A

 Proofs of Corollary 28 and Proposition 29

A.1 Proof of Corollary 28

We just substitute the upper bounds

$$d \leq N^{N-1} \quad \text{and} \quad h(P) \leq N^{2N^{N^2}}$$

from Corollary 24 on d and H , respectively, in the parameters of Lemma 26 and also recall Remark 27. We note that we use some crude inequalities to simplify the bound.

More precisely, one verifies that for $N \geq 4$ we have

$$41 \times 3^{2N} 2^{-N+1} N^{-1} \leq 2^{5N}.$$

Hence, in Lemma 26 we can now take

$$c_0 \leq 41 \times 3^{2N} 2^{-N+1} D^{N+1} N^{2N-1} \leq 2^{5N} D^{N+1} N^{2N}. \quad (30)$$

Furthermore, simple calculus shows that $\ln(9x) \leq x$ for $x \geq 4$, hence

$$\ln(9DN) \leq DN.$$

Using this and the trivial bounds

$$1 + 6D \leq 2^3 D \quad \text{and} \quad 1 + 6N \leq 2^3 N,$$

66:18 Sets of Linear Forms Which Are Hard to Compute

we now obtain

$$\begin{aligned}
c_1 &= 2^{2-N} 3^{2N+1} D^{N+1} N^N + (1+6D) 2^{4-N} 3^{2N} D^N N^N \ln(9ND) \\
&\quad + 2^{4-N} 3^{2N} D^{N+1} N^N (1+6N) \ln \mathfrak{h}_a(\alpha), \\
&\leq 2^{2-N} 3^{2N+1} D^{N+1} N^N + 2^{7-N} 3^{2N} D^{N+2} N^{N+1} \\
&\quad + 2^{7-N} 3^{2N} D^{N+1} N^{N+1} \ln \mathfrak{h}_a(\alpha), \\
&\leq (2^{2-N} 3^{2N+1} D^{-1} N^{-1} + 2^{7-N} 3^{2N}) D^{N+2} N^{N+1} \\
&\quad + 2^{7-N} 3^{2N} D^{N+1} N^{N+1} \ln \mathfrak{h}_a(\alpha) \\
&\leq (2^{-N} 3^{2N+1} + 2^{7-N} 3^{2N}) D^{N+2} N^{N+1} \\
&\quad + 2^{7-N} 3^{2N} D^{N+1} N^{N+1} \ln \mathfrak{h}_a(\alpha).
\end{aligned}$$

Since, for $N \geq 4$, we have

$$2^{-N} 3^{2N+1} + 2^{7-N} 3^{2N} = (3+128) 2^{-N} 3^{2N} = 131 \times 2^{-N} 3^{2N} \leq 2^{4N}$$

and certainly the same bound for just the second term $2^{7-N} 3^{2N}$, we derive

$$c_1 \leq 2^{4N} D^{N+1} N^{N+1} (D + \ln \mathfrak{h}_a(\alpha)). \quad (31)$$

Finally, for c_2 , using $1+6D \leq 8D$ we have

$$c_2 = 2^{7-N} 3^{2N} D^{N+1} N^N \leq 2^{4N} D^{N+1} N^N. \quad (32)$$

We now collect (30), (31) and (32) and obtain

$$\begin{aligned}
c_0 d^N &\leq 2^{5N} N^{2N} D^{N+1} N^{N(N-1)} = 2^{5N} D^{N+1} N^{N^2+N}, \\
c_1 d^N &\leq 2^{4N} N^{N+1} D^{N+1} (D + \ln \mathfrak{h}_a(\alpha)) N^{N(N-1)} \\
&\quad = 2^{4N} D^{N+2} N^{N^2+1} + 2^{4N} D^{N+1} N^{N^2+1} \ln \mathfrak{h}_a(\alpha), \\
c_2 d^N \ln d &\leq 2^{4N} N^N D^{N+1} N^{N(N-1)} (N-1) \ln N \leq 2^{4N} D^{N+1} N^{N^2+1} \ln N.
\end{aligned}$$

Therefore, we have the inequality

$$\begin{aligned}
c_1 d^N + c_2 d^N \ln d + 72 \max\{1, \mathfrak{h}_a(\alpha)\} \\
\leq 2^{4N} D^{N+2} N^{N^2+1} + 2^{4N} D^{N+1} N^{N^2+1} \ln N \\
+ \left(2^{4N} D^{N+1} N^{N^2+1} + 72 \right) \max\{1, \mathfrak{h}_a(\alpha)\}. \quad (33)
\end{aligned}$$

We now observe that

$$2^{4N} D^{N+2} N^{N^2+1} + 2^{4N} D^{N+1} N^{N^2+1} \ln N \leq 2^{4N+1} D^{N+2} N^{N^2+2} \ln N$$

and

$$2^{4N} D^{N+1} N^{N^2+1} + 72 \leq 2^{4N+1} D^{N+1} N^{N^2+1} \leq 2^{4N+1} D^{N+1} N^{N^2+1} \ln N.$$

Hence, the inequality (33) simplifies as follows:

$$\begin{aligned}
c_1 d^N + c_2 d^N \ln d + 72 \max\{1, \mathfrak{h}_a(\alpha)\} \\
\leq 2^{4N+1} D^{N+1} N^{N^2+2} (D + \max\{1, \mathfrak{h}_a(\alpha)\}) \ln N,
\end{aligned}$$

and thus,

$$\exp(c_1 d^N + c_2 d^N \ln d + 72 \max\{1, \mathfrak{h}_a(\boldsymbol{\alpha})\}) \leq N^{2^{4N+1} D^{N+1} N^{N^2+2} (D + \max\{1, \mathfrak{h}_a(\boldsymbol{\alpha})\})}.$$

Finally

$$\ln H = \ln h(P) \leq 2N^{N^2} \ln N$$

and we conclude

$$\begin{aligned} \ln H + \exp(c_1 d^N + c_2 d^N \ln d + 72 \max\{1, \mathfrak{h}_a(\boldsymbol{\alpha})\}) \\ \leq 2N^{2^{4N+1} D^{N+1} N^{N^2+2} (D + \max\{1, \mathfrak{h}_a(\boldsymbol{\alpha})\})}. \end{aligned}$$

Therefore, combining this bound with the above bound on $c_0 d^N$, by Lemma 26 we have

$$\ln |Q(e^{\alpha_1}, \dots, e^{\alpha_N})| \geq -2^{5N+1} D^{N+1} N^{N^2+N} N^{2^{4N+1} D^{N+1} N^{N^2+2} (D + \max\{1, \mathfrak{h}_a(\boldsymbol{\alpha})\})}.$$

Elementary calculus shows that for $N \geq 4$ we have

$$2^{5N+1} D^{N+1} N^{N^2+N} \leq N^{2^{4N+1} D^{N+1} N^{N^2+1}}.$$

Hence

$$\begin{aligned} \ln |Q(e^{\alpha_1}, \dots, e^{\alpha_N})| &\geq -N^{2^{4N+2} D^{N+1} N^{N^2+2} (D + \max\{1, \mathfrak{h}_a(\boldsymbol{\alpha})\})} \\ &\geq -N^{2^{5N} D^{N+1} N^{N^2+2} (D + \max\{1, \mathfrak{h}_a(\boldsymbol{\alpha})\})}, \end{aligned}$$

and the result follows.

A.2 Proof of Proposition 29

Since $[\mathbb{Q}(\alpha^{1/N}) : \mathbb{Q}] = N$, we see that $\alpha_k = \alpha^{k/N}$, $k = 1, \dots, N$, are linearly independent over \mathbb{Q} and $\mathbb{Q}(\alpha_1, \dots, \alpha_N) = \mathbb{Q}(\alpha_N)$. Thus, for D in Corollary 28 we have $D = N$.

Let $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_N)$. By definition, $h(\boldsymbol{\alpha}) = \alpha$. We contend that $\mathfrak{h}_a(\boldsymbol{\alpha}) = \alpha$ as well.

Since all α_k , $k = 1, \dots, N$, are algebraic integers, their p -adic norms are less than 1. Therefore,

$$\mathfrak{h}_a(\boldsymbol{\alpha}) = \prod_{\nu|\infty} \max_{1 \leq k \leq N} \{1, |\alpha_k|_\nu\}^{D_\nu/N},$$

where (in this context) ∞ denotes the Archimedean value on \mathbb{Q} .

Since for all $\nu | \infty$ and all $k = 1, \dots, N$,

$$\max\{1, |\alpha_k|_\nu\} = \alpha_k = \alpha^{k/N}$$

and by [6, Corollary 1, Section II.1]

$$\sum_{\nu|\infty} D_\nu = N,$$

we derive

$$\mathfrak{h}_a(\boldsymbol{\alpha}) = \prod_{\nu|\infty} \alpha^{D_\nu/N} = \alpha.$$

66:20 Sets of Linear Forms Which Are Hard to Compute

Now, the result follows from Corollary 18 with $\mathfrak{Q} = \mathfrak{Q}_{m,n}$, Corollary 25 and Corollary 28 by simple calculations.

Indeed, let

$$\delta_{s,t} = e^{\alpha^{((s-1)n+t)/N}}, \quad s = 1, \dots, m, \quad t = 1, \dots, n.$$

be the components of the vector $\boldsymbol{\delta} \in \mathbb{R}^N$ (indexed by $(s-1)n+t$).

For any $Q \in \mathfrak{Q}$ and $\boldsymbol{\mu} \in \mathbb{R}^N$ with $|\boldsymbol{\mu}| < 1$, by Corollary 25 (in which we interpret $\boldsymbol{\delta}$ and $\boldsymbol{\mu}$ as N -dimensional vectors), we have

$$|\nabla Q(\boldsymbol{\delta} + \boldsymbol{\mu})| < N^{3N^{N^2}} (e^a + 1)^{N^{N-1}} \leq N^{3N^{N^2}} (e^{N-1} + 1)^{N^{N-1}} \leq N^{3N^{N^2}} e^{N^N} \leq N^{4N^{N^2}}.$$

On the other hand, recalling that $D = N$ and $h(\boldsymbol{\alpha}) = \alpha$, by Corollary 28 we have

$$\begin{aligned} |Q(\boldsymbol{\delta})| &> \exp\left(-N^{2^{5N}} N^{N^2+N+3(N+\alpha)}\right) \\ &\geq \exp\left(-N^{2^{5N}} N^{N^2+N+3(2N-1)}\right) \\ &\geq \exp\left(-N^{2^{5N+1}} N^{N^2+N+4}\right). \end{aligned}$$

Hence

$$\frac{|Q(\boldsymbol{\delta})|}{|\nabla Q(\boldsymbol{\delta} + \boldsymbol{\mu})|} \geq N^{-4N^{N^2}} \exp\left(-N^{2^{5N+1}} N^{N^2+N+4}\right) \geq \exp\left(-2N^{2^{5N+1}} N^{N^2+N+4}\right).$$

Furthermore, since $N \geq 4$, we have

$$2N^{2^{5N+1}} N^{N^2+N+4} \leq N^{2^{5N+2}} N^{N^2+N+4} \leq N^{2^{6N}} N^{N^2+N+4} \leq N^{N^{N^2+4N+4}} \leq N^{N^{3N^2}}.$$

Note that, by (21), the condition $|\Delta - \Gamma| < 1$ of Corollary 18 is redundant.

B Density of matrices defining sets of linear forms of maximal additive complexity

B.1 Complexity of matrices

For a matrix Δ and a vector $\boldsymbol{x} = (x_1, \dots, x_n)^T$ of n indeterminates as in (1) and (2), respectively, we denote the additive complexity of the set of linear forms $\Delta\boldsymbol{x}$ by $\mathcal{C}(\Delta)$ and call it the complexity of Δ .

B.2 The case of finite fields

Let \mathbb{F} be a finite field of q elements. In this section we show that “almost all” $m \times n$ matrices over \mathbb{F} , are of high complexity.

We may assume that $m \leq \frac{q^n - 1}{q - 1}$, because the number of non-zero linear forms in n indeterminates over \mathbb{F} is $q^n - 1$ and each form can be scaled by $q - 1$ non-zero elements of \mathbb{F} .

The proof is by the counting argument similar to that of [10, Lemma, Section 5]. For the sake of completeness, we reproduce it below.

For a positive integers C , m and n we denote by $S(C, m, n)$ the set of all $m \times n$ matrices over \mathbb{F} of complexity not exceeding C :

$$S_{\mathbb{F}}(C, m, n) = \{\Delta \in \mathbb{F}^{m \times n} : \mathcal{C}(\Delta) \leq C\}.$$

First we need a bound on the cardinality $\#S_{\mathbb{F}}(C, m, n)$ of this set.

► **Proposition 34.** *We have*

$$\#S_{\mathbb{F}}(C, m, n) < (C + n)^{2C+m} q^{C+m}.$$

Proof. For a positive integer m a linear algorithm in n indeterminates of length C defines at most

$$L_{\mathbb{F}}(C, m) = \binom{C}{m}$$

sets of m linear forms, each of which is associated with

$$M_{\mathbb{F}}(m) = (q - 1)^m m!$$

matrices of the size $m \times n$. Namely, we have $(q - 1)^m$ scalar multiplications and $m!$ permutations, respectively, of the matrix rows.

Next we are going to count the number of linear algorithms over \mathbb{F} in n indeterminates of length C , denoted by $A_{\mathbb{F}}(C, n)$.

By definition,

- $A_{\mathbb{F}}(1, n) \leq n^2(q - 1)$ and
- $A_{\mathbb{F}}(C + 1, n) \leq A_{\mathbb{F}}(C, n)(C + n)^2(q - 1)$,

where the factors $(C + n)^2$ and $(q - 1)$ come from the last addition $u_{C+1} = v + \alpha w$ of the algorithm,

$$v, w \in \{x_1, \dots, x_n\} \cup \{u_1, \dots, u_C\}$$

and $\alpha \neq 0$. Recall that all algorithms under consideration are normalized.

Solving the above recursion, we obtain

$$A_{\mathbb{F}}(C, n) \leq \left(\frac{(C + n - 1)!}{(n - 1)!} \right)^2 (q - 1)^C.$$

Thus,

$$\begin{aligned} \#S_{\mathbb{F}}(C, m, n) &\leq A_{\mathbb{F}}(C, n) L_{\mathbb{F}}(C, m) M_{\mathbb{F}}(m) \\ &< \left(\frac{(C + n - 1)!}{(n - 1)!} \right)^2 (q - 1)^C \binom{C}{m} (q - 1)^m m! \\ &< (C + n)^{2C+m} (q - 1)^{C+m} < (C + n)^{2C+m} q^{C+m}, \end{aligned}$$

which concludes the proof. ◀

► **Theorem 35.** *Let $\varepsilon, \kappa > 0$ be such that $2\kappa + \varepsilon < 1$ and let*

$$C_{\kappa, m, n} = \frac{\kappa mn}{\log_q(mn)} - n.$$

Then

$$\lim_{\substack{n \rightarrow \infty \\ q^{\varepsilon n} \geq m}} \frac{\#S_{\mathbb{F}}(C_{\kappa, m, n}, m, n)}{q^{mn}} = 0.$$

Proof. It suffices to show that

$$\lim_{\substack{n \rightarrow \infty \\ q^{\varepsilon n} \geq m}} (\log_q \#S_{\mathbb{F}}(C_{\kappa, m, n}, m, n) - mn) = -\infty. \quad (34)$$

66:22 Sets of Linear Forms Which Are Hard to Compute

By Proposition 34 we have

$$\log_q \#S_{\mathbb{F}}(C_{\kappa,m,n}, m, n) - mn < (2C_{\kappa,m,n} + m) \log_q(C_{\kappa,m,n} + n) + C_{\kappa,m,n} + m - mn.$$

Recalling the definition of $C_{\kappa,m,n}$ and that $\kappa \leq 1$, we obtain

$$\begin{aligned} & \log_q \#S_{\mathbb{F}}(C_{\kappa,m,n}, m, n) - mn \\ & < \left(\frac{2\kappa mn}{\log_q(mn)} - 2n + m \right) \log_q \left(\frac{\kappa mn}{\log_q(mn)} \right) + \frac{\kappa mn}{\log_q(mn)} - n + m - mn \\ & \leq \left(\frac{2\kappa mn}{\log_q(mn)} + m \right) \log_q(mn) + \frac{mn}{\log_q(mn)} + m - mn \\ & = 2\kappa mn + m \log_q m + m \log_q n + \frac{mn}{\log_q(mn)} + m - mn. \end{aligned}$$

Under the condition $q^{\varepsilon n} \geq m$, we now obtain

$$\begin{aligned} \log_q \#S_{\mathbb{F}}(C_{\kappa,m,n}, m, n) - mn & < 2\kappa mn + \varepsilon mn + m \log_q n + \frac{mn}{\log_q(mn)} + m - mn \\ & = (2\kappa + \varepsilon - 1 + o(1)) mn, \end{aligned}$$

and since $2\kappa + \varepsilon < 1$, we have (34). ◀

B.3 The case of rationals

In this case matrices with rational entries, since the set of polynomials $\mathfrak{Q}_{m,n}$, defined by (20), is (m, n) -complete, for for each matrix (1) such that $\mathcal{C}(\Delta) < m(n-1)$,

$$Q_{m,n}(\delta_{1,1}, \dots, \delta_{m,n}) = 0,$$

where $Q_{m,n} = \prod_{Q \in \mathfrak{Q}_{m,n}} Q$.

Hence the entries of $m \times n$ rational matrices of complexity $\mathcal{C}(\Delta) < m(n-1)$ form a very sparse set in \mathbb{Q}^{mn} (after we represent them as mn -dimensional vector). Namely, this set is a hypersurface of dimension $mn - 1$. In particular, almost all rational matrices (in terms on natural density) are of the maximal complexity $m(n-1)$.

Abstract

An infinite sequence $\langle u_n \rangle_n$ of real numbers is *holonomic* (also known as *P-recursive* or *P-finite*) if it satisfies a linear recurrence relation with polynomial coefficients. Such a sequence is said to be *positive* if each $u_n \geq 0$, and *minimal* if, given any other linearly independent sequence $\langle v_n \rangle_n$ satisfying the same recurrence relation, the ratio $u_n/v_n \rightarrow 0$ as $n \rightarrow \infty$.

In this paper we give a Turing reduction of the problem of deciding positivity of second-order holonomic sequences to that of deciding minimality of such sequences. More specifically, we give a procedure for determining positivity of second-order holonomic sequences that terminates in all but an exceptional number of cases, and we show that in these exceptional cases positivity can be determined using an oracle for deciding minimality.

1 Introduction

Holonomic sequences (also known as *P-recursive* or *P-finite* sequences) are infinite sequences of real (or complex) numbers that satisfy a linear recurrence relation with polynomial coefficients. Holonomic sequences play a critical role in many areas of mathematics and computer science – particularly combinatorics, analysis of algorithms, and number theory; see, for instance [31, 6, 7] or the seminal paper [40]. A spectacular application can be found in groundbreaking work by Apéry in the 1970s, who used certain holonomic sequences satisfying the second-order recurrence relation

$$n^3 u_n = (34n^3 - 51n^2 + 27n - 5)u_{n-1} - (n-1)^3 u_{n-2}$$

to prove that $\zeta(3) := \sum_{n=1}^{\infty} n^{-3}$ is irrational [1].

Formally, a holonomic sequence satisfies a recurrence relation of the form:

$$p_{k+1}(n)u_n = p_k(n)u_{n-1} + \cdots + p_1(n)u_{n-k}$$

where $p_{k+1}, \dots, p_1 \in \mathbb{Q}[n]$ are polynomials with rational coefficients and $p_1 \neq 0$. We define the *order* of the recurrence to be k . Assuming that $p_{k+1}(n) \neq 0$ for each non-negative integer n , the above recurrence uniquely defines an infinite sequence once the initial values u_{-k+1}, \dots, u_0 are specified. By extension, if a holonomic sequence satisfies a recurrence of order k , but no recurrence of smaller order, then we say that the sequence has order k . The class of holonomic sequences who satisfy recurrence relations with constant (rather than polynomial) coefficients are known as *C-finite* sequences. Furthermore, every algebraic sequence of real numbers (i.e., whose ordinary generating function is algebraic) is also holonomic.

The study of identities for holonomic sequences appears frequently in the literature. However, as noted by Kauers and Pillwein, “*in contrast, . . . almost no algorithms are available for inequalities*” [17]. For example, the *Positivity Problem* (i.e., whether every term of a given sequence is non-negative) for *C-finite* sequences is only known to be decidable at low orders, and there is strong evidence that the problem is mathematically intractable in general [28, 30]; see also [12, 20, 29]. For holonomic sequences that are not *C-finite*, very few decision procedures currently exist for Positivity, although several partial results and heuristics are known (see, for example [17, 21, 26, 27, 32, 33, 39]). In particular, in [27], the authors exhibit semi-decision procedures for determining positivity of second-order holonomic sequences for which the degrees of the polynomial coefficients satisfy certain constraints.

Another extremely important property of holonomic sequences is *minimality*; a sequence $\langle u_n \rangle_n$ is a minimal solution if, given any other linearly independent sequence $\langle v_n \rangle_n$ satisfying the same recurrence relation, the ratio u_n/v_n converges to 0. Minimal holonomic sequences play a crucial rôle, among others, in numerical calculations and asymptotics, as noted for example in [11, 4, 5, 8, 9, 10] – see also the references therein. Unfortunately, there is also ample evidence that determining algorithmically whether a given holonomic sequence is minimal is a very challenging task, for which no satisfactory solution is at present known to exist.

One of our main results concerns the relationship between positivity and minimality of sequences $\langle u_n \rangle_{n=-1}^{\infty}$ satisfying second-order polynomial recurrences:¹

$$p_3(n)u_n = p_2(n)u_{n-1} + p_1(n)u_{n-2}. \tag{1}$$

¹ Indexing the sequence from -1 (rather than the more usual 0) makes no significant mathematical difference, but provides notational expediency in the sequel.

We shall assume throughout that neither p_1 nor p_2 is identically zero. Indeed, if $p_1 \equiv 0$ then $\langle u_n \rangle_{n=-1}^\infty$ satisfies a first-order recurrence, while if $p_2 \equiv 0$ then $\langle u_n \rangle_{n=-1}^\infty$ is the interleaving of two sequences that satisfy first-order recurrences. But it is trivial to determine the positivity of first-order holonomic sequences.² Moreover, by working with a tail of the sequence $\langle u_n \rangle_{n=-1}^\infty$ (equivalently, shifting the index n) we can assume that $p_1(n), p_2(n), p_3(n) \neq 0$ for all $n \geq -1$.

Our main contributions are as follows: we characterise the positivity of the sequence $\langle u_n \rangle_{n=-1}^\infty$ in (1) in terms of its *initial ratio* u_0/u_{-1} . Specifically, from the recurrence we obtain a single closed subinterval $P \subseteq \mathbb{R}$ such that the sequence is positive if and only if $u_0/u_{-1} \in P$. We moreover show that the endpoints of P can be represented as polynomial continued fractions, allowing them to be computed to arbitrary precision. By approximating the endpoints of P to sufficient accuracy we can decide positivity in all cases except when the initial ratio happens to coincide with an endpoint of P . However, we show that such exceptional cases can be handled using an oracle for deciding minimality. Thus we obtain one of our main results, Theorem 3.1: for second-order holonomic sequences, the Positivity Problem Turing-reduces to the Minimality Problem.

2 Preliminaries

2.1 continued fractions

An (infinite) *continued fraction*

$$\mathbf{K}_{n=1}^{\infty} \frac{a_n}{b_n} := \frac{a_1}{b_1 + \frac{a_2}{b_2 + \frac{a_3}{b_3 + \ddots}}}$$

is defined by an ordered pair of sequences $\langle a_n \rangle_n$ and $\langle b_n \rangle_n$ of complex numbers where $a_n \neq 0$ for each $n \in \mathbb{N}$. Herein we shall always assume that $\langle a_n \rangle_n$ and $\langle b_n \rangle_n$ are real-valued rational functions. A continued fraction *converges* to a value $f = \mathbf{K}(a_n/b_n)$ if its *sequence of approximants* $\langle f_n \rangle_{n=1}^\infty$ converges to f in $\hat{\mathbb{R}} = \mathbb{R} \cup \{\infty\}$. The sequence $\langle f_n \rangle_n$ is recursively defined so that

$$f_n = \mathbf{K}_{m=1}^n \frac{a_m}{b_m} := \frac{a_1}{b_1 + \frac{a_2}{b_2 + \ddots + \frac{a_n}{b_n}}}$$

We respectively call $\langle a_n \rangle_n$ and $\langle b_n \rangle_n$ the sequences of *partial numerators* and *partial denominators* (together the *partial quotients*) of the continued fraction $\mathbf{K}(a_n/b_n)$. Let $\langle A_n \rangle_{n=-1}^\infty$ and $\langle B_n \rangle_{n=-1}^\infty$ satisfy the recurrence relation $u_n = b_n u_{n-1} + a_n u_{n-2}$ with initial

² The ratio of consecutive terms of a first-order holonomic sequence is a rational function, which has an ultimately constant sign.

values $A_{-1} = 1, A_0 = 0, B_{-1} = 0,$ and $B_0 = 1$. As a pair, $\langle A_n \rangle_{n=-1}^\infty$ and $\langle B_n \rangle_{n=-1}^\infty$ form a basis for the solution space of the recurrence. We call $\langle A_n \rangle_n$ and $\langle B_n \rangle_n$ the sequences of *canonical numerators* and *canonical denominators* of $\mathbb{K}(a_n/b_n)$ because $f_n = A_n/B_n$ for each $n \in \mathbb{N}$.

The following determinant formula is well-known (see, for example, [23, Lemma 4, §IV]).

► **Lemma 2.1.** *Suppose that $\langle u_n \rangle_n$ and $\langle v_n \rangle_n$ are both solutions to the recurrence relation $u_n = b_n u_{n-1} + a_n u_{n-2}$. Then*

$$u_n v_{n-1} - u_{n-1} v_n = (u_0 v_{-1} - u_{-1} v_0) \prod_{k=1}^n (-a_k).$$

Two continued fractions are *equivalent* if they have the same sequence of approximants. The following theorem is attributed to Seidel in [23, §II.2.2].

► **Theorem 2.2.** *The continued fractions $\mathbb{K}(a_n/b_n)$ and $\mathbb{K}(c_n/d_n)$ are equivalent if and only if there exists a sequence $\langle r_n \rangle_{n=0}^\infty$ with $r_0 = 1$ and $r_n \neq 0$ for each $n \in \mathbb{N}$ such that $c_n = r_n r_{n-1} a_n$ and $d_n = r_n b_n$ for each $n \in \mathbb{N}$.*

2.2 Śleszyński–Pringsheim continued fractions

A continued fraction $\mathbb{K}_{n=1}^\infty(a_n/b_n)$ is a *Śleszyński–Pringsheim continued fraction* if $|b_n| \geq |a_n| + 1$ for each $n \in \mathbb{N}$. As before, let $\langle f_n \rangle_n$ be the sequence of approximants associated with such a continued fraction. The following properties are well-known [23, §I.4]. For the open unit interval $(-1, 1) \subset \mathbb{R}$, $a_n/(b_n + (-1, 1)) \subseteq (-1, 1)$ and we have that $f_n \in (-1, 1)$ for each $n \in \mathbb{N}$. Further, it can be shown that $\langle f_n \rangle_n$ converges to a finite value f with $0 < |f| \leq 1$. We will use the following convergence result, which can be derived from the Śleszyński–Pringsheim Theorem (we reproduce the proof in [24, §3.2.4] below).

► **Theorem 2.3.** *Let $\langle f_n \rangle_n$ and $\langle B_n \rangle_n$ be the respective sequences of approximants and canonical denominators for a Śleszyński–Pringsheim continued fraction $\mathbb{K}_{n=1}^\infty(a_n/b_n)$ with $a_n < 0$ and $b_n \geq 1 - a_n$ for each $n \in \mathbb{N}$. Then*

$$B_{n+1} > B_n \geq \sum_{k=0}^n \prod_{m=1}^k (b_m - 1) \geq \sum_{k=0}^n \prod_{m=1}^k |a_m|,$$

$\langle f_n \rangle_n$ is strictly decreasing, and $-1 < f_n < f_{n-1} < 0$.

Proof. We prove by induction that $\langle B_n \rangle_n$ is a strictly increasing sequence. First, $B_0 - B_{-1} = 1$. Second, for our induction hypothesis, let us assume that $B_{n-1} - B_{n-2} > 0$ and $B_{n-2} \geq 0$. Then, using the recurrence relation and our additional assumptions on the coefficients, we have

$$B_n - B_{n-1} = (b_n - 1)B_{n-1} - (-a_n)B_{n-2} \geq (b_n - 1)(B_{n-1} - B_{n-2}).$$

Repeated application of this technique gives

$$B_n - B_{n-1} \geq (B_{n-1} - B_{n-2})(b_n - 1) \geq (B_0 - B_{-1}) \prod_{m=1}^n (b_m - 1) \geq \prod_{m=1}^n |a_m| > 0,$$

from which the desired inequalities follow. We apply the determinant formula to the sequences $\langle A_n \rangle_n$ and $\langle B_n \rangle_n$ (see Lemma 2.1) to obtain

$$f_n - f_{n-1} = -\frac{\prod_{k=1}^n -a_k}{B_n B_{n-1}} < 0.$$

Thus $\langle f_n \rangle_n$ is a strictly decreasing sequence with $f_1 = a_1/b_1 < 0$. The bounds follow from the aforementioned convergence properties of Śleszyński–Pringsheim continued fractions. ◀

2.3 Second-order linear recurrences and continued fractions

Recall that a non-trivial solution $\langle u_n \rangle_{n=-1}^\infty$ of the recurrence $u_n = b_n u_{n-1} + a_n u_{n-2}$ is *minimal* provided that, for all other linearly independent solutions $\langle v_n \rangle_{n=-1}^\infty$ of the same recurrence, we have $\lim_{n \rightarrow \infty} u_n/v_n = 0$. Since the vector space of solutions has dimension two, it is equivalent for a sequence $\langle u_n \rangle_{n=-1}^\infty$ to be minimal for there to exist a linearly independent sequence $\langle v_n \rangle_{n=-1}^\infty$ satisfying the above property. In such cases the solution $\langle v_n \rangle_n$ is called *dominant*.

Note that if $\langle u_n \rangle_n$ and $\langle v_n \rangle_n$ are linearly independent solutions of the above recurrence such that u_n/v_n converges in $\hat{\mathbb{R}}$ then the recurrence relation has a minimal solution [23, §IV]. If, in addition, $\langle u_n \rangle_n$ is minimal then all solutions of the form $\langle c u_n \rangle_n$ where $c \neq 0$ are also minimal. If $\langle u_n \rangle_n$ and $\langle v_n \rangle_n$ are respectively minimal and dominant solutions of the recurrence, then together they form a basis of the solution space.

► **Remark 2.4.** When a second-order recurrence relation admits minimal solutions, it is often beneficial (from a numerical standpoint) to provide a basis of solutions where one of the elements is a minimal solution. Such a basis is used to approximate any element of the vector space of solutions: taking $\langle u_n \rangle_n$ and $\langle v_n \rangle_n$ as above, a general solution $\langle z_n \rangle_n$ is given by $z_n = \alpha_1 u_n + \alpha_2 v_n$.

Let $\langle u_n \rangle_{n=-1}^\infty$ be a non-trivial solution of the recurrence relation $u_n = b_n u_{n-1} + a_n u_{n-2}$, where $a_n \neq 0$ for all n . If $u_{n-1} \neq 0$ then we can rearrange the relation to obtain

$$-\frac{u_{n-1}}{u_{n-2}} = \frac{a_n}{b_n - \frac{u_n}{u_{n-1}}} \quad (2)$$

for each $n \in \mathbb{N}$. In the event that $u_{n-2} = 0$ we take the usual interpretation in $\hat{\mathbb{R}}$. Since $\langle u_n \rangle_n$ is non-trivial and $a_n \neq 0$ for each $n \in \mathbb{N}$, the sequence $\langle u_n \rangle_n$ does not vanish at two consecutive indices. Thus if $u_{n-1} = 0$ then $u_{n-2}, u_n \neq 0$ and so both the left-hand and the right-hand sides of the last equation are well-defined in $\hat{\mathbb{R}}$ and are equal to 0. Thus the sequence with terms $-u_n/u_{n-1}$ is well-defined in $\hat{\mathbb{R}}$ for each $n \in \mathbb{N}$. A sequence $\langle t_n \rangle_{n=0}^\infty$ where $t_n := -u_n/u_{n-1}$ for each $n \in \mathbb{N}$ and $\langle u_n \rangle_n$ non-trivial is called a *tail sequence*. A tail sequence for $\mathbf{K}(a_n/b_n)$ is wholly determined by its initial value t_0 .

Given a convergent continued fraction $\mathbf{K}_{n=1}^\infty(a_n/b_n)$ it is easily shown that the sequence $\langle f^{(m)} \rangle_{m=0}^\infty$ with terms $f^{(m)} := \mathbf{K}_{n=m+1}^\infty(a_n/b_n)$ is a tail sequence. In the literature the sequence $\langle f^{(m)} \rangle_{m=0}^\infty$ is the *sequence of tails* of $\mathbf{K}_{n=1}^\infty(a_n/b_n)$ [23, §2.1].

The next theorem due to Pincherle [34] connects the existence of minimal solutions for a second-order recurrence to the convergence of the associated continued fraction (see also [8, 23, 3]).

► **Theorem 2.5 (Pincherle).** *Let $\langle a_n \rangle_{n=1}^\infty$ and $\langle b_n \rangle_{n=1}^\infty$ be real-valued sequences such that each of the terms a_n is non-zero. First, the recurrence $u_n = b_n u_{n-1} + a_n u_{n-2}$ has a minimal solution if and only if the continued fraction $\mathbf{K}(a_n/b_n)$ converges in $\hat{\mathbb{R}}$. Second, if $\langle u_n \rangle_n$ is a minimal solution of this recurrence then the limit of $\mathbf{K}(a_n/b_n)$ is $-u_0/u_{-1}$. As a consequence, the sequence of canonical denominators $\langle B_n \rangle_{n=-1}^\infty$ is a minimal solution if and only if the value of $\mathbf{K}(a_n/b_n)$ is $\infty \in \hat{\mathbb{R}}$.*

► **Remark 2.6.** The convergence properties of continued fractions whose partial quotients are polynomials has long fascinated researchers. It is notable that the sequence of partial denominators in the continued fraction expansion of $\pi = 3 + \mathbf{K}_{n=1}^{\infty}(1/b_n)$ beginning $\langle b_n \rangle_n = \langle 7, 15, 1, 292, 1, 1, 1, 2, 1, 3, 1, \dots \rangle$ behaves erratically. In contrast, Lord Brouncker (as reported by Wallis in [37]³) gave a continued fraction expansion for $4/\pi$ as follows:

$$\frac{4}{\pi} = 1 + \mathbf{K}_{n=1}^{\infty} \frac{(2n-1)^2}{2}.$$

Likewise, Apéry's constant $\zeta(3)$ has a continued fraction expansion (see [35])

$$\zeta(3) = \frac{6}{5 + \mathbf{K}_{n=1}^{\infty} (-n^6 / (34n^3 + 51n^2 + 27n + 5))}$$

whose partial quotients are ultimately polynomials. Motivated by such constructions, Bowman and Mc Laughlin [2] (see also [25]) coined the term *polynomial continued fraction (PCF)*. A polynomial continued fraction $\mathbf{K}(a_n/b_n)$ has algebraic partial quotients such that for sufficiently large $n \in \mathbb{N}$, a_n and b_n are determined by polynomials in $\mathbb{Q}[n]$.

We call the problem of determining whether a given convergent polynomial continued fraction is equal to a particular algebraic number the *PCF Equality Problem*. The proof of the following corollary is a straightforward application of Theorem 2.5.

► **Corollary 2.7.** *The PCF Equality Problem and the Minimality Problem for second-order holonomic sequences are irreducible.*

Proof. A minimality-preserving transformation takes as input a solution $\langle u_n \rangle_n$ of recurrence $p_3(n)u_n = p_2(n)u_{n-1} + p_1(n)u_{n-2}$ and outputs a solution $\langle v_n \rangle_n$, with $v_n = u_n \prod_{j=0}^n p_3(j)$, of recurrence $v_n = p_2(n)v_{n-1} + p_1(n)p_3(n-1)v_{n-2}$. Clearly, $\langle u_n \rangle_n$ is a minimal solution if and only if $\langle v_n \rangle_n$ is a minimal solution.

The latter of the two recurrence relations is associated with the polynomial continued fraction $\mathbf{K}(a_n/b_n)$ with partial quotients $b_n = p_2(n)$ and $a_n = p_1(n)p_3(n-1)$ for each $n \in \mathbb{N}$. Note that by our assumption that $p_1(n), p_3(n) \neq 0$ for all $n \geq -1$ (see the Introduction) we have that $a_n \neq 0$, as required in our definition of a continued fraction. By Theorem 2.5, $\langle v_n \rangle_n$ is a minimal solution if and only if $\mathbf{K}(a_n/b_n)$ converges to the limit $-v_0/v_{-1}$. Thus if one has an oracle that can determine the value of a polynomial continued fraction, then one can determine whether $\langle v_n \rangle_n$ is a minimal solution. Since minimality is preserved by this transformation, one can determine whether $\langle u_n \rangle_n$ is a minimal solution.

Conversely, given a polynomial continued fraction $\mathbf{K}(a_n/b_n)$ and an algebraic number $\xi \in \mathbb{R}$, let us construct the holonomic sequence $\langle v_n \rangle_{n=-1}^{\infty}$ as follows. For each $n \in \mathbb{N}$, let $v_n = b_n v_{n-1} + a_n v_{n-2}$ with initial conditions $v_{-1} = 1$ and $v_0 = -\xi$. By Theorem 2.5, the sequence $\langle v_n \rangle_n$ is a minimal solution of the recurrence relation if and only if the continued fraction $\mathbf{K}(a_n/b_n)$ converges to the value $-u_0/u_{-1} = \xi$. Hence if one has an oracle that can determine whether a given holonomic sequence is a minimal solution, then one can test the value of a polynomial continued fraction. ◀

Determining whether a given continued fraction converges has attracted much attention (historical accounts are given in [23, 24]). The following theorem collects together results from the literature; the first statement follows as a consequence of Worpitzky's Theorem (see [24, Theorem 3.29]) and the convergence results in [15], whilst the second statement follows from the Lane–Wall characterisation of convergence [24, Theorem 3.3].

³ See the translation by Stedall [38].

► **Theorem 2.8.** *Let $\mathbb{K}(\kappa_n/1)$ be a continued fraction with $\langle \kappa_n \rangle_n$ a function in $\mathbb{Q}(n)$. If $\kappa_n < 0$ for all sufficiently large $n \in \mathbb{N}$, then $\mathbb{K}(\kappa_n/1)$ converges to a value in $\hat{\mathbb{R}}$ if and only if, either*

- $\lim_{n \rightarrow \infty} \kappa_n$ exists and is strictly above $-1/4$, or
- $\lim_{n \rightarrow \infty} \kappa_n = -1/4$ and moreover $\kappa_n \geq -1/4 - 1/(4n)^2 - 1/(4n \log n)^2$ for all sufficiently large n .

► **Remark 2.9.** Note that since κ_n is assumed to be a rational function in the above, the eventual inequality $\kappa_n \geq -1/4 - 1/(4n)^2 - 1/(4n \log n)^2$ can be effectively decided, whence convergence of the continued fraction can be ascertained.

The fact that the coefficients $-1/16$ in Theorem 2.8 are best possible is discussed in [14, 13, 23, 24]. For example, if $\kappa_n = -1/4 - \varepsilon/n^2 + \mathcal{O}(1/n^3)$ where $\varepsilon > 1/16$, or $\kappa_n = -1/4 - \varepsilon_1/n + \mathcal{O}(1/n^2)$ where $\varepsilon_1 > 0$, then the continued fraction $\mathbb{K}(\kappa_n/1)$ diverges. We note that later independent work by Kooman and Tijdeman [19, 18] establishes the same results (as a consequence of their results for linear recurrence sequences).

3 Positivity reduces to Minimality

The goal of this section is to show that, for second-order holonomic sequences, the Positivity Problem Turing-reduces to the Minimality Problem; in other words, given an oracle for the Minimality Problem, one can decide the Positivity Problem.

► **Theorem 3.1.** *For the class of recurrence relations*

$$u_n = b_n u_{n-1} + a_n u_{n-2} \tag{3}$$

whose coefficients are rational functions in $\mathbb{Q}(n)$, the Positivity Problem Turing-reduces to the Minimality Problem.

3.1 reduction argument

Let $\langle u_n \rangle_n$ be a sequence satisfying the second-order relation (1). Recall from the Introduction that we can assume without loss of generality that none of the polynomial coefficients in this recurrence relation has a root $n \geq -1$. Additionally we can assume that $\text{sign}(p_3) = +$ on \mathbb{N} . (Herein we denote the sign of a non-zero number by an element of $\{+, -\}$ with the obvious interpretation.) Thus we define the *signature* of a recurrence relation (1) (or its normalisation (3)) as the ordered pair $(\text{sign}(p_2), \text{sign}(p_1))$. It is useful to consider subcases determined by the signature of the recurrence relation $u_n = b_n u_{n-1} + a_n u_{n-2}$. The Positivity Problem is trivial when the signature of the recurrence is either $(+, +)$ or $(-, -)$. It remains to consider the cases $(-, +)$ and $(+, -)$.

Let $\langle u_n \rangle_n$ satisfy a recurrence with signature $(-, +)$. Then a simple substitution argument gives

$$u_{2n} = (b_{2n} b_{2n-1} + a_{2n} + a_{2n-1} b_{2n}/b_{2n-2}) u_{2n-2} - (a_{2n-1} a_{2n-2} b_{2n}/b_{2n-2}) u_{2n-4}.$$

The sequence of odd terms $\langle u_{2n-1} \rangle_n$ satisfies a similar recurrence relation with signature $(+, -)$. Thus the Positivity Problem for the $(-, +)$ case reduces to determining the Positivity Problem for two recurrences with signature $(+, -)$.

We come to the final case: recurrences with signature $(+, -)$. Let $\langle A_n \rangle_{n=-1}^\infty$ and $\langle B_n \rangle_{n=-1}^\infty$ be the canonical solutions as above. In this case $A_1 = a_1 < 0$ and so one can assume that $u_0 > 0$.⁴ It is useful to normalise recurrence (3). Let $\kappa_n := a_n/(b_n b_{n-1})$, and consider

$$w_n = w_{n-1} + \kappa_n w_{n-2}. \tag{4}$$

Then $\langle w_n \rangle_n$ with $w_{-1} = u_{-1}$ and $w_n := u_n/(\prod_{k=0}^n b_k)$ is a solution to (4) if and only if $\langle u_n \rangle_n$ is a solution to (3). We note minimality, positivity, and signature $(+, -)$ are invariant under this transformation. Such properties follow from our assumption that each $b_n > 0$ and the equivalence transformations for continued fractions in Theorem 2.2.

In light of this reduction, the next result is an immediate corollary of Theorem 2.5 and Remark 2.9.

► **Corollary 3.2.** *Given a recurrence relation of the form (3), it is decidable whether the recurrence admits a minimal solution.*

In the work that follows we split the $(+, -)$ case into subcases depending on whether the limit $\lim_{n \rightarrow \infty} \kappa_n$ exists and, if it exists, its value κ . It turns out that such a recurrence relation admits a non-trivial positive solution if and only if the associated continued fraction converges (see Theorem 2.8).

► **Lemma 3.3.** *Suppose that the continued fraction $\mathbb{K}(\kappa_n/1)$ diverges in $\hat{\mathbb{R}}$. Then there are no non-trivial positive solutions to recurrence (4).*

Proof. Suppose, for a contradiction, that $\langle w_n \rangle_n$ is a positive sequence and non-trivial solution of recurrence (4). Notice that two consecutive terms in $\langle w_n \rangle_n$ cannot both vanish since $\langle w_n \rangle_n$ is non-trivial. Furthermore, $w_n > 0$ for all $n \geq 0$ since otherwise $w_n = 0$ and $w_{n+1} = \kappa_{n+1} w_{n-1} < 0$. We first show that the sequence $\langle B_n \rangle_n$ is also positive.

If $w_{-1} = 0$ then $\langle w_n \rangle_n$ is a constant multiple of $\langle B_n \rangle_n$ and we have nothing to show. Otherwise, $w_{-1} > 0$ and let $\langle \check{w}_n \rangle_n$ be a solution sequence of recurrence (4) such that $\check{w}_{-1} = w_{-1}$ and $\check{w}_0 > w_0$. We then have $\check{w}_n > w_n$ for all $n \in \mathbb{N}$. Indeed, proceeding by induction on n , by Lemma 2.1,

$$\check{w}_n w_{n-1} - \check{w}_{n-1} w_n = (\check{w}_0 w_{-1} - \check{w}_{-1} w_0) \prod_{k=1}^n (-\kappa_k) = (\check{w}_0 - w_0) w_{-1} \prod_{k=1}^n (-\kappa_k) > 0$$

implying that $\check{w}_n w_{n-1} > \check{w}_{n-1} w_n$. The induction hypothesis $\check{w}_{n-1} > w_{n-1}$ (with $n \geq 1$) implies that $\check{w}_{n-1} w_n > w_{n-1} w_n$ as $w_n > 0$ by assumption. It follows that $\check{w}_n w_{n-1} > w_{n-1} w_n$, and thus $\check{w}_n > w_n$.

Notice now that $\langle \check{w}_n - w_n \rangle_n$ is a positive sequence and non-trivial solution of recurrence (4). For each $n \in \{-1, 0, \dots\}$ we have $\check{w}_n - w_n = (\check{w}_0 - w_0) B_n$ and so conclude that $B_n > 0$ for each $n \in \mathbb{N}$.

Let $\langle f_n \rangle_n$ be the sequence of approximants associated with $\mathbb{K}(\kappa_n/1)$. We now apply Lemma 2.1 to the sequences $\langle A_n \rangle_n$ and $\langle B_n \rangle_n$, and our conclusion that $B_n > 0$ for each $n \in \mathbb{N}$, to obtain

$$f_n - f_{n-1} = -\frac{\prod_{k=1}^n -\kappa_k}{B_n B_{n-1}} < 0.$$

Thus $\langle f_n \rangle_n$ is monotonic and therefore convergent in $\hat{\mathbb{R}}$, a contradiction to the divergence of $\mathbb{K}(\kappa_n/1)$. ◀

⁴ Indeed, if $u_0 < 0$ then the sequence is not positive; whereas if $u_0 = 0$, then in turn the sequence is either identically zero, or $u_1 < 0$.

In what follows, “*eventually*” statements shall always assume that a property holds for each $n + N$ where $N \in \mathbb{N}$ is a fixed computable constant. Our assumption on the signature means that $a_{n+N} < 0$ and $b_{n+N} > 0$ for each $n \in \mathbb{N}$. Without loss of generality, we can take $N = 0$ in the upcoming statements and results by considering tails of continued fractions as appropriate.

From Theorem 2.8 and Lemma 3.4 (below) we characterise the boundary for a recurrence relation of the form (4) to admit positive solutions. The proof of Lemma 3.4 uses standard analytic tools for continued fractions of limit parabolic type with a particular choice of parameter sequence $\langle g_n \rangle_n$. More general discussions are given in [16, 22, 23].

► **Lemma 3.4.** *Suppose that eventually*

$$\kappa_n \geq -1/4 - 1/(4n)^2 - 1/(4n \log n)^2. \tag{5}$$

Then the sequence of approximants of the continued fraction $\mathbf{K}_{n=1}^\infty(\kappa_n/1)$ is strictly decreasing and converges to a finite value.

Proof. Without loss of generality we assume that (5) holds for each $n \in \mathbb{N}$. Let $g_0 = g_1 = g_2 = 1$ and $g_n := 1/2 + 1/(4n) + 1/(4n \log n)$ for each $n \geq 3$. The continued fractions $\mathbf{K}_{n=1}^\infty(\kappa_n/1)$ and

$$g_0 \mathbf{K}_{n=1}^\infty \left(\frac{\kappa_n / (g_{n-1} g_n)}{1/g_n} \right) \tag{6}$$

are equivalent; one can prove this assertion by applying Theorem 2.2 with the transformation choice $\tau_n = 1/(b_n g_n)$ for each $n \in \mathbb{N}$. Then, by assumption, $|\kappa_n| \leq g_{n-1}(1 - g_n)$ for each $n \in \mathbb{N}$. Thus

$$1 - \frac{\kappa_n}{g_{n-1} g_n} = \frac{g_{n-1} g_n - \kappa_n}{g_{n-1} g_n} \leq \frac{1}{g_n}.$$

We deduce that the partial numerators and denominators in (6) satisfy the assumptions in Theorem 2.3. Thus the sequence of approximants $\langle f_n \rangle_{n=1}^\infty$ associated with (6) is strictly decreasing and converges to a finite value. The desired result follows. ◀

► **Lemma 3.5.** *Suppose that $\langle w_n \rangle_{n=-1}^\infty$ is a solution to (4) with signature $(+, -)$ such that (5) holds for each $n \in \mathbb{N}$. Let $\langle f_n \rangle_n$ be the sequence of approximants for the associated continued fraction $\mathbf{K}(\kappa_n/1)$. Assume that $w_{-1} > 0$. Given $m \in \mathbb{N}$, we have that $-w_0/w_{-1} < f_m$ if and only if $w_m > 0$.*

Proof. Let $\langle A_n \rangle_n$ and $\langle B_n \rangle_n$ be the sequences of canonical numerators and denominators associated with $\mathbf{K}(\kappa_n/1)$. The continued fractions $\mathbf{K}(\kappa_n/1)$ and (6) are equivalent; in addition, the latter is a Śleszyński–Pringsheim continued fraction whose associated sequence of canonical denominators is non-negative (by Theorem 2.3). The transformation between these two continued fractions preserves the positivity property and so we deduce that each term in $\langle B_n \rangle_n$ is also non-negative.

For each $n \in \mathbb{N}$, $w_n = w_{-1} A_n + w_0 B_n$. Since $B_n > 0$, $-w_0/w_{-1} < A_n/B_n = f_n$ if and only if $w_n > 0$, as desired. ◀

We are now in a position to characterise positive solutions to recurrence (4).

► **Proposition 3.6.** *Suppose that $\langle w_n \rangle_{n=-1}^\infty$ is a solution of recurrence (4) with signature $(+, -)$ such that (5) holds for all $n \in \mathbb{N}$. First, the continued fraction $\mathbf{K}_{n=1}^\infty(\kappa_n/1)$ converges to a finite limit $f < 0$. Second, the sequence $\langle w_n \rangle_{n=-1}^\infty$ with $w_{-1}, w_0 > 0$ is positive if and only if $-w_0/w_{-1} \leq f$.*

Proof. As observed in the proof of Lemma 3.4, $\mathbb{K}(\kappa_n/1)$ and (6) are equivalent continued fractions. The former converges to a negative value $f \in \mathbb{R}$ because the latter is a Śleszyński–Pringsheim continued fraction that satisfies the assumptions in Theorem 2.3.

Let $\langle w_n \rangle_{n=-1}^\infty$ be a solution to recurrence (4). By Lemma 3.5, we have that, for all $n \in \mathbb{N}$, $w_n > 0$ if and only if $-w_0/w_{-1} < f_n$. Moreover, by Theorem 2.3, the sequence $\langle f_n \rangle_n$ is strictly decreasing; it follows that $w_n > 0$ for all $n \in \mathbb{N}$ if and only if $-w_0/w_{-1} \leq f$. ◀

The difficulty one encounters when determining positivity arises when $-w_0/w_{-1}$ is equal to the value f . In other words, we can decide positivity of dominant sequences. Indeed, one can always detect if a non-trivial solution $\langle w_n \rangle_n$ is not positive, i.e., $-w_0/w_{-1} > f$ by computing a sufficient number of terms until one finds an $N \in \mathbb{N}$ such that $w_N < 0$. The dominant positive sequences are considered in the following proposition whose proof is delayed to Section 4.

► **Proposition 3.7.** *Let $\langle w_n \rangle_{n=-1}^\infty$ be a non-trivial solution of (4) with signature $(+, -)$ and suppose that (5) holds for each $n \in \mathbb{N}$. Then one can detect if $-w_0/w_{-1} < f$.*

We deduce that if one can decide whether a holonomic sequence $\langle u_n \rangle_n$ that solves recurrence (3) is minimal, then one can decide whether $\langle u_n \rangle_n$ is a positive solution.

Proof of Theorem 3.1. Assume that one has an oracle for the Minimality Problem for solutions $\langle u_n \rangle_{n=-1}^\infty$ to recurrences of the form (3). Note that if $\langle u_n \rangle_{n=-1}^\infty$ is *not* positive, this can be substantiated in finite time by simple enumeration. It thus remain to show how one can ascertain positivity. We can assume without loss of generality that the recurrence has signature $(+, -)$. As previously mentioned, the problem of determining the positivity of solutions $\langle u_n \rangle_n$ of (3) is equivalent to the problem of determining the positivity of solutions $\langle w_n \rangle_n$ of (4).

Consider a recurrence relation of the form (4) with signature $(+, -)$. By Theorem 2.8, we can decide whether or not $\mathbb{K}(\kappa_n/1)$ converges. If $\mathbb{K}(\kappa_n/1)$ diverges, then by Lemma 3.3, the recurrence has no non-trivial positive solutions. Suppose now that $\mathbb{K}(\kappa_n/1)$ converges to $f \in \hat{\mathbb{R}}$. Then, by Remark 2.9, inequality (5) holds; by Proposition 3.6, it follows that f is finite and a given solution $\langle w_n \rangle_n$ is positive if and only if $-w_0/w_{-1} \leq f$. The condition $-w_0/w_{-1} < f$ is recursively enumerable by Proposition 3.7. Finally, by Theorem 2.5, $-w_0/w_{-1} = f$ if and only if the sequence is minimal, and hence equality of $-w_0/w_{-1}$ and f can be checked by an oracle for Minimality. ◀

3.2 A characterisation of positivity

We end this section by characterising positive solutions to recurrence (3) in terms of the ratio of the initial terms belonging to a certain closed interval. Here we understand a closed interval to be empty, a single point, an interval with finite endpoints, or a half-line (including ∞).

► **Proposition 3.8.** *Consider a recurrence of the form (3) for which the coefficients $\langle a_n \rangle_n$ and $\langle b_n \rangle_n$ have constant sign on \mathbb{N} . There exists a closed interval P such that a non-trivial solution $\langle u_n \rangle_n$, with $u_{-1}, u_0 \geq 0$, to the recurrence is positive if and only if $u_0/u_{-1} \in P$. Moreover, the endpoints of the interval can be expressed using polynomial continued fractions.*

Proof. In the cases where the recurrence has signature $(+, +)$ or $(-, -)$, we can set $P = [0, \infty) \cup \{\infty\}$ ($[0, \infty]$ for short) and $P = \emptyset$, respectively.

Consider now a recurrence with signature $(+, -)$. If it is of the form (4), then we have the following: if the associated continued fraction $\mathbf{K}(\kappa_n/1)$ diverges, then there are no non-trivial positive solutions by Lemma 3.3, and we set $P = \emptyset$. If it converges to f (in particular (5) holds), we may set $P = [-f, \infty]$ as is immediate from Proposition 3.6.

Assume then that the recurrence is not of the form (4). The transformation from $\langle u_n \rangle_n$ to a solution $\langle w_n \rangle_n$ to a recurrence of the form (4) preserves minimality and positivity. Hence, if the associated continued fraction $\mathbf{K}(a_n/b_n)$ does not converge, then there are no non-trivial positive solutions and we may set $P = \emptyset$. If it converges, then so does the continued fraction $\mathbf{K}(\kappa_n/1)$; say it converges to f . Then a non-trivial solution to the recurrence is positive if and only if $u_0/u_{-1} = w_0/(b_0w_{-1}) \in [-f/b_0, \infty]$.

We are left with recurrences (3) with signature $(-, +)$. Let $\langle f_n \rangle_n$ denote the sequence of approximants of the associated continued fraction. One can show by straightforward induction that the sequence $\langle B_n \rangle_n$ is alternating in sign for $n \in \mathbb{N}$: the even terms are positive and the odd terms are negative. Let us write a solution $\langle u_n \rangle_n$, with $u_{-1}, u_0 \geq 0$, as $u_n = u_{-1}A_n + u_0B_n$. We have $u_n \geq 0$ if and only if $u_0/u_{-1} \geq -A_n/B_n = -f_n$ when n is even and $u_0/u_{-1} \leq -A_n/B_n = -f_n$ when n is odd. Now the continued fraction $\mathbf{K}(a_n/b_n)$ is equivalent to $-\mathbf{K}(a_n/-b_n)$. By [23, Theorem 2, §III], $\langle -f_{2n} \rangle_n$ is strictly increasing and has finite limit $-f'$, while $\langle -f_{2n-1} \rangle_n$ is strictly decreasing and has finite limit $-f''$. Moreover, $-f' \leq -f''$. It follows that $\langle u_n \rangle_n$ is positive if and only if $u_0/u_{-1} \in [-f', -f'']$.

That the (finite) endpoints of the above intervals can be described using polynomial continued fractions follows from similar minimality-preserving transformations as performed in the proof of Corollary 2.7 and, in the case of the points f', f'' , from results in [23, §II.2.4]. \blacktriangleleft

4 Detecting positive and dominant solutions

The goal of this section is to prove Proposition 3.7, as such, we will suppose that (5) holds for each $n \in \mathbb{N}$ in the following. The proof follows from the results in Corollary 4.2 and Corollary 4.6.

Broadly speaking, we describe a semi-algorithm with inputs $\langle w_n \rangle_n$. This semi-algorithm terminates in finite time for sequences that are dominant with output “*input is a positive sequence*” or “*input is not a positive sequence,*” as appropriate. The semi-algorithm is non-terminating when given a minimal solution as an input. In terminating instances, the running time depends upon the distance between $-w_0/w_{-1}$ and $\mathbf{K}_{n=1}^\infty(\kappa_n/1)$.

The sequence of approximants $\langle f_n \rangle_{n=1}^\infty$ associated with $\mathbf{K}_{n=1}^\infty(\kappa_n/1)$ is recursively defined by a composition of linear fractional transformations $f_n := s_1 \circ \dots \circ s_n(0)$ where $s_n(w) = \kappa_n/(1+w)$ for each $n \in \{1, 2, \dots\}$ and $w \in \hat{\mathbb{R}}$. The tail sequences of $\mathbf{K}(\kappa_n/1)$ are also recursively defined by linear fractional transformations: given such a tail sequence $\langle t_n \rangle_n$, $s_n^{-1}(t_{n-1}) = t_n$ for each $n \in \mathbb{N}$ (by (2)).

For each n , the linear fractional transformation s_n above has two fixed points $\omega_n^\pm := \frac{1}{2}(-1 \pm \sqrt{1 + 4\kappa_n})$. By (5), $\langle \sqrt{1 + 4\kappa_n} \rangle_n$ converges to a real value. We split our analysis into two cases depending on whether κ_n converges to $-1/4$. These subcases are common in the literature (cf. [23, §5]) as some of the convergence properties of the continued fraction $\mathbf{K}(\kappa/1)$ (with $\kappa := \lim_{n \rightarrow \infty} \kappa_n$) hold for the continued fraction $\mathbf{K}(\kappa_n/1)$. In fact, the subcases of *limit hyperbolic-* and *parabolic type* are named for the classification of the limiting linear fractional transformation $s(w) = \kappa/(1+w)$.

4.1 limit hyperbolic type

A continued fraction $\mathbb{K}(\kappa_n/1)$ is of *limit hyperbolic type* if the finite value $\kappa := \lim_{n \rightarrow \infty} \kappa_n$ satisfies $\kappa > -1/4$. In this case the sequences $\langle \omega_n^+ \rangle_n$ and $\langle \omega_n^- \rangle_n$ converge to distinct limits ω^+ and ω^- , respectively. We shall assume, without loss of generality, that aforementioned eventually statements hold for each $n \in \mathbb{N}$.

The next result is given in the literature. A more general result for asymptotic properties of tail sequences associated with a continued fraction of limit hyperbolic type is given in [24, Theorem 4.13].

► **Theorem 4.1.** *Suppose that $\mathbb{K}(\kappa_n/1)$ is of limit hyperbolic type. The sequence of tails $\langle f^{(n)} \rangle_n$ converges to ω^+ . A tail sequence $\langle t_n \rangle_n$ with $t_0 \neq f^{(0)}$ converges to ω^- .*

► **Corollary 4.2.** *Suppose that $\mathbb{K}(\kappa_n/1)$ is of limit hyperbolic type. One can detect if a solution sequence $\langle w_n \rangle_n$ of recurrence (4) is positive and dominant.*

Proof. Let $\langle t_n \rangle_n$ be the tail sequence associated with a non-trivial solution $\langle w_n \rangle_n$. By Theorem 4.1, a tail sequence $\langle t_n \rangle_n$ associated with a dominant solution converges to ω^- in the limit, whilst the tail sequence $\langle f^{(n)} \rangle_n$ associated with a minimal solution converges to ω^+ in the limit.

There is a computable $N \in \mathbb{N}$ such that for all $n \geq N$, the two fixed points of s_n^{-1} are separated: $\omega_n^- < (\omega^- + \omega^+)/2 = -1/2 < \omega_n^+$. If $m > N$ and $t_m < -1/2$ then $\langle t_{n+m} \rangle_n$ is bounded from above by $-1/2$. This is established by induction. The base case is ensured by the assumption $t_m < -1/2$. Now let $n \geq m$ such that $t_n < -1/2$, we have that $t_{n+1} = s_{n+1}^{-1}(t_n) = \frac{\kappa_{n+1}}{t_n} - 1$. Assume first that $\omega_{n+1}^- < t_n$, then $t_{n+1} = s_{n+1}^{-1}(t_n) \leq t_n < -1/2$ as t_n lies between the two fixed points of s_{n+1} . Otherwise, if $\omega_{n+1}^- \geq t_n$, then

$$t_{n+1} = s_{n+1}^{-1}(t_n) = \frac{\kappa_{n+1}}{t_n} - 1 \leq \frac{\kappa_{n+1}}{\omega_{n+1}^-} - 1 = s_{n+1}^{-1}(\omega_{n+1}^-) = \omega_{n+1}^- < -1/2$$

which completes the induction step.

Thus we can detect if a tail sequence is associated with a dominant solution. Moreover, this observation allows us to detect whether a dominant solution is positive in finite time. ◀

4.2 limit parabolic type

A continued fraction $\mathbb{K}(\kappa_n/1)$ is of *limit parabolic type* if $\lim_{n \rightarrow \infty} \kappa_n = -1/4$. In this case both $\langle \omega_n^+ \rangle_n$ and $\langle \omega_n^- \rangle_n$ converge to $-1/2$.

The limit parabolic case is subtler than the limit hyperbolic case; this is best illustrated by the following result: all tail sequences converge to the same limit (see the general case [24, Theorem 4.17]).

► **Theorem 4.3.** *Let $\mathbb{K}(\kappa_n/1)$ be a continued fraction of limit parabolic type such that (5) holds for each $n \in \mathbb{N}$. Each tail sequence $\langle t_n \rangle_n$ associated with $\mathbb{K}(\kappa_n/1)$ converges to $-1/2$.*

From our assumption that (5) holds for each $n \in \mathbb{N}$, we have bounds on the sequence of tails $f^{(n-1)} := \mathbb{K}_{m=n}^{\infty}(\kappa_m/1)$ by the following generalisation of Worpitzky's Theorem (see, for example, [24, Theorem 3.30]).

► **Theorem 4.4.** *Let $\langle \kappa_n \rangle_n$ be a sequence such that (5) holds for $n \in \mathbb{N}$. Then $\mathbb{K}(\kappa_n/1)$ converges to a finite value f with $0 < |f| \leq 1$ and $|f^{(n)}| \leq g_n$ for each n where $g_0 = 1$ and $g_n := 1/2 + 1/(4n) + 1/(4n \log n)$ for each $n \in \mathbb{N}$.*

The inequalities given in the proof of the next lemma follow from the observation that $s_n^{-1}: (-\infty, 0) \rightarrow (-1, \infty)$ given by $s_n^{-1}(w) = -1 + \kappa_n/w$ is a monotonic bijection.

► **Lemma 4.5.** *Suppose that $\mathbb{K}(\kappa_n/1)$ is of limit parabolic type such that (5) holds for each $n \in \mathbb{N}$. Let $\langle t_n \rangle_n$ be a tail sequence such that $f^{(0)} - t_0 > 0$. Then there exists an $N \in \mathbb{N}$ such that $t_N < -g_N < f^{(N)}$.*

Proof. First, note that one can deduce from Theorem 4.4 that $-g_n < f^{(n)} < 0$ for each $n \in \mathbb{N}$ (otherwise there is an m such that $f^{(m+1)} < -g_{m+1}$). Now let $\langle t_n \rangle_n$ be a tail sequence associated with the continued fraction $\mathbb{K}_{n=1}^{\infty}(\kappa_n/1)$ such that $f^{(0)} - t_0 > 0$. Suppose, for a contradiction, that $-g_n < t_n$ for each $n \in \mathbb{N}$. Thus $\sum_{n=1}^{\infty} \prod_{k=1}^n (-\frac{1+t_n}{t_n})$ diverges to ∞ by comparison with $\sum_{n=1}^{\infty} \prod_{k=1}^n (\frac{1-g_n}{g_n})$; the latter series is known to diverge as $\mathbb{K}_{n=1}^{\infty}(\frac{-g_{n-1}(1-g_n)}{1-g_n})$ is a convergent continued fraction (the full argument, which is beyond the scope of this paper, is given in [36]). However, by Waadeland's Tail Theorem [36, Theorem 1], divergence of $\sum_{n=1}^{\infty} \prod_{k=1}^n (-\frac{1+t_n}{t_n})$ implies that $t_0 = \mathbb{K}_{n=1}^{\infty}(\kappa_n/1) = f^{(0)}$, which contradicts our assumption that $f^{(0)} - t_0 > 0$. ◀

► **Corollary 4.6.** *Suppose that $\mathbb{K}(\kappa_n/1)$ is of limit parabolic type such that (5) holds for each $n \in \mathbb{N}$. One can detect if a solution sequence $\langle w_n \rangle_n$ of recurrence (4) is positive and dominant.*

Proof. Let $\langle t_n \rangle_n$ be the tail sequence associated with a non-trivial solution $\langle w_n \rangle_n$. If $\langle w_n \rangle_n$ is dominant and positive, one has $f^{(0)} - t_0 > 0$ by Proposition 3.6. Moreover, by Lemma 4.5, there exists an $N \in \mathbb{N}$ such that for $t_N < -g_N < f^{(N)}$. Hence one can use the threshold of $-g_N$ to detect whether a solution sequence is dominant and positive. ◀

Improved Upper Bounds for the Rigidity of Kronecker Products

Bohdan Kivva   

University of Chicago, IL, USA

Abstract

The *rigidity* of a matrix A for target rank r is the minimum number of entries of A that need to be changed in order to obtain a matrix of rank at most r . At MFCS'77, Valiant introduced matrix rigidity as a tool to prove circuit lower bounds for linear functions and since then this notion received much attention and found applications in other areas of complexity theory. The problem of constructing an explicit family of matrices that are sufficiently rigid for Valiant's reduction (Valiant-rigid) still remains open. Moreover, since 2017 most of the long-studied candidates have been shown not to be Valiant-rigid.

Some of those former candidates for rigidity are Kronecker products of small matrices. In a recent paper (STOC'21), Alman gave a general non-rigidity result for such matrices: he showed that if an $n \times n$ matrix A (over any field) is a Kronecker product of $d \times d$ matrices M_1, \dots, M_k (so $n = d^k$) ($d \geq 2$) then changing only $n^{1+\varepsilon}$ entries of A one can reduce its rank to $\leq n^{1-\gamma}$, where $1/\gamma$ is roughly $2^d/\varepsilon^2$.

In this note we improve this result in two directions. First, we do not require the matrices M_i to have equal size. Second, we reduce $1/\gamma$ from exponential in d to roughly $d^{3/2}/\varepsilon^2$ (where d is the maximum size of the matrices M_i), and to nearly linear (roughly d/ε^2) for matrices M_i of sizes within a constant factor of each other.

As an application of our results we significantly expand the class of Hadamard matrices that are known not to be Valiant-rigid; these now include the Kronecker products of Paley-Hadamard matrices and Hadamard matrices of bounded size.

1 Introduction

1.1 Recent upper bounds on rigidity

In his celebrated MFCS'77 paper [13], Leslie Valiant introduced the notion of matrix rigidity as a tool to prove lower bounds for arithmetic circuits. Since then, several other important problems in complexity theory have been reduced to proving rigidity lower bounds for explicit families of matrices (see, e.g., [12, 7] and the survey [10]).

► **Definition 1.** Let \mathbb{F} be a field. For a matrix $A \in \mathbb{F}^{n \times m}$ and a target rank $0 \leq r \leq \min(n, m)$ let $R_{\mathbb{F}}(A, r)$ denote the minimum number of non-zero entries in a matrix $Z \in \mathbb{F}^{n \times m}$ such that $\text{rank}(A - Z) \leq r$. The function $R_{\mathbb{F}}(A, \cdot)$ is called the rigidity of A over \mathbb{F} .

Valiant [13] proved that if for some $\varepsilon > 0$ the sequence of matrices $A_n \in \mathbb{F}^{n \times n}$ satisfies

$$R_{\mathbb{F}}(A_n, n/\log \log n) \geq n^{1+\varepsilon}, \quad (1)$$

then the linear functions $x \mapsto A_n x$ cannot be computed by arithmetic circuits of size $O(n)$ and depth $O(\log n)$. Following [5], we say that a family of matrices A_n is *Valiant-rigid* if it satisfies Eq. (1) for some $\varepsilon > 0$ and all sufficiently large n . By saying that a family \mathcal{F} of matrices is not Valiant-rigid we mean that none of the subsequences of matrices of \mathcal{F} of increasing order is Valiant-rigid.

The problem of constructing explicit Valiant-rigid matrices has been attacked for more than four decades, but still remains open (see the survey [10]). Over this time a few candidates of Valiant-rigid families were proposed that included Hadamard matrices [11, 12], circulants [4], Discrete Fourier Transform (DFT) matrices [13], incidence matrices of projective planes over a finite field [13].

In 2017, Alman and Williams [2] proved, that, contrary to expectations, the Walsh–Hadamard matrices are not Valiant-rigid over \mathbb{Q} . Subsequently, most of other long-studied candidates for rigidity were shown not to be Valiant-rigid. Dvir and Edelman [5] proved that G -circulants¹ are not Valiant-rigid over \mathbb{F}_p for G the additive group of \mathbb{F}_p^n . Dvir and Liu [6] proved that DFT matrices, circulant matrices, and more generally, G -circulant matrices for any abelian group G , are not Valiant-rigid over \mathbb{C} . Moreover, as observed in [3], the results of Dvir and Liu imply that the Paley–Hadamard matrices and the Vandemonde matrices with a geometric progression as generators are not Valiant-rigid over \mathbb{C} , and the incidence matrices of projective planes over finite fields are not Valiant-rigid either over \mathbb{F}_2 (contrary to Valiant’s suggestion [13]) or over \mathbb{C} .

Upper bounds on the rigidity of the Kronecker powers of a fixed matrix play an important role in these results. Indeed, the Walsh–Hadamard matrices are just the Kronecker powers of $H_2 = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$. Furthermore, in order to show that DFT and circulant matrices are not Valiant-rigid, as the first step, Dvir and Liu [6] prove that generalized Walsh–Hadamard matrices (Kronecker powers of a DFT matrix) are not Valiant-rigid.

Hence, one may expect that strong upper bounds on the rigidity of Kronecker products of small matrices may lead to upper bounds on the rigidity of interesting new families of matrices, and so will further contribute to our intuition of where not to look for Valiant-rigid matrices.

Recently, Josh Alman [1] proved that Kronecker products of square matrices of any *fixed* size are not Valiant-rigid. More precisely, he proved the following result.

► **Theorem 2 (Alman).** Given $d \geq 2$ and $\varepsilon > 0$, there exists $\gamma = \Omega\left(\frac{d \log d}{2^d} \cdot \frac{\varepsilon^2}{\log^2(1/\varepsilon)}\right)$ such that the following holds for any sequence of matrices $M_1, M_2, \dots, M_k \in \mathbb{F}^{d \times d}$. Let $M = \bigotimes_{i=1}^k M_i$ and $n = d^k$. Then $R_{\mathbb{F}}(M, n^{1-\gamma}) \leq n^{1+\varepsilon}$.

¹ For a finite abelian group G , a G -circulant is a $|G| \times |G|$ matrix of the form $M(f)$ with entries $M(f)_{xy} = f(x - y)$ ($x, y \in G$) where f is any function with domain G .

1.2 Our results: improved bounds, non-uniform sizes

In this note we improve Alman’s result in two directions. First, we do not require the matrices M_i to have equal size. Second, we reduce $1/\gamma$ from exponential in d to roughly $d^{3/2}/\varepsilon^2$ (where d is the maximum size of the matrices), and to nearly linear (roughly d/ε) for matrices M_i of sizes within a constant factor of each other.

This means that for matrices of equal size we get a meaningful reduction of the rank already for $k = \tilde{O}_\varepsilon(d)$, in contrast to Alman’s result that kicks in when k reaches about 2^d .

► **Theorem 3.** *Given $d \geq 2$ and $\varepsilon > 0$, there exists $\gamma = \Omega\left(\frac{1}{d^{3/2} \log^3(d)} \cdot \frac{\varepsilon^2}{\log^2(1/\varepsilon)}\right)$ such that the following holds for any sequence of matrices M_1, M_2, \dots, M_k where $M_i \in \mathbb{F}^{d_i \times d_i}$ for some $d_i \leq d$. Let $M = \bigotimes_{i=1}^k M_i$ and $n = \prod_{i=1}^k d_i$. If $n \geq d^{1/\gamma}$, then $R_{\mathbb{F}}(M, n^{1-\gamma}) \leq n^{1+\varepsilon}$.*

If the d_i are within a constant factor of each other, we obtain the following stronger result.

► **Theorem 4.** *Given $d \geq 2$, $\varepsilon > 0$, and a constant $c > 0$, there exists $\gamma = \Omega_c\left(\frac{1}{d \log d} \cdot \frac{\varepsilon^2}{\log^2(1/\varepsilon)}\right)$ such that the following holds for any sequence of matrices M_1, M_2, \dots, M_k where $M_i \in \mathbb{F}^{d_i \times d_i}$ and $cd \leq d_i \leq d$. Let $M = \bigotimes_{i=1}^k M_i$ and $n = \prod_{i=1}^k d_i$. If $n \geq d^{1/\gamma}$, then $R_{\mathbb{F}}(M, n^{1-\gamma}) \leq n^{1+\varepsilon}$.*

In the above theorem, the dependence of γ on c is nearly linear and the explicit formula can be found in Corollary 22.

The key strength of our results is that we do not need to assume uniform size of the matrices participating in the Kronecker product. Previous approaches depended on uniform size because of their reliance either on a polynomial method, or on an induction on the size of the matrix. As an applications of the bound for matrices of non-uniform size we show that our results significantly expand the class of Hadamard matrices that are known not to be Valiant-rigid. We show that the Kronecker products of Paley-Hadamard matrices and Hadamard matrices of bounded size are not Valiant-rigid (see Sec. 1.4).

Another strength of our improvement is that our bounds are sufficiently strong to be fed into the machinery developed by Dvir and Liu [6] for matrices of “well-factorable” size. Hence, we expect that this improvement might lead to further applications.

We note, that our bound on γ in Theorem 4 matches the Dvir–Liu bounds for Kronecker powers of specific classes of matrices, such as the generalized Walsh–Hadamard matrices and DFT matrices² of direct products of small abelian groups.

We also note that our upper bounds, similarly to upper bounds in recent work [2, 5, 6, 1], apply to a stronger notion of rigidity, called *row-column rigidity*.

► **Definition 5 (Row-column rigidity).** *For a matrix $A \in \mathbb{F}^{n \times n}$ and a target rank $0 \leq r \leq n$, let $R_{\mathbb{F}}^{rc}(A, r)$ be the minimal t for which there exists $Z \in \mathbb{F}^{n \times n}$ such that $\text{rank}(A - Z) \leq r$ and every row and column of Z has at most t non-zero entries.*

In Theorems 2, 3, and 4 the conclusion can be replaced by $R_{\mathbb{F}}^{rc}(M, n^{1-\gamma}) \leq n^\varepsilon$. Clearly, the latter statement is stronger, as for any $A \in \mathbb{F}^{n \times n}$ the inequality $R_{\mathbb{F}}(A, r) \leq n \cdot R_{\mathbb{F}}^{rc}(A, r)$ holds. The row-column versions of Theorems 3, and 4 are stated and proved as Theorem 24 and Corollary 23.

² The DFT (Discrete Fourier Transform) matrix of a finite abelian group G is the character table of G .

1.3 The field

We should point out that Theorems 2-4 make no assumption about the field \mathbb{F} , and they use elements of \mathbb{F} for the rank reduction. This is in contrast to the results of Dvir and Liu who require a field extension to achieve their rank reduction.

If the field \mathbb{F} is the field of definition of the matrix A , in [3] we call the corresponding rigidity function $R_{\mathbb{F}}(A, \cdot)$ the *strict rigidity* of A . If $\overline{\mathbb{F}}$ denotes the algebraic closure of \mathbb{F} then we call $R_{\overline{\mathbb{F}}}(A, \cdot)$ the *absolute rigidity* of A because, as shown in [3], this gives the smallest possible rigidity among all extension fields. A gap between these two quantities is demonstrated in [3]. Note that an upper bound on strict rigidity is a stronger statement than the same upper bound on absolute rigidity.

In this terminology, Dvir and Liu give upper bounds on absolute rigidity, whereas Alman's result and our results give upper bounds on strict rigidity.

1.4 Application of our results: rigidity upper bounds for Hadamard matrices

We recall that an *Hadamard matrix* is a square matrix whose entries are $+1$ and -1 and whose rows are mutually orthogonal. In addition to many other interesting properties, it was long believed that one can find a family of Valiant-rigid matrices among Hadamard matrices.

Contrary to expectations, two of the most well-studied families of Hadamard matrices were recently shown to be not Valiant-rigid. In 2017, Alman and Williams [2] proved that Walsh-Hadamard matrices are not strictly Valiant-rigid. As a corollary to [6], in [3] it was shown that Paley-Hadamard matrices are not absolutely Valiant-rigid. These results inspired the following conjecture.

► **Conjecture 6** (Babai). *The family of known Hadamard matrices is not strictly Valiant-rigid.*

We mention that in addition to infinite families, new classes of Hadamard matrices arise as Kronecker products of a steadily growing starter set of small Hadamard matrices with other known Hadamard matrices (see, e.g., surveys [8, 9]). Indeed, note that if H_1 and H_2 are Hadamard matrices, then $H_1 \otimes H_2$ is an Hadamard matrix as well.

As an application of our results for Kronecker products of matrices of non-uniform size we further expand the family of Hadamard matrices that are known not to be Valiant-rigid.

► **Theorem 7.** *Let \mathcal{F}_0 be the family of Paley-Hadamard matrices and Hadamard matrices of bounded size. Let \mathcal{F} be the family of all matrices that can be obtained as Kronecker products of some matrices from \mathcal{F}_0 . Then \mathcal{F} is not absolutely Valiant-rigid.*

► **Remark 8.** We note that Hadamard matrices are naturally defined over \mathbb{Q} , while the theorem above shows that matrices in \mathcal{F} are not sufficiently rigid when we make changes from \mathbb{C} . It is still open whether Paley-Hadamard matrices are strictly Valiant-rigid. If one proves that Paley-Hadamard matrices satisfy the inequality from Eq. (2), our proof will immediately yield the stronger version of the theorem above, that \mathcal{F} is not strictly Valiant-rigid.

► **Remark 9.** We note that Theorem 7 does not follow from Alman's original upper bound for rigidity of Kronecker products (Theorem 2).

A more general version of Theorem 7 can be stated for Kronecker products of matrices of bounded size and matrices that are sufficiently not rigid.

► **Theorem 10.** Let $0 < \varepsilon < 1/2$ and $b \geq 2$. Let \mathcal{F} be a family of matrices over \mathbb{F} , such that for every $d \times d$ matrix $A \in \mathcal{F}$ either $d \leq b$, or

$$R_{\mathbb{F}}^{rc}(A, d^{1-\gamma}) \leq d^\varepsilon \quad \text{for } \gamma = \frac{12(\log \log d)^2}{\varepsilon^3 \log d}. \quad (2)$$

Then, for every sequence of matrices $M_1, M_2, \dots, M_k \in \mathcal{F}$, the $n \times n$ matrix $M = \bigotimes_{i \in [k]} M_i$ either satisfies $R_{\mathbb{F}}^{rc}(M, n/\log n) \leq n^{6\varepsilon}$, or n is bounded above by a function of b and ε .

► **Corollary 11.** Let \mathcal{F} be a family of square matrices over \mathbb{F} . If for every $0 < \varepsilon < 1/2$ there exists $b \geq 2$ such that \mathcal{F} satisfies the assumptions of Theorem 10, then the family of Kronecker products of matrices from \mathcal{F} is not Valiant-rigid over \mathbb{F} .

We prove Theorems 7 and 10 in Section 5.

1.5 Our approach

In order to prove Theorem 2, Alman [1] first uses a beautiful trick to deduce the claim for Kronecker products of 2×2 matrices. He observes that it is sufficient to prove the claim for $R = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$. The Kronecker powers of R have low rigidity since they are very sparse. After that, he applies induction on the size d of the matrices involved in the Kronecker product. The technically involved induction argument leads to the factor 2^{-d} in γ .

Our proof is simpler and omits induction. Instead, we observe that an idea, somewhat similar to Alman’s proof of the base case $d = 2$, can be applied for any d .

Our key observation is that any $d \times d$ matrix can be written as a product of at most $2d$ very sparse matrices and $2d$ permutation matrices.

Specifically, for a vector $x \in \mathbb{F}^d$ define a $d \times d$ matrix

$$G_d(x) = \begin{pmatrix} I_{d-1} & x \\ 0 & \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \dots & 0 & x_1 \\ 0 & 1 & 0 \dots & 0 & x_2 \\ \dots & & & & \\ 0 & 0 & 0 \dots & 1 & x_{d-1} \\ 0 & 0 & 0 \dots & 0 & x_d \end{pmatrix}. \quad (3)$$

We are going to call the matrices of this form the *V-matrices* for the pattern of their non-zero entries. Next, it is not hard to verify that any $d \times d$ matrix can be written as

$$A = P_1 \cdot G_d(y)^T \cdot \begin{pmatrix} B & 0 \\ 0 & \lambda \end{pmatrix} \cdot G_d(x) \cdot P_2,$$

where $\lambda \in \{0, 1\} \subseteq \mathbb{F}$, $B \in \mathbb{F}^{(d-1) \times (d-1)}$ and P_1, P_2 are permutation matrices. By repeating this procedure for B at most $d - 2$ times one ends up with a product of $2d - 2$ V-matrices, a diagonal matrix, and permutation matrices (see Section 2.1).

As was observed in [6], the row-column rigidity of the product can be controlled by the row-column rigidity of each component.

► **Lemma 12.** For arbitrary $d \times d$ matrices A and B over a field \mathbb{F}

$$R_{\mathbb{F}}^{rc}(A \cdot B, r + s) \leq R_{\mathbb{F}}^{rc}(A, r) \cdot R_{\mathbb{F}}^{rc}(B, s). \quad (4)$$

Recall that a *monomial matrix* is a matrix where each row and each column has at most one non-zero element. A matrix is monomial exactly if it is the product of a diagonal matrix and a permutation matrix. A Kronecker product of monomial matrices is itself a monomial matrix. Moreover, if P is a monomial matrix then $R_{\mathbb{F}}^{rc}(P, 0) = 1$. Thus, in order to prove Theorem 4 one only needs to show strong upper bounds on row-column rigidity for Kronecker products of V-matrices.

To bound the row-column rigidity of a matrix M that is a Kronecker product of V-matrices one needs to observe that most of the non-zero entries are concentrated in just a few columns and rows, and so these entries form a low-rank matrix.

We discuss our strategy for upper bounds on rigidity of Kronecker products in Section 2. We prove Theorem 4 for the case of matrices of equal size in Section 3. We discuss rigidity bounds for matrices of unequal sizes in Section 4. Some standard tail bounds for binomial distributions are reviewed in Appendix A. We expand the family of Hadamard matrices known not to be Valiant rigid in Section 5. The proof of Obs. 14 omitted in Section 2 is provided in Appendix B.

1.6 Notation

We use $[n]$ to denote the set $\{1, 2, \dots, n\}$. \mathbb{F} denotes a field. Throughout the paper we use \vec{d} to denote the vector (d_1, d_2, \dots, d_k) , where each $d_i \geq 2$. We define $[\vec{d}] = [d_1] \times [d_2] \times \dots \times [d_k]$. We say that $X \in \mathbb{F}^{\vec{d}}$ if $X = (X_1, X_2, \dots, X_k)$, where $X_i \in \mathbb{F}^{d_i}$.

We use standard asymptotic notation. Let $f(n), g(n)$ be non-negative functions. We say that $f(n) = O(g(n))$ if there exists a constant C such that $f(n) \leq Cg(n)$ for all sufficiently large n . We say that $f(n) = \Omega(g(n))$ if $g(n) = O(f(n))$. Finally, $f(n) = \Theta(g(n))$ if $f(n) = O(g(n))$ and $f(n) = \Omega(g(n))$.

2 A strategy for upper bounds on the rigidity of Kronecker products

2.1 Expressing a matrix as a product of V-matrices

Recall that for a vector $x \in \mathbb{F}^d$ we define a $d \times d$ V-matrix

$$G_d(x) = \begin{pmatrix} I_{d-1} & x \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \dots & 0 & x_1 \\ 0 & 1 & 0 \dots & 0 & x_2 \\ \dots & & & & \\ 0 & 0 & 0 \dots & 1 & x_{d-1} \\ 0 & 0 & 0 \dots & 0 & x_d \end{pmatrix}. \quad (5)$$

Let $\vec{d} = (d_1, d_2, \dots, d_k)$. For $X = (X_1, X_2, \dots, X_k)$ with $X_i \in \mathbb{F}^{d_i}$ for $i \in [k]$, define

$$G_{\vec{d}}(X) = \bigotimes_{i=1}^k G_{d_i}(X_i). \quad (6)$$

In the case when \vec{d} consists of k equal coordinates $d_i = d$, we use notation $G_{d,k}(X) := G_{\vec{d}}(X)$.

► **Definition 13.** *A square matrix P is called a permutation matrix, if every row and every column of P has precisely one non-zero entry, which is equal to 1.*

Recall, that arbitrary permutation of columns (rows) of a matrix can be represented by right (left, respectively) multiplication by a permutation matrix.

The multiplication of an $m \times d$ matrix A by $G_d(x)$ from the right corresponds to keeping the first $d - 1$ columns of A unchanged and replacing the last column of A with a linear combination of the columns of A with the coefficients given by x . We make the following observation.

► **Observation 14.** For any matrix $A \in \mathbb{F}^{d \times d}$ there exist $B \in \mathbb{F}^{(d-1) \times (d-1)}$, vectors $x, y \in \mathbb{F}^d$, $\lambda \in \{0, 1\} \subseteq \mathbb{F}$ and permutation matrices $P_1, P_2 \in \mathbb{F}^{d \times d}$ such that

$$A = P_1 \cdot G_d(y)^T \cdot \begin{pmatrix} B & 0 \\ 0 & \lambda \end{pmatrix} \cdot G_d(x) \cdot P_2. \quad (7)$$

Proof. See Appendix B. ◀

► **Corollary 15.** For any matrix $A \in \mathbb{F}^{d \times d}$ there exist a diagonal matrix W , $2(d - 1)$ vectors X_i, Y_i for $i \in [d - 1]$, and $2(d - 1)$ permutation matrices P_i, Q_i for $i \in [d - 1]$ such that

$$A = Q_1 \cdot G_d(Y_1)^T \cdot Q_2 \cdot \dots \cdot G_d(Y_{d-1})^T \cdot W \cdot G_d(X_{d-1}) \cdot P_{d-1} \cdot \dots \cdot G_d(X_1) \cdot P_1. \quad (8)$$

Proof. Let $t \in [d - 1]$. Observe that for $x \in \mathbb{F}^t$ and the vector $y \in \mathbb{F}^d$, whose first $d - t$ coordinates are 0, and last t coordinates are equal to the corresponding coordinates of x ,

$$\begin{pmatrix} G_{d-t}(x) & 0 \\ 0 & I_t \end{pmatrix} = P_1 G_d(y) P_2, \quad (9)$$

where I_t is the $t \times t$ identity matrix and P_1, P_2 are the permutation matrices that exchange the first $d - t$ and the last t rows and columns, respectively.

Then, the claim of the corollary follows from Observation 14 by applying it recursively $d - 1$ times to the remaining top-left block B , until we are left with a diagonal matrix. ◀

By combining the above corollary with Lemma 12 we obtain the following inequality.

► **Lemma 16.** Let $d \geq 2$, $r \leq d^k$ and $M_1, M_2, \dots, M_k \in \mathbb{F}^{d \times d}$. Then

$$R_{\mathbb{F}}^{rc} \left(\bigotimes_{i=1}^k M_i, (2d - 2)r \right) \leq \left(\max_{X \in \mathbb{F}^{d \times k}} R_{\mathbb{F}}^{rc} (G_{d,k}(X), r) \right)^{2d-2}. \quad (10)$$

Proof. By Corollary 15, for each $i \in [k]$ there exist $2(d - 1)$ vectors $X_i^{(j)}, Y_i^{(j)} \in \mathbb{F}^d$, $2(d - 1)$ permutation matrices $P_i^{(j)}, Q_i^{(j)}$ and a diagonal matrix W_i such that

$$M_i = \prod_{j=1}^{d-1} \left(Q_i^{(j)} \cdot G_d(Y_i^{(j)})^T \right) \cdot W_i \cdot \prod_{j=1}^{d-1} \left(G_d(X_i^{(d-j)}) \cdot P_i^{(d-j)} \right).$$

Then, using that $(A_1 \otimes B_1) \cdot (A_2 \otimes B_2) = (A_1 A_2) \otimes (B_1 B_2)$ holds for any matrices, we get

$$\bigotimes_{i=1}^k M_i = \prod_{j=1}^{d-1} \left(\bigotimes_{i=1}^k Q_i^{(j)} \bigotimes_{i=1}^k G_d(Y_i^{(j)})^T \right) \cdot \left(\bigotimes_{i=1}^k W_i \right) \cdot \prod_{j=1}^{d-1} \left(\bigotimes_{i=1}^k G_d(X_i^{(d-j)}) \bigotimes_{i=1}^k P_i^{(d-j)} \right).$$

Let $X^{(j)} \in \mathbb{F}^{d \times k}$ be a matrix whose i -th column is $X_i^{(j)}$. Define $Y^{(j)} \in \mathbb{F}^{d \times k}$ similarly. Let

$$Q^{(j)} = \bigotimes_{i=1}^k Q_i^{(j)}, \quad P^{(j)} = \bigotimes_{i=1}^k P_i^{(j)}, \quad W = \bigotimes_{i=1}^k W_i. \quad (11)$$

68:8 Improved Upper Bounds for the Rigidity of Kronecker Products

Then, $Q^{(j)}$ and $P^{(j)}$ are permutation matrices, and W is a diagonal matrix, and

$$M = \bigotimes_{i=1}^k M_i = \prod_{j=1}^{d-1} \left(Q^{(j)} \cdot G_{d,k}(Y^{(j)})^T \right) \cdot W \cdot \prod_{j=1}^{d-1} \left(G_{d,k}(X^{(d-j)}) \cdot P^{(d-j)} \right). \quad (12)$$

Thus, by Lemma 12,

$$\begin{aligned} R_{\mathbb{F}}^{rc}(M, (2d-2)r) &\leq \prod_{j=1}^{d-1} R_{\mathbb{F}}^{rc}(G_{d,k}(Y^{(j)}), r) \cdot \prod_{j=1}^{d-1} R_{\mathbb{F}}^{rc}(G_{d,k}(X^{(j)}), r) \leq \\ &\leq \left(\max_{X \in \mathbb{F}^{d \times k}} R_{\mathbb{F}}^{rc}(G_{d,k}(X), r) \right)^{2d-2}. \end{aligned} \quad (13)$$

◀

Furthermore, we note that a similar statement holds for Kronecker products of matrices of not necessarily equal size.

► **Lemma 17.** *Let $d_i \geq 2$ and $M_i \in \mathbb{F}^{d_i \times d_i}$ for $i \in [k]$. Assume $d_k \geq d_i$ for $i \in [k]$. Then*

$$R_{\mathbb{F}}^{rc} \left(\bigotimes_{i=1}^k M_i, (2d_k - 2)r \right) \leq \left(\max_{X \in \mathbb{F}^{\vec{d}}} R_{\mathbb{F}}^{rc}(G_{\vec{d}}(X), r) \right)^{2d_k - 2}. \quad (14)$$

Proof. For M_i with $d_i < d_k$ we multiply the decomposition given by Corollary 15, by $2(d_k - d_i)$ identity matrices from the left and from the right, so that every M_i is decomposed into the product of precisely $4d_k - 3$ matrices. After this, the proof is identical to the proof of the previous lemma. ◀

2.2 General approach to upper bounds for the rigidity of $G_{\vec{d}}(X)$

As we see from Lemmas 16 and 17, in order to prove Theorems 3 and 4 it is sufficient to bound the row-column rigidity of Kronecker products of V-matrices. We describe a general approach to such bounds.

The key observation is that most of the non-zero entries of $G_{\vec{d}}(X)$ are concentrated in just a few columns and a few rows. Hence, after deleting these columns and rows we expect to get a matrix with very sparse rows and columns.

Recall, that for $\vec{d} = (d_1, d_2, \dots, d_k)$ we define $[\vec{d}] = [d_1] \times [d_2] \times \dots \times [d_k]$. The rows and the columns of $G_{\vec{d}}(X)$ are indexed by tuples in $[\vec{d}]$.

For a $d_i \times d_i$ V-matrix, all rows, except the d_i -th row, have up to two non-zero entries, while the d_i -th row has only one non-zero entry. For V-matrices, all columns, except the last one, have one non-zero entry and the last column may have up to d_i non-zero entries. Therefore, the densest rows are indexed by tuples with a small number of i -th coordinates being equal d_i and the densest columns are indexed by tuples with a large number of i -th coordinates being equal d_i , for $i \in [k]$.

Let $w : \mathbb{R} \rightarrow (0, \infty)$ be a function. Define a score of a string $x \in [\vec{d}]$ as

$$s(x) = \sum_{i=1}^k w(d_i) \mathbf{1}[x_i = d_i]. \quad (15)$$

Consider the uniform distribution on $[\vec{d}]$. Then $\chi(i) = w(d_i)\mathbf{1}[x_i = d_i]$ are independent random variables, and $s(x) = \sum_{i=1}^k \chi(i)$ with

$$\mathbb{E}_x[s(x)] = \sum_{i=1}^k \frac{w(d_i)}{d_i} \quad \text{and} \quad \text{Var}[s(x)] = \sum_{i=1}^k w(d_i)^2 \left(\frac{d_i - 1}{d_i^2} \right). \quad (16)$$

For $\delta > 0$ we define a pair of sets of strings of high and low scores, respectively

$$\mathcal{C}(\delta) = \{x \in [\vec{d}] \mid s(x) \geq \mathbb{E}_y[s(y)] + \delta\} \quad \text{and} \quad \mathcal{R}(\delta) = \{x \in [\vec{d}] \mid s(x) \leq \mathbb{E}_y[s(y)] - \delta\}. \quad (17)$$

These sets correspond to indices of the most dense columns and rows, respectively. Note, that one may use concentration inequalities to bound the sizes of these sets (see Appendix A). The matrix E defined by the union of the rows of $G_{\vec{d}}(X)$ in $\mathcal{R}(\delta)$ and the columns of $G_{\vec{d}}(X)$ in $\mathcal{C}(\delta)$ has low rank. Now we want to count the number of non-zero entries in rows and columns of $G_{\vec{d}}(X) - E$. Define

$$T_c(\delta, y) = \{x \in [\vec{d}] \setminus \mathcal{R}(\delta) \mid \forall i : y_i \in \{x_i, d_i\}\} \quad \text{and} \quad M_c(\delta) = \max_{y \in [\vec{d}] \setminus \mathcal{C}(\delta)} |T_c(\delta, y)|; \quad (18)$$

$$T_r(\delta, x) = \{y \in [\vec{d}] \setminus \mathcal{C}(\delta) \mid \forall i : y_i \in \{x_i, d_i\}\} \quad \text{and} \quad M_r(\delta) = \max_{x \in [\vec{d}] \setminus \mathcal{R}(\delta)} |T_r(\delta, x)|. \quad (19)$$

With this notation, we have the following inequality.

► **Lemma 18.** *Let $\delta > 0$. Then, for any $X \in \mathbb{F}^{\vec{d}}$,*

$$R_{\mathbb{F}}^{rc}(G_{\vec{d}}(X), |\mathcal{C}(\delta)| + |\mathcal{R}(\delta)|) \leq \max(M_c(\delta), M_r(\delta)).$$

Proof. Let E be the matrix obtained from $G_{\vec{d}}(X)$ by changing to 0 every entry that is not in a column with index in $\mathcal{C}(\delta)$ and is not in a row with index in $\mathcal{R}(\delta)$. Then

$$\text{rank}(E) \leq |\mathcal{C}(\delta)| + |\mathcal{R}(\delta)|. \quad (20)$$

Let $Z = G_{\vec{d}}(X) - E$ and $x, y \in [\vec{d}]$. Observe that the entry of $G_{\vec{d}}(X)$ with coordinates (x, y) is non-zero only if for every $i \in [k]$ either $x_i = y_i$ or $y_i = d_i$. Therefore, every row of Z has at most $M_r(\delta)$ non-zero entries, and every column of Z has at most $M_c(\delta)$ non-zero entries. ◀

Hence, in order to prove an upper bound on the rigidity of $G_{\vec{d}}(X)$, one just may come up with a good choice of weights w and a threshold $\delta > 0$ which make all the quantities $|\mathcal{C}(\delta)|$, $|\mathcal{R}(\delta)|$, $M_c(\delta)$ and $M_r(\delta)$ small.

3 Rigidity of Kronecker products of matrices of uniform size

Now, we show how the approach, described above, provides a strong upper bound on the rigidity of Kronecker products of matrices of uniform size. We follow the notation introduced earlier.

► **Theorem 19.** *Given $d \geq 2$ and $0 < \varepsilon < 1$, there exists $\gamma = \Theta\left(\frac{1}{d \log d} \cdot \frac{\varepsilon^2}{\log^2(1/\varepsilon)}\right)$ such that for all $k \geq 1$ and $X \in \mathbb{F}^{d \times k}$ we have $R_{\mathbb{F}}^{rc}(G_{d,k}(X), n^{1-\gamma}) \leq n^{\varepsilon/d}$, where $n = d^k$.*

68:10 Improved Upper Bounds for the Rigidity of Kronecker Products

Proof. We use the approach described in the previous section. We take $w(x) = 1$, then $s(x)$ given by Eq. (15) counts the number of coordinates equal to d . A simple computation gives

$$\mathbb{E}[s(x)] = k/d \quad \text{and} \quad \text{Var}[s(x)] = k(d-1)/d^2. \quad (21)$$

Then, by the Bernstein inequality (see Corollary 32), for $\delta < 1/d$,

$$|\mathcal{C}(\delta k)| = d^k \cdot \mathbb{P}[s(x) \geq k/d + \delta k] \leq \exp\left(\left(\ln d - \frac{\delta^2 d}{3}\right)k\right). \quad (22)$$

$$|\mathcal{R}(\delta k)| = d^k \cdot \mathbb{P}[s(x) \leq k/d - \delta k] \leq \exp\left(\left(\ln d - \frac{\delta^2 d}{3}\right)k\right). \quad (23)$$

Therefore, for $\delta = \Theta\left(\frac{\varepsilon}{\log(1/\varepsilon)d}\right)$,

$$|\mathcal{R}(\delta k)| + |\mathcal{C}(\delta k)| \leq d^{(1-\gamma)k} = n^{1-\gamma}, \quad \text{for some } \gamma = \Theta\left(\frac{\varepsilon^2}{d \log d \log^2(1/\varepsilon)}\right). \quad (24)$$

For a string $x \in [d]^k$ define the set $S_x = \{i \mid x_i = d\}$. Recall, that for every $y \in [d]^k \setminus \mathcal{C}(\delta k)$ we have $|S_y| \leq k(1/d + \delta)$ and for every $x \in [d]^k \setminus \mathcal{R}(\delta k)$ we have $|S_x| \geq k(1/d - \delta)$.

For each $y \in [d]^k \setminus \mathcal{C}(\delta k)$, a vector $x \in T_c(\delta k, y)$ can be described by picking a subset U of S_y of the size at most $2\delta k$ such that $U = S_y \setminus S_x$ and by picking $x_j \in [d-1]$ for every $j \in U$. So, by Lemma 33,

$$|T_c(\delta k, y)| \leq \sum_{i \leq 2\delta k} \binom{|S_y|}{i} (d-1)^i \leq \left(\frac{e|S_y|(d-1)}{2\delta k}\right)^{2\delta k} \leq \exp(2\delta \ln(3/\delta)k). \quad (25)$$

Similarly, for every row index $x \in [d]^k \setminus \mathcal{R}(\delta k)$, a column $y \in T_r(\delta k, x)$ can be described by picking a subset $U \subseteq [k] \setminus S_x$ of size at most $2\delta k$ and by setting $y_j = d$ for $j \in U$ and $y_j = x_j$ for $j \notin U$. Hence, by Lemma 33,

$$|T_r(\delta k, x)| \leq \sum_{i \leq 2\delta k} \binom{k - |S_x|}{i} \leq \left(\frac{ek}{2\delta k}\right)^{2\delta k} \leq \exp(2\delta \ln(2/\delta)k). \quad (26)$$

Therefore,

$$\max(M_c(\delta k), M_r(\delta k)) \leq \exp(2\delta \ln(3/\delta)k) \leq d^{\varepsilon k/d}, \quad \text{for some } \delta = \Theta\left(\frac{\varepsilon}{\log(1/\varepsilon)d}\right). \quad (27)$$

Hence, the conclusion of the theorem follows from Lemma 18. \blacktriangleleft

Finally, we can deduce our improved bound for the rigidity of Kronecker products of matrices of uniform size.

► Theorem 20. *Given $d \geq 2$ and $0 < \varepsilon < 1$, there exists $\gamma = \Omega\left(\frac{1}{d \log d} \cdot \frac{\varepsilon^2}{\log^2(1/\varepsilon)}\right)$ such that the following holds for any $M_1, M_2, \dots, M_k \in \mathbb{F}^{d \times d}$ with $k > 1/\gamma$. Let $M = \bigotimes_{i=1}^k M_i$ and $n = d^k$. Then*

$$R_{\mathbb{F}}^{rc}(M, n^{1-\gamma}) \leq n^{\varepsilon}, \quad \text{and so} \quad R_{\mathbb{F}}(M, n^{1-\gamma}) \leq n^{1+\varepsilon}.$$

Proof. By Theorem 19 and Lemma 16, for $\varepsilon' = \varepsilon/2$ we have

$$R_{\mathbb{F}}^{rc}(M, 2d \cdot d^{(1-\gamma')k}) \leq d^{2\varepsilon'k} \quad \text{for some } \gamma' = \Theta\left(\frac{\varepsilon^2}{\log^2(1/\varepsilon)d \log d}\right).$$

Pick $\gamma = \gamma'/3$ and note that for $k > 1/\gamma$ we have $2d \cdot d^{-2\gamma k} \leq 2d \cdot d^{-2} \leq 1$. \blacktriangleleft

4 Rigidity bounds for matrices of unequal sizes

In this section we show how a similar approach may be used to show upper bounds on the rigidity of Kronecker products of matrices of not necessarily equal sizes.

► **Theorem 21.** *Let $0 < \varepsilon < 1$ and let $w(x) \geq 1$ be a non-decreasing function. There exists an absolute constant $c > 0$ such that the following is true. Let $2 \leq d_1 \leq d_2 \leq \dots \leq d_k$ be integers. Let $L > 0$ and $K > 0$ be such that*

- (i) $\sum_{i=1}^k w(d_i)/d_i \leq K \left(\sum_{i=1}^k \log d_i / \log d_k \right) \cdot (w(d_1)/d_k)$, and
- (ii) $\sum_{i=1}^k w(d_i)/d_i \geq L \left(\sum_{i=1}^k \log d_i / \log d_k \right) \cdot (w(d_k)/d_k)$.

Let $n = \prod_{i=1}^k d_i$. Consider arbitrary matrices $M_i \in \mathbb{F}^{d_i \times d_i}$ and let $M = \bigotimes_{i=1}^k M_i$. Then

$$R_{\mathbb{F}}^{rc}(M, 2d_k \cdot n^{1-\gamma}) \leq n^\varepsilon \quad \text{where} \quad \gamma = \frac{cL\varepsilon^2}{d_k \log d_k \cdot K^2 \log^2(K/\varepsilon)}.$$

Proof. We follow the notation of Section 2.2. Recall that

$$m := \mathbb{E}[s(x)] = \sum_{i=1}^k w(d_i)/d_i \quad \text{and} \quad \text{Var}[s(x)] = \sum_{i=1}^k w(d_i)^2 \left(\frac{d_i - 1}{d_i^2} \right) \leq w(d_k)m. \quad (28)$$

Then, by the Bernstein inequality, for $0 < \delta < 1$,

$$\begin{aligned} |\mathcal{C}(\delta m)| &= n \cdot \mathbb{P}[s(x) \geq m + \delta m] \leq n \cdot \exp\left(-\frac{\delta^2 m^2 / 2}{\text{Var}[s(x)] + \delta w(d_k)m/3}\right) \leq \\ &\leq n \cdot \exp\left(-\frac{\delta^2 m}{3w(d_k)}\right). \end{aligned} \quad (29)$$

and similarly,

$$|\mathcal{R}(\delta m)| = n \cdot \mathbb{P}[s(x) \leq m - \delta m] \leq n \cdot \exp\left(-\frac{\delta^2 m}{3w(d_k)}\right). \quad (30)$$

Now we want to bound the number of entries in $T_c(\delta m, y)$ and $T_r(\delta m, x)$. For $x \in [d]$ define $S_x = \{i \in [n] \mid x_i = d_i\}$.

Let $x \in [d] \setminus \mathcal{R}(\delta m)$ and $y \in T_r(\delta m, x)$, by definition, $S_x \subseteq S_y$ and

$$\sum_{i \in S_y \setminus S_x} w(d_i) \leq 2\delta m. \quad (31)$$

Thus, $t := |S_y \setminus S_x| \leq 2\delta m/w(d_1) =: t_{\max}$. Assumption (i) implies that

$$t_{\max} \leq 2\delta K \ln(n)/(d_k \ln d_k).$$

At the same time, $t_{\max} \geq 2\delta \cdot (kw(d_1)/d_k)/w(d_1) = 2\delta k/d_k$. Note that $y \in T_r(\delta m, x)$ is uniquely defined by $S_y \setminus S_x$. Thus, by Lemma 33,

$$\begin{aligned} T_r(\delta m, x) &\leq \sum_{i=0}^{t_{\max}} \binom{k}{i} \leq \exp\left(t_{\max} \ln\left(\frac{ek}{t_{\max}}\right)\right) \leq \\ &\leq \exp(\ln n \cdot 2\delta K \ln(2d_k/\delta)/(d_k \ln d_k)). \end{aligned} \quad (32)$$

68:12 Improved Upper Bounds for the Rigidity of Kronecker Products

Similarly, for $y \in [\vec{d}] \setminus \mathcal{C}(\delta m)$ we have $x \in T_c(\delta m, y)$ only if $S_x \subseteq S_y$ and Eq. (31) is satisfied. Clearly, $|S_y| \leq m(1 + \delta)/w(d_1) \leq 2m/w(d_1)$, and $t = |S_y \setminus S_x|$ satisfies $t \leq t_{\max}$. Hence, by Lemma 33,

$$\begin{aligned} T_c(\delta m, y) &\leq \sum_{i=0}^{t_{\max}} \binom{|S_y|}{t_{\max}} d_k^i \leq d_k^{t_{\max}} \sum_{i=0}^{t_{\max}} \binom{2m/w(d_1)}{t_{\max}} \\ &\leq \exp(t_{\max} \ln(3\delta^{-1}) + t_{\max} \ln d_k) \leq \exp(\ln n \cdot 2\delta K \ln(3\delta^{-1})/d_k). \end{aligned} \quad (33)$$

Therefore, there exists $\delta = \Theta((\varepsilon/K)/\log(K/\varepsilon))$ such that

$$\max(M_r(\delta m), M_c(\delta m)) \leq n^{\varepsilon/(2d_k)}.$$

Moreover, for such choice of δ , by assumption (ii) and Eq. (29)-(30), we obtain

$$|\mathcal{C}(\delta m)| + |\mathcal{R}(\delta m)| \leq n \exp(-\delta^2 L \ln(n)/(3d_k \ln d_k)) \leq n^{1-\gamma}. \quad (34)$$

Thus, the claim follows from Lemma 18 and Lemma 17. \blacktriangleleft

Observe that Theorem 20 is a special case of Theorem 21 with $K = L = 1$. More generally, we can get the same bound on γ for the case when all the d_i are within a constant factor of each other.

► **Corollary 22.** *Given $0 < \varepsilon, c \leq 1$, and $d \geq 2$, there exists $\gamma = \Omega\left(\frac{c\varepsilon^2}{d \log(d) \log(1/c) \log^2(1/(c\varepsilon))}\right)$ such that the following holds for any sequence of matrices M_1, M_2, \dots, M_k where $M_i \in \mathbb{F}^{d_i \times d_i}$ and $cd \leq d_i \leq d$. Let $M = \bigotimes_{i=1}^k M_i$ and $n = \prod_{i=1}^k d_i$. If $n \geq d^{1/\gamma}$, then $R_{\mathbb{F}}^{rc}(M, n^{1-\gamma}) \leq n^\varepsilon$.*

Proof. Observe that the assumptions of Theorem 21 are satisfied for $w(x) = 1$ with $K = L \leq (1/c) \log(1/c)$. Let γ' be the constant provided by Theorem 21. We take $\gamma = \gamma'/3$ and note that $n^{2\gamma} \geq 2d$. Hence, $R_{\mathbb{F}}^{rc}(M, n^{1-\gamma}) \leq n^\varepsilon$. \blacktriangleleft

Next, we eliminate the lower bound constraint on the d_i , at the cost of a slightly worse dependence of γ on d . (Theorem 24 below). In preparation for proving Theorem 24, we state its special case where all but at most one of the d_i are restricted to the interval $[\sqrt{d}, d]$.

► **Corollary 23.** *Given $d \geq 2$ and $0 < \varepsilon < 1$, there exists $\gamma = \Omega\left(\frac{\varepsilon^2}{d^{3/2} \log(d) \log^2(d/\varepsilon)}\right)$ such that the following holds. Consider any $d_i \leq d$ and $M_i \in \mathbb{F}^{d_i \times d_i}$ for $i \in [k]$. Let $M = \bigotimes_{i=1}^k M_i$ and $n = \prod_{i=1}^k d_i$. Assume that $d_i \geq \sqrt{d}$ for all $i \geq 2$. If $n \geq d^{1/\gamma}$. Then $R_{\mathbb{F}}^{rc}(M, n^{1-\gamma}) \leq n^\varepsilon$.*

Proof. Define $w(d_i) = 1$. Then, the assumptions of Theorem 21 are satisfied for $K = L \leq 4\sqrt{d}$. Indeed, for $d_k \leq d$ and $d_2 \geq \sqrt{d}$ and $k > d$, we have the following trivial bounds

$$\sum_{i=1}^k \log(d_i)/\log(d_k) \geq (k-1)/2 \quad \text{and} \quad \sum_{i=1}^k 1/d_i \leq (k-1)/\sqrt{d} + 1 \leq 2(k-1)/\sqrt{d}. \quad (35)$$

Hence, by Theorem 21, there exists $\gamma' = \Omega\left(\frac{\varepsilon^2}{d^{3/2} \log(d) \log^2(d/\varepsilon)}\right)$ such that

$$R_{\mathbb{F}}^{rc}(M, 2dn^{1-\gamma'}) \leq n^\varepsilon.$$

Take $\gamma = \gamma'/3$. Finally, note that the assumption $n \geq d^{1/\gamma}$ implies that $n^{2\gamma} \geq 2d$ and $k \geq d$. Hence, $R_{\mathbb{F}}^{rc}(M, n^{1-\gamma}) \leq n^\varepsilon$. ◀

Finally, we prove our main result by eliminating $d_i \geq \sqrt{d}$ constraint using a bin packing argument.

► **Theorem 24.** *Given $d \geq 2$ and $0 < \varepsilon < 1$, there exists $\gamma = \Omega\left(\frac{\varepsilon^2}{d^{3/2} \log(d) \log^2(d/\varepsilon)}\right)$ such that the following holds for any sequence of matrices M_1, M_2, \dots, M_k where $M_i \in \mathbb{F}^{d_i \times d_i}$ and $2 \leq d_i \leq d$. Let $M = \bigotimes_{i=1}^k M_i$ and $n = \prod_{i=1}^k d_i$. If $n \geq d^{1/\gamma}$, then $R_{\mathbb{F}}^{rc}(M, n^{1-\gamma}) \leq n^\varepsilon$.*

Proof. Let us split the d_i into the smallest possible number k' of bins, such that the product of numbers in each bin is at most d . Let a_j be the product of the numbers in bin $j \in [k']$ and let A_j be the Kronecker product of the corresponding matrices. Then at most one a_i is $\leq \sqrt{d}$. Hence, the theorem follows from Corollary 23. ◀

5 Application to rigidity upper bounds for Hadamard matrices

As an application of our improved bounds, we show that the family of Kronecker products of sufficiently not rigid matrices and matrices of bounded size is not Valiant-rigid.

► **Theorem 25.** *Let $0 < \varepsilon < 1/2$ and $b \geq 2$. Let \mathcal{F} be a family of matrices over \mathbb{F} , such that for every $d \times d$ matrix $A \in \mathcal{F}$ either $d \leq b$, or*

$$R_{\mathbb{F}}^{rc}(A, d^{1-\gamma}) \leq d^\varepsilon \quad \text{for } \gamma = \frac{12(\log \log d)^2}{\varepsilon^3 \log d}. \quad (36)$$

Then, for every sequence of matrices $M_1, M_2, \dots, M_k \in \mathcal{F}$, the $n \times n$ matrix $M = \bigotimes_{i \in [k]} M_i$ either satisfies $R_{\mathbb{F}}^{rc}(M, n/\log n) \leq n^{6\varepsilon}$, or n is bounded above by a function of b and ε .

As an immediate application of Theorem 25, we significantly expand the family of Hadamard matrices known to be not Valiant rigid (Theorem 7). We rely on the rigidity upper bound for Paley-Hadamard matrices established in [6, 3].

► **Theorem 26** ([6, 3]). *There exist constants $c_1 > 0$ and $c_2 > 0$ such that for all $\varepsilon > 0$ and an arbitrary $d \times d$ Paley-Hadamard matrix A we have $R_{\mathbb{C}}^{rc}\left(A, \frac{d}{\exp(\varepsilon^{c_1} (\log d)^{c_2})}\right) \leq d^\varepsilon$.*

We restate Theorem 7 for convenience.

► **Theorem 27.** *Let \mathcal{F}_0 be the family of Paley-Hadamard matrices and Hadamard matrices of bounded size. Let \mathcal{F} be the family of all matrices that can be obtained as Kronecker products of some matrices from \mathcal{F}_0 . Then \mathcal{F} is not absolutely Valiant-rigid.*

Proof. Fix $\varepsilon > 0$. By Theorem 26, the inequality

$$\gamma = \frac{\varepsilon^{c_1}}{(\log d)^{1-c_2}} \geq \frac{12(\log \log d)^2}{\varepsilon^3 \log d} \Leftrightarrow \frac{(\log d)^{c_2}}{(\log \log d)^2} \geq 12\varepsilon^{-3-c_1}$$

holds for all sufficiently large d . Thus, the claim of the theorem follows from Theorem 25. ◀

68:14 Improved Upper Bounds for the Rigidity of Kronecker Products

In order to prove Theorem 25, we use the following inequality that relates the row-column rigidity of the Kronecker product of a pair of matrices to the row-column rigidities of each of the matrices participating in the product.

► **Lemma 28** (Dvir, Liu [6, Lemma 4.9]). *Let A be an $n \times n$ matrix and B be an $m \times m$ matrix. Then*

$$R_{\mathbb{F}}^{rc}(A \otimes B, r_a m + r_b n) \leq R_{\mathbb{F}}^{rc}(A, r_a) \cdot R_{\mathbb{F}}^{rc}(B, r_b)$$

In the pair of lemmas below we show that the Kronecker product of arbitrary many sufficiently large and sufficiently not rigid matrices is sufficiently not rigid itself. These lemmas are essentially the proof content of Lemma 4.10 in [6], which was stated and proved for more specific needs.

► **Lemma 29.** *Let $2 \leq b \leq d_1 \leq \dots \leq d_k \leq b^2$ be integers. Let $0 < \varepsilon < 1$ and $\gamma > 0$ such that $\gamma \log(b) \geq 2 \log(3/\varepsilon)$ and $b \geq 3/\varepsilon$. Assume that for every $i \in [k]$, M_i is a $d_i \times d_i$ matrix over \mathbb{F} that satisfies*

$$R_{\mathbb{F}}^{rc}(M_i, d_i^{1-\gamma}) \leq d_i^\varepsilon.$$

Define $M = \bigotimes_{i \in [k]} M_i$ and $n = \prod_{i \in [k]} d_i$. Then,

$$R_{\mathbb{F}}^{rc}(M, n^{1-\varepsilon\gamma/4}) \leq n^{4\varepsilon}.$$

Proof. By the assumptions of the lemma, we can write $M_i = A_i + E_i$, where $A_i, E_i \in \mathbb{F}^{d_i \times d_i}$, $\text{rank}(A_i) \leq d_i^{1-\gamma}$, and E_i has at most d_i^ε non-zero entries in every row and column. Then

$$\bigotimes_{i \in [k]} M_i = \bigotimes_{i \in [k]} (A_i + E_i) = \sum_{S \subseteq [k]} \bigotimes_{i \in S} A_i \bigotimes_{j \in [k] \setminus S} E_j \quad (37)$$

Now all the summands can be split into two groups: when $|S| \geq \varepsilon k$ and when $|S| < \varepsilon k$. We are going to bound the rank of the sum of the first group and the number of non-zero entries of the sum of the second group.

$$\begin{aligned} \text{rank} \left(\sum_{S \subseteq [k], |S| \geq \varepsilon k} \bigotimes_{i \in S} A_i \bigotimes_{j \in [k] \setminus S} E_j \right) &\leq \sum_{S \subseteq [k], |S| = \varepsilon k} \text{rank} \left(\bigotimes_{i \in S} A_i \right) \prod_{j \in [k] \setminus S} d_j \leq \\ &\leq \binom{k}{\varepsilon k} \max_{S \subseteq [k], |S| = \varepsilon k} \prod_{i \in S} d_i^{1-\gamma} \prod_{j \in [k] \setminus S} d_j \leq \left(\frac{3}{\varepsilon} \right)^{\varepsilon k} \cdot n \cdot b^{-\varepsilon k \gamma} \end{aligned} \quad (38)$$

Since $b^\gamma \geq (3/\varepsilon)^2$ and $n \leq b^{2k}$, we have

$$\text{rank} \left(\sum_{S \subseteq [k], |S| \geq \varepsilon k} \bigotimes_{i \in S} A_i \bigotimes_{j \in [k] \setminus S} E_j \right) \leq n \cdot b^{-\varepsilon k \gamma / 2} \leq n^{1-\varepsilon\gamma/4} \quad (39)$$

Next, consider the remaining terms

$$E = \sum_{S \subseteq [k], |S| < \varepsilon k} \bigotimes_{i \in S} A_i \bigotimes_{j \in [k] \setminus S} E_j. \quad (40)$$

Using Lemma 33, every column and every row of E has at most

$$\left(\sum_{i=0}^{\varepsilon k} \binom{k}{i} \right) (b^2)^{\varepsilon k} \prod_{i \in [k]} d_i^\varepsilon \leq \left(\frac{3}{\varepsilon} \right)^{\varepsilon k} n^{2\varepsilon} n^\varepsilon \leq b^{\varepsilon k} n^{3\varepsilon} \leq n^{4\varepsilon} \quad (41)$$

non-zero entries. ◀

► **Lemma 30.** *Let $2 \leq b \leq d_1 \leq \dots \leq d_k$ be integers. Let $0 < \varepsilon < 1$ and $\gamma_1, \gamma_2, \dots, \gamma_k > 0$ be such that $b \geq 3/\varepsilon$ and for all $i \in [k]$ we have $\gamma_i \cdot \log d_i \geq 4 \log(3/\varepsilon)$. Assume that for every $i \in [k]$, M_i is a $d_i \times d_i$ matrix over \mathbb{F} , that satisfies $R_{\mathbb{F}}^{rc}(M_i, d_i^{1-\gamma_i}) \leq d_i^\varepsilon$.*

Define $M = \bigotimes_{i \in [k]} M_i$ and $n = \prod_{i \in [k]} d_i$. Then,

$$R_{\mathbb{F}}^{rc}(M, n^{1-\psi}) \leq n^{5\varepsilon} \quad \text{for} \quad \psi = \frac{\varepsilon^2 \min_i \gamma_i}{4 \log \log d_k} - \frac{\log \log \log d_k}{\log n}$$

Proof. Let $I_t = \{i \mid d_i \in (b^{2^t}, b^{2^{t+1}}]\}$ for $t = 1, \dots, L = \log \log d_k$. Let $A_t = \bigotimes_{i \in I_t} M_i$ and $n_t = \prod_{i \in I_t} d_i$. Let $\gamma = \min_i \gamma_i$. By Lemma 29,

$$R_{\mathbb{F}}^{rc}(A_t, n_t^{1-\varepsilon\gamma/4}) \leq n_t^{4\varepsilon} \quad (42)$$

Let $S = \{t \mid n_t \geq n^{\varepsilon/L}\}$ and $N_S = \prod_{t \in S} n_t$. Then, by Lemma 28,

$$R_{\mathbb{F}}^{rc}\left(\bigotimes_{t \in S} A_t, N_S \left(\sum_{t \in S} n_t^{-\varepsilon\gamma/4}\right)\right) \leq N_S^{4\varepsilon}. \quad (43)$$

Hence,

$$R_{\mathbb{F}}^{rc}\left(\bigotimes_{t \in S} A_t, L \cdot N_S n^{-\varepsilon^2\gamma/(4L)}\right) \leq N_S^{4\varepsilon} \quad (44)$$

Observe that, $n/N_S \leq (n^{\varepsilon/L})^L \leq n^\varepsilon$. Thus, $R_{\mathbb{F}}^{rc}\left(\bigotimes_{t \in [L] \setminus S} A_t, 0\right) \leq n^\varepsilon$. Hence, by Lemma 28,

$$R_{\mathbb{F}}^{rc}(M, n^{1-\psi}) \leq n^{5\varepsilon}, \quad (45)$$

as $n^{-\psi} = \log \log d_k \cdot n^{-\varepsilon^2\gamma/(4 \log \log d_k)} = L n^{-\varepsilon^2\gamma/(4L)}$. ◀

Finally, we are ready to prove Theorem 25.

Proof of Theorem 25. Define $b_\varepsilon = 3/\varepsilon$ and $b_* = \max(b, b_\varepsilon)$. Let $\gamma_b = c_0 \frac{1}{b_*^{3/2} \log^3(b_*)}$.

$\frac{\varepsilon^2}{\log^2(1/\varepsilon)}$, where $c_0 > 0$ is the constant given by Theorem 24. We may assume $c_0 < 1$. Define $N_b = b_*^{24/(\varepsilon\gamma_b)}$.

Denote the size of M_i by d_i for $i \in [k]$ and let $S = \{i \in [k] \mid d_i \leq b_*\}$. Let

$$F = \bigotimes_{i \in S} M_i \quad \text{and} \quad H = \bigotimes_{j \in [k] \setminus S} M_j. \quad (46)$$

Denote by N_F and N_H be the orders of F and H , respectively. Then $N_F \cdot N_H = n$. Let $d_{\max} = \max_i d_i$. By Lemma 30,

$$R_{\mathbb{F}}^{rc}(M, N_H^{1-\psi_H}) \leq N_H^{5\varepsilon}, \quad (47)$$

where

$$\psi_H \geq \frac{\varepsilon^2}{4 \log \log d_{\max}} \cdot \frac{12(\log \log d_{\max})^2}{\varepsilon^3 \log d_{\max}} - \frac{\log \log \log d_{\max}}{\log N_H} \geq \frac{2 \log \log n}{\varepsilon \log n}. \quad (48)$$

At the same time, by Theorem 24, if $N_F \geq N_b$, then

$$R_{\mathbb{F}}^{rc} \left(F, N_F^{1-\gamma_b} \right) \leq N_F^{\varepsilon}. \quad (49)$$

Note, since $b_* \geq 3/\varepsilon$, we have

$$\log \log N_b \leq \log(1/\gamma_b) + 2 \log(b_*) \leq 12 \log(b_*) \leq \gamma_b \varepsilon \log N_b / 2. \quad (50)$$

So, in the case $n \geq N_F \geq N_b$ we have $\gamma_b \geq \frac{2 \log \log n}{\varepsilon \log n}$.

If $\min(N_H, N_F) \geq n^{\varepsilon}$ and $N_F \geq N_b$, then, by Lemma 28,

$$\begin{aligned} R_{\mathbb{F}}^{rc} \left(M, n / \log n \right) &\leq R_{\mathbb{F}}^{rc} \left(M, n(n^{-\varepsilon\psi_H} + n^{-\varepsilon\gamma_b}) \right) \leq \\ &\leq R_{\mathbb{F}}^{rc} \left(H \cdot F, n(N_H^{-\psi_H} + N_F^{-\gamma_b}) \right) \leq R_{\mathbb{F}}^{rc} \left(H, N_H^{1-\psi_H} \right) \cdot R_{\mathbb{F}}^{rc} \left(F, N_F^{1-\gamma_b} \right) \leq n^{5\varepsilon}. \end{aligned} \quad (51)$$

If $N_F \leq n^{\varepsilon}$, then $N_H \geq n^{\varepsilon}$, and by Lemma 28,

$$R_{\mathbb{F}}^{rc} \left(M, n / \log n \right) \leq R_{\mathbb{F}}^{rc} \left(M, N_F N_H^{1-\psi_H} \right) \leq N_H^{5\varepsilon} \cdot R_{\mathbb{F}}^{rc} \left(F, 0 \right) \leq N_H^{5\varepsilon} \cdot N_F \leq n^{6\varepsilon}. \quad (52)$$

Similarly, if $N_H \leq n^{\varepsilon}$ and $N_F \geq N_b$, then $R_{\mathbb{F}}^{rc} \left(M, n / \log n \right) \leq n^{6\varepsilon}$.

Finally, if $N_b > N_F \geq n^{\varepsilon}$, then the size of M is bounded by a function of b and ε . ◀

A Tail bounds

In this appendix we review a classical concentration inequality which we apply to the binomial distribution.

► **Theorem 31** (Bernstein inequality). *Let $L \geq 0$ and $\delta > 0$. Let X_1, \dots, X_n be independent random variables satisfying $|X_i - \mathbb{E}(X_i)| \leq L$ for $i \in [n]$. Let $X = \sum_{i=1}^n X_i$. Then we have*

$$\mathbb{P}(X \geq \mathbb{E}(X) + \delta) \leq \exp\left(-\frac{\delta^2/2}{\sum_{i=1}^n \text{Var}(X_i) + L\delta/3}\right).$$

► **Corollary 32.** *Let $d > 1$. Let X_i be i. i. d. $\{0, 1\}$ -valued random variables such that $\mathbb{P}(X_i = 1) = 1 - \mathbb{P}(X_i = 0) = 1/d$ for $i \in [n]$. Let $X = \sum_{i=1}^n X_i$. Let $\delta < 1/d$. Then*

$$\mathbb{P}\left[X \geq \left(\frac{1}{d} + \delta\right)n\right] \leq \exp\left(-\frac{\delta^2 n}{3d}\right) \quad \text{and} \quad \mathbb{P}\left[X \leq \left(\frac{1}{d} - \delta\right)n\right] \leq \exp\left(-\frac{\delta^2 n}{3d}\right).$$

Proof. Note that $\mathbb{E}(X_i) = 1/d$ and $\text{Var}(X_i) = (d-1)/d^2$. The first bound follows from Theorem 31 with $L = (d-1)/d$. The second bound follows from Theorem 31 with $L = (d-1)/d$ by applying it to $Y_i = \mathbb{E}(X_i) - X_i$. ◀

We also use the following elementary bound.

► **Lemma 33.** *Let $0 \leq k \leq n$. Then $\sum_{i=0}^k \binom{n}{i} \leq \left(\frac{en}{k}\right)^k$.*

B Proof of Observation 14

In this appendix we prove Observation 14.

► **Observation 34.** *For any matrix $A \in \mathbb{F}^{d \times d}$ there exists $B \in \mathbb{F}^{(d-1) \times (d-1)}$, vectors $x, y \in \mathbb{F}^d$, $\lambda \in \{0, 1\} \subseteq \mathbb{F}$ and permutation matrices $P_1, P_2 \in \mathbb{F}^{d \times d}$ such that*

$$A = P_1 \cdot G_d(y)^T \cdot \begin{pmatrix} B & 0 \\ 0 & \lambda \end{pmatrix} \cdot G_d(x) \cdot P_2. \quad (53)$$

Proof. We consider two cases. First, assume that A has rank d . In this case, the basis vector e_d can be written as a linear combination of the columns A_i of A . Moreover, by changing the order of columns (by some permutation matrix, say Q_1) we may assume that the coefficient in front of the last column is non-zero. In other words, there exist coefficients μ_1, \dots, μ_d , with $\mu_d \neq 0$ such that

$$e_d = \mu_1(AQ_1)_1 + \mu_2(AQ_1)_2 + \dots + \mu_d(AQ_1)_d.$$

Define $x_i = -\mu_i/\mu_d$ for $i \in [d-1]$ and $x_d = \frac{1}{\mu_d}$. Denote by A' the matrix consisting of the first $d-1$ columns of AQ_1 . Then

$$AQ_1 = \begin{pmatrix} A' & 0_{d-1} \\ & 1 \end{pmatrix} G_d(x). \quad (54)$$

68:18 Improved Upper Bounds for the Rigidity of Kronecker Products

Since A has full rank, the first $d - 1$ rows of A' span \mathbb{F}^{d-1} . So the last row of A' can be written as a linear combination of the first $d - 1$ rows. Hence, for some vector $y \in \mathbb{F}^d$ with $y_d = 1$,

$$(A')^T = (B \ 0_{d-1}) G_d(y) \quad \Rightarrow \quad A Q_1 = G_d(y)^T \cdot \begin{pmatrix} B & 0 \\ 0 & 1 \end{pmatrix} \cdot G_d(x). \quad (55)$$

If A has rank less than d , there exists a column and a row of A that can be expressed as a linear combination of all other columns and rows of A , respectively. By changing the order of rows and columns we may assume that these are d -th column and d -th row. Then, similarly as above, we see that A can be written in the form (53) with $\lambda = 0$. ◀

The Power of One Clean Qubit in Communication Complexity

Abstract

We study quantum communication protocols, in which the players' storage starts out in a state where one qubit is in a pure state, and all other qubits are totally mixed (i.e. in a random state), and no other storage is available (for messages or internal computations). This restriction on the available quantum memory has been studied extensively in the model of quantum circuits, and it is known that classically simulating quantum circuits operating on such memory is hard when the additive error of the simulation is exponentially small (in the input length), under the assumption that the polynomial hierarchy does not collapse.

We study this setting in communication complexity. The goal is to consider larger additive error for simulation-hardness results, and to not use unproven assumptions.

We define a complexity measure for this model that takes into account that standard error reduction techniques do not work here. We define a clocked and a semi-unclocked model, and describe efficient simulations between those.

We characterize a one-way communication version of the model in terms of weakly unbounded error communication complexity.

Our main result is that there is a quantum protocol using one clean qubit only and using $O(\log n)$ qubits of communication, such that any classical protocol simulating the acceptance behaviour of the quantum protocol within additive error $1/\text{poly}(n)$ needs communication $\Omega(n)$.

We also describe a candidate problem, for which an exponential gap between the one-clean-qubit communication complexity and the randomized communication complexity is likely to hold, and hence a classical simulation of the one-clean-qubit model within *constant* additive error might be hard in communication complexity. We describe a geometrical conjecture that implies the lower bound.

1 Introduction

The computational power of quantum models of computation with different memory restrictions has been studied in order to understand the use of imperfectly implemented qubits. Some possible types of memory restrictions include having only few qubits that are in a pure state plus an abundance of qubits that start in the totally mixed state [12], having memory that starts in an incompressible state that needs to be returned unchanged at the end of the computation, plus some limited auxiliary space available [8], or simply having very little

memory for the computation [2, 20, 16, 3]. The underlying idea in these topics is to study the power of models of quantum computing in which the quantum memory is weak, but the control of this memory is good. This is in contrast to the study of models of quantum computation, where the underlying memory is good, but the control is weak, or restricted, such as the Boson-Sampling model [1]. Both are a step towards understanding the power of quantum computing models that are closer to being implementable than the standard circuit model, and eventually to demonstrate quantum supremacy (i.e., to show that for some problem (of possibly small practical interest) quantum computers that can be built outperform classical computers demonstrably).

This paper explores the potential of a model of quantum communication that uses memory containing only a small number of qubits that start in a known pure state, in particular the power of a having only a single clean qubit (plus many qubits that start in the totally mixed state, i.e., start in a random state).

The one-clean-qubit model proposed by Knill and Laflamme [21] is a model of quantum computing where the memory starts in the tensor product of a single qubit in a pure state $|0\rangle$ with the other m qubits that are in the completely-mixed state, with no further storage allowed. This initial state is described by the density matrix $\rho = |0\rangle\langle 0| \otimes \frac{I}{2^m}$.

The model was originally motivated by the nuclear magnetic resonance (NMR) approach to quantum computing, where the initial state may be highly mixed. Quantum circuits operating on such memory are able to perform tasks that look hard classically, such as estimating Jones polynomials, computing Schatten p -norms, spectral density approximation, testing integrability, computation of fidelity decay [21, 34, 9, 30, 31], just to name a few. [12] showed that quantum circuits under the one-clean-qubit restriction cannot be efficiently classically simulated unless the polynomial hierarchy collapses to the second level. In other words, assuming that the polynomial hierarchy does not collapse, polynomial size quantum circuit operating under the one-clean qubits restriction can have acceptance/rejection probabilities such that any classical randomized circuit that has the same acceptance/rejection probabilities up to additive error $1/\exp(n)$ must have superpolynomial size. We note here that we will not consider simulations with multiplicative error in this paper, since those pose a much stronger requirement on the simulation, for instance the simulating algorithm must replicate events of tiny probability with approximately the same probability, and hence such simulations are much less interesting.

In this paper, we study the hardness of simulating the one-clean-qubit model classically in the model of communication complexity. We will consider simulations of the one-clean-qubit model with different amounts of additive errors, namely $\frac{1}{\text{poly}(n)}$ and $O(1)$.

Organization

After some preliminaries in Section 2, in Section 3 we discuss related work. In Section 4, we sketch our results. In Section 5 we develop our model of quantum communication with one clean qubit. We motivate the main complexity measure and introduce the concepts of clocked and semi-unclocked protocols. Section 6 is about our characterization of one-way communication complexity in our model. Section 8 discusses our main result, which concerns the hardness of classically simulating the one-clean-qubit model with additive error.

2 Preliminaries

Communication Complexity

Yao's [38] model of communication complexity consists of two players, Alice and Bob, who are each given private inputs $x \in X$ and $y \in Y$ respectively. In addition, they both know the function f and agree to a certain communication protocol beforehand. The task they wish to perform is to compute $z = f(x, y)$. Having no knowledge of each others' inputs, they have to communicate with each other in order to obtain the result z . Communication complexity asks the question "how much communication is needed to compute $f(x, y)$?", and assumes that the players have unlimited computational power.

For formal definitions regarding standard types of communication protocols see [24], regarding quantum communication complexity see [11]. We will use the following notations:

► **Definition 1.** $Q(f), R(f)$ denote the quantum (without entanglement) and randomized (with public coin) communication complexities of a function f with error $1/3$. A subscript like $Q_\epsilon(f)$ denotes other errors ϵ .

3 Related Work

There has been a lot of research focusing on the hardness of classical simulations of restricted models of quantum computing under certain assumptions [5, 1, 37, 29, 14, 26, 36, 6, 35]. That is to say, a reasonable assumption in complexity theory leads to the impossibility of efficient sampling by a classical computer according to an output probability distribution that can be generated by a quantum computation model. For instance, it is proven that classical simulation with multiplicative error of the IQP model [5] and Boson sampling [1] is hard, unless the polynomial-time hierarchy collapses.

It is interesting to ask if such a result holds for the one-clean-qubit model as well. Over the past few years, the one-clean-qubit model has been shown to be capable of efficiently solving problems where no efficient classical algorithm is known, such as estimating Jones polynomials, computing Schatten p -norms, spectral density approximation, testing integrability and computation of fidelity decay [21, 34, 9, 30, 31]. It has been conjectured that the one-clean-qubit model can be more powerful than classical computing for some problems. However, there has been no proof for such a conjecture. In [27], it is shown that if the output probability distribution of the one-clean-qubit model can be classically efficiently approximated (with at most an exponentially small additive error) then $BQP \subseteq BPP$. Although the belief that $BQP \neq BPP$ is equivalent to that of $P \neq NP$ or that the polynomial hierarchy does not collapse, there is still a good case for it and the assumption is necessary for simulation hardness anyway. Therefore the results in [27] suggest that the one-clean-qubit model is unlikely to be classically efficiently simulatable with exponentially small additive error.

[26] introduced $DQC1_k$, a modified version of the one-clean-qubit model where the workspace starts with one clean qubit and k qubits are measured at the end of the computation. They showed that the $DQC1_k$ model cannot be efficiently classically simulated for $k \geq 3$ (within constant multiplicative error) unless the polynomial hierarchy collapses.

Later on, [26] showed via circuit complexity that the one-clean-qubit model cannot be efficiently classically simulated with $\frac{1}{\exp(n)}$ additive error unless the polynomial hierarchy collapses to the second level.

All existing results regarding the efficient classical simulation of the one-clean-qubit model are conditional (e.g. rely on non-collapse of the polynomial hierarchy) and require simulations to have exponentially small additive error.

We also mention work on classical memory-restricted communication complexity (e.g. [7]) in which some similar issues appear as in this work.

4 Overview of Results

- Definition of a complexity measure for the one-clean-qubit model in communication complexity:
The complexity measure (cost) of a one-clean-qubit protocol is given by $c \cdot \left(\frac{1}{2\epsilon}\right)$, where c is the communication and ϵ is the bias. We define a clocked and a semi-unclocked version.
- Simulation of a clocked k -clean-qubit models using only one-clean qubit is inexpensive:
Such simulations cost $(c + 1) \cdot \left(\frac{2^k}{\epsilon}\right)^2$, where c is the communication and ϵ is the bias.
- The clocked k -clean-qubit model can be simulated by the semi-unclocked one-clean-qubit model:
Such simulations incur a cost of $O(c \log c) \cdot \left(\frac{2^k}{\epsilon}\right)^2$, where c is the communication and ϵ is the bias.
- Upper and lower bounds on the complexity measure of the one-way one-clean-qubit communication complexity model:
The complexity measure of the one-way one-clean-qubit communication complexity model denoted as $Q_{[1]}^{A \rightarrow B}(f)$ is bounded by $2^{\Omega(PP(f)) - O(\log n)} \leq Q_{[1]}^{A \rightarrow B}(f) \leq 2^{O(PP(f))}$. See [17] for the definition of $PP(f)$.
- Classically simulating the one-clean-qubit model with $\frac{1}{poly(n)}$ additive error requires an exponential increase in communication:
We consider the *MIDDLE* problem and give a quantum protocol with one-clean qubit that requires $O(\log n)$ communication while any classical simulation with $\frac{1}{poly(n)}$ additive error requires $\Omega(n)$ communication.
We stress that in previous results about the hardness of simulating the one-clean-qubit model (in circuit complexity) the additive error must be of size at most $1/exp(n)$ for the simulation to be hard, which stems from low probability events being considered that one would never observe realistically. That means that running the one-clean-qubit circuit as an experiment, and observing an outcome that contradicts classicality is an event that happens only with exponentially small probability, and the classical simulation is only hard because of such extremely low probability events. Our result also uses low probability events, but $1/poly(n)$ is much more reasonable, and the events are observable when repeating such a protocol $poly(n)$ times.
- Simulating the one-clean-qubit model with constant additive error:
We consider a problem ABC as a candidate to show that simulating the one-clean-qubit model with *constant* additive error is hard, and construct a quantum protocol that requires $O(\log n)$ communication using one clean qubit for ABC . We conjecture that any classical simulation with constant additive error requires $\Omega(\sqrt{n})$ communication and give a matching upper bound.

Disclaimer: All I 's used in this paper are identity matrices whose dimensions are clear from the context.

5 Communication Complexity of the One-Clean-Qubit Model

5.1 The One-Clean-Qubit Model

► **Definition 2** (*k*-Clean-Qubit Model). *In a k -clean-qubit protocol, all storage initially consists of only k qubits in a clean state $|0\rangle$, while the rest (m qubits) are in the totally mixed state. The players communicate as in a standard quantum protocol. Only at the end of the computation, a single, arbitrary projective measurement (not depending on the inputs) is performed.*

By this definition, all storage in the one-clean-qubit model consists of only one qubit in a clean state $|0\rangle$, while the rest (m qubits) are in the totally mixed state. This can be described by the density matrix

$$\rho = |0\rangle\langle 0| \otimes \frac{I}{2^m}. \quad (1)$$

A protocol in this model for a function f communicates c qubits. Assume the protocol has a bias of ϵ and hence an error of $\frac{1}{2} - \epsilon$. In general, it is not possible to improve the error to, say, $\frac{1}{3}$. Analogous to allowing the computation to be repeated $O(\frac{1}{\epsilon^2})$ times until a correctness probability of at least $\frac{2}{3}$ is achieved, we define the cost of the (unrepeated) protocol to be $c \cdot (\frac{1}{\epsilon})^2$ qubits.

► **Definition 3** ($Q_{[1]}(f)$). *Let \mathcal{P} denote a one-clean-qubit clocked (explained later) protocol for a function $f : X \times Y \rightarrow \{0, 1\}$, such that 0-inputs are accepted with probability at most $p - \epsilon$ and 1-inputs are accepted with probability at least $p + \epsilon$ for some constant $p > 0$ and that uses communication c at most on all inputs. The cost of \mathcal{P} is then c/ϵ^2 .*

We denote the complexity measure of the clocked one-clean-qubit model by $Q_{[1]}(f) = \inf_{\mathcal{P}} \frac{\text{communication}(\mathcal{P})}{\text{bias}(\mathcal{P})^2}$, where the infimum is over all protocols \mathcal{P} for f .

The motivation behind Definition 3 is that it seems unlikely that the success probability can always be amplified arbitrarily. Therefore, we allow the protocol to run with an arbitrarily bad bias but include the cost that it would take to bring this bias up by a standard amplification (repeat the computation $O(\frac{1}{\text{bias}^2})$ times): in the situation described in Definition 3 by a standard Chernoff bound repeating $t = 4/\epsilon^2$ times (and accepting if at least pt runs accepted) would lead to error at most $1/3$.

There is no prior entanglement allowed in this model because the EPR-pairs could be used to create more pure qubits, simply by sending one qubit from one communicating party to another, who can then make the state $|00\rangle$. It is also essential that measurements are performed only at the end of the computation, or a pure state could be obtained by measuring the state (1).

In our paper, we allow arbitrary projective measurements in the one-clean-qubit model. There are papers such as [34] and [27] defining the one-clean-qubit model in a way such that it measures only one qubit at the end of the computation. However, in Theorem 8, we show that there is only negligible difference between these definitions in communication complexity.

5.2 Clocked and Semi-unclocked Models

We consider two types of models: the clocked model and the semi-unclocked model.

► **Definition 4** (Clocked model). *In the clocked model, the message in round i is computed by a unitary that can depend on i . In other words, the protocol knows i without having to store i anywhere. The communication channel of a clocked model is ghosted, i.e. different qubits can be communicated in different rounds.*

Protocols in the clocked model implicitly use a counter to tell the protocol which round it is in. This counter could be considered as extra classical storage, so we define another model that does not allow this. In that model, however, protocols still need to know when to stop, and that in a sense is a counter, just one that cannot be used “inside” the protocol. Since no intermediate measurements are allowed, we simply switch the protocol off after the correct number of rounds, and measure.

Figure 1 Clocked model.

► **Definition 5 (Semi-unclocked model).** *In the semi-unclocked model, the same unitary must be applied in every round. The protocol terminates after a fixed number of rounds. The communication channel of a semi-unclocked model is fixed, i.e., the same qubits have to be communicated in every round.*

Figure 2 Semi-unclocked model.

► **Example 6.** The inner product modulo 2 problem is defined as $IP_2(x, y) = \sum_i x_i y_i \pmod 2$, where $x, y \in \{0, 1\}^n$. Under the clocked model \hat{P} shown in Figure 3, let U_x^i be Alice’s unitary and let V_y^i be Bob’s for $i = 1 \dots n$. We start with two clean qubits. The first qubit is meant to store Alice’s x_i while the second stores $\sum_i x_i y_i \pmod 2$. The protocol (informally) goes as follows:

In the first round, Alice stores x_1 in the first qubit and sends the two qubits to Bob, who multiplies x_1 in the first qubit with his y_1 and stores the product in the second qubit. He then sends the first qubit back to Alice. For every round $i = 2, \dots, n$,

1. U_x^i first XORs $|x_{i-1}\rangle$ on the first qubit with x_{i-1} , thereby restoring the qubit to $|0\rangle$, before storing the value x_i in it.
2. Alice sends the first qubit to Bob.
3. V_y^i multiplies y_i with x_i (stored in the first qubit) and adds the product to the sum stored in the second qubit modulo 2.
4. Bob sends the first qubit back to Alice.

The communication terminates after a total number of $2n - 1$ rounds and the bias is $\frac{1}{2}$ (i.e. zero error). Bob does the measurement, the total communication is $2n$.

Figure 3 Clocked two-clean-qubit model for computation of inner product modulo 2.

\hat{P} can be simulated with a clocked one-clean-qubit protocol that uses 1 clean qubit and 2 mixed qubits. The unitary \mathcal{M} does the following:

$$\mathcal{M} : \begin{cases} |0\rangle \otimes |0\rangle \otimes |0\rangle \mapsto |1\rangle \otimes |0\rangle \otimes |0\rangle \\ |0\rangle \otimes |z_1\rangle \otimes |z_2\rangle \mapsto |0\rangle \otimes |z_1\rangle \otimes |z_2\rangle \end{cases},$$

where $|z_1\rangle$ or $|z_2\rangle \neq |0\rangle$. Extend to a unitary arbitrarily. In other words, \mathcal{M} flips the first qubit if the next two qubits are both in the $|0\rangle$ state (this happens with probability $\frac{1}{4}$). After applying \mathcal{M} , the protocol is carried out as per \hat{P} . The measurement is done as follows:

- If the first qubit is $|0\rangle$, a “coin toss” is being performed for the output (e.g. measure yet another mixed qubit).
- If the first qubit is $|1\rangle$, the measurement is done as per \hat{P} .

Note that the two measurements can be combined into one.

Therefore, we get an error probability of $\frac{3}{4} \cdot \frac{1}{2} = \frac{3}{8}$, and a bias of $\frac{1}{8}$. The total communication is $2n + 1$ and hence the cost is $64(2n + 1) = O(n)$.

We now compare the k -clean-qubit model with the one-clean-qubit model and also the clocked model with the semi-unclocked model. We prove the following theorems:

► **Theorem 7.** *Given a clocked k -clean-qubit protocol \mathcal{P} for a function f that has communication c and a bias of ϵ , there exists a clocked one-clean-qubit protocol $\tilde{\mathcal{P}}$ for f that has communication c (or $c + 1$ depending on which player does the measurement), and a bias of $\frac{\epsilon}{2^k}$.*

Proof. The clocked k -clean-qubit protocol \mathcal{P} illustrated in Figure 4 has communication c and a bias of ϵ . Hence, it has an error probability of $\frac{1}{2} - \epsilon$ and cost $\frac{c}{\epsilon^2}$. Denote by U_x^i Alice’s unitaries and by V_y^i Bob’s unitaries for $i = 1, \dots, r$. Note that U_x^i is defined as a unitary on all qubits, but acts only on Alice’s qubits.

■ **Figure 4** Clocked k -clean-qubits protocol \mathcal{P} .

\mathcal{P} can be modified into a clocked one-clean-qubit protocol $\tilde{\mathcal{P}}$ as in Figure 5 with about the same amount of communication.

■ **Figure 5** Clocked one-clean-qubit model $\tilde{\mathcal{P}}$.

In $\tilde{\mathcal{P}}$, the unitary A does a bit flip on the first qubit if the next k qubits are in the $|0\rangle$ state, and does nothing otherwise. All the $k + m$ mixed qubits undergo the same series of unitary transformation as in \mathcal{P} . The measurement in $\tilde{\mathcal{P}}$ is done as follows:

- If the first qubit is $|0\rangle$, a “coin toss” is being done.
- If the first qubit is $|1\rangle$, the measurement is carried out as per \mathcal{P} .

Note that the two measurements can be combined into one.

The communication in $\tilde{\mathcal{P}}$ is c or $c + 1$, depending on which player does the measurement. If the measurement is done by the player who begins the communication, the communication is c . Otherwise, the first qubit has to be sent to the other player for the measurement to be done, causing the communication to be increased to $c + 1$.

The error probability of $\tilde{\mathcal{P}}$ can be computed to be

$$\left(1 - \frac{1}{2^k}\right) \cdot \frac{1}{2} + \frac{1}{2^k} \cdot \left(\frac{1}{2} - \epsilon\right) = \frac{1}{2} - \frac{\epsilon}{2^k}.$$

Hence, the bias decreases from ϵ to $\frac{\epsilon}{2^k}$.

The cost of $\tilde{\mathcal{P}}$ is given by $c \cdot \left(\frac{2^k}{\epsilon}\right)^2$ or $(c + 1) \cdot \left(\frac{2^k}{\epsilon}\right)^2$. ◀

► **Theorem 8.** Given a clocked k -clean-qubit protocol $\tilde{\mathcal{P}}$ for a function $f : X \times Y \rightarrow \{0, 1\}$ with a ghosted communication channel, that does an arbitrary projective measurement with two outcomes, has communication c and a bias of ϵ , there exists a semi-unclocked one-clean-qubit protocol \mathcal{P}_f for f with a fixed communication channel, that does a measurement on one qubit, has communication $O(c \log c)$ and a bias of $\Omega(\frac{\epsilon}{2^k})$.

Proof. From Theorem 7, a clocked k -clean qubit protocol $\tilde{\mathcal{P}}$ with a ghosted communication channel that does an arbitrary projective measurement and has communication c and a bias of ϵ , can be modified into a clocked one-clean-qubit protocol \mathcal{P} with a ghosted communication channel, that does an arbitrary projective measurement, has communication $c + 1$ and bias $\frac{\epsilon}{2^k}$. The total number of qubits is $m + k + 1$, with 1 clean qubit.

We would like to turn \mathcal{P} into a protocol \mathcal{P}' that measures only one qubit in the computational basis. This can be done by adding an extra clean qubit and replacing the measurement in \mathcal{P} with a unitary operator U_S and a measurement that measures the newly added qubit in the standard basis. U_S does the following:

$$U_S : \begin{cases} |a\rangle |b_i\rangle \mapsto |a\rangle |b_i\rangle, \text{ for } b_i \in B \\ |a\rangle |b_i\rangle \mapsto |a \oplus 1\rangle |b_i\rangle, \text{ for } b_i \notin B \end{cases} ,$$

where $a \in \{0, 1\}$ and $B = \{b_1, \dots, b_l\}$ is the basis of the subspace $S \subseteq \mathbb{C}^{m+k+1}$, which is a constituent of the observable used to measure the quantum state in \mathcal{P} .

In other words, U_S flips the first qubit on any basis vector $b_i \notin B$, and does nothing otherwise. The resulting protocol \mathcal{P}' is as follows:

■ **Figure 6** Clocked two-clean-qubit protocol that measures one qubit \mathcal{P}' .

► **Remark 9.** A clocked protocol with a ghosted communication channel can be easily converted to one with fixed channel in which Alice and Bob take turns to send one qubit each. This at most doubles the communication.

In the new protocol, the communication channel is fixed, the total communication is increased to at most $2(c + 1)$, and the bias remains unchanged.

According to [34], the probability of measuring 0 (which corresponds to acceptance) can be made to depend only on the trace of a unitary operator as shown below.

Consider the following trace estimation protocol \mathcal{P}_{main} illustrated in Figure 7,

■ **Figure 7** Trace estimation protocol \mathcal{P}_{main} .

which contains the unitary operator \mathcal{P}'' shown in Figure 8. \mathcal{P}_{main} accepts with probability

$$\frac{1}{2} + \frac{\text{Re}(\text{Tr}(\mathcal{P}''))}{2^{d+1}},$$

where $d = m + k + 5$ is the number of qubits in \mathcal{P}'' and $\text{Re}(x)$ is the real part of x .

■ **Figure 8** \mathcal{P}'' .

Let I_ℓ denote the 2^ℓ -dimensional identity matrix. We have that

$$\text{Tr}[(|0\rangle\langle 0| \otimes I_{m+k+1})\mathcal{P}'(|0\rangle^2 \langle 0|^2 \otimes I_{m+k})\mathcal{P}'^\dagger] = \frac{1}{8}\text{Tr}[\mathcal{P}''],$$

because $\text{Tr}[\mathcal{P}''] = \sum_{x \in \{0,1\}^{m+k+5}} \langle x | \mathcal{P}'' | x \rangle$, and so for instance basis vectors $|x\rangle$ that have a 1 in qubit 1 contribute nothing to the sum due to the rightmost CNOT. Similarly, the other CNOTs correspond to the other projection one the left hand side. This equation also shows that the right-hand-side trace is real: up to scaling the left hand side corresponds to a probability of measuring 0 when running \mathcal{P}' on the two-clean-qubit state.

The acceptance probability of \mathcal{P}_{main} is given by

$$\begin{aligned} p_0 &= \frac{1}{2} + \frac{\text{Tr}[\mathcal{P}'']}{2^{k+m+6}} \\ &= \frac{1}{2} + \frac{8 \cdot \text{Tr}[(|0\rangle\langle 0| \otimes I_{m+k+1})\mathcal{P}'(|0\rangle^2 \langle 0|^2 \otimes I_{m+k})\mathcal{P}'^\dagger]}{2^{k+m+6}} \\ &= \frac{1}{2} + \frac{8 \cdot 2^{k+m} \cdot (\frac{1}{2} + \frac{\epsilon}{2^k})}{2^{k+m+6}} \\ &= \frac{1}{2} + \frac{1}{16} + \frac{\epsilon}{2^{k+3}} \end{aligned}$$

► **Remark 10.** The factor of 8 instead of 4 as in [34] is due to the presence of three CNOT gates/extra qubits instead of two.

The communication of \mathcal{P}_{main} is four times the communication of \mathcal{P}' , since \mathcal{P}'' runs \mathcal{P}' backwards and forwards, and because the clean control qubit in \mathcal{P}_{main} must be communicated in every round (every round communicates only one qubit in \mathcal{P}'), i.e. the communication becomes $8(c+1)$. The bias decreases to $\frac{\epsilon}{2^{k+3}}$ and is around $\frac{1}{2} + \frac{1}{16}$ instead of $\frac{1}{2}$.

Lastly, we turn \mathcal{P}_{main} into a semi-unclocked protocol \mathcal{P}_f by adding $\log r$ mixed qubits to act as a counter, where r is the number of rounds. The resulting protocol looks as follows:

In \mathcal{P}_f , $\hat{U}_x = (H \otimes I) \cdot U_x \cdot (H \otimes I)$, where

$$U_x : |z\rangle|i\rangle \mapsto (U_x^i |z\rangle) |i\rangle$$

69:10 Communication Complexity with One Clean Qubit

■ **Figure 9** Semi-unlocked one-clean-qubit protocol that measure one qubit \mathcal{P}_f .

and $\hat{V}_y = (H \otimes I) \cdot V_y \cdot (H \otimes I)$, where

$$V_y : |z\rangle |i\rangle \mapsto (V_y^i |z\rangle) |i+1 \pmod r\rangle,$$

for all $z \in \{0, 1\}^{k+m+6}$, for all $i \in \{0, 1\}^{\log r}$ and where U_x^i and V_y^i are the unitaries from \mathcal{P}'' .

This means that, starting from a random j on the counter, the unitaries \hat{V}_y and \hat{U}_x apply V_y^i and U_x^i in the correct, but shifted order. Also note that the Hadamard operators cancel out in between consecutive unitaries, and only the first and last have an effect.

► **Fact 11** (Cyclic property of matrix trace). *The trace of a product of three or more square matrices is invariant under cyclic permutations of the order of multiplication of the matrices.*

Since the acceptance probability of \mathcal{P}_{main} depends only on the trace of the product of the sequence of unitary operators in \mathcal{P}'' , it follows from Fact 11 that the counter can start from any arbitrary $j \pmod r$ without affecting the acceptance probability of \mathcal{P}_f .

The protocol terminates after r rounds of communication. Note that $r = \Theta(c)$, the total communication is now $8(c+1) + O(c \log c) = O(c \log c)$. The bias remains unchanged from \mathcal{P}_{main} , i.e. $\Omega(\frac{\epsilon}{2^k})$. ◀

Applying Theorem 8 to Example 6 gives the following.

► **Corollary 12.** *The semi-unlocked one-clean-qubit quantum communication complexity of IP_2 is $O(n \log n)$.*

6 One-way Complexity with One Clean Qubit

6.1 The Upper Bound on $Q_{[1]}^{A \rightarrow B}(f)$

Let $Q_{[1]}^{A \rightarrow B}(f)$ denote the complexity measure of a one-way two-player one-clean-qubit protocol. We define a one-way two-player one-clean-qubit protocol as follows:

► **Definition 13** (One-way two-player one-clean-qubit protocol). *The computation in the one-way version of one-clean-qubit protocols starts with a single qubit in the clean state and the rest of the qubits in the totally mixed state. The first player applies her unitary on an arbitrary number of qubits, sends some of the qubits to the next player who also applies his unitary on an arbitrary number of qubits, and does a measurement. The cost is defined as for general one-clean qubit protocols. This can be described by the figure below:*

■ **Figure 10** One-round one-clean-qubit protocol.

Note that this type of protocol is semi-unlocked by definition.

We show an upper bound in terms of the weakly unbounded-error communication complexity.

► **Definition 14** (Weakly unbounded-error protocol, PP). *In a weakly unbounded-error (randomized) protocol (PP protocol), the function f is computed correctly with probability greater than $\frac{1}{2}$ by a classical private coin protocol. The cost of the protocol with a maximum error (over all inputs) of $\frac{1}{2} - \epsilon$ and a maximum communication of c , is given by $PP(f) = c - \lceil \log \epsilon \rceil$. [17]*

We show the following theorem for the upper bound on the communication complexity of the one-clean-qubit one-way protocols (in the appendix):

► **Theorem 15.** $Q_{[1]}^{A \rightarrow B}(f) \leq 2^{O(PP(f))}$.

6.2 The Lower Bound on $Q_{[1]}^{A \rightarrow B}(f)$

► **Theorem 16.** *For all $f : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ we have $Q_{[1]}^{A \rightarrow B}(f) \geq 2^{\Omega(PP(f)) - O(\log n)}$.*

The proof relies only on the fact that an efficient one-way one-clean-qubit protocol needs to achieve a large enough bias. The communication needed to do so is immaterial for our lower bound, which is quite interesting. In other words, there is a threshold to the bias which simply cannot be passed even if we allow more qubits to be sent. This is in sharp contrast to many common modes of communication with error.

The bound on the achievable bias comes from margin complexity, an important concept in learning theory [25].

Before we delve into the proof we need a few definitions. We define the notion of rectangles and two complexity measures: discrepancy and margin complexity.

► **Definition 17** (Rectangle [24]). *A rectangle in $X \times Y$ is a subset $R \subseteq X \times Y$ such that $R = A \times B$ for some $A \subseteq X$ and $B \subseteq Y$.*

► **Definition 18** (Communication matrix [24]). *The communication matrix M_f of a function $f : X \times Y \rightarrow \{0, 1\}$ is an $(|X| \times |Y|)$ -dimensional matrix, whose rows are indexed by the elements of X and the columns by the elements of Y . The (x, y) entry of M_f is simply defined as $f(x, y)$.*

► **Definition 19** (Discrepancy [24]). *Let $f : X \times Y \rightarrow \{0, 1\}$ be a function, R be any rectangle in the communication matrix, and μ be a probability distribution on $X \times Y$. The discrepancy of f according to μ is*

$$disc_{\mu}(f) = \max_R \left| \Pr_{\mu}[f(x, y) = 0 \text{ and } (x, y) \in R] - \Pr_{\mu}[f(x, y) = 1 \text{ and } (x, y) \in R] \right|.$$

Denote $disc(f) = \min_{\mu} disc_{\mu}(f)$ as the discrepancy of f over all distributions μ on $X \times Y$.

It is known that $PP(f) \geq \Omega(\log(\frac{1}{disc(f)}))$ from Fact 2.8 in [17], and from Theorem 8.1 in [17] we get $PP(f) \leq O(\log(\frac{1}{disc(f)}) + \log n)$.

► **Definition 20** (Margin [25]). *For a function $f : X \times Y \rightarrow \{0, 1\}$, let M_f denote the sign matrix where all entries are $M_f(x, y) = (-1)^{f(x, y)}$. The margin of M_f is given by:*

$$m(M_f) = \sup_{\{a_x\}, \{b_y\}} \min_{x, y} \frac{|\langle a_x | b_y \rangle|}{\|a_x\|_2 \|b_y\|_2},$$

where the supremum is over all systems of vectors (of any length) $\{a_x\}_{x \in X}, \{b_y\}_{y \in Y}$ such that $\text{sign}(\langle a_x | b_y \rangle) = M_f(x, y)$ for all x, y .

69:12 Communication Complexity with One Clean Qubit

The notion of margin complexity determines the extent to which a given class of functions can be learned by large margin classifiers, which is an important class of machine learning algorithms [25].

The proof of Theorem 16 is in the appendix.

7 The Trivial Lower Bound on $Q_{[1]}(f)$

The lower bound on the two-way one-clean-qubit communication complexity $Q_{[1]}(f) \geq \Omega(Q(f))$ is trivial since one-clean-qubit protocols can be turned into standard quantum protocols at their cost. In Appendix C we discuss this lower bound for some well-known functions.

8 Hardness of Classically Simulating the One-Clean-Qubit Model

We now turn to *simulations* of quantum protocols with the one-clean-qubit restriction by randomized protocols. The most demanding definition of simulating a quantum protocol by a randomized protocol is that the randomized protocol must replicate the acceptance probabilities of a given quantum protocol on all inputs, up to some additive error¹.

Our weaker (one-sided) definition of an ϵ -error simulation is:

► **Definition 21** (ϵ -error simulation of a quantum protocol). *Given a quantum protocol \mathcal{P} for a function $f : X \times Y \rightarrow \{0, 1\}$ such that for all inputs $(x, y) \in X \times Y$, \mathcal{P} accepts 1-inputs with probability at least α and accepts 0-inputs with probability at most β . A classical simulation of \mathcal{P} with additive error of ϵ is one that accepts 1-inputs with probability at least $\alpha - \epsilon$ and accepts 0-inputs with probability at most $\beta + \epsilon$.*

► Remark 22. The above definition is nontrivial only if $\alpha - \epsilon > \beta + \epsilon$.

8.1 Simulating the One-Clean-Qubit Model with Polynomially Small Additive Error

We show the following lemma (see the appendix):

► **Lemma 23.** *Given any two-round (Alice \rightarrow Bob \rightarrow Alice) k -clean-qubit quantum protocol (with communication $2k$ and where both messages contain only the k clean qubits) for a function f that accepts 0-inputs with probability at most q and accepts 1-inputs with probability at least p , there exists a two-round one-clean qubit protocol (with communication $2k$) for the same function that accepts 0-inputs with probability at most $\frac{q}{2^k}$ and accepts 1-inputs with probability at least $\frac{p}{2^k}$.*

► **Theorem 24.** *In communication complexity, there exists a function $f : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ and a one-clean-qubit quantum protocol \mathcal{P} with communication $O(\log n)$ such that simulating \mathcal{P} classically with an allowance of $\frac{1}{n^4}$ additive error requires $\Theta(n)$ communication.*

Proof. Consider the function below:

$$MIDDLE(x, y) = 0 \Leftrightarrow \sum_i x_i y_i = \frac{n}{2}, \quad MIDDLE(x, y) = 1 \Leftrightarrow \sum_i x_i y_i \neq \frac{n}{2},$$

¹ We only consider additive error.

where $x, y \in \{0, 1\}^n$. With Lemma 23 in mind, we design a standard quantum protocol first. We would like to compute the state $\frac{1}{\sqrt{n}} \sum_{i=1}^n (-1)^{x_i y_i} |i\rangle$. This can be done by executing the following quantum protocol \mathcal{P} :

1. Alice prepares the state $\frac{1}{\sqrt{n}} \sum_{i=1}^n |i\rangle |x_i\rangle$ and sends it to Bob.
2. Bob applies his unitary, which maps the state he received from Alice to $\frac{1}{\sqrt{n}} \sum_{i=1}^n (-1)^{x_i y_i} |i\rangle |x_i\rangle$ and sends the result to Alice.
3. Alice XORs the last qubit with x_i and then traces out that qubit to obtain $\frac{1}{\sqrt{n}} \sum_{i=1}^n (-1)^{x_i y_i} |i\rangle$, applies a Hadamard transformation and does a complete measurement in the computational basis. The protocol outputs 1 if it measures the all-zero string and outputs 0 otherwise.

This protocol requires $2 \log n + 2$ communication and uses $\log n + 1$ clean qubits. Finally, we transform the above protocol into a one-clean-qubit protocol according to Lemma 23.

Now we compute the acceptance probabilities of the standard quantum protocol above. Note that $\langle \cdot | \cdot \rangle$ denotes the inner product.

$$\begin{aligned} \langle H(\frac{1}{\sqrt{n}} \sum_{i=1}^n |i\rangle (-1)^{x_i y_i}) | 00 \dots 0 \rangle &= \langle \frac{1}{\sqrt{n}} \sum_{i=1}^n |i\rangle (-1)^{x_i y_i} | H(|00 \dots 0\rangle) \rangle \\ &= \langle \frac{1}{\sqrt{n}} \sum_{i=1}^n |i\rangle (-1)^{x_i y_i} | \frac{1}{\sqrt{n}} \sum_{i=1}^n |i\rangle \rangle. \end{aligned} \quad (2)$$

For the case where $\langle x, y \rangle = \sum_{i=1}^n x_i y_i = \frac{n}{2}$, we have $\frac{n}{2}$ 0's and $\frac{n}{2}$ 1's among the $x_i y_i$ and hence, (2) for this case equals to zero, which implies that the protocol rejects 0-inputs with certainty.

For the case where $\langle x, y \rangle = \sum_{i=1}^n x_i y_i = \frac{n}{2} + t$, we have $\frac{n}{2} - t$ 0's and $\frac{n}{2} + t$ 1's and hence, the amplitude from (2) is $\frac{1}{\sqrt{n}} \cdot (\frac{n}{2} + t - (\frac{n}{2} - t)) \frac{1}{\sqrt{n}} = \frac{2t}{n}$, which implies an acceptance probability of $(\frac{2t}{n})^2 = \frac{4t^2}{n^2}$.

Notice that the gap between 0- and 1-inputs is $\frac{4t^2}{n^2}$. Now, simulating \mathcal{P} using only one clean qubit does not change the communication but reduces the acceptance probability of 1-inputs from $\frac{4t^2}{n^2}$ to $\frac{2t^2}{n^3}$ and does not change the acceptance probability of 0-inputs. The gap between the acceptance probability of 0-inputs and 1-inputs is now $\frac{2t^2}{n^3} - 0 = \frac{2t^2}{n^3}$.

We will focus on the 1-inputs with $t = -1$.

We then show that classically simulating the one-clean-qubit protocol with $\frac{1}{n^4}$ additive error for the function $MIDDLE(x, y)$ requires $\Omega(n)$ communication. For this, we use Razborov's analysis of the rectangle bound for the Disjointness problem[32] together with a reduction and the fact that the rectangle bound is not sensitive to acceptance probabilities being small. This shows that any classical protocol that simulates the above quantum protocol within additive error $1/n^4$ needs communication $\Omega(n)$. Details are in Appendix E. ◀

8.2 Simulating the One-Clean-Qubit Model with Constant Additive Error

Previous results about the hardness of simulating the one-clean-qubit model (in circuit complexity) require the additive simulation error to be exponentially small. In the previous subsection we have shown that in communication complexity additive error $1/poly(n)$ is already enough to give a separation (which is also not based on unproven assumptions). Here we consider pushing this even further: can the one-clean-qubit model be simulated classically with constant additive error?

69:14 Communication Complexity with One Clean Qubit

Showing hardness of a classical simulation with constant additive error is equivalent to showing a separation between $Q_{[1]}(f)$ and $R(f)$: regarding both complexity measures efficient error reduction is possible². And showing hardness of a simulation of a quantum protocol for f within a small constant error means showing $R(f)$ is large.

The strength of the one-clean-qubit model is trace-estimation. Any communication-like unitary can have its trace estimated by a quantum protocol with only one clean qubit (compare the proof of Theorem 8). So we look for a hard problem along those lines. A two-party one-way quantum protocol is not a good choice, since the trace of the product of unitaries applied by Alice and Bob is a vector inner product and can be estimated well by known randomized protocols with small error, if the gap of acceptance between one-inputs and zero-inputs is large [23].

For technical reasons (cyclic property of matrix trace), looking for the simplest problem that should exhibit a separation we consider the three-player number-in-hand model³.

We conjecture the following:

► **Conjecture 25.** *There exists a function f and a one-clean-qubit quantum protocol \mathcal{P} that computes f exactly with communication $O(\log n)$ such that simulating \mathcal{P} classically with an allowance of constant additive error requires $\Omega(\sqrt{n})$ communication.*

Consider the number-in-hand ABC (promise) problem involving three parties: Alice, Bob and Charlie, who are each given $n \times n$ matrices A , B and C respectively, where $A, B, C \in SO_n$, where SO_n is the special orthogonal group. The ABC problem is described by the following function:

$$ABC(A, B, C) = 1 \iff ABC = I, \quad ABC(A, B, C) = 0 \iff ABC = -I.$$

► **Lemma 26.** *There exists a three-player number-in-hand one-clean-qubit protocol that solves ABC exactly with communication $O(\log n)$.*

Proof. The initial state starts off with one qubit in a pure state $|0\rangle$ and $\log n$ totally mixed qubits. The protocol goes as follows:

1. Alice applies a Hadamard transformation to the clean qubit and obtains $\sigma = H|0\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$. She then tensors it with an arbitrary state ρ on $\log n$ qubits (for example $\frac{I}{n}$) and we denote the resulting state as ζ . She then applies her controlled- A unitary to ζ and gets ζ' . Alice send ζ' to Bob.
2. Bob applies his controlled- B unitary to ζ' and gets ζ'' . Bob sends ζ'' to Charlie.
3. Charlie applies his controlled- C unitary to ζ'' and gets ζ''' . He then applies a Hadamard transformation to the first qubit in ζ''' and does a measurement.

The protocol is illustrated in Figure 11.

■ **Figure 11** One-clean-qubit protocol for ABC .

² We defined $Q_{[1]}$ so.

³ In the three-player number-in-hand model, each player sees only their own input.

If $ABC = I$, the composite of controlled A , B and C is the same as that of a controlled-identity unitary, which does nothing to σ . When σ undergoes a Hadamard transformation before being measured, it becomes the $|0\rangle$ state. The protocol outputs 1 if it measures $|0\rangle$. If $ABC = -I$, the composite of controlled A , B and C is similar to that of a controlled- Z unitary, which does a phase flip on $|1\rangle$ in σ , changing it into $\frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)$. We denote the phase-flipped σ as σ' . When σ' undergoes a Hadamard transformation before being measured, it becomes the $|1\rangle$ state. The protocol outputs 0 if it measures $|1\rangle$. ◀

Note that the quantum protocol uses the arbitrary state ρ (here $\rho = I/n$) as a catalyst as in [8]. Regarding the randomized complexity of ABC , we prove the following theorem:

► **Theorem 27.** $R(ABC) \leq O(\sqrt{n})$.

See the full version [18] for the proof.

Let us note here that with minor modifications, both the quantum and classical protocols for ABC are one-way and can be run in any order among the players, e.g. Charlie to Alice to Bob or Alice to Charlie to Bob.

It remains an open problem to derive a matching lower bound for the randomized communication complexity of ABC .

► **Conjecture 28.** $R(ABC) \geq \Omega(\sqrt{n})$ as long as n is even.

We now consider a geometric conjecture that implies Conjecture 28. This conjecture says that if we take two sufficiently large subsets of SO_n (the special orthogonal group), choose two operators independently from them, and multiply them, we get something similar to the uniform distribution on all of SO_n .

► **Conjecture 29.** *There are constants $\delta > 0, \gamma > 1$ such that the following is true:*

Let $M, R \subseteq SO_n$ and, for the Haar measure μ on SO_n , let $\mu(M), \mu(R) \geq 2^{-\delta\sqrt{n}}$. Denote by τ the density function of the probability distribution that arises, when $B \in M$ and $C \in R$ are chosen uniformly from these sets independently, and the matrix product BC is formed. Then $\text{Prob}_{A \in SO_n}(\tau(A) \notin [1/\gamma, \gamma]) \leq 2^{-\delta\sqrt{n}}$.

Conjecture 28 follows from Conjecture 29 by an application of the rectangle bound from communication complexity: A large rectangle/box $L \times M \times R$, where $L, M, R \subseteq SO_n$ leads to a τ that is similar to the uniform distribution. Only an exponentially small subset of matrices $A \in SO_n$ has $\tau(A)$ not constant. This also implies that $E_{A \in L} \tau(A) = \Theta(1)$, if we throw out the small subset of $A \in L$ where $\tau(A)$ is too large (this does not affect size or error much.) Denote by β_C the density function of the distribution where a random $B \in M$ is multiplied to a fixed C . $\tau(A) = E_{C \in R} \beta_C(A^*)$.

Define $H = \{(A, B, C) : A, B, C \in SO_n \text{ and } ABC = I\}$ and $G = \{(A, B, C) : A, B, C \in SO_n \text{ and } ABC = -I\}$. It is easy to show that $E_{A \in L} E_{C \in R} [\beta_C(A)] = \frac{\mu(L \times M \times R | H)}{\mu(L \times M \times R)}$. That means that $\mu(L \times M \times R | H)$ and $\mu(L \times M \times R | G)$ differ by at most a constant factor and $L \times M \times R$ has constant error under the distribution that puts weight 1/2 on each of G, H . Hence the rectangle/box $L \times M \times R$ has large error. We use that n is even because otherwise $-I \notin SO_n$. Furthermore in the case of odd n Alice, Bob, and Charlie can simply compute $\det(ABC) = \det(A)\det(B)\det(C)$ in order to determine whether $ABC = I$ or $ABC = -I$. This does not work in the case of even n of course.

We also note that the corresponding conjecture is wrong for O_n , since SO_n is a subgroup of measure 1/2 that serves as a counterexample. Note that SO_n does not have any proper subgroups of size larger than 0.

As weaker conjecture, in which the stated probability is upper bounded by a small constant would be sufficient to give a lower bound on one-way protocols and might be much easier to achieve. We note that in [19] we have recently shown a lower bound for the related aBc problem, in which Alice and Charlie receive vectors from the sphere instead of matrices in a generalized one-way setting. Note that the protocol for Theorem 27 really solves the aBc problem.

9 Conclusion

We investigate a communication complexity model in which all storage consist initially of only one clean qubit plus other qubits that start in the totally mixed state, and where only one projective measurement can be done in the end. Since error reduction is not possible efficiently in this model we define an appropriate complexity measure depending on the bias.

We introduce the notions of clocked protocols with ghosted communication channel and semi-unclocked protocols with fixed communication channel for this model. Efficient simulations of clocked k -clean-qubits protocols by clocked one-clean-qubit protocols as well as simulations of clocked k -clean-qubit protocols by semi-unclocked one-clean-qubit protocols are described. Remarkably, the semi-unclocked model is only less efficient by a logarithmic factor compared to the clocked model.

We study one-way protocols in the model and are able to almost pinpoint their complexity in terms of PP-communication complexity: $2^{\Omega(PP(f)) - O(\log n)} \leq Q_{[1]}^{A \rightarrow B}(f) \leq 2^{O(PP(f))}$, implying that functions when computed using the one-clean-qubit model have a cost of at most $2^{O(m)}$, where m is the input length, and that this is tight for some functions (one-way).

Classically simulating a certain one-clean-qubit protocol for the $MIDDLE(x, y)$ problem with $\frac{1}{\text{poly}(n)}$ additive error is hard, as a classical simulation with such error requires $\Theta(n)$ communication, compared to the $O(\log n)$ communication of the one-clean-qubit protocol.

We conjecture that classically simulating the one-clean-qubit protocol we give for the three-player number-in-hand ABC problem with constant additive error requires $\Omega(\sqrt{n})$ communication, compare to the $O(\log n)$ communication in the one-clean-qubit protocol. We show the corresponding upper bound on $R(ABC)$.

