\omega$ contains all transitions in \mathcal{T}' . Now let N_0, N_1, \dots, N_j be the infinity sets induced by the negative sample words $a^\omega, (ba)^\omega, \dots, (b^j a)^\omega$. It is easily verified that $P = N_0 \cup N_1 \cup \dots \cup N_j$, thus satisfying the conditions for Lemma 2. This means that \mathcal{T}' cannot be Parity-consistent with S^i and hence no b -transition from b^{j-1} to any b^l with $l < j$ is kept.

Once this b -chain of length $i - 1$ is constructed, we simply need to verify that inserting both the a - and b -transition from b^{i-1} to ε does not lead to an inconsistent transition system. Since only positive sample words contain i consecutive occurrences of b , the b -transition from b^{i-1} to ε occurs exclusively in the infinity set induced by positive but not negative words. Thus a consistent parity condition exists and **Sprout** constructs a DPA recognizing L_i . ◀

5 Active Learning

We consider the standard minimal adequate teacher (MAT) active learning scenario [1], in which the learning algorithm has access to a teacher that can answer membership queries and equivalence queries for the target language, and returns a counterexample if the automaton for an equivalence query is not correct. A natural extension to ω -automata considers membership queries for ultimately periodic words and equivalence queries with ultimately periodic words as counterexamples (see [16]).

Since there is a polynomial time active learning algorithm for deterministic weak automata [16], a natural next candidate for polynomial time active learning are deterministic automata with an informative right congruence. However, the theorem below basically shows that this class is as hard for active learning as general regular ω -languages.

► **Theorem 12.** *Let $\Omega \in \text{Acc}$ be an acceptance type, and consider the active learning setting with membership and equivalence queries for ultimately periodic words. There is a polynomial time active learning algorithm for deterministic automata of type Ω with informative right congruence if, and only if, there is a polynomial time active learning algorithm for general deterministic automata of type Ω .*

Proof (sketch). Assume that AL_{IRC} is an active learning algorithm for automata with informative right congruence of type Ω . The arguments used below work for all acceptance types $\Omega \in \text{Acc}$. For simplicity we use the parity condition in the following.

Our goal is to use AL_{IRC} in order to define an active learning algorithm AL for general DPA that runs in polynomial time if AL_{IRC} does. The rough idea is as follows: We have to learn an automaton \mathcal{A} for a target language $L \subseteq \Sigma^\omega$ that does not have an IRC, in general. Such an automaton \mathcal{A} can be turned into an automaton with IRC by adding new letters to the alphabet, and then extending the automaton such that from each state a different word over these new letters is accepted. Restricted to the original alphabet, this extended automaton still accepts the same language as before. Since the new automaton has an IRC, we can use AL_{IRC} to learn it. The only problem with this approach is that we do not know the target automaton \mathcal{A} , so we cannot simply extend it and let AL_{IRC} learn the extension. However, we can simulate a teacher for AL_{IRC} that answers queries of AL_{IRC} such that these answers are consistent with such an extension of \mathcal{A} . We give the answers such that they only reveal information on the original target language L . Hence, AL_{IRC} first has to learn, in some sense, an automaton for L in order to obtain information on the newly added letters in the extension.

More formally, define an extended alphabet $\Sigma_\star = \Sigma \dot{\cup} \{\star, 0, 1\}$ with new letters $\star, 0, 1$ that do not occur in Σ . Now let $L \subseteq \Sigma^\omega$ be a target language which we want to learn. Our algorithm AL simulates AL_{IRC} over the alphabet Σ_\star . Note that AL has access to a teacher T that answers queries for the language L over the alphabet Σ . We define a teacher T_{IRC} that answers queries that are asked by AL_{IRC} during its simulation as follows:

- *Membership query for a word $w = uv^\omega$:* If none of the newly introduced symbols occur in w , i.e. $w \in \Sigma^\omega$ then we simply copy the answer $T(w)$. Otherwise w must contain $0, 1$ or \star in which case T_{IRC} always gives a negative answer.
- *Equivalence query for an automaton \mathcal{A} :* We construct a new automaton \mathcal{B} by removing from \mathcal{A} all transitions on symbols $0, 1$ or \star and pruning any unreachable states. \mathcal{B} is then given to T for an equivalence query. If $T(\mathcal{B})$ returns a counterexample w , then this is used as the result of $T_{IRC}(\mathcal{A})$.

Otherwise the automaton \mathcal{B} must recognize the target language L . In this case, the simulation of AL_{IRC} is stopped, and our algorithm AL returns \mathcal{B} .

It can be shown that this algorithm AL learns the target language L in polynomial time if AL_{IRC} is a polynomial time algorithm. ◀

So the property of an IRC does not help for active learning, while for passive learning in the limit it seems to make the problem simpler. We finish this section with the observation that polynomial time active learning is at least as hard as learning in the limit with polynomial time and data, given that the class \mathcal{K} of target automata satisfies the following properties (which are satisfied by standard classes of deterministic automata):

20:16 Constructing Deterministic ω -Automata from Examples

- (P1) It is decidable in polynomial time if a given word is accepted by a given automaton from \mathcal{K} .
- (P2) For a given sample S , one can construct in polynomial time an automaton from \mathcal{K} that is consistent with S .
- (P3) If two automata from \mathcal{K} are not equivalent, then there exists a word of polynomial size witnessing the difference.

► **Proposition 13.** *Consider a class \mathcal{K} of finite automata for which properties (P1)–(P3) are satisfied. If there is a polynomial time active learning algorithm for \mathcal{K} , then \mathcal{K} can be learned in the limit with polynomial time and data.*

Proof (sketch). Assume that there is a polynomial time active learning algorithm $AL_{\mathcal{K}}$ for target automata from \mathcal{K} . A passive learner can simulate an execution of $AL_{\mathcal{K}}$ in which equivalence queries are always answered with the smallest counterexample. A characteristic sample can be constructed from all the words that are used in such an execution of $AL_{\mathcal{K}}$. ◀

6 Conclusion

We have presented polynomial time algorithms for checking the consistency of a (partial) deterministic transition system with a set of positive and negative ultimately periodic words for the acceptance conditions Büchi, generalized Büchi, parity, and Rabin. Since co-Büchi and Streett conditions are dual to Büchi and Rabin conditions, respectively, one also obtains algorithms for these conditions by flipping negative and positive examples.

The consistency algorithms allow us to extend the principle of the RPNI algorithm from finite to infinite words, leading to the polynomial time algorithm **Sprout** that constructs a deterministic ω -automaton from given ultimately periodic examples. We have shown that **Sprout** can learn deterministic automata for languages with an IRC in the limit with polynomial time and data. While **Sprout** is not restricted to IRC languages, there are regular ω -languages which it cannot learn. It is obviously an interesting open question whether there is an algorithm that learns deterministic automata for general regular ω -languages with polynomial time and data. Our results in Section 5 show that finding such an algorithm is not more difficult than finding an active learning algorithm that learns deterministic automata for IRC languages from membership and equivalence queries.

Abstract

We initiate the study of computational complexity of graph coverings, aka locally bijective graph homomorphisms, for *graphs with semi-edges*. The notion of graph covering is a discretization of coverings between surfaces or topological spaces, a notion well known and deeply studied in classical topology. Graph covers have found applications in discrete mathematics for constructing highly symmetric graphs, and in computer science in the theory of local computations. In 1991, Abello et al. asked for a classification of the computational complexity of deciding if an input graph covers a fixed target graph, in the ordinary setting (of graphs with only edges). Although many general results are known, the full classification is still open. In spite of that, we propose to study the more general case of covering graphs composed of normal edges (including multiedges and loops) and so-called semi-edges. Semi-edges are becoming increasingly popular in modern topological graph theory, as well as in mathematical physics. They also naturally occur in the local computation setting, since they are lifted to matchings in the covering graph. We show that the presence of semi-edges makes the covering problem considerably harder; e.g., it is no longer sufficient to specify the vertex mapping induced by the covering, but one necessarily has to deal with the edge mapping as well. We show some solvable cases and, in particular, completely characterize the complexity of the already very nontrivial problem of covering one- and two-vertex (multi)graphs with semi-edges. Our NP-hardness results are proven for simple input graphs, and in the case of regular two-vertex target graphs, even for bipartite ones. We remark that our new characterization results also strengthen previously known results for covering graphs without semi-edges, and they in turn apply to an infinite class of simple target graphs with at most two vertices of degree more than two. Some of the results are moreover proven in a more general setting (e.g., finding k -tuples of pairwise disjoint perfect matchings in regular graphs, or finding equitable partitions of regular bipartite graphs).

1 Introduction

1.1 Graph coverings and complexity

The notion of a *graph covering* is a discretization of coverings between surfaces or topological spaces, a notion well known and deeply studied in classical topology. Graph coverings have found many applications. Primarily as a tool for construction of highly symmetric graphs [5, 15, 24, 27], or for embedding complete graphs in surfaces of higher genus [48].

Graph coverings attracted attention of computer scientists as well. Angluin [2] exploited graph covers when introducing models of local computations, namely by showing that a graph and its cover cannot be distinguished by local computations. Later, Litovsky et al. [39] proved that planar graphs and series-parallel graphs cannot be recognized by local computations, and Courcelle and Metivier [14] showed that in fact no nontrivial minor-closed class of graphs can. In both of these results, graph coverings were used as the main tool, as well as in more recent papers of Chalopin et al. [8, 9]. Here, the authors presented a model for distributed computations and addressed the algorithmic complexity of problems associated with such a model. To this end, they used the existing results on NP-completeness of the covering problem to provide their hardness results. In [10], the authors study a close relation of packing bipartite graphs to a special variant of graph coverings called *pseudo-coverings*.

Another connection to algorithmic theory comes through the notions of the *degree partition* and the *degree refinement matrix* of a graph. These notions were introduced by Corneill [12, 13] in hope of solving the graph isomorphism problem efficiently. It can be easily seen that a graph and all of its covers have the same degree refinement matrix. Motivated by this observation, Angluin and Gardiner [3] proved that any two finite regular graphs of the same valency have a finite common cover, and conjectured the same for every two finite graphs with the same degree refinement matrix, which was proved by Leighton [37].

The stress on finiteness of the common cover is natural. For every matrix, there exists a universal cover, an infinite tree, that covers all graphs with this degree refinement matrix. Trees are planar graphs, and this inspired an at first sight innocent question of which graphs allow a finite planar cover. Negami observed that projective planar graphs do (in fact, their double planar covers characterize their projective embedding), and conjectured that these two classes actually coincide [46]. Despite a serious effort of numerous authors, the problem is still open, although the scope for possible failure of Negami's conjecture has been significantly reduced [4, 28, 29].

A natural computational complexity question is how difficult is to decide, given two graphs, if one covers the other one. This question is obviously at least as difficult as the graph isomorphism problem (consider two given graphs on the same number of vertices). It was proven NP-complete by Bodlaender [7] (in the case of both graphs being part of the input). Abello et al. [1] initiated the study of the computational complexity of the H -cover problem for a fixed target graph H by showing that deciding if an input graph covers the dumbbell graph $W(0, 1, 1, 1, 0)$ (in our notation from Section 4) is NP-complete (note that the dumbbell

graph has loops, and they also allowed the input graph to contain loops). Furthermore, they asked for a complete characterization of the computational complexity, depending on the parameter graphs H . Such a line of research was picked by Kratochvíl, Proskurowski and Telle, who completely characterized the complexity for simple target graphs with at most 6 vertices [33], and then noted that in order to fully characterize the complexity of the H -cover problem for simple target graphs, it is sufficient (but also necessary) to classify it for mixed colored multigraphs with minimum degree at least three [30]. The latter result gives a hope for a more concise description of the characterization, but is also in line with the original motivation from topological graph theory, where loops and multiedges are widely considered.

The complexity of covering 2-vertex multigraphs was fully characterized in [30], the characterization for 3-vertex undirected multigraphs can be found in [34]. The most general NP-hardness result known so far is the hardness of covering simple regular graphs of valency at least three [32, 17]. More recently, Bílka et al. [6] proved that covering several concrete small graphs (including the complete graphs K_4 , K_5 and K_6) remains NP-hard for planar inputs. This shows that planarity does not help in graph covering problems in general, yet the conjecture that the H -COVER problem restricted to planar inputs is at least as difficult as for general inputs, provided H itself has a finite planar cover, remains still open. Planar graphs have also been considered by Fiala et al. [19] who showed that for planar input graphs, H -REGULARCOVER is in FPT when parameterized by H . This is in fact the first and only paper on the complexity of regular covers, i.e., covering projections determined by a regular action of a group of automorphisms on the covering graph.

Graph coverings were also extensively studied under a unifying umbrella of *locally constrained homomorphisms*. In these relaxations, homomorphisms can be either locally injective or locally surjective and not necessarily locally bijective. The computational complexity of locally surjective homomorphisms has been classified completely, with respect to the fixed target graph [22]. Though the complete classification of the complexity of locally injective homomorphisms is still out of sight, it has been proved for its list variant [16]. The problem is also interesting for its applied motivation – a locally injective homomorphism into the complement of a path of length k corresponds to an $L(2, 1)$ -labeling of span k , an intensively studied notion stemming from the theory of frequency assignment. Further generalizations include the notion of $H(p, q)$ -coloring, a homomorphism into a fixed target graph H with additional rules on the neighborhoods of the vertices [18, 35]. To find more about locally injective homomorphisms, see e.g. [41, 11] or [21]. For every fixed graph H , the existence of a locally injective homomorphism to H is provably at least as hard as the H -cover problem. In this sense our hardness results extend the state of the art also for the problem of existence of locally injective homomorphisms.

1.2 Graphs with semi-edges

The notion of *semi-edges* has been introduced in the modern topological graph theory and it is becoming more and more frequently used (the terminology has not yet stabilized; semi-edges are often called half-edges, and sometimes fins). Mednykh and Nedela recently wrote a monograph [44] in which they summarize and survey the ambitions and efforts behind generalizing the notion of graph coverings to the graphs with semi-edges. This generalization, as the authors pinpoint, is not artificial as such graphs emerge “in the situation of taking quotients of simple graphs by groups of automorphisms which are semiregular on vertices and darts (arcs) and which may fix edges”. As the authors put it: “A problem arises when one wants to consider quotients of such graphs (graphs embedded to surfaces) by an involution fixing an edge e but transposing the two incident vertices. The edge e is halved and mapped

to a semi-edge – an edge with one free end.” This direction of research proved to be very fruitful and provided many applications and generalizations to various parts of algebraic graph theory. For example, Malnič et al. [42] considered semi-edges during their study of abelian covers and as they write “...in order to have a broader range of applications we allow graphs to have semi-edges.” To highlight a few other contributions, the reader is invited to consult [45, 43], the surveys [36] and (aforementioned) [44], and finally for more recent results the series of papers [19, 23, 20]. It is also worth noting that the concept of graphs with semi-edges was introduced independently and naturally in mathematical physics by Getzler and Karpanov [26].

In the view of the theory of local computations, semi-edges and their covers prove very natural, too, and it is even surprising that they have not been considered before in the context. If a computer network is constructed as a cover of a small template, the preimages of normal edges in the covering projection are matchings completely connecting nodes of two types (the end-vertices of the covered edge). Preimages of loops are disjoint cycles with nodes of the same type. And preimages of semi-edges are matchings on vertices of the same type. The role of semi-edges was spotted by Woodhouse et. al. [51, 49] who have generalized the fundamental theorem of Leighton on finite common covers of graphs with the same degree refinement matrix to graphs with semi-edges.

Our goal is to initiate the study of the computational complexity of covering graphs with semi-edges, and the current paper is opening the door in this direction.

1.3 Formal definitions

In this subsection we formally define what we call *graphs*. A graph has a set of vertices and a set of edges (also referred to as links). As it is standard in topological graph theory, we automatically allow multiple edges and loops. Every ordinary edge is connecting two vertices, every loop is incident with only one vertex. On top of these, we also allow *semi-edges*. Each semi-edge is also incident with only one vertex. The difference between loops and semi-edges is that a loop contributes two to the degree of its vertex, while a semi-edge only one. A very elegant description of ordinary edges, loops and semi-edges through the concept of *darts* is used in more algebraic-based papers on covers. The following formal definition is a reformulation of the one given in [44].

► **Definition 1.** A graph is a triple (D, V, Λ) , where D is a set of darts, and V and Λ are each a partition of D into disjoint sets. Moreover, all sets in Λ have size one or two.

With this definition, the *vertices* of a graph (D, V, Λ) are the sets of V (note that empty sets correspond to isolated vertices, and since we are interested in covers of connected graphs by connected ones, we assume that all sets of V are nonempty). The sets of Λ are referred to as *links*, and they are of three types – loops (2-element sets with both darts from the same set of V), (ordinary) edges (2-element sets intersecting two different sets of V), and semi-edges (1-element sets). After this explanation it should be clear that this definition is equivalent to a definition of multigraphs which is standard in the graph theory community:

► **Definition 2.** A graph is an ordered triple (V, Λ, ι) , for $\Lambda = E \cup L \cup S$, where ι is the incidence mapping $\iota : \Lambda \rightarrow V \cup \binom{V}{2}$ such that $\iota(e) \in V$ for all $e \in L \cup S$ and $\iota(e) \in \binom{V}{2}$ for all $s \in E$.

For a comparison of Definitions 1 and 2, see Figure 1. Since we consider multiple edges of the same type incident with the same vertex (or with the same pair of vertices), the edges are given by their names and the incidence mapping ι expresses which vertex (or vertices) “belong” to a particular edge. The degree of a vertex is then defined as follows.

■ **Figure 1** An example of a graph presented in a usual graph-theoretical way (left) and using the dart-based Definition 1 (right).

► **Definition 3.** For a graph $G = (V, \Lambda = E \cup L \cup S, \iota)$, the degree of a vertex $u \in V$ is defined as

$$\deg_G(u) = p_S(u) + p_E(u) + 2p_L(u),$$

where $p_S(u)$ ($p_L(u)$) is the number of semi-edges $e \in S$ (of loops $e \in L$) such that $\iota(e) = u$, and $p_E(u)$ is the number of ordinary edges $e \in E$ such that $u \in \iota(e)$.

We call a graph G *simple* if $p_S(u) = p_L(u) = 0$ for every vertex $u \in V(G)$ (the graph has no loops or semi-edges) and $\iota(e) \neq \iota(e')$ for every two distinct $e, e' \in E$ (the graph has no multiple (ordinary) edges). We call G *semi-simple* if $p_S(u) \leq 1$ and $p_L(u) = 0$ for every vertex $u \in V(G)$ and $\iota(e) \neq \iota(e')$ for every two distinct $e, e' \in E$.

Note that in the language of Definition 1, the degree of a vertex $v \in V$ is simply $|v|$. And in this language, the main object of our study, a *graph cover* (or equivalently a *covering projection*), is defined as follows.

► **Definition 4.** We say that a graph $G = (D_G, V_G, \Lambda_G)$ covers a connected graph $H = (D_H, V_H, \Lambda_H)$ (denoted as $G \rightarrow H$) if there exists a map $f : D_G \rightarrow D_H$ such that:

- For every $u \in V_G$, there is a $u' \in V_H$ such that the restriction of f onto u is a bijection between u and u' .
- For every $e \in \Lambda_G$, there is an $e' \in \Lambda_H$ such that $f(e) = e'$.

The map f is called *graph cover* (or *covering projection*).

One must appreciate how compact and elegant this definition is after translating it into the language of Definition 2 in Proposition 5, which otherwise is the definition of (multi)graph covering in the standard language of Definition 2.

► **Proposition 5.** A graph G covers a graph H if and only if G allows a pair of mappings $f_V : V(G) \rightarrow V(H)$ and $f_\Lambda : \Lambda(G) \rightarrow \Lambda(H)$ such that

1. $f_\Lambda(e) \in L(H)$ for every $e \in L(G)$ and $f_\Lambda(e) \in S(H)$ for every $e \in S(G)$,
2. $\iota(f_\Lambda(e)) = f_V(\iota(e))$ for every $e \in L(G) \cup S(G)$,
3. for every link $e \in \Lambda(G)$ such that $f_\Lambda(e) \in S(H) \cup L(H)$ and $\iota(e) = \{u, v\}$, we have $\iota(f_\Lambda(e)) = f_V(u) = f_V(v)$,
4. for every link $e \in \Lambda(G)$ such that $f_\Lambda(e) \in E(H)$ and $\iota(e) = \{u, v\}$ (note that it must be $f_V(u) \neq f_V(v)$), we have $\iota(f_\Lambda(e)) = \{f_V(u), f_V(v)\}$,
5. for every loop $e \in L(H)$, $f^{-1}(e)$ is a disjoint union of loops and cycles spanning all vertices $u \in V(G)$ such that $f_V(u) = \iota(e)$,
6. for every semi-edge $e \in S(H)$, $f^{-1}(e)$ is a disjoint union of edges and semi-edges spanning all vertices $u \in V(G)$ such that $f_V(u) = \iota(e)$, and
7. for every edge $e \in E(H)$, $f^{-1}(e)$ is a disjoint union of edges (i.e., a matching) spanning all vertices $u \in V(G)$ such that $f_V(u) \in \iota(e)$.

■ **Figure 2** An example of a covering. The vertex mapping of the covering from G to H is determined by the shape of the vertices, the edge mapping by the colors of the edges.

See an example of a covering projection in Fig. 2. Conditions 1–4. express the fact that f_V and f_E commute with ι , i.e., that f is a homomorphism from G to H . Conditions 5–7 express that this homomorphism is locally bijective (for every ordinary edge e incident with $f_V(u)$ in H , there is exactly one ordinary edge of G which is incident with u and mapped to e by f_E ; for every semi-edge e incident to $f_V(u)$ in H , there is exactly one semi-edge, or exactly one ordinary edge (but not both) in G incident with u and mapped to e by f_E ; and for every loop e incident with $f_V(u)$ in H , there is exactly one loop or exactly two ordinary edges (but not both) of G which are incident with u and mapped to e by f_E).

Even though the aforementioned definitions of graphs and graph covers through darts are compact and elegant, in the rest of the paper we shall work with the standard definition of graphs and the equivalent description of graph covers given by Proposition 5, because they are better suited for describing the reductions and understanding the illustrative figures.

It is clear that a covering projection (more precisely, its vertex mapping) preserves degrees. One may ask when (or if) a degree preserving vertex mapping can be extended to a covering projection. An obvious necessary condition is described by the following definition.

► **Definition 6.** A vertex mapping $f_V : V(G) \rightarrow V(H)$ between graphs G and H is called degree-obedient if

1. for any two distinct vertices $u, v \in V(H)$ and any vertex $x \in f_V^{-1}(u)$, the number of ordinary edges e of H such that $\iota(e) = \{u, v\}$ equals the number of ordinary edges of G with one end-vertex x and the other one in $f_V^{-1}(v)$, and
2. for every vertex $u \in V(H)$ and any vertex $x \in f_V^{-1}(u)$, the value $p_{S(H)}(u) + 2p_{L(H)}(u)$ equals $p_{S(G)}(x) + 2p_{L(G)}(x) + r$, where r is the number of edges of G with one end-vertex x and the other one from $f_V^{-1}(u) \setminus \{x\}$,
3. for every vertex $u \in V(H)$ and any vertex $x \in f_V^{-1}(u)$, $p_{S(G)}(x) \leq p_{S(H)}(u)$.

Finally, let us recall that the product $G \times H$ of graphs G and H is defined as the graph with the vertex set being the Cartesian product $V(G) \times V(H)$ and with vertices (u, v) and (u', v') being adjacent in $G \times H$ if and only if u is adjacent to u' , and v is adjacent to v' .

1.4 Overview of our results

The first major difference between graphs with and without semi-edges is that for target graphs without semi-edges, every degree-obedient vertex mapping to it can be extended to a covering. This is not true anymore when semi-edges are allowed (consider a one-vertex graph with three semi-edges, every 3-regular graph allows a degree-obedient mapping onto it, but only the 3-edge-colorable ones are covering it). In Section 2 we show that the situation is not as bad if the source graph is bipartite. In Theorem 10 we prove that if the source graph is

bipartite and has no semi-edges, then every degree-obedient vertex mapping can be extended to a covering, while if semi-edges are allowed in the bipartite source graph, it can at least be decided in polynomial time if a degree-obedient mapping can be extended to a covering.

All other results concern the complexity of the following decision problem

PROBLEM: H -COVER
 INPUT: A graph G .
 QUESTION: Does G cover H ?

In order to present our results in the strongest possible form, we aim at proving the hardness results for restricted classes of input graphs, while the polynomial ones for the most general inputs. In particular, we only allow simple graphs as inputs when we prove NP-hardness, and on the other hand, we allow loops, multiple edges as well as semi-edges when we present polynomial-time algorithms.

The first NP-hardness result is proven in Theorem 11, namely that covering semi-simple regular graphs of valency at least 3 is NP-hard even for simple bipartite input graphs. In Sections 3 and 4 we give a complete classification of the computational complexity of covering graphs with one and two vertices. This extends the main result of [30] to graphs with semi-edges. Moreover, we strengthen the hardness results of [30] considerably by showing that all NP-hard cases of covering regular two-vertex graphs (even those without semi-edges) remain NP-hard for simple *bipartite* input graphs. It must be noted that through the reduction from [31], our results on the complexity of covering one- or two-vertex graphs provide characterization results on infinitely many simple graphs which contain at most two vertices of degrees greater than 2.

All considered computational problems are clearly in the class NP, and thus we only concentrate on the NP-hardness proofs in the NP-completeness results. We restrict our attention to connected target graphs, in which case it suffices to consider only connected input graphs. In this case every cover is a k -fold cover for some k , which means that the preimage of every vertex has the same size.

2 The impact of semi-edges

In this section we demonstrate the huge difference between covering graphs with and without semi-edges. First, we discuss the necessity of specifying the edge mapping in a covering projection. In other words, we discuss when a degree mapping can always be extended to a covering, and when this question can be decided efficiently. The following proposition follows straightforwardly from the definitions.

► **Proposition 7.** *For every graph covering projection between two graphs, the vertex mapping induced by this projection is degree-obedient.*

► **Proposition * 8.** *If H has no semi-edges, then for any graph G , any degree-obedient mapping from the vertex set of G onto the vertex set of H can be extended to a graph covering projection of G to H .*

Proof sketch. For simple graphs G , this is proved already in [30]. If multiple edges and loops are allowed, we use a similar approach. The key point is that Petersen theorem [47] about 2-factorization of regular graphs of even valence is true for multigraphs without semi-edges as well, and the same holds true for König-Hall theorem [40] on 1-factorization of regular bipartite multigraphs. ◀

As we will see soon, the presence of semi-edges changes the situation a lot. Even for simple graphs, degree-obedient vertex mappings to a graph with semi-edges may not extend to a graph covering projection, and the possibility of such an extension may even be NP-complete.

► **Observation 9.** *Let $F(3,0)$ be the graph with one vertex and three semi-edges pending on this vertex. Then a graph covers $F(3,0)$ if and only if it is 3-regular and 3-edge-colorable. Testing 3-edge-colorability is well known to be NP-hard even for simple graphs.*

However, if the input graph is bipartite, the situation gets much easier.

► **Theorem * 10.** *If a graph G is bipartite, then for any graph H , it can be decided in polynomial time whether a degree-obedient mapping from the vertex set of G onto the vertex set of H can be extended to a graph covering projection of G to H . In particular, if G has no semi-edges and is bipartite, then every degree-obedient mapping from the vertex set of G onto the vertex set of H can be extended to a graph covering projection of G to H .*

Proof sketch. To prove this statement, it is enough to analyze the edges of H and their preimages in G according to the following classification:

- For each vertex pair $x \neq y \in V(H)$ inducing $k \geq 0$ parallel edges in H , their preimage forms a k -regular subgraph $G_{x,y}$ of bipartite G , and hence $G_{x,y}$ is k -edge colorable which immediately gives a covering projection for these edges.
- For each vertex $x \in V(H)$ with $b \geq 0$ semi-edges and $c \geq 0$ loops incident to x in H , these semi-edges and loops lift to a $(b + 2c)$ -regular subgraph \widetilde{G}_x of G . The algorithmic task now is to decide whether \widetilde{G}_x admits a factor projecting onto the semi-edges incident to x (this is efficiently solvable, e.g., by network flows since \widetilde{G}_x is again bipartite). If the answer is true, a projection of the remaining edges onto the loops incident to x always exists by Petersen theorem. ◀

Now we prove the first general hardness result, namely that covering semi-simple regular graphs is always NP-complete (this is the case when every vertex of the target graph is incident with at most one semi-edge, and the graph has no multiple edges nor loops). See Fig. 3 for examples of semi-simple graphs H defining such hard cases.

■ **Figure 3** Examples of small semi-simple graphs which define NP-complete covering problems.

► **Theorem 11.** *Let H be a semi-simple k -regular graph, with $k \geq 3$. Then the H -COVER problem is NP-complete even for simple bipartite input graphs.*

Proof. Consider $H' = H \times K_2$. This graph is simple, k -regular and bipartite, hence the H' -COVER problem is NP-complete by [32]. Given an input k -regular graph G , it is easy to see that G covers H' if and only if it is bipartite and covers H . Since bipartiteness can be checked in polynomial time, the claim follows. ◀

3 One-vertex target graphs

We start the section by proving a slightly more general hardness result, which may be of interest on its own. In particular, it implies that for every $d \geq 3$, it is NP-complete to decide if a simple d -regular graph contains an even 2-factor, i.e., a spanning 2-regular subgraph whose every cycle has even length.

► **Theorem * 12.** *For every $k \geq 2$ and every $d \geq k + 1$, it is NP-complete to decide if a simple d -regular graph contains k pairwise disjoint perfect matchings.*

Proof sketch. The complement of the union of k pairwise disjoint perfect matchings in a $(k + 1)$ -regular graph is a perfect matching as well, and thus a $(k + 1)$ -regular graph contains k pairwise disjoint perfect matchings if and only if it is $(k + 1)$ -edge colorable. Hence for $d = k + 1$, the claim follows from the NP-completeness of d -edge colorability of d -regular graphs which has been proven by Leven and Galil [38].

■ **Figure 4** An illustration to the construction of the graph G' in the proof of Theorem 12.

For $d \geq k + 2$, we reduce from the previous case, as we sketch next. If G is a $(k + 1)$ -regular instance (of the k disjoint perfect matchings problem), we construct an equivalent d -regular instance G' starting from two copies G_1 and G_2 of G , as shown in Fig. 4. Then for each vertex u of G , we connect its two copies u_1, u_2 (in G_1, G_2) by $d - k - 1$ paths of length 2, and add copies of a suitable gadget H to the middle vertices of those paths. The purpose of this gadget is two-fold – it raises all degrees to d , and it prevents edges of the incident path from being used in a perfect matching since the gadget is of an even order. It is routine to finish the construction and to show that G contains k disjoint perfect matchings if and only if G' does so. ◀

Now we are ready to prove a dichotomy theorem on the complexity of covering one-vertex graphs. Let us denote by $F(b, c)$ the one-vertex graph with b semi-edges and c loops.

► **Theorem * 13.** *The $F(b, c)$ -COVER problem is polynomial-time solvable if $b \leq 1$, or $b = 2$ and $c = 0$, and it is NP-complete otherwise, even for simple graphs.*

Proof sketch. The high-level idea is similar to the second point of the proof of Theorem 10: The input graph G possibly covering $F(b, c)$ should better be $(b + 2c)$ -regular (which can be easily checked), and it remains to argue that such G covers $F(b, c)$ if and only if it contains b pairwise disjoint perfect matchings (then a covering projection onto the c loops follows easily). The cases of $b = 0$, $b = 1$, or $b = 2$ and $c = 0$ can be efficiently solved using standard tools, while the remaining cases are hard from Theorem 12 by setting $k = b$ and $d = b + 2c$. ◀

4 Two-vertex target graphs

Let $W(k, m, \ell, p, q)$ be the two-vertex graph with k semi-edges and m loops at one vertex, p loops and q semi-edges at the other one, and $\ell > 0$ multiple edges connecting the two vertices (these edges are referred to as *bars*). In other words, $W(k, m, \ell, p, q)$ is obtained from the disjoint union of $F(k, m)$ and $F(q, p)$ by connecting their vertices by ℓ parallel edges. For an example see the graph H from Fig. 2 which is isomorphic to both $W(1, 1, 2, 1, 0)$ and $W(0, 1, 2, 1, 1)$.

► **Theorem 14.** *The $W(k, m, \ell, p, q)$ -COVER problem is solvable in polynomial time in the following cases*

1. $k + 2m \neq 2p + q$ and ($k \leq 1$ or $k = 2$ and $m = 0$) and ($q \leq 1$ or $q = 2$ and $p = 0$)
2. $k + 2m = 2p + q$ and $\ell = 1$ and $k = q \leq 1$ and $m = p = 0$
3. $k + 2m = 2p + q$ and $\ell > 1$ and $k = m = p = q = 0$

and it is NP-complete otherwise.

Note that case 1 applies to non-regular target graph W , while cases 2 and 3 apply to regular graphs W , i.e., they cover all cases when $k + 2m + \ell = 2p + q + \ell$.

We will refer to the vertex with k semi-edges as *blue* and the vertex with q semi-edges as *red*. In a covering projection $f = (f_V, f_E)$ from a graph G onto $W(k, m, \ell, p, q)$, we view the restricted vertex mapping f_V as a coloring of $V(G)$. We call a vertex $u \in V(G)$ blue (red) if f_V maps u onto the blue (red, respectively) vertex of $W(k, m, \ell, p, q)$. In order to keep the text clear and understandable, we divide the proof into a sequence of claims in separate subsections. This will also allow us to state several hardness results in a stronger form.

4.1 Polynomial parts of Theorem 14

We follow the case-distinction from the statement of Theorem 14:

1. If $k + 2m \neq 2p + q$, then the two vertex degrees of $W(k, m, \ell, p, q)$ are different, and the vertex restricted mapping is uniquely defined for any possible graph covering projection from the input graph G to $W(k, m, \ell, p, q)$. For this coloring of G , if it exists, we check if it is degree-obedient. If not, then G does not cover $W(k, m, \ell, p, q)$. If yes, we check using Theorem 12 whether the blue subgraph of G covers $F(k, m)$ and whether the red subgraph of G covers $F(q, p)$. If any one of them does not, then G does not cover $W(k, m, \ell, p, q)$. If both of them do, then G covers $W(k, m, \ell, p, q)$, since the “remaining” subgraph of G formed by edges with one end-vertex red and the other one blue is ℓ -regular and bipartite, thus covering the ℓ parallel edges of $W(k, m, \ell, p, q)$ (Proposition 8).
2. In case 2, the input graph G covers $W(1, 0, 1, 0, 1)$ only if G is 2-regular. If this holds, then G is a disjoint union of cycles, and it is easy to see that a cycle covers $W(1, 0, 1, 0, 1)$ if and only if its length is divisible by 4. For the subcase of $k = q = 0$, see the next point.
3. The input graph G covers $W(0, 0, \ell, 0, 0)$ only if it is a bipartite ℓ -regular graph without semi-edges, but in that case it does cover $W(0, 0, \ell, 0, 0)$, as follows from Proposition 8.

4.2 NP-hardness for non-regular target graphs

► **Proposition * 15.** *Let the parameters k, m, p, q be such that $k + 2m \neq 2p + q$, and ($(k \geq 3$ or $k = 2$ and $m \geq 1)$, or $(q \geq 3$ or $q = 2$ and $p \geq 1)$). Then the $W(k, m, \ell, p, q)$ -COVER problem is NP-complete.*

Proof sketch. The proof essentially relies on the reductions from the preceding section. The parameters ensure that after deleting the ℓ ordinary edges from the target graph, we end up with two graphs, $F(k, m)$ and $F(p, q)$, where at least one of them identifies one of the hard cases of covering one-vertex graphs. We then utilize a special gadget by which we connect the vertices of instances of $F(k, m)$ -COVER and $F(p, q)$ -COVER to get a graph G' . We further claim that we can decide both of these instances if and only if G' covers $W(k, m, \ell, p, q)$. The argument is significantly simplified by the determination of images of vertices due to the different degrees of vertices in the target graph. ◀

4.3 NP-hardness for connected regular target graphs

The aim of this subsection is to conclude the proof of Theorem 14 by showing the NP-hardness for the case of $\ell \geq 1$ and $k + 2m = 2p + q$. We will actually prove a result which is more general in two directions. Firstly, we formulate the result in the language of colorings of vertices, and secondly, we prove the hardness for bipartite inputs. This might seem surprising, as we have seen in Section 2 that bipartite graphs can make things easier. Moreover, this strengthening in fact allows us to prove the result in a unified, and hence simpler, way.

Note that the following definition of a relaxation of usual proper 2-coloring resembles the so-called *defective 2-coloring* (see survey of Wood [50]). However, the definitions are not equivalent.

► **Definition 16.** A (b, c) -coloring of a graph is a 2-coloring of its vertices such that every vertex has b neighbors of its own color and c neighbors of the other color.

► **Observation 17.** For any parameters k, m, ℓ, p, q such that $k + 2m = 2p + q$, a bipartite graph G with no semi-edges covers $W(k, m, \ell, p, q)$ if and only if it allows a $(k + 2m, \ell)$ -coloring.

Proof. On one hand, any graph covering projection from G to $W(k, m, \ell, p, q)$ induces a $(k + 2m, \ell)$ -coloring of G , provided $k + 2m = 2p + q$. On the other hand, a $(k + 2m, \ell)$ -coloring of G is a degree-obedient vertex mapping from G to $W(k, m, \ell, p, q)$, again provided that $k + 2m = 2p + q$. If G is bipartite and has no semi-edges, then this mapping can be extended to a graph covering projection by Theorem 10. ◀

In view of the previous observation, we will be proving the NP-hardness results for the problem (b, c) -COLORING which takes a graph G on input and asks if G allows a (b, c) -coloring.

► **Theorem* 18.** For every pair of positive integers b, c such that $b + c \geq 3$, the (b, c) -COLORING problem is NP-complete even for simple bipartite graphs.

Proof sketch. First observe that the (b, c) -COLORING and (c, b) -COLORING problems are polynomially equivalent on bipartite graphs, as the colorings are mutually interchangeable by switching the colors in one class of the bi-partition. Thus we may consider only $b \geq c$.

■ **Figure 5** A 20-vertex auxiliary graph H_1 , used in the first part of the proof of Theorem 18, and its possible partial $(2, 1)$ -colorings.

NP-hardness of the $(2, 1)$ -COLORING is proved by a reduction from NAE-3-SAT [25] by using three kinds of building blocks: a clause gadget (here $K_{1,3}$), a vertex gadget enforcing the same color on selected subset of vertices, and a garbage collection that allows to complete the coloring to a cubic graph, that as a part contains the vertex and clause gadgets linked together to represent a given instance of NAE-3-SAT. This reduction is the actual core of the proof, and is briefly sketched in Figures 5 and 6. The former one shows a special gadget

■ **Figure 6** Garbage collection and the overall construction for the first part of Theorem 18. Clause gadgets are in the corners of the figure b).

■ **Figure 7** An illustration of the constructions used in the proof of Theorem 18; a reduction to $(b, 1)$ -COLORING on the left, and a reduction to (b, c) -COLORING on the right.

H_1 used in the color-enforcing constructions of this reduction. For every variable, copies of H_1 are concatenated into a chain, whose one side is connected to ensure that the coloring P_2 (or its inverse) is the only admissible $(2,1)$ -coloring, the other side transfers this information as the truth valuation of the variable to the clause gadgets of clauses containing it. The latter figure sketches the garbage collection and the overall construction of the reduction.

The result on $(2,1)$ -COLORING, in particular, implies that $W(0, 2, 1, 2, 0)$ -COVER is NP-complete for simple bipartite input graphs, whereas the semi-edgeless dumbbell graph $W(0, 2, 1, 2, 0)$ is the smallest semi-edgeless graph whose covering is NP-complete.

Further on, we reduce $(2, 1)$ -COLORING to $(b, 1)$ -COLORING by using two copies of the instance of $(2, 1)$ -COLORING and linking them together by suitable graphs called bridges, that enforce replication of colors for the desired coloring. See a brief sketch in Fig. 7 (left). In view of the initial observation, at this point we know that $(b, 1)$ -COLORING and $(1, b)$ -COLORING are NP-complete on bipartite inputs for all $b \geq 2$.

Then we reduce $(1, c)$ -COLORING to (b, c) -COLORING with $b > c$. Again we take two copies of an instance of $(1, c)$ -COLORING, say a $(1 + c)$ -regular graph G . As sketched in Fig. 7 (right), we construct an auxiliary graph H with two vertices of degree $b - 1$ (called the “connector” vertices), all other vertices being of degree $b + c$ (these are called the “inner” vertices). This bridge graph is such that in every two-coloring of its vertices, such that all inner vertices have exactly b neighbors of their own color and exactly c neighbors of the opposite color, while the connector vertices have at most b neighbors of their own color and at most c neighbors of the opposite color, in every such a coloring the connector vertices and their neighbors always get the same color. And, moreover, such a coloring exists. We then take two copies of G and for every vertex of G , identify its copies with the connector vertices of a copy of the bridge graph (thus we have as many copies of the bridge graph as is the number of vertices of G). The above stated properties of the bridge graph guarantee that the new graph allows a (b, c) -coloring if and only if G allows a $(1, c)$ -coloring.

It is worth mentioning that we have provided two different constructions of the bridge gadget. A general one for the case of $b \geq c + 2$ and a specific one for the case of $b = c + 1$. It is a bit surprising that the case analysis needed to prove the properties of the bridge graph is much more involved for the specific construction in the case of $b = c + 1$.

Finally, for (b, b) -COLORING with $b \geq 2$ we establish a completely different reduction from a special variant of satisfiability $(k\text{-in-}2k)$ -SAT $_q$, a generalization of NAE-3-SAT. ◀

Theorem 18 and Observation 17 imply the following proposition, which concludes the proof of Theorem 14.

► **Proposition 19.** *The $W(k, m, \ell, p, q)$ -COVER problem is NP-complete for simple bipartite input graphs for all parameter sets such that $k + 2m = 2p + q \geq 1$, $\ell \geq 1$, and $k + 2m + \ell \geq 3$.*

5 Conclusion

The main goal of this paper is to initiate the study of the computational complexity of covering graphs with semi-edges. We have exhibited a new level of difficulty that semi-edges bring to coverings by showing a connection to edge-colorings. We have presented a complete classification of the computational complexity of covering graphs with at most two vertices, which is already a quite nontrivial task. In the case of one-vertex target graphs, the problem becomes polynomial-time solvable if the input graph is bipartite, while in the case of two-vertex target graphs, bipartiteness of the input graphs does not help. This provides a strengthening of known results of covering two-vertex graphs without semi-edges.

It is worth noting that the classification in [30] concerns a more general class of *colored mixed* (multi)graphs. I.e., graphs which may have both directed and undirected edges and whose edges come with assigned colors which must be preserved by the covering projections. It turns out that covering a two-vertex (multi)graph is NP-hard if and only if it is NP-hard for at least one of its maximal monochromatic subgraphs. It can be shown that the same holds true when semi-edges are allowed (note that all semi-edges must be undirected only).

We end up with an intriguing open problem.

► **Problem.** *Do there exist graphs H_1 and H_2 , both without semi-edges, such that H_1 covers H_2 , and such that the H_1 -COVER is polynomial-time solvable and H_2 -COVER is NP-complete?*

If semi-edges are allowed, then $H_1 = W(0, 0, 3, 0, 0)$ and $H_2 = F(3, 0)$ is such a pair. All further examples that we can obtain generalize this observation. They are unique in the sense that NP-completeness of H_2 -COVER follows from the NP-completeness of the edge-colorability problem of general graphs which becomes polynomially solvable for bipartite instances.

Abstract

Even though coherent control of quantum operations appears to be achievable in practice, it is still not yet well understood. Among theoretical challenges, standard completely positive trace preserving (CPTP) maps are known not to be appropriate to represent coherently controlled quantum channels. We introduce here a graphical language for coherent control of general quantum channels inspired by practical quantum optical setups involving polarising beam splitters (PBS). We consider different situations of coherent control and disambiguate CPTP maps by considering purified channels, an extension of Stinespring’s dilation.

First, we show that in classical control settings, the observational equivalence classes of purified channels correspond to the standard definition of quantum channels (CPTP maps). Then, we propose a refinement of this equivalence class generalising the “half quantum switch” situation, where one is allowed to coherently control which quantum channel is applied; in this case, quantum channel implementations can be distinguished using a so-called transformation matrix. A further refinement characterising observational equivalence with general extended PBS-diagrams as contexts is also obtained. Finally, we propose a refinement that could be used for more general coherent control settings.

1 Introduction

Unlike the usual sequential and parallel compositions, coherent control allows one to perform two or more quantum evolutions in superposition. It is fairly easy with quantum optics – an important player in the development of quantum technologies – to construct setups that perform some coherent control. A polarising beam splitter (PBS) precisely allows one to do that: by reflecting for instance horizontally polarised particles and transmitting vertically polarised ones, it lets the polarisation control the path, and thereby the physical devices

encountered, in a coherent way [10, 16]. This finds some interesting applications for quantum information processing (e.g., for error filtration [11]), including the ability to perform some operations in an indefinite causal order, as for instance in the so-called quantum switch [6]. Intuitively, given two quantum operations A and B and a control qubit, a quantum switch consists in applying A followed by B (resp. B followed by A) when the control qubit is in state $|0\rangle$ (resp. $|1\rangle$). When the control qubit is in a superposition, we get a superposition of the two possible orders. Quantum switch can be used to speed up information processing tasks, e.g. deciding whether two operators are commuting or anticommuting [5, 2]. Actual implementations of the quantum switch have been experimentally realised [12].

General quantum evolutions – a.k.a. quantum channels – are commonly represented as completely positive trace preserving (CPTP) maps. CPTP maps can naturally be composed in sequence and in parallel. However, it has been realised that the description of quantum channels in terms of CPTP maps is not appropriate for some particular setups involving coherent control [15, 1, 7, 13]. One indeed needs some more information about their practical implementation to unambiguously determine the behaviour of such setups, and it was recently proposed to complete the description of channels by so-called transformation matrices [1], or vacuum extensions [7, 13].

Here we consider a general class of setups involving PBS, and study how these can be used to coherently control quantum channels. We build upon the graphical language of PBS-diagrams introduced in [8], in which the controlled operations were “pure” (typically, unitary), and extend it to allow for the control of more general quantum channels. As the description of channels as CPTP maps is inadequate here, we propose to work with *purified channels* based on a unitary extension of Stinespring’s dilation [17].

We address the question of the observational equivalence of purified channels, and show that different purified channels can be indistinguishable. To do so, we use PBS-diagrams to formalise three kinds of *contexts*: when the context is PBS-free, we recover that two purified channels are indistinguishable if and only if they lead to the same CPTP map. When the context allows for PBS but no polarisation flips, we recover the characterisation in terms of superoperators and transformation matrices which was introduced for a particular setup [1]. When we allow for arbitrary contexts, we obtain a characterisation of observational equivalence involving “second-level” superoperators and transformation matrices. We finally open the discussion to more general coherent-control settings, and propose a refined equivalence relation as a candidate for characterising channel (in)distinguishability in such scenarios.

The omitted proofs are available in the full version of the paper [3].

2 PBS-diagrams

PBS-diagrams were introduced in [8] as a language for coherent control of “pure” quantum evolutions. They aim at describing practical scenarios where a flying particle goes through an experimental setup, and is routed via polarising beam splitters. In addition to its polarisation, the particle carries some “data” register, whose state is described in some Hilbert space \mathcal{H} , and on which a number “pure” linear (typically, unitary) operators are applied.

Here we shall enrich the pure PBS-diagram language so as to incorporate the coherent control of more general quantum channels. To this purpose, we start by defining an abstract version of PBS-diagrams that we call *bare diagrams*, and which we equip with a word path semantics describing the trajectory and change of polarisation of a particle that enters the diagram through some given input wire: the word path semantics gives its new polarisation and position at the output of the diagram, together with a word over some alphabet describing

the sequence of *bare gates* – where the quantum channels we want to control are located – crossed. Subscribing to the idea that any general quantum operation can be seen as a unitary evolution of the system under consideration and its environment, we then define *purified channels*, which can be coherently controlled in a similar way to the PBS-diagrams of [8]. Replacing bare gates with purified channels, we obtain an extension¹ of the graphical language of [8], which we call *extended PBS-diagrams* and which we equip with a quantum semantics obtained after discarding the (inaccessible) environments of all gates.

2.1 Bare PBS-diagrams

2.1.1 Syntax

A *bare PBS-diagram* is made of polarising beam splitters \bowtie , polarisation flips \ominus , and bare gates \square_a . Every bare gate is indexed by a unique label (here, a) used to identify the gate in the diagram. These building blocks are connected via wires represented using the identity — or the swap \bowtie . The empty diagram is denoted by $[\]$. Diagrams can be combined by means of sequential composition \circ , parallel composition \oplus ,² and trace $Tr(\cdot)$, which represents a feedback loop.

We define a typing judgement $\Gamma \vdash D : n$, where Γ is the alphabet containing all gate indices,³ to guarantee that the diagrams are well-formed – in particular, that the gate indices are unique – using a linear typing discipline:

► **Definition 1** (Bare PBS-diagram). *A bare PBS-diagram $\Gamma \vdash D : n$ (with $n \in \mathbb{N}$) is inductively defined as:*

$$\emptyset \vdash [\] : 0 \quad \emptyset \vdash \text{—} : 1 \quad \emptyset \vdash \ominus : 1 \quad \emptyset \vdash \bowtie : 2 \quad \emptyset \vdash \bowtie : 2 \quad \{a\} \vdash \square_a : 1$$

$$\frac{\Gamma_1 \vdash D_1 : n \quad \Gamma_2 \vdash D_2 : n \quad \Gamma_1 \cap \Gamma_2 = \emptyset}{\Gamma_1 \cup \Gamma_2 \vdash D_2 \circ D_1 : n} \quad \frac{\Gamma_1 \vdash D_1 : n_1 \quad \Gamma_2 \vdash D_2 : n_2 \quad \Gamma_1 \cap \Gamma_2 = \emptyset}{\Gamma_1 \cup \Gamma_2 \vdash D_1 \oplus D_2 : n_1 + n_2} \quad \frac{\Gamma \vdash D : n + 1}{\Gamma \vdash Tr(D) : n}$$

Graphical representation. PBS-diagrams form a graphical language: compositions and trace are respectively depicted as follows (for diagrams generically depicted as \boxed{D}):

$$\boxed{D_2} \circ \boxed{D_1} = \boxed{D_1} \boxed{D_2} \quad \boxed{D_1} \oplus \boxed{D_2} = \begin{array}{c} \boxed{D_1} \\ \boxed{D_2} \end{array} \quad Tr(\boxed{D}) = \begin{array}{c} \boxed{D} \\ \boxed{D} \end{array}$$

Examples of bare PBS-diagrams are given in Fig. 1 below. Note that two *a priori* distinct constructions, like for instance $Tr(\square_a \oplus \bowtie)$ and $\square_a \oplus Tr(\bowtie)$, can lead to the same graphical representation \square_a . To avoid ambiguity, we define diagrams modulo a structural

congruence detailed in Appendix A. Roughly speaking, the structural congruence guarantees that (i) two constructions leading to the same graphical representation are equivalent, and (ii) a diagram can be deformed at will (without changing its topology), e.g.:

$$\begin{array}{c} \bowtie \\ \text{—} \end{array} = \text{—} \quad \begin{array}{c} \boxed{D_1} \\ \boxed{D_2} \end{array} \bowtie = \begin{array}{c} \boxed{D_2} \\ \boxed{D_1} \end{array} \bowtie \quad \begin{array}{c} \text{—} \\ \text{—} \end{array} = \text{—} \quad \begin{array}{c} \boxed{D_1} \\ \boxed{D_2} \end{array} = \begin{array}{c} \boxed{D_2} \\ \boxed{D_1} \end{array}$$

¹ Strictly speaking, the PBS-diagrams of [8] did not require the operations inside the gates to be unitary, while here we impose such a restriction *a priori*. One could however also consider non-unitary operations in our framework here, although one would lose our motivation based on the unitary extension of Stinespring's dilation.

² Denoted \otimes in [8]. Here we change the notation to reflect how the parallel composition affects the structure of the Hilbert space describing the position of the particle (see Section 2.2).

³ We may write simply $D : n$, or even just D , when Γ is not relevant or is clear from the context.

■ **Figure 1** Two examples of bare PBS-diagrams, with the same word path semantics: $(D, \uparrow, 0) \xrightarrow{abab} (\uparrow, 0)$ and $(D, \rightarrow, 0) \xrightarrow{\epsilon} (\rightarrow, 0)$.

Note in particular that the length of the wires does not matter. Physically, if these diagrams were to be realised in practical setups, this would mean that the experiment should be insensible to the time at which the particle would go through the various elements; if needed one could always add (possibly polarisation-dependent) delay lines (e.g., ) to correct for a possible time mismatch between different paths.

2.1.2 Word path semantics

The word path semantics describes the trajectory of a particle which enters a bare PBS-diagram $\Gamma \vdash D : n$ with a polarisation in the standard basis state $c \in \{\rightarrow, \uparrow\}$ (horizontal or vertical) and from a definite position $p \in [n] := \{0, \dots, n-1\}$. Because of the polarising beam splitters, the trajectory of the particle depends on its polarisation: we take it to be reflected when the polarisation is horizontal, and transmitted when the polarisation is vertical. The “negation” \ominus flips the polarisation, while the gates do not act on the polarisation. The word path semantics of a diagram describes, given an initial polarisation and position, the final polarisation and position together with the sequence of gates – represented by a word over Γ – that the particle goes through:

► **Definition 2** (Word path semantics). *Given a bare PBS-diagram $\Gamma \vdash D : n$, a polarisation $c \in \{\rightarrow, \uparrow\}$ and a position $p \in [n]$, let $(D, c, p) \xrightarrow{w} (c', p')$ with $w \in \Gamma^*$ a word over Γ (or just $(D, c, p) \Rightarrow (c', p')$ for the empty word $w = \epsilon$) be inductively defined as follows:*

$$(\rightarrow, c, 0) \Rightarrow (c, 0) \quad (\ominus \rightarrow, \uparrow, 0) \Rightarrow (\rightarrow, 0) \quad (\ominus \rightarrow, \rightarrow, 0) \Rightarrow (\uparrow, 0)$$

$$(\rightarrow \curvearrowright, c, p) \Rightarrow (c, 1-p) \quad (\rightarrow \curvearrowleft, \rightarrow, p) \Rightarrow (\rightarrow, p) \quad (\rightarrow \curvearrowleft, \uparrow, p) \Rightarrow (\uparrow, 1-p)$$

$$(\rightarrow \square_a, c, 0) \xrightarrow{a} (c, 0) \quad \frac{(D_1, c, p) \xrightarrow{w_1} (c', p') \quad (D_2, c', p') \xrightarrow{w_2} (c'', p'')}{(D_2 \circ D_1, c, p) \xrightarrow{w_1 w_2} (c'', p'')} (\circ)$$

$$\frac{D_1 : n_1 \quad p < n_1 \quad (D_1, c, p) \xrightarrow{w} (c', p')}{(D_1 \oplus D_2, c, p) \xrightarrow{w} (c', p')} (\oplus_1) \quad \frac{D_1 : n_1 \quad p \geq n_1 \quad (D_2, c, p-n_1) \xrightarrow{w} (c', p')}{(D_1 \oplus D_2, c, p) \xrightarrow{w} (c', p'+n_1)} (\oplus_2)$$

$$\frac{D : n+1 \quad \forall i \in \{0, \dots, k\}, (D, c_i, p_i) \xrightarrow{w_i} (c_{i+1}, p_{i+1}) \quad (p_{i+1} = n) \Leftrightarrow (i < k)}{(Tr(D), c_0, p_0) \xrightarrow{w_0 \dots w_k} (c_{k+1}, p_{k+1})} (\mathbb{T}_k)$$

with $k = 0, 1$, and 2.

We denote by $w_{c,p}^D \in \Gamma^*$ the word, $c_{c,p}^D \in \{\uparrow, \rightarrow\}$ the polarisation, and $p_{c,p}^D \in [n]$ the position s.t. $(D, c, p) \xrightarrow{w_{c,p}^D} (c_{c,p}^D, p_{c,p}^D)$.

The word path semantics is invariant modulo structural congruence (i.e., diagram deformation). Moreover, note that despite the traces which form feedback loops, the word path semantics is well-defined.⁴ Indeed, a particle entering the diagram through some input wire cannot go through a feedback loop (or any other part of the diagram) twice with the same polarisation, which justifies that k only needs to go up to 2 in Rule (\mathbb{T}_k) above. Intuitively, if a particle goes twice in a feedback loop with the same polarisation then it will loop forever; but because of time symmetry this also means that the particle went through the feedback loop infinitely many times in the past, which contradicts the fact that it entered through an input wire. See Appendix B for details about the formal proofs of these facts.

For similar reasons, each gate cannot appear more than twice along any path, or even in the family of all the possible paths of a diagram:

► **Proposition 3.** *Given a bare PBS-diagram $\Gamma \vdash D : n$, $\forall a \in \Gamma$, one has $\sum_{c \in \{\rightarrow, \uparrow\}, p \in [n]} |w_{c,p}^D|_a \leq 2$, where $|w|_a$ denotes the number of occurrences of a in the word w . Moreover, if D is \ominus -free then for any c one has $\sum_{p \in [n]} |w_{c,p}^D|_a \leq 1$.*

The converse is also true:

► **Proposition 4.** *For any family of words $\{w_{c,p}\}_{(c,p) \in \{\rightarrow, \uparrow\} \times [n]}$ such that every letter appears at most twice in the whole family, there exists a bare PBS-diagram $D : n$ such that $w_{c,p} = w_{c,p}^D$ for all c, p . Furthermore if for any $c \in \{\rightarrow, \uparrow\}$, every letter appears at most once in $\{w_{c,p}\}_{p \in [n]}$, the bare PBS-diagram D can be chosen \ominus -free.*

Note that the proof of Proposition 4 is constructive. For instance, the family $\{w_{\uparrow,0} = abab, w_{\rightarrow,0} = \epsilon\}$ can be obtained from the diagram of Fig. 1 (Right). The solution is not unique in general and there is actually a simpler diagram, see Fig. 1 (Left), with the same word path semantics.

2.2 Extended PBS-diagrams

We will now introduce extended PBS-diagrams by filling every bare gate with the description of a quantum channel. As recalled in the introduction, however, defining the coherent control of general channels (as we wish to do with PBS-diagrams) in an unambiguous way is not trivial. Here we propose to do so through the notion of purified channels, which are an extension of Stinespring’s dilation of quantum channels [17].

2.2.1 Purified channels

A standard paradigm for quantum channels acting on a Hilbert space \mathcal{H} is to describe them as CPTP maps, or superoperators $\mathcal{L}(\mathcal{H}) \rightarrow \mathcal{L}(\mathcal{H})$,⁵ where $\mathcal{L}(\mathcal{H})$ denotes the set of linear operators on \mathcal{H} . As exemplified e.g. in [15, 1], this representation is however ambiguous when it comes to describing quantum coherent control: two quantum channels with the same superoperator can behave differently in a coherent-control setting.

A possible way to overcome this issue is to “go to the Church of the larger Hilbert space”, according to which any quantum channel can be interpreted as a pure quantum operation acting on both the quantum system and an environment. Mathematically, this corresponds to Stinespring’s dilation theorem [17], which states that any CPTP map acting

⁴ Definition 2 does not provide any word path semantics for diagrams of type $D : 0$. In fact, no word path semantics needs to be defined for such diagrams, as there is no position p defining any input wire. Note also that for diagrams $D : n$ containing fully closed subdiagrams (e.g., of the form $D = D_1 \oplus D_2$ with $D_2 : 0$), the semantics does not depend on these fully closed subdiagrams.

⁵ As this is the case of interest in PBS-diagrams (with \mathcal{H} corresponding to the data register), we consider here channels with the same input and output Hilbert spaces.

on a Hilbert space \mathcal{H} can be implemented with an isometry $V : \mathcal{H} \rightarrow \mathcal{H} \otimes \mathcal{E}$, where \mathcal{E} denotes the Hilbert space attached to the environment, followed by a partial trace of the latter. Note that in this representation, the isometry V can be understood as encoding both the creation of the environment \mathcal{E} and the evolution of the joint system $\mathcal{H} \otimes \mathcal{E}$. Indeed, V can always be decomposed into an environment initialisation $|\varepsilon\rangle \in \mathcal{E}$ and a unitary evolution $U : \mathcal{H} \otimes \mathcal{E} \rightarrow \mathcal{H} \otimes \mathcal{E}$ such that $V = U(I_{\mathcal{H}} \otimes |\varepsilon\rangle)$, where $I_{\mathcal{H}}$ denotes the identity operator over \mathcal{H} . In our approach to defining coherent control for quantum channels, we will precisely abide by this description in terms of unitary purifications, which we formalise as follows:

► **Definition 5 (Purified channel).** *Given a Hilbert space \mathcal{H} , a purified \mathcal{H} -channel (or simply purified channel, for short) is a triplet $[U, |\varepsilon\rangle, \mathcal{E}]$, where \mathcal{E} is the local environment Hilbert space, $|\varepsilon\rangle \in \mathcal{E}$ is the environment initial state, and $U : \mathcal{H} \otimes \mathcal{E} \rightarrow \mathcal{H} \otimes \mathcal{E}$ is a unitary operator representing the evolution of the joint system. We denote the set of purified \mathcal{H} -channels by $\mathfrak{C}(\mathcal{H})$.*

As seen above, it directly follows from Stinespring’s dilation theorem that any CPTP map $\mathcal{L}(\mathcal{H}) \rightarrow \mathcal{L}(\mathcal{H})$ can be represented by a purified \mathcal{H} -channel, which is however not unique. Reciprocally, with any purified \mathcal{H} -channel $[U, |\varepsilon\rangle, \mathcal{E}]$, we naturally associate the CPTP map $\mathcal{S}_{[U, |\varepsilon\rangle, \mathcal{E}]}^{(1)} : \mathcal{L}(\mathcal{H}) \rightarrow \mathcal{L}(\mathcal{H}) = \rho \mapsto \text{Tr}_{\mathcal{E}}(U(\rho \otimes |\varepsilon\rangle\langle\varepsilon|)U^\dagger)$, where $\text{Tr}_{\mathcal{E}}$ denotes the partial trace over \mathcal{E} , and which we shall represent graphically, using the circuit notations of Appendix C,⁶ as follows: $\mathcal{S}_{[U, |\varepsilon\rangle, \mathcal{E}]}^{(1)} = |\varepsilon\rangle \text{---} \boxed{U} \text{---} |\varepsilon\rangle$.

One may however not trace out the environment straight away. In fact, decomposing Stinespring’s dilation into an environment state initialisation and a unitary evolution of the joint system, as we did above, allows one to apply the same channel several times in a coherent manner if a particle goes through a gate several times. In that case we will consider that the same unitary is applied each time, without re-initialising the environment state (which we assume to not evolve between two applications of the channel).

2.2.2 From bare to extended PBS-diagrams

We are now in a position to define extended PBS-diagrams of type $\mathcal{H}^{(n)}$, which are essentially bare PBS-diagrams of type n , where the gate indices are replaced by purified \mathcal{H} -channels. Hence, instead of bare gates $\text{---} \boxed{a} \text{---}$, an extended PBS-diagram contains gates of the form $\text{---} \boxed{[U, |\varepsilon\rangle]} \text{---}$, parametrised by a purified channel $[U, |\varepsilon\rangle, \mathcal{E}] \in \mathfrak{C}(\mathcal{H})$ (where the Hilbert space \mathcal{E} is not represented explicitly, in order not to overload the diagrams).

This leads to the following inductive definition:

► **Definition 6 (Extended PBS-diagram).** *An extended PBS-diagram $D : \mathcal{H}^{(n)}$ (with $n \in \mathbb{N}$) is inductively defined as:*

$$\begin{array}{c}
 \boxed{} : \mathcal{H}^{(0)} \quad \text{---} : \mathcal{H}^{(1)} \quad \boxed{\ominus} : \mathcal{H}^{(1)} \quad \text{---} \text{---} : \mathcal{H}^{(2)} \quad \boxed{\otimes} : \mathcal{H}^{(2)} \quad \frac{[U, |\varepsilon\rangle, \mathcal{E}] \in \mathfrak{C}(\mathcal{H})}{\boxed{[U, |\varepsilon\rangle]} : \mathcal{H}^{(1)}} \\
 \\
 \frac{D_1 : \mathcal{H}^{(n)} \quad D_2 : \mathcal{H}^{(n)}}{D_2 \circ D_1 : \mathcal{H}^{(n)}} \quad \frac{D_1 : \mathcal{H}^{(n_1)} \quad D_2 : \mathcal{H}^{(n_2)}}{D_1 \oplus D_2 : \mathcal{H}^{(n_1+n_2)}} \quad \frac{D : \mathcal{H}^{(n+1)}}{\text{Tr}(D) : \mathcal{H}^{(n)}}
 \end{array}$$

⁶ To manipulate unitary operations and CPTP maps, it is convenient to use such circuit-like graphical representations, which correspond to standard circuit notations for “pure” operations, supplemented with a ground symbol $\text{---} \lfloor \text{---}$ for the case of CPTP maps; see Appendix C for details.

Extended PBS-diagrams are defined up to the same structural congruence as for bare PBS-diagrams. It is convenient to explicitly define the map which, given a family of purified channels, transforms a bare diagram into the corresponding extended PBS-diagram:⁷

► **Definition 7.** *Given a bare PBS-diagram $\Gamma \vdash D' : n$ and a family of purified \mathcal{H} -channels $\mathcal{G} = ([U_a, |\varepsilon_a\rangle, \mathcal{E}_a])_{a \in \Gamma}$ indexed by elements of Γ , let $[D']_{\mathcal{G}} : \mathcal{H}^{(n)}$ be the extended PBS-diagram inductively defined as $[-\square_a]([U_a, |\varepsilon_a\rangle, \mathcal{E}_a]) = -\overline{[U_a, |\varepsilon_a\rangle]}$, $\forall g \in \{\overline{[\]}, -, \ominus, \bowtie, \overline{\bowtie}\}$, $[g]_{\emptyset} = g$, $[D'_2 \circ D'_1]_{\mathcal{G}_1 \uplus \mathcal{G}_2} = [D'_2]_{\mathcal{G}_2} \circ [D'_1]_{\mathcal{G}_1}$, $[D'_1 \oplus D'_2]_{\mathcal{G}_1 \uplus \mathcal{G}_2} = [D'_1]_{\mathcal{G}_1} \oplus [D'_2]_{\mathcal{G}_2}$ and $[Tr(D')]_{\mathcal{G}} = Tr([D']_{\mathcal{G}})$, where \uplus is the disjoint union.*

For any extended PBS-diagram $D : \mathcal{H}^{(n)}$, there exists a bare diagram $\Gamma \vdash D' : n$ and an indexed family of purified \mathcal{H} -channels \mathcal{G} s.t. $[D']_{\mathcal{G}} = D$. We call D' an *underlying bare diagram* of D (which is unique, up to relabelling of the gates).

2.2.3 Quantum semantics

We now equip the extended PBS-diagrams with a quantum semantics, which is a CPTP map acting on the complete state of the particle that goes through it, i.e., its joint polarisation, position and data state. To describe the quantum semantics of an extended PBS-diagram $D : \mathcal{H}^{(n)}$, it is convenient to rely on an underlying bare diagram $\Gamma \vdash D' : n$ and a family of purified channels \mathcal{G} s.t. $[D']_{\mathcal{G}} = D$ (so as to keep track of the environment spaces and be able to identify them via the bare gate indices).

As we defined them, every purified channel comes with its local environment and a unitary evolution acting on both the data register and its local environment. In order to define the overall evolution of the diagram, we consider the global environment as the tensor product of these local environments, and extend every unitary transformation to a global transformation acting on the data register and the global environment:

► **Definition 8.** *Given an indexed family of purified \mathcal{H} -channels $\mathcal{G} = ([U_a, |\varepsilon_a\rangle, \mathcal{E}_a])_{a \in \Gamma}$, let $\mathcal{E}_{\mathcal{G}} := \bigotimes_{a \in \Gamma} \mathcal{E}_a$, $|\varepsilon_{\mathcal{G}}\rangle := \bigotimes_{a \in \Gamma} |\varepsilon_a\rangle \in \mathcal{E}_{\mathcal{G}}$, and $\forall a \in \Gamma$, let $V_a^{\mathcal{G}} := U_a \bigotimes_{x \in \Gamma \setminus \{a\}} I_{\mathcal{E}_x} \in \mathcal{L}(\mathcal{H} \otimes \mathcal{E}_{\mathcal{G}})$.*

If a particle enters an extended PBS-diagram D with a definite polarisation and position in some basis states $|c\rangle \in \mathbb{C}^{\{\rightarrow, \uparrow\}}$ and $|p\rangle \in \mathbb{C}^{[n]}$, respectively, the sequence of transformations applied to the particle and the global environment when the particle goes through the diagram can be deduced from the word path semantics of the underlying bare diagram D' :

$$|c\rangle \otimes |p\rangle \otimes |\psi\rangle \otimes |\varepsilon_{\mathcal{G}}\rangle \mapsto |c_{c,p}^{D'}\rangle \otimes |p_{c,p}^{D'}\rangle \otimes V_{w_{c,p}^{D'}}^{\mathcal{G}}(|\psi\rangle \otimes |\varepsilon_{\mathcal{G}}\rangle)$$

where $w_{c,p}^{D'}$, $c_{c,p}^{D'}$, and $p_{c,p}^{D'}$ are given by the word path semantics, i.e., $(D', c, p) \xrightarrow{w_{c,p}^{D'}} (c_{c,p}^{D'}, p_{c,p}^{D'})$, and $V_w^{\mathcal{G}}$ is inductively defined as $V_{\epsilon}^{\mathcal{G}} := I_{\mathcal{H} \otimes \mathcal{E}}$ and $\forall a \in \Gamma, \forall w \in \Gamma^*$, $V_{aw}^{\mathcal{G}} := V_w^{\mathcal{G}} V_a^{\mathcal{G}}$.

One can actually consider inputting a particle in an arbitrary initial state (i.e., including superpositions of polarisation and position); the transformation applied by the diagram is then obtained from the one above, by linearity. This leads us to define the following:

► **Definition 9.** *Given a bare PBS-diagram $\Gamma \vdash D' : n$ and a family of purified \mathcal{H} -channels \mathcal{G} indexed with Γ , let*

$$U_{D'}^{\mathcal{G}} := \sum_{c \in \{\rightarrow, \uparrow\}, p \in [n]} |c_{c,p}^{D'}\rangle \langle c| \otimes |p_{c,p}^{D'}\rangle \langle p| \otimes V_{w_{c,p}^{D'}}^{\mathcal{G}}$$

⁷ To clarify which kind of diagram we are dealing with, in this subsection we use primed names (e.g., D') when referring to bare PBS-diagrams, and nonprimed names for extended PBS-diagrams.

The triplet $[U_{D'}^{\mathcal{G}}, |\varepsilon_{\mathcal{G}}\rangle, \mathcal{E}_{\mathcal{G}}]$ is nothing but a purified $(\mathbb{C}^{\{\rightarrow, \uparrow\}} \otimes \mathbb{C}^{[n]} \otimes \mathcal{H})$ -channel, which describes the action of the corresponding extended PBS-diagram on the complete state of the particle. Once the particle exits the diagram, the environments of all purified channels are not accessible anymore. As is well-known, the statistics of any “input/output test”, which consists in preparing an arbitrary input state of the particle and measuring the output in an arbitrary basis, then only depend on the CPTP map (the superoperator) induced by $U_{D'}^{\mathcal{G}}$, above, with all environments initially prepared in the global state $|\varepsilon_{\mathcal{G}}\rangle$, and after tracing out all environment spaces – i.e., using circuit-like notations: $|\varepsilon_{\mathcal{G}}\rangle\langle\varepsilon_{\mathcal{G}}| \text{---} \boxed{U_{D'}^{\mathcal{G}}} \text{---} |_{\parallel}$. This superoperator thus precisely captures input/output (in)distinguishability: two quantum channels have the same superoperator if and only if they are indistinguishable in any input/output test. This provides the ground for our definition of the following quantum semantics:

► **Definition 10** (Quantum Semantics). *Given an extended PBS-diagram $D : \mathcal{H}^{(n)}$, let $\llbracket D \rrbracket : \mathcal{L}(\mathbb{C}^{\{\rightarrow, \uparrow\}} \otimes \mathbb{C}^{[n]} \otimes \mathcal{H}) \rightarrow \mathcal{L}(\mathbb{C}^{\{\rightarrow, \uparrow\}} \otimes \mathbb{C}^{[n]} \otimes \mathcal{H})$ be the superoperator defined as*

$$\llbracket D \rrbracket := \rho \mapsto \text{Tr}_{\mathcal{E}_{\mathcal{G}}}(U_{D'}^{\mathcal{G}}(\rho \otimes |\varepsilon_{\mathcal{G}}\rangle\langle\varepsilon_{\mathcal{G}}|)U_{D'}^{\mathcal{G}\dagger}) = |\varepsilon_{\mathcal{G}}\rangle\langle\varepsilon_{\mathcal{G}}| \text{---} \boxed{U_{D'}^{\mathcal{G}}} \text{---} |_{\parallel}$$

where $\Gamma \vdash D' : n$ is an underlying bare diagram and \mathcal{G} is an indexed family of purified \mathcal{H} -channels s.t. $[D']_{\mathcal{G}} = D$.

Note that the quantum semantics is preserved by the “only topology matters” structural congruence on diagrams. Indeed, it is defined using only the family \mathcal{G} and the word path semantics of its underlying bare diagram D' , which is invariant modulo diagram deformation. It is clear that when deforming D we do not have to change D' and \mathcal{G} , since it suffices to deform D' accordingly.

3 Observational equivalence of purified channels

In this section we address the problem of deciding whether two purified channels $[U, |\varepsilon\rangle, \mathcal{E}]$ and $[U', |\varepsilon'\rangle, \mathcal{E}']$ can be distinguished in an experiment involving coherent control, within the framework of PBS-diagrams just established. We introduce for that the notion of *contexts*, which are extended PBS-diagrams with a “hole”: if for any context, filling its hole with $[U, |\varepsilon\rangle, \mathcal{E}]$ or $[U', |\varepsilon'\rangle, \mathcal{E}']$ leads to diagrams with the same quantum semantics, then the two purified channels $[U, |\varepsilon\rangle, \mathcal{E}]$ and $[U', |\varepsilon'\rangle, \mathcal{E}']$ are indistinguishable within our framework, even with the help of the coherent control provided by extended PBS-diagrams.

3.1 Contexts

A context is an extended PBS-diagram with a *hole*, i.e., a (unique) particular empty gate, without any purified channel specified *a priori*. Equivalently a context can be seen as a bare PBS-diagram partially filled: all but one gate are filled with purified channels. Formally:

- **Definition 11** (Context). *A context $C[\cdot] : \mathcal{H}^{(n)}$ (with $n \in \mathbb{N}$) is inductively defined as follows:*
- The hole gate $\text{---} \square \text{---} : \mathcal{H}^{(1)}$ is a context;
 - If $C[\cdot] : \mathcal{H}^{(n)}$ is a context and $D : \mathcal{H}^{(n)}$ is an extended PBS-diagram then $D \circ C[\cdot] : \mathcal{H}^{(n)}$ and $C[\cdot] \circ D : \mathcal{H}^{(n)}$ are contexts;
 - If $C[\cdot] : \mathcal{H}^{(n)}$ is a context and $D : \mathcal{H}^{(m)}$ is an extended PBS-diagram then $D \oplus C[\cdot] : \mathcal{H}^{(m+n)}$ and $C[\cdot] \oplus D : \mathcal{H}^{(n+m)}$ are contexts;
 - If $C[\cdot] : \mathcal{H}^{(n+1)}$ is a context then $\text{Tr}(C[\cdot]) : \mathcal{H}^{(n)}$ is a context.

Like bare and extended PBS-diagrams, contexts are defined up to structural congruence.

► **Definition 12** (Substitution). *For any context $C[\cdot] : \mathcal{H}^{(n)}$ and any purified \mathcal{H} -channel $[U, |\varepsilon\rangle, \mathcal{E}]$, let $C[U, |\varepsilon\rangle, \mathcal{E}] : \mathcal{H}^{(n)}$ be the extended PBS-diagram obtained by replacing the single hole \square in $C[\cdot]$ by the purified channel $\boxed{U, |\varepsilon\rangle}$.*

After some purified channel is plugged in, contexts allow one to compare the quantum semantics $\llbracket C[U, |\varepsilon\rangle, \mathcal{E}] \rrbracket$ and $\llbracket C[U', |\varepsilon'\rangle, \mathcal{E}'] \rrbracket$ induced by different purified channels $[U, |\varepsilon\rangle, \mathcal{E}]$ and $[U', |\varepsilon'\rangle, \mathcal{E}']$. We consider in the following three subclasses of contexts, depending on the kind of coherent control one may allow to distinguish purified channels: whether we exclude the use of PBS (\boxtimes), of polarisation flips (“negations” \ominus), or whether we allow both. This leads us to define the following equivalence relations:

► **Definition 13** (Observational equivalences). *Given two purified \mathcal{H} -channels $[U, |\varepsilon\rangle, \mathcal{E}]$ and $[U', |\varepsilon'\rangle, \mathcal{E}']$, we consider the three following refinements of observational equivalences (for $i \in \{0, 1, 2\}$): $[U, |\varepsilon\rangle, \mathcal{E}] \approx_i [U', |\varepsilon'\rangle, \mathcal{E}']$ if $\forall C[\cdot] \in \mathcal{C}_i$, $\llbracket C[U, |\varepsilon\rangle, \mathcal{E}] \rrbracket = \llbracket C[U', |\varepsilon'\rangle, \mathcal{E}'] \rrbracket$, where:*

- \mathcal{C}_0 is the set of \boxtimes -free contexts $C[\cdot] : \mathcal{H}^{(1)}$;
- \mathcal{C}_1 is the set of \ominus -free contexts $C[\cdot] : \mathcal{H}^{(1)}$;
- \mathcal{C}_2 is the set of all contexts $C[\cdot] : \mathcal{H}^{(1)}$.

Note that contexts in \mathcal{C}_0 do not perform any coherent control; these consist in just a linear sequence of gates and negations, possibly composed in parallel with closed loops (i.e., traces of such sequences), including a hole gate somewhere. It is clear, by deformation of diagrams, that more general contexts can always be described as follows:

► **Proposition 14.** *For any context $C[\cdot] \in \mathcal{C}_2$ there exists an extended PBS-diagram D such that $C[\cdot] = \boxed{D, \square}$. Moreover if $C[\cdot] \in \mathcal{C}_1$ then D can be chosen \ominus -free.*

► **Remark 15.** In Definition 13 we only consider contexts with a single input/output wire. This is because we intend to use contexts to distinguish purified channels; now, if one can distinguish two purified channels with a context of type $\mathcal{H}^{(n)}$ but no context of type $\mathcal{H}^{(1)}$, then intuitively this means that the extra power comes from the preparation of the initial state and/or some particular measurement, which are not represented in the context. Actually, except in the \mathcal{C}_0 case, allowing multiple input/output wires does not increase the distinguishability power of the contexts.

3.2 Observational equivalence using PBS-free contexts

Let us start by characterising which purified channels are indistinguishable by \boxtimes -free contexts in \mathcal{C}_0 . Not surprisingly, we recover the usual indistinguishability by input/output tests, which is captured by the fact that the two purified channels lead to the same superoperator:⁸

► **Definition 16** ((First-level) Superoperator). *Given a purified \mathcal{H} -channel $[U, |\varepsilon\rangle, \mathcal{E}]$, let $\mathcal{S}_{[U, |\varepsilon\rangle, \mathcal{E}]}^{(1)} : \mathcal{L}(\mathcal{H}) \rightarrow \mathcal{L}(\mathcal{H}) = \rho \mapsto \text{Tr}_{\mathcal{E}}(U(\rho \otimes |\varepsilon\rangle\langle\varepsilon|)U^\dagger)$ be the (“first-level”) superoperator of $[U, |\varepsilon\rangle, \mathcal{E}]$. Graphically,*

$$\mathcal{S}_{[U, |\varepsilon\rangle, \mathcal{E}]}^{(1)} := \begin{array}{c} \text{---} \\ \text{---} \end{array} \boxed{U} \begin{array}{c} \text{---} \\ \text{---} \end{array} \begin{array}{c} \text{---} \\ \text{---} \end{array}$$

⁸ In other words, if two purified channels can be distinguished using a \boxtimes -free context, then they could already be distinguished with simply an input/output test (or with a trivial context \square).

► **Theorem 17.** *Given two purified \mathcal{H} -channels $[U, |\varepsilon\rangle, \mathcal{E}]$ and $[U', |\varepsilon'\rangle, \mathcal{E}']$, $[U, |\varepsilon\rangle, \mathcal{E}] \approx_0 [U', |\varepsilon'\rangle, \mathcal{E}']$ iff they have the same (first-level) superoperator. Graphically,*

$$[U, |\varepsilon\rangle, \mathcal{E}] \approx_0 [U', |\varepsilon'\rangle, \mathcal{E}'] \quad \text{iff} \quad \begin{array}{c} \text{---} \\ | \varepsilon \rangle \text{---} \boxed{U} \text{---} \\ \text{---} \end{array} = \begin{array}{c} \text{---} \\ | \varepsilon' \rangle \text{---} \boxed{U'} \text{---} \\ \text{---} \end{array} \quad (\text{S1})$$

3.3 Observational equivalence using negation-free contexts

Allowing contexts with PBS significantly increases their power to distinguish purified channels. In [1], a particular kind of coherent control – namely, the “*first half of a quantum switch*” [6, 2, 12] – has been considered, which can be rephrased using contexts of the form:

The authors proved that with these particular contexts, two purified channels leading to the same (first-level) superoperator are indistinguishable if and only if they also have the same (first-level) transformation matrix, which is defined as follows⁹

► **Definition 18** ((First-level) Transformation Matrix). *Given a purified \mathcal{H} -channel $[U, |\varepsilon\rangle, \mathcal{E}]$, let $T_{[U, |\varepsilon\rangle, \mathcal{E}]}^{(1)} := (I_{\mathcal{H}} \otimes \langle \varepsilon |) U (I_{\mathcal{H}} \otimes |\varepsilon \rangle) \in \mathcal{L}(\mathcal{H})$ be the (“first-level”) transformation matrix of $[U, |\varepsilon\rangle, \mathcal{E}]$. Graphically,*

$$T_{[U, |\varepsilon\rangle, \mathcal{E}]}^{(1)} := \begin{array}{c} \text{---} \\ | \varepsilon \rangle \text{---} \boxed{U} \text{---} \\ \langle \varepsilon | \end{array}$$

We extend this result to any $\text{---} \ominus \text{---}$ -free context.

► **Theorem 19.** *Given two purified \mathcal{H} -channels $[U, |\varepsilon\rangle, \mathcal{E}]$ and $[U', |\varepsilon'\rangle, \mathcal{E}']$, $[U, |\varepsilon\rangle, \mathcal{E}] \approx_1 [U', |\varepsilon'\rangle, \mathcal{E}']$ iff they have the same (first-level) superoperator and the same (first-level) transformation matrix. Graphically,*

$$[U, |\varepsilon\rangle, \mathcal{E}] \approx_1 [U', |\varepsilon'\rangle, \mathcal{E}'] \quad \text{iff} \quad \left\{ \begin{array}{l} \begin{array}{c} \text{---} \\ | \varepsilon \rangle \text{---} \boxed{U} \text{---} \\ \text{---} \end{array} = \begin{array}{c} \text{---} \\ | \varepsilon' \rangle \text{---} \boxed{U'} \text{---} \\ \text{---} \end{array} \quad (\text{S1}) \\ \begin{array}{c} \text{---} \\ | \varepsilon \rangle \text{---} \boxed{U} \text{---} \\ \langle \varepsilon | \end{array} = \begin{array}{c} \text{---} \\ | \varepsilon' \rangle \text{---} \boxed{U'} \text{---} \\ \langle \varepsilon' | \end{array} \quad (\text{T1}) \end{array} \right.$$

One can illustrate how the transformation matrices enter the game by considering for example the following context :

By plugging in $[U, |\varepsilon\rangle, \mathcal{E}]$, the extended PBS-diagram maps a pure input state $\frac{|\rightarrow\rangle + |\uparrow\rangle}{\sqrt{2}} \otimes |\psi\rangle \in \mathbb{C}^{\{\rightarrow, \uparrow\}} \otimes \mathcal{H}$ (together with the environment initial state $|\varepsilon\rangle \in \mathcal{E}$) to the state $\frac{1}{\sqrt{2}}|\rightarrow\rangle \otimes |\psi\rangle \otimes |\varepsilon\rangle + \frac{1}{\sqrt{2}}|\uparrow\rangle \otimes U(|\psi\rangle \otimes |\varepsilon\rangle)$, so that after tracing out the environment a cross term $\frac{1}{2}|\uparrow\rangle\langle\rightarrow| \otimes \text{Tr}_{\mathcal{E}}[U(|\psi\rangle\langle\psi| \otimes |\varepsilon\rangle\langle\varepsilon|)] = \frac{1}{2}|\uparrow\rangle\langle\rightarrow| \otimes T_{[U, |\varepsilon\rangle, \mathcal{E}]}^{(1)}|\psi\rangle\langle\psi|$ appears.

⁹ Originally, in [1], the transformation matrix was defined for a given unitary purification of a CPTP map $S : \mathcal{L}(\mathcal{H}) \rightarrow \mathcal{L}(\mathcal{H})$ in the form $U : |\psi\rangle_{\mathcal{H}} \otimes |\varepsilon\rangle \mapsto \sum_i K_i |\psi\rangle_{\mathcal{H}} \otimes |i\rangle_{\mathcal{E}}$ (where the K_i 's are Kraus operators of S , and where an environment space \mathcal{E} was introduced, with an orthonormal basis $\{|i\rangle_{\mathcal{E}}\}_i$ and an initial state $|\varepsilon\rangle$), as $T := \sum_i \langle \varepsilon | i \rangle_{\mathcal{E}} K_i$. This is indeed consistent with our Definition 18 here, as with these notations $U(I_{\mathcal{H}} \otimes |\varepsilon\rangle) = \sum_i K_i \otimes |i\rangle_{\mathcal{E}}$, so that $(I_{\mathcal{H}} \otimes \langle \varepsilon |) U (I_{\mathcal{H}} \otimes |\varepsilon\rangle) = \sum_i \langle \varepsilon | i \rangle_{\mathcal{E}} K_i = T$.

We note also that the two conditions (S1) and (T1) are nonredundant, i.e., one does not imply the other. Indeed, there exist cases where $\mathcal{S}_{[U,|\varepsilon],\mathcal{E}]}^{(1)} = \mathcal{S}_{[U',|\varepsilon'],\mathcal{E}']}^{(1)}$ but $T_{[U,|\varepsilon],\mathcal{E}]}^{(1)} \neq T_{[U',|\varepsilon'],\mathcal{E}']}^{(1)}$ (e.g., given any \mathcal{H} , $\mathcal{E} = \mathcal{E}' = \mathbb{C}$, $U = I_{\mathcal{H}}$, $U' = -I_{\mathcal{H}}$ and $|\varepsilon\rangle = |\varepsilon'\rangle = |1\rangle$), and cases where $\mathcal{S}_{[U,|\varepsilon],\mathcal{E}]}^{(1)} \neq \mathcal{S}_{[U',|\varepsilon'],\mathcal{E}']}^{(1)}$ but $T_{[U,|\varepsilon],\mathcal{E}]}^{(1)} = T_{[U',|\varepsilon'],\mathcal{E}']}^{(1)}$ (e.g., $\mathcal{H} = \mathcal{E} = \mathcal{E}' = \mathbb{C}^2$, $U = I_{\mathcal{H}} \otimes X$, $U' = X \otimes X$ and $|\varepsilon\rangle = |\varepsilon'\rangle = |0\rangle$).¹⁰

3.4 Observational equivalence using general contexts

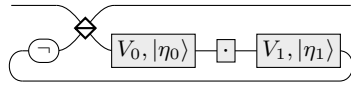

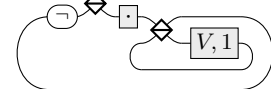

We will now see that allowing negations (\neg) increases the power of contexts to distinguish purified channels. To characterise the indistinguishability of purified channels with arbitrary contexts, we introduce *second-level* superoperators and *second-level* transformation matrices:

► **Definition 20** (Second-level Superoperator and Transformation Matrix). *Given a purified \mathcal{H} -channel $[U, |\varepsilon], \mathcal{E}]$, let $\mathcal{S}_{[U,|\varepsilon],\mathcal{E}]}^{(2)} : \mathcal{L}(\mathcal{H}^{\otimes 2}) \rightarrow \mathcal{L}(\mathcal{H}^{\otimes 2}) = \rho \mapsto \text{Tr}_{\mathcal{E}}(U^{(2)}(\rho \otimes |\varepsilon\rangle\langle\varepsilon|)U^{(2)\dagger})$ be the “second-level” superoperator and $T_{[U,|\varepsilon],\mathcal{E}]}^{(2)} := (I_{\mathcal{H}^{\otimes 2}} \otimes \langle\varepsilon|)U^{(2)}(I_{\mathcal{H}^{\otimes 2}} \otimes |\varepsilon\rangle) \in \mathcal{L}(\mathcal{H}^{\otimes 2})$ be the “second-level” transformation matrix of $[U, |\varepsilon], \mathcal{E}]$, where $U^{(2)} := (I_{\mathcal{H}} \otimes U)(\mathfrak{S} \otimes I_{\mathcal{E}})(I_{\mathcal{H}} \otimes U)$ and $\mathfrak{S} := |\psi_1\rangle \otimes |\psi_2\rangle \mapsto |\psi_2\rangle \otimes |\psi_1\rangle$ is the swap operator. Graphically, $U^{(2)} = \overline{\boxed{U}} \overline{\boxed{U}}$,*

$$\mathcal{S}_{[U,|\varepsilon],\mathcal{E}]}^{(2)} := \overline{\boxed{U}} \overline{\boxed{U}} \quad \text{and} \quad T_{[U,|\varepsilon],\mathcal{E}]}^{(2)} := \langle\varepsilon| \overline{\boxed{U}} \overline{\boxed{U}} |\varepsilon\rangle$$

► **Theorem 21.** *Given two purified \mathcal{H} -channels $[U, |\varepsilon], \mathcal{E}]$ and $[U', |\varepsilon'], \mathcal{E}']$, $[U, |\varepsilon], \mathcal{E}] \approx_2 [U', |\varepsilon'], \mathcal{E}']$ iff they have the same (first level) transformation matrix, the same second level superoperator and the same second level transformation matrix. Graphically,*

$$[U, |\varepsilon], \mathcal{E}] \approx_2 [U', |\varepsilon'], \mathcal{E}'] \quad \text{iff} \quad \left\{ \begin{array}{l} |\varepsilon\rangle \overline{\boxed{U}} \langle\varepsilon| = |\varepsilon'\rangle \overline{\boxed{U'}} \langle\varepsilon'| \quad (\text{T1}) \\ |\varepsilon\rangle \overline{\boxed{U}} \overline{\boxed{U}} \langle\varepsilon| = |\varepsilon'\rangle \overline{\boxed{U'}} \overline{\boxed{U'}} \langle\varepsilon'| \quad (\text{S2}) \\ |\varepsilon\rangle \overline{\boxed{U}} \overline{\boxed{U}} \langle\varepsilon| = |\varepsilon'\rangle \overline{\boxed{U'}} \overline{\boxed{U'}} \langle\varepsilon'| \quad (\text{T2}) \end{array} \right.$$

The contexts used in the proof to show that the constraints (S2) and (T2) are required are of the form  and , respectively, for some specific choices of purified channels $[V_0, |\eta_0\rangle, \mathcal{H} \otimes \mathbb{C}^2]$, $[V_1, |\eta_1\rangle, \mathcal{H} \otimes \mathbb{C}^2]$ and $[V, 1, \mathbb{C}]$. Hence, if either the second level superoperators or the second level transformation matrices of two purified channels differ, then the channels can be distinguished by using such contexts.

One may have expected the condition (S1) – i.e., that the two channels have the same first-level superoperator – to also appear in Theorem 21 (as it did in the previous two cases). This would however have been redundant, as can be seen from the following remark:

¹⁰ Where $X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$.

► Remark 22. Two purified channels $[U, |\varepsilon\rangle, \mathcal{E}]$ and $[U', |\varepsilon'\rangle, \mathcal{E}']$ having the same second level superoperator also have the same first level superoperator, i.e., Condition (S2) implies (S1).

We note, on the other hand, that the three remaining conditions (T1), (S2) and (T2) are nonredundant. I.e., for each of the three there exist cases where only this condition is not satisfied, and where $[U, |\varepsilon\rangle, \mathcal{E}]$ and $[U', |\varepsilon'\rangle, \mathcal{E}']$ can be distinguished. E.g., with $\mathcal{E} = \mathcal{E}' = \mathbb{C}$, $U = I_{\mathcal{H}}, U' = -I_{\mathcal{H}}, |\varepsilon\rangle = |\varepsilon'\rangle = 1$, only (T1) fails to hold; with $\mathcal{H} = \mathcal{E} = \mathcal{E}' = \mathbb{C}^2$, $U = \text{CNOT}, U' = (\sqrt{Z} \otimes Z)\text{CNOT}, |\varepsilon\rangle = |\varepsilon'\rangle = |0\rangle$, only (S2) fails to hold; and with $\mathcal{H} = \mathcal{E} = \mathcal{E}' = \mathbb{C}^2$, $U = I_{\mathcal{H}} \otimes X, U' = I_{\mathcal{H}} \otimes ZX, |\varepsilon\rangle = |\varepsilon'\rangle = |0\rangle$, only (T2) fails to be satisfied.¹¹

4 Observational equivalence beyond PBS-diagrams

In this section, we define a new equivalence relation, inspired by the uniqueness (up to an isometry) of Stinespring's dilations, which subsumes the observational equivalences defined so far. For that let us first introduce an isometry-based preorder over purified channels:

► **Definition 23.** Given two purified \mathcal{H} -channels $[U, |\varepsilon\rangle, \mathcal{E}]$ and $[U', |\varepsilon'\rangle, \mathcal{E}']$, one has $[U, |\varepsilon\rangle, \mathcal{E}] \triangleleft_{iso} [U', |\varepsilon'\rangle, \mathcal{E}']$ if there exists an isometry $W: \mathcal{E} \rightarrow \mathcal{E}'$ s.t. $W|\varepsilon\rangle = |\varepsilon'\rangle$ and $(I_{\mathcal{H}} \otimes W)U = U'(I_{\mathcal{H}} \otimes W)$. In pictures:

$$|\varepsilon\rangle \text{---} \boxed{W} \text{---} = |\varepsilon'\rangle \quad \begin{array}{c} \mathcal{H} \\ \text{---} \\ \boxed{U} \\ \text{---} \\ \mathcal{E} \end{array} \text{---} \begin{array}{c} \mathcal{H} \\ \text{---} \\ \boxed{W} \\ \text{---} \\ \mathcal{E}' \end{array} = \begin{array}{c} \mathcal{H} \\ \text{---} \\ \boxed{W} \\ \text{---} \\ \mathcal{E}' \end{array} \text{---} \begin{array}{c} \mathcal{H} \\ \text{---} \\ \boxed{U'} \\ \text{---} \\ \mathcal{E}' \end{array}$$

Note that \triangleleft_{iso} is not an equivalence relation. It is not symmetric; moreover, its symmetric closure is not transitive.¹² This leads us to consider the following:

► **Definition 24 (Iso-equivalence).** The iso-equivalence of purified channels is defined as the symmetric and transitive closure of \triangleleft_{iso} : $\approx_{iso} := \triangleleft_{iso}^*$.

The iso-equivalence is a candidate for characterising indistinguishability of purified channels in more general coherent-control settings. Actually, if $[U, |\varepsilon\rangle, \mathcal{E}]$ and $[U', |\varepsilon'\rangle, \mathcal{E}']$ are two iso-equivalent purified channels, then intuitively, in any coherent-control setting, $[U, |\varepsilon\rangle, \mathcal{E}]$ can be replaced by $[U', |\varepsilon'\rangle, \mathcal{E}']$ without changing the global behaviour. Indeed, the evolution of the environment associated with the purified channel is roughly speaking the same (up to the isometry W): initialised in the state $W|\varepsilon\rangle$ (and with the data register in the state $|\phi\rangle$), the application of U' leads to the state $U'(I_{\mathcal{H}} \otimes W)(|\phi\rangle \otimes |\varepsilon\rangle)$, which is equal to $(I_{\mathcal{H}} \otimes W)U(|\phi\rangle \otimes |\varepsilon\rangle)$. So applying U' somehow first cancels the application of W , then applies U , and finally applies W again – which will be cancelled again by the next application of U' , and so on. The last application of W is absorbed when the environment is traced out. In pictures:

¹¹ Where $Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$, $\sqrt{Z} = \begin{pmatrix} 1 & 0 \\ 0 & i \end{pmatrix}$ and $\text{CNOT} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}$.

¹² Taking $\mathcal{H} = \mathbb{C}$, one has $[1, 1, \mathbb{C}] \triangleleft_{iso} [I_{\mathbb{C}^2}, |0\rangle, \mathbb{C}^2]$ (with $W = |0\rangle$) but $\neg([I_{\mathbb{C}^2}, |0\rangle, \mathbb{C}^2] \triangleleft_{iso} [1, 1, \mathbb{C}])$ (as there is no isometry from \mathbb{C}^2 to \mathbb{C}). With the Pauli operator $Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ one also has $[1, 1, \mathbb{C}] \triangleleft_{iso} [Z, |0\rangle, \mathbb{C}^2]$ (again with $W = |0\rangle$), but $[I_{\mathbb{C}^2}, |0\rangle, \mathbb{C}^2]$ and $[Z, |0\rangle, \mathbb{C}^2]$ are not in relation since there is no unitary W such that $WI_{\mathbb{C}^2} = ZW$ (as $I_{\mathbb{C}^2}$ and Z have distinct eigenvalues).

In the framework of PBS-diagrams, one can actually show that the iso-equivalence subsumes, but does not coincide with the \approx_2 -equivalence (which in turn subsumes the \approx_1 - and \approx_0 -equivalences).

► **Proposition 25.** $\approx_{iso} \subsetneq \approx_2 \subsetneq \approx_1 \subsetneq \approx_0$.

Proof. [$\approx_{iso} \subseteq \approx_2$] Since \approx_2 is an equivalence relation it is enough to show that $\triangleleft_{iso} \subseteq \approx_2$. If $[U, |\varepsilon\rangle, \mathcal{E}] \triangleleft_{iso} [U', |\varepsilon'\rangle, \mathcal{E}']$, then the three conditions of Theorem 21 are satisfied, implying $[U, |\varepsilon\rangle, \mathcal{E}] \approx_2 [U', |\varepsilon'\rangle, \mathcal{E}']$.

[$\approx_2 \neq \approx_{iso}$] We consider the following two purified \mathbb{C} -channels: $[X, |0\rangle, \mathbb{C}^3]$ and $[XN, |0\rangle, \mathbb{C}^3]$ where $X = |x\rangle \mapsto |x-1 \bmod 3\rangle$ and $N = |x\rangle \mapsto (-1)^x|x\rangle$ are two (qutrit) unitary transformations. The two purified channels are \approx_2 -equivalent as they satisfy the conditions of Theorem 21. In order to show that they are not iso-equivalent, note that if two purified \mathbb{C} -channels $[U, |\varepsilon\rangle, \mathcal{E}]$ and $[U', |\varepsilon'\rangle, \mathcal{E}']$ are iso-equivalent then for any $k \geq 0$ one has $\langle \varepsilon | U^k | \varepsilon \rangle = \langle \varepsilon' | W U^k | \varepsilon \rangle = \langle \varepsilon' | U'^k W | \varepsilon \rangle = \langle \varepsilon' | U'^k | \varepsilon' \rangle$. Since $\langle 0 | X^3 | 0 \rangle = 1 \neq -1 = \langle 0 | (XN)^3 | 0 \rangle$, it follows that $[X, |0\rangle, \mathbb{C}]$ and $[XN, |0\rangle, \mathbb{C}]$ are indeed not iso-equivalent.

[$\approx_2 \subsetneq \approx_1 \subsetneq \approx_0$] The inclusions are clear from the characterisations of Theorems 17, 19 and 21, together with Remark 22. The fact that the inclusions are strict follows from the observations that the various conditions appearing in these theorems are non-redundant. ◀

Although for PBS-diagrams, the \approx_2 -equivalence characterises the observational equivalence of purified channels, it could thus be that more general coherent-control settings may distinguish \approx_2 -equivalent channels. For instance one can imagine including nonpolarising beam splitters, or more general rotations of the polarisation than just the negation, or even settings with “higher-dimensional polarisations”, which would allow a particle to go more than twice through each gate. Such a setting would be able for instance to distinguish the pair of purified channels used in the proof of Proposition 25.

We conjecture that two purified channels are not iso-equivalent if and only if they can be distinguished by some coherently-controlled quantum computation. Here, the notion of coherently-controlled quantum computation is left loosely defined, and corresponds intuitively to some generalisation of PBS-diagrams allowing a particle to go through a gate an arbitrary number of times.

5 Discussion

In this work, we have extended the PBS-diagrams framework of [8] to allow for the coherent control of more general quantum channels, described as purified channels. By defining observational equivalence relations, we have characterised which purified channels are distinguishable depending on the class of contexts allowed (defined as PBS-diagrams with a hole). We also proposed the more refined iso-equivalence, which appears as a candidate for channel indistinguishability in more general coherent-control setups than PBS-diagrams.

However, unlike the previous equivalence relations that can be verified with simple criteria – by comparing superoperators and transformation matrices – the iso-equivalence, defined as a transitive closure, is *a priori* not as easy to check in general.

The framework of PBS-diagrams considered here has a number of limitations, which could be lifted in future works. For instance, it would be of practical interest to allow for nonpolarising beam splitters and more general operations on the polarisation; to consider using higher-dimensional control systems, with generalised PBS; or to consider several particles going through the diagrams, possibly correlating the different local environments for future uses of the diagrams, and/or inducing interference effects. We note also that in our description of purified channels, the state of the environment does not evolve by itself, except when the flying particle goes through the channel and the unitary U is applied to the joint system. In fact, as long as each channel is used at most twice (as it was case in this paper), any free evolution of the environment between two uses could be included in U ; however, introducing such an evolution could make a difference if the channels are used more than twice, and the evolution is different between different uses.

Other open questions raised by our work here include equipping extended PBS-diagrams with an equational theory, as was done in [8] for the case of “pure” PBS-diagrams; lifting our observational equivalences to the diagrams themselves; and investigating more general coherent-control settings, to check in particular whether our iso-equivalence is indeed the good definition for general distinguishability, and if it has a more operational characterisation.

A Structural congruence of PBS-diagrams

Bare PBS-diagrams, extended PBS-diagrams and contexts are defined up to the congruence generated by the following equalities (with all $n, m, k \geq 0$), where I_n is the “identity diagram” $I_n := \oplus^n(-)$ (graphically: $I_n = n\{\overline{\quad}\}$, with $I_0 = \{\overline{\quad}\}$); $\sigma_{1,n}$ is the “first-wire-goes-last diagram” defined inductively by $\sigma_{1,0} := -$ and $\sigma_{1,n+1} := (I_n \oplus \times) \circ (\sigma_{1,n} \oplus -)$ (graphically: $\sigma_{1,n} = n\{\overline{\quad}\}$); and $D : n$ denotes here either a bare PBS-diagram $D : n$, an extended PBS-diagram $D : \mathcal{H}^{(n)}$, or a context $C[\cdot] : \mathcal{H}^{(n)}$:

- *Neutrality of the identity:* for any $D : n$,

$$D \circ I_n = D = I_n \circ D$$

- *Neutrality of the empty diagram:* for any $D : n$,

$$\text{Tr}^m((I_n \oplus D_2) \circ D_1) = \text{Tr}^m(D_1 \circ (I_n \oplus D_2))$$

where Tr^m denotes the m^{th} power of the trace operation.

- *Superposing:* for any $D_1 : n$ and $D_2 : m + 1$,

$$\text{Tr}(D_1 \oplus D_2) = D_1 \oplus \text{Tr}(D_2)$$

- *Yanking:*

$$\text{Tr}(\infty) = -$$

These equalities are the coherence axioms of a traced PROP, that is, a PROP that is also a traced symmetric monoidal category. An explicit definition of the concept of traced PROP is given in [8]. See also [14] and [18] for a definition of PROPs and further details about them.

B Well-definedness of the word path semantics and compatibility with the structural congruence

It can be proved in the same way as for Propositions 5 and 6 in [8], that the word path semantics is well-defined despite the restriction that $k \leq 2$ in Rule (T_k) , that it is deterministic (i.e., that for any bare diagram $D : n$, polarisation $c \in \{\rightarrow, \uparrow\}$ and position $p \in [n]$, there exist some unique c', p' and w such that $(D, c, p) \xrightarrow{w} (c', p')$ – which allows us to define $c_{c,p}^D$, $p_{c,p}^D$ and $w_{c,p}^D$), and that conversely, for any target polarisation c' and position p' , there exist

c and p such that $(D, c, p) \xrightarrow{w} (c', p')$ for some w (in other words, the map $(c, p) \mapsto (c_{c,p}^D, p_{c,p}^D)$ is a bijection). We give here some additional details about the fact that it is invariant modulo diagram deformation:

► **Proposition 26.** *The word path semantics is invariant modulo diagram deformation.*

Proof. One has to check, for each of the equalities given in Appendix A, that the two sides have the same word path semantics. This is straightforward in each case except for dinaturality. In this case we first prove that Rule (\mathbb{T}_k^m) below follows from those of Definition 2:

$$\frac{D : n + m \quad \forall i \in \{0, \dots, k\}, (D, c_i, p_i) \xrightarrow{w_i} (c_{i+1}, p_{i+1}) \quad (p_{i+1} \geq n) \Leftrightarrow (i < k)}{(Tr^m(D), c_0, p_0) \xrightarrow{w_0 \dots w_k} (c_{k+1}, p_{k+1})} (\mathbb{T}_k^m)$$

for all $k, m \in \mathbb{N}$.

To prove this, we proceed by induction on m . The case $m = 0$ is trivial, and the case $m = 1$ corresponds to Rule (\mathbb{T}_k) of Definition 2 (the rule follows even for $k \geq 3$ since it is then not possible to satisfy its premises).

Now, assume that Rule (\mathbb{T}_k^m) follows from those of Definition 2. Let $D : n + m + 1$. Let $c_0 \in \{\rightarrow, \uparrow\}$ and $p_0 \in [n]$. Let $(c_1, p_1), \dots, (c_{k+1}, p_{k+1})$ be the (unique) sequence of couples such that $\forall i \in \{0, \dots, k\}, (D, c_i, p_i) \xrightarrow{w_i} (c_{i+1}, p_{i+1})$ and $(p_{i+1} \geq n) \Leftrightarrow (i < k)$ (that is, $k + 1$ is the first index after 0 such that $p_{k+1} < n$). Let $(c_{i_0}, p_{i_0}), \dots, (c_{i_{k'}+1}, p_{i_{k'}+1})$, with $0 = i_0 < i_1 < \dots < i_{k'} < i_{k'+1} = k + 1$, be the subsequence of $(c_1, p_1), \dots, (c_{k+1}, p_{k+1})$ where all couples with $p_i = n + m$ have been removed. For each $j \in \{0, \dots, k'\}$, by Rule (\mathbb{T}_k) one has $(Tr(D), c_{i_j}, p_{i_j}) \xrightarrow{w_{i_j} \dots w_{i_{j+1}-1}} (c_{i_{j+1}}, p_{i_{j+1}})$. Additionally, one has $Tr(D) : n + m$ and $(p_{i_{j+1}} \geq n) \Leftrightarrow (j < k')$, so that by Rule (\mathbb{T}_k^m) , one has $(Tr^{m+1}(D), c_0, p_0) \xrightarrow{w_0 \dots w_k} (c_{k+1}, p_{k+1})$, which validates Rule (\mathbb{T}_k^{m+1}) .

Given Rule (\mathbb{T}_k^m) for all k, m , we check the compatibility of the word path semantics with dinaturality as follows: given any $D_1 : n + m$ and $D_2 : m$ with $n, m \geq 0$, on the one hand one has

$$\left\{ \begin{array}{ll} ((I_n \oplus D_2) \circ D_1, c, p) \xrightarrow{w_{c,p}^{D_1}} (c_{c,p}^{D_1}, p_{c,p}^{D_1}) & \text{if } p_{c,p}^{D_1} < n \\ ((I_n \oplus D_2) \circ D_1, c, p) \xrightarrow{w_{c,p}^{D_1} w_{(c_{c,p}^{D_1}), (p_{c,p}^{D_1}-n)}^{D_2}} (c_{(c_{c,p}^{D_1}), (p_{c,p}^{D_1}-n)}^{D_2}, p_{(c_{c,p}^{D_1}), (p_{c,p}^{D_1}-n)}^{D_2}) + n & \text{if } p_{c,p}^{D_1} \geq n \end{array} \right.$$

so that given $c_0 \in \{\rightarrow, \uparrow\}$ and $p_0 \in [n]$, if one has a sequence $((I_n \oplus D_2) \circ D_1, c_0, p_0) \xrightarrow{w_0} (c_1, p_1), \dots, ((I_n \oplus D_2) \circ D_1, c_k, p_k) \xrightarrow{w_k} (c_{k+1}, p_{k+1})$ with $(p_{i+1} \geq n) \Leftrightarrow (i < k)$, then one has a sequence $(D_1, c_0, p_0) \xrightarrow{w'_0} (c'_1, p'_1), (D_2, c'_1, p'_1 - n) \xrightarrow{w''_1} (c_1, p_1 - n), (D_1, c_1, p_1) \xrightarrow{w'_1} (c'_1, p'_1), \dots, (D_1, c_{k-1}, p_{k-1}) \xrightarrow{w'_{k-1}} (c'_k, p'_k), (D_2, c'_k, p'_k - n) \xrightarrow{w''_k} (c_k, p_k - n), (D_1, c_k, p_k) \xrightarrow{w'_k} (c_{k+1}, p_{k+1})$ with $\forall i \in \{0, \dots, k-1\}, w'_i w''_{i+1} = w_i$, and $w'_k = w_k$, so that $(Tr^m((I_n \oplus D_2) \circ D_1), c_0, p_0) \xrightarrow{w'_0 w''_1 \dots w'_{k-1} w''_k w'_k} (c_{k+1}, p_{k+1})$.

On the other hand, one has

$$\left\{ \begin{array}{ll} (D_1 \circ (I_n \oplus D_2), c, p) \xrightarrow{w_{c,p}^{D_1}} (c_{c,p}^{D_1}, p_{c,p}^{D_1}) & \text{if } p < n \\ (D_1 \circ (I_n \oplus D_2), c, p) \xrightarrow{w_{c,p-n}^{D_2} w_{(c_{c,p-n}, (p_{c,p-n}+n))}^{D_1}} (c_{(c_{c,p-n}, (p_{c,p-n}+n))}^{D_1}, p_{(c_{c,p-n}, (p_{c,p-n}+n))}^{D_1}) & \text{if } p \geq n \end{array} \right.$$

so that given $c_0 \in \{\rightarrow, \uparrow\}$ and $p_0 \in [n]$, if one has a sequence $(D_1 \circ (I_n \oplus D_2), c_0, p_0) \xrightarrow{\tilde{w}_0} (c'_1, p'_1), \dots, (D_1 \circ (I_n \oplus D_2), c'_k, p'_k) \xrightarrow{\tilde{w}_k} (c'_{k+1}, p'_{k+1})$ with $(p_{i+1} \geq n) \Leftrightarrow (i < k)$, then one has a sequence $(D_1, c_0, p_0) \xrightarrow{w'_0} (c'_1, p'_1), (D_2, c'_1, p'_1 - n) \xrightarrow{w'_1} (c_1, p_1 - n), (D_1, c_1, p_1) \xrightarrow{w'_1} (c'_1, p'_1), \dots, (D_1, c_{k-1}, p_{k-1}) \xrightarrow{w'_{k-1}} (c'_k, p'_k), (D_2, c'_k, p'_k - n) \xrightarrow{w'_k} (c_k, p_k - n), (D_1, c_k, p_k) \xrightarrow{w'_k} (c_{k+1}, p_{k+1})$ with $w'_0 = \tilde{w}_0$ and $\forall i \in \{0, \dots, k-1\}, w'_i w'_i = \tilde{w}_i$, so that one has $(c'_{k+1}, p'_{k+1}) = (c_{k+1}, p_{k+1})$ and $(Tr^m(D_1 \circ (I_n \oplus D_2)), c_0, p_0) \xrightarrow{w'_0 w'_1 \dots w'_{k-1} w'_k w'_k} (c_{k+1}, p_{k+1})$. This proves that the two sides of the equality have the same semantics. ◀

C Circuit notations

In this paper, we further develop the graphical representation of coherent control by means of PBS-diagrams, but we also use circuit-like notations when it is convenient to represent sequential and parallel compositions of linear transformations $\mathcal{H}_{\text{in}} \rightarrow \mathcal{H}_{\text{out}}$ for some Hilbert spaces \mathcal{H}_{in} and \mathcal{H}_{out} (e.g., unitary operations, density matrices or matrices of the form $|i\rangle\langle j|$) and linear maps $\mathcal{L}(\mathcal{H}_{\text{in}}) \rightarrow \mathcal{L}(\mathcal{H}_{\text{out}})$ (i.e., superoperators). We briefly review these circuit-like notations: given a linear transformation $U : \mathcal{H}_1 \otimes \dots \otimes \mathcal{H}_n \rightarrow \mathcal{H}'_1 \otimes \dots \otimes \mathcal{H}'_k$,

$$\begin{array}{c} \mathcal{H}_1 \\ \vdots \\ \mathcal{H}_n \end{array} \boxed{U} \begin{array}{c} \mathcal{H}'_1 \\ \vdots \\ \mathcal{H}'_k \end{array}$$

is a circuit of type $\mathcal{H}_1 \otimes \dots \otimes \mathcal{H}_n \rightarrow \mathcal{H}'_1 \otimes \dots \otimes \mathcal{H}'_k$. Note that the Hilbert spaces on the wires are generally omitted when these are clear from the context.

The identity operator on a Hilbert space is represented as a wire. Sequential composition consists in plugging two circuits (with the appropriate types) in a row, and tensor product consists in putting two circuits in parallel, e.g., for any linear maps $U : \mathcal{H}_0 \rightarrow \mathcal{H}_1$, $V : \mathcal{H}_1 \rightarrow \mathcal{H}_2$, $W : \mathcal{H}_2 \rightarrow \mathcal{H}_3$:

$$\begin{array}{c} \mathcal{H}_0 \\ \boxed{U} \\ \mathcal{H}_1 \end{array} \begin{array}{c} \mathcal{H}_1 \\ \boxed{V} \\ \mathcal{H}_2 \end{array} = \begin{array}{c} \mathcal{H}_0 \\ \boxed{V \circ U} \\ \mathcal{H}_2 \end{array} \quad \begin{array}{c} \mathcal{H}_0 \\ \boxed{U} \\ \mathcal{H}_1 \end{array} \begin{array}{c} \mathcal{H}_2 \\ \boxed{W} \\ \mathcal{H}_3 \end{array} = \begin{array}{c} \mathcal{H}_0 \\ \boxed{U \otimes W} \\ \mathcal{H}_3 \end{array}$$

The associativity of both \circ and \otimes , and the mixed-product property $((U' \otimes V') \circ (U \otimes V)) = (U' \circ U) \otimes (V' \circ V)$ for some $U : \mathcal{H}_0 \rightarrow \mathcal{H}_1$, $U' : \mathcal{H}_1 \rightarrow \mathcal{H}_2$, $V : \mathcal{H}_3 \rightarrow \mathcal{H}_4$, $V' : \mathcal{H}_4 \rightarrow \mathcal{H}_5$ guarantee the nonambiguity of the circuit-like notations. Quantum states (resp. their adjoints) can be added to input (resp. output) wires, e.g., $|\varphi\rangle \boxed{U} \langle\psi| = \langle\psi|U|\varphi\rangle$.

With the swap $\begin{array}{c} \mathcal{H}_1 \\ \mathcal{H}_2 \end{array} \begin{array}{c} \mathcal{H}_2 \\ \mathcal{H}_1 \end{array} = |\varphi_1\rangle \otimes |\varphi_2\rangle \mapsto |\varphi_2\rangle \otimes |\varphi_1\rangle$, and with quantum states $|\varphi\rangle \in \mathcal{H}$ (resp. their adjoints $\langle\psi| \in \mathcal{H}^\dagger$) seen as linear transformations $\mathbb{C} \rightarrow \mathcal{H}$ (resp. $\mathcal{H} \rightarrow \mathbb{C}$), circuits form a strict symmetric monoidal category. That is, in addition to the fact that the notation is not ambiguous, circuits can be deformed at will (as long as their topology is preserved) without changing the transformation that is represented.

Following [9, 4], we further extend these notations to represent linear maps $\mathcal{L}(\mathcal{H}_{\text{in}}) \rightarrow \mathcal{L}(\mathcal{H}_{\text{out}})$, using the “ground” symbol \dashv . Given a “pure” (i.e., \dashv -free) circuit, plugging one (or several) \dashv in its output wire(s) corresponds essentially to tracing out the corresponding systems – or more precisely, to defining the map that takes an operator (typically, a density matrix, ρ) acting on the input Hilbert spaces, applies the linear map defined by the circuit (as in $\rho \mapsto U\rho U^\dagger$), and traces out the systems to which the ground symbol is attached, e.g.,

$$\begin{array}{c} \mathcal{H}_1 \\ \mathcal{H}_2 \\ \mathcal{H}_3 \end{array} \left[\begin{array}{c} \mathcal{H}'_1 \\ U \\ \mathcal{H}'_2 \\ \mathcal{H}'_3 \end{array} \right]_{\perp} = \rho \mapsto \text{Tr}_{\mathcal{H}'_2 \otimes \mathcal{H}'_3} (U \rho U^\dagger)$$

$$\begin{array}{c} \mathcal{H}_0 \\ |\varphi\rangle \end{array} \left[\begin{array}{c} \mathcal{H}_1 \\ V \\ \varepsilon \end{array} \right]_{\perp} = \rho \mapsto \text{Tr}_{\mathcal{E}} (V(\rho \otimes |\varphi\rangle\langle\varphi|)V^\dagger)$$

where the top example defines a map $\mathcal{L}(\mathcal{H}_1 \otimes \mathcal{H}_2 \otimes \mathcal{H}_3) \rightarrow \mathcal{L}(\mathcal{H}'_1)$, and the bottom example defines a map $\mathcal{L}(\mathcal{H}_0) \rightarrow \mathcal{L}(\mathcal{H}_1)$. We say that such circuits are of type $\mathcal{L}(\mathcal{H}_{\text{in}}) \rightarrow \mathcal{L}(\mathcal{H}_{\text{out}})$.

► **Remark 27.** With these definitions, for a circuit with input Hilbert spaces $\mathcal{H}_1, \dots, \mathcal{H}_n$ and output Hilbert spaces $\mathcal{H}'_1, \dots, \mathcal{H}'_k$ to represent a linear map $\mathcal{L}(\mathcal{H}_1 \otimes \dots \otimes \mathcal{H}_n) \rightarrow \mathcal{L}(\mathcal{H}'_1 \otimes \dots \otimes \mathcal{H}'_k)$, it must contain at least one \perp symbol. As a consequence the CPTP map $\rho \mapsto U \rho U^\dagger$ cannot be represented as \boxed{U} (which is a “pure” circuit) but for instance as \boxed{U} .

Note that one can consider \perp as a generator $\mathcal{L}(\mathcal{H}) \rightarrow \mathcal{L}(\mathbb{C}) = \mathbb{C}$ and place it anywhere in the circuit. Because of the strict symmetric monoidal structure of \perp -free circuits and the fact that $\bigcap_{\perp} = \perp$, this does not create ambiguity since all ways of pulling the \perp symbols to the right give the same linear map. Moreover, circuits with this additional generator still form a strict symmetric monoidal category.

Reconfiguring Independent Sets on Interval Graphs

Abstract

We study reconfiguration of independent sets in interval graphs under the token sliding rule. We show that if two independent sets of size k are reconfigurable in an n -vertex interval graph, then there is a reconfiguration sequence of length $\mathcal{O}(k \cdot n^2)$. We also provide a construction in which the shortest reconfiguration sequence is of length $\Omega(k^2 \cdot n)$.

As a counterpart to these results, we also establish that **Independent Set Reconfiguration** is PSPACE-hard on incomparability graphs, of which interval graphs are a special case.

1 Introduction

Let G be a graph and let k be a positive integer. The *reconfiguration graph* $R_k(G)$ of independent sets of size k in G has as its vertex set the set of all independent sets of size k in G and two independent sets I, J of size k in G are adjacent in $R_k(G)$ whenever $I \Delta J = \{u, v\}$ and $uv \in E(G)$.

When two sets I and J are in the same component of $R_k(G)$ we say that I and J are *reconfigurable*. In such case, we can perform the following transformation process: (1) start by placing one token on each vertex of I ; (2) in each step move one of the tokens to a neighboring vertex in G but always keep the property that the vertices occupied by tokens induce an independent set in G ; (3) finish with tokens occupying all vertices of J . Let (I_0, \dots, I_m) be a path from I to J in $R_k(G)$ so $I_0 = I, I_m = J$. For $i \in \{1, \dots, m\}$, let (u_i, v_i) be a pair of vertices in G such that $I_{i-1} \setminus I_i = \{u_i\}$ and $I_i \setminus I_{i-1} = \{v_i\}$. We say that the sequence $((u_1, v_1), \dots, (u_m, v_m))$ is a *reconfiguration sequence* from I to J in G .

A large body of research is focused on the computational complexity of the corresponding decision problem – **Independent Set Reconfiguration**: given a graph G and two independent sets I and J , determine whether I and J are reconfigurable. If we do not assume anything about the input graph this problem is PSPACE-complete, thus it is natural to investigate how its complexity changes when input graphs are restricted to a particular class of graphs. Demaine et al. [4] showed that the problem can be solved in polynomial time on trees. Lokshtanov and Mouawad [8] proved that it remains PSPACE-complete on bipartite graphs.

Hearn and Demaine [6] showed that it is PSPACE-complete on planar graphs. There are polynomial time algorithms for the class of cographs [7] as well as claw-free graphs [2]. For a general survey of problems related to reconfiguration see [9].

