¹ Let $A = \begin{pmatrix} x & x+1 \\ x & x+1 \end{pmatrix}$ then there does not exist any null vector of the form $\begin{pmatrix} f \\ 1 \end{pmatrix}$ or $\begin{pmatrix} 1 \\ f \end{pmatrix}$ for any $f \in \mathbb{Z}_2[x]$

2 Preliminaries

We begin by stating the definition of the complexity class $\oplus\text{L}$.

- **Definition 3.** $\oplus\text{L}$ is the class of decision problems solvable by an NL machine such that
 - If the answer is “yes”, then the number of accepting paths is odd.
 - If the answer is “no”, then the number of accepting paths is even.

By a slight abuse of notation, we say a function class is in $\oplus\text{L}$ if each of its bits can be computed in $\oplus\text{L}$. We will have the occasion to use only constantly many bits because we are working mod 2^k .

Given an $n \times n$ matrix $A = (a_{ij})_{i,j \in [n]}$, determinant and permanent of A are defined as

$$\det(A) = \sum_{\sigma \in S_n} \text{sgn}(\sigma) \prod_{i=1}^n a_{i\sigma(i)} \quad \text{perm}(A) = \sum_{\sigma \in S_n} \prod_{i=1}^n a_{i\sigma(i)}$$

The permanent of a matrix can be regarded as the weighted sum of cycle covers of an undirected graph. This gives a combinatorial interpretation to a seemingly pure algebraic quantity. We shall use this bridge to illustrate an application of our parallel polynomial permanent.

Let G be a weighted undirected graph (not necessarily loopless) with the associated weight function w .

- **Definition 4.** We say $C \subseteq V(G) \times V(G)$ is a cycle cover of G if
 - $(u, v) \in C \implies \{u, v\} \in E(G)$
 - C is a union of vertex-disjoint simple directed cycles in G
 - every vertex is incident to some directed edge in C

Note: loops are allowed as simple cycles in the above definition.

- **Definition 5.** For any cycle cover C we denote the weight of C by $\tilde{w}(C) = \prod_{e \in C} w(e)$

The above definition is well-defined because any directed edge (u, v) or (v, u) in our cycle cover correspond to the same edge $\{u, v\}$ in our underlying undirected graph. And hence both these directed edges get the same weight, that is $w((u, v)) = w((v, u)) = w(\{u, v\})$. In literature, such type of weight functions are commonly referred to as *symmetric* weight functions.

- **Definition 6.** Let $V(G) = [n]$ then we say $A = (a_{ij})_{i,j \in [n]}$ is the $(n \times n)$ adjacency matrix of G if

$$a_{ij} = \begin{cases} w(e) & \text{if } e = \{i, j\} \in E(G) \\ 0 & \text{otherwise} \end{cases}$$

- **Observation 7.** $\text{perm}(A) = \sum \tilde{w}(C)$ where the sum is taken over all cycle covers C of G

3 Permanent over \mathfrak{R} Mod 2^k

To begin with, we fix some general notation. Let $p(x)$ be an irreducible polynomial over $\mathbb{Z}_2[x]$ such that $\deg(p(x))$ is at most $\text{poly}(n)$. Denote by \mathbb{F} the finite field of characteristic 2 which is realized as $\mathbb{Z}_2[x]/(p(x))$ and by $\mathfrak{R}_k = \mathbb{Z}[x]/(2^k, p(x))$. In particular $\mathfrak{R}_1 \cong \mathbb{F}$. Now as already discussed, we essentially replace \mathbb{Z} by \mathfrak{R} in the algorithm of [3]. We are ready to state the main theorem.

► **Theorem 8.** *Let $k \geq 1$ be fixed and $A \in \mathfrak{R}^{n \times n}$. We can compute $\text{perm}(A) \pmod{2^k}$ in $\oplus L$*

Proof is by induction on k . We start with the base case $k = 1$. Note that $\text{perm}(A) \equiv \det(A) \pmod{2}$. Using corollary 17 we can find $\text{perm}(A) \pmod{2}$ in $\oplus L$. Now suppose $k > 1$, we shall reduce it to computing several such determinants modulo 2, all of which can be computed in parallel. In doing so, we first illustrate an algorithm which is sequential and then we shall see how to parallelize it.

3.1 Sequential algorithm for computing permanent modulo 2^k

We present the algorithm from [3] for computing permanent modulo 2^k but translated within our framework. Let $A = (a_{ij})_{i,j \in [n]} \in \mathfrak{R}^{n \times n}$ be such that $\det(A) \equiv 0 \pmod{2}$. Therefore we can find a non-zero vector $v \in \mathbb{F}^n$ such that $A^T v = 0$ over \mathbb{F} . Assume without loss of generality $v_1 = 1$.

Let r_i denote the i^{th} row of A and define A' to be the matrix where the 1^{st} row in matrix A is replaced with $\sum_i v_i r_i$. Now if we expand the permanent along the first row then we get

$$\text{perm}(A') = \sum_{i=1}^n v_i \text{perm}(A[1 \leftarrow i]) = \text{perm}(A) + \sum_{i=2}^n v_i \text{perm}(A[1 \leftarrow i]) \quad (1)$$

where $A[i \leftarrow j]$ is the matrix A but with i^{th} row replaced with the j^{th} row. For $I, J \subseteq [n]$ denote by $A[\widehat{I}, \widehat{J}]$ the matrix obtained from A by deleting rows indexed by I and columns indexed by J . With this equation, modulo 2^k computation reduces to modulo 2^{k-1} computations of the minors as follows:

$$\text{perm}(A') = \sum_{j=1}^n \left(\sum_{i=1}^n v_i a_{ij} \right) \text{perm}(A[\widehat{\{1\}}, \widehat{\{j\}}])$$

Since $A^T v = 0 \pmod{2}$, we can write $\sum_i v_i a_{ij} = 2b_j \pmod{2^k}$ for some $b_j \in \mathfrak{R}_k$, therefore, we can re-write the above permanents as:

$$\text{perm}(A') \pmod{2^k} = 2 \left(\sum_{j=1}^n b_j \text{perm}(A[\widehat{\{1\}}, \widehat{\{j\}}]) \pmod{2^{k-1}} \right)$$

Similarly, expanding $\text{perm}(A[1 \leftarrow i])$ along the 1^{st} and i^{th} rows, we get the reduction:

$$\begin{aligned} \text{perm}(A[1 \leftarrow i]) &= \sum_{j \neq i} a_{ij} a_{il} \text{perm}(A[\widehat{\{1, i\}}, \widehat{\{j, l\}}]) \\ \text{perm}(A[1 \leftarrow i]) \pmod{2^k} &= 2 \left(\sum_{j < l} a_{ij} a_{il} \text{perm}(A[\widehat{\{1, i\}}, \widehat{\{j, l\}}]) \pmod{2^{k-1}} \right) \end{aligned}$$

Substituting these equations back in 1, we get

$$\begin{aligned} \text{perm}(A) \pmod{2^k} &= 2 \left(\sum_{j=1}^n b_j \text{perm}(A[\widehat{\{1\}}, \widehat{\{j\}}]) \pmod{2^{k-1}} \right) \\ &\quad - 2 \sum_{i=2}^n v_i \left(\sum_{\substack{j, l=1 \\ j < l}}^n a_{ij} a_{il} \text{perm}(A[\widehat{\{1, i\}}, \widehat{\{j, l\}}]) \pmod{2^{k-1}} \right) \end{aligned}$$

36:6 Parallel Polynomial Permanent

Since addition and multiplication in \mathfrak{R}_k is in $\oplus\mathbb{L}$ (see 14) we get that $\text{perm}(A) \pmod{2^k}$ $\oplus\mathbb{L}$ -reduces to $\text{perm}(\cdot) \pmod{2^{k-1}}$. Hence by induction, we can compute $\text{perm}(A) \pmod{2^k}$ in $\oplus\mathbb{L}$, provided that $\text{perm}(A) \equiv 0 \pmod{2}$.

Let us see how to drop this assumption. We expand the permanent of A along the i^{th} row, then

$$\text{perm}(A) = \sum_j a_{ij} \text{perm}(A[\widehat{\{i\}}, \widehat{\{j\}}])$$

If $\text{perm}(A) \not\equiv 0 \pmod{2}$, then $\exists i, j$ such that $\text{perm}(A[\widehat{\{i\}}, \widehat{\{j\}}]) \not\equiv 0 \pmod{2}$. We can find this pair (i, j) by running over all n^2 possibilities and evaluating $\text{perm}(A[\widehat{\{i\}}, \widehat{\{j\}}]) \pmod{2}$ using corollary 17, as already discussed above. Consider the matrix C where all entries are same as A except the $(i, j)^{\text{th}}$ entry which is replaced with $a_{ij} + y$. Then, we get $\text{perm}(C) = \text{perm}(A) + y \text{perm}(A[\widehat{\{i\}}, \widehat{\{j\}}])$. Notice that $\text{perm}(A) + y \text{perm}(A[\widehat{\{i\}}, \widehat{\{j\}}]) \equiv 0 \pmod{2}$ is a linear equation in y over the field \mathbb{F} and so there exists a unique $y \in \mathbb{F}$ which satisfies this equation, which is $y_0 = \text{perm}(A) \text{perm}(A[\widehat{\{i\}}, \widehat{\{j\}}])^{-1} \pmod{2}$ and can be computed using corollaries 14, 15 and 17. Setting $y = y_0$ we get $\text{perm}(C) \equiv 0 \pmod{2}$, so we can compute $\text{perm}(C) \pmod{2^k}$ and then compute $\text{perm}(A[\widehat{\{i\}}, \widehat{\{j\}}])$ recursively as $A[\widehat{\{i\}}, \widehat{\{j\}}]$ is a smaller $(n-1) \times (n-1)$ size matrix. Hence we obtain $\text{perm}(A) = \text{perm}(C) - y_0 \text{perm}(A[\widehat{\{i\}}, \widehat{\{j\}}]) \pmod{2^k}$. This yields a sequential algorithm for computing permanent modulo 2^k over \mathfrak{R} .

3.2 Parallel algorithm for computing permanent modulo 2^k

The bottleneck was finding i, j such that $A[\widehat{\{i\}}, \widehat{\{j\}}]$ is non-singular over \mathbb{F} . We fix this by again appealing to the fact that we are working over a field, and modifying A such that all leading principal minors are non-zero. This modification essentially derives from the following fact.

► **Theorem 9** ([14, Corollary 1]). *Let A be an invertible matrix over a field \mathbb{F} , then all leading principal minors are non-zero iff A admits an LU decomposition*

Every invertible matrix admits a PLU factorization [14] so let $A = PLU$. Denote by $Q = P^{-1}$, then $QA = LU$. Since Q is also a permutation matrix, we get that $\text{perm}(QA) = \text{perm}(A)$ (because permanent is invariant under row swaps). Therefore, it suffices to give a $\oplus\mathbb{L}$ algorithm to find Q so that we can replace A by QA which is an invertible matrix such that all leading principal minors are non-zero. Thus computing $\text{perm}(A) \pmod{2^k}$ reduces to the problem of computing (in parallel) permanent modulo 2^k of $n-1$ matrices with $\text{perm} \equiv 0 \pmod{2}$. This gives a $\oplus\mathbb{L}$ algorithm to compute permanent modulo 2^k over \mathfrak{R} .

To find Q , we closely follow [9]. For each $1 \leq i \leq n$, let A_i be the matrix formed from A by only taking the first i columns. Let A_i^j matrix obtained from A_i by only taking the first j rows. We construct a set $S_i \subseteq [n]$ inductively as follows:

- Base case: $l \in S_i$ if $\text{rank}(A_i^l) = 1$ and $\text{rank}(A_i^k) = 0$ for all $k < l$
- Include $j \in S_i$ iff $\text{rank}(A_i^j) = 1 + \text{rank}(A_i^{j-1})$

Since $\text{rank}(A_i) = i$, we get $|S_i| = i$. Furthermore note that $S_i \subset S_{i+1}$. So let $S_1 = \{s_1\}$ and for each $i \geq 2$, denote by $s_i \in S_i \setminus S_{i-1}$. Consider the following permutation $Q = (n, s_n) \dots (2, s_2)(1, s_1)$. Thus Q is our desired permutation, such that QA has all leading principal minors non-zero.

As a corollary, we immediately get our desired result.

► **Corollary 10** (Theorem 1 restated). *Given an $n \times n$ matrix $A = (a_{ij})_{i,j \in [n]}$ over $\mathbb{Z}[x]$ with $\deg(a_{ij})$ at most $\text{poly}(n)$, we can compute $\text{perm}(A) \pmod{2^k}$ in $\oplus\mathbf{L}$ for any fixed $k \geq 1$*

Proof. Let $N = n \max\{\deg(a_{ij})\} + 1$ and choose $l = \lceil \log_3(N/2) \rceil$. Consider $p(x) = x^{2 \cdot 3^l} + x^{3^l} + 1$ which is irreducible over $\mathbb{Z}_2[x]$ (see [27] Theorem 1.1.28)

Since $\deg(p(x)) \geq N > \deg(\text{perm}(A))$, using this $p(x)$ in above theorem, we get $\text{perm}(A) \pmod{2^k}$ for any fixed k . ◀

► **Remark.** See appendix A for a complete worked out example of the above algorithm.

3.3 Complexity Analysis

We discuss the complexity results for arithmetic operations over the ring \mathfrak{R}_k and matrix operations over the field \mathbb{F} , which were required in our above algorithm. To begin with, we state a well-known fact about integer polynomial matrix multiplication modulo 2. This shall form our basis for showing computations over \mathbb{F} in $\oplus\mathbf{L}$.

► **Lemma 11** (Folklore [5]). *Let $A_1, A_2, \dots, A_n \in \mathbb{Z}_2[x]^{n \times n}$ then the product $A_1 A_2 \dots A_n$ can be computed in $\oplus\mathbf{L}$*

To obtain an analogous result over \mathbb{F} we first perform multiplication over $\mathbb{Z}_2[x]$ and then divide all entries by $p(x)$, using the following polynomial division, as demonstrated by Hesse, Allender and Barrington in [12], to get that iterated matrix product over \mathbb{F} is in $\oplus\mathbf{L}$

► **Lemma 12** ([12, Corollary 6.5]). *Given $g(x), p(x) \in \mathbb{Z}[x]$ of degree at most $\text{poly}(n)$, we can compute $g(x) \pmod{p(x)}$ in $\text{DLOGTIME} - \text{uniform } \text{TC}^0 \subseteq \mathbf{L}$*

In particular, it follows that given an irreducible polynomial $p(x)$ (over $\mathbb{Z}_2[x]$), then for any $g(x) \in \mathbb{Z}[x]$ of degree at most $\text{poly}(n)$ we can find $g(x) \pmod{2^k, p(x)}$ in $\oplus\mathbf{L}$, for any fixed $k \geq 1$.