A Open Problems

- Prove Conjecture 28 or the weaker version mentioned above that establishes a lower bound for one-way protocols.
- What are some nontrivial lower bounds on $Q_{[1]}(f)$, for instance what are $Q_{[1]}(DISJ)$ and $Q_{[1]}(ViS)$ (Vector in Subspace [15])? We conjecture that $Q_{[1]}(DISJ) = \Omega(n)$ based on the difficulty of trying to compute the function in the one-clean-qubit model. Suppose that ViS can be computed in the one-clean-qubit communication model efficiently (say with $poly(\log)$ communication), then arbitrary one-way quantum protocols can be simulated with low communication in the one-clean-qubit model. However, we assume that such a supposition seems unlikely and hence we conjecture that $Q_{[1]}(ViS)$ is fairly large, possibly even $Q_{[1]}(ViS) = \Omega(n)$.
- Is $Q_{[1]}(f) > n$ for any function? A candidate for this problem would be a random function chosen from all functions $f : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$. It would be interesting if the one-clean-qubit model can compute all or most $f : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ with linear cost.
- What are some examples of functions in which $Q_{[1]}(f) \gg R(f)$ or $Q_{[1]}(f) \ll R(f)$? For instance, for the two-player ABC problem, ABC_2 , described as follows:

$$ABC_2(A_1, A_2, B_1, B_2) = 1 \Leftrightarrow A_1 B_1 A_2 B_2 = I,$$

$$ABC_2(A_1, A_2, B_1, B_2) = 0 \Leftrightarrow A_1 B_1 A_2 B_2 = -I,$$

where A_1, A_2 are Alice's unitaries and B_1, B_2 are Bob's unitaries, $Q_{[1]}(ABC_2) = O(\log n)$. What is $R(ABC_2)$?

- Are there any specific lower bound methods for the semi-unclocked one-clean-qubit protocol?

B Proofs Concerning One-Way Protocols

B.1 Proof of Theorem 15

Consider a c -bit PP -communication protocol \mathcal{P} with bias ϵ where Alice sends a message $T(x)$ of length c to Bob⁴.

1. We define Alice's unitary U_A^x such that
 - If $z = T(x)$, then $U_A^x : |0\rangle|z_1 \cdots z_c\rangle \mapsto |1\rangle|z_1 \cdots z_c\rangle$
 - If $z \neq T(x)$, then $U_A^x : |0\rangle|z_1 \cdots z_c\rangle \mapsto |0\rangle|z_1 \cdots z_c\rangle$
 and extend to a unitary in any possible way, for all $z \in \{0, 1\}^c$. Alice applies U_A^x to the initial state, and computes $U_A^x(|0\rangle\langle 0| \otimes \frac{I}{2^c})U_A^{x\dagger}$.
2. Alice then sends the result σ to Bob. This requires $c + 1$ qubits of communication.
3. Upon receiving σ from Alice, Bob tensors it with $\frac{I}{2}$ and obtains the state $\sigma \otimes \frac{I}{2}$. Bob then applies the unitary V_B^y to the state $\sigma \otimes \frac{I}{2}$, in particular, $V_B^y(\sigma \otimes \frac{I}{2})V_B^{y*}$, as follows

$$V_B^y : \begin{cases} |0\rangle|z_1 \cdots z_{c+1}\rangle \mapsto |0\rangle|z_{c+1}\rangle|z_1 \cdots z_c\rangle \\ |1\rangle|z_1 \cdots z_{c+1}\rangle \mapsto |1\rangle U_B^y \otimes I |z_1 \cdots z_{c+1}\rangle, \end{cases}$$

for all $z \in \{0, 1\}^{c+1}$. That is to say, if the first qubit of $\sigma \otimes \frac{I}{2}$ is 1, V_B^y will apply the protocol unitary U_B^y . Otherwise, a “coin toss” is done by flipping the last qubit over to the second position.

4. Lastly, he does the measurement on the second qubit.

The probability of the correct message is $\frac{1}{2^c}$. With a protocol of bias ϵ (and hence and error of $\frac{1}{2} - \epsilon$), the acceptance probability of the message is $\frac{1}{2^c}(\frac{1}{2} + \epsilon)$. On the other hand, the acceptance probability of the message in the “coin toss” is given by $\frac{1}{2}(1 - \frac{1}{2^c})$. Therefore, we have the total acceptance probability:

$$\begin{aligned} (1 - \frac{1}{2^c})\frac{1}{2} + \frac{1}{2^c}(\frac{1}{2} + \epsilon) &= \frac{1}{2} - \frac{1}{2^{c+1}} + \frac{1}{2^{c+1}} + \frac{\epsilon}{2^c} \\ &= \frac{1}{2} + \frac{\epsilon}{2^c} \end{aligned} \quad (3)$$

The total cost of the protocol is bounded as follows:

$$Q_{[1]}^{A \rightarrow B}(f) \leq (c + 1) \cdot \frac{1}{\epsilon'^2} = (c + 1) \cdot 2^{2c} \cdot \frac{1}{\epsilon^2} \leq 2^{2PP(f)} \cdot (PP(f) + 1) \leq 2^{O(PP(f))}, \quad (4)$$

where $\epsilon' = \frac{\epsilon}{2^c}$ from (3).

B.2 Proof of Theorem 16

Proof. Assume that the protocol measures the first qubit in the computational basis (if not, then a similar construction as in Theorem 8 can be used to make this true). The probability of measuring zero is given by $\frac{1}{2} + \frac{\text{tr}(I_A \otimes U_B^y \cdot U_A^x \otimes I_B)}{2^{m+1}}$ [34], where m is the total number of qubits involved and the bias is the term $\frac{\text{tr}(I_A \otimes U_B^y \cdot U_A^x \otimes I_B)}{2^{m+1}}$. Note that I_A and I_B act on the private qubits of Alice and Bob respectively. Let $U_A^x \otimes I_B = A_x$ and $I_A \otimes U_B^y = B_y$, and it follows that

$$\frac{\text{tr}(I_A \otimes U_B^y \cdot U_A^x \otimes I_B)}{2^{m+1}} = \frac{\text{tr}(B_y A_x)}{2^{m+1}} = \frac{\langle b_y | a_x^T \rangle}{2^{m+1}} = \frac{\langle b_y | a_x^T \rangle}{2\|a_x\|_2\|b_y\|_2},$$

⁴ PP -protocols can be assumed to be one-way without loss of generality [4]

69:20 Communication Complexity with One Clean Qubit

where a_x and b_y are the matrices A_x and B_y viewed as vectors, since A_x and B_y are unitary and hence $\|a_x\|_2 = \|b_y\|_2 = 2^{\frac{m}{2}}$. If the protocol has bias ϵ , then $\frac{\langle b_y | a_x^T \rangle}{2^{m+1}} \geq \epsilon$ for $f(x, y) = 1$ and $\frac{\langle b_y | a_x^T \rangle}{2^{m+1}} \leq -\epsilon$ for $f(x, y) = 0$.

► **Remark 30.** The size of the unitary matrices does not matter, which is good, since there can be an arbitrarily number of private qubits used by the players but never communicated.

We know from the above that the best possible bias satisfies $2\epsilon \leq m(f)$. From Theorem 3.1 in [25] which states that $\text{disc}(A) = \Theta(m(A))$, and from Theorem 8.1 in [17], which states that $PP(f) \leq O(-\log \text{disc}(f) + \log n)$ we have

$$Q_{[1]}^{A \rightarrow B}(f) \geq \frac{4}{m^2(f)} \geq 2^{\Omega(PP(f)) - O(\log n)}. \quad \blacktriangleleft$$

► **Remark 31.** This lower bound holds regardless of how much communication is involved: it follows from the fact that one-way one-clean qubit protocols cannot achieve a better bias.

C The Trivial Lower Bound

$Q(f)$ for some functions is given as below [22, 33, 10, 11, 28]:

- The equality function (EQ) defined as

$$EQ(x, y) = 1 \iff x = y \quad , \quad EQ(x, y) = 0 \iff x \neq y,$$

where $x, y \in \{0, 1\}^n$, has $Q(EQ) = \Theta(\log n)$.

Note: No public coin or entanglement.

- The disjointness function (DISJ) defined as

$$DISJ(x, y) = 1 \iff x \cap y = \emptyset \quad , \quad DISJ(x, y) = 0 \iff x \cap y \neq \emptyset,$$

where $x, y \in \{0, 1\}^n$, has $Q(DISJ) = \Theta(\sqrt{n})$.

Note: $\Omega(\sqrt{n}) \leq Q_{[1]}(DISJ) \leq O(n)$.

- The inner product modulo two function (IP_2) defined as

$$IP_2(x, y) = \sum_i x_i y_i \pmod{2},$$

where $x, y \in \{0, 1\}^n$, has $Q(IP_2) = \Theta(n)$.

Note: $Q_{[1]}^{A \rightarrow B}(IP_2) = 2^{\Theta(n)}$ while $Q_{[1]}(IP_2) = \Theta(n)$.

- The vector in subspace function (ViS) defined as

$$ViS(v, H_0) = 1 \iff v \in H_0 \quad , \quad ViS(v, H_0) = 0 \iff v \in H_0^\perp,$$

where $v \in \mathbb{R}^n$ and $H_0 \subseteq \mathbb{R}^n$ is a subspace with dimension $\frac{n}{2}$, has $Q(ViS) = \Theta(\log n)$.

- The index function (INDEX) defined as

$$INDEX(x, i) = x_i,$$

where $x \in \{0, 1\}^n$ and $1 \leq i \leq n$ has $Q(INDEX) = \Theta(\log n)$.

$Q_{[1]}(EQ)$, $Q_{[1]}(ViS)$ and $Q_{[1]}(INDEX)$ are basically unknown: the lower bounds we know are $\Omega(\log n)$, but the upper bounds we have are $O(n)$ for $INDEX$ and EQ , while Theorem 7 implies $Q_{[1]}(ViS) = O(n^2 \log n)$.

D Proof of Lemma 23

In the quantum protocol, Alice prepares the first message $|\phi_x\rangle$ by applying a protocol unitary $W_x^{(1)}$ to the all-zero state on the k clean qubits, and sends it to Bob. Bob then applies the protocol unitary $V_y^{(1)}$ to the message sent by Alice and sends the result back to her. Alice then applies her second unitary $W_x^{(2)}$ and does a measurement. This protocol has communication $2k$ and accepts 0-inputs with probability at most q and accepts 1-inputs with probability at least p , where $p > q$.

Given any state $|\phi_x\rangle$, we can find an orthonormal basis $\beta_x = \{|\beta_1\rangle \cdots |\beta_{2^k}\rangle\}$ that includes $|\phi_x\rangle$ so that $|\phi_x\rangle$ is a member of the basis and $\sum_{i=1}^{2^k} \frac{|\beta_i\rangle\langle\beta_i|}{2^k} = \frac{I}{2^k}$, such that the state $I/2^k$ is the uniform distribution on the elements in the basis. Consider a one-clean-qubit protocol that simulates the above quantum protocol and goes as follows:

1. We define Alice's unitary $W_x'^{(1)}$ such that
 - If $|\beta_i\rangle = |\phi_x\rangle$, then $W_x'^{(1)} : |0\rangle|\beta_i\rangle \mapsto |1\rangle|\beta_i\rangle$
 - If $|\beta_i\rangle \neq |\phi_x\rangle$, then $W_x'^{(1)} : |0\rangle|\beta_i\rangle \mapsto |0\rangle|\beta_i\rangle$
 and extend to a unitary in any possible way. where $|\beta_i\rangle \in \beta_x$. Alice applies $W_x'^{(1)}$ to the initial state, in particular, computes $\sigma_x = W_x'^{(1)}(|0\rangle\langle 0| \otimes \frac{I}{2^k})W_x'^{(1)\dagger}$.
2. Alice then sends the last k qubits to Bob.
3. Bob applies the unitary $V_y^{(1)}$ to the qubits he received from Alice, in particular computes $\sigma_y = I \otimes V_y^{(1)}(\sigma_x)I \otimes V_y^{(1)\dagger}$, where $\dim(I)=2$. Bob sends the qubits back to Alice.
4. Alice applies her unitary $W_x^{(2)}$ (tensored with identity on the first qubit) to σ_y and measures the first qubit. She outputs 0 if she obtains a measurement result of $|0\rangle$. On the other hand, if she obtains a measurement of $|1\rangle$, she proceeds to execute the measurement of the original quantum protocol. In this case, the acceptance probability of 0-inputs is at most $\frac{q}{2^k}$ and the acceptance probability for 1-inputs is at least $\frac{p}{2^k}$. Note that the two measurements can be combined into one.

The simulation of a k -clean-qubit quantum protocol by a one-clean-qubit protocol is shown in Figure 12:

Figure 12 Simulation by a one-clean-qubit protocol.

E The Simulation Lower Bound

First, we insert dummies into the first $\frac{n}{2} - 1$ entries of each string (set all to 1) and the remaining entries are drawn according to a distribution defined in [32].

Consider the linear program (LP) for the rectangle bound (see [13]) as follows, where we set the acceptance probability for 1-inputs to be at least $\alpha = \frac{1}{n^3}$. We consider an additive error of $\frac{1}{n^4}$ and the simulation is required to accept 0-inputs with probability at most $\frac{1}{n^4}$ and accept 1-inputs with probability at least $\frac{2}{n^3} - \frac{1}{n^4} \geq \frac{1}{n^3} = \alpha$. Recall that we consider as 1-inputs only those x, y with $\sum_i x_i y_i = \frac{n}{2} - 1$, and as 0-inputs those with $\sum_i x_i y_i = \frac{n}{2}$.

69:22 Communication Complexity with One Clean Qubit

Denote by \mathcal{R} the set of all rectangles in the communication matrix.

Primal

$$\begin{aligned} & \text{minimize} && \sum_{R \in \mathcal{R}} W_R \\ & \text{subject to} && \sum_{\{R \in \mathcal{R} \mid x, y \in R\}} W_R \geq \alpha, && \text{for all } x, y : \sum_i x_i y_i = \frac{n}{2} - 1 \\ & && \sum_{\{R \in \mathcal{R} \mid x, y \in R\}} -W_R \geq -\frac{1}{n^4}, && \text{for all } x, y : \sum_i x_i y_i = \frac{n}{2} \\ & && W_R \geq 0 \end{aligned}$$

Dual

$$\begin{aligned} & \text{maximize} && \sum_{\{x, y \mid \sum_i x_i y_i = \frac{n}{2} - 1\}} \alpha \gamma_{xy} - \sum_{\{x, y \mid \sum_i x_i y_i = \frac{n}{2}\}} \frac{1}{n^4} \sigma_{xy} \\ & \text{subject to} && \sum_{\{x, y \in R \mid \sum_i x_i y_i = \frac{n}{2} - 1\}} \gamma_{xy} - \sum_{\{x, y \in R \mid \sum_i x_i y_i = \frac{n}{2}\}} \sigma_{xy} \leq 1 && \text{for all } R \in \mathcal{R} \\ & && \sigma_{xy}, \gamma_{xy} \geq 0 \end{aligned}$$

A protocol \mathcal{P} that accepts 1-inputs with probability at least $\frac{1}{n^3}$ and accepts 0-inputs with probability at most $\frac{1}{n^4}$ can be viewed as a probability distribution on deterministic protocols. Each deterministic protocol (in a randomized public-coin protocol) can be represented by a protocol tree. The probabilities of decision trees are given as p_1, p_2, \dots, p_t . Every leaf in each decision tree has an attached rectangle, and a decision: accept or reject. We consider only the rectangles which lead to acceptance, and we assign weight 0 to those rectangles that do not appear in any protocol tree at an accepting leaf and weight $W_R = \sum_{\{i \mid R \text{ accepted in tree } i\}} p_i$

for rectangles appearing in protocol trees i .

▷ **Claim 32.** The constraints in the primal LP hold.

Proof.

- Let (x, y) be a 1-input. Summing up all the probabilities of the decision trees where (x, y) is in a 1-rectangle, we get the LHS of the first inequality constraint, which also corresponds to the acceptance probability, which must exceed α on the RHS.
- Let (x, y) be a 0-input. Adding up the probabilities of decision trees where (x, y) appears in a 1-rectangle will give the LHS of the second inequality constraints, which is at most $1/n^4$ because that is the maximum additive error allowed.
- The nonnegativity constraint is automatically fulfilled since W_R 's are sums of probabilities which must be at least zero. ◁

▷ **Claim 33.** If there is a classical protocol that accepts 1-inputs with probability $\geq \alpha$ and 0-inputs with probability $\leq 1/n^4$ and communication c then there exists a solution of cost 2^c for the primal LP.

Proof. The contribution of each decision tree to W_R is at most $2^c \cdot p_i$, since there are at most 2^c leaves in each decision tree. Therefore,

$$\sum_{R \in \mathcal{R}} W_R \leq \sum_{i=1}^t 2^c \cdot p_i = 2^c. \quad \triangleleft$$

Therefore, in a $\frac{1}{n^4}$ -error simulation of a quantum protocol (that accepts 1-inputs with probability at least $\frac{2}{n^3}$ and accepts 0-inputs with probability 0), the simulating randomized protocol (with communication c) must accept 1-inputs with probability at least $\frac{2}{n^3} - \frac{1}{n^4} \geq \frac{1}{n^3}$ and accept 0-inputs with probability at most $\frac{1}{n^4}$, and hence yield a solution to the primal LP of cost at most 2^c . By LP duality the primal and its dual have the same cost, and we want to show the lower bound for the cost. Hence, we work with the dual.

▷ Claim 34. The cost of the LP is $2^{\Omega(n)}$.

See the full version [18] for the proof.

Connecting Constructive Notions of Ordinals in Homotopy Type Theory

Nicolai Kraus

University of Strathclyde, UK

Chuangjie Xu  

fortiss GmbH, München, Germany

Abstract

In classical set theory, there are many equivalent ways to introduce ordinals. In a constructive setting, however, the different notions split apart, with different advantages and disadvantages for each. We consider three different notions of ordinals in homotopy type theory, and show how they relate to each other: A notation system based on Cantor normal forms, a refined notion of Brouwer trees (inductively generated by zero, successor and countable limits), and wellfounded extensional orders. For Cantor normal forms, most properties are decidable, whereas for wellfounded extensional transitive orders, most are undecidable. Formulations for Brouwer trees are usually partially decidable. We demonstrate that all three notions have properties expected of ordinals: their order relations, although defined differently in each case, are all extensional and wellfounded, and the usual arithmetic operations can be defined in each case. We connect these notions by constructing structure preserving embeddings of Cantor normal forms into Brouwer trees, and of these in turn into wellfounded extensional orders. We have formalised most of our results in cubical Agda.

1 Introduction

The use of ordinals is a powerful tool when proving that processes terminate, when justifying induction and recursion [20, 24], or in (meta)mathematics generally. Unfortunately, the standard definition of ordinals is not very well-behaved constructively, meaning that additional work is required before this tool can be deployed in constructive mathematics or program verification tools based on constructive type theory such as Agda [33], Coq [15] or Lean [18]. Constructively, the classical notion of ordinal fragments into a number of inequivalent

definitions, each with pros and cons. For example, “syntactic” ordinal notation systems [10, 36, 38] are popular with proof theorists, as their concrete character typically mean that equality and the order relation on ordinals are decidable. However, truly infinitary operations such as taking the limit of a countable sequence of ordinals are usually not constructible. We will consider a simple ordinal notation system based on Cantor normal forms [32], designed in such a way that there are no “junk” terms not denoting real ordinals.

Another alternative (based on notation systems by Church [14] and Kleene [28]), popular in the functional programming community, is to consider “Brouwer ordinal trees” \mathcal{O} inductively generated by zero, successor and a “supremum” constructor

$$\text{sup} : (\mathbb{N} \rightarrow \mathcal{O}) \rightarrow \mathcal{O}$$

which forms a new tree for every countable sequence of trees [8, 16, 26]. By the inductive nature of the definition, constructions on trees can be carried out by giving one case for zero, one for successors, and one for suprema, just as in the classical theorem of transfinite induction. However calling the constructor sup is wishful thinking; $\text{sup}(s)$ does not faithfully represent the suprema of the sequence s , since we do not have that e.g. $\text{sup}(s_0, s_1, s_2, \dots) = \text{sup}(s_1, s_0, s_2, \dots)$ – each sequence gives rise to a new tree, rather than identifying trees representing the same suprema. We use the notion of higher inductive types [17, 30] from homotopy type theory [40] to remedy the situation and make a type of Brouwer trees which faithfully represents ordinals. Since our ordinals now can be infinitary, we lose decidability of equality and order relations, but we retain the possibility of classifying an ordinal as a zero, a successor or a limit.

One can also consider extensional wellfounded orders, a variation on the classical set-theoretical axioms more suitable for a constructive treatment [39], which was transferred to the setting of homotopy type theory in the HoTT book [40, Chapter 10], and significantly extended by Escardó [23]. One is then forced to give up most notions of decidability – it is not even possible to decide if a given ordinal is zero, a successor or a limit. However many operations can still be defined on such ordinals, and properties such as wellfoundedness can still be proven. This is also the notion of ordinal most closely related to the traditional notion, and thus the most obviously “correct” notion in a classical setting.

All in all, each of these approaches gives quite a different feel to the ordinals they represent: Cantor normal forms emphasise syntactic manipulations, Brouwer trees how every ordinal can be classified as a zero, successor or limit, and extensional wellfounded orders the set theoretic properties of ordinals. As a consequence, each notion of ordinals is typically used in isolation, with no interaction or opportunities to transfer constructions and ideas from one setting to another – e.g., do the arithmetic operations defined on Cantor normal forms obey the same rules as the arithmetic operations defined on Brouwer trees? The goal of this paper is to answer such questions by connecting together the different notions. We do this firstly by introducing an abstract axiomatic framework of what we expect of any notion of ordinal, and explore to what extent the notions above satisfy these axioms, and secondly by constructing faithful embeddings between the notions, which shows that they all represent a correct notion of ordinal from the point of view of classical set theory.

Contributions

- We identify an axiomatic framework for ordinals and ordinal arithmetic that we use to compare the situations above in the setting of homotopy type theory.
- We define arithmetic operations on Cantor normal forms [32] and prove them uniquely correct with respect to our abstract axiomatisation. This notion of correctness has not been verified for Cantor normal forms previously, as far as we know.

- We construct a higher inductive-inductive type of Brouwer trees, and prove that their order is both wellfounded and extensional – properties which do not hold simultaneously for previous definitions of ordinals based on Brouwer trees. Further, we define arithmetic operations, and show that they are uniquely correct.
- We prove that the “set-theoretic” notion of ordinals [40, Section 10.3] satisfies our axiomatisation of addition and multiplication, and give constructive “taboos”, showing that many operations on these ordinals are not possible constructively.
- We relate and connect these different notions of ordinals by constructing order preserving embeddings from more decidable notions into less decidable ones.

Formalisation and Full Proofs

We have formalised the material on Cantor normal forms and Brouwer trees in cubical Agda [43] at <https://cj-xu.github.io/agda/constructive-ordinals-in-hott/>; see also Escardó’s formalisation [23] of many results on “set-theoretic” ordinals in HoTT. We have marked theorems with formalised and partly formalised proofs using the QED symbols  and  respectively; they are also clickable links to the corresponding machine-checked statement. Moreover, pen-and-paper proofs for all our results can be found in the the arXiv version of the paper.

Our formalisation uses the `{-# TERMINATING #-}` pragma to work around one known bug (issue #4725) and one limitation of the termination checker of Agda: recursive calls hidden under a propositional truncation are not seen to be structurally smaller. Such recursive calls when proving a proposition are justified by the eliminator presentation of [21] (although it would be non-trivial to reduce our mutual definitions to eliminators).

2 Underlying Theory and Notation

We work in and assume basic familiarity with homotopy type theory (HoTT), i.e. Martin-Löf type theory extended with higher inductive types and the univalence axiom [40]. The central concept of HoTT is the Martin-Löf identity type, which we write as $a = b$ – we write $a \equiv b$ for definitional equality. We use Agda notation $(x : A) \rightarrow B(x)$ for the type of dependent functions, and write simply $A \rightarrow B$ if B does not depend on $x : A$. If the type in the domain can be inferred from context, we may simply write $\forall x.B(x)$ for $(x : A) \rightarrow B(x)$. Freely occurring variables are assumed to be \forall -quantified.

We denote the type of dependent pairs by $\Sigma(x : A).B(x)$, and its projections by `fst` and `snd`. We write $A \times B$ if B does not depend on $x : A$. We write \mathcal{U} for a universe of types; we assume that we have a cumulative hierarchy $\mathcal{U}_i : \mathcal{U}_{i+1}$ of such universes closed under all type formers, but we will leave universe levels typically ambiguous.

We call a type A a *proposition* if all elements of A are equal, i.e. if $(x : A) \rightarrow (y : A) \rightarrow x = y$ is provable. We write $\mathbf{hProp} = \Sigma(A : \mathcal{U}).\text{isProp}(A)$ for the type of propositions, and we implicitly insert a first projection if necessary, e.g. for $A : \mathbf{hProp}$, we may write $x : A$ rather than $x : \text{fst}(A)$. A type A is a *set*, $A : \mathbf{hSet}$, if $(x = y) : \mathbf{hProp}$ for every $x, y : A$.

By $\exists(x : A).B(x)$, we mean the *propositional truncation* of $\Sigma(x : A).B(x)$, and if $(a, b) : \Sigma(x : A).B(x)$ then $|(a, b)| : \exists(x : A).B(x)$. The elimination rule of $\exists(x : A).B(x)$ only allows to define functions into propositions. By convention, we write $\exists k.P(k)$ for $\exists(k : \mathbb{N}).P(k)$. Finally, we write $A \uplus B$ for the sum type, $\mathbf{0}$ for the empty type, $\mathbf{1}$ for the type with exactly one element `*`, $\mathbf{2}$ for the type with two elements `ff` and `tt`, and $\neg A$ for $A \rightarrow \mathbf{0}$.

The *law of excluded middle* (LEM) says that, for every proposition P , we have $P \uplus \neg P$. Since we explicitly work with constructive notions of ordinals, we do not assume LEM, but rather use it as a *taboo*: a statement is not provable constructively if it implies LEM. Another, weaker, constructive taboo is the *weak limited principle of omniscience* WLPO: It says that any sequence $s : \mathbb{N} \rightarrow \mathbf{2}$ is either constantly ff, or it is not constantly ff.

3 Three Constructions of Types of Ordinals

We consider three concrete notions of ordinals in this paper, together with their order relations $<$ and \leq . The first notion is the one of *Cantor normal forms*, written Cnf , whose order is decidable. The second, written Brw , are *Brouwer Trees*, implemented as a higher inductive-inductive type. Finally, we consider the type Ord of ordinals that were studied in the HoTT book [40], whose order is undecidable, in general. In the current section, we briefly give the three definitions and leave the discussion of results for afterwards.

3.1 Cantor Normal Forms as a Subset of Binary Trees

In classical set theory, every ordinal α can be written uniquely in Cantor normal form

$$\alpha = \omega^{\beta_1} + \omega^{\beta_2} + \dots + \omega^{\beta_n} \text{ with } \beta_1 \geq \beta_2 \geq \dots \geq \beta_n \quad (1)$$

for some natural number n and ordinals β_i . If $\alpha < \varepsilon_0$, then $\beta_i < \alpha$, and we can represent α as a finite binary tree (with a condition) as follows [10, 12, 25, 32]. Let \mathcal{T} be the type of unlabeled binary trees, i.e. the inductive type with suggestively named constructors $0 : \mathcal{T}$ and $\omega^- \mathbin{+} - : \mathcal{T} \times \mathcal{T} \rightarrow \mathcal{T}$. Let the relation $<$ be the *lexicographical order*, i.e. generated by the following clauses:

$$\begin{aligned} 0 &< \omega^a \mathbin{+} b \\ a < c &\rightarrow \omega^a \mathbin{+} b < \omega^c \mathbin{+} d \\ b < d &\rightarrow \omega^a \mathbin{+} b < \omega^a \mathbin{+} d. \end{aligned}$$

We have the map $\text{left} : \mathcal{T} \rightarrow \mathcal{T}$ defined by $\text{left}(0) := 0$ and $\text{left}(\omega^a \mathbin{+} b) := a$ which gives us the left subtree (if it exists) of a tree. A tree is a *Cantor normal form* (CNF) if, for every $\omega^s \mathbin{+} t$ that the tree contains, we have $\text{left}(t) \leq s$, where $s \leq t := (s < t) \uplus (s = t)$; this enforces the condition in (1). For instance, both trees $1 := \omega^0 \mathbin{+} 0$ and $\omega := \omega^1 \mathbin{+} 0$ are CNFs. Formally, the predicate isCNF is defined inductively by the two clauses

$$\begin{aligned} &\text{isCNF}(0) \\ &\text{isCNF}(s) \rightarrow \text{isCNF}(t) \rightarrow \text{left}(t) \leq s \rightarrow \text{isCNF}(\omega^s \mathbin{+} t). \end{aligned}$$

We write $\text{Cnf} := \Sigma(t : \mathcal{T}).\text{isCNF}(t)$ for the type of Cantor normal forms. We often omit the proof of $\text{isCNF}(t)$ and call the tree t a CNF if no confusion is caused.

3.2 Brouwer Trees as a Quotient Inductive-Inductive Type

As discussed in the introduction, *Brouwer ordinal trees* (or simply *Brouwer trees*) are in functional programming often inductively generated by the usual constructors of natural numbers (*zero* and *successor*) and a constructor that gives a Brouwer tree for every sequence of Brouwer trees. To state a refined (*correct* in a sense that we will make precise and prove) version, we need the following notions:

Let A be a type and $\prec : A \rightarrow A \rightarrow \mathbf{hProp}$ be a binary relation. If f and g are two sequences $\mathbb{N} \rightarrow A$, we say that f is *simulated by* g , written $f \lesssim g$, if $f \lesssim g := \forall k. \exists n. f(k) \prec g(n)$. We say that f and g are *bisimilar* with respect to \prec , written $f \approx^\prec g$, if we have both $f \lesssim g$ and $g \lesssim f$. A sequence $f : \mathbb{N} \rightarrow A$ is *increasing* with respect to \prec if we have $\forall k. f(k) \prec f(k+1)$. We write $\mathbb{N} \xrightarrow{\prec} A$ for the type of \prec -increasing sequences. Thus an increasing sequence f is a pair $f \equiv (\bar{f}, p)$ with p witnessing that \bar{f} is increasing, but we keep the first projection implicit and write $f(k)$ instead of $\bar{f}(k)$.

Our type of Brouwer trees is a *quotient inductive-inductive type* [2], where we simultaneously construct the type $\mathbf{Brw} : \mathbf{hSet}$ together with a relation $\leq : \mathbf{Brw} \rightarrow \mathbf{Brw} \rightarrow \mathbf{hProp}$. The constructors for \mathbf{Brw} are

```

zero : Brw
succ : Brw → Brw
limit : (ℕ  $\xrightarrow{\prec}$  Brw) → Brw
bisim: (f g : ℕ  $\xrightarrow{\prec}$  Brw) → f  $\approx^\leq$  g → limit f = limit g,

```

where we write $x < y$ for $\text{succ } x \leq y$ in the type of limit . Simulations thus use \leq and the *increasing* predicate uses \prec , as one would expect. The truncation constructor, ensuring that \mathbf{Brw} is a set, is kept implicit in the paper (but is explicit in the Agda formalisation).

The constructors for \leq are the following, where each constructor is implicitly quantified over the variables $x, y, z : \mathbf{Brw}$ and $f : \mathbb{N} \xrightarrow{\prec} \mathbf{Brw}$ that it contains:

```

 $\leq$ -zero      : zero  $\leq$  x
 $\leq$ -trans     : x  $\leq$  y → y  $\leq$  z → x  $\leq$  z
 $\leq$ -succ-mono: x  $\leq$  y → succ x  $\leq$  succ y
 $\leq$ -cocone    : (k : ℕ) → x  $\leq$  f(k) → x  $\leq$  limit f
 $\leq$ -limiting  : (∀k. f(k)  $\leq$  x) → limit f  $\leq$  x

```

The truncation constructor, which ensures that $x \leq y$ is a proposition, is again kept implicit.

We hope that the constructors of \mathbf{Brw} and \leq are self-explanatory. \leq -cocone ensures that $\text{limit } f$ is indeed an upper bound of f , and \leq -limiting witnesses that it is the *least* upper bound or, from a categorical point of view, the (co)limit of f .

By restricting to limits of increasing sequences, we can avoid multiple representations of the same ordinal (as otherwise e.g. $a = \text{limit}(\lambda_. a)$). It is possible to drop this restriction, if one also strengthens the bisim constructor to witness antisymmetry – however we found this version of \mathbf{Brw} significantly harder to work with.

3.3 Extensional Wellfounded Orders

The third notion of ordinals that we consider is the one studied in the HoTT book [40]. This is the notion which is closest to the classical definition of an ordinal as a set with a trichotomous, wellfounded, and transitive order, without a concrete representation. Requiring trichotomy leads to a notion that makes many constructions impossible in a setting where the law of excluded middle is not assumed. Therefore, when working constructively, it is better to replace the axiom of trichotomy by *extensionality*.

Concretely, an ordinal in the sense of [40, Def 10.3.17] is a type¹ X together with a relation $\prec : X \rightarrow X \rightarrow \mathbf{hProp}$ which is *transitive*, *extensional* (any two elements of X with the same predecessors are equal), and *wellfounded* (every element is accessible, where accessibility is the least relation such that x is accessible if every predecessor of x is accessible.) – we will recall the precise definitions in Section 4. We write \mathbf{Ord} for the type of ordinals in this sense. Note the shift of universes that happens here: the type \mathbf{Ord}_i of ordinals with $X : \mathcal{U}_i$ is itself in \mathcal{U}_{i+1} . We are mostly interested in \mathbf{Ord}_0 , but note that \mathbf{Ord}_0 lives in \mathcal{U}_1 , while \mathbf{Cnf} and \mathbf{Brw} both live in \mathcal{U}_0 .

We also have a relation on \mathbf{Ord} itself. Following [40, Def 10.3.11 and Cor 10.3.13], a *simulation* between ordinals (X, \prec_X) and (Y, \prec_Y) is a function $f : X \rightarrow Y$ such that:

(a) f is monotone: $(x_1 \prec_X x_2) \rightarrow (f x_1 \prec_Y f x_2)$; and

(b) for all $x : X$ and $y : Y$, if $y \prec_Y f x$, then we have an $x_0 \prec_X x$ such that $f x_0 = y$.

We write $X \leq Y$ for the type of simulations between (X, \prec_X) and (Y, \prec_Y) . Given an ordinal (X, \prec) and $x : X$, the *initial segment* of elements below x is given as $X_{/x} := \Sigma(y : X). y \prec x$. Following [40, Def 10.3.19], a simulation $f : X \leq Y$ is *bounded* if we have $y : Y$ such that f induces an equivalence $X \simeq Y_{/y}$. We write $X < Y$ for the type of bounded simulations. This completes the definition of \mathbf{Ord} together with type families \leq and $<$.

4 An Abstract Axiomatic Framework for Ordinals

Which properties do we expect a type of ordinals to have? In this section, we go up one level of abstraction. We consider a type A with type families $<$ and $\leq : A \rightarrow A \rightarrow \mathcal{U}$, and discuss the properties that A with $<$ and \leq can have. In Section 3, we introduced each of the types \mathbf{Cnf} , \mathbf{Brw} , and \mathbf{Ord} together with its relations $<$ and \leq . Note that \leq is the reflexive closure of $<$ in the case of \mathbf{Cnf} , but for \mathbf{Brw} and \mathbf{Ord} , this is not constructively provable. In this section, we consider which properties they satisfy.

4.1 General Notions

A is a *set* if it satisfies the principle of unique identity proofs, i.e. if every identity type $a = b$ with $a, b : A$ is a proposition. Similarly, $<$ and \leq are *valued in propositions* if every $a < b$ and $a \leq b$ is a proposition. A relation $<$ is *reflexive* if we have $a < a$, *irreflexive* if it is pointwise not reflexive $\neg(a < a)$, *transitive* if $a < b \rightarrow b < c \rightarrow a < c$, and *antisymmetric* if $a < b \rightarrow b < a \rightarrow a = b$. Further, the relation $<$ is *connex* if $(a < b) \uplus (b < a)$ and *trichotomous* if $(a < b) \uplus (a = b) \uplus (b < a)$.

► **Theorem 1.** *Each of \mathbf{Cnf} , \mathbf{Brw} , and \mathbf{Ord} is a set, and their relations $<$ and \leq are all valued in propositions. In each case, both $<$ and \leq are transitive, $<$ is irreflexive, and \leq is reflexive and antisymmetric. For \mathbf{Cnf} , the relation $<$ is trichotomous and \leq connex; for \mathbf{Ord} , these statements are equivalent to the law of excluded middle. ◀⚙️*

Proving that \leq for \mathbf{Brw} is antisymmetric is challenging because of the path constructors in the inductive-inductive definition of Brouwer trees. Antisymmetry and other technical properties discussed below require us to characterise the relation \leq more explicitly, using an encode-decode argument [29]. By induction on x and y , we define the family \mathbf{Code} such that $(\mathbf{Code} x y) \leftrightarrow (x \leq y)$. The cases for point constructors are unsurprising; for example, we define

¹ Note that [40, Def 10.3.17] asks for X to be a set, but this follows from the rest of the definition and we therefore drop this requirement.

$$\begin{aligned} \text{Code}(\text{limit } f)(\text{succ } y) &::= \forall k. \text{Code}(f k)(\text{succ } y) \\ \text{Code}(\text{limit } f)(\text{limit } g) &::= \forall k. \exists n. \text{Code}(f k)(g n) . \end{aligned}$$

The difficult part is defining `Code` for the path constructor `bisim`. If for example we have $g \approx h$, we need to show that $\text{Code}(\text{limit } f)(\text{limit } g) = \text{Code}(\text{limit } f)(\text{limit } h)$. The core argument is easy; using the bisimulation $g \approx h$, one can translate between indices for g and h with the appropriate properties. However, this example already shows why this becomes tricky: The bisimulation gives us inequalities (\leq), but the translation requires instances of `Code`, which means that $\text{toCode} : (x \leq y) \rightarrow (\text{Code } x y)$ has to be defined *mutually* with `Code`. This is still not sufficient: In total, the mutual higher inductive-inductive construction needs to simultaneously prove and construct `Code`, `toCode`, versions of transitivity and reflexivity of `Code` as well several auxiliary lemmas. The complete definition is presented in the Agda formalisation (file `BrouwerTree.Code`). Once the definition of `Code` is shown correct, many technical properties are simple consequences.

From now on, we will assume that A is a set and that $<$ and \leq are valued in propositions.

4.2 Extensionality and Wellfoundedness

Following [40, Def 10.3.9], we call a relation $<$ *extensional* if, for all $a, b : A$, we have $(\forall c. c < a \leftrightarrow c < b) \rightarrow b = a$, where \leftrightarrow denotes “if and only if” (functions in both directions). Extensionality of $<$ for `Brw` is true, but non-trivial – note that it fails for the “naive” version of `Brw`, where the path constructor `bisim` is missing.

► **Theorem 2.** *For each of `Cnf`, `Brw`, `Ord`, both $<$ and \leq are extensional.* ◀⚙️

We use the inductive definition of accessibility and wellfoundedness (with respect to $<$) by Aczel [1]. Concretely, the type family $\text{acc} : A \rightarrow \mathcal{U}$ is inductively defined by the constructor

$$\text{access} : (a : A) \rightarrow ((b : A) \rightarrow b < a \rightarrow \text{acc}(b)) \rightarrow \text{acc}(a).$$

An element $a : A$ is called *accessible* if $\text{acc}(a)$, and $<$ is *wellfounded* if all elements of A are accessible. It is well known that the following induction principle can be derived from the inductive presentation [40]:

► **Lemma 3 (Transfinite Induction).** *Let $<$ be wellfounded and $P : A \rightarrow \mathcal{U}$ be a type family such that $\forall a. (\forall b < a. P(b)) \rightarrow P(a)$. Then, it follows that $\forall a. P(a)$.* ◀⚙️

In turn, transfinite induction can be used to prove that there is no infinite decreasing sequence if $<$ is wellfounded: $\neg(\Sigma(f : \mathbb{N} \rightarrow A).(i : \mathbb{N}) \rightarrow f(i+1) < f(i))$. A direct corollary is that if $<$ is wellfounded and valued in propositions, then its reflexive closure $(x < y) \uplus (x = y)$ is also valued in propositions, as $b < a$ and $b = a$ are mutually exclusive propositions.

► **Theorem 4.** *For each of `Cnf`, `Brw`, `Ord`, the relation $<$ is wellfounded.* ◀⚙️

The proof for `Brw` again makes crucial use of our encode-decode characterisation of \leq . Whenever $x < \text{limit } f$, we can use the characterisation to find an $n : \mathbb{N}$ such that $x < f(n)$, which allows us to proceed with an inductive proof of wellfoundedness. Note that the results stated so far in particular mean that `Cnf` and `Brw` can be seen as elements of `Ord` themselves.

4.3 Classification as Zero, a Successor, or a Limit

All standard formulations of ordinals allow us to determine a minimal ordinal *zero* and (constructively) calculate the *successor* of an ordinal, but only some allows us to also calculate the *supremum* or *limit* of a collection of ordinals.

4.3.1 Assumptions

We have so far not required a relationship between $<$ and \leq , but we now need to do so in order for the concepts we define to be meaningful. We assume:

- (A1) $<$ is transitive and irreflexive;
- (A2) \leq is reflexive, transitive, and antisymmetric;
- (A3) we have $(<) \subseteq (\leq)$ and $(< \circ \leq) \subseteq (<)$.

The third condition 3 means that $(b < a) \rightarrow (b \leq a)$ and $(c < b) \rightarrow (b \leq a) \rightarrow (c < a)$. The “symmetric” variation

$$(\leq \circ <) \subseteq (<)$$

is true for Cnf and Brw, but for Ord, it is equivalent to the law of excluded middle – hence, we do not assume it. This constructive failure is known, and can be seen as motivation for *plump* ordinals [39, 37]. Of course, the above assumptions are satisfied if \leq is the reflexive closure of $<$, but we again emphasise that this is not necessarily the case.

► **Theorem 5.** *For each of Cnf, Brw, Ord, assumptions 1 to 3 are satisfied.* 

For the remaining concepts, we assume that $<$ and \leq satisfy the discussed assumptions.

4.3.2 Zero and (Strong) Successors

Let a be an element of A . It is *zero*, or *bottom*, if it is at least as small as any other element

$$\text{is-zero}(a) := \forall b. a \leq b, \tag{2}$$

and we say that the triple $(A, <, \leq)$ has a zero if we have an inhabitant of the type $\Sigma(z : A). \text{is-zero}(z)$. Both the types “being a zero” and “having a zero” are propositions.

► **Theorem 6.** *Cnf, Brw, Ord each have a zero.* 

We say that a is a *successor* of b if it is the least element strictly greater² than b :

$$(a \text{ is-suc-of } b) := (b < a) \times \forall x > b. x \geq a.$$

We say that $(A, <, \leq)$ has *successors* if there is a function $s : A \rightarrow A$ which calculates successors, i.e. such that $\forall b. s(b)$ is-suc-of b . “Calculating successors” and “having successors” are propositional properties, i.e. if a function that calculates successors exists, then it is unique. The following statement is simple but useful. Its proof uses assumption 3.

► **Lemma 7.** *Let $s : A \rightarrow A$ be given. The function s calculates successors if and only if $\forall b x. (b < x) \leftrightarrow (s b \leq x)$.* 

² Note that $>$ and \geq are the obvious symmetric notations for $<$, \leq ; they are *not* newly assumed relations.

Dual to “ a is the least element strictly greater than b ” is the statement that “ b is the greatest element strictly below a ”, in which case it is natural to call b the *predecessor* of a . If a is the successor of b and b the predecessor of a , then we call a the *strong successor* of b :

$$a \text{ is-str-suc-of } b := a \text{ is-suc-of } b \times \forall x < a. x \leq b.$$

We say that A has *strong successors* if there is $s : A \rightarrow A$ which calculates strong successors, i.e. such that $\forall b. s(b)$ is-str-suc-of b . The additional information contained in a strong successor play an important role in our technical development. A function $f : A \rightarrow A$ is *<-monotone* or *≤-monotone* if it preserves the respective relation.

► **Theorem 8.** *Each of the three types Cnf, Brw, Ord has strong successors. The successor functions of Cnf and Brw are both <- and ≤-monotone. For the successor function of Ord, either monotonicity property is equivalent to the law of excluded middle.* ◀⚙️

For Cnf, the successor function is given by adding a leaf, for Brw by the constructor with the same name, and for Ord, one forms the coproduct with the unit type.

4.3.3 Suprema and Limits

Finally, we consider *suprema/least upper bounds* of \mathbb{N} -indexed sequences. We say that a is a *supremum* or the *least upper bound* of $f : \mathbb{N} \rightarrow A$, if a is at least as large as every f_i , and if any other x with this property is at least as large as a :

$$(a \text{ is-sup-of } f) := (\forall i. f_i \leq a) \times (\forall x. (\forall i. f_i \leq x) \rightarrow a \leq x).$$

We say that $(A, <, \leq)$ has *suprema* if there is a function $\sqcup : (\mathbb{N} \rightarrow A) \rightarrow A$ which calculates suprema, i.e. such that $(f : \mathbb{N} \rightarrow A) \rightarrow (\sqcup f)$ is-sup-of f . The supremum of a sequence is unique if it exists, i.e. the type of suprema is propositional for a given sequence f . Both the properties “calculating suprema” and “having suprema” are propositions.

Every $a : A$ is trivially the supremum of the sequence constantly a , and therefore, “being a supremum” does not describe the usual notion of *limit ordinals*. One might consider a a *proper* supremum of f if a is pointwise strictly above f , i.e. $\forall i. f_i < a$. This is automatically guaranteed if f is increasing with respect to $<$, and in this case, we call a the *limit* of f :

$$\begin{aligned} _ \text{ is-lim-of } _ : A \rightarrow (\mathbb{N} \xrightarrow{<} A) \rightarrow \mathcal{U} \\ a \text{ is-lim-of } (f, q) := a \text{ is-sup-of } f. \end{aligned}$$

We say that A has *limits* if there is a function $\text{limit} : (\mathbb{N} \xrightarrow{<} A) \rightarrow A$ that calculates limits.

Note that Cnf cannot have limits since one can construct a sequence (see Theorem 22) which comes arbitrarily close to ε_0 . This motivates the restriction to *bounded* sequences, i.e. a sequence f with a $b : \text{Cnf}$ such that $f_i < b$ for all i .

► **Theorem 9.** *Cnf does not have suprema or limits. Brw has limits of increasing sequences by construction. Ord also has limits of increasing sequences, and moreover limits of weakly increasing sequences (i.e. sequences increasing with respect to ≤).*

Assuming the law of exclude middle, Cnf has suprema (and thus limits) of arbitrary bounded sequences. If Cnf has limits of bounded increasing sequences, then the weak limited principle of omniscience (WLPO) is derivable. ◀⚙️

We expect that it is not constructively possible to calculate suprema (or even binary joins) in Brw, as it seems this would make it possible to decide if a limit reaches past $\omega + 1$ or not, which is a constructive taboo.

4.3.4 Classifiability

For classical set-theoretic ordinals, every ordinal is either zero, a successor, or a limit. We say that a notion of ordinals which allows this is has classification. This is very useful, as many theorems that start with “for every ordinal” have proofs that consider the three cases separately. In the same way as not all definitions of ordinals make it possible to calculate limits, only some formulations make it possible to constructively classify any given ordinal. We already defined what it means to be a zero in (2). We now also define what it means for $a : A$ to be a strong successor or a limit:

$$\text{is-str-suc}(a) := \Sigma(b : A).(a \text{ is-str-suc-of } b) \quad \text{is-lim}(a) := \exists f : \mathbb{N} \rightarrow A. a \text{ is-lim-of } f.$$

All of $\text{is-zero}(a)$, $\text{is-str-suc}(a)$ and $\text{is-lim}(a)$ are propositions; note that this is true even though $\text{is-str-suc}(a)$ is defined without a propositional truncation.

► **Lemma 10.** *Any $a : A$ can be at most one out of $\{\text{zero}, \text{strong successor}, \text{limit}\}$, and in a unique way. In other words, the type $\text{is-zero}(a) \uplus \text{is-str-suc}(a) \uplus \text{is-limit}(a)$ is a proposition.*

We say that an element of A is *classifiable* if it is zero or a strong successor or a limit. We say $(A, <, \leq)$ has *classification* if every element of A is classifiable. By Lemma 10, $(A, <, \leq)$ has classification exactly if the type $\text{is-zero}(a) \uplus \text{is-str-suc}(a) \uplus \text{is-limit}(a)$ is contractible.

► **Theorem 11.** *Cnf and Brw have classification. Ord having classification would imply the law of excluded middle.*

Classifiability corresponds to a case distinction, but the useful principle from classical ordinal theory is the related induction principle:

► **Definition 12** (classifiability induction). *We say that $(A, <, \leq)$ satisfies the principle of classifiability induction if the following holds: For every family $P : A \rightarrow \mathbf{hProp}$ such that*

$$\begin{aligned} \text{is-zero}(a) &\rightarrow P(a) \\ (a \text{ is-str-suc-of } b) &\rightarrow P(b) \rightarrow P(a) \\ (a \text{ is-lim-of } f) &\rightarrow (\forall i. P(f_i)) \rightarrow P(a), \end{aligned}$$

we have $\forall a. P(a)$.

Note that classifiability induction does *not* ask for successors or limits to be computable. Using Lemma 10, we get that classifiability induction implies classification. For the reverse, we need a further assumption:

► **Theorem 13.** *Assume $(A, <, \leq)$ has classification and satisfies the principle of transfinite induction. Then $(A, <, \leq)$ satisfies the principle of classifiability induction.*

It is also standard in classical set theory that classifiability induction implies transfinite induction: showing P by transfinite induction corresponds to showing $\forall x < a. P(x)$ by classifiability induction. In our setting, this would require strong additional assumptions, including the assumption that $(x \leq a)$ is equivalent to $(x < a) \uplus (x = a)$, i.e. that \leq is the reflexive closure of $<$. The standard proof works with several strong assumptions of this form, but we do not consider this interesting or useful, and concentrate on the results which work for the weaker assumptions that are satisfied for Brw and Ord (see Section 4.3.1).

► **Theorem 14.** *Cnf and Brw satisfy classifiability induction, while Ord satisfying it again implies excluded middle.*

4.4 Arithmetic

Using the predicates $\text{is-zero}(a)$, a is-suc-of b , and a is-sup-of f , we can define what it means for $(A, <, \leq)$ to have the standard arithmetic operations. We still work under the assumptions declared in Section 4.3.1 – in particular, we do not assume that e.g. limits can be calculated, which is important to make the theory applicable to Cnf .

► **Definition 15** (having addition). *We say that $(A, <, \leq)$ has addition if there is a function $+ : A \rightarrow A \rightarrow A$ which satisfies the following properties:*

$$\begin{aligned} \text{is-zero}(a) &\rightarrow c + a = c \\ a \text{ is-suc-of } b &\rightarrow d \text{ is-suc-of } (c + b) \rightarrow c + a = d \\ a \text{ is-lim-of } f &\rightarrow b \text{ is-sup-of } (\lambda i. c + f_i) \rightarrow c + a = b \end{aligned} \tag{3}$$

We say that A has unique addition if there is exactly one function $+$ with these properties.

Note that (3) makes an assumption only for (strictly) *increasing* sequences f ; this suffices to define a well-behaved notion of addition, and it is not necessary to include a similar requirement for arbitrary sequences. Since $(\lambda i. c + f_i)$ is a priori not necessarily increasing, the middle term of (3) has to talk about the supremum, not the limit.

Completely analogously to addition, we can formulate multiplication and exponentiation, again without assuming that successors or limits can be calculated:

► **Definition 16** (having multiplication). *Assuming that A has addition, we say that it has multiplication if we have a function $\cdot : A \rightarrow A \rightarrow A$ that satisfies the following properties:*

$$\begin{aligned} \text{is-zero}(a) &\rightarrow c \cdot a = a \\ a \text{ is-suc-of } b &\rightarrow c \cdot a = c \cdot b + c \\ a \text{ is-lim-of } f &\rightarrow b \text{ is-sup-of } (\lambda i. c \cdot f_i) \rightarrow c \cdot a = b \end{aligned}$$

A has unique multiplication if it has unique addition and there is exactly one function \cdot with the above properties.

► **Definition 17** (having exponentiation). *Assume A has addition and multiplication. We say that A has exponentiation with base c if we have a function $\text{exp}(c, -) : A \rightarrow A$ that satisfies the following properties:*

$$\begin{aligned} \text{is-zero}(b) &\rightarrow a \text{ is-suc-of } b \rightarrow \text{exp}(c, b) = a \\ a \text{ is-suc-of } b &\rightarrow \text{exp}(c, a) = \text{exp}(c, b) \cdot c \\ a \text{ is-lim-of } f &\rightarrow \neg \text{is-zero}(c) \rightarrow b \text{ is-sup-of } (\text{exp}(c, f_i)) \rightarrow \text{exp}(c, a) = b \\ a \text{ is-lim-of } f &\rightarrow \text{is-zero}(c) \rightarrow \text{exp}(c, a) = c \end{aligned}$$

A has unique exponentiation with base c if it has unique addition and multiplication, and if $\text{exp}(c, -)$ is unique.

► **Theorem 18.** *Cnf has addition, multiplication, and exponentiation with base ω (all unique), Brw has addition, multiplication and exponentiation with every base (all unique), and Ord has addition and multiplication.* 

70:12 Connecting Constructive Notions of Ordinals

For Cnf, arithmetic is defined by pattern matching on the trees. Addition³ is given as

$$\begin{aligned} 0 + b &::= b \\ a + 0 &::= a \\ (\omega^a + c) + (\omega^b + d) &::= \begin{cases} \omega^b + d & \text{if } a < b \\ \omega^a + (c + (\omega^b + d)) & \text{otherwise,} \end{cases} \end{aligned}$$

multiplication as

$$\begin{aligned} 0 \cdot b &::= 0 \\ a \cdot 0 &::= 0 \\ a \cdot (\omega^0 + d) &::= a + a \cdot d \\ (\omega^a + c) \cdot (\omega^b + d) &::= (\omega^{a+b} + 0) + (\omega^a + c) \cdot d \quad \text{if } b \neq 0, \end{aligned}$$

and exponentiation with base ω by $\omega^a ::= \omega^a + 0$. These definitions are standard. Novel is our proof of correctness in the sense of Definitions 15–17, which we achieve by defining the inverse operations of subtraction and division.

Arithmetic on Brw is defined by recursion on the second argument, following the clauses of the specifications in Definitions 15–17. Since the constructor `limit` only accepts an increasing sequence, it is necessary to prove mutually with the definition that the operations are monotone and preserve increasing sequences. However, the case $c = 0$ needs to be treated separately since neither pointwise multiplication nor exponentiation with 0 preserves increasingness. This makes it crucial to use classification (Theorem 11) and, in particular, that it is decidable whether $c : \text{Brw}$ is zero.

Addition on Ord is given by disjoint union $A \uplus B$ (with $\text{inl}(a) \prec_{A \uplus B} \text{inr}(b)$), and multiplication by Cartesian product $A \times B$ with the reverse lexicographical order. We expect that exponentiation cannot be defined constructively: the “obvious” definition via function spaces gives a wellfounded order assuming the law of excluded middle [27], but it seems unlikely that it can be avoided.

5 Interpretations Between the Notions

In this section, we show how our three notions of ordinals can be connected via structure preserving embeddings.

5.1 From Cantor Normal Forms to Brouwer Trees

The arithmetic operations of Brw allow the construction of a function $\text{CtoB} : \text{Cnf} \rightarrow \text{Brw}$ in a canonical way. We define $\text{CtoB} : \text{Cnf} \rightarrow \text{Brw}$ by:

$$\begin{aligned} \text{CtoB}(0) &::= \text{zero} \\ \text{CtoB}(\omega^a + b) &::= \omega^{\text{CtoB}(a)} + \text{CtoB}(b) \end{aligned}$$

► **Theorem 19.** *The function CtoB preserves and reflects $<$ and \leq , i.e., $a < b \leftrightarrow \text{CtoB}(a) < \text{CtoB}(b)$, and $a \leq b \leftrightarrow \text{CtoB}(a) \leq \text{CtoB}(b)$.* 

³ Caveat: $+$ is a notation for the tree constructor, while $+$ is an operation that we define. We use parenthesis so that all operations can be read with the usual operator precedence.

To show that CtoB preserves $<$, we first prove that Brouwer trees of the form ω^x are additive principal: if $a < \omega^x$ then $a + \omega^x = \omega^x$ – a property not true for the “naive” version of Brouwer trees without path constructors. By reflecting \leq and antisymmetry, we have:

► **Corollary 20.** *The function CtoB is injective.* ◀⚙️

We note that CtoB also preserves all arithmetic operations on Cnf. For multiplication, this relies on $\iota(n) \cdot \omega^x = \omega^x$ for Brw, where $\iota : \mathbb{N} \rightarrow \text{Brw}$ embeds the natural numbers as Brouwer trees, and $\omega := \text{limit } \iota$ – see our formalisation for details.

► **Theorem 21.** *CtoB commutes with addition, multiplication, and exponentiation with base ω .* ◀⚙️

Lastly, as expected, Brouwer trees define bigger ordinals than Cantor normal forms: when embedded into Brw, all Cantor normal forms are below ε_0 , the limit of the increasing sequence $\omega, \omega^\omega, \omega^{\omega^\omega}, \dots$

► **Theorem 22.** *For all $a : \text{Cnf}$, we have $\text{CtoB}(a) < \text{limit } (\lambda k. \omega \uparrow\uparrow k)$, where $\omega \uparrow\uparrow 0 := \omega$ and $\omega \uparrow\uparrow (k + 1) := \omega^{\omega \uparrow\uparrow k}$.* ◀⚙️

5.2 From Brouwer Trees to Extensional Wellfounded Orders

As Brw comes with an order that is extensional, wellfounded, and transitive, it can itself be seen as an element of Ord. Every “subtype” of Brw (constructed by restricting to trees smaller than a given tree) inherits this property, giving a canonical function from Brouwer trees to extensional, wellfounded orders. We define

$$\text{BtoO}(a) = \Sigma(y : \text{Brw}).(y < a).$$

with order relation $(y, p) < (y', p')$ if $y < y'$. This extends to a function $\text{BtoO} : \text{Brw} \rightarrow \text{Ord}$. The first projection gives a simulation $\text{BtoO}(a) \leq \text{Brw}$. Using extensionality of Brw, this implies that BtoO is an embedding from Brw into Ord. Using that $<$ on Brw is propositional, and that carriers of orders are sets, it is also not hard to see that BtoO is order-preserving:

► **Lemma 23.** *The function $\text{BtoO} : \text{Brw} \rightarrow \text{Ord}$ is injective, and preserves $<$ and \leq .* ◀⚙️

A natural question is whether the above result can be strengthened further, i.e. whether BtoO is a simulation. Using LEM to find a minimal simulation witness, this is possible:

► **Theorem 24.** *Under the assumption of the law of excluded middle, the function $\text{BtoO} : \text{Brw} \rightarrow \text{Ord}$ is a simulation.* ◀

We do not know whether the reverse of Theorem 24 is provable, but from the assumption that BtoO is a simulation, we can derive another constructive taboo:

► **Theorem 25.** *If the map $\text{BtoO} : \text{Brw} \rightarrow \text{Ord}$ is a simulation, then WLPO holds.* ◀

We trivially have $\text{BtoO}(\text{zero}) = \mathbf{0}$. One can further prove that BtoO commutes with limits, i.e. $\text{BtoO}(\text{limit}(f)) = \text{lim}(\text{BtoO} \circ f)$. However, BtoO does *not* commute with successors; it is easy to see that $\text{BtoO } x \uplus \mathbf{1} \leq \text{BtoO}(\text{succ } x)$, but the other direction implies WLPO. This also means that BtoO does not preserve the arithmetic operations but “over-approximates” them, i.e. we have $\text{BtoO}(x + y) \geq \text{BtoO } x \uplus \text{BtoO } y$ and $\text{BtoO}(x \cdot y) \geq \text{BtoO } x \times \text{BtoO } y$.

6 Conclusions and Future Directions

We have demonstrated that three very different implementations of ordinal numbers, namely Cantor normal forms (Cnf), Brouwer ordinal trees (Brw), and extensional wellfounded orders (Ord), can be studied in a single abstract setting in the context of homotopy type theory. We hope that our development may shed light on other constructive or formalised approaches to ordinals also in other settings [31, 7, 6, 34].

Cantor normal forms are a formulation where most properties are decidable, while the opposite is the case for extensional wellfounded orders. Brouwer ordinal trees sit in the middle, with some of its properties being decidable. This aspect is not discussed in full in this paper; we only have included Theorem 14. It is easy to see that, for $x : \text{Brw}$, it is decidable whether x is finite; in other words, the predicate $(\omega \leq _) : \text{Brw} \rightarrow \mathbf{hProp}$ is decidable, while $(\omega < _)$ is decidable if and only if WLPO holds.

If x is finite, then the predicates $(x = _)$, $(x \leq _)$, and $(x < _)$ are also decidable. We have a further proof that, if $c : \text{Cnf}$ is smaller than ω^2 , then the families $(\text{CtoB } c \leq _)$ and $(\text{CtoB } c < _)$ are *semidecidable*, where semidecidability can be defined using the *Sierpinski space* [3, 13, 42].

Thus, each of the canonical maps $\text{CtoB} : \text{Cnf} \rightarrow \text{Brw}$ and $\text{BtoO} : \text{Brw} \rightarrow \text{Ord}$ embeds the “more decidable” formulation of ordinals into the “less decidable” one. Naturally, they both also include a “smaller” type of ordinals into a “larger” one: While every element of Cnf represents an ordinal below ϵ_0 , Brw can go much further. It would be interesting to consider more powerful ordinal notation systems such as those based on the Veblen functions [41, 35] or collapsing functions [4, 9], and see how these compare to Brouwer trees. Another avenue for potentially extending Cantor normal forms would be using *superleaves* [19]; we do not know how such a “bigger” version of Cnf would compare to Brw.

Since Brw can be viewed as an element of Ord, the latter can clearly reach larger ordinals than the former. This is of course not surprising; the Burali-Forti argument [5, 11] shows that lower universes cannot reach the same ordinals as higher universes. Another obstruction for Brw to reach the full power of Ord is the fact that Brw only includes limits of \mathbb{N} -indexed sequences. To overcome this problem, one can similarly construct higher number classes as quotient inductive-inductive types, e.g. a type Brw_3 closed under limits of Brw-indexed sequences, and then more generally types Brw_{n+1} closed under limits of Brw_n -indexed sequences, and so on.

Finally, there are interesting connections between the ordinals we can represent and the proof-theoretic strength of the ambient type theory: each proof of wellfoundedness for a system of ordinals is also a lower bound for the strength of the type theory it is constructed in. It is well known that definitional principles such as simultaneous inductive-recursive definitions [22] and higher inductive types [30] can increase the proof-theoretical strength, and so, we hope that they can also be used to faithfully represent even larger ordinals.

Abstract

In recent work, Gourvès, Lesca, and Wilczynski (IJCAI 17) propose a variant of the classic housing markets model in which the matching between agents and objects evolves through Pareto-improving swaps between pairs of agents who are adjacent in a social network. To explore the swap dynamics of their model, they pose several basic questions concerning the set of reachable matchings, and investigate the computational complexity of these questions when the graph structure of the social network is a star, path, or tree, or is unrestricted.

We are interested in how to direct the agents to swap objects with each other in order to arrive at a reachable matching that is both efficient and most agreeable. In particular, we study the computational complexity of reaching a Pareto-efficient matching that maximizes the number of agents who prefer their match to their initial endowments. We consider various graph structures of the social network: path, star, tree, or being unrestricted. Additionally, we consider two assumptions regarding preference relations of agents: strict (ties among objects not allowed) or weak (ties among objects allowed). By designing two polynomial-time algorithms and two NP-hardness reductions, we resolve the complexity of all cases not yet known. Our main contributions include a polynomial-time algorithm for path networks with strict preferences and an NP-hardness result in a star network with weak preferences.

1 Introduction

Model. Matching indivisible objects to agents is a fundamental problem in both computer science and economics. In a seminal work, Shapley and Scarf [22] introduced the notion of a housing market, which corresponds to the special case of one-sided matching in which there are an equal number of agents and objects, each agent is initially endowed with a distinct object, and each agent is required to be matched to exactly one object. Fruitful applications have arisen from the housing market problem: assigning virtual machines to servers in cloud computers, and allocating graduates to trainee positions. There are two different assumptions regarding preference relations of agents. One is strict, which is a full ordinal list of all objects, and the other one is weak, where agents are allowed to be indifferent between objects. Both preference relations have been widely studied.

However, in practice, assuming that any agent is able to trade with any other agent is a quite strong assumption. Agents tend to trade with agents that they know and trust, and it is hard to let two agents who do not trust each other exchange their objects even if they can mutually get benefits. So Gourvès et al. [13] initiated the line of research on the house market problem where the agents are embedded in a social network. A pair of agents are allowed to swap objects with each other only if (1) both of them will be better off after the swap and (2) they are directly connected (socially tied) via the network. The underlying social network is modeled as an undirected graph. They investigate the swap dynamics of

the housing market problem in this model by considering the following three computational problems. The first problem, Reachable Object (RO), asks whether there is a sequence of swaps that results in matching a given agent to a given target object. The second problem, Reachable Matching (RM), asks whether there is a sequence of swaps that results in a given target matching. The third problem, Pareto Efficiency (PE), asks how to find a sequence of swaps that results in a Pareto-efficient matching with respect to the set of reachable matchings. Of particular relevance to the present paper is the last problem. We remark that like Gourvès et al., our focus is on Pareto-efficient matchings among reachable matchings (to be formally defined in Section 2). In particular, we focus on reachable matchings that are not Pareto-dominated by a reachable matching, rather than by an arbitrary matching as in the standard meaning. Specifically, we are interested in finding a sequence of swaps that yields a Pareto-efficient matching that maximizes the number of agents who prefer their match to their initial endowments.

Maximum Votes Pareto-Efficient Matching. In housing markets, we typically seek a matching between houses and agents that optimizes some social objects. Pareto efficiency has been widely considered in the context of housing allocation [2, 4, 22], which appears to be the minimal requirement for an allocation to be socially acceptable. However, in the context of social network, Pareto efficiency among reachable matchings is not sufficient to be socially acceptable. In the example of Fig. 1, there is a Pareto-efficient matching that improves only two agents, while there is another Pareto-efficient matching that improves everyone, as shown in Fig. 1.

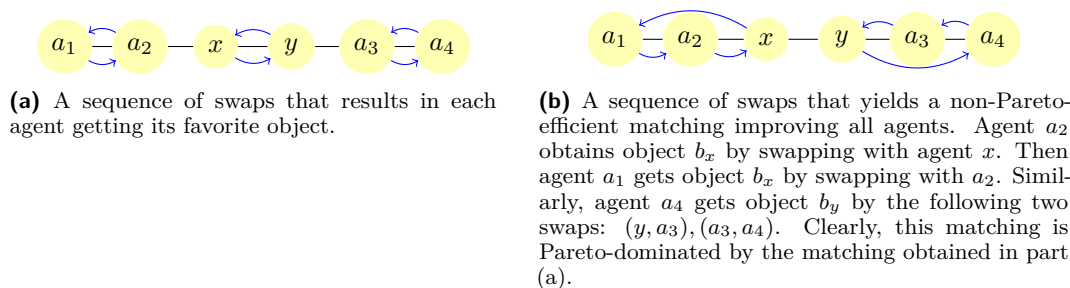

■ **Figure 1** Consider an instance with six agents in $\{a_1, a_2, a_3, a_4, a_5, a_6\}$ and six objects in $\{b_1, b_2, b_3, b_4, b_5, b_6\}$. The boxed objects represent the initial endowments. Initially, only the swaps between agents a_1 and a_2 , and a_2 and a_3 are possible. If we let agents a_1 and a_2 swap their objects first, then we obtain a Pareto-efficient matching in which a_1, a_2 get their best objects. If we let a_2 and a_3 swap their objects first, then additional swaps between pairs (a_1, a_2) and (a_3, a_4) become possible. Indeed, the sequence of swaps, $\{a_2, a_3\}$, $\{a_1, a_2\}$, $\{a_3, a_4\}$, $\{a_4, a_5\}$, and $\{a_5, a_6\}$, yields a different Pareto-efficient matching that improves all agents.

There is a vast literature on refining Pareto-efficiency in object allocation with endowments. Various refining directions are considered, such as fairness ([6, 12]), welfare-maximization ([1, 10]), and stability ([22]). In this work, we propose to refine Pareto-efficiency in the direction of popularity. The notion of popularity was introduced by Abraham et al. [5] for object allocation without endowments. Popularity has gained a lot of attention in the recent past (we refer to the survey by Cseh [11] on this topic). Popular matchings are defined based on comparisons of two matchings with respect to the votes of the agents. Consider an election between two matchings M and M' where vertices are voters. In this M versus M' election, each agent a votes for the matching in $\{M, M'\}$ that agent a prefers, i.e., where agent a gets a better assignment. We say a matching is popular if it never loses a head-to-head election against any matching in the voting instance where matchings are candidates and vertices are voters. However, popular matchings do not always exist: Abraham et al. construct an instance with three agents for which there is no popular matching.

To adapt the popularity notion to housing markets, we introduce the notion of maximum votes matching. We consider the same voting scheme, but focus on the comparison with the initial endowments. Given a reachable matching μ , an agent a votes for the matching if it prefers the object assigned by this matching to its initial object. We refer to the number of agents that prefer μ to the initial matching as the voting number of μ . We define a maximum votes matching to be a reachable matching with the maximum voting number. We remark that maximum votes matchings always exist.

Clearly, not all Pareto efficient matchings have the same voting number. Also, a maximum votes matching is not necessarily a Pareto-efficient matching. Consider the example shown in Fig. 2. Part (a) shows a sequence of swaps that gives a Pareto-efficient matching improving all agents. Part (b) shows a sequence of swaps that also yields a matching that improves all agents, but is not Pareto-efficient. Thus, it is natural to consider the problem of finding a Pareto-efficient matching that has the largest voting number. We refer to this problem as the maximum votes Pareto-efficient (MVPE) matching problem. In particular, the set of MVPE matchings is precisely the intersection of the following two sets: (1) the set of matchings that are Pareto efficient among reachable matchings; (2) the set of reachable matchings with the maximum voting number.

■ **Figure 2** An example in which a non-Pareto-efficient matching improves the most agents. Consider an instance with six agents in $\{a_1, a_2, x, y, a_3, a_4\}$ and six objects in $\{b_1, b_2, b_x, b_y, b_3, b_4\}$. The preferences of the agents and the initial endowments (represented as boxed objects) are given below. The arrows in the figures show where the initial object of each agent goes.

$$\begin{array}{lll}
 a_1 : b_2 > b_x > \boxed{b_1} & x : b_y > b_2 > \boxed{b_x} & a_3 : b_4 > b_y > \boxed{b_3} \\
 a_2 : b_1 > b_x > \boxed{b_2} & y : b_x > b_3 > \boxed{b_y} & a_4 : b_3 > b_y > \boxed{b_4}
 \end{array}$$

Related work. Gourvès et al. [13] study these three problems, RO, RM and PE, in four different graph classes, paths, stars, trees, and general graphs. They only consider strict preferences, and thus they consider twelve problems in total. They study these twelve problems with the goal of either exhibiting a polynomial-time algorithm or establishing NP-completeness. For some of these problems, it is a relatively straightforward exercise to design a polynomial-time algorithm (even for the search version). In particular, this is the case for all three problems on stars, for PE on paths, and for RM on trees (which subsumes RM on paths). Gourvès et al. [13] present an elegant reduction from 2P1N-SAT [23] to establish the NP-completeness of RO on trees. They leverage this result to establish the NP-completeness of RM on general graphs via a reduction from RO on trees. Then, they make use of the latter reduction to establish the NP-hardness of PE on general graphs. The

work of Gourvès et al. [13] left two of the twelve problems open: RO on paths and PE on trees. Subsequently, two sets of authors independently presented polynomial-time algorithms for RO on paths [14, 7]. To the best of our knowledge, PE on trees remains open.

Huang and Xiao [15] study RO and PE with weak preferences. They establish NP-hardness for RO on paths with weak preferences and give a polynomial-time algorithm for RO on stars with weak preferences. Then, they establish NP-hardness for PE on paths with weak preferences via a reduction from RO on paths with weak preferences. They left PE on stars with weak preferences open. Furthermore, they show that finding a reachable matching maximizing total social welfare is NP-hard for a star or a path with weak preferences.

Bentert et al. [7] consider the case where the preference lists have bounded length. Saffidine and Wilczynski [21] propose an alternative version of RO where an agent can be guaranteed a certain level of satisfaction regardless of the actual exchanges. Müller and Bentert [20] study RM on cliques and cycles. Aspects related to social connectivity are also addressed in recent work on envy-free allocations [8, 9] and on a trade-off between efficiency and fairness [16].

There are several works on ensuring popularity. For settings where a popular matching does not exist, Kavitha et al. [18] study how to minimally augment the preferences to guarantee the existence of a popular matching. This problem has been shown to be NP-hard. Another way to ensure popularity is to consider mixed matchings, i.e., lotteries over matchings; and the popularity property is straightforward to carry over; Kavitha et al. [17] show that a popular mixed matching always exists and propose an efficient algorithm to find one. McCutchen [19] proposes a least-unpopularity criterion to find the “most” popular matching; finding this least-unpopular matching is NP-hard.

Our results. Our main contributions are summarized in Table 1. Our main positive result is a polynomial-time algorithm for finding a maximum votes Pareto-efficient matching in a path network with strict preferences. To achieve this result, we first present an algorithm for finding a maximum votes matching by studying the structure of a reachable matching in a path network. Specifically, we show that the improved agents in any reachable matching can be decomposed into a set of agent intervals, where each agent interval is a set of consecutive agents in the path and all agents in this interval can improve their allocation by swapping objects within the interval. Moreover, given a disjoint union of such agent intervals, we can recover a sequence of swaps improving agents in this disjoint union. Thus, we reduce the problem of computing the maximum votes number to the problem of finding the disjoint union of such agent intervals that covers the most agents; polynomial-time algorithms are known for the latter problem.

To find a maximum votes Pareto-efficient matching, observe that there is a maximum votes matching that is also Pareto-efficient. Thus, to find a maximum votes Pareto-efficient matching, it is enough to find a Pareto-efficient matching among maximum votes matchings. To achieve that, we carefully adapt the serial dictatorship algorithm [3] to ensure that each time a dictator agent a is assigned to an object b , where the current partial assignment remains consistent with a maximum votes matching. In particular, we present a subroutine to find the most favorite object b that can be assigned to agent a such that there is a sequence of swaps letting a get b and improving the most agents. In Section 3.4, we use a delicate induction argument to prove the correctness of this subroutine.

In Section 4, we present a simple polynomial-time algorithm for finding a maximum votes Pareto-efficient matching on stars with strict preferences shown

■ **Table 1** Our results and related work. Results in parentheses are implied by other table entries.

	Strict	Weak
Path	poly-time [Section 3]	NP-hard ([15])
Star	poly-time [Section 4]	NP-hard [Section 4]
Tree	NP-hard [Section 5]	(NP-hard)
General	(NP-hard)	(NP-hard)

In terms of negative results, in Section 4, we show that the MVPE problem in star networks with weak preferences is NP-hard by designing a novel reduction from the 3-SAT problem. In Section 5, we prove that the MVPE problem in tree networks with strict preferences is NP-hard by reducing from the RO problem in tree networks with strict preferences, which is known to be NP-complete [13].

Due to space restrictions, some of the proofs are omitted, or are merely sketched. Complete proofs will be provided in the full version of this paper.

2 Preliminaries

We define an object allocation framework (OAF) on a social network as a triple $F = (A, B, \geq, E)$ where A is a set of agents, B is a set of objects such that $|A| = |B|$, \geq is a collection of linear orderings $\{\geq_a\}_{a \in A}$ over B such that \geq_a specifies the preferences (including ties) of agent a over B , and E is the edge set of a social network between agents in A , i.e., the social network is the undirected graph (A, E) .

We define a matching μ of a given OAF $F = (A, B, \geq, E)$ as a subset of $A \times B$ such that no agent or object belongs to more than one pair in μ . (Put differently, μ is a matching in the complete bipartite graph of agents and objects.) We say that such a matching is perfect if $|\mu| = |A|$. For any matching μ , we define $\text{agents}(\mu)$ (resp., $\text{objects}(\mu)$) as the set of all matched agents (resp., objects) with respect to μ . For any matching μ and any agent a that is matched in μ , we use the shorthand notation $\mu(a)$ to refer to the object matched to agent a . For any matching μ and any object b that is matched in μ , we use the notation $\mu^{-1}(b)$ to refer to the agent matched to object b .

For any OAF $F = (A, B, \geq, E)$, any perfect matching μ of F , and any edge $e = (a, a')$ in E , we define an exchange operation on edge e as $\mu' = \mu \setminus \{(a, \mu(a)), (a', \mu(a'))\} \cup \{(a, \mu(a')), (a', \mu(a))\}$, where μ' is the new matching obtained by applying the exchange operation on edge e . We say the exchange is rational if $\mu(a') \geq_a \mu(a)$ and $\mu(a) \geq_{a'} \mu(a')$, denoted as $\mu \rightarrow_{F,e} \mu'$. We call a rational exchange a *swap*. We use $\mu \rightarrow_F \mu'$ to denote that $\mu \rightarrow_{F,e} \mu'$ for some edge e . We write $\mu \rightsquigarrow_F \mu'$ if there exists a sequence of matchings $\mu = \mu_0, \dots, \mu_k = \mu'$ of matchings of F such that $\mu_{i-1} \rightarrow_F \mu_i$ for $1 \leq i \leq k$.

We define a configuration as a pair $\chi = (F, \mu)$ where F is an OAF and μ is a perfect matching of F . We say that χ is a path or star or tree configuration if the social network in F is a path or star or tree. For any configuration $\chi = (F, \mu)$, we define $\text{reach}(\chi)$ as the set of all perfect matchings μ' of F such that $\mu \rightsquigarrow_F \mu'$.

A matching μ Pareto-dominates a matching μ' if $\mu(a) \geq_a \mu'(a)$ for all agents a in A , and there is at least one agent b in B such that $\mu(b) >_b \mu'(b)$. A matching is Pareto-efficient if it is not Pareto-dominated by another matching. Throughout this paper, we restrict the definition of Pareto-efficiency to the set of reachable matchings. A matching μ is Pareto-efficient with respect to a configuration χ if μ belongs to $\text{reach}(\chi)$ and μ is not Pareto-dominated by another matching in $\text{reach}(\chi)$.

Maximum Votes Pareto-Efficient Matching Problem. Given a configuration $\chi = (F, \mu)$ and a matching μ' , we use $\text{votes}_F(\mu', \mu)$ to denote the number of agents who prefer μ' to μ . We say $\text{votes}_F(\mu', \mu)$ is the voting number of matching μ' . The maximum votes Pareto-efficient matching problem is equivalent to the following optimization problem:

$$\operatorname{argmax}_{\tau \in \text{reach}(\chi) \wedge \tau \text{ is Pareto-efficient}} \text{votes}_F(\tau, \mu).$$

For a given configuration χ , we use $\text{mv}(\chi)$ to denote the largest voting number of a matching in $\text{reach}(\chi)$. We refer to $\text{mv}(\chi)$ as the voting number of χ .

3 Path Network

In this section, we study the maximum votes Pareto-efficient matching problem in a path configuration. We begin by introducing some notations. For any nonnegative integer n , we define $[n]$ as $\{1, \dots, n\}$. Without loss of generality, in this subsection we restrict attention to OAFs of the form $F = ([n], [n], \geq, \{(b, b+1) \mid 1 \leq b < n\})$ for some positive integer n . We use $[i, j]$ to denote the set of agents between agent i and agent j (inclusive). Let $\Pi = \mu_0, \mu_1, \dots, \mu_k$ denote a sequence of matchings where $\mu_i \rightarrow_F \mu_{i+1}$ for $0 \leq i \leq k-1$, i.e., μ_{i+1} is obtained from μ_i by a swap. We have the following observations.

► **Observation 1.** *Each object only moves in one direction or stays at its initial position in Π .*

We say an object is right-moving (left-moving) in Π if it moves to the right (left). The following observation says that while implementing the sequence of swaps Π , the relative location of any two objects moving in the same direction on the path does not change, i.e., if an object b is located to the left (right) of another object b' , then object b will always be to the left (right) of object b' .

► **Observation 2.** *Let $\Pi = \mu_0, \mu_1, \dots, \mu_k$ denote a sequence of matchings. For any two objects b and b' where $\mu_0^{-1}(b) < \mu_0^{-1}(b')$ that move along the same direction in Π , we have $\mu^{-1}(b) < \mu^{-1}(b')$ for all μ in Π .*

Let $\kappa(j, k)$ denote a canonical sequence of exchanges that assigns object j to agent k by directly moving it along the dipath from j to k . Formally, if $j < k$, $\kappa(j, k) = (j, j+1), (j+1, j+2), \dots, (k-1, k)$. If $j \geq k$, $\kappa(j, k) = (j, j-1), (j-1, j-2), \dots, (k+1, k)$. A sequence of exchanges Π is said to be a sequence of swaps if all its exchanges are rational, denoted as $\text{rational}(\Pi)$. We remark that $\kappa(j, k)$ was defined, and some associated properties were proved, by Gourvès et. al [13]. The following lemma presents a useful structural property.

► **Lemma 3.** *Let $\chi = (F, \mu)$ denote a path configuration, let a denote a leaf agent in χ , and let a' denote an agent in χ . If there is a matching μ'' in $\text{reach}(\chi)$ such that $\mu''(a) = \mu(a')$, then (1) $\text{rational}(\kappa(a', a))$ holds, and (2) μ'' belongs to $\text{reach}((F, \mu'))$, where μ' is the matching reached from μ via $\kappa(a', a)$.*

3.1 Maximum Votes Pareto-Efficient Matching

In this section, we present a polynomial-time algorithm for finding a maximum votes Pareto-efficient matching given a path configuration. In order to find an MVPE matching, we first present an algorithm for computing the maximum voting number of a given configuration $\chi = (F, \mu)$, i.e., for computing $\text{mv}(\chi)$. We then compute an MVPE matching by combining

this algorithm with the serial dictatorship algorithm [3]. In the serial dictatorship algorithm, we let agents pick whatever best object they are left with in an arbitrary sequential order. In our case, agents pick objects according to the order of their IDs, i.e., the smallest agent picks first and the largest agent picks last. Assuming that agent a picks object b , we need to meet three additional requirements. First, object b can be assigned to agent a via a sequence of swaps. Second, after object b is assigned to agent a via a sequence of swaps, we obtain a new matching μ' and a new configuration $\chi' = (F, \mu')$. We need to maintain the invariant that there exists a matching τ in $\text{reach}(\chi')$ such that $\text{votes}_F(\tau, \mu) = \text{mv}(\chi)$. Third, object b is the most preferred object of agent a subjects to the first two constraints.

The above three constraints along with the property of serial dictatorship are sufficient for us to prove that the eventual matching we obtain is an MVPE matching. Now, let us first present our algorithm for computing the maximum votes matching of $\text{reach}(\chi)$.

3.2 Maximum Number of Votes

Throughout this section, let $\chi = (F, \mu)$ denote a path configuration. Below we present Algorithm 1, which computes the largest voting number of matching in $\text{reach}(\chi)$.

► **Definition 4** (Directional sequence). *A directional sequence is a sequence of R, L, or S symbols. For any agent i , the i th symbol represents the final moving state of its initial object. Symbol R indicates that it moves to the right. Symbol L indicates that it moves to the left. Symbol S indicates that it does not move.*

For any matching ν in $\text{reach}(\chi)$, we define an associated directional sequence as follows. For agent i , if its initial object $\mu(i)$ moves to the left in ν (i.e., the position $\nu^{-1}(\mu)$ of object μ_i is smaller than the initial position i in μ), then the i th symbol in the directional sequence is L, i.e., the object is left-moving. If it is moved to the right, then the i th symbol is R, i.e., the object is right-moving. If it is stationary, then the i th symbol is S. We use $DS(\nu)$ to denote the directional sequence of ν and $DS(\nu([i, j]))$ to denote the subsequence $DS(\nu)[i, j]$ with respect to agents in $[i, j]$ only.

► **Definition 5** (RL-block). *We define an RL-block as a directional sequence of the form $R^m L^n = RRR\dots RLLL\dots L$ where m, n are positive.*

Remark: Any agent with symbol S in $DS(\nu)$ does not get a better allocation in ν ; any agent with symbol R or L gets improved by ν due to the definition of swaps. Therefore, given a matching ν in $\text{reach}(\chi)$, we can decompose $[n]$ into a set of maximal intervals such that all agents in each interval get moved or improved. Let $\text{Decompose}(\nu)$ denote the set of maximal intervals decomposed from $[n]$ according to ν .

► **Observation 6.** *Given a matching ν in $\text{reach}(\chi)$, $DS(\nu)$ can be uniquely decomposed into a disjoint union of RL-blocks and S symbols.*

Given a matching ν in $\text{reach}(\chi)$, by applying Observation 6 on the directional sequence $DS(\nu)$, we observe that for any interval $[i, j]$ in $\text{Decompose}(\nu)$, the interval $[i, j]$ can be uniquely partitioned as a set of sub-intervals such that for each sub-interval $[i', j']$, $DS(\nu)[i', j']$ is an RL-block. We refer to this partition as the RL-decomposition of interval $[i, j]$.

Given a maximal interval $[i, j]$ in $\text{Decompose}(\nu)$, let $\text{RLD}([i, j])$ denote the set $\{[i', j'] \subseteq [i, j] \mid DS(\nu)[i', j'] \text{ is an RL-block}\}$ that contains those subintervals of $[i, j]$ that are also RL-blocks. Let $\text{RLD}(\nu)$ denote the set $\bigcup_{[i, j] \in \text{Decompose}(\nu)} \text{RLD}([i, j])$.

► **Definition 7** (RL-interval). We say that an interval $[i, j]$ is an RL-interval if at least one of the following condition holds: (1) $\text{rational}(\kappa(j, i))$; (2) $\text{rational}(\kappa(i, j))$; (3) there exists an integer k such that $i < k < j$, $\text{rational}(\kappa(k + 1, i))$, and $\text{rational}(\kappa(k, j))$.

From the above definition, we can obtain the following observation.

► **Observation 8.** For any RL-interval $[i, j]$, there exists a sequence of swaps between agents in $[i, j]$ that improves all agents in the interval.

► **Lemma 9.** Let ν be a matching in $\text{reach}(\chi)$ and let $[i, j]$ be in $\text{RLD}(\nu)$, interval $[i, j]$ is an RL-interval.

Proof. Let $R^m L^{j-i+1-m}$ denote the RL-block $DS(\nu)[i, j]$. Let b_1 and b_2 denote the initial endowment of agent $i + m - 1$ and agent $i + m$ in χ , respectively. Then, b_1 is the rightmost right-moving object and b_2 is the leftmost left-moving object. Then, from Observations 1 and 2, we have $\nu^{-1}(b_1) = j$ and $\nu^{-1}(b_2) = i$; otherwise the initial endowments of agent i and agent j are stationary. Thus, we have a reachable matching ν mapping b_1 to leaf agent j , and mapping b_2 to leaf agent i . By Lemma 3, $\kappa(i + m - 1, j)$ and $\kappa(i + m, i)$ are both rational. ◀

Let \mathcal{I} denote the set of all RL-intervals in χ . Let $\Psi(\mathcal{I})$ denote the set $\{X \subseteq \mathcal{I} \mid \text{all intervals in } X \text{ are disjoint}\}$.

► **Lemma 10.** For any matching ν in $\text{reach}(\chi)$, the set of intervals $\text{RLD}(\nu)$ is an element in $\Psi(\mathcal{I})$.

Proof. Since \mathcal{I} contains all RL-intervals in χ and each interval in $\text{RLD}(\nu)$ is an RL-interval (Lemma 9), the set of intervals $\text{RLD}(\nu)$ is a subset of \mathcal{I} . Also, all intervals in $\text{RLD}(\nu)$ are clearly disjoint. ◀

► **Lemma 11.** For any set of intervals D in $\Psi(\mathcal{I})$, there exists a matching ν in $\text{reach}(\chi)$ such that $\text{RLD}(\nu) = D$.

Proof. We explicitly construct such a matching as follows. For each RL-interval $[i, j]$ in D , from Observation 8, we know there exists a sequence of swaps that improves all agents in $[i, j]$. Thus, matching ν can be constructed by applying such a sequence of swaps for each interval $[i, j]$ in D on the initial matching μ . ◀

Let $\text{MCDI}(\mathcal{I})$ denote the maximum coverage of some disjoint intervals in \mathcal{I} , i.e., the maximum size of the union of disjoint intervals in \mathcal{I} .

► **Lemma 12.** $\text{mv}(\chi) = \text{MCDI}(\mathcal{I})$.

Proof. Lemma 10 implies that $\text{mv}(\chi) \leq \text{MCDI}(\mathcal{I})$. Assume by contradiction that $\text{mv}(\chi) < \text{MCDI}(\mathcal{I})$. Then, there exists a set D in $\Psi(\mathcal{I})$ such that $\text{mv}(\chi) < \sum_{[i,j] \in D} j - i + 1$. By Lemma 11, there exists a matching ν in $\text{reach}(\chi)$ such that $\text{RLD}(\nu) = D$. For matching ν , we have $\text{votes}_F(\nu, \mu) = \sum_{[i,j] \in \text{RLD}(\nu)} j - i + 1 = \sum_{[i,j] \in D} j - i + 1 > \text{mv}(\chi)$, a contradiction. ◀

Using the above lemma, to compute the maximum votes of a configuration, we only need to compute the maximum coverage of disjoint intervals in \mathcal{I} . Algorithm 1 has two steps. The nested for loops compute all the RL-intervals \mathcal{I} for a given χ . The second step invokes the maximum disjoint interval algorithm on \mathcal{I} .

Algorithm 1 $MV(\chi)$.

Input: A configuration $\chi = (F, \mu_0)$
Output: The maximum votes number of χ

```

 $\mathcal{I} \leftarrow \emptyset$ 
for  $i \leftarrow 1$  to  $n - 1$  do
  for  $j \leftarrow i + 1$  to  $n$  do
    if  $\exists k \in [i, j]$  s.t.  $\text{rational}(\kappa(k, j)) \wedge \text{rational}(\kappa(k + 1, i))$  then
       $\mathcal{I} \leftarrow \mathcal{I} \cup \{[i, j]\}$ 
    end
  end
end
Return  $MCDI(\mathcal{I})$ 

```

3.3 Weighted Version of Maximum Votes Matching

We remark that there is a polynomial-time algorithm solving a weighted version of finding a maximum votes matching. Formally, let $W : [n] \rightarrow \mathbb{R}$ denote a weight function assigning each agent a in $[n]$ a real value $W(a)$. For any matchings μ', μ of F , let $\text{votes}_F(\mu', \mu, W) = \sum_{a \in [n]; \mu'(a) >_a \mu(a)} W(a)$, i.e., the total weight of the agents that prefer μ' to μ . In addition, let $\text{mv}(\chi, W) = \max_{\mu' \in \text{reach}(\chi)} \text{votes}_W(\mu', \mu)$.

To allow for the weight function W , we reduce the problem of computing $\text{mv}(\chi, W)$ to compute the maximal sum of weights of disjoint intervals in \mathcal{I} , where each interval $[i, j]$ in \mathcal{I} has weight $\sum_{k \in [i, j]} W(k)$. To compute the maximum weighted coverage of disjoint intervals in \mathcal{I} , we construct a directed graph $G = (\mathcal{I}, E)$ as follows. Each node in G is a interval $[i, j]$ in \mathcal{I} . For every two nodes $[i, j]$ and $[i', j']$, there is a directed edge from node $[i, j]$ to node $[i', j']$ if $j < i'$. Moreover, each node has a cost equal to the weight of the corresponding interval. Note that this graph is acyclic, and it takes $O(n^2)$ time to find a most weighted path in an acyclic graph.

3.4 MVPE algorithm

In this section, we present Algorithm 3 for finding an MVPE matching given a path configuration. Our main idea is to apply a serial dictatorship procedure. To simplify the presentation, we focus on the leftmost agent a in any path configuration $\chi = (F, \mu)$ on agents $[a, n]$. We seek the best possible object b for the leftmost agent a such that there exists a maximum votes matching τ in $\text{reach}(\chi)$ with $\tau(a) = b$. Note that Lemma 3 implies that $\text{rational}(\kappa(\mu^{-1}(b), a))$ holds. We then apply $\kappa(\mu^{-1}(b), a)$ in χ to let agent a match object b . Hence, we get a new configuration χ' on agents $[a + 1, n]$ by truncating the leftmost agent a along with its assigned object b . We then recurse on the leftmost agent $a + 1$ in χ' .

However, when we recurse on χ' , the situation is a bit different than in χ . The applied sequence of swaps $\kappa(\mu^{-1}(b), a)$ has improved agents between agent a and $\mu^{-1}(b)$ in χ , and also in χ' . These agents will vote when this serial dictatorship procedure ends. Thus, when we recurse on χ' , in order to ensure that the resulting matching is a maximum vote matching, we need to find a matching maximizing votes among agents on the right side of $\mu^{-1}(b)$ in χ' , rather than all agents.

Formally, we introduce some notations. For any agent interval $[i, j]$ that is a subset of $[n]$, let $\chi[i, j]$ and $\mu[i, j]$ denote the truncated configuration and truncated matching induced by agents in $[i, j]$, respectively. Let $\text{mv}(\chi, [i, j])$ denote the maximum number of agents in $[i, j]$

that can be improved by any reachable matching in $\text{reach}(\chi)$, $\text{votes}_F(\mu', \mu, [i, j])$ denote the number of agents in $[i, j]$ that prefer μ' to μ , and $\text{MVM}(\chi, [i, j])$ denote the set of reachable matchings achieving $\text{mv}(\chi, [i, j])$.

We are prepared to introduce our recursive subroutine called BOLA (best object for the leftmost agent), shown as Algorithm 2. Given a configuration $\chi = (F, \mu)$ on agents $[a, n]$ and an agent $a' \geq a$, Algorithm 2 finds the leftmost agent a 's most preferred object b^* such that there exists a μ' in $\text{MVM}(\chi, [a', n])$ with $\mu'(a) = b^*$. In Algorithm 2, agent a' is used to limit the objects that agent a can be possibly matched with. Specifically, Algorithm 2 only considers objects that are initially owned by agents in $[a', n]$. In Algorithm 2, we need to compute $\text{mv}(\chi, [a, n])$ for a given χ on the agents in $[a, n]$. This can be done by applying the weighted version of Algorithm 1 as discussed in Section 3.3.

Fig. 4 shows a possible execution of Algorithm 2. Here, Algorithm 2 runs with a configuration χ on the agents in $[a, n]$ and an agent a' in $[a, n]$, and it finds an object b^* initially owned by agent i that satisfies the two **if** conditions.

■ **Figure 4** A demo example for Algorithm 2.

■ **Algorithm 2** $\text{BOLA}(\chi, a')$.

Input: A configuration $\chi = (F, \mu)$ with agents $[a, n]$, an agent $a' \in [a, n]$
Output: The most preferred object b^* of the leftmost agent, where there is a matching μ' in $\text{MVM}(\chi, [a', n])$ assigning b^* to a

// Remark: a is the leftmost agent in χ
 $b^*, V \leftarrow \mu(a), \text{mv}(\chi, [a', n])$
for $i \leftarrow a$ **to** n **do**
 if $\mu(i) \geq_a b^* \wedge \text{rational}(\kappa(i, a))$ **then**
 // Remark: i denotes an agent
 $\mu^* \leftarrow$ the matching that results from applying $\kappa(i, a)$ to μ
 $\chi^* \leftarrow (F, \mu^*)$
 $a'' \leftarrow \max(i + 1, a')$
 if $\text{votes}(\mu^*, \mu, [a', a'' - 1]) + \text{mv}(\chi^*, [a'', n]) = V$ **then**
 $b^* \leftarrow \mu(i)$
 end
 end
end
return b^*

Lemma 13 characterizes all possible maximum votes matchings in terms of the two **if** conditions used in Algorithm 2. Next we use Lemma 13 to prove Lemma 14, which is our main correctness lemma. It implies that to find the leftmost agent a 's most preferred object b^* such that $\exists \mu' \in \text{MVM}(\chi, [a', n]) : \mu'(a) = b^*$, we can iterate through all objects that satisfy the two **if** conditions and find the best one for agent a .

► **Lemma 13.** *Let $\chi = (F, \mu)$ denote an configuration, let $[a, n]$ denote the set of agents in χ , and let a' denote an agent in $[a, n]$. Let τ denote a matching in $\text{reach}(\chi)$. Let $b = \tau(a)$, and $a'' = \max(\mu^{-1}(b) + 1, a')$. Then, the matching τ belongs to $\text{MVM}(\chi, [a', n])$ if and only if the following two conditions hold:*

- (1) $\text{rational}(\kappa(\mu^{-1}(b), a))$;
- (2) $\text{votes}(\mu', \mu, [a', a'' - 1]) + \text{mv}(\chi'[a + 1, n], [a'', n]) = \text{mv}(\chi, [a', n])$, where μ' is obtained from applying $\kappa(\mu^{-1}(b), a)$ to μ and $\chi' = (F, \mu')$.

► **Lemma 14.** *Algorithm 2 with an input χ on agents $[a, n]$ and an agent a' in $[a, n]$ returns the most preferred object b^* of agent a 's such that there exists a matching μ' in $\text{MVM}(\chi, [a', n])$ with $\mu'(a) = b^*$.*

Proof. It is straightforward to verify that the returned b^* satisfies two conditions (1) and (2) in Lemma 13. Therefore, Lemma 13 implies that there exists a matching μ' in $\text{MVM}(\chi, [a', n])$ with $\mu'(a) = b^*$.

Then we prove that b^* is the agent a 's most preferred object. Assume by contradiction that there is another b is more most preferred to agent a than b^* and $\exists \mu' \in \text{MVM}(\chi, [a', n]) : \mu'(a) = b$. By Lemma 13, two conditions (1) and (2) in Lemma 13 holds and thus the algorithm will return b instead, a contradiction. ◀

We now present Algorithm 3 that uses Algorithm 2 as a building block to find an MVPE matching. In Algorithm 3, we maintain a partial matching τ_i , which is a matching involving only agents in $[1, i]$. At the i th iteration, we invoke the BOLA subroutine to find the agent i 's most preferred object b^* that satisfies the condition in Lemma 14. Then we apply $\kappa(b^*, i)$ to assign object b^* to agent i and remove agent i from the configuration afterwards.

Let $P(i)$ denote the predicate: there exists ν in $\text{MVM}(\chi, [1, n])$ such that τ_i is a subset of ν . Algorithm 3 maintains the invariant: $P(i)$ holds for all i in $[n]$. This invariant ensures that the final matching τ_n returned by Algorithm 3 is a matching in $\text{MVM}(\chi, [1, n])$. The serial dictatorship mechanism ensures that τ_n is also a Pareto-efficient matching.

■ **Algorithm 3** $\text{MVPEM}(\chi)$.

Input: A configuration $\chi = (F, \mu)$
Output: An MVPE matching of χ

$\mu_1, a_1, \chi_1, \tau_0 \leftarrow \mu, 1, \chi, \emptyset$
for $i \leftarrow 1$ **to** n **do**
 /* i is the index of an agent */
 $b_i \leftarrow \text{BOLA}(\chi_i, a_i)$
 $a'_i \leftarrow \mu_i^{-1}(b_i)$
 $a_{i+1} \leftarrow \max(a'_i + 1, a_i)$
 $\mu' \leftarrow$ the matching that results from applying $\kappa(a'_i, i)$ to μ_i
 /* Assign b_i to agent i and truncate it from χ */
 $\tau_i, \mu_{i+1}, \chi_{i+1} \leftarrow \tau_{i-1} + (i, b_i), \mu'[i + 1, n], (F, \mu_{i+1})$
end
return τ_n

► **Theorem 15.** *The matching τ_n returned by Algorithm 3 is an MVPE matching.*

4 Star Network

In this section, we consider the case when the social network is a star. Our results are twofold. We first present a polynomial-time algorithm for finding an MVPE matching in a star network when preferences are strict. We then show that finding an MVPE matching in a star network with weak preferences is NP-hard.

For the case of strict preferences, we present a simple polynomial-time algorithm for finding an MVPE matching. The main idea of the algorithm is to use the fact that any swap involves a center agent and a non-center agent to reduce the MVPE problem to the problem of finding a longest path in a directed acyclic graph.

► **Theorem 16.** *There is a polynomial-time algorithm finding an MVPE matching in a star network with strict preferences.*

Proof. Let O denote the center agent, and let $[n]$ denote the set of leaf agents. Let μ denote the initial matching. Note that every swap in a star network always involves the center agent. Moreover, notice that any leaf agent can change its object at most once in any valid sequence of swaps. To see this, observe that once an object moves from the center to a leaf, it can never return to the center. Thus, any sequence of swaps can be represented as an ordered list of leaf agents. Let $L = (i_1, i_2, \dots, i_k)$ denote such a list, where k belongs to $[n]$. Note that $\mu(i_j) <_O \mu(i_{j+1})$ for all j in $[k-1]$, where O is the center agent.

We first show how to find a maximum votes matching, and then prove that any maximum votes matching is also Pareto-efficient.

To find a maximum votes matching in star networks, it is equivalent to find a longest ordered list of leaves corresponding to a sequence of swaps, since a leaf agent gets improved if and only if it is included in the list. This problem reduces to the search of a longest path in a directed acyclic graph $G = (\{O\} \cup [n], E')$. The edge set E' contains a directed edge from a to a' if and only if agent a' belongs to $[n]$, $\mu(a') >_O \mu(a)$, and $\mu(a) >_{a'} \mu(a')$. There is a path from O to a' in the digraph if and only if the center can get the initial endowment of agent a' . It is straightforward to see that there exists a polynomial-time algorithm solving this longest path problem in G .

Next we prove that any maximum votes matching ν is Pareto-efficient. Assume for the sake of contradiction that reachable matching ν' Pareto-dominates ν . Consider the ordered lists of agents L and L' corresponding to the sequences of swaps for reaching ν and ν' , respectively. Since ν' Pareto-dominates ν , any agent in L that gets a better allocation in ν also gets a better allocation in ν' , i.e., belongs to L' . Furthermore, since ν is a maximum votes matching, the ordered list L is the longest ordered list of agents. Therefore, the list L' is contained in L . (Otherwise, L' contains all agents in L and is longer than L , which contradicts the assumption that L is the longest ordered list of agents.) That is, L' has the same agents as in L , and hence $L' = L$ as all agents in the ordered lists are sorted by the preferences of center agent O . Therefore, we have $\nu' = \nu$, a contradiction. ◀

4.1 Weak Preference

IN this section, we show that finding an MVPE matching is NP-hard in a star network with weak preferences. We first introduce the notion of a center object sequence. For all sequences of matchings $\Pi = \mu_0, \dots, \mu_k$, we define the corresponding center object sequence π as the list of objects owned by the center agent O , i.e., $\pi = [\mu_0(O), \dots, \mu_k(O)]$. We use $\pi[i]$ to denote $\mu_i(O)$, and for any object b , we use $\pi(b)$ to denote the index of first occurrence of b in π , and $\pi(b) = -1$ if b does not belong to π . We have the following observations for the center object sequence.

► **Observation 17.** *Let X be a non-center agent with initial endowment x such that x belongs to π . Then, $\pi[\pi(x) - 1] \geq_X x$.*

Notice that $\pi[\pi(x) - 1]$ is the object used by center agent O to swap x from agent X .

► **Observation 18.** *Let X be an agent with initial object x . Then, agent X is improved by Π if and only if x belongs to π .*

We now establish NP-hardness by proving that it is NP-hard to find a maximum votes matching.

Construction. We use a reduction from the 3-SAT. In an instance of 3-SAT, we are given a propositional formula ϕ that is the conjunction of m clauses C_1, \dots, C_m . Each clause C_i is the disjunction of three literals, where each literal is either a variable or the negation of a variable. The set of variables is x_1, \dots, x_n . Given a formula ϕ , we construct a corresponding star configuration $\chi_\phi = (F, \mu)$ with $3n + 3m + 1$ agents such that for any 3-SAT formula ϕ with n variables and m clauses, ϕ is satisfiable if and only if χ_ϕ has largest voting number $2n + 3m$.

We begin by creating the set of agents A . For each variable index i , there are three agents in A : S_i, T_i, F_i . For each clause $C_j = l_{j,0} \cup l_{j,1} \cup l_{j,2}$, there are three agents $P_{j,0}, P_{j,1}, P_{j,2}$ in A . There is also a center agent O . Thus there are a total of $3m + 3n + 1$ agents in A .

For each agent in A , we use the corresponding lower case letter to denote its initial object. For example, agent $P_{1,2}$ initially holds object $p_{1,2}$. For agents T_i and F_i in a variable gadget with $i \in [n]$, their initial objects are t_i and f_i , representing whether the corresponding variable x_i is true or false. Furthermore, for each literal $l_{j,k}$ of variable x_w , we associate instance an object $a_{j,k}$ defined as follows. If $l_{j,k} = x_w$, then $a_{j,k} = t_w$; otherwise, $a_{j,k} = f_w$. For example, if $l_{j,k} = x_{15}$, then $a_{j,k} = t_{15}$, and if $l_{j,k} = \bar{x}_7$, then $a_{j,k} = f_7$.

For agent preferences, we only consider the objects that each agent prefers at least as its initial object; other objects can be put behind its initial endowment in any order. The center agent O is indifferent to all objects. We use boxed objects to indicate the initial endowments, and objects in a bracket are indifferent to an agent. For agents S_i, T_i, F_i , their preferences from most preferred to least preferred are $S_i : (t_i, f_i), (o, \boxed{s_i})$, $T_i : s_i, \boxed{t_i}$, $F_i : s_i, \boxed{f_i}$. For each k in $\{0, 1, 2\}$, $P_{j,k} : p_{j,k-1}, a_{j,k}, \boxed{p_{j,k}}$, where $p_{j,-1} = p_{j,2}$.

We now present some properties of our gadgets.

► **Lemma 19.** *Let S_i, T_i, F_i be the three agents in the variable gadget corresponding to a variable x_i , $\Pi = \mu_0, \dots, \mu_k$ be a sequence of matchings, and π denote the corresponding center object sequence of Π . Then at most two agents in $\{S_i, T_i, F_i\}$ are improved by Π . If exactly two agents of $\{S_i, T_i, F_i\}$ are improved, then exactly one of $\{t_i, f_i\}$ belongs to π .*

Proof. Notice that if agent T_i or F_i is improved, then either T_i or F_i gets object s_i by the preferences of T_i and F_i . However, in a matching, s_i can be matched to one agent. Therefore, Π cannot improve T_i and F_i . That is, at most two agents in $\{S_i, T_i, F_i\}$ are improved by Π . If exactly two agents of $\{S_i, T_i, F_i\}$ get improved, then exactly one agent in $\{T_i, F_i\}$ is improved, and hence exactly one of $\{t_i, f_i\}$ belongs to π by Observation 18. ◀

► **Lemma 20.** *Let $C_j = l_{j,0} \cup l_{j,1} \cup l_{j,2}$ denote a clause. For each k in $\{0, 1, 2\}$, let $P_{j,k}$ denote the agent corresponding to literal $l_{j,k}$, let $p_{j,k}$ denote the initial object of $P_{j,k}$, and let $a_{j,k}$ in $\{t_i, f_i \mid i \in [n]\}$ denote the object associated with literal $l_{j,k}$. Let $\Pi = \mu_0, \dots, \mu_k$ be a sequence of matchings, and π denote the corresponding center object sequence of Π . If none of $a_{j,0}, a_{j,1}, a_{j,2}$ is in π , then none of $p_{j,0}, p_{j,1}, p_{j,2}$ is in π .*

Proof. We prove the contrapositive. Assume that there is an object in $\{p_{j,0}, p_{j,1}, p_{j,2}\}$ that belongs to π . Let $p_{j,k}$ denote the object with minimum $\pi(p_{j,k})$ where k belongs to $\{0, 1, 2\}$. By Observation 17, $\pi[\pi(p_{j,k}) - 1] \geq_{P_{j,k}} p_{j,k}$. By the preferences of $P_{j,k}$, $\pi[\pi(p_{j,k}) - 1]$ belongs

to $\{a_{j,k}, p_{j,k-1}\}$ with $p_{j,-1} = p_{j,2}$. Moreover, by the assumption $p_{j,k}$ is the object with minimum $\pi(p_{j,k})$, $\pi[\pi(p_{j,k}) - 1]$ does not belong to $\{p_{j,0}, p_{j,1}, p_{j,2}\}$. Therefore, $\pi[\pi(p_{j,k}) - 1]$ is $a_{j,k}$, and hence π contains object $a_{j,k}$. \blacktriangleleft

Using the above properties of our gadgets, it is not hard to verify the correctness of our reduction. Formally, we prove following two lemmas, one for each reduction direction.

► **Lemma 21.** *If $\text{mv}(\chi_\phi) = 2n + 3m$, then ϕ is satisfiable.*

Proof. By Lemma 19, there are at least n agents that are not improved. Moreover, the center agent O initially holds one of most preferred objects, and hence cannot be improved. Therefore, there are at most $2n + 3m$ agents that are improved. If χ_ϕ achieves the largest voting number $2n + 3m$, then there are exactly two agents that are improved in each variable gadget and all three agents that are improved in each clause gadget.

By Lemma 19, for all i in $[n]$, there is exactly one object in $\{t_i, f_i\}$ in π . If t_i is in π , then let variable x_i be true, otherwise let x_i be false. Therefore, we get an assignment A_π from π . We then show that A_π is a satisfiable assignment, i.e., each clause C_j in ϕ is true with respect to assignment A_π . For the sake of contradiction, assume that there exists a clause C_j that is false. Hence, all of the literals $l_{j,0}, l_{j,1}, l_{j,2}$ in C_j are false under assignment A_π . Let $a_{j,0}, a_{j,1}, a_{j,2} \in \{t_i, f_i \mid i \in [n]\}$ be the objects associated with literals $l_{j,0}, l_{j,1}, l_{j,2}$, respectively. We deduce that none of $a_{j,0}, a_{j,1}, a_{j,2}$ is in π . By Lemma 20, π does not contain $\{p_{j,0}, p_{j,1}, p_{j,2}\}$. That is, agents $P_{j,0}, P_{j,1}, P_{j,2}$ is not improved by π due to Observation 18. \blacktriangleleft

► **Lemma 22.** *If there is a satisfiable assignment for ϕ , then $\text{mv}(\chi_\phi) = 2n + 3m$.*

Proof. Let A_ϕ be a satisfiable assignment for ϕ . For each i in $[n]$, if x_i is true in assignment A_ϕ , then let b_i denote object t_i ; otherwise, let b_i denote object f_i .

Now we show how to obtain a sequence of swaps according to objects (b_1, \dots, b_n) . Let \mathcal{C} denote a temporary set, which is initialized to be the set of all clauses $\{C_1, C_2, \dots, C_m\}$. For each i in $[n]$, let B_i denote the initial owner of b_i , i.e., $B_i = T_i$ if $b_i = t_i$ and $B_i = F_i$ otherwise. We construct the sequence of swaps as follows. For each object b_i , we do the following swaps:

1. Perform two swaps $(O, S_i), (O, B_i)$ to let center agent O get b_i and S_i get object o .
2. If there are a clause C_j in \mathcal{C} and a literal $l_{j,k}$ in C_j such that object b_i is the associated object $a_{j,k}$, then we perform the following steps:
 - Perform these swaps in sequence: $(O, P_{j,k}), (O, P_{j,k \oplus 1}), (O, P_{j,k \oplus 2}), (O, P_{j,k})$, where \oplus denotes the addition module 3. Remark that by doing so, agent $P_{j,k}$ gets its most preferred object for all k in $\{0, 1, 2\}$ and center agent O still holds b_i .
 - Remove the clause C_j from \mathcal{C} .
3. In the end, perform the swap (O, S_i) . Remark: After this swap, agent O gets object o and S_i get one of its most preferred object b_i . We then proceed to consider object b_{i+1} .

We now show that the sequence of swaps constructed above improves $2n + 3m$ agents. First of all, by applying the above sequence of swaps, for all i in $[n]$, agent S_i is matched to object b_i and agent B_i is matched to object s_i . Thus, the above sequence of swaps improves $2n$ agents in variable gadgets. Then, we consider agents in clause gadgets. Since A_ϕ is a satisfiable assignment for ϕ , for all clause C_j there exists some literal $l_{j,k}$ of variable x_i such that $l_{j,k}$ is true under assignment A_ϕ . Therefore, by the definition of object $a_{j,k}$, we deduce that $a_{j,k}$ is b_i . Thus, all agents associated with clause C_j are improved. That is, the above sequence of swaps improves all agents in clause gadgets. There are $3m$ agents in clause gadgets. To sum up, there are $2n + 3m$ agents that are improved in total. \blacktriangleleft

► **Theorem 23.** *Finding an MVPE matching on stars with weak preferences is NP-hard.*

5 Tree Network

► **Theorem 24.** *Finding an MVPE matching on trees with strict preferences is NP-hard.*

We establish Theorem 24 by proving that it is NP-hard to find a maximum votes matching. The latter result is obtained via a reduction to reachable object problem on trees, which was shown to be NP-complete by Gourvès et al. [13].

6 Conclusion

To refine Pareto-efficiency, we study the complexity of finding a maximum votes Pareto-efficient matching when a group of agents exchange their objects along a social network. By presenting two polynomial-time algorithms and two NP-hardness results, we shed light on the frontiers between tractable and intractable cases in terms of the structures of the social network and whether ties in preference are allowed. A challenging open question is to completely characterize the social network structures for which case the MVPE problem is polynomial-time solvable.

Abstract

This paper analyses models of a spatial logic with path operators based on the class of neighbourhood spaces, also called pretopological or closure spaces, a generalisation of topological spaces. For this purpose, we distinguish two dimensions: the type of spaces on which models are built, and the type of allowed paths. For the spaces, we investigate general neighbourhood spaces and the subclass of quasi-discrete spaces, which closely resemble graphs. For the paths, we analyse the cases of quasi-discrete paths, which consist of an enumeration of points, and topological paths, based on the unit interval. We show that the logic admits finite models over quasi-discrete spaces, both with quasi-discrete and topological paths. Finally, we prove that for general neighbourhood spaces, the logic does not have the finite model property, either for quasi-discrete or topological paths.

1 Introduction

The safe and correct operation of systems in a wide range of application domains is increasingly dependent on spatial reasoning to evaluate the structure of space and how space might evolve over time. Examples include target counting in wireless sensor networks [19, 2], cyber-physical systems [22], transport systems [9], structural analysis [17], and medical imaging [6]. *Neighbourhood spaces*, also known as closure or pretopological spaces [23, 14], have emerged as a popular formalism in these scenarios due to their ability to natively represent topological spaces but also simple graphs and simple directed graphs. In this paper, we focus on *SLCS*, a modal logic introduced by Ciancia et al. [11] for the specification and verification of spatial properties over neighbourhood spaces. This logic features a closure modality \mathcal{N} (near) and path modalities \mathcal{R} (reachable from) and \mathcal{P} (propagates to). While model checking algorithms and software support have been developed, the model theory of this logic is still not well understood. In particular, it is not known what kind of spaces can be expressed by various classes of formulas. Answering this question is complicated by how the near modality interacts with the path modalities which is substantially different from the modality interactions in discrete modal logic.

We make the following research contributions:

1. we show that SLCS does not admit finite models on general neighbourhood spaces;
2. we prove that there are formulas that are only satisfiable on infinite models even when restricting to either quasi-discrete paths (similar to paths on graphs) or standard topological paths;
3. we define a finite model construction using filtration arguments for models with quasi-discrete underlying spaces and quasi-discrete or topological paths.

Related Work

The analysis of SLCS is increasingly gaining traction both in Theoretical Computer Science and Topology.

In recent work [18], we presented bisimulations for SLCS formulas using path operators that show the equivalence of formulas between bisimilar models. Ciancia et al. [12] used co-algebraic methods to present bisimulations over quasi-discrete models that are well-matched (i.e., they characterise the class of quasi-discrete models), but did not extend this result to arbitrary spaces. Importantly, the authors restricted the set of SLCS formulas to omit path operators. Castelnovo and Miculan [7] defined a categorical semantics for various fragments of SLCS using hyperdoctrines with paths and investigated how to extend the logic to other spaces with closure operators, such as probabilistic automata.

Rieser [20] used the unit interval to define and analyse a homotopy theory for closure spaces, that is, how paths can be transformed into one another. Bubenik and Milićević [5] further investigated how different generalisations of the unit interval yield different path objects. None of these definitions is immediately applicable to SLCS paths, which are much more concrete.

2 Neighbourhood Spaces

In this section we recall the notions of neighbourhood spaces and some related results from general topology we will use in this paper. Our main reference is [23]. For additional general results on these topics and for the proofs of the results reported here, we refer the reader to this source.

► **Definition 1 (Filter).** *Given a set X , a filter F on X is a subset of $\mathbb{P}(X)$, such that F is closed under intersections, whenever $Y \in F$ and $Y \subseteq Z$, then also $Z \in F$, and finally $\emptyset \notin F$.*

► **Definition 2 (Neighbourhood Space).** *Let X be a set, and let $\eta: X \rightarrow \mathbb{P}(\mathbb{P}(X))$ be a function from X to the set of filters on it, where every $\eta(x)$ is such that $x \in \bigcap_{N \in \eta(x)} N$. We call η a neighbourhood system on X , and $\mathcal{X} = (X, \eta)$ a neighbourhood space. For every set $A \subseteq X$, we have the (unique) interior and closure operators defined as follows.*

$$\mathcal{I}_\eta(A) = \{x \in A \mid A \in \eta(x)\} \quad \mathcal{C}_\eta(A) = \{x \in X \mid \forall N \in \eta(x): A \cap N \neq \emptyset\}$$

An element $x \in X$ has a minimal neighbourhood if there exists $N \in \eta(x)$ such that $N \subseteq N'$ for any neighbourhood $N' \in \eta(x)$. We use $N_{\min}(x)$ to refer to the minimal neighbourhood of x . If each element $x \in X$ has a minimal neighbourhood, then we call \mathcal{X} quasi-discrete. Finally, if for every element $x \in X$ and any neighbourhood $N \in \eta(x)$, there is a neighbourhood $M \in \eta(x)$, such that for every $y \in M$, we have also that $N \in \eta(y)$, then \mathcal{X} is topological.

Neighbourhood spaces as we introduced them are exactly the *pretopological spaces* as defined by Choquet [8] and the *closure spaces* introduced by Čech [23], as shown by Kent and Min [16].¹ Furthermore, a topological neighbourhood space is just a topological space as usual.

► **Definition 3** (Connectedness ([23] 20.B.1)). *Let $\mathcal{X} = (X, \eta)$ be a neighbourhood space. Two subsets U and V of X are semi-separated, if $\mathcal{C}(U) \cap V = U \cap \mathcal{C}(V) = \emptyset$. A subset U of \mathcal{X} is connected, if it is not the union of two non-empty, semi-separated sets. The space \mathcal{X} is connected, if X is connected.*

We also introduce a special kind of connected neighbourhood space, endowed with a linear order.

► **Definition 4** (Index Space). *If (I, η) is a connected neighbourhood space and $\leq \subseteq I \times I$ a linear order on I with the bottom element $0 \in I$, then we call $\mathcal{I} = (I, \eta, \leq, 0)$ an index space.*

In the following sections, we will often use the concept of continuous functions. Generally, we will use the notation $f[A]$ for the image of a set $A \subseteq X$ under a function $f: X \rightarrow Y$.

► **Definition 5** (Continuous Function ([23] 16 A.4)). *Let $\mathcal{X}_i = (X_i, \eta_i)$ for $i \in \{1, 2\}$ be two neighbourhood spaces. A function $f: X_1 \rightarrow X_2$ is continuous at x_1 , if for every $N_2 \in \eta_2(f(x_1))$, there is an $N_1 \in \eta_1(x_1)$ such that $f[N_1] \subseteq N_2$. Equivalently, for every $Y \subseteq X_1$, if $x_1 \in \mathcal{C}_1(Y)$, then $f(x_1) \in \mathcal{C}_2(f[Y])$. If f is continuous at every $x_1 \in X_1$, we simply say that f is continuous. We will also write $f: \mathcal{X}_1 \rightarrow \mathcal{X}_2$.*

Observe that this coincides with the well-known definition of continuous functions on topological spaces.

► **Definition 6** (Path). *For an index space \mathcal{I} and a neighbourhood space \mathcal{X} , a continuous function $p: \mathcal{I} \rightarrow \mathcal{X}$ is an \mathcal{I} -path on \mathcal{X} . If $p(0) = x$, we will also write $p: x \rightsquigarrow \infty$ to denote a path starting in x .*

Two typical index spaces are $\mathcal{I}_{\mathbb{R}} = ([0, 1], \eta_{\mathbb{R}}, \leq, 0)$, the unit interval with the standard topology based on open intervals, and $\mathcal{I}_{\mathbb{N}} = (\mathbb{N}, \eta_{\mathbb{N}}, \leq, 0)$, where $\eta_{\mathbb{N}}$ is given by the quasi-discrete neighbourhood system induced by the successor relation. That is, the minimal neighbourhood of each point n is given by $\{n, n + 1\}$. We call $\mathcal{I}_{\mathbb{R}}$ -paths *topological paths* and $\mathcal{I}_{\mathbb{N}}$ -paths *quasi-discrete paths*.

► **Definition 7** (Separation and Distinguishability). *Let $\mathcal{X} = (X, \eta)$ be a neighbourhood space and $x, y \in X$ be two distinct points of \mathcal{X} . If $\eta(x) \neq \eta(y)$, we say that x and y are distinguishable in \mathcal{X} . If there is both an $N \in \eta(x)$ such that $y \notin N$ and an $M \in \eta(y)$ such that $x \notin M$, then we call x and y T_1 -separated. Equivalently, in terms of closures, two distinct points x and y are distinguishable, if $x \notin \mathcal{C}(\{y\})$ or $y \notin \mathcal{C}(\{x\})$. They are T_1 -separated, if $(\{x\} \cap \mathcal{C}(\{y\})) \cup (\mathcal{C}(\{x\}) \cap \{y\}) = \emptyset$.*

The space \mathcal{X} is a symmetric space (or R_0 -space), if every two distinguishable points are T_1 -separated.

The following lemma implies that quasi-discrete paths that visit a non-quasi discrete point on a symmetric space cannot get back into “quasi-discrete territory”.

¹ To be exact, Kent and Min’s definition of neighbourhood spaces is more general than ours, as they do not require the neighbourhood systems to be filters. In fact, they show that a neighbourhood space where each neighbourhood system is a filter constitutes a pretopological space.

■ **Figure 1** Example of a topological path on a quasi-discrete space.

► **Lemma 8.** *Let $\mathcal{Q} = (Q, \eta_{\mathcal{Q}})$ be a quasi-discrete space and $\mathcal{X} = (X, \eta)$ be a non-quasi-discrete, but symmetric space. Furthermore let $x \in X$ be a point that does not have a minimal neighbourhood. Any continuous function $f: \mathcal{Q} \rightarrow \mathcal{X}$ that visits x at some point q can only visit points that are indistinguishable from x at any $q' \in N_{\min}(q)$. In terms of closures, this is equivalent to the following condition: if $q \in \mathcal{C}(\{q'\})$, then $f(q')$ is indistinguishable from x .*

Proof. Let $f: \mathcal{Q} \rightarrow \mathcal{X}$ be a continuous function with $f(q) = x$ and for some $q' \in N_{\min}(q)$, we have $f(q') = y$ where x and y are distinguishable. Hence, there is an $N \in \eta(x)$ such that $y \notin N$. However, for any $M \in \eta_{\mathcal{Q}}(q)$, we have that $N_{\min}(q) \subseteq M$, which of course means also $q' \in M$. But $f(q') \notin N$, so $f[M] \not\subseteq N$. So f is not continuous at q , which contradicts the assumption on f . ◀

We will often refer to the fact that quasi-discrete spaces closely resemble graphs: we can consider the points in the minimal neighbourhood of a point x to be connected to x by an edge. The following example provides a better understanding of the difference in behaviour of topological and quasi-discrete paths over quasi-discrete neighbourhood spaces.

► **Example 9.** Consider the quasi-discrete neighbourhood space \mathcal{X} in Fig. 1a. Any path p defined over $\mathcal{I}_{\mathbb{N}}$ is such that for any $i \in \mathcal{I}_{\mathbb{N}}$, if $p(i) = x$ or $p(i) = z$, then $p(j) = p(i)$ for any $j \geq i$. However, path p defined in Fig. 1b is a valid path when considering topological paths.

3 Spatial Logic for Neighbourhood Spaces

In this section, we briefly recall SLCS on general neighbourhood spaces. To that end, we first present spatial models based on neighbourhood spaces and then present the syntax and semantics of SLCS.

► **Definition 10** (Neighbourhood Model). *Let $\mathcal{X} = (X, \eta)$ be a neighbourhood space, \mathcal{I} an index space, AP a countable set of propositional atoms, and let $\nu: X \rightarrow \mathbb{P}(AP)$ be a valuation. Then $\mathcal{M} = (\mathcal{X}, \mathcal{I}, \nu)$ is a neighbourhood model over \mathcal{I} -paths. We will also write $\mathcal{M} = (X, \eta, \nu)$ to denote neighbourhood models, if the index space is clear from the context.*

We lift all suitable definitions from Sect. 2 to neighbourhood models in the obvious ways. For example, we will speak of continuous functions between the underlying spaces of two models as continuous functions between the models.

We will often use the special case of models with quasi-discrete spaces over quasi-discrete paths, since such models are graph-like models with standard paths on graphs.

► **Definition 11** (Purely Quasi-Discrete Models). *Let \mathcal{X} be a quasi-discrete neighbourhood space. A model $\mathcal{M} = (\mathcal{X}, \mathcal{I}_{\mathbb{N}}, \nu)$ over quasi-discrete paths is a purely quasi-discrete neighbourhood model.*

► **Definition 12** (Syntax of SLCS).

$$\varphi, \psi ::= p \mid \neg\varphi \mid \varphi \wedge \psi \mid \mathcal{N}\varphi \mid \varphi \mathcal{R}\psi \mid \varphi \mathcal{P}\psi$$

\mathcal{N} is read as near, \mathcal{R} is read as reachable from, and \mathcal{P} is read as propagates to.

The intuition behind the modalities is as follows. A point satisfies $\mathcal{N}\varphi$, if it is contained in the closure of the set of points satisfying φ . Hence, even if it does not satisfy φ itself, it is close to a point that does. A point x satisfies $\varphi \mathcal{R}\psi$ if there is a point y satisfying ψ such that x is reachable from y via a path where every point on this path between x and y satisfies φ . Propagation is in a sense the converse modality, i.e., if there is a point y satisfying ψ such that there is a path starting in x and reaching y at some index, and all points in between satisfy φ , then x satisfies $\varphi \mathcal{P}\psi$. This intuition is formalised in the following semantics.

► **Definition 13** (Path Semantics of SLCS). *Let $\mathcal{M} = ((X, \eta), \mathcal{I}, \nu)$ be a neighbourhood model and $x \in X$. The path semantics of SLCS with respect to \mathcal{M} are defined inductively as follows.*

$$\begin{aligned} \mathcal{M}, x \models p & \quad \text{iff } p \in \nu(x) \\ \mathcal{M}, x \models \neg\varphi & \quad \text{iff not } \mathcal{M}, x \models \varphi \\ \mathcal{M}, x \models \varphi \wedge \psi & \quad \text{iff } \mathcal{M}, x \models \varphi \text{ and } \mathcal{M}, x \models \psi \\ \mathcal{M}, x \models \mathcal{N}\varphi & \quad \text{iff } x \in \mathcal{C}(\{y \mid \mathcal{M}, y \models \varphi\}) \\ \mathcal{M}, x \models \varphi \mathcal{R}\psi & \quad \text{iff there is } p: y \rightsquigarrow \infty \text{ and } n \text{ such that } p(n) = x \text{ and } \mathcal{M}, y \models \psi \\ & \quad \text{and for all } 0 < i < n: \mathcal{M}, p(i) \models \varphi \\ \mathcal{M}, x \models \varphi \mathcal{P}\psi & \quad \text{iff there is } p: x \rightsquigarrow \infty \text{ and } n \text{ such that } \mathcal{M}, p(n) \models \psi \\ & \quad \text{and } \forall i: 0 < i < n \implies \mathcal{M}, p(i) \models \varphi \end{aligned}$$

In addition to the defined Boolean operators, we also allow for the other common derivable connectives. Specifically, $\varphi \vee \psi = \neg(\neg\varphi \wedge \neg\psi)$, $\top = \varphi \vee \neg\varphi$, $\perp = \neg\top$, $\varphi \rightarrow \psi = \neg\varphi \vee \psi$, and $\varphi \leftrightarrow \psi = (\varphi \rightarrow \psi) \wedge (\psi \rightarrow \varphi)$. For a class of models \mathfrak{M} , we say that φ is *valid* in \mathfrak{M} if, and only if, $\mathcal{M}, x \models \varphi$ for every $\mathcal{M} = ((X, \eta), \mathcal{I}, \nu) \in \mathfrak{M}$ and $x \in X$.

► **Definition 14** (Relative Equivalence). *Let Σ be a subformula closed set of SLCS formulas, \mathcal{M} a neighbourhood model, and $x, y \in \mathcal{M}$ be two points of \mathcal{M} . Then x and y are equivalent relative to Σ iff they satisfy the same formulas in Σ , i.e., $x \simeq_{\Sigma} y$ iff $\{\varphi \in \Sigma \mid \mathcal{M}, x \models \varphi\} = \{\varphi \in \Sigma \mid \mathcal{M}, y \models \varphi\}$. This is an equivalence relation, and we will denote the equivalence classes of x by $[x]_{\Sigma}$ and $[x]$, if Σ is clear from the context.*

The following lemmas present properties of formulas on different classes of models. We start with the most familiar class: purely quasi-discrete models. On these models, we have a clear connection between the near modality and the propagate path operator.

► **Lemma 15.** *On all purely quasi-discrete neighbourhood models $\mathcal{M} = (\mathcal{X}, \mathcal{I}_{\mathbb{N}}, \nu)$ we have that $\mathcal{M}, x \models \mathcal{N}\varphi$ iff $\mathcal{M}, x \models \varphi \vee \perp \mathcal{P}\varphi$.*

Proof. If $\mathcal{M}, x \models \varphi$, the equivalence is clear. Otherwise, assume $\mathcal{M}, x \models \perp \mathcal{P}\varphi$. This means that there is a point y and a path $p: x \rightsquigarrow \infty$ such that $p(1) = y$ and $\mathcal{M}, y \models \varphi$. Since p is continuous, this means that there is a neighbourhood N of 0 such that $p[N] \subseteq N_{\min}(x)$. Since every neighbourhood of 0 contains 1, this means $y \in N_{\min}(x)$, and so $\mathcal{M}, x \models \mathcal{N}\varphi$. The other direction is similar. ◀

If we consider quasi-discrete models over topological paths, this connection is less clear. The main reason for this is that over topological graphs, $\perp \mathcal{P} \varphi$ is equivalent to φ , which is easy to prove. However, we can still establish a bit less obvious connection between the modalities.

► **Lemma 16.** *On quasi-discrete models over topological paths, $(a \wedge \mathcal{N}(b \wedge \neg a)) \rightarrow \mathcal{N}(\neg a \wedge (b \mathcal{P} a))$ is valid.*

Proof. Let $\mathcal{M} = (\mathcal{X}, \mathcal{I}_{\mathbb{R}}, \nu)$ with $\mathcal{X} = (X, \eta)$ be a quasi-discrete model and let $x \in X$ such that $\mathcal{M}, x \models a \wedge \mathcal{N}(b \wedge \neg a)$. That is, $x \models a$ and $x \in \mathcal{C}(\{y \mid \mathcal{M}, y \models b \wedge \neg a\})$. Since \mathcal{X} is quasi-discrete, this means that there is a $y \in N_{min}(x)$ such that $\mathcal{M}, y \models b \wedge \neg a$. Then, the path $p: \mathcal{I}_{\mathbb{R}} \rightarrow \mathcal{X}$ with $p(i) = y$ for $i < 1$ and $p(i) = x$ for $i = 1$ is a witness for $\mathcal{M}, y \models b \mathcal{P} a$. This function is indeed continuous: Consider $N \in \eta(p(i))$. If $i < 1$, we can always choose an $N_i \in \eta_{\mathcal{I}}(i)$ such that $\forall j \in N_i$ we have $j < 1$, since \mathcal{I} has arbitrarily small neighbourhoods, which means $p[N_i] = \{y\} \subseteq N$. If $i = 1$, we have for any neighbourhood $N_i \in \eta_{\mathcal{I}}(i)$, that is $p[N_i] \subseteq \{x, y\} \subseteq N_{min}(x) \subseteq N$. Furthermore, $p(0) = y$, and for $n = 1$, we have $p(n) = x$, and for all $0 < i < n$, $\mathcal{M}, p(i) \models b$. Since $y \in N_{min}(x)$, we have that $\mathcal{M}, x \models \mathcal{N}(\neg a \wedge (b \mathcal{P} a))$. ◀

Furthermore, on any kind of model over topological paths, we get that the reachable and propagate modalities are equivalent. Intuitively, this is clear, since for topological paths, there is no inherent direction on the index space, in contrast to the quasi-discrete index space, where the successor relation is directed.

► **Lemma 17.** *On any neighbourhood model over topological paths $\mathcal{M} = (\mathcal{X}, \mathcal{I}_{\mathbb{R}}, \nu)$ we have that $\mathcal{M}, x \models \varphi \mathcal{P} \psi$ iff $\mathcal{M}, x \models \varphi \mathcal{R} \psi$.*

Proof. Let $\mathcal{M} = ((X, \eta), \mathcal{I}_{\mathbb{R}}, \nu)$ be a neighbourhood model over topological paths, and $x \in X$ a point of \mathcal{M} such that $\mathcal{M}, x \models \varphi \mathcal{P} \psi$. So there is a path $p: \mathcal{I}_{\mathbb{R}} \rightarrow \mathcal{M}$ and $n \in [0, 1]$, such that $p(0) = x$, $p(n) = y$ and $\mathcal{M}, y \models \psi$, and $\forall k: 0 < k < n$, we have $\mathcal{M}, p(k) \models \varphi$. Since p is topological, we can assume without loss of generality that $n = 1$. Now the path p' defined by $p'(i) = p(1 - i)$ is a witness for $\mathcal{M}, x \models \varphi \mathcal{R} \psi$. Indeed, let $N \in \eta(p'(i))$ be a neighbourhood of $p'(i)$. By definition of p' , we have $p'(i) = p(1 - i)$. We know that p is continuous at $1 - i$, so there is a neighbourhood $N' \in \eta_i(1 - i)$ such that $p[N'] \subseteq N$. But, we also have that $N^i = \{j \mid 1 - j \in N'\}$ is a neighbourhood of i and, since $p'(j) = p(1 - j)$, we have that $p'[N^i] \subseteq N$ as well. So, p' is continuous. Furthermore, $p'(0) = p(1)$, so $\mathcal{M}, p'(0) \models \psi$, $p'(1) = x$, and for all k with $0 < k < 1$, we have $\mathcal{M}, p'(k) \models \varphi$, by definition of p' . The other direction is similar. ◀

4 No Finite Model Property for Arbitrary Neighbourhood Spaces

In this section, we prove that SLCS does not have the finite model property if we consider the class of all neighbourhood models. That is, we show that there exist SLCS formulas that are satisfiable only over models $\mathcal{M} = ((X, \eta), \mathcal{I}, \nu)$ where X is not finite. Our first observation is that there are satisfiable formulas that are not satisfiable on purely quasi-discrete models.

► **Lemma 18.** *There exist SLCS satisfiable formulas that are not satisfiable on any finite model over quasi-discrete paths.*

Proof. Consider model $\mathcal{M} = ((\mathbb{R}, \eta_{\mathbb{R}}), \mathcal{I}_{\mathbb{R}}, \nu)$ in Fig. 2. It follows that $\mathcal{M}, 1 \models \mathcal{N} a \wedge \neg a \wedge \neg(\perp \mathcal{P} a)$. By Lemma 15, this formula is a contradiction on purely quasi-discrete models. Finally, since every finite space is quasi-discrete, the lemma holds. ◀

■ **Figure 2** Model $\mathcal{M} = ((\mathbb{R}, \eta_{\mathbb{R}}), \mathcal{I}_{\mathbb{R}}, \nu)$ such that $\mathcal{M}, 1 \models \mathcal{N}a \wedge \neg a \wedge \neg(\perp \mathcal{P}a)$.

There are two key differences between the model in Fig. 2 and purely quasi-discrete models: the type of underlying space, and the type of paths allowed. So, we now restrict both of these dimensions one after the other. First, we show that SLCS does not admit finite models over topological paths, if we consider the full set of neighbourhood spaces, by constructing a counterexample based on the result of Lemma 16.

► **Lemma 19.** *There exist SLCS formulas that are satisfiable on models with topological paths, but not on any finite model with topological paths.*

Proof. We construct a topological model $\mathcal{M} = (\mathcal{X}, \mathcal{I}_{\mathbb{R}}, \nu)$ that contains a point satisfying $a \wedge \mathcal{N}(b \wedge \neg a) \wedge \neg \mathcal{N}(\neg a \wedge (b \mathcal{P}a))$. For the topological space, we use the *topologists sine curve*. For that purpose, let $S = \{(r, \sin \frac{1}{r}) \mid 0 < r \leq 1\}$. The space is then defined by $\mathcal{X} = (X, \eta)$, where $X = \{(0, 0)\} \cup S$, and η is the neighbourhood system induced by treating this set as a subset of the Euclidean plane \mathbb{R}^2 . That is, $N \in \eta(x)$ if there is an open ball of some radius r around x , i.e., some $B_r = \{y \mid \|x - y\| < r\}$, where $\|\cdot\|$ is the Euclidean distance, such that $N \supseteq B_r \cap X$. We set the valuation ν by $\nu((0, 0)) = \{a\}$ and $\nu(x) = \{b\}$ for $x \neq (0, 0)$.

Now, every neighbourhood of $(0, 0)$ contains a value from S , and thus $\mathcal{M}, (0, 0) \models a \wedge \mathcal{N}(b \wedge \neg a)$. Furthermore, it is well known [21] that in this space, $(0, 0)$ is not path-connected to S , which means that no path starting in any point $s \in S$ can reach $(0, 0)$. This implies, that no point $s \in S$ satisfies $b \mathcal{P}a$, since there is no path that ever reaches a point that satisfies a . So, no point on the model satisfies $\neg a \wedge (b \mathcal{P}a)$. In particular, this means that $\mathcal{M}, (0, 0) \models \neg \mathcal{N}(\neg a \wedge (b \mathcal{P}a))$. So, we have $\mathcal{M}, (0, 0) \models a \wedge \mathcal{N}(b \wedge \neg a) \wedge \neg \mathcal{N}(\neg a \wedge (b \mathcal{P}a))$. But this formula is not satisfiable on any quasi-discrete model with topological paths, according to Lemma 16. Since finite models are quasi-discrete, SLCS does not generally admit finite models over topological paths. ◀

Finally, even when considering only quasi-discrete paths, there are SLCS formulas which are not satisfiable on finite models.

► **Lemma 20.** *There exist SLCS formulas that are satisfiable on models with quasi-discrete paths, but not on any finite model with quasi-discrete paths.*

Proof. Let X be an infinite, uncountable set and let $\mathcal{X} = (X', \eta)$ be the double pointed countable complement topology over X (see [21]). For this definition, let \mathcal{Y} be the set of all subsets of X , such that for every $Y \in \mathcal{Y}$, either $Y = \emptyset$, or the complement of Y is countable. X' is constructed from X by “doubling” all points, i.e., $X' = \{x' \mid x \in X\} \cup X$, where each x' is a new, distinct, element to the x it is constructed from. Then, let \mathcal{Y}' be the doubling of every set in \mathcal{Y} in a similar way, and η be defined by $\eta(x) = \{N \mid \exists Y \in \mathcal{Y}' : Y \subseteq N \wedge x \in Y\}$. Note that this definition implies that for any y and its doubled point y' , we have $\eta(y) = \eta(y')$. Define $\mathcal{M} = (\mathcal{X}, \mathcal{I}_{\mathbb{N}}, \nu)$ by letting $x, x' \in X'$ be a designated pair of points in X' and ν be given by $\nu(y) = \{a\}$, if $y \in \{x, x'\}$ and $\nu(y) = \{b\}$ otherwise.

Now consider any neighbourhood $N \in \eta(x)$. There is always some $y \in N$ that is different from x and x' , since otherwise the complement of N would be uncountable. Hence, every neighbourhood N contains some element y with $\mathcal{M}, y \models b$, which implies $\mathcal{M}, x \models \mathcal{N}b$. However, since the underlying space of \mathcal{M} is symmetric, by Lemma 8, any quasi-discrete

path starting in x may only visit x or x' , which both do not satisfy b . Hence $\mathcal{M}, x \not\models \perp \mathcal{P} b$. So, $\mathcal{N} b \wedge \neg(\perp \mathcal{P} b)$ is satisfiable on this model. But no finite model can satisfy this formula, since it is necessarily purely quasi-discrete. \blacktriangleleft

5 Finite Model Property for Quasi-Discrete Spaces

In this section, we prove that SLCS admits finite models if we restrict the class of models to quasi-discrete models. That is, the models correspond to directed graphs. Our approach is similar to standard approaches in modal logic [4]. In particular, we use filtrations with respect to a subformula closed set Σ for both types of models. Since topological paths and quasi-discrete paths behave very differently, we further distinguish the class into models over quasi-discrete paths and over topological paths.

5.1 Quasi-Discrete Spaces with Quasi-Discrete Paths

In this subsection, we prove that SLCS has the finite model property on purely quasi-discrete neighbourhood models. That is, the paths are similar to typical paths on graph structures.

The following lemma allow us to transfer information about the satisfaction of the path operators to other points.

► **Lemma 21.** *Let \mathcal{M} be a purely quasi-discrete neighbourhood model and $x, y \in \mathcal{M}$ two points such that $y \in N_{min}(x)$. Then the following hold.*

1. *If $\mathcal{M}, y \models \varphi$ and $\mathcal{M}, y \models \varphi \mathcal{P} \psi$, then also $\mathcal{M}, x \models \varphi \mathcal{P} \psi$.*
2. *If $\mathcal{M}, x \models \varphi \mathcal{R} \psi$ and $\mathcal{M}, x \models \varphi$, then also $\mathcal{M}, y \models \varphi \mathcal{R} \psi$.*

Proof. We only prove the first statement as the second is similar.

From $\mathcal{M}, y \models \varphi \mathcal{P} \psi$ we know that there is a path $p: \mathcal{I} \rightarrow \mathcal{M}$ with $p(0) = y$ and an index $n \in \mathcal{I}$ such that $\mathcal{M}, p(n) \models \psi$ and for all $0 < i < n$, we have $\mathcal{M}, p(i) \models \varphi$. Now consider the continuous function $p_x: \mathcal{I} \rightarrow \mathcal{M}$ given by $p_x(0) = x$ and $p_x(i+1) = p(i)$. Then p_x is indeed a path, since \mathcal{M} is quasi-discrete and $y \in N_{min}(x)$. Also, we have $\mathcal{M}, p_x(n+1) \models \psi$ and, since $\mathcal{M}, y \models \varphi$, for all $0 < i < n+1$, we have $\mathcal{M}, p_x(i) \models \varphi$. Hence $\mathcal{M}, x \models \varphi \mathcal{P} \psi$. \blacktriangleleft

We now define filtrations for purely quasi-discrete models. Most parts of this definition are standard, when we consider \mathcal{N} similar to an existential modality. For the two path operators, we added additional properties that allow us to transfer information about the existence of paths from the filtration back to the original model.

► **Definition 22 (Filtration).** *Let Σ be a subformula closed set of SLCS formulas, and $\mathcal{M} = (X, \eta, \nu)$ a purely quasi-discrete neighbourhood model. We call a purely quasi-discrete neighbourhood model $\mathcal{M}_f = (X_f, \eta_f, \nu_f)$ a filtration of \mathcal{M} through Σ , if it satisfies the following conditions:*

1. $X_f = \{[x]_\Sigma \mid x \in X\}$
2. *if $y \in N_{min}(x)$, then $[y] \in N_{min}([x])$*
3. *if $[y] \in N_{min}([x])$, then for each $\mathcal{N}\varphi \in \Sigma$, we have that if $\mathcal{M}, y \models \varphi$, then $\mathcal{M}, x \models \mathcal{N}\varphi$*
4. *if there is a sequence $[x_0] \dots [x_n]$ with $[x_{i+1}] \in N_{min}([x_i])$ for all $0 \leq i < n$, then for every $\varphi \mathcal{P} \psi \in \Sigma$, we have that whenever $\mathcal{M}, x_i \models \varphi$ for each $0 < i < n$ and $\mathcal{M}, x_n \models \psi$, then also $\mathcal{M}, x_0 \models \varphi \mathcal{P} \psi$*
5. *if there is a sequence $[x_0] \dots [x_n]$ with $[x_{i+1}] \in N_{min}([x_i])$ for all $0 \leq i < n$, then for every $\varphi \mathcal{R} \psi \in \Sigma$, we have that whenever $\mathcal{M}, x_i \models \varphi$ for each $0 < i < n$ and $\mathcal{M}, x_n \models \psi$, then also $\mathcal{M}, x_0 \models \varphi \mathcal{R} \psi$*
6. $\nu_f([x]) = \{p \in AP \mid \mathcal{M}, x \models p\}$

As usual, satisfiability of formulas in Σ is preserved between a model and its filtration through Σ . So our filtration is properly defined.

► **Lemma 23.** *Let \mathcal{M}_f be a filtration of \mathcal{M} through Σ . Then for all $\varphi \in \Sigma$, we have $\mathcal{M}, x \models \varphi$ iff $\mathcal{M}_f, [x] \models \varphi$.*

Proof. We proceed by induction on the structure of formulas. The base case for atomic propositions is immediate by Def. 22. The cases for the boolean operators are standard.

The case for $\varphi = \mathcal{N}\psi$ is similar to standard modal logic [4]: we have $\mathcal{M}, x \models \mathcal{N}\psi$ iff $x \in \mathcal{C}(\{y \mid \mathcal{M}, y \models \psi\})$ which by definition of the closure is equivalent to $\forall N \in \eta(x): N \cap \{y \mid \mathcal{M}, y \models \psi\} \neq \emptyset$. On quasi-discrete models, this is equivalent to $\exists y \in N_{\min}(x): \mathcal{M}, y \models \psi$. By property 2 of filtrations and the induction hypothesis, this implies $\exists [y] \in N_{\min}([x]): \mathcal{M}_f, [y] \models \psi$. Applying similar equivalences as before, we get that $\mathcal{M}_f, [x] \models \mathcal{N}\psi$. Conversely, assume we have $\mathcal{M}_f, [x] \models \mathcal{N}\psi$. With the same reasoning as above, this is equivalent to $\exists [y] \in N_{\min}([x]): \mathcal{M}_f, [y] \models \psi$. By the induction hypothesis, we get $\mathcal{M}, y \models \psi$, and from property 3 of filtrations, we have $\mathcal{M}, x \models \mathcal{N}\psi$.

Now consider $\varphi = \psi \mathcal{P} \chi$. If $\mathcal{M}, x \models \psi \mathcal{P} \chi$, this is equivalent to the existence of a path $p: x \rightsquigarrow \infty$ and a n and $\mathcal{M}, p(n) \models \chi$ as well as $\forall i: 0 < i < n$, we have $\mathcal{M}, p(i) \models \psi$. That is, there is a sequence x_0, \dots, x_n such that $x_0 = x$ and $x_{i+1} \in N_{\min}(x_i)$ for all $i < n$. By property 2, we have $[x_{i+1}] \in N_{\min}([x_i])$ for all $i < n$, and by the induction hypothesis, $\mathcal{M}_f, [x_n] \models \chi$ and for all $0 < i < n$, we get $\mathcal{M}_f, [x_i] \models \psi$. That is, $\mathcal{M}_f, [x] \models \psi \mathcal{P} \chi$. Conversely, assume $\mathcal{M}_f, [x] \models \psi \mathcal{P} \chi$. Then there is a sequence $[x_0], \dots, [x_n]$ such that $[x_{i+1}] \in N_{\min}([x_i])$ for all $0 \leq i < n$, and $\mathcal{M}_f, [x_n] \models \chi$, as well as for all $0 < i < n$, we get $\mathcal{M}_f, [x_i] \models \psi$. By the induction hypothesis, we get $\mathcal{M}, x_n \models \chi$ and $\mathcal{M}, x_i \models \psi$ for every $0 < i < n$. Hence, by property 4, and since $x_0 \simeq x$, we have $\mathcal{M}, x \models \psi \mathcal{P} \chi$.

The case for $\psi \mathcal{R} \chi$ is similar, by using property 5. ◀

Finally, we prove that there is always a filtration through Σ for any given purely quasi-discrete model. This definition corresponds to the usual definition of smallest filtration [4].

► **Lemma 24.** *Let Σ be a subformula closed set of formulas and \mathcal{M} a purely quasi-discrete model. Furthermore, let X_Σ be the set of equivalence classes of \simeq_Σ , ν_Σ be defined as in Def. 22 (6), and $\eta_s([x]) = \langle \{[y] \mid \exists y', x': y' \in [y] \wedge x' \in [x] \wedge y' \in N_{\min}(x')\} \rangle$ for each $[x] \in X_\Sigma$. Then the model $(X_\Sigma, \eta_s, \nu_\Sigma)$ is a filtration of \mathcal{M} through Σ .*

Proof. Properties 1, 2 and 6 are immediate. So now assume that $[y] \in N_{\min}([x])$ and let $\mathcal{N}\varphi \in \Sigma$ such that $\mathcal{M}, y \models \varphi$. Then by definition of η_s , there are $x' \in [x]$ and $y' \in [y]$ such that $y' \in N_{\min}(x')$. Since $y \simeq_\Sigma y'$, we have $\mathcal{M}, y' \models \varphi$, and due to $y' \in N_{\min}(x')$, this implies $x' \in \mathcal{C}(\{y \mid \mathcal{M}, y \models \varphi\})$, which means $\mathcal{M}, x' \models \mathcal{N}\varphi$. Since $x \simeq_\Sigma x'$, this implies $\mathcal{M}, x \models \mathcal{N}\varphi$. Hence property 3 holds.

For proving property 4, we proceed by induction on the length of sequence $[x_0] \dots [x_n]$. For the base case, we have $\mathcal{M}, x_0 \models \psi$, which implies $\mathcal{M}, x_0 \models \varphi \mathcal{P} \psi$. So, assuming the property holds for suited sequences of length up to n , consider a sequence $[x_0] \dots [x_n]$ such that the conditions of the property are satisfied. In particular, $[x_1] \dots [x_n]$ is a sequence, where $[x_{i+1}] \in N_{\min}([x_i])$, and for all $1 < i < n$ we have $\mathcal{M}, x_i \models \varphi$ and $\mathcal{M}, x_n \models \psi$. Hence, by the induction hypothesis, $\mathcal{M}, x_1 \models \varphi \mathcal{P} \psi$. Furthermore, by assumption on the sequence, we get $\mathcal{M}, x_1 \models \varphi$. Now, by the definition of η_s , we know that there are $x'_0 \in [x_0]$ and $x'_1 \in [x_1]$ such that $x'_1 \in N_{\min}(x'_0)$, and since $x_1 \simeq x'_1$, both $\mathcal{M}, x'_1 \models \varphi$ as well as $\mathcal{M}, x'_1 \models \varphi \mathcal{P} \psi$ hold. Hence, by Lemma 21 (1), we have $\mathcal{M}, x'_0 \models \varphi \mathcal{P} \psi$, and since $x_0 \simeq x'_0$, also $\mathcal{M}, x_0 \models \varphi \mathcal{P} \psi$.

Property 5 can be proven similarly to the previous case, but using Lemma 21 (2). ◀

■ **Figure 3** Example of path simplification.

From the definition of filtration and Lemmas 23 and 24, where X_Σ is finite as the set of subformulas of a formula is finite, we obtain our first finite model property result.

► **Theorem 25.** *If φ is a SLCS formula that is satisfiable on a purely quasi-discrete neighbourhood model, then φ is satisfiable on a finite purely quasi-discrete neighbourhood model.*

5.2 Quasi-Discrete Spaces with Topological Paths

In this section, we prove that SLCS also admits finite models for the class of quasi-discrete models over topological paths. This case is interesting, since topological paths behave very differently from quasi-discrete paths. For example, topological paths are not required to comply with the direction of the edges of the underlying graph.

► **Example 26.** Consider the model in Fig. 3a. We can define a topological path p as in Fig. 3b. This function is indeed continuous. For $i < \frac{1}{2}$, the function is constant, since it is constant. At $i = \frac{1}{2}$, we have that for the minimal neighbourhood $N_{\min}(w) = \{w, x, y\}$, we can always find a neighbourhood N' of $\frac{1}{2}$ that does not contain 1, and so $p[N'] \subseteq N_{\min}(w)$. If $\frac{1}{2} < i < 1$, then $N_{\min}(p(i)) = \{x, y\}$, and we can choose any neighbourhood $N' \in \eta(i)$ that does not contain values less than $\frac{1}{2}$ and greater or equal to 1 to show continuity. At 1, the function is continuous for similar reasons as at $\frac{1}{2}$. So the function is a path.

However, path p contains many “superfluous detours” in the set $\{x, y\}$. A simpler path would be path p' in Fig. 3c, or a variation in which p' maps to y instead of x . This path only visits points that were visited by p as well, but omits these detours.

The following Lemma formalises the intuition explained in Example 26. We will use it to normalise the paths used as witnesses for the satisfaction of the propagate modality when we prove the existence of filtrations.

► **Remark 27.** From this point onward, we will use the following slight abuse of notation. For two indices $r, s \in [0, 1]$, we write $p[r, s] = \{p(i) \mid r < i < s\}$ to denote the values of a path p on the open interval between r and s . If $p[r, s]$ is a singleton (i.e., p is constant on the interval (r, s)), we will also treat $p[r, s]$ as a single value, to avoid unnecessary parentheses.

► **Lemma 28 (Path Simplification).** *Let $\mathcal{M} = ((X, \eta), \mathcal{I}_{\mathbb{R}}, \nu)$ a neighbourhood model, where (X, η) is a quasi-discrete space, and let $p: [0, 1] \rightarrow X$ be a path on \mathcal{M} such that p has a finite image. Then there is a path p' and a sequence of indices i_0, \dots, i_n with $i_0 = 0$, $i_n = 1$ and $i_r < i_{r+1}$ for all $r < n$, such that*

1. $p'(i) = p(i)$ for all the indices in the sequence,
2. p' is constant on each open interval (i_r, i_{r+1}) ,
3. $p'[i_r, i_{r+1}] \neq p'[i_s, i_{s+1}]$ for $r \neq s$,
4. if $p'(i_{r+1}) \neq p'[i_r, i_{r+1}]$, then $p'[i_r, i_{r+1}] \in N_{\min}(p'(i_{r+1}))$,
5. if $p'(i_r) \neq p'[i_r, i_{r+1}]$, then $p'[i_r, i_{r+1}] \in N_{\min}(p'(i_r))$,
6. if $p(i) \neq p'(i)$, then there are $r, s \in [0, 1]$ and $y \in X$ with $r < i < s$ such that $p(r) = p(s) = y$ and $p'(r) = p'(s) = y$.

Proof. Let \mathcal{M} and p be as required, let $x \in X$ be a point in the space, and $0 \leq s \leq 1$ an index. We indicate by $\text{sI}(p, x, s)$ the smallest subinterval I of $[s, 1]$ such that $\forall i \in [s, 1] \setminus I$ it holds that $p(i) \neq x$. Let a be the infimum (resp., supremum) of $\text{sI}(p, x, s)$, then it follows that $\forall N \in \eta(a)$ there exists an $i \in N \cap \text{sI}(p, x, s)$ such that $p(i) = x$.

We now construct the sequence of indices i_0, \dots, i_n and the path p' . We set $i_0 = 0$, $p'(0) = p(0)$, and then proceed as follows starting from $\text{sI}(p, p(0), i_0)$.

Consider an index i_k , a point $x \in X$, and let a be the supremum of $\text{sI}(p, x, i_k)$. We set $p'(i) = x$ for all $i_k < i < a$, we set $p'(a) = p(a)$, and

1. if $a \notin \text{sI}(p, x, i_k)$, we set $i_{k+1} = a$, and then proceed with $\text{sI}(p, p(a), i_{k+1})$;
2. otherwise (i.e., $a \in \text{sI}(p, x, i_k)$), we need to find a possible way to proceed with the path following the index a . That is, we need to find the right point and index for the function sI . Let $S = \{y \in N_{\min}(p(a)) \mid \forall N \in \eta(a): y \in p[N \cap [a, 1]]\} \setminus \{p(a)\}$. Observe that $S \neq \emptyset$ as p is a continuous function on X , and any point in S is a good candidate for the continuation of the construction. Now we need to understand whether or not to move from the index i_k to the index i_{k+1} . If $i_k = a$, then we proceed by choosing any of the $y \in S$ and considering $\text{sI}(p, y, i_k)$. Otherwise, we proceed by choosing any of the $y \in S$, setting $i_{k+1} = a$, and considering $\text{sI}(p, y, i_{k+1})$.

Since p has a finite image, the process above terminates when $i_k = 1$.

Now let p' be the path constructed as above. Properties 1, 2 and 3 are immediate results of the construction of p' . Let us show that property 4 holds, and consider the case where $p'(i_{r+1}) \neq p'[i_r, i_{r+1}]$. By construction we know that i_{r+1} is the supremum of $\text{sI}(p, x, i_r)$, which means that $\forall N \in \eta(i_{r+1}) \exists i \in N \cap (i_r, i_{r+1})$ with $p(i) = x = p'[i_r, i_{r+1}]$. By continuity of p it must hold that $\exists N' \in \eta(i_{r+1})$ such that $p[N'] \subseteq N_{\min}(p(i_{r+1}))$. As $p'[i_r, i_{r+1}] \in p[N']$, then $p'[i_r, i_{r+1}] \in N_{\min}(p'(i_{r+1}))$. Property 5 follows immediately from point 2 above since we select y among the elements in the minimal neighbourhood. Finally we consider property 6. Let i be an index such that $p(i) \neq p'(i)$. By property 1, we know that i cannot be any of the indices in the resulting sequence. Let i_k and i_{k+1} be the two indices in the resulting sequence such that $i_k < i < i_{k+1}$. By definition of $\text{sI}(p, p'(i), i_k)$, there must exist two indices r and s such that $p(r) = p(s) = p'(i)$, and $i_k \leq r < i < s \leq i_{k+1}$. By property 2 $p'[i_k, i_{k+1}] = p'(i)$, and the property holds. \blacktriangleleft

Similarly to the case with quasi-discrete paths, the following lemma allow us to transfer information about the satisfaction of the path operator to neighbouring points.

► **Lemma 29.** *Let \mathcal{M} be a quasi-discrete neighbourhood model over topological paths and $x, y \in \mathcal{M}$ two points. Then the following hold.*

1. *If $y \in N_{\min}(x)$, $\mathcal{M}, y \models \varphi$ and $\mathcal{M}, y \models \varphi \mathcal{P} \psi$, then also $\mathcal{M}, x \models \varphi \mathcal{P} \psi$.*
2. *If $x \in N_{\min}(y)$, $\mathcal{M}, x \models \varphi$, $\mathcal{M}, y \models \varphi$ and $\mathcal{M}, y \models \varphi \mathcal{P} \psi$, then also $\mathcal{M}, x \models \varphi \mathcal{P} \psi$.*

Proof. Case (1): Let p and n be witnesses for $\mathcal{M}, y \models \varphi \mathcal{P} \psi$. There are two cases to consider. In the first case, p stays on y for an infinite number of indices. That is, the initial segment of p is not a singleton. Then we can define p' by $p'(0) = x$ and $p'(i) = p(i)$ for $i > 0$. Since p is continuous p' is continuous for every $i > 0$. For $i = 0$, we can take any neighbourhood $N \in \eta_{\mathbb{R}}(0)$ that only extends into the initial segment of p , where $p(j) = y$ for any $i \in N$ with $i \neq 0$. Then $p'[N] \subseteq N_{\min}(x)$. So p' is also continuous at 0, and since $\mathcal{M}, y \models \varphi$, it is a witness for $\mathcal{M}, x \models \varphi \mathcal{P} \psi$. In the other case, p stays on y for the single index 0, and then moves to some point z . Then we define p' by $p'(0) = x$, $p'(i) = y$ for $0 < i \leq \frac{1}{2}$ and $p'(i) = p(2i - 1)$ for $i > \frac{1}{2}$. Similar to the case above, p' is continuous at 0. Since the constant path is continuous, p' is continuous at $0 < i < \frac{1}{2}$. And since p is continuous at $2i - 1$, p' is continuous at i for $i \geq \frac{1}{2}$. Furthermore, with $n' = \frac{1}{2}(n + 1)$, p' is a witness for $\mathcal{M}, x \models \varphi \mathcal{P} \psi$.

Case (2): By assumption on y , there is a path $p: \mathbb{R} \rightarrow \mathcal{M}$ and a value n , such that $p(0) = y$, $\mathcal{M}, p(n) \models \psi$ and for all i with $0 < i < n$, we have $\mathcal{M}, p(i) \models \varphi$. Using this path, we can construct the path p' by setting $p'(i) = x$ if $i < \frac{1}{2}$ and $p'(i) = p(2i - 1)$ for $i \geq \frac{1}{2}$. This function is continuous, and thus a path. Furthermore, we have $\mathcal{M}, p'(n+1) \models \psi$, and of course for all i with $0 < i < \frac{1}{2}(n+1)$ we have $\mathcal{M}, p'(i) \models \varphi$. So this path is a witness for $\mathcal{M}, x \models \varphi \mathcal{P} \psi$. \blacktriangleleft

We now proceed with the definition of filtrations for quasi-discrete models over topological paths. As can be expected, the definition differs from Def. 22 only in the treatment of paths. Instead of explicitly enumerating the equivalence classes on a path, we only assume the existence of a path on the filtration, and then transfer the satisfaction back to the original model. Furthermore, we do not need to consider the reachability path operator, since it is equivalent to the propagate modality, by Lemma 17.

► **Definition 30** (Filtration with Topological Paths). *Let Σ be a subformula closed set of SLCS formulas, and $\mathcal{M} = ((X, \eta), \mathcal{I}_{\mathbb{R}}, \nu)$ a neighbourhood model, where (X, η) is a quasi-discrete space. We call the neighbourhood model $\mathcal{M}_f = ((X_f, \eta_f), \mathcal{I}_{\mathbb{R}}, \nu_f)$ a filtration of \mathcal{M} over topological paths through Σ , if it satisfies the following conditions:*

1. $X_f = \{[x]_{\Sigma} \mid x \in X\}$
2. if $y \in N_{\min}(x)$, then $[y] \in N_{\min}([x])$
3. if $[y] \in N_{\min}([x])$, then for each $\mathcal{N} \varphi \in \Sigma$, we have that if $\mathcal{M}, y \models \varphi$, then $\mathcal{M}, x \models \mathcal{N} \varphi$
4. if $\pi: [0, 1] \rightarrow X_f$ is a path on \mathcal{M}_f where $\pi(i) = [x_i]$, then for every $\varphi \mathcal{P} \psi \in \Sigma$, we have that whenever $\mathcal{M}, x_i \models \varphi$ for each $0 < i < n$ and $\mathcal{M}, x_n \models \psi$, then also $\mathcal{M}, x_0 \models \varphi \mathcal{P} \psi$
5. $\nu_f([x]) = \{p \in AP \mid \mathcal{M}, x \models p\}$

As in the purely quasi-discrete case, satisfaction of all formulas in the subformula closed set Σ is preserved on filtrations through Σ .

► **Lemma 31.** *Let \mathcal{M}_f be a filtration of the quasi-discrete model \mathcal{M} over topological paths through Σ . Then for all $\varphi \in \Sigma$, we have $\mathcal{M}, x \models \varphi$ iff $\mathcal{M}_f, [x] \models \varphi$.*

Proof. We proceed by induction on the structure of formulas. The base case for atomic propositions is immediate by Def. 30. The cases for the boolean operators are standard and the case for $\varphi = \mathcal{N} \psi$ is exactly as for Lemma 23.

Now consider $\varphi = \psi \mathcal{P} \chi$. If $\mathcal{M}, x \models \psi \mathcal{P} \chi$, this is equivalent to the existence of a path $p: x \rightsquigarrow \infty$ and a n and $\mathcal{M}, p(n) \models \chi$ as well as $\forall i: 0 < i < n$, we have $\mathcal{M}, p(i) \models \psi$. Observe that for any j and k such that $p(k) \in N_{\min}(p(j))$, we have $[p(k)] \in N_{\min}([p(j)])$ by property 2. Furthermore, for any j , we know that there is a $N \in \eta(j)$ such that $p[N] \subseteq N_{\min}(p(j))$ by continuity of p . So, these two facts together imply that $\forall k \in N$, we have $[p(k)] \in N_{\min}([p(j)])$. Hence we can define $\pi: [0, 1] \rightarrow X_f$ by $\pi(i) = [p(i)]$ and then have that π is a path on \mathcal{M}_f such that $\pi(0) = [x]$. Furthermore, by the induction hypothesis, for all i with $0 < i < n$, we have $\mathcal{M}_f, \pi(i) \models \psi$ and $\mathcal{M}_f, \pi(n) \models \chi$. This of course means $\mathcal{M}_f, [x] \models \psi \mathcal{P} \chi$.

Conversely, assume $\mathcal{M}_f, [x] \models \psi \mathcal{P} \chi$. Then there is a path $\pi: [0, 1] \rightarrow X_f$ such that $\pi(0) = [x]$, for all i with $0 < i < n$ we have $\mathcal{M}_f, \pi(i) \models \psi$ and $\mathcal{M}_f, \pi(n) \models \chi$. Let $\pi(i) = [x_i]$, then we get by the induction hypothesis that $\mathcal{M}, x_i \models \psi$ for all i with $0 < i < n$ and $\mathcal{M}, x_n \models \chi$. By property 4 we get $\mathcal{M}, x_0 \models \psi \mathcal{P} \chi$ and by $x \simeq x_0$, we get $\mathcal{M}, x \models \psi \mathcal{P} \chi$.

The case for $\varphi = \psi \mathcal{R} \chi$ is immediate by Lemma 17 and the previous case. \blacktriangleleft

The main part left in this section is to show that filtrations exist. This is more complicated than in the purely quasi-discrete case, due to the different behaviour of topological paths. However, if we restrict ourselves to *finite* sets Σ , then we can normalise the paths on the

filtration according to Lemma 28, and use these simpler paths to establish satisfaction of the path modalities on the original model. Since we are only interested in filtrations through the set of subformulas induced by a single formula, this suffices for our purpose.

► **Lemma 32.** *Let Σ be a finite subformula closed set of formulas and \mathcal{M} a quasi-discrete model over topological paths. Furthermore, let X_Σ be the set of equivalence classes of \simeq_Σ , ν_Σ be defined as in Def. 30 (5), and $\eta_s([x]) = \langle \{[y] \mid \exists y', x': y' \in [y] \wedge x' \in [x] \wedge y \in N_{\min}(x)\} \rangle$ for each $[x] \in X_\Sigma$. Then the model $\mathcal{M}_\Sigma = ((X_\Sigma, \eta_s), \mathcal{I}_\mathbb{R}, \nu_\Sigma)$ is a filtration of \mathcal{M} over topological paths through Σ .*

Proof. First observe that \mathcal{M}_Σ is indeed a quasi-discrete neighbourhood model over topological paths, since the underlying space of \mathcal{M}_Σ is finite, and any finite neighbourhood space is quasi-discrete. We focus only on proving property 4 as all the others are already proved in Lemma 24.

Let $\pi: [0, 1] \rightarrow X_f$ be a path as required. If $n = 0$ so that $\mathcal{M}, x_n \models \psi$, this means $\mathcal{M}, x_0 \models \psi$, and so trivially $\mathcal{M}, x_0 \models \varphi \mathcal{P} \psi$. So, without loss of generality, we assume $n = 1$. With $\pi(i) = [x_i]$, we have $\mathcal{M}, x_i \models \varphi$ for $0 < i < 1$ and $\mathcal{M}, x_1 \models \psi$. Since the set of equivalence classes is finite, we can use Lemma 28 to get a path $\sigma: [0, 1] \rightarrow X_f$, with $x_0 \in \sigma(0)$ and $x_1 \in \sigma(1)$. Furthermore, the properties of σ in Lemma 28 ensure that for all $0 < i < 1$, if $\sigma(i) = [x'_i]$, then $\mathcal{M}, x'_i \models \varphi$.

Now, let $S = \{[z] \mid \exists i: \sigma(i) = [z]\}$ be the image of σ . Since S is finite, we define an order on S by setting $[z_i] < [z_j]$ iff there exist s and t with $s < t$ such that $\sigma(s) = [z_i]$ and $\sigma(t) = [z_j]$. By Lemma 28 and since the index space is totally ordered, this order is well-defined. So, in the following we will denote S by the sequence $[z_0], [z_1], \dots, [z_r]$.

We proceed to prove that $\mathcal{M}, x_0 \models \varphi \mathcal{P} \psi$ by induction on then length r of this sequence. If $r = 0$, then $[z_0] = [x_1]$. Since $z_0 \simeq x_0 \simeq x_1$ and $\mathcal{M}, x_1 \models \psi$, we get $\mathcal{M}, x_0 \models \psi$, and thus $\mathcal{M}, x_0 \models \varphi \mathcal{P} \psi$.

Assume that the property holds for all such sequences for a length up to r , and consider $[z_0], [z_1], [z_2], \dots, [z_r], [z_{r+1}]$. First, we can see that since σ is a path, the sequence $[z_1], [z_2], \dots, [z_r], [z_{r+1}]$ also induces a path that satisfies the precondition of the property. So, we get by the induction hypothesis $\mathcal{M}, z_1 \models \varphi \mathcal{P} \psi$. We now need to examine the relation between $[z_0]$ and $[z_1]$. To that end, we first consider the preimages of both classes: $I_0 = \{i \mid \sigma(i) = [z_0]\}$ and $I_1 = \{i \mid \sigma(i) = [z_1]\}$. Furthermore, let j be the supremum of I_0 . Recall that by Lemma 28, we have a sequence of indices i_0, i_1, \dots that partitions the interval $[0, 1]$ according to the values of σ . Now there are two possibilities for the relation between $[z_0]$ and $[z_1]$ according to σ .

1. If $i \in I_0$, then either $i = i_0 = 0$, or $i = i_1$. In the first case, $[z_0] = \sigma(i_0) \neq \sigma[i_0, i_1] = [z_1]$, and so $[z_1] \in N_{\min}([z_0])$ by Lemma 28 (5). In the other case, we have $[z_1] = \sigma[i_1, i_2]$, and so $[z_0] = \sigma(i_1) \neq \sigma[i_1, i_2] = [z_1]$. Again, by Lemma 28 (5), we have $[z_1] \in N_{\min}([z_0])$. By construction of \mathcal{M}_f there are $y_0, y_1 \in \mathcal{M}$ such that $y_1 \in N_{\min}(y_0)$ and $y_0 \in [z_0]$ and $y_1 \in [z_1]$. By assumption, we have $\mathcal{M}, x_0 \models \varphi$ as well, so by $x_0 \simeq z_0 \simeq y_0$, we get $\mathcal{M}, y_0 \models \varphi$ and $\mathcal{M}, y_1 \models \varphi \mathcal{P} \psi$. Then we have $\mathcal{M}, y_0 \models \varphi \mathcal{P} \psi$ from Lemma 29 (1) and thus $\mathcal{M}, x_0 \models \varphi \mathcal{P} \psi$.
2. Otherwise, we have $i \notin I_0$, and thus $i \in I_1$. Then certainly $i = i_1$, and so $[z_1] = \sigma(i_1) \neq \sigma[i_0, i_1] = [z_0]$. By Lemma 28 (4), we get $[z_0] \in N_{\min}([z_1])$. By construction of \mathcal{M}_f there are $y_0, y_1 \in \mathcal{M}$ such that $y_0 \in N_{\min}(y_1)$ and $y_0 \in [z_0]$ and $y_1 \in [z_1]$. However, in this case we also have that $i_1 > 0$, since otherwise $[z_0] = [z_1]$, which contradicts Property 3 of Lemma 28. So there is an $x \in [z_0]$, such that $\mathcal{M}, x \models \varphi$ by the properties of σ . Since $x \simeq y_0$, this means $\mathcal{M}, y_0 \models \varphi$. By assumption on σ , we have $\mathcal{M}, y_1 \models \varphi$ and since $y_1 \simeq z_1$, we also have $\mathcal{M}, y_1 \models \varphi \mathcal{P} \psi$. So, Lemma 29 (2) gives us $\mathcal{M}, y_0 \models \varphi \mathcal{P} \psi$, and with $x_0 \simeq z_0 \simeq y_0$ we can conclude the proof. ◀

The definition of filtrations together with Lemmas 31 and 32 yield the finite model property. Note that we can apply Lemma 32, as the set of subformulas of a formula is finite.

► **Theorem 33.** *If φ is a SLCS formula that is satisfiable on a quasi-discrete neighbourhood model over topological paths, then φ is satisfiable on a finite quasi-discrete neighbourhood model over topological paths.*

6 Conclusion

We have shown that SLCS does not have the finite model property over arbitrary neighbourhood models. Furthermore, we have proven that even when restricting to only quasi-discrete paths, there are still formulas that can only be satisfied on infinite models. Finally, we have shown that SLCS has the finite model property over models with underlying quasi-discrete neighbourhood spaces and quasi-discrete or topological paths. These results highlight that the types of spaces allowed have a much stronger impact on the existence of finite models than the types of paths allowed.

Our results are specific to the two types of paths we analysed. While these are the most common ones, it is possible to consider other definitions. Bubenik and Milićević [5] introduced other types of paths over neighbourhood spaces and analysed their properties. For example, they defined an index space based on a finite set $J = \{1, \dots, m\}$, which is close to the idea of a quasi-discrete space. However, the neighbourhood system on this index space is very different from our setting, since it includes both the predecessor and the successor in the minimal neighbourhood of a point. Several of their other index spaces are even more different. An interesting research direction for future work is to study how these types of paths interact with the operators of SLCS.

A more applied strand of research is to analyse some of the extensions of SLCS. A natural first step would be to consider the temporal extension of SLCS with operators from CTL [10] and prove whether it has the finite model property. This would build upon previous results stating that CTL has the finite model property [15] and the combinations of logics that admit finite models typically also admit finite models [13]. Similarly, interesting future work would be to analyse the extension of SLCS with set-based operators introduced by Ciancia et al. [11], and the metric extensions by Bartocci et al. [1]. Finally, a model-theoretic study of a variant of SLCS presented by Bezhanišvili et al. would be interesting [3]. This variant is defined with a semantics based on polyhedra in continuous spaces, which is in some sense “in between” the class of quasi-discrete, graph-like models, and the class of general, arbitrary neighbourhood spaces.

Our results are a further step towards a comprehensive model theory for SLCS. Understanding how the models of SLCS behave can guide how and where we may apply this logic, as well as its extensions.

Recursive Backdoors for SAT

Abstract

A strong backdoor in a formula φ of propositional logic to a tractable class \mathcal{C} of formulas is a set B of variables of φ such that every assignment of the variables in B results in a formula from \mathcal{C} . Strong backdoors of small size or with a good structure, e.g. with small backdoor treewidth, lead to efficient solutions for the propositional satisfiability problem SAT.

In this paper we propose the new notion of *recursive backdoors*, which is inspired by the observation that in order to solve SAT we can independently recurse into the components that are created by partial assignments of variables. The quality of a recursive backdoor is measured by its *recursive backdoor depth*. Similar to the concept of backdoor treewidth, recursive backdoors of bounded depth include backdoors of unbounded size that have a certain treelike structure. However, the two concepts are incomparable and our results yield new tractability results for SAT.

1 Introduction

The problem of checking whether a formula of propositional logic in conjunctive normal form (CNF) is satisfiable (SAT) is one of the most central problems in computer science. The problem is often seen as the canonical NP-complete problem [1] and conjectured to be not solvable in sub-exponential time [10]. Despite this theoretical hardness result, state-of-the-art SAT solvers are able to efficiently solve multi-million variable instances arising from real-world applications. We refer to the recent survey of Ganesh and Vardi [4], who try to explain this “unreasonable effectiveness of SAT solvers”. SAT is known to be solvable in polynomial time on several restricted classes of formulas, e.g. on Horn and 2CNF formulas. However, this classification falls short of explaining the practical efficiency of SAT solvers, as many efficiently solvable instances do not belong to any of these classes.

Parameterized complexity theory offers a refined view on the complexity of problems. Instead of measuring complexity only with respect to the input size n , one or more parameters are taken into account. Optimally, one can establish fixed-parameter tractability with respect to a parameter k , that is, a running time of $f(k) \cdot n^c$ for some computable function f and a constant c . In case the parameter k is small on a given class of instances, this may lead to efficient algorithms even if the inputs are large. Even though SAT solvers may not be explicitly tailored to use these parameters, it is conceivable that they implicitly exploit the

structure that is imposed by them. This poses the question of parametric characterizations of real-world application instances that can be solved efficiently. One very important parameter to explain tractability is *treewidth*, which intuitively measures how tree-like an instance is, and which can be used to obtain fixed-parameter tractability for SAT [15].

A second very successful parametric approach was introduced by Williams et al. [17]. For a formula φ , a *strong backdoor* to a given class \mathcal{C} of formulas is a set of variables of φ such that for every assignment of these variables one obtains a formula in \mathcal{C} . Similarly, a *weak backdoor* to \mathcal{C} for a satisfiable formula is a set of variables of φ such that some assignment of these variables leads to a formula in \mathcal{C} . These notions elegantly allow to lift tractability results from classes \mathcal{C} to classes that are *close* to \mathcal{C} . Given a formula and a strong backdoor of size k to a tractable class, one can decide satisfiability by checking 2^k tractable instances. For small k this yields efficient algorithms as noted by Nishimura et al. [11], who first studied the parameterized complexity of backdoor detection.

A lot of effort has been invested to develop fpt algorithms for backdoor detection to various tractable base classes \mathcal{C} , for example to classes of bounded treewidth [9] or heterogeneous classes [7]. Treewidth is a width measure for graphs that can however be applied to measure the complexity of formulas by considering the incidence graphs of formulas. The incidence graph of a formula has one vertex for each variable and one vertex for each clause. A variable vertex is connected with a clause vertex when the variable is contained positively or negatively in the clause. In the following, we will often use graph theoretic terminology for formulas, and this always refers to the incidence graph of the formula.