Bonamy and Bousquet [1] presented an algorithm that given an interval graph G and two independent sets of size k in G verifies if the independent sets are reconfigurable in $\mathcal{O}(n^3)$ time. Curiously, their proof does not say anything meaningful about the length of the reconfiguration sequence if the two independent sets are reconfigurable. Since there are at most $\binom{n}{k}$ independent sets of size k , we get a trivial bound on the length of the reconfiguration sequence, namely: $\mathcal{O}(n^k)$. The question whether every two reconfigurable independent sets in an interval graph are connected by a reconfiguration sequence of polynomial length of degree independent of k was raised by Bousquet [3], which we answer in the affirmative in Theorem 1.

1.1 Our results

In this paper we will be mainly considering interval graphs. Our main results are stated in Theorems 1 and 2 below.

► **Theorem 1.** *Let G be an n -vertex interval graph and k be a positive integer. Then every component of $R_k(G)$ has diameter in $\mathcal{O}(k \cdot n^2)$.*

Moreover, there is a polynomial time algorithm that given G , k , and two independent sets I, J of size k in G decides if I and J are reconfigurable and if so outputs a reconfiguration sequence connecting them of length $\mathcal{O}(k \cdot n^2)$.

A lower bound construction shows that the bound on the length of a reconfiguration sequence given in Theorem 1 is close to tight.

► **Theorem 2.** *For all integers $m \geq 1$ and $k \geq 1$, there is an interval graph $G_{m,k}$ with $|V(G_{m,k})|$ in $\mathcal{O}(m+k)$ and two reconfigurable independent sets I, J of size k in $G_{m,k}$ such that every reconfiguration sequence connecting I and J in G is of length $\Omega(k^2 \cdot m)$.*

In light of Theorem 2, so long as $k \in \Theta(m)$, the bound of Theorem 1 is asymptotically tight. However, if k is small compared to n , the bounds of Theorems 1 and 2 can differ by a factor of $\mathcal{O}(n)$. This leads to an interesting problem in its own right. The authors are not aware of any example giving a superlinear lower bound on the length of a reconfiguration sequence when the number of tokens is constant – *even on the class of all graphs*. Specifically, the case $k = 2$ remains open.

Interval graphs are a special case in the more general class of incomparability graphs. As a somewhat expected (and indeed easy) result we have obtained the following theorem.

► **Theorem 3.** *Independent Set Reconfiguration is PSPACE-hard on incomparability graphs, even on incomparability graphs of posets of width at most w for some constant $w \in \mathbb{N}$.*

Another interesting specialization of the incomparability graphs are *permutation graphs*. In [5] the authors show a polynomial time algorithm solving Independent Set Reconfiguration on bipartite permutation graphs. We suspect that general permutation graphs should be amenable to methods similar to the tools we use here on interval graphs, however we have not been able to successfully apply them.

► **Conjecture 4.** *Independent Set Reconfiguration is solvable in polynomial time when restricted to permutation graphs.*

2 Preliminaries

A *component* of a graph G is a non-empty induced subgraph of G that is connected and is vertex-maximal under these properties. The *length* of a path is the number of edges in the path. The distance of two vertices u, v in a graph G is the minimum length of a path connecting u and v in G . The *diameter* of a connected graph is the maximum distance between any pair of vertices in the graph.

A graph G is an *interval graph* if the vertices of G can be associated with intervals on the real line in such a way that two vertices are adjacent in G if and only if the corresponding intervals intersect. Given an interval graph we will always fix an interval representation and identify the vertices with the corresponding intervals. We will also assume that all the endpoints of intervals in the representation are pairwise distinct. This can be easily achieved by perturbing the endpoints where it is needed.

Let S be a reconfiguration sequence from I to J in G . We sometimes say that we *apply* S to I in G and obtain an independent set $S(I)$. When $S = ((u, v))$ we also simply say that we *apply* a pair (u, v) to I and obtain $S(I) = (I \setminus \{u\}) \cup \{v\}$.

Given a sequence S , we denote by $S|_t$ the prefix of S of length t (so $S|_0$ is the empty sequence). Given a reconfiguration sequence $S = ((u_1, v_1), \dots, (u_m, v_m))$ from I to J in G , clearly for each $t \in \{0, \dots, m\}$, the prefix $S|_t$ is a reconfiguration sequence from I to the set $S|_t(I)$ in G . Thus, we also have $S|_0(I) = I$.

3 Upper bound: The Algorithm

In this section we are going to prove Theorem 1. For brevity, we omit implementation details as well as running time analyses of the algorithms outlined in this section. We note that a straightforward implementation of Algorithm 3 below (which is the procedure whose existence implies Theorem 1) would yield a $\mathcal{O}(n^3)$ algorithm.

Let G be an n -vertex interval graph and let k be a positive integer. We fix an interval representation of G distinguishing all the endpoints. There are two natural linear orderings on the vertices of G : \leq_{left} the order increasing along the left endpoints of the intervals and \leq_{right} the order increasing along the right endpoints of the intervals.

An independent set in G is a set of pairwise disjoint intervals, as such they are naturally ordered on the line. Thus given an independent set $A = \{a_1, \dots, a_\ell\}$ in G we will treat it as a tuple of intervals (a_1, \dots, a_ℓ) with $a_1 < \dots < a_\ell$ on the line. We define the projection $\pi_i(A) = a_i$ for each $i \in \{1, \dots, \ell\}$. Also when we apply (u, v) to an independent set A , we say that (u, v) *moves the i -th token* of A when $u = a_i$.

Let ℓ be a positive integer and let \mathcal{C} be a non-empty family of independent sets each of size ℓ in G . For $j \in \{1, \dots, \ell\}$ we define

$$\text{ex}_j(\mathcal{C}, \text{left}) = \min_{\leq_{\text{right}}} \{\pi_j(A) : A \in \mathcal{C}\}, \quad \text{ex}_j(\mathcal{C}, \text{right}) = \max_{\leq_{\text{left}}} \{\pi_j(A) : A \in \mathcal{C}\}.$$

For $p \in \{0, \dots, \ell\}$, we define the p -*extreme set* of \mathcal{C} to be

$$\bigcup_{1 \leq j \leq p} \{\text{ex}_j(\mathcal{C}, \text{left})\} \cup \bigcup_{p+1 \leq j \leq \ell} \{\text{ex}_j(\mathcal{C}, \text{right})\}.$$

We are going to show (Lemma 7) that every component \mathcal{C} of $R_k(G)$ contains all its p -extreme sets for $p \in \{0, \dots, k\}$. This gives a foundation for our algorithm: given two independent sets I and J as the input, we are going to devise two reconfiguration sequences,

23:4 Reconfiguring Independent Sets on Interval Graphs

transforming I into the $(k-1)$ -extreme set of its component in $R_k(G)$ and J into the $(k-1)$ -extreme set of its component in $R_k(G)$ respectively. As the $(k-1)$ -extreme set is a function of a connected component, we conclude that I and J are reconfigurable if and only if the obtained $(k-1)$ -extreme sets are equal. Thus, the essence of our work is to show that every independent set I can be reconfigured in $\mathcal{O}(k \cdot n^2)$ steps into the $(k-1)$ -extreme set of its component in $R_k(G)$.

The technical lemma below is our basic tool used to reason about and manipulate reconfiguration sequences.

► **Lemma 5.** *Let $A = (a_1, \dots, a_\ell)$ and $X = (x_1, \dots, x_\ell)$ be two independent sets in G and let $S = ((u_1, v_1), \dots, (u_m, v_m))$ be a reconfiguration sequence from A to X . With $\mathcal{A} = \{S|_t(A) : t \in \{0, \dots, m\}\}$ we denote the set of all independent sets traversed from A to X along S . Suppose that there are $i, j \in \{0, \dots, \ell+1\}$ with $i < j$ such that*

$$\begin{aligned} \text{ex}_i(\mathcal{A}, \text{left}) &= x_i \quad \text{if } i \geq 1, \text{ and} \\ \text{ex}_j(\mathcal{A}, \text{right}) &= x_j \quad \text{if } j \leq \ell. \end{aligned}$$

Then $A' = (x_1, x_2, \dots, x_i, a_{i+1}, \dots, a_{j-1}, x_j, \dots, x_\ell)$ is also an independent set in G . Moreover, if we let S' be S restricted to those pairs (u_t, v_t) with u_t being at a position p with $i < p < j$ in $S|_{t-1}(A)$, then S' is a reconfiguration sequence from A' to X in G .

► **Remark 6.** Since none of the first i tokens nor the last $\ell+1-j$ tokens are affected by S' we can alternatively conclude that S' transforms $(a_{i+1}, \dots, a_{j-1})$ into $(x_{i+1}, \dots, x_{j-1})$ in $G \setminus \bigcup_{p \notin \{i+1, \dots, j-1\}} N[x_p]$

Proof. Let $B = (b_1, \dots, b_\ell)$ be a set in \mathcal{A} . The *aligned* set of B is defined as $(x_1, \dots, x_i, b_{i+1}, \dots, b_{j-1}, x_j, \dots, x_\ell)$. We claim that the aligned set of B is an independent set in G . Note that some of the three parts $Y_1 = (x_1, \dots, x_i)$, $Y_2 = (b_{i+1}, \dots, b_{j-1})$, $Y_3 = (x_j, \dots, x_\ell)$ might be empty. Since all three parts are contained in an independent set, i.e. X or B , all we need to show is that (1) if Y_1 and Y_2 are non-empty, then x_i is completely to the left of b_{i+1} , and (2) if Y_2 and Y_3 are non-empty, then b_{j-1} is completely to the left of x_j . Thus, suppose that Y_1 and Y_2 are non-empty, so x_i and b_{i+1} exist. By the assumptions of the lemma $x_i = \text{ex}_i(\mathcal{A}, \text{left}) \leq_{\text{right}} b_i$ and clearly b_i is completely to the left of b_{i+1} . Therefore, x_i is completely to the left of b_{i+1} as desired. Symmetrically, if Y_2 and Y_3 are non-empty, then $b_{j+1} \leq_{\text{left}} x_{j+1}$ and b_j is completely to the left of b_{j+1} . Therefore, b_j is completely to the left of x_{j+1} as desired.

Since A' is the aligned set of A , we conclude that A' is independent in G . Let m' be the length of S' and $S' = ((u'_1, v'_1), \dots, (u'_{m'}, v'_{m'}))$. Since S' is a subsequence of S , we can fix $\varphi(t)$, for each $t \in \{1, \dots, m'\}$ such that the pair $(u_{\varphi(t)}, v_{\varphi(t)})$ in S corresponds to (u'_t, v'_t) in S' . Let $A_{\varphi(t)} = S|_{\varphi(t)}(A)$ and $A'_t = S'|_t(A')$. By construction we have

$$\begin{aligned} \pi_p(A'_t) &= \pi_p(X) && \text{if } p \in \{1, \dots, i\} \cup \{j, \dots, \ell\} \\ \pi_p(A'_t) &= \pi_p(A_{\varphi(t)}) && \text{if } p \in \{i+1, \dots, j-1\}. \end{aligned}$$

Thus for each $t \in \{0, \dots, m'\}$ we have that $S'|_t(A')$ is the aligned set of $A_{\varphi(t)} \in \mathcal{A}$. Therefore $S'|_t(A')$ is independent in G which completes the proof that S' is a reconfiguration sequence from A' to X . ◀

► **Lemma 7.** *Let H be a non-empty induced subgraph of G , let $\ell \in \{1, \dots, k\}$, and let \mathcal{C} be a component of $R_\ell(H)$. For every $p \in \{0, \dots, \ell\}$, the p -extreme set of \mathcal{C} is independent in H and lies in \mathcal{C} .*

Proof. Fix $p \in \{0, \dots, \ell\}$. Let $X = (x_1, \dots, x_\ell)$ be the p -extreme set of \mathcal{C} . We claim that for every $i \in \{0, \dots, p\}$ and $j \in \{p+1, \dots, \ell+1\}$, there is a set $A_{i,j} \in \mathcal{C}$ such that for all $q \in \{1, \dots, i\} \cup \{j, \dots, \ell\}$, we have $\pi_q(A_{i,j}) = x_q$. We prove this claim by induction on $m = i + (\ell + 1 - j)$. For the base case, when $m = 0$, so $i = 0$ and $j = \ell + 1$, we simply choose $A_{0,\ell+1}$ to be any element in \mathcal{C} .

For the inductive step, consider $m > 0$, so $i > 0$ or $j < \ell + 1$. The two cases are symmetric, so let us consider only the first one. Thus suppose $i > 0$ and therefore by the induction hypothesis, we get an independent set $A_{i-1,j} \in \mathcal{C}$ of the form

$$(x_1, \dots, x_{i-1}, a_i, \dots, a_{j-1}, x_j, \dots, x_\ell),$$

where a_i, \dots, a_{j-1} are some vertices of H . Let $B \in \mathcal{C}$ such that $\pi_i(B) = \text{ex}_i(\mathcal{C}, \text{left}) = x_i$. Since $B, A_{i-1,j} \in \mathcal{C}$, there is a reconfiguration sequence S from B to $A_{i-1,j}$. By Lemma 5, we obtain that

$$(x_1, \dots, x_{i-1}, x_i, b_{i+1}, \dots, b_{j-1}, x_j, \dots, x_\ell) \in \mathcal{C}.$$

This set witnesses the inductive condition for (i, j) and finishes the inductive step. \blacktriangleleft

When $k = 1$, there is a single token in the graph which moves along a path in the interval graph. This is a rather trivial setting still, we give explicit functions (Algorithm 1) to have a good base for the general strategy.

Algorithm 1 A simple algorithm for moving a single token.

```

1: function PUSH_TOKEN_LEFT( $H, u$ )
2:    $w := \min_{\leq_{\text{right}}} \{v \in V(H) : v \text{ is reachable from } u \text{ in } H\}$ 
3:   let  $(v_0, \dots, v_m)$  be the shortest path from  $u$  to  $w$  in  $H$ 
4:   return  $[w, ((v_0, v_1), \dots, (v_{m-1}, v_m))]$ 
5: function PUSH_TOKEN_RIGHT( $H, u$ )
6:    $w := \max_{\leq_{\text{left}}} \{v \in V(H) : v \text{ is reachable from } u \text{ in } H\}$ 
7:   let  $(v_0, \dots, v_m)$  be the shortest path from  $u$  to  $w$  in  $H$ 
8:   return  $[w, ((v_0, v_m), \dots, (v_{m-1}, v_m))]$ 

```

Proposition 8. *Let H be an interval graph, and u be a vertex in H . Then $\text{PUSH_TOKEN_LEFT}(H, u)$ outputs the \leq_{right} -minimum vertex w in the component of u in H and a witnessing u - w path $(v_0, v_1), \dots, (v_{m-1}, v_m)$ in H , where $v_0 = u, v_m = w$ and $v_m <_{\text{right}} \dots <_{\text{right}} v_2 <_{\text{right}} v_1$ and if $m \geq 2$, $v_2 <_{\text{right}} v_0$.*

Symmetrically, $\text{PUSH_TOKEN_RIGHT}(H, u)$ outputs the \leq_{left} -maximum vertex w in the component of u in H and a witnessing u - w path $(v_0, v_1), \dots, (v_{m-1}, v_m)$ in H , where $v_0 = u, v_m = w$ and $v_m >_{\text{left}} \dots >_{\text{left}} v_2 >_{\text{left}} v_1$ and if $m \geq 2$, $v_2 >_{\text{left}} v_0$.

Proof. We prove the first part of the statement about $\text{PUSH_TOKEN_LEFT}(H, u)$. The second part is symmetric. Consider a shortest path $v_0 v_1 \dots v_m$ from u to w in H . Note that there is no point on the line that belongs to three intervals in the path as otherwise we could make the path shorter. It is easy to see that v_{i+1} left overlaps v_i , i.e., $v_{i+1} <_{\text{right}} v_i$ and $v_{i+1} <_{\text{left}} v_i$ for all $i \in \{0, \dots, m-1\}$ possibly except two cases: v_m may be contained in v_{m-1} and (if $m \geq 2$) v_1 may contain v_0 . See Figure 1 for an illustration of such a shortest path in an interval graph. \blacktriangleleft

For $k = 2$, we give an algorithm, see Algorithm 2, that finds a short reconfiguration from a given independent set A in H to the 1-extreme set of the component of A in a reconfiguration graph $R_2(H)$.

23:6 Reconfiguring Independent Sets on Interval Graphs

■ **Figure 1** A shortest path from v_0 to v_7 where v_7 is an interval with leftmost right endpoint.

■ **Algorithm 2** A specialized algorithm finding the 1-extreme set of the component of the given set A in $R_2(H)$.

```

1: function PUSHAPART( $H, A$ )
2:    $a := \pi_1(A)$   $b := \pi_2(A)$ 
3:    $S := ()$ 
4:   do
5:      $[a, S_1] := \text{PUSHTOKENLEFT}(H \setminus N[b], a)$ 
6:      $[b, S_2] := \text{PUSHTOKENRIGHT}(H \setminus N[a], b)$ 
7:      $S := \text{CONCAT}(S, S_1, S_2)$ 
8:   while  $\text{CONCAT}(S_1, S_2) \neq \emptyset$ 
9:   return  $(a, b), S$ 

```

► **Proposition 9.** *Let H be an interval graph and A be an independent set of size 2 in H . Then $\text{PUSHAPART}(H, A)$ outputs the 1-extreme set of the component of A in $R_2(H)$ and a reconfiguration sequence from A to the 1-extreme set of length at most $2|V(H)|$.*

Proof. Suppose that $\text{PUSHAPART}(H, A)$ outputs (a^*, b^*) and let (x_1, x_2) be the 1-extreme set of the component \mathcal{C} of A in $R_2(H)$. Suppose to the contrary that $(a^*, b^*) \neq (x_1, x_2)$. Thus, either $x_1 = \text{ex}_1(\mathcal{C}, \text{left}) <_{\text{right}} a^*$ or $b^* <_{\text{left}} \text{ex}_2(\mathcal{C}, \text{right}) = x_2$.

Consider a path $((a_0, b_0), \dots, (a_m, b_m))$ from (a^*, b^*) to (x_1, x_2) in $R_2(G)$. Let i be the smallest index such that $a_i <_{\text{right}} a_0 = a^*$ or $b^* <_{\text{left}} b_i$. This index is well-defined as $i = m$ satisfies the condition and obviously $i > 0$. Now suppose that $a_i <_{\text{right}} a^*$. The proof of the other case goes symmetrically. By the minimality of i we have

$$a_i <_{\text{right}} a^* \leq_{\text{right}} a_{i-1} \quad \text{and} \quad b_i = b_{i-1} \leq_{\text{left}} b^*.$$

The inequalities on the right endpoints of a_i , a^* , and a_{i-1} imply that these three intervals form a connected subgraph of H , because a_i and a_{i-1} must intersect as they are adjacent. Since a_{i-1} and a_i are in the same component of $H \setminus N[b_i]$, we conclude that a^* is also in that component. Finally, since $b_i \leq_{\text{left}} b^*$ we conclude that a_{i-1} , a^* , a_i are together in the same component of $H \setminus N[b^*]$. See Figure 2 that illustrates all these inequalities. Consider the last

■ **Figure 2** $a_i <_{\text{right}} a^* \leq_{\text{right}} a_{i-1}$ and $b_i \leq_{\text{left}} b^*$. The intervals a_i , a^* , a_{i-1} are together in a component of $H \setminus N[b_i]$ and so they are together in a component of $H \setminus N[b^*]$ as well.

iteration of the loop in $\text{PUSHAPART}(H, A)$. The variables a and b keep the values a^* and b^* in this iteration. In particular $\text{PUSHTOKENLEFT}(H \setminus N[b^*], a^*)$ did not change the value of a . This is a contradiction as by Proposition 8 $\text{PUSHTOKENLEFT}(H \setminus N[b^*], a^*)$ outputs the \leq_{right} minimum vertex in the component of a^* in $H \setminus N[b^*]$ but we already know that a^* is not \leq_{right} -minimum there.

Now, let us prove the claim about the length of the output reconfiguration sequence S . Let $(a_0, b_0), \dots, (a_m, b_m)$ be the path in $R_2(H)$ corresponding to S , that is $(a_t, b_t) = S|_t(A)$ for $t \in \{0, \dots, m\}$. Suppose that $(a, b) = (a^0, b^0)$ at the beginning of the loop in line 4 and $(a, b) = (a^1, b^1)$ after pushing left and right in lines 5-6. By Proposition 8, we know that $a^1 \leq_{\text{right}} a^0$ and $b^0 \leq_{\text{left}} b^1$ and every intermediate configuration (a', b') on the path satisfies $a^1 \leq_{\text{right}} a' \leq_{\text{right}} a^0$ and $b^0 \leq_{\text{left}} b' \leq_{\text{left}} b^1$ with a possible exception of the first move from a^0 and the first move from b^0 . This way we see that the total number of steps without the exceptional moves is at most $|V(H)|$ and each interval in H can be the target of at most one exceptional move. This gives a bound $2|V(H)|$, as desired. \blacktriangleleft

We present now our main reconfiguration algorithm, see Algorithm 3.

Algorithm 3 A general algorithm finding the $(k-1)$ -extreme set of the component of the given set A in $R_k(G)$.

```

1: function RECONFIGURE( $G, k, A$ )
2:   for  $i \in \{1, 2, \dots, k\}$  do
3:      $a_i := \pi_i[A]$ 
4:      $\text{lex}_i := a_i$   $\triangleright \text{lex}_k$  is unused
5:      $\text{rex}_i := a_i$   $\triangleright \text{rex}_1$  is unused
6:    $j := 1$ ;  $S = ()$ 
7:   while  $j < k$  do
8:      $[(a_j, a_{j+1}), S'] := \text{PUSHAPART}(G \setminus \bigcup_{i \neq j, j+1} N[a_i], \{a_j, a_{j+1}\})$ 
9:      $S.\text{APPEND}(S')$ 
10:     $\gamma = 1$ 
11:    if  $(a_j, a_{j+1}) \neq (\text{lex}_j, \text{rex}_{j+1})$  then
12:       $\text{lex}_j := a_j$ 
13:       $\text{rex}_{j+1} := a_{j+1}$ 
14:      if  $j > 1$  then  $\gamma = -1$ 
15:     $j := j + \gamma$ 
16:  return  $(a_1, \dots, a_k), S$ 

```

► Lemma 10. *Let $k \geq 2$ and let A be an independent set of size k in G . Then $\text{RECONFIGURE}(G, k, A)$ outputs the $(k-1)$ -extreme set of the component of A in $R_k(G)$ and a reconfiguration sequence from A to this set of length $\mathcal{O}(k \cdot n^2)$.*

Proof. We begin our consideration of Algorithm 3 by noting two invariants.

\triangleright **Claim 11.** Every time Algorithm 3 reaches line 15, we have

$$(a_1, \dots, a_k) = (\text{lex}_1, \dots, \text{lex}_j, \text{rex}_{j+1}, \dots, \text{rex}_k).$$

Proof. Note that the equation holds after the initialization in lines 4-5. Later on, the values of (a_1, \dots, a_k) are updated only in line 8 and if so then corresponding values of lex and rex are updated in lines 12-13. \blacktriangleleft

\triangleright **Claim 12.** For every $j \in \{2, \dots, k\}$, the values held by lex_j are nonincreasing with respect to \leq_{right} . Symmetrically, for every $j \in \{1, \dots, k-1\}$, the values held by rex_j are nondecreasing with respect to \leq_{left} .

Proof. We prove the statement by induction over the iterations steps in Algorithm 3. Consider the moment when the values of lext_j and rext_{j+1} are updated in lines 12-13. Let $(\ell_1, \ell_2, \dots, \ell_k)$ and (r_1, r_2, \dots, r_k) be the values held by vectors lext and rext just after this update. Let $(\ell'_1, \dots, \ell'_k)$ and (r'_1, \dots, r'_k) be the values held by vectors lext and rext just after the previous update of lext_j or rext_{j+1} in lines 12-13 or the initial values of these vectors (assigned in lines 4-5) if there was no previous update. All we need to show is that $\ell_j \leq_{\text{right}} \ell'_j$ and $r'_{j+1} \leq_{\text{left}} r_{j+1}$.

By Claim 11 we know that the algorithm had tokens in $(\ell'_1, \dots, \ell'_j, r'_{j+1}, \dots, r'_k)$ and after applying some reconfiguration sequence, say $S = ((u_1, v_1), \dots, (u_m, v_m))$, it reached the configuration $(\ell_1, \dots, \ell_j, r_{j+1}, \dots, r_k)$. Let $\mathcal{A} = \{S|_t(A) : t \in \{0, \dots, m\}\}$.

By induction hypothesis the statement holds for all the updates applied so far by Algorithm 3. In particular, ℓ_{j-1} is the \leq_{right} -minimal position of the $(j-1)$ -th token so far and r_{j+2} is the \leq_{left} -maximal position of the $(j+2)$ -th token so far (assuming that these tokens exist). Thus,

$$\begin{aligned} \ell_{j-1} &= \text{ex}_{j-1}(\mathcal{A}, \text{left}) && \text{if } j-1 \geq 1, \\ r_{j+2} &= \text{ex}_{j+2}(\mathcal{A}, \text{right}) && \text{if } j+2 \leq k. \end{aligned}$$

Therefore, we may apply Lemma 5 and Remark 6 and conclude that (ℓ'_j, r'_{j+1}) and (ℓ_j, r_{j+1}) are in the same component of $R_2(G \setminus \bigcup_{i \neq j, j+1} N[a_i])$. By Proposition 9, the execution of

PUSHAPART in line 8 outputs the 1-extreme set, namely (ℓ_j, r_{j+1}) , of the component of (ℓ'_j, r'_{j+1}) in $R_2(G \setminus \bigcup_{i \neq j, j+1} N[a_i])$. Therefore, $\ell_j \leq_{\text{right}} \ell'_j$ and $r_{j+1} \geq_{\text{left}} r'_{j+1}$, as desired. \triangleleft

\triangleright Claim 13. Consider a moment when Algorithm 3 reaches the line 15 and $\gamma = 1$. Let α be the value of variable j prior to the update. Let (ℓ_1, \dots, ℓ_k) , (r_1, \dots, r_k) be the values held at this moment by vectors lext and rext , respectively. Then,

$$\begin{aligned} \ell_i &= \text{ex}_i(\mathcal{C}, \text{left}) && \text{for } i \in \{1, \dots, \alpha\}, \\ r_{\alpha+1} &= \text{ex}_{\alpha+1}(\mathcal{C}, \text{right}), \end{aligned}$$

where \mathcal{C} is the component of $(\ell_1, \dots, \ell_\alpha, r_{\alpha+1})$ in $R_{\alpha+1}(G \setminus \bigcup_{i > \alpha+1} N[r_i])$. In particular, $(\ell_1, \dots, \ell_\alpha, r_{\alpha+1})$ is the α -extreme set in \mathcal{C} .

Proof. We proceed by induction on α . First we deal with $\alpha = 1$. When Algorithm 3 starts an iteration of the while loop with $j = 1$, then by Claim 11 (and initialization in lines 4-5), we have $(a_3, \dots, a_k) = (r_3, \dots, r_k)$. By Proposition 9, PUSHAPART($G \setminus \bigcup_{i > 2} N[r_i], \{a_1, a_2\}$) executed in line 8 outputs the 1-extreme set of the component of $\{a_1, a_2\}$ in $R_2(G \setminus \bigcup_{i > 2} N[r_i])$. After the update in lines 12-13, this set is stored in $\{\text{lext}_1, \text{rext}_2\} = \{\ell_1, r_2\}$ when Algorithm 3 reaches the line 15, as desired.

Let us assume that $\alpha > 1$ and that the claim holds for all smaller values of α . Consider an iteration of the while loop with $j = \alpha$ such that Algorithm 3 reaches line 15 with $\gamma = 1$. Let (ℓ_1, \dots, ℓ_k) , (r_1, \dots, r_k) be the values held at this moment by vectors lext and rext , respectively. For convenience, we call this iteration the *present* iteration.

Now starting from the present iteration consider the last iteration before with $j = \alpha - 1$. We call this iteration the *past* iteration. Clearly, the past iteration had to conclude with $\gamma = 1$ and all iterations between the past and the present (there could be none) must have the value of variable $j \geq \alpha$ and those with $j = \alpha$ must conclude with $\gamma = 1$. This implies that the values of $(\text{lext}_1, \dots, \text{lext}_\alpha)$ and $(\text{rext}_2, \dots, \text{rext}_{\alpha+1})$ did not change between the past and the present iterations so they constantly are $(\ell_1, \dots, \ell_\alpha)$ and $(r_2, \dots, r_{\alpha+1})$.

Let \mathcal{D} be the connected component of $(\ell_1, \ell_2, \dots, \ell_{\alpha-1}, r_\alpha)$ in $R_\alpha(G \setminus N[r_{\alpha+1}])$. The inductive assumption for the past iteration yields:

$$\begin{aligned} \ell_i &= \text{ex}_i(\mathcal{D}, \text{left}) && \text{for } i \in \{1, \dots, \alpha-1\}, \text{ and} && (\star) \\ r_\alpha &= \text{ex}_\alpha(\mathcal{D}, \text{right}), \end{aligned}$$

Note that in the iteration immediately following the past iteration (this was an iteration with $\alpha = j$ and may be the present iteration) the only token movement was the travel of the j -th token from r_α to ℓ_α (the $(j+1)$ -th token stays at $r_{\alpha+1}$). In particular, there is a path from r_α to ℓ_α in $G \setminus (N[\ell_{\alpha-1}] \cup N[r_{\alpha+1}])$. Therefore, there is a path connecting $(\ell_1, \dots, \ell_{\alpha-1}, r_\alpha)$ and $(\ell_1, \dots, \ell_\alpha)$ in $R_\alpha(G \setminus N[r_{\alpha+1}])$, so both independent sets are in \mathcal{D} .

Now we argue, that

$$\ell_\alpha = \text{ex}_\alpha(\mathcal{D}, \text{left}).$$

Indeed, take any $(v_1, v_2, \dots, v_\alpha) \in \mathcal{D}$ and we aim to show that $\ell_\alpha \leq_{\text{right}} v_\alpha$. As (v_1, \dots, v_α) and $(\ell_1, \dots, \ell_\alpha)$ are in one component of the reconfiguration graph $R_\alpha(G \setminus N[r_{\alpha+1}])$ and by (\star) , we may apply Lemma 5 to conclude that $(\ell_1, \ell_2, \dots, \ell_{\alpha-1}, v_\alpha)$ also lies in \mathcal{D} . Moreover by Remark 6, the vertices ℓ_α and v_α are connected by a path in $G \setminus (N[\ell_{\alpha-1}] \cup N[r_{\alpha+1}])$. Thus by Proposition 9, PUSHAPART executed in the present iteration guarantees that $\ell_\alpha \leq_{\text{right}} v_\alpha$ as claimed.

Let \mathcal{C} be the component of $(\ell_1, \dots, \ell_\alpha, r_{\alpha+1})$ in $R_{\alpha+1}(G \setminus \bigcup_{i>\alpha+1} N[r_i])$. We proceed to argue that

$$r_{\alpha+1} = \text{ex}_{\alpha+1}(\mathcal{C}, \text{right}).$$

Assume for the sake of contradiction that there is some $A \in \mathcal{C}$, such that $r_{\alpha+1} <_{\text{left}} \pi_{\alpha+1}(A)$ and fix such an A with a shortest possible reconfiguration sequence $S = ((u_1, v_1), \dots, (u_m, v_m))$ from $(\ell_1, \dots, \ell_\alpha, r_{\alpha+1})$ to A in $R_{\alpha+1}(G \setminus \bigcup_{i>\alpha+1} N[r_i])$. Let $A_t = S|_t((\ell_1, \dots, \ell_\alpha, r_{\alpha+1}))$, for all $t \in \{0, \dots, m\}$. By the choice of A and S , for every $t \in \{0, \dots, m-1\}$ we have $\pi_{\alpha+1}(A_t) \leq_{\text{left}} r_{\alpha+1}$. We apply now Lemma 5 (with $i = 0$, $j = \alpha + 1$) to a path from $A_0 = (\ell_1, \dots, \ell_\alpha, r_{\alpha+1})$ to A_{m-1} and conclude that for each $t \in \{0, \dots, m-1\}$ the set $A'_t = (\pi_1(A_t), \dots, \pi_\alpha(A_t), r_{\alpha+1})$ is an independent set in \mathcal{C} . Consider now a path of independent sets of size α formed by dropping the $(\alpha + 1)$ -th coordinate of each set in the path $(A'_0, \dots, A'_{m-1}, A_m)$. Since $(\pi_1(A_0), \dots, \pi_\alpha(A_0)) = (\ell_1, \dots, \ell_\alpha) \in \mathcal{D}$, the whole path lives in \mathcal{D} . Therefore, by (\star) we have

$$\ell_i \leq_{\text{right}} \pi_i(A_t),$$

for all $t \in \{0, \dots, m\}$ and $i \in \{1, \dots, \alpha\}$. But this in turn allows us to apply Lemma 5 and Remark 6 once more (this time with $i = \alpha$, $j = \alpha + 2$) to a path from $(\ell_1, \dots, \ell_\alpha, r_{\alpha+1})$ to A_m and we conclude that $r_{\alpha+1}$ and $\pi_{\alpha+1}(A_m)$ are in the same component of $G \setminus \left(N[\ell_\alpha] \cup \bigcup_{i>\alpha+1} N[r_i] \right)$. But PUSHAPART executed in the present iteration outputs $(\ell_\alpha, r_{\alpha+1})$ while $r_{\alpha+1} <_{\text{left}} \pi_{\alpha+1}(A_m)$. This contradicts Proposition 9 and completes the proof that $r_{\alpha+1} = \text{ex}_{\alpha+1}(\mathcal{C}, \text{right})$.

It remains to prove that $\ell_i = \text{ex}_i(\mathcal{C}, \text{left})$ for all $i \in \{1, \dots, \alpha\}$. Pick an arbitrary $A = (v_1, v_2, \dots, v_{\alpha+1}) \in \mathcal{C}$. Since we already know that $r_{\alpha+1} = \text{ex}_{\alpha+1}(\mathcal{C}, \text{right})$, we can apply Lemma 5 (with $i = 0$, $j = \alpha + 1$) to a path from $(\ell_1, \dots, \ell_\alpha, r_{\alpha+1})$ to $(v_1, v_2, \dots, v_{\alpha+1})$, and we conclude that there is a reconfiguration sequence transforming (v_1, \dots, v_α) into $(\ell_1, \dots, \ell_\alpha)$ in $G \setminus N[r_{\alpha+1}]$. Thus, this path lies in \mathcal{D} and the desired inequalities $\ell_i \leq_{\text{right}} v_i$ for all $i \in \{1, \dots, \alpha\}$ follow by (\star) . \triangleleft

23:10 Reconfiguring Independent Sets on Interval Graphs

Clearly, Claims 13 and 11 establish the correctness of the algorithm. Equipped with the invariant given by Claim 12, we can bound the length of the returned reconfiguration sequence. Indeed, observe that in each iteration of the while loop in line 7 either lext_j decreases wrt. \leq_{right} , or rext_{j+1} increases wrt. \leq_{left} while j drops by 1, or j increases by 1. Now this implies that the outer loops can iterate at most $4nk + k$, as the quantity

$$j + 2 \sum_{i=1}^k \text{Index}_{\leq_{\text{left}}}(\text{rext}_i) + (n - \text{Index}_{\leq_{\text{right}}}(\text{lext}_i) + 1),$$

where $\text{Index}_{\leq}(x)$ denotes the position of element x in a given linear order \leq on some fixed finite set, increases by at least one in each iteration and it is at most $4nk + k$.

As seen in Proposition 9, each call of the procedure PUSHAPART returns a sequence consisting of at most $2n$ moves. Therefore, the length of reconfiguration sequence returned by Algorithm 3 is at most $8kn^2 + 2kn \in \mathcal{O}(kn^2)$. This completes the proof of Theorem 1. ◀

4 Lower bound: The Example

We present a family of graphs $\{G_{m,k}\}_{m,k \geq 1}$, such that $|V(G_{m,k})| = 8k + 2m - 5$ and $R_k(G_{m,k})$ contains a component of diameter at least $\frac{k^2}{4} \cdot m$. This will prove Theorem 2.

Fix integers $m, k \geq 1$. We will describe a family of intervals $\mathcal{I}_{m,k}$. The graph $G_{m,k}$ will be simply the intersection graph of $\mathcal{I}_{m,k}$. We construct the family in three steps. We initialize $\mathcal{I}_{m,k}$ with $(k-1) + (m+2k-1) + k$ pairwise disjoint intervals:

$$a_{k-1}, \dots, a_1, v_1, \dots, v_{m+2k-1}, b_1, \dots, b_k,$$

listed with their natural left to right order on the line. We call these intervals, the *base* intervals. Let $N = m + 2k - 1$. We put into $\mathcal{I}_{m,k}$ further $N - 1$ intervals:

$$v_{1,2}, v_{2,3}, \dots, v_{N-1,N},$$

where for each $i \in \{1, \dots, N-1\}$, the interval $v_{i,i+1}$ is an open interval with the left endpoint in the middle of v_i and the right endpoint in the middle of v_{i+1} . We call these intervals the *path* intervals. Finally, we put into $\mathcal{I}_{m,k}$ two groups of *long* intervals:

$$\ell_1, \dots, \ell_{k-1} \text{ and } r_1, \dots, r_k,$$

where for each $i \in \{1, \dots, k-1\}$ the interval ℓ_i is the open interval with the left endpoint coinciding with the left endpoint of a_i and the right endpoint coinciding with the right endpoint of $v_{N-(k-1)-i}$. Symmetrically, for each $i \in \{1, \dots, k\}$ the interval r_i is the open interval with the left endpoint coinciding with the left endpoint of v_{k-i+1} and the right endpoint coinciding with the right endpoint of b_i . This completes the construction of $\mathcal{I}_{m,k}$. See Figure 3.

Consider two independent sets $I = (v_1, \dots, v_k)$ and $J = (b_1, \dots, b_k)$ in $G_{m,k}$.

► **Lemma 14.** *The sets I and J are in the same component of $R_k(G_{m,k})$ and every reconfiguration sequence from I to J has length at least $\frac{k^2}{4} \cdot m$.*

Proof. We put most of the effort to prove the second part of the statement, that every reconfiguration sequence from I to J has length at least $\frac{k^2}{4} \cdot m$.

■ **Figure 3** The graph $G_{6,3}$ with two distinguished independent sets $I = \{v_1, v_2, v_3\}$ and $J = \{b_1, b_2, b_3\}$.

We define a sequence of independent sets (see Figure 4):

$$\begin{aligned}
 C_0 &= (v_1, \dots, v_k) = I, \\
 C_1 &= (v_1, \dots, v_{k-1}, r_1), \\
 C_2 &= (\ell_1, v_{N-(k-1)}, \dots, v_N, b_1), \\
 &\vdots \\
 C_{2i-1} &= (a_{i-1}, \dots, a_1, v_1, \dots, v_{k-1}, r_i), \\
 C_{2i} &= (\ell_i, v_{N-(k-i-2)}, \dots, v_N, b_1, \dots, b_i), \\
 &\vdots \\
 C_{2k} &= (b_1, \dots, b_k) = J.
 \end{aligned}$$

■ **Figure 4** The sets C_1, \dots, C_6 in $G_{6,3}$.

It is easy to construct a path from C_j to C_{j+1} in $R_k(G_{m,k})$ for $j \in \{0, \dots, 2k - 1\}$ which proves that I, J are in the same component of $R_k(G_{m,k})$.

Let (K_0, \dots, K_M) be a path in $R_k(G_{m,k})$ from I to J . The proof will follow from two claims. The first one is that (C_0, \dots, C_{2k}) is a subsequence of (K_0, \dots, K_M) , and the second one is that for every $i \in \{1, \dots, k - 1\}$ every path from C_{2i-1} to C_{2i} is of length at least $(k - 2i - 1) \cdot m$. A symmetric argument can be used to bound the distance between C_{2i} and C_{2i+1} which we omit here as it would only improve the final lower bound by a constant factor.

23:12 Reconfiguring Independent Sets on Interval Graphs

Let P be the set of path intervals in $G_{m,k}$. Define for each $i \in \{1, \dots, k-1\}$ the following graphs:

$$H_{2i-1} = G_{m,k}[\{a_{i-1}, \dots, a_1, v_1, \dots, v_N, b_1, \dots, b_i\} \cup P],$$

$$H_{2i} = G_{m,k}[\{a_i, \dots, a_1, v_1, \dots, v_N, b_1, \dots, b_i\} \cup P].$$

Note that $C_0 = K_0$ and $C_{2k} = K_M$, so C_0 and C_{2k} occurs in (K_0, \dots, K_M) . Fix $j \in \{0, \dots, 2k-2\}$. Suppose that the independent set C_j occurs in (K_0, \dots, K_M) and fix such an occurrence. We will argue that C_{j+1} must occur afterwards in the sequence.

Observe that all base intervals from C_j are in H_j . However $b_k \notin H_j$ and $b_k \in K_M$, hence to reconfigure from C_j to K_M eventually a token has to be moved to some base interval not in H_j . Thus, let X_j be the set of base intervals not in H_j , i.e.

$$X_j = \begin{cases} \{a_{k-1}, \dots, a_i\} \cup \{b_{i+1}, \dots, b_k\} & \text{if } j \text{ is odd,} \\ \{a_{k-1}, \dots, a_{i+1}\} \cup \{b_{i+1}, \dots, b_k\} & \text{if } j \text{ is even.} \end{cases}$$

Note that the only neighbours of intervals in X_j are long. Let Y be the first independent set in (K_0, \dots, K_M) that occurs after the fixed occurrence of C_j and contains a long interval u_0 neighbouring some element in X_j . We claim that $Y = C_{j+1}$.

First, we show that $u_0 = \ell_i$ if $j = 2i-1$ and $u_0 = r_{i+1}$ if $j = 2i$ respectively. Assume for now that $j = 2i-1$. Observe that for all $p \in \{1, \dots, i-1\}$ we have $N(\ell_p) \cap X_j = \emptyset$ and consequently $u_0 \neq \ell_p$. On the other hand, for all $p \in \{i+1, \dots, k-1\}$ we have $\alpha(H_j \setminus N(\ell_p)) < k-1$. Therefore, whenever $u_0 = \ell_p$ there is a token in Y that is not in H_j . This contradicts the minimality of Y . Moreover, for all $p \in \{1, \dots, i+1\}$ we have $N(r_p) \cap X_j = \emptyset$ in turn implying that $u_0 \neq r_p$. On the other hand, for all $p \in \{i+2, \dots, k-1\}$ we have $\alpha(H_j \setminus N(r_p)) < k-1$, thus, $u_0 \neq r_p$. This leaves only one possible option of $u_0 = \ell_i$. The case $j = 2i$ follows a symmetric argument. See Figure 5.

Recall that all $k-1$ elements of $Y \setminus \{u_0\}$ must be in H_j . It is easy to see that when $j = 2i-1$ then $H_j \setminus N(\ell_{i+1})$ has exactly one independent set of size $k-1$, namely: $\{v_{N-(k-i-2)}, \dots, v_N, b_1, \dots, b_i\}$, symmetrically when $j = 2i$ then $H_j \setminus N(r_{i+1})$ has exactly one independent set of size $k-1$, namely: $\{a_i, \dots, a_1, v_1, \dots, v_{k-1}\}$. This proves that $Y = C_{j+1}$.

■ **Figure 5** The set H_3 for $G_{6,3}$. We interpret $H_3 \setminus N(u)$ as the space where $k-1$ tokens can “hide”. All base neighbours of ℓ_1, r_1 , and r_2 are in H_3 . Also, $\alpha(H_3 \setminus N(r_3)) = 1 < 2$. This gives $u_0 = \ell_2$.

Let us now prove that for a fixed $i \in \{1, \dots, k-1\}$ every path from C_{2i-1} to C_{2i} in $R_k(G_{m,k})$ is of length at least $(k-2i-1) \cdot m$.

Fix the shortest reconfiguration sequence from C_{2i-1} to C_{2i} . As tokens do not interchange their relative positions, note that tokens starting at the positions (v_1, \dots, v_{k-2i}) in C_{2i-1} must finish at the positions $(v_{N-(k-2i-1)}, \dots, v_N)$ in C_{2i} . We call these tokens *heavy*. Their left to right ordinal numbers are $i, \dots, k-i$, and there are exactly $s := k-2i-1$ of them.

We prove that a heavy token cannot use any of the long intervals during the reconfiguration. By the first part of the proof we know that on the shortest path from C_{2i-1} to C_{2i} only base intervals from H_{2i-1} can be used. For each long interval u we define H_u^ℓ as a graph induced by all intervals v in $H_{2i-1} \setminus N(u)$ completely to the left of u . Analogously, define H_u^r as the graph induced by all $v \in H_{2i-1} \setminus N(u)$ completely to the right to u . Finally, put

$$n_\ell(u) = \alpha(H_u^\ell) \text{ and } n_r(u) = \alpha(H_u^r).$$

Assume that a heavy token uses a fixed long interval w on the path from C_{2i-1} to C_{2i} . Armed with the knowledge of the ordinal numbers of the heavy tokens, we see that: $n_\ell(w) \geq i-1$ and $n_r(w) \geq i$. Elementary computation shows that for every long interval u either $n_\ell(u) < i-1$ or $n_r(u) < i$, which proves that no such long interval w exists.

As heavy tokens cannot use long intervals, each of them has to use base and path intervals forcing it to make at least $2(N-s+1) \geq m$ steps. Therefore, we need at least $s \cdot m$ steps in the path.

Summing up all required steps, we conclude, that every path from I to J in $R_k(G_{m,k})$ has length at least $\frac{k^2}{4} \cdot m$. ◀

5 Hardness result for incomparability graphs

In this section, we present a simple reduction showing that Independent Set Reconfiguration is PSPACE-hard on incomparability graphs in general. Note that interval graphs are incomparability graphs of interval orders. The proof exhibits a reduction from H -Word Reachability defined in [10]. For the readers' convenience we state the definition of this problem here. If H is a digraph (possibly with loops) and $a = a_1 a_2 \dots a_n \in V(H)^*$ then a is an H -word, if for any $i \in \{1, \dots, n-1\}$ we have $a_i a_{i+1} \in E(H)$. In the H -Word Reachability we are given two H -words of the same length a and b , and the question is whether one can transform a into b by changing one letter at a time in such a way that each intermediate word is an H -word.

► **Theorem 15** ([10], Theorem 3). *There exists a digraph H for which the H -Word Reachability is PSPACE-complete.*

► **Theorem 16.** *There exists a constant $w \in \mathbb{N}$, such that Independent Set Reconfiguration is PSPACE-hard on incomparability graphs of posets of width at most w .*

Proof. We demonstrate a reduction from H -Word Reachability for arbitrary H ; the result will follow from Theorem 15.

Fix an instance of H -Word Reachability consisting of two H -words a and b of equal length n . We will construct a poset of width at most $2|V(H)|$, and two independent sets A, B in its incomparability graph, such that A is reconfigurable to B if and only if our starting instance is a yes instance of H -Word Reachability. Define the poset $P_n(H)$ as $(V(H) \times \{1, \dots, n\}, \prec)$ where \prec is defined as follows:

$$(x, i) \prec (y, j) \iff (j = i + 1 \text{ and } xy \in E(H)) \text{ or } (j > i + 1).$$

By the definition of \prec each set of the form $V(H) \times \{i\}$ is an antichain, thus for any chain C in $P_n(H)$ of cardinality n and any $i \in \{1, \dots, n\}$, we have $|(V(H) \times \{i\}) \cap C| = 1$. Therefore, any chain C of cardinality n , can be written as $C = \{(x_1, 1), (x_2, 2), \dots, (x_n, n)\}$. Observe that for each $i \in \{1, \dots, n-1\}$ we have $(x_i, i) \prec (x_{i+1}, i+1) \iff x_i x_{i+1} \in E(H)$. This implies that the first coordinates $x_1 x_2 \dots x_n$ of the elements of chain C form an H -word. Conversely,

given an H -word consisting of n letters $y_1y_2\dots y_n$ the set $\{(y_1, 1), (y_2, 2), \dots, (y_n, n)\}$ is a chain of cardinality n in $P_n(H)$. It follows that a word $x_1x_2\dots x_n$ is an H -word if and only if $\{(x_1, 1), \dots, (x_n, n)\}$ is an independent set in the incomparability graph $\text{Inc}(P_n(H))$.

Let $a = a_1a_2\dots a_n$ and $b = b_1b_2\dots b_n$ be the two given H -words of length n . We define $A = \{(a_1, 1), (a_2, 2), \dots, (a_n, n)\}$ and $B = \{(b_1, 1), (b_2, 2), \dots, (b_n, n)\}$. These are two independent sets in $\text{Inc}(P_n)$. Using the fact that for each $i \in \{1, \dots, n\}$ the set $V(H) \times \{i\}$ is a clique in $\text{Inc}(P_n(H))$, we infer that each edge in $R_n(P_n)$ corresponds to a move of the form $((x, i), (y, i))$ for some $i \in \{1, \dots, n\}$. Thus A is reconfigurable into B if and only if one can transform a into b one letter at a time keeping each intermediate word an H -word.

All that remains is to observe that we can construct the incomparability graph of $P_n(H)$ together with the sets A and B for a fixed H in logarithmic space, and that the width of $P_n(H)$ is always at most $2|V(H)|$. ◀

Abstract

The modal μ -calculus can only express bisimulation-invariant properties. It is a simple consequence of Kleene's Fixpoint Theorem that on structures with finite bisimulation quotients, the fixpoint iteration of any formula converges after finitely many steps. We show that the converse does not hold: we construct a word with an infinite bisimulation quotient that is locally regular so that the iteration for any fixpoint formula of the modal μ -calculus on it converges after finitely many steps. This entails decidability of μ -calculus model-checking over this word. We also show that the reason for the discrepancy between infinite bisimulation quotients and trans-finite fixpoint convergence lies in the fact that the μ -calculus can only express regular properties.

1 Introduction

The modal μ -calculus \mathcal{L}_μ , as it was introduced by Kozen [17], has become a de-facto standard yardstick amongst formal specification languages for programs. It is obtained in a principally simple way, namely by extending standard modal logic with extremal fixpoint quantifiers. Since most operators used in temporal logics can be characterised as least or greatest fixpoints, \mathcal{L}_μ can embed standard temporal logics like CTL, LTL and CTL* [10]. \mathcal{L}_μ is also, in a sense, the largest regular program specification logic as it is equi-expressive to the bisimulation-invariant fragment of Monadic Second-Order Logic [13]. Hence, studying its model-theoretic properties helps to answer questions after what can and cannot be formally expressed about programs in regular specification languages.

Fixpoint formulas in \mathcal{L}_μ denote sets of states in a labelled transition system (LTS), and Kleene's Fixpoint Theorem [16] can be used to approximate such fixpoints in a chain of sets: for instance, the semantics of some fixpoint definition $\mu X.\varphi(X)$ can be approximated from below by the sequence of sets X^i , where $X^0 = \emptyset$ and X^{i+1} is obtained as the semantics of $\varphi(X^i)$. For infinite structures, it is generally necessary to extend this sequence to trans-finite ordinal numbers. Over any LTS whose state space forms a set, this sequence must stabilise eventually at precisely the least fixpoint of φ .

Recent times have seen increased interest in the details of this process, regarding questions of when exactly it stabilises, and how this depends on the underlying structure and formula in question. Such questions are not simplified by fixpoint alternation – the ability to nest mutually dependent fixpoint definitions of different kinds. It is known that, over the class

of all LTS, this is unavoidable in that alternation-free formulas do not capture all of \mathcal{L}_μ 's expressiveness [5]. However, some classes of structures are known, for instance words, over which any \mathcal{L}_μ formula is equivalent to an alternation-free one [15].

The first notable result regarding the question of fixpoint stabilisation in \mathcal{L}_μ is that it is decidable whether an \mathcal{L}_μ formula is equivalent to a modal one [20]. Other and more recent research concerns the ordinals at which fixpoint iteration stabilises, in particular which ordinals are candidates for such a bound. This concerns the question whether, for a given formula $\mu X.\varphi$, there is some ordinal α such that fixpoint iteration X^0, X^1, \dots stabilises after at most α steps over *any* LTS. Such a (minimal) α is called the *closure ordinal* of $\mu X.\varphi$. Czarnecki [9] shows that, for each ordinal $\alpha < \omega^2$, there is some \mathcal{L}_μ formula with closure ordinal α . Afshari and Leigh [1] show that, for alternation-free formulas, ω^2 is a tight upper bound for closure ordinal candidates. [12] shows that ω_1 is the closure ordinal of some \mathcal{L}_μ formula, and [19] shows that all ordinals below ω^ω are closure ordinals for some formula in the two-way μ -calculus, i.e. the extension of \mathcal{L}_μ by backwards modalities. The situation in the intuitionistic setting is studied in e.g. [11].

The present paper is concerned with a slightly different but related question: we ask for closure ordinals on particular structures, i.e. at which ordinal do the iteration processes of *all* \mathcal{L}_μ formulas stabilise? Similar problems have been investigated by Barwise and Moschovakis in the context of first-order logic, see e.g. [4]. The problem of finding closure ordinals of classes of structures relates to the previous problem, since the former closure ordinals obviously bound the latter over the given class. Hence, studying closure ordinals of classes of structures contributes to the understanding of closure ordinals of formulas.

For \mathcal{L}_μ , the cardinality of the structure in question is an obvious upper bound for its closure ordinal. Hence, on finite structures, fixpoint iteration must necessarily stabilise at some finite bound that is uniform for all formulas. This simple observation extends to structures with a *finite bisimulation quotient*, as an immediate consequence of \mathcal{L}_μ 's inability to distinguish bisimilar states. An interesting question arises as the converse of this: does an inherently infinite structure, i.e. one whose bisimulation quotient is infinite, allow formulas to have an infinite fixpoint iteration process? Put differently, are there structures with an infinite bisimulation quotient such that fixpoint iteration for *any* \mathcal{L}_μ formula converges after finitely many steps? It is tempting to equate having a finite bisimulation quotient with the finite convergence of all \mathcal{L}_μ fixpoints, yet the answer to the latter question is “yes”.

We construct an LTS – in fact, an infinite word w_∞ – which has an infinite bisimulation quotient but all \mathcal{L}_μ formulas are equivalent to some finite approximation over it. Locally it seems to be regular, and no \mathcal{L}_μ formula can “see” the non-regular global pattern in it. Hence, \mathcal{L}_μ fixpoints cannot exploit this non-regularity in order to only stabilise after more than finitely many iteration steps. Local regularity means that w_∞ is self-similar: it is made of building blocks of increasing size, and some postfixes of it are w_∞ again if one maps suitable building blocks to certain symbols in the word's alphabet.

The result on finite convergence over w_∞ is obtained by first reducing the question for arbitrary \mathcal{L}_μ formulas to that of alternation-free ones. The aforementioned alternation-hierarchy collapse cannot simply be used off-the-shelf here as it makes no statement about the preservation of (in-)finiteness of closure ordinals. We then reduce the question to that for \mathcal{L}_μ formulas only containing fixpoints of one sort. We transform this into the analysis of runs of a very rudimentary fragment of alternating parity automata over w_∞ , exploiting its self-similar structure. Decidability of \mathcal{L}_μ model checking over w_∞ follows as a corollary.

Finally, we show that the reason for the discrepancy between infinite bisimulation quotients and infinite \mathcal{L}_μ closure ordinals is to be found in the regularity of \mathcal{L}_μ 's expressive power. We show that there are formulas of HFL – a natural higher-order extension of \mathcal{L}_μ [22] – that do

not have finite convergence on w_∞ . This is interesting because HFL can define the Kleene fixpoint iteration for \mathcal{L}_μ [8], and this can be used to disentangle fixpoint alternation, albeit at the cost of blow-up in formula size and type order, and the restriction to structures on which each \mathcal{L}_μ formula is equivalent to some finite approximation. Thus, the result of the paper at hand implies that this is not necessarily restricted a priori to structures with finite bisimulation quotients, as the aforementioned w_∞ is a counterexample.

The paper is organised as follows. In Sect. 2 we recall necessary preliminaries. In Sect. 3 we take a detailed look at fixpoint iteration for \mathcal{L}_μ formulas to make the notion of “finite convergence” formal. In Sect. 4 we develop an automata-theoretic criterion for a class of words to have finite convergence. We use this in Sect. 5 to prove finite convergence for w_∞ . Sect. 6 contains the considerations on modal fixpoints of higher-order on w_∞ . Sect. 7 concludes with remarks on further work.

2 Preliminaries

Words and languages. An *alphabet* is a finite, nonempty set Σ of *letters*, denoted by a, b, \dots . A Σ -word is a finite or infinite sequence of letters. Infinite words are also called ω -words. The empty word is denoted by ε . We write $w = a_1 a_2 \dots a_n$ for finite words, and $w = a_1 a_2 \dots$ for infinite words. Given two finite words u and v with $v \neq \varepsilon$, then $u \cdot v^\omega$ is an infinite word. In both the finite and the infinite case, $w[i]$ denotes the i -th letter of w . Σ^* is the set of finite Σ -words, a subset of which is a Σ -*language* (of finite words). Languages of ω -words have no role in this paper. If the alphabet is clear from context, we simply speak of words and languages.

Words are a special case of labelled transition systems for which the notion of bisimilarity is well-known. We can simplify the definition for word structures and call two positions in a word *bisimilar* if they have the same postfix, i.e. if the rest of the word is the same from both positions. Obviously, an ω -word with two bisimilar positions is ultimately periodic. The bisimulation quotient of a word is the quotient w.r.t. bisimilarity. It is either the word itself (when all positions are mutually non-bisimilar), or a lasso-shaped representation of it (when at least two, and then necessarily all following pairs of positions are bisimilar).

The modal μ -calculus. We introduce the modal μ -calculus in its linear-time version only. Let Σ be an alphabet, let \mathcal{X} be a set of fixpoint variables. The syntax of the linear-time μ -calculus in negation normal form, just \mathcal{L}_μ from now on, is given by the grammar

$$\varphi ::= a \mid \varphi \vee \varphi \mid \varphi \wedge \varphi \mid \bigcirc \varphi \mid X \mid \mu X. \varphi \mid \nu X. \varphi$$

where $X \in \mathcal{X}$ and $a \in \Sigma$. Other connectives such as \mathbf{tt} , \mathbf{ff} , \rightarrow etc. are defined as usual. Note that negation is definable using De Morgan, $\neg a \equiv \bigvee_{b \neq a} b$ and duality between μ and ν .

The notion of a subformula is standard. The *size* $|\varphi|$ of a formula φ is the number of its distinct subformulas. Fixpoint quantifiers $\sigma \in \{\mu, \nu\}$ act as variable binders. The notion of free and bound occurrence, as well as that of a closed formula are as usual. In a formula $\sigma X. \varphi$, the subformula φ is the *defining* formula of X . A variable bound by μ is a *least-fixpoint variable*. It is a *greatest-fixpoint variable* if it is bound by ν .

We assume formulas to be *well-named* in the sense that each fixpoint variable is bound at most once. Clearly, any formula is equivalent to a well-named one via renaming of variables. In a well-named formula φ , there is a function fp_φ that maps each fixpoint variable to the defining formula of this variable. We drop the index if φ is clear from context. Well-namedness induces a partial order $<_{\text{fp}}$ defined via $X <_{\text{fp}} Y$ iff $\text{fp}_\varphi(X)$ is a proper subformula of $\text{fp}_\varphi(Y)$. Note that, if $X <_{\text{fp}} Y$, then X has no free occurrences in $\text{fp}_\varphi(Y)$.

24:4 Finite Convergence of μ -Calculus Fixpoints on Genuinely Infinite Structures

We call a formula *unipolar* if it only contains one kind of fixpoint quantifiers. We call a formula *alternation-free* if no variable bound by a least fixpoint quantifier appears freely in the defining formula of a greatest fixpoint quantifier, and vice versa. In alternation-free formulas, the fixpoint variables can be partitioned into sets $\mathcal{X}_1, \dots, \mathcal{X}_k$ such that

- fixpoint variables do not appear freely in the defining formulas of variables from another set of the partition,
- all variables of one set have the same polarity, and
- for all $X \in \mathcal{X}_i$ and $Y \in \mathcal{X}_j$ with $i \neq j$: if $X <_{\text{fp}} Y$ then $j < i$.

A closed formula that contains no fixpoint quantifiers is in Basic Modal Logic (ML). The notion of *modal depth* $\text{md}(\varphi)$ of φ is defined as usual: $\text{md}(a) = 0$, $\text{md}(\psi_1 \vee \psi_2) = \text{md}(\psi_1 \wedge \psi_2) = \max\{\text{md}(\psi_1), \text{md}(\psi_2)\}$ and $\text{md}(\bigcirc \psi) = 1 + \text{md}(\psi)$.

Let $\eta: \mathcal{X} \rightarrow 2^{\mathbb{N}}$ be an *environment*. The semantics of an \mathcal{L}_μ formula on an ω -word w is a set of positions defined inductively as follows:

$$\begin{aligned} \llbracket a \rrbracket_\eta^w &= \{i \in \mathbb{N} \mid w[i] = a\} & \llbracket X \rrbracket_\eta^w &= \eta(X) \\ \llbracket \varphi \wedge \psi \rrbracket_\eta^w &= \llbracket \varphi \rrbracket_\eta^w \cap \llbracket \psi \rrbracket_\eta^w & \llbracket \mu X. \varphi \rrbracket_\eta^w &= \bigcap \{U \subseteq \mathbb{N} \mid \llbracket \varphi \rrbracket_{\eta[X \mapsto U]}^w \subseteq U\} \\ \llbracket \varphi \vee \psi \rrbracket_\eta^w &= \llbracket \varphi \rrbracket_\eta^w \cup \llbracket \psi \rrbracket_\eta^w & \llbracket \nu X. \varphi \rrbracket_\eta^w &= \bigcup \{U \subseteq \mathbb{N} \mid U \subseteq \llbracket \varphi \rrbracket_{\eta[X \mapsto U]}^w\} \\ \llbracket \bigcirc \varphi \rrbracket_\eta^w &= \{i \in \mathbb{N} \mid i + 1 \in \llbracket \varphi \rrbracket_\eta^w\} \end{aligned}$$

We say that φ is *satisfiable* under η over w if $\llbracket \varphi \rrbracket_\eta^w \neq \emptyset$. It is *valid*, written $\models \varphi$, if $\llbracket \varphi \rrbracket_\eta^w = \mathbb{N}$ for all w and η .

Two closed \mathcal{L}_μ formulas φ and ψ are *equivalent*, written $\varphi \equiv \psi$, if they define the same set on all words. We write $\varphi \equiv_w \psi$ to denote that φ and ψ define the same set on w , and $\varphi \equiv_{\mathcal{C}} \psi$ for a class of words \mathcal{C} if φ and ψ define the same set on all words in \mathcal{C} .

Trivial Automata. A *trivial* Σ -automaton (TrA) has the form (Q, δ, q_I, F, b) where

- Q is a finite nonempty set of states with initial state $q_I \in Q$ and final states $F \subseteq Q$,
- $\delta: (Q \setminus F) \times \Sigma \rightarrow Q$ is the transition function and
- $b \in \{0, 1\}$.

A *run* of \mathcal{A} starting from some position i in some ω -word w is a finite or infinite sequence q_0, q_1, \dots of states with $q_0 = q_I$ and $q_{j+1} = \delta(q_j, w_{j+i})$. Note that if such a sequence is finite, then the last state must necessarily be in F since δ is total on $Q \setminus F$. A run is *accepting* if it is finite and $b = 1$, or if it is infinite and $b = 0$. The set of positions in an ω -word defined by \mathcal{A} is the set of positions from which it has an accepting run. Two TrA are equivalent if they define the same set on every infinite Σ -word.

We write $q \xrightarrow{v} q'$ for $q, q' \in Q, v \in \Sigma^*$ to denote that \mathcal{A} will be in state q' after reading the finite word v starting from q . This includes the case in which \mathcal{A} does not read the entirety of v since it stops beforehand. In this case, $q' \in F$.

Trivial automata are reminiscent of DFA but they operate on infinite words. They can be thought of as restricted parity automata with a single priority b . If $b = 1$ then no infinite run is accepting. Acceptance is typically still possible by hitting a state and alphabet symbol to which the transition function assigns \mathfrak{tt} (as a Boolean combination of states). By making acceptance explicit through final states instead, we can define these trivial automata to be deterministic which is useful in proofs later on.

► **Lemma 1.** *Any unipolar \mathcal{L}_μ formula is equivalent to a TrA.*

Proof. (Sketch) It is well-known that \mathcal{L}_μ formulas on words can be translated into alternating parity automata (APA) [23]. Unipolar formulas result in APA of a single priority: 1 for least, 0 for greatest fixpoints. Since the APA has only one priority, determinisation is possible through a double powerset construction, paying attention to states with no successors by either introducing a sink state, or by making them final. ◀

3 Unfolding of Fixpoint Formulas

Single fixpoints. We formalise the notion of finite fixpoint convergence. First consider the case of a formula with a single fixpoint. Let $\mu X.\varphi$ be a formula, η be an environment, and w be a word. Then φ defines a monotonic function $f: T \mapsto \llbracket \varphi \rrbracket_{\eta[X \mapsto T]}^w$. Approximations to the least fixpoint are defined via

$$T_X^0 = \emptyset, \quad T_X^{i+1} = f(T_X^i) = \llbracket \varphi \rrbracket_{\eta[X \mapsto T_X^i]}^w, \quad T_X^\omega = \bigcup_{i \in \mathbb{N}} T_X^i.$$

Since we restrict ourselves to word structures with no branching, we do not need to consider approximations beyond ω , and by Kleene's Fixpoint Theorem we have $T_X^\omega = \llbracket \mu X.\varphi \rrbracket_\eta^w$.

Note that the T_X^i are definable in \mathcal{L}_μ by (renaming instances of) formulas φ^i via $\varphi^0 = \mathbf{ff}$, $\varphi^{i+1} = \varphi[\varphi^i/X]$ independently of w and η . We call φ^i the *i th unfolding* of $\mu X.\varphi$. If over w we have $T_X^i = T_X^\omega$ for some i then the fixpoint is equivalent to its i th unfolding, and the set defined by it can also be defined by a formula without the fixpoint. The definitions for greatest fixpoints are analogue, except that one starts with \mathbb{N} instead of \emptyset , and with \mathbf{tt} instead of \mathbf{ff} .

Multiple and nested fixpoints. For formulas containing more than one fixpoint subformula, possibly in a nested way, it is less clear what it means for these subformulas to be “unfolded n times”, as there is some ambiguity w.r.t. the order in which the participating formulas are to be unfolded. The literature also contains no standard agreed-upon definition. Instead, one of the following three constructions is employed as the respective authors see fit: Unfolding bottom-up, unfolding top-down, or unfolding on demand, following a construction seen in e.g. [21]. We review all three of them here and show that they produce the same formula (cf. Lem. 7). Hence, using either of them as suitable is permissible, and the results obtained in Sect. 5 later on hold for any of these reasonable interpretations of finite fixpoint convergence.

This thorough discussion is necessitated by two reasons: Note that we have very strict requirements with respect to unfolding procedures in the sense that, for an “ n th unfolding”, whenever a fixpoint is to be unfolded during the procedure, it is unfolded exactly n times. This differs from other notions where the amount of unfoldings can vary from fixpoint to fixpoint as long as some fixpoint-free formula is produced. Moreover, contrary to the case of only one fixpoint, monotonicity of the unfolding can be lost for formulas that are not unipolar, contradicting what one might intuitively assume (cf. Ex. 8), in particular w.r.t. stabilisation of the process.

The first unfolding procedure is quite straightforward: Pick a formula that is minimal w.r.t. $<_{\text{fp}}$ and unfold it n times. Clearly, this procedure terminates after k steps, if the formula in question contains k fixpoint definitions. However, it is not immediately clear whether a common n exists if one is interested in producing a formula equivalent to the original one over some structure.

► **Definition 2** (Bottom-up unfolding). Define $\hat{\mu} := \mathbf{ff}$ and $\hat{\nu} := \mathbf{tt}$. Let $n \geq 0$ and let φ be an \mathcal{L}_μ formula. Let X_1, \dots, X_k be an enumeration of its fixpoint variables such that X_i is bound by some $\sigma X_i.\psi_i$, and $X_i \not\prec_{\text{fp}} X_j$ for $j > i$. Let $\varphi_k^n, \dots, \varphi_0^n$ with $\varphi_k^n = \varphi$ be a sequence of formulas defined via

$$\psi_i^0 = \hat{\sigma}_i, \quad \psi_i^{j+1} = \text{fp}_{\varphi_i^n}(X_i)[\psi_i^j/X_i], \quad \varphi_{i-1}^n = \varphi_i^n[\psi_i^n/\sigma_i X_i. \text{fp}_{\varphi_i^n}(X_i)]$$

Then φ_0^n is the n th bottom-up unfolding of φ .

► **Example 3.** Let $\varphi = \nu X. \bigcirc(\mu Y.X \wedge Y)$ and let $n = 2$. Clearly $Y <_{\text{fp}} X$. Hence, $\psi_2^2 = X \wedge (X \wedge \mathbf{ff})$ whence $\varphi_1^2 = \nu X. \bigcirc(X \wedge (X \wedge \mathbf{ff}))$. Moreover $\psi_1^1 = \bigcirc(\mathbf{tt} \wedge (\mathbf{tt} \wedge \mathbf{ff}))$ and, hence, $\varphi_0^2 = \bigcirc(\bigcirc(\mathbf{tt} \wedge (\mathbf{tt} \wedge \mathbf{ff})) \wedge (\bigcirc(\mathbf{tt} \wedge (\mathbf{tt} \wedge \mathbf{ff})) \wedge \mathbf{ff}))$.

The second procedure is perhaps the most straightforward one: Given some formula that contains fixpoints, and some n , pick some fixpoint definition that is maximal w.r.t. $<_{\text{fp}}$ and unfold it n times. Given that this may duplicate fixpoint definitions that are smaller w.r.t. $<_{\text{fp}}$, this requires renaming and raises questions regarding termination of the procedure. Moreover, if one is interested into producing equivalent formulas over some structure, it is, again, not immediately clear whether a common n exists that can be used for all fixpoint definitions simultaneously. We start with an example.

► **Example 4.** Consider again the formula $\nu X. \bigcirc(\mu Y.X \wedge Y)$. Let $\psi = \bigcirc(\mu Y.X \wedge Y)$. By unfolding X twice as per above, we obtain the sequence of formulas $\psi^0 = \mathbf{tt}, \psi^1 = \bigcirc(\mu Y.\mathbf{tt} \wedge Y), \psi^2 = \bigcirc(\mu Y.(\bigcirc(\mu Y.\mathbf{tt} \wedge Y)) \wedge Y)$. Not only are there now two fixpoint definitions involving Y , their variables are also comparable via $<_{\text{fp}}$. However, by renaming one of them, we obtain the formula $\bigcirc(\mu Y.(\bigcirc(\mu Y'.\mathbf{tt} \wedge Y')) \wedge Y)$. Note that the two variables are not mutually recursive since Y does not appear in the defining formula of Y' .

Since the two variables are comparable, and $Y >_{\text{fp}} Y'$, we proceed by unfolding it which, after renaming, results in $\bigcirc((\bigcirc(\mu Y'.\mathbf{tt} \wedge Y')) \wedge ((\bigcirc(\mu Y''.\mathbf{tt} \wedge Y'')) \wedge \mathbf{ff}))$.

Again, we obtain two fixpoint definitions. However, this time, the two variables in question are not comparable via $<_{\text{fp}}$, whence the order of unfolding is obviously not important. We unfold Y' first and obtain $\bigcirc((\bigcirc(\mathbf{tt} \wedge (\mathbf{tt} \wedge \mathbf{ff}))) \wedge ((\bigcirc(\mu Y''.\mathbf{tt} \wedge Y'')) \wedge \mathbf{ff}))$ and then, after unfolding Y'' , the formula $\bigcirc((\bigcirc(\mathbf{tt} \wedge (\mathbf{tt} \wedge \mathbf{ff}))) \wedge ((\bigcirc(\mathbf{tt} \wedge (\mathbf{tt} \wedge \mathbf{ff}))) \wedge \mathbf{ff}))$.

This is the same formula as the one obtained by bottom-up unfolding in Ex. 3. This is in fact no coincidence, cf. Lemma 7 below.

► **Definition 5** (Top-down unfolding). Let $n \geq 0$ and let φ be an \mathcal{L}_μ formula. Define a sequence $\varphi_0^n, \varphi_1^n, \dots$ where $\varphi_0^n = \varphi$, and φ_{i+1}^n is obtained from φ_i^n via the following process: if φ_i^n contains no fixpoint definitions, $\varphi_{i+1}^n = \varphi_i^n$. Otherwise, let X be a variable that is maximal w.r.t. $<_{\text{fp}}$ in φ_i^n . Let $\sigma X.\psi$ be the subformula that defines X . Define $\psi^0 = \hat{\sigma}$ and $\psi^{j+1} = \psi[\psi^j/X]$. Then $\varphi_{i+1}^n = \varphi_i^n[\psi^{i+1}/\sigma X.\psi]$ where ψ^{i+1} is a copy of ψ^i made well-named via renaming of variables. If $\varphi_i^n = \varphi_{i+1}^n$, then the n th top-down unfolding of φ is φ_i^n .

As already said, is not immediately obvious that the above process terminates, but Ex. 4 already gives a hint. Unfolding a fixpoint formula may duplicate other, inner fixpoint formulas but the duplicates are independent of each other. Unfolding the outer may create further duplicates of inner duplicates, but these are not mutually recursive, which gives a termination argument.

In order to not deal with ambiguities around the termination of the process, and to avoid issues around unfolding formulas containing free fixpoint variables (cf. the bottom-up approach), we review a third definition of the n th unfolding of a fixpoint formula centered

around tracking for each fixpoint how often it has been unfolded already. This procedure is also folklore and based on the well-known notion of μ -signatures [21] or techniques used to unfold parity automata into \mathcal{L}_μ -formulas [7].

► **Definition 6.** Let $n \geq 0$ and let φ be an \mathcal{L}_μ formula. Let X_1, \dots, X_k be an enumeration of its fixpoint variables such that $X_i \not\prec_{\text{fp}} X_j$ for $j > i$ and such that σ_i denotes the (polarity of the) fixpoint quantifier for X_i . For a tuple $s = (c_1, \dots, c_k)$ let $s(i) = c_i$ if $1 \leq i \leq k$ and, if $s(i) > 0$, define $s[i--]$ as the k -tuple $(c_1, \dots, c_i - 1, n, \dots, n)$.

Define φ^n as φ^{s_I} , where $s_I = (n, \dots, n)$ and ψ^s is given inductively as

$$\begin{aligned} a^s &= a & (\psi_1 \vee \psi_2)^s &= \psi_1^s \vee \psi_2^s \\ (\neg\psi)^s &= \neg\psi^s & (\psi_1 \wedge \psi_2)^s &= \psi_1^s \wedge \psi_2^s \\ (\bigcirc\psi)^s &= \bigcirc\psi^s & X_i^s = (\sigma X_i. \text{fp}_\varphi(X_i))^s &= \begin{cases} \hat{\sigma}_i & , \text{ if } s[i] = 0 \\ \text{fp}_\varphi(X_i)^{s[i--]} & , \text{ otherwise.} \end{cases} \end{aligned}$$

Clearly, φ^{s_I} is well-defined and fixpoint-free. Well-definedness follows from the fact that $s[i--]$ is smaller than s in the lexicographical ordering. Note that we do not have to deal with well-namedness since no intermediate formulas containing fixpoint definitions occur due to the inductive definition centered around s .

We now establish that all three definitions given above actually produce the same formulas:

► **Lemma 7.** Let φ be an \mathcal{L}_μ formula. Then the bottom-up unfolding of φ (cf. Def. 2) and the top-down unfolding of φ (cf. Def. 5) are equivalent to the unfolding defined in Def. 6. In particular, the top-down unfolding is well-defined.

The proof has been moved to the appendix. It mostly consists of tracking the various substitutions.

We say that φ is equivalent to its n th unfolding over some word w if $\varphi \equiv_w \varphi^n$ for all $m \geq n$, i.e. if φ^n defines the same set on each of these words, and so do all further unfoldings. Note that, contrary to the case of a single fixpoint variable, it is not automatically the case that if $\varphi^n \equiv_w \varphi$, then $\varphi^{n+1} \equiv_w \varphi$. To illustrate this, consider the following example:

► **Example 8.** Let $\varphi = \nu X. \mu Y. (a \wedge \bigcirc X) \vee \bigcirc Y$. It defines the set of all positions after which a occurs infinitely often. Its first unfoldings are

$$\begin{aligned} \varphi^0 &= \text{tt} \\ \varphi^1 &= (a \wedge \bigcirc \text{tt}) \vee \bigcirc \text{ff} \equiv a \\ \varphi^2 &= (a \wedge \bigcirc((a \wedge \bigcirc \text{tt}) \vee \bigcirc((a \wedge \bigcirc \text{tt}) \vee \bigcirc \text{ff}))) \\ &\quad \vee \bigcirc((a \wedge \bigcirc((a \wedge \bigcirc \text{tt}) \vee \bigcirc((a \wedge \bigcirc \text{tt}) \vee \bigcirc \text{ff}))) \vee \bigcirc \text{ff}) \\ &\equiv (a \wedge \bigcirc(a \vee \bigcirc a)) \vee \bigcirc((a \wedge \bigcirc(a \vee \bigcirc a))) \end{aligned}$$

Take $w = (ba)^\omega$. Then φ^0 obviously defines \mathbb{N} , while φ^1 defines $\{2n+1 \mid n \in \mathbb{N}\}$ and then φ^2 again defines \mathbb{N} and so do all further approximations. Similar examples can be constructed to separate any two approximations. In fact, over a word of the form $b^1 a b^2 a b^3 a \dots$, the formula φ is not equivalent to any of its unfoldings φ^i with $i \geq 1$, but still defines \mathbb{N} .

Note that φ from Ex. 8 is not unipolar. For unipolar formulas, monotonicity can be used to show that $\models \varphi^i \rightarrow \varphi^{i+1}$ for least fixpoint formulas, resp. $\models \varphi^{i+1} \rightarrow \varphi^i$ for greatest fixpoint formulas holds for all i .

4 Finite Fixpoint Convergence for \mathcal{L}_μ

In this section we define the notion of a word having finite convergence, i.e. the property that all formulas, or all formulas of a certain kind, are equivalent to a finite unfolding over this word. We also develop a sufficient criterion in terms of runs of TrA, for this to hold.

► **Definition 9.** *Let w be an infinite word and let Φ be a set of \mathcal{L}_μ formulas. We say that w has finite convergence for Φ if, for every $\varphi \in \Phi$, there is n such that φ is equivalent to φ^n over w . We say that w has finite convergence for \mathcal{L}_μ , if the above holds for the set of all \mathcal{L}_μ formulas.*

The rest of the section is devoted to reducing finite convergence over w for the set of \mathcal{L}_μ formulas to a rather simple criterion on the runs of TrA over w . Lemmas 10 and 11 establish that, if a word has finite convergence for the set of alternation-free formulas, it also has finite convergence for the set of all \mathcal{L}_μ formulas. The rest of the section establishes a criterion for a word to have finite convergence for the set of alternation-free formulas.

► **Lemma 10.** *Let w be an infinite word that has finite convergence for the set of all alternation-free \mathcal{L}_μ formulas. Then, every closed \mathcal{L}_μ formula φ of the form $\sigma X.\psi$ is equivalent over w to one in ML, and so are all its approximations X^i . Moreover, there is some i such that φ agrees with X^i over w .*

Proof. Let w and $\varphi = \mu X.\psi$. The case of $\sigma = \nu$ is analogous. By [15], φ is equivalent to an alternation-free formula over the class of all words. Then, by the assumption of the lemma, there is $\varphi' \in \text{ML}$ that is equivalent to this alternation-free formula, obtained via some finite unfolding of φ . Now let X^i be the i th approximation of φ and let ψ_i be the \mathcal{L}_μ formula that defines it. Note that it possibly contains fixpoint definitions, since the only fixpoint to be unfolded is X . However, with the same argument as before we obtain that ψ_i also must be equivalent to some alternation-free formula and, hence, to some formula ψ'_i in ML.

Regarding the claim that one of the approximations is already equivalent to φ , assume that this is not the case. Since the ψ'_i are obtained as formulas equivalent to finite approximations of φ , we must have that for each $i \in \mathbb{N}$, there must be some position $j_i \in \llbracket \psi'_{i+1} \rrbracket^w \setminus \llbracket \psi'_i \rrbracket^w$ and, hence $j_i \in \llbracket \varphi' \rrbracket^w \setminus \llbracket \psi'_i \rrbracket^w$. Consider the set $\Phi = \{\varphi'\} \cup \{\neg\psi'_i \mid i \in \mathbb{N}\}$. We show that it is satisfiable using the Compactness Theorem for ML. Consider any finite subset Ψ of Φ , w.l.o.g. it is of the form $\{\varphi'\} \cup \{\neg\psi'_i \mid i \leq k\}$ for some k . By the above, Ψ is satisfiable by a postfix of w , starting at j_k . Hence, Φ is also satisfiable, i.e. there is an ω -word w' that satisfies φ' , but none of the ψ'_i . This is a contradiction, since $\llbracket \varphi' \rrbracket^{w'} = \bigcup_{i \in \mathbb{N}} \llbracket \psi'_i \rrbracket^{w'}$ by definition. This contradiction stems from the assumption that there is not already some i such that $\psi'_i \equiv_w \varphi' \equiv_w \varphi$. This finishes the proof. ◀

► **Lemma 11.** *Let w be an infinite word. If w has finite convergence for the set of all alternation-free \mathcal{L}_μ formulas, it has finite convergence for the set of all \mathcal{L}_μ formulas.*

Proof. Let φ be an \mathcal{L}_μ formula. Using Lem. 10, we can obtain a non-uniform unfolding φ' of φ that is equivalent to φ over w , i.e. we show that there is m such that, following the pattern of the top-down unfolding procedure in Def. 5, for each fixpoint subformula there is some $n \leq m$ such that unfolding it n times yields an equivalent subformula. In a second step, we show that we also obtain a formula equivalent to φ if we unfold all fixpoint subformulas exactly m times. This is not immediately obvious due to the non-monotonicity seen in Ex. 8.

Towards the first goal, define a sequence $\varphi_0, \varphi_1, \dots$ where $\varphi_0 = \varphi$, and φ_{i+1} is obtained from φ_i via the following process, similarly to the top-down unfolding: if φ_i contains no fixpoint definitions $\varphi_{i+1} = \varphi_i$. Otherwise, let X be a variable in φ_i that is maximal w.r.t

$<_{\text{fp}}$. Let $\sigma X.\psi$ be the subformula that defines X . By Lem. 10, there is some m_i such that the m_i th unfolding of ψ is equivalent to $\sigma X.\psi$, defined via $\psi^0 = \hat{\sigma}$ and $\psi^{i+1} = \psi[\psi^i/X]$. Then $\varphi'_{i+1} = \varphi_i[\psi^{m_i+1}/\sigma X.\psi]$ resulting from the $(m_i + 1)$ th unfolding of X . Let φ_{i+1} be a obtained from φ'_{i+1} via renaming such that φ_{i+1} is well-named. Note that the amount of times each fixpoint is unfolded varies. This is where the above differs from the top-down unfolding. The above process stabilises for the same reason the top-down unfolding is well-defined: unfolding an outermost fixpoint formula will create closed formulas, i.e. the ψ^i as described above are all closed. Hence, while unfolding an outermost fixpoint X can duplicate fixpoints smaller than X w.r.t $<_{\text{fp}}$, the defining formulas of the duplicates reside in different instances of the ψ^i and, hence, are not mutually recursive. In particular, unfolding a formula in ψ^{i+1} may create further duplicates by replicating ψ^i , but since ψ^i is closed, these further duplicates can then be unfolded independently of each other.

Hence, let φ' be the formula that results once this process stabilises. Note that, however, the unfolding is not necessarily uniform. Let $m = 1 + \max\{m_i \mid i \in \mathbb{N}\}$. Since the process stabilises, this maximum exists. We claim that φ is equivalent to φ^m over w . We show this by unfolding φ using the top-down procedure. Note that above, we have established that, for each fixpoint X in the process, there is some $m_i < m$ such that unfolding it $m_i + 1$ times, once it is X 's turn, results in a formula equivalent to the one before. We now show that this property is kept if we instead unfold it m times. Let X be such a variable, and assume that the property holds so far. Note that X must be outermost by now. Let $\sigma X.\psi$ be the defining formula of X . We compare ψ^{m_i} and ψ^m , which are equivalent due to Lem. 10. Note that ψ^{m_i+1} and ψ^{m_i} are equivalent due to the definition of m_i . Since $m \geq m_i$, we have that $\psi^m = \psi^{m_i+k}$ for some k , and it contains ψ^{m_i} as a subformula. Since that subformula is closed, clearly the invariant holds for all fixpoint definitions in ψ^{m_i} , since the process inside this subformula will play out exactly like before. If $m_i + 1 = m$, we are done. Otherwise, consider a subformula in $\psi^{m_i+1+k'}$ for some $k' \leq m - m_i - 1$, but not in ψ^{m_i+1} , i.e., it is in the extra part of the formula due to the extra unfolding. Since $\psi^{m_i+1} \equiv_w \psi^{m_i}$ by definition, we also have that $\psi^{m_i+k'} \equiv_w \psi^{m_i}$. In other words, the part of the formula where X used to be, but some ψ^j has been substituted, is equivalent over w due to the definition of m_i . Moreover, both substituted formulas are closed and, hence, can be exchanged without interfering with unfolding of fixpoint formulas. Hence, for the purposes of fixpoint unfolding, all fixpoint formulas in ψ^m , but not in ψ^{m_i+1} behave like a fixpoint formula in ψ^{m_i+1} , but not in ψ^{m_i} . Since the invariant holds for the latter, it must also hold for the former.

It follows that we can make the unfolding uniform by just using the top-down unfolding process with m . Moreover, any $m' \geq m$ yields the same result by the same reasoning. This finishes the proof. \blacktriangleleft

► **Remark 12.** Note that Lem. 11 yields more than just the collapse of \mathcal{L}_μ to ML over w which can already be inferred from the collapse of \mathcal{L}_μ to alternation-free \mathcal{L}_μ over the class of all words (see [15]). Lem. 11 yields that every \mathcal{L}_μ formula φ is equivalent, over w , not only to some ML formula, but one obtained as an unfolding of φ (cf. also the remarks after Def. 9).

► **Lemma 13.** *Let w be an infinite word. If w has finite convergence for the set of all unipolar \mathcal{L}_μ formulas, it has finite convergence for the set of all alternation-free \mathcal{L}_μ formulas.*

The proof is a standard induction on the alternation classes using the fact that alternation-free \mathcal{L}_μ is obtained by capture-avoiding substitution of unipolar formulas. It is spelled out in the appendix.

24:10 Finite Convergence of μ -Calculus Fixpoints on Genuinely Infinite Structures

► **Definition 14.** Let w be an ω -word and \mathcal{A} be a TrA. We say that \mathcal{A} has k -bounded runs on w if all finite runs of \mathcal{A} in w are of length k or less. We say that TrA have bounded runs on w if, for every TrA \mathcal{A} , there is k such that \mathcal{A} has k -bounded runs on w .

Clearly, if \mathcal{A} has k -bounded runs on w , then acceptance of \mathcal{A} can be expressed by a ML-formula of modal depth at most k , i.e., there is some ML-formula φ of modal depth at most k such that $\llbracket \varphi \rrbracket^w = \{i \mid \mathcal{A} \text{ accepts from } i\}$.

► **Lemma 15.** Let w be an infinite word. If TrA have bounded runs over w then w has finite convergence for all unipolar formulas.

Proof. We only show the result for least fixpoint formulas; for greatest it is analogous. Let w be given, φ be unipolar containing only least fixpoints, and φ^i be its i th unfolding. Since φ is unipolar, it is equivalent to a TrA \mathcal{A} by Lem. 1. By the assumption, there is k such that if \mathcal{A} halts on w from some position then it halts in k steps or less. Hence, acceptance of \mathcal{A} on w can be expressed by some ML formula ψ , which means that ψ is equivalent to φ over w . Then, similar to the proof of Lem. 10, we can use the Compactness Theorem to obtain that φ is already equivalent to some φ^i . ◀

Lemmas 11, 13 and 15 yield the following.

► **Corollary 16.** Let w be an infinite word. If TrA have bounded runs on w , then w has finite convergence for \mathcal{L}_μ .

5 A Word with Finite Convergence

We are now ready to give the construction of a word with finite fixpoint convergence. Let $\Sigma = \{a, b\}$. We define w_∞ using the following mutually recursive definitions of families of finite words α_i, β_i :

$$\alpha_0 = a \quad , \quad \beta_0 = b \quad , \quad \alpha_{i+1} = \alpha_i \alpha_i \beta_i \alpha_i \alpha_i \quad , \quad \beta_{i+1} = \beta_i \beta_i \alpha_i \beta_i \beta_i$$

For example, $\alpha_2 = aabaa aabaa bbabb aabaa aabaa$. Then $w_\infty = \alpha_0 \alpha_1 \dots$.

We obtain the following properties of w_∞ :

► **Lemma 17.** Let w_∞ be as above. Then it holds that

1. the length of α_i and β_i is 5^i ,
2. α_i and β_i do not overlap, i.e. the minimal size for a word that contains both of them is $2 \cdot 5^i$,
3. the postfix of w_∞ starting after position $\sum_{j=0}^{i-1} 5^j$, i.e. at the first occurrence of α_i , can be considered a word in $\{\alpha_i, \beta_i\}^\omega$,
4. α_i , respectively β_i occurs at most 4 times in a row before the other one occurs.
5. the distance from any position to the next occurrence of one of α_i or β_i is at most $5^i - 1$,
6. The postfix of w_∞ starting after position $\sum_{j=0}^{i-1} 5^j$ is $h(w_\infty)$ for the homomorphism h with $h(a) = \alpha_i$ and $h(b) = \beta_i$,
7. w_∞ has an infinite bisimulation quotient.

Proof. Item 1 is an immediate consequence of the definition of w_∞ . Item 2 follows from a straightforward induction: The claim is obvious for $i = 0$, and for $i > 0$ we note that any potential overlap of α_{i+1} and β_{i+1} either induces overlap of α_i and β_i , or contradicts the fact that α_{i+1} contains only one occurrence of β_i . Item 3 follows from the construction of α_{i+1} , resp. β_{i+1} . Towards Item 4, we use Item 2 to note that consecutive occurrences of α_i , resp.

β_i must occur aligned to the building pattern of w_∞ , i.e. following the pattern exhibited in Item 3 applied to α_{i+1} and β_{i+1} . The claim then follows directly from the construction of α_{i+1} and β_{i+1} .

Regarding Item 5, note that, by Item 3, eventually, w_∞ consists entirely of a sequence of α_i and β_i . Hence, one must occur after a distance of at most $5^i - 1$. Moreover, since the first occurrence of α_i is at position $\sum_{j=0}^{i-1} 5^j \leq 5^i - 1$, the claim also holds for the initial part of the word. Item 6 follows from Item 3 and the building pattern of w_∞ .

It remains to prove Item 7, i.e. that w_∞ has an infinite bisimulation quotient. This holds since all positions of the form $\sum_{j=0}^{i-1} 5^j$, i.e. the first occurrences of α_i for $i \in \mathbb{N}$, are pairwise not bisimilar. Towards this, note that α_i^3 is the word following at position $\sum_{j=0}^{i-1} 5^j$, since the α_{i+1} following the first occurrence of α_i begins with α_i^2 . Conversely, all positions of the form $\sum_{j=0}^{i'-1} 5^j$ with $i' > i$ mark the beginning of the first $\alpha_{i'}$, which begins with $\alpha_i^2 \beta_i$ by construction. Hence, the positions $\sum_{j=0}^{i-1} 5^j$ and $\sum_{j=0}^{i'-1} 5^j$ for $i' > i$ are not bisimilar, which yields infinitely many pairwise not bisimilar positions. ◀

The aim now is to show that TrA have finite runs on w_∞ . Let $\mathcal{A} = (Q, \delta, q_I, F, b)$ be a TrA, fixed for the remainder of the section. W.l.o.g. $b = 1$ for the remainder of the section, the proof for $b = 0$ is completely symmetric. Consider the subsets $A_0, A_1, \dots \subseteq Q$ and $B_0, B_1, \dots \subseteq Q$ defined via $q \in A_i$ iff $q \xrightarrow{\alpha_i} q'$ for some $q' \in F$ and $q \in B_i$ iff $q \xrightarrow{\beta_i} q'$ for some $q' \in F$.

Clearly, $A_i \subseteq A_{i+1}$ for all $i \geq 0$ since α_{i+1} starts with α_i , whence any word that begins with α_{i+1} also begins with α_i . Moreover, since $|Q| < \infty$, there must be $i, h \in \mathbb{N}$ such that $A_j = A_i$ for all $j \geq i$ and $B_j = B_h$ for all $j \geq h$. Let $k = 1 + \max\{i, h\}$, $A = A_k$ and $B = B_k$. Note that $A \cap B$ can be nonempty, and both A and B can be empty. Let $M = Q \setminus (A \cup B)$. Then M is the set of states such that \mathcal{A} will not have accepted if it reads α_j or β_j for any j .

We now show that the self-similarity (cf. Lem. 17.6) and w_∞ eventually becoming almost featureless from the perspective of a bounded-memory automaton (cf. Lem. 17.3), together imply that a TrA can get trapped in M if it does not escape it fast enough.

► **Lemma 18.** *Let $q \in M$ and $j \geq k$. Then $q \xrightarrow{\alpha_j} q'$ for some $q' \in M$, and $q \xrightarrow{\beta_j} q'$ for some $q' \in M$.*

Proof. Let $q_0 \in M$, $j \geq k$. Remember that $\alpha_j = \alpha_{j-1}^2 \beta_{j-1} \alpha_{j-1}^2$. Note that $q_0 \xrightarrow{\alpha_{j-1}} q_1$ for some $q_1 \notin A$, because otherwise $q_0 \xrightarrow{\alpha_j} q_2$ for some $q_2 \in F$ contradicting $q_0 \in M$. Moreover, $q_0 \xrightarrow{\alpha_{j-1} \alpha_{j-1}} q_2$ for some $q_2 \notin A$. If it were the case that $q_2 \in A$, then there would be q_1 with $q_0 \xrightarrow{\alpha_{j-1}} q_1$ and $q_1 \xrightarrow{\alpha_{j-1}} q_2$. Since $q_2 \in A$, there must be $q_3 \in F$ such that $q_2 \xrightarrow{\alpha_{j-1}} q_3$. Hence, $q_1 \xrightarrow{\alpha_j} q_3$, which implies $q_1 \in A$. This contradicts the previous result, whence $q_2 \notin A$.

In summary, $q \xrightarrow{\alpha_{j-1}} q'$ or $q \xrightarrow{\alpha_{j-1} \alpha_{j-1}} q'$ for a state $q \in M$ implies $q' \notin A$ and it can be easily inferred that $q \xrightarrow{\alpha_{j-1} \alpha_{j-1}} q'$ also implies $q' \notin B$. The same holds symmetrically for β_{j-1} . Now, these findings can be used to prove the lemma. Per assumption, the automaton does not halt reading α_j starting from q_0 . Hence, there are q_1, q_2, q_3 such that $q_0 \xrightarrow{\alpha_{j-1} \alpha_{j-1}} q_1$, $q_1 \xrightarrow{\beta_{j-1}} q_2$ and $q_2 \xrightarrow{\alpha_{j-1} \alpha_{j-1}} q_3$. From the findings above it immediately follows that $q_1 \in M$. With the symmetric arguments for β_j it follows that $q_2 \notin B$ and from the fact that $q_0 \in M$ it also follows that $q_2 \notin A$, whence $q_2 \in M$. Then, with the same arguments as for q_1 and, we obtain that $q_3 \in M$, too. The case for β_j is analogous. ◀

We are now ready to prove that all TrA are bounded over the word w .

► **Theorem 19.** *TrA have bounded runs on w_∞ .*

Proof. Let \mathcal{A} be a TrA, M, k be as above and let l be some position in w_∞ . We show that if \mathcal{A} accepts from position l , then it does so within $6 \cdot 5^k - 1$ many steps. Let l' be the first position after l from which α_k or β_k starts. Let u be the word from position l to position l' . If $q_T \xrightarrow{u} q$ for $q \in F$, we are done since by Lem. 17.5 we have $|u| \leq 5^k - 1$.

Otherwise, let $\gamma_1 \cdots \gamma_5$ be the sequence of length $5 \cdot 5^k$ following l' , which necessarily consists of α_k and β_k by Lem. 17.3. We prove that \mathcal{A} must accept within this sequence. Let q_0, q_1, \dots, q_5 with $q = q_0$ be the sequence of states such that $q_i \xrightarrow{\gamma_{i+1}} q_{i+1}$. Then $q_i \notin M$ for all $0 \leq i \leq 5$, for otherwise, by Lem. 17.3 and Lem. 18, \mathcal{A} does not accept at all from l since the run gets trapped in M , which contradicts the assumption on acceptance from l . By Lem. 17.4 the sequence $\gamma_1 \cdots \gamma_5$ must contain two consecutive α_k followed by β_k or two consecutive β_k followed by α_k . W.l.o.g. suppose that two consecutive α_k are followed by β_k and that this concerns $\gamma_1, \gamma_2, \gamma_3$. If $q_0 \in A, q_1 \in A$ or $q_2 \in B$, we are done, since acceptance follows within the next γ_i . The remaining possibility is that all of $q_0, q_1 \in B \setminus A$ and $q_2 \in A \setminus B$ hold. However, this is not possible: Since $q_1 \xrightarrow{\alpha_k} q_2$ and $q_2 \in A$ implies that there must be $q' \in F$ such that $q_2 \xrightarrow{\alpha_k} q'$, we have that $q_1 \xrightarrow{\alpha_{k+1}} q'$ which implies $q_1 \in A$. Hence, \mathcal{A} either accepts within $l' - l + 5 \cdot 5^k \leq 6 \cdot 5^k - 1$ steps from l , or does not accept from l at all. \blacktriangleleft

Putting this together with the results obtained in the previous section we obtain the following.

► **Corollary 20.** w_∞ has finite convergence for \mathcal{L}_μ (but no finite bisimulation quotient).

This follows from Cor. 16 and Lem. 17.7.

► **Remark 21.** Closer inspection of the proofs in this section yields two additional results. It follows from the proof of Lem. 18 that if $A_i = A_{i+1}$, then $A_i = A_j$ for all $j \geq i$. Hence, k can actually be computed effectively by computing the A_i and the B_i until both sequences stabilise. Moreover, the results of Lem. 18 and Thm. 19 do not rely on the exact form of w_∞ , but rather its pattern, and the results from Sec. 4 do not make any assumptions on the word in question. It is possible to generalise the proof to words constructed via

$$\alpha'_0 = a \quad , \quad \beta'_0 = b \quad , \quad \alpha'_{i+1} = \alpha_i^m \beta_i^m \alpha_i^m \quad , \quad \beta'_{i+1} = \beta_i^m \alpha_i^m \beta_i^m$$

where $m > 1$. I.e. the importance is the symmetry between the α'_i and β'_i , as well as the use of two copies of α'_i at the beginning of α'_{i+1} etc. Moreover, this sequence of finite words does not have to be strictly monotonic in the use of its building blocks, i.e., the result also holds for words of the form $\alpha'_{i_0} \alpha'_{i_1} \cdots$, where $i_j \leq i_{j+1}$ for all $j \geq 0$. The case where the pattern eventually stabilises is not very interesting, of course, but bounded runs for TrA and, hence finite convergence of \mathcal{L}_μ still follow for the case where for all $k \in \mathbb{N}$ there is j such that $i_j \leq k$, i.e., the word uses α'_i of unbounded length as building blocks.

6 Infinite Convergence Through Higher-Order

We now show that the finite convergence of \mathcal{L}_μ formulas on the word w_∞ from Sec. 5 is due to the well-known fact that the expressive power of \mathcal{L}_μ is restricted to regular properties. In contrast, finite convergence does not hold anymore for a higher-order extension of \mathcal{L}_μ with non-regular expressiveness: Higher-Order Modal Fixpoint Logic (HFL). It extends \mathcal{L}_μ by the ability to form function definitions via λ abstraction. We refer to the literature or the appendix for a detailed introduction into HFL [22].

Let $\tau = (\mathbb{N} \rightarrow \mathbb{N}) \rightarrow (\mathbb{N} \rightarrow \mathbb{N}) \rightarrow \mathbb{N}$ be the set-theoretic type of functions that consume two functions of type $\mathbb{N} \rightarrow \mathbb{N}$ and return a natural number. Consider the HFL formula

$$\varphi = (\nu(X : \tau). \lambda(f, g : \mathbb{N} \rightarrow \mathbb{N}). f(\mathbf{tt}) \wedge X(f^2 \circ g \circ f^2, g^2 \circ f \circ g^2)) (\langle b \rangle, \langle a \rangle).$$

Here, $\psi = \lambda(f, g : \mathbb{N} \rightarrow \mathbb{N}). f(\mathbf{tt}) \wedge \dots$ defines an anonymous function that takes as input two functions f and g of type $\mathbb{N} \rightarrow \mathbb{N}$ and returns the expression defined by the conjunction. The left conjunct, for example, defines the result of applying f to the set defined by \mathbf{tt} , i.e. \mathbb{N} . The formula $\langle a \rangle$ defines the function $S \mapsto \{i \mid w[i] = a \text{ and } i + 1 \in S\}$, and similarly for $\langle b \rangle$. The fixpoint X itself is now of higher-order, and it is equivalent to the expression $\bigwedge_{i \in \mathbb{N}} \psi^i$, where $\psi^0 = \lambda(f, g : \mathbb{N} \rightarrow \mathbb{N}). \mathbf{tt}$ and $\psi^{i+1} = \psi[\psi^i/X]$. Applying this expression to the original arguments $\langle b \rangle, \langle a \rangle$ in φ and using some β -reduction, we obtain that φ is equivalent to

$$\psi^0(\langle b \rangle, \langle a \rangle) \wedge \psi^1(\langle b \rangle, \langle a \rangle) \wedge \psi^2(\langle b \rangle, \langle a \rangle) \wedge \dots$$

With standard arguments about λ -expressions and modal logic, we obtain that $\psi^i(\langle b \rangle, \langle a \rangle)$ defines the set of positions such that all the α_j for $j < i$ follow, where α_j is as in Sec. 5. Hence, we can conclude that φ defines the set of positions i in w_∞ of Sec. 5 such that the postfix following i starts with α_j for all $j \in \mathbb{N}$.

► **Theorem 22.** *The extension HFL^2 of \mathcal{L}_μ by second-order functions does not have finite convergence on w_∞ .*

Proof. Following the argument above, we get $\llbracket \varphi \rrbracket^{w_\infty} = \emptyset$. However, from the previous analysis we can see that a position $\sum_{i=0}^{j-1} 5^i$, namely the starting point of the first α_j in w_∞ , is still contained in the j th approximant $(\bigwedge_{0 \leq i \leq j} \psi^i(\langle b \rangle, \langle a \rangle))$ but not in the $j + 1$ st one. Hence, φ does not have finite convergence on w_∞ . ◀

► **Remark 23.** It is possible to strengthen Thm. 22 by constructing a formula in HFL^1 , the first-order extension of \mathcal{L}_μ . (We have $\mathcal{L}_\mu = \text{HFL}^0$.) But the construction is complicated and requires further insight into the semantics of HFL, so it is left out for space considerations.

7 Conclusion

We have presented a further contribution to the theory of closure ordinals for μ -calculus, namely the – possibly surprising – fact that having finite bisimulation quotients is not an equivalent but a strictly stronger property than having finite fixpoint convergence, and that this discrepancy is due to \mathcal{L}_μ 's relatively restricted expressive power. As a corollary, we obtain decidability of \mathcal{L}_μ model checking over w_∞ (and the class of words built like it), i.e. for given φ and i , it is decidable whether φ holds at position i in w_∞ . This follows since every \mathcal{L}_μ formula is equivalent to one in ML over w_∞ and it is easily decidable whether the letter at some position is an a or a b . The use of the Compactness Theorem in Lem. 11 might look prohibitively non-constructive, but the result follows from the constructive nature of the proof up to alternation-free \mathcal{L}_μ (cf. Rem. 12). Note that this result does not follow from results around morphic words (cf. e.g. [2]), since w_∞ is not morphic. Hence, the construction of w_∞ can be used as the basis for a new class of infinite structures with decidable \mathcal{L}_μ model checking beyond pushdown processes. However, the design follows a pattern quite similar to morphic words, and we plan to investigate possible links between the two concepts.

There are some other directions into which our research can be extended: for further technical developments the theory of finite convergence has been formulated over classes of structures, even though it has been used here for a single word structure only. It remains

to be seen how far the construction pattern can be stretched, i.e. what a largest class of structures with finite convergence is. One may leave the world of words without losing the ability to reduce from the entire \mathcal{L}_μ to the alternation-free fragment as there are richer classes of structures with corresponding collapse of the alternation hierarchy [14].

The type hierarchy in HFL – which is strict in terms of expressiveness [3] – gives rise to the question whether for each level i , there is a class of structures on which HFL^i has finite convergence but HFL^{i+1} does not. Here, we have answered the question for $i = 0$. For $i > 0$ this is tricky as these higher-order logics lack comparable automata-theoretic support, cf. [6].

A Proof of Lemma 7

► **Lemma 7.** *Let φ be an \mathcal{L}_μ formula. Then the bottom-up unfolding of φ (cf. Def. 2) and the top-down unfolding of φ (cf. Def. 5) are equivalent to the unfolding defined in Def. 6. In particular, the top-down unfolding is well-defined.*

Proof. We first show that the top-down unfolding of φ is equivalent to the unfolding defined in Def. 6. W.l.o.g. let $\varphi = \sigma_{j+1}X_{j+1}.\psi_{j+1}$ be a formula with fixpoint variables X_1, \dots, X_k such that at most X_1, \dots, X_j for $j \leq k-1$ appear freely in φ . Let $n \geq 0$. We show that

$$(\psi_{j+1}[\psi_1/X_1, \dots, \psi_j/X_j])^{(i, n, \dots, n)} \equiv (\psi_{j+1}^i[\psi_1/X_1, \dots, \psi_j/X_j])^n \quad (1)$$

for closed and fixpoint-free formulas ψ_1, \dots, ψ_j and $i \leq n$. Note that the left term refers to the unfolding according to Def. 6, while the right one refers to the i th unfolding of the single fixpoint X_{j+1} , followed by the n th top-down unfolding of all remaining fixpoint-subformulas. The claim of the Lemma regarding the top-down unfolding procedure then follows with $j = 0$ and $i = n$.

We start with an induction over j . For the base case $j = k-1$ it follows that ψ_j does contain only one fixpoint-subformula and together with the observation that the ψ_1, \dots, ψ_j are closed and fixpoint-free formulas, both sides of Eq. 1 coincide with a single fixpoint unfolding. Let $j < k-1$ and assume that the result has been shown for all j' with $j < j' \leq k-1$ and for all $i \leq n$. We show the result for j by induction on i . For $i = 0$, we have that $\psi_{j+1}^0 = \hat{\sigma}_{j+1}$ and, hence $(\psi_{j+1}^0[\psi_1/X_1, \dots, \psi_j/X_j])^n = \hat{\sigma}_{j+1}$ and $(\psi_{j+1}[\psi_1/X_1, \dots, \psi_j/X_j])^{(0, n, \dots, n)} = \hat{\sigma}_{j+1}$ as well. Next let $i > 0$ and assume that the result has been proven for all $i' \leq i$. We show this case by another induction on the structure of ψ_{j+1} . The base case a , as well as the boolean cases and \bigcirc are straightforward. The interesting cases are the base case of a fixpoint variable $X_{j'}$ for $j' \leq j$, the case of X_{j+1} itself and the case of a fixpoint definition of the

form $\sigma_{j'} X_{j'} \cdot \psi_{j'}$ for $j' > j + 1$. The first case results in the same subformula, because in both versions of the unfolding $\psi_{j'}$ is substituted for $X_{j'}$ before the unfolding, and this is a closed and fixpoint-free formula. For X_{j+1} itself, we use the induction hypothesis of the induction over i , namely that $(X_{j+1}[\psi_1/X_1, \dots, \psi_j/X_j])^{(i, n, \dots, n)} = (\psi_{j+1}[\psi_1/X_1, \dots, \psi_j/X_j])^{(i-1, n, \dots, n)}$ is equivalent to $(\psi_{j+1}^{i-1}[\psi_1/X_1, \dots, \psi_j/X_j])^n$. For the case of a formula of the form $\sigma_{j'} X_{j'} \cdot \psi_{j'}$, we use the induction hypothesis for the induction over j , namely that

$$\begin{aligned} & (\psi_{j'}[\psi_1/X_1, \dots, \psi_j/X_j, \psi'_{j+1}/X_{j+1}, \psi'_{j+2}/X_{j+2}, \dots, \psi'_{j'-1}/X_{j'-1}])^{(n, \dots, n)} \equiv \\ & (\psi_{j'}^n[\psi_1/X_1, \dots, \psi_j/X_j, \psi''_{j+1}/X_{j+1}, \psi''_{j+2}/X_{j+2}, \dots, \psi''_{j'-1}/X_{j'-1}])^n \end{aligned}$$

for $\psi'_{j+1} = (\psi_{j+1}[\psi_1/X_1, \dots, \psi_j/X_j])^{(i-1, n, \dots, n)}$ and $\psi''_{j+1} = (\psi_{j+1}^{i-1}[\psi_1/X_1, \dots, \psi_j/X_j])^n$, which, by the induction hypothesis of the induction over i , are equivalent.¹ This finishes the induction over ψ_{j+1} and with it, the induction over i , and the induction over j .

For the bottom-up unfolding of Def. 2, we show equivalence to the unfolding from Def. 6 by showing that unfolding an innermost formula will not change the formula generated by either procedure. The result then follows by an induction over the ordering of fixpoints used in the bottom-up unfolding. Let φ be a fixpoint formula, and let X_1, \dots, X_k be an enumeration of its fixpoint variables such that $X_i \not\prec_{\text{fp}} X_j$ for $j > i$, and let $\sigma_i X_i \cdot \psi_i$ be the defining formula of X_i . Let $\varphi[\psi_k^n/\sigma_k X_k \cdot \psi_k]$ be the formula obtained by unfolding X_k n times. If we can show that, for all subformulas ψ of φ , and for all $s = (i_1, \dots, i_{k-1}, n)$, we have $\psi^s \equiv (\psi[\psi_k^n/\sigma_k X_k \cdot \psi_k])^s$, we are done. We show this by induction on the lexicographical ordering of the tuple, i.e starting with $s = (0, \dots, 0, n)$, for which the result clearly holds. Assume that we have shown it for all s' that are lexicographically smaller than s . We show the result by another induction on ψ . The base case a , the boolean cases, and the case \bigcirc are straightforward. The interesting cases are a variable X_j for $j < k$, a fixpoint definition of the form $\sigma_j X_j \cdot \psi_j$ for $j < k$, and the fixpoint definition of the form $\sigma_k X_k \cdot \psi_k$. For the case of X_j , if $s(j) = 0$, the result is immediate. For the case that $s(j) > 0$, and for the case of $\sigma_j X_j \cdot \psi_j$, the formula to be substituted is $\text{fp}(X_j)^{s[j--]}$, respectively $(\text{fp}(X_j)[\psi_k^n/\sigma_k X_k \cdot \psi_k])^{s[j--]}$, for which the result holds since $s[j--]$ is lexicographically smaller than s . For the case $\sigma_k X_k \cdot \psi_k$, there are two possibilities. If $s(j) = 0$ for all $0 \leq j < k$, then the result follows from the base case. If not, note that X_k is minimal w.r.t. $\prec_f p$ and, hence, its defining formula $\text{fp}(X_k) = \psi_k$ contains no fixpoint definitions itself. However, it can contain free fixpoint variables from among the X_1, \dots, X_{k-1} . We first note that, by definition, $\text{fp}(X_k)^s$ for $s = (i_1, \dots, i_{k-1}, n)$ is equivalent to $\psi_k^n[\psi_1/X_1, \dots, \psi_{k-1}/X_{k-1}]$, where ψ_j is $\hat{\sigma}_j$ if $s[j] = 0$ and $\text{fp}(X_j)^{s[j--]}$ otherwise. But, using the induction hypothesis for the ψ_i , this is exactly $(\sigma_k X_k \cdot \psi_k[\psi_k^n/\sigma_k X_k \cdot \psi_k])[\psi_1/X_1, \dots, \psi_{k-1}/X_{k-1}]$. This finishes the proof. \blacktriangleleft

B Proof of Lemma 13

► **Lemma 13.** *Let w be an infinite word. If w has finite convergence for the set of all unipolar \mathcal{L}_μ formulas, it has finite convergence for the set of all alternation-free \mathcal{L}_μ formulas.*

Proof. Let φ an alternation-free \mathcal{L}_μ formula. The set of fixpoint variables of φ can be partitioned into the sets $\mathcal{X}_1, \dots, \mathcal{X}_k$ as described in Sec. 2. First, we show by induction on these sets that all fixpoint-subformulas of φ can be unfolded starting from \mathcal{X}_k and ending with \mathcal{X}_1 while preserving equivalence over w . First, note that for all $X \in \mathcal{X}_k$ there is no fixpoint-subformula in $\text{fp}(X)$ that has a different polarity. This implies that all fixpoint-subformulas of

¹ The equality $\psi'_l = \psi''_l$ for $j + 2 \leq l \leq j' - 1$ can also be inferred via induction for a previous j' .

φ with $X \in \mathcal{X}_k$ are unipolar, but not necessarily closed. If we take a fixpoint-subformula with $X \in \mathcal{X}_k$ such that there is no $X' \in \mathcal{X}_k$ with $X' <_{\text{fp}} X$ it follows from the alternation-freeness of φ that $\text{fp}(X)$ is also closed and, thus, by the assumption of the lemma that there is an equivalent unfolding over w . If we replace all such fixpoint-subformulas with their respective equivalent unfolding we have unfolded all fixpoint-subformulas with $X \in \mathcal{X}_k$. Under the assumption that all fixpoint subformulas with $X \in \mathcal{X}_i$ are already unfolded, we can infer with the same arguments that there is an equivalent unfolding for all fixpoint subformulas of \mathcal{X}_{i-1} . By the principle of induction this shows that there is some equivalent finite unfolding of φ over w . What is left to argue is that there is a uniform one, i.e., that there is n such that φ^n is equivalent to φ . Note that for each closed, unipolar fixpoint subformula $\sigma X.\psi$ with equivalent unfolding ψ^m it holds that $\psi^{m'}$ with $m' \geq m$ is equivalent as well. As the number of fixpoint subformulas in φ is finite, n is given by the maximum number of unfoldings needed for any fixpoint subformula. \blacktriangleleft

C Additional Material for Section 6

We give a brief introduction to HFL on words. A more thorough introduction for HFL on arbitrary LTS can be found in e.g. [22]. We also point out that the exposition in Sect. 6 makes use of syntactic sugar that is not directly covered by the pure syntax. The constructs, however, are all straightforward using only principles which are standard in λ -calculi. For instance further below we explain that the subformula $\langle a \rangle$ is used to abbreviate something like $\lambda x.\langle a \rangle x$, so this simply makes use of η -conversion.

Types. Consider the set of types defined via

$$\tau ::= \bullet \mid \tau \rightarrow \tau.$$

The type \bullet is the base type of subsets of \mathbb{N} , for example those defined by an \mathcal{L}_μ formula. A type $\tau_1 \rightarrow \tau_2$ is inhabited by monotone functions from τ_1 to τ_2 .

Such a type induces a lattice over a given word w via the following definition

$$\begin{aligned} \llbracket \bullet \rrbracket^w &= (\mathcal{P}(\mathbb{N}), \subseteq) \\ \llbracket \tau_1 \rightarrow \tau_2 \rrbracket^w &= (\llbracket \tau_2 \rrbracket^w \rightarrow \llbracket \tau_1 \rrbracket^w, \sqsubseteq_{\tau_1 \rightarrow \tau_2}) \end{aligned}$$

where $\llbracket \tau_2 \rrbracket^w \rightarrow \llbracket \tau_1 \rrbracket^w$ denotes the set of functions from $\llbracket \tau_1 \rrbracket^w$ to $\llbracket \tau_2 \rrbracket^w$ and $\sqsubseteq_{\tau_1 \rightarrow \tau_2}$ is defined as the pointwise order via $f \sqsubseteq_{\tau_1 \rightarrow \tau_2} g$ iff $f(x) \sqsubseteq_{\tau_2} g(x)$ for all $x \in \llbracket \tau_1 \rrbracket^w$. Here, \sqsubseteq_\bullet ordinary set inclusion \subseteq . All these lattices are complete since $\llbracket \bullet \rrbracket^w$ is complete, and a lattice of functions is complete if the functions are into a complete lattice and ordered pointwise.

Syntax. Let $\mathcal{V} = \{x, y, \dots\}$ be a set of λ variables. The syntax of HFL extends that of \mathcal{L}_μ to

$$\varphi ::= a \mid \varphi \vee \varphi \mid \varphi \wedge \varphi \mid \bigcirc \varphi \mid X \mid x \mid \mu(X : \tau).\varphi \mid \nu(X : \tau).\varphi \mid \lambda(x : \tau).\varphi \mid \varphi \varphi$$

where τ is a type.

The intuition behind the operators that are new in comparison to \mathcal{L}_μ is as follows.

- $\lambda x.\varphi$ defines an anonymous function that consumes an argument, bound to x , and returns the value of φ if x is set to that argument.
- $\varphi \psi$ denotes the application of ψ to φ , and
- the fixpoints can now be of higher order, i.e. define function type objects.

$$\begin{array}{c}
 \frac{}{\Gamma \vdash a : \bullet} \quad \frac{}{\Gamma, X : \tau \vdash X : \tau} \quad \frac{}{\Gamma, x : \tau \vdash x : \tau} \quad \frac{\Gamma \vdash \varphi_1 : \bullet \quad \Gamma \vdash \varphi_2 : \bullet}{\Gamma \vdash \varphi_1 \vee \varphi_2 : \bullet} \\
 \\
 \frac{\Gamma \vdash \varphi_1 : \bullet \quad \Gamma \vdash \varphi_2 : \bullet}{\Gamma \vdash \varphi_1 \wedge \varphi_2 : \bullet} \quad \frac{\Gamma \vdash \varphi : \bullet}{\Gamma \vdash \bigcirc \varphi : \bullet} \quad \frac{\Gamma, X : \tau \vdash \varphi : \tau'}{\Gamma \vdash \lambda(X : \tau). \varphi : \tau \rightarrow \tau'} \quad \frac{\Gamma, X : \tau \vdash \varphi : \tau}{\Gamma \vdash \mu(X : \tau). \varphi : \tau} \\
 \\
 \frac{\Gamma, X : \tau \vdash \varphi : \tau}{\Gamma \vdash \nu(X : \tau). \varphi : \tau} \quad \frac{\Gamma \vdash \varphi : \tau \rightarrow \tau' \quad \Gamma \vdash \varphi' : \tau}{\Gamma \vdash \varphi \varphi' : \tau'}
 \end{array}$$

■ **Figure 1** The type system of HFL.

Note that we have chosen not to introduce negation. HFL admits negation normal form [18], whence negation only needs to occur on front of atomic propositions. Over words, the formula $\neg a$ however is equivalent to $\bigvee_{b \in \Sigma, b \neq a} b$ as stated for \mathcal{L}_μ already, so negation can be avoided altogether.

An advantage of this avoidance of negation is the simplification of the type system to monotone functions only. The original definition of HFL includes negation as a syntactic construct at the expense of a slightly more complex type systems which needs to keep track of antitonicity information so that fixpoints are guaranteed to exist due to monotonicity.

Without this, the only purpose of the type system is to avoid misapplications as in $a b$ for instance which cannot be given proper meaning. Another example is $a \vee \lambda(x : \mathbb{N}). x \wedge b$.

In the absence of negation, an HFL formula φ is said to be well-typed if the statement $\emptyset \vdash \varphi$ can be derived via the rules shown in Fig. 1. The sequence Γ on the left of a typing statement is called a typing context and collects typing hypotheses.

Semantics. In order to endow well-typed HFL formulas with semantics, we extend environments to \mathcal{V} , i.e. environments can also store values for λ -variables which may be higher-order objects depending on the type of the variable. The semantics of an HFL formula φ is given inductively as per the following:

$$\begin{aligned}
 \llbracket a \rrbracket_\eta^w &= \{i \in \mathbb{N} \mid w[i] = a\} \\
 \llbracket X \rrbracket_\eta^w &= \eta(X) \\
 \llbracket x \rrbracket_\eta^w &= \eta(x) \\
 \llbracket \varphi \vee \psi \rrbracket_\eta^w &= \llbracket \varphi \rrbracket_\eta^w \cup \llbracket \psi \rrbracket_\eta^w \\
 \llbracket \varphi \wedge \psi \rrbracket_\eta^w &= \llbracket \varphi \rrbracket_\eta^w \cap \llbracket \psi \rrbracket_\eta^w \\
 \llbracket \bigcirc \varphi \rrbracket_\eta^w &= \{i \in \mathbb{N} \mid i + 1 \in \llbracket \varphi \rrbracket_\eta^w\} \\
 \llbracket \lambda(x : \tau). \varphi \rrbracket_\eta^w &= f \in \llbracket \tau \rightarrow \tau' \rrbracket^w \quad \text{where f.a. } d \in \llbracket \tau \rrbracket^w . f(d) = \llbracket \varphi \rrbracket_{\eta[x \mapsto d]}^w \\
 &\quad \text{with } \tau' \text{ the type of } \varphi \\
 \llbracket \varphi \psi \rrbracket_\eta^w &= \llbracket \varphi \rrbracket_\eta^w (\llbracket \psi \rrbracket_\eta^w) \\
 \llbracket \mu(X : \tau). \varphi \rrbracket_\eta^w &= \bigsqcap \{d \subseteq \llbracket \tau \rrbracket^w \mid \llbracket \varphi \rrbracket_{\eta[X \mapsto d]}^w \sqsubseteq_\tau d\} \\
 \llbracket \nu(X : \tau). \varphi \rrbracket_\eta^w &= \bigsqcup \{d \subseteq \llbracket \tau \rrbracket^w \mid d \sqsubseteq_\tau \llbracket \varphi \rrbracket_{\eta[X \mapsto d]}^w\}
 \end{aligned}$$

The formula φ from Sect. 6. We give some additional explanation about the formula φ defined in Sec. 6. Recall that

$$\varphi = (\nu(X : \tau). \lambda(f, g : \mathbb{N} \rightarrow \mathbb{N}). f(\mathbf{tt}) \wedge X(f^2 \circ g \circ f^2, g^2 \circ f \circ g^2)) (\langle b \rangle, \langle a \rangle).$$

Notation such as $\lambda(f, g : \mathbb{N} \rightarrow \mathbb{N}). \dots$ can easily be seen to be an abbreviation of the longer $\lambda(f : \dots). \lambda(g : \dots). \dots$, and the same goes for the application to X written in a similar style. Clearly, neither function composition nor the function $\langle a \rangle$ are in the official syntax of HFL. The function $\langle a \rangle$ can be written in standard syntax as $\lambda(x : \mathbb{N}). a \wedge \bigcirc x$. Function composition, here between five functions, is an abbreviation for $\lambda(x : \mathbb{N}). f(f(g(f(f(x))))))$, respectively $\lambda(x : \mathbb{N}). g(g(f(g(g(x))))))$.