► **Corollary 13.** *Let $A_1, A_2, \dots, A_n \in \mathbb{F}^{n \times n}$ such that the degree of each entry is at most $\text{poly}(n)$ then the product $A_1 A_2 \dots A_n$ can be computed in $\oplus\mathbf{L}$*

Now we discuss arithmetic over \mathfrak{R}_k

► **Lemma 14.** *Let $k \geq 1$ be fixed then the following operations can be done in $\oplus\mathbf{L}$*

- *Multiplication : Given $a, b \in \mathfrak{R}_k$ compute ab*
- *Iterated Addition: Given $c_1, c_2, \dots, c_n \in \mathfrak{R}_k$ compute $\sum_i c_i$*

Proof. We use the fact that the arithmetic operations mentioned in the statement of lemma, but over \mathbb{Z}_{2^k} are in $\oplus\mathbf{L}$ (see for e.g. [12])

- Let $a(x), b(x) \in \mathfrak{R}_k$ and write $a(x) = \sum_{i=0}^D a_i x^i$ and $b(x) = \sum_{i=0}^{D'} b_i x^i$, then $a(x)b(x) = \sum_{i=0}^{D+D'} \left(\sum_{j=0}^i a_j b_{i-j} \right) x^i$. Finally, using lemma 12, divide $a(x)b(x)$ by $p(x)$ to obtain $ab \in \mathfrak{R}_k$
- Similarly, let $c_1(x), c_2(x), \dots, c_n(x) \in \mathfrak{R}_k$ and write $c_i(x) = \sum_{j=0}^{D_i} c_{ij} x^j$ for each $i \in [n]$, then $\sum_{i=1}^n c_i(x) = \sum_{j=0}^{\max\{D_i\}} \left(\sum_{i=1}^n c_{ij} \right) x^j$ where we assume $c_{ij} = 0$ if $j > D_i$. ◀

Our algorithm also requires computing inverse of non-zero elements. To compute inverse over \mathbb{F}^* we adopt the techniques from Fich and Tompa [8, 10]. Since $\mathbb{F} = \mathbb{Z}_2[x]/(p(x))$ with $N = \deg(p(x))$ which is at most $\text{poly}(n)$, then given $a \in \mathbb{F}^*$, we observe that $a^{-1} = a^{q-2}$ where $q = 2^N = |\mathbb{F}|$.

36:8 Parallel Polynomial Permanent

We interpret this equation over $\mathbb{Z}_2[x]$, that is we need to compute $a(x)^{q-2} \pmod{p(x)}$ over $\mathbb{Z}_2[x]$. First we show how to compute $a(x)^2 \pmod{p(x)}$. Construct the $N \times N$ matrix Q whose i^{th} row $(Q_{i,0}, Q_{i,1}, \dots, Q_{i,N-1})$ is defined as:

$$\sum_{j=0}^{N-1} Q_{i,j} x^j = x^{2i} \pmod{p(x)}$$

for each $0 \leq i \leq N-1$. Matrix Q can be computed in $\oplus L$ using the division lemma 12. Then the elements of the row vector $(a_0, a_1, \dots, a_{N-1})Q$ are the coefficients of $a(x)^2 \pmod{p(x)}$ as explained in section 3 of [10]. Furthermore, the coefficients of $a(x)^{2^k} \pmod{p(x)}$ are given by $(a_0, a_1, \dots, a_{N-1})Q^k$. From lemma 11 we get that $a(x)^{2^k} \pmod{p(x)}$ can be computed in $\oplus L$, for any k bounded by $\text{poly}(n)$. Therefore, writing $q-2 = (c_0, c_1, \dots, c_{N-1})$ in binary,

$$a(x)^{q-2} \pmod{p(x)} = \prod_{i=0}^{N-1} a(x)^{c_i 2^i} \pmod{p(x)}$$

can be computed in $\oplus L$, which gives us a^{-1} .

► **Corollary 15.** *Let $a \in \mathbb{F}$ then $a^{-1} \in \mathbb{F}$ can be computed in $\oplus L$*

Mahajan and Vinay [18] describe a way to reduce the computation of a determinant over a commutative ring to a semi-unbounded logarithmic depth circuit with addition and multiplication gates over the ring. In fact, the following is an easy consequence of their result:

► **Lemma 16 (Mahajan-Vinay [18]).** *Let $A \in R^{n \times n}$ be a matrix over a commutative ring. Then there exist $M \in R^{(2n^2) \times (2n^2)}$ and two vectors $a, b \in R^{2n^2}$ such that $\det(A) = a^T M b$. Moreover, each entry of the matrix M_{ij} and the vectors a, b is one of the entries $A_{i',j'}$ or a constant from $\{0, 1\}$ and the mapping ϕ where for every $(i, j) \in [2n^2] \times [2n^2]$, $\phi(i, j) \in A_{[n] \times [n]} \cup \{0, 1\}$ is computable in Logspace.*

Proof. (Sketch) In [18], given a matrix A they construct a graph H_A whose vertex set is $\{s, t_+, t_-\} \cup Q$ where $Q = \{[p, h, u, i] : p \in \{0, 1\}, h, u \in [n], i \in \{0, \dots, n-1\}\}$. Moreover, the edges are one of the following forms $(s, q), (q, q'), (q, t_+)$ and (q, t_-) where $q, q' \in Q$ and have weights $w(q, q')$ that each depend on a single entry of A or are one of the constants 0, 1. Moreover the mapping is very simple to describe. Let us focus on the induced subgraph $H_A[Q]$. Notice that $|Q| = 2n^3$ and each “layer” of $H_A[Q]$ is identical. In other words, $e_i = \langle [p, h, u, i], [p', h', u', i+1] \rangle$ is an edge in $H_A[Q]$ iff $e_j = \langle [p, h, u, j], [p', h', u', j+1] \rangle$ is an edge in $H_A[Q]$ and both have the same weights for every $i, j \in \{0, \dots, n-1\}$. Thus define the matrix M by putting $M_{[p,h,u],[p',h',u']}$ as the weight of any of the edges e_i .

Finally to define a, b : let $a_{[n \bmod 2, 1, 1]} = 1$ and $a_q = 0$ for all other q . $b_{[1, h, u]} = a_{uh}$ and $b_{[0, h, u]} = -a_{uh}$. The correctness of our Lemma then follows from the proof of Lemma 2 of [18]. ◀

Using above lemma 16, we reduce determinant over \mathbb{F} to matrix powering over \mathbb{F} , which can be computed in $\oplus L$ using corollary 13. Hence we get

► **Corollary 17.** *Let $A \in \mathbb{F}^{n \times n}$ then $\det(A)$ can be computed in $\oplus L$*

Now we demonstrate two results: computing rank and a null vector a matrix over \mathbb{F} in $\oplus L$. We use Mulmuley’s algorithm [19], which requires finding determinant over the ring $\mathbb{F}[y, t]$, which reduces to matrix powering over $\mathbb{F}[y, t]$ by the above result. We shall further reduce this to matrix powering over \mathbb{F} as follows: Let R be an arbitrary commutative ring. We associate with each polynomial $f(x) = \sum_{i=0}^{d-1} f_i x^i \in R[x]$ a $d \times d$ lower-triangular matrix

$$P(f) = \begin{bmatrix} f_0 & & & & \\ f_1 & f_0 & & & \\ f_2 & f_1 & f_0 & & \\ \vdots & \vdots & \vdots & \ddots & \\ f_{d-1} & f_{d-2} & f_{d-3} & \dots & f_0 \end{bmatrix} \in R^{d \times d}$$

Suppose we have two polynomials $f(x)$ and $g(x)$ of degree d_1 and d_2 respectively. We can interpret them as degree $d_1 + d_2$ polynomials (with higher exponent coefficients as 0). Then we have that $P(f + g) = P(f) + P(g)$ and $P(fg) = P(f)P(g)$.

► **Theorem 18.** *Let R be any commutative ring and A_1, A_2, \dots, A_n be $n \times n$ matrices over $R[x]$ such that the degree of each entry is at most $\text{poly}(n)$. Denote by $\mathbf{A} = \prod A_i$. There exists $\text{poly}(n) \times \text{poly}(n)$ matrices B_1, B_2, \dots, B_n over R such that the coefficient of x^k in \mathbf{A}_{ij} is equal to $\mathbf{B}_{\psi(i,j,k)}$ where $\mathbf{B} = \prod B_i$ and ψ is logspace computable.*

In other words, iterated matrix multiplication over $R[x]$ is logspace reducible to iterated matrix multiplication over R .

Proof. Let $N = n \max_{i,j,k \in [n]} \{\deg((A_i)_{jk})\}$ where $(A_i)_{jk}$ denotes the $(j, k)^{\text{th}}$ entry of A_i . By our assumption, N is at most $\text{poly}(n)$. Now for each $1 \leq i \leq n$, compute the matrix $B_i \in R^{N \times N}$ obtained from A_i by replacing each polynomial $(A_i)_{jk}$ with the $N \times N$ matrix $P((A_i)_{jk})$. These matrices B_i can be computed in log space. Now the coefficient of x^k in \mathbf{A}_{ij} can be read from the entry $\mathbf{B}_{\psi(i,j,k)}$ where $\psi(i, j, k) = ((i-1)N + k + 1, (j-1)N + 1)$ is logspace computable. The correctness follows from our observation $P(fg) = P(f)P(g)$. ◀

► **Remark.** This gives us an alternate proof of the fact that iterated matrix multiplication over $\mathbb{Z}_2[x]$ is in $\oplus\mathbf{L}$, as it follows immediately from the definition of $\oplus\mathbf{L}$ that iterated matrix multiplication over \mathbb{Z}_2 is in $\oplus\mathbf{L}$.

► **Lemma 19** ([19]). *Let $A \in \mathbb{F}^{m \times n}$ then $\text{rank}(A)$ can be computed in $\oplus\mathbf{L}$*

Proof. We can assume that A is a square ($n \times n$) symmetric matrix because otherwise replace A with $\begin{pmatrix} 0 & A \\ A^T & 0 \end{pmatrix}$ which has rank twice that of A . Let Y be an $n \times n$ diagonal matrix with the $(i, i)^{\text{th}}$ entry as y^{i-1} . And let m be the smallest number such that t^m has a non-zero coefficient in the characteristic polynomial of YA , that is $\det(tI - YA)$. Then rank of $A = n - m$.

Suffices to show that $\det(tI - YA)$ can be computed in $\oplus\mathbf{L}$. Notice that $(tI - YA) \in \mathbb{F}[y, t]^{n \times n}$ and so $\det(tI - YA)$ is logspace reducible to matrix powering over $\mathbb{F}[y, t]$. Using the canonical isomorphism $\mathbb{F}[y, t] \cong \mathbb{F}[y][t]$, repeated application of theorem 18 logspace reduces it to matrix powering over \mathbb{F} . ◀

► **Observation 20.** *Let $A \in \mathbb{F}^{n \times n}$ be an invertible matrix then A^{-1} can be computed in $\oplus\mathbf{L}$*

This follows from the fact that computing A^{-1} involves computing the determinant of A and n^2 cofactors, that is determinants of n^2 matrices of size $(n-1) \times (n-1)$. Notice that this also requires inverting the determinant, an element of \mathbb{F}^* , which has been explained above.

► **Corollary 21.** *Let $A \in \mathbb{F}^{n \times n}$ then finding a non-trivial null vector (if it exists) is in $\oplus\mathbf{L}$*

36:10 Parallel Polynomial Permanent

Proof. Let $\text{rank}(A) = m$, then permute the rows and columns of A so that we can express $A = \begin{pmatrix} B & C \\ D & E \end{pmatrix}$ such that B is an invertible $m \times m$ matrix. Let $\begin{pmatrix} x \\ y \end{pmatrix}$ be a column vector where $x \in \mathbb{F}^m$ and $y \in \mathbb{F}^{n-m}$, such that

$$A \begin{pmatrix} x \\ y \end{pmatrix} = 0 \implies \begin{pmatrix} B & C \\ D & E \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = 0$$

This reduces to the set of equations: $Bx + Cy = 0$ and $Dx + Ey = 0$. But the later is a redundant set of equations because $\begin{pmatrix} D & E \end{pmatrix}$ can be written in terms of $\begin{pmatrix} B & C \end{pmatrix}$. More precisely, there exists a matrix $V \in \mathbb{F}^{(n-m) \times m}$ such that $D = VB$ and $E = VC$ and so $Dx + Ey = VBx + VCy = V(Bx + Cy) = 0$. Therefore setting $x = \mathbf{1}$ and $y = -B^{-1}C\mathbf{1}$, gives us the desired null vector. So it suffices to give a $\oplus\text{L}$ algorithm to transform A to the form as specified above, which follows from [9]. Let A_i be the matrix formed from first i rows of A . We construct a set $S \subseteq [n]$ as follows:

- Base case: $i \in S$ if $\text{rank}(A_i) = 1$ and $\text{rank}(A_j) = 0$ for all $j < i$
- Include $k \in S$ iff $\text{rank}(A_k) = 1 + \text{rank}(A_{k-1})$

It follows that $|S| = m$ and let $S = \{i_1 < i_2 < \dots < i_m\}$ and P_r be the permutation matrix described by $(m, i_m) \dots (2, i_2)(1, i_1)$. Then $P_r A$ is the required matrix having first m rows as linearly independent. Next, consider the matrix $A' = (P_r A)^T$ and apply the above algorithm to get a permutation matrix P_c such that first m rows of $P_c A'$ are linearly independent. Then $P_r A P_c^T$ is the required matrix such that the leading principal m -minor is non-singular. ◀

4 Permanent via Interpolation

We now demonstrate another technique to compute permanent modulo 2^k , which doesn't resort to computations over exponentially sized fields. This proceeds by choosing small degree polynomial $p(x)$. The techniques developed in this section are new and hence interesting by themselves.

First we mention a result from [15] used to interpolate the coefficients of a polynomial.

► **Lemma 22** ([15, Lemma 3.1]). *Let \mathbb{F} be a finite, characteristic 2, field of order q .*

$$\sum_{a \in \mathbb{F}^*} a^m = \begin{cases} 0 & \text{if } q-1 \nmid m \\ 1 & \text{otherwise} \end{cases}$$

This dichotomy allows us to extract coefficients of any integer polynomial.