Apart from various base classes, alternative measures of quality of backdoors have been proposed. Backdoor trees generalize backdoor sets into decision trees, whose quality is measured by their number of leaves [14]. Recently backdoor trees have been further generalized to backdoor DNFs [12]. Ganian et al. [5] introduced the notion of backdoor treewidth, which permits fpt backdoor detection for backdoors of unbounded size. Even though backdoors of bounded treewidth can be arbitrarily large, they showed that SAT is fixed-parameter tractable when parameterized by the backdoor treewidth with respect to the classes \mathcal{C} of Horn, Anti-Horn and 2CNF formulas. They also consider backdoors that split an input constraint satisfaction problem into components that may belong to different tractable classes [6]. Other recent notions of backdoors can be found in the literature such as the notions of learning-sensitive backdoors [3] and learning-sensitive backdoors with restarts [18]. For an overview of additional works we refer to the survey by Gaspers and Szeider [8] as well as to the upcoming book chapter by Samer and Szeider [16].

In this paper we introduce the new notions of *strong* and *weak recursive backdoors* as generalizations of backdoor sets and backdoor trees. Strong recursive backdoors extend backdoor trees by not only branching on truth values but also recursively branching into the independent components of the formula that may arise after the partial assignment of variables. We measure the quality of recursive backdoors by the depth of their branching trees. The splitting into components allows recursive backdoors of bounded depth to contain an unbounded number of variables. Our definition, together with the observation that after the assignment of a variable one can independently solve the sub-instances in the arising components, reveals a new potential of backdoors for SAT.

The main power of recursive backdoors, but also the difficulty in their study, is that by assigning a variable we do not recurse into the components that are created by deleting that variable, but into the components that are created by deleting parts of the neighborhood of the variable. We show that detecting weak recursive backdoors even to the class \mathcal{C}_0 of

edgeless incidence graphs is $W[2]$ -hard. Our main technical contribution is an fpt algorithm that, given a formula φ and a parameter k , either decides satisfiability of φ or correctly concludes that φ has no strong recursive backdoor to \mathcal{C}_0 of depth at most k . Even for the class \mathcal{C}_0 this yields tractability results that cannot be achieved by backdoor treewidth.

We provide background in Section 2. We define recursive backdoors in Section 3 and Section 4 is devoted to a sketch of the fpt algorithm. The rest of the paper is devoted to the formal presentation and correctness proof of that algorithm. Due to space constraints we present the hardness proof only in the appended full version of the paper. Also some proofs of the main result are deferred to the appendix.

2 Preliminaries

Propositional Logic. We consider formulas of propositional logic in conjunctive normal form (CNF), represented by finite sets of clauses, and in the following when we speak of a formula we will always mean a CNF formula. We write $x, y, z \dots$ for variables and $\star, \diamond \in \{+, -\}$ for polarities. A literal is a variable with an assigned polarity. We write x_+ for the positive literal x , x_- for the negative literal \bar{x} , and x_\star for a literal with arbitrary polarity. Every clause is a finite set of literals. We assume that no clause contains a complementary pair x_+, x_- . For a formula φ , we write $\text{var}(\varphi)$ and $\text{cl}(\varphi)$ to refer to the sets of variables and clauses of φ , respectively. We say that a variable x is positive (resp. negative) in a clause c if $x_+ \in c$ (resp. $x_- \in c$), and we write $\text{var}(c)$ for the set of variables x with $x_\star \in c$ and $\text{lit}(c)$ for the set of literals in c . For a formula φ we let $\text{var}(\varphi) = \bigcup_{c \in \varphi} \text{var}(c)$.

The *width* of c is $|\text{var}(c)|$ and the *length* of φ is $\sum_{c \in \varphi} |\text{var}(c)|$, denoted $|c|$ and $|\varphi|$, respectively. We call a clause a *d-clause* if it has width exactly d . We say that a formula has *maximal clause degree* d if each of its clauses has width at most d . We write \mathcal{C}_d to refer to the class of CNF formulas with maximal clause degree d . Especially \mathcal{C}_0 denotes the class of empty formulas, that either contain only empty clauses or no clauses at all.

A *truth assignment* τ is a mapping from a set of variables, denoted by $\text{var}(\tau)$, to $\{+, -\}$. A truth assignment τ satisfies a clause c if c contains at least one literal x_\star with $\tau(x) = \star$. A truth assignment τ of $\text{var}(\varphi)$ satisfies the formula φ if it satisfies all clauses of φ .

Given a formula φ and a truth assignment τ , $\varphi[\tau]$ denotes the formula obtained from φ by removing all clauses that are satisfied by τ and by removing from the remaining clauses all literals x_\star with $\tau(x) \neq \star$. Note that for every formula φ and assignment τ we have $\text{var}(\varphi[\tau]) \cap \text{var}(\tau) = \emptyset$. If τ and τ' are assignments with $\text{var}(\tau) \cap \text{var}(\tau') = \emptyset$, then we write $\tau \cup \tau'$ for the unique assignment extending both τ and τ' .

Graphs. We will only consider graphs that arise as incidence graphs of formulas. The incidence graph G_φ of a formula φ is a bipartite graph with vertices $\text{var}(\varphi) \cup \text{cl}(\varphi)$. Slightly abusing notation we usually do not distinguish between a formula and its incidence graph. E.g. we speak of the variables and clauses of G_φ , which we denote by $\text{var}(G_\varphi)$ and $\text{cl}(G_\varphi)$ respectively. Vice versa, we speak e.g. of components of φ with implicit reference to the incidence graph G_φ . We drop the subscript φ if it is clear from the context. The edges of G are partitioned into two parts E_+ (positive edges) and E_- (negative edges), where a variable x is connected to a clause c by an edge E_\star if $x_\star \in \text{lit}(c)$. For an assignment τ we naturally define $G[\tau]$ as the incidence graph of $\varphi[\tau]$. If τ assigns only a single variable $x \mapsto \star$ we write $G[x_\star]$ for $G[\tau]$. Note that for every assignment τ , $G[\tau]$ is an induced subgraph of G . For a vertex v the closed \star -neighborhood of v is defined as $N_\star[v] := \{w : \{v, w\} \in E_\star\}$. For $W \subseteq V$ we write $G[W]$ for the subgraph induced by W and $G - W$ for $G[V \setminus W]$.

We refrain from formally defining treewidth and refer to the literature for background. A graph H is a minor of a graph G if H can be obtained from G by deleting edges and vertices and by contracting edges. To compare our new definition of recursive backdoors with backdoor treewidth, we mention that if a graph contains a $k \times k$ grid as a minor, then it has treewidth at least k [13].

Parameterized Complexity. A parameterized problem is called fixed-parameter tractable (fpt) if there exists an algorithm deciding the problem in time $f(k) \cdot n^c$, where n is the input size, k is the parameter, f is a computable function and c is a constant. An algorithm witnessing fixed-parameter tractability of a problem is called an fpt-algorithm for the problem.

To show that a problem is likely to not be fpt one can show that it is $W[i]$ -hard for some $i \geq 1$. For this, it is sufficient to give a parameterized reduction from a known $W[i]$ -hard problem. We refer to the book [2] for extensive background on parameterized complexity theory.

Backdoors. Let \mathcal{C} be a class of formulas and let φ be a formula. A set $B \subseteq \text{var}(\varphi)$ is a *strong backdoor* of φ to \mathcal{C} if for every assignment $\tau: B \rightarrow \{+, -\}$ the formula $\varphi[\tau]$ belongs to \mathcal{C} . Note that for some assignments τ the formula $\varphi[\tau]$ may not be satisfiable, even though φ is satisfiable. Hence, in the following definition of a weak backdoor we require that φ is satisfiable. If φ is satisfiable, then a set $B \subseteq \text{var}(\varphi)$ is a *weak backdoor* of φ to the class \mathcal{C} if there exists an assignment $\tau: B \rightarrow \{+, -\}$ such that $\varphi[\tau]$ is a satisfiable formula in \mathcal{C} . The classical measure for the complexity or quality of a backdoor is its size.

An important recent approach to measure the complexity of a backdoor is to take its structure into account. The *treewidth of a backdoor* B is defined as the treewidth of the graph with vertex set B where two variables x and y are connected by an edge if there exists a path from a neighbor of x to a neighbor of y in $G - B$ [5]. Ganian et al. [5] also consider backdoors that split the input CNF formula into components that each may belong to a different tractable class \mathcal{C} .

Permissive Backdoor Detection. In their survey Gaspers and Szeider [8] differ between a strict and a permissive version of the backdoor detection problem. Given a backdoor definition \mathcal{B} and a corresponding quality measure μ (e.g. strong backdoors to 2CNF measured by their size) as well as a formula φ and a parameter k . The strict backdoor detection problem, denoted as \mathcal{B} -DETECTION, asks whether or not $\mu(\varphi) \leq k$ holds. The permissive backdoor detection problem, denoted as $\text{SAT}(\mu)$, asks to either decide the satisfiability of φ or conclude that $\mu(\varphi) > k$ holds. The permissive version of the problem grants more freedom in algorithm design, as trivial instances can be solved without calculating the backdoor measure. However as Gaspers and Szeider point out, hardness proofs seem to be much harder for the permissive version.

3 Recursive Backdoors

Strong Recursive Backdoors. Our new concept of recursive backdoors is based on the observation that we can handle the components of $G[x_\star]$ independently whenever a variable x has been assigned. A *strong recursive backdoor* (SRB) of an incidence graph G to a class \mathcal{C} is a rooted labeled tree, where every node is either labeled with a subgraph of G or with a variable in $\text{var}(G)$. The root of the tree is labeled with G . Whenever an inner node is labeled with a connected graph H , then it has one child labeled with a variable. Whenever

it is labeled with a disconnected graph, then it has one child for each of its components, labeled with the graph induced by that component. Whenever an inner node is labeled with a variable x , then its parent is labeled with a graph H , and its two children are labeled with $H[x_+]$ and $H[x_-]$, respectively. Every leaf node is labeled with a graph from \mathcal{C} . We call the nodes of the tree *variable nodes* or *component nodes*, according to their labeling.

The *depth* of a strong recursive backdoor is the maximal number of variable nodes from its root to one of its leaves. The *strong recursive backdoor depth* to a class \mathcal{C} ($\text{srbd}_{\mathcal{C}}$) of an incidence graph G is the minimal depth of a strong recursive backdoor of G to \mathcal{C} . We give the following equivalent definition:

► **Definition 3.1** (Strong Recursive Backdoor Depth).

$$\text{srbd}_{\mathcal{C}}(G) = \begin{cases} 0 & \text{if } G \in \mathcal{C} \\ 1 + \min_{x \in \text{var}(G)} \max_{\star \in \{+, -\}} \text{srbd}_{\mathcal{C}}(G[x_{\star}]) & \text{if } G \notin \mathcal{C} \text{ and } G \\ & \text{is connected} \\ \max \{ \text{srbd}_{\mathcal{C}}(H) : H \text{ connected component of } G \} & \text{otherwise} \end{cases}$$

To get a better understanding of strong recursive backdoor depth we give an example of a family of incidence graphs with unbounded backdoor treewidth to 2CNF but constant strong recursive backdoor depth to \mathcal{C}_0 , the class of edgeless graphs. For any $k \geq 0$, define the graph G_k as follows. We start with a $k \times k$ grid of clause vertices $\{c_{1,1}, \dots, c_{k,k}\}$, depicted in yellow in Figure 1. We connect a private variable vertex to each of the corners $c_{1,1}, c_{1,k}, c_{k,1}, c_{k,k}$ of the grid. We now replace each edge of the grid by a path of length 6 (containing 5 vertices). Every second vertex on a new path is a clause vertex, connected to the two adjacent variable vertices. Furthermore, we add a special variable vertex x that is connected alternatingly with positive and negative polarity (depicted in green and blue in the figure) to the clause vertices on the new paths. Variable vertices are depicted as white vertices in the figure.

Since every clause $c_{i,j}$ is connected to at least 3 variables, every backdoor set B to 2CNF will have to contain at least one variable of every $c_{i,j}$. This implies that the B -torso of G will always contain a $k \times k$ grid as a minor, hence, will have treewidth at least k . We refer to [5, Definition 1] for the precise notions of B -torso and *backdoor treewidth*.

A strong recursive backdoor to \mathcal{C}_0 with x as its root splits every grid clause into a separate component of constant size and therefore has constant depth.

■ **Figure 1** From left to right: G_3 , $G_3[x_+]$, and $G_3[x_-]$.

Conversely, for the base class \mathcal{C}_0 , formulas whose incidence graph is a long path, e.g. $(x_1 \wedge x_2) \vee (x_2 \wedge x_3) \vee \dots \vee (x_n \wedge x_{n+1})$, have constant backdoor treewidth, but unbounded strong recursive backdoor depth, as we will see in Lemma 5.2. We conclude that recursive backdoors and backdoor treewidth are incomparable.

SAT Solving and SAT Counting using Strong Recursive Backdoors. Similar to regular strong backdoor sets, strong recursive backdoors allow for polynomial time SAT Solving and SAT Counting if the backdoor is given as part of the input. First, we observe that even though it may have an unbounded branching degree, the size of a recursive backdoor is still linear in the size of its formula.

► **Lemma 3.2.** *Let T be a strong recursive backdoor with depth k of a formula φ to a class \mathcal{C} . The number of leaf nodes in T , as well as the sum of number of vertices contained in leaf nodes is bound by $2^k \cdot |\varphi|$.*

Proof. Proof by induction on k and $|\varphi|$. The bound trivially holds when $k = 0$ or $|\varphi| = 1$ and the backdoor consists of a single leaf node.

In the inductive step, a variable node increases the backdoor depth and at most doubles the number of leaves and their contained vertices, as it branches on both polarities. A component node does not increase the backdoor depth, but branches over disjoint components of strictly smaller size. As the sum of the vertices contained in the components is equal to $|\varphi|$, the number of leaves and contained vertices is again bounded by $2^k \cdot |\varphi|$. ◀

We can use this observation to construct a straight-forward bottom-up algorithm:

► **Proposition 3.3.** *For every class \mathcal{C} where satisfiability checking (resp. counting the number of satisfying assignments) can be done in polynomial time, for every formula φ and integer k , given a strong recursive backdoor with depth k of φ to \mathcal{C} , we can test the satisfiability (resp. count the number of satisfying assignments) of φ in time $2^k \cdot \text{poly}(|\varphi|)$.*

Proof. By Lemma 3.2, we know that we have at most $2^k \cdot |\varphi|$ instances labeling leaves, which can be solved in polynomial time. For variable nodes, the instance labeling the node is satisfiable if and only if at least one of its two children is labeled with a satisfiable instance. The number of satisfiable assignments is the sum of the satisfiable assignments for its children. For component nodes, the instance labeling the node is satisfiable if and only if all of its children are labeled with satisfiable instances. The number of satisfiable assignments is the product of the satisfiable assignments for its children. ◀

Weak Recursive Backdoors. Recall that in the definition of weak backdoors we consider only satisfiable formulas and aim to find an assignment τ that leads to a satisfiable formula $\varphi[\tau] \in \mathcal{C}$. This is also the case in the following definition of weak recursive backdoor depth:

► **Definition 3.4** (Weak Recursive Backdoor Depth).

$$\text{wrbd}_{\mathcal{C}}(G) = \begin{cases} 0 & \text{if } G \in \mathcal{C} \text{ and } G \text{ is satisfiable} \\ \infty & \text{if } G \in \mathcal{C} \text{ and } G \text{ is unsatisfiable} \\ 1 + \min_{x \in \text{var}(G)} \min_{\star \in \{+, -\}} \text{wrbd}_{\mathcal{C}}(G[x_{\star}]) & \text{if } G \notin \mathcal{C} \text{ and } G \text{ is connected} \\ \max \{ \text{wrbd}_{\mathcal{C}}(H) : H \text{ connected component of } G \} & \text{otherwise} \end{cases}$$

SAT Solving using Weak Recursive Backdoors. We can use the notion of weak recursive backdoors for SAT as follows. As the existence of a weak recursive backdoor for some formula φ implies that φ is satisfiable, we do not assume that the backdoor is given with the input this time.

► **Proposition 3.5.** *For every class \mathcal{C} for which we can test membership and satisfiability in polynomial time, for every formula φ and integer k , we can test whether φ has weak recursive backdoor depth at most k in time $(2 \cdot |\varphi|)^k \cdot \text{poly}(|\varphi|)$.*

Proof. Branch over all $2 \cdot |\varphi|$ possible truth assignments of a single variable in φ . Recurse into the components arising through the assignment, until branching depth k or a formula from \mathcal{C} is reached. The leaves of the branching tree are labeled as satisfiable, if they are satisfiable members of \mathcal{C} , which can be tested in time $\text{poly}(|\varphi|)$. Component (resp. variable) branching nodes are labeled as satisfiable, if all (resp. any) of their children are labeled as satisfiable. It is now easy to see that $\text{wrbd}_{\mathcal{C}}(\varphi) \leq k$ if and only if the root node of the branching tree is labeled as satisfiable. By the same argument as in Lemma 3.2, the branching tree has at most $(2 \cdot |\varphi|)^k \cdot |\varphi|$ leaves. Therefore the presented algorithm runs in time $(2 \cdot |\varphi|)^k \cdot \text{poly}(|\varphi|)$. ◀

Note that when k is small, even this running time is a major improvement over the worst case running time of 2^{cn} implied by the exponential time hypothesis (ETH).

We will now continue with a sketch of the fpt algorithm for strong recursive backdoor detection to the class of empty formulas.

4 Proof Sketch

Our goal is to show that the permissive backdoor detection problem $\text{SAT}(\text{srbd}_{\mathcal{C}_0})$ is fixed-parameter tractable. That is, we aim to decide for a given formula φ and parameter k whether φ is satisfiable or does not have a strong recursive backdoor of depth k to the class \mathcal{C}_0 of empty formulas i.e. $\text{srbd}_{\mathcal{C}_0}(\varphi) > k$. Our approach is based on two main observations: Formulas with strong recursive backdoor depth k to \mathcal{C}_0 have both a maximal clause degree k (see Lemma 5.1) and a diameter bounded by $\lambda_k := 4 \cdot 2^k$ in each connected component (see Lemma 5.2).

We are going to design a recursive algorithm that in every step finds a bounded depth SRB that reduces the maximal clause degree of φ by one, or proves that the strong recursive backdoor depth of φ is larger than k . We extend the SRB by recursively branching on its leaves until we reach \mathcal{C}_0 . Since φ has maximal clause degree k this yields a bounded depth SRB to \mathcal{C}_0 in fpt running time.

First, take a look at the special case where $G := G_\varphi$ contains a clause c of width k , i.e. a k -clause. By our first observation, the existence of c implies that $\text{srbd}_{\mathcal{C}_0}(G) \geq k$. Note that the degree of c can only be reduced by assigning a variable in its neighborhood.

Next, consider the case where G contains two disjoint $(k-1)$ -clauses c_1, c_2 in the same connected component. Since G has limited diameter, there exists a path P of length $\leq \lambda_k$ between them. Since c_1 and c_2 are part of the same component we are only allowed to assign one variable to reduce the backdoor depth of that component to $k-1$. No matter which variable we choose, since c_1 and c_2 are disjoint, one of them will continue to exist in the reduced graph, which will then have backdoor depth at least $k-1$ and again, the existence of c_1, c_2 , and P implies that $\text{srbd}_{\mathcal{C}_0}(G) \geq k$.

Given a maximal clause degree d , we generalize this strategy for arbitrary depths $k = d + j$ by searching for so called *obstruction-trees*. An obstruction-tree for depth k is a structured set of vertices, whose existence in G will guarantee that G has a strong recursive backdoor depth of at least k . We start by searching for d -clauses as obstruction-trees for depth d . We search for obstruction-trees for depth $d + j + 1$ by searching for two obstruction-trees of depth $d + j$ that have disjoint neighborhoods and are connected by a path of bounded length. A schematic depiction of obstruction-trees for maximal clause degree d and backdoor depths $d, d + 1$, and $d + 2$ is shown in Figure 2. Since the obstruction-trees are based on d -clauses we can construct an fpt algorithm that either finds an obstruction-tree or a small backdoor which reduces the maximal clause degree of G to $d - 1$.

The algorithm to find obstruction-trees, described in Proposition 5.9, is at the heart of our proof. We use this algorithm to solve G by recursively searching for obstruction-trees for depth $k + 1$. In each round we either abort and conclude that G has strong recursive backdoor depth at least $k + 1$ or reduce d and recurse until we arrive at \mathcal{C}_0 , where we can trivially check satisfiability. If the graph splits into multiple components we can handle the components separately and aggregate the results.

■ **Figure 2** Schematic depiction of an obstruction-tree for maximal clause degree d and strong recursive backdoor depth $d + 2$. Here, the notation “ $ot_{i,d}$ ” stands for the notion of (i, d, k) -obstruction-tree, as formally defined in Definition 5.3.

5 Permissive Strong Recursive Backdoor Detection to \mathcal{C}_0 Is FPT

We start by formalizing and proving the observations made in Section 4.

► **Lemma 5.1** (Limited Clause Degree). *For every incidence graph G and integer d , if $\text{srb}_{\mathcal{C}_0}(G) \leq d$, then G has maximal clause degree at most d , i.e. $G \in \mathcal{C}_d$.*

Proof. Proof by induction on d .

Base Case: $d = 0$. If $\text{srb}_{\mathcal{C}_0}(G) \leq 0$, then $G \in \mathcal{C}_0$.

Induction Step: Let d be an integer and G an incidence graph with $\text{srb}_{\mathcal{C}_0}(G) \leq d + 1$. Let c be any clause in G . Let H be the connected component of c in G . By assumption, $\text{srb}_{\mathcal{C}_0}(H) \leq d + 1$, and there must be a variable vertex x such that for every literal x_\star we have $\text{srb}_{\mathcal{C}_0}(H[x_\star]) \leq d$. By induction, we also have that $H[x_\star] \in \mathcal{C}_d$.

Case 1: x is not connected to c . Then c is still intact in $H[x_\star]$ and by induction contains at most d variables.

Case 2: x is connected to c by an edge with polarity $+$. Then c still exists in $H[x_-]$ and by induction has degree at most d in $H[x_-]$. Therefore c contains at most $d + 1$ variables in G .

Case 3: The case that x is connected to c by an edge with polarity $-$ is analogous to *Case 2*. In all cases, c contains at most $d + 1$ variables in G , and therefore $G \in \mathcal{C}_{d+1}$. ◀

► **Lemma 5.2** (Low Diameter). *Let G be a incidence graph. If either $\text{srbd}_{\varphi_0}(G) \leq k$ or $\text{wrbd}_{\varphi_0}(G) \leq k$, then every connected component of G has a diameter of at most $4 \cdot 2^k - 4$.*

Proof. Proof by induction on k . For brevity we write $\text{bd}(G) \leq k$ for the fact that either $\text{wrbd}_{\varphi_0}(G) \leq k$ or $\text{srbd}_{\varphi_0}(G) \leq k$.

Base Case: $k = 0$. In this case, G is edgeless, and the statement holds.

Induction Step: Assume towards a contradiction that $\text{bd}(G) \leq k + 1$ and that G has a connected component H of diameter at least $4 \cdot 2^{k+1} - 3$. Hence H contains two vertices connected by a shortest path $P = (v_1, \dots, v_m)$ with $m = 4 \cdot 2^{k+1} - 2$ (such that if v_i is a clause vertex, then v_{i+1} is a variable vertex, and if v_i is a variable vertex, then v_{i+1} is a clause vertex). Also there exists a literal y_\star such that y is a variable vertex in H witnessing that $\text{bd}(G) \leq k + 1$. Since P is a shortest path from v_1 to v_m , y can only be connected to at most 2 clauses in P at distance 2 from each other. Let v_{i-1} and v_{i+1} be the two clauses connected to y (the reasoning also works with only one or zero such v_j). Now assigning y_\star can split P by deleting v_{i-1} and v_{i+1} . We then have that $G[y_\star]$ still contains (v_1, \dots, v_{i-2}) and (v_{i+2}, \dots, v_m) as shortest paths. One of those two paths will include at least

$$\left\lceil \frac{m-3}{2} \right\rceil = \left\lceil \frac{4 \cdot 2^{k+1} - 2 - 3}{2} \right\rceil = \left\lceil 4 \cdot 2^k - \frac{5}{2} \right\rceil = 4 \cdot 2^k - 2$$

vertices. One component of $H[y_\star]$ therefore has a diameter of at least $4 \cdot 2^k - 3$. This contradicts the fact that, by induction, $\text{bd}(H[y_\star]) \leq k$. Therefore we have $\text{bd}(G) \leq k + 1$. ◀

In the rest of the paper, we use $\lambda_k = 4 \cdot 2^k$ for brevity.

5.1 Obstruction-Trees

We now turn to the concept of obstruction-trees. We first define them and then prove some of their properties. The main property, proved in Proposition 5.6, is that the existence of such trees witnesses a lower bound for the depth of a strong recursive backdoor to the class \mathcal{C}_0 .

► **Definition 5.3** (Obstruction-Trees and Destroy Neighborhoods). *For all integers k, d and incidence graphs G in \mathcal{C}_d , we inductively for $i \geq d$ define the notion of an (i, d, k) -obstruction-tree T of G with elements $V(T)$ and destroy-neighborhood $N_G^\dagger[T]$. We use $\text{cla}(T)$ and $\text{var}(T)$ to denote the clauses and variables of $V(T)$.*

For a set $T = \{c, x_1, \dots, x_d\}$, where c is a d -clause of G with $\text{var}(c) = \{x_1, \dots, x_d\}$, we have:

1. T is a (d, d, k) -obstruction-tree.
2. $V(T)$ are the elements of T .
3. $N_G^\dagger[T] := \text{var}(T) = \{x_1, \dots, x_d\}$.

Inductively, for a triple $T = (T_1, P, T_2)$ where T_1 and T_2 are (i, d, k) -obstruction-trees of G such that $N_G^\dagger[T_1] \cap N_G^\dagger[T_2] = \emptyset$, and P is a path of length at most λ_k connecting T_1 and T_2 , we have:

73:10 Recursive Backdoors for SAT

1. T is an $(i + 1, d, k)$ -obstruction-tree.
2. $V(T) := V(T_1) \cup V(P) \cup V(T_2)$.
3. $N_G^\dagger[T] := \text{var}(T) \cup \{x : \text{there exist } c_1, c_2 \in \text{cla}(T) \text{ with } \{x, c_1\} \in E_+ \text{ and } \{x, c_2\} \in E_-\}$.

Observe that $V(T)$ is a connected subset of G . We now show, that our definition of a destroy neighborhood is a small set of variables, that shields the obstruction-tree from the rest of the graph. Remember that $\lambda_k = 4 \cdot 2^k$.

► **Proposition 5.4** (N^\dagger Is Small). *For all integers i, d, k with $d \leq k$, for every incidence graph G in \mathcal{C}_d , and every (i, d, k) -obstruction-tree T of G , we have $|V(T)| \leq 3^{i-d} \cdot \lambda_k$ and $|N_G^\dagger[T]| \leq 3^{i-d} \cdot \lambda_k \cdot d$.*

► **Proposition 5.5** (N^\dagger Is a Destroy Neighborhood). *For all integers i, d, k , every incidence graph G in \mathcal{C}_d , every (i, d, k) -obstruction-tree T of G , and every variable x of G , if $x \notin N_G^\dagger[T]$, then T is also an (i, d, k) -obstruction-tree in at least one of $G[x_+]$ and $G[x_-]$.*

Due to space constraints, both proofs were moved to Appendix A.1 and Appendix A.2. We now turn to the main property of obstruction-trees, which explains why this notion is relevant in this context.

► **Proposition 5.6** (Obstruction-Trees Obstruct). *For all integers i, d, k and every incidence graph G in \mathcal{C}_d , if there is an (i, d, k) -obstruction-tree T of G , then $\text{srbd}_{\mathcal{C}_0}(G) \geq i$.*

Proof. Proof by induction on i .

Base Case: $i = d$. Follows immediately from Lemma 5.1.

Induction Step: Let T be an $(i + 1, d, k)$ -obstruction-tree of G , and assume towards a contradiction that $\text{srbd}_{\mathcal{C}_0}(G) < i + 1$. By Definition 5.3 we get T_1 and T_2 , two (i, d, k) -obstruction-trees connected by a path P . Additionally in every connected component H of G , $\text{srbd}_{\mathcal{C}_0}(H) < i + 1$ holds as well. Since $V(T)$ is connected, there exists one component H containing T . Then, there must exist a variable x in H such that $\text{srbd}_{\mathcal{C}_0}(H[x_+]) < i$ and $\text{srbd}_{\mathcal{C}_0}(H[x_-]) < i$. Assume $x \notin N_H^\dagger[T_1]$. Then by Proposition 5.5 we get that T_1 remains an (i, d, k) -obstruction-tree in either $H[x_+]$ or $H[x_-]$. We use the induction hypothesis to conclude that one of the graphs has strong recursive backdoor depth at least i and we get a contradiction. Assume $x \in N_H^\dagger[T_1]$. Then $x \notin N_H^\dagger[T_2]$ by Definition 5.3 and we can make the same argument. ◀

Finally, and for technical reasons, we need to show that if we assign a variable, we do not increase the strong recursive backdoor depth. Also if we find an obstruction-tree after assigning some variables, then it is also an obstruction-tree in the original graph with the same destroy neighborhood.

► **Lemma 5.7** ($\text{srbd}_{\mathcal{C}_0}$ Is Closed Under Assignments). *For every integer k , every incidence graph G , and every literal x_\star in G , if $\text{srbd}_{\mathcal{C}_0}(G) \leq k$, then $\text{srbd}_{\mathcal{C}_0}(G[x_\star]) \leq k$.*

► **Proposition 5.8** (Obstruction-Trees Can Be Lifted). *For all integers i, d, k with $d \leq i$ and $d \leq k$, every incidence graph G in \mathcal{C}_d , every obstruction-tree T and every literal x_\star of G , if T is an (i, d, k) -obstruction-tree of $H := G[x_\star]$, then it is also an (i, d, k) -obstruction-tree of G and we have $N_G^\dagger[T] = N_H^\dagger[T]$.*

The proofs of these statements can be found in Appendix A.3 and Appendix A.4.

5.2 Algorithms

We finally turn to the algorithm. We first show that we can efficiently compute an obstruction-tree, or make progress towards computing a strong recursive backdoor to \mathcal{C}_0 . Making progress here means decreasing the clause degree of the graph. At every step, the algorithm may stop if it concludes that $\text{srbd}_{\mathcal{C}_0}(G) > k$.

► **Proposition 5.9** (Obstruction-Trees Are Easy to Compute). *There is an algorithm that, given three integers i, d, k , with $d \leq i \leq k + 1$, and an incidence graph G in \mathcal{C}_d , in time $2^{2^{\mathcal{O}(k)}} \cdot |G|$ either*

1. returns an (i, d, k) -obstruction-tree T , or
2. returns a strong recursive backdoor B to \mathcal{C}_{d-1} of depth at most $g(i, d, k) := 3^{i-d} \cdot \lambda_k \cdot d$, or
3. concludes that $\text{srbd}_{\mathcal{C}_0}(G) > k$.

Proof. We fix d, k and prove the claims by induction on i and $|G|$.

Base Case: When $i = d$, we search for a clause c connected to d variables. If we find c , then c is a (d, d, k) -obstruction-tree and we return it. If there is no such clause, then G is also in \mathcal{C}_{d-1} , and the leaf node labeled G is a strong recursive backdoor to \mathcal{C}_{d-1} .

Induction Step on i : We now fix i and assume that we have a working algorithm with parameters (i, d, k) for any incidence graph $G \in \mathcal{C}_d$. We now explain by induction on $|G|$ how to build an algorithm with parameters $(i + 1, d, k)$.

Base Case: In the base case $|G| = 1$, then $G \in \mathcal{C}_0$, and there is nothing to do.

Induction Step on $|G|$ when G is not connected: All connected components of G have size strictly smaller than G , and we can run the algorithm with parameters $(i + 1, d, k)$ on each. If in one connected component H , we find an $(i + 1, d, k)$ -obstruction-tree T , then T is also an $(i + 1, d, k)$ -obstruction-tree of G and we are done. If for one connected component H we have $\text{srbd}_{\mathcal{C}_0}(H) > k$, then it also holds that $\text{srbd}_{\mathcal{C}_0}(G) > k$. Finally, if for every connected component H we find a strong recursive backdoor B_H to \mathcal{C}_{d-1} of depth at most $g(i + 1, d, k)$, we can merge them to build a recursive backdoor B to \mathcal{C}_{d-1} for G . In order to do this, we insert a root node labeled G , whose children are all the B_H . Since we do not insert a variable node, B has still depth at most $g(i + 1, d, k)$.

Induction Step on $|G|$ when G is connected: In this case, we use the induction hypothesis on G with parameters (i, d, k) . If the algorithm provides a strong recursive backdoor or concludes that $\text{srbd}_{\mathcal{C}_0}(G) > k$, we are done. We focus on the case where the algorithm returns an (i, d, k) -obstruction-tree T_1 for G and $N_G^\dagger[T_1]$. We define \mathcal{T} as the set of all possible truth assignments to the variables of $N_G^\dagger[T_1]$. For every τ in \mathcal{T} , we define $H_\tau := G[\tau]$. On every H_τ we run the algorithm given by induction with parameters (i, d, k) .

Case 1: For at least one H_τ we have that $\text{srbd}_{\mathcal{C}_0}(H_\tau) > k$. By Lemma 5.7, $\text{srbd}_{\mathcal{C}_0}(G) > k$ follows.

Case 2: For at least one H_τ we find an (i, d, k) -obstruction-tree T_2 . By Proposition 5.8, T_2 is also an (i, d, k) -obstruction-tree in G and $N_{H_\tau}^\dagger[T_2] = N_G^\dagger[T_2]$. Since none of the variables in $N_G^\dagger[T_1]$ appear in H_τ , we have that $N_G^\dagger[T_1] \cap N_G^\dagger[T_2] = \emptyset$. We run a BFS algorithm to find a shortest path P between a vertex of T_1 and T_2 in G . If P has length greater than λ_k , we can conclude that $\text{srbd}_{\mathcal{C}_0}(G) > k$ by Lemma 5.2. If P has length at most λ_k , we have that $T = (T_1, P, T_2)$ is an $(i + 1, d, k)$ -obstruction-tree in G .

73:12 Recursive Backdoors for SAT

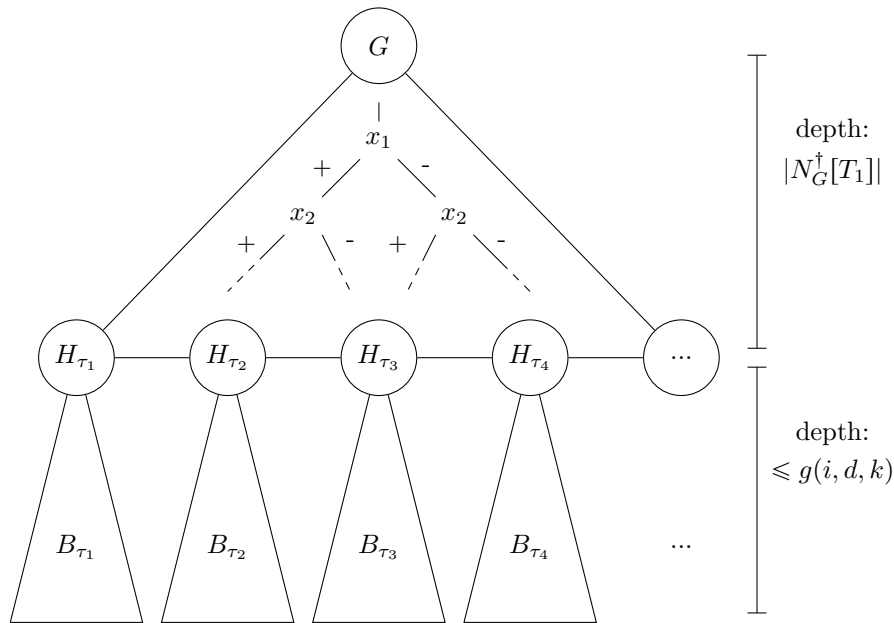

The process of constructing T is depicted in Figure 3. In the first panel we see that we have found T_2 in the graph H_τ . H_τ is an induced subgraph of G in which the variables of τ have been assigned and which therefore does not contain T_1 (see hatched area). In the second panel we lift T_2 into G , which also contains T_1 . In the third panel, all that's left to do is to combine T_1 and T_2 into T , which then is an obstruction-tree for G .

■ Figure 3 Searching an obstruction-tree.

Case 3: For every H_τ we find a strong recursive backdoor B_τ to \mathcal{C}_0 of depth at most $g(i, d, k)$. In this case, we can combine them and build a strong recursive backdoor B of G to \mathcal{C}_{d-1} . To do so, we start with the complete binary tree, where at each step we branch over one variable in $N_G^\dagger[T_1]$. At depth $|N_G^\dagger[T_1]|$, each node corresponds to an assignment τ of \mathcal{T} . We then finish the tree by plugging in B_τ in the branch corresponding to τ . B is a strong recursive backdoor of G to \mathcal{C}_{d-1} , and its depth is bounded by: $|N_G^\dagger[T_1]| + g(i, d, k) \leq g(i + 1, d, k)$.

The process of merging backdoors is depicted in Figure 4. The backdoors B_τ are depicted as trees, whose root nodes are merged by and form the leaves of a full binary tree over the variables of $N_G^\dagger[T_1]$.

■ Figure 4 Merging backdoors.

Time Complexity: The proof for the time complexity can be found in Appendix A.5. ◀

We now use the result of Proposition 5.9 sufficiently many times so that the degree of the input graph reaches 0. Again, at any point, the algorithm may stop and conclude that $\text{srbd}_{\mathcal{C}_0}(G) > k$. Remember that $\lambda_k = 4 \cdot 2^k$.

► **Theorem 5.10.** *There is an algorithm that, given as input an integer k and an incidence graph G , in time $2^{2^{\mathcal{O}(k)}} \cdot |G|$ either:*

1. *returns a strong recursive backdoor of G to \mathcal{C}_0 of depth at most $3^k \cdot \lambda_k \cdot k^2$, or*
2. *concludes that $\text{srbd}_{\mathcal{C}_0}(G) > k$.*

Proof. Let d be the maximal degree of a clause in G . If $d > k$ conclude that $\text{srbd}_{\mathcal{C}_0}(G) > k$ by Lemma 5.1. Otherwise handle G using induction on d to search for a SRB to \mathcal{C}_0 of depth at most $3^k \cdot \lambda_k \cdot d^2$:

Base Case: $G \in \mathcal{C}_0$ and the node labeled G is a SRB to \mathcal{C}_0 of depth 0.

Induction Step: $G \in \mathcal{C}_{d+1}$. Run the algorithm presented in Proposition 5.9 with parameters $(k+1, d+1, k)$ on G . If it concludes that $\text{srbd}_{\mathcal{C}_0}(G) > k$, or returns a $(k+1, d+1, k)$ -obstruction-tree, conclude that $\text{srbd}_{\mathcal{C}_0}(G) > k$ by Proposition 5.6. If a SRB B is returned, then B will have depth at most $3^{k+1-(d+1)} \cdot \lambda_k \cdot (d+1) \leq 3^k \cdot \lambda_k \cdot (d+1)$ and every leaf of B will be labeled with a graph H in \mathcal{C}_d .

We then apply the algorithm given by the induction hypothesis to every H . If for one H we get that $\text{srbd}_{\mathcal{C}_0}(H) > k$, conclude that $\text{srbd}_{\mathcal{C}_0}(G) > k$ by Lemma 5.7. If for every H we get a SRB B_H to \mathcal{C}_0 of depth at most $3^k \cdot \lambda_k \cdot d^2$, we use the results to build a SRB to \mathcal{C}_0 for G . To do so, we replace the leaf labeled H in B with B_H for every H . As a result, B will be extended to be a SRB for G to \mathcal{C}_0 with depth at most $3^k \cdot \lambda_k \cdot (d+1)^2$.

Time Complexity: The proof for the time complexity can be found in Appendix A.6. ◀

► **Corollary 5.11.** *Given a formula φ and a parameter k there is an algorithm that solves $\text{SAT}(\text{srbd}_{\mathcal{C}_0})$ in time $2^{2^{\mathcal{O}(k)}} \cdot |\varphi|$.*

Proof. We compute the satisfiability of φ in two steps. First run the algorithm given in Theorem 5.10 with parameters φ and k in time $2^{2^{\mathcal{O}(k)}} \cdot |\varphi|$. If the algorithm concludes that $\text{srbd}_{\mathcal{C}_0}(\varphi) > k$ we are finished. Otherwise a SRB with depth at most $3^k \cdot \lambda_k \cdot k^2$ of φ to \mathcal{C}_0 is returned.

Second, we make use of the calculated SRB by running the algorithm described in Proposition 3.3, to determine the satisfiability of φ . The satisfiability of a formula in \mathcal{C}_0 can be checked in constant time: If it contains no clause, then all clauses are trivially satisfied. If it contains at least one clause, then that clause is empty and unsatisfiable. Therefore the second step runs in time $\mathcal{O}(2^{3^k \cdot \lambda_k \cdot k^2} \cdot |\varphi|)$. Adding up the running times, we get a total time complexity of $2^{2^{\mathcal{O}(k)}} \cdot |\varphi|$. ◀

6 Weak Recursive Backdoor Detection to \mathcal{C}_0 Is $W[2]$ -Hard

In this section, we show that the parametrized problem of detecting a weak recursive backdoor of depth k to the class of edgeless graphs is $W[2]$ -hard when parametrized by k .

► **Theorem 6.1.** *WEAK-RECURSIVE- \mathcal{C}_0 -BACKDOOR-DETECTION is $W[2]$ -hard.*

Due to space constraints, the proof was moved to Appendix A.7.

7 Conclusion

We have proposed the new notions of *strong* and *weak recursive backdoors*, which exploit the structure of formulas that can be recursively split into independent parts by partial assignments. Recursive backdoors are measured by their depth and can contain, even at bounded depth, an unbounded number of variables. In our work we have focused on the tractable base class of empty formulas \mathcal{C}_0 . We have shown, that detecting weak recursive backdoors to \mathcal{C}_0 is $W[2]$ -hard. Our main technical contribution is an fpt algorithm that detects strong recursive backdoors of bounded depth to \mathcal{C}_0 . Even for \mathcal{C}_0 this extends tractable SAT Solving to a new class of formulas.

Our result raises the question of whether the detection of strong recursive backdoors can be expanded to larger base classes such as 2CNF or Horn. Especially 2CNF seems to be in reach, as similar to \mathcal{C}_0 , incidence graphs of formulas with bounded recursive backdoor depth to 2CNF have a bounded clause degree. This is the first ingredient for our algorithm to \mathcal{C}_0 . However our algorithm is limited to finding backdoors to \mathcal{C}_0 , as the second ingredient, which is bounded incidence graph diameter, is not given when searching for backdoors to 2CNF.

A Omitted Proofs

A.1 Proof of Proposition 5.4

Proof. The second claim easily follows the first one. The set $N_T^\dagger[G]$ contains $\text{var}(T)$ and at most the variables connected to a clause from $\text{cla}(T)$. Since $G \in \mathcal{C}_d$, we get that $|N_G^\dagger[T]| \leq |V(T)| \cdot d$. Now we prove that $|V(T)| \leq 3^{i-d} \cdot \lambda_k$ by induction on i .

Base Case: T is an (d, d, k) -obstruction-tree. By definition, $|V(T)| = |T| = d + 1 \leq 3^{d-d} \cdot \lambda_k$.

Induction Step: T is an $(i + 1, d, k)$ -obstruction-tree. Then $T = (T_1, P, T_2)$ such that T_1 and T_2 are (i, d, k) -obstruction-trees of G and $|V(T)| \leq |V(T_1)| + |V(P)| + |V(T_2)|$. We apply our induction hypothesis to conclude that both $V(T_1)$ and $V(T_2)$ have at most $3^{i-d} \cdot \lambda_k$ elements. P has at most λ_k elements by definition. We conclude that $|V(T)| \leq 3 \cdot 3^{i-d} \cdot \lambda_k = 3^{i+1-d} \cdot \lambda_k$. ◀

A.2 Proof of Proposition 5.5

In order to prove Proposition 5.5, we first prove an intermediate result:

► **Proposition A.1** (Obstruction-Trees Are only Influenced by Adjacent Variables). *For all integers i, d, k , every incidence graph G in \mathcal{C}_d , every (i, d, k) -obstruction-tree T of G , every variable x in G , and every polarity \star , if $x \notin \text{var}(T)$ and for all $c \in \text{cla}(T)$ we have $\{x, c\} \notin E_\star$, then T is still an (i, d, k) -obstruction-tree in $G[x_\star]$.*

Proof. Proof by induction on i .

Base Case: $i = d$. Then T contains a d -clause c and its adjacent variables $\text{var}(T)$. If $x \notin \text{var}(T)$, then T remains untouched and continues to be a (d, d, k) -obstruction-tree of $G[x_\star]$.

Induction Step: $i > d$. Then $T = (T_1, P, T_2)$, where T_1 and T_2 are (i, d, k) -obstruction-trees of G . Assume $x \notin \text{var}(T)$ and for all $c \in \text{cla}(T)$ we have $\{x, c\} \notin E_\star$. Since $\text{cla}(T_1)$ and $\text{cla}(T_2)$ are both subsets of $\text{cla}(T)$ we can apply our induction hypothesis and conclude that T_1 and T_2 are still (i, d, k) -obstruction-trees of $G[x_\star]$. Since $G[x_\star]$ is a subgraph of G we know that $N_{G[x_\star]}^\dagger[T_1] \cap N_{G[x_\star]}^\dagger[T_2]$ is still empty. Since x is not contained in $\text{var}(P) \subseteq \text{var}(T)$ and is also not connected to a clause of $\text{cla}(P) \subseteq \text{cla}(T)$ by polarity \star , we conclude that P still is a path of the same length in $G[x_\star]$. It follows that T must be $(i + 1, d, k)$ -obstruction-tree in $G[x_\star]$. ◀

73:16 Recursive Backdoors for SAT

We now continue with the proof of Proposition 5.5:

Proof. Assume towards a contradiction that $x \notin N_G^\dagger[T]$ and T is no (i, d, k) -obstruction-tree of $G[x_+]$ and $G[x_-]$. If T is no (i, d, k) -obstruction-tree in $G[x_+]$, then by Proposition A.1, either $x \in \text{var}(T)$ or there exists a clause c_1 connected to x by a positive edge. Since the former contradicts with $x \notin N_G^\dagger[T]$, we have that c_1 exists. Now assume that T is also no (i, d, k) -obstruction-tree in $G[x_-]$. By the same reasoning conclude that there exists a clause c_2 connected to x by a negative edge. From the existence of both c_1 and c_2 connected with different polarities to x we conclude that $x \in N_G^\dagger[T]$ and get a contradiction. \blacktriangleleft

A.3 Proof of Lemma 5.7

Proof. Proof by induction on k .

Base Case: $k = 0$. Then G is edgeless and remains edgeless when a variable is assigned.

Induction Step: Let G be an incidence graph such that $\text{srbd}_{\emptyset_0}(G) \leq k + 1$, and let x_\star be any literal of G . If G is connected, then by Definition 3.1 there exists a variable y such that $\text{srbd}_{\emptyset_0}(G[y_\star]) \leq k$. If $x = y$, then $\text{srbd}_{\emptyset_0}(G[x_\star]) \leq k + 1$ holds trivially. If $x \neq y$ then we apply our induction hypothesis and because $\text{srbd}_{\emptyset_0}(G[y_\star]) \leq k$ get that $\text{srbd}_{\emptyset_0}(G[y_\star, x_\star]) \leq k$. This leads to $\text{srbd}_{\emptyset_0}(G[x_\star, y_\star]) \leq k$, which again implies that $\text{srbd}_{\emptyset_0}(G[x_\star]) \leq k + 1$ holds. If G contains multiple components, then the same argument applies for the component that contains x and the other components remain unchanged. \blacktriangleleft

A.4 Proof of Proposition 5.8

Proof. Proof by induction on i .

Base Case: $i = d$. Then T contains a d -clause c and its variables x_1, \dots, x_d in H and $N_H^\dagger[T]$ contains all x_i . Since G has maximal clause degree d , c must also be a d -clause in G with the same neighborhood.

Induction Step: Assume T is an $(i + 1, d, k)$ obstruction-tree of H . Then $T = (T_1, P, T_2)$ such that T_1 and T_2 are (i, d, k) -obstruction-trees of H , and P is a path of length at most λ_k . By applying the induction hypothesis, we get that T_1 and T_2 are also (i, d, k) -obstruction-trees of G and that $N_G^\dagger[T_1] = N_H^\dagger[T_1]$ and $N_G^\dagger[T_2] = N_H^\dagger[T_2]$ are disjoint. P obviously still is a path of length at most λ_k in G , so T is indeed an $(i + 1, d, k)$ -obstruction-tree of G .

We now show that $N_H^\dagger[T] = N_G^\dagger[T]$. Since H is an induced subgraph of G , we get that $N_H^\dagger[T] \subseteq N_G^\dagger[T]$. To show $N_H^\dagger[T] \supseteq N_G^\dagger[T]$, pick any variable y from $N_G^\dagger[T]$. If $y \in \text{var}(T)$ we get that $y \in N_H^\dagger[T]$ by definition. If y is positively connected to c_1 and negatively connected to c_2 for two clauses $c_1, c_2 \in \text{cla}(T)$, then $y \neq x$, since otherwise the assignment of y in H would delete a clause from T , which contradicts the fact that T is an $(i + 1, d, k)$ -obstruction-tree in H . Since y is not equal to x , its edges to c_1 and c_2 are not affected by the assignment of x in H and again $y \in N_H^\dagger[T]$ holds. It follows that $N_G^\dagger[T] = N_H^\dagger[T]$. \blacktriangleleft

A.5 Time Complexity of Proposition 5.9

Proof. Let us prove by induction that the time complexity of the algorithm presented in Proposition 5.9 is $2^{2^{O(k)}} \cdot |G|$. This clearly holds when $|G| = 1$, or when $i = d$. We now move on to the induction and analyze the run of the algorithm with parameters $(i + 1, d, k)$ on a graph G .

First, note that when we split among several connected components these components are disjoint. The sum of the sizes of these components is the size of the G . Unifying the recursive backdoor, given by the components, by adding a common root node takes at most linear time, which is consistent with our hypothesis.

Second, when the graph is connected we first run the algorithm with parameters (i, d, k) . If the run does not stop there, we have an (i, d, k) -obstruction-tree T . We then consider a number of truth assignments that is bounded by $2^{N_G^{\dagger}[T]}$. For each of these assignment, we run again our algorithm with parameters (i, d, k) , on graphs smaller than G .

If we find a second (i, d, k) -obstruction-tree we then only need to compute shortest path, which can be performed in linear time. If every truth assignment provides a backdoor-tree, plugging them together only takes time linear in the number of possible truth assignments.

All together the procedure stays linear and the constant factor gets multiplied by a factor of the form $O\left(2^{N_G^{\dagger}[T]}\right)$ each time i decreases by one. By Proposition 5.4, this is bounded by $O\left(2^{3^{i-d} \cdot \lambda_k \cdot d}\right)$. Using that both $d \leq k$ and $i \leq k + 1$, this is of the form $2^{2^{O(k)}}$. As i can decrease by one at most $i - d$ many times (and therefore at most i many times) until we get to a base case, we get that the final constant factor is of the form $\left(2^{2^{O(k)}}\right)^i = 2^{i2^{O(k)}} = 2^{2^{O(k)}}$.

We finally have that the overall complexity of a run with parameters (i, d, k) on a graph G is bounded by $2^{2^{O(k)}} \cdot |G|$. ◀

A.6 Time Complexity of Theorem 5.10

Proof. Let $f(k) \cdot |G|$ be the time complexity of Proposition 5.9 and $g(k, d)$ be $3^k \cdot \lambda_k \cdot d$. We prove the time complexity of $2^{g(k,d) \cdot d} \cdot f(k) \cdot |G|$ by induction on d . If $d = 0$ then we only have to construct a single node, which can be done in constant time. For graphs in \mathcal{C}_{d+1} , running the algorithm of Proposition 5.9 can be done in time $f(k) \cdot |G|$. If we do not find a SRB, we can abort. Otherwise we find a SRB of depth at most $g(k, d + 1)$ such that all its leaves are members of \mathcal{C}_d . We can apply our induction hypothesis and assume that for a single leaf H , we can finish in time $2^{g(k,d) \cdot d} \cdot f(k) \cdot |H|$. Since the sum of the number of vertices in all leafs of the backdoor is at most $2^{g(k,d+1)} \cdot |G|$, we get that full algorithm has a running time in

$$f(k) \cdot |G| + 2^{g(k,d) \cdot d} \cdot f(k) \cdot 2^{g(k,d+1)} \cdot |G| \leq 2^{g(k,d+1) \cdot (d+1)} \cdot f(k) \cdot |G|.$$

Since both $2^{g(k,d) \cdot d}$ and $f(k)$ are in $2^{2^{O(k)}}$, the overall time complexity of the algorithm is in $2^{2^{O(k)}} \cdot |G|$. ◀

A.7 Proof of Theorem 6.1

Proof. We are going to show the W[2]-hardness of WEAK-RECURSIVE- \mathcal{C}_0 -BACKDOOR-DETECTION (WR- \mathcal{C}_0 -BD) by reduction from the W[2]-complete SET COVER problem [2, Theorem 13.28]. An instance I of the SET COVER problem is composed of a universe U , an integer k , and a set $S \subseteq P(U)$. I is a yes-instance if there exists a subset L of S with size at most k , such that the union of all sets in L is equal to U .

We reduce $I = (S, U, k)$ to the WR- \mathcal{C}_0 -BD instance $(\varphi, k + 1)$, where φ is a CNF formula over the variables $\{b_1, \dots, b_{k+2}, s_1, \dots, s_n\}$, where $n = |S|$. This formula is constructed in the following way:

73:18 Recursive Backdoors for SAT

For each element of the universe $u \in U$ a corresponding clause σ_u is created, which we call *element-clauses*. For each set S_i a corresponding variable vertex s_i is created, which we call *set-variables*. Then s_i and σ_u are connected by a positive edge when $u \in S_i$. Therefore in the incidence graph, s_i dominates all the clauses whose corresponding elements are contained in S_i .

In addition, we create $k + 2$ fresh variables b_i . Each are individually and positively connected to a fresh clause β_i . Furthermore, all b_i are negatively connected to all σ_u , creating a $K_{k+2,|U|}$ bi-clique. More formally, we have:

$$\begin{aligned}\beta_i &:= b_i \\ \sigma_u &:= \bigvee_{i=1}^{k+2} \neg b_i \vee \bigvee_{\{i \leq n : u \in S_i\}} s_i \\ \varphi &:= \bigwedge_{i=1}^{k+2} \beta_i \wedge \bigwedge_{u \in U} \sigma_u\end{aligned}$$

We will now prove that this is in fact a valid reduction.

\Rightarrow : If $I = (\{S_1, \dots, S_n\}, U, k)$ is a yes-instance, there exists a set of indices $J \subseteq \{1, \dots, n\}$ of at most size k such that $\bigcup_{j \in J} S_j = U$. We construct the weak recursive backdoor $\{s_{j+} | j \in J\}$ of size and depth at most k that dominates all element clauses. Once every variable s_j has been assigned, every element-clause σ_u has been satisfied. Only the $k + 2$ clauses β_i remain. These clauses are disjoint. We can therefore complete the backdoor by adding at depth $k + 1$ every literal b_i simultaneously.

\Leftarrow : Let $I = (S, U, k)$ be an instance for the SET COVER, and assume that $I' = (\varphi, k)$ is a yes-instance. Then there must exist a weak recursive backdoor of depth at most k that reduces φ to an edgeless graph. In order to satisfy every β_i clause, each of the b_i literals must be contained in the backdoor. Therefore the size of the backdoor is at least $k + 2$. Since the backdoor can have depth at most $k + 1$, at least two of the β_i clauses have to be split into disconnected components and satisfied separately at some point.

Since every variable b_i is connected to every element-clause σ_u , the graph only contains one connected component, as long as a clause σ_u is not satisfied. Since the literals $\neg b_i$ cannot be part of the backdoor, there must be a set of only set-variables that when assigned satisfy every element-clause. In order to not exceed the recursion depth of $k + 1$, that set must be of size at most k . Having a set of at most k set variables satisfying every element-clause implies the existence of a set cover of U of at most k elements. So I is a yes-instance. \blacktriangleleft

Parallel Algorithms for Power Circuits and the Word Problem of the Baumslag Group

Caroline Mattes ✉

Institut für Formale Methoden der Informatik (FMI), University of Stuttgart, Germany

Armin Weiß ✉ 

Institut für Formale Methoden der Informatik (FMI), University of Stuttgart, Germany

Abstract

Power circuits have been introduced in 2012 by Myasnikov, Ushakov and Won as a data structure for non-elementarily compressed integers supporting the arithmetic operations addition and $(x, y) \mapsto x \cdot 2^y$. The same authors applied power circuits to give a polynomial-time solution to the word problem of the Baumslag group, which has a non-elementary Dehn function.

In this work, we examine power circuits and the word problem of the Baumslag group under parallel complexity aspects. In particular, we establish that the word problem of the Baumslag group can be solved in NC – even though one of the essential steps is to compare two integers given by power circuits and this, in general, is shown to be P-complete. The key observation is that the depth of the occurring power circuits is logarithmic and such power circuits can be compared in NC.

1 Introduction

The *word problem* of a finitely generated group G is as follows: does a given word over the generators of G represent the identity of G ? It was first studied by Dehn as one of the basic algorithmic problems in group theory [8]. Already in the 1950s, Novikov and Boone succeeded to construct finitely presented groups with an undecidable word problem [5, 33]. Nevertheless, many natural classes of groups have an (efficiently) decidable word problem – most prominently the class of linear groups (groups embeddable into a matrix group over some field): their word problem is in LOGSPACE [22, 38] – hence, in particular, in NC, i.e., decidable by Boolean circuits of polynomial size and polylogarithmic depth.

There are various other results on word problems of groups in small parallel complexity classes defined by circuits. For example the word problems of solvable linear groups are even in TC^0 (constant depth with threshold gates) [19] and the word problems of Baumslag-Solitar groups and of right-angled Artin groups are AC^0 -Turing-reducible to the word problem of a non-abelian free group [42, 18]. Moreover, Thompson’s groups are co-context-free [21] and hyperbolic groups have word problem in LOGCFL [23]. All these classes are contained within NC. On the other hand, there are also finitely presented groups with a decidable word problem but with arbitrarily high complexity [36].

A mysterious class of groups under this point of view are one-relator groups, i.e. groups that can be written as a free group modulo a normal subgroup generated by a single element (*relator*). Magnus [26] showed that one-relator groups have a decidable word problem; his algorithm is called the Magnus breakdown procedure (see also [25, 27]). Nevertheless, the

complexity remains an open problem – although it is not even clear whether the word problems of one-relator groups are solvable in elementary time, in [3] the question is raised whether they are actually decidable in polynomial time.

In 1969 Gilbert Baumslag defined the group $\mathbf{G}_{1,2} = \langle a, b \mid bab^{-1}a = a^2bab^{-1} \rangle$ as an example of a one-relator group which enjoys certain remarkable properties. It is infinite and non-abelian, but all its finite quotients are cyclic and, thus, it is not residually finite [4]. Moreover, Gersten showed that the Dehn function of $\mathbf{G}_{1,2}$ is non-elementary [15] and Platonov [34] made this more precise by proving that it is (roughly) $\tau(\log n)$ where $\tau(0) = 1$ and $\tau(i + 1) = 2^{\tau(i)}$ for $i \geq 0$ is the tower function (note that he calls the group Baumslag-Gersten group). Since the Dehn function gives an upper bound on the complexity of the word problem, the Baumslag group was a candidate for a group with a very difficult word problem. Indeed, when applying the Magnus breakdown procedure to an input word of length n , one obtains as intermediate results words of the form $v_1^{x_1} \cdots v_m^{x_m}$ where $v_i \in \{a, b, bab^{-1}\}$, $x_i \in \mathbb{Z}$, and $m \leq n$. The issue is that the x_i might grow up to $\tau(\log n)$; hence, this algorithm has non-elementary running time. However, as foreseen by the above-mentioned conjecture, Myasnikov, Ushakov and Won succeeded to show that the word problem of $\mathbf{G}_{1,2}$ is, indeed, decidable in polynomial time [30]. Their crucial contribution was to introduce so-called *power circuits* in [31] for compressing the x_i in the description above.

Roughly speaking, a *power circuit* is a directed acyclic graph (a dag) where the edges are labelled by ± 1 . One can define an evaluation of a vertex P as two raised to the power of the (signed) sum of the successors of P . Note that this way the value $\tau(n)$ of the tower function can be represented by an n -vertex power circuit – thus, power circuits allow for a non-elementary compression. The crucial feature for the application to the Baumslag group is that power circuits not only efficiently support the operations $+$, $-$, and $(x, y) \mapsto x \cdot 2^y$, but also the test whether $x = y$ or $x < y$ for two integers represented by power circuits can be done in polynomial time. The main technical part of the comparison algorithm is the so-called reduction process, which computes a certain normal form for power circuits.

Based on these striking results, Diekert, Laun and Ushakov [10, 9] improved the algorithm for power circuit reduction and managed to decrease the running time for the word problem of the Baumslag group from $\mathcal{O}(n^7)$ down to $\mathcal{O}(n^3)$. They also describe a polynomial-time algorithm for the word problem of the famous Higman group H_4 [16]. In [32] these algorithms have been implemented in C++. Subsequently, more applications of power circuits to these groups emerged: in [20] a polynomial time solution to the word problem in generalized Baumslag and Higman groups is given, in [12, 11] the conjugacy problem of the Baumslag group is shown to be strongly generically in P and in [2] the same is done for the conjugacy problem of the Higman group. Here “generically” roughly means that the algorithm works for most inputs (for details on the concept of generic complexity, see [17]).

Other examples where compression techniques lead to efficient algorithms in group theory can be found e.g. in [13, 14] or [24, Theorems 4.6, 4.8 and 4.9]. Finally, notice that in [29] the word search problem for the Baumslag group has been examined using parametrized complexity.

Contribution. The aim of this work is to analyze power circuits and the word problem of the Baumslag group under the view of parallel (circuit) complexity. For doing so, we first examine so-called *compact* representations of integers and show that ordinary binary representations can be converted into compact representations by constant depth circuits (i.e., in AC^0 – see Section 3). We apply this result in the power circuit reduction process, which is the main technical contribution of this paper. While [31, 10] give only polynomial

time algorithms, we present a more refined method and analyze it in terms of parametrized circuit complexity. The parameter here is the depth D of the power circuit. More precisely, we present threshold circuits of depth $\mathcal{O}(D)$ for power circuit reduction – implying our first main result:

► **Proposition A.** *The problem of comparing two integers given by power circuits of logarithmic depth is in TC^1 (decidable by logarithmic-depth, polynomial-size threshold circuits).*

We then analyze the word problem of the Baumslag group carefully. A crucial step is to show that all appearing power circuits have logarithmic depth. Using Proposition A we succeed to describe a TC^1 algorithm for computing the Britton reduction of uv if u and v are already Britton-reduced (Britton reductions are the basic step in the Magnus breakdown procedure – see Section 5 for a definition). This leads to the following result:

► **Theorem B.** *The word problem of the Baumslag group $\mathbf{G}_{1,2}$ is in TC^2 .*

In the final part of the paper we prove lower bounds on comparison in power circuits, and thus, on power circuit reduction. In particular, this emphasizes the relevance of Proposition A and shows that our parametrized analysis of power circuit reduction is essentially the best one can hope for. Moreover, Theorem C highlights the importance of the logarithmic depth bound for the power circuits appearing during the proof of Theorem B.

► **Theorem C.** *The problem of comparing two integers given by power circuits is P-complete.*

Power circuits can be seen in the broader context of arithmetic circuits and arithmetic complexity. Thus, results on power circuits also give further insight into these arithmetic circuits. Notice that the corresponding logic over natural numbers with addition and 2^x has been shown to be decidable by Semënov [37]. In the full version [28] we show that, indeed, for every power circuit with a marking M there is an arithmetic circuit of polynomial size with $+$, $-$, and 2^x -gates evaluating to the same number and vice-versa.

Due to space constraints we present only short outlines of the proofs for our main theorems; the full proofs as well as further details can be found in the full version on arXiv [28]. Details of the reduction process also can be found in the appendix.

2 Notation and preliminaries

General notions. We use standard \mathcal{O} -notation for functions from \mathbb{N} to non-negative reals $\mathbb{R}^{\geq 0}$, see e.g. [7]. Throughout, the logarithm \log is with respect to base two. The *tower function* $\tau: \mathbb{N} \rightarrow \mathbb{N}$ is defined by $\tau(0) = 1$ and $\tau(i+1) = 2^{\tau(i)}$ for $i \geq 0$. It is primitive recursive, but $\tau(6)$ written in binary cannot be stored in the memory of any conceivable real-world computer. We denote the support of a function $f: X \rightarrow \mathbb{R}$ by $\sigma(f) = \{x \in X \mid f(x) \neq 0\}$. Furthermore, the interval of integers $\{i, \dots, j\} \subseteq \mathbb{Z}$ is denoted by $[i..j]$ and we define $[n] = [0..n-1]$. We write $\mathbb{Z}[1/2] = \{p/2^q \in \mathbb{Q} \mid p, q \in \mathbb{Z}\}$ for the set of dyadic fractions.

Let Σ be a set. The set of all words over Σ is denoted by $\Sigma^* = \bigcup_{n \in \mathbb{N}} \Sigma^n$. The length of a word $w \in \Sigma^*$ is denoted by $|w|$. A dag is a directed acyclic graph. For a dag Γ we write $\text{depth}(\Gamma)$ for its depth, which is the length (number of edges) of a longest path in Γ .

Complexity. We assume the reader to be familiar with the complexity classes LOGSPACE and P (polynomial time); see e.g. [1] for details. Most of the time, however, we use circuit complexity within NC.

Throughout, we assume that languages L (resp. inputs to functions f) are encoded over the binary alphabet $\{0, 1\}$. A Boolean circuit is a dag where the vertices are either input gates x_1, \dots, x_n , or NOT, AND, or OR gates. There are one or more designated output gates

and there is an order given on the output gates. All gates may have unbounded fan-in (i.e., there is no bound on the number of incoming wires). Let $k \in \mathbb{N}$. A language $L \subseteq \{0, 1\}^*$ belongs to AC^k if there exists a family $(C_n)_{n \in \mathbb{N}}$ of Boolean circuits such that $x \in L \cap \{0, 1\}^n$ if and only if the (unique) output gate of C_n evaluates to 1 when assigning $x = x_1 \cdots x_n$ to the input gates. Moreover, C_n may contain at most $n^{\mathcal{O}(1)}$ gates and have depth $\mathcal{O}(\log^k n)$. Likewise AC^k -computable functions are defined.

The class TC^k is defined analogously with the difference that also MAJORITY gates are allowed (a MAJORITY gate outputs 1 if its input contains more 1s than 0s). Moreover, $\text{NC} = \bigcup_{k \geq 0} \text{TC}^k = \bigcup_{k \geq 0} \text{AC}^k$. For more details on circuits we refer to [40]. Our algorithms (or circuits) rely on two basic building blocks which can be done in TC^0 :

► **Example 1.** Iterated addition is the following problem: on input of n binary numbers A_1, \dots, A_n each having n bits, compute $\sum_{i=1}^n A_i$. This is well-known to be in TC^0 – see e.g. [40, Theorem 1.37] for a proof.

► **Example 2.** Let $(k_1, v_1), \dots, (k_n, v_n)$ be a list of n key-value pairs (k_i, v_i) equipped with a total order on the keys k_i such that it can be decided in TC^0 whether $k_i < k_j$. Then the problem of sorting the list according to the keys is in TC^0 : the desired output is a list $(k_{\pi(1)}, v_{\pi(1)}), \dots, (k_{\pi(n)}, v_{\pi(n)})$ for some permutation π such that $k_{\pi(i)} \leq k_{\pi(j)}$ for all $i < j$.

We briefly describe a circuit family to do so: The first layer compares all pairs of keys k_i, k_j in parallel. For all i and j the next layer computes a Boolean value $P(i, j)$ which is true if and only if $|\{\ell \mid k_\ell < k_i\}| = j$. The latter is computed by iterated addition. As a final step the j -th output pair is set to (k_i, v_i) if and only if $P(i, j)$ is true.

► **Remark 3.** The class NC is contained in P if we consider uniform circuits. Roughly speaking, a circuit family is called *uniform* if the n -input circuit can be computed efficiently from the string 1^n . In order not to overload the presentation, throughout, we state all our results in the non-uniform case – all uniformity considerations are left to the reader.

Parametrized circuit complexity. In our work we also need some parametrized version of the classes TC^k , which we call *depth-parametrized* TC^k . Let $\text{par}: \{0, 1\}^* \rightarrow \mathbb{N}$ (called the *parameter*). Consider a family of circuits $(C_{n,D})_{n,D \in \mathbb{N}}$ such that $C_{n,D}$ contains at most $n^{\mathcal{O}(1)}$ gates (independently of D)¹ and has depth $\mathcal{O}(D \cdot \log^k n)$. A language L is said to be accepted by this circuit family if for all n and D and all $x \in \{0, 1\}^n$ with $\text{par}(x) \leq D$ we have $x \in L$ if and only if $C_{n,D}$ evaluates to 1 on input x . Similarly, $f: \{0, 1\}^* \rightarrow \{0, 1\}^*$ is computed by $(C_{n,D})_{n,D \in \mathbb{N}}$ if for all n and D and all $x \in \{0, 1\}^n$ with $\text{par}(x) \leq D$ the circuit $C_{n,D}$ evaluates to $f(x)$ on input x . We define DepParaTC^k as the class of languages (resp. functions) for which there are such parametrizations $\text{par}: \{0, 1\}^* \rightarrow \mathbb{N}$ and families of circuits $(C_{n,D})_{n,D \geq 0}$. Note that this is not a standard definition – but it perfectly fits our purposes.

► **Lemma 4.** Let $C > 0, k, \ell \in \mathbb{N}$ and $\text{par}: \{0, 1\}^* \rightarrow \mathbb{N}$ such that $\{w \in \{0, 1\}^* \mid \text{par}(w) \leq C \cdot \lfloor \log |w| \rfloor^\ell\} \in \text{TC}^{k+\ell}$ and $L \in \text{DepParaTC}^k$ (parametrized by par). Then $\tilde{L} = \{w \in L \mid \text{par}(w) \leq C \cdot \lfloor \log |w| \rfloor^\ell\}$ is in $\text{TC}^{k+\ell}$.

Power circuits. Consider a pair (Γ, δ) where Γ is a set of n vertices and δ is a mapping $\delta: \Gamma \times \Gamma \rightarrow \{-1, 0, +1\}$. Notice that $(\Gamma, \sigma(\delta))$ is a directed graph. Throughout we require that $(\Gamma, \sigma(\delta))$ is acyclic – i.e., it is a dag. In particular, $\delta(P, P) = 0$ for all vertices P . A

¹ Here and in most other natural applications the parameter D is bounded by the input size n . In this case, we could let the size of $C_{n,D}$ be a polynomial in both n and D – without changing the actual class.

marking is a mapping $M: \Gamma \rightarrow \{-1, 0, +1\}$. Each node $P \in \Gamma$ is associated in a natural way with a marking $\Lambda_P: \Gamma \rightarrow \{-1, 0, +1\}$, $Q \mapsto \delta(P, Q)$ called its successor marking. We define the evaluation $\varepsilon(P) \in \mathbb{R}_{>0}$ of a node ($\varepsilon(M) \in \mathbb{R}$ of a marking resp.) bottom-up in the dag by induction: leaves (nodes of out-degree 0) evaluate to 1 and, in general,

$$\varepsilon(P) = 2^{\varepsilon(\Lambda_P)} \quad \text{for a node } P, \quad \varepsilon(M) = \sum_P M(P)\varepsilon(P) \quad \text{for a marking } M.$$

► **Definition 5.** A power circuit is a pair (Γ, δ) with $\delta: \Gamma \times \Gamma \rightarrow \{-1, 0, +1\}$ such that $(\Gamma, \sigma(\delta))$ is a dag and all nodes evaluate to some positive natural number in $2^{\mathbb{N}}$.

The size of a power circuit is the number of nodes $|\Gamma|$. By abuse of language, we also simply call Γ a power circuit and suppress δ whenever it is clear. If M is a marking on Γ and $S \subseteq \Gamma$, we write $M|_S$ for the restriction of M to S . Let (Γ', δ') be a power circuit, $\Gamma \subseteq \Gamma'$, $\delta = \delta'|_{\Gamma \times \Gamma}$, and $\delta'|_{\Gamma \times (\Gamma' \setminus \Gamma)} = 0$. Then (Γ, δ) itself is a power circuit. We call it a *sub-power circuit* and denote this by $(\Gamma, \delta) \leq (\Gamma', \delta')$ or, if δ is clear, by $\Gamma \leq \Gamma'$.

If M is a marking on $S \subseteq \Gamma$, we extend M to Γ by setting $M(P) = 0$ for $P \in \Gamma \setminus S$. With this convention, every marking on Γ also can be seen as a marking on Γ' if $\Gamma \leq \Gamma'$.

► **Example 6.** A power circuit of size n can realize $\tau(n)$ since a directed path of n nodes represents $\tau(n)$ as the evaluation of the last node. The following power circuit realizes $\tau(6)$ using 6 nodes:

► **Example 7.** We can represent every integer in the range $[-2^n - 1, 2^n - 1]$ as the evaluation of some marking in a power circuit with node set $\{P_0, \dots, P_{n-1}\}$ with $\varepsilon(P_i) = 2^i$ for $i \in [n]$. Thus, we can convert the binary notation of an n -bit integer into a power circuit with n vertices and $\mathcal{O}(n \log n)$ edges (each successor marking requires at most $\lfloor \log n \rfloor + 1$ edges). For an example of a marking representing the integer 23, see Figure 1.

■ **Figure 1** Each integer $z \in [-63..63]$ can be represented by a marking in the following power circuit. The marking given in blue is representing the number 23.

► **Definition 8.** We call a marking M compact if for all $P, Q \in \sigma(M)$ with $P \neq Q$ we have $|\varepsilon(\Lambda_P) - \varepsilon(\Lambda_Q)| \geq 2$. A reduced power circuit of size n is a power circuit (Γ, δ) with Γ given as a sorted list $\Gamma = (P_0, \dots, P_{n-1})$ such that all successor markings are compact and $\varepsilon(P_i) < \varepsilon(P_j)$ whenever $i < j$. In particular, all nodes have pairwise distinct evaluations.

It turns out to be crucial that the nodes in Γ are sorted by their values. Still, sometimes it is convenient to treat Γ as a set – we write $P \in \Gamma$ or $S \subseteq \Gamma$ with the obvious meaning. For more details on power circuits see [10, 31].

► **Remark 9.** If (Γ, δ) is a reduced power circuit with $\Gamma = (P_0, \dots, P_{n-1})$, we have $\delta(P_i, P_j) = 0$ for $j \geq i$. Thus, the order on Γ by evaluations is also a topological order on the dag $(\Gamma, \sigma(\delta))$.

3 Compact signed-digit representations

► **Definition 10.**

- (i) A sequence $B = (b_0, \dots, b_{m-1})$ with $b_i \in \{-1, 0, +1\}$ for $i \in [m]$ is called a signed-digit representation of $\text{val}(B) = \sum_{i=0}^{m-1} b_i \cdot 2^i \in \mathbb{Z}$.
- (ii) The digit-length of $B = (b_0, \dots, b_{m-1})$ is the maximal i with $b_{i-1} \neq 0$.
- (iii) The sequence $B = (b_0, \dots, b_{m-1})$ is called compact if $b_i b_{i-1} = 0$ for all $i \in [1..m-1]$ (i.e., no two successive digits are non-zero).

Henceforth, we abbreviate “compact signed-digit representation” with csdr. A non-negative binary number is the special case of a signed-digit representation where all b_i are 0 or 1 (note that, in general, they are not compact). In particular, every integer k can be represented as a signed-digit representation. However, in general, a signed-digit representation for an integer k is not unique. In [31, Section 2.1] a linear-time algorithm for calculating csdrs has been given; here we aim for optimizing the parallel complexity.

► **Theorem 11.** *The following is in AC^0 :*

- Input: A binary number $A = (a_0, \dots, a_{m-1})$.
Output: A compact signed-digit representation of A .

Proof sketch. Computation of the csdr is in the spirit of a carry-lookahead adder: On input of the binary number $A = (a_0, \dots, a_{m-1})$ we define

$$c_i = \bigvee_{1 \leq j \leq i} \left(a_j \wedge a_{j-1} \wedge \bigwedge_{j < k \leq i} (a_k \vee a_{k-1}) \right), \quad \text{and} \quad b_i = (a_i \oplus c_i) \cdot (-1)^{a_{i+1}}.$$

Here \oplus denotes the *exclusive or* and we treat the Boolean values 0, 1 as a subset of the integers. Then $B = (b_0, \dots, b_{m-1}, b_m)$ can be calculated in AC^0 using the above formulas. The main part of the proof consists in showing that B , indeed, is compact and that $\text{val}(B) = \text{val}(A)$. This is done by induction using the recurrence $c_0 = 0$ and $c_i = (a_i \wedge a_{i-1}) \vee (c_{i-1} \wedge (a_i \vee a_{i-1}))$ for $i \geq 1$. ◀

► **Lemma 12** ([31, Lemma 4]). *Let $A = (a_0, \dots, a_{m-1})$, $B = (b_0, \dots, b_{m-1})$ be csdrs. Then:*

- (i) $\text{val}(A) = \text{val}(B)$ if and only if $a_i = b_i$ for all $i \in [m]$.
- (ii) Assume there is some i with $a_i \neq b_i$ and let $i_0 = \max\{i \in [m] \mid a_i \neq b_i\}$. Then $\text{val}(A) < \text{val}(B)$ if and only if $a_{i_0} < b_{i_0}$.

From this lemma together with Theorem 11 it follows that each $k \in \mathbb{Z}$ can be uniquely represented by a compact signed digit representation $\text{CR}(k)$. Likewise for a signed digit representation A , we write $\text{CR}(A)$ for its compact signed digit representation.

If A and B are signed digit representations, it follows from Theorem 11 and Lemma 12 that we can calculate $\text{CR}(A)$ and $\text{CR}(A + B)$ and decide whether $\text{val}(A) < \text{val}(B)$ in AC^0 .

4 Operations on power circuits

Basic operations. Before we consider the computation of reduced power circuits, which is our main result in this section, let us introduce some more notation on power circuits and recall the basic operations from [31, 10] under circuit complexity aspects.

► **Definition 13.** *Let (Γ, δ) be a reduced power circuit with $\Gamma = (P_0, \dots, P_{n-1})$.*

- (i) A chain C of length $\ell = |C|$ in Γ starting at $P_i = \text{start}(C)$ is a sequence $(P_i, \dots, P_{i+\ell-1})$ such that $\varepsilon(P_{i+j+1}) = 2 \cdot \varepsilon(P_{i+j})$ for all $j \in [\ell - 1]$.

- (ii) We call a chain C maximal if it cannot be extended in either direction. We denote the set of all maximal chains by \mathcal{C}_Γ .
- (iii) There is a unique maximal chain C_0 containing the node P_0 of value 1. We call C_0 the initial maximal chain of Γ and denote it by $C_0 = C_0(\Gamma)$.

For an example of a power circuit with three maximal chains, see Figure 2.

Figure 2 This power circuit is an example for a reduced power circuit with three maximal chains: The first one consists of the nodes of values 1, 2, 4, 8, the next one is formed by the nodes of values 2^8 and 2^9 and the node of value 2^{2^9} is a maximal chain of length 1.

► **Proposition 14.** Let $\Delta \in \{=, \neq, <, \leq, >, \geq\}$. The following problem is in AC^0 :

Input: A reduced power circuit (Γ, δ) with compact markings L, M and $k \in \left[0 .. \left\lfloor \frac{2^{|C_0|+1}}{3} \right\rfloor\right]$ given in binary.
Question: Is $\varepsilon(L) \Delta \varepsilon(M) + k$?

► **Lemma 15.** The following problems are all in TC^0 :

- (a) **Input:** A power circuit (Π, δ_Π) together with markings K and L .
Output: A power circuit $(\Pi', \delta_{\Pi'})$ with a marking M such that $\varepsilon(M) = \varepsilon(K) + \varepsilon(L)$ and $(\Pi, \delta_\Pi) \leq (\Pi', \delta_{\Pi'})$, $|\Pi'| \leq 2 \cdot |\Pi|$ and $\text{depth}(\Pi') = \text{depth}(\Pi)$.
- (b) **Input:** A power circuit (Π, δ_Π) together with a marking L .
Output: A marking M in the power circuit (Π, δ_Π) such that $\varepsilon(M) = -\varepsilon(L)$.
- (c) **Input:** A power circuit (Π, δ_Π) together with markings K and L such that $\varepsilon(L) \geq 0$.
Output: A power circuit $(\Pi', \delta_{\Pi'})$ with a marking M such that $\varepsilon(M) = \varepsilon(K) \cdot 2^{\varepsilon(L)}$ and $(\Pi, \delta_\Pi) \leq (\Pi', \delta_{\Pi'})$, $|\Pi'| \leq 3 \cdot |\Pi|$ and $\text{depth}(\Pi') \leq \text{depth}(\Pi) + 1$.

Lemma 15 applies the constructions from [31, Section 7] and [10, Section 2]. For (c) it can be summarized as follows: Add L to the successor marking of every node in $\sigma(K)$. To prevent other nodes from changing their value, first create disjoint copies of $\sigma(K)$ and $\sigma(L)$.

► **Remark 16.** Since membership in AC^0 often highly depends on the encoding of the input, we assume that power circuits are given in a suitable way, e.g. as an $n \times n$ matrix representing δ where each entry from $\{0, \pm 1\}$ is encoded using two bits, similarly for markings. If the power circuit is reduced, the nodes appear sorted according to their values.

We need these assumptions for proving the AC^0 -bound in Proposition 14. However, in the following, we do not consider these encoding issues because, as soon as we are dealing with TC^0 circuits, there is a lot of freedom how to encode inputs. Also note that in Lemma 15 we only state membership in TC^0 , although, with some proper work (and suitable encodings), one could also show AC^0 .

Power circuit reduction

While compact markings on a reduced power circuit yield unique representations of integers, in an arbitrary power circuit (Π, δ_Π) we can have two markings L and M such that $L \neq M$ but $\varepsilon(L) = \varepsilon(M)$. Therefore, given an arbitrary power circuit, we wish to produce a reduced power circuit for comparing markings. This is done by the following theorem, which is our main technical result on power circuits.

► **Theorem 17.** *The following is in DepParaTC^0 parametrized by $\text{depth}(\Pi)$:*

- Input:** A power circuit (Π, δ_Π) together with a marking M on Π .
Output: A reduced power circuit (Γ, δ) together with a compact marking \tilde{M} on Γ such that $\varepsilon(\tilde{M}) = \varepsilon(M)$.

For a power circuit (Π, δ_Π) with a marking M we call the power circuit (Γ, δ) together with the marking \tilde{M} obtained by Theorem 17 the *reduced form* of Π .

The proof of Theorem 17 consists of several steps, which we introduce on the next pages. The high-level idea is as follows: Like in [31, 10], we keep the invariant that there is an already reduced part and a non-reduced part (initially the non-reduced part is Π). The main difference is that in one iteration we insert *all* the nodes of the non-reduced part that have only successors in the reduced part into the reduced part. Each iteration can be done in TC^0 ; after $\text{depth}(\Pi) + 1$ iterations we obtain a reduced power circuit.

Insertion of new nodes. The following procedure is a basic tool for the reduction process. Let (Γ, δ) be a reduced power circuit and I be a set of nodes with $\Gamma \cap I = \emptyset$. Assume that for every $P \in I$ there exists a marking $\Lambda_P: \Gamma \rightarrow \{-1, 0, 1\}$ such that Λ_P is compact and $\varepsilon(\Lambda_P) \geq 0$ for all $P \in I$, and $\varepsilon(\Lambda_P) \neq \varepsilon(\Lambda_Q)$ for all $P, Q \in I \cup \Gamma$ with $P \neq Q$.

We wish to add I to the reduced power circuit (Γ, δ) . For this, we set $\Gamma' = \Gamma \cup I$ and define $\delta': \Gamma' \times \Gamma' \rightarrow \{-1, 0, 1\}$ in the obvious way: $\delta'|_{\Gamma \times \Gamma} = \delta$, $\delta'|_{\Gamma' \times I} = 0$ and $\delta'(P, Q) = \Lambda_P(Q)$ for $(P, Q) \in I \times \Gamma$. Now, (Γ', δ') is a power circuit with $(\Gamma, \delta) \leq (\Gamma', \delta')$ and for every $P \in I$ the map Λ_P is the successor marking of P . Moreover, each node of Γ' has a unique value. Since for every node $P \in \Gamma'$ the marking Λ_P is a compact marking on the reduced power circuit Γ , by Proposition 14, for $P, Q \in \Gamma'$ we are able to decide in AC^0 whether $\varepsilon(\Lambda_Q) \leq \varepsilon(\Lambda_P)$. Therefore, by Example 2 we can sort Γ' according to the values of the nodes in TC^0 and, hence, assume that $\Gamma' = (P_0, \dots, P_{|\Gamma'| - 1})$ is in increasing order. This yields the following:

► **Lemma 18 (INSERTNODES).** *The following problem is in TC^0 :*

- Input:** A power circuit (Γ, δ) and a set I with the properties described above.
Output: A reduced power circuit (Γ', δ') such that $(\Gamma, \delta) \leq (\Gamma', \delta')$ and such that for every $P \in I$ there is a node Q in Γ' with $\Lambda_Q = \Lambda_P$. In addition, $|\Gamma'| = |\Gamma| + |I|$, and $|\mathcal{C}_{\Gamma'}| \leq |\mathcal{C}_\Gamma| + |I|$.

The three steps of the reduction process. The reduction process for a power circuit (Π, δ_Π) with a marking M consists of several iterations. Each iteration starts with a power circuit $(\Gamma_i \cup \Xi_i, \delta_i)$ such that Γ_i is a reduced sub-power circuit and a marking M_i with $\varepsilon(M_i) = \varepsilon(M)$. The aim of one iteration is to integrate the vertices $\text{Min}(\Xi_i) \subseteq \Xi_i$ into Γ_i where $\text{Min}(\Xi_i)$ is defined by $\text{Min}(\Xi_i) = \{P \in \Xi_i \mid \sigma(\Lambda_P) \subseteq \Gamma_i\}$ and to update the marking M_i accordingly. Each iteration consists of the three steps **UPDATENODES**, **EXTENDCHAINS**, and **UPDATERMARKINGS**, which can be done in TC^0 . We have $\Xi_{i+1} = \Xi_i \setminus \text{Min}(\Xi_i)$. Thus, the full reduction process consists of $\text{depth}(\Pi) + 1$ many TC^0 computations. Let us now describe these three steps. The proofs of these Lemmas can be found in the appendix.

We write $(\Gamma \cup \Xi, \delta) = (\Gamma_i \cup \Xi_i, \delta_i)$ for the power circuit at the start of one iteration. Let us fix its precise properties: $\Gamma \cap \Xi = \emptyset$, $(\Gamma, \delta|_{\Gamma \times \Gamma}) \leq (\Gamma \cup \Xi, \delta)$ is a reduced power circuit and $\Lambda_P|_\Gamma$ is a compact marking for every $P \in \Xi$. Moreover, we assume that $|C_0(\Gamma)| \geq \lceil \log(|\Xi|) \rceil + 1$.

► **Lemma 19** (UPDATENODES). *The following problem is in TC^0 :*

Input: A power circuit $(\Gamma \cup \Xi, \delta)$ as above.

Output: A reduced power circuit (Γ', δ') such that $(\Gamma, \delta|_{\Gamma \times \Gamma}) \leq (\Gamma', \delta')$ and such that for every node $Q \in \text{Min}(\Xi)$ there exists a node $P \in \Gamma'$ with $\varepsilon(P) = \varepsilon(Q)$. In addition, $|\Gamma'| \leq |\Gamma| + |\text{Min}(\Xi)|$, and $|C_{\Gamma'}| \leq |C_\Gamma| + |\text{Min}(\Xi)|$.

► **Lemma 20** (EXTENDCHAINS). *The following problem is in TC^0 :*

Input: A reduced power circuit (Γ', δ') and $\mu \in \mathbb{N}$ such that $\mu \leq \lfloor \frac{2|C_0(\Gamma')|+1}{3} \rfloor$.

Output: A reduced power circuit (Γ'', δ'') such that $(\Gamma', \delta') \leq (\Gamma'', \delta'')$ and such that for each $P \in \Gamma'$ and each $i \in [0.. \mu]$ there is a node $Q \in \Gamma''$ with $\varepsilon(\Lambda_Q) = \varepsilon(\Lambda_P) + i$. In addition, $|\Gamma''| \leq |\Gamma'| + |C_{\Gamma'}| \cdot \mu$, and $|C_{\Gamma''}| \leq |C_{\Gamma'}|$.

In the following, (Γ', δ') denotes the power circuit obtained by UPDATENODES when starting with $(\Gamma \cup \Xi, \delta)$, and (Γ'', δ'') denotes the power circuit obtained by EXTENDCHAINS with $\mu = \lceil \log(|\text{Min}(\Xi)|) \rceil + 1$ on input of the power circuit (Γ', δ') (observe that, by the assumption $|C_0(\Gamma)| \geq \lceil \log(|\Xi|) \rceil + 1$, the condition on μ in Lemma 20 is satisfied). The value of μ is chosen to make sure that in the following lemma one can make the markings compact. Indeed, if $\text{Min}(\Xi) = \{P_1, \dots, P_k\}$ and all P_i have the same evaluation and are marked with 1 by M , then we might need a node of value $2^\mu \cdot \varepsilon(P_1)$ in order to make M compact.

► **Lemma 21** (UPDATERMARKINGS). *The following problem is in TC^0 :*

Input: The power circuit (Γ'', δ'') as a result of EXTENDCHAINS with $\mu = \lceil \log(|\text{Min}(\Xi)|) \rceil + 1$ and a marking M on $\Gamma \cup \Xi$.

Output: A marking \tilde{M} on $\Gamma'' \cup (\Xi \setminus \text{Min}(\Xi))$ such that $\varepsilon(\tilde{M}) = \varepsilon(M)$ and $\tilde{M}|_{\Gamma''}$ is compact.

Proof sketch of Theorem 17. We start with an initial reduced power circuit (Γ_0, δ_0) (a chain of length $\lceil \log(|\Pi|) \rceil + 1$) and a non-reduced part $\Xi_0 = \Pi$ and successively apply the three steps (Lemma 19, 20, and 21) to obtain a sequence of power circuits $(\Gamma_i \cup \Xi_i, \delta_i)$ and markings M_i for $i = 0, 1 \dots$ with $\Xi_{i+1} = \Xi_i \setminus \text{Min}(\Xi_i)$ while keeping the invariants $(\Gamma_i, \delta_i|_{\Gamma_i \times \Gamma_i}) \leq (\Gamma_i \cup \Xi_i, \delta_i)$, Γ_i is reduced, $\Gamma_{i-1} \leq \Gamma_i$, $\Xi_i \subseteq \Xi_{i-1}$, and $\varepsilon(M_i) = \varepsilon(M)$. After $\text{depth}(\Pi) + 1$ iterations we reach $\Xi_{d+1} = \Xi_d \setminus \text{Min}(\Xi_d) = \emptyset$ where $d = \text{depth}(\Pi)$. Thus, $(\Gamma, \delta) = (\Gamma_{d+1}, \delta_{d+1})$ is a reduced power circuit and M_{d+1} is a compact marking on Γ_{d+1} with $\varepsilon(M_{d+1}) = \varepsilon(M)$.

▷ **Claim 22.** Let $d = \text{depth}(\Pi)$ and $\Gamma_0, \dots, \Gamma_{d+1}$ be as constructed above. Then for all i we have $|C_{\Gamma_i}| \leq |\Pi| + 1$ and $|\Gamma_i| \leq (|\Pi| + 1)^2 \cdot (\log(|\Pi|) + 2)$.

Let $D \in \mathbb{N}$ and assume that $\text{depth}(\Pi) \leq D$. By Lemma 19, 20, and 21, each iteration can be done in TC^0 . The construction of the markings \tilde{M}_i and $\tilde{\Lambda}_P$ during UPDATERMARKINGS can be done in parallel – so it is in TC^0 , although Lemma 21 is stated only for a single marking. Now, the crucial observation is that, due to Claim 22, the input size for each iteration is polynomial in the original input size of (Π, δ_Π) . Therefore, we can compose the individual iterations and obtain a circuit of polynomial size and depth bounded by $\mathcal{O}(D)$. ◀

► **Remark 23.**

(1) While Theorem 17 is only stated for one input marking, the construction works within the same complexity bounds for any number of markings on (Π, δ_Π) since during UPDATERMARKINGS these all can be updated in parallel.

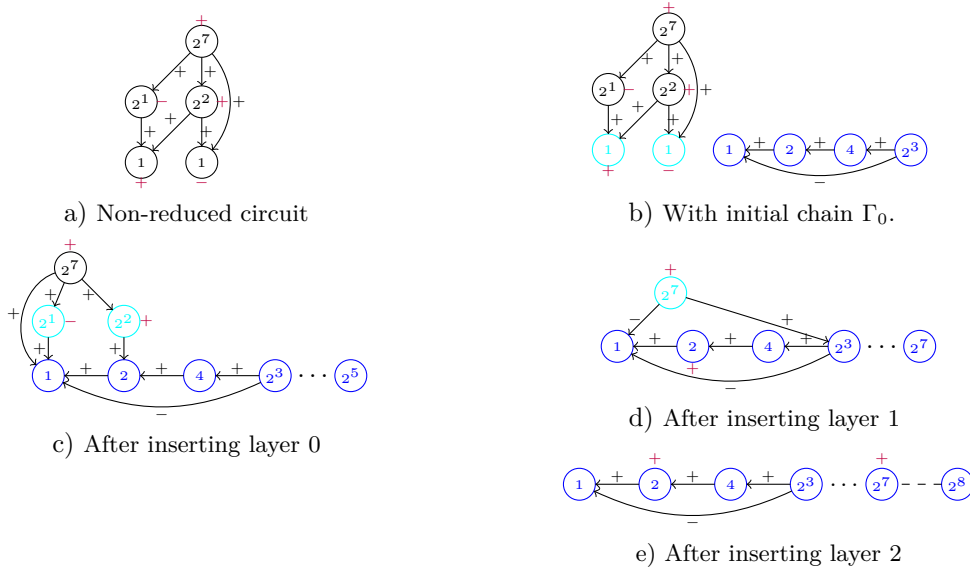

■ **Figure 3** The three steps of power circuit reduction. The already reduced part consist of **blue nodes** and $\text{Min}(\Xi_i)$ is colored in **cyan**. The **red signs** indicate a marking. Three dots \dots in between two nodes mean that we omitted some nodes. A dashed edge $--$ means that we actually omitted the outgoing edges of the right node.

- (2) Moreover, note that for every maximal chain $C \in \mathcal{C}_\Gamma$ there exists a node $Q \in \Pi$ (i.e., in the original power circuit) such that $\varepsilon(Q) = \varepsilon(\text{start}(C))$. This is because new chains are only created during UPDATENODES, the other steps only extend already existing chains.
- (3) Further observe that $|\sigma(\tilde{M})| \leq |\sigma(M)|$. Looking at the construction of \tilde{M} we see that we first make sure that M does not mark two nodes of the same value, then we make the marking compact. Both operations do not increase the number of nodes in the support of the marking.

► **Example 24.** In Figure 3 we illustrate what happens in the steps UPDATENODES, EXTENDCHAINS and UPDATEMARKINGS during the reduction process. Picture a) shows our starting situation. In b) we already inserted the nodes of value 2^3 and 2^{32} into the reduced part. Now the reduced part consists of three chains: one starting at the node of value 1 and the nodes 2^5 and 2^{32} as chains of length 1. Because $|\text{Min}(\Xi)| = 3$, we have to extend each chain by three nodes or until two chains merge. So in c) we obtain two chains, one from 1 to 2^8 and the one from 2^{32} to 2^{35} . In d) we then updated the markings and deleted the nodes from $\text{Min}(\Xi)$.

► **Example 25.** In Section 4 we give an example of the complete power circuit reduction process by showing the result after each iteration. We start with a non-reduced power circuit of depth 2 in a). This power circuit has size 5, so we first construct the starting chain of length 4 in b). Part c) and d) show the result after inserting layer 0 and layer 1, respectively. In e) we finally inserted all layers and thus have constructed the reduced power circuit.

For comparing two markings L and M on an arbitrary power circuit, we can proceed as follows: first compute the difference (Lemma 15), then reduce the power circuit (Theorem 17) and, finally, compare the resulting compact marking with zero (Proposition 14). This shows the next corollary and, together with Lemma 4, also proves Proposition A.

■ **Figure 4** The complete process of power circuit reduction – inserting layer after layer. For the meaning of the colors, see Figure 3.

► **Corollary 26.** *The following is in DepParaTC^0 parametrized by $\text{depth}(\Pi)$:*

- Input: A power circuit (Π, δ_Π) together with markings L, M on Π .
 Question: Is $\varepsilon(L) \leq \varepsilon(M)$?

Operations with floating point numbers. In the following, we want to represent a number $r \in \mathbb{Z}[1/2]$ using markings in a power circuit. For this, we use a floating point representation. Observe that for each such $r \in \mathbb{Z}[1/2] \setminus \{0\}$ there exist unique $u, e \in \mathbb{Z}$ with u odd such that $r = u \cdot 2^e$.

► **Definition 27.** *A power circuit representation of $r \in \mathbb{Z}[1/2]$ consists of a power circuit (Π, δ_Π) together with a pair of markings (U, E) on Π such that $\varepsilon(U)$ is either zero or odd and $r = \varepsilon(U) \cdot 2^{\varepsilon(E)}$.*

► **Lemma 28.** *The following problems are in DepParaTC^0 parametrized by $\text{depth}(\Pi)$:*

- Input: A power circuit representation for $r, s \in \mathbb{Z}[1/2]$ over a power circuit (Π, δ_Π) and a marking M on Π .
 Output A: A power circuit representation of $\varepsilon(M) \in \mathbb{Z}[1/2]$ over a power circuit $(\tilde{\Pi}, \delta_{\tilde{\Pi}})$.
 Output B: A power circuit representation of $r \cdot 2^{\varepsilon(M)}$ over a power circuit $(\tilde{\Pi}, \delta_{\tilde{\Pi}})$.
 Output C: A power circuit representation of $-r$ over (Π, δ_Π) .
 Output D: If $\frac{r}{s}$ is a power of two, a marking L in a power circuit $(\tilde{\Pi}, \delta_{\tilde{\Pi}})$ such that $\varepsilon(L) = \log_2(\frac{r}{s})$ (otherwise the output is undefined).
 Output E: A power circuit representation of $r + s$ over a power circuit $(\tilde{\Pi}, \delta_{\tilde{\Pi}})$.
 Output F: Is $r \in \mathbb{Z}$? If yes, a marking L in a power circuit $(\tilde{\Pi}, \delta_{\tilde{\Pi}})$ such that $\varepsilon(L) = r$.
 Question G: Is $r \triangle 0$ for $\triangle \in \{=, \neq, <, \leq, >, \geq\}$?

In all cases we have $(\Pi, \delta_\Pi) \leq (\tilde{\Pi}, \delta_{\tilde{\Pi}})$, $|\tilde{\Pi}| \in \mathcal{O}(|\Pi|)$, and $\text{depth}(\tilde{\Pi}) = \text{depth}(\Pi) + \mathcal{O}(1)$.

Proof sketch. We only outline the proof for the first point, which is the most difficult one. The other points follow rather easily using Corollary 26 and Lemma 15. Given a marking M , we wish to compute markings U, E such that $\varepsilon(M) = \varepsilon(U) \cdot 2^{\varepsilon(E)}$ and $\varepsilon(U)$ is zero or odd.

First, we construct the reduced form (Γ, δ) of Π to obtain a compact marking \tilde{M} on Γ such that $\varepsilon(M) = \varepsilon(\tilde{M}) = \sum_{i=1}^k \tilde{M}(Q_i) \cdot 2^{\varepsilon(\Lambda_{Q_i})}$ where $\sigma(\tilde{M}) = \{Q_1, \dots, Q_k\} \subseteq \Gamma$ and the Q_i are ordered according to their value. This is possible in DepParaTC^0 according to Theorem 17. It is easy to see that $|\sigma(\tilde{M})| \leq |\sigma(M)|$.

Our aim is $\varepsilon(E) = \varepsilon(\Lambda_{Q_1})$ and $\varepsilon(U) = \sum_{i=1}^k \tilde{M}(Q_i) \cdot 2^{\varepsilon(\Lambda_{Q_i}) - \varepsilon(E)}$. For this, we add nodes S_i to Π with $\varepsilon(\Lambda_{S_i}) = \varepsilon(\Lambda_{Q_i}) - \varepsilon(E)$ for $i \in [1..k]$ as follows: Looking closely at the reduction process, we can find nodes $R_i \in \Pi$ and integers $m_i \in [0..|\Gamma|]$ such that $\varepsilon(\Lambda_{Q_i}) = \varepsilon(\Lambda_{R_i}) + m_i$. To define markings M_i that evaluate to m_i , we construct nodes of depth 1 and values 2^j for $j \in [0.. \lceil \log(|\Gamma|) \rceil]$ in Π . Then $\Lambda_{S_i} = \Lambda_{R_i} + M_i - E$. So $U(S_i) = \tilde{M}(Q_i)$ for $i \in [1..k]$ and $E = \Lambda_{R_1} + M_1$ satisfies $\varepsilon(M) = \varepsilon(U) \cdot 2^{\varepsilon(E)}$. ◀

5 The word problem of the Baumslag group

Before we start solving the word problem of the Baumslag group, let us fix our notation from group theory. Let G be a group and $\eta: \Sigma^* \rightarrow G$ a surjective monoid homomorphism. We treat words over Σ both as words and as their images under η . We write $v =_G w$ with the meaning that $\eta(v) = \eta(w)$. The word problem of G is as follows: given a word $w \in \Sigma^*$, is $w =_G 1$? For further background on group theory, we refer to [25].

The Baumslag-Solitar group and the Baumslag group. The Baumslag-Solitar group is defined by $\mathbf{BS}_{1,2} = \langle a, t \mid tat^{-1} = a^2 \rangle$. We have $\mathbf{BS}_{1,2} \cong \mathbb{Z}[1/2] \rtimes \mathbb{Z}$ via the isomorphism $a \mapsto (1, 0)$ and $t \mapsto (0, 1)$. The multiplication in $\mathbb{Z}[1/2] \rtimes \mathbb{Z}$ is defined by $(r, m) \cdot (s, n) = (r + 2^m s, m + n)$. In the following we use $\mathbf{BS}_{1,2}$ and $\mathbb{Z}[1/2] \rtimes \mathbb{Z}$ as synonyms.

A convenient way to understand the Baumslag group $\mathbf{G}_{1,2}$ is as an HNN extension² of the Baumslag-Solitar group:

$$\mathbf{G}_{1,2} = \langle \mathbf{BS}_{1,2}, b \mid bab^{-1} = t \rangle = \langle a, t, b \mid tat^{-1} = a^2, bab^{-1} = t \rangle.$$

Note that the letter t can be seen as an abbreviation for bab^{-1} ; by removing it, we obtain exactly the presentation $\langle a, b \mid bab^{-1}a = a^2bab^{-1} \rangle$. Moreover, $\mathbf{BS}_{1,2}$ is a subgroup of $\mathbf{G}_{1,2}$ via the canonical embedding. We have $b(q, 0)b^{-1} = (0, q)$, so a conjugation by b “flips” the two components of the semi-direct product (if possible). Henceforth, we will use the alphabet $\Sigma = \{1, a, a^{-1}, t, t^{-1}, b, b^{-1}\}$ to represent elements of $\mathbf{G}_{1,2}$ (the letter 1 represents the group identity; it is there for padding reasons).

Britton reductions. Britton reductions are a standard way to solve the word problem in HNN extensions. Let $\Delta = \mathbf{BS}_{1,2} \cup \{b, b^{-1}\}$ be an infinite alphabet (note that $\Sigma \subseteq \Delta$). A word $w \in \Delta^*$ is called *Britton-reduced* if it is of the form $w = (s_0, n_0)\beta_1(s_1, n_1) \cdots \beta_\ell(s_\ell, n_\ell)$ with $\beta_i \in \{b, b^{-1}\}$ and $(s_i, n_i) \in \mathbf{BS}_{1,2}$ for all i (i.e., w does not have two successive letters from $\mathbf{BS}_{1,2}$) and there is no factor of the form $b(q, 0)b^{-1}$ or $b^{-1}(0, k)b$ with $q, k \in \mathbb{Z}$. If w is not Britton-reduced, one can apply one of the rules $(r, m)(s, n) \rightarrow (r + 2^m s, m + n)$, $b(q, 0)b^{-1} \rightarrow (0, q)$, or $b^{-1}(0, k)b \rightarrow (k, 0)$ in order to obtain a shorter word representing the same group element. The following lemma is well-known (see also [25, Section IV.2]).

► **Lemma 29** (Britton’s Lemma for $\mathbf{G}_{1,2}$ [6]). *Let $w \in \Delta^*$ be Britton-reduced. Then $w \in \mathbf{BS}_{1,2}$ as a group element if and only if w does not contain any letter b or b^{-1} . In particular, $w =_{\mathbf{G}_{1,2}} 1$ if and only if $w = (0, 0)$ or $w = 1$ as a word.*

² Named after Graham Higman, Bernhard H. Neumann and Hanna Neumann. For a precise definition, we refer to [25]. This is also the way how the Magnus breakdown procedure works.

► **Example 30.** Define words $w_0 = t$ and $w_{n+1} = b w_n a w_n^{-1} b^{-1}$ for $n \geq 0$. Then we have $|w_n| = 2^{n+2} - 3$ but $w_n =_{\mathbf{G}_{1,2}} t^{\tau(n)}$. While the length of the word w_n is only exponential in n , the length of its Britton-reduced form is $\tau(n)$.

Conditions for Britton reductions. The idea to obtain a parallel algorithm for the word problem is to compute a Britton reduction of uv given that both u and v are Britton-reduced. For this, we have to find a maximal suffix of u which cancels with a prefix of v . The following lemma is our main tool for finding the longest canceling suffix.

► **Lemma 31.** *Let $w = \beta_1(r, m)\beta_2 x \beta_2^{-1}(s, n)\beta_1^{-1} \in \Delta^*$ with $\beta_1, \beta_2 \in \{b, b^{-1}\}$ such that $\beta_1(r, m)\beta_2$ and $\beta_2^{-1}(s, n)\beta_1^{-1}$ both are Britton-reduced and $\beta_2 x \beta_2^{-1} =_{\mathbf{G}_{1,2}} (q, k) \in \mathbf{BS}_{1,2}$ (in particular, $k = 0$ and $q \in \mathbb{Z}$, or $q = 0$).*

Then $w \in \mathbf{BS}_{1,2}$ if and only if the respective condition in the following table is satisfied. Moreover, if $w \in \mathbf{BS}_{1,2}$, then $w =_{\mathbf{G}_{1,2}} \hat{w}$ according to the last column of the table.

β_1	β_2	Condition	\hat{w}
b	b	$r + 2^{m+k}s \in \mathbb{Z}, \quad m + n + k = 0$	$(0, r + 2^{-n}s)$
b	b^{-1}	$r + 2^m(q + s) \in \mathbb{Z}, \quad m + n = 0$	$(0, r + 2^m(q + s))$
b^{-1}	b	$r + 2^{m+k}s = 0$	$(n + \log(\frac{-r}{s}), 0)$
b^{-1}	b^{-1}	$r + 2^m(q + s) = 0$	$(m + n, 0)$

Notice that in the case $\beta_1 = b^{-1}$ and $\beta_2 = b$, we have $r \neq 0$ and $s \neq 0$.

► **Example 32.** Let us illustrate how to read Lemma 31 by giving an example. Let $w = \beta_1(r_1, m_1)\beta_2 x \beta_2^{-1}(s_1, n_1)\beta_1^{-1} \in \Delta^*$ with the same properties as in Lemma 31, in particular, $\beta_2 x \beta_2^{-1} =_{\mathbf{G}_{1,2}} (q, k) \in \mathbf{BS}_{1,2}$. Further assume that $\beta_1 = \beta_2 = b$. Then, according to Lemma 31, $w \in \mathbf{BS}_{1,2}$ if and only if $m_1 + n_1 = -k$ and $r_1 + 2^{m_1+k} \cdot s_1 \in \mathbb{Z}$. So we need to compute k .

Assume that $(q, k) =_{\mathbf{G}_{1,2}} \beta_2 x \beta_2^{-1} = \beta_2(r_2, m_2)\beta_3 x' \beta_3^{-1}(s_2, n_2)\beta_2^{-1}$ for some r_2, m_2, s_2, n_2 . Moreover, consider the case that $\beta_3 = b$. By applying Lemma 31 again we obtain that $(q, k) = (0, r_2 + 2^{-n_2} \cdot s_2)$. Hence, $w \in \mathbf{BS}_{1,2}$ if and only if $m_1 + n_1 + (r_2 + 2^{-n_2} \cdot s_2) = 0$ and $r_1 + 2^{m_1+r_2+2^{-n_2} \cdot s_2} \cdot s_1 \in \mathbb{Z}$. If both conditions are satisfied, then $w =_{\mathbf{G}_{1,2}} (0, r_1 + 2^{-n_1} s_1)$.

Proof sketch of Lemma 31. Consider the case that $\beta_1 = b$ and $\beta_2 = b$: Since $\beta_2 x \beta_2^{-1} \in \mathbf{BS}_{1,2}$, we have $\beta_2 x \beta_2^{-1} =_{\mathbf{G}_{1,2}} (0, k)$ for some $k \in \mathbb{Z}$. Therefore, we obtain

$$(r, m)\beta_2 x \beta_2^{-1}(s, n) =_{\mathbf{G}_{1,2}} (r, m)(0, k)(s, n) =_{\mathbf{G}_{1,2}} (r + 2^{m+k}s, m + k + n).$$

Thus, since $\beta_1 = b$, we have $w \in \mathbf{BS}_{1,2}$ if and only if $r + 2^{m+k}s \in \mathbb{Z}$ and $m + n + k = 0$. Moreover, if the latter conditions are satisfied, we have $w =_{\mathbf{G}_{1,2}} b(r + 2^{m+k}s, 0)b^{-1} = b(r + 2^{-n}s, 0)b^{-1} =_{\mathbf{G}_{1,2}} (0, r + 2^{-n}s)$. This shows the first row of the table in Lemma 31. The other rows follow with a similar calculation. ◀

Let us fix the following notation for elements $v, w \in \mathbf{G}_{1,2}$ written as words over Δ :

$$u = (r_h, m_h)\beta_h \cdots (r_1, m_1)\beta_1(r_0, m_0), \quad v = (s_0, n_0)\tilde{\beta}_1(s_1, n_1) \cdots \tilde{\beta}_\ell(s_\ell, n_\ell) \quad (1)$$

with $(r_j, m_j), (s_j, n_j) \in \mathbb{Z}[1/2] \times \mathbb{Z}$ and $\beta_j, \tilde{\beta}_j \in \{b, b^{-1}\}$. We define

$$uw[i, j] = \beta_i(r_{i-1}, m_{i-1}) \cdots \beta_1(r_0, m_0) (s_0, n_0)\tilde{\beta}_1 \cdots (s_{j-1}, n_{j-1})\tilde{\beta}_j.$$

74:14 Parallel Algorithms for the Baumslag Group

Notice that as an immediate consequence of Britton's Lemma we obtain that, if u and v as in (1) are Britton-reduced and $uv[i, i] \in \mathbf{BS}_{1,2}$ for some i , then also $uv[j, j] \in \mathbf{BS}_{1,2}$ for all $j \leq i$. Moreover, uv is Britton-reduced if and only if $\beta_1(r_0, m_0)(s_0, n_0)\beta_1 \notin \mathbf{BS}_{1,2}$.

For $\ell \in \mathbb{N}$ let \mathcal{X}_ℓ denote some set of ℓ variables. Denote by $\text{PowExp}(\mathcal{X}_\ell)$ the set of expressions which can be made up from the variables \mathcal{X}_ℓ using the operations $+$, $-$, $(r, s) \mapsto r \cdot 2^s$ if $s \in \mathbb{Z}$ (and undefined otherwise), and $(r, s) \mapsto \log(r/s)$ if $\log(r/s) \in \mathbb{Z}$ (and undefined otherwise).

► **Lemma 33.** *For every $\vec{\beta} \in \{b, b^{-1}, \perp\}^4$ there are expressions $\theta_{\vec{\beta}}, \xi_{\vec{\beta}}, \varphi_{\vec{\beta}}, \psi_{\vec{\beta}} \in \text{PowExp}(\mathcal{X}_{12})$ such that the following holds: Let $u, v \in \mathbf{G}_{1,2}$ as in (1) be Britton-reduced and assume that $uv[i-1, i-1] \in \mathbf{BS}_{1,2}$ and $\beta_i = \vec{\beta}_i^{-1}$ and let $V_i = \{r_j, s_j, m_j, n_j \mid j \in \{i-1, i-2, i-3\}\}$. If $\vec{\beta} = (\beta_i, \beta_{i-1}, \beta_{i-2}, \beta_{i-3})$ (where $\beta_j = \perp$ for $j \leq 0$), then*

1. $uv[i, i] \in \mathbf{BS}_{1,2}$ if and only if $\theta_{\vec{\beta}}(V_i) \in \mathbb{Z}$ and $\xi_{\vec{\beta}}(V_i) = 0$,
2. if $uv[i, i] \in \mathbf{BS}_{1,2}$, then $uv[i, i] =_{\mathbf{G}_{1,2}} (\varphi_{\vec{\beta}}(V_i), \psi_{\vec{\beta}}(V_i))$.

Be aware that here we have to read the set V_i of cardinality (at most) 12 as assignment to the variables \mathcal{X}_{12} . In particular, given that $uv[i-1, i-1] \in \mathbf{BS}_{1,2}$, one can decide whether $uv[i, i] \in \mathbf{BS}_{1,2}$ by looking at only constantly many letters of uv – this is the crucial observation we shall be using for describing an NC algorithm for the word problem of $\mathbf{G}_{1,2}$ (see Lemma 34 below).

Proof. W.l.o.g. $i \geq 4$. We follow the approach of Example 32. By assumption we know that there exist $q, k \in \mathbb{Z}$ such that $uv[i-1, i-1] =_{\mathbf{G}_{1,2}} (q, k) \in \mathbf{BS}_{1,2}$. According to the conditions in Lemma 31, to show Lemma 33 it suffices to find expressions $\varphi_{\vec{\beta}}(V_i), \psi_{\vec{\beta}}(V_i)$ for q and k respectively. If $(\beta_{i-1}, \beta_{i-2}) \neq (b, b^{-1})$, this follows directly from the rightmost column in Lemma 31. Otherwise, we know that $(\beta_{i-2}, \beta_{i-3}) \neq (b, b^{-1})$ and so we obtain the expressions for q and k by applying Lemma 31 to $uv[i-2, i-2]$ (note that $uv[i-2, i-2] \in \mathbf{BS}_{1,2}$ because $uv[i-1, i-1] \in \mathbf{BS}_{1,2}$). This proves the lemma. ◀

The algorithm. A power circuit representation of $u \in \mathbf{G}_{1,2}$ written as in (1) consists of the sequence $(\beta_h, \dots, \beta_1)$ and a power circuit (Π, δ_Π) with markings U_i, E_i, M_i for $i \in [0..h]$ such that (U_i, E_i) is a power circuit representation of r_i (see Definition 27) and $m_i = \varepsilon(M_i)$.

► **Lemma 34.** *The following problem is in DepParaTC^0 parametrized by $\max_i \text{depth}(\Pi_i)$:*

- Input:** Britton-reduced power circuit representations of $u, v \in \mathbf{G}_{1,2}$ over power circuits Π_1, Π_2 .
- Output:** A Britton-reduced power circuit representation of $w \in \mathbf{G}_{1,2}$ over a power circuit Π' such that $w =_{\mathbf{G}_{1,2}} uv$ and $\text{depth}(\Pi') = \max_i \text{depth}(\Pi_i) + \mathcal{O}(1)$ and $|\Pi'| \in \mathcal{O}(|\Pi_1| + |\Pi_2|)$.

Proof. Let Π be the disjoint union of Π_1 and Π_2 . We need to find the maximal i such that $uv[i, i] \in \mathbf{BS}_{1,2}$. This can be done as follows: By Lemma 28 one can evaluate the expressions $\theta_{\vec{\beta}}(V_i)$ and $\xi_{\vec{\beta}}(V_i)$ of Lemma 33 and test the conditions $\theta_{\vec{\beta}}(V_i) \in \mathbb{Z}$ and $\xi_{\vec{\beta}}(V_i) = 0$ in DepParaTC^0 . For every i this can be done independently in parallel giving us Boolean values indicating whether $uv[i-1, i-1] \in \mathbf{BS}_{1,2}$ implies $uv[i, i] \in \mathbf{BS}_{1,2}$. Now, we have to find only the maximal i_0 such that for all $j \leq i_0$ this implication is true. Since $uv[0, 0] = 1 \in \mathbf{BS}_{1,2}$, it follows inductively that $uv[i, i] \in \mathbf{BS}_{1,2}$ for all $i \leq i_0$. Moreover, as the implication $uv[i_0, i_0] \in \mathbf{BS}_{1,2} \implies uv[i_0+1, i_0+1] \in \mathbf{BS}_{1,2}$ fails, we have $uv[j, j] \notin \mathbf{BS}_{1,2}$ for $j \geq i_0+1$.

Now, using the expressions $\varphi_{\tilde{\beta}}, \psi_{\tilde{\beta}}$ from Lemma 33 one can compute again using Lemma 28 $(q, k) = (\varphi_{\tilde{\beta}}(V_{i_0}), \psi_{\tilde{\beta}}(V_{i_0})) =_{\mathbf{G}_{1,2}} uv[i_0, i_0]$ in DepParaTC^0 . Again using Lemma 28, we can compute in DepParaTC^0 $(s, m) = (r_{i_0}, m_{i_0})(q, k)(s_{i_0}, n_{i_0})$ as a power circuit representation over a power circuit $(\Pi', \delta_{\Pi'})$ with $(\Pi, \delta_{\Pi}) \leq (\Pi', \delta_{\Pi'})$, $|\Pi'| \in \mathcal{O}(\Pi)$ and $\text{depth}(\Pi') \in \text{depth}(\Pi) + \mathcal{O}(1)$. Now, the output is

$$(r_h, m_h)\beta_h \cdots (r_{i_0+1}, m_{i_0+1})\beta_{i_0+1} (s, m) \tilde{\beta}_{i_0+1}(s_{i_0+1}, n_{i_0+1}) \cdots \tilde{\beta}_\ell(s_\ell, n_\ell). \quad \blacktriangleleft$$

Instead of Theorem B, we prove the following slightly more general result. Theorem B then easily follows by Britton's Lemma. Recall that $\Sigma = \{1, a, a^{-1}, t, t^{-1}, b, b^{-1}\}$.

► **Theorem 35.** *The following problem is in TC^2 :*

Input: A word $w \in \Sigma^*$.

Output: A power circuit representation for a Britton-reduced word $w_{\text{red}} \in \Delta^*$ such that $w =_{\mathbf{G}_{1,2}} w_{\text{red}}$ and the underlying power circuit has depth $\mathcal{O}(\log |w|)$.

Proof sketch. Let $w = w_1 \cdots w_n$ with $w_j \in \Sigma$ be the input. First, we transform each letter w_j into a power circuit representation. Then, the first layer computes the Britton reduction of two-letter words using Lemma 34, the next layer takes always two of these Britton-reduced words and joins them to a new Britton-reduced word and so on. After $\log n$ layers a single Britton-reduced word remains. The crucial observation is that, due to Lemma 34, the size of the power circuits stays polynomial in n and their depth in $\mathcal{O}(\log n)$. Thus, by Lemma 4 each application of Lemma 34 is in TC^1 and the whole computation in TC^2 . \blacktriangleleft

6 P-hardness of power circuit comparison

Finally, we prove some hardness results on comparison in power circuits. In particular, they imply that Theorem 17 is optimal in a certain sense. Here, we use LOGSPACE-reductions.

► **Proposition 36.** *The following problem is NL-hard:*

Input: Given a power circuit and markings M, K .

Question: Is $\varepsilon(M) = \varepsilon(K)$?

The proof of Proposition 36 is a straightforward reduction from s - t -connectivity. For comparison with \leq , we obtain a more interesting hardness result:

► **Theorem 37.** *The following problem is P-complete:*

Input: A power circuit (Π, δ_{Π}) and nodes $R, S \in \Pi$ such that for all $P \in \Pi$ the marking Λ_P is compact and for all $P \neq Q$, $\varepsilon(P) \neq \varepsilon(Q)$.

Question: Is $\varepsilon(R) \leq \varepsilon(S)$?

A weaker form of this result already has been stated in the second author's dissertation [41], but it never appeared in a refereed journal or conference proceedings. Notice that the only feature the power circuit in Theorem 37 lacks for being reduced is the sorting of the nodes. In particular, under the assumption $\text{NC} \neq \text{P}$, it is not possible to sort the nodes of a given power circuit in NC.

► **Remark 38.**

(a) It is an immediate consequence of Theorem 37 that the comparison problem of two markings in a power circuit is P-complete. This is because for two nodes R and S in a power circuit (Π, δ_{Π}) we have $\varepsilon(R) \leq \varepsilon(S)$ if and only if $\varepsilon(\Lambda_R) \leq \varepsilon(\Lambda_S)$.

■ **Figure 5** Power circuit for an OR gate g_i .

■ **Figure 6** Power circuit for a NOT gate g_i on level k .

- (b) If the input is given as in Theorem 37, we can check in AC^0 whether $\varepsilon(R) = \varepsilon(S)$ because this is the case if and only if $\Lambda_R(P) = \Lambda_S(P)$ for all $P \in \Gamma$ (see Lemma 12). This can be viewed as a hint that also in an arbitrary power circuit testing for equality might be easier than comparing for less than.

► **Corollary 39.** *The following problem is P-complete:*

Input: A power circuit representation of $w \in \mathbf{G}_{1,2}$.

Question: Is $w \in \mathbf{BS}_{1,2}$?

Proof sketch of Theorem 37. By [31, Proposition 49], we only need to show the hardness part. We give a reduction from the $\text{CIRCUITVALUEPROBLEM}$ which is P-complete (see [39, Thm. 10.44]). We start with a circuit \mathcal{C} of size L and depth D consisting of *input gates*, NOT gates, OR gates (of fan-in two) and one *output gate*. W.l.o.g. the circuit is layered: input gates are on level 0, and gates on level k only receive inputs from level $k - 1$. After fixing an evaluation $\text{eval}(x) \in \{0, 1\}$ for all input gates x , each gate g evaluates to a truth value $\text{eval}(g) \in \{0, 1\}$ in a natural way. The task is to compute $\text{eval}(\text{output})$. We construct a power circuit (Γ, δ) such that for every gate g on level k in \mathcal{C} there exists a node P_g in Γ satisfying

$$\begin{aligned} \tau(L - 1) < \varepsilon(\Lambda_{P_g}) &\leq \tau(2k + L) - 2 && \text{if } \text{eval}(g) = 0, \\ \tau(2k + L) &\leq \varepsilon(\Lambda_{P_g}) \leq \tau(2k + L + 1) - 2 && \text{if } \text{eval}(g) = 1. \end{aligned} \quad (2)$$

For this, we first create nodes X_k , R_k and S_k such that $\varepsilon(X_k) = 2^k$, $\varepsilon(R_k) = \tau(2k + L)$, $\varepsilon(S_k) = \tau(2k + L - 1)/2$. For an input gate g_i we set $\varepsilon(\Lambda_{P_{g_i}}) = \tau(L - 1) + i$ if $\text{eval}(g_i) = 0$ and $\varepsilon(\Lambda_{P_{g_i}}) = \tau(L) + i$ otherwise. For the *output gate* with incoming edge from gate u , we define $\varepsilon(\Lambda_{P_{\text{output}}}) = \varepsilon(P_u)$. Figure 5 and 6 illustrate the construction for OR and NOT gates. Now all nodes of Γ have pairwise different evaluations in $2^{\mathbb{N}}$ (this is essentially because we always add i to the successor marking) and compact successor markings. A rather tedious but straightforward induction shows Equation (2). Let us consider an OR gate as in Figure 5 as example: if both $\varepsilon(\Lambda_{P_u}), \varepsilon(\Lambda_{P_v}) \leq \tau(2(k - 1) + L) - 2$, then $\varepsilon(\Lambda_{P_g}) \leq 2^{2^{\varepsilon(\Lambda_{P_u})} + 2^{\varepsilon(\Lambda_{P_v})}} \leq 2^{2 \cdot 2^{\tau(2(k-1)+L)-2}} \leq \tau(2k + L) - 2$. On the other hand, if $\varepsilon(\Lambda_{P_u}) \geq \tau(2(k - 1) + L)$, then also $\varepsilon(\Lambda_{P_g}) \geq 2^{2^{\varepsilon(\Lambda_{P_u})}} \geq \tau(2k + L)$. The other cases of the induction follow similarly.

Thus, we have that $\varepsilon(P_{\text{output}}) \geq \varepsilon(R_D)$ if and only if $\text{eval}(\text{output}) = 1$. ◀

Conclusion. We showed that the word problem of the Baumslag group can be solved in TC^2 . The proof relies on the fact that all power circuits used during the execution of the algorithm have logarithmic depth. The-23 comparison problem for such power circuits is in TC^1 , although for arbitrary power circuits it is P-complete. We conclude with some open problems:

- Is it possible to reduce the complexity of the word problem of the Baumslag group any further – e.g. to find a LOGSPACE algorithm? Can we prove some non-trivial lower bounds (the word problem is NC^1 -hard as $\mathbf{G}_{1,2}$ contains a non-abelian free group [35])?
- The problem of comparing two markings on a power circuit for equality is NL-hard – is it also P-complete like comparison with less than?
- Is the word problem of the Baumslag group with power circuit representations as input P-complete? (By Corollary 39 this holds for the subgroup membership problem for $\mathbf{BS}_{1,2}$ in $\mathbf{G}_{1,2}$. Moreover, as a consequence of Proposition 36, the word problem is NL-hard.)
- By Corollary 26 for every k the comparison problem for power circuits of depth $\log^k n$ is in TC^k . Moreover, the proof of Theorem 37 can be modified to show that the same problem is hard for AC^k under AC^0 -Turing-reductions. Thus, the question remains whether, indeed, this problem is complete for TC^k under AC^0 -Turing-reductions.

A Details on power circuit reduction

In the following we present more details concerning the reduction process for power circuits. We give the proofs of the three steps UPDATENODES, EXTENDCHAINS, UPDATEMARKINGS and of Theorem 17. We need the following definition and lemmas. Their proofs can be found in the full version on arXiv [28].

► **Lemma 40.** *Let A be a csdr and let $B = (b_0, \dots, b_{n-1})$ be a csdr of digit-length n such that $b_i = n - i \bmod 2$ (i.e., $b_{n-1} = 1$ and then B alternates between 0 and 1). Then we have*

- (i) $\text{val}(B) = \lfloor \frac{2^{n+1}}{3} \rfloor$,
- (ii) $\text{val}(A) \leq \text{val}(B)$ if and only if the digit-length of A is at most n or $\text{val}(A) \leq 0$.

► **Definition 41.** *Let M be a marking in the reduced power circuit (Γ, δ) and let $C = (P_i, \dots, P_{i+\ell-1}) \in \mathcal{C}_\Gamma$ and define $a_j = M(P_{i+j})$ for $i \in [\ell]$. Then we write $\text{digit}_C(M) = (a_0, \dots, a_{\ell-1})$.*

► **Lemma 42.** *Let (Γ, δ) be a reduced power circuit. Let L and M be compact markings in Γ such that $\varepsilon(L) > \varepsilon(M)$ and let $0 \leq k \leq \lfloor \frac{2^{|C_0|+1}}{3} \rfloor$. Then $\varepsilon(L) \leq \varepsilon(M) + k$ if and only if $\varepsilon(M|_{\Gamma \setminus C_0}) = \varepsilon(L|_{\Gamma \setminus C_0})$ and $\varepsilon(L|_{C_0}) \leq \varepsilon(M|_{C_0}) + k$.*

For the proof of Lemma 19, we define the following equivalence relation \sim_ε on $\Gamma \cup \text{Min}(\Xi)$: $P \sim_\varepsilon Q$ if and only if $\varepsilon(P) = \varepsilon(Q)$. For $P \in \Gamma \cup \text{Min}(\Xi)$ we write $[P]_\varepsilon$ for the equivalence class containing P .

Proof of Lemma 19. Define $I \subseteq \text{Min}(\Xi)$ by taking one representative of each \sim_ε -class not containing a node of Γ . Such a set I can be computed in TC^0 : Clearly, $\text{Min}(\Xi)$ can be computed in TC^0 . The \sim_ε -classes can be computed in AC^0 by Proposition 14. Finally, for defining I one has to pick representatives, which can be done in TC^0 . Now, we can apply Lemma 18 to insert I into Γ in TC^0 . This yields our power circuit (Γ', δ') . The size bounds follow now immediately from those in Lemma 18. ◀

Proof of Lemma 20. First assume that $|C_0| = 1$. Then $|\Gamma'| = 1$ and $\mu \leq 1$. If $\mu = 1$, then just one node has to be created, namely the one of value 2 and we are done. Thus, in the following we can assume that $|C_0| \geq 2$. Now, the proof of Lemma 20 consists of two steps: first, we extend only the chain C_0 to some longer (and long enough) chain in order to make sure that the values of the (compact) successor markings of the nodes we wish to introduce can be represented within the power circuit; only afterwards we add the new nodes as described in the lemma.

Step 1: We first want to extend the chain C_0 to the chain \tilde{C}_0 of minimal length such that \tilde{C}_0 is a maximal chain, $C_0 \subseteq \tilde{C}_0$, and the last node of \tilde{C}_0 is not already present in Γ' . The resulting power circuit will be denoted by $\tilde{\Gamma}$. We define

$$i_0 = \min \{i \in [|\Gamma'|] \mid \varepsilon(\Lambda_{P_{i+1}}) - \varepsilon(\Lambda_{P_i}) > 2\}.$$

We use the convention that $P_{|\Gamma'|}$ has value infinity, so i_0 indeed exists. Furthermore, we define

$$I = \{i \in [0..i_0] \mid \varepsilon(\Lambda_{P_{i+1}}) - \varepsilon(\Lambda_{P_i}) \geq 2\}.$$

Thus, in order to obtain $\tilde{\Gamma}$, we need to insert a new node between P_i and P_{i+1} into Γ' for each $i \in I$ (resp. one node above P_{i_0}). Since the successor markings of these new nodes might point to some of the other new nodes, we cannot apply Lemma 18 as a black-box. Instead, we need to take some more care: the rough idea is that, first, we compute all positions I where new nodes need to be introduced (I is as defined above), then we compute csdrs for the respective successor markings, and, finally, we introduce these new nodes all at once knowing that all nodes where the successor markings point to are also introduced at the same time. In order to map the positions of nodes in Γ' to positions of nodes in $\tilde{\Gamma}$, we introduce a function $\lambda: [|\Gamma'|] \rightarrow \mathbb{N}$ with $\lambda(i) = i + |I \cap [0..i-1]|$.

Observe that $\lambda(i) = i$ for $i \in [C_0]$, and $\lambda(i+1) = \lambda(i) + 2$ for $i \in I$, and $\lambda(j) = j + |I|$ for $j \geq i_0 + 1$.

For each $i \in I$ we introduce a node Q_i whose successor marking we will specify later such that $\varepsilon(Q_i) = 2\varepsilon(P_i)$. We define the new power circuit $\tilde{\Gamma} = (\tilde{P}_0, \dots, \tilde{P}_{|\Gamma'|+|I|-1})$ by

$$\tilde{P}_j = \begin{cases} P_i & \text{if } j = \lambda(i) \\ Q_i & \text{if } j = \lambda(i) + 1 \text{ and } i \in I. \end{cases}$$

Notice that, if $j = \lambda(i) + 1$ for some $i \in I$, then $j \neq \lambda(i)$ for any i – hence, \tilde{P}_j is well-defined in any case.

The nodes $\tilde{P}_0, \dots, \tilde{P}_{\lambda(i_0)+1}$ will form the chain \tilde{C}_0 as claimed above. Moreover, we have $\Gamma' \subseteq \tilde{\Gamma}$ and $\tilde{\Gamma}$ is sorted increasingly. The successor markings of nodes from Γ' remain unchanged (i.e., $\Lambda_{\tilde{P}_{\lambda(i)}}(\tilde{P}_{\lambda(j)}) = \Lambda_{P_i}(P_j)$ for $i, j \in [|\Gamma'|]$ and $\Lambda_{\tilde{P}_{\lambda(i)}}(Q_j) = 0$ for $j \in I$).

For every $i \in I$ we define the successor marking of the node Q_i by

$$\text{digit}_{\tilde{C}_0}(\Lambda_{Q_i}) = \text{CR}(\varepsilon(\Lambda_{P_i}) + 1) \quad \text{and} \quad \Lambda_{Q_i}|_{\tilde{\Gamma} \setminus \tilde{C}_0} = 0.$$

Be aware that, since $Q_i \in \tilde{C}_0$, also the successor marking of Q_i (of value $\varepsilon(\Lambda_{P_i}) + 1$) can be represented using only the nodes from \tilde{C}_0 (see Remark 9), so this is, indeed, a meaningful definition (be aware that to represent $\varepsilon(\Lambda_{P_i}) + 1$, we might need some of the additional nodes Q_i , but never a node that is not part of the chain \tilde{C}_0). Clearly, this yields $\varepsilon(\Lambda_{Q_i}) = \varepsilon(\Lambda_{P_i}) + 1$ as desired.

We obtain a reduced power circuit $(\tilde{\Gamma}, \tilde{\delta})$ with $(\Gamma', \delta') \leq (\tilde{\Gamma}, \tilde{\delta})$ where the map $\tilde{\delta}: \tilde{\Gamma} \rightarrow \{-1, 0, 1\}$ is defined by the successor markings. Moreover, $\tilde{C}_0 \subseteq \tilde{\Gamma}$ has the required properties.

It remains to show that $\tilde{\Gamma}$ can be computed in TC^0 : As $|C_0| \geq 2$, according to Proposition 14, we are able to decide in AC^0 whether the markings Λ_{P_i} and $\Lambda_{P_{i+1}}$ differ by 1, 2, or more than 2 – for all $i \in [|\Gamma'|]$ in parallel. Now, i_0 can be determined in TC^0 via its definition as above. Likewise I and the function λ can be computed in TC^0 . Using Theorem 11, $\text{CR}(\varepsilon(\Lambda_{P_i}) + 1)$ for $i \in I$ can be computed in AC^0 (since $|\tilde{C}_0| \leq 2 \cdot |\Gamma'|$) showing that altogether $\tilde{\Gamma}$ can be computed in TC^0 .

Step 2: The second step is to add nodes above each chain of $\tilde{\Gamma}$ as required in the Lemma. The outcome will be denoted by (Γ'', δ'') . We start by defining

$$\begin{aligned} d_i &= \min\{\varepsilon(\Lambda_{\tilde{P}_{i+1}}) - \varepsilon(\Lambda_{\tilde{P}_i}) - 1, \mu\} && \text{for } i \in [|\tilde{\Gamma}|] \setminus \{|\tilde{C}_0| - 1\} \quad \text{and} \\ d_i &= \min\{\varepsilon(\Lambda_{\tilde{P}_{i+1}}) - \varepsilon(\Lambda_{\tilde{P}_i}) - 1, \mu - 1\} && \text{for } i = |\tilde{C}_0| - 1. \end{aligned}$$

In order to obtain (Γ'', δ'') from $(\tilde{\Gamma}, \tilde{\delta})$, for every $i \in [|\tilde{\Gamma}|]$ and every $h \in [1..d_i]$ we have to insert a node $R^{(i,h)}$ such that $\varepsilon(\Lambda_{R^{(i,h)}}) = \varepsilon(\Lambda_{\tilde{P}_i}) + h$. Observe that the numbers d_i can be computed in TC^0 : since

$$\mu + 1 \leq \left\lfloor \frac{2^{|\tilde{C}_0|+1}}{3} \right\rfloor + 1 \leq \left\lfloor \frac{2^{|\tilde{C}_0|}}{3} \right\rfloor + 1 \leq \left\lfloor \frac{2^{|\tilde{C}_0|+1}}{3} \right\rfloor,$$

by Proposition 14, we can check in AC^0 whether $\varepsilon(\Lambda_{\tilde{P}_{i+1}}) \leq \varepsilon(\Lambda_{\tilde{P}_i}) + k$ with $k \leq \mu + 1$. If $i = |\tilde{C}_0| - 1$ we choose $k = \mu$, otherwise $k = \mu + 1$. If the respective inequality holds, we obtain by Lemma 42 that $\varepsilon(\Lambda_{\tilde{P}_{i+1}}) - \varepsilon(\Lambda_{\tilde{P}_i}) - 1 = \varepsilon(\Lambda_{\tilde{P}_{i+1}}|_{\tilde{C}_0}) - \varepsilon(\Lambda_{\tilde{P}_i}|_{\tilde{C}_0}) - 1$. For the latter we have signed-digit representations of digit-length at most $|\tilde{C}_0|$. Hence, this difference can be computed in TC^0 .

Since $\tilde{P}_{|\tilde{C}_0|-1} \notin \Gamma'$ and in Step 1 we have not introduced any vertex above $\tilde{P}_{|\tilde{C}_0|-1}$, we know that $\tilde{P}_{|\tilde{C}_0|-1}$ is not marked by $\Lambda_{\tilde{P}}$ for any $\tilde{P} \in \tilde{\Gamma}$. Therefore, for all $i \in [|\tilde{\Gamma}|]$ we have $\varepsilon(\Lambda_{\tilde{P}_i}|_{\tilde{C}_0}) + \mu \leq \left\lfloor \frac{2^{|\tilde{C}_0|}}{3} \right\rfloor + \left\lfloor \frac{2^{|\tilde{C}_0|+1}}{3} \right\rfloor \leq 2 \left\lfloor \frac{2^{|\tilde{C}_0|}}{3} \right\rfloor$ and, hence, by Lemma 40, $\varepsilon(\Lambda_{\tilde{P}_i}|_{\tilde{C}_0}) + h$ can be represented as a compact marking using only nodes from \tilde{C}_0 for every $h \in [1..d_i]$. Thus, for every $d_i \neq 0$ and every $h \in [1..d_i]$ we define a successor marking of $R^{(i,h)}$ by

$$\text{digit}_{\tilde{C}_0}(\Lambda_{R^{(i,h)}}) = \text{CR}(\varepsilon(\Lambda_{\tilde{P}_i}|_{\tilde{C}_0}) + h) \quad \text{and} \quad \Lambda_{R^{(i,h)}}|_{\tilde{\Gamma} \setminus \tilde{C}_0} = \Lambda_{\tilde{P}_i}|_{\tilde{\Gamma} \setminus \tilde{C}_0}.$$

Again, we know that $|\tilde{C}_0| \leq 2|\tilde{\Gamma}'|$. With Theorem 11 we are able to calculate $\text{CR}(\varepsilon(\Lambda_{\tilde{P}_i}|_{\tilde{C}_0}) + h)$ in AC^0 .

Now we set $I = \{R^{(i,h)} \mid d_i \neq 0, h \in [1..d_i]\}$. According to Lemma 18 we are able to construct in TC^0 a reduced power circuit (Γ'', δ'') such that $(\tilde{\Gamma}, \tilde{\delta}) \leq (\Gamma'', \delta'')$ and such that for each $R \in I$ there exists a node $Q \in \Gamma''$ with $\varepsilon(Q) = \varepsilon(R)$.

Considering the size of Γ'' , observe that during the whole construction, for every node $P_i \in \Gamma'$ we create at most μ new nodes between P_i and P_{i+1} . Moreover, we only create new nodes between P_i and P_{i+1} if P_i is the last node of a maximal chain of Γ' . Furthermore, notice that the only node of Γ' above which we have introduced new nodes in both Step 1 and Step 2 is the second largest node of \tilde{C}_0 : in Step 1 we have created one new node and in Step 2 we have created at most $\mu - 1$ new nodes above it. Thus, for every chain of Γ' we have introduced at most μ new nodes. Thus, $|\Gamma''| \leq |\Gamma'| + |\mathcal{C}_{\Gamma'}| \cdot \mu$. Finally, the new nodes we create only prolongate the already existing chains, so we do not create any new chains. This finishes the proof of the lemma. \blacktriangleleft

Proof of Lemma 21. Consider again the equivalence relation \sim_ε as defined above on $\Gamma'' \cup \text{Min}(\Xi)$. For the equivalence class of a node $P \in \Gamma'' \cup \text{Min}(\Xi)$ we write $[P]_\varepsilon$. We will define the marking \tilde{M} on Γ'' by defining it on each maximal chain. Recall that we can view M as a marking on $\Gamma'' \cup \Xi$ by defining $M(P) = 0$ if $P \notin \Gamma \cup \Xi$.

Let $C = (P_i, \dots, P_{i+h-1}) \in \mathcal{C}_{\Gamma''}$ be a maximal chain of length h and let

$$S = \bigcup_{P \in C} [P]_\varepsilon = \bigcup_{P \in C} \{Q \in \Gamma'' \cup \text{Min}(\Xi) \mid \varepsilon(Q) = \varepsilon(P)\} \subseteq \Gamma'' \cup \text{Min}(\Xi).$$

74:22 Parallel Algorithms for the Baumslag Group

We wish to find a compact marking \tilde{M}_C with support contained in $C \subseteq \Gamma''$ and evaluation $\varepsilon(\tilde{M}_C) = \varepsilon(M|_S)$. First define the integer

$$Z_{M,C} = \sum_{r=0}^{h-1} \left(\sum_{Q \in [P_{i+r}]_\varepsilon} M(Q) \right) 2^r.$$

Then we have

$$\begin{aligned} Z_{M,C} \cdot \varepsilon(\text{start}(C)) &= \sum_{r=0}^{h-1} \sum_{Q \in [P_{i+r}]_\varepsilon} M(Q) 2^r \cdot \varepsilon(\text{start}(C)) \\ &= \sum_{Q \in S} M(Q) \varepsilon(Q) = \varepsilon(M|_S). \end{aligned}$$

Thus, defining \tilde{M}_C by $\text{digit}_C(\tilde{M}_C) = \text{CR}(Z_{M,C})$ gives our desired marking.

However, be aware that, for this, we have to show that the digit-length of $\text{CR}(Z_{M,C})$ is at most $|C| = h$. Let k be maximal such that $P_{i+k} \in \Gamma'$. Then, in particular, no node in S with higher evaluation than P_{i+k} is marked by M . Moreover, by the properties of $\text{EXTENDCHAINS}(\lceil \log(|\text{Min}(\Xi)|) \rceil + 1)$, we have $h - 1 - k \geq \lceil \log(|\text{Min}(\Xi)|) \rceil + 1$. Therefore,

$$\begin{aligned} Z_{M,C} &\leq \text{val}(\text{digit}_C(M)) + |\text{Min}(\Xi)| \cdot 2^k \\ &\leq \frac{1}{3} \cdot 2^{k+2} + 2^{k+\log(|\text{Min}(\Xi)|)} && \text{(by Lemma 40)} \\ &\leq \frac{4}{3} \cdot \left(2^k + 2^{k+\log(|\text{Min}(\Xi)|)} \right) \\ &\leq \frac{2}{3} \cdot 2^{k+\lceil \log(|\text{Min}(\Xi)|) \rceil + 2}. \end{aligned}$$

Thus, by Lemma 40, the digit-length of $\text{CR}(Z_{M,C})$ is at most $k + \lceil \log(|\text{Min}(\Xi)|) \rceil + 2 \leq h$. As an easy consequence of Proposition 14, the maximal chains can be determined in TC^0 . Now, for every maximal chain C the (binary) number $Z_{M,C}$ can be computed in TC^0 using iterated addition and made compact in AC^0 using Theorem 11. Thus, the marking \tilde{M}_C can be computed in TC^0 . The marking \tilde{M} as desired in the lemma is simply defined by $\tilde{M}|_{\Xi \setminus \text{Min}(\Xi)} = M|_{\Xi \setminus \text{Min}(\Xi)}$ and $\tilde{M}|_C = \tilde{M}_C|_C$ for $C \in \mathcal{C}_{\Gamma''}$ – all the markings \tilde{M}_C can be computed in parallel. \blacktriangleleft

Proof of Theorem 17. Now we are ready to describe the full reduction process based on the three steps described above. We aim for a DepParaTC^0 circuit where the input is parametrized by the depth of the power circuit. The input is some arbitrary power circuit (Π, δ_Π) together with a marking M on Π . We start with some initial reduced power circuit (Γ_0, δ_0) and some non-reduced part $\Xi_0 = \Pi$ and successively apply the three steps to obtain power circuits $(\Gamma_i \cup \Xi_i, \delta_i)$ and markings M_i for $i = 0, 1, \dots$ while keeping the following invariants:

- $(\Gamma_i, \delta_i|_{\Gamma_i \times \Gamma_i}) \leq (\Gamma_i \cup \Xi_i, \delta_i)$ (i.e., there are no edges from Γ_i to Ξ_i),
- Γ_i is reduced,
- $\Gamma_{i-1} \leq \Gamma_i$ and $\Xi_i \subseteq \Xi_{i-1}$,
- $\varepsilon(M_i) = \varepsilon(M)$.

Moreover, as long as $\Xi_{i-1} \neq \emptyset$ we assure that $\text{depth}(\Xi_i) < \text{depth}(\Xi_{i-1})$.

We first construct the initial reduced power circuit $(\Gamma_0, \tilde{\delta}_0)$ which consists exactly of a chain of length $\ell = \lceil \log(|\Pi|) \rceil + 1$. This can be done as follows: Let $\Gamma_0 = (P_0, \dots, P_{\ell-1}) = C_0$ and define successor markings by $\text{digit}_{C_0}(\Lambda_{P_i}) = \text{CR}(i)$ for $i \in [\ell]$. This defines $\tilde{\delta}_0$. Now we set $\Xi_0 = \Pi$ and we define $\delta_0: (\Gamma_0 \cup \Xi_0) \times (\Gamma_0 \cup \Xi_0) \rightarrow \{-1, 0, 1\}$ by $\delta_0|_{\Gamma_0 \times \Gamma_0} = \tilde{\delta}_0$,

$\delta_0|_{\Xi_0 \times \Xi_0} = \delta_\Pi$ and $\delta = 0$ otherwise. We extend the marking M to Γ_0 by setting $M(P) = 0$ for all $P \in \Gamma_0$. So we obtain a power circuit of the form $(\Gamma_0 \cup \Xi_0, \delta_0)$ with the properties described above.

Now let the power circuit $(\Gamma_i \cup \Xi_i, \delta_i)$ together with the marking M_i be the input for the $i + 1$ -th iteration meeting the above described invariants. We write $\tilde{\delta}_i = \delta_i|_{\Gamma_i \times \Gamma_i}$. Now we apply the three steps from above:

1. Using UPDATENODES (Lemma 19) we compute a reduced power circuit (Γ'_i, δ'_i) with $(\Gamma_i, \tilde{\delta}_i) \leq (\Gamma'_i, \delta'_i)$ such that for every $P \in \text{Min}(\Xi_i)$ there is some $Q \in \Gamma'_i$ with $\varepsilon(Q) = \varepsilon(P)$.
2. Using EXTENDCHAINS (Lemma 20) with $\mu = \lceil \log(|\text{Min}(\Xi_i)|) \rceil + 1$ we extend each maximal chain in (Γ'_i, δ'_i) by at most $\lceil \log(|\text{Min}(\Xi_i)|) \rceil + 1$ nodes. Notice that $\lceil \log(|\text{Min}(\Xi_i)|) \rceil + 1 \leq \lceil \log(|\Pi|) \rceil + 1$ and so, as $\Gamma_0 \leq \Gamma'_i$, the condition $\mu \leq \left\lfloor \frac{2^{\lceil C_0(\Gamma'_i) \rceil + 1}}{3} \right\rfloor$ in Lemma 20 is satisfied. The result of this step is denoted by (Γ''_i, δ''_i) .
3. We apply UPDATEMARKINGS (Lemma 21) to obtain markings \tilde{M}_i and $\tilde{\Lambda}_P$ for $P \in \Xi_i \setminus \text{Min}(\Xi_i)$ on $\Gamma''_i \cup (\Xi_i \setminus \text{Min}(\Xi_i))$ such that $\varepsilon(\tilde{M}_i) = \varepsilon(M_i)$ and $\varepsilon(\tilde{\Lambda}_P) = \varepsilon(\Lambda_P)$. Observe that these markings restricted to Γ''_i are compact.
4. Each iteration ends by setting $\Gamma_{i+1} = \Gamma''_i$ and $\Xi_{i+1} = \Xi_i \setminus \text{Min}(\Xi_i)$ and $M_{i+1} = \tilde{M}_i$. Finally, δ_{i+1} is defined as δ''_i on Γ_{i+1} and via the successor markings $\tilde{\Lambda}_P$ for $P \in \Xi_{i+1}$.

After exactly $\text{depth}(\Pi) + 1$ iterations we reach $\Xi_{d+1} = \Xi_d \setminus \text{Min}(\Xi_d) = \emptyset$ where $d = \text{depth}(\Pi)$. In this case we do not change the resulting power circuit any further. It is clear from Lemma 19, Lemma 20 and Lemma 21 that throughout the above-mentioned invariants are maintained. Thus, $(\Gamma, \delta) = (\Gamma_{d+1}, \delta_{d+1})$ is a reduced power circuit and for every node $P \in \Pi$ there exists a node $Q \in \Gamma_{d+1}$ such that $\varepsilon(Q) = \varepsilon(P)$ and M_{d+1} is a compact marking on Γ_{d+1} with $\varepsilon(M_{d+1}) = \varepsilon(M)$.

▷ **Claim 43** (see Claim 22). Let $d = \text{depth}(\Pi)$ and $\Gamma_0, \dots, \Gamma_{d+1}$ be as constructed above. Then for all i we have $|\mathcal{C}_{\Gamma_i}| \leq |\Pi| + 1$ and $|\Gamma_i| \leq (|\Pi| + 1)^2 \cdot (\log(|\Pi|) + 2)$.

Proof. According to Lemma 19 and Lemma 20 we have $|\mathcal{C}_{\Gamma_{i+1}}| \leq |\mathcal{C}_{\Gamma_i}| + |\text{Min}(\Xi_i)|$. Further observe that Π is the disjoint union of the $\text{Min}(\Xi_j)$ for $j \in [0..d]$. Since $|\mathcal{C}_{\Gamma_0}| = 1$, we obtain for all $i \in [0..d]$ that

$$|\mathcal{C}_{\Gamma_{i+1}}| \leq |\mathcal{C}_{\Gamma_i}| + |\text{Min}(\Xi_i)| \leq 1 + \sum_{0 \leq j \leq i} |\text{Min}(\Xi_j)| \leq |\Pi| + 1. \quad (3)$$

Again by Lemma 19 and Lemma 20 we have

$$\begin{aligned} |\Gamma_{i+1}| &\leq |\Gamma'_i| + |\mathcal{C}_{\Gamma'_i}| \cdot (\lceil \log(|\text{Min}(\Xi_i)|) \rceil + 1) && \text{(by Lemma 20)} \\ &\leq |\Gamma_i| + |\text{Min}(\Xi_i)| + (|\mathcal{C}_{\Gamma_i}| + |\text{Min}(\Xi_i)|) \cdot (\lceil \log(|\text{Min}(\Xi_i)|) \rceil + 1) && \text{(by Lemma 19)} \\ &\leq |\Gamma_i| + |\text{Min}(\Xi_i)| + (|\Pi| + 1) \cdot (\lceil \log(|\Pi|) \rceil + 1). && \text{(by (3))} \end{aligned}$$

Since $|\Gamma_0| = \lceil \log(|\Pi|) \rceil + 1$, we obtain by induction that

$$\begin{aligned} |\Gamma_i| &\leq |\Gamma_0| + \sum_{0 \leq j \leq i-1} |\text{Min}(\Xi_j)| + i \cdot (|\Pi| + 1) \cdot (\log(|\Pi|) + 2) \\ &\leq (\lceil \log(|\Pi|) \rceil + 1) + |\Pi| + i \cdot (|\Pi| + 1) \cdot (\log(|\Pi|) + 2) \\ &\leq (i + 1) \cdot (|\Pi| + 1) \cdot (\log(|\Pi|) + 2) \end{aligned}$$

for all $i \in [1..d + 1]$. The last inequality is due to the fact that $|\Pi| + 1 \geq 2$ and $\log(|\Pi|) + 2 \geq 2$. Since $d + 1 \leq |\Pi|$, we obtain $|\Gamma_i| \leq (|\Pi| + 1)^2 \cdot (\log(|\Pi|) + 2)$. ◁

74:24 Parallel Algorithms for the Baumslag Group

Let $D \in \mathbb{N}$ and assume that $\text{depth}(\Pi) \leq D$. By Lemma 19, Lemma 20 and Lemma 21 each iteration of the three steps above can be done in TC^0 . Notice here that the construction of the markings \tilde{M}_i and $\tilde{\Lambda}_P$ during `UPDATERMARKINGS` can be done in parallel – so it is in TC^0 , although Lemma 21 is stated only for a single marking. Now, the crucial observation is that, due to Claim 43, the input size for each iteration is polynomial in the original input size of (Π, δ_Π) . Therefore, we can compose the individual iterations and obtain a circuit of polynomial size and depth bounded by $\mathcal{O}(D)$. Thus, we have described a DepParaTC^0 circuit (parametrized by $\text{depth}(\Pi)$) for the problem of computing a reduced form for (Π, δ_Π) . This completes the proof of Theorem 17. ◀

The Complexity of Transitively Orienting Temporal Graphs

Abstract

In a *temporal network* with discrete time-labels on its edges, entities and information can only “flow” along sequences of edges whose time-labels are non-decreasing (resp. increasing), i.e. along temporal (resp. strict temporal) paths. Nevertheless, in the model for temporal networks of [Kempe, Kleinberg, Kumar, JCSS, 2002], the individual time-labeled edges remain undirected: an edge $e = \{u, v\}$ with time-label t specifies that “ u communicates with v at time t ”. This is a symmetric relation between u and v , and it can be interpreted that the information can flow in either direction. In this paper we make a first attempt to understand how the direction of information flow on one edge can impact the direction of information flow on other edges. More specifically, naturally extending the classical notion of a transitive orientation in static graphs, we introduce the fundamental notion of a *temporal transitive orientation* and we systematically investigate its algorithmic behavior in various situations. An orientation of a temporal graph is called *temporally transitive* if, whenever u has a directed edge towards v with time-label t_1 and v has a directed edge towards w with time-label $t_2 \geq t_1$, then u also has a directed edge towards w with some time-label $t_3 \geq t_2$. If we just demand that this implication holds whenever $t_2 > t_1$, the orientation is called *strictly temporally transitive*, as it is based on the fact that there is a strict directed temporal path from u to w . Our main result is a conceptually simple, yet technically quite involved, polynomial-time algorithm for recognizing whether a given temporal graph \mathcal{G} is transitively orientable. In wide contrast we prove that, surprisingly, it is NP-hard to recognize whether \mathcal{G} is strictly transitively orientable. Additionally we introduce and investigate further related problems to temporal transitivity, notably among them the *temporal transitive completion* problem, for which we prove both algorithmic and hardness results.

1 Introduction

A *temporal* (or *dynamic*) network is, roughly speaking, a network whose underlying topology changes over time. This notion concerns a great variety of both modern and traditional networks; information and communication networks, social networks, and several physical systems are only few examples of networks which change over time [26,38,41]. Due to its vast applicability in many areas, the notion of temporal graphs has been studied from different perspectives under several different names such as *time-varying*, *evolving*, *dynamic*, and *graphs over time* (see [13–15] and the references therein). In this paper we adopt a simple and natural model for temporal networks which is given with discrete time-labels on the edges of a graph, while the vertex set remains unchanged. This formalism originates in the foundational work of Kempe et al. [27].

► **Definition 1** (Temporal Graph [27]). *A temporal graph is a pair $\mathcal{G} = (G, \lambda)$, where $G = (V, E)$ is an underlying (static) graph and $\lambda : E \rightarrow \mathbb{N}$ is a time-labeling function which assigns to every edge of G a discrete-time label.*

Mainly motivated by the fact that, due to causality, entities and information in temporal graphs can only “flow” along sequences of edges whose time-labels are non-decreasing (resp. increasing), Kempe et al. introduced the notion of a (*strict*) *temporal path*, or (*strict*) *time-respecting path*, in a temporal graph (G, λ) as a path in G with edges e_1, e_2, \dots, e_k such that $\lambda(e_1) \leq \dots \leq \lambda(e_k)$ (resp. $\lambda(e_1) < \dots < \lambda(e_k)$). This notion of a temporal path naturally resembles the notion of a *directed* path in the classical static graphs, where the direction is from smaller to larger time-labels along the path. Nevertheless, in temporal paths the individual time-labeled edges remain undirected: an edge $e = \{u, v\}$ with time-label $\lambda(e) = t$ can be abstractly interpreted as “ u communicates with v at time t ”. Here the relation “communicates” is symmetric between u and v , i.e. it can be interpreted that the information can flow in either direction.

In this paper we make a first attempt to understand how the direction of information flow on one edge can impact the direction of information flow on other edges. More specifically, naturally extending the classical notion of a transitive orientation in static graphs [23], we introduce the fundamental notion of a *temporal transitive orientation* and we thoroughly investigate its algorithmic behavior in various situations. Imagine that v receives information from u at time t_1 , while w receives information from v at time $t_2 \geq t_1$. Then w *indirectly* receives information from u through the intermediate vertex v . Now, if the temporal graph correctly records the transitive closure of information passing, the directed edge from u to w must exist and must have a time label $t_3 \geq t_2$. In such a *transitively oriented* temporal graph, whenever an edge is oriented from a vertex u to a vertex w with time-label t , we have that *every* temporal path from u to w arrives no later than t , and that there is no temporal path from w to u . Different notions of temporal transitivity have also been used for automated temporal data mining [40] in medical applications [39], text processing [45]. Furthermore, in behavioral ecology, researchers have used a notion of orderly (transitive) triads A-B-C to quantify dominance among species. In particular, animal groups usually form dominance hierarchies in which dominance relations are transitive and can also change with time [32].

One natural motivation for our temporal transitivity notion may come from applications where confirmation and verification of information is vital, where vertices may represent entities such as investigative journalists or police detectives who gather sensitive information. Suppose that v queried some important information from u (the information source) at time t_1 , and afterwards, at time $t_2 \geq t_1$, w queried the important information from v (the intermediary). Then, in order to ensure the validity of the information received, w might want to verify it by *subsequently* querying the information directly from u at some time $t_3 \geq t_2$. Note that w might first receive the important information from u through various other intermediaries, and using several channels of different lengths. Then, to maximize confidence about the information, w should query u for verification only after receiving the information from the latest of these indirect channels.

It is worth noting here that the model of temporal graphs given in Definition 1 has been also used in its extended form, in which the temporal graph may contain multiple time-labels per edge [34]. This extended temporal graph model has been used to investigate temporal paths [3, 9, 11, 16, 34, 47] and other temporal path-related notions such as temporal analogues of distance and diameter [1], reachability [2] and exploration [1, 3, 20, 21], separation [22, 27, 48], and path-based centrality measures [12, 28], as well as recently non-path problems too such as temporal variations of coloring [37], vertex cover [4], matching [35], cluster editing [18], and maximal cliques [8, 25, 46]. However, in order to better investigate and illustrate the inherent combinatorial structure of temporal transitivity orientations, in this paper we mostly follow the original definition of temporal graphs given by Kempe et al. [27] with one time-label per edge [7, 17, 19]. Throughout the paper, whenever we assume multiple time-labels per edge we will state it explicitly; in all other cases we consider a single label per edge.

In static graphs, the transitive orientation problem has received extensive attention which resulted in numerous efficient algorithms. A graph is called *transitively orientable* (or a *comparability* graph) if it is possible to orient its edges such that, whenever we orient u towards v and v towards w , then the edge between u and w exists and is oriented towards w . The first polynomial-time algorithms for recognizing whether a given (static) graph G on n vertices and m edges is comparability (i.e. transitively orientable) were based on the notion of *forcing* an orientation and had running time $O(n^3)$ (see Golumbic [23] and the references therein). Faster algorithms for computing a transitive orientation of a given comparability graph have been later developed, having running times $O(n^2)$ [43] and $O(n + m \log n)$ [29], while the currently fastest algorithms run in linear $O(n + m)$ time and are based on efficiently computing a modular decomposition of G [30, 31]; see also Spinrad [44]. It is fascinating that, although all the latter algorithms compute a valid transitive orientation if G is a comparability graph, they fail to recognize whether the input graph is a comparability graph; instead they produce an orientation which is non-transitive if G is not a comparability graph. The fastest known algorithm for determining whether a given orientation is transitive requires matrix multiplication, currently achieved in $O(n^{2.37286})$ time [5].

Our contribution. In this paper we introduce the notion of *temporal transitive orientation* and we thoroughly investigate its algorithmic behavior in various situations. An orientation of a temporal graph $\mathcal{G} = (G, \lambda)$ is called *temporally transitive* if, whenever u has a directed edge towards v with time-label t_1 and v has a directed edge towards w with time-label $t_2 \geq t_1$, then u also has a directed edge towards w with some time-label $t_3 \geq t_2$. If we just demand that this implication holds whenever $t_2 > t_1$, the orientation is called *strictly* temporally transitive, as it is based on the fact that there is a strict directed temporal path from u to w . Similarly, if we demand that the transitive directed edge from u to w has time-label $t_3 > t_2$, the orientation is called *strongly* (resp. *strongly strictly*) temporally transitive.

Although these four natural variations of a temporally transitive orientation seem superficially similar to each other, it turns out that their computational complexity (and their underlying combinatorial structure) varies massively. Indeed we obtain a surprising result in Section 3: deciding whether a temporal graph \mathcal{G} admits a *temporally transitive* orientation is solvable in polynomial time (Section 3.2), while it is NP-hard to decide whether it admits a *strictly temporally transitive* orientation (Section 3.1). On the other hand, it turns out that, deciding whether \mathcal{G} admits a *strongly* or a *strongly strictly* temporal transitive orientation is (easily) solvable in polynomial time as they can both be reduced to 2SAT satisfiability.

Our main result is that, given a temporal graph $\mathcal{G} = (G, \lambda)$, we can decide in polynomial time whether \mathcal{G} is transitively orientable, and at the same time we can output a temporal transitive orientation if it exists. Although the analysis and correctness proof of our algorithm is technically quite involved, our algorithm is simple and easy to implement, as it is based on the notion of *forcing* an orientation.¹ Our algorithm extends and generalizes the classical polynomial-time algorithm for computing a transitive orientation in static graphs described by Golumbic [23]. The main technical difficulty in extending the algorithm from the static to the temporal setting is that, in temporal graphs we cannot simply use orientation forcings to eliminate the condition that a *triangle* is not allowed to be cyclically oriented. To resolve this issue, we first express the recognition problem of temporally transitively orientable graphs as a Boolean satisfiability problem of a *mixed* Boolean formula $\phi_{3\text{NAE}} \wedge \phi_{2\text{SAT}}$. Here $\phi_{3\text{NAE}}$ is a 3NAE (i.e. 3-NOT-ALL-EQUAL) formula and $\phi_{2\text{SAT}}$ is a 2SAT formula. Note that every clause $\text{NAE}(\ell_1, \ell_2, \ell_3)$ of $\phi_{3\text{NAE}}$ corresponds to the condition that a specific triangle in the temporal graph cannot be cyclically oriented. However, although deciding whether $\phi_{2\text{SAT}}$ is satisfiable can be done in linear time with respect to the size of the formula [6], the problem Not-All-Equal-3-SAT is NP-complete [42].

Our algorithm iteratively produces at iteration j a formula $\phi_{3\text{NAE}}^{(j)} \wedge \phi_{2\text{SAT}}^{(j)}$, which is computed from the previous formula $\phi_{3\text{NAE}}^{(j-1)} \wedge \phi_{2\text{SAT}}^{(j-1)}$ by (almost) simulating the classical greedy algorithm that solves 2SAT [6]. The 2SAT-algorithm proceeds greedily as follows. For every variable x_i , if setting $x_i = 1$ (resp. $x_i = 0$) leads to an immediate contradiction, the algorithm is forced to set $x_i = 0$ (resp. $x_i = 1$). Otherwise, if each of the truth assignments $x_i = 1$ and $x_i = 0$ does not lead to an immediate contradiction, the algorithm arbitrarily chooses to set $x_i = 1$ or $x_i = 0$, and thus some clauses are removed from the formula as they were satisfied. The argument for the correctness of the 2SAT-algorithm is that new clauses are *never added* to the formula at any step. The main technical difference between the 2SAT-algorithm and our algorithm is that, in our case, the formula $\phi_{3\text{NAE}}^{(j)} \wedge \phi_{2\text{SAT}}^{(j)}$ is *not* necessarily a sub-formula of $\phi_{3\text{NAE}}^{(j-1)} \wedge \phi_{2\text{SAT}}^{(j-1)}$, as in some cases we need to also add clauses. Our main technical result is that, nevertheless, at every iteration j the formula $\phi_{3\text{NAE}}^{(j)} \wedge \phi_{2\text{SAT}}^{(j)}$ is satisfiable if and only if $\phi_{3\text{NAE}}^{(j-1)} \wedge \phi_{2\text{SAT}}^{(j-1)}$ is satisfiable. The proof of this result (see Theorem 9) relies on a sequence of structural properties of temporal transitive orientations which we establish. This phenomenon of deducing a polynomial-time algorithm for an algorithmic graph problem by deciding satisfiability of a mixed Boolean formula (i.e. with both clauses of two and three literals) occurs rarely; this approach has been successfully used for the efficient recognition of simple-triangle (known also as “PI”) graphs [33].

In the second part of our paper (Section 4) we consider a natural extension of the temporal orientability problem, namely the *temporal transitive completion* problem. In this problem we are given a (partially oriented) temporal graph \mathcal{G} and a natural number k , and the question

¹ That is, orienting an edge from u to v *forces* us to orient another edge from a to b .

is whether it is possible to add at most k new edges (with the corresponding time-labels) to \mathcal{G} such that the resulting temporal graph is (strongly/strictly/strongly strictly) transitively orientable. We prove that all four versions of temporal transitive completion are NP-complete, even when the input temporal graph is completely unoriented. In contrast we show that, if the input temporal graph \mathcal{G} is *directed* (i.e. if every time-labeled edge has a fixed orientation) then all versions of temporal transitive completion are solvable in polynomial time. As a corollary of our results it follows that all four versions of temporal transitive completion are fixed-parameter-tractable (FPT) with respect to the number q of unoriented time-labeled edges in \mathcal{G} .

In the third and last part of our paper (Section 5) we consider the *multilayer transitive orientation* problem. In this problem we are given an undirected temporal graph $\mathcal{G} = (G, \lambda)$, where $G = (V, E)$, and we ask whether there exists an orientation F of its edges (i.e. with exactly one orientation for each edge of G) such that, for every “time-layer” $t \geq 1$, the (static) oriented graph induced by the edges having time-label t is transitively oriented in F . Problem definitions of this type are commonly referred to as multilayer problems [10]. Observe that this problem trivially reduces to the static case if we assume that each edge has a single time-label, as then each layer can be treated independently of all others. However, if we allow \mathcal{G} to have multiple time-labels on every edge of G , then we show that the problem becomes NP-complete, even when every edge has at most two labels.

Due to space constraints, some of our results are deferred to a full version [36].

2 Preliminaries and Notation

Given a (static) undirected graph $G = (V, E)$, an edge between two vertices $u, v \in V$ is denoted by the unordered pair $\{u, v\} \in E$, and in this case the vertices u, v are said to be *adjacent*. If the graph is directed, we will use the ordered pair (u, v) (resp. (v, u)) to denote the oriented edge from u to v (resp. from v to u). For simplicity of the notation, we will usually drop the parentheses and the comma when denoting an oriented edge, i.e. we will denote (u, v) just by uv . Furthermore, $\widehat{uv} = \{uv, vu\}$ is used to denote the set of both oriented edges uv and vu between the vertices u and v .

Let $S \subseteq E$ be a subset of the edges of an undirected (static) graph $G = (V, E)$, and let $\widehat{S} = \{uv, vu : \{u, v\} \in S\}$ be the set of both possible orientations uv and vu of every edge $\{u, v\} \in S$. Let $F \subseteq \widehat{S}$. If F contains *at least one* of the two possible orientations uv and vu of each edge $\{u, v\} \in S$, then F is called an *orientation* of the edges of S . F is called a *proper orientation* if it contains *exactly one* of the orientations uv and vu of every edge $\{u, v\} \in S$. Note here that, in order to simplify some technical proofs, the above definition of an orientation allows F to be not proper, i.e. to contain *both* uv and vu for a specific edge $\{u, v\}$. However, whenever F is not proper, this means that F can be discarded as it cannot be used as a part of a (temporal) transitive orientation. For every orientation F denote by $F^{-1} = \{vu : uv \in F\}$ the *reversal* of F . Note that $F \cap F^{-1} = \emptyset$ if and only if F is proper.

In a temporal graph $\mathcal{G} = (G, \lambda)$, where $G = (V, E)$, whenever $\lambda(\{v, w\}) = t$ (or simply $\lambda(v, w) = t$), we refer to the tuple $(\{v, w\}, t)$ as a *time-edge* of \mathcal{G} . A triangle of (G, λ) on the vertices u, v, w is a *synchronous triangle* if $\lambda(u, v) = \lambda(v, w) = \lambda(w, u)$. Let $G = (V, E)$ and let F be a proper orientation of the whole edge set E . Then (\mathcal{G}, F) , or (G, λ, F) , is a *proper orientation* of the temporal graph \mathcal{G} . A *partial proper orientation* F of $\mathcal{G} = (G, \lambda)$ is an orientation of a subset of E . To indicate that the edge $\{u, v\}$ of a time-edge $(\{u, v\}, t)$ is oriented from u to v (that is, $uv \in F$ in a (partial) proper orientation F), we use the term $((u, v), t)$, or simply (uv, t) . For simplicity we may refer to a (partial) proper orientation just as a (partial) orientation, whenever the term “proper” is clear from the context.

75:6 The Complexity of Transitively Orienting Temporal Graphs

A static graph $G = (V, E)$ is a *comparability graph* if there exists a proper orientation F of E which is *transitive*, that is, if $F \cap F^{-1} = \emptyset$ and $F^2 \subseteq F$, where $F^2 = \{uv : uv, vw \in F\}$ [23]. Analogously, in a temporal graph $\mathcal{G} = (G, \lambda)$, where $G = (V, E)$, we define a proper orientation F of E to be *temporally transitive*, if:

whenever (uv, t_1) and (vw, t_2) are oriented time-edges in (\mathcal{G}, F) such that $t_2 \geq t_1$, there exists an oriented time-edge (wu, t_3) in (\mathcal{G}, F) , for some $t_3 \geq t_2$.

In the above definition of a temporally transitive orientation, if we replace the condition “ $t_3 \geq t_2$ ” with “ $t_3 > t_2$ ”, then F is called *strongly temporally transitive*. If we instead replace the condition “ $t_2 \geq t_1$ ” with “ $t_2 > t_1$ ”, then F is called *strictly temporally transitive*. If we do both of these replacements, then F is called *strongly strictly temporally transitive*. Note that strong (strict) temporal transitivity implies (strict) temporal transitivity, while (strong) temporal transitivity implies (strong) strict temporal transitivity. Furthermore, similarly to the established terminology for static graphs, we define a temporal graph $\mathcal{G} = (G, \lambda)$, where $G = (V, E)$, to be a (*strongly/strictly*) *temporal comparability graph* if there exists a proper orientation F of E which is (*strongly/strictly*) *temporally transitive*.

We are now ready to formally introduce the following decision problem of recognizing whether a given temporal graph is temporally transitively orientable or not.

TEMPORAL TRANSITIVE ORIENTATION (TTO)

Input: A temporal graph $\mathcal{G} = (G, \lambda)$, where $G = (V, E)$.

Question: Does \mathcal{G} admit a temporally transitive orientation F of E ?

In the above problem definition of TTO, if we ask for the existence of a strictly (resp. strongly, or strongly strictly) temporally transitive orientation F , we obtain the decision problem STRICT (resp. STRONG, or STRONG STRICT) TEMPORAL TRANSITIVE ORIENTATION (TTO).

Let $\mathcal{G} = (G, \lambda)$ be a temporal graph, where $G = (V, E)$. Let $G' = (V, E')$ be a graph such that $E \subseteq E'$, and let $\lambda' : E' \rightarrow \mathbb{N}$ be a time-labeling function such that $\lambda'(u, v) = \lambda(u, v)$ for every $\{u, v\} \in E$. Then the temporal graph $\mathcal{G}' = (G', \lambda')$ is called a *temporal supergraph* of \mathcal{G} . We can now define our next problem definition regarding computing temporally orientable supergraphs of \mathcal{G} .

TEMPORAL TRANSITIVE COMPLETION (TTC)

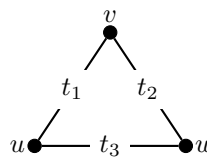

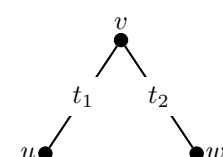

Input: A temporal graph $\mathcal{G} = (G, \lambda)$, where $G = (V, E)$, a (partial) orientation F of \mathcal{G} , and an integer k .

Question: Does there exist a temporal supergraph $\mathcal{G}' = (G', \lambda')$ of (G, λ) , where $G' = (V, E')$, and a transitive orientation $F' \supseteq F$ of \mathcal{G}' such that $|E' \setminus E| \leq k$?

Similarly to TTO, if we ask in the problem definition of TTC for the existence of a strictly (resp. strongly, or strongly strictly) temporally transitive orientation F' , we obtain the decision problem STRICT (resp. STRONG, or STRONG STRICT) TEMPORAL TRANSITIVE COMPLETION (TTC).

Now we define our final problem which asks for an orientation F of a temporal graph $\mathcal{G} = (G, \lambda)$ (i.e. with exactly one orientation for each edge of G) such that, for every “time-layer” $t \geq 1$, the (static) oriented graph defined by the edges having time-label t is transitively oriented in F . This problem does not make much sense if every edge has exactly one time-label in \mathcal{G} , as in this case it can be easily solved by just repeatedly applying any known static transitive orientation algorithm. Therefore, in the next problem definition, we assume that in the input temporal graph $\mathcal{G} = (G, \lambda)$ every edge of G potentially has multiple time-labels, i.e. the time-labeling function is $\lambda : E \rightarrow 2^{\mathbb{N}}$.

■ **Table 1** Orientation conditions imposed by a triangle (left) and an induced path of length two (right) in the underlying graph G for the decision problems (STRICT/STRONG/STRONG STRICT) TTO. Here, \top means that no restriction is imposed, \perp means that the graph is not orientable, and in the case of triangles, “non-cyclic” means that all orientations except the ones that orient the triangle cyclicly are allowed.

					
	$t_1 = t_2 = t_3$	$t_1 < t_2 = t_3$	$t_1 \leq t_2 < t_3$	$t_1 = t_2$	$t_1 < t_2$
TTO	non-cyclic	$wu = wv$	$vw \implies uw$ $vu \implies wu$	$uv = wv$	$uv \implies vw$
STRONG TTO	\perp	$wu \wedge wv$	$vw \implies uw$ $vu \implies wu$	$uv = wv$	$uv \implies vw$
STRICT TTO	\top	non-cyclic	$vw \implies uw$ $vu \implies wu$	\top	$uv \implies vw$
STR. STR. TTO	\top	$vu \implies wu$ $uv \implies wv$	$vw \implies uw$ $vu \implies wu$	\top	$uv \implies vw$

MULTILAYER TRANSITIVE ORIENTATION (MTO)

Input: A temporal graph $\mathcal{G} = (G, \lambda)$, where $G = (V, E)$ and $\lambda : E \rightarrow 2^{\mathbb{N}}$.

Question: Is there an orientation F of the edges of G such that, for every $t \geq 1$, the (static) oriented graph induced by the edges having time-label t is transitively oriented?

3 The recognition of temporally transitively orientable graphs

In this section we investigate the computational complexity of all variants of TTO. We show that TTO as well as the two variants STRONG TTO and STRONG STRICT TTO, are solvable in polynomial time, whereas STRICT TTO turns out to be NP-complete.

The main idea of our approach to solve TTO and its variants is to create Boolean variables for each edge of the underlying graph G and interpret setting a variable to 1 or 0 with the two possible ways of directing the corresponding edge.

More formally, for every edge $\{u, v\}$ we introduce a variable x_{uv} and setting this variable to 1 corresponds to the orientation uv while setting this variable to 0 corresponds to the orientation vu . Now consider the example of Figure 1(a), i.e. an induced path of length two in the underlying graph G on three vertices u, v, w , and let $\lambda(u, v) = 1$ and $\lambda(v, w) = 2$. Then the orientation uv “forces” the orientation wv . Indeed, if we otherwise orient $\{v, w\}$ as vw , then the edge $\{u, w\}$ must exist and be oriented as uw in any temporal transitive orientation, which is a contradiction as there is no edge between u and w . We can express this “forcing” with the implication $x_{uv} \implies x_{wv}$. In this way we can deduce the constraints that all triangles or induced paths on three vertices impose on any (strong/strict/strong strict) temporal transitive orientation. We collect all these constraints in Table 1.

When looking at the conditions imposed on temporal transitive orientations collected in Table 1, we can observe that all conditions except “non-cyclic” are expressible in 2SAT. Since 2SAT is solvable in linear time [6], it immediately follows that the strong variants of temporal transitivity are solvable in polynomial time, as the next theorem states.