The intuition given for the semantics of φ is already close to the true semantics of φ . Since the Kleene Fixpoint Theorem applies in this setting, too, we can use it to obtain the semantics of φ on w_∞ . As in Sec. 6, write ψ for the defining formula of $\lambda f, g. f(\mathbf{tt}) \wedge X(f^2 \circ g \circ f^2, g^2 \circ f \circ g^2)$, write ψ^0 for $\lambda f, g. \mathbf{tt}$ and ψ^{i+1} for $\psi[\psi^i/X]$. Given some functions f and g , we introduce the following functions:

$$\begin{aligned} f_1(x) &= f(x) & f_{i+1} &= f_i(f_i(g_i(g_i(g_i(x)))))) \\ g_1(x) &= g(x) & g_{i+1} &= g_i(g_i(f_i(g_i(g_i(x)))))) \end{aligned}$$

Then ψ^i defines the function $f, g \mapsto f_1(\mathbf{tt}) \wedge f_2(\mathbf{tt}) \wedge \dots \wedge f_i(\mathbf{tt})$ by induction on i . Hence, the semantics of X is $f, g \mapsto \bigwedge_{i \in \mathbb{N}} f_i(\mathbf{tt})$. Applied to the arguments $\langle a \rangle$ and $\langle b \rangle$, this yields, by abuse of notation, $\bigwedge_{i \in \mathbb{N}} \langle \alpha_i \rangle \mathbf{tt}$, which is as claimed in Sec 6. The remarks on the infinite convergence process of φ on w_∞ then follow.

Dots & Boxes Is PSPACE-Complete

Abstract

Exactly 20 years ago at MFCS, Demaine posed the open problem whether the game of Dots & Boxes is PSPACE-complete. Dots & Boxes has been studied extensively, with for instance a chapter in Berlekamp et al. *Winning Ways for Your Mathematical Plays*, a whole book on the game *The Dots and Boxes Game: Sophisticated Child's Play* by Berlekamp, and numerous articles in the *Games of No Chance* series. While known to be NP-hard, the question of its complexity remained open. We resolve this question, proving that the game is PSPACE-complete by a reduction from a game played on propositional formulas.

1 Introduction

Dots & Boxes is a popular paper-and-pencil game that is played by two players on a grid of dots. The players take turns connecting two adjacent dots. If a player completes the fourth side of a unit box, the player is awarded a point and an additional turn. When no more moves can be made, the player with the highest score wins the game.¹

Originally described in 1883 [29], Dots & Boxes has since received a considerable amount of attention in the research community. In *Winning Ways for Your Mathematical Plays*, Berlekamp, Conway, and Guy [6] were among the first to discuss a number of interesting mathematical properties of the game. Later, Berlekamp [5] wrote an entire book *The Dots-and-Boxes game: Sophisticated Child's Play* about the game, in particular discussing winning strategies in particular positions. Since then, the mathematics of Dots & Boxes and variants have been discussed in many papers and books [1, 2, 7, 12, 16, 21, 22, 26, 30, 31, 33, 34]. There is also a rich body of work on solvers for Dots & Boxes [3, 4, 11, 27, 35].

Berlekamp et al. [6] argue that deciding the winner of a generalized version of Dots & Boxes, called *Strings-and-Coins*, is NP-hard. In this game, players take turns in removing edges of a given graph, scoring a point when they isolate a vertex. When restricted to the dual graph of a square grid, this corresponds to a dual formulation of Dots & Boxes. Eppstein [17] notes that the reduction given by Berlekamp et al. should extend to Dots & Boxes, and a formal proof of the NP-hardness is given in [8].

Exactly 20 years ago at MFCS, Demaine posed the open problem whether Dots & Boxes is PSPACE-complete [13]. Bounded two-player games, like Dots & Boxes, (that is, games in which the number of moves is bounded) naturally lie in PSPACE, since a Turing machine using space polynomial in the board size is able to search the entirety of the game

¹ For a visual explanation of the game see <https://youtu.be/KboGyIi1P6k>, last accessed 6.5.2021

space. PSPACE-hardness of many bounded two-player games is shown by a reduction from *Generalized Geography*, which is proven PSPACE-complete by Lichtenstein and Sipser [28]. For example, the PSPACE-completeness of Reversi [24], uncooperative UNO [14], and Tic-Tac-Toe [23] were shown by a reduction from Generalized Geography. However, unlike Dots & Boxes, the setting of Generalized Geography prescribes a stricter order on players' moves, making a reduction to Dots & Boxes challenging to obtain.

In their seminal work, Hearn and Demaine [20, 21] introduce *Constraint Logic*, a framework for analyzing complexity of games and puzzles. Inspired by Flake and Baum's proof of Rush Hour [18], it specifies a type of game played on a constraint graph. The framework includes bounded/unbounded state spaces and single/two-player variations. In the same work, Hearn and Demaine go on to provide a number of simpler reductions for various known PSPACE-complete games (including Rush Hour), as well as new proofs for several PSPACE-complete games. However, the Constraint Logic framework is intended for proving hardness of partisan games (games in which the moves available to the two players are different), whereas Dots & Boxes is not a partisan game.

Strings-and-Coins and the related game of *Nimstring* were very recently (while we were preparing this submission) proven to be PSPACE-complete by Demaine and Diomidov [15] by a reduction from a game on a DNF formula $G_{pos}(\text{POS DNF})$ [32]. But, as they point out, their results do not apply to Dots & Boxes, since the game positions they construct rely on multi-graphs (which additionally are neither planar nor have a maximum degree of 4). Specifically, they propagate signals through multi-edges consisting of a polynomial number of parallel edges, and the winner is the player who removes the last edge. As consequence, our reduction bears little commonalities with theirs.

In this paper, we prove that Dots & Boxes is PSPACE-complete by a reduction from $G_{pos}(\text{POS CNF})$. The starting point of our construction are strategies for Dots & Boxes endgames that were also used to prove NP-hardness. However, the NP-hardness is proven by having one player be in control, such that there is only one way for the other player to respond. This de facto makes the game into a 1-player game. For PSPACE-hardness we need both players to have choices, making it a true 2-player game. This gives a lot of freedom to the players, and makes it much more difficult to construct gadgets to control the gameplay, in particular because moves and scoring opportunities for one player – if not played immediately – are also available to the other player.

In Section 1.1 we discuss the gameplay of Dots & Boxes, and introduce terminology coined by Berlekamp et al. [6]. In Section 2 we present the general structure of our reduction, and then describe our gadgets in Section 3. In Section 4 we first show properties of optimal play for both players and finally prove PSPACE-hardness.

1.1 Dots & Boxes

On the surface, Dots & Boxes is quite a simple game. The starting and a typical final position for a 10×10 grid are shown in Figure 1. We refer to the players playing the blue and the red colors as Trudy and Fred, respectively. The color of a line connecting two dots indicates which player drew it, and the color of a box indicates which player closed it.

Consider a dual graph G of a board of Dots & Boxes, where a node in G corresponds to a box or the unbounded face, and a pair of nodes in G is connected with an edge if the corresponding move is still available, i.e., the line between the boxes has not been drawn. Let the *degree* of a box be the degree of the corresponding node in G .

■ **Figure 1** Typical starting, intermediate, and final position of a Dots & Boxes game.

In Dots & Boxes, a typical game usually results in a board state that consists exclusively of moves that open the possibility for the opponent to claim a number of boxes in their next turn (see Figure 1b). That is, in this state there are no degree-1 boxes, but any move made by a player creates a degree-1 box that can be immediately claimed by the opponent. Consider such a board configuration S and any available move ℓ in it. At least one box b incident to ℓ has degree two in S (before the move ℓ is made). Consider a maximal component σ of degree-2 boxes in S containing b . There are two cases, either σ is a *chain* ending in boxes of degree higher than two (or the outer face), or σ is a *cycle*. Then we say that a player making the move ℓ *opens* the chain (cycle) σ for the opponent.

To devise a good strategy for Dots & Boxes, it is important to note that a player is not obliged to claim a box whenever they can. It is sometimes beneficial for a player to sacrifice a small number of boxes for long-term gain. Consider the position in Figure 2, and let it be Fred's (red) turn. Here, Fred could claim the bottom three boxes (Figure 2 (top)). However, after doing so Fred has to make an extra move, allowing Trudy (blue) to claim the remaining four boxes and win the game. But by sacrificing two boxes (Figure 2 (bottom)), Fred can force Trudy to make another move and open the middle chain for him to claim. That way, Fred loses two boxes in the bottom chain, but gains all four boxes in the middle chain.

In *Winning Ways*, Berlekamp et al. [6] refer to the moves sacrificing a small number of boxes but passing the turn onto the opponent as *double-dealing* moves. Double-dealing moves can be made in chains of boxes, sacrificing two boxes, and in cycles, sacrificing four boxes (see Figure 3). Each double-dealing move is usually immediately followed by the opponent making at least one *double-cross* move, i.e., a move that closes two boxes at once. Note that

■ **Figure 2** Two possible plays that Fred (red) can do. Fred can choose to claim all the available boxes (top) and lose the game, or to perform a double-dealing move sacrificing two boxes (bottom, second state, edge 2), and win the game. The order of the edges that are played by Trudy or Fred in one turn is indicated by edge labels. This example is borrowed from *Winning Ways*, chapter 16 [6].

■ **Figure 3** Double-dealing move by Fred (red). If Trudy (blue) opens a chain (or a cycle), Fred can claim a sequence of boxes. To pass the turn back to Trudy, Fred can leave two (or four) boxes unclaimed.

double-dealing moves are only possible in *long* chains of at least three boxes, and in cycles. (Chains of length one do not have enough boxes for a double-dealing move, and a chain of length two can be opened by selecting the middle edge, thus preventing the opponent from playing a double-dealing move.)

Berlekamp et al. [6] refer to moves opening a long chain or a cycle as *loony* moves. Making a loony move is not always a choice, since at some point in the game, all unclaimed boxes are part of long chains and cycles as in Figure 1b. Such positions are referred to as a *loony endgame*. Note that in chains of length ≥ 4 and cycles of length ≥ 8 , the player making the double-dealing moves scores at least as many boxes as their opponent. Thus, in loony endgames with chains of length ≥ 4 and cycles of length ≥ 8 , under optimal play, the game consists of one player making loony moves (opening chains and cycles), and the other player claiming all but two or four boxes, and making double-dealing moves to pass the turn back to the opponent [6]. Here, the player making the double-dealing moves is always better off, since each chain or cycle yields at least as many boxes to this player as it yields to their opponent. This player is thus referred to as being *in control* of the game. The benefit of being in control can be seen in Figure 1c, which is the end result of Trudy being in control of the loony endgame shown in Figure 1b.

In *Winning Ways*, Berlekamp et al. [6] argue that the player not in control has to maximize the number of disjoint cycles to maximize their score, because double-dealing moves in cycles yield twice as many boxes as double-dealing moves in chains. Since this property is important for our reduction, we restate it here and, for completeness, present the argument in the appendix.

► **Lemma 1.** *Let the configuration of a loony endgame contain k boxes with degree higher than 2, let T be the sum of the degrees of these boxes, and let c be the maximum number of disjoint cycles in the configuration. Then, the player who is not in control can claim at most $4c + T - 2k - 4$ boxes.*

Note that in this lemma we only count boxes; even though the outer face contributes to the degrees of adjacent boxes, it is not counted here.

2 Structure of the construction

To show that Dots & Boxes is PSPACE-hard we reduce from the game $G_{pos}(\text{POS CNF})$, introduced and proven PSPACE-complete by Schaefer [32]. The game is played by two players, Trudy and Fred, on a positive CNF formula \mathcal{F} . The players take turns picking a variable that has not yet been chosen. Variables picked by Trudy are set to TRUE, variables picked by Fred are set to FALSE. When all variables have been chosen, the game ends. Trudy wins if formula \mathcal{F} evaluates to TRUE, and Fred wins if formula \mathcal{F} evaluates to FALSE.

■ **Figure 4** A choice of a cycle can encode the value of a signal.

Given a positive CNF formula \mathcal{F} with n variables and m clauses, we construct an instance of Dots & Boxes in which Trudy has a winning strategy if and only if she also has a winning strategy in the corresponding instance of $G_{pos}(\text{POS CNF})$. For simplicity we assume that n is even, so that Trudy and Fred get to assign values to the same number of variables. If the number of variables in \mathcal{F} is odd, we can introduce dummy variables without changing the outcome of a game such that the total number of the variables becomes even. For each variable and clause of \mathcal{F} we construct a **variable** and a **clause** gadget, respectively. We place the **variable** gadgets in a row at the top of the board of Dots & Boxes, and the **clause** gadgets in a row at the bottom. We connect the **variable** gadgets to their corresponding **clause** gadgets using the **wire** gadgets, which transfer the values of the variables to the clauses. If a clause consists of more than one variable, the wires from these variables must pass through an **or** gadget. Since the signals propagating from the variables may need to cross each other, we construct a **crossover** gadget that preserves the values in the two crossing wires. In our instance of Dots & Boxes, only the gadgets contain available moves. The remaining boxes on the board have all the incident edges present.

As we detail in Section 4, after the values of the variables are set, the game enters a loony endgame where Fred is in control. Then Trudy's winning strategy reduces to selecting a maximum set of disjoint cycles \mathcal{C}_{\max} in the remaining configuration (Lemma 1). In the remainder of this paper, we describe a strategy for both players referred to as *regular play*. Later, we will show that following the regular strategies is optimal for both players, in the sense that it maximizes their scores. Under regular play, Trudy opens all the chains outside of \mathcal{C}_{\max} first, gaining two boxes per chain, and opens the chosen cycles last, gaining four boxes per cycle except the last one. Regular play for Fred is to ensure that he will be in control when the loony endgame starts. After entering the loony endgame, regular play for Fred is simply making double-dealing moves until his very last turn.

Most of our gadgets consist of partially overlapping cycles of boxes. The choice of a set of disjoint cycles determines the value of a signal. For example, in Figure 4 the choice of the left vs. right cycle can encode the value TRUE vs. FALSE. Of course, Trudy could join the cycles together to select the outermost cycle, but this, as we show later, will not be more beneficial.

As both players must have a choice in picking which variable to set, the instance of Dots & Boxes cannot yet be in a loony endgame. Thus, the **variable** gadgets, which we describe in Section 3.4, contain non-loony moves instrumental in setting the value of a variable. We ensure that under regular play the variables are set in alternating fashion, where Trudy sets them to TRUE, and Fred sets them to FALSE. Once all variables are set, the loony endgame is entered. At this point Fred is in control of the game, and it is up to Trudy to maximize her score by maximizing the number of disjoint cycles in \mathcal{C}_{\max} . The regular play by Trudy results in a correct propagation of the signals from the variables to the clauses.

To ensure that regular play by both players in the instance of Dots & Boxes corresponds to a valid $G_{pos}(\text{POS CNF})$ game, our gadgets need to give a specific number of boxes to

Trudy depending on the signal values. We will show that after the variable values have been set, under regular play, Trudy can maximize her score only if the signals are propagated correctly. Every gadget, except for the clause, yields the same number of disjoint cycles independent of the signals passing through the gadget. Only the clause gadget gives more cycles to Trudy if a TRUE signal reaches it. Exactly half of the variables are set to TRUE, and half to FALSE. Thus we can tune the starting score count such that the game is won by Trudy if and only if all the clauses are satisfied.

3 Gadgets

In this section we provide the details of the gadgets used in our reduction. When describing the gadgets below, for a simpler exposition, we assume that the moves that Trudy and Fred make follow the following sequence. First, in the first n moves Trudy and Fred set all the variables to TRUE and FALSE respectively. Afterwards, when the loony endgame is entered, the order in which Trudy selects which cycles to add to the disjoint set of cycles \mathcal{C}_{\max} is from the top to bottom, that is, from the variables, through the outgoing wires, through the crossover and or gadgets, and finally down to the clause gadgets. Later, in Lemma 7, we will show that, indeed, under regular play Trudy and Fred start by setting all the variables. Furthermore, we will argue that the outcome of the game depends only on the choice of the cycles in \mathcal{C}_{\max} , and not on the order in which Trudy selects them.

3.1 Basic wiring

Signals from the variable gadgets are propagated to the clause gadgets through wires. A wire gadget consists of a chain of an even number of partially overlapping cycles (see Figure 5). The first cycle in the wire overlaps with the gadget from which the signal is propagated, and the last cycle overlaps with the gadget towards which the signal is propagated. Consider some wire w , let C_i be its first cycle overlapping with gadget G_i , and let C_o be its last cycle overlapping with gadget G_o . If C_i is disjoint from the cycles of G_i that Trudy adds to \mathcal{C}_{\max} , then we say that the input signal to the wire is TRUE; otherwise, if C_i overlaps with one of the cycles of G_i in \mathcal{C}_{\max} , the input value is FALSE. If Trudy does not add C_o to \mathcal{C}_{\max} , then the output signal is TRUE, and the output signal is FALSE otherwise.

■ **Figure 5** A wire gadget consisting of four overlapping cycles and two ways of selecting disjoint cycles. Shown in green are the connections to the adjacent gadgets. Selecting odd cycles in \mathcal{C}_{\max} corresponds to TRUE (top), and selecting even cycles corresponds to FALSE (bottom).

To ensure that Fred always follows the strategy of double-dealing moves, we require that each maximal chain of degree-2 boxes in a wire gadgets contain at least four boxes. That way, Fred receives at least as many boxes in each chain (and cycle) as Trudy, and thus for Fred being in control is always beneficial [6].

Note that, besides the lower bound on the length of a chain, the size and the embedding of the overlapping cycles in a wire can be chosen freely. Thus wires are very flexible in connecting components together, which facilitates the construction.

► **Lemma 2.** *Let a wire w consist of $2k$ partially overlapping cycles. Then, under regular play, if the signal in w changes from FALSE to TRUE, then Trudy can select at most $k - 1$ disjoint cycles from w to add to \mathcal{C}_{\max} . Otherwise, under regular play, Trudy can select k disjoint cycles from w to add to \mathcal{C}_{\max} .*

Proof. As we show in Lemma 7, after the first n moves, which Trudy and Fred make in the variable gadgets, the game enters a loony endgame with Fred in control. If the output signal in the wire matches the input signal, then only one of C_i or C_o of w are in \mathcal{C}_{\max} . Then Trudy can select all odd (if $C_i \in \mathcal{C}_{\max}$) or all even (if $C_o \in \mathcal{C}_{\max}$) cycles to add to \mathcal{C}_{\max} , which results in k disjoint cycles. If the the input signal is TRUE, and the output signal is FALSE, then both C_i and C_o are in \mathcal{C}_{\max} . Then Trudy can, for example, select $k - 1$ odd cycles and C_o to add to \mathcal{C}_{\max} , which again results in k cycles in total.

If, however, the input signal is FALSE, and the output signal is TRUE, then neither C_i nor C_o can be in \mathcal{C}_{\max} . This leaves a chain of $2k - 2$ cycles, of which at most $k - 1$ disjoint cycles can be selected to be added to \mathcal{C}_{\max} . ◀

In our construction we ensure that Trudy can win only if she gets k disjoint cycles from a wire, and thus under regular play she cannot flip a signal propagating from a variable from FALSE to TRUE. Flipping a signal from TRUE to FALSE is not beneficial for Trudy, as her goal is to satisfy all the clauses. Nevertheless, flipping a signal from TRUE to FALSE leads to the same number of boxes for her (at least locally within a wire), and is thus allowed.

3.2 Crossover gadget

Since the graph representing G_{pos} (POS CNF) is not necessarily planar, wires may need to cross each other in our construction. We describe a **crossover gadget** that allows two signals to cross while preserving the signal values. The gadget has two inputs and two outputs

■ **Figure 6** The crossover gadget. Connections to the adjacent wires are shown in green.

■ **Figure 7** A possible choice of a set of disjoint cycles. The selection has fourth degree rotational symmetry.

on the opposite sides of the gadget. Let $C_{1,i}$ and $C_{2,i}$ be the input cycles of the gadget, and $C_{1,o}$ and $C_{2,o}$ be the output cycles (see Figure 6). An input cycle $C_{*,i}$ is in \mathcal{C}_{\max} if the corresponding input signal is TRUE, and otherwise it is FALSE. An output cycle $C_{*,o}$ is not in \mathcal{C}_{\max} if the output signal is TRUE, and otherwise it is FALSE.

There are four pairwise overlapping cycles $C_a, C_b, C_c,$ and C_d in the middle of the gadget, forming a cross shape. Only one of these cycles can be added to \mathcal{C}_{\max} . A choice of which of these cycles is added to \mathcal{C}_{\max} is in one-to-one correspondence to the input signal values (see Figure 7).

► **Lemma 3.** *Under regular play, if a signal in a crossover gadget changes from FALSE to TRUE, then Trudy can select at most 4 disjoint cycles from the gadget to add to \mathcal{C}_{\max} . Otherwise, under regular play, Trudy can select 5 disjoint cycles from the gadget.*

Proof. If the output signals in the crossover gadget match the input signals, then only one of each pair $\{C_{1,i}, C_{1,o}\}$ and $\{C_{2,i}, C_{2,o}\}$ are in \mathcal{C}_{\max} . Since the four center cycles $C_a, C_b, C_c,$ and C_d all share a single square, only one of these four cycles can be chosen. Then Trudy can select a corresponding cycle from the middle of the gadget, and two more cycles from each signal. For example, a selection of five disjoint cycles for the case when the first input signal is FALSE and the second is TRUE is shown in Figure 7. If an input signal is TRUE, and the corresponding output signal is FALSE, then both $C_{*,i}$ and $C_{*,o}$ are in \mathcal{C}_{\max} . Then Trudy can, for example, make exactly the same choice as in the case where the output signal would have been TRUE.

Assume now, w.l.o.g., that the signal corresponding to $C_{1,i}$ and $C_{1,o}$ changes from FALSE to TRUE in the gadget. That is, neither $C_{1,i}$ nor $C_{1,o}$ are in \mathcal{C}_{\max} . Let C' and C'' be the cycles in the gadget adjacent to $C_{1,i}$ and $C_{1,o}$ respectively. Thus, among cycles $C', C'', C_a, C_b, C_c,$ and C_d at most two cycles can be in \mathcal{C}_{\max} , and therefore at most four cycles can be chosen to be in \mathcal{C}_{\max} . ◀

3.3 Or gadget

The or gadget consists of three pairwise overlapping cycles (see Figure 8 (left)). Two of the cycles partially overlap with an end cycle of an input wire, and one cycle partially overlaps with the output cycle. Let $C_{1,w}$ and $C_{2,w}$ be the last cycles of the two input wire gadgets, and let $C_{1,i}$ and $C_{2,i}$ be the cycles of an or gadget adjacent to these two wires respectively. Let C_o be the third cycle of the or gadget, which is adjacent to an output wire. Cycles $C_{1,w}$ and $C_{2,w}$ are not in \mathcal{C}_{\max} if the input from their corresponding wire is TRUE, and are in \mathcal{C}_{\max} if their input is FALSE. If C_o is not in \mathcal{C}_{\max} then the output of the or gadget is TRUE, and if it is in \mathcal{C}_{\max} then the output value is FALSE. Only one of the three cycles in the or gadget can be selected to be added to \mathcal{C}_{\max} , and thus the output of the gadget can be TRUE only if one of $C_{1,w}$ or $C_{2,w}$ is in \mathcal{C}_{\max} .

■ **Figure 8** The or gadget (left) and the three possible combinations of the input values (right). From left to right: two TRUE inputs, one TRUE and one FALSE input, and two FALSE inputs. The boxes highlighted in green belong to a cycle in an adjacent wire gadget.

► **Lemma 4.** *Under regular play, if both input signals in an or gadget are FALSE but the output signal is TRUE, then Trudy cannot add any cycles from the gadget to \mathcal{C}_{\max} . Otherwise, under regular play, Trudy can select 1 cycle from the gadget to add to \mathcal{C}_{\max} .*

Proof. First consider the case when one of the input signals in the or gadget is TRUE. W.l.o.g., let the signal from the first wire be TRUE, that is $C_{1,w}$ is not in \mathcal{C}_{\max} . Then Trudy can select $C_{1,i}$ to add to \mathcal{C}_{\max} and thus the output from the or gadget would correspond to TRUE. Trudy may as well choose C_o to add to \mathcal{C}_{\max} and make the output of the gadget to be FALSE. In either case, one cycle from the gadget is in \mathcal{C}_{\max} .

If both input signals are FALSE, then both cycles $C_{1,w}$ and $C_{2,w}$ are in \mathcal{C}_{\max} . Thus none of $C_{1,i}$ and $C_{2,i}$ can be in \mathcal{C}_{\max} . Trudy can choose to add C_o to \mathcal{C}_{\max} and make the output of the gadget to be FALSE. If, however, Trudy chooses to make the output of the or gadget TRUE, then C_o is not in \mathcal{C}_{\max} , and thus Trudy cannot select a single cycle to add to \mathcal{C}_{\max} from this or gadget. ◀

3.4 Variable gadget

The variable gadget is responsible for the assignment of TRUE and FALSE values to the variables of the G_{pos} (POS CNF) instance. It consists of two components: the *value-setting component* (see Figure 9) designed to set the value of the variable, and the *fan-out component* designed to duplicate the variable signal. The whole construction is presented in Figure 10. Let C_1 , C_2 , and C_3 be the three cycles in the value-setting component. The variable gadget is the only gadget that contains non-loony moves; there are two non-loony moves (shown in purple in the figure) at the intersection of C_1 and C_2 .

Regular play by both Trudy and Fred is to set all the variables in the first n moves, such that Fred always sets a variable to FALSE and Trudy – to TRUE. Figure 11 shows the two possible value assignments of the variable gadgets. To set a variable to FALSE, Fred plays one of the non-loony moves in the corresponding variable gadget. Then Trudy responds by claiming the one box available (see Figure 11 (left)). This results in the cycles C_1 and C_2 getting merged. To set a variable to TRUE, Trudy opens a side chain of C_2 (see Figure 11 (right)). Then Fred responds by claiming every box in the opened chain, and proceeds to setting the next variable. Note that after Trudy’s move the non-loony moves in the gadget become loony moves (as they are now a part of a long chain).

■ **Figure 9** The value-setting component of the variable gadget. There are two non-loony moves (purple) available, of which only one can be played as a non-loony move.

■ **Figure 10** The complete variable gadget consisting of the value-setting component and the fan-out component. Outgoing wires are shown in green.

■ **Figure 11** The variable is set to FALSE (left) and TRUE (right).

We make two observations which will be useful when proving correctness of the construction and the properties of the regular play in Section 4. First, observe that the non-loony moves come in pairs, one in each variable, such that, for each pair, either both moves in the pair are still non-loony or neither is anymore. We refer to them as *non-loony pairs*. Second, note that in the process of assigning values to the variable gadgets, Trudy gets a box for each variable set to FALSE by Fred, and zero boxes for each variable set to TRUE by herself.

Once the value of a variable is set, it propagates to the outgoing wires through the fan-out component of the variable gadget. The fan-out component simply consists of one cycle C_4 overlapping with the cycle C_3 (see Figure 10), to which multiple wires can be attached. After the variable is set, Trudy can add at most two cycles from it to \mathcal{C}_{\max} . Then, if the variable is set to FALSE, cycle C_4 has to be one of the two selected cycles, and thus the signal propagated into the wires is FALSE. If the variable is set to TRUE, Trudy can add C_1 and C_3 to \mathcal{C}_{\max} , and thus propagate the TRUE value into the wires. By considering the various cases under regular play, we obtain the following lemma.

► **Lemma 5.** *Under regular play, after a variable gadget is assigned a value, if it is set to FALSE but the output signal is TRUE, then Trudy can add at most 1 cycle from the gadget to \mathcal{C}_{\max} . Otherwise, under regular play, Trudy can add 2 cycles from the gadget to \mathcal{C}_{\max} .*

Proof. As we show in Lemma 7, optimal play of both Trudy and Fred results in them setting all the variables according to the rules described above in the first n moves. Afterwards the game enters a loony endgame with Fred in control.

If a variable gadget is set to TRUE, then there are three cycles left in the gadget: two overlapping cycles C_3 and C_4 , and the cycle C_1 connected to C_3 by a chain. Then Trudy can select C_1 and one of C_3 or C_4 to add to \mathcal{C}_{\max} .

If the variable gadget is set to FALSE, then there are still three cycles left in the gadget, but now these cycles are forming a chain where each consecutive pair of cycles is overlapping. Thus, if the output value is FALSE, then C_4 and the merged cycle of C_1 and C_2 can be added to \mathcal{C}_{\max} . On the other hand, if the output value is TRUE then C_4 cannot be in \mathcal{C}_{\max} , and from the remaining two cycles, only one can be selected to be added to \mathcal{C}_{\max} . ◀

3.5 Clause gadget

Finally, we describe a clause gadget that yields more boxes to Trudy if the signal entering the clause corresponds to TRUE. A clause gadget is simply an extra cycle extending the end of a wire gadget to an odd length. Figure 12 shows the gadget, and the two possible assignments of this gadget. Whenever the signal is TRUE, it is possible for Trudy to create a disjoint cycle in the gadget which gives her four boxes. If the signal is FALSE, Trudy can only make a chain in this gadget which yields only two boxes. Again, by considering the various cases that can occur under regular play, we obtain the following lemma.

■ **Figure 12** The clause gadget (left) yields four boxes to Trudy if the input signal is TRUE (middle), and only two boxes when the input is FALSE (right). Boxes highlighted in green belong to the last cycle in the adjacent wire.

► **Lemma 6.** *Under regular play, if the clause gadget is set to TRUE, then Trudy can add 1 cycle to \mathcal{C}_{\max} . Otherwise, under regular play, Trudy cannot add any cycle from the clause gadget to \mathcal{C}_{\max} .*

Proof. If the input signal to the clause gadget is TRUE, the adjacent cycle to the clause gadget is not in \mathcal{C}_{\max} . Therefore, a the cycle of the gadget can be added to \mathcal{C}_{\max} . When in the loony endgame, this cycle yields four boxes to Trudy after Fred makes a double-dealing move.

Otherwise, if the input signal is FALSE, the adjacent cycle is in \mathcal{C}_{\max} , and from the clause gadget only a chain is left. This chain yields only two boxes to Trudy after Fred makes a double-dealing move. ◀

4 Players' strategies and PSPACE-completeness

With the gadgets described above, we construct a Dots & Boxes instance for any G_{pos} (POS CNF) instance such that Trudy can win the Dots & Boxes instance if and only if she can win the corresponding G_{pos} (POS CNF) instance. We lay out the variable gadgets, attach a corresponding number of wire gadgets, pass the wires through or gadgets, using crossover gadgets to cross signals, and finally connect wires to the clause gadgets. An example of our construction is given in Figure 13 in the appendix.

The initial score we set to the Dots & Boxes instance depends on the number of gadgets of each type in the construction. By Lemma 1 the total score in the loony endgame depends on the number of disjoint cycles c , the number of boxes k with degree higher than two, and their total degree T . The configuration of the loony endgame, and thus the values k and T , is changed only when the variable gadgets are being assigned their values. We will argue below that, under regular play, exactly half of the variables are set to TRUE and half are set to FALSE. Thus the total values of k and T are the same, no matter which variables are assigned to which values. If Trudy can satisfy formula \mathcal{F} of the G_{pos} (POS CNF) game, she can claim some $c_{\max} = |\mathcal{C}_{\max}|$ cycles in the corresponding Dots & Boxes instance. Therefore, by Lemma 1, she can claim $4c_{\max} + T - 2k - 4$ boxes in the loony endgame, and $n/2$ boxes from the variables set to FALSE. Let N be the total number of unclaimed boxes in our Dots & Boxes instance. Then, Fred gets $N - n/2 - (4c_{\max} + T - 2k - 4)$ boxes. We set the initial scores of Trudy and Fred such that Trudy's final score is one larger than Fred's if she can satisfy \mathcal{F} . Otherwise, her score will be strictly less than Fred's.

Next, we describe the regular strategies for Trudy and Fred, both before the loony endgame is entered and in the loony endgame.

Regular strategies for Trudy and Fred in the loony endgame. We first discuss both strategies in the loony endgame, assuming that all variables have already been assigned a value as described in Section 3.4. As we argue below, Fred can always ensure that he is in control of the loony endgame. It is always beneficial for Fred to stay in control, as then all the chains and cycles in the loony endgame configuration yield at least as many boxes to him as to Trudy.

In the loony endgame, Trudy can choose which chains and cycles to open. To maximize her score, Trudy is going to select a maximum number of disjoint cycles C_{\max} in the loony endgame (see Lemma 1). This can be done by first making a loony move in all chains, to which Fred responds by claiming all but two boxes, finishing with a double-dealing move in order to stay in control. Afterwards, Trudy makes loony moves in the remaining cycles, to which Fred responds again by claiming all but four boxes, finishing with a double-dealing moves each time, except for in the final cycle.

Regular strategy for Trudy before the loony endgame. Trudy's strategy before the loony endgame is to set enough variable gadgets to TRUE in order to satisfy all the clauses. By Lemmas 1 and 6, Trudy gains more boxes from each satisfied clause. Therefore, the regular strategy for Trudy is to claim the boxes opened by Fred when setting variables to FALSE, and to set variables to TRUE, by using a loony move in a side chain of cycle C_2 of the variables. As we show in Lemma 7, if Fred deviates from setting variables to FALSE, and plays a loony move when there are non-loony moves available, Trudy can adopt Fred's regular strategy and dominate the rest of the game by ensuring that she ends up in control when the loony endgame is entered.

Regular strategy for Fred before the loony endgame. Fred's strategy is to ensure that he is in control when the loony endgame starts, and it can be described completely as responses to what Trudy does. By our assumption the number of variables in \mathcal{F} is even, thus initially the number of non-loony move pairs is even. Fred's strategy is then to keep the number of non-loony move pairs even at the start of every one of Trudy's turns. Then, once the number of non-loony moves reaches zero (and the loony endgame is reached), it is Trudy's turn, and Fred is in control. Specifically, Fred responds to Trudy's moves in the following way:

- If Trudy follows regular play and makes a loony move in a variable to set it to TRUE, then Fred simply claims all boxes in the chain opened by Trudy (without making a double-dealing move), and makes a non-loony move in another variable to set it to FALSE.
- If Trudy deviates from her strategy by making a non-loony move, setting a variable to FALSE, there must be at least one other non-loony move pair available to Fred. Therefore, Fred claims the box opened by Trudy, and makes a non-loony move, thereby setting another variable to FALSE. The number of non-loony pairs is again even at the start of Trudy's next turn.
- If Trudy deviates from her strategy by opening a chain with a loony move that does not remove a non-loony pair, Fred responds with claiming all but two (or four in case of a cycle) boxes and ends with a double-dealing move. The number of non-loony pairs remains even before Trudy's next turn.

Using this strategy, Fred can set a variable to FALSE each time Trudy sets a variable to any value, as well as gain control in the loony endgame.

Note that the order of moves in these strategies is not enforced. Trudy can play loony moves she would play in the loony endgame even if there are still non-loony moves available, as long as these moves do not interfere with the values set (or to be set) in the corresponding

variables. For Fred, we consider it part of his regular strategy to simply respond to these moves as if the game was already in the loony endgame, since otherwise he would be in danger of losing control. Indeed, if Fred does not make a double-dealing move, the number of non-loony moves will no longer be even at the start of Trudy's turn, and Fred loses control of the loony endgame. Thus, it is not more beneficial for any player to make a move in any other gadget than the variable gadgets while there are still variables that have not been set.

► **Lemma 7.** *Deviating from the regular strategies described above is sub-optimal for Fred and cannot be more beneficial for Trudy.*

Proof. Trivially, Trudy and Fred always claim open boxes before making their move, except when Fred makes double-dealing moves. Otherwise the opponent can claim these boxes next turn.

First, consider the regular strategies in the loony endgame. If Trudy deviates from her strategy and does not select the maximum number of disjoint cycles, by Lemma 1 her score will be too low and she loses the game. Therefore, the regular loony endgame strategy for Trudy as described above is optimal. If, at any point in the loony endgame, except for his last move, Fred does not make a double-dealing move, he loses control. Since being in control is always beneficial in our construction, this play is sub-optimal.

The regular strategies described for before the loony endgame are also optimal. Observe that, under the described strategies, the value-setting component of a variable yields the same number of boxes to Trudy independent of whether it is set to TRUE or to FALSE. Indeed, if it is set to TRUE, the component contains three boxes with degree 3, while setting the variable to TRUE does not give any boxes to Trudy; if the variable is set to FALSE, the component contains two boxes with degree 3, but setting the value gives Trudy one box. Thus, the value-setting component contributes the same number of points to Trudy's final score independent of the value.

If Trudy deviates from her strategy by making a non-loony move and setting a variable to FALSE, she loses one box to Fred. Furthermore, setting a variable to FALSE can never help Trudy to satisfy formula \mathcal{F} . Thus, such a move is sub-optimal.

If Trudy deviates from her strategy by making a loony move in any other gadget than the variable gadget, there are two options: either she makes a move that leads to the same score as the strategy described above, or she makes a move that contradicts the setting of the variables and reduces her total score. The former case does not have any bad repercussions for Trudy. Fred will respond with a double-dealing move, otherwise Trudy would take control of the endgame. Thus, we can reorder the sequence of Trudy's moves and assume that she first sets all the variables. However, in the latter case, the move reduces the number of possible disjoint cycles, and thus leads to Trudy's loss in the game. Therefore, deviating from the regular strategy is never more beneficial for Trudy.

If Fred deviates from his strategy before the loony endgame, then Trudy can adopt his strategy and ensure that the number of non-loony move pairs is even at the start of each of Fred's turn. Since, if Fred is not in control of the loony endgame, he loses the game, deviating from his strategy is not optimal. ◀

Combining the lemmas above, we obtain the main theorem.

► **Theorem 8.** *Dots & Boxes is PSPACE-complete.*

Proof. A game of Dots & Boxes is finished after a polynomial number of turns. Thus, all possible sequences of moves can be explored using polynomial sized memory. This implies that Dots & Boxes is in PSPACE.

We now show that Dots & Boxes is PSPACE-hard. Given a G_{pos} (POS CNF) formula \mathcal{F} , we construct a Dots & Boxes instance δ following the description above. We argue that Trudy can win \mathcal{F} if and only if Trudy can satisfy δ .

If Trudy can satisfy \mathcal{F} , then there must be a variable assignment following the G_{pos} (POS CNF) rules such that Trudy can ensure that every clause is connected to at least one variable which has been set to TRUE, regardless of what Fred does. Therefore, there can be at most $n/2$ variables that need to be set to TRUE by Trudy. Hence, Trudy can set the corresponding variable gadgets in δ to TRUE, and if needed set the remaining variables available to her to TRUE in any order. Thus, by Lemmas 2–6, Trudy can propagate the TRUE values down to all the clauses, that is, she can select the maximum number of disjoint cycles from all the gadgets, including all the clause gadgets, leading to the winning score in δ .

In order for Trudy to win δ , the set of disjoint cycles \mathcal{C}_{\max} that she selects must contain a cycle from every clause gadget, and the maximum number of cycles from all the other gadgets. By Lemmas 2–7, this can be done only if the output signals from each gadget conform to their input signals, and thus there must be a set of variable gadgets set to TRUE whose signal is propagated all the way down to all the clause gadgets. In δ Trudy and Fred have to alternate choosing which variable gadgets get set to TRUE and FALSE, respectively. Thus, if Trudy has a winning strategy in δ , no matter how Fred plays, she can always pick a subset of variable gadgets to assign, such that every clause gadget obtains a TRUE signal. This results in a winning strategy for Trudy to win the G_{pos} (POS CNF) game on \mathcal{F} .

Thus, Dots & Boxes is PSPACE-complete. ◀

5 Conclusion

We proved that Dots & Boxes is PSPACE-complete, resolving a long-standing open problem. There exist a number of other intriguing open problems related to Dots & Boxes. Does restricting the game to a $k \times n$ grid for a small k make the game easier? How large does k need to be to make the problem PSPACE-hard or even just NP-hard? These are challenging questions, given that even for a $1 \times n$ grid Dots & Boxes is not yet fully understood [12, 19, 25]. Another direction of further research is the complexity of variants of Dots & Boxes, in particular of *misère* Dots & Boxes [12], of Dots & Boxes under normal play (where the last player to move wins), of Dots & Boxes on other grids, or even of Dots & Boxes with more than two players as it was originally described by Lucas [29]. One variant that our result resolves is *Dots & Polygons*, since the reduction from Dots & Boxes to *Dots & Polygons* that was used to prove NP-hardness [8] now directly also shows PSPACE-hardness.

Our result can be interpreted as proving that *Strings and coins* restricted to grid graphs is PSPACE-complete. What is the complexity of *Strings and coins* on other restricted graph classes, for instance outerplanar graphs (which generalize $1 \times n$ grids)?

This may also be a good moment to revisit other games, which are known to be PSPACE-complete on general graphs, but for which the complexity on grid graphs is open. This, for instance, includes *NoGo*, *Fjords* (on hexagonal grids), *Cats-and-Dogs* and *GraphDistance*, which are known to be PSPACE-complete for planar graphs [9, 10].

A Example game

■ **Figure 13** Example reduction from the G_{pos} (POS CNF) formula $(w \vee x) \wedge (w \vee y) \wedge (x \vee z)$. The construction can be divided into four sections: a variable, crossover, or, and clause section. Each section contains only the corresponding gadgets and wire gadgets that connect different gadgets together.

B Omitted proofs

► **Lemma 1.** *Let the configuration of a loony endgame contain k boxes with degree higher than 2, let T be the sum of the degrees of these boxes, and let c be the maximum number of disjoint cycles in the configuration. Then, the player who is not in control can claim at most $4c + T - 2k - 4$ boxes.*

Proof. Let Fred be in control of the game. To simplify the argument, w.l.o.g., we assume that the last move made by Trudy is made in a cycle. Let c denote the number loony moves made by Trudy in a disjoint cycle and let ℓ be the number of loony moves made by Trudy in chains. All but the last loony move in a disjoint cycle or chain yield 4 or 2 boxes for Trudy, respectively. Thus, the score gained by Trudy in the loony endgame is

$$4c + 2\ell - 4.$$

Consider the dual graph $G = (V, E)$ to the Dots & Boxes instance. In it, a node corresponds to a box, and an edge connects two nodes if the two corresponding adjacent boxes do not have a line drawn between them. Suppose G has k nodes with degree higher than 2. We define T to be the sum of the degrees of these nodes:

$$T = \sum_{\{v \in V \mid \text{degree}(v) > 2\}} \text{degree}(v).$$

A loony move on a disjoint cycle does not change T , since all disjoint cycles only contain boxes of degree 2. A loony move on a chain, however, decreases the degree of the box at both ends of the chain by 1. Furthermore, whenever the degree of a box reduces from 3 to 2 the degree of this box is no longer counted in T . Thus

$$T = 2\ell + 2k,$$

which means the score for Trudy will be

$$4c + T - 2k - 4.$$

Since T and k are fixed, the score is maximized when the number of loony moves in disjoint cycles is maximized. ◀

Uncertain Curve Simplification

Abstract

We study the problem of polygonal curve simplification under uncertainty, where instead of a sequence of exact points, each uncertain point is represented by a region which contains the (unknown) true location of the vertex. The regions we consider are disks, line segments, convex polygons, and discrete sets of points. We are interested in finding the shortest subsequence of uncertain points such that no matter what the true location of each uncertain point is, the resulting polygonal curve is a valid simplification of the original polygonal curve under the Hausdorff or the Fréchet distance. For both these distance measures, we present polynomial-time algorithms for this problem.

1 Introduction

In this paper, we study the topic of curve simplification under uncertainty. There are many classical algorithms dealing with curve simplification with different distance metrics; however, it is typically assumed that the locations of points making up the curves are known precisely, which often does not suit real-life data. An example highlighting the necessity of taking uncertainty into account comes with GPS data, where each measured location is inherently imprecise, and the real location is likely to be within a certain distance from the measurement. This imprecision can be modelled as a disk (or some other shape if the GPS signals are blocked or reflected by rocks, buildings, etc.). Curve simplification is used to reduce the noise-to-signal ratio in the trajectory data before applying other algorithms or when storing large amounts of data. In both cases modelling uncertainty could reduce the error introduced by simplifying imprecise curves while maintaining a short, efficient representation of the data.

There is a large volume of foundational work on curve simplification [4], including work on vertex-constrained simplification, such as the algorithms by Ramer and by Douglas and Peucker [17, 34] using the Hausdorff distance, by Agarwal et al. [3] using the Fréchet distance, by Imai and Iri [23] using either, and various improvements and related approaches [7, 8, 10, 16, 21, 22, 31, 36]. The Imai–Iri algorithm involves computing the *shortcut graph*, which captures all the possible simplifications of a curve, and then finding a path through the graph

■ **Figure 1** (a) An uncertain curve modelled with convex polygons and a realisation. (b) A valid simplification under the Hausdorff distance with the threshold ϵ : for every realisation, the subsequence is within distance ϵ from the full sequence. (c) An invalid simplification: there is a realisation for which the subsequence is not within distance ϵ from the full sequence.

with minimal edge count from the start to the end node, yielding the shortest simplification. We adapt this approach to the setting with uncertainty. It seems natural to apply disk stabbing to test shortcuts [22]; we discuss why this does not work in our setting in Section 3.

There are recent advances in the study of uncertainty in computational geometry, with work on optimising various measures on uncertain points [24, 25, 26, 28, 30], triangulations [11, 29, 37], visibility in uncertain polygons [15], and other problems [1, 2, 18, 19, 20, 27, 32, 35]. There is work by Ahn et al. [5], and, more recently, by Buchin et al. [9, 33] on various minimisation and maximisation variants of curve similarity with the Fréchet distance under uncertainty, and other work combining trajectory analysis and uncertainty [6, 13, 14]. To our knowledge, there is no previous work studying curve simplification under uncertainty.

We use the locational model for uncertainty: we know that each point exists, but not its exact location. It can be modelled as a discrete set of points, of which one is the true location; this model uses *indecisive* points. We also use *imprecise* points, modelled as compact continuous sets, such as disks, line segments, or convex polygons; the true location is one unknown point from the set. An *uncertain curve* is a sequence of uncertain points of the same kind. A *realisation* of an uncertain curve is a polygonal curve obtained by taking one point from each uncertain point. We solve the following problem (see Figure 1): *given an uncertain curve as a sequence of n uncertain points, find the shortest subsequence of the points such that for any realisation of the curve, the realisation restricted to the subsequence is a valid simplification*. We give efficient algorithms for this problem for the Hausdorff and the Fréchet distance. They run in $\mathcal{O}(n^3)$ time for uncertainty modelled with disks or line segments and in $\mathcal{O}(n^3k^3)$ time for convex polygons and indecisive points with k vertices.

2 Preliminaries

Denote¹ $[n] \stackrel{\text{def}}{=} \{1, 2, \dots, n\}$ for any $n \in \mathbb{N}^{>0}$. Given two points $p, q \in \mathbb{R}^2$, denote their Euclidean distance with $\|p - q\|$.

¹ We use $:=$ and $=$ to denote assignment, $\stackrel{\text{def}}{=}$ for equivalent quantities in definitions or to point out equality by earlier definition, and \equiv in other contexts. We also use \equiv , but its usage is always explained.

Denote a *sequence* of points in \mathbb{R}^2 with $\pi = \langle p_1, \dots, p_n \rangle$. For only two points $p, q \in \mathbb{R}^2$, we also write pq instead of $\langle p, q \rangle$. Denote a subsequence of a sequence π from index i to j with $\pi[i : j] = \langle p_i, p_{i+1}, \dots, p_j \rangle$. This notation can also be applied if we interpret π as a *polygonal curve* on n vertices (of *length* n). It is defined by linearly interpolating between the successive points in the sequence and can be seen as a continuous function, for $i \in [n - 1]$ and $\alpha \in [0, 1]$: $\pi(i + \alpha) = (1 - \alpha)p_i + \alpha p_{i+1}$.

We also introduce the notation for the order of points along a curve. Let $p := \pi(a)$ and $q := \pi(b)$ for $a, b \in [1, n]$. Then $p \prec q$ iff $a < b$, $p \preceq q$ iff $a \leq b$, and $p \equiv q$ iff $a = b$. Note that we can have $p = q$ for $a \neq b$ if the curve intersects itself.

Finally, given points $p, q, r \in \mathbb{R}^2$, define the distance from p to the segment qr as $d(p, qr) \stackrel{\text{def}}{=} \min_{t \in qr} \|p - t\|$.

An *uncertainty region* $U \subset \mathbb{R}^2$ describes a possible location of a true point: it has to be inside the region, but there is no information as to where exactly. We use several uncertainty models, so the regions U are of different shape. An *indecisive point* is a form of an uncertain point where the uncertainty region is represented as a discrete set of points, and the true point is one of them: $U = \{p^1, \dots, p^k\}$, with $k \in \mathbb{N}^{>0}$ and $p^i \in \mathbb{R}^2$ for all $i \in [k]$. *Imprecise points* are modelled with uncertainty regions that are compact continuous sets. In particular, we consider *disks* and *polygonal closed convex sets*. We denote a disk with the centre $c \in \mathbb{R}^2$ and the radius $r \in \mathbb{R}^{\geq 0}$ as $D(c, r)$. Formally, $D(c, r) \stackrel{\text{def}}{=} \{p \in \mathbb{R}^2 \mid \|p - c\| \leq r\}$. Define a *polygonal closed convex set (PCCS)* as a closed convex set with bounded area that can be described as the intersection of a *finite* number of closed half-spaces. Note that this definition includes both convex polygons and line segments (in 2D). Given a PCCS U , let $V(U)$ denote the set of vertices of U , i.e. vertices of a convex polygon or endpoints of a line segment.

We call a sequence of uncertainty regions an *uncertain curve*: $\mathcal{U} = \langle U_1, \dots, U_n \rangle$. If we pick a point from each uncertainty region of \mathcal{U} , we get a polygonal curve π that we call a *realisation* of \mathcal{U} and denote it with $\pi \in \mathcal{U}$. That is, if for some $n \in \mathbb{N}^{>0}$ we have $\pi = \langle p_1, \dots, p_n \rangle$ and $\mathcal{U} = \langle U_1, \dots, U_n \rangle$, then $\pi \in \mathcal{U}$ if and only if $p_i \in U_i$ for all $i \in [n]$.

Suppose we are given a polygonal curve $\pi = \langle p_1, \dots, p_n \rangle$, a threshold $\varepsilon \in \mathbb{R}^{>0}$, and a curve built on the subsequence of vertices of π for some set $I = \{i_1, \dots, i_\ell\} \subseteq [n]$, i.e. $\sigma = \langle p_{i_1}, \dots, p_{i_\ell} \rangle$ with $i_j < i_{j+1}$ for all $j \in [\ell - 1]$ and $\ell \leq n$. We call σ an ε -*simplification* of π if for each segment $\langle p_{i_j}, p_{i_{j+1}} \rangle$, we have $\delta(\langle p_{i_j}, p_{i_{j+1}} \rangle, \pi[i_j : i_{j+1}]) \leq \varepsilon$, where δ denotes some distance measure, e.g. the Hausdorff or the Fréchet distance.

The *Hausdorff distance* between two sets $P, Q \subset \mathbb{R}^2$ is defined as

$$d_H(P, Q) \stackrel{\text{def}}{=} \max \left\{ \sup_{p \in P} \inf_{q \in Q} \|p - q\|, \sup_{q \in Q} \inf_{p \in P} \|p - q\| \right\}.$$

For two polygonal curves π and σ in \mathbb{R}^2 , since π and σ are closed and bounded, we get

$$d_H(\pi, \sigma) = \max \left\{ \max_{p \in \pi} \min_{q \in \sigma} \|p - q\|, \max_{q \in \sigma} \min_{p \in \pi} \|p - q\| \right\}.$$

The *Fréchet distance* is often described through an analogy with a person and a dog walking along their respective curves without backtracking, where the Fréchet distance is the shortest leash needed for such a walk. Formally, consider a set of *reparametrisations* Φ_ℓ of length ℓ , defined as continuous non-decreasing surjective functions $\phi : [0, 1] \rightarrow [1, \ell]$. Given two polygonal curves π and σ of lengths m and n , respectively, we can define the Fréchet distance as

$$d_F(\pi, \sigma) \stackrel{\text{def}}{=} \inf_{\alpha \in \Phi_m, \beta \in \Phi_n} \max_{t \in [0, 1]} \|\pi(\alpha(t)) - \sigma(\beta(t))\|.$$

We refer to the pair of reparametrisations as an *alignment*. We often consider the Fréchet distance between a curve $\pi = \langle p_1, \dots, p_n \rangle$ and a line segment $p_1 p_n$, for some $n \in \mathbb{N}^{\geq 3}$. In this setting, the alignment can be described in a more intuitive way; see also Figure 2. It can be described as a sequence of locations on the line segment with which the vertices of the curve are aligned, $\langle s_2, \dots, s_{n-1} \rangle$, where $s_i \in [1, 2]$ for all $i \in \{2, \dots, n-1\}$ and $s_i \leq s_{i+1}$ for all $i \in \{2, \dots, n-2\}$. To see that, assign $s_1 := 1$ and $s_n := 2$ and construct a helper reparametrisation $\phi : [0, 1] \rightarrow [1, n]$, defined as $\phi(t) = (n-1) \cdot t + 1$ for any $t \in [0, 1]$. Construct another reparametrisation $\psi : [1, n] \rightarrow [1, 2]$, defined as

$$\psi(t) = \begin{cases} s_{\lfloor t \rfloor} \cdot (1 - t + \lfloor t \rfloor) + s_{\lfloor t \rfloor + 1} \cdot (t - \lfloor t \rfloor) & \text{if } t \in [1, n), \\ s_n & \text{if } t = n. \end{cases}$$

Note that ϕ and $\psi \circ \phi$ satisfy the definition of reparametrisations for π and $p_1 p_n$, respectively.

We also define an *alignment* between a curve and a line segment for the Hausdorff distance (see Figure 2). It represents the map from the curve to the line segment, where each point on the curve is mapped to the closest point on the line segment. It is given by a sequence $\langle s_1, \dots, s_n \rangle$, where $s_i \in [1, 2]$ for all $i \in [n]$, such that $p_1 p_n(s_i) = \operatorname{argmin}_{p' \in p_1 p_n} \|p' - p_i\|$. In other words, $p_1 p_n(s_i)$ is the closest point to p_i for all $i \in [n]$; as we discuss in Appendix A.1, the Hausdorff distance is realised as the distance between p_i and $p_1 p_n(s_i)$ for some $i \in [n]$. Therefore, establishing such an alignment and checking that $\|p_1 p_n(s_i) - p_i\| \leq \varepsilon$ for all $i \in [n]$ allows us to check that $d_H(\pi, p_1 p_n) \leq \varepsilon$ for some $\varepsilon \in \mathbb{R}^{>0}$.

We are discussing the following problem: given an uncertain curve $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $n \in \mathbb{N}^{\geq 3}$ and $U_i \subset \mathbb{R}^2$ for all $i \in [n]$, and the threshold $\varepsilon \in \mathbb{R}^{>0}$, find a minimal-length subsequence $\mathcal{U}' = \langle U_{i_1}, \dots, U_{i_\ell} \rangle$ of \mathcal{U} with $\ell \leq n$, such that for any realisation $\pi \in \mathcal{U}$, the corresponding realisation $\pi' \in \mathcal{U}'$ forms an ε -simplification of π under some distance measure δ . We solve this problem for the Hausdorff and the Fréchet distance for uncertainty modelled with indecisive points, line segments, disks, and convex polygons.

3 Overview of the Approach

We first present the summary of our approach. On the highest level, we use the *shortcut graph*. Each uncertain point of a curve $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ corresponds to a vertex. An edge connects two vertices i and j if and only if the distance between any realisation of $\mathcal{U}[i : j]$ and the corresponding line segment from U_i to U_j is below the threshold. The path with the fewest edges from vertex 1 to vertex n then corresponds to the simplification using fewest uncertain points. So, we construct the shortcut graph and find the shortest path between two vertices. The key idea is that we find shortcuts that are valid for *all* realisations, so any sequence of shortcuts can be chosen.

In order to construct the shortcut graph, we need to check whether an edge should be added to the graph, i.e. whether a shortcut is *valid*. It is natural to think that shortcut testing can be solved by disk stabbing with disks of suitable radius, as in the work by Guibas et al. [22]. The idea would then be, given the distance threshold ε , to replace the uncertainty regions with the intersection of ε -disks over all the points of a region; this way we would e.g. replace disks of radius r by disks of radius $\varepsilon - r$, and then check if a shortcut stabs these regions. However, except for disks, this approach does not work – the reader can see this by trying to apply the method on an uncertainty region shaped as a long line segment (or a skinny convex polygon) that is parallel to the potential shortcut line segment. The intersection of ε -disks may be empty, while clearly one can create an alignment for both the Hausdorff and the Fréchet distance. For disks the approach is more suitable; however, when

■ **Figure 2** Left: Alignment for the Hausdorff distance. Right: Alignment for the Fréchet distance. In both cases, the alignment is described as the sequence $\langle s_1 := p_1, s_2, s_3, s_4, s_5, s_6 := p_6 \rangle$.

testing a shortcut, the first and the last disk of a shortcut fulfil a different function than the intermediate disks. This means that we can rephrase the problem for the intermediate disks of a shortcut as disk stabbing, but not for the first and the last disk, as the quantifiers in the problem are different. Furthermore, the work by Guibas et al. [22] does not provide running time guarantees for disks of different radii, and the initialisation in their approach is not applicable in our setting with no restriction on disk intersections. So, we need to use a different approach to test shortcuts.

The approach is different for the Hausdorff and the Fréchet distance and for each uncertainty model. For the first and the last uncertain point of the shortcut, we state in Section 5 that there are several critical pairs of realisations that need to be tested explicitly, and then for any other pair of realisations, we know that the distance is also below the threshold. Testing each pair corresponds to finding the distance between a precise line segment and any realisation of an uncertain curve; we discuss this in Section 4 and show the procedures to do this in detail in Appendix A.

► **Theorem 1.** *We can find the shortest vertex-constrained simplification of an uncertain curve, such that for any realisation the simplification is valid, both for the Hausdorff and the Fréchet distance, in time $\mathcal{O}(n^3)$ for uncertainty modelled with disks and line segments, and in time $\mathcal{O}(n^3k^3)$ for uncertainty modelled with indecisive points and convex polygons, where k is the number of options or vertices and n is the length of the curve.*

4 Shortcut Testing: Intermediate

Here we discuss testing a shortcut with the first and the last points fixed, i.e. we want to check $\max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} \delta(\pi, p_1 p_n) \leq \varepsilon$ for $\delta := d_H$ and $\delta := d_F$. We can do so in linear time in all the models; here we show the intuitive explanation, and we treat this topic in detail in Appendix A. We solve the following problem.

► **Problem 2.** Given an uncertain curve $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ on $n \in \mathbb{N}^{\geq 3}$ uncertain points in \mathbb{R}^2 , as well as realisations $p_1 \in U_1, p_n \in U_n$, check if the largest Hausdorff or Fréchet distance between \mathcal{U} and its one-segment simplification is below a threshold $\varepsilon \in \mathbb{R}^{>0}$ for any realisation with the fixed start and end points, i.e. for $\delta := d_H$ or $\delta := d_F$, verify

$$\max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} \delta(\pi, p_1 p_n) \leq \varepsilon.$$

Hausdorff distance. It is a well-known fact that the Hausdorff distance between the curve and the line segment that simplifies that curve is the largest distance from a vertex of the curve to the line segment, so $d_H(\pi, \langle \pi(1), \pi(n) \rangle) = \max_{i \in [n]} d(\pi(i), \langle \pi(1), \pi(n) \rangle)$ for a polygonal curve π of length n . (See Figure 2.) We can use the same idea in the uncertain setting; however, for indecisive curves, we can choose any realisation for each intermediate point, so we need to test all of them, so we need the largest distance from any realisation of any indecisive point to the line segment. Then for indecisive points, given a curve $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $U_i = \{p_i^1, \dots, p_i^k\}$ for all $i \in [n]$, we have $\max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} \delta(\pi, p_1 p_n) = \max_{i \in [n]} \max_{j \in [k]} d(p_i^j, p_1 p_n)$. For disks, line segments, and convex polygons, the key point is the same: all of the realisations of the intermediate points need to be close enough to the given line segment. For disks, we can simply check the furthest points, which are one radius further away from the line segment than the disk centre. For line segments and convex polygons, it suffices to test all the vertices.

Fréchet distance. For the Fréchet distance, there is also an intuitive procedure in the precise setting [22, Lemma 8]. We can align each vertex from the curve with the earliest possible point in the line segment. Each next point cannot be aligned before the previous points, so choosing the earliest possible alignment point maximises the possibilities for the remainder of the curve. (See Figure 2: s_4 is as close as possible to p_1 .) We use the same approach in the uncertain setting; however, for indecisive points, as any realisation of a point is possible, we need to choose the realisation that pushes the earliest alignment forward the most, as this is the most restrictive realisation for the remainder of the curve. In more detail, we iteratively find the value for s_i . Given s_{i-1} , we find the earliest t_i^j along the segment for each realisation p_i^j of U_i , such that $\|t_i^j - p_i^j\| \leq \varepsilon$ and $s_{i-1} \preceq t_i^j$. Then we pick $s_i := \max_{j \in [k]} t_i^j$, in terms of \preceq . We continue this procedure until the end of the segment, starting with $s_1 := p_1$ and assigning $s_n := p_n$. In one direction, the sequence of s_i we find corresponds to a possible realisation; in the other direction, we can see that for any $i \in \{2, \dots, n-1\}$, we have $s_{i-1} \preceq t_i^j \preceq s_i$ for all $j \in [k]$; so for any other realisation the alignment is in order, as well. We can show for line segments and convex polygons that we again only need to focus on the vertices. For disks, we instead reframe the problem as that of disk stabbing. Instead of testing closeness from all points of some $D(c, r)$ to the line segment, we can check if the line segment stabs $D(c, \varepsilon - r)$ for the threshold ε . Then the correct alignment order corresponds to picking points inside disks in order. Again, choosing the earliest possible one is key.

5 Shortcut Testing: All Points

In the previous section, we have covered testing a shortcut, given that the first and the last points are fixed. Here we remove the restriction on the endpoints.

► **Problem 3.** Given an uncertain curve $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ on $n \in \mathbb{N}^{\geq 3}$ uncertain points in \mathbb{R}^2 , check if the largest Hausdorff or Fréchet distance between \mathcal{U} and its one-segment simplification is below a threshold $\varepsilon \in \mathbb{R}^{>0}$ for any realisation, i.e. for $\delta := d_H$ or $\delta := d_F$, verify $\max_{\pi \in \mathcal{U}} \delta(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon$.

For the indecisive points, we can simply check all pairs from $U_1 \times U_n$; this is quite easy to show.

► **Lemma 4.** Given $n, k \in \mathbb{N}^{>0}$, $n \geq 3$, and $\delta := d_H$ or $\delta := d_F$, for any indecisive curve $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $U_i = \{p_i^1, \dots, p_i^k\}$ for all $i \in [n]$ and $p_i^j \in \mathbb{R}^2$ for all $i \in [n]$, $j \in [k]$, we have

$$\max_{\pi \in \mathcal{U}} \delta(\pi, \langle \pi(1), \pi(n) \rangle) = \max_{a \in [k]} \max_{b \in [k]} \max_{\sigma \in \mathcal{U}, \sigma(1) \equiv p_1^a, \sigma(n) \equiv p_n^b} \delta(\sigma, p_1^a p_n^b).$$

■ **Figure 3** Left: Illustration for Observation 5. The convex hull of the disks is highlighted in black. The order in which the outer tangents touch the disks is the same. Right: Illustration for Definition 6. Here O_1 (t_1 to t_2) is to the right of O_2 (u_1 to u_2).

Proof. We can derive

$$\begin{aligned}
 & \max_{\pi \in \mathcal{U}} \delta(\pi, \langle \pi(1), \pi(n) \rangle) \\
 & \quad \{\text{Def. } \Subset\} \\
 & = \max_{p_1 \in U_1, \dots, p_n \in U_n} \delta(\langle p_1, \dots, p_n \rangle, p_1 p_n) \\
 & = \max_{p_1 \in U_1} \max_{p_n \in U_n} \max_{p_2 \in U_2, \dots, p_{n-1} \in U_{n-1}} \delta(\langle p_1, \dots, p_n \rangle, p_1 p_n) \\
 & \quad \{\text{Def. } \Subset\} \\
 & = \max_{p_1 \in U_1} \max_{p_n \in U_n} \max_{\sigma \in \mathcal{U}, \sigma(1) \equiv p_1, \sigma(n) \equiv p_n} \delta(\sigma, p_1 p_n) \\
 & = \max_{a \in [k]} \max_{b \in [k]} \max_{\sigma \in \mathcal{U}, \sigma(1) \equiv p_1^a, \sigma(n) \equiv p_n^b} \delta(\sigma, p_1^a p_n^b),
 \end{aligned}$$

as was to be shown. ◀

That is to say, for either Hausdorff or Fréchet distance we can simply test the shortcut using the corresponding procedure from Lemma 16 or Lemma 20, and do so for each combination of the start and end points. We can then test an indecisive shortcut of length n overall in time $\mathcal{O}(k^2 \cdot nk) = \mathcal{O}(nk^3)$.

We now proceed to show the approach for disks and polygonal closed convex sets. The procedure is the same for the Hausdorff and the Fréchet distance, but differs between disks and PCCSs, since disks have some convenient special properties.

5.1 Disks

► **Observation 5.** *Suppose we are given two non-degenerate disks $D_1 := D(p_1, r_1)$ and $D_2 := D(p_2, r_2)$ with $D_1 \not\subseteq D_2$ and $D_2 \not\subseteq D_1$. We make the following observations.*

- *There are exactly two outer tangents to the disks, and the convex hull of $D_1 \cup D_2$ consists of an arc from D_1 , an arc from D_2 , and the outer tangents.*
- *Assume the lines of the outer tangents intersect. When viewed from the intersection point, the order in which the tangents touch the disks is the same, i.e. either both first touch D_1 and then D_2 , or the other way around. If the lines are parallel, the same statement holds when viewed from points on the tangent lines at infinity. (See Figure 3.)*

To see that the second point is true, note that the distance from the intersection point to the tangent points of a disk is the same for both tangent lines. These observations mean that we can restrict our attention to the area bounded by the outer tangents and define an ordering in the resulting strip.

► **Definition 6.** Given two distinct non-degenerate disks $D_1 := D(p_1, r_1)$ and $D_2 := D(p_2, r_2)$, consider a strip defined by the lines that form the outer tangents to the disks. Assume we have two circular arcs O_1, O_2 that intersect both tangents and lie inside the strip. Define s_1 and v_1 to be the points where one of the tangents touches D_1 and D_2 , respectively, and let t_1 and u_1 be the points where O_1 and O_2 intersect that tangent, respectively. Define the order on the tangents from D_1 to D_2 , so $s_1 \prec v_1$. Define points s_2, t_2, u_2, v_2 similarly for the other tangent. We say that O_2 is to the right of O_1 if either $t_i = u_i$ for $i \in \{1, 2\}$ and the radius of O_1 is larger than that of O_2 ; or if otherwise $t_i \preceq u_i$ for $i \in \{1, 2\}$ and O_1 and O_2 do not properly intersect. We say that O_2 is to the left of O_1 if either $t_i = u_i$ for $i \in \{1, 2\}$ and the radius of O_1 is smaller than that of O_2 ; or if otherwise $u_i \preceq t_i$ for $i \in \{1, 2\}$ and O_1 and O_2 do not properly intersect. (See Figure 3 for a visual interpretation.)

We state the main result: it suffices to check the tangents to the first and the last disk and the order of the intermediate disks.

► **Lemma 7.** Given $n \in \mathbb{N}^{\geq 3}$, for any imprecise curve modelled with disks $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $U_i = D(c_i, r_i)$ for all $i \in [n]$ and $c_i \in \mathbb{R}^2$, $r_i \in \mathbb{R}^{\geq 0}$ for all $i \in [n]$, and assuming $U_1 \neq U_n$, we have with $\delta \in \{d_H, d_F\}$ that $\max_{\pi \in \mathcal{U}} \delta(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon$ if and only if both of the following are true:

$$\blacksquare \max \left\{ \max_{\pi \in \mathcal{U}, \pi(1) \equiv s, \pi(n) \equiv t} \delta(\pi, st), \max_{\pi \in \mathcal{U}, \pi(1) \equiv u, \pi(n) \equiv v} \delta(\pi, uv) \right\} \leq \varepsilon,$$

where $s, u \in U_1$, $t, v \in U_n$, and st and uv are the outer tangents to $U_1 \cup U_n$;

► for each $i \in \{2, \dots, n-1\}$, the right arc of the disk $D(c_i, \varepsilon - r_i)$ bounded by the intersection points with the tangent lines is to the right of the right arc of U_1 and the left arc of the disk $D(c_i, \varepsilon - r_i)$ is to the left of the left arc of U_n .

Proof. We first prove the claim for $\delta = d_H$. Assume the right side of the lemma statement holds. First of all, as we have $\max_{\pi \in \mathcal{U}, \pi(1) \equiv s, \pi(n) \equiv t} d_H(\pi, st) \leq \varepsilon$, we know that for all $i \in \{2, \dots, n-1\}$, we have $d(c_i, st) + r_i \leq \varepsilon$, or $d(c_i, st) \leq \varepsilon - r_i$, so st stabs each disk $D(c_i, \varepsilon - r_i)$ (see Lemma 18 in Appendix A.1). We can draw a similar conclusion for uv . Therefore, each disk $D(c_i, \varepsilon - r_i)$ crosses the entire strip bounded by the tangent lines, with the intersection points splitting it into the left and the right circular arcs. We can thus apply Definition 6 to these arcs, as stated in the lemma.

First suppose that the disks U_1 and U_n do not intersect. Then for any line segment from U_1 to U_n and any disk $D' := D(c_i, \varepsilon - r_i)$, we exit D' after exiting U_1 and enter D' before entering U_n . Hence, for any line pq with $p \in U_1$ and $q \in U_n$ and any $i \in \{2, \dots, n-1\}$, we can find a point $w \in pq \cap D'$; this means that indeed $\max_{w' \in U_i} d(w', pq) \leq \varepsilon$ (see Lemma 22 in Appendix A.2). As this holds for all disks and any choice of p and q , we conclude that $\max_{\pi \in \mathcal{U}} d_H(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon$.

Now assume that the disks U_1 and U_n intersect. If we consider the line segments pq with $p \in U_1$, $q \in U_n$, we end up in the previous case if either $p \notin U_1 \cap U_n$ or $q \notin U_1 \cap U_n$. So assume that the segment pq lies entirely in the intersection $U_1 \cap U_n$. However, it can be seen that for each disk $D' := D(c_i, \varepsilon - r_i)$, the left boundary of the intersection is to the right of the left boundary of the disk, and the right boundary of the intersection is to the left of the right boundary of the disk; hence, $pq \subset U_1 \cap U_n \subseteq D'$. Therefore, we have $\max_{w' \in U_i} d(w', pq) \leq \varepsilon$, and so also in this case $\max_{\pi \in \mathcal{U}} d_H(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon$.

We now assume that the right side of the lemma statement is false and show that then $\max_{\pi \in \mathcal{U}} d_H(\pi, \langle \pi(1), \pi(n) \rangle) > \varepsilon$. If $\max_{\pi \in \mathcal{U}, \pi(1) \equiv s, \pi(n) \equiv t} d_H(\pi, st) > \varepsilon$, then immediately $\max_{\pi \in \mathcal{U}} d_H(\pi, \langle \pi(1), \pi(n) \rangle) > \varepsilon$. Same holds for uv . So, assume those statements hold; then it must be that for at least one intermediate disk the arcs do not lie to the left or to the

■ **Figure 4** Having established the alignments along the two tangents, we can connect them to create a sequence of paths.

right of the arcs of the respective disks. Assume this is disk i , so the disk $D' := D(c_i, \varepsilon - r_i)$. W.l.o.g. assume that the right arc of the disk does not lie entirely to the right of the right arc of U_1 . The argument for the left arc w.r.t. U_n is symmetric.

There must be at least one point p' on the right arc of U_1 that lies outside of D' . Assume for now that U_1 and U_n are disjoint. Then a line segment $p'q$ for any $q \in U_n$ does not stab D' , so $\max_{w' \in U_1} d(w', pq) > \varepsilon$, and so $\max_{\pi \in \mathcal{U}} d_H(\pi, \langle \pi(1), \pi(n) \rangle) > \varepsilon$. If U_1 and U_n intersect, then either p' is outside of the intersection and of D' and there is a point $q \in U_n$ such that $p'q$ does not stab D' ; or we can pick the degenerate line segment $p'p'$, as $p' \in U_1 \cap U_n$, and so $p'p'$ also does not stab D' . In either case, we conclude that $\max_{\pi \in \mathcal{U}} d_H(\pi, \langle \pi(1), \pi(n) \rangle) > \varepsilon$.

For $\delta = d_F$, first assume that $\max_{\pi \in \mathcal{U}} d_F(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon$. As $d_F(\pi, \sigma) \geq d_H(\pi, \sigma)$ for any curves π, σ , this also means that $\max_{\pi \in \mathcal{U}} d_H(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon$. Furthermore, immediately we get that $\max_{\pi \in \mathcal{U}, \pi(1) \equiv s, \pi(n) \equiv t} d_F(\pi, st) \leq \varepsilon$, and the same for uv , which yields the right side of the lemma as shown above.

Now assume that the right side holds. As for the Hausdorff distance, we know that the disks cross the entire strip and that Definition 6 applies. It remains to show that for any line segment pq with $p \in U_1, q \in U_n$, there is a valid alignment that maintains the correct ordering and bottleneck distance, assuming it exists for every realisation for st and uv . Consider a valid alignment established for st and uv , so the sequence of points a_i on st and b_i on uv that are mapped to U_i . We can always find such points for each individual U_i (see Lemma 21 in Appendix A.2), and as we know that the Fréchet distance is below the threshold for st and uv , there is such a valid alignment, i.e. we know that $a_i \preceq a_{i+1}$ and $b_i \preceq b_{i+1}$ for all $i \in [n-1]$.

For the rest of the proof, the rough idea is as follows. We can create paths from a_i to b_i so that every segment pq with $p \in U_1$ and $q \in U_n$ crosses these paths in the correct order, thus proving that a Fréchet alignment exists. When U_1 and U_n are disjoint, these paths are simply geodesic paths within the region bounded by the two tangents and the U_1 and U_n . If they intersect, we can instead create these paths by connecting a_i to the top intersection point of the disks and b_i to the bottom intersection point, as in Figure 4. Note that when the two disks intersect and the segment pq goes through the intersection, it may not cross the paths at all; however, every point in the intersection is close enough to all intermediate disks. We now discuss this idea in more detail.

First suppose that the disks U_1 and U_n do not intersect. Consider the region R bounded by the outer tangents and the disk arcs that are not part of the convex hull of $U_1 \cup U_n$. We connect, for each $i \in \{2, \dots, n-1\}$, a_i to b_i with a geodesic shortest path in R , as in Figure 4. We claim that for any line segment pq defined above, the intersection points of the shortest paths with the segment give a valid alignment, yielding $\max_{\pi \in \mathcal{U}, \pi(1) \equiv p, \pi(n) \equiv q} d_F(\pi, pq) \leq \varepsilon$. As the choice of pq was arbitrary, this will complete the proof.

To show that the alignment is valid, we need to show that the order is correct and that the distances fall below the threshold. First consider the case where the geodesic shortest path for point i does not touch the boundary formed by arcs of region R . In this case, it is simply a line segment $a_i b_i$. Note that by definition $a_i, b_i \in D(c_i, \varepsilon - r_i)$; as disks are convex, also $a_i b_i \subset D(c_i, \varepsilon - r_i)$; thus, the intersection point p'_i of pq with $a_i b_i$ is in $D(c_i, \varepsilon - r_i)$, so by Lemma 21, $\max_{w \in U_i} \|p'_i - w\| \leq \varepsilon$. Furthermore, note that $a_i \preceq a_{i+1}$ and $b_i \preceq b_{i+1}$; thus, the line segments $a_i b_i$ and $a_{i+1} b_{i+1}$ cannot cross, so also $p'_i \preceq p'_{i+1}$.

Now w.l.o.g. consider the case where the geodesic shortest path for point i touches the arc of U_1 . The geodesic shortest paths do not cross: on the path from a_i (or b_i) to the arc they form a tangent to the arc, thus for $a_i \preceq a_{i+1}$ the tangent point for a_i comes before that of a_{i+1} when going along the arc from s to u . So, just as in the previous case, these line segments cannot cross. Having reached the arc, both shortest paths will follow it, as otherwise the path would not be a shortest path; thus, the arcs do not cross, either. Finally, a path from the previous case does not touch any path that touches the arc boundary of R by definition. Finally, note that the condition that we have established on the right arcs of disks being to the right of the right arc of U_1 (and symmetric for the left arcs and U_n) means that the geodesic shortest paths that touch the arc boundary of R stay within the respective disks $D(c_i, \varepsilon - r_i)$. Thus, we have established that for all i we have $p'_i \preceq p'_{i+1}$ and $\max_{w \in U_i} \|p'_i - w\| \leq \varepsilon$, concluding the proof for disjoint U_1 and U_n .

Finally, consider the case where U_1 intersects U_n . Above we used geodesic paths within the region R . However, when U_1 intersects U_n , R consists of two disconnected regions. Observe that one region contains a_i and the other contains b_i . To connect a_i with b_i we use the geodesic from a_i to the intersection point of the two inner boundaries of U_1 and U_n that is in the same region of R , the geodesic from b_i to the other intersection point of the inner boundaries, and join these two by a line segment between the intersection points. Any line segment from a point in U_1 to a point in U_n crosses these paths in order, just like in the previous case. If the line segment goes through the intersection, note that any point in the intersection is close enough to all the intermediate objects, as the intersection is the subset of each disk. So, any point in the intersection can be chosen to establish the trivially in-order alignment to all the intermediate objects. ◀

It is worth noting that the case of $U_1 = U_n$ is similar to how we treat the intersection $U_1 \cap U_n$; however, our definition for the ordering between two disks does not apply. So, if $U_1 = U_n$, then $\max_{\pi \in \mathcal{U}} \delta(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon$ if and only if $U_1 \subseteq D(c_i, \varepsilon - r_i)$ for all $i \in \{2, \dots, n-1\}$.

5.2 Non-intersecting PCCSs

Suppose the regions are modelled by convex polygons. Consider first the case where the interiors of U_1 and U_n do not intersect, so at most they share a boundary segment.

► **Observation 8.** *Given an uncertain curve modelled by convex polygons $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with the interiors of U_1 and U_n not intersecting, note:*

- *There are two outer tangents to the polygons U_1 and U_n , and the convex hull of $U_1 \cup U_n$ consists of a convex chain from U_1 , a convex chain from U_n , and the outer tangents.*
- *Let C_i be the convex chain from U_i that is not part of the convex hull for $i \in \{1, n\}$. Then for $\delta := d_H$ or $\delta := d_F$,*

$$\max_{\pi \in \mathcal{U}} \delta(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon \iff \max_{\pi \in \mathcal{U}, \pi(1) \in C_1, \pi(n) \in C_n} \delta(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon.$$

■ **Figure 5** Left: Illustration for Observation 8. The convex hull of the polygons is shown in grey. The dotted chains are C_1 and C_n . Any line segment pq with $p \in U_1$ and $q \in U_n$ crosses C_1 and C_n . Right: Illustration for the procedure. The region R is triangulated.

■ **Figure 6** An example set of curves $A = \{A_2, A_3\}$ discussed in Lemmas 9 and 10.

To see that the second observation is true, note that one direction is trivial. In the other direction, note that any line segment pq with $p \in U_1$, $q \in U_n$ crosses both C_1 and C_n , say, at $p' \in C_1$ and $q' \in C_n$. We know that there is a valid alignment for $p'q'$, both for the Hausdorff and the Fréchet distance; we can then use this alignment for pq . See Figure 5.

We claim that we can check $\max_{\pi \in \mathcal{U}} d_H(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon$ using the following procedure (see Figure 5).

1. Triangulate the region R bounded by two convex chains C_1 and C_n and the outer tangents.
2. For each line segment st of the triangulation with $s \in C_1$, $t \in C_n$, and for either $\delta := d_H$ or $\delta := d_F$, check that $\max_{\pi \in \mathcal{U}, \pi(1) \equiv s, \pi(n) \equiv t} \delta(\pi, st) \leq \varepsilon$.

First of all, observe that we can compute a triangulation, and that every triangle has two points from one convex chain and one point from the other chain. If all three points were from the same chain, then the triangle would lie outside of R . Now consider some line segment pq with $p \in C_1$, $q \in C_n$. To complete the argument, it remains to show that the checks in step 2 mean that also $\max_{\pi \in \mathcal{U}, \pi(1) \equiv p, \pi(n) \equiv q} \delta(\pi, pq) \leq \varepsilon$. Observe that the triangles span across the region R , so when going from one tangent to the other within R we cross all the triangles. Therefore, we can number the edges of the triangles that go from C_1 to C_n , in the order of occurrence on such a path, from 1 to k . Denote the alignment established on line $j \in [k]$ with the sequence of a_i^j , for $i \in \{2, \dots, n-1\}$; this alignment can be established both for $\delta := d_H$ and $\delta := d_F$. We can establish polygonal curves $A_i := \langle a_i^1, \dots, a_i^k \rangle$; they all stay within R (see Figure 6). We claim that for any line segment pq defined above, we can establish a valid alignment from intersection points of pq and A_i . We do this separately for the Fréchet and the Hausdorff distance.

► **Lemma 9.** *Given a set of curves $A := \{A_2, \dots, A_{n-1}\}$ in R described above for $\delta := d_H$ and a line segment pq with $p \in C_1$, $q \in C_n$, we have $\max_{\pi \in \mathcal{U}, \pi(1) \equiv p, \pi(n) \equiv q} d_H(\pi, pq) \leq \varepsilon$.*

Proof. Note that pq crosses each A_i at least once. We can take any one crossing for each i and establish the alignment. Consider such a crossing point p'_i . It falls in some triangle bounded by a segment from either C_1 or C_n and two line segments that contain points a_i^j and a_i^{j+1} for some $j \in [k-1]$. We know, using Lemma 19, that $\max_{w \in U_i} \|a_i^j - w\| \leq \varepsilon$ and $\max_{w \in U_i} \|a_i^{j+1} - w\| \leq \varepsilon$. Consider any point $w' \in U_i$. Then, using Lemma 14 with $c := d := w'$, we find that $\|w' - p'_i\| \leq \varepsilon$. Therefore, also $\max_{w \in U_i} \|p'_i - w\| \leq \varepsilon$; using Lemma 19, we conclude that indeed $\max_{\pi \in \mathcal{U}, \pi(1) \equiv p, \pi(n) \equiv q} d_H(\pi, pq) \leq \varepsilon$. ◀

26:12 Uncertain Curve Simplification

For the Fréchet distance, we can use the same argument to show closeness; however, we need more care to establish the correct order for the alignment.

► **Lemma 10.** *Given a set of curves $A := \{A_2, \dots, A_{n-1}\}$ in R described above for $\delta := d_F$ and a line segment pq with $p \in C_1$, $q \in C_n$, we have $\max_{\pi \in \mathcal{U}, \pi(1) \equiv p, \pi(n) \equiv q} d_F(\pi, pq) \leq \varepsilon$.*

Proof. Compared to Lemma 9, instead of taking any intersection point of pq with each A_i , we take the *last* intersection point. First, we need to show that curves A_i and A_{i+1} do not cross for any $i \in [n-1]$. Each curve A_i crosses each triangle once, so it suffices to show that a segment $a_i^j a_i^{j+1}$ does not cross $a_{i+1}^j a_{i+1}^{j+1}$. Indeed, as $a_i^j \preceq a_{i+1}^j$ and $a_i^{j+1} \preceq a_{i+1}^{j+1}$, these line segments cannot cross.

Now consider, for each $i \in \{2, \dots, n-1\}$, the polygon P_i bounded by C_1 , A_i , and the corresponding segments of the outer tangents. With the previous statement, it is easy to see that $P_2 \subseteq P_3 \subseteq \dots \subseteq P_{n-1}$. Assume this is not the case, so some $P_i \not\subseteq P_{i+1}$. Then there is a point $z \in P_i$, but $z \notin P_{i+1}$. The point z falls into some triangle with lines j and $j+1$. In this triangle, it means that z is between C_1 and $a_i^j a_i^{j+1}$, but not between C_1 and $a_{i+1}^j a_{i+1}^{j+1}$. However, as these segments do not cross, this would imply that $a_{i+1}^j \prec a_i^j$, but then the check in step 2 would not pass for line j .

Consider the points at which the line segment pq leaves the polygons P_i for the last time. From the definition it is obvious that $p \in P_i$ for all $i \in \{2, \dots, n-1\}$, so this is well-defined. Clearly, due to the subset relationship, the order of such points p'_i is correct, i.e. $p'_i \preceq p'_{i+1}$. Furthermore, each such $p'_i \in A_i$, so using the arguments of Lemma 9 we can show that also the distances are below ε . Thus, we conclude that indeed $\max_{\pi \in \mathcal{U}, \pi(1) \equiv p, \pi(n) \equiv q} d_F(\pi, pq) \leq \varepsilon$. ◀

The proofs of Lemmas 9 and 10 show us how to solve the problem for two convex polygons with non-intersecting interiors. We can also use them directly for the case of line segments that do not intersect except at endpoints.

► **Lemma 11.** *Given $n \in \mathbb{N}^{\geq 3}$, for any imprecise curve modelled with line segments $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $U_i = p_i^1 p_i^2 \subset \mathbb{R}^2$ for all $i \in [n]$, given a threshold $\varepsilon \in \mathbb{R}^{>0}$, and given that $U_1 \cap U_n \subset \{p_1^1, p_1^2\}$, and assuming that the triangles $p_1^1 p_n^1 p_1^2$ and $p_1^2 p_n^2 p_1^1$ form a triangulation of the convex hull of $U_1 \cup U_n$, we have $\max_{\pi \in \mathcal{U}} \delta(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon$ if and only if*

$$\max \left\{ \begin{array}{l} \max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1^1, \pi(n) \equiv p_n^1} \delta(\pi, p_1^1 p_n^1), \quad \max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1^2, \pi(n) \equiv p_n^2} \delta(\pi, p_1^2 p_n^2), \\ \max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1^2, \pi(n) \equiv p_n^1} \delta(\pi, p_1^2 p_n^1) \end{array} \right\} \leq \varepsilon.$$

We should note that in this particular case it is not necessary to use a triangulation, so we can get rid of the second term; also in the previous proofs a convex partition could work instead, but a triangulation is easier to define.

5.3 Intersecting PCCSs

We now discuss the situation where the interiors of U_1 and U_n intersect, or where line segments U_1 and U_n cross. The argument is the same for $\delta := d_H$ and $\delta := d_F$.

Line segments. Assume line segments $U_1 \stackrel{\text{def}}{=} p_1^1 p_1^2$ and $U_n \stackrel{\text{def}}{=} p_n^1 p_n^2$ cross; call their intersection point s . Then we can use Lemma 11 separately on pairs of $\{p_1^1 s, s p_1^2\} \times \{p_n^1 s, s p_n^2\}$. These pairs cover the entire set of realisations pq with $p \in U_1$, $q \in U_n$, completing the checks.

► **Lemma 12.** *Given $n \in \mathbb{N}^{\geq 3}$, for any imprecise curve modelled with line segments $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $U_i = p_i^1 p_i^2 \subset \mathbb{R}^2$ for all $i \in [n]$, given a threshold $\varepsilon \in \mathbb{R}^{>0}$, we can check for both $\delta := d_H$ and $\delta := d_F$, using procedures above, that $\max_{\pi \in \mathcal{U}} \delta(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon$.*

Convex polygons. Convex polygons whose interiors intersect can be partitioned along the intersection lines, so into a convex polygon $R := U_1 \cap U_n$ and two sets of polygons $\mathcal{P}_1 := \{P_1^1, \dots, P_1^k\}$ and $\mathcal{P}_n := \{P_n^1, \dots, P_n^\ell\}$ for some $k, \ell \in \mathbb{N}^{>0}$. Just as for line segments, we can look at pairs from $\mathcal{P}_1 \times \mathcal{P}_n$ separately. The pairs where R is involved are treated later. Consider some $(P, Q) \in \mathcal{P}_1 \times \mathcal{P}_n$. Note that P and Q are convex polygons with a convex cut-out, so the boundary forms a convex chain, followed by a concave chain. We need to compute some convex polygons P' and Q' with non-intersecting interiors that are equivalent to P and Q , so that we can apply the approaches from Section 5.2.

We claim that we can simply take the convex hull of P and Q to obtain P' and Q' . Clearly, the resulting polygons will be convex. Also, the concave chains of P are bounded by points s and t and are replaced with the line segment st ; same happens for Q with point u and v . The points s, t, u, v are points of intersection of original polygons U_1 and U_n , so they lie on the boundary of R , and their order along that boundary can only be s, t, u, v or s, t, v, u . Thus, it cannot happen that st crosses uv , and it cannot be that uv is in the interior of the convex hull of P , as otherwise R would not be convex. Hence, the interiors of P' and Q' cannot intersect, so they satisfy the necessary conditions.

Finally, we need to show that the solution for (P', Q') is equivalent to that for (P, Q) . One direction is trivial, as $P \subseteq P'$ and $Q \subseteq Q'$; for the other direction, consider any line segment that leaves P through the concave chain. In our approach, we test the lines starting in s and t ; the established alignments are connected into paths. The paths A_i do not cross st . So, any alignment in the region of $\text{CH}(P \cup Q) \setminus (P \cup Q)$ can also be made in the region $\text{CH}(P' \cup Q') \setminus (P' \cup Q')$. So, this approach yields valid solutions for all pairs not involving R .

Now consider the pair (R, R) . A curve may now consist of a single point, so the approach for the Fréchet and the Hausdorff distance is the same: all the points of U_i need to be close enough to all the points of R . To check that, observe that the pair of points $p \in U_i$ and $q \in R$ that has maximal distance has the property that p is an extreme point of U_i in direction qp and q is an extreme point of R in direction pq . So, it suffices, starting at the rightmost point of U_i and leftmost point of R in some coordinate system, to then rotate clockwise around both regions keeping track of the distance between tangent points. Note that only vertices need to be considered, as the extremal point cannot lie on an edge.

Finally, any other pair that involves R is covered by the stronger case of (R, R) : for any line we can align every intermediate object with any point in R . To elaborate, the cases above are not truly a case distinction, as *all* of these combinations should hold; so given a line segment for a pair (P, R) or (R, Q) for some $P \in \mathcal{P}_1$, $Q \in \mathcal{P}_n$, we can pick any point of the segment that lies inside R to establish the alignment, deferring to the stronger previous case (R, R) . Also observe that some line segments covered by the case (P, Q) with $P \in \mathcal{P}_1$, $Q \in \mathcal{P}_n$ may go through R ; this does not impose any unnecessary constraints, so it does not matter that the cases can overlap.

► **Lemma 13.** *Given $n \in \mathbb{N}^{\geq 3}$, for any imprecise curve modelled with convex polygons $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $U_i \subset \mathbb{R}^2$ for all $i \in [n]$ and $V(U_i) = \{p_i^1, \dots, p_i^k\}$ for all $i \in [n]$, $k \in \mathbb{N}^{>0}$, given a threshold $\varepsilon \in \mathbb{R}^{>0}$, we can check for $\delta := d_H$ and $\delta := d_F$, using procedures above, that $\max_{\pi \in \mathcal{U}} \delta(\pi, \langle \pi(1), \pi(n) \rangle) \leq \varepsilon$.*

6 Combining Steps

In the previous sections, we have shown how to check if a shortcut of length $n \geq 3$ is valid under the Hausdorff or the Fréchet distance, for indecisive points, disks, line segments, and convex polygons. It is easy to see that a shortcut of length $n = 2$ is always valid. Therefore,

■ **Table 1** Running time of our approach in each setting. For indecisive points, k is the number of options per point. For convex polygons, k is the number of vertices.

	Indecisive	Disks	Line segments	Convex polygons
Hausdorff distance	$\mathcal{O}(n^3k^3)$	$\mathcal{O}(n^3)$	$\mathcal{O}(n^3)$	$\mathcal{O}(n^3k^3)$
Fréchet distance	$\mathcal{O}(n^3k^3)$	$\mathcal{O}(n^3)$	$\mathcal{O}(n^3)$	$\mathcal{O}(n^3k^3)$

we can use the previously described procedures to construct a shortcut graph; any path in such a graph from the vertex 1 to vertex n corresponds to a valid simplification, so the shortest path gives us the result we need.

► **Theorem 1.** *We can find the shortest vertex-constrained simplification of an uncertain curve, such that for any realisation the simplification is valid, both for the Hausdorff and the Fréchet distance, in time $\mathcal{O}(n^3)$ for uncertainty modelled with disks and line segments, and in time $\mathcal{O}(n^3k^3)$ for uncertainty modelled with indecisive points and convex polygons, where k is the number of options or vertices and n is the length of the curve.*

Proof. Correctness of the approaches has been shown before. We now analyse the running time, also shown in Table 1. For the running time, observe that we need $\mathcal{O}(n^2T)$ time in any setting, due to the shortcut graph construction.

For indecisive points, when testing a shortcut we do $\mathcal{O}(nk)$ -time testing for $\mathcal{O}(k^2)$ combinations of starting and ending points, where k is the number of options per point. For disks, we do a linear number of constant-time checks and two linear-time checks, getting $T \in \mathcal{O}(n)$. For line segments, we also do two (three) linear-time checks per part; two line segments can be split into at most two parts each, so we repeat the process four times. Either way, we get $T \in \mathcal{O}(n)$.

Finally, for convex polygons, assume the complexity of each polygon is at most k . Assume the partitioning resulting from two intersecting polygons yields ℓ_1 and ℓ_2 parts for the first and the second polygon, respectively. Denote the two polygons P and Q and the resulting parts with P_1, \dots, P_{ℓ_1} and Q_1, \dots, Q_{ℓ_2} , respectively. Suppose part P_i has complexity k_i and part Q_j has complexity k'_j , so $|V(P_i)| = k_i$ and $|V(Q_j)| = k'_j$ for some $i \in [\ell_1]$, $j \in [\ell_2]$. We know that every vertex of the original polygons occurs in a constant number of parts, so $\sum_{i=1}^{\ell_1} k_i \in \mathcal{O}(k)$ and $\sum_{j=1}^{\ell_2} k'_j \in \mathcal{O}(k)$; we also know $\ell_1 + \ell_2 \in \mathcal{O}(k)$. We consider all pairs from P and Q , and for each pair we triangulate and do the checks on the triangulation. The triangulation can be done in time $\mathcal{O}((k_i + k'_j) \cdot \log(k_i + k'_j))$, yielding $\mathcal{O}(k_i + k'_j)$ lines, each of which is tested in time $\mathcal{O}(nk)$. The testing dominates, so we need $\mathcal{O}((k_i + k'_j) \cdot nk)$ time. We are interested in

$$\sum_{i=1}^{\ell_1} \sum_{j=1}^{\ell_2} \mathcal{O}((k_i + k'_j) \cdot nk) = \mathcal{O}(nk) \cdot \sum_{i=1}^{\ell_1} \sum_{j=1}^{\ell_2} \mathcal{O}(k_i + k'_j) = \mathcal{O}(nk^3).$$

So, $T \in \mathcal{O}(nk^3)$ both for the Fréchet and the Hausdorff distance. ◀

7 Conclusion

We have presented approaches for finding the optimal simplification of an uncertain curve under various uncertainty models for the Hausdorff and the Fréchet distance. To recap, we can use Lemmas 7, 12, and 13 and the procedure for indecisive points to test a single shortcut. Constructing a shortcut graph yields the solution. In future work, it would be

interesting to see, similarly to the precise simplification approaches, if an improvement in the running time is possible to subcubic time, or whether one can show a conditional lower bound [8]. It would also be interesting to consider what uncertainty means in the context of global simplification; our approach does not seem easily transferable.

A Shortcut Testing: Intermediate Points

In this appendix, we discuss testing a single shortcut where we fix the realisations of the first and the last uncertain point. We provided intuitive explanations in Section 4 and discuss the details here. We state some basic facts about the Hausdorff and the Fréchet distance in the precise setting (see the full version [12] for the proofs) and use them to design simple algorithms for testing shortcuts in the uncertain settings.

A.1 Hausdorff Distance

We start by recalling some useful facts about the Hausdorff distance in the precise setting.

► **Lemma 14.** *Given points $a, b, c, d \in \mathbb{R}^2$ forming segments ab and cd , the largest distance from one segment to the other is $\max_{p \in ab} d(p, cd) = \max\{d(a, cd), d(b, cd)\}$.*

► **Lemma 15.** *Given $n \in \mathbb{N}^{>0}$, for any precise curve $\pi = \langle p_1, \dots, p_n \rangle$ with $p_i \in \mathbb{R}^2$ for all $i \in [n]$, we have $d_H(\pi, p_1 p_n) = \max_{i \in [n]} d(p_i, p_1 p_n)$.*

Indecisive points. We generalise the setting to include imprecision. We first claim that the straightforward setting with indecisive points permits an easy solution using Lemma 15; the proof can be found in the full version [12].

► **Lemma 16.** *Given $n, k \in \mathbb{N}^{>0}$, for any indecisive curve $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $n \geq 3$, $U_i = \{p_i^1, \dots, p_i^k\}$ for all $i \in [n]$ and $p_i^j \in \mathbb{R}^2$ for all $i \in [n]$, $j \in [k]$, and given some $p_1 \in U_1$ and $p_n \in U_n$, we have $\max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} d_H(\pi, p_1 p_n) = \max_{i \in \{2, \dots, n-1\}} \max_{j \in [k]} d(p_i^j, p_1 p_n)$.*

Note that this means that when the start and end realisations are fixed, we can test that a shortcut is valid using the lemma above in time $\mathcal{O}(nk)$ for a shortcut of length n .

26:18 Uncertain Curve Simplification

Disks. We proceed to present the way to test shortcuts for fixed realisations of the first and the last points when the imprecision is modelled using disks. In the next arguments the following form of a triangle inequality is useful (again, see the full version [12] for details).

► **Lemma 17.** For any $p, q \in \mathbb{R}^2$ and a line segment ab on $a, b \in \mathbb{R}^2$, $d(p, ab) \leq \|p - q\| + d(q, ab)$.

► **Lemma 18.** Given $n \in \mathbb{N}^{\geq 3}$, for any imprecise curve modelled with disks $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $U_i = D(c_i, r_i)$ for all $i \in [n]$ and $c_i \in \mathbb{R}^2$, $r_i \in \mathbb{R}^{\geq 0}$ for all $i \in [n]$, and given some $p_1 \in U_1$ and $p_n \in U_n$, we have

$$\max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} d_H(\pi, p_1 p_n) = \max_{i \in \{2, \dots, n-1\}} (d(c_i, p_1 p_n) + r_i).$$

Proof. Assume the setting of the lemma. We derive

$$\begin{aligned} \max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} d_H(\pi, p_1 p_n) &= \{\text{Lemma 15}\} \max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} \max_{i \in [n]} d(\pi(i), p_1 p_n) \\ &= \{\text{Def. } \Subset, d(p_1, p_1 p_n) = d(p_n, p_1 p_n) = 0\} \max_{i \in \{2, \dots, n-1\}} \max_{p \in U_i} d(p, p_1 p_n). \end{aligned}$$

It remains to show that $\max_{p \in U_i} d(p, p_1 p_n) = d(c_i, p_1 p_n) + r_i$ for any $i \in \{2, \dots, n-1\}$.

Pick $p' := \operatorname{argmax}_{p \in U_i} d(p, p_1 p_n)$. Note that by Lemma 17, $d(p', p_1 p_n) \leq \|p' - c_i\| + d(c_i, p_1 p_n)$. Furthermore, as $p' \in U_i$, by definition of U_i we have $\|p' - c_i\| \leq r_i$. Thus, $\max_{p \in U_i} d(p, p_1 p_n) \leq d(c_i, p_1 p_n) + r_i$, and we need to show the other direction.

Now pick a point $q' := \operatorname{argmin}_{q \in p_1 p_n} \|q - c_i\|$, so that $d(c_i, p_1 p_n) = \|q' - c_i\|$. Draw the line through c_i and q' and pick the point p' on that line on the boundary of U_i on the opposite side of q w.r.t. c_i . Clearly, $\|p' - c_i\| = r_i$ and $q' = \operatorname{argmin}_{q \in p_1 p_n} \|q - p'\|$. Thus,

$$d(p', p_1 p_n) = \|p' - q'\| = \|q' - c_i\| + \|p' - c_i\| = d(c_i, p_1 p_n) + r_i.$$

Note that $p' \in U_i$, so we conclude $\max_{p \in U_i} d(p, p_1 p_n) \geq d(c_i, p_1 p_n) + r_i$. ◀

This lemma allows us to test a shortcut in time $\mathcal{O}(n)$ for a shortcut of length n .

Polygonal closed convex sets.

► **Lemma 19.** Given $n, k \in \mathbb{N}^{>0}$, $n \geq 3$, for any imprecise curve modelled with PCCSs $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $U_i \subset \mathbb{R}^2$ and $V(U_i) = \{p_i^1, \dots, p_i^k\}$ for all $i \in [n]$, and given some $p_1 \in U_1$ and $p_n \in U_n$, we have

$$\max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} d_H(\pi, p_1 p_n) = \max_{i \in \{2, \dots, n-1\}} \max_{v \in V(U_i)} d(v, p_1 p_n).$$

Proof. Assume the setting of the lemma. As before, derive

$$\begin{aligned} \max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} d_H(\pi, p_1 p_n) &= \{\text{Lemma 15}\} \max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} \max_{i \in [n]} d(\pi(i), p_1 p_n) \\ &= \{\text{Def. } \Subset, d(p_1, p_1 p_n) = d(p_n, p_1 p_n) = 0\} \max_{i \in \{2, \dots, n-1\}} \max_{p \in U_i} d(p, p_1 p_n). \end{aligned}$$

To show that the claim holds, it remains to show that for any PCCS U and a line segment ab , $\max_{p \in U} d(p, ab) = \max_{v \in V(U)} d(v, ab)$. Firstly, as $V(U) \subset U$, we immediately have $\max_{p \in U} d(p, ab) \geq \max_{v \in V(U)} d(v, ab)$. Consider any $p \in U$. We show that there is some $v \in V(U)$ such that $d(v, ab) \geq d(p, ab)$, completing the proof, with a case distinction on p .

■ **Algorithm 1** Testing a shortcut on an indecisive curve with the Fréchet distance.

Require: $\mathcal{U} = \langle U_1, \dots, U_n \rangle$, $n, k \in \mathbb{N}^{>0}$, $\forall i \in [n] : U_i = \{p_i^1, \dots, p_i^k\}$, $\forall i \in [n], j \in [k] : p_i^j \in \mathbb{R}^2$, $\varepsilon \in \mathbb{R}^{>0}$, $p_1 \in U_1, p_n \in U_n$

- 1: **function** CHECKFRÉCHETIND($\mathcal{U}, p_1, p_n, n, k, \varepsilon$)
- 2: $s_1 := 1$
- 3: **for** $i \in \{2, \dots, n-1\}$ **do**
- 4: $T_i := \emptyset$
- 5: **for** $j \in [k]$ **do**
- 6: $S_i^j := \{t \in [s_{i-1}, 2] \mid \|p_i^j - p_1 p_n(t)\| \leq \varepsilon\}$
- 7: **if** $S_i^j = \emptyset$ **then**
- 8: **return** False
- 9: $T_i := T_i \cup \min S_i^j$
- 10: $s_i := \max T_i$
- 11: **return** True

- $p \in V(U)$. Then pick $v := p$, and we are done.
- $p \notin V(U)$, but p is on the boundary of U . Consider the vertices $v, w \in V(U)$ with $p \in vw$. Using Lemma 14, we note $\max_{q \in vw} d(q, ab) = \max\{d(v, ab), d(w, ab)\}$. W.l.o.g. suppose $d(v, ab) \geq d(w, ab)$. Then for v indeed we have $d(v, ab) \geq d(p, ab)$.
- p is in the interior of U (cannot occur for line segments). Find the point $q' := \operatorname{argmin}_{q \in ab} \|p - q\|$, so $d(p, ab) = \|p - q'\|$. Draw the line through p and q' ; let p' be the point on that line on the boundary of U on the opposite side of q' w.r.t. p . Clearly, $q' = \operatorname{argmin}_{q \in ab} \|p' - q\|$, so $d(p', ab) > d(p, ab)$. Then we can find a vertex $v \in V(U)$ as in the previous cases, yielding $d(v, ab) \geq d(p', ab) > d(p, ab)$.

This covers all the cases, so the statement holds. ◀

As before, this lemma gives us a simple way to test the shortcut with fixed realisations of the first and the last points in time $\mathcal{O}(nk)$ for a shortcut of length n and PCCSs with k vertices.

A.2 Fréchet Distance

We omit results for the Fréchet distance in the precise setting here; see the full version [12].

Indecisive points. The idea is that in the precise case we can always align greedily as we move along the line segment. In this case, we also need to find the realisation for each indecisive point that makes for the ‘worst’ greedy choice.

► **Lemma 20.** *Given $n, k \in \mathbb{N}^{>0}$ and $\varepsilon \in \mathbb{R}^{>0}$, for any indecisive trajectory $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $U_i = \{p_i^1, \dots, p_i^k\}$ for all $i \in [n]$ and $p_i^j \in \mathbb{R}^2$ for all $i \in [n], j \in [k]$, and given some $p_1 \in U_1$ and $p_n \in U_n$, we have, using Algorithm 1,*

$$\max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} d_F(\pi, p_1 p_n) \leq \varepsilon \iff \text{CHECKFRÉCHETIND}(\mathcal{U}, p_1, p_n, n, k, \varepsilon) = \text{True}.$$

Proof. First, assume that $\max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} d_F(\pi, p_1 p_n) \leq \varepsilon$. In the algorithm, we compute some set S_i^j for each p_i^j and then pick one value from it and add it to T_i ; from T_i we then pick a single value as s_i . So, $s_i \in S_i^j$ for some $j_i \in [k]$, on every iteration $i \in \{2, \dots, n-1\}$. Consider a realisation $\pi \in \mathcal{U}$ with $\pi(1) \equiv p_1$, $\pi(n) \equiv p_n$, and $\pi(i) \equiv p_i^{j_i}$ for every $i \in \{2, \dots, n-1\}$, where j_i is chosen as the value corresponding to s_i . Then we know $d_F(\pi, p_1 p_n) \leq \varepsilon$. So, there is an alignment that can be given as a sequence of n positions, $t_i \in [1, 2]$, such that $\|\pi(i) - p_1 p_n(t_i)\| \leq \varepsilon$ and $t_i \leq t_{i+1}$ for all i . The alignment is established by interpolating between the consecutive points on the curves (see Section 2).

26:20 Uncertain Curve Simplification

We now show by induction that $s_i \leq t_i$ for all i . For $i = 2$, we get, for the chosen j_2 , $s_2 := \min\{t \in [1, 2] \mid \|p_2^{j_2} - p_1 p_n(t)\| \leq \varepsilon\}$. As we have $t_2 \in \{t \in [1, 2] \mid \|p_2^{j_2} - p_1 p_n(t)\| \leq \varepsilon\}$, we get $s_2 \leq t_2$. Now assume the statement holds for some i , then for $i + 1$ we get $s_{i+1} := \min\{t \in [s_i, 2] \mid \|p_{i+1}^{j_{i+1}} - p_1 p_n(t)\| \leq \varepsilon\}$; we can rephrase this so that

$$s_{i+1} \stackrel{\text{def}}{=} \min(\{t \in [1, 2] \mid \|p_{i+1}^{j_{i+1}} - p_1 p_n(t)\| \leq \varepsilon\} \cap [s_i, 2]).$$

So, there are two options.

- $s_{i+1} = s_i$. Then we know $s_{i+1} = s_i \leq t_i \leq t_{i+1}$.
- $s_{i+1} > s_i$. Then we can use the same argument as for $i = 2$ to find that $s_{i+1} \leq t_{i+1}$.

Now we know that for every i , $t_i \in S_i^{j_i}$ for the choice of j_i described above. Therefore, for any $p_{i+1}^{j_{i+1}}$ there is always a realisation prefix such that any valid alignment has $t_{i+1} \geq s_i$; as we know that there is a valid alignment for every realisation, we conclude that every S_i^j is non-empty. Thus, the algorithm returns True.

Now assume that the algorithm returns True. Consider any realisation $\pi \in \mathcal{U}$. We claim that there is a valid alignment, described with a sequence of $t_i \in [1, 2]$ for $i \in \{2, \dots, n-1\}$, such that $s_{i-1} \leq t_i \leq s_i$ and $\|p_1 p_n(t_i) - \pi(i)\| \leq \varepsilon$. Denote the realisation $\pi \stackrel{\text{def}}{=} \langle p_1, p_2^{j_2}, p_3^{j_3}, \dots, p_{n-1}^{j_{n-1}}, p_n \rangle$, so the sequence $\langle j_2, \dots, j_{n-1} \rangle$ describes the choices of the realisation. Consider the set $S_i^{j_i}$ for any $i \in \{2, \dots, n-1\}$. We know that it is non-empty, otherwise the algorithm would have returned False. We claim that we can pick $t_i = \min S_i^{j_i}$ for every i . By definition, $S_i^{j_i} \subseteq [1, 2]$ and $\|p_1 p_n(t_i) - \pi(i)\| \leq \varepsilon$. We also trivially get that $s_{i-1} \leq t_i$. Finally, note that $t_i \in T_i$, and $s_i := \max T_i$, so $t_i \leq s_i$.

This argument shows that $t_i \leq t_{i+1}$ for every i , and that $\|p_1 p_n(t_i) - \pi(i)\| \leq \varepsilon$. Therefore, $d_F(\pi, p_1 p_n) \leq \varepsilon$. As this works for any realisation with $\pi(1) \equiv p_1$ and $\pi(n) \equiv p_n$, we conclude $\max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} d_F(\pi, p_1 p_n) \leq \varepsilon$. ◀

Disks. To show the generalisation to disks, it is helpful to reframe the problem as that of disk stabbing for appropriate disks. We state some useful facts first (see the full version [12]).

► **Lemma 21.** *Given a disk $D_1 := D(c, r)$ with $c \in \mathbb{R}^2$, $r \in \mathbb{R}^{\geq 0}$, a threshold $\varepsilon \in \mathbb{R}^{> 0}$, and a point $p \in \mathbb{R}^2$, define $D_2 := D(c, \varepsilon - r)$. We have $\max_{p' \in D_1} \|p - p'\| \leq \varepsilon \iff p \in D_2$.*

► **Lemma 22.** *Given a disk $D_1 := D(c, r)$ with $c \in \mathbb{R}^2$, $r \in \mathbb{R}^{\geq 0}$, $\varepsilon \in \mathbb{R}^{> 0}$, and a line segment pq with $p, q \in \mathbb{R}^2$, define $D_2 := D(c, \varepsilon - r)$. Then $\max_{p' \in D_1} d(p', pq) \leq \varepsilon \iff pq \cap D_2 \neq \emptyset$.*

■ **Algorithm 2** Testing a shortcut on an imprecise curve modelled with disks with the Fréchet distance.

Require: $\mathcal{U} = \langle U_1, \dots, U_n \rangle$, $n \in \mathbb{N}^{> 0}$, $\forall i \in [n] : U_i = D(c_i, r_i)$, $\forall i \in [n] : c_i \in \mathbb{R}^2, r_i \in \mathbb{R}^{\geq 0}$, $\varepsilon \in \mathbb{R}^{> 0}$, $p_1 \in U_1$, $p_n \in U_n$

```

1: function CHECKFRÉCHETDISKS( $\mathcal{U}, p_1, p_n, n, \varepsilon$ )
2:    $s_1 := 1$ 
3:   for  $i \in \{2, \dots, n-1\}$  do
4:      $S_i := \{t \in [s_{i-1}, 2] \mid \|c_i - p_1 p_n(t)\| \leq \varepsilon - r_i\}$ 
5:     if  $S_i = \emptyset$  then
6:       return False
7:      $s_i := \min S_i$ 
8:   return True

```

► **Lemma 23.** *Given $n \in \mathbb{N}^{>0}$ and $\varepsilon \in \mathbb{R}^{>0}$, for any imprecise curve modelled with disks $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $U_i = D(c_i, r_i)$ for all $i \in [n]$ and $c_i \in \mathbb{R}^2$, $r_i \in \mathbb{R}^{\geq 0}$ for all $i \in [n]$, and given some $p_1 \in U_1$ and $p_n \in U_n$, we have, using Algorithm 2,*

$$\max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} d_F(\pi, p_1 p_n) \leq \varepsilon \iff \text{CHECKFRÉCHETDISKS}(\mathcal{U}, p_1, p_n, n, \varepsilon) = \text{True}.$$

Proof. We use Lemma 22 to change the problem: rather than establishing an alignment that comes in the correct order and satisfies the distance constraints, we do disk stabbing and pick the stabbing points in the correct order. So, we have $\max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} d_F(\pi, p_1 p_n) \leq \varepsilon$ if and only if there exists a sequence of points $p'_i \in p_1 p_n \cap D(c_i, \varepsilon - r_i)$ for all $i \in \{2, \dots, n-1\}$ such that $p'_i \preceq p'_{i+1}$ along $p_1 p_n$ for all $i \in \{2, \dots, n-2\}$. We show that this is exactly what Algorithm 2 computes in the full version [12]. ◀

■ **Algorithm 3** Testing a shortcut on an imprecise curve modelled with PCCSs with the Fréchet distance.

Require: $\mathcal{U} = \langle U_1, \dots, U_n \rangle$, $n, k \in \mathbb{N}^{>0}$, $\forall i \in [n] : U_i$ is a PCCS, $V(U_i) = \{p_i^1, \dots, p_i^k\}$, $\forall i \in [n], j \in [k] : p_i^j \in \mathbb{R}^2$, $\varepsilon \in \mathbb{R}^{>0}$, $p_1 \in U_1$, $p_n \in U_n$

- 1: **function** CHECKFRÉCHETPCCS($\mathcal{U}, p_1, p_n, n, k, \varepsilon$)
- 2: $s_1 := 1$
- 3: **for** $i \in \{2, \dots, n-1\}$ **do**
- 4: $T_i := \emptyset$
- 5: **for** $j \in [k]$ **do**
- 6: $S_i^j := \{t \in [s_{i-1}, 2] \mid \|p_i^j - p_1 p_n(t)\| \leq \varepsilon\}$
- 7: **if** $S_i^j = \emptyset$ **then**
- 8: **return** False
- 9: $T_i := T_i \cup \min S_i^j$
- 10: $s_i := \max T_i$
- 11: **return** True

Polygonal closed convex sets.

► **Lemma 24.** *Given $n, k \in \mathbb{N}^{>0}$ and $\varepsilon \in \mathbb{R}^{>0}$, for any imprecise curve modelled with PCCSs $\mathcal{U} = \langle U_1, \dots, U_n \rangle$ with $U_i \subset \mathbb{R}^2$ and $V(U_i) = \{p_i^1, \dots, p_i^k\}$ for all $i \in [n]$, and given some $p_1 \in U_1$ and $p_n \in U_n$, we have, using Algorithm 3,*

$$\max_{\pi \in \mathcal{U}, \pi(1) \equiv p_1, \pi(n) \equiv p_n} d_F(\pi, p_1 p_n) \leq \varepsilon \iff \text{CHECKFRÉCHETPCCS}(\mathcal{U}, p_1, p_n, n, k, \varepsilon) = \text{True}.$$

Proof. As we have shown in Lemma 19, it suffices to test the vertices of a PCCS to establish that the distance from every point to the line segment is below the threshold. It remains to show that the extreme alignment (in terms of ordering) for the Fréchet distance is also achieved at a vertex. This case then becomes identical to the indecisive points case, so we can use Lemma 20 to show correctness.

Consider an arbitrary point $t \in U_i$ and let s be the earliest point in the ε -disk around t that is on pq . Clearly, if t is in the interior of U_i , then we can take any t' on the line through t parallel to pq and get the corresponding s' with $s \prec s'$. So, assume t is on the boundary of U_i . Suppose that $t \in uv$ with $u, v \in V(U_i)$. Rotate and translate the coordinate plane so that pq lies on the x -axis. Derive the equation for the line containing uv , say, $y' = kx' + b$. First consider $k = 0$, so the line containing uv is parallel to the line containing pq . In this case, clearly, moving along uv in the direction coinciding with the direction from p to q

26:22 Uncertain Curve Simplification

■ **Figure 7** Illustration for the computation in Lemma 24.

increases the x -coordinate of point of interest, so moving to a vertex is optimal. Now assume $k > 0$. If $k < 0$, reflect the coordinate plane about $y = 0$. Geometrically, it is easy to see (Figure 7) that the coordinate of interest can be expressed as

$$x = x' - \sqrt{\varepsilon^2 - y'^2} = \frac{y' - b}{k} - \sqrt{\varepsilon^2 - y'^2}.$$

We want to maximise x by picking the appropriate y' . We take the derivative: $dx/dy' = 1/k + y'/\sqrt{\varepsilon^2 - y'^2}$. We equate it to 0 to find the critical point of the function, $y'_0 = -\varepsilon/\sqrt{k^2 + 1}$. We can check that for $y' < y'_0$, the value of the derivative is negative, and for $y' > y'_0$ it is positive, so at $y' = y'_0$ we achieve a local minimum. There are no other critical points, so to maximise x , we want to move away from the local minimum as far as possible. As we are limited to the line segment uv , the maximum is achieved at an endpoint. ◀

Fractional Homomorphism, Weisfeiler-Leman Invariance, and the Sherali-Adams Hierarchy for the Constraint Satisfaction Problem

Abstract

Given a pair of graphs \mathbf{A} and \mathbf{B} , the problems of deciding whether there exists either a homomorphism or an isomorphism from \mathbf{A} to \mathbf{B} have received a lot of attention. While graph homomorphism is known to be NP-complete, the complexity of the graph isomorphism problem is not fully understood. A well-known combinatorial heuristic for graph isomorphism is the Weisfeiler-Leman test together with its higher order variants. On the other hand, both problems can be reformulated as integer programs and various LP methods can be applied to obtain high-quality relaxations that can still be solved efficiently. We study so-called fractional relaxations of these programs in the more general context where \mathbf{A} and \mathbf{B} are not graphs but arbitrary relational structures. We give a combinatorial characterization of the Sherali-Adams hierarchy applied to the homomorphism problem in terms of fractional isomorphism. Collaterally, we also extend a number of known results from graph theory to give a characterization of the notion of fractional isomorphism for relational structures in terms of the Weisfeiler-Leman test, equitable partitions, and counting homomorphisms from trees. As a result, we obtain a description of the families of CSPs that are closed under Weisfeiler-Leman invariance in terms of their polymorphisms as well as decidability by the first level of the Sherali-Adams hierarchy.

1 Introduction

The graph isomorphism and homomorphism problems, that is, the problems of deciding, given input graphs \mathbf{A} and \mathbf{B} , whether \mathbf{A} is isomorphic (respectively homomorphic) to \mathbf{B} , have been the subject of extensive research. Despite an important research effort, it is still an open problem to determine whether the isomorphism problem for graphs can be solved in polynomial time. The recent quasipolynomial algorithm for the problem presented by Babai [4] is widely regarded as a major breakthrough in theoretical computer science.

In turn, the complexity of the graph homomorphism problem has also been intensively studied in combinatorics (see [21]) as well as in a more general setting, known as the Constraint Satisfaction Problem (CSP), where \mathbf{A} and \mathbf{B} are not required to be graphs but can be arbitrary relational structures. The CSP is general enough to encompass problems from areas as diverse as artificial intelligence, optimization, computer algebra, computational biology, computational linguistics, among many other. In contrast with the graph isomorphism problem it was quickly established that the homomorphism problem is NP-complete even for graphs, as it can encode graph coloring. Consequently, an important research effort has been put into identifying tractable fragments of the problem, in particular by fixing the target structure \mathbf{B} . This culminated in the recent major result of Bulatov [8] and Zhuk [37], which confirmed a conjecture by Feder and Vardi [15] that, given a fixed target structure \mathbf{B} , the homomorphism problem for \mathbf{B} is either solvable in polynomial time or NP-complete.

Linear programming relaxations, among other relaxations such as SDP-based, have been largely used in the study of both the isomorphism and the homomorphism problem. In fact, the isomorphism problem for graphs \mathbf{A} , \mathbf{B} can be reformulated as an integer program which asks whether there exists a permutation matrix X such that $XN_{\mathbf{A}} = N_{\mathbf{B}}X$, where $N_{\mathbf{A}}$ and $N_{\mathbf{B}}$ are the adjacency matrices of \mathbf{A} , \mathbf{B} respectively. If we relax this condition to only require that X is doubly stochastic, we obtain what is known as fractional isomorphism.

Fractional isomorphism has a combinatorial counterpart in the 1-dimensional Weisfeiler-Leman (1-WL) algorithm [26], also known as colour refinement. In particular, it was shown in [34, 35] and [30] that \mathbf{A} and \mathbf{B} are fractionally isomorphic if and only if 1-WL does not distinguish between them. 1-WL produces a sequence of colourings c_0, c_1, \dots of the nodes of a graph by means of an iterative refinement procedure which assigns a pair of nodes to the same colour class of c^i if they belong to the same class of c^{i-1} , and additionally they have the same number of neighbours of each colour in c^{i-1} . The algorithm keeps iterating until a fixed point is reached. The Weisfeiler-Leman algorithm is a very powerful heuristic to test for graph isomorphism: if two graphs are distinguished by 1-WL (that is, they give rise to distinct fixed-point colourings up to renaming of the vertices), then this is a witness that the graphs are not isomorphic. In fact, it was shown that 1-WL decides the isomorphism problem on almost all graphs (that is, all but $o(2^{\binom{n}{2}})$ graphs on n vertices for every n) [5].