► **Lemma 23** ([15, Corollary 3.2]). *Let $f(x) = \sum_{i=0}^d c_i x^i$ be a polynomial with integer coefficients and $q > d+1$, then for any $0 \leq t \leq d$,*

$$\sum_{a \in \mathbb{F}^*} a^{q-1-t} f(a) = c_t \pmod{2}$$

But this gives us the coefficients modulo 2 only. How do we get coefficients modulo 2^k ?

The crucial observation here is that the above sum was computed over \mathbb{F} . So instead we do so over \mathfrak{R} by identifying a copy of $\mathbb{F}^* \hookrightarrow \mathfrak{R}$, and then we have

$$\sum_{a \in \mathbb{F}^*} a^m = \begin{cases} 2\alpha_m & \text{if } q-1 \nmid m \\ 2\beta_m + 1 & \text{otherwise} \end{cases}$$

where $\alpha_m, \beta_m \in \mathfrak{R}$.

Now we use repeated squaring method to obtain our desired modulo 2^k result.

► **Lemma 24.** $\forall m \geq 0, k \geq 1$

$$\sum_{a_1, \dots, a_{2^k-1} \in \mathbb{F}^*} (a_1 a_2 \cdots a_{2^k-1})^m = \left(\sum_{a \in \mathbb{F}^*} a^m \right)^{2^{k-1}} = \begin{cases} 0 \pmod{2^k} & \text{if } q-1 \nmid m \\ 1 \pmod{2^k} & \text{otherwise} \end{cases}$$

Note: We remind the reader that the computation here is done over \mathfrak{R}_k

Proof. Fix any $m \geq 0$. Clearly $(2\alpha_m)^{2^{k-1}} \equiv 0 \pmod{2^k}$.

Suffices to show $(2\beta_m + 1)^{2^{k-1}} \equiv 1 \pmod{2^k}$. This follows from induction on k . For $k = 1$ the result holds as stated above. Assume that for some $k \geq 1$, the result holds. Then we have $(2\beta_m + 1)^{2^{k-1}} = 2^k \gamma_{m,k} + 1$ where $\gamma_{m,k} \in \mathfrak{R}$

$$(2\beta_m + 1)^{2^k} = \left((2\beta_m + 1)^{2^{k-1}} \right)^2 = (2^k \gamma_{m,k} + 1)^2 = 1 \pmod{2^{k+1}} \quad \blacktriangleleft$$

Using this we can interpolate coefficients of an integer polynomial as follows:

$$\sum_{a_1, \dots, a_{2^k-1} \in \mathbb{F}^*} (a_1 \dots a_{2^k-1})^{q-1-t} f(a_1 \dots a_{2^k-1}) = c_t \pmod{2^k}$$

Finally let $A(x)$ be an $n \times n$ matrix of integer polynomials and the permanent polynomial be

$$\text{perm}(A(x)) = \sum_{i=0}^N c_i x^i$$

From the above lemma it follows that

$$\sum_{a_1, a_2, \dots \in \mathbb{F}^*} (a_1 a_2 \cdots)^{q-1-t} \text{perm}(A(a_1 a_2 \cdots)) = c_t \pmod{2^k}$$

provided that our field \mathbb{F} is of order at least $N + 2$. For this, fix $l = \lceil \frac{\log \log N}{\log 3} \rceil$ so that $2^{2 \cdot 3^l} > N + 1$. Hence the field obtained from the irreducible polynomial $p(x) = x^{2 \cdot 3^l} + x^{3^l} + 1$ ([27] Theorem 1.1.28) serves the purpose. It suffices to compute $|\mathbb{F}^*|^{2^{k-1}} = O(N^{2^{k-1}})$ many permanents over \mathfrak{R}_k to obtain all the coefficients c_t modulo 2^k , all of which can be computed in parallel. Hence, we can compute the permanent of A modulo 2^k over $\mathbb{Z}[x]$ in $\oplus \mathbb{L}$.

5 Shortest Disjoint Cycles

Now that we have a $\oplus \mathbb{L}$ algorithm to compute permanent mod 2^k for matrices over $\mathbb{Z}[x]$, we are all set to demonstrate a parallel algorithm for shortest two disjoint paths. But we notice that we can place this problem in a more general framework of shortest disjoint cycles. Let us first formally define these problems.

SDP(k): Given a weighted undirected graph with k pairs of marked vertices $\{(s_i, t_i) \mid 1 \leq i \leq k\}$, find the minimum of sum of weight of paths between each pair s_i and t_i such that all paths are pairwise disjoint.

SDC(l, k): Given a weighted undirected graph with k marked vertices, find the minimum of sum of weight of l cycles such that they pass through all the marked vertices and are pairwise disjoint and each cycle is incident to at least one of the marked vertices.

36:12 Parallel Polynomial Permanent

► **Note.** We only consider *non-trivial cycles* that is we don't consider self-loops in the above problem.

Given an instance of the $SDP(2)$ problem, join the pairs of vertices (s_1, t_1) and (s_2, t_2) with new vertices u_1 and u_2 respectively, as show in Figure 1. Notice that any two disjoint cycles passing through u_1 and u_2 give us two disjoint paths between (s_1, t_1) and (s_2, t_2) .

■ **Figure 1** Converting an instance of $SDP(2)$ to $SDC(2,2)$.

Similarly, connecting the k -pairs of vertices via another new vertex and edges of weight $x^0 = 1$, gives us a reduction from k disjoint paths to k disjoint cycles via k vertices. Since this reduction preserves the weight of the path/cycle, it is indeed a reduction from $SDP(k)$ to $SDC(k,k)$.

To apply the techniques of [2] to disjoint cycles problem, we instead consider the following variant $SDCE(l,k)$: Given a weighted undirected graph with k marked *edges*, find the minimum of sum of weight of l cycles such that they pass through all the marked edges and are pairwise disjoint.

It can be easily seen that for a fixed k there is a logspace reduction from $SDC(l,k)$ to $SDCE(l,k)$ as follows: Let $(G, \{v_1, v_2, \dots, v_k\})$ be an instance of $SDC(l,k)$. Assume without loss of generality that the marked vertices form an independent set, or otherwise split the edge into two by introducing a new vertex in the middle. For each i , choose a vertex u_i , a neighbour of v_i , such that $i \neq j \implies u_i \neq u_j$, we solve $(G, \{e_1, e_2, \dots, e_k\})$ an instance of $SDCE(l,k)$ where $e_i = \{u_i, v_i\}$ and output the smallest solution amongst all the instances of $SDCE$ thus created. Since for each i , $\deg(v_i) < n$, number of instances of $SDCE$ created are bounded by $O(n^k)$ all of which can be solved in parallel as k is fixed.

5.1 Pre-processing

Given a graph $G = (V, E, w)$ and k marked edges $\{e_i = \{s_i, t_i\}\}_{i \leq k}$, assign weight $x^{w(e)}$ to the edge e of G and add self loops (weight 1) on all vertices except $\{s_i, t_i\}_{i \leq k}$. Observe that all the non-zero terms appearing in the permanent of adjacency matrix correspond to a cycle cover in G . To force these k -edges in our cycle cover, we direct these edges in a certain way which we shall call as a *pattern*.

Formally, define a pattern P as an ordered pairing of terminals of given edges $\{s_i, t_i \mid 1 \leq i \leq k\}$. Furthermore, we view each undirected edge $\{u, v\}$ in G as two directed edges (u, v) and (v, u) with the same weight. For any pattern P , define a pattern graph G_P with the same vertex/edge set as of G but such that if $(u, v) \in P$ then all outgoing edges from u , except edge (u, v) , are deleted. We denote by A_P the adjacency matrix of G_P .

Now we shall show how to solve the $SDCE(1,k)$ problem for any $k \geq 1$. This algorithm essentially follows from the work of [28]. Next, we also present how to solve the $SDCE(2,k)$ problem for any $k \geq 2$. As far as we know, no algorithm (better than brute force) was known apriori to our work for $k \geq 3$.

5.2 Shortest Cycle

Let $\{e_i = \{s_i, t_i\}\}_{i \leq k}$ be given k -edges. For each binary sequence $b = (b_1, b_2, \dots, b_{k-1})$ of length $k - 1$, consider the following pattern P_b :

- $(s_1, t_1) \in P_b$
- $\forall 2 \leq i \leq k$, if $b_{i-1} = 0$ then $(s_i, t_i) \in P_b$ else $(t_i, s_i) \in P_b$

So $\{P_b\}_b$ is the collection of patterns with the orientation of e_1 fixed and all possible orientations of the other edges $\{e_i\}_{i \geq 2}$, as dictated by each binary sequence.

▷ **Claim 25.** Under the assumption that the shortest cycle is unique, the smallest exponent with non-zero coefficient in $f_1(x) \pmod{2}$ is the weight of unique shortest cycle passing through the given edges, where

$$f_1(x) = \sum_b \text{perm}(A_{P_b})$$

Proof. Let C be any cycle cover which consists of at least 2 non-trivial cycles. Consider the cycle in C which doesn't contain edge e_1 - there are two ways of orienting this cycle, namely clockwise and counter-clockwise. So this cycle cover contributes to $f_1(x)$ for at least two such b -sequences and so it vanishes modulo $f_1 \pmod{2}$.

Thus the only terms that survive in $f_1 \pmod{2}$ are the cycle covers which consist of one cycle passing through all the given edges and self-loops on the remaining vertices, and furthermore number of cycles of this weight must be odd.

Since the shortest weight cycle was unique by our assumption, we get the desired result. \triangleleft

To drop the assumption that a unique minimum weight solution exists, we instead assign modified weights $2nmw(e) + w'(e)$ where $n = |V(G)|$, $m = |E(G)|$, $w(e)$ is the given weight of edge e and $w'(e) \in \{0, 2, \dots, 2m - 1\}$ is chosen independently and uniformly at random for each edge e . Then isolation lemma [20] tells us that, with probability $\frac{1}{2}$, the minimum weight cycle is unique. Hence if the term x^j survives as the smallest exponent with non-zero coefficient term in $f_1(x) \pmod{2}$ then we get the weight of shortest cycle as $\lfloor j/2nm \rfloor$.

But this gives us only a randomized $\oplus L$ algorithm (that is RNC algorithm). To further show that a common poly weight scheme exists for all graphs of size n , we use the well-known result of [21] which immediately places this problem in $\oplus L/\text{poly}$. For completeness sake, we provide a proof of this fact in the appendix B.

5.3 Shortest Two Disjoint Cycles

We shall first prove the following stronger result:

► **Theorem 26.** *Given a set of k -edges $\{e_i\}_{i \leq k}$, we can find weight of the shortest two disjoint cycles passing through these edges such that e_1 and e_2 appear in different cycles in $\oplus L/\text{poly}$ (and RNC)*

Let $\{P_b\}_b$ be the patterns as defined above. Furthermore, for each binary sequence $c = (c_1, c_2, \dots, c_{k-2})$ of length $k - 2$, define pattern Q_c as

- $(s_1, s_2) \in Q_c$
- $(t_1, t_2) \in Q_c$
- $\forall 3 \leq i \leq k$, if $c_{i-2} = 0$ then $(s_i, t_i) \in Q_c$ else $(t_i, s_i) \in Q_c$

36:14 Parallel Polynomial Permanent

With a combination of these patterns, we can get our desired cycle covers. We claim that the non-zero terms appearing in

$$f_2(x) = \sum_b \text{perm}(A_{P_b}) - \sum_c \text{perm}(A_{Q_c})$$

correspond to cycle covers in G_{P_b} such that edges e_1 and e_2 appear in different cycles.

To prove our claim, we need to argue that the cycle covers of G_{P_b} in which e_1 and e_2 appear in the same cycle are exactly the cycle covers of G_{Q_c} . Let

$$\mathcal{C}_Q = \bigsqcup_c \text{cycle covers of } G_{Q_c}$$

$$\mathcal{C}_P = \bigsqcup_b \text{cycle covers of } G_{P_b} \text{ such that edges } e_1 \text{ and } e_2 \text{ appear in the same cycle}$$

where each cycle cover is counted with repetitions in \mathcal{C}_P and \mathcal{C}_Q .

▷ **Claim 27.** There is a one-one correspondence between \mathcal{C}_P and \mathcal{C}_Q .

Proof. We define the mapping $\varphi : \mathcal{C}_P \rightarrow \mathcal{C}_Q$ as follows. Given a cycle cover in \mathcal{C}_P , remove the edges e_1 and e_2 and add edges (s_1, s_2) and (t_1, t_2) , refer to Figure 2 below.

■ **Figure 2** Bijection between \mathcal{C}_P and \mathcal{C}_Q .

To show that this is a well-defined mapping and indeed a bijection, we partition \mathcal{C}_P into type 1 and type 2 cycle covers, depending upon the orientation of the edge e_2 . Consider the cycle in which e_1 and e_2 appear together. Then if the edge e_2 is oriented as (s_2, t_2) then we call it type 1 cycle cover otherwise we call it a type 2 cycle cover.

Similarly, we partition \mathcal{C}_Q into type 1 and type 2 cycle covers. If the edges $\{s_1, s_2\}$ and $\{t_1, t_2\}$ appear in the same cycle then we call it a type 1 cycle cover otherwise we call it a type 2 cycle cover.

Fix a type 1 cycle cover of \mathcal{C}_P . Then it contains a cycle of the form

$$(s_1 \xrightarrow{e_1} t_1 \rightarrow P_1 \rightarrow s_2 \xrightarrow{e_2} t_2 \rightarrow P_2 \rightarrow s_1)$$

Applying φ to this cycle cover we get the cycle

$$(s_1 \xrightarrow{e_1} s_2 \rightarrow P_1^{\text{reverse}} \rightarrow t_1 \xrightarrow{e_2} t_2 \rightarrow P_2^{\text{reverse}} \rightarrow s_1)$$

and the other cycles remain intact. This constitutes a type 1 cycle cover in \mathcal{C}_Q

Similarly, consider a type 2 cycle cover of \mathcal{C}_P with the cycle

$$(s_1 \xrightarrow{e_1} t_1 \rightarrow P_1 \rightarrow t_2 \xrightarrow{e_2} s_2 \rightarrow P_2 \rightarrow s_1)$$

Applying φ to this cycle cover we get two cycles

$$(s_1 \xrightarrow{e_1} s_2 \rightarrow P_2^{\text{reverse}} \rightarrow s_1)$$

$$(t_1 \xrightarrow{e_2} t_2 \rightarrow P_1^{\text{reverse}} \rightarrow t_1)$$

and the other cycles remain intact. This constitutes a type 2 cycle cover in \mathcal{C}_Q .