► **Theorem 2.** *STRONG TTO and STRONG STRICT TTO are solvable in polynomial time.*

In the variants TTO and STRICT TTO, however, we can have triangles which impose a “non-cyclic” orientation of three edges (Table 1). This can be naturally modeled by a not-all-equal (NAE) clause.² However, if we now naïvely model the conditions with a Boolean formula, we obtain a formula with 2SAT clauses and 3NAE clauses. Deciding whether such a formula is satisfiable is NP-complete in general [42]. Hence, we have to investigate these two variants more thoroughly.

The only difference between the triangles that impose these “non-cyclic” orientations in these two problem variants is that, in TTO, the triangle is *synchronous* (i.e. all its three edges have the same time-label), while in STRICT TTO two of the edges are synchronous and the third one has a smaller time-label than the other two. As it turns out, this difference of the two problem variants has important implications on their computational complexity. In fact, we obtain a surprising result: TTO is solvable in polynomial time while STRICT TTO is NP-complete.

3.1 Strict TTO is NP-Complete

In this section we show that in contrast to the other variants, STRICT TTO is NP-complete.

► **Theorem 3.** *STRICT TTO is NP-complete even if the temporal input graph has only four different time labels.*

3.2 A polynomial-time algorithm for TTO

Let $G = (V, E)$ be a static undirected graph. There are various polynomial-time algorithms for deciding whether G admits a transitive orientation F . However our results in this section are inspired by the transitive orientation algorithm described by Golumbic [23], which is based on the crucial notion of *forcing* an orientation. The notion of forcing in static graphs is illustrated in Figure 1 (a): if we orient the edge $\{u, v\}$ as uv (i.e., from u to v) then we are forced to orient the edge $\{v, w\}$ as wv (i.e., from w to v) in any transitive orientation F of G . Indeed, if we otherwise orient $\{v, w\}$ as vw (i.e. from v to w), then the edge $\{u, w\}$ must exist and it must be oriented as uw in any transitive orientation F of G , which is a contradiction as $\{u, w\}$ is not an edge of G . Similarly, if we orient the edge $\{u, v\}$ as vu then we are forced to orient the edge $\{v, w\}$ as vw . That is, in any transitive orientation F of G we have that $uv \in F \Leftrightarrow vw \in F$. This forcing operation can be captured by the binary forcing relation Γ which is defined on the edges of a static graph G as follows [23].

$$uv \Gamma u'v' \quad \text{if and only if} \quad \begin{cases} \text{either } u = u' \text{ and } \{v, v'\} \notin E \\ \text{or } v = v' \text{ and } \{u, u'\} \notin E \end{cases} . \quad (1)$$

We now extend the definition of Γ in a natural way to the binary relation Λ on the edges of a temporal graph (G, λ) , see Equation (2). For this, observe from Table 1 that the only cases, where we have $uv \in F \Leftrightarrow vw \in F$ in any temporal transitive orientation of (G, λ) , are

² A not all equal clause is a set of literals and it evaluates to **true** if and only if at least two literals in the set evaluate to different truth values.

■ **Figure 1** The orientation uv forces the orientation wu and vice-versa in the examples of (a) a static graph G where $\{u, v\}, \{v, w\} \in E(G)$ and $\{u, w\} \notin E(G)$, and of (b) a temporal graph (G, λ) where $\lambda(u, w) = 3 < 5 = \lambda(u, v) = \lambda(v, w)$.

when (i) the vertices u, v, w induce a path of length 2 (see Figure 1 (a)) and $\lambda(u, v) = \lambda(v, w)$, as well as when (ii) u, v, w induce a triangle and $\lambda(u, w) < \lambda(u, v) = \lambda(v, w)$. The latter situation is illustrated in the example of Figure 1 (b). The binary forcing relation Λ is only defined on pairs of edges $\{u, v\}$ and $\{u', v'\}$ where $\lambda(u, v) = \lambda(u', v')$, as follows.

$$uv \Lambda u'v' \text{ if and only if } \lambda(u, v) = \lambda(u', v') = t \text{ and } \begin{cases} u = u' \text{ and } \{v, v'\} \notin E, \text{ or} \\ v = v' \text{ and } \{u, u'\} \notin E, \text{ or} \\ u = u' \text{ and } \lambda(v, v') < t, \text{ or} \\ v = v' \text{ and } \lambda(u, u') < t. \end{cases} \quad (2)$$

Note that, for every edge $\{u, v\} \in E$ we have that $uv \Lambda uv$. The forcing relation Λ for temporal graphs shares some properties with the forcing relation Γ for static graphs. In particular, the reflexive transitive closure Λ^* of Λ is an equivalence relation, which partitions the edges of each set $E_t = \{\{u, v\} \in E : \lambda(u, v) = t\}$ into its Λ -implication classes (or simply, into its *implication classes*). Two edges $\{a, b\}$ and $\{c, d\}$ are in the same Λ -implication class if and only $ab \Lambda^* cd$, i.e. there exists a sequence $ab = a_0b_0 \Lambda a_1b_1 \Lambda \dots \Lambda a_kb_k = cd$, with $k \geq 0$. Note that, for this to happen, we must have $\lambda(a_0, b_0) = \lambda(a_1, b_1) = \dots = \lambda(a_k, b_k) = t$ for some $t \geq 1$. Such a sequence is called a Λ -chain from ab to cd , and we say that ab (eventually) Λ -forces cd . Furthermore note that $ab \Lambda^* cd$ if and only if $ba \Lambda^* dc$. For the next lemma, we use the notation $\widehat{A} = \{uv, vu : uv \in A\}$.

► **Lemma 4.** *Let A be a Λ -implication class of a temporal graph (G, λ) . Then either $A = A^{-1} = \widehat{A}$ or $A \cap A^{-1} = \emptyset$.*

► **Definition 5.** *Let F be a proper orientation and A be a Λ -implication class of a temporal graph (G, λ) . If $A \subseteq F$, we say that F respects A .*

► **Lemma 6.** *Let F be a proper orientation and A be a Λ -implication class of a temporal graph (G, λ) . Then F respects either A or A^{-1} (i.e. either $A \subseteq F$ or $A^{-1} \subseteq F$), and in either case $A \cap A^{-1} = \emptyset$.*

The next lemma, which is crucial for proving the correctness of our algorithm, extends an important known property of the forcing relation Γ for static graphs [23, Lemma 5.3] to the temporal case.

► **Lemma 7 (Temporal Triangle Lemma).** *Let (G, λ) be a temporal graph and with a synchronous triangle on the vertices a, b, c , where $\lambda(a, b) = \lambda(b, c) = \lambda(c, a) = t$. Let A, B, C be three Λ -implication classes of (G, λ) , where $ab \in C$, $bc \in A$, and $ca \in B$, where $A \neq B^{-1}$ and $A \neq C^{-1}$.*

1. *If some $b'c' \in A$, then $ab' \in C$ and $c'a \in B$.*
2. *If some $b'c' \in A$ and $a'b' \in C$, then $c'a' \in B$.*
3. *No edge of A touches vertex a .*

Deciding temporal transitivity using Booleansatisfiability. Starting with any undirected edge $\{u, v\}$ of the underlying graph G , we can clearly enumerate in polynomial time the whole Λ -implication class A to which the oriented edge uv belongs (cf. Equation (2)). If the reversely directed edge $vu \in A$ then Lemma 4 implies that $A = A^{-1} = \widehat{A}$. Otherwise, if $vu \notin A$ then $vu \in A^{-1}$ and Lemma 4 implies that $A \cap A^{-1} = \emptyset$. Thus, we can also decide in polynomial time whether $A \cap A^{-1} = \emptyset$. If we encounter a Λ -implication class A such that $A \cap A^{-1} \neq \emptyset$, then it follows by Lemma 6 that (G, λ) is not temporally transitively orientable.

In the remainder of the section we will assume that $A \cap A^{-1} = \emptyset$ for every Λ -implication class A of (G, λ) , which is a *necessary* condition for (G, λ) to be temporally transitively orientable. Moreover it follows by Lemma 6 that, if (G, λ) admits a temporally transitively orientation F , then either $A \subseteq F$ or $A^{-1} \subseteq F$. This allows us to define a Boolean variable x_A for every Λ -implication class A , where $x_A = \overline{x_{A^{-1}}}$. Here $x_A = 1$ (resp. $x_{A^{-1}} = 1$) means that $A \subseteq F$ (resp. $A^{-1} \subseteq F$), where F is the temporally transitively orientation which we are looking for. Let $\{A_1, A_2, \dots, A_s\}$ be a set of Λ -implication classes such that $\{\widehat{A}_1, \widehat{A}_2, \dots, \widehat{A}_s\}$ is a partition of the edges of the underlying graph G .³ Then any truth assignment τ of the variables x_1, x_2, \dots, x_s (where $x_i = x_{A_i}$ for every $i = 1, 2, \dots, s$) corresponds bijectively to one possible orientation of the temporal graph (G, λ) , in which every Λ -implication class is oriented consistently.

Now we define two Boolean formulas $\phi_{3\text{NAE}}$ and $\phi_{2\text{SAT}}$ such that (G, λ) admits a temporal transitively orientation if and only if there is a truth assignment τ of the variables x_1, x_2, \dots, x_s such that both $\phi_{3\text{NAE}}$ and $\phi_{2\text{SAT}}$ are simultaneously satisfied. Intuitively, $\phi_{3\text{NAE}}$ captures the “non-cyclic” condition from Table 1 while $\phi_{2\text{SAT}}$ captures the remaining conditions. Here $\phi_{3\text{NAE}}$ is a 3NAE formula, i.e., the disjunction of clauses with three literals each, where every clause $\text{NAE}(\ell_1, \ell_2, \ell_3)$ is satisfied if and only if at least one of the literals $\{\ell_1, \ell_2, \ell_3\}$ is equal to 1 and at least one of them is equal to 0. Furthermore $\phi_{2\text{SAT}}$ is a 2SAT formula, i.e., the disjunction of 2CNF clauses with two literals each, where every clause $(\ell_1 \vee \ell_2)$ is satisfied if and only if at least one of the literals $\{\ell_1, \ell_2\}$ is equal to 1.

For simplicity of the presentation we also define a variable x_{uv} for every directed edge uv . More specifically, if $uv \in A_i$ (resp. $uv \in A_i^{-1}$) then we set $x_{uv} = x_i$ (resp. $x_{uv} = \overline{x_i}$). That is, $x_{uv} = \overline{x_{vu}}$ for every undirected edge $\{u, v\} \in E$. Note that, although $\{x_{uv}, x_{vu} : \{u, v\} \in E\}$ are defined as variables, they can equivalently be seen as *literals* in a Boolean formula over the variables x_1, x_2, \dots, x_s . The process of building all Λ -implication classes and all variables $\{x_{uv}, x_{vu} : \{u, v\} \in E\}$ is given by Algorithm 1.

Description of the 3NAE formula $\phi_{3\text{NAE}}$. The formula $\phi_{3\text{NAE}}$ captures the “non-cyclic” condition of the problem variant TTO (presented in Table 1). The formal description of $\phi_{3\text{NAE}}$ is as follows. Consider a synchronous triangle of (G, λ) on the vertices u, v, w . Assume that $x_{uv} = x_{vw}$, i.e., x_{uv} is the same variable as x_{vw} . Then the pair $\{uv, vw\}$ of oriented edges belongs to the same Λ -implication class A_i . This implies that the triangle on the vertices u, v, w is never cyclically oriented in any proper orientation F that respects A_i or A_i^{-1} . Note that, by symmetry, the same happens if $x_{vw} = x_{uw}$ or if $x_{wu} = x_{vu}$. Assume, on the contrary, that $x_{uv} \neq x_{vw}$, $x_{vw} \neq x_{uw}$, and $x_{wu} \neq x_{vu}$. In this case we add to $\phi_{3\text{NAE}}$ the clause $\text{NAE}(x_{uv}, x_{vw}, x_{wu})$. Note that the triangle on u, v, w is transitively oriented if and only if $\text{NAE}(x_{uv}, x_{vw}, x_{wu})$ is satisfied, i.e., at least one of the variables $\{x_{uv}, x_{vw}, x_{wu}\}$ receives the value 1 and at least one of them receives the value 0.

³ Here we slightly abuse the notation by identifying the undirected edge $\{u, v\}$ with the set of both its orientations $\{uv, vu\}$.

■ **Algorithm 1** Building the Λ -implication classes and the edge-variables.

Input: A temporal graph (G, λ) , where $G = (V, E)$.

Output: The variables $\{x_{uv}, x_{vu} : \{u, v\} \in E\}$, or the announcement that (G, λ) is temporally not transitively orientable.

```

1:  $s \leftarrow 0$ ;  $E_0 \leftarrow E$ 
2: while  $E_0 \neq \emptyset$  do
3:    $s \leftarrow s + 1$ ; Let  $\{p, q\} \in E_0$  be arbitrary
4:   Build the  $\Lambda$ -implication class  $A_s$  of the oriented edge  $pq$  (by Equation (2))
5:   if  $qp \in A_s$  then  $\{A_s \cap A_s^{-1} \neq \emptyset\}$ 
6:     return “NO”
7:   else
8:      $x_s$  is the variable corresponding to the directed edges of  $A_s$ 
9:     for every  $uv \in A_s$  do
10:       $x_{uv} \leftarrow x_s$ ;  $x_{vu} \leftarrow \overline{x_s}$   $\{x_{uv}$  and  $x_{vu}$  become aliases of  $x_s$  and  $\overline{x_s}\}$ 
11:     $E_0 \leftarrow E_0 \setminus \widehat{A_s}$ 
12: return  $\Lambda$ -implication classes  $\{A_1, A_2, \dots, A_s\}$  and variables  $\{x_{uv}, x_{vu} : \{u, v\} \in E\}$ 

```

Description of the 2SAT formula $\phi_{2\text{SAT}}$. The formula $\phi_{2\text{SAT}}$ captures all conditions apart from the “non-cyclic” condition of the problem variant TTO (presented in Table 1). The formal description of $\phi_{2\text{SAT}}$ is as follows. Consider a triangle of (G, λ) on the vertices u, v, w , where $\lambda(u, v) = t_1$, $\lambda(v, w) = t_2$, $\lambda(w, v) = t_3$, and $t_1 \leq t_2 \leq t_3$. If $t_1 < t_2 = t_3$ then we add to $\phi_{2\text{SAT}}$ the clauses $(x_{uv} \vee x_{vw}) \wedge (x_{vw} \vee x_{wu})$; note that these clauses are equivalent to $x_{wu} = x_{vw}$. If $t_1 \leq t_2 < t_3$ then we add to $\phi_{2\text{SAT}}$ the clauses $(x_{vw} \vee x_{uv}) \wedge (x_{uv} \vee x_{wu})$; note that these clauses are equivalent to $(x_{vw} \Rightarrow x_{uv}) \wedge (x_{vu} \Rightarrow x_{wu})$. Now consider a path of length 2 that is induced by the vertices u, v, w , where $\lambda(u, v) = t_1$, $\lambda(v, w) = t_2$, and $t_1 \leq t_2$. If $t_1 = t_2$ then we add to $\phi_{2\text{SAT}}$ the clauses $(x_{vu} \vee x_{wv}) \wedge (x_{vw} \vee x_{uv})$; note that these clauses are equivalent to $(x_{uv} = x_{wv})$. Finally, if $t_1 < t_2$ then we add to $\phi_{2\text{SAT}}$ the clause $(x_{vu} \vee x_{wv})$; note that this clause is equivalent to $(x_{uv} \Rightarrow x_{wv})$.

Brief outline of the algorithm. In the *initialization phase*, we exhaustively check which truth values are *forced* in $\phi_{3\text{NAE}} \wedge \phi_{2\text{SAT}}$ by using the subroutine INITIAL-FORCING. During the execution of INITIAL-FORCING, we either replace the formulas $\phi_{3\text{NAE}}$ and $\phi_{2\text{SAT}}$ by the equivalent formulas $\phi_{3\text{NAE}}^{(0)}$ and $\phi_{2\text{SAT}}^{(0)}$, respectively, or we reach a contradiction by showing that $\phi_{3\text{NAE}} \wedge \phi_{2\text{SAT}}$ is unsatisfiable.

► **Observation 8.** *The temporal graph (G, λ) is transitively orientable if and only if $\phi_{3\text{NAE}}^{(0)} \wedge \phi_{2\text{SAT}}^{(0)}$ is satisfiable.*

The *main phase* of the algorithm starts once the formulas $\phi_{3\text{NAE}}^{(0)}$ and $\phi_{2\text{SAT}}^{(0)}$ have been computed. Then we iteratively try assigning to each variable x_i the truth value 1 or 0. Once we have set $x_i = 1$ (resp. $x_i = 0$) during the iteration $j \geq 1$ of the algorithm, we call algorithm BOOLEAN-FORCING (see Algorithm 3) as a subroutine to check which implications this value of x_i has on the current formulas $\phi_{3\text{NAE}}^{(j-1)}$ and $\phi_{2\text{SAT}}^{(j-1)}$ and which other truth values of variables are forced. The correctness of BOOLEAN-FORCING can be easily verified by checking all subcases of BOOLEAN-FORCING. During the execution of BOOLEAN-FORCING, we either replace the current formulas by $\phi_{3\text{NAE}}^{(j)}$ and $\phi_{2\text{SAT}}^{(j)}$, or we reach a contradiction by showing that, setting $x_i = 1$ (resp. $x_i = 0$) makes $\phi_{3\text{NAE}}^{(j-1)} \wedge \phi_{2\text{SAT}}^{(j-1)}$ unsatisfiable. If each of the truth assignments $\{x_i = 1, x_i = 0\}$ leads to such a contradiction, we return that (G, λ)

75:12 The Complexity of Transitively Orienting Temporal Graphs

■ **Algorithm 2** INITIAL-FORCING.

Input: A 2-SAT formula $\phi_{2\text{SAT}}$ and a 3-NAE formula $\phi_{3\text{NAE}}$

Output: A 2-SAT formula $\phi_{2\text{SAT}}^{(0)}$ and a 3-NAE formula $\phi_{3\text{NAE}}^{(0)}$ such that $\phi_{2\text{SAT}}^{(0)} \wedge \phi_{3\text{NAE}}^{(0)}$ is satisfiable if and only if $\phi_{2\text{SAT}} \wedge \phi_{3\text{NAE}}$ is satisfiable, or the announcement that $\phi_{2\text{SAT}} \wedge \phi_{3\text{NAE}}$ is not satisfiable.

- 1: $\phi_{3\text{NAE}}^{(0)} \leftarrow \phi_{3\text{NAE}}$; $\phi_{2\text{SAT}}^{(0)} \leftarrow \phi_{2\text{SAT}}$ {initialization}
- 2: **for** every variable x_i appearing in $\phi_{3\text{NAE}}^{(0)} \wedge \phi_{2\text{SAT}}^{(0)}$ **do**
- 3: **if** BOOLEAN-FORCING $\left(\phi_{3\text{NAE}}^{(0)}, \phi_{2\text{SAT}}^{(0)}, x_i, 1\right) = \text{“NO”}$ **then**
- 4: **if** BOOLEAN-FORCING $\left(\phi_{3\text{NAE}}^{(0)}, \phi_{2\text{SAT}}^{(0)}, x_i, 0\right) = \text{“NO”}$ **then**
- 5: **return** “NO” {both $x_i = 1$ and $x_i = 0$ invalidate the formulas}
- 6: **else**
- 7: $\left(\phi_{3\text{NAE}}^{(0)}, \phi_{2\text{SAT}}^{(0)}\right) \leftarrow \text{BOOLEAN-FORCING}\left(\phi_{3\text{NAE}}^{(0)}, \phi_{2\text{SAT}}^{(0)}, x_i, 0\right)$
- 8: **else**
- 9: **if** BOOLEAN-FORCING $\left(\phi_{3\text{NAE}}^{(0)}, \phi_{2\text{SAT}}^{(0)}, x_i, 0\right) = \text{“NO”}$ **then**
- 10: $\left(\phi_{3\text{NAE}}^{(0)}, \phi_{2\text{SAT}}^{(0)}\right) \leftarrow \text{BOOLEAN-FORCING}\left(\phi_{3\text{NAE}}^{(0)}, \phi_{2\text{SAT}}^{(0)}, x_i, 1\right)$
- 11: **for** every clause NAE(x_{uv}, x_{vw}, x_{wu}) of $\phi_{3\text{NAE}}^{(0)}$ **do**
- 12: **for** every variable x_{ab} **do**
- 13: **if** $x_{ab} \xrightarrow{*}_{\phi_{2\text{SAT}}^{(0)}} x_{uv}$ and $x_{ab} \xrightarrow{*}_{\phi_{2\text{SAT}}^{(0)}} x_{vw}$ **then** {add $(x_{ab} \Rightarrow x_{uw})$ to $\phi_{2\text{SAT}}^{(0)}$ }
- 14: $\phi_{2\text{SAT}}^{(0)} \leftarrow \phi_{2\text{SAT}}^{(0)} \wedge (x_{ba} \vee x_{uw})$
- 15: Repeat lines 2 and 11 until no changes occur on $\phi_{2\text{SAT}}^{(0)}$ and $\phi_{3\text{NAE}}^{(0)}$
- 16: **return** $\left(\phi_{3\text{NAE}}^{(0)}, \phi_{2\text{SAT}}^{(0)}\right)$

is a *no*-instance. Otherwise, if at least one of the truth assignments $\{x_i = 1, x_i = 0\}$ does not lead to such a contradiction, we follow this truth assignment and proceed with the next variable.

As we prove in our *main technical result* of this section (Theorem 9), $\phi_{3\text{NAE}}^{(j-1)} \wedge \phi_{2\text{SAT}}^{(j-1)}$ is satisfiable if and only if $\phi_{3\text{NAE}}^{(j)} \wedge \phi_{2\text{SAT}}^{(j)}$ is satisfiable. Note that, during the execution of the algorithm, we can *both add and remove* clauses from $\phi_{2\text{SAT}}^{(j)}$. On the other hand, we can *only remove* clauses from $\phi_{3\text{NAE}}^{(j)}$. Thus, at some iteration j , we obtain $\phi_{3\text{NAE}}^{(j)} = \emptyset$, and after that iteration we only need to decide satisfiability of $\phi_{2\text{SAT}}^{(j)}$ which can be done efficiently [6].

We are now ready to present in the next theorem our main technical result of this section.

► **Theorem 9.** *For every iteration $j \geq 1$ of the algorithm, $\phi_{3\text{NAE}}^{(j)} \wedge \phi_{2\text{SAT}}^{(j)}$ is satisfiable if and only if $\phi_{3\text{NAE}}^{(j-1)} \wedge \phi_{2\text{SAT}}^{(j-1)}$ is satisfiable.*

Using Theorem 9, we can now conclude this section with the next theorem.

► **Theorem 10.** *TTO can be solved in polynomial time.*

Proof sketch. First recall by Observation 8 that the input temporal graph (G, λ) is transitively orientable if and only if $\phi_{3\text{NAE}}^{(0)} \wedge \phi_{2\text{SAT}}^{(0)}$ is satisfiable.

■ **Algorithm 3** BOOLEAN-FORCING.

Input: A 2-SAT formula ϕ_2 , a 3-NAE formula ϕ_3 , and a variable x_i of $\phi_2 \wedge \phi_3$, and a truth value $\text{VALUE} \in \{0, 1\}$

Output: A 2-SAT formula ϕ'_2 and a 3-NAE formula ϕ'_3 , obtained from ϕ_2 and ϕ_3 by setting $x_i = \text{VALUE}$, or the announcement that $x_i = \text{VALUE}$ does not satisfy $\phi_2 \wedge \phi_3$.

```

1:  $\phi'_2 \leftarrow \phi_2$ ;  $\phi'_3 \leftarrow \phi_3$ 
2: while  $\phi'_2$  has a clause  $(x_{uv} \vee x_{pq})$  and  $x_{uv} = 1$  do
3:   Remove the clause  $(x_{uv} \vee x_{pq})$  from  $\phi'_2$ 
4: while  $\phi'_2$  has a clause  $(x_{uv} \vee x_{pq})$  and  $x_{uv} = 0$  do
5:   if  $x_{pq} = 0$  then return “NO”
6:   Remove the clause  $(x_{uv} \vee x_{pq})$  from  $\phi'_2$ ;  $x_{pq} \leftarrow 1$ 
7: for every variable  $x_{uv}$  that does not yet have a truth value do
8:   if  $x_{uv} \xrightarrow{*} \phi'_2 x_{vu}$ , where  $\phi''_2 = \phi'_2 \setminus \phi_2$  then  $x_{uv} \leftarrow 0$ 
9:   for every clause  $\text{NAE}(x_{uv}, x_{vw}, x_{wu})$  of  $\phi'_3$  do {synchronous triangle on vertices  $u, v, w$ }
10:  if  $x_{uv} \xrightarrow{*} \phi'_2 x_{vw}$  then {add  $(x_{uv} \Rightarrow x_{uw}) \wedge (x_{uv} \Rightarrow x_{vw})$  to  $\phi'_2$ }
11:   $\phi'_2 \leftarrow \phi'_2 \wedge (x_{vu} \vee x_{uw}) \wedge (x_{wu} \vee x_{vw})$ 
12:  Remove the clause  $\text{NAE}(x_{uv}, x_{vw}, x_{wu})$  from  $\phi'_3$ 
13:  if  $x_{uv}$  already got the value 1 or 0 then
14:    Remove the clause  $\text{NAE}(x_{uv}, x_{vw}, x_{wu})$  from  $\phi'_3$ 
15:    if  $x_{vw}$  and  $x_{wu}$  do not have yet a truth value then
16:      if  $x_{uv} = 1$  then {add  $(x_{vw} \Rightarrow x_{uw})$  to  $\phi'_2$ }
17:       $\phi'_2 \leftarrow \phi'_2 \wedge (x_{vw} \vee x_{uw})$ 
18:      else { $x_{uv} = 0$ ; in this case add  $(x_{uv} \Rightarrow x_{vw})$  to  $\phi'_2$ }
19:       $\phi'_2 \leftarrow \phi'_2 \wedge (x_{wu} \vee x_{vw})$ 
20:      if  $x_{vw} = x_{uv}$  and  $x_{wu}$  does not have yet a truth value then
21:         $x_{wu} \leftarrow 1 - x_{uv}$ 
22:      if  $x_{vw} = x_{wu} = x_{uv}$  then return “NO”
23: Repeat lines 2, 4, 7, and 9 until no changes occur on  $\phi'_2$  and  $\phi'_3$ 
24: if both  $x_{uv} = 0$  and  $x_{uv} = 1$  for some variable  $x_{uv}$  then return “NO”
25: return  $(\phi'_2, \phi'_3)$ 

```

Let (G, λ) be a *yes*-instance. Then, by iteratively applying Theorem 9 it follows that $\phi_{3\text{NAE}}^{(j)} \wedge \phi_{2\text{SAT}}^{(j)}$ is satisfiable, for every iteration j of the algorithm. Recall that, at the end of the last iteration k of the algorithm, $\phi_{3\text{NAE}}^{(k)} \wedge \phi_{2\text{SAT}}^{(k)}$ is empty. Then the algorithm gives the arbitrary truth value $x_i = 1$ to every variable x_i which did not yet get any truth value yet. This is a correct decision as all these variables are not involved in any Boolean constraint of $\phi_{3\text{NAE}}^{(k)} \wedge \phi_{2\text{SAT}}^{(k)}$ (which is empty). Finally, the algorithm orients all edges of G according to the corresponding truth assignment. The returned orientation F of (G, λ) is temporally transitive as every variable was assigned a truth value according to the Boolean constraints throughout the execution of the algorithm.

Now let (G, λ) be a *no*-instance. We will prove that, at some iteration $j \leq 0$, the algorithm will “NO”. Suppose otherwise that the algorithm instead returns an orientation F of (G, λ) after performing k iterations. Then clearly $\phi_{3\text{NAE}}^{(k)} \wedge \phi_{2\text{SAT}}^{(k)}$ is empty, and thus

■ **Algorithm 4** Temporal transitive orientation.

Input: A temporal graph (G, λ) , where $G = (V, E)$.

Output: A temporal transitive orientation F of (G, λ) , or the announcement that (G, λ) is temporally not transitively orientable.

```

1: Execute Algorithm 1 to build the  $\Lambda$ -implication classes  $\{A_1, A_2, \dots, A_s\}$  and the Boolean
   variables  $\{x_{uv}, x_{vu} : \{u, v\} \in E\}$ 
2: if Algorithm 1 returns “NO” then return “NO”
3: Build the 3NAE formula  $\phi_{3\text{NAE}}$  and the 2SAT formula  $\phi_{2\text{SAT}}$ 
4: if INITIAL-FORCING  $(\phi_{3\text{NAE}}, \phi_{2\text{SAT}}) \neq$  “NO” then {Initialization phase}
5:    $(\phi_{3\text{NAE}}^{(0)}, \phi_{2\text{SAT}}^{(0)}) \leftarrow$  INITIAL-FORCING  $(\phi_{3\text{NAE}}, \phi_{2\text{SAT}})$ 
6: else  $\{\phi_{3\text{NAE}} \wedge \phi_{2\text{SAT}}$  leads to a contradiction $\}$ 
7:   return “NO”
8:  $j \leftarrow 1$ ;  $F \leftarrow \emptyset$  {Main phase}
9: while a variable  $x_i$  appearing in  $\phi_{3\text{NAE}}^{(j-1)} \wedge \phi_{2\text{SAT}}^{(j-1)}$  did not yet receive a truth value do
10:  if BOOLEAN-FORCING  $(\phi_{3\text{NAE}}^{(j-1)}, \phi_{2\text{SAT}}^{(j-1)}, x_i, 1) \neq$  “NO” then
11:     $(\phi_{3\text{NAE}}^{(j)}, \phi_{2\text{SAT}}^{(j)}) \leftarrow$  BOOLEAN-FORCING  $(\phi_{3\text{NAE}}^{(j-1)}, \phi_{2\text{SAT}}^{(j-1)}, x_i, 1)$ 
12:  else  $\{x_i = 1$  leads to a contradiction $\}$ 
13:    if BOOLEAN-FORCING  $(\phi_{3\text{NAE}}^{(j-1)}, \phi_{2\text{SAT}}^{(j-1)}, x_i, 0) \neq$  “NO” then
14:       $(\phi_{3\text{NAE}}^{(j)}, \phi_{2\text{SAT}}^{(j)}) \leftarrow$  BOOLEAN-FORCING  $(\phi_{3\text{NAE}}^{(j-1)}, \phi_{2\text{SAT}}^{(j-1)}, x_i, 0)$ 
15:    else
16:      return “NO”
17:     $j \leftarrow j + 1$ 
18: for  $i = 1$  to  $s$  do
19:  if  $x_i$  did not yet receive a truth value then  $x_i \leftarrow 1$ 
20:  if  $x_i = 1$  then  $F \leftarrow F \cup A_i$  else  $F \leftarrow F \cup \overline{A_i}$ 
21: return the temporally transitive orientation  $F$  of  $(G, \lambda)$ 

```

clearly satisfiable. Therefore, iteratively applying Theorem 9 implies that $\phi_{3\text{NAE}}^{(0)} \wedge \phi_{2\text{SAT}}^{(0)}$ is also satisfiable, and thus (G, λ) is temporally transitively orientable by Observation 8, which is a contradiction to the assumption that (G, λ) be a *no*-instance.

Lastly, we prove that our algorithm runs in polynomial time. The Λ -implication classes of (G, λ) can be clearly computed in polynomial time. Our algorithm calls a subroutine BOOLEAN-FORCING at most four times for every variable in $\phi_{3\text{NAE}}^{(0)} \wedge \phi_{2\text{SAT}}^{(0)}$. BOOLEAN-FORCING iteratively adds and removes clauses from the 2SAT part of the formula, while it can only remove clauses from the 3NAE part. Whenever a clause is added to the 2SAT part, a clause of the 3NAE part is removed. Therefore, as the initial 3NAE formula has at most polynomially-many clauses, we can add clauses to the 2SAT part only polynomially-many times. Hence, we have an overall polynomial running time. ◀

4 Temporal Transitive Completion

We now study the computational complexity of TEMPORAL TRANSITIVE COMPLETION (TTC). In the static case, the so-called *minimum comparability completion* problem, i.e. adding the smallest number of edges to a static graph to turn it into a comparability graph, is known to be NP-hard [24]. Note that minimum comparability completion on static graphs is a special case of TTC and thus it follows that TTC is NP-hard too. Our other variants, however, do not generalize static comparability completion in such a straightforward way. Note that for STRICT TTC we have that the corresponding recognition problem STRICT TTO is NP-complete (Theorem 3), hence it follows directly that STRICT TTC is NP-hard. For the remaining two variants of our problem, we show in the following that they are also NP-hard, giving the result that all four variants of TTC are NP-hard. Furthermore, we present a polynomial-time algorithm for all four problem variants for the case that all edges of underlying graph are oriented, see Theorem 12. This allows directly to derive an FPT algorithm for the number of unoriented edges as a parameter.

► **Theorem 11.** *All four variants of TTC are NP-hard, even when the input temporal graph is completely unoriented.*

We now show that TTC can be solved in polynomial time, if all edges are already oriented, as the next theorem states.

► **Theorem 12.** *An instance (\mathcal{G}, F, k) of TTC where $\mathcal{G} = (G, \lambda)$ and $G = (V, E)$, can be solved in $O(m^2)$ time if F is an orientation of E , where $m = |E|$.*

Using Theorem 12 we can now prove that TTC is fixed-parameter tractable (FPT) with respect to the number of unoriented edges in the input temporal graph \mathcal{G} .

► **Corollary 13.** *Let $I = (\mathcal{G} = (G, \lambda), F, k)$ be an instance of TTC, where $G = (V, E)$. Then I can be solved in $O(2^q \cdot m^2)$, where $q = |E| - |F|$ and m the number of time edges.*

5 Deciding Multilayer Transitive Orientation

In this section we prove that MULTILAYER TRANSITIVE ORIENTATION (MTO) is NP-complete, even if every edge of the given temporal graph has at most two labels. Recall that this problem asks for an orientation F of a temporal graph $\mathcal{G} = (G, \lambda)$ (i.e. with exactly one orientation for each edge of G) such that, for every “time-layer” $t \geq 1$, the (static) oriented graph defined by the edges having time-label t is transitively oriented in F . As we discussed in Section 2, this problem makes more sense when every edge of G potentially has multiple time-labels, therefore we assume here that the time-labeling function is $\lambda : E \rightarrow 2^{\mathbb{N}}$.

► **Theorem 14.** *MTO is NP-complete, even on temporal graphs with at most two labels per edge.*

Abstract

We study spreading processes in temporal graphs, i. e., graphs whose connections change over time. These processes naturally model real-world phenomena such as infectious diseases or information flows. More precisely, we investigate how such a spreading process, emerging from a given set of sources, can be contained to a small part of the graph. To this end we consider two ways of modifying the graph, which are (1) deleting connections and (2) delaying connections. We show a close relationship between the two associated problems and give a polynomial time algorithm when the graph has tree structure. For the general version, we consider parameterization by the number of vertices to which the spread is contained. Surprisingly, we prove W[1]-hardness for the deletion variant but fixed-parameter tractability for the delaying variant.

1 Introduction

Reachability is a fundamental problem in graph theory and algorithmics [38, 39, 33, 17] and quite well-understood. With the emergence of temporal graphs,¹ the concept of reachability was extended to the dimension of time using *temporal paths* [34, 6]. For a vertex s to reach another vertex z in a temporal graph, there must not only be a path between them but the edges of this path have to appear in chronological order. This requirement makes temporal reachability non-symmetric and non-transitive, which stands in contrast to reachability in normal (static) graphs. Reachability is arguably one of the most central concepts in temporal graph algorithmics and has been studied under various aspects, such as path finding [40, 5, 9, 11], vertex separation [34, 28, 41], finding spanning subgraphs [12, 4], temporal graph exploration [25, 23, 26, 7, 24, 3], and others [35, 2, 10, 32].

¹ Temporal graphs are graphs whose edge set changes over discrete time.

Perhaps the most prominent application of temporal graph reachability is currently epidemiology, dealing with effective prevention or containment of disease spreading [1]. Here, minimizing the reachability of vertices in a temporal graph by manipulating the temporal graph corresponds to minimizing the spread of an infection in various networks by some countermeasures. Application instances for this scenario may be drawn from physical contacts [27, 19] or airline flights [8, 13], but also social networks [31, 14], cattle movements [36], or computer networks [37].

Enright et al. [21] studied the problem of deleting k time-edges² such that no single vertex can reach more than r other vertices and showed its NP-hardness and W[1]-hardness for the parameter k , even in very restricted settings. Here, we shift the focus to a set of multiple given sources, thus studying the following problem, which has not been considered for computational complexity analysis yet (to the best of our knowledge).

MINIMIZING TEMPORAL REACHABILITY BY DELETING (MINREACHDELETE)

Input: A temporal graph \mathcal{G} , a set of sources vertices S , and integers k, r .

Question: Can we delete at most k time-edges s.t. at most r vertices are reachable from S ?

Imaginably, removing edges or vertices is not the most *infrastructure friendly* approach to restrict reachability. To address this, other operations have been studied. Enright et al. [22] considered restricting the reachability by just changing the relative order in which edges are active. Deligkas and Potapov [15] considered restricting the reachability by a merging operation of consecutive edge sets of the temporal graph and by a delay operation of time-edges by δ time steps, i.e., moving a time-edge from time t to $t + \delta$. In particular, they introduced a delay variant of MINREACHDELETE.

MINIMIZING TEMPORAL REACHABILITY BY DELAYING (MINREACHDELAY)

Input: A temporal graph \mathcal{G} , a set of sources vertices $S \subseteq V$, and integers k, r, δ .

Question: Can we delay at most k time-edges by δ s.t. at most r vertices are reachable from S ?

This is the central problem studied in this paper. Throughout the whole paper we assume for all instances of MINREACHDELETE and MINREACHDELAY that $0 < |S| \leq r$. We remark that technically Deligkas and Potapov [15] formulate the problem slightly differently, allowing delays of *up to* δ to appear. However, a simple argument can be given to see that this distinction is not significant: Clearly, delaying a time-edge reduces the number of reachable vertices only if the undelayed time-edge could be reached from some source $s \in S$. But when this is the case, increasing the delay of that time-edge can never increase the set of vertices reachable from S . The reason is that, while increasing the delay might enable some source $s' \in S \setminus \{s\}$ to reach a vertex v , that vertex v would be reached from s in any case.

Deligkas and Potapov [15] showed that MINREACHDELAY is NP-hard and W[1]-hard when parameterized by k , even if underlying graph has lifetime $\tau = 2$. A close look into the proof reveals that this also holds for MINREACHDELETE.

Our contribution. We study how MINREACHDELETE and MINREACHDELAY relate to each other. We show that both problems are polynomial-time solvable on trees. Moreover, there is an intermediate reduction from MINREACHDELETE to MINREACHDELAY indicating that MINREACHDELAY seems generally harder than MINREACHDELETE. However, surprisingly, this is no longer true when we parameterize the problems by the number r of reachable vertices. Here, we develop a max-flow-based branching strategy and obtain fixed-parameter

² That is, an edge at a point in time.

tractability for MINREACHDELAY while MINREACHDELETE remains W[1]-hard. This makes MINREACHDELAY particularly interesting for applications where the number of reachable vertices should be very small, e.g. when trying to contain the spread of dangerous diseases.

2 Preliminaries

We define \mathbb{N} as the positive natural numbers, $[a, b] := \{i \in \mathbb{Z} \mid a \leq i \leq b\}$, and $[n] := [1, n]$. For a function $f: V \rightarrow \mathbb{Z}$ and subset $X \subseteq V$ we denote by $f(X)$ the sum $\sum_{x \in V} f(x)$. We use standard notation from graph theory [16]. We say for a (directed) graph G that $G - X := G[V(G) \setminus X]$ is the induced subgraph of G when the vertices in X are removed, and $G \setminus Y := (V(G), E(G) \setminus Y)$ is the subgraph when the edges in Y are removed, where X is a vertex set and Y is an edge set. For any predicate P , the Iverson bracket $[P]$ is 1 if P is true and 0 otherwise.

Parameterized complexity. Let Σ denote a finite alphabet. A parameterized problem $L \subseteq \{(x, k) \in \Sigma^* \times \mathbb{N} \cup \{0\}\}$ is a subset of all instances (x, k) from $\Sigma^* \times \mathbb{N} \cup \{0\}$, where k denotes the *parameter*. A parameterized problem L is in FPT (is *fixed-parameter tractable*) if there is an algorithm that decides every instance (x, k) for L in $f(k) \cdot |x|^{O(1)}$ time, where f is any computable function only depending on the parameter. If a parameterized problem L is W[1]-hard, then it is presumably not fixed-parameter tractable. We refer to Downey and Fellows [18] for details.

Temporal graphs. A *temporal graph* \mathcal{G} consists of a set of vertices V (or $V(\mathcal{G})$), and a sequence of edge sets $(E_i)_{i \in [\tau]}$ where each E_i is a set of unordered pairs from V . The number τ is called the *lifetime* of \mathcal{G} . The elements of $\mathcal{E}(\mathcal{G}) := \bigcup_{i \in [\tau]} E_i \times \{i\}$ are called the *time-edges* of \mathcal{G} . Furthermore \mathcal{G} has a *traversal time* function $\gamma: \mathcal{E}(\mathcal{G}) \rightarrow \mathbb{N}$ specifying the time it takes to traverse each time-edge. The temporal graph \mathcal{G} is then written as the tuple $(V, (E_i)_{i \in [\tau]}, \gamma)$. Often we assume γ to be the constant function $\gamma \equiv 1$ and then simply write $\mathcal{G} = (V, (E_i)_{i \in [\tau]})$. The *underlying graph* of \mathcal{G} is the graph $(V, \bigcup_{i=1}^{\tau} E_i)$. For a time-edge set Y and temporal graph \mathcal{G} , we denote by $\mathcal{G} \setminus Y$ the temporal graph where $V(\mathcal{G} \setminus Y) = V(\mathcal{G})$ and $\mathcal{E}(\mathcal{G} \setminus Y) = \mathcal{E}(\mathcal{G}) \setminus Y$. A *temporal s-z-path* in \mathcal{G} is a sequence of time-edges $P = (e_i = (\{v_{i-1}, v_i\}, t_i))_{i=1}^m$ where

1. $v_0 = s$ and $v_m = z$,
2. the sequence of edges $(\{v_{i-1}, v_i\})_{i=1}^m$ forms an *s-z-path* in the underlying graph of \mathcal{G} , and
3. $t_{i+1} \geq t_i + \gamma(e_i)$ for all $i \in [m - 1]$.

The *arrival time* of P is $t_m + \gamma(e_m)$. The set of vertices of P is denoted by $V(P) = \{v_i \mid 0 \leq i \leq m\}$. A vertex w is *reachable* from v in \mathcal{G} (at time t) if there exists a temporal v - w -path in \mathcal{G} (with arrival time at most t). In particular, every vertex reaches itself via a trivial path. Furthermore, w is reachable from $S \subseteq V$ if there is a temporal s - w -path for some $s \in S$, and the set of all vertices reachable from S is denoted the *reachable set* $R_{\mathcal{G}}(S)$. We drop the index \mathcal{G} if it is clear from the context. *Delaying* a time-edge $(\{v, w\}, t)$ by δ refers to replacing it with the time-edge $(\{v, w\}, t + \delta)$. For a temporal graph \mathcal{G} and a time-edge set $X \subseteq \mathcal{E}(\mathcal{G})$ we denote by $\mathcal{G} \nearrow_{\delta} X$ the temporal graph \mathcal{G} where the time-edges in X are delayed by δ .

Preliminary observations. We present an intermediate polynomial-time reduction from the MINREACHDELETE to MINREACHDELAY.

► **Lemma 1.** *Given an instance $I = (\mathcal{G} = (V, (E_i)_{i \in [\tau]}, S, k, r)$ of MINREACHDELETE , we can compute in linear time, an instance $J = (\mathcal{G}' = (V', (E'_i)_{i=1}^{6\tau+1}), S', k, r', \delta = 3\tau)$ of MINREACHDELAY such that the feedback vertex number³ of the underlying graph of \mathcal{G} and \mathcal{G}' is the same, and I is a yes-instance if and only if J is a yes-instance.*

Proof. We construct $\mathcal{G}' = (V', (E'_i)_{i=1}^{3\tau+\delta+1})$ in the following way. Set

$$\begin{aligned} V_e &:= \{e_{uv}, e_{vu} \mid (\{v, u\}, t) \in \mathcal{E}(\mathcal{G})\}, & V_s &:= \{s_{vu} \mid e_{vu} \in V_e\}, \\ V' &:= V \cup V_e \cup V_s, \text{ and} & S' &:= S \cup V_s. \end{aligned}$$

Begin with $E'_i = \emptyset$ for all $i \in [3\tau]$. Then, add for each time-edge $(\{v, u\}, t) \in \mathcal{E}(\mathcal{G})$, the time-edges $(\{v, e_{vu}\}, 3t - 2)$, $(\{v, e_{vu}\}, 3t)$, $(\{e_{vu}, e_{uv}\}, 3t - 1)$, $(\{u, e_{uv}\}, 3t - 2)$, and $(\{u, e_{uv}\}, 3t)$ to \mathcal{G}' . Afterwards, add the time-edge $(\{s_{vu}, e_{vu}\}, 6\tau + 1 = 3\tau + \delta + 1)$ for each $e_{vu} \in V_e$. Finally we set $r' := r + |V' \setminus V|$. Since we add for each time-edge of \mathcal{G} a constant number of vertices and time-edges to \mathcal{G}' , we have that $|\mathcal{G}'| \in O(|\mathcal{G}|)$ and \mathcal{G}' can be computed in linear time. Moreover, the underlying graph G' of \mathcal{G}' is obtained from the underlying graph G of \mathcal{G} by subdividing edges and adding leaves, thus G and G' have the same feedback vertex number. It remains to prove that the two instances are equivalent.

(\Rightarrow): Let X be a solution for I . Then, set $X' := \{(\{e_{vu}, e_{uv}\}, 3t - 1) \mid (\{v, u\}, t) \in X\}$. Pick $s \in S$ and $v \in V$ arbitrary. Note that for each temporal s - v -path P' in \mathcal{G}' , we can construct a temporal s - v -path P in \mathcal{G} which uses a time-edge $(\{u, w\}, t)$ if and only if P' uses the time-edge $(\{e_{uw}, e_{wu}\}, 3t - 1)$. Furthermore, any temporal s - v -path in $\mathcal{G}' \nearrow_\delta X'$ cannot use any delayed time-edge. As s and v are arbitrary, this proves $R_{\mathcal{G}' \nearrow_\delta X'}(S') \cap V \subseteq R_{\mathcal{G} \setminus X}(S)$. Thus, at most $r + |V' \setminus V| = r'$ vertices are reachable from S' in $\mathcal{G}' \nearrow_\delta X'$, thus J is a yes-instance.

(\Leftarrow): Let X' be a solution for J . Begin by observing that delaying any time-edges between V_s and V_e has no effect. Consequently, $R_{\mathcal{G}' \nearrow_\delta X'}(V_s) = V_s \cup V_e$ for every possible choice of X' . Therefore X' is a valid solution if and only if $|R_{\mathcal{G}' \nearrow_\delta X'}(S) \cap V| \leq r' - |V_s \cup V_e| = r$, i.e., we only need to study the reachability between vertices in V . Because of this, delaying a time-edge connecting two vertices of V_e has the same effect as deleting that time-edge. Next, observe that instead of delaying some time-edge $(\{v, e_{vu}\}, t)$ which connects vertices of V and V_e , the same or better reduction of reachability is achieved by instead delaying $(\{e_{vu}, e_{uv}\}, t')$, with $t' \in \{t - 1, t + 1\}$ chosen appropriately. Due to this, we may assume without loss of generality that $X' \subseteq \{(\{e_{vu}, e_{uv}\}, 3t - 1) \mid (\{v, u\}, t) \in \mathcal{E}(\mathcal{G})\}$.

Set $X := \{(\{v, u\}, t) \mid (\{e_{uv}, e_{vu}\}, 3t - 1) \in X'\}$. Let $s \in S$ and $v \in V$ be arbitrary. Note that for each temporal s - v -path P in \mathcal{G} , we can construct a temporal s - v -path P' in \mathcal{G}' as above. Thus $R_{\mathcal{G} \setminus X}(S) \subseteq R_{\mathcal{G}' \nearrow_\delta X'}(S) \cap V$. Since we already observed that $|R_{\mathcal{G}' \nearrow_\delta X'}(S') \cap V| \leq r$, we conclude that I is a yes-instance. ◀

Note that the reduction in Lemma 1 preserves the size k of the solution and the feedback vertex number of the underlying graph. We remark that, in exchange for dropping the latter property, one can modify the reduction to instead have $|S'| = |S|$, by simply adding time-edges from S to V_s before all other time-edges. However, in any case the size r' of the reachable set in J is unbounded in terms of the size r of the reachable set in I . Unless $\text{FPT} = \text{W}[1]$, this is unavoidable as we learn in the next section.

³ That is, the minimum number of vertices needed to hit all cycles in an undirected graph.

3 Parameterized by the Reachable Set Size

In this section the study MINREACHDELAY and MINREACHDELETE parameterized by the reachable set size r . In particular, our main result in this section is the fixed-parameter tractability of MINREACHDELAY parameterized by r . This is in stark contrast to the $W[1]$ -hardness of MINREACHDELETE parameterized by r which we show first.

► **Theorem 2.** *MINREACHDELETE parameterized by r is $W[1]$ -hard, even if $\tau = 2$.*

Proof. We present a parameterized reduction from the $W[1]$ -hard [18] CLIQUE problem parameterized by ℓ , where given a graph $H = (U, F)$ we are asked whether H contains a clique of size ℓ .

Let $H = (U, F)$ be a graph, where $|F| = m$. We construct an instance $I = (\mathcal{G}, \{s\}, k = m - \binom{\ell}{2}, r = 1 + \ell + \binom{\ell}{2})$ of MINREACHDELETE , where $\mathcal{G} := (V, (E_i)_{i \in [2]})$ is the temporal graph given by

$$\begin{aligned} V &:= U \cup \{s\} \cup \{e_f \mid f \in F\}, \\ E_1 &:= \{\{s, e_f\} \mid f \in F\}, \quad \text{and} \quad E_2 := \{\{e_{\{u,v\}}, u\}, \{e_{\{u,v\}}, v\} \mid \{u, v\} \in F\}. \end{aligned}$$

Note that I can be constructed in polynomial time.

(\Rightarrow): Let $C = (V', F')$ be a clique of size ℓ in H . We set $X := \{(\{s, e_f\}, 1) \mid f \in F \setminus F'\}$. Note that $|X| \leq k$ and that for each edge $f \in F$ we can reach e_f from s if and only if $f \in F'$. Hence, by the construction of \mathcal{G} , a vertex $u \in U$ is reachable from s in $\mathcal{G} \setminus X$ if and only if $u \in V'$. Hence, we can reach $1 + \binom{\ell}{2} + \ell$ many vertices from s in $\mathcal{G} \setminus X$. Thus, I is a *yes*-instance.

(\Leftarrow): Let $X \subseteq \mathcal{E}(\mathcal{G})$ be a solution for I . Without loss of generality, we can assume that X does not contain a time-edge $(\{e_f, u\}, 2)$, because it can be replaced by $(\{e_f, s\}, 1)$. Observe that at least $\binom{\ell}{2}$ vertices from $\{e_f \mid f \in F\}$ are reachable from s in $\mathcal{G} \setminus X$. Since $r = 1 + \binom{\ell}{2} + \ell$, we can reach from s at most ℓ vertices from U . Hence, $U \cap R_{\mathcal{G} \setminus X}(\{s\})$ must form a clique of size ℓ in H . ◀

Due to Theorem 2, we know that there is presumably no $f(r) \cdot |\mathcal{G}|^{O(1)}$ -time algorithm to decide whether we can keep the reachable set of a vertex s of \mathcal{G} small (at most r vertices), by deleting at most k time-edges. However, this changes when we delay (instead of deleting) at most k edges. Formally, we show the following.

► **Theorem 3.** *MINREACHDELAY is solvable in $O(r! \cdot k \cdot |\mathcal{G}|)$ time.*

The proof of Theorem 3 is structured as follows.

Step 1 (reduction to slowing): We reduce MINREACHDELAY to an auxiliary problem which we call MINREACHSLOW . Here, instead of *delaying* a time-edge (moving it δ layers forward in time) we *slow* it, i. e., increase the time required to traverse it by δ .

Step 2 (flow-based techniques): Our new target now is a fixed-parameter algorithm for MINREACHSLOW . Since we do not aim to preserve a specific temporal graph class, we simplify the input by replacing S with a single-source s . Then we transform the temporal graph \mathcal{G} into a (non-temporal) directed graph D in which the deletion of an edge corresponds to slowing a temporal edge in \mathcal{G} . Using this, we derive a max-flow-based polynomial-time algorithm which checks whether the source s can be prevented from reaching any vertices outside of a given set R by slowing at most k time-edges in \mathcal{G} .

Step 3 (resulting search-tree): We are aiming for a search-tree algorithm for MINREACHSLOW. Let R be a set of vertices and suppose that our max-flow-based algorithm failed to prevent s from reaching any vertices outside of R . Now, if there exists a solution for the given instance of MINREACHSLOW, then we can identify less than $|R|$ vertices such that at least one of them will be always reached from s . We can then try adding each of them to R , gradually building a search-tree to find the solution.

Henceforth the details follow. Instead of solving MINREACHDELAY directly, we reduce it to an auxiliary problem introduced next. Let $\mathcal{G} = (V, (E_i)_{i \in [\tau]}, \gamma)$ be a temporal graph. *Slowing* a time-edge $(\{v, w\}, t)$ by δ refers to increasing $\gamma(\{v, w\}, t)$ by δ . We define $\mathcal{G} \uparrow_\delta X := (V, (E_i)_{i \in [\tau]}, \gamma')$ where $\gamma'(e) := \gamma(e) + \delta \cdot [e \in X]$. Our auxiliary problem is the following.

MINIMIZING TEMPORAL REACHABILITY BY SLOWING (MINREACHSLOW)

Input: A temporal graph $\mathcal{G} = (V, (E_i)_{i \in [\tau]}, \gamma)$, a set of sources $S \subseteq V$, and integers k, r, δ .

Question: Is there a time-edge set $X \subseteq \mathcal{E}(\mathcal{G})$ of size at most k such that $|R_{\mathcal{G} \uparrow_\delta X}(S)| \leq r$?

By the following, solving an instance of MINREACHSLOW also solves MINREACHDELAY.

► **Lemma 4.** *An instance $I = (\mathcal{G} = (V, (E_i)_{i \in [\tau]}, \gamma), S, k, r, \delta)$ of MINREACHDELAY is a yes-instance if and only if $J = (\mathcal{G}, S, k, r, \delta)$ is a yes-instance of MINREACHSLOW.*

Proof.

(\Rightarrow): Let $X \subseteq \mathcal{E}(\mathcal{G})$ be a solution for I . Note that for every temporal v - w -path P in $\mathcal{G} \uparrow_\delta X$, we can construct a temporal v - w -path P' in $\mathcal{G} \nearrow_\delta X$ by replacing a time-edge $(e, t) \in P$ with $(e, t + \delta)$ whenever $(e, t) \in X$. Hence, the reachable set of $s \in S$ in $\mathcal{G} \nearrow_\delta X$ is a superset of the reachable set of s in $\mathcal{G} \uparrow_\delta X$. Thus, J is a yes-instance.

(\Leftarrow): Let $X \subseteq \mathcal{E}(\mathcal{G})$ be an inclusion-minimal solution for J . We claim that every vertex reachable from S in $\mathcal{G} \nearrow_\delta X$ by some time t is also reachable from S in $\mathcal{G} \uparrow_\delta X$ until time t . Suppose for contradiction that the claim does not hold true for some vertex z and let t be the time S reaches z in $\mathcal{G} \nearrow_\delta X$. We may assume z to be chosen to minimize t . Clearly $t > 0$, i. e., $z \notin S$. Let P be a temporal s - z -path in $\mathcal{G} \nearrow_\delta X$ with arrival time t and $s \in S$. Let u be the penultimate vertex of P and $(\{u, z\}, t')$ the last time-edge of P . By minimality of t , u must be reachable from S by time t' also in $\mathcal{G} \uparrow_\delta X$. Since all time-edges of $\mathcal{E}(\mathcal{G}) \setminus X$ appear in $\mathcal{G} \nearrow_\delta X$ and $\mathcal{G} \uparrow_\delta X$ with identical traversal times, the last time-edge $(\{u, z\}, t')$ of P must be in $\mathcal{E}(\mathcal{G} \nearrow_\delta X) \setminus (\mathcal{E}(\mathcal{G}) \setminus X)$. Thus $(\{u, z\}, t' - \delta) \in X$. By minimality of X , there must be a source $s' \in S$ and a temporal s' - u -path P' in $\mathcal{G} \uparrow_\delta X$ reaching either u or z at time $t' - \delta$. If P' reaches z , then this is clearly a contradiction. But if P' reaches u , then appending $(\{u, z\}, t - \delta)$ to P' produces a temporal s' - z -path in $\mathcal{G} \uparrow_\delta X$ arriving at time t , thus also a contradiction. ◀

In the remainder of this section, we show that MINREACHSLOW is fixed-parameter tractable, when parameterized by r . Formally, we aim for the following theorem, which in turn clearly implies Theorem 3 by the means of Lemma 4.

► **Theorem 5.** *MINREACHSLOW can be solved in $O(r! \cdot k \cdot |\mathcal{G}|)$ time.*

The remainder of this section is dedicated to proving Theorem 5. The advantage of considering MINREACHSLOW instead of MINREACHDELAY is that we do not have to deal with new time-edges appearing due to the delay operation. This allows us to translate the reachability of a temporal graph to a (non-temporal) directed graph specially tailored to MINREACHSLOW.

In particular, the removal of some edges in the directed graph corresponds to slowing the corresponding time-edges by δ in the temporal graph. Before giving the details of the construction, we first reduce to the case where S is a singleton.

► **Lemma 6.** *Given an instance $I = (\mathcal{G} = (V, (E_i)_{i \in [\tau]}, S, k, r, \delta)$ of MINREACHSLOW , we can construct in linear time a instance $J = (\mathcal{G}', \{s\}, k, r + 1, \delta)$ of MINREACHSLOW such that I is a yes-instance if and only if J is a yes-instance.*

Proof. We set $\mathcal{G}' := (V \cup \{s\}, (E'_i)_{i \in [\tau + \delta + 1]})$ where s is a new vertex, $E'_1 := \{\{s, s'\} \mid s' \in S\}$, $E'_i := \emptyset$ for all $i \in [\delta + 1] \setminus \{1\}$, and $E'_{i + \delta + 1} := E_i$ for all $i \in [\tau]$. Observe that slowing an edge in E'_1 has no effect. Thus, I is a yes-instance if and only if J is a yes-instance. Clearly, J can be computed in linear time. ◀

A network (D, c) consists of a directed graph $D = (V, A)$ and edge capacities $c: A \rightarrow \mathbb{N}_0 \cup \{\infty\}$. A function $f: A \rightarrow \mathbb{N} \cup \{0\}$ is an s - z -flow for two distinct vertices $s, z \in V$ if

- $\forall e \in A: f(e) \leq c(e)$ and
- $\forall v \in V \setminus \{s, z\}: \sum_{(u,v) \in A} f((u,v)) = \sum_{(v,u) \in A} f((v,u))$.

The value of f is denoted by $|f| := \sum_{(s,v) \in A} f((s,v))$. An arc set $C \subseteq A$ is an s - z -cut of a network $((V, A), c)$ if $s, z \in V$ and there is no s - z -path in $(V, A \setminus C)$. The capacity of the s - z -cut C is $c(C) := \sum_{e \in C} c(e)$.

Let $\mathcal{G} = (V, (E_i)_{i \in [\tau]}, \gamma)$ be a temporal graph. We define the temporal neighborhood of a vertex $v \in V$ at time point $t \in [\tau]$ as the set $N_{\mathcal{G}}(v, t) := \bigcup_{i=t}^{\tau} N_{(V, E_i)}(v)$ containing all neighbors of v in the layers t through τ .

For any $s \in R \subseteq V$ and $\delta \in \mathbb{N}$, we define the flow network $\mathcal{F}(\mathcal{G}, s, R, \delta) := (D, c)$ where $D = (V', A)$ is the directed graph defined by

$$V' := \{s^0, z\} \cup \left\{ \begin{array}{l} e_1, e_2, v^t, w^t, v^{t+\gamma(e)}, w^{t+\gamma(e)}, \\ v^{t+\gamma(e)+\delta}, w^{t+\gamma(e)+\delta} \end{array} \mid v, w \in R \text{ and } e = (\{v, w\}, t) \in \mathcal{E}(\mathcal{G}) \right\}$$

and

$$A := \left\{ (v^t, v^{t'}) \mid v^t \in V', t' = \min\{i \mid i > t \text{ and } v^i \in V'\} \neq \infty \right\} \quad (1)$$

$$\cup \left\{ \begin{array}{l} (v^t, e_1), (w^t, e_1), (e_1, e_2), \\ (e_2, v^{t+\gamma(e)}), (e_2, w^{t+\gamma(e)}), \\ (v^t, w^{t+\gamma(e)+\delta}), (w^t, v^{t+\gamma(e)+\delta}) \end{array} \mid v, w \in R \text{ and } e = (\{v, w\}, t) \in \mathcal{E}(\mathcal{G}) \right\} \quad (2)$$

$$\cup \{(v^t, z) \mid v \in R, t = \max\{i \mid N_{\mathcal{G}}(v, i) \not\subseteq R\} \neq -\infty\}. \quad (3)$$

and we set $c((e_1, e_2)) = 1$ for all $e \in \mathcal{E}(\mathcal{G})$ and $c(a) = \infty$ for all other $a \in A$. Consider Figure 1 for an illustration.

■ **Figure 1** Left: An excerpt of a temporal graph \mathcal{G} containing the time-edge $e = (\{v, w\}, 3)$ and $\gamma(e) = 1$. Right: An excerpt of the flow network $\mathcal{F}(\mathcal{G}, s, R, \delta = 1)$ showing the corresponding part for e , where solid arcs have capacity ∞ and the dashed arc has capacity 1.

► **Lemma 7.** For any given $\mathcal{G} = (V, (E_i)_{i \in [\tau]}, \gamma)$, $s \in R \subseteq V$, and $k, \delta \in \mathbb{N}$, one can test in $O(k \cdot |\mathcal{G}|)$ time whether $\mathcal{F}(\mathcal{G}, s, R, \delta)$ has a s^0 -z-flow of value at least $k + 1$ and compute such a flow or a maximum flow otherwise.

Proof. Note, that the flow network $\mathcal{F}(\mathcal{G}, s, R, \delta)$ can be computed in $O(|\mathcal{G}|)$ time by iterating over $\mathcal{E}(\mathcal{G})$ first forward and then backwards once. Then we can compute a flow of value $k + 1$ or of maximum value, whichever is smaller, by running at most $k + 1$ rounds of the Ford-Fulkerson algorithm [29]. This gives a overall running time of $O(k \cdot |\mathcal{G}|)$ time. ◀

► **Lemma 8.** Let $\mathcal{G} = (V, (E_i)_{i \in [\tau]}, \gamma)$, $s \in R \subseteq V$, $\delta \in \mathbb{N}$, and $((V', A), c) := \mathcal{F}(\mathcal{G}, s, R, \delta)$. Let $X \subseteq \mathcal{E}(\mathcal{G})$ and $C := \{(e_1, e_2) \in A \mid e \in X\}$. For any $x^t \in V'$, there is a s^0 - x^t -path in $(V', A \setminus C)$ if and only if $\mathcal{G} \uparrow_\delta X$ contains a temporal s - x -path with arrival time at most t .

Proof. Let γ' be the traversal time function of $\mathcal{G} \uparrow_\delta X$, i. e., $\gamma'(e) := \gamma(e) + \delta \cdot [e \in X]$.

(\Leftarrow): Let P be a temporal s - x -path in $\mathcal{G} \uparrow_\delta X$ for some vertex $x \in V$ and let t be the arrival time of P . Then we construct a s^0 - x^t -path \hat{P} in $(V', A \setminus C)$ as follows. Start with \hat{P} being just the vertex s^0 and perform the following two steps for every time-edge $e = (\{v, w\}, b)$ of P in order.

1. Note that the currently last vertex of \hat{P} is v^c for some $c \leq b$. As long as $c < b$, append to \hat{P} the arc (v^c, v^d) where $d > c$ is chosen minimal (cf. (1)). Afterwards, the currently last vertex of \hat{P} is v^b .
2. If $e \notin X$, i. e., $(e_1, e_2) \notin C$, then append to \hat{P} the arcs (v^b, e_1) , (e_1, e_2) , and $(e_2, w^{b+\gamma(e)})$ (cf. (2)). Otherwise, if $e \in X$, i. e., $\gamma'(e) = \gamma(e) + \delta$, then append to \hat{P} the arc $(v^b, w^{b+\gamma(e)+\delta})$. Note that in both cases the new last vertex of \hat{P} is $w^{b+\gamma'(e)}$.

(\Rightarrow): Let P be a s^0 - x^t -path in $(V', A \setminus C)$. Then we construct a s - x -path P' with arrival time at most t in $\mathcal{G} \uparrow_\delta X$ as follows. Start with P' being just the vertex s (with arrival time 0) and repeat the following steps until all arcs of P have been processed.

1. Let b be the arrival time of P' and v the last vertex. Note that the last vertex of P is v^c for some $c \geq b$. Ignore all arcs of P up to the last arc containing v^c for some $c \geq b$.
2. If the next three arcs in P are (v^c, e_1) , (e_1, e_2) , $(e_2, w^{c+\gamma(e)})$ for some time-edge $e = (\{v, w\}, c) \in \mathcal{E}(\mathcal{G})$, then append to P' that time-edge e . Note that, by assumption, $(e_1, e_2) \notin C$, thus $e \notin X$, and thus the arrival time of e is $c + \gamma(e) = c + \gamma(e)$.
3. Otherwise the next arc in P must be $(v^c, w^{c+\gamma(e)+\delta})$ for some time-edge $e = (\{v, w\}, c) \in \mathcal{E}(\mathcal{G})$. Then append to P' that time-edge e . Note that the arrival time of e is $c + \gamma'(e) \leq c + \gamma(e) + \delta$. ◀

We now show that we can use Lemma 7 to check whether s can be prevented from reaching any vertices outside of R by slowing at most k time-edges by δ each.

► **Lemma 9.** For any given $\mathcal{G} = (V, (E_i)_{i \in [\tau]}, \gamma)$, $s \in R \subseteq V$, $\delta \in \mathbb{N}$, and $k \in \mathbb{N} \cup \{0\}$, the maximum s^0 -z-flow in $\mathcal{F}(\mathcal{G}, s, R, \delta)$ has value at most k if and only if there is a set X of at most k time-edges such that s can not reach any vertices outside of R in $\mathcal{G} \uparrow_\delta X$.

Proof. Write $((V', A), c) := F := \mathcal{F}(\mathcal{G}, s, R, \delta)$.

(\Rightarrow): Let the maximum s^0 -z-flow f in F have value at most k . Moreover, let C be a s^0 -z-cut of minimum capacity. From the max-flow min-cut theorem [30], we know that $c(C) \leq k$. Note that $C \subseteq \{(e_1, e_2) \in A \mid e \in \mathcal{E}(\mathcal{G})\}$, since all other edges have infinite capacity. Hence, $|C| \leq k$. Now set $X := \{e \in \mathcal{E}(\mathcal{G}) \mid (e_1, e_2) \in C\}$. Assume towards a contradiction that there

is a temporal s - x -path P in $\mathcal{G} \uparrow_\delta X$ for some $x \in V \setminus R$. We may take P to be minimal, thus the penultimate vertex y of P is contained in R . By Lemma 8 there is a s^0 - y^t -path \hat{P} in $(V', A \setminus C)$ where t is the time P reaches y . The fact that P afterwards proceeds to x and (3) in the definition of \mathcal{F} imply that $(V', A \setminus C)$ contains a path from y^t to x . This contradicts C being a s^0 - z -cut in (V', A) .

(\Leftarrow): Let X be a time-edge set as assumed. By assumption $R_{\mathcal{G} \uparrow_\delta X}(\{s\}) \subseteq R$. We claim that $C = \{(e_1, e_2) \mid e \in X\} \subseteq A$ is a s^0 - z -cut in (V', A) , which implies that the maximum value of an s^0 - z -flow in F is at most $c(C) \leq k$ [30]. So suppose towards a contradiction that there is a s^0 - z -path P in $(V', A \setminus C)$. Let $x^t \in V$ be the penultimate vertex of P . Then there is a s - x -path P' in $\mathcal{G} \uparrow_\delta X$ with arrival time at most t by Lemma 8. The final arc of P is (x^t, z) . Hence, (x^t, z) must be contained in (3), i. e., we can extend P' by some time-edge to end at a vertex in $V \setminus R$. This contradicts our assumption $R_{\mathcal{G} \uparrow_\delta X}(\{s\}) \subseteq R$. \blacktriangleleft

If $\mathcal{F}(\mathcal{G}, s, R, \delta)$ contains a s^0 - z -flow of value $k + 1$, then we want to find a small set $Y \subseteq V(\mathcal{G}) \setminus R$ of vertices such that $Y \cap R_{\mathcal{G} \uparrow_\delta X}(s) \neq \emptyset$ for every $X \subseteq \mathcal{E}(\mathcal{G})$ with $|X| \leq k$ and $|R_{\mathcal{G} \uparrow_\delta X}(s)| \leq r$.

► Lemma 10. *Let $\mathcal{G} = (V, (E_i)_{i \in [r]}, \gamma)$, $s \in R \subseteq V$, $\delta, r \in \mathbb{N}$, and $k \in \mathbb{N} \cup \{0\}$. Assume that $\mathcal{F}(\mathcal{G}, s, R, \delta)$ has a s^0 - z -flow of value $k + 1$. We can compute in $O(k \cdot |A|)$ time a set $Y \subseteq V \setminus R$ of size at most $|R|$ such that $Y \cap R_{\mathcal{G} \uparrow_\delta X}(s) \neq \emptyset$ holds for every $X \subseteq \mathcal{E}(\mathcal{G})$ with $|X| \leq k$ and $|R_{\mathcal{G} \uparrow_\delta X}(s)| \leq r$.*

Proof. Let f be a s^0 - z -flow of value $k + 1$ in $((V', A), c) := \mathcal{F}(\mathcal{G}, s, R, \delta)$. We may assume f to never use an arc (v^t, w^t) whenever A contains some arc (v^b, z) with $b \geq t$, as we could otherwise redirect f to use that latter arc (of infinite capacity) instead. Note that performing this modification can be done in $O(k \cdot |A|)$ time. Now set

$$H := \{(v, t) \mid v^t \in V' \text{ and } (v^t, z) \in A, f((v^t, z)) > 0\}$$

By (3), we have $|H| \leq |R|$ and $N_{\mathcal{G}}(v, t) \setminus R \neq \emptyset$ for all $(v, t) \in H$. Construct the vertex set Y by picking for each $(v, t) \in H$ one arbitrary vertex from $N_{\mathcal{G}}(v, t) \setminus R$. Hence $|Y| \leq |H| \leq |R|$ and $Y \cap R = \emptyset$.

It remains to prove that $R_{\mathcal{G} \uparrow_\delta X}(s) \cap Y \neq \emptyset$, with $X \subseteq \mathcal{E}(\mathcal{G})$ being an arbitrary solution for the MINREACHSLOW-instance $(\mathcal{G}, \{s\}, k, r, \delta)$. Define $C := \{(e_1, e_2) \in A \mid e \in X\}$. Since f has value $k + 1 > c(C)$, there is a s^0 - v^t -path P in $(V', A \setminus C)$ where each edge $e \in E(P)$ has $f(e) > 0$ and $(v, t) \in H$. By Lemma 8, there is a temporal s - v -path P' in $\mathcal{G} \uparrow_\delta X$ with arrival time at most t . Note that through P' , vertex s can reach v as well as all vertices of $N_{\mathcal{G} \uparrow_\delta X}(v, t) = N_{\mathcal{G}}(v, t)$. Hence, the vertex $u \in Y$ which we picked for $(v, t) \in H$ from $N_{\mathcal{G}}(v, t) \setminus R$ is in $R_{\mathcal{G} \uparrow_\delta X}(s)$ – thus the claim is proven. \blacktriangleleft

Now we are ready to prove of Theorem 5. The corresponding search-tree algorithm is listed as Algorithm 11.

Proof of Theorem 5. Let $I = (\mathcal{G}, S, k, r, \delta)$ be the given instance of MINREACHSLOW. By Lemma 6, we can assume $S = \{s\}$ after linear time preprocessing. We now prove that Algorithm 11 solves $(\mathcal{G}, \{s\}, k, r, \delta)$ in $O(r! \cdot k \cdot |\mathcal{G}|)$ time.

Let I be a *no*-instance. Observe that line 5 ensures that at all times $|R| \leq r$. Then, by Lemma 9, $\mathcal{F}(\mathcal{G}, s, R, \delta)$ will for all $s \in R \subseteq V$ have a s^0 - z -flow of value $k + 1$. Hence, line 4, and thus Algorithm 11 will never return *yes*.

■ **Algorithm 11** Pseudocode of the algorithm behind Theorem 5.

Input: An instance $I = (\mathcal{G}, \{s\}, k, r, \delta)$ of MINREACHSLOW.
Output: *yes* if I is a *yes*-instance and otherwise *no*.

- 1 **return** $g(\{s\})$, where
- 2 **function** $g(R)$ **is**
- 3 Compute a s^0 -z-flow f in $\mathcal{F}(\mathcal{G}, s, R, \delta)$ by Lemma 7
- 4 **if** f is of value at most k **then return** *yes*
- 5 **if** $|R| \geq r$ **then return** *no*
- 6 Compute a set $Y \subseteq V \setminus R$ by Lemma 10
- 7 **foreach** $v \in Y$ **do**
- 8 **if** $g(R \cup \{v\}) = \text{yes}$ **then return** *yes*
- 9 **return** *no*

Let I be a *yes*-instance. Thus there is a set X of at most k time-edges such that $|R_{\mathcal{G}\uparrow_\delta X}(s)| \leq r$. We claim that $g(R')$ returns *yes* for all R' with $s \in R' \subseteq R_{\mathcal{G}\uparrow_\delta X}(s)$. We prove this by reverse induction on $|R'|$. In the base case where $R = R_{\mathcal{G}\uparrow_\delta X}(s)$, $g(R)$ returns *yes* by Lemma 9. Now assume the claim to hold whenever $|R| = q$ and let R be of size $q - 1$ with $s \in R \subseteq R_{\mathcal{G}\uparrow_\delta X}(s)$. Assume that $\mathcal{F}(\mathcal{G}, s, R, k, \delta)$ has a s^0 -z-flow of value $k + 1$, otherwise we are done (by line 4). By Lemma 10, the set Y computed in line 6 contains a vertex $u \in R_{\mathcal{G}\uparrow_\delta X}(s) \setminus R$. Thus, $g(R \cup \{u\})$ returns *yes* by induction hypothesis. Hence, by line 8, $g(R)$ return *yes*, completing the induction. In particular, $g(\{s\})$ returns *yes*, therefore Algorithm 11 is correct.

To bound the running time, note that each call $g(R)$ makes at most $|Y| \leq |R|$ recursive calls by Lemma 10. In each of these recursive calls the cardinality of R increases by one until $|R| = r$, so the recursion depth is at most r by line 5. Hence, we can observe by an inductive argument that the search tree has $d!$ many nodes at depth d , where the root is at depth 1. Hence, the search tree has at most $r!$ many leaves and thus $O(r!)$ many nodes in total. By Lemma 7 and Lemma 10, lines 3 and 6 take at most $O(k \cdot |\mathcal{G}|)$ time. Hence, the overall running time is bounded by $O(r! \cdot k \cdot |\mathcal{G}|)$. ◀

4 A Polynomial-Time Algorithm for Forests

In this section we present an algorithm that solves MINREACHDELETE and MINREACHDELAY in polynomial time on temporal graphs where the underlying graph is a tree or a forest. This is a quite severe yet well-motivated restriction of the input [20, 22, 21], since it could serve as the starting point for FPT-algorithms for “distance-to-forest”-parameterizations.

► **Theorem 12.** *MINREACHDELETE and MINREACHDELAY are polynomial-time solvable if the underlying graph is a forest.*

Actually we even provide an polynomial-time algorithm for a generalized version of MINREACHDELAY. Then, polynomial-time solvability of MINREACHDELETE follows from Lemma 1, since it is forest preserving. We define the generalized problem as follows:

WEIGHTED MINREACHDELAY ON FORESTS

Input: A temporal graph $\mathcal{G} = (V, (E_i)_{i \in [\tau]}, \gamma)$ whose underlying graph is a forest, a weight function $w: V \rightarrow \mathbb{N} \cup \{0, \infty\}$, a set $F \subseteq \mathcal{E}(\mathcal{G})$ of undelayable time-edges, a set of sources $S \subseteq V$, and integers k, r, δ .

Question: Does there exist a time-edge set $X \subseteq \mathcal{E}(\mathcal{G}) \setminus F$ of size at most k such that $w(R_{\mathcal{G} \nearrow_{\delta} X}(S)) \leq r$?

In the remainder of this section, we show how to solve this problem using dynamic programming in polynomial time. Informally speaking, our dynamic program works as follows. As a preprocessing step we unfold vertices of large degree, reducing to an equivalent instance of maximum degree 3. Then we root each underlying tree at an arbitrary vertex and build a dynamic programming table, starting at the leaves. More precisely, we compute a table entry for each combination of a vertex v , a budget k , a time step t , and a flag indicating whether v is first reached from a child or from its parent. This table entry then contains a minimum reachable subset of the subtree rooted at v that can be achieved by applying k delay operations to that subtree.

► **Theorem 13.** *WEIGHTED MINREACHDELAY ON FORESTS is polynomial-time solvable if the underlying graph is a forest.*

Proof. Assume for now that the underlying graph of \mathcal{G} is a tree, rooted at an arbitrary leaf. We denote by T_v the subtree with root $v \in V$. We use the reaching time ∞ to denote “never”. By convention, a vertex can reach itself at time 0. Define $\mathbb{N}^* := \mathbb{N} \cup \{0, \infty\}$.

We first show how to transform the underlying graph into a binary tree. This will highly simplify the description of the dynamic programming table. Replace each vertex v of degree $\deg(v) > 3$ by a path on $\deg(v) - 2$ new vertices, where each edge of that path is undelayable, appears at each time step and always has traversal time 0. Distribute the edges formerly incident to v among the new vertices such that each of them has degree 3. Set the weight of the path’s first vertex to the weight of v , and the weight of all other path vertices to 0. Note that this modification produces an equivalent instance of maximum degree at most 3, while increasing the number of vertices only by a constant factor.

We extend the notion of reachability to vertex-time pairs $(s, t) \in S \times [\tau]$ by saying that (s, t) reaches $v \in V$ in \mathcal{G} if there exists a temporal s - v -path starting at time t or later. For a set $A \subseteq V \times [\tau]$, $R_{\mathcal{G}}(A)$ is the set of all vertices, reachable from any member of A in \mathcal{G} . We say a vertex v is reached *through* another vertex w if there is a temporal path from a source $s \in S$ to v that uses w .

Let $v \in V$, $k \in \mathbb{N}$. Define $\mathcal{T}_{v,k}$ as the set of temporal graphs obtained from T_v by applying up to k delay operations. Partition $\mathcal{T}_{v,k}$ into $\{\mathcal{T}_{v,k,t} \mid t \in \mathbb{N}^*\}$, where $\mathcal{T}_{v,k,t}$ contains those graphs in which v is reached from $S \cap V(T_v)$ exactly at time t . Finally, we set for each $t \in \mathbb{N}^*$

$$D[v, k, t, \text{false}] = \min \{w(R_T(S \cap V(T_v))) \mid T \in \mathcal{T}_{v,k,t}\} \quad \text{and}$$

$$D[v, k, t, \text{true}] = \min \left\{ w(R_T(S \cap V(T_v)) \cup R_T(\{(v, t)\})) \mid T \in \bigcup_{t' \geq t} \mathcal{T}_{v,k,t'} \right\}.$$

where the minimum of an empty set is ∞ by convention. It is convenient to also define these entries as ∞ whenever $k < 0$. Roughly speaking, $D[v, k, t, \iota]$ contains the minimal weight reached in T_v under the assumption that up to k delay operations are applied to T_v , that v is first reached at time t , and that

- v is reached by a source in $S \cap V(T_v)$ at time t if $\iota = \text{false}$,
- v is reached by a source in $S \setminus V(T_v)$ at time t if $\iota = \text{true}$.

Note that v might be reached simultaneously from $S \cap V(T_v)$ and $S \setminus V(T_v)$.

76:12 Temporal Reachability Minimization: Delaying vs. Deleting

We next show how to compute $D[v, k, t, \iota]$ recursively, starting at the leaf vertices. Observe that $D[v, k, t, \iota] = \infty$ whenever $v \in S$ is a source and $t > 0$. Thus, this case shall be excluded in the following.

If v has no children. If $\iota = \mathbf{false}$ and $v \notin S$ and $t < \infty$, then $D[v, k, t, \mathbf{false}] = \infty$ as there is no way that v can be reached from a source in $S \cap V(T_v) = \emptyset$. Otherwise,

$$D[v, k, t, \iota] = w(v) \cdot [t < \infty].$$

If v has exactly one child v' . If $\iota = \mathbf{false}$ and $v \notin S$, then v must be reached through v' at time t . In this case the minimal total weight reached in $T_{v'}$ is

$$D_1 := \min_{t' \leq t} D[v', k - \kappa(t', t), t', \mathbf{false}],$$

where $\kappa(t', t)$ is the minimal number of delays that need to occur on the edge $\{v, v'\}$ to ensure that (v', t') reaches v at time t but not earlier. (Set $\kappa(t', t) = \infty$ if this is impossible.) Consequently, if $v \notin S$, then

$$D[v, k, t, \mathbf{false}] = w(v) \cdot [t < \infty] + D_1.$$

If $\iota = \mathbf{true}$ or $v \in S$, then there are two possibilities. If v' is reached through v at time t' , with t' being the first time v' is reached from S , then the minimal total weight reached in $T_{v'}$ is

$$D_2 := \min_{t' \geq t} D[v', k - \kappa(t, t'), t', \mathbf{true}].$$

Otherwise, v' must be reached from a source in $S \cap V(T_{v'})$ at time t' , thus the minimal total weight reached in $T_{v'}$ is

$$D_3 := \min_{t'} D[v', k - \hat{\kappa}(t', t), t', \mathbf{false}],$$

where $\hat{\kappa}(t', t)$ is the minimal number of delays that need to occur on $\{v, v'\}$ to ensure that (v, t) cannot reach v' before time t' and (v', t') cannot reach v before time t . (Again, set $\hat{\kappa}(t', t) = \infty$ if this is impossible.) Thus we obtain for the case that $\iota = \mathbf{true}$ or $v \in S$ that

$$D[v, k, t, \iota] = w(v) \cdot [t < \infty] + \min\{D_2, D_3\}.$$

If v has two children v', v'' . The situation is similar to that of only one child vertex, although more possible cases have to be distinguished. We omit the tedious details. However, it is clear that $D[v, k, t, \iota]$ can be computed by simply trying all possible tuples $(t', t'', k', k'', i', i'', l', l'')$ where t', t'' are the times at which v', v'' are reached; k', k'' are the number of delays occurring in $T_{v'}, T_{v''}$; i', i'' are the number of delays occurring on the edges $\{v, v'\}, \{v, v''\}$; and l', l'' describe whether v', v'' are reached from a source in their respective subtrees at time t' and t'' , respectively. The number of such tuples and the time required to process each of them is clearly polynomial in $t + k + |\mathcal{G}|$.

After having computed all entries $D[v, k, t, \iota]$, the solution of the MINREACHDELAY instance (\mathcal{G}, k) can be found as the value of

$$R[\hat{v}, k] := \min_t D[\hat{v}, k, t, \mathbf{false}],$$

where \hat{v} is the root vertex of \mathcal{G} .

It remains to consider the case that the underlying graph of \mathcal{G} is a disconnected forest. In this case simply apply the above algorithm to each connected component. Afterwards, determining the optimal way to split the overall budget between the connected components can be computed by a simple dynamic program. Define $X[i, k]$ as the minimum weight reached in the first i trees if up to k time-edges are delayed and use the fact that

$$X[1, k] = \min_{k' \leq k} (R[\hat{v}_1, k'])$$

and for all $i > 1$

$$X[i, k] = \min_{k' \leq k} (R[\hat{v}_i, k'] + X[i-1, k-k']),$$

where \hat{v}_j is the root of the j^{th} tree. ◀

5 Conclusion

While both problem variants, MINREACHDELETE and MINREACHDELAY, are polynomial-time solvable on forests and W[1]-hard when parameterized by k , even if the lifetime is $\tau = 2$, their complexities diverge when we parameterize by the number r of reachable vertices. Here, MINREACHDELETE is W[1]-hard while for MINREACHDELAY we found a fixed-parameter tractable algorithm. This makes MINREACHDELAY particularly interesting for applications where the number of reachable vertices should be very small, e.g. when trying to contain the spread of dangerous diseases.

On the practical side we want to point out that our algorithm for MINREACHDELAY parameterized by r uses only linear space, and its search-tree-based approach makes it fit for optimization techniques like further data reduction rules or pruning using lower bounds. Furthermore, our max-flow-based branching technique can be turned into a r -approximation for minimizing the number r of reachable vertices by delaying k time-edges. To do so, instead of branching into all choices of $v \in Y$ in line 8 of Algorithm 11, simply invoke $g(R \cup Y)$. Refining the presented technique towards better approximation guarantees seems to be a promising research direction. Moreover, when focusing on specific applications, it is natural to exploit application-dependent graph properties towards designing more efficient algorithms. In particular: which well-motivated temporal graph classes beyond trees allow e.g. polynomial-time solvability of MINREACHDELETE or MINREACHDELAY? Finally, from the viewpoint of parameterized complexity the parameters k and r are settled, but the landscape of structural parameters is still waiting to be explored.

A Timecop’s Chase Around the Table

Abstract

We consider the cops and robbers game variant consisting of one cop and one robber on time-varying graphs (TVG). The considered TVGs are edge periodic graphs, i.e., for each edge, a binary string s_e determines in which time step the edge is present, namely the edge e is present in time step t if and only if the string s_e contains a 1 at position $t \bmod |s_e|$. This periodicity allows for a compact representation of an infinite TVG. We prove that even for very simple underlying graphs, i.e., directed and undirected cycles the problem whether a cop-winning strategy exists is NP-hard and W[1]-hard parameterized by the number of vertices. Our second main result are matching lower bounds for the ratio between the length of the underlying cycle and the least common multiple (lcm) of the lengths of binary strings describing edge-periodicities over which the graph is robber-winning. Our third main result improves the previously known EXPTIME upper bound for PERIODIC COP & ROBBER on general edge periodic graphs to PSPACE-membership.

1 Introduction

In general, a *time-varying graph* (TVG) describes a graph that varies over time. For most applications, this variation is limited to the availability or weight of edges meaning that edges are only present at certain time-steps or the time needed to cross an edge changes over time. TVGs are of great interest in the area of *dynamic networks* [4, 9, 10, 11] such as *mobile ad hoc networks* [19] and *vehicular networks* modeling traffic load factors on a road network [7]. In those networks, the topology naturally changes over time and TVGs are used to reflect this dynamic behavior. Quite recently, TVGs became of interest in the context of graph games such as competitive diffusion games and Voronoi games [2]. There are plenty of representations for TVGs in the literature which are not equivalent in general. For instance, in [4] a TVG is defined as a tuple $\mathcal{G} = (V, E, \mathcal{T}, \rho, \zeta)$ where V is a set of vertices, $E \subseteq V \times V \times L$ is a set of labeled edges (with labels from a set L), $\mathcal{T} \subseteq \mathbb{T}$ is the *lifetime* of the graph, \mathbb{T} is the temporal domain and assumed to be \mathbb{N} for discrete systems and \mathbb{R}^+ for continuous systems, $\rho: E \times \mathcal{T} \rightarrow \{0, 1\}$ is the *presence function* indicating whether an edge e is present in time step t , and $\zeta: E \times \mathcal{T} \rightarrow \mathbb{T}$ is the latency function indicating the time needed to cross edge e in time step t . We call the graph $G = (V, E)$ the *underlying graph* of \mathcal{G} . The literature has not yet agreed on how the function ρ (and ζ) are given in the input. This is of significant importance, if ρ exhibits periodicity with respect to single edges in the context of computational complexity. We say that a TVG belongs to the class of TVGs featuring *periodicity of edges*, defined as class 8 in [4], if $\forall e \in E, \forall t \in \mathcal{T}, \forall k \in \mathbb{N}, \rho(e, t) = \rho(e, t + kp_e)$

for some $p_e \in \mathbb{T}$, depending on e , and the underlying graph G is connected. For these TVGs, the function ρ can be represented for each edge $e \in E$ as a binary string of size p_e concatenating the values of $\rho(e, t)$ for $0 \leq t < p_e$. Note that the period of the whole graph \mathcal{G} is then the least common multiple (lcm for short) of all string lengths p_e describing edge periods. Therefore, the underlying graph G of \mathcal{G} can have exponentially many different sub-graphs G_t representing a snapshot of \mathcal{G} at time t . This exponential blow-up is a huge challenge in determining the precise complexity of problems for TVGs featuring periodicity of edges as discussed in more detail in Section 5 and 6. Often, for general TVGs a representation containing all sub-graphs representing snapshots over the whole lifetime of the graph is chosen when the complexity of decision problems over TVGs are considered [1, 13]. An approach to unify the representation of TVGs is given in [18], also including the existence of vertices being effected over time. This approach represents $\rho(e, t)$ by enhancing an edge $e = (u, v)$ with the departure time t_d at u and the arrival time t_a at v , where t_a might be smaller than t_d in order to model periodicity. As for TVGs with periodicity of edges where ρ is represented as a binary string for each edge the periodicity of the TVG \mathcal{G} might be exponential in its representation using the approach in [18] would also cause an exponential blow-up in the representation of \mathcal{G} , as a decrement of the time value could only be used after a whole period of the graph, rather than after the period of one edge. An other class of TVGs based on periodicity was considered in the field of robotics to model motion planning tasks if time dependent obstacles are present [17]. There, the availability of the vertices in the graph changes periodically and each edge needs a constant number of time steps to be crossed. An edge $e = \{u, v\}$ is only present if in the time span needed to cross e both endpoints are u and v are still present. In [17] the periodic function describing the availability of a vertex and the function describing the time needed to cross an edge is represented by an on-line program and can hence handle values exponential in their representation. This is crucial in the PSPACE-hardness proof of the reachability problem for graphs in this class presented in [17]. There, the hardness is obtained by a reduction from the halting problem for linear space-bounded deterministic Turing machines where a configuration of the Turing machine is encoded in the time step. In the reduction, the periodicity of a single vertex as well as the time needed to cross an edge is of value exponential in the tape length-bound. Note that this representation of periodicity is exponentially more compact than in our setting and thus the result of [17] does not translate to our setting.

We will stick in the following to the model describing TVG featuring periodicity of edges where the function $\rho(e, t)$ is represented as a binary string. For this representation, Erlebach and Spooner [8] introduced recently a variant of the famous cops and robber problem which is intensively studied for static graphs [3]. In the static setting, the game is played on a given graph and includes a single robber and a set of k -cops. The cops and robber occupy vertices and the cops choose their vertices first. Then, in each round the players alternate turns and the cops move first. Thereby, each cop can move to an adjacent vertex or pass and stay on her vertex. The same holds for the robber. We say that a graph is *k-cop-winning*, if there exists a strategy for the k cops in which they finally catch the robber, i.e., a cop occupies the same vertex as the robber. If the context is clear, we call a 1-cop-winning graph a *cop-winning* graph. If a graph is not cop-winning, we call it *robber-winning*. A special interest on the game of cops and robbers lied in characterizing graphs which are *k-cop-winning*. While for one cop, the cop-winning graphs where understood in 1978 and independently 1983 [16, 15] as those featuring a special kind of ordering on the vertex set, called a *cop-win* or *eliminating* order, the case for k cops was long open and solved in 2009 by exploiting a linear structure of a certain power of the graph [5].

In 2020 Erlebach and Spooner [8] connected the two discussed graph-theoretical topics of great interest by introducing a cops and robber game for *edge periodic graphs*. These are TVGs featuring periodicity of edges as discussed above. They gave an algorithm which determines if the given edge periodic graph is k -cop-winning, which runs in time $\mathcal{O}(\text{lcm} \cdot k \cdot |G|^{k+2})$, where lcm is the least common multiple of all length of binary strings describing $\rho(e, t)$ and G is the underlying graph. As lcm can be exponentially in the input size, they proposed the question of whether this problem is NP-hard. This question was answered positively for a one-cop version, also in 2020, by Morawietz, Rehs, and Weller [14] for TVGs of which the underlying graph has a constant size vertex cover or where two edges have to be removed to obtain a cycle. Moreover, they showed that the problem is W[1]-hard when parameterized by the size of the underlying graph G even in these restricted cases, that is, they showed that there is presumably no algorithm solving the problem in time $f(|G|) \cdot n^{\mathcal{O}(1)}$ for any computable function f . In other words, the exponential growth of the running time of every algorithm solving the problem has to depend on the length of binary strings describing $\rho(e, t)$.

Our contribution. In this work, we show, that the NP-hardness holds for even simpler classes of edge periodic graphs, namely for directed and undirected cycles. Moreover, we show that the W[1]-hardness when parameterized by $|G|$ even holds for these restricted instances (Section 3). The quite restricted class of undirected cycles was also studied in [8] where an upper bound on the length of the cycle with respect to the lcm was given for which each edge periodic cycle is robber winning. To be more precise, for an edge periodic cycle on n vertices it holds that if $n \geq 2 \cdot \ell \cdot \text{lcm}$, then the graph is robber winning. Here, $\ell = 1$ if lcm is at least two times the longest size of a binary string describing $\rho(e, t)$ and $\ell = 2$, otherwise. For these upper bounds only non-matching lower bounds were given, i.e., a family of cop-winning edge periodic cycles with length $3 \cdot \text{lcm}$ for $\ell = 2$ and $1.5 \cdot \text{lcm}$ for $\ell = 1$ are given. These lower bounds left a gap of size $0.5 \cdot \ell \cdot \text{lcm}$. In this work, we show that the given upper bounds are tight by closing this gap by giving families of cop-winning edge periodic cycles of length $2 \cdot \ell \cdot \text{lcm} - 1$ (Section 4). Finally, we improve the currently best EXPTIME upper bound shown in [8] for the problem, whether a given edge periodic graph is cop-winning to PSPACE (Section 5). We conclude with a discussion on the restricted class of directed edge periodic cycles indicating that due to the compact representation of the edge periodic graphs, which does not introduce additional amounts of freedom, the standard complexity classes, such as NP and PSPACE might not be suitable to precisely characterize the complexity of this problem (Section 6).

2 Preliminaries

For a string $w = w_0 w_1 \dots w_n$ with $w_i \in \{0, 1\}$, for $0 \leq i \leq n$, we denote with $w[i]$ the symbol w_i at position i in w . We write the concatenation of strings u and v as $u \cdot v$. For non-negative integers $i \leq j$ we denote with $[i, j]$ the interval of natural numbers n with $i \leq n \leq j$.

An *edge periodic (temporal) graph* $\mathcal{G} = (V, E, \tau)$ (see also [8]) consists of a graph $G = (V, E)$ (called the *underlying graph*) and a function $\tau : E \rightarrow \{0, 1\}^*$ where τ maps each edge e to a sequence $\tau(e) \in \{0, 1\}^*$ such that e exists in a time step $t \geq 0$ if and only if $\tau(e)[t]^\circ = 1$, where $\tau(e)[t]^\circ := \tau(e)[t \bmod |\tau(e)|]$. For an edge e and non-negative integers $i \leq j$ we inductively define $\tau(e)[[i, j]]^\circ = \tau(e)[i]^\circ \cdot \tau(e)[[i+1, j]]^\circ$ and $\tau(e)[[j, j]]^\circ = \tau(e)[j]^\circ$. If $\tau(e) = 1$, we call e a *1-edge*. Every edge e exists in at least one time step, that is, for each edge e there is some $t_e \in [0, |\tau(e)| - 1]$ with $\tau(e)[t_e] = 1$. We might abbreviate i repetitions of the same symbol σ in $\tau(e)$ as σ^i . Let $L_{\mathcal{G}} = \{|\tau(e)| \mid e \in E\}$ be the set of all edge periods

■ **Figure 1** Edge periodic cycle \mathcal{G} (left) together with snapshots $\mathcal{G}(t)$ for $0 \leq t \leq 4$.

of some edge periodic graph $\mathcal{G} = (V, E, \tau)$ and let $\text{lcm}(L_{\mathcal{G}})$ be the least common multiple of all periods in $L_{\mathcal{G}}$. We call an edge periodic graph \mathcal{G} with an underlying graph consisting of a single cycle an *edge periodic cycle*. We denote with $\mathcal{G}(t)$ the sub-graph of G present in time step t . We do not assume that \mathcal{G} is connected in any time step. We will discuss directed and undirected edge periodic graphs. If not stated otherwise, we assume an edge periodic graph to be undirected. We illustrate the notion of edge periodic cycles in Figure 1 showing an edge periodic cycle \mathcal{G} together with $\mathcal{G}(t)$ for the first 5 time steps. We now define the considered cops and robbers variant on edge periodic graphs with one single cop. Here, first the cop chooses her start vertex in $\mathcal{G}(0)$, then the robber chooses his start vertex in $\mathcal{G}(0)$. Then, in each time step t , the cop and robber move to an adjacent vertex over an edge which is present in $\mathcal{G}(t)$ or pass and stay on their vertex. Thereby, the cop moves first, followed by the robber. We say that the cop catches the robber, if there is some time step t for which the cop and the robber are on the same vertex after the cop moved. If the cop has a strategy to catch the robber regardless which start vertex the robber chooses, we say that \mathcal{G} is *cop-winning* and call the strategy implemented by the cop a *cop-winning strategy*. If for all cop start vertices, there exists a start vertex and strategy for the robber to elude the cop indefinitely, we call \mathcal{G} *robber-winning*. The described game is a zero-sum game, i.e., \mathcal{G} is either cop-winning or robber-winning.

PERIODIC COP & ROBBER

Input: An edge periodic graph $\mathcal{G} = (V, E, \tau)$.

Question: Is \mathcal{G} cop-winning?

3 It's hard to run around a table

In this section, we show that the NP-hardness of PERIODIC COP & ROBBER already holds if the input graphs are very restricted. More precisely, we show that PERIODIC COP & ROBBER is NP-hard and W[1]-hard when parameterized by $|G|$, even for directed and undirected edge periodic cycles \mathcal{G} .

► **Theorem 1.** *PERIODIC COP & ROBBER on directed or undirected edge periodic cycles is NP-hard, and W[1]-hard parameterized by the size of the underlying graph G .*

Both, the undirected and directed case of Theorem 1 is shown by a reduction of the PERIODIC CHARACTER ALIGNMENT problem which was shown to be both NP-hard and W[1]-hard when parameterized by $|X|$ in [14].

PERIODIC CHARACTER ALIGNMENT

Input: A finite set $X \subseteq \{0, 1\}^*$ of binary strings.

Question: Is there a position i , such that $x[i]^\circ = 1$ for all $x \in X$, where $x[i]^\circ := x[i \bmod |x|]$?

■ **Figure 2** PERIODIC COP & ROBBER instance constructed from a PERIODIC CHARACTER ALIGNMENT instance with set of strings $X = \{x_1, \dots, x_m\}$ in the proof of Lemma 2. For $x_j \in X$ the edge labels are defined as $\xi(x_j) := \xi(x_j[0]) \cdot \xi(x_j[1]) \cdot \dots \cdot \xi(x_j[|x_j| - 1])$, with $\xi(c) := 0c^m 01^m$ for $c \in \{0, 1\}$. The upper chain corresponds to the vertices r_j and the lower chain to the vertices ℓ_j .

We begin with considering the case of undirected edge periodic cycles and then proceed by adapting the obtained construction for directed edge periodic cycles.

► **Lemma 2.** *PERIODIC COP & ROBBER on undirected edge periodic cycles is NP-hard and W[1]-hard parameterized by the size of the underlying graph G .*

Proof. We first sketch the idea of the construction. It is helpful to consider Figure 2 in the following. We represent each string in X by an edge label. The constructed cycle will consist of two chains connected by two special edges. In the first chain, the elements in X are increasingly listed in some fixed order as individual edge labels each. In the second chain the same edge labels are listed decreasingly in the same order. This will allow the cop and the robber to occupy antipolar vertices with the same edge labels on incident edges. Hence, while the cop is on one chain and the robber on the other chain, the robber can mimic the movements of the cop. The two chains are connected by two special edges for which their edge labels are complementary in one position of the labels and identical in all other positions. This will allow the cop to switch between the chains in a certain time step while the robber is trapped on his chain. In this situation, the cop will be able to catch the robber if and only if there is a position i , such that $x[i]^\circ = 1$ for all $x \in X$, in which case all edges of the chains will be present for some period.

We now proceed with the formal proof. Let X be an instance of PERIODIC CHARACTER ALIGNMENT. We describe how to construct in polynomial time an instance $\mathcal{G} = (V, E, \tau)$ of PERIODIC COP & ROBBER, where \mathcal{G} is an undirected edge periodic cycle such that X is a yes-instance of PERIODIC CHARACTER ALIGNMENT if and only if \mathcal{G} is a yes-instance of PERIODIC COP & ROBBER.

Let $|X| = m$ and $\{x_1, \dots, x_m\}$ be the elements of X . We set $V := \{\ell_j, r_j \mid 0 \leq j \leq m\}$ and $E := \{\{\ell_{j-1}, \ell_j\}, \{r_{j-1}, r_j\} \mid 1 \leq j \leq m\} \cup \{\{\ell_0, r_m\}, \{\ell_m, r_0\}\}$. Next, we set $\tau(\{\ell_0, r_m\}) := 10^m 10^m$ and $\tau(\{\ell_m, r_0\}) := 00^m 10^m$. Let $\xi(c) := 0c^m 01^m$ for all $c \in \{0, 1\}$. Finally, we set $\tau(\{\ell_{j-1}, \ell_j\}) := \tau(\{r_{j-1}, r_j\}) := \xi(x_j[0]) \cdot \xi(x_j[1]) \cdot \dots \cdot \xi(x_j[|x_j| - 1])$ for each $x_j \in X$. Note that the length of each edge label is divisible by $q := 2m + 2$. For $i \geq 0$, let $T_i := [q \cdot i, q \cdot (i + 1) - 1]$ denote the i -th time block, that is, the q consecutive time steps starting from $q \cdot i$. Note that the j -th edge label limited to the i -th time block $\tau(\{\ell_{j-1}, \ell_j\})[T_i]^\circ = \tau(\{r_{j-1}, r_j\})[T_i]^\circ$ is exactly $\xi(x_j[i]^\circ)$.

Next, we show that X is a yes-instance of PERIODIC CHARACTER ALIGNMENT if and only if \mathcal{G} is a yes-instance of PERIODIC COP & ROBBER.

(\Rightarrow) Let i be a position such that $x[i]^\circ = 1$ for all $x \in X$. We describe the winning strategy for the cop. She should choose the vertex ℓ_0 as her start vertex and should never move until the beginning t of the i -th time block T_i . Since $x[i]^\circ = 1$ for all $x \in X$, $\tau(\{\ell_{j-1}, \ell_j\})[T_i]^\circ = \tau(\{r_{j-1}, r_j\})[T_i]^\circ = \xi(1) = 01^m 01^m$. Consequently, in time step t only the edge $\{\ell_0, r_m\}$ exists and in the following m time steps, all edges except $\{\ell_0, r_m\}$ and $\{\ell_m, r_0\}$ exist.

If the robber is currently on some vertex r_j , then the cop should move to r_m in time step t . Otherwise, the cop should stay on ℓ_0 in this time step. By the fact that the edge $\{\ell_m, r_0\}$ does not exist in time step t , we obtain that, at the beginning of time step $t + 1$, both players are either on vertices labeled with r or labeled with ℓ . Since all edges of the two paths (ℓ_0, \dots, ℓ_m) and (r_0, \dots, r_m) exist in the time steps $[t + 1, t + m]$, the cop can catch the robber in at most m time steps, since neither $\{\ell_0, r_m\}$ nor $\{\ell_m, r_0\}$ exists in any of the time steps $[t + 1, t + m]$. Consequently, \mathcal{G} is a yes-instance of PERIODIC COP & ROBBER.

(\Leftarrow) Suppose that X is a no-instance of PERIODIC CHARACTER ALIGNMENT. We describe a winning strategy for the robber. In the following, we say that the vertex ℓ_j is the *mirror vertex* of r_j and vice versa. Moreover, we say that the robber *mirrors the move* of the cop at some time step t , if the cop is on the mirror vertex of the robber at the beginning of time step t and the robber moves to the mirror vertex of the vertex the cop ends on in time step t .

The start vertex of the robber should be the mirror vertex of the start vertex of the cop. If it is possible, then the robber should always mirror the moves of the cop.

Note that the only move the robber *cannot* mirror is if the cop traverses the edge $\{\ell_m, r_0\}$ at the beginning of some i -th time block.

We show that the robber has a strategy to end on the mirror vertex during the i -th time block and evade the cop until then.

Assume w.l.o.g., that the cop moves from ℓ_m to r_0 and, thus, the robber is currently on r_m . Since X is a no-instance of PERIODIC CHARACTER ALIGNMENT, there is at least one $x_j \in X$ with $x_j[i]^\circ = 0$. Hence, $\tau(\{\ell_{j-1}, \ell_j\})[T_i]^\circ = \tau(\{r_{j-1}, r_j\})[T_i]^\circ = \xi(0) = 00^m 01^m$. Consequently, the cop cannot catch the robber in the first $m + 1$ time steps of the i -th time block. Hence, the robber should stay on this vertex until the beginning of time step $q \cdot i + m + 1$.

If the cop moves from r_0 to ℓ_m in time step $q \cdot i + m + 1$, the robber is again on the mirror vertex of the cop and is able to mirror all of the cop's moves in the remaining time steps of this time block. Otherwise, the cop stays on some vertex r_p . In this case, the robber should move to ℓ_0 . Since the edges $\{\ell_0, r_m\}$ and $\{\ell_m, r_0\}$ do not exist in the remaining time steps of this time block, the cop cannot catch the robber in this time block. Moreover, since all edges of the path (ℓ_0, \dots, ℓ_m) exist in the last m time steps of the i -th time block, the robber can move along the path (ℓ_0, \dots, ℓ_m) and reach the mirror vertex of the cop in at most m time steps. Consequently, we can show via induction, that the robber has an infinite evasive strategy and, thus, \mathcal{G} is a no-instance of PERIODIC COP & ROBBER. Since PERIODIC CHARACTER ALIGNMENT is W[1]-hard when parameterized by $|X|$ and $|V| = |E| = 2 \cdot |X| + 2$, we obtain that PERIODIC COP & ROBBER is W[1]-hard when parameterized by the size of the underlying graph of \mathcal{G} even on undirected edge periodic cycles. \blacktriangleleft

Next, we adapt the previous construction for *directed* edge periodic cycles. It is helpful to consider Figure 3 in the following. In the adaption, we only have one chain listing the elements of X . The end vertex of this chain is connected to a new vertex s which is again connected to the start vertex of the chain. The edges incident with s will act as the two edges connecting the two chains in the previous construction by delaying the robber, such that the cop can catch him if all edges corresponding to X are present in some time period.

► **Lemma 3.** *PERIODIC COP & ROBBER on directed edge periodic cycles is NP-hard, and W[1]-hard parameterized by the size of the underlying graph.*

Proof. Again, we reduce from PERIODIC CHARACTER ALIGNMENT. Let X be an instance of PERIODIC CHARACTER ALIGNMENT. We describe how to construct an instance $\mathcal{G} = (V, E, \tau)$ of PERIODIC COP & ROBBER, where \mathcal{G} is a directed edge periodic cycle. Let $|X| = m$ and $\{x_1, \dots, x_m\}$ be the elements of X . We set $V := \{v_j \mid$

■ **Figure 3** PERIODIC COP & ROBBER instance constructed from a PERIODIC CHARACTER ALIGNMENT instance with set of strings $X = \{x_1, \dots, x_m\}$ in the proof of Lemma 3. For $x_j \in X$ the edge labels are defined by the homomorphism $\xi(x_j) := \xi(x_j[0]) \cdot \xi(x_j[1]) \cdot \dots \cdot \xi(x_j[|x_j| - 1])$, with $\xi(c) := c^m 01^m 1$ for $c \in \{0, 1\}$.

$0 \leq j \leq m\} \cup \{s\}$ and $E := \{(v_{j-1}, v_j) \mid 1 \leq j \leq m\} \cup \{(v_m, s), (s, v_0)\}$. Next, we set $\tau((v_m, s)) := 0^m 10^m 0$ and $\tau((s, v_0)) := 0^m 00^m 1$. Let $\xi(c) := c^m 01^m 1$ for all $c \in \{0, 1\}$. Finally, we set $\tau((v_{j-1}, v_j)) := \xi(x_j[0]) \cdot \xi(x_j[1]) \cdot \dots \cdot \xi(x_j[|x_j| - 1])$ for each $x_j \in X$.

Note that the length of each edge label is divisible by $q := 2m + 2$. For $t \geq 0$, let $T_t := [q \cdot t, q \cdot (t + 1) - 1]$ denote the t -th time block, that is, the q consecutive time steps starting from $q \cdot t$. Note that the j -th edge label limited to the t -th time block $\tau((v_{j-1}, v_j))[T_t]^\circ$ is exactly $\xi(x_j[t]^\circ)$. Next, we show that X is a yes-instance of PERIODIC CHARACTER ALIGNMENT if and only if \mathcal{G} is a yes-instance of PERIODIC COP & ROBBER.

(\Rightarrow) Let t be a position such that $x[t]^\circ = 1$ for all $x \in X$. We describe the winning strategy for the cop. The cop should choose the vertex v_0 as her start vertex and should never move until the beginning $t^* := q \cdot t$ of the t -th time block. By construction and the fact that $x_i[t]^\circ = 1$ for each $x_i \in X$, $\tau((v_{i-1}, v_i))[T_t]^\circ = \xi(1) = 1^m 01^m 1$. Hence, the cop can move from vertex v_i to vertex v_{i+1} in time step $t^* + i$ for each $i \in [0, m - 1]$ and, thus, reach the vertex v_m in time step $t^* + m - 1$. Moreover, the cop can then move to the vertex s in time step $t^* + m$. By construction, $\tau((s, v_0))[t^* + j]^\circ = 0$ for each $j \in [0, m]$. Hence, the cop has a winning strategy since she started at vertex v_0 and moved over every vertex of V while the robber was not able to traverse the edge (s, v_0) .

(\Leftarrow) Suppose that for every position t , there is some $x_j \in X$ with $x_j[t]^\circ = 0$. We show that the robber has a winning strategy. For some time step, let w_C and w_R denote the vertex of the cop, respectively robber in this time step. We call the vertex v_0 safe for all vertices of $V \setminus \{v_0, s\}$, we call v_m safe for v_0 and s , and we call s safe for v_0 . Let u_C be the start vertex of the cop, then the robber should choose a vertex which is safe for u_C as his start vertex.

▷ **Claim 4.** Let $t^* = t \cdot q$ be the beginning of the t -th time block for some $t \geq 0$, let u_C be the vertex of the cop at time step t^* and u_R be the vertex of the robber at time step t^* . If u_R is safe for u_C , then the robber has a strategy such that the cop cannot catch him in the t -th time block and the robber ends on a vertex that is safe for the vertex of the cop at the end of the t -th time block.

Proof.

Case 1: $u_C \in V \setminus \{s, v_0\}$ and $u_R = v_0$. The robber should wait on vertex v_0 until the beginning of time step $t^* + m$. Since the edge (s, v_0) only exists in the last time step of the t -th time block, the cop cannot catch the robber in any of these time steps. If the cop does not traverse the edge (v_m, s) in time step $t^* + m$, then the robber should stay on vertex v_0 until the beginning of the next time block. Since the edge (v_m, s) only exists in time steps t' with $t' \bmod q = m$, it follows that the cop ends on some vertex of $V \setminus \{s, v_0\}$ at the end of the t -th time block. Thus, at the beginning of the $(t + 1)$ -th time block, the vertex of the robber is safe for the vertex of the cop.

Otherwise, the cop traverses the edge (v_m, s) in time step $t^* + m$. Then, the robber should traverse the edge (v_{i-1}, v_i) in time step $t^* + m + i$ for each $i \in [1, m]$, while the cop has to wait on s . Hence, the robber reaches v_m in time step $t^* + q - 2$. In time step $t^* + q - 1$, the cop can either stay on s or move to v_0 . In both cases the robber should stay on v_m which is safe for both s and v_0 .

Case 2: $u_C = s$ and $u_R = v_m$. Since the edge (s, v_0) only exists in the last time step of the t -th time block, the cop has to stay on s until the beginning of time step $t^* + q - 1$. In time step $t^* + q - 1$, the cop can either stay on s or move to v_0 . In both cases the robber stays on v_m which is safe for both s and v_0 .

Case 3: $u_C = v_0$ and $u_R \in \{v_m, s\}$. Let $j \in [1, m]$ such that $x_j[t]^\circ = 0$, recall that by definition of τ it follows that $\tau((v_{j-1}, v_j))[T_t]^\circ = 0^m 01^m 1$. Thus, the cop cannot reach the vertex v_m in the first $m + 1$ time steps of the t -th time block. In time step $t^* + m$, the robber should stay on s if s is his current vertex or traverse the edge (v_m, s) , otherwise. Since this is the only time step in which this edge exists in the t -th time block, the cop cannot catch the robber in this time block. Until the beginning of time step $t^* + q - 1$, the robber should stay on s . If the cop ends her turn on vertex v_0 , then the robber should stay on s . Otherwise, the robber should traverse the edge (s, v_0) in time step $t^* + q - 1$. In both cases, the vertex of the robber is safe for the vertex of the cop at the beginning of the $(t + 1)$ -th time block. \triangleleft

By using Claim 4, one can show via induction, that the robber has an infinite evasive strategy and, thus, \mathcal{G} is a no-instance of PERIODIC COP & ROBBER. \blacktriangleleft

For the next section, we will stick to edge periodic cycles and consider families of cop-winning *undirected* edge periodic cycles.

4 Sharp bounds on the length required to ensure robber-winning edge periodic cycles

In [8], an upper bound on the cycle length of an edge periodic cycle in dependence of $\text{lcm}(L_{\mathcal{G}})$, required to ensure an robber winning strategy, was given. Namely, for $|V| = n$, the graph \mathcal{G} is robber winning if $n \geq 2 \cdot \ell \cdot \text{lcm}(L_{\mathcal{G}})$, where $\ell = 1$ if $\text{lcm}(L_{\mathcal{G}}) \geq 2 \cdot \max(L_{\mathcal{G}})$, and $\ell = 2$, otherwise ([8, Theorem 3]). So far, these bounds were not sharp, as for instance, in [8], the only lower bounds are given by cop winning strategies for families of edge periodic cycles with $n = 1.5 \cdot \text{lcm}(L_{\mathcal{G}})$ for $\ell = 1$ ([8, Theorem 5]), and $n = 3 \cdot \text{lcm}(L_{\mathcal{G}})$ for $\ell = 2$ and $\max(L_{\mathcal{G}}) = \text{lcm}(L_{\mathcal{G}})$ ([8, Theorem 4]). We show that both upper bounds ensuring a robber winning strategy are sharp by presenting infinite families of cop-winning edge periodic cycles with $n = 2 \cdot \ell \cdot \text{lcm}(L_{\mathcal{G}}) - 1$ vertices.

► **Theorem 5.** *For every $k \geq 3$ and $\ell \in \{1, 2\}$, there exists a cop-winning edge periodic cycle $\mathcal{G} = (V, E, \tau)$ with $\max(L_{\mathcal{G}}) = k$ and $n = 2 \cdot \ell \cdot \text{lcm}(L_{\mathcal{G}}) - 1$ vertices, where $\text{lcm}(L_{\mathcal{G}}) \geq 2k$ if $\ell = 1$, and $\text{lcm}(L_{\mathcal{G}}) = k$, otherwise.*

In order to prove Theorem 5, we give families of edge periodic cycles for $\ell = 1$ and $\ell = 2$, each, beginning with $\ell = 2$, i.e., the case that $\text{lcm}(L_{\mathcal{G}}) < 2 \cdot \max(L_{\mathcal{G}})$.

► **Lemma 6.** *For every $k \geq 2$ there exists an edge periodic cycle $\mathcal{G} = (V, E, \tau)$ with $\text{lcm}(L_{\mathcal{G}}) = k = \max(L_{\mathcal{G}})$, and $n = 4k - 1$ vertices that is cop-winning.*

Proof. Consider the edge periodic cycle $\mathcal{G}_k = (V, E, \tau)$ depicted in Figure 4 with $|V| = 4k - 1$. This graph admits a cop winning strategy if the cop picks the highlighted vertex with index 0 as her start vertex. The vertices are indexed by positive numbers indicating their

■ **Figure 4** Cycle with $4 \cdot k - 1$ vertices and $\text{lcm}(L_G) = k$ with a cop winning strategy from the start vertex marked in red. Edges not drawn (depicted by dots) are 1-edges; for all other edges, $\tau(e)$ is explicitly noted (with gray background). The clockwise [counterclockwise] distance of each vertex to the start vertex of the cop is given as a positive [negative] number.

■ **Table 1** Time steps with corresponding positions of cop and robber in the edge periodic cycle depicted in Figure 4. All positions are *after* moving in this time step. The time step s denotes the start configuration. Recall that the cop moves first.

time step	pos. cop	pos. robber	time step	pos. cop	pos. robber
s	0	$2k - 1$	s	0	$-(2k - 1)$
0	1	$2k - 1$	$k - 1$	$-(k)$	$-(2k)$
$k - 1$	k	$2k$	k	$-(k + 1)$	$-(2k + 1)$
$2k - 3$	$2k - 2$	$3k - 2$	$2k - 2$	$-(2k - 1)$	$-(3k - 1)$
$2k - 2$	$2k - 1$	$3k - 2$	$2k - 1$	$-(2k)$	$-(3k)$
$2k - 1$	$2k$	$3k - 2$	$3k - 3$	$-(3k - 2)$	$-(4k - 2)$
$2k$	$2k + 1$	$3k - 1$	$3k$	$-(3k + 1)$	0
$3k - 3$	$3k - 2$	$4k - 4$	$4k - 3$	$-(4k - 2)$	$-(k - 3)$
$3k$	$3k - 1$	0	$4k$	0	$-(k)$
$3k + 1$	$3k$	0	$5k - 1$	$-(k - 1)$	$-(k)$
$4k - 1$	$4k - 2$	0	$5k$	$-(k)$	$-(k)$
$4k$	0	$-(k)$			

clockwise distance to the start vertex of the cop, and with negative numbers indicating their counterclockwise distance. Let the cop pick vertex 0. We consider the antipolar vertices $+(2k - 1)$ and $-(2k - 1)$ as potential start vertices of the robber. We show that if the robber picks vertex $+(2k - 1)$, then the cop has a winning strategy by continuously running clockwise, starting in time step zero, and if the robber picks vertex $-(2k - 1)$, the same applies running counterclockwise. Note that these two positions represent extrema and being able to catch the robber at these vertices implies being able to catch him at all vertices in the graph. Table 1 shows the positions of the cop and robber for these strategies for $k \geq 4$. For each time step, the position after both players moved are depicted; s is the start configuration. We abbreviate consecutive 1-edges and only depict the time steps and positions when one of the players reaches a non-trivial edge. For the cases of $k = 2$ and $k = 3$ the cop catches the robber earlier than depicted in Table 1, namely in step $t = 6$ clockwise and $t = 8$ counterclockwise for $k = 2$ and in step $t = 6$ clockwise and $t = 9$ counterclockwise for $k = 3$ if the robber chooses the corresponding antipolar start vertices. Details on case $k = 2$ and $k = 3$, and a concrete example for $k = 4$, can be found in the appendix. ◀

■ **Figure 5** Cycle with $6 \cdot k - 1$ vertices and $\text{lcm}(L_{\mathcal{G}}) = 3k$ with a cop winning strategy from the start vertex 0 where $k = 2^m$ and $m \geq 2$. Edges not drawn (depicted by dots) or edges without an explicit label are 1-edges; for all other edges, $\tau(e)$ is explicitly noted (with gray background).

For the case that $\ell = 1$, i.e., when $\text{lcm}(L_{\mathcal{G}}) \geq 2 \cdot \max(L_{\mathcal{G}})$, we slightly adapt the family of graphs depicted in Figure 4. Note that for $\max(L_{\mathcal{G}}) = 2$ there is no edge periodic cycle $\mathcal{G} = (V, E, \tau)$ with $\text{lcm}(L_{\mathcal{G}}) > \max(L_{\mathcal{G}}) = 2$.

► **Lemma 7.** *For every $k \geq 3$ with $k \neq 2^m$ for all $m \in \mathbb{N}$, there exists an edge periodic cycle $\mathcal{G} = (V, E, \tau)$ with $\text{lcm}(L_{\mathcal{G}}) = 2 \cdot \max(L_{\mathcal{G}}) = 2 \cdot k$, and $n = 2 \cdot 2k - 1$ vertices that is cop-winning.*

Proof. For the case $\ell = 1$ we introduce an artificial edge label in the edge periodic cycle in Figure 4, such that the $\text{lcm}(L_{\mathcal{G}})$ is exactly $2k$. This edge will not affect the run of the cop. Its purpose is to introduce a factor 2 in the number of vertices compensating the missing factor 2 from the variable ℓ . Therefore, note that the edge $e_{1,2}$ connecting vertex $+1$ and $+2$ is taken by the cop only once, in the clockwise run in time step 1 and in the counterclockwise run in time step $4k - 3$. Hence, the cop only crosses the edge in an odd time step. We can write k as $k = 2^i \cdot j$ where j is an odd number with $j > 1$ since $k \neq 2^m$. Then, introducing a string $\tau(e_{1,2}) = 01^{2^{i+1}-1}$ of length 2^{i+1} yields a least common multiple of $\text{lcm}(L_{\mathcal{G}}) = 2^{i+1} \cdot j = 2 \cdot k$. ◀

In the case of $\max(L_{\mathcal{G}}) = k = 2^m$ for some $m \in \mathbb{N}$, it holds that for the smallest possible value of $\text{lcm}(L_{\mathcal{G}})$ with $\text{lcm}(L_{\mathcal{G}}) > \max(L_{\mathcal{G}})$, we have $\text{lcm}(L_{\mathcal{G}}) \geq 3 \cdot \max(L_{\mathcal{G}})$. Hence, in these cases we need a separate family of graphs.

► **Lemma 8.** *For every $k = 2^m$ with $m \geq 2$, there exists an edge periodic cycle $\mathcal{G} = (V, E, \tau)$ with $\text{lcm}(L_{\mathcal{G}}) = 3 \cdot \max(L_{\mathcal{G}}) = 3 \cdot k$, and $n = 6 \cdot k - 1$ vertices that is cop-winning.*

Proof. Consider the edge periodic cycle $\mathcal{G}_k = (V, E, \tau)$ depicted in Figure 5 with $|V| = 6k - 1$. This graph admits a cop winning strategy if the cop picks the highlighted vertex with index 0 as her start vertex. The vertices are indexed by positive numbers indicating their clockwise distance to the start vertex of the cop. Let the cop pick vertex 0. We show that if the robber picks vertex $3k - 1$, then the cop has a winning strategy by continuously running clockwise, starting in time step zero. Since for each j , starting from vertex 0, the label of the j -th edge clockwise is equal to the label of the j -th edge counterclockwise, the same applies running counterclockwise if the robber picks vertex $3k$. Note that these two positions represent extrema and being able to catch the robber at these vertices implies being able to catch him at all vertices in the graph. Suppose that the robber picks vertex $3k - 1$. Since $k = 2^m$ for some $m \geq 2$, $\frac{3}{2} \cdot k$ and $\frac{9}{2} \cdot k$ are divisible by 3. Hence for each $j \in [1, 6k - 3]$, the cop can traverse the edge $\{j, j + 1\}$ in time step j and, thus, reach the vertex $5k - 1$ in time step $5k - 2$. We show that, starting from vertex $3k - 1$ and running clockwise, the robber cannot reach vertex $5k$ prior than time step $5k - 1$. This then implies, that the cop catches

the robber after at most $5k - 2$ time steps. Note that the first time the robber can traverse the edge $\{3k - 1, 3k\}$ is at time step $k - 1$. Hence, the robber reaches the vertex $3k + 2$ not prior than time step $k + 1$. Since k is not divisible by 3, the robber cannot traverse the edge $\{3k + 2, 3k + 3\}$ in time step $k + 2$. Thus, the robber cannot reach the vertex $4k - 1$ prior than time step $2k$ and consequently, he cannot traverse the edge $\{4k - 1, 4k\}$ prior than time step $3k - 1$. Hence, the robber reaches the vertex $\frac{9}{2}k - 1$ not prior than time step $\frac{7}{2}k - 2$. Since k is not divisible by 3, the robber cannot traverse the edge $\{\frac{9}{2}k - 1, \frac{9}{2}k\}$ in time step $\frac{7}{2}k - 1$. Thus, the robber cannot reach the vertex $5k - 1$ prior than time step $4k$ and consequently, he cannot traverse the edge $\{5k - 1, 5k\}$ prior than time step $5k - 1$. Hence, the statement holds. A concrete example for $k = 4$ can be found in the appendix. ◀

5 Complexity upper bounds

The main result of this section is that the PERIODIC COP & ROBBER problem for *general* edge periodic graphs can be solved in polynomial space. Note that two-player games may take exponentially many turns and hence containment in PSPACE is not obvious. In our case, already the period of graphs on which the game is played is exponential in general. This prohibits a standard incremental PSPACE algorithm approach. We show that despite the potentially exponential period of the sequence of graphs $\mathcal{G}(t)$ we show that we can determine whether the cop has a winning strategy by sweeping through the configuration space in a way that we only consider polynomially many vertices in each step. The fact that we only consider one cop and one robber is here crucial for the polynomial bound.

► **Theorem 9.** *PERIODIC COP & ROBBER for edge periodic graphs is contained in PSPACE.*

For general edge periodic graphs, the PERIODIC COP & ROBBER problem was reduced in [8] to a variant of the AND-OR GRAPH REACHABILITY problem [6] via an exponential time reduction. The AND-OR GRAPH REACHABILITY problem is a two player game where players move a token in an AND-OR graph from a source to a target. An AND-OR graph is a graph $G = (V_\wedge \cup V_\vee, E)$ where the set of vertices is partitioned into a set of AND vertices V_\wedge and a set of OR vertices V_\vee . If the token is on an OR vertex, then player 0 moves the token, otherwise player 1 moves the token. Player 0 wins if the token finally reaches the target. The AND-OR GRAPH REACHABILITY problem is known to be PTIME-complete [12]. The reduction in [8] unrolls the edge periodic graph into its configuration graph. Considering the PERIODIC COP & ROBBER problem, we define for an edge periodic graph $\mathcal{G} = (V, E, \tau)$, the *configuration graph* $\mathcal{C}_\mathcal{G} = (V_{\mathcal{C}_\mathcal{G}}, E_{\mathcal{C}_\mathcal{G}})$ of \mathcal{G} with node set $V \times V \times \{c, r\} \times [\text{lcm}(L_\mathcal{G})]$. Here, a node (u_c, u_r, s, t) denotes in the temporal snapshot graph $\mathcal{G}(t)$, that the cop is on vertex u_c , the robber on vertex u_r , and the cop moves next if $s = c$, otherwise the robber moves next. A node (u_c, u_r, s, t) is connected with a directed edge to some node $(u'_c, u'_r, s', (t + 1) \bmod \text{lcm}(L_\mathcal{G}))$, if $s = c$, $s' = r$, $u'_r = u_r$, and $u'_c = u_c$ or u_c and u'_c are connected by an edge which is present in time step t . If $s = r$ the same holds for c and r interchanged. Hence, the configuration graph $\mathcal{C}_\mathcal{G}$ is of size $\mathcal{O}(|V|^2 \cdot \text{lcm}(L_\mathcal{G}))$.

The configuration graph $\mathcal{C}_\mathcal{G}$ is then turned into an AND-OR graph by declaring nodes (u_c, u_r, s, t) with $s = c$ as OR vertices and nodes with $s = r$ as AND vertices. As $\text{lcm}(L_\mathcal{G})$ can be of size exponential in $|L_\mathcal{G}|$, it follows from [8] that PERIODIC COP & ROBBER is contained in EXPTIME. Note that the exponential blow-up comes from the very deterministic process of unrolling the edge periodic graph into a TVG with global periodicity $\text{lcm}(L_\mathcal{G})$. Representing this TVG in a framework which only allows for global periodicity, such as the setting in [18], would require a representation of the TVG in size $\mathcal{O}(\text{lcm}(L_\mathcal{G}))$ and allow for a polynomial time reduction to the AND-OR GRAPH REACHABILITY problem yielding membership in PTIME for PERIODIC COP & ROBBER in this setting.

In the following, we show how use the structural properties of the configuration graph $\mathcal{C}_{\mathcal{G}}$ to solve the AND-OR GRAPH REACHABILITY for $\mathcal{C}_{\mathcal{G}}$ in polynomial space. We begin with giving an upper bound on the length of a shortest chase in \mathcal{G} .

► **Lemma 10.** *Let $\mathcal{G} = (V, E, \tau)$ be an edge periodic graph. If \mathcal{G} is cop-winning, then the robber can be caught within $n^2 \cdot \text{lcm}(L_{\mathcal{G}})$ rounds.*

Proof. Consider the configuration graph $\mathcal{C}_{\mathcal{G}} = (V_{\mathcal{C}_{\mathcal{G}}}, E_{\mathcal{C}_{\mathcal{G}}})$ of \mathcal{G} . Note that two configurations of a PERIODIC COP & ROBBER game on the same temporal snapshot graph with identical positions of the cop and robber in different time steps t and t' which differ by a multiple of $\text{lcm}(L_{\mathcal{G}})$ are indistinguishable as configurations of the game. Hence, the size of $\mathcal{C}_{\mathcal{G}}$ is bounded by $2n^2 \cdot \text{lcm}(L_{\mathcal{G}})$.

Now let π be a shortest sequence of configurations for the start vertices v_c and v_r such that π ends with a cop-winning configuration. If $|\pi| > 2n^2 \cdot \text{lcm}(L_{\mathcal{G}})$, then π contains two indistinguishable configurations π_{i_1} and π_{i_2} . Clearly, the cop made no progress towards capturing the robber in the sequence $\pi_{i_1}, \dots, \pi_{i_2-1}$. As π_{i_1} and π_{i_2} are indistinguishable, removing the sequence $\pi_{i_1}, \dots, \pi_{i_2-1}$ from π yields a shorter sequence of configurations ending in a cop-winning configurations violating the assumed minimality of π . ◀

Proof of Theorem 9. We will follow the ideas from [8] of reducing the PERIODIC COP & ROBBER problem to a variant of the AND-OR GRAPH REACHABILITY problem. Therefore, we will need the notion of *attractors* in an AND-OR graph. Let $G = (V, E)$ be an AND-OR graph with $V = V_{\wedge} \cup V_{\vee}$. Instead of considering a single target, we consider a set T of targets and say that player 0 wins if the token finally reaches any state in T . Let $s \in V$ be the start vertex. Intuitively, the set of attractors of G is the set of vertices from which player 0 can win the game. More formally, we inductively define the set of attractors Attr of T as:

$$\begin{aligned} \text{Attr}^0 &= T, \\ \text{Attr}^{i+1} &= \text{Attr}_i \cup \{v \in V_{\wedge} \mid \forall \{u, v\} \in E: u \in \text{Attr}^i\} \cup \\ &\quad \{v \in V_{\vee} \mid \exists \{u, v\} \in E: u \in \text{Attr}^i\}, \\ \text{Attr} &= \bigcup_{i \geq 0} \text{Attr}^i. \end{aligned}$$

Let $\mathcal{G} = (V, E, \tau)$ be the input edge periodic graph and let $\mathcal{C}_{\mathcal{G}} = (V_{\mathcal{C}_{\mathcal{G}}}, E_{\mathcal{C}_{\mathcal{G}}})$ be the configuration graph of \mathcal{G} . We will also identify $\mathcal{C}_{\mathcal{G}}$ as an AND-OR graph by declaring nodes (u_c, u_r, s, t) of $\mathcal{C}_{\mathcal{G}}$ with $s = c$ as OR vertices and nodes with $s = r$ as AND vertices. We define the set of nodes $T = \{(u_c, u_r, s, t) \in V_{\mathcal{C}_{\mathcal{G}}} \mid u_c = u_r\}$ as the target set of the AND-OR graph $\mathcal{C}_{\mathcal{G}}$. We will now prove that the ideas from [8] of solving the PERIODIC COP & ROBBER game by checking if (i) there is some vertex u_c such that for all vertices $u_r \in V$, the node $(u_c, u_r, c, 0) \in V_{\mathcal{C}_{\mathcal{G}}}$ is an attractor in the AND-OR graph $\mathcal{C}_{\mathcal{G}}$, can be implemented in polynomial space. Note that the set of attractors in $\mathcal{C}_{\mathcal{G}}$ corresponds to the set of configurations from which the cop has a winning strategy. We use Lemma 10 to unroll the configuration graph in order to obtain a leveled directed acyclic graph (DAG) which has width n^2 in each level and through which we can sweep level by level in order to verify property (i).

By Lemma 10 we know that in order to verify property (i) it is sufficient to consider paths of length at most $2n^2 \cdot \text{lcm}(L_{\mathcal{G}})$ in $\mathcal{C}_{\mathcal{G}}$ (the factor 2 is due to the alternation of players). As the configuration graph is cyclic (due to modulo counting by $\text{lcm}(L_{\mathcal{G}})$) we unroll the graph n^2 times to allow for different time steps up to $n^2 \cdot \text{lcm}(L_{\mathcal{G}})$. The obtained DAG is big enough to contain any shortest chase starting in any time step $t \leq \text{lcm}(L_{\mathcal{G}})$. The so obtained graph $\mathcal{C}'_{\mathcal{G}}$ consists of the node set $V'_{\mathcal{C}_{\mathcal{G}}} = V \times V \times \{c, r\} \times [n^2 \cdot \text{lcm}(L_{\mathcal{G}})]$ and the edge set $E'_{\mathcal{C}_{\mathcal{G}}}$

extending $E_{\mathcal{G}}$ as $((u_c, u_r, s, t), (u'_c, u'_r, s', t')) \in E_{\mathcal{C}'_{\mathcal{G}}}$ if and only if $t' \in \{t, t+1\}$, $((u_c, u_r, s, t \bmod \text{lcm}(L_{\mathcal{G}})), (u'_c, u'_r, s', t' \bmod \text{lcm}(L_{\mathcal{G}}))) \in E_{\mathcal{C}'_{\mathcal{G}}}$ and $t, t' \leq n^2 \cdot \text{lcm}(L_{\mathcal{G}}) - 1$. Verifying property (i) then corresponds to a reachability game in the AND-OR graph associated with $\mathcal{C}'_{\mathcal{G}}$ with target set $T = \{(u_c, u_r, s, t) \in V_{\mathcal{C}'_{\mathcal{G}}} \mid u_c = u_r\}$ which can be solved using the notion of attractors. Note that in $\mathcal{C}'_{\mathcal{G}}$ only nodes with identical time steps or t and $t+1$ are connected. Hence, in order to compute which nodes with time step t belong to the set of attractors, we need to only know which nodes with time step $t+1$ are attractors. Since $\mathcal{C}'_{\mathcal{G}}$ is a DAG we can start in the level with $t = n^2 \cdot \text{lcm}(L_{\mathcal{G}}) - 1$ of $\mathcal{C}'_{\mathcal{G}}$.

$$\begin{aligned} \text{Attr}_r^{n^2 \cdot \text{lcm}(L_{\mathcal{G}}) - 1} &:= \{(u_c, u_r, r, n^2 \cdot \text{lcm}(L_{\mathcal{G}}) - 1) \mid u_c = u_r\}, \\ \text{Attr}_r^t &:= \{(u_c, u_r, r, t) \mid \forall ((u_c, u_r, r, t), (u'_c, u'_r, c, t+1)) \in E_{\mathcal{C}'_{\mathcal{G}}} : (u'_c, u'_r, c, t+1) \\ &\quad \in \text{Attr}_c^{t+1}\} \cup \{(u_c, u_r, r, t) \mid u_c = u_r\}, \text{ for } n^2 \cdot \text{lcm}(L_{\mathcal{G}}) - 2 \geq t \geq 0, \\ \text{Attr}_c^t &:= \{(u_c, u_r, c, t) \mid \exists ((u_c, u_r, c, t), (u'_c, u'_r, r, t)) \in E_{\mathcal{C}'_{\mathcal{G}}} : (u'_c, u'_r, r, t) \in \text{Attr}_r^t\} \\ &\quad \cup \{(u_c, u_r, c, t) \mid u_c = u_r\}, \text{ for } n^2 \cdot \text{lcm}(L_{\mathcal{G}}) - 1 \geq t \geq 0. \end{aligned}$$

For each level $n^2 \cdot \text{lcm}(L_{\mathcal{G}}) - 1 \geq t \geq 0$ we only need to keep the last level ($t+1$ if existent)¹ of $\mathcal{C}'_{\mathcal{G}}$ in memory in order to compute the sets Attr_c^t and Attr_r^t of nodes (u_c, u_r, s, t) in $\mathcal{C}'_{\mathcal{G}}$ from which the cop has a winning strategy where s equals the sub-script. Note that $\bigcup_{0 \leq t \leq n^2 \cdot \text{lcm}(L_{\mathcal{G}}) - 1} \text{Attr}_c^t \cup \text{Attr}_r^t = \text{Attr}$. In order to verify property (i) we only need to keep the current and latest sets $\text{Attr}_c^t, \text{Attr}_r^t, \text{Attr}_c^{t+1}, \text{Attr}_r^{t+1}$ in memory yielding a polynomial space algorithm. ◀

6 Discussion

While we improved the currently known upper bound for the PERIODIC COP & ROBBER problem on edge periodic graphs from EXPTIME to PSPACE and improved the lower bounds, of being NP-hard, to include also the very restrictive classes of directed and undirected edge periodic cycles, a gap in the complexity of PERIODIC COP & ROBBER remains. It is worth noticing that on one side the chosen representation of edge periodic graphs is quite compact, as a natural proof for a cop-winning strategy might be of exponential length in the input size, since the periodicity of the whole graph is the least common multiple of the periodicity of each edge, which prevents the use of a simple guess & check approach for NP-membership. On the other side, the chosen representation is still exponentially larger than the representation by on-line programs used in [17] where PSPACE-completeness for the reachability problem on a related but different class of periodic TVGs was obtained.

If we consider *directed* edge periodic *cycles*, then determining whether the given cycle is cop-winning boils down to deterministically simulating the chase starting from a (guessed) cop vertex and time step, as the optimal strategies for the cop and robber are both to keep running whenever possible (without bumping into the cop). For the robber the optimal start vertex is directly behind the cop. Since $\text{lcm}(L_{\mathcal{G}})$ can be exponentially large in the size of \mathcal{G} the only known upper bound on the number of steps in the simulation of the chase starting in time step t is exponential in the size of \mathcal{G} , while the chase does not reveal any complexity. The simulation could even be performed by a log-space Turing-Machine being equipped with

¹ Note that we can easily compute the snapshot $\mathcal{G}(n^2 \cdot \text{lcm}(L_{\mathcal{G}})) = \mathcal{G}(0)$ by drawing all edges with $\tau(e)[0]^{\circ} = 1$; and from $\mathcal{G}(t)$ for some time step t , the snapshot $\mathcal{G}(t-1)$ by shifting the pointer in each $\tau(e)$ one step to the left. Therefore, we can compute from each level $t+1$ of $\mathcal{C}'_{\mathcal{G}}$ the level t in polynomial time and space.

a clock which allows for modulo queries of logarithmic size. To better understand the precise complexity of PERIODIC COP & ROBBER on directed edge periodic cycles, the theoretical analysis of potential families of cycles with shortest cop-winning strategies of exponential size would be of great interest and might indicate the necessity for a new complexity class consisting of simple simulation problems with exponential duration time.

A Details on Lemma 6

We explicitly give the edge periodic cycles for $k = 2$, $k = 3$, and $k = 4$ in the proof of Lemma 6. For $k = 2$ and $k = 3$ the chase of the cop will be shorter than described in Table 1 and for $k \geq 4$ the chase will be exactly as described in general in Table 1. The edge periodic cycle for $k = 2$ is depicted in Figure 6 and the chase is described in Table 2. For $k = 3$ the edge periodic cycle is depicted in Figure 7 and the chase is described in Table 3. Finally, for $k = 4$, the edge periodic cycle is depicted in Figure 8 and the explicit chase is described in Table 4. Note that Table 4 is identical to Table 1 if we set $k = 4$ in Table 1.

■ **Figure 6** Edge periodic cycle for the case $k = 2$ in Lemma 6 with $4 \cdot k - 1 = 7$ vertices and $\text{lcm}(L_{\mathcal{G}}) = 2$ with a cop winning strategy from the start vertex marked in red. Edges without edge label are 1-edges; for all other edges, $\tau(e)$ is explicitly noted (with gray background).

■ **Table 2** Time steps with corresponding positions of cop and robber in the edge periodic cycle depicted in Figure 6. All positions are *after* moving in this time step. The time step s denotes the start configuration. Recall that the cop moves first.

Syntactic Minimization Of Nondeterministic Finite Automata

Robert S. R. Myers ✉

Abstract

Nondeterministic automata may be viewed as succinct programs implementing deterministic automata, i.e. complete specifications. Converting a given deterministic automaton into a small nondeterministic one is known to be computationally very hard; in fact, the ensuing decision problem is PSPACE-complete. This paper stands in stark contrast to the status quo. We restrict attention to *subatomic* nondeterministic automata, whose individual states accept unions of syntactic congruence classes. They are general enough to cover almost all structural results concerning nondeterministic state-minimality. We prove that converting a monoid recognizing a regular language into a small subatomic acceptor corresponds to an NP-complete problem. The NP certificates are solutions of simple equations involving relations over the syntactic monoid. We also consider the subclass of *atomic* nondeterministic automata introduced by Brzozowski and Tamm. Given a deterministic automaton and another one for the reversed language, computing small atomic acceptors is shown to be NP-complete with analogous certificates. Our complexity results emerge from an algebraic characterization of (sub)atomic acceptors in terms of deterministic automata with semilattice structure, combined with an equivalence of categories leading to succinct representations.

1 Introduction

Regular languages arise from a multitude of different perspectives: operationally via finite-state machines, model-theoretically via monadic second-order logic, and algebraically via finite monoids. In practice, *deterministic* finite automata (dfas) and *nondeterministic* finite automata (nfas) are two of the most common representations. Although the former may be exponentially larger than the latter, there is no known efficient procedure for converting dfas into small nfas, e.g. state-minimal ones. Jiang and Ravikumar proved the corresponding decision problem (does an equivalent nfa with a given number of states exist?) to be PSPACE-complete [14, 15], suggesting that exhaustively enumerating candidates is necessary. One possible strategy towards tractability is to restrict the target automata to suitable *subclasses* of nfas. The challenge is to identify subclasses permitting more efficient computation (e.g. lowering the PSPACE bound to an NP bound, enabling the use of SAT solvers), while still being general enough to cover succinct acceptors of regular languages.

In our present paper we will show that the class of *subatomic nfas* naturally meets the above requirements. An nfa accepting the language L is subatomic if each individual state accepts a union of syntactic congruence classes of L . In recent work [26] we observed that almost all known results on the structure of small nfas, e.g. for unary [6, 13], bideterministic [30],

topological [1] and biRFSA languages [19], implicitly construct small subatomic nfes. This firmly indicates that the latter form a rich class of acceptors despite their seemingly restrictive definition, i.e. in many settings computing small nfes amounts to computing small subatomic ones. Restricting to subatomic nfes yields useful additional structure; in fact, their theory is tightly linked to the algebraic theory of regular languages and the representation theory of monoids. This suggests an *algebraic* counterpart of the dfa to nfa conversion problem: given a finite monoid recognizing some regular language, compute an equivalent small subatomic nfa. Denoting its decision version (does an equivalent subatomic nfa with a given number of states exist?) by $\mathbf{MON} \rightarrow \mathbf{NFA}_{\text{syn}}$, our main result is:

► **Theorem.** The problem $\mathbf{MON} \rightarrow \mathbf{NFA}_{\text{syn}}$ is NP-complete.

In addition we also investigate *atomic nfes*, a subclass of subatomic nfes earlier introduced by Brzozowski and Tamm [4]. Similar to the subatomic case, their specific structure naturally invokes the problem of converting a pair of dfas accepting mutually reversed languages into a small atomic nfa. Denoting its decision version by $\mathbf{DFA} + \mathbf{DFA}^r \rightarrow \mathbf{NFA}_{\text{atm}}$, we get:

► **Theorem.** The problem $\mathbf{DFA} + \mathbf{DFA}^r \rightarrow \mathbf{NFA}_{\text{atm}}$ is NP-complete.

The short certificates witnessing that both problems are in NP are solutions of *equations* involving relations over the syntactic congruence or the Nerode left congruence, respectively.

The above two theorems sharply contrast the PSPACE-completeness of the general dfa to nfa conversion problem, but also previous results on its sub-PSPACE variants. The latter are either concerned with particular regular languages such as finite or unary ones [11, 13], or with target nfes admitting only very weak forms of nondeterminism, such as unambiguous automata [15] or dfas with multiple initial states [22]. In contrast, our present work applies to all regular languages and the restriction to (sub)atomic nfes is a purely *semantic* one.

Our results are fundamentally based upon a category-theoretic perspective on atomic and subatomic acceptors. At its heart are two equivalences of categories as indicated below:

$$\mathbf{JSL}_f^{\text{op}} \xleftarrow[\text{Structure theory}]{\simeq} \mathbf{JSL}_f \xleftarrow[\text{Complexity theory}]{\simeq} \mathbf{Dep}.$$

As shown in [26], the *structure theory* of (sub)atomic nfes emerges by interpreting them as dfes endowed with semilattice structure, and relating them to their dual automata under the familiar self-duality of the category \mathbf{JSL}_f of finite semilattices. Similarly, the *complexity theory* of (sub)atomic nfes developed in the present paper rests on the equivalence between \mathbf{JSL}_f and a category \mathbf{Dep} (see Definition 3.1) that yields succinct relational representations of finite semilattices by their irreducible elements. To derive the NP-completeness theorems, we reinterpret semilattice automata associated to (sub)atomic nfes inside \mathbf{Dep} . We regard this conceptually simple and natural categorical approach as a key contribution of our paper.

2 Atomic and Subatomic NFAs

We start by setting up the notation and terminology used in the rest of the paper, including the key concept of a (sub)atomic nfa that underlies our complexity results. Readers are assumed to be familiar with basic category [21].

Semilattices. A (*join-*)*semilattice* is a poset (S, \leq_S) in which every finite subset $X \subseteq S$ has a least upper bound (a.k.a. join) $\bigvee X$. A *morphism* between semilattices is a map preserving finite joins. If S is finite as we often assume, every subset $X \subseteq S$ also has a greatest lower

bound (a.k.a. meet) $\bigwedge X$, given by the join of its lower bounds. In particular, S has a least element $\perp_S = \bigvee \emptyset$ and a greatest element $\top_S = \bigwedge \emptyset$. An element $j \in S$ is *join-irreducible* if $j = \bigvee X$ implies $j \in X$ for every subset $X \subseteq S$. Dually, $m \in S$ is *meet-irreducible* if $m = \bigwedge X$ implies $m \in X$. We put

$$J(S) = \{ j \in S : j \text{ is join-irreducible} \} \quad \text{and} \quad M(S) = \{ m \in S : m \text{ is meet-irreducible} \}.$$

Note $\perp_S \notin J(S)$ and $\top_S \notin M(S)$. The join-irreducibles form the least set of *join-generators* of S , i.e. every element of S is a join of elements from $J(S)$, and every other subset $J \subseteq S$ with that property contains $J(S)$. Dually, $M(S)$ is the least set of *meet-generators* of S .

Let $\mathbb{2} = \{0, 1\}$ be the two-element semilattice with $0 \leq 1$. Morphisms $i: \mathbb{2} \rightarrow S$ correspond to elements of S via $i \mapsto i(1)$. Morphisms $f: S \rightarrow \mathbb{2}$ correspond to *prime filters* via $f \mapsto f^{-1}[1]$. If S is finite, these are precisely the subsets $F_{s_0} = \{s \in S : s \not\leq_S s_0\}$ for any $s_0 \in S$.

We denote by **JSL** the category of join-semilattices and their morphisms. Its full subcategory **JSL_f** of finite semilattices is self-dual [17]: there is an equivalence functor

$$\mathbf{JSL}_f^{\text{op}} \xrightarrow{\cong} \mathbf{JSL}_f$$

mapping (S, \leq_S) to the *opposite semilattice* $S^{\text{op}} = (S, \geq_S)$ obtained by reversing the order, and a morphism $f: S \rightarrow T$ to the morphism $f_*: T^{\text{op}} \rightarrow S^{\text{op}}$ sending $t \in T$ to the \leq_S -greatest element $s \in S$ with $f(s) \leq_T t$. Thus, f and f_* satisfy the adjoint relationship

$$f(s) \leq_T t \quad \text{iff} \quad s \leq_S f_*(t)$$

for all $s \in S$ and $t \in T$. The morphism f is injective (equivalently a **JSL_f**-monomorphism) iff f_* is surjective (equivalently a **JSL_f**-epimorphism).

Relations. A *relation* between sets X and Y is a subset $\mathcal{R} \subseteq X \times Y$. We write $\mathcal{R}(x, y)$ if $(x, y) \in \mathcal{R}$. For $x \in X$ and $A \subseteq X$ we put

$$\mathcal{R}[x] = \{ y \in Y : \mathcal{R}(x, y) \} \quad \text{and} \quad \mathcal{R}[A] = \bigcup_{x \in A} \mathcal{R}[x].$$

The *converse* of \mathcal{R} is the relation $\check{\mathcal{R}} \subseteq Y \times X$ (alternatively \mathcal{R}^\smile) where $\check{\mathcal{R}}(y, x)$ iff $\mathcal{R}(x, y)$ for $x \in X$ and $y \in Y$. The *composite* of $\mathcal{R} \subseteq X \times Y$ and $\mathcal{S} \subseteq Y \times Z$ is the relation $\mathcal{R}; \mathcal{S} \subseteq X \times Z$ where $\mathcal{R}; \mathcal{S}(x, z)$ iff there exists $y \in Y$ with $\mathcal{R}(x, y)$ and $\mathcal{S}(y, z)$. Let **Rel** denote the category whose objects are sets and whose morphisms are relations with the above composition. The identity morphism on X is the identity relation $\text{id}_X \subseteq X \times X$ with $\text{id}_X(x, y)$ iff $x = y$.

A *biclique* of a relation $\mathcal{R} \subseteq X \times Y$ is subset of the form $B_1 \times B_2 \subseteq \mathcal{R}$, where $B_1 \subseteq X$ and $B_2 \subseteq Y$. A set \mathcal{C} of bicliques forms a *biclique cover* if $\mathcal{R} = \bigcup \mathcal{C}$. The *bipartite dimension* of \mathcal{R} , denoted $\text{dim}(\mathcal{R})$, is the minimum cardinality of any biclique cover.

Languages. Let Σ^* be the set of finite words over an alphabet Σ including the empty word ε . A *language* is a subset L of Σ^* . We let $\bar{L} = \Sigma^* \setminus L$ denote the *complement* and $L^r = \{w^r : w \in L\}$ the *reverse* of L , where $\varepsilon^r = \varepsilon$ and $w^r = a_n \dots a_1$ for $w = a_1 \dots a_n$. The *left derivatives* and *two-sided derivatives* of L are, respectively, given by $u^{-1}L = \{w \in \Sigma^* : uw \in L\}$ and $u^{-1}Lv^{-1} = \{w \in \Sigma^* : uww \in L\}$ for $u, v \in \Sigma^*$; moreover for $U \subseteq \Sigma^*$ put $U^{-1}L = \bigcup_{u \in U} u^{-1}L$. For each fixed $L \subseteq \Sigma^*$, the following sets of languages will play a prominent role:

$$\text{LD}(L) \subseteq \text{SLD}(L) \subseteq \text{BLD}(L) \subseteq \text{BLRD}(L)$$

where $\text{LD}(L) = \{u^{-1}L : u \in \Sigma^*\}$ is the set of left derivatives, and $\text{SLD}(L)$, $\text{BLD}(L)$, $\text{BLRD}(L)$ denote its closure under finite unions, all set-theoretic boolean operations, and all set-theoretic boolean operations and two-sided derivatives, respectively. The final three form \cup -semilattices, and the final two are boolean algebras w.r.t. the set-theoretic operations.

A language L is *regular* if $\text{LD}(L)$ is a finite set; then the other three sets are finite too. The finite semilattices $\text{SLD}(L)$ and $\text{SLD}(L')$ are related by the fundamental isomorphism

$$\text{dr}_L : [\text{SLD}(L')]^{\text{op}} \xrightarrow{\cong} \text{SLD}(L), \quad K \mapsto (\overline{K^r})^{-1}L, \quad (2.1)$$

see [26, Proposition 3.13]. Equivalently, the map dr_L sends $V^{-1}L' \in \text{SLD}(L')$ to the largest element of $\text{SLD}(L)$ disjoint from V^r . It is closely connected to the *dependency relation* of L ,

$$\mathcal{DR}_L \subseteq \text{LD}(L) \times \text{LD}(L'), \quad \mathcal{DR}_L(u^{-1}L, v^{-1}L') : \iff uv^r \in L \quad \text{for } u, v \in \Sigma^*. \quad (2.2)$$

In fact, by [26, Theorem 3.15] we have

$$\mathcal{DR}_L(u^{-1}L, v^{-1}L') \iff u^{-1}L \not\subseteq \text{dr}_L(v^{-1}L') \quad \text{for } u, v \in \Sigma^*. \quad (2.3)$$

Since the boolean algebra $\text{BLD}(L)$ is generated by the left derivatives of L , its atoms (= join-irreducibles) are the congruence classes of the *Nerode left congruence* $\sim_L \subseteq \Sigma^* \times \Sigma^*$,

$$u \sim_L v \quad \text{iff} \quad \forall x \in \Sigma^* : u \in x^{-1}L \iff v \in x^{-1}L \quad \text{iff} \quad (u^r)^{-1}L' = (v^r)^{-1}L'. \quad (2.4)$$

Note that this relation is left-invariant, i.e. $u \sim_L v$ implies $wu \sim_L wv$ for all $w \in \Sigma^*$.

Similarly, the atoms of $\text{BLRD}(L)$ are the congruence classes of the *syntactic congruence* $\equiv_L \subseteq \Sigma^* \times \Sigma^*$, i.e. the monoid congruence on the free monoid Σ^* defined by

$$u \equiv_L v \quad \text{iff} \quad \forall x, y \in \Sigma^* : u \in x^{-1}Ly^{-1} \iff v \in x^{-1}Ly^{-1}. \quad (2.5)$$

The quotient monoid $\text{syn}(L) = \Sigma^*/\equiv_L$ is called the *syntactic monoid* of L , and the canonical map $\mu_L : \Sigma^* \rightarrow \text{syn}(L)$ sending $u \in \Sigma^*$ to its congruence class $[u]_{\equiv_L}$ is the *syntactic morphism*.

Automata. Fix a finite alphabet Σ . A *nondeterministic finite automaton* (a.k.a. *nfa*) $N = (Q, \delta, I, F)$ consists of a finite set Q (the states), relations $\delta = (\delta_a \subseteq Q \times Q)_{a \in \Sigma}$ (the transitions), and sets $I, F \subseteq Q$ (the initial states and final states). We write $q_1 \xrightarrow{a} q_2$ whenever $q_2 \in \delta_a[q_1]$. The language $L(N, q)$ *accepted* by a state $q \in Q$ consists of all words $w \in \Sigma^*$ such that $\delta_w[q] \cap F \neq \emptyset$, where $\delta_w \subseteq Q \times Q$ is the extended transition relation $\delta_{a_1}; \dots; \delta_{a_n}$ for $w = a_1 \dots a_n$ and $\delta_\varepsilon = \text{id}_Q$. The language *accepted* by N is defined $L(N) = \bigcup_{i \in I} L(N, i)$.

An nfa N is a *deterministic finite automaton* (a.k.a. *dfa*) if $I = \{q_0\}$ is a singleton set and each transition relation is a function $\delta_a : Q \rightarrow Q$. A dfa is a **JSL-dfa** if Q is a finite semilattice, each $\delta_a : Q \rightarrow Q$ is a semilattice morphism, and $F \subseteq Q$ forms a prime filter. It is often useful to represent a **JSL-dfa** in terms of morphisms

$$\mathfrak{2} \xrightarrow{i} Q \xrightarrow{\delta_a} Q \xrightarrow{f} \mathfrak{2}$$

where i is the unique morphism with $i(1) = q_0$ and f is given by $f(q) = 1$ iff $q \in F$. A **JSL-dfa morphism** from $A = (Q, \delta, i, f)$ to $A' = (Q', \delta', i', f')$ is a **JSL_f-morphism** $h : Q \rightarrow Q'$ preserving transitions via $h \circ \delta_a = \delta'_a \circ h$, preserving the initial state via $i' = h \circ i$, and both preserving and reflecting the final states via $f = f' \circ h$. Equivalently, h is a dfa morphism that is also a semilattice morphism, so in particular $L(A) = L(A')$. If Q is a subsemilattice of Q' and $h : Q \rightarrow Q'$ is the inclusion map, then A is called a *sub JSL-dfa* of A' .

Fix a regular language L . Viewed as a \cup -semilattice, $\text{BLRD}(L)$ carries the structure of a **JSL**-dfa with transitions $K \xrightarrow{a} a^{-1}K$, initial state L , and finals $\{K : \varepsilon \in K\}$. This restricts to sub **JSL**-dfas $\text{BLD}(L)$ and $\text{SLD}(L)$. Moreover $\text{LD}(L)$ forms a sub-dfa of $\text{SLD}(L)$, well-known [5] to be the *state-minimal dfa* for L , so we denote it by $\text{dfa}(L)$. The syntactic monoid $\text{syn}(L)$ is isomorphic to the *transition monoid* of $\text{dfa}(L)$, i.e. the monoid of all extended transition maps $\delta_w : \text{LD}(L) \rightarrow \text{LD}(L)$ ($w \in \Sigma^*$) with multiplication given by composition [27].

Analogously $\text{SLD}(L)$ is the *state-minimal JSL-dfa* for L . Up to isomorphism, it is the unique **JSL**-dfa for L that is **JSL-reachable** (i.e. every state is a join of states reachable from the initial state via transitions) and *simple* (i.e. distinct states accept distinct languages).

Nfas, dfas and **JSL**-dfas are expressively equivalent and accept precisely the regular languages. In particular, to every **JSL**-dfa $A = (Q, \delta, q_0, F)$ one can associate an equivalent nfa $J(A)$, the *nfa of join-irreducibles* [1, 2, 25]. Its states are given by the set $J(Q)$ of join-irreducibles of Q ; for any $q_1, q_2 \in J(Q)$ and $a \in \Sigma$ there is a transition $q_1 \xrightarrow{a} q_2$ in $J(A)$ iff $q_2 \leq_Q \delta_a(q_1)$; a state $q \in J(Q)$ is initial iff $q \leq_S q_0$, and final iff $q \in F$. For any $q \in J(Q)$, we have $L(A, q) = L(J(A), q)$. The *canonical residual finite state automaton* [7] for a regular language L is given by $N_L = J(\text{SLD}(L))$, the nfa of join-irreducibles of its minimal **JSL**-dfa.

Atomic and subatomic nfas. An nfa accepting the language $L \subseteq \Sigma^*$ is called *atomic* [4] if each state accepts a language from $\text{BLD}(L)$, and *subatomic* [26] if each state accepts a language from $\text{BLRD}(L)$. The *nondeterministic atomic complexity* $\text{natm}(L)$ of a regular language L is the least number of states of any atomic nfa accepting L . The *nondeterministic syntactic complexity* $\text{nsyn}(L)$ is the least number of states of any subatomic nfa accepting L . Subatomic nfas are intimately connected to syntactic monoids: the atoms of $\text{BLRD}(L)$ are the elements of $\text{syn}(L)$, so an nfa accepting L is subatomic iff its individual states accept unions of syntactic congruence classes. Additionally $\text{nsyn}(L)$ can be characterized via *boolean representations* of $\text{syn}(L)$, i.e. monoid morphisms $\varrho : \text{syn}(L) \rightarrow \mathbf{JSL}_f(S, S)$ into the endomorphisms of a finite semilattice [26]. For a detailed exposition we refer to *op. cit.*

These complexity measures are related to the *nondeterministic state complexity* $\text{ns}(L)$, i.e. the least number of states of any (unrestricted) nfa accepting L . In particular,

$$\dim(\mathcal{DR}_L) \leq \text{ns}(L) \leq \text{nsyn}(L) \leq \text{natm}(L). \quad (2.6)$$

The first inequality is due to Gruber and Holzer [10] (see also [26, Theorem 4.8] for a purely algebraic proof), while the others arise by restricting admissible nondeterministic acceptors.

Importantly, small atomic and subatomic nfas can be characterized in terms of **JSL**-dfas. The following theorem involves two commuting diagrams of semilattice morphisms, whose lower and upper paths are the canonical **JSL**-dfas described earlier.

► **Theorem 2.1.** *Let $L \subseteq \Sigma^*$ be a regular language.*

1. $\text{natm}(L)$ is the least number k such that there exists a finite semilattice S with $|J(S)| \leq k$ and **JSL**_f-morphisms p, q and τ_a ($a \in \Sigma$) making the left-hand diagram below commute.
2. $\text{nsyn}(L)$ is the least number k such that there exists a finite semilattice S with $|J(S)| \leq k$ and **JSL**_f-morphisms p, q and τ_a ($a \in \Sigma$) making the right-hand diagram below commute.

Proof. We only prove part (1), the proof of (2) being completely analogous.

Suppose there exists a finite semilattice S with $|J(S)| = k$ and \mathbf{JSL}_f -morphisms p, q and $(\tau_a)_{a \in \Sigma}$ making the left diagram commute. Then $A = (S, \tau, p \circ i, f' \circ q)$ is a \mathbf{JSL} -dfa and $p: \mathbf{SLD}(L) \rightarrow A$ and $q: A \rightarrow \mathbf{BLD}(L)$ are \mathbf{JSL} -dfa morphisms. Since \mathbf{JSL} -dfa morphisms preserve the accepted language, and every state $K \in \mathbf{BLD}(L)$ accepts the language K , it follows that A accepts L and every state of A accepts a language from $\mathbf{BLD}(L)$. Thus the nfa $J(A)$ of join-irreducibles corresponding to A is an atomic nfa for L with k states.

Conversely, assume $N = (Q, \delta, I, F)$ is a k -state atomic nfa accepting L . Form the \cup -semilattice $S = \text{langs}(N)$ of all languages $L(N, X)$ accepted by subsets $X \subseteq Q$. Note that $\mathbf{SLD}(L) \subseteq S \subseteq \mathbf{BLD}(L)$: the first inclusion holds because $u^{-1}L = L(N, \delta_w[I]) \in S$ for every $u \in \Sigma^*$, and the second one because N is atomic. We define the semilattice endomorphisms

$$\tau_a: S \rightarrow S \quad \text{by} \quad \tau_a(K) = a^{-1}K \quad \text{for } K \in S,$$

Letting $p: \mathbf{SLD}(L) \rightarrow S$ and $q: S \rightarrow \mathbf{BLD}(L)$ denote the inclusions, the left diagram commutes. Moreover $|J(S)| \leq k$ since S is join-generated by the elements $L(N, q)$ for $q \in Q$. \blacktriangleleft

3 Representing Finite Semilattices as Finite Relations

We have seen that atomic and subatomic nfes amount to certain dfes with semilattice structure. To obtain our NP-completeness results concerning the computation of small (sub)atomic acceptors we will study succinct representations of the corresponding \mathbf{JSL}_f -diagrams from Theorem 2.1. For this purpose, we start with the following key observation:

Any finite semilattice S is completely determined by its *poset of irreducibles* [23], i.e. the relation $\preceq_S \subseteq J(S) \times M(S)$ between join-irreducibles and meet-irreducibles.

We now prove that this extends to an *equivalence* between the category \mathbf{JSL}_f of finite semilattices and another category called \mathbf{Dep} . Its objects are the relations between finite sets and its morphisms represent semilattice morphisms as relations. The equivalence is inspired by Moshier's *categories of contexts* [16, 24] and will serve as the conceptual basis of our work.

► **Definition 3.1** (The category of dependency relations). The objects of the category \mathbf{Dep} are the relations $\mathcal{R} \subseteq \mathcal{R}_s \times \mathcal{R}_t$ between finite sets. Far less obviously,

a morphism $\mathcal{P}: \mathcal{R} \rightarrow \mathcal{S}$ is a relation $\mathcal{P} \subseteq \mathcal{R}_s \times \mathcal{S}_t$ that factorizes through \mathcal{R} and \mathcal{S} , i.e. the left \mathbf{Rel} -diagram below commutes for some $\mathcal{P}_l \subseteq \mathcal{R}_s \times \mathcal{S}_s$ and $\mathcal{P}_u \subseteq \mathcal{S}_t \times \mathcal{R}_t$.

The identity morphism for \mathcal{R} is $\text{id}_{\mathcal{R}} = \mathcal{R}$, see the central diagram below. The composite $\mathcal{P}; \mathcal{Q}: \mathcal{R} \rightarrow \mathcal{T}$ of $\mathcal{P}: \mathcal{R} \rightarrow \mathcal{S}$ and $\mathcal{Q}: \mathcal{S} \rightarrow \mathcal{T}$ is any of the five equivalent relational compositions

starting from the bottom left corner and ending at the top right corner of the rightmost diagram below; that is, $\mathcal{P} \circledast \mathcal{Q} := \mathcal{P}_l; \mathcal{Q}_l; \mathcal{T} = \mathcal{P}_l; \mathcal{Q} = \mathcal{P}_l; \mathcal{S}; \mathcal{Q}_u = \mathcal{P}; \mathcal{Q}_u = \mathcal{R}; \mathcal{P}_u; \mathcal{Q}_u$. (Note that we use the symbol \circledast for composition in **Dep** and $;$ for composition in **Rel**, and recall that $(-)^{\check{}}$ denotes the converse relation.)

One readily verifies that **Dep** is a well-defined category; in particular, the composition is independent of the choice of the lower and upper witnesses $(-)_l$ and $(-)_u$.

► **Remark 3.2.**

1. Using the converse upper witness may seem strange. Although technically unnecessary, it fits the self-duality of **Dep** taking the converse on objects and morphisms. Moreover $f; \check{\mathcal{L}}_T = \check{\mathcal{L}}_S; f_*$ for any **JSL_f**-morphism $f: S \rightarrow T$ via the adjoint relationship; that is, f induces a **Dep**-morphism from $\check{\mathcal{L}}_S$ to $\check{\mathcal{L}}_T$ with lower witness f and upper witness f_* .
2. The witnesses of a **Dep**-morphism $\mathcal{P}: \mathcal{R} \rightarrow \mathcal{S}$ are closed under unions. The maximal lower witness $\mathcal{P}_- \subseteq \mathcal{R}_s \times \mathcal{S}_s$ is given by

$$\mathcal{P}_-(x, y) : \iff S[y] \subseteq \mathcal{P}[x] \quad \text{for } x \in \mathcal{R}_s, y \in \mathcal{S}_s,$$

and the maximal upper witness $\mathcal{P}_+ \subseteq \mathcal{S}_t \times \mathcal{R}_t$ by

$$\mathcal{P}_+(y, x) : \iff \check{\mathcal{R}}[x] \subseteq \check{\mathcal{P}}[y] \quad \text{for } x \in \mathcal{R}_t, y \in \mathcal{S}_t.$$

► **Theorem 3.3** (Fundamental equivalence). *The categories **JSL_f** and **Dep** are equivalent.*

1. The equivalence functor $\text{Pirr}: \mathbf{JSL}_f \rightarrow \mathbf{Dep}$ maps a finite semilattice S to the **Dep**-object

$$\text{Pirr}(S) := \check{\mathcal{L}}_S \subseteq J(S) \times M(S),$$

and a **JSL_f**-morphism $f: S \rightarrow T$ to the **Dep**-morphism

$$\text{Pirr}(f): \text{Pirr}(S) \rightarrow \text{Pirr}(T), \quad \text{Pirr}(f)(j, m) : \iff f(j) \check{\mathcal{L}}_T m \quad \text{for } j \in J(S), m \in M(T).$$

2. The inverse $\text{Open}: \mathbf{Dep} \rightarrow \mathbf{JSL}_f$ maps a **Dep**-object \mathcal{R} to its semilattice of open sets

$$\text{Open}(\mathcal{R}) := (\{\mathcal{R}[X] : X \subseteq \mathcal{R}_s\}, \subseteq),$$

and a **Dep**-morphism $\mathcal{P}: \mathcal{R} \rightarrow \mathcal{S}$ to the **JSL_f**-morphism

$$\text{Open}(\mathcal{P}): \text{Open}(\mathcal{R}) \rightarrow \text{Open}(\mathcal{S}), \quad \text{Open}(\mathcal{P})(O) := \mathcal{P}_+[O] \quad \text{for } O \in \text{Open}(\mathcal{R}),$$

where $\mathcal{P}_+ \subseteq \mathcal{S}_t \times \mathcal{R}_t$ is the maximal upper witness of \mathcal{P} .

► **Remark 3.4.** In the definition of $\text{Pirr}(S)$ one may replace $J(S)$ and $M(S)$ by any two sets $J, M \subseteq S$ of join- and meet-generators modulo **Dep**-isomorphism. Indeed, since the equivalence functor Open reflects isomorphisms, this follows immediately from the **JSL_f**-isomorphism $\text{Open}(\check{\mathcal{L}}_S \cap J \times M) \cong \text{Open}(\check{\mathcal{L}}_S \cap J(S) \times M(S))$ given by $O \mapsto O \cap M(S)$.

► **Remark 3.5.** Bijectively relabeling the domain and codomain of a relation defines a **Dep**-isomorphism, the witnesses being the relabelings.

We now show that for every regular language L , the semilattices $\text{SLD}(L)$, $\text{BLD}(L)$ and $\text{BLRD}(L)$ equipped with their canonical **JSL**-dfa structure (see Section 2) translate under the equivalence functor Pirr into familiar concepts from automata theory. The translations are summarized in Table 1 and explained in Examples 3.6–3.8 below.

■ **Table 1** Canonical **JSL**-dfas and their corresponding **Dep**-structures.

JSL_f			Dep		
$\mathbb{2} \xrightarrow{i} \text{SLD}(L) \xrightarrow{\delta_a} \text{SLD}(L) \xrightarrow{f} \mathbb{2}$	$\xrightarrow{\delta_a}$	\xrightarrow{f}	$\text{id}_1 \xrightarrow{\mathcal{I}} \mathcal{DR}_L \xrightarrow{\mathcal{DR}_{L,a}} \mathcal{DR}_L \xrightarrow{\mathcal{F}} \text{id}_1$	$\xrightarrow{\mathcal{DR}_{L,a}}$	$\xrightarrow{\mathcal{F}}$
$\mathbb{2} \xrightarrow{i'} \text{BLD}(L) \xrightarrow{\delta'_a} \text{BLD}(L) \xrightarrow{f'} \mathbb{2}$	$\xrightarrow{\delta'_a}$	$\xrightarrow{f'}$	$\text{id}_1 \xrightarrow{\mathcal{I}'} \text{id}_{\Sigma^*/\sim_L} \xrightarrow{\mathcal{D}'_a} \text{id}_{\Sigma^*/\sim_L} \xrightarrow{\mathcal{F}'} \text{id}_1$	$\xrightarrow{\mathcal{D}'_a}$	$\xrightarrow{\mathcal{F}'}$
$\mathbb{2} \xrightarrow{i''} \text{BLRD}(L) \xrightarrow{\delta''_a} \text{BLRD}(L) \xrightarrow{f''} \mathbb{2}$	$\xrightarrow{\delta''_a}$	$\xrightarrow{f''}$	$\text{id}_1 \xrightarrow{\mathcal{I}''} \text{id}_{\text{syn}(L)} \xrightarrow{\mathcal{D}''_a} \text{id}_{\text{syn}(L)} \xrightarrow{\mathcal{F}''} \text{id}_1$	$\xrightarrow{\mathcal{D}''_a}$	$\xrightarrow{\mathcal{F}''}$

► **Example 3.6** (State-minimal **JSL**-dfa vs. dependency relation \mathcal{DR}_L). Let us start with the observation that $\text{SLD}(L)$ is join-generated by $\text{LD}(L)$ and meet-generated by $\text{dr}_L[\text{LD}(L')]$. The latter follows via the fundamental isomorphism (2.1). Then

$$\text{Pirr}(\text{SLD}(L))(u^{-1}L, \text{dr}_L(v^{-1}L')) \stackrel{\text{def.}}{\iff} u^{-1}L \not\subseteq \text{dr}_L(v^{-1}L') \stackrel{(2.3)}{\iff} \mathcal{DR}_L(u^{-1}L, v^{-1}L')$$

for every $u^{-1}L \in J(\text{SLD}(L))$ and $v^{-1}L' \in J(\text{SLD}(L'))$. Thus,

$$\text{Pirr}(\text{SLD}(L)) \text{ is a bijective relabeling of } \mathcal{DR}_L \text{ restricted to } J(\text{SLD}(L)) \times J(\text{SLD}(L')).$$

By Remark 3.4 we know $\text{Pirr}(\text{SLD}(L))$ is isomorphic to the domain-codomain extension $\not\subseteq \subseteq \text{LD}(L) \times \text{dr}_L[\text{LD}(L')]$ and thus also to the dependency relation \mathcal{DR}_L by Remark 3.5. Then the **JSL**-dfa structure of the semilattice $\text{SLD}(L)$ translates into the category of dependency relations as shown in Table 1, where id_1 is the identity relation on $1 = \{*\}$ and

$$\begin{aligned} \mathcal{I} &\subseteq 1 \times \text{LD}(L'), & \mathcal{DR}_{L,a} &\subseteq \text{LD}(L) \times \text{LD}(L'), & \mathcal{F} &\subseteq \text{LD}(L) \times 1, \\ \mathcal{I}(*, v^{-1}L') &\Leftrightarrow v \in L', & \mathcal{DR}_{L,a}(u^{-1}L, v^{-1}L') &\Leftrightarrow uav' \in L, & \mathcal{F}(u^{-1}L, *) &\Leftrightarrow u \in L. \end{aligned}$$

► **Example 3.7** ($\text{BLD}(L)$ vs. the Nerode left congruence \sim_L). In Section 2 we observed that the atoms of the boolean algebra $\text{BLD}(L)$ are the congruence classes of the Nerode left congruence. Then the co-atoms are their relative complements, and

$$\text{Pirr}(\text{BLD}(L))([u]_{\sim_L}, \overline{[v]_{\sim_L}}) \stackrel{\text{def.}}{\iff} [u]_{\sim_L} \not\subseteq \overline{[v]_{\sim_L}} \iff [u]_{\sim_L} = [v]_{\sim_L}.$$

By Remark 3.5, we see that $\text{BLD}(L)$ corresponds to the **Dep**-object $\text{id}_{\Sigma^*/\sim_L}$, and its **JSL**-dfa structure translates into the category of dependency relations as indicated in Table 1, where

$$\begin{aligned} \mathcal{I}' &\subseteq 1 \times \Sigma^*/\sim_L, & \mathcal{D}'_a &\subseteq \Sigma^*/\sim_L \times \Sigma^*/\sim_L, & \mathcal{F}' &\subseteq \Sigma^*/\sim_L \times 1, \\ \mathcal{I}'(*, [u]_{\sim_L}) &\Leftrightarrow u \in L, & \mathcal{D}'_a([u]_{\sim_L}, [v]_{\sim_L}) &\Leftrightarrow [v]_{\sim_L} \subseteq a^{-1}[u]_{\sim_L}, & \mathcal{F}'([u]_{\sim_L}, *) &\Leftrightarrow u \sim_L \varepsilon. \end{aligned}$$

We note that the above relations induce an nfa

$$(\Sigma^*/\sim_L, (\mathcal{D}'_a)_{a \in \Sigma}, \mathcal{I}'[*], \check{\mathcal{F}}'[*]) \quad \text{known as the } \acute{a}tomaton \text{ for the language } L [4].$$

► **Example 3.8** ($\text{BLRD}(L)$ vs. the syntactic monoid $\text{syn}(L)$). Analogously, the boolean algebra $\text{BLRD}(L)$ corresponds to the **Dep**-object $\text{id}_{\text{syn}(L)}$. Its semilattice dfa structure translates into the category of dependency relations as shown in Table 1, where

$$\begin{aligned} \mathcal{I}'' &\subseteq 1 \times \text{syn}(L), & \mathcal{D}''_a &\subseteq \text{syn}(L) \times \text{syn}(L), & \mathcal{F}'' &\subseteq \text{syn}(L) \times 1, \\ \mathcal{I}''(*, [u]_{\equiv_L}) &\Leftrightarrow u \in L, & \mathcal{D}''_a([u]_{\equiv_L}, [v]_{\equiv_L}) &\Leftrightarrow [v]_{\equiv_L} \subseteq a^{-1}[u]_{\equiv_L}, & \mathcal{F}''([u]_{\equiv_L}, *) &\Leftrightarrow u \equiv_L \varepsilon. \end{aligned}$$

We conclude this section with two lemmas establishing important properties of the equivalence. The first concerns the bipartite dimension of relations (see Section 2):

► **Lemma 3.9.** *Let \mathcal{R} be a relation between finite sets.*

1. $\dim(\mathcal{R})$ is the least $|J(S)|$ of any injective \mathbf{JSL}_f -morphism $m: \text{Open}(\mathcal{R}) \rightarrow S$.
 2. $\dim(\mathcal{R})$ is invariant under isomorphism, i.e. $\mathcal{R} \cong \mathcal{S}$ in \mathbf{Dep} implies $\dim(\mathcal{R}) = \dim(\mathcal{S})$.
- The second explicitly describes the join- and meet-irreducibles of the semilattice $\text{Open}(\mathcal{R})$.