However, it is also easy to see that 1-WL fails on some very simple instances, such as regular graphs. To address these limitations, the original Weisfeiler-Leman algorithm has been extended so that at every iteration on a graph \mathbf{A} it produces a colouring of the set of k -tuples ($k > 1$) of nodes of \mathbf{A} . It was initially conjectured that this hierarchy of increasingly powerful methods, known as the k -dimensional Weisfeiler-Leman (k -WL) algorithm, would provide a polynomial time graph isomorphism test at least for graphs of bounded degree. While this conjecture was proved to be incorrect [10], k -WL turns out to have a number of useful applications, such as the important role it plays in the aforementioned quasipolynomial algorithm of Babai.

In addition, the k -WL algorithm has proven to be very robust and has a number of equivalent formulations. In [14], a new characterization was given in terms of counting homomorphisms: for every $k \geq 1$, \mathbf{A} and \mathbf{B} are indistinguishable by the k -WL algorithm if for every graph \mathbf{T} of treewidth at most k , the number of homomorphisms from \mathbf{T} to \mathbf{A} is equal to the number of homomorphisms from \mathbf{T} to \mathbf{B} . Further, it has been shown in [10] that \mathbf{A} and \mathbf{B} are indistinguishable by the k -WL algorithm if and only if they are indistinguishable in the logic C^{k+1} consisting of all FO formulas with counting quantifiers that have at most $k + 1$ variables.

Similarly to the Weisfeiler-Leman hierarchy for fractional isomorphism, any LP relaxation of an integer 0/1-program, like that of graph isomorphism, can be further strengthened by sequentially applying so-called lift-and-project methods from mathematical programming in order to obtain a hierarchy of increasingly tighter relaxations which can still be solved efficiently. The main idea behind these is to add auxiliary variables and valid inequalities to an initial relaxation of a 0/1 integer program. These methods, which include Lovász-Schrijver [27] and Sherali-Adams [32], have been used to study classical problems in combinatorial optimization such as Max-Cut, Vertex Cover, Maximal Matching, among many others.

Quite surprisingly, Atserias and Maneva [3] and Malkin [28] were able to lift the connection between the 1-WL algorithm and fractional isomorphism to show a close correspondence between the higher levels of the SA hierarchy for the graph isomorphism problem and the k -WL algorithm (and, hence, with the logic C^{k+1}). This correspondence was further tightened in [20].

Let us now turn our attention to the homomorphism problem. Here, LP relaxations have been intensively used in the more general setting of the Constraint Satisfaction Problem and, most usually, in the approximation of its optimization versions such as MaxCSP, consisting of finding a map from the universe of \mathbf{A} to the universe of \mathbf{B} that maximizes the number of constraints satisfied, among other variants. For instance, a simple linear programming relaxation yields a 2-approximation algorithm for the Vertex Cover problem, and no better polynomial time approximation algorithm is known.

One of the simplest and most widespread LP relaxations of the homomorphism problem (see for example [24]) has an algebraic characterization that very much resembles that of fractional isomorphism. For the sake of simplicity we shall present it here in the restricted case of graphs. Let us start with the algebraic formulation of fractional isomorphism which can be, alternatively, expressed as the existence of a pair of doubly stochastic matrices X and Y such that $XM_{\mathbf{A}} = M_{\mathbf{B}}Y$ and $M_{\mathbf{A}}Y^T = X^TM_{\mathbf{B}}$, where $M_{\mathbf{A}}$ denotes the *incidence* matrix of \mathbf{A} . If we relax this condition to only require that X and Y are left stochastic and, additionally, we drop the second equation, then we obtain a relaxation of graph homomorphism, which we call fractional homomorphism. With some minor variations depending on whether the objective function is present (as in MaxCSP) or not and how repeated elements in a tuple are treated, this LP formulation has been extensively used [7, 12, 13, 18, 23, 24].

We consider relaxations arising from the application of the Sherali-Adams (SA) method. Giving an explicit description of the inequalities produced by the SA method for homomorphism might be relatively cumbersome (because the constraints of the input structures \mathbf{A} and \mathbf{B} must be encoded in the polytope-defining inequalities rather than in the objective function as in the optimization variants) even when the target structure \mathbf{B} is fixed. Hence, we consider a simpler family of LP inequalities, interleaved with the SA hierarchy, of which fractional homomorphism corresponds to the first level. Our hierarchy coincides with the usual SA hierarchy for MaxCSP [11, 17, 33, 36] where the objective function has been turned into a constraint.

Our main result is a combinatorial characterization of this family of LP relaxations which, abusing slightly notation, we still shall refer to as $SA^k, k \geq 1$. Along the way, we extend a number of the aforementioned results from graph isomorphism to general isomorphism between relational structures which yields a hierarchy of relaxations of (relational structure) isomorphism. Our results show that, for every $k \geq 1$, the k th level relaxation of the homomorphism problem, that is, SA^k , is tightly related with the corresponding k th level relaxation of isomorphism, which we denote using \equiv_k .

Let us consider the first level of the hierarchy, i.e, fractional homomorphism and fractional isomorphism. In the case of graphs \equiv_1 -equivalence coincides precisely with 1-WL equivalence. Here we show that a structure \mathbf{A} is fractionally homomorphic to a structure \mathbf{B} if and only if there exists a sequence of structures $\mathbf{X}_0, \mathbf{X}_1, \dots, \mathbf{X}_n$ with $\mathbf{A} = \mathbf{X}_0$, $\mathbf{B} = \mathbf{X}_n$, and for every $i < n$, \mathbf{X}_i is either homomorphic or \equiv_1 -equivalent to \mathbf{X}_{i+1} . The correspondence for any higher level k is obtained by replacing \mathbf{X}_0 and \mathbf{X}_n by suitably defined structures \mathbf{A}_k^* , \mathbf{B}_k^* that allow to reduce the k^{th} level of the hierarchy to the first level.

In particular, it follows that feasibility in SA^k is preserved by structures that are \equiv_k -equivalent.

In essence, this is due to the fact that the LP relaxation of homomorphism inherits the symmetries of \mathbf{A} and \mathbf{B} . There are, indeed, several results exploring the symmetries of an LP program in a similar fashion. In [3] such types of symmetries are used to transfer results between the logic C^k and LP relaxations of several combinatorial problems, whereas [19] aims to identify the partition classes (as in the WL algorithm) of the variables and constraints of an LP program so that, by identifying those in the same class, the LP size is reduced. That being said, the main interest of our result lies precisely in the opposite direction: that is, the fact that the fractional homomorphism LP relaxation is able to certify that \mathbf{A} is not homomorphic to \mathbf{B} unless \mathbf{A} belongs to the backwards closure of \mathbf{B} under homomorphism and \equiv_1 equivalence, or, even more strongly, unless \mathbf{A} is homomorphic to a structure \mathbf{X}_1 which is \equiv_1 -equivalent to a structure \mathbf{X}_2 which in turn is homomorphic to \mathbf{B} .

We apply our results to study the following question: for which structures \mathbf{B} is the set $\text{CSP}(\mathbf{B})$, which contains all the structures homomorphic to \mathbf{B} , closed under 1-WL equivalence. This question arises in the context of solving CSPs in a distributed manner [9] where the elements of the input instance (nodes, edges) are distributed among agents which communicate with each other by sending messages through fixed communication channels. Using our main results we can rederive the classification obtained in [9] using substantially different techniques.

2 Preliminaries

Relational structures

For a positive integer n , We denote by $[n]$ the set $\{1, \dots, n\}$. We shall denote tuples in boldface. Let $\mathbf{a} = (a_1, \dots, a_k) \in A^k$. We use $\mathbf{a}[i]$ to denote a_i and $\{\mathbf{a}\}$ to denote the set of variables which occur in \mathbf{a} . For every tuple $\mathbf{i} = (i_1, \dots, i_n) \in [k]^n$ we use $\pi_{\mathbf{i}} \mathbf{a}$ to denote the *projection* of \mathbf{a} to \mathbf{i} , i.e, the tuple $(a_{i_1}, \dots, a_{i_n})$. If $I \subseteq [k]$ we might abuse slightly notation and use $\pi_I \mathbf{a}$ to refer to $\pi_{\mathbf{i}} \mathbf{a}$ where \mathbf{i} is the tuple that contains the elements of I in increasing order. For every function f on a domain containing $\{\mathbf{a}\}$, we denote by $f(\mathbf{a})$ the coordinate-wise application of f to \mathbf{a} .

Given a set A and a positive integer k , a k -ary *relation* over A is a subset of A^k . A *signature* σ is a finite collection of relation symbols, each with an associated arity. We shall use $\text{arity}(R)$ to denote the arity of a relation symbol R . A *relational structure* \mathbf{A} over σ , or simply a σ -structure, consists of a set A called the *universe* of \mathbf{A} , and a relation $R(\mathbf{A})$ over A for each $R \in \sigma$ of the corresponding arity. We denote by $\mathcal{C}_{\mathbf{A}}$ the set $\{(\mathbf{a}, R) \mid \mathbf{a} \in R(\mathbf{A}), R \in \sigma\}$. Elements (\mathbf{a}, R) of $\mathcal{C}_{\mathbf{A}}$ will alternatively be denoted $R(\mathbf{a})$ and will be referred to as *constraints*. We shall usually use the same boldface and (standard) capital letter to refer to a structure and its universe, respectively.

A *graph* is a relational structure whose signature consists of a single binary relation that is symmetric and non-reflexive.

Let \mathbf{A}, \mathbf{B} be σ -structures. A *homomorphism* from \mathbf{A} to \mathbf{B} is a map $h : A \rightarrow B$ such that for every $R \in \sigma$ and every $\mathbf{a} \in R(\mathbf{A})$ it holds that $h(\mathbf{a}) \in R(\mathbf{B})$. If there exists a homomorphism from \mathbf{A} to \mathbf{B} we say that \mathbf{A} is homomorphic to \mathbf{B} and we write $\mathbf{A} \rightarrow \mathbf{B}$. We shall use $\text{Hom}(\mathbf{A}; \mathbf{B})$ to denote the number of homomorphisms from \mathbf{A} to \mathbf{B} . The problem of deciding, given two similar structures \mathbf{A} and \mathbf{B} , whether \mathbf{A} is homomorphic to \mathbf{B} is known as the *Constraint Satisfaction Problem* (CSP). If we fix the target structure \mathbf{B} so that the input is only \mathbf{A} , then we obtain the Constraint Satisfaction Problem over \mathbf{B} , denoted $\text{CSP}(\mathbf{B})$.

An *isomorphism* from \mathbf{A} to \mathbf{B} is a bijective map $f : A \rightarrow B$ such that for every $R \in \sigma$ and every $\mathbf{a} \in A^{\text{arity}(R)}$ it holds that $\mathbf{a} \in R(\mathbf{A})$ if and only if $f(\mathbf{a}) \in R(\mathbf{B})$.

The *union* $\mathbf{A} \cup \mathbf{B}$ of two σ -structures \mathbf{A} and \mathbf{B} is the structure \mathbf{C} with $C = A \cup B$ and $R(\mathbf{C}) = R(\mathbf{A}) \cup R(\mathbf{B})$ for every $R \in \sigma$. The *disjoint union* of two structures \mathbf{A} and \mathbf{B} is the structure $\mathbf{A} \cup \mathbf{C}$ where \mathbf{C} is any σ -structure isomorphic to \mathbf{B} satisfying $A \cap C = \emptyset$. We say that a structure is *connected* if it cannot be expressed as the disjoint union of two structures. We say that \mathbf{A} is a *substructure* of \mathbf{B} if $\mathbf{A} \cup \mathbf{B} = \mathbf{B}$. If, in addition, $R(\mathbf{A}) = R(\mathbf{B}) \cap A^{\text{arity}(R)}$ for every $R \in \sigma$ then \mathbf{A} is the substructure of \mathbf{B} *induced* by A .

Tree-like structures

We define the *factor graph*¹ of a structure \mathbf{A} to be the bipartite graph with nodes $A \cup \mathcal{C}_{\mathbf{A}}$ and where every $R(\mathbf{a})$ in $\mathcal{C}_{\mathbf{A}}$ is joined by an edge with every $a \in \{\mathbf{a}\}$.

Then, we say that a structure \mathbf{T} is an *ftree* (factor tree) if its factor graph is a tree in the ordinary graph-theoretic sense. If \mathbf{Q} is a substructure of \mathbf{T} and \mathbf{Q} is an ftree then we say that \mathbf{Q} is a *subftree* of \mathbf{T} .

A *tree-decomposition* of a structure \mathbf{A} is a pair (G, β) where $G = (V, E)$ is a tree and $\beta : V \rightarrow \mathcal{P}(A)$ is a mapping such that the following conditions are satisfied:

1. For every constraint $R(\mathbf{a})$ in $\mathcal{C}_{\mathbf{A}}$ there exists a node $v \in V$ such that $\{\mathbf{a}\} \subseteq \beta(v)$
2. If $a \in \beta(u) \cap \beta(v)$ then $a \in \beta(w)$ for every node w in the unique path in G joining u to v .

The *width* of a tree-decomposition (G, β) is $\max\{|\beta(v)| \mid v \in V\} - 1$ and the *treewidth* of \mathbf{A} is defined as the smallest width among all its tree-decompositions.

The Sherali–Adams hierarchy

In this presentation we follow [3]. Let $P \subseteq [0, 1]^n$ be a polytope $\{\mathbf{x} \in \mathbb{R}^n : M\mathbf{x} \geq \mathbf{b}, 0 \leq \mathbf{x} \leq 1\}$ for a matrix $M \in \mathbb{R}^{m \times n}$, and a column vector $\mathbf{b} \in \mathbb{R}^m$. We denote the convex hull of the $\{0, 1\}$ -vectors in P by $P^{\mathbb{Z}}$. The sequence of Sherali-Adams relaxations of $P^{\mathbb{Z}}$ is the sequence of polytopes $P = P^1 \supseteq P^2 \supseteq \dots$ where P^k is defined in the following way.

Each inequality in $M\mathbf{x} \geq \mathbf{b}$ is multiplied by all possible terms of the form $\prod_{i \in I} x_i \prod_{j \in J} (1 - x_j)$ where $I, J \subseteq [n]$ satisfy $|I \cup J| \leq k - 1$ and $I \cap J = \emptyset$. This leaves a system of polynomial inequalities, each of degree at most k . Then, this system is *linearized* and hence relaxed in the following way: each square x_i^2 is replaced by x_i and each resulting monomial $\prod_{i \in K} x_i$ is replaced by a variable y_K . In this way we obtain a polytope P_L^k . Finally, P_L^k is projected back to n dimensions by defining

$$P^k := \{\mathbf{x} \in \mathbb{R}^n : \text{there exists } \mathbf{y} \in P_L^k \text{ such that } \mathbf{y}_{\{i\}} = \mathbf{x}_i \text{ for each } i \in [n]\}.$$

We note here that $P^{\mathbb{Z}} \subseteq P^k$ for every $k \geq 1$.

¹ We note that the definition of factor graph presented here differs from that in [9], in which the edges are labelled. We also note that the notion of factor graph, although similar, differs in several ways from the incidence multigraph (see [25]) as the latter allows for parallel edges.

In order to apply the SA method to the homomorphism problem there are different possible choices for the polytope P (encoding a relaxation of homomorphism) to start with, each one then yielding a different hierarchy.

Here we shall adapt a SA-based family of relaxations commonly used in optimization variants of CSP [11, 17, 33, 36] which we transform into a relaxation of (plain) CSP by just turning the objective function into a set of new restrictions. Hence, the resulting system of inequalities is not, strictly speaking, obtained using the SA method. Nonetheless, we shall abuse slightly notation and still use SA^k to refer to our system of inequalities.

In fact, giving an explicit description of all inequalities obtained using the SA method for any natural polytope P encoding the LP relaxation for a *general* CSP in our setting is a bit cumbersome (because the constraints of the CSP are encoded in the polytope-defining inequalities instead of the objective function as in CSP optimization variants). Hence, it seems sensible to settle for a good approximation as SA^k . Indeed, as it can be seen in Appendix A, the sequence of relaxations SA^k is tightly interleaved with the sequence P^k obtained by the SA method, in stricto sensu, for a natural choice of initial polytope P .

Given two structures \mathbf{A} and \mathbf{B} , the system of inequality $\text{SA}^k(\mathbf{A}, \mathbf{B})$ for the homomorphism problem over (\mathbf{A}, \mathbf{B}) contains a variable $p_V(f)$ for every $V \subseteq A$ with $1 \leq |V| \leq k$ and every $f : V \rightarrow B$, and a variable $p_{R(\mathbf{a})}(f)$ for every $R(\mathbf{a}) \in \mathcal{C}_{\mathbf{A}}$ and every $f : \{\mathbf{a}\} \rightarrow B$. Each variable must take a value in the range $[0, 1]$. The variables are constrained by the following conditions:

$$\sum_{f:V \rightarrow B} p_V(f) = 1 \quad V \subseteq A \text{ s.t. } |V| \leq k \quad (\text{SA1})$$

$$p_U(f) = \sum_{g:V \rightarrow B, g|_U=f} p_V(g) \quad U \subseteq V \subseteq A \text{ s.t. } |V| \leq k, f : U \rightarrow B \quad (\text{SA2})$$

$$p_U(f) = \sum_{g:V \rightarrow B, g|_U=f} p_{R(\mathbf{a})}(g) \quad R(\mathbf{a}) \in \mathcal{C}_{\mathbf{A}}, U \subseteq \{\mathbf{a}\} = V \text{ s.t. } |U| \leq k, f : U \rightarrow B \quad (\text{SA3})$$

$$p_{R(\mathbf{a})}(f) = 0 \quad R(\mathbf{a}) \in \mathcal{C}_{\mathbf{A}}, f : \{\mathbf{a}\} \rightarrow B \text{ s.t. } f(\mathbf{a}) \notin R(\mathbf{B}) \quad (\text{SA4})$$

For the particular case of $k = 1$ we shall use the simplified notation $p_v(f(v))$ to denote the variable $p_V(f)$ for a singleton set $V = \{v\}$ and a function $f : V \rightarrow B$.

The transformation $*_k$

For every $k > 0$ we define an operator $*_k$ that maps a structure into a new structure. As we shall see later this operator will allow to reduce SA^k feasibility to SA^1 feasibility.

Let \mathbf{A} be a σ -structure. Then we define the universe of \mathbf{A}_k^* to be $A_k^* := \cup_{j \leq k} A^j \cup \mathcal{C}_{\mathbf{A}}$. Additionally, \mathbf{A}_k^* contains the following relations:

$$\begin{aligned} T_{j,S}(\mathbf{A}_k^*) &= \{(a_1, \dots, a_j) \in A^j \mid a_i = a_{i'} \forall i, i' \in S\} & j \leq k, S \subseteq [j] \\ T_{j,\mathbf{i}}(\mathbf{A}_k^*) &= \{(\mathbf{a}, \pi_{\mathbf{i}} \mathbf{a}) \mid \mathbf{a} \in A^j\} & j', j \leq k, \mathbf{i} \in [j]^{j'} \\ R_S(\mathbf{A}_k^*) &= \{(a_1, \dots, a_{\text{arity}(R)}) \in R(\mathbf{A}) \mid a_i = a_{i'} \forall i, i' \in S\} & R \in \sigma, S \subseteq [\text{arity}(R)] \\ R_{\mathbf{i}}(\mathbf{A}_k^*) &= \{(R(\mathbf{a}), \pi_{\mathbf{i}} \mathbf{a}) \mid \mathbf{a} \in R(\mathbf{A})\} & R \in \sigma, j \leq k, \mathbf{i} \in [\text{arity}(R)]^j. \end{aligned}$$

Then we have:

► **Lemma 1.** *Let \mathbf{A}, \mathbf{B} be σ -structures. Then $\text{SA}^k(\mathbf{A}, \mathbf{B})$ is feasible if and only if $\text{SA}^1(\mathbf{A}_k^*, \mathbf{B}_k^*)$ is feasible.*

Iterated degree, fractional isomorphism, and equitable partitions

In order to prove our main result we need to lift the known equivalence between fractional isomorphism and the WL algorithm from graphs to relational structures.

Let $L := \{(S, R) \mid R \in \sigma, S \subseteq [\text{arity}(R)]\}$ be a set, the elements of which we shall call *labels*. We construct the *matrix representation* $M_{\mathbf{A}}$ of a σ -structure \mathbf{A} as follows (it will be convenient to assume that the indices of the rows and columns of a matrix are arbitrary sets). $M_{\mathbf{A}}$ is an $A \times \mathcal{C}_{\mathbf{A}}$ matrix whose entries are elements of L . In particular, for all $a \in A$ and $R(\mathbf{a}) \in \mathcal{C}_{\mathbf{A}}$, we have that $M_{\mathbf{A}}[a, R(\mathbf{a})] = (S, R)$ where S is the set containing all elements $i \in [\text{arity}(R)]$ such that $a = \mathbf{a}[i]$.

In a nutshell we are lifting from graph isomorphism to matrix isomorphism, where two matrices are isomorphic if they are identical modulo a permutation of the rows and columns. To formalize this, it will be convenient to associate \mathbf{A} with a set of 0-1 incidence matrices. In particular, for every $\ell \in L$ we define $M_{\mathbf{A}}^{\ell} \in \{0, 1\}^{A \times \mathcal{C}_{\mathbf{A}}}$ as follows: $M_{\mathbf{A}}^{\ell}[a, R(\mathbf{a})] = 1$ if $M_{\mathbf{A}}[a, R(\mathbf{a})] = \ell$ and $M_{\mathbf{A}}^{\ell}[a, R(\mathbf{a})] = 0$ otherwise. In [19], relaxations of matrix isomorphism are also considered although in that setting the matrices have real entries and the goal is different from ours.

We now describe a procedure akin to the 1-dimensional Weisfeiler-Leman algorithm to calculate iterative refinements of a colouring of the universe and constraint set of a relational structure. While there are syntactical differences, when run on graphs this procedure is equivalent for all purposes to 1-WL. For every $k \geq 0$ and $x \in A \cup \mathcal{C}_{\mathbf{A}}$, we define inductively the *iterated degree* $\delta_k^{\mathbf{A}}(x)$ of x on \mathbf{A} as follows. We set $\delta_0^{\mathbf{A}}(x)$ to be one of two arbitrary symbols that distinguish elements of A from elements of $\mathcal{C}_{\mathbf{A}}$. For $k \geq 1$ we set $\delta_k^{\mathbf{A}}(a) = \{ \{ (\ell, \delta_{k-1}^{\mathbf{A}}(\mathbf{a}, R)) \mid M_{\mathbf{A}}^{\ell}[a, R(\mathbf{a})] = 1 \} \}$ and $\delta_k^{\mathbf{A}}(\mathbf{a}, R) = \{ \{ (\ell, \delta_{k-1}^{\mathbf{A}}(a)) \mid M_{\mathbf{A}}^{\ell}[a, R(\mathbf{a})] = 1 \} \}$, where double curly brackets denote that $\delta_k^{\mathbf{A}}(x)$ is a multiset.

We say that \mathbf{A} and \mathbf{B} have the same iterated degree sequence if for every $k \geq 0$, $\{ \{ \delta_k^{\mathbf{A}}(a) \mid a \in A \cup \mathcal{C}_{\mathbf{A}} \} \} = \{ \{ \delta_k^{\mathbf{B}}(b) \mid b \in B \cup \mathcal{C}_{\mathbf{B}} \} \}$. Note that if there exists a matrix isomorphism from \mathbf{A} to \mathbf{B} (or alternatively, \mathbf{A} and \mathbf{B} are isomorphic) then \mathbf{A} and \mathbf{B} have the same iterated degree sequence, but the converse does not hold.

The notion of equitable partition is key in the proof of the equivalence of the different characterizations of fractional isomorphism. We present its adaptation to relational structures. A *partition* of a σ -structure \mathbf{A} is a pair (P, Q) where $P = \{P_i \mid i \in I\}$ is a partition of A and $Q = \{Q_j \mid j \in J\}$ is a partition of $\mathcal{C}_{\mathbf{A}}$. We say that (P, Q) is *equitable* if for every $i \in I$, $j \in J$, and $\ell \in L$, there are integers $c_{i,j}^{\ell}, d_{j,i}^{\ell}$, called the *parameters* of the partition, such that for every every $i \in I$, every $a \in P_i$, every $\ell \in L$, and every $j \in J$, we have

$$|\{(\mathbf{a}, R) \in Q_j \mid M_{\mathbf{A}}[a, R(\mathbf{a})] = \ell\}| = c_{i,j}^{\ell} \quad (\text{P1})$$

and, similarly, for every $j \in J$, every $R(\mathbf{a}) \in Q_j$, every $\ell \in L$, and every $i \in I$ we have

$$|\{a \in P_i \mid M_{\mathbf{A}}[a, (\mathbf{a}, R)] = \ell\}| = d_{j,i}^{\ell}. \quad (\text{P2})$$

We say that two structures \mathbf{A}, \mathbf{B} have a *common equitable partition* if there are equitable partitions $(\{P_i^{\mathbf{A}} \mid i \in I\}, \{Q_j^{\mathbf{A}} \mid j \in J\})$ and $(\{P_i^{\mathbf{B}} \mid i \in I\}, \{Q_j^{\mathbf{B}} \mid j \in J\})$ of \mathbf{A} and \mathbf{B} with the same parameters satisfying $|P_i^{\mathbf{A}}| = |P_i^{\mathbf{B}}|$ for every $i \in I$ and $|Q_j^{\mathbf{A}}| = |Q_j^{\mathbf{B}}|$ for every $j \in J$. We note that if \mathbf{A} and \mathbf{B} are connected it is not necessary to verify this latter requirement and, instead, it is enough to check that $|A| = |B|$.

A matrix M of non-negative real numbers is said to be *left* (resp. *right*) *stochastic* if all its columns (resp. rows) sum to 1. Note that we do not require M to be square. A *doubly stochastic matrix* is a square matrix that is both left and right stochastic.

► **Theorem 2.** *Let \mathbf{A}, \mathbf{B} be σ -structures. The following are equivalent:*

1. *There exist doubly stochastic matrices X, Y such that $XM_{\mathbf{A}}^{\ell} = M_{\mathbf{B}}^{\ell}Y$ and $M_{\mathbf{A}}^{\ell}Y^T = X^T M_{\mathbf{B}}^{\ell}$ for every $\ell \in L$;*
2. *\mathbf{A} and \mathbf{B} have the same iterated degree sequence;*
3. *\mathbf{A} and \mathbf{B} have a common equitable partition;*
4. *$\text{Hom}(\mathbf{T}, \mathbf{A}) = \text{Hom}(\mathbf{T}, \mathbf{B})$ for all σ -ftrees \mathbf{T} .*

If, additionally, \mathbf{A} and \mathbf{B} are graphs, then the following is also equivalent:

5. *There exists a doubly stochastic matrix X such that $XN_{\mathbf{A}} = N_{\mathbf{B}}X$ where $N_{\mathbf{A}}$ and $N_{\mathbf{B}}$ denote the adjacency matrices of \mathbf{A} and \mathbf{B} respectively.*

We refer the reader to the full version of this paper for the proof. The equivalence between (1), (2) and (3) is an immediate generalization of the equivalence between the algebraic and combinatorial characterizations of fractional graph isomorphism (see for example [31]), while (4) generalizes the corresponding characterization of graphs from [14] in terms of counting homomorphisms from trees. Also, note that condition (5) shows that our definition coincides with the standard notion of fractional isomorphism when \mathbf{A} and \mathbf{B} are graphs.

Similarly to the case of graphs, the notion of fractional isomorphism captured in Theorem 2 can be strengthened giving rise to a hierarchy of increasingly tighter relaxations. In particular, for every $k \geq 1$, we shall denote $\mathbf{A} \equiv_k \mathbf{B}$ whenever \mathbf{A}_k^* and \mathbf{B}_k^* satisfy the conditions of Theorem 2.

It is easy to see that the case $k = 1$ would be unchanged if one replaces \mathbf{A}_1^* and \mathbf{B}_1^* by \mathbf{A} and \mathbf{B} respectively and, hence, Theorem 2 characterizes \equiv_1 . For other small values of k other than $k = 1$, \equiv_k is a bit more difficult to characterize. However, as long as k is at least as large as the arity of any relation in the signature then we have the following result.

► **Lemma 3.** *Let r be the maximum arity among all relations in σ and assume that $r \leq k$. Then for every pair of structures \mathbf{A}, \mathbf{B} the following are equivalent:*

1. $\mathbf{A} \equiv_k \mathbf{B}$
2. $\text{Hom}(\mathbf{Q}; \mathbf{A}) = \text{Hom}(\mathbf{Q}; \mathbf{B})$ for every structure \mathbf{Q} of treewidth $< k$.

This result, which follows easily from condition (4) in Theorem 2, is inspired by a similar result [14] which states that two graphs \mathbf{A}, \mathbf{B} are indistinguishable by the k -WL algorithm if and only if $\text{Hom}(\mathbf{Q}; \mathbf{A}) = \text{Hom}(\mathbf{Q}; \mathbf{B})$ for every graph \mathbf{Q} of treewidth $\leq k$. It is not that surprising that a similar result can be shown for \equiv_k since, after all, the k -WL algorithm can be seen as the 1-WL algorithm applied to k -ary tuples. However, note that the bound on the treewidth differs in one unit between k -WL and \equiv_k . Still, using Lemma 3 it can be shown that for $r \leq k$, \equiv_k can be alternatively characterized in logical terms extending, again, an analogous result for k -WL [22]. More precisely, $\mathbf{A} \equiv_k \mathbf{B}$ if and only if \mathbf{A} and \mathbf{B} satisfy the same formulas in the k -variable fragment of first-order logic with counting quantifiers, denoted C^k (we omit the definition as it will not be needed).

2.1 Main results

The main result of this paper is a new characterization in terms of fractional isomorphism of the Sherali-Adams relaxation of the homomorphism problem.

► **Theorem 4.** *Let \mathbf{A}, \mathbf{B} be relational structures. Then, the following are equivalent:*

1. $\text{SA}^k(\mathbf{A}, \mathbf{B})$ is feasible;
2. *There exists a sequence of structures $\mathbf{X}_0, \dots, \mathbf{X}_n$ such that $\mathbf{X}_0 = \mathbf{A}_k^*$, $\mathbf{X}_n = \mathbf{B}_k^*$, and for all $i = 0, \dots, n-1$ we have that $\mathbf{X}_i \rightarrow \mathbf{X}_{i+1}$ or $\mathbf{X}_i \equiv_1 \mathbf{X}_{i+1}$;*
3. *There exist structures $\mathbf{X}_1, \mathbf{X}_2$ such that $\mathbf{A}_k^* \rightarrow \mathbf{X}_1$, $\mathbf{X}_1 \equiv_1 \mathbf{X}_2$, and $\mathbf{X}_2 \rightarrow \mathbf{B}_k^*$.*

Theorem 4 is an immediate consequence, using Lemma 1, of the following Theorem.

► **Theorem 5.** *Let \mathbf{A}, \mathbf{B} be relational structures. Then, the following are equivalent:*

1. $\text{SA}^1(\mathbf{A}, \mathbf{B})$ is feasible;
2. There exist left stochastic matrices X, Y such that for every $\ell = (S, R) \in L$, it holds that $XM_{\mathbf{A}}^{\ell} \leq \sum_{\ell'} M_{\mathbf{B}}^{\ell'} Y$ where ℓ' ranges over all $(S', R) \in L$ with $S \subseteq S'$;
3. There exists a sequence of structures $\mathbf{X}_0, \dots, \mathbf{X}_n$ such that $\mathbf{X}_0 = \mathbf{A}$, $\mathbf{X}_n = \mathbf{B}$, and for all $i = 0, \dots, n-1$ we have that $\mathbf{X}_i \rightarrow \mathbf{X}_{i+1}$ or $\mathbf{X}_i \equiv_1 \mathbf{X}_{i+1}$;
4. There exist structures $\mathbf{X}_1, \mathbf{X}_2$ such that $\mathbf{A} \rightarrow \mathbf{X}_1$, $\mathbf{X}_1 \equiv_1 \mathbf{X}_2$, and $\mathbf{X}_2 \rightarrow \mathbf{B}$.

If in addition \mathbf{A} and \mathbf{B} have no loops (meaning that there are no repeated elements in any constraint) then the following condition is also equivalent:

5. There exist left stochastic matrices X, Y such that for every $\ell \in L$ it holds that $XM_{\mathbf{A}}^{\ell} = M_{\mathbf{B}}^{\ell} Y$.

Note that for graphs condition (5) of the above theorem is naturally seen as the homomorphism counterpart of the notion of fractional isomorphism (see condition (1) in Lemma 2). Consequently, we shall say that \mathbf{A} is fractionally homomorphic to \mathbf{B} whenever \mathbf{A} and \mathbf{B} satisfy the conditions of Theorem 5.

While Theorems 4 and 5 have applications, for instance in the field of Constraint Satisfaction Problems (see Section 4), we believe that their main interest is that they shed light on the LP relaxations for homomorphism as they show that fractional homomorphism and its higher order counterparts can be decomposed into a sequence of basic, better studied morphisms, a fact which we find interesting on its own. Additionally, they establish a close link between LP relaxations for isomorphism and homomorphism, which were introduced initially in different fields.

3 Proof of Theorem 5

The equivalence (1) \Leftrightarrow (2) is merely syntactic. In particular we shall show that there is a one-to-one satisfiability-preserving correspondence between pairs of matrices and variable assignments of $\text{SA}^1(\mathbf{A}, \mathbf{B})$. However, we first need to massage a bit the two formulations. First, we can assume that for every $R^A(\mathbf{a}) \in \mathcal{C}_{\mathbf{A}}$ and $R^B(\mathbf{b}) \in \mathcal{C}_{\mathbf{B}}$, the corresponding entry in Y is null unless $R^A = R^B$ and $f(\mathbf{a}) = \mathbf{b}$ for some $f : \{\mathbf{a}\} \rightarrow \{\mathbf{b}\}$, since otherwise there is no way that Y can be part of a feasible solution. Secondly, we note that the feasibility of $\text{SA}^1(\mathbf{A}, \mathbf{B})$ does not change if in (SA3) we replace $=$ by \leq obtaining a new set of inequalities (which to avoid confusion we shall denote by (SA3')) and, in addition, we add for every $R(\mathbf{a}) \in \mathcal{C}_{\mathbf{A}}$ the equality

$$\sum_{f: \{\mathbf{a}\} \rightarrow B} p_{R(\mathbf{a})}(f) = 1. \quad (\text{SA5})$$

Finally, note that in $\text{SA}^1(\mathbf{A}, \mathbf{B})$ we can ignore (SA2).

Then we can establish the following correspondence between pairs of matrices X, Y and assignments $\text{SA}^1(\mathbf{A}, \mathbf{B})$: for every $a \in A$ and $b \in B$, we set $p_a(b) = X[b, a]$ and for every $R(\mathbf{a}) \in \mathcal{C}_{\mathbf{A}}$ and $f : \{\mathbf{a}\} \rightarrow B$ we define $p_{R(\mathbf{a})}(f) = Y[R(f(\mathbf{a})), R(\mathbf{a})]$. Then, it is easy to see that (SA3') corresponds to $XM_{\mathbf{A}}^{\ell} \leq \sum_{\ell' \in L_{\ell}} M_{\mathbf{B}}^{\ell'} Y$ for every $\ell \in L$ (where $L_{(S,R)} := \{(S', R) \in L \mid S \subseteq S'\}$), X being left stochastic corresponds to (SA1), and Y being left stochastic corresponds to (SA5).

The equivalence (1) \Leftrightarrow (5) is obtained as in (1) \Leftrightarrow (2). We just need to notice that when \mathbf{A} and \mathbf{B} have no loops, then none of the entries in $M_{\mathbf{A}}$ and $M_{\mathbf{B}}$ contain any label $\ell = (S, R) \in L$ where $|S| > 1$ and hence it is only necessary to consider labels $\ell = (S, R) \in L$ where S is a singleton. Observe that, in this case, the equation in (2) becomes $XM_{\mathbf{A}}^{\ell} \leq M_{\mathbf{B}}^{\ell} Y$

since for every label $\ell = (S, R)$ where S is a singleton, the only label (S', R) with $S \subseteq S'$ and $M_{\mathbf{B}}^{\ell}$ not a zero matrix is ℓ itself. Finally, in order to replace \leq by $=$ in the previous equation we just need to use (SA3) instead of (SA3').

Notice that (4) \implies (3) is trivial.

The proof of (3) \implies (2) is by induction on n . If $n = 0$ the claim is immediate, so assume that $n \geq 1$. Let $\mathbf{X}_0, \mathbf{X}_1, \dots, \mathbf{X}_n$ be a sequence of structures satisfying (3). By the induction hypothesis, there exist left stochastic matrices X, Y such that $XM_{\mathbf{X}_1}^{\ell} \leq \sum_{\ell' \in L_{\ell}} M_{\mathbf{X}_n}^{\ell'} Y$ for all $\ell \in L$.

If $\mathbf{X}_0 \equiv_1 \mathbf{X}_1$ then it follows from Theorem 2 that there exist doubly stochastic matrices X' and Y' such that $X'M_{\mathbf{X}_0}^{\ell} = M_{\mathbf{X}_1}^{\ell} Y'$ for all $\ell \in L$, and so it is easy to verify that XX', YY' are such that (2) holds. Assume that $\mathbf{X}_0 \not\equiv_1 \mathbf{X}_1$. We shall show that there exist left stochastic matrices X' and Y' such that for all $b \in B$, for all $R(\mathbf{a}) \in \mathcal{C}_{\mathbf{A}}$, and for all $\ell \in L$ there exists $\hat{\ell} = \hat{\ell}(b, R(\mathbf{a}), \ell) \in L_{\ell}$ such that $XA^{\ell}[b, R(\mathbf{a})] \leq B^{\hat{\ell}}Y[b, R(\mathbf{a})]$. Assuming that this holds, again it follows by the induction hypothesis that XX', YY' are left stochastic matrices such that $XX'M_{\mathbf{X}_0}^{\ell} \leq \sum_{\ell' \in L_{\ell}} M_{\mathbf{X}_n}^{\ell'} YY'$ for all $\ell \in L$.

Let h be a homomorphism from \mathbf{A} to \mathbf{B} . We define $X'[b, a] = 1$ if $b = h(a)$ and $X'[b, a] = 0$ otherwise. Similarly, we set $Y'[R^B(\mathbf{b}), R^A(\mathbf{a})] = 1$ if $\mathbf{b} = h(\mathbf{a})$ and $R^B = R^A$ and $Y'[R^B(\mathbf{b}), R^A(\mathbf{a})] = 0$ otherwise. It is easy to see that X' and Y' are left stochastic. Now let $\ell = (S, R) \in L$, $b \in B$ and $R(\mathbf{a}) \in \mathcal{C}_{\mathbf{A}}$. If $M_{\mathbf{A}}^{\ell}[a, R(\mathbf{a})] = 0$ for all $a \in A$ then $XM_{\mathbf{A}}^{\ell}[b, R(\mathbf{a})] = 0$ and there is nothing to prove. So we can assume that there is $a \in A$ such that for all $i \in [\text{arity}(R)]$, $\mathbf{a}[i] = a$ if and only if $i \in S$. Then we have that $XM_{\mathbf{A}}^{\ell}[b, R(\mathbf{a})] = 1$ if $b = h(a)$, and $XM_{\mathbf{A}}^{\ell}[b, R(\mathbf{a})] = 0$ otherwise. Again in the latter case there is nothing to prove so let us assume that $b = h(a)$. It follows that $h(\mathbf{a}[i]) = b$ for all $i \in S$ and hence there exists $\hat{\ell} = (R, S')$ with $S \subseteq S'$ such that $M_{\mathbf{B}}^{\hat{\ell}}[b, R(h(\mathbf{a}))] = 1$, which completes the proof.

It only remains to prove (1) \implies (4). Assume that \mathbf{A} and \mathbf{B} satisfy (1). Further, we can assume that there exists an integer $m > 0$ such that all variables in the feasible solution of $\text{SA}^1(\mathbf{A}, \mathbf{B})$ take rational values of the form n/m for some integer n . Let Y be the set of all tuples $((b_1, c_1), \dots, (b_m, c_m)) \in (B \times [m])^m$ satisfying the following conditions:

- $(b_i, c_i) \neq (b_{i'}, c_{i'})$ for every $i \neq i' \in [m]$ (i.e., the tuple has no repeated elements), and
- for every $i \in [m]$, c_i is at most $|\{j \in [m] \mid b_j = b_i\}|$.

In other words, Y is the set of tuples that can be obtained if in every tuple $(b_1, \dots, b_m) \in B^m$ we replace all occurrences, say n , of any symbol $b \in B$ by n ‘‘copies’’ $(b, 1), \dots, (b, n)$, in any possible order. Let $\Pi : Y \rightarrow B^m$ be the function mapping $((b_1, c_1), \dots, (b_m, c_m))$ to (b_1, \dots, b_m) .

Let $X = A \times Y$. For every permutation τ on $[m]$ and any m -ary tuple $\mathbf{z} = (z_1, \dots, z_m) \in Z^m$ where Z is any arbitrary set we shall use $\mathbf{z} \circ \tau$ to denote the tuple $(z_{\tau(1)}, \dots, z_{\tau(m)})$. This notation is justified by the fact that we can see formally \mathbf{z} as a mapping from $[m]$ to Z . For any $x = (a, \mathbf{y}) \in X$, we shall abuse notation and write $x \circ \tau$ to denote $(a, \mathbf{y} \circ \tau)$.

For any two \mathbf{z}, \mathbf{z}' in any of the sets B^m, Y or X , we shall write $\mathbf{z} \sim \mathbf{z}'$ iff there exists some permutation τ on $[m]$ such that $\mathbf{z}' = \mathbf{z} \circ \tau$.

For every multiset $U = \{\{b_1, \dots, b_m\}\}$ of m elements from B , we shall fix one arbitrary element of Y , denoted $\langle U \rangle$, satisfying that the multiset of variables in $\Pi(\langle U \rangle)$ coincides with U . We shall abuse slightly notation and for every $\mathbf{b} = (b_1, \dots, b_m) \in B^m$ we shall also use $\langle \mathbf{b} \rangle$ to denote $\langle \{\{b_1, \dots, b_m\}\} \rangle$. Clearly if $\mathbf{b} \sim \mathbf{b}'$ then $\langle \mathbf{b} \rangle = \langle \mathbf{b}' \rangle$. Moreover, for every $\mathbf{b} \in B^m$ we shall denote by $\mathbf{y}^{\mathbf{b}}$ the tuple $((b_1, c_1), \dots, (b_m, c_m)) \in Y$ obtained by choosing $c_i < c_j$ whenever $b_i = b_j$ and $i < j$. Notice that $\Pi(\mathbf{y}) = \mathbf{b}$ and $\mathbf{y}^{\mathbf{b}} \sim \langle \mathbf{b} \rangle$.

Now we shall show how to construct two structures \mathbf{X}_1 and \mathbf{X}_2 which satisfy condition (4). The domain of both \mathbf{X}_1 and \mathbf{X}_2 is X . The constraints of \mathbf{X}_1 and \mathbf{X}_2 are constructed as follows. Let J be the set of all triplets (R, T, \mathbf{a}) where $R \in \sigma$, $\mathbf{a} \in A^{\text{arity}(R)}$, and T is a multiset of size m of tuples in $R(\mathbf{B})$ such that for every $s, s' \in [\text{arity}(R)]$:

$$\mathbf{a}[s] = \mathbf{a}[s'] \Rightarrow \forall \mathbf{t} \in T(\mathbf{t}[s] = \mathbf{t}[s']).$$

In other words, T only contains tuples $\mathbf{t} \in R(\mathbf{B})$ such that $\mathbf{t} = f(\mathbf{a})$ for some function $f : \{\mathbf{a}\} \rightarrow B$. Then for every $(R, T, \mathbf{a}) \in J$ and $d \in [2]$, we define Q_j^d to be the set of $m!$ constraints obtained in the following way. Fix any arbitrary ordering $\mathbf{t}_1, \dots, \mathbf{t}_m$ of the tuples in T and let $\mathbf{b}_1, \dots, \mathbf{b}_r \in B^m$, $r = \text{arity}(R)$ such that $\mathbf{b}_s[i] = \mathbf{t}_i[s]$ for every $i \in [m]$ and $s \in [r]$. Then, for every permutation $\tau \in [m]$, we include constraint $R((a_1, \langle \mathbf{b}_1 \rangle) \circ \tau, \dots, (a_r, \langle \mathbf{b}_r \rangle) \circ \tau)$ in Q_j^1 and constraint $R((a_1, \mathbf{y}^{\mathbf{b}_1}) \circ \tau, \dots, (a_r, \mathbf{y}^{\mathbf{b}_r}) \circ \tau)$ in Q_j^2 , where $\mathbf{a} = (a_1, \dots, a_r)$.

Finally, we define $C_{\mathbf{X}_d}$, $d \in [2]$ to be $\cup_{j \in J} Q_j^d$ (note that for each $d \in [2]$, all sets Q_j^d , $j \in J$ are disjoint). To complete the proof it only remains to show that \mathbf{X}_1 and \mathbf{X}_2 satisfy condition (4).

▷ **Claim 6.** \mathbf{A} is homomorphic to \mathbf{X}_1 .

Proof. Let p be a feasible solution of $\text{SA}^1(\mathbf{A}, \mathbf{B})$. We define a mapping $h : A \rightarrow X$ by setting $h(a) = (a, \langle \mathbf{c}_a \rangle)$, where $\mathbf{c}_a \in B^m$ is any tuple satisfying that every element $b \in B$ occurs exactly $m \cdot p_a(b)$ times. We shall show that h is a homomorphism from \mathbf{A} to \mathbf{X}_1 . Let $R \in \sigma$, $\mathbf{a} = (a_1, \dots, a_r) \in R(\mathbf{A})$ where $r = \text{arity}(R)$, and consider the multiset $T = \{\mathbf{t}_1, \dots, \mathbf{t}_m\}$ of tuples in $R(\mathbf{B})$ obtained by picking each tuple $\mathbf{t}_i = f_i(\mathbf{a}) \in R(\mathbf{B})$ exactly $m \cdot p_{R(\mathbf{a})}(f_i)$ times (note that we are using implicitly (SA4) to guarantee the existence of T). For every $s, s' \in [r]$ satisfying $a_s = a_{s'}$ it follows from the construction of T that $\mathbf{t}[s] = \mathbf{t}[s']$ for every $\mathbf{t} \in T$, and hence $(R, T, \mathbf{a}) \in J$. Let $\mathbf{t}_1, \dots, \mathbf{t}_m$ be the ordering of the elements in T associated to (R, T, \mathbf{a}) in the construction of \mathbf{X}_1 and $\mathbf{b}_1, \dots, \mathbf{b}_r$ be the tuples obtained by setting $\mathbf{b}_s[i] = \mathbf{t}_i[s]$ for $i \in [m]$ and $s \in [r]$. Then, it follows that \mathbf{X}_1 contains the constraint $R((a_1, \langle \mathbf{b}_1 \rangle), \dots, (a_r, \langle \mathbf{b}_r \rangle))$. It follows again from (SA3) that for every $s \in [r]$ $\mathbf{c}_{a_s} \sim \mathbf{b}_s$ and hence $(a_s, \langle \mathbf{b}_s \rangle)$ is precisely $h(a_s)$ as desired. ◁

▷ **Claim 7.** \mathbf{X}_2 is homomorphic to \mathbf{B} .

Proof. Let $h : X \rightarrow B$ be the function mapping any (a, \mathbf{y}) to $\pi_1(\Pi(\mathbf{y}))$. It is immediate that h defines a homomorphism from \mathbf{X}_2 to \mathbf{B} . ◁

▷ **Claim 8.** \mathbf{X}_1 and \mathbf{X}_2 have a common equitable partition.

Proof. We shall prove that (P, Q^1) and (P, Q^2) define a common equitable partition of \mathbf{X}_1 and \mathbf{X}_2 where $P = \{P_i \mid i \in I\}$ is the partition given by the equivalence relation \sim on X and $Q^d = \{Q_j^d \mid j \in J\}$, $d \in [2]$ are as defined in the construction of \mathbf{X}_1 and \mathbf{X}_2 .

This follows immediately from the following fact. Let $d \in [2]$, $i \in I$, $j \in J$, and $\ell \in L$. Then exactly one of the following conditions holds:

1. There is no $x \in P_i$ and $C \in Q_j^d$ such that $M_{\mathbf{X}_d}[x, C] = \ell$;
2. There exists a one-to-one correspondence between the elements of P_i and Q_j^d such that for every pair (x, C) of associated elements, $M_{\mathbf{X}_d}[x, C] = \ell$.

Furthermore, for every $i \in I$, $j \in J$, and $\ell \in L$, condition (1) holds for $d = 1$ if and only if it holds for $d = 2$.

Let us prove it. Let $j = (R, T, \mathbf{a})$ and let $\mathbf{b}_1, \dots, \mathbf{b}_r$ and $\mathbf{y}^{\mathbf{b}_1}, \dots, \mathbf{y}^{\mathbf{b}_r}$ be as in the construction of Q_j^d (where $r = \text{arity}(R)$). We first observe that for every $x \in P_i$, every $C = R(x_1, \dots, x_r) \in Q_j^d$, and every permutation τ on $[m]$, $M_{\mathbf{X}_d}[x, C] = \ell \Leftrightarrow M_{\mathbf{X}_d}[x \circ \tau, C \circ \tau] = \ell$ where we use $C \circ \tau$ to denote $R(x_1 \circ \tau, \dots, x_r \circ \tau)$. It then follows that if (1) fails then (2) must hold.

Now it only remains to see that (1) holds for $d = 1$ if and only if (1) holds for $d = 2$. Clearly, this follows immediately if the relation symbol in ℓ is different from R , so we can assume that $\ell = (R, S)$ for some $S \subseteq [r]$. We then note that if there is some pair (x, C) violating (1), then $M_{\mathbf{X}_d}[x \circ \tau, C \circ \tau] = \ell$ for all permutations τ on $[m]$, and hence C can be chosen to be any constraint in Q_j^d . Hence, if we choose $R((a_1, \langle \mathbf{b}_1 \rangle), \dots, (a_r, \langle \mathbf{b}_r \rangle))$ for $d = 1$ and $R((a_1, \mathbf{y}^{\mathbf{b}_1}), \dots, (a_r, \mathbf{y}^{\mathbf{b}_r}))$ for $d = 2$, in order to complete the proof it is enough to show that for every $s, s' \in [r]$, $(a_s, \langle \mathbf{b}_s \rangle) = (a_{s'}, \langle \mathbf{b}_{s'} \rangle) \Leftrightarrow (a_s, \mathbf{y}^{\mathbf{b}_s}) = (a_{s'}, \mathbf{y}^{\mathbf{b}_{s'}})$.

The direction (\Leftarrow) is immediate. For the direction (\Rightarrow) assume that s, s' satisfy the left-hand side. Since $a_s = a_{s'}$ it follows that $\mathbf{b}_s = \mathbf{b}_{s'}$. Since $\mathbf{y}^{\mathbf{b}_s}$ and $\mathbf{y}^{\mathbf{b}_{s'}}$ are determined in a unique way from \mathbf{b}_s and $\mathbf{b}_{s'}$ respectively, we are done. \triangleleft

4 Some Applications

As an immediate consequence of Theorem 4 we obtain that feasibility of the k^{th} Sherali-Adams relaxation of the homomorphism problem is closed under \equiv_k .

► **Corollary 9.** *Let \mathbf{A} , \mathbf{A}' and \mathbf{B} be σ -structures and suppose that $\mathbf{A} \equiv_k \mathbf{B}$. Then, $\text{SA}^k(\mathbf{A}, \mathbf{B})$ is feasible if and only if $\text{SA}^k(\mathbf{A}', \mathbf{B})$ is feasible.*

We note that if the maximum arity on the signature σ is at most k , then the previous corollary can be alternatively stated in the following way: if \mathbf{A} and \mathbf{A}' are C^k -equivalent then $\text{SA}^k(\mathbf{A}, \mathbf{B})$ is feasible if and only if $\text{SA}^k(\mathbf{A}', \mathbf{B})$ is feasible. Then, one could be tempted to use this observation to transfer results from LP relaxations to logical definability. In particular one could infer that if SA^k decides correctly $\text{CSP}(\mathbf{B})$ then it is definable in the logic $C_{\infty, \omega}^k$ which is the extension of C^k consisting of all formulas made from atomic formulas and equality by means of finitary and infinitary conjunctions, negations, and standard and counting quantifiers. However, this is of limited interest as it follows by combining [2] and [6] that $\text{CSP}(\mathbf{B})$ would also be definable in the much weaker logic $L_{\infty, \omega}^{\max(k, 3)}$ where counting quantifiers are not allowed. Consequently, the previous corollary is most likely to find applications in obtaining lower bounds on the Sherali-Adams rank for concrete instances of CSP.

However, the principal novelty in our result is precisely the opposite direction, which leads to an alternative combinatorial characterization of the Sherali-Adams relaxation. A concrete application is the answer to the following question: for which structures \mathbf{B} is $\text{CSP}(\mathbf{B})$ closed under \equiv_1 -equivalence? This question arises in the context of the distributed CSP [9] where the variables and constraints of an instance are distributed among agents which communicate with each other by sending messages through fixed communication channels. In fact, the connection between the Weisfeiler-Leman algorithm and distributed computation goes back to the influential paper of Angluin on networks of processors [1]. For the distributed CSP, one of the most natural configurations for the communication network is essentially identical to the factor graph [16]. It then follows, under some technical requirements (agent anonymity and synchronicity) that any distributed message passing algorithm will necessarily behave in an identical manner on every two input instances that are \equiv_1 -equivalent and, hence, it follows that $\text{CSP}(\mathbf{B})$ can only be solved by a distributed algorithm if $\text{CSP}(\mathbf{B})$ is closed under \equiv_1 -equivalence.

This question was already answered in [9] where it was shown that $\text{CSP}(\mathbf{B})$ is closed under \equiv_1 if and only if \mathbf{B} has symmetric polymorphisms of all arities, where a k -ary symmetric polymorphism of a σ -structure \mathbf{B} is any homomorphism h from \mathbf{B}^k to \mathbf{B} that is invariant under the permutation of its arguments (the reader can safely ignore the definition of symmetric polymorphism as we will be using it as a black-box). The proof in [9] makes use of a result from [24] stating that $\text{CSP}(\mathbf{B})$ has symmetric polymorphisms of all arities if and only if it is solvable by an LP relaxation known as the basic linear programming relaxation (BLP). Although BLP is slightly different from SA^1 , both coincide over instances (\mathbf{A}, \mathbf{B}) where \mathbf{A} has no loops (i.e., every constraint has no repeated elements). It is then very easy to obtain the following characterization:

► **Lemma 10.** *Let \mathbf{B} be a fixed finite σ -structure. The following are equivalent:*

1. $\text{CSP}(\mathbf{B})$ is closed under \equiv_1 -equivalence;
2. SA^1 decides $\text{CSP}(\mathbf{B})$;
3. BLP decides $\text{CSP}(\mathbf{B})$;
4. \mathbf{B} has symmetric polymorphisms of all arities.

Proof (Sketch). (1) \Leftrightarrow (2) follows from Theorem 5 and (3) \Leftrightarrow (4) from [24]. Hence, it is only necessary to verify (2) \Leftrightarrow (3). We use the following fact which follows from the Sparse Incomparability Lemma [29]: for every instance \mathbf{A} of $\text{CSP}(\mathbf{B})$, there exists a structure \mathbf{A}' with no loops such that $\mathbf{A}' \rightarrow \mathbf{A}$ and $\mathbf{A} \rightarrow \mathbf{B}$ iff $\mathbf{A}' \rightarrow \mathbf{B}$. Now, assume that BLP does not solve $\text{CSP}(\mathbf{B})$. This means that there exists a structure \mathbf{A} not homomorphic to \mathbf{B} and such that $\text{BLP}(\mathbf{A}, \mathbf{B})$ is feasible. Now, let \mathbf{A}' be the structure given by the Sparse Incomparability Lemma. Since $\mathbf{A}' \rightarrow \mathbf{A}$ it follows that $\text{BLP}(\mathbf{A}', \mathbf{B})$ is feasible, and, since \mathbf{A}' has no loops, $\text{SA}^1(\mathbf{A}', \mathbf{B})$ is feasible as well. Since \mathbf{A}' is not homomorphic to \mathbf{B} it follows that SA^1 does not solve $\text{CSP}(\mathbf{B})$. The same argument can be used to show the converse although it is not necessary as it also follows immediately by comparing the inequalities of SA^1 and BLP. ◀

A Applying the SA method to the Homomorphism problem

Here we shall show that the family of relaxations SA^k considered in the present paper is closely interleaved with the system of relaxations obtained by applying the SA method to a natural choice of initial polytope P .

Let \mathbf{A} and \mathbf{B} be σ -structures. We define polytope $P = P(\mathbf{A}, \mathbf{B})$ using a system of inequalities. The variables of the system are $x_{a,b}$ for each $a \in A$ and $b \in B$. Each variable must take a value in the range $[0, 1]$. We remark that by fixing some arbitrary ordering on the variables in $x_{a,b}$ we can represent any assignment on the variables $x_{a,b}$ with a tuple $\mathbf{x} \in \mathbb{R}^n$ with $n = |A| \cdot |B|$. Therefore we shall abuse notation and use $\mathbf{x}_{a,b}$ to refer to the value in \mathbf{x} corresponding to variable $x_{a,b}$.

The variables are subject to the following inequalities.

$$\sum_{b \in B} x_{a,b} = 1 \text{ for every } a \in A, \tag{1}$$

$$\sum_{\mathbf{a} \in \{\mathbf{a}\}} x_{\mathbf{a}, f(\mathbf{a})} \leq |\{\mathbf{a}\}| - 1 \quad \begin{array}{l} \text{for each } R \in \sigma, \mathbf{a} \in R(\mathbf{A}), \\ \text{and } f : \{\mathbf{a}\} \rightarrow B \text{ with } f(\mathbf{a}) \notin R(\mathbf{B}). \end{array} \quad (2)$$

Note that if h is a homomorphism from \mathbf{A} to \mathbf{B} then the assignment setting $x_{\mathbf{a}, h(\mathbf{a})} = 1$ for every $\mathbf{a} \in A$ and the rest of variables to zero is feasible.

Now let $P^k, k \geq 1$ be the sequence of polytopes obtained using the SA method. The next lemma shows that the sequence of relaxations defined by SA^k and P^k are interleaved.

► **Lemma 11.** *Let $k \geq 1$ and let r be the maximum arity of a relation in σ . Then*

1. *If $P^k \neq \emptyset$ and $r \leq k$ then SA^k is feasible.*
2. *If SA^{k+r-1} is feasible then $P^k \neq \emptyset$*

Proof. (1). Assume that $P^k \neq \emptyset$ and let \mathbf{y} be a feasible solution of P_L^k . We shall construct a feasible solution of SA^k . First, set every variable of the form $p_V(f)$ to y_K where $K = \{(a, f(a)) \mid a \in V\}$. We first observe that this assignment satisfies (SA1) and (SA2). Indeed, let $U \subseteq A$ with $|U| < k$, let $f : U \rightarrow B$, and let $I = \{(u, f(u)) : u \in U\}$. Then, multiplying the equality (1) with $a \in A \setminus U$ by $\prod_{i \in I} x_i$ and linearizing we obtain equality (SA2) for U, f , and $V = U \cup \{a\}$. In this way we can obtain all equalities in (SA2) for $|U| + 1 = |V|$. We note here that the rest of equalities in (SA2) along all equalities in (SA1) can be obtained as a linear combination.

Secondly, let us set the rest of variables. For every $(\mathbf{a}, R) \in \mathcal{C}_{\mathbf{A}}$ and $f : \{\mathbf{a}\} \rightarrow B$, set $p_{(\mathbf{a}, R)}(f)$ to be y_K where $K = \{(a, f(a)) \mid a \in \{\mathbf{a}\}\}$ (note that we are using implicitly the fact that $r \leq k$). Then, (SA3) follows directly from (SA2). Finally, it only remains to show that (SA4) is also satisfied. Indeed, for every $f(\mathbf{a}) \notin R(\mathbf{B})$ we obtain equality $p_{(\mathbf{a}, R)}(f) = 0$ if we multiply (2) by the term $\prod_{i \in K}$ and linearize. We want to note that, in fact, (1) also holds under the weaker assumption $r \leq k + 1$, but the proof is slightly more involved.

(2). Assume that SA^{k+r-1} is feasible. We construct a feasible solution \mathbf{y} of P_L^k as follows. For every $K \subseteq A \times B$ which satisfies $K = \{(a, f(a)) \mid a \in U\}$ for some $U \subseteq A$ with $|U| \leq k$ and $f : U \rightarrow B$, we set $y_K := p_U(f)$. Otherwise, we set y_K to zero.

Let us show that this assignment satisfies all inequalities in P_L^k . Let

$$\mathbf{c}^T \mathbf{y} \leq \mathbf{d} \quad (3)$$

be any inequality defining P_L^k . Since (3) is obtained by multiplying an inequality which contains at most r variables by a term of at most $k - 1$ variables, there exists a set $V \subseteq A$ with $|V| \leq r + k - 1$ such that for every variable y_K appearing in (3), V satisfies $K \subseteq V \times B$. Note that, by (SA1), variables $p_V(g), g : V \rightarrow B$ define a probability distribution. For every $g : V \rightarrow B$ in the support of this distribution, consider the assignment \mathbf{x}^g that sets $\mathbf{x}_{v,b}^g = 1$ if $v \in V$ and $b = g(v)$ and $x_{v,b} = 0$ otherwise.

Inequality (3) has been obtained by multiplying an inequality from (1) or (2) by a term and linearizing. We claim that in both cases, the inequality that has generated (3) is satisfied by \mathbf{x}^g . If the inequality generating (3) is $\sum_{b \in B} x_{a,b} = 1$ for some $a \in A$ this follows simply from the fact that $a \in V$. Assume now that (3) has been generated by inequality $\sum_{\mathbf{a} \in \{\mathbf{a}\}} x_{\mathbf{a}, f(\mathbf{a})} \leq |\{\mathbf{a}\}| - 1$. In this case note that $\{\mathbf{a}\} \subseteq V$ and then the claim follows from (SA3) and (SA4). This finalizes the proof of the claim.

Consequently, since \mathbf{x}^g is integral it follows that the assignment \mathbf{y}^g defined as $\mathbf{y}_K^g = \prod_{i \in K} \mathbf{x}_i^g$ satisfies (3). Finally, note that if we set $\alpha^g = p_V(g)$, then for every $K \subseteq V \times B$, \mathbf{y}_K is precisely given by the convex combination $\sum_g \alpha^g \mathbf{y}_K^g$. ◀

B Proof of Lemma 1

► **Lemma 1.** *Let \mathbf{A}, \mathbf{B} be σ -structures. Then $SA^k(\mathbf{A}, \mathbf{B})$ is feasible if and only if $SA^1(\mathbf{A}_k^*, \mathbf{B}_k^*)$ is feasible.*

Proof (Sketch). The proof is purely syntactical although it is convenient to massage first a bit the LP formulations $SA^k(\mathbf{A}, \mathbf{B})$ and $SA^1(\mathbf{A}_k^*, \mathbf{B}_k^*)$. We shall refer to the solutions of $SA^k(\mathbf{A}, \mathbf{B})$ and $SA^1(\mathbf{A}_k^*, \mathbf{B}_k^*)$ by appropriately indexed sets of variables p, q respectively.

- In $SA^k(\mathbf{A}, \mathbf{B})$, it follows from (SA4) that we can safely replace all variables $p_{R(\mathbf{a})}(f)$ with $f(\mathbf{a}) \notin R(\mathbf{B})$ by 0.
- In $SA^1(\mathbf{A}_k^*, \mathbf{B}_k^*)$ we are required a bit more of work. First, for each $j \leq k$ and each $\mathbf{a} \in A^j$, it follows from conditions (SA3) and (SA4) for $T_{j,S}$ ($S \subseteq [j]$) that for every $x \in B_k^*$, $q_{\mathbf{a}}(x)$ must take value 0 unless $x = f(\mathbf{a})$ for some function $f : \{\mathbf{a}\} \rightarrow B$. Hence, in a first stage we set $q_{\mathbf{a}}(x)$ to zero for each $j \leq k$, each $\mathbf{a} \in A^j$ and each x that is not a tuple of the form $f(\mathbf{a})$ for some function $f : \{\mathbf{a}\} \rightarrow B$.

Furthermore, it follows from condition (SA3) for $T_{j,i}$ that $q_{\mathbf{a}}(f(\mathbf{a})) = q_{\mathbf{a}'}(f(\mathbf{a}'))$ for every \mathbf{a}, \mathbf{a}' satisfying $\{\mathbf{a}\} = \{\mathbf{a}'\}$ and every $f : \{\mathbf{a}\} \rightarrow B$. Hence, in a second stage, for each $V \subseteq A$ with $|V| \leq k$ and every $f : V \rightarrow B$ we identify all variables $q_{\mathbf{a}}(f(\mathbf{a}))$ which satisfy $\{\mathbf{a}\} = V$.

Then, consider now the variables of the form $q_{R(\mathbf{a})}(x)$, $x \in B_k^*$. It follows from conditions (SA3) and (SA4) for R_S ($S \subseteq [\text{arity}(R)]$) that $q_{R(\mathbf{a})}(x)$ must be set to 0 unless $x = R(f(\mathbf{a}))$ for some function $f : \{\mathbf{a}\} \rightarrow B$.

The other variables in $SA^1(\mathbf{A}_k^*, \mathbf{B}_k^*)$ are of the form $q_C(f)$ where $C \in \mathcal{C}_{\mathbf{A}_k^*}$. As we shall see they can always safely be identified with some of the other variables. Let us start first with the case in which C is a unary constraint. If $C = T_{j,S}(\mathbf{a})$ or $C = R_S(\mathbf{a})$, then it follows from (SA3) that $q_C(f) = q_{\mathbf{a}}(f(\mathbf{a}))$. Assume now that C is a binary constraint, that is $C = T_{j,i}(\mathbf{a}, \pi_i \mathbf{a})$ or $C = R_i(\mathbf{a}, \pi_i \mathbf{a})$. It follows again from (SA3) that $q_C(f) = q_{\mathbf{a}}(f(\mathbf{a}))$

Now we are ready to prove the lemma. In particular, consider the following one-to-one correspondence between the assignments in $SA^k(\mathbf{A}, \mathbf{B})$ and $SA^1(\mathbf{A}_k^*, \mathbf{B}_k^*)$:

- Every variable $p_V(f)$ in $SA^k(\mathbf{A}, \mathbf{B})$ is assigned as variable $q_{\mathbf{a}}(f(\mathbf{a}))$ in $SA^1(\mathbf{A}_k^*, \mathbf{B}_k^*)$ where \mathbf{a} is any tuple satisfying $\{\mathbf{a}\} = V$.
- Every variable $p_{R(\mathbf{a})}(f)$ in $SA^k(\mathbf{A}, \mathbf{B})$ is assigned as variable $q_{R(\mathbf{a})}(R(f(\mathbf{a})))$ in $SA^1(\mathbf{A}_k^*, \mathbf{B}_k^*)$.

It is not difficult to see that this correspondence preserves feasibility. ◀

C Proof of Lemma 3

► **Lemma 3.** *Let r be the maximum arity among all relations in σ and assume that $r \leq k$. Then for every pair of structures \mathbf{A}, \mathbf{B} the following are equivalent:*

1. $\mathbf{A} \equiv_k \mathbf{B}$
2. $\text{Hom}(\mathbf{Q}; \mathbf{A}) = \text{Hom}(\mathbf{Q}; \mathbf{B})$ for every structure \mathbf{Q} of treewidth $< k$.

From Theorem 2 it follows that for a pair of σ -structures \mathbf{A} and \mathbf{B} , $\mathbf{A}_k^* \equiv_k \mathbf{B}_k^*$ if and only if $\text{Hom}(\mathbf{T}, \mathbf{A}_k^*) = \text{Hom}(\mathbf{T}, \mathbf{B}_k^*)$ for every σ_k^* -ftree \mathbf{T} . So it only remains to prove the following.

▷ **Claim 12.** Assume that $r \leq k$. Then the following are equivalent:

1. $\text{Hom}(\mathbf{Q}, \mathbf{A}) = \text{Hom}(\mathbf{Q}, \mathbf{B})$ for every σ -structure \mathbf{Q} of treewidth $< k$;
2. $\text{Hom}(\mathbf{T}, \mathbf{A}_k^*) = \text{Hom}(\mathbf{T}, \mathbf{B}_k^*)$ for every σ_k^* -ftree \mathbf{T} .

Proof. (1) \Rightarrow (2). Let \mathbf{T} be a σ^* -ftree. It follows immediately that if (1) holds then both \mathbf{A} and \mathbf{B} must have the same number of elements and constraints. It then follows that (2) holds for \mathbf{T} if it consists of a single element and no constraints at all. Consequently we can safely assume that all elements in \mathbf{T} participate in at least one constraint.

In what follows $\mathbf{D}_k^* \in \{\mathbf{A}_k^*, \mathbf{B}_k^*\}$. Let t be any node in T . Since t participates in a constraint it follows that the possible image of t in homomorphism from \mathbf{T} is heavily restricted. In particular, if the image of t according to some homomorphism from \mathbf{T} to \mathbf{D}_k^* is in D^j for some $j \leq k$ then necessarily the image of t in any homomorphism from \mathbf{T} to any structure $\mathbf{C}_k^* \in \{\mathbf{A}_k^*, \mathbf{B}_k^*\}$ must be in C^j . This means that we can safely add constraint $T_{j,\emptyset}(t)$ to \mathbf{T} without altering $\text{Hom}(\mathbf{T}, \mathbf{A}_k^*)$ or $\text{Hom}(\mathbf{T}, \mathbf{B}_k^*)$.

Likewise, if some homomorphism from \mathbf{T} to a structure \mathbf{D}_k^* maps t to a constraint $R(\mathbf{d})$, then likewise we can assume that constraint $R_\emptyset(t)$ belongs to \mathbf{T} .

To complete the proof we shall show that it is always possible to construct from \mathbf{T} a σ -structure \mathbf{Q} of treewidth $< k$ such that $|\text{Hom}(\mathbf{T}, \mathbf{D}_k^*)| = |\text{Hom}(\mathbf{Q}, \mathbf{D})|$. It is convenient to construct \mathbf{Q} in two stages. First, let us construct a σ -structure \mathbf{P} (not necessarily of treewidth $< k$) satisfying that $|\text{Hom}(\mathbf{T}, \mathbf{D}_k^*)| = |\text{Hom}(\mathbf{P}, \mathbf{D})|$. We shall allow to use equalities in \mathbf{P} , i.e., constraints of the form $p_1 = p_2$, indicating that p_1 and p_2 must be assigned to the same element in D .

We shall define \mathbf{P} along with a function α mapping every element t of \mathbf{T} to a j -ary tuple of elements in \mathbf{P} ($j \leq k$) inductively on the number of elements of \mathbf{T} as follows.

Assume (base case) that \mathbf{T} contains a unique element t . As discussed above we can assume that \mathbf{T} contains constraint $T_{j,\emptyset}(t)$ for some $j \leq k$ or $R_\emptyset(t)$ for some $R \in \sigma$. In the first case, we set the universe of \mathbf{P} to contain j new elements p_1, \dots, p_j . Furthermore, for every unary constraint $T_{j,S}(t)$ in \mathbf{T} and every $i, i' \in S$, we include in \mathbf{P} the equality $p_i = p_{i'}$, and we define $\alpha(t) = (p_1, \dots, p_j)$. In the second case, we set the universe of \mathbf{P} to contain $\text{arity}(R)$ new elements $p_1, \dots, p_{\text{arity}(R)}$ and we include in \mathbf{P} the constraint $R(p_1, \dots, p_{\text{arity}(R)})$. Similarly to the previous case, for every unary constraint $R_S(t)$ in \mathbf{T} and every $i, i' \in S$, we include in \mathbf{P} the equality $p_i = p_{i'}$. Finally, we set $\alpha(t) = (p_1, \dots, p_{\text{arity}(R)})$.

Let us consider now the inductive case. Let t_1 and t_2 be nodes that participate in a binary constraint $U(t_1, t_2)$ (recall that U is either $T_{j,\mathbf{i}}$ or $R_{\mathbf{i}}$) in \mathbf{T} . By removing this constraint \mathbf{T} gets divided in two ftrees \mathbf{T}_1 and \mathbf{T}_2 such that \mathbf{T}_1 contains t_1 and \mathbf{T}_2 contains t_2 . Now, assume that \mathbf{P}_i and α_i are already constructed for \mathbf{T}_i , $i = 1, 2$. We are ready to define \mathbf{P} . First, we compute the disjoint union of \mathbf{P}_1 and \mathbf{P}_2 . Then, we add some further equalities depending on constraint $U(t_1, t_2)$. Consider first the case that $U = T_{j_1,\mathbf{i}}$, $\mathbf{i} = (i_1, \dots, i_{j_2}) \in [j_1]^{j_2}$ for some $j_1, j_2 \leq k$ and let $\alpha_i(t_i) = (p_{i_1}^{i_1}, \dots, p_{i_{j_2}}^{i_{j_2}})$, $i = 1, 2$. Then, for every $\ell \leq j_2$ we add the equality $p_\ell^2 = p_\ell^1$. Finally, for every $t \in T$ we define $\alpha(t)$ to be $\alpha_i(t)$ where \mathbf{T}_i contains t . The procedure is identical for $U = R_{\mathbf{i}}$, where we just substitute j_1 by $\text{arity}(R)$. It follows immediately from the definition that $\text{Hom}(\mathbf{P}, \mathbf{D}) = \text{Hom}(\mathbf{T}, \mathbf{D}_k^*)$.

Finally, let us define \mathbf{Q} to be the structure obtained by identifying (i.e., merging into a single element) all elements in \mathbf{P} joined by a chain of equalities. It is immediate that $\text{Hom}(\mathbf{P}, \mathbf{D}) = \text{Hom}(\mathbf{Q}, \mathbf{D})$.

We shall conclude by giving a tree-decomposition (G, β) of \mathbf{Q} of width $< k$. In particular, let G be the tree where the vertex set is precisely the universe of \mathbf{T} and two different nodes are adjacent if both participate in some common constraint in \mathbf{T} and let $\beta(t) = \{\alpha(t)\}$.

(2) \Rightarrow (1). Let \mathbf{Q} be a σ -structure of treewidth $< k$ and let $\mathbf{D} \in \{\mathbf{A}, \mathbf{B}\}$. We note here that we can assume that \mathbf{Q} is connected since if \mathbf{Q} is the disjoint union of structures \mathbf{Q}_1 and \mathbf{Q}_2 then $\text{Hom}(\mathbf{Q}, \mathbf{D}) = \text{Hom}(\mathbf{Q}_1, \mathbf{D}) \cdot \text{Hom}(\mathbf{Q}_2, \mathbf{D})$. We shall show that there exists a σ_k^* -ftree \mathbf{T} such that $\text{Hom}(\mathbf{T}, \mathbf{D}_k^*) = \text{Hom}(\mathbf{Q}, \mathbf{D})$. Let (G, β) be a tree-decomposition of

width at most k of \mathbf{Q} . It is well-known and easy to prove that, since \mathbf{Q} is connected we can always construct (G, β) in such a way that for every pair u, v of adjacent nodes in G , $\beta(u) \subseteq \beta(v)$ or $\beta(v) \subseteq \beta(u)$. Furthermore, it is easy to see that we can further enforce that for every constraint $R(\mathbf{q})$ in \mathbf{Q} there exists a node $v \in G$ such that $\beta(v) = \{\mathbf{q}\}$.

The universe T of \mathbf{T} is $V \cup \mathcal{C}_{\mathbf{Q}}$ where V is the node-set of G . Furthermore \mathbf{T} contains the following constraints.

Let us start with the unary constraints. Let t be an element in \mathbf{T} . If $t = v \in G$ then we include in \mathbf{T} a constraint $T_{j_v, \emptyset}(t)$ where $j_v = |\beta(v)|$. Otherwise, if $t = R(\mathbf{q}) \in \mathcal{C}_{\mathbf{Q}}$ then we include in \mathbf{T} all constraints $R_{\{i, i'\}}(t)$ where $\mathbf{q}[i] = \mathbf{q}[i']$.

Now, let us turn our attention to the binary constraints. Fix some arbitrary ordering on Q and for every $v \in V$ let $\mathbf{q}^v = (q_1^v, \dots, q_{j_v}^v)$ be an array containing the nodes in $\beta(v)$ following this fixed order.

Then, for every edge (u, v) in G include constraint $T_{j_u, \mathbf{i}}(u, v)$ where $\mathbf{i} = (i_1, \dots, i_{j_v})$ is defined as follows. First, we assume without loss of generality that $\beta(v) \subseteq \beta(u)$. Then, for every $\ell \leq j_v$, i_ℓ is defined to be such that $\mathbf{q}^u[i_\ell] = \mathbf{q}^v[\ell]$.

Finally, for every constraint $t = R(\mathbf{q})$ in \mathbf{Q} we pick some element $v \in V$ satisfying $\{\mathbf{q}\} = \beta(v)$ and we add the constraint $R_{\mathbf{i}}(t, v)$ with $\mathbf{i} = (i_1, \dots, i_{j_v})$ where i_ℓ satisfies $\mathbf{q}[i_\ell] = \mathbf{q}^v[\ell]$. It is immediate to see that \mathbf{T} is an ftree and that $\text{Hom}(\mathbf{Q}, \mathbf{D}) = \text{Hom}(\mathbf{T}, \mathbf{D}_k^*) \triangleleft$

A Decidable Equivalence for a Turing-Complete, Distributed Model of Computation

Arnaldo Cesco

Roberto Gorrieri  

Department of Computer Science and Engineering, University of Bologna, Italy

Abstract

Place/Transition Petri nets with inhibitor arcs (PTI nets for short), which are a well-known Turing-complete, distributed model of computation, are equipped with a decidable, behavioral equivalence, called *pti-place bisimilarity*, that conservatively extends place bisimilarity defined over Place/Transition nets (without inhibitor arcs). We prove that *pti-place bisimilarity* is sensible, as it respects the causal semantics of PTI nets.

1 Introduction

Place/Transition Petri nets with inhibitor arcs (PTI nets, for short), originally introduced in [2], are a well-known (see, e.g., [7, 19, 26]), Turing-complete (as proved first by Agerwala in [1]), distributed model of computation, largely exploited, e.g., for modeling systems with priorities [17], for performance evaluation of distributed systems [3] and to provide π -calculus [24, 28] with a net semantics [8].

As finite PTI nets constitute a Turing-complete model of computation, essentially all the properties of interest are undecidable, notably the reachability problem, and so even termination: it is undecidable whether a deadlock marking is reachable from the initial one. Also interleaving bisimulation equivalence is undecidable for finite PTI nets, as it is already undecidable [20] on the subclass of finite P/T nets [27]. Similarly, one can prove that also well-known truly-concurrent behavioral equivalences, such as *fully-concurrent* bisimilarity [6], are undecidable [12] for finite PTI nets. Despite this, we show that it is possible to define a *sensible*, behavioral equivalence which is actually *decidable* on finite PTI nets. This equivalence, we call *pti-place bisimilarity*, is a conservative extension of *place bisimilarity on finite P/T nets*, introduced in [4] as an improvement of *strong bisimulation* [25], (a relation proposed by Olderog in [25] on safe nets which fails to induce an equivalence relation), and recently proved decidable in [16].

Place bisimilarity on finite P/T nets is an equivalence over markings, based on relations over the *finite set of net places*, rather than over the (possibly infinite) set of net markings. This equivalence is very natural and intuitive: as a place can be interpreted as a sequential process type (and each token in this place as an instance of a sequential process of that type), a place bisimulation states which kinds of sequential processes (composing the distributed system represented by the finite P/T net) are to be considered as equivalent. Moreover, this equivalence does respect the causal behavior of P/T nets, as van Glabbeek proved in [29] that it is slightly finer than *structure preserving bisimilarity* [29], in turn slightly finer than *fully-concurrent bisimilarity* [6].

We extend this idea in order to be applicable to PTI nets. Informally, a binary relation R over the set S of places is a *pti-place bisimulation* if for all markings m_1 and m_2 which are *bijectively* related via R (denoted by $(m_1, m_2) \in R^\oplus$, where R^\oplus is called the *additive closure* of R), if m_1 can perform transition t_1 , reaching marking m'_1 , then m_2 can perform a transition t_2 , reaching m'_2 , such that

- the pre-sets of t_1 and t_2 are related by R^\oplus , the label of t_1 and t_2 is the same, the post-sets of t_1 and t_2 are related by R^\oplus , and also $(m'_1, m'_2) \in R^\oplus$, as required by a place bisimulation [4, 16], but additionally it is required that
- whenever $(s, s') \in R$, s belongs to the inhibiting set of t_1 if and only if s' belongs to the inhibiting set of t_2 ;

and symmetrically if m_2 moves first. Two markings m_1 and m_2 are *pti-place bisimilar*, denoted by $m_1 \sim_p m_2$, if a pti-place bisimulation R exists such that $(m_1, m_2) \in R^\oplus$.

We prove that pti-place bisimilarity is an equivalence, but it is not coinductive as the union of pti-place bisimulations may be not a pti-place bisimulation; so, in general, there is not a largest pti-place bisimulation, rather many maximal pti-place bisimulations. In fact, pti-place bisimilarity is the relation on markings given by the union of the additive closure of each maximal pti-place bisimulation. We also prove that \sim_p is sensible, as it respects the causal semantics of PTI nets. As a matter of fact, following the approach in [9, 10], we define a novel, process-oriented, bisimulation-based, behavioral semantics for PTI nets, called *causal-net bisimilarity*, and we prove that this is slightly coarser than pti-place bisimilarity.

The other main contribution of this paper is to show that \sim_p is decidable for finite PTI nets. As a place relation $R \subseteq S \times S$ is finite if the set S of places is finite, there are finitely many place relations for a finite net. We can list all these place relations, say R_1, R_2, \dots, R_n . It is possible to decide whether R_i is a pti-place bisimulation by checking two *finite* conditions over a *finite* number of marking pairs: this is a non-obvious observation, as a pti-place bisimulation requires that the pti-place bisimulation conditions hold for the infinitely many pairs (m_1, m_2) belonging to R_i^\oplus . Hence, to decide whether $m_1 \sim_p m_2$, it is enough to check, for $i = 1, \dots, n$, whether R_i is a pti-place bisimulation and, in such a case, whether $(m_1, m_2) \in R_i^\oplus$.

The paper is organized as follows. Section 2 recalls the basic definitions about PTI nets, including their causal semantics. Section 3 deals with pti-place bisimilarity, shows that it is an equivalence relation, that it is not coinductive, and that it is slightly finer than causal-net bisimilarity. Section 4 shows that \sim_p is decidable. Finally, Section 5 discusses some related literature and future research.

2 Basic definitions about P/T nets and PTI nets

► **Definition 1 (Multiset).** Let \mathbb{N} be the set of natural numbers. Given a finite set S , a multiset over S is a function $m : S \rightarrow \mathbb{N}$. The support set $\text{dom}(m)$ of m is $\{s \in S \mid m(s) \neq 0\}$. The set of all multisets over S , denoted by $\mathcal{M}(S)$, is ranged over by m . We write $s \in m$ if $m(s) > 0$. The multiplicity of s in m is given by the number $m(s)$. The size of m , denoted by $|m|$, is the number $\sum_{s \in S} m(s)$, i.e., the total number of its elements. A multiset m such that $\text{dom}(m) = \emptyset$ is called empty and is denoted by θ . We write $m \subseteq m'$ if $m(s) \leq m'(s)$ for all $s \in S$. Multiset union $_ \oplus _$ is defined as follows: $(m \oplus m')(s) = m(s) + m'(s)$. Multiset difference $_ \ominus _$ is defined as follows: $(m_1 \ominus m_2)(s) = \max\{m_1(s) - m_2(s), 0\}$. The scalar product of a number j with m is the multiset $j \cdot m$ defined as $(j \cdot m)(s) = j \cdot (m(s))$. By s_i we also denote the multiset with s_i as its only element. Hence, a multiset m over $S = \{s_1, \dots, s_n\}$ can be represented as $k_1 \cdot s_1 \oplus k_2 \cdot s_2 \oplus \dots \oplus k_n \cdot s_n$, where $k_j = m(s_j) \geq 0$ for $j = 1, \dots, n$.

► **Definition 2** (Place/Transition Petri net). A labeled, finite Place/Transition Petri net (P/T net for short) is a tuple $N = (S, A, T)$, where

- S is the finite set of places, ranged over by s (possibly indexed),
- A is the finite set of labels, ranged over by ℓ (possibly indexed), and
- $T \subseteq (\mathcal{M}(S) \setminus \{\emptyset\}) \times A \times (\mathcal{M}(S) \setminus \{\emptyset\})$ is the finite set of transitions, ranged over by t (possibly indexed).

Given a transition $t = (m, \ell, m')$, we use the notation:

- $\bullet t$ to denote its pre-set m (which cannot be empty) of tokens to be consumed;
- $l(t)$ for its label ℓ , and
- t^\bullet to denote its post-set m' (which cannot be an empty multiset) of tokens to be produced.

Hence, transition t can be also represented as $\bullet t \xrightarrow{l(t)} t^\bullet$. We also define the flow function $\text{flow} : (S \times T) \cup (T \times S) \rightarrow \mathbb{N}$ as follows: for all $s \in S$, for all $t \in T$, $\text{flow}(s, t) = \bullet t(s)$ and $\text{flow}(t, s) = t^\bullet(s)$. We will use F to denote the flow relation $\{(x, y) \in (S \times T) \cup (T \times S) \mid \text{flow}(x, y) > 0\}$. Finally, we define pre-sets and post-sets also for places as follows: $\bullet s = \{t \in T \mid s \in \bullet t\}$ and $s^\bullet = \{t \in T \mid s \in t^\bullet\}$. Note that while the pre-set (post-set) of a transition is, in general, a multiset, the pre-set (post-set) of a place is a set.

► **Definition 3** (Place/Transition net with inhibitor arcs). A finite Place/Transition net with inhibitor arcs (PTI net for short) is a tuple $N = (S, A, T, I)$, where

- (S, A, T) is a finite P/T net;
- $I \subseteq S \times T$ is the inhibiting relation.

Given a transition $t \in T$, we denote by ${}^\circ t$ its inhibiting set $\{s \in S \mid (s, t) \in I\}$ of places to be tested for absence of tokens. Hence, a transition t can be also represented as $(\bullet t, {}^\circ t) \xrightarrow{l(t)} t^\bullet$.

We use the standard graphical convention for Petri nets. In particular, a pair (s, t) in the inhibiting relation I is graphically represented by an arc from s to t ending with a small circle on the transition side.

► **Definition 4** (Marking, PTI net system). A PTI net system $N(m_0)$ is a tuple (S, A, T, I, m_0) , where (S, A, T, I) is a PTI net and m_0 is a multiset over S , called the initial marking. We also say that $N(m_0)$ is a marked net.

► **Definition 5** (Token game). A transition t is enabled at m , denoted $m[t]$, if $\bullet t \subseteq m$ and ${}^\circ t \cap \text{dom}(m) = \emptyset$. The execution, or firing, of t enabled at m produces the marking $m' = (m \ominus \bullet t) \oplus t^\bullet$, written $m[t]m'$.

► **Definition 6** (Firing sequence, reachable marking, safe net). A firing sequence starting at m is defined inductively as follows:

- $m[\epsilon]m$ is a firing sequence (where ϵ denotes an empty sequence of transitions) and
- if $m[\sigma]m'$ is a firing sequence and $m'[t]m''$, then $m[\sigma t]m''$ is a firing sequence.

The set of reachable markings from m is $[m] = \{m' \mid \exists \sigma. m[\sigma]m'\}$. A PTI system $N = (S, A, T, I, m_0)$ is safe if for each marking $m \in [m_0]$, we have that $m(s) \leq 1$ for all $s \in S$.

2.1 Causal semantics for P/T nets and PTI nets

We outline some definitions about the causal semantics of P/T nets, adapted from the literature (cf., e.g., [6, 29, 13, 25]).

► **Definition 7** (Acyclic net). A P/T net $N = (S, A, T)$ is acyclic if its flow relation F is acyclic (i.e., $\nexists x$ such that $x F^+ x$, where F^+ is the transitive closure of F).

The concurrent semantics of a marked P/T net is defined by a class of particular acyclic safe nets, where places are not branched (hence they represent a single run) and all arcs have weight 1. This kind of net is called *causal net*. We use the name C (possibly indexed) to denote a causal net, the set B to denote its places (called *conditions*), the set E to denote its transitions (called *events*), and L to denote its labels.

► **Definition 8** (Causal P/T net). *A causal net is a finite marked net $C(m_0) = (B, L, E, m_0)$ satisfying the following conditions:*

1. C is acyclic;
 2. $\forall b \in B \quad |\bullet b| \leq 1 \wedge |b^\bullet| \leq 1$ (i.e., the places are not branched);
 3. $\forall b \in B \quad m_0(b) = \begin{cases} 1 & \text{if } \bullet b = \emptyset \\ 0 & \text{otherwise;} \end{cases}$
 4. $\forall e \in E \quad \bullet e(b) \leq 1 \wedge e^\bullet(b) \leq 1$ for all $b \in B$ (i.e., all the arcs have weight 1).
- We denote by $\text{Min}(C)$ the set m_0 , and by $\text{Max}(C)$ the set $\{b \in B \mid b^\bullet = \emptyset\}$.

Note that any reachable marking of a causal net is a set, i.e., this net is *safe*; in fact, the initial marking is a set and, assuming by induction that a reachable marking m is a set and enables e , i.e., $m[e]m'$, then also $m' = (m \ominus \bullet e) \oplus e^\bullet$ is a set, as the net is acyclic and because of the condition on the shape of the post-set of e (weights can only be 1).

As the initial marking of a causal P/T net is fixed by its shape (according to item 3 of Definition 8), in the following, in order to make the notation lighter, we often omit the indication of the initial marking (also in their graphical representation), so that the causal net $C(m_0)$ is denoted by C .

► **Definition 9** (Moves of a causal P/T net). *Given two causal nets $C = (B, L, E, m_0)$ and $C' = (B', L, E', m_0)$, we say that C moves in one step to C' through e , denoted by $C[e]C'$, if $\bullet e \subseteq \text{Max}(C)$, $E' = E \cup \{e\}$ and $B' = B \cup e^\bullet$.*

► **Definition 10** (Folding and Process). *A folding from a causal P/T net $C = (B, L, E, m_0)$ into a P/T net system $N(m_0) = (S, A, T, m_0)$ is a function $\rho : B \cup E \rightarrow S \cup T$, which is type-preserving, i.e., such that $\rho(B) \subseteq S$ and $\rho(E) \subseteq T$, satisfying the following:*

- $L = A$ and $l(e) = l(\rho(e))$ for all $e \in E$;
- $\rho(m_0) = m_0$, i.e., $m_0(s) = |\rho^{-1}(s) \cap m_0|$;
- $\forall e \in E, \rho(\bullet e) = \bullet \rho(e)$, i.e., $\rho(\bullet e)(s) = |\rho^{-1}(s) \cap \bullet e|$ for all $s \in S$;
- $\forall e \in E, \rho(e^\bullet) = \rho(e)^\bullet$, i.e., $\rho(e^\bullet)(s) = |\rho^{-1}(s) \cap e^\bullet|$ for all $s \in S$.

A pair (C, ρ) , where C is a causal net and ρ a folding from C to a net system $N(m_0)$, is a process of $N(m_0)$.

► **Definition 11** (Moves of a P/T process). *Let $N(m_0) = (S, A, T, m_0)$ be a net system and let (C_i, ρ_i) , for $i = 1, 2$, be two processes of $N(m_0)$. We say that (C_1, ρ_1) moves in one step to (C_2, ρ_2) through e , denoted by $(C_1, \rho_1) \xrightarrow{e} (C_2, \rho_2)$, if $C_1[e]C_2$ and $\rho_1 \subseteq \rho_2$.*

Following [9, 10], we define here a possible causal semantics for PTI nets. In order to maintain the pleasant property that a process univocally determines the causal dependencies among its events, it is not enough to just enrich causal P/T nets with inhibitor arcs. Indeed, the reason why a condition is empty may influence the causal relation of events. To solve the problem, in [9, 10] inhibitor arcs are partitioned into two sets: *before* inhibitor arcs and *after* inhibitor arcs. If a condition is connected to an event by a before inhibitor arc, the event fires because the condition has not held yet; if they are connected by an after inhibitor arc, the event fires because the condition does not hold anymore.

► **Definition 12** (Causal PTI net). A causal PTI net is a tuple $C(m_0) = (B, L, E, Y^{be}, Y^{af}, m_0)$ satisfying the following conditions, denoting the flow relation of C by F :

1. (B, L, E, m_0) is a causal P/T net;
2. $(B, L, E, Y^{be} \cup Y^{af}, m_0)$ is a marked PTI net;
3. before and after requirements are met, i.e.
 - (a) If $b Y^{be} e$, then there exists $e' \in E$ such that $e' F b$, and
 - (b) If $b Y^{af} e$, then there exists $e' \in E$ such that $b F e'$;
4. relation $F \cup \prec_{af} \cup \prec_{be}$ is acyclic, where $\prec_{af} = F^{-1} \circ Y^{af}$ and $\prec_{be} = (Y^{be})^{-1} \circ F^{-1}$.

We denote by $Min(C)$ the set m_0 , and by $Max(C)$ the set $\{b \in B \mid b^\bullet = \emptyset\}$.

Relation $\prec_{af} \subseteq E \times E$ states that $e \prec_{af} e'$ if e consumes the token in a place b inhibiting e' : this is clearly a causal dependency. Instead, relation $\prec_{be} \subseteq E \times E$ states that $e \prec_{be} e'$ if e' produces a token in a place b inhibiting e : this is clearly a temporal precedence, because the two events can be causally independent, yet they cannot occur in any order, as if e' occurs, then e is disabled.

► **Definition 13** (Folding and PTI process). A folding from a causal PTI net $C = (B, L, E, Y^{be}, Y^{af}, m_0)$ into a PTI net system $N(m_0) = (S, A, T, I, m_0)$ is a function $\rho : B \cup E \rightarrow S \cup T$, which is type-preserving, i.e., such that $\rho(B) \subseteq S$ and $\rho(E) \subseteq T$, satisfying the following:

- ρ is a P/T folding from (B, L, E, m_0) into (S, A, T, m_0) ;
- for all $s \in S$ and $e \in E$, if $(s, \rho(e)) \in I$ then for all $b \in B$ such that $\rho(b) = s$, it holds $(b, e) \in Y^{be} \cup Y^{af} \cup F^{-1}$, and
for all $b \in B$ and $e \in E$, if $(b, e) \in Y^{be} \cup Y^{af}$ then $(\rho(b), \rho(e)) \in I$.

A pair (C, ρ) , where C is a causal PTI net and ρ a folding from C to a PTI net system $N(m_0)$, is a PTI process of $N(m_0)$.

Each inhibitor arc in the causal net has a corresponding inhibitor arc in the net system. The only case where a condition b is not connected by an inhibitor arc to an event e is when b is in the post-set of e : as b starts to hold only after e occurs, the only possibility is to put a before arc. This would make the relation \prec_{be} reflexive, invalidating item 4 of Definition 12. However, since b is in the post-set of e , we are sure that e happens before b is fulfilled, hence making useless the presence of a before inhibitor arc. For this reason, with the requirement $(b, e) \in Y^{be} \cup Y^{af} \cup F^{-1}$, we ask for the presence of an inhibitor arc only if there exists no flow from e to b .

► **Definition 14** (Moves of a PTI process). Let $N(m_0) = (S, A, T, I, m_0)$ be a PTI net system and let (C_i, ρ_i) , for $i = 1, 2$, be two PTI processes of $N(m_0)$, where $C_i = (B_i, L, E_i, Y_i^{be}, Y_i^{af}, m_0)$. We say that (C_1, ρ_1) moves in one step to (C_2, ρ_2) through e , denoted by $(C_1, \rho_1) \xrightarrow{e} (C_2, \rho_2)$, if the following hold:

- $e \subseteq Max(C_1)$, $E_2 = E_1 \cup \{e\}$, $B_2 = B_1 \cup e^\bullet$, $\rho_1 \subseteq \rho_2$, i.e. the P/T process of (C_1, ρ_1) moves in one step through e to the P/T process of (C_2, ρ_2) .
- Given two relations \mathcal{B} and \mathcal{A} , defined as
 - $\forall b \in e^\bullet, \forall e' \in E_1$ we have $b \mathcal{B} e'$ if and only if $(\rho_2(b), \rho_2(e')) \in I$,
 - $\forall b \in B_2$ such that $b^\bullet \neq \emptyset$, we have $b \mathcal{A} e$ if and only if $(\rho_2(b), \rho_2(e)) \in I$,
 we have $\{b \in B_2 \mid b \mathcal{A} e\} \cap Max(C_1) = \emptyset$.
- Finally, $Y_2^{be} = Y_1^{be} \cup \mathcal{B}$ and $Y_2^{af} = Y_1^{af} \cup \mathcal{A}$.

The item $\{b \in B_2 \mid b \mathcal{A} e\} \cap Max(C_1) = \emptyset$ models the fact that a transition can fire only if all its inhibiting places are free. Indeed, an event can fire only if its (so far known) inhibiting conditions are not maximal. Note that, by construction, before arcs can connect

■ **Figure 1** A marked PTI net and two PTI causal nets corresponding to its two maximal processes.

only new inhibiting conditions to past events and in particular we do not allow before arcs connecting a condition in the post-set of a newly added event e with the event e itself. Moreover, after arcs can only connect old inhibiting conditions to the new event e and since $\{b \in B_2 \mid b \mathcal{A} e\} \cap \text{Max}(C_1) = \emptyset$, the old inhibiting conditions cannot be in the pre-set of the newly added event e . Therefore, both relations \prec_2^{be} and \prec_2^{af} are acyclic, and since F_2 is acyclic too, (C_2, ρ_2) is truly a process of $N(m_0)$.

► **Example 15.** Consider the three nets in Figure 1, where we use the graphical convention that *before* inhibitor arcs and *after* inhibitor arcs are represented by lines between a condition and an event: the former labeled by b , the latter labeled by a . The initial marking of N is $m_0 = s_1 \oplus s_3$. The shape of a process generated by $N(m_0)$ may depend on the order of transitions in a given transition sequence. As a matter of fact, transition sequences containing the same transitions but in a different order may generate different processes, e.g. C_1 and C_2 . Indeed, C_1 represents the transition sequence $t_1 t_3 t_2$, while C_2 represents the transition sequence $t_2 t_1 t_3$. In the former case, t_1 fires first, so that t_2 can only fire after the inhibiting token in s_2 has been cleaned up by transition t_3 : therefore the causal net has an after arc between b_2 and e_2 . In the latter case, t_2 is the first transition to fire and there are no tokens in the inhibiting place b_2 , therefore the causal net has a before arc between b_2 and e_2 . Note that the underlying causal P/T net of these two processes is the same, but before and after inhibitor arcs are different.

We are now ready to introduce a novel behavioral relation for PTI nets, namely causal-net bisimulation, which is an interesting relation in its own right, as the induced equivalence, namely *causal-net bisimilarity*, on P/T nets coincides with *structure-preserving bisimilarity* [29], and so it is slightly finer than *fully-concurrent bisimilarity* [6]. However, since we conjecture that causal-net bisimilarity is undecidable (already on finite P/T nets), we will use this behavioral relation only for comparison with pti-place bisimilarity, showing the the latter is a finer, but decidable, approximation of the former.

► **Definition 16 (Causal-net bisimulation).** Let $N = (S, A, T, I)$ be a PTI net. A causal-net bisimulation is a relation R , composed of triples of the form (ρ_1, C, ρ_2) , where, for $i = 1, 2$, (C, ρ_i) is a process of $N(m_{0i})$ for some m_{0i} , such that if $(\rho_1, C, \rho_2) \in R$ then

- i) $\forall t_1, C', \rho'_1$ such that $(C, \rho_1) \xrightarrow{e} (C', \rho'_1)$, where $\rho'_1(e) = t_1$, $\exists t_2, \rho'_2$ such that $(C, \rho_2) \xrightarrow{e} (C', \rho'_2)$, where $\rho'_2(e) = t_2$, and $(\rho'_1, C', \rho'_2) \in R$;
- ii) symmetrically, $\forall t_2, C', \rho'_2$ such that $(C, \rho_2) \xrightarrow{e} (C', \rho'_2)$, where $\rho'_2(e) = t_2$, $\exists t_1, \rho'_1$ such that $(C, \rho_1) \xrightarrow{e} (C', \rho'_1)$, where $\rho'_1(e) = t_1$, and $(\rho'_1, C', \rho'_2) \in R$.

Two markings m_1 and m_2 of N are *cn-bisimilar*, denoted by $m_1 \sim_{cn} m_2$, if there exists a causal-net bisimulation R containing a triple $(\rho_1^0, C^0, \rho_2^0)$, where C^0 contains no events and $\rho_i^0(\text{Min}(C^0)) = \rho_i^0(\text{Max}(C^0)) = m_i$ for $i = 1, 2$.

If $m_1 \sim_{cn} m_2$, then these two markings have the same causal PTI nets, so that the executions originating from the two markings have the same causal dependencies (determined by F and \prec_{af}) and the same temporal dependencies (determined by \prec_{be}). Causal-net bisimilarity \sim_{cn} is an equivalence relation (see the preliminary version of this paper [11]).

3 Pti-place bisimilarity

We now present pti-place bisimilarity, which conservatively extends *place bisimilarity* [4, 16] to the case of PTI nets. First, an auxiliary definition.

3.1 Additive closure and its properties

► **Definition 17** (Additive closure). *Given a PTI net $N = (S, A, T, I)$ and a place relation $R \subseteq S \times S$, we define a marking relation $R^\oplus \subseteq \mathcal{M}(S) \times \mathcal{M}(S)$, called the additive closure of R , as the least relation induced by the following axiom and rule.*

$$\frac{}{(\theta, \theta) \in R^\oplus} \quad \frac{(s_1, s_2) \in R \quad (m_1, m_2) \in R^\oplus}{(s_1 \oplus m_1, s_2 \oplus m_2) \in R^\oplus}$$

Note that two markings are related by R^\oplus only if they have the same size; in fact, the axiom states that the empty marking is related to itself, while the rule, assuming by induction that m_1 and m_2 have the same size, ensures that $s_1 \oplus m_1$ and $s_2 \oplus m_2$ have the same size.

► **Proposition 18.** *For each relation $R \subseteq S \times S$, if $(m_1, m_2) \in R^\oplus$, then $|m_1| = |m_2|$.*

Note also that the membership $(m_1, m_2) \in R^\oplus$ may be proved in several different ways, depending on the chosen order of the elements of the two markings and on the definition of R . For instance, if $R = \{(s_1, s_3), (s_1, s_4), (s_2, s_3), (s_2, s_4)\}$, then $(s_1 \oplus s_2, s_3 \oplus s_4) \in R^\oplus$ can be proved by means of the pairs (s_1, s_3) and (s_2, s_4) , as well as by means of (s_1, s_4) , (s_2, s_3) . An alternative way to define that two markings m_1 and m_2 are related by R^\oplus is to state that m_1 can be represented as $s_1 \oplus s_2 \oplus \dots \oplus s_k$, m_2 can be represented as $s'_1 \oplus s'_2 \oplus \dots \oplus s'_k$ and $(s_i, s'_i) \in R$ for $i = 1, \dots, k$.

► **Proposition 19** ([14]). *For each place relation $R \subseteq S \times S$, the following hold:*

1. *If R is an equivalence relation, then R^\oplus is an equivalence relation.*
2. *If $R_1 \subseteq R_2$, then $R_1^\oplus \subseteq R_2^\oplus$, i.e., the additive closure is monotone.*
3. *If $(m_1, m_2) \in R^\oplus$ and $(m'_1, m'_2) \in R^\oplus$, then $(m_1 \oplus m'_1, m_2 \oplus m'_2) \in R^\oplus$, i.e., the additive closure is additive.*
4. *If R is an equivalence relation and, moreover, $(m_1 \oplus m'_1, m_2 \oplus m'_2) \in R^\oplus$ and $(m_1, m_2) \in R^\oplus$, then $(m'_1, m'_2) \in R^\oplus$, i.e., the additive closure of an equivalence place relation is subtractive.*

When R is an equivalence relation, it is rather easy to check whether two markings are related by R^\oplus . An algorithm, described in [14], establishes whether an R -preserving bijection exists between the two markings m_1 and m_2 of equal size k in $O(k^2)$ time. Another algorithm, described in [22, 15], checks whether $(m_1, m_2) \in R^\oplus$ in $O(n)$ time, where n is the size of S . However, these performant algorithms heavily rely on the fact that R is an equivalence relation, hence also subtractive (case 4 of Proposition 19). If R is not an equivalence relation, which is typical for place bisimulations, the naive algorithm for checking whether $(m_1, m_2) \in R^\oplus$ would simply consider m_1 represented as $s_1 \oplus s_2 \oplus \dots \oplus s_k$, and then would scan all the possible permutations of m_2 , each represented as $s'_1 \oplus s'_2 \oplus \dots \oplus s'_k$, to check that $(s_i, s'_i) \in R$ for $i = 1, \dots, k$. Of course, this naive algorithm has worst-case complexity $O(k!)$.

► **Example 20.** Consider $R = \{(s_1, s_3), (s_1, s_4), (s_2, s_4)\}$, which is not an equivalence relation. Suppose we want to check that $(s_1 \oplus s_2, s_4 \oplus s_3) \in R^\oplus$. If we start by matching $(s_1, s_4) \in R$, then we fail because the residual (s_2, s_3) is not in R . However, if we permute the second marking to $s_3 \oplus s_4$, then we succeed because the required pairs (s_1, s_3) and (s_2, s_4) are both in R .

Nonetheless, the problem of checking whether $(m_1, m_2) \in R^\oplus$ has polynomial time complexity because it can be considered as an instance of the problem of finding a perfect matching in a bipartite graph, where the nodes of the two partitions are the tokens in the two markings, and the edges are defined by the relation R . In fact, the definition of the bipartite graph takes $O(k^2)$ time (where $k = |m_1| = |m_2|$) and, then, the Hopcroft-Karp-Karzanov algorithm [18] for computing the maximum matching has worst-case time complexity $O(h\sqrt{k})$, where h is the number of the edges in the bipartite graph ($h \leq k^2$) and to check whether the maximum matching is perfect can be done simply by checking that the size of the matching equals the number of nodes in each partition, i.e., k . Hence, in evaluating the complexity of the algorithm in Section 4, we assume that the complexity of checking whether $(m_1, m_2) \in R^\oplus$ is in $O(k^2\sqrt{k})$.

A related problem is that of computing, given a marking m_1 of size k , the set of all the markings m_2 such that $(m_1, m_2) \in R^\oplus$. This problem can be solved with a worst-case time complexity of $O(n^k)$ because each of the k tokens in m_1 can be related via R to n places at most.

Now we list some necessary, and less obvious, properties of additively closed place relations that will be useful in the following.

► **Proposition 21** ([14]). *For each family of place relations $R_i \subseteq S \times S$, the following hold:*

1. $\emptyset^\oplus = \{(\emptyset, \emptyset)\}$, i.e., the additive closure of the empty place relation yields a singleton marking relation, relating the empty marking to itself.
2. $(\mathcal{I}_S)^\oplus = \mathcal{I}_M$, i.e., the additive closure of the identity on places $\mathcal{I}_S = \{(s, s) \mid s \in S\}$ yields the identity relation on markings $\mathcal{I}_M = \{(m, m) \mid m \in \mathcal{M}(S)\}$.
3. $(R^\oplus)^{-1} = (R^{-1})^\oplus$, i.e., the inverse of an additively closed relation R equals the additive closure of its inverse R^{-1} .
4. $(R_1 \circ R_2)^\oplus = (R_1^\oplus) \circ (R_2^\oplus)$, i.e., the additive closure of the composition of two place relations equals the compositions of their additive closures.

3.2 Pti-place bisimulation and its properties

We are now ready to introduce pti-place bisimulation, which is a non-interleaving behavioral relation defined over the net places. Note that for P/T nets, place bisimulation [4, 16] and pti-place bisimulation coincide because $I = \emptyset$.

► **Definition 22** (Pti-place bisimulation). *Let $N = (S, A, T, I)$ be a PTI net. A pti-place bisimulation is a relation $R \subseteq S \times S$ such that if $(m_1, m_2) \in R^\oplus$ then*

1. $\forall t_1$ such that $m_1[t_1]m'_1$, $\exists t_2$ such that $m_2[t_2]m'_2$ and
 - (a) $(\bullet t_1, \bullet t_2) \in R^\oplus$, $(t_1^\bullet, t_2^\bullet) \in R^\oplus$, $l(t_1) = l(t_2)$, and $(m_1 \ominus \bullet t_1, m_1 \ominus \bullet t_2) \in R^\oplus$,
 - (b) $\forall s, s' \in S. (s, s') \in R \Rightarrow (s \in \circ t_1 \Leftrightarrow s' \in \circ t_2)$.
2. $\forall t_2$ such that $m_2[t_2]m'_2$, $\exists t_1$ such that $m_1[t_1]m'_1$ and
 - (a) $(\bullet t_1, \bullet t_2) \in R^\oplus$, $(t_1^\bullet, t_2^\bullet) \in R^\oplus$, $l(t_1) = l(t_2)$, and $(m_1 \ominus \bullet t_1, m_1 \ominus \bullet t_2) \in R^\oplus$,
 - (b) $\forall s, s' \in S. (s, s') \in R \Rightarrow (s \in \circ t_1 \Leftrightarrow s' \in \circ t_2)$.

Two markings m_1 and m_2 are pti-place bisimilar, denoted by $m_1 \sim_p m_2$, if there exists a pti-place bisimulation R such that $(m_1, m_2) \in R^\oplus$.

Note that, by additivity of R^\oplus (cf. Proposition 19), from $(m_1 \ominus \bullet t_1, m_2 \ominus \bullet t_2) \in R^\oplus$ and $(t_1^\bullet, t_2^\bullet) \in R^\oplus$ we derive $(m_1', m_2') \in R^\oplus$, which is the condition required in the original definition of place bisimulation in [4]. Our slightly stronger formulation is more adequate for the proof of Theorem 27.

Conditions 1(b) and 2(b) make sure that the relation R respects the inhibiting behavior of places. Indeed, an inhibiting place for one of the two transitions cannot be related via R to a non-inhibiting place for the other transition. These conditions might appear rather restrictive, and one may wonder whether they can be weakened or omitted altogether. However, their presence is strictly necessary in the crucial step of the proof of Lemma 29. Moreover, these conditions are also essential for proving Theorem 27.

► **Example 23.** Consider the PTI net N_1 in Figure 2. Not only the loop labeled by b on the left is unwound on the right, but also the a -labeled transition on the left is replicated three times on the right. The relation

$$R = \{(s_0, s_5), (s_1, s_{11}), (s_2, s_4), (s_2, s_7), (s_3, s_6), (s_3, s_8), (s_3, s_9), (s_3, s_{10})\}$$

is a pti-place bisimulation and so, e.g., $2 \cdot s_2 \oplus s_3 \sim_p s_4 \oplus s_7 \oplus s_9$.

Now consider the PTI net N_2 in Figure 2. In this case, the b -labeled transition on the left can be matched by the b -labeled transition on the right, even if their inhibiting set differ in size, because both (s_1, s_1') and (s_3, s_1') are in the following bisimulation. Indeed, the relation

$$R' = \{(s_1, s_1'), (s_2, s_2'), (s_3, s_1'), (s_4, s_4'), (s_5, s_4'), (s_6, s_4')\}$$

is a pti-place bisimulation and so, e.g., $s_1 \oplus s_3 \oplus 2 \cdot s_2 \oplus s_5 \sim_p 2 \cdot s_1' \oplus 2 \cdot s_2' \oplus s_4'$.

► **Example 24.** Consider the PTI net in Figure 3, depicting two models of unbounded producer-consumer with priority.

In the left part, denoted as *UPAC* for readability, the producer p can generate two products of type a and b and stock them in w_a and w_b (for “warehouse”) respectively. Transitions o_a and o_b model the order of a client c from the warehouse, which may then be shipped (place s) and delivered (transition d). Product a has priority both in the production and ordering phases, and this is modelled by two inhibiting arcs between w_a and b and o_b . Roughly speaking, if there is an a in the warehouse, then no b can be produced or ordered. Moreover, only one product of type a can be stored in either w_a or w_a' , as the inhibiting arcs between a warehouse for a and the other a -transition do not allow to perform the latter until the former has been freed by the execution of transition o_a .

In the right part, denoted as *UPBC*, we duplicate the production and ordering phases of product b , and remove one of the two lines of product a . The behavior of the system remains the same, and this is proved by the pti-place bisimulation

$$R = \{(p, \bar{p}), (w_a, \bar{w}_a), (w_a', \bar{w}_a), (w_b, \bar{w}_b), (w_b, \bar{w}_b'), (s, \bar{s}), (c, \bar{c})\}.$$

We now prove that \sim_p is an equivalence relation.

► **Proposition 25.** *For each PTI net $N = (S, A, T, I)$, relation $\sim_p \subseteq \mathcal{M}(S) \times \mathcal{M}(S)$ is an equivalence relation.*

Proof. Direct consequence of the fact that for each PTI net $N = (S, A, T, I)$, the following hold:

1. The identity relation $\mathcal{I}_S = \{(s, s) \mid s \in S\}$ is a pti-place bisimulation;
2. the inverse relation $R^{-1} = \{(s', s) \mid (s, s') \in R\}$ of a pti-place bisimulation R is a pti-place bisimulation;

28:10 A Decidable Equivalence

■ **Figure 2** Two PTI nets, whose transitions are labeled either by a or by b .

3. the relational composition $R_1 \circ R_2 = \{(s, s'') \mid \exists s'. (s, s') \in R_1 \wedge (s', s'') \in R_2\}$ of two pti-place bisimulations R_1 and R_2 is a pti-place bisimulation.

See Appendix A.1 for details. ◀

By Definition 22, pti-place bisimilarity can be defined in the following way:

$$\sim_p = \bigcup \{R^\oplus \mid R \text{ is a pti-place bisimulation}\}.$$

By monotonicity of the additive closure (Proposition 19(2)), if $R_1 \subseteq R_2$, then $R_1^\oplus \subseteq R_2^\oplus$.

Hence, we can restrict our attention to maximal pti-place bisimulations only:

$$\sim_p = \bigcup \{R^\oplus \mid R \text{ is a maximal pti-place bisimulation}\}.$$

However, it is not true that

$$\sim_p = \left(\bigcup \{R \mid R \text{ is a maximal pti-place bisimulation}\} \right)^\oplus$$

because the union of pti-place bisimulations may be not a pti-place bisimulation (as already observed for place bisimulation in [4, 16]), so that its definition is not coinductive.

► **Example 26.** Consider the net in Figure 4, whose transitions are $t_1 = (s_2, s_3) \xrightarrow{a} s_1$, $t_2 = (s_2 \oplus s_3, \theta) \xrightarrow{a} s_5$ and $t_3 = (s_3, s_2) \xrightarrow{a} s_4$. Clearly, R_1 and R_2 , defined as follows, are both maximal pti-place bisimulations.

$$R_1 = \{(s_2, s_2), (s_3, s_3)\} \cup (\{s_1, s_4, s_5\} \times \{s_1, s_4, s_5\})$$

$$R_2 = \{(s_2, s_3), (s_3, s_2)\} \cup (\{s_1, s_4, s_5\} \times \{s_1, s_4, s_5\})$$

■ **Figure 3** A PTI net representing two unbounded producers/consumers with priority. For simplicity, we display the labels of transitions instead of their names.

Note that the union $R = R_1 \cup R_2$ is not a pti-place bisimulation as, for example, $(2 \cdot s_2, s_2 \oplus s_3) \in R^\oplus$, but the pti-place bisimulation conditions are not satisfied. Indeed, if $2 \cdot s_2$ moves first by $2 \cdot s_2[t_1]s_1 \oplus s_2$, then $s_2 \oplus s_3$ can only try to respond with $s_2 \oplus s_3[t_2]s_5$ since t_1 and t_3 are inhibited. However, this is not possible because we have that $(\bullet t_1, \bullet t_2) \notin R^\oplus$, and, even worse, $(s_2, \theta) \notin R^\oplus$.

3.3 Pti-place bisimilarity is finer than causal-net bisimilarity

► **Theorem 27** (Pti-place bisimilarity implies causal-net bisimilarity). *Let $N = (S, A, T, I)$ be a PTI net and m_1, m_2 two of its markings. If $m_1 \sim_p m_2$, then $m_1 \sim_{cn} m_2$.*

Proof. See Appendix A.2. ◀

There are at least the following three important technical differences between causal-net bisimilarity and pti-place bisimilarity.

1. A causal-net bisimulation is a very complex relation – composed of cumbersome triples of the form (ρ_1, C, ρ_2) – that must contain infinitely many triples if the net system offers a never-ending behavior. On the contrary, a pti-place bisimulation is always a very simple finite relation over the finite set S of places.
2. A causal net bisimulation proving that $m_1 \sim_{cn} m_2$ is a relation specifically designed for showing that m_1 and m_2 generate the same causal nets, step by step. If we want to prove that, e.g., $n \cdot m_1$ and $n \cdot m_2$ are causal-net bisimilar (which may not hold!), we have to construct a new causal-net bisimulation to this aim. Instead, a pti-place bisimulation

■ Figure 4 A PTI net.

■ Figure 5 Two PTI nets.

R relates those places which are considered equivalent under all the possible R -related contexts. Hence, if R justifies that $m_1 \sim_p m_2$ as $(m_1, m_2) \in R^\oplus$, then for sure the same R justifies that $n \cdot m_1$ and $n \cdot m_2$ are pti-place bisimilar, as also $(n \cdot m_1, n \cdot m_2) \in R^\oplus$.

3. Finally, while pti-place bisimilarity is decidable (see the next section), it is not known whether causal-net bisimilarity is decidable on finite PTI nets.¹

However, these technical advantages of pti-place bisimilarity over causal-net bisimilarity are balanced by an increased discriminating power of the former over the latter, that, in some cases, might appear even excessive, as the following intriguing example shows.

► **Example 28.** Consider the net in Figure 5. First of all, note that $s_2 \sim_{cn} s'_2$, because both are stuck markings. However, we have that $2 \cdot s_2 \not\sim_{cn} 2 \cdot s'_2$ because $2 \cdot s_2$ is stuck, while $2 \cdot s'_2$ can perform b . This observation is enough to conclude that $s_2 \not\sim_p s'_2$, because a pti-place bisimulation R relates places that are equivalent under any R -related context: if $(s_2, s'_2) \in R$ then $(2 \cdot s_2, 2 \cdot s'_2) \in R^\oplus$, but these two markings do not satisfy the pti-place bisimulation conditions, so R is not a pti-place bisimulation.

Nonetheless, it is interesting to observe that $s_1 \sim_{cn} s'_1$, because they generate the same causal PTI nets, step by step; moreover, even for any $n \geq 1$ we have $n \cdot s_1 \sim_{cn} n \cdot s'_1$. However, $s_1 \not\sim_p s'_1$ because it is not possible to build a pti-place bisimulation R containing the pair (s_1, s'_1) . The problem is that it would be necessary to include, into the candidate pti-place relation R , also the pair (s_2, s'_2) , which is not a pti-place bisimulation pair, as discussed above. Therefore, no pti-place bisimulation R can relate s_1 and s'_1 .

¹ Esparza observed [12] that, for finite P/T nets with at least two unbounded places, all the behavioral relations ranging from interleaving bisimilarity to fully-concurrent bisimilarity [6] are undecidable. Even if his proof does not apply to causal-net bisimilarity, we conjecture that this equivalence is undecidable as well.

4 Pti-place bisimilarity is decidable

In order to prove that \sim_p is decidable, we first need a technical lemma which states that it is decidable to check whether a place relation $R \subseteq S \times S$ is a pti-place bisimulation.

► **Lemma 29.** *Given a finite PTI net $N = (S, A, T, I)$ and a place relation $R \subseteq S \times S$, it is decidable whether R is a pti-place bisimulation.*

Proof. It is enough to check two finite conditions on transitions and places of the net; full detail in Appendix A.3. ◀

► **Theorem 30** (Pti-place bisimilarity is decidable). *Given a PTI net $N = (S, A, T, I)$, for each pair of markings m_1 and m_2 , it is decidable whether $m_1 \sim_p m_2$.*

Proof. If $|m_1| \neq |m_2|$, then $m_1 \not\sim_p m_2$ by Proposition 18. Otherwise, we can assume that $|m_1| = k = |m_2|$. As $|S| = n$, the set of all the place relations over S is of size 2^n . Let us list such relations as: R_1, R_2, \dots, R_{2^n} . Hence, for $i = 1, \dots, 2^n$, by Lemma 29 we can decide whether the place relation R_i is a pti-place bisimulation and, in such a case, we can check whether $(m_1, m_2) \in R_i^\oplus$ in $O(k^2\sqrt{k})$ time. As soon as we have found a pti-place bisimulation R_i such that $(m_1, m_2) \in R_i^\oplus$, we stop concluding that $m_1 \sim_p m_2$. If none of the R_i is a pti-place bisimulation such that $(m_1, m_2) \in R_i^\oplus$, then we can conclude that $m_1 \not\sim_p m_2$. Since this procedure might scan all place relations, the worst-case complexity of the algorithm is exponential in the number of places n . ◀

5 Conclusion

Pti-place bisimilarity is the only decidable behavioral equivalence for finite PTI nets, which constitute a powerful, Turing-complete distributed model of computation, widely used in theory and applications of concurrency (e.g., [1, 3, 9, 7, 8, 17, 19, 26]). Thus, it is the only equivalence for which it is possible (at least, in principle) to verify algorithmically the (causality-preserving) correctness of an implementation by exhibiting a pti-place bisimulation between its specification and implementation. It is also sensible, because it respects the causal behavior of PTI nets, since it is finer than causal-net bisimilarity. Of course, pti-place bisimilarity is a rather discriminating behavioral equivalence, as illustrated in Example 28, and a proper evaluation of its usefulness on real case studies is left for future research.

In our interpretation, (pti-)place bisimilarity is an attempt of giving semantics to *unmarked*, rather than marked, nets, shifting the focus from the usually undecidable question *When are two markings equivalent?* to the decidable (but more restrictive) question *When are two places equivalent?* A possible answer to the latter question may be: two places are equivalent if, whenever the same number of tokens are put on these two places, the behavior of the marked nets is the same. If we reinterpret Example 28 in this perspective, we clearly see that place s_2 and place s'_2 cannot be considered as equivalent because, even if the marking s_2 and s'_2 are equivalent (as they are both stuck), the marking $2 \cdot s_2$ is not equivalent to the marking $2 \cdot s'_2$ (as only the latter can move). More specifically, a (pti-)place bisimulation R considers two places s_1 and s_2 as equivalent if $(s_1, s_2) \in R$, as, by definition of (pti-)place bisimulation, they must behave the same in any R -related context.