Therefore, φ is a well-defined mapping and furthermore type i cycle covers of \mathcal{C}_P are mapped to type i cycle covers of \mathcal{C}_Q , $i \in \{1, 2\}$. Now consider $\psi : \mathcal{C}_Q \rightarrow \mathcal{C}_P$ defined as follows. Given a cycle cover in \mathcal{C}_Q , remove the edges (s_1, s_2) and (t_1, t_2) in the cycle and insert edges e_1 and e_2 with the orientation decided by the type. By an similar argument as above, we get that ψ is well-defined and clearly ψ is inverse of φ . \triangleleft

Now suppose C is a cycle cover of G such that edges e_1 and e_2 appear in different cycles. We have two cases:

Case 1: number of non-trivial cycles in C is more than 2. Consider any two non-trivial cycles in C such that e_1 is not incident on them. We can orient these two cycles in both clockwise and anti-clockwise direction and so we get that C is a cycle cover in G_{P_b} for at least 4 b -sequences. Hence, the term corresponding to C cancels out in $f_2 \pmod{4}$

Case 2: number of non-trivial cycles is exactly two. Then C is a cycle cover in G_{P_b} for exactly two b -sequences, that is the cycle passing through e_2 has two possible orientations whereas cycle passing through e_1 has a fixed orientation (as orientation of e_1 remains fixed in all G_{P_b}). Hence, the term corresponding to C appears with a coefficient of two in $f_2 \pmod{4}$. Therefore, the non-zero terms in $f_2 \pmod{4}$ correspond to only the cycle covers in which edges e_1 and e_2 appear in different cycles and number of non-trivial cycles is exactly 2. Assuming a unique shortest two disjoint cycle exists, it's weight can be obtained from the smallest exponent with a non-zero coefficient in $f_2 \pmod{4}$. Finally, to drop this assumption, we again assign random weights as done previously to ensure that the minimum weight solution is unique, with high probability. Furthermore, as in the previous case, we can again follow the proof of [21] to obtain a $\oplus\text{L/poly}$ algorithm. This completes the proof of Theorem 26.

► **Corollary 28** (Theorem 2 restated). *Given a set of k -edges $\{e_i\}_{i \leq k}$, we can find weight of the shortest two cycles passing through these edges in $\oplus\text{L/poly}$ (and RNC)*

Proof. For each pair of edges e_i and e_j , we can find weight of the shortest cycles separating them using the above algorithm. Hence taking the minimum over all pairs, we get our desired result. \blacktriangleleft

5.4 Constructing Cycles

We remark that under the assumption that the shortest cycle(s) are unique, we can recover these cycles C just from the knowledge of their weight $w(C)$. This follows the standard strategy of solving search via isolation as in [20]: for each edge $e \notin \{e_1, \dots, e_k\}$, delete the edge e and call the resulting graph G_e . Running our algorithm on $(G_e, \{e_1, \dots, e_k\})$, if the shortest cycle(s) weight is more than $w(C)$, then discard e otherwise add e to the set C , which gives us the required cycle(s). Doing this procedure in parallel for each edge e , it can be easily seen that we can recover C in $\oplus\text{L/poly}$ (or RNC).

6 Conclusion

We started by recognizing the appropriate algebraic structure \mathfrak{R} over which we can present a parallel algorithm to compute permanent modulo 2^k . Then we saw two techniques to get permanent over $\mathbb{Z}[x] \pmod{2^k}$ from $\mathfrak{R} \pmod{2^k}$. First method was to choose a large enough irreducible polynomial for our ring \mathfrak{R} . Another method was to interpolate over the ring \mathfrak{R} , which was an extension of the commonly known interpolation over finite fields.

Then we considered applications for parallel polynomial permanent. This includes a direct parallelization of the shortest two disjoint paths problem as given by [2]. Another direct application, although which required some modification, was finding shortest cycle passing through given vertices [28]. We further presented a common framework to view the above mentioned problems. This also aided us in further generalizing and obtaining a parallel algorithm to find shortest two disjoint cycles in any weighted undirected graph.

The more general question of computing permanent over arbitrary commutative rings of characteristic 2^k for $k \geq 2$ still remains open. On the other hand, using the framework we presented, we ask if it is possible to obtain shortest k disjoint cycles for $k \geq 3$ in RNC or even perhaps in randomized polynomial time?

 Examples

Example 1

Let $A = \begin{pmatrix} 1 & x+1 & x+2 \\ x & x^2 & x^2+x \\ x^2 & 3 & x^2+3 \end{pmatrix}$, $p(x) = x^6 + x^3 + 1$ be the irreducible polynomial and we

want to evaluate $\text{perm}(A) \pmod{4}$ over the ring $\mathfrak{R} = \mathbb{Z}[x]/(p(x))$. First of all, a direct computation gives us $\text{perm}(A) = 2x^5 + 6x^4 + 2x^3 + 12x^2 + 12x$. Now we demonstrate the steps taken by our algorithm.

Step 1: We start by evaluating $\text{perm}(A) \pmod{2}$. We directly notice here that last column is the sum of first two columns and so $\det(A) = 0 \implies \text{perm}(A) \equiv 0 \pmod{2}$

Step 2: Since $\det(A) \equiv 0 \pmod{2}$, we solve the equation $A^T v = 0$ over \mathbb{F} by our method as

$$\text{follows: } \begin{pmatrix} 1 & x & x^2 \\ x+1 & x^2 & 1 \\ x & x^2+x & x^2+1 \end{pmatrix} \begin{pmatrix} v_1 \\ v_2 \\ v_3 \end{pmatrix} = 0$$

Since rank of the principal 2×2 submatrix is already 2, we set $v_3 = 1$ and solve the equation: $\begin{pmatrix} v_1 \\ v_2 \end{pmatrix} = - \begin{pmatrix} 1 & x \\ x+1 & x^2 \end{pmatrix}^{-1} \begin{pmatrix} x^2 \\ 1 \end{pmatrix}$ to get $v_1 = x^3 + 1$ and $v_2 = x^5 + x$.

Step 3: For each $j = 1, 2, 3$, we find b_j such that $\sum_i v_i a_{ij} = 2b_j \pmod{4}$

$$\begin{aligned} j = 1 : & \quad (x^3 + 1) + x(x^5 + x) + x^2 = 2x^2 \\ j = 2 : & \quad (x+1)(x^3 + 1) + x^2(x^5 + x) + 3 = 2x^3 \\ j = 3 : & \quad (x+2)(x^3 + 1) + (x^2 + x)(x^5 + x) + x^2 + 3 = 2x^3 + 2x^2 \end{aligned}$$

Step 4: We have the formula

$$\begin{aligned} \text{perm}(A) \pmod{4} &= 2 \left(\sum_{j=1}^3 b_j \text{perm}(A[\widehat{\{3\}}, \widehat{\{j\}}]) \pmod{2} \right) \\ &\quad - 2 \sum_{i=1}^2 v_i \left(\sum_{\substack{j,k=1 \\ j < k}}^3 a_{ij} a_{ik} \text{perm}(A[\widehat{\{3, i\}}, \widehat{\{j, k\}}]) \pmod{2} \right) \end{aligned}$$

Step 4.1:

$$\begin{aligned} \text{perm}(A[\widehat{\{3\}}, \widehat{\{1\}}]) &= \text{perm} \begin{pmatrix} x+1 & x+2 \\ x^2 & x^2+x \end{pmatrix} = x \pmod{2} \\ \text{perm}(A[\widehat{\{3\}}, \widehat{\{2\}}]) &= \text{perm} \begin{pmatrix} 1 & x+2 \\ x & x^2+x \end{pmatrix} = x \pmod{2} \\ \text{perm}(A[\widehat{\{3\}}, \widehat{\{3\}}]) &= \text{perm} \begin{pmatrix} 1 & x+1 \\ x & x^2 \end{pmatrix} = x \pmod{2} \\ \implies \sum_{j=1}^3 b_j \text{perm}(A[\widehat{\{3\}}, \widehat{\{j\}}]) &= ((x^3) + (x^4) + (x^4 + x^3)) = 0 \pmod{2} \end{aligned}$$

Step 4.2:

$$\begin{aligned}
& \sum_{\substack{j,k=1 \\ j < k}}^3 a_{1j}a_{1k} \text{perm}(A[\widehat{\{1,3\}}, \widehat{\{j,k\}}]) \\
&= (x+1)(x^2+x) + (x+2)x^2 + (x+1)(x+2)x = x^3 + x^2 + x \pmod{2} \\
& \sum_{\substack{j,k=1 \\ j < k}}^3 a_{2j}a_{2k} \text{perm}(A[\widehat{\{2,3\}}, \widehat{\{j,k\}}]) \\
&= x^3(x+2) + x(x^2+x)(x+1) + x^2(x^2+x) = x^4 + x^3 + x^2 \pmod{2} \\
& \sum_{i=1}^2 v_i \left(\sum_{\substack{j,k=1 \\ j < k}}^3 a_{ij}a_{ik} \text{perm}(A[\widehat{\{3,i\}}, \widehat{\{j,k\}}]) \pmod{2} \right) = x^5 + x^4 + x^3 \pmod{4}
\end{aligned}$$

Therefore, $\text{perm}(A) \pmod{4} = 2x^5 + 2x^4 + 2x^3$ which matches with our direct computation.

Example 2

Consider $A = \begin{pmatrix} 1 & x & x^2 \\ x & x^2 & 1 \\ 1 & x^2 & x \end{pmatrix}$, and so $\text{perm}(A) = x^5 + x^4 + x^2 + x$. Therefore, we now have $\det(A) \not\equiv 0 \pmod{2}$

Step 1: Find Q such that QA has all leading principal minors are non-zero. In this case, we

$$\text{will get } Q = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix} \implies QA = \begin{pmatrix} 1 & x & x^2 \\ 1 & x^2 & x \\ x & x^2 & 1 \end{pmatrix}$$

Step 2: Consider matrix C whose all entries are same as A except the last one which

is incremented by y , that is $C = \begin{pmatrix} 1 & x & x^2 \\ 1 & x^2 & x \\ x & x^2 & 1+y \end{pmatrix}$, then $\text{perm}(C) = \text{perm}(A) +$

$y \text{perm}(A[\widehat{\{3\}}, \widehat{\{3\}}])$. Again construct C' same as $A[\widehat{\{3\}}, \widehat{\{3\}}]$ but replace the last entry

incremented by y' , that is $C' = \begin{pmatrix} 1 & x \\ x & x^2 + y' \end{pmatrix} \implies \text{perm}(C') = \text{perm}(A[\widehat{\{3\}}, \widehat{\{3\}}]) +$

$y' \text{perm}(A[\widehat{\{2,3\}}, \widehat{\{2,3\}}])$. Written as one equation, we get

$$\text{perm}(A) = \text{perm}(C) - y(\text{perm}(C') - y'a_{11})$$

In this equation, both C, C' are matrices with $\det \equiv 0 \pmod{2}$ with the correct choice of y, y' , which were:

$$y_0 = \text{perm}(A) \text{perm}(A[\widehat{\{3\}}, \widehat{\{3\}}])^{-1} \pmod{2} = (x^5 + x^4 + x^2 + x)(x^4 + x^3 + x^2) = x^3 + 1$$

$$y'_0 = \text{perm}(A[\widehat{\{3\}}, \widehat{\{3\}}]) \text{perm}(A[\widehat{\{2,3\}}, \widehat{\{2,3\}}])^{-1} \pmod{2} = x^2 + x$$

So we can compute $\text{perm}(C)$ and $\text{perm}(C')$ by above method and substitute it into previous equation to get $\text{perm}(A) \pmod{4}$.

B Weights as a Polynomial Advice

Our proof is based on [21]. Call a weighted undirected graph (G, w) (w is the given weight function on edges) *min- k -unique*, if for any k marked edges on G , there exists unique shortest l disjoint cycles passing through these k edges. Our goal is to show for each $n > 0$ there exists a set of n^2 weight functions w_1, \dots, w_{n^2} such that given a graph G on n vertices, (G, w_i) is *min- k -unique* for some $i \in [1, n^2]$.

Given a graph G on n vertices and k marked edges e_1, \dots, e_k , let $\mathcal{F}(e_1, \dots, e_k)$ be the family of all l disjoint cycles passing through e_1, \dots, e_k . Using isolation lemma [20], if w is a random weight function, that is each edge is assigned a weight from $[1, 4n^{2k+2}]$ independently and uniformly at random, then probability that $\mathcal{F}(e_1, \dots, e_k)$ has a unique minimum weight element is at least $1 - 1/4n^{2k}$. Therefore, probability that (G, w) is not *min- k -unique* for a random weight function w is at most

$$\Pr[\exists e_1, \dots, e_k : \mathcal{F}(e_1, \dots, e_k) \text{ doesn't have a minimum weight element}] \leq \sum_{e_1, \dots, e_k} \frac{1}{4n^{2k}} \leq 1/4$$

Now we claim that there exists a set of n^2 weight functions $W = (w_1, \dots, w_{n^2})$ such that for any given graph G on n vertices, (G, w_i) is *min- k -unique* for some $1 \leq i \leq n^2$. We say W is *bad* if it doesn't meet this criteria and in particular W is *bad for G* , if none of (G, w_i) is *min- k -unique*. For a randomly chosen W , that is each w_i is chosen independently and uniformly at random, then

$$\begin{aligned} \Pr[W \text{ is bad for } G] &\leq \Pr[\forall i : (G, w_i) \text{ is not min-}k\text{-unique}] \leq \left(\frac{1}{4}\right)^{n^2} \\ \implies \Pr[W \text{ is bad}] &\leq \Pr[\exists G : W \text{ is bad for } G] \leq 2^{n^2} \left(\frac{1}{4}\right)^{n^2} < 1 \end{aligned}$$

Hence there exists some $W = (w_1, \dots, w_{n^2})$ which satisfies the above property and so W is the required poly advice. To complete the argument for $SDCE(1, k), SDCE(2, k) \in \oplus L$, we obtain the weight of shortest cycle(s), using each of the weight functions w_i and output the minimum amongst them.