► **Notation 3.10.** For $\mathcal{R} \subseteq \mathcal{R}_s \times \mathcal{R}_t$ we define the following operator on the power set of \mathcal{R}_t :

$$\text{in}_{\mathcal{R}}: \mathcal{P}(\mathcal{R}_t) \rightarrow \mathcal{P}(\mathcal{R}_t), \quad Y \mapsto \bigcup \{ \mathcal{R}[X] : X \subseteq \mathcal{R}_s \text{ and } \mathcal{R}[X] \subseteq Y \}.$$

Thus, $\text{in}_{\mathcal{R}}(Y)$ is the largest open set of \mathcal{R} contained in $Y \subseteq \mathcal{R}_t$.

► **Lemma 3.11.** *Let $\mathcal{R} \subseteq \mathcal{R}_s \times \mathcal{R}_t$ be a relation between finite sets.*

1. $J(\text{Open}(\mathcal{R}))$ consists of all sets $\mathcal{R}[x]$ ($x \in \mathcal{R}_s$) that cannot be expressed as a union of smaller such sets, i.e. $\mathcal{R}[x] = \bigcup_{i \in I} \mathcal{R}[x_i]$ implies $\mathcal{R}[x] = \mathcal{R}[x_i]$ for some $i \in I$.
2. $M(\text{Open}(\mathcal{R}))$ consists of all sets $\text{in}_{\mathcal{R}}(\mathcal{R}_t \setminus \{y\})$ such that $\check{\mathcal{R}}[y]$ lies in $J(\text{Open}(\check{\mathcal{R}}))$.

4 Nuclear Languages and Lattice Languages

As a further technical tool, we now introduce two classes of regular languages. They are well-behaved w.r.t. their small nfas and will emerge at the heart of our NP-completeness proofs in Section 5. Their definition rests on the notion of a *nuclear morphism* in \mathbf{JSL}_f , originating from the theory of symmetric monoidal closed categories [12, 28]. Recall that a finite semilattice is a *distributive lattice* if $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$ for all elements x, y, z .

► **Definition 4.1** (Nuclear language). A \mathbf{JSL}_f -morphism $f: S \rightarrow T$ is *nuclear* if it factorizes through a finite distributive lattice, i.e. $f = (S \xrightarrow{g} D \xrightarrow{h} T)$ for some finite distributive lattice D and \mathbf{JSL}_f -morphisms g, h . A regular language $L \subseteq \Sigma^*$ is *nuclear* if the transition morphisms $\delta_a = a^{-1}(-): \text{SLD}(L) \rightarrow \text{SLD}(L)$ ($a \in \Sigma$) of its minimal \mathbf{JSL} -dfa are nuclear.

► **Example 4.2** (BiRFSAs). A regular language L is *biRFSAs* [19] if $(N_L)^r \cong N_{L^r}$, that is, the canonical residual finite state automata for L and L^r (see Section 2) are reverse-isomorphic. In [26, Example 5.7] we proved that the biRFSAs languages are precisely those whose semilattice $\text{SLD}(L)$ is distributive. Thus biRFSAs languages are nuclear.

There is a natural subclass of nuclear languages which need not be biRFSAs:

► **Definition 4.3** (Lattice language). For any $S \in \mathbf{JSL}_f$ we define the language $L(S) \subseteq \Sigma^*$,

$$\Sigma := \{ \langle j \rangle : j \in J(S) \} \cup \{ |m\rangle : m \in M(S) \} \quad \text{and} \quad L(S) := \bigcap_{j \leq_S m} \overline{\Sigma^* \langle j \rangle |m\rangle \Sigma^*}.$$

Then Σ is the disjoint union of $J(S)$ and $M(S)$ (with the notation $\langle j \rangle$ and $|m\rangle$ used to distinguish between elements of the two summands), and $L(S)$ consists of all words over Σ not containing any factor $\langle j \rangle |m\rangle$ with $j \leq_S m$.

► **Lemma 4.4.** *For any $S \in \mathbf{JSL}_f$, the language $L(S)$ is nuclear and $S \cong \text{SLD}(L(S))$.*

Crucially, for nuclear and lattice languages some of the relations (2.6) hold with equality:

► **Proposition 4.5.**

1. If L is a nuclear language then $\text{ns}(L) = \dim(\mathcal{DR}_L)$.
2. If $L = L(S)$ is a lattice language then $\text{natm}(L) = \text{nsyn}(L) = \text{ns}(L) = \dim(\mathcal{DR}_L)$.

These equalities are the key fact making our reductions in the next section work.

5 Complexity of Computing Small (Sub)Atomic Acceptors

We are ready to present our main complexity results on small (sub)atomic nfes. First we consider the slightly simpler atomic case, phrased as the following decision problem:

DFA + DFA^r → NFA_{atm}

Input: Two dfas A and B such that $L(A) = L(B)^r$ and a natural number k .

Task: Decide whether there exists a k -state atomic nfa equivalent to A , i.e. $\text{natm}(L(A)) \leq k$.

► **Remark 5.1.** Taking mutually reverse dfas (A, B) as input permits an efficient computation of the dependency relation $\mathcal{DR}_L \subseteq \text{LD}(L) \times \text{LD}(L^r)$ of $L = L(A)$. One may assume A and B are minimal dfas, so that their state sets Q_A and Q_B are in bijective correspondence with $\text{LD}(L)$ and $\text{LD}(L^r)$. For $p \in Q_A$ choose some $w_A(p) \in \Sigma^*$ sending the initial state to p ; analogously choose $w_B(q) \in \Sigma^*$ for $q \in Q_B$. Then \mathcal{DR}_L is a bijective relabeling of

$$\widetilde{\mathcal{DR}}_L \subseteq Q_A \times Q_B \quad \text{where} \quad \widetilde{\mathcal{DR}}_L(p, q) :\iff A \text{ accepts } w_A(p)w_B(q)^r,$$

so it is computable in polynomial time from A and B . A completely analogous argument applies to the relations \mathcal{I} , $\mathcal{DR}_{L,a}$ and \mathcal{F} from Example 3.6.

► **Theorem 5.2.** *The problem DFA + DFA^r → NFA_{atm} is NP-complete.*

We establish the upper and lower bound separately in the next two propositions. Both their proofs are based on the fundamental equivalence between **JSL_f** and **Dep**.

► **Proposition 5.3.** *The problem DFA + DFA^r → NFA_{atm} is in NP.*

Proof.

1. One can check in polynomial time whether a given pair (A, B) of dfas forms a valid input, i.e. satisfies $L(A) = L(B)^r$. In fact, this condition is equivalent to $\overline{L(A)} \cap L(B)^r = \overline{L(B)} \cap L(A)^r = \emptyset$. Using the standard methods for complementing dfas and reversing and intersecting nfes, one can construct nfes for $\overline{L(A)} \cap L(B)^r$ and $\overline{L(B)} \cap L(A)^r$ of size polynomial in $|A|$ and $|B|$, the number of states of A and B , and check for emptiness by verifying that no final state is reachable from the initial states.
2. Let A and B be dfas accepting the languages L and L^r , respectively, and let k be a natural number. We claim the following three statements to be equivalent:
 - a. There exists an atomic nfa accepting L with at most k states.
 - b. There exists a finite semilattice S with $|J(S)| \leq k$ and **JSL_f**-morphisms p, q and τ_a ($a \in \Sigma$) making the left diagram below commute.
 - c. There exists a **Dep**-object $\mathcal{S} \subseteq \mathcal{S}_s \times \mathcal{S}_t$ with $|\mathcal{S}_s| \leq k$ and $|\mathcal{S}_t| \leq |B|$ and **Dep**-morphisms \mathcal{P}, \mathcal{Q} and \mathcal{T}_a ($a \in \Sigma$) making the right diagram below commute (cf. Example 3.6/3.7).

$$\begin{array}{ccc}
 \text{BLD}(L) & \xrightarrow{\delta'_a} & \text{BLD}(L) \\
 \uparrow i' & & \uparrow f' \\
 \mathbb{2} & & \mathbb{2} \\
 \downarrow i & & \downarrow f \\
 \text{SLD}(L) & \xrightarrow{\delta_a} & \text{SLD}(L)
 \end{array}
 \quad
 \begin{array}{ccc}
 \text{id}_{\Sigma^*/\sim_L} & \xrightarrow{\mathcal{D}'_a} & \text{id}_{\Sigma^*/\sim_L} \\
 \uparrow \mathcal{I}' & & \uparrow \mathcal{F}' \\
 \text{id}_1 & & \text{id}_1 \\
 \downarrow \mathcal{I} & & \downarrow \mathcal{F} \\
 \mathcal{DR}_L & \xrightarrow{\mathcal{DR}_{L,a}} & \mathcal{DR}_L
 \end{array}
 \quad (5.1)$$

In fact, (a) \Leftrightarrow (b) was shown in Theorem 2.1(1), and (b) \Leftrightarrow (c) follows from the equivalence between \mathbf{JSL}_f and \mathbf{Dep} . To see this, note that in the left diagram we may assume q to be injective; otherwise, factorize q as $q = q' \circ e'$ with e surjective and q' injective and work with q' instead of q . By the self-duality of \mathbf{JSL}_f , dualizing q yields a surjective morphism from $\mathbf{BLD}(L) \cong \mathbf{BLD}(L)^{\text{op}}$ to S^{op} . Thus,

$$|M(S)| = |J(S^{\text{op}})| \leq |J(\mathbf{BLD}(L))| = |\Sigma^*/\sim_L| = |\mathbf{LD}(L^r)| \leq |B|.$$

In the two last steps, we use that the congruence classes of \sim_L correspond bijectively to left derivatives of L^r by (2.4), and that $\mathbf{LD}(L^r)$ is the set of states of the minimal dfa for L^r .

By Example 3.6 and 3.7 the upper and lower path of the left diagram in \mathbf{JSL}_f correspond under the equivalence functor Pirr to the upper and lower path of the right diagram in \mathbf{Dep} . Therefore, Theorem 3.3 shows the two diagrams to be equivalent.

3. From (a) \Leftrightarrow (c) we deduce that the relations \mathcal{S} , \mathcal{P} , \mathcal{Q} and \mathcal{T}_a ($a \in \Sigma$) constitute a short certificate for the existence of an atomic nfa for L with at most k states. Commutativity of the right diagram can be checked in polynomial time because all the relations appearing in the upper and lower path can be efficiently computed from the given dfas A and B . Indeed, for the lower path we have already noted this in Remark 5.1, and the upper path emerges from the minimal dfa for L^r , using that $\Sigma^*/\sim_L \cong \mathbf{LD}(L^r)$. \blacktriangleleft

► **Remark 5.4.** An alternative proof that $\mathbf{DFA} + \mathbf{DFA}^r \rightarrow \mathbf{NFA}_{\text{atm}}$ is in NP uses the following characterization of atomic nfes. Given an nfa N , let $\text{rsc}(N^r)$ denote the dfa obtained by determinizing the reverse nfa N^r via the subset construction and restricting to its reachable part. Then N is atomic iff $\text{rsc}(N^r)$ is a minimal dfa [4, Corollary 2]. Thus, given a pair (A, B) of mutually reversed dfas, to decide whether $\text{natm}(L(A)) \leq k$ one may guess a k -state nfa N and verify that $\text{rsc}(N^r)$ is a minimal dfa equivalent to B . One advantage of our above categorical argument is that it yields simple certificates in the form of \mathbf{Dep} -morphisms subject to certain commutative diagrams, which amount to solutions of equations in \mathbf{Rel} . The latter may be directly computed using a SAT solver, leading to a practical approach to finding small atomic acceptors (cf. [9]). To this effect, let us note that the proof of Proposition 5.3 actually shows how to *construct* small atomic nfes rather than just deciding their existence: every certificate $\mathcal{S}, \mathcal{P}, \mathcal{Q}, \mathcal{T}_a$ ($a \in \Sigma$) yields an atomic nfa with states \mathcal{S}_s , transitions given by $(\mathcal{T}_a)_- \subseteq \mathcal{S}_s \times \mathcal{S}_s$ for $a \in \Sigma$, initial states $(\mathcal{I} \mathbin{\text{;}} \mathcal{P})_-[*] \subseteq \mathcal{S}_s$ and final states $(\mathcal{Q} \mathbin{\text{;}} \mathcal{F}')_-[*] \subseteq \mathcal{S}_s$. (Recall that $\mathbin{\text{;}}$ denotes composition in \mathbf{Dep} and $(-)_-$ denotes the maximum lower witness of a \mathbf{Dep} -morphism, see Remark 3.2.) In fact, this is precisely the nfa of join-irreducibles of the \mathbf{JSL} -dfa $(S, \tau, p \circ i, f' \circ q)$ induced by the left diagram in (5.1). Analogous reasoning also applies to the computation of small subatomic nfes treated in Theorem 5.7 below.

► **Proposition 5.5.** *The problem $\mathbf{DFA} + \mathbf{DFA}^r \rightarrow \mathbf{NFA}_{\text{atm}}$ is NP-hard.*

Proof. We devise a polynomial-time reduction from the NP-complete problem **BICLIQUE COVER** [8]: given a pair (\mathcal{R}, k) of a relation $\mathcal{R} \subseteq \mathcal{R}_s \times \mathcal{R}_t$ between finite sets and a natural number k , decide whether \mathcal{R} has a biclique cover of size at most k , i.e. $\dim(\mathcal{R}) \leq k$.

For any (\mathcal{R}, k) , let $S = \text{Open}(\mathcal{R})$ be the finite semilattice of open sets corresponding to the \mathbf{Dep} -object \mathcal{R} , cf. Theorem 3.3, and let $L = L(S)$ be its lattice language. We claim that the desired reduction is given by

$$(\mathcal{R}, k) \longmapsto (\text{dfa}(L), \text{dfa}(L^r), k),$$

78:12 Syntactic Minimization of Nondeterministic Finite Automata

where $\text{dfa}(L)$ and $\text{dfa}(L')$ are the minimal dfas for L and L' . Thus, we need to prove that (a) $\dim(\mathcal{R}) = \text{natm}(L)$, and (b) the two dfas can be computed in polynomial time from \mathcal{R} .

Ad (a). We have the following sequence of **Dep**-isomorphisms:

$$\mathcal{R} \xleftarrow[\text{Thm 3.3}]{\cong} \text{Pirr}(\text{Open}(\mathcal{R})) = \text{Pirr}(S) \xleftarrow[\text{Lem 4.4}]{\cong} \text{Pirr}(\text{SLD}(L(S))) = \text{Pirr}(\text{SLD}(L)) \xleftarrow[\text{Ex 3.6}]{\cong} \mathcal{DR}_L.$$

Lemma 3.9(2) and Proposition 4.5 then imply $\dim(\mathcal{R}) = \dim(\mathcal{DR}_L) = \text{natm}(L)$.

Ad (b). Let $J(\text{Open}(\mathcal{R})) = \{j_1, \dots, j_n\}$ and $M(\text{Open}(\mathcal{R})) = \{m_1, \dots, m_p\}$. Then $\text{dfa}(L)$ and $\text{dfa}(L')$ are the automata depicted below, where L and L' are their respective initial states.

Both automata can be computed in polynomial time from \mathcal{R} using Lemma 3.11. \blacktriangleleft

Next, we turn to the computation of small subatomic nfas. While in the atomic case the input language was specified by a pair of dfas, we now assume an algebraic representation:

► **Definition 5.6.** A *monoid recognizer* is a triple (M, h, F) of a finite monoid M , a map $h: \Sigma \rightarrow M$ and a subset $F \subseteq M$. The language *recognized* by (M, h, F) is given by $L(M, h, F) = \bar{h}^{-1}[F]$, where $\bar{h}: \Sigma^* \rightarrow M$ is the unique extension of h to a monoid morphism.

It is well-known [27] that a language L is regular iff it has a monoid recognizer. In this case, a *minimal* monoid recognizer for L is given by $(\text{syn}(L), \mu_L, F_L)$ where $\mu_L: \Sigma \rightarrow \text{syn}(L)$ is the domain restriction of the syntactic morphism and $F_L = \{[w]_{\equiv_L} : w \in L\}$. It satisfies $|\text{syn}(L)| \leq |M|$ for every recognizer (M, h, F) of L . Consider the following decision problem:

MON \rightarrow **NFA**_{syn}

Input: A monoid recognizer (M, h, F) and a natural number k .

Task: Decide whether there exists a k -state subatomic nfa accepting $L(M, h, F)$.

Here we assume that the monoid M is explicitly given by its multiplication table.

► **Theorem 5.7.** *The problem **MON** \rightarrow **NFA**_{syn} is NP-complete.*

Proof sketch. The proof is conceptually similar to the one of Theorem 5.2. To show the problem to be in NP, one uses the algebraic characterization of $\text{nsyn}(L)$ in Theorem 2.1(2) and translates the ensuing **JSL**_f-diagram into **Dep**. To show NP-hardness, one reduces from **BICLIQUE COVER** via

$$(\mathcal{R}, k) \mapsto ((\text{syn}(L), \mu_L, F_L), k),$$

where again $L = L(\text{Open}(\mathcal{R}))$. \blacktriangleleft

Our complexity results indicate a trade-off, i.e. computing small subatomic nfas requires a less succinct representation of the input language. Generally, $|\text{dfa}(L)|, |\text{dfa}(L')| \leq |\text{syn}(L)|$ and the syntactic monoid can be far larger – even for nuclear languages.

► **Example 5.8.** For any natural number n consider the dfa $A_n = (\{0, \dots, n-1\}, \delta, 1, \{1\})$ over the alphabet $\Sigma = \{\pi, \tau\}$ with $\delta_\pi(i) = i + 1 \pmod n$ for $i = 0, \dots, n-1$, and $\delta_\tau(0) = 1$, $\delta_\tau(1) = 0$, $\delta_\tau(i) = i$ otherwise. Let $L_n = L(A_n)$ denote its accepted language. Then:

1. Both A_n and its reverse nfa are minimal dfas; in particular, $|\text{dfa}(L_n)| = |\text{dfa}(L_n^r)| = n$.
2. We have $|\text{syn}(L_n)| = n!$. To see this, recall that $\text{syn}(L_n)$ is the transition monoid of $A_n \cong \text{dfa}(L_n)$. It is generated by the n -cycle $\delta_\pi = (0\ 1\ \dots\ n-1)$ and the transposition $\delta_\tau = (0\ 1)$; then it equals the symmetric group S_n on n letters.
3. By part (1) the language L_n is *bideterministic* [30], i.e. accepted by a dfa whose reverse nfa is deterministic. This implies that the left derivatives of L_n are pairwise disjoint, so $\text{SLD}(L_n)$ is a boolean algebra. In particular, L_n is a nuclear language.

We finally further justify the inputs of $\mathbf{DFA} + \mathbf{DFA}^r \rightarrow \mathbf{NFA}_{\text{atm}}$ and $\mathbf{MON} \rightarrow \mathbf{NFA}_{\text{syn}}$: the two modified problems $\mathbf{DFA} \rightarrow \mathbf{NFA}_{\text{atm}}$ and $\mathbf{DFA} \rightarrow \mathbf{NFA}_{\text{syn}}$ where only a (single) dfa is given are computationally much harder.

► **Theorem 5.9.** $\mathbf{DFA} \rightarrow \mathbf{NFA}_{\text{atm}}$ and $\mathbf{DFA} \rightarrow \mathbf{NFA}_{\text{syn}}$ are PSPACE-complete.

Proof. This follows by inspecting Jiang and Ravikumar's [15] argument that $\mathbf{DFA} \rightarrow \mathbf{NFA}$ is PSPACE-complete. These authors give a polynomial-time reduction from the PSPACE-complete problem **UNIVERSALITY OF MULTIPLE DFAS**, which asks whether a given list A_1, \dots, A_n of dfas over the same alphabet Σ satisfies $\bigcup_i L(A_i) = \Sigma^*$. For any A_1, \dots, A_n they construct a dfa A over some alphabet Γ and a natural number k such that:

1. If $\bigcup_i L(A_i) \neq \Sigma^*$, then every nfa accepting $L(A)$ requires at least $k+1$ states.
2. If $\bigcup_i L(A_i) = \Sigma^*$, then there exists an nfa accepting $L(A)$ with k states.

In the proof of (2), an explicit k -state nfa $N = (Q, \delta, \{q_0\}, F)$ with $L(N) = L(A)$ is given, see [15, Fig. 1]. It has the property that, after ε -elimination, for every state q there exists $w \in \Gamma^*$ with $\delta_w[q_0] = \{q\}$. This implies that every state q accepts a left derivative $w^{-1}L(N)$, i.e. N is a *residual* nfa [7]. In particular, N is both atomic and subatomic. Consequently, $(A_1, \dots, A_n) \mapsto (A, k)$ is also a reduction to both $\mathbf{DFA} \rightarrow \mathbf{NFA}_{\text{atm}}$ and $\mathbf{DFA} \rightarrow \mathbf{NFA}_{\text{syn}}$. ◀

6 Applications

We conclude this paper by outlining some useful consequences of our NP-completeness results concerning the computation of small nfes for specific classes of regular languages.

6.1 Nuclear Languages

As shown above, nuclear languages form a natural common generalization of bideterministic, biRFSA, and lattice languages. Let $\mathbf{DFA} + \mathbf{DFA}^r \rightarrow \mathbf{NFA}$ be the variant of $\mathbf{DFA} + \mathbf{DFA}^r \rightarrow \mathbf{NFA}_{\text{atm}}$ where the target nfes are arbitrary, i.e. the task is to decide $\text{ns}(L(A)) \leq k$. Then:

► **Theorem 6.1.** For nuclear languages, the problem $\mathbf{DFA} + \mathbf{DFA}^r \rightarrow \mathbf{NFA}$ is NP-complete.

In fact, by Proposition 4.5(1) we have $\text{ns}(L) = \dim(\mathcal{DR}_L)$ for nuclear languages, so NP certificates are given by biclique covers. The NP-hardness proof is identical to the one of Theorem 5.2: the reduction involves a lattice language, which is nuclear by Lemma 4.4.

6.2 Unary languages

For unary regular languages $L \subseteq \{a\}^*$, every two-sided derivative $(a^i)^{-1}L(a^j)^{-1}$ is equal to the left derivative $(a^{i+j})^{-1}L$. Therefore, we have $\text{natm}(L) = \text{nsyn}(L)$ and the minimal dfa for L is the dfa structure of the syntactic monoid. From Theorem 5.7 we thus derive

► **Theorem 6.2.** *For unary languages, the problem $\mathbf{DFA} \rightarrow \mathbf{NFA}_{\text{syn}}$ is in NP.*

This theorem generalizes the best-known complexity result for unary nfas, which asserts that the problem $\mathbf{DFA} \rightarrow \mathbf{NFA}$ is in NP for *unary cyclic languages* [13], i.e. unary regular languages whose minimal dfa is a cycle. In fact, for any such language L we have shown in [26, Example 5.1] that $\text{nsyn}(L) = \text{ns}(L)$, hence $\mathbf{DFA} \rightarrow \mathbf{NFA}$ coincides with $\mathbf{DFA} \rightarrow \mathbf{NFA}_{\text{syn}}$.

6.3 Group languages

A regular language is called a *group language* if its syntactic monoid forms a group. Several equivalent characterizations of group languages are known; for instance, they are precisely the languages accepted by measure-once quantum finite automata [3]. Concerning their state-minimal (sub)atomic acceptors, we have the following result:

► **Proposition 6.3.** *For any group language L , we have $\text{nsyn}(L) = \text{natm}(L)$.*

Therefore, Theorem 5.2 implies

► **Theorem 6.4.** *For group languages, $\mathbf{DFA} + \mathbf{DFA}^r \rightarrow \mathbf{NFA}_{\text{syn}}$ is in NP.*

The complexity of the general $\mathbf{DFA} + \mathbf{DFA}^r \rightarrow \mathbf{NFA}_{\text{syn}}$ problem is left as an open problem.

7 Conclusion and Future Work

Approaching from an algebraic and category-theoretic angle we have studied the complexity of computing small (sub)atomic nondeterministic machines. We proved this to be much more tractable than the general case, viz. NP-complete as opposed to PSPACE-complete, provided that one works with a representation of the input language by a pair of dfas or a finite monoid, respectively. There are several interesting directions for future work.

The particular form of our main two NP-complete problems suggests an investigation of their variants $\mathbf{DFA} + \mathbf{DFA}^r \rightarrow \mathbf{NFA}$ and $\mathbf{MON} \rightarrow \mathbf{NFA}$ computing unrestricted nfas. The reductions used in the proof of Theorem 5.2 and 5.7 show both problems to be NP-hard, and we have seen in Theorem 6.1 that they are in NP for nuclear languages. The complexity of the general case is left as an open problem.

The classical algorithm for state minimization of nfas is the Kameda-Weiner method [18], recently given a fresh perspective based on atoms of regular languages [29]. The algorithm involves an enumeration of biclique covers of the dependency relation \mathcal{DR}_L . Since our base equivalence $\mathbf{JSL}_f \simeq \mathbf{Dep}$ reveals a close relationship between biclique covers and semilattice morphisms (e.g. Lemma 3.9), we envision a purely algebraic account of the Kameda-Weiner method. We should also compare our canonical machines to the Universal Automaton [20], a language-theoretic presentation of the Kameda-Weiner algorithm. For example, our morphisms preserve the language whereas the Universal Automaton uses simulations.

Finally, the classes of nuclear and lattice languages – introduced as technical tools for our NP-completeness proofs – deserve to be studied in their own right. For instance, we expect to uncover connections between lattice languages and the characterization of finite simple non-unital semirings which are not rings [31, Theorem 1.7].

Idempotent Turing Machines

Keisuke Nakano   

Research Institute of Electrical Communication, Tohoku University, Sendai, Japan

Abstract

A function f is said to be idempotent if $f(f(x)) = f(x)$ holds whenever $f(x)$ is defined. This paper presents a computation model for idempotent functions, called an idempotent Turing machine. The computation model is necessarily and sufficiently expressive in the sense that not only does it always compute an idempotent function but also every idempotent computable function can be computed by an idempotent Turing machine. Furthermore, a few typical properties of the computation model such as robustness and universality are shown. Our computation model is expected to be a basis of special-purpose (or domain-specific) programming languages in which only but all idempotent computable functions can be defined.

1 Introduction

A function f whose domain and codomain are equal is said to be *idempotent* if $f(f(x)) = f(x)$ holds whenever $f(x)$ is defined. The idempotence of functions plays an essential role in a wide area of computer science. For example, some program optimization and parallelization do work only when core functions are idempotent; bidirectional transformation is well-behaved only when backward (putback) functions must be idempotent [4, 5, 15]. Moreover, a string sanitizer that removes or escapes potentially dangerous characters to prevent cross-site scripting attacks must be idempotent. Non-idempotent sanitizers are known to make the server vulnerable against double encoding attacks [16]. In such situations, we need to decide if a given function is idempotent or not. However, the idempotence of computable functions is undecidable in general.

To solve the problem, we may design a domain-specific language so that every function defined in the language either is always idempotent as far as it follows the syntax of the language or can be statically verified to be idempotent. Hooimeijer et al. [8] developed the BEK language for describing string sanitizers, which can be checked to perform their appropriate behaviour including idempotence. In this linguistic approach, programmers can define only idempotent functions. However, the restriction may be too strong to exclude idempotent functions that they want to define.

This paper gives a solution to this problem by a computation model, called an *idempotent Turing machine*, which exactly characterizes all idempotent computable functions. More specifically, the computation model is expressive enough for idempotent functions in the sense that every idempotent Turing machine computes an idempotent function and every idempotent computable function can be computed by an idempotent Turing machine. Because of the latter statement, we can claim that a language is sufficiently expressive for idempotent functions if it is capable of simulating any other idempotent Turing machines.

The present work follows along the lines of prior work of Axelsen and Glück [2] on *reversible Turing machines*, which are (locally) forward and backward deterministic Turing machines. They have shown that a reversible Turing machine is expressive enough for computing injective functions under *function semantics* under which the meaning of a Turing machine is specified by a function whose input and output correspond to strings on the tape at the initial and final configuration, respectively. We will adopt the function semantics to show the expressiveness of idempotent Turing machines in the present paper. In addition, two more desirable properties of idempotent Turing machines are shown under the function semantics, which have been shown for reversible Turing machines by Axelsen and Glück: the robustness under tape reduction and the existence of a universal machine. The author [14] has also followed along this line to introduce involutory Turing machines as a computation model for involution which is its own inverse.

Our contribution of the present paper is summarized as follows:

- An idempotent Turing machine is proposed as a particular form of a multitape Turing machine. Every idempotent Turing machine computes an idempotent function.
- An idempotent Turing machine is shown to be expressive enough to specify idempotent functions, i.e., every idempotent function is computed by an idempotent Turing machine.
- An idempotent Turing machine is shown to be robust under tape reduction, i.e., every multitape idempotent Turing machine can be simulated by a single-tape Turing machine.
- A universal idempotent Turing machine is shown to exist in terms of an appropriate redefinition of universality [2] i.e., there is an idempotent Turing machine which simulates any other idempotent Turing machine from the description of that machine.

After all of the above are presented, this paper concludes with the related work and a discussion on future work. Some proofs are provided in Appendix A.

2 Preliminaries

An *alphabet* is a finite set of symbols. The set of all strings over an alphabet Σ is denoted by Σ^* . For convenience, we regard a nested tuple of strings as a flattened one, e.g., $((w_1, w_2), w_3)$ and $(w_1, (w_2, w_3))$ may be identified with (w_1, w_2, w_3) for $w_1, w_2, w_3 \in \Sigma^*$.

For a (binary) relation $R \subseteq A \times B$, $a R b$ stands for $(a, b) \in R$. The identity relation $Id_A \subseteq A \times A$ is $\{(a, a) \mid a \in A\}$. The composition of two relations $R \subseteq A \times B$ and $S \subseteq B \times C$, denoted by $S \circ R$, is given as $\{(a, c) \mid \exists b \in B, a R b \wedge b S c\}$. For a relation $R \subseteq A \times B$ over two sets A and B , the *inverse relation* $R^{-1} \subseteq B \times A$ is defined by $\{(b, a) \mid a R b\}$. A relation $R \subseteq A \times A$ is said to be *symmetric* if $R^{-1} = R$. A relation $R \subseteq A \times B$ is said to be *functional* if $a R b_1$ and $a R b_2$ imply $b_1 = b_2$ for any $a \in A$ and $b_1, b_2 \in B$. A functional relation $R \subseteq A \times B$, written by $R : A \rightarrow B$, is simply called a (partial) *function* and $R(a)$ with $a \in A$ stands for $b \in B$ such that $a R b$ if exists. We may write $a \mapsto b$ for an element (a, b) in a functional relation. A function $R : A \rightarrow B$ is said to be *total* if $R(a) \in B$ is defined for any $a \in A$. A function $R : A \rightarrow B$ is said to be *injective* if R^{-1} is functional. For any injective function $R : A \rightarrow B$ it is easy to see that $R^{-1} \circ R \subseteq Id_A$ and $R \circ R^{-1} \subseteq Id_B$ hold. A function $R : A \rightarrow A$ is called *idempotent* if $R \circ R = R$ holds.

3 Turing Machines

The notion of Turing machines is one of the best-known computation model which can implement any computable functions. Many variants of Turing machines have been proposed in the literature in which a single tape or multiple tapes are used, tapes are one-ended or

doubly-infinite, and a head peeks only single cell or multiple adjacent cells. Since they are known to be equi-expressive [17], we basically follow the definition given by Axelsen and Glück [2]. In this section, we define a Turing machine and show its basic properties. We also present a reversible Turing machine, which plays an important role for our main results.

3.1 Syntax and Semantics of Turing machines

A Turing machine manipulates symbols on a doubly-infinite tape of cells according to an internal state and a fixed transition relation.

► **Definition 1** (*k*-tape Turing machine). A *k*-tape Turing machine T is a tuple $(Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ where Q is a finite set of *states*, Σ is a *tape alphabet* not containing the special blank symbol \sqcup , $q_{\text{ini}} \in Q$ is the *initial state*, $q_{\text{fin}} \in Q$ is the *final state*, and $\Delta = \Delta^{\text{sym}} \uplus \Delta^{\leftrightarrow}$ is a ternary relation defining a set of *transition rules* where

$$\begin{aligned} \Delta^{\text{sym}} &\subseteq (Q \setminus \{q_{\text{fin}}\}) \times (\Sigma_{\sqcup} \times \Sigma_{\sqcup})^k \times (Q \setminus \{q_{\text{ini}}\}) \\ \Delta^{\leftrightarrow} &\subseteq (Q \setminus \{q_{\text{fin}}\}) \times \{\leftarrow, \blacklozenge, \rightarrow\}^k \times (Q \setminus \{q_{\text{ini}}\}) \end{aligned}$$

in which Σ_{\sqcup} stands for $\Sigma \uplus \{\sqcup\}$. A *symbol rule* in Δ^{sym} has the form $(q, (s_1 \Rightarrow s'_1, \dots, s_k \Rightarrow s'_k), q')$ with $s_1, \dots, s_k, s'_1, \dots, s'_k \in \Sigma_{\sqcup}$. A *move rule* in Δ^{\leftrightarrow} has the form $(q, (d_1, \dots, d_k), q')$ with $d_1, \dots, d_k \in \{\leftarrow, \blacklozenge, \rightarrow\}$. The second component of a transition rule is called an *action*. In particular, an action in $\{(s, s) \mid s \in \Sigma_{\sqcup}\}^k \cup \{\blacklozenge\}^k$ is called a *null action*.

As presented in [2], transition rules are separated into symbol rules and move rules for our convenience of further discussion, in particular, about the inversion of Turing machines. Although these two kinds of actions are caused by a single rule in ordinary Turing machines [17], the separation of rules does not change the expressiveness of functions. It is easy to simulate a transition rule in an ordinary Turing machine by two transition rules and extra states in the present model.

A configuration of a *k*-tape Turing machine is specified by the current internal state and *k* tapes with their tape head. Each configuration can be characterized by $\langle l, s, r \rangle \in \Sigma_{\sqcup}^{\omega} \times \Sigma_{\sqcup} \times \Sigma_{\sqcup}^{\omega}$ where s is the symbol at its head position and l and r are the left and right tapes of the head. Note that Σ_{\sqcup}^{ω} is a set of infinite strings over Σ_{\sqcup} going infinitely to the right. Accordingly l is “mirrored” where its first symbol is the immediate left one of the head.

► **Definition 2** (Configuration). A *configuration* of a *k*-tape Turing machine $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ is a tuple $(q, \langle l_1, s_1, r_1 \rangle, \dots, \langle l_k, s_k, r_k \rangle)$ where $q \in Q$ is an *internal state*, $l_i, r_i \in \Sigma_{\sqcup}^{\omega}$ for each $i = 1, \dots, k$ are the left and right of the *i*-th tape head, and $s_i \in \Sigma_{\sqcup}$ for each $i = 1, \dots, k$ is the symbol at the *i*-th tape head. The set of all configurations of T is written by \mathcal{C}_T .

► **Definition 3** (Configuration step). Let $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a *k*-tape Turing machine. Then a single *configuration step* is defined as a relation \vdash_T over \mathcal{C}_T such that

$$(q, \tau_1, \dots, \tau_k) \vdash_T (q', \tau'_1, \dots, \tau'_k)$$

holds for each transition rule $(q, a, q') \in \Delta$ where

- when $a = (s_1 \Rightarrow s'_1, \dots, s_k \Rightarrow s'_k)$, $(\tau_i, \tau'_i) = (\langle l, s_i, r \rangle, \langle l, s'_i, r \rangle)$ holds with some $l, r \in \Sigma_{\sqcup}^{\omega}$ for all $i = 1, \dots, k$;
 - when $a = (d_1, \dots, d_k)$ with $d_i \in \{\leftarrow, \blacklozenge, \rightarrow\}$,
 - $(\tau_i, \tau'_i) = (\langle s'l, s, r \rangle, \langle l, s', sr \rangle)$ holds with some $l, r \in \Sigma_{\sqcup}^{\omega}$ and $s, s' \in \Sigma_{\sqcup}$ if $d_i = \leftarrow$
 - $(\tau_i, \tau'_i) = (\langle l, s, r \rangle, \langle l, s, r \rangle)$ holds with some $l, r \in \Sigma_{\sqcup}^{\omega}$ and $s, s' \in \Sigma_{\sqcup}$ if $d_i = \blacklozenge$
 - $(\tau_i, \tau'_i) = (\langle l, s, s'r \rangle, \langle sl, s', r \rangle)$ holds with some $l, r \in \Sigma_{\sqcup}^{\omega}$ and $s, s' \in \Sigma_{\sqcup}$ if $d_i = \rightarrow$
- for all $i = 1, \dots, k$.

79:4 Idempotent Turing Machines

The subscript T may be omitted if clear from the context.

The semantics of a k -tape Turing machine T is given by a relation over k strings based on \vdash_T^* as follows. In the rest of the paper, a finite string $w \in \Sigma^*$ is used to represent an infinite string $w \sqcup^\omega \in \Sigma_\sqcup^\omega$; thereby, ε denotes \sqcup^ω .

► **Definition 4** (Semantics of Turing machines). Let $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a k -tape Turing machine. The *semantics* of T , denoted by $\llbracket T \rrbracket$, is given by the relation

$$\begin{aligned} \llbracket T \rrbracket = \{ & ((w_1, \dots, w_k), (w'_1, \dots, w'_k)) \in (\Sigma^*)^k \times (\Sigma^*)^k \\ & \mid (q_{\text{ini}}, \langle \varepsilon, \sqcup, w_1 \rangle, \dots, \langle \varepsilon, \sqcup, w_k \rangle) \vdash_T^* (q_{\text{fin}}, \langle \varepsilon, \sqcup, w'_1 \rangle, \dots, \langle \varepsilon, \sqcup, w'_k \rangle) \}. \end{aligned}$$

Recall that we may write $\llbracket T \rrbracket(w_1, \dots, w_k) = (w'_1, \dots, w'_k)$ if $\llbracket T \rrbracket$ is functional.

Following [14], we define the notion of *tidiness* of Turing machines, which is required for further discussion in particular, on the concatenation of Turing machines defined later. Roughly speaking, the tidiness of a Turing machine indicates that the initial configuration is valid if and only if so is the final one. The validity has been called a standard configuration in [1, 2].

► **Definition 5** (Tidiness of Turing machine). A k -tape Turing machine $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ is said to be *tidy* if for any sequence $(q_{\text{ini}}, \langle l_1, s_1, r_1 \rangle, \dots, \langle l_k, s_k, r_k \rangle) \vdash_T^* (q_{\text{fin}}, \langle l'_1, s'_1, r'_1 \rangle, \dots, \langle l'_k, s'_k, r'_k \rangle)$ of computation steps, the following two conditions

- $(l_i, s_i, r_i) \in \{\varepsilon\} \times \{\sqcup\} \times \Sigma^*$ for each $i = 1, \dots, k$
 - $(l'_i, s'_i, r'_i) \in \{\varepsilon\} \times \{\sqcup\} \times \Sigma^*$ for each $i = 1, \dots, k$
- are equivalent.

In the rest of the paper, every k -tape Turing machine is assumed to be tidy. We may call it the *tidiness assumption*.

We shall show two examples of Turing machines whose semantics are both idempotent. As we will see later, due to the form of their transition rules, the second example is an idempotent Turing machine but the first example is not. The main theorem of the present paper claims that any non-idempotent Turing machine has an equivalent idempotent Turing machine whenever its semantics is idempotent, though.

► **Example 6.** The 1-tape Turing machine $T_{\text{ralz}} = (Q, \{0, 1\}, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ where

$$\begin{aligned} Q &= \{q_{\text{ini}}, q_{\text{move}}, q_{\text{ralz}}, q_{\text{back}}, q_{\text{fin}}\} \\ \Delta &= \{(q_{\text{ini}}, \sqcup \rightarrow \sqcup, q_{\text{move}}), (q_{\text{move}}, \rightarrow, q_{\text{ralz}}), (q_{\text{ralz}}, 0 \rightarrow \sqcup, q_{\text{move}}), \\ &\quad (q_{\text{ralz}}, 1 \rightarrow 1, q_{\text{back}}), (q_{\text{ralz}}, \sqcup \rightarrow \sqcup, q_{\text{back}}), (q_{\text{back}}, \leftarrow, q_{\text{fin}})\} \end{aligned}$$

computes the function that removes all leading zeros, i.e., we have $\llbracket T_{\text{ralz}} \rrbracket(0 \dots 0w) = w$ for $w \in \{\varepsilon\} \cup \{1v \mid v \in \{0, 1\}^*\}$.

► **Example 7.** The 2-tape Turing machine $T_{\text{copy}} = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ where

$$\begin{aligned} Q &= \{q_{\text{ini}}, q_{\text{move}}, q_{\text{copy}}, q_{\text{defer}}, q_{\text{trail}}, q_{\text{erase}}, q_{\text{return}}, q_{\text{back}}, q_{\text{check}}, q_{\text{fin}}\} \\ \Delta &= \{(q_{\text{ini}}, (\sqcup \rightarrow \sqcup, \sqcup \rightarrow \sqcup), q_{\text{move}}), (q_{\text{move}}, (\rightarrow, \rightarrow), q_{\text{copy}})\} \cup \\ &\quad \{(q_{\text{copy}}, (s_1 \rightarrow s_2, s_2 \rightarrow s_2), q_{\text{move}}) \mid s_1 \in \Sigma_\sqcup, s_2 \in \Sigma\} \cup \\ &\quad \{(q_{\text{copy}}, (s \rightarrow s, \sqcup \rightarrow \sqcup), q_{\text{trail}}) \mid s \in \Sigma\} \cup \\ &\quad \{(q_{\text{copy}}, (\sqcup \rightarrow \sqcup, \sqcup \rightarrow \sqcup), q_{\text{back}}), (q_{\text{trail}}, (\rightarrow, \rightarrow), q_{\text{defer}})\} \cup \end{aligned}$$

$$\begin{aligned}
& \{(q_{\text{defer}}, (s \Rightarrow s, \sqcup \Rightarrow \sqcup), q_{\text{trail}}) \mid s \in \Sigma\} \cup \\
& \{(q_{\text{defer}}, (\sqcup \Rightarrow \sqcup, \sqcup \Rightarrow \sqcup), q_{\text{return}}), (q_{\text{return}}, (\leftarrow, \leftarrow), q_{\text{erase}})\} \cup \\
& \{(q_{\text{erase}}, (s \Rightarrow \sqcup, \sqcup \Rightarrow \sqcup), q_{\text{return}}) \mid s \in \Sigma\} \cup \{(q_{\text{erase}}, (s \Rightarrow s, s \Rightarrow s), q_{\text{back}}) \mid s \in \Sigma_{\sqcup}\} \cup \\
& \{(q_{\text{check}}, (s \Rightarrow s, s \Rightarrow s), q_{\text{back}}) \mid s \in \Sigma\} \cup \{(q_{\text{back}}, (\leftarrow, \leftarrow), q_{\text{check}}), (q_{\text{check}}, (\sqcup \Rightarrow \sqcup, \sqcup \Rightarrow \sqcup), q_{\text{fin}})\}
\end{aligned}$$

computes the function that copies the second string to the first, i.e., we have $\llbracket T_{\text{copy}} \rrbracket(w_1, w_2) = (w_2, w_2)$ for $w_1, w_2 \in \Sigma^*$. The 2-tape Turing machine T_{copy} can be straightforwardly generalized into $2k$ -tape Turing machine $T_{\text{copy}(k)}$ so that $\llbracket T_{\text{copy}(k)} \rrbracket(w_1, \dots, w_k, v_1, \dots, v_k) = (v_1, \dots, v_k, v_1, \dots, v_k)$ holds for $w_1, \dots, w_k, v_1, \dots, v_k \in \Sigma^*$. In particular, $T_{\text{copy}(1)} = T_{\text{copy}}$.

The second example could be given with fewer states and transition rules by merging q_{defer} with q_{copy} , q_{trail} with q_{move} , q_{erase} with q_{check} , and q_{return} with q_{back} , and removing some redundant rules. However, the smaller alternative is against the condition to be an idempotent Turing machine which will be presented in the next section. The Turing machine T_{copy} of the present form will play an important role in the proof of expressiveness of idempotent Turing machines.

Definition 4 implies that the semantics of a Turing machine returns a tuple that consists of the same number of strings as a given input. However, when the function either only accepts or always returns the empty string on some tapes, we may regard it as a function whose input or output tuple consists of fewer strings following the formalization by Axelsen and Glück [2]. For example, let T be a 3-tape Turing machine over Σ such that $\llbracket T \rrbracket(w_1, w_2, w_3) = (w'_1, w'_2, w'_3)$ implies $w_2 = w_3 = w'_2 = \varepsilon$. Then we may say that T computes a function $f : \Sigma^* \rightarrow \Sigma^* \times \Sigma^*$ defined by $f(w) = (v_1, v_2)$ where $\llbracket T \rrbracket(w, \varepsilon, \varepsilon) = (v_1, \varepsilon, v_2)$ holds. We may simply write $\llbracket T \rrbracket = f$ by ignoring empty input/output strings.

► **Definition 8** (Forward/backward determinism). Let $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a k -tape Turing machine. Then T is *forward deterministic* if, for any distinct pair $(q, a_1, q_1), (q, a_2, q_2) \in \Delta$ of transition rules with the common source state $q \in Q$, their actions a_1 and a_2 have the form of $(s_{1,1} \Rightarrow s'_{1,1}, \dots, s_{1,k} \Rightarrow s'_{1,k})$ and $(s_{2,1} \Rightarrow s'_{2,1}, \dots, s_{2,k} \Rightarrow s'_{2,k})$, respectively, such that $s_{1,i} \neq s_{2,i}$ holds for some $i = 1, \dots, k$. The Turing machine T is *backward deterministic* if, for any distinct pair $(q_1, a_1, q), (q_2, a_2, q) \in \Delta$ of transition rules with the common target state $q \in Q$, their actions a_1 and a_2 have the form of $(s_{1,1} \Rightarrow s'_{1,1}, \dots, s_{1,k} \Rightarrow s'_{1,k})$ and $(s_{2,1} \Rightarrow s'_{2,1}, \dots, s_{2,k} \Rightarrow s'_{2,k})$, respectively, such that $s'_{1,i} \neq s'_{2,i}$ holds for some $i = 1, \dots, k$.

Example 6 and Example 7 are both forward deterministic but not backward deterministic. It is easy to see that every configuration step induced by a forward deterministic Turing machine is functional. In the rest of the paper, we deal with only forward deterministic Turing machines, and hence their semantics are all functional. We may simply say Turing machines even for forward deterministic ones.

Turing machines can be concatenated to synthesize a single one which computes the composition of their semantics.

► **Definition 9** (Concatenation of Turing machines). Let $\{T_i = (Q_i, \Sigma, q_{\text{ini},i}, q_{\text{fin},i}, \Delta_i)\}_{i=1,\dots,n}$ be a family of k -tape Turing machines where Q_1, \dots, Q_n are disjoint without loss of generality. Their *concatenation*, denoted by $T_n \circ \dots \circ T_1$, is a k -tape Turing machine $T = (Q_1 \uplus \dots \uplus Q_n, \Sigma, q_{\text{ini},1}, q_{\text{fin},n}, \Delta)$ where $\Delta = \Delta_1 \uplus \dots \uplus \Delta_n \uplus \{(q_{\text{fin},i-1}, \underbrace{(\blacklozenge, \dots, \blacklozenge)}_k, q_{\text{ini},i}) \mid i = 2, \dots, n\}$.

When Q_1, \dots, Q_n are not disjoint, every state in either should be renamed before the concatenation.

► **Proposition 10** (Semantics of concatenation of Turing machines). *For k -tape reversible Turing machines T_1, \dots, T_n , we have $\llbracket T_n \circ \dots \circ T_1 \rrbracket = \llbracket T_n \rrbracket \circ \dots \circ \llbracket T_1 \rrbracket$.*

Proof. It can be shown straightforwardly with taking notice of the tidiness assumption. ◀

3.2 Reversible Turing Machines

We define a reversible Turing machine, which can be used for the proof of expressiveness of idempotent Turing machines.

► **Definition 11** (Reversible Turing machine). A k -tape Turing machine T is *reversible* if T is forward and backward deterministic.

► **Example 12.** The 2-tape reversible Turing machine $T_{dup} = (\{q_{ini}, q_{move}, q_{copy}, q_{back}, q_{check}, q_{fin}\}, \Sigma, q_{ini}, q_{fin}, \Delta)$ where

$$\begin{aligned} \Delta = & \{(q_{ini}, (\sqcup \rightarrow \sqcup, \sqcup \rightarrow \sqcup), q_{move}), (q_{move}, (\rightarrow, \rightarrow), q_{copy})\} \cup \\ & \{(q_{copy}, (s \rightarrow s, \sqcup \rightarrow s), q_{move}) \mid s \in \Sigma\} \cup \{(q_{copy}, (\sqcup \rightarrow \sqcup, \sqcup \rightarrow \sqcup), q_{back})\} \cup \\ & \{(q_{check}, (s \rightarrow s, s \rightarrow s), q_{back}) \mid s \in \Sigma\} \cup \{(q_{back}, (\leftarrow, \leftarrow), q_{check}), (q_{check}, (\sqcup \rightarrow \sqcup, \sqcup \rightarrow \sqcup), q_{fin})\} \end{aligned}$$

computes the function $\llbracket T_{dup} \rrbracket$, which satisfies $\llbracket T_{dup} \rrbracket(w, \varepsilon) = (w, w)$ for $w \in \Sigma^*$. The 2-tape reversible Turing machine T_{dup} can be straightforwardly generalized into $2k$ -tape reversible Turing machine $T_{dup(k)}$ so that $\llbracket T_{dup(k)} \rrbracket(w_1, \dots, w_k, \underbrace{\varepsilon, \dots, \varepsilon}_k) = (w_1, \dots, w_k, w_1, \dots, w_k)$ holds for $w_1, \dots, w_k \in \Sigma^*$. In particular, we have $T_{dup(1)} = T_{dup}$.

Although the Turing machines T_{dup} and T_{copy} are similar in a sense that they both output pairs of the same string, T_{dup} differs in that the second component of its input is restricted to the empty string. Because of this difference, $\llbracket T_{dup} \rrbracket$ is not idempotent while so is $\llbracket T_{copy} \rrbracket$.

As seen from the definition, a Turing machine obtained by inverting all transition rules of a reversible Turing machine is also reversible. Its semantics is naturally the inverse function of the semantics of the original reversible Turing machine as formally stated below.

► **Definition 13** (Inversion of reversible Turing machines). Let $T = (Q, \Sigma, q_{ini}, q_{fin}, \Delta)$ be a k -tape reversible Turing machine. We define $T^{-1} = (Q, \Sigma, q_{fin}, q_{ini}, \Delta^{-1})$ with $\Delta^{-1} = \{(p, a^{-1}, q) \mid (q, a, p) \in \Delta\}$ where $(a_1, \dots, a_k)^{-1} = (a_1^{-1}, \dots, a_k^{-1})$, $(s \rightarrow s')^{-1} = (s' \rightarrow s)$, $(\leftarrow)^{-1} = (\rightarrow)$, $(\blacklozenge)^{-1} = (\blacklozenge)$, and $(\rightarrow)^{-1} = (\leftarrow)$.

► **Proposition 14** (Bennet [3]). *Let $T = (Q, \Sigma, q_{ini}, q_{fin}, \Delta)$ be a k -tape reversible Turing machine. Then, T^{-1} forms a k -tape reversible Turing machine such that $\llbracket T^{-1} \rrbracket = \llbracket T \rrbracket^{-1}$.*

In reversible Turing machines, by definition, there is no distinct pair of configurations that have the same successive configuration. This implies that the semantics of a reversible Turing machine is always injective.

Axelsen and Glück [2] have shown its converse, i.e., every injective computable function can be defined by a reversible Turing machine. Their proof is constructive so that an equivalent reversible Turing machine can be constructed effectively from a given non-reversible Turing machine whose semantics is injective.

► **Theorem 15** (Expressiveness of reversible Turing machines [2]). *The reversible Turing machines can compute exactly all injective computable functions. That is, given a k -tape Turing machine T such that $\llbracket T \rrbracket$ is injective, there is a k -tape reversible Turing machine T' such that $\llbracket T' \rrbracket = \llbracket T \rrbracket$.*

4 Idempotent Turing Machines

We introduce an idempotent Turing machine and its properties, expressiveness, robustness, and universality.

4.1 Definition and Expressiveness

An idempotent Turing machine is defined by imposing a restriction upon the form of transition rules of a standard Turing machine. Informally, the key of the restriction forces every valid run to include an internal configuration C such that the sequence of configuration steps from C to the final configuration can also become a valid run by concatenating its reversed sequence at the front. Note that in the obtained run, the initial and final tapes contain the same string. This indicates that $\llbracket T \rrbracket(y) = y$ holds for any x and y such that $\llbracket T \rrbracket(x) = y$ for the Turing machine T , which concludes that $\llbracket T \rrbracket$ is idempotent. Formally, idempotent Turing machines are defined as below.

► **Definition 16** (Idempotent Turing machine). Let $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a k -tape forward deterministic Turing machine. Then T is said to be *idempotent* if there exist a set $Q' \subset Q$ of states and a total function $\psi : Q' \rightarrow Q \setminus Q'$ that satisfy the following conditions:

- (I-1) $q_{\text{ini}} \notin Q'$, $q_{\text{fin}} \in Q'$, and $\psi(q_{\text{fin}}) = q_{\text{ini}}$;
- (I-2) there is no transition rule $(q', a, q) \in \Delta$ with $q' \in Q'$ and $q \in Q \setminus Q'$;
- (I-3) there is a transition rule $(\psi(p'), a^{-1}, \psi(q')) \in \Delta$ for each $(q', a, p') \in \Delta$ with $p', q' \in Q'$; and
- (I-4) there is a transition rule $(\psi(q'), a_0, q') \in \Delta$ with a null action a_0 for each $(q, a, q') \in \Delta$ with $q \in Q \setminus Q'$ and $q' \in Q'$.

Each state $q' \in Q'$ is called a *rear state* and the function ψ is called a *rear state map*.

Definition 16 implies that every valid sequence of configuration steps of an idempotent Turing machine can be split into two parts of non-rear and rear states because of the (I-1) and (I-2) conditions. Moreover, with the (I-3) and (I-4) conditions, we can conclude that the semantics of an idempotent Turing machine is idempotent.

► **Theorem 17** (Semantics of idempotent Turing machine). Let $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a k -tape idempotent Turing machine. Then $\llbracket T \rrbracket$ is idempotent.

Proof. For simplicity of the proof, only the case of $k = 1$ is shown. The proof can be easily generalized to the other cases. Let $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a 1-tape idempotent Turing machine with a set Q' of rear states and a rear state map ψ . It suffices to show that $\llbracket T \rrbracket(v) = v$ holds for any $v = \llbracket T \rrbracket(w)$ with $w \in \Sigma^*$. Suppose that $v = \llbracket T \rrbracket(w)$ for some $v, w \in \Sigma^*$. Because of the definition of idempotent Turing machines, there must exist a valid sequence of configuration steps of the form

$$(q_{\text{ini}}, \langle \varepsilon, \sqcup, w \rangle) \vdash (q_1, \langle l_1, s_1, r_1 \rangle) \vdash \dots \vdash (q_m, \langle l_m, s_m, r_m \rangle) \vdash \\ (q'_1, \langle l'_1, s'_1, r'_1 \rangle) \vdash \dots \vdash (q'_n, \langle l'_n, s'_n, r'_n \rangle) \vdash (q_{\text{fin}}, \langle \varepsilon, \sqcup, v \rangle)$$

with $q_1, \dots, q_m \in Q \setminus Q'$ and $q'_1, \dots, q'_n \in Q'$ from the (I-1) and (I-2) conditions. Because of the (I-4) condition, there is a transition rule $(\psi(q'_1), a_0, q'_1) \in \Delta$ with a null action a_0 . Then we have a valid sequence

$$(q_{\text{ini}}, \langle \varepsilon, \sqcup, v \rangle) \vdash (\psi(q'_n), \langle l'_n, s'_n, r'_n \rangle) \vdash \dots \vdash (\psi(q'_1), \langle l'_1, s'_1, r'_1 \rangle) \vdash \\ (q'_1, \langle l'_1, s'_1, r'_1 \rangle) \vdash \dots \vdash (q'_n, \langle l'_n, s'_n, r'_n \rangle) \vdash (q_{\text{fin}}, \langle \varepsilon, \sqcup, v \rangle)$$

due to the (I-1) and (I-3) conditions, which demonstrates $\llbracket T \rrbracket(v) = v$. ◀

79:8 Idempotent Turing Machines

The Turing machine T_{copy} introduced in Example 7 can be shown to be idempotent accompanied by a set Q' of rear states and a rear state map ψ specified by

$$Q' = \{q_{fin}, q_{check}, q_{back}\} \quad \psi = \{q_{fin} \mapsto q_{ini}, q_{check} \mapsto q_{move}, q_{back} \mapsto q_{copy}\}.$$

The conditions **(I-1)** and **(I-2)** obviously hold. The condition **(I-3)** can be confirmed by the correspondence of the pairs of transition rules,

$$\begin{array}{ll} (q_{check}, (\sqcup \rightarrow \sqcup, \sqcup \rightarrow \sqcup), q_{fin}) & (q_{ini}, (\sqcup \rightarrow \sqcup, \sqcup \rightarrow \sqcup), q_{move}) \\ (q_{back}, (\leftarrow, \leftarrow), q_{check}) & (q_{move}, (\rightarrow, \rightarrow), q_{copy}) \\ (q_{check}, (s \rightarrow s, s \rightarrow s), q_{back}) & (q_{copy}, (s \rightarrow s, s \rightarrow s), q_{move}) \end{array}$$

with $s \in \Sigma$. The condition **(I-4)** holds because of the transition rule $(q_{copy}, (\sqcup \rightarrow \sqcup, \sqcup \rightarrow \sqcup), q_{back})$. The general Turing machine $T_{copy(k)}$ can be checked to be idempotent as well.

In contrast, the 1-tape Turing machine T_{ralz} introduced in Example 6 and the smaller alternative of T_{copy} mentioned after Example 7 are not idempotent even though their semantics is idempotent. As for T_{ralz} , we can check it as follows. In order to satisfy the conditions **(I-1)** and **(I-3)**, the q_{back} state cannot be a rear state. Then it is impossible to satisfy the condition **(I-4)**. In general we can decide whether a given Turing machine is idempotent.

► **Proposition 18** (Decidability of idempotence of Turing machines). *Let T be a k -tape Turing machine. It is decidable whether T is idempotent.*

Proof. The proof depends on the finiteness of the set of states and accordingly the finiteness of the choice of the set of rear states and the rear state map, which is required to be idempotent. ◀

The proof above indicates just the existence an extremely naive procedure for the decision problem. The complexity of the decision procedure is beyond double exponential to the number of states. We leave for future work a more efficient algorithm.

Note that the decision problem is only to decide if a Turing machine is idempotent but not to decide if the Turing machine computes an idempotent function. The latter problem is obviously undecidable. However, we will prove that an equivalent idempotent Turing machine can be constructed whenever the Turing machine computes an idempotent function.

Idempotent functions are closed under *conjugation* with injective functions, i.e., for any idempotent function f and injective function g , the conjugate $g^{-1} \circ f \circ g$ is idempotent. The following lemma shows that the idempotent Turing machines have a similar property which will be used to prove the main theorem. The proof of this lemma is given in Appendix A.

► **Lemma 19** (Closed under conjugation). *Let T be a k -tape idempotent Turing machine. For any k -tape reversible Turing machine T_r , the k -tape reversible Turing machine $T_r^{-1} \circ T \circ T_r$ is idempotent.*

Now we are ready to prove expressiveness of the idempotent Turing machines which is one of the main theorems in the present paper.

► **Theorem 20** (Expressiveness of idempotent Turing machines). *The idempotent Turing machines can compute any idempotent computable function. More specifically, given a k -tape Turing machine T such that $\llbracket T \rrbracket$ is idempotent, there is a $2k$ -tape idempotent Turing machine T' such that $\llbracket T' \rrbracket = \llbracket T \rrbracket$.*

Proof sketch. Let T be a k -tape Turing machine such that $\llbracket T \rrbracket : \Sigma^k \rightarrow \Sigma^k$ is idempotent. Consider a (partial) function $f : \Sigma^{2k} \rightarrow \Sigma^{2k}$ such that $f(w_1, \dots, w_k, w_{k+1}, \dots, w_{2k}) = (w_1, \dots, w_k, \llbracket T \rrbracket(w_1, \dots, w_k))$ holds only if $\llbracket T \rrbracket(w_1, \dots, w_k)$ is defined and $w_{k+1} = \dots = w_{2k} = \varepsilon$ holds. Since the function f is injective and computable, we can construct a $2k$ -tape reversible Turing machine T_f such that $\llbracket T_f \rrbracket = f$ by Theorem 15. Then, define a $2k$ -tape Turing machine $T' = T_f^{-1} \circ T_{\text{copy}(k)} \circ T_f$ where $T_{\text{copy}(k)}$ is a $2k$ -tape idempotent Turing machine introduced in Example 7. The Turing machine T' is idempotent due to Lemma 19 and a simple calculation can verify $\llbracket T' \rrbracket = \llbracket T \rrbracket$ as shown in Appendix A. ◀

4.2 Robustness under Tape Reduction

Single-tape Turing machines are as expressive as multitape Turing machines [17]. This property is known as one of the robustness of Turing machines. We will see the property for idempotent Turing machines, i.e., every multitape idempotent Turing machine has an equivalent single-tape idempotent Turing machine. To this end, we simulate a k -tuple of strings with a single string by an encoding function $\text{enc} : (\Sigma^*)^k \rightarrow (\Sigma \uplus \{\$, \})^*$ using a special symbol $\$$ not in Σ . The encoding function is defined as

$$\text{enc}(s_{1,1}s_{1,2}\dots s_{1,n}, \dots, s_{k,1}s_{k,2}\dots s_{k,n}) = s_{1,1}\dots s_{k,1}s_{1,2}\dots s_{k,2}s_{1,n}\dots s_{k,n}$$

with the maximum length n of the input strings where the symbol $\$$ is filled at the end of the shorter strings as necessary, e.g., $\text{enc}(\text{ab}, \text{cdef}, \text{ghi}) = \text{acgbdh\$ei\$f\$}$. The encoding function is injective and computable where k is fixed. We will write $\Sigma_{\$}$ for $\Sigma \uplus \{\$, \}$ and enc may be used even for encoded strings, i.e., $\text{enc} : (\Sigma_{\$}^*)^k \rightarrow \Sigma_{\* .

We first show how to construct a 2-tape idempotent Turing machine equivalent to a given multitape idempotent Turing machine. This is easily shown by the expressiveness of idempotent Turing machines.

► **Theorem 21** (Reduction to 2-tape idempotent Turing machine). *Let T be a k -tape idempotent Turing machine. Then there exists a 2-tape idempotent Turing machine T' that simulates T , that is, $\llbracket T \rrbracket(w_1, \dots, w_k) = (v_1, \dots, v_k)$ if and only if $\llbracket T' \rrbracket(\text{enc}(w_1, \dots, w_k), \varepsilon) = (\text{enc}(v_1, \dots, v_k), \varepsilon)$.*

Proof. Let T be a k -tape idempotent Turing machine. Consider a function $f : \Sigma_{\$}^* \rightarrow \Sigma_{\* satisfying $f(\text{enc}(w_1, \dots, w_k)) = \text{enc}(\llbracket T \rrbracket(w_1, \dots, w_k))$ for any $w_1, \dots, w_k \in \Sigma^*$ only if $\llbracket T \rrbracket(w_1, \dots, w_k)$ is defined. Since f is computable, we have a 1-tape Turing machine that computes f . Note that f is idempotent because of the idempotence of $\llbracket T \rrbracket$. Therefore, there exists a 2-tape idempotent Turing machine that computes f by Theorem 20 with $k = 1$. ◀

The theorem above is not satisfactory because it still requires at least two tapes to simulate arbitrary multitape idempotent Turing machines. We need a further idea to show the robustness under the tape reduction down to a single tape. The idea is similar to that of the proof for expressiveness. We employ a 1-tape idempotent Turing machine T_{blur} , which behaves like T_{copy} as shown by the following lemma. Its proof is given in Appendix A.

► **Lemma 22.** *There exists a 1-tape idempotent Turing machine T_{blur} computing the idempotent function $f_{\text{blur}} : \Sigma_{\$}^* \rightarrow \Sigma_{\* , which satisfies $f_{\text{blur}}(\varepsilon) = \varepsilon$ and $f_{\text{blur}}(s_1s_2w) = s_1s_1f_{\text{blur}}(w)$ for any $s_1, s_2 \in \Sigma_{\$}$ and $w \in \Sigma_{\* .*

Now we are ready to prove the robustness under tape reduction for idempotent Turing machines. In the proof of the robustness theorem, the idempotent Turing machine T_{blur} plays a similar role to $T_{\text{copy}(k)}$ in the proof of Theorem 20.

► **Theorem 23** (Robustness of idempotent Turing machines). *Let $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a k -tape idempotent Turing machine. Then there exists a 1-tape idempotent Turing machine T' such that $\llbracket T \rrbracket(w_1, \dots, w_k) = (v_1, \dots, v_k)$ if and only if $\llbracket T' \rrbracket(\text{enc}(w_1, \dots, w_k)) = \text{enc}(v_1, \dots, v_k)$.*

Proof sketch. Let $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a k -tape idempotent Turing machine. Consider a function $f : \Sigma_{\#}^* \rightarrow \Sigma_{\#}^*$ satisfying $f(\text{enc}(w_1, \dots, w_k)) = \text{enc}(\llbracket T \rrbracket(w_1, \dots, w_k))$, $\text{enc}(w_1, \dots, w_k)$ for any $w_1, \dots, w_n \in \Sigma^*$ only if $\llbracket T \rrbracket(w_1, \dots, w_k)$ is defined. Since the function f is injective and computable, we can construct a 1-tape Turing machine T_f such that $\llbracket T_f \rrbracket = f$ by Theorem 15. Then, define a 1-tape Turing machine $T' = T_f^{-1} \circ T_{\text{blur}} \circ T_f$ where T_{blur} is an idempotent Turing machine given in Lemma 22. The Turing machine T' is idempotent because of Lemma 19 and a simple calculation can verify $\llbracket T' \rrbracket \circ \text{enc} = \text{enc} \circ \llbracket T \rrbracket$ as shown in Appendix A. ◀

4.3 Universality

A standard Turing machine is called *universal* if it is capable of simulating an arbitrary Turing machine on arbitrary input. A universal Turing machine takes a pair of strings: one is the description of the given Turing machine T , which is typically provided as the Gödel number $\ulcorner T \urcorner$ as a string; another is an input w of T . Then it is expected to return the output string $\llbracket T \rrbracket(w)$. In essence, a universal Turing machine U must satisfy $\llbracket U \rrbracket(\ulcorner T \urcorner, x) = \llbracket T \rrbracket(w)$ for any Turing machine T and its input string w .

With regard to idempotent Turing machines, there is no universal machines in the sense above, i.e., no idempotent Turing machine simulate arbitrary idempotent Turing machines. Since the domain and codomain of idempotent functions must be equal, the universal machine cannot be idempotent. Therefore, we relax the definition of universality as Axelsen and Glück have done to introduce the universality of reversible Turing machines [2] where the universal machine returns not only the expected output string but also the given Turing machine itself. Under this relaxed definition, the universal machine computes an idempotent function as far as the given Turing machine is idempotent.

► **Definition 24** (Universality). *A k -tape idempotent Turing machine U is said to be *IdTM-universal* if $\llbracket U \rrbracket(\ulcorner T \urcorner, w) = (\ulcorner T \urcorner, \llbracket T \rrbracket(w))$ holds for any idempotent Turing machine T and its input string w .*

In the present paper, a universal model of ordinary Turing machines is called a *classically universal Turing machine* to distinguish from our IdTM-universal machines.

It is not difficult to show the existence of an IdTM-universal machine because of the expressiveness of idempotent Turing machines.

► **Theorem 25.** *There exists an IdTM-universal idempotent Turing machine.*

Proof. Let f be a function satisfying $f(\ulcorner T \urcorner, w) = (\ulcorner T \urcorner, \llbracket T \rrbracket(w))$ for any idempotent Turing machine T and its input string w . Note that f is idempotent because $f(f(\ulcorner T \urcorner, w)) = f(\ulcorner T \urcorner, \llbracket T \rrbracket(w)) = (\ulcorner T \urcorner, \llbracket T \rrbracket(\llbracket T \rrbracket(w))) = (\ulcorner T \urcorner, \llbracket T \rrbracket(w))$ where the last equality comes from the idempotence of $\llbracket T \rrbracket$. By Theorem 20, we obtain an idempotent Turing machine U that computes f . ◀

The theorem above just shows the existence of an universal machine, which is considered impractical as noticed in the prior work [1, 2, 14] because its proof relies on Theorem 15 (via Theorem 20), which is the expressive theorem of reversible Turing machine. As mentioned in [2], the proof of Theorem 15 is based on very inefficient generate-and-test method by

McCarthy [12]. To avoid this problem, we shall show the construction of an universal Turing machine without Theorem 15 where we construct a universal idempotent Turing machine from a classically universal Turing machine. Following the existing work [1, 2, 14], we employ Bennett's trick with Landauer's trace embedding to construct a special type of reversible Turing machines that computes the function $\lambda x.(x, f(x))$ for an arbitrary computable function f . We present a multitape version of the theorem as below. Its proof is provided in Appendix A.

► **Proposition 26** (Bennett's trick [3]). *Let T be a k -tape Turing machine. There exists a $(2k + 1)$ -tape reversible Turing machine $\text{Ben}_k(T)$ such that $\llbracket \text{Ben}_k(T) \rrbracket(w_1, \dots, w_k, \underbrace{\varepsilon, \dots, \varepsilon}_{k+1}) = (w_1, \dots, w_k, \llbracket T \rrbracket(w_1, \dots, w_k), \varepsilon)$ for any input w_1, \dots, w_k of T .*

With the Bennett's trick, we can construct a universal idempotent Turing machine from a classically universal Turing machine.

► **Theorem 27** (IdTM-universal Turing machine constructed with Bennett's trick). *Let U be a (2-tape) classically universal Turing machine, i.e., $\llbracket U \rrbracket(\ulcorner T \urcorner, w) = (\ulcorner T \urcorner, \llbracket T \rrbracket(w))$ for any Turing machine T and its input w . Then a 5-tape idempotent Turing machine $U' = \text{Ben}_2(U)^{-1} \circ T'_{\text{copy}(2)} \circ \text{Ben}_2(U)$ is IdTM-universal where $T'_{\text{copy}(2)}$ is obtained by adding one extra tape as the fifth tape to $T_{\text{copy}(2)}$, i.e., $\llbracket T'_{\text{copy}(2)} \rrbracket(w_1, w_2, w_3, w_4, w_5) = (w_3, w_4, w_3, w_4, w_5)$.*

Proof sketch. Let U be a 2-tape classically universal Turing machine such that $\llbracket U \rrbracket(\ulcorner T \urcorner, w) = (\ulcorner T \urcorner, \llbracket T \rrbracket(w))$ for any Turing machine T and its input w . Note that the Turing machine $U' = \text{Ben}_2(U)^{-1} \circ T'_{\text{copy}(2)} \circ \text{Ben}_2(U)$ is idempotent due to the idempotence of $T'_{\text{copy}(2)}$ and Lemma 19. In addition, we can show the 5-tape idempotent Turing machine U' is IdTM-universal, that is, $\llbracket U' \rrbracket(\ulcorner T \urcorner, w, \varepsilon, \varepsilon, \varepsilon) = (\ulcorner T \urcorner, \llbracket T \rrbracket(w), \varepsilon, \varepsilon, \varepsilon)$ holds for any Turing machine T and its input w as shown in Appendix A. ◀

The author [14] has constructed a universal machine for involutory Turing machines using Bennett's trick in a way similar to Theorem 27. The difference is that he uses the Turing machine permuting some of tapes for the center one of the composition instead of $T'_{\text{copy}(2)}$.

5 Related work

This work proposes idempotent Turing machines, which can compute exactly all idempotent computable functions. The present work has followed along the lines of prior work on special Turing machines for particular classes of computable functions [1, 2, 14] under function semantics, in which the meaning of a Turing machine is specified by a function whose input and output correspond to strings on the tape at the initial and final configuration, respectively.

Axelsen and Glück [1, 2] have investigated several properties of reversible Turing machines under function semantics. Even though the notion of reversible Turing machines had been already introduced and studied before the work [3, 11], Axelsen and Glück gave much clearer semantics to reversible Turing machines to observe what they compute. They showed that reversible Turing machines can compute exactly all injective computable functions. They also proved the robustness under tape and symbol reduction: 1-tape 3-symbol reversible Turing machines can simulate arbitrary multitape reversible Turing machines. Furthermore, they showed the existence of universal reversible Turing machines under an appropriate redefinition of universality and gave an efficient construction of a universal machine. The present work has followed their approach and utilized their results even though idempotent functions are not necessarily injective.

79:12 Idempotent Turing Machines

The author [14] introduced involutory Turing machines and showed that they can compute exactly all involutory computable functions, which are own inverse, i.e., a function f such that $f(f(x)) = x$ holds whenever $f(x)$ is defined. He naturally followed Axelsen and Glück's work since every involutory function is injective. He defined an involutory Turing machine as a Turing machine whose transition rules are related each other under an involutory map over states. The idea is found in discrete time-symmetric systems [6,9]. In the present work, we refer to the idea to define an idempotent Turing machine with the rear state map.

Besides Turing machines, there are many other model of computable functions, e.g., untyped lambda calculus, combinatory logic, and term/string rewriting systems. We could consider a restricted model of them for idempotent functions. We have selected Turing machines because there is a well-studied subclass of the model, namely reversible Turing machine, for injective functions that can be invertible. A candidate of other such models would be Mu et al's injective language `Inv` [13] in which every function is defined by a few primitives including the fixed-point operator. They have shown that the `Inv` language is expressive enough to simulate reversible Turing machines. However, it is not simple to utilize the injective language for a computational model of idempotent functions. We need to add more primitives to describe non-injective functions and impose some syntactic restrictions to define only idempotent functions. It would be interesting if such a programming language can be defined, though.

6 Conclusion

We have introduced a computation model for idempotent functions, called an idempotent Turing machine. This model is necessarily and sufficiently expressive: every idempotent Turing machine computes an idempotent function and every idempotent function can be computed by an idempotent Turing machine. The class of Turing machines has been shown to be robust under tape reduction. We have also shown the existence of an universal idempotent Turing machine and its construction.

Our computation model is expected to be a basis of special-purpose (or domain-specific) programming languages in which only but all idempotent computable functions can be defined. A computation model is said to be *Turing-complete* if it can simulate any Turing machine. The notion of Turing-completeness is often used to show the expressiveness of not only a computation model but also a programming language or a set of machine instructions. For reversible computation, the notion of *r-Turing completeness* has been proposed [1,2,19]. There have been reversible programming languages, e.g., Janus with dynamic storage [18], reversible flowchart language [19], and R-WHILE [7], that have been shown to be *r-Turing complete*. Similarly, the notion of *idempotent-Turing-completeness* can be defined and applied to a special-purpose (or domain-specific) programming languages in which only but all idempotent computable functions can be defined. Such a special programming language will be required for string sanitizers, automated program optimizers, and bidirectional transformation.

In addition, it is interesting to consider computational models that exactly cover all computable functions with some constraints in the general case. Axelsen and Glück [1] have shown that reversible Turing machines can exactly cover injective computable functions. The author [14] has shown a computational model that exactly covers involutory computable functions, and he shows such a result for idempotent functions in the present paper. It is a natural question to ask what kind of semantic constraints on computable functions corresponds to syntactically constrained Turing machines in general, which is left for future work.

A Proofs of Lemmas, Theorems and Proposition

This Appendix provides proofs that are omitted or condensed in the main text.

► **Lemma 19** (Closed under conjugation). *Let T be a k -tape idempotent Turing machine. For any k -tape reversible Turing machine T_r , the k -tape reversible Turing machine $T_r^{-1} \circ T \circ T_r$ is idempotent.*

Proof. Let $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a k -tape idempotent Turing machine with a set $Q' \subset Q$ of rear states and a rear state map ψ . Let $T_r = (Q_r, \Sigma_r, q_{\text{ini},r}, q_{\text{fin},r}, \Delta_r)$ be a k -tape reversible Turing machine where Q and Q_r are disjoint without loss of generality. In order to concatenate T_r , T , and T_r^{-1} following Definition 9, we rename every state $q \in Q_r$ of T_r^{-1} with \widehat{q} . Let \widehat{Q}_r be a set of states of T_r^{-1} , i.e., $\widehat{Q}_r = \{\widehat{q} \mid q \in Q_r\}$ and $\Delta_r^{-1} = \{(\widehat{p}, a^{-1}, \widehat{q}) \mid (q, a, p) \in \Delta_r\}$. Then we can define $T_c = T_r^{-1} \circ T \circ T_r$, which is to be shown idempotent, as $T_c = (Q_c, \Sigma, q_{\text{ini},r}, \widehat{q_{\text{ini},r}}, \Delta_c)$ where

$$\begin{aligned} Q_c &= Q_r \uplus Q \uplus \widehat{Q}_r \\ \Delta_c &= \Delta_r \uplus \Delta \uplus \{(\widehat{p}, a^{-1}, \widehat{q}) \mid (q, a, p) \in \Delta_r\} \uplus \{(q_{\text{fin},r}, \underbrace{(\diamond, \dots, \diamond)}_k), q_{\text{ini}}\}, \{(q_{\text{fin}}, \underbrace{(\diamond, \dots, \diamond)}_k), \widehat{q_{\text{fin},r}}\}. \end{aligned}$$

Let Q'_c be a subset of Q_c defined by $Q' \uplus \widehat{Q}_r$. We define a function $\psi_c : Q'_c \rightarrow Q_c \setminus Q'_c$ as

$$\psi_c(q) = \begin{cases} \psi(q) & (q \in Q') \\ q_r & (q = \widehat{q}_r \in \widehat{Q}_r) \end{cases}$$

where the codomain of ψ_c is $(Q \setminus Q') \uplus Q_r$ that is equal to $Q_c \setminus Q'_c$.

We shall check the four conditions of Q'_c and ψ_c for T_c to be idempotent.

- The **(I-1)** condition holds since $q_{\text{ini},r} \in Q_r \subset Q_c \setminus Q'_c$, $\widehat{q_{\text{ini},r}} \in \widehat{Q}_r \subset Q'_c$, and $\psi_c(\widehat{q_{\text{ini},r}}) = q_{\text{ini},r}$.
- The **(I-2)** condition holds because of the definition of concatenation and the **(I-2)** condition for T .
- Concerning the **(I-3)** condition, suppose that we have $(q', a, p') \in \Delta_c$ with $p', q' \in Q'_c = Q' \uplus \widehat{Q}_r$. Since it is impossible to have $p' \in Q' \subset Q$ and $q' \in \widehat{Q}_r$ due to the construction of Δ_c , we divide it into three cases:
 - When $p', q' \in Q'$, we have $(\psi_c(p'), a^{-1}, \psi_c(q')) \in \Delta_c$ because of the **(I-3)** condition of T with $\psi_c(p') = \psi(p')$, $\psi_c(q') = \psi(q')$, and $\Delta \subset \Delta_c$;
 - When $p' \in \widehat{Q}_r$ and $q' \in Q'$, we must have $p' = \widehat{q_{\text{fin},r}}$ and $q' = q_{\text{fin}}$ according to the construction of Δ_c . Hence, we have $(\psi_c(p'), a^{-1}, \psi_c(q')) \in \Delta_c$ because of $\psi_c(p') = q_{\text{fin},r}$, $\psi_c(q') = \psi(q_{\text{fin}}) = q_{\text{ini}}$, and the construction of Δ_c ; and
 - When $p', q' \in \widehat{Q}_r$, there exist $p_r, q_r \in Q_r$ such that $p' = \widehat{p}_r$ and $q' = \widehat{q}_r$. Hence, we have $(\psi_c(p'), a^{-1}, \psi_c(q')) \in \Delta_c$ because of $\psi_c(p') = p_r$, $\psi_c(q') = q_r$, and the construction of Δ_c with Δ_r .

Thus, the condition **(I-3)** holds.

- Concerning **(I-4)** condition, suppose that we have $(q, a, q') \in \Delta_c$ with $q \in (Q_c \setminus Q') = (Q \setminus Q' \uplus Q_r)$ and $q' \in Q'_c = Q' \uplus \widehat{Q}_r$. From the construction of Δ_c , we must have $q \in Q \setminus Q'$ and $q' \in Q'$. Thus, we obtain $q = \psi(q') = \psi_c(q')$ and $a = a^{-1}$ because of the condition **(I-4)** of T .

Therefore we conclude that T_c is idempotent with the set Q_c of rear states and the rear state map ψ_c . ◀

► **Theorem 20** (Expressiveness of idempotent Turing machines). *The idempotent Turing machines can compute any idempotent computable function. More specifically, given a k -tape Turing machine T such that $\llbracket T \rrbracket$ is idempotent, there is a $2k$ -tape idempotent Turing machine T' such that $\llbracket T' \rrbracket = \llbracket T \rrbracket$.*

Proof. Let T be a k -tape Turing machine such that $\llbracket T \rrbracket : \Sigma^k \rightarrow \Sigma^k$ is idempotent. Consider a (partial) function $f : \Sigma^{2k} \rightarrow \Sigma^{2k}$ such that $f(w_1, \dots, w_k, w_{k+1}, \dots, w_{2k}) = (w_1, \dots, w_k, \llbracket T \rrbracket(w_1, \dots, w_k))$ holds only if $\llbracket T \rrbracket(w_1, \dots, w_k)$ is defined and $w_{k+1} = \dots = w_{2k} = \varepsilon$ holds. Since the function f is injective and computable, we can construct a $2k$ -tape reversible Turing machine T_f such that $\llbracket T_f \rrbracket = f$ by Theorem 15.

Let us define a $2k$ -tape Turing machine $T' = T_f^{-1} \circ T_{\text{copy}(k)} \circ T_f$ where $T_{\text{copy}(k)}$ is a $2k$ -tape idempotent Turing machine introduced in Example 7. Since T' is idempotent because of Lemma 19, it suffices to show $\llbracket T' \rrbracket = \llbracket T \rrbracket$, i.e., $\llbracket T' \rrbracket(w_1, \dots, w_k, \underbrace{\varepsilon, \dots, \varepsilon}_k) = (\llbracket T \rrbracket(w_1, \dots, w_k), \underbrace{\varepsilon, \dots, \varepsilon}_k)$. This can be shown by

$$\begin{aligned}
\llbracket T' \rrbracket(w_1, \dots, w_k, \varepsilon, \dots, \varepsilon) &= \{ \text{by the definition of } T' \text{ and Proposition 10} \} \\
&\quad \llbracket T_f^{-1} \rrbracket(\llbracket T_{\text{copy}(k)} \rrbracket(\llbracket T_f \rrbracket(w_1, \dots, w_k, \varepsilon, \dots, \varepsilon))) \\
&= \{ \text{by the definition of } T_f \text{ and Proposition 14} \} \\
&\quad \llbracket T_f \rrbracket^{-1}(\llbracket T_{\text{copy}(k)} \rrbracket(w_1, \dots, w_k, \llbracket T \rrbracket(w_1, \dots, w_k))) \\
&= \{ \text{by the definition of } T_{\text{copy}(k)} \} \\
&\quad \llbracket T_f \rrbracket^{-1}(\llbracket T \rrbracket(w_1, \dots, w_k), \llbracket T \rrbracket(w_1, \dots, w_k)) \\
&= \{ \text{by the idempotence of } \llbracket T \rrbracket \} \\
&\quad \llbracket T_f \rrbracket^{-1}(\llbracket T \rrbracket(w_1, \dots, w_k), \llbracket T \rrbracket(\llbracket T \rrbracket(w_1, \dots, w_k))) \\
&= \{ \text{by the semantics of } T_f \text{ and its injectivity} \} \\
&\quad (\llbracket T \rrbracket(w_1, \dots, w_k), \varepsilon, \dots, \varepsilon). \quad \blacktriangleleft
\end{aligned}$$

► **Lemma 22.** *There exists a 1-tape idempotent Turing machine T_{blur} computing the idempotent function $f_{\text{blur}} : \Sigma_{\$}^* \rightarrow \Sigma_{\* , which satisfies $f_{\text{blur}}(\varepsilon) = \varepsilon$ and $f_{\text{blur}}(s_1 s_2 w) = s_1 s_1 f_{\text{blur}}(w)$ for any $s_1, s_2 \in \Sigma_{\$}$ and $w \in \Sigma_{\* .*

Proof. Let $T = (Q, \Sigma_{\$}, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a 1-tape Turing machine where

$$\begin{aligned}
Q &= \{q_{\text{ini}}, q_{\text{mov}}, q_{\text{read}}, q_{\text{back}}, q_{\text{pick}}, q_{\text{fin}}\} \cup \bigcup_{s \in \Sigma_{\$}} \{q_{\text{mem}(s)}, q_{\text{write}(s)}, q_{\text{keep}(s)}, q_{\text{check}(s)}\} \\
\Delta &= \{(q_{\text{ini}}, \sqcup \rightarrow \sqcup, q_{\text{mov}}), (q_{\text{mov}}, \rightarrow, q_{\text{read}}), (q_{\text{pick}}, \sqcup \rightarrow \sqcup, q_{\text{fin}}), (q_{\text{back}}, \leftarrow, q_{\text{pick}}), (q_{\text{read}}, \sqcup \rightarrow \sqcup, q_{\text{back}})\} \cup \\
&\quad \{(q_{\text{read}}, s \rightarrow s, q_{\text{mem}(s)}) \mid s \in \Sigma_{\$}\} \cup \{(q_{\text{mem}(s)}, \rightarrow, q_{\text{write}(s)}) \mid s \in \Sigma_{\$}\} \cup \\
&\quad \{(q_{\text{write}(s)}, s' \rightarrow s, q_{\text{mov}}) \mid s, s' \in \Sigma_{\$}\} \cup \{(q_{\text{pick}}, s \rightarrow s, q_{\text{keep}(s)}) \mid s \in \Sigma_{\$}\} \cup \\
&\quad \{(q_{\text{keep}(s)}, \leftarrow, q_{\text{check}(s)}) \mid s \in \Sigma_{\$}\} \cup \{(q_{\text{check}(s)}, s \rightarrow s, q_{\text{back}}) \mid s \in \Sigma_{\$}\}.
\end{aligned}$$

79:16 Idempotent Turing Machines

Then T is found to be idempotent by the set $Q' \subset Q$ of rear states and the rear state map ψ defined as

$$Q' = \{q_{\text{fin}}, q_{\text{pick}}, q_{\text{back}}\} \cup \bigcup_{s \in \Sigma_{\S}} \{q_{\text{check}(s)}, q_{\text{keep}(s)}\}$$

$$\psi = \{q_{\text{fin}} \mapsto q_{\text{ini}}, q_{\text{pick}} \mapsto q_{\text{mov}}, q_{\text{back}} \mapsto q_{\text{read}}\} \cup \bigcup_{s \in \Sigma_{\S}} \{q_{\text{check}(s)} \mapsto q_{\text{mem}(s)}, q_{\text{keep}(s)} \mapsto q_{\text{write}(s)}\}$$

since the four conditions obviously hold. We can check that T computes the function f_{blur} in the statement as follows. Firstly the relation

$$(q_{\text{read}}, \langle \varepsilon, s, ws'w' \rangle) \vdash^* (q_{\text{read}}, \langle \overleftarrow{f_{\text{blur}}(sw)}, s', w' \rangle)$$

holds for any $s, s' \in \Sigma_{\S}$ and $w, w' \in \Sigma_{\S}^*$ where the length of w is odd and \overleftarrow{x} denotes the reversed string of x , which can be proved by induction on the length of w . Moreover the relation

$$(q_{\text{back}}, \langle \overleftarrow{sw}, s', w' \rangle) \vdash^* (q_{\text{back}}, \langle \varepsilon, s, ws'w' \rangle)$$

holds for any $s, s' \in \Sigma_{\S}$ and $w, w' \in \Sigma_{\S}^*$ where the length of w and w' are odd and the strings sw and $s'w'$ are in the domain of f_{blur} , i.e., every even-numbered symbol in them is the same as the previous symbol. This can also be proved by induction on the length of w . Then, we have the relation

$$(q_{\text{ini}}, \langle \varepsilon, \sqcup, w \rangle) \vdash^* (q_{\text{fin}}, \langle \varepsilon, \sqcup, f_{\text{blur}}(w) \rangle)$$

whenever the length of w is even, which indicates that T computes f_{blur} . ◀

► **Theorem 23** (Robustness of idempotent Turing machines). *Let $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a k -tape idempotent Turing machine. Then there exists a 1-tape idempotent Turing machine T' such that $\llbracket T \rrbracket(w_1, \dots, w_k) = (v_1, \dots, v_k)$ if and only if $\llbracket T' \rrbracket(\text{enc}(w_1, \dots, w_k)) = \text{enc}(v_1, \dots, v_k)$.*

Proof. Let $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a k -tape idempotent Turing machine. Consider a function $f : \Sigma_{\S}^* \rightarrow \Sigma_{\S}^*$ satisfying

$$f(\text{enc}(w_1, \dots, w_k)) = \text{enc}(\text{enc}(\llbracket T \rrbracket(w_1, \dots, w_k)), \text{enc}(w_1, \dots, w_k))$$

for any $w_1, \dots, w_n \in \Sigma^*$ only if $\llbracket T \rrbracket(w_1, \dots, w_k)$ is defined. Since the function f is injective and computable, we can construct a 1-tape Turing machine T_f such that $\llbracket T_f \rrbracket = f$ by Theorem 15.

Let us define a 1-tape Turing machine $T' = T_f^{-1} \circ T_{\text{blur}} \circ T_f$ where the idempotent Turing machine T_{blur} is given by Lemma 22. Note that

$$f_{\text{blur}}(\text{enc}(x, y)) = \text{enc}(x, x) \tag{1}$$

holds for any $x, y \in \Sigma_{\S}^*$. Since T' is idempotent because of Lemma 19, it suffices to show T' simulates T under encoding with enc . This can be shown by

$$\begin{aligned} \llbracket T' \rrbracket(\text{enc}(w_1, \dots, w_k)) &= \{ \text{by the definition of } T' \text{ and Proposition 10} \} \\ &\llbracket T_f^{-1} \rrbracket(\llbracket T_{\text{blur}} \rrbracket(\llbracket T_f \rrbracket(\text{enc}(w_1, \dots, w_k)))) \end{aligned}$$

$$\begin{aligned}
&= \{ \text{by the semantics of } T_f \text{ and Proposition 14} \} \\
&\quad \llbracket T_f \rrbracket^{-1}(\llbracket T_{blur} \rrbracket(\text{enc}(\text{enc}(\llbracket T \rrbracket(w_1, \dots, w_k))), \text{enc}(w_1, \dots, w_k))) \\
&= \{ \text{by the semantics of } T_{blur} \text{ with Equation (1)} \} \\
&\quad \llbracket T_f \rrbracket^{-1}(\text{enc}(\text{enc}(\llbracket T \rrbracket(w_1, \dots, w_k))), \text{enc}(\llbracket T \rrbracket(w_1, \dots, w_k))) \\
&= \{ \text{by the idempotence of } T \text{ and Theorem 17} \} \\
&\quad \llbracket T_f \rrbracket^{-1}(\text{enc}(\text{enc}(\llbracket T \rrbracket(\llbracket T \rrbracket(w_1, \dots, w_k))), \text{enc}(\llbracket T \rrbracket(w_1, \dots, w_k)))) \\
&= \{ \text{by the injectivity of } f \text{ and the semantics of } f^{-1} \} \\
&\quad \text{enc}(\llbracket T \rrbracket(w_1, \dots, w_k)).
\end{aligned}$$

◀

► **Proposition 26** (Bennett's trick [3]). *Let T be a k -tape Turing machine. There exists a $(2k + 1)$ -tape reversible Turing machine $\text{Ben}_k(T)$ such that $\llbracket \text{Ben}_k(T) \rrbracket(w_1, \dots, w_k, \underbrace{\varepsilon, \dots, \varepsilon}_{k+1}) =$*

$(w_1, \dots, w_k, \llbracket T \rrbracket(w_1, \dots, w_k), \varepsilon)$ for any input w_1, \dots, w_k of T .

Proof. Let $T = (Q, \Sigma, q_{\text{ini}}, q_{\text{fin}}, \Delta)$ be a k -tape Turing machine. Firstly, by Landauer embedding [10], we can construct a $(k + 1)$ -tape Turing machine T_L such that

$$\llbracket T_L \rrbracket(w_1, \dots, w_k, \varepsilon) = (\llbracket T \rrbracket(w_1, \dots, w_k), \text{trace}(T, w_1, \dots, w_k))$$

where the function *trace* encodes the history of applied transition rules on the run into Σ^* . Since the history tells the previous configuration for each step, the Turing machine T_L is backward deterministic, that is, reversible. We extend T_L with k extra tapes in between working tapes and the history tape where the extra tapes are never touched during computation. Let T'_L be the $(2k + 1)$ -reversible Turing machine obtained by the extension. Then we have

$$\llbracket T'_L \rrbracket(w_1, \dots, w_k, v_1, \dots, v_k, \varepsilon) = (\llbracket T \rrbracket(w_1, \dots, w_k), v_1, \dots, v_k, \text{trace}(T, w_1, \dots, w_k))$$

for $w_1, \dots, w_k, v_1, \dots, v_k \in \Sigma^*$. In addition, we similarly extend the $2k$ -tape Turing machine $T_{\text{dup}(k)}$ with one extra tape to obtain $(2k + 1)$ -tape Turing machine $T'_{\text{dup}(k)}$ such that

$$\llbracket T'_{\text{dup}(k)} \rrbracket(w_1, \dots, w_k, \underbrace{\varepsilon, \dots, \varepsilon}_k, v) = (w_1, \dots, w_k, w_1, \dots, w_k, v)$$

holds for $w_1, \dots, w_k, v \in \Sigma^*$.

Let us define the $(2k + 1)$ -tape Turing machine $\text{Ben}_k(T) = T'^{-1}_L \circ T'_{\text{dup}(k)} \circ T'_L$ which is reversible because so are all constituents. Because of the domain of $T_{\text{dup}(k)}$ and the semantics of T'_L , the input of the Turing machine $\text{Ben}_k(T)$ is restricted to $(2k + 1)$ -tuples of strings whose $(k + 1)$ -th through $2k + 1$ -th strings are the empty string. Therefore the equation in the statement can be checked by

$$\begin{aligned}
&\llbracket \text{Ben}_k(T) \rrbracket(w_1, \dots, w_k, \underbrace{\varepsilon, \dots, \varepsilon}_k, \varepsilon) \\
&= \{ \text{by the definition of } \text{Ben}_k(T) \text{ and Proposition 10} \} \\
&\quad \llbracket T'^{-1}_L \rrbracket(\llbracket T'_{\text{dup}(k)} \rrbracket(\llbracket T'_L \rrbracket(w_1, \dots, w_k, \underbrace{\varepsilon, \dots, \varepsilon}_k, \varepsilon))) \\
&= \{ \text{by the semantics of } T'_L \text{ and Proposition 14} \} \\
&\quad \llbracket T'_L \rrbracket^{-1}(\llbracket T'_{\text{dup}(k)} \rrbracket(\llbracket T \rrbracket(w_1, \dots, w_k), \underbrace{\varepsilon, \dots, \varepsilon}_k, \text{trace}(T, w_1, \dots, w_k))))
\end{aligned}$$

79:18 Idempotent Turing Machines

$$\begin{aligned}
&= \{ \text{by the semantics of } T'_{dup(k)} \} \\
&\quad \llbracket T'_L \rrbracket^{-1}(\llbracket T \rrbracket(w_1, \dots, w_k), \llbracket T \rrbracket(w_1, \dots, w_k), \text{trace}(T, w_1, \dots, w_k)) \\
&= \{ \text{by the inverse of the semantics of } T'_L \} \\
&\quad (w_1, \dots, w_k, \llbracket T \rrbracket(w_1, \dots, w_k), \varepsilon). \quad \blacktriangleleft
\end{aligned}$$

► **Theorem 27** (IdTM-universal Turing machine constructed with Bennett's trick). *Let U be a (2-tape) classically universal Turing machine, i.e., $\llbracket U \rrbracket(\ulcorner T \urcorner, w) = (\ulcorner T \urcorner, \llbracket T \rrbracket(w))$ for any Turing machine T and its input w . Then a 5-tape idempotent Turing machine $U' = \text{Ben}_2(U)^{-1} \circ T'_{copy(2)} \circ \text{Ben}_2(U)$ is IdTM-universal where $T'_{copy(2)}$ is obtained by adding one extra tape as the fifth tape to $T_{copy(2)}$, i.e., $\llbracket T'_{copy(2)} \rrbracket(w_1, w_2, w_3, w_4, w_5) = (w_3, w_4, w_3, w_4, w_5)$.*

Proof. Let U be a 2-tape classically universal Turing machine such that $\llbracket U \rrbracket(\ulcorner T \urcorner, w) = (\ulcorner T \urcorner, \llbracket T \rrbracket(w))$ for any Turing machine T and its input w . Note that the Turing machine $U' = \text{Ben}_2(U)^{-1} \circ T'_{copy(2)} \circ \text{Ben}_2(U)$ is idempotent due to Lemma 19. We shall show the 5-tape idempotent Turing machine U' is IdTM-universal, that is, $\llbracket U' \rrbracket(\ulcorner T \urcorner, w, \varepsilon, \varepsilon, \varepsilon) = (\ulcorner T \urcorner, \llbracket T \rrbracket(w), \varepsilon, \varepsilon, \varepsilon)$ holds for any Turing machine T and its input w . Because of the domain of $\text{Ben}_2(U)$, the input of the Turing machine U' is restricted to 5-tuples whose third through fifth are the empty string. Therefore, the statement can be verified by

$$\begin{aligned}
\llbracket U' \rrbracket(\ulcorner T \urcorner, w, \varepsilon, \varepsilon, \varepsilon) &= \{ \text{by the definition of } U' \text{ and Proposition 10} \} \\
&\quad \llbracket \text{Ben}_2(U)^{-1} \rrbracket(\llbracket T'_{copy(2)} \rrbracket(\llbracket \text{Ben}_2(U) \rrbracket(\ulcorner T \urcorner, w, \varepsilon, \varepsilon, \varepsilon))) \\
&= \{ \text{by the semantics of } \text{Ben}_2(U) \text{ and } U \} \\
&\quad \llbracket \text{Ben}_2(U)^{-1} \rrbracket(\llbracket T'_{copy(2)} \rrbracket(\ulcorner T \urcorner, w, \ulcorner T \urcorner, \llbracket T \rrbracket(w), \varepsilon)) \\
&= \{ \text{by the semantics of } T'_{copy(2)} \} \\
&\quad \llbracket \text{Ben}_2(U)^{-1} \rrbracket(\ulcorner T \urcorner, \llbracket T \rrbracket(w), \ulcorner T \urcorner, \llbracket T \rrbracket(w), \varepsilon) \\
&= \{ \text{by the idempotence of } T \text{ and Theorem 17} \} \\
&\quad \llbracket \text{Ben}_2(U)^{-1} \rrbracket(\ulcorner T \urcorner, \llbracket T \rrbracket(w), \ulcorner T \urcorner, \llbracket T \rrbracket(\llbracket T \rrbracket(w)), \varepsilon) \\
&= \{ \text{by the inverse of the semantics of } \text{Ben}_2(U) \} \\
&\quad (\ulcorner T \urcorner, \llbracket T \rrbracket(w), \varepsilon, \varepsilon, \varepsilon). \quad \blacktriangleleft
\end{aligned}$$

Abstract

We initiate the study of effective pointwise ergodic theorems in resource-bounded settings. Classically, the convergence of the ergodic averages for integrable functions can be arbitrarily slow [14]. In contrast, we show that for a class of PSPACE L^1 functions, and a class of PSPACE computable measure-preserving ergodic transformations, the ergodic average exists and is equal to the space average on every EXP random. We establish a partial converse that PSPACE non-randomness can be characterized as non-convergence of ergodic averages. Further, we prove that there is a class of resource-bounded randoms, *viz.* SUBEXP-space randoms, on which the corresponding ergodic theorem has an exact converse - a point x is SUBEXP-space random if and only if the corresponding effective ergodic theorem holds for x .

1 Introduction

In Kolmogorov’s program to found information theory on the theory of algorithms, we investigate whether individual “random” objects obey probabilistic laws, *i.e.*, properties which hold in sample spaces with probability 1. Indeed, a vast and growing literature establishes that *every* Martin-Löf random sequence (see for example, [4] or [19]) obeys the Strong Law of Large Numbers [24], the Law of Iterated Logarithm [25], and surprisingly, the Birkhoff Ergodic Theorem [26, 17, 10, 1] and the Shannon-McMillan-Breiman theorem [8, 9, 21]. In effective settings, the theorem for Martin-Löf random points implies the classical theorem since the set of Martin-Löf randoms has Lebesgue measure 1, and hence is stronger.

In this work, we initiate the study of ergodic theorems in resource-bounded settings. This is a difficult problem, since classically, the convergence speed in ergodic theorems is known to be arbitrarily slow (e.g. see Bishop [3], Krengel [14], and V’yugin [26]). However, we establish ergodic theorems in resource-bounded settings which hold on every resource-bounded random object of a particular class. The main technical hurdle we overcome is the lack of sharp tail bounds. The only general tail bound in ergodic settings is the maximal ergodic inequality. This yields only an inverse linear bound in the error bound, in contrast to the inverse exponential bounds in the Chernoff and the Azuma-Hoeffding inequalities.

We first establish an unconditional result. – For the entire class of PSPACE L^1 functions on Bernoulli systems, the ergodic average exists and is equal to the space average on all EXP randoms. We utilize a non-trivial connection with the theory of uniform distribution of sequences modulo 1 [15, 16, 20, 18] to prove this result.

In the general case, rapid L^1 convergence of subsequences of ergodic averages suffices to establish the same consequence that the ergodic average exists and is equal to the space average on all EXP randoms. In general, such assumptions are unavoidable since an adaptation of V’yugin’s counterexample [26] shows that there are PSPACE computable ergodic Markov systems where the convergence rate to the ergodic average is not even computable.

Conversely, we ask whether we can characterize non-randomness using the failure of the PSPACE ergodic theorem. Franklin and Towsner [5] show that for every non-Martin-Löf random x , there is an effective ergodic system where the ergodic average at x does not converge to the space average. We first show that our PSPACE effective ergodic theorem admits a partial converse of this form. PSPACE non-randoms can be characterized as points where the PSPACE ergodic theorem fails.

We know that the set of EXP randoms is a subset of the set of PSPACE randoms. Since the forward direction holds on the smaller set of randoms, it is important to know whether there is a class of resource-bounded randoms on which an effective ergodic theorem holds with an exact converse. We show that the class of SUBEXP-space randoms is one such. We summarize our results in Table 1.

The proofs of these results are adapted from the techniques of Rute [21], Ko [13], Galatolo, Hoyrup & Rojas [7, 11], and Huang & Stull [12].¹ Our proofs involve several new quantitative estimates, which may of general interest.

■ **Table 1** Summary of the results involving PSPACE/SUBEXP-space systems.

Class of functions	Convergence of ergodic averages (Theorems)	
	$\forall f(A_n^f \rightarrow \int f d\mu)$	$\exists f(A_n^f \not\rightarrow \int f d\mu)$
PSPACE L^1	EXP randoms (6.2)	PSPACE nonrandoms (7.1)
SUBEXP-space L^1	SUBEXP-space randoms (8.11)	SUBEXP-space nonrandoms (8.12)

2 Preliminaries

Let $\Sigma = \{0, 1\}$ be the binary alphabet. Denote the set of all finite binary strings by Σ^* and the set of infinite binary strings by Σ^∞ . For $\sigma \in \Sigma^*$ and $y \in \Sigma^* \cup \Sigma^\infty$, we write $\sigma \sqsubseteq y$ if σ is a prefix of y . For any infinite string y and any finite string σ , $\sigma[n]$ and $y[n]$ denotes the character at the n^{th} position in y and σ respectively. For any infinite string y and any finite string σ , $\sigma[n, m]$ and $y[n, m]$ represents the strings $\sigma[n]\sigma[n + 1] \dots \sigma[m]$ and $y[n]y[n + 1] \dots y[m]$ respectively. We denote finite strings using small Greek letters like σ , α etc. The length of a finite binary string σ is denoted by $|\sigma|$.

¹ There are alternative approaches to the proof in Martin-Löf settings, like that of V’yugin [26]. However, the tool he uses for establishing the result is a lower semicomputable test defined on infinite sequences - this is difficult to adapt to resource-bounded settings requiring the output value within bounded time or space. Moreover, the functions in V’yugin’s approach are continuous. We consider the larger class of L^1 functions, which can be discontinuous in general.

For $\sigma \in \Sigma^*$, the *cylinder* $[\sigma]$ is the set of all infinite sequences with σ as a prefix. χ_σ denotes the characteristic function of $[\sigma]$. For any set of strings $S \subseteq \Sigma^*$, $[S]$ is the union of $[\sigma]$ over all $\sigma \in S$. Extending the notation, χ_S denotes the characteristic function of $[S]$. The Borel σ -algebra generated by the set of all cylinders is denoted by $\mathcal{B}(\Sigma^\infty)$.

Unless specified otherwise, any $n \in \mathbb{N}$ is represented in the binary alphabet. As is typical in resource-bounded settings, some integer parameters are represented in unary. The set of unary strings is represented as 1^* , and the representation of $n \in \mathbb{N}$ in unary is 1^n , a string consisting of n ones. For any $n_1, n_2 \in \mathbb{N}$, $[n_1, n_2]$ represents the set $\{n \in \mathbb{N} : n_1 \leq n \leq n_2\}$.

Throughout the paper we take into account the number of cells used in the output tape and the working tape when calculating the space complexity of functions. We assume a finite representation for the set of rational numbers \mathbb{Q} satisfying the following: there exists a $c \in \mathbb{N}$ such that if $r \in \mathbb{Q}$ has a representation of length l then $r \leq 2^{lc}$. Following the works of Hoyrup, and Rojas [11], we introduce the notion of a PSPACE-probability Cantor space by endowing the Cantor space with a PSPACE-computable probability measure.

► **Definition 2.1.** *Consider the Cantor space $(\Sigma^\infty, \mathcal{B}(\Sigma^\infty))$. A Borel probability measure $\mu : \mathcal{B}(\Sigma^\infty) \rightarrow [0, 1]$, is a PSPACE-probability measure if there is a PSPACE machine $M : \Sigma^* \times 1^* \rightarrow \mathbb{Q}$ such that for every $\sigma \in \Sigma^*$, and $n \in \mathbb{N}$, we have that $|M(\sigma, 1^n) - \mu([\sigma])| \leq 2^{-n}$.*

In order to define PSPACE (EXP) randomness using PSPACE (EXP) tests we require the following method for approximating sequences of open sets in Σ^∞ in polynomial space (exponential time).

► **Definition 2.2** (PSPACE/EXP sequence of open sets [12]). *A sequence of open sets $\langle U_n \rangle_{n=1}^\infty$ is a PSPACE sequence of open sets if there exists a sequence of sets $\langle S_n^k \rangle_{k,n \in \mathbb{N}}$ where $S_n^k \subseteq \Sigma^*$ such that*

1. $U_n = \bigcup_{k=1}^\infty [S_n^k]$, where for any $m > 0$, $\mu(U_n - \bigcup_{k=1}^m [S_n^k]) \leq 2^{-m}$.
2. There exists a controlling polynomial p such that $\max\{|\sigma| : \sigma \in \bigcup_{k=1}^m S_n^k\} \leq p(n+m)$.
3. The function $g : \Sigma^* \times 1^* \times 1^* \rightarrow \{0, 1\}$ such that $g(\sigma, 1^n, 1^m) = 1$ if $\sigma \in S_n^m$, and 0 otherwise, is decidable by a PSPACE machine.

The definition of EXP sequence of open sets is similar but the bound in condition 2 is replaced with $2^{p(n+m)}$ and the machine in condition 3 is an EXP-time machine.

Henceforth, we study the notion of resource bounded randomness on (Σ^∞, μ) .

► **Definition 2.3** (PSPACE/EXP randomness [23]). *A sequence of open sets $\langle U_n \rangle_{n=1}^\infty$ is a PSPACE test if it is a PSPACE sequence of open sets and for all $n \in \mathbb{N}$, $\mu(U_n) \leq 2^{-n}$.*

A set $A \subseteq \Sigma^\infty$ is PSPACE null or PSPACE non-random if there is a PSPACE test $\langle U_n \rangle_{n=1}^\infty$ such that $A \subseteq \bigcap_{n=1}^\infty U_n$, and is PSPACE random otherwise. The EXP analogues of the above concepts are defined similarly except that $\langle U_n \rangle_{n=1}^\infty$ is an EXP sequence of open sets.

By considering the sequence $\langle \bigcup_{i=1}^k S_n^i \rangle_{k,n \in \mathbb{N}}$ instead of $\langle S_n^k \rangle_{k,n \in \mathbb{N}}$, without loss of generality, we can assume that for each n , $\langle S_n^k \rangle_{k=1}^\infty$ is an increasing sequence of sets. Since every PSPACE test is an EXP test, every EXP random is PSPACE random.

In order to establish our ergodic theorem, it is convenient to define a PSPACE version of Solovay tests, where the relaxation is that the measures of the sets U_n can be any sufficiently fast convergent sequence. We later show that this captures the same set of randoms as PSPACE tests.

► **Definition 2.4** (PSPACE Solovay test). *A sequence of open sets $\langle U_n \rangle_{n=1}^\infty$ is a PSPACE Solovay test if it is a PSPACE sequence of open sets and there is a polynomial p such that $\sum_{n=p(m)+1}^\infty \mu(U_n) \leq 2^{-m}$ for all $m \in \mathbb{N} \setminus \{0\}$.² A set $A \subseteq \Sigma^\infty$ is PSPACE Solovay null or PSPACE Solovay non-random if there exists a PSPACE Solovay test $\langle U_n \rangle_{n=1}^\infty$ such that $A \subseteq \bigcap_{i=1}^\infty \bigcup_{n=i}^\infty U_n$, and is PSPACE Solovay random otherwise.*

► **Theorem 2.5.** *A set $A \subseteq \Sigma^\infty$ is PSPACE null if and only if A is PSPACE Solovay null.*

The set of PSPACE Solovay randoms and PSPACE randoms are equal, hence to prove PSPACE randomness results, it suffices to form Solovay tests.

3 PSPACE L^1 computability

The resource-bounded ergodic theorems in our work hold for PSPACE- L^1 functions, the PSPACE analogue of integrable functions. In this section, we briefly recall standard definitions for PSPACE computable L^1 functions and measure-preserving transformations. The justifications and proofs of equivalences of various notions are present in Stull's thesis [22] and [23]. We initially define PSPACE sequence of simple functions, and define PSPACE integrable functions based on approximations using these functions.

► **Definition 3.1** (PSPACE sequence of simple functions [23]). *A sequence of simple functions $\langle f_n \rangle_{n=1}^\infty$, where each $f_n : \Sigma^\infty \rightarrow \mathbb{Q}$, is a PSPACE sequence of simple functions if*

1. *There is a controlling polynomial p such that for each n , there exists $k(n) \in \mathbb{N}$, $\{d_1, d_2, \dots, d_{k(n)}\} \subseteq \mathbb{Q}$ and $\{\sigma_1, \sigma_2, \dots, \sigma_{k(n)}\} \subseteq \Sigma^{p(n)}$ satisfying $f_n = \sum_{i=1}^{k(n)} d_i \chi_{\sigma_i}$.*
2. *There is a PSPACE machine M such that for each $n \in \mathbb{N}$, and $\sigma \in \Sigma^*$, $M(1^n, \sigma)$ outputs $f_n(\sigma 0^\infty)$ if $|\sigma| \geq p(n)$ and ? otherwise.*

Note that since M is a PSPACE machine, $\{d_1, d_2 \dots d_{k(n)}\}$ is a set of PSPACE representable numbers. Now, we define PSPACE L^1 -computable functions in terms of limits of convergent PSPACE sequence of simple functions.

► **Definition 3.2** (PSPACE L^1 -computable functions [23]). *A function $f \in L^1(\Sigma^\infty, \mu)$ is PSPACE L^1 -computable if there exists a PSPACE sequence of simple functions $\langle f_n \rangle_{n=1}^\infty$ such that for every $n \in \mathbb{N}$, $\|f - f_n\| \leq 2^{-n}$. The sequence $\langle f_n \rangle_{n=1}^\infty$ is called a PSPACE L^1 -approximation of f .*

A sequence of L^1 functions $\langle f_n \rangle_{n=1}^\infty$ converging to f in the L^1 -norm need not have pointwise limits. Hence the following concept ([21]) is important in studying the pointwise ergodic theorem in the setting of L^1 -computability

► **Definition 3.3** (\tilde{f} for PSPACE L^1 -computable f). *Let $f \in L^1(\Sigma^\infty, \mu)$ be PSPACE L^1 -computable and with a PSPACE L^1 approximation $\langle f_n \rangle_{n=1}^\infty$. Define $\tilde{f} : \Sigma^\infty \rightarrow \mathbb{R} \cup \{\text{undefined}\}$ by $\tilde{f}(x) = \lim_{n \rightarrow \infty} f_n(x)$ if this limit exists, and is undefined otherwise.³*

To define ergodic averages, we restrict ourselves to the following class of transformations.

² This implies that $\sum_{n=1}^\infty \mu(U_n) < \infty$.

³ The definition of \tilde{f} is dependent on the choice of the approximating sequence $\langle f_n \rangle_{n=1}^\infty$. However, due to Lemma 4.3, we use \tilde{f} in a sequence independent manner.

► **Definition 3.4** (PSPACE simple transformation). *A measurable function $T : (\Sigma^\infty, \mu) \rightarrow (\Sigma^\infty, \mu)$ is a PSPACE simple transformation if there is a controlling constant c and a PSPACE machine M such that for any $\sigma \in \Sigma^*$, $T^{-1}([\sigma]) = \cup_{i=1}^{k(\sigma)} [\sigma_i]$ where the following properties hold.*

1. $\{\sigma_i\}_{i=1}^{k(\sigma)}$ is a prefix free set and for all $1 \leq i \leq k(\sigma)$, $|\sigma_i| \leq |\sigma| + c$
2. For each $\sigma, \alpha \in \Sigma^*$,

$$M(\sigma, \alpha) = \begin{cases} 1 & \text{if } |\alpha| \geq |\sigma| + c \text{ and } \alpha 0^\infty \in T^{-1}([\sigma]) \\ 0 & \text{if } |\alpha| \geq |\sigma| + c \text{ and } \alpha 0^\infty \notin T^{-1}([\sigma]) \\ ? & \text{otherwise} \end{cases}$$

PSPACE computability as defined above, relates naturally to convergence of L^1 norms. But the pointwise ergodic theorem deals with almost everywhere convergence, and its resource-bounded versions deal with convergence on every random point. We introduce the modes of convergence we deal with in the present work.

► **Definition 3.5** (PSPACE-rapid limit point). *A real number a is a PSPACE-rapid limit point of the real number sequence $\langle a_n \rangle_{n=1}^\infty$ if there exists a polynomial p such that for all $m \in \mathbb{N}$, $\exists k \leq 2^{p(m)}$ such that $|a_k - a| \leq 2^{-m}$.*

Note that this requires rapid convergence only on a subsequence, which may not be a computable subsequence of the full sequence. The following definition is the L^1 version of the above.

► **Definition 3.6** (PSPACE-rapid L^1 -limit point). *A function $f \in L^1(\Sigma^\infty, \mu)$ is a PSPACE-rapid L^1 -limit point of a sequence $\langle f_n \rangle_{n=1}^\infty$ of functions in $L^1(\Sigma^\infty, \mu)$ if 0 is a PSPACE-rapid limit point of $\|f_n - f\|_1$.*

Now we define PSPACE analogue of almost everywhere convergence ([21]).

► **Definition 3.7** (PSPACE-rapid almost everywhere convergence). *A sequence of measurable functions $\langle f_n \rangle_{n=1}^\infty$ is PSPACE-rapid almost everywhere convergent to a measurable function f if there exists a polynomial p such that for all m_1 and m_2 ,*

$$\mu \left(\left\{ x : \sup_{n \geq 2^{p(m_1+m_2)}} |f_n(x) - f(x)| \geq 2^{-m_1} \right\} \right) \leq 2^{-m_2}.$$

Notation. Let $A_n^{f,T} = \frac{f + f \circ T + f \circ T^2 + \dots + f \circ T^{n-1}}{n}$ denote the n^{th} Birkhoff average for any function f and transformation T . We prove the ergodic theorem in measure preserving systems where $\int f d\mu$ is a PSPACE-rapid L^1 -limit point of $A_n^{f,T}$. In the rest of the paper we denote $A_n^{f,T}$ simply by A_n^f . The transformation T involved in the Birkhoff sum is implicit.

PSPACE rapidity of A_n^f is a stronger version of \ln^2 -ergodicity introduced in [6].

► **Lemma 3.8.** *Let $T : \Sigma^\infty \rightarrow \Sigma^\infty$ be any measurable transformation and $f \in L^\infty(\Sigma^\infty, \mu)$. $\int f d\mu$ is a PSPACE-rapid L^1 -limit point of A_n^f if and only if there exists $c > 0$ and $k \in \mathbb{N}$ such that for all $n > 0$,*

$$\left| \frac{1}{n} \sum_{i=0}^{n-1} \int f \circ T^i \cdot f - \left(\int f \right)^2 d\mu \right| \leq \frac{c}{2^{(\ln n)^{\frac{1}{k}}}}.$$

4 PSPACE-rapid almost everywhere convergence of ergodic averages

We present PSPACE versions of Theorem 2 and Proposition 5 from [7], relating the L^1 convergence of A_n^f to $\int f$ to its almost everywhere convergence. The main estimate which we require in this section is the maximal ergodic inequality, which we now recall.

► **Lemma 4.1** (Maximal ergodic inequality [2]). *If $f \in L^1(\Sigma^\infty, \mu)$ and $\delta > 0$ then $\mu(\{x : \sup_{n \geq 1} |A_n^f(x)| > \delta\}) \leq (\|f\|_1)\delta^{-1}$.*

Using this lemma, we now prove the almost everywhere convergence of ergodic averages.

► **Theorem 4.2.** *Let f be any function in $L^1(\Sigma^\infty, \mu)$ and let T be a measure preserving transformation. If $\int f d\mu$ is a PSPACE-rapid L^1 -limit point of A_n^f then A_n^f is PSPACE-rapid almost everywhere convergent to $\int f d\mu$.*

If $f \in L^\infty$, the converse of Theorem 4.2 can be easily obtained by expanding $\|A_n^f - \int f d\mu\|_1$.

Now, we prove some auxiliary results that are useful in the proof of the PSPACE ergodic theorem. The following fact was shown in [12]. However, for our ergodic theorem we require an alternate proof of this fact using techniques from [21].

► **Lemma 4.3.** *Let $\langle f_n \rangle_{n=1}^\infty, \langle g_n \rangle_{n=1}^\infty$ be PSPACE sequence of simple functions which converges PSPACE-rapid almost everywhere to $f \in L^1(\Sigma^\infty, \mu)$. Then, for all EXP random x , $\lim_{n \rightarrow \infty} f_n(x)$ and $\lim_{n \rightarrow \infty} g_n(x)$ exist, and are equal.*

The following immediately follows from the above lemma.

► **Corollary 4.4.** *Let $f \in L^1(\Sigma^\infty, \mu)$ be a PSPACE L^1 -computable function with L^1 approximating PSPACE sequences of simple functions $\langle f_n \rangle_{n=1}^\infty$ and $\langle g_n \rangle_{n=1}^\infty$. Then, for all EXP random x $\lim_{n \rightarrow \infty} f_n(x)$ and $\lim_{n \rightarrow \infty} g_n(x)$ exist, and are equal.*

The following properties satisfied by PSPACE simple transformations and PSPACE L^1 -computable functions are useful in our proof of the PSPACE ergodic theorem.

► **Lemma 4.5.** *Let f be a PSPACE L^1 -computable function over the Bernoulli space. Let $I_f : \Sigma^\infty \rightarrow \Sigma^\infty$ be the constant function taking the value $\int f d\mu$ over all $x \in \Sigma^\infty$. Then, I_f is PSPACE L^1 -computable and $I_f(x) = \int f d\mu$ for all EXP random x .*

► **Lemma 4.6.** *Let f be a PSPACE L^1 -computable function with an L^1 approximating PSPACE sequence of simple functions $\langle f_n \rangle_{n=1}^\infty$. Let T be a PSPACE simple transformation and p be a polynomial. Then, $\langle A_n^{f_{p(n)}} \rangle_{n=1}^\infty$ is a PSPACE sequence of simple functions.*

5 Unconditional PSPACE ergodic theorem for the Bernoulli space

We now prove an unconditional version of our main result, namely, that for PSPACE L^1 computable functions, the ergodic average exists, and is equal to the space average, on every EXP random in the canonical setting of the Bernoulli space. We utilize the almost everywhere convergence results proved in the previous section, to prove the convergence on every PSPACE/EXP random. We first show that in the Bernoulli space, every PSPACE L^1 function exhibits PSPACE rapidity of A_n^f . The proof of this theorem is a non-trivial application of techniques from uniform distribution of sequences modulo 1 [15, 20, 16, 18].

► **Theorem 5.1.** *Let $f \in L^1(\Sigma^\infty, \mathcal{B}(\Sigma^\infty), \mu)$ where μ is the Bernoulli measure $\mu(\sigma) = \frac{1}{2^{|\sigma|}}$ and let T be the left shift transformation. If f is PSPACE L^1 -computable, then there exists a polynomial q satisfying the following: given any $m \in \mathbb{N}$, for all $n \geq 2^{q(m)}$, $\|A_n^f - \int f d\mu\|_1 \leq 2^{-m}$.*

An equivalent statement is the following: The left-shift transformation on the Bernoulli probability measure is PSPACE ergodic⁴. Theorem 5.1 gives an explicit bound on the speed of convergence in the L^1 ergodic theorem for an interesting class of functions over the Bernoulli space. Such bounds do not exist in general for the L^1 ergodic theorem as demonstrated by Krengel in [14].

The above theorem can be obtained from the following assertion regarding PSPACE-rapid convergence of characteristic functions of long enough cylinders.

► **Lemma 5.2.** *Let T be the left shift transformation $T : (\Sigma^\infty, \mathcal{B}(\Sigma^\infty), \mu) \rightarrow (\Sigma^\infty, \mathcal{B}(\Sigma^\infty), \mu)$ where μ is the Bernoulli measure $\mu(\sigma) = 2^{-|\sigma|}$. There exist polynomials q_1, q_2 such that for any $m \in \mathbb{N}$ and $\sigma \in \Sigma^*$ with $|\sigma| \geq q_1(m)$ we get $\|A_n^{\chi_\sigma} - \mu(\sigma)\|_1 \leq 2^{-m}$ for all $n \geq |\sigma|^{3 \cdot 2^{q_2(m)}}$.*

Proof sketch. The major difficulty in directly approximating $\|A_n^{\chi_\sigma} - \mu(\sigma)\|_1$ is that for any $n, m \in \mathbb{N}$, $A_n^{\chi_\sigma}$ and $A_m^{\chi_\sigma}$ may not be *independent*. In order to overcome this, we use constructions similar to those used in proving Pillai's theorem (see [20], [16] for normal numbers, [18] for continued fractions) in order to approximate each $A_n^{\chi_\sigma}$ with sums of *disjoint* averages as follows.

$$A_n^{\chi_\sigma}(x) = \frac{\sum_{i=1}^{\lfloor \frac{n}{k} \rfloor} X_i^{1,1}(x)}{n} + \sum_{p=2}^{\lfloor \log_2(\frac{n}{k}) \rfloor} \sum_{j=1}^{k-1} \frac{\sum_{i=1}^{\lfloor \frac{n}{2^{p-1}k} \rfloor} X_i^{p,j}}{n} + \frac{(k-1) \cdot O(\log n)}{n}, \quad \text{where}$$

$$X_i^{1,1}(x) = \begin{cases} 1 & \text{if } x[ik+1, (i+1)k] = \sigma \\ 0 & \text{otherwise,} \end{cases} \quad \text{and}$$

$$X_i^{p,j}(x) = \begin{cases} 1 & \text{if } x[2^{p-2}k-j+1, 2^{p-2}k-j+k] = \sigma \\ 0 & \text{otherwise} \end{cases}$$

The first two terms on the right of the equation turns out to be averages of independent Bernoulli random variables. Hence, elementary results from probability theory regarding independent Bernoulli random variables can be used to show that $A_n^{\chi_\sigma}$ converges to $\int f d\mu$ sufficiently fast. ◀

We remark that since Lemma 5.2 is true with the L^1 -norm replaced by the L^2 -norm, Theorem 5.1 is also true in the L^2 setting. i.e, if a function f is PSPACE L^2 -computable (replacing L^1 norms with L^2 norms in definition 3.2) then there exists a polynomial q satisfying the following: given any $m \in \mathbb{N}$, for all $n \geq 2^{q(m)}$, $\|A_n^f - \int f d\mu\|_2 \leq 2^{-m}$. Hence, for PSPACE L^2 -computable functions and the left shift transformation T , we get bounds on the convergence speed in the von-Neumann's ergodic theorem.

It is easy to verify that if T is a PSPACE simple transformation then for any $n \geq 2$, T^n is also a PSPACE simple transformation. We need the following stronger assertion in the proof of the ergodic theorem.

⁴ Equivalently, there exists a constant c such that for all $n > 0$, $\|A_n^f - \int f d\mu\|_1 \leq 2^{-\lfloor \log(n)^{\frac{1}{c}} \rfloor}$.

► **Lemma 5.3.** *Let $T : (\Sigma^\infty, \mu) \rightarrow (\Sigma^\infty, \mu)$ be a PSPACE simple transformation with controlling constant c . There exists a PSPACE machine N such that for each $n \in \mathbb{N}$ and $\sigma, \alpha \in \Sigma^*$,*

$$N(1^n, \sigma, \alpha) = \begin{cases} 1 & \text{if } |\alpha| \geq |\sigma| + cn \text{ and } \alpha 0^\infty \in T^{-n}([\sigma]) \\ 0 & \text{if } |\alpha| \geq |\sigma| + cn \text{ and } \alpha 0^\infty \notin T^{-n}([\sigma]) \\ ? & \text{otherwise} \end{cases}$$

Proof of Lemma 5.3. Let M be the machine witnessing the fact that T is a PSPACE simple transformation with the polynomial space complexity bound $p(n)$. Let the machine N do the following on input $(1^n, \sigma, \alpha)$:

1. If $\alpha < |\sigma| + cn$, then output ?.
2. If $n = 1$ then, run $M(\sigma, \alpha)$ and output the result of this simulation.
3. Else:
 - a. For all strings α' of length $|\sigma| + c(n-1)$ do the following:
 - i. If $N(1^{n-1}, \sigma, \alpha') = 1$ then, output 1 if $M(\alpha', \alpha) = 1$.
4. If no output is produced in the above steps, output 0.

When $n = 1$, N uses at most $p(|\sigma| + |\alpha| + cn) + O(1)$ space. Inductively, assume that for $n = k$, N uses at most $(2k-1)p(|\sigma| + |\alpha| + cn) + O(1)$ space. For $n = k+1$, the storage of α' and the two simulations inside step 3a can be done in $2p(|\sigma| + |\alpha| + cn) + (2k-1)p(|\sigma| + |\alpha| + cn) + O(1) = (2(k+1) - 1)p(|\sigma| + |\alpha| + cn) + O(1)$ space. Hence, N is a PSPACE machine. ◀

Now, we prove the unconditional ergodic theorem for PSPACE L^1 functions over the Bernoulli space. The proof involves adaptations of techniques from Rute [21], together with new quantitative bounds which yield the result within prescribed resource bounds.

► **Theorem 5.4.** *Let T be the left shift transformation $T : (\Sigma^\infty, \mathcal{B}(\Sigma^\infty), \mu) \rightarrow (\Sigma^\infty, \mathcal{B}(\Sigma^\infty), \mu)$ where μ is the Bernoulli measure $\mu(\sigma) = 2^{-|\sigma|}$. Then, for any PSPACE L^1 -computable f ,*

$$\lim_{n \rightarrow \infty} \widetilde{A}_n^f = \int f d\mu \text{ on EXP randoms.}$$

Proof of Theorem 5.4. Let $\langle f_m \rangle_{m=1}^\infty$ be any PSPACE sequence of simple functions L^1 approximating f . We initially approximate A_n^f with a PSPACE sequence of simple functions $\langle g_n \rangle_{n=1}^\infty$ which converges to $\int f d\mu$ on EXP randoms. Then we show that \widetilde{A}_n^f has the same limit as g_n on PSPACE randoms and hence on EXP randoms.

For each n , it is easy to verify that $\langle A_n^{f_m} \rangle_{m=1}^\infty$ is a PSPACE sequence of simple functions L^1 approximating A_n^f with the same rate of convergence. Using techniques similar to those in Lemma 4.3 and Corollary 4.4, we can obtain a polynomial p such that

$$\mu \left(\left\{ x : \sup_{m \geq p(n+i)} |A_n^{f_m}(x) - A_n^{f_{p(n+i)}}(x)| \geq \frac{1}{2^{n+i+1}} \right\} \right) \leq \frac{1}{2^{n+i+1}}.$$

For every $n > 0$, let $g_n = A_n^{f_{p(n)}}$. We initially show that $\langle g_n \rangle_{n=1}^\infty$ converges to $\int f d\mu$ on EXP randoms. Let $m_1, m_2 \geq 0$. From Theorem 4.2, A_n^f is PSPACE-rapid almost everywhere convergent to $\int f d\mu$. Hence there is a polynomial q such that

$$\mu \left(\left\{ x : \sup_{n \geq 2^{q(m_1+m_2)}} |A_n^f(x) - \int f d\mu| \geq \frac{1}{2^{m_1+1}} \right\} \right) \leq \frac{1}{2^{m_2+1}}.$$

Let $N(m_1, m_2) = \max\{2m_1, 2m_2, 2^{q(m_1+m_2)}\}$. Then,

$$\sum_{n \geq N(m_1, m_2)} \frac{1}{2^{k+1}} = \frac{1}{2^{N(m_1, m_2)}} \leq \min \left\{ \frac{1}{2^{m_1+1}}, \frac{1}{2^{m_2+1}} \right\}.$$

Let

$$G_n = \left\{ x : \sup_{n \geq N(m_1, m_2)} |g_n - \int f d\mu| > \frac{1}{2^{m_1}} \right\}.$$

Now, we have

$$\begin{aligned} \mu(G_n) &\leq \sum_{n \geq N(m_1, m_2)} \mu \left(\left\{ x : |g_n - A_n^f(x)| > \frac{1}{2^{m_1+1}} \right\} \right) \\ &\quad + \mu \left(\left\{ x : \sup_{n \geq 2^{q(m_1+m_2)}} |A_n^f(x) - \int f d\mu| \geq \frac{1}{2^{m_1+1}} \right\} \right) \\ &\leq \sum_{n \geq N(m_1, m_2)} \frac{1}{2^{n+1}} + \frac{1}{2^{m_2+1}} \\ &\leq \frac{1}{2^{m_2}}. \end{aligned}$$

Note that $N(m_1, m_2)$ is bounded by $2^{(m_1+m_2)^c}$ for some $c \in \mathbb{N}$. Hence, g_n is PSPACE-rapid almost everywhere convergent to $\int f d\mu$. From Lemma 4.6 it follows that $\langle g_n \rangle_{n=1}^\infty = \langle A_n^{f_{p(n)}} \rangle_{n=1}^\infty$ is a PSPACE sequence of simple functions (in parameter n). Let $I_f : \Sigma^\infty \rightarrow \Sigma^\infty$ be the constant function taking the value $\int f d\mu$ over all $x \in \Sigma^\infty$. From the above observations and Lemma 4.3 we get that $\lim_{n \rightarrow \infty} g_n(x) = I_f(x)$ for any x which is EXP random. From Lemma 4.5, we get that $\lim_{n \rightarrow \infty} g_n(x) = \int f d\mu$ for any x which is EXP random.

We now show that $\lim_{n \rightarrow \infty} \tilde{A}_n^f = \lim_{n \rightarrow \infty} g_n$ on PSPACE randoms. Define

$$U_{n,i} = \left\{ x : \max_{p(n+i) \leq m \leq p(n+i+1)} |A_n^f(x) - A_n^{f_{p(n+i)}}(x)| \geq \frac{1}{2^{n+i+1}} \right\}.$$

We already know $\mu(U_{n,i}) \leq \frac{1}{2^{n+i+1}}$. $U_{n,i}$ can be shown to be polynomial space approximable in parameters n and i in the following sense. There exists a sequence of sets of strings $\langle S_{n,i} \rangle_{i,n \in \mathbb{N}}$ and polynomial p satisfying the following conditions:

1. $U_{n,i} = [S_{n,i}]$.
2. There exists a *controlling polynomial* r such that $\max\{|\sigma| : \sigma \in S_{n,i}\} \leq r(n+i)$.
3. The function $g : \Sigma^* \times 1^* \times 1^* \rightarrow \{0, 1\}$ such that

$$g(\sigma, 1^n, 1^i) = \begin{cases} 1 & \text{if } \sigma \in S_{n,i} \\ 0 & \text{otherwise,} \end{cases}$$

is decidable by a PSPACE machine.

The above claims can be established by using techniques similar to those in Lemma 4.6 and Lemma 4.3. We show the construction of a machine N computing the function g above. Let M_f be a computing machine and let q be a controlling polynomial for $\langle f_n \rangle_{n=1}^\infty$. Let c be a controlling constant for T . Let M' be the machine from Lemma 5.3. Machine N on input $(\sigma, 1^n, 1^i)$ does the following:

80:10 Ergodic Theorems and Converses for PSPACE Functions

1. If $|\sigma| > q(p(n+i+1)) + cn$, then output 0.
2. Compute $A_n^{f_{p(n+i)}}(\sigma 0^\infty)$ as in Lemma 4.6 by using M_f and M' and store the result.
3. For each $m \in [p(n+i), p(n+i+1)]$ do the following:
 - a. Compute $A_n^{f_m}(\sigma 0^\infty)$ as in Lemma 4.6 by using M_f and M' and store the result.
 - b. Check if $|A_n^{f_m}(\sigma 0^\infty) - A_n^{f_{p(n+i)}}(\sigma 0^\infty)| \geq \frac{1}{2^{n+i+1}}$. If so, output 1.
4. Output 0.

It can be easily verified that N is a PSPACE machine. $r(n+i) = q(p(n+i+1)) + cn$ is a controlling polynomial for $\langle U_{n,i} \rangle_{n,i \in \mathbb{N}}$. Define

$$V_m = \bigcup_{\substack{n,i \geq 0 \\ n+i=m}} U_{n,i}.$$

Note that

$$\mu(V_m) \leq \frac{m}{2^m}.$$

It can be shown that for any j ,

$$\sum_{n>j} \frac{m}{2^m} = \frac{1}{2^{j-1}} + \frac{j}{2^j}.$$

Given any $k \geq 0$, let $p(k) = 3(k+1)$. Hence, we have

$$\sum_{n=p(k)+1}^{\infty} \frac{m}{2^m} = \frac{1}{2^{3(k+1)}} + \frac{3(k+1)}{2^{3(k+1)}} < \frac{1}{2^{k+1}} + \frac{1}{2^{k+1}} \frac{3(k+1)}{2^{2(k+1)}} < \frac{2}{2^{k+1}} = \frac{1}{2^k}.$$

The last inequality holds since $3(k+1) < 2^{2(k+1)}$ for all $k \geq 0$. Since each V_m is a finite union of sets from $\langle U_{n,i} \rangle_{n,i \in \mathbb{N}}$, the machine computing $\langle U_{n,i} \rangle_{n,i \in \mathbb{N}}$ can be easily modified to construct a machine witnessing that $\langle V_m \rangle_{m=1}^{\infty}$ is a PSPACE approximable sequence of sets. From these observations, it follows that $\langle V_m \rangle_{m=1}^{\infty}$ is a PSPACE Solovay test. Let x be a PSPACE random. x is in at most finitely many V_m and hence in at most finitely many $U_{n,i}$. Hence for some large enough N for all $n \geq N$, $i \geq 0$ and for all m such that $p(n+i) \leq m \leq p(n+i+1)$, we have $|A_n^{f_m}(x) - A_n^{f_{p(n+i)}}(x)| < \frac{1}{2^{n+i+1}}$. It follows that for all $n \geq N$ and for all $m \geq p(n)$ that

$$|A_n^{f_m}(x) - g_n(x)| = |A_n^{f_m}(x) - A_n^{f_{p(n)}}(x)| \leq \sum_{i=0}^{\infty} \frac{1}{2^{n+i+1}} \leq 2^{-n}.$$

Therefore, $\lim_{n \rightarrow \infty} \tilde{A}_n^f(x) = \lim_{n \rightarrow \infty} g_n(x)$ on all PSPACE random x and hence on all x which is EXP random.

Hence, we have shown that $\lim_{n \rightarrow \infty} \tilde{A}_n^f = \int f d\mu$ on EXP randoms which completes the proof of the theorem. \blacktriangleleft

6 General PSPACE ergodic theorem

We now extend Theorem 5.4 into the setting of PSPACE-probability Cantor spaces. V'yugin [26] shows that the speed of a.e. convergence to ergodic averages in computable ergodic systems is not computable in general. This leads us to consider some assumption on the rapidity of convergence in resource-bounded settings. We show that the requirement

on L^1 rapidity of convergence of A_n^f is sufficient to derive our result. Several probabilistic laws like the Law of Large Numbers, Law of Iterated Logarithm satisfy this criterion, hence the assumption is sufficiently general. Moreover, Theorem 5.1 shows that in the canonical example of Bernoulli systems with the left-shift, every PSPACE L^1 function exhibits PSPACE rapidity of A_n^f , showing that the latter property is not artificial. We prove the general PSPACE ergodic theorem for transformations which satisfy PSPACE ergodicity.

► **Definition 6.1** (PSPACE ergodic transformations). *A measurable function $T : (\Sigma^\infty, \mu) \rightarrow (\Sigma^\infty, \mu)$ is PSPACE ergodic if T is a PSPACE simple measure preserving transformation such that for any PSPACE L^1 -computable $f \in L^1(\Sigma^\infty, \mu)$, $\int f d\mu$ is a PSPACE-rapid L^1 limit point of A_n^f .*

Now, we prove the main result of our work.

► **Theorem 6.2.** *Let $(\Sigma^\infty, \mathcal{B}(\Sigma^\infty), \mu)$ be a PSPACE-probability Cantor space. Let $T : (\Sigma^\infty, \mathcal{B}(\Sigma^\infty), \mu) \rightarrow (\Sigma^\infty, \mathcal{B}(\Sigma^\infty), \mu)$ be a PSPACE ergodic measure preserving transformation. Then, for any PSPACE L^1 -computable f , $\lim_{n \rightarrow \infty} \widetilde{A}_n^f = \int f d\mu$ on EXP randoms.*

Proof. Observe that Lemma 4.3, Corollary 4.4 and Lemma 4.6 are true in the setting of PSPACE-probability Cantor spaces. The proof of Lemma 4.5 can be extended to the setting of PSPACE-probability Cantor spaces in a straightforward manner. Since T is PSPACE ergodic, we get that $\int f d\mu$ is a PSPACE-rapid L^1 -limit point of A_n^f . Now, the theorem follows from these observations and the same techniques as in the proof of Theorem 5.4. ◀

The convergence notions involved in proving the PSPACE/SUBEXP-space ergodic theorems and their interrelationships are summarized in Figure 1.

■ **Figure 1** Relationships between the major convergence notions involving PSPACE simple measure preserving transformations. $A_n^f \dashrightarrow \int f d\mu$ denotes that $\int f d\mu$ is a PSPACE-rapid L^1 -limit point of A_n^f . PSPACE/SUBEXP-space ergodicity is required only for obtaining the ergodic theorems from PSPACE a.e convergence.

7 A partial converse to the PSPACE Ergodic Theorem

In this section we give a partial converse to the PSPACE ergodic theorem (Theorem 6.2). We show that for any PSPACE null x , there exists a function f and transformation T satisfying all the conditions in Theorem 6.2 such that $\widetilde{A}_n^f(x)$ does not converge to $\int f d\mu$.

Let us first observe that due to Corollary 4.4, Theorem 6.2 is equivalent to the following:

► **Theorem.** *Let T be a PSPACE ergodic measure preserving transformation such that for any PSPACE L^1 -computable f , $\int f d\mu$ is an PSPACE-rapid L^1 -limit point of A_n^f . Let $\{g_{n,i}\}$ be any collection of simple functions such that for each n , $\langle g_{n,i} \rangle_{i=1}^\infty$ is a PSPACE L^1 -approximation of \widetilde{A}_n^f . Then, $\lim_{n \rightarrow \infty} \lim_{i \rightarrow \infty} g_{n,i}(x) = \int f d\mu$ for any EXP random x .*

80:12 Ergodic Theorems and Converses for PSPACE Functions

Hence, the ideal converse to Theorem 6.2 is the following:

► **Theorem.** *Given any EXP null x , there exists a PSPACE ergodic measure preserving transformation T and PSPACE L^1 -computable $f \in L^1(\Sigma^\infty, \mu)$ such that the following conditions are true:*

1. $\int f d\mu$ is an PSPACE-rapid limit point of A_n^f .
2. There exists a collection of simple functions $\{g_{n,i}\}$ such that for each n , $\langle g_{n,i} \rangle_{i=1}^\infty$ is a PSPACE L^1 -approximation of A_n^f but $\lim_{n \rightarrow \infty} \lim_{i \rightarrow \infty} g_{n,i}(x) \neq \int f d\mu$.

But, we show the following partial converse to Theorem 6.2.

► **Theorem 7.1.** *Given any PSPACE null x , there exists a PSPACE L^1 -computable $f \in L^1(\Sigma^\infty, \mu)$ such that for any PSPACE simple measure preserving transformation, the following conditions are true:*

1. For all $n \in \mathbb{N}$, $\|A_n^f - \int f d\mu\|_1 = 0$. Hence, $\int f d\mu$ is an PSPACE-rapid L^1 -limit point of A_n^f .
2. There exists a collection of simple functions $\{g_{n,i}\}$ such that for each n , $\langle g_{n,i} \rangle_{i=1}^\infty$ is a PSPACE L^1 -approximation of A_n^f but $\lim_{n \rightarrow \infty} \lim_{i \rightarrow \infty} g_{n,i}(x) \neq \int f d\mu$.

A proof of the above theorem requires the construction in the following lemma.

► **Lemma 7.2.** *Let $\langle U_n \rangle_{n=1}^\infty$ be a PSPACE test. Then there exists a sequences of sets $\langle \widehat{S}_n \rangle_{n=1}^\infty$ such that for each $n \in \mathbb{N}$, $\widehat{S}_n \subseteq \Sigma^*$ satisfying the following conditions:*

1. $\mu([\widehat{S}_n]) \leq 2^{-n}$.
2. $\bigcap_{m=1}^\infty \bigcup_{n=m}^\infty [\widehat{S}_n] \supseteq \bigcap_{n=1}^\infty U_n$.
3. There exists $c \in \mathbb{N}$ such that for all n , $\sigma \in \widehat{S}_n$ implies $|\sigma| \leq n^c$.
4. There exists a PSPACE machine N such that $N(\sigma, 1^n) = 1$ if $\sigma \in \widehat{S}_n$ and 0 otherwise.

Proof of Theorem 7.1. Let $\langle V_n \rangle_{n=1}^\infty$ be any PSPACE test such that $x \in \bigcap_{n=1}^\infty V_n$. From Lemma 7.2, there exists a collection of sets $\langle \widehat{S}_n \rangle_{n=1}^\infty$ such that $\bigcap_{m=1}^\infty \bigcup_{n=m}^\infty [\widehat{S}_n] \supseteq \bigcap_{n=1}^\infty V_n$. Let,

$$U_n = \{\sigma : [\sigma] \in \widehat{S}_i \text{ for some } i \text{ such that } 2n+1 \leq i \leq 2(n+1)+1\}$$

Let $f_n = n\chi_{U_n}$. Since

$$\mu(U_n) \leq \sum_{i=2n+1}^{2(n+1)+1} \frac{1}{2^i} \leq \frac{1}{2^{2n}},$$

it follows that

$$\|f_n\|_1 \leq \frac{n}{2^{2n}} \leq \frac{1}{2^n}.$$

Using the properties of $\langle \widehat{S}_n \rangle_{n=1}^\infty$, it can be shown that $\langle f_n \rangle_{n=1}^\infty$ is a PSPACE L^1 -approximation of $f = 0$. We construct a machine M computing $\langle f_n \rangle_{n=1}^\infty$. The other conditions are easily verified. Let N be the machine from Lemma 7.2. On input $(1^n, \sigma)$, M does the following:

1. If $|\sigma| < (2(n+1)+1)^c$ then, output ?.
2. Else, for each $i \in [2n+1, 2(n+1)+1]$ do the following:
 - a. For each $\alpha \subseteq \sigma$, do the following:
 - i. If $N(1^i, \alpha) = 1$ then, output n .
3. Output 0.

M uses at most polynomial space and computes $\langle f_n \rangle_{n=1}^\infty$. Define

$$g_{n,i} = \frac{f_i + f_i \circ T + \cdots + f_i \circ T^{n-1}}{n}$$

For any fixed $n \in \mathbb{N}$, since T is a PSPACE simple transformation, as in Lemma 4.6 it can be shown that $\langle g_{n,i} \rangle_{i=1}^\infty$ is a PSPACE L^1 -approximation of A_n^f . We know that there exist infinitely many m such that $x \in \widehat{S}_m$. For any such m , let i be the unique number such that $2i + 1 \leq m \leq 2(i + 1) + 1$. For this i , $f_i(x) = i$. This shows that there exist infinitely many i such that $f_i(x) = i$. Since each f_i is a non-negative function, it follows that there are infinitely many i with $g_{n,i} \geq i/n$. Hence, if $\lim_{i \rightarrow \infty} g_{n,i}(x)$ exists, then it is equal to ∞ . It may be the case that $\lim_{i \rightarrow \infty} g_{n,i}(x)$ does not exist. In either case, $\lim_{n \rightarrow \infty} \lim_{i \rightarrow \infty} g_{n,i}(x)$ cannot be equal to $\int f d\mu = 0$. Hence, our construction satisfies all the desired conditions. \blacktriangleleft

8 An ergodic theorem for SUBEXP-space randoms and its converse

In the previous sections, we demonstrated that for PSPACE L^1 -computable functions and PSPACE simple transformations, the Birkhoff averages converge to the desired value over EXP randoms. However, the converse holds only over PSPACE non-randoms. The two major reasons for this *gap* are the following: PSPACE-rapid convergence necessitates exponential length cylinders while constructing the randomness tests, and PSPACE L^1 -computable functions are not strong enough to *capture* all PSPACE randoms. In this section, we demonstrate that for a different notion of randomness - SUBEXP-space randoms and a larger class of L^1 -computable functions (SUBEXP-space L^1 -computable), we can prove the ergodic theorem on the randoms and obtain its converse on the non-randoms. Analogous to Towsner and Franklin [5], we demonstrate that the ergodic theorem for PSPACE simple transformations and SUBEXP-space L^1 -computable functions satisfying PSPACE rapidity, fails for exactly this class of non-random points. We first introduce SUBEXP-space tests and SUBEXP-space randomness.

► **Definition 8.1** (SUBEXP-space sequence of open sets). *A sequence of open sets $\langle U_n \rangle_{n=1}^\infty$ is a SUBEXP-space sequence of open sets if there exists a sequence of sets $\langle S_n^k \rangle_{k,n \in \mathbb{N}}$, where $S_n^k \subseteq \Sigma^*$ such that*

1. $U_n = \bigcup_{k=1}^\infty [S_n^k]$, where for any $m > 0$, $\mu(U_n - \bigcup_{k=1}^m [S_n^k]) \leq m^{-\log(m)}$.
2. There exists a controlling polynomial p such that $\max\{|\sigma| : \sigma \in \bigcup_{k=1}^m S_n^k\} \leq 2^{p(\log(n) + \log(m))}$.
3. The function $g : \Sigma^* \times 1^* \times 1^* \rightarrow \{0, 1\}$ such that $g(\sigma, 1^n, 1^m) = 1$ if $\sigma \in S_n^m$, and 0 otherwise, is decidable by a PSPACE machine.

► **Definition 8.2** (SUBEXP-space randomness). *A sequence of open sets $\langle U_n \rangle_{n=1}^\infty$ is a SUBEXP-space test if it is a SUBEXP-space sequence of open sets and for all $n \in \mathbb{N}$, $\mu(U_n) \leq n^{-\log(n)}$.*

*A set $A \subseteq \Sigma^\infty$ is SUBEXP-space null if there is a SUBEXP-space test $\langle U_n \rangle_{n=1}^\infty$ such that $A \subseteq \bigcap_{n=1}^\infty U_n$ and is SUBEXP-space random otherwise.*⁵

The slower decay rate of $n^{-\log(n)} = 2^{-\log(n)^2}$ enables us to obtain an ergodic theorem and an exact converse in the SUBEXP-space setting. The following result is useful in manipulating sums involving terms of the form $2^{-(\log(n))^k}$ for $k \geq 2$.

⁵ It is easy to see that the set of SUBEXP-space randoms is smaller than the set of PSPACE randoms. But, we do not know if any inclusion holds between SUBEXP-space randoms and EXP-randoms.

80:14 Ergodic Theorems and Converses for PSPACE Functions

► **Lemma 8.3.** For any $m \in \mathbb{N}$, $\sum_{n=2(2m^2+1)}^{\infty} \frac{n}{n^{\log(n)}} \leq \frac{1}{m^{\log(m)}}$.

A similar inequality holds on replacing $n/n^{\log(n)}$ with $1/n^{\log(n)}$. Now, we introduce the Solovay analogue of SUBEXP-space randomness and prove that these notions are analogous.

► **Definition 8.4** (SUBEXP-space Solovay test). A sequence of open sets $\langle U_n \rangle_{n=1}^{\infty}$ is a SUBEXP-space Solovay test if it is a SUBEXP-space sequence of open sets and there exists a polynomial p such that $\forall m \geq 0$, $\sum_{n=p(m)+1}^{\infty} \mu(U_n) \leq m^{-\log(m)}$. A set $A \subseteq \Sigma^{\infty}$ is SUBEXP-space Solovay null if there exists a SUBEXP-space Solovay test $\langle U_n \rangle_{n=1}^{\infty}$ such that $A \subseteq \bigcap_{i=1}^{\infty} \bigcup_{n=i}^{\infty} U_n$, and is SUBEXP-space Solovay random otherwise.

► **Lemma 8.5.** A set $A \subseteq \Sigma^{\infty}$ is SUBEXP-space null if and only if A is SUBEXP-space Solovay null.

Now, we define SUBEXP-space analogues of concepts from Section 3.

► **Definition 8.6** (SUBEXP-space sequence of simple functions). A sequence of simple functions $\langle f_n \rangle_{n=1}^{\infty}$ where each $f_n : \Sigma^{\infty} \rightarrow \mathbb{Q}$ is a SUBEXP-space sequence of simple functions if

1. There is a controlling polynomial p such that for each n , there exists $k(n) \in \mathbb{N}$, $\{d_1, d_2, \dots, d_{k(n)}\} \subseteq \mathbb{Q}$ and $\{\sigma_1, \sigma_2, \dots, \sigma_{k(n)}\} \subseteq \Sigma^{2^{p(\log(n))}}$ such that $f_n = \sum_{i=1}^{k(n)} d_i \chi_{\sigma_i}$, where χ_{σ_i} is the characteristic function of the cylinder $[\sigma_i]$.
2. There is a PSPACE machine M such that for each $n \in \mathbb{N}$, $\sigma \in \Sigma^*$, $M(1^n, \sigma)$ outputs $f_n(\sigma 0^{\infty})$ if $|\sigma| \geq 2^{p(\log(n))}$ and ? otherwise.

► **Definition 8.7** (SUBEXP-space L^1 -computable functions). A function $f \in L^1(\Sigma^{\infty}, \mu)$ is SUBEXP-space L^1 -computable if there exists a SUBEXP-space sequence of simple functions $\langle f_n \rangle_{n=1}^{\infty}$ such that for every $n \in \mathbb{N}$, $\|f - f_n\| \leq n^{-\log(n)}$. The sequence $\langle f_n \rangle_{n=1}^{\infty}$ is called a SUBEXP-space L^1 -approximation of f .

We require the following equivalent definitions of PSPACE-rapid convergence notions for working in the setting of SUBEXP-space randomness.

► **Lemma 8.8.** A real number a is a PSPACE-rapid limit point of the real number sequence $\langle a_n \rangle_{n=1}^{\infty}$ if and only if there exists a polynomial p such that for all $m \in \mathbb{N}$, $\exists k \leq 2^{p(\log(m))}$ such that $|a_k - a| \leq m^{-\log(m)}$.

► **Lemma 8.9.** A sequence of measurable functions $\langle f_n \rangle_{n=1}^{\infty}$ is PSPACE-rapid almost everywhere convergent to a measurable function f if and only if there exists a polynomial p such that for all m_1 and m_2 ,

$$\mu \left(\left\{ x : \sup_{n \geq 2^{p(\log(m_1) + \log(m_2))}} |f_n(x) - f(x)| \geq \frac{1}{m_1^{\log(m_1)}} \right\} \right) \leq \frac{1}{m_2^{\log(m_2)}}.$$

The same technique used in the proof of Lemma 8.8 can be used to prove this claim.

Before addressing the main result, let us define SUBEXP-space ergodicity.

► **Definition 8.10** (SUBEXP-space ergodic transformations). A measurable function $T : (\Sigma^{\infty}, \mu) \rightarrow (\Sigma^{\infty}, \mu)$ is SUBEXP-space ergodic if T is a PSPACE simple transformation such that for any SUBEXP-space L^1 -computable $f \in L^1(\Sigma^{\infty}, \mu)$, $\int f d\mu$ is a PSPACE-rapid L^1 limit point of $A_n^{f, T}$.

Lemma 4.3, Corollary 4.4 and Lemma 4.6 have analogous results in the SUBEXP-space setting. We prove the SUBEXP-space ergodic theorem below.

► **Theorem 8.11.** *Let $T : (\Sigma^\infty, \mathcal{B}(\Sigma^\infty), \mu) \rightarrow (\Sigma^\infty, \mathcal{B}(\Sigma^\infty), \mu)$ be a SUBEXP-space ergodic measure preserving transformation. Then, for any SUBEXP-space L^1 -computable f , $\lim_{n \rightarrow \infty} \widetilde{A}_n^f = \int f d\mu$ on SUBEXP-space randoms.*

An important reason for investigating SUBEXP-space randomness is that the SUBEXP-space ergodic theorem has an exact converse unlike the PSPACE ergodic theorem which only seems to have a partial converse (Theorem 7.1).

► **Theorem 8.12.** *Given any SUBEXP-space null x , there exists a SUBEXP-space L^1 -computable $f \in L^1(\Sigma^\infty, \mu)$ such that for any PSPACE simple measure preserving transformation, the following conditions are true:*

1. *For all $n \in \mathbb{N}$, $\|A_n^f - \int f d\mu\|_1 = 0$. Hence, $\int f d\mu$ is an PSPACE-rapid L^1 -limit point of A_n^f .*
2. *There exists a collection of simple functions $\{g_{n,i}\}$ such that for each n , $\langle g_{n,i} \rangle_{i=1}^\infty$ is a SUBEXP-space L^1 -approximation of A_n^f but $\lim_{n \rightarrow \infty} \lim_{i \rightarrow \infty} g_{n,i}(x) \neq \int f d\mu$.*

The proofs of both Theorem 8.11 and Theorem 8.12 are similar to those of Theorem 6.2 and Theorem 7.1, but requires Lemma 8.3 for minimizing summations of the form $\sum n^{-\log(n)}$ appearing in the error bounds.

A Proof of Theorem 5.1

Proof of Theorem 5.1. Let $\langle f_n \rangle_{n=1}^\infty$ be a PSPACE sequence of simple functions witnessing the fact that f is PSPACE L^1 -computable. Let p be a controlling polynomial and let t be a polynomial upper bound for the space complexity of the machine associated with $\langle f_n \rangle_{n=1}^\infty$. Let q_1, q_2 be the polynomials from Lemma 5.2. Let $c \in \mathbb{N}$ be any number such that if a $r \in \mathbb{Q}$ has a representation of length l then $r \leq 2^{l^c}$ (see Section 2). Observe that for any $m \in \mathbb{N}$,

$$\begin{aligned} \|A_n^f - \int f d\mu\|_1 &\leq \|A_n^f - A_n^{f_{q_1(m+3)}}\|_1 + \|A_n^{f_{q_1(m+3)}} - \int f_{q_1(m+3)} d\mu\|_1 + \left\| \int f_{q_1(m+3)} d\mu - \int f d\mu \right\|_1 \\ &\leq \frac{1}{2^{q_1(m+3)}} + \|A_n^{f_{q_1(m+3)}} - \int f_{q_1(m+3)} d\mu\|_1 + \frac{1}{2^{q_1(m+3)}}. \\ &\leq \frac{1}{2^{m+3}} + \|A_n^{f_{q_1(m+3)}} - \int f_{q_1(m+3)} d\mu\|_1 + \frac{1}{2^{m+3}}. \end{aligned}$$

We know that there exist $\{\sigma_1, \sigma_2 \dots \sigma_k\} \subseteq \Sigma^{p(q_1(m+3))}$ such that $A_n^{f_{q_1(m+3)}} = \sum_{i=1}^{k(q_1(m+3))} d_i \chi_{\sigma_i}$ where each $d_i \leq 2^{t(q_1(m+3)+p(q_1(m+3)))^c}$. Hence,

$$\|A_n^{f_{q_1(m+3)}} - \int f_{q_1(m+3)} d\mu\|_1 \leq 2^{t(q_1(m+3)+p(q_1(m+3)))^c} \sum_{i=1}^{k(q_1(m+3))} \|A_n^{\chi_{\sigma_i}} - \mu(\sigma_i)\|_1$$

Since $|\sigma_i| \geq p(q_1(m+3)) \geq q_1(m+3)$, using Lemma 5.2, for

$$n \geq p(q_1(m+3))^3 2^{q_2(t(q_1(m+3)+p(q_1(m+3)))^c + p(q_1(m+3)) + m + 3)}$$

we get that,

$$\begin{aligned} \|A_n^{f_{q_1(m+3)}} - \int f_{q_1(m+3)} d\mu\|_1 &\leq \frac{2^{t(q_1(m+3)+p(q_1(m+3)))^c + p(q_1(m+3))}}{2^{t(q_1(m+3)+p(q_1(m+3)))^c + p(q_1(m+3)) + m + 3}} \\ &\leq \frac{1}{2^{m+3}}. \end{aligned}$$

Hence, for all $n \geq p(q_1(m+3))^3 2^{q_2(t(q_1(m+3)+p(q_1(m+3)))^c + p(q_1(m+3)) + m + 3)}$ we have $\|A_n^f - \int f d\mu\|_1 \leq 3 \cdot 2^{-(m+3)} < 2^{-m}$. \blacktriangleleft

Proof of Lemma 5.2. The major difficulty in directly approximating $\|A_n^{X_\sigma} - \mu(\sigma)\|_1$ is that for any $n, m \in \mathbb{N}$, $A_n^{X_\sigma}$ and $A_m^{X_\sigma}$ may not be *independent*. In order to overcome this, we use constructions similar to those used in proving Pillai's theorem (see [20], [16] for normal numbers, [18] for continued fractions) in order to approximate each $A_n^{X_\sigma}$ with sums of *disjoint* averages. These *disjoint* averages turns out to be averages of independent random variables. Hence, elementary results from probability theory regarding independent random variables can be used to show that $A_n^{X_\sigma}$ converges to $\int f d\mu$ sufficiently fast.

Observe that for any $x \in \Sigma^\infty$

$$A_n^{X_\sigma}(x) = \frac{|\{i \in [0, n-1] \mid T^i x \in [\sigma]\}|}{n}$$

Let $k = |\sigma|$. As in the proof of Theorem 3.1 from [18], the following is a decomposition of the above term as *disjoint* averages,

$$\frac{|\{i \in [0, n-1] \mid T^i x \in [\sigma]\}|}{n} = g_1(n) + g_2(n) + \cdots + g_{(1 + \lfloor \log_2 \frac{n}{k} \rfloor)}(n) + \frac{(k-1) \cdot O(\log n)}{n}$$

where

$$g_p(n) = \begin{cases} \frac{|\{i \mid T^{ki} x \in [\sigma], 0 \leq i \leq \lfloor n/k \rfloor\}|}{n} & \text{if } p = 1 \\ \frac{\sum_{j=1}^{k-1} |\{i \mid T^{(2^{p-1})ki} x \in [S_j], 0 \leq i \leq \lfloor n/2^{p-1}k \rfloor\}|}{n} & \text{if } 1 < p \leq (1 + \lfloor \log_2(n/k) \rfloor) \\ 0 & \text{otherwise,} \end{cases}$$

and S_j is the finite collection of $2^{(p-1)}k$ length blocks s.t σ occurs in it at starting position $(2^{(p-2)}k - j + 1)^{th}$ position i.e S_j is the set of strings of the form, $u a_1 a_2 \dots a_k v$ where u is some string of length $2^{p-2}k - j$, and v is some string of length $2^{p-2}k - k + j$.

When $p = 1$,

$$g_1(n) = \frac{\sum_{i=1}^{\lfloor \frac{n}{k} \rfloor} X_i^{1,1}}{n}$$

where

$$X_i^{1,1}(x) = \begin{cases} 1 & \text{if } x[ik+1, (i+1)k] = \sigma \\ 0 & \text{otherwise} \end{cases}$$

When $1 < p \leq \lfloor \log_2(n/k) \rfloor$,

$$g_p(n) = \frac{\sum_{i=1}^{\lfloor \frac{n}{2^{p-1}k} \rfloor} \sum_{j=1}^{k-1} X_i^{p,j}}{n}$$

where,

$$X_i^{p,j}(x) = \begin{cases} 1 & \text{if } x[2^{p-2}k - j + 1, 2^{p-2}k - j + k] = \sigma \\ 0 & \text{otherwise} \end{cases}$$

Hence,

$$A_n^{X_\sigma}(x) = \frac{\sum_{i=1}^{\lfloor \frac{n}{k} \rfloor} X_i^{1,1}(x)}{n} + \sum_{p=2}^{\lfloor \log_2(\frac{n}{k}) \rfloor} \sum_{j=1}^{k-1} \frac{\sum_{i=1}^{\lfloor \frac{n}{2^{p-1}k} \rfloor} X_i^{p,j}}{n} + \frac{(k-1) \cdot O(\log n)}{n}$$

80:18 Ergodic Theorems and Converses for PSPACE Functions

An important observation that we use later in the proof is that for any fixed p and j , $\{X_i^{p,j}\}_{i=1}^{\infty}$ is a collection of i.i.d Bernoulli random variables such that $\mu(\{x : X_i^{p,j}(x) = 1\}) = 2^{-|s|}$. We will show that the conclusion of the lemma holds when $q_1(m) = 2(m+6)$ and $q_2(m) = 5(m+6)$. For any $m \in \mathbb{N}$,

$$\left\| \sum_{p=m+5+2}^{\infty} \sum_{j=1}^{k-1} \frac{1}{n} \sum_{i=1}^{\lfloor \frac{n}{2^{p-1}k} \rfloor} X_i^{p,j} \right\|_2 \leq \sum_{p=m+5+2}^{\infty} \frac{1}{2^{p-1}} \leq \frac{1}{2^{m+5}} \quad (1)$$

And for $n \geq |\sigma|^{32} 2^{2(m+5)} > |\sigma|^2 2^{2(m+5)}$,

$$\left\| \frac{(k-1)O(\log(n))}{n} \right\|_2 = \left\| \frac{(k-1)O(\log(n))}{\sqrt{n}\sqrt{n}} \right\|_2 \leq \left| \frac{k-1}{\sqrt{n}} \right| \leq \left| \frac{k-1}{k2^{m+5}} \right| \leq \frac{1}{2^{m+5}} \quad (2)$$

Let,

$$D_{n,m}^{\sigma}(x) = \frac{\sum_{i=1}^{\lfloor \frac{n}{k} \rfloor} X_i^{1,1}(x)}{n} + \sum_{p=2}^{m+5+2} \sum_{j=1}^{k-1} \frac{\sum_{i=1}^{\lfloor \frac{n}{2^{p-1}k} \rfloor} X_i^{p,j}}{n}$$

From (1) and (2), we get that

$$\|A_n^{\chi\sigma} - D_{n,m}^{\sigma}\|_2 \leq \frac{2}{2^{m+5}}.$$

Let,

$$E_{n,m}^{\sigma}(x) = \left(\frac{\sum_{i=1}^{\lfloor \frac{n}{k} \rfloor} X_i^{1,1}(x)}{\lfloor \frac{n}{k} \rfloor} - \frac{1}{2^k} \right) \frac{\lfloor \frac{n}{k} \rfloor}{n} + \sum_{p=2}^{m+5+2} \sum_{j=1}^{k-1} \left(\frac{\sum_{i=1}^{\lfloor \frac{n}{2^{p-1}k} \rfloor} X_i^{p,j}}{\lfloor \frac{n}{2^{p-1}k} \rfloor} - \frac{1}{2^k} \right) \frac{\lfloor \frac{n}{2^{p-1}k} \rfloor}{n}$$

Now,

$$D_{n,m}^{\sigma}(x) - E_{n,m}^{\sigma}(x) = \frac{1}{2^k k} + \sum_{p=2}^{m+5+2} \sum_{j=1}^{k-1} \frac{1}{2^k} \frac{\lfloor \frac{n}{2^{p-1}k} \rfloor}{n}$$

It follows that,

$$\begin{aligned} \|D_{n,m}^{\sigma}(x) - E_{n,m}^{\sigma}\|_2 &\leq \frac{1}{2^k} + \sum_{p=2}^{m+5+2} \sum_{j=1}^{k-1} \frac{1}{2^k 2^{p-1}k} \\ &\leq \frac{1}{2^k} + \sum_{p=2}^{m+5+2} \frac{1}{2^k 2^{p-1}} \\ &\leq \frac{1}{2^k} + \sum_{p=2}^{m+5+2} \frac{1}{2^k} \\ &\leq \frac{m+5+2}{2^k} \end{aligned}$$

Hence, if $|\sigma| = k \geq q_1(m) = m + 5 + 2 + m + 5$ then,

$$\|D_{n,m}^\sigma(x) - E_{n,m}^\sigma\|_2 \leq \frac{1}{2^{m+5}}$$

and,

$$\begin{aligned} \|A_n^{X_\sigma} - \mu(\sigma)\|_2 &\leq \|A_n^{X_\sigma} - D_{n,m}^\sigma\|_2 + \|D_{n,m}^\sigma(x) - E_{n,m}^\sigma\|_2 + \|E_{n,m}^\sigma\|_2 + \frac{1}{2^k} \\ &\leq \frac{3}{2^{m+5}} + \|E_{n,m}^\sigma\|_2 + \frac{1}{2^{2m+12}} \\ &\leq \frac{4}{2^{m+5}} + \|E_{n,m}^\sigma\|_2. \end{aligned}$$

Hence, in order to show that for all $n \geq |\sigma|^3 2^{q_2(m)}$, $\|A_n^{X_\sigma} - \mu(\sigma)\|_1 \leq \|A_n^{X_\sigma} - \mu(\sigma)\|_2 \leq 2^{-m}$, it is enough to show that for all $n \geq |\sigma|^3 2^{q_2(m)}$, $\|E_{n,m}^\sigma\|_2 \leq 2^{-(m+5)}$. Observe that

$$\|E_{n,m}^\sigma\|_2 \leq \left\| \frac{1}{\lfloor \frac{n}{k} \rfloor} \sum_{i=1}^{\lfloor \frac{n}{k} \rfloor} X_i^{1,1}(x) - \frac{1}{2^k} \right\|_2 + \sum_{p=2}^{m+5+2} \sum_{j=1}^{k-1} \left\| \frac{1}{\lfloor \frac{n}{2^{p-1}k} \rfloor} \sum_{i=1}^{\lfloor \frac{n}{2^{p-1}k} \rfloor} X_i^{p,j} - \frac{1}{2^k} \right\|_2.$$

Let Y_1, Y_2, \dots, Y_n be i.i.d Bernoulli random variables,

$$\begin{aligned} \left\| \frac{1}{n} \sum_{i=1}^n Y_i - \mathbf{E}(Y_1) \right\|_2 &= \sqrt{\mathbf{E} \left(\left(\frac{1}{n} \sum_{i=1}^n Y_i - \mathbf{E}(Y_1) \right)^2 \right)} \\ &= \sqrt{\text{Var} \left(\frac{1}{n} \sum_{i=1}^n Y_i \right)} \\ &= \sqrt{\frac{1}{n^2} n \text{Var}(Y_1)} \\ &\leq \frac{\sqrt{\text{Var}(Y_1)}}{\sqrt{n}} \\ &\leq \frac{1}{2\sqrt{n}} \end{aligned}$$

The last inequality follows from the fact that the variance of Bernoulli random variables are always bounded by $\frac{1}{4}$. Hence, if $n \geq |\sigma|^3 2^{q_2(m)} = |\sigma|^3 2^{5(m+6)}$ then,

$$\left\lfloor \frac{n}{k} \right\rfloor > k^2 2^{4(m+6)}$$

and

$$\left\lfloor \frac{n}{2^{p-1}k} \right\rfloor \geq \frac{k^3 2^{5(m+6)}}{2^{m+5+1}k} > k^2 2^{4(m+6)}.$$

Hence for all $n \geq |\sigma|^3 2^{q_2(m)} = |\sigma|^3 2^{5(m+6)}$,

$$\begin{aligned} \|E_{n,m}^\sigma\|_2 &\leq \frac{1}{2k2^{2(m+6)}} + (m+6)k \frac{1}{2k2^{2(m+6)}} \\ &< \frac{1}{2^{m+6}} + \frac{1}{2^{m+6}} \\ &\leq \frac{1}{2^{m+5}}. \end{aligned}$$

Hence we obtain the desired conclusion. ◀

On Guidable Index of Tree Automata

Damian Niwiński  

Institute of Informatics, University of Warsaw, Poland

Michał Skrzypczak  

Institute of Informatics, University of Warsaw, Poland

Abstract

We study guidable parity automata over infinite trees introduced by Colcombet and Löding, which form an expressively complete subclass of all non-deterministic tree automata. We show that, for any non-deterministic automaton, an equivalent guidable automaton with the smallest possible index can be effectively found. Moreover, if an input automaton is of a special kind, i.e. it is deterministic or game automaton then a guidable automaton with an optimal index can be deterministic (respectively game) automaton as well. Recall that the problem whether an equivalent non-deterministic automaton with the smallest possible index can be effectively found is open, and a positive answer is known only in the case when an input automaton is a deterministic, or more generally, a game automaton.

1 Introduction

Rabin automata on infinite trees constitute one of the most expressive formalisms based on finite-state recognisability. Introduced by Rabin in the proof of his seminal decidability result [19] as an enhancement of the more basic concept of Büchi automata on ω -words [2], tree automata continue to attract attention of researchers, and make a crossing point of various areas like logic, games, set-theoretic topology, fixed-point calculi, and theory of verification. It is an intriguing fact that a number of questions, which are by now well understood for automata on ω -words, are still largely unsolved for automata on trees. This concerns in particular decidability questions like effective measurability and effective classification within various hierarchies based on topology, or on the structure of automata. While it is plausible that we reach the frontiers of decidability here, there is neither any evidence that these problems may not be decidable.

Among the hierarchies mentioned above, the Rabin-Mostowski index hierarchy has attracted a special attention, owing to its close relation to an alternation hierarchy in the μ -calculus (cf. [1, 17]), and to the complexity of the non-emptiness problem. It refers to the acceptance criterion, which for infinite computations is conveniently expressed in terms of colours associated with the automaton states, that may or should repeat infinitely often. In a general setting, the criterion specifies explicitly the requested combinations of colours (Muller criterion), which refines the original Büchi criterion that has just requested some “good” colour to repeat infinitely often. While the Büchi and Muller criteria are equivalent for non-deterministic automata on ω -words [2], they are not for automata on trees as noted already by Rabin [20]. The parity criterion is derived from Büchi’s idea by distinguishing between “good” and “bad” colours and requesting that the highest-ranked colour repeating infinitely often is good. This is implemented by representing good and bad colours by even and odd integers, respectively. An *index* is a set of colours $\{i, i+1, \dots, j\}$ used by an automaton; its size corresponds to the number of alternations between good and bad

colours. The parity criterion is expressively equivalent to the Muller criterion, but it is more succinct and leads to the better complexity of the non-emptiness problem, up to our present knowledge. (See [21] for an insightful discussion of other meaningful criteria.)

The complexity of the non-emptiness problem for automata on infinite trees is actually a pertinent open question. While the problem is NP-complete for automata with the original Rabin acceptance criterion [9], it is expectedly more feasible for automata with the parity criterion, being in turn equivalent to the celebrated problem of solving parity games [10]. It is well-known that the complexity of this last problem has been recently improved [4] roughly from $n^{\mathcal{O}(d)}$ to $n^{\mathcal{O}(\log d)}$, where n is the number of positions and d the number of priorities (colours). This yields a quasi-polynomial solution for the non-emptiness problem for parity tree automata as well, with d corresponding to the size of automaton's index. Whether this improvement makes the quest for a small index more or less important may be the subject of discussion. In prospective applications in the model checking, the index d is derived from the formula whereas n corresponds to the size of the system, and is usually much bigger than d , so that even a small improvement of the index may be advantageous. But in any case, the recent development for parity games shows that the index is an essential parameter in understanding the problem.

The relevance of this parameter has been noticed already by Mostowski [15]. While it is known that in general an arbitrarily high index is needed for non-deterministic [16] as well as for alternating [1] automata, it is generally open if an automaton with an optimal index can be effectively found. Algorithms were given only in the special cases, where the input automaton is deterministic [18], or more generally it is a so-called game automaton [11].

An interesting approach has been undertaken by Colcombet and Löding [7], who reduced the non-deterministic index problem of parity tree automata to a problem of an apparently different nature, concerning the asymptotic behaviour of counters in some automata related to the (classical) star-height problem. In the course of their proof, these authors introduced an auxiliary concept of a *guidable tree automaton*, which in our opinion has a compelling potential and deserves to be better understood. Intuitively, a guidable automaton behaves almost like a deterministic automaton if it is given (as a kind of oracle) the non-deterministic choices of *any* other automaton running on the same tree. Colcombet and Löding [7] showed in particular that any automaton can be transformed into an equivalent guidable automaton, which essentially realises a strategy of Pathfinder in the celebrated game introduced by Gurevich and Harrington [13]. Although a guidable automaton is unsurprisingly not unique, it nevertheless constitutes a kind of a normal form of a non-deterministic automaton. It should be stressed that canonical forms are generally missing in the theory of automata on infinite objects, which is one of the sources of difficulties there. Therefore, we believe that the idea of guidable automata is worth to pursue.

In the present paper we show how to effectively compute an equivalent guidable automaton with the smallest possible index – among all guidable automata – without any restriction on the input automaton. We also revisit the concept of game automata mentioned above and show, relying on the construction of a guidable automaton by Colcombet and Löding [7], that any game automaton is itself guidable. Moreover, if an input automaton is a game or deterministic automaton then a guidable automaton with an optimal index can be a game (respectively, deterministic) automaton as well.

Unfortunately, the guidable index can be in general arbitrarily worse than the smallest possible index of an equivalent non-deterministic automaton, we are primarily searching for. We believe however, that the games used in our proofs may be of potential interest for the main problem. Note that similar games have been used in a recent work [5] (see [6]) to decide separability of regular tree languages by deterministic and game automata.

2 Basic notions

The set of natural numbers $\{0, 1, \dots\}$ is denoted ω . An *alphabet* is any finite non-empty set Σ of *letters*. By Σ^* we denote the set of *words* (i.e. finite sequences) over an alphabet Σ . By $u|_n$ we denote the finite sequence consisting of the first n symbols of u . The empty sequence is denoted ϵ . By $|u|$ we denote the length of a finite sequence u .

A Σ -labelled *tree* (shortly *tree*) is a function $t: \{\mathsf{L}, \mathsf{R}\}^* \rightarrow \Sigma$, where $\mathsf{L} \neq \mathsf{R}$ are two special symbols called *directions*. The set of all such trees is denoted Tr_Σ . If Σ and Γ are two alphabets then each pair of trees $t_1 \in \text{Tr}_\Sigma$ and $t_2 \in \text{Tr}_\Gamma$ induces their *product* $t_1 \otimes t_2 \in \text{Tr}_{\Sigma \times \Gamma}$, with $(t_1 \otimes t_2)(u) \stackrel{\text{def}}{=} (t_1(u), t_2(u))$. Given a tree language $L \subseteq \text{Tr}_{\Sigma \times \Gamma}$, its *projection* onto Σ is the set of trees $t_1 \in \text{Tr}_\Sigma$, such that there exists a tree $t_2 \in \text{Tr}_\Gamma$, for which $t_1 \otimes t_2 \in L$.

An infinite sequence of directions $b \in \{\mathsf{L}, \mathsf{R}\}^\omega$ is called a *branch*. Similarly, a *path* in a tree $t \in \text{Tr}_A$ is a sequence $(a_n, d_n)_{n \in \omega} \in (\Sigma \times \{\mathsf{L}, \mathsf{R}\})^\omega$, such that $a_n = t(d_0 \cdots d_{n-1})$ for $n = 0, 1, \dots$

An *index* is a non-empty finite range of natural numbers $C = \{i, i+1, \dots, j\} \subseteq \omega$. Elements $c \in C$ are called *priorities*. We say that an infinite sequence of priorities $(c_n)_{n \in \omega}$ is *parity accepting* if $\limsup_{n \rightarrow \infty} c_n \equiv 0 \pmod{2}$. Otherwise, we say that such a sequence is *parity rejecting*.