The decidability result for pti-place bisimilarity is based on the fact that the net model is finite, even if the associated reachability graph may be unboundedly large or even infinite: indeed, one can decide pti-place bisimilarity simply checking a large, but finite, number of conditions on the shape of the finite net, rather than inspecting its (possibly, infinitely many) reachable markings.

Turing completeness is achieved in PTI nets by means of their ability to test for zero. Other Turing-complete models of computation may exploit different mechanisms to this aim. For instance, in the π -calculus [24, 28] Turing completeness is achieved by means of the ability to generate unboundedly new names (by means of the interplay between recursion and the restriction operator), but this feature is not describable by means of a finite net model [8, 23]. For this reason, we think it is hard to find a sensible, decidable behavioral equivalence for the whole π -calculus.

To the best of our knowledge, this is the second paper proving the decidability of a behavioral equivalence for a Turing-complete formalism. In fact, in [21] it is proved that (interleaving) bisimilarity is decidable for a small process calculus, called HOcore, with higher-order communication (but without restriction), that is, nonetheless, Turing-complete.

Future work will be devoted to see whether the pti-place bisimulation idea can be extended to other, possibly even larger classes of nets, such as *lending* Petri nets [5], where transitions are allowed to consume tokens from a place even if it does not contain enough tokens, thus enabling negative-valued markings.

A Properties of pti-place bisimilarity

A.1 Pti-place bisimilarity is an equivalence

► **Proposition 31.** *For each PTI net $N = (S, A, T, I)$, the following hold:*

1. *The identity relation $\mathcal{I}_S = \{(s, s) \mid s \in S\}$ is a pti-place bisimulation;*
2. *the inverse relation $R^{-1} = \{(s', s) \mid (s, s') \in R\}$ of a pti-place bisimulation R is a pti-place bisimulation;*
3. *the relational composition $R_1 \circ R_2 = \{(s, s'') \mid \exists s'. (s, s') \in R_1 \wedge (s', s'') \in R_2\}$ of two pti-place bisimulations R_1 and R_2 is a pti-place bisimulation.*

Proof. The proof is almost standard, due to Proposition 21.

(1) \mathcal{I}_S is a pti-place bisimulation as for each $(m, m) \in \mathcal{I}_S^\oplus$ whatever transition t the left (or right) marking m performs a transition (say, $m[t]m'$), the right (or left) instance of m in the pair does exactly the same transition $m[t]m'$ and, of course, $(\bullet t, \bullet t) \in \mathcal{I}_S^\oplus$, $(t \bullet, t \bullet) \in \mathcal{I}_S^\oplus$, $l(t) = l(t)$, $(m \ominus \bullet t, m \ominus \bullet t) \in \mathcal{I}_S^\oplus$, by Proposition 21(2), and, also, $\forall s \in S. (s, s) \in \mathcal{I}_S \Rightarrow (s \in \circ t \Leftrightarrow s \in \circ t)$, as required by the pti-place bisimulation definition.

(2) Suppose $(m_2, m_1) \in (R^{-1})^\oplus$ and $m_2[t_2]m'_2$. By Proposition 21(3) $(m_2, m_1) \in (R^\oplus)^{-1}$ and so $(m_1, m_2) \in R^\oplus$. Since R is a pti-place bisimulation, item 2 of the bisimulation game ensures that there exist t_1 and m'_1 such that $m_1[t_1]m'_1$, with $(\bullet t_1, \bullet t_2) \in R^\oplus$, $l(t_1) = l(t_2)$, $(t_1^\bullet, t_2^\bullet) \in R^\oplus$ and $(m_1 \ominus \bullet t_1, m_2 \ominus \bullet t_2) \in R^\oplus$; moreover, $\forall s, s' \in S. (s, s') \in R \Rightarrow (s \in {}^\circ t_1 \Leftrightarrow s' \in {}^\circ t_2)$. Summing up, if $(m_2, m_1) \in (R^{-1})^\oplus$, to the move $m_2[t_2]m'_2$, m_1 replies with the move $m_1[t_1]m'_1$, such that (by Proposition 21(3)) $(\bullet t_2, \bullet t_1) \in (R^{-1})^\oplus$, $l(t_2) = l(t_1)$, $(t_2^\bullet, t_1^\bullet) \in (R^{-1})^\oplus$, $(m_2 \ominus \bullet t_2, m_1 \ominus \bullet t_1) \in (R^{-1})^\oplus$ and, moreover, $\forall s, s' \in S. (s', s) \in R^{-1} \Rightarrow (s' \in {}^\circ t_2 \Leftrightarrow s \in {}^\circ t_1)$, as required. The case when m_1 moves first is symmetric and thus omitted.

(3) Suppose $(m, m'') \in (R_1 \circ R_2)^\oplus$ and $m[t_1]m_1$. By Proposition 21(4), we have that $(m, m'') \in R_1^\oplus \circ R_2^\oplus$, and so there exists m' such that $(m, m') \in R_1^\oplus$ and $(m', m'') \in R_2^\oplus$. As $(m, m') \in R_1^\oplus$ and R_1 is a pti-place bisimulation, if $m[t_1]m_1$, then there exist t_2 and m_2 such that $m'[t_2]m_2$ with $(\bullet t_1, \bullet t_2) \in R_1^\oplus$, $l(t_1) = l(t_2)$, $(t_1^\bullet, t_2^\bullet) \in R_1^\oplus$ and $(m \ominus \bullet t_1, m' \ominus \bullet t_2) \in R_1^\oplus$; moreover, $\forall s, s' \in S. (s, s') \in R_1 \Rightarrow (s \in {}^\circ t_1 \Leftrightarrow s' \in {}^\circ t_2)$. But as $(m', m'') \in R_2^\oplus$ and R_2 is a pti-place bisimulation, we have also that there exist t_3 and m_3 such that $m''[t_3]m_3$ with $(\bullet t_2, \bullet t_3) \in R_2^\oplus$, $l(t_2) = l(t_3)$, $(t_2^\bullet, t_3^\bullet) \in R_2^\oplus$ and $(m' \ominus \bullet t_2, m'' \ominus \bullet t_3) \in R_2^\oplus$; moreover, $\forall s', s'' \in S. (s', s'') \in R_2 \Rightarrow (s' \in {}^\circ t_2 \Leftrightarrow s'' \in {}^\circ t_3)$. Summing up, for $(m, m'') \in (R_1 \circ R_2)^\oplus$, if $m[t_1]m_1$, then there exist t_3 and m_3 such that $m''[t_3]m_3$ and (by Proposition 21(4)) $(\bullet t_1, \bullet t_3) \in (R_1 \circ R_2)^\oplus$, $l(t_1) = l(t_3)$, $(t_1^\bullet, t_3^\bullet) \in (R_1 \circ R_2)^\oplus$ and $(m \ominus \bullet t_1, m'' \ominus \bullet t_3) \in (R_1 \circ R_2)^\oplus$; moreover, $\forall s, s'' \in S. (s, s'') \in R_1 \circ R_2 \Rightarrow (s \in {}^\circ t_1 \Leftrightarrow s'' \in {}^\circ t_3)$, as required. The case when m'' moves first is symmetric and so omitted. \blacktriangleleft

► **Proposition 32.** *For each PTI net $N = (S, A, T, I)$, relation $\sim_p \subseteq \mathcal{M}(S) \times \mathcal{M}(S)$ is an equivalence relation.*

Proof. Direct consequence of Proposition 31. \blacktriangleleft

A.2 Pti-place bisimilarity is finer than causal-net bisimilarity

► **Theorem 33** (Pti-place bisimilarity implies causal-net bisimilarity). *Let $N = (S, A, T, I)$ be a PTI net and m_1, m_2 two of its markings. If $m_1 \sim_p m_2$, then $m_1 \sim_{cn} m_2$.*

Proof. If $m_1 \sim_p m_2$, then there exists a pti-bisimulation R_1 such that $(m_1, m_2) \in R_1^\oplus$. Let us consider

$$R_2 \stackrel{def}{=} \{(\rho_1, C, \rho_2) \mid (C, \rho_1) \text{ is a PTI process of } N(m_1) \text{ and} \\ (C, \rho_2) \text{ is a PTI process of } N(m_2) \text{ and} \\ \forall b \in B (\rho_1(b), \rho_2(b)) \in R_1\}.$$

We want to prove that R_2 is a causal-net bisimulation. First of all, consider a triple of the form $(\rho_1^0, C^0, \rho_2^0)$, where C^0 is the causal PTI net without events and ρ_1^0, ρ_2^0 are such that $\rho_i^0(\text{Min}(C^0)) = \rho_i^0(\text{Max}(C^0)) = \rho_i^0(B^0) = m_i$ for $i = 1, 2$, and $(\rho_1^0(b), \rho_2^0(b)) \in R_1$ for all $b \in B^0$. Then $(\rho_1^0, C^0, \rho_2^0)$ must belong to R_2 , because (C^0, ρ_i^0) is a process of $N(m_i)$, for $i = 1, 2$ and, by hypothesis, $(m_1, m_2) \in R_1^\oplus$. Hence, if R_2 is a causal-net bisimulation, then the triple $(\rho_1^0, C^0, \rho_2^0) \in R_2$ ensures that $m_1 \sim_{cn} m_2$.

Assume $(\rho_1, C, \rho_2) \in R_2$. In order for R_2 to be a cn-bisimulation, we must prove that

- (i) $\forall t_1, C', \rho'_1$ such that $(C, \rho_1) \xrightarrow{e} (C', \rho'_1)$, where $\rho'_1(e) = t_1$, $\exists t_2, \rho'_2$ such that $(C, \rho_2) \xrightarrow{e} (C', \rho'_2)$, where $\rho'_2(e) = t_2$, and $(\rho'_1, C', \rho'_2) \in R_2$;
- (ii) symmetrical, if (C, ρ_2) moves first.

Assume $(C, \rho_1) \xrightarrow{e} (C', \rho'_1)$ with $\rho'_1(e) = t_1$. Since $(\rho_1, C, \rho_2) \in R_2$, for all $b \in \text{Max}(C)$ we have $(\rho_1(b), \rho_2(b)) \in R_1$ and therefore $(\rho_1(\text{Max}(C)), \rho_2(\text{Max}(C))) \in R_1^\oplus$. Since $\rho_1(\text{Max}(C)) [t_1] \rho'_1(\text{Max}(C'))$ and R_1 is a pti-place bisimulation, there exist t_2, m_2 such that $\rho_2(\text{Max}(C)) [t_2] m_2$ with $(\bullet t_1, \bullet t_2) \in R_1^\oplus$, $l(t_1) = l(t_2)$, $(t_1^\bullet, t_2^\bullet) \in R_1^\oplus$, $(\rho_1(\text{Max}(C)) \ominus \bullet \rho'_1(e), \rho_2(\text{Max}(C)) \ominus \bullet \rho'_2(e)) \in R_1^\oplus$ and, moreover, $\forall s, s' \in S. (s, s') \in R_1 \Rightarrow (s \in \circ t_1 \Leftrightarrow s' \in \circ t_2)$. Note that, since $(t_1^\bullet, t_2^\bullet) \in R_1^\oplus$ and $(\rho_1(\text{Max}(C)) \ominus \bullet \rho'_1(e), \rho_2(\text{Max}(C)) \ominus \bullet \rho'_2(e)) \in R_1^\oplus$, by additivity of additive closure (cf. Proposition 19), $(\rho_1(\text{Max}(C)) \ominus \bullet \rho'_1(e) \oplus t_1^\bullet, \rho_2(\text{Max}(C)) \ominus \bullet \rho'_2(e) \oplus t_2^\bullet) \in R_1^\oplus$, i.e. $(\rho'_1(\text{Max}(C')), m_2) \in R^\oplus$.

Therefore, since t_1 and t_2 have the same pre-sets/post-sets up to R_1 , it is possible to derive $(C, \rho_2) \xrightarrow{e} (C'', \rho'_2)$, where ρ'_2 is such that $\rho'_2(e) = t_2$ and $(\rho'_1(b), \rho'_2(b)) \in R_1$ for each $b \in e^\bullet$ (which is really possible because $(t_1^\bullet, t_2^\bullet) \in R_1^\oplus$). Now we prove that $C' = C''$. The underlying P/T parts of C' and C'' are obviously the same (so C' and C'' have the same events, the same conditions and the same flow relation), therefore we have to check that also the newly added (after/before) inhibitor arcs are the same, i.e.,

- $\forall b \in B'$ such that $b^\bullet \neq \emptyset$ we have $b \mathcal{A}_1 e \iff b \mathcal{A}_2 e$, and
- $\forall b \in e^\bullet \forall e' \in E$ we have $b \mathcal{B}_1 e' \iff b \mathcal{B}_2 e'$,

where we denote \mathcal{A}_1 (resp. \mathcal{B}_1) the after (before) inhibitor arcs obtained by extending C to C' and \mathcal{A}_2 (resp. \mathcal{B}_2) the after (before) inhibitor arcs obtained by extending C to C'' . However, these additional requests are trivially satisfied because we know that $\forall s, s' \in S. (s, s') \in R_1 \Rightarrow (s \in \circ t_1 \Leftrightarrow s' \in \circ t_2)$. In fact, if $b \mathcal{A}_1 e$, then, by Definition 13, there is an inhibitor arc from $\rho_1(b)$ to t_1 , i.e., $\rho_1(b) \in \circ t_1$. Since $(\rho_1(b), \rho_2(b)) \in R_1$, this implies that $\rho_2(b) \in \circ t_2$ and so $b \mathcal{A}_2 e$. The implication on the other side is symmetrical, and therefore omitted. The argument for relations $\mathcal{B}_1, \mathcal{B}_2$ is the same, and therefore omitted.

To conclude, we have $C' = C''$. Thus, $(C, \rho_2) \xrightarrow{e} (C', \rho'_2)$ with $\rho'_2(e) = t_2$ and $(\rho'_1(b), \rho'_2(b)) \in R_1$ for each $b \in e^\bullet$. Hence, for all $b' \in B'$ it holds that $(\rho'_1(b'), \rho'_2(b')) \in R_1$, because for all $b' \in B$ this holds by hypothesis and for all $b' \in e^\bullet$ this follows by construction (thanks to the fact that $(t_1^\bullet, t_2^\bullet) \in R_1^\oplus$). As a consequence $(\rho'_1, C', \rho'_2) \in R_2$.

The case where (C, ρ_2) moves first is symmetrical and therefore omitted. Thus, R_2 is a causal-net bisimulation and, since $(\rho_1^0, C^0, \rho_2^0) \in R_2$, we have $m_1 \sim_{cn} m_2$. ◀

A.3 It is decidable whether a place relation is a pti-place bisimulation

► **Lemma 34.** *Given a finite PTI net $N = (S, A, T, I)$ and a place relation $R \subseteq S \times S$, it is decidable whether R is a pti-place bisimulation.*

Proof. We want to prove that R is a pti-place bisimulation if and only if the following two finite conditions are satisfied:

1. $\forall t_1$ such that $\bullet t_1 [t_1]$, $\forall m$ such that $(\bullet t_1, m) \in R^\oplus$, $\exists t_2$ such that $\bullet t_2 [t_2]$ and
 - (a) $\bullet t_2 = m$,
 - (b) $(t_1^\bullet, t_2^\bullet) \in R^\oplus$, $l(t_1) = l(t_2)$,
 - (c) $\forall s, s' \in S. (s, s') \in R \Rightarrow (s \in \circ t_1 \Leftrightarrow s' \in \circ t_2)$.
2. $\forall t_2$ such that $\bullet t_2 [t_2]$, $\forall m$ such that $(m, \bullet t_2) \in R^\oplus$, $\exists t_1$ such that $\bullet t_1 [t_1]$ and
 - (a) $\bullet t_1 = m$,
 - (b) $(t_1^\bullet, t_2^\bullet) \in R^\oplus$, $l(t_1) = l(t_2)$,
 - (c) $\forall s, s' \in S. (s, s') \in R \Rightarrow (s \in \circ t_1 \Leftrightarrow s' \in \circ t_2)$.

First we prove the implication from left to right, only for condition 1, as the other is symmetrical. If R is a pti-place bisimulation and $(\bullet t_1, m) \in R^\oplus$, then from $\bullet t_1 [t_1] t_1^\bullet$ it follows that there exists t_2 such that $\bullet t_2 [t_2] t_2^\bullet$ with $\bullet t_2 = m$, $(t_1^\bullet, t_2^\bullet) \in R^\oplus$, $l(t_1) = l(t_2)$ and, moreover, $\forall s, s' \in S. (s, s') \in R \Rightarrow (s \in \circ t_1 \Leftrightarrow s' \in \circ t_2)$. Therefore, conditions (a), (b) and (c) are trivially satisfied.

Now we prove the implication from right to left, i.e., if conditions 1 and 2 hold for R , then R is a pti-place bisimulation. Suppose $(m_1, m_2) \in R^\oplus$ and $m_1[t_1]m'_1$. Let $q = \{(s_1, s'_1), (s_2, s'_2), \dots, (s_k, s'_k)\}$ be any multiset of associations that can be used to prove that $(m_1, m_2) \in R^\oplus$. So this means that $m_1 = s_1 \oplus s_2 \oplus \dots \oplus s_k$, $m_2 = s'_1 \oplus s'_2 \oplus \dots \oplus s'_k$ and that $(s_i, s'_i) \in R$ for $i = 1, \dots, k$. If $m_1[t_1]m'_1$, then $m'_1 = m_1 \ominus \bullet t_1 \oplus t_1^\bullet$. Consider the multiset of associations $p = \{(\bar{s}_1, \bar{s}'_1), \dots, (\bar{s}_h, \bar{s}'_h)\} \subseteq q$, with $\bar{s}_1 \oplus \dots \oplus \bar{s}_h = \bullet t_1$.

Note that $(\bullet t_1, \bar{s}'_1 \oplus \dots \oplus \bar{s}'_h) \in R^\oplus$ and that $\bullet t_1[t_1]$. Hence, by condition 1, there exists a transition t_2 such that $\bullet t_2[t_2]$, $\bullet t_2 = \bar{s}'_1 \oplus \dots \oplus \bar{s}'_h$, $(t_1^\bullet, t_2^\bullet) \in R^\oplus$, $l(t_1) = l(t_2)$, and $\forall s, s' \in S. (s, s') \in R \Rightarrow (s \in \circ t_1 \Leftrightarrow s' \in \circ t_2)$. By hypothesis, $\circ t_1 \cap \text{dom}(m_1) = \emptyset$, so since $(m_1, m_2) \in R^\oplus$ and condition (c) holds, we have that $\circ t_2 \cap \text{dom}(m_2) = \emptyset$. Therefore, since $\bullet t_2 \subseteq m_2$, also $m_2[t_2]m'_2$ is firable, where $m'_2 = m_2 \ominus \bullet t_2 \oplus t_2^\bullet$, and we have that $(\bullet t_1, \bullet t_2) \in R^\oplus$, $(t_1^\bullet, t_2^\bullet) \in R^\oplus$, $l(t_1) = l(t_2)$, $(m_1 \ominus \bullet t_1, m_2 \ominus \bullet t_2) \in R^\oplus$ and, moreover, $\forall s, s' \in S. (s, s') \in R \Rightarrow (s \in \circ t_1 \Leftrightarrow s' \in \circ t_2)$, as required, where $(m_1 \ominus \bullet t_1, m_2 \ominus \bullet t_2) \in R^\oplus$ holds as, from the set q of matching pairs for m_1 and m_2 , we have removed those in p .

If $m_2[t_2]m'_2$, then we have to use an argument symmetric to the above, where condition 2 is used instead. Hence, we have proved that conditions 1 and 2 are enough to prove that R is a pti-place bisimulation.

Finally, the complexity of this procedure is as follows. For condition 1, we have to consider all the net transitions, and for each t_1 we have to consider all the markings m such that $(\bullet t_1, m) \in R_i^\oplus$, and for each pair (t_1, m) we have to check whether there exists a transition t_2 such that $m = \bullet t_2$, $l(t_1) = l(t_2)$, $(t_1^\bullet, t_2^\bullet) \in R_i^\oplus$ and, moreover, that $\forall s, s' \in S. (s, s') \in R \Rightarrow (s \in \circ t_1 \Leftrightarrow s' \in \circ t_2)$. And the same for condition 2. Hence, this procedure has worst-case time complexity $O(q \cdot n^p \cdot q \cdot (p^2 \sqrt{p} + n^2 \cdot p))$, where $q = |T|$, $n = |S|$ and p is the least number such that $|\bullet t| \leq p$, $|\circ t| \leq p$, and $|t^\bullet| \leq p$ for all $t \in T$, as the number of markings m related via R_i to $\bullet t_1$ is n^p at most, checking whether $(t_1^\bullet, t_2^\bullet) \in R_i^\oplus$ takes $O(p^2 \sqrt{p})$ in the worst case and, finally, checking the conditions on the inhibiting sets is $n^2 \cdot p$ at most. ◀

Black-Box Hypotheses and Lower Bounds

Abstract

What sort of code is so difficult to analyze that every potential analyst can discern essentially no information from the code, other than its input-output behavior? In their seminal work on program obfuscation, Barak, Goldreich, Impagliazzo, Rudich, Sahai, Vadhan, and Yang (CRYPTO 2001) proposed the Black-Box Hypothesis, which roughly states that every property of Boolean functions which has an efficient “analyst” and is “code independent” can also be computed by an analyst that only has black-box access to the code. In their formulation of the Black-Box Hypothesis, the “analysts” are arbitrary randomized polynomial-time algorithms, and the “codes” are general (polynomial-size) circuits. If true, the Black-Box Hypothesis would immediately imply $\text{NP} \not\subseteq \text{BPP}$.

We consider generalized forms of the Black-Box Hypothesis, where the set of “codes” \mathcal{C} and the set of “analysts” \mathcal{A} may correspond to other efficient models of computation, from more restricted models such as AC^0 to more general models such as nondeterministic circuits. We show how lower bounds of the form $\mathcal{C} \not\subseteq \mathcal{A}$ often imply a corresponding Black-Box Hypothesis for those respective codes and analysts. We investigate the possibility of “complete” problems for the Black-Box Hypothesis: problems in \mathcal{C} such that they are not in \mathcal{A} if and only if their corresponding Black-Box Hypothesis is true. Along the way, we prove an equivalence: for nondeterministic circuit classes \mathcal{C} , the “ \mathcal{C} -circuit satisfiability problem” is not in \mathcal{A} if and only if the Black-Box Hypothesis is true for analysts in \mathcal{A} .

1 Introduction

What kind of code “behaves” like a black box to any code analyst? In particular, what programs are so difficult to analyze that every potential analyst can discern essentially no information from the code, other than its input-output behavior? Such questions are of great importance in cryptography and formal verification: what sort of code is difficult to verify without considerable resources? What kind of code can be obfuscated? What properties of functions can be automatically tested?

A priori, the answers to such questions depend on three factors:

1. The complexity of the code: what instructions are allowed in the code, the computational complexity (e.g. time/space/size/depth complexity) of the algorithm implemented by the code, and so on.
2. The complexity of the analyst: what sorts of operations the analyst can perform, and how much resources it has (time/space/size/depth) to analyze the code.
3. The actual function being computed by the code. If the function itself is trivial or extremely complicated, this could affect how “black box” it can possibly look.

In this paper, we consider these three factors carefully, and study obfuscation from a different direction compared to most existing literature on the subject. In particular, we propose generalized forms of the “Black-Box Hypothesis” considered in Barak, Goldreich, Impagliazzo, Rudich, Sahai, Vadhan, and Yang [5] and show how such questions are intimately related to lower bound questions.

A Complexity-Theoretic View

In the pioneering work of Barak et al. [5] on obfuscation, the authors also proposed a compelling conjecture about black-box obfuscation that they called a “Scaled-Down Rice’s Theorem” [5, Conjecture 5.1]; the conjecture has recently been renamed the *Black Box Hypothesis* (BBH) [20, 14]. Informally, the Black-Box Hypothesis posits that, when code is represented as a small Boolean circuit, and a code analyst is represented as an efficient (polynomial-time) randomized algorithm, the only possible analysis tasks are ones that could have been performed using only the input-output behavior of the code (and not the code itself).

While the original Black-Box Hypothesis is still a major open problem, other natural variants of the hypothesis may be tractable for us to resolve, **unconditionally**. We consider variants of the Black-Box Hypothesis in a more general complexity-theoretic setting, where the complexity of the analyst, the complexity of the code being analyzed, and the function to be obfuscated (the “box”) are carefully taken into account. For example, we consider the case where the “analyst function” is taken from a “low” complexity class \mathcal{A} (smaller than P, polynomial time), and the box is also from a “low” complexity class \mathcal{C} .

More formally, we study abstract forms of the Black-Box Hypothesis (sometimes abbreviated as BBH in the following). Let \mathcal{C} be a set of circuits and let \mathcal{A} be a complexity class that permits oracles in its definition. We say that a property $P : \mathcal{C} \rightarrow \{0, 1\}$ of \mathcal{C} is *semantic* if $P(C) = P(C')$ for all pairs of circuits C and C' in \mathcal{C} which compute the same function.

► **Hypothesis 1** (*C-Black-Box Hypothesis for \mathcal{A}*). [Informal Statement, cf. Hypothesis 14] *Let $P : \mathcal{C} \rightarrow \{0, 1\}$ be any semantic property computable by some analyst $A' \in \mathcal{A}$. Then there is a **black-box** analyst $A \in \mathcal{A}$ such that for every s and every circuit $C \in \mathcal{C}$ of size s on n inputs, $A^C(1^n 0^{s-n}) = P(C)$.*

In prior work, the class of analysts \mathcal{A} was always set to be BPP, and the class of circuits \mathcal{C} was generally set to be unrestricted circuits of fan-in two. In that full form, proving the BBH would also prove $\text{NP} \not\subseteq \text{BPP}$, so that is presently out of reach! (The BBH could also end up being false, of course.) By considering a range of natural possible choices for the weak analysts \mathcal{A} and the circuit sets \mathcal{C} , we can try to delineate precisely how weak the analysts from \mathcal{A} need to be, in order for \mathcal{C} -circuits to *provably* behave like black boxes, and to relate the corresponding Black-Box Hypotheses to other core problems within complexity.

1.1 Our Results

We demonstrate several interesting relationships between circuit lower bounds and Black-Box Hypotheses in the generalized setting. First, we prove that certain instances of the Black-Box Hypothesis are true, from known circuit lower bounds. In fact we give a generic connection from lower bounds to Black-Box Hypotheses. We also give some converse results, showing that Black-Box Hypotheses imply certain circuit lower bounds. Finally, in some settings, we can show that certain problems are “complete” for a Black-Box Hypothesis, in the sense that proving the Black-Box Hypothesis is *equivalent* to proving a lower bound against the aforementioned problem.

Black-Box Hypotheses For Restricted Analysts, From Lower Bounds

In Section 4, we explore situations in which known lower bounds imply Black-Box Hypotheses. We first consider Hypothesis 14 where the classes of analysts \mathcal{A} are restricted, and the set of potential “boxes” \mathcal{C} consists of *unrestricted circuits*. We show that one can prove a \mathcal{C} -Black-Box Hypothesis for \mathcal{A} , when the given set of boxes \mathcal{C} is sufficiently powerful and the set of analysts \mathcal{A} is limited. *We find this to be counterintuitive.* It could have been the case that, when the set of boxes \mathcal{C} is powerful, an analyst with access to the code of such a powerful box might be able to learn something interesting about it, and gain more power than if it only had black-box access. However, it turns out that when the boxes are sufficiently powerful, no analyst can learn any *semantic* property.

We find that, under very general conditions, circuit lower bounds against \mathcal{A} (as an algorithmic class) imply the Black-Box Hypothesis for \mathcal{A} (as an analyst class).

► **Theorem 2** (Informal Statement, cf. Theorem 16). *Let \mathcal{A} be a circuit class (of analysts), and let f be a Boolean function computable with (general) circuits of size at most $t(n)$. Suppose $f \notin \mathcal{A}$, and suppose \mathcal{A} is closed under projections from n variables onto $O(t(n) \log t(n))$ variables. Then the (general) Black-Box Hypothesis for \mathcal{A} is true.*

The full formal version of the theorem appears in Section 4 as Theorem 16. Intuitively, we apply a “input-switching” trick which reduces the task of computing f on an input \mathbf{y} to the task of deciding *any* non-trivial semantic property P on a circuit $D_{\mathbf{y}}$.¹ In particular, given an analyst A computing P , we show how to map every Boolean string \mathbf{y} (a potential input for f) into a circuit $D_{\mathbf{y}}$ whose input-output behavior (and in particular, whether $D_{\mathbf{y}}$ satisfies the property P) depends on the value $f(\mathbf{y})$. At a high level, $D_{\mathbf{y}}$ takes an input \mathbf{x} , evaluates $f(\mathbf{y})$, and then (depending on $f(\mathbf{y})$) evaluates and outputs either $C_1(\mathbf{x})$ or $C_2(\mathbf{x})$, where C_1 and C_2 are fixed circuits (independent of \mathbf{y}), exactly one of which satisfies the property P . In essence, we are “switching” the input \mathbf{y} with a circuit $D_{\mathbf{y}}$ which can evaluate f , and for which we can determine P . Then, we can run A on $D_{\mathbf{y}}$ *without ever evaluating f directly*, and use its answer to determine $f(\mathbf{y})$.

The conditions we impose on \mathcal{A} are quite general, so Theorem 16 has several direct corollaries. For example, recall AC^0 is the class of unbounded fan-in circuits of constant depth over AND, OR, and NOT.

► **Corollary 3.** *The BBH for (polynomial-size) AC^0 analysts is true. Moreover, the BBH for $2^{n^{o(1)}}$ -size AC^0 is true.*

In particular, Theorem 16 implies that for every subexponential-size AC^0 circuit family $\{A_n\}$ that is given the code of an arbitrary (general) circuit C as input, if $\{A_n\}$ computes a semantic property (i.e., its output depends only on the function computed by C , not the code of C) then $\{A_n\}$ must compute a trivial property (all-zeroes or all-ones). Similarly:

Let TC_2^0 be the class of unbounded fan-in circuits of depth-two over MAJORITY, AND, OR, and NOT.

► **Corollary 4.** *The BBH for (polynomial-size) TC_2^0 is true. Moreover, the BBH for $2^{n^{1-\varepsilon}}$ -size TC_2^0 analysts is true for every $\varepsilon > 0$.*

¹ At this level of generality, the idea is similar in spirit to one of the proofs of Rice’s Theorem [19] which shows that any non-trivial semantic property of Turing machines is undecidable, by way of a reduction from the Halting Problem. However, Rice’s proof techniques do not translate to finite circuits, so we prove Theorem 16 differently.

A Generalization

Next, we turn to an even more general setting of Black-Box Hypotheses, where both the class \mathcal{A} of “analysts” and the set \mathcal{C} of “boxes” can vary. Here we find that, roughly speaking, if \mathcal{A} and \mathcal{C} jointly satisfy some natural closure properties, and there are functions computable by boxes in \mathcal{C} but not by analysts in \mathcal{A} , then the \mathcal{C} -Black-Box Hypothesis for \mathcal{A} still holds.

► **Theorem 5** (Informal Statement, cf. Theorem 18 and Theorem 20). *Let \mathcal{A} be a circuit (analyst) class, let \mathcal{C} be a set of circuits, and let $f \notin \mathcal{A}$ be a Boolean function. Suppose there is an analyst in \mathcal{A} which, given input \mathbf{y} , generates a circuit $D_{\mathbf{y}} \in \mathcal{C}$ whose input-output behavior depends on the value of $f(\mathbf{y})$. Then the \mathcal{C} -Black-Box Hypothesis for \mathcal{A} is true.*

We prove two formal versions of this theorem in Section 4.1, as Theorem 18 and Theorem 20. These theorems are general enough that \mathcal{C} does not *have* to be a class of circuits *per se*: other non-uniform computational models, such as branching programs or span programs, would also work. The intuition and proof techniques are similar to those used in Theorem 16, but given the extra conditions on \mathcal{A} , we can tailor the input-switching reduction from Theorem 16 to the set \mathcal{C} in order to produce stronger results. For example:

► **Corollary 6.** *For all primes p , the $\text{AC}^0[p]$ -Black-Box Hypothesis for (poly-size) AC^0 holds.*

Theorem 20 implies that for every AC^0 circuit family $\{A_n\}$ that tries to analyze the code of a given $\text{AC}^0[p]$ circuit C , if $\{A_n\}$ computes a semantic property of C , then that property must be trivial. More generally, we can conclude the following.

► **Theorem 7.** *For all depths $d \geq 2$ and all distinct primes $p \neq q$, the $\text{AC}_d^0[p]$ -Black-Box Hypothesis for $2^{s^{o(1)}}$ -size $\text{AC}^0[q]$ analysts is true.*

That is, even if in the above, $\{A_n\}$ can have subexponential size, use MOD_q gates, and fail on input circuits C with depth greater than a fixed constant d , $\{A_n\}$ must *still* compute a trivial property. Similarly:

► **Theorem 8.** *For all depths $d \geq 2$, the AC_d^0 -Black-Box Hypothesis for $2^{s^{o(1)}}$ -size AC_{d-1}^0 analysts is true.*

Equivalences With Lower Bounds?

So far, our results show how lower bound statements of the form $\mathcal{C} \not\subseteq \mathcal{A}$ can sometimes be applied to prove the corresponding \mathcal{C} -Black-Box Hypothesis for \mathcal{A} analysts. A natural next question is, could Black-Box Hypotheses (for various pairs of boxes and analysts) be *equivalent* to proving lower bounds? As a first step, in Section 5 we prove conditional lower bounds against some analyst classes \mathcal{A} , assuming some \mathcal{C} -Black-Box Hypothesis for \mathcal{A} .

► **Theorem 9** (Informal Statement, cf. Theorem 28). *Suppose every analyst in \mathcal{A} has subexponential-size circuits, and let \mathcal{C} be a “reasonable” set of circuits (left undefined here). If the \mathcal{C} -Black-Box Hypothesis for \mathcal{A} is true, then the circuit satisfiability problem for \mathcal{C} -circuits is not in \mathcal{A} .*

Roughly speaking, we observe that if the \mathcal{C} -circuit Evaluation problem (\mathcal{C} -EVAL) is not in \mathcal{A} , then the \mathcal{C} -Black-Box Hypothesis for \mathcal{A} is **true**, and if the \mathcal{C} -circuit Satisfiability problem (\mathcal{C} -SAT) is in \mathcal{A} , then the \mathcal{C} -Black-Box Hypothesis for \mathcal{A} is **false**. However, \mathcal{C} -SAT is generally harder than \mathcal{C} -EVAL.

To better understand how lower bounds connect to Black-Box Hypotheses, we propose a notion of *BBH-completeness* for computational problems. Very roughly, we want a \mathcal{C} -BBH-complete problem Π to have the property that $\Pi \in \mathcal{C}$, and for a general analyst class \mathcal{A} , if $\Pi \notin \mathcal{A}$ then the \mathcal{C} -BBH for \mathcal{A} is true. We show that for *nondeterministic* circuit classes \mathcal{C} , both \mathcal{C} -SAT and \mathcal{C} -EVAL are \mathcal{C} -BBH-complete.

► **Theorem 10** (Informal Statement, cf. Theorem 31). *Suppose every analyst in \mathcal{A} has subexponential-size circuits, and let \mathcal{C} be a nondeterministic circuit class with “natural” closure properties. Then \mathcal{C} -EVAL and \mathcal{C} -SAT are both \mathcal{C} -BBH-complete for \mathcal{A} .*

Theorem 31 shows that lower bounds for the satisfiability problem are equivalent in some sense to proving that nondeterministic circuits behave like black boxes. Impagliazzo, Kabanets, Kolokolova, McKenzie, and Romani [14] considered the question of whether one can show the Black-Box Hypothesis is equivalent to $\text{NP} \not\subseteq \text{P/poly}$, with some partial results. A consequence of Theorem 31 is that $\text{NP} \not\subseteq \text{P/poly}$ is equivalent to the Black-Box Hypothesis when polynomial-size circuits are the analysts and *nondeterministic circuits* are the boxes. In this light, it would be very interesting if one could show the Black-Box Hypothesis is actually equivalent to $\text{NP} \not\subseteq \text{P/poly}$: it would show that two rather different-looking forms of the Black-Box Hypothesis are in fact equivalent.

Finally, we note that the aforementioned work of Impagliazzo et al. on BBH [14, 20] yields another kind of equivalence between a different variant of black-box hypothesis and a circuit lower bound.

► **Theorem 11** (Follows from [14], informal, cf. Theorem 33). *The following are equivalent:*

1. *The Circuit Satisfiability problem, CKT-SAT, is not in P/poly .*
2. *Any symmetric property P that can be decided in P/poly with white-box access to the input circuit can also be decided in P/poly with black-box access to the input circuit.*

We view this interpretation of their result as further promising evidence towards more general connections between black-box hypotheses and circuit lower bounds.

Organization

Section 2 covers significant prior work related to black-box hypotheses. Section 3 carefully discusses how to generalize the Black-Box Hypothesis for various sets of “analysts” and sets of “boxes”. Section 4 proves our main theorems, showing how circuit lower bounds imply Black-Box Hypotheses in a very generic way. Section 5 considers how we might prove equivalences between Black-Box Hypotheses and lower bounds. Section 6 concludes. The appendices include missing proofs, as well as additional related work.

2 Background

In this paper we assume basic familiarity with computational complexity, especially circuit complexity (knowledge of the first 13 chapters of Arora and Barak [4] would suffice). Throughout the paper, we will recall notation and definitions as needed. Sometimes (as is common in complexity) we will blur the distinction between the analyst class \mathcal{A} as a set of circuit *families* (computing some decision problems) and the actual decision problems computed by analysts in \mathcal{A} .

We will study generic versions of the circuit evaluation and circuit satisfiability problems. In the \mathcal{C} -EVAL problem, we are given a circuit C from a set \mathcal{C} and an input x , and wish to know if $C(x) = 1$. In the \mathcal{C} -SAT problem, we are given a circuit from a set \mathcal{C} and wish to know if there is an x such that $C(x) = 1$. The CKT-SAT problem is \mathcal{C} -SAT where \mathcal{C} is the set of arbitrary Boolean circuits (without loss of generality, each gate has fan-in two).

Historically, researchers interested in so-called “black-box hypotheses” were looking for what they called a “scaled-down” Rice’s Theorem. In the following paragraphs, we provide a brief overview of this research.

Rice’s Theorem

We briefly recall the statement and implications of Rice’s Theorem. Let \mathcal{M} be the set of Turing Machines. We say a property $P : \mathcal{M} \rightarrow \{0, 1\}$ of Turing Machines is *semantic* if $P(M)$ depends only on the (possibly partial) function computed by M . That is, for any TMs M_1 and M_2 with the same input-output behavior, $P(M_1) = P(M_2)$. A property P is *non-trivial* if there are $M_1, M_2 \in \mathcal{M}$ such that $P(M_1) \neq P(M_2)$. In his 1951 doctoral thesis, Henry Rice proved the following sweeping result:

► **Theorem 12** ([19]). *Every non-trivial semantic property of Turing Machines is undecidable.*

Rice’s powerful theorem states that any interesting property that we might want to test of a given program is undecidable, assuming the property being tested depends only on the *function computed by the program*. That is, any property that could in principle be tested using only black-box access to the program, is undecidable given a *description* of the program. Rice’s theorem generalizes (and can be proved from) the undecidability of the TM-SAT problem of determining whether a given TM accepts any string at all.

The Black Box Hypothesis

In their pioneering obfuscation work, Barak et al. [5] consider the question: *can Rice’s Theorem be scaled down in a way that would be useful to complexity theory?* Specifically, let us assume we are not interested in *all* Turing Machines, but rather in the set of efficient algorithms; for example, those represented by Boolean circuits. One can still define properties that are non-trivial and semantic when restricted to the set of Boolean circuits. In this setting, all such properties P are decidable, because the language of a circuit is simply its 2^n -bit truth table, which can be computed in finite time. However, one might want to know something about the *computational complexity* of such properties. In this setting, the circuit satisfiability problem CKT-SAT is an analogue of TM-SAT. Although CKT-SAT is decidable, it is NP-hard, so one might hope to be able to replace undecidability in Rice’s Theorem with NP-hardness.

In earlier work, Borchert and Stephan [8] note that using circuits instead of Turing Machines and NP-hardness instead of undecidability is not enough to prove an analogue of Rice’s Theorem. For every string x , the property $\{M \in \mathcal{M} : M(x) = 1\}$ is undecidable by Rice’s Theorem, but the circuit analogue is decidable in polynomial time: it is simply the circuit evaluation problem! Borchert and Stephan’s response to this issue is to look at function properties depending on more complex measures, such as the *number* of SAT assignments of a given circuit (in other words, the property is a symmetric Boolean function in the truth table of the circuit). They show that any non-trivial “counting” property of circuits is UP-hard; the UP-hardness were improved in [13].

Barak et al. [5] gave a different response to the above issue. They observe the property $\{C : C(x) = 1\}$ for circuits C is still “trivial” in some sense: it can be efficiently determined given only *black-box* oracle access to the input circuit. This observation led Barak et al. to formulate the following conjecture. For two circuits C and C' on n -bit inputs, we write $C \equiv C'$ when C and C' compute the same n -bit function.

► **Conjecture 13** (Black Box Hypothesis [5]). *Suppose $L \subseteq \{0, 1\}^*$ satisfies the property that for all C and C' such that $C \equiv C'$, we have $C \in L \iff C' \in L$. If $L \in \text{BPP}$, then there is a probabilistic polynomial time algorithm S that decides L given only oracle access to C and $0^n 1^{|C|-n}$ as input, i.e.,*

$$C \in L \implies \Pr \left[S^C \left(0^n 1^{|C|-n} \right) = 1 \right] > \frac{2}{3}$$

$$C \notin L \implies \Pr \left[S^C \left(0^n 1^{|C|-n} \right) = 1 \right] < \frac{1}{3}.$$

That is, the BBH claims that every “white box” semantic property of circuits that is decidable in randomized poly-time can also be decided in randomized poly-time with “black box” access to the circuit. If the conjecture were true, then a strong form of $P \neq \text{NP}$ would follow: $P = \text{NP}$ implies that circuit satisfiability is solvable in polynomial-time when we have “white-box” access to the input circuit, but the SAT problem requires $\Omega(2^n)$ time to solve with only black-box oracle access to the input circuit.

Impagliazzo et al. [14] proved interesting results towards understanding BBH. They show a partial converse of the observation from the previous paragraph: if the BBH is false for certain kinds of properties, then the circuit satisfiability problem has sub-exponential size circuits. Since we know that BBH implies $P \neq \text{NP}$, this suggests that it may be difficult to resolve BBH regardless of its truth or falsity. Romani’s master thesis [20] gives an excellent overview of the BBH and this work.

An additional section on “Other Related Work” appears in Appendix A.

3 Generalized Black-Box Hypotheses

We study the Black-Box Hypothesis (Conjecture 13) in a more general setting. Specifically, instead of considering $L \in \text{BPP}$ and a randomized uniform algorithm S from Conjecture 13, we study the family of hypotheses that arise when L and S come from various (possibly non-uniform) circuit classes, which may be weaker or stronger than probabilistic poly-time.

Let us set up some notation. For a circuit C , we let $\langle C \rangle$ denote the *binary description* of C . Note that if C has size s , then $\langle C \rangle$ is a binary string of length $O(s \log s)$, which we call the *description length* of C .

Let \mathcal{C} be a set of circuits. A *property* of circuits in \mathcal{C} is a function $P : \mathcal{C} \rightarrow \{0, 1\}$. A property S is *semantic* iff for any two circuits $C_1, C_2 \in \mathcal{C}$ computing the same function (that is, $\forall \mathbf{x}, C_1(\mathbf{x}) = C_2(\mathbf{x})$), $P(C_1) = P(C_2)$. Recall a circuit family is an infinite sequence of circuits, one for each possible input length; circuit families compute functions of the form $f : \{0, 1\}^* \rightarrow \{0, 1\}$ in the natural way. We say that a circuit family $\{A_s\}$ *computes* P if for every circuit $C \in \mathcal{C}$ with description length s , $A_s(\langle C \rangle) = P(C)$.

We define a **circuit class** \mathcal{A} to be a set of circuit families; our analyst classes \mathcal{A} will have this form. By convention, an *oracle circuit* C may have oracle gates of arbitrary fan-in, but we will think of C as taking an oracle O with a fixed number of inputs. If C contains oracle gates with a different number of inputs than the given oracle O , then we define such oracle gates to output the constant 0 (regardless of O).

We formulate a generalization of the Black Box Hypothesis, which we call the \mathcal{C} -Black Box Hypothesis for \mathcal{A} (\mathcal{C} -BBH for \mathcal{A}), in the following way.

► **Hypothesis 14** (Generalized Black Box Hypothesis: \mathcal{C} -BBH for \mathcal{A}). *Let P be a semantic property of circuits in \mathcal{C} . Let $\{A'_s\} \in \mathcal{A}$ be a circuit family that computes P . Then there exists a circuit family $\{A_s\} \in \mathcal{A}^{\mathcal{C}}$ such that $A_s(1^n 0^{s-n}) = 1$ iff $P(C) = 1$.*

That is, the \mathcal{C} -BBH for \mathcal{A} hypothesizes that every semantic property of \mathcal{C} -circuits that can be decided by \mathcal{A} -analysts with “white box” access to the \mathcal{C} -circuit, can also be decided by \mathcal{A} -analysts with only black-box access to the circuit. When \mathcal{C} is the set of all Boolean circuits, we refer to the \mathcal{C} -BBH for \mathcal{A} simply as the “BBH for \mathcal{A} ”. Note that if we replace \mathcal{A} in the above with BPP, we recover Conjecture 13.

3.1 Encoding Circuits

Unfortunately, if we allow the class of analysts \mathcal{A} to be an arbitrary circuit class, we can encounter some strange (and counterintuitive) consequences. For instance, suppose \mathcal{A} is AC^0 , the circuit families over AND, OR, and NOT with constant-depth, polynomial size, and unbounded fan-in. We can construct an oracle circuit family $\{A_s\}$ such that $A_s^C(1^n 0^{s-n}) = \text{PARITY}(n)$, the parity of the number of inputs of C (A_s^C ignores C , and just computes the parity of strings of the form $1^* 0^*$). Depending on how the description $\langle C \rangle$ is represented, this behavior may not be computable by *any* white-box AC^0 circuit family $\{A'_s\}$, since PARITY is not in AC^0 [1, 9]! We would like to avoid this sort of behavior, because as in Conjecture 13, the oracle circuit family A is supposed to capture some notion of *triviality*. In order for the “BBH for \mathcal{A} ” to be meaningful, it should be that the white-box circuit family A' is at least as powerful as the black-box family A . To this end, we shall require the binary descriptions of circuits to contain all the information given freely to the oracle family. Specifically, we assume that the description of a circuit C with n input wires is prefixed by $1^n 0$, and that the first n wires in $\langle C \rangle$ are the input wires.

4 Circuit Lower Bounds Imply Black-Box Hypotheses

What can we prove about the BBH for general pairs of circuit sets and analysts \mathcal{C} , \mathcal{A} ? First, we can show there are interesting pairs for which the \mathcal{C} -BBH for \mathcal{A} is true in a strong way: every semantic property is in fact trivial. The following theorem shows that, whenever lower bounds hold against a circuit class \mathcal{A} satisfying some simple conditions, the (general) BBH for \mathcal{A} is true. First, we recall a definition.

► **Definition 15.** A projection from n variables onto m variables is a function $\pi : \{0, 1\}^n \rightarrow \{0, 1\}^m$ such that for every j , there exists i such that the j^{th} coordinate of $\pi(\mathbf{x})$ depends only on the i^{th} coordinate of \mathbf{x} .

Observe that a projection is a kind of very weak reduction which can be computed not only very efficiently but also very *locally*. By requiring closure under such a weak class of reductions, we aim to keep \mathcal{A} as general as possible.

► **Theorem 16.** Let \mathcal{A} be a circuit class, $f : \{0, 1\}^* \rightarrow \{0, 1\}$ be a decision problem, and $s : \mathbb{N} \rightarrow \mathbb{N}$ be a monotone function with the properties:

1. f is computable by a size- $s(n)$ circuit family, but f is not computable by any family in \mathcal{A} .
2. Either $\{\text{OR}_n \circ \text{AND}_2\} \subseteq \mathcal{C} \in \mathcal{A}$ for some family \mathcal{C} , or $\{\text{OR}_n \circ \text{AND}_2\} \subseteq \mathcal{C} \in \mathcal{A}$ for some family \mathcal{C} . That is, either \mathcal{A} contains a family that either computes the read-once n -clause 2-DNFs on $2n$ variables, or it contains a family that computes the n -clause 2-CNFs on $2n$ variables.
3. \mathcal{A} is closed under composition with projections from n variables onto $O(s(n) \log s(n))$ variables.

Then for every property P over the set of all circuits, if P is semantic and computable in \mathcal{A} , then for all n , P restricted to circuits on n -bit inputs is also trivial. In particular, the (general) BBH for \mathcal{A} is true.

Proof. Let \mathcal{A} and f satisfy the above properties, and let $\{F_n\}$ be a size- $s(n)$ circuit family computing f . Let P be a semantic property computable in \mathcal{A} .

First, we will prove that P is trivial. The idea is that, if P is not trivial, we can use a circuit family for P to construct a circuit in \mathcal{A} for computing f , a contradiction to the assumed lower bound on f (assumption 1).

Let $k \in \mathbb{N}$. P is semantic, so assume WLOG that for every k -input circuit K_0 computing the constant 0 function, $P(K_0) = 0$. Assume for sake of contradiction that there is a k -input C_k such that $P(C_k) = 1$. Let $n \in \mathbb{N}$ be our desired input length; we want to build a circuit computing f on n -bit inputs. For an n -bit vector \mathbf{y} , define the following circuit $D_{\mathbf{y}}$ with k input wires \mathbf{x} , with \mathbf{y} hard-coded as n constant wires:

$$D_{\mathbf{y}}(\mathbf{x}) := C_k(\mathbf{x}) \wedge F_n(\mathbf{y}).$$

The circuit $D_{\mathbf{y}}$ computes some Boolean function on k input bits. For a fixed C_k , define the function ρ_{C_k} that maps the n -bit input \mathbf{y} to the description $\langle D_{\mathbf{y}} \rangle$ of $D_{\mathbf{y}}$ as defined above. Observe that for all \mathbf{x} and \mathbf{y} , $D_{\mathbf{y}}(\mathbf{x}) = C_k(\mathbf{x})$ if $f(\mathbf{y}) = 1$, and otherwise $D_{\mathbf{y}}(\mathbf{x}) = 0$. Because P is semantic, $P(D_{\mathbf{y}}) = P(C_k) = 1$ if $f(\mathbf{y}) = 1$, and $P(D_{\mathbf{y}}) = 0$ otherwise. In other words, we have $P(D_{\mathbf{y}}) = f(\mathbf{y})$ for all \mathbf{y} .

Note the size of $D_{\mathbf{y}}$ is $t(k) + \|C_k\| + 1$, where $\|C_k\|$ denotes the size of C_k (which is independent of n), so $D_{\mathbf{y}}$ has description length $O(s(n) \log s(n))$. For a fixed C_k , $\rho_{C_k}(\mathbf{y}) = \langle D_{\mathbf{y}} \rangle$ depends only the n -bit vector \mathbf{y} . In particular, within the description $\langle D_{\mathbf{y}} \rangle$, the descriptions $\langle C_k \rangle$ and $\langle F_n \rangle$ are both independent of \mathbf{y} , so the only bits in $\langle D_{\mathbf{y}} \rangle$ that vary with \mathbf{y} are those describing the hard-coded constant \mathbf{y} itself. Hence each bit in $\langle D_{\mathbf{y}} \rangle$ depends on at most one bit of \mathbf{y} . That is, ρ_{C_k} is a projection from n variables onto $O(s(n) \log s(n))$ variables.

Since \mathcal{A} is closed under such projections (assumption 3), and P is computable in \mathcal{A} by assumption, the circuit

is also computable in \mathcal{A} . However, $P(D_{\mathbf{y}}) = f(\mathbf{y})$, which is not computable in \mathcal{A} , a contradiction. It follows that for all C_k on k inputs, $P(C_k) = 0$, so P (on circuits containing k inputs) is trivial.

We now turn to proving that there exists an oracle circuit family $\{A_s\}$ in \mathcal{A} such that for any circuit C of size s on n inputs, $A_s^C(1^n 0^{s-n}) = P(C)$. In fact we prove the stronger claim that there exists a circuit family $\{A_s\}$ in \mathcal{A} (with no oracle gates) such that for any circuit C of size s on n inputs, $A_s(1^n 0^{s-n}) = P(C)$. To this end, let $X = \{n \in \mathbb{N} : \exists C \text{ on } n \text{ inputs with } P(C) = 1\}$. First, suppose that \mathcal{A} contains a family that can compute $\{\text{OR}_n \circ \text{AND}_2\}$. For $s \in \mathbb{N}$, let A_s be the circuit of the form

$$\bigvee_{i \in X \cap [s]} (x_i \wedge \neg x_{i+1}).$$

29:10 Black-Box Hypotheses and Lower Bounds

By assumptions 2 and 3 (closure under projections from n to $2n$ variables), such circuits are in \mathcal{A} . If instead \mathcal{A} contains $\{\text{AND}_n \circ \text{OR}_2\}$, we let A_s be the circuit of the form

$$\bigwedge_{i \in [s] \setminus X} (\neg x_i \vee x_{i+1}).$$

Now $A_s(1^n 0^{s-n}) = 1$ iff $n \in X$ (using no oracle gates). Since P is trivial, for all circuits C on n inputs, $A_s(1^n 0^{s-n}) = 1$ iff $P(C) = 1$, as desired. ◀

The above proof can be thought of as an “input-switching” trick. We start with the fact that P is non-trivial on some k -bit input circuits. We use the description of a k -input circuit witnessing non-triviality, along with the description of a circuit computing f on n -bit inputs, to construct the description of a larger circuit $D_{\mathbf{y}}$ with n “free variables” \mathbf{y} . By feeding n -bit \mathbf{y} into that description, and feeding that description into P , we obtain the description of an \mathcal{A} -circuit computing f .

Theorem 16 has many immediate corollaries. For example:

► **Reminder of Corollary 3.** *The BBH for (polynomial-size) AC^0 is true. Moreover, the BBH for $2^{n^{o(1)}}$ -size AC^0 is true.*

Proof. Take \mathcal{A} to be AC^0 and f to be the PARITY function in Theorem 16, using the fact that PARITY does not have subexponential-size AC^0 circuits [12]. ◀

► **Reminder of Corollary 4.** *The BBH for (polynomial-size) TC_2^0 is true. Moreover, the BBH for $2^{n^{1-\varepsilon}}$ -size TC_2^0 is true for every $\varepsilon > 0$.*

Proof. Take \mathcal{A} to be TC_2^0 and f to be the INNERPRODUCT function (mod 2) in Theorem 16, using the fact that INNERPRODUCT requires $2^{\Omega(n)}$ -size TC_2^0 circuits [3]. ◀

4.1 Generalization

The proof of Theorem 16 critically relies on the fact that the circuit $D_{\mathbf{y}}$ can be arbitrarily large and complex in comparison to its input. If we restrict \mathcal{C} to contain only “simple” circuits and allow A'_s to behave arbitrarily on circuits not in \mathcal{C} , then we would need to be more careful to ensure that $D_{\mathbf{y}}$ is still in \mathcal{C} . By extending the input-switching trick from Theorem 16, we can restrict the circuit set \mathcal{C} in some interesting ways and still prove the corresponding Black-Box Hypotheses.

► **Definition 17.** *Let \mathcal{C} be a set of circuits, and let f and g be Boolean functions. We say that a function $I : \mathcal{C} \times \{0, 1\}^* \rightarrow \{0, 1\}^*$ is an input-switching function for \mathcal{C} and f iff for some bit b , for every circuit $C \in \mathcal{C}$ and every Boolean string \mathbf{y} , $I(C, \mathbf{y})$ is the description $\langle D_{\mathbf{y}} \rangle$ of a circuit $D_{\mathbf{y}}$ with the same number of inputs as C such that $D_{\mathbf{y}}(\mathbf{x}) = C(\mathbf{x})$ when $f(\mathbf{y}) = b$ and $D_{\mathbf{y}}(\mathbf{x}) = g(\mathbf{x})$ otherwise.*

► **Theorem 18.** *Let \mathcal{A} be a circuit class, $f : \{0, 1\}^* \rightarrow \{0, 1\}$ be a decision problem, and \mathcal{C} be a set of circuits with the properties:*

1. \mathcal{A} computes neither f nor $\neg f$.
2. \mathcal{A} is closed under composition with an input-switching function I for \mathcal{C} and f , in the sense that for every function g computable by a circuit family in \mathcal{A} and for every $C \in \mathcal{C}$, the function $\mathbf{y} \mapsto g(I(C, \mathbf{y}))$ is also computable by a circuit family in \mathcal{A} .

Then for every property P over \mathcal{C} , if P is semantic and computable in \mathcal{A} , then for all input lengths n , P restricted to circuits on n -bit inputs is also trivial. Furthermore, if \mathcal{A} also contains $\{\text{OR}_n \circ \text{AND}_2\}$ (or $\{\text{AND}_n \circ \text{OR}_2\}$), then the \mathcal{C} -BBH for \mathcal{A} is true.

The proof is in Appendix B.

The preconditions for Theorem 18 are somewhat too restrictive to be applied easily in many cases, so we strengthen it further. To this end, we first define a relation \sim_n on sets of circuits.

► **Definition 19.** For sets \mathcal{C}_1 and \mathcal{C}_2 of circuits, say that $\mathcal{C}_1 \sim_n \mathcal{C}_2$ iff there exist n -input circuits $C_1 \in \mathcal{C}_1$ and $C_2 \in \mathcal{C}_2$ such that $C_1 \equiv C_2$ (that is, C_1 and C_2 compute precisely the same Boolean function).

The relation \sim_n enables us to more easily reason about semantic properties across several sets of differently structured circuits.

► **Theorem 20.** Let \mathcal{A} be a circuit class, $f : \{0, 1\}^* \rightarrow \{0, 1\}$ be a decision problem, $\mathcal{C} = \bigcup_{i \in \mathbb{N}} \mathcal{C}_i$ be a set of circuits, and $I : \mathcal{C} \times \{0, 1\}^* \rightarrow \{0, 1\}^*$ a function with the properties:

1. \mathcal{A} computes neither f nor $\neg f$.
2. \mathcal{A} is closed under composition with I .
3. For all i , the restriction of I to $\mathcal{C}_i \times \{0, 1\}^*$ is an input-switching function for \mathcal{C}_i and f .
4. For every input size $n \in \mathbb{N}$, the transitive closure of \sim_n on $\{\mathcal{C}_i\}$ is the universal relation on $\{\mathcal{C}_i\}$.

Then for every property P over \mathcal{C} , if P is semantic and computable in \mathcal{A} , then for all input lengths n , P restricted to circuits on n -bit inputs is also trivial. Furthermore, if \mathcal{A} also contains $\{OR_n \circ AND_2\}$ (or $\{AND_n \circ OR_2\}$), then the \mathcal{C} -BBH for \mathcal{A} is true.

Proof. Let P be a property over \mathcal{C} . Applying Theorem 18 to \mathcal{A} , f , and to each \mathcal{C}_i , for all n and all i , the restrictions of P to circuits in each \mathcal{C}_i with n -bit inputs is trivial. Since P is semantic, if $i \sim_n j$, then the restriction of P to circuits in $\mathcal{C}_i \cup \mathcal{C}_j$ with n -bit inputs is also trivial. Finally since the transitive closure of \sim_n is universal, by induction we have that for every n , the restriction of P to circuits in \mathcal{C} with n -bit inputs is trivial. ◀

4.2 Examples

We now define some input-switching functions. First, let f be any function computable by a circuit family $\{F_n\}$, and let $D_{\mathcal{C}, \mathbf{y}}$ be the circuit defined as follows, where \mathbf{x} are the input wires and \mathbf{y} are hard-coded as n constant wires:

$$D_{\mathcal{C}, \mathbf{y}}(\mathbf{x}) := C(\mathbf{x}) \wedge F_n(\mathbf{y}).$$

If F_n has size $s(n)$, then the map $\mathbf{y} \mapsto \langle D_{\mathcal{C}, \mathbf{y}} \rangle$ (where $\langle D_{\mathcal{C}, \mathbf{y}} \rangle$ is the description of $D_{\mathcal{C}, \mathbf{y}}$) is both an input-switching function and a projection from n variables onto the $O(s(n) \log s(n))$ variables describing $D_{\mathcal{C}, \mathbf{y}}$, so we recover Theorem 16.

Recall that $AC_d^0[p]$ denotes circuit families of depth d with unbounded fan-in AND, OR, and MOD_p gates.

► **Reminder of Corollary 6.** For all primes p , the $AC^0[p]$ -Black-Box Hypothesis for (polynomial-size) AC^0 is true. Moreover, the $AC^0[p]$ -Black-Box Hypothesis for $2^{s^{o(1)}}$ -size AC^0 is true.

Proof. Follows from Theorem 18. We make use of the fact that the MOD_p function is computable in linear size $AC^0[p]$ but requires exponential size in AC^0 , and that in AC^0 we can mask a given $AC^0[p]$ circuit with a given MOD_p function.

29:12 Black-Box Hypotheses and Lower Bounds

Let \mathcal{A} be $2^{s^{o(1)}}$ -size AC^0 , $f = \text{MOD}_p$, and $\mathcal{C} = \text{AC}^0[p]$. We now define a circuit $D_{C,\mathbf{y}}$ with the same number of inputs as C as

$$D_{C,\mathbf{y}}(\mathbf{x}) := C(\mathbf{x}) \wedge \text{MOD}_p(\mathbf{y}).$$

Then for all \mathbf{x} and \mathbf{y} , $D_{C,\mathbf{y}}(\mathbf{x}) = C(\mathbf{x})$ if $\text{MOD}_p(\mathbf{y}) = 1$, and $D_{C,\mathbf{y}}(\mathbf{x}) = 0$ otherwise. Now the map $(C, \mathbf{y}) \mapsto \langle D_{C,\mathbf{y}} \rangle$ is an input-switching function for \mathcal{C} and MOD_p . Furthermore, we can think of the map $\mathbf{y} \mapsto \langle D_{C,\mathbf{y}} \rangle$ as a projection from n variables \mathbf{y} onto $\Theta(n \log n)$ variables describing $D_{C,\mathbf{y}}$, so \mathcal{A} is closed under composition with I . Now from Theorem 18, every semantic property P over \mathcal{C} computable in \mathcal{A} is trivial, so the \mathcal{C} -BBH for \mathcal{A} is true. \blacktriangleleft

If we invoke Theorem 20 instead of Theorem 18, we can get an even stronger result.

► **Theorem 21.** *For all depths $d \geq 2$ and distinct primes $p \neq q$, the $\text{AC}_d^0[p]$ -BBH for $2^{s^{o(1)}}$ -size $\text{AC}^0[q]$ is true.*

The proof is in Appendix C. The proof of Theorem 21 relies on the fact that small $\text{AC}^0[q]$ circuits cannot evaluate some function that can be evaluated with small $\text{AC}^0[p]$ circuits (namely a single MOD_p gate). We can prove a similar result using the depth- d Sipser function, which is easy for AC^0 circuits of depth d but hard for depth $d - 1$ [22, 12].

► **Definition 22.** *The Sipser function $f^{d,n} : \{0, 1\}^{\sqrt{\frac{n}{\log n}}} \times \{0, 1\}^{n^{d-2}} \times \{0, 1\}^{\sqrt{\frac{1}{2}dn \log n}} \rightarrow \{0, 1\}$ is defined as follows:*

$$\begin{aligned} \text{If } d \text{ is odd, then } f^{d,n}(\mathbf{x}) &= \bigwedge_{i_1=1}^{\sqrt{\frac{n}{\log n}}} \bigvee_{i_2=1}^n \bigwedge_{i_3=1}^n \cdots \bigwedge_{i_d=1}^{\sqrt{\frac{1}{2}dn \log n}} x_{i_1, \dots, i_d}. \\ \text{If } d \text{ is even, then } f^{d,n}(\mathbf{x}) &= \bigwedge_{i_1=1}^{\sqrt{\frac{n}{\log n}}} \bigvee_{i_2=1}^n \bigwedge_{i_3=1}^n \cdots \bigvee_{i_d=1}^{\sqrt{\frac{1}{2}dn \log n}} x_{i_1, \dots, i_d}. \end{aligned}$$

► **Theorem 23.** *For all depths $d \geq 2$, the AC_d^0 -BBH for $2^{s^{o(1)}}$ -size AC_{d-1}^0 is true.*

The proof is in Appendix D.

5 Some Black-Box Hypotheses Imply Lower Bounds

In Section 4, we showed that many circuit lower bounds of the form $\mathcal{C}' \not\subseteq \mathcal{A}$ can be used to prove a corresponding \mathcal{C} -Black-Box Hypothesis for \mathcal{A} (for a set of boxes \mathcal{C} that suitably captures the complexity class \mathcal{C}'). Now we consider the converse question: can Black-Box Hypotheses also be used to prove circuit lower bounds? For certain sets \mathcal{C} of boxes and classes \mathcal{A} of analysts, it turns out that the \mathcal{C} -Black-Box Hypothesis for \mathcal{A} does in fact imply lower bounds against \mathcal{A} .

For a function $s : \mathbb{N} \rightarrow \mathbb{N}$, let $\text{CIRCUIT}(s(n))$ denote the set of (general) Boolean circuits on n inputs of size at most $s(n)$, for every n . (Note this is different from $\text{SIZE}(s(n))$, which is the class of *languages* computed by circuit families of size at most $s(n)$.) As a starting point, the following simple proposition was essentially noted by Barak et al. [5].

► **Proposition 24.** *If $\text{NP} \subset \text{P}/\text{poly}$, then for every polynomial p , the $\text{CIRCUIT}(p(n))$ -BBH for P/poly is false.*

Proof. Take P to be the CKT-SAT property (that is, $P(C) = 0$ iff the circuit C encodes the all-zeroes function). By assumption, $P \in \text{P/poly}$, but even with randomness, $\Omega(2^n)$ oracle queries are needed to determine whether a size- $p(n)$ circuit on n inputs is the all-zeroes function. For every polynomial q , the polynomial $q \circ p$ is $o(2^n)$, so there is no size- $q(s)$ circuit family making $\Omega(2^n)$ oracle queries on size- $p(n)$ circuits. ◀

In fact, Proposition 24 can be strengthened by replacing CKT-SAT with the property $P(C) = 1$ iff C has a satisfying assignment that sets the first k inputs to 0 (for some appropriately large k).

► **Proposition 25.** *If $\text{NP} \subset \text{SIZE}(2^{n^{o(1)}})$, then for every polynomial p , the $\text{CIRCUIT}(p(n))$ -BBH for P/poly is false.*

Propositions 24 and 25 are arguably not particularly useful, since very few researchers believe the hypotheses of these propositions. However, they still do illustrate an interesting observation, and we may be able to generalize them in a useful manner. Let \mathcal{C} -SAT be the satisfiability problem for circuits from the set \mathcal{C} . One might hope to prove the following generalization of Proposition 24, for every circuit set \mathcal{C} and every analyst class \mathcal{A} :

► **Hypothesis 26** (The Satisfiability Black-Box Hypothesis). *If $\mathcal{C}\text{-SAT} \in \mathcal{A}$, then the \mathcal{C} -BBH for \mathcal{A} is false.*

In this fully generic form, there are some simple counterexamples to Hypothesis 26. For instance, if \mathcal{A} contains *all* Boolean functions, then (for every set \mathcal{C}) $\mathcal{C}\text{-SAT} \in \mathcal{A}$. However, the \mathcal{C} -BBH for \mathcal{A} is *true*, because \mathcal{A} can decide *any* semantic property with only black-box access to the circuit being analyzed. Hence we require additional restrictions on \mathcal{C} and \mathcal{A} to make the hypothesis interesting. In particular, we would like \mathcal{A} to contain only functions of subexponential circuit complexity, and for a sufficiently simple function f , we would like \mathcal{C} circuits to be able to compute f efficiently.

Recall that a Boolean function $f : \{0,1\}^* \rightarrow \{0,1\}$ is a *point function* if there is an $\mathbf{a} \in \{0,1\}^*$ such that for all \mathbf{x} , $f(\mathbf{x}) = 1 \iff \mathbf{x} = \mathbf{a}$. The following notion of “reasonability” for circuit sets will be useful in multiple contexts.

► **Definition 27** (Reasonability). *A set \mathcal{C} of circuits is reasonable if there is a polynomial p such that for all point functions f , there is a circuit family $\{C_n\} \subset \mathcal{C}$ of size at most $p(n)$ computing f .*

We can show that if \mathcal{C} is reasonable and \mathcal{A} has subexponential-size circuits, then Hypothesis 26 is true. The following can be viewed as a kind of converse of Theorem 16.

► **Theorem 28.** *If \mathcal{C} is reasonable, $\mathcal{A} \subseteq \text{SIZE}(2^{n^{o(1)}})$, and $\mathcal{C}\text{-SAT} \in \mathcal{A}$, then the \mathcal{C} -BBH for \mathcal{A} is false.*

Proof. Assume \mathcal{C} is reasonable, \mathcal{A} has subexponential-size circuits, and $\mathcal{C}\text{-SAT} \in \mathcal{A}$. As in Proposition 24, we take P to be the satisfiability property. By assumption, $P \in \mathcal{A}$. Even with randomness, $\Omega(2^n)$ oracle queries are required to determine whether a circuit of size $p(n)$ on n inputs computes the constant 0 function. However, an \mathcal{A} circuit can make at most $2^{n^{o(1)}}$ queries to its oracle when given an input of size $p(n)$. Per the reasonableness of \mathcal{C} , there are both satisfiable and unsatisfiable \mathcal{C} -circuits of size $p(n)$, so \mathcal{A} , with only black-box access to a \mathcal{C} -circuit, cannot compute P . ◀

The preconditions for Theorem 28 are very general; most complexity classes of interest only deal with functions of subexponential complexity and can compute point functions efficiently. However, this weak condition is sufficient to remove the simple counterexamples.

5.1 A Notion of BBH-Completeness

For very general circuit sets \mathcal{C} and classes \mathcal{A} of analysts, we have shown (roughly) in Section 4 that

$$\mathcal{C} \not\subseteq \mathcal{A} \implies \mathcal{C}\text{-BBH for } \mathcal{A},$$

and in the previous paragraphs that for “reasonable” \mathcal{A} and \mathcal{C} ,

$$\mathcal{C}\text{-BBH for } \mathcal{A} \implies \mathcal{C}\text{-SAT} \not\subseteq \mathcal{A}.$$

For many pairs of classes \mathcal{C} and \mathcal{A} , we have

$$\mathcal{C}\text{-EVAL} \not\subseteq \mathcal{A} \iff \mathcal{C} \not\subseteq \mathcal{A}.$$

So the results of Section 4 imply, at least for many natural pairs \mathcal{C}, \mathcal{A} , that \mathcal{C} -EVAL lower bounds imply BBHs. However, \mathcal{C} -SAT is generally a harder problem than \mathcal{C} -EVAL, so there remains a gap between the lower bounds that provably imply a Black-Box Hypothesis, and those lower bounds provably implied by a Black-Box Hypothesis.

A natural question is then, which of these implications can be strengthened? **Is there a single problem on \mathcal{C} circuits, such that proving a lower bound for it is equivalent to proving a \mathcal{C} -Black-Box Hypothesis?** In particular, is proving either $\mathcal{C}\text{-EVAL} \not\subseteq \mathcal{A}$ or $\mathcal{C}\text{-SAT} \not\subseteq \mathcal{A}$ *equivalent* to proving the \mathcal{C} -BBH for \mathcal{A} ? Similar to other completeness notions in complexity theory, we propose a concept of BBH-completeness to study equivalences between circuit lower bounds and Black-Box Hypotheses.²

► **Definition 29** (BBH-completeness). *Let \mathcal{C} be a set of circuits and \mathcal{A} a complexity class. A Boolean function f is complete for the \mathcal{C} -BBH for \mathcal{A} (or \mathcal{C} -BBH-complete for \mathcal{A}) iff*

$$\mathcal{C}\text{-BBH for } \mathcal{A} \iff f \notin \mathcal{A}.$$

When \mathcal{A} is either implicitly understood or general, we say that f is \mathcal{C} -BBH-complete.

Are there natural pairs $(\mathcal{C}, \mathcal{A})$ for which either \mathcal{C} -EVAL or \mathcal{C} -SAT is \mathcal{C} -BBH-complete for \mathcal{A} ?

The Case of Nondeterministic Boxes. For the case of sets \mathcal{C} of nondeterministic circuits, the answer is **yes**. To state our theorem, we require one new concept. Recall that a nondeterministic circuit C has a sequence of “normal” inputs \mathbf{x} as well as a sequence of “auxiliary” nondeterministic inputs \mathbf{y} , and we say that C accepts \mathbf{x} if there is a setting of \mathbf{y} such that $C(\mathbf{x}, \mathbf{y}) = 1$.

► **Definition 30.** *For a given circuit C , a nondeterminization of C is a circuit C' in which normal inputs to C have been converted into auxiliary nondeterministic inputs. A set \mathcal{C} of circuits is closed under nondeterminization if $C \in \mathcal{C}$ implies that every nondeterminization of C is also in \mathcal{C} .*

² It must be said that both authors are not entirely comfortable with the following definition of BBH-completeness. Ideally, the following would be a consequence of f being BBH-complete, and the actual definition would involve a notion of reducibility. However, in order to give a completeness concept that fits all possible classes \mathcal{A} and \mathcal{C} at a high level of generality, it does not seem possible to use reductions: a sound reducibility notion would inevitably have to depend on \mathcal{A} (in particular, its allowed “sizes” and its closure properties) directly.

► **Theorem 31.** *Let \mathcal{C} be a reasonable set of circuits closed under nondeterminization. Assume \mathcal{A} has circuits of size $2^{n^{o(1)}}$ and that \mathcal{A} is closed under composition with an input-switching function for \mathcal{C} and \mathcal{C} -EVAL. Then \mathcal{C} -EVAL and \mathcal{C} -SAT are \mathcal{C} -BBH-complete for \mathcal{A} .*

Proof. We wish to prove that the following are equivalent:

1. \mathcal{C} -BBH for \mathcal{A}
2. \mathcal{C} -SAT $\notin \mathcal{A}$
3. \mathcal{C} -EVAL $\notin \mathcal{A}$

(1) \implies (2) Follows from Theorem 28.

(2) \implies (3) We reduce \mathcal{C} -SAT to \mathcal{C} -EVAL by observing that changing the inputs of a nondeterministic circuit into auxiliary nondeterministic inputs preserves satisfiability. Hence, given a nondeterministic circuit C , we can convert *all* of its input bits into additional nondeterministic auxiliary inputs to obtain a circuit C' , and then determine whether C' is still satisfiable. However, C' has no remaining free inputs, so determining satisfiability of C' is simply the problem of *evaluating* C' (with no inputs).

(3) \implies (1) Follows from Theorem 18. ◀

Interpreting Impagliazzo et al. as an Equivalence. Recently, Impagliazzo et al. [14] proved that if the BBH is false for certain kinds of function properties, then the circuit satisfiability problem has sub-exponential size circuits. In particular, they show that CKT-SAT has $2^{n^{o(1)}}$ -size circuits if a property P is highly sensitive on a function f that has sub-exponential size circuits.

Impagliazzo et al. indicate that in some sense CKT-SAT is BBH-complete, at least for large analyst classes \mathcal{A} . Specifically, if we consider only *symmetric* semantic properties, i.e., properties that depend only on the number of ones in the truth table of the input circuit, we can define the following conjecture:

► **Hypothesis 32 (Symmetric-BBH).** *Let P be a semantic and symmetric property of circuits. Let $\{A'_s\}$ be a polynomial size circuit family. Assume that for every circuit C of size s on n inputs, $A'_s(C) = 1$ iff $P(C) = 1$. Then there exists a polynomial size oracle circuit family $\{A_s\}$ such that $A_s^C(1^n 0^{s-n}) = 1$ iff $P(C) = 1$.*

Now [14] implies:

► **Theorem 33 (Follows from [14]).** *The following are equivalent:*

1. CKT-SAT is not in P/poly.
2. The Symmetric-BBH is true.

Proof. The forward direction is Corollary 4.3 in [14]. For the converse direction, observe that CKT-SAT is a symmetric property that requires exponentially many black-box oracle queries (and in particular, cannot be solved in P/poly with only black-box access to the input circuit). Hence if the Symmetric-BBH is true, then CKT-SAT also cannot be solved in P/poly with white-box access to the input circuit, i.e., CKT-SAT \notin P/poly. ◀

6 Conclusion

In this paper, we introduced *generalized* Black-Box Hypotheses, which parameterize both the type of “box” being analyzed, and the type of “analyst” examining such boxes. We showed that generalized Black-Box Hypotheses can follow generically from circuit lower bounds, and we showed how lower bounds for the circuit satisfiability problem are essentially equivalent to Black-Box Hypotheses where the “boxes” correspond to nondeterministic circuits. We conclude with some additional interesting directions to consider.

What Other Lower Bounds Are Implied by Black-Box Hypotheses? In Section 5 we noted a simple example of a lower bound implying a BBH: the \mathcal{C} -BBH for \mathcal{A} implies \mathcal{C} -SAT $\notin \mathcal{A}$. However, this lower bound is rather weak-looking: \mathcal{C} -SAT is NP-complete for many very simple \mathcal{C} . Are there circuit-analysis problems which are likely *not* to be NP-complete, which would still be implied by a Black-Box Hypothesis? We find this to be a very interesting question, and we currently do not have good candidates for such a problem.

Randomized Lower Bounds and Their Black-Box Hypotheses. We have shown that (deterministic) worst-case lower bounds can lead to results about analyzing circuits as boxes. What results can be derived from *average-case* or *randomized* lower bounds? We have obtained some preliminary results in this direction. For instance, if our analyst class \mathcal{A} consists of *randomized* algorithms rather than deterministic ones, we can still prove connections between lower bounds against \mathcal{A} and BBHs for \mathcal{A} , along the lines of Section 4. There are likely other connections like this to be found within the vast landscape of complexity theory.

Black-Box Hypotheses From More Lower Bounds? While we have shown that various Black-Box Hypotheses do follow from certain lower bounds in a generic way, some lower bounds don't seem to imply a Black-Box Hypothesis. For example, a circuit-size hierarchy is well-known: for nice functions s , there are functions computable with size- $s(n)$ circuits that do not have circuits of size less than $s(n) - 5n$ (cf. [15]). This suggests the possibility that, for analysts \mathcal{A} implemented by circuits of size less than $s(n) - 5n$, and boxes \mathcal{C} which are circuits of size at least $s(n)$, the \mathcal{C} -Black-Box Hypothesis for \mathcal{A} is true. However, our current methods are unable to prove such a sharp result. Are there other intermediate lower bounds (weaker than against e.g. \mathcal{C} -EVAL) that would still imply Black-Box Hypotheses?

A Other Related Work

Obfuscation in Cryptography

In recent years, the theory of program obfuscation has exploded into a huge subject area within cryptography, starting with an influential paper of Barak et al. [5] which crystallized several key definitions and proved key impossibility results for obfuscation. Two major concepts they proposed are *virtual black-box obfuscation* (VBB for short) and *indistinguishability obfuscation* (iO for short), which we now describe briefly.

A VBB obfuscator \mathcal{O} would take any efficient program/circuit C of size s , and output the code of an “obfuscated” $\mathcal{O}(C)$ such that, for every probabilistic polynomial time (PPT) adversary A , there is another PPT adversary A' , such that the probability A outputs 1 on

the input $\mathcal{O}(C)$ is very close to the probability that A' outputs 1 on $(1^n, 1^s)$ when *given* C as an oracle. That is, whatever computation A is doing on the code of $\mathcal{O}(C)$, A' can simulate that knowing only the size of C , its number of inputs, and with input-output access to C . Barak et al. showed that there are tasks for which VBB obfuscation is *impossible* assuming one-way functions exist. The notion of iO asks for a weaker guarantee: for all PPT A , and all pairs of size- s circuits C_1, C_2 such that $C_1 \equiv C_2$, the probability A outputs 1 on C_1 is very close to the probability A outputs 1 on C_2 . In contrast to VBB, iO is possible under plausible hardness conjectures (e.g., [11, 10, 6]), and it turns out to be very powerful, capable of implementing deniable encryption, public-key encryption from one-way functions, multiparty key exchange, and more (e.g., [21, 7]).

All of the above work on building obfuscation requires hardness assumptions that are unproved (and are typically much stronger than $P \neq NP$), and study how we might efficiently transform arbitrary code into obfuscated code, relative to some class of adversarial analysts.

We briefly note the connection between VBB and the BBH. One can think of a VBB obfuscator as an efficient mapping from general circuits to “obfuscated class of circuits”, a *restricted subclass* of circuits, such that the BBH holds when the analyzable code \mathcal{C} must come from this restricted subclass. Namely, the VBB property says that, for any efficient analyst that takes circuits from this class as input, there is an efficient black-box analyst that can carry out essentially the same analyses. That is, when VBB is possible, there is a “promise” class of circuits (the image of the obfuscator) for which a black-box hypothesis is true. Accordingly, Barak et al. [5] showed that a “promise” version of the BBH is false, assuming one-way functions exist.

Automated Formal Verification

Additionally, settings in which the Black-Box Hypothesis is false are of great interest in automated formal verification. One central question is the following: what properties of a program’s input-output behavior can be more efficiently tested by analyzing the program’s code, than by treating it as a black box and simply running it on selected inputs? Many properties of interest depend on the program’s behavior on all possible inputs, which may be infeasible (or even impossible) to determine exhaustively. One may instead want to analyze the code of the program in order to determine whether or not it satisfies the given property. This may still be impossible, as many properties of interest are Turing-complete when considered over the space of all possible programs. However, by restricting the class of programs being tested, some such verification problems can become feasible, cf. [16, 17, 2]. In fact, in any setting where the class of programs being analyzed is restricted such that the black box hypothesis is *false*, there *must* exist properties that can be tested by analyzing the program but not by treating it as a black box.

B Proof of Theorem 18

► **Reminder of Theorem 18.** Let \mathcal{A} be a circuit class, $f : \{0, 1\}^* \rightarrow \{0, 1\}$ be a decision problem, and \mathcal{C} be a set of circuits with the properties:

1. \mathcal{A} contains neither f nor $\neg f$.
2. \mathcal{A} is closed under composition with an input-switching function I for \mathcal{C} and f , in the sense that for every function g computable by a circuit family in \mathcal{A} and for every $C \in \mathcal{C}$, the function $\mathbf{y} \mapsto g(I(C, \mathbf{y}))$ is also computable by a circuit family in \mathcal{A} .

Then for every property P over \mathcal{C} , if P is semantic and computable in \mathcal{A} , then for all input lengths n , P restricted to circuits on n -bit inputs is also trivial. Furthermore, if \mathcal{A} also contains $\{\text{OR}_n \circ \text{AND}_2\}$ (or $\{\text{AND}_n \circ \text{OR}_2\}$), then the \mathcal{C} -BBH for \mathcal{A} is true.

Proof. Let \mathcal{A} and f satisfy the above properties, and let I be the input-switching function for \mathcal{C} and f . Let P be a semantic property computable in \mathcal{A} .

First, we will prove that P is trivial. The idea is that, if P is not trivial, we can use a circuit family for P to construct a circuit in \mathcal{A} for computing f , a contradiction to the assumed lower bound on f .

Let $k \in \mathbb{N}$. Assume WLOG that for every circuit G computing g on k inputs, $P(G) = 0$. Assume for sake of contradiction that there is a k -input C_k such that $P(C_k) = 1$. For an n -bit input \mathbf{y} , consider the circuit $D_{\mathbf{y}} = I(C_k, y)$. Note that $D_{\mathbf{y}}$ computes some Boolean function on k input bits. From the definition of I , $D_{\mathbf{y}}(\mathbf{x}) = C_k(\mathbf{x})$ if $f(\mathbf{y}) = b$, and otherwise $D_{\mathbf{y}}(\mathbf{x}) = G(\mathbf{x})$. Because P is semantic, $P(D_{\mathbf{y}}) = P(C_k) = 1$ if $f(\mathbf{y}) = b$, and $P(D_{\mathbf{y}}) = P(G) = 0$ otherwise. In other words, we have $P(D_{\mathbf{y}}) = b \otimes f(\mathbf{y})$ for all \mathbf{y} .

Since \mathcal{A} is closed under composition with $I(C_k, -)$, and P is computable in \mathcal{A} by assumption, the circuit

is also computable in \mathcal{A} . However, $P(D_{\mathbf{y}}) = f(\mathbf{y})$ or $\neg f(\mathbf{y})$, which are not computable in \mathcal{A} , a contradiction. It follows that for all C_k on k inputs, $P(C_k) = 0$, so P (on circuits containing k inputs) is trivial.

As in Theorem 16, there exists a circuit family $\{A_s\}$ in \mathcal{A} (with no oracle gates) such that for any circuit C of size s on n inputs, $A_s(1^n 0^{s-n}) = P(C)$. ◀

C Proof of Theorem 21

▶ **Reminder of Theorem 21.** For all depths $d \geq 2$ and distinct primes $p \neq q$, the $\text{AC}_d^0[p]$ -BBH for $2^{s^{o(1)}}$ -size $\text{AC}^0[q]$ is true.

Proof. Follows from Theorem 20. We make use of the fact that the MOD_p function is computable in linear size $\text{AC}_d^0[p]$ but requires exponential size in $\text{AC}^0[q]$ [18, 23], and that in AC^0 we can mask a given $\text{AC}_d^0[p]$ circuit with a given MOD_p function, without increasing its depth.

Let $d \geq 2$, \mathcal{A} be $2^{s^{o(1)}}$ -size $\text{AC}^0[q]$, $f = \text{MOD}_p$, $\mathcal{C} = \text{AC}_d^0[p]$, $\mathcal{C}_1 = \text{OR} \circ \text{AC}_{d-1}^0[p]$, $\mathcal{C}_2 = \text{AND} \circ \text{AC}_{d-1}^0[p]$, and $\mathcal{C}_3 = \text{MOD}_p \circ \text{AC}_{d-1}^0[p]$. (Note that $\mathcal{C} = \mathcal{C}_1 \cup \mathcal{C}_2 \cup \mathcal{C}_3$.) We now define a function $I : \mathcal{C} \times \{0, 1\}^* \rightarrow \{0, 1\}^*$, so that $I(C, \mathbf{y}) = \langle D_{\mathbf{y}} \rangle$, where $D_{\mathbf{y}}$ has the same number of inputs as C . We condition on whether the input circuit C comes from \mathcal{C}_1 , \mathcal{C}_2 , or \mathcal{C}_3 .

Case 1. If $C \in \mathcal{C}_1$, then it has the form $\vee_m \circ C'$, where C' is a depth- $(d-1)$ circuit with n inputs and m outputs, and \vee_m is an OR of fan-in m . For a k -bit vector \mathbf{y} , we construct $D_{\mathbf{y}}$ as follows:

29:20 Black-Box Hypotheses and Lower Bounds

Then for all \mathbf{x} and \mathbf{y} , $D_{\mathbf{y}}(\mathbf{x}) = C(\mathbf{x})$ if $\text{MOD}_p(\mathbf{y}) = 0$, and $D_{\mathbf{y}}(\mathbf{x}) = 1$ otherwise. Hence the restriction of I to $\mathcal{C}_1 \times \{0, 1\}^*$ is an input-switching function for \mathcal{C}_1 and f .

Case 2. If $C \in \mathcal{C}_2$, we construct $D_{\mathbf{y}}$ similarly to case (1). Assuming $C = \wedge_m \circ C'$ for the same sort of C' , we can construct $D_{\mathbf{y}}$ as follows:

Then for all \mathbf{x} and \mathbf{y} , $D_{\mathbf{y}}(\mathbf{x}) = C(\mathbf{x})$ if $\text{MOD}_p(\mathbf{y}) = 1$, and $D_{\mathbf{y}}(\mathbf{x}) = 0$ otherwise. Hence the restriction of I to $\mathcal{C}_2 \times \{0, 1\}^*$ is an input-switching function for \mathcal{C}_2 and f .

Case 3. If $C \in \mathcal{C}_3$, then C is a MOD_p gate of fan-in m , composed with some depth- $(d - 1)$ circuit C' having n inputs and m outputs. We define a $\otimes_{m \times k}$ gate to take $m + k$ inputs $x_1, \dots, x_m, y_1, \dots, y_k$, and output $x_i \cdot y_j$ for all i, j , and define a circuit $D'_{\mathbf{y}}(\mathbf{x})$ as follows:

Note that for C of depth d , $D'_{\mathbf{y}}$ has depth $d + 1$. However, when treating \mathbf{y} as a constant, each $C'(\mathbf{x})_i \wedge y_j$ simplifies to a single wire (either $C'(\mathbf{x})_i$ if $y_j = 1$, or the constant 0 if $y_j = 0$). Performing these simplifications and removing the layer of AND gates, we get a circuit $D_{\mathbf{y}}$ of depth d . (Note that each bit in $\langle D_{\mathbf{y}} \rangle$ still only depends on at most one bit of \mathbf{y} .) Now for all \mathbf{x} and \mathbf{y} , $D_{\mathbf{y}}(\mathbf{x}) = \text{MOD}_p(C'(\mathbf{x}) \otimes \mathbf{y}) = \text{MOD}_p(C'(\mathbf{x})) \times \text{MOD}_p(\mathbf{y}) = C(\mathbf{x}) \times \text{MOD}_p(\mathbf{y})$. That is, $D_{\mathbf{y}}(\mathbf{x}) = C(\mathbf{x})$ if $\text{MOD}_p(\mathbf{y}) = 1$, and $D_{\mathbf{y}}(\mathbf{x}) = 0$ otherwise. Hence the restriction of I to $\mathcal{C}_3 \times \{0, 1\}^*$ is an input-switching function for \mathcal{C}_3 and f .

Next, we observe that in every case, each bit in $\langle D_{\mathbf{y}} \rangle$ depends on only one bit of \mathbf{y} , so \mathcal{A} is closed under composition with I (a projection). Finally, there are circuits C_1, C_2, C_3 , which have an OR, AND, and MOD_p output gate (respectively), yet $C_1 \equiv C_2 \equiv C_3$ (e.g. they can ignore their input and output the constant 0). Hence \sim_k as defined in Theorem 20 is the universal relation. Now from Theorem 20, every semantic property P over \mathcal{C} computable in \mathcal{A} is trivial, so the \mathcal{C} -BBH for \mathcal{A} is true. ◀

D Proof of Theorem 23

► **Reminder of Theorem 23.** For all depths $d \geq 2$, the AC_d^0 -BBH for $2^{s^{o(1)}}$ -size AC_{d-1}^0 is true.

Proof. We proceed as in Theorem 21. Let $d \geq 2$, f be the depth- d Sipser function, \mathcal{A} be $2^{s^{o(1)}}$ -size AC_{d-1}^0 , $\mathcal{C} = \text{AC}_d^0$, $\mathcal{C}_1 = \text{AND} \circ \text{AC}_{d-1}^0$, and $\mathcal{C}_2 = \text{OR} \circ \text{AC}_{d-1}^0$. (Note that $\mathcal{C} = \mathcal{C}_1 \cup \mathcal{C}_2$.) We now define a function $I : \mathcal{C} \times \{0, 1\}^* \rightarrow \{0, 1\}^*$, so that $I(C, \mathbf{y}) = \langle D_{\mathbf{y}} \rangle$, where $D_{\mathbf{y}}$ has the same number of inputs as C . We condition on whether the input circuit C comes from \mathcal{C}_1 or \mathcal{C}_2 .

Case 1. If $C \in \mathcal{C}_1$, then it has the form $\wedge_m \circ C'$, where C' is a depth- $(d-1)$ circuit with n inputs and m outputs, and \wedge_m is an AND of fan-in m . Let $k \in \mathbb{N}$, and take $n' = (2k/d)^{1/(d-1)}$, so that $f^{d,n'}$ has k inputs. For a k -bit vector \mathbf{y} , we construct $D'_{\mathbf{y}}$ as follows:

Here, $F^{d,n'}$ denotes the obvious depth- d circuit computing the Sipser function $f^{d,n'}$. Now by collapsing the output AND gate of $F^{d,n'}$ into the \wedge_{m+1} , we obtain a depth- d circuit $D_{\mathbf{y}}$ on n inputs such that $D_{\mathbf{y}}(\mathbf{x}) = C(\mathbf{x})$ if $f^{d,n'}(\mathbf{y}) = 1$, and $D_{\mathbf{y}}(\mathbf{x}) = 0$ otherwise. Hence the restriction of I to $\mathcal{C}_1 \times \{0, 1\}^*$ is an input-switching function for \mathcal{C}_1 and f .

Case 2. If $C \in \mathcal{C}_2$, then it has the form $\vee_m \circ C'$. In this case, we construct the circuit $D'_{\mathbf{y}}$ as follows:

Here $F'^{d,n'}$ denotes the circuit obtained by replacing all AND gates in $F^{d,n'}$ with OR gates and vice-versa, and negating all of the input wires. By collapsing the output OR gate of $F'^{d,n'}$ into the \vee_{m+1} , we obtain a depth- d circuit $D_{\mathbf{y}}$ on n inputs such that $D_{\mathbf{y}}(\mathbf{x}) = C(\mathbf{x})$ if $f^{d,n'}(\mathbf{y}) = 1$, and $D_{\mathbf{y}}(\mathbf{x}) = 1$ otherwise. Hence the restriction of I to $\mathcal{C}_2 \times \{0, 1\}^*$ is an input-switching function for \mathcal{C}_2 and f .

29:22 Black-Box Hypotheses and Lower Bounds

As before, we observe that each bit in $\langle D_{\mathbf{y}} \rangle$ depends on at most one bit of \mathbf{y} , and that there are circuits C_1 and C_2 which have an AND and OR output gate (respectively) and compute the constant 0 function. Applying Theorem 20, every semantic property P over \mathcal{C} computable in \mathcal{A} is trivial, so the \mathcal{C} -BBH for \mathcal{A} is true. ◀

Abstract

ZX-Calculus is a versatile graphical language for quantum computation equipped with an equational theory. Getting inspiration from Geometry of Interaction, in this paper we propose a token-machine-based asynchronous model of both pure ZX-Calculus and its extension to mixed processes. We also show how to connect this new semantics to the usual standard interpretation of ZX-diagrams. This model allows us to have a new look at what ZX-diagrams compute, and give a more local, operational view of the semantics of ZX-diagrams.

1 Introduction

Quantum computing is a model of computation where data is stored on the state of particles governed by the laws of quantum physics. The theory is well established enough to have allowed the design of quantum algorithms whose applications are gathering interests from both public and private actors [29, 31, 17].

One of the fundamental properties of quantum objects is to have a *dual* interpretations. In the first one, the quantum object is understood as a *particle*: a definite, localized point in space, distinct from the other particles. Light can be for instance regarded as a set of photons. In the other interpretation, the object is understood as a *wave*: it is “spread-out” in space, possibly featuring interference. This is for instance the interpretation of light as an electromagnetic wave.

The standard model of computation uses *quantum bits* (qubits) for storing information and *quantum circuits* [30] for describing quantum operations with quantum gates, the quantum version of Boolean gates. Although the pervasive model for quantum computation, quantum circuits’ operational semantics is only given in an intuitive manner. A quantum circuit is understood as some sequential, low-level assembly language where quantum gates are opaque black-boxes. In particular, quantum circuits do not natively feature any formal operational semantics giving rise to abstract reasoning, equational theory or well-founded rewrite system.

From a denotational perspective, quantum circuits are literal description of tensors and applications of linear operators. These can be described with the historical matrix interpretation [30], or with the more recent sum-over-paths semantics [1, 6] – this can be

regarded as a *wave-style semantics*. In such a semantics, the state of all of the quantum bits of the memory is mathematically represented as a vector in a (finite dimensional) Hilbert space: the set of quantum bits is a *wave* flowing in the circuit, from the inputs to the output, while the computation generated by the list of quantum gates is a linear map from the Hilbert space of inputs to the Hilbert space of outputs.

In recent years, an alternative model of quantum computation with better formal properties than quantum circuits has emerged: the ZX-Calculus [7]. Originally motivated by a categorical interpretation of quantum theory, the ZX-Calculus is a graphical language that represents linear maps as special kinds of graphs called *diagrams*. Unlike the quantum circuit framework, the ZX-Calculus comes with a sound and complete [24, 33], well-defined equational theory on a small set of canonical generators making it possible to reason on quantum computation by means of local graph rewriting.

The canonical semantics of a ZX diagram consists in a linear operator. This operator can be represented as a matrix or through the more recent sum-over-path semantics [35]. But in both cases, these semantics give a purely functional, *wave-style* interpretation to the diagram. Nonetheless, this graphical language – and its equational theory – has been shown to be amenable to many extensions and is being used in a wide spectrum of applications ranging from quantum circuit optimization [14, 4], verification [25, 15, 13] and representation such as MBQC patterns [16] or error-correction [12, 11].

The standard models for both quantum circuits and ZX-Calculus is therefore based on a wave-style interpretation. An alternative operational interpretation of quantum circuit following a *particle-style* semantics has recently been investigated in the literature [9]. In this model, quantum bits are intuitively seen as *tokens* flowing inside the wires of the circuit. Formally, a quantum circuit is interpreted as a token-based automata, based on Geometry of Interaction (GoI) [21, 20, 19, 22]. Among its many instantiations, GoI can be seen as a procedure to interpret a proof-net [23] – graphical representation of proofs of linear logic [18] – as a token-based automaton [10, 2]. The flow of a token inside a proof-net characterises an invariant of the proof – its computational content. This framework is used in [9] to formalize the notion of qubits-as-tokens flowing inside a higher-order term representing a quantum computation – that is, computing a quantum circuit. However, in this work, quantum gates are still regarded as black-boxes, and tokens are purely classical objects *requiring synchronicity*: to fire, a two-qubit gate needs its two arguments to be ready.

As a summary, despite their ad-hoc construction, quantum circuits can be seen from two perspectives: computation as a flow of particles (i.e. tokens), and as a wave passing through the gates. On the other hand, although ZX-Calculus is a well-founded language, it still misses such a particle-style perspective.

In this paper, we aim at giving a novel insight on the computational content of a ZX term in an asynchronous way, emphasizing the graph-like behavior of a ZX-diagram.

Following the idea of using a token machine to exhibit the computational content of a proof-net or a quantum circuit, we present in this paper a token machine for the ZX-Calculus. To exemplify the versatility of the approach, we show how to extend it to mixed processes [8, 5]. To assess the validity of the semantics, we show how it links to the standard interpretation of ZX-diagrams. While the standard interpretation of ZX-diagrams proceeds with diagram decomposition as tensors and products of matrices, the tokens flowing inside the diagram really exploits the connectivity of the diagram.

This ability illustrates one fundamental difference between our approach and the one in [9]. The latter follows a *classical control* approach: if qubits can be in superposition, each qubit inhabits a token sitting in *one single* position in the circuit. For instance, on the circuit on the right, the state of the two tokens

$|\bullet\bullet\rangle$ is $\frac{\sqrt{2}}{2}(|00\rangle + |10\rangle)$. Although the two tokens can be regarded as being in superposition, their *position* is not. In our system, tokens and positions can be superposed. The second fundamental difference lies in the *asynchronicity* of our token-machine. Unlike [9], we rely on the canonical generators of ZX-diagrams: tokens can travel through these nodes in an asynchronous manner. For instance, in the above circuit the orange token has to wait for the blue token before crossing the CNOT gate. As illustrated in Table 1, in our system one token can interact with multi-wire nodes. Finally, as formalized in Theorem 27, a third difference is that compared to [9], the token-machine we present is *non-oriented*: in the circuit above, tokens have to start on the left and flow towards the right of the circuit whereas our system is agnostic on where tokens initially “start”.

Plan of the paper. The paper is organized as follows: in Section 2 we present the ZX-Calculus and its standard interpretation into **Qubit**, and its axiomatization.

In Section 3 we present the actual asynchronous token machine and its semantics and show that it is sound and complete with regard to the standard interpretation of ZX-diagrams. Finally, in Section 4 we present an extension of the ZX-Calculus to mixed processes and adapt the token machine to take this extension into account. Proofs are in the appendix.

2 The ZX-Calculus

The ZX-Calculus is a powerful graphical language for reasoning about quantum computation introduced by Bob Coecke and Ross Duncan [7]. A term in this language is a graph – called a *string diagram* – built from a core set of primitives. In the standard interpretation of ZX-Calculus, a string diagram is interpreted as a matrix. The language is equipped with an equational theory preserving the standard interpretation.

2.1 Pure Operators

The so-called *pure* ZX-diagrams are generated from a set of primitives, given on the right: the Identity, Swap, Cup, Cap, Green-spider and H-gate:

$$\left\{ \begin{array}{l} e_0, \quad \text{Cup} \quad e_1, e_0, \quad \text{Cap} \quad e_1, e_0, \quad \text{H-gate} \quad e_1, e_n, e_0, e_1 \\ \text{Identity} \quad e_0, \quad \text{Swap} \quad e_1, e_0, \quad \text{Green-spider} \quad \alpha, \quad \text{H-gate} \quad e_1, e_n, e_0, e_1 \end{array} \right\}_{\substack{n, m \in \mathbb{N} \\ \alpha \in \mathbb{R} \\ e_i, e'_i \in \mathcal{E}}}$$

We shall be using the following labeling convention: wires (edges) are labeled with e_i , taken from an infinite set of labels \mathcal{E} . We take for granted that distinct wires have distinct labels. The real number α attached to the green spiders is called the *angle*. ZX-diagrams are read top-to-bottom: dangling top edges are the *input edges* and dangling edges at the bottom are *output edges*. For instance, Swap has 2 input and 2 output edges, while Cup has 2 input edges and no output edges. We write $\mathcal{E}(D)$ for the set of edge labels in the diagram D , and $\mathcal{I}(D)$ (resp. $\mathcal{O}(D)$) for the list of input edges (resp. output edges) of D . We denote $::$ the concatenation of lists.

30:4 Geometry of Interaction for ZX-Diagrams

ZX-primitives can be composed either sequentially or in parallel:

$$D_2 \circ D_1 := \begin{array}{c} \dots \\ \boxed{D_1} \\ \dots \\ \boxed{D_2} \\ \dots \end{array} \qquad D_1 \otimes D_2 := \begin{array}{cc} \dots & \dots \\ \boxed{D_1} & \boxed{D_2} \\ \dots & \dots \end{array}$$

We write \mathbf{ZX} for the set of all ZX-diagrams. Notice that when composing diagrams with $(_ \circ _)$, we “join” the outputs of the top diagram with the inputs of the bottom diagram. This requires that the two sets of edges have the same cardinality. The junction is then made by relabeling the input edges of the bottom diagram by the output labels of the top diagram.

► **Convention 1.** We define a second spider, red this time, by composition of Green-spiders and H-gates, as shown below.

$$\begin{array}{c} \dots \\ \bullet \\ \dots \end{array} := \begin{array}{c} \dots \\ \square \square \\ \bullet \\ \square \square \\ \dots \end{array}$$

► **Convention 2.** We write σ for a permutation of wires, i.e any diagram generated by $\left\{ \begin{array}{c} | \\ | \end{array} , \begin{array}{c} \diagup \\ \diagdown \end{array} \right\}$ with sequential and parallel composition. We write the Cap as η and the Cup as ϵ . We write $Z_k^n(\alpha)$ (resp, X_k^n) for the green-node (resp, red-node) of n inputs, k outputs and parameter α and H for the H-gate. In the remainder of the paper we omit the edge labels when not necessary. Finally, by abuse of notation a green or red node with no explicit parameter holds the angle 0: $\begin{array}{c} \dots \\ \bullet \\ \dots \end{array} := \begin{array}{c} \dots \\ \bullet \\ \dots \end{array}^0$ and $\begin{array}{c} \dots \\ \bullet \\ \dots \end{array} := \begin{array}{c} \dots \\ \bullet \\ \dots \end{array}^0$.

2.2 Standard Interpretation

We understand ZX-diagrams as linear operators through the *standard interpretation*. Informally, wires are interpreted with the two-dimensional Hilbert space, with orthonormal basis written as $\{|0\rangle, |1\rangle\}$, in Dirac notation [30]. Vectors of the form $|.\rangle$ (called “kets”) are considered as columns vector, and therefore $|0\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$, $|1\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$, and $\alpha|0\rangle + \beta|1\rangle = \begin{pmatrix} \alpha \\ \beta \end{pmatrix}$. Horizontal juxtaposition of wires is interpreted with the *Kronecker*, or *tensor* product. The tensor product of spaces \mathcal{V} and \mathcal{W} whose bases are respectively $\{v_i\}_i$ and $\{w_j\}_j$ is the vector space of basis $\{v_i \otimes w_j\}_{i,j}$, where $v_i \otimes w_j$ is a formal object consisting of a pair of v_i and w_j . We denote $|x\rangle \otimes |y\rangle$ as $|xy\rangle$. In the interpretation of spiders, we use the notation $|0^m\rangle$ to represent an m -fold tensor of $|0\rangle$. As a shortcut notation, we write $|\phi\rangle$ for column vectors consisting of a linear combinations of kets. Shortcut notations are also used for two very useful states: $|+\rangle := \frac{|0\rangle+|1\rangle}{\sqrt{2}}$ and $|-\rangle := \frac{|0\rangle-|1\rangle}{\sqrt{2}}$. Dirac also introduced the notation “bra” $\langle x|$, standing for a row vector. So for instance, $\alpha\langle 0| + \beta\langle 1|$ is $(\alpha \ \beta)$. If $|\phi\rangle = \alpha|0\rangle + \beta|1\rangle$, we then write $\langle\phi|$ for the vector $\bar{\alpha}\langle 0| + \bar{\beta}\langle 1|$ (with $\bar{(\cdot)}$ the complex conjugation). The notation for tensors of bras is similar to the one for kets. For instance, $\langle x| \otimes \langle y| = \langle xy|$. Using this notation, the scalar product is transparently the product of a row and a column vector: $\langle\phi|\psi\rangle$, and matrices can be written as sums of elements of the form $|\phi\rangle\langle\psi|$. For instance, the identity on \mathbb{C}^2 is $\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \begin{pmatrix} 1 & 0 \end{pmatrix} + \begin{pmatrix} 0 \\ 1 \end{pmatrix} \begin{pmatrix} 0 & 1 \end{pmatrix} = |0\rangle\langle 0| + |1\rangle\langle 1|$. For more information on how Hilbert spaces, tensors, compositions and bras and kets work, we invite the reader to consult e.g. [30].

In the standard interpretation [7], a diagram D is mapped to a map between finite dimensional Hilbert spaces of dimensions some powers of 2: $\llbracket D \rrbracket \in \mathbf{Qubit} := \{\mathbb{C}^{2^n} \rightarrow \mathbb{C}^{2^m} \mid n, m \in \mathbb{N}\}$.

■ **Figure 1** Connectivity rules. D represents any ZX-diagram, and σ, σ' any permutation of wires.

If D has n inputs and m outputs, its interpretation is a map $\llbracket D \rrbracket : \mathbb{C}^{2^n} \rightarrow \mathbb{C}^{2^m}$ (by abuse of notation we shall use the notation $\llbracket D \rrbracket : n \rightarrow m$). It is defined inductively as follows.

$$\begin{aligned}
 \left[\begin{array}{c} \dots \\ D_1 \\ \dots \\ D_2 \\ \dots \end{array} \right] &= \left[\begin{array}{c} \dots \\ D_2 \\ \dots \end{array} \right] \circ \left[\begin{array}{c} \dots \\ D_1 \\ \dots \end{array} \right] & \left[\begin{array}{c} \dots \\ D_1 \\ \dots \end{array} \right] \left[\begin{array}{c} \dots \\ D_2 \\ \dots \end{array} \right] &= \left[\begin{array}{c} \dots \\ D_1 \\ \dots \end{array} \right] \otimes \left[\begin{array}{c} \dots \\ D_2 \\ \dots \end{array} \right] \\
 \left[\begin{array}{c} | \\ | \end{array} \right] &= id_{\mathbb{C}^2} = |0\rangle\langle 0| + |1\rangle\langle 1| & \left[\begin{array}{c} \diagup \\ \diagdown \end{array} \right] &= \sum_{i,j \in \{0,1\}} |ji\rangle\langle ij| \\
 \left[\begin{array}{c} \curvearrowright \end{array} \right] &= \left[\begin{array}{c} \smile \end{array} \right]^\dagger = |00\rangle + |11\rangle & \left[\begin{array}{c} \blacksquare \end{array} \right] &= |+\rangle\langle 0| + |-\rangle\langle 1| \\
 \left[\begin{array}{c} \dots \\ \alpha \\ \dots \\ \alpha \\ \dots \end{array} \right] &= |0^m\rangle\langle 0^n| + e^{i\alpha} |1^m\rangle\langle 1^n| & \left[\begin{array}{c} \dots \\ \alpha \\ \dots \\ \alpha \\ \dots \end{array} \right] &= |+\rangle\langle +|^n + e^{i\alpha} |-\rangle\langle -|^n
 \end{aligned}$$

2.3 Properties and structure

In this section, we list several definitions and known results that we shall be using in the remainder of the paper. See e.g. [34] for more information.

Universality. ZX-diagrams are *universal* in the sense that for any linear map $f : n \rightarrow m$, there exists a diagram D of **ZX** such that $\llbracket D \rrbracket = f$.

The price to pay for universality is that different diagrams can possibly represent the same quantum operator. There exists however a way to deal with this problem: an equational theory. Several equational theories have been designed for various fragments of the language [3, 26, 24, 27, 28, 33].

Core axiomatization. Despite this variety, any ZX axiomatization builds upon the core set of equations provided in Figure 1, meaning that edges really behave as wires that can be bent, tangled and untangled. They also enforce the irrelevance on the ordering of inputs and outputs for spiders. Most importantly, these rules preserve the standard interpretation given in Section 2.2. We will use these rules – sometimes referred to as “*only connectivity matters*” –, and the fact that they preserve the semantics extensively in the proofs of the results of the paper.

Completeness. The ability to transform a diagram D_1 into a diagram D_2 using the rules of some axiomatization zx (e.g. the core one presented in Figure 1) is denoted $\text{zx} \vdash D_1 = D_2$.

The axiomatization is said to be *complete* whenever any two diagrams representing the same operator can be turned into one another using this axiomatization. Formally:

$$\llbracket D_1 \rrbracket = \llbracket D_2 \rrbracket \iff \text{zx} \vdash D_1 = D_2.$$

It is common in quantum computing to work with restrictions of quantum mechanics. Such restrictions translate to restrictions to particular sets of diagrams – e.g. the $\frac{\pi}{4}$ -fragment which consists of all ZX-diagrams where the angles are multiples of $\frac{\pi}{4}$. There exists axiomatizations that were proven to be complete for the corresponding fragment (all the aforementioned references tackle the problem of completeness).

The developments of this paper are given for the ZX-Calculus in its most general form, but everything in the following also works for fragments of the language.

Input and output wires. An important result which will be used in the rest of the paper is the following:

► **Theorem 3** (Choi-Jamiołkowski). *There are isomorphisms between $\{D \in \mathbf{ZX} \mid D : n \rightarrow m\}$ and $\{D \in \mathbf{ZX} \mid D : n - k \rightarrow k + m\}$ (when $k \leq n$).*

To see how this can be true, simply add cups or caps to turn input edges to output edges (or vice versa), and use the fact that we work modulo the rules of Figure 1.

When $k = n$, this isomorphism is referred to as the *map/state duality*. A related but more obvious isomorphism between ZX-diagrams is obtained by permutation of input wires (resp. output wires).

2.4 Notions of Graph Theory in ZX

Theorem 3 is essential: it allows us to transpose notions of graphs into ZX-Calculus. It is for instance possible to define a notion of connectivity.

► **Definition 4** (Connected Components). *Let D be a non-empty \mathbf{ZX} -diagram. Consider all of the possible decompositions with $D_1, \dots, D_k \in \mathbf{ZX}$ and σ, σ' permutations of wires:*

The largest such k is called the number of connected components of D . It induces a decomposition. The induced D_1, \dots, D_n are called the connected components of D . If D has only one connected component, we say that D is connected.

We can also consider the notions of paths, distance and cycles of usual multi-graphs. We denote $\text{Paths}(e_0, e_n)$ the set of paths from edge e_0 to e_n . We denote $\text{Paths}(D)$ (resp. $\text{Cycles}(D)$) the set of paths (resp. cycles) of diagram D . For a path p , we denote $|p|$ its length. We denote $d(e_0, e_n)$ the distance i.e. the length of the shortest path between e_0 and e_n .

3 A Token Machine for ZX-diagrams

Inspired by the Geometry of Interaction [21, 20, 19, 22] and the associated notion of token machine [10, 2] for proof nets [23], we define here a first token machine on pure ZX-diagrams. The token consists of an edge of the diagram, a direction (either going up, noted \uparrow , or down, noted \downarrow) and a bit (state). The idea is that, starting from an input edge the token will traverse the graph and duplicate itself when encountering an n -ary node (such as the green and red) into each of the input / output edges of the node. Notice that it is not the case for token machines for proof-nets where the token never duplicates itself. This duplication is necessary to make sure we capture the whole linear map encoded by the ZX-diagram. Due

to this duplication, two tokens might collide together when they are on the same edge and going in different directions. The result of such a collision will depend on the states held by both tokens. For a cup, cap or identity diagram, the token will simply traverse it. As for the Hadamard node the token will traverse it and become a superposition of two tokens with opposite states. Therefore, as tokens move through a diagram, some may be added, multiplied together, or annihilated.

► **Definition 5** (Tokens and Token States). *Let D be a ZX-diagram. A token in D is a triplet $(e, d, b) \in \mathcal{E}(D) \times \{\downarrow, \uparrow\} \times \{0, 1\}$. We shall omit the commas and simply write $(e d b)$. The set of tokens on D is written $\mathbf{tk}(D)$. A token state s is then a multivariate polynomial over \mathbb{C} , evaluated in $\mathbf{tk}(D)$. We define $\mathbf{tkS}(D) := \mathbb{C}[\mathbf{tk}(D)]$ the algebra of multivariate polynomials over $\mathbf{tk}(D)$.*

In the token state $t = \sum_i \alpha_i t_{1,i} \cdots t_{n_i,i}$, where the $t_{k,i}$'s are tokens, the components $\alpha_i t_{1,i} \cdots t_{n_i,i}$ are called the terms of t .

A monomial $(e_1 d_1, b_1) \cdots (e_n d_n, b_n)$ encodes the state of n tokens in the process of flowing in the diagram D . A token state is understood as a *superposition* – a linear combination – of multi-tokens flowing in the diagram.

► **Convention 6.** In token states, the sum (+) stands for the superposition while the product stands for additional tokens within a given diagram. We follow the usual convention of algebras of polynomials: for instance, if t_i stands for some token $(e_i d_i b_i)$, then $(t_1 + t_2)t_3 = (t_1 t_3) + (t_2 t_3)$, that is, the superposition of t_1, t_2 flowing in D and t_1, t_3 flowing in D . Similarly, we consider token states modulo commutativity of sum and product, so that for instance the monomial $t_1 t_2$ is the same as $t_2 t_1$. Notice that 0 is an absorbing element for the product ($0 \times t = 0$) and that 1 is a neutral element for the same operation ($1 \times t = t$).

3.1 Diffusion and Collision Rules

The tokens in a ZX-diagram D are meant to move inside D . The set of rules presented in this section describes an *asynchronous* evolution, meaning that given a token state, we will rewrite only one token at a time. The synchronous setting is discussed in Section 5.

► **Definition 7** (Asynchronous Evolution). *Token states on a diagram D are equipped with two transition systems:*

- a collision system (\rightsquigarrow_c), whose effect is to annihilate tokens;
- a diffusion sub-system (\rightsquigarrow_d), defining the flow of tokens within D .

The two systems are defined as follows. With $X \in \{d, c\}$ and $1 \leq j \leq n_i$, if $t_{i,j}$ are tokens in $\mathbf{tk}(D)$, then using Convention 6,

$$\sum_i \alpha_i t_{i,1} \cdots t_{i,j} \cdots t_{i,n_i} \rightsquigarrow_X \sum_i \alpha_i t_{i,1} \cdots \left(\sum_k \beta_k t'_k \right) \cdots t_{i,n_i}$$

provided that $t_{i,j} \rightsquigarrow_X \sum_k \beta_k t'_k$ according to the rules of Table 1. In the table, each rule corresponds to the interaction with the primitive diagram constructor on the left-hand-side. Variables x and b span $\{0, 1\}$, and \neg stands for the negation. In the green-spider rules, $e^{i\alpha x}$ stands for the complex number $\cos(\alpha x) + i \sin(\alpha x)$ and not an edge label.

Finally, as it is customary for rewrite systems, if (\rightarrow) is a step in a transition system, (\rightarrow^) stands for the reflexive, transitive closure of (\rightarrow) .*

We aim at a transition system marrying both collision and diffusion steps. However, for consistency of the system, the order in which we apply them is important as illustrated by the following example.

■ **Table 1** Asynchronous token-state evolution, for all $x, b \in \{0, 1\}$.

	$(e_0 \downarrow x)(e_0 \uparrow x) \rightsquigarrow_c 1$	$(e_0 \downarrow x)(e_0 \uparrow \neg x) \rightsquigarrow_c 0$	(Positive/Negative Collision)
	$(e_b \downarrow x) \rightsquigarrow_d (e_{\neg b} \uparrow x)$		( -diffusion)
	$(e_b \uparrow x) \rightsquigarrow_d (e_{\neg b} \downarrow x)$		( -diffusion)
	$(e_k \downarrow x) \rightsquigarrow_d e^{i\alpha x} \prod_{i \neq k} (e_i \uparrow x) \prod_j (e'_j \downarrow x)$		( -Diffusion)
	$(e'_k \uparrow x) \rightsquigarrow_d e^{i\alpha x} \prod_{j \neq k} (e'_j \downarrow x) \prod_i (e_i \uparrow x)$		
	$(e_0 \downarrow x) \rightsquigarrow_d (-1)^x \frac{1}{\sqrt{2}} (e_1 \downarrow x) + \frac{1}{\sqrt{2}} (e_1 \downarrow \neg x)$		( -Diffusion)
	$(e_1 \uparrow x) \rightsquigarrow_d (-1)^x \frac{1}{\sqrt{2}} (e_0 \uparrow x) + \frac{1}{\sqrt{2}} (e_0 \uparrow \neg x)$		

► **Example 8.** Consider the equality given by the ZX equational theories:  = .

If we drop a token with bit 0 at the top, we hence expect to get a single token with bit 0 at the bottom. We underline the token that is being rewritten at each step. This is what we get when giving the priority to collisions:

$$\begin{array}{c} a \\ \bullet \\ b \text{---} c \\ \bullet \\ d \end{array} \quad :: \quad (a \downarrow 0) \rightsquigarrow_d \underline{(b \downarrow 0)}(c \downarrow 0) \rightsquigarrow_d (d \downarrow 0) \underline{(c \uparrow 0)}(c \downarrow 0) \rightsquigarrow_c (d \downarrow 0)$$

Notice that the collision $(c \uparrow 0)(c \downarrow 0)$ rewrites to 1, and therefore the product $(d \downarrow 0) \times 1 = (d \downarrow 0)$. If however we decide to ignore the priority of collisions, we may end up with a non-terminating run, unable to converge to $(d \downarrow 0)$:

$$(a \downarrow 0) \rightsquigarrow_d \underline{(b \downarrow 0)}(c \downarrow 0) \rightsquigarrow_d (d \downarrow 0) \underline{(c \uparrow 0)}(c \downarrow 0) \rightsquigarrow_d (d \downarrow 0)(a \uparrow 0) \underline{(b \downarrow 0)}(c \downarrow 0) \rightsquigarrow_d \dots$$

We therefore set a rewriting strategy as follows.

► **Definition 9 (Collision-Free).** A token state s of $\mathbf{tkS}(D)$ is called collision-free if for all $s' \in \mathbf{tkS}(D)$, we have $s \not\rightsquigarrow_c s'$.

► **Definition 10 (Token Machine Rewriting System).** We define a transition system \rightsquigarrow as exactly one \rightsquigarrow_d rule followed by all possible \rightsquigarrow_c rules. In other words, $t \rightsquigarrow u$ if and only if there exists t' such that $t \rightsquigarrow_d t' \rightsquigarrow_c^* u$ and u is collision-free.

In [9], a token arriving at an input of a gate is blocked until all the inputs of the gates are populated by a token, at which point all the tokens go through at once (while obviously changing the state). The control is purely classical: it is causal. In our approach, the state of the system is global and there is no explicit notion of qubit. Instead, tokens collect the operation that is to be applied to the input qubits.

3.2 Strong Normalization and Confluence

The token machine Rewrite System of Definition 10 ensures that the collisions that can happen always happen. The system does not a priori forbid two tokens on the same edge, provided that they have the same direction. However this is something we want to avoid as

there is no good intuition behind it: We want to link the token machine to the standard interpretation, which is not possible if two tokens can appear on the same edge.

In this section we show that, under a notion of well-formedness characterizing token uniqueness on each edge, the Token State Rewrite System (\rightsquigarrow) is strongly normalizing and confluent.

► **Definition 11** (Polarity of a Term in a Path). *Let D be a ZX-diagram, and $p \in \text{Paths}(D)$ be a path in D . Let $t = (e, d, x) \in \mathbf{tk}(D)$. Then:*

$$P(p, t) = \begin{cases} 1 & \text{if } e \in p \text{ and } e \text{ is } d\text{-oriented} \\ -1 & \text{if } e \in p \text{ and } e \text{ is } \neg d\text{-oriented} \\ 0 & \text{if } e \notin p \end{cases}$$

We extend the definition to subterms $\alpha t_1 \dots t_m$ of a token-state s :

$$P(p, 0) = P(p, 1) = 0, \quad P(p, \alpha t_1 \dots t_m) = P(p, t_1) + \dots + P(p, t_m).$$

In the following, we shall simply refer to such subterms as “terms of s ”.

► **Example 12.** In the (piece of) diagram presented on the right, the blue directed line $p = (e_0, e_1, e_2, e_3, e_4)$ is a path. The orientation of the edges in the path is represented by the arrow heads, and e_3 for instance is \downarrow -oriented in p which implies that we have $P(p, (e_3 \uparrow x)) = -1$.

► **Definition 13** (Well-formedness). *Let D be a ZX-diagram, and $s \in \mathbf{tkS}(D)$ a token state on D . We say that s is well-formed if for every term t in s and every path $p \in \text{Paths}(D)$ we have $P(p, t) \in \{-1, 0, 1\}$.*

► **Proposition 14** (Invariance of Well-Formedness). *Well-formedness is preserved by (\rightsquigarrow): if $s \rightsquigarrow^* s'$ and s is well-formed, then s' is well-formed.*

Well-formedness prevents the unwanted scenario of having two tokens on the same wire, and oriented in the same direction (e.g. $(e_0 \downarrow x)(e_0 \downarrow y)$). As shown in the Proposition 15, this property is in fact stronger.