C Hafnians and counting perfect matchings modulo 2^k

Similar to permanent and determinant, another pair of well-studied algebraic analogous functions on a matrix are hafnians and pfaffians. Let $A = (a_{ij})$ be a symmetric $2n \times 2n$ matrix over integers, hafnian is defined as

$$\text{hf}(A) = \frac{1}{2^n n!} \sum_{\sigma \in S_{2n}} \prod_{j=1}^n a_{\sigma(2j-1), \sigma(2j)} \quad (2)$$

Note that the diagonal entries of A don't contribute in the calculation of hafnians and hence we can assume them to be 0. Let $B = (b_{ij})$ be a skew-symmetric $2n \times 2n$ matrix, pfaffian is defined as

$$\text{pf}(B) = \frac{1}{2^n n!} \sum_{\sigma \in S_{2n}} \text{sgn}(\sigma) \prod_{j=1}^n b_{\sigma(2j-1), \sigma(2j)} \quad (3)$$

But notice that $\text{hf}(A) \equiv \text{pf}(A) \pmod{2}$. [17] have shown that $\text{pf}(A)$ can be computed in NC and hence as an immediate consequence we get that $\text{hf}(A) \pmod{2}$ can be computed in NC. We can reduce the computation of hafnian to several hafnians of smaller submatrices using the following lemma. Denote by $A[i, j]$ the matrix obtained from A by deleting rows i and j , columns i and j .

► **Lemma 29** ([13, Lemma 2.2]).

$$\text{hf}(A) = \sum_{j:j \neq i} a_{ij} \text{hf}(A[i, j])$$

$$\text{hf}(A) = a_{ij} \text{hf}(A[i, j]) + \sum_{pq:p, q \notin \{i, j\}, p \neq q} (a_{ip}a_{jq} + a_{iq}a_{jp}) \text{hf}(A[i, j, p, q])$$

Assume $\text{pf}(A) \equiv 0 \pmod{2}$, then $\det(A) \equiv 0 \pmod{2}$ and we can find a vector $v \in \mathbb{Z}_2^{2n}$ such that $Av = A^T v = 0 \pmod{2}$. Assume without loss of generality $v_1 = 1$.

Let r_i, c_i denote the i^{th} row and i^{th} column of A respectively.

- Construct A' by replacing first row with $\sum v_i r_i$ and then replacing first column with $\sum v_i c_i$
- Construct A_i by replacing first row with r_i and first column with c_i .

Then we check that

$$\begin{aligned} \text{hf}(A') &= \sum_{j>1} \left(\sum_{i \geq 1} v_i a_{ij} \right) \text{hf}(A[1, j]) \\ &= \sum_{i \geq 1} v_i \left(\sum_{j>1} a_{ij} \text{hf}(A[1, j]) \right) \\ &= \sum_{j>1} a_{1j} \text{hf}(A[1, j]) + \sum_{i>1} v_i \left(\sum_{j>1} a_{ij} \text{hf}(A[1, j]) \right) \\ &= \text{hf}(A) + \sum_{i>1} v_i \text{hf}(A_i) \end{aligned}$$

Computing $\text{hf}(A')$: since $A^T v = 0 \pmod{2} \implies \sum_{i \geq 1} v_i a_{ij} = 2b_j \pmod{2^k}$ for some $c_j \in \mathbb{Z}$ and hence

$$\begin{aligned} \text{hf}(A') &= \sum_{j>1} \left(\sum_{i \geq 1} v_i a_{ij} \right) \text{hf}(A[1, j]) \\ &= \sum_{j>1} 2b_j \text{hf}(A[1, j]) \\ \implies \text{hf}(A') \pmod{2^k} &= 2 \left(\sum_{j>1} b_j \text{hf}(A[1, j]) \pmod{2^{k-1}} \right) \end{aligned}$$

36:22 Parallel Polynomial Permanent

Computing $\text{hf}(A_i)$:

$$\begin{aligned} \text{hf}(A_i) &= a_{ii}\text{hf}(A[1, i]) + \sum_{pq:p, q \notin \{1, i\}, p \neq q} 2a_{ip}a_{iq}\text{hf}(A[1, i, p, q]) \\ \implies \text{hf}(A_i) \pmod{2^k} &= 2 \left(\sum_{pq:p, q \notin \{1, i\}, p \neq q} a_{ip}a_{iq}\text{hf}(A[1, i, p, q]) \pmod{2^{k-1}} \right) \end{aligned}$$

Thus, we can compute $\text{hf}(A) \pmod{2^k}$ provided $\text{pf}(A) \equiv 0 \pmod{2}$.

Now if $\text{pf}(A) \not\equiv 0 \pmod{2}$, then we can find $(i, j), i \neq j$ such that $\text{hf}(A[i, j]) \not\equiv 0 \pmod{2}$. Consider the matrix C where all entries are same as in A except a_{ij} is replaced with $a_{ij} + 1$, then we get $\text{hf}(C) = \text{hf}(A) + \text{hf}(A[i, j])$. Since $\text{hf}(C) \equiv 0 \pmod{2}$, we can compute $\text{hf}(C) \pmod{2^k}$ as described above and since $\text{hf}(A[i, j])$ is a $(n-2) \times (n-2)$ matrix, we compute it's hafnian recursively modulo 2^k . Therefore, we can compute $\text{hf}(A) = \text{hf}(C) - \text{hf}(A[i, j]) \pmod{2^k}$.

This gives us a P algorithm for computing hafnians modulo 2^k .

Counting perfect matchings modulo 2^k

Let G be an undirected graph and A_G denote the adjacency matrix of the graph G . If G has odd number of vertices, then clearly there aren't any perfect matchings. Otherwise it is straight-forward to see that number of perfect matchings in G is same as the value $\text{hf}(A_G)$. Hence the result follows.

On the Relative Power of Linear Algebraic Approximations of Graph Isomorphism

Anuj Dawar  

Department of Computer Science and Technology, University of Cambridge, UK

Danny Vagnozzi 

Department of Computer Science and Technology, University of Cambridge, UK

Abstract

We compare the capabilities of two approaches to approximating graph isomorphism using linear algebraic methods: the *invertible map tests* (introduced by Dawar and Holm) and proof systems with algebraic rules, namely *polynomial calculus*, *monomial calculus* and *Nullstellensatz calculus*. In the case of fields of characteristic zero, these variants are all essentially equivalent to the Weisfeiler-Leman algorithms. In positive characteristic we show that the distinguishing power of the monomial calculus is no greater than the invertible map method by simulating the former in a fixed-point logic with solvability operators. In turn, we show that the distinctions made by this logic can be implemented in the Nullstellensatz calculus.

1 Introduction

The *graph isomorphism problem* consists in deciding whether there is an edge-preserving bijection between the vertex sets of two given graphs. Computationally, this problem is polynomial-time equivalent to finding the partition into orbits of the action of the automorphism group of a given graph on its vertex set. More generally, it is polynomial-time equivalent to computing the partition into orbits of the *induced* action of the automorphism group on the k^{th} power of the vertex set for any fixed k [20] (we shall refer to this partition as the *k-orbit partition* for a graph). The complexity of these problems is notoriously unresolved: while there are reasons to believe that they are not NP-complete, it is still an open problem as to whether they are in P. The best known upper bound to their computational time is quasi-polynomial, which follows from a breakthrough by Babai [2].

There has been a recent surge of interest in linear-algebraic approaches to the graph isomorphism problem (see for example [4, 12, 17, 19, 22]). In this paper, we consider two distinct methods for incorporating algorithms for solving linear systems into graph isomorphism solvers and compare them. The first is based on the use of algebraic proofs systems, such as the polynomial calculus and the second are generalizations of the Weisfeiler-Leman method, based on stability conditions and coherent algebras.

For every $k \in \mathbb{N}$, the k -Weisfeiler-Leman algorithm is a generalization of naïve colour refinement, giving an approximation of the k -orbit partition. For a graph with vertex set V , each of these algorithms outputs in time $|V|^{O(k)}$ a canonical labelled partition of V^k satisfying a stability condition and respecting local isomorphism. Informally, they can be seen as forming a family of algorithms, each defining a notion of equivalence on both graphs and tuples of vertices of graphs. A result by Cai, Fürer and Immerman [7] shows how to construct graphs Γ_k of size $O(k)$ for which the k -Weisfeiler-Leman algorithm fails to produce the k -orbit partition. In the same paper, it is shown that the equivalence classes of the output partition of the k -Weisfeiler-Leman algorithm coincide with the equivalence classes of k -tuples of vertices distinguished by *counting logic* formulae with at most $k + 1$ variables. Thus, one deduces from the tight connection made by Immerman and Lander (see Theorem 2.3 in [9]), that the equivalence notions defined by the Weisfeiler-Leman family of algorithms delimit the expressive power of *fixed point logic with counting* (FPC). Intuitively, one such limitation is the expressibility of solvability of systems of linear equations over finite fields, since the above mentioned constructions by Cai, Fürer and Immerman are essentially graph encodings of systems of linear equations over \mathbb{Z}_2 [1]. This has therefore prompted research into families of algorithms graded by the natural numbers, whose notion of equivalence on tuples of vertices of graphs is conceptually a linear algebraic invariance over some field \mathbb{F} . One such family is that of the *invertible map tests* over a field \mathbb{F} , first defined in [12]. For any graph, the k^{th} algorithm of this family also produces a canonical labelled partition of k -tuples of its vertices, satisfying a stability condition and respecting local isomorphism, thus giving another notion of equivalence on both graphs and k -tuples of vertices thereof. For a fixed characteristic, the output of the k -invertible map tests is independent of the field; as such, \mathbb{F} will hereafter be taken to be a prime field without loss of generality. One can claim that the family of equivalences on tuples defined by the Weisfeiler-Leman algorithms and that defined by the invertible map tests over \mathbb{Q} *simulate* each other in the following sense. For every $k \in \mathbb{N}$, there is some $k' \in \mathbb{N}$ such that for any graph, any pair of k -tuples of its vertices distinguished by the k -Weisfeiler-Leman algorithm are distinguished by the k' -invertible map test over \mathbb{Q} . Conversely, for every $k \in \mathbb{N}$ there is a $k' \in \mathbb{N}$ such that for any graph, any pair of k -tuples of vertices distinguished by the k -invertible map test over \mathbb{Q} is distinguished by the k' -Weisfeiler-Leman algorithm. If the characteristic of \mathbb{F} is positive the former statement holds, but not the latter; indeed, it is shown in [18] and [10] how one can construct graphs $\Gamma_{k,p}$ for each $k \in \mathbb{N}$ and prime number p , for which the 3-invertible map test over \mathbb{Z}_p outputs the 3-orbit partition, but the output of the k -invertible map test over \mathbb{Z}_q with $q \neq p$ is strictly coarser than the k -orbit partition. A recent construction due to Lichter [19] suggests a way of getting graphs, for any value of k , on which the k -orbit partition cannot be obtained by the k -invertible map test over \mathbb{Z}_q for any q whatsoever.

Another approach to approximating the orbit partition is that of algebraic proof systems [3, 8]. These systems are the subject of very active study in the area of proof complexity. They have been studied specifically in the context of graph isomorphism in [4] and [17]. In particular, the proof systems studied are the *polynomial calculus* (PC), and the weaker *Nullstellensatz calculus* (NC) and *monomial calculus* (MC). Each of these gives, for a fixed field \mathbb{F} a set of rules \mathcal{R} dictating how new polynomials, with coefficients in \mathbb{F} , may be derived from an initial set of polynomials, which we shall refer to as *axioms*. In the context of graph isomorphism, we encode any graph Γ on a vertex set V as a set of axioms $\text{Ax}(\Gamma) \subset \mathbb{F}[\{x_{uv} | u, v \in V\}]$, i.e. a collection of polynomials over variables x_{uv} corresponding to potential edges in the graph. An \mathcal{R} -derivation of the polynomial $x_{u_1 v_1} x_{u_2 v_2} \dots x_{u_k v_k}$ can then be seen as a proof that the tuples $\vec{u}, \vec{v} \in V^k$ are distinguishable. Say that such a derivation has *degree* d if all

polynomials occurring in the derivation have degree at most d . For each of the calculi, fixing the degree d gives us a polynomial-time algorithm for checking the existence of a derivation and hence a polynomial-time approximation of the orbit partition for graphs. Again, we may restrict \mathbb{F} to a prime field without loss of generality.

The question we address in this paper is how the approximations of the orbit partition obtained by these algebraic proof systems compare with those we get from the invertible map test. In the case of fields of characteristic zero, the answer is quite clear, as both approaches yield algorithms that are (up to constant factors) equivalent to the Weisfeiler-Leman algorithms. This is shown for the invertible map tests in [13] and for the polynomial calculus in [17]. In the case of positive characteristic, we show (in Section 4) the definability of derivations of MC in FPS(p), an extension of fixed-point logic with quantifiers for the solvability of systems of linear equations over fields of characteristic p . This implies, in particular, that the approximation of the orbit partition obtained by MC in characteristic p is no finer than that obtained by the invertible map test in characteristic p .

► **Theorem 1.** *For any prime number p , $k \in \mathbb{N}$ and $\vec{u}, \vec{v} \in V^k$, there is a $k' \in \mathbb{N}$ such that if $x_{u_1 v_1} \dots x_{u_k v_k}$ has a degree k MC derivation over \mathbb{Z}_p from $\text{Ax}(\Gamma)$, then \vec{u} and \vec{v} are distinguished by the k' -invertible map test over \mathbb{Z}_p .*

In the other direction, we show that NC is able to simulate (as far as the graph isomorphism problem is concerned) PC in characteristic zero and at least MC in positive characteristic.

► **Theorem 2.**

1. *For any $k \in \mathbb{N}$ and $\vec{u}, \vec{v} \in V^k$, there is a $k' \in \mathbb{N}$ such that if $x_{u_1 v_1} \dots x_{u_k v_k}$ has a degree k PC derivation of over \mathbb{Q} from $\text{Ax}(\Gamma)$, then there is also a degree k' NC derivation over \mathbb{Q} from $\text{Ax}(\Gamma)$.*
2. *For any prime number p , $k \in \mathbb{N}$ and $\vec{u}, \vec{v} \in V^k$, there is a $k' \in \mathbb{N}$ such that if $x_{u_1 v_1} \dots x_{u_k v_k}$ has a degree k MC derivation over \mathbb{Z}_p from $\text{Ax}(\Gamma)$, then it also has a degree k' NC derivation over \mathbb{Z}_p from $\text{Ax}(\Gamma)$.*

From this, a strengthening of Theorem 6.3 in [4] also follows. Let V be the vertex set of $\Gamma_{k,p}$ as above.

► **Theorem 3.** *If $\vec{u}, \vec{v} \in V^3$ are not in the same equivalence class of the 3-orbit partition of $\Gamma_{k,p}$, then $x_{u_1 v_1} x_{u_2 v_2} x_{u_3 v_3}$ has a degree 3 NC derivation over \mathbb{Z}_p from $\text{Ax}(\Gamma_{k,p})$.*

Due to lack of space we omit the proofs of a number of results. These can be found in the extended version [14].