A *non-deterministic C-parity tree automaton* (shortly *non-deterministic automaton*) is a tuple $\mathcal{A} = \langle \Sigma, Q^{\mathcal{A}}, q_{\mathsf{I}}^{\mathcal{A}}, \Delta^{\mathcal{A}}, \Omega^{\mathcal{A}} \rangle$, where Σ is an alphabet, $Q^{\mathcal{A}}$ a finite set of *states*, $q_{\mathsf{I}}^{\mathcal{A}} \in Q^{\mathcal{A}}$ an *initial state*, $\Delta^{\mathcal{A}} \subseteq Q^{\mathcal{A}} \times \Sigma \times Q^{\mathcal{A}} \times Q^{\mathcal{A}}$ a *transition relation*; and $\Omega^{\mathcal{A}}: Q^{\mathcal{A}} \rightarrow C$ a *priority mapping*. An element $(q, a, q_{\mathsf{L}}, q_{\mathsf{R}}) \in \Delta^{\mathcal{A}}$ is called a *transition* of the automaton \mathcal{A} . We say that such a transition is *from* the state q and is *over* the letter a . We make a proviso that, unless stated otherwise, all automata in consideration are *trimmed*, that is, for each state $q \in Q^{\mathcal{A}}$ and letter $a \in \Sigma$, there is at least one transition from q over a in $\Delta^{\mathcal{A}}$. When an automaton \mathcal{A} is known from the context then we skip the superscript and write just Q , Δ , etc.

We extend the notions of parity accepting (resp. rejecting) sequences of priorities to sequences of states by applying Ω , i.e. a sequence of states $(q_n)_{n \in \omega}$ is *parity accepting* (resp. *parity rejecting*) in \mathcal{A} if the priorities $(\Omega(q_n))_{n \in \omega}$ are parity accepting (resp. parity rejecting).

Given a tree $t \in \text{Tr}_\Sigma$, a *run* of an automaton \mathcal{A} over t is a tree $\rho \in \text{Tr}_Q$ such that $\rho(\epsilon) = q_{\mathsf{I}}$ and, for each node $u \in \{\mathsf{L}, \mathsf{R}\}^*$, the tuple

$$(\rho(u), t(u), \rho(u_{\mathsf{L}}), \rho(u_{\mathsf{R}}))$$

is a transition of \mathcal{A} . Such a run is *accepting* if, for every branch $b \in \{\mathsf{L}, \mathsf{R}\}^\omega$, the sequence of states $q_n \stackrel{\text{def}}{=} \rho(b|_n)$ for $n = 0, 1, \dots$ is *parity accepting*. The set of trees over which a given automaton \mathcal{A} has some accepting run is called the *language* of \mathcal{A} and is denoted $L(\mathcal{A})$. If $q \in Q$ is a state of an automaton \mathcal{A} then by $L(\mathcal{A}, q)$ we denote the language of the automaton \mathcal{A} with the initial state set to q . We say that q is *productive* if $L(\mathcal{A}, q) \neq \emptyset$. Thus $L(\mathcal{A}) \neq \emptyset$ iff the initial state $q_{\mathsf{I}}^{\mathcal{A}}$ is productive.

A set of trees is a *regular tree language* if it is of the form $L(\mathcal{A})$ for some non-deterministic automaton \mathcal{A} .

An automaton \mathcal{A} is *deterministic* if for every state $q \in Q$ and letter $a \in \Sigma$ there exists a unique transition in $\Delta^{\mathcal{A}}$ starting from q over a . A deterministic automaton has exactly one run over each tree $t \in \text{Tr}_\Sigma$ and this run can be constructed inductively in a top-down way.

Guidable automata

The notion of a guiding function and one automaton guiding another was introduced in [7], here we follow the exposition from [14].

Fix two non-deterministic automata \mathcal{A} and \mathcal{B} over the same alphabet Σ . A *guiding function* from \mathcal{B} to \mathcal{A} is a function $g: Q^{\mathcal{A}} \times \Delta^{\mathcal{B}} \rightarrow \Delta^{\mathcal{A}}$ such that $g(p, (q, a, q_L, q_R)) = (p, a, p_L, p_R)$ for some $p_L, p_R \in Q^{\mathcal{A}}$ (i.e. the function g is compatible with the state p and the letter a). If $\rho \in \text{Tr}_{Q^{\mathcal{B}}}$ is a run of \mathcal{B} over a tree $t \in \text{Tr}_{\Sigma}$ then we define the tree $\vec{g}(\rho) \in \text{Tr}_{Q^{\mathcal{A}}}$, inductively as follows. We let $\vec{g}(\rho)(\epsilon) \stackrel{\text{def}}{=} q_1^{\mathcal{A}}$ and, for each $u \in \{\text{L}, \text{R}\}^*$, if $\vec{g}(\rho)(u) = p \in Q^{\mathcal{A}}$, $t(u) = a$, and γ is a transition of \mathcal{B} taken in u , i.e. $\gamma \stackrel{\text{def}}{=} (\rho(u), a, \rho(u_L), \rho(u_R))$, and if finally $g(p, \gamma) = (p, a, p_L, p_R) \in \Delta^{\mathcal{A}}$, then we let,

$$\vec{g}(\rho)(u_L) \stackrel{\text{def}}{=} p_L, \quad \vec{g}(\rho)(u_R) \stackrel{\text{def}}{=} p_R.$$

Notice that directly by the definition, the tree $\vec{g}(\rho)$ is a run of \mathcal{A} over t . We say that a guiding function $g: Q^{\mathcal{A}} \times \Delta^{\mathcal{B}} \rightarrow \Delta^{\mathcal{A}}$ *preserves acceptance* if whenever ρ is an accepting run of \mathcal{B} then $\vec{g}(\rho)$ is an accepting run of \mathcal{A} . We say that an automaton \mathcal{B} *guides* an automaton \mathcal{A} (denoted $\mathcal{B} \hookrightarrow \mathcal{A}$), if there exists a guiding function $g: Q^{\mathcal{A}} \times \Delta^{\mathcal{B}} \rightarrow \Delta^{\mathcal{A}}$ which preserves acceptance. In particular, it implies that $L(\mathcal{B}) \subseteq L(\mathcal{A})$.

An automaton \mathcal{A} is *guidable* if it can be guided by any automaton \mathcal{B} such that $L(\mathcal{B}) = L(\mathcal{A})$ (in fact one can equivalently require that $L(\mathcal{B}) \subseteq L(\mathcal{A})$, see [14, Remark 4.5]).

The main result concerning guidable automata is the following theorem.

► **Theorem 1** ([7, Theorem 1], see also [14, Theorem 4.7]). *For every regular tree language L there exists a guidable automaton recognising L . Moreover, such an automaton can be effectively constructed from any non-deterministic automaton for L .*

Since we will rely on the exact structure of such an automaton, we recall the crucial steps in the construction. First, let \mathcal{A} be a non-deterministic automaton recognising the given language L . Assume that $\mathcal{A}' = \langle \Sigma, Q', q'_1, \Delta', \Omega' \rangle$ is any automaton recognising the complement of L .

An important role in this construction is played by *selectors*, i.e. functions $f: \Delta' \rightarrow \{\text{L}, \text{R}\}$ (in other words $f \in \{\text{L}, \text{R}\}^{\Delta'}$). Consider a product tree $t \otimes \tau \in \text{Tr}_{\Sigma \times \{\text{L}, \text{R}\}^{\Delta'}}$ and one of its paths $((a_n, f_n), d_n)_{n \in \omega}$. We say that this path is *losing* if there exists a sequence of transitions $(\delta'_n = (p_n, a_n, p_{L,n}, p_{R,n}))_{n \in \omega}$ of \mathcal{A}' which is *\mathcal{A}' -accepting* in the following sense:

- $p_0 = q_1^{\mathcal{A}'}$,
- $\forall n \in \omega. p_{n+1} = p_{d_n, n} \wedge d_n = f_n(\delta'_n)$,
- the sequence of states $(p_n)_{n \in \omega}$ is parity accepting in \mathcal{A}' .

Lemma 1.15 in [14] provides a deterministic automaton $\text{Winning}(\mathcal{A}')$ over the alphabet $\Sigma \times \{\text{L}, \text{R}\}^{\Delta'}$. The crucial properties of this automaton are stated in the following fact.

► **Fact 2.** *The automaton $\text{Winning}(\mathcal{A}')$ accepts a product tree $t \otimes \tau \in \text{Tr}_{\Sigma \times \{\text{L}, \text{R}\}^{\Delta'}}$ if and only if none of its paths is losing. The projection of $L(\text{Winning}(\mathcal{A}'))$ onto Σ is the original language L , i.e. the complement of $L(\mathcal{A}')$.*

By $\text{Complement}(\mathcal{A}')$ we denote the non-deterministic automaton obtained from the automaton $\text{Winning}(\mathcal{A}')$ by projecting the transitions of $\text{Winning}(\mathcal{A}')$ onto the coordinate Σ : each transition of the form $(q, (a, f), q_L, q_R)$ is replaced by (q, a, q_L, q_R) ; yielding a non-deterministic automaton recognising L . We say that a transition (q, a, q_L, q_R) of $\text{Complement}(\mathcal{A}')$ is *arising* from $f \in \{\text{L}, \text{R}\}^{\Delta'}$ if $(q, (a, f), q_L, q_R)$ is a transition of $\text{Winning}(\mathcal{A}')$.

Notice that in fact the only non-determinism of the automaton $\text{Complement}(\mathcal{A}')$ comes from the projection from the alphabet $\Sigma \times \{\text{L}, \text{R}\}^{\Delta'}$ onto Σ . Therefore, to define a guiding function to guide the automaton $\text{Complement}(\mathcal{A}')$, whenever specifying a transition of $\text{Complement}(\mathcal{A}')$, it is enough to provide a selector $f \in \{\text{L}, \text{R}\}^{\Delta'}$ and then take the unique transition arising from f .

► **Lemma 3** (See the proof of [14, Theorem 4.7]). *The automaton $\text{Complement}(\mathcal{A}')$ is guidable.*

3 Guidability relation

The guidability relation $\mathcal{B} \hookrightarrow \mathcal{A}$ can be seen as a reduction, showing that one automaton uses *less non-determinism* than the other one. Thus, one would naturally expect this relation to be transitive, which is indeed the case.

► **Proposition 4.** *If $\mathcal{C} \hookrightarrow \mathcal{B}$ and $\mathcal{B} \hookrightarrow \mathcal{A}$ then $\mathcal{C} \hookrightarrow \mathcal{A}$.*

A proof of this fact is implicit in [14, Proposition 4.11], where it is shown how to compose two guiding functions $g^{\mathcal{B}}$ and $g^{\mathcal{A}}$ into a winning strategy in a game characterising guidability, called *weak inclusion game*, see [14, page 78]. However, the transitivity of the relation \hookrightarrow has not been explicitly stated before. Therefore, for the sake of completeness, we provide a proof of Proposition 4 here.

First, we recall the notion of the *weak inclusion game* $\mathcal{G}_{\text{guide}}(\mathcal{B}, \mathcal{A})$ from [14, page 78] which is used to characterise when an automaton \mathcal{B} guides another automaton \mathcal{A} , and consequently to decide whether a non-deterministic automaton is guidable. We introduce a small modification, justified below, using the following concept: a transition $(q, a, q_{\text{L}}, q_{\text{R}})$ is *productive* if both states $q_{\text{L}}, q_{\text{R}}$ are productive (cf. Section 2).

The positions of the game $\mathcal{G}_{\text{guide}}(\mathcal{B}, \mathcal{A})$ are of the form $(p, q) \in Q^{\mathcal{A}} \times Q^{\mathcal{B}}$. The initial position (p_0, q_0) is $(q_1^{\mathcal{A}}, q_1^{\mathcal{B}})$. At an n th round for $n = 0, 1, \dots$ which starts in a position (p_n, q_n) :

1. \forall chooses a letter $a_n \in \Sigma$,
2. \forall chooses a productive transition $\gamma_n = (q_n, a_n, q_{\text{L},n}, q_{\text{R},n}) \in \Delta^{\mathcal{B}}$; if there is no productive transition from q_n over a_n then \forall loses immediately,
3. \exists chooses a transition $\delta_n = (p_n, a_n, p_{\text{L},n}, p_{\text{R},n}) \in \Delta^{\mathcal{A}}$,
4. \forall chooses a direction $d_n \in \{\text{L}, \text{R}\}$.

The next position (p_{n+1}, q_{n+1}) of the game is $(p_{d_n,n}, q_{d_n,n})$.

The winning condition for \exists expresses, that if the sequence of states $(q_n)_{n \in \omega}$ is parity accepting in \mathcal{B} then the sequence of states $(p_n)_{n \in \omega}$ is parity accepting in \mathcal{A} .

► **Lemma 5** ([14, Proposition 4.9]). *The player \exists wins the above game $\mathcal{G}_{\text{guide}}(\mathcal{B}, \mathcal{A})$ if and only if $\mathcal{B} \hookrightarrow \mathcal{A}$. Moreover, the player \exists has a positional winning strategy.*

The requirement that the transitions chosen by \forall in step 2 are productive is added because of the case when $L(\mathcal{B}) = \emptyset$. In this corner case the relation $\mathcal{B} \hookrightarrow \mathcal{A}$ holds trivially whereas the characterisation as stated in [14, Proposition 4.9] seems to fail. For the sake of completeness we recall the proof of Proposition 4.9 from [14], taking into account our modification.

Proof. The fact that the game is determined and the player \exists has a positional winning strategy follows from the general theory of infinite games (see, e.g. [21, 12]); indeed the winning criterion of $\mathcal{G}_{\text{guide}}(\mathcal{B}, \mathcal{A})$ can be easily presented as a union of parity criteria and hence it is a so-called Rabin criterion. Clearly, the fact that \exists can also win in finite time does not affect the positional determinacy for this player.

Now if \mathcal{B} guides \mathcal{A} then an acceptance-preserving guiding function $g: Q^{\mathcal{A}} \times \Delta^{\mathcal{B}} \rightarrow \Delta^{\mathcal{A}}$ yields a positional strategy for \exists : in a position (p_n, q_n) , given the choice by \forall of a transition $\gamma_n = (q_n, a_n, q_{L,n}, q_{R,n}) \in \Delta^{\mathcal{B}}$, \exists chooses $\delta_n = g(p_n, \gamma_n)$. Conversely, a positional winning strategy of \exists induces a partial function $\tilde{g}: Q^{\mathcal{A}} \times \Delta^{\mathcal{B}} \rightarrow \Delta^{\mathcal{A}}$ that is defined for $p \in Q^{\mathcal{A}}$ and $\gamma = (q, a, q_L, q_R) \in \Delta^{\mathcal{B}}$ whenever the position (p, q) is winning for \exists and the transition γ is productive. We extend \tilde{g} to a total guiding function $g: Q^{\mathcal{A}} \times \Delta^{\mathcal{B}} \rightarrow \Delta^{\mathcal{A}}$ that for all other arguments is defined in any way; note that it is always possible since, by our proviso, the automaton \mathcal{A} is trimmed. By the assumption, the initial position $(q_I^{\mathcal{A}}, q_I^{\mathcal{B}})$ is winning. Then the fact that \tilde{g} has been derived from a winning strategy implies that the function g preserves acceptance. \blacktriangleleft

► **Remark 6.** Based on the above lemma, the notion that a guiding function *preserves acceptance* can be equivalently rephrased as follows. Consider any sequence of productive transitions $(\gamma_n = (q_n, a_n, q_{L,n}, q_{R,n}))_{n \in \omega}$ of \mathcal{B} and a sequence of directions $(d_n)_{n \in \omega}$. Assume that $q_0 = q_I^{\mathcal{B}}$ and $q_{n+1} = q_{d_n, n}$ for $n = 0, 1, \dots$. Let $\delta_n = (p_n, a_n, p_{L,n}, p_{R,n})$ be defined inductively for $n = 0, 1, \dots$ by $p_0 \stackrel{\text{def}}{=} q_I^{\mathcal{A}}$, $\delta_n = g(p_n, \gamma_n)$, and $p_{n+1} = p_{d_n, n}$. Then the condition that g *preserves acceptance* boils down to saying that if $(q_n)_{n \in \omega}$ is parity accepting in \mathcal{B} then $(p_n)_{n \in \omega}$ is parity accepting in \mathcal{A} .

We can now move to a proof of Proposition 4. Assume that $g^{\mathcal{B}}$ and $g^{\mathcal{A}}$ are two guiding functions which preserve acceptance, witnessing that $\mathcal{C} \leftrightarrow \mathcal{B}$ and $\mathcal{B} \leftrightarrow \mathcal{A}$.

We will show that \exists has a winning strategy in $\mathcal{G}_{\text{guide}}(\mathcal{C}, \mathcal{A})$, using the set of states of \mathcal{B} as a memory structure. More precisely, \exists keeps track of an additional state $r_n \in Q^{\mathcal{B}}$ with $r_0 \stackrel{\text{def}}{=} q_I^{\mathcal{B}}$. Consider an n th round starting in a position (p_n, q_n) with a memory state r_n of \exists . Assume that \forall has played $a_n \in \Sigma$ and $\gamma_n \in \Delta^{\mathcal{C}}$ as above. Let $\gamma'_n = (r_n, a_n, r_{L,n}, r_{R,n}) \stackrel{\text{def}}{=} g^{\mathcal{B}}(r_n, \gamma_n) \in \Delta^{\mathcal{B}}$ be the transition of \mathcal{B} given by $g^{\mathcal{B}}$. Note that if the transition γ_n was productive then γ'_n must be productive as well. Similarly, let $\delta_n \stackrel{\text{def}}{=} g^{\mathcal{A}}(p_n, \gamma'_n)$ be the transition of \mathcal{A} given by $g^{\mathcal{A}}$. Let \exists play δ_n as her choice in that round. Once the round is finished, let the new memory state of \exists be $r_{n+1} \stackrel{\text{def}}{=} r_{d_n, n}$.

► **Claim 7.** The strategy defined above is in fact winning for \exists .

Proof. Consider a play of $\mathcal{G}_{\text{guide}}(\mathcal{C}, \mathcal{A})$ that was played according to the above strategy. Let $(r_n)_{n \in \omega}$ be the sequence of memory states of \exists used during that play. Assume that $(q_n)_{n \in \omega}$ is parity accepting in \mathcal{C} . Since $g^{\mathcal{B}}$ represents a winning strategy of \exists in $\mathcal{G}_{\text{guide}}(\mathcal{C}, \mathcal{B})$, we know that $(r_n)_{n \in \omega}$ is parity accepting in \mathcal{B} . Therefore, we can use the fact that $g^{\mathcal{A}}$ represents a winning strategy of \exists in $\mathcal{G}_{\text{guide}}(\mathcal{B}, \mathcal{A})$ and entail that $(p_n)_{n \in \omega}$ is parity accepting in \mathcal{A} . \triangleleft

This concludes the proof of Proposition 4.

► **Corollary 8** (See [14, Proposition 4.11]). *Consider an automaton \mathcal{A} and a guidable automaton \mathcal{B} , both recognising the same language L . Then the automaton \mathcal{A} is guidable if and only if $\mathcal{B} \leftrightarrow \mathcal{A}$.*

Note that the above corollary combined with Lemma 5 and Theorem 1 yield a procedure to decide whether a non-deterministic automaton is guidable ([14, Theorem 4.7]).

4 Game automata as guidable automata

It is straightforward to see that deterministic automata are guidable (the function g in the definition above does not depend on the argument in $\Delta^{\mathcal{B}}$). Hence, guidable automata can be viewed as a semantic extension of deterministic automata. However, there already

exists an established notion of automata naturally extending the deterministic ones, namely the *game automata*, see [8]. In this section we recall this notion in the framework of non-deterministic automata, and prove the following new result.

► **Proposition 9.** *Every game automaton is guidable.*

Since every deterministic automaton is also game, we get a syntactic stratification:

$$\text{Deterministic} \subsetneq \text{Game} \subsetneq \text{Guidable}, \quad (1)$$

with each consecutive class not only containing more automata but also recognising more languages. Theorem 1 means that the last class in this stratification is expressively complete for all regular tree languages.

We say that a non-deterministic tree automaton \mathcal{A} is a *game automaton* if it satisfies the following two properties. First of all, Q contains a non-initial all-accepting state $\top \in Q$: $\Omega(\top)$ is even and for each letter $a \in A$ there is a unique transition starting from \top over a , namely (\top, a, \top, \top) (thus $L(\mathcal{A}, \top) = \text{Tr}_\Sigma$). Moreover, for a state $q \in Q - \{\top\}$ and a letter $a \in \Sigma$ we say that (q, a) is in one of the following *modes*:

- **conjunctive:** there is a unique transition starting from q over a of the form (q, a, q_L, q_R) with both q_L and q_R distinct from \top ;
- **disjunctive:** there are exactly two transitions starting from q over a , one of the form (q, a, q_L, \top) and the other of the form (q, a, \top, q_R) , with both q_L and q_R distinct from \top .

The above definition is a direct translation of the alternating formulation of game automata into the format of non-deterministic automata. The two modes above correspond to the use of \wedge or \vee in the transition formula $\delta(q, a)$, see [11, Definition 3.2].

Before we move to a proof of Proposition 9, we need to recall that game automata admit a syntactic complementation construction. Fix a game automaton $\mathcal{A} = \langle \Sigma, Q, q_I, \Delta, \Omega \rangle$. Consider another game automaton denoted \mathcal{A}^c defined as $\mathcal{A}^c = \langle \Sigma, Q, q_I, \Delta', \Omega' \rangle$, where Δ' and Ω' are defined as follows. First of all, $\Omega'(q) \stackrel{\text{def}}{=} \Omega(q) + 1$ for all q distinct than \top and $\Omega'(\top) \stackrel{\text{def}}{=} \Omega(\top)$. Moreover, Δ' contains the following transitions:

- for each $a \in \Sigma$ we have $(\top, a, \top, \top) \in \Delta'$;
- if $q \in Q - \{\top\}$ and $a \in \Sigma$ are in conjunctive mode and $(q, a, q_L, q_R) \in \Delta$ then the mode of (q, a) in \mathcal{A}^c is disjunctive, with (q, a, q_L, \top) and (q, a, \top, q_R) in Δ' ;
- if $q \in Q - \{\top\}$ and $a \in \Sigma$ are in disjunctive mode and (q, a, q_L, \top) , $(q, a, \top, q_R) \in \Delta$ then the mode of (q, a) in \mathcal{A}^c is conjunctive, with $(q, a, q_L, q_R) \in \Delta'$.

The following fact is an immediate consequence of the alternating semantics of game automata, see [11, page 24:7].

► **Fact 10.** *The automaton \mathcal{A}^c is also a game automaton and $L(\mathcal{A}^c) = \text{Tr}_\Sigma - L(\mathcal{A})$.*

The rest of this section is devoted to a proof of Proposition 9. Fix a game automaton $\mathcal{A} = \langle \Sigma, Q, q_I, \Delta, \Omega \rangle$ and let $\mathcal{A}' \stackrel{\text{def}}{=} \mathcal{A}^c$ denote its syntactic complement defined as above. Let Δ' be the set of transitions of \mathcal{A}' . Notice that (up to subtracting 2 from Ω) the automaton $(\mathcal{A}')^c$ is equal to the original automaton \mathcal{A} . We will now apply the procedure of constructing a guidable automaton for L . Recall that this procedure involves a deterministic automaton $\text{Winning}(\mathcal{A}')$ that accepts a product tree $t \otimes \tau \in \text{Tr}_{\Sigma \times \{\text{L,R}\}^{\Delta'}}$ if and only if none of its paths is losing. The desired guidable automaton $\text{Complement}(\mathcal{A}')$ is then obtained from $\text{Winning}(\mathcal{A}')$ by projection on the component Σ . The automaton $\text{Winning}(\mathcal{A}')$ itself is not concretely specified; it can be any deterministic automaton with the required property. We

will define it in such a way that the eventual automaton $\text{Complement}(\mathcal{A}')$ will coincide with the original automaton \mathcal{A} . It is convenient here to use a variant of a deterministic automaton where transitions leading to non-productive states are undefined, so that there is always *at most one* transition rather than exactly one. (So we momentarily suspend our proviso that all automata are trimmed, but the projection automaton will be trimmed again.) Let $\mathcal{A}_w = \langle \Sigma \times \{\mathsf{L}, \mathsf{R}\}^{\Delta'}, Q, q_I, \Delta_w, \Omega \rangle$; that is, the automaton shares the states and the priority function with \mathcal{A} . The transitions of \mathcal{A}_w are defined as follows.

- For each $a \in \Sigma$ and $f \in \{\mathsf{L}, \mathsf{R}\}^{\Delta'}$, we have $(\top, (a, f), \top, \top) \in \Delta_w$.
- If (q, a) are in disjunctive mode in \mathcal{A} , and $(q, a, q_L, \top), (q, a, \top, q_R) \in \Delta$, which implies that $(q, a, q_L, q_R) \in \Delta'$, and if $f: (q, a, q_L, q_R) \mapsto d$ (for $f \in \{\mathsf{L}, \mathsf{R}\}^{\Delta'}$) then the unique transition of \mathcal{A}_w from q over (a, f) is $(q, (a, f), q_L, \top)$ or $(q, (a, f), \top, q_R)$ depending on whether $d = \mathsf{L}$ or $d = \mathsf{R}$.
- If (q, a) are in conjunctive mode in \mathcal{A} , and $(q, a, q_L, q_R) \in \Delta$, which implies that $(q, a, q_L, \top), (q, a, \top, q_R) \in \Delta'$, and if moreover the selector f “behaves properly” in the sense that $f: (q, a, q_L, \top) \mapsto \mathsf{L}$ and $f: (q, a, \top, q_R) \mapsto \mathsf{R}$ then the unique transition of \mathcal{A}_w from q over (a, f) is $(q, (a, f), q_L, q_R)$. In all other cases, a transition from q over (a, f) is undefined.

Now, it is clear that an automaton $\text{Complement}(\mathcal{A}_w)$ obtained from \mathcal{A} by replacing each transition $(q, (a, f), q_L, q_R)$ by (q, a, q_L, q_R) (cf. Section 2) coincides with the original automaton \mathcal{A} . So the proof of Proposition 9 boils down to the following.

▷ **Claim 11.** The automaton \mathcal{A}_w accepts a product tree $t \otimes \tau \in \text{Tr}_{\Sigma \times \{\mathsf{L}, \mathsf{R}\}^{\Delta'}}$ if and only if none of its paths is losing.

Proof. Let the automaton \mathcal{A}_w accept a product tree $t \otimes \tau \in \text{Tr}_{\Sigma \times \{\mathsf{L}, \mathsf{R}\}^{\Delta'}}$ by a unique run τ . For the sake of contradiction, suppose that there exists a losing path $((a_n, f_n), d_n)_{n \in \omega}$ along with a sequence of transitions $(\delta'_n = (p_n, a_n, p_{\mathsf{L}, n}, p_{\mathsf{R}, n}))_{n \in \omega}$ of \mathcal{A}' , such that $p_0 = q_I^{\mathcal{A}'}$, and $\forall n \in \omega, p_{n+1} = p_{d_n, n} \wedge d_n = f_n(\delta'_n)$. Let $(q_n)_{n \in \omega}$ be the sequence of states visited by the run τ on this path, i.e. $q_n = \tau(d_0 \dots d_{n-1})$. We verify by induction on n that $q_n = p_n \neq \top$. Clearly $q_n = q_I^{\mathcal{A}} = q_I^{\mathcal{A}'} = p_0 \neq \top$. Suppose the claim holds for n . If (q_n, a_n) is in conjunctive mode in \mathcal{A} with the unique transition (q_n, a_n, q_L, q_R) (with $q_L, q_R \neq \top$) then (p_n, a_n) (with $p_n = q_n$) is in disjunctive mode in \mathcal{A}' , with two possible transitions. Let $\delta'_n = (p_n, a_n, p_{\mathsf{L}, n}, p_{\mathsf{R}, n}) = (q_n, a_n, q_L, \top)$; the other case is symmetric. It follows from the definition of \mathcal{A}_w that in this case $f_n: \delta'_n \mapsto \mathsf{L}$, as otherwise the next transition would not be defined and the run τ would not be accepting. Clearly, the transition of \mathcal{A}_w used at this point is $(q_n, (a_n, f_n), q_L, q_R)$. Therefore, we have $d_{n+1} = \mathsf{L}$ and $q_{n+1} = q_L = p_{n+1} \neq \top$, as required. If (q_n, a_n) is in disjunctive mode in \mathcal{A} and hence $\delta'_n = (p_n, a_n, p_{\mathsf{L}, n}, p_{\mathsf{R}, n})$ is the unique transition of \mathcal{A}' from $p_n = q_n$ over a_n , and moreover $f_n: \delta'_n \mapsto d_n$ then the transition of \mathcal{A}_w from q_n over (a_n, f_n) is $(p_n, (a_n, f_n), p_{\mathsf{L}, n}, \top)$ or $(q, (a_n, f_n), \top, p_{\mathsf{R}, n})$ depending on whether $d_n = \mathsf{L}$ or $d_n = \mathsf{R}$, but in any case we have $q_{n+1} = q_L = p_{n+1} \neq \top$, as required.

As the sequence of states $(q_n)_{n \in \omega}$ is parity accepting in \mathcal{A}_w (hence also in \mathcal{A}), it cannot be at the same time parity accepting in \mathcal{A}' , which yields a contradiction.

Now let $t \otimes \tau \in \text{Tr}_{\Sigma \times \{\mathsf{L}, \mathsf{R}\}^{\Delta'}}$ be a product tree not accepted by \mathcal{A}_w . There are two possibilities: either the unique run of \mathcal{A}_w on $t \otimes \tau$ is non-accepting, or there is no (complete) run at all, because the transitions are blocked at some place. We will show that in both cases there is a losing path in $t \otimes \tau$. Suppose first that in a run ρ of \mathcal{A}_w on $t \otimes \tau$ there is a path $(q_n, d_n)_{n \in \omega}$, with $q_0 = q_I^{\mathcal{A}}$ and $q_{n+1} = \rho(d_0 \dots d_n)$, such that the sequence $(q_n)_{n \in \omega}$ is parity rejecting. Thus in particular $q_n \neq \top$, for all n . Let $a_n = t(d_0 \dots d_{n-1})$ and $f_n = \tau(d_0 \dots d_{n-1})$. We will define inductively a sequence of transitions $(\delta'_n = (p_n, a_n, p_{\mathsf{L}, n}, p_{\mathsf{R}, n}))_{n \in \omega}$ of \mathcal{A}'

with $p_n = q_n$, which along with the sequence $(d_n)_{n \in \omega}$ will witness a losing path. As usual, we consider two cases. If (q_n, a_n) are in disjunctive mode in \mathcal{A} then we let $\delta'_n \stackrel{\text{def}}{=} (q_n, a_n, q_L, q_R)$, where the last is the unique transition of \mathcal{A}' from q_n over a_n . Suppose further that $f_n: (q_n, a_n, q_L, q_R) \mapsto \mathbb{L}$ (the other case is symmetric). Then the transition used by the automaton \mathcal{A}_w is $(q_n, (a_n, f_n), q_L, \top)$, and we know that $q_{n+1} = q_L$ (because it is different from \top), hence $d_n = \mathbb{L}$ and the local condition of a losing path is satisfied. If (q_n, a_n) are in conjunctive mode in \mathcal{A} with the transition (q_n, a_n, q_L, q_R) then, since the transition of \mathcal{A}_w over (a_n, f_n) is defined, we know that f_n “behaves properly”, i.e. $f_n: (q_n, a_n, q_L, \top) \mapsto \mathbb{L}$ and $f: (q_n, a_n, \top, q_R) \mapsto \mathbb{R}$. Suppose $d_n = \mathbb{L}$ (the other case is symmetric), hence $q_{n+1} = q_L$. We let $\delta'_n \stackrel{\text{def}}{=} (q_n, a_n, q_L, \top)$; then again the local condition of a losing path is satisfied. Thus we have obtained a losing path in $t \otimes \tau$, as expected.

Now suppose that there is no run of \mathcal{A}_w on $t \otimes \tau$. We may however define a *partial run*, i.e. a mapping $\rho: \text{dom} \rightarrow Q$, where $\text{dom} \subseteq \{\mathbb{L}, \mathbb{R}\}^*$ is closed under initial segment, such that $\rho(\epsilon) = q_I^A$, and whenever $\tau(v) = q$ and the transition $(q, (t(v), \rho(v)), q_L, q_R)$ of \mathcal{A}_w is defined then $\rho(v\mathbb{L}) = q_L$ and $\rho(v\mathbb{R}) = q_R$. Since ρ is not complete, there must be a finite path d_0, \dots, d_{m-1} , such that $\rho(d_0, \dots, d_{m-1}) = q$, $t(d_0, \dots, d_{m-1}) = a$, $\tau(d_0, \dots, d_{m-1}) = f$, and there is no transition of \mathcal{A}_w from q over (a, f) . (It is possible that $m = 0$.) This means that (q, a) are in conjunctive mode in \mathcal{A} with the transition (q, a, q_L, w_R) , but f does not “behave properly”; for example $f: (q, a, q_L, \top) \mapsto \mathbb{R}$ (the other case is symmetric). Let $q_i = \rho(d_0 \dots d_{i-1})$, for $i = 0, \dots, m$. We define a finite sequence $\delta'_0, \dots, \delta'_{m-1}$ of transitions of \mathcal{A}' corresponding to the path d_0, \dots, d_{m-1} , exactly as in the previous case, satisfying the local condition of a losing path, with $p_i = q_i$, and hence $p_m = q_m = q$. Now, under the assumption that $f: (q, a, q_L, \top) \mapsto \mathbb{R}$, we let $\delta'_m \stackrel{\text{def}}{=} (q, a, q_L, \top)$, $d_m = \mathbb{R}$, and $p_{m+1} = \top$. Then we can clearly prolong this path to a losing path (with δ'_n , for $n \geq m+1$ being a transition for \top).

This concludes the proof of Claim 11, and hence also of Proposition 9. \triangleleft

5 Decidability of guidable index

In this section we provide the main result of the present article:

► **Theorem 12.** *Given a regular language of infinite trees $L \subseteq \text{Tr}_\Sigma$ and an index $C = \{i, \dots, j\}$ it is decidable whether there exists a guidable C -parity automaton which recognises L .*

Let $\mathcal{A} = \langle \Sigma, Q^A, q_I^A, \Delta^A, \Omega^A \rangle$ be a guidable parity automaton for the given language L , which can be constructed as in Theorem 1.

Consider the following game, played between two players called \exists and \forall . The positions of the game are pairs of states $Q^A \times Q^A$ of the automaton \mathcal{A} , the initial position (p_0, p'_0) is (q_I^A, q_I^A) . At an n th round for $n = 0, 1, \dots$ which starts in a position $(p_n, p'_n) \in Q^A \times Q^A$:

1. \exists chooses a priority $c_n \in C$,
2. \forall chooses a transition $\delta_n = (p_n, a_n, p_{L,n}, p_{R,n}) \in \Delta^A$ from p_n over some letter $a_n \in \Sigma$,
3. \exists chooses a transition $\delta'_n = (p'_n, a_n, p'_{L,n}, p'_{R,n}) \in \Delta^A$ from p'_n over the same letter $a_n \in \Sigma$,
4. \forall chooses a direction $d_n \in \{\mathbb{L}, \mathbb{R}\}$.

The next position of the game (p_{n+1}, p'_{n+1}) is $(p_{d_n, n}, p'_{d_n, n})$.

The winning condition for \exists in that game is the conjunction of the following two conditions:

- W1** If the sequence of states $(p_n)_{n \in \omega}$ is parity accepting in \mathcal{A} then the sequence of priorities $(c_n)_{n \in \omega}$ must be also parity accepting.
- W2** If the sequence of priorities $(c_n)_{n \in \omega}$ is parity accepting then the sequence of states $(p'_n)_{n \in \omega}$ is parity accepting in \mathcal{A} .

Clearly the winning condition of the game is ω -regular so the winner effectively has a finite memory winning strategy [3]. The rest of this section is devoted to a proof of the following proposition.

► **Proposition 13.** *The player \exists wins the game above if and only if there exists a guidable C -parity automaton \mathcal{B} which recognises the language $L = L(\mathcal{A})$.*

► **Corollary 14.** *The problem of existence of a guidable C -parity automaton recognising a given regular language is decidable. Moreover, it is possible to effectively construct such an automaton whenever it exists.*

The construction of a guidable automaton for the language recognised by a given non-deterministic automaton may involve a double-exponential growth in the number of states [14, Proposition 4.8]. Therefore, already the size of the above game is in general double-exponential in the given representation of L . Since the index of the constructed automaton \mathcal{A} is only single-exponential, there exists a double-exponential deterministic parity automaton with single-exponentially many priorities verifying the conjunction of the winning conditions W1 and W2 (cf. [6, Section 7]). It all implies that the complexity of the proposed algorithm is 2-EXPTIME.

Soundness

Assume that \exists has a (finite memory) winning strategy in the game above. Such a strategy consists of a finite set of memory values M ; the initial memory value $m_I \in M$; a memory update function of the type:

$$\tau: Q^{\mathcal{A}} \times Q^{\mathcal{A}} \times M \times \Delta^{\mathcal{A}} \times \{\mathsf{L}, \mathsf{R}\} \rightarrow M,$$

which updates the memory value depending on the choices of the opponent in a given round; and two skolemised decision functions:

- $\bar{c}: Q^{\mathcal{A}} \times Q^{\mathcal{A}} \times M \rightarrow C$ which gives the choices of the priorities c_n depending only on the position of the game and the memory value in M ,
- $\bar{\delta}': Q^{\mathcal{A}} \times Q^{\mathcal{A}} \times M \times \Delta^{\mathcal{A}} \rightarrow \Delta^{\mathcal{A}}$ which gives the choices of the transitions δ'_n depending on the position of the game, the memory value in M , and the choice of the transition δ_n made by \forall in the given round.

We construct a non-deterministic automaton \mathcal{B} which guesses the choices of the transitions $\delta_n \in \Delta^{\mathcal{A}}$ and simulates the above strategy. Together with a definition of \mathcal{B} , we define a guiding function $g^{\mathcal{B}}: Q^{\mathcal{B}} \times \Delta^{\mathcal{A}} \rightarrow \Delta^{\mathcal{B}}$ that will be used to witness that $\mathcal{A} \leftrightarrow \mathcal{B}$.

Let the set of states of the automaton \mathcal{B} be $Q^{\mathcal{A}} \times Q^{\mathcal{A}} \times M$. The initial state is $(q_I^{\mathcal{A}}, q_I^{\mathcal{A}}, m_I)$. The priority of a state (p, p', m) is $\bar{c}(p, p', m)$. Given a state (p, p', m) of \mathcal{B} and a transition $\delta = (p, a, p_L, p_R) \in \Delta^{\mathcal{A}}$ we define $g^{\mathcal{B}}((p, p', m), \delta)$ as the transition $\left((p, p', m), a, (p_L, p'_L, m_L), (p_R, p'_R, m_R) \right)$ such that $\bar{\delta}'(p, p', m, \delta) = \delta' = (p', a, p'_L, p'_R) \in \Delta^{\mathcal{A}}$ and for each direction $d \in \{\mathsf{L}, \mathsf{R}\}$ we have $\tau(p, p', m, \delta, d) = m_d$. The set of transitions of \mathcal{B} consists of all the transitions $g^{\mathcal{B}}((p, p', m), \delta)$ for $(p, p', m) \in Q^{\mathcal{B}}$ and $\delta \in \Delta^{\mathcal{A}}$. This concludes the definition of the automaton \mathcal{B} .

In the following two proofs we will rely on the path-wise definition of when a guiding function preserves acceptance, see Remark 6.

The following fact follows directly from the assumption that we began with a winning strategy of \exists and therefore its choices satisfy the winning condition W1.

► **Fact 15.** *The guiding function $g^{\mathcal{B}}$ defined above preserves acceptance. Thus, it witnesses that $\mathcal{A} \hookrightarrow \mathcal{B}$ and in particular $L(\mathcal{A}) \subseteq L(\mathcal{B})$.*

► **Lemma 16.** *We have $\mathcal{B} \hookrightarrow \mathcal{A}$ and in particular $L(\mathcal{B}) \subseteq L(\mathcal{A})$.*

Proof. We can use the decision function $\bar{\delta}^r$ as a guide function $g^{\mathcal{A}}: Q^{\mathcal{A}} \times \Delta^{\mathcal{B}} \rightarrow \Delta^{\mathcal{A}}$. More formally, consider a transition γ of \mathcal{B} that is of the form $g^{\mathcal{B}}((p, p', m), \delta)$ for some¹ $\delta \in \Delta^{\mathcal{A}}$. Let $g^{\mathcal{A}}(p', \gamma) = \bar{\delta}^r(p, p', m, \delta)$; the remaining values of $g^{\mathcal{A}}(p'', \gamma)$ with the first argument p'' different than p' that comes from γ are irrelevant.

The fact that $g^{\mathcal{A}}$ preserves acceptance follows directly from the assumption that we began with a winning strategy of \exists and therefore its choices satisfy the winning condition W2. ◀

The two above observations allow us to use Corollary 8 to learn the following fact.

► **Fact 17.** *The automaton \mathcal{B} is guidable and recognises the language $L = L(\mathcal{A})$.*

Since \mathcal{B} is a C -parity automaton, the above fact concludes this direction of the proof.

Completeness

We will now show that if there exists a guidable C -parity automaton \mathcal{B} which recognises L then \exists has a winning strategy in the game above. Let $\mathcal{B} = \langle \Sigma, Q^{\mathcal{B}}, q_1^{\mathcal{B}}, \Delta^{\mathcal{B}}, \Omega^{\mathcal{B}} \rangle$ be such a guidable automaton.

Fix two guiding functions $g^{\mathcal{A}}: Q^{\mathcal{A}} \times \Delta^{\mathcal{B}} \rightarrow \Delta^{\mathcal{A}}$ and $g^{\mathcal{B}}: Q^{\mathcal{B}} \times \Delta^{\mathcal{A}} \rightarrow \Delta^{\mathcal{B}}$, witnessing that $\mathcal{B} \hookrightarrow \mathcal{A}$ and $\mathcal{A} \hookrightarrow \mathcal{B}$, respectively.

Let the memory structure of the constructed strategy of \exists consists of the set of states of \mathcal{B} . The initial memory value q_0 is $q_1^{\mathcal{B}}$. In an n th round of the game that starts in a position $(p_n, p'_n) \in Q^{\mathcal{A}} \times Q^{\mathcal{A}}$ and with a memory value $q_n \in Q^{\mathcal{B}}$ let \exists play as follows:

- \exists plays the priority $c_n \stackrel{\text{def}}{=} \Omega^{\mathcal{B}}(q_n)$,
- \forall plays a transition $\delta_n = (p_n, a_n, p_{L,n}, p_{R,n}) \in \Delta^{\mathcal{A}}$, which is mapped by $g^{\mathcal{B}}$ to a transition $\gamma = (q_n, a_n, q_{L,n}, q_{R,n}) \stackrel{\text{def}}{=} g^{\mathcal{B}}(q_n, \delta) \in \Delta^{\mathcal{B}}$,
- \exists plays the transition $\delta'_n = (p'_n, a_n, p'_{L,n}, p'_{R,n}) \stackrel{\text{def}}{=} g^{\mathcal{A}}(p'_n, \gamma) \in \Delta^{\mathcal{A}}$,
- \forall plays a direction $d_n \in \{L, R\}$,

and the next memory value q_{n+1} is $q_{d_n, n}$.

The following fact is an immediate consequence of the assumptions that the functions $g^{\mathcal{B}}$ and $g^{\mathcal{A}}$ map accepting runs into accepting runs, see Remark 6.

► **Lemma 18.** *The strategy defined above is winning for \exists .*

Proof. Consider an infinite play of the game where \exists played according to the above defined strategy. First consider the winning condition W1. Assume that the sequence of states $(p_n)_{n \in \omega}$ is parity accepting in \mathcal{A} . Therefore, by the assumption on $g^{\mathcal{B}}$ we know that the sequence of states $(q_n)_{n \in \omega}$ is parity accepting in \mathcal{B} . But the choice of priorities c_n as $\Omega^{\mathcal{B}}(q_n)$ guarantees that the sequence of priorities $(c_n)_{n \in \omega}$ must also be parity accepting.

Now consider the winning condition W2 and assume that the sequence of priorities $(c_n)_{n \in \omega}$ is parity accepting. Therefore, the sequence of states $(q_n)_{n \in \omega}$ must be parity accepting in \mathcal{B} . Based on the assumption on $g^{\mathcal{A}}$ we know that the sequence of states $(p'_n)_{n \in \omega}$ must be parity accepting in \mathcal{A} . ◀

¹ In fact the transition δ is uniquely determined by γ .

6

 Index transfer results

In this section we show results binding deterministic, game, and guidable indices of languages, as expressed by the following proposition.

► **Proposition 19.** *Assume that $L \subseteq \text{Tr}_\Sigma$ can be recognised by some deterministic (resp. game) automaton and by some guidable C -parity automaton. Then L can be recognised by a deterministic (resp. game) C -parity automaton.*

First consider the case of deterministic automata. Let \mathcal{D} be any deterministic automaton recognising L and let \mathcal{A} be a guidable C -parity automaton recognising L . Let $g^{\mathcal{A}}: Q^{\mathcal{A}} \times \Delta^{\mathcal{D}} \rightarrow \Delta^{\mathcal{A}}$ be a guiding function witnessing that $\mathcal{D} \hookrightarrow \mathcal{A}$.

Consider the automaton \mathcal{B} constructed as a product of \mathcal{D} and \mathcal{A} . More formally, the set of states of \mathcal{B} is $Q^{\mathcal{D}} \times Q^{\mathcal{A}}$; the initial state of \mathcal{B} is $(q_{\top}^{\mathcal{D}}, q_{\top}^{\mathcal{A}})$; the priority function is defined as $\Omega^{\mathcal{B}}(q, p) = \Omega^{\mathcal{A}}(p)$; and the transitions of \mathcal{B} are of the form

$$((q, p), a, (q_L, p_L), (q_R, p_R)) \in \Delta^{\mathcal{B}}$$

where $\gamma = (q, a, q_L, q_R)$ is the unique transition of \mathcal{D} from q over a and $\delta = (p, a, p_L, p_R) \stackrel{\text{def}}{=} g^{\mathcal{A}}(p, \gamma) \in \Delta^{\mathcal{A}}$ is the transition given by the guiding function $g^{\mathcal{A}}$. Directly from the definition we see that \mathcal{B} is a deterministic C -parity automaton. Therefore, the following fact concludes the proof of Proposition 19 in the case of deterministic automata.

► **Lemma 20.** $L(\mathcal{B}) = L$.

Proof. The fact that $L(\mathcal{B}) \subseteq L(\mathcal{A})$ is immediate, as each accepting run of \mathcal{B} encodes an accepting run of \mathcal{A} over the same tree. On the other hand, if $t \in L(\mathcal{D})$ then the assumptions on $g^{\mathcal{A}}$ imply that the unique run of \mathcal{B} over t must be accepting. ◀

We now move to the proof of Proposition 19 in the case of game automata. Similarly as before, take any game automaton \mathcal{D} recognising L and let \mathcal{A} be a guidable C -parity automaton recognising L .

We first modify the automaton \mathcal{A} by adding an additional state \top of even priority and a transition of the form (\top, a, \top, \top) for each letter $a \in \Sigma$. Now, for each state $p \in Q^{\mathcal{A}} - \{\top\}$ such that $L(\mathcal{A}, p) = \text{Tr}_\Sigma$, remove this state and replace each occurrence of p by \top in all the transitions of \mathcal{A} . Clearly, these modifications do not change the language recognised by \mathcal{A} . Moreover, if the original automaton was guidable then the new one is also guidable. For the sake of simplicity we assume that from this moment on \mathcal{A} denotes the modified automaton. Let $g^{\mathcal{A}}: Q^{\mathcal{A}} \times \Delta^{\mathcal{D}} \rightarrow \Delta^{\mathcal{A}}$ be a guiding function witnessing that $\mathcal{D} \hookrightarrow \mathcal{A}$.

The automaton \mathcal{B} is defined analogously as in the deterministic case, as a product of the automata \mathcal{D} and \mathcal{A} using the guiding function $g^{\mathcal{A}}$. We additionally restrict the set of states of \mathcal{B} to those that can be reached from the initial state $(q_{\top}^{\mathcal{D}}, q_{\top}^{\mathcal{A}})$ using the transitions of \mathcal{B} .

▷ **Claim 21.** If a state (\top, p) is reachable from the initial state of \mathcal{B} by the transitions of \mathcal{B} then $L(\mathcal{A}, p) = \text{Tr}_\Sigma$, which means that $p = \top$.

Proof. Since all the transitions of \mathcal{B} follow the guiding function $g^{\mathcal{A}}$, whenever a state (q, p) is reachable in the automaton \mathcal{B} , we know that it is a winning position of \exists in the weak inclusion game $\mathcal{G}_{\text{guide}}(\mathcal{D}, \mathcal{A})$, see Lemma 5. This guarantees that $L(\mathcal{D}, q) \subseteq L(\mathcal{A}, p)$, and as $L(\mathcal{D}, \top) = \text{Tr}_\Sigma$, we know that $L(\mathcal{A}, p) = \text{Tr}_\Sigma$. ◀

The above claim implies that \mathcal{B} is in fact a game automaton with the shape of transitions inherited from \mathcal{D} and (\top, \top) playing the role of the state \top of \mathcal{B} . Since the priority function $\Omega^{\mathcal{B}}$ is again inherited from \mathcal{A} , \mathcal{B} is a C -parity automaton.

It remains to show that $L(\mathcal{B}) = L$. Similarly as in the deterministic case, the inclusion $L(\mathcal{B}) \subseteq L(\mathcal{A})$ is immediate as each accepting run of \mathcal{B} encodes an accepting run of \mathcal{A} . On the other hand, the inclusion $L(\mathcal{D}) \subseteq L(\mathcal{B})$ is direct from the assumptions on $g^{\mathcal{A}}$ – each accepting run of \mathcal{D} is mapped by $g^{\mathcal{A}}$ into an accepting run of \mathcal{B} .

This concludes the proof of Proposition 19.

Consequences

By combining Proposition 19 and Proposition 9 (or by direct construction) we can observe the following.

► **Remark 22.** If $L \subseteq \text{Tr}_{\Sigma}$ is recognised by some deterministic automaton and by some game C -parity automaton then L can be recognised by a deterministic C -parity automaton.

Thus the stratification from (1) preserves indices of the languages: if a language happens to be recognisable by a less expressive automaton then its parity index is the same from the point of view of both less and more expressive classes.

On the other hand, it is known that there is no such transfer when moving between deterministic and (general) non-deterministic automata. Indeed, we have the following property on ω -words.

► **Fact 23** ([22]). *For each $C = \{i, \dots, j\} \subseteq \omega$ there exists a regular language of ω -words, which can be recognised by a non-deterministic $\{1, 2\}$ -parity (Büchi) ω -word automaton, but not by any deterministic C -parity ω -word automaton.*

This property can be easily shifted to infinite trees (e.g., by considering the set of all trees whose leftmost branch belongs to a given regular language of ω -words). Thus we obtain the following consequence of Proposition 19.

► **Corollary 24.** *For each $C = \{i, \dots, j\} \subseteq \omega$ there exists a regular tree language L which can be recognised by some deterministic automaton and some non-deterministic $\{1, 2\}$ -parity automaton but not by any deterministic, game, nor guidable C -parity automaton.*

7 Conclusions

The present work is focused on the class of guidable automata. We show that they syntactically extend the previously studied classes of deterministic and game automata. Moreover, we provide an algorithm solving the guidable index problem. Finally, we show that for the three considered classes of deterministic, game, and guidable automata, the index can be transferred. As a negative consequence of this fact (Corollary 24) we show that there is no correspondence between the general non-deterministic index of a regular tree language and its guidable index.

Although these results do not bring a direct progress in the general non-deterministic index problem; we hope that they may be useful in at least two ways.

First, we believe that the class of guidable automata is worth separate attention. As our new results indicate, this class of tree automata is tractable and extends the previously considered classes of *structurally simple* automata: deterministic and game. This is especially important as, contrarily to the other two classes, guidable automata are expressively complete for all regular tree languages.

Second, the present results indicate a new way of approaching the index problems, by providing new game-based techniques. In particular, we believe that the interplay between the two sequences of transitions, δ_n and δ'_n , constructed in the game from Section 5, gives some insight on ways of forcing the players to witness the existence of certain objects.

Abstract

We prove new complexity results for FEEDBACK VERTEX SET and EVEN CYCLE TRANSVERSAL on H -free graphs, that is, graphs that do not contain some fixed graph H as an induced subgraph. In particular, we prove that both problems are polynomial-time solvable for sP_3 -free graphs for every integer $s \geq 1$; here, the graph sP_3 denotes the disjoint union of s paths on three vertices. Our results show that both problems exhibit the same behaviour on H -free graphs (subject to some open cases). This is in part explained by a new general algorithm we design for finding in a graph G a largest induced subgraph whose blocks belong to some finite class \mathcal{C} of graphs. We also compare our results with the state-of-the-art results for the ODD CYCLE TRANSVERSAL problem, which is known to behave differently on H -free graphs.

1 Introduction

For a set of graphs \mathcal{F} , an \mathcal{F} -transversal of a graph G is a set of vertices that intersects the vertex set of every (not necessarily induced) subgraph of G that is isomorphic to some graph of \mathcal{F} . The problem MIN \mathcal{F} -TRANSVERSAL (also called \mathcal{F} -DELETION) is to find an \mathcal{F} -transversal of minimum size (or size at most k , in the decision variant). Graph transversals form a central topic in Discrete Mathematics and Theoretical Computer Science, both from a structural and an algorithmic point of view.

If \mathcal{F} is the set of all cycles, the set of all even cycles or odd cycles, then we obtain the problems FEEDBACK VERTEX SET, EVEN CYCLE TRANSVERSAL and ODD CYCLE TRANSVERSAL, respectively. All three problems are NP-complete; hence, they have been studied for special graph classes, in particular *hereditary* graph classes, that is, classes closed under vertex deletion. Such classes can be characterized by a (unique) set \mathcal{H} of minimal forbidden induced subgraphs. Then, in order to initiate a systematic study, it is standard to first consider the case where \mathcal{H} has size 1, say $\mathcal{H} = \{H\}$ for some graph H .

We aim to extend known complexity results for FEEDBACK VERTEX SET for H -free graphs and to perform a new, similar study for EVEN CYCLE TRANSVERSAL (for which, so far, mainly parameterized complexity results exist [2, 3, 11, 12]). To describe the known and new results we need some terminology. The cycle and path on r vertices are denoted C_r and P_r , respectively. The *disjoint union* of two vertex-disjoint graphs G_1 and G_2 is the graph $G_1 + G_2 = (V(G_1) \cup V(G_2), E(G_1) \cup E(G_2))$. We write sG for the disjoint union of s copies of G . For a set $S \subseteq V$, let $G[S]$ be the subgraph of G induced by S . We write $H \subseteq_i G$ (or $G \supseteq_i H$) if H is an induced subgraph of G .

1.1 Known Results

By Poljak's construction [14], for every integer $g \geq 3$, FEEDBACK VERTEX SET is NP-complete for graphs of girth at least g (the *girth* of a graph is the length of its shortest cycle). The same holds for ODD CYCLE TRANSVERSAL [7]. It is also known that FEEDBACK VERTEX SET [13] and ODD CYCLE TRANSVERSAL [7] are NP-complete for line graphs and thus for claw-free graphs (the claw is the 4-vertex star). Hence, both problems are NP-complete for the class of H -free graphs whenever H has a cycle or claw. A graph with no cycles and no claws is a forest of maximum degree at most 2. Thus, it remains to consider the case where H is a *linear forest*, that is, a collection of disjoint paths. Both problems are polynomial-time solvable on permutation graphs [5] and thus on P_4 -free graphs [5], on sP_2 -free graphs for every $s \geq 1$ [7] and on $(sP_1 + P_3)$ -free graphs for every $s \geq 0$ [9]. Additionally, FEEDBACK VERTEX SET is polynomial-time solvable on P_5 -free graphs [1], and ODD CYCLE TRANSVERSAL is NP-complete for $(P_2 + P_5, P_6)$ -free graphs [9]. A similar NP-hardness result for FEEDBACK VERTEX SET or EVEN CYCLE TRANSVERSAL is unlikely: for every linear forest H , both problems are quasipolynomial-time solvable on H -free graphs [9] (see Section 4 for details).

1.2 Our Results

We first note that MIN \mathcal{F} -TRANSVERSAL is polynomially equivalent to MAX INDUCED \mathcal{F} -SUBGRAPH, the problem of finding a maximum-size induced subgraph of the input graph G that does not belong to \mathcal{F} (where we assume that G has at least one such subgraph). We say that MAX INDUCED \mathcal{F} -SUBGRAPH is the *complementary* problem of MIN \mathcal{F} -TRANSVERSAL, and vice versa. For example, setting $\mathcal{F} = \{P_2\}$ yields the well-known complementary problems MIN VERTEX COVER and MAX INDEPENDENT SET.

Using the complementary perspective, we now argue that FEEDBACK VERTEX SET and EVEN CYCLE TRANSVERSAL are closely related, in contrast to ODD CYCLE TRANSVERSAL. A graph G is *biconnected* if it has at least two vertices, is connected, and $G - u$ is connected for every $u \in V(G)$. A *block* of a graph G is an inclusion-wise maximal biconnected subgraph of G . We now let \mathcal{C} be a set of biconnected graphs. A graph G is a \mathcal{C} -*block graph* if every block of G is isomorphic to some graph in \mathcal{C} . If $\mathcal{C} = \{P_2\}$, then \mathcal{C} -block graphs are precisely forests, and if $\mathcal{C} = \{P_2, C_3, C_5, C_7, \dots\}$, then \mathcal{C} -block graphs are called *odd cacti*. It is well known that a graph is an odd cactus if and only if it does not contain any even cycle as a subgraph. Hence, the complementary problems of EVEN CYCLE TRANSVERSAL and FEEDBACK VERTEX SET are somewhat similar: in particular, both forests and odd cacti have bounded treewidth and their blocks have a very simple structure. This is in stark contrast to ODD CYCLE TRANSVERSAL, whose complementary problem is to find a large induced bipartite subgraph, which might be arbitrarily complicated.

The commonality of complementary problems of EVEN CYCLE TRANSVERSAL and FEEDBACK VERTEX SET leads to the following optimization problem, where \mathcal{C} is some fixed class of biconnected graphs, that is, \mathcal{C} is not part of the input but specified in advance. Note that we consider the more general setting in which every vertex v of G is equipped with a weight $\mathfrak{w}(v) > 0$, and we must find a solution with maximum total weight, respectively.

MAX \mathcal{C} -BLOCK GRAPH

Instance: a graph $G = (V, E)$ with a vertex weight function $\mathfrak{w} : V \rightarrow \mathbb{Q}^+$.

Objective: find a maximum-weight set $X \subseteq V$ such that $G[X]$ is a \mathcal{C} -block graph.

We observe that MAX \mathcal{C} -BLOCK GRAPH is well-defined for every set \mathcal{C} , including $\mathcal{C} = \emptyset$, as every independent set in a graph forms a solution. A restriction of the MAX \mathcal{C} -BLOCK GRAPH problem was introduced and studied from a parameterized complexity perspective by Bonnet et al. [4] as BOUNDED \mathcal{C} -BLOCK VERTEX DELETION (so from the complementary perspective) where each block must in addition have bounded size.

In Section 2 we slightly extend a previously known result, concerning the so-called *blob graphs* [10]. This extended version of the result forms a key ingredient for the proof of our main result, shown in Section 3, which is the following theorem for sP_3 -free graphs (these are the graphs that become a disjoint union of cliques after removing the vertices of any induced $(s-1)P_3$ and their neighbours).

► **Theorem 1.** *For every integer $s \geq 1$ and every finite class \mathcal{C} of biconnected graphs, MAX \mathcal{C} -BLOCK GRAPH can be solved in polynomial time for sP_3 -free graphs.*

Theorem 1 implies the corresponding result for FEEDBACK VERTEX SET, as it is equivalent to MAX $\{P_2\}$ -BLOCK GRAPH. The condition for \mathcal{C} to be finite is critical for our proof technique. Nevertheless, we still have the corresponding result for EVEN CYCLE TRANSVERSAL as well: for sP_3 -free graphs, the cases $\mathcal{C} = \{P_2, C_3, C_5, C_7, \dots\}$ and $\mathcal{C} = \{P_2, C_3, C_5, \dots, C_{4s-3}\}$ are equivalent. Note that we cannot make such an argument for ODD CYCLE TRANSVERSAL, as arbitrarily large bicliques are $2P_3$ -free.

► **Corollary 2.** *For every integer $s \geq 1$, FEEDBACK VERTEX SET and EVEN CYCLE TRANSVERSAL can be solved in polynomial time for sP_3 -free graphs.*

Corollary 2 extends the aforementioned results for FEEDBACK VERTEX SET on sP_2 -free graphs and $(sP_1 + P_3)$ -free graphs. In Section 4 we observe that as a direct consequence of a more general result [1], EVEN CYCLE TRANSVERSAL is polynomial-time solvable for P_5 -free graphs. There we also prove that EVEN CYCLE TRANSVERSAL is NP-complete for graphs of large girth and for line graphs, and consequently, for H -free graphs where H contains a cycle or a claw. Hence, FEEDBACK VERTEX SET and EVEN CYCLE TRANSVERSAL behave similarly on H -free graphs, subject to a number of open cases, which we listed in Table 1.

2 Blob Graph of Graphs With No Large Linear Forest

Let $G = (V, E)$ be a graph. A (*connected*) *component* is a maximal connected subgraph of G . The *neighbourhood* of a vertex $u \in V$ is the set $N_G(u) = \{v \mid uv \in E\}$. For $U \subseteq V$, we let $N_G(U) = \bigcup_{u \in U} N(u) \setminus U$. Two sets $X_1, X_2 \subseteq V(G)$ are *adjacent* if $X_1 \cap X_2 \neq \emptyset$ or there exists an edge with one endpoint in X_1 and the other in X_2 . The *blob graph* G° of G is defined as follows.

$$V(G^\circ) := \{X \subseteq V(G) \mid G[X] \text{ is connected}\} \text{ and } E(G^\circ) := \{X_1 X_2 \mid X_1 \text{ and } X_2 \text{ are adjacent}\}.$$

Gartland et al. [10] showed that for every graph G , the length of a longest induced path in G° is equal to the length of a longest induced path in G . We slightly generalize this result.

■ **Table 1** The complexity of FEEDBACK VERTEX SET (FVS), EVEN CYCLE TRANSVERSAL (ECT) and ODD CYCLE TRANSVERSAL (OCT) on H -free graphs for a linear forest H . All three problems are NP-complete for H -free graphs when H is not a linear forest (see also Section 4). The two blue cases (one for FVS, one for ECT) are the *algorithmic* contributions of this paper. We write $H \subseteq_i H'$ if H is an induced subgraph of H' . See Section 1.1 for references to the known results in the table.

	polynomial-time	unresolved	NP-complete
FVS	$H \subseteq_i P_5$ or sP_3 for $s \geq 1$	$H \supseteq_i P_1 + P_4$	none
ECT	$H \subseteq_i P_5$ or sP_3 for $s \geq 1$	$H \supseteq_i P_1 + P_4$	none
OCT	$H = P_4$ or $H \subseteq_i sP_1 + P_3$ or sP_2 for $s \geq 1$	$H = sP_1 + P_5$ for $s \geq 0$ or $H = sP_1 + tP_2 + uP_3 + vP_4$ for $s, t, u \geq 0, v \geq 1$ with $\min\{s, t, u\} \geq 1$ if $v = 1$, or $H = sP_1 + tP_2 + uP_3$ for $s, t \geq 0,$ $u \geq 1$ with $u \geq 2$ if $t = 0$	$H \supseteq_i P_6$ or $P_2 + P_5$

► **Theorem 3.** *For every linear forest H , a graph G contains H as an induced subgraph if and only if G° contains H as an induced subgraph.*

Proof. As G is an induced subgraph of G° , the (\Rightarrow) implication is immediate. We prove the (\Leftarrow) implication by induction on the number k of connected components of H . If $k = 1$, then the claim follows directly from the aforementioned result of Gartland et al. [10]. So assume that $k \geq 2$ and the statement holds for all linear forests H with fewer than k connected components. Let P' be one of the connected components of H , and define $H' := H - P'$.

Suppose that G° contains an induced subgraph isomorphic to H . Let \mathcal{X} be the set of vertices of G° , such that $G^\circ[\mathcal{X}]$ is isomorphic to H . Furthermore, let $\mathcal{Y} \subseteq \mathcal{X}$ be the set of vertices that induce in $G^\circ[\mathcal{X}]$ the component P' of H , that is, $G^\circ[\mathcal{Y}]$ is isomorphic to P' .

Let $Y \subseteq V(G)$ be the union of sets in \mathcal{Y} . Note that $G^\circ[\mathcal{Y}]$ is an induced subgraph of $(G[Y])^\circ$. Thus, by the inductive assumption, $G[Y]$ contains an induced copy of P' .

Let $X \subseteq V(G)$ be the union of sets in $\mathcal{X} \setminus \mathcal{Y}$. Since the copy of H in G° is induced, we know that in G° there are no edges between $\mathcal{X} \setminus \mathcal{Y}$ and \mathcal{Y} . This is equivalent to saying that $X \cap N[Y] = \emptyset$. So we conclude that $G^\circ[\mathcal{X} \setminus \mathcal{Y}]$ is an induced subgraph of $(G - N[Y])^\circ$. Since $G^\circ[\mathcal{X} \setminus \mathcal{Y}]$, and thus $(G - N[Y])^\circ$, contains an induced copy of H' , by the inductive assumption we know that $G - N[Y]$ contains an induced copy of H' . Combining this subgraph with the induced copy of P' in $G[Y]$, we obtain an induced copy of H in G . ◀

3 The Proof of Theorem 1

We start with analyzing the structure of sP_3 -free \mathcal{C} -block graphs in Section 3.1, where \mathcal{C} is any finite class of biconnected graphs. Then, in Section 3.2, we present our algorithm for MAX \mathcal{C} -BLOCK GRAPH on sP_3 -free graphs.

3.1 Blocks and Terminals in sP_3 -free Graphs

From now on, let \mathcal{C} be a finite class of biconnected graphs. For some fixed positive integer s , let $G = (V, E)$ be an sP_3 -free graph with n vertices and vertex weights $\mathbf{w}: V \rightarrow \mathbb{Q}^+$. Let $X \subseteq V$ such that $F = G[X]$ is a \mathcal{C} -block graph. A component of F is *trivial* if it is a single vertex or a single block, otherwise it is *non-trivial*. Let F' be the graph obtained from F by removing all trivial components. Note that F' and F are sP_3 -free, as G is sP_3 -free.

■ **Figure 1** Left: a graph F' . Blue shapes are blocks, squares are terminals, and dots are non-terminal cutvertices. Right: $\text{BCF}(F')$, rooted in the cutvertex v . Blue diamonds are blocks; w is a terminal of type 1, u and x are terminals of type 2, and y is a terminal of both types. The remaining cutvertices are not terminals. We also use this example with this particular $\text{BCF}(F')$ in later figures.

We denote the set of cutvertices of F' and the set of blocks of F' by $\text{Cutvertices}(F')$ and $\text{Blocks}(F')$, respectively. The *block-cut forest* $\text{BCF}(F')$ of F' has vertex set $\text{Cutvertices}(F') \cup \text{Blocks}(F')$ and an edge set that consists of all edges xb such that $x \in \text{Cutvertices}(F')$ and $b \in \text{Blocks}(F')$, and x belongs to b . By definition, each component of F' has a cutvertex; we pick an arbitrary one as root for the corresponding tree in $\text{BCF}(F')$ to get a parent-child relation. Each leaf of $\text{BCF}(F')$ belongs to $\text{Blocks}(F')$, and we call such blocks *leaf blocks*.

A cutvertex x of F' is a *terminal of type 1* if x has at least two children in $\text{BCF}(F')$ that are leaves, whereas x is a *terminal of type 2* if there exists a leaf block, whose great-grandparent in $\text{BCF}(F')$ is x . In the latter case, there is a three-edge downward path from x to a leaf in $\text{BCF}(F')$; see also Fig. 1. Let d be the maximum number of vertices of a graph in \mathcal{C} .

► **Lemma 4.** *At most $d \cdot (s - 1)$ vertices of F' are terminals of type 1.*

Proof. For contradiction, suppose that there are at least $d \cdot (s - 1) + 1$ terminals of type 1. We observe that F' is d -colourable. Indeed, each block has at most d vertices, so d colours are sufficient to colour each block. Furthermore, we can permute the colours in each block, so that the colourings agree on cutvertices.

This implies that there is an independent set X of size at least s , whose every element is a terminal of type 1. For each such terminal v , let its *private* P_3 be a 3-vertex path with v as the central vertex and each endpoint belonging to a different leaf block that is a child of v in $\text{BCF}(F')$. Note that each private P_3 is induced. Furthermore, the private P_3 's of vertices in X are pairwise non-adjacent: this follows from the definition of terminals of type 1 and the fact that X is independent. Thus we have found an induced sP_3 in F , a contradiction. ◀

► **Lemma 5.** *At most $(d + 1) \cdot (s - 1)$ vertices of F' are terminals of type 2.*

Proof. For contradiction, suppose that there are at least $(d + 1) \cdot (s - 1) + 1$ terminals of type 2. Observe that F' has a proper $(d + 1)$ -colouring f , satisfying the following two properties:

1. the vertices in each block receive pairwise distinct colours and
 2. if b is a block, then any vertex of b receives a colour which is different than the colour of the cutvertex which is the great-grandparent of b in $\text{BCF}(F')$ (if such a cutvertex exists).
- It is easy to find such a colouring of each tree in $\text{BCF}(F')$ by choosing an arbitrary colour for the root and proceeding in a top-down fashion. Suppose we want to colour the block b and its parent in $\text{BCF}(F')$ is the cutvertex v . Recall that b has at most d vertices and exactly one of them is already coloured. Furthermore, we want to avoid the colour of the grandparent of v (if such a vertex exists), so we have sufficiently many free colours to colour each vertex of $b \setminus \{v\}$ with a different one.

Now, by our assumption, there is a set X of at least s terminals of type 2 that received the same colour in f . For each $v \in X$, we define its *private* P_3 as follows. Recall that by the definition of a terminal of type 2, there is a leaf block b , whose great-grandparent in $\text{BCF}(F')$ is v . The private P_3 of v is given by the first three vertices on a shortest path P from v to b . Note that in the extreme case it might happen that both b and its grandparent in $\text{BCF}(F')$ are edges, but P always has at least three vertices.

Clearly, each private P_3 is an induced path. We claim that the private P_3 's associated with the vertices of X are non-adjacent. For contradiction, suppose otherwise. Let v_1, v_2 be distinct vertices of X , and let v_i, x_i, y_i be the consecutive vertices of the private P_3 associated with v_i . Let b_i be the block containing v_i and x_i .

First, observe that the sets $\{v_1, x_1, y_1\}$ and $\{v_2, x_2, y_2\}$ are disjoint. Indeed, we know that $v_1 \neq v_2$ and because $\text{BCF}(F')$ is a rooted tree, we have that $\{x_1, y_1\} \cap \{x_2, y_2\} = \emptyset$. Furthermore, recall that $f(v_1) = f(v_2)$ and by the definition of f , we have that the colours of x_i and of y_i are different from the colour of v_i .

So now suppose that there is an edge with one endpoint in $\{v_1, x_1, y_1\}$ and the other in $\{v_2, x_2, y_2\}$. Clearly this edge cannot join v_1 and v_2 , as the colouring f is proper. Furthermore, there is no edge between $\{x_1, y_1\}$ and $\{x_2, y_2\}$, as v_1 and v_2 are cutvertices of a rooted tree. Suppose that v_2 is adjacent to x_1 (the case that v_1 is adjacent to x_2 is symmetric). As each vertex of b_1 gets a different colour in f , we observe that v_2 cannot belong to b_1 . Thus x_1 is a cutvertex. However, by the second property of f , we obtain that the colour of v_2 must be different than the colour of v_1 , a contradiction.

So finally suppose that v_2 is adjacent to y_1 . Note that then y_1 cannot belong to a leaf block, meaning that y_1 belongs to b_1 . Similarly to the previous paragraph, the definition of f implies that the colour of v_2 must be different than the colour of v_1 , a contradiction.

Thus we have found an induced sP_3 in F' , a contradiction. \blacktriangleleft

Lemmas 4 and 5 imply the following.

► **Lemma 6.** *The number of terminals of F' is at most $(2d + 1) \cdot (s - 1)$.*

If v is a terminal of type 2, then by definition there is a cutvertex w that belongs to both a block containing v as well as to some leaf block. We call such w a *witness* of v . We now partition the set of blocks of F' into the following subsets; see also Fig. 2:

- \mathcal{B}_{i_1} is the set of leaf blocks containing a terminal of type 1,
- \mathcal{B}_{i_2} is the set of leaf blocks containing a witness w that is not a terminal of type 1,
- \mathcal{B}_{i_3} is the set of remaining leaf blocks, that is, the ones with a cutvertex that is neither a terminal nor a witness,
- \mathcal{B}_w is the set of blocks with precisely two cutvertices, one of which is a terminal of type 2 and the other one the non-terminal witness of that type-2 terminal, and
- \mathcal{B}_{in} is the set of all remaining blocks.

■ **Figure 2** The classification of blocks of the example of Figure 1.

Note that blocks in \mathcal{B}_{t_2} and \mathcal{B}_w come in pairs, that is, for each block B in one of these sets, there is exactly one block B' in the other set, such that B and B' share a vertex (it is the witness w , using the notation introduced above). We will consider these two blocks as one object. Formally, a *double-block* is a graph consisting of two blocks sharing a cutvertex. Let \mathcal{B}_d be the family of double-blocks of F' obtained from blocks in \mathcal{B}_{t_2} and \mathcal{B}_w in the way described above, i.e., \mathcal{B}_d consists of graphs $G[V(B) \cup V(B')]$, where $B \in \mathcal{B}_{t_2}$, $B' \in \mathcal{B}_w$ and $V(B) \cap V(B') \neq \emptyset$. Note that each double-block in \mathcal{B}_d has fewer than $2d$ vertices and contains exactly one terminal of type 2.

A *backbone* of a component Z of F' is a minimum tree T_Z contained in Z that connects all terminals of F' that belong to Z ; observe that all leaves of T_Z are terminals. The *skeleton* S of F' is the graph obtained from F' by removing all vertices from the blocks in \mathcal{B}_{t_1} except terminals of type 1 and all vertices from the double-blocks in \mathcal{B}_d except terminals of type 2. Note that every backbone is a subgraph of S .

3.2 The Algorithm

Outline. Our polynomial-time algorithm consists of the following two phases:

1. *Branching Phase*, which consists of the following three steps:
 1. guessing the terminals of F' ;
 2. guessing the backbones of the components of F' ; and
 3. guessing the skeleton of F' , and
2. *Completion Phase*, where we extend the partial solutions obtained in the Branching Phase to complete ones by finding non-skeleton vertices of F' and trivial components of F' ; we do this by:
 1. reducing the problem to MAX WEIGHT INDEPENDENT SET for sP_3 -free graphs using the blob graph construction in Section 2, and
 2. solving this problem using the polynomial-time algorithm of Brandstädt and Mosca [6].

We now describe our algorithm, prove its correctness and perform a running time analysis.

Branching Phase. This phase of our algorithm consists of a series of guesses, where we find certain vertices and substructures in G . The total number of vertices to be guessed will be $\mathcal{O}(s^2 d^2)$. Since we guess them exhaustively, this results in a recursion tree with $\mathcal{O}(n^{\mathcal{O}(s^2 d^2)})$ leaves. As both s and d are constants, this bound is polynomial in n . We will ensure that

■ **Figure 3** Step 1 of the Branching Phase. Left: the graph F' . Right: the terminals of F' .

the optimum solution $F = G[X]$ will be found in the call corresponding to at least one of the leaves of the recursion tree. Based on the properties of F , we will expect the guessed vertices to satisfy certain conditions. If, at some point, the guessed vertices do not satisfy these conditions, we just terminate the current call, as it will not lead us to find F . This will be applied implicitly throughout the execution of the algorithm.

The branching phase is illustrated in Figures 3–5. We use the convention that gray/black elements are still unknown and blue elements are the ones that we have already guessed.

Step 1. Guessing the terminals of F' . We guess the set $C \subseteq V$ of terminals of F' . By Lemma 6, the total number of terminals is bounded by $(2d + 1) \cdot (s - 1) \leq 3ds$. Furthermore, for each terminal, we guess its type (1, 2, or both). This results in $3^{|C|} \leq 3^{3ds}$ possibilities. We also guess the partition of C , corresponding to the connected components of F . This results in at most $|C|^{|C|} \leq (3ds)^{3ds}$ additional branches. In total, we have $\mathcal{O}(n^{\mathcal{O}(ds)})$ branches.

Step 2. Guessing the backbone of each component of F' . Let Z be a component of F' . Let $C_Z \subseteq C$ be the subset of terminals that are in Z . Let T_Z be the backbone of Z . Let T'_Z be the tree obtained from T_Z by contracting every path in T_Z whose internal vertices are all non-terminals and of degree 2 to an edge. Note that every non-terminal vertex of T'_Z has degree at least 3. Since T'_Z has at most $|C_Z|$ vertices of degree at most 2, by the handshaking lemma we observe that the total number of vertices of T'_Z is at most $2|C_Z|$. Recall that every edge of T'_Z corresponds to an induced path in T_Z . Since F' is sP_3 -free and thus P_{4s-1} -free, we conclude that T_Z has at most $2|C_Z| \cdot (4s - 2) \leq 8s \cdot |C_Z|$ vertices.

Let T be the forest whose components are the guessed backbones of the components of F' . Note that the total number of vertices of T is at most $\sum_Z 8s \cdot |C_Z| = 8s \cdot |C| \leq 24ds^2$. Thus we may guess the whole forest T , which results in $\mathcal{O}(n^{\mathcal{O}(ds^2)})$ branches.

Step 3. Guessing the skeleton of F' . Let T be the forest guessed in the previous step; recall that T has at most $24ds^2$ vertices. We guess the partition of $E(T)$ corresponding to *blocks* of F' ; note that a vertex v may be in several blocks: this happens precisely if v is a cutvertex in F' . This results in at most $|E(T)|^{\mathcal{O}(|E(T)|)} \leq |V(T)|^{\mathcal{O}(|V(T)|)} \leq (ds)^{\mathcal{O}(ds^2)}$ branches.

We now discuss some properties of the (double-)blocks. We use the names of vertices as in the definitions introduced in Section 3.1, recall also Fig. 2. The crucial observation is that now there is a branch, where:

■ **Figure 4** Step 2 of the Branching Phase. Left: the tree T'_Z . Right: the tree T_Z .

■ **Figure 5** Step 3 of the Branching Phase. Left: our knowledge about F' after guessing the blocks in \mathcal{B}_{l_3} . Right: our knowledge about F' after guessing the blocks in \mathcal{B}_{in} .

- For each block in \mathcal{B}_{l_1} , we have guessed its cutvertex and no other vertices.
- For each block in \mathcal{B}_{l_2} , we have not guessed any vertices.
- For each block in \mathcal{B}_{l_3} , we have guessed its cutvertex v connecting it to the rest of F' and no other vertices; note that v is not a terminal. Moreover, for each such v there is at most one block in \mathcal{B}_{l_3} .
- For each block in \mathcal{B}_w , we have guessed its cutvertex v that does not belong to a block in \mathcal{B}_{l_2} and we guessed no other vertices. Thus, for each double-block in \mathcal{B}_d , we have guessed its cutvertex connecting it to the rest of F' and no other vertices.
- For each block in \mathcal{B}_{in} , we have guessed at least two vertices.

Now we proceed to the final guessing step, see Fig. 5. First, we guess all blocks in \mathcal{B}_{l_3} . Note that we can do it, as (i) we know their cutvertices, (ii) the number of these cutvertices is at most $|V(T)| \leq 24ds^2$, (iii) each cutvertex is contained in at most one block from \mathcal{B}_{l_3} , and (iv) each block has at most d vertices. This results in at most $n^{\mathcal{O}(|V(T)| \cdot d)} = n^{\mathcal{O}(d^2 s^2)}$ branches.

Next, we guess all blocks in \mathcal{B}_{in} . Again, we can do it as (i) we know at least two vertices of such a block, (ii) the number of these blocks is at most $|E(T)| \leq 24ds^2$, and (iii) each block has at most d vertices. This results in at most $n^{\mathcal{O}(|V(T)| \cdot d)} = n^{\mathcal{O}(d^2 s^2)}$ further branches.

The following claim summarizes the outcome of the guessing phase of the algorithm.

▷ **Claim A.** In time $\mathcal{O}(n^{\mathcal{O}(s^2 d^2)})$ we can enumerate a collection \mathcal{S} of $\mathcal{O}(n^{\mathcal{O}(s^2 d^2)})$ triples (S, C_1, C_2) , where $S \subseteq V$ and $C_1, C_2 \subseteq S$ such that \mathcal{S} has the following property. Let $X \subseteq V$, such that $F = G[X]$ is a \mathcal{C} -block graph. Let $X' \subseteq X$ be the vertex set of the graph F' obtained from F by removing all trivial components. Then there is at least one triple $(S, C_1, C_2) \in \mathcal{S}$, where

82:10 Feedback Vertex Set and Even Cycle Transversal for H -Free Graphs

- a) C_1 is the set of terminals of type 1 in F' ,
- b) C_2 is the set of terminals of type 2 in F' ,
- c) $G[S]$ is the skeleton of F' .

Completion Phase. Let \mathcal{S} be the collection from Claim A and let $(S, C_1, C_2) \in \mathcal{S}$ be a triple that satisfies the properties listed in the statement of Claim A for an optimum solution $F = G[X]$. Let $\mathcal{X} := \mathcal{X}_0 \cup \mathcal{X}_1 \cup \mathcal{X}_2$ be the family of subsets of V with:

$$\begin{aligned}\mathcal{X}_0 &:= \{\{v\} \mid v \in V\}, \\ \mathcal{X}_1 &:= \{B \subseteq V \mid G[B] \in \mathcal{C}\}, \text{ and} \\ \mathcal{X}_2 &:= \{B \subseteq V \mid B \text{ is a double-block whose blocks are in } \mathcal{C}\},\end{aligned}$$

Let $G^{\mathcal{C}}$ be the graph whose vertex set is \mathcal{X} , and edges join sets that are adjacent in G . Furthermore, we define a weight function $\mathfrak{w}^{\mathcal{C}}: \mathcal{X} \rightarrow \mathbb{Q}^+$ as

$$\mathfrak{w}^{\mathcal{C}}(A) = \sum_{v \in A} \mathfrak{w}(v).$$

Note that in order to complete S to the optimum solution $F = G[X]$, we need to determine:

- all blocks in \mathcal{B}_{l_1} ,
- all double-blocks in \mathcal{B}_d ,
- all trivial components of F .

Note that the vertex sets of all these subgraphs are in the family \mathcal{X} and they form an independent set in $G^{\mathcal{C}}$. Furthermore, since X is of maximum weight, the total weight of selected subsets must be maximized. Thus the idea behind the last step is to reduce the problem to solving MAX WEIGHT INDEPENDENT SET in an appropriately defined subgraph of $G^{\mathcal{C}}$ and weights $\mathfrak{w}^{\mathcal{C}}$.

To ensure that the selected subsets are consistent with our guess $(S, C_1, C_2) \in \mathcal{S}$, we will remove certain vertices from $G^{\mathcal{C}}$. In particular, let \mathcal{X}' consist of the sets $A \in \mathcal{X}$, such that:

1. $A \in \mathcal{X}_0 \cup \mathcal{X}_1$ and A is non-adjacent to S ; these are the candidates for trivial components of F ,
2. $A \in \mathcal{X}_1$ and A intersects S in exactly one vertex, which is in C_1 ; these are the candidates for blocks in \mathcal{B}_{l_1} ,
3. $A \in \mathcal{X}_2$ and A intersects S in exactly one vertex, which is in C_2 and is not the cutvertex of $G[A]$; these are the candidates for double-blocks in \mathcal{B}_d .

Now let $\mathcal{I} \subseteq \mathcal{X}'$ be an independent set of $G^{\mathcal{C}}$, and let $S' = \bigcup_{A \in \mathcal{I}} A$. It is straightforward to verify that if $(S, C_1, C_2) \in \mathcal{S}$ satisfies the properties listed in Claim A, then $G[S \cup S']$ is a \mathcal{C} -block graph. Thus, in one of the branches, we will find the optimum solution $F = G[X]$.

Now let us argue that the last step can be performed in polynomial time. First, observe that $|\mathcal{X}| \leq n + n^d + n^{2d} = n^{\mathcal{O}(d)}$ and the family \mathcal{X} can be exhaustively enumerated in time $n^{\mathcal{O}(d)}$. Next, \mathcal{X}' can be computed in time polynomial in $|\mathcal{X}|$, and thus in n . This implies that the graph $G^{\mathcal{C}}[\mathcal{X}']$ can be computed in time polynomial in n . We observe that $G^{\mathcal{C}}$, and thus $G^{\mathcal{C}}[\mathcal{X}']$, is an induced subgraph of the blob graph G° , introduced in Section 2. Hence, by Theorem 3, we conclude that $G^{\mathcal{C}}[\mathcal{X}']$ is sP_3 -free.

The final ingredient is the polynomial-time algorithm for MAX WEIGHT INDEPENDENT SET in sP_3 -free graphs by Brandstädt and Mosca [6]. Its running time on an n' -vertex graph is $n'^{\mathcal{O}(s)}$. Since the number of vertices of $G^{\mathcal{C}}[\mathcal{X}']$ is $n^{\mathcal{O}(d)}$, we conclude that a maximum-weight independent set in $G^{\mathcal{C}}[\mathcal{X}']$ can be found in time $n^{\mathcal{O}(sd)}$.

Summing up, in the guessing phase, in time $n^{\mathcal{O}(s^2 d^2)}$ we enumerate the family \mathcal{S} of size $n^{\mathcal{O}(s^2 d^2)}$. Then, for each member (S, C_1, C_2) of \mathcal{S} , we try to extend the partial solution to a complete one. This takes time $n^{\mathcal{O}(sd)}$ per element of \mathcal{S} . Among all found solutions, we return the one with maximum weight. The total running time of the algorithm is $n^{\mathcal{O}(s^2 d^2)}$, which is polynomial in n , since s and d are constants. This completes the proof of Theorem 1.

4 More Results for Even Cycle Transversal on H -Free Graphs

In this section we prove that subject to a number of unsolved cases, the complexity of EVEN CYCLE TRANSVERSAL for H -free graphs coincides with the one for FEEDBACK VERTEX SET.

CMSO₂ and Even Cycle Transversal. *Monadic Second-Order Logic* (MSO₂) over graphs consists of formulas with vertex variables, edge variables, vertex set variables, and edge set variables, quantifiers, and standard logic operators. We also have a predicate $\text{inc}(v, e)$, indicating that the vertex v belongs to the edge e . *Counting Monadic Second-Order Logic* (CMSO₂) is an extension of MSO₂ which allows atomic formulas of the form $|X| \equiv p \pmod q$, where X is a set variable and $0 \leq p < q$ are integers.

Abrishami et al. [1, Theorems 5.3 and 7.3] proved that for any fixed CMSO₂ formula Φ and any constant t , the following problem is polynomial-time solvable: given a P_5 -free graph G with weight function $\mathfrak{w} : V(G) \rightarrow \mathbb{Q}^+$, find a maximum-weight set $X \subseteq V(G)$, such that $G[X]$ is of treewidth at most t and satisfies Φ . This immediately yields a polynomial-time algorithm for FEEDBACK VERTEX SET in P_5 -free graphs: just take $t = 1$ and a trivial formula Φ that is satisfied for all graphs (see also [1]).

A similar argument can also be applied for EVEN CYCLE TRANSVERSAL. First, note that every odd cactus has treewidth at most 2. Hence, it remains to show an appropriate CMSO₂ formula Φ that enforces $G[X]$ to be an odd cactus. We will again look from the complementary perspective: we need to say that $G[X]$ has no even cycle. For this, it is enough to say that there is no set E' of edges in $G[X]$, such that: (i) each vertex of X is incident to 0 or 2 edges from E' , (ii) the edges from E' induce a connected subgraph of $G[X]$, and (iii) the number of edges in E' is even. Properties (i) and (ii) are easily expressible in MSO₂, see [8, Section 7.4], and property (iii) is expressed by the formula $|E'| \equiv 0 \pmod 2$, which is allowed in CMSO₂. This immediately yields the following corollary.

► **Corollary 7.** EVEN CYCLE TRANSVERSAL is polynomial-time solvable for P_5 -free graphs.

Finally, the problem of finding a maximum-weight subset that induces a constant-treewidth graph satisfying some fixed CMSO₂ formula can be solved in *quasipolynomial time* for P_r -free graphs for any fixed r [10]. This implies a quasipolynomial-time algorithm for FEEDBACK VERTEX SET and EVEN CYCLE TRANSVERSAL for H -free graphs if H is a linear forest.

Hardness Results. An *odd cycle factor* of a graph G is a set of odd cycles such that every vertex of G belongs to exactly one of them. The ODD CYCLE FACTOR problem, which asks if a graph has an odd cycle factor, is known to be NP-complete [15]. The *line graph* $L(G)$ of a graph $G = (V, E)$ has vertex set E and an edge between two distinct vertices e and f if and only if e and f share an end-vertex in G .

The proof of our next result for line graphs is somewhat similar to a proof for ODD CYCLE TRANSVERSAL of [7] but uses some different arguments as well.

► **Theorem 8.** EVEN CYCLE TRANSVERSAL is NP-complete for line graphs.

82:12 Feedback Vertex Set and Even Cycle Transversal for H -Free Graphs

Proof. Let $G = (V, E)$ be an instance of ODD CYCLE FACTOR with n vertices and m edges. We claim that G has an odd cycle factor if and only if its line graph $L := L(G)$ has an even cycle transversal of size at most $m - n$, see Fig. 6.

First suppose G has an odd cycle factor. Then there is $E' \subseteq E$, such that $|E'| = n$ and $L[E']$ is a disjoint union of odd cycles. Hence, $S := E \setminus E'$ is an even cycle transversal of L of size $|E| - n = m - n$. Now suppose L has an even cycle transversal S with $|S| \leq m - n$. Let $E' := E \setminus S$. As $|E| = m$, we have $|E'| \geq n$.

We prove the following claim.

▷ **Claim B.** Every component of $L[E']$ is either an odd cycle or the line graph of a tree.

Proof. Let D be a component of $L[E']$. If D has no cycle, then D is a path, as L is a line graph and thus is claw-free. Hence, D is the line graph of a path, and thus a tree.

So suppose D has a cycle C . Then C is odd and induced, as $L[E']$ is an odd cactus. If D has no vertices except for the ones of C , then D is an odd cycle and we are done. Suppose otherwise.

First, assume that C has at least five vertices. Since D has vertices outside C , there is a vertex of C with a neighbour outside C . Hence, D contains either an even cycle or an induced claw, both of which are not possible. So now suppose that C has at most four vertices. Then C is a triangle, as D has no even cycles. Since D is an induced subgraph of L , there exists a subgraph T of G such that $D = L(T)$. As D is a connected graph with at least four vertices, containing a triangle, T is a connected graph with at least four vertices.

We aim to show that T is a tree. For contradiction, suppose that T contains a cycle C_T . Then C_T must be a triangle, as otherwise D would contain an even cycle or an odd cycle with at least five vertices. Let a, b, c be the vertices of C_T . As T is connected and has at least four vertices, at least one of $\{a, b, c\}$, say a , must have a neighbour $d \notin \{b, c\}$. However, the edges $ad - ab - bc - ac$ form a C_4 in D , a contradiction with D being an odd cactus. So we conclude that T contains no cycles and thus T is a tree. ◁

Each component of $L[E']$ that is an odd cycle corresponds to an odd cycle in G . By Claim B, each component D of $L[E']$ that is not an odd cycle is the line graph of some subtree T of G . So, if D has r vertices, then T has $r + 1$ vertices. Furthermore, the vertex sets of G corresponding to distinct components of $L[E']$ are pairwise disjoint. Suppose that $L[E']$ has $p \geq 0$ components that are not odd cycles. Let Q be the set of vertices incident to at least one edge of E' . Then $n = |V(G)| \geq |Q| = |E'| + p \geq n + p$. Hence, $p = 0$ and $|Q| = n$. So, the components of $L[E']$ correspond to an odd cycle factor of G . This completes the proof. ◀

We make a straightforward observation similar to an observation for FEEDBACK VERTEX SET [7, 14], except that we must subdivide edges of a graph an even number of times.

► **Theorem 9.** For every $p \geq 3$, EVEN CYCLE TRANSVERSAL is NP-complete for graphs of girth at least p .

Proof. We reduce from EVEN CYCLE TRANSVERSAL for general graphs by noting the following. Namely, the size of a minimum even cycle transversal in G is equal to the size of a minimum even cycle transversal in the graph G' obtained from G by subdividing every edge $2p$ times, and the girth of G' is at least p . ◀

The next theorem is analogous to the one for FEEDBACK VERTEX SET; see also Table 1.

■ **Figure 6** Left: a graph G with an odd cycle factor. Middle: the graph $L = L(G)$ and the set E' (red). Black vertices form an even cycle factor. Right: the odd cactus $L[E']$.

► **Theorem 10.** *Let H be a graph. Then EVEN CYCLE TRANSVERSAL for H -free graphs is polynomial-time solvable if $H \subseteq_i sP_3$ for some $s \geq 1$ or $H \subseteq_i P_5$, and it is NP-complete if H is not a linear forest.*

Proof. If $H \subseteq_i sP_3$, use Corollary 2, and if $H \subseteq_i P_5$, use Corollary 7. If H is not a linear forest, then it has a cycle or a claw. If H has a cycle, then we apply Theorem 9 for $p = |V(H)| + 1$. Otherwise, H has an induced claw and we apply Theorem 8. ◀

5 Conclusions

We prove that for a large family of graphs \mathcal{F} , the MIN \mathcal{F} -TRANSVERSAL problem is polynomial-time solvable on sP_3 -free graphs (for every $s \geq 1$). The two best-known problems in this framework are FEEDBACK VERTEX SET and EVEN CYCLE TRANSVERSAL. Our result for FEEDBACK VERTEX SET generalizes two known results from the literature [7, 9]. We also prove that in contrast to the situation for ODD CYCLE TRANSVERSAL, all other known complexity results for FEEDBACK VERTEX SET on H -free graphs hold for EVEN CYCLE TRANSVERSAL as well. Hence, so far both problems behave the same on special graph classes, and it would be interesting to prove polynomial equivalency of the two problems more generally. Table 1 still shows some missing cases for each of the three problems.

In particular, we highlight a borderline case:

Is each of the three problems is polynomial-time solvable for $(P_1 + P_4)$ -free graphs?

The main obstacle is that we know no polynomial-time algorithm for finding a maximum induced disjoint union of stars in a $(P_1 + P_4)$ -free graph; note that such a subgraph could be a potential optimal solution for each of the three problems.

We also recall that FEEDBACK VERTEX SET and EVEN CYCLE TRANSVERSAL can be solved in quasipolynomial time for P_r -free graphs [10] for every $r \geq 1$, whereas ODD CYCLE TRANSVERSAL is NP-complete even for P_6 -free graphs [9]. An affirmative answer to the above question for FEEDBACK VERTEX SET and EVEN CYCLE TRANSVERSAL would be a first step in proving that these two problems are polynomial-time solvable on P_6 -free graphs. If that turns out to be the case, then we will have further evidence that these two problems, restricted to H -free graphs, differ in their complexity from ODD CYCLE TRANSVERSAL.

Stabilization Bounds for Influence Propagation from a Random Initial State

Pál András Papp ✉

ETH Zürich, Switzerland

Roger Wattenhofer ✉

ETH Zürich, Switzerland

Abstract

We study the stabilization time of two common types of influence propagation. In majority processes, nodes in a graph want to switch to the most frequent state in their neighborhood, while in minority processes, nodes want to switch to the least frequent state in their neighborhood. We consider the sequential model of these processes, and assume that every node starts out from a uniform random state.

We first show that if nodes change their state for any small improvement in the process, then stabilization can last for up to $\Theta(n^2)$ steps in both cases. Furthermore, we also study the proportional switching case, when nodes only decide to change their state if they are in conflict with a $\frac{1+\lambda}{2}$ fraction of their neighbors, for some parameter $\lambda \in (0, 1)$. In this case, we show that if $\lambda < \frac{1}{3}$, then there is a construction where stabilization can indeed last for $\Omega(n^{1+c})$ steps for some constant $c > 0$. On the other hand, if $\lambda > \frac{1}{2}$, we prove that the stabilization time of the processes is upper-bounded by $O(n \cdot \log n)$.

1 Introduction

Dynamically changing colorings in a graph can be used to model various situations when entities of a network are in a specific state, and they occasionally decide to change their state based on the states of their neighbors. Such colorings are essentially a form of distributed automata, where the nodes can represent anything from brain cells to rival companies; as such, the study of these processes has applications in almost every branch of science.

One prominent example of such colorings is a *majority process*, where each node wants to switch to the color that is most frequent in its neighborhood. These processes are used to model a wide range of phenomena in social sciences, e.g. the spreading of political opinions in social networks, or the adoption of different social media platforms [16, 7, 20].

Another example is the dual setting of a *minority process*, where each node wants to switch to the least frequent color among its neighbors. Minority processes can model settings where nodes would prefer to differentiate from each other, e.g. frequency selection in wireless networks, or selecting a production strategy in a market economy [6, 21, 9].

In our paper, we analyze the stabilization time of majority and minority processes, i.e. the number of steps until no node wants to change its color anymore. We study the processes in the *sequential* (or asynchronous) model, where in every step, exactly one node switches its color. As such, stabilization time in the sequential model describes the total number of switches before the process terminates.

Compared to a synchronous setting, the sequential model has the advantage that neighbors are never switching at the exact same time; this prevents the process from ending up in an infinitely repeating periodic pattern. This property is indeed a reasonable assumption in many application areas, including the examples mentioned above: you are highly unlikely to e.g. switch your wireless frequency at the exact same time as your neighbors, or change your political opinion at the exact same time as your friends.

We study the maximal stabilization time of the processes in general graphs, assuming that the initial coloring of nodes is chosen uniformly at random. This setting may be relevant for a worst-case analysis in applications where the only thing we can influence is the initial coloring. For example, a wireless service provider might have no control over the topology of the network or the times when clients decide to switch their frequency, but it could easily ensure that its devices are initialized with a randomly chosen frequency.

An important parameter of the model is the switching rule, i.e. the threshold at which a node decides to switch to the opposite color. Two very natural rules are (i) basic switching, when nodes decide to switch for any small improvement, and (ii) proportional switching, when we have a real parameter $\lambda \in (0, 1)$, and nodes only change their color if they are motivated to switch by a $\frac{1+\lambda}{2}$ fraction of their neighborhood.

In our paper, we study the stabilization time for both basic and proportional switching. As a warm-up (in Section 5), we first show that in case of basic switching, both minority and majority processes can take $\Omega(n^2)$ steps to stabilize with high probability, matching a naive upper bound of $O(n^2)$. This follows from an extension of the lower-bound construction in [27] to the random-initialized case.

Our main contributions (Sections 6 and 7) are stabilization bounds in case of proportional switching:

- for proportional switching with $\lambda < \frac{1}{3}$, we present a construction that w.h.p. exhibits a superlinear stabilization time of $\Omega(n^{1+c})$ for a constant $c > 0$ that depends on λ .
- for proportional switching with $\lambda > \frac{1}{2}$, we show that w.h.p. the process always stabilizes in $O(n \cdot \log n)$ steps, essentially matching a straightforward lower bound of $\Omega(n)$.

2 Related work

Majority and minority processes have been extensively studied from numerous different perspectives since the early 1980s [15, 11]. Most of the results focus on the simplest case of two colors, since this already captures the interesting properties of the process, and a generalization to more colors is often straightforward.

Many different variants of these processes have been inspired by application areas ranging from particle physics to social science, as in case of e.g. Ising systems or the voter model [23, 22]. In particular, there is extensive literature on more sophisticated process definitions that aim to provide a more realistic model for a specific application, such as social opinion dynamics or virus infection spreading [2, 1, 8, 25].

In case of majority processes, there is a particular interest in analyzing how a small set of nodes can influence the final state [35, 34, 14, 33, 3]. For both processes, there are also numerous works on the analysis of stable states [17, 5, 21, 18, 4]. However, in contrast to our work, most of these earlier results assume a synchronous setting, and only study the process on specific graph topologies, e.g. cliques, grids or Erdős-Rényi random graphs.

There is a recent line of work on stabilization time in general graphs; however, these results assume a worst-case initial coloring. For basic switching, the work of [12] shows that in the sequential adversarial and synchronous models, stabilization can last for $\tilde{\Omega}(n^2)$

steps, matching a straightforward upper bound of $O(n^2)$. A similar lower bound is known for minority processes [27]. On the other hand, the two processes exhibit very different behavior in a benevolent sequential model: majority processes always stabilize in $O(n)$ time, while minority processes can last for quadratically many steps [12, 27].

On the other hand, if we consider general graphs with proportional switching, then the sequential processes are known to exhibit a worst-case runtime between quadratic and linear, depending on the parameter λ of the switching rule [29]. Stabilization time in this case is characterized by a non-elementary function $f(\lambda)$ that monotonically and continuously decreases from 1 to 0 on the interval $[0, 1]$. The results of [29] show that for any $\varepsilon > 0$, stabilization time is upper-bounded by $O(n^{1+f(\lambda)+\varepsilon})$, and the process can indeed last for $\Omega(n^{1+f(\lambda)-\varepsilon})$ steps. Our results are an interesting contrast to this, showing that if we randomize the initial state, then the process can only take $\Omega(n^{1+c})$ steps for smaller λ values.

For general weighted graphs and a worst-case initial coloring, an exponential lower bound has also been shown for both majority [19] and minority [28] processes.

There are also various works that assume a randomized initial coloring, but these results focus on special classes of graphs. For majority processes, stabilization time from a randomized initial state has been analyzed in Erdős-Rényi random graphs, grids, tori and expanders [13, 26, 10, 24]. For minority processes, the works of [30, 31, 32] study stabilization in cliques, cycles, trees and tori. As such, to our knowledge, stabilization time from a randomized initial coloring has not yet been studied in general graphs.

3 Model definition and tools

3.1 Preliminaries

We study the processes on simple, unweighted, undirected graphs $G(V, E)$ with node set V and edge set E . We denote the nodes of the graph by u or v , and the number of nodes in the graph by n . For a specific node v , we denote the neighborhood of v by $N(v)$, and the degree of v by $d_v = |N(v)|$. For ease of presentation, we usually define the size of our graph constructions in terms of an (almost) linear parameter m , and in the end, we select a value of m that ensures $m \in \tilde{\Theta}(n)$.

As common in this area, we focus on the case of two colors. That is, we say that a *coloring* of the graph is a function $\gamma : V \rightarrow \{\text{black}, \text{white}\}$. For a specific coloring γ , we define $N_s(v) = \{u \in N(v) \mid \gamma(v) = \gamma(u)\}$ as the neighbors of v with the same color, and $N_o(v) = \{u \in N(v) \mid \gamma(v) \neq \gamma(u)\}$ as the neighbors of v with the opposite color.

We use the concept of *conflicts* to define both majority and minority processes in a general form. We say that there is a *conflict* on the edge (u, v) if this edge motivates v to change its color; more formally, if $u \in N_o(v)$ in case of a majority process, and if $u \in N_s(v)$ in case of a minority process. We use $N_c(v)$ to denote the conflicting neighbors of v under γ , i.e. $N_c(v) = N_o(v)$ for majority and $N_c(v) = N_s(v)$ for minority.

Given a specific coloring γ , we say that node v is *switchable* if $|N_c(v)|$ is larger than a specific threshold, which is defined by the so-called *switching rule* (discussed in detail in the next subsection). If v is switchable, then it can change its color to the opposite color (i.e. it can *switch*). We also use the word *balance* to refer to the metric $\frac{|N_c(v)|}{d_v}$ in general, which indicates how close node v is to being switchable.

A *majority/minority process* is a sequence of colorings of the graph G (known as *states*). Every state is obtained from the previous state by switching a switchable node in the previous state. We assume that exactly one node switches in each step, which is often known as the

sequential or asynchronous model of the process. In our paper, we also assume that the initial state of the process is a *uniform random coloring*, i.e. each node is white with probability $\frac{1}{2}$ and black with probability $\frac{1}{2}$, independently from other nodes.

We say that a state of the process is *stable* if there are no more switchable nodes in the graph. The number of steps in the process (from the initial state until a stable state is reached) is known as the *stabilization time* of the process.

We study the processes in general graphs, and we are interested in the longest possible stabilization time of a process, i.e. if in each step, the next node to switch among the switchable nodes is selected by an adversary who maximizes stabilization time. In other words, we study the worst-case stabilization of a graph on n nodes under the worst possible ordering of switches.

We also use basic tools from probability theory, such as the union bound and the Chernoff bound, and the concept of an event happening *with high probability* (*w.h.p.*). For completeness, a brief summary of these techniques is provided in the full version of the paper.

3.2 Switching rules

Another important parameter of the processes is the condition that allows nodes to switch their color. There are two natural candidates for such a switching rule:

► **I. Basic switching:** *node v is switchable if $|N_c(v)| > \frac{1}{2} \cdot d_v$.*

► **II. Proportional switching:** *node v is switchable if $|N_c(v)| \geq \frac{1+\lambda}{2} \cdot d_v$.*

Note that both rules ensure that the overall number of conflicts in the graph strictly decreases in each switching step. Since there are at most $|E| = O(n^2)$ conflicts in the graph initially, we obtain a straightforward upper bound of $O(n^2)$ on the stabilization time.

In case of basic switching, a node switches its color for an arbitrarily small improvement. Alternatively, if we denote the complement of $N_c(v)$ by $N_{\bar{c}}(v) := N(v) \setminus N_c(v)$, we can also formulate this rule as $|N_c(v)| - |N_{\bar{c}}(v)| > 0$. In case of the worst possible initial coloring, this rule is known to allow a stabilization time of $\Theta(n^2)$ [27, 12, 18].

In contrast to this, proportional switching is defined for a specific parameter $\lambda \in (0, 1]$, and it requires that v is in conflict with a specific portion of its neighborhood, with $\frac{1+\lambda}{2} \in (\frac{1}{2}, 1]$. This is often a more realistic approach if nodes have a large degree, or if switching also induces some cost in an application area. Equivalently, we can rephrase this rule as $|N_c(v)| - |N_{\bar{c}}(v)| \geq \lambda \cdot d_v$. This shows that whenever v switches, the total number of conflicts in the graph decreases by at least $\lambda \cdot d_v$, and v can have at most $\frac{1+\lambda}{2} \cdot d_v - \lambda \cdot d_v = \frac{1-\lambda}{2} \cdot d_v$ conflicts on the incident edges after the switch.

In case of a worst-case initial coloring, the maximal stabilization time for proportional switching is between quadratic and linear, following a monotonously decreasing non-elementary function $f(\lambda)$ described in [29]. Since this non-elementary function also plays a role in our lower bound, we discuss $f(\lambda)$ in the full version for completeness.

Note that for a very small λ value approaching 0, we can obtain basic switching as a special case of proportional switching in the limit.

3.3 Application of earlier results

We also apply the basic ideas behind some of the constructions from previous work, which were used to show similar lower bounds for a worst-case initial coloring.

Construction idea for basic switching. Recall that the result of [27] provides a quadratic lower bound on the stabilization time of minority processes.

► **Theorem** (from [27]). *Consider minority processes under the basic switching rule. There exists a class of graphs and an initial coloring with a stabilization time of $\Omega(n^2)$.*

The main idea of the construction is to have a set P of m nodes, attached to two further sets A and B of size m . The construction makes sure that every node in A and B wants to switch to the opposite color. Then we switch these nodes in an alternating fashion: one from A , one from B , one from A again, and so on. The set P is designed such that its neighborhood is approximately balanced, and thus after each of these steps, the entire set P is switchable. Switching P after each step gives a sequence of $m \cdot 2m = \Theta(n^2)$ switches.

Black box construction for proportional switching. We also use the result of [29], which provides a lower bound construction for any $\lambda \leq \frac{1}{3}$ in case of proportional switching and worst-case initial coloring. We apply this graph as a black box in our constructions, and refer to it as the PROP construction.

► **Theorem** (from [29]). *Consider majority/minority processes under proportional switching for any $\lambda \leq \frac{1}{3}$. There exists a class of graphs and an initial coloring with a stabilization time of $\Omega(n^{1+f(\lambda)-\epsilon})$ for the function f and for any $\epsilon > 0$.*

4 Basic observations

4.1 Initially balanced sets

Since we start from a uniform random initial coloring, a basic tool in our proofs is the fact that w.h.p., a large set of nodes has a balanced distribution of the colors initially.

► **Definition 1** (ϵ -balanced set). *Given a specific coloring, we say that a set of nodes S is ϵ -balanced if the number of white nodes in S is within $[(\frac{1}{2} - \epsilon) \cdot |S|, (\frac{1}{2} + \epsilon) \cdot |S|]$.*

► **Lemma 2.** *Let S_1, \dots, S_k be subsets of nodes in G such that $|S_i| \geq c_0 \cdot \log n$ for some constant c_0 for all $i \in \{1, \dots, k\}$, and $k \leq n$. Then for any constant $\epsilon > 0$, there is a c_0 such that w.h.p., each set S_i is initially ϵ -balanced.*

Proof. Let us select $c_0 = \frac{3}{2\epsilon}$. According to the Chernoff bound, the probability that S_i is not ϵ -balanced is at most

$$2 \cdot e^{-4\epsilon^2 \cdot \frac{1}{6} \cdot |S_i|} \leq 2 \cdot e^{-\frac{2}{3}\epsilon^2 \cdot c_0 \cdot \log n} = 2 \cdot n^{-2}.$$

If we take a union bound over all the $k \leq n$ subsets, the probability that any of them is not ϵ -balanced is at most $n \cdot 2 \cdot n^{-2} = 2 \cdot n^{-1}$, so w.h.p. the claim indeed holds. ◀

In particular, we can select a high constant c_0 , and refer to nodes v with $d_v \geq c_0 \cdot \log n$ as *high-degree* nodes, and the remaining nodes as *low-degree* nodes. Then Lemma 2 can be rephrased into the following claim:

► **Corollary 3.** *For any $\epsilon > 0$, there exists a c_0 such that w.h.p. the following claim holds: for all the high-degree nodes v in G , $N(v)$ is initially ϵ -balanced.*

4.2 Linear lower bound

Note that we can easily provide an example of linear stabilization time, even for proportional switching with any $\lambda \in (0, 1)$.

Consider an edge graph, i.e. a connected component with only two adjacent nodes u and v . With a probability of $\frac{1}{2}$, node v is initially switchable in this graph, for both majority/minority processes (since it has the opposite/same color as u , respectively). Let us take $\frac{n}{2}$ independent copies of this single-edge graph; this gives $\frac{n}{2}$ nodes in the role of v . Then $\frac{n}{4}$ of these nodes are switchable in expectation, and with a Chernoff bound, one can show that at least $\frac{n}{8}$ are switchable w.h.p.. We can switch these $\frac{n}{8}$ nodes in any order to obtain a sequence of $\frac{n}{8} \in \Omega(n)$ switches.

5 Lower bound constructions for basic switching

For basic switching, we can give an example of quadratic stabilization time by a suitable extension of the construction in [27] to the random-initialized setting.

In our analysis, we refer to a set of nodes as a *group* if they all have exactly the same neighborhood. In our figures, we denote groups by double-sided circles, with the cardinality shown beside the group, and an edge between two groups denotes a complete bipartite connection between the corresponding sets. Note that the nodes of a group always prefer the same color.

► **Theorem 4.** *Consider majority/minority processes under the basic switching rule, starting from a uniform random initial coloring. There exists a class of graphs that exhibit a stabilization time of $\Omega(n^2)$ with high probability in this model.*

We now outline the main ideas of these graphs, with the details discussed in the full version.

5.1 Minority processes

For minority processes, consider the graph in Figure 1, which is essentially an extension of the graph in [27] with a complete bipartite connection between A_0 and B_0 . For simplicity, we add an extra node to ensure that P has an odd degree. The graph has $5m + 3$ nodes, and thus $m \in \Theta(n)$.

Regardless of the initial coloring, each node in A_0 has the same preferred color, since they all have exactly the same neighbors and they have an odd degree. Thus we can switch each node in A_0 to this preferred color (if it did not have this color already). Assume w.l.o.g. that this color is white. Since now A_0 is white entirely, we can switch each node in B_0 to black. With this, the preferred color of each node in A becomes black, and the preferred color of each node in B becomes white.

An intuitive description of the remaining sequence is as follows. Both A and B have approximately $\frac{m}{2}$ nodes (and w.h.p. at least $\frac{m}{3}$ nodes) that have the same color as the group above. These nodes are now all switchable, regardless of the color of nodes in P . We disregard the remaining nodes, and only focus on these $\frac{m}{3}$ switchable nodes in A and B .

Initially, the neighborhood of P is w.h.p. ϵ -balanced. Hence by switching only $\epsilon \cdot m$ of nodes either in A or in B , we can ensure that P has exactly one more white neighbor than black, which allows us to switch the entire group P to black. Then by switching one node in A to black, P will have one more black neighbor than white, so P becomes switchable again. We can then switch the nodes in A and B in an alternating fashion; this ensures that P always has one more same-colored neighbor after each step, which makes P switchable again. This process allows us to switch the nodes of P altogether $\Theta(m)$ times, which already adds up to a sequence of $\Theta(m^2) = \Theta(n^2)$ switches.

■ **Figure 1** Lower bound constructions of $\Omega(n^2)$ steps in case of basic switching, for minority processes (left) and majority processes (right). Recall that double-sided circles denote groups, and edges between groups denote a complete bipartite connection between the two groups.

5.2 Majority processes

The case of majority processes is more involved, since in this case, it is more difficult to ensure that the groups A_0 and B_0 attain different colors.

Instead of connecting A_0 to B_0 , we connect A_0 to $\Theta(\log m)$ further groups of size $\Theta(\frac{m}{\log m})$, denoted by $A_{1,1}, A_{1,2}, \dots$. Finally, we add $\Theta(\log m)$ more distinct groups $A_{2,1}, A_{2,2}, \dots$, also on $\Theta(\frac{m}{\log m})$ nodes each, and we create a complete bipartite connection between $A_{1,i}$ and $A_{2,i}$. We attach the same structures to group B_0 in a symmetric manner; see Figure 1 for an overview of the construction.

The main idea of the construction is as follows. With probability $\frac{1}{2}$, the group $A_{1,i}$ has more white nodes than black initially, which allows us to switch $A_{2,i}$ entirely to white. Since the groups $A_{1,i}$ are independent, there is indeed w.h.p. an index \hat{i} such that the group $A_{2,\hat{i}}$ can be switched entirely to white. The neighbors of $A_{1,\hat{i}}$ are initially approximately balanced, so after recoloring all the $\Theta(\frac{m}{\log m})$ nodes in $A_{2,\hat{i}}$ to white, $A_{1,\hat{i}}$ has more white neighbors than black; this allows us to switch all of $A_{1,\hat{i}}$ to white. We note while our previous steps all follow directly from Corollary 3, this specific step requires a slightly stronger version of the Chernoff bound.

We can then apply a similar reasoning on the group A_0 : since it was w.h.p. balanced initially, and turning $A_{1,\hat{i}}$ to white has increased the number of its white neighbors by $\Theta(\frac{m}{\log m})$ w.h.p., we can also turn the entire group A_0 white. In a similar fashion, we can use groups $B_{2,\hat{i}}$ and $B_{1,\hat{i}}$ to switch each node in B_0 black w.h.p..

Once A_0 is white and B_0 is black, we again have $\Theta(m)$ switchable nodes in both A and B , and thus we can apply the same alternating method as in the minority case.

6 Proportional switching: lower bound for $\lambda < \frac{1}{3}$

We now show that for proportional switching with small λ values, stabilization time can indeed be superlinear. Note that $\lambda < \frac{1}{3}$ implies that $\frac{1+\lambda}{2} = \frac{2}{3} - \delta$ for some $\delta > 0$.

We present our lower bound construction for majority processes; however, since our graph is bipartite, we can easily adapt this result to minority processes by inverting the colors in one of the color classes. More details of this technique are available in the full version.

■ **Figure 2** High-level illustration of the proportional lower bound construction for any $\lambda < \frac{1}{3}$.

► **Theorem 5.** Consider majority/minority processes under the proportional switching rule for any $\lambda < \frac{1}{3}$, starting from a uniform random initial coloring. For any $\varepsilon > 0$, there exists a class of graphs that exhibit a stabilization time of $\Omega\left(n^{1+f\left(\frac{2-\lambda}{1-\lambda}\right)-\varepsilon}\right)$ with high probability.

In a simplified formulation, this means that there exists a constant $c > 0$ such that there is a construction with a stabilization time of $\Omega(n^{1+c})$ in this setting.

We divide our construction technique into five main *phases*, and discuss them separately. In each phase of the construction, we will refer to some edges of the nodes as *output* edges, which go to the following phase of the construction. In a specific phase, we always achieve a desired behavior without any change on these output neighbors yet. An overview of the entire construction is available in Figure 2.

As before, we define our construction in terms of a parameter $m = \tilde{\Theta}(n)$, and discuss the value of m in the end.

- First, in the *Opening Phase*, our goal is to create a set S_0 of constant-degree nodes such that (i) each node in S_0 has 1 output edge to the next phase, and (ii) for any parameter $p < 1$, we can switch each node in S_0 to black with a probability of at least p , independently from the remaining nodes.
- In the *Collection Phase*, we use our Opening Phase construction to produce another set S_1 where (i) each node in S_1 has $c_0 \cdot \log n$ output edges for a large enough constant c_0 , and (ii) w.h.p. we can switch all the nodes in S_1 to black.
- In the *Growing Phase*, we begin with this node set $S_{2,1} := S_1$, and add a range of further levels $S_{2,2}, S_{2,3}, \dots$ of the same size. Every level $S_{2,i}$ is only connected to the previous and next levels $S_{2,i-1}$ and $S_{2,i+1}$. The levels will have an exponentially increasing output degree, and hence in at most $\ell \approx \log m$ steps, we arrive at a final level $S_{2,\ell}$ where each node has an output degree of $\Theta(m)$. As in case of S_1 , we show that we can w.h.p. turn each node in $S_{2,i}$ (and finally, in $S_{2,\ell}$) black.
- In the *Control Phase*, we use $S_{2,\ell}$ to produce a set S_3 where each node still has an output degree of $\Theta(m)$. We will ensure that (i) there is a specific point in the process where each node in S_3 is switchable to black, and (ii) later, there is a specific point in the process where each node in S_3 is switchable to white.

■ Finally, in the *Simulation Phase*, we take an instance of the PROP construction, and we use our set S_3 to force each node in this construction to take the desired “initial” color. We can then simulate the behavior of PROP as a black box, which is known to provide a superlinear stabilization time from this artificially enforced worst-case initial coloring. In this section, we outline the main ideas behind each of these phase. More details of the construction are discussed in the full version.

We note that the second and third phases can be generalized to any λ up to $\frac{1}{2}$; however, there is no straightforward way to do this for the remaining phases.

6.1 Opening Phase

To construct the set S_0 , first consider a node v with $d_v = 3$: one neighbor labeled as an output, and two further neighbors u_1 and u_2 . Initially, we have an $\frac{1}{2}$ chance that v is already black. Even if v is not black initially, we can switch it black if both u_1 and u_2 are black initially: we have $\frac{1+\lambda}{2} < \frac{2}{3}$, so 2 black neighbors out of 3 are indeed enough to make v switchable. The probability that initially v is white but u_1 and u_2 are black is $(\frac{1}{2})^3 = \frac{1}{8}$, so altogether, we can turn v black with a probability of $p_1 = \frac{5}{8}$.

Now assume that we take two such nodes that can be switched black with probability $\frac{5}{8}$, we denote them by u'_1 and u'_2 , and we connect their outputs to a new node v' . Again, v' is already black initially with probability $\frac{1}{2}$; if not, we can turn v' black if both u'_1 and u'_2 are switched black, which happens with a probability of p_1^2 . This provides a black v' with a probability of $p_2 = \frac{1}{2} + \frac{1}{2} \cdot (\frac{5}{8})^2 = \frac{89}{128}$.

We can continue this in a recursive manner, always taking two copies of the previous construction, and connecting them to a new root node. After i steps, we end up with a full binary tree on $2^{i+1} - 1$ nodes. This provides a black root node with a probability of p_i , defined by the recurrence

$$p_0 = \frac{1}{2} \quad \text{and} \quad p_{i+1} = \frac{1}{2} + \frac{1}{2} \cdot p_i^2.$$

One can easily show that $\lim_{i \rightarrow \infty} p_i = 1$. Hence for any constant parameter $p < 1$, there is an i such that $p_i \geq p$, and thus creating i layers with this method ensures that we can switch the final node black with probability at least p .

In order to build our set S_0 , we can simply take $m_0 = |S_0|$ independent copies of this tree. Since p is a constant, i and the tree size $2^{i+1} - 1$ are also constants; thus the whole phase only requires $O(m_0)$ nodes altogether.

6.2 Collection Phase

Let us introduce a logarithmic parameter $d_0 = c_0 \cdot \log n$. Given our Opening Phase construction S_0 , our next step is to create a smaller set S_1 on $m_1 = \frac{1}{4 \cdot d_0} \cdot m_0$ nodes. Recall that all the m_0 nodes in S_0 had exactly 1 output edge; this allows us to connect each $v \in S_1$ to $4 \cdot d_0$ distinct nodes in S_0 . We also add d_0 further output edges to each $v \in S_1$ to provide a connection to the next phase.

Since each node in S_0 becomes black with probability p independently, a Chernoff bound shows that v has at least $(p - \epsilon) \cdot 4 \cdot d_0$ black neighbors in S_0 with a probability of $1 - O(n^{-2})$. This already makes v switchable to black, since $d_v = 5 \cdot d_0$, and thus for the appropriate p and ϵ values we have

$$\frac{(p - \epsilon) \cdot 4 \cdot d_0}{5 \cdot d_0} \approx \frac{4}{5} > \frac{2}{3} > \frac{1 + \lambda}{2}.$$

Applying a union bound over all nodes $v \in S_1$, we get that w.h.p. the entire set S_1 can be switched to black.

6.3 Growing Phase

Given our set S_1 from the Collection Phase, the next step is to iteratively build a range of levels $S_{2,i}$ for $i = 1, 2, \dots$. Each of these levels has the same size $|S_{2,i}| = m_1$, but on the other hand, their degrees increase exponentially: the output degree of each node in $S_{2,i+1}$ is always twice as big as the output degree of the nodes in $S_{2,i}$.

We achieve this by connecting every pair of subsequent levels as a regular bipartite graph. Let us begin with $S_{2,1} := S_1$. Recall that each node in S_1 has d_0 output edges, so $S_{2,1}$ and $S_{2,2}$ will form a d_0 -regular bipartite graph. We then connect $S_{2,2}$ and $S_{2,3}$ as a $2 \cdot d_0$ -regular bipartite graph, $S_{2,3}$ and $S_{2,4}$ as a $4 \cdot d_0$ -regular bipartite graph, and so on. Thus in any level, we have a value d such that each node has d edges to the previous and $2d$ edges to the next level, and this value d doubles with each new level. Since the degrees grow exponentially, after about $\log m_1$ levels, we reach a last level $S_{2,\ell}$ where the output degree is $\Theta(m_1)$.

We use an induction to prove that we can w.h.p. turn all nodes black in each $S_{2,i}$. This is already known for $S_{2,1} = S_1$ initially. In the general case, let v be an arbitrary node of $S_{2,i}$. Since each v has at least d_0 output edges to $S_{2,i+1}$, we can use Lemma 2 to show that the output neighborhood of every node is initially ϵ -balanced. This means that for any $v \in S_{2,i}$, at least $(\frac{1}{2} - \epsilon) \cdot 2d = (1 - 2\epsilon) \cdot d$ outputs are already black initially. Due to the induction, we can turn all the d remaining neighbors in $S_{2,i-1}$ black, altogether giving $(2 - 2\epsilon) \cdot d$ black neighbors of v . With $d_v = 3 \cdot d$, this amounts to a ratio of $\frac{2-2\epsilon}{3}$ black nodes in $N(v)$. Since we have $\frac{1+\lambda}{2} = \frac{2}{3} - \delta$, a sufficiently small choice of ϵ always ensures that this ratio is above $\frac{1+\lambda}{2}$, and thus v is switchable to black. Hence each node in $S_{2,i}$ can indeed be turned black, which completes our induction.

6.4 Control Phase

In the following Control Phase, we create a new set S_3 on m_3 nodes. The goal of this phase is to ensure that at a specific point in the process, each $v \in S_3$ switches to black, and then at a later point, each $v \in S_3$ is switchable to white.

In order to be able to initialize a PROP construction on m nodes in the final phase, each node in S_3 will have an output degree of m , for some parameter m . A detailed analysis shows that for a large constant $\alpha > 1$, a choice of $m_3 = \frac{1}{\alpha} \cdot m_1$ and $m = \frac{1}{2} \cdot m_3$ suffices for our purposes.

To achieve the desired switching behavior for S_3 , we first create two copies of the previous phases: one of them ending with a level $S_{2,\ell}^b$ on $\alpha \cdot m$ nodes where w.h.p. each nodes switches to black, and the other one ending with a last level $S_{2,\ell}^w$ on $2\alpha \cdot m$ nodes where w.h.p. each node switches to white in a symmetric manner. We connect each node in S_3 to every node in both $S_{2,\ell}^b$ and $S_{2,\ell}^w$. As a result, each $v \in S_3$ has a degree of $d_v = (3\alpha + 1) \cdot m$. Note that the output degree of both $S_{2,\ell}^b$ and $S_{2,\ell}^w$ is $\Theta(m_1) = \Theta(\alpha \cdot m_3)$, so for α large enough, they can indeed be connected to each node in S_3 .

Now consider the neighbors of a node $v \in S_3$. First $S_{2,\ell}^b$ becomes black and v 's neighborhood in $S_{2,\ell}^w$ is ϵ -balanced; this gives at least $\alpha \cdot m + (\frac{1}{2} - \epsilon) \cdot 2\alpha \cdot m = 2\alpha \cdot m \cdot (1 - \epsilon)$ black neighbors in $N(v)$, amounting to a $\frac{2\alpha \cdot (1-\epsilon)}{3\alpha+1}$ fraction of d_v . As $\frac{1+\lambda}{2} = \frac{2}{3} - \delta$, for a sufficiently small ϵ and sufficiently large α , we can ensure that this ratio is larger than $\frac{1+\lambda}{2}$, and thus v is indeed switchable. We switch each $v \in S_3$ to black at this point.

After this, we turn each node in $S_{2,\ell}^w$ white. Nodes in S_3 now have $2\alpha \cdot m$ white neighbors at least; this again ensures that each $v \in S_3$ is now switchable to white. However, for our purposes in the last phase, we will only switch half of the nodes in S_3 white at this point (denoted by S_3^w), and leave the remaining part black (denoted by S_3^b).

6.5 Simulation Phase

Finally, we use the PROP construction on m nodes to obtain superlinear stabilization time. Given a node v in PROP, assume w.l.o.g. that v is initially black in the example sequence of PROP; we can apply the same technique for white nodes in a symmetric manner.

Our main idea is to connect v to some new nodes in S_3^b and S_3^w . When S_3^b and S_3^w both switch to black, this allows us to switch v to its desired initial color (black). Then when S_3^w switches back to white, the new neighbors become balanced, and thus the switchability of v will again depend on its original neighbors within PROP. However, with these extra connections, the original $N(v)$ is now only a smaller fraction of v 's total neighborhood, so this only allows us to simulate PROP with a smaller parameter $\lambda' < \lambda$.

More specifically, if v has original degree d'_v within the PROP construction, then we connect v to $\frac{1}{2} \cdot \frac{1+\lambda}{1-\lambda} \cdot d'_v$ arbitrary nodes in both S_3^b and S_3^w . We point out that our choice of $m = \frac{1}{2} \cdot m_3$ is indeed sufficient for this: since $\lambda < \frac{1}{3}$ implies $\frac{1+\lambda}{1-\lambda} < 2$, every node in the PROP construction needs at most $\frac{1}{2} \cdot \frac{1+\lambda}{1-\lambda} \cdot d'_v < d'_v$ new edges to both S_3^b and S_3^w . Hence with $d'_v < m$ in the PROP construction, it is indeed enough to have m nodes in the sets S_3^b and S_3^w . Furthermore, since each node in S_3 has an output degree of m , we can also connect a node in S_3^b or S_3^w to as many nodes in the PROP construction as necessary.

With v connected to $\frac{1}{2} \cdot \frac{1+\lambda}{1-\lambda} \cdot d'_v$ nodes in both S_3^b and S_3^w , the new degree of v is now

$$d_v = \left(1 + \frac{1+\lambda}{1-\lambda}\right) \cdot d'_v = \frac{2}{1-\lambda} \cdot d'_v,$$

so v requires $\frac{1+\lambda}{2} \cdot d_v = \frac{1+\lambda}{1-\lambda} \cdot d'_v$ conflicts to be switchable. Hence when S_3^b and S_3^w are both switched black, this is already enough to switch v black, since the two sets provide $2 \cdot \frac{1}{2} \cdot \frac{1+\lambda}{1-\lambda} \cdot d'_v = \frac{1+\lambda}{1-\lambda} \cdot d'_v$ black neighbors to v together. Later S_3^w switches to white; then for the rest of the process, v has $\frac{1}{2} \cdot \frac{1+\lambda}{1-\lambda} \cdot d'_v$ neighbors of both colors in S_3 .

Let us now select $\lambda' = \frac{2\lambda}{1-\lambda}$, and apply the PROP construction for λ' as a black box. If v was switchable in the original PROP graph, it is also switchable in our construction. This allows us to run the entire sequence of $m^{1+f(\lambda')-\varepsilon}$ steps in PROP. Then together with the $\frac{1}{2} \cdot \frac{1+\lambda}{1-\lambda} \cdot d'_v$ additional conflicts to either S_3^b or S_3^w , v has at least $\frac{1+\lambda}{1-\lambda} \cdot d'_v = \frac{1+\lambda}{2} \cdot d_v$ conflicts in our construction, and thus it is indeed switchable.

Hence we can indeed simulate the behavior of PROP in our construction: whenever v is switchable in the original PROP graph, it is also switchable in our construction. This allows us to run the entire sequence of $m^{1+f(\lambda')-\varepsilon}$ steps in PROP, giving a sequence of $m^{1+f(\frac{2\lambda}{1-\lambda})-\varepsilon}$ steps in terms of our λ .

One can observe that our construction contains only $O(m \cdot \log m)$ nodes altogether, thus allowing a choice of $m = \Theta(\frac{n}{\log n})$. This results in about

$$n^{1+f(\frac{2\lambda}{1-\lambda})-\varepsilon} \cdot \log n^{-(1+f(\frac{2\lambda}{1-\lambda})-\varepsilon)}$$

steps for the PROP sequence in terms of n . Since such a PROP construction exists for any $\varepsilon > 0$, we can get rid of the second factor in this lower bound by simply applying the same proof with a smaller value $\hat{\varepsilon} < \varepsilon$. Thus the claim of Theorem 5 follows.

7 Proportional switching: upper bound for $\lambda > \frac{1}{2}$

We now show that with $\lambda = \frac{1}{2} + \delta$ for some $\delta > 0$, stabilization happens w.h.p. in $\tilde{O}(n)$ time. The only probabilistic element of this proof is the assumption that initially all high-degree nodes have an ε -balanced neighborhood; this indeed holds w.h.p., as we have seen before in Corollary 3.

83:12 Stabilization Bounds for Influence Propagation from a Random Initial State

The idea of the proof is that even though there might be $\Theta(n^2)$ conflicts in the graph initially, only a few of these conflicts can propagate through the graph. Let us call a conflict on edge (u, v) in our current coloring an *original conflict* if it has been on the edge since the beginning of the process, i.e. if every previous state (including the initial state) already had a conflict on (u, v) .

► **Definition 6** (Active/Rigid conflicts). *We say that a conflict on edge (u, v) is rigid if it is an original conflict, and both u and v are high-degree nodes. Otherwise, the conflict is active.*

Our proof is obtained as a result of three observations: that (i) there are only a few active conflicts in the graph initially, (ii) the number of active conflicts decreases in each step of the process, and (iii) the process stabilizes when there are no more active conflicts. Since the second point is the most complex out of the three claims, we first discuss it separately.

► **Lemma 7.** *The number of active conflicts strictly decreases in each step.*

Proof. Consider a specific step of the process, and let v be the node that switches in this step. Assume first that v is a low-degree node. In this case, v can only have active conflicts on its incident edges at any point in the process: initially, all conflicts of v are active by definition, and all the newly created conflicts in the process are also active. Since the number of conflicts on v 's incident edges decreases when v switches, the total number of active conflicts also decreases in this step.

Now assume that v is a high-degree node. Since $N(v)$ is initially ϵ -balanced, it has at most $(\frac{1}{2} + \epsilon) \cdot d_v$ rigid conflicts in the beginning, and since all the newly created conflicts in the process are active, it also has at most $(\frac{1}{2} + \epsilon) \cdot d_v$ rigid conflicts at any later point in the process. However, if v switches, then it must have at least $\frac{1+\lambda}{2} \cdot d_v$ incident conflicts; this implies that at least $\frac{1+\lambda}{2} \cdot d_v - (\frac{1}{2} + \epsilon) \cdot d_v$ of these conflicts are active. When v switches, it creates at most $\frac{1-\lambda}{2} \cdot d_v$ new (active) conflicts. Thus, to show that the number of active conflicts decreases, we only require

$$\frac{1+\lambda}{2} \cdot d_v - \left(\frac{1}{2} + \epsilon\right) \cdot d_v > \frac{1-\lambda}{2} \cdot d_v,$$

which is equivalent to $\lambda > \frac{1}{2} + \epsilon$. This holds for a sufficiently small choice of $\epsilon < \delta$. ◀

This already allows us to prove our upper bound.

► **Theorem 8.** *Consider majority/minority processes under the proportional switching rule for any $\lambda > \frac{1}{2}$, starting from a uniform random initial coloring. Any graph has a stabilization time of $O(n \cdot \log n)$ with high probability in this model.*

Proof. In any initial coloring, the number of active conflicts is at most $O(n \cdot \log n)$: each low-degree node has at most $c_0 \cdot \log n$ incident edges, and the number of low-degree nodes is at most n . Lemma 7 shows that the number of active conflicts decreases in each step, so there are no active conflicts in the graph after at most $O(n \cdot \log n)$ steps.

Once there are no more active conflicts, the coloring is stable, since nodes cannot be switchable without an active conflict on the incident edges. More specifically, due to the ϵ -balanced property, all high-degree nodes v have at most $(\frac{1}{2} + \epsilon) \cdot d_v$ rigid conflicts on the incident edges, which is smaller than $\frac{1+\lambda}{2} \cdot d_v$ if we have $\epsilon < \frac{\lambda}{2}$. Low-degree nodes, on the other hand, can never have rigid conflicts on the incident edges at all. Thus the process indeed stabilizes in $O(n \cdot \log n)$ steps. ◀

■ **Figure 3** Our upper and lower bounds on stabilization time in the proportional case.

8 Conclusion

Our results show that the behavior of the processes from a randomized initial coloring is rather straightforward in case of the basic switching rule: stabilization time can indeed tightly match the naive upper bound of $O(n^2)$.

However, in case of proportional switching, our work does leave some open questions. Figure 3 illustrates our upper and lower bounds for this case. The most apparent open question is the behavior of the process for the $\lambda \in [\frac{1}{3}, \frac{1}{2}]$ case; in this interval, we only have the straightforward lower bound of Section 4.2. While the figure gives the impression that stabilization time might also have a $\tilde{O}(n)$ upper bound in this case, it remains for future work to prove or disprove this claim.

Furthermore, even for $\lambda < \frac{1}{3}$ when stabilization is known to be superlinear, one might also be interested in devising upper bounds. Currently, the best known upper bound is that of $O(n^{1+f(\lambda)+\varepsilon})$ from [29], which even applies for the worst-case initial coloring.

Abstract

We study the problem $\#EDGESUB(\Phi)$ of counting k -edge subgraphs satisfying a given graph property Φ in a large host graph G . Building upon the breakthrough result of Curticapean, Dell and Marx (STOC 17), we express the number of such subgraphs as a finite linear combination of graph homomorphism counts and derive the complexity of computing this number by studying its coefficients.

Our approach relies on novel constructions of low-degree Cayley graph expanders of p -groups, which might be of independent interest. The properties of those expanders allow us to analyse the coefficients in the aforementioned linear combinations over the field \mathbb{F}_p which gives us significantly more control over the cancellation behaviour of the coefficients. Our main result is an exhaustive and fine-grained complexity classification of $\#EDGESUB(\Phi)$ for minor-closed properties Φ , closing the missing gap in previous work by Roth, Schmitt and Wellnitz (ICALP 21).

Additionally, we observe that our methods also apply to modular counting. Among others, we obtain novel intractability results for the problems of counting k -forests and matroid bases modulo a prime p . Furthermore, from an algorithmic point of view, we construct algorithms for the problems of counting k -paths and k -cycles modulo 2 that outperform the best known algorithms for their non-modular counterparts.

In the course of our investigations we also provide an exhaustive parameterized complexity classification for the problem of counting graph homomorphisms modulo a prime p .

Extended Abstract

In this work we study the problem of counting small patterns in large host graphs. With applications in a diverse set of disciplines such as constraint satisfaction problems [13, 7], database theory [15, 8] and network science [34, 1, 41], it is unsurprising that this problem has received significant attention from the viewpoint of parameterized and fine-grained complexity theory in recent years [2, 17, 33, 9, 12, 11, 5, 37, 38, 28, 39].

We continue this line of work and study the problem of counting k -edge subgraphs that satisfy a graph property Φ : For any fixed Φ , the problem $\#\text{EDGESUB}(\Phi)$ asks, on input a graph G and a positive integer k , to compute the number of (not necessarily induced) subgraphs with k edges in G that satisfy Φ . In particular, we focus on instances in which k is significantly smaller than G . Formally, we choose k to be the *parameter* of the problem and ask for which Φ there is a function f such that $\#\text{EDGESUB}(\Phi)$ can be solved in time $f(k) \cdot |V(G)|^{O(1)}$; in this case we call the problem *fixed-parameter tractable* with respect to the parameter k .

If $\#\text{EDGESUB}(\Phi)$ is not fixed-parameter tractable, it is desirable to improve the exponent of $|V(G)|$ in the running time as far as possible. For example, the best known algorithm for counting k -edge subgraphs [11] can be used to solve $\#\text{EDGESUB}(\Phi)$ in time $f(k) \cdot |V(G)|^{0.174k+o(k)}$ [39]. Additionally, it was shown in recent work that $\#\text{EDGESUB}(\Phi)$ is fixed-parameter tractable whenever Φ has *bounded matching number*, that is, whenever there is a constant upper bound on the size of the largest matching of any graph satisfying Φ [39]. If, for each k , the property Φ is true for only one graph on k edges, then the previous fixed-parameter tractability result is best possible: In this case, $\#\text{EDGESUB}(\Phi)$ becomes an instance of the counting version of the parameterized subgraph isomorphism problem which has been fully classified by Curticapean and Marx [12].

However, for arbitrary Φ , much less is known about the complexity of $\#\text{EDGESUB}(\Phi)$. In [39], two of the authors, together with Wellnitz, presented first results for more general properties such as connectivity, Eulerianity and, in particular, an *almost* exhaustive classification for minor-closed properties Φ , leaving (partially) open the case of forbidden minors of degree at most 2. In this work, we close this gap and provide a full dichotomy result:

► **Theorem 1.** *Let Φ be a minor-closed graph property. If Φ is trivially true or of bounded matching number, then $\#\text{EDGESUB}(\Phi)$ is fixed-parameter tractable. Otherwise, $\#\text{EDGESUB}(\Phi)$ is $\#\text{W}[1]$ -hard and, assuming the Exponential Time Hypothesis, it cannot be solved in time*

$$f(k) \cdot |G|^{o(k/\log k)}$$

for any function f .

Here, $\#\text{W}[1]$ is the parameterized counting analogue of NP; a formal definition is provided in the full version. Particular cases for which we obtain novel intractability results are given by the following (minor-closed) properties; the formal intractability results are stated and proved in the full version as well.

- $\Phi(H) = 1$ if H is a forest.
- $\Phi(H) = 1$ if H is a linear forest.
- $\Phi(H) = 1$ if the tree-depth of H is bounded by a constant.
- $\Phi(H) = 1$ if the Colin de Verdière Invariant of H is bounded by a constant.

Additionally, we investigate the property of being bipartite. For this case, we present not only a novel fine-grained lower bound, but also a $\#\text{W}[1]$ -hardness result, which was not known before.

► **Theorem 2.** *Let Φ be the property of being bipartite. Then $\#\text{EDGESUB}(\Phi)$ is $\#\text{W}[1]$ -hard and, assuming the Exponential Time Hypothesis, it cannot be solved in time*

$$f(k) \cdot |G|^{o(k/\log k)}$$

for any function f .

Our hardness results crucially rely on a novel construction of families of low-degree Cayley graph expanders of p -groups, which might be of independent interest. We will present the new Cayley graph expanders in the following theorem; their construction, as well as their role in the hardness proofs for $\#\text{EDGESUB}(\Phi)$ will be elaborated on in the technical discussion.

► **Theorem 3.** *Let $p \geq 3$ be a prime number, and $d \geq 2$ be an integer. We assume that $d \geq (p+3)/2$ if $p \geq 7$.*

Then there is an explicit construction of a sequence of finite p -groups Γ_i of orders that tend to infinity, with symmetric generating sets S_i of cardinality $2d$ such that the Cayley graphs $\mathcal{C}(\Gamma_i, S_i)$ form a family of expanders (of fixed valency $2d$ on a set of vertices of p -power orders and with vertex transitive automorphism groups).

Our methods do not only apply to exact counting, but also to modular pattern counting problems: Here the goal is to compute the number of occurrences of the pattern *modulo a fixed prime p* . In classical complexity theory, the study of modular counting problems has a rich history, such as the algorithm for computing the permanent modulo 2^ℓ [44], the so-called accidental algorithms [45], Toda's Theorem [43], classifications for modular $\#\text{CSPs}$ and Holants [24, 25] and the line of research on the modular homomorphism counting problem [16, 20, 21, 22, 26, 18, 27], only to name a few.

While results are scarcer, the *parameterized* complexity of modular (pattern) counting problems has also been studied in recent years [4, 14, 10], and we contribute to this line of research as follows: First, we provide a novel intractability result for modular counting of forests and matroid bases. We write $\#_p\text{FORESTS}$ for the problem of, given a graph G and a positive integer k , computing the number of forests with k edges in G , modulo p . Similarly, we write $\#_p\text{BASES}$ for the problem of, given a linear matroid M of rank k in matrix representation, computing the number of bases of M , modulo p ; the parameter of both problems is given by k .

► **Theorem 4.** *For each prime $p \geq 3$, the problems $\#_p\text{FORESTS}$ and $\#_p\text{BASES}$ are $\text{Mod}_p\text{W}[1]$ -hard and, assuming the randomised Exponential Time Hypothesis, cannot be solved in time $f(k) \cdot |G|^{o(k/\log k)}$ (resp. $f(k) \cdot |M|^{o(k/\log k)}$), for any function f .*

Here, $\text{Mod}_p\text{W}[1]$ is the parameterized modular counting version of NP. Roughly speaking, a problem is $\text{Mod}_p\text{W}[1]$ if it is at least as hard as counting k -cliques modulo p ; we give a formal definition in the full version. Additionally, we provide an algorithmic result for counting k -paths and k -cycles modulo 2:

► **Theorem 5.** *The problems of counting k -paths and k -cycles in a graph G modulo 2 can be solved in time $k^{O(k)} \cdot |V(G)|^{k/6+O(1)}$.*

We emphasize that the algorithm in the previous theorem is faster than the best known algorithms for (non-modular) counting of k -cycles/ k -paths, which run in time $k^{O(k)} \cdot |V(G)|^{13k/75+o(k)}$ [11]. Furthermore, it follows from a result by Curticapean, Dell and Husfeldt [10] that counting k -paths modulo 2 is $\text{Mod}_2\text{W}[1]$ -hard, implying that we cannot hope for an algorithm for k -paths running in time $f(k) \cdot |V(G)|^{O(1)}$. Finally, we study the parameterized complexity of counting homomorphisms modulo p . In the classical setting, the related problem of modular counting homomorphisms with *right-hand side* restrictions received much attention: For any fixed graph H , the problem $\#_p\text{HOMSTO}(H)^1$ asks, on input a graph G , to compute the number of homomorphisms from G to H modulo p . Despite significant effort [16, 20, 21, 22, 26, 18, 27], the problem has not been fully classified for each graph H .²

In this work, we consider the related *left-hand side* version of the problem. Adapting the definitions of Grohe, Dalmau and Jonsson [23, 13] for detecting and exact counting of homomorphisms, we define a problem $\#_p\text{HOM}(\mathcal{H})$ for each class of graphs \mathcal{H} and for each prime p : This problem expects as input a graph $H \in \mathcal{H}$ and an arbitrary graph G , and the goal is to compute the number of homomorphisms from H to G , modulo p . The problem is parameterized by the size of H , that is, we assume H to be significantly smaller than G .

It is known that the decision version $\text{HOM}(\mathcal{H})$ is fixed-parameter tractable (even solvable in polynomial time) if the treewidth of the cores of \mathcal{H} is bounded by a constant, and $\text{W}[1]$ -hard otherwise [23]. Similarly, the (exact) counting version $\#\text{HOM}(\mathcal{H})$ is known to be fixed-parameter tractable (even solvable in polynomial time) if the treewidth of the graphs of \mathcal{H} is bounded by a constant, and $\#\text{W}[1]$ -hard otherwise [13].

In case of counting modulo p , we establish an exhaustive classification for $\#_p\text{HOM}(\mathcal{H})$ along what we call the *p -reduced quotients* of the graphs in \mathcal{H} . Let H be a graph and let α be an automorphism of H of order p . Then we define the quotient graph H/α to have a vertex for each orbit of the action of α on $V(H)$, and two vertices corresponding to orbits \mathcal{O}_1 and \mathcal{O}_2 are made adjacent if and only if there are vertices $v_1 \in \mathcal{O}_1$ and $v_2 \in \mathcal{O}_2$ such that $\{v_1, v_2\} \in E(H)$. This induces a finite (possibly trivial) sequence $H = H_1, \dots, H_\ell$ where for $i = 1, \dots, \ell - 1$ we set $H_{i+1} = H_i/\alpha_i$ for some automorphism α_i of order p of H_i and where the last graph H_ℓ does not have an automorphism of order p . Then $H_p^* := H_\ell$ is called the *p -reduced quotient* of H .³ We will see that H_p^* is well-defined by proving that each of the aforementioned sequences yields the same graph, up to isomorphism.

Let us now state our classification for $\#_p\text{HOM}(\mathcal{H})$. In what follows, given a class \mathcal{H} , we write \mathcal{H}_p^* for the p -reduced quotients without self-loops of graphs in \mathcal{H} . We first present the algorithmic part:

► **Theorem 6.** *Let $p \geq 2$ be a prime and let \mathcal{H} be a class of graphs. The problem $\#_p\text{HOM}(\mathcal{H})$ can be solved in time*

$$\exp(\text{poly}(|V(H)|)) \cdot |V(G)|^{\text{tw}(H_p^*)+O(1)}.$$

In particular, $\#_p\text{HOM}(\mathcal{H})$ is fixed-parameter tractable if the treewidth of \mathcal{H}_p^ is bounded.*

Here tw denotes treewidth.

¹ For $p = 2$, the problem is usually denoted by $\oplus\text{HOMSTO}(H)$.

² However, very recently a full classification was announced by Bulatov and Kazemina [6].

³ We remark that H_p^* is related to the notion of involution-free reductions used in the analysis of the right-hand side version of the problem [16, 22]. However, the difference is that the p -reduced quotient identifies non-fixed points of an order- p automorphism by including a vertex for each orbit, while the involution-free reduction just deletes all non-fixed points.

► **Remark 7.** Using the quasi-polynomial time algorithm for GI due to Babai [3], we will also show how the algorithm in the previous theorem can be improved to run in quasi-polynomial time in the input length $|V(H)| + |V(G)|$. Additionally, proving that the construction of the p -reduced quotient is at least as hard as the graph automorphism problem, we observe that a polynomial-time algorithm is unlikely, unless the construction of the p -reduced quotients can be avoided.

For the intractability part of our classification, we show that unbounded treewidth of \mathcal{H}_p^* yields hardness:

► **Theorem 8.** *Let $p \geq 2$ be a prime and let \mathcal{H} be a computable class of graphs. If the treewidth of \mathcal{H}_p^* is unbounded, then $\#_p\text{HOM}(\mathcal{H})$ is $\text{Mod}_p\mathbb{W}[1]$ -hard and, assuming the randomised Exponential Time Hypothesis, cannot be solved in time*

$$f(|H|) \cdot |G|^{o(\text{tw}(H_p^*)/\log \text{tw}(H_p^*))}$$

for any function f .

Can You Beat Treewidth?

We conclude the presentation of our results by commenting on the factor of $1/(\log \dots)$ in the exponents of all of our fine-grained lower bounds. This factor is related to the conjecture of whether it is possible to “beat treewidth” [31]. In particular, we point out that the factor can be dropped in *all* of our lower bounds if this conjecture, formally stated as Conjecture 1.3 in [32], is true.

Technical Overview

Our central approach follows the so-called Complexity Monotonicity framework due to Curticapean, Dell and Marx [11]. We express the counting problems considered in this work as formal linear combination of homomorphism counts, which allows us to derive the complexity of the problem at hand by analyzing the coefficients.

More precisely, let us fix a graph property Φ and a positive integer k . Given a graph G , we furthermore write $\#\text{EdgeSub}(\Phi, k \rightarrow G)$ for the number of k -edge subgraphs of G that satisfy Φ . It was shown in [39] that there exists a function of finite support $a_{\Phi, k}$ from graphs to rationals such that for every graph G we have

$$\#\text{EdgeSub}(\Phi, k \rightarrow G) = \sum_H a_{\Phi, k}(H) \cdot \#\text{Hom}(H \rightarrow G), \quad (1)$$

where $\#\text{Hom}(H \rightarrow G)$ is the number of graph homomorphisms from H to G . Curticapean, Dell and Marx [11] have shown that computing a linear combination as in (1) is *precisely as hard as* computing its hardest term. Fortunately, the complexity of counting and detecting homomorphisms from H to G is thoroughly classified [13, 31]: Roughly speaking, the higher the treewidth of H , the harder it is to compute the number of homomorphisms from H to G . Therefore, proving hardness of computing $\#\text{EdgeSub}(\Phi, k \rightarrow G)$ reduces to the purely combinatorial problem of determining which of the coefficients $a_{\Phi, k}(H)$ in (1) for high-treewidth graphs H are non-zero.

Unfortunately, it has turned out that the coefficients of such linear combinations for related pattern counting problems are often determined by (or even equal to) a variety of algebraic and topological invariants, whose analysis is known to be a difficult problem in its own right. For example, in case of the vertex-induced subgraph counting problem, the

■ **Figure 1** Illustration of the construction of a fractured graph. The left picture shows a vertex v of a graph H with incident edges $E_H(v) = \{\bullet, \bullet, \bullet, \bullet, \bullet\}$. The right picture shows the splitting of v in the construction of the fractured graph $H\#\sigma$ for a fracture σ satisfying that the partition σ_v contains two blocks $B_1 = \{\bullet, \bullet, \bullet\}$, and $B_2 = \{\bullet, \bullet, \bullet\}$.

coefficient of the clique is the reduced Euler characteristic of a simplicial graph complex [37], the coefficient of the biclique is the so-called alternating enumerator [14], and, more generally, the coefficients of dense graphs are related to the h - and f -vectors associated with the property of the patterns that are to be counted [38]. In all of the previous works mentioned here, the complexity analysis of the respective pattern counting problems therefore amounted to understanding the cancellation behaviour of those invariants. To do so, the papers used tools from combinatorial commutative algebra and, to some extent, topological fixed-point theorems.

In case of $\#\text{EDGESUB}(\Phi)$, two of the authors, together with Wellnitz, observed that the coefficients of high-treewidth low-degree vertex-transitive graphs can be analysed much easier than generic graphs of high treewidth such as the clique or the biclique [39]. First, it was shown that the coefficient of a graph H with k edges in (1) is equal to the *indicator* of Φ and H , defined as follows:⁴

$$a(\Phi, H) := \sum_{\sigma \in \mathcal{L}(\Phi, H)} \prod_{v \in V(H)} (-1)^{|\sigma_v| - 1} (|\sigma_v| - 1)!. \quad (2)$$

Here, $\mathcal{L}(\Phi, H)$ is the set of *fractures* σ of H such that the associated *fractured graph* $H\#\sigma$ satisfies Φ . Here, a fracture of a graph H is a tuple $\sigma = (\sigma_v)_{v \in V(H)}$, where σ_v is a partition of the set of edges $E_H(v)$ of H incident to v . Given a fracture ρ of H , the fractured graph $H\#\rho$ is obtained from H by splitting each vertex $v \in V(H)$ according to σ_v ; an illustration is provided in Figure 1.

As a consequence, the $\#\text{W}[1]$ -hardness results of Theorems 1 and 2 can be obtained if we find a family of graphs H of unbounded treewidth, such that $a(\Phi, H) \neq 0$ for infinitely many graphs H in this family. The almost tight conditional lower bound under the Exponential Time Hypothesis will, additionally, require sparsity of the graphs. In combination with the main observation in [39], stating that the indicator $a(\Phi, H)$ can be analysed much easier for vertex-transitive graphs, we propose that regular Cayley graph expanders are the right choice for the family of graphs to be considered. Indeed, those graphs are sparse, have high treewidth and are always vertex transitive. A particular family of Cayley graph expanders was already used in [39], but it turned out to be impossible to prove Theorems 1 and 2 relying only on this family of Cayley graph expanders; we discuss this in detail in the full version.

⁴ To be precise, the identity in (2) was obtained for a coloured version of $\#\text{EDGESUB}(\Phi)$. However, we will mostly rely on this result in a blackbox manner; all details of the coloured version necessary for the treatment in this paper will be carefully introduced when needed.

In this work, we therefore present novel constructions of families of low-degree Cayley graph expanders. Those will not only allow us to prove most of our main theorems by analysing their indicators, but might be of independent interest. For the sake of presentation, we decided to encapsulate the treatment of our constructions in separate sections, both in the extended abstract and the main part of the paper. We hope that this makes the paper accessible both for readers primarily interested in the novel construction of Cayley graph expanders, as well as for readers mainly interested in the analysis of the pattern counting problems. In particular, this last group may safely skip the next subsection and rely only on Theorem 3.

Construction of Low-Degree Cayley Graph Expanders

We prove Theorem 3 via an explicit construction of the groups Γ_i and the symmetric generating sets S_i in the full version, motivated by number theoretic objects. In what follows we present an overview of our construction.

Let us fix a prime $p \geq 3$. The starting point is an explicit arithmetic lattice (a discrete subgroup) in a group of generalized quaternions over a function field in characteristic p . The quaternion algebra is at the heart of the mathematical properties of extracting the finite p -groups and the expansion property of the resulting Cayley graphs, but it is not crucial for understanding the construction. Concretely, for any choice of elements $\alpha \neq \beta \in \mathbb{Z}/(p-1)\mathbb{Z}$ we construct an infinite group $\Gamma_{p;\alpha,\beta}$ defined in terms of $2(p+1)$ generators a_k, b_j (where the indices k, j run through sets $K, J \subseteq \mathbb{Z}/(p^2-1)\mathbb{Z}$ defined depending on α, β) and relations of length 4. The set of relations is described by explicit algebraic equations in the field \mathbb{F}_{p^2} . In [40] these groups were realized by mapping the generators a_k, b_j to explicit generalized quaternions, leading ultimately to an explicit injective group homomorphism

$$\Psi: \Gamma_{p;\alpha,\beta} \rightarrow \mathrm{GL}_3(\mathbb{F}_p[[t]]). \tag{3}$$

In other words, every element of $\Gamma_{p;\alpha,\beta}$ is sent to an invertible 3×3 -matrix whose entries are power series in some formal variable t , whose coefficients live in the finite field \mathbb{F}_p with p elements. This is made explicit for $p = 3$ in the full version, but could also be made explicit for any $p \geq 5$. Since the applications do not depend on concrete matrices, we merely state its existence.

To construct the finite p -groups Γ_i , consider the group homomorphism

$$\pi_i: \mathrm{GL}_3(\mathbb{F}_p[[t]]) \rightarrow \mathrm{GL}_3(\mathbb{F}_p[t]/(t^{i+1}))$$

taking a matrix with power series entries and truncating the power series after the term of order t^i . Then the group $\mathrm{GL}_3(\mathbb{F}_p[t]/(t^{i+1}))$ is finite, and we define Γ_i to be the image of the group $\Gamma_{p;\alpha,\beta}$ under the composition $\pi_i \circ \Psi$. These groups Γ_i are easily shown to be p -groups and they are what is called congruence quotients (by construction). The generators a_k, b_j from the construction of $\Gamma_{p;\alpha,\beta}$ map to symmetric generating sets T_i of Γ_i , i.e., to the set of cosets $a_k N_i, b_j N_i$ when $\Gamma_i = \Gamma_{p;\alpha,\beta}/N_i$ is considered as a factor group. Using results from [40], we know that the Cayley graphs $G_i = \mathcal{C}(\Gamma_i, T_i)$ associated to the congruence quotient groups Γ_i with respect to the generating sets T_i are expanders. This argument is worked out in [40] by Rungtanapirom and two of the authors, and it is based on a similar approach in the classical papers by Lubotzky, Phillips and Sarnak [30] and by Morgenstern [35]. We note here that the results of [40] ultimately rely on deep number theoretic results, namely a translation of the spectrum of the adjacency operator into Satake parameters of an associated automorphic representation and most crucially on work of Drinfeld on the geometric Langlands programme for GL_2 .

At this point we have proven Theorem 3 for the particular valency $2d = 2(p + 1)$. In order to obtain the more general valencies stated in the theorem (which will be crucial for some of our reductions), we recall in Section 3.1 of the full version that a uniformly controlled change of the generating sets T_i of the groups Γ_i (the generators must be mutually expressible in words of uniformly bounded length) preserves the expander property. This change of generating set is best performed by finding a smaller generating set for the underlying infinite group $\Gamma_{p;\alpha,\beta}$. This is done in Proposition 3.7 in the full version, reducing to $d = (p + 3)/2$ for all $p \geq 3$. The reduction is based on the explicit form of the relations and a combinatorial group theoretic result from [42] on the local permutation structure of the underlying geometric square complex. To improve even further for $p = 3$ we consider in Section 3.3 of the full version a concrete presentation of $\Gamma_{3;0,1}$ which is shown to reduce to 2 generators. For $p = 5$, an explicit example given in the full version achieves a reduction to 2 generators for $\Gamma_{5;0,2}$. In the last step, we will then show that by adding generators (as necessary) we obtain Theorem 3 for all d 's in the range that the theorem promises.

While this is not needed for the purposes of our hardness results, all of the constructions above are explicit, certainly in the weak sense that for a fixed p , the sequence of graphs G_i from Theorem 3 is computable. We also would like to emphasize again, that the expanders constructed for the proof of Theorem 3 consist of vertex transitive graphs, of prime power number of vertices, with a fairly low bound on the degree. All of this is made possible by working with very specific generalized quaternion groups in positive characteristic.

Analysis of the Indicators

Having established the existence of the low-degree Cayley graph expanders, we turn back to the analysis of the indicator

$$a(\Phi, H) = \sum_{\sigma \in \mathcal{L}(\Phi, H)} \prod_{v \in V(H)} (-1)^{|\sigma_v|-1} (|\sigma_v| - 1)! \tag{4}$$

Recall that we claimed the analysis of $a(\Phi, H)$ to be easier for vertex-transitive graphs. Let us now elaborate on this claim. First of all, we restate the formal definition of Cayley graphs for readers who skipped the explicit construction of our expanders: the *Cayley graph* of a group Γ together with a symmetric generating set⁵ $S \subseteq \Gamma$ is the graph $G = \mathcal{C}(\Gamma, S)$ with vertex set $V(G) = \Gamma$ and edge set

$$E(G) = \{(x, xs) \in V(G) \times V(G); x \in \Gamma, s \in S\}.$$

Since S is symmetric, with any edge (x, xs) the Cayley graph also contains the edge with opposite orientation $(xs, x) = (xs, (xs)s^{-1})$. Hence we consider Cayley graphs as the underlying unoriented graph.

Given a Cayley graph G as above, the group Γ acts on the graph by letting $g \in \Gamma$ send the vertex $v \in V(G) = \Gamma$ to gv . This action extends to the set of fractures $\mathcal{L}(\Phi, H)$ and since the terms $\prod_{v \in V(H)} (-1)^{|\sigma_v|-1} (|\sigma_v| - 1)!$ in the formula (4) are shown to be invariant under this action, the group Γ naturally permutes these summands. Since our Cayley graph expanders G_i arise from p -groups Γ_i , it follows that when evaluating the indicator $a(\Phi, G_i)$ modulo p , only those contributions from fractures fixed under Γ_i survive. Now recall that σ_v is a partition of the edges incident to v . The fixed-point fractures σ will satisfy that all σ_v are equal if we identify the edges incident to v with the elements of the generating set. Since, for

⁵ This means a subset $S \subseteq \Gamma$ of the group that generates this group and satisfies $S^{-1} = S$.

fixed p , our Cayley graph expanders have constant degree, we can thus prove the indicator to be non-zero modulo p by considering just a constant number of fractures. This approach was first used in [39], and we will show that it becomes significantly more powerful if applied to our novel Cayley graph expanders.

Now let us illustrate and sketch this approach for the property Φ of being bipartite, that is, for proving Theorem 2. By Theorem 3, there is a family \mathcal{G} of 5-group Cayley graph expanders of degree 6. For graphs $G \in \mathcal{G}$, we can show that the indicator $a(\Phi, G)$ does not vanish, given that Φ is the property of being bipartite. Theorem 2 will then follow by the argument outlined above; the detailed and formal proof is presented in the full version.

In the first step, given a graph $G = \mathcal{C}(\Gamma_i, S_i) \in \mathcal{G}$ we need to establish which fixed-point fractures σ are contained in $\mathcal{L}(\Phi, G)$, that is, for which σ the fractured graph $G\#\sigma$ is bipartite. Since fixed-point fractures $\sigma = (\sigma_v)_{v \in V(G)}$ of G satisfy that all σ_v correspond to one particular partition of S_i , we will ease notation and identify σ with this partition. Using that S_i is a symmetric set of generators of cardinality 6, that is, $S_i = \{g_1, g_2, g_3, g_1^{-1}, g_2^{-1}, g_3^{-1}\}$, we define a graph $\mathcal{H}(\sigma)$ as follows: It has a vertex w^B for each block B of σ , and its set of (multi)edges is given by

$$E(\mathcal{H}(\sigma)) = \left\{ \{w^B, w^{B'}\} : \text{one multiedge for each } g \in \{g_1, g_2, g_3\} \text{ s.t. } g \in B, g^{-1} \in B' \right\}. \quad (5)$$

Note that we see $\mathcal{H}(\sigma)$ as a graph with possible loops and possible multiedges. In particular, the graph $\mathcal{H}(\sigma)$ has precisely 3 edges.

The important property of $\mathcal{H}(\sigma)$, which we prove in the full version, is that $\mathcal{H}(\sigma)$ is bipartite if and only if $G\#\sigma$ is bipartite. Consequently, for Φ being the property of being bipartite, the indicator $a(\Phi, G)$ is given by the following drastically simplified⁶ expression, if considered modulo 5:

$$a(\Phi, G) \equiv \sum_{\sigma: \mathcal{H}(\sigma) \text{ is bipartite}} (-1)^{|\sigma|-1} \cdot (|\sigma| - 1)! \pmod{5}, \quad (6)$$

where the sum is over partitions σ of S_i . We provide the evaluation of the above expression in Table 1 and observe that the result is $-16 \not\equiv 0 \pmod{5}$. Since this argument applies to all members of the family of 5-group Cayley graph expanders, we conclude that the indicator is non-zero infinitely often, which ultimately proves Theorem 2.

The proof of Theorem 1 will follow a comparable technique, but it will require multiple, more involved cases.

Extension to Modular Counting

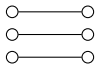

Our understanding of the cancellation behaviour of the indicators $a(\Phi, H)$ modulo p does not only allow us to analyse the complexity of exact counting of k -edge subgraphs satisfying Φ , but also extends to counting k -edge subgraphs modulo p .

To this end, we provide the necessary set-up for parameterized modular counting. In particular, the basis for our intractability results on the modular counting versions is given by the *decision* problem of detecting so-called colour-prescribed homomorphisms, which is known to be hard for graphs of high treewidth due to Marx [31]. Using a version of the Schwartz-Zippel-Lemma due to Williams et al. [46], we are able to reduce an instance I of

⁶ A priori, the formula (4) leads to the version of formula (6) with all summands taken to the power $|V(G)|$. However, since the number of vertices is a power of $p = 5$, by Fermat's little theorem it can be omitted.

84:10 Parameterized (Modular) Counting and Cayley Graph Expanders

■ **Table 1** List of bipartite graphs $\mathcal{H}(\sigma)$ for 3 generators; here we give the isomorphism class of $\mathcal{H}(\sigma)$, the number of partitions σ with the corresponding isomorphism class, the number of blocks of sigma and the total contribution to $a(\Phi, G) \pmod 5$ for the property Φ of being bipartite.

$\mathcal{H}(\sigma)$	No. of σ	$ \sigma $	$(-1)^{ \sigma -1} \cdot (\sigma - 1)!$
	1	6	$-120 \cdot 1$
	12	5	$24 \cdot 12$
	24	4	$-6 \cdot 24$
	8	4	$-6 \cdot 8$
	6	4	$-6 \cdot 6$
	24	3	$2 \cdot 24$
	4	2	$-1 \cdot 4$
Total contribution			$-16 \equiv 4 \pmod 5$

this problem to an instance I' , such that, with high probability, I' has precisely one solution if I has at least one solution, and I' has no solutions if I has no solutions. In a second step, the obtained instance I' can then easily be reduced to the modular counting version for each prime p . Since the first step of this reduction is randomised, we need to assume the randomised Exponential Time Hypothesis for our fine-grained lower bounds.

Afterwards, we prove a variant of the Complexity Monotonicity principle for modular counting in the case of colour-prescribed homomorphisms. As a consequence, our hardness results for modular subgraph counting problems, including Theorem 4, can be proved following the same strategy as outlined in the previous subsection.

Moreover, instead of only presenting intractability results, we investigate whether the expression as a linear combination of homomorphism counts can also be used to achieve improved algorithms for modular subgraph counting problems. And indeed, considering the linear combination (1) modulo 2 for the property Φ of being a path or a cycle, allows us to prove that each graph H with degree at least 5 vanishes in the linear combination, that is, $a_{\Phi, k}(H) = 0$. More precisely, we will prove this for a version of the problem in which two vertices of the k -paths or the k -cycles are already fixed. This must be done to avoid automorphisms of even order, which turns out to be necessary for (1) to be well-defined modulo 2, since some of the coefficients $a_{\Phi, k}(H) = 0$ are of the form $\#\text{Aut}(H)^{-1}$.

The algorithms for counting k -paths and k -cycles modulo 2 turn then out to be very simple: Essentially, we will see that it suffices to guess the two fixed vertices, and thereafter the algorithm evaluates Equation (1) modulo 2, by computing each non-vanishing term using a standard treewidth-based dynamic programming algorithm for counting homomorphisms. Since each graph H whose coefficient survives modulo 2 has degree at most 4, we can rely on known results on the treewidth of bounded degree graphs [19]. Ultimately, this allows us to prove Theorem 5.

Finally, our classification for counting homomorphisms modulo p builds upon the well-established algorithms and reduction sequences used both in the classification for the decision problem [23], as well as in the classification for the exact counting problem [13]. However, the difficulty in proving our classification for counting modulo p is due to graphs H which have high treewidth but admit automorphisms of order p . For those graphs, we can neither rely on an algorithm for exact counting, nor does the known hardness proof transfer.

We solve this problem by considering the p -reduced quotients. Let us denote the function that maps a graph G to the number of homomorphisms from H to G , modulo p , by $\#_p \text{Hom}(H \rightarrow \star)$. We show that for each graph H we have

$$\#_p \text{Hom}(H \rightarrow \star) = \#_p \text{Hom}(H_p^* \rightarrow \star).$$

As a consequence, it suffices to consider the p -reduced quotients for our classification. Since, by definition, those graphs do not admit an automorphism of order p , we are able to show that the known methods for proving classifications for homomorphism problems apply.

Let us conclude by pointing out that, while proving that the p -reduced quotient is uniquely defined up to isomorphism, we also establish a modular variant of Lovász' criterion for graph isomorphism via homomorphism counts (see Chapter 5 in [29]):

► **Lemma 9.** *Let H and H' be graphs, neither of which has an automorphism of order p . Suppose that for all graphs G we have that*

$$\#_p \text{Hom}(H \rightarrow G) = \#_p \text{Hom}(H' \rightarrow G).$$

Then H and H' are isomorphic.

We point out that the previous result can be considered a dual version of [16, Lemma 3.10].

Conclusion and Open Questions

All of our hardness results for modular subgraph counting problems only apply to primes $p \geq 3$ and have, using the randomised Exponential Time Hypothesis as a slightly stronger assumption, the same complexity as their counterparts from exact counting. However, for $p = 2$ the complexity landscape seems different: We obtained an improvement for counting k -cycles and k -paths modulo 2. Moreover, there are known instances of the counting version of the parameterized subgraph isomorphism problem, such as counting k -matchings, where exact counting, as well as counting modulo p for each prime $p \geq 3$ is fixed-parameter **intractable**, while the computation becomes fixed-parameter tractable if done modulo 2 [9, 10].

Since, additionally, many of our hardness proofs do not apply to the case of counting modulo 2, we propose a thorough investigation of the complexity of the parameterized subgraph counting problem modulo 2 as the next step in this line of research. As a starting point, we suggest the problem of counting bipartite k -edge subgraphs modulo 2: While our

proofs extend to counting such subgraphs modulo p for some primes $p \geq 3$, a computer-aided search revealed that, for $p = 2$, our approach *cannot* work for any family of Cayley graph expanders of degree at most 12; details are provided in the full version. Indeed, we conjecture that our methods for proving intractability can be used to show that the problem is intractable for each prime $p > 2$, but not for $p = 2$, which leads to the question of whether this problem might be fixed-parameter tractable.

There are also interesting open questions concerning p -group Cayley graph expanders with low degree. To describe them, fix some prime p and consider the set $D(p) \subseteq \mathbb{Z}_{\geq 0}$ of integers d such that there exists a sequence of finite p -groups Γ_i of orders that tend to infinity, with symmetric generating sets S_i of cardinality $2d$ such that the Cayley graphs $\mathcal{C}(\Gamma_i, S_i)$ form a family of expanders. With any $d \in D(p)$ actually any $d' \geq d$ also lies in $D(p)$, because we can find a uniform bound on the length of a word in S_i to produce a new additional generator for Γ_i , showing $d + 1 \in D(p)$. So the ultimate question is the following:

► **Question 10.** What is the behaviour of the function $p \mapsto d(p) = \min D(p)$?

Since 2-regular graphs are never expanders, we know that $d(p) \geq 2$ for all primes p . Moreover, combining the construction of [36] (for $p = 2$) with our constructions and some further examples that we computed, we obtain the following values and bounds for the function d :

p	$p \in \{2, 3, 5, 7, 11, 13\}$	$17 \leq p \leq 83$	$89 \leq p$
$d(p)$	2	$d(p) \in \{2, 3\}$	$2 \leq d(p) \leq (p + 3)/2$

Based on this experimental evidence we make the following conjecture:

► **Conjecture 11.** For every prime $p \geq 3$ there is a group among the $\Gamma_{p,\alpha,\beta}$ that is 3-generated. In particular, there are p -group Cayley graph expanders of fixed valency $2d$ for all $p \geq 3$ and all $d \geq 3$.

If the conjecture is satisfied, the function d above would be uniformly bounded from above by 3.

Abstract

We study three levels in a hierarchy of nondeterminism: A nondeterministic automaton \mathcal{A} is *determinizable by pruning* (DBP) if we can obtain a deterministic automaton equivalent to \mathcal{A} by removing some of its transitions. Then, \mathcal{A} is *good-for-games* (GFG) if its nondeterministic choices can be resolved in a way that only depends on the past. Finally, \mathcal{A} is *semantically deterministic* (SD) if different nondeterministic choices in \mathcal{A} lead to equivalent states. Some applications of automata in formal methods require deterministic automata, yet in fact can use automata with some level of nondeterminism. For example, DBP automata are useful in the analysis of online algorithms, and GFG automata are useful in synthesis and control. For automata on finite words, the three levels in the hierarchy coincide. We study the hierarchy for Büchi, co-Büchi, and weak automata on infinite words. We show that the hierarchy is strict, study the expressive power of the different levels in it, as well as the complexity of deciding the membership of a language in a given level. Finally, we describe a probability-based analysis of the hierarchy, which relates the level of nondeterminism with the probability that a random run on a word in the language is accepting.

1 Introduction

Nondeterminism is a fundamental notion in theoretical computer science. It allows a computing machine to examine several possible actions simultaneously. For automata on finite words, nondeterminism does not increase the expressive power, yet it leads to an exponential succinctness [25].

A prime application of automata theory is specification, verification, and synthesis of reactive systems [29, 15]. Since we care about the on-going behavior of nonterminating systems, the automata run on infinite words. Acceptance in such automata is determined according to the set of states that are visited infinitely often along the run. In *Büchi* automata [9], the acceptance condition is a subset α of states, and a run is accepting iff it visits α infinitely often. Dually, in *co-Büchi* automata, a run is accepting iff it visits α only finitely often. We also consider *weak* automata, which are a special case of both Büchi and co-Büchi automata in which no cycle contains both states in α and states not in α . We use three-letter acronyms in $\{D, N\} \times \{F, B, C, W\} \times \{W\}$ to describe the different classes of automata. The first letter stands for the branching mode of the automaton (deterministic or nondeterministic); the second for the acceptance condition type (finite, Büchi, co-Büchi or weak); and the third indicates that we consider automata on words.

For automata on infinite words, nondeterminism may increase the expressive power and also leads to an exponential succinctness. For example, NBWs are strictly more expressive than DBWs [19], whereas NCWs are as expressive as DCWs [21]. In some applications of the automata-theoretic approach, such as model checking, algorithms can

be based on nondeterministic automata, whereas in other applications, such as synthesis and control, they cannot. There, the advantages of nondeterminism are lost, and algorithms involve a complicated determinization construction [26] or acrobatics for circumventing determinization [18]. Essentially, the inherent difficulty of using nondeterminism in synthesis and control lies in the fact that each guess of the nondeterministic automaton should accommodate all possible futures.

A study of nondeterministic automata that can resolve their nondeterministic choices in a way that only depends on the past started in [16], where the setting is modeled by means of tree automata for derived languages. It then continued by means of *good for games* (GFG) automata [12].¹ A nondeterministic automaton \mathcal{A} over an alphabet Σ is GFG if there is a strategy g that maps each finite word $u \in \Sigma^*$ to the transition to be taken after u is read; and following g results in accepting all the words in the language of \mathcal{A} . Note that a state q of \mathcal{A} may be reachable via different words, and g may suggest different transitions from q after different words are read. Still, g depends only on the past, namely on the word read so far. Obviously, there exist GFG automata: deterministic ones, or nondeterministic ones that are *determinizable by pruning* (DBP); that is, ones that just add transitions on top of a deterministic automaton. In fact, the GFG automata constructed in [12] are DBP.² Beyond the theoretical interest in DBP automata, they are used for modelling online algorithms: by relating the “unbounded look ahead” of optimal offline algorithms with nondeterminism, and relating the “no look ahead” of online algorithms with determinism, it is possible to reduce questions about the competitive ratio of online algorithms and the memory they require to questions about DBPness [2, 3].

In terms of expressive power, it is shown in [16, 24] that GFG-NXWs, for $X \in \{B, C\}$, are as expressive as DXWs. For automata on finite words, GFG-NFWs are always DBP [16, 22]. For automata on infinite words, GFG-NBW and GFG-NCW need not be DBP [5]. Moreover, the best known determinization construction for GFG-NBW is quadratic, and determinization of GFG-NCW has a tight exponential blow-up [14]. Thus, GFG automata on infinite words are (possibly even exponentially) more succinct than deterministic ones. Further research studies characterization, typeness, complementation, and further constructions and decision procedures for GFG automata [14, 7, 4], as well as an extension of the GFG setting to pushdown ω -automata [20] and to alternating automata [8, 6].

A nondeterministic automaton is *semantically deterministic* (SD, for short) if its non-deterministic choices lead to states with the same language. Thus, for every state q of the automaton and letter $\sigma \in \Sigma$, all the σ -successors of q have the same language. Beyond the fact that semantically determinism is a natural relaxation of determinism, and thus deserves consideration, SD automata naturally arise in the setting of GFG automata. Indeed, though not all GFG automata are DBP, it is not hard to see that they can all be pruned to an SD automaton [14]. Moreover, such a pruning can be done in polynomial time, and so we assume, without loss of generality, that all GFG automata are SD. Thus, SD can be thought also as a natural relaxation of GFG.

Thus, we obtain the following hierarchy, from deterministic to nondeterministic automata, where each level is a special case of the levels to its right.

¹ GFGness is also used in [11] in the framework of cost functions under the name “history-determinism”.

² As explained in [12], the fact that the GFG automata constructed there are DBP does not contradict their usefulness in practice, as their transition relation is simpler than the one of the embodied deterministic automaton and it can be defined symbolically.

For automata on finite words, all levels of the hierarchy coincide in their expressive power. In fact, the three internal levels coincide already in the syntactic sense: every SD-NFW is DBP. Also, given an NFW, deciding whether it is SD, GFG or DBP, can each be done in polynomial time [2].

For Büchi and co-Büchi automata, the picture is less clear, and is the subject of our research. Before we describe our results, let us mention that an orthogonal level of determinism is that of *unambiguous* automata, namely automata that have a single accepting run on each word in their languages. An unambiguous NFW need not be SD, and a DBP-NFW need not be unambiguous. It is known, however, that a GFG unambiguous NFW, NCW, or NBW, is DBP [7].