► **Proposition 15** (Full Characterisation of Well-Formed Terms). *Let D be a ZX-diagram, and $s \in \mathbf{tkS}(D)$ be not well-formed, i.e. there exists a term t in s , and $p \in \text{Paths}(D)$ such that $|P(p, t)| \geq 2$. Then we can rewrite $s \rightsquigarrow s'$ such that a term in s' has a product of at least two tokens of the form $(e_0, d, _)$.*

Although well-formedness prevents products of tokens on the same wire, it does not guarantee termination: for this we need to consider polarities along cycles.

► **Proposition 16** (Invariant on Cycles). *Let D be a ZX-diagram, and $c \in \text{Cycles}(D)$ a cycle. Let t_1, \dots, t_n be tokens, and s be a token state such that $t_1 \dots t_n \rightsquigarrow^* s$. Then for every non-null term t in s we have $P(c, t_1 \dots t_n) = P(c, t)$.*

30:10 Geometry of Interaction for ZX-Diagrams

This proposition tells us that the polarity is preserved inside a cycle. By requiring the polarity to be 0, we can show that the token machine terminates. This property is defined formally in the following.

► **Definition 17** (Cycle-Balanced Token State). *Let D be a ZX-diagram, and t a term in a token state on D . We say that t is cycle-balanced if for all cycles $c \in \text{Cycles}(D)$ we have $P(c, t) = 0$. We say that a token state is cycle-balanced if all its terms are cycle-balanced.*

To show that being cycle-balanced implies termination, we need the following intermediate lemma. This essentially captures the fact that a token in the diagram comes from some other token that “traveled” in the diagram earlier on.

► **Lemma 18** (Rewinding). *Let D be a ZX-diagram, and t be a term in a well-formed token state on D , and such that $t \rightsquigarrow^* \sum_i \lambda_i t_i$, with $(e_n, d, x) \in t_1$. If t is cycle-balanced, then there exists a path $p = (e_0, \dots, e_n) \in \text{Paths}(D)$ such that e_n is d -oriented in p , and $P(p, t) = 1$.*

We can now prove strong-normalization.

► **Theorem 19** (Termination of well-formed, cycle-balanced token state). *Let D be a ZX-diagram, and $s \in \mathbf{tkS}(D)$ be well-formed. The token state s is strongly normalizing if and only if it is cycle-balanced.*

Intuitively, this means that tokens inside a cycle will cancel themselves out if the token state is cycle-balanced. Since cycles are the only way to have a non-terminating token machine, we are sure that our machine will always terminate.

► **Proposition 20** (Local Confluence). *Let D be a ZX-diagram, and $s \in \mathbf{tkS}(D)$ be well-formed and collision-free. Then, for all $s_1, s_2 \in \mathbf{tkS}(D)$ such that $s_1 \leftarrow s \rightsquigarrow s_2$, there exists $s' \in \mathbf{tkS}(D)$ such that $s_1 \rightsquigarrow^* s' \leftarrow s_2$.*

► **Corollary 21** (Confluence). *Let D be a ZX-diagram. The rewrite system \rightsquigarrow is confluent for well-formed, collision-free and cycle-balanced token states.*

► **Corollary 22** (Uniqueness of Normal Forms). *Let D be a ZX-diagram. A well-formed and cycle-balanced token state admits a unique normal form under the rewrite system \rightsquigarrow .*

3.3 Semantics and Structure of Normal Forms

In this section, we discuss the structure of normal forms, and relate the system to the standard interpretation presented in Section 2.

► **Proposition 23** (Single-Token Input). *Let $D : n \rightarrow m$ be a connected ZX-diagram with $\mathcal{I}(D) = [a_i]_{0 < i \leq n}$ and $\mathcal{O}(D) = [b_i]_{0 < i \leq m}$, $0 < k \leq n$ and $x \in \{0, 1\}$, such that:*

$$[[D]] \circ (id_{k-1} \otimes |x\rangle \otimes id_{n-k}) = \sum_{q=1}^{2^{m+n-1}} \lambda_q |y_{1,q}, \dots, y_{m,q}\rangle \langle x_{1,q}, \dots, x_{k-1,q}, x_{k+1,q}, \dots, x_{n,q}|$$

$$\text{Then: } (a_k \downarrow x) \rightsquigarrow^* \sum_{q=1}^{2^{m+n-1}} \lambda_q \prod_i (b_i \downarrow y_{i,q}) \prod_{i \neq k} (a_i \uparrow x_{i,q})$$

This proposition conveys the fact that dropping a single token in state x on wire a_k gives the same semantics as the one obtained from the standard interpretation on the ZX-diagram, with wire a_k connected to the state $|x\rangle$.

Proposition 23 can be made more general. However, we first need the following result on ZX-diagrams:

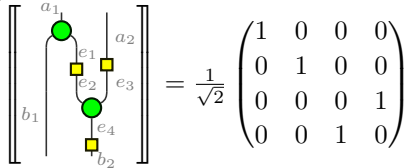

► **Lemma 24** (Universality of Connected ZX-Diagrams). *Let $f : \mathbb{C}^{2^n} \rightarrow \mathbb{C}^{2^m}$. There exists a connected ZX-diagram $D_f : n \rightarrow m$ such that $\llbracket D_f \rrbracket = f$.*

► **Proposition 25** (Multi-Token Input). *Let D be a connected ZX-diagram with $\mathcal{I}(D) = [a_i]_{1 \leq i \leq n}$ and $\mathcal{O}(D) = [b_i]_{1 \leq i \leq m}$; with $n \geq 1$.*

$$\text{If: } \llbracket D \rrbracket \circ \left(\sum_{q=1}^{2^n} \lambda_q |x_{1,q}, \dots, x_{n,q}\rangle \right) = \sum_{q=1}^{2^m} \lambda'_q |y_{1,q}, \dots, y_{m,q}\rangle$$

$$\text{then: } \sum_{q=1}^{2^n} \lambda_q \prod_{i=1}^n (a_i \downarrow x_{i,q}) \rightsquigarrow^* \sum_{q=1}^{2^m} \lambda'_q \prod_{i=1}^m (b_i \downarrow y_{i,q})$$

► **Example 26** (CNOT). In the ZX-Calculus, the CNOT-gate (up to some scalar) can be

constructed as follows:  $= \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}$

On classical inputs, this gate applies the NOT-gate on the second bit if and only if the first bit is at 1. Therefore if we apply the state $|10\rangle$ to it we get $\frac{1}{\sqrt{2}}|11\rangle$.

We demonstrate how the token machine can be used to get this result. Following Proposition 25, we start by initialising the Token Machine in the token state $(a_1 \downarrow 1)(a_2 \downarrow 0)$, matching the input state $|10\rangle$.

We underline each step that is being rewritten, and take the liberty to sometimes do several rewrites in parallel at the same time.

$$\begin{aligned} (a_1 \downarrow 1)(a_2 \downarrow 0) &\rightsquigarrow_d (b_1 \downarrow 1)(e_1 \downarrow 1)(a_2 \downarrow 0) \rightsquigarrow_d (b_1 \downarrow 1)(e_1 \downarrow 1) \frac{1}{\sqrt{2}} \left((e_3 \downarrow 0) + (e_3 \downarrow 1) \right) \\ &\rightsquigarrow_d \frac{1}{\sqrt{2}} (b_1 \downarrow 1)(e_1 \downarrow 1) \left((e_2 \uparrow 0)(e_4 \downarrow 0) + (e_2 \uparrow 1)(e_4 \downarrow 1) \right) \\ &\rightsquigarrow_d \frac{1}{2} (b_1 \downarrow 1) \left((e_2 \downarrow 0) - (e_2 \downarrow 1) \right) \left((e_2 \uparrow 0)(e_4 \downarrow 0) + (e_2 \uparrow 1)(e_4 \downarrow 1) \right) \\ &\rightsquigarrow_c^2 \frac{1}{2} (b_1 \downarrow 1) \left((e_4 \downarrow 0) + ((e_2 \downarrow 0) - (e_2 \downarrow 1))(e_2 \uparrow 1)(e_4 \downarrow 1) \right) \\ &\rightsquigarrow_c^2 \frac{1}{2} (b_1 \downarrow 1) \left((e_4 \downarrow 0) - (e_4 \downarrow 1) \right) \\ &\rightsquigarrow_d \frac{1}{2\sqrt{2}} (b_1 \downarrow 1) \left((b_2 \downarrow 0) + (b_2 \downarrow 1) - (b_2 \downarrow 0) + (b_2 \downarrow 1) \right) \\ &= \frac{1}{\sqrt{2}} (b_1 \downarrow 1)(b_2 \downarrow 1) \end{aligned}$$

The final token state corresponds to $\frac{1}{\sqrt{2}}|11\rangle$, as described by Proposition 25. Notice that during the run, each invariants presented before holds and that due to confluence we could have rewritten the tokens in any order and still obtain the same result.

This proposition is a direct generalization of Proposition 23. It shows we can compute the output of a diagram provided a particular input state. We can also recover the semantics of the whole operator by initialising the starting token state in a particular configuration.

► **Theorem 27** (Arbitrary Wire Initialisation). *Let D be a connected ZX-diagram, with $\mathcal{I}(D) = [a_i]_{1 \leq i \leq n}$, $\mathcal{O}(D) = [b_i]_{1 \leq i \leq m}$, and $e \in \mathcal{E}(D) \neq \emptyset$ such that $(e \downarrow x)(e \uparrow x) \rightsquigarrow^* t_x$ for $x \in \{0, 1\}$ with t_x terminal (the rewriting terminates by Corollary 22). Then:*

$$\llbracket D \rrbracket = \sum_{q=1}^{2^{m+n}} \lambda_q |y_{1,q} \dots y_{m,q}\rangle \langle x_{1,q} \dots x_{n,q}| \implies t_0 + t_1 = \sum_{q=1}^{2^{m+n}} \lambda_q \prod_i (b_i \downarrow y_{i,q}) \prod_i (a_i \uparrow x_{i,q}).$$

30:12 Geometry of Interaction for ZX-Diagrams

► **Example 28.** If we take back the diagram from Example 26 and decide to initialize any wire e of the diagram in the state $(e \downarrow 0)(e \uparrow 0) + (e \downarrow 1)(e \uparrow 1)$ and apply the rewriting as in Theorem 27 we in fact end up with the token state $\frac{1}{\sqrt{2}} \left((a_1 \uparrow 0)(a_2 \uparrow 0)(b_1 \downarrow 0)(b_2 \downarrow 0) + (a_1 \uparrow 0)(a_2 \uparrow 1)(b_1 \downarrow 0)(b_2 \downarrow 1) + (a_1 \uparrow 1)(a_2 \uparrow 0)(b_1 \downarrow 1)(b_2 \downarrow 1) + (a_1 \uparrow 1)(a_2 \uparrow 1)(b_1 \downarrow 1)(b_2 \downarrow 0) \right)$ which matches the actual matrix of the standard interpretation.

► **Remark 29.** At this point, it is legitimate to wonder about the benefits of the token machine over the standard interpretation for computing the semantics of a diagram. Let us first notice that when computing the semantics of a diagram à la Theorem 27, we get in the token state one term per non-null entry in the associated matrix (the one obtained by the standard interpretation).

We can already see that the token-based interpretation can be interesting if the matrix is sparse, the textbook case being Z_n^n whose standard interpretation requires a $2^n \times 2^n$ matrix, while the token-based interpretation only requires two terms (each with $2n$ tokens).

Secondly, we can notice that we can “mimic” the standard interpretation with the token machine. Consider a diagram decomposed as a product of slices (tensor product of generators) for the standard interpretation. Then, for the token machine, without going into technical details, we can follow the strategy that consists in moving token through the diagram one slice at a time. This essentially computes the matrix associated with each slice and its composition.

The point of the token machine however, is that it is versatile enough to allow for more original strategies, some of which may have a worst complexity, but also some of which may have a better one.

4 Extension to Mixed Processes

The token machine presented so far worked for so-called *pure* quantum processes i.e. with no interaction with the environment. To demonstrate how generic our approach is, we show how to adapt it to the natural extension of *mixed* processes, represented with completely positive maps (CPM). This in particular allows us to represent quantum measurements.

4.1 ZX-diagrams for Mixed Processes

The interaction with the environment can be modeled in the ZX-Calculus by adding a unary generator $\underline{\perp}$ to the language [8, 5], that intuitively enforces the state of the wire to be classical. We denote with \mathbf{ZX}^{\perp} the set of diagrams obtained by adding $\underline{\perp}$ this generator.

Similar to what is done in quantum computation, the standard interpretation $\llbracket \cdot \rrbracket^{\perp}$ for \mathbf{ZX}^{\perp} maps diagrams to CPMs. If $D \in \mathbf{ZX}$ we define $\llbracket D \rrbracket^{\perp}$ as $\rho \mapsto \llbracket D \rrbracket^{\dagger} \circ \rho \circ \llbracket D \rrbracket$, and we set $\llbracket \underline{\perp} \rrbracket^{\perp}$ as $\rho \mapsto \text{Tr}(\rho)$, where $\text{Tr}(\rho)$ is the trace of ρ .

There is a canonical way to map a \mathbf{ZX}^{\perp} -diagram to a \mathbf{ZX} -diagram in a way that preserves the semantics: the so-called CPM-construction [32]. We define the map (conveniently named) CPM as the map that preserves compositions $(_ \circ _)$ and $(_ \otimes _)$ and such that:

$$\forall D \in \mathbf{ZX}, \text{CPM} \left(\begin{array}{c} | \dots | \\ \boxed{D} \\ | \dots | \end{array} \right) = \begin{array}{c} \overbrace{\left(\begin{array}{c} \dots \\ \boxed{D} \\ \dots \end{array} \right)}^{\alpha} \\ \underbrace{\left(\begin{array}{c} \dots \\ \boxed{D} \\ \dots \end{array} \right)}_{\alpha} \end{array} \quad \text{CPM}(\underline{\perp}) = \cup$$

Where $\llbracket D \rrbracket^{\text{cj}}$ is D where every angle α has been changed to $-\alpha$.

defined as:
$$\sum_{q=1}^{2^{m+n}} \lambda_q \prod_j (p_j, d_j, x_{j,q}, y_{j,q}) \mapsto \sum_{q=1} \lambda_q \prod_j (p_j, d_j, x_{j,q})(\overline{p_j}, d_j, y_{j,q})$$

Since $\text{CPM}(D)$ can be seen as two copies of D where $\underline{\quad}$ is replaced by \cup , each token in D corresponds to two tokens in $\text{CPM}(D)$, at the same spot but in the two copies of D . The two states x and y represent the states of the two corresponding tokens.

We can then show that this rewriting system is consistent:

► **Theorem 32.** *Let D be a \mathbf{ZX}^{\neq} -diagram, and $t_1, t_2 \in \mathbf{tkS}^{\neq}(D)$. Then whenever $t_1 \rightsquigarrow_{\neq} t_2$ we have $\text{CPM}(t_1) \rightsquigarrow^{\{1,2\}} \text{CPM}(t_2)$.*

The notions of polarity, well-formedness and cycle-balancedness can be adapted, and we get strong normalization (Theorem 19), confluence (Corollary 21), and uniqueness of normal forms (Corollary 22) for well-formed and cycle-balanced token states.

5 Conclusion and Future Work

In this paper, we presented a novel *particle-style* semantics for ZX-Calculus. Based on a token-machine automaton, it emphasizes the *asynchronicity* and *non-orientation* of the computational content of a ZX-diagram. Compared to existing token-based semantics of quantum computation such as [9], our proposal furthermore support decentralized tokens where the position of a token can be in superposition.

As quantum circuits can be mapped to ZX-diagrams, our token machines induce a notion of asynchronicity for quantum circuits. This contrasts with the notion of token machine defined in [9] where some form of synchronicity is enforced.

Our token machines give us a new way to look at how a ZX-diagram computes with a more local, operational approach. This could lead to extensions of the ZX-Calculus with more expressive logical and computational constructs, such as recursion.

As a final remark, we notice that this formalism naturally extends to other graphical languages for qubit quantum computation, and even for tensor networks. It suffices to adapt the diffusion rewriting steps to the generators at hand, which is always possible in the setting of finite dimensional Hilbert spaces, and if needs be to adapt the states in tokens to the dimension of the wire they go through (e.g. if a wire in a tensor network is of dimension 4, the state spans $\{0, 1, 2, 3\}$).

Diameter Versus Certificate Complexity of Boolean Functions

University of Texas at Austin, TX, USA

Abstract

In this paper, we introduce a measure of Boolean functions we call *diameter*, that captures the relationship between certificate complexity and several other measures of Boolean functions. Our measure can be viewed as a variation on alternating number, but while alternating number can be exponentially larger than certificate complexity, we show that diameter is always upper bounded by certificate complexity. We argue that estimating diameter may help to get improved bounds on certificate complexity in terms of sensitivity, and other measures.

Previous results due to Lin and Zhang [20] imply that $s(f) \geq \Omega(n^{1/3})$ for transitive functions with constant alternating number. We improve and extend this bound and prove that $s(f) \geq \sqrt{n}$ for transitive functions with constant alternating number, as well as for transitive functions with constant diameter. We also show that $bs(f) \geq \Omega(n^{3/7})$ for transitive functions under the weaker condition that the “minimum” diameter is constant.

Furthermore, we prove that the log-rank conjecture holds for functions of the form $f(x \oplus y)$ for functions f with diameter bounded above by a polynomial of the logarithm of the Fourier sparsity of the function f .

1 Introduction

The alternating number of a Boolean function f , denoted $alt(f)$, measures how close the function is to being monotone. It was first studied by Markov [22], who showed that the minimum number of negation gates to compute f by any Boolean circuit is exactly $\lceil \log_2(alt(f) + 1) \rceil$. This led to further studies of alternating number in connection to understanding the effect of negation gates in various contexts such as circuit complexity [31, 34, 26, 27], learning theory [8], and cryptography [16].

Our work is motivated by an interesting paper of Lin and Zhang [20], who studied functions with small alternating number in the context of the sensitivity conjecture, and the log-rank conjecture for XOR functions. The sensitivity conjecture of Nisan and Szegedy [28] states that several important complexity measures, for example block sensitivity $bs(f)$, certificate complexity $C(f)$, and degree $deg(f)$ (over the reals) are all upper bounded by a polynomial of sensitivity $s(f)$. The sensitivity conjecture has been recently proved by Huang [17], who showed that for any Boolean function f , $deg(f) \leq s(f)^2$. Huang’s result was further strengthened by Laplante et al. [19] and Aaronson et al. [1]. Both conjectures have been open for several decades, and – until Huang’s result resolving the sensitivity conjecture – were verified only for a few special classes of Boolean functions. The log-rank conjecture is still open even for XOR functions.

31:2 Diameter vs. Certificate Complexity

Both conjectures can be easily verified to hold for monotone Boolean functions. Lin and Zhang [20] showed that both conjectures remain true for functions that are close to monotone, that is for functions with small alternating number. More precisely, they showed that the conjectures hold for functions with constant alternating number, as well as for functions with alternating number bounded above by some relevant complexity measures of the functions, such as sensitivity in the case of the sensitivity conjecture, and Fourier sparsity in the case of the log-rank conjecture for XOR functions. Thus, their work extended the class of functions where the conjectures can be verified. On the other hand, Dinesh and Sarma [14] presented a function f such that $alt(f)$ is exponentially larger than the certificate complexity $C(f)$. This means that the sensitivity conjecture and the log-rank conjecture for XOR functions cannot be proved in the general case by providing upper bounds on alternating number.

Diameter of Boolean functions. In this paper, we introduce a measure of Boolean functions we call *diameter*, that captures the relationship between certificate complexity and several other measures of Boolean functions. To define the diameter of a Boolean function f , we first consider the “distance” between a vertex of the Boolean cube and subcubes where the function f is constant. However, instead of measuring distance by the number of edges of the Boolean cube along a path (which would correspond to Hamming distance), we allow flipping several bits in one step. We consider paths in the Boolean cube, where one step of the path involves flipping a block of input bits of the function, thus each step specifies a subcube. We require that each step along a path corresponds to a subcube, where the subfunction of f satisfies certain conditions. We define several variants, by considering different classes of Boolean functions that can appear as subfunctions on the subcubes associated with the steps of a path.

For example, in the first variant of our measure, the requirement is that each step along the path corresponds to flipping bits of a minimal sensitive block of the function f . That is, for a step $x^{(i)}, x^{(i+1)}$ along such a path, the requirement is that $f(x^{(i)}) \neq f(x^{(i+1)})$, but $f(x^{(i)}) = f(y)$ for every $y \neq x^{(i+1)}$ from the subcube defined by the bits where $x^{(i)}$ and $x^{(i+1)}$ differ. Notice that this condition means that the subfunction of f restricted to the subcube associated with each step is either the AND function (when $f(x^{(i)}) = 0$) or the NAND function (when $f(x^{(i)}) = 1$). Generalizing this idea, we define several variants of our measure by specifying the class \mathcal{H} of functions that can appear as subfunctions along the steps of a legal path.

Once we specified which steps are legal along a path for a given variant of our measure, we proceed as follows. For a given input x , we define the diameter of f on x as the length of the shortest “legal” path from \bar{x} (the complement of x) to any certificate of f on x , that is to any constant subcube containing x . Then, similarly to standard complexity measures like certificate complexity, we take the maximum over all inputs. Depending on the class \mathcal{H} of functions we allow to appear as subfunctions along the steps of a path, we obtain variants of our measure.

Comparison of diameter with alternating number. Our measure is motivated by alternating number, but it is quite different from it.

First, the similarity is that both measures involve considering paths in the Boolean cube, where one step of the path involves flipping a block of input bits of the function, thus each step specifies a subcube. For alternating number, the requirement on the function values on the subcubes is that the function takes different values on the two opposite (all 0 and all 1) points of the subcubes. For our measure, we consider different classes of Boolean functions that can appear as subfunctions on the subcubes associated with a path.

We note that the definition of alternating number also requires that a path is monotone, (that is the set of 1 bits of an input x on the path must be a subset of the 1 bits of any input that appears later in the path). We do not impose such requirement. In contrast to alternating number, diameter does not measure closeness to monotonicity.

Furthermore, alternating number considers the longest “legal” path between just two specific points, the all 0 input and the all 1 input. For our measure, we consider the shortest “legal” path between inputs x and subcubes corresponding to certificates of the function on the complementary input \bar{x} .

We note that in general, diameter and alternating number are incomparable, and we provide examples that illustrate this. However, an important distinction is that while alternating number can be exponentially larger than certificate complexity [14], each variant of our measure considered in this paper is upper bounded by certificate complexity, up to constant factors.

Diameter vs certificate complexity. We define the following variants, depending on the class \mathcal{H} of functions we allow to appear as subfunctions along the steps of a path: dia_{\wedge} where \mathcal{H} consists of the functions AND and NAND (these are the possible subfunctions associated with minimal sensitive blocks, as discussed above), dia_s where \mathcal{H} includes all functions with full sensitivity, dia_{deg} where \mathcal{H} includes all functions with full real degree, dia_{deg_2} where \mathcal{H} includes all functions with full \mathbb{F}_2 -degree.

Note that each of the classes we consider contains the functions AND and NAND since both of these functions have full sensitivity, full \mathbb{F}_2 -degree and full real degree. Thus, each of the measures $dia_s(f)$, $dia_{deg}(f)$ and $dia_{deg_2}(f)$ is upper bounded by $dia_{\wedge}(f)$, for every Boolean function f . On the other hand, as we illustrate by examples, $dia_s(f)$, $dia_{deg}(f)$ and $dia_{deg_2}(f)$ may be significantly smaller than $dia_{\wedge}(f)$, thus considering these variants may lead to stronger bounds. Furthermore, since $deg_2(f) \leq deg(f)$, we have that $dia_{deg}(f) \leq dia_{deg_2}(f)$. We also present examples showing that $dia_{deg}(f)$ may be significantly smaller than $dia_{deg_2}(f)$.

We prove that for all the classes \mathcal{H} considered in this paper,

$$dia_{\mathcal{H}}(f) \leq dia_{\wedge}(f) \leq 2C(f).$$

Depending on the class \mathcal{H} , we can lower bound $dia_{\mathcal{H}}$ by certificate complexity divided by specific complexity measures, such as sensitivity. We show that for any Boolean function f , $C(f)/s(f)$ is upper bounded by $dia_s(f)$ and thus we can upper bound certificate complexity as follows:

$$C(f) \leq dia_s(f)s(f) \leq dia_{\wedge}(f)s(f).$$

Similarly, considering the classes \mathcal{H} consisting of Boolean functions with full real degree and full \mathbb{F}_2 -degree, respectively, we get the following bounds relating diameter and certificate complexity. For any Boolean function f , $C(f) \leq dia_{deg}(f)deg(f) \leq dia_{\wedge}(f)deg(f)$ and $C(f) \leq dia_{deg_2}(f)deg_2(f) \leq dia_{\wedge}(f)deg_2(f)$.

Other variants. One could consider more versions of our measure, for various other classes \mathcal{H} . Another class that is natural to consider in connection to the log-rank conjecture for XOR functions is taking \mathcal{H} to be the class of Boolean functions with full Fourier sparsity, that is functions such that all their Fourier coefficients are nonzero. We do not discuss this variant in more details, as the results are analogous to our results on dia_{deg_2} with similar applications.

31:4 Diameter vs. Certificate Complexity

We would like to mention another version of our definitions, that turns out to be helpful in proving some of our results for special classes of Boolean functions. Several papers in the literature consider minimum certificate complexity, defined as $C_{min}(f) = \min_x C(f, x)$. Similarly, while we define diameter as $dia_{\mathcal{H}}(f) = \max_x dia_{\mathcal{H}}(f, x)$, we also consider minimum diameter defined as $dia_{min, \mathcal{H}}(f) = \min_x dia_{\mathcal{H}}(f, x)$.

Results on transitive functions with small diameter. There has been a long line of work trying to estimate the sensitivity and block sensitivity for transitive functions [32] and also for special classes of transitive functions such as symmetric functions and graph properties [38, 33], minterm transitive functions and cyclically invariant functions [10, 2, 15], transitive functions with sparse DNFs [12].

It has been conjectured that all transitive functions must have “large” sensitivity and block sensitivity. No examples of transitive functions are known on n input bits with $o(n^{1/3})$ sensitivity. Chakraborty [10] constructed a transitive function on n variables with sensitivity $\Theta(n^{1/3})$. It is noted in [12] that an argument in [32] together with Huang’s result gives that any transitive function f on n variables has $s(f) \geq \Omega(n^{1/6})$.

Previous results due to Lin and Zhang [20] imply that $s(f) \geq \Omega(n^{1/3})$ for transitive functions with constant alternating number. We improve and extend this bound and prove that $s(f) \geq \sqrt{n}$ for transitive functions with constant alternating number, as well as for transitive functions with constant diameter, considering dia_s or dia_{\wedge} .

Regarding block sensitivity, it has been conjectured that $\Omega(n^{3/7})$ is a lower bound on the block sensitivity of all transitive functions. There is an example of a transitive function f due to Amano [2] that has $bs(f) = \theta(n^{3/7})$, and no transitive function is known with smaller block sensitivity. Sun [32] proved a lower bound of $n^{1/3}$ on the block sensitivity for all transitive functions. Since block sensitivity is at least sensitivity, our result above also implies that for transitive functions with constant alternating number or constant diameter (dia_s or dia_{\wedge}), $bs(f) \geq \Omega(\sqrt{n})$. We prove that the conjectured $\Omega(n^{3/7})$ lower bound holds under a weaker condition, for all transitive functions with constant *minimum* diameter ($dia_{min, s}$ or $dia_{min, \wedge}$).

Log-rank conjecture for XOR functions with small diameter. The log-rank conjecture for functions of the form $f(x \oplus y)$ has been proved when f belongs to certain special classes such as monotone or linear threshold functions [25], symmetric functions [39], functions with low \mathbb{F}_2 -degree or small spectral norm [35], AC^0 functions [18], read- k functions [11], and functions with constant alternating number by Lin and Zhang [20]. We prove that the log-rank conjecture holds for functions of the form $f(x \oplus y)$ for functions f with dia_{deg_2} or dia_{\wedge} bounded above by a polynomial of the logarithm of the Fourier sparsity of f .

Further motivation for considering diameter. As we noted above, $dia_{\mathcal{H}}(f) \leq 2C(f)$ for any f and any class \mathcal{H} that contains the functions AND and NAND. Huang’s result implies that $C(f) = O(s(f)^5)$, which in turn implies that for any f , and any class \mathcal{H} that contains the functions AND and NAND, (which means for every class considered in this paper), we have

$$dia_{\mathcal{H}}(f) = O(s(f)^5).$$

Obtaining new upper bounds on $dia_{\mathcal{H}}$ could lead to the following interesting consequences:

- An independent proof of the upper bound $dia_{\mathcal{H}}(f) \leq poly(s(f))$ for dia_s or dia_{\wedge} could lead to an independent, purely combinatorial proof of the sensitivity conjecture.

- Improving the upper bound on dia_s or dia_\wedge in terms of sensitivity to $dia_{\mathcal{H}}(f) \leq O(s(f)^2)$, would improve the current best upper bounds on block sensitivity and certificate complexity to $bs(f) \leq C(f) \leq O(s(f)^3)$.

In connection to this question, we note that there are Boolean functions with $dia_s(f)$ (and thus $dia_\wedge(f)$) at least $\Omega(s(f)^{2-o(1)})$, since [3] exhibited a function with $C(f) = \Omega(s(f)^{3-o(1)})$ improving previous results of [6] and [5].

- Proving that $dia_{deg}(f) \leq deg(f)$ would imply the bound $C(f) \leq O(s(f)^4)$, using Huang's result, but improving its current implication which gives only $C(f) \leq O(s(f)^5)$. It would also imply that $C(f) \leq O(deg(f)^2)$, improving the current best bound giving $C(f) \leq deg(f)^3$ by [24].

We note that there are Boolean functions with $dia_{deg}(f)$ (and thus $dia_{deg_2}(f)$ and $dia_\wedge(f)$) at least $\Omega(deg(f)^{1-o(1)})$, since there are Boolean functions with $C(f) = \Omega(deg(f)^{2-o(1)})$ which was shown recently in [3] improving the previous $\Omega(deg(f)^{1.63})$ bound of [29].

- Upper bounds on $dia_{\mathcal{H}}$ (considering an appropriate \mathcal{H}) for specific classes of Boolean functions could give stronger upper bounds on block sensitivity or certificate complexity in terms of sensitivity than currently known for these classes, and could verify the log-rank conjecture for XOR functions for new classes.

2 Preliminaries

Let $f : \{0, 1\}^n \rightarrow \{0, 1\}$ be a Boolean function and $x \in \{0, 1\}^n$ be any input. For $i \in [n]$ we denote by x^i the input obtained by flipping the i -th bit of x . More generally, for $S \subseteq [n]$ we denote by x^S the input obtained by flipping the bits of x in all coordinates in the subset S .

For any two inputs $x, y \in \{0, 1\}^n$, we say $x \prec y$ if $x_i \leq y_i$ for all $i \in [n]$.

► **Definition 2.1** (Sensitivity). *The sensitivity $s(f, x)$ of a Boolean function f on input x is the number of coordinates $i \in [n]$ such that $f(x) \neq f(x^i)$. The sensitivity of f is defined as $s(f) = \max\{s(f, x) : x \in \{0, 1\}^n\}$.*

► **Definition 2.2** (Block Sensitivity). *The block sensitivity $bs(f, x)$ of a Boolean function f on input x is the maximum number of pairwise disjoint subsets S_1, \dots, S_k of $[n]$ such that for each $i \in [k]$ $f(x) \neq f(x^{S_i})$. The block sensitivity of f is defined as $bs(f) = \max\{bs(f, x) : x \in \{0, 1\}^n\}$.*

► **Definition 2.3** (Partial assignment, subcube and subfunction). *Given an integer $n > 0$, a partial assignment α is a function $\alpha : [n] \rightarrow \{0, 1, \star\}$. A partial assignment α corresponds naturally to a setting of n variables (x_1, x_2, \dots, x_n) to $\{0, 1, \star\}$ where x_i is set to $\alpha(i)$.*

The variables set to \star are called unassigned or free, and we say that the variables set to 0 or 1 are fixed. We say that $x \in \{0, 1\}^n$ agrees with α if $x_i = \alpha(i)$ for all i such that $\alpha(i) \neq \star$. The set of all inputs $x \in \{0, 1\}^n$ agreeing with α constitutes a subcube which we denote by \mathcal{S}_α .

The size of a partial assignment α is defined as the number of fixed variables of α and denoted as $|\alpha|$.

For a function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, we denote by f_α the subfunction obtained by restricting f to the subcube \mathcal{S}_α .

► **Definition 2.4** (Certificate). *For a function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ and input $x \in \{0, 1\}^n$ a partial assignment α is a certificate of f on x if x agrees with α , and any input y agreeing with α satisfies $f(y) = f(x)$.*

We denote the set of all certificates of f on x by $\Gamma_f(x)$.

31:6 Diameter vs. Certificate Complexity

► **Definition 2.5** (Certificate Complexity). *The certificate complexity $C(f, x)$ of a Boolean function f on input x is the size of the smallest certificate of f on x . The certificate complexity of f is defined as $C(f) = \max\{C(f, x) : x \in \{0, 1\}^n\}$. The minimum certificate complexity of f is defined as $C_{\min}(f) = \min\{C(f, x) : x \in \{0, 1\}^n\}$.*

► **Definition 2.6** (Alternating path). *For a Boolean function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, an alternating path is defined as any sequence of inputs $x^{(0)}, x^{(1)}, x^{(2)}, \dots, x^{(t)}$, $x^{(i)} \in \{0, 1\}^n$ for $i \in \{0, 1, \dots, t\}$, that satisfies the following properties:*

- $x^{(0)} = 0^n$
- $x^{(i)} \prec x^{(i+1)}$ for all $i \in \{0, 1, \dots, t-1\}$.
- $f(x^{(i)}) \neq f(x^{(i+1)})$ for all $i \in \{0, 1, \dots, t-1\}$

where $a \prec b$ denotes the property that the set of bits set to 1 in a forms a subset of the set of bits set to 1 in b .

► **Definition 2.7** (Alternating Number of a function). *For a Boolean function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, the alternating number of f , $\text{alt}(f)$, is defined as the maximum length of any alternating path of f .*

► **Definition 2.8** (Invariance Group). *A Boolean function $f: \{0, 1\}^n \rightarrow \{0, 1\}$ is invariant under a permutation $\sigma: [n] \rightarrow [n]$, if for any $x \in \{0, 1\}^n$, $f(x_1, \dots, x_n) = f(x_{\sigma(1)}, \dots, x_{\sigma(n)})$. The set of all permutations under which f is invariant forms a group, called the invariance group of f .*

► **Definition 2.9** (Transitive Function). *A Boolean function is transitive if its invariance group Γ is transitive, that is, for each $i, j \in [n]$, there is a $\sigma \in \Gamma$ such that $\sigma(i) = j$.*

For example, the set of all permutations on n bits, denoted by S_n is a transitive group of permutations. Another example of a transitive group of permutations is the set of all *cyclic shifts* on n bits, denoted by $\text{Shift}_n = \{\xi_0, \xi_1, \dots, \xi_{n-1}\}$, where the permutation ξ_j cyclically shifts the string by j positions.

Communication Complexity. We consider a setting with two parties Alice and Bob and a fixed Boolean function $f: \{0, 1\}^{2n} \rightarrow \{0, 1\}$. For $x, y \in \{0, 1\}^n$, input x is provided to Alice and input y to Bob. Their collective objective is to compute $f(x, y)$.

The communication complexity of f , denoted $CC(f)$, is the maximum value of the minimum number of bits exchanged by Alice and Bob in order to compute $f(x, y)$, where the maximum is taken over all input pairs $(x, y) \in \{0, 1\}^{2n}$.

The communication matrix corresponding to f , denoted M_f , is a $2^n \times 2^n$ matrix with rows indexed by all possible values of $x \in \{0, 1\}^n$ i.e. Alice's part of the input and columns indexed by all possible values of $y \in \{0, 1\}^n$ i.e. Bob's part of the input. It can be shown that $CC(f) \geq \log \text{rank}(M_f)$ [23].

The Log-rank conjecture proposed by Lovász and Saks [21] asks whether the communication complexity of a function can also be upper bounded by a polynomial in logarithm of the rank of its communication matrix as:

► **Conjecture 2.10.** *For any function $f: \{0, 1\}^{2n} \rightarrow \{0, 1\}$,*

$$CC(f) \leq \text{poly}(\log \text{rank}(M_f))$$

Please see Section A in the Appendix for more definitions and background.

2.1 Previous results

We now state some previous results that we use in our proofs.

First we state a couple of lemmas from a recent paper by Chabul and Gál [12].

► **Lemma 2.11** (Lemma 8 from [12]). *For any non-constant transitive function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, we have $C(f, 0^n) \cdot s(f) \geq n$ and $C(f, 1^n) \cdot s(f) \geq n$.*

► **Lemma 2.12** (Lemma 9 from [12]). *For any non-constant transitive function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, and an integer $5 \leq r \leq 15$, if $C_{\min}(f) \leq n^{3/r}$, then $bs(f) \geq \Omega(n^{1-\frac{4}{r}})$.*

We now state a lemma from the paper of Lin and Zhang [20]:

► **Lemma 2.13** (Lemma 12 from [20]). *For any function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, the following two statements hold:*

$$\max\{C(f, 0^n), C(f, 1^n)\} \leq alt(f) \cdot s(f)$$

$$\max\{C(f, 0^n), C(f, 1^n)\} \leq alt(f) \cdot deg_2(f)$$

We include more details about the approach and previous results of Lin and Zhang [20] in Section A.1 in the Appendix.

3 Diameters of Boolean functions

We begin with some notation. For the Boolean cube \mathcal{B}_n , a path is any sequence of inputs $x^{(0)}, x^{(1)}, x^{(2)}, \dots, x^{(t)}$ where $x^{(i)} \in \{0, 1\}^n$ for $i \in \{0, 1, \dots, t\}$. We define the length of such a path to be the number of steps t . For a path $x^{(0)}, x^{(1)}, x^{(2)}, \dots, x^{(t)}$, we define a sequence of partial assignments $\{\beta^{(0)}, \beta^{(1)}, \dots, \beta^{(t-1)}\}$ where $\beta^{(i)} : [n] \rightarrow \{0, 1, \star\}$ is defined as follows: $\beta_j^{(i)} = x_j^{(i)}$ for all $j \in [n]$ such that $x_j^{(i)} = x_j^{(i+1)}$ and $\beta_j^{(i)} = \star$ otherwise.

Note that we can view each step $x^{(i)} \rightarrow x^{(i+1)}$ on a path as flipping the bits where $x^{(i)}$ and $x^{(i+1)}$ differ. The free variables of the partial assignment $\beta^{(i)}$ are exactly these bits. Thus, for a Boolean function f , the subfunction $f_{\beta^{(i)}}$ depends on the bits where $x^{(i)}$ and $x^{(i+1)}$ differ.

► **Definition 3.1** (\mathcal{H} -distance between an input and a certificate). *Let \mathcal{H} be a class of Boolean functions. For a Boolean function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, input $x \in \{0, 1\}^n$ and a partial assignment $\alpha : [n] \rightarrow \{0, 1, \star\}$ corresponding to a subcube where f is constant, we define an \mathcal{H} -path from x to α as any path $x^{(0)}, x^{(1)}, \dots, x^{(t)}$ that satisfies the following properties:*

- $x^{(0)} = x$
- $x^{(t)}$ agrees with α
- The subfunction $f_{\beta^{(i)}}$ belongs to class \mathcal{H} for each $i \in \{0, 1, \dots, t-1\}$.

We define the \mathcal{H} -distance between x and α with respect to f , denoted $dist_{f, \mathcal{H}}(x, \alpha)$, to be the length of a shortest \mathcal{H} -path from x to α .

► **Definition 3.2** (\mathcal{H} -diameter of a function). *For a Boolean function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, input $x \in \{0, 1\}^n$, and a class of Boolean functions \mathcal{H} , we use the notation*

$$dia_{\mathcal{H}}(f, x) = \min_{\alpha \in \Gamma_f(x)} dist_{f, \mathcal{H}}(\bar{x}, \alpha).$$

Recall that \bar{x} denotes the complement of x and $\Gamma_f(x)$ denotes the set of all certificates of f on x .

We define the \mathcal{H} -diameter of f as:

$$dia_{\mathcal{H}}(f) = \max_{x \in \{0, 1\}^n} dia_{\mathcal{H}}(f, x).$$

31:8 Diameter vs. Certificate Complexity

In this work, we will be concerned with the \mathcal{H} -diameter of functions for the following classes \mathcal{H} :

- AND diameter denoted $dia_{\wedge}(f)$: Corresponds to the class \mathcal{H} that includes the function AND and its negation the NAND function.
- Sensitivity diameter denoted $dia_s(f)$: Defined by the class \mathcal{H} with functions that have sensitivity equal to the number of input variables.
- Real degree diameter denoted as $dia_{deg}(f)$: Corresponding to the class of functions \mathcal{H} with real degree equal to the number of input variables.
- \mathbb{F}_2 -degree diameter denoted as $dia_{deg_2}(f)$: Defined by the class \mathcal{H} that include functions with \mathbb{F}_2 -degree equal to the number of variables.

Note that since the functions AND and NAND belong to each of the classes we consider in this paper, and since $deg_2(f) \leq deg(f)$ for any Boolean function f , we have

$$dia_s(f) \leq dia_{\wedge}(f) \tag{1}$$

and

$$dia_{deg}(f) \leq dia_{deg_2}(f) \leq dia_{\wedge}(f) \tag{2}$$

Similarly to minimum certificate complexity, we also define the minimum version of the diameter:

► **Definition 3.3** (Min \mathcal{H} -diameter of a function). *For a Boolean function $f: \{0, 1\}^n \rightarrow \{0, 1\}$ and a class of Boolean functions \mathcal{H} , we define the min \mathcal{H} -diameter of f as:*

$$dia_{min, \mathcal{H}}(f) = \min_{x \in \{0, 1\}^n} dia_{\mathcal{H}}(f, x).$$

and we define the closure of the min \mathcal{H} -diameter of f as:

$$dia_{min, \mathcal{H}}^{clo}(f) = \max_{\alpha} dia_{min, \mathcal{H}}(f_{\alpha})$$

where the maximum is taken over all possible partial assignments α on n variables, or in other words, over all possible subfunctions f_{α} of f .

Note that for any function f and class \mathcal{H} , we have $dia_{min, \mathcal{H}}(f) \leq dia_{min, \mathcal{H}}^{clo}(f) \leq dia_{\mathcal{H}}(f)$.

3.1 Upper bounds on diameters

► **Lemma 3.4.** *For any function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, we have:*

$$dia_{\wedge}(f) \leq 2C(f)$$

Proof. For any input $x \in \{0, 1\}^n$, we shall prove that $dia_{\wedge}(f, x) \leq 2C(f, x)$.

Let α be a certificate of f on x achieving $|\alpha| = C(f, x)$. We shall construct an AND-NAND path $x^{(0)}, x^{(1)}, \dots, x^{(t)}$ from \bar{x} to α , with length $t \leq 2|\alpha|$.

We start with $x^{(0)} = \bar{x}$ as required. We now give an inductive description of our construction. Let us assume that we have found the first $i + 1$ vertices of the path i.e. $x^{(0)}, x^{(1)}, \dots, x^{(i)}$. Then we get the next vertex $x^{(i+1)}$ in the following way based on the value of $f(x^{(i)})$:

1. Case 1: $f(x^{(i)}) = f(x)$

If $x^{(i)}$ agrees with α , then we have successfully found the required \mathcal{H} -path from \bar{x} to α and we can stop.

Otherwise, if $x^{(i)}$ does not agree with α , then we choose $x^{(i+1)} = (x^{(i)})^S$ where S is any minimal sensitive block of f on $x^{(i)}$ such that S does not contain any index where $x^{(i)}$ and α agree. Note that such a block S must exist because otherwise, the set of bits where $x^{(i)}$ and α agree would be a certificate of f , which would contradict the minimality of the certificate α .

We note that in this case, $x^{(i+1)}$ agrees with α on at least as many bits as $x^{(i)}$ agrees with α .

2. Case 2: $f(x^{(i)}) \neq f(x)$

In this case, we first observe that the set T of all the bits where $x^{(i)}$ and α disagree constitutes a sensitive block for f on $x^{(i)}$. Therefore, there exists a subset $S \subset T$ which is a minimal sensitive block of f on $x^{(i)}$. We then choose $x^{(i+1)} = (x^{(i)})^S$.

Note that the number of bits where $x^{(i+1)}$ agrees with α is strictly greater than the number of bits where $x^{(i)}$ agrees with α .

First we note that since each step consists of flipping a minimal sensitive block, each of the subfunctions $f_{\beta^{(i)}}$ is either AND or NAND: Recall that the subfunction $f_{\beta^{(i)}}$ depends on the bits where $x^{(i)}$ and $x^{(i+1)}$ differ. So for example, if $f(x^{(i)}) = 0$, then the subfunction $f_{\beta^{(i)}}$ is 0 everywhere except when all its free variables agree with $x^{(i+1)}$.

Further, since an AND-NAND path is also an alternating path, the value of $f(x^{(i)})$ alternates between 0 and 1. Therefore, the above described procedure to construct the AND-NAND path alternates between case 1 and case 2.

Also, as noted before, the number of bits where $x^{(i+1)}$ agrees with α is strictly greater than the number of bits where $x^{(i)}$ agrees with α in case 2, whereas in case 1, we can guarantee that this number does not decrease. Since the procedure alternates between the two cases, $x^{(i+2)}$ must agree with α on at least one more bit than $x^{(i)}$, for $i \in \{0, 1, \dots, t-2\}$. Therefore, the procedure must terminate in at most $2|\alpha|$ steps, implying that $t \leq 2|\alpha|$. ◀

Next, note that since each of our measures is upper bounded by certificate complexity (as we proved above), known upper bounds on certificate complexity imply that for each class \mathcal{H} considered in this paper, we have $dia_{\mathcal{H}}(f) \leq O(s(f)^5)$ (using Huang's result [17]) and $dia_{\mathcal{H}}(f) \leq O(deg(f)^3)$ by [24].

Improving these upper bounds would have interesting consequences, as we described in the introduction.

3.2 Upper bounds on certificate complexity in terms of diameters

► **Lemma 3.5.** *For any function $f: \{0, 1\}^n \rightarrow \{0, 1\}$ and input $x \in \{0, 1\}^n$, we have:*

$$C(f, x) \leq dia_s(f, x) \cdot s(f) \leq dia_{\wedge}(f, x) \cdot s(f) \quad (3)$$

$$C(f, x) \leq dia_{deg}(f, x) \cdot deg(f) \leq dia_{\wedge}(f, x) \cdot deg(f) \quad (4)$$

$$C(f, x) \leq dia_{deg_2}(f, x) \cdot deg_2(f) \leq dia_{\wedge}(f, x) \cdot deg_2(f) \quad (5)$$

Proof. We shall first prove inequality 3.

Let α be a certificate of f on x and $x^{(0)}, x^{(1)}, \dots, x^{(t)}$ be a corresponding full sensitivity path from \bar{x} to α that achieves the minimum value of $dist_{f,s}(\bar{x}, \alpha)$.

31:10 Diameter vs. Certificate Complexity

Then note that every fixed bit of the certificate α must be contained in $\beta^{(i)}$ for some $i \in \{0, 1, \dots, t-1\}$ since $x^{(t)}$ agrees with α and $x^{(0)}$ (i.e. \bar{x}) disagrees with all the fixed bits of α .

Therefore, $|\beta^{(0)}| + |\beta^{(1)}| + \dots + |\beta^{(t-1)}| \geq |\alpha|$. So there must exist an $i \in \{0, 1, \dots, t-1\}$ such that $|\beta^{(i)}| \geq \frac{|\alpha|}{t}$. Now consider the subfunction $f_{\beta^{(i)}}$. Since we considered a full sensitivity path, this subfunction has sensitivity $|\beta^{(i)}|$. Therefore, $s(f) \geq |\beta^{(i)}| \geq \frac{|\alpha|}{t}$.

This implies that $s(f) \cdot \text{dist}_{f,s}(\bar{x}, \alpha) \geq |\alpha|$.

Taking the minimum over all the certificates for f on x gives the first part of inequality 3. The second part follows due to inequality 1. The other two inequalities follow by an analogous argument. ◀

Lemma 3.5 immediately implies the following two theorems.

► **Theorem 3.6.** *For any function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, we have:*

1. $C(f) \leq \text{dia}_s(f) \cdot s(f) \leq \text{dia}_\wedge(f) \cdot s(f)$
2. $C(f) \leq \text{dia}_{\text{deg}}(f) \cdot \text{deg}(f) \leq \text{dia}_\wedge(f) \cdot \text{deg}(f)$
3. $C(f) \leq \text{dia}_{\text{deg}_2}(f) \cdot \text{deg}_2(f) \leq \text{dia}_\wedge(f) \cdot \text{deg}_2(f)$.

Proof. Let x be the input achieving $C(f, x) = C(f)$. Then, equation 3 gives:

$$\begin{aligned} C(f) &= C(f, x) \\ &\leq \text{dia}_s(f, x) \cdot s(f) \\ &\leq \text{dia}_s(f) \cdot s(f). \end{aligned}$$

This gives the first part of the first statement of the theorem, the second part follows by equation 1. The other statements follow similarly from Lemma 3.5 and equation 2. ◀

► **Theorem 3.7.** *For any function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, we have:*

1. $C_{\min}(f) \leq \text{dia}_{\min,s}(f) \cdot s(f) \leq \text{dia}_{\min,\wedge}(f) \cdot s(f)$
2. $C_{\min}(f) \leq \text{dia}_{\min,\text{deg}}(f) \cdot \text{deg}(f) \leq \text{dia}_{\min,\wedge}(f) \cdot \text{deg}(f)$
3. $C_{\min}(f) \leq \text{dia}_{\min,\text{deg}_2}(f) \cdot \text{deg}_2(f) \leq \text{dia}_{\min,\wedge}(f) \cdot \text{deg}_2(f)$.

Proof. Let x be the input for which the minimum value of $\text{dia}_s(f, x)$ is achieved. Then, equation 3 gives:

$$\begin{aligned} C_{\min}(f) &\leq C(f, x) \\ &\leq \text{dia}_s(f, x) \cdot s(f) \\ &= \text{dia}_{\min,s}(f) \cdot s(f). \end{aligned}$$

The first statement of the theorem follows.

Similarly equations 4 and 5, respectively, imply the second and third statements of the theorem. ◀

4 Results for families of functions with small diameters

4.1 Transitive functions with small diameters

In this section, we improve the lower bounds on sensitivity of transitive functions with constant alternating number that follow from the work of Lin and Zhang [20] and then also prove a similar result for transitive functions with constant AND diameter. We then proceed to prove lower bounds on block sensitivity of transitive functions with constant minimum AND diameter.

► **Lemma 4.1.** *For any non-constant transitive function $f: \{0, 1\}^n \rightarrow \{0, 1\}$ the following two statements hold:*

$$s(f)^2 \cdot \text{alt}(f) \geq n$$

$$s(f) \cdot \text{deg}_2(f) \cdot \text{alt}(f) \geq n$$

Proof. Recall that Lemma 2.11 gives that:

$$C(f, 0^n) s(f) \geq n$$

The first part of Lemma 2.13 gives that:

$$C(f, 0^n) \leq \text{alt}(f) \cdot s(f)$$

Together they imply the first statement of the lemma.

The second statement follows similarly using the second part of Lemma 2.13. ◀

Note that this implies $s(f) \geq \sqrt{n}$ for transitive functions with constant alternating number, giving the best possible bound for such functions.

The first statement of Lemma 4.1 is tight for the TRIBES function on n variables: TRIBES is monotone and therefore has $\text{alt}(f) = 1$. Also, TRIBES is transitive as noted in [30]. It is easy to see that TRIBES has $s(f) = \sqrt{n}$.

► **Lemma 4.2.** *For any non-constant transitive function $f: \{0, 1\}^n \rightarrow \{0, 1\}$ the following two statements hold:*

$$s(f)^2 \cdot \text{dia}_\wedge(f) \geq n,$$

$$s(f) \cdot \text{deg}_2(f) \cdot \text{dia}_\wedge(f) \geq n.$$

Proof. Recall that Lemma 2.11 gives that:

$$C(f, 0^n) s(f) \geq n$$

Further equation 3 gives that:

$$C(f, 0^n) \leq \text{dia}_\wedge(f, 0^n) \cdot s(f)$$

Therefore, we get:

$$\text{dia}_\wedge(f, 0^n) \cdot s(f)^2 \geq n$$

which implies the first part of the lemma.

A similar argument gives the second part of the lemma using equation 5. ◀

► **Corollary 4.3.** *For any non-constant transitive function $f: \{0, 1\}^n \rightarrow \{0, 1\}$ with constant alternating number or constant AND diameter $\text{dia}_\wedge(f) = O(1)$, we have:*

$$s(f) \geq \Omega(\sqrt{n})$$

We now prove a lower bound on the block sensitivity of transitive functions under the weaker condition of having constant minimum AND diameter.

► **Lemma 4.4.** *For any non-constant transitive function $f: \{0, 1\}^n \rightarrow \{0, 1\}$ with $\text{dia}_{\min, \wedge}(f) = O(1)$, we have:*

$$bs(f) \geq \Omega(n^{3/7})$$

Proof. We have two cases:

31:12 Diameter vs. Certificate Complexity

Case 1: $C_{min}(f) \geq n^{3/7}$. The first part of Theorem 3.7 implies that $C_{min}(f) \leq dia_{min,\wedge}(f) \cdot s(f) \leq O(s(f))$, since $dia_{min,\wedge}(f) = O(1)$.

Then $n^{3/7} \leq C_{min}(f) \leq O(s(f)) \leq O(bs(f))$ and we are done.

Case 2: $C_{min}(f) \leq n^{3/7}$. Now we use Lemma 2.12 with $r = 7$. This implies that if any transitive function f has $C_{min}(f) \leq n^{3/7}$, then $bs(f) \geq n^{3/7}$, implying the statement of the Lemma in this case. \blacktriangleleft

4.2 Implications to the log-rank conjecture for XOR functions

For any $f: \{0,1\}^n \rightarrow \{0,1\}$, the corresponding XOR function $f \circ \oplus: \{0,1\}^{2n} \rightarrow \{0,1\}$ is defined as: $f \circ \oplus(x, y) = f(x \oplus y)$, where $x \oplus y$ is the bitwise XOR of $x, y \in \{0,1\}^n$.

Lin and Zhang [20] proved that the log-rank conjecture holds for XOR functions $f \circ \oplus$ such that $alt(f)$ is at most polynomial in $\log \|\hat{f}\|_0$ (see Theorem A.11).

In this section, we prove that the log-rank conjecture holds for functions of the form $f(x \oplus y)$ such that the \mathbb{F}_2 -degree diameter of f is upper bounded by a polynomial in the logarithm of the Fourier sparsity of f .

First we prove an analogous result to Theorem A.11 implying the log-rank conjecture for XOR functions with bounded \mathbb{F}_2 -degree diameter. In contrast to the proof of Theorem A.11, we do not need to upper bound $C_{min}^{clo}(f)$, since Theorem 3.6 proves an upper bound directly on $C(f)$ in terms of the product of $dia_{deg_2}(f)$ and $deg_2(f)$ for any function f . This gives us the following result confirming the log-rank conjecture for functions $f \circ \oplus$ with $dia_{deg_2}(f)$ upper bounded by a polynomial in the logarithm of the Fourier sparsity of f :

► **Theorem 4.5.** *For any function $f: \{0,1\}^n \rightarrow \{0,1\}$, we have:*

$$CC(f \circ \oplus) \leq 2dia_{deg_2}(f) \log^2 rank(M_{f \circ \oplus})$$

Proof. Recall the third statement of Theorem 3.6 which states that:

$$C(f) \leq dia_{deg_2}(f) \cdot deg_2(f)$$

Along with Lemma A.10, we get that:

$$\begin{aligned} CC(f \circ \oplus) &\leq 2C(f) \cdot \log rank(M_{f \circ \oplus}) \\ &\leq 2dia_{deg_2}(f) \cdot deg_2(f) \cdot \log rank(M_{f \circ \oplus}) \\ &\leq 2dia_{deg_2}(f) \cdot \log^2 rank(M_{f \circ \oplus}) \end{aligned}$$

Here the last inequality follows from Lemmas A.6 and A.9. \blacktriangleleft

We note that the statement of Theorem 4.5 also holds with $dia_{\wedge}(f)$ replacing $dia_{deg_2}(f)$, since the \mathbb{F}_2 -degree diameter is upper bounded by the AND diameter for any function f as noted in equation 2. We state Theorem 4.5 with $dia_{deg_2}(f)$ instead of $dia_{\wedge}(f)$ because it gives a stronger statement since there exist functions with dia_{deg_2} much smaller than dia_{\wedge} as illustrated by Example 5.2.

Next we prove a common strengthening of Theorem A.11 and Theorem 4.5. We show that the communication complexity of a function of the form $f(x \oplus y)$ can also be upper bounded in terms of the closure of its min \mathbb{F}_2 -degree diameter and the square of the log of rank of its communication matrix $M_{f \circ \oplus}$.

► **Theorem 4.6.** *For any function $f: \{0,1\}^n \rightarrow \{0,1\}$:*

$$CC(f \circ \oplus) \leq 2dia_{min,deg_2}^{clo}(f) \cdot \log^2 rank(M_{f \circ \oplus})$$

Proof. From the third statement of Theorem 3.7, we have that:

$$C_{min}^{clo}(f) \leq dia_{min,deg_2}^{clo}(f) \cdot deg_2(f)$$

Combining this with Lemmas A.6, A.9 and A.10 gives the result. ◀

As we shall note in Lemma 4.7, $dia_{min,deg_2}(f) \leq dia_{min,\wedge}(f) \leq alt(f)$. Since alternating number is a downward non-increasing measure, this implies that $dia_{min,deg_2}^{clo}(f) \leq alt(f)$. Furthermore, Example 5.4 gives a family of functions $f: \{0,1\}^n \rightarrow \{0,1\}$ with alternating number exponentially larger than all our diameters. This shows that Theorem 4.6 is a strictly stronger statement than Theorem A.11.

By definition, we have that for any function f , $dia_{min,deg_2}^{clo}(f) \leq dia_{deg_2}(f)$. Therefore, Theorem 4.6 is a potentially stronger statement than Theorem 4.5. As of now, we are not aware of any example function f separating $dia_{min,deg_2}^{clo}(f)$ from $dia_{deg_2}(f)$. However, we remark that the TRIBES function separates $dia_{min,\wedge}^{clo}(f)$ from $dia_{\wedge}(f)$ as noted in Section 5.8.

We illustrate with examples in Section 5 that, in general, the alternating number of a function and its \mathcal{H} -diameter are incomparable for the different classes \mathcal{H} that we consider. However, in the following lemma, we show that the min AND diameter, and consequently, the min \mathcal{H} -diameter for all our different classes \mathcal{H} , are upper bounded by the alternating number.

► **Lemma 4.7.** *For any function $f: \{0,1\}^n \rightarrow \{0,1\}$, we have,*

$$dia_{min,\wedge}(f) \leq alt(f)$$

Proof. We prove the following relationship, which immediately implies the statement of the lemma:

$$dia_{\wedge}(f, 1^n) \leq alt(f) \tag{6}$$

Let $alt(f) = t$ and let $\mathcal{Q} = x^{(0)}, x^{(1)}, \dots, x^{(t)}$ be an alternating path of length t .

Now, we construct an AND-NAND path $\mathcal{Q}' = z^{(0)}, z^{(1)}, \dots, z^{(t)}$ from 0^n to a certificate α of 1^n in the following way:

Let $z^{(0)} = x^{(0)} = 0^n$. Let $z^{(1)} \leq x^{(1)}$ be a minimal element such that $f(z^{(1)}) = f(x^{(1)})$. Recall that by the definition of alternating path, $f(x^{(i)}) \neq f(x^{(i+1)})$. Thus, the set of variables where $z^{(0)}$ and $z^{(1)}$ differ forms a minimal sensitive block for f on $z^{(0)}$: for all $y \neq z^{(1)}$ such that $z^{(0)} \prec y \prec z^{(1)}$, $f(y) = f(z^{(0)})$ but $f(z^{(1)}) \neq f(z^{(0)})$.

In general, for $i \in \{0, 1, \dots, t-1\}$, let $z^{(i+1)} \prec x^{(i+1)}$ be a minimal element such that $f(z^{(i+1)}) = f(x^{(i+1)})$, and $z^{(i)} \prec z^{(i+1)}$. Thus, the set of variables where $z^{(i)}$ and $z^{(i+1)}$ differ forms a minimal sensitive block for f on $z^{(i)}$. As we noted before (see Section 3.1) subfunctions over a set of variables that forms a minimal sensitive block are either the AND or the NAND function. Thus, for the path \mathcal{Q}' , each subfunction f_{β^i} is either an AND or a NAND.

We will thus get an AND-NAND path $z^{(0)}, z^{(1)}, \dots, z^{(t)}$ of length t . Note that $z^{(t)}$ must agree with some certificate of 1^n , since otherwise, we can get an alternating path for f of length greater than t in the following way: consider the alternating path $\mathcal{Q}' = z^{(0)}, z^{(1)}, \dots, z^{(t)}$. Since $z^{(t)}$ does not agree with any certificate of 1^n , the partial assignment α defined as $\alpha_i = 1$ whenever $z_i^{(t)} = 1$ and $\alpha_i = \star$ otherwise, is not a certificate of f . This implies the existence of an input $z^{(t+1)}$ such that $z^{(t)} \prec z^{(t+1)}$ and $f(z^{(t)}) \neq f(z^{(t+1)})$. Therefore, the path $\mathcal{Q}'' = z^{(0)}, z^{(1)}, \dots, z^{(t)}, z^{(t+1)}$ is an alternating path of length $t+1$ contradicting the fact that $alt(f) = t$.

Therefore, the path $z^{(0)}, z^{(1)}, \dots, z^{(t)}$ is an AND-NAND path from 0^n to some certificate of f on 1^n and the statement follows. ◀

5 Separating Examples

In this section, we give several examples, separating various types of diameters from alternating number and from each other.

5.1 Separating $dia_s(f)$ from $dia_{\wedge}(f)$

The following example has constant sensitivity diameter, whereas its AND diameter equals the number of input variables.

► **Example 5.1.** Let $f: \{0,1\}^n \rightarrow \{0,1\}$ be the PARITY function on n bits i.e. $PARITY(x) = \bigoplus_{i \in [n]} x_i$.

It is easy to see that $dia_{\wedge}(PARITY) = n$, since for any partial assignment α , the subfunction $PARITY_{\alpha}$ belongs to the AND-NAND class only if α fixes all but 1 variable.

On the other hand, for any input $x \in \{0,1\}^n$, $dia_s(PARITY, x) = 1$. This is because we can consider α to be the certificate fixing all the bits of x and then the path \bar{x}, x is a valid \mathcal{H} -path since $s(PARITY) = n$ (i.e. $PARITY$ induced on the “entire cube” has full sensitivity).

5.2 Separating $dia_{deg}(f)$ (and also $dia_{deg_2}(f)$) from $dia_{\wedge}(f)$

The next example has constant values for both its real degree diameter as well as \mathbb{F}_2 -degree diameter, but has large AND diameter.

► **Example 5.2.** Define $f: \{0,1\}^n \rightarrow \{0,1\}$ as follows:

$$\begin{aligned} f(0^n) &= 1, \\ f(x) &= \bigoplus_{i \in [n]} x_i \text{ otherwise.} \end{aligned}$$

It is easy to show that $dia_{\wedge}(f) = n$ by a similar argument as in example 5.1.

Also, we note that $deg_2(f) = n$. This follows from a result of Beigel and Bernasconi [4], stating that for any Boolean function, $deg_2(f) = n$ iff $|f^{-1}(1)|$ is odd.

Therefore, by an analogous argument as in example 5.1, for any input $x \in \{0,1\}^n$, $dia_{deg_2}(f, x) = 1$. (We can again consider α to be the certificate fixing all the bits of x and the path \bar{x}, x is a valid \mathcal{H} -path since $deg_2(f) = n$.)

Therefore, we have $dia_{deg_2}(f) = 1$.

We also have that for any Boolean function f , $deg_2(f) \leq deg(f)$ (see for example, proposition 6.23 in [30]).

Therefore, $deg(f) = n$, and by a similar argument as for the \mathbb{F}_2 -degree, $dia_{deg}(f) = 1$.

We note that the PARITY function from example 5.1 also separates $dia_{deg}(f)$ from $dia_{\wedge}(f)$. This is because $dia_{deg}(PARITY) = 1$ as we discuss below, whereas $dia_{\wedge}(PARITY) = n$ as noted in Example 5.1.

5.3 Separating $dia_{deg}(f)$ from $dia_{deg_2}(f)$

Recall from equation 2 that $dia_{deg}(f) \leq dia_{deg_2}(f)$ for any boolean function f . To separate $dia_{deg}(f)$ from $dia_{deg_2}(f)$, we consider again the PARITY function discussed in Example 5.1. It is easy to see that $deg_2(PARITY) = 1$. Moreover, for any partial assignment $\alpha: [n] \rightarrow \{0, 1, \star\}$, the subfunction $PARITY_{\alpha}$ is also a PARITY function on the free bits and therefore, $deg_2(PARITY_{\alpha}) = 1$. So we have $dia_{deg_2}(PARITY) = n$. However, $deg(PARITY) = n$, by the characterization due to Shi and Yao (see in the survey [9]) which states that for

any function $f: \{0,1\}^n \rightarrow \{0,1\}$, $\text{deg}(f) = n$ iff the number of 1-inputs with an even number of 1's does not equal the number of 1-inputs with an odd number of 1's. Therefore, $\text{dia}_{\text{deg}}(\text{PARITY}) = 1$.

5.4 Separating $\text{dia}_s(f)$ and $\text{dia}_{\text{deg}_2}(f)$ from each other

The measures $\text{dia}_s(f)$ and $\text{dia}_{\text{deg}_2}(f)$ are incomparable, and we provide examples separating them in both directions.

We again revisit the PARITY function considered in Example 5.1 to illustrate a function with small $\text{dia}_s(f)$ and large $\text{dia}_{\text{deg}_2}(f)$. As noted before, $\text{dia}_{\text{deg}_2}(\text{PARITY}) = n$, whereas $\text{dia}_s(\text{PARITY}) = 1$, achieving the required separation.

To illustrate a separation in the other direction, we consider the TRIBES function on n^2 bits that has $\text{dia}_s(\text{TRIBES}) = \Theta(n)$ as we shall see in Example 5.3. However, $\text{deg}_2(\text{TRIBES}) = n^2$ and therefore, $\text{dia}_{\text{deg}_2}(\text{TRIBES}) = 1$.

5.5 Separating $\text{dia}_s(f)$ from $\text{dia}_{\text{deg}}(f)$

We now mention a separating example with $\text{dia}_{\text{deg}}(f)$ much smaller than $\text{dia}_s(f)$. The TRIBES function (see also Example 5.3) on n^2 bits has $\text{dia}_s(\text{TRIBES}) = \Theta(n)$. However, $\text{deg}(\text{TRIBES}) = n^2$ and therefore, $\text{dia}_{\text{deg}}(\text{TRIBES}) = 1$.

We are not aware of any examples as yet, separating these measures in the other direction. We do believe these measures to be incomparable, and it would be an interesting exercise to find functions f with $\text{dia}_s(f)$ asymptotically smaller than $\text{dia}_{\text{deg}}(f)$.

5.6 Example with $\text{alt}(f)$ smaller than $\text{dia}_s(f)$ (and also $\text{dia}_\wedge(f)$)

We now present an example where the alternating number is much smaller than $\text{dia}_\wedge(f)$ as well as $\text{dia}_s(f)$.

► **Example 5.3.** Consider the TRIBES function $f: \{0,1\}^{n^2} \rightarrow \{0,1\}$ defined as:

$$\text{TRIBES}(x_{11}, x_{12}, \dots, x_{1n}, x_{21}, \dots, x_{2n}, \dots, x_{n1}, \dots, x_{nn}) = \bigvee_{i \in [n]} \bigwedge_{j \in [n]} x_{ij}$$

We first note that since TRIBES is monotone, $\text{alt}(\text{TRIBES}) = 1$.

We shall show that $\text{dia}_\wedge(\text{TRIBES}) \geq 2n - 1$.

Consider the 1-input $x = 1^n(0^2 1^{n-2})^{n-1}$. In other words, the first block of n bits of x are set to 1, the remaining $n - 1$ blocks of n bits each have the first 2 bits set to 0 and the rest set to 1.

Note that $\text{TRIBES}(x) = 0$.

Now, let $x^{(0)}, x^{(1)}, \dots, x^{(t)}$ be any valid AND-NAND path from x to α where α is a certificate of \bar{x} . (Note that we have switched the roles of x and \bar{x} in this example for convenience.)

Since $\text{TRIBES}(x^{(0)}) \neq f(x^{(1)}) = 0$, the partial assignment $\beta^{(0)}$ must have free bits belonging to the first block of n bits, and moreover, it cannot contain any free bits from any of the other blocks, in order for the function $\text{TRIBES}_{\beta^{(0)}}$ to belong to the AND-NAND class.

For the next step, since $\text{TRIBES}(x^{(2)}) = 1$, it is necessary that both 0-bits must be flipped from one of the remaining blocks. In other words, the partial assignment $\beta^{(1)}$ must have exactly two free variables corresponding to the first two bits of some block (other than the first block).

Again, as before, the partial assignment $\beta^{(2)}$ must contain free variables from the block which now only contains 1-bits.

In this way, any shortest valid AND-NAND path must alternate between changing some block to contain only 1-bits (thereby changing the function value to 1), and then flipping some 1-bit in that block to 0 (changing the function value to 0).

Eventually, every block will contain a bit that was flipped from a 1 to a 0, and the set of these bits shall constitute a certificate of \bar{x} .

Therefore, we have that $\text{dia}_{\wedge}(\text{TRIBES}) \geq 2n - 1$. We note that this bound is tight up to constant factors, as can be seen from Theorem B.1 which implies that $\text{dia}_{\wedge}(\text{TRIBES}) \leq O(n)$.

A similar argument also works to show that $\text{dia}_s(\text{TRIBES}) \geq 2n - 1$, and therefore, $\text{dia}_s(\text{TRIBES}) = \theta(n)$ due to Theorem B.1.

However, since $\text{deg}(\text{TRIBES}) = n^2$, we have that $\text{dia}_{\text{deg}}(\text{TRIBES}) = 1$.

Similarly, $\text{deg}_2(\text{TRIBES}) = n^2$ and therefore, $\text{dia}_{\text{deg}_2}(\text{TRIBES}) = 1$.

5.7 Example with $\text{alt}(f)$ larger than all our diameters

We refer to an example from [13] that separates $\text{alt}(f)$ from $C(f)$ (and consequently, from all of our diameters).

► **Example 5.4.** Let f be the function constructed in [13] as an example where $\text{alt}(f)$ is exponentially larger than $DT(f)$ and therefore also $C(f)$ (since $DT(f) \geq C(f)$). We note that since $\text{dia}_{\wedge}(f) \leq 2C(f)$ due to Lemma 3.4, f also acts as a separating example where $\text{alt}(f)$ is exponentially larger than $\text{dia}_{\wedge}(f)$, and therefore, also exponentially larger than $\text{dia}_s(f)$, $\text{dia}_{\text{deg}_2}(f)$ and $\text{dia}_{\text{deg}}(f)$.

5.8 Separating $\text{dia}_{\min, \wedge}^{\text{clo}}(f)$ from $\text{dia}_{\wedge}(f)$ and $\text{dia}_{\min, s}^{\text{clo}}(f)$ from $\text{dia}_s(f)$

For separating $\text{dia}_{\min, \wedge}^{\text{clo}}(f)$ from $\text{dia}_{\wedge}(f)$, we revisit the TRIBES function considered in Example 5.3. As noted in that example, $\text{dia}_{\wedge}(\text{TRIBES}) = \Theta(n)$. On the other hand, we have that $\text{dia}_{\min, \wedge}^{\text{clo}}(\text{TRIBES}) \leq \text{alt}(\text{TRIBES}) = 1$, thereby achieving the required separation. The same separation is also achieved for the TRIBES function between $\text{dia}_{\min, s}^{\text{clo}}(f)$ and $\text{dia}_s(f)$ by an analogous argument.

A Further Background

► **Definition A.1** (Real degree of a function). *A polynomial p over the reals with n variables is said to represent a Boolean function $f: \{0, 1\}^n \rightarrow \{0, 1\}$ if $p(x) = f(x)$ for all $x \in \{0, 1\}^n$. The degree of the unique multilinear polynomial over the reals representing f is defined to be the degree of f , and is denoted as $\deg(f)$.*

► **Definition A.2** (\mathbb{F}_2 degree of a function). *For any Boolean function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, the degree of the unique multilinear polynomial over \mathbb{F}_2 representing f is called as the \mathbb{F}_2 degree of f , denoted $\deg_2(f)$.*

► **Definition A.3** (Decision tree complexity). *A decision tree evaluating a function $f: \{0, 1\}^n \rightarrow \{0, 1\}$ is a rooted binary tree with internal nodes labeled by variables and leaves labeled by $\{0, 1\}$. The depth of a decision tree is defined as the length of a longest root to leaf path in the tree.*

For any input $x \in \{0, 1\}^n$, the label at the leaf reached by following the decision tree queries is the evaluation of the decision tree on x . The decision tree is said to compute the function f if it evaluates to $f(x)$ on every input $x \in \{0, 1\}^n$. The decision tree complexity of a boolean function f , denoted $DT(f)$, is defined as the smallest possible depth of any decision tree computing f .

► **Definition A.4** (Fourier sparsity of a function). Any function $f: \{0, 1\}^n \rightarrow \{0, 1\}$ can be uniquely represented as

$$f(x) = \sum_{S \subseteq [n]} \hat{f}(S) (-1)^{\sum_{i \in S} x_i}$$

This is said to be the Fourier expansion of f and the coefficients $\hat{f}(S)$ are called the Fourier coefficients of f . The number of non-zero Fourier coefficients of f is defined to be the Fourier sparsity of f , denoted $\|\hat{f}\|_0$.

We note that usually the Fourier representation is considered for functions of the form $f: \{0, 1\}^n \rightarrow \{+1, -1\}$. We use this version of the definition because it exactly captures the rank of the communication matrix for XOR functions (see Section A.1).

A.1 The approach of Lin and Zhang

We review the approach of Lin and Zhang [20] which we build upon in Section 4.2.

We first define the closure of min Certificate Complexity which was implicit in the approach of [35], and defined in [20]:

► **Definition A.5** (Closure of min Certificate Complexity; [35, 20]). For a function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, we define the closure of the min certificate complexity of f as:

$$C_{min}^{clo}(f) = \max_{\alpha} C_{min}(f_{\alpha})$$

where the maximum is taken over all possible partial assignments α on n variables, or in other words, over all possible subfunctions f_{α} of f .

Note that $C_{min}^{clo}(f) \leq C(f)$.

They also note that it is possible to define the closure for any complexity measure $M(f)$ for function f as $M^{clo}(f) = \max_{\alpha} M(f_{\alpha})$, where the maximum is taken over all subfunctions f_{α} of f . A measure M is said to be downward non-increasing if for any function f , it holds that $M(f_{\alpha}) \leq M(f)$ for any subfunction f_{α} of f . Note that the measures sensitivity, block sensitivity, certificate complexity, decision tree complexity, \mathbb{F}_2 -degree, Fourier sparsity, alternating number are all downward non-increasing. It follows from the definition of downward non-increasing measures that whenever measure M is downward non-increasing, it holds that $M^{clo}(f) = M(f)$.

We first note the following result from [7] stating that the rank of the communication matrix $M_{f \circ \oplus}$ exactly equals the Fourier sparsity of f :

► **Lemma A.6** ([7]). For any function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, we have: $\text{rank}(M_{f \circ \oplus}) = \|\hat{f}\|_0$.

Next, we note the following lemma about communication complexity of XOR functions:

► **Lemma A.7** ([25]). For any function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, we have: $CC(f \circ \oplus) \leq 2DT(f)$.

31:20 Diameter vs. Certificate Complexity

The following lemma upper bounds the decision tree complexity in terms of the product of its certificate complexity and \mathbb{F}_2 -degree. We note that the second inequality follows because $C_{min}^{clo}(f) \leq C(f)$.

► **Lemma A.8** ([36, 37, 20]). *For any function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, we have:*

$$DT(f) \leq C_{min}^{clo}(f) \cdot deg_2(f) \leq C(f) \cdot deg_2(f)$$

The \mathbb{F}_2 -degree of any function is upper bounded by the logarithm of its Fourier sparsity as proved in [7]:

► **Lemma A.9** ([7]). *For any function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, we have: $deg_2(f) \leq \log \|\hat{f}\|_0$.*

Lemmas A.6, A.7, A.8, A.9 imply the following result as also noted in [20]:

► **Lemma A.10** ([20]). *For any function $f: \{0, 1\}^n \rightarrow \{0, 1\}$:*

$$CC(f \circ \oplus) \leq 2C_{min}^{clo}(f) \cdot \log rank(M_{f \circ \oplus}) \leq 2C(f) \cdot \log rank(M_{f \circ \oplus})$$

It follows from Lemma A.10 that proving an upper bound on the certificate complexity of a function f in terms of a polynomial in $\log rank(M_{f \circ \oplus})$ would imply the log-rank conjecture for the corresponding XOR function $f \circ \oplus$.

Another approach towards proving the log-rank conjecture for XOR functions would be to upper bound $C_{min}^{clo}(f)$ directly. One way to achieve this for a class of functions would be to prove an upper bound of the form $C_{min}(f) \leq M(f)$ where $M(f)$ is a complexity measure that is downward non-increasing, since that would imply the bound $C_{min}^{clo}(f) \leq M(f)$, thereby proving the log-rank conjecture for functions $f \circ \oplus$ with bounded value of $M(f)$. Lin and Zhang [20] use this approach to prove that the log-rank conjecture holds for XOR functions $f \circ \oplus$ which are such that $alt(f)$ is at most polynomial in $\log \|\hat{f}\|_0$.

In particular, they achieve this by proving that for every boolean function f , $C_{min}(f) \leq alt(f)deg_2(f)$. Since both $alt(f)$ and $deg_2(f)$ are downward non-increasing, they get the following result:

► **Theorem A.11** (Theorem 2 from [20]). *For any function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, we have:*

$$CC(f \circ \oplus) \leq 2alt(f) \cdot \log^2 rank(M_{f \circ \oplus})$$

B Diameter under OR-composition

In this section, we study the behavior of diameters under OR-composition. In particular, we prove that any diameter of the OR-composition of two functions is upper bounded by a sum of their corresponding individual diameters (plus a constant factor).

In what follows, for two functions $f, g: \{0, 1\}^n \rightarrow \{0, 1\}$, we define the OR-composed function $f \vee g: \{0, 1\}^{2n} \rightarrow \{0, 1\}$ as $f \vee g(x_1, x_2) = 1$ if $f(x_1) = 1$ or $g(x_2) = 1$, and $f \vee g(x_1, x_2) = 0$ otherwise, for $x_1, x_2 \in \{0, 1\}^n$.

We now prove a result relating the diameter of OR-composition of two functions with their individual diameters as mentioned before:

► **Theorem B.1.** *For any functions $f, g: \{0, 1\}^n \rightarrow \{0, 1\}$, we have:*

$$dia_{\wedge}(f \vee g) \leq dia_{\wedge}(f) + dia_{\wedge}(g) + 3$$

Proof. Consider any input $(x_1, x_2) \in \{0, 1\}^{2n}$. We have two cases as follows:

Case 1: $f \vee g(x_1, x_2) = 0$. Consider the AND-NAND path $z_1^{(0)}, z_1^{(1)}, \dots, z_1^{(t_1)}$ (where $\bar{x}_1 = z_1^{(0)}$) achieving $\text{dia}_\wedge(f, x_1)$ and the AND-NAND path $z_2^{(0)}, z_2^{(1)}, \dots, z_2^{(t_2)}$ (where $\bar{x}_2 = z_2^{(0)}$) achieving $\text{dia}_\wedge(g, x_2)$.

We first deal with the case when $f(\bar{x}_1) = 0$ and $g(\bar{x}_2) = 0$. Observe that the following is a valid AND-NAND path for $f \vee g$:

$$(z_1^{(0)}, z_2^{(0)}), (z_1^{(0)}, z_2^{(1)}), \dots, (z_1^{(0)}, z_2^{(t_2)}), (z_1^{(1)}, z_2^{(t_2)}), (z_1^{(2)}, z_2^{(t_2)}), \dots, (z_1^{(t_1)}, z_2^{(t_2)}).$$

This follows because of the simple observation, that for any input $(a, b) \in \{0, 1\}^{2n}$, if $g(b) = 0$, then $f \vee g(a, b) = f(a)$. Due to this observation, in the first t_2 steps of the above path, the input to f is fixed to $z_1^{(0)}$ which is such that $f(z_1^{(0)}) = 0$. Therefore, throughout these steps, we have that $f \vee g(z_1^{(0)}, z_2^{(i)}) = g(z_2^{(i)})$ for any $i \in \{0, 1, \dots, t_2\}$. Since $z_2^{(0)}, z_2^{(1)}, \dots, z_2^{(t_2)}$ is a valid AND-NAND path of g , the first t_2 steps form valid steps of an AND-NAND path of $f \vee g$.

Similarly, since $z_2^{(t_2)}$ agrees with a certificate for g on x_2 , it holds that $g(z_2^{(t_2)}) = 0$. Therefore, for the next t_1 steps of the path, it holds that $f \vee g(z_1^{(i)}, z_2^{(t_2)}) = f(z_1^{(i)})$ for any $i \in \{0, 1, \dots, t_1\}$, and a similar argument goes through as for the first t_2 steps of the path.

Finally, since $z_1^{(t_1)}$ agrees with a certificate for f on x_1 and $z_2^{(t_2)}$ agrees with a certificate for g on x_2 , the input $(z_1^{(t_1)}, z_2^{(t_2)})$ agrees on a certificate for $f \vee g$ on the input (x_1, x_2) . We therefore get a valid AND-NAND path for the function $f \vee g$ of length $t_1 + t_2$.

Now, we consider the case when $f(\bar{x}_1) = 1$ and $g(\bar{x}_2) = 0$. In this case, we first perform an additional step of flipping the bits of any minimal sensitive block B for f on \bar{x}_1 to get to a 0-input of f i.e. \bar{x}_1^B . We then follow the argument of the previous case, and without changing the input to f , take t_2 steps corresponding to the AND-NAND path for g i.e. $z_2^{(0)}, z_2^{(1)}, \dots, z_2^{(t_2)}$. We then “undo” the first step by flipping back the bits of B in the input corresponding to f to get to the input $(\bar{x}_1, z_2^{(t_2)})$. Finally, we take the t_1 steps of the AND-NAND path for f starting from input \bar{x}_1 to get a valid AND-NAND path of total length $t_1 + t_2 + 2$.

Similar argument works for the case when $f(\bar{x}_1) = 0$ and $g(\bar{x}_2) = 1$.

Finally, the case with $f(\bar{x}_1) = 1$ and $g(\bar{x}_2) = 1$ goes through a similar argument, with the difference that the first step involves simultaneously flipping minimal sensitive blocks for both f and g , on the respective inputs \bar{x}_1 and \bar{x}_2 , to get input $(\bar{x}_1^{B_1}, \bar{x}_2^{B_2})$, say. The next step flips back these bits only for g to get the input $(\bar{x}_1^{B_1}, \bar{x}_2)$. The argument then proceeds as in the previous case, where we take the AND-NAND path for g starting from input \bar{x}_2 , followed by flipping back the bits of block B_1 for the input to f , followed by the AND-NAND path for f starting from input \bar{x}_1 .

This gives a valid AND-NAND path of length $t_1 + t_2 + 3$ for $f \vee g$ starting from input (\bar{x}_1, \bar{x}_2) .

Case 2: $f \vee g(x_1, x_2) = 1$. Wlog, assume that $g(x_2) = 1$.

In this case, we follow a similar proof strategy as in Case 1, with the difference that in this case, we only need to follow the steps corresponding to a valid AND-NAND path for g starting from \bar{x}_2 , since in this case, a certificate for g on x_2 would also be a certificate for $f \vee g$ on (x_1, x_2) . Apart from that, we follow a similar argument, where we first flip appropriate blocks of bits, if necessary, to ensure that we are at a 0-input of f . We then follow the AND-NAND path for g to get a certificate for $f \vee g$ on (x_1, x_2) . This gives an AND-NAND path for $f \vee g$ of length at most $t_2 + 2$. ◀

31:22 Diameter vs. Certificate Complexity

We remark that Theorem B.1 also holds for the three other diameters we consider i.e. for $dia_{deg}(f)$, $dia_{deg_2}(f)$ and $dia_s(f)$ by an analogous argument.

Note that the TRIBES function $f: \{0, 1\}^{n^2} \rightarrow \{0, 1\}$ as discussed in Example 5.3 is an OR-composition of n copies of the AND_n function (i.e. the AND function on n bits). Since $dia_{\wedge}(AND_n) = 1$, Theorem B.1 implies the bound: $dia_{\wedge}(TRIBES) \leq \Theta(n)$. As seen in Example 5.3, $dia_{\wedge}(TRIBES) \geq 2n - 1$ and therefore, this bound is asymptotically tight for the TRIBES function.

However, Theorem B.1 does not always give a tight bound for OR-composed functions, as can be seen from the example of the function $OR_n: \{0, 1\}^n \rightarrow \{0, 1\}$ i.e. the OR function on n bits. OR_n is also an OR-composition of n copies of the function $g: \{0, 1\} \rightarrow \{0, 1\}$ with single-bit inputs, where $g(x) = x$. Since $dia_{\wedge}(g) = 1$, Theorem B.1 gives the bound $dia_{\wedge}(OR_n) \leq \Theta(n)$. This bound is not tight since it holds that $dia_{\wedge}(OR_n) = 1$.

Budgeted Dominating Sets in Uncertain Graphs

Abstract

We study the *Budgeted Dominating Set* (BDS) problem on uncertain graphs, namely, graphs with a probability distribution p associated with the edges, such that an edge e exists in the graph with probability $p(e)$. The input to the problem consists of a vertex-weighted uncertain graph $\mathcal{G} = (V, E, p, \omega)$ and an integer *budget* (or *solution size*) k , and the objective is to compute a vertex set S of size k that maximizes the expected total domination (or total weight) of vertices in the closed neighborhood of S . We refer to the problem as the *Probabilistic Budgeted Dominating Set* (PBDS) problem. In this article, we present the following results on the complexity of the PBDS problem.

1. We show that the PBDS problem is NP-complete even when restricted to uncertain *trees* of diameter at most four. This is in sharp contrast with the well-known fact that the BDS problem is solvable in polynomial time in trees. We further show that PBDS is W[1]-hard for the budget parameter k , and under the *Exponential time hypothesis* it cannot be solved in $n^{o(k)}$ time.
2. We show that if one is willing to settle for $(1 - \epsilon)$ approximation, then there exists a PTAS for PBDS on trees. Moreover, for the scenario of uniform edge-probabilities, the problem can be solved optimally in polynomial time.
3. We consider the parameterized complexity of the PBDS problem, and show that Uni-PBDS (where all edge probabilities are identical) is W[1]-hard for the parameter pathwidth. On the other hand, we show that it is FPT in the combined parameters of the budget k and the treewidth.
4. Finally, we extend some of our parameterized results to planar and apex-minor-free graphs.

Our first hardness proof (Thm. 1) makes use of the new problem of k -SUBSET Σ -II MAXIMIZATION (k -SPM), which we believe is of independent interest. We prove its NP-hardness by a reduction from the well-known k -SUM problem, presenting a close relationship between the two problems.

1 Introduction

Background and Motivation. Many optimization problems in network theory deal with placing resources in key vertices in the network so as to maximize coverage. Some practical contexts where such coverage problems occur include placing mobile towers in wireless networks to maximize reception, assigning emergency vehicle centers in a populated area to guarantee fast response, opening production plants to ensure short distribution lines, and so on. In the context of social networks, the problem of spreading influencers so as to affect as many of the network members as possible has recently attracted considerable interest.

Coverage problems may assume different forms depending on the optimized parameter. A basic “full coverage” variant is the classical *dominating set* problem, which asks to find a *minimum* vertex set S such that each vertex not in S is *dominated by* S , i.e., is adjacent to at least one vertex in S . In the dual *budgeted dominating set (BDS)* problem, given a bound k (the budget), it is required to find a set S of size at most k *maximizing* the number of covered vertices. Over *vertex weighted* graphs, the goal is to maximize the total *weight* of the covered vertices, also known as the *domination*. It is this variant that we’re concerned with here.

Traditionally, coverage problems involve a fixed network of static topology. The picture becomes more interesting when the network structure is uncertain, due to potential edge connections and disconnections or link failures. Pre-selection of resource locations at the design stage becomes more challenging in such partial-information settings.

In this work, we study the problem in one of the most fundamental settings, where the input is a graph whose edges fail independently with a given probability. The goal is to find a k -element set that maximizes the *expected* (1-hop) coverage (or domination). Our results reveal that the probabilistic versions of the coverage problem are significantly harder than their deterministic counterparts, and analyzing them require more elaborate techniques.

An *uncertain graph* \mathcal{G} is a triple (V, E, p) , where V is a set of n vertices, $E \subseteq V \times V$ is a set of m edges, and the function $p : E \rightarrow [0, 1]$ assigns a probability of existence to each edge in E . So an m edge uncertain graph \mathcal{G} represents a probability space consisting of 2^m graphs, sometimes called *possible worlds*, derived by sampling each edge $e \in E$ independently with probability $p(e)$. For $H = (V, E' \subseteq E)$, the event of sampling H as a possible world, denoted $H \sqsubseteq \mathcal{G}$, occurs with probability $\Pr(H \sqsubseteq \mathcal{G}) = \prod_{e \in E'} p(e) \prod_{e \in E \setminus E'} (1 - p(e))$. The notion of possible worlds dates back to Leibniz and *possible world semantics (PWS)* is well-studied in the modal logic literature, beginning with the work of Kripke.

Our work focuses on budgeted dominating sets on vertex-weighted uncertain graphs, i.e., the *Probabilistic Budgeted Dominating Set (PBDS)* problem. The input consists of a vertex-weighted uncertain graph $\mathcal{G} = (V, E, p, \omega)$, with a weight function $\omega : V \rightarrow \mathbb{Q}^+$ and an integer budget k . Set $p(vv) = 1$ for every v . For a vertex u and a set $S \subseteq V$, denote by $\Pr(u \sim S) = 1 - \prod_{v \in S} (1 - p(uv))$ the probability that $u \in S$ or u is connected to some vertex in S . For sets $S_1, S_2 \subseteq V$, the expected coverage (or domination) of S_1 by S_2 is defined as $\mathcal{C}(S_1, S_2) = \sum_{v \in S_1} (w(v) \Pr(v \sim S_2))$. The PBDS problem aims to find a set S of size k that maximizes $\mathcal{C}(V, S)$ over the possible worlds. Its decision version is defined as follows.

Probabilistic budgeted dominating set (PBDS)

Input: A vertex-weighted uncertain graph $\mathcal{G} = (V, E, p, \omega)$, an integer k and a target domination value t .

Question: Is there a set $S \subseteq V$ of size at most k such that $\mathcal{C}(V, S) \geq t$?

Our Results and Discussion. The budgeted dominating set problem is known to have a polynomial time solution on trees. A natural question is if the same applies to the probabilistic version of the problem. We answer this question negatively, showing the following.

► **Theorem 1.** *The PBDS problem is NP-hard on uncertain trees of diameter 4. Furthermore, (i) the PBDS problem on uncertain trees is W[1]-hard for the parameter k , and (ii) an $n^{o(k)}$ time solution to PBDS will falsify the Exponential time hypothesis.*

In order to prove the theorem, we introduce the following problem.

SUBSET $\Sigma - \Pi$ MAXIMIZATION (k -SPM)

Input: A multiset $\mathcal{A} = \{(x_1, y_1), \dots, (x_N, y_N)\}$ of N pairs of positive rationals, an integer k , and a rational t .

Question: Is there a set $S \subseteq [N]$ of size exactly k satisfying $\sum_{i \in S} x_i - \prod_{i \in S} y_i \geq t$?

To establish the complexity of the k -SPM problem, we present a polynomial time reduction from k -SUM to k -SPM, thereby proving that both k -PBDS and k -SPM are NP-hard. Moreover, Downey and Fellows [23] showed that the k -SUM problem is W[1]-hard, implying that if k -SUM has an FPT solution with parameter k , then the W hierarchy collapses. This provides our second hardness result.

► **Theorem 2.** *The k -SPM problem is W[1]-hard for the parameter k . Furthermore, any $N^{o(k)}$ time solution to k -SPM falsify the Exponential time hypothesis.*

The k -SUM problem can be solved easily in $\tilde{O}(n^{\lceil k/2 \rceil})$ time. However, it has been a long-standing open problem to obtain any polynomial improvement over this bound [1, 47]. Patrascu and Williams [48] showed an $n^{o(k)}$ time algorithm for k -SUM falsifies the famous *Exponential time hypothesis* (ETH). Hence, our polynomial time reductions also imply that any algorithm optimally solving k -PBDS or k -SPM must require $n^{\Omega(k)}$ time unless ETH fails.

► **Theorem 3.** *Under the k -SUM conjecture, for any $\varepsilon > 0$, there does not exist an $n^{\lceil k/2 \rceil - \varepsilon}$ time algorithm to PBDS problem on vertex-weighted uncertain trees.*

An intriguing question is whether the k -SPM is substantially harder than k -SUM. For the simple scenario of $k = 2$, the 2-SUM problem has an $O(n \log n)$ time solution. However, it is not immediately clear whether the 2-SPM problem has a truly sub-quadratic time solution (i.e., $O(n^{2-\varepsilon})$ time for some $\varepsilon > 0$). We leave this as an open question. This is especially of interest due to the following result.

► **Theorem 4.** *Let $1 \leq c < 2$ be the smallest real such that 2-SPM problem has an $\tilde{O}(n^c)$ time algorithm. Then, there exists an $\tilde{O}((dn)^{c \lceil k/2 \rceil + 1})$ time algorithm for optimally solving k -PBDS on trees with arbitrary edge-probabilities, for some constant $d > 0$.*

Given the hardness of k -PBDS on uncertain trees, it is of interest to develop efficient approximation algorithms. Clearly, the expected neighborhood size of a vertex set is a submodular function, and thus it is known that the greedy algorithm yields a $(1 - 1/e)$ -approximation for the PBDS problem in general uncertain graphs [39, 46]. For uncertain trees, we improve this by presenting a fully polynomial-time approximation scheme for PBDS.

► **Theorem 5.** *For any integer k , and any n -vertex tree with arbitrary edge probabilities, a $(1 - \epsilon)$ -approximate solution to the optimal probabilistic budgeted dominating set (PBDS) of size k can be computed in time $\tilde{O}(k^2 \epsilon^{-1} n^2)$.*

We also consider a special case that the number of distinct probability edges on the input uncertain tree is bounded above by some constant γ .

► **Theorem 6.** *For any integer k , and an n -vertex tree \mathcal{T} with at most γ edge probabilities, an optimal solution for the PBDS problem on \mathcal{T} can be computed in time $\tilde{O}(k^{(\gamma+2)}n)$.*

We investigate the complexity of PBDS on bounded treewidth graphs. The hardness construction on bounded treewidth graphs is much more challenging. Due to this inherent difficulty, we focus on the *uniform* scenario, where all edge probabilities $p(e)$ are identical. We refer to this version of the problem as *Uni-PBDS*. We show that for any $0 < q < 1$, the Uni-PBDS problem with edge-probability q is $W[1]$ -hard for the pathwidth parameter of the input uncertain graph \mathcal{G} . In contrast, the BDS problem (when all probabilities are one) is FPT when parameterized by the pathwidth of the input graph.

► **Theorem 7.** *Uni-PBDS is $W[1]$ -hard w.r.t. the pathwidth of the input uncertain graph.*

Then, we consider the Uni-PBDS problem with combined k and treewidth parameters. We show that the Uni-PBDS problem can be formulated as a variant of the Extended Monadic Second order (EMS) problem due to Arnborg et al. [6], to derive an FPT algorithm for the Uni-PBDS problem parameterized by the treewidth of \mathcal{G} and k .

► **Theorem 8.** *For any integer k , and any n -vertex uncertain graph of treewidth w with uniform edge probabilities, k -Uni-PBDS can be solved in time $O(f(k, w)n^2)$, and thus is FPT in the combined parameter involving k and w . By dynamic programming on a nice tree decomposition we can show that $f(k, w)$ is $k^{O(w)}$ (we do not present this here).*

Finally, using the structural property of dominating sets from Fomin et al. [28], we derive FPT algorithms parameterized by the budget k in apex-minor-free graphs and planar graphs.

► **Theorem 9.** *For any integer k , and any n -vertex weighted planar or apex-minor free graph, the Uni-PBDS problem can be solved in time $2^{O(\sqrt{k} \log k)} n^{O(1)}$.*

Related Work. Uncertain graphs have been used in the literature to model the uncertainty among relationships in protein-protein interaction networks in bioinformatics [7], road networks [8, 37] and social networks [22, 39, 52, 54]. Connectivity [9, 10, 33, 38, 51, 53], network flows [27, 31], structural-context similarity [55], minimum spanning trees [26], coverage [16, 34, 35, 44, 43], and community detection [11, 49] are well-studied problems on uncertain graphs. In particular, budgeted coverage problems model a wide variety of interesting combinatorial optimization problems on uncertain graphs. For example, the classical facility location problem [36, 40] is a variant of coverage. As another example, in a classical work, Kempe, Kleinberg, and Tardos [39] study influence maximization problem as an expected coverage maximization problem in uncertain graphs. They consider the scenario where influence propagates probabilistically along relationships, under different influence propagation models, like the *Independent Cascade (IC)* and *Linear Threshold (LT)* models, and show that choosing k influencers to maximize the expected influence is NP-hard in the IC model. The coverage problem in the presence of uncertainty was studied extensively also in sensor placement and w.r.t. the placement of light sources in computer vision. SS A special case of the budgeted coverage problem is the *Most Reliable Source (MRS)* problem, where given an uncertain graph $\mathcal{G} = (V, E, p)$, the goal is to find a vertex $u \in V$ such that the expected number of vertices in u 's connected component is maximized. To the best of our knowledge, the computational complexity of MRS is not known, but

it is polynomial time solvable on some specific graph classes like trees and series-parallel graphs [12, 19, 20, 21, 43]. Domination is another special kind of coverage and its complexity is very well-studied. The classical dominating set (DS) problem is known to be $W[2]$ -hard in general graphs [23], and on planar graphs it is fixed parameter tractable with respect to the size of the dominating-set as the parameter [32]. Further, on H -minor-free graphs, the dominating-set problem is solvable in subexponential time [4, 17]. It also admits a linear kernel on H -minor-free graphs and graphs of bounded expansion [3, 25, 29, 30, 50]. On graphs of treewidth bounded by w , the classical dynamic programming approach [15] can be applied to show that the DS problem is FPT when parameterized by w . The *Budgeted Dominating Set (BDS)* problem is known to be NP-hard [42] as well as $W[1]$ -hard for the budget parameter [23]. Furthermore, a subexponential parameterized algorithm is known for BDS on apex-minor-free graphs [28]. The treewidth-parameterized FPT algorithm for the dominating-set problem can be adapted to solve the BDS problem in time $O(3^{wn})$. In particular, for trees there exists a linear running time algorithm. PBDS was studied as MAX-EXP-COVER-1-RF in the survey paper [45], and given a dynamic programming algorithm on a nice tree decomposition with runtime $2^{O(w \cdot \Delta)} n^{O(1)}$, where Δ is the maximum degree of G . The question whether PBDS has a treewidth parameterized FPT algorithm remained unresolved; it is settled in the negative in this work.

2 Preliminaries

Consider a simple undirected graph $G = (V, E)$ with vertex set V and edge set E , and let $n = |V|$ and $m = |E|$. Given a vertex subset $S \subseteq V$, the subgraph induced by S is denoted by $G[S]$. For a vertex $v \in V$, $N(v)$ denotes the set of neighbors of v and $N[v] = N(v) \cup \{v\}$ is the closed neighborhood of v . Let $\deg(v)$ denote the degree of the vertex v in G . A vertex subset $S \subseteq V$ is said to be a *dominating set* of G if every vertex $u \in V \setminus S$ has a neighbor $v \in S$. For an integer $r > 0$, a vertex subset $S \subseteq V$ is said to be an *r -dominating set* of G if for every vertex $u \in V \setminus S$ there exists a vertex $v \in S$ at distance at most r from u . A graph H is said to be an *apex* if it can be made planar by the removal of at most one vertex. A graph G is said to be *apex-minor-free* if it does not contain as its minor some fixed apex graph H . All planar graphs are apex-minor-free as they do not contain as minor the apex graphs $K_{3,3}$ and K_5 . The notations \mathbb{R} , \mathbb{Q} and \mathbb{N} denote, respectively, the sets of real, rational, and natural numbers (including 0). For integers $a \leq b$, define $[a, b]$ to be the set $\{a, a + 1, \dots, b\}$, and for $b > 0$ let $[b] \equiv [1, b]$. Other than this, we follow standard graph theoretic and parameterized complexity terminology [15, 18, 24].

Tree Decomposition. A *Tree decomposition* of an undirected graph $G = (V, E)$ is a pair (T, X) , where T is a tree whose set of nodes is $X = \{X_i \subseteq V \mid i \in V(T)\}$, such that

1. for each edge $uv \in E$, there is an $i \in V(T)$ such that $u, v \in X_i$,
2. for each edge $uv \in E$, there is an $i \in V(T)$ such that $u, v \in X_i$, and
3. for each vertex $v \in V$ the set of nodes $\{i \mid v \in X_i\}$ forms a subtree of T .

The *width* of a tree decomposition (T, X) equals $\max_{i \in V(T)} |X_i| - 1$. The treewidth of a graph G is the minimum width over all tree decompositions of G .

A tree decomposition (T, X) is *nice* if T is rooted by a node r with $X_r = \emptyset$ and every node in T is either an *insert node*, *forget node*, *join node* or *leaf node*. Thereby, a node $i \in V(T)$ is an insert node if i has exactly one child j such that $X_i = X_j \cup \{v\}$ for some $v \notin X_j$; it is a forget node if i has exactly one child j such that $X_i = X_j \setminus \{v\}$ for some $v \in X_j$; it is a join node if i has exactly two children j and h such that $X_i = X_j = X_h$; and it is a leaf node if $X_i = \emptyset$. Given a tree decomposition of width w , a nice tree decomposition of width w and $O(wn)$ nodes can be obtained in linear time [41].

A tree decomposition $(\mathcal{T}, \mathcal{X})$ is said to be a *path decomposition* if \mathcal{T} is a path. The *pathwidth* of a graph G is minimum width over all possible path decompositions of G . Let $\text{pw}(G)$ and $\text{tw}(G)$ denote the pathwidth and treewidth of the graph G , respectively. The pathwidth of a graph G is one lesser than the minimum clique number of an interval supergraph H which contains G as an induced subgraph. It is well-known that the maximal cliques of an interval graph can be linearly ordered so that for each vertex, the maximal cliques containing it occur consecutively in the linear order. This gives a path decomposition of the interval graph. A path decomposition of the graph G is the path decomposition of the interval supergraph H which contains G as an induced subgraph. In our proofs we start with the path decomposition of an interval graph and then reason about the path decomposition of graphs that are constructed from it.

Uncertain Graphs. For an uncertain graph $\mathcal{G} = (V, E, p, \omega)$, the vertex weights and the probabilities associated with the edges are given as rationals. The treewidth and diameter of \mathcal{G} are the same as the treewidth and diameter of its maximal possible world, $G = (V, E)$.

Numerical Approximation. When analyzing our polynomial reductions, we employ numerical analysis techniques to bound the error in numbers obtained as products of an exponential and the root of an integer. We use the following well-known bound on the error in approximating an exponential function by the sum of the lower degree terms in the series expansion.

► **Lemma 10** ([5]). For $z \in [-1, 1]$, e^z can be approximated using the Lagrange remainder as

$$e^z = 1 + z + \frac{z^2}{2!} + \frac{z^3}{3!} + \dots + \frac{z^Q}{Q!} + R_Q(z)$$

where $|R_Q(z)| \leq e/(Q+1)! \leq 1/2^Q$.

We use the following lemma for bounding the error in multiplying approximate values.

► **Lemma 11.** For any set $\{d_1, \dots, d_k\}$ of k reals in the range $[0, 1]$,

$$\prod_{i \in [k]} (1 - d_i) \geq 1 - \sum_{i \in [k]} d_i.$$

Proof. The proof is by induction on k . The base case of $k = 1$ trivially holds. For any two reals $a, b \in [0, 1]$, $(1 - a)(1 - b) \geq 1 - (a + b)$. Applying this result iteratively yields that for any $k \geq 1$, if $\prod_{i \in [k-1]} (1 - d_i) \geq 1 - (\sum_{i \in [k-1]} d_i)$, then

$$\prod_{i \in [k]} (1 - d_i) \geq \left(1 - \left(\sum_{i \in [k-1]} d_i\right)\right)(1 - d_k) \geq 1 - \sum_{i \in [k]} d_i.$$

The claim follows. ◀

3 Hardness Results on Trees

3.1 k -SPM hardness

We first show that the k -SUBSET $\Sigma - \Pi$ MAXIMIZATION (k -SPM) problem is NP-hard by a reduction from the k -SUM problem. Let $\langle X, k \rangle$ with $X = \{x_1, \dots, x_N\}$ be an instance of the k -SUM problem. Let $L = 1 + \max_{i \in [N]} |x_i|$.

Denote by $\langle \mathcal{A}, k, t \rangle$ an instance of the k -SPM problem. Given an instance $\langle X, k \rangle$ of k -SUM, we compute the array $\mathcal{A}(X) = \{(\tilde{x}_i, \tilde{y}_i) \mid i \in [N]\}$ of the k -SPM problem as follows. For $1 \leq i \leq N$, set $\tilde{x}_i := (L + x_i)/(kL)$.

Let $Q = 3 \log_2(kL)$. For $i \in [N]$, define $y_i = e^{x_i/(kL)}$, and let \tilde{y}_i be a rational approximation of y_i that is computed using Lemma 10 such that $0 \leq y_i - \tilde{y}_i \leq 1/2^Q$. The new instance of the k -SPM problem is $\langle \mathcal{A}(X), k, t = 0 \rangle$.

Observe that for each $i \in [N]$, $\tilde{y}_i \geq y_i - 1/2^Q \geq e^{-1/k} - 1/(kL)^3 \geq 1/2$, for $k \geq 3$. Thus, the elements of $\mathcal{A}(X)$ are positive rationals. The next lemma provides a crucial property of any set S of vertices of size k .

► **Lemma 12.** *Let $\lambda = \frac{1}{(2kL)^2}$. For each $S \subseteq [N]$ of size k , $0 \leq \prod_{i \in S} y_i - \prod_{i \in S} \tilde{y}_i \leq \lambda$.*

Proof. Let $\alpha = 1/(kL)^3$. We have:

$$\begin{aligned} \prod_{i \in S} y_i - \prod_{i \in S} \tilde{y}_i &\leq \prod_{i \in S} y_i - \prod_{i \in S} (y_i - \alpha) = \prod_{i \in S} y_i \left(1 - \prod_{i \in S} \left(1 - \frac{\alpha}{y_i}\right)\right) \\ &\leq \prod_{i \in S} y_i \left(\sum_{i \in S} \frac{\alpha}{y_i}\right) \leq e^{\sum_{i \in S} x_i/(kL)} \alpha k e^{1/k} \leq \alpha k e^2 \leq \frac{1}{4(kL)^2}, \end{aligned}$$

where the second inequality is obtained by Lemma 11. The claim follows. ◀

We now establish the correctness of the reduction.

► **Theorem 13.** *The k -SUM problem is polynomial-time reducible to k -SPM.*

Proof. Let $M = \sum_{i \in [N]} (x_i + L)$. Define a real valued function $F(z) = z - e^{-1+z}$ with domain $[0, M/(kL)]$. Observe that $F(1) = 0$ and the derivative is $F'(1) = 0$. The function $F(\cdot)$ is clearly concave, which indicates that:

- (i) $F(z) \leq 0$, for each $z \in [0, M/(kL)]$,
- (ii) $F(z)$ obtains its unique maximum at $z = 1$, where its value is 0, and
- (iii) When restricted to the values in the set $\{z/(kL) \mid z \in [0, M] \text{ is an integer}\}$, $F(z)$ obtains its second largest value at $z = 1 - 1/(kL)$.

For any $S \subseteq [N]$, denote $z_S = \sum_{i \in S} \tilde{x}_i$. For a set $S \subseteq [N]$ of size k , we have:

$$\sum_{i \in S} \tilde{x}_i - \prod_{i \in S} y_i = z_S - e^{\sum_{i \in S} x_i/(kL)} = z_S - e^{\sum_{i \in S} \tilde{x}_i/(kL) - 1/k} \quad (1)$$

$$= z_S - e^{-1} \cdot e^{z_S/(kL)} = F(z_S). \quad (2)$$

By combining Lemma 12 and Eq. (2), we obtain the following.

$$F(z_S) \leq \sum_{i \in S} \tilde{x}_i - \prod_{i \notin S} \tilde{y}_i \leq F(z_S) + \lambda.$$

On the other hand, for any set $S \subseteq [N]$ of size k for which $F(z_S) < 0$, we have $F(z_S) \leq F(1 - 1/(kL)) = (1 - 1/(kL)) - e^{-1/(kL)}$.

$$F(z_S) \leq F(1 - 1/(kL)) = (1 - 1/(kL)) - e^{-1/(kL)}.$$

Further,

$$1 - \frac{1}{kL} - e^{-1/(kL)} \leq \left(1 - \frac{1}{kL}\right) - \left(1 - \frac{1}{kL} + \frac{1}{2(kL)^2} - \frac{1}{6(kL)^3}\right) \leq -\frac{1}{4(kL)^2} = -\lambda.$$

So, for a set S , $\sum_{i \in S} \tilde{x}_i - \prod_{i \in S} \tilde{y}_i \geq 0$ if and only if $\sum_{i \in S} \tilde{x}_i = 1$, or equivalently $\sum_{i \in S} x_i = 0$. It follows that $\langle X, k \rangle$ is a yes instance of the k -SUM problem if and only if $\langle \mathcal{A}(X), k, t = 0 \rangle$ is a yes instance of the k -SPM problem. The time to compute \tilde{x}_i and \tilde{y}_i from x_i is polynomial in $Q \cdot \log_2(kL)$, for $1 \leq i \leq N$. Thus, the time-complexity of our reduction is $N \cdot \log_2^{O(1)}(kL)$, which is at most polynomial in N as long as $L = 2^{O(N)}$. Hence, the k -SUM problem is polynomial-time reducible to the k -SPM problem. ◀

■ **Figure 1** Illustration of the lower bound of Theorem 1. Here $p_i = 1 - y_i/(X_{\max} \cdot Y_{\max})$ and $q_i = x_i/(X_{\max} \cdot Y_{\max})^k$ for $i \in [N]$.

Proof of Theorem 2. The reduction given in the proof of Theorem 13 is a parameter preserving reduction for the parameter k . That is, the parameters in the instances of the k -SUM and the k -SPM problem are same in values and the constructed instance of the k -SPM problem is of size polynomial in the input size of the k -SUM instance. Thus, the reduction preserves the parameter k . Since the k -SUM problem is known to be $W[1]$ -hard for the parameter k [2, 23], the k -SPM problem is also $W[1]$ -hard for the parameter k . Further, it is known that under the Exponential time hypothesis (ETH), there cannot exist an $o(N^k)$ time solution for the k -SUM problem [48], so it follows that under ETH there is no $o(N^k)$ time algorithm for k -SPM as well. ◀

3.2 Hardness of PBDS on Uncertain Trees

In this subsection, we show the hardness results for the PBDS problem on trees, establishing Theorem 1. In order to achieve this, we present a polynomial time reduction from k -SPM to PBDS on unweighted trees.

Proof of Theorem 1. In order to prove our claim, we provide a reduction from k -SPM to PBDS. Given an instance $\langle \mathcal{A} = ((x_1, y_1), \dots, (x_N, y_N)), k, t \rangle$ of the k -SPM problem, where t is a rational, an equivalent instance of the PBDS problem is constructed as follows. Let $n = N^2 + N + 1$. Construct an uncertain tree $\mathcal{T} = (V, E, p)$, where the vertex set V consists of three disjoint sets, namely, $A = \{a_0\}$, $B = \{b_1, \dots, b_N\}$, and $C = \{c_{11}, c_{12}, \dots, c_{NN}\}$ (see Figure 1). Note that the uncertain tree \mathcal{T} is considered to be unweighted or unit weight on the vertices. The vertex a_0 is connected by edges to the vertices in B . For each $1 \leq i \leq n$, the vertex b_i is connected by edges to the vertices $c_{i1} \dots, c_{iN}$. Let $X_{\max} = \max\{1, x_1, x_2, \dots, x_N\}$ and $Y_{\max} = \max\{1, y_1, y_2, \dots, y_N\}$. To complete the construction, define the probability function $p : E \rightarrow [0, 1]$ as follows:

$$p(v\bar{v}) = \begin{cases} r_i = 1 - (y_i)/(X_{\max} \cdot Y_{\max}), & \text{if } v\bar{v} = a_0b_i \text{ for } 1 \leq i \leq N, \\ q_i = x_i/(X_{\max} \cdot Y_{\max})^k, & \text{if } v\bar{v} = b_i c_{i1} \text{ for } 1 \leq i \leq N, \\ 1, & \text{otherwise.} \end{cases}$$

Since $x_i, y_i \geq 0$ for each $1 \leq i \leq n$, we have that $p(v, \bar{v}) \in [0, 1]$ is rational for every $(v, \bar{v}) \in E$. This completes the construction of the instance for the PBDS problem. We show that the given instance $\langle \mathcal{A}, k, t \rangle$ is a yes instance of k -SPM if and only if \mathcal{T} has a set S of size k such that $\mathcal{C}(V, S) \geq 1 + (N - 1)k + t/(X_{\max} Y_{\max})^k$.

Let S_{opt} be a set of size k maximizing $\mathcal{C}(V, S_{opt})$ in \mathcal{T} . We show $S_{opt} \subseteq B$. Assume, to the contrary, that there exists some $z \in S_{opt}$ satisfying $z \notin B$. Consider $i \in [N]$ such that none of the vertices c_{i1}, \dots, c_{iN} lie in S_{opt} . Such i must exist since $|S_{opt}| = k$. If $z \in C$, then replacing z by b_i results in a set $S' = S_{opt} \setminus \{z\} \cup \{b_i\}$ such that $\mathcal{C}(V, S') \geq \mathcal{C}(V, S_{opt}) + N - 3$,

contradicting the optimality of S_{opt} . Hence, S_{opt} must be contained in $A \cup B$. In this case, z must be a_0 . Now the set $S' = S_{opt} \setminus \{z\} \cup \{b_i\}$ is such that $\mathcal{C}(V, S') \geq \mathcal{C}(V, S_{opt}) + N/2 - 2$. Since $N \geq 6$, this contradicts the optimality of S_{opt} . It follows that $S_{opt} \subseteq B$.

Next, consider a set $S \subseteq B$ of size k , and let $I_S = \{i \in [N] \mid b_i \in S\}$. We have

$$\begin{aligned} \mathcal{C}(V, S) &= \left(1 - \prod_{i \in I_S} (1 - p(a_0, b_i))\right) + \left(\sum_{i \in I_S} (p(b_i, c_{i1}) + N - 1)\right) \\ &= 1 + (N - 1)k + \sum_{i \in I_S} x_i / (X_{\max} \cdot Y_{\max})^k - \prod_{i \in I_S} y_i / (X_{\max} \cdot Y_{\max}) \\ &= 1 + (N - 1)k + (X_{\max} \cdot Y_{\max})^{-k} \left(\sum_{i \in I_S} x_i - \prod_{i \in I_S} y_i\right). \end{aligned}$$

This formulation of the coverage function shows that the given instance $\langle \mathcal{A}, k, t \rangle$ is a yes instance of k -SPM if and only if \mathcal{T} has a set S of vertices of size k such that $\mathcal{C}(V, S) \geq 1 + (N - 1)k + t / (X_{\max} Y_{\max})^k$. Thus, the k -SPM problem is reduced in polynomial time to PBDS on unweighed trees.

It remains to prove NP-hardness, W[1]-hardness, and $n^{o(k)}$ lower-bound under ETH. Note that the above reduction is a parameterized preserving reduction for the parameter k . That is, the parameter k in the k -SPM problem is the solution size (also called k) parameter for the PBDS problem. Since the k -SPM problem (i) is NP-hard, (ii) is W[1]-hard for the parameter k , and (iii) cannot have time complexity $n^{o(k)}$ under the Exponential time hypothesis (by Theorem 2), it follows that the same hardness results hold for PBDS as well. Therefore, the PBDS problem on uncertain trees (i) is NP-hard, (ii) is W[1]-hard for the parameter k , and (iii) cannot have time complexity $n^{o(k)}$ if ETH holds true. ◀

The k -SUM conjecture [1, 47] states that the k -SUM, for the parameters N and k , requires at least $N^{\lceil k/2 \rceil - o(1)}$ time.

► **Conjecture 14** (*k -SUM Conjecture*). *There do not exist a $k \geq 2$, an $\varepsilon > 0$, and an algorithm that succeeds (with high probability) in solving k -SUM in $N^{\lceil k/2 \rceil - \varepsilon}$ time.*

Proof of Theorem 3. Consider the uncertain tree \mathcal{T} constructed in the proof of Theorem 1. We set $n_0 = 0$. Modify the original construction of \mathcal{T} by deleting the $N - 2$ vertices: $c_{i3}, c_{i4}, \dots, c_{iN}$, and setting $\omega_{c_{i2}} = N - 1$, for $1 \leq i \leq N$. Thus the tree contains exactly $n = 3N + 1$ vertices. Now, k -SUM is reducible to k -SPM, and k -SPM is reducible to PBDS, both in polynomial time, and, moreover the parameter k remains unaltered and the size of problem grows by at most constant factor. This shows that, for $\varepsilon > 0$, an $n^{\lceil k/2 \rceil - \varepsilon}$ time algorithm to weighted PBDS implies an $N^{\lceil k/2 \rceil - \Omega(\varepsilon)}$ time algorithm to k -SUM, thereby, falsifying the k -SUM conjecture. ◀

Note that since the PBDS problem is NP-hard on trees, it is also para-NP-hard [15, 24] for the treewidth parameter.

4 Hardness of Uni-PBDS for the pathwidth parameter

In this section, we show that even for the restricted case of uniform probabilities, the Uni-PBDS problem is W[1]-hard for the pathwidth parameter, and thus also for treewidth (Theorem 7). This is shown by a reduction from the MULTI-COLORED CLIQUE problem to the Uni-PBDS problem. It is well-known that the MULTI-COLORED CLIQUE problem is W[1]-hard for the parameter solution size [23].

MULTI-COLORED CLIQUE

Input: A positive integer k and a k -colored graph G .

Parameter: k

Question: Does there exist a clique of size k with one vertex from each color class?

Let $(G = (V, E), k)$ be an input instance of the MULTI-COLORED CLIQUE problem, with n vertices and m edges. Let $V = (V_1, \dots, V_k)$ denote the partition of the vertex set V in the input instance. We assume, without loss of generality, $|V_i| = n$ for each $i \in [k]$. For each $1 \leq i \leq k$, let $V_i = \{u_{i,\ell} \mid 1 \leq \ell \leq n\}$.

4.1 Gadget based reduction from Multi-Colored Clique

Let (G, k) be an instance of the MULTI-COLORED CLIQUE problem. For any probability $0 < p < 1$, and for any integer f such that $f > \max\{knm, n + k^2/p\}$, our reduction constructs an uncertain graph \mathcal{G} . The output of the reduction is an instance (\mathcal{G}, k', t') of the Uni-PBDS problem where each edge has probability p , $k' = (n + 1)(m + kn)$ and $t' = (kn + m)((n + 1)fp + n + np + 1 + 2(1 - (1 - p)^n)) + 4\binom{k}{2}(1 - (1 - p)^{n+1})$. In the presentation below, we show that this choice of k' and t' ensures that there is a set of size k' with expected domination at least t' in \mathcal{G} if and only if G has a multi-colored clique of size k .

We first construct a gadget graph to represent the vertices and edges of the input instance of the MULTI-COLORED CLIQUE problem. We construct two types of gadgets, \mathcal{D} and \mathcal{I} in the reduction, illustrated in Figure 2 (in Appendix A.1). The gadget \mathcal{I} is the primary gadget and \mathcal{D} is a secondary gadget used to construct \mathcal{I} . When we refer to a gadget, we mean the primary gadget \mathcal{I} unless the gadget \mathcal{D} is specified. For each vertex and edge in the given graph, our reduction has a corresponding gadget. The gadget \mathcal{D} is defined as follows.

Gadget of type \mathcal{D} . Given a pair of vertices u and v , the gadget $\mathcal{D}_{u,v}$ consists of vertices u , v , and f additional vertices. The vertices u and v are made adjacent to every other vertex. We refer to the vertices u and v as *heads*, and remaining vertices of $\mathcal{D}_{u,v}$ as *tails*, and u and v are said to be connected by the gadget $\mathcal{D}_{u,v}$.

► **Observation 15.** *The pathwidth of a gadget of type \mathcal{D} is 2.*

Gadget of type \mathcal{I} . We begin the construction of the gadget with $2n$ vertices partitioned into two sets where each partition contains n vertices. Let $A = \{a_1, \dots, a_n\}$ and $C = \{c_1, \dots, c_n\}$ be this partition. For each $i \in [n]$, vertices a_i and c_i are connected by the gadget \mathcal{D}_{a_i, c_i} . Let h_a and h_c be two additional vertices connected by the gadget \mathcal{D}_{h_a, h_c} . The vertices in the sets A and C are made adjacent to h_a and h_c , respectively. This completes the construction of the gadget. In the reduction, a gadget of type \mathcal{I} is denoted by the symbol \mathcal{I} along with an appropriate subscript based on whether the gadget is associated with a vertex or an edge.