Notational conventions

All sets are finite unless stated otherwise. Given two sets V and I , a tuple in V^I is denoted by \vec{v} , and its i^{th} entry by v_i , for each $i \in I$. We use the notation $(v_i)_{i \in I}$ to denote the element of V^I with i^{th} element equal to v_i . We set $[k] = \{1, 2, \dots, k\} \subset \mathbb{N}$ and define $[k]^{(r)} = \{\vec{x} \in [k]^r \mid x_i \neq x_j \forall i, j \in [r], i \neq j\}$ for $r \leq k$. For any $\vec{v} \in V^k$, $\vec{u} \in V^r$, and $\vec{i} \in [k]^{(r)}$ we define $\vec{v} \langle \vec{i}, \vec{u} \rangle \in V^k$ to be the tuple with entries

$$(\vec{v} \langle \vec{i}, \vec{u} \rangle)_j = \begin{cases} u_{i_s} & \text{if } j = i_s \text{ for some } s \in [r] \\ v_j & \text{otherwise.} \end{cases}$$

In other words, $\vec{v} \langle \vec{i}, \vec{u} \rangle$ is the tuple obtained from \vec{v} by substituting the elements of \vec{u} in the positions specified by \vec{i} . Given two tuples $\vec{v} \in V^r$ and $\vec{w} \in V^s$, their *concatenation* is denoted by $\vec{v} \cdot \vec{w} \in V^{r+s}$. For a relation $R \subseteq V^2$ we define the *adjacency matrix* of R to be the $V \times V$ matrix whose (u, v) entry is 1 if $(u, v) \in R$ and 0 otherwise.

2 Preliminaries

2.1 Labelled partitions and refinement operators

A *labelled partition* of a set A is a map $\gamma : A \rightarrow X$, where X is a set of elements sometimes referred to as *colours*, and $\gamma(a)$ as the colour of a in γ . Denote the class of labelled partitions of A by $\mathcal{P}(A)$. For partitions \mathfrak{R} and \mathfrak{S} on A we write $\mathfrak{R} \preceq_A \mathfrak{S}$ and say that \mathfrak{S} *refines* \mathfrak{R} if, whenever $a, b \in A$ are in the same equivalence class of \mathfrak{S} , they are also in the same equivalence class of \mathfrak{R} . We extend the partial order \preceq_A to labelled partitions by writing $\gamma \preceq_A \rho$ to mean that the equivalence relation $\{(a, b) \mid \rho(a) = \rho(b)\}$ refines the relation $\{(a, b) \mid \gamma(a) = \gamma(b)\}$. Note that this does not require that the co-domains of γ and ρ are the same or indeed related in any way.

Define an action of $\text{Sym}(k)$ on V^k by setting \vec{v}^π to be the element of V^k with i^{th} entry $v_{\pi^{-1}(i)}$. $\gamma \in \mathcal{P}(V^k)$ is said to be *invariant* if $\gamma(\vec{u}) = \gamma(\vec{v})$ implies $\gamma(\vec{u}^\pi) = \gamma(\vec{v}^\pi)$ for all $\pi \in \text{Sym}(k)$ and $\vec{u}, \vec{v} \in V^k$.

For $t \in [k]$, the *t-projection* of γ is defined to be the labelled partition $\text{pr}_t \gamma \in \mathcal{P}(V^t)$ such that for all $\vec{u} \in V^t$

$$\text{pr}_t \gamma(\vec{u}) = \gamma(u_1, u_2, \dots, u_t, \dots, u_t).$$

For $\vec{v} \in V^k$, with t, k as above, we similarly define $\text{pr}_t \vec{v}$ to be the t -tuple (v_1, v_2, \dots, v_t) .

► **Definition 4** (Refinement operator). *A k -refinement operator is a map R which, for any set V , assigns to each $\gamma \in \mathcal{P}(V^k)$ a partition $R \circ \gamma \in \mathcal{P}(V^k)$ such that $\gamma \preceq R \circ \gamma$ and it is monotone; that is, $\gamma \preceq \rho \implies R \circ \gamma \preceq R \circ \rho$.*

We say that $\gamma \in \mathcal{P}(V^k)$ is *R-stable* if $R \circ \gamma = \gamma$. Given an $X \in \mathcal{P}(V^k)$, define a sequence of labelled partitions by $X^0 = X$ and $X^{i+1} = R \circ X^i$. Then, there is some s such that for all $i, i \geq s$ implies that X^i is *R-stable*. For the minimal such s we denote X^s by $[X]^R$.

In order to define the refinement operator leading to the invertible map test (in Section 3.1 below), we need the notion of character vectors. Let $\vec{v} \in V^k$ be a k -tuple of vertices, $\vec{i} \in [k]^{(2r)}$ a $2r$ -tuple of indices and $\gamma \in \mathcal{P}(V^k)$ a labelled partition of V^k . For a pair $\vec{x}, \vec{y} \in V^r$ of r -tuples of vertices, $\gamma(\vec{v} \langle \vec{i}, \vec{x} \cdot \vec{y} \rangle)$ is the colour of the tuple obtained by substituting \vec{x}, \vec{y} into \vec{v} in the positions specified by \vec{i} . For each $\sigma \in \text{Im}(\gamma)$, we define the $V^r \times V^r$ matrix χ_σ with 0/1 entries as the adjacency matrix of the relation $\{(\vec{x}, \vec{y}) \in (V^r)^2 \mid \gamma(\vec{v} \langle \vec{i}, \vec{x} \cdot \vec{y} \rangle) = \sigma\}$. The (\vec{i}, \vec{v}) -*character vector* of γ is then defined to be the tuple $\vec{\chi} = (\chi_\sigma)_{\sigma \in \text{Im}(\gamma)}$.

2.2 Extensions of first order and inflationary fixed point logics

We assume the reader has some familiarity with first-order (FO) and fixed-point logics (FP), and logical interpretations. Details can be found in [16]. Throughout the paper, for a logic \mathcal{L} , we denote by \mathcal{L}_k the class of all \mathcal{L} -formulae (over some pre-specified vocabulary) with at most k variables. We use \mathcal{C} to denote the *counting logics* as in [21]. Let \mathfrak{A} be a structure with universe V and fix $\vec{u}, \vec{v} \in V^k$. We say that some \mathcal{L}_k formula $\phi(\vec{z})$ *distinguishes* $(\mathfrak{A}, \vec{z} \mapsto \vec{u})$ from $(\mathfrak{A}, \vec{z} \mapsto \vec{v})$ if either $\mathfrak{A} \models \phi(\vec{u})$ and $\mathfrak{A} \not\models \phi(\vec{v})$ or $\mathfrak{A} \not\models \phi(\vec{u})$ and $\mathfrak{A} \models \phi(\vec{v})$. For a logic \mathcal{L} we denote its extension via *solvability quantifiers* slv_p over a finite field of characteristic p by $\mathcal{L}+\text{S}(p)$. Let $\phi(\vec{x}, \vec{y}, \vec{z})$ be a formula of such a logic, where $\vec{x}, \vec{y}, \vec{z}$ are i, j, k -tuples of variables respectively. Then $\text{slv}_p(\vec{x}\vec{y}.\phi(\vec{x}, \vec{y}, \vec{z}))$ is also a $\mathcal{L}+\text{S}(p)$ formula. See [11, 17] for more about these quantifiers. The semantics of this quantifier is as follows. To each structure with universe V and k -tuple $\vec{v} \in V^k$, we associate the $V^i \times V^j$ matrix $S_\phi^{\vec{v}}$ over $\{0, 1\} \subseteq \mathbb{Z}_p$ with (\vec{r}, \vec{s}) -entry equal to 1 if, and only if, $\mathfrak{A} \models \phi(\vec{r}, \vec{s}, \vec{v})$. Then, $(\mathfrak{A}, \vec{z} \mapsto \vec{v}) \models \text{slv}_p(\vec{x}\vec{y}.\phi(\vec{x}, \vec{y}, \vec{z}))$ if, and only if, there is some $\vec{a} \in \mathbb{Z}_p^{V^j}$ such that $S_\phi^{\vec{v}} \vec{a} = \mathbf{1}$.

When \mathcal{L} is FP or FO, we denote $\mathcal{L}+\text{S}(p)$ by $\text{FPS}(p)$ or $\text{FOS}(p)$ respectively.

3 Refinement operators and proof systems with algebraic rules

We give an overview of the refinement operators and proof systems of interest.

3.1 The invertible map tests

The equivalence relations on tuples of vertices induced by the invertible map tests have been originally introduced in [12], under the guise of a pebble game with algebraic rules on a pair of graphs. Algorithmically, one can find these equivalence classes by computing a fixed point of the *invertible map operators* $\text{IM}_{k,r}^{\mathbb{F}}$, as defined in Sections 8 of [13]. Each of these is a k -refinement operator such that for $\gamma \in \mathcal{P}(V^k)$, the colour of $\vec{v} \in V^k$ in the partition $\text{IM}_{k,r}^{\mathbb{F}} \circ \gamma$ is given by a tuple whose entries are $\gamma(\vec{v})$ and the equivalence classes under matrix conjugation of the (\vec{i}, \vec{v}) -character vectors of γ , for all $\vec{i} \in [k]^{(2r)}$. Without going into the details, one can show that γ is $\text{IM}_{k,r}^{\mathbb{F}}$ -stable if for all $\vec{u}, \vec{v} \in V^k$ and $\vec{i} \in [k]^{(2r)}$

$$\gamma(\vec{u}) = \gamma(\vec{v}) \implies \exists M \in \text{GL}_{V^r} \text{ s.t. } \forall \sigma \in \text{Im}(\gamma)(\mathbb{F}), M\chi_{\sigma}M^{-1} = \xi_{\sigma}$$

where $(\chi_{\sigma})_{\sigma \in \text{Im}(\gamma)}$ and $(\xi_{\sigma})_{\sigma \in \text{Im}(\gamma)}$ are the (\vec{i}, \vec{v}) and (\vec{i}, \vec{u}) -character vectors of γ respectively.

For a graph Γ on V , let $\alpha_{k,\Gamma}$ be a canonical labelled partition of V^k into atomic types of Γ .¹ Define the k -refinement operator $\text{IM}_k^{\mathbb{F}}$ so that for $\gamma \in \mathcal{P}(V^k)$, the colour of $\vec{v} \in V^k$ in $\text{IM}_k^{\mathbb{F}} \circ \gamma$ is given by a tuple whose entries are the colours of \vec{v} in $\text{IM}_{k,r}^{\mathbb{F}} \circ \gamma$, for all $r \leq k/2$. Formally,

$$\text{IM}_k^{\mathbb{F}} \circ \gamma(\vec{v}) = (\text{IM}_{k,1}^{\mathbb{F}} \circ \gamma(\vec{v}), \text{IM}_{k,2}^{\mathbb{F}} \circ \gamma(\vec{v}), \dots, \text{IM}_{k,\lfloor k/2 \rfloor}^{\mathbb{F}} \circ \gamma(\vec{v})).$$

Then, the output of the k -invertible map test over \mathbb{F} is the labelled partition $[\alpha_{k,\Gamma}]^{\text{IM}_k^{\mathbb{F}}}$. It is explained in Proposition 4.6 in [13] how one can obtain this partition in time $|V|^{\mathcal{O}(k)}$ by iteratively applying $\text{IM}_k^{\mathbb{F}}$ to $\alpha_{k,\Gamma}$. Note that for a fixed characteristic, the choice of \mathbb{F} is irrelevant: indeed, if k -tuples $A, B \in \text{Mat}_V(\mathbb{F})^k$ are related by matrix conjugation over \mathbb{F} if, and only if, they are related by matrix conjugation over any field extension of \mathbb{F} [15]. Since the entries of the character vectors are 01-matrices, we may assume, without loss of generality, that \mathbb{F} is a prime field. Hereafter, we shall then indicate the operators $\text{IM}_{k,r}^{\mathbb{F}}$ and $\text{IM}_k^{\mathbb{F}}$ by $\text{IM}_{k,r}^c$ and IM_k^c respectively, where c is the characteristic of \mathbb{F} .

3.2 Counting logics operators

It is useful to express the partition of k -tuples into equivalence classes under finite variable counting logics as the fixed point of a refinement operator. For this purpose, the k -refinement operators $C_{k,r}$, for $r < k$, have been defined so that for any $\gamma \in \mathcal{P}(V^k)$, the colour of $\vec{v} \in V^k$ in $C_{k,r} \circ \gamma$ is given by a tuple whose entries are $\gamma(\vec{v})$ and the multisets of colours in γ of the tuples which can be obtained by substituting an r -tuple into \vec{v} (see Section 4 of [13]). In particular, γ is $C_{k,r}$ -stable if, and only if, for all $\vec{i} \in [k]^{(r)}$ and $\sigma \in \text{Im}(\gamma)$, the size of the set $\{\vec{x} \in V^r \mid \gamma(\vec{v}(\vec{i}, \vec{x})) = \sigma\}$ is independent of the choice of \vec{v} from within its equivalence class in γ . As such, for a graph Γ on V , $\vec{u}, \vec{v} \in V^k$ are in the same equivalence class of $[\alpha_{k,\Gamma}]^{C_{k,1}}$ if, and only if, there are no C_k formulae distinguishing $(\mathfrak{A}_{\Gamma}, \vec{z} \mapsto \vec{u})$ from $(\mathfrak{A}_{\Gamma}, \vec{z} \mapsto \vec{v})$. The combinatorial properties of $C_{k,r}$ -stable partitions can be used to show the relation between

¹ By *canonical* we mean *invariant under isomorphism*. That is, if Γ and Γ' are graphs on V and V' respectively and $\vec{u} \in V^k$ and $\vec{v} \in (V')^k$, then $\alpha_{k,\Gamma}(\vec{u}) = \alpha_{k,\Gamma'}(\vec{v})$ if, and only if, the mapping $u_i \rightarrow v_i$ is an isomorphism of the subgraphs induced by the vertices in \vec{u} and \vec{v} .

the distinguishing powers of finite variable fragments of counting logics and the invertible map tests. In short, the invertible map test over fields of characteristic zero is not more distinguishing than counting logic, but over fields of positive characteristic it is. To be precise, with Γ, \vec{u}, \vec{v} as above, the following holds:

For any field \mathbb{F} , if the k -invertible map test over \mathbb{F} does not distinguish \vec{u} and \vec{v} in Γ , then there are no \mathcal{C}_{k-1} -formulae distinguishing $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{u})$ from $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v})$.