We study the following aspect and questions about the hierarchy.

Strictness. Recall that not all GFG-NBWs and GFG-NCWs are DBP [5], and examples for this include also SD automata. On the other hand, all GFG-NWWs (in fact, all GFG-NXWs whose language can be recognized by a DWW) are DBP [7]. We show that SD-NXWs need not be GFG for all $X \in \{B, C, W\}$. Of special interest is our result on weak automata, whose properties typically agree with these of automata on finite words. Here, while all SD-NFWs are GFG, this is not the case for SD-NWWs.

Expressive power. It is known that for all $X \in \{B, C, W\}$, GFG-NXWs are as expressive as DXWs. We extend this result to semantic determinism and show that while SD-NXWs need not be GFG, they are not more expressive, thus SD-NXWs are as expressive as DXWs. Since an SD-NXW need not be GFG, this extends the known frontier of nondeterministic Büchi and weak automata that are not more expressive than their deterministic counterpart.

Deciding the determinization level of an automaton. It is already known that deciding the GFGness of a given NXW, for $X \in \{B, C, W\}$, can be done in polynomial time [2, 14, 4]. On the other hand, deciding whether a given NCW is DBP is NP-complete [13]. We complete the picture in three directions. First, we show that NP-completeness of deciding DBPness applies also to NBWs. Second, we show that in both cases, hardness applies even when the given automaton is GFG. Thus, while it took the community some time to get convinced that not all GFG automata are DBP, in fact it is NP-complete to decide whether a given GFG-NBW or GFG-NCW is DBP. Third, we study also the problem of deciding whether a given NXW is SD, and show that it is PSPACE-complete. Note that our results imply that the nondeterminism hierarchy is not monotone with respect to complexity: deciding DBPness, which is closest to determinism, is NP-complete, then GFGness can be checked in polynomial time, and finally SDness is PSPACE-complete. Also, as PSPACE-hardness of checking SDness applies already to NWWs, we get another, even more surprising, difference between weak automata and automata on finite words. Indeed, for NFWs, all the three levels of nondeterminism coincide and SDness can be checked in polynomial time.

A probability-based analysis of the different levels. Consider a nondeterministic automaton \mathcal{A} . We say that \mathcal{A} is *almost-DBP* if we can prune transitions from \mathcal{A} and obtain a deterministic automaton \mathcal{A}' such that the probability of a random word to be in $L(\mathcal{A}) \setminus L(\mathcal{A}')$ is 0. Thus, while \mathcal{A}' need not accept all the words in $L(\mathcal{A})$, it rejects only a negligible fragment of $L(\mathcal{A})$. Clearly, if \mathcal{A} is DBP, then it is almost-DBP. A typical analysis of the performance of an

on-line algorithm compares its performance with that of an off-line algorithm. The notion of almost-DBPness captures cases where the on-line algorithm performs, with probability 1, as good as the offline algorithm. We study the almost-DBPness of GFG and SD automata. We show that while for Büchi (and hence also weak) automata, semantic determinism implies almost-DBPness, thus every SD-NBW is almost-DBP, for co-Büchi automata semantic determinism is not enough, and we need GFGness. Thus, there is an SD-NCW that is not almost-DBP, yet all GFG-NCWs are almost-DBP.

2 Preliminaries

2.1 Automata

For a finite nonempty alphabet Σ , an infinite *word* $w = \sigma_1 \cdot \sigma_2 \cdots \in \Sigma^\omega$ is an infinite sequence of letters from Σ . A *language* $L \subseteq \Sigma^\omega$ is a set of infinite words. For $i, j \geq 0$, we use $w[1, i]$ to denote the (possibly empty) prefix $\sigma_1 \cdot \sigma_2 \cdots \sigma_i$ of w , use $w[i + 1, j]$ to denote the (possibly empty) infix $\sigma_{i+1} \cdot \sigma_{i+2} \cdots \sigma_j$ of w , and use $w[i + 1, \infty]$ to denote its suffix $\sigma_{i+1} \cdot \sigma_{i+2} \cdots$. We sometimes refer also to languages of finite words, namely subsets of Σ^* . We denote the empty word by ϵ .

A *nondeterministic automaton* over infinite words is $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$, where Σ is an alphabet, Q is a finite set of *states*, $q_0 \in Q$ is an *initial state*, $\delta : Q \times \Sigma \rightarrow 2^Q \setminus \emptyset$ is a *transition function*, and α is an *acceptance condition*, to be defined below. For states q and s and a letter $\sigma \in \Sigma$, we say that s is a σ -successor of q if $s \in \delta(q, \sigma)$. Note that \mathcal{A} is *total*, in the sense that it has at least one successor for each state and letter. If $|\delta(q, \sigma)| = 1$ for every state $q \in Q$ and letter $\sigma \in \Sigma$, then \mathcal{A} is *deterministic*.

A *run* of \mathcal{A} on $w = \sigma_1 \cdot \sigma_2 \cdots \in \Sigma^\omega$ is an infinite sequence of states $r = r_0, r_1, r_2, \dots \in Q^\omega$, such that $r_0 = q_0$, and for all $i \geq 0$, we have that $r_{i+1} \in \delta(r_i, \sigma_{i+1})$. We extend δ to sets of states and finite words in the expected way. Thus, $\delta(S, u)$ is the set of states that \mathcal{A} may reach when it reads the word $u \in \Sigma^*$ from some state in $S \subseteq 2^Q$. Formally, $\delta : 2^Q \times \Sigma^* \rightarrow 2^Q$ is such that for every $S \subseteq 2^Q$, finite word $u \in \Sigma^*$, and letter $\sigma \in \Sigma$, we have that $\delta(S, \epsilon) = S$, $\delta(S, \sigma) = \bigcup_{s \in S} \delta(s, \sigma)$, and $\delta(S, u \cdot \sigma) = \delta(\delta(S, u), \sigma)$. The transition function δ induces a transition relation $\Delta \subseteq Q \times \Sigma \times Q$, where for every two states $q, s \in Q$ and letter $\sigma \in \Sigma$, we have that $\langle q, \sigma, s \rangle \in \Delta$ iff $s \in \delta(q, \sigma)$. For a state $q \in Q$ of \mathcal{A} , we define \mathcal{A}^q to be the automaton obtained from \mathcal{A} by setting the initial state to be q . Thus, $\mathcal{A}^q = \langle \Sigma, Q, q, \delta, \alpha \rangle$.

The acceptance condition α determines which runs are “good”. We consider here the *Büchi* and *co-Büchi* acceptance conditions, where $\alpha \subseteq Q$ is a subset of states. We use the terms α -states and $\bar{\alpha}$ -states to refer to states in α and in $Q \setminus \alpha$, respectively. For a run r , let $\text{inf}(r) \subseteq Q$ be the set of states that r traverses infinitely often. Thus, $\text{inf}(r) = \{q \in Q : q = r_i \text{ for infinitely many } i\}$. A run r of a Büchi automaton is *accepting* iff it visits states in α infinitely often, thus $\text{inf}(r) \cap \alpha \neq \emptyset$. Dually, a run r of a co-Büchi automaton is accepting iff it visits states in α only finitely often, thus $\text{inf}(r) \cap \alpha = \emptyset$. A run that is not accepting is *rejecting*. Note that as \mathcal{A} is nondeterministic, it may have several runs on a word w . The word w is accepted by \mathcal{A} if there is an accepting run of \mathcal{A} on w . The language of \mathcal{A} , denoted $L(\mathcal{A})$, is the set of words that \mathcal{A} accepts. Two automata are *equivalent* if their languages are equivalent.

Consider a directed graph $G = \langle V, E \rangle$. A *strongly connected set* in G (SCS, for short) is a set $C \subseteq V$ such that for every two vertices $v, v' \in C$, there is a path from v to v' . A SCS is *maximal* if it is maximal w.r.t containment, that is, for every non-empty set $C' \subseteq V \setminus C$, it holds that $C \cup C'$ is not a SCS. The *maximal strongly connected sets* are also termed *strongly connected components* (SCCs, for short). The *SCC graph* of G is the graph defined over the

SCCs of G , where there is an edge from an SCC C to another SCC C' iff there are two vertices $v \in C$ and $v' \in C'$ with $\langle v, v' \rangle \in E$. A SCC is *ergodic* iff it has no outgoing edges in the SCC graph.

An automaton $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$ induces a directed graph $G_{\mathcal{A}} = \langle Q, E \rangle$, where $\langle q, q' \rangle \in E$ iff there is a letter $\sigma \in \Sigma$ such that $\langle q, \sigma, q' \rangle \in \Delta$. The SCCs and SCCs of \mathcal{A} are those of $G_{\mathcal{A}}$. The α -free SCCs of \mathcal{A} are the SCCs of \mathcal{A} that do not contain states from α .

A Büchi automaton \mathcal{A} is *weak* [23] if for each SCC C in $G_{\mathcal{A}}$, either $C \subseteq \alpha$ (in which case we say that C is an accepting SCC) or $C \cap \alpha = \emptyset$ (in which case we say that C is a rejecting SCC). Note that a weak automaton can be viewed as both a Büchi and a co-Büchi automaton, as a run of \mathcal{A} visits α infinitely often, iff it gets trapped in an accepting SCC, iff it visits states in $Q \setminus \alpha$ only finitely often.

We denote the different classes of automata by three-letter acronyms in $\{D, N\} \times \{F, B, C, W\} \times \{W\}$. The first letter stands for the branching mode of the automaton (deterministic or nondeterministic); the second for the acceptance condition type (finite, Büchi, co-Büchi or weak); and the third indicates that we consider automata on words. For example, NBWs are nondeterministic Büchi word automata.

2.2 Probability

Consider the probability space $(\Sigma^\omega, \mathbb{P})$ where each word $w = \sigma_1 \cdot \sigma_2 \cdot \sigma_3 \cdots \in \Sigma^\omega$ is drawn by taking the σ_i 's to be independent and identically distributed $\text{Unif}(\Sigma)$. Thus, for all positions $i \geq 1$ and letters $\sigma \in \Sigma$, the probability that σ_i is σ is $\frac{1}{|\Sigma|}$. Let $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$ be a deterministic automaton, and let $G_{\mathcal{A}} = \langle Q, E \rangle$ be its induced directed graph. A *random walk on \mathcal{A}* , is a random walk on $G_{\mathcal{A}}$ with the probability matrix $P(q, p) = \frac{|\{\sigma \in \Sigma : \langle q, \sigma, p \rangle \in \Delta\}|}{|\Sigma|}$. It is not hard to see that $\mathbb{P}(L(\mathcal{A}))$ is precisely the probability that a random walk on \mathcal{A} is an accepting run. Note that with probability 1, a random walk on \mathcal{A} reaches an ergodic SCC $C \subseteq Q$, where it visits all states infinitely often. It follows that $\mathbb{P}(L(\mathcal{A}))$ equals the probability that a random walk on \mathcal{A} reaches an ergodic accepting SCC.

2.3 Automata with Some Nondeterminism

Consider a nondeterministic automaton $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$. We say that two states $q, s \in Q$ are *equivalent*, denoted $q \sim_{\mathcal{A}} s$, if $L(\mathcal{A}^q) = L(\mathcal{A}^s)$. Then, \mathcal{A} is *semantically deterministic* (SD, for short) if different nondeterministic choices in \mathcal{A} lead to equivalent states. Thus, for every state $q \in Q$ and letter $\sigma \in \Sigma$, all the σ -successors of q are equivalent: for every two states $s, s' \in \delta(q, \sigma)$, we have that $s \sim_{\mathcal{A}} s'$.

An automaton \mathcal{A} is *good for games* (GFG, for short) if its nondeterminism can be resolved based on the past, thus on the prefix of the input word read so far. Formally, \mathcal{A} is GFG if there exists a *strategy* $f : \Sigma^* \rightarrow Q$ such that the following hold:

1. The strategy f is consistent with the transition function. That is, $f(\epsilon) = q_0$, and for every finite word $u \in \Sigma^*$ and letter $\sigma \in \Sigma$, we have that $\langle f(u), \sigma, f(u \cdot \sigma) \rangle \in \Delta$.
2. Following f causes \mathcal{A} to accept all the words in its language. That is, for every infinite word $w = \sigma_1 \cdot \sigma_2 \cdots \in \Sigma^\omega$, if $w \in L(\mathcal{A})$, then the run $f(w[1, 0]), f(w[1, 1]), f(w[1, 2]), \dots$, which we denote by $f(w)$, is an accepting run of \mathcal{A} on w .

We say that the strategy f *witnesses* \mathcal{A} 's GFGness. For an automaton \mathcal{A} , we say that a state q of \mathcal{A} is GFG if \mathcal{A}^q is GFG. Note that every deterministic automaton is GFG. Also, every GFG automaton can be made SD. Indeed, removal of transitions that are not used by a strategy that witnesses \mathcal{A} 's GFGness does not reduce the language of \mathcal{A} and results in an SD automaton. Moreover, by [14, 4], the detection of such transitions can be done in polynomial time.

We say that a nondeterministic automaton \mathcal{A} is *determinizable by pruning* (DBP) if we can remove some of the transitions of \mathcal{A} and get a deterministic automaton \mathcal{A}' that recognizes $L(\mathcal{A})$. We then say that \mathcal{A}' is a *deterministic pruning* of \mathcal{A} . Note that every DBP nondeterministic automaton is GFG. Indeed, the deterministic pruning of \mathcal{A} induces a witness strategy.

3 The Different Levels and Their Expressive Power

In this section we study syntactic and semantic hierarchies induced by the different levels of nondeterminism. For two classes \mathcal{C}_1 and \mathcal{C}_2 of automata, we use $\mathcal{C}_1 \preceq \mathcal{C}_2$ to indicate that every automaton in \mathcal{C}_1 is also in \mathcal{C}_2 . Accordingly, $\mathcal{C}_1 \prec \mathcal{C}_2$ if $\mathcal{C}_1 \preceq \mathcal{C}_2$ yet there are automata in \mathcal{C}_2 that are not in \mathcal{C}_1 . We first show that the nondeterminism hierarchy is strict, except for all GFG-NWWs being DBP. The latter is not surprising, as all GFG-NFWs are DBP. On the other hand, unlike the case of finite words, we show that not all SD-NWWs are GFG. In fact the result holds already for NWWs that accept co-safety languages, namely all whose states except for an accepting sink are rejecting.

► **Theorem 1** (Syntactic Hierarchy). *For $X \in \{B, C, W\}$, we have that $DXW \prec DBP\text{-}NXW \preceq GFG\text{-}NXW \prec SD\text{-}NXW \prec NXW$. For $X \in \{B, C\}$, the second inequality is strict.*

Proof. By definition, each class is a special case of the one to its right. We prove strictness. It is easy to see that the first and last strict inequalities hold. Indeed, for all $X \in \{B, C, W\}$, consider a nonempty DXW \mathcal{A} , and obtain an NXW \mathcal{B} by adding to \mathcal{A} a σ -transition from the initial state to a new rejecting state, for a letter σ such that \mathcal{A} accepts some word that starts with σ . Then, \mathcal{B} is a DBP-NXW that is not a DXW. Also, as at least one σ -successor of the initial state of \mathcal{A} is not empty, \mathcal{B} is an NXW that is not a SD-NXW.

The relation between DBPness and GFGness has already been studied. It is shown in [5] that GFG-NXW need not be DBP for $X \in \{B, C\}$, and shown in [7] that GFG-NWW are DBP. It is left to relate GFGness and SDness. Consider the NWW \mathcal{W} in Figure 1. It is not hard to check that \mathcal{W} is indeed weak, it is SD, as all its states recognize the language $\{a, b\}^\omega$, yet is not GFG, as every strategy has a word with which it does not reach q_{acc} – a word that forces each visit in q_a and q_b to be followed by a visit in q_0 .

■ **Figure 1** An SD-NWW that is not GFG.

Hence GFG-NWW \prec SD-NWW. As weak automata are a special case of Büchi and co-Büchi, strictness for them follows. ◀

We continue to study expressive power. Now, for two classes \mathcal{C}_1 and \mathcal{C}_2 of automata, we say that \mathcal{C}_1 is less expressive than \mathcal{C}_2 , denoted $\mathcal{C}_1 \leq \mathcal{C}_2$, if every automaton in \mathcal{C}_1 has an equivalent automaton in \mathcal{C}_2 . Since NCW=DCW, we expect the hierarchy to be strict only in the cases of Büchi and weak automata. As we now show, however, semantically deterministic automata are not more expressive than deterministic ones also in the case of Büchi and weak automata.

► **Theorem 2** (Expressiveness Hierarchy). *For $X \in \{B, W\}$, we have that $DXW = DBP\text{-}NXW = GFG\text{-}NXW = SD\text{-}NXW < NXW$.*

Proof. In [16, 14], the authors suggest variants of the subset construction that determinize GFG-NBWs. As we argue below, the construction in [14] is correct also when applied to SD-NBWs. Moreover, it preserves weakness. Thus, $DBW = SD\text{-}NBW$ and $DWW = SD\text{-}NWW$. Also, the last inequality follows from the fact $DBW < NBW$ and $DWW < NWW$ [19].

Given an NBW $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$, the DBW generated in [14]³ is $\mathcal{A}' = \langle \Sigma, Q', q'_0, \delta', \alpha' \rangle$, where $Q' = 2^Q$, $q'_0 = \{q_0\}$, $\alpha' = \{S \in 2^Q : S \subseteq \alpha\}$, and the transition function δ' is defined for every subset $S \in 2^Q$ and letter $\sigma \in \Sigma$ as follows. If $\delta(S, \sigma) \cap \alpha = \emptyset$, then $\delta'(S, \sigma) = \delta(S, \sigma)$. Otherwise, namely if $\delta(S, \sigma) \cap \alpha \neq \emptyset$, then $\delta'(S, \sigma) = \delta(S, \sigma) \cap \alpha$.

The key observation about the correctness of the construction is that when \mathcal{A} is an SD-NBW, then for all reachable states S of \mathcal{A}' , we have that $q \sim_{\mathcal{A}} q'$ for all states $q, q' \in S$. Indeed, if \mathcal{A} is SD, then for every two states $q, q' \in Q$, letter $\sigma \in \Sigma$, and transitions $\langle q, \sigma, s \rangle, \langle q', \sigma, s' \rangle \in \Delta$, if $q \sim_{\mathcal{A}} q'$, then $s \sim_{\mathcal{A}} s'$. Also, by the definition of δ' , every reachable state S of \mathcal{A}' contains only α -states or only $\bar{\alpha}$ -states. As we formally prove in Appendix A, these properties guarantee that indeed $L(\mathcal{A}') = L(\mathcal{A})$ and that weakness of \mathcal{A} is maintained in \mathcal{A}' . ◀

4 Deciding the Nondeterminism Level of an Automaton

In this section we study the complexity of the problem of deciding the nondeterminism level of a given automaton. Note we refer here to the syntactic class (e.g., deciding whether a given NBW is GFG) and not to the semantic one (e.g., deciding whether a given NBW has an equivalent GFG-NBW). Indeed, by Theorem 2, the latter boils down to deciding whether the language of a given NXW can be recognized by a DXW, which is well known: the answer is always “yes” for an NCW, and the problem is PSPACE-complete for NBWs and NWWs [17].⁴

Our results are summarized in Table 1. The entries there describe both the case in which the given automaton is a general NXW, and the case in which the given automaton is an NXW that belongs to a level, that is one level to the right of the questioned one (for example, deciding DBPness of a GFG automaton). In fact, the complexity of the two cases coincide, with one exception: deciding whether a given NWW is DBP, which is PTIME in general, and is $O(1)$ when the given NWW is GFG, in which case the answer is always “yes”.

► **Theorem 3.** *Deciding whether an NXW is semantically deterministic is PSPACE-complete, for $X \in \{B, C, W\}$.*

Proof. Membership in PSPACE is easy, as we check SDness by polynomially many checks of language equivalence. Formally, given an NXW $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$, a PSPACE algorithm goes over all states $q \in Q$, letters σ , and σ -successors s and s' of q , and checks that $s \sim_{\mathcal{A}} s'$. Since language equivalence can be checked in PSPACE [28] and there are polynomially many checks to perform, we are done.

³ The construction in [14] assumes automata with transition-based acceptance, and (regardless of this) is slightly different: when α is visited, \mathcal{A}' continues with a single state from the set of successors. The key point, however, is the same: \mathcal{A} being SD enables \mathcal{A}' to maintain only subsets of states, rather than Safra trees, which makes determinization much easier.

⁴ The proof in [17] is for NBWs, yet the arguments there apply also for weak automata.

■ **Table 1** Deciding the level of an NXW. The results are valid also in the case the given NXW is one level to the right in the nondeterminism hierarchy. Two exceptions are the cases of deciding the DBPness of a GFG NCW and GFG NWW, where the results are specified in ().

	DBP	GFG	SD
NBW	NP-complete Th. 4	PTIME [4]	PSPACE-complete Th. 3
NCW	NP-complete [13] (Th. 8)	PTIME [14]	PSPACE-complete Th. 3
NWW	PTIME ($O(1)$) [14, 4]([7])	PTIME [14, 4]	PSPACE-complete Th. 3

Proving PSPACE-hardness, we do a reduction from polynomial-space Turing machines. Given a Turing machine T with space complexity $s : \mathbb{N} \rightarrow \mathbb{N}$, we construct in time polynomial in $|T|$ and $s(0)$, an NWW \mathcal{A} of size linear in T and $s(0)$, such that \mathcal{A} is SD iff T accepts the empty tape⁵. Clearly, this implies a lower bound also for NBWs and NCWs. Let $n_0 = s(0)$. Thus, each configuration in the computation of T on the empty tape uses at most n_0 cells. We assume, without loss of generality, that once T reaches a final (accepting or rejecting) state, it erases the tape, moves with its reading head to the leftmost cell, and moves to the initial state. Thus, all computations of T are infinite and after visiting a final configuration for the first time, they consists of repeating the same finite computation on the empty tape that uses n_0 tape cells.

We define \mathcal{A} so that it accepts a word w iff (C1) w is not a suffix of an encoding of a legal computation of T that uses at most n_0 cells, or (C2) w includes an encoding of the initial configuration of T on the empty tape and the final configuration after it, is accepting.

It is not hard to see that if T accepts the empty tape, then \mathcal{A} is universal (that is, accepts all words). Indeed, each word w is either not a suffix of an encoding of a legal computation of T that uses at most n_0 cells, in which case w is accepted thanks to C1. Otherwise, the encoding of the computation of T on the empty tape is a subword of w , in which case w eventually includes an encoding of the initial configuration of T on the empty tape, and the final configuration after it is accepting, and thus w is accepted thanks to C2. Also, if T rejects the empty tape, then \mathcal{A} rejects the word that encodes the computation of T on the empty tape. Indeed, C1 is not satisfied, and since every encoding of the initial configuration is followed by an encoding of the rejecting computation of T , the final configuration after it is rejecting, and so C2 is not satisfied too.

In order to define \mathcal{A} so that it is SD iff T accepts the empty tape, we define all its states to be universal iff T accepts the empty tape. Intuitively, we do it by letting \mathcal{A} guess and check the existence of an infix that witnesses satisfaction of C1 or C2, and also let it, at each point of its operation, go back to the initial state, where it can guess again. Note that when T accepts the empty tape, all the suffixes of a word w satisfy C1 or C2. Thus, \mathcal{A} making a bad guess does not prevent it from later branching into an accepting run.

⁵ This is sufficient, as one can define a generic reduction from every language L in PSPACE as follows. Let T_L be a Turing machine that decides L in polynomial space $f(n)$. On input w for the reduction, the reduction considers the machine T_w that on every input, first erases the tape, writes w on its tape, and then runs as T_L on w . Then, the reduction outputs an automaton \mathcal{A} , such that T_w accepts the empty tape iff \mathcal{A} is SD. Note that the space complexity of T_w is $s(n) = \max(n, f(|w|))$, and that w is in L iff T_w accepts the empty tape. Since \mathcal{A} is constructed in time polynomial in $s(0) = f(|w|)$ and $|T_w| = \text{poly}(|w|)$, it follows that the reduction is polynomial in $|w|$.

We now describe the operation of \mathcal{A} in more detail (see Figure 2).

■ **Figure 2** The structure of the NWW constructed in Theorem 3.

In its initial state, \mathcal{A} guesses which of $C1$ and $C2$ is satisfied. In case \mathcal{A} guesses that $C1$ is satisfied, it guesses the place in which w includes a violation of the encoding. As we detail in Appendix B, this amounts to guessing a violation of the transition function of T : in each step, \mathcal{A} may guess that the next three letters encode a position in a configuration and the letter to come n_0 letters later, namely at the same position in the successive configuration, is different from the one that should appear in a legal encoding of two successive configurations. If a violation is detected, \mathcal{A} moves to an accepting sink. Otherwise, \mathcal{A} returns to the initial state and w gets another chance to be accepted. In case \mathcal{A} guesses that $C2$ is satisfied, it guesses the place in which w encodes an initial configuration. If \mathcal{A} guesses a position of an initial configuration, but the guess fails, then \mathcal{A} goes back to the initial state. If the guess succeeds, \mathcal{A} waits for an accepting configuration of T . If an accepting configuration arrives before a rejecting one, then \mathcal{A} moves to an accepting sink. Otherwise, if a rejecting configuration arrives before an accepting one, then \mathcal{A} returns to the initial state. Also, whenever \mathcal{A} waits to witness some behavior, namely, waits to guess a position of an initial state, waits to guess a position of a violation, or waits to see a final configuration, it may nondeterministically, upon reading the next letter, return to the initial state. It is not hard to see that \mathcal{A} can be defined in size linear in T and n_0 . As the only accepting states of \mathcal{A} is the accepting sink, it is clearly weak, and in fact describes a co-safety language.

We prove that T accepts the empty tape iff \mathcal{A} is SD. First, if T rejects the empty tape, then \mathcal{A} is not SD. To see this, consider the word w_ε that encodes the computation of T on the empty tape, and let w'_ε be a word that is obtained from w_ε by making a single violation in the first letter. That is, $w'_\varepsilon[2, \infty] = w_\varepsilon[2, \infty]$, and $w'_\varepsilon[1, 1] \neq w_\varepsilon[1, 1]$. Note that $w'_\varepsilon \in L(\mathcal{A})$ since it has a violation. Note also that any proper suffix of w'_ε encodes a suffix of a computation of T that uses at most n_0 tape cells and does not have of a final accepting configuration, and hence is not in $L(\mathcal{A})$. Consequently, the word w'_ε can be accepted by \mathcal{A} only by guessing a violation that is caused by the first letter. In particular, if we guess to wait for the initial configuration upon reading the first letter, then we cannot branch to an accepting run. This shows that \mathcal{A} is not SD. For the other direction, we show that if T accepts the empty tape, then all the states of \mathcal{A} are universal. First, note that each infinite word w is either not a suffix of a legal encoding of a computation of T that uses at most n_0 tape cells, in which case it is in the language of \mathcal{A} by $C1$, or it is a suffix of a legal encoding of a computation that uses only n_0 tapes cells, and is eventually an encoding of the computation of T on the empty tape, in which case, as T accepts the empty tape, w is in the language of \mathcal{A} according to $C2$. Thus, the initial state of \mathcal{A} is universal. Now by the definition of \mathcal{A} , for every infinite word w and for all states q of \mathcal{A} that are not the accepting sink, there is a path from q to the initial state that is labeled by a prefix of w . Thus, the language of all states is universal, and they are all equivalent. This clearly implies that \mathcal{A} is SD.

Thus, we conclude that T accepts the empty tape iff \mathcal{A} is SD. In Appendix B, we give the full technical details of the construction of \mathcal{A} . ◀

► **Theorem 4.** *The problem of deciding whether a given GFG-NBW is DBP is NP-complete.*

Proof. For membership in NP, observe we can check that a witness deterministic pruning \mathcal{A}' is equivalent to \mathcal{A} by checking whether $L(\mathcal{A}) \subseteq L(\mathcal{A}')$. Since \mathcal{A}' is deterministic, the latter can be checked in polynomial time. For NP-hardness, we describe a parsimonious polynomial time reduction from SAT. That is, given a CNF formula φ , we construct a GFG-NBW \mathcal{A}_φ such that there is a bijection between assignments to the variables of φ and DBWs embodied in \mathcal{A}_φ , and an assignment satisfies φ iff its corresponding embodied DBW is equivalent to \mathcal{A}_φ . In particular, φ is satisfiable iff \mathcal{A}_φ is DBP.

Consider a SAT instance φ over the variable set $X = \{x_1, \dots, x_n\}$ and with $m \geq 1$ clauses $C = \{c_1, \dots, c_m\}$. For $n \geq 1$, let $[n] = \{1, 2, \dots, n\}$. For a variable $x_k \in X$, let $C_k^0 \subseteq C$ be the set of clauses in which x_k appears negatively, and let $C_k^1 \subseteq C$ be the set of clauses in which x_k appears positively. For example, if $c_1 = x_1 \vee \neg x_2 \vee x_3$, then c_1 is in C_1^1 , C_2^0 , and C_3^1 . Assume that all clauses depend on at least two different variables (that is, no clause is a tautology or forces an assignment to a single variable). Let $\Sigma_{n,m} = X \cup C$, and let $R_{n,m} = (X \cdot C)^* \cdot \{x_1 \cdot c_j \cdot x_2 \cdot c_j \cdots x_n \cdot c_j : j \in [m]\} \subseteq \Sigma_{n,m}^*$. We construct a GFG-NBW \mathcal{A}_φ that recognizes $L_{n,m} = (R_{n,m})^\omega$, and is DBP iff φ is satisfiable.

Let $D_{n,m}$ be a DFW that recognizes $R_{n,m}$ with $O(n \cdot m)$ states, a single accepting state p , and an initial state q_0 that is visited only once in all runs. For example, we can define $D_{n,m} = \langle \Sigma_{n,m}, Q_{n,m}, q_0, \delta_{n,m}, \{p\} \rangle$ as follows: from q_0 , the DFW expects to read only words in $(X \cdot C)^*$ – upon a violation of this pattern, it goes to a rejecting sink. Now, if the pattern is respected, then with $X \setminus \{x_1\}$, the DFW goes to two states where it loops with $C \cdot (X \setminus \{x_1\})$ and, upon reading x_1 from all states that expect to see letters in X , it branches with each c_j , for all $j \in [m]$, to a path where it hopes to detect an $x_2 \cdot c_j \cdots x_n \cdot c_j$ suffix. If the detection is completed successfully, it goes to the accepting state p . Otherwise, it returns to the two-state loop.

Now, we define $\mathcal{A}_\varphi = \langle \Sigma_{n,m}, Q_\varphi, p, \delta_\varphi, \{q_0\} \rangle$, where $Q_\varphi = Q_{n,m} \cup \{q_k^i : (i, k) \in \{0, 1\} \times [n]\}$. The idea behind \mathcal{A}_φ is as follows. From state p (that is, the accepting state of $D_{n,m}$, which is now the initial state of \mathcal{A}_φ), the NBW \mathcal{A}_φ expects to read a letter in X . When it reads x_k , for $1 \leq k \leq n$, it nondeterministically branches to the states q_k^0 and q_k^1 . Intuitively, when it branches to q_k^0 , it guesses that the clause that comes next is one that is satisfied when $x_k = 0$, namely a clause in C_k^0 . Likewise, when it branches to q_k^1 , it guesses that the clause that comes next is one that is satisfied when $x_k = 1$, namely a clause in C_k^1 . When the guess is successful, \mathcal{A}_φ moves to the α -state q_0 . When the guess is not successful, it returns to p . Implementing the above intuition, transitions from the states $Q_{n,m} \setminus \{p\}$ are inherited from $D_{n,m}$, and transitions from the states in $\{q_k^i : (i, k) \in \{0, 1\} \times [n]\} \cup \{p\}$ are defined as follows (see also Figure 3).

- For all $k \in [n]$, we have that $\delta_\varphi(p, x_k) = \{q_k^0, q_k^1\}$.
- For all $k \in [n]$, $i \in \{0, 1\}$, and $j \in [m]$, if $c_j \in C_k^i$, then $\delta_\varphi(q_k^i, c_j) = \{q_0\}$. Otherwise, $\delta_\varphi(q_k^i, c_j) = \{p\}$. For example, if $c_1 = x_1 \vee \neg x_2 \vee x_3$, then $\delta_\varphi(q_2^0, c_1) = \{q_0\}$ and $\delta_\varphi(q_2^1, c_1) = \{p\}$.

Note that p is the only nondeterministic state of \mathcal{A}_φ and that for every deterministic pruning of \mathcal{A}_φ , all the words in $(X \cdot C)^\omega$ have an infinite run in the pruned automaton. This run, however, may eventually loop in $\{p\} \cup \{q_k^0, q_k^1 : k \in [n]\}$. Note also, that for readability purposes, the automaton \mathcal{A}_φ is not total. Specifically, the states of \mathcal{A}_φ are partitioned into

■ **Figure 3** The transitions to and from the states q_k^0 and q_k^1 in \mathcal{A}_φ .

states that expect to see letters in X and states that expect to see letters in C . In particular, all infinite paths in \mathcal{A}_φ are labeled by words in $(X \cdot C)^\omega$. Thus, when defining a GFG strategy g for \mathcal{A}_φ , we only need to define g on prefixes in $(X \cdot C)^* \cup (X \cdot C)^* \cdot X$.

In the following propositions, we prove that \mathcal{A}_φ is a GFG NBW recognizing $L_{n,m}$, and that \mathcal{A}_φ is DBP iff φ is satisfiable. ◀

► **Proposition 5.** $L(\mathcal{A}_\varphi) \subseteq L_{n,m}$.

Proof. As already mentioned, all infinite paths of \mathcal{A}_φ , accepting or rejecting, are labeled by words in $(X \cdot C)^\omega$. Further, any accepting run of \mathcal{A}_φ has infinitely many sub-runs that are accepting finite runs of $D_{n,m}$. Since $L_{n,m} = (R_{n,m})^\omega = (X \cdot C)^\omega \cap (\infty R_{n,m})$, it follows that $L(\mathcal{A}_\varphi) \subseteq L_{n,m}$. ◀

► **Proposition 6.** *There exists a strategy $g : \Sigma^* \rightarrow Q_\varphi$ for \mathcal{A}_φ that accepts all words in $L_{n,m}$. Formally, for all $w \in L_{n,m}$, the run $g(w) = g(w[1, 0]), g(w[1, 1]), g(w[1, 2]), \dots$, is an accepting run of \mathcal{A}_φ on w .*

Proof. The definition of $L_{n,m}$ is such that when reading a prefix that ends with a subword of the form $x_1 \cdot c_j$, for some $j \in [m]$, then we can guess that the word continues with $x_2 \cdot c_j \cdot x_3 \cdot c_j \cdots x_n \cdot c_j$; thus that c_j is the clause that is going to repeat. Therefore, when we are at state p after reading a word that ended with $x_1 \cdot c_j$, and we read x_2 , it is a good GFG strategy to move to a state q_2^i such that the assignment $x_2 = i$ satisfies c_j (if such $i \in \{0, 1\}$ exists; otherwise the strategy can choose arbitrary between q_2^0 and q_2^1), and if the run gets back to p , the strategy continues with assignments that hope to satisfy c_j , until the run gets to q_0 or another occurrence of x_1 is detected. Note that while it is not guaranteed that for all $k \in [n]$ there is $i \in \{0, 1\}$ such that the assignment $x_k = i$ satisfies c_j , it is guaranteed that such an i exists for at least two different k 's (we assume that all clauses depend on at least two variables). Thus, even though we a priori miss an opportunity to satisfy c_j with an assignment to x_1 , it is guaranteed that there is another $2 \leq k \leq n$ such that c_j can be satisfied by x_k .

We define g inductively as follows. Recall that \mathcal{A}_φ is nondeterministic only in the state p , and so in all other states, the strategy g follows the only possible transition. First, for all $k \in [n]$, we define $g(x_k) = q_k^0$. Let $v \in (X \cdot C)^* \cdot X$, be such that g has already been defined on v and let $j \in [m]$. Since $v \notin (X \cdot C)^*$, we have that $g(v) \neq p$ and so $g(v \cdot c_j)$ is uniquely defined. We continue and define g on $u = v \cdot c_j \cdot x_k$, for all $k \in [n]$. If $g(v \cdot c_j) \neq p$, then $g(u)$ is uniquely defined. Otherwise, $g(v \cdot c_j) = p$ and we define $g(u)$ as follows,

- If $k = 1$, then we define $g(u) = q_1^0$.
- If $k > 1$ and x_k participates in c_j , then we define $g(u) = q_k^i$, where $i \in \{0, 1\}$ is minimal with $c_j \in C_k^i$. That is, i is the minimal assignment to x_k that satisfies c_j .
- If $k > 1$ and x_k does not participate in c_j , then the value of c_j is not affected by the assignment to x_k , and in that case we define $g(u) = q_k^0$.

The reason for the distinction between the cases $k = 1$ and $k > 1$ is that when we see a finite word that ended with $c_j \cdot x_1$, then there is no special reason to hope that the next letter is going to be c_j . This is in contrast, for example, to the case we have seen a word that ends with $c_{j'} \cdot x_1 \cdot c_j \cdot x_2$, where it is worthwhile to guess we are about to see c_j as the next letter.

By the definition of g , it is consistent with Δ_φ . In Appendix C we formally prove that g is a winning GFG strategy for \mathcal{A}_φ . Namely, that for all $w \in L_{n,m}$, the run $g(w)$ on w , generated by g is accepting. ◀

We now examine the relation between prunings of \mathcal{A}_φ and assignments to φ . Consider an assignment $i_1, \dots, i_n \in \{0, 1\}$, for X . I.e., $x_k = i_k$ for all $k \in [n]$. Then a possible memoryless GFG strategy, is to always move from p to $q_k^{i_k}$ when reading x_k . This in fact, describes a one to one correspondence, between assignments and prunings of \mathcal{A}_φ . Assume that the assignment $i_k \in \{0, 1\}$, for $k \in [n]$, satisfies φ , then the corresponding pruning recognizes $L_{n,m}$. Indeed, instead of trying to satisfy the last read clause c_j , we may ignore this extra information, and rely on the fact that one of the assignments $x_k = i_k$ is going to satisfy c_j . In other words, the satisfiability of φ allows us to ignore the history and still accept all words in $L_{n,m}$, which makes \mathcal{A}_φ DBP. On the other hand, if an assignment does not satisfy some clause c_j , then the corresponding pruning will fail to accept the word $(x_1 \cdot c_j \cdots x_n \cdot c_j)^\omega$, which shows that if φ is not satisfiable then \mathcal{A}_φ is not DBP. In Appendix C we formally prove that there is a one to one correspondence between prunings of \mathcal{A}_φ and assignments to φ , and that an assignment satisfies φ iff the corresponding pruning recognizes $L_{n,m}$, implying Proposition 7.

► **Proposition 7.** *The formula φ is satisfiable iff the GFG-NBW \mathcal{A}_φ is DBP.*

We continue to co-Büchi automata. In [13], the authors prove that deciding the DBPness of a given NCW is NP-complete. For the lower bound, they describe a reduction from the *Hamiltonian-cycle* problem. Essentially, given a connected graph $G = \langle [n], E \rangle$, the reduction outputs an NCW \mathcal{A}_G over the alphabet $[n]$ that is obtained from G by adding self loops to all vertices, labelling the loop at a vertex i by the letter i , and labelling the edges from vertex i to all its neighbours in G by every letter $j \neq i$. Then, the co-Büchi condition requires a run to eventually get stuck at a self-loop⁶. Accordingly, $L(\mathcal{A}_G) = [n]^* \cdot \bigcup_{i \in [n]} i^\omega$.

It is not hard to see that \mathcal{A}_G is GFG. Indeed, a GFG strategy can decide to which neighbour of i to proceed with a letter $j \neq i$ by following a cycle c that traverses all the vertices of the graph G . Since when we read $j \neq i$ at vertex i we move to a neighbour state, then by following the cycle c upon reading i^ω , we eventually reach the vertex i and get stuck at the i -labeled loop. Thus, the NP-hardness result of [13] apply already for GFG-NCWs, and we can conclude with the following.

► **Theorem 8.** *The problem of deciding whether a given GFG-NCW is DBP is NP-complete.*

5 A probability-Based Analysis of the Different Levels

Consider a nondeterministic automaton \mathcal{A} . We say that \mathcal{A} is *almost-DBP* if there is a deterministic pruning \mathcal{A}' of \mathcal{A} such that $\mathbb{P}(L(\mathcal{A}) \setminus L(\mathcal{A}')) = 0$. Thus, while \mathcal{A}' need not accept all the words accepted by \mathcal{A} , it rejects only a negligible set of words in $L(\mathcal{A})$. Clearly, if \mathcal{A} is DBP, then it is almost-DBP. In this section we study the almost-DBPness of GFG

⁶ The exact reduction is more complicated and involves an additional letter $\#$ that forces each deterministic pruning of \mathcal{A}_G to proceed to the same neighbour of i upon reading a letter $j \neq i$ from the vertex i .

and SD automata. We show that while for Büchi (and hence also weak) automata, semantic determinism implies almost-DBPness, thus every SD-NBW is almost-DBP, for co-Büchi automata semantic determinism is not enough, and we need GFGness. Thus, there is an SD-NCW that is not almost-DBP, yet all GFG-NCWs are almost-DBP.

We first show that, unsurprisingly, not all NBWs are almost-DBP.

► **Theorem 9.** *There is an NBW that is not almost-DBP.*

Proof. Consider the NBW \mathcal{A}_1 in Figure 4. It is not hard to see that $L(\mathcal{A}_1) = \{a, b\}^\omega$, and so $\mathbb{P}(L(\mathcal{A}_1)) = 1$. Moreover, every deterministic pruning of \mathcal{A}_1 is such that q_{rej} is reachable from all states, which implies that $\{q_{rej}\}$ is the only ergodic SCC of any pruning. Since $\{q_{rej}\}$ is α -free, it follows that every deterministic pruning of \mathcal{A}_1 recognizes a language of measure zero, and hence \mathcal{A}_1 is not almost-DBP. As an example, consider the deterministic pruning \mathcal{A}'_1 described on the right hand side of Figure 4. The only ergodic SCC of \mathcal{A}'_1 is α -free, and as such $\mathbb{P}(L(\mathcal{A}'_1)) = 0$. ◀

■ **Figure 4** An NBW that is not almost-DBP.

We continue to the positive result about Büchi automata. Consider an NBW $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$. We define a *simple stochastic Büchi game* $\mathcal{G}_{\mathcal{A}}$ as follows.⁷ The game is played between Random and Eve. The positions of Random are Q , these of Eve are $Q \times \Sigma$. The game starts from position q_0 . A round in the game starts at some position $q \in Q$ and proceeds as follows.

1. Random picks a letter $\sigma \in \Sigma$ uniformly, and the game moves to position (q, σ) .
2. Eve picks a transition $(q, \sigma, p) \in \Delta$, and the game moves to position p .

A probabilistic strategy for Eve is $f : (Q \times \Sigma)^+ \rightarrow [0, 1]^Q$, where for all histories $x \in (Q \times \Sigma)^*$ and positions of Eve $(q, \sigma) \in Q \times \Sigma$, the function $d = f(x \cdot (q, \sigma)) : Q \rightarrow [0, 1]$, is a distribution on Q such that $d(p) \neq 0$ implies that $p \in \delta(q, \sigma)$. As usual, we say that a strategy f is *memoryless*, if it depends only on the current position, thus for all histories $x, y \in (Q \times \Sigma)^*$ and positions of Eve $(q, \sigma) \in Q \times \Sigma$, it holds that $f(x \cdot (q, \sigma)) = f(y \cdot (q, \sigma))$. A strategy for Eve is *pure* if for all histories $x \in (Q \times \Sigma)^*$ and positions of Eve $(q, \sigma) \in Q \times \Sigma$, there is a position $p \in \delta(q, \sigma)$ such that $f(x \cdot (q, \sigma))(p) = 1$. When Eve plays according to a strategy f , the outcome of the game can be viewed as a run $r_f = q_f^0, q_f^1, q_f^2, \dots$ in \mathcal{A} , over a random word $w_f \in \Sigma^\omega$. (The word that is generated in a play is independent of the strategy of Eve, but we use the notion w_f to emphasize that we are considering the word that is generated in a play where Eve plays according to f).

Let $Q_{rej} = \{q \in Q : \mathbb{P}(L(\mathcal{A}^q)) = 0\}$. The outcome r_f of the game is *winning* for Eve iff r_f is accepting, or r_f visits Q_{rej} . Note that for all positions $q \in Q_{rej}$ and $p \in Q$, if p is reachable from q , then $p \in Q_{rej}$. Hence, the winning condition can be defined by the Büchi

⁷ In [10] these games are called simple $1\frac{1}{2}$ -player games with Büchi winning objectives and almost-sure winning criterion.

objective $\alpha \cup Q_{rej}$. Note that r_f is winning for Eve iff $\text{inf}(r_f) \subseteq Q_{rej}$ or $\text{inf}(r_f) \cap \alpha \neq \emptyset$. We say that f is an *almost-sure winning* strategy, if r_f is winning for Eve with probability 1, and Eve *almost-sure wins* in $\mathcal{G}_{\mathcal{A}}$ if she has an almost-sure winning strategy.

► **Theorem 10.** *All SD-NBWs are almost-DBP.*

Proof. We first show that Eve has a probabilistic strategy to win $\mathcal{G}_{\mathcal{A}}$ with probability 1, even without assuming that \mathcal{A} is semantically deterministic. Consider the probabilistic strategy g where from (q, σ) , Eve picks one of the σ -successors of q uniformly by random. Note that this strategy is memoryless, and hence the outcome of the game can be thought as a random walk in \mathcal{A} that starts at q_0 and gives positive probabilities to all transitions. Thus, with probability 1, the run r_g is going to reach an ergodic SCC of \mathcal{A} and visit all its states. If the run r_g reaches an α -free ergodic SCC, then $\text{inf}(r_g) \subseteq Q_{rej}$, and hence r_g is then winning for Eve. Otherwise, r_g reaches a non α -free ergodic SCC, and with probability 1, it visits all the states in that SCC. Thus, with probability 1, we have $\text{inf}(r_g) \cap \alpha \neq \emptyset$, and r_g is winning for Eve. Overall, Eve wins $\mathcal{G}_{\mathcal{A}}$ with probability 1 when playing according to g .

Hence, by pure memoryless determinacy of simple stochastic parity games [10], we may consider a pure memoryless winning strategy f for Eve in $\mathcal{G}_{\mathcal{A}}$. We say that r_f is *correct* if $w_f \in L(\mathcal{A})$ implies that r_f is accepting. Note that $w_f \notin L(\mathcal{A})$ always implies that r_f is rejecting. We show that if \mathcal{A} is SD, then r_f is correct with probability 1, where f is a pure memoryless winning strategy for Eve. Since f is pure memoryless, it induces a pruning of \mathcal{A} . Denote this pruning by \mathcal{A}^f . We may think of r_f as a random walk in \mathcal{A}^f . With probability 1, the walk r_f reaches an ergodic SCC C of \mathcal{A}^f , and visits all its states. Since f is a winning strategy, we know that $C \subseteq Q_{rej}$ or $C \cap \alpha \neq \emptyset$ with probability 1. If $C \cap \alpha \neq \emptyset$, then clearly r_f is accepting with probability 1, and hence is correct with probability 1. Otherwise, $C \subseteq Q_{rej}$, but then we claim that $w_f \in L(\mathcal{A})$ with probability 0. For $i \geq 1$, let w_f^i be the i -th letter of w_f , and for $i \geq 0$ let q_f^i be the i -th state in r_f . Then, by semantically determinism, for all $i \geq 0$, it holds that $w_f \in L(\mathcal{A})$ iff $w_f[i+1, \infty] \in L(\mathcal{A}^{q_f^i})$. Moreover, the word $w_f[i+1, \infty]$ is independent of q_f^i , and hence for all $q \in Q$ and $i \geq 0$, the event $w_f[i+1, \infty] \in L(\mathcal{A}^q)$ is independent of q_f^i . Thus, for all $q \in Q$ and $i \geq 0$, it holds that $\mathbb{P}(w_f \in L(\mathcal{A}) | q_f^i = q) = \mathbb{P}(w_f[i+1, \infty] \in L(\mathcal{A}^q)) = \mathbb{P}(L(\mathcal{A}^q))$. Hence, by definition of Q_{rej} , and by the fact that Q_{rej} is finite, we have that $\mathbb{P}(w_f \in L(\mathcal{A}) | r_f^i \in Q_{rej}) = 0$ for all $i \geq 0$, and so $\mathbb{P}(w_f \in L(\mathcal{A}) | r_f \text{ visits } Q_{rej}) = 0$. Overall, we showed that $\mathbb{P}(r_f \text{ is correct}) = 1$.

Notice that $\mathbb{P}(L(\mathcal{A}) \setminus L(\mathcal{A}^f))$, is precisely the probability that a random word w_f is in $L(\mathcal{A})$ but not accepted by \mathcal{A}^f . Namely, the probability that r_f is not correct. Hence, $\mathbb{P}(L(\mathcal{A}) \setminus L(\mathcal{A}^f)) = 0$, and \mathcal{A} is almost-DBP. ◀

We continue to co-Büchi automata and show that unlike the case of Büchi, here semantic determinism does not imply almost-DBPness.

► **Theorem 11.** *There is an SD-NCW that is not almost-DBP.*

Proof. Consider the NCW \mathcal{A}_2 in Figure 5. It is not hard to see that $L(\mathcal{A}_2) = \{a, b\}^\omega$, and hence $\mathbb{P}(L(\mathcal{A}_2)) = 1$. In fact all the states q of \mathcal{A}_2 have $L(\mathcal{A}_2^q) = \{a, b\}^\omega$, and so it is semantically deterministic. Moreover, every deterministic pruning of \mathcal{A}_2 is strongly connected and not α -free. It follows that any deterministic pruning of \mathcal{A}_2 recognizes a language of measure zero, and hence \mathcal{A}_2 is not almost-DBP. As an example, consider the deterministic pruning \mathcal{A}'_2 described on the right hand side of Figure 5. It is easy to see that \mathcal{A}'_2 is strongly connected and not α -free, and as such, $\mathbb{P}(L(\mathcal{A}'_2)) = 0$. ◀

■ **Figure 5** An SD-NCW that is not almost-DBP.

Consider a language $L \subseteq \Sigma^\omega$ of infinite words. We say that a finite word $x \in \Sigma^*$ is a *good prefix* for L if $x \cdot \Sigma^\omega \subseteq L$. Then, L is a *co-safety* language if every word in L has a good prefix [1]. Let $co\text{-safe}(L) = \{x \cdot w \in \Sigma^\omega : x \text{ is a good prefix of } L\}$. Clearly, $co\text{-safe}(L) \subseteq L$. The other direction is not necessarily true. For example, if $L \subseteq \{a, b\}^\omega$ is the set of all words with infinitely many a 's, then $co\text{-safe}(L) = \emptyset$. In fact, $co\text{-safe}(L) = L$ iff L is a co-safety language. As we show now, when L is NCW-recognizable, we can relate L and $co\text{-safe}(L)$ as follows.

► **Lemma 12.** *If L is NCW-recognizable, then $\mathbb{P}(L(\mathcal{A}) \setminus co\text{-safe}(L(\mathcal{A}))) = 0$.*

Proof. Consider an NCW-recognizable language L . Since $NCW=DCW$, there is a DCW \mathcal{D} that recognizes $L(\mathcal{A})$. Assume without loss of generality that \mathcal{D} has a single state q with $L(\mathcal{A}^q) = \Sigma^\omega$, in particular, $C = \{q\}$ is the only ergodic α -free SCC of \mathcal{A} . Then, for every word $w \in \Sigma^\omega$, we have that $w \in co\text{-safe}(L)$ iff the run of \mathcal{D} on w reaches C . Hence, the probability that $w \in L(\mathcal{A}) \setminus co\text{-safe}(L(\mathcal{A}))$ equals the probability that $inf(r)$ is α -free but is not an ergodic SCC of \mathcal{D} . Since the later happens w.p 0, we have that $\mathbb{P}(L(\mathcal{A}) \setminus co\text{-safe}(L(\mathcal{A}))) = 0$. ◀

By Lemma 12, pruning an NCW in a way that would make it recognize $co\text{-safe}(L(\mathcal{A}))$ results in a DCW that approximates \mathcal{A} , and thus witnesses that \mathcal{A} is almost-DBP. We now show that for GFG-NCWs, such a pruning is possible, and conclude that GFG-NCWs are almost-DBP.

► **Theorem 13.** *All GFG-NCWs are almost-DBP.*

Proof. Let $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$ be a GFG-NCW. Consider the NCW $\mathcal{A}' = \langle \Sigma, Q, q_0, \delta, \alpha' \rangle$, where $\alpha' = \alpha \cup \{q \in Q : L(\mathcal{A}^q) \neq \Sigma^\omega\}$. We prove that \mathcal{A}' is a GFG-NCW with $L(\mathcal{A}') = co\text{-safe}(L(\mathcal{A}))$. Consider a word $w \in L(\mathcal{A}')$, and let $r = q_0, q_1, q_2, \dots$ be an accepting run of \mathcal{A}' on w . There exists a prefix $x \in \Sigma^*$ of w such that r reaches some $q \notin \alpha'$ when reading x . Hence $L(\mathcal{A}^q) = \Sigma^\omega$, and so $x \cdot \Sigma^\omega \subseteq L(\mathcal{A})$. That is, x is a good prefix and $w \in co\text{-safe}(L(\mathcal{A}))$. Thus, $L(\mathcal{A}') \subseteq co\text{-safe}(L(\mathcal{A}))$.

In order to see that \mathcal{A}' is GFG and that $co\text{-safe}(L(\mathcal{A})) \subseteq L(\mathcal{A}')$, we consider a GFG strategy f of \mathcal{A} and use it as a strategy for \mathcal{A}' . We need to prove that for all $w \in co\text{-safe}(L(\mathcal{A}))$, the run r that f generates on w eventually visits only states $q \notin \alpha'$. Since $co\text{-safe}(L(\mathcal{A})) \subseteq L(\mathcal{A})$, we know that $inf(r) \cap \alpha = \emptyset$. It is left to show that r eventually visits only states $q \in Q$ with $L(\mathcal{A}^q) = \Sigma^\omega$. Observe that if $x \in \Sigma^*$ is a good prefix of $L(\mathcal{A})$, then for all $y \in \Sigma^*$, we have that $x \cdot y$ is also a good prefix. Moreover, if $x \in \Sigma^*$ is a good prefix, then since f is a GFG strategy, it follows that for all $u \in \Sigma^\omega$ the run $f(x \cdot u)$ is accepting, and hence $u \in L(\mathcal{A}^{f(x)})$. I.e., $L(\mathcal{A}^{f(x)}) = \Sigma^\omega$. Thus, w has only finitely many bad prefixes, and so $f(x) \in \{q \in Q : L(\mathcal{A}^q) \neq \Sigma^\omega\}$ for only finitely many prefixes x of w . That is, $inf(r) \cap \alpha' = \emptyset$, and f is a GFG strategy for \mathcal{A}' .

So, \mathcal{A}' is a GFG-NCW with $L(\mathcal{A}') = \text{co-safe}(L(\mathcal{A}))$. Since $\text{co-safe}(L(\mathcal{A}))$ is co-safe, it is DWW-recognizable [27]. By [7], GFG-NCWs whose language is DWW-realizable are DBP. Let δ' be the restriction δ to a deterministic transition function such that $\mathcal{D}' = \langle \Sigma, Q, q_0, \delta', \alpha' \rangle$ is a DCW with $L(\mathcal{D}') = L(\mathcal{A}') = \text{co-safe}(L(\mathcal{A}))$. Consider now the DCW $\mathcal{D} = \langle \Sigma, Q, q_0, \delta', \alpha \rangle$ that is obtained from \mathcal{D}' by replacing α' with α . It is clear that \mathcal{D} is a pruning of \mathcal{A} . Note that, $\alpha \subseteq \alpha'$, and hence $\text{co-safe}(L(\mathcal{A})) = L(\mathcal{D}') \subseteq L(\mathcal{D})$. That is, \mathcal{D} is a pruning of \mathcal{A} that approximates $L(\mathcal{A})$ up to a negligible set, and \mathcal{A} is almost-DBP. ◀

A Determinization of a SD-NBW

Given an SD-NBW $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$, the DBW generated in [14] is $\mathcal{A}' = \langle \Sigma, Q', q'_0, \delta', \alpha' \rangle$, where $Q' = 2^Q$, $q'_0 = \{q_0\}$, $\alpha' = \{S \in 2^Q : S \subseteq \alpha\}$, and the transition function δ' is defined for every subset $S \in 2^Q$ and letter $\sigma \in \Sigma$ as follows. If $\delta(S, \sigma) \cap \alpha = \emptyset$, then $\delta'(S, \sigma) = \delta(S, \sigma)$. Otherwise, if $\delta(S, \sigma) \cap \alpha \neq \emptyset$, then $\delta'(S, \sigma) = \delta(S, \sigma) \cap \alpha$.

Thus, we proceed as the standard subset construction, except that whenever a constructed set contains a state in α , we leave in the set only states in α . Accordingly, every reachable state $S \in Q'$ contains only α -states of \mathcal{A} or only $\bar{\alpha}$ -states of \mathcal{A} . Note that as \mathcal{A} is SD, then for every two states $q, q' \in Q$, letter $\sigma \in \Sigma$, and transitions $\langle q, \sigma, s \rangle, \langle q', \sigma, s' \rangle \in \Delta$, if $q \sim_{\mathcal{A}} q'$, then $s \sim_{\mathcal{A}} s'$. Consequently, every reachable state S of \mathcal{A}' consists of \mathcal{A} -equivalent states. Without loss of generality, we restrict \mathcal{A}' to its reachable states.

The following two propositions follow immediately from the definitions:

► **Proposition 14.** *Consider states $q \in Q$ and $S \in Q'$, a letter $\sigma \in \Sigma$, and transitions $\langle q, \sigma, q' \rangle$ and $\langle S, \sigma, S' \rangle$ of \mathcal{A} and \mathcal{A}' , respectively. If q is \mathcal{A} -equivalent to the states in S , then q' is \mathcal{A} -equivalent to the states in S' .*

► **Proposition 15.** *Consider a state S of \mathcal{A}' and a letter $\sigma \in \Sigma$. If $\langle S, \sigma, S' \rangle \in \Delta'$ and $S' \notin \alpha'$, then all the σ -successors of a state $s \in S$ are in $S' \setminus \alpha$.*

We can now prove the correctness of the construction:

► **Proposition 16.** *The automata \mathcal{A} and \mathcal{A}' are equivalent.*

Proof. We first prove that $L(\mathcal{A}') \subseteq L(\mathcal{A})$. Let $r_{\mathcal{A}'} = S_0, S_1, S_2, \dots$ be an accepting run of \mathcal{A}' on a word $w = \sigma_1 \cdot \sigma_2 \cdot \dots$. We construct an accepting run of \mathcal{A} on w . Since $r_{\mathcal{A}'}$ is accepting, there are infinitely many positions j_1, j_2, \dots with $S_{j_i} \in \alpha'$. We also define $j_0 = 0$. Consider the DAG $G = \langle V, E \rangle$, where

- $V \subseteq Q \times \mathbb{N}$ is the union $\bigcup_{i \geq 0} (S_{j_i} \times \{i\})$.
- $E \subseteq \bigcup_{i \geq 0} (S_{j_i} \times \{i\}) \times (S_{j_{i+1}} \times \{i+1\})$ is such that for all $i \geq 0$, it holds that $E(\langle s', i \rangle, \langle s, i+1 \rangle)$ iff there is a finite run from s' to s over $w[j_i + 1, j_{i+1}]$. Then, we label this edge by the run from s' to s .

By the definition of \mathcal{A}' , for every $j \geq 0$ and state $s_{j+1} \in S_{j+1}$, there is a state $s_j \in S_j$ such that $\langle s_j, \sigma_j, s_{j+1} \rangle \in \Delta$. Thus, it follows by induction that for every $i \geq 0$ and state $s_{i+1} \in S_{j_{i+1}}$, there is a state $s_i \in S_{j_i}$ such that there is a finite run from s_i to s_{i+1} on $w[j_i + 1, j_{i+1}]$. Thus, the DAG G has infinitely many reachable vertices from the vertex $\langle q_0, 0 \rangle$. Also, as the nondeterminism degree of \mathcal{A} is finite, so is the branching degree of G . Thus, by König's Lemma, G includes an infinite path, and the labels along the edges of this path define a run of \mathcal{A} on w . Since for all $i \geq 1$, the state S_{j_i} is in α' , and so all the states in S_{j_i} are in α , this run is accepting, and we are done.

For the other direction, assume that $w = \sigma_1 \cdot \sigma_2 \cdot \dots \in L(\mathcal{A})$, and let $r = r_0, r_1, \dots$ be an accepting run of \mathcal{A} on w . Let S_0, S_1, S_2, \dots be the run of \mathcal{A}' on w , and assume, by way of contradiction, that there is a position $j \geq 0$ such that S_j, S_{j+1}, \dots is an α -free run on the suffix $w[j + 1, \infty]$. Then, an iterative application of Proposition 15 implies that all the runs of a state $s_j \in S_j$ on $w[j + 1, \infty]$ are α -free in \mathcal{A} . Also, an iterative application of Proposition 14 implies that $r_j \sim_{\mathcal{A}} s_j$, and since r is an accepting run of \mathcal{A} , it holds that \mathcal{A}^{s_j} has an accepting run on $w[j + 1, \infty]$, and we have reached a contradiction. ◀

It is left to prove that weakness of \mathcal{A} is preserved in \mathcal{A}' .

► **Proposition 17.** *If \mathcal{A} is an NWW, then \mathcal{A}' is a DWW.*

Proof. Assume by way of contradiction that there are reachable states $S \in \alpha'$ and $S' \notin \alpha'$, and an infinite run $r_{\mathcal{A}'} = S_0, S_1, S_2, \dots$ that visits both S and S' infinitely often. Recall that a reachable state in Q' contains only α -states of \mathcal{A} or only $\bar{\alpha}$ -states of \mathcal{A} . Hence, S' contains only $\bar{\alpha}$ -states of \mathcal{A} .

As in the proof of Proposition 16, the run $r_{\mathcal{A}'}$ induces an infinite run $r_{\mathcal{A}} = s_0, s_1, s_2, \dots$, where for all positions $j \geq 0$, it holds that $s_j \in S_j$. Since the run $r_{\mathcal{A}'}$ visits S infinitely often, then $r_{\mathcal{A}}$ visits infinitely many α -states. Likewise, since $r_{\mathcal{A}'}$ visits S' infinitely often, then $r_{\mathcal{A}}$ also visits infinitely many $\bar{\alpha}$ -states. This contradicts the weakness of \mathcal{A} , and we are done. ◀

B Details of the Reduction in Theorem 3

We describe the technical details of the construction of \mathcal{A} . Let $T = \langle \Gamma, Q, \rightarrow, q_0, q_{acc}, q_{rej} \rangle$, where Γ is the working alphabet, Q is the set of states, $\rightarrow \subseteq Q \times \Gamma \times Q \times \Gamma \times \{L, R\}$ is the transition relation (we use $(q, a) \rightarrow (q', b, \Delta)$ to indicate that when T is in state q and it reads the input a in the current tape cell, it moves to state q' , writes b in the current tape cell, and its reading head moves one cell to the left/right, according to Δ), q_0 is the initial

state, q_{acc} is the accepting states, and q_{rej} is the rejecting one. The transitions function \rightarrow is defined also for the final states q_{acc} and q_{rej} : when a computation of T reaches them, it erases the tape, goes to the leftmost cell in the tape, and moves to the initial state q_0 . Recall that $s : \mathbb{N} \rightarrow \mathbb{N}$ is the polynomial space function of T . Thus, when T runs on the empty tape, it uses at most $n_0 = s(0)$ cells.

We encode a configuration of T on a word of length at most n_0 by a word of the form $\#\gamma_1\gamma_2 \dots (q, \gamma_i) \dots \gamma_{n_0}$. That is, a configuration starts with $\#$, and all its other letters are in Γ , except for one letter in $Q \times \Gamma$. The meaning of such a configuration is that the j 'th cell in T , for $1 \leq j \leq n_0$, is labeled γ_j , the reading head points at cell i , and T is in state q . For example, the initial configuration of T is $\#(q_0, b)b \dots b$ (with $n_0 - 1$ occurrences of b 's) where b stands for an empty cell. We can now encode a computation of T by a sequence of configurations.

Let $\Sigma = \{\#\} \cup \Gamma \cup (Q \times \Gamma)$ and let $\#\sigma_1 \dots \sigma_{n_0} \#\sigma'_1 \dots \sigma'_{n_0}$ be two successive configurations of T . We also set σ_0, σ'_0 , and σ_{n_0+1} to $\#$. For each triple $\langle \sigma_{i-1}, \sigma_i, \sigma_{i+1} \rangle$ with $1 \leq i \leq n_0$, we know, by the transition relation of T , what σ'_i should be. In addition, the letter $\#$ should repeat exactly every $n_0 + 1$ letters. Let $next(\langle \sigma_{i-1}, \sigma_i, \sigma_{i+1} \rangle)$ denote our expectation for σ'_i . That is,

- $next(\langle \gamma_{i-1}, \gamma_i, \gamma_{i+1} \rangle) = next(\langle \#, \gamma_i, \gamma_{i+1} \rangle) = next(\langle \gamma_{i-1}, \gamma_i, \# \rangle) = \gamma_i$.
- $next(\langle (q, \gamma_{i-1}), \gamma_i, \gamma_{i+1} \rangle) = next(\langle (q, \gamma_{i-1}), \gamma_i, \# \rangle) = \begin{cases} \gamma_i & \text{If } (q, \gamma_{i-1}) \rightarrow (q', \gamma'_{i-1}, L) \\ (q', \gamma_i) & \text{If } (q, \gamma_{i-1}) \rightarrow (q', \gamma'_{i-1}, R) \end{cases}$
- $next(\langle \gamma_{i-1}, (q, \gamma_i), \gamma_{i+1} \rangle) = next(\langle \#, (q, \gamma_i), \gamma_{i+1} \rangle) = next(\langle \gamma_{i-1}, (q, \gamma_i), \# \rangle) = \gamma'_i$ where $(q, \gamma_i) \rightarrow (q', \gamma'_i, \Delta)$ ⁸.
- $next(\langle \gamma_{i-1}, \gamma_i, (q, \gamma_{i+1}) \rangle) = next(\langle \#, \gamma_i, (q, \gamma_{i+1}) \rangle) = \begin{cases} \gamma_i & \text{If } (q, \gamma_{i+1}) \rightarrow (q', \gamma'_{i+1}, R) \\ (q', \gamma_i) & \text{If } (q, \gamma_{i+1}) \rightarrow (q', \gamma'_i, L) \end{cases}$
- $next(\langle \sigma_{n_0}, \#, \sigma'_1 \rangle) = \#$.

Consistency with $next$ now gives us a necessary condition for a word to encode a legal computation that uses n_0 tape cells.

In order to accept words that satisfy C1, namely detect a violation of $next$, the NWW \mathcal{A} use its nondeterminism and guesses a triple $\langle \sigma_{i-1}, \sigma_i, \sigma_{i+1} \rangle \in \Sigma^3$ and guesses a position in the word, where it checks whether the three letters to be read starting this position are σ_{i-1}, σ_i , and σ_{i+1} , and checks whether $next(\langle \sigma_{i-1}, \sigma_i, \sigma_{i+1} \rangle)$ is not the letter to come $n_0 + 1$ letters later. Once \mathcal{A} sees such a violation, it goes to an accepting sink. If $next$ is respected, or if the guessed triple and position is not successful, then \mathcal{A} returns to its initial state. Also, at any point that \mathcal{A} still waits to guess a position of a triple, it can guess to return back to the initial state.

In order to accept words that satisfy C2, namely detect an encoding of the initial configuration of T on the empty tape and a final configuration after it that is accepting, the NWW \mathcal{A} guesses a position where it compares the next $n_0 + 1$ letters with $\#(q_0, b)b \dots b$. If the initial configuration is indeed detected, it waits for letters in $\{q_{acc}, q_{rej}\} \times \Gamma$. If a letter with q_{acc} arrives before a letter with q_{rej} , then \mathcal{A} goes to the accepting sink. Otherwise if a letter with q_{rej} arrives before a letter with q_{acc} , then \mathcal{A} returns back to the initial state. Also, at any point that \mathcal{A} still waits to detect the initial configuration, or when it waits to

⁸ We assume that the reading head of T does not “fall” from the right or the left boundaries of the tape. Thus, the case where $(i = 1)$ and $(q, \gamma_i) \rightarrow (q', \gamma'_i, L)$ and the dual case where $(i = n_0)$ and $(q, \gamma_i) \rightarrow (q', \gamma'_i, R)$ are not possible.

see a letter in $\{q_{acc}, q_{rej}\} \times \Gamma$, it can guess to return back to the initial state. Note that we could have added the option to keep on waiting for q_{acc} even if q_{rej} arrives first. Indeed, if w includes the initial configuration and both q_{rej} and q_{acc} afterwards, then there must be a violation of *next*.

C Correctness and full details of the reduction in Theorem 4

We first prove that the GFG strategy g defined in Proposition 6 satisfies two essential properties. Then, in Lemma 20, we show that these properties imply that g is a winning GFG strategy for \mathcal{A}_φ .

► **Lemma 18.** *For all $u \in (X \cdot C)^*$ and $v \in R_{n,m}$, if $g(u) = p$, then there is a prefix $y \in (X \cdot C)^*$ of v such that $g(u \cdot y) = q_0$.*

Proof. Let $j \in [m]$ and $2 \leq k \leq n$, be such that v ends with the word $x_k \cdot c_j \cdot x_{k+1} \cdot c_j \cdots x_n \cdot c_j$, and k is the minimal index that is greater than 1, for which x_k participates in c_j . Since we assume that each of the clauses of φ depend on at least two variables, such $k > 1$ exists. Let $i \in \{0, 1\}$ be minimal with $c_j \in C_k^i$, and let $z \in (X \cdot C)^*$ be a prefix of v such that $v = z \cdot x_k \cdot c_j \cdots x_n \cdot c_j$. If there is a prefix $y \in (X \cdot C)^*$ of z , such that $g(u \cdot y) = q_0$ then we are done. Otherwise, $g(u \cdot z) = p$. By definition of g and the choice of k , we know that $g(u \cdot z \cdot x_k) = q_k^i$, where the assignment $x_k = i$ satisfies c_j . Thus, if we take $y = z \cdot x_k \cdot c_j$, then $g(u \cdot y) = q_0$, and y is a prefix of v . ◀

► **Lemma 19.** *For all $u \in (X \cdot C)^*$ and $v \in R_{n,m}$, if $g(u) = q_0$, then there is a prefix $z \in (X \cdot C)^*$ of v such that $g(u \cdot z) = p$.*

Proof. This follows immediately from the fact that $D_{n,m}$ is a DFW that recognizes $R_{n,m}$ and p is the only accepting state of $D_{n,m}$. Thus, we may take z to be the minimal prefix of v that is in $R_{n,m}$. ◀

Recall that a GFG strategy $g : \Sigma^* \rightarrow Q$ has to agree with the the transitions of \mathcal{A}_φ . That is, for all $w \in (X \cdot C)^*$, $x_k \in X$, and $c_j \in C$, it holds that $(g(w), x_k, g(w \cdot x_k))$ and $(g(w \cdot x_k), c_j, g(w \cdot x_k \cdot c_j))$ are in Δ_φ . In addition, if g satisfies the conditions in Lemmas 18 and 19, we say that g supports a (p, q_0) -circle.

► **Lemma 20.** *If $g : \Sigma^* \rightarrow Q$ is consistent with Δ_φ and supports a (p, q_0) -circle, then for all words $w \in L_{n,m}$, the run $g(w)$ is accepting.*

Proof. Consider a word $w \in L_{n,m} = (R_{n,m})^\omega$. Observe that if $w' \in (X \cdot C)^\omega$ is a suffix of w , then $w' \in L_{n,m}$, and hence has a prefix in $R_{n,m}$. Thus, if g supports a (p, q_0) -circle, there exist $y_1, z_1 \in (X \cdot C)^*$, such that $y_1 \cdot z_1$ is a prefix of w , $g(y_1) = q_0$, and $g(y_1 \cdot z_1) = p$. Let $w' \in (X \cdot C)^\omega$ be the suffix of w with $w = y_1 \cdot z_1 \cdot w'$. By the above, $w' \in L_{n,m}$, and we can now apply again the assumption on g to obtain $y_2, z_2 \in (X \cdot C)^*$ such that $y_2 \cdot z_2$ is a prefix of w' , $g(y_1 \cdot z_1 \cdot y_2) = q_0$, and $g(y_1 \cdot z_1 \cdot y_2 \cdot z_2) = p$. By iteratively applying this argument, we construct $\{y_i, z_i : i \geq 1\} \subseteq (X \cdot C)^*$, such that $w^i = y_1 \cdot z_1 \cdot y_2 \cdot z_2 \cdots y_{i-1} \cdot z_{i-1} \cdot y_i$ is a prefix of w , and $g(w^i) = q_0$, for all $i \geq 1$. We conclude that $q_0 \in \inf(g(w))$, and hence $g(w)$ is accepting. ◀

It is easy to see that there is a correspondence between assignments to the variables in X and deterministic prunnings of \mathcal{A}_φ . Indeed, a pruning of p amounts to choosing, for each $k \in [n]$, a value $i_k \in \{0, 1\}$: the assignment $x_k = i_k$ corresponds to keeping the transition $\langle p, x_k, q_k^{i_k} \rangle$ and removing the transition $\langle p, x_k, q_k^{-i_k} \rangle$. For an assignment $a : X \rightarrow \{0, 1\}$, we

denote by \mathcal{A}_φ^a the deterministic pruning of \mathcal{A}_φ that is associated with a . We prove that a satisfies φ iff \mathcal{A}_φ^a is equivalent to \mathcal{A}_φ . Thus, the number of deterministic prunnings of \mathcal{A}_φ that result in a DBW equivalent to \mathcal{A}_φ , equals to the number of assignments that satisfy φ . In particular, φ is satisfiable iff \mathcal{A}_φ is DBP. This concludes the proof of the lower bound in Theorem 4.

► **Proposition 21.** *For every assignment $a : X \rightarrow \{0, 1\}$, we have that $L(\mathcal{A}_\varphi^a) = L(\mathcal{A}_\varphi)$ iff φ is satisfied by a .*

Proof. Assume first that φ is not satisfied by a . We prove that $L_{n,m} \neq L(\mathcal{A}_\varphi^a)$. Let $j \in [m]$ be such that c_j is not satisfied by a . I.e, for all $k \in [n]$ the assignment $x_k = i_k$ does not satisfy c_j . Since q_k^i is reachable in \mathcal{A}_φ^a iff $i = i_k$, and all c_j -labeled transitions from $\{q_k^i : k \in [n]\}$ are to p , it follows that the run of \mathcal{A}_φ^a on $\{x_1 \cdot c_j \cdot x_2 \cdot c_j \cdots x_n \cdot c_j\}^\omega$ never visits q_0 , and hence is rejecting. Thus, $(x_1 \cdot c_j \cdot x_2 \cdot c_j \cdots x_n \cdot c_j)^\omega \in L_{n,m} \setminus L(\mathcal{A}_\varphi^a)$.

For the other direction, we assume that a satisfies φ and prove that $L(\mathcal{A}_\varphi^a) = L_{n,m}$. Let $g^a : \Sigma^* \rightarrow Q$ be the memoryless strategy that correspond to the pruning \mathcal{A}_φ^a . By Lemma 20, it is sufficient proving that g^a supports a (p, q_0) -circle. Note that every strategy for $L_{n,m}$ satisfies Lemma 19. Indeed, the proof only uses the fact that $D_{n,m}$ is a DFW that recognizes $R_{n,m}$ with a single accepting state p . Thus, we only need to prove that g^a satisfies Lemma 18. That is, for all $u \in (X \cdot C)^*$ and $v \in R_{n,m}$, if $g^a(u) = p$, then there is a prefix $y \in (X \cdot C)^*$ of v , such that $g^a(u \cdot y) = q_0$. Consider such words u and v , and let $j \in [m]$ be such that c_j is the last letter of v . Let $k \in [n]$ be the minimal index for which $c_j \in C_k^{i_k}$, and let $z \in (X \cdot C)^*$ be a prefix of v such that $v = z \cdot x_k \cdot c_j \cdot x_{k+1} \cdot c_j \cdots x_n \cdot c_j$. If there exists a prefix $y \in (X \cdot C)^*$ of z such that $g^a(u \cdot y) = q_0$, then we are done. Otherwise, the finite run of \mathcal{A}_φ^a on z from p , returns back to p , and hence $g^a(u \cdot z) = p$. Now $g^a(u \cdot z \cdot x_k) = q_k^{i_k}$, and since $x_k = i_k$ satisfies c_j we have $g^a(u \cdot z \cdot x_k \cdot c_j) = q_0$. Thus, we may take $y = z \cdot x_k \cdot c_j$ which is a prefix of v , and we are done. ◀

Boolean Automata and Atoms of Regular Languages

Hellis Tamm ✉

Department of Software Science, Tallinn University of Technology, Estonia

Abstract

We examine the role that atoms of regular languages play in boolean automata. We observe that the size of a minimal boolean automaton of a regular language is directly related to the number of atoms of the language. We present a method to construct minimal boolean automata, using the atoms of a given regular language. The “illegal” cover problem of the Kameda-Weiner method for NFA minimization implies that using the union operation only to construct an automaton from a cover – as is the case with NFAs –, is not sufficient. We show that by using the union and the intersection operations (without the complementation operation), it is possible to construct boolean automata accepting a given language, for a given maximal cover.

1 Introduction

Nondeterministic finite automata (NFAs) were introduced by Rabin and Scott [19] in 1959, and since then this model of computation has been extended in many ways. Notably, in 1976, Kozen [14] introduced a model of parallel computation based on a generalization of nondeterminism which was later developed into the notion of alternating finite automaton (AFA) by Chandra, Kozen, and Stockmeyer [7]. Independently from this work, Brzozowski and Leiss [5] introduced an equivalent concept of a boolean finite automaton (BFA), using a different notation. Often, the notions of AFA and BFA are used interchangeably. We use the terminology and notation of [5].

The transition function of a BFA uses boolean combinations of its states, generalizing the notion of NFAs which can be interpreted as using unions of states as transition targets. However, the expressive powers of BFAs and NFAs are the same, that is, BFAs only accept regular languages [5, 7]. Importantly, BFAs can succinctly represent regular languages: for any $n \geq 1$ there exists a BFA with n states such that the minimal deterministic finite automaton (DFA) of the same language has $2^{(2^n)}$ states [7, 16]. Also, it is known that any regular language is accepted by an n -state boolean automaton if and only if its reverse language is accepted by a DFA with at most 2^n states [15, 16]. However, there are languages such that their boolean, nondeterministic, and deterministic complexities coincide [17].

Atoms [6] of a regular language L can be considered as its building blocks, since any quotient of L , including L itself, is a disjoint union of atoms. Recently, several old results of automata theory have been revisited using atoms of regular languages: Brzozowski’s double-reversal method for minimizing a DFA [4] was generalized in [6], the Kameda-Weiner

method of finding a minimal NFA [13] was reinterpreted in terms of atoms and generalized in [21], and lower bound methods for the size of an NFA [3, 10, 11] were presented in terms of quotients and atoms of regular languages in [22].

We examine the role that atoms play in boolean automata. We show that the size of a minimal BFA of a regular language is directly related to the number of atoms of that language. More exactly, we observe that if a language L has m atoms, then a minimal BFA of L has $\lceil \log_2 m \rceil$ states. Furthermore, we show how to construct a minimal BFA using the atoms of a given language. We note that constructions of a minimal BFA presented in the literature [16, 15, 9] have been using a DFA of the reverse language. We think that using atoms to build BFAs is more natural and goes well with the narrative of considering atoms as building blocks of a language. Our method of constructing a minimal BFA using the atoms of a language ensures that the resulting BFA is atomic; that is, the languages associated with the states of a BFA are unions of atoms. Consequently, every regular language has an atomic minimal BFA; however, we also show that a minimal BFA is not necessarily atomic. For comparison, not every language has an atomic minimal NFA [6]. Symmetric difference NFAs – a subclass of boolean automata that use only the symmetric difference operation in the transition function – are known to be able to succinctly represent some regular languages [24]. Interestingly, every minimal symmetric difference NFA is atomic [23].

We revisit the Kameda-Weiner method of NFA minimization [13] which constructs NFAs from grid covers of a special matrix. However, not every cover yields an NFA that would accept a given language. The problem of “illegal” covers of the Kameda-Weiner matrix has been of interest for decades [13, 11, 21, 22]. We show that one can construct a BFA for a given language, using any cover of the Kameda-Weiner matrix. One can see this result as a solution to the problem of interpreting grid covers of the Kameda-Weiner matrix in terms of finite automata accepting a given language. The “illegal” cover problem implies that using the union operation only to construct such an automaton – as is the case with NFAs –, is not sufficient. We show that by using the union and the intersection operations (without the complementation operation), it is possible to construct boolean automata accepting a given language, for a given maximal cover. We note that by a result in [9], for any BFA of n states, there is an equivalent BFA with $2n$ states that uses the union and the intersection operations only. However, in certain cases, our method can produce such a BFA with less states.

We mention that learning regular languages via AFAs has been studied in [1, 2].

We also note that recently, symbolic versions of AFAs and BFAs have been introduced [8, 20], and it has been claimed that in the symbolic setting, these two automata models become importantly different [20].

2 Automata, Languages, and Equations

A *boolean finite automaton (BFA)* is a quintuple $\mathcal{B} = (Q, \Sigma, \delta, f_0, F)$ where $Q = \{q_0, \dots, q_{n-1}\}$ is a finite, non-empty set of *states*, Σ is a finite non-empty *alphabet*, $\delta : Q \times \Sigma \rightarrow B_Q$ is the *transition function*, where B_Q is the free boolean algebra generated by Q , $f_0 \in B_Q$ is the *initial function* in B_Q , and $F \subseteq Q$ is the set of *final states*. We denote the empty word by ε . The transition function is extended to the function $\delta : B_Q \times \Sigma^* \rightarrow B_Q$ as follows. For every $q_i \in Q$, $a \in \Sigma$, $w \in \Sigma^*$, and $f \in B_Q$, $\delta(q_i, \varepsilon) = q_i$, and $\delta(q_i, aw) = f_{i,a}(\delta(q_0, w), \dots, \delta(q_{n-1}, w))$, where $f_{i,a}(q_0, \dots, q_{n-1}) = \delta(q_i, a)$, and $\delta(f, w) = f(\delta(q_0, w), \dots, \delta(q_{n-1}, w))$. Let $\varphi : Q \rightarrow \{0, 1\}$ be defined by setting $\varphi(q_i) = 1$ if $q_i \in F$, and $\varphi(q_i) = 0$ otherwise, for $q_i \in Q$. The *language accepted* by a BFA \mathcal{B} is $L(\mathcal{B}) = \{w \in \Sigma^* \mid \delta(f_0, w)(\varphi(q_0), \dots, \varphi(q_{n-1})) = 1\}$. Two boolean automata are *equivalent* if they accept the same language. The *right language* of a state q of \mathcal{B} is $L(\mathcal{B}_q)$, where $\mathcal{B}_q = (Q, \Sigma, \delta, q, F)$.

If the functions f_0 and $\delta(q, a)$ are unions of states for every $q \in Q$ and $a \in \Sigma$, then \mathcal{B} is a *nondeterministic finite automaton (NFA)*. Traditionally, for NFAs these functions have been presented as sets of states. We prefer to use the traditional notation of an NFA $\mathcal{N} = (Q, \Sigma, \delta, I, F)$, where Q , Σ , and F are as in BFA, $I \subseteq Q$ is the set of *initial states*, and $\delta : Q \times \Sigma \rightarrow 2^Q$ is the *transition function*. The *reverse* of an NFA $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ is the NFA $\mathcal{N}^R = (Q, \Sigma, \delta^R, F, I)$, where $q \in \delta^R(p, a)$ if and only if $p \in \delta(q, a)$ for $p, q \in Q$ and $a \in \Sigma$.

If $f_0 \in Q$ and $\delta(q, a) \in Q$ for every $q \in Q$ and $a \in \Sigma$, then \mathcal{B} is a *deterministic finite automaton (DFA)*. The *boolean (nondeterministic, deterministic, respectively) complexity* of a regular language L , denoted by $bc(L)$ ($nc(L)$, $dc(L)$, respectively) is the minimal number of states of a boolean (nondeterministic, deterministic, respectively) automaton of L .

A *boolean system of equations (BSE)* B with variables L_0, \dots, L_{n-1} is a set of language equations

$$L_i = \bigcup_{a \in \Sigma} aF_{i,a}(L_0, \dots, L_{n-1}) \cup L_i^\varepsilon, \quad i = 0, \dots, n-1, \quad (1)$$

where $F_{i,a}$ is a boolean function of the variables L_0, \dots, L_{n-1} , $L_i^\varepsilon = \{\varepsilon\}$ if $\varepsilon \in L_i$, and $L_i^\varepsilon = \emptyset$ otherwise, together with the initial function $F_0(L_0, \dots, L_{n-1})$. The language defined by a BSE B is $L(B) = F_0(L_0, \dots, L_{n-1})$.

Any BSE defines a BFA and *vice versa*. There is a one-one correspondence between the state set $Q = \{q_0, \dots, q_{n-1}\}$ of a BFA \mathcal{B} and the set of language variables $\{L_0, \dots, L_{n-1}\}$ of the corresponding BSE B ; there is a transition from $q_i \in Q$ with $a \in \Sigma$ to a boolean function $f_{i,a}$ in BQ if and only if $F_{i,a}$ is the corresponding function of variables $\{L_0, \dots, L_{n-1}\}$ where the *disjunction* (\vee), *conjunction* (\wedge), and *negation* (\neg) operations are replaced by the set operations *union* (\cup), *intersection* (\cap), and *complement* ($\bar{}$), respectively, and the constants 0 and 1 are replaced by \emptyset and Σ^* , respectively, and a similar correspondence is between the initial functions f_0 and F_0 . Also, any state q_i of \mathcal{B} is final if and only if $L_i^\varepsilon = \{\varepsilon\}$. In the rest of the paper, we treat boolean automata and their corresponding systems of equations interchangeably.

The *left quotient*, or simply *quotient*, of a language L by a word $w \in \Sigma^*$ is the language $w^{-1}L = \{x \in \Sigma^* \mid wx \in L\}$. It is well known that the left quotients of L are the right languages of the states of the minimal DFA of L .

An *atom* of a regular language L with quotients K_0, \dots, K_{n-1} is any non-empty language of the form $\widetilde{K}_0 \cap \dots \cap \widetilde{K}_{n-1}$, where \widetilde{K}_i is either K_i or \overline{K}_i , and \overline{K}_i is the complement of K_i with respect to Σ^* [6]. An atom is *initial* if it has L (rather than \overline{L}) as a term; it is *final* if it contains ε . There is exactly one final atom, the atom $\widehat{K}_0 \cap \dots \cap \widehat{K}_{n-1}$, where $\widehat{K}_i = K_i$ if $\varepsilon \in K_i$, and $\widehat{K}_i = \overline{K}_i$ otherwise. If $\overline{K}_0 \cap \dots \cap \overline{K}_{n-1}$ is an atom, then it is called the *negative atom*, all the other atoms are *positive*. Thus atoms of L are pairwise disjoint languages uniquely determined by L ; they define a partition of Σ^* . Every quotient K_i (including L) is a (possibly empty) union of atoms. Hence, atoms can be considered as building blocks of regular languages. We also note that atoms of L are the classes of the *left congruence* \equiv_L of L defined as follows: for $x, y \in \Sigma^*$, $x \equiv_L y$ if for every $u \in \Sigma^*$, $ux \in L$ if and only if $uy \in L$ [12].

Let $A = \{A_0, \dots, A_{m-1}\}$ be the set of atoms of L , let I_A be the set of initial atoms, and let A_{m-1} be the final atom. The *átomaton* of L is the NFA $\mathcal{A} = (A, \Sigma, \alpha, I_A, \{A_{m-1}\})$ where $A_j \in \alpha(A_i, a)$ if and only if $A_j \subseteq a^{-1}A_i$, for all $A_i, A_j \in A$ and $a \in \Sigma$. It was shown in [6] that the atoms of L are the right languages of the states of the átomaton, and that the reverse NFA of the átomaton is the minimal DFA of the reverse language L^R of L .

86:4 Boolean Automata and Atoms of Regular Languages

The BSE corresponding to the átomaton \mathcal{A} , also called the *atom equations*, is as follows:

$$A_i = \bigcup_{a \in \Sigma} a \left(\bigcup_{A_j \subseteq a^{-1}A_i} A_j \right) \cup A_i^\varepsilon, \quad i = 0, \dots, m-1, \quad (2)$$

where $A_i^\varepsilon = \emptyset$ for $i = 0, \dots, m-2$, and $A_{m-1}^\varepsilon = \{\varepsilon\}$, with the initial function $L = \bigcup_{A_i \in I_A} A_i$.
A BFA \mathcal{B} is *atomic* if the right languages of its states are unions of atoms of $L(\mathcal{B})$.

3 Boolean Atoms

Let L be a regular language over Σ and let \mathcal{B} be a BFA of L with variables L_0, \dots, L_{n-1} .

A *boolean atom* of \mathcal{B} is any non-empty language $\widetilde{L}_0 \cap \dots \cap \widetilde{L}_{n-1}$, where \widetilde{L}_i is either L_i or its complement \overline{L}_i with respect to Σ^* . Similarly to the atoms of L , boolean atoms of \mathcal{B} are pairwise disjoint, defining a partition of Σ^* .

We study the relationship between boolean atoms of \mathcal{B} and atoms of L . To avoid confusion between these two notions, we also call the atoms of L the *language atoms*.

► **Proposition 1.** *Every atom of L is a union of boolean atoms of \mathcal{B} .*

Proof. Every quotient of L (including L itself) is obtained as a boolean combination of some L_i 's. Hence, every quotient of L can be expressed as a union of intersections involving uncomplemented and complemented variables from $\{L_0, \dots, L_{n-1}\}$. By adding in the missing variables, every quotient can be expressed as a union of boolean atoms. Also, the complement of any quotient is a union of boolean atoms. Since an intersection of unions of boolean atoms is a union of boolean atoms, the proposition holds. ◀

► **Corollary 2.** *Every boolean atom of \mathcal{B} is a subset of some atom of L .*

Proof. Since both the boolean atoms of \mathcal{B} and the atoms of L define a partition of Σ^* , the corollary follows from Proposition 1. ◀

► **Proposition 3.** *A BFA \mathcal{B} is atomic if and only if its boolean atoms are equal to the atoms of L .*

Proof. First assume that \mathcal{B} is atomic. Then every language L_i is a union of some atoms of L , and so is its complement \overline{L}_i . Therefore, any boolean atom $B_i = \widetilde{L}_0 \cap \dots \cap \widetilde{L}_{n-1}$ is an intersection of unions of language atoms, which is a union of language atoms. On the other hand, by Corollary 2, B_i is a subset of some language atom. We conclude that B_i is equal to some atom of L .

Conversely, if the boolean atoms of \mathcal{B} are equal to the atoms of L , then since every L_i is a union of boolean atoms, it is as well a union of language atoms. Hence, \mathcal{B} is atomic. ◀

We note that boolean atoms are a generalization of *partial atoms* of NFAs, introduced in [6]. More exactly, given an NFA with its language equations, its partial atoms are the boolean atoms of the corresponding BFA.

4 Constructing Minimal Boolean Automata Using Atoms

It is known that if a regular language L is accepted by an n -state BFA, then the reverse language L^R is accepted by a DFA with at most 2^n states [7, 16]. We also recall the following theorem by Leiss [16]:

► **Theorem 4.** *Let \mathcal{D} be a DFA with m states. There exists a BFA with $\lceil \log_2 m \rceil$ states which accepts the reverse language of \mathcal{D} .*

Consequently, a minimal BFA of a language L has $\lceil \log_2 m \rceil$ states, where m is the number of states of the minimal DFA of L^R . Since the átomon of L is isomorphic to the reverse automaton of the minimal DFA of L^R [6], we make the following observation:

► **Theorem 5.** *A minimal BFA of a regular language L has $\lceil \log_2 m \rceil$ states, where m is the number of atoms of L .*

We note that Leiss [16] also describes a method to construct a BFA of L^R with $\lceil \log_2 m \rceil$ states by using a DFA of L with m states. Also, Kozen [15] (p. 327) discusses how to construct an AFA of L with k states by using a DFA of L^R with 2^k states, and vice versa.

We present a method to construct a minimal BFA of a regular language, by using its atoms.

Let L be a regular language over an alphabet Σ , and let $A = \{A_0, \dots, A_{m-1}\}$ be the set of atoms of L , with a subset $I_A \subseteq A$ of initial atoms and the final atom A_{m-1} . Let $k = \lceil \log_2 m \rceil$. We show how to construct an atomic BFA with k variables L_0, \dots, L_{k-1} denoting some (not yet identified) languages over Σ . Let us consider the set S of all intersections in the form $\widetilde{L}_0 \cap \dots \cap \widetilde{L}_{k-1}$ where \widetilde{L}_i is either L_i or \overline{L}_i . Clearly, there are 2^k such intersections, and the union of all these intersections is Σ^* . Also, we note that since $k = \lceil \log_2 m \rceil$, the inequality $m \leq 2^k$ holds.

Let us denote any intersection in S by $X_P = \bigcap_{i \in P} L_i \cap \bigcap_{i \in \overline{P}} \overline{L}_i$, where $P \subseteq \{0, \dots, k-1\}$ and $\overline{P} = \{0, \dots, k-1\} \setminus P$. Now, let us choose any subset $S_m = \{X_{P_0}, \dots, X_{P_{m-1}}\}$ of S consisting of m intersections, and set any $X_{P_j} \in S_m$ to be equal to some atom A_j of L . We note that S_m is the set of boolean atoms of the BFA we will be constructing, and by Proposition 3, this BFA will be atomic. For instance, we may choose $P_0 = \{0, \dots, k-1\}$, $P_1 = \{0, \dots, k-2\}$, $P_2 = \{0, \dots, k-3, k-1\}$, $P_3 = \{0, \dots, k-3\}$, etc., and form the following equations between the boolean atoms and the atoms of L :

$$\begin{aligned} L_0 \cap L_1 \cap \dots \cap L_{k-2} \cap L_{k-1} &= A_0, \\ L_0 \cap L_1 \cap \dots \cap L_{k-2} \cap \overline{L}_{k-1} &= A_1, \\ L_0 \cap L_1 \cap \dots \cap \overline{L}_{k-2} \cap L_{k-1} &= A_2, \\ L_0 \cap L_1 \cap \dots \cap \overline{L}_{k-2} \cap \overline{L}_{k-1} &= A_3, \\ &\dots \\ \widetilde{L}_0 \cap \widetilde{L}_1 \cap \dots \cap \widetilde{L}_{k-2} \cap \widetilde{L}_{k-1} &= A_{m-1}, \end{aligned}$$

where \widetilde{L}_i is L_i if $n_i = 0$, and \widetilde{L}_i is \overline{L}_i if $n_i = 1$, where $n_0 n_1 \dots n_{k-1}$ is the binary representation of the number $m-1$ using k bits. For every $X_{P_j} \notin S_m$, that is, for $j = m, \dots, 2^k - 1$, we let $X_{P_j} = \emptyset$.

Clearly, every language L_i , where $i = 0, \dots, k-1$, is the union of those boolean atoms X_{P_j} , where L_i is uncomplemented, that is, $L_i = \bigcup_{i \in P_j} X_{P_j}$.

We derive boolean equations for L_0, \dots, L_{k-1} , using the equations above together with the atom equations (2):

$$\begin{aligned} L_i &= \bigcup_{i \in P_j} X_{P_j} = \bigcup_{i \in P_j} A_j = \bigcup_{i \in P_j} \left(\bigcup_{a \in \Sigma} a \left(\bigcup_{A_h \subseteq a^{-1} A_j} A_h \right) \cup A_j^\varepsilon \right) = \\ &\quad \bigcup_{a \in \Sigma} a \left(\bigcup_{i \in P_j} \bigcup_{A_h \subseteq a^{-1} A_j} X_{P_h} \right) \cup \bigcup_{i \in P_j} A_j^\varepsilon, \end{aligned}$$

that is, we obtain the equations

$$L_i = \bigcup_{a \in \Sigma} a \left(\bigcup_{i \in P_j} \bigcup_{A_h \subseteq a^{-1}A_j} X_{P_h} \right) \cup L_i^\varepsilon, \quad i = 0, \dots, k-1, \quad (3)$$

where $L_i^\varepsilon = \{\varepsilon\}$ if $i \in P_{m-1}$, and $L_i^\varepsilon = \emptyset$ otherwise.

We also notice that $L = \bigcup_{A_h \subseteq L} A_h = \bigcup_{A_h \subseteq L} X_{P_h}$. That is, since L is a union of some of its atoms A_h , it is the union of the corresponding boolean atoms X_{P_h} . Hence, the equations (3) together with the initial function $L = \bigcup_{A_h \subseteq L} X_{P_h}$ form an atomic minimal BFA of L .

In case our goal would be to obtain an atomic minimal BFA with the initial function $L = L_0$, we would have to be able to assign all the initial atoms of L to boolean atoms which have L_0 (rather than $\overline{L_0}$) as a term, and all the other language atoms to boolean atoms with $\overline{L_0}$. It is not difficult to see that this is possible if and only if the condition

$$m - 2^{\lceil \log_2 m \rceil - 1} \leq |I_A| \leq 2^{\lceil \log_2 m \rceil - 1} \quad (4)$$

holds.

The method described above constructs an atomic minimal BFA of a language. However, there may exist non-atomic minimal BFAs as well. The following example illustrates the constructions of minimal BFAs and presents a case of a non-atomic minimal BFA.

► **Example 6.** Let us consider a regular language L from [6, 18], defined by the following nondeterministic system of equations, with $L = L_0$:

$$\begin{aligned} L_0 &= aL_1 \cup b(L_1 \cup L_2), \\ L_1 &= aL_3 \cup b(L_0 \cup L_3), \\ L_2 &= a(L_0 \cup L_2 \cup L_3) \cup \varepsilon, \\ L_3 &= aL_3 \cup bL_1. \end{aligned}$$

It was shown in [6] that the corresponding NFA is a minimal NFA of L , however, it is not atomic. The language L has 6 atoms, denoted by A, B, C, D, E , and F , from which B, D , and F are the initial atoms, and A is the final atom. The atom equations are as follows:

$$\begin{aligned} A &= a(A \cup B) \cup \varepsilon, \\ B &= aC \cup bA, \\ C &= b(B \cup D), \\ D &= bC, \\ E &= aD, \\ F &= a(E \cup F) \cup b(E \cup F), \end{aligned}$$

with the initial function $L = B \cup D \cup F$. One can verify that $L_0 = B \cup D \cup F$, $L_1 = C \cup E \cup F$, and $L_3 = D \cup E \cup F$, whereas $L_2 = A \cup E \cup F'$, where $F' = a(E \cup F)$ is a subset of F .

The boolean atoms of the original system of equations are found as the following non-empty intersections:

$$\begin{aligned} L_0 \cap L_1 \cap L_2 \cap L_3 &= F', \\ L_0 \cap L_1 \cap \overline{L_2} \cap L_3 &= F \setminus F', \\ L_0 \cap \overline{L_1} \cap \overline{L_2} \cap L_3 &= D, \\ L_0 \cap \overline{L_1} \cap \overline{L_2} \cap \overline{L_3} &= B, \\ \overline{L_0} \cap L_1 \cap L_2 \cap L_3 &= E, \\ \overline{L_0} \cap L_1 \cap \overline{L_2} \cap \overline{L_3} &= C, \\ \overline{L_0} \cap \overline{L_1} \cap L_2 \cap \overline{L_3} &= A. \end{aligned}$$

Hence, the boolean atoms are A, B, C, D, E, F' , and $F \setminus F'$. We note that F is a union of two boolean atoms, while the other language atoms coincide with boolean atoms.

In the following, we drop the union symbols when representing unions of atoms; for example, $B \cup D \cup F$ is denoted by BDF . A minimal BFA of this language has $\lceil \log_2 6 \rceil = 3$ states. We construct an atomic minimal BFA by the approach described above. Let us denote the states of a minimal BFA by variables L_0, L_1, L_2 , and form the following equations:

$$\begin{aligned} L_0 \cap L_1 \cap L_2 &= A, \\ L_0 \cap L_1 \cap \overline{L_2} &= B, \\ L_0 \cap \overline{L_1} \cap L_2 &= C, \\ L_0 \cap \overline{L_1} \cap \overline{L_2} &= D, \\ \overline{L_0} \cap L_1 \cap L_2 &= E, \\ \overline{L_0} \cap L_1 \cap \overline{L_2} &= F, \\ \overline{L_0} \cap \overline{L_1} \cap L_2 &= \emptyset, \\ \overline{L_0} \cap \overline{L_1} \cap \overline{L_2} &= \emptyset. \end{aligned}$$

From these equations we obtain $L_0 = ABCD$, $L_1 = ABEF$, and $L_2 = ACE$. All the variables correspond to final states because the corresponding languages contain the final atom A . Using the atom equations, we get the following equations:

$$\begin{aligned} ABCD &= aABC \cup bABCD \cup \varepsilon, \\ ABEF &= aABCDEF \cup bAEF \cup \varepsilon, \\ ACE &= aABD \cup bBD \cup \varepsilon, \end{aligned}$$

with $L = BDF$. By replacing atoms with the corresponding boolean expressions over the variables L_0, L_1 , and L_2 , and after a few straightforward simplifications, we obtain the following system of equations, with $L = \overline{L_2}$:

$$\begin{aligned} L_0 &= a(L_0 \cap (L_1 \cup L_2)) \cup bL_0 \cup \varepsilon, \\ L_1 &= a\Sigma^* \cup b((L_1 \cap L_2) \cup \overline{L_0}) \cup \varepsilon, \\ L_2 &= a((L_0 \cap L_1) \cup (\overline{L_1} \cap \overline{L_2})) \cup b(L_0 \cap \overline{L_2}) \cup \varepsilon. \end{aligned}$$

These equations form an atomic minimal BFA for L .

We may also obtain a minimal BFA for L with $L = L_0$, since the condition (4) holds for L . For instance, we could have the atom assignments as follows (with the rest of the intersections set to be empty):

$$\begin{aligned} L_0 \cap L_1 \cap L_2 &= B, \\ L_0 \cap L_1 \cap \overline{L_2} &= D, \\ L_0 \cap \overline{L_1} \cap L_2 &= F, \\ \overline{L_0} \cap L_1 \cap L_2 &= A, \\ \overline{L_0} \cap L_1 \cap \overline{L_2} &= C, \\ \overline{L_0} \cap \overline{L_1} \cap L_2 &= E. \end{aligned}$$

Now we obtain the languages $L_0 = BDF$, $L_1 = ABCD$, and $L_2 = ABEF$, where L_1 and L_2 correspond to the final states. Using the atom equations, we get the following equations:

$$\begin{aligned} BDF &= aCEF \cup bACEF, \\ ABCD &= aABC \cup bABCD \cup \varepsilon, \\ ABEF &= aABCDEF \cup bAEF \cup \varepsilon, \end{aligned}$$

with $L = BDF$. Similarly as above, we obtain the following language equations, with $L = L_0$:

$$\begin{aligned} L_0 &= a((\overline{L_0} \cap \overline{L_2}) \cup (\overline{L_1} \cap L_2)) \cup b(\overline{L_0} \cup (L_0 \cap \overline{L_1})), \\ L_1 &= a((L_1 \cap L_2) \cup (\overline{L_0} \cap \overline{L_2})) \cup bL_1 \cup \varepsilon, \\ L_2 &= a\Sigma^* \cup b((\overline{L_0} \cap L_2) \cup (L_0 \cap \overline{L_1})) \cup \varepsilon. \end{aligned}$$

These equations form another atomic minimal BFA of L .

We can also construct a non-atomic minimal BFA for L . Let us take $L_0 = BDF$, $L_1 = CEF$, and $L_2 = ADEF'$, where L_2 is a final state. We note that L_2 is not atomic. Using the atom equations and the equation for F' , we get the following equations:

$$\begin{aligned} BDF &= aCEF \cup bACEF, \\ CEF &= aDEF \cup bBDEF, \\ ADEF' &= aABDEF \cup bC \cup \varepsilon, \end{aligned}$$

with $L = BDF$. We obtain the following language equations, with $L = L_0$:

$$\begin{aligned} L_0 &= aL_1 \cup b((\overline{L_0} \cap \overline{L_1} \cap L_2) \cup L_1), \\ L_1 &= a((L_0 \cap L_1) \cup (L_0 \cap L_2) \cup (L_1 \cap L_2)) \cup b(L_0 \cup (L_1 \cap L_2)), \\ L_2 &= a(L_0 \cup L_2) \cup b(\overline{L_0} \cap L_1 \cap \overline{L_2}) \cup \varepsilon. \end{aligned}$$

These equations form a non-atomic minimal BFA of L . ┘

5 Boolean Automata and Quotient-Atom Matrix

Kameda and Weiner [13] studied the problem of finding a minimal NFA of a language L , using a matrix based on the states of the minimal DFAs of L and L^R . They suggested a method of constructing NFAs, utilizing grid covers of this matrix. However, an NFA formed this way does not necessarily accept L . Therefore, the method of finding a minimal NFA tests grid covers of the matrix in the order of increasing size to see if they are “legal”. The first legal NFA, that is, an NFA found to accept L , is a minimal one.

In this section, we revisit the Kameda-Weiner method and its recent reinterpretation in terms of atoms of the language [21]. We will show that if one aims to form a BFA rather than an NFA, then the problem of “illegal” covers disappears. That is, one can form a BFA for L , using any cover of the quotient-atom matrix.

First, we describe the Kameda-Weiner method in terms of quotients and atoms as presented in [21]. It was shown in [21] that the matrix used by Kameda and Weiner can be viewed as the *quotient-atom matrix* of the language, that is, the matrix with its rows corresponding to the non-empty quotients, and the columns, to the positive atoms of the language. Any (i, j) -entry of this matrix is 1 if the quotient K_i has the atom A_j as its subset, and 0 otherwise. A *grid* of the matrix is the direct product $g = P \times R$ of a set P of quotients with a set R of atoms, such that every atom in R is a subset of every quotient in P . A grid $g = P \times R$ is *maximal* if there is no other grid $g' = P' \times R'$ such that $P \subseteq P'$ and $R \subseteq R'$. A *grid cover* of the matrix is a set $G = \{g_0, \dots, g_{k-1}\}$ of grids, such that every 1-entry (K_i, A_j) belongs to some grid g_h of G . A grid cover is maximal if it consists of maximal grids. Clearly, any grid cover can be made maximal by replacing every non-maximal grid $g = P \times R$ in it by the maximal grid $g' = P' \times R'$ such that $P \subseteq P'$ and $R \subseteq R'$.

Let f_G be the function that assigns to every non-empty quotient K_i the subset of G , consisting of grids $g = P \times R$ such that $K_i \in P$. The Kameda-Weiner method constructs the NFA $\mathcal{N}_G = (G, \Sigma, \eta_G, I_G, F_G)$, where G is a maximal grid cover, $I_G = f_G(K_0)$, $g \in F_G$ if and only if $g \in f_G(K_i)$ implies that $\varepsilon \in K_i$, and transition function is computed by the so-called *intersection rule* $\eta_G(g, a) = \bigcap_{K_i \in P} f_G(a^{-1}K_i)$, for a grid $g = P \times R$ in G and $a \in \Sigma$. The NFA \mathcal{N}_G may or may not accept L . A cover G is called “legal” if $L(\mathcal{N}_G) = L$. To find a minimal NFA of a language L , covers of the matrix are tested in the order of increasing size to see if they are legal; the first legal NFA is a minimal one.

In [21], the Kameda-Weiner method was interpreted in terms of atoms, with the key observation being that any maximal grid can be seen as the set of atoms it involves. We call a set $\{L_0, \dots, L_{k-1}\}$ of languages a *language cover* for L if for every L_i there is a quotient

K_j such that $L_i \subseteq K_j$ and if every quotient of L is a union of some L_i 's. A language cover $\{L_0, \dots, L_{k-1}\}$ is *atomic* if every L_i , where $i = 0, \dots, k-1$, is a union of atoms of L . Now, for any grid cover $G = \{g_0, \dots, g_{k-1}\}$ there is a corresponding atomic language cover $C = \{U(R_0), \dots, U(R_{k-1})\}$, where $g_i = P_i \times R_i$ and $U(R_i) = \bigcup_{A_j \in R_i} A_j$ for $i = 0, \dots, k-1$. The following theorem was proved in [21]:

► **Theorem 7.** *Let $G = \{g_0, \dots, g_{k-1}\}$ be a cover consisting of maximal grids $g_i = P_i \times R_i$, $i = 0, \dots, k-1$, and let $\mathcal{N}_G = (G, \Sigma, \eta_G, I_G, F_G)$ be the corresponding NFA, obtained by the intersection method. It holds that $g_i \in I_G$ if and only if $U(R_i) \subseteq L$, and $g_i \in F_G$ if and only if $\varepsilon \in U(R_i)$. For any $g_i, g_j \in G$ and $a \in \Sigma$, $g_j \in \eta_G(g_i, a)$ if and only if the inclusion $U(R_j) \subseteq a^{-1}U(R_i)$ holds.*

By Theorem 7, it is easy to see that forming the NFA \mathcal{N}_G corresponds to defining this NFA with variables L_0, \dots, L_{k-1} using the language equations

$$L_i = \bigcup_{a \in \Sigma} a \left(\bigcup_{U(R_j) \subseteq a^{-1}U(R_i)} L_j \right) \cup L_i^\varepsilon, \quad i = 0, \dots, k-1, \quad (5)$$

where $L_i^\varepsilon = \{\varepsilon\}$ if $\varepsilon \in U(R_i)$, and $L_i^\varepsilon = \emptyset$ otherwise, and the initial function $\bigcup_{U(R_i) \subseteq L} L_i$. We recall that this NFA not necessarily accepts L .

Gruber and Holzer [11] defined a canonical bipartite graph G_L of a language, which is a graph representation of the Kameda-Weiner matrix. By denoting the bipartite dimension of G_L , that is, the minimum number of bicliques to cover the edges of G_L , by $d(G_L)$, it is clear that the size of the minimal grid cover of the quotient-atom matrix is equal to $d(G_L)$. It has been a long-standing problem to identify languages with a legal minimal cover [11, 13, 21, 22].

It is known that $dc(L) \leq 2^{d(G_L)}$ [11]. Since $dc(L^R) = m$, where m is the number of atoms of L [6], and $d(G_{L^R}) = d(G_L)$ [11, 13], we get that $m \leq 2^{d(G_L)}$. By Theorem 5, a minimal BFA of L has $bc(L) = \lceil \log_2 m \rceil$ states, implying that $bc(L) \leq d(G_L)$. Hence, the following statement holds:

► **Theorem 8.** *A minimal BFA of a regular language L has at most $d(G_L)$ states.*

Theorem 8 provides an upper bound to the size of a minimal BFA of a language in terms of the size of a minimal cover of the quotient-atom matrix/graph of the language. Since a minimal NFA has at least $d(G_L)$ states [11, 13, 21], the inequalities

$$bc(L) \leq d(G_L) \leq nc(L)$$

hold. Also, we can state the following corollary:

► **Corollary 9.** *A minimal NFA is a minimal BFA of L if and only if the equalities $bc(L) = d(G_L) = nc(L)$ hold.*

In the following sections, we present two methods to construct a BFA, using a cover of the quotient-atom matrix/graph.

5.1 Constructing a General BFA

Given a language cover $C = \{L_0, \dots, L_{k-1}\}$ of L , we call any non-empty intersection $\widetilde{L}_0 \cap \dots \cap \widetilde{L}_{k-1}$ where \widetilde{L}_i is either L_i or \overline{L}_i , a *cover atom* of C . Similarly to the atoms of L , cover atoms are pairwise disjoint and their union is Σ^* .

The following proposition is a slightly modified version of the result in [6]¹:

¹ The result in [6] concerns the case where the language cover consists of the right languages of an NFA accepting L ; however, its proof holds for any cover.

86:10 Boolean Automata and Atoms of Regular Languages

► **Proposition 10.** *Given a language cover C of L , every cover atom of C is a subset of some atom of L .*

We note that cover atoms of the cover $K = \{K_0, \dots, K_{n-1}\}$ consisting of the quotients of L , are clearly the atoms of L . Moreover, the following proposition holds:

► **Proposition 11.** *The cover atoms of a cover C of L are equal to the atoms of L if and only if C is atomic.*

Proof. Let $C = \{L_0, \dots, L_{k-1}\}$ be an atomic language cover of L , meaning that every $L_i \in C$ is a union of atoms of L . In this case every complement language $\overline{L_i}$, for $i = 0, \dots, k-1$, is also a union of atoms. Therefore, any cover atom as an intersection of unions of atoms, is a union of atoms. However, since by Proposition 10, any cover atom is a subset of some atom of L , we conclude that cover atoms are equal to the atoms of L .

If the cover C is not atomic, then there is some $L_i \in C$ that is not a union of atoms of L . However, since L_i is the union of those cover atoms that have L_i uncomplemented in their intersection, there exists at least one non-atomic cover atom of C . ◀

Let us now consider any grid cover $G = \{g_0, \dots, g_{k-1}\}$ of the quotient-atom matrix and the corresponding language cover $C = \{U(R_0), \dots, U(R_{k-1})\}$ of L , with $g_i = P_i \times R_i$ and $U(R_i) = \bigcup_{A_j \in R_i} A_j$ for $i = 0, \dots, k-1$. Let the set of cover atoms of C be $X = \{X_0, \dots, X_{\ell-1}\}$. Since the cover C is atomic, by Proposition 11, the cover atoms of C are the atoms of L . Hence, any atom A_h of L can be expressed as $A_h = \bigcap_{A_h \in R_i} U(R_i) \cap \bigcap_{A_h \notin R_i} \overline{U(R_i)}$.

Now, we can form a BFA with the set $\{L_0, \dots, L_{k-1}\}$ of variables, using the correspondence between the variables L_i and the languages $U(R_i)$, where $i = 0, \dots, k-1$. We obtain the following equations for a BFA, using the atom expressions above and the atom equations (2):

$$L_i = \bigcup_{a \in \Sigma} a \left(\bigcup_{A_j \in R_i} \bigcup_{A_h \subseteq a^{-1}A_j} \left(\bigcap_{A_h \in R_i} L_i \cap \bigcap_{A_h \notin R_i} \overline{L_i} \right) \right) \cup L_i^\varepsilon, \quad i = 0, \dots, k-1, \quad (6)$$

where $L_i^\varepsilon = \{\varepsilon\}$ if $\varepsilon \in U(R_i)$, and $L_i^\varepsilon = \emptyset$ otherwise. The initial function of the BFA is $L = \bigcup_{U(R_i) \subseteq L} L_i$. Clearly, this BFA is atomic, because every L_i is a union of atoms. We also note that boolean atoms of this BFA are equal to the cover atoms.

5.2 Constructing a BFA Without Complementation

We show that any maximal grid cover can be used to construct a BFA that uses the union and the intersection operations only, without a need for the complementation operation. We use the following definition from [21]:

► **Definition 12.** *A set R of atoms is maximal if $R = \{A_j \mid A_j \subseteq \bigcap_{U(R) \subseteq K_i} K_i\}$, where $U(R) = \bigcup_{A_j \in R} A_j$ is the union of atoms in R .*

We observe that the intersection of any quotients of L corresponds to a maximal set of atoms:

► **Proposition 13.** *Given any set $P \subseteq K$ of quotients of L , the set $R = \{A_j \mid A_j \subseteq \bigcap_{K_h \in P} K_h\}$ of atoms in their intersection, is maximal.*

Proof. Let $P \subseteq K$ be any set of quotients of L and let $R = \{A_j \mid A_j \subseteq \bigcap_{K_h \in P} K_h\}$ be the set of atoms in their intersection. Since $U(R) = \bigcap_{K_h \in P} K_h = \bigcap_{U(R) \subseteq K_i} K_i$, we get that $R = \{A_j \mid A_j \subseteq \bigcap_{U(R) \subseteq K_i} K_i\}$. Thus, R is maximal. ◀

► **Proposition 14.** *If a set R of atoms is maximal, then the set $\{A_j \mid A_j \subseteq a^{-1}U(R)\}$, where $a \in \Sigma$, is also maximal.*

Proof. Let R be a maximal set of atoms and $a \in \Sigma$. Then $U(R) = \bigcap_{U(R) \subseteq K_i} K_i$ and we get $a^{-1}U(R) = a^{-1} \bigcap_{U(R) \subseteq K_i} K_i = \bigcap_{U(R) \subseteq K_i} a^{-1}K_i$. Since for any quotient K_i of L , $a^{-1}K_i$ is also a quotient of L , the language $a^{-1}U(R)$ is equal to an intersection of some quotients. By Proposition 13, we conclude that the set $\{A_j \mid A_j \subseteq a^{-1}U(R)\}$ is maximal. ◀

Let us consider a maximal grid cover $G = \{g_0, \dots, g_{k-1}\}$ of the quotient-atom matrix and the corresponding language cover $C = \{U(R_0), \dots, U(R_{k-1})\}$ of L , with $g_i = P_i \times R_i$ and $U(R_i) = \bigcup_{A_j \in R_i} A_j$ for $i = 0, \dots, k-1$. It is known that any maximal grid involves a maximal set of atoms [21]. Hence, every R_i , where $i = 0, \dots, k-1$, is a maximal set of atoms. We denote by $P_{i,a}$, where $a \in \Sigma$, the set $P_{i,a} = \{K_h \mid a^{-1}U(R_i) \subseteq K_h\}$ of those quotients of L that include $a^{-1}U(R_i)$ as a subset. By Proposition 14, the equality $a^{-1}U(R_i) = \bigcap_{K_h \in P_{i,a}} K_h$ holds. Also, we recall that every quotient K_h is a union of some elements of the cover C , that is, $K_h = \bigcup_{U(R_i) \subseteq K_h} U(R_i)$.

We construct a BFA with the set $\{L_0, \dots, L_{k-1}\}$ of variables, using the correspondence between the variables L_i and the languages $U(R_i)$, where $i = 0, \dots, k-1$. The language equations are as follows:

$$L_i = \bigcup_{a \in \Sigma} a \left(\bigcap_{K_h \in P_{i,a}} \bigcup_{U(R_j) \subseteq K_h} L_j \right) \cup L_i^\varepsilon, \quad i = 0, \dots, k-1, \quad (7)$$

where $L_i^\varepsilon = \{\varepsilon\}$ if $\varepsilon \in U(R_i)$, and $L_i^\varepsilon = \emptyset$ otherwise. The initial function is $L = \bigcup_{U(R_i) \subseteq L} L_i$. This BFA is atomic, since every L_i is a union of atoms of L .

We note that the BFA corresponding to the equations (7) uses only the union and the intersection operations. That is, the complementation operation is not needed when we use a maximal cover as a basis for the states of a BFA.

One can see this result as a solution to the problem of interpreting grid covers of the Kameda-Weiner matrix, or equivalently, biclique edge covers of the quotient-atom graph, in terms of finite automata accepting a given language. The “illegal” cover problem mentioned above implies that using the union operation only to construct such an automaton – as is the case with NFAs –, is not sufficient. However, we showed that with the union and the intersection operations it is possible to construct boolean automata accepting a given language, for a given maximal cover.

We note that by a result in [9], for any BFA of n states, there is an equivalent BFA with $2n$ states that uses the union and the intersection operations only. However, since the inequality $bc(L) \leq d(G_L)$ holds for any language L , and because we can construct a BFA with $d(G_L)$ states, using the union and the intersection operations only, our method can produce such a BFA for any language L for which the inequality $d(G_L) < 2bc(L)$ holds, with less states.

6 Conclusions

We have started a study of the role that atoms of a regular language have in the context of boolean automata, their relationship with boolean atoms, and how they can be used to construct BFAs.

The problem of “illegal” covers of the Kameda-Weiner matrix used for NFA minimization has been of interest for a long time. We presented a new interpretation of the covers in terms of BFAs, so that every cover becomes “legal”. We showed that it is sufficient to use the union and the intersection operations to construct a BFA for a given language, corresponding to a maximal cover of the matrix. Moreover, the resulting BFAs are atomic.

These are part of the evidence of the significant role that atoms play in the theory of automata.

Abstract

We introduce the notion of a Gödel fibration, which is a fibration categorically embodying both the logical principles of traditional Skolemization (we can exchange the order of quantifiers paying the price of a functional) and the existence of a prenex normal form presentation for every logical formula. Building up from Hofstra’s earlier fibrational characterization of de Paiva’s categorical Dialectica construction, we show that a fibration is an instance of the Dialectica construction if and only if it is a Gödel fibration. This result establishes an intrinsic presentation of the Dialectica fibration, contributing to the understanding of the Dialectica construction itself and of its properties from a logical perspective.

1 Introduction

Historically, the Dialectica interpretation was devised by Gödel [10] to prove the (relative) consistency of arithmetic. The interpretation allowed him to reduce the problem of proving the consistency of first-order arithmetic to the problem of proving the consistency of a simply-typed system of computable functionals, the well-known *System T*. The key feature of the translation is that it (mostly) constructively turns formulae of arbitrary quantifier complexity into formulae of the form $\exists x \forall y \alpha(x, y)$.

Over the years, several authors have explained the Dialectica interpretation in categorical terms. In particular, de Paiva [7] introduced the notion of *Dialectica categories* as an internal version of Gödel’s Dialectica Interpretation. The idea is to construct a category $\mathfrak{Dial}(\mathbb{C})$ from a category \mathbb{C} with finite limits. The main focus in de Paiva’s original work is on the categorical structure of the category $\mathfrak{Dial}(\mathbb{C})$ obtained, as this notion of a Dialectica category turns out to be also a model of Girard’s Linear Logic [9].

This construction was first generalized by Hyland, who investigated the Dialectica construction associated to a fibred preorder [12]. Later Biering in her PhD work [3] studied the Dialectica construction for an arbitrary cloven fibration.

Meanwhile Hofstra [11] wrote an exposition and interpretation of the Dialectica construction from a modern categorical perspective, emphasizing its universal properties. His work gives centre stage to the well-known concepts of pseudo-monads, simple products and co-products. We take Hofstra’s work as the basis for our work here.

Hofstra shows that the original Dialectica construction \mathfrak{Dial} can be seen as the composition of two free constructions \mathfrak{Sum} and \mathfrak{Prod} , which are the simple sum (or co-product) and product completions, respectively. These completions are fully dual, so we only need to study one and can then deduce results for the other construction. However the whole Dialectica construction is not fully dual, as indicated by the order of the composition of the completions. Our work explains when the Dialectica construction can be performed, which hypotheses are necessary for the categorical construction, which properties of the construction are preserved and why. Most importantly we are able to connect these preservation properties to the logic of the original interpretation, leading up to the definition of what we call a Gödel fibration.

Our contributions

The main contributions of this paper are the following.

1. *We formalize the notion of fibrational quantifier-free formula.* Given Hofstra’s characterization it is clear that instances of the Dialectica construction should have simple products and co-products, as the construction introduces completions under these. What else is necessary to get a Dialectica construction? The first novelty of this work is the characterization of “covering quantifier-free objects” of a fibration. These objects correspond to formulas in the logic system that are quantifier-free. As usually happens in a categorical framework, a syntactical notion of “being quantifier-free” needs to be formalized in terms of a universal property. The logical intuition behind our definition, is that an element α of a fibration \mathfrak{p} is called *quantifier-free* if it satisfies the following universal property, expressed in the internal language of \mathfrak{p} : if there is a proof π of a statement $\exists i\beta(i)$ assuming α , then there exists a *witness* t , which depends on the proof π , together with a proof of $\beta(t)$. Moreover, this must hold for every re-indexing $\alpha(f)$, because in logic if $\alpha(x)$ is quantifier-free then $\alpha(x)[f/x] = \alpha(f)$ is quantifier-free too. The covering requirement, as usual, means that, for every formula of the form $i : I \mid \alpha(i)$, there exists a formula $\beta(i, a, b)$ quantifier-free that is provably equivalent to it $\alpha(i) \dashv\vdash \exists a\forall b\beta(i, a, b)$. Notice that these requirements reflect Gödel’s original translation and, at the same time, they recall standard conditions used in category theory to say that a category is *free* for a given structure. One could think for example about the condition of having enough projectives in the exact completion of Carboni [5].
2. *We introduce the notion of a Gödel fibration.* A Gödel fibration is a fibration with simple products and simple co-products, which, most importantly, admits a class of formal sub-objects which are *free from products and co-products* and *cover* all the elements of the fibre. Then we prove that a Gödel fibration is a fibration categorically embodying both the logical principle of traditional Skolemization and the existence of a prenex normal presentation for every logical formula.
3. *We provide an intrinsic presentation of the Dialectica fibration.* We prove that a given fibration is an instance of the Dialectica construction if and only if it is a Gödel fibration. This result helps understanding the existing notion of Dialectica fibration from a logical perspective because it shows which properties an arbitrary fibration should satisfy to be an instance of the Dialectica construction. In other words, given a fibration \mathfrak{p} there exists a fibration $\bar{\mathfrak{p}}$ such that $\mathfrak{p} \cong \mathfrak{Dial}(\bar{\mathfrak{p}})$ if and only if \mathfrak{p} is a Gödel fibration. From a categorical perspective, we have classified the free-algebras for the Dialectica pseudo-monad.

4. We prove that fibrations associated to the Dialectica construction satisfy a strong constructive feature in terms of witnesses. We have shown that in the internal language of, say Hofstra’s Dialectica fibration $\mathfrak{Dial}(\mathfrak{p})$, i.e. in the logic theory that canonically corresponds to this categorical notion, if there is a proof π of a statement $\exists i \alpha(i)$, then there exists a *witness* t , which depends on the proof π , together with a proof of $\alpha(t)$. This principle is sometimes called the Rule of Choice. For example, Regular Logic (<https://ncatlab.org/nlab/show/regular+logic>) satisfies this principle, see [24].

Related work

In the present paper we provide an intrinsic characterization of the free algebras of the pseudo-monad $\mathfrak{Dial}(-)$ introduced by Hofstra in [11], i.e. we provide necessary and sufficient conditions for a (cloven and split) fibration to be of the form $\mathfrak{Dial}(\mathfrak{p})$ for some fibration \mathfrak{p} . Hofstra’s categorical presentation of the Dialectica construction generalizes to the fibrational setting the original construction introduced by de Paiva [7]. In particular, we recall the structural analysis due to Hyland [12] and Biering [2], where the first fibrational presentations of the Dialectica construction were introduced. For a complete presentation of the theory of fibrations and its connection to type theory, we refer the reader to Jacobs [13], and to [4] for an introduction to pseudomonads.

More recently, modern reformulations of the Dialectica interpretation based on the linearized version of de Paiva have been introduced, aiming to provide categorical models for type theory. A relevant example of this line of work is Moss and von Glehn [17], where the authors are interested not in the original construction, but in a modified version of Gödel’s Dialectica interpretation for models of intensional Martin-Löf type-theory, using the notion of fibred display map category. Their work focus on the preservation of the type constructors, while they drop the layer of predicates from their Dialectica propositions, considering only those Dialectica propositions of the form $\exists x \forall y \top$. In fact, they call their construction the *polynomial model*, explaining that this name fits better, because they are considering the *predicate-free* Dialectica construction. On a similar line, we mention the work of Pédrot [18], investigating the validity of a Dialectica-like construction in a dependent setting. Different variations of the Dialectica interpretation have been devised for automata, e.g. the work of Pradic and Riba [19].

Finally, Topos- and tripos-theoretic versions of the Dialectica construction have been studied by Biering in [3], while the recent work of Shulman [20], describes a “polycategorical” version of a generalization of the Dialectica construction. Other applications of completions involving universal and existential quantifiers can be found in [24, 23, 8], where similar constructions are presented in the language of doctrines.

2 Revisiting categorical quantifiers

One of the pillars of categorical logic is Lawvere’s crucial intuition which considers logical languages and theories as indexed categories and studies their 2-categorical properties. In this setting connectives and quantifiers are characterized in terms of adjointness relations [14, 15, 16].

In this fibrational setting, the intuition is that the base category \mathbf{B} of a fibration $\mathfrak{p}: \mathbf{E} \rightarrow \mathbf{B}$ represents the category of (type-theoretical) contexts, a fibre \mathbf{E}_I represents the propositions $\alpha(i)$ in the context I , and the morphisms are proofs. Cartesian morphisms of \mathfrak{p} induce a *re-indexing* or substitution operation. From this perspective, the simple form of quantification

is described in terms of adjoints to weakening functors π^* along projections π . For example, existential quantification is given by an operation $\coprod_{\pi^*} : \mathbf{E}_{A \times B} \rightarrow \mathbf{E}_A$, which sends a proposition $\alpha(a, b)$ to $\exists b \alpha(a, b)$.

Now we briefly recall the formal definition of a fibration with simple products (or simple universal quantification) and coproducts (or simple existential quantification). For a complete presentation of the theory of fibrations and its connection to type theory, we refer the reader to Jacobs [13]. In this work, we will assume that a fibration \mathbf{p} is always *cloven and split*, i.e. that the re-indexing operation is functorial (these definitions can be found in pages 47 and 49 of [13]).

► **Definition 2.1.** *We say a fibration $\mathbf{p}: \mathbf{E} \rightarrow \mathbf{B}$ over a category \mathbf{B} with finite products has **simple coproducts** when the weakening functors π^* have left adjoints \coprod_{π} satisfying the Beck-Chevalley Condition (abbreviated as *BCC*), i.e. for every pullback square of the form*

$$\begin{array}{ccc} I \times X & \xrightarrow{\pi_I} & I \\ f \times \text{id} \downarrow & & \downarrow f \\ J \times X & \xrightarrow{\pi_J} & J \end{array}$$

the canonical natural transformation $f^* \coprod_{\pi_J} \Rightarrow \coprod_{\pi_I} (f \times \text{id})^*$ is an isomorphism.

Dually, we say that a fibration $\mathbf{p}: \mathbf{E} \rightarrow \mathbf{B}$ has **simple products** when the weakening functors π^* have right adjoints \prod_{π} satisfying *BCC*.

For more details about the notion of fibration having simple coproducts (or simple products) we refer to [13, Def. 1.9.1].

When one deals with quantification, for example in first-order logic, it is very common to assert something like *a formula α is quantifier-free*. This assertion has a natural meaning from a syntactic point of view, but it is not clear how it should be presented from a categorical perspective. The aim of the following definitions, which are generalizations of definitions in [24] to the fibrational setting, is to capture the common property of those elements of a given fibration $\mathbf{p}: \mathbf{E} \rightarrow \mathbf{B}$ which will appear as quantifier-free propositions in the internal language of the fibration \mathbf{p} . We start by defining when an element of a fibre of \mathbf{p} is free from the existential quantifier, and then we dualize the definition for the universal quantifier. (Recall that the symbols \coprod and \prod represent the logical quantifiers \exists and \forall .)

The logical intuition behind the next definition is that an element α is *existential-free* if it satisfies the following universal property: if there is a proof π of a statement $\exists i \beta(i)$ assuming α , then there exists a *witness* t , which depends on the proof π , together with a proof of $\beta(t)$. Moreover, we require that this holds for every re-indexing $\alpha(f)$ because in logic quantifier-free propositions are stable under substitution, i.e. if $\alpha(x)$ is quantifier-free then $\alpha(f)$ is quantifier-free.

► **Definition 2.2.** *Let $\mathbf{p}: \mathbf{E} \rightarrow \mathbf{B}$ be a fibration with simple coproducts. An object α of the fibre \mathbf{E}_I is said to be **\coprod -quantifier-free** if it enjoys the following universal property. For every arrow f and every projection π_A in \mathbf{B} as follows:*

$$A \times B \xrightarrow{\pi_A} A \xrightarrow{f} I$$

and every vertical arrow:

$$f^* \alpha \xrightarrow{h} \prod_{\pi_A} \beta$$

of \mathbf{E}_A , where β is an object of the fibre $\mathbf{E}_{A \times B}$, there exist a unique arrow $A \xrightarrow{g} B$ of \mathbf{B} and a unique vertical arrow $f^* \alpha \xrightarrow{\bar{h}} \langle 1_A, g \rangle^* \beta$ of \mathbf{E}_A such that:

$$h = \left(f^* \alpha \xrightarrow{\bar{h}} \langle 1_A, g \rangle^* \beta \xrightarrow{\langle 1_A, g \rangle^* \eta_\beta} \langle 1_A, g \rangle^* \left(\prod_{\pi_A}^* \beta \right) = \prod_{\pi_A} \beta \right)$$

where $\beta \xrightarrow{\eta_\beta} \prod_{\pi_A}^* \beta$ is the unit at β of the adjunction $\prod_{\pi_A} \dashv \prod_{\pi_A}^*$.

Clarifying the concrete meaning of Definition 2.2, the given object α of \mathbf{E}_I represents a formula $\alpha(i)$. Given an arrow $A \xrightarrow{f} I$ a term $f(a) : I$ is in the context $a : A$, and it is the case that $f^* \alpha$ represents the corresponding formula $\alpha(f(a))$. The object β of $\mathbf{E}_{A \times B}$ corresponds to a formula $\beta(a, b)$, the object $\prod_{\pi_A} \beta$ represents the formula $(\exists b)\beta(a, b)$, which is in the same context $a : A$ of $\alpha(f(a))$. Meanwhile, the object $\langle 1_A, g \rangle^* \beta$ is again the re-indexing of $\beta(a, b)$ through an arrow $A \xrightarrow{\langle 1_A, g \rangle} A \times B$, hence it represents the formula $\beta(a, g(a))$, which is in the same context $a : A$ of $\alpha(f(a))$ and $(\exists b)\beta(a, b)$.

Thus the property we require of the formula $\alpha(i)$ is the following: whenever there is a proof (an arrow h of the fibre) of $(\exists b)\beta(a, b)$ from $\alpha(f(a))$ (for some term $f(a) : I$ in the context $a : A$), then there is a unique term $g(a) : B$ in the context $a : A$ together with a unique proof \bar{h} of $\beta(a, g(a))$ from $\alpha(f(a))$, in such a way that, adding at the end of the proof \bar{h} the canonical proof of $(\exists b)\beta(a, b)$ from $\beta(a, g(a))$ (which is represented by the re-indexing of the unit at β of the adjunction $\prod_{\pi_A} \dashv \prod_{\pi_A}^*$), we get back to the proof h itself of $(\exists b)\beta(a, b)$ from $\alpha(f(a))$. The uniqueness requirement of the term and the proof is due to the proof-relevant nature of fibrations.

Observe that this is precisely the universal property, that we presented before Definition 2.2, enjoyed by a formula which is free from existential quantification.

► **Remark 2.3.** Notice that if we consider a fibration \mathbf{p} with simple coproducts, then one can define a sub-fibration $\mathbf{p}' \rightarrow \mathbf{p}$ such that the fibres of \mathbf{p}' are given by \prod -quantifier-free objects, and the base category of \mathbf{p}' is the same of \mathbf{p} . This follows since \prod -quantifier-free objects are stable under re-indexing by definition.

The next concept we are going to need in the categorical setting reminds us of the *existence of a prenex normal form* in logic. Recall, for example from [6], that in (classical) first-order logic (FOL) every formula is equivalent to some formula in prenex normal form.

► **Definition 2.4.** We say that a fibration with simple coproducts $\mathbf{p} : \mathbf{E} \rightarrow \mathbf{B}$ has **enough \prod -quantifier-free objects** if, for every object I of \mathbf{B} and for every element $\alpha \in \mathbf{E}_I$, there exist an object A and a \prod -quantifier-free object β in $\mathbf{E}_{I \times A}$ such that $\alpha \cong \prod_{\pi_I} \beta$.

By duality we can define the same concept with respect to the universal quantifier.

► **Definition 2.5.** Let $\mathbf{p} : \mathbf{E} \rightarrow \mathbf{B}$ be a fibration with simple products. An object α of the fibre \mathbf{E}_I is said to be **\prod -quantifier-free** if it enjoys the following universal property: for every arrow f and every projection π_A in \mathbf{B} as follows:

$$A \times B \xrightarrow{\pi_A} A \xrightarrow{f} I$$

and every vertical arrow:

$$\prod_{\pi_A} \beta \xrightarrow{h} f^* \alpha$$

87:6 The Gödel Fibration

of \mathbf{E}_A , where β is an object of the fibre $\mathbf{E}_{A \times B}$, there exist a unique arrow $A \xrightarrow{g} B$ of \mathbf{B} and a unique vertical arrow $\langle 1_A, g \rangle^* \beta \xrightarrow{\bar{h}} f^* \alpha$ of \mathbf{E}_A such that:

$$h = \left(\prod_{\pi_A} \beta = \langle 1_A, g \rangle^* (\pi_A^* \prod_{\pi_A} \beta) \xrightarrow{\langle 1_A, g \rangle^* \varepsilon_\beta} \langle 1_A, g \rangle^* \beta \xrightarrow{\bar{h}} f^* \alpha \right)$$

where $\pi_A^* \prod_{\pi_A} \beta \xrightarrow{\varepsilon_\beta} \beta$ is the counit at β of the adjunction $\pi_A^* \dashv \prod_{\pi_A}$.

► **Definition 2.6.** We say that a fibration with simple products $\mathbf{p}: \mathbf{E} \rightarrow \mathbf{B}$ has **enough- \prod -quantifier-free objects** if, for every object I of \mathbf{B} and for every element $\alpha \in \mathbf{E}_I$, there exist an object A and a \prod -quantifier-free object β in $\mathbf{E}_{I \times A}$ such that $\alpha \cong \prod_{\pi_I}(\beta)$.

Now we can introduce a particular kind of fibration called a *Skolem fibration*. The name is chosen because these fibrations satisfy a version of the traditional principle of *Skolemization*, as presented in [10] and [11].

► **Definition 2.7.** A fibration $\mathbf{p}: \mathbf{E} \rightarrow \mathbf{B}$ is called a **Skolem fibration** if:

- its base category \mathbf{B} is cartesian closed;
- the fibration \mathbf{p} has simple products and simple coproducts;
- the fibration \mathbf{p} has enough \prod -quantifier-free objects.
- \prod -quantifier-free objects are stable under simple products, i.e. if $\alpha \in \mathbf{E}_I$ is a \prod -quantifier-free object, then $\prod_{\pi}(\alpha)$ is a \prod -quantifier-free object for every projection π from I .

Notice that the last point of Definition 2.7 implies that, given a Skolem fibration $\mathbf{p}: \mathbf{E} \rightarrow \mathbf{B}$, the sub-fibration $\mathbf{p}': \mathbf{E}' \rightarrow \mathbf{B}$ of \prod -quantifier-free objects of \mathbf{p} defined in Remark 2.3 has simple products.

► **Proposition 2.8 (Skolemization).** Every Skolem fibration \mathbf{p} validates the principle:

$$\forall x \exists y \alpha(i, x, y) \cong \exists f \forall x \alpha(i, x, fx).$$

Proof. Let us consider an element $\alpha \in E_{A_1 \times A_2 \times B}$ and a \prod -quantifier-free object $\gamma \in E_{A_1}$. Hence, for every arrow $\pi_1^*(\gamma) \xrightarrow{h} \prod_{\langle \pi_1, \pi_2 \rangle}(\alpha)$, there is a unique pair (g, \bar{h}) where $A_1 \times A_2 \xrightarrow{g} B$ and $\pi_1^*(\gamma) \xrightarrow{\bar{h}} \langle \pi_1, \pi_2, g \rangle^*(\alpha)$. Since \mathbf{B} has exponents, then we have that g induces a unique arrow $A_1 \xrightarrow{m} B^{A_2}$ such $\langle \pi_1, \pi_2, g \rangle = \langle \pi_1, \pi_2, \text{ev} \langle \pi_1, \pi_2 \rangle \rangle \langle \pi_1, \pi_2, m \pi_1 \rangle$. Therefore we have an arrow

$$\pi_1^*(\gamma) \xrightarrow{\bar{h}} \langle \pi_1, \pi_2, m \pi_1 \rangle^*(\langle \pi_1, \pi_2, \text{ev} \langle \pi_1, \pi_2 \rangle \rangle(\alpha)).$$

Since \mathbf{p} has simple products, \bar{h} induces a unique arrow

$$\gamma \xrightarrow{\bar{\bar{h}}} \prod_{\pi_1} \langle \pi_1, \pi_2, m \pi_1 \rangle^*(\langle \pi_1, \pi_2, \text{ev} \langle \pi_1, \pi_2 \rangle \rangle(\alpha)).$$

Notice that the following square

$$\begin{array}{ccc} A_1 \times A_2 & \xrightarrow{\pi_1} & A_1 \\ \langle \pi_1, \pi_2, m \pi_1 \rangle \downarrow & & \downarrow \langle id_{A_1}, m \rangle \\ A_1 \times A_2 \times B^{A_2} & \xrightarrow{\langle \pi_1, \pi_3 \rangle} & A_1 \times B^{A_2} \end{array}$$

is a pullback, hence by the BCC we have that $\prod_{\pi_1} \langle \pi_1, \pi_2, m\pi_1 \rangle^* \cong \langle \text{id}_{A_1}, m \rangle^* \prod_{\langle \pi_1, \pi_3 \rangle}$. Thus, we get that an arrow f induces a unique pair of arrows (m, \bar{h}) , but again (since \mathfrak{p} has enough \prod -quantifier-free objects) this pair represents a unique arrow of the fibre $E_{A_1}(\gamma, \prod_{\pi_3} \prod_{\langle \pi_1, \pi_1 \rangle} (\langle \pi_1, \pi_2, \text{ev}\langle \pi_1, \pi_2 \rangle \rangle(\alpha)))$, i.e. the fibre

$$E_{A_1 \times A_2}(\pi_1^*(\gamma), \prod_{\langle \pi_1, \pi_2 \rangle} (\alpha))$$

is isomorphic to

$$E_{A_1}(\gamma, \prod_{\pi_1} \prod_{\langle \pi_1, \pi_3 \rangle} (\langle \pi_1, \pi_2, \text{ev}\langle \pi_1, \pi_2 \rangle \rangle(\alpha)))$$

and this means exactly that

$$\prod_{\pi_1} \prod_{\langle \pi_1, \pi_2 \rangle} (\alpha) \cong \prod_{\pi_1} \prod_{\langle \pi_1, \pi_3 \rangle} (\langle \pi_1, \pi_2, \text{ev}\langle \pi_1, \pi_2 \rangle \rangle(\alpha)).$$

The proof for the general case where γ is a generic element of the fibre and not a \prod -quantifier-free object, follows by the observation that the arrows $\pi_1^*(\gamma) \rightarrow \beta$ are in bijection with those of the form $\pi_1^*(\gamma') \rightarrow \prod_{\pi_2} \beta$ for appropriate projections, and where γ' is the \prod -quantifier-free element which covers γ . ◀

Combining Definitions 2.4, 2.6 and 2.7, we introduce the notion of a *Gödel fibration*. The idea is that a Gödel fibration is a Skolem fibration, such that every formula $\alpha(i)$ is equivalent to a formula in *prenex normal form* with respect to \mathfrak{p} , i.e. there exists a formula $\beta(x, y, i)$ free from quantifiers, such that $\alpha(i) \cong \exists x \forall y \beta(x, y, i)$.

► **Definition 2.9.** A Skolem fibration $\mathfrak{p}: E \rightarrow B$ is called a **Gödel fibration** if the sub-fibration $\mathfrak{p}': E' \rightarrow B$, whose elements are \prod -quantifier-free objects, has enough \prod -quantifier-free objects.

► **Remark 2.10.** Observe that if we consider a Gödel fibration $\mathfrak{p}: E \rightarrow B$, an element which is a \prod -quantifier-free object in the sub-fibration \mathfrak{p}' could not be \prod -quantifier-free object of the Gödel fibration. This because in Definition 2.9 of Gödel fibration, the universal property of being a \prod -quantifier-free object is required to hold only with respect to the \prod -quantifier-free objects of \mathfrak{p} .

The following proposition is an immediate consequence of Definition 2.9.

► **Proposition 2.11** (Prenex normal form). In a Gödel fibration $\mathfrak{p}: E \rightarrow B$, for every element α of a fibre E_I there exists an element β such that

$$\alpha(i) \cong \exists x \forall y \beta(x, y, i)$$

and β is \prod -quantifier-free in the sub-fibration \mathfrak{p}' of \prod -quantifier-free objects of \mathfrak{p} .

Proof. Let us consider an element α of the fibre E_I . Since \mathfrak{p} is a Gödel fibration, hence in particular a Skolem fibration, the fibration \mathfrak{p} has enough \prod -quantifier-free objects, and hence there exists an element γ in the fibre $E_{I \times X}$ such that $\alpha \cong \prod_{\pi_I}(\gamma)$. Therefore, since the sub-fibration \mathfrak{p}' has enough \prod -quantifier-free objects, there exists a \prod -quantifier-free object β of \mathfrak{p}' in the fibre $E_{I \times X \times Y}$ such that $\gamma \cong \prod_{\pi_X}(\beta)$, and hence $\alpha \cong \prod_{\pi_I} \prod_{\pi_X}(\beta)$. ◀

3 The Dialectica monad

In this section we assume that $p: E \rightarrow B$ is a cloven and split fibration whose base category B has finite products. First we recall from Hofstra's [11] the free construction $\mathfrak{S}um(-)$ which adds simple sums (or coproducts) to a fibration, and then the dual construction $\mathfrak{P}rod(-)$ which freely adds simple products. Then, we present the Dialectica construction $\mathfrak{D}ial(-)$ and its decomposition in terms of simple coproducts and products completions.

Simple coproducts completion. The category $\mathfrak{S}um(p)$ has:

- as **objects** triples (I, X, α) , where I and X are objects of the base category B and α is an object of the fibre $E_{I \times X}$;
- as **morphisms** triples $(I, X, \alpha) \xrightarrow{(f_0, f_1, \phi)} (J, Y, \beta)$, where $I \xrightarrow{f_0} J$ and $I \times X \xrightarrow{f_1} Y$ are arrows of B and $\alpha(i, x) \xrightarrow{\phi} \beta(f_0(i), f_1(i, x))$ is a morphism of the fibre category $E_{I \times X}$.

The category $\mathfrak{S}um(p)$ is fibred over B via the first component projection and this fibration is denoted by $\mathfrak{S}um(p): \mathfrak{S}um(p) \rightarrow B$. This fibration is called the *simple coproduct (or sum) completion* of p . The intuition behind this definition is that an object (I, X, α) of the fibre category $\mathfrak{S}um(p)_I$ represents a formula $(\exists x : X)\alpha(i, x)$. The assignment $p \mapsto \mathfrak{S}um(p)$ extends to a KZ pseudo-monad on the 2-category of cloven split fibrations, see [11, Theorem 3.9].

► **Remark 3.1 (A presentation of $\mathfrak{S}um(p)$ reindexing functors).** Let $p: E \rightarrow B$ be a cloven and split fibration. Let $I \xrightarrow{f} J$ be an arrow of B and let (J, Y, β) be an object of $\mathfrak{S}um(p)_J$. Then the triple:

$$(I \xrightarrow{f} J, I \times Y \xrightarrow{\pi_Y} Y, \langle f\pi_I, \pi_Y \rangle^* \beta \xrightarrow{1_{\langle f\pi_I, \pi_Y \rangle^* \beta}} \langle f\pi_I, \pi_Y \rangle^* \beta)$$

is $\mathfrak{S}um(p)$ -cartesian $(I, Y, \langle f\pi_I, \pi_Y \rangle^* \beta) \rightarrow (J, Y, \beta)$ over $I \xrightarrow{f} J$. In particular $\mathfrak{S}um(p)$ is endowed with a cloven and split structure. If:

$$(J, Y, \beta) \xrightarrow{(J \times Y \xrightarrow{g} Y', \beta \xrightarrow{\gamma} \langle \pi_J, g \rangle^* \beta')} (J, Y', \beta')$$

is an arrow of $\mathfrak{S}um(p)_J$ (observe the omission of the first component, as it is forced to be the identity arrow on J) then its f -reindexing is the pair:

$$(I, Y, \langle f\pi_I, \pi_Y \rangle^* \beta) \xrightarrow{(g\langle f\pi_I, \pi_Y \rangle, \langle f\pi_I, \pi_Y \rangle^* \gamma)} (I, Y', \langle f\pi_I, \pi_{Y'} \rangle^* \beta')$$

of $\mathfrak{S}um(p)_I$, whose first component is the arrow $I \times Y \xrightarrow{g\langle f\pi_I, \pi_Y \rangle} Y'$ of B and whose second one is the arrow:

$$\langle f\pi_I, \pi_Y \rangle^* \beta \xrightarrow{\langle f\pi_I, \pi_Y \rangle^* \gamma} \langle f\pi_I, \pi_Y \rangle^* \langle \pi_J, g \rangle^* \beta' = \langle \pi_I, g\langle f\pi_I, \pi_Y \rangle \rangle^* \langle f\pi_I, \pi_{Y'} \rangle^* \beta'$$

of $E_{I \times Y}$.

Now, let us assume that f is a projection $J \times K \xrightarrow{\pi_J} J$. In this particular case (in which we are mostly interested) such an annoying presentation *collapses* into the following easier one: the π_J -weakening of the arrow (g, γ) of $\mathfrak{S}um(p)_J$ is the pair:

$$(J \times K, Y, \langle \pi_J, \pi_Y \rangle^* \beta) \xrightarrow{(g\langle \pi_J, \pi_Y \rangle, \langle \pi_J, \pi_Y \rangle^* \gamma)} (J \times K, Y', \langle \pi_J, \pi_{Y'} \rangle^* \beta')$$

of $\mathfrak{S}um(p)_I$, whose first component is the arrow $J \times K \times Y \xrightarrow{g\langle \pi_J, \pi_Y \rangle} Y'$ of B and whose second one is the arrow:

$$\langle \pi_J, \pi_Y \rangle^* \beta \xrightarrow{\langle \pi_J, \pi_Y \rangle^* \gamma} \langle \pi_J, \pi_Y \rangle^* \langle \pi_J, g \rangle^* \beta' = \langle \langle \pi_J, \pi_K \rangle, g\langle \pi_J, \pi_Y \rangle \rangle^* \langle \pi_J, \pi_{Y'} \rangle^* \beta'$$

of $E_{J \times K \times Y}$.

► **Remark 3.2** ($\mathfrak{S}\text{um}(\mathfrak{p})$ has simple coproducts). Let \mathfrak{p} be a cloven and split fibration and let us consider a projection $J \times K \xrightarrow{\pi_J} J$ of \mathbf{B} . The left adjoint \coprod_{π_J} of the π_J -weakening π_J^* in $\mathfrak{S}\text{um}(\mathfrak{p})$ exists and sends an arrow:

$$(J \times K, Y, \beta) \xrightarrow{(J \times K \times Y \xrightarrow{g} Y', \beta \xrightarrow{\gamma} \langle (\pi_J, \pi_K), g \rangle^* \beta')} (J \times K, Y', \beta')$$

of $\mathfrak{S}\text{um}(\mathfrak{p})_{J \times K}$ to the arrow:

$$(J, K \times Y, \beta) \xrightarrow{(J \times K \times Y \xrightarrow{\langle \pi_K, g \rangle} K \times Y', \beta \xrightarrow{\gamma} \langle \pi_J, \langle \pi_K, g \rangle \rangle^* \beta')} (J, K \times Y', \beta')$$

of $\mathfrak{S}\text{um}(\mathfrak{p})_J$, which we also denote as:

$$\coprod_{\pi_J} (J \times K, Y, \beta) \xrightarrow{\coprod_{\pi_J} (g, \gamma)} \coprod_{\pi_J} (J \times K, Y', \beta').$$

► **Remark 3.3.** Let $\mathfrak{p}: \mathbf{E} \rightarrow \mathbf{B}$ be a fibration and consider its simple coproduct completion $\mathfrak{S}\text{um}(\mathfrak{p}): \mathfrak{S}\text{um}(\mathfrak{p}) \rightarrow \mathbf{B}$. As a consequence of Remark 3.2, every element (I, A, α) of the fibre $\mathfrak{S}\text{um}(\mathfrak{p})_I$ is isomorphic to an object of the form $\coprod_{\pi_I} (I \times A, 1, \alpha')$.

Notice that, by dualising the previous construction, one gets the notion of simple product completion together with its analogous version of the previous characterization.

Simple products completion. The category $\mathfrak{P}\text{rod}(\mathfrak{p})$ is the one:

- whose **objects** are triples (I, X, α) , where I and X are objects of the base category \mathbf{B} and α is an object of the fibre $\mathbf{E}_{I \times X}$;
 - whose **morphisms** are triples $(I, X, \alpha) \xrightarrow{(f_0, f_1, \phi)} (J, Y, \beta)$, where $I \xrightarrow{f_0} J$ and $I \times Y \xrightarrow{f_1} X$ are arrows of \mathbf{B} and $\alpha(i, f_1(i, y)) \xrightarrow{\phi} \beta(f_0(i), y)$ is a morphism of the fibre category $\mathbf{E}_{I \times X}$.
- Again, the category $\mathfrak{P}\text{rod}(\mathfrak{p})$ is fibred over \mathbf{B} via first component projection and this fibration is denoted by $\mathfrak{P}\text{rod}(\mathfrak{p}): \mathfrak{P}\text{rod}(\mathfrak{p}) \rightarrow \mathbf{B}$ and called **simple product completion** of \mathfrak{p} . The intuition behind this definition is that an object (I, X, α) of the fibre category $\mathfrak{P}\text{rod}(\mathfrak{p})_I$ represents a formula $(\forall x : X)\alpha(i, x)$.

► **Proposition 3.4** (Hofstra [11]). *There is an isomorphism of fibrations:*

$$\mathfrak{P}\text{rod}(\mathfrak{p}) \cong \mathfrak{S}\text{um}(\mathfrak{p}^{\text{op}})^{\text{op}}$$

which is natural in \mathfrak{p} .

Here one has to recall that \mathfrak{p}^{op} stands for the *fibrewise opposite* of \mathfrak{p} , see [13] or [11, Def. 2.8].

Again, the assignment $\mathfrak{p} \mapsto \mathfrak{P}\text{rod}(\mathfrak{p})$ extends to a co-KZ pseudo-monad on the 2-category of cloven split fibrations, and its 2-category of pseudo-algebras is equivalent to the 2-category of fibrations with simple products, see [11, Theorem 3.12].

We conclude this section by recalling the presentation of the Dialectica construction and its presentation via the product-coproduct completions.

Dialectica construction. Let $\mathfrak{p}: \mathbf{E} \rightarrow \mathbf{B}$ be a fibration. Define a category $\mathfrak{D}\text{ial}(\mathfrak{p})$ as follows:

- **objects** are quadruples (I, X, U, α) where I, X and U are objects of the base category \mathbf{B} and $\alpha \in \mathbf{E}_{I \times X \times U}$ is an objects of the fibre of \mathfrak{p} over $I \times X \times U$;
- a **morphism** from (I, X, U, α) to (J, Y, V, β) is a quadruple (f, f_0, f_1, ϕ) where

87:10 The Gödel Fibration

1. $I \xrightarrow{f} J$ is a morphism in \mathbf{B} ;
2. $I \times X \xrightarrow{f_0} Y$ is a morphism in \mathbf{B} ;
3. $I \times X \times V \xrightarrow{f_1} U$ is a morphism in \mathbf{B} ;
4. $\alpha(i, x, f_1(i, x, v)) \xrightarrow{\phi} \beta(f(i), f_0(i, x), v)$ is an arrow in the fibre over $I \times X \times V$.

This is a fibration on \mathbf{B} with the projection on the first component. Hofstra's key observation is that the construction of the fibration $\mathfrak{Dial}(\mathfrak{p})$ can be decomposed in two steps.

► **Lemma 3.5** (Hofstra [11]). *There is an isomorphism of fibrations, natural in \mathfrak{p} :*

$$\mathfrak{Dial}(\mathfrak{p}) \cong \mathfrak{Sum}(\mathfrak{Prod}(\mathfrak{p})).$$

Notice that the pseudo-functor $\mathfrak{Sum}(\mathfrak{Prod}(-))$ is not a pseudo-monad in general, but, in the case the base category \mathbf{B} of a fibration $\mathfrak{p}: \mathbf{E} \rightarrow \mathbf{B}$ is cartesian closed, one can show that there exists a pseudo-distributive law

$$\mathfrak{Prod}\mathfrak{Sum} \xrightarrow{\lambda} \mathfrak{Sum}\mathfrak{Prod}$$

of pseudo-monads, see [11, Theorem 4.4]. Therefore, by the known equivalence between liftings of pseudo-monads and pseudo-distributive laws, see for example [21, 22], in this case we have that $\mathfrak{Sum}(\mathfrak{Prod}(-))$ is a pseudo-monad.

A notably advantage of this algebraic presentation of the dialectica construction, is that the principle of Skolemisation is represented by the pseudo-distributive law λ .

► **Theorem 3.6** (Hofstra [11]). *When the base category \mathbf{B} of a fibration \mathfrak{p} is cartesian closed, the fibration $\mathfrak{Dial}(\mathfrak{p})$ satisfies the principle*

$$\forall x \exists y \alpha(i, x, y) \cong \exists f \forall x \alpha(i, x, fx)$$

for every α .

4 An intrinsic characterization of Dialectica fibrations

The main goal of this section is to connect the notion of Gödel fibration with that of Dialectica construction, proving that a given fibration \mathfrak{p} is an instance of the Dialectica construction, i.e. there exists a fibration \mathfrak{p}' such that $\mathfrak{p} \cong \mathfrak{Dial}(\mathfrak{p}')$, if and only if \mathfrak{p} is a Gödel fibration. This result allows us to give an intrinsic definition of a Dialectica fibration because it shows which *properties* an arbitrary fibration should satisfy to be an instance of the Dialectica construction. Moreover, our proof of this equivalence is constructive, in the sense that when \mathfrak{p} is a Gödel fibration, we are able to explicitly define and construct the fibration \mathfrak{p}' such that $\mathfrak{p} \cong \mathfrak{Dial}(\mathfrak{p}')$.

To show this, we take the advantage of Hofstra's decomposition $\mathfrak{Dial}(-) \cong \mathfrak{Sum}(\mathfrak{Prod}(-))$, and we start by showing how fibrations which are instances of the free construction $\mathfrak{Sum}(-)$ (and $\mathfrak{Prod}(-)$) can be described in terms of fibrations with \coprod -quantifier-free objects (and \prod -quantifier-free objects).

► **Proposition 4.1.** *Let $\mathfrak{p}: \mathbf{E} \rightarrow \mathbf{B}$ be a fibration, and let us consider the simple coproduct completion $\mathfrak{Sum}(\mathfrak{p})$. Let I be an object of \mathbf{B} and let α be an object of its fibre \mathbf{E}_I . Then every object of the form $(I, 1, \alpha)$ in the fibre $\mathfrak{Sum}(\mathfrak{p})_I$ is a \coprod -quantifier-free element of $\mathfrak{Sum}(\mathfrak{p})$. Moreover, the \coprod -quantifier-free objects of $\mathfrak{Sum}(\mathfrak{p})$ are up to isomorphism the elements of the form $(I, 1, \alpha)$.*

Proof. First we prove that every element of the form $(I, 1, \alpha)$ is a \coprod -quantifier-free object. Let us consider an arrow

$$\eta_{\mathfrak{p}}(\alpha) = (I, 1, \alpha) \xrightarrow{(f, \phi)} \coprod_{\pi_I} (I \times A, B, \beta)$$

where $I \xrightarrow{f = \langle g_1, g_2 \rangle} A \times B$. We are going to prove that

$$\eta_{\mathfrak{p}}(\alpha) \xrightarrow{(g_2, \phi)} \langle 1_I, g_1 \rangle^* (I \times A, B, \beta)$$

is an arrow of $\mathfrak{S}\text{um}(\mathfrak{p})_I$ and that $(f, \phi) = (\langle 1_I, g_1 \rangle^* \eta_{\beta})(g_2, \phi)$, where η_{β} is the unit at $(I \times A, B, \beta)$ of the adjunction $\coprod_{\pi_I} \dashv \pi_I^*$.

Moreover, we have to prove that such a choice of arrows $I \xrightarrow{g} A$ of \mathfrak{B} and $\eta_{\mathfrak{p}}(\alpha) \xrightarrow{\bar{h}} \langle 1_I, h \rangle^* (I \times A, B, \beta)$ of $\mathfrak{S}\text{um}(p)_I$ is unique. That is, whenever the equality:

$$(f, \phi) = (\langle 1_I, g \rangle^* \eta_{\beta}) \bar{h}$$

holds, it is the case that $g = g_1$ and $\bar{h} = (g_2, \phi)$.

By Remarks 3.1 and 3.2, it is the case that $\coprod_{\pi_I} (I \times A, B, \beta) = (I, A \times B, \beta)$, and that $\langle 1_I, g_1 \rangle^* (I, A \times B, \beta) = (I, B, \langle \pi_I, g_1 \pi_I, \pi_B \rangle^* \beta)$, where π_I and π_B are the projections from $I \times B$. Then:

$$\eta_{\mathfrak{p}}(\alpha) \xrightarrow{(g_2, \phi)} \langle 1_I, g_1 \rangle^* (I \times A, B, \beta) = (I, B, \langle \pi_I, g_1 \pi_I, \pi_B \rangle^* \beta)$$

is a morphism of $\mathfrak{S}\text{um}(\mathfrak{p})_I$ since $I \xrightarrow{g_2} B$ is an arrow of \mathfrak{B} and:

$$\alpha \xrightarrow{\phi} \langle 1_I, g_2 \rangle^* \langle \pi_I, g_1 \pi_I, \pi_B \rangle^* \beta = \langle 1_I, g_1, g_2 \rangle^* \beta = \langle 1_I, f \rangle^* \beta$$

is a vertical morphism of \mathfrak{E}_I . Observe that η_{β} is the transpose along the adjunction $\coprod_{\pi_I} \dashv \pi_I^*$ of the identity arrow of $(I, A \times B, \beta) = \coprod_{\pi_I} (I \times A, B, \beta)$. Hence η_{β} is the arrow:

$$(I \times A, B, \beta) \xrightarrow{(\pi_{A \times B}, 1_{\beta})} (I \times A, A \times B, \langle \pi_I, \pi_{A \times B} \rangle^* \beta)$$

and its $\langle 1_I, g_1 \rangle$ -reindexing is the arrow:

$$(I, B, \langle \pi_I, g_1 \pi_I, \pi_B \rangle^* \beta) \xrightarrow{(\langle g_1 \pi_I, \pi_B \rangle, 1_{\langle \pi_I, g_1 \pi_I, \pi_B \rangle^* \beta})} (I, A \times B, \beta)$$

whose precomposition by (g_2, ϕ) yields indeed the arrow (f, ϕ) .

Let us assume that the equality:

$$(f, \phi) = (\langle 1_I, g \rangle^* \eta_{\beta}) \bar{h} \tag{1}$$

holds for some arrow $I \xrightarrow{g} A$ of \mathfrak{B} and $\eta_{\mathfrak{p}}(\alpha) \xrightarrow{\bar{h} = (h_2, \psi)} \langle 1_I, h \rangle^* (I \times A, B, \beta)$ of $\mathfrak{S}\text{um}(p)_I$. As it is the case that:

$$\langle 1_I, g \rangle^* \eta_{\beta} = (\langle g \pi_I, \pi_B \rangle, 1_{\langle \pi_I, g \pi_I, \pi_B \rangle^* \beta})$$

one might compute the right-hand side of the equality (1) and infer the equality:

$$(f, \phi) = (\langle g, h_2 \rangle, \psi)$$

which implies that $g = g_1$ and $\bar{h} = (h_2, \psi) = (g_2, \phi)$.

87:12 The Gödel Fibration

Finally, notice that Whenever f is an arrow $A \rightarrow I$ of \mathbf{B} , it is the case that the f -reindexing of $(I, 1, \alpha)$ is the triple $(A, 1, f^*\alpha)$, which is still a *quantifier-free formula*, that is, its second component is terminal in \mathbf{B} .

Conversely, let us assume that the triple (I, A, α) is \coprod -quantifier-free and let us consider its identity arrow $(I, A, \alpha) \rightarrow (I, A, \alpha) = \coprod_{\pi_I} (I \times A, 1, \alpha)$. By \coprod -quantifier-freeness, there are an arrow $I \xrightarrow{g} A$ of \mathbf{B} and an arrow:

$$(I, A, \alpha) \xrightarrow{(I \times A \xrightarrow{1} 1, \alpha \xrightarrow{\phi} \pi_I^* \langle 1_I, g \rangle^* \alpha = \langle \pi_I, g \pi_I \rangle^* \alpha)} \langle 1_I, g \rangle^* (I \times A, 1, \alpha) = (I, 1, \langle 1_I, g \rangle^* \alpha)$$

of $\mathfrak{S}\text{um}(\mathfrak{p})_I$ such that the identity arrow $(\pi_A, 1_\alpha)$ of (I, A, α) equals the composition:

$$\left((I, A, \alpha) \xrightarrow{(I \times A \xrightarrow{1} 1, \phi)} (I, 1, \langle 1_I, g \rangle^* \alpha) \xrightarrow{(g, 1_{\langle 1_I, g \rangle^* \alpha})} (I, A, \alpha) \right)$$

where the pair $(g, 1_{\langle 1_I, g \rangle^* \alpha})$ is nothing but the $\langle 1_I, g \rangle$ -reindexing of the unit at $(I \times A, 1, \alpha)$ of the adjunction $\coprod_{\pi_I} \dashv \pi_I^*$. We infer by this arrow equality that it needs to be the case that $(I \times A \xrightarrow{\pi_A} A) = (I \times A \xrightarrow{\pi_I} I \xrightarrow{g} A)$ and that:

$$(\alpha \xrightarrow{\phi} \langle \pi_I, g \pi_I \rangle^* \alpha = \langle \pi_I, \pi_A \rangle^* \alpha = \alpha \xrightarrow{1_\alpha} \alpha) = 1_\alpha$$

which means that $\phi = 1_\alpha$. Finally we observe that the composition:

$$(I, 1, \langle 1_I, g \rangle^* \alpha) \xrightarrow{(g, 1_{\langle 1_I, g \rangle^* \alpha})} (I, A, \alpha) \xrightarrow{(I \times A \xrightarrow{1} 1, \phi = 1_\alpha)} (I, 1, \langle 1_I, g \rangle^* \alpha)$$

equals the identity arrow $(I \times 1 \xrightarrow{1} 1, 1_{\langle 1_I, g \rangle^* \alpha})$. This concludes that the pair $(I \times A \xrightarrow{1} 1, 1_\alpha)$ is actually an isomorphism $(I, A, \alpha) \cong (I, 1, \langle 1_I, g \rangle^* \alpha)$. \blacktriangleleft

► **Remark 4.2.** Let $\mathfrak{p}: \mathbf{E} \rightarrow \mathbf{B}$ be a fibration and let I be an object of \mathbf{B} . Let us consider an arrow $(I, A, \alpha) \xrightarrow{(f, \phi)} (I, B, \beta)$ of $\mathfrak{S}\text{um}(\mathfrak{p})_I$. W.l.o.f we can assume (I, A, α) to be of the form $\coprod_{\pi_I} (I \times A, 1, \alpha)$, see Remark 3.3, so we might consider its transpose $(I \times A, 1, \alpha) \xrightarrow{(1_{I \times A}, f, \phi)} \pi_I^* (I, B, \beta) = (I \times A, B, \langle \pi_I, \pi_B \rangle^* \beta)$, which is the unique arrow making the following diagram:

$$\begin{array}{ccc} \coprod_{\pi_I} (I \times A, 1, \alpha) & \xrightarrow{(1_{I \times A}, f, \phi)} & (I, B, \beta) \\ \coprod_{\pi_I} (1_{I \times A}, f, \phi) \downarrow & \nearrow \varepsilon_{(I, B, \beta)} & \\ \coprod_{\pi_I} \pi_I^* (I, B, \beta) & & \end{array}$$

commute. Moreover, as $(I \times A, B, \langle \pi_I, \pi_B \rangle^* \beta) = \coprod_{\pi_{I \times A}} (I \times A \times B, 1, \langle \pi_I, \pi_B \rangle^* \beta)$, see Proposition 4.1, the arrow $(1_{I \times A}, f, \phi)$ factors uniquely as the arrow:

$$(I \times A, 1, \alpha) \xrightarrow{(1, \phi)} \langle 1_{I \times A}, f \rangle^* (I \times A \times B, 1, \langle \pi_I, \pi_B \rangle^* \beta) = (I \times A, 1, \langle \pi_I, f \rangle^* \beta)$$

(which can be uniquely expressed as the image $(\bar{\mathfrak{p}} \hookrightarrow \mathfrak{S}\text{um}(\bar{\mathfrak{p}}))\phi$ of the arrow $\alpha \xrightarrow{\phi} \langle \pi_I, f \rangle^* \beta$ of $\bar{E}_{I \times A}$) followed by the arrow:

$$(I \times A, 1, \langle \pi_I, f \rangle^* \beta) \xrightarrow{\langle 1_{I \times A}, f \rangle^* \eta_{(I \times A \times B, 1, \langle \pi_I, \pi_B \rangle^* \beta)}} \coprod_{\pi_{I \times A}} (I \times A \times B, 1, \langle \pi_I, \pi_B \rangle^* \beta)$$

which is the $\langle 1_{I \times A}, f \rangle$ -reindexing of the unit:

$$(I \times A \times B, 1, \langle \pi_I, \pi_B \rangle^* \beta) \xrightarrow{\eta_{(I \times A \times B, 1, \langle \pi_I, \pi_B \rangle^* \beta)}} (I \times A \times B, B, \langle \pi_I, \pi_B \rangle^* \beta)$$

of the adjunction $\coprod_{\pi_{I \times A}} \dashv \pi_{I \times A}^*$.

Notice that in Proposition 4.1 the elements of the form $(I, 1, \alpha)$ represent propositions which are free from the existential quantifier.

► **Remark 4.3.** The analogous of Remark 4.2 can be proved for a fibration having enough \coprod -quantifier-free objects. In other words, in this kind of fibration the arrows of the fibres are completely described by arrows between quantifier-free objects, unit and counit of adjunctions given by coproducts.

Now we have all the tools to give an *intrinsic* description of the free-algebras for the pseudo-monad which adds the simple coproducts to a given fibration.

► **Theorem 4.4.** *A fibration $\mathfrak{p}: \mathbf{E} \rightarrow \mathbf{B}$ with simple coproducts is an instance of simple coproduct completion if and only if it has enough \coprod -quantifier-free objects. Moreover, in this case $\mathfrak{p} \cong \mathfrak{S}\mathfrak{u}\mathfrak{m}(\mathfrak{p}')$ where \mathfrak{p}' is the subfibration of \coprod -free-quantifiers objects of \mathfrak{p} .*

Proof. We define $\mathfrak{p}': \mathbf{E}' \rightarrow \mathbf{B}$ the full-subfibration of $\mathfrak{p}: \mathbf{E} \rightarrow \mathbf{B}$ such that the objects of \mathbf{E}' are the \coprod -quantifier-free objects. By the universal property of the inclusion morphism $\mathfrak{p}' \hookrightarrow \mathfrak{S}\mathfrak{u}\mathfrak{m}(\mathfrak{p})$, there is unique a morphism of fibrations with simple coproducts $F: \mathfrak{S}\mathfrak{u}\mathfrak{m}(\mathfrak{p}') \rightarrow \mathfrak{p}$ commuting with the inclusion morphisms $\mathfrak{p}' \xrightarrow{\eta_{\mathfrak{p}'}} \mathfrak{S}\mathfrak{u}\mathfrak{m}(\mathfrak{p}')$ and $\mathfrak{p}' \hookrightarrow \mathfrak{p}$. We claim that F is an equivalence of fibrations. Firstly we observe that F is essentially surjective and then we show that it is fully faithful. From now on, whenever π is a projection in \mathbf{B} , we indicate as \coprod_{π} the left adjoint to the π -weakening w.r.t. $\mathfrak{S}\mathfrak{u}\mathfrak{m}(\mathfrak{p}')$ and as \sum_{π} the one w.r.t. \mathfrak{p} . Observe that:

$$F(I, 1, \gamma) = F(\mathfrak{p}' \xrightarrow{\eta_{\mathfrak{p}'}} \mathfrak{S}\mathfrak{u}\mathfrak{m}(\mathfrak{p}'))\gamma = (\mathfrak{p}' \hookrightarrow \mathfrak{p})\gamma = \gamma$$

for every I in \mathbf{B} and every γ in \mathbf{E}'_I .

Essential surjectivity. Let α be an object of \mathbf{E} and let I be the object $\mathfrak{p}\alpha$ of \mathbf{B} . Since \mathfrak{p} has enough \coprod -quantifier-free objects, there are J in \mathbf{B} and β in $\mathbf{E}_{I \times J}$ such that $\sum_{\pi_I} \beta \cong \alpha$. Since F preserves simple coproducts, it is the case that:

$$F(I, J, \beta) = F \coprod_{\pi_I} (I \times J, 1, \beta) = \sum_{\pi_I} F(I \times J, 1, \beta) = \sum_{\pi_I} \beta$$

and we are done. Observe that (I, J, β) is an object of \mathbf{E}_I , hence the functor $\mathbf{E}_I \rightarrow \mathbf{E}'_I$ induced by F is essentially surjective as well.

Full faithfulness. It suffices to prove that the morphism F of fibrations over \mathbf{B} gives rise to an equivalence $\mathbf{E}_I \rightarrow \mathbf{E}'_I$, for any given object I of \mathbf{B} (see [13]). As the essential surjectivity of $F \upharpoonright_{\mathbf{E}_I}: \mathbf{E}_I \rightarrow \mathbf{E}'_I$ follows by the previous part, we only need to observe its full faithfulness.

By Remark 4.2 we write a given arrow $(I, A, \alpha) \xrightarrow{(f, \phi)} (I, B, \beta)$ of \mathbf{E}_I as the composition:

$$\varepsilon_{(I, B, \beta)} \left(\coprod_{\pi_I} \langle 1_{I \times A}, f \rangle^* \eta_{(I \times A \times B, 1, \langle \pi_I, \pi_B \rangle^* \beta)} \right) \left(\coprod_{\pi_I} (\mathfrak{p}' \hookrightarrow \mathfrak{S}\mathfrak{u}\mathfrak{m}(\mathfrak{p}')) \phi \right)$$

and this factorisation is unique, because of the uniqueness of adjoint transposition, because of the uniqueness-part of Proposition 4.1 and because of faithfulness of the functor $\mathfrak{p}' \hookrightarrow \mathfrak{S}\mathfrak{u}\mathfrak{m}(\mathfrak{p}')$. As F is forced to preserve simple coproducts and commutes with the inclusion morphisms $\mathfrak{p}' \xrightarrow{\eta_{\mathfrak{p}'}} \mathfrak{S}\mathfrak{u}\mathfrak{m}(\mathfrak{p}')$ and $\mathfrak{p}' \hookrightarrow \mathfrak{p}$, the arrow $F(f, \phi)$ equals the composition:

$$\varepsilon_{(\sum_{\pi_I} \beta)} \left(\sum_{\pi_I} \langle 1_{I \times A}, f \rangle^* \eta_{(\pi_I, \pi_B)^* \beta} \right) \left(\sum_{\pi_I} \phi \right)$$

which is indeed an arrow $\sum_{\pi_I} \alpha \rightarrow \sum_{\pi_I} \beta$. Observe that, analogously, every arrow $\sum_{\pi_I} \alpha \rightarrow \sum_{\pi_I} \beta$ of \mathbf{E}'_I can be uniquely factored as such a composition, again by the existence and the uniqueness of the adjoint transposition, by Definition 2.2 (recall that \mathbf{p} is assumed to have \llbracket -quantifier-free objects) and by full faithfulness of $\mathbf{p}' \hookrightarrow \mathbf{p}$. Hence the function:

$$\mathbf{E}_I((I, A, \alpha), (I, B, \beta)) \rightarrow \mathbf{E}'_I\left(\sum_{\pi_I} \alpha, \sum_{\pi_I} \beta\right)$$

induced by $F \upharpoonright_{\mathbf{E}_I}$ is bijective, i.e. $F \upharpoonright_{\mathbf{E}_I}$ is fully faithful. \blacktriangleleft

Notice that the characterization of Theorem 4.4 can be obtained also for the simple product completion because of the equivalence the equivalence $\mathfrak{Prod}(\mathbf{p}) \cong \mathfrak{Sum}(\mathbf{p}^{\text{op}})^{\text{op}}$, see Proposition 3.4.

► **Theorem 4.5.** *A fibration $\mathbf{p}: \mathbf{E} \rightarrow \mathbf{B}$ with simple products is an instance of simple product completion if and only if it has enough \llbracket -quantifier-free objects. Moreover, in this case $\mathbf{p} \cong \mathfrak{Prod}(\mathbf{p}'')$ where \mathbf{p}'' is the subfibration of \llbracket -free-quantifiers objects of \mathbf{p} .*

Proof. It follows by Theorem 4.4 and Proposition 3.4. \blacktriangleleft

Combining Lemma 3.5, Theorem 4.4 and Theorem 4.5 we can prove the main result of our work, which allows us to recognize if an arbitrary fibration \mathbf{p} is an instance of the Dialectica construction or not, and if it is, we can construct the fibration $\bar{\mathbf{p}}$ such that $\mathfrak{Dial}(\bar{\mathbf{p}}) \cong \mathbf{p}$.

► **Theorem 4.6.** *Let $\mathbf{p}: \mathbf{E} \rightarrow \mathbf{B}$ be a fibration with products, coproducts and such that \mathbf{B} is cartesian closed. Then there exists a fibration $\bar{\mathbf{p}}$ such that for $\mathfrak{Dial}(\bar{\mathbf{p}}) \cong \mathbf{p}$ if and only if \mathbf{p} is a Gödel fibration.*

Proof. By Lemma 3.5 we have that $\mathfrak{Dial}(-) \cong \mathfrak{Sum}(\mathfrak{Prod}(-))$. Therefore, the result follows from Theorem 4.5 and Theorem 4.4 by directly rephrasing the sequential application of these results. \blacktriangleleft

► **Remark 4.7.** Notice that from a pure categorical perspective Theorem 4.6 provides a characterization of the free-algebras of the pseudo-monad $\mathfrak{Dial}(-)$.

5 Conclusion

Our results develop the original Dialectica construction from both a categorical and logical perspectives, which contributes to a deeper understanding of the construction.