▷ **Claim 16.** *The pathwidth of a gadget of type \mathcal{I} is at most 4.*

Description of the reduction. For $1 \leq i < j \leq k$, let $E_{i,j} = \{xy \mid x \in V_i, y \in V_j\}$ be the set of edges with one end point in V_i and the other in V_j in G . For each $1 \leq i < j \leq k$, the graph \mathcal{G} has an induced subgraph \mathcal{G}_i corresponding to V_i , and has an induced subgraph $\mathcal{G}_{i,j}$ for the edge set $E_{i,j}$. We refer to \mathcal{G}_i as a vertex-partition block and $\mathcal{G}_{i,j}$ as an edge-partition block. Inside block \mathcal{G}_i , there is a gadget of type \mathcal{I} for each vertex in V_i , and in the block $\mathcal{G}_{i,j}$, there is a gadget for each edge in $E_{i,j}$. For a vertex $u_{i,x}$, \mathcal{I}_x denotes the gadget corresponding to $u_{i,x}$ in the partition V_i , and for an edge e , \mathcal{I}_e denotes the gadget corresponding to e . The blocks are appropriately connected by connector vertices which are defined below.

We start by defining the structure of a block denoted by B . The definition of the block applies to both the vertex-partition block and the edge-partition block. A block B consists of gadgets and additional vertices as follows (See Figure 3 in Appendix A.1).

- The block B corresponding to the vertex-partition block \mathcal{G}_i for any $i \in [k]$ is described as follows: for each $\ell \in [n]$, add a gadget \mathcal{I}_ℓ to the vertex-partition block \mathcal{G}_i , to represent the vertex $u_{i,\ell} \in V_i$. In addition to the gadgets, we add $n + 1$ vertices to the block B described as follows: Let $F(B) = \{b_1, \dots, b_n, d_i\}$ be the set of additional vertices that are added to the block B . For each $\ell \in [n]$, the vertices in the set C of the gadget \mathcal{I}_ℓ in the block B are made adjacent to b_ℓ . For each $\ell \in [n]$, the vertices in the set A of the gadget \mathcal{I}_ℓ in the block B are made adjacent to d_i .
- The block B corresponding to the edge-partition block $\mathcal{G}_{i,j}$ for any $1 \leq i < j \leq k$ is described as follows: for each $e \in E_{i,j}$, add a gadget \mathcal{I}_e in the edge-partition block $\mathcal{G}_{i,j}$, to represent the edge e . In addition to the gadgets, we add $|E_{i,j}| + 1$ vertices to the block B described as follows: Let $F(B) = \{b_e \mid e \in E_{i,j}\} \cup \{d_{i,j}\}$ be the set of additional vertices that are added to the block B . For each $e \in E_{i,j}$, the vertices in the set C of the gadget \mathcal{I}_e in the block B are made adjacent to b_e . For each $e \in E_{i,j}$, the vertices in the set A of the gadget \mathcal{I}_e in the block B are made adjacent to $d_{i,j}$.

The blocks defined above are connected by the connector vertices described next. These connector vertices are used to connect the edge-partition blocks and vertex-partition blocks, and thus ensure that each edge in G is appropriately represented in \mathcal{G} . Let $R = \{r_{i,j}^i, s_{i,j}^i, r_{i,j}^j, s_{i,j}^j \mid 1 \leq i < j \leq k\}$ be the connector vertices. The blocks are connected based on the cases described below. The connections involving the \mathcal{I} gadgets in two vertex-partition blocks and an \mathcal{I} gadget in an edge-partition block is illustrated in Figure 4 in Appendix A.1. First, we describe the connection of vertex-partition blocks corresponding V_i and V_j to the appropriate connector vertices. Following this, we describe the connection of the two vertex-partition blocks to the edge-partition block corresponding to $E_{i,j}$ through the appropriate connector vertices.

For each $i \in [k]$, each $i < j \leq k$ and each $\ell \in [n]$,

- for each $1 \leq t \leq \ell$, a_t in the gadget \mathcal{I}_ℓ of \mathcal{G}_i is made adjacent to $s_{i,j}^i$, and
- for each $\ell \leq t \leq n$, a_t in the gadget \mathcal{I}_ℓ of \mathcal{G}_i is made adjacent to the vertex $r_{i,j}^i$.

For each $i \in [k]$, each $1 \leq j < i$ and each $\ell \in [n]$,

- for each $1 \leq t \leq \ell$, a_t in the gadget \mathcal{I}_ℓ of \mathcal{G}_i is made adjacent to the vertex $s_{j,i}^i$, and
- for each $\ell \leq t \leq n$, a_t in the gadget \mathcal{I}_ℓ of \mathcal{G}_i is made adjacent to the vertex $r_{j,i}^i$.

Now, we describe the edges to connect the \mathcal{I} gadgets in the vertex-partition blocks \mathcal{G}_i and \mathcal{G}_j and to the appropriate \mathcal{I} gadgets in the edge-partition block $\mathcal{G}_{i,j}$. For each $1 \leq i < j \leq k$, and for each $e = u_{i,x}u_{j,y} \in E_{i,j}$,

- for each $1 \leq t \leq x$, a_t in the gadget \mathcal{I}_e of $\mathcal{G}_{i,j}$ is made adjacent to the vertex $r_{i,j}^i$, and
- for each $x \leq t \leq n$, a_t in the gadget \mathcal{I}_e of $\mathcal{G}_{i,j}$ is made adjacent to the vertex $s_{i,j}^i$.
- for each $1 \leq t \leq y$, a_t in the gadget \mathcal{I}_e of $\mathcal{G}_{i,j}$ is made adjacent to the vertex $r_{i,j}^j$, and
- for each $y \leq t \leq n$, a_t in the gadget \mathcal{I}_e of $\mathcal{G}_{i,j}$ is made adjacent to the vertex $s_{i,j}^j$.

This completes the construction of the graph \mathcal{G} with $O(mn^2)$ vertices and $O(mn^3)$ edges.

▷ **Claim 17.** The pathwidth of a block B is at most 6.

The following lemma bounds the pathwidth of the graph \mathcal{G} by a polynomial in k .

▶ **Lemma 18.** *The pathwidth of the graph \mathcal{G} is at most $4\binom{k}{2} + 6$.*

Due to space constraints, we have deferred the complete proof to the expanded version.

Proof of Theorem 7. Given an instance (G, k) of MULTI-COLORED CLIQUE, the instance (\mathcal{G}, k') is constructed in polynomial time where k' and t' are polynomial in input size. By Lemma 18, the pathwidth of \mathcal{G} is a quadratic function of k . Finally, we can also show that the Uni-PBDS instance (\mathcal{G}, k', t') output by the reduction is equivalent to the MULTI-COLORED CLIQUE instance (G, k) that was input to the reduction. Since MULTI-COLORED CLIQUE is known to be $W[1]$ -hard for the parameter k , it follows that the Uni-PBDS problem is $W[1]$ -hard with respect to the pathwidth parameter of the input graph. ◀

This completes the proof of Theorem 7.

5 PBDS on Trees: PTAS and Exact Algorithm

In this section, we present our algorithmic results for the PBDS problem on trees. Throughout this section, assume \mathcal{T} is rooted at some vertex r . For each $x \in V$, denote by $\text{PAR}(x)$ the parent of x in V , and by $\mathcal{T}(x)$ the subtree of \mathcal{T} rooted at x .

5.1 PTAS for PBDS on Trees

For each $v \in V$ and each $b \in [0, k]$, define $\mathcal{Y}_v(\text{par}, \text{curr}, b)$ to be the optimal value of $\mathcal{C}(V(\mathcal{T}(v)), S)$ where par and curr are boolean indicator variables that, respectively, denote whether or not $\text{PAR}(v)$ and v are in S (written below as $I_{\text{PAR}(v) \in S}$ and $I_{v \in S}$), and b denotes the number of descendants of v in S . Formally, $\mathcal{Y}_v(\text{par}, \text{curr}, b)$ is represented as follows:

$$\arg \max \left\{ \sum_{x \in \mathcal{T}(v)} \mathcal{C}(x, S) \mid S \subseteq V, |S \cap (\mathcal{T}(v) \setminus v)| = b, \text{curr} = I_{v \in S}, \text{par} = I_{\text{PAR}(v) \in S} \right\}$$

The main idea behind our PTAS is to use the rounding method. Instead of computing \mathcal{Y}_x , we compute its approximation, represented as $\widehat{\mathcal{Y}}_x$. This is done in a bottom-up fashion, starting from leaf nodes of \mathcal{T} . For each $x \in V$, define $\delta(x)$ to be $|\mathcal{Y}_x - \widehat{\mathcal{Y}}_x|$. Throughout our algorithm, we maintain the invariant that $\widehat{\mathcal{Y}}_x \leq \mathcal{Y}_x$, for every $x \in V$.

We now present an algorithm to compute $\widehat{\mathcal{Y}}$. Since \mathcal{Y}_x is easy to compute for a leaf x , we set $\widehat{\mathcal{Y}}_x = \mathcal{Y}_x$. For a leaf x , $\mathcal{Y}_x(\text{par}, \text{curr}, b)$ is (i) undefined if $b \neq 0$, (ii) ω_x if $\text{curr} = 1, b = 0$, (iii) $\omega_x p_{(\text{PAR}(x), x)}$ if $\text{par} = 1, \text{curr} = 0, b = 0$, and (iv) zero otherwise. Consider a non-leaf v . Let z_1, \dots, z_t be v 's children in \mathcal{T} , and z_0 be v 's parent in \mathcal{T} (if exists). Let $\mathcal{L}(\beta)$, for $\beta \geq 0$, denote the collection of all integral vectors $\sigma = (b_1, \text{curr}_1, \dots, b_t, \text{curr}_t)$ of length $2t$ satisfying (i) $\text{curr}_i \in \{0, 1\}$ and $b_i \geq 0$, for $i \in [1, t]$, and (ii) $\sum_{i \in [1, t]} (b_i + \text{curr}_i) = \beta$. In our representation of σ as $(b_1, \text{curr}_1, \dots, b_t, \text{curr}_t)$, the term curr_i corresponds to the indicator variable representing whether or not z_i lies in our tentative set S , and b_i corresponds to the cardinality of $S \cap (V(\mathcal{T}(z_i)) \setminus z_i)$. Further, for $i \in [1, t]$, let $\mathcal{L}_i(\beta)$ be the collection of those vectors $\sigma = (b_1, \text{curr}_1, \dots, b_t, \text{curr}_t) \in \mathcal{L}(\beta)$ that satisfy $b_j, \text{curr}_j = 0$ for $j > i$.

For a given $\text{curr}, \text{par}, b \geq 0$, we now explain the computation of $\widehat{\mathcal{Y}}_v(\text{par}, \text{curr}, b)$. Assume that we have already computed the approximate values $\widehat{\mathcal{Y}}_{z_i}$ ($i \in [1, t]$) corresponding to v 's children in \mathcal{T} . Setting $W = \max_{u \in V} \omega_u$, and using the scaling factor $M = \epsilon W/n$, let

$$A(\sigma) = \begin{cases} \omega_v, & \text{if curr}=1, \\ M \left[\frac{\omega_v}{M} \left(1 - (1 - \text{par} \cdot p_{(z_0, v)}) \cdot \prod_{\substack{i \in [1, t] \\ \text{curr}_i=1}} (1 - p_{(z_i, v)}) \right) \right], & \text{otherwise,} \end{cases} \quad (3)$$

$$B(\sigma) = \sum_{i \in [1, t]} \widehat{\mathcal{Y}}_{z_i}(\text{curr}, \text{curr}_i, b_i), \quad (4)$$

$$\widehat{\mathcal{Y}}_v(\text{par}, \text{curr}, b) = \max_{\sigma \in \mathcal{L}(b)} (A(\sigma) + B(\sigma)). \quad (5)$$

In order to efficiently compute $\widehat{\mathcal{Y}}_v$, we define the notion of *preferable* vectors. For any two vectors $\sigma_1, \sigma_2 \in \mathcal{L}(\beta)$, we say that σ_1 is *preferred* over σ_2 (and write $\sigma_1 \geq \sigma_2$) if both (i) $A(\sigma_1) \geq A(\sigma_2)$, and (ii) $B(\sigma_1) \geq B(\sigma_2)$. For $i \in [1, t]$, let $\mathcal{L}_i^*(\beta)$ be a *maximal* subset of $\mathcal{L}_i(\beta)$ such that $\sigma_1 \not\geq \sigma_2$ for any two vectors $\sigma_1, \sigma_2 \in \mathcal{L}_i^*(\beta)$.

Define $\phi_v = |\{A(\sigma) \mid \sigma \in \mathcal{L}(\beta), \text{ for } \beta \in [0, k]\}|$. The following observation is immediate by the definition of \mathcal{L}_i^* .

► **Observation 19.** For each $i \in [1, t]$ and $\beta \in [0, k]$, $|\mathcal{L}_i^*(\beta)| \leq \phi_v$.

In order to compute $\widehat{\mathcal{Y}}_v(\text{par}, \text{curr}, b)$, we explicitly compute and store $\mathcal{L}_i^*(\beta)$, for $1 \leq i \leq t$. The set $\mathcal{L}_1^*(\beta)$ is quite easy to compute. Let $\sigma_1 = (\beta, 0, 0, \dots, 0)$ and $\sigma_2 = (\beta - 1, 1, 0, \dots, 0)$ be the only two vectors lying in $\mathcal{L}_1(\beta)$. Then $\mathcal{L}_1^*(\beta)$ is that vector among σ_1 and σ_2 that maximizes the sum $A(\sigma) + B(\sigma)$.

The lemma below provides an iterative procedure for computing the sets $\mathcal{L}_i^*(\beta)$, for $i \geq 2$.

► **Lemma 20.** For every $i, \beta \geq 1$, the set $\mathcal{L}_i^*(\beta)$ can be computed from $\mathcal{L}_{i-1}^*(\beta)$ in time $\widetilde{O}(\beta + \sum_{\alpha \in [0, \beta]} |\mathcal{L}_{i-1}^*(\alpha)|)$.

Proof. Initialize $\mathcal{L}_i^*(\beta)$ to \emptyset . At each stage, maintain the list $\mathcal{L}_i^*(\beta)$ sorted by the values $A(\cdot)$, and reverse-sorted by the values $B(\cdot)$. Our algorithm to compute $\mathcal{L}_i^*(\beta)$ involves the following steps.

1. For each $\text{curr} \in \{0, 1\}$ and $b \in [0, \beta]$, first compute a set $\mathcal{P}_{b, \text{curr}}$ obtained by replacing the values b_i and curr_i in each $\sigma \in \mathcal{L}_{i-1}^*(\beta - (\text{curr} + b))$ by b and curr respectively. Let $\mathcal{P} = \bigcup_{b \in [0, \beta], \text{curr} \in \{0, 1\}} \mathcal{P}_{b, \text{curr}}$.
2. For each $\sigma \in \mathcal{P}$, check in $O(\log |\mathcal{P}|)$ time if there is a $\sigma' \in \mathcal{L}_i^*(\beta)$ that is preferred over σ (i.e. $\sigma' \geq \sigma$). If no such σ' exists, then (a) add σ to $\mathcal{L}_i^*(\beta)$, and (b) remove all those σ'' from $\mathcal{L}_i^*(\beta)$ that are less preferred than σ , that is, $\sigma'' < \sigma$.

The runtime of the algorithm is $O(\beta + |\mathcal{P}| \log |\mathcal{P}|)$ which is at most $\widetilde{O}(\beta + \sum_{\alpha \in [0, \beta]} |\mathcal{L}_{i-1}^*(\alpha)|)$.

Next we now prove its correctness. Consider a $\sigma = (b_1, \text{curr}_1, \dots, b_t, \text{curr}_t) \in \mathcal{L}_i(\beta)$. It suffices to show that if $\sigma \notin \mathcal{P}_{b_i, \text{curr}_i}$, then there exists a $\sigma' \in \mathcal{P}_{b_i, \text{curr}_i}$ satisfying $\sigma' \geq \sigma$. Let σ_0 be obtained from σ by replacing b_i, curr_i with 0. Since $\sigma \notin \mathcal{P}_{b_i, \text{curr}_i}$, it follows that $\sigma_0 \notin \mathcal{L}_{i-1}(\beta - (b_i + \text{curr}_i))$. So there must exist a vector $\sigma'_0 = (b'_1, \text{curr}'_1, \dots, b'_t, \text{curr}'_t) \in \mathcal{L}_{i-1}(\beta - (b_i + \text{curr}_i))$ satisfying $A(\sigma'_0) \geq A(\sigma_0)$ and $B(\sigma'_0) \geq B(\sigma_0)$. Let σ' be the vector obtained from σ'_0 by replacing b'_i, curr'_i with b_i, curr_i . It can be easily verified from Eq. (3) and (4), that $A(\sigma') \geq A(\sigma)$ and $B(\sigma') \geq B(\sigma)$. Since the constructed σ' indeed lies in $\mathcal{P}_{b_i, \text{curr}_i}$, the proof follows. ◀

The following claim is an immediate corollary of Lemma 20.

► **Lemma 21.** The value of $\widehat{\mathcal{Y}}_v(\text{par}, \text{curr}, b)$, for any $\text{par}, \text{curr} \in \{0, 1\}$ and $b \in [0, k]$, is computable in $\widetilde{O}(b \cdot \deg(v) \cdot \phi_v)$ time, given the values of $\widehat{\mathcal{Y}}_{z_i}$ for $i \leq t$.

Proof. Observe that $\widehat{\mathcal{Y}}_v(\text{par}, \text{curr}, b) = \max_{\sigma \in \mathcal{L}_i^*(b)} (A(\sigma) + B(\sigma))$, where $A(\sigma)$ and $B(\sigma)$ are as defined in Eq. (3) and (4). By Observation 19 and Lemma 20, the total computation time of the set $\mathcal{L}_i^*(b)$ is at most $\widetilde{O}(b \cdot t \cdot \phi_v)$, which is equal to $\widetilde{O}(b \cdot \deg(v) \cdot \phi_v)$. ◀

Lemma 21 implies that starting from leaf nodes, the values $\widehat{\mathcal{Y}}_x(\text{par}, \text{curr}, b)$ can be computed in bottom-up manner, for each valid choice of triplet $(\text{par}, \text{curr}, b)$ and each $x \in V$, in total time $\widetilde{O}(k^2 n \cdot \max_{v \in V} \phi_v)$. We now prove $\phi_v = O(\epsilon^{-1} n)$. If $\text{curr} = 1$, then $A(\sigma)$ takes only one value. If $\text{curr} = 0$, then the value of $A(\sigma)$ is a multiple of M and is also bounded above by W . This implies that the number of distinct values $A(\sigma)$ can take is indeed bounded by $W/M = O(\epsilon^{-1} n)$.

► **Proposition 22.** *Computing $\widehat{\mathcal{Y}}_x$ for all $x \in V$ takes in total $\widetilde{O}(k^2 n \cdot \max_{x \in V} \phi_x) = \widetilde{O}(k^2 \epsilon^{-1} n^2)$ time.*

5.2 Approximation Analysis of PTAS on Trees

We provide here the approximation analysis of the $(1 - \epsilon)$ -bound. Let

$$\begin{aligned} S_{opt} &= \arg \max_{S \subseteq V, |S|=k} \mathcal{C}(V, S) = \arg \max_{S \subseteq V, |S|=k} \sum_{x \in V} \omega_x \Pr(x \sim S), \\ \widehat{S}_{opt} &= \arg \max_{S \subseteq V, |S|=k} \left(\sum_{x \in S} \omega_x \Pr(x \sim S) + \sum_{x \in V \setminus S} M \left\lfloor \frac{\omega_x \Pr(x \sim S)}{M} \right\rfloor \right). \end{aligned}$$

Observe that $\max\{\mathcal{Y}_r(0, 0, k), \mathcal{Y}_r(0, 1, k-1)\} = \mathcal{C}(V, S_{opt})$ and $\max\{\widehat{\mathcal{Y}}_r(0, 0, k), \widehat{\mathcal{Y}}_r(0, 1, k-1)\} = \mathcal{C}(V, \widehat{S}_{opt})$. The following lemma proves that \widehat{S}_{opt} indeed achieves a $(1 - \epsilon)$ -approximation bound.

► **Lemma 23.** $(1 - \epsilon) \mathcal{C}(V, S_{opt}) \leq \mathcal{C}(V, \widehat{S}_{opt}) \leq \mathcal{C}(V, S_{opt})$.

Proof. In order to prove the first inequality, we first show that $\mathcal{C}(V, S_{opt}) - \mathcal{C}(V, \widehat{S}_{opt}) \leq \epsilon \mathcal{C}(V, S_{opt})$.

$$\begin{aligned} \mathcal{C}(V, S_{opt}) - \mathcal{C}(V, \widehat{S}_{opt}) &\leq \max_{\substack{S \subseteq V \\ |S|=k}} \left(\sum_{x \in V} \omega_x \Pr(x \sim S) - \sum_{x \in S} \omega_x \Pr(x \sim S) - \sum_{x \in V \setminus S} M \left\lfloor \frac{\omega_x \Pr(x \sim S)}{M} \right\rfloor \right) \\ &\leq (n - k)M \leq \epsilon W \leq \epsilon \mathcal{C}(V, S_{opt}). \end{aligned}$$

Next, for each $x \in V$ and $S \subseteq V$, we have $M \lfloor M^{-1} \omega_x \Pr(x \sim S) \rfloor \leq \omega_x \Pr(x \sim S)$, thereby implying that $\mathcal{C}(V, \widehat{S}_{opt}) \leq \mathcal{C}(V, S_{opt})$. This completes our proof. ◀

Proof of Theorem 5. For any integer k , any n -vertex tree \mathcal{T} with arbitrary edge probabilities, and for every $\epsilon > 0$, a $(1 - \epsilon)$ approximate solution can be computed in time $\widetilde{O}(k^2 \epsilon^{-1} n^2)$. This follows from Proposition 22 and Lemma 23. This completes the proof Theorem 5. ◀

5.3 Linear-time algorithm for Uni-PBDS on Trees

We next establish our result for the scenario of Uni-PBDS on trees (Thm. 6). In fact, this result holds for a somewhat broader scenario, wherein, for each vertex x , the cardinality of $\text{PROB}_x = \{p_e \mid e \text{ is incident to } x\}$ is bounded above by some constant γ .

Proof of Theorem 6. Observe that the only place where approximation was used in our PTAS was in bounding the number of distinct values that can be taken by $A(\sigma)$ in Eq. (3). In order to obtain an exact solution for the bounded probabilities setting, the only modification performed in our algorithm is to redefine $A(\sigma)$ as follows.

$$A(\sigma) = \omega_v \cdot I_{(curr=1)} + \omega_v \left(1 - (1 - par \cdot p_{(z_0, v)}) \cdot \prod_{\substack{i \in [1, t] \\ curr_i=1}} (1 - p_{(z_i, v)}) \right) \cdot I_{(curr \neq 1)}.$$

It can be verified that the algorithm correctly computes \mathcal{Y}_x at each step, that is, $\delta(x)$ is essentially zero. The time it takes to compute $\mathcal{Y}_v(par, curr, b)$, for a non-leaf v , crucially depends on the cardinality of $\{A(\sigma) \mid \sigma \in \mathcal{L}_t^*(b)\}$, where t is the number of children of v in \mathcal{T} . Observe that the number of distinct values $A(\sigma)$ can take is at most $b^{|\text{PROB}_x|} = O(k^\gamma)$. This along with Lemma 22 implies that the total runtime of our exact algorithm is $\widetilde{O}(k^{\gamma+2} n)$. ◀

5.4 Solving PBDS optimally on general trees

Let $c \geq 1$ be the smallest real such that 2-SPM problem has an $\tilde{O}(N^c)$ time algorithm. We will show that in such a case, k -PBDS can be solved optimally on trees with arbitrary probabilities in $\tilde{O}((\delta N)^{c \lceil k/2 \rceil + 1})$ time, for a constant $\delta > 0$.

For any node $v \in \mathcal{T}$, let \mathcal{T}_v^i , for $1 \leq i \leq \deg(v)$, represent the components of the subgraph $\mathcal{T} \setminus \{v\}$. We start with the following lemma (proved in Appendix B.1), which is easy to prove using a standard counting argument.

► **Lemma 24.** *For any set S of size k in \mathcal{T} , there exist a node $v \in \mathcal{T}$ and an index $q \in [1, \deg(v)]$ such that the cardinalities of the sets $S \cap (\bigcup_{i \leq q} \mathcal{T}_v^i)$, $S \cap (\mathcal{T}_v^q)$ and $S \cap (\bigcup_{i \geq q} \mathcal{T}_v^i)$ are all bounded by $k/2$.*

For the rest of this section, we refer to a tuple (v, q) satisfying the conditions stated in Lemma 24 as a *valid pair*. Let us suppose we are provided with a valid pair (v, q) . For sake of convenience, we assume that \mathcal{T} is rooted at node v . Let $U_0 = \mathcal{T}_v^q$, $U_1 = \bigcup_{i \leq q} \mathcal{T}_v^i$, and $U_2 = \bigcup_{i \geq q} \mathcal{T}_v^i$. Also let $\{x_1, \dots, x_\alpha\}$ be the children of v in U_1 , where $\alpha = q - 1$; let $\{y_1, \dots, y_\beta\}$ be the children of v in U_2 , where $\beta = \deg(v) - q$; and let z be q^{th} child of v .

An important observation is that if the optimal S contains v , then the problem is easily solvable in $O(k^2 \cdot n^{k/2})$ time, as then the structures U_0 , U_1 and U_2 become independent. Indeed, it suffices to consider all $O(k^2)$ partitions of $k - 1$ into triplet (c_0, c_1, c_2) consisting of integers in the range $[0, k/2]$, and next we iterate over all the $c_i \leq k/2$ subsets in U_i . This takes in total $O(k^2 n^{k/2})$ time. So the challenge is to solve the problem when v is not contained in S . Assuming (v, q) is a valid pair, and v is not contained in the optimal S , the solution S to k -PBDS is the union $S_0 \cup S_1 \cup S_2$ of the tuple $(S_0, S_1, S_2) \in U_0 \times U_1 \times U_2$ that maximizes

$$\mathcal{C}(U_0, S_0) + \mathcal{C}(U_1, S_1) + \mathcal{C}(U_2, S_2) + \omega_v \left(1 - (1 - d \cdot p(v, z)) \cdot \prod_{\substack{i \in [1, \alpha] \\ x_i \in S_1}} (1 - p(v, x_i)) \prod_{\substack{j \in [1, \beta] \\ y_j \in S_2}} (1 - p(v, y_j)) \right) \quad (6)$$

where d is an indicator variable denoting whether or not $z \in S_0$, and $|S_1|, |S_2|, |S_3|$ are integers in the range $[0, k/2]$ that sum up to k .

Define Γ to be set of all quadruples (d, c_0, c_1, c_2) comprising of integers in the range $[0, k/2]$ such that $d \in \{0, 1\}$ and $c_0 + c_1 + c_2 = k$. For each $\gamma = (d, c_0, c_1, c_2) \in \Gamma$, let

$$\begin{aligned} \mathcal{L}_\gamma^1 &= \left\{ \left(\frac{\mathcal{C}(U_1, S_1)}{\omega_v (1 - d \cdot p(v, z))}, \prod_{\substack{i \in [1, \alpha] \\ x_i \in S_1}} (1 - p(v, x_i)) \right) \mid S_1 \subseteq U_1 \text{ is of size } c_1 \right\}, \\ \mathcal{L}_\gamma^2 &= \left\{ \left(\frac{\mathcal{C}(U_2, S_2)}{\omega_v (1 - d \cdot p(v, z))}, \prod_{\substack{j \in [1, \beta] \\ y_j \in S_2}} (1 - p(v, y_j)) \right) \mid S_2 \subseteq U_2 \text{ is of size } c_2 \right\}, \\ Z_\gamma &= \max \left\{ \mathcal{C}(U_0, S_0) \mid S_0 \subseteq U_0 \text{ is of size } c_0, \text{ and } d = I_{z \in S_0} \right\}. \end{aligned}$$

So, the maximization considered in Eq. (6) is equivalent to the following optimization:

$$\max_{\substack{\gamma = (d, c_0, c_1, c_2) \in \Gamma \\ (a, b) \in \mathcal{L}_\gamma^1, (\bar{a}, \bar{b}) \in \mathcal{L}_\gamma^2}} \omega_v + Z_\gamma + \left(\omega_v (1 - d \cdot p(v, z)) \right) (a + \bar{a} - b\bar{b}). \quad (7)$$

In the next lemma we show that optimizing the above expression is equivalent to solving $|\Gamma| = O(k^2)$ different 2-SPM problems (each of size $O(n^{k/2})$).

► **Lemma 25.** Let $A = ((a_1, b_1), \dots, (a_N, b_N))$ and $\bar{A} = ((\bar{a}_1, \bar{b}_1), \dots, (\bar{a}_N, \bar{b}_N))$ be two arrays. Then, solving the maximization problem $\max_{i_0, j_0} (a_{i_0} + \bar{a}_{j_0} - b_{i_0} \bar{b}_{j_0})$, can be transformed in linear time to the following equivalent 2-SPM:

$$\mathcal{L} = ((Q + a_1, Rb_1), \dots, (Q + a_N, Rb_N), (-Q + \bar{a}_1, R^{-1}\bar{b}_1), \dots, (-Q + \bar{a}_N, R^{-1}\bar{b}_N)) ,$$

where $Q = \max_{i,j} (b_i \bar{b}_j) + 2 \max_{i,j} (a_i + \bar{a}_j)$ and $R = \sqrt{4Q / \min_i (b_i)^2}$.

Proof. Consider the following 2-SPMs obtained by two equal partitions of \mathcal{L} :

$$\begin{aligned} \mathcal{L}^1 &= ((Q + a_1, Rb_1), \dots, (Q + a_N, Rb_N)) , \text{ and} \\ \mathcal{L}^2 &= (-Q + \bar{a}_1, R^{-1}\bar{b}_1), \dots, (-Q + \bar{a}_N, R^{-1}\bar{b}_N) . \end{aligned}$$

Observe that the optimal value of \mathcal{L}^1 is bounded above by $2Q + 2 \max_i (a_i) - R^2 \min_i (\bar{b}_i)^2$ which is strictly less than $-Q$. Similarly, the optimal value of \mathcal{L}^2 is bounded above by $2Q + 2 \max_i (\bar{a}_i) - \min_i (\bar{b}_i)^2 / R^2$, which is again strictly less than $-Q$.

Now the answer to the optimization problem $\max_{i_0, j_0} (a_{i_0} + \bar{a}_{j_0} - b_{i_0} \bar{b}_{j_0})$ is at least $-Q$. This clearly shows that the solution to \mathcal{L} cannot be obtained by its restrictions \mathcal{L}^1 and \mathcal{L}^2 . Hence, the maximization problem $\max_{i_0, j_0} (a_{i_0} + \bar{a}_{j_0} - b_{i_0} \bar{b}_{j_0})$ is equivalent to solving the 2-SPM \mathcal{L} . ◀

Proof of Theorem 4. The time to compute $\mathcal{L}_\gamma^1, \mathcal{L}_\gamma^2, Z_\gamma$, for a given γ , is $\tilde{O}(n^{k/2})$. By transformation presented in Lemma 25, it follows that the total time required to optimize the expression in Eq. (7) is $k^{O(1)} \cdot n^{c \lceil k/2 \rceil}$, which is at most $O((\delta n)^{c \lceil k/2 \rceil + 1})$, for some constant $\delta \geq 1$. Now recall that Eq. (7) provides an optimal solution assuming (v, q) is a valid pair, and v is not contained in optimal S . Even when (v, q) is a valid pair, and v is contained in the optimal S , the time complexity turns out to be $O(k^2 \cdot n^{k/2})$. Iterating over all choices of pair (v, q) incurs an additional multiplicative factor of n in the runtime. ◀

6 Parameterization based on graph structure

In this section, we state our results on structural parameterizations of the Uni-PBDS problem. First, following the approach of Arnborg et al. [6], we formulate the MSOL formula for the Uni-PBDS problem where the quantifier rank of the formula is $O(k)$ (outlined in Appendix C.1). This indeed yields an FPT algorithm for the Uni-PBDS problem parameterized by budget k and the treewidth of the input graph.

In addition, we show that the Uni-PBDS problem is FPT for the budget parameter on apex-minor-free graphs. In particular we show that, for any integer k , and any n -vertex weighted apex-minor free graph with uniform edge probability, the Uni-PBDS problem can be solved in time $(2^{O(\sqrt{k} \log k)} n^{O(1)})$.

Due to space constraints, we defer our complete constructions and proofs to the upcoming full-version of the paper.

A Remainder of Section 4

A.1 Figures illustrated in the reduction

Figure 2 (a) The gadget \mathcal{I} for $n = 4$. (b) The gadget \mathcal{D} . The zigzag edges in \mathcal{I} between two vertices u and v is replaced by the gadget $\mathcal{D}_{u,v}$.

Figure 3 Illustration of a vertex block \mathcal{G}_i for a $V_i, i \in [k]$. Note the n \mathcal{I} gadgets for the n vertices in V_i . Similarly, an edge block $\mathcal{G}_{i,j}$ for some $1 \leq i < j \leq k$ has $|E_{i,j}|$ -many \mathcal{I} gadgets.

B Deferred Details from Section 5.4

B.1 Solving PBDS exactly on Trees

► **Reminder of Lemma 24.** For any set S of size k in \mathcal{T} , there exists a node $v \in \mathcal{T}$ and an index $q \in [1, \deg(v)]$ such that the cardinality of sets: $S \cap (\cup_{i \leq q} T_v^i)$, $S \cap (T_v^q)$, and $S \cap (\cup_{i \geq q} T_v^i)$, are all bounded by $k/2$.

Proof. We first show that there exists a node v in \mathcal{T} satisfying the property $|S \cap T_v^i| \leq k/2$, for each $i \in [1, \deg(v)]$. Consider a node $u \in \mathcal{T}$. If u satisfies the above mentioned property then we are done. Otherwise, there exists an index $j \in [1, \deg(u)]$ for which $|S \cap T_u^j| \geq k/2$. This implies the number of elements of S lying in $\{u\} \cup (T_u^1 \cup \dots \cup T_u^{j-1}) \cup (T_u^{j+1} \cup \dots \cup T_u^{\deg(u)})$ is at most $k/2$. In such a case we replace u by its j^{th} neighbor. Repeating the process eventually leads to the required node v .

32:22 Budgeted Dominating Sets in Uncertain Graphs

$$\text{Uni-PBDS} = \exists X \exists Y_0 \exists Y_1 \cdots \exists Y_k \left(\begin{aligned} & \text{PART}(X, Y_0, Y_1, \dots, Y_k) \wedge \\ & \forall x \forall y \left((y \in Y_0 \wedge x \in X) \rightarrow \neg(\text{adj}(x, y)) \right) \\ & \forall y \left(\bigwedge_{i=1}^k (y \in Y_i \rightarrow \text{INC}_i(y, X)) \right) \end{aligned} \right)$$

► **Lemma 26.** *The quantifier rank of Uni-PBDS is $O(k)$.*

Proof. There are $k + 2$ initial quantifiers for the sets X, Y_0, Y_1, \dots, Y_k . For two MSOL formulas ϕ and ψ with quantifier rank $\text{qr}(\phi)$ and $\text{qr}(\psi)$, respectively, $\text{qr}(\phi \wedge \psi) = \text{qr}(\phi \vee \psi) = \max\{\text{qr}(\phi), \text{qr}(\psi)\}$. Therefore, $\text{qr}(\text{Uni-PBDS})$ is bounded as follows:

$$\begin{aligned} \text{qr}(\text{Uni-PBDS}) &= k + 2 + \max\{\text{qr}(\text{PART}), 1 + \text{qr}(\text{INC})\} \\ &= k + 2 + \max\{1, 1 + \max\{\text{qr}(\text{SIZE}), 2\}\} \\ &\leq k + 2 + k = 2k + 3 = O(k) \end{aligned} \quad \blacktriangleleft$$

We now show that the Uni-PBDS problem is fixed-parameter tractable in parameters k and treewidth by expressing the maximization problem on the MSOL formula as a minor variation of *extended monadic second-order extremum problem* as described by Arnborg et. al. [6].

Proof of Theorem 8. For each $0 \leq i \leq k$, define the weight function w^i associated with the set variable Y_i as follows: for each $v \in V(G)$, $w_v^i = (1 - (1 - p)^i)w(v)$. The difference between the weight function in [6] and our problem is that in their paper $w(v)$ is considered to be constant value, for all vertices, for the set variable Y_i . Observe, however, that the running time of their algorithm does not change as long as w_v^i can be computed in polynomial time, which is the case in our definition. Therefore, our maximization problem is now formulated as a variant of the EMS maximization problem in [6]:

$$\text{Maximize } \sum_{u \in X} w(u) + \sum_{i=0}^k \sum_{u \in Y_i} w_v^i \cdot y_v^i \text{ over partitions } (X, Y_0, Y_1, \dots, Y_k) \text{ satisfying Uni-PBDS}$$

Using Theorem 5.6 in [6] along with the additional observation, we make, that w_v^i can be efficiently computed, an optimal solution for the Uni-PBDS problem can be computed in time $f(\text{qr}(\text{Uni-PBDS}), w) \cdot \text{poly}(n)$, where $f(\text{qr}(\text{Uni-PBDS}), w)$ is a function which does not depend on n - it depends only on the quantifier rank of Uni-PBDS and the treewidth. By Lemma 26, $\text{qr}(\text{Uni-PBDS}) = O(k)$, and thus by [6], $f(\text{qr}(\text{Uni-PBDS}), w) = f(O(k), w)$. This shows that Uni-PBDS is FPT with respect the parameters k and treewidth. Hence the theorem is proved. \blacktriangleleft

On the Complexity of the Escape Problem for Linear Dynamical Systems over Compact Semialgebraic Sets

Abstract

We study the computational complexity of the Escape Problem for discrete-time linear dynamical systems over compact semialgebraic sets, or equivalently the Termination Problem for affine loops with compact semialgebraic guard sets. Consider the fragment of the theory of the reals consisting of negation-free $\exists\forall$ -sentences without strict inequalities. We derive several equivalent characterisations of the associated complexity class which demonstrate its robustness and illustrate its expressive power. We show that the Compact Escape Problem is complete for this class.

1 Introduction

In ambient space \mathbb{R}^n , a *discrete linear dynamical system* is an orbit $(X_t)_{t \in \mathbb{N}}$ defined by an initial vector X_0 and a matrix A through the recursion $X_{t+1} = AX_t$. Linear dynamical systems are fundamental models across science and engineering, and the computability and complexity of decision problems concerning them are of both theoretical and practical importance.

In the study of dynamical systems, especially in control theory, considerable attention has been given to analysing *invariant sets*, i.e., subsets of \mathbb{R}^n from which no trajectory can escape; see, e.g., [10, 5, 2, 21]. Our focus in the present paper is on sets with the dual property that *no trajectory remains trapped*. Such sets play a key role in analysing *liveness* properties:

progress is ensured by guaranteeing that all trajectories (i.e., from any initial starting point) must eventually reach a point at which they “escape” (temporarily or permanently) the set in question, thereby forcing a system transition to take place.

More precisely, given a rational matrix A and a semialgebraic set $K \subseteq \mathbb{R}^n$, one may consider the *Discrete Escape Problem (DEP)* which asks, for all starting points X_0 in K , whether the corresponding orbit of the discrete linear dynamical system $(X_t)_{t \in \mathbb{N}}$ eventually escapes K . By “escaping” K , we simply mean going outside of K – we are unconcerned whether the trajectory might re-enter K at a later time.

The restriction of DEP to the case in which K is a *convex polytope* – alternately known as *termination of linear programs* over either the reals or the rationals – was already studied and shown decidable in the seminal papers [24, 6], albeit with no complexity bounds nor upper bounds on the number of iterations required to escape.

In this paper we study the *Compact Escape Problem (CEP)*, a version of DEP where in addition we assume that the semialgebraic set K is compact. In practice, of course, this is usually not a burdensome restriction; in most cyber-physical systems applications, for instance, all relevant sets will be compact (see, e.g., [1]).

CEP was recently shown to be decidable for arbitrary compact semialgebraic sets in [18], via *non-constructive* methods; consequently – as pointed out in that paper – no non-trivial complexity bounds could be given. The main contribution of the present work is to precisely pin down the complexity of CEP in terms of the first-order theory of the reals; more precisely, we identify a natural fragment for which CEP is complete.

Recall that the theory of the reals is concerned with the structure \mathbb{R} over the signature $\langle \mathbb{Z}, +, \times, \leq, < \rangle$. Tarski famously showed that this theory is decidable and admits quantifier elimination, with state-of-the-art techniques based on Collins’s *Cylindrical Algebraic Decomposition* [12] that have complexity doubly exponential in the number of quantifiers. Asymptotically faster but arguably impractical quantifier elimination algorithms due to [14, 16, 20] have running time doubly exponential in the number of quantifier alternations, singly exponential in the dimension, and polynomial in the rest of the data. The *existential* fragment of the theory of the reals was famously shown to lie between NP and PSPACE in [9].

In this paper, we consider the class of formulas consisting of positive Boolean combinations of non-strict polynomial inequalities prefixed by a single alternation of a block of existential and a block of universal quantifiers. Let us denote by $\exists \forall_{\leq} \mathbb{R}$ the complexity class of all problems reducible in polynomial time to the decision problem for this fragment. Using sophisticated results from real algebraic geometry we show that $\exists \forall_{\leq} \mathbb{R}$ corresponds to the decision problem for another fragment of $\exists \forall$ -sentences in which the quantifiers are restricted to range over compact sets, a result of independent interest. Finally, using techniques from Diophantine approximation and algebraic number theory we show that the Compact Escape Problem is complete for this class.

1.1 Overview

We formally define the Compact Escape Problem (CEP) as the following decision problem:

Given as input

- A matrix $A \in \mathbb{Q}^{n \times n}$ with rational entries,
 - A list \mathcal{P} of polynomials in $\mathbb{Z}[x_1, \dots, x_n]$,
 - A propositional formula $\Phi(x_1, \dots, x_n)$ which combines atomic predicates of the form $P(x_1, \dots, x_n) \leq 0$ with $P \in \mathcal{P}$ by means of the propositional connectives \vee and \wedge ,
- subject to the promise that the set $K = \{x \in \mathbb{R}^n \mid \Phi(x)\}$ is compact, decide whether for all $x \in K$ there exists $k \in \mathbb{N}$ such that $A^k x \notin K$.*

We assume that the polynomials P_j in the list \mathcal{P} are encoded as lists $\langle (\alpha_{j,k}, c_{j,k}) \rangle_{k=1, \dots, s_j}$ of pairs of multi-indexes $\alpha_{j,k} \in \mathbb{N}^n$, whose entries are encoded in unary, and coefficients $c_{j,k} \in \mathbb{Z}$, encoded in binary, such that

$$P_j(x_1, \dots, x_n) = \sum_{k=1}^{s_j} c_{j,k}(x_1, \dots, x_n)^{\alpha_{j,k}}. \quad (1)$$

Note that the analogous problem for affine maps $x \mapsto Ax + b$ reduces to CEP, as a point $x \in K$ escapes the compact set K under iterations of the affine map $Ax + b$ if and only if the point $(x, 1) \in K \times \{1\}$ escapes $K \times \{1\}$ under iterations of the linear map $B(x, z) = Ax + bz$.

We capture the computational complexity of this decision problem by showing that it is equivalent to the decision problem for a fragment of the theory of the reals.

Let $\exists\forall_{\leq}\mathbb{R}$ denote the decision problem for sentences of the form

$$\exists X \in \mathbb{R}^n. \forall Y \in \mathbb{R}^m. (\Phi_{0,\leq}(X, Y)), \quad (2)$$

where $\Phi_{0,\leq}$ is a positive Boolean combination of non-strict polynomial inequalities. Evidently, this class lies between the existential fragment of the theory of the reals (without restriction on the types of inequalities) and the full $\exists\forall$ -fragment.

The main result of this paper is the following:

► **Theorem 1.** *The compact escape problem is complete for the complexity class $\exists\forall_{\leq}\mathbb{R}$.*

The proof consists of three steps:

First, we show that for any sentence of the form

$$\exists X \in [-1, 1]^n. \forall Y \in [-1, 1]^m. (\Phi_{0,\leq}(X, Y)), \quad (3)$$

where $\Phi_{0,\leq}$ is a positive Boolean combination of non-strict polynomial inequalities, one can compute a matrix $A \in \mathbb{Q}^{(n+2m) \times (n+2m)}$ and a compact set $K \subseteq \mathbb{R}^{n+2m}$ such that (A, K) is a negative instance of the compact escape problem if and only if (3) holds true.

Secondly, given any instance (A, K) with $A \in \mathbb{Q}^{n \times n}$ and $K \subseteq \mathbb{R}^n$ we can compute in polynomial time a sentence of the form

$$\exists X \in [-1, 1]^m. \forall Y \in [-1, 1]^\ell. (\Psi_{0,\leq}(Y) \rightarrow \Phi_{0,\leq}(X, Y)), \quad (4)$$

where $\Psi_{0,\leq}$ and $\Phi_{0,\leq}$ are a positive Boolean combination of non-strict polynomial inequalities, such that (4) holds true if and only if (A, K) is a negative instance of the compact escape problem.

Finally, we prove that the decision problems for sentences of the form (2), (3), and (4) are all equivalent.

2 Preliminaries

2.1 Fragments of the theory of the reals

The statement and proof of Theorem 1 require complexity classes induced by decision problems for fragments of the the first-order theory of the reals. The main goal of this subsection is to formally define these complexity classes.

Thus, let \mathcal{L} be the first-order language with signature $\langle \mathbb{Z}, +, \times, <, \leq \rangle$, propositional connectives, \wedge and \vee , and quantifiers \exists and \forall . For complexity purposes, we assume that integer constants are encoded in binary. See, e.g., [23, 25] for an introduction to first-order

33:4 On the Complexity of the Compact Escape Problem

logic. We interpret all formulas in \mathcal{L} in the structure of real numbers. Thus, we say that two formulas are equivalent if their interpretations in \mathbb{R} are equivalent. The restriction to the connectives \vee and \wedge is of course insubstantial, and we will make free use of the connectives \neg and \rightarrow throughout this paper, understanding them as syntactic sugar.

Let QFF denote the set of quantifier-free formulas in \mathcal{L} . Let QFF_{\leq} (resp. $\text{QFF}_{<}$) denote the subset of QFF consisting of those formulas that do not contain the relational symbol “ $<$ ” (resp. “ \leq ”). Note that the negation of a QFF_{\leq} -formula is a $\text{QFF}_{<}$ -formula and vice versa.

We define the sets of formulas $\Sigma_{n,\leq}$ and $\Pi_{n,\leq}$ inductively as follows:

1. Let $\Sigma_{0,\leq} = \Pi_{0,\leq} = \text{QFF}_{\leq}$.
2. A formula $\Psi(y_1, \dots, y_s)$ belongs to $\Sigma_{n+1,\leq}$ if and only if it is of the form

$$\Psi(y_1, \dots, y_s) = (\exists x_1) \dots (\exists x_t) \cdot \Phi(x_1, \dots, x_t, y_1, \dots, y_s),$$

where Φ belongs to $\Pi_{n,\leq}$.

3. Dually, a formula $\Psi(y_1, \dots, y_s)$ belongs to $\Pi_{n+1,\leq}$ if and only if it is of the form

$$\Psi(y_1, \dots, y_s) = (\forall x_1) \dots (\forall x_t) \cdot \Phi(x_1, \dots, x_t, y_1, \dots, y_s),$$

where Φ belongs to $\Sigma_{n,\leq}$.

We define $\Sigma_{n,<}$ and $\Pi_{n,<}$ (resp. Σ_n and Π_n) analogously, starting with $\text{QFF}_{<}$ -formulas (resp. QFF -formulas).

By convention we denote vectors of variables $X = (x_1, \dots, x_t)$ by upper case letters and introduce the shorthand notations $\exists X$ and $\forall X$ for blocks of quantifiers $(\exists x_1) \dots (\exists x_t)$ and $(\forall x_1) \dots (\forall x_t)$. Recall that a first-order formula Φ is called a sentence if it does not contain any free variables.

The *decision problem* for a class \mathcal{C} of first-order formulas in the language \mathcal{L} is the following: Given a sentence that belongs to \mathcal{C} decide whether the sentence holds true in the universe of real numbers.

It is natural to ask how the decision problems for the classes we have introduced above are related with respect to polynomial-time reductions. By taking the negation of formulas it is easy to see that the decision problem for Σ_n is equivalent to that of Π_n , the decision problem for $\Sigma_{n,\leq}$ is equivalent to that of $\Pi_{n,<}$, and the decision problem for $\Sigma_{n,<}$ is equivalent to that of $\Pi_{n,\leq}$. As such it suffices to consider the “ Σ ”-classes in the following.

By a standard trick, any QFF-formula $\Phi(X)$ with free variables X can be converted in polynomial time into an equivalent formula $\exists Y. f(X, Y) = 0$ where f is a single polynomial. It follows that if n is odd then the decision problems for the classes Σ_n and $\Sigma_{n,\leq}$ are polynomial-time equivalent and if n is even then the decision problems for the classes Σ_n and $\Sigma_{n,<}$ are polynomial-time equivalent.

Of course, for $n = 0$ the decision problem is trivial for all three classes. For $n = 1$ we have the following remarkable result:

► **Theorem 2** ([22]). *The decision problems for Σ_1 and $\Sigma_{1,<}$ are polynomial-time equivalent.*

We thus have polynomial-time reductions for decision problems as indicated below:

$$(\Sigma_0 \equiv \Sigma_{0,\leq} \equiv \Sigma_{0,<}) \rightarrow (\Sigma_1 \equiv \Sigma_{1,\leq} \equiv \Sigma_{1,<}) \rightarrow \Sigma_{2,\leq} \rightarrow (\Sigma_2 \equiv \Sigma_{2,<}) \rightarrow \Sigma_{3,<} \rightarrow \dots$$

It is open to the best of our knowledge whether there exists a reduction of the decision problem for Σ_2 to that of $\Sigma_{2,\leq}$. The techniques from [22] do not seem to carry over to higher orders of quantifier alternations.

We study the decision problem for the class $\Sigma_{2,\leq}$ in greater detail. Let us denote by $\exists\forall_{\leq}\mathbb{R}$ the complexity class of all problems reducible in polynomial time to this decision problem. To demonstrate the robustness of this complexity class and gauge its computational

power we give a number of equivalent characterisations. It turns out that, somewhat surprisingly, the decision problem for $\Sigma_{2,\leq}$ -sentences is equivalent to the decision problem for exists-forall-sentences whose quantifiers are restricted to range over compact sets.

Let $X = (x_1, \dots, x_n)$ be a vector of variables. Let y be a variable or a constant. We write $|X| \leq y$ as an abbreviation for the formula $\bigwedge_{j=1}^n (-y \leq x_j \leq y)$. Of course, this syntactic construct will only have the intended semantics if our context ensures that $y \geq 0$, and we will only use it in such situations.

Write $I = [-1, 1]$. Let $\Phi_0(X, Y, Z)$ be a quantifier-free formula in \mathcal{L} . We introduce the syntactic abbreviation

$$\exists X \in I^n. \forall Y \in I^m. (\Phi_0(X, Y, Z))$$

for the formula

$$\exists X \in \mathbb{R}^n. \forall Y \in \mathbb{R}^m. (|Y| > 1 \vee (|X| \leq 1 \wedge \Phi_0(X, Y, Z)))$$

in the language \mathcal{L} .

We have the following result, whose proof is the focus of Section 3:

► **Theorem 3.** *The decision problems for the following three classes of sentences are equivalent with respect to polynomial-time reduction:*

1. *The class $\Sigma_{2,\leq}$, consisting of sentences of the form*

$$\exists X \in \mathbb{R}^m. \forall Y \in \mathbb{R}^n. (\Phi_{0,\leq}(X, Y)),$$

where $\Phi_{0,\leq}$ is a QFF_{\leq} -formula.

2. *The class $\mathfrak{b}\text{-}\Sigma_{2,\leq}$, consisting of sentences of the form*

$$\exists X \in I^m. \forall Y \in I^n. (\Phi_{0,\leq}(X, Y)),$$

where $\Phi_{0,\leq}$ is a QFF_{\leq} -formula.

3. *The class $\mathfrak{b}\text{-}\Sigma_{2,\leq}^{++}$, consisting of sentences of the form*

$$\exists X \in I^m. \forall Y \in I^n. (\Psi_{0,\leq}(Y) \rightarrow \Phi_{0,\leq}(X, Y)),$$

where $\Phi_{0,\leq}$ and $\Psi_{0,\leq}$ are QFF_{\leq} -formulas.

It is obvious that the decision problem for $\mathfrak{b}\text{-}\Sigma_{2,\leq}$ -sentences reduces to that of $\mathfrak{b}\text{-}\Sigma_{2,\leq}^{++}$ -sentences. Note however that it is not clear that a reduction should exist in either direction between $\Sigma_{2,\leq}$ and $\mathfrak{b}\text{-}\Sigma_{2,\leq}$. On the one hand, the latter class only allows for quantification over bounded sets, which seems to make it more restrictive. On the other hand, $\mathfrak{b}\text{-}\Sigma_{2,\leq}$ -sentences involve strict inequalities and hence do not belong to the class $\Sigma_{2,\leq}$. Let us denote by $\mathfrak{b}\text{-}\exists\forall_{\leq}\mathbb{R}$ and by $\mathfrak{b}\text{-}\exists\forall_{\leq}^{++}\mathbb{R}$ the complexity classes induced respectively by the decision problem for $\mathfrak{b}\text{-}\Sigma_{2,\leq}$ -sentences and by the decision problem for $\mathfrak{b}\text{-}\Sigma_{2,\leq}^{++}$ -sentences.

A remark is in order on the robustness of our definition of the class $\exists\forall_{\leq}\mathbb{R}$ under different encodings of polynomials. In practice it is common to encode a polynomial P as a list $\langle\langle\alpha_j, c_j\rangle\rangle_{j=1,\dots,m}$ where $\alpha_j \in \mathbb{N}^n$ are multi-indexes and $c_j \in \mathbb{Z}$ are integers satisfying (1). This is the encoding we have chosen in the definition of CEP. By contrast, the polynomials that occur in atomic predicates of a formula in the language \mathcal{L} are encoded as terms over the signature $\langle\mathbb{Z}, +, \times\rangle$. While one can translate the encoding (1) to a term over the signature $\langle\mathbb{Z}, +, \times\rangle$ in polynomial time, a term of size N can encode a polynomial whose number of non-zero coefficients grows exponentially in N , so that a polynomial-time translation in the

other direction is not possible in general. One may hence raise the justified objection that the reduction of CEP to the decision problem for $\Sigma_{2,\leq}$ sentences could hide an exponential overhead in the encoding of the polynomials. Moreover, in order to show $\exists\forall_{\leq}\mathbb{R}$ -hardness of CEP we need to convert a compact set which is encoded as a QFF $_{\leq}$ -formula into an equivalent formula whose atoms use the encoding (1). We show in Theorem 20 that we can efficiently convert any $\Sigma_{2,\leq}$ -sentence into an equivalent one whose atoms have degree at most 4. This resolves the issue, for a uniform bound on the degrees allows one to translate back and forth in polynomial time between the two encodings of polynomials. While an analogous result for Σ_2 -sentences (and, e.g., QFF $_{\leq}$ -formulas) is straightforward (see e.g. [22, Lemma 3.2] or the proof of Theorem 20 below for a proof idea), the argument becomes much more involved for $\Sigma_{2,\leq}$ -sentences. It relies on many of the results that are established in the sequel. Thus, for the majority of this paper we have to insist on our specific choice of encoding.

2.2 Mathematical tools

Our characterisation of the complexity class $\exists\forall_{\leq}\mathbb{R}$ requires two sophisticated results from effective real algebraic geometry: Singly exponential quantifier elimination and a doubly exponential bound on a ball meeting all components of a semialgebraic set. We use the following singly exponential quantifier elimination result given in [3]. For a historical overview on this type of result see [3, Chapter 14, Bibliographical Notes].

► **Theorem 4** ([3, Theorem 14.16]). *Let \mathcal{P} be a set of at most s polynomials with integer coefficients, each of degree at most d , in $k + n_1 + \dots + n_\ell$ variables. Let τ be a bound on the bitsize of the coefficients of all $P \in \mathcal{P}$. Let*

$$\Phi_\ell(Y) = (Q_1 X_1) \dots (Q_\ell X_\ell) \cdot (\Psi_0(Y, X_1, \dots, X_\ell)),$$

where $Q_j \in \{\exists, \forall\}$ are alternating blocks of quantifiers, be a formula over the language \mathcal{L} , all of whose atoms involve polynomials contained in \mathcal{P} . Assume that the size of the block of variables Y is k and that the size of the block of variables X_j is n_j .

Then there exists an equivalent quantifier-free formula

$$\omega_0(Y) = \bigvee_{i=1}^I \bigwedge_{j=1}^{J_i} \bigvee_{m=1}^{M_{i,j}} P_{i,j,m}(Y) \bowtie_{i,j,m} 0.$$

over \mathcal{L} , where:

1. $I \leq s^{(n_1+1)\dots(n_\ell+1)(k+1)} d^{O(n_1\dots n_\ell k)}$.
2. $J_i \leq s^{(n_1+1)\dots(n_\ell+1)} d^{O(n_1\dots n_\ell)}$.
3. $M_{i,j} \leq d^{O(n_1\dots n_\ell)}$.
4. The degrees of the polynomials $P_{i,j,m}$ are bounded by $d^{O(n_1\dots n_\ell)}$.
5. The bitsize of the coefficients of the polynomials $P_{i,j,m}$ is bounded by $\tau d^{O(n_1\dots n_\ell k)}$.

Recall that a *sign condition* on a family \mathcal{P} of polynomials in n variables is a mapping $\sigma: \mathcal{P} \rightarrow \{-1, 0, 1\}$. The *realisation* of a sign condition σ in \mathbb{R}^n is the set

$$\text{Real}(\sigma) = \{X \in \mathbb{R}^n \mid \forall P \in \mathcal{P}. \text{sign}(P(X)) = \sigma(P)\}.$$

A sign condition σ is called *realisable* if its realisation is non-empty. Equivalently, a sign condition is a formula over the language \mathcal{L} involving only conjunctions.

The next theorem is due to Vorobjov [26]. See also [15, Lemma 9] and [4, Theorem 4].

► **Theorem 5.** *There exists an integer constant β' with the following property: Let \mathcal{P} be a set of s polynomials with integer coefficients in n variables of degree at most $d \geq 2$. Assume that the bit-size of the coefficients of each polynomial in \mathcal{P} is at most τ . Then there exists a ball centred at the origin of radius at most*

$$2^{\tau d^{\beta'(n+1)}}$$

which intersects every connected component of every realisable sign condition on \mathcal{P} in \mathbb{R}^n .

Our proof of $\exists\forall\leq\mathbb{R}$ -completeness of CEP combines spectral methods with two well-known but nontrivial results on algebraic numbers. We require a version of Kronecker's theorem on simultaneous Diophantine approximation. See [19, Corollary 3.1] for a proof.

► **Theorem 6.** *Let $(\lambda_1, \dots, \lambda_m)$ be complex algebraic numbers of modulus 1. Consider the free Abelian group*

$$L = \{(n_1, \dots, n_m) \in \mathbb{Z}^m \mid \lambda_1^{n_1} \cdots \lambda_m^{n_m} = 1\}.$$

Let $(\beta_1, \dots, \beta_s)$ be a basis of L . Let $\mathbb{T}^m = \{(z_1, \dots, z_m) \in \mathbb{C}^m \mid |z_j| = 1\}$ denote the complex unit m -torus. Then the closure of the set $\{(\lambda_1^k, \dots, \lambda_m^k) \in \mathbb{T}^m \mid k \in \mathbb{N}\}$ is the set $S = \{(z_1, \dots, z_m) \in \mathbb{T}^m \mid \forall j \leq s. (z_1, \dots, z_m)^{\beta_j} = 1\}$.

Moreover, for all $\varepsilon > 0$ and all $(z_1, \dots, z_m) \in S$ there exist infinitely many indexes k such that $|\lambda_j^k - z_j| < \varepsilon$ for $j = 1, \dots, m$.

Moreover, the integer multiplicative relations between given complex algebraic numbers in the unit circle can be elicited in polynomial time. For a proof see [8, 17]. We assume the standard encoding of algebraic numbers, see [11] for details.

► **Theorem 7.** *Let $(\lambda_1, \dots, \lambda_m)$ be complex algebraic numbers of modulus 1. Consider the free Abelian group*

$$L = \{(n_1, \dots, n_m) \in \mathbb{Z}^m \mid \lambda_1^{n_1} \cdots \lambda_m^{n_m} = 1\}.$$

Then one can compute in polynomial time a basis $(\beta_1, \dots, \beta_s) \in (\mathbb{Z}^m)^s$ for L . Moreover, the integer entries of the basis elements β_j are bounded polynomially in the size of the encodings of $\lambda_1, \dots, \lambda_m$.

3 Proof of Theorem 3

Our proof of Theorem 3 will use Theorems 4 and 5. The latter are formulated in terms of the algebraic complexity of a family of polynomials. We will reformulate them in terms of the bitsize of a formula in the language \mathcal{L} .

The *matrix size* μ of a first-order formula

$$\Psi(Y) = (Q_1 X_1) \cdots (Q_\ell X_\ell). (\Phi_0(Y, X_1, \dots, X_\ell)),$$

where $Q_j \in \{\exists, \forall\}$ is the number of bits required to write down the quantifier-free part $\Phi_0(Y, X_1, \dots, X_\ell)$. The *dimensions* of the formula $\Psi(Y)$ are the numbers m, n_1, \dots, n_ℓ , where m is the dimension of Y . The *size* σ of the formula $\Psi(Y)$ is the number of bits required to write down the whole formula. Note that we have $\sigma = O(m + n_1 + \dots + n_\ell + \mu)$.

Observe that if $\Phi(X)$ is a QFF-formula of (matrix) size μ and $P(X) \bowtie 0$ is an atom of Φ then P has degree at most μ and its coefficients are bounded in bitsize by μ . The following is an immediate corollary to Theorem 4:

► **Theorem 8.** *There exists a constant α with the following property:*

Let

$$(Q_1 X_1) \dots (Q_\ell X_\ell) \cdot \Phi_0(Y, X_1, \dots, X_\ell)$$

be a first-order formula in the language \mathcal{L} of matrix size μ and with dimensions m, n_1, \dots, n_ℓ . Then there exists an equivalent quantifier-free formula $\Psi_0(Y)$ of size at most

$$\mu^{\alpha^{\ell+1} \cdot ((m+1) \cdot (n_1+1) \cdots (n_\ell+1))}.$$

Theorem 5 entails the following:

► **Corollary 9.** *There exists a constant β with the following property: Let $\Phi_0(X)$ be a quantifier-free formula in the language \mathcal{L} of matrix size μ and dimension $n \geq 1$. Then the sentence $\exists X \in \mathbb{R}^n. (\Phi_0(X))$ is equivalent to the sentence*

$$\exists X. \left(|X| \leq 2^{\mu^{\beta(n+1)}} \wedge \Phi_0(X) \right)$$

Theorem 8 and Corollary 9 will allow us to efficiently convert certain formulas into equivalent ones whose quantifiers range over bounded intervals of doubly exponential size in the input data. By the standard repeated squaring trick such formulas can further be efficiently converted into equivalent ones whose quantifiers range over the interval $I = [-1, 1]$. See Lemma 25 in Appendix A for a precise statement and proof.

3.1 Showing $\exists \forall_{\leq} \mathbb{R} \subseteq \mathbf{b}\text{-}\exists \forall_{\leq} \mathbb{R}$

We now show that the decision problem $\exists \forall_{\leq} \mathbb{R}$ reduces to $\mathbf{b}\text{-}\exists \forall_{\leq} \mathbb{R}$ in polynomial time.

We first bound the existential quantifier. This bound does not yet require the quantifier-free part of the sentence to involve only non-strict inequalities.

► **Lemma 10.** *Let $\exists X \in \mathbb{R}^n. \forall Y \in \mathbb{R}^m. (\Phi_0(X, Y))$. be a sentence over the language \mathcal{L} of matrix size μ . Then, denoting $I = [-1, 1]$, we can compute in polynomial time an equivalent sentence of the form*

$$\exists X \in I^{m+N}. \forall Y \in \mathbb{R}^m. (\Psi_0(X, Y)).$$

Proof. Consider the formula $\chi_1(X) = \forall Y \in \mathbb{R}^m. (\Phi_0(X, Y))$. By Theorem 8 this formula is equivalent to a quantifier-free formula $\chi_0(X)$ of size at most $\mu^{\alpha^2(n+1)(m+1)}$. By Corollary 9 the sentence $\exists X \in \mathbb{R}^n. (\chi_0(X))$ is equivalent to the sentence

$$\exists X \in \mathbb{R}^n. \left(|X| \leq 2^{\mu^{\alpha^2 \beta (n+1)^2 (m+1)}} \wedge \chi_0(X) \right).$$

Hence, our original sentence is equivalent to the sentence

$$\exists X \in \mathbb{R}^n. \forall Y \in \mathbb{R}^m. \left(|X| \leq 2^{\mu^{\alpha^2 \beta (n+1)^2 (m+1)}} \wedge \Phi_0(X, Y) \right).$$

Now, we can compute in polynomial time a positive integer N in unary such that we have $\mu^{\alpha^2 \beta (n+1)^2 (m+1)} \leq 2^N$. By (the proof of) Lemma 25 in Appendix A we obtain an equivalent sentence as claimed. ◀

Next we derive a similar bound for the universal quantifier in terms of the bound for the existential one. This will require the assumption that all inequalities are non-strict. The reason for this is the following simple continuity property of QFF $_{<}$ -formulas, which can fail for general formulas in the language \mathcal{L} :

► **Proposition 11.** *Let $\Phi_0(X)$ be a $\text{QFF}_{<}$ -formula with a vector of n free variables X . Assume that $x \in \mathbb{R}^n$ is such that $\Phi_0(x)$ holds true. Then there exists $\varepsilon > 0$ such that $\Phi_0(\tilde{x})$ holds true for all $\tilde{x} \in \mathbb{R}^n$ with $|x - \tilde{x}| < \varepsilon$.*

Proof. By structural induction on the formula Φ . The base case follows from the fact that polynomials are continuous functions. The induction steps are easy. ◀

► **Lemma 12.** *Let $B \in \mathbb{N}$ be a positive integer constant. Let*

$$\Psi = \forall X \in \mathbb{R}^n. \exists Y \in \mathbb{R}^m. (|X| > B \vee \Phi_0(X, Y))$$

be a $\Pi_{2,<}$ -sentence. Then the sentence Ψ holds true over the reals if and only if the sentence

$$\Psi' = \exists C \in \mathbb{R}. \forall X \in \mathbb{R}^n. \exists Y \in \mathbb{R}^m. (|X| > B \vee (Y \leq C \wedge \Phi(X, Y)))$$

holds true over the reals.

Proof. Clearly, Ψ' implies Ψ , so that if Ψ is false then Ψ' is false.

Suppose now that Ψ is true. Let $K = \{X \in \mathbb{R}^n \mid |X| \leq B\}$. Then, by assumption, for all $X \in K$ there exists $Y(X) \in \mathbb{R}^m$ such that $\Phi(X, Y(X))$ holds true. It follows from Proposition 11 that there exists $\varepsilon(X) > 0$ such that $\Phi(X', Y(X))$ holds true for all X' with $|X - X'| < \varepsilon(X)$. The set $\{\text{Ball}(X, \varepsilon(X)) \mid X \in K\}$, where $\text{Ball}(X, c)$ denotes the ball of radius c centered at X , is an open cover of K . The set K is compact, so that this cover has a finite subcover $\text{Ball}(X_1, \varepsilon(X_1)), \dots, \text{Ball}(X_s, \varepsilon(X_s))$. It follows that for all $X \in K$ there exists $j \in \{1, \dots, s\}$ such that $\Phi(X, Y(X_j))$ holds true. Thus, the formula Ψ' holds true with $C = \max\{|Y(X_1)|, \dots, |Y(X_s)|\}$. ◀

Note that the conclusion of Lemma 12 does not hold true in general for $\Pi_{2,\leq}$ -formulas. For instance, the formula

$$\forall x \in [-1, 1]. \exists y \in \mathbb{R}. (x^2(1 - xy) \leq 0)$$

is clearly true, but the formula

$$\exists C \in \mathbb{R}. \forall x \in [-1, 1]. \exists y \in [-C, C]. (x^2(1 - xy) \leq 0)$$

is clearly false.

► **Lemma 13.** *Given a sentence of the form*

$$\exists X \in I^n. \forall Y \in \mathbb{R}^m. (\Phi_{0,\leq}(X, Y)),$$

where $\Phi_{0,\leq}$ is a QFF_{\leq} -formula, we can compute in polynomial time an equivalent $\mathfrak{b}\text{-}\Sigma_{\leq}$ -sentence

$$\exists X \in I^n. \forall Y \in I^{n+M}. (\Psi_{0,\leq}(X, Y)).$$

Proof Sketch. The proof combines Lemma 12 with proof ideas similar to those used in the proof of Lemma 10. See [13, Lemma 14] for details. ◀

Lemmas 10 and 13 together yield the inclusion $\exists\forall_{\leq}\mathbb{R} \subseteq \mathfrak{b}\text{-}\exists\forall_{\leq}\mathbb{R}$.

33:10 On the Complexity of the Compact Escape Problem

3.2 Showing $\mathbf{b}\text{-}\exists\forall_{\leq}\mathbb{R} \subseteq \exists\forall_{\leq}\mathbb{R}$

We next establish the inclusion $\mathbf{b}\text{-}\exists\forall_{\leq}\mathbb{R} \subseteq \exists\forall_{\leq}\mathbb{R}$. The key lemma is the following:

► **Lemma 14.** *Let*

$$\exists \varepsilon > 0. (Q_1 X \in \mathbb{R}^n). (Q_2 Y \in \mathbb{R}^m). (\Phi_0(\varepsilon, X, Y))$$

be a sentence over the language \mathcal{L} of matrix size μ . If this sentence holds true, then there exists $\varepsilon > 2^{-\mu^{4\alpha^3\beta(n+1)(m+1)}}$ witnessing the existential quantifier.

Proof. Consider the formula

$$\chi_2(\varepsilon) = (Q_1 X \in \mathbb{R}^n). (Q_2 Y \in \mathbb{R}^m). (\Phi_0(\varepsilon, X, Y)).$$

By Theorem 8 this formula is equivalent to a quantifier-free formula $\chi_0(\varepsilon)$ of size at most $\mu^{2\alpha^3(n+1)(m+1)}$. Let $\chi'_0(\varepsilon)$ be the sentence that results from χ_0 by replacing each atom in $P(\varepsilon) \bowtie 0$ in χ_0 , where P has degree d , with the atom $\varepsilon^d P(1/\varepsilon) \bowtie 0$. Then, evidently, a number $\varepsilon > 0$ satisfies $\chi_0(\varepsilon)$ if and only if $1/\varepsilon$ satisfies $\chi'_0(\varepsilon)$ and vice versa.

By Corollary 9 the sentence $\exists x \in \mathbb{R}. (x > 0 \wedge \chi'_0(x))$ is equivalent to the sentence

$$\exists x \in \mathbb{R}. \left(x > 0 \wedge |x| \leq 2^{\mu^{4\alpha^3\beta(n+1)(m+1)}} \wedge \chi'_0(x) \right).$$

The result follows. ◀

► **Theorem 15.** *Given a $\mathbf{b}\text{-}\Sigma_{2,\leq}$ -sentence*

$$\exists X \in I^m. \forall Y \in I^m. (\Phi_{0,\leq}(X, Y))$$

we can compute in polynomial time an equivalent $\Sigma_{2,\leq}$ -sentence.

Proof Sketch. The proof combines Lemma 14 and Proposition 11 with similar ideas as in the proof of Lemma 10. See [13, Theorem 16] for details. ◀

3.3 Showing $\mathbf{b}\text{-}\exists\forall_{\leq}^{++}\mathbb{R} \subseteq \mathbf{b}\text{-}\exists\forall_{\leq}\mathbb{R}$

Finally we show the inclusion $\mathbf{b}\text{-}\exists\forall_{\leq}^{++}\mathbb{R} \subseteq \mathbf{b}\text{-}\exists\forall_{\leq}\mathbb{R}$.

We will in fact show a stronger but more technical result. Recall that the Hausdorff distance of two non-empty compact subsets K and L of a metric space X is given by

$$d(K, L) = \max\left\{ \sup_{x \in K} d(x, L), \sup_{x \in L} d(x, K) \right\},$$

where, as usual, $d(x, K) = \inf_{y \in K} d(x, y)$. This distance function makes the non-empty compact subsets of a metric space into a metric space $\mathcal{F}(X)$ of its own.

► **Theorem 16.** *Consider a sentence of the form*

$$\exists X \in I^n. \forall Y \in I^m. (\Psi_{0,\leq}(X, Y) \rightarrow \Phi_{0,\leq}(X, Y)),$$

where $\Psi_{0,\leq}(X, Y)$ and $\Phi_{0,\leq}(X, Y)$ are QFF $_{\leq}$ -formulas. Assume that the set-valued function $F(X) = \{Y \in I^m \mid \Psi_{0,\leq}(X, Y)\}$ either maps some $X \in I^n$ to the empty set or is continuous as a map of type $I^n \rightarrow \mathcal{F}(I^m)$. Then we can compute in polynomial time an equivalent $\mathbf{b}\text{-}\Sigma_{2,\leq}$ -sentence.

We prepare the proof of Theorem 16 with three simple observations.

► **Lemma 17.** *Given a sentence of the form*

$$\exists X \in I^n . \forall Y \in I^m . (H(X, Y) > 0),$$

where H is a multivariate polynomial with integer coefficients we can compute in polynomial time an equivalent $\mathfrak{b}\text{-}\Sigma_{2, \leq}$ -sentence.

Proof. The sentence is equivalent to the sentence

$$\exists \varepsilon > 0 . \exists X \in I^n . \forall Y \in I^m . (H(X, Y) \geq \varepsilon).$$

By Lemma 14 this sentence is equivalent to the sentence

$$\exists \varepsilon \in I . \exists X \in I^n . \forall Y \in I^m . \left(\varepsilon \geq 2^{\mu^{4\alpha^3\beta(n+1)(m+1)}} \wedge H(X, Y) \geq \varepsilon \right),$$

where μ is the size of h . Compute in polynomial time an integer N such that $\mu^{4\alpha^3\beta(n+1)(m+1)} \leq 2^N$ and apply Lemma 25 to obtain the result. ◀

► **Lemma 18.** *Let $P \in \mathbb{Z}[X]$ be a polynomial in n variables, encoded by a term T over the signature $\langle \mathbb{Z}, +, \times \rangle$. Then we can compute in polynomial time an integer N (in binary) such that $|P(I^n)| \leq N$.*

Proof. We can view T as a tree whose nodes are elements of the set $\{+, \times\}$ and whose leaves are either variables or constants. Let $c_1, \dots, c_s \in \mathbb{Z}$ denote the integer constants that occur in T . Let $M = \max\{2, |c_1|, \dots, |c_s|\}$.

Let S be the tree which is obtained by substituting M for all leaves in T . Then S encodes a positive integer B . This integer B is clearly an upper bound for the absolute value of P over I^n . By an easy induction argument B is bounded by M^{N_T} , where N_T is the number of nodes of T . The number M^{N_T} can be computed using at most N_T arithmetic operations. Its bitsize is bounded by $N_T\tau$, where τ is a bound on the bitsizes of the numbers c_1, \dots, c_s . ◀

► **Proposition 19.** *Let $\Phi(X)$ be a quantifier-free formula over the language \mathcal{L} whose atoms consist of equalities only. Then we can compute in polynomial time a polynomial $Q \in \mathbb{Z}[X]$ such that $\Phi(X)$ is equivalent to the formula $Q(X) = 0$.*

Proof. Construct a new formula $\Phi'(X)$ that results from $\Phi(X)$ by replacing each atom $P(X) = 0$ in $\Phi(X)$ by the atom $P(X)^2 = 0$.

Now construct a polynomial $Q_{\Phi'}$ by structural induction on Φ' as follows:

1. If $\Phi'(X) \equiv (P(X) = 0)$ then let $Q_{\Phi'} = P$.
2. If $\Phi'(X) \equiv \Psi(X) \vee \omega(X)$ then let $Q_{\Phi'} = Q_{\Psi} \cdot Q_{\omega}$.
3. If $\Phi'(X) \equiv \Psi(X) \wedge \omega(X)$ then let $Q_{\Phi'} = Q_{\Psi} + Q_{\omega}$.

It is easy to see that $Q_{\Phi'}$ can be computed in polynomial time from Φ . It has the desired property by construction. ◀

We are now in a position to prove Theorem 16.

Proof of Theorem 16. The proof is a reduction to Lemma 17.

As a preparation we assign to every QFF $_{\leq}$ -formula Φ a continuous function f_{Φ} such that $\Phi(X)$ holds true if and only if $f_{\Phi}(X) \leq 0$:

1. If $\Phi(X) = (P(X) \leq 0)$ then let $f_{\Phi}(X) = P(X)$.
2. If $\Phi(X) = \Psi(X) \vee \chi(X)$ then let $f_{\Phi}(X) = \min\{f_{\Psi}(X), f_{\chi}(X)\}$.
3. If $\Phi(X) = \Psi(X) \wedge \chi(X)$ then let $f_{\Phi}(X) = \max\{f_{\Psi}(X), f_{\chi}(X)\}$.

33:12 On the Complexity of the Compact Escape Problem

Now assume we are given a sentence

$$\exists X \in I^n. \forall Y \in I^m. (\Psi(X, Y) \rightarrow \Phi(X, Y)) \quad (5)$$

as above. The negation of this sentence is equivalent to the sentence

$$\forall X \in I^n. \exists Y \in I^m. (\Psi(X, Y) \wedge f_\Phi(X, Y) > 0). \quad (6)$$

Let us for now assume that the set $K(X) = \{Y \in I^m \mid \Psi(X, Y)\}$ is non-empty for all $X \in I^n$. Then by assumption this set depends continuously on X in the Hausdorff metric. It follows by elementary calculus that the function $h(X) = \max_{Y \in K(X)} f_\Phi(X, Y)$ is well-defined and continuous.

We further have, by compactness of I^n , that the function $h(X)$ attains its minimum in I^n . By definition of f_Φ , the sentence (6) holds true if and only if $\min_{x \in I^n} h(x) > 0$ if and only if there exists $\varepsilon > 0$ such that $\min_{x \in I^n} h(x) > \varepsilon$. Thus, the sentence (6) is equivalent to the sentence

$$\exists \varepsilon > 0. \forall X \in I^n. \exists Y \in I^m. (\Psi(X, Y) \wedge f_\Phi(X, Y) > \varepsilon).$$

So far we have proved this equivalence under the assumption that the compact set $K(X) = \{Y \in I^m \mid \Psi(X, Y)\}$ is non-empty for all X . But if the set $K(X)$ is empty for some X then both (6) and the above sentence are false, so that the two sentences are certainly equivalent.

Let $\chi(X, Y)$ be the formula that results from Φ by swapping all occurrences of \vee and \wedge and by replacing all atoms $P(X, Y) \leq 0$ in Φ by the atom $P(X, Y) > \varepsilon$. One easily checks that the above sentence is further equivalent to the sentence

$$\exists \varepsilon > 0. \forall X \in I^n. \exists Y \in I^m. (\Psi(X, Y) \wedge \chi(X, Y)).$$

It follows from 10 that there exists a witness ε for the existential quantifier with $\varepsilon > 2^{-\mu^{4\alpha^3\beta(n+1)(m+1)}}$. We can compute in polynomial time an integer N such that we have $\mu^{4\alpha^3\beta(n+1)(m+1)} \leq 2^N$. Consider the formula $\chi(X, Y)$. By Lemma 18 we can compute in polynomial time an integer L such that $|P(X, Y)| \leq L$ for all $(X, Y) \in I^n \times I^m$. We can hence replace each atom $P(X, Y) > 0$ in $\chi(X, Y)$ with the equivalent formula

$$\exists u \in [-L, L]. \exists v \in [-2^{2^N}, 2^{2^N}]. (P(X, Y) = u^2 \wedge uv = 1),$$

where u and v are fresh variables. By Proposition 19 the formula $\chi(X, Y)$ is equivalent to a formula of the form

$$\exists U \in [-L, L]^s. \exists V \in [-2^{2^N}, 2^{2^N}]^s. (Q(X, Y, U, V) = 0)$$

where Q is computable in polynomial time from $\chi(X, Y)$ and s is the number of atoms in $\chi(X, Y)$.

Now, consider the formula $\Psi(X, Y)$. By Lemma 18 we can compute in polynomial time an integer M such that for all atoms $P(X, Y) \leq 0$ in $\Psi(Y)$ the polynomial P satisfies $|P(X, Y)| \leq M$ for all $(X, Y) \in I^n \times I^m$. The atom is hence equivalent to $\exists w \in [-M, M]. P(X, Y) = -w^2$, where w is a fresh variable. Again by Proposition 19, letting t denote the number of atoms in $\Psi(X, Y)$ we can hence compute in polynomial time a formula $\exists W \in [-M, M]^t. R(X, Y, W) = 0$, which is equivalent to $\Psi(X, Y)$.

In total the sentence (6) is equivalent to the sentence

$$\forall X \in I^n. \exists Y \in I^m. \exists U \in [-L, L]^s. \exists V \in [-2^{2^N}, 2^{2^N}]^s. \exists W \in [-M, M]^t. (R(X, Y, W) + Q(X, Y, U, V) = 0).$$

In the above we have used that the functions R and Q admit only non-negative values by construction. We may assume that $2^{2^N} \geq \max\{L, M\}$. Arguing as in the proof of Lemma 25 in Appendix A, we can introduce auxiliary variables $B \in I^{N+1}$ to obtain an equivalent sentence

$$\forall X \in I^n. \exists Y \in I^m. \exists U \in I^s. \exists V \in I^s. \exists W \in I^t. \exists B \in I^{N+1}. (H(X, Y, U, V, W, B) = 0)$$

which is computable in polynomial time from our original sentence (5).

The sentence (5) is hence equivalent to the sentence

$$\exists X \in I^n. \forall Y \in I^m. \forall U \in I^s. \forall V \in I^s. \forall W \in I^t. \forall B \in I^{N+1}. (H(X, Y, U, V, W, B) > 0).$$

Again, we have used that H only admits non-negative values by construction. The result now follows from Lemma 17. \blacktriangleleft

The inclusion $\mathbf{b}\text{-}\exists\forall_{\leq}^+\mathbb{R} \subseteq \mathbf{b}\text{-}\exists\forall_{\leq}\mathbb{R}$ follows from the special case of Theorem 16 where the formula $\Psi_{0, \leq}(Y)$ does not depend on X .

Theorem 16, in its general form, finally allows us to prove that the complexity class $\exists\forall_{\leq}\mathbb{R}$ is robust under different encodings of polynomials.

► Theorem 20. *Given a \mathcal{C} -sentence, where $\mathcal{C} \in \{\Sigma_{2, \leq}, \mathbf{b}\text{-}\Sigma_{2, \leq}, \mathbf{b}\text{-}\Sigma_{2, \leq}^p\}$ we can compute in polynomial time an equivalent \mathcal{C} -sentence whose atoms involve polynomials of degree at most four. In particular we can compute in polynomial time a sentence whose atoms involve polynomials encoded as in (1).*

The proof of Theorem 20 requires the following proposition, which is easily established using elementary calculus:

► Proposition 21. *Let X and Y be metric spaces.*

1. *Let $F: X \rightarrow \mathcal{F}(Y)$ and $G: X \rightarrow \mathcal{F}(Z)$ be continuous with respect to the Hausdorff metric. Then the map*

$$H: X \rightarrow \mathcal{F}(Y) \times \mathcal{F}(Z), H(x) = F(x) \times G(x)$$

is continuous with respect to the Hausdorff metric as well.

2. *Let $F: X \rightarrow \mathcal{F}(Y)$ be continuous with respect to the Hausdorff metric. Let $f: Y \rightarrow Z$ be a continuous function. Then the function*

$$H: X \rightarrow \mathcal{F}(Y \times Z), H(x) = F(x) \times f(F(x))$$

is continuous with respect to the Hausdorff metric.

Proof of Theorem 20. We prove the result for $\mathbf{b}\text{-}\Sigma_{2, \leq}$ -sentences. The result for $\Sigma_{2, \leq}$ -sentences follows by applying the reductions from Lemmas 10 and 12, bounding the degrees of the atoms of the resulting $\mathbf{b}\text{-}\Sigma_{2, \leq}$ -sentence, and translating back to a $\Sigma_{2, \leq}$ -sentence using Theorem 15. By inspecting the proof of Theorem 15 we observe that the degree does not increase by this translation, since we only add new constraints, all of which involve polynomials of degree at most 2. The result for $\mathbf{b}\text{-}\Sigma_{2, \leq}^+$ -sentences is implicitly contained in the below proof.

To a term T over the signature $\langle \mathbb{Z}, +, \times \rangle$ we assign a variable z_T and a formula η_T , where η_T is inductively defined as follows:

33:14 On the Complexity of the Compact Escape Problem

1. If T is a variable x_j then $\eta_T = \langle z_T = x_j \rangle$.
2. If T is a constant c then $\eta_T = \langle z_T = c \rangle$.
3. If T is of the form $U \times V$, then $\eta_T = \langle \eta_U \wedge \eta_V \wedge z_T = z_U \times z_V \rangle$
4. If T is of the form $U + V$, then $\eta_T = \langle \eta_U \wedge \eta_V \wedge z_T = z_U + z_V \rangle$.

The formula η_T is computable in polynomial time from T . Its atoms have degree at most two.

Let $P(X, Y) \leq 0$ be an atom in $\Phi_{\leq}(X, Y)$, where P is encoded by a term T . Let η_T be the formula associated with T as above. Then the formula $P(X, Y) \leq 0$ is equivalent to the formula $\forall Z. (\eta_T(X, Y, Z) \rightarrow z_T \leq 0)$.

More generally, the sentence $\exists X \in I^n. \forall Y \in I^m. \Phi_{\leq}(X, Y)$ is equivalent to the sentence

$$\exists X \in I^n. \forall Y \in I^m. \forall Z \in \mathbb{R}^M. \left(\eta_{T_1}(X, Y, Z) \wedge \cdots \wedge \eta_{T_s}(X, Y, Z) \rightarrow \widehat{\Phi}_{\leq}(Z) \right),$$

where T_1, \dots, T_s are the term representations of the atoms in $\Phi_{\leq}(X, Y)$ and $\widehat{\Phi}_{\leq}(Z)$ is obtained from $\Phi_{\leq}(X, Y)$ by substituting each atom $P(X, Y) \leq 0$ with term representation T_j by the atom $z_{T_j} \leq 0$.

We can further compute in polynomial time an integer N in binary such that the above sentence is equivalent to

$$\exists X \in I^n. \forall Y \in I^m. \forall Z \in [-N, N]^M. \left(\eta_{T_1}(X, Y, Z) \wedge \cdots \wedge \eta_{T_s}(X, Y, Z) \rightarrow \widehat{\Phi}_{\leq}(Z) \right),$$

By the proof of Lemma 25 we can have Z range over $[-1, 1]^M$ up to introducing further auxiliary variables and adding a conjunction of quadratic polynomial equations to the formula $\widehat{\Phi}$. For notational convenience, let us simply assume that the sentence is equivalent to

$$\exists X \in I^n. \forall Y \in I^m. \forall Z \in I^M. \left(\eta_{T_1}(X, Y, Z) \wedge \cdots \wedge \eta_{T_s}(X, Y, Z) \rightarrow \widehat{\Phi}_{\leq}(Z) \right).$$

This sentence involves polynomials of degree at most 2.

Let us write $\eta(X, Y, Z) = \bigwedge_{j=1}^s \eta_{T_j}(X, Y, Z)$. It remains to show that the set

$$\{(Y, Z) \in I^m \times I^M \mid \eta(X, Y, Z)\}$$

depends continuously on X in the Hausdorff metric. It then follows from Theorem 16 that we can compute in polynomial time an equivalent $\Sigma_{2, \leq}$ -sentence. By an inspection of the proof of Theorem 16, the degree of the atoms is at most doubled in this new sentence.

Now, The formula η is a conjunction of atoms of the form $z_j = x_k$, $z_j = y_k$, $z_j = c$, $z_j = z_k + z_\ell$, or $z_j = z_k \times z_\ell$.

We prove the result by structural induction, using Proposition 21. For a formula $\eta(X, Y, Z)$ with $n + m + s$ free variables (X, Y, Z) write $F_\eta: I^n \rightarrow \mathcal{F}(I^{m+s})$ for the map that sends $X \in I^n$ to the set $\{(Y, Z) \in I^m \times I^s \mid \eta(X, Y, Z)\}$.

If $\eta(X, Y, z)$ is of the form $z = x_k$, $z = y_k$, or $z = c$ then the function F_η is easily seen to be continuous.

If $\eta(X, Y, z_1, \dots, z_s) = \nu(X, Y, z_1, \dots, z_{s-1}) \wedge \mu(X, Y, z_s)$ where $\mu(X, Y, z_s)$ is of the form $z_s = x_k$, $z_s = y_k$, or $z_s = c$ then

$$F_\eta(X) = F_\nu(X) \times \{z_s \in \mathbb{R} \mid \mu(X, Y, z_s)\}.$$

Continuity of F_η follows from the first part of Proposition 21.

If $\eta(X, Y, z_1, \dots, z_s) = \nu(X, Y, z_1, \dots, z_{s-1}) \wedge \mu(X, Y, z_j, z_k, z_s)$ where $\mu(X, Y, z_j, z_k, z_s)$ is of the form $z_s = z_j \square z_k$ with $\square \in \{+, \times\}$, then

$$F_\eta(X) = F_\nu(X) \times f(F_\nu(X)),$$

where $f(Y, z_1, \dots, z_{s-1}) = z_j \square z_k$. Continuity of F_η follows from the second part of Proposition 21. ◀

4 The complexity of deciding the Compact Escape Problem

We show that CEP is complete for the complexity class $\exists\forall_{\leq}\mathbb{R}$. Formally this is achieved by locating CEP between the complexity classes $\mathbf{b}\text{-}\exists\forall_{\leq}\mathbb{R}$ and $\mathbf{b}\text{-}\exists\forall_{\leq}^{++}\mathbb{R}$ and applying Theorem 3.

Let us first show that CEP is $\exists\forall_{\leq}\mathbb{R}$ -hard. As a preparation we need to construct in polynomial time an arbitrary finite number of irrational rotations with independent angles:

► **Lemma 22.** *Given $n \in \mathbb{N}$ in unary we can compute in polynomial time a set of points $q_1, \dots, q_n \in \mathbb{T}^1 \subseteq \mathbb{C}$ with rational real and imaginary part such that the only integer solution $(e_1, \dots, e_n) \in \mathbb{Z}^n$ to the equation $q_1^{e_1} \cdots q_n^{e_n} = 1$ is the zero vector.*

Proof. See [13, Lemma 20]. ◀

► **Theorem 23.** *The Compact Escape Problem is $\exists\forall_{\leq}\mathbb{R}$ -hard.*

Proof. By Theorem 3 the decision problem for $\mathbf{b}\text{-}\Sigma$ -sentences is $\exists\forall_{\leq}\mathbb{R}$ -complete. It hence suffices to reduce this problem to CEP.

Thus, given a $\mathbf{b}\text{-}\Sigma_{2,\leq}$ -sentence $\Psi_{2,\leq} = \exists x \in I^n. \forall y \in I^m. (\Phi_{0,\leq}(x, y))$ we compute in polynomial time a compact set K and a rational matrix $A \in \mathbb{Q}^{(n+2m) \times (n+2m)}$ such that there exists a point $x \in K$ with $A^k x \in K$ for all $n \in \mathbb{N}$ if and only if $\Psi_{2,\leq}$ holds true.

By Theorem 20 we may assume that all polynomials that occur in $\Psi_{2,\leq}$ have degree at most 4.

Consider the compact set

$$K = \{(x, u_1, v_1, \dots, u_m, v_m) \in I^n \times I^{2m} \mid u_j^2 + v_j^2 = 1, \Phi_{0,\leq}(x, u_1, \dots, u_m)\}.$$

Use Lemma 22 to compute rational numbers $a_1, \dots, a_m, b_1, \dots, b_m \in \mathbb{Q}$ such that the numbers $a_j + ib_j$ do not admit any non-trivial integer multiplicative relations. Denote by I_n the $(n \times n)$ -identity matrix. Let $R \in \mathbb{Q}^{2m \times 2m}$ be the matrix corresponding to the linear transform which sends a vector $(x_1, y_1, \dots, x_m, y_m) \in \mathbb{Q}^{2m}$ to the vector

$$(a_1 x_1 - b_1 y_1, b_1 x_1 + a_1 y_1, \dots, a_m x_m - b_m y_m, b_m x_m + a_m y_m).$$

Let $A \in \mathbb{Q}^{(n+2m) \times (n+2m)}$ be defined as follows:

$$A = \begin{pmatrix} I_n & \\ & R \end{pmatrix}.$$

Then for all $x \in K$ we have by Theorem 6

$$\overline{\mathcal{O}_A(x)} = \{x\} \times \{(u_1, v_1, \dots, u_m, v_m) \in I^{2m} \mid u_j^2 + v_j^2 = 1\}.$$

It follows that $\overline{\mathcal{O}_A(x)} \subseteq K$ if and only if $\Phi_{0,\leq}(x, u_1, \dots, u_m)$ holds true for all $u_1, \dots, u_m \in I^m$.

Thus, the instance (A, K) of CEP is a negative instance if and only if the sentence $\Psi_{2,\leq}$ holds true. We can compute (A, K) in polynomial time from $\Psi_{2,\leq}$. This is almost immediately obvious, except that the polynomial inequalities that represent K must be encoded as lists of coefficients, while the polynomial inequalities in $\Psi_{2,\leq}$ are given as terms over the signature $\langle \mathbb{Z}, +, \times \rangle$. But since the polynomials that occur in $\Psi_{2,\leq}$ have degree at most 4 we can efficiently compute a list of coefficients from the term representations. ◀

Conversely, we have:

► **Theorem 24.** *The Compact Escape Problem is contained in $\exists\forall_{\leq}\mathbb{R}$.*

Proof Sketch. The full proof is given in Appendix B. We will only briefly sketch the proof idea here.

Suppose we are given a matrix $A \in \mathbb{Q}^{n \times n}$ with rational entries and a family of polynomials \mathcal{P} together with a negation-free propositional formula which encodes a compact set $K \subseteq \mathbb{R}^n$. We can compute in polynomial time from this data a QFF $_{\leq}$ -formula Φ which encodes K . We will show that the existence of a point in K that is trapped under A is expressible as a $\mathbf{b}\text{-}\Sigma_{2,\leq}^{++}$ -sentence. Together with Theorem 3 this yields the result. Let us assume for the sake of simplicity that A is diagonalisable over the complex numbers. The general case employs the Jordan normal form. It is not more difficult but requires more cumbersome notation.

We compute the complex eigenvalues $\lambda_1, \dots, \lambda_m, \lambda_{m+1}, \dots, \lambda_{m+b}, \lambda_{m+b+1}, \dots, \lambda_{m+b+s}$ of A , counted with multiplicity. The eigenvalues are labelled such that $\lambda_1, \dots, \lambda_m$ have modulus 1, such that $\lambda_{m+1}, \dots, \lambda_{m+b}$ have modulus strictly greater than 1, and such that $\lambda_{m+b+1}, \dots, \lambda_{m+b+s}$ have modulus strictly smaller than 1. Using [7] we can compute in polynomial time base change matrices Q and Q^{-1} such that $D = Q^{-1}AQ$ is a diagonal matrix.

Let $x \in K$ be a starting point. If the complex vector $Q^{-1}x$ has a non-zero component $(Q^{-1}x)_j$ with $m+1 \leq j \leq m+b$ then the orbit of x under A is unbounded, and hence forced to leave the bounded set K .

Now assume that $(Q^{-1}x)_j = 0$ for all $m+1 \leq j \leq m+b$. All components $(Q^{-1}x)_j$ with $j \geq m+b+1$ converge to zero under the iteration of A in the sense that the sequence $(Q^{-1}(A^k x))_j$ converges to zero as $k \rightarrow \infty$. It follows that the closure of the orbit of x under A is equal to the range of the semialgebraic function

$$f(x, z) = Q \operatorname{diag}(z_1, \dots, z_m, 0, \dots, 0) Q^{-1}x,$$

where z_1, \dots, z_m range over the closure of the sequence $(\lambda_1^k, \dots, \lambda_m^k)_k$ in the torus \mathbb{T}^m . By Theorem 6 the closure of this sequence is an algebraic subset of \mathbb{T}^m , cut out by the integer multiplicative relations between the eigenvalues $\lambda_1, \dots, \lambda_m$. By Theorem 7 a QFF $_{\leq}$ -formula $\Psi(Z)$ encoding this algebraic set, up to identifying \mathbb{T}^m with a subset of the real hypercube $I^{2m} \subseteq \mathbb{R}^{2m}$.

It follows that we can express the existence of a trapped point by the following “informal” sentence:

$$\begin{aligned} &\exists X \in I^n. \forall Z \in I^{2n}. \\ &(\Psi(Z) \rightarrow (X \in K \wedge ((Q^{-1}X)_{m+1} = 0 \wedge \dots \wedge (Q^{-1}X)_{m+b} = 0) \wedge f(X, Z) \in K)). \end{aligned}$$

Thanks to the polytime computability of Q and Q^{-1} we can compute in polynomial time formulas that express the relations $(Q^{-1}X)_j = 0$ for $j = m+1, \dots, m+b$, and $f(X, Z) \in K$. This allows us to compute in polynomial time a $\mathbf{b}\text{-}\Sigma_{\leq}^{++}$ -sentence which is equivalent to the above “informal” sentence. ◀

A Removing doubly exponential bounds

► **Lemma 25.** *Given an integer N in unary and a sentence*

$$(Q_1 X_1).(Q_2 X_2).\dots(Q_s X_s).\Phi_0(X_1, \dots, X_s),$$

we can in polynomial time in the size of the sentence and N compute a sentence

$$\exists B \in [-1, 1]^{N+1}.(Q_1 X_1; |X_1| \leq 1).(Q_2 X_2; |X_2| \leq 1).\dots(Q_s X_s; |X_s| \leq 1). \\ \Psi_0(B, X_1, \dots, X_s)$$

which is equivalent to the sentence

$$(Q_1 X_1; |X_1| \leq 2^{2^N}).(Q_2 X_2; |X_2| \leq 2^{2^N}).\dots(Q_s X_s; |X_s| \leq 2^{2^N}).\Phi_0(X_1, \dots, X_s).$$

Here, the notation $(Q_j; |X_j| \leq c)$ indicates that the quantifier is restricted to the set

$$\{X_j \in \mathbb{R}^{n_j} \mid |X_{j,1}| \leq c, \dots, |X_{j,n_j}| \leq c\}.$$

Further, if Φ_0 is a QFF $_{\leq}$ -formula then so is Ψ_0 .

Proof. Introduce fresh variables b_0, \dots, b_N . Let Ψ'_0 be the formula that results from Φ_0 by replacing each atom

$$P(X_1, \dots, X_s) \bowtie 0$$

in Φ_0 , where $\bowtie \in \{\leq, <, =\}$, by the atom

$$b_N^{d_P} \cdot P(X_1/b_N, \dots, X_s/b_N) \bowtie 0,$$

where d_P is the total degree of P . Let Ψ_0 be the formula

$$\Psi'_0 \wedge 2b_0 = 1 \wedge b_1 = b_0^2 \cdots \wedge b_N = b_{N-1}^2. \quad \blacktriangleleft$$

B Proof of Theorem 24

We start with a technical lemma:

► **Lemma 26.** *Let $A \in \mathbb{R}^{n \times n}$ be a real matrix. Denote by*

$$\lambda_1, \dots, \lambda_m, \lambda_{m+1}, \dots, \lambda_{m+b}, \lambda_{m+b+1}, \dots, \lambda_{m+b+s}$$

the complex eigenvalues of A , counted with geometric multiplicity. Let $\lambda_1, \dots, \lambda_m$ have modulus 1. Let $\lambda_{m+1}, \dots, \lambda_{m+b}$ have modulus strictly greater than 1. Let $\lambda_{m+b+1}, \dots, \lambda_{m+b+s}$ have modulus strictly smaller than 1. Fix a Jordan basis $v_{j,k}$ of \mathbb{C}^n where $v_{j,1}$ is an eigenvector of λ_j and $(A - \lambda_j I)v_{j,k} = v_{j,k-1}$ for all $k > 1$.

Let B denote the span of the vectors $v_{j,k}$ with $m+1 \leq j \leq m+b$ and the vectors $v_{j,k}$ with $1 \leq j \leq m$ and $k > 1$.

Let C denote the span of the vectors $v_{j,k}$ with $m+b+1 \leq j \leq m+b$.

Let Q be the matrix that sends the standard basis of \mathbb{C}^n to the basis

$$v_{1,1}, \dots, v_{m,1},$$

$$v_{1,2}, \dots, v_{1,t_1}, \dots, v_{m,2}, \dots, v_{m,t_m},$$

$$v_{m+1,1}, \dots, v_{v_{m+1},t_{m+1}}, \dots, v_{m+b+1,1}, \dots, v_{m+b+1,t_{m+b+1}}.$$

Let

$$f: \mathbb{R}^n \times \mathbb{T}^m \rightarrow \mathbb{C}^n, f(x, z) = Q \begin{pmatrix} z_1 & & & & & \\ & \ddots & & & & \\ & & z_m & & & \\ & & & 0 & & \\ & & & & \ddots & \\ & & & & & 0 \end{pmatrix} Q^{-1} \begin{pmatrix} x_1 \\ \vdots \\ x_n \end{pmatrix}$$

Let $S \subseteq \mathbb{T}^m$ be the closure of the set $\{(\lambda_1^k, \dots, \lambda_m^k) \mid k \in \mathbb{N}\}$ in \mathbb{T}^m .

Let $K \subseteq \mathbb{R}^n$ be a compact set. Let $x \in K$. Then for all $k \in \mathbb{N}$ we have $A^k x \in K$ if and only if both of the following two conditions are satisfied:

1. Let $N = m + (t_1 - 1) + \dots + (t_m - 1) + t_{m+1} + \dots + t_{m+b}$. For all $m < j \leq N$ we have $(Q^{-1}x)_j = 0$.
2. $f(x, S) \subseteq K$.

Proof. Let $x \in K$.

Assume that $A^k x \in K$ for all $k \in \mathbb{N}$. Let $J = Q^{-1}AQ$. Let us again write $N = m + (t_1 - 1) + \dots + (t_m - 1) + t_{m+1} + \dots + t_{m+b}$. If there exists $m < j \leq N$ such that $(Q^{-1}x)_j \neq 0$ then $Q^{-1}x$ has a non-zero component in a generalised eigenspace of A which corresponds to an eigenvalue of modulus strictly greater than 1 or it has a non-zero component in a generalised eigenspace of A corresponding to an eigenvalue of modulus 1 which is not an eigenspace. In both cases the absolute value of $A^k x = QJ^k(Q^{-1}x)$ is unbounded as $k \rightarrow \infty$. Since K is assumed to be bounded it follows that $A^k x$ leaves K after finitely many steps.

Now, assume that $(Q^{-1}x)_j = 0$ for all $m < j \leq N$. We claim that $f(x, S)$ is the set of accumulation points of the orbit of x under A . The result then follows immediately.

First, observe that we have by construction

$$A = Q \begin{pmatrix} \lambda_1 & & & & & \\ & \ddots & & & & \\ & & \lambda_m & & & \\ & & & 0 & & \\ & & & & \ddots & \\ & & & & & 0 \\ & & & & & R \end{pmatrix} Q^{-1}$$

where R is an $(s \times s)$ -matrix with $|R^k| \rightarrow 0$ as $k \rightarrow \infty$.

Now, let $z \in S$. We claim that $f(x, z)$ is an accumulation point of the sequence $(A^k x)_{k \in \mathbb{N}}$. Let $\varepsilon > 0$. By Theorem 6 there exist infinitely many $k \in \mathbb{N}$ such that $|\lambda_j^k - z_j| < \varepsilon/2$. For all sufficiently large n we have $|R^k| < \varepsilon/2$. It follows that for each such k we have $|(A^k x) - f(x, z)| < \varepsilon$. Thus, $f(x, z)$ is an accumulation point of the sequence $(A^k x)_k$.

Conversely, let $y \in K$ be an accumulation point of the sequence $(A^k x)_k$. Let $(n_k)_k$ be a sequence of natural numbers such that the sequence $(A^{n_k} x)_k$ converges to y . Since the torus \mathbb{T}^m is compact, the sequence $(\lambda_1^{n_k}, \dots, \lambda_m^{n_k})_k$ has a convergent subsequence. Thus, let $(k_{j_\ell})_\ell$ denote a subsequence of $(k_j)_j$ such that the sequence $(\lambda_1^{k_{j_\ell}}, \dots, \lambda_m^{k_{j_\ell}})_\ell$ converges to a limit $z = (z_1, \dots, z_m) \in \mathbb{T}^m$. Then the sequence $(A^{k_{j_\ell}} x)_\ell$ converges to both $f(x, z)$ and y . It follows that $y = f(x, z)$. ◀

33:20 On the Complexity of the Compact Escape Problem

Now, let us prove Theorem 24.

By Theorem 3 the decision problems for $\mathbf{b}\text{-}\Sigma_{2,\leq}^{++}$ -sentences is contained in $\exists\forall_{\leq}\mathbb{R}$. We reduce the Compact Escape Problem to this problem.

Suppose we are given a matrix $A \in \mathbb{Q}^{n \times n}$ with rational entries, a family of polynomials \mathcal{P} in n free variables, represented in the standard encoding, and a negation-free propositional formula $\Phi(X)$ over atoms of the form $P \leq 0$, where $P \in \mathcal{P}$. We can convert the standard encodings of the polynomials $P \in \mathcal{P}$ into terms over the signature $\langle \mathbb{Z}, +, \times \rangle$ in polynomial time. We can hence convert the formula $\Phi(X)$ into a QFF_{\leq} -formula in polynomial time. By very slight abuse of notation, let us denote this QFF_{\leq} -formula by $\Phi(X)$ as well. Let $K \subseteq \mathbb{R}^n$ denote the set encoded by $\Phi(X)$.

By [7] we can compute in polynomial time the complex eigenvalues of A

$$\lambda_1, \dots, \lambda_m, \lambda_{m+1}, \dots, \lambda_{m+b}, \lambda_{m+b+1}, \dots, \lambda_{m+b+s}$$

and the matrices Q and Q^{-1} as in Lemma 26. We can further compute the real and imaginary parts of the eigenvalues $\lambda_1, \dots, \lambda_{m+b+s}$ in polynomial time. More precisely, letting $\alpha_j = \text{Re}(\lambda_j)$ denote the real part of λ_j , and $\beta_j = \text{Im}(\lambda_j)$ the imaginary part, we can compute in polynomial time:

1. Univariate polynomials with integer coefficients $h_1, \dots, h_{m+b+s}, g_1, \dots, g_{m+b+s}$, such that $h_j(\alpha_j) = g_j(\beta_j) = 0$ for all $j = 1, \dots, m+b+s$.
2. Rational numbers $a_1, b_1, c_1, d_1, \dots, a_{m+b+s}, b_{m+b+s}, c_{m+b+s}, d_{m+b+s}$, such that α_j is the unique root of h_j in the real interval $[a_j, b_j]$ and β_j is the unique root of g_j in the real interval $[c_j, d_j]$.
3. For $j = 1, \dots, n$ and $k = 1, \dots, n$ bivariate polynomials $L_{0,j,k} \in \mathbb{Q}[u, v]$, $L_{1,j,k} \in \mathbb{Q}[u, v]$, and indexes $\ell_{j,k} \in \{1, \dots, m+b+s\}$ such that the matrix Q at row j and column k is given by the complex algebraic number $L_{0,j,k}(\alpha_{\ell_{j,k}}, \beta_{\ell_{j,k}}) + iL_{1,j,k}(\alpha_{\ell_{j,k}}, \beta_{\ell_{j,k}})$.
4. For $j = 1, \dots, n$ and $k = 1, \dots, n$ bivariate polynomials $R_{0,j,k} \in \mathbb{Q}[u, v]$, $R_{1,j,k} \in \mathbb{Q}[u, v]$, and indexes $r_{j,k} \in \{1, \dots, m+b+s\}$ such that the matrix R^{-1} at row j and column k is given by the complex algebraic number $R_{0,j,k}(\alpha_{r_{j,k}}, \beta_{r_{j,k}}) + iR_{1,j,k}(\alpha_{r_{j,k}}, \beta_{r_{j,k}})$.

By Theorem 7 we can compute in polynomial time a finite set $\gamma_1, \dots, \gamma_s \in \mathbb{Z}^m$ of generators of the free abelian group of integer multiplicative relations between the complex eigenvalues $\lambda_1, \dots, \lambda_m$. The size of the integer entries of $\gamma_1, \dots, \gamma_s$ – and not just their bitsize – is bounded polynomially in the size of the input. It follows that we can compute in polynomial time a QFF_{\leq} -formula $\Psi(C, D)$ with $2m$ free variables that expresses for two given real vectors $C \in \mathbb{R}^n$, $D \in \mathbb{R}^n$ that the complex vector $C + iD$ is contained in the set

$$S = \{(z_1, \dots, z_m) \in \mathbb{T}^m \mid (z_1, \dots, z_m)^{\gamma_j} = 1, j = 1, \dots, s\}.$$

By Theorem 6 the set S is equal to the closure of the set $\{(\lambda_1^k, \dots, \lambda_m^k) \mid k \in \mathbb{N}\}$.

Let $f: \mathbb{R}^n \times \mathbb{T}^m \rightarrow \mathbb{C}^n$ be defined as in Lemma 26, i.e.,

$$f(x, z) = Q \text{diag}(z_1, \dots, z_m, 0, \dots, 0) Q^{-1} x.$$

Since we can compute the matrices Q and Q^{-1} in polynomial time as above, we can compute in polynomial time polynomials $F_{k,j} \in \mathbb{Q}[U, V][C, D]$ for $k = 1, \dots, n$, $j = 1, \dots, n$, where U and V are vectors of $m+b+s$ variables, such that

$$\text{Re } f(X, C + iD) = \left(\sum_{j=1}^n F_{1,j}(\vec{\alpha}, \vec{\beta})(C, D) \cdot X_j, \dots, \sum_{j=1}^n F_{n,j}(\vec{\alpha}, \vec{\beta})(C, D) \cdot X_j \right). \quad (7)$$

Note that the result is a polynomial with real algebraic coefficients. More precisely, the right hand side of the above equation is an element of the ring

$$\mathbb{Q}[\alpha_1, \dots, \alpha_{m+b+s}, \beta_1, \dots, \beta_{m+b+s}][X, C, D].$$

Define $N = m + (t_1 - 1) + \dots + (t_m - 1) + t_{m+1} + \dots + t_{m+b}$ as in Lemma 26. By Lemma 26 the existence of a point in K that is trapped under A is equivalent to the “informal” sentence

$$\begin{aligned} \exists X \in I^n. \forall Y \in \mathbb{T}. \\ (Y \in S \rightarrow (X \in K \wedge ((Q^{-1}X)_{m+1} = 0 \wedge \dots \wedge (Q^{-1}X)_N = 0) \wedge f(X, Y) \in K)). \end{aligned} \quad (8)$$

We construct in polynomial time from A and Φ a $\mathbf{b}\text{-}\Sigma_{\leq}^{++}$ -sentence

$$\begin{aligned} \exists U \in I^{m+b+s}. \exists V \in I^{m+b+s}. \exists X \in I^n. \forall C \in I^m. \forall D \in I^m. \\ (\Psi(C, D) \rightarrow (\chi(U, V) \wedge \Phi(X) \wedge \omega(U, V, X) \wedge \xi(U, V, X, C, D))). \end{aligned} \quad (9)$$

Recall that the formula $\Psi(C, D)$ expresses that the complex number $C + iD$ is contained in the set S . Intuitively speaking, the formula $\chi(U, V)$ will express that the variables U and V represent the real and imaginary parts of the eigenvalues $\lambda_1, \dots, \lambda_{m+b+s}$. The formula $\omega(U, V, X)$ will express that $(Q^{-1}X)_k = 0$ for $k = m + 1, \dots, m + b + s$. The formula $\xi(U, V, X, C, D)$ will express that $f(X, C + iD) \in K$.

More formally, let

$$\chi(U, V) = \bigwedge_{j=1}^{m+b+s} (h_j(U) = 0 \wedge a_j \leq U \leq b_j \wedge g_j(V) = 0 \wedge c_j \leq V \leq d_j).$$

Let

$$\omega(U, V, X) = \bigwedge_{k=m+1}^N \bigwedge_{s=0}^1 \left(\sum_{j=1}^n R_{s,k,j}(U_{r_j,k}, V_{r_j,k}) \cdot X_j = 0 \right),$$

Let $\xi(U, V, X, C, D)$ be the formula which is obtained from Φ by replacing each atom $P(X_1, \dots, X_n) \leq 0$ in Φ by the atom

$$P \left(\sum_{j=1}^n F_{1,j}(U, V)(C, D) \cdot X_j, \dots, \sum_{j=1}^n F_{n,j}(U, V)(C, D) \cdot X_j \right) \leq 0,$$

Note that this substitution can be performed in polynomial time. The polynomial P is given by a term t over the signature $\langle \mathbb{Z}, +, \times \rangle$. A term representing the new atom is obtained by substituting in the term t the occurrence of each variable X_k by the polynomial-size term $\sum_{j=1}^n F_{k,j}(U, V)(C, D) \cdot X_j$.

Now, observing that the formula $\chi(U, V)$ forces U and V to be equal respectively to the vector of real and imaginary parts of the eigenvalues $\lambda_1, \dots, \lambda_{m+b+s}$ it follows by construction that the $\mathbf{b}\text{-}\Sigma_{\leq}^{++}$ -sentence (9) is equivalent to the informal sentence (8) and hence expresses the existence of a trapped point. There is only one small argument required: By (7) the formula $\xi(\vec{\alpha}, \vec{\beta}, X, C, D)$ expresses that $\text{Re } f(X, C + iD) \in K$ rather than $f(X, C + iD) \in K$. But if $\Psi(C, D)$ holds true then $C + iD \in S$, so that $f(X, C + iD)$ is real-valued, for instance since it is contained in the closure of the orbit of $A^k x$ by the proof of Lemma 26.

Deciding the truth of the sentence (9) is therefore equivalent to deciding non-termination of the Escape Problem instance (A, K) .

The Pseudo-Skolem Problem is Decidable

Abstract

We study fundamental decision problems on linear dynamical systems in discrete time. We focus on *pseudo-orbits*, the collection of trajectories of the dynamical system for which there is an arbitrarily small perturbation at each step. Pseudo-orbits are generalizations of orbits in the topological theory of dynamical systems. We study the pseudo-orbit problem, whether a state belongs to the pseudo-orbit of another state, and the pseudo-Skolem problem, whether a hyperplane is reachable by an ϵ -pseudo-orbit for every ϵ . These problems are analogous to the well-studied orbit problem and Skolem problem on unperturbed dynamical systems. Our main results show that the pseudo-orbit problem is decidable in polynomial time and the Skolem problem on pseudo-orbits is decidable. The former extends the seminal result of Kannan and Lipton from orbits to pseudo-orbits. The latter is in contrast to the Skolem problem for linear dynamical systems, which remains open for proper orbits.

1 Introduction

A (discrete-time) linear dynamical system in m dimensions is defined by a linear map $x \mapsto Ax$ for an $m \times m$ rational matrix A . The map specifies how an individual state (a real-valued vector in m dimensions) evolves over time; a trajectory starting from a state s is given by the sequence (s, As, A^2s, \dots) . Linear dynamical systems are fundamental models in many different domains of science and engineering, and the computability and complexity of decision problems for linear dynamical systems are of both theoretical and practical interest.

The *orbit* of a point s is the smallest set containing s and closed under the dynamic map. The *orbit problem* for linear dynamical systems asks, given s and t , if t is in the orbit of s [11]. In a seminal paper, Kannan and Lipton [12] showed that the orbit problem can be decided in polynomial time. However, a natural generalization of the orbit problem, the *Skolem problem*, in which we ask whether the orbit of a given state s intersects a given hyperplane, turns out to be notoriously difficult and remains open after many decades [20, 16]. A breakthrough occurred in the mid-1980s, when Mignotte *et al.* [14] and Vereshchagin [21] independently showed decidability in dimension 4 or less. These deep results make essential use of Baker’s theorem on linear forms in logarithms (which earned Baker the Fields Medal in 1970), as well as a p-adic analogue of Baker’s theorem due to van der Poorten. Unfortunately, little progress on that front has since been recorded.

The orbit and Skolem problems are defined on the exact dynamics of the linear system. In dynamical systems theory, one is often interested in “rough” dynamics of a system – in topological terms, we wish to study closed sets containing the orbit. Orbits arising from linear dynamics are usually not closed sets. Indeed the orbit of the point 1 under the map $x \mapsto \frac{1}{2}x$ does not contain the limit point 0. One way to retain closure is through *pseudo-orbits* [8], a concept going back several decades. A pseudo-orbit generalizes the orbit by allowing arbitrarily small imprecisions throughout the dynamics. For a precision $\epsilon > 0$, we say t is in the ϵ -pseudo-orbit of s if there is a sequence of points $(s = s_0, s_1, \dots, s_n = t)$ with $n > 0$ such that $\|As_i - s_{i+1}\| < \epsilon$ for each $i \in \{0, \dots, n - 1\}$. That is, an ϵ -pseudo-orbit contains a sequence of points that would be indistinguishable from an orbit if each state were known only up to precision ϵ . Finally, t is in the pseudo-orbit of s if it is in the ϵ -pseudo-orbit of s for all $\epsilon > 0$.

One can provide a computational analogue of pseudo-orbits (see [17]). Alice is simulating the trajectory of a dynamical system but in every iteration, her computation has a rounding error ϵ . An infinitely powerful adversary, Bob, rounds Alice’s result in an arbitrary fashion to a new state within a distance of ϵ of the actual outcome. A state t is pseudo-reachable from s iff Bob can fool Alice into believing that t is reachable in the simulation no matter how accurate her simulation is.

We can formulate analogous decision problems on pseudo-orbits. The *pseudo-orbit problem* asks, given a linear dynamical system and two states s and t , whether t is in the pseudo-orbit of s . The *hyperplane pseudo-reachability* (or pseudo-Skolem) problem asks, given a linear dynamical system, an initial state s , and a hyperplane, if there is an ϵ -pseudo orbit from s that intersects the hyperplane for every $\epsilon > 0$.

In this paper, we study decision problems for pseudo-orbits of linear dynamical systems. We show that **the pseudo-orbit problem is decidable in polynomial time** and that **the Skolem problem is decidable in full generality on pseudo-orbits**.

We proceed in two steps. First, we generalize Kannan and Lipton’s analysis to show that the pseudo-orbit problem can be decided in polynomial time. Our proof involves a careful examination of the eigenvalues of the matrix A , similar to Kannan and Lipton’s proof. More generally, we show that pseudo-reachability to a bounded semi-algebraic set is decidable.

Next, we consider the hyperplane pseudo-reachability (a.k.a. pseudo-Skolem) problem. Our proof again proceeds by a case analysis on the eigenvalues of A . The most challenging case is when there is an eigenvalue of modulus greater than 1. We analyze a series whose terms are polynomial-exponential functions of $n \in \mathbb{N}$ associated with the dynamics. We show that the infimum of this sum can be effectively computed. The proof of effective computability uses tools from Diophantine approximation as well as a reduction to the decision problem for the theory of real closed fields

We show that the dynamics pseudo-reaches the hyperplane in case the infimum of the above sum is 0. If the infimum is non-zero, we prove that we can find an effective bound N such that the dynamics pseudo-reaches the hyperplane iff, for sufficiently small ϵ , it pseudo-reaches the hyperplane within N steps.

Putting everything together, we conclude that the pseudo-Skolem problem is decidable.

Other related work. The study of pseudo-orbits goes back to Anosov, Bowen, and Conley [1, 3, 8]. Conley [8] formulated the fundamental theorem of dynamical systems: the iteration of any continuous, possibly non-linear, map on a compact metric space decomposes the space into a chain-recurrent part (the pseudo-orbit analogue of a period orbit) and a gradient-like part. Our results imply that deciding if a state is chain recurrent is decidable for linear systems.

In linear systems theory, *controllability* is a fundamental property of linear systems [19]. Controllability states that the system can be controlled from any point to any other point. However, this may require unboundedly large control actions. A pseudo-orbit can be seen as a stronger notion, where we ask if the dynamics can be controlled from a starting point to an ending point no matter how small the control input is: if a state belongs to the pseudo-orbit, then for every ϵ , there is a sequence of control inputs each bounded in norm by ϵ that steers the system to that state.

2 Linear Dynamical Systems

Notation. The sets of natural numbers (including zero), rational numbers, real numbers, and algebraic numbers are denoted by \mathbb{N} , \mathbb{Q} , \mathbb{R} , and $\overline{\mathbb{Q}}$, respectively. We assume a standard representation of algebraic numbers in terms of their defining polynomials, by which we can perform arithmetic operations and test equality in polynomial time in their representation (see, e.g., [6]).

For any column vector $x = [x_1, x_2, \dots, x_m]^\top \in \mathbb{R}^m$, we use the notations $\|x\|_2 := \sqrt{x^\top x}$ and $\|x\|_\infty := \max_i |x_i|$ to indicate respectively the two norm and infinity norm of x . For any matrix $A = [a_{ij}]_{i,j} \in \mathbb{R}^{m \times m}$, we define $\|A\|_2$ and $\|A\|_\infty$ to indicate respectively the (induced) two norm and infinity norm of A . Note that $\|Ax\|_2 \leq \|A\|_2 \|x\|_2$ and $\|Ax\|_\infty \leq \|A\|_\infty \|x\|_\infty$ for all $x \in \mathbb{R}^m$. We write $\mathbf{0} \in \mathbb{R}^m$ for the zero vector and $\mathbf{1} \in \mathbb{R}^m$ for the all-ones vector. We denote by $\rho(A)$ the spectral radius of a matrix A , which is the largest absolute value of the eigenvalues of A . For any $A \in \mathbb{R}^{m \times m}$ and any $\gamma > \rho(A)$, recall that there is a constant $c > 0$ such that $\|A^n\|_2 \leq c\gamma^n$ for all $n \in \mathbb{N}$.

Discrete-Time Linear Dynamical Systems. An m -dimensional discrete-time linear dynamical system is specified by an $m \times m$ matrix A of rational numbers. The *trajectory* determined by an initial state $x_0 \in \mathbb{R}^m$ is the sequence $(x_n)_{n \geq 0}$ given by

$$x_{n+1} = Ax_n, \quad (n \in \mathbb{N}).$$

We call the set $\mathcal{O}(A, x_0) := \{x_n \mid n \in \mathbb{N}\}$ the *orbit* of x_0 .