If the k -invertible map test over \mathbb{Q} distinguishes \vec{u} from \vec{v} in Γ , then there is some \mathcal{C}_{2k-1} -formula distinguishing $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{u})$ from $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v})$.²

3.3 Solvability operators

In order to construct a refinement operator whose stable points reflect the properties of $\text{FOS}(p)$, we consider a weakened version of the invertible map operators, whose action on labelled partitions can be computed solely by solving systems of linear equations. To achieve this, we proceed by defining an equivalence relation \sim_{sol} on the character vectors, which can be seen as a relaxation of the conjugation relation \sim .

Let $\mathfrak{P}_V(\mathbb{F}) = \{A \in \text{Mat}_V(\mathbb{F}) \mid \sum_{w \in V} A_{wv} = \sum_{w \in V} A_{uw} = 1, \forall u, v \in V\}$. Or, equivalently, $\mathfrak{P}_V(\mathbb{F})$ is the set of matrices $A \in \text{Mat}_V(\mathbb{F})$ such that $\mathbf{1}_V$ is an eigenvector of both A and A^t , with corresponding eigenvalue 1. Set \mathbb{J}_V to be the $V \times V$ all-ones matrix and for a set I , let

$$\mathcal{X}_V^I(\mathbb{F}) = \{\vec{A} \in \text{Mat}_V(\mathbb{F})^I \mid \sum_{s \in I} A_s = \mathbb{J}_V \text{ and } \forall i \in I, \exists j, A_i^t = A_j\}.$$

Note that if γ is invariant and $\vec{i} \in [k]^{(2r)}$, then any (\vec{i}, \vec{v}) -character $\vec{\chi}$ of γ is an element of $\mathcal{X}_V^{\text{Im}(\gamma)}(\mathbb{F})$, since

$$\sum_{\sigma \in \text{Im}(\gamma)} \chi_\sigma = \mathbb{J}_{V^r} \quad (1)$$

and by invariance of γ , for any $\sigma \in \text{Im}(\gamma)$ there is some σ' such that $(\chi_\sigma)^t = \chi_{\sigma'}$. Define the relation \sim_{sol} on $\mathcal{X}_V^I(\mathbb{F})$ as follows: $\vec{A} \sim_{\text{sol}} \vec{B}$ if there is some $S \in \mathfrak{P}_V(\mathbb{F})$ such that $A_i S = S B_i$ for all $i \in I$.

► **Lemma 5.** \sim_{sol} is an equivalence relation on $\mathcal{X}_V^I(\mathbb{F})$.

Proof. Clearly, $\vec{A} \sim_{\text{sol}} \vec{A}$, since $\mathbb{I}_V \in \mathfrak{P}_V(\mathbb{F})$ and $A_i \mathbb{I}_V = \mathbb{I}_V A_i$ for all $i \in I$. Suppose $\vec{A} \sim_{\text{sol}} \vec{B}$. Let $S \in \mathfrak{P}_V(\mathbb{F})$ satisfy $A_i S = S B_i$ for all $i \in I$. Then $B_i^t S^t = S^t A_i^t$ and thus, from the definition of \mathcal{X}_V^I , $B_i S^t = S^t A_i$ for all $i \in I$. Since $S^t \in \mathfrak{P}_V(\mathbb{F})$, $\vec{B} \sim_{\text{sol}} \vec{A}$. Finally, suppose $\vec{A} \sim_{\text{sol}} \vec{B}$ and $\vec{B} \sim_{\text{sol}} \vec{C}$. Let $S, T \in \mathfrak{P}_V(\mathbb{F})$ satisfy $A_i S = S B_i$ and $B_i T = T C_i$ for all $i \in I$. Then $A_i S T = S B_i T = S T C_i$. Since S, T, S^t and T^t must all have $\mathbf{1}_{V^r}$ as eigenvector, with corresponding eigenvalue 1, so must ST and $(ST)^t$. Hence, $ST \in \mathfrak{P}_V(\mathbb{F})$ and $\vec{A} \sim_{\text{sol}} \vec{C}$. ◀

² This is a direct consequence of the following generalizations of Lemmata 7.1 and 7.3 in [13] respectively:
for all $k, r \in \mathbb{N}$ with $2r < k$,

1. The k -projection of a graph-like $\text{IM}_{k+r,r}^c$ -stable partition is $\text{C}_{k,r}$ -stable for any characteristic c .
2. The k -projection of a graph-like $\text{C}_{k+r,r}$ -stable partition is $\text{IM}_{k,r}^0$ -stable.

The authors prove it only for the case $r = 1$, but a similar argument holds for any $r \in \mathbb{N}$.

For $k, r \in \mathbb{N}$ with $2r \leq k$, a field \mathbb{F} , and an invariant $\gamma \in \mathcal{P}(V^k)$, we define the *solvability operators* $S_{k,r}^{\mathbb{F}}$ by setting $S_{k,r}^{\mathbb{F}} \circ \gamma$ to be the labelled partition for which the colour of $\vec{v} \in V^k$ is a tuple whose entries are $\gamma(\vec{v})$ and the equivalence classes under the relation \sim_{sol} of the (\vec{i}, \vec{v}) -character vectors of γ , for all $\vec{i} \in [k]^{(2r)}$. Formally:

$$S_{k,r}^{\mathbb{F}} \circ \gamma : \begin{array}{ccc} V^k & \rightarrow & \text{Im}(\gamma) \times (\mathcal{X}_{V^r}^{\text{Im}(\gamma)}(\mathbb{F}) / \sim_{\text{sol}})^{[k]^{(2r)}} \\ \vec{v} & \mapsto & (\gamma(\vec{v}), (\vec{\chi}_{\vec{i}})_{\vec{i} \in [k]^{(2r)}}), \end{array}$$

where $\vec{\chi}_{\vec{i}}$ is the (\vec{i}, \vec{v}) -character vector of γ .

As before, since the entries of the matrices in the character vector are all 0 and 1, we may restrict \mathbb{F} to being a prime field without loss of generality, and denote $S_{k,r}^{\mathbb{F}}$ by $S_{k,r}^c$, where $c = \text{char}(\mathbb{F})$. It is easy to show that $S_{k,r}^c$ is monotone on the class of invariant partitions of V^k and is thus a k -refinement operator when considered with this domain restriction.

For the remainder of this section, we assume that $\gamma \in \mathcal{P}(V^k)$ is invariant and that $\vec{\chi}$ and $\vec{\xi}$ are the (\vec{i}, \vec{v}) and (\vec{i}, \vec{u}) -character vectors of γ respectively, for some fixed $\vec{i} \in [k]^{(2r)}$. The following is a direct consequence of the definition of $S_{k,r}^c$.

► **Proposition 6.** *Let \mathbb{F} be the prime field of characteristic c . For all $k, r \in \mathbb{N}$, with $2r \leq k$, $S_{k,r}^c \circ \gamma(\vec{u}) = S_{k,r}^c \circ \gamma(\vec{v})$ if, and only if, $\gamma(\vec{u}) = \gamma(\vec{v})$ and for each $\vec{i} \in [k]^{(2r)}$ there exist some $M \in \mathfrak{P}_{V^r}(\mathbb{F})$ such that for all $\sigma \in \text{Im}(\gamma)$, $\chi_{\sigma} M = M \xi_{\sigma}$. In particular, γ is $S_{k,r}^c$ -stable if, and only if, for all $\vec{u}, \vec{v} \in V^k$ and $\vec{i} \in [k]^{(2r)}$*

$$\gamma(\vec{u}) = \gamma(\vec{v}) \implies \exists M \in \mathfrak{P}_{V^r}(\mathbb{F}) \text{ s.t. } \forall \sigma \in \text{Im}(\gamma), \chi_{\sigma} M = M \xi_{\sigma} \quad \forall \sigma \in \text{Im}(\gamma).$$

We now show some useful properties of the operators $S_{k,r}^c$.

► **Lemma 7.** *An $\text{IM}_{k,r}^c$ -stable partition is $S_{k,r}^c$ -stable.*

Proof. Let \mathbb{F} be the prime field of characteristic c . Suppose γ is $\text{IM}_{k,r}^c$ -stable and let $\gamma(\vec{u}) = \gamma(\vec{v})$. Then, for all $\vec{i} \in [k]^{(2r)}$, there is some $M \in GL_{V^r}(\mathbb{F})$ such that $M^{-1} \chi_{\sigma} M = \xi_{\sigma}$ for all $\sigma \in \text{Im}(\gamma)$. By equation 1, $M \mathbb{J}_{V^r} = \mathbb{J}_{V^r} M$ and thus, both M and M^t have $\mathbf{1}_{V^r}$ as eigenvector with corresponding non-zero eigenvalue $\lambda \in \mathbb{F}$. Since, $\frac{1}{\lambda} M \in \mathfrak{P}_{V^r}(\mathbb{F})$, the result follows. ◀

► **Lemma 8.** *If γ is $S_{k,r}^c$ -stable the following hold:*

1. *If $\gamma(\vec{u}) = \gamma(\vec{v})$, and γ is graph-like, then for all $\vec{i} \in [k]^{(2r)}$ and $\sigma \in \text{Im}(\gamma)$, $\{\vec{w} \in V^r \mid \gamma(\vec{u}(\vec{i}, \vec{w} \cdot \vec{w})) = \sigma\}$ is non-empty if, and only if, $\{\vec{w} \in V^r \mid \gamma(\vec{v}(\vec{i}, \vec{w} \cdot \vec{w})) = \sigma\}$ is non-empty.*
2. *If $c = 0$, then γ is $C_{k,2r}$ -stable.*

Note that if $c = 0$, the second statement implies the first (refer to Section 4 and 5 of [13] for more details on properties of $C_{k,r}$ -stability).

Proof. Suppose $\{\vec{w} \in V^r \mid \gamma(\vec{u}(\vec{i}, (\vec{w} \cdot \vec{w}))) = \sigma\}$ is non-empty. Since γ is graph-like, χ_{σ} must have all the non-zero entries on the diagonal. Hence, for any $M \in \mathfrak{P}_{V^r}(\mathbb{F})$, $\chi_{\sigma} M$ and, consequently $M \xi_{\sigma}$ must be non-zero. As such, $\{\vec{w} \in V^r \mid \gamma(\vec{v}(\vec{i}, (\vec{w} \cdot \vec{w}))) = \sigma\}$ is non-empty. The converse can be argued by symmetry, thus showing (1).

For (2), it suffices to show that: if $A, B \in \text{Mat}_V(\mathbb{F})$ are 01-matrices and $AM = MB$ for some $M \in \mathfrak{P}_V(\mathbb{F})$ then A and B have the same number of non-zero entries if $\text{char}(\mathbb{F}) = 0$. Indeed, note that if α and β are the number of non-zero entries of A and B respectively, then $\alpha \mathbb{J}_V = \mathbb{J}_V A \mathbb{J}_V$ and $\beta \mathbb{J}_V = \mathbb{J}_V B \mathbb{J}_V$. Since $M \mathbb{J}_V = \mathbb{J}_V M = \mathbb{J}_V$,

$$\alpha \mathbb{J}_V = \mathbb{J}_V A \mathbb{J}_V = \mathbb{J}_V A M \mathbb{J}_V = \mathbb{J}_V M B \mathbb{J}_V = \mathbb{J}_V B \mathbb{J}_V = \beta \mathbb{J}_V,$$

whence $\alpha = \beta$. ◀

In particular, if $r = 1$, statement (1) above implies that there is some $x \in V$ such that $\text{pr}_{k-1}\gamma(\text{pr}_{k-1}\vec{u}(i, x)) = \sigma$ if, and only if, there is some $y \in V$, such that $\text{pr}_{k-1}\gamma(\text{pr}_{k-1}\vec{v}(i, y)) = \sigma$. Furthermore, from (2) and Lemma 5.7 in [13], $\text{pr}_{k-1}\gamma$ is C_{k-1} stable.

► **Corollary 9.** *Let $\gamma = [\alpha_{k,\Gamma}]^{S_{k,1}^c}$ for some graph Γ on V . If $\text{pr}_{k-1}\gamma(\vec{u}) = \text{pr}_{k-1}\gamma(\vec{v})$, there are no first-order formulae distinguishing $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{u})$ from $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v})$. In addition, if $c = 0$, there are no C_{k-1} -formulae distinguishing $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{u})$ from $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v})$.*

Similarly to the invertible map operators, we define the k -refinement operator S_k^c so that for $\gamma \in \mathcal{P}(V^k)$, the colour of $\vec{v} \in V^k$ in $S_k^c \circ \gamma$ is given by a tuple whose entries are the colours of \vec{v} in $S_{k,r}^c \circ \gamma$, for all $r < k/2$; that is,

$$S_k^c \circ \gamma(\vec{v}) = (S_{k,1}^c \circ \gamma(\vec{v}), S_{k,2}^c \circ \gamma(\vec{v}), \dots, S_{k,\lfloor k/2 \rfloor}^c \circ \gamma(\vec{v})).$$

The next statement will be the crux of our main results.