Our main result Theorem 4.6, provides an internal characterization of fibrations which are instances of the Dialectica construction, highlighting the key features a fibration should satisfy, namely it must be a Gödel fibration, to be an instance of the Dialectica construction.

Our presentation in terms of Gödel fibrations underlines a double nature of Dialectica fibrations: they satisfy principles which are typical of classical logic, such as the existence of a prenex normal form presentation for formulae, but they also satisfy principles normally associated to intuitionistic logic. For example, they satisfy the existence of terms witnessing a proof: for every proof of $\alpha \vdash \exists x \beta(x)$ where α is quantifier-free, we have a proof of $\alpha \vdash \beta(t)$ for some term t .

Dialectica-like constructions are pervasive in several areas of mathematics and computer science, and we briefly describe some future work, based on our previous analysis. We wonder if the decomposition introduced by Hofstra can be extended or modified to provide similar results for *cousins* of the Dialectica construction. In particular, we believe that this decomposition, combined with the results presented in [23], could be generalized to the context of dependent type theory.

There are two fibrations which seem to share common features with the Dialectica construction. In particular, we would like to investigate and compare the fibrations arising from work by Abramsky and Väänänen [1] on the Hodges semantics for independence-friendly logic and the Dialectica tripos, which is a model of separation logic [3].

Finally, the strong constructive features of Dialectica fibrations we have shown suggest that these kinds of fibrations could lead to interesting applications in constructive foundations for mathematics and proof theory.

Abstract

We introduce three general compositionality criteria over operational semantics and prove that, when all three are satisfied together, they guarantee weak bisimulation being a congruence. Our work is founded upon Turi and Plotkin’s mathematical operational semantics and the coalgebraic approach to weak bisimulation by Brengos. We demonstrate each criterion with various examples of success and failure and establish a formal connection with the simply WB cool rule format of Bloom and van Glabbeek. In addition, we show that the three criteria induce lax models in the sense of Bonchi et al.

1 Introduction

The problem of *full abstraction* for programming language semantics [21, 13], i.e. the perfect agreement between a denotational and an operational specification, has been both significant and enduring. It requires that the denotational semantics, which bestows each program with a denotation, a meaning, is sufficiently coarse that it does not distinguish terms behaving the same operationally. At the same time, the denotational semantics must remain a *congruence* [36], to make the semantics *compositional*: the denotation of a composite term is fully determined by the denotations of its subterms irrespective of their internal structure.

From an operational point of view, the choice of behavioral equivalence is generally open. Bisimilarity, trace equivalence, weak bisimilarity etc. are all potentially applicable. However, bisimilarity is often too strong for practical purposes. For instance, labelled transition systems [39] (LTS) may perform invisible steps which are not ignored by bisimilarity as opposed to *weak* bisimilarity [18, 19]. This is taken a step further in programming language semantics, where a natural definition of program equivalence is that of the *largest adequate* (w.r.t. observing termination) *congruence* relation [25]. This relation is also known as *contextual equivalence*, the crown jewel of program equivalences, and can be reformulated in a more explicit manner as *Morris-style* contextual equivalence [20, 13, 24], i.e. indistinguishability under all program contexts.

Despite being the subject of vigorous research, proving that coarser behavioral equivalences are congruences remains a hard problem. Weak bisimilarity in particular stands out as a popular equivalence that has seen widespread usage in the literature yet has been proven hard to reason with [30, 31, 3]. To that end, various powerful methods exist for proving congruence-closedness of bisimilarity, like Howe’s method [15, 16] and *logical relations* [10, 22, 23], yet the machinery involved is complicated and non-trivial to execute correctly. In addition, there have been the so-called *cool congruence formats* for weak bisimulation introduced by Bloom [4] and van Glabbeek [37] that ensure weak bisimilarity being a congruence, but only if the semantics adhere to the rule formats.

In this work, we propose three general *compositionality criteria* over operational specifications that, when all three are satisfied, guarantee weak bisimilarity being a congruence. The foundation of our approach is categorical: on the one hand, the framework of *mathematical operational semantics* introduced by Turi and Plotkin [35] acts as an ideal abstract setting to explore programming language semantics. On the other hand, the coalgebraic approach introduced by Brengos [8, 9] describes a seamless way to define weak bisimulation in categories of coalgebras, should the underlying behavior be monadic and equipped with an order structure. With that in mind, the three criteria, which we name *continuity*, *unitality* and *observability*, essentially characterize how the semantics interact with the order structure of the behavior.

Related work

As mentioned earlier, Bloom and van Glabbeek have introduced the cool congruence formats; weak bisimulation for any system given in these formats is guaranteed to be a congruence. In this work we are also able to establish a formal connection with the *simply WB cool* format for LTSs (Theorem 3.16), specifically that any system given in the simply WB cool rule format automatically satisfies the three criteria. In that sense, our three criteria form a broader, less restrictive approach on the same problem (extended beyond LTSs). Furthermore, the many examples provided by van Glabbeek [37] help explain this connection and at the same time act as excellent hands-on case studies for our three criteria.

Apart from the aforementioned work of Brengos, various approaches at the hard problem of coalgebraic weak bisimulation have been proposed [27, 29, 12, 5]. Of particular interest is the work of Bonchi et al. [6] on up-to techniques [7] for weak bisimulations in the context of mathematical operational semantics. The main theoretical device in their work is that of a *lax model*, a relaxation of the notion of a *bialgebra*. We relate lax models with our work by showing that specifications satisfying the three criteria induce lax models (Theorem 3.21) and argue that, as a formal method, our criteria are significantly easier to prove.

Paper outline

In Section 2.1 we introduce Turi and Plotkin’s mathematical operational semantics [35] as well as the two “running” example systems used throughout the paper. In Section 2.2 we present the work of Brengos on weak bisimulation [8, 9] and show how it applies to our two examples. We expand on our contribution in Section 3, where we introduce the three criteria and put them to the test against our main examples as well as examples from van Glabbeek [37]. We subsequently formalize the connection of our three criteria with the simply WB cool rule format (Theorem 3.16) and then move on to present our main theorem (Theorem 3.18). Finally, in Section 3.3 we show how our three criteria induce lax models in the sense of Bonchi et al. [6].

2 Preliminaries

2.1 Mathematical Operational Semantics

We first summarize the basic framework of Turi and Plotkin's *mathematical operational semantics* [35]. The idea is that operational semantics correspond to *distributive laws* of varying complexity on a base category \mathbb{C} . For our work we need only consider the most important form of distributive laws, that of *GSOS laws* [35], as they are in an 1-1 correspondence with the historically significant *GSOS rule format* [26].

► **Definition 2.1.** *Let endofunctors $\Sigma, B : \mathbb{C} \rightarrow \mathbb{C}$ on a cartesian category \mathbb{C} . A GSOS law of Σ over B is a natural transformation $\rho : \Sigma(\text{Id} \times B) \Rightarrow B\Sigma^*$, where Σ^* is the free monad over Σ .*

Endofunctors Σ and B are understood as the syntax and behavior (resp.) of a system whereas ρ represents the semantics. Over the course of the paper we will also be using an alternative representation of GSOS laws given by the following correspondence.

► **Proposition 2.2.** *GSOS laws $\rho : \Sigma(\text{Id} \times B) \Rightarrow B\Sigma^*$ are equivalent to natural transformations $\lambda : \Sigma^*(\text{Id} \times B) \Rightarrow B\Sigma^*$ respecting the structure of Σ^* as follows:*

$$\begin{array}{ccc}
 \Sigma^*\Sigma^*(\text{Id} \times B) & \xrightarrow{\Sigma^*(\Sigma^*\pi_1, \lambda)} & \Sigma^*(\text{Id} \times B)\Sigma^* & \xrightarrow{\lambda_{\Sigma^*}} & B\Sigma^*\Sigma^* & & \text{Id} \times B & & \\
 \downarrow \mu_{(\text{Id} \times B)} & & & & \downarrow B\mu & & \eta_{(\text{Id} \times B)} \downarrow & \searrow B\eta \circ \pi_2 & \\
 \Sigma^*(\text{Id} \times B) & \xrightarrow{\lambda} & B\Sigma^* & & \Sigma^*(\text{Id} \times B) & \xrightarrow{\lambda} & B\Sigma^* & &
 \end{array}$$

► **Remark 2.3.** We shall be calling both GSOS laws ρ and natural transformations λ , as used in Proposition 2.2, *GSOS laws* for the sake of brevity.

GSOS laws induce *bialgebras*, i.e. algebra-coalgebra pairs that agree with the semantics.

► **Definition 2.4.** *A bialgebra for a GSOS law $\lambda : \Sigma^*(\text{Id} \times B) \Rightarrow B\Sigma^*$ (resp. $\rho : \Sigma(\text{Id} \times B) \Rightarrow B\Sigma^*$) is a Σ -algebra, B -coalgebra pair $\Sigma X \xrightarrow{g} X \xrightarrow{h} BX$ that commutes with λ (ρ):*

$$\begin{array}{ccc}
 \Sigma^* X \xrightarrow{g^\#} X \xrightarrow{h} BX & & \Sigma X \xrightarrow{g} X \xrightarrow{h} BX \\
 \downarrow \Sigma^*(1, h) & \uparrow Bg^\# & \downarrow \Sigma(1, h) & \uparrow Bg^\# \\
 \Sigma^*(X \times BX) \xrightarrow{\lambda} B\Sigma^* X & & \Sigma(X \times BX) \xrightarrow{\rho} B\Sigma^* X
 \end{array}$$

Where $g^\#$ is the \mathcal{EM} -algebra induced by g . A bialgebra morphism from $\Sigma X \xrightarrow{g} X \xrightarrow{h} BX$ to $\Sigma Y \xrightarrow{j} Y \xrightarrow{k} BY$ is a map $f : X \rightarrow Y$ that is both a Σ -algebra and a B -coalgebra morphism.

If $a : \Sigma A \xrightarrow{\cong} A$ is the initial Σ -algebra, the algebra of terms, and $z : Z \xrightarrow{\cong} BZ$ is the final B -coalgebra, the coalgebra of behaviors, the following proposition promotes a GSOS law to an *operational semantics* of a language, in the form of a morphism f mapping programs living in A to behaviors in Z .

► **Proposition 2.5** (From [17, 35]). *Let endofunctors $\Sigma, B : \mathbb{C} \rightarrow \mathbb{C}$ on a cartesian category \mathbb{C} such that $a : \Sigma A \xrightarrow{\cong} A$ is the initial Σ -algebra and $z : Z \xrightarrow{\cong} BZ$ is the final B -coalgebra. Every GSOS law $\lambda : \Sigma^*(\text{Id} \times B) \Rightarrow B\Sigma^*$ induces a unique initial λ -bialgebra $\Sigma A \xrightarrow{a} A \xrightarrow{h} BA$, the operational model of the language, and a unique final λ -bialgebra $\Sigma Z \xrightarrow{g} Z \xrightarrow{z} BZ$, the denotational model. In addition, there exists a unique λ -bialgebra morphism $f : A \rightarrow Z$, mapping every program in A to its behavior in Z .*

The fact that $\text{map } f : A \rightarrow Z$ is an algebra homomorphism is a fundamental well-behavedness property of GSOS laws, as it implies that bisimilarity, defined as equality under f , is a *congruence*, i.e. is respected by all syntactic operators.

The categorical interpretation of GSOS rules can be better understood by the following examples, which serve as the “running” examples of this paper.

► **Example 2.6** (A *While* language). We introduce *While*, a basic imperative language with a mutable state, whose syntax is generated by the following grammar:

$$\langle \text{prog} \rangle ::= \text{skip} \mid v := \langle \text{expr} \rangle \mid \langle \text{prog} \rangle ; \langle \text{prog} \rangle \mid \text{while } \langle \text{expr} \rangle \langle \text{prog} \rangle$$

The statements are the standard **skip**, assignment $:=$, sequential composition $;$ and **while**-loops. Expressions and assignments act on a variable store whose type we denote as S and we shall be writing $[e]_s$ to denote evaluation of an expression e under variable store s .

The syntax of *While* corresponds to the **Set**-endofunctor $\Sigma \triangleq \top \uplus (V \times \text{Exp}) \uplus \text{Id}^2 \uplus (\text{Exp} \times \text{Id})$, with the set of *While*-programs A as the carrier of the initial Σ -algebra $a : \Sigma A \xrightarrow{\cong} A$. The typical behavior functor for deterministic systems with mutable state is $[S \times (\{\checkmark\} \uplus \text{Id})]^S$, where $\{\checkmark\} \cong \top$ is populated by the element that denotes *termination*, but we will instead use $T \triangleq [\mathcal{P}_c(S \times (\{\checkmark\} \uplus \text{Id}))]^S$, where \mathcal{P}_c is the *countable* power-set monad. This way the behavior can be equipped with both a monadic and an order structure, given by inclusion (see Section 2.2), while also allowing for non-determinism. The carrier of the final coalgebra $z : Z \xrightarrow{\cong} TZ$ is the set of behaviors acting on variable stores S returning countably many new stores and possibly new behaviors.

$$\begin{array}{ccc} \text{skip} \frac{}{s, \text{skip} \rightarrow s, \checkmark} & \text{asn} \frac{}{s, v := e \rightarrow s_{[v \leftarrow [e]_s]}, \checkmark} & \text{seq1} \frac{s, p \rightarrow s', \checkmark}{s, p; q \rightarrow s', q} \\ \text{seq2} \frac{s, p \rightarrow s', p'}{s, p; q \rightarrow s', p'; q} & \text{w1} \frac{[e]_s = 0}{s, \text{while } e \text{ } p \rightarrow s, \checkmark} & \text{w2} \frac{[e]_s \neq 0 \quad q \triangleq \text{while } e \text{ } p}{s, q \rightarrow s, p; q} \end{array}$$

The above semantics determines a GSOS law $\rho : \Sigma(\text{Id} \times T) \Longrightarrow T\Sigma^*$ in the category **Set** of sets and (total) functions, or equivalently a natural transformation $\lambda : \Sigma^*(\text{Id} \times T) \Longrightarrow T\Sigma^*$. This example is covered in the literature [34, 33], but we include the definition for posterity.

► **Definition 2.7** (GSOS law of *While*).

$$\begin{array}{ll} \rho_X : \Sigma(X \times TX) & \rightarrow T\Sigma^* X \\ (x, f) ; (y, g) & \mapsto \lambda s. (\{(s', y) \mid (s', \checkmark) \in f(s)\} \cup \{(s', (x' ; y)) \mid (s', x') \in f(s)\}) \\ \text{while } e (x, f) & \mapsto \lambda s. \begin{cases} \{(s, (x ; \text{while } e \text{ } x))\} & \text{if } [e]_s \neq 0 \\ \{(s, \checkmark)\} & \text{if } [e]_s = 0 \end{cases} \\ \text{skip} & \mapsto \lambda s. \{(s, \checkmark)\} \\ v := e & \mapsto \lambda s. \{(s_{[v \leftarrow ev]}, \checkmark)\} \text{ for } ev = [e]_s \end{array}$$

To see how the semantics is connected to the GSOS law, consider rules seq1 and seq2, corresponding to the first line in ρ . Roughly, writing $s, p \rightarrow s', \checkmark$ denotes that $(s', \checkmark) \in f(s)$. The fact that $s, p \rightarrow s', \checkmark$ and $s, p \rightarrow s', q$ are rule premises is reflected in the construction of the set of transitions. Note also that q is used in the conclusion of rules seq1 and seq2. Similarly in ρ we can see that y is present in both the left and right side of ρ , which is why the shape of the behavior of subterms is $X \times TX$ rather than simply TX .

► **Example 2.8** (A simple process calculus). We introduce a simple process calculus, or *SPC* for short, based on the classic *Calculus of communicating systems* introduced by Milner [18]. Its syntax is generated by the following grammar:

$$\langle p \rangle ::= 0 \mid \delta. \langle p \rangle \mid \langle p \rangle \parallel \langle p \rangle \mid \langle p \rangle + \langle p \rangle$$

From left to right we have the *null process* 0, *prefixing* of a process p with action $\delta \in \Delta_\tau = \Delta \cup \overline{\Delta} \cup \{\tau\}$ living in a set composed of actions Δ , coactions $\overline{\Delta}$ and an *internal* action τ , *parallel composition* and finally *non-deterministic choice*.

$$\begin{array}{ccc} \text{sum1} \frac{P \xrightarrow{\delta} P'}{P + Q \xrightarrow{\delta} P'} & \text{sum2} \frac{Q \xrightarrow{\delta} Q'}{P + Q \xrightarrow{\delta} Q'} & \text{com1} \frac{P \xrightarrow{\delta} P'}{P \parallel Q \xrightarrow{\delta} P' \parallel Q} \\ \text{com2} \frac{Q \xrightarrow{\delta} Q'}{P \parallel Q \xrightarrow{\delta} P \parallel Q'} & \text{syn} \frac{\alpha \in \Delta \quad P \xrightarrow{\alpha} P' \quad Q \xrightarrow{\overline{\alpha}} Q'}{P \parallel Q \xrightarrow{\tau} P' \parallel Q'} & \text{prefix} \frac{}{\delta.P \xrightarrow{\delta} P} \end{array}$$

Similarly to Example 2.6, the semantics forms a GSOS law $\rho : \Sigma(\text{Id} \times T) \Longrightarrow T\Sigma^*$ in **Set** for $\Sigma \triangleq \top \uplus (\Delta_\tau \times \text{Id}) \uplus \text{Id}^2 \uplus \text{Id}^2$ and $T \triangleq \mathcal{P}_c(\Delta_\tau \times \text{Id})$. In this case, the carrier of the final coalgebra $z : Z \xrightarrow{\cong} TZ$ is the set of all strongly extensional (meaning that distinct children of nodes are not bisimilar), countably-branching, Δ_τ -labelled trees [2, §4].

► **Definition 2.9** (GSOS law of *SPC*).

$$\begin{array}{ll} \rho_X : \Sigma(X \times TX) & \mapsto \quad T\Sigma^* X \\ \delta.(x, W) & \mapsto \quad \{(\delta, x)\} \\ (x, X) \parallel (y, Z) & \mapsto \quad \{(\delta, (x' \parallel y)) \mid (\delta, x') \in W\} \cup \{(\delta, (x \parallel y')) \mid (\delta, y') \in Z\} \cup \\ & \quad \{(\tau, (x' \parallel y')) \mid (\alpha, x') \in W \wedge (\overline{\alpha}, y') \in Z\} \\ (x, W) + (y, Z) & \mapsto \quad W \cup Z \end{array}$$

2.2 Order-enrichment

Order-enriched categories [38] typically equip their hom-sets with an *order* structure. While there are many forms of order-enrichment, one “nice” such form that is convenient for our purposes is $\omega\text{-Cpo}_{id}^\vee$ -enrichment.

► **Definition 2.10** ([9, §2.3]). *A category \mathbb{C} is $\omega\text{-Cpo}_{id}^\vee$ -enriched when*

- *Every hom-set $\mathbb{C}(X, Y)$ carries a partial order \leq and has all finite joins \vee .*
- *Composition is left-distributive over finite joins, i.e. given any morphisms f, g, i with suitable domains and codomains, $i \circ (f \vee g) = i \circ f \vee i \circ g$.*
- *Every ascending ω -chain $f_0 \leq f_1 \leq \dots$ for $f_i \in \mathbb{C}(X, Y)$ has a supremum $\bigvee_i f_i \in \mathbb{C}(X, Y)$.*
- *Composition $- \circ - : \mathbb{C}(X, Y) \times \mathbb{C}(Y, Z) \rightarrow \mathbb{C}(X, Z)$ is continuous, meaning that for any ascending ω -chains f_i, g_i and morphisms f, g with suitable (co)domains, we have*

$$g \circ \bigvee_i f_i = \bigvee_i (g \circ f_i) \quad \text{and} \quad \left(\bigvee_i g_i \right) \circ f = \bigvee_i (g_i \circ f)$$

For reasons that will become clear in Section 2.3, we are interested in monads whose Kleisli category is $\omega\text{-Cpo}_{id}^\vee$ -enriched as we are looking to use them as behaviors in our distributive laws and exploit their order structure. Examples of such monads are the powerset \mathcal{P} [9, §4.1], the countable powerset \mathcal{P}_c [9, §4.3] and the convex combination monad \mathcal{CM} [9, §4.3].

► **Example 2.11** (Continuation of Example 2.6). The monad structure $\langle T, \eta, \mu \rangle$ for $T \triangleq [\mathcal{P}_c(S \times (\{\checkmark\} \uplus \text{Id}))]^S$ is given by $\eta(x)(s) = \{(s, x)\}$ and $\mu(f)(s) = \bigcup_{(s', g) \in f(s)} \begin{cases} (s', \checkmark) & \text{if } g = \checkmark \\ g(s') & \text{if } g \neq \checkmark \end{cases}$.

The $\omega\text{-Cpo}_{id}^\vee$ -enrichment of $\mathcal{Kl}(T)$ stems from the fact that the countable powerset monad \mathcal{P}_c is itself $\omega\text{-Cpo}_{id}^\vee$ -enriched¹. More specifically, we have $f \leq g \iff \forall x, s. f(x)(s) \subseteq g(x)(s)$, $f \vee g \triangleq \lambda x. \lambda s. [f(x)(s) \cup g(x)(s)]$ and $\bigvee_i f_i = \lambda x. \lambda s. \bigcup_i f_i(x)(s)$.

► **Example 2.12** (Continuation of Example 2.8). The monad structure $\langle T, \eta, \mu \rangle$ for $T \triangleq \mathcal{P}_c(\Delta_\tau \times \text{Id})$ was developed by Brengos [8, §4.1] as a central, demonstrative example of the role of monads in coalgebraic weak bisimulation. The unit is simply $\eta(x) = \{(\tau, x)\}$ and the join $\mu_X : \mathcal{P}_c[\Delta_\tau \times \mathcal{P}_c(\Delta_\tau \times X)] \rightarrow \mathcal{P}_c(\Delta_\tau \times X)$ is $\mu = \mu_{\mathcal{P}_c} \circ \mathcal{P}_c \mu_\Delta \circ \mu_{\mathcal{P}_c} \circ \mathcal{P}_c st$ where $st_{X,Y} : X \times \mathcal{P}_c Y \rightarrow \mathcal{P}_c(X \times Y)$ is the *tensorial strength* of \mathcal{P}_c given by

$$st_{X,Y}(x, Y) = \{(x, y) \mid y \in Y\}$$

and $\mu_\Delta : \Delta_\tau \times \Delta_\tau \times X \rightarrow \mathcal{P}_c \Delta_\tau X$ is

$$\mu_\Delta = \begin{cases} (\delta, \tau, x) \mapsto \{(\delta, x)\} \\ (\tau, \delta, x) \mapsto \{(\delta, x)\} \\ (\delta_1, \delta_2, x) \mapsto \emptyset \quad \text{when } \delta_1, \delta_2 \neq \tau. \end{cases}$$

In other words, μ will disallow any two-step transition that outputs two visible labels in a row and allow everything else, but only after redundant invisible labels are removed. The motivation behind the definition of μ will become clear in Section 2.3. As for the $\omega\text{-Cpo}_{id}^\vee$ -enrichment of $\mathcal{Kl}(T)$, it is also a consequence of $\mathcal{Kl}(\mathcal{P}_c)$ being $\omega\text{-Cpo}_{id}^\vee$ -enriched, with $f \leq g \iff f(x) \subseteq g(x)$, $f \vee g \triangleq \lambda x. [f(x) \cup g(x)]$ and $\bigvee_i f_i = \lambda x. \bigcup_i f_i(x)$.

2.3 Free monads in $\omega\text{-Cpo}_{id}^\vee$ -enriched categories

We now turn our attention to the coalgebraic approach to weak bisimulation of Brengos [8, 9]. The main idea is that given an endomorphism $\alpha : X \rightarrow X$ in an $\omega\text{-Cpo}_{id}^\vee$ -enriched category, there exists the *free monad* over α , α^* . This process, which we call the *reflexive transitive closure* of α or simply the *rt-closure* of α , can be used to derive saturated transition systems or the *multi-step* evaluation relation of a programming language.

► **Remark 2.13.** In general, a *monad* in a bicategory K is an endomorphism $\epsilon : X \rightarrow X$ equipped with 2-cells $\eta : 1_X \rightarrow \epsilon$ and $\mu : \epsilon \circ \epsilon \rightarrow \epsilon$ subject to the conditions $\mu \circ \epsilon \eta = \mu \circ \eta \epsilon = 1_\epsilon$ and $\mu \circ \epsilon \mu = \mu \circ \mu \epsilon$. One can recover the classic definition of a monad by taking the strict 2-category **Cat** of categories, functors and natural transformation as K . In order-enriched categories, where there is at most one 2-cell between morphisms, usually denoted by \leq , monads are simply endomorphisms $\epsilon : X \rightarrow X$ satisfying $1_X \leq \epsilon$ and $\epsilon \circ \epsilon \leq \epsilon$. Monads in order-enriched categories are known as *closure operators*.

► **Definition 2.14** ([9, Definition 3.6]). *An order-enriched category \mathbb{K} admits free monads if for any endomorphism $\alpha : X \rightarrow X$ there exists a monad α^* such that*

- $\alpha \leq \alpha^*$
- if $\alpha \leq \beta$ for a monad $\beta : X \rightarrow X$ then $\alpha^* \leq \beta$.

The free monad of an endomorphism in $\omega\text{-Cpo}_{id}^\vee$ -enriched categories is the least solution of a certain assignment or, equivalently, the supremum of an ascending ω -chain.

► **Proposition 2.15** ([9, §3.2]). *For an $\omega\text{-Cpo}_{id}^\vee$ -enriched category \mathbb{C} , the free monad $(-)^* : \forall X. \mathbb{C}(X, X) \rightarrow \mathbb{C}(X, X)$ of $\alpha : X \rightarrow X$ is given by $\alpha^* \triangleq \mu x. 1 \vee x \circ \alpha = \bigvee_{n < \omega} (1 \vee \alpha)^n$.*

¹ We (slightly abusively) say that a monad T is $\omega\text{-Cpo}_{id}^\vee$ -enriched whenever $\mathcal{Kl}(T)$ is.

Free monads in $\omega\text{-Cpo}_{id}^{\vee}$ -enriched categories enjoy a number of interesting properties.

► **Lemma 2.16** (Properties of free monads). *For all $\alpha : X \rightarrow X$, $\beta : Y \rightarrow Y$, we have*

- i. $\forall f : X \rightarrow Y. f \circ \alpha \leq \beta \circ f \implies f \circ \alpha^* \leq \beta^* \circ f$
- ii. $\alpha^{**} = \alpha^*$
- iii. $\alpha^* = \alpha^* \circ \alpha^*$
- iv. $1^* = 1$.

We can now revisit Example 2.6 and Example 2.8 to witness how the rt-closure acts on each operational model $h : A \rightarrow TA$. Note that throughout the paper we shall be using the notation $- \diamond -$ to denote composition in Kleisli categories.

► **Example 2.17** (Continuation of Example 2.6). The rt-closure (free monad) h^* of the operational model $h : A \rightarrow TA$ amounts to the reflexive, transitive closure of h . The initial stage $(1 \vee h)^0 = 1_{\mathcal{Kl}(T)} = \eta_A$ takes care of the *reflexive* step, while stages $(1 \vee h)^{n+1} = (1 \vee h)^n \diamond (1 \vee h) = (1 \vee h)^n \vee ((1 \vee h)^n \diamond h)$ amount to the inductive, *transitive* step, which acts according to the definition of monadic composition. For instance, $(s, \text{skip} ; \text{skip})$ weakly transitions to $(s, \text{skip} ; \text{skip})$, (s, skip) and (s, \checkmark) .

► **Example 2.18** (Continuation of Example 2.8). The rt-closure h^* amounts to the saturation of $h : A \rightarrow TA$. The unit η establishes $p \xrightarrow{\tau} p$ as a silent step in h^* for $p \in A$ whereas μ ensures that one-step transitions in the saturated system *cannot* produce more than one visible label, i.e. they will always be of the sort of $p \xrightarrow{\tau^*} q \xrightarrow{\delta} r \xrightarrow{\tau^*} s$ or $p \xrightarrow{\tau^*} q$. The reader may refer to [8, 9] for more details.

2.4 Weak bisimulation

We are now ready to define *weak bisimulation* as a special case of an *Aczel-Mendler bisimulation* [1, 32].

► **Definition 2.19.** *Let $f : X \rightarrow FX$ be a coalgebra for a functor $F : \mathbb{C} \rightarrow \mathbb{C}$. An Aczel-Mendler bisimulation, or simply bisimulation, for f is a relation $(\text{span}) X \xleftarrow{r_1} R \xrightarrow{r_2} X$ which is the carrier of a coalgebra $e : R \rightarrow FR$ that lifts to a span of coalgebra homomorphisms, i.e. making the following diagram commute.*

$$\begin{array}{ccccc} FX & \xleftarrow{Fr_1} & FR & \xrightarrow{Fr_2} & FX \\ f \uparrow & & e \uparrow & & f \uparrow \\ X & \xleftarrow{r_1} & R & \xrightarrow{r_2} & X \end{array}$$

In our setting we elect to use the “unoptimized” definition of weak bisimulation as bisimulation on a saturated system, mainly due to its simplicity. Regardless, under the mild condition that *arbitrary cotupling in $\mathcal{Kl}(T)$ is monotonic*, which is true in all of our examples, this definition of weak bisimulation coincides with the traditional one [8, §6].

► **Definition 2.20.** *Assume a coalgebra $h : X \rightarrow TX$ for an $\omega\text{-Cpo}_{id}^{\vee}$ -enriched monad $\langle T, \eta, \mu \rangle$. A weak bisimulation for h is a bisimulation for h^* .*

Two elements $x, y \in X$ are (*weakly*) *bisimilar*, written as $(x \approx y) x \sim y$, if there is a (weak) bisimulation that contains them. If $z : Z \rightarrow TZ$ is the final T -coalgebra, then for every coalgebra $h : X \rightarrow TX$ we write $h^\dagger : X \rightarrow Z$ for the unique coalgebra homomorphism from h to z and h^{\dagger} for the one from h^* to z . The following theorem presents the principle of weak coinduction, i.e. that weakly bisimilar elements are mapped to the same weak behavior.

► **Theorem 2.21** ([8, Theorem 6.8]). *Let $\langle T, \eta, \mu \rangle$ be an $\omega\text{-Cpo}_{\text{id}}^{\vee}$ -enriched monad with final coalgebra $z : Z \rightarrow TZ$. If T preserves weak pullbacks, then the greatest weak bisimulation for a coalgebra $h : X \rightarrow TX$ exists and coincides with the pullback of the equality span $\langle 1_Z, 1_Z \rangle : Z \rightrightarrows Z \times Z$ along $h^\dagger \times h^\dagger : X \times X \rightarrow Z \times Z$.*

The \dagger construction can be applied to any coalgebra, including the final coalgebra $z : Z \rightarrow TZ$. The following lemma shows that h^\dagger can also be recovered via z^\dagger and h^\dagger , a fact that will turn out to be useful in Section 3.

► **Lemma 2.22** ([8, Lemma 6.9]). *For any $h : X \rightarrow TX$, we have $h^\dagger = z^\dagger \circ h^\dagger$.*

3 Weak bisimulation congruence semantics

The theory introduced in Section 2.2 sets the stage for our three compositionality criteria, which ensure that weak bisimilarity is a congruence. In addition, we shall test the criteria on *While* and *SPC* and establish a correspondence with the simply WB cool rule format of van Glabbeek (see [37], definition also included in Appendix A), both formally and through examples, as it also guarantees weak bisimilarity being a congruence and comes with less overhead compared to the WB cool format. Finally, we shall briefly touch on the work of Bonchi et al. [6] and show that systems satisfying the three criteria induce lax models.

3.1 The three compositionality criteria

Simply put, the three criteria ensure that semantics interact with the order structure of the behavior functor in a sensible way. They are *abstract* in that they apply to any GSOS law $\lambda : \Sigma^*(\text{Id} \times T) \Longrightarrow T\Sigma^*$ when $\langle T, \eta, \mu \rangle$ is an $\omega\text{-Cpo}_{\text{id}}^{\vee}$ -enriched monad. As such, we assume the existence of such a T and λ throughout Section 3. We present and explore each criterion individually starting with the simplest of the three.

► **Criterion 1** (Continuity). *For any ascending ω -chain $f_0 \leq f_1 \leq \dots : X \rightarrow TX$ the following condition applies:*

$$\lambda \circ \Sigma^* \langle 1, \bigvee_i f_i \rangle = \bigvee_i \lambda \circ \Sigma^* \langle 1, f_i \rangle \quad (1)$$

Alternatively, we can write the above using $\rho : \Sigma(\text{Id} \times T) \Longrightarrow T\Sigma^*$ as

$$\rho \circ \Sigma \langle 1, \bigvee_i f_i \rangle = \bigvee_i \rho \circ \Sigma \langle 1, f_i \rangle. \quad (2)$$

► **Proposition 3.1.** *Equation (1) and Equation (2) are equivalent.*

We can compare Criterion 1 to the *local continuity* property of lifted functors in Kleisli categories [14, §2.3], i.e. lifted functors respecting the $\omega\text{-Cpo}_{\text{id}}^{\vee}$ -enrichment structure of the category. When it comes to semantics, the following example from van Glabbeek [37, Example 2] underlines what sort of rules may violate Criterion 1.

► **Example 3.2** (Illegal rules). Let us extend *SPC* with a new unary operator, $\llbracket \langle p \rangle \rrbracket$, subject to the following GSOS rules applying to specific actions $\alpha, b \in \Delta$:

$$\text{pos} \frac{P \xrightarrow{\tau} P'}{\llbracket P \rrbracket \xrightarrow{\tau} \llbracket P' \rrbracket} \quad \text{neg} \frac{P \xrightarrow{a} \cdot}{\llbracket P \rrbracket \xrightarrow{b} 0}$$

Rule **neg** allows a process that cannot perform an a -transition to terminate with a b -transition. This rule violates Criterion 1, which can be witnessed by testing the criterion with $(f_0(p) = \{(\tau, p')\}) \leq (f_1(p) = \{(a, q), (\tau, p')\})$, as only f_0 is able to induce a b -transition. In addition, weak bisimulation fails to be a congruence as $\tau.\alpha.0 \approx \alpha.0$ but $\lfloor \tau.\alpha.0 \rfloor \not\approx \lfloor \alpha.0 \rfloor$.

Rule **neg** in the above example includes a negative premise. A GSOS specification that has no negative premises - conclusions are never negative - is called *positive*. Positive GSOS specifications correspond to *monotone* GSOS laws (see [11] and also [6, Equation 7]), in the sense that $g \leq f \implies \lambda \circ \Sigma^* \langle 1, g \rangle \leq \lambda \circ \Sigma^* \langle 1, f \rangle$. This is weaker than continuity (Criterion 1), in that continuous GSOS laws are monotone but not the other way around, but one has to look very hard to find semantics that are monotone yet not continuous.

► **Example 3.3** (A non-continuous monotone rule). We substitute the set of visible actions of *SPC* with \mathbb{N} and define a new operator, $\lfloor _ \rfloor$, subject to rule **mon** $\frac{P \xrightarrow{\infty}}{\lfloor P \rfloor \xrightarrow{\tau} 0}$, where

$P \xrightarrow{\infty}$ denotes that P can perform an infinite number of transitions, i.e. set $\{(\delta, P') \mid P \xrightarrow{\delta} P'\}$ is infinite. Even though this is a monotone rule, it is not continuous. Consider for instance the ascending ω -chain $f_i : X \rightarrow TX$ for some set of processes X with $f_i(x) = \{(0, x), (1, x) \dots (i, x)\}$. Notice that $(\tau, x) \subseteq \lambda \circ \Sigma^* \langle 1, \bigvee_i f_i \rangle$, but $(\tau, x) \not\subseteq \bigvee_i \lambda \circ \Sigma^* \langle 1, f_i \rangle$.

► **Example 3.4** (Continuation of Example 2.6). Back to our *While* language, Criterion 1 is trivially true for all terms except for sequential composition, which is slightly more involved. In this case, we can see that $\rho_X((x, \bigvee_i f_i(x)) ; (y, \bigvee_i f_i(y)))$ is mapped to

$$\begin{aligned} \lambda s. \{ (s', y) \mid (s', \checkmark) \in \bigvee_i f_i(x)(s) \} \cup \{ (s', (x' ; y)) \mid (s', x') \in \bigvee_i f_i(y)(s) \} \\ = \lambda s. \bigvee_i \{ (s', y) \mid (s', \checkmark) \in f_i(x)(s) \} \cup \{ (s', (x' ; y)) \mid (s', x') \in f_i(y)(s) \}, \end{aligned}$$

which is precisely $\bigvee_i (\rho_X((x, f_i(x)) ; (y, f_i(y))))$.

► **Example 3.5** (Continuation of Example 2.8). The transitions of prefix expressions such as δP are, for any given P , independent of (the transitions of) P thus the prefix rule is trivially continuous. Transitions for parallel composition and non-deterministic choice are basically unions of transitions of their subterms and hence satisfy Criterion 1.

► **Criterion 2** (Unitality). For any $f : X \rightarrow TX$,

$$\begin{array}{ccc} \Sigma^* X & \xrightarrow{(\lambda_X \circ \Sigma^* \langle 1, f \rangle)^*} & \\ \Sigma^* \langle 1, \eta_X \vee f \rangle \downarrow & \leq & \\ \Sigma^* (X \times TX) & \xrightarrow{\lambda_X} & T\Sigma^* X \end{array}$$

This criterion characterizes how the semantics deal with internal steps, here represented by the monadic unit η . The right path on the diagram represents the rt-closed (weak) transitions of a composite term, the subterms of which (strongly) transition according to f . On the other hand, the left path represents the strong transitions of a composite term, the subterms of which may also perform internal steps. This criterion, which somewhat resembles the identity condition for lifting functors to Kleisli categories [14, §2.2], dictates that adding arbitrary internal steps to subterms should not lead to extraneous, meaningful observations.

88:10 Abstract Congruence Criteria for Weak Bisimilarity

► **Remark 3.6.** A slightly stronger but simpler formulation of Criterion 2 based on ρ is

$$\begin{array}{ccc} \Sigma X & \xrightarrow{(\rho_X \circ \Sigma\langle 1, f \rangle) \vee (\eta_X \circ \theta_X)} & \\ \Sigma\langle 1, \eta_X \vee f \rangle \downarrow & \leq & \\ \Sigma(X \times TX) & \xrightarrow{\rho_X} & T\Sigma^* X \end{array}$$

where $\theta : \Sigma \Longrightarrow \Sigma^*$ is the universal natural transformation sending Σ to its free monad. Compared to the original criterion, which asks for the transitions induced by internal steps to *eventually* appear on the right side, this version asks for said transition to appear either on *step 0*, the *reflexive*, identity step (hence the added $\eta_X \circ \theta_X$), or *step 1*, i.e. the transitions induced immediately by f . We can apply similar logic to Proposition 3.1 to show that this version of Criterion 2 is stronger.

Criterion 2 works in the same way as the “patience rule” requirement of the simply WB cool rule format [37, Definition 8, item 2], which dictates that the only rules with τ -premises are patience rules. For instance, the patience rule for a unary operator $o(p)$ is $\frac{p \xrightarrow{\tau} p'}{o(p) \xrightarrow{\tau} o(p')}$. It is clear that patience rules are achieving the same effect of forcing composite terms to *only* relay silent steps of subterms.

► **Example 3.7** ([37, Example 4]). We extend SPC with $\lfloor _ \rfloor$ and introduce the following impatient rules:

$$\text{pat} \frac{P \xrightarrow{\tau} P'}{\lfloor P \rfloor \xrightarrow{\tau} \lfloor P' \rfloor} \quad \text{imp} \frac{P \xrightarrow{\tau} P'}{\lfloor P \rfloor \xrightarrow{c} \lfloor P' \rfloor}$$

Rule **imp** violates Criterion 2, as taking $f = \lambda x. \emptyset$ will not induce the c -transition present in the left path. Weak bisimulation fails to be a congruence as $0 \approx \tau.0$ but $\lfloor 0 \rfloor \not\approx \lfloor \tau.0 \rfloor$.

► **Example 3.8** (Continuation of Example 2.6). Language *While* actually respects the stronger version of Criterion 2 found in Remark 3.6. For **skip**, assignment and **while**-loops the transitions induced by $\rho_X \circ \Sigma\langle 1, f \rangle$ are the same regardless of f . This is not the case for sequential composition, but we observe that the left path always leads to $s, x; y \rightarrow s, x; y$, which is covered by the added $\eta_X \circ \theta_X$ on the right path.

► **Example 3.9** (Continuation of Example 2.8). SPC provides for a good example of failure of Criterion 2 as it echoes the well-known fact that weak bisimilarity is not compatible with non-deterministic choice in a manner similar to Example 3.7. In particular, the left path always assigns $x+y$ transitions $\{(\tau, x), (\tau, y)\}$ but for $f = \lambda x. \emptyset$ we have $(\lambda_X \circ \Sigma^*\langle 1, f \rangle)^* = \{(\tau, x+y)\}$. Clearly $\{(\tau, x), (\tau, y)\} \not\subseteq \{(\tau, x+y)\}$ and so Criterion 2 is not satisfied. We can witness the incompatibility of non-deterministic choice by taking a cue from the failing instance and use a process which has no transitions, i.e. the null process: $0 \approx \tau.0$ but $\delta.0 + 0 \not\approx \delta.0 + \tau.0$.

► **Criterion 3** (Observability). For any $f : X \rightarrow TX$,

$$\lambda_X \circ \Sigma^*\langle 1, f \diamond f \rangle \leq (\lambda_X \circ \Sigma^*\langle 1, f \rangle)^* \tag{3}$$

Equivalently, we can reformulate the above as

$$\rho_X \circ \Sigma\langle 1, f \diamond f \rangle \leq (\lambda_X \circ \Sigma^*\langle 1, f \rangle)^* \circ \theta_X \tag{4}$$

where $\theta : \Sigma \Longrightarrow \Sigma^*$ is the universal natural transformation sending Σ to its free monad.

► **Remark 3.10.** The fact that Equation (3) and Equation (4) are equivalent can be proved in a manner similar to Proposition 3.1.

This criterion is roughly a weakening of the associativity condition for liftings to Kleisli categories [14, §2.2]. We can think of $f \diamond f$ as a two-step transition applied to subterms and $\lambda_X \circ \Sigma^* \langle 1, f \diamond f \rangle$ as the act of a context inspecting zero or more subterms performing that two-step transition. The criterion relates the information obtained by contexts when inspecting two-step transitions as opposed to inspecting each step individually, possibly many times over. Specifically, it ensures that the former always carries *less* information than the latter. A further way to interpret this criterion is that inspecting an effect *now* instead of *later* does not produce new outcomes.

Criterion 3 is more complex to explain in terms of the simply WB cool format, as requirements 1,3,4,5 in Definition 8 from van Glabbeek [37] all contribute towards observations on visible transitions not being affected by silent transitions, regardless of when the latter occur. First, let us look at *straightness*. An operator is straight if it has no rules where a variable occurs multiple times in the left-hand side of its premises. The following example shows how non-straight rules can lead to issues.

► **Example 3.11** ([37, Example 3]). Let operator $\llbracket _ \rrbracket$ subject to the following rules applying to specific $a, b, c \in \Delta$:

$$\text{pat} \frac{P \xrightarrow{\tau} P'}{\llbracket P \rrbracket \xrightarrow{\tau} \llbracket P' \rrbracket} \quad \text{cur} \frac{P \xrightarrow{a} Q \quad P \xrightarrow{b} W}{\llbracket P \rrbracket \xrightarrow{c} \llbracket Q \rrbracket}$$

We can see how rule **cur** violates Criterion 3 by taking $f(p) = \{(a, q), (\tau, w)\}$, $f(q) = \{(\tau, q)\}$ and $f(w) = \{(b, w)\}$. Since $(f \diamond f)(p) = \{(a, q), (b, w)\}$, running $\lambda_X \circ \Sigma^* \langle 1, f \diamond f \rangle$ on $\llbracket p \rrbracket$ induces a c -transition, which does not occur on the right side. With rule **cur** weak bisimilarity is not a congruence, as $\alpha.0 + b.0 + \tau.b.0 \approx \alpha.0 + \tau.b.0$ but $\llbracket \alpha.0 + b.0 + \tau.b.0 \rrbracket \not\approx \llbracket \alpha.0 + \tau.b.0 \rrbracket$.

Requirements 3 and 4 in the definition of the simply WB cool format underline how the *lack* of patience rules can affect observations.

► **Example 3.12** ([37, Example 5]). Consider operator $\llbracket _ \rrbracket$ subject to rule **oba** $\frac{P \xrightarrow{a} P'}{\llbracket P \rrbracket \xrightarrow{\tau} 0}$ applying to a specific action a . Rule **oba** fails Criterion 3 with $f(p) = \{(\tau, q)\}$ and $f(q) = \{(a, w)\}$, making $(f \diamond f)(p) = \{(a, w)\}$. Running $\lambda_X \circ \Sigma^* \langle 1, f \diamond f \rangle$ on $\llbracket p \rrbracket$ induces a τ -transition, which does not occur on the right side. We can see how $\alpha.0 \approx \tau.\alpha.0$ but $\llbracket \alpha.0 \rrbracket \not\approx \llbracket \tau.\alpha.0 \rrbracket$.

The final requirement is that of *smoothness*. A straight operator for an LTS is smooth if it has no rules where a variable occurs both in the target and in the left-hand side of a premise. Non-smooth rules can also cause problems, as evidenced by the following example.

► **Example 3.13** ([37, Example 7]). Let operator $\llbracket _ \rrbracket$ with the following rules:

$$\text{play} \frac{P \xrightarrow{\delta} P'}{\llbracket P \rrbracket \xrightarrow{\delta} \llbracket P' \rrbracket} \quad \text{pause} \frac{P \xrightarrow{\delta} P'}{\llbracket P \rrbracket \xrightarrow{\delta} \llbracket P \rrbracket}$$

Non-smooth rule **pause** also violates Criterion 3. Take $f(p) = \{(\tau, q)\}$ and $f(q) = \{(a, w)\}$, making $(f \diamond f)(p) = \{(a, w)\}$. Running $\lambda_X \circ \Sigma^* \langle 1, f \diamond f \rangle$ on $\llbracket p \rrbracket$ induces a -transition $(a, \llbracket p \rrbracket)$, but the only a -transitions induced on the other side are $(a, \llbracket q \rrbracket)$ and $(a, \llbracket w \rrbracket)$ instead. Weak bisimilarity fails to be a congruence, with $\alpha.0 + \tau.b.0 \approx \alpha.0 + \tau.b.0 + b.0$ but $\llbracket \alpha.0 + \tau.b.0 \rrbracket \not\approx \llbracket \alpha.0 + \tau.b.0 + b.0 \rrbracket$. The difference here is that only $\llbracket \alpha.0 + \tau.b.0 + b.0 \rrbracket$ is able to perform an α -transition after a b -transition.

► **Example 3.14** (Continuation of Example 2.6). The situation for Criterion 3 is less obvious for both `while`-loops and sequential composition, but still trivial for `skip` and assignment statements. Using the simpler ρ -based formulation of Criterion 3, we have that for `while`-loops, the induced transition is not affected by transitions of subterms, hence $\rho_X \circ \Sigma\langle 1, f \diamond f \rangle$ is always included in the first iteration of $(\lambda_X \circ \Sigma^*\langle 1, f \rangle)^* \circ \theta$.

Showing that the criterion is satisfied by an expression $x; y$ for any $x, y \in X$ requires case analysis of $(f \diamond f)(x)$ only, as the rule ignores y . The two cases are:

- $(t, z) \in (f \diamond f)(x)(s)$. In this case x did not terminate, but rather went through an intermediate transition t', z' . According to rule `seq2`, the transition produced by $\rho_X \circ \Sigma\langle 1, f \diamond f \rangle$ is $s, x; y \rightarrow t, z; y$. Going over to $(\lambda_X \circ \Sigma^*\langle 1, f \rangle)^* \circ \theta$, the first iteration produces $s, x; y \rightarrow t', z'; y$, and in the second we get $t', z'; y \rightarrow t, z; y$, which is the same result.
- $(t, \checkmark) \in (f \diamond f)(x)(s)$. Here, x terminated producing t either immediately $((t, \checkmark) \in f(x)(s))$ or in two steps $((s', x') \in f(x)(s)$ and $(t, \checkmark) \in f(x')(s'))$. In any case, the transition produced by $\rho_X \circ \Sigma\langle 1, f \diamond f \rangle$ is $s, x; y \rightarrow t, y$. Depending on when x terminated, this transition will be “caught” in either the first or the second iteration of $(\lambda_X \circ \Sigma^*\langle 1, f \rangle)^* \circ \theta$.

► **Example 3.15** (Continuation of Example 2.8). When instantiated to *SPC*, the criterion essentially asks if the act of “forgetting” invisible steps of subterms, as imposed by the rules of monadic composition in $\mathcal{Kl}(T)$, gives rise to new transitions for a composite term. In most cases, this is evidently true; consider for instance the parallel composition of two terms $P \parallel Q$, for which $P \xrightarrow{\tau} P' \xrightarrow{\delta} P''$, i.e. $(\tau, P') \in f(P)$ and $(\delta, P'') \in f(P')$. Forgetting the invisible step gives $P \xrightarrow{\delta} P''$ $((\delta, P'') \in (f \diamond f)(P))$, so by rule `com1` we have $P \parallel Q \xrightarrow{\delta} P'' \parallel Q$ on the left-hand side. This transition will occur after two iterations on the right-hand side, as in $P \parallel Q \xrightarrow{\tau} P' \parallel Q \xrightarrow{\delta} P'' \parallel Q$.

Rule `syn` is especially interesting, as it showcases the full power of Criterion 3. There are four different cases where `syn` induces a transition $P \parallel Q \xrightarrow{\tau} P'' \parallel Q''$ on the left side, namely

- $P \xrightarrow{\tau} P' \xrightarrow{\alpha} P''$ and $Q \xrightarrow{\tau} Q' \xrightarrow{\bar{\alpha}} Q''$
- $P \xrightarrow{\tau} P' \xrightarrow{\alpha} P''$ and $Q \xrightarrow{\bar{\alpha}} Q' \xrightarrow{\tau} Q''$
- $P \xrightarrow{\alpha} P' \xrightarrow{\tau} P''$ and $Q \xrightarrow{\bar{\alpha}} Q' \xrightarrow{\tau} Q''$
- $P \xrightarrow{\alpha} P' \xrightarrow{\tau} P''$ and $Q \xrightarrow{\tau} Q' \xrightarrow{\bar{\alpha}} Q''$.

The third and fourth case work similarly to the first and second (resp.) and so we focus on the latter. Either way, the right side of Criterion 3 needs three iterations (meaning $(\lambda_X \circ \Sigma^*\langle 1, f \rangle) \diamond (\lambda_X \circ \Sigma^*\langle 1, f \rangle) \diamond (\rho_X \circ \Sigma\langle 1, f \rangle)$) in order to produce transition $P \parallel Q \xrightarrow{\tau} P'' \parallel Q''$. In the first case, each iteration executes (in sequence) rules `com1`, `com2` and `syn` leading to $P \parallel Q \xrightarrow{\tau} P' \parallel Q \xrightarrow{\tau} P' \parallel Q' \xrightarrow{\tau} P'' \parallel Q''$. In the second case the order changes with rules `com1`, `syn` and `com2` inducing $P \parallel Q \xrightarrow{\tau} P' \parallel Q \xrightarrow{\tau} P'' \parallel Q' \xrightarrow{\tau} P'' \parallel Q''$.

Up to this point, the connection of our criteria with the simply WB cool format has remained informal. The following theorem turns this connection to a formal correspondence.

► **Theorem 3.16.** *Any language in the simply WB cool format satisfies the three compositionality criteria.*

The converse is not true, as for example any simple non-smooth rule satisfying the three criteria, such as $[x] \xrightarrow{c} x$, is not simply WB cool. A proof of Theorem 3.16 is provided in Appendix B.2.

3.2 An algebra for a †

We are now ready to move on to the main theorem of our work, namely the existence of a compatible algebra structure for morphism $h^\dagger : A \rightarrow Z$ mapping every term in A to its weak behavior in Z . First, we present the following intermediate result that plays a catalytic role in the main theorem and is noteworthy in its own right.

► **Proposition 3.17.** *Let $\lambda : \Sigma^*(\text{Id} \times T) \Longrightarrow T\Sigma^*$ be a GSOS law of Σ over T with T being an $\omega\text{-Cpo}_{\text{id}}^\vee$ -enriched monad. If λ satisfies the three compositionality criteria, then for any T -coalgebra $f : X \rightarrow TX$ we have $(\lambda \circ \Sigma^*\langle 1, f^* \rangle)^* = (\lambda \circ \Sigma^*\langle 1, f \rangle)^*$.*

Proof. By antisymmetry on the order structure \leq of T . To avoid unnecessary clutter, for the rest of the proof we shall be writing $\lambda \circ \Sigma^*\langle 1, f \rangle$ as $\bar{\Sigma}f$ and the 1 in $\bar{\Sigma}(1 \vee f)$ will stand for η , the identity morphism in $\mathcal{Kl}(T)$.

- Via Criterion 1 and Lemma 2.16 we have $f \leq f^* \implies \bar{\Sigma}f \leq \bar{\Sigma}f^* \implies (\bar{\Sigma}f)^* \leq (\bar{\Sigma}f^*)^*$. In other words, $(\lambda \circ \Sigma^*\langle 1, f \rangle)^* \leq (\lambda \circ \Sigma^*\langle 1, f^* \rangle)^*$.
- We first show that $\bar{\Sigma}(1 \vee f)^n \leq (\bar{\Sigma}f)^*$ for all $n \in \mathbb{N}$ by induction on n . For $n = 0$ and $n = 1$ and by Criterion 1 (as $1 \leq (1 \vee f)$) and Criterion 2,

$$\bar{\Sigma}(1 \vee f)^0 = \bar{\Sigma}1 \leq \bar{\Sigma}(1 \vee f) = \bar{\Sigma}(1 \vee f)^1 \leq (\bar{\Sigma}f)^* \quad (5)$$

We now have to show that $\bar{\Sigma}((1 \vee f)^{n+1} \diamond (1 \vee f)) \leq (\bar{\Sigma}f)^*$ for some n by making use of the inductive hypothesis $\bar{\Sigma}(1 \vee f)^{n+1} \leq (\bar{\Sigma}f)^*$. To that end, we first note that $1 \leq (1 \vee f)$ and thus, due to $\omega\text{-Cpo}_{\text{id}}^\vee$ -enrichment, we have that for all $n \in \mathbb{N}$,

$$1 \vee f \leq (1 \vee f) \diamond (1 \vee f) \leq \dots \leq (1 \vee f)^{n+1} \implies (1 \vee f)^{n+1} \diamond (1 \vee f) \leq (1 \vee f)^{n+1} \diamond (1 \vee f)^{n+1} \quad (6)$$

Next, by (6), Criterion 1 and Criterion 3,

$$\bar{\Sigma}((1 \vee f)^{n+1} \diamond (1 \vee f)) \leq \bar{\Sigma}((1 \vee f)^{n+1} \diamond (1 \vee f)^{n+1}) \leq (\bar{\Sigma}(1 \vee f)^{n+1})^* \quad (7)$$

The induction hypothesis gives $\bar{\Sigma}(1 \vee f)^{n+1} \leq (\bar{\Sigma}f)^*$ and so (7) becomes

$$\bar{\Sigma}((1 \vee f)^{n+1} \diamond (1 \vee f)) \leq (\bar{\Sigma}(1 \vee f)^{n+1})^* \leq (\bar{\Sigma}f)^{**} = (\bar{\Sigma}f)^* \quad (8)$$

Inequalities (8) and (5) complete the inductive proof that $\forall n \in \mathbb{N}. \bar{\Sigma}(1 \vee f)^n \leq (\bar{\Sigma}f)^*$. Finally, by Proposition 2.15 and Criterion 1:

$$\bar{\Sigma}f^* = \bar{\Sigma} \bigvee_{n < \omega} (1 \vee f)^n = \bigvee_{n < \omega} \bar{\Sigma}(1 \vee f)^n$$

We just proved that every link in the ω -chain is smaller than $(\bar{\Sigma}f)^*$, and thus $\bar{\Sigma}f^* \leq (\bar{\Sigma}f)^*$.

By Definition 2.14, this becomes $(\bar{\Sigma}f^*)^* \leq (\bar{\Sigma}f)^*$, i.e. $(\lambda \circ \Sigma^*\langle 1, f^* \rangle)^* \leq (\lambda \circ \Sigma^*\langle 1, f \rangle)^*$.

Having shown both directions, we end up with $(\lambda \circ \Sigma^*\langle 1, f^* \rangle)^* = (\lambda \circ \Sigma^*\langle 1, f \rangle)^*$. ◀

In other words, the transition system of (arbitrarily deep) contexts with subterms in X is *weakly* equivalent that of contexts having access to all the weak transitions of subterms in X . Proposition 3.17 is what enables the formation of a compatible algebra structure for $h^\dagger : A \rightarrow Z$ by applying it to the final coalgebra $z : Z \xrightarrow{\cong} BZ$. It is currently unclear if the converse of Proposition 3.17 holds.

► **Theorem 3.18 (Main theorem).** *Let $\lambda : \Sigma^*(\text{Id} \times T) \Longrightarrow T\Sigma^*$ be a GSOS law of Σ over T with T being an $\omega\text{-Cpo}_{\text{id}}^\vee$ -enriched monad. If λ satisfies the three compositionality criteria, then for $\Sigma A \xrightarrow{a} A \xrightarrow{h} TA$ and $\Sigma Z \xrightarrow{g} Z \xrightarrow{z} TZ$ as in Proposition 2.5, h^\dagger is a Σ -algebra homomorphism from $a : \Sigma A \xrightarrow{\cong} A$ to $z^\dagger \circ g : \Sigma Z \rightarrow Z$.*

88:14 Abstract Congruence Criteria for Weak Bisimilarity

Proof. We first observe that the following diagram commutes due to finality of z (top left and bottom rectangle) and naturality of λ . Note that the horizontal lines are all T -coalgebras and $g^\#$ is the \mathcal{EM} -algebra induced by the denotational model g .

$$\begin{array}{ccccc}
 \Sigma^* Z & \xrightarrow{\Sigma^* \langle 1, z^* \rangle} & \Sigma^* (Z \times TZ) & \xrightarrow{\lambda} & T\Sigma^* Z \\
 \Sigma^*(z^\dagger) \downarrow & & \downarrow \Sigma^*(\text{Id} \times T)(z^\dagger) & & \downarrow T\Sigma^*(z^\dagger) \\
 \Sigma^* Z & \xrightarrow{\Sigma^* \langle 1, z \rangle} & \Sigma^* (Z \times TZ) & \xrightarrow{\lambda} & T\Sigma^* Z \\
 g^\# \downarrow & & & & \downarrow Tg^\# \\
 Z & \xrightarrow{\cong} & Z & \xrightarrow{z} & TZ
 \end{array}$$

Since rt-closing preserves T -coalgebra homomorphisms, rt-closing the T -coalgebras and finality of z gives us

$$\begin{array}{ccc}
 \Sigma^* Z & \xrightarrow{(\lambda \circ \Sigma^* \langle 1, z^* \rangle)^*} & T\Sigma^* Z \\
 \Sigma^*(z^\dagger) \downarrow & & \downarrow T\Sigma^*(z^\dagger) \\
 \Sigma^* Z & \xrightarrow{(\lambda \circ \Sigma^* \langle 1, z \rangle)^*} & T\Sigma^* Z \\
 g^\# \downarrow & & \downarrow Tg^\# \\
 Z & \xrightarrow{z^*} & TZ \\
 z^\dagger \downarrow & & \downarrow Tz^\dagger \\
 Z & \xrightarrow{\cong} & TZ
 \end{array}$$

Via Proposition 3.17 we have $(\lambda \circ \Sigma^* \langle 1, z^* \rangle)^* = (\lambda \circ \Sigma^* \langle 1, z \rangle)^*$. Since all homomorphisms on final coalgebras are unique, we see that $z^\dagger \circ g^\# = z^\dagger \circ g^\# \circ \Sigma^*(z^\dagger)$, which in turn makes the following diagram commute:

$$\begin{array}{ccccc}
 \Sigma Z & \xrightarrow{\theta_Z} & \Sigma^* Z & \xrightarrow{g^\#} & Z \\
 \Sigma z^\dagger \downarrow & & \Sigma^* z^\dagger \downarrow & & \downarrow z^\dagger \\
 \Sigma Z & \xrightarrow{\theta_Z} & \Sigma^* Z & \xrightarrow{z^\dagger \circ g^\#} & Z
 \end{array}$$

Where $\theta : \Sigma \implies \Sigma^*$ is the universal natural transformation sending Σ to its free monad. But $g^\# \circ \theta = g$ and so we can conclude

$$z^\dagger \circ g = z^\dagger \circ g \circ \Sigma z^\dagger \tag{9}$$

$$\implies z^\dagger \circ g \circ \Sigma h^\dagger = z^\dagger \circ g \circ \Sigma z^\dagger \circ \Sigma h^\dagger \tag{10}$$

$$\implies z^\dagger \circ h^\dagger \circ a = z^\dagger \circ g \circ \Sigma(z^\dagger \circ h^\dagger) \tag{11}$$

$$\implies h^\dagger \circ a = z^\dagger \circ g \circ \Sigma h^\dagger. \tag{12}$$

Equation (10) gives (11) due to h^\dagger being a bialgebra morphism and finally we have (12) by Lemma 2.22, which finishes the proof. \blacktriangleleft

Weak bisimilarity being a congruence is thus a simple corollary of Theorems 2.21 and 3.18.

► Corollary 3.19. *Let $\lambda : \Sigma^*(\text{Id} \times T) \implies T\Sigma^*$ be a GSOS law of Σ over weak-pullback preserving functor T with T being an $\omega\text{-Cpo}_{id}^\vee$ -enriched monad as in Theorem 3.18. If λ satisfies the three compositionality criteria, weak bisimilarity in λ is a congruence.*

3.3 Lax models for weak bisimulation

Up-to techniques for bisimulation [19, 28] are techniques that simplify reasoning about behavioral equivalences, the main idea being that instead of having to show that two processes are included in a bisimulation relation, one can show that they are included in a different relation which is *sound* with respect to bisimulation. Bonchi et al. [6, Corollary 22] proved that weak bisimulation up-to contextual closure is a compatible (and hence sound) up-to technique for systems specified in the simply WB cool rule format. This result is a corollary of their main theorem [6, Theorem 20], which requires the underlying system to be *positive* and also the saturated transition system to be a *lax model* for the given specification, requirements that are automatically true for systems in the simply WB cool format.

As mentioned in Section 3.1, the abstract equivalent of positivity for GSOS specifications is monotonicity, which is weaker than continuity (Criterion 1). Thus, a GSOS law satisfying the three compositionality criteria is monotone. As for lax models, our behaviors come with an order structure and hence we can give the following definition.

► **Definition 3.20** (Lax models for GSOS laws). *Let $\lambda : \Sigma^*(\text{Id} \times T) \Longrightarrow T\Sigma^*$ be a GSOS law of Σ over T with T being an $\omega\text{-Cpo}_{\text{Id}}^{\vee}$ -enriched monad. A lax λ -model is a Σ -algebra and T -coalgebra pair $\Sigma X \xrightarrow{g} X \xrightarrow{h} TX$ making the following diagram commute laxly:*

$$\begin{array}{ccccc} \Sigma^* X & \xrightarrow{g^\#} & X & \xrightarrow{h} & TX \\ \Sigma^*(1, h) \downarrow & & \vee \! \! \! \vee & & \uparrow Tg^\# \\ \Sigma^*(X \times TX) & \xrightarrow{\lambda} & & \xrightarrow{\lambda} & T\Sigma^* X \end{array}$$

Where $g^\#$ is the respective \mathcal{EM} -algebra induced by g .

In other words, a lax model is a relaxed version of a bialgebra (Definition 2.4), implying that *only*, but not necessarily *all*, weak transitions of a composite term can be deduced from the weak transitions of its subterms. One non-example of a lax model is $\Sigma A \xrightarrow{a} A \xrightarrow{h^*} BA$ of *SPC* from Example 2.8. We can use the same problematic case as Example 3.9: the lower path on the bialgebra diagram for process $\delta.0 + 0$ reveals transition $\delta.0 + 0 \xrightarrow{\tau} 0$, which is not a transition of $\delta.0 + 0$.

For all their nice properties, there is little indication as to which GSOS laws have lax models and why. Thus, in the context of our work, it is sensible to ask if the three congruence criteria are adequate with respect to producing lax models for GSOS laws, with the following theorem asserting that this is indeed the case.

► **Theorem 3.21.** *Let $\lambda : \Sigma^*(\text{Id} \times T) \Longrightarrow T\Sigma^*$ be a GSOS law of Σ over T with T being an $\omega\text{-Cpo}_{\text{Id}}^{\vee}$ -enriched monad. If λ satisfies the three compositionality criteria, then for any λ -bialgebra $\Sigma X \xrightarrow{g} X \xrightarrow{h} TX$, $\Sigma X \xrightarrow{g} X \xrightarrow{h^*} TX$ is a lax λ -model.*

Proof. By Lemma 2.16 and the definition of a bialgebra we have $Tg^\# \circ (\lambda_X \circ \Sigma^*(1, h))^* = h^* \circ g^\#$. Thus, to prove that $\Sigma X \xrightarrow{g} X \xrightarrow{h^*} TX$ is lax λ -model, it suffices to show that $\lambda \circ \Sigma^*(1, h^*) \leq (\lambda \circ \Sigma^*(1, h))^*$. by Proposition 3.17 and Definition 2.14 we indeed have that $\lambda \circ \Sigma^*(1, h^*) \leq (\lambda \circ \Sigma^*(1, h))^* = (\lambda \circ \Sigma^*(1, h))^*$. ◀

It is worth noting that compatibility of the up-to context technique for weak bisimulation entails the congruence property of weak bisimilarity, which means that there is an alternative route to Corollary 3.19 via Proposition 3.17 and [6, Theorem 20]. With that in mind, can lax models work as a formal method for proving congruence of weak bisimilarity like our

three criteria? The problem is that proving laxness of a model (typically the initial, rt-closed model $\Sigma A \xrightarrow{a} A \xrightarrow{h^*} TA$) involves non-trivial reasoning on an rt-closed system that is itself defined inductively on the structure of terms. Conversely, our three criteria are significantly easier to establish as they characterize a GSOS law acting on a single layer of syntax.

4 Conclusion

In this paper we presented three abstract criteria over operational semantics, given in the form of Turi and Plotkin's bialgebraic semantics, that guarantee weak bisimilarity being a congruence. We believe that the criteria gracefully balance between generality and usefulness but, as is often the case with abstract results, this is something hard to assess accurately. What is equally important however is that each of the criteria can be given an intuitive explanation as to the kind of restriction it imposes on the semantics. We hope that these insights can contribute towards a conclusive answer to the general problem of full abstraction: the definition of the best adequate denotational semantics, the underlying equivalence of which coincides with contextual equivalence.

A The simply WB cool rule format

In this section we introduce a few notions relevant to the simply WB cool rule format taken from [37]. For some n -ary operator o in a language \mathcal{L} , the *rules of o* are all the rules with source $o(x_1, \dots, x_n)$. The following characterize GSOS rules based on the shape(s) of its premise(s) and the shape of its conclusion.

- An operator in \mathcal{L} is *straight* if it has no rules in which a variable occurs multiple times in the left-hand side of its premises.
- An operator is *smooth* if it is straight and has no rules in which a variable occurs both in the target and in the left-hand side of a premise.
- An argument $i \in \mathbb{N}$ of an operator o is *active* if there is a rule of o in which x_i is the left-hand side of a premise.
- A variable x occurring in a term t is *receiving in t* if t is the target of a rule in \mathcal{L} in which x is the right-hand side of a premise. An argument $i \in \mathbb{N}$ of an operator o is *receiving* if a variable x is receiving in a term t that has a subterm $o(v_1, \dots, v_n)$ with x occurring in v_i .
- A rule of the form of
$$\frac{x_i \xrightarrow{\tau} y}{o(x_1, \dots, x_n) \xrightarrow{\tau} o(x_1, \dots, x_n)[y/x_i]}$$
 for $1 \leq i \leq n$ is called a *patience rule* for the i th argument of o , where $t[y/x]$ stands for term t with all occurrences of x replaced by y .

We can now give the complete definition of the simply WB cool rule format.

► **Definition A.1.** A GSOS language \mathcal{L} is simply WB cool if it is positive and the following conditions are all true.

1. All operators in \mathcal{L} are straight.
2. The only rules in \mathcal{L} with τ -premises are patience rules.
3. Every active argument of an operator has a patience rule.
4. Every receiving argument of an operator has a patience rule.
5. All operators in \mathcal{L} are smooth.

B Selected proofs

In this section of the appendix we include the proofs of Proposition 3.1 and Theorem 3.16.

B.1 Equivalence of the two representations of the continuity criterion

Proof of Proposition 3.1. We introduce the friendlier notation $\bar{\Sigma}f$ in place of $\lambda \circ \Sigma^*\langle 1, f \rangle$ for any $f : X \rightarrow TX$. (1) \implies (2) is immediate since $\rho = \lambda \circ \theta$, where $\theta : \Sigma \implies \Sigma^*$ is the universal natural transformation sending Σ to its free monad. For (2) \implies (1), we first note that for each “link” f_i , $\bar{\Sigma}f_i$ is (equivalently) defined via “structural recursion with accumulators” (see [35, Theorem 5.1]), i.e. it is the unique morphism making the following diagram commute.

$$\begin{array}{ccc}
 \Sigma\Sigma^*X & \xrightarrow{\mu \circ \theta_{\Sigma^*}} & \Sigma^*X \xleftarrow{\eta} X \\
 \downarrow \Sigma\langle 1, \bar{\Sigma}f_i \rangle & & \bar{\Sigma}f_i \downarrow \exists! \swarrow T\eta \circ f_i \\
 \Sigma(\text{Id} \times T)\Sigma^*X & \xrightarrow{\rho_{\Sigma^*}} T\Sigma^*\Sigma^*X \xrightarrow{T\mu} T\Sigma^*X &
 \end{array}$$

This makes $\bar{\Sigma}f_i$ the (necessarily unique) *homomorphic extension* of $T\mu \circ \rho_{\Sigma^*}$ along $T\eta \circ f_i$. Continuity of composition in $\mathcal{Kl}(T)$ gives

$$T\eta \circ \bigvee_i f_i = \bigvee_i (T\eta \circ f_i) \quad (13)$$

$T\eta \circ f_i = \bar{\Sigma}f_i \circ \eta$, thus $\bigvee_i (\bar{\Sigma}f_i \circ \eta)$ exists and also

$$\bigvee_i (\bar{\Sigma}f_i \circ \eta) = \left(\bigvee_i \bar{\Sigma}f_i \right) \circ \eta \quad (14)$$

Via similar reasoning, we have

$$T\mu \circ \bigvee_i (\rho_{\Sigma^*} \circ \Sigma\langle 1, \bar{\Sigma}f_i \rangle) = \bigvee_i (T\mu \circ \rho_{\Sigma^*} \circ \Sigma\langle 1, \bar{\Sigma}f_i \rangle) \quad (15)$$

$$\bigvee_i (\bar{\Sigma}f_i \circ \mu \circ \theta_{\Sigma^*}) = \left(\bigvee_i \bar{\Sigma}f_i \right) \circ \mu \circ \theta_{\Sigma^*} \quad (16)$$

Equation (2) allows us to rewrite Equation (15) as

$$T\mu \circ \rho_{\Sigma^*} \circ \Sigma\langle 1, \bigvee_i \bar{\Sigma}f_i \rangle = \bigvee_i (T\mu \circ \rho_{\Sigma^*} \circ \Sigma\langle 1, \bar{\Sigma}f_i \rangle) \quad (17)$$

By taking the supremum over i of the i -dependent arrows in the previous diagram, Equation (13), (14), (16) and (17) allow us to present $\bigvee_i \bar{\Sigma} f_i$ as a morphism that makes the following diagram commute.

$$\begin{array}{ccccc}
 \Sigma \Sigma^* X & \xrightarrow{\mu \circ \theta_{\Sigma^*}} & \Sigma^* X & \xleftarrow{\eta} & X \\
 \downarrow \Sigma \langle 1, \bigvee_i \bar{\Sigma} f_i \rangle & & \downarrow \bigvee_i \bar{\Sigma} f_i & & \swarrow T\eta \circ \bigvee_i f_i \\
 \Sigma(\text{Id} \times T)\Sigma^* X & \xrightarrow{\rho_{\Sigma^*}} & T\Sigma^* \Sigma^* X & \xrightarrow{T\mu} & T\Sigma^* X
 \end{array}$$

But there can only be one such morphism, namely $\bar{\Sigma}(\bigvee_i f_i)$, the unique homomorphic extension of $T\mu \circ \rho_{\Sigma^*}$ along $T\eta \circ \bigvee_i f_i$. In other words, $\bigvee_i \bar{\Sigma} f_i = \bar{\Sigma}(\bigvee_i f_i)$. ◀

B.2 Correspondence with the simply WB cool rule format

Proof of Theorem 3.16. In order to prove that any language \mathcal{L} in the simply WB cool format automatically satisfies the three criteria, it suffices to show that (the GSOS law induced by) any arbitrary rule in \mathcal{L} satisfies them. First of all, we know that rules in the simply WB cool format are of the form $\frac{\{x_i \xrightarrow{c_i} y_i \mid i \in I\}}{o(x_1, \dots, x_n) \xrightarrow{\alpha} t}$ for $I \subseteq \{1, \dots, n\}$ [37, §3], or

simply $\frac{\{x_i \xrightarrow{c_i} y_i \mid i \in I\}}{o(\vec{x}) \xrightarrow{\alpha} t}$, where o is an n -ary operator. We thus consider an arbitrary rule in the above form and proceed by distinguishing by the number of active arguments.

B.2.1 0 active arguments

All cases are trivial.

B.2.2 1 active argument

The rule is of the form $\frac{x_j \xrightarrow{c} y}{o(\vec{x}) \xrightarrow{\alpha} t}$ meaning that the rule is active on a position j . There is only a single premise because of the first requirement (straightness) in Definition A.1.

B.2.2.1 Patience rule

If $c = \tau$ then by the second requirement of Definition A.1 this rule has to be a patience rule

$$\text{of the form } \frac{x_j \xrightarrow{\tau} y}{o(\vec{x}) \xrightarrow{\tau} o(\vec{x})[y/x_j]}.$$

Criterion 1.

$$\begin{aligned}
 \bigvee_i \rho(o(\vec{x}), f_i(\vec{x})) &= \bigvee_i \{\tau, o(\vec{x})[y/x_j] \mid (\tau, y_i) \in f_i(x_j)\} = \\
 \{\tau, o(\vec{x})[y/x_j] \mid (\tau, y_i) \in \bigvee_i (f_i(x_j))\} &= \rho(o(\vec{x}), \bigvee_i (f_i(\vec{x})))
 \end{aligned}$$

Criterion 2. $\rho(o(\vec{x}), (\eta \vee f)(\vec{x}))$ induces a single transition $o(\vec{x}) \xrightarrow{\tau} o(\vec{x})$ for all f , which is included in $\eta_x \circ \theta_X$.

Criterion 3. The only transitions in $\rho(o(\vec{x}, (f \diamond f)(\vec{x})))$ are $o(\vec{x}) \xrightarrow{\tau} o(\vec{x})[z/x_j]$ when $x_j \xrightarrow{\tau} y \xrightarrow{\tau} z$, i.e. $(\tau, y) \in f(x_j), (\tau, z) \in g(y)$ for some y, z . Running $(\lambda_X \circ \Sigma^*(1, f)) \diamond (\rho_X \circ \Sigma(1, f))$ ², which is the second iteration on the right side, we can see that $o(\vec{x}) \xrightarrow{\tau} o(\vec{x})[y/x_j] \xrightarrow{\tau} o(\vec{x})[z/y]$, which satisfies the criterion.

B.2.2.2 Impatient rule

This time we have $c \neq \tau$ which entails, by the third requirement of Definition A.1, the presence of a patience rule for argument j .

Criterion 1. Similar to B.2.2.1.

$$\begin{aligned} \bigvee_i \rho(o(\vec{x}, f_i(\vec{x}))) &= \bigvee_i \{c, o(\vec{x})[y/x_j] \mid (c, y_i) \in f_i(x_j)\} = \\ &\{c, o(\vec{x})[y/x_j] \mid (c, y_i) \in \bigvee_i (f_i(x_j))\} = \rho(o(\vec{x}, \bigvee_i (f_i(\vec{x}))) \end{aligned}$$

Criterion 2. Similarly to B.2.2.1, the presence of the patience rule for argument j means that there is always transition $o(\vec{x}) \xrightarrow{\tau} o(\vec{x})$ for all f on the left side, which is included on the right side by $\eta_x \circ \theta_X$. The transitions induced by f exist on both sides.

Criterion 3. Transitions on the left side occur if and only if there are w, z such that $x_j \xrightarrow{\tau} w \xrightarrow{c} z$ or $x_j \xrightarrow{c} w \xrightarrow{\tau} z$, i.e. $(\tau, w) \in f(x_j), (c, z) \in f(w)$ or $(c, w) \in f(x_j), (\tau, z) \in f(w)$. We also have to distinguish between y in premise $x_j \xrightarrow{c} y$ being receiving in t or not. For each case, we give the transition(s) on the left side (of Criterion 3) and the respective iteration step where the left-side transitions appear on the right side (of Criterion 3).

1. y is not receiving, $x_j \xrightarrow{\tau} w \xrightarrow{c} z$.
 - $\rho_X \circ \Sigma(1, f \diamond f)$: $o(\vec{x}) \xrightarrow{\alpha} t$
 - $(\lambda_X \circ \Sigma^*(1, f)) \diamond (\rho_X \circ \Sigma(1, f))$: $o(\vec{x}) \xrightarrow{\tau} o(\vec{x})[w/x_j] \xrightarrow{\alpha} t$
2. y is not receiving, $x_j \xrightarrow{c} w \xrightarrow{\tau} z$.
 - $\rho_X \circ \Sigma(1, f \diamond f)$: $o(\vec{x}) \xrightarrow{\alpha} t$
 - $\rho_X \circ \Sigma(1, f)$: $o(\vec{x}) \xrightarrow{\alpha} t$
3. y is receiving, $x_j \xrightarrow{\tau} w \xrightarrow{c} z$.
 - $\rho_X \circ \Sigma(1, f \diamond f)$: $o(\vec{x}) \xrightarrow{\alpha} t(z)$
 - $(\lambda_X \circ \Sigma^*(1, f)) \diamond (\rho_X \circ \Sigma(1, f))$: $o(\vec{x}) \xrightarrow{\tau} o(\vec{x})[w/x_j] \xrightarrow{\alpha} t(z)$
4. y is receiving, $x_j \xrightarrow{c} w \xrightarrow{\tau} z$

This is the trickiest case. Let us look back at the rule in question (with y receiving), which is $\frac{x_j \xrightarrow{c} y}{o(\vec{x}) \xrightarrow{\alpha} t(y)}$. The key observation is that requirement 4 in Definition A.1,

requiring that every receiving argument of an operator has a patience rule, implies that no matter how complex the receiving expression $t(y)$ is, there will be patience rules in place to ensure a derivation amounting to $\frac{x \xrightarrow{\tau} y}{s(x) \xrightarrow{\tau} s(y)}$ for each sub-expression $s(y)$

in $t(y)$ that “receives” y . The number of iterations on the right-hand required in order to trigger all necessary patience rules depends on the number of sub-expressions s .

For example, let $t(y) \triangleq d(e(l(y, 0)), e(l(0, y)))$, where d, l are binary operations, e is a unary operation and 0 is some term. Due to requirement 4, d, l, e will all have patience

² Recall that $(\lambda_X \circ \Sigma^*(1, f)) \circ \theta = \rho_X \circ \Sigma(1, f)$.

rules in all positions and we need exactly two iterations to trigger the two patience rules in each of the positions of d . More generally,

- $\rho_X \circ \Sigma\langle 1, f \diamond f \rangle: o(\vec{x}) \xrightarrow{\alpha} t(z)$
- $(\lambda_X \circ \Sigma^*\langle 1, f \rangle)^* \diamond (\rho_X \circ \Sigma\langle 1, f \rangle): o(\vec{x}) \xrightarrow{\alpha} t(w) \xrightarrow{\tau^*} t(z)$.

B.2.3 2 or more active arguments

We first note that the only rules with τ -premises are patience rules, which are already covered in B.2.2.1 and so we move on to $c_1, c_2 \neq \tau$ with the rule being of the form of

$$\frac{x_i \xrightarrow{c_1} y_1 \quad x_j \xrightarrow{c_2} y_2}{o(\vec{x}) \xrightarrow{\alpha} t}$$

The third requirement of Definition A.1 means that there are patience rules for arguments i and j in o .

Criterion 1. Similar to the case for Criterion 1 in B.2.2.1.

Criterion 2. Similar to the case for Criterion 2 in B.2.2.1.

Criterion 3. There are four separate cases where a transition occurs in $\rho(o(\vec{x}, (f \diamond f)(\vec{x})))$, as a c_1 -transition and a c_2 -transition may occur in either step for both subterms.

1. $x_i \xrightarrow{\tau} w_1 \xrightarrow{c_1} z_1$ and $x_j \xrightarrow{\tau} w_2 \xrightarrow{c_2} z_2$
2. $x_i \xrightarrow{\tau} w_1 \xrightarrow{c_1} z_1$ and $x_j \xrightarrow{c_2} w_2 \xrightarrow{\tau} z_2$
3. $x_i \xrightarrow{c_1} w_1 \xrightarrow{\tau} z_1$ and $x_j \xrightarrow{c_2} w_2 \xrightarrow{\tau} z_2$
4. $x_i \xrightarrow{c_1} w_1 \xrightarrow{\tau} z_1$ and $x_j \xrightarrow{\tau} w_2 \xrightarrow{c_2} z_2$.

In addition, y_1 and y_2 can each be either receiving or not receiving in t and, as this affects transitions the same way as y being receiving in B.2.2.2.

1. $x_i \xrightarrow{\tau} w_1 \xrightarrow{c_1} z_1$ and $x_j \xrightarrow{\tau} w_2 \xrightarrow{c_2} z_2$

Here, whether y_1 and y_2 are receiving or not does not make a difference and we write $t(y_1, y_2)$ to denote a term which potentially has instances of y_1 and y_2 .

- $\rho_X \circ \Sigma\langle 1, f \diamond f \rangle: o(\vec{x}) \xrightarrow{\alpha} t(z_1, z_2)$
- $(\lambda_X \circ \Sigma^*\langle 1, f \rangle) \diamond (\lambda_X \circ \Sigma^*\langle 1, f \rangle) \diamond (\rho_X \circ \Sigma\langle 1, f \rangle):$
 $o(\vec{x}) \xrightarrow{\tau} o(\vec{x})[w_1/x_i] \xrightarrow{\tau} o(\vec{x})[w_1/x_i][w_2/x_j] \xrightarrow{\alpha} t(z_1, z_2)$

We can see that we need to iterate three times on the right-hand side: one to trigger the patience rule on position i , one to trigger the patience rule on position j on the new term and one more to trigger the main rule.

2. $x_i \xrightarrow{\tau} w_1 \xrightarrow{c_1} z_1$ and $x_j \xrightarrow{c_2} w_2 \xrightarrow{\tau} z_2$

In this case y_2 being receiving makes a difference, while y_1 does not. Let us first deal with the non-receiving case for y_2 .

- $\rho_X \circ \Sigma\langle 1, f \diamond f \rangle: o(\vec{x}) \xrightarrow{\alpha} t(z_1)$
- $(\lambda_X \circ \Sigma^*\langle 1, f \rangle) \diamond (\rho_X \circ \Sigma\langle 1, f \rangle): o(\vec{x}) \xrightarrow{\tau} o(\vec{x})[w_1/x_i] \xrightarrow{\alpha} t(z_1)$

The first iteration will trigger the patience rule for i , while the second produces the α -transition. Variable y_2 is not receiving and so nothing else is needed. On the other hand, if y_2 is receiving, we see that

- $\rho_X \circ \Sigma\langle 1, f \diamond f \rangle: o(\vec{x}) \xrightarrow{\alpha} t(z_1, z_2)$
- $(\lambda_X \circ \Sigma^*\langle 1, f \rangle)^* \diamond (\lambda_X \circ \Sigma^*\langle 1, f \rangle) \diamond (\rho_X \circ \Sigma\langle 1, f \rangle):$
 $o(\vec{x}) \xrightarrow{\tau} o(\vec{x})[w_1/x_i] \xrightarrow{\alpha} t(z_1, w_2) \xrightarrow{\tau^*} t(z_1, z_2)$

Similarly to the fourth case of Criterion 3 in B.2.2.2, requirement 4 in Definition A.1 guarantees that there will be a sequence of patience rules that gives $t(z_1, w_2) \xrightarrow{\tau^*} t(z_1, z_2)$.

$$3. x_i \xrightarrow{c_1} w_1 \xrightarrow{\tau} z_1 \text{ and } x_j \xrightarrow{c_2} w_2 \xrightarrow{\tau} z_2$$

If y_1 and y_2 are not receiving, this is very similar to the first case. If y_1 and/or y_2 are receiving, then requirement 4 in Definition A.1 comes into play in the same manner as before. For instance, if both y_1 and y_2 are receiving:

$$\begin{aligned} &= \rho_X \circ \Sigma\langle 1, f \diamond f \rangle: o(\vec{x}) \xrightarrow{\alpha} t(z_1, z_2) \\ &= (\lambda_X \circ \Sigma^*\langle 1, f \rangle)^* \diamond (\lambda_X \circ \Sigma^*\langle 1, f \rangle)^* \diamond (\rho_X \circ \Sigma\langle 1, f \rangle): \\ &\quad o(\vec{x}) \xrightarrow{\alpha} t(w_1, w_2) \xrightarrow{\tau^*} t(z_1, w_2) \xrightarrow{\tau^*} t(z_1, z_2) \end{aligned}$$

$$4. x_i \xrightarrow{c_1} w_1 \xrightarrow{\tau} z_1 \text{ and } x_j \xrightarrow{\tau} w_2 \xrightarrow{c_2} z_2$$

Very similar to the second case.

In the presence of three or more active arguments we can apply the same principles, the only difference being that the maximum number of necessary iterations on the right side will be higher, as more patience rules will have to be triggered. ◀

Quantum Multiple-Valued Decision Diagrams in Graphical Calculi

Renaud Vilmart   

Université Paris-Saclay, CNRS, ENS Paris-Saclay, Inria,
Laboratoire Méthodes Formelles, 91190, Gif-sur-Yvette, France

Abstract

Graphical calculi such as the ZH-calculus are powerful tools in the study and analysis of quantum processes, with links to other models of quantum computation such as quantum circuits, measurement-based computing, etc.

A somewhat compact but systematic way to describe a quantum process is through the use of quantum multiple-valued decision diagrams (QMDDs), which have already been used for the synthesis of quantum circuits as well as for verification.

We show in this paper how to turn a QMDD into an equivalent ZH-diagram, and vice-versa, and show how reducing a QMDD translates in the ZH-Calculus, hence allowing tools from one formalism to be used into the other.

1 Introduction

Graphical calculi for quantum computation such as the ZX-Calculus [9], the ZW-Calculus [10] and the ZH-Calculus [2] are powerful yet intuitive tools for the design and analysis of quantum processes. They have already been successfully applied to the study of measurement-based quantum computing [15], error correction through the operations of lattice surgery on surface codes [12, 13], as well as for the optimisation of quantum circuits [4, 11, 22]. Their strong links with “sums-over-paths” [1, 23, 28], as well as their respective complete equational theories [4, 16, 21, 27], make them good candidates for automated verification [7, 14, 17].

An important question, whose answer benefits a lot of these different aspects, is the one of synthesis. Given a description of a quantum process, how do we turn it into a ZX-diagram? This all depends on the provided description. It was already shown how to efficiently get a diagram from quantum circuits [4], from a measurement-based process [15], from a sequence of lattice surgery operations [13], from “sums-over-paths” [23], or even from the whole matrix representation of the process [20]. Although this last translation is efficient in the size of the matrix, the size of the matrix itself grows exponentially in the number of qubits, so few processes will actually be given in terms of their whole matrix.

The matrix representation however has an advantage: it is (essentially) unique. Two quantum operators are operationally the same if and only if their matrix representations are colinear. This is to be contrasted with all the different previous examples, where for instance two different quantum circuits may implement the same operator.

The form of the ZX-diagram obtained from a quantum state by [20] is that of a binary tree: a branching in the tree corresponds to a cut in half of the represented vector, while the leaves of the tree exactly correspond to the entries in the vector. It is however possible to exploit redundancies in the entries of the vector, by merging similar subtrees. Doing so alters

the notion of normal form by compacting it, whilst retaining its uniqueness property. This can be done at the level of the ZX-diagram using its equational theory, and in particular some equality that is reminiscent to that of a bialgebra rule. Doing this from a proper tree on the other hand gives rise to a quantum version of a decision diagram, which has already been introduced in [24]. The so-called quantum multiple-valued decision diagrams (QMDDs) [25] have since then been used to synthesise quantum circuits [26] or to perform verification of quantum programs [5, 6].

We hence aim in this paper at showing the links between the aforementioned graphical calculi and QMDDs. We in particular show how to translate from one formalism to the other, and how the reduction of a QMDD translates in the graphical languages. As a consequence, tools developed in one formalism may be transported and used in the other. Additionally, this result together with the aforementioned results in the graphical languages, relates the QMDDs to measurement-based computation, lattice surgery operations, “sums-over-paths”, etc.

In Section 2, we present the ZH-calculus, the graphical language we will use in this paper for convenience. We then present in Section 3 the quantum multiple-valued decision diagrams. In Section 4, we show how to turn a QMDD into a ZH-diagram that represents the same quantum operator. In Section 5, we show an algorithm to turn a ZH-diagram into QMDD form, which can be used to get the QMDD description of any ZH-diagram.

2 The ZH-Calculus

We aim in this paper at showing links between quantum multiple-valued decision diagrams and graphical languages for quantum computing: ZX, ZW and ZH. Since any of the three languages can be translated in the other two [2, 16, 19], we may simply choose one. It so happens that the closest to QMDDs we have is the ZH-Calculus. We hence present here this language.

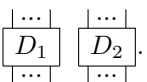

2.1 ZH-Diagrams

A ZH-diagram $D : k \rightarrow \ell$ with k inputs and ℓ outputs is generated by:

- $Z_m^n : n \rightarrow m ::$  called Z-spiders
- $H_m^n(r) : n \rightarrow m ::$  called H-spiders
- $id : 1 \rightarrow 1 ::$ 
- $\sigma : 2 \rightarrow 2 ::$ 
- $\eta : 0 \rightarrow 2 ::$ 
- $\epsilon : 2 \rightarrow 0 ::$ 

where $n, m \in \mathbb{N}$ and $r \in \mathbb{C}$. In the following, we may write H-spiders with no parameter, in which case, the implied parameter is -1 by convention.

Diagrams can then be composed either sequentially:  (if the number of output of the

top diagram matches the number of inputs of the bottom one), or in parallel: .

It is customary to define the additional two “X-spiders”:

$$\begin{array}{c} \dots \\ \vdots \\ \bullet \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} := \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \quad \text{and} \quad \begin{array}{c} \dots \\ \vdots \\ \neg \bullet \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} := \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array}$$

ZH-diagrams can be understood as quantum operators thanks to the *standard interpretation* $\llbracket \cdot \rrbracket$ which maps any ZH-diagram $D : n \rightarrow m$ to a complex matrix $\llbracket D \rrbracket \in \mathbb{C}^{2^m} \times \mathbb{C}^{2^n}$, and which is inductively defined as:

$$\begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} = \llbracket D_2 \rrbracket \circ \llbracket D_1 \rrbracket \quad \llbracket \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \rrbracket = \llbracket D_1 \rrbracket \otimes \llbracket D_2 \rrbracket$$

$$\llbracket \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} \rrbracket = 2^m \begin{array}{c} \overbrace{\begin{pmatrix} 1 & 0 & \dots & \dots & 0 \\ 0 & 0 & & & \vdots \\ \vdots & & \ddots & & \vdots \\ \vdots & & & 0 & 0 \\ 0 & \dots & \dots & 0 & 1 \end{pmatrix}}^{2^n} \\ \vdots \\ \vdots \\ \vdots \\ \vdots \end{array} \quad \llbracket \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} \rrbracket = 2^m \begin{array}{c} \overbrace{\begin{pmatrix} 1 & \dots & \dots & 1 \\ \vdots & \ddots & & \vdots \\ \vdots & & 1 & 1 \\ 1 & \dots & 1 & r \end{pmatrix}}^{2^n} \\ \vdots \\ \vdots \\ \vdots \\ \vdots \end{array}$$

$$\llbracket | \rrbracket = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad \llbracket \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} \rrbracket = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \quad \llbracket \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} \rrbracket = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 1 \end{pmatrix}$$

The standard interpretation of the X-spiders can then be obtained by composition. We underline that $\llbracket \begin{array}{c} \dots \\ \vdots \\ \bullet \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} \rrbracket = |0\rangle := \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ and that $\llbracket \begin{array}{c} \dots \\ \vdots \\ \neg \bullet \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} \rrbracket = |1\rangle := \begin{pmatrix} 0 \\ 1 \end{pmatrix}$.

We have used here the Dirac notation, where a quantum state i.e. a vector is denoted $|\psi\rangle$. We recall that $\langle \psi |$ is defined as $|\psi\rangle^\dagger$ where $(\cdot)^\dagger$ yields the transconjugate of a matrix.

The language is universal, i.e. any quantum operator can be represented as a ZH-diagram [2]:

$$\forall f \in \mathbb{C}^{2^m} \times \mathbb{C}^{2^n}, \exists D \in \mathbf{ZH}(n, m), \llbracket D \rrbracket = f$$

An important result that we will use in the following is the fact that there is an isomorphism between $\mathbf{ZH}(n, m)$ and $\mathbf{ZH}(0, m + n)$, i.e. any ZH-diagram $D : n \rightarrow m$ can be turned into a *state* $D' : 0 \rightarrow m + n$ in a reversible manner. This is called the *map/state duality* [9, 8, 18].

Graphically, this isomorphism is obtained by $\psi_{n,m}(D) = \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array}$ and $\psi_{n,m}^{-1}(D') = \begin{array}{c} \dots \\ \vdots \\ \square \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array}$,

and the fact that this is indeed an isomorphism comes from the fact that:

$$\begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} = \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} \quad \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} = \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array} \begin{array}{c} \dots \\ \vdots \\ \vdots \\ \vdots \\ \dots \end{array}$$

Notice that this definition of the map/state duality differs from more usual ones by a rearranging of the wires. This is useful in the following to better relate state-QMDDs to proper QMDDs.

2.2 Equational Theory

The previous equalities constitute the first of a series of axioms that makes up an equational theory for the language. The axioms are summed up in Figure 1.

■ **Figure 1** Rules of the ZH-Calculus.

The previous equality is actually part of an implicit set of axioms of the language, aggregated under the paradigm “only connectivity matters”, which states that all deformations of diagrams are allowed.

When we can turn a diagram D_1 into another diagram D_2 by a succession of the transformations in Figure 1, we usually write $ZH \vdash D_1 = D_2$, however, to keep things simple, we will abbreviate it as $D_1 = D_2$ in this paper. This set of rules was proven to be sound and complete [2], that is:

$$\forall D_1, D_2 \in \mathbf{ZH}(n, m), \llbracket D_1 \rrbracket = \llbracket D_2 \rrbracket \iff ZH \vdash D_1 = D_2$$

Two useful lemmas that will be important in the following can be derived from the previous axiomatisation, as proved in [3]:

► **Lemma 1.**

$$\begin{array}{c} \dots \\ \circ \\ \hline 0 \\ \hline \circ \\ \dots \end{array} = \frac{1}{2} \begin{array}{c} \dots \\ \circ \\ \hline \circ \\ \hline \circ \\ \dots \end{array}$$

► **Lemma 2.**

$$\begin{array}{c} \hline 0 \\ \hline \circ \end{array} = \bullet$$

In the following, since $\llbracket r \rrbracket = r$ and since it represents a global scalar, we may “forget the box”, and write $\begin{array}{c} \dots \\ \hline r \\ \hline D \\ \hline \dots \end{array}$ simply as $r \begin{array}{c} \dots \\ \hline D \\ \hline \dots \end{array}$. The equation $\begin{array}{c} \hline r \\ \hline s \end{array} = \begin{array}{c} \hline rs \end{array}$ is also derivable [3], which means that following the convention, different global scalars will get multiplied. For instance, we have $(r_1 \cdot D_1) \otimes (r_2 \cdot D_2) = (r_1 r_2) \cdot (D_1 \otimes D_2)$.

2.3 New Constructions

To make the link between decision diagrams and ZH-diagrams, we feel it is simpler to

introduce two new constructions: $\begin{array}{c} \hline \square \\ \hline \square \end{array} := \frac{1}{2} \begin{array}{c} \hline \square \\ \hline \square \\ \hline \bullet \end{array}$ and $\begin{array}{c} \hline \cup \\ \hline \end{array} := \begin{array}{c} \hline 0 \\ \hline \circ \\ \hline \bullet \end{array} = \frac{1}{2} \begin{array}{c} \hline \square \\ \hline \square \\ \hline \bullet \end{array}$

of which we may compute the standard interpretation:

$$\llbracket \begin{array}{c} \hline \cup \\ \hline \end{array} \rrbracket = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \text{ and } \llbracket \begin{array}{c} \hline \square \\ \hline \square \end{array} \rrbracket = \begin{pmatrix} 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}.$$

 corresponds to the diagram  of the ZW-Calculus [10], it is very close to the so-called W-state. It can also be found in [3] in the context of the ZH-calculus. The interaction of this building block with classical states is given by:

► **Lemma 3.**

► **Lemma 4.**

The pair $(\text{triangle with dot}, \text{dot})$ can be seen as a commutative monoid, which means that, on top of Lemma 3, the following is true:

► **Lemma 5.**

► **Lemma 6.**

Proof. Proof for associativity can be found in [3], and commutativity is obvious from the definition of the operator. ◀

This allows us to use a generalised version of this diagram, with arbitrary number of inputs, defined inductively as follows: $\text{triangle with dot} := \text{dot}$ and $\text{triangle with dot} := \text{triangle with dot}$. In practice, in the following, we will not use the case 0 inputs. We will however use the case 1 extensively, which we will assume simplified: $\text{triangle with dot} = \text{vertical line}$

The second diagram is the ZH version of the gadget used in the normal forms of [20], and it can be understood as follows:

$$\left[\text{trapezoid with dot} \right] = \langle 0 | \otimes \left[\text{vertical line with dot} \right] + \langle 1 | \otimes \left[\text{vertical line with dot} \right]$$

so it is a diagram that builds $\text{vertical line with dot}$ and whose leftmost wire controls whether or not the outputs are swapped. This can be checked diagrammatically:

► **Lemma 7.**

► **Lemma 9.**

► **Lemma 8.**

► **Lemma 10.**

3 Quantum Multiple-valued Decision Diagrams

Quantum multiple-valued decision diagrams (QMDD) were introduced to store quantum unitaries in a way that is efficient in certain cases, similarly to binary decision diagrams for representing decision problems. In the following, we use the map/state duality to turn every map into a state. As a consequence, QMDDs are adapted to “state-QMDDs” as follows:

- **Definition 11.** A state-QMDD (SQMDD) is a tuple $(s, V, u_0, t, H, h, E, \omega)$ where:
- $s \in \mathbb{C}$ is called the overall scalar
 - $V \neq \emptyset$ is a set of vertices
 - $u_0, t \in V$ are two distinguished vertices, called respectively root and terminal node
 - $u_0 = t \iff V = \{t\}$, i.e. u_0 and t coincide only if V only contains one vertex
 - $H \in \mathbb{N}$ is the height of the SQMDD
 - $h : V \mapsto \{0, \dots, H\}$ maps each vertex to their height in the SQMDD
 - $h(u) = 0 \iff u = t$
 - $E : V \setminus \{t\} \rightarrow V^2$ maps any non-terminal vertex to a pair of vertices. These are the edges of the SQMDD
 - If $E(u) = (v_0, v_1)$ then $h(v_i) < h(u)$ for $i \in \{0, 1\}$
 - $\forall v \in V \setminus \{u_0\}, \exists u \in V, v \in E(u)$, i.e. all vertices have at least one parent
 - $\omega : V \setminus \{t\} \rightarrow \mathbb{C}^2$ maps edges to complex weights

Notice that the requirement on the heights of two endpoints of an edge also enforces the fact that an SQMDD is acyclical.

When drawing a SQMDD, it is relevant to set all the same-height nodes at the same height in the representation. It is also customary to omit writing weights of 1, as well as the vertices’ names (we write instead their height). We highlight the root by an incoming wire, and distinguish the terminal node by drawing it as a square, instead of a circle for the other nodes (following [24]’s convention). Finally, we display the overall scalar as a weight on the incoming edge of the root, and if $h(u_0) = H$, we omit H , which we otherwise specify at the top of the SQMDD.

► **Example 12.** The diagram:

is a graphical representation of an SQMDD.

► **Remark 13.** SQMDDs can be seen as a more fine-grained version of proper QMDDs. Indeed, using the map/state duality $\psi_{n,m}$ defined above amounts to decomposing a QMDD vertex  into . This for instance allows us to apply a swap  only on one side of a circuit/diagram, while the associated QMDD notion of variable reordering requires swapping the whole qubit i.e. apply a swap on both sides of the circuit. A similar presentation of QMDDs for states can be found in [29].

We can define two natural constructions from any SQMDD of height ≥ 1 :

► **Definition 14.** Let $\mathfrak{D} = (s, V, u_0, t, H, h, E, \omega)$ be a SQMDD with $H \geq 1$. We denote $\ell(\mathfrak{D})$ the diagram obtained from \mathfrak{D} by:

- If $h(u_0) = H$:
 - replacing the overall scalar s by $s \cdot \pi_0 \omega(u_0)$
 - removing all nodes (and subsequent edges) that cannot be reached by $\pi_0 E(u_0)$
 - replacing the root u_0 by $\pi_0 E(u_0)$
- decreasing the height H by 1

Where π_0 and π_1 are the usual left and right projectors of a pair.

We can similarly build $r(\mathfrak{D})$ by replacing π_0 by π_1 in the definition.

► **Example 15.** With \mathfrak{D} the SQMDD defined in the previous example:

We can now use these constructions to understand SQMDDs as representations of quantum states.

► **Definition 16.** For any SQMDD \mathfrak{D} , $[[\mathfrak{D}]]$ is the (unnormalised) quantum state inductively defined as:

- $[[\begin{smallmatrix} s \\ 0 \end{smallmatrix}]] = s = s | \rangle$
- $[[\mathfrak{D}]] = |0\rangle \otimes [[\ell(\mathfrak{D})]] + |1\rangle \otimes [[r(\mathfrak{D})]]$

(here $| \rangle$ is used to represent the vector (1) i.e. the canonical 0-qubit state).

► **Example 17.** With \mathfrak{D} the diagram of example 12:

$$[[\mathfrak{D}]] = \frac{3}{\sqrt{2}} \left(1 \ 0 \ 0 \ 0 \ \frac{1}{\sqrt{2}} \ \frac{1}{\sqrt{2}} \ \frac{1}{\sqrt{2}} \ \frac{1}{\sqrt{2}} \ -\frac{1}{\sqrt{2}} \ 0 \ 0 \ 0 \ -i \ 0 \ -i \ 0 \right)^T$$

The definition of SQMDDs given here does not only differ from that of [24] by the fact that we only consider states, but also by the fact that our definition is laxer. As a consequence, different SQMDDs can have the same interpretation. To address this problem, we can give a set of rewrite rules that will reduce the “size” of the SQMDD while preserving its interpretation. We give in Figure 2 this set of rewrite rules, expressed graphically. Notice that the rules use the graphical notation to encompass transformations on the root and the overall scalar.

It is fairly easy to see that this rewriting terminates. Let us denote $\text{deg}(t)$ the arity of t , i.e. the number of occurrences of t in $E(V \setminus \{t\})$. Notice that $\text{deg}(t) < 2|V|$. For $u \in V \setminus \{t\}$, define:

$$\delta(u) := \begin{cases} 0 & \text{if } \pi_0(\omega(u)) = 1 \vee (\pi_0(\omega(u)) = 0 \wedge \pi_1(\omega(u)) \in \{0, 1\}) \\ 1 & \text{otherwise} \end{cases}$$

Consider now for any SQMDD the quantity $\left(|V|, 2|V| - \text{deg}(t), \sum_{u|h(u)=1} \delta(u), \dots, \sum_{u|h(u)=H} \delta(u) \right)$, and the lexicographical order over these. We can see that this quantity is reduced by any rewrite.

■ **Figure 2** Simplification rules for QMDDs.

When none of these rewrite rules can be applied on an SQMDD, it is called irreducible. Notice that in an irreducible SQMDD, using the notions of [24], no non-terminal vertex is redundant, and all non-terminal vertices are normalised and unique. Hence, an irreducible SQMDD is what [24] properly calls a QMDD, from which we get:

► **Theorem 18** ([24]). *For any quantum state $|\psi\rangle \in \mathbb{C}^{2^n}$, there exists a unique irreducible SQMDD \mathfrak{D} (of height n) such that $\llbracket \mathfrak{D} \rrbracket = |\psi\rangle$.*

4 From SQMDDs to ZH

From any SQMDD, it is possible to build a ZH-diagram whose interpretation will be the same, in a fairly straightforward manner, using the two syntactic sugars defined above. We denote $[\cdot]^{ZH}$ this map. We define it on every “layer” of an SQMDD, that is, on all the nodes of the same height $\leq H$. Such a layer is mapped to a ZH-diagram as follows:

This construction adds a wire to the left. It is the “effective” wire of the layer, the one that will constitute the output qubit in the quantum state. If there is no node of height h , the construction still add a wire on the left, disconnected from everything: \circlearrowleft . Omitted in the

previous definition is the mapping of the weights on wires, which are simply: $r \mapsto \text{gate}(r)$,

as well that of the terminal node, for which we have: $\text{node}(0) \mapsto \text{terminal node}$. Finally, the particular

state $\text{node}(1)$ is plugged on top of the root: $\text{node}(1) \mapsto \text{gate}(1)$ (if the root has height $< H$ we technically have empty layers on top of the root, hence the $\text{node}(1)$'s).

The full SQMDD is then mapped as follows, where L is the layer of interest, and A and B will themselves be inductively decomposed layer by layer:

► **Example 19.**

This interpretation $[\cdot]^{ZH}$ was not chosen at random: it builds a quantum state with the intended semantics.

► **Proposition 20.** For any SQMDD \mathfrak{D} , $[[\mathfrak{D}]^{ZH}] = [\mathfrak{D}]$.

Proof. Since \bullet and $\neg\bullet$ represent $|0\rangle$ and $|1\rangle$ respectively, we have, for any ZH-diagram $D : 0 \rightarrow n$:

$$\left[\begin{array}{c} D \\ \vdots \end{array} \right] = |0\rangle \otimes \left[\begin{array}{c} D \\ \bullet \end{array} \right] + |1\rangle \otimes \left[\begin{array}{c} D \\ \neg\bullet \end{array} \right]$$

Now, let \mathfrak{D} be an SQMDD, and $D := [\mathfrak{D}]^{ZH}$. We proceed by induction on H the height of \mathfrak{D} , where the base case is obvious. We then focus on the root u_0 . We need to distinguish two cases:

• $H > h(u_0)$: In this case, $\ell(\mathfrak{D}) = r(\mathfrak{D})$ which entails $[\mathfrak{D}] = (|0\rangle + |1\rangle) \otimes [\ell(\mathfrak{D})]$. It can be easily seen that $[\mathfrak{D}]^{ZH} = \bigcirc [\ell(\mathfrak{D})]^{ZH}$, hence $[[\mathfrak{D}]^{ZH}] = \left[\bigcirc \right] \otimes [[\ell(\mathfrak{D})]^{ZH}] = (|0\rangle + |1\rangle) \otimes [[\ell(\mathfrak{D})]^{ZH}]$

• $H = h(u_0)$: Then, $D = \left[\begin{array}{c} \neg\bullet \\ \diagdown \\ D' \\ \vdots \end{array} \right]$. We hence have:

$$\begin{aligned} [[\mathfrak{D}]^{ZH}] &= \left[\begin{array}{c} \neg\bullet \\ \diagdown \\ D' \\ \vdots \end{array} \right] = |0\rangle \otimes \left[\begin{array}{c} \bullet \\ \diagdown \\ D' \\ \vdots \end{array} \right] + |1\rangle \otimes \left[\begin{array}{c} \neg\bullet \\ \diagdown \\ D' \\ \vdots \end{array} \right] \\ &= |0\rangle \otimes \left[\begin{array}{c} \bullet \\ \bullet \\ D' \\ \vdots \end{array} \right] + |1\rangle \otimes \left[\begin{array}{c} \bullet \\ \bullet \\ D' \\ \vdots \end{array} \right] \end{aligned}$$

where the last equality is obtained thanks to Lemmas 7 and 9. We now need to show that

$\llbracket \begin{array}{c} \bullet \bullet \\ \boxed{D'} \\ \vdots \end{array} \rrbracket = \llbracket [\ell(\mathcal{D})]^{ZH} \rrbracket$ and similarly with the right hand side. We can actually show that

we can reduce $\begin{array}{c} \bullet \bullet \\ \boxed{D'} \\ \vdots \end{array}$ to $[\ell(\mathcal{D})]^{ZH}$ using the following rewrites (provable in ZH):

$$\begin{array}{c} \bullet \\ \neg \\ \circ \\ \boxed{r} \\ \vdots \end{array} \rightarrow r \begin{array}{c} \neg \\ \bullet \\ \vdots \end{array} \quad (1) \quad \begin{array}{c} \bullet \\ \diagup \diagdown \\ \square \\ \vdots \end{array} \rightarrow \begin{array}{c} \circ \\ \bullet \bullet \\ \vdots \end{array} \quad (2) \quad \begin{array}{c} \bullet \\ \circ \\ \boxed{r} \\ \vdots \end{array} \rightarrow \begin{array}{c} \bullet \\ \vdots \end{array} \quad (3)$$

$$\begin{array}{c} \bullet \dots \\ \cup \\ \vdots \end{array} \rightarrow \begin{array}{c} \dots \\ \cup \\ \vdots \end{array} \quad (4) \quad \begin{array}{c} \dots \\ \diagup \diagdown \\ \circ \\ \vdots \end{array} \rightarrow \begin{array}{c} \dots \\ \diagdown \diagup \\ \circ \\ \vdots \end{array} \quad (5)$$

Rewrite 1 ensures that if the left wire was weighted, the weight itself gets factored in the overall scalar.

Rewrites 2 and 3 destroy all the nodes that are not descendent of the left child of the root. Rewrite 4 dictates that if \bullet arrives at a node with several parents, the behaviour depends

on what happens to the others parents (if all parents are destroyed, \cup will get \bullet to all its inputs, which will result in \bullet , hence pursuing the destruction of subsequent nodes). It also shows what happens to \bullet when it arrives at the terminal node.

Finally, Rewrite 5 simply normalises the connected Z-spiders one can obtain from Rewrite 2.

This rewrite strategy goes on as long as some \bullet exist in the diagram, until they all disappear from Rewrite 4, in which situation we get the diagram one would have obtained from $\ell(\mathcal{D})$. Similarly, we see that $\begin{array}{c} \bullet \bullet \\ \boxed{D'} \\ \vdots \end{array}$ reduces to $[r(\mathcal{D})]^{ZH}$. Hence, by soundness of the rewrite strategy, we do have:

$$\llbracket [\mathcal{D}]^{ZH} \rrbracket = |0\rangle \otimes \llbracket [\ell(\mathcal{D})]^{ZH} \rrbracket + |1\rangle \otimes \llbracket [r(\mathcal{D})]^{ZH} \rrbracket$$

which by induction hypothesis means $\llbracket [\mathcal{D}]^{ZH} \rrbracket = \llbracket \mathcal{D} \rrbracket$. ◀

This proof introduces a small rewrite strategy, that will be used in the following, in particular to simplify a ZH-diagram in SQMDD form.

5 Setting a ZH-Diagram in SQMDD Form

If any SQMDD can be turned into a ZH-diagram, the reciprocal requires some work. In the following, we describe an algorithm that turns any ZH-diagram into SQMDD form, i.e. into a ZH-diagram that is in the image of $[\cdot]^{ZH}$, using its equational theory.

5.1 SQMDD Reduction

We start to show that all the simplification rules for SQMDDs can be derived directly into the ZH-Calculus. For this, we need the following lemmas:

► Lemma 21.

► Lemma 24.

► Lemma 27.

► Lemma 22.

► Lemma 25.

► Lemma 28.

► Lemma 23.

► Lemma 26.

► Proposition 29. For any simplification rule $\mathfrak{D}_1 \xrightarrow{r} \mathfrak{D}_2$, the following diagram commutes:

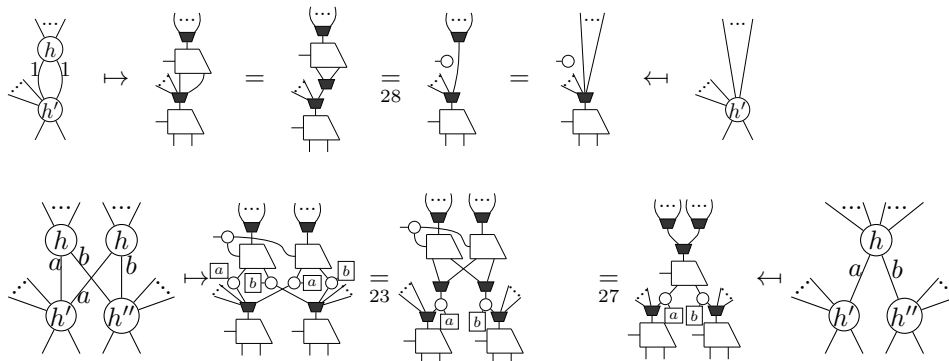

Proof. We start with the first rewrite of Figure 2, where $a \neq 0$:

The proof for the rewrite where $a = 0$ and b diffuses instead is similar. When applied to the root, the proofs are the same with the additional equality $\overline{\bullet} \circ r \rightarrow r \bullet$.

The rule $\overline{\bullet} \circ r \rightarrow r \bullet$ is a direct consequence of the rewrite strategy of the proof of Proposition 20.

The case where the two children are the same is very similar:

Thanks to this proof, we now have a strategy to systematically reduce any ZH-diagram that is in SQMDD form. We then show how to put a ZH-diagram in SQMDD form in the first place.

5.2 SQMDD form of Generators and Compositions

We now show that all the generators of the ZH-Calculus can be put in SQMDD form, and furthermore that the compositions of diagrams in SQMDD form can be put in SQMDD form.

► **Proposition 30.** *Suppose D' differs from a diagram D in SQMDD form by replacing some of its  by .* We then have: $ZH \vdash D = D'$.

This result actually still holds for any commutative monoid whose neutral element is . A straightforward analysis yields that such monoids are of the form $\begin{pmatrix} 1 & 0 & 0 & a \\ 0 & 1 & 1 & b \end{pmatrix}$ for $a, b \in \mathbb{C}$.

This result will be used in the proposition that follows, but notice that it can also be used to simplify the ZH-diagram obtained from an SQMDD.

Now, we can show that all the generators can be set in SQMDD form:

► **Proposition 31.** *The generators of the ZH-Calculus can be set in SQMDD form:*

We then need to show that the composition of diagrams in SQMDD form can be put in SQMDD form.

► **Proposition 32.** *The parallel composition of ZH-diagrams in SQMDD form can be put in SQMDD form, by joining the root of the right diagram to the terminal node of the diagram on the left.*

Since we work only with quantum states after using the map/state duality, what accounts for sequential composition is the linking of two ZH-diagrams in SQMDD form through \cup . This element can be decomposed into two primitives: $\cup = \begin{pmatrix} \cup \\ \circ \end{pmatrix}$. We hence show that applying each of these two primitives to a ZH-diagram in SQMDD form can be put in SQMDD form. To simplify the proof, we first show that swapping two outputs of a state in SQMDD can be put in SQMDD form.

► **Proposition 33.** *Let D be a ZH-diagram in SQMDD form. Applying \bowtie on two of its outputs can be put in SQMDD form. By repeated application of \bowtie , any permutation of the outputs of D can be put in SQMDD form.*

We can then move on to the two subproofs that show that applying \cup to a diagram in SQMDD form can be turned in SQMDD form:

► **Proposition 34.** *Let D be a ZH-diagram in SQMDD form. Applying \cup on two of its outputs can be put in SQMDD form.*

► **Proposition 35.** *Let D be a ZH-diagram in SQMDD form. Applying \circ on any of its outputs can be put in SQMDD form.*

Combining the previous propositions, we get the expected result:

► **Theorem 36.** *Any ZH-diagram can be put in reduced SQMDD form.*

This theorem gives an algorithm to translate any ZH-diagram into an SQMDD. Indeed, since a diagram D in reduced SQMDD form is in the image of $[\cdot]^{ZH}$ (which is injective), it now suffices to take its inverse to get a proper SQMDD.

Decision Problems for Origin-Close Top-Down Tree Transducers

Sarah Winter 

Université libre de Bruxelles, Brussels, Belgium

Abstract

Tree transductions are binary relations of finite trees. For tree transductions defined by non-deterministic top-down tree transducers, inclusion, equivalence and synthesis problems are known to be undecidable. Adding origin semantics to tree transductions, i.e., tagging each output node with the input node it originates from, is a known way to recover decidability for inclusion and equivalence. The origin semantics is rather rigid, in this work, we introduce a similarity measure for transducers with origin semantics and show that we can decide inclusion, equivalence and synthesis problems for origin-close non-deterministic top-down tree transducers.

1 Introduction

In this paper we study decision problems for top-down tree transducers over finite trees with origin semantics. Rounds [30] and Thatcher [31] independently invented tree transducers (their model is known today as top-down tree transducer) as a generalization of finite state word transducers in the context of natural language processing and compilers in the beginning of the 1970s. Nowadays, there is a rich landscape of various tree transducer models used in many fields, for example, syntax-directed translation [18], databases [29, 20], linguistics [27, 5], programming languages [33, 28], and security analysis [23].

Unlike tree automata, tree transducers have undecidable inclusion and equivalence problems [13]. This is already the case for word transducers [19, 17]. The intractability of, e.g., the equivalence problem for transducers (whether two given transducers recognize the same transduction, that is, the same relation) mainly stems from the fact that two transducers recognizing the same transduction may produce their outputs very differently. One transducer may produce its output fast and be ahead of the other. In general, there is an infinite number of transducers for a single transduction. To overcome this difficulty Bojanczyk [1] has introduced origin semantics, that is, additionally, there is an origin function that maps output positions to their originating input positions. The main result of [1] is a machine-independent characterization of transductions defined by deterministic two-way transducers with origin semantics. Word transducers with origin semantics were further investigated in [2], and properties of subclasses of transductions with origin semantics definable by one-way word transducers have been studied in [14, 9]. Under origin semantics, many interesting problems become decidable, e.g., equivalence of one-way word transducers. This is not surprising as a transduction now incorporates *how* it translates an input word into an output word providing much more information.

In [16], the authors have initiated a study of several decision problems for different tree transducer models on finite trees with origin semantics. More concretely, they studied inclusion, equivalence, injectivity and query determinacy problems for top-down tree transducers, tree transducers definable in monadic second order logic, and top-down tree-to-word transducers. They showed (amongst other results) that inclusion and equivalence become decidable for all models except tree-to-string transducers with origin semantics.

In general, there has been an interest to incorporate some kind of origin information (i.e., *how* a transduction works) into tree transductions, in order to gain more insight on different tree transductions, see, e.g., [32, 11, 26].

However, the origin semantics is rather rigid. To mitigate this, in [15], the authors have introduced a similarity measure between (one-way) word transducers with origin semantics which amounts to a measure that compares the difference between produced outputs on the same input prefix, in short, the measure compares their output delays. They show that inclusion, equivalence, and sequential uniformization (see next paragraph) problems become decidable for transducers that have bounded output delay. These problems are undecidable for word transducers in general, see [19, 17, 7]. The introduction of this similarity measure has triggered similar works on two-way word transducers, see [4, 3].

In order to obtain decidability results (in a less rigid setting than origin semantics), we initiate the study of inclusion, equivalence, and uniformization problems for top-down tree transducers under similarity measures which are based on the behavior of the transducers.

A uniformization of a binary relation is a function that selects for each element of the domain of the relation an element in its image. Synthesis problems are closely related to *effective* uniformization problems; algorithmic synthesis of specifications (i.e., relations) asks for effective uniformization by functions that can be implemented in a specific way. The classical setting is Church's synthesis problem [8], where logical specifications over infinite words are considered. Büchi and Landweber [6] showed that for specifications in monadic second order logic, that is, specifications that can be translated into synchronous finite automata, it is decidable whether they can be realized by a synchronous sequential transducer. Later, decidability has been extended to asynchronous sequential transducers [22, 21]. Detailed studies of the synthesis of sequential transducers from synchronous and asynchronous finite automata on finite words are provided in [15, 34], for an overview see [7].

Uniformization questions in this spirit have been first studied for relations over finite trees in [25, 24]. The authors have considered tree-automatic relations, that is, relations definable by tree automata over a product alphabet. They have shown that for tree-automatic relations definable by deterministic top-down tree automata uniformization by deterministic top-down tree transducers (which are a natural extension of sequential transducer on words) is decidable. However, for non-deterministic top-down tree automata it becomes undecidable.

Our contribution is the introduction of two similarity measures for top-down tree transducers. The first measure is an extension of the output delay measure introduced for word transducers in [15] to tree transducers. Comparing top-down tree transducers based on their output delay has also been done in e.g., [12], we use the same notion of delay to define our measure. Unfortunately, while decidability for major decision problems is regained in the setting of word transducers, we show that it is not in the setting of tree transducers. The second similarity measure is more closely connected to the origin semantics. We define two transducers as origin-close if there is a bound on the distance of two positions which are origins of the same output node by the two transducers. Our main result is that inclusion, equivalence and uniformization by deterministic top-down tree transducers is decidable for origin-close top-down tree transducers.

The paper is structured as follows. In Section 2 we provide definitions and terminology used throughout the paper. In Section 3 we present two similarity measures for (top-down tree) transducers and provide a comparison of their expressiveness, and in Section 4 we consider decision problems for origin-close top-down tree transducers.

2 Preliminaries

Words, trees, and contexts. An *alphabet* Σ is a finite non-empty set of *letters* or *symbols*. A finite *word* is a finite sequence of letters. The set of all finite words over Σ is denoted by Σ^* . The length of a word $w \in \Sigma^*$ is denoted by $|w|$, the empty word is denoted by ε . We write $u \sqsubseteq w$ if there is some v such that $w = uv$ for $u, v \in \Sigma^*$. A subset $L \subseteq \Sigma^*$ is called *language* over Σ . A *ranked alphabet* Σ is an alphabet where each letter $f \in \Sigma$ has a rank $rk(f) \in \mathbb{N}$. The set of letters of rank i is denoted by Σ_i . A tree domain dom is a non-empty finite subset of $(\mathbb{N} \setminus \{0\})^*$ such that dom is prefix-closed and for each $u \in (\mathbb{N} \setminus \{0\})^*$ and $i \in \mathbb{N} \setminus \{0\}$ if $ui \in dom$, then $uj \in dom$ for all $1 \leq j < i$. We speak of ui as successor of u for each $u \in dom$ and $i \in \mathbb{N} \setminus \{0\}$, and the \sqsubseteq -maximal elements of dom are called *leaves*.

A (finite Σ -labeled) *tree* is a mapping $t : dom_t \rightarrow \Sigma$ such that for each node $u \in dom_t$ the number of successors of u is a rank of $t(u)$. The height h of a tree t is the length of its longest path, i.e., $h(t) = \max\{|u| \mid u \in dom_t\}$. The set of all Σ -labeled trees is denoted by T_Σ . A subset $T \subseteq T_\Sigma$ is called *tree language* over Σ .

A *subtree* $t|_u$ of a tree t at node u is defined by $dom_{t|_u} = \{v \in \mathbb{N}^* \mid uv \in dom_t\}$ and $t|_u(v) = t(uv)$ for all $v \in dom_{t|_u}$. In order to formalize concatenation of trees, we introduce the notion of special trees. A *special tree* over Σ is a tree over $\Sigma \cup \{\circ\}$ such that \circ has rank zero and occurs exactly once at a leaf. Given $t \in T_\Sigma$ and $u \in dom_t$, we write $t[\circ/u]$ for the special tree that is obtained by deleting the subtree at u and replacing it by \circ . Let S_Σ be the set of special trees over Σ . For $t \in S_\Sigma$ and $s \in T_\Sigma$ or $s \in S_\Sigma$ let the *concatenation* $t \cdot s$ be the tree that is obtained from t by replacing \circ with s .

Let X_n be a set of n variables $\{x_1, \dots, x_n\}$ and Σ be a ranked alphabet. We denote by $T_\Sigma(X_n)$ the set of all trees over Σ which additionally can have variables from X_n at their leaves. We define X_0 to be the empty set, the set $T_\Sigma(\emptyset)$ is equal to T_Σ . Let $X = \bigcup_{n>0} X_n$. A tree from $T_\Sigma(X)$ is called *linear* if each variable occurs at most once. For $t \in T_\Sigma(X_n)$ let $t[x_1 \leftarrow t_1, \dots, x_n \leftarrow t_n]$ be the tree that is obtained by substituting each occurrence of $x_i \in X_n$ by $t_i \in T_\Sigma(X)$ for every $1 \leq i \leq n$.

A tree from $T_\Sigma(X_n)$ such that all variables from X_n occur exactly once and in the order x_1, \dots, x_n when reading the leaf nodes from left to right, is called *n-context* over Σ . Given an *n-context*, the node labeled by x_i is referred to as *i*th hole for every $1 \leq i \leq n$. A special tree can be seen as a 1-context, a tree without variables can be seen as a 0-context. If C is an *n-context* and $t_1, \dots, t_n \in T_\Sigma(X)$ we write $C[t_1, \dots, t_n]$ instead of $C[x_1 \leftarrow t_1, \dots, x_n \leftarrow t_n]$.

Tree transductions, origin mappings, and uniformizations. Let Σ, Γ be ranked alphabets. A *tree transduction* (from T_Σ to T_Γ) is a relation $R \subseteq T_\Sigma \times T_\Gamma$. Its *domain*, denoted $\text{dom}(R)$, is the projection of R on its first component. Given trees t_1, t_2 , an *origin mapping* of t_2 in t_1 is a function $o : dom_{t_2} \rightarrow dom_{t_1}$. Given $v \in dom_{t_2}$, $u \in dom_{t_1}$, we say v has origin u if $o(v) = u$. Examples are depicted in Figures 1g and 2. A *uniformization* of a tree transduction $R \subseteq T_\Sigma \times T_\Gamma$ is a function $f : \text{dom}(R) \rightarrow T_\Gamma$ such that $(t, f(t)) \in R$ for all $t \in \text{dom}(R)$.

Top-down tree transducers. We consider top-down tree transducers, which read the tree from the root to the leaves in a parallel fashion and produce finite output trees in each step that are attached to the already produced output.

A *top-down tree transducer* (a TDTT) is of the form $\mathcal{T} = (Q, \Sigma, \Gamma, q_0, \Delta)$ consisting of a finite set of states Q , a finite input alphabet Σ , a finite output alphabet Γ , an initial state $q_0 \in Q$, and Δ is a finite set of transition rules of the form

$$q(f(x_1, \dots, x_i)) \rightarrow w[q_1(x_{j_1}), \dots, q_n(x_{j_n})],$$

where $f \in \Sigma_i$, w is an n -context over Γ , $q, q_1, \dots, q_n \in Q$ and variables $x_{j_1}, \dots, x_{j_n} \in X_i$. A *deterministic* TDTT (a DTDTT) has no two rules with the same left-hand side.

We now introduce a non-standard notion of configurations which is more suitable to prove our results. Usually, a configuration is a partially transformed input tree; the upper part is the already produced output, the lower parts are remainders of the input tree. Here, we keep the input and output tree separate and introduce a mapping from nodes of the output tree to nodes of the input tree from where the transducer continues to read. A visualization of several configurations is given in Figure 1.

A *configuration* of a top-down tree transducer is a triple $c = (t, t', \varphi)$ of an input tree $t \in T_\Sigma$, an output tree $t' \in T_{\Gamma \cup Q}$ and a function $\varphi : D_{t'} \rightarrow \text{dom}_t$, where

- $t'(u) \in \Gamma_i$ for each $u \in \text{dom}_{t'}$ with $i > 0$ successors, and
- $t'(u) \in \Gamma_0$ or $t'(u) \in Q$ for each leaf $u \in \text{dom}_{t'}$, and
- $D_{t'} \subseteq \text{dom}_{t'}$ with $D_{t'} = \{u \in \text{dom}_{t'} \mid t'(u) \in Q\}$, i.e., φ maps every node from the output tree t' that has a state-label to a node of the input tree t .

Let $c_1 = (t, t_1, \varphi_1)$ and $c_2 = (t, t_2, \varphi_2)$ be configurations of a top-down tree transducer over the same input tree. We define a *successor relation* $\rightarrow_{\mathcal{T}}$ on configurations as usual by applying one rule. Figure 1 illustrates a configuration sequence explained in Example 1 below. Formally, for the application of a rule, we define $c_1 \rightarrow_{\mathcal{T}} c_2 \Leftrightarrow$

- There is a state-labeled node $u \in D_{t'}$ of the output tree t_1 that is mapped to a node $v \in \text{dom}_t$ of the input tree t , i.e., $\varphi_1(u) = v$, and
- there is a rule $t_1(u) (t(v)(x_1, \dots, x_i)) \rightarrow w[q_1(x_{j_1}), \dots, q_n(x_{j_n})] \in \Delta$ such that the output tree is correctly updated, i.e., $t_2 = t_1[\circ/u] \cdot w[q_1, \dots, q_n]$, and
- the mapping φ_2 is correctly updated, i.e., $\varphi_2(u') = \varphi_1(u')$ if $u' \in D_{t_1} \setminus \{u\}$ and $\varphi_2(u') = v.j_i$ if $u' = u.u_i$ with u_i is the i th hole in w .

Furthermore, let $\rightarrow_{\mathcal{T}}^*$ be the reflexive and transitive closure of $\rightarrow_{\mathcal{T}}$. From here on, let φ_0 always denote the mapping $\varphi_0(\varepsilon) = \varepsilon$. A configuration (t, q_0, φ_0) is called *initial configuration* of \mathcal{T} on t . A configuration sequence starting with an initial configuration where each configuration is a successor of the previous one is called a *run*. For a tree $t \in T_\Sigma$ let $\mathcal{T}(t) \subseteq T_{\Gamma \cup Q}$ be the set of *final transformed outputs* of a computation of \mathcal{T} on t , that is the set $\{t' \mid (t, q_0, \varphi_0) \rightarrow_{\mathcal{T}}^* (t, t', \varphi) \text{ s.t. there is no successor configuration of } (t, t', \varphi)\}$. Note, we explicitly do not require that the final transformed output is a tree over Γ . In the special case that $\mathcal{T}(t)$ is a singleton set $\{t'\}$, we also write $\mathcal{T}(t) = t'$. The *transduction* $R(\mathcal{T})$ induced by a TDTT \mathcal{T} is $R(\mathcal{T}) = \{(t, t') \mid t' \in \mathcal{T}(t) \cap T_\Gamma\}$. The class of relations definable by TDTTs is called the class of *top-down tree transductions*, conveniently denoted by TDTT.

Let \mathcal{T} be a TDTT, and let $\rho = c_0 \dots c_n$ be a run of \mathcal{T} on an input tree $t \in T_\Sigma$ that results in an output tree $s \in T_\Gamma$. The *origin function* o of ρ maps a node u of the output tree to the node v of the input tree that was read while producing u , formally $o : \text{dom}_s \rightarrow \text{dom}_t$ with $o(u) = v$ if there is some i , such that $c_i = (t, t_i, \varphi_i)$, $c_{i+1} = (t, t_{i+1}, \varphi_{i+1})$ and $\varphi_i(u) = v$ and $t_{i+1}(u) = s(u)$, see Figure 1. We define $R_o(\mathcal{T})$ to be the set

$$\{(t, s, o) \mid t \in T_\Sigma, s \in T_\Gamma \text{ and } \exists \rho : (t, q_0, \varphi) \rightarrow_{\mathcal{T}}^* (t, s, \varphi') \text{ with origin } o\}.$$

► **Example 1.** Let Σ be a ranked alphabet given by $\Sigma_2 = \{f\}$, $\Sigma_1 = \{g, h\}$, and $\Sigma_0 = \{a\}$. Consider the TDTT \mathcal{T} given by $(\{q\}, \Sigma, \Sigma, \{q\}, \Delta)$ with $\Delta = \{q(a) \rightarrow a, q(g(x_1)) \rightarrow q(x_1), q(h(x_1)) \rightarrow h(q(x_1)), q(f(x_1, x_2)) \rightarrow f(q(x_1), q(x_2))\}$. For each $t \in T_\Sigma$ the transducer deletes

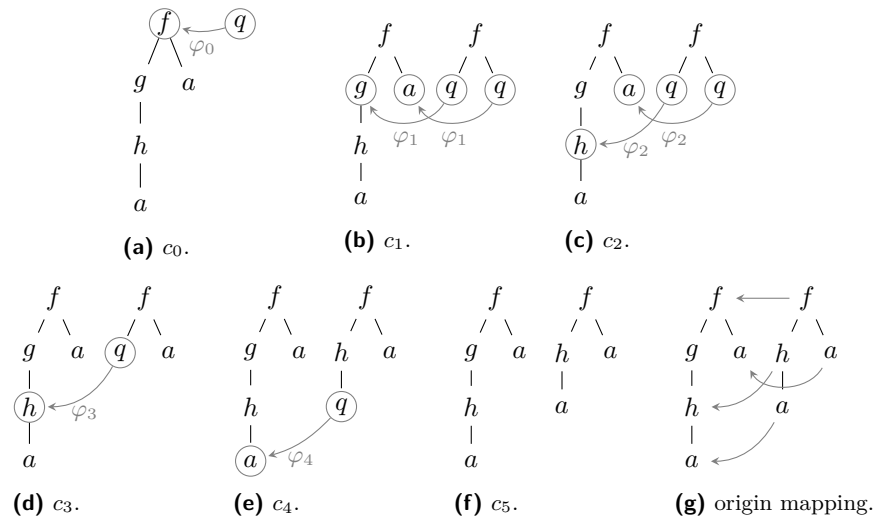

Figure 1 The configuration sequence c_0 to c_5 of \mathcal{T} on $f(g(h(a)), a)$ and resulting origin mapping from Example 1.

Figure 2 Origin mappings o, o' . We have that $dist(o(111), o'(111))$, that is, the distance of the origins of the leaf node, is the length of the shortest path from node 111 to node 211 which is 6.

all occurrences of g in t . Consider $t := f(g(h(a)), a)$. A possible sequence of configurations of \mathcal{T} on t is $c_0 \rightarrow^5 c_5$ such that $c_0 := (t, q, \varphi_0)$ with $\varphi_0(\varepsilon) = \varepsilon$, $c_1 := (t, f(q, q), \varphi_1)$ with $\varphi_1(1) = 1$, $\varphi_1(2) = 2$, $c_2 := (t, f(q, q), \varphi_2)$ with $\varphi_2(1) = 11$, $\varphi_2(2) = 2$, $c_3 := (t, f(q, a), \varphi_3)$ with $\varphi_3(1) = 11$, $c_4 := (t, f(h(q), a), \varphi_4)$ with $\varphi_4(11) = 111$, and $c_5 := (t, f(h(a), a), \varphi_5)$. A visualization of this sequence and resulting origin mapping is shown in Figure 1.

► **Example 2.** Let Σ, Γ be given by $\Sigma_2 = \{f\}$, $\Sigma_0 = \{a\}$, $\Gamma_1 = \{h\}$, and $\Gamma_0 = \{b\}$. Consider the TDTT \mathcal{T} given by $(\{q\}, \Sigma, \Gamma, \{q\}, \Delta)$ with $\Delta = \{ q(a) \rightarrow b, q(f(x_1, x_2)) \rightarrow h(q(x_1)), q(f(x_1, x_2)) \rightarrow h(q(x_2)) \}$. Basically, when reading an f -labeled node, the TDTT can non-deterministically decide whether to continue reading in left or the right subtree. In Figure 2 two origin mappings $o: dom_s \rightarrow dom_t$ and $o': dom_s \rightarrow dom_t$ are given that are result of runs of \mathcal{T} on $t = f(f(f(a, a), a), a), f(f(a, a), a), a)$ with final output $s = h(h(h(b)))$.

In this work, we focus on decision problems for transducers with origin semantics. To begin with, we introduce some notations and state relevant known results in this context.

Shorthand notations. Let \mathcal{C} denote a class of transducers with origin semantics, e.g., TDTT or DTDTT. Given a class \mathcal{C} and $\mathcal{T}_1, \mathcal{T}_2 \in \mathcal{C}$, if $R(\mathcal{T}_1) \subseteq R(\mathcal{T}_2)$ (resp. $R_o(\mathcal{T}_1) \subseteq R_o(\mathcal{T}_2)$), we write $\mathcal{T}_1 \subseteq \mathcal{T}_2$ (resp. $\mathcal{T}_1 \subseteq_o \mathcal{T}_2$). Furthermore, if $R(\mathcal{T}_1) = R(\mathcal{T}_2)$ (resp. $R_o(\mathcal{T}_1) = R_o(\mathcal{T}_2)$),

we write $\mathcal{T}_1 = \mathcal{T}_2$ (resp. $\mathcal{T}_1 =_o \mathcal{T}_2$). Given classes $\mathcal{C}_1, \mathcal{C}_2$, $\mathcal{T}_1 \in \mathcal{C}_1$, and $\mathcal{T}_2 \in \mathcal{C}_2$, if \mathcal{T}_1 defines a function f that is a uniformization of $R(\mathcal{T}_2)$, we say \mathcal{T}_1 uniformizes \mathcal{T}_2 , if additionally $\mathcal{T}_1 \subseteq_o \mathcal{T}_2$, we say \mathcal{T}_1 origin uniformizes \mathcal{T}_2 .

Decision problems. The *inclusion* resp. *origin inclusion problem* for a class \mathcal{C} asks, given $\mathcal{T}_1, \mathcal{T}_2 \in \mathcal{C}$, whether $\mathcal{T}_1 \subseteq \mathcal{T}_2$ resp. $\mathcal{T}_1 \subseteq_o \mathcal{T}_2$. The *equivalence* resp. *origin equivalence problem* for a class \mathcal{C} asks, given $\mathcal{T}_1, \mathcal{T}_2 \in \mathcal{C}$, whether $\mathcal{T}_1 = \mathcal{T}_2$ resp. $\mathcal{T}_1 =_o \mathcal{T}_2$. Lastly, the *uniformization* resp. *origin uniformization problem* for classes $\mathcal{C}_1, \mathcal{C}_2$ asks, given $\mathcal{T}_2 \in \mathcal{C}_2$, whether there exists $\mathcal{T}_1 \in \mathcal{C}_1$ such that \mathcal{T}_1 uniformizes (resp. origin uniformizes) \mathcal{T}_2 .

As mentioned in the introduction, generally, a transduction can be defined by several transducers behaving very differently, making many problems intractable. Adding origin semantics to transducers, i.e., seeing the transducer behavior as part of the transduction, allows to recover decidability. The following is known for the class TDDT.

► **Theorem 3** ([13]). *Inclusion and equivalence are undecidable for the class TDDT.*

► **Theorem 4** ([16]). *Origin inclusion and origin equivalence are decidable for the class TDDT.*

Turning to uniformization problems, it is known that every TDDT is uniformizable by a DTDDT with regular lookahead (a DTDDT^R), that is, the transducer can check membership of the subtrees of a node in regular tree-languages before processing the node.

► **Theorem 5** ([10]). *Every TDDT has a DTDDT^R-uniformization.*

However, when requiring that the input should be transformed on-the-fly (without regular lookahead), the uniformization problem becomes undecidable. In [7], it was shown that it is undecidable whether a one-way (non-deterministic) word transducer has a uniformization by a sequential transducer (that is, basically, a one-way deterministic transducer). So, we get undecidability in the tree setting for free (as stated in Theorem 6). This problem has not been investigated with origin semantics so far. We show decidability (also for more relaxed versions), see Theorem 16.

► **Theorem 6.** *DTDDT^R-uniformization is undecidable for the class TDDT.*

Since the origin semantics is rather rigid, in the next section, we introduce two similarity measures between transducers which are based on their behavior and re-investigate the introduced decision problems for transducers with “similar” behavior.

3 Similarity measures for transducers

An idea that naturally comes to mind is to say that two transducers behave similarly if for two computations over the same input that yield the same output their respective origin mappings are “similar”.

The other idea is to say that two computations are similar if their output delay is small, roughly meaning that for the same prefix (for an adequate notion of prefix for trees) of the input the so-far produced output is of similar size. Decision problems using this measure have already been investigated for (one-way) word transducers [15], we lift the measure to top-down tree transducers.

Origin distance. Given a tree t , let the distance between two nodes $u, v \in \text{dom}_t$, written $\text{dist}(u, v)$, be the shortest path between u and v (ignoring the edge directions), an example is given in Figure 2.

Given $\mathcal{T}, \mathcal{T}_1, \mathcal{T}_2 \in \mathcal{C}$, where \mathcal{C} is a class of transducers with origin semantics. We say (t, s, o) is *k-origin included* in $R_o(\mathcal{T})$, written $(t, s, o) \in_k R_o(\mathcal{T})$, if there is $(t, s, o') \in R_o(\mathcal{T})$ such that $\text{dist}(o(i), o'(i)) \leq k$ for all $i \in \text{dom}_s$. We say \mathcal{T}_1 is *k-origin included* in \mathcal{T}_2 , written $\mathcal{T}_1 \subseteq_k \mathcal{T}_2$, if $(s, t, o) \in_k R_o(\mathcal{T}_2)$ for all $(s, t, o) \in R_o(\mathcal{T}_1)$. We say \mathcal{T}_1 and \mathcal{T}_2 are *k-origin equivalent*, written $\mathcal{T}_1 =_k \mathcal{T}_2$, if $\mathcal{T}_1 \subseteq_k \mathcal{T}_2$ and $\mathcal{T}_2 \subseteq_k \mathcal{T}_1$. We say \mathcal{T}_1 *k-origin uniformizes* \mathcal{T}_2 if $\mathcal{T}_1 \subseteq_k \mathcal{T}_2$ and \mathcal{T}_1 uniformizes \mathcal{T}_2 . The *k-origin* decision problems are defined as expected.

We need some additional notations, before we can introduce the concept of delay.

Partial and prefix trees. Let N_Σ be the set of all trees over Σ which can have symbols from Σ , that is, symbols with rank ≥ 0 , at their leaves. The set N_Σ is the set of all *partial trees* over Σ . Note that N_Σ includes T_Σ . We say a tree $t' \in N_\Sigma$ is a *prefix tree* of a tree $t \in N_\Sigma$, written $t' \sqsubseteq t$, if $\text{dom}_{t'} \subseteq \text{dom}_t$, and $t'(u) = t(u)$ for all $u \in \text{dom}_{t'}$. Given $t_1, t_2 \in N_\Sigma$, its *greatest common prefix*, written $t_1 \wedge t_2$, is the tree $t \in N_\Sigma$ such that dom_t is the largest subset of $\text{dom}_{t_1} \cap \text{dom}_{t_2}$ such that $t \sqsubseteq t_1$ and $t \sqsubseteq t_2$. Removing $t_1 \wedge t_2$ from t_1 and t_2 naturally yields a set of partial trees (we omit a formal definition) called *difference trees*. These notions are visualized in Figure 3.

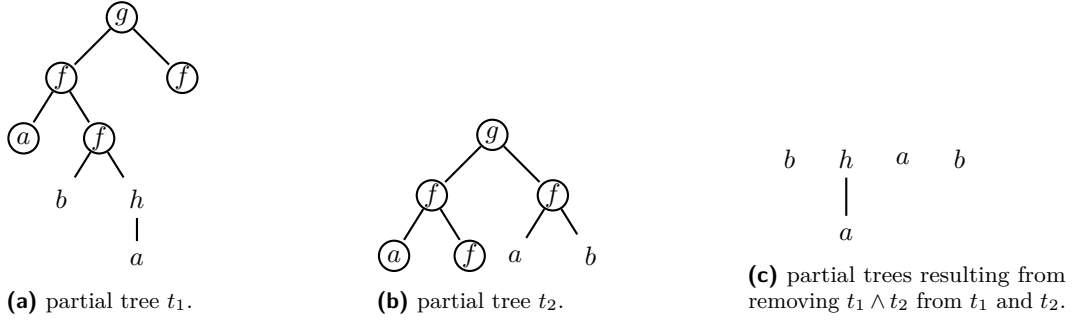

Delay. Given words w_1, w_2 , to compute their delay, we remove their greatest common prefix $w = w_1 \wedge w_2$, say $w_1 = wv_1$ and $w_2 = wv_2$, and their delay is the maximum of the length of their respective reminders, i.e., $\max\{|v_1|, |v_2|\}$. We lift this to trees, given (partial) trees t_1, t_2 , we remove their greatest common prefix $t_1 \wedge t_2$ from t_1 and t_2 which yields a set S of partial trees, we define their delay as $\text{delay}(t_1, t_2) = \max\{h(t) + 1 \mid t \in S\}$. An example is given in Figure 3. Note that for trees over unary and leaf symbols (a way to see words) the definitions for words and trees are equal. Recall that the length of the word a is one, but the height of the tree a is zero.

In order to define a similarity measure between transducers using delay, we take two transducer runs on the same input and compute the delay between their produced outputs throughout their runs. Although we have defined delay between words and trees, we only provide a formal definition for top-down tree transducers. However, for word transducers, examples are given in Example 17, and a formal definition can be found in [15].

Now, let \mathcal{T}_1 and \mathcal{T}_2 be TDTTs, and ρ_1 and ρ_2 be runs of \mathcal{T}_1 and \mathcal{T}_2 , respectively, over the same input tree $t \in T_\Sigma$ such that $\rho_1: (t, q_0^{\mathcal{T}_1}, \varphi_0) \rightarrow_{\mathcal{T}_1}^* (t, t_1, \varphi)$ with $t_1 \in T_\Gamma$, and $\rho_2: (t, q_0^{\mathcal{T}_2}, \varphi_0) \rightarrow_{\mathcal{T}_2}^* (t, t_2, \varphi')$ with $t_2 \in T_\Gamma$.

Basically, we take a look at all configurations that occur in the runs and compute the delay between the output trees of compatible configurations where compatible means in both configurations the same prefix (level-wise, see below) of the input tree has been processed.

Let us be a bit more clear what we mean with compatible. Note that when comparing two configuration sequences (i.e., runs) of word transducers the notion of “have processed the same input so far” is clear. For tree transducers, in one configuration sequence, a left-hand subtree might be processed before the right-hand subtree, and in another configuration sequence vice versa. Since these computation steps are done in a parallel fashion (just written down in an arbitrary order in the configuration sequence), we need to make sure to compare configurations where the subtrees have been processed equally far (we call this level-wise). Also, a tree transducer might not even read the whole input tree, as, e.g., in Example 2. We also (implicitly) take care of this in our definition.

■ **Figure 3** The greatest common prefix of the partial trees t_1 and t_2 , $t_1 \wedge t_2$, is marked with circles in t_1 and t_2 . The delay between t_1 and t_2 is computed from their non-common parts as $\text{delay}(t_1, t_2) = \max\{h(t) + 1 \mid t \in \{b, h(a), a\}\} = 2$.

The result is the maximum of the delay between output trees of compatible configurations. Given $t \in T_\Sigma$, let $\text{Pref}_{\text{level}}(t)$ denote the set of all prefix trees of t such that if a node at level i is kept, then all other nodes at level i are kept, i.e., for $t = f(h(a), h(a))$, $\text{Pref}_{\text{level}}(t)$ contains $f(h, h)$, but not $f(h(a), h)$. Given an intermediate configuration (t, t'_i, φ') of the run ρ_i , we recall that $t'_i \in T_{\Gamma \cup Q_{\mathcal{T}_i}}$ meaning t'_i contains states of \mathcal{T}_i as leaves. Let $t'_i|_\Gamma$ denote the partial tree obtained from t'_i by removing all non- Γ -labelled nodes. We define $\text{delay}(\rho_1, \rho_2)$ as

$$\max\{\text{delay}(t'_1|_\Gamma, t'_2|_\Gamma) \mid \text{there is } t' \in \text{Pref}_{\text{level}}(t), \text{ there is } (t, t'_1, \varphi') \text{ in } \rho_1 \text{ with } t'_1 \in \mathcal{T}_1(t'), \\ \text{and, there is } (t, t'_2, \varphi'') \text{ in } \rho_2 \text{ with } t'_2 \in \mathcal{T}_2(t')\}.$$

The conditions $t'_1 \in \mathcal{T}_1(t')$ and $t'_2 \in \mathcal{T}_2(t')$ are introduced to make sure that all input nodes that can be processed from t' are processed in the selected configurations.

We introduce (shorthand) notations. Let $\mathcal{T}_1, \mathcal{T}_2 \in \mathcal{C}$, where \mathcal{C} is a class of transducers. Given $(t, s) \in R(\mathcal{T}_1)$, we say (t, s) is k -delay included in $R(\mathcal{T}_2)$, written $(t, s) \in_{\mathbb{D}_k} R(\mathcal{T}_2)$, if there are runs ρ and ρ' of \mathcal{T}_1 and \mathcal{T}_2 , respectively, with input t and output s such that $\text{delay}(\rho, \rho') \leq k$. We say \mathcal{T}_1 is k -delay included in \mathcal{T}_2 , written $\mathcal{T}_1 \subseteq_{\mathbb{D}_k} \mathcal{T}_2$, if $(t, s) \in_{\mathbb{D}_k} R(\mathcal{T}_2)$ for all $(t, s) \in R(\mathcal{T}_1)$. We say \mathcal{T}_1 and \mathcal{T}_2 are k -delay equivalent, written $\mathcal{T}_1 =_{\mathbb{D}_k} \mathcal{T}_2$, if $\mathcal{T}_1 \subseteq_{\mathbb{D}_k} \mathcal{T}_2$ and $\mathcal{T}_2 \subseteq_{\mathbb{D}_k} \mathcal{T}_1$. We say \mathcal{T}_1 k -delay uniformizes \mathcal{T}_2 if $\mathcal{T}_1 \subseteq_{\mathbb{D}_k} \mathcal{T}_2$ and \mathcal{T}_1 uniformizes \mathcal{T}_2 . The k -delay decision problems are defined as expected.

In order to get a better understanding of the expressiveness and differences between the two similarity measures, we first explore their properties on word transductions since words are a particular case of trees (i.e., monadic trees).

Word transducers. We denote by FST a *finite state transducer*, the class of word transductions recognized by FSTs is the class of *rational transductions*, conveniently also denoted by FST. We omit a formal definition of FSTs, because they are not considered outside of this section. An FST is *sequential* if its transitions are input-deterministic, more formally, a DTDTT over ranked alphabets with only unary and leaf symbols can be seen as an FST.

The results below concern origin distance, the same results were proven for delay in [15].

► **Proposition 7.**

1. There exist FSTs $\mathcal{T}_1, \mathcal{T}_2$ such that $\mathcal{T}_1 \subseteq \mathcal{T}_2$, but $\mathcal{T}_1 \not\subseteq_k \mathcal{T}_2$ for all $k \geq 0$.
2. There exist FSTs $\mathcal{T}_1, \mathcal{T}_2$ such that $\mathcal{T}_1 = \mathcal{T}_2$, but $\mathcal{T}_1 \not\equiv_k \mathcal{T}_2$ for all $k \geq 0$.
3. There exists an FST \mathcal{T} such that \mathcal{T} is sequentially uniformizable, but \mathcal{T} is not k -origin sequentially uniformizable for all $k \geq 0$.

(a) We have $\mathcal{T}_1 = \mathcal{T}_2$, and $\mathcal{T}_1 =_{\mathbb{D}_1} \mathcal{T}_2$, but $\mathcal{T}_1 \neq_k \mathcal{T}_2$ for all $k \geq 0$; \mathcal{T}' is a sequential uniformizer of \mathcal{T} .

(b) We have $\mathcal{T}_3 = \mathcal{T}_4$, and $\mathcal{T}_3 =_1 \mathcal{T}_4$, but $\mathcal{T}_3 \neq_{\mathbb{D}_k} \mathcal{T}_4$ for all $k \geq 0$.

■ **Figure 4** Comparing origin distance and delay for word transducers, see the proof of Proposition 7 and Example 17.

Proof. First, consider the FSTs $\mathcal{T}_1, \mathcal{T}_2$ depicted in Figure 4a. Both recognize the same function $f: \{a, b, c\}^* \rightarrow \{a\}^*$ defined as $f(ab^*c) = a$. Clearly, $\mathcal{T}_1 \subseteq \mathcal{T}_2$ and $\mathcal{T}_1 = \mathcal{T}_2$. However, the origin distance between \mathcal{T}_1 and \mathcal{T}_2 is unbounded. In \mathcal{T}_1 , the origin of the single output letter a is always the first input letter. In contrast, in \mathcal{T}_2 , the origin of the output letter a is always the last input letter. Secondly, consider the FSTs $\mathcal{T}, \mathcal{T}'$ depicted in Figure 4a. The recognized relation $\mathcal{R}(\mathcal{T}) \subseteq \{a, b, A, B\}^* \times \{a, b\}^*$ consists of $\{(ab^n A, ab^n) \mid n \in \mathbb{N}\}$ and $\{(ab^n B, ab^m) \mid 0 \leq m \leq 2n - 1, n \in \mathbb{N}\}$. The sequential transducer \mathcal{T}' recognizes the function $f: \{a, b, A, B\}^* \rightarrow \{a, b\}^*$ defined by $f(ab^n X) = ab^n$ for $X \in \{A, B\}$ and all $n \in \mathbb{N}$. Clearly, \mathcal{T}' is a sequential uniformization of \mathcal{T} . However, no sequential uniformization with bounded origin distance exists, see Appendix B. ◀

We give an example (depicted in Figure 4 and described in detail in Example 17) that shows that the two notions are orthogonal to each other. However, if we restrict the class FST to *real-time*¹ FST, that is, word transducers such that in every transition exactly one input symbol is read, the notion of delay is more powerful than origin distance, see below. It is important to note that we have proven Proposition 7 for real-time FSTs which are equivalent to TDFTs on monadic trees, i.e., Proposition 7 is true for the class TDFT.

► **Proposition 8.** *Let $\mathcal{T}_1, \mathcal{T}_2$ be real-time FSTs, if $\mathcal{T}_1 \subseteq_i \mathcal{T}_2$ for some $i \geq 0$, then $\mathcal{T}_1 \subseteq_{\mathbb{D}_j} \mathcal{T}_2$ for some $j \geq 0$.*

The notion of bounded delay is suitable to regain decidability.

► **Theorem 9** ([15]). *Given $k \geq 0$, k -delay inclusion, k -delay equivalence and k -delay sequential uniformization are decidable for the class FST.*

Ideally, we would like to lift Theorem 9 from word to tree transducers, but it turns out that the notion of delay is too expressive to yield decidability results for tree transducers as shown in the next paragraph.

¹ ε -transitions (as, e.g., the loop in \mathcal{T}_3 from Figure 4, not be confused with non-producing transitions) are standard for FST, and non-standard for TDFT in the literature. We consider “real-time” TDFT by default.

Tree transducers. It is undecidable whether a given tree-automatic relation has a uniformization by a synchronous DTDTT [24]. A DTDTT is called synchronous if for one processed input node one output node is produced as, e.g., in Example 2. Tree-automatic relations are a subclass of the relations that are recognizable by synchronous TDTT. To prove the result, the authors showed that

► **Lemma 10** ([24]). *There exists a synchronous TDTT \mathcal{T}_M , based on a Turing machine M , that is 0-delay DTDTT-uniformizable iff M halts on the empty input.*

In the proof, for a TM M , a DTDTT \mathcal{T}'_M is constructed such that \mathcal{T}'_M 0-delay uniformizes \mathcal{T}_M iff M halts on the empty input. Recall that this implies that $\mathcal{T}'_M \subseteq_{\mathbb{D}_0} \mathcal{T}_M$ iff M halts on the empty input. Consequently, we obtain that

► **Theorem 11.** *Given $k \geq 0$, k -delay inclusion and k -delay DTDTT-uniformization are undecidable for the class TDTT (even for $k = 0$).*

We do not know whether k -equivalence is decidable for a given $k \geq 0$. Note that Theorem 11 does not imply that 0-origin inclusion and 0-origin DTDTT-uniformization is undecidable for the class TDTT. For the class FST, the notions of 0-origin and 0-delay fall together, but for TDTT this is no longer the case. Recall the TDTT given in Example 2 and its unique runs that yield the origin mappings depicted in Figure 2. The delay between these runs is zero, but their origin mappings are different. An analysis of the (un)decidability proof(s) in [24] pins the problems down to the fact that in the specification and in the possible implementations the origins for the same output node lie on different paths in the input tree. For trees, this fact has no influence when measuring the delay between computations (as seen in Example 2). However, it is recognizable using the origin distance as measure. Since the notion of delay is so powerful that the decision problems under bounded delay become undecidable for tree transducers (see Theorem 11) in contrast to word transducers (see Theorem 9), in the next section, we focus on bounded origin distance.

4 Decision problems for origin-close transducers

We show that the decision problems become decidable for top-down tree transducers with bounded origin distance, see Theorem 16. The next part is devoted to explaining our proof ideas and introducing our main technical lemma (Lemma 13) which is used in all proofs.

Origin-close transductions are representable as regular tree languages. Given $k \geq 0$, and a TDTT \mathcal{T} , we construct an infinite tree $H_{\mathcal{T},k}$, given as the unfolding of a finite graph $G_{\mathcal{T},k}$, such that a node in this infinite tree represents an input sequence from a finite input tree and an output sequence (where the intuition is that this output sequence was produced while processing this input sequence). The idea is that in $H_{\mathcal{T},k}$, we define choices (aka. strategies) of two so-called players In and Out, where a strategy t of In together with a strategy s of Out defines an input tree t , an output tree s , and an origin mapping $o: dom_s \rightarrow dom_t$ of s in t . We can annotate the tree $H_{\mathcal{T},k}$ with the strategies t and s which yields a tree $H_{\mathcal{T},k} \hat{\curvearrowright} t \hat{\curvearrowright} s$. We use this game-like view for all considered decision problems. We illustrate this view.

► **Example 12.** Recall the TDTT \mathcal{T} over Σ and Γ given in Example 2. First, we explain how the graph $G_{\mathcal{T},0}$ looks like. Its unfolding is the infinite tree $H_{\mathcal{T},0}$ (with annotations t and s) depicted in Figure 5. We have three types of nodes: $\{\varepsilon, 1, 2\}$ to indicate that the current node is the root, a first or a second child. The maximum rank of Σ is two, hence $\{\varepsilon, 1, 2\}$. These nodes belong to In who can choose the input label, represented by nodes $\{f, a\}$. Then

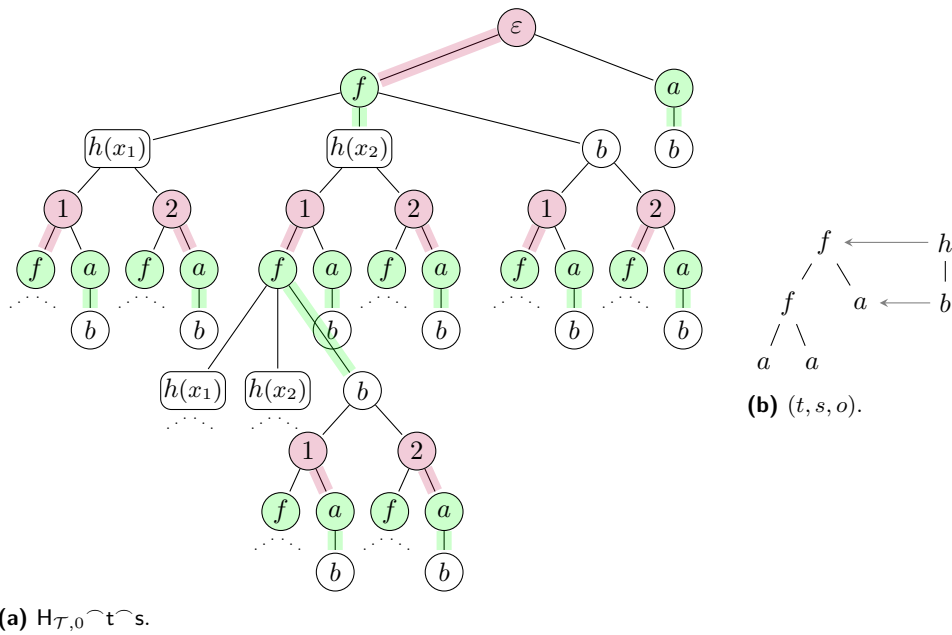

Figure 5 Infinite tree $H_{\mathcal{T},0}$ based on \mathcal{T} from Example 2. On red nodes In must make a choice, on green nodes Out must make a choice. Their respective strategies t and s which define their choices are highlighted on the edges in red and green, respectively. Together, t and s encode the input tree $t = f(f(a, a), a)$, the output tree $s = h(b)$ and origin mapping $o: dom_s \rightarrow dom_t$ as depicted. Note that since t and s are strategies, choices are made whatever the other player does, that is why in $H_{\mathcal{T},0} \hat{\sim} t \hat{\sim} s$, we also have, e.g., a green annotation at node 1112 even though In picked node 1111.

Out chooses which output (from $T_{\Gamma}(X)$) should be produced while processing a node. Since $k = 0$, and all right-hand sides of rules in \mathcal{T} have height at most one, only outputs of height at most one are suitable to maintain origin distance $k = 0$. For input f possible choices are $h(x_1)$ and $h(x_2)$, indicating whether to continue to process the left or the right subtree, or b . For input a only output b is possible. After the output, edges to $\{1, \dots, rk(\sigma)\}$ exist, where σ is the last seen input letter. Further explanation is given in Figure 5.

We present our main technical lemma which states that origin-close transductions are representable as tree language recognizable by a parity tree automaton (a PTA).

► **Lemma 13.** *Given $k \geq 0$ and a TDDT \mathcal{T} , there exists a PTA that recognizes the tree language $\{H_{\mathcal{T},k} \hat{\sim} t \hat{\sim} s \mid (t, s, o) \in_k R_o(\mathcal{T})\}$.*

Proof sketch. The infinite tree $H_{\mathcal{T},k} \hat{\sim} t \hat{\sim} s$ encodes a triple (t, s, o) . We construct a PTA (which has in fact a safety acceptance condition) that guesses a run of \mathcal{T} over the input tree t with output tree s that yields an origin mapping o' such that $(t, s, o') \in R_o(\mathcal{T})$ and $dist(o(i), o'(i)) \leq k$ which implies that $(t, s, o) \in_k R_o(\mathcal{T})$.

Checking whether $dist(o(i), o'(i)) \leq k$ can be done on-the-fly because the origin distance is bounded which implies that the difference trees of so-far produced output by the guessed run and the productions encoded by the annotations are of bounded size. Thus, they can be stored in the state space of the PTA. Even though the construction idea is rather simple, the implementation and correctness proof are non-trivial. We face two difficulties. Firstly, we have to account for the fact that in o and o' origins for the same output node can lie on different paths of the input tree. However, since their distance is bounded, the

amount of shared information that the PTA has to check on different paths is also bounded. Secondly, it is possible to have non-linear transformation rules (that is, rules with copy, e.g., $q(f(x_1, x_2)) \rightarrow f(q_1(x_2), q_2(x_2))$) which adds another layer of complication. This causes that an unbounded number of output nodes can have the same input node as origin. We require that $H_{\mathcal{T},k} \hat{\tau} \hat{s}$ is a tree over a ranked alphabet, hence we have to bound the number of output choices that can be made at an input node. We show that it suffices to only make a bounded number of output choices for each input node. The main insight is that when two continuations of the output tree depend on the same continuation of the input tree, then it suffices to only consider one of them (because the other one can be continued in the same way) if they share the same relevant information where relevant basically means that the state that \mathcal{T} has reached (guessed by the PTA) at these two output nodes and the output difference trees compared to Out 's choices (given by s) are the same. ◀

Solving decision problems for origin-close transducers. We show that deciding k -origin inclusion and equivalence for TDTTs reduces to deciding language inclusion for PTAs.

► **Proposition 14.** *Given $k \geq 0$, k -origin inclusion and k -origin equivalence are decidable for the class TDTT.*

Proof. Let $\mathcal{T}_1, \mathcal{T}_2$ be TDTTs over the same input and output alphabet. If $\mathcal{T}_1 \subseteq_k \mathcal{T}_2$, then $(t, s, o) \in R_o(\mathcal{T}_1)$ implies that $(t, s, o) \in_k R_o(\mathcal{T}_1)$ for all $(t, s, o) \in R_o(\mathcal{T}_1)$. Lemma 13 yields that there are PTAs $\mathcal{A}_1, \mathcal{A}_2$ that recognize $\{H_{\mathcal{T}_1,0} \hat{\tau} \hat{s} \mid (t, s, o) \in R_o(\mathcal{T}_1)\}$ and $\{H_{\mathcal{T}_2,k} \hat{\tau} \hat{s} \mid (t, s, o) \in_k R_o(\mathcal{T}_2)\}$, respectively. Basically, we want to check that $L(\mathcal{A}_1) \subseteq L(\mathcal{A}_2)$. However, we have to overcome a slight technical difficulty. If there are trees $H_{\mathcal{T}_1,0} \hat{\tau}_1 \hat{s}_1 \in L(\mathcal{A}_1)$ and $H_{\mathcal{T}_2,k} \hat{\tau}_2 \hat{s}_2 \in L(\mathcal{A}_2)$ such that for their encoded triples (t_1, s_1, o_1) and (t_2, s_2, o_2) holds that $t_1 = t_2$, $s_1 = s_2$ and o_1 and o_2 have an origin difference of at most k , i.e., $(t_1, s_1, o_1) \in_k \mathcal{R}_0(\mathcal{T}_2)$, it not necessarily holds that $H_{\mathcal{T}_1,0} \hat{\tau}_1 \hat{s}_1 \in L(\mathcal{A}_2)$. This is due to the fact that the base trees $H_{\mathcal{T}_1,0}$ and $H_{\mathcal{T}_2,k}$ look different in general because choices for Out in the first tree are based on the rules of \mathcal{T}_1 and without origin distance and in the latter tree based on the rules of \mathcal{T}_2 with k -origin distance. We only care whether the paths reachable by following the annotations τ_1 and s_1 through $H_{\mathcal{T}_1,0}$ and the paths reachability by following the annotations τ_2 and s_2 through $H_{\mathcal{T}_2,k}$ are the same. Thus, we introduce the operation *purge* which applied to a tree annotated with strategies of In and Out removes all non-strategy paths. It is not difficulty to see that the sets $L_1 := \{\text{purge}(H_{\mathcal{T}_1,0} \hat{\tau} \hat{s}) \mid (t, s, o) \in R_o(\mathcal{T}_1)\}$ and $L_2 := \{\text{purge}(H_{\mathcal{T}_2,k} \hat{\tau} \hat{s}) \mid (t, s, o) \in_k R_o(\mathcal{T}_2)\}$ are also PTA-recognizable. Hence, in order to check whether $\mathcal{T}_1 \subseteq_k \mathcal{T}_2$, we have to check whether $L_1 \subseteq L_2$, which is decidable. We have shown that k -origin inclusion for TDTTs is decidable, consequently, k -origin equivalence for TDTTs is decidable for all $k \geq 0$. ◀

We show that checking whether a TDTT is k -origin DTDTT-uniformizable reduces to deciding emptiness of PTAs.

► **Proposition 15.** *Given $k \geq 0$, k -origin DTDTT-uniformization is decidable for the class TDTT.*

Proof. Given a TDTT \mathcal{T} , by Lemma 13, there is a PTA that recognizes

$$\{H_{\mathcal{T},k} \hat{\tau} \hat{s} \mid (t, s, o) \in_k R_o(\mathcal{T})\}.$$

By closure under complementation and intersection, there is a PTA that recognizes

$$\{H_{\mathcal{T},k} \hat{\tau} \hat{s} \mid (t, s, o) \notin_k R_o(\mathcal{T})\}.$$

By closure under projection, there is a PTA that recognizes

$$\{\mathsf{H}_{\mathcal{T},k} \hat{\ } \mathsf{s} \mid \exists \mathbf{t} : (t, s, o) \notin_k R_o(\mathcal{T})\}.$$

By closure under complementation and intersection, there is a PTA that recognizes

$$\{\mathsf{H}_{\mathcal{T},k} \hat{\ } \mathsf{s} \mid \forall \mathbf{t} : (t, s, o) \in_k R_o(\mathcal{T})\}.$$

By closure under projection, there is a PTA that recognizes

$$\{\mathsf{H}_{\mathcal{T},k} \mid \exists \mathbf{s} : \forall \mathbf{t} : (t, s, o) \in_k R_o(\mathcal{T})\}.$$

Let \mathcal{A} denote the PTA obtained in the last construction step. We show that \mathcal{T} is k -origin DTDTT-uniformizable iff $L(\mathcal{A}) \neq \emptyset$. We have that $L(\mathcal{A}) = \{\mathsf{H}_{\mathcal{T},k} \mid \exists \mathbf{s} : \forall \mathbf{t} : (t, s, o) \in_k R_o(\mathcal{T})\}$. Colloquially, this means that we can fix output choices that only depend on the previously seen input choices, which exactly describes DTDTT-uniformizability.

Assume \mathcal{T} is k -origin DTDTT-uniformizable, say by a DTDTT \mathcal{T}' . There exists a strategy of Out in $\mathsf{H}_{\mathcal{T},k}$ that copies the computations of \mathcal{T}' . Clearly, since \mathcal{T}' is deterministic, we obtain that $\exists \mathbf{s} : \forall \mathbf{t} : (t, s, o) \in_k R_o(\mathcal{T})$, \mathbf{s} can be chosen to be the strategy that copies \mathcal{T}' . Thus, $L(\mathcal{A}) \neq \emptyset$.

For the other direction, assume that $L(\mathcal{A}) \neq \emptyset$. This implies that also the set $\{\mathsf{H}_{\mathcal{T},k} \hat{\ } \mathsf{s} \mid \forall \mathbf{t} : (t, s, o) \in_k R_o(\mathcal{T})\}$ is non-empty and PTA recognizable. Since the set is PTA recognizable, it contains a regular infinite tree (meaning the tree has a finite representation). This tree implicitly contains a finite representation of some strategy \mathbf{s} such that $\forall \mathbf{t} : (t, s, o) \in_k R_o(\mathcal{T})$. Hence, the strategy \mathbf{s} can be translated into a finite-state DTDTT that k -origin uniformizes \mathcal{T} . \blacktriangleleft

Finally, combining Propositions 14 and 15, we obtain our main result.

► **Theorem 16.** *Given $k \geq 0$, k -origin inclusion, k -origin equivalence, and k -origin DTDTT-uniformization are decidable for the class TDDT.*

5 Conclusion

We introduced two similarity measures for TDDTs based on their behavior and studied decision problems for similar TDDTs. For TDDTs with bounded delay, the decision problems remain undecidable. For origin-close TDDTs they become decidable. For future work, we plan to consider other tree transducer models. In [16], it was shown that origin inclusion and origin equivalence are decidable for MSO tree transducers and macro tree transducers.

A

 Missing example

► **Example 17.** To begin with, consider the FSTs $\mathcal{T}_1, \mathcal{T}_2$ depicted in Figure 4a, we already explained in the proof of Proposition 7 that $\mathcal{T}_1 = \mathcal{T}_2$, but $\mathcal{T}_1 \neq_k \mathcal{T}_2$ for all $k \geq 0$, i.e., their origin distance is unbounded. However, their delay is bounded by 1. It is easy to see that $\mathcal{T}_1 =_{\mathbb{D}_1} \mathcal{T}_2$, because their difference in the length of their outputs for the same input is at most one letter. Now, consider the FSTs $\mathcal{T}_3, \mathcal{T}_4$ depicted in Figure 4b. Both recognize the relation $\{(ab, c^n) \mid n \in \mathbb{N}\}$, hence, $\mathcal{T}_3 = \mathcal{T}_4$. Clearly, their origin distance is bounded by 1. The whole output either has the first or the second letter as origin. However, $\mathcal{T}_3 \neq_{\mathbb{D}_k} \mathcal{T}_4$ for all $k \geq 0$, i.e., their delay is unbounded. For any k , take the consider the unique runs that admit output c^{k+1} in \mathcal{T}_3 and \mathcal{T}_4 , respectively. We compare these runs for the input prefix a , \mathcal{T}_3 already has produced c^{k+1} , and \mathcal{T}_4 no output so far. Their delay is $k + 1$.

B

 Missing proofs of Propositions 7 and 8

► **Proposition 7.**

1. There exist FSTs $\mathcal{T}_1, \mathcal{T}_2$ such that $\mathcal{T}_1 \subseteq \mathcal{T}_2$, but $\mathcal{T}_1 \not\subseteq_k \mathcal{T}_2$ for all $k \geq 0$.
2. There exist FSTs $\mathcal{T}_1, \mathcal{T}_2$ such that $\mathcal{T}_1 = \mathcal{T}_2$, but $\mathcal{T}_1 \neq_k \mathcal{T}_2$ for all $k \geq 0$.
3. There exists an FST \mathcal{T} such that \mathcal{T} is sequentially uniformizable, but \mathcal{T} is not k -origin sequentially uniformizable for all $k \geq 0$.

Proof. Secondly, consider the FSTs $\mathcal{T}, \mathcal{T}'$ depicted in Figure 4a. The recognized relation $\mathcal{R}(\mathcal{T}) \subseteq \{a, b, A, B\}^* \times \{a, b\}^*$ consists of $\{(ab^n A, ab^n) \mid n \in \mathbb{N}\}$ and $\{(ab^n B, ab^m) \mid 0 \leq m \leq 2n - 1, n \in \mathbb{N}\}$. The sequential transducer \mathcal{T}' recognizes the function $f: \{a, b, A, B\}^* \rightarrow \{a, b\}^*$ defined by $f(ab^n X) = ab^n$ for $X \in \{A, B\}$ and all $n \in \mathbb{N}$. Clearly, \mathcal{T}' is a sequential uniformization of \mathcal{T} . However, no sequential uniformization with bounded origin distance exists. Towards a contradiction, assume there is sequential transducer \mathcal{T}'' that uniformizes \mathcal{T} such that $\mathcal{T}'' \subseteq_k \mathcal{T}$ for some $k \geq 0$. Consider the input word $ab^{2k} A$, in \mathcal{T} there is only one run with the input which yields the output ab^{2k} and the origin of the i th output letter is the i th input letter for all i . Since $\mathcal{T}'' \subseteq_k \mathcal{T}$ there exists a run of \mathcal{T}'' on $ab^{2k} A$ that yields ab^{2k} and the origin of the first b in the output is at latest the k th b in the input. Now, consider the input $ab^{6k} B$, the output of \mathcal{T}'' on $ab^{6k} B$ is ab^{6k} . Since \mathcal{T}'' is sequential, the the runs of \mathcal{T}'' on $ab^{2k} A$ and $ab^{6k} B$ are the same up to the input ab^{2k} , thus, also for the output ab^{6k}

the origin first output b is at latest the k th b in the input. Now we compare this with all possible runs in \mathcal{T} on $ab^{6k}B$ that also yield ab^{6k} . Note that \mathcal{T} (after producing the first b) must always produce two b at once, thus in order to produce ab^{6k} for the input $ab^{6k}B$, the production of b can only start after while reading the second half of the input. This implies that the first output has an origin in the second half of input which has a distance of more than k (at least $2k$) to the k th b in the input. ◀

► **Proposition 8.** *Let $\mathcal{T}_1, \mathcal{T}_2$ be real-time FSTs, if $\mathcal{T}_1 \subseteq_i \mathcal{T}_2$ for some $i \geq 0$, then $\mathcal{T}_1 \subseteq_{\mathbb{D}_j} \mathcal{T}_2$ for some $j \geq 0$.*

Proof. Let $\mathcal{T}_1, \mathcal{T}_2$ be real-time FSTs such that $\mathcal{T}_1 \subseteq_i \mathcal{T}_2$ for some $i \geq 0$. Let ℓ be the maximum number of output letters that \mathcal{T}_1 produces in a computation step. Consider any $(u, v, o_1) \in R_o(\mathcal{T}_1)$, since $\mathcal{T}_1 \subseteq_i \mathcal{T}_2$, there is $(u, v, o_2) \in R_o(\mathcal{T}_2)$ such that $dist(o_1(d), o_2(d)) \leq i$ for all $d \in dom_v$. Let ρ_1 and ρ_2 be the corresponding runs of \mathcal{T}_1 and \mathcal{T}_2 , respectively. We show that $delay(\rho_1, \rho_2) \leq \ell \cdot i$ which implies that $\mathcal{T}_1 \subseteq_{\mathbb{D}_{\ell \cdot i}} \mathcal{T}_2$. Let $u = a_1 \cdots a_n$ and $v = b_1 \cdots b_m$. Pick any prefix of u , say $a_1 \cdots a_k$, and consider the prefixes of the runs ρ_1 and ρ_2 such that the input $a_1 \cdots a_k$ has been processed. Let $b_1 \cdots b_{k_1}$ and $b_1 \cdots b_{k_2}$ be the respective produced outputs. Wlog., let $k_1 \leq k_2$. If $k_1 = k_2$, then the output delay for the prefix $a_1 \cdots a_k$ is zero. So assume $k_1 < k_2$. We have to show that $|b_{k_1+1} \cdots b_{k_2}|$ is less than $\ell \cdot i$. Since the origin mappings of ρ_1 and ρ_2 , that is, o_1 and o_2 , have a distance of at most i , we know that the origin of $b_{k_1+1} \cdots b_{k_2}$ in ρ_1 is no later than at the letter a_{k+i} . On $a_{k+1} \cdots a_{k+i}$, \mathcal{T}_1 can produce at most $\ell \cdot i$ output letters. Consequently, $|b_{k_1+1} \cdots b_{k_2}| \leq \ell \cdot i$. ◀