For any $\epsilon > 0$, an ϵ -perturbed linear dynamical system has state trajectories $(x_n)_{n \geq 0}$ such that

$$x_{n+1} = Ax_n + d_n, \quad (n \in \mathbb{N}),$$

where A is as before and $d_n \in [-\epsilon, \epsilon]^m$ for all n . For an initial state $x_0 \in \mathbb{R}^m$, we define the ϵ -pseudo-orbit $\tilde{\mathcal{O}}_\epsilon(A, x_0)$ of the dynamics as the set of states reachable in the perturbed dynamics. More formally, define

34:4 The Pseudo-Skolem Problem is Decidable

- for $n = 0$, $\tilde{\mathcal{O}}_\epsilon^{(n)}(A, x_0) := \{x_0\}$,
- for all $n \in \mathbb{N}$, $\tilde{\mathcal{O}}_\epsilon^{(n+1)}(A, x_0) := \{Ax + d \in \mathbb{R}^m \mid x \in \tilde{\mathcal{O}}_\epsilon^{(n)}(A, x_0), d \in [-\epsilon, \epsilon]^m\}$, and
- $\tilde{\mathcal{O}}_\epsilon(A, x_0) := \bigcup_{n \geq 0} \tilde{\mathcal{O}}_\epsilon^{(n)}(A, x_0)$.

Finally, we define the *pseudo-orbit* $\tilde{\mathcal{O}}(A, x_0) := \bigcap_{\epsilon > 0} \tilde{\mathcal{O}}_\epsilon(A, x_0)$ as the intersection of all the ϵ -pseudo orbits of x_0 , for all $\epsilon > 0$. Clearly, $\mathcal{O}(A, x) \subseteq \tilde{\mathcal{O}}(A, x)$ for any A and x .

We will make use of the following characterization, which follows directly from the definition: Any $t \in \tilde{\mathcal{O}}_\epsilon(A, s)$ is of the form $t = A^n s + \sum_{i=0}^{n-1} A^i d_{n-i-1}$ for some $n \in \mathbb{N}$ and some sequence of perturbations d_i with $\|d_i\|_\infty \leq \epsilon$.

We also need the following properties of $\tilde{\mathcal{O}}_\epsilon(A, x)$ and $\tilde{\mathcal{O}}(A, x)$.

▷ **Claim 1 (Transitivity).** For every A and $\epsilon > 0$, and for states $s, t, u \in \mathbb{R}^m$, if $t \in \tilde{\mathcal{O}}_\epsilon(A, s)$ and $u \in \tilde{\mathcal{O}}_\epsilon(A, t)$ then $u \in \tilde{\mathcal{O}}_\epsilon(A, s)$. If $t \in \tilde{\mathcal{O}}(A, s)$ and $u \in \tilde{\mathcal{O}}(A, t)$, then $u \in \tilde{\mathcal{O}}(A, s)$.

▷ **Claim 2 (Closure).** For every A , $\epsilon > 0$, and state $s \in \mathbb{R}^m$, the sets $\tilde{\mathcal{O}}_\epsilon(A, s)$ and $\tilde{\mathcal{O}}(A, s)$ are closed sets.

► **Problem 3 (Orbit problem).** Given $A \in \mathbb{Q}^{m \times m}$ and $s, t \in \mathbb{Q}^m$, decide whether $t \in \mathcal{O}(A, s)$.

A celebrated result of Kannan and Lipton [12] shows that the Orbit Problem is decidable in polynomial time.

► **Theorem 4 ([12]).** *The orbit problem is decidable in polynomial time.*

In this paper, we study the following problems.

► **Problem 5 (Pseudo-orbit problem).** Given $A \in \mathbb{Q}^{m \times m}$ and $s, t \in \mathbb{Q}^m$, decide whether $t \in \tilde{\mathcal{O}}(A, s)$.

► **Problem 6 (Hyperplane pseudo-reachability problem).** Given $A \in \mathbb{Q}^{m \times m}$, $s \in \mathbb{Q}^m$, and a hyperplane $c^T \cdot x = v$ for $c, v \in \mathbb{Q}^m$, decide whether $\tilde{\mathcal{O}}_\epsilon(A, s)$ intersects the hyperplane for all $\epsilon > 0$.

The following summarizes our main theorem.

► **Theorem 7 (Main Theorem).**

1. *The pseudo-orbit problem is decidable in polynomial time.*
2. *The hyperplane pseudo-reachability problem is decidable.*

The rest of the paper is devoted to the proof of this theorem.

2.1 Preliminaries

First we establish that pseudo-orbits can be translated with change of bases.

► **Proposition 8.** *For matrices $A, B, Q \in \mathbb{R}^{m \times m}$ with $A = QBQ^{-1}$ and for any $x \in \mathbb{R}^m$, we have $Q\tilde{\mathcal{O}}_{\gamma_2}(B, Q^{-1}x) \subseteq \tilde{\mathcal{O}}_\epsilon(A, x) \subseteq Q\tilde{\mathcal{O}}_{\gamma_1}(B, Q^{-1}x)$, where $\gamma_1 = \epsilon \|Q^{-1}\|_\infty$ and $\gamma_2 = \epsilon / \|Q\|_\infty$. Moreover, $\tilde{\mathcal{O}}(A, x) = Q\tilde{\mathcal{O}}(B, Q^{-1}x)$.*

We will use Proposition 8 with matrix A represented using the *Jordan canonical form*.

Jordan Decomposition. For a given rational square matrix A one can compute *change of basis matrix* Q and *Jordan normal form* J so that $A = QJQ^{-1}$ and $J = \text{diag}(J_1, J_2, \dots, J_z)$ with J_i representing the i^{th} Jordan block taking the following form

$$J_i = \begin{bmatrix} \Lambda_i & 1 & 0 & \dots & 0 & 0 \\ 0 & \Lambda_i & 1 & \dots & 0 & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & \Lambda_i & 1 \\ 0 & 0 & 0 & \dots & 0 & \Lambda_i \end{bmatrix}, \quad (1)$$

where Λ_i denotes the i^{th} eigenvalue of A . The size of J_i is equal to the multiplicity of the eigenvalue Λ_i and is denoted by $\kappa(\Lambda_i)$.

Real Jordan form. For any $A \in \mathbb{R}^{n \times n}$ having complex eigenvalues, matrices Q and J in the Jordan normal form could have complex entries. In this case, the complex eigenvalues form complex conjugate pairs and give a *real Jordan form*: there are *real matrices* Q and J such that $A = QJQ^{-1}$ and $J = \text{diag}(J_1, J_2, \dots, J_z)$. The matrix J_i represents the i^{th} real Jordan block corresponding to either a real eigenvalue Λ_i or a complex pair $\Lambda_i = a_i \pm jb_i$. It is equal to (1) for real Λ_i and has the following form for the complex pair $\Lambda_i = a_i \pm jb_i$,

$$J_i = \begin{bmatrix} \Lambda_i & I_{2 \times 2} & 0_{2 \times 2} & \dots & 0_{2 \times 2} & 0_{2 \times 2} \\ 0_{2 \times 2} & \Lambda_i & I_{2 \times 2} & \dots & 0_{2 \times 2} & 0_{2 \times 2} \\ \vdots & \vdots & \ddots & \ddots & \vdots & \vdots \\ 0_{2 \times 2} & 0_{2 \times 2} & 0_{2 \times 2} & \dots & \Lambda_i & I_{2 \times 2} \\ 0_{2 \times 2} & 0_{2 \times 2} & 0_{2 \times 2} & \dots & 0_{2 \times 2} & \Lambda_i \end{bmatrix}, \quad (2)$$

where with abuse of notation, we have indicated $\Lambda_i = \begin{bmatrix} a_i & -b_i \\ b_i & a_i \end{bmatrix}$. $I_{2 \times 2}$ and $0_{2 \times 2}$ denote identity and fully zero matrices of size 2 by 2.

The real Jordan normal form and the change of basis matrices Q and Q^{-1} can be computed in polynomial time (see [4] and also Appendix D).

Computing matrix powers. If $A = QJQ^{-1}$, then we have $A^n = QJ^nQ^{-1}$ for $n \in \mathbb{N}$, where $J^n = \text{diag}(J_1^n, J_2^n, \dots, J_z^n)$ and

$$J_i^n = \begin{bmatrix} \Lambda_i^n & n\Lambda_i^{n-1} & \binom{n}{2}\Lambda_i^{n-2} & \dots & \binom{n}{k-1}\Lambda_i^{n-k+1} \\ 0 & \Lambda_i^n & n\Lambda_i^{n-1} & \dots & \binom{n}{k-2}\Lambda_i^{n-k+2} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & n\Lambda_i^{n-1} \\ 0 & 0 & 0 & \dots & \Lambda_i^n \end{bmatrix}.$$

3 The pseudo-orbit problem is decidable in polynomial time

In this section, we show that Problem 5 is decidable in polynomial time. Fix a matrix A and let J be the real Jordan form for A . Proposition 8 shows that $\tilde{\mathcal{O}}(A, x)$ can be obtained from the pseudo-orbit $\tilde{\mathcal{O}}(J, x)$. Our decidability proof involves a case analysis on the modulus of the eigenvalues of J . We first consider the cases where J is a single block, i.e.,

$$J = \begin{bmatrix} \Lambda & I & & \\ & \Lambda & \ddots & \\ & & \ddots & I \\ & & & \Lambda \end{bmatrix} \text{ with } \Lambda = \begin{bmatrix} a & -b \\ b & a \end{bmatrix} \text{ and } I = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \text{ or } \Lambda = [r] \text{ and } I = [1], \quad (3)$$

with real matrix entries $a, b, r \in \mathbb{R}$.

We shall case split on the spectral radius $\rho(J)$, which is the absolute value of the unique eigenvalue of the Jordan block J . We consider three cases: $\rho(J) < 1$, $\rho(J) = 1$ and $\rho(J) > 1$. The following lemma will be useful in relating the first and third cases. Its proof is simply by reversing time.

► **Lemma 9** (Reversibility Lemma). *For any invertible matrix $A \in \mathbb{R}^{m \times m}$, $x \in \tilde{\mathcal{O}}_\epsilon(A, s)$ implies $s \in \tilde{\mathcal{O}}_\gamma(A^{-1}, x)$ with $\gamma = \epsilon \|A^{-1}\|_\infty$. Moreover,*

$$x \in \tilde{\mathcal{O}}(A, s) \iff s \in \tilde{\mathcal{O}}(A^{-1}, x). \quad (4)$$

► **Lemma 10** (Eigenvalues inside the unit circle). *Let $J \in \mathbb{R}^{m \times m}$ be a Jordan block of the form (3) with $\rho(J) < 1$. For every $s \in \mathbb{R}^m$,*

$$\tilde{\mathcal{O}}(J, s) = \mathcal{O}(J, s) \cup \{0\} = \overline{\mathcal{O}(J, s)},$$

where $\overline{\mathcal{O}(J, s)}$ denotes the closure of the orbit.

Proof. We prove the lemma by showing there is a constant $C > 0$ satisfying

$$\overline{\mathcal{O}(J, s)} \stackrel{*}{=} \mathcal{O}(J, s) \cup \{0\} \stackrel{**}{\subseteq} \tilde{\mathcal{O}}(J, s) \stackrel{\dagger}{\subseteq} \bigcap_{\epsilon > 0} \bigcup_{z \in \mathcal{O}(J, s)} \mathcal{B}(z, C\epsilon) \stackrel{\S}{\subseteq} \overline{\mathcal{O}(J, s)}, \quad (5)$$

where $\mathcal{B}(z, \epsilon) := \{y \in \mathbb{R}^m \mid \|z - y\|_2 \leq \epsilon\}$ is the closed ball with respect to two norm with center z and radius ϵ . It is easy to see that equality (*) holds since all the eigenvalues of J are inside the unit circle, $\lim_{n \rightarrow \infty} J^n = 0$, and 0 is the only limiting point of any state trajectory.

It is also easy to see that inclusion (**) is correct. Note that for any $\epsilon > 0$, $\mathcal{O}(J, s) \subseteq \tilde{\mathcal{O}}_\epsilon(J, s)$ and the set $\tilde{\mathcal{O}}_\epsilon(J, s)$ is closed by definition. Taking intersection over $\epsilon > 0$, we get $\mathcal{O}(J, s) \subseteq \tilde{\mathcal{O}}(J, s)$ with $\tilde{\mathcal{O}}(J, s)$ being a closed set. Therefore, $\overline{\mathcal{O}(J, s)} \subseteq \tilde{\mathcal{O}}(J, s)$.

We now choose a value of C which allows us to prove inclusion (†). First pick γ such that $\rho(J) < \gamma < 1$. Next choose c_1 to be a constant (which is guaranteed to exist) satisfying $\|J^n\|_2 \leq c_1 \gamma^n$ for all $n \in \mathbb{N}$, and finally set $C := c_1 m / (1 - \gamma)$. We show that $\tilde{\mathcal{O}}_\epsilon(J, s) \subseteq \bigcup_{z \in \mathcal{O}(J, s)} \mathcal{B}(z, C\epsilon)$ for any $\epsilon > 0$. Take any $x \in \tilde{\mathcal{O}}_\epsilon(J, s)$. Then there is a sequence (d_0, d_1, \dots) and $n \in \mathbb{N}$ such that $\|d_i\|_\infty \leq \epsilon$ and $x = J^n s + \sum_{i=0}^{n-1} J^i d_{n-i-1}$. Now

$$\|x - J^n s\|_2 = \left\| \sum_{i=0}^{n-1} J^i d_{n-i-1} \right\|_2 \leq \sum_{i=0}^{n-1} \|J^i\|_2 \|d_{n-i-1}\|_2 \leq \sum_{i=0}^{n-1} c_1 \gamma^i m \epsilon \leq \frac{c_1 m \epsilon}{1 - \gamma} = C\epsilon,$$

We then get $x \in \mathcal{B}(z, C\epsilon)$ for $z := J^n s \in \mathcal{O}(J, s)$.

The inclusion § can be proven by taking an arbitrary point $y \notin \overline{\mathcal{O}(J, s)}$ and showing that there is an $\epsilon > 0$ for which $y \notin \mathcal{B}(z, C\epsilon)$ for all $z \in \mathcal{O}(J, s)$. Note that the complement of $\overline{\mathcal{O}(J, s)}$ is an open set, which means there is a $\theta > 0$ such that $\mathcal{B}(y, \theta) \cap \overline{\mathcal{O}(J, s)} = \emptyset$. Taking ϵ such that $C\epsilon < \theta$ will give the intended result. ◀

Additionally, we prove the following lemma (that will be useful later) about the behaviour of pseudo-orbits when all eigenvalues are inside the unit circle.

► **Lemma 11.** *Let $A \in \mathbb{R}^{m \times m}$ and $s \in \mathbb{R}^m$. If $\rho(A) < 1$, then for every $\delta > 0$ there exists an effectively computable $N \in \mathbb{N}$ and $\epsilon > 0$ such that after time N , all ϵ -pseudo-orbits are contained inside the ball $\mathcal{B}(\mathbf{0}, \delta)$.*

Proof. Let $(x_n)_{n \in \mathbb{N}}$ denote an ϵ -pseudo-orbit starting from s with a sequence of disturbances $(d_n)_{n \in \mathbb{N}}$. Suppose $\rho(A) < 1$ and let $\gamma \in (\rho(A), 1)$. There is a constant $c > 0$ satisfying $\|A^n\|_2 \leq c\gamma^n$ for all n . Then we get

$$\begin{aligned} \|x_n\|_2 &= \left\| A^n s + \sum_{k=0}^{n-1} A^k d_{n-k-1} \right\|_2 \leq \|A^n\|_2 \|s\|_2 + \sum_{k=0}^{n-1} \|A^k\|_2 \|d_{n-k-1}\|_2 \\ &\leq c\gamma^n \|s\|_2 + \sum_{k=0}^{n-1} m\epsilon c\gamma^k \leq c\gamma^n \|s\|_2 + \frac{m\epsilon c}{1-\gamma}. \end{aligned}$$

Taking $\epsilon = \delta(1-\gamma)/(2mc)$ and N with $\gamma^N \|s\|_2 \leq \delta/(2c)$ gives the intended result. ◀

► **Lemma 12 (Eigenvalues outside the unit circle).** *Let $J \in \mathbb{R}^{m \times m}$ be a Jordan block of the form (3) with $\rho(J) > 1$. We have $\tilde{\mathcal{O}}(J, \mathbf{0}) = \mathbb{R}^m$ and $\tilde{\mathcal{O}}(J, s) = \mathcal{O}(J, s)$ if $s \neq \mathbf{0}$.*

Proof. In this case, J is invertible and all eigenvalues of J^{-1} are inside the unit circle. We apply the Reversibility Lemma 9 and Lemma 10.

$$x \in \tilde{\mathcal{O}}(J, s) \iff s \in \tilde{\mathcal{O}}(J^{-1}, x) \iff s \in \mathcal{O}(J^{-1}, x) \cup \{\mathbf{0}\} \iff s = \mathbf{0} \text{ or } x \in \mathcal{O}(J, s).$$

Therefore, any x is in $\tilde{\mathcal{O}}(J, s)$ if $s = \mathbf{0}$, and $\tilde{\mathcal{O}}(J, s) = \mathcal{O}(J, s)$ for $s \neq \mathbf{0}$. ◀

► **Lemma 13 (Eigenvalues on the unit circle).** *Let $J \in \mathbb{R}^{m \times m}$ be a Jordan block of the form (3) with $\rho(J) = 1$. For every $s \in \mathbb{R}^m$, we have $\tilde{\mathcal{O}}(J, s) = \mathbb{R}^m$.*

Proof. The key part of the proof is to show that $\mathbf{0} \in \tilde{\mathcal{O}}(A, s)$ for any s and for any A having the eigenvalues on the unit circle. Once we show this, we know that $s \in \tilde{\mathcal{O}}(A^{-1}, \mathbf{0})$ is true for any s and any matrix A due to the Reversibility lemma. Stated for the inverse of A and any x , we get $x \in \tilde{\mathcal{O}}(A, \mathbf{0})$. Since pseudo-orbits are transitive, we have $x \in \tilde{\mathcal{O}}(A, s)$ for any x and s , which is the intended result.

We show $\mathbf{0} \in \tilde{\mathcal{O}}(A, s)$ equivalently by replacing A with its Jordan form J and doing induction on the structure of J . The proof has two stages. The first stage is to show that $\mathbf{0} \in \tilde{\mathcal{O}}(J, s)$ for all s when J has a single block simple eigenvalues. The second stage is to show that we can sequentially increase the multiplicity of eigenvalues and multiple blocks.

Base case. Suppose $J = \begin{bmatrix} a & -b \\ b & a \end{bmatrix}$ with $a^2 + b^2 = 1$ or $J = r$ with $|r| = 1$. Observe that the multiplication by J does not increase the two norm of a vector. Hence setting

$$d_n = \begin{cases} -\epsilon \cdot \frac{Jx_n}{\|Jx_n\|_2} & \text{if } \|Jx_n\|_\infty > \epsilon, \\ -Jx_n & \text{otherwise,} \end{cases}$$

we obtain the ϵ -pseudo-orbit $(x_0 = s, x_1, x_2, \dots, x_m, \mathbf{0}, \mathbf{0}, \dots)$ from any s where $\|x_k\|_2 = \|x_{k-1}\|_2 - \epsilon$ for $k \leq m$, which gives $\mathbf{0} \in \tilde{\mathcal{O}}(J, s)$.

Inductive case. We show that if $\mathbf{0} \in \tilde{\mathcal{O}}(J_1, s_1)$ and $\mathbf{0} \in \tilde{\mathcal{O}}(J_2, s_2)$ for all s_1 and s_2 of appropriate dimensions, we also have $\mathbf{0} \in \tilde{\mathcal{O}}(J, s)$ with $J = \begin{bmatrix} J_1 & B \\ 0 & J_2 \end{bmatrix}$ for any B and any s with appropriate dimensions. Let us partition any state $x = (x^1, x^2)$ according to the dimensions of J_1 and J_2 . Let $\epsilon > 0$ and $s = (s^1, s^2)$. By the assumption, there exist ϵ -perturbations $(d_0^2, d_1^2, \dots, d_{N-1}^2)$ that bring s^2 to $\mathbf{0}$ under J_2 . Let $d_n = (\mathbf{0}, d_n^2)$ for $0 \leq n < N$ be a sequence of ϵ -perturbations for the linear system with mapping J . We obtain the sequence $(x_0 = s, x_1, \dots, x_N)$ with $x_N^2 = \mathbf{0}$: the ϵ -perturbations d_0, \dots, d_{N-1} have brought the second coordinate to $\mathbf{0}$. By the assumption, we also have $\mathbf{0} \in \tilde{\mathcal{O}}_\epsilon(J_1, x_N^1)$, which gives ϵ -perturbations (d_0^1, \dots, d_M^1) that bring x_N^1 to $\mathbf{0}$ under J_1 . Let us expand the sequence of perturbations for the linear system J with $d_{n+N} = (d_n^1, \mathbf{0})$ for $0 \leq n \leq M$. It is easy to see that (d_0, \dots, d_{N+M}) bring the system from s to $\mathbf{0}$ due to the structure of J that is upper triangular. ◀

We now consider the general case where J has multiple blocks.

► **Definition 14.** Let $J \in \mathbb{R}^{m \times m}$ be a real Jordan block matrix and $s \in \mathbb{R}^m$. We define

$$\Delta(J, s) := \begin{cases} \mathbb{R}^m & \text{if } \rho(J) = 1 \text{ or, } \rho(J) > 1 \text{ and } s = \mathbf{0}, \\ \{\mathbf{0}\} & \text{if } \rho(J) < 1, \\ \emptyset & \text{otherwise.} \end{cases}$$

The following lemma states that certain points in the pseudo-orbit of real Jordan blocks are ϵ -pseudo reachable exactly at any sufficiently large time step, for every $\epsilon > 0$. The lemma provides the flexibility to “synchronize” reaching parts of the state for different Jordan blocks.

► **Lemma 15 (Synchronization Lemma).** Let $J \in \mathbb{R}^{m \times m}$ be a Jordan block with eigenvalue λ . For $s \in \mathbb{R}^m$, $t \in \Delta(J, s)$ if and only if for every $\epsilon > 0$ there exists $N_\epsilon \in \mathbb{N}$ such that for all $N > N_\epsilon$, there exists an ϵ -pseudo-orbit $(x_i)_{i \in \mathbb{N}}$ of s under J such that $x_N = t$.

Proof.

- $|\lambda| < 1$ and $\Delta(J, s) = \{\mathbf{0}\}$. By Lemma 10, $\mathbf{0} \in \tilde{\mathcal{O}}(J, s)$ and hence for every $\epsilon > 0$, there exists N_ϵ such that $t = \mathbf{0}$ can be ϵ -pseudo reached at time N_ϵ . Now simply observe that once an ϵ -pseudo-orbit reaches $\mathbf{0}$, it can remain there forever by setting all future perturbations to zero. To prove the other direction, suppose $t \neq \mathbf{0}$. By Lemma 11, there must exist a time bound T such that for sufficiently small ϵ , all ϵ -pseudo-orbits of s after time T are contained in $\mathcal{B}(\mathbf{0}, \frac{\|t\|_2}{2})$. Hence for sufficiently small ϵ no N_ϵ with the the specified property can exist.
- $|\lambda| = 1$ and $\Delta(J, s) = \mathbb{R}^m$. In the proof of Lemma 13, for every $t \in \mathbb{R}^m$ and $\epsilon > 0$ we construct an ϵ -pseudo-orbit from s that visits $\mathbf{0}$ followed by t . Let N_ϵ be the number of steps required to ϵ -reach t . We can postpone visiting t to any time step $N > N_\epsilon$ by simply waiting at the point $\mathbf{0}$ for $N - N_\epsilon$ steps.
- $|\lambda| > 1$, $s = \mathbf{0}$ and $\Delta(J, s) = \mathbb{R}^m$. Similarly to the case above, in Lemma 12 for each ϵ we construct an ϵ -pseudo-orbit that visits t at time N_ϵ , and reaching t can be delayed arbitrarily by spending a necessary number of steps at $\mathbf{0}$ at the beginning.
- $|\lambda| > 1$, $s \neq \mathbf{0}$ and $\Delta(J, s) = \emptyset$. Let $t \in \mathbb{R}^m$. In this case, observe that there must exist a time bound T such that for sufficiently small ϵ , all ϵ -pseudo-orbits of s after time T are contained outside $\mathcal{B}(\mathbf{0}, 2\|t\|_2)$. Hence for sufficiently small ϵ no N_ϵ with the the specified property can exist. ◀

There are two modes of pseudo reachability: via orbit, or at larger and larger time steps for smaller ϵ .

► **Lemma 16.** *Let $A \in \mathbb{R}^{m \times m}$ and $s, t \in \mathbb{R}^m$. If there exists N such that for every ϵ , t is ϵ -pseudo-reachable from s within the first N steps, then $t \in \mathcal{O}(A, s)$.*

Proof. Suppose such N exists. By continuity of the map $x \mapsto Ax$, for every $\delta > 0$ there exists $\epsilon > 0$ such that for every $\epsilon' < \epsilon$ and ϵ' -pseudo-orbit $(x_i)_{i \in \mathbb{N}}$, $\|x_i - A^i s\|_2 < \delta$ for $0 \leq i < N$. Hence the intersection of the first N elements of all ϵ -pseudo-orbits is exactly $\{s, As, \dots, A^{N-1}s\}$. ◀

► **Lemma 17.** *For $J = \text{diag}(J_1, \dots, J_l)$ in real Jordan normal form and $s \in \mathbb{R}^m$,*

$$\tilde{\mathcal{O}}(J, s) = \mathcal{O}(J, s) \cup \prod_{i=1}^l \Delta(J_i, s_i).$$

Proof. Suppose $t = (t_1, \dots, t_l) \in \prod_{i=1}^l \Delta(J_i, s_i)$. That is, for every ϵ and $1 \leq i \leq l$ there exists an ϵ -pseudo-orbit $(x_j^i)_{j \in \mathbb{N}}$ of s_i under J_i that reaches t_i . By Lemma 15, for every ϵ there exist ϵ -pseudo-orbits $(y_j^i)_{j \in \mathbb{N}}$ of s_1, \dots, s_l that reach t_1, \dots, t_l , respectively, at the same time N . That is, $y_N^i = t_i$ for $1 \leq i \leq m$. Hence $(y_i^1, \dots, y_i^l)_{i \in \mathbb{N}}$ is an ϵ -pseudo-orbit of s under J that reaches t .

Now suppose $t \in \tilde{\mathcal{O}}(J, s) \setminus \mathcal{O}(J, s)$. We prove, by a case analysis on J_i , that $t_i \in \Delta(J_i, s_i)$ for $1 \leq i \leq l$. The main idea is that if t is pseudo-reachable but not reachable, then in order to reach it via an ϵ -pseudo-orbit one will need longer and longer time horizons as $\epsilon \rightarrow 0$ (Lemma 16).

1. $\rho(J_i) < 1$. Since t is not in the orbit, we can find a sequence $N_1 < N_2 < \dots$ of time steps and $\epsilon_1 > \epsilon_2 > \dots$ of perturbations such that t is ϵ_j -reachable from s earliest at time N_j . In particular, t_i is ϵ_j reachable from s_i at time N_j for every j . But by Lemma 11 this means that $|t_i| < \delta$ for every $\delta > 0$. Hence $t_i = \mathbf{0} \in \Delta(J_i, s_i)$.
2. $\rho(J_i) = 1$. Since in this case $\Delta(J_i, s_i) = \mathbb{R}^{\kappa(i)}$, trivially $t_i \in \Delta(J_i, s_i)$.
3. $\rho(J_i) > 1$ and $s_i = \mathbf{0}$. Since in this case too $\Delta(J_i, s_i) = \mathbb{R}^{\kappa(i)}$, trivially $t_i \in \Delta(J_i, s_i)$.
4. $\rho(J_i) > 1$ and $s_i \neq \mathbf{0}$. This case cannot arise, as similarly to Case 1, one can argue that if pseudo-reaching t_i requires larger and larger time steps as $\epsilon \rightarrow 0$, then $|t_i| > \delta$ for every δ . But in this case no such t_i can exist. ◀

Proof. (of Theorem 7(1)). We now put everything together to show the pseudo-orbit problem is decidable in polynomial time. Given $A \in \mathbb{Q}^{m \times m}$, and $s, t \in \mathbb{Q}^m$, we compute (in polynomial time) matrices $Q, J, Q^{-1} \in (\mathbb{R} \cap \overline{\mathbb{Q}})^{m \times m}$ such that $A = QJQ^{-1}$ and J is in real Jordan normal form (Appendix D). Then, we compute $t' = Q^{-1}t$ and $s' = Q^{-1}s$, and by Proposition 8 we have that $t \in \tilde{\mathcal{O}}(A, s)$ if and only if $t' \in \tilde{\mathcal{O}}(J, s')$. It remains to decide whether $t' \in \tilde{\mathcal{O}}(J, s')$. For this we use the characterization described in Lemma 17. To decide whether $t' \in \mathcal{O}(J, s')$, observe that $Q^{-1}t \in \mathcal{O}(J, Q^{-1}s) \iff t \in \mathcal{O}(A, s)$, and whether $t \in \mathcal{O}(A, s)$ is an instance of the Orbit Problem and can be decided in polynomial time.¹ Finally, it remains to check whether $t_i \in \Delta(J_i, s_i)$ for each block J_i , which can be done easily given the simplicity of $\Delta(J_i, s_i)$. ◀

We end the section with an application of Theorem 7(1). A set S is *pseudo-reachable* from s under A if for every $\epsilon > 0$, there exists a point $x_\epsilon \in S$ that is ϵ -pseudo-reachable from s under A . An *algebraic* set is the set of zeros of a collection of polynomials. A *semialgebraic*

¹ Technically, [12] consider the orbit problem for rational inputs and we require the orbit problem where the input can contain algebraic numbers. However, a polynomial time algorithm is still possible.

34:10 The Pseudo-Skolem Problem is Decidable

set is a union of algebraic sets and projections of algebraic sets. We show (in Appendix B.2) that we can decide if a bounded semialgebraic set is pseudo-reachable, by reducing the problem to the pseudo-orbit problem.

► **Theorem 18.** *Given $A \in \mathbb{Q}^{m \times m}$, $x_0 \in \mathbb{Q}^m$, and a bounded semialgebraic set S , it is decidable if S is pseudo-reachable from x_0 under A .*

4 Hyperplane pseudo-reachability is decidable

In this section, we prove Theorem 7(2). First we consider the case where we are given:

- a hyperplane $H = \{x \in \mathbb{R}^m : c^\top x = v\}$ with $(c, v) \in (\mathbb{R} \cap \overline{\mathbb{Q}})^m \times (\mathbb{R} \cap \overline{\mathbb{Q}})$,
- $J = \text{diag}(J_1, \dots, J_z) \in (\mathbb{R} \cap \overline{\mathbb{Q}})^{m \times m}$ in real Jordan normal form, and
- a starting point $x_0 \in (\mathbb{R} \cap \overline{\mathbb{Q}})^m$.

We show how to decide if for every $\epsilon > 0$ there exists an ϵ -pseudo-orbit $(x_i)_{i \in \mathbb{N}}$ of x_0 under J that *hits* the hyperplane H , i.e. $c^\top x_N - v = 0$ for some $N \in \mathbb{N}$.

A block J_i is *relevant* with respect to hyperplane $H = \{x : c^\top x = v\}$ if the coefficients of c at the coordinates corresponding to J_i are not all 0. Intuitively, dimensions corresponding to blocks that are not relevant can simply be omitted from the analysis as they do not play a role in determining whether a point is in H or not. *Relevant eigenvalues* of J are the eigenvalues of relevant blocks. The *relevant spectral radius*, written $\rho_H(J)$, is the largest modulus of all relevant eigenvalues. Our proof is based on a case analysis on the relevant spectral radius of J . We shall see that the proof is simple when the relevant spectral radius is ≤ 1 but requires more technical ideas when it is > 1 .

► **Lemma 19** (Case $\rho_H(J) \leq 1$). *Fix a matrix J in real Jordan normal form, a starting state x_0 , and a hyperplane $H = \{x : c^\top x = v\}$.*

1. *If $\rho_H(J) = 1$, then H is pseudo-reachable.*
2. *If $\rho_H(J) < 1$ and $\mathbf{0} \in H$ then H is pseudo-reachable. If $\rho_H(J) < 1$ and $\mathbf{0} \notin H$, there exists an effectively computable time bound N such that H is pseudo-reachable if and only if there exists $0 \leq i \leq N$ such that $J^i x_0 \in H$ (that is, H is reachable from x_0 under J after at most N steps).*

Proof. First suppose $\rho_H(J) = 1$. We write $J = \text{diag}(J_h, J_r)$, where $\rho_H(J_h) = 1$ and $\rho_H(J_r) < 1$ (observe that wlog we can assume the blocks of J have non-decreasing spectral radius when listed from top to bottom) and correspondingly set $s = (s_h, s_r)$, $c = (c_h, c_r)$. Note that $c_h \neq 0$ by the relevance of at least one of eigenvalues of modulus 1.

By Lemma 10 we know $\mathbf{0} \in \tilde{\mathcal{O}}(J_r, s_r)$. By Lemma 13, we can select y such that $c_h^\top y - v = 0$ and $y \in \tilde{\mathcal{O}}(J_h, s_h)$. Therefore, invoking Lemma 15, for every $\epsilon > 0$ we can find $N \in \mathbb{N}$ and construct ϵ -pseudo-orbits $(x_n^h)_{n \in \mathbb{N}}$ and $(x_n^r)_{n \in \mathbb{N}}$ such that $x_N^h = y$ and $x_N^r = \mathbf{0}$, which implies that for the ϵ -pseudo-orbit $x_n = (x_n^h, x_n^r)$, $c^\top x_N - v = c_h^\top y + c_r^\top \mathbf{0} - v = 0$ as desired.

Now suppose $\rho_H(J) < 1$.

Case 1: $v = 0$. Since $\mathbf{0} \in H$ and the origin is pseudo-reachable from x_0 (Lemma 10), H is pseudo-reachable.

Case 2: $v \neq 0$. Using Lemma 11, and setting $\delta = |v|/(2\|c\|_2)$, we can find $\epsilon > 0$ and horizon $N \in \mathbb{N}$ after which every ϵ -pseudo-orbit is trapped in $\mathcal{B}(0, \delta)$. Thus, the hyperplane cannot be pseudo-reached after time N , as the hyperplane does not intersect with $\mathcal{B}(0, \delta)$. It remains to check if the hyperplane is pseudo-reachable at any of the first N time-steps. In fact, for a bounded time interval, a hyperplane is pseudo-reachable iff it is reachable. This is

because the effect of finitely many disturbance terms (d_0, \dots, d_{N-1}) can be made arbitrarily small for small enough ϵ . Therefore, decidability in this case only requires checking if the bounded orbit $(y_n)_{0 \leq n \leq N}$ hits the hyperplane before the time horizon N , that is, if there exists a time-step $0 \leq n \leq N$ such that $c^\top y_n - v = 0$, which is clearly decidable. ◀

We now consider the case $\rho_H(J) > 1$. The main ideas of our proof are as follows:

1. A point x_n in the ϵ -pseudo orbit belongs to the hyperplane (c, v) if $c^\top x_n - v = 0$. In particular, $c^\top x_n - v$ can be written as a sum over exponential polynomials in eigenvalues of different sizes.
2. We factor out the scaling factor corresponding to the top eigenvalues, leaving a sum over normalized eigenvalues, together with a sum over disturbances (of order ϵ) and additional terms which go to zero with large n .
3. We relate hyperplane pseudo-reachability to the limit inferior of the sum over normalized eigenvalues. If the limit is zero, we show the hyperplane is pseudo-reachable. If the limit is positive, we show there is an effective bound N such that if the hyperplane is pseudo-reachable, it is reachable within N steps.
4. We apply results from Diophantine approximation and the theory of reals to compute the limit inferior of the sum over normalized eigenvalues.

Fix $J = \text{diag}(J_1, \dots, J_l) \in (\mathbb{R} \cap \overline{\mathbb{Q}})^{m \times m}$, a starting point $x_0 \in (\mathbb{R} \cap \overline{\mathbb{Q}})^m$, and a hyperplane $H = \{x \in \mathbb{R}^m \mid c^\top x = v\}$ with $c, v \in (\mathbb{R} \cap \overline{\mathbb{Q}})^m$. We assume without loss of generality that all blocks are relevant.

Step 1: Analysing $c^\top x_n - v$. Let $L = \rho_H(J) > 1$ be the largest modulus of a relevant eigenvalue of J and suppose the blocks are arranged in non-increasing order of the modulus of eigenvalues. In particular, let $t \leq l$ be such that the first t blocks (t for “top”) have $\rho(J_1) = \dots = \rho(J_t) = L > 1$. We call the eigenvalues of these blocks the *top eigenvalues*. The remaining blocks satisfy $L > \rho(J_{t+1}) \geq \dots \geq \rho(J_l)$.

Let $(d_i)_{i \in \mathbb{N}}$ be a sequence of perturbations and $(x_i)_{i \in \mathbb{N}}$ the resulting pseudo-orbit. We have that for all time steps n ,

$$c^\top x_n - v = c^\top \left(J^n x_0 + \sum_{k=0}^{n-1} J^k d_{n-k-1} \right) - v = \sum_{i=1}^l \left(c^i J_i^n x_0^i + c^i \sum_{k=0}^{n-1} J_i^k d_{n-k-1}^i \right) - v,$$

where for all $1 \leq i \leq l$, c^i , x_n^i , d_n^i are projections of c^\top , x_n and d_n , respectively, onto the coordinates governed by J_i . Observe that c^i is a row vector for every i .

Step 2: Normalized sum. We define a normalized version of this sum by factoring out L^n (the size of the top eigenvalues) and n^D , where we define D in such a way that we normalize polynomials in n that appear in the sum. Observe that for $1 \leq i \leq t$ (the top eigenvalues),

$$c^i J_i^n = \begin{cases} \left[p_1^i(n) \lambda^n + \overline{p_1^i(n) \lambda^n} \quad \dots \quad p_{2\kappa(i)}^i(n) \lambda^n + \overline{p_{2\kappa(i)}^i(n) \lambda^n} \right] & \text{if } J_i \text{ has eigenvalues } \lambda, \bar{\lambda} \\ \left[p_1^i(n) \rho^n \quad \dots \quad p_{\kappa(i)}^i(n) \rho^n \right] & \text{if } J_i \text{ has a single eigenvalue } \rho \end{cases}$$

for polynomials $p_1^i, \dots, p_{\kappa(i)}^i$ (with algebraic coefficients) where $\kappa(i)$ is the multiplicity of the block J_i .

We define D to be the largest number such that the monomial n^D appears with a non-zero coefficient in at least one of $c^i J_i^n$ for $1 \leq i \leq t$. (Note that if all entries of c are non-zero $D + 1$ is equal to the largest multiplicity of a top eigenvalue block of J , as can be seen from the description of powers of a Jordan block in Section 2.)

34:12 The Pseudo-Skolem Problem is Decidable

We can now define

$$f(n) := \frac{c^\top \cdot x_n - v}{L^n n^D} = \sum_{i=1}^l \left(c^i \frac{J_i^n}{L^n n^D} x_0^i + c^i \sum_{k=0}^{n-1} \frac{J_i^k}{L^n n^D} d_{n-k-1}^i \right) - \frac{v}{L^n n^D}$$

For notational convenience we define vector-valued functions $g^i(n) := c^i \frac{J_i^n}{L^n n^D}$ for $1 \leq i \leq l$. The following technical lemma summarizes the relevant properties of these scaled terms.

► **Lemma 20 (Normalization Lemma).**

1. For $1 \leq i \leq t$ (top eigenvalues), $\|g^i(n)\|_\infty = O(1)$ (with respect to n).
2. For $t+1 \leq i \leq l$ (non-top eigenvalues), $\lim_{n \rightarrow \infty} \|g^i(n)\|_\infty = 0$.
3. There exists $1 \leq j \leq t$ and effectively computable $N \in \mathbb{N}$ and $C > 0$ such that $n > N \implies \|g^j(n)\|_\infty > C$.

Proof. We address each point individually.

- 1: For $1 \leq i \leq t$ let J_i have eigenvalues λ and $\bar{\lambda}$ (the case where J_i has a single real eigenvalue is similar but simpler) and observe that

$$g^i(n) = \left[\frac{p_1^i(n)}{n^D} \left(\frac{\lambda}{L}\right)^n + \frac{\overline{p_1^i(n)}}{n^D} \left(\frac{\bar{\lambda}}{L}\right)^n \quad \dots \quad \frac{p_{2\kappa(i)}^i(n)}{n^D} \left(\frac{\lambda}{L}\right)^n + \frac{\overline{p_{2\kappa(i)}^i(n)}}{n^D} \left(\frac{\bar{\lambda}}{L}\right)^n \right].$$

By the definition of top eigenvalues, $|\lambda| = L$ and thus $\frac{\lambda}{L}$ and $\frac{\bar{\lambda}}{L}$ have modulus 1. By construction of n^D , the polynomials $p_1^i(n), \dots, p_{2\kappa(i)}^i(n)$ all have degree at most D and hence the terms $\frac{p_1^i(n)}{n^D}, \dots, \frac{p_{2\kappa(i)}^i(n)}{n^D}$ are bounded from above by a constant.

- 2: For $t+1 \leq i \leq l$ let J_i have eigenvalues λ and $\bar{\lambda}$ and observe that

$$g^i(n) = \left[\frac{p_1^i(n)}{n^D} \left(\frac{\lambda}{L}\right)^n + \frac{\overline{p_1^i(n)}}{n^D} \left(\frac{\bar{\lambda}}{L}\right)^n \quad \dots \quad \frac{p_{\kappa(i)}^i(n)}{n^D} \left(\frac{\lambda}{L}\right)^n + \frac{\overline{p_{\kappa(i)}^i(n)}}{n^D} \left(\frac{\bar{\lambda}}{L}\right)^n \right].$$

By construction $|\lambda| < L$ and thus $\gamma := \frac{\lambda}{L}$ and $\bar{\gamma}$ have moduli $|\gamma|, |\bar{\gamma}| < 1$. The polynomials $p_1^i(n), \dots, p_{\kappa(i)}^i(n)$ may not be asymptotically bounded by n^D (since n^D was constructed only considering top eigenvalues). However, it is clear that the exponentially vanishing $\left(\frac{\lambda}{L}\right)^n$ and $\left(\frac{\bar{\lambda}}{L}\right)^n$ will dominate the polynomials and all entries of $g^i(n)$ will thus vanish.

- 3: Observe that by construction of n^D , there must exist a top eigenvalue block J_j ($1 \leq j \leq t$) for which at least one polynomial in $c^j J_j^n$ has degree D . Let $r > D$ be the multiplicity of the block J_j , which has the form of a real Jordan matrix with a single block (Eq. (3)) with sub-blocks Λ . One can write

$$c^j J_j^n = \begin{bmatrix} c_r^j & c_{r-1}^j & \dots & c_0^j \end{bmatrix} \begin{pmatrix} \Lambda^n & n\Lambda^{n-1} & \binom{n}{2}\Lambda^{n-1} & \dots & \binom{n}{r-1}\Lambda^{n-r+1} \\ 0 & \Lambda^n & n\Lambda^{n-1} & \dots & \binom{n}{r-2}\Lambda^{n-r+2} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & n\Lambda^{n-1} \\ 0 & 0 & 0 & \dots & \Lambda^n \end{pmatrix}, \quad (6)$$

where c_k^j for $1 \leq k \leq r$ corresponds to a row vector of size two or one, respectively, when Λ is a 2×2 or 1×1 matrix. Analyzing this product, we see that $c_r^j, \dots, c_{D+1}^j = \mathbf{0}$, $c_D^j \neq \mathbf{0}$ and the single entry of $c^j J_j^n$ whose polynomial component has degree D is exactly $c_D^j \binom{n}{D} \Lambda^{n-D}$.

We define $\hat{\Lambda} := \Lambda/L$. Note that $\|\hat{\Lambda}\|_2 = 1$. Now observe that for this block J_j , we have

$$g^j(n) = \frac{1}{L^{n_n D}} c^j J_i^n = c_D^j \frac{1}{D!} \hat{\Lambda}^n + \frac{1}{n} (O(1)).$$

Therefore, there exists sufficiently large N such that for all $n \in \mathbb{N}$,

$$n > N \implies \left\| \frac{1}{L^{n_n D}} c^j J_j^n \right\|_\infty > \frac{1}{2} \left\| c_D^j \frac{1}{D!} \hat{\Lambda}^n \right\|_\infty > \frac{\|c_D^j\|_2}{4D!}.$$

Thus we have shown Point 3 with $C = \frac{\|c_D^j\|_2}{4D!}$. \blacktriangleleft

Step 3: Conditions for reachability and non-reachability. Now we are ready to attack our original problem. Going back, H is ϵ -pseudo-reachable if and only if $f(n) = 0$ for some disturbance sequence $(d_i)_{i \in \mathbb{N}}$ with $d_i \in [-\epsilon, \epsilon]^m$ for all i . We analyze how $f(n)$ can be brought to 0 in this way.

► **Lemma 21.** *Let*

$$D = \liminf_{n \rightarrow \infty} \left| \sum_{i=1}^t g^i(n) x_0^i \right|. \quad (7)$$

If $D = 0$, then H is pseudo-reachable. If $D > 0$, there exists a computable time bound N such that H is pseudo-reachable if and only if it is reachable (in the standard sense) within the first N steps.

Proof. Suppose $D = 0$. Take an arbitrary $\epsilon > 0$. We argue that H is ϵ -pseudo-reachable. Recall that

$$\begin{aligned} f(n) &= \sum_{i=1}^l \left(c^i \frac{J_i^n}{L^{n_n D}} x_0^i + c^i \sum_{k=0}^{n-1} \frac{J_i^k}{L^{n_n D}} d_{n-k-1}^i \right) - \frac{v}{L^{n_n D}} \\ &= \sum_{i=1}^l \left(g^i(n) x_0^i + c^i \sum_{k=0}^{n-1} \frac{J_i^k}{L^{n_n D}} d_{n-k-1}^i \right) - \frac{v}{L^{n_n D}}. \end{aligned}$$

Let I be such that $\|g^I(n)\|_\infty > C$, for $C > 0$ and sufficiently large n (Point 3 of the Normalization Lemma). We construct a pseudo-orbit with all perturbations set to zero except d_0^I and obtain

$$f(n) = c^I \frac{J_I^{n-1}}{L^{n_n D}} d_0^I + \sum_{i=1}^t g^i(n) x_0^i + \sum_{i=t+1}^l c^i \frac{J_i^n}{L^{n_n D}} x_0^i - \frac{v}{L^{n_n D}}.$$

Intuitively, we will use the term $c^I \frac{J_I^{n-1}}{L^{n_n D}} d_0^I$ to cancel out the remaining summands above, but we have to argue that this can be done using a disturbance of size at most ϵ . Moreover, observe that $c^I \frac{J_I^{n-1}}{L^{n_n D}}$ is very close to $g^I(n)$. Formally, we first find N large enough such that

- $\|g^I(N)\|_\infty > C$,
- $\left\| \sum_{i=t+1}^l c^i \frac{J_i^N}{L^{N N D}} x_0^i - \frac{v}{L^{N N D}} \right\|_\infty < \frac{C^2}{\|J_i\|_\infty} \frac{\epsilon}{2}$ (possible because for $t+1 \leq i \leq l$, $\rho(J_i) < 1$ and $L > 1$), and
- $\left\| \sum_{i=1}^t g^i(N) x_0^i \right\|_\infty < \frac{C^2}{\|J_i\|_\infty} \frac{\epsilon}{2}$ (possible because $\liminf_{n \rightarrow \infty} \left\| \sum_{i=1}^t g^i(n) x_0^i \right\| = 0$).

34:14 The Pseudo-Skolem Problem is Decidable

Finally, we determine the value of d_0^I . Without loss of generality, assume that $g^I(N)$ is of the form $[C' \ \dots]$ where $|C'| > C$, that is the first entry of $g^I(N)$ is large. We then observe that $c^I \frac{J_I^{N-1}}{L^N N^D} d_0^I = g^I(N) J_I^{-1} d_0^I$ and set

$$d_0^I = J_I \cdot \left[-\frac{1}{C'} \left(\sum_{i=1}^t g^i(N) x_0^i + \sum_{i=t+1}^l c^i \frac{J_i^N}{L^N N^D} x_0^i - \frac{v}{L^N N^D} \right) \ 0 \ 0 \ \dots \ 0 \right]^\top$$

to obtain

$$c^I \frac{J_I^{N-1}}{L^N N^D} d_0^I = - \left(\sum_{i=1}^t g^i(N) x_0^i + \sum_{i=t+1}^l c^i \frac{J_i^N}{L^N N^D} x_0^i - \frac{v}{L^N N^D} \right)$$

and hence $f(N) = 0$.

Now suppose $D > 0$. Recall

$$\begin{aligned} f(n) &= \sum_{i=1}^l \left(g^i(n) x_0^i + c^i \sum_{k=0}^{n-1} \frac{J_i^k}{L^n n^D} d_{n-k-1}^i \right) - \frac{v}{L^n n^D} \\ &= \sum_{i=1}^t g^i(n) x_0^i + \sum_{i=t+1}^l c^i \frac{J_i^n}{L^n n^D} x_0^i + \sum_{i=1}^l c^i \sum_{k=0}^{n-1} \frac{J_i^k}{L^n n^D} d_{n-k-1}^i - \frac{v}{L^n n^D}. \end{aligned}$$

In this case we shall construct a time bound N after which for all sufficiently small value of ϵ , the term $\sum_{i=1}^t g^i(n) x_0^i$ will dominate the other summands. Let $2\Delta > 0$ be a lower bound on $\liminf_{n \rightarrow \infty} \left| \sum_{i=1}^t g^i(n) x_0^i \right| > 0$. We shall see how to obtain such a bound effectively later (Lemma 22). We compute N with the following properties.

- For all $n > N$, $\left| \sum_{i=1}^t g^i(n) x_0^i \right| > \Delta$. Possible because $\liminf_{n \rightarrow \infty} \left| \sum_{i=1}^t g^i(n) x_0^i \right| > 2\Delta$.
- For all $n > N$, $\left| \sum_{i=t+1}^l c^i \frac{J_i^n}{L^n n^D} x_0^i \right|, \left| \frac{v}{L^n n^D} \right| \ll \Delta$. The former is possible because for $t+1 \leq i \leq l$, $\rho(J_i) < L$.
- For sufficiently small ϵ , for all $n > N$, $\left| c^i \sum_{k=0}^{n-1} \frac{J_i^k}{L^n n^D} d_{n-k-1}^i \right| \ll \Delta$ for $1 \leq i \leq l$. To see that this is always possible, observe that

$$\left| c^i \sum_{k=0}^{n-1} \frac{J_i^k}{L^n n^D} d_{n-k-1}^i \right| \leq \sum_{k=0}^{n-1} \left\| c^i \frac{J_i^k}{L^n n^D} \right\|_\infty M \epsilon \text{ (where fixed } M \text{ bounds the matrix dimension)}$$

and

$$\lim_{n \rightarrow \infty} \sum_{k=0}^n \left\| c^i \frac{J_i^k}{L^n n^D} \right\|_\infty \leq \lim_{n \rightarrow \infty} \sum_{k=0}^n \left\| c^i \frac{1}{L^{n-k}} \frac{J_i^k}{L^k k^D} \right\|_\infty = \lim_{n \rightarrow \infty} \sum_{k=0}^n \left\| \frac{1}{L^{n-k}} g^i(k) \right\|_\infty.$$

Recalling Point 1 of the Normalization Lemma, $\|g^i(n)\|_\infty = O(1)$ and hence

$$\lim_{n \rightarrow \infty} \sum_{k=0}^n \left\| \frac{1}{L^{n-k}} g^i(k) \right\|_\infty = O(1),$$

by bounding the sum $\sum_{k=0}^n \left\| \frac{1}{L^{n-k}} g^i(k) \right\|_\infty$ from above by a geometric sequence. Therefore, $\sum_{k=0}^{n-1} \left\| c^i \frac{J_i^k}{L^n n^D} \right\|_\infty M \epsilon$ can be made $\ll \Delta$ by choosing ϵ to be sufficiently small.

Once we have chosen N , by the properties above we will have that for all $n > N$, for sufficiently small ϵ ,

$$|f(n)| \geq \left| \sum_{i=1}^t g^i(n) x_0^i \right| - \left| \sum_{i=t+1}^l c^i \frac{J_i^n}{L^n n^D} x_0^i + \sum_{i=1}^l c^i \sum_{k=0}^{n-1} \frac{J_i^k}{L^n n^D} d_{n-k-1}^i - \frac{v}{L^n n^D} \right| > 0.$$

Therefore, H is pseudo-reachable if and only if for every $\epsilon > 0$, H is ϵ -pseudo-reachable within the first N steps. By Lemma 16, this is the case if and only if H is reachable within the first N steps. ◀

Step 4: Analyzing $\liminf_{n \rightarrow \infty} |\sum_{i=1}^t g^i(n)x_0^i|$. Consider a single term $g^i(n)x_0^i$. Writing $x_0^i = [X_0 \ X_1 \ \dots \ X_z]^\top$, where $X_1, \dots, X_z \in \mathbb{R}$, we have

$$g^i(n)x_0^i = \sum_{r=1}^z \left(\frac{p_r^i(n)}{n^D} \left(\frac{\lambda}{L} \right)^n + \overline{\frac{p_r^i(n)}{n^D} \left(\frac{\lambda}{L} \right)^n} \right) X_z.$$

Let $\gamma_i = \frac{\lambda}{L}$. Note that $|\gamma_i| = 1$. By the construction of n^D , none of the polynomials have a term of degree higher than D . Therefore, we can absorb the constants X_r and the monomial n^D into the polynomials, sum the terms up, and write them as polynomials in $\frac{1}{n}$. That is,

$$g^i(n)x_0^i = q^i(1/n)\gamma_i^n + \overline{q^i(1/n)\gamma_i^n}$$

for suitable polynomials q^i with algebraic coefficients. Thus

$$\liminf_{n \rightarrow \infty} \left| \sum_{i=1}^t g^i(n)x_0^i \right| = \liminf_{n \rightarrow \infty} \left| \sum_{i=1}^t q^i(1/n)\gamma_i^n + \overline{q^i(1/n)\gamma_i^n} \right|$$

We defer the proof of the following lemma, which requires tools from Diophantine analysis and the theory of reals, to the next section.

► **Lemma 22.** *Let $\gamma_1, \dots, \gamma_t$ be algebraic numbers with modulus 1. Let q^1, \dots, q^t be polynomials with algebraic coefficients. The quantity*

$$\liminf_{n \rightarrow \infty} \left| \sum_{i=1}^t q^i(1/n)\gamma_i^n + \overline{q^i(1/n)\gamma_i^n} \right|$$

can be effectively computed. If it is greater than zero, there is an effectively computable N satisfying the requirement of Lemma 21.

Proof of Theorem 7 (2). We are now ready to aggregate our case analysis into the proof the pseudo-reachability in hyperplanes is decidable. Given $A \in \mathbb{Q}^{m \times m}$, $x_0 \in \mathbb{Q}^m$ and $H = \{x : c^\top \cdot x = 0\}$, we first convert A to real Jordan normal form as described in Section 2 to obtain $J = Q^{-1}AQ$. We then perform a coordinate transform on x_0 and H to obtain $H' = \{x : c^\top Qx = 0\}$ and $x'_0 = Q^{-1}x_0$. The original problem is now equivalent to pseudo-reachability of H' from x'_0 under J .

Next, we remove dimensions from $x'_0, c^\top Q$ and J that do not correspond to relevant blocks and determine the relevant spectral radius $\rho_H(J)$ of J . If $\rho_H(J) = 1$ then H' is reachable by Lemma 19(1). If $\rho_H(J) < 1$, then by Lemma 19(2), H' is pseudo-reachable if and only if $\mathbf{0} \in H'$ or $x'_0, Jx'_0, \dots, J^N x'_0$ hits H' , where N is the computable bound in the Lemma.

Finally, we consider the case where $\rho_H(J) > 1$. Let J_1, \dots, J_t be the blocks of J with $\rho(J) = \rho_H(J)$ and $c^1, \dots, c^t, x_0^1, \dots, x_0^t$ be the corresponding coordinates of $c^\top Q$ and x'_0 , respectively. Finally, compute the value of $\liminf_{n \rightarrow \infty} \left| \sum_{i=1}^t g^i(n)x_n^i \right|$ using Lemma 22 and use Lemma 21 to either immediately conclude reachability or to compute the bound N and determine reachability by checking if $x'_0, Jx'_0, \dots, J^N x'_0$ hits H' .

5 Proof of Lemma 22

We now prove a generalization of Lemma 22. Let $\lambda_1, \dots, \lambda_m$ be algebraic numbers of modulus 1 and let p_1, \dots, p_m be polynomials with algebraic coefficients. Let n range over the natural numbers. We show how to effectively determine the value of $\liminf_{n \rightarrow \infty} |\sum_{j=1}^m p_j(1/n)\lambda_j^n|$. Moreover, if the value is strictly greater than 0, we show we can find an explicit bound Δ and $N \in \mathbb{N}$ such that for all $n > N$, we have $|\sum_{j=1}^m p_j(1/n)\lambda_j^n| > \Delta$. Lemma 22 follows as a special case.

We require some technical machinery from the theory of Diophantine approximations. We need the following theorem of Masser [13]. A proof can be found in [5] or [9].

► **Theorem 23** ([13]). *Let $m \in \mathbb{N}$ be fixed and let $\lambda_1, \dots, \lambda_m$ be complex algebraic numbers each of modulus 1. Consider the free Abelian group*

$$L = \{(v_1, \dots, v_m) \in \mathbb{Z}^m : \lambda_1^{v_1} \lambda_2^{v_2} \dots \lambda_m^{v_m} = 1\}.$$

L has a basis $\{\vec{\ell}_1, \dots, \vec{\ell}_p\} \subseteq \mathbb{Z}^m$ (with $p \leq m$), where the entries of each of the $\vec{\ell}_j$ are all polynomially bounded in the total description length of $\lambda_1, \dots, \lambda_m$. Moreover, such a basis can be also computed in time polynomial in the total description length.

Let L be as described in Theorem 23 above and suppose we have computed a basis $\{\vec{\ell}_1, \dots, \vec{\ell}_p\} \subseteq \mathbb{Z}^m$. For each $j \in \{1, \dots, p\}$, let $\vec{\ell}_j = (\ell_{j,1}, \dots, \ell_{j,m})$. Now we define a set

$$T := \{(z_1, \dots, z_m) \in \mathbb{C}^m : |z_1| = \dots = |z_m| = 1 \text{ and} \\ \text{for each } j \in \{1, \dots, p\}, z_1^{\ell_{j,1}} \dots z_m^{\ell_{j,m}} = 1\} \quad (8)$$

Notice that $|z| = 1 \iff \operatorname{Re}(z)^2 + \operatorname{Im}(z)^2 - 1 = 0$, and the $\ell_{j,k}$ are fixed integers, and thus the conditions above can be written as polynomials in the real and imaginary parts of z . Thus T is an algebraic set.

We now state a version of Kronecker's theorem on simultaneous Diophantine approximation. A derivation of this version of the theorem from the standard version ([10] Chap 23) can be found in [15].

► **Theorem 24** (Kronecker's theorem, density version). *Let T be defined from $\lambda_1, \dots, \lambda_m$ as in (8). Then $\{(\lambda_1^n, \dots, \lambda_m^n) : n \in \mathbb{N}\}$ is a dense subset of T .*

Theorem 24 enables us to compute the \liminf by minimizing a function over a compact algebraic set:

► **Theorem 25.** *Let $\lambda_1, \dots, \lambda_m$ be complex numbers of modulus 1. Let p_1, \dots, p_m be polynomials (with algebraic coefficients) with constant terms c_1, \dots, c_m respectively. Let $\mathbf{z} = (z_1, \dots, z_m)$ and $\mathbf{c} = (c_1, \dots, c_m)$. We have that*

$$\liminf_{n \rightarrow \infty} \left| \sum_{j=1}^m p_j(1/n)\lambda_j^n \right| = \liminf_{n \rightarrow \infty} \left| \sum_{j=1}^m c_j \lambda_j^n \right| = \inf_{\mathbf{z} \in T} |\mathbf{c}^\top \cdot \mathbf{z}| = \min_{\mathbf{z} \in T} |\mathbf{c}^\top \cdot \mathbf{z}|,$$

where T is the algebraic set computed in (8) as the closure of $\{(\lambda_1^n, \dots, \lambda_m^n) : n \in \mathbb{N}\}$.

To prove the theorem, we need the following lemma that shows that we can replace the polynomials by their constant terms.

► **Lemma 26.** Let $\lambda_1, \dots, \lambda_m$ be complex numbers of modulus 1. Let p_1, \dots, p_m be polynomials (with algebraic coefficients) with constant terms c_1, \dots, c_m respectively. Then

$$\liminf_{n \rightarrow \infty} \left| \sum_{j=1}^m p_j(1/n)\lambda_j^n \right| = \liminf_{n \rightarrow \infty} \left| \sum_{j=1}^m c_j \lambda_j^n \right|.$$

Proof. (of Theorem 25). The first equality follows from Lemma 26 and the second follows from Theorem 24. The third equality holds because the function $\mathbf{z} \mapsto |\mathbf{c}^\top \cdot \mathbf{z}|$ is continuous and T is compact. ◀

Now, since T is an algebraic set, the minimum $\min_{\mathbf{z} \in T} |\mathbf{c}^\top \cdot \mathbf{z}|$ can be expressed in the theory of reals with addition and multiplication (omitting the encoding of absolute values):

$$\exists \mathbf{z} \in T. v = |\mathbf{c}^\top \cdot \mathbf{z}| \wedge \forall \mathbf{z}' \in T. v \leq |\mathbf{c}^\top \cdot \mathbf{z}'|$$

Therefore, by Tarski's theorem [18, 2, 7], we can characterize the unique v that attains the minimum.

Suppose the minimum v is some number $B > 0$. In this case, we require a bound $\Delta \in \mathbb{R}$ and $N \in \mathbb{N}$ such that $|\sum_{j=1}^m p_j(1/n)\lambda_j^n| > B$ for all $n > N$. By emulating the proof of Lemma 26, we can find a bound N such that for all $n > N$, we have $|\sum_{j=1}^m p_j(1/n)\lambda_j^n| > B/2$. The required bounds are $\Delta = B/2$ and this N .

This concludes the proof of Lemma 22 and therefore also Theorem 7.

A Proof of Proposition 8

We want to show

$$Q \tilde{\mathcal{O}}_{\gamma_2}(B, Q^{-1}x) \subseteq \tilde{\mathcal{O}}_{\epsilon}(A, x) \subseteq Q \tilde{\mathcal{O}}_{\gamma_1}(B, Q^{-1}x), \quad (9)$$

where $\gamma_1 = \epsilon \|Q^{-1}\|_{\infty}$ and $\gamma_2 = \epsilon / \|Q\|_{\infty}$.

Take any $y \in \tilde{\mathcal{O}}_{\epsilon}(A, x)$. We show that $Q^{-1}y \in \tilde{\mathcal{O}}_{\gamma_1}(B, Q^{-1}x)$ to get the right-hand side of (9). Since $y \in \tilde{\mathcal{O}}_{\epsilon}(A, x)$, there is a state trajectory (x_0, x_1, \dots) and a sequence (d_0, d_1, \dots) such that $x_0 = x$, $x_{n+1} = Ax_n + d_n$, $d_n \in [-\epsilon, \epsilon]^m$ for all $n \in \mathbb{N}$, and y appears in the state trajectory. We construct a new state trajectory (y_0, y_1, \dots) and the sequence $(\bar{d}_0, \bar{d}_1, \dots)$ with the transformation $x_n = Qy_n$ and $d_n = Q\bar{d}_n$. Then we have $y_{n+1} = Q^{-1}AQy_n + Q^{-1}d_n = By_n + \bar{d}_n$. Note that $\|\bar{d}_n\|_{\infty} = \|Q^{-1}d_n\|_{\infty} \leq \|Q^{-1}\|_{\infty} \|d_n\|_{\infty} \leq \gamma_1$. Since y appears in the state trajectory (x_0, x_1, \dots) , $Q^{-1}y$ appears in the state trajectory (y_0, y_1, \dots) with $y_0 = Q^{-1}x_0 = Q^{-1}x$. Therefore, $Q^{-1}y \in \tilde{\mathcal{O}}_{\gamma_1}(B, Q^{-1}x)$ which results in $y \in Q \tilde{\mathcal{O}}_{\gamma_1}(B, Q^{-1}x)$.

To prove the left-hand side of (9), We invoke the right-hand side by replacing (A, B, Q, x, ϵ) with $(B, A, Q^{-1}, Q^{-1}x, \gamma_2)$. This gives $\tilde{\mathcal{O}}_{\gamma_2}(B, Q^{-1}x) \subseteq Q^{-1} \tilde{\mathcal{O}}_{\gamma'_1}(A, x)$ with $\gamma'_1 = \gamma_2 \|Q\|_{\infty}$. Setting $\gamma'_1 = \epsilon$ proves the left-hand side of (9).

To prove that $\tilde{\mathcal{O}}(A, x) = Q \tilde{\mathcal{O}}(B, Q^{-1}x)$, we take intersection of all the sides in (9) over $\epsilon > 0$:

$$\bigcap_{\epsilon > 0} Q \tilde{\mathcal{O}}_{\gamma_2}(B, Q^{-1}x) \subseteq \bigcap_{\epsilon > 0} \tilde{\mathcal{O}}_{\epsilon}(A, x) \subseteq \bigcap_{\epsilon > 0} Q \tilde{\mathcal{O}}_{\gamma_1}(B, Q^{-1}x).$$

Due to the linear relation between γ_1 and γ_2 with ϵ , we get

$$Q \tilde{\mathcal{O}}(B, Q^{-1}x) \subseteq \tilde{\mathcal{O}}(A, x) \subseteq Q \tilde{\mathcal{O}}(B, Q^{-1}x) \quad \Rightarrow \quad \tilde{\mathcal{O}}(A, x) = Q \tilde{\mathcal{O}}(B, Q^{-1}x).$$

B Proofs from Section 3

B.1 Proof of Lemma 9

Any $t \in \tilde{\mathcal{O}}_\epsilon(A, s)$ is of the form $t = A^n s + \sum_{i=0}^{n-1} A^i d_{n-i-1}$ for some $n \in \mathbb{N}$ and some d_i with $\|d_i\|_\infty \leq \epsilon$. This means $s = A^{-n} t + \sum_{i=0}^{n-1} A^{-i} d'_{n-i-1}$ with $d'_{n-1-i} = A^{-1} d_i$. Since $\|d'_{n-1-i}\|_\infty \leq \|A^{-1}\|_\infty \epsilon$, we get $s \in \tilde{\mathcal{O}}_\gamma(A^{-1}, t)$. To get (4), notice that

$$t \in \tilde{\mathcal{O}}(A, s) \Rightarrow t \in \bigcap_{\epsilon > 0} \tilde{\mathcal{O}}_\epsilon(A, s) \Rightarrow s \in \bigcap_{\gamma > 0} \tilde{\mathcal{O}}_\gamma(A^{-1}, t) \Rightarrow s \in \tilde{\mathcal{O}}(A^{-1}, t).$$

Applying the same argument to the matrix A^{-1} will give the other side of (4).

B.2 Proof of Theorem 18

We show that S is pseudo-reachable from x_0 under A if and only if there exists $x \in \bar{S}$ that is pseudo-reachable from x_0 under A , allowing us to restrict our attention to compact sets and the existence of a pseudo-reachable point in a set as opposed to pseudo-reachability of the set as a whole. Deciding pseudo-reachability then reduces to checking whether $\bar{S} \cap \tilde{\mathcal{O}}(J, x_0) = \emptyset$, which can be computed using Lemma 17.

Suppose S is pseudo-reachable. Let $(\epsilon_i)_{i \in \mathbb{N}}$ be a sequence of positive numbers with $\lim_{\epsilon \rightarrow 0} \epsilon_i = 0$, and $(x_i)_{i \in \mathbb{N}}$ be a sequence of elements of S such that x_i is ϵ_i -pseudo-reachable for all $i \geq 0$. By the Bolzano–Weierstrass theorem, boundedness of S implies that $(x_i)_{i \in \mathbb{N}}$ must have a limit point x in \bar{S} . To argue that x is pseudo-reachable, let $\epsilon > 0$. Since x is the limit point of $(x_i)_{i \in \mathbb{N}}$, there must exist an $\frac{\epsilon}{2}$ -pseudo-orbit $(y_i)_{i \in \mathbb{N}}$ containing a point y_N such that $\|x - y_N\|_\infty < \frac{\epsilon}{2}$. Therefore, x is ϵ -pseudo-reachable from s via the sequence $s, y_1, \dots, y_{N-1}, x$.

Now suppose $x \in \bar{S}$ is pseudo-reachable. To argue that S is pseudo-reachable, let $\epsilon > 0$. Since $x \in \bar{S}$, there must exist a point $x' \in S$ such that $\|x' - x\|_\infty < \frac{\epsilon}{2}$. Since x is $\frac{\epsilon}{2}$ -pseudo-reachable, x' must be ϵ -pseudo-reachable.

C Proof of Lemma 26

We can write $p_j(1/n)$ as $c_j + \sum_{i=1}^{d_j} c_{(j,i)} \frac{1}{n^i}$, where c_j is the constant term, $c_{(j,i)}$ are the other coefficients, and d_j is the degree. Define $A_j = \sum_{i=1}^{d_j} |c_{(j,i)}|$ and observe that

$$|p_j(1/n) - c_j| < \left| \sum_{i=1}^{d_j} c_{(j,i)} \frac{1}{n^i} \right| < \frac{\sum_{i=1}^{d_j} |c_{(j,i)}|}{n} = \frac{A_j}{n}$$

Thus for any ϵ , setting $N_j(\epsilon) = \lceil A_j/\epsilon \rceil$ ensures that

$$n > N_j(\epsilon) \implies |p_j(1/n) - c_j| < \epsilon.$$

Define $N(\epsilon) = \max_{j \in \{1, \dots, m\}} N_j(\epsilon/m)$.

▷ **Claim 27.** Let S_n be defined as $|\sum_{j=1}^m c_j \lambda_j^n|$. For all $\epsilon > 0$,

$$S_n - \epsilon \leq \left| \sum_{j=1}^m p_j(1/n) \lambda_j^n \right| \leq S_n + \epsilon$$

Taking the limit inferior of each term gives us the desired result.

34:20 The Pseudo-Skolem Problem is Decidable

Proof of Claim 27. We write

$$\left| \sum_{j=1}^m p_j(1/n) \lambda_j^n \right| = \left| \sum_{j=1}^m (c_j + p_j(1/n) - c_j) \lambda_j^n \right|,$$

which gives us

$$S_n - \left| \sum_{j=1}^m (p_j(1/n) - c_j) \lambda_j^n \right| \leq \left| \sum_{j=1}^m p_j(1/n) \lambda_j^n \right| \leq S_n + \left| \sum_{j=1}^m (p_j(1/n) - c_j) \lambda_j^n \right|$$

and thus

$$S_n - \sum_{j=1}^m |(p_j(1/n) - c_j) \lambda_j^n| \leq \left| \sum_{j=1}^m p_j(1/n) \lambda_j^n \right| \leq S_n + \sum_{j=1}^m |(p_j(1/n) - c_j) \lambda_j^n|,$$

by elementary properties of sums of absolute values. Observing that λ_j s have absolute value 1, we can reduce the proposition above to

$$S_n - \sum_{j=1}^m |(p_j(1/n) - c_j)| \leq \left| \sum_{j=1}^m p_j(1/n) \lambda_j^n \right| \leq S_n + \sum_{j=1}^m |(p_j(1/n) - c_j)|.$$

Now setting $n > N(\epsilon) = \max_{j \in \{1, \dots, m\}} N_j(\epsilon/m)$, we have $|(p_j(1/n) - c_j)| < \epsilon/m$ for all j , which gives us

$$S_n - \epsilon \leq \left| \sum_{j=1}^m p_j(1/n) \lambda_j^n \right| \leq S_n + \epsilon \quad \triangleleft$$

D Computing real JNF in polynomial time

We discuss how to compute the the real Jordan normal form of A in polynomial time. First compute, in polynomial time, the (complex) Jordan normal form J' and matrices T, T^{-1} such that $A = T J' T^{-1}$ using the algorithm from [4].

Computing J . Suppose, without loss of generality, that

$$J' = \text{diag}(J'_1, J'_2, \dots, J'_{2k-1}, J'_{2k}, J'_{2k+1}, \dots, J'_{2k+z})$$

where for $1 \leq j \leq k$, the Jordan blocks J'_{2j-1} and J'_{2j} have the same dimension and have conjugate eigenvalues $\lambda_j = a_j + b_j i$ and $\bar{\lambda} = a_j - b_j i$, respectively. The blocks $J'_{2k+1}, \dots, J'_{2k+z}$, on the other hand, have real eigenvalues. J is obtained by replacing, for each $1 \leq j \leq k$, $\text{diag}(J'_{2j-1}, J'_{2j})$ with a real Jordan block of the same dimension with $\Lambda = \begin{bmatrix} a & -b \\ b & a \end{bmatrix}$ and keeping the blocks $J'_{2k+1}, \dots, J'_{2k+z}$ unchanged.

Computing P . Let $\kappa(j)$ denote the multiplicity of the Jordan block J'_i for $1 \leq i \leq 2k+z$, and $v_1^1, \dots, v_{\kappa(1)}^1, \dots, v_1^{2k}, \dots, v_{\kappa(2k)}^{2k}, \dots, v_1^{2k+z}, \dots, v_{\kappa(2k+z)}^{2k+z} \in \overline{\mathbb{Q}}^m$ be the columns of T . It will be the case that for all $1 \leq j \leq k$ and l , $v_l^{2j-1} = v_l^{2j}$ in the sense that $v_l^{2j-1} = x_l^j + y_l^j i$ and $v_l^{2j} = x_l^j - y_l^j i$ for vectors $x_l^j, y_l^j \in \mathbb{R}^m$. Moreover, for $j > 2k$, $v_l^{2j} \in \mathbb{R}^m$. Finally, columns of P are obtained from columns of T as follows. For $1 \leq j \leq k$ and all l , replace v_l^{2j-1} with x_l^j and v_l^{2j} with y_l^j and keep v_l^{2k+z} for all l and $m > 0$ unchanged, in the same way the proof of existence of real Jordan normal form proceeds.

Computing P^{-1} . Summarizing the construction above, P is obtained from T by replacing columns $x + yi$ and $x - yi$, $x, y \in \mathbb{R}^m$ by x and y , respectively. Since $x = \frac{1}{2}(x + yi) + \frac{1}{2}(x - yi)$ and $y = -\frac{1}{2}i(x + yi) + \frac{1}{2}i(x - yi)$, this construction is linear and we can write $P = T \cdots A$ for some $A \in \mathbb{C}^{m \times m}$ with entries in $\{\frac{1}{2}, -\frac{1}{2}, \frac{1}{2}i, -\frac{1}{2}i, 1, 0\}$. Moreover, the linear transformation is clearly invertible: $x + yi = 1 \cdot x + iy$ and $x - yi = 1 \cdot x - (-i)y$, and hence $A^{-1} \in \mathbb{C}^{m \times m}$ with entries in $\{1, i, -i\}$. Finally, compute P^{-1} via $P = TA \implies P^{-1} = A^{-1}T^{-1}$, observing that we already know how to compute T^{-1} in polynomial time.

Abstract

Probabilistic complexity classes, despite capturing the notion of feasibility, have escaped any treatment by the tools of so-called implicit-complexity. Their inherently semantic nature is of course a barrier to the characterization of classes like BPP or ZPP, but not all classes are semantic. In this paper, we introduce a recursion-theoretic characterization of the probabilistic class PP, using recursion schemata with pointers.

1 Introduction

Implicit computational complexity aims at introducing and studying characterizations of complexity classes by recursion theory, proof theory, and programming language tools. This has allowed to shed some light on the impact of programming and recursion schemes to resource consumption. As an example, nested recursion on notation is known to be harmful to time complexity, and thus needs to be appropriately controlled if one wants to stay within the realm of polynomial time computable functions, as shown by Bellantoni-Cook and Leivant in their works on safe and tiered recursion [2, 9].

If one wants to go beyond polynomial time, a way of enriching recursion schemes without breaking the correspondence with (relatively small) complexity classes is the use of recursion schemes based on *pointers* [3], which leads to characterizations of NP and FPSPACE (the class of *functions* corresponding to PSPACE), [14, 13].

One family of complexity classes between polytime and polyspace which has so far escaped any implicit treatment are the probabilistic ones. Our goal in this paper is precisely the one of exploring the potential of pointers in recursion-theoretic contexts as a tool to characterize

¹ corresponding author

probabilistic classes of computational complexity. In this work we study PP, the class of decision problems solvable by probabilistic Turing machines in polynomial time with an error probability of less than $\frac{1}{2}$ for all instances. The class PP was originally defined by Gill in [6]. It is well-known that PP contains NP and that it is contained in PSPACE; it is open whether these inclusions are proper or not.

Our strategy consists in extending the existing recursion scheme for NP going towards the one for FSPACE, but without going too far. Surprisingly, this is possible despite the inherently quantitative nature of PP's acceptance criterion. This way, we obtain the first purely recursion-theoretic characterization of the probabilistic class PP.

This characterization is described in two stages, \mathbf{ST}_P and \mathbf{ST}_{PP} , where \mathbf{ST}_P characterizes the class of functions computable in polynomial time by deterministic Turing machines, FPTIME – see [2]. \mathbf{ST}_{PP} results then from “strengthening” \mathbf{ST}_P with a scheme designed to characterize the decision problems of PP. That scheme is the tree-recursion scheme of FSPACE [13], but with a fixed step function. Therefore, the characterization of the class PP given here is aligned with the existing recursion-theoretic characterizations of FPTIME and FSPACE.

2 Algebras, Functions, and Complexity Classes

In this section, we introduce some preliminary concepts that will accompany us in the rest of the paper. In particular, we will show how binary strings and functions over them allow us to capture standard, deterministic classes like FPTIME and FSPACE.

2.1 Algebras and Recursion Schemes

Let us consider the word algebra \mathbb{W} , i.e. the algebra generated by one nullary and two unary constructors, respectively indicated as ϵ , \mathbf{S}_0 and \mathbf{S}_1 . The algebra \mathbb{W} can naturally be interpreted over the set $\{0, 1\}^*$ of all binary words. We abbreviate \mathbf{S}_0x and \mathbf{S}_1x as $x0$ and $x1$, respectively. We consider a predecessor symbol \mathbf{P} of arity 1, and a conditional function symbol \mathbf{C} of arity 4. They are defined as follows: $\mathbf{P}(\epsilon) = \epsilon$, $\mathbf{P}(xi) = x$ and $\mathbf{C}(\epsilon, x, y_0, y_1) = x$, $\mathbf{C}(zi, x, y_0, y_1) = y_i$, $i \in \{0, 1\}$.

Recursion schemes on the algebra \mathbb{W} can be built in two different ways:

1. First of all, one can proceed by *recursion on notation*, namely by building a function f out of g and h by stipulating that $f(\epsilon, \bar{x}) = g(\epsilon, \bar{x})$ and $f(zi, \bar{x}) = h(zi, \bar{x}, f(z, \bar{x}))$, where $i \in \{0, 1\}$;
2. Secondly, one can also build f through *tree-recursion with pointers* from g and h , namely by $f(p, \epsilon, \bar{x}) = g(p, \epsilon, \bar{x})$ and $f(p, zi, \bar{x}) = h(p, zi, \bar{x}, f(p0, z, \bar{x}), f(p1, z, \bar{x}))$, $i \in \{0, 1\}$.

In both the recursion schemes above, g is designated as the *base function* and h as the *step function*. In tree-recursion, the first input of f is called the *pointer*. Noticeably, the characterization of PP presented here results from considering the scheme (2) with a fixed step function. Informally, the step function that we fix is a FPTIME function corresponding to binary addition (we add the number of accepting configurations), but with some nuances in order to capture the probabilistic class PP.

Above and along the paper, \bar{x} abbreviates x_1, \dots, x_n for some natural number n . Moreover, $|\bar{x}| = (|x_1|, \dots, |x_n|)$ where, for $1 \leq k \leq n$, $|x_k|$ denotes the length of x_k , i.e. the number of \mathbf{S}_0 and \mathbf{S}_1 in x_k . We extend these notations to function symbols.

2.2 Capturing Polynomial Time and Space: \mathbf{ST}_P and $\mathbf{ST}_{FPSPACE}$

If either recursion on notation or tree recursion are applied without any restriction, there is no hope to capture interesting complexity classes: in either case we end up capturing the whole class of primitive recursion. From now on, then, we adopt the framework introduced by Bellantoni-Cook [2], which has proved to be quite useful in appropriately restricting function algebras so as to capture small complexity classes. In particular, function terms have two sorts of input positions, dubbed *normal* and *safe*. As is customary, we write normal and safe input positions by this order, separated by semicolon, e.g. in the expression $f(\bar{x}; \bar{y})$, the parameters in \bar{x} are normal while those in \bar{y} are safe.

We are now in a position to define the three closure operators which we will employ in the following, and which will be

► **Definition 1** (Closure Operators). *Let g, h, \bar{r} and \bar{s} be sorted functions. The following are three ways of building a new sorted function term out of (some of) them.*

■ **Sorted Composition**, SC , by which we can build the sorted function f such that

$$f(\bar{x}; \bar{y}) = h(\bar{r}(\bar{x}); \bar{s}(\bar{x}; \bar{y}))$$

■ **Sorted Recursion on Notation**, SR , which allows us to derive the sorted function f by a recursion scheme:

$$f(\epsilon, \bar{x}; \bar{y}) = g(\epsilon, \bar{x}; \bar{y})$$

$$f(z0, \bar{x}; \bar{y}) = h(z0, \bar{x}; \bar{y}, f(z, \bar{x}; \bar{y}))$$

$$f(z1, \bar{x}; \bar{y}) = h(z1, \bar{x}; \bar{y}, f(z, \bar{x}; \bar{y})).$$

■ **Sorted Tree-Recursion**, STR , which derives the sorted function f , again by recursion

$$f(p, \epsilon, \bar{x}; \bar{y}) = g(p, \epsilon, \bar{x}; \bar{y})$$

$$f(p, z0, \bar{x}; \bar{y}) = h(p, z0, \bar{x}; \bar{y}, f(p0, z, \bar{x}; \bar{y}), f(p1, z, \bar{x}; \bar{y}))$$

$$f(p, z1, \bar{x}; \bar{y}) = h(p, z1, \bar{x}; \bar{y}, f(p0, z, \bar{x}; \bar{y}), f(p1, z, \bar{x}; \bar{y}))$$

A few observations about the two recursion operators are helpful now. Please note that, according to the semi-colon discipline, both the *pointer* p and the *recursion variable* z are in normal input positions, while the results of *recursive calls* go into safe input positions. This, in particular, prevents the results of recursive calls to be fed to a function itself defined by recursion on that same variable, ultimately avoiding a blowup in size and complexity.

► **Definition 2** (Function Algebras). *Let \mathcal{I} be the class of function terms including the constructors of \mathbb{W} (i.e. the functions $\epsilon, \mathbf{S}_0, \mathbf{S}_1$), the predecessor \mathbf{P} , the conditional \mathbf{C} , and the projection functions (over both input sorts).*

1. \mathbf{ST}_P is the closure of \mathcal{I} under SC and SR ;
2. $\mathbf{ST}_{FPSPACE}$ is the closure of \mathcal{I} under SC and STR .

As known results one has that:

► **Proposition 3.**

1. \mathbf{ST}_P characterizes $FPTIME$ and $\mathbf{ST}_{FPSPACE}$ characterizes $FPSPACE$ – see, respectively, [2] and [13];
2. $\mathbf{ST}_P \subseteq \mathbf{ST}_{FPSPACE}$, as classes of input-sorted function terms.

Notice that in this framework one can run a recursion over an output of a function which is itself defined by recursion. There are some other properties concerning \mathbf{ST}_P that we use in the paper. We summarize them here for further reference – see [2] and [14], Remark 2.

► Remark 4.

1. Let $f(\bar{x})$ be a polytime function. Then $f(\bar{x};)$ is in \mathbf{ST}_P .
2. For any polynomial (with natural coefficients) q , there exists a term $t \in \mathbf{ST}_P$ such that $\forall \bar{x} \ q(|\bar{x}|) = |t(\bar{x};)|$;
3. For any polytime function F there exist a function term f , in \mathbf{ST}_P , and a monotone polynomial q_F such that $\forall \bar{w} \forall y \ |y| \geq q_F(|\bar{w}|) \Rightarrow F(\bar{w}) = f(y; \bar{w})$.

3 The Algebra \mathbf{ST}_{PP}

In this section, we define a function algebra \mathbf{ST}_{PP} , based on \mathbf{ST}_P and on the tree-recursion scheme with pointers. The main idea behind \mathbf{ST}_{PP} is to constrain $\mathbf{ST}_{FPSPACE}$ in such a way that tree-recursion is restricted to a very specific step function. The next section is devoted to introducing and motivating this function.

3.1 On the \boxplus Function

In the following, we will extensively work with the following FPTIME functions:

- The unary function *read* which, on input w , returns 10 if the last bit of w is 1, and 0 otherwise;
- Addition on binary words *seen as* natural numbers, indicated as $+$. It results from considering the following

0	1	10	11	100	...	(binary words)
↓	↓	↓	↓	↓		
0	1	2	3	4	...	(natural numbers)

and the usual addition over \mathbb{N} , extending it to all binary words assuming that the empty string ϵ and words starting with 0 all correspond to $0 \in \mathbb{N}$. For instance, $+(10, 10) = 100$, while $+(00, 10) = 10$. We use infix notation for $+$;

- The binary function \oplus such that $\oplus(w, v)$ is $read(w) + read(v)$, for which we also use the infix notation. As an example, $01 \oplus 100 \oplus 1 = read(01) + read(100) + read(1) = 10 + 0 + 10 = 100$. The function \oplus only depends on the last bit of its two arguments. Notice that any finite sum $\sum_n read(w_n)$ is always a binary word ending with 0, because for every such binary word w it holds that $read(w)$ is 0 or 10;
- The binary function $\#$ defined as follows:

$$\#(z, w) = \begin{cases} 1 & \text{if } w > 2^{|z|} \\ 0 & \text{otherwise,} \end{cases}$$

where $2^{|z|}$ is the binary representation of the natural number $2^{|z|}$, i.e., it holds that $2^{|\epsilon|} = 1$ and that $2^{|z|} = \mathbf{S}_0(2^{|z|})$.

We reserve the symbol $+$ for the binary addition as described above. Whenever needed, we use $+\mathbb{N}$ to denote the usual addition over the natural numbers. The “greater than” relation defined over binary words ordered by length and, within the same length, lexicographically is indicated as $>$;

Finally, let the function \boxplus be a polytime function satisfying the following equations (where i ranges over $\{0, 1\}$):

$$\begin{aligned} \boxplus(\epsilon, i, w_0, w_1) &= \#(i, w_0 \oplus w_1), \\ \boxplus(p, i, w_0, w_1) &= w_0 \oplus w_1, && \text{if } p \neq \epsilon \\ \boxplus(\epsilon, zi, w_0, w_1) &= \#(zi, w_0 + w_1), && \text{if } z \neq \epsilon, \\ \boxplus(p, zi, w_0, w_1) &= w_0 + w_1, && \text{if } p, z \neq \epsilon, \end{aligned}$$

The conditions imposed now will become clear later. \boxplus is a polytime function. Therefore Remark 4(1) ensures the existence of a term in \mathbf{ST}_P – let us reuse the symbol \boxplus to denote it – such that $\boxplus(p, z, w_0, w_1;) = \boxplus(p, z, w_0, w_1)$. The input-sorted function $\boxplus \in \mathbf{ST}_P$ is used as step function in the tree-recursion scheme.

3.2 The Algebra \mathbf{ST}_{PP}

It is now time to introduce the function algebra which constitutes the main contribution of this paper, and which will be proved to characterize the class \mathbf{PP} in the coming section.

- **Definition 5.** \mathbf{ST}_{PP} is the closure of \mathbf{ST}_P under \mathbf{SC}_P and $\mathbf{TR}[\boxplus]$, where
- **Restricted sorted composition**, \mathbf{SC}_P , allows to build a sorted function f out of h and $\bar{r}, \bar{s} \in \mathbf{ST}_P$ as follows:

$$f(\bar{x}; \bar{y}) = h(\bar{r}(\bar{x}); \bar{s}(\bar{x}; \bar{y}))$$

- **Tree-recursion with step function** \boxplus derives the function f out of $g \in \mathbf{ST}_P$ as follows:

$$\begin{aligned} f(p, \epsilon, \bar{x};) &= g(p, \epsilon, \bar{x};) \\ f(p, z0, \bar{x};) &= \boxplus(p, z0, f(p0, z, \bar{x};), f(p1, z, \bar{x};);) \\ f(p, z1, \bar{x};) &= \boxplus(p, z1, f(p0, z, \bar{x};), f(p1, z, \bar{x};);) \end{aligned}$$

As already noticed, under this input-sorted discipline recursive calls are usually taken as safe arguments of the step function. However, that becomes irrelevant when the recursion scheme imposes a fixed step function – like in $\mathbf{TR}[\boxplus]$. The definition of any function term in \mathbf{ST}_{PP} involves at most one application of $\mathbf{TR}[\boxplus]$. This is a consequence of having the base function of $\mathbf{TR}[\boxplus]$ – g – and the inner functions of \mathbf{SC}_P – \bar{r} and \bar{s} – all in \mathbf{ST}_P .

It is known that $P \subseteq PP \subseteq \mathbf{PSPACE}$. On the term system side we observe that the correspondent inclusions are preserved.

- **Remark 6.** $\mathbf{ST}_P \subseteq \mathbf{ST}_{PP} \subseteq \mathbf{ST}_{\mathbf{FPSPACE}}$, as classes of input-sorted function terms. The first inclusion is obvious, the second makes use of items (2) and (3) of Remark 4.

In the rest of this section, we will explain how the $\mathbf{TR}[\boxplus]$ scheme somehow mimics the acceptance condition underlying \mathbf{PP} . Suppose a function is obtained through $\mathbf{TR}[\boxplus]$ from a base function g ; then its evaluation on an input $(p, z, \bar{x};)$, for $z \neq \epsilon$ gives rise to a tree similar to that in Figure 1, where the pointer p and the recursion input z are omitted. By using them (the first and the second inputs of \boxplus), one is able to obtain different outputs for \boxplus depending on the level it occurs in the tree above. Therefore, according to the definition of \boxplus , one can distinguish two different situations.

- If f is evaluated on arguments in the form $(\epsilon, z, \bar{x};)$, then the tree from Figure 1 becomes the one in Figure 2(a). Again, inputs are omitted. One reads from the leaves, and by performing binary addition at all internal nodes one brings up to the root of the tree the

■ **Figure 1** The unfolding of $f(p, z, \bar{x})$.

■ **Figure 2** The unfolding of $f(p, z, \bar{x})$, depending on the value of p .

information about how many times 1 occurs at the leaves. Notice that the function #, after performing the binary addition operation, returns 1 if the sum meets the threshold (i.e. if strictly more than half of the leaves are labeled by 1) and 0 otherwise.

- If f is evaluated on arguments in the form (p, z, \bar{x}) , where $p \neq \epsilon$, then the tree becomes the one in Figure 2(b). The pointer increases along the paths of the tree. So, the first input of \boxplus does not assume the value ϵ . Therefore, the test function # is not called. Recall that \oplus reads the last bit of the leaves, coding the 1's by 10 (i.e. by the binary representation of 2). It should be clear that all nodes are labeled by strings ending by 0 (because they are binary representation of even numbers). In particular, the value returned to the root of the tree is a 0-1 word ending by 0.

4 ST_{PP} Characterizes PP

In this section, we prove that the algebra ST_{PP} we introduced in the previous section indeed characterizes our target class, namely PP.

We adopt the definition of PP given in [1]. In particular, we consider non-deterministic Turing machines as the underlying model of computation, and we make the assumption that every step of the computation can be made in *exactly two* possible ways. Thus, in the course of the computation, every configuration of the machine has exactly two next configurations. Machines are “clocked” by some constructible function, and the number of steps in each computation is exactly the number of steps allowed by the clock. If a final state is reached before this number of steps, then the computation is continued, doing nothing up to this number of steps. Moreover, every computation ends in a final state, which can be either ACCEPT or REJECT. A *probabilistic Turing machine* M , PTM for short, is a non-deterministic Turing machine as above in which acceptance is defined quantitatively rather than logically: the input \bar{x} is accepted if, and only if, *more than half* of the computations of M on \bar{x} end in the ACCEPT final state.

PP is the class of boolean functions (or languages) computed (resp. accepted) by polynomially clocked PTMs. While PP is a class of two valued functions, \mathbf{ST}_{PP} corresponds to a class of functions whose values can range over binary words. As a consequence, our correspondence theorem will say that $\mathcal{B}(\mathbf{ST}_{\text{PP}})$ coincides with PP, where $\mathcal{B}(\mathbf{ST}_{\text{PP}})$ denotes the boolean part of \mathbf{ST}_{PP} .

4.1 The Lower Bound

In this subsection, we will prove that \mathbf{ST}_{PP} is powerful enough to capture the behavior of any polynomially clocked probabilistic Turing machine. This proves that \mathbf{ST}_{PP} is at least as expressive as our target complexity class.

► **Lemma 7.** *Polynomially clocked PTMs can be simulated by functions in \mathbf{ST}_{PP} .*

Proof. Let M be a PTM which is clocked by some polynomial q (on the length of the input). We are going to simulate M by \mathbf{ST}_{PP} function terms. Let us assume, without any loss of generality, that machine configurations are encoded by binary words so that codes end by the code of the respective state. Codes of accepting final states end by 1 and any other state ends by 0. One may assume that, for a given input \bar{x} , all the configuration codes have the same length, $l(|\bar{x}|)$, which is polynomial on $|\bar{x}|$. Notice that all non-terminating configurations have two successor configurations. Therefore, we can split the transition function δ of M into two δ_0 and δ_1 . Let c be a \mathbf{ST}_{PP} function such that $c(\bar{x};)$ is the code of the initial configuration. Similarly, let t be a \mathbf{ST}_{PP} function such that $|t(\bar{x};)| = q(|\bar{x}|)$. (That t can be defined in \mathbf{ST}_{PP} come from the fact that q is a polynomial, cf. Remark 4(2)). For $i \in \{0, 1\}$, one may consider polytime computable functions Δ_i which, for a given configuration code w , return the next configuration code according to δ_i , or return w itself if there is no next configuration according to δ_i . Thus, by Remark 4(3), there exists a function term $\hat{\Delta}_i$ in \mathbf{ST}_{P} and a polynomial q_{Δ_i} such that $\forall w \forall y \ |y| \geq q_{\Delta_i}(|w|) \Rightarrow \Delta_i(w) = \hat{\Delta}_i(y; w)$. Replacing, in the previous expression, y by $L_{\Delta_i}(\bar{x};)$ one has that $\forall w \forall \bar{x} \ |L_{\Delta_i}(\bar{x};)| \geq q_{\Delta_i}(|w|) \Rightarrow \Delta_i(w) = \hat{\Delta}_i(L_{\Delta_i}(\bar{x};); w)$, where L_{Δ_i} is a \mathbf{ST}_{P} term as follows. Given an input \bar{x} , all configuration codes w satisfy $|w| = l(|\bar{x}|)$ where l is polynomial in $|\bar{x}|$. Thus, $q_{\Delta_i}(|w|)$ is equal to $(q_{\Delta_i} \circ l)(|\bar{x}|)$. The composition of polynomials is a polynomial, and so $q_{\Delta_i} \circ l$ is a polynomial in $|\bar{x}|$. Therefore, by Remark 4(2), there exists a function term L_{Δ_i} in \mathbf{ST}_{P} such that $|L_{\Delta_i}(\bar{x};)| = (q_{\Delta_i} \circ l)(|\bar{x}|)$. Now, recalling that $q_{\Delta_i}(|w|)$ is $(q_{\Delta_i} \circ l)(|\bar{x}|)$, one has $|L_{\Delta_i}(\bar{x};)| \geq q_{\Delta_i}(|w|)$ (thus, a fortiori $|L_{\Delta_i}(\bar{x};)| \geq q_{\Delta_i}(|w|)$). Therefore, for any input \bar{x} , given a configuration code w , $\Delta_i(w) = \hat{\Delta}_i(L_{\Delta_i}(\bar{x};); w)$ where $\hat{\Delta}_i$ and L_{Δ_i} are in \mathbf{ST}_{P} . This means that (reusing the symbol Δ_i) we can consider a function term $\Delta_i(\bar{x}; w) = \hat{\Delta}_i(L_{\Delta_i}(\bar{x};); w)$ in \mathbf{ST}_{P} , which for any input \bar{x} and a given configuration code w returns the next configuration code according to δ_i . Let us define an auxiliary sorted function, called *RUN*. *RUN* is defined, in \mathbf{ST}_{P} , by SR. For a path p and a (initial) configuration code $c(\bar{x};)$, *RUN* simulates the (sequential) computation performed by M along the branch p starting with the configuration code $c(\bar{x};)$.

$$\begin{aligned} \text{RUN}(\epsilon, \bar{x};) &= c(\bar{x};) \\ \text{RUN}(p0, \bar{x};) &= \Delta_0(\bar{x}; \text{RUN}(p, \bar{x};)) \\ \text{RUN}(p1, \bar{x};) &= \Delta_1(\bar{x}; \text{RUN}(p, \bar{x};)) \end{aligned}$$

Let us consider the function f defined by $\text{TR}[\boxplus]$ in \mathbf{ST}_{PP} :

$$\begin{aligned} f(p, \epsilon, \bar{x};) &= \text{RUN}(p, \bar{x};) \\ f(p, z0, \bar{x};) &= \boxplus(p, z0, f(p0, z, \bar{x};), f(p1, z, \bar{x};);) \\ f(p, z1, \bar{x};) &= \boxplus(p, z1, f(p0, z, \bar{x};), f(p1, z, \bar{x};);). \end{aligned}$$

By construction, one has that $M(\bar{x}) = f(\epsilon, t(\bar{x};), \bar{x};)$. ◀

As a consequence, one can prove the following.

► **Proposition 8.** *PP is contained in $\mathcal{B}(\mathbf{ST}_{PP})$.*

Proof. Any boolean function in PP can by definition be computed by a polynomially clocked PTM. It is thus immediate to conclude, from the previous lemma, that PP is contained in $\mathcal{B}(\mathbf{ST}_{PP})$. ◀

Before moving to the dual result, it is instructive to take a further look at how Lemma 7 is proved. Actually, closure of \mathbf{ST}_{PP} by $\text{TR}[\boxplus]$ is exploited just once. However, that single use of $\text{TR}[\boxplus]$ takes a non-boolean function as base function. So, although PP is a class of boolean functions, the non-boolean functions of the algebra play a crucial role in the characterization. To show that the boolean functions of the algebra, whose definitions involve $\text{TR}[\boxplus]$ with arbitrary polytime base functions, remain within the complexity class PP is nontrivial, and is essentially what we are going to prove in the next section.

4.2 The Upper Bound

Knowing that \mathbf{ST}_P characterizes FPTIME, it is clear that $\mathcal{B}(\mathbf{ST}_P)$ – which corresponds to P, the class of the polytime boolean-functions – is contained in PP. But how about the inclusion between $\mathcal{B}(\mathbf{ST}_{PP})$ and PP? This is precisely what we are going to prove in this section.

We first of all need the following lemma, which tells us, essentially, that $\text{TR}[\boxplus]$ makes sense from the point of view of the class PP. In this statement only boolean base functions are considered.

► **Lemma 9.** *Let G be in P and let F be a function defined as follows:*

$$\begin{aligned} F(p, \epsilon, \bar{x}) &= G(p, \epsilon, \bar{x}) \\ F(p, z0, \bar{x}) &= \boxplus(p, z0, F(p0, z, \bar{x}), F(p1, z, \bar{x})) \\ F(p, z1, \bar{x}) &= \boxplus(p, z1, F(p0, z, \bar{x}), F(p1, z, \bar{x})). \end{aligned}$$

Then the function F_ϵ defined as $F_\epsilon(z, \bar{x}) = F(\epsilon, z, \bar{x})$, is in PP. Moreover, if G is computable in time t_G (on the sum of the length of its inputs), then $F(\epsilon, z, \bar{x})$ is clocked by $c \cdot |z| +_{\mathbb{N}} t_G(|p| +_{\mathbb{N}} |z| +_{\mathbb{N}} \sum_i |x_i|) +_{\mathbb{N}} 1$, for some constant c .

Proof. In order to compute F_ϵ it is enough to compute something with the following structure

where G is in P and, at each step, the first input (pointer) increases one bit and the second input (recursion input) decreases one bit. At the root of the tree the pointer is ϵ , and at all leaves the recursion input is ϵ . Therefore, what we really have is

Intuitively this is clearly in PP. In order to prove it we consider PTMs with as many tapes as the arity of F (and G). We also assume that each component of the input is placed in one of the tapes (by the order that they show up), i.e. the n -th input is on the n -th tape, and that the machines are initialized with the heads scanning the right most non-empty cell (if there is one).

Let BRANCH be a TM with initial state q_B , which works according to two transition functions – Left and Right. Informally speaking, Left adds the bit “0” at the end of the first input (in the first tape), and deletes the last bit of the second input (in the second tape). The heads move one cell to the right and one cell to the left, respectively. Right proceeds in an analogous way, but adds the bit “1”. This can be done in constant time.

G is in P, so there exists a deterministic TM, M_G , which computes the boolean function G , let us say, in time bounded by t_G . We denote by q_G the initial state of M_G , and we assume that the output – 0 or 1 – is written in the last tape.

A PTM for F , M_F , can then be described as follows:

- (1) if the head of the second tape scans ϵ , go to (3);
otherwise, go to state q_B and (2);
- (2) run BRANCH and (1);
- (3) go to state q_G and (4);
- (4) run M_G .

We say that final configurations of M_F are accepting configurations if, and only if, the rightmost bit of the last tape is 1.

To determine the computing time of M_F notice that the only possibility of going into a loop is when an instruction calls a previous one, i.e. in (2). Moreover, notice that, inputting p, z, \bar{x} to the machine, (1) is called $|z|$ -times, and each loop uses constant time. Therefore, before reaching the instruction (3) the machine performs $c \cdot |z|$ steps, for some constant c . (3) is one step, and (4) uses, at most, t_G steps (notice that the inputs change along the process, but the sum of their lengths remains constant). Thus M_F runs in time bounded by $c \cdot |z| +_{\mathbb{N}} t_G(|p| +_{\mathbb{N}} |z| +_{\mathbb{N}} \sum_i |x_i|) +_{\mathbb{N}} 1$.

M_F accepts (ϵ, z, \bar{x}) if, and only if, more than half of the computations of M_F on (ϵ, z, \bar{x}) end in the ACCEPT final state. Noticing that M_F final configurations are M_G final configurations, we have that M_F accepts (ϵ, z, \bar{x}) if, and only if, more than half of $G(p, \epsilon, \bar{x})$ with $|p| = |z|$ end by 1. Abbreviate $0 \cdots 0$ and $1 \cdots 1$, of length $|z|$, by $0^{|z|}$ and $1^{|z|}$ respectively. Considering the lexicographic order, between $0^{|z|}$ and $1^{|z|}$ we have all 0 – 1 words with $|z|$ bits. There are $2^{|z|}$ different paths p of length $|z|$. So, M_F accepts (ϵ, z, \bar{x}) if, and only if², $\sum_{p=0^{|z|}}^{1^{|z|}} \text{last-bit of } G(p, \epsilon, \bar{x}) > \frac{2^{|z|}}{2}$, or equivalently, if and only if $\sum_{p=0^{|z|}}^{1^{|z|}} 2 \cdot \text{last-bit of } G(p, \epsilon, \bar{x}) > 2^{|z|}$. This is exactly what TR[⊕] tests: \oplus doubles the last bit of it inputs and add them; $+$ adds the inputs; and $\#$ (at the root of the tree) tests whether the global sum (i.e. $\sum_{p=0^{|z|}}^{1^{|z|}} 2 \cdot \text{last-bit of } G(p, \epsilon, \bar{x})$) is greater than $2^{|z|}$ – it returns 1 if YES, and 0 otherwise. ◀

² In numeric notation.

35:10 The Probabilistic Class PP

Let us now show that any boolean function in \mathbf{ST}_{PP} can be seen as one in the class PP.

► **Proposition 10.** $\mathcal{B}(\mathbf{ST}_{PP})$ is contained in PP.

Proof. It is enough to show that, for all $f \in \mathbf{ST}_{PP}$, the function F such that $F(\bar{x}, \bar{y})$ is 1 if $f(\bar{x}; \bar{y})$ ends by 1, and $F(\bar{x}, \bar{y}) = 0$ otherwise, is in PP. We prove this by induction on the definition of the function terms inside \mathbf{ST}_{PP} .

Whenever the scheme $\text{TR}[\boxplus]$ is not involved in the definition of f , one has that $f \in \mathbf{ST}_P$ and therefore the result is immediate. Thus, the relevant cases are the ones where the $\text{TR}[\boxplus]$ is used in the definition of the function term. There are two cases:

■ First of all, let f be defined by $\text{TR}[\boxplus]$ with base function $g \in \mathbf{ST}_P \subseteq \mathbf{ST}_{PP}$. Let $G \in \text{PP}$ be given by induction hypothesis. Consider

$$F(p, z, \bar{x}) = \begin{cases} G(p, \epsilon, \bar{x}) & \text{if } z = \epsilon \\ 0 & \text{if } p, z \neq \epsilon \\ f(\epsilon, z, \bar{x};) & \text{if } p = \epsilon \wedge z \neq \epsilon. \end{cases}$$

F results from easy case distinctions involving three functions: G and the constant function equal to 0 are in PP. Notice that for $z \neq \epsilon$, $f(\epsilon, z, \bar{x};) = \text{TR}[\boxplus](g)(\epsilon, z, \bar{x};) = \text{TR}[\boxplus](\text{last-bit of } g)(\epsilon, z, \bar{x};)$, where **last-bit of** w is $\mathbf{C}(w, 0, 0, 1;)$. g belongs to FPTIME , so **last-bit of** g is a boolean function in P. Thus, for $z \neq \epsilon$, $f(\epsilon, z, \bar{x};)$ is equal to a function $-\text{TR}[\boxplus](\text{last-bit of } g)(\epsilon, z, \bar{x};) -$ which is in PP due to Lemma 9. So, $F \in \text{PP}$. It remains to prove that

$$F(p, z, \bar{x}) = \begin{cases} 1 & \text{if } f(p, z, \bar{x};) \text{ ends by 1} \\ 0 & \text{otherwise.} \end{cases}$$

Let us further distinguish three sub-cases:

1. If $z = \epsilon$, then

$$F(p, \epsilon, \bar{x}) = G(p, \epsilon, \bar{x}) = \begin{cases} 1 & \text{if } g(p, \epsilon, \bar{x};) \text{ ends by 1} \\ 0 & \text{otherwise} \end{cases} = \begin{cases} 1 & \text{if } f(p, \epsilon, \bar{x};) \text{ ends by 1} \\ 0 & \text{otherwise.} \end{cases}$$

2. If $p, z \neq \epsilon$, then $f(p, z, \bar{x})$ is the value returned to the root of a tree as described in Figure 2(b) of Section 3, because the function $\#$ is not involved (the pointer only increases along the recursion, therefore if it is not ϵ at the root, it is never ϵ). Thus, as explained in Section 3, the value returned to root of the tree is the binary representation of an even number. Therefore, $f(p, z, \bar{x})$ does not end by the bit 1. Consequently, in this case, $F(p, z, \bar{x}) = 0$.

3. If $p = \epsilon$ and $z \neq \epsilon$ then, noticing that $f(\epsilon, z, \bar{x};)$ is a single bit, we have that

$$F(\epsilon, z, \bar{x}) = f(\epsilon, z, \bar{x};) = \begin{cases} 1 & \text{if } f(p, \epsilon, \bar{x};) \text{ ends by 1} \\ 0 & \text{otherwise.} \end{cases}$$

Hence, the function $F \in \text{PP}$ defined above, is 1 if f ends by 1, and it is 0 otherwise.

■ If f is defined by SC_P , let us say $f(\bar{x}; \bar{y}) = h(\bar{r}(\bar{x};); \bar{s}(\bar{x}; \bar{y}))$ with $\bar{r}, \bar{s} \in \mathbf{ST}_P$. By induction hypothesis for h , the function H such that $H(\bar{x}, \bar{y})$ is 1 if $h(\bar{x}; \bar{y})$ ends by 1, $H(\bar{x}, \bar{y}) = 0$ otherwise, is in PP. Let M_H be a PTM computing H in polynomial time p_H . \bar{r}, \bar{s} are in \mathbf{ST}_P , so let $M_{\bar{r}}$ and $M_{\bar{s}}$ be the correspondent deterministic Turing machines working in polynomial time. One may define the desired machine for F in the obvious way. First

running the deterministic polytime machines $M_{\bar{r}}$ and $M_{\bar{s}}$ in order to produce the input $(\bar{r}(\bar{x}); \bar{s}(\bar{x}; \bar{y}))$. Let us say that this is done in time dominated by $p_{\bar{r}, \bar{s}}(|\bar{x}|, |\bar{y}|)$. Second, running M_H on this input. The resulting machine is a PTM which computes F and works in time dominated by $p_{\bar{r}, \bar{s}}(|\bar{x}|, |\bar{y}|) +_{\mathbb{N}} p_H(|\bar{r}(\bar{x})|, |\bar{s}(\bar{x}; \bar{y})|)$. Evoking now the monotonicity of the polynomials and knowing that the length of \mathbf{ST}_P functions (i.e. FPTIME functions) is polynomial bounded – let us say $|\bar{r}(\bar{x})| \leq q_{\bar{r}}(|\bar{x}|)$ and $|\bar{s}(\bar{x}; \bar{y})| \leq q_{\bar{s}}(|\bar{x}|, |\bar{y}|)$ for some polynomials $q_{\bar{r}}$ and $q_{\bar{s}}$ – we have that the working time of M_F , on the input \bar{x}, \bar{y} , is bounded by the polynomial $p_{\bar{r}, \bar{s}}(|\bar{x}|, |\bar{y}|) +_{\mathbb{N}} p_H(q_{\bar{r}}(|\bar{x}|), q_{\bar{s}}(|\bar{x}|, |\bar{y}|))$.

This finishes the proof. \blacktriangleleft

4.3 Wrapping Up

From Proposition 8 and Proposition 10 one concludes that

► **Theorem 11.** \mathbf{ST}_{PP} characterizes PP (i.e. $PP = \mathcal{B}(\mathbf{ST}_{PP})$).

This establishes a purely recursion theoretic characterization of the probabilistic class of complexity PP by adding a specific form of tree-recursion to \mathbf{FPTIME} functions. One should notice that the step function of the tree-recursion makes use of the pointer p and the recursion variable z . The same happens in the characterization of $\mathbf{FPSPACE}$ given in [13], but it contrasts with the similar characterization of \mathbf{NP} given in [14]. For \mathbf{NP} the tree-recursion scheme is actually a tree-iteration scheme, i.e. pointers and recursion variable are used only at the bottom (and not all the way along the tree). There the pointers and recursion variable are not taken as inputs of the step function. It is, for instance, not known which class one obtains by restricting the tree-recursion of [13] to tree-iteration.

Whenever working with the tree-recursion scheme or with restricted forms of it, as it is the case here and in the papers mention above, one adopts \mathbb{W} (i.e. 0 – 1 words) as base algebra, instead of \mathbb{N} . The pointers and the tree-recursion scheme have a natural formulation over \mathbb{W} , but the present work can be rewritten in numeric notation. Actually, the seminal paper of Bellantoni and Cook for \mathbf{FPTIME} [2], which uses recursion on notation only, is in numeric notation.

A similar characterization of PP can be obtained working in a non-sorted context, by use of explicit bounds on the recursion on notation scheme. Such formulation of PP is based on Cobham’s characterization of \mathbf{FPTIME} [4] and uses the $\mathbf{TR}[\boxplus]$ scheme neglecting the “;”. There is no need of imposing explicit bounds to the non-sorted version of $\mathbf{TR}[\boxplus]$, because due to the fixed step function the scheme is implicitly polynomial bounded.

5 Related Work

The recursion-theoretic approach to implicit computational complexity has proved to be remarkably robust, with many different classes between logarithmic and polynomial space characterized by various forms of recursion schemes [2, 9, 10, 11, 12, 13, 14]. Tree recursion with pointers, in particular, is known to be capable of capturing classes larger than \mathbf{P} . But no probabilistic class of complexity was known to admit a recursion-theoretic characterization, so our result is certainly novel. With the given syntactic approach, one cannot expect to capture truly semantic classes like \mathbf{BPP} and \mathbf{ZPP} , but it may serve as a recursion-theoretic substratum for characterizations of these classes. In addition, it may provide as basis for proof-theoretic characterizations as provided for \mathbf{FPTIME} and related classes by Strahm [15] or for the polynomial hierarchy of functions in [8].

Other logical approaches to computational complexity have faced the challenge of characterizing probabilistic classes. As an example, a study of randomization and derandomization in descriptive complexity is due to Eickmeyer and Grohe [5], who were also able to characterize BPP in fixed-point logic with counting. The relationships between theories of bounded arithmetic and probabilistic complexity classes have been studied by Jerábek [7]. The present work complements these approaches by exploiting the framework of safe/tiered recursion [2, 9].

Parallel Polynomial Permanent Mod Powers of 2 and Shortest Disjoint Cycles

Samir Datta ✉

Abstract

We present a parallel algorithm for permanent mod 2^k of a matrix of univariate integer polynomials. It places the problem in $\oplus L \subseteq NC^2$. This extends the techniques of Valiant [26], Braverman, Kulkarni and Roy [3] and Björklund and Husfeldt [2] and yields a (randomized) parallel algorithm for shortest two disjoint paths improving upon the recent (randomized) polynomial time algorithm [2].

We also recognize the disjoint paths problem as a special case of finding disjoint cycles, and present (randomized) parallel algorithms for finding a shortest cycle and shortest two disjoint cycles passing through any given fixed number of vertices or edges.

1 Introduction

The problem of computing the determinant of a matrix has been a very well studied problem in the past, and several fast (both sequential and parallel) algorithms are known. On the contrary, Valiant in his seminal paper [26] showed that computing permanent of a matrix, an algebraic analogue of determinant, is hard. However modulo 2, determinant and permanent are equal and so building up on this, he presented an algorithm for computing permanent of an integer matrix modulo small powers of 2. The algorithm uses Gaussian elimination which is known to be highly sequential and so it is desirable to have a parallel algorithm. This was resolved by [3] who presented a $\oplus L \subseteq NC$ algorithm.

Moreover, NC algorithms for computing determinant of matrices over arbitrary commutative rings are also known, e.g. [18]. We would like to ask a similar question for the permanent. One natural extension would be to consider the ring of polynomials with integer coefficients. In this paper, we present an NC algorithm to compute permanent of matrices over integer polynomials modulo 2^k for any fixed k .

► **Theorem 1.** *Let $k \geq 1$ be fixed and A be an $n \times n$ matrix of integer polynomials, such that the degree of each entry is at most $\text{poly}(n)$. We can compute $\text{perm}(A) \pmod{2^k}$ in $\oplus L \subseteq NC^2$*

In the second half of the paper, we consider some applications of our parallel polynomial permanent algorithm. One direct consequence is that we are now able to parallelize the shortest two disjoint paths problem [2]. Furthermore, we generalize this problem by adding more constraints on the disjoint paths - that the paths should pass through any given set of edges. This can also be viewed as a problem of finding two disjoint cycles, for which we present a randomized parallel algorithm, using the techniques from [28] and [2].

► **Theorem 2.** *Let $k \geq 1$ be fixed and G be an undirected graph with k marked vertices. We can find shortest two disjoint cycles passing through the marked vertices in $\oplus\text{L}/\text{poly}$ (and RNC).*

Finally, we notice that a similar approach gives us an algorithm to compute Hafnians modulo 2^k of symmetric matrices of integers. Unfortunately, unlike the case of the permanent, we weren't able to extend this to a parallel algorithm. But nevertheless it gives a direct proof of the fact that counting number of perfect matchings modulo 2^k , in any general graph, is in P, as proved in [3].

1.1 Historical Survey

The problem of computing permanent of an integer matrix was first shown to be NP-hard by Valiant, where he also presented a $O(n^{4k-3})$ running time algorithm to compute permanent modulo 2^k . It was also shown that computing permanent modulo any odd prime still remains hard. Zanko [29] gave a proof for hardness of permanent under many-one reductions strengthening the result from the weaker Turing reductions used by Valiant. Later, Braverman, Kulkarni and Roy [3] presented a parallel $\oplus\text{SPACE}(k^2 \log n)$ algorithm for computing permanent modulo 2^k . Björklund and Husfeldt [2] presented a $d^3 n^{O(k)}$ time algorithm to compute permanent modulo 2^k of matrices over integer polynomials where the entries are of degree at most d .

Finding k disjoint paths in a graph has been a well studied problem in the past: given a graph (undirected/directed) and k pairs of terminals $(s_i, t_i)_{1 \leq i \leq k}$, find k pairwise vertex-disjoint paths P_i from s_i to t_i , if they exist.

When k is not fixed (and is part of input) then the problem is known to be NP-hard even for undirected planar graphs [16]. Linear time algorithms are known when further restricting directed planar graphs to the case: when all terminals lie on outer face [25], or when all the s_i -terminals lie on one common face while all the t_i -terminals lie on another common face [22]. If we further ask for paths with minimal total length in the latter problem, then [7] presented a $O(kn \log n)$ running time algorithm to achieve the same.

When k is fixed, the problem remains NP-hard for directed graphs, even for $k = 2$ [11], who had also given a poly time algorithm for the restricted case of directed acyclic graphs. In the restricted setting of directed planar graphs, [24] presented a $n^{O(k)}$ running time algorithm, which was further improved to a fixed parameter tractable algorithm by [4].

Shifting our focus to undirected graphs, the celebrated work of Robertson and Seymour [23] gave a $O(n^3)$ algorithm for finding k disjoint paths in an undirected graph, for any fixed k . [6] gave a parallel algorithm for class of planar graphs where all the terminals lie either on one or two faces. All this while, the question of finding *shortest* disjoint paths in general undirected graphs, remained open for many years until recently, Björklund and Husfeldt [2] gave a polynomial time algorithm for finding the shortest two disjoint paths. For general k , this problem still remains open. Björklund and Husfeldt also gave a parallel algorithm to count shortest two disjoint paths but only for cubic planar graphs [1].

1.2 Our Techniques

To compute permanent of a matrix A over integer polynomials, we closely follow the analysis of [3] but immediately hit an obstacle. They give a reduction from $\text{perm}(A) \pmod{4}$ to several computations of $\text{perm}(\cdot) \pmod{2}$, which crucially uses the fact that \mathbb{Z}_2 is a field. More precisely, when mimicking the proof, firstly it is required to find a non-trivial solution of $Av = 0$ with the property that at least one of the entries of this vector is invertible. This fails¹ over $\mathbb{Z}_2[x]$. Moreover, their algorithm also uses the fact that a non-singular matrix admits a LU decomposition iff all the leading principal minors are non-zero, which is known to hold in general only for matrices over fields.

Therefore, replacing \mathbb{Z}_{2^k} with $\mathbb{Z}_{2^k}[x]$ in their analysis doesn't work as $\mathbb{Z}_2[x]$ isn't a field while \mathbb{Z}_2 is. Furthermore, any finite field \mathbb{F} of characteristic 2 only corresponds to modulo 2 arithmetic. We need a way to extend the field structure so that it supports modulo 2^k arithmetic as well. If \mathbb{F} was realized as $\mathbb{Z}_2[x]/(p(x))$ where $p(x)$ is irreducible over \mathbb{Z}_2 then a possible candidate is the ring $\mathbb{Z}[x]/(2^k, p(x))$. Therefore, the appropriate algebraic structure to consider would be the ring $\mathfrak{R} = \mathbb{Z}[x]/(p(x))$.

Now we see that replacing \mathbb{Z} with \mathfrak{R} solves the above mentioned problems in the analysis, primarily because of the fact that $\mathfrak{R} \pmod{2}$ is a finite characteristic 2 field. With a slight bit of modification in the proof, we achieve that: given a matrix A over \mathfrak{R} , we can find $\text{perm}(A) \pmod{2^k}$ or in other words if A is a matrix over $\mathbb{Z}[x]$, we can compute $\text{perm}(A) \pmod{2^k, p(x)}$.

We are still not done because our aim was to compute $\text{perm}(A) \pmod{2^k}$ over $\mathbb{Z}[x]$. To achieve that, we choose $p(x)$ such that its degree is larger than the degree of polynomial $\text{perm}(A)$. This requires doing computations over a large field. Alternatively, we develop a new way of interpolation over \mathfrak{R} , which allows us to choose $p(x)$ such that its degree is of logarithmic order of degree $\text{perm}(A)$, but with a tradeoff of computing several (polynomially many) more permanents. We present this technique for its novelty.

Wahlström [28] addressed the question of finding a cycle passing through given vertices. We ask if we can also find shortest such cycle. And furthermore, can we also find shortest two disjoint cycles passing through these vertices? We combine techniques of [28] and [2] to answer the above questions, by reducing them to computing permanents modulo 2 of 2^{k-1} and modulo 4 of $2^{k-1} + 2^{k-2}$ matrices respectively. These matrices are adjacency matrix of what we refer to as *pattern* graphs. Notice that for $k = 2$ finding shortest two disjoint cycles corresponds to finding shortest two disjoint paths (by connecting each pair of terminals with a common vertex), and in this case our pattern graphs are exactly those presented in [2].

1.3 Organization of the Paper

In section 2, we first introduce the preliminaries and the notation that we shall be using throughout this paper. In the next section 3, we present proof of our main theorem 1 about computing permanent modulo 2^k , following which we also discuss the complexity of certain computations over the ring \mathfrak{R} which shows that our algorithm is in $\oplus\text{L}$. We also present an alternative proof for our main theorem in section 4 which uses new techniques. Then we present applications of our result that is finding shortest disjoint cycles, in section 5.

Finally, we discuss an example of our permanent algorithm and we show that using the same techniques as above we can also compute Hafnians and hence it gives an alternate proof of the already known result that counting perfect matchings modulo 2^k is in P. These are listed in the appendix for lack of space.