► **Theorem 10.** *For any prime number p , if $\gamma = [\alpha_{k,\Gamma}]^{S_k^p}$ and $\gamma(\vec{u}) = \gamma(\vec{v})$, there are no $\text{FOS}_{k-1}(p)$ formulae distinguishing $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{u})$ from $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v})$.*

Proof. We proceed by induction on the structure of $\text{FOS}(p)$ formulae $\phi(\vec{z})$, where \vec{z} is a k -tuple of pairwise distinct variables. If $\phi(\vec{z})$ contains only atomic formulae, boolean connectives and first order quantifiers, the statement holds by Corollary 9. Assume that for some $\phi(\vec{z}) \in \text{FOS}_k(p)$, $\mathfrak{A}_\Gamma \models \phi(\vec{u}) \iff \mathfrak{A}_\Gamma \models \phi(\vec{v})$, and suppose $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v}) \models \text{slv}_p[\vec{x}\vec{y}.\phi(\vec{z}(\vec{i}, \vec{x} \cdot \vec{y}))]$, where $\vec{i} \in [k]^{(2r)}$ and \vec{x}, \vec{y} are r -tuples of distinct variables (distinct from variables in the tuple \vec{z}). Let $S^{\vec{v}}$ be the adjacency matrix of the relation $\{(\vec{a}, \vec{b}) \in V^r \times V^r \mid (\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v}) \models \phi(\vec{v}(\vec{i}, \vec{a} \cdot \vec{b}))\}$, and similarly define $S^{\vec{u}}$. Then, there is some $\vec{a} \in \mathbb{Z}_p^{V^r}$ such that $S^{\vec{v}}\vec{a} = \mathbf{1}_{V^r}$. By the induction hypothesis, $S^{\vec{u}} = \sum_{\sigma \in I} \chi_\sigma$ and $S^{\vec{v}} = \sum_{\sigma \in I} \xi_\sigma$ for some $I \subseteq \text{Im}(\gamma)$. Since there exists $M \in \mathfrak{P}_{V^r}(\mathbb{Z}_p)$ such that $\chi_\sigma M = M\xi_\sigma$ for all $\sigma \in \text{Im}(\gamma)$, we have

$$S^{\vec{v}}\vec{a} = \mathbf{1}_{V^r} \implies MS^{\vec{v}}\vec{a} = \mathbf{1}_{V^r} \implies S^{\vec{u}}(M\vec{a}) = \mathbf{1}_{V^r},$$

from which it follows that $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{u}) \models \text{slv}_p[\vec{x}\vec{y}.\phi(\vec{z}(\vec{i}, \vec{x} \cdot \vec{y}))]$. Using a symmetric argument, we conclude that $\text{slv}_p[\vec{x}\vec{y}.\phi(\vec{z}(\vec{i}, \vec{x} \cdot \vec{y}))]$ does not distinguish $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{u})$ from $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v})$ and the result follows by induction. ◀

3.4 Polynomial, monomial and Nullstellensatz calculi

The idea behind *polynomial calculus* (PC), *monomial calculus* (MC) and *Nullstellensatz calculus* (NC) is that of encoding Boolean formulae as multivariate polynomials and concluding that they are inconsistent if the polynomials do not have a common root. The PC inference rules for a set of axioms $A \subset \mathbb{F}[x_1, \dots, x_n]$ are as follows:

1. \bar{f} for all $f \in A$.
2. *Multiplication rule:* $\frac{f}{xf}$ for all derived polynomials f , and variables $x \in \{x_1, \dots, x_n\}$.
3. *Linearity rule:* $\frac{f,g}{\lambda f + \mu g}$ for all derived polynomials f, g and $\lambda, \mu \in \mathbb{F}$.

The inference rules for MC are obtained by restricting f in the multiplication rule to be an axiom times a monomial or a monomial. By further restricting f to be an axiom times a monomial, one obtains the NC inference rules. The *degree* of a PC (or MC or NC) derivation is the maximum degree of all polynomials involved in the derivation, and a PC (or MC or NC, respectively) *refutation* of A is a derivation of 1 from A using PC (or MC or NC, respectively) rules. We are really interested in roots where the variables are assigned 0/1-values, so as to encode the Boolean framework. To enforce this, we assume that the axioms always includes the polynomials $x^2 - x$ for all $x \in \{x_1, \dots, x_n\}$. We may therefore restrict our focus to multilinear polynomials exclusively.

We denote by PC_k the proof system using the same inference rules as PC with the added constraint that all derivations must have degree at most k , and we use the same convention for MC_k and NC_k . Though these proof systems with bounded degree are not complete, their refutations can be decided in polynomial time in the number of variables.

For a graph Γ on V we define $\text{Ax}(\Gamma) \subseteq \mathbb{F}[\{x_{uv} \mid u, v \in V\}]$ to be the set of axioms containing the following polynomials:

1. $\sum_{u \in V} x_{uv} - 1$ for all $v \in V$.
2. $\sum_{u \in V} x_{vu} - 1$ for all $v \in V$.
3. $x_{uv}x_{u'v'}$ if the map $u \mapsto u', v \mapsto v'$ is not a local isomorphism in Γ .
4. $x_{uv}^2 - x_{uv}$ for all $u, v \in V$.

For $\vec{u}, \vec{v} \in V^k$, we further define $\text{Ax}(\Gamma_{\vec{u} \rightarrow \vec{v}})$ to contain the above plus $x_{v_i u_i} - 1$ for all $i \in [k]$.

When considering these axiom we assume, without loss of generality, that \mathbb{F} is a prime field. Let $\equiv_{\text{PC}_k}^c$ be the relation on V^k , where $\vec{u} \equiv_{\text{PC}_k}^c \vec{v}$ if there is no degree k PC refutation of $\text{Ax}(\Gamma_{\vec{u} \rightarrow \vec{v}})$ over the prime field of characteristic c , and similarly define $\equiv_{\text{MC}_k}^c$ and $\equiv_{\text{NC}_k}^c$.

► **Lemma 11.** $\equiv_{\text{PC}_k}^c, \equiv_{\text{MC}_k}^c$ and $\equiv_{\text{NC}_k}^c$ are equivalence relations on V^k .

Proof. Clearly, $\vec{u} \equiv_{\text{PC}_k}^c \vec{u}$. Indeed, the polynomials in the ideal generated by $\text{Ax}(\Gamma_{\vec{u} \rightarrow \vec{u}})$ have the common root $x_{rs} = \delta_{rs}$, where δ_{rs} is the Kronecker delta. Hence, the ideal generated by $\text{Ax}(\Gamma_{\vec{u} \rightarrow \vec{u}})$ is non-trivial. The set $\text{Ax}(\Gamma)$ is invariant under the transformation $x_{rs} \rightarrow x_{sr}$ for all $r, s \in V$. Thus, $\vec{u} \equiv_{\text{PC}_k}^c \vec{v} \implies \vec{v} \equiv_{\text{PC}_k}^c \vec{u}$.

Suppose $\vec{u} \equiv_{\text{PC}_k}^c \vec{v}$ and $\vec{v} \equiv_{\text{PC}_k}^c \vec{w}$. Let π be the map $v_i \rightarrow w_i$ for $i \in [k]$. Note that π is well defined, for if $v_i = v_j$ for some $i \neq j$ and $\pi(v_i) \neq \pi(v_j)$, then $x_{v_i w_i} x_{v_j w_j} \in \text{Ax}(\Gamma)$ - a contradiction. For $A \subseteq V^2$, define A^π as follows:

$$A^\pi = \begin{cases} \{(r, \pi(s)) \mid (r, s) \in A\} & \text{if for all } (r, s) \in A \text{ there is some } j \text{ such that } s = v_j; \\ \{(r, \pi^{-1}(s)) \mid (r, s) \in A\} & \text{if for all } (r, s) \in A \text{ there is some } j \text{ such that } s = w_j; \text{ and} \\ A & \text{otherwise.} \end{cases}$$

For a multilinear polynomial $f = \sum a_A X_A$, let $f^\pi = \sum a_A X_{A^\pi}$. We show by induction on the PC inference rules that there is a PC_k derivation of p if, and only if, there is PC_k derivation of f^π . Indeed, if f is in $\text{Ax}(\Gamma)$, then so is f^π . Suppose there is a PC_k derivation of f, g, f^π and g^π . Then there is a PC_k derivation of $(\lambda f + \mu g)^\pi = \lambda f^\pi + \mu g^\pi$. Finally, suppose the degree of f is less than k , and suppose, without loss of generality that $f = X_A$ for some $A \subseteq V^2$. Then, there is a PC_k derivation of $X_{A \cup \{(r,s)\}}$ for any $r, s \in V$. By checking case by case, it follows that there is a PC_k derivation of $(X_{A \cup \{(r,s)\}})^\pi$. Since $(A^\pi)^\pi = A$ and hence, $(f^\pi)^\pi = f$, there is a PC_k derivation of f if, and only if, there is a PC_k derivation of f^π . In particular, since there is no PC_k derivation of $X_{\{(v_i, w_i) \mid i \in [k]\}}$, there is no derivation of $(X_{\{(u_i, v_i) \mid i \in [k]\}})^\pi = X_{\{(u_i, w_i) \mid i \in [k]\}}$. Whence, $\vec{u} \equiv_{\text{PC}_k}^c \vec{w}$. ◀

It is easy to see that the relation $\equiv_{\text{PC}_k}^c$ refines $\equiv_{\text{MC}_k}^c$ which, in turn, refines $\equiv_{\text{NC}_k}^c$, since a NC_k refutation is a MC_k refutation which is also a PC_k refutation. More precisely:

► **Lemma 12.** For any graph on V and $\vec{u}, \vec{v} \in V^k$, $\vec{u} \equiv_{\text{PC}_k}^c \vec{v} \implies \vec{u} \equiv_{\text{MC}_k}^c \vec{v} \implies \vec{u} \equiv_{\text{NC}_k}^c \vec{v}$.

For $c = 0$, Grohe et al. have characterized these relations in terms of counting logics:

Let Γ be a graph on V and $\vec{u}, \vec{v} \in V^k$. Then $\vec{u} \equiv_{\text{MC}_k}^0 \vec{v}$ if, and only if, no \mathcal{C}_k formula distinguishes $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{u})$ from $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v})$ (Theorem 4.4 in [4]). Furthermore, if $\vec{u} \not\equiv_{\text{PC}_k}^0 \vec{v}$, there a $k' = O(k)$, such that some $\mathcal{C}_{k'}$ formula distinguishes $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{u})$ from $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v})$ (Theorem 6.6 in [17]).

Our main results attempt to give a similar characterization for $c > 0$ in terms of logics with solvability quantifiers.

4 Definability of monomial calculus refutations over finite fields

At the core of the proof of Theorem 1 is the definability of monomial calculus refutations in $\text{FPS}(p)$. More precisely, the main objective of this section is to prove the following statement (we will explain what we mean by structural encoding in Section 4.1).

► **Lemma 13.** *Let \mathfrak{A} be a structural encoding of a finite set of polynomials P of degree at most d , over a finite field \mathbb{F} of positive characteristic p . For any $k \in \mathbb{N}$ there is a $\text{FPS}(p)$ formula $\phi_{d,k}$ such that $\mathfrak{A} \models \phi_{d,k}$ if, and only if, there is an MC_k refutation of P over \mathbb{F} .³*

For the sake of argument, we assume that $\mathbb{F} = \mathbb{Z}_p$. We first recall how to express the solvability of linear equations with coefficients other than 0 and 1.

4.1 Defining solvability of linear equations over finite fields

For each prime number p , let LIN_p be a relational vocabulary with the following symbols:

1. A binary relational symbol \mathbf{A}_q for each $q \in \mathbb{Z}_p$.
2. A unary relational symbol \mathbf{b}_q for each $q \in \mathbb{Z}_p$.

Let $A \in \text{Mat}_{E \times V}(\mathbb{Z}_p)$ and $\vec{b} \in \mathbb{Z}_p^E$. A LIN_p -structure \mathfrak{A} with universe $V \cup E$ (V for variables and E for equations) is a structural encoding of the system of linear equations $A\vec{x} = \vec{b}$ if, for all $e \in E, v \in V$, $\mathfrak{A} \models \mathbf{A}_q(e, v)$ if $A_{ev} = q$ and $\mathfrak{A} \models \mathbf{b}_q(e)$ if $b_e = q$.

Recall Lemma 4.1 in [11].

► **Lemma 14.** *There is a quantifier free interpretation \mathcal{I} of LIN_p into LIN_p such that if \mathfrak{A} encodes the system of linear equations $A\vec{x} = \vec{b}$, then:*

1. $\mathcal{I}(\mathfrak{A})$ encodes a system of linear equations $A'\vec{y} = \mathbf{1}$, where $\mathbf{1}$ is the all 1s vector of appropriate length and A' is a 01-matrix.
2. $A'\vec{y} = \mathbf{1}$ has a solution if, and only if, $A\vec{x} = \vec{b}$ has a solution.

Thus, $\mathcal{I}(\mathfrak{A}) \models \text{slv}_p(xy.\mathbf{A}_1(x, y))$ if, and only if, $A\vec{x} = \vec{b}$ has a solution and hence, there is a $\text{FOS}(p)$ formula Φ such that $\mathfrak{A} \models \Phi$ if, and only if, the system encoded by \mathfrak{A} has a solution.

4.2 Idea of proof of Lemma 13

Deciding whether a set of axioms has a monomial calculus refutations of a given degree can be understood as the following procedure. The input is a finite set of multilinear polynomials P from the ring $\mathbb{F}[x_1, \dots, x_r]$, and the output is **REFUTE** or **NOREFUTE**. We denote the multilinear monomial $x_{a_1}x_{a_2} \dots x_{a_r}$ by X_A where $A = \{a_1, a_2, \dots, a_r\}$, so that for a polynomial f , $X_A f = x_{a_1}x_{a_2} \dots x_{a_r} f$. In this form, X_\emptyset denotes 1.

INPUT: $P \subset \mathbb{F}[x_1, \dots, x_r]$

OUTPUT: **REFUTE** or **NOREFUTE**.

Initialize $\mathcal{S} = \{X_A f \mid f \in P, \deg(X_A f) \leq k\}$.

while $\text{span}_{\mathbb{F}} \mathcal{S}$ has changed since last round or $1 \notin \text{span}_{\mathbb{F}} \mathcal{S}$ **do**

$\mathcal{M} \leftarrow \{A \subseteq [r] \mid |A| < k, X_A \in \text{span}_{\mathbb{F}} \mathcal{S}\}$.

$\mathcal{S} \leftarrow \mathcal{S} \cup \{X_B \mid |B| \leq k, \exists A \in \mathcal{M}, A \subseteq B\}$.

end while

if $1 \in \text{span}_{\mathbb{F}} \mathcal{S}$ **then**

OUTPUT **REFUTE**

else output **NOREFUTE**.

end if

³ Note that it is possible to derive a similar result independent of the parameter d . Since $d = 2$ for axioms of the form $\text{Ax}(\Gamma)$, the statement of Lemma 13 suffices for our purpose.

Note that to verify the condition of the **while** loop, one need not store in memory the set $\text{span}_{\mathbb{F}}\mathcal{S}$ (whose size is exponential in the input); this can be done by checking the solvability of linear equations. The number of iterations of the **while** loop is at most the number of multilinear monomials of degree at most k , thus ensuring that the procedure runs in polynomial time. Crucially, at each iteration of the **while** loop, the \mathbb{F} -span of \mathcal{S} has a *canonical* generating set.

Recall that we are assuming that $\mathbb{F} = \mathbb{Z}_p$. By viewing polynomials over \mathbb{Z}_p as vectors in the standard basis given by monomials, we encode P as a structure \mathfrak{A} with universe V over the vocabulary $\text{POLY}_p = (\text{Var}, \text{U}, \text{C}_0, \text{C}_1, \dots, \text{C}_{p-1})$, where:

1. $V = P \cup \{x_i \mid i \in [r]\} \cup \{1\}$.
2. Var and U are unary relational symbol with $\mathfrak{A} \models \text{Var}(v)$ if, and only if, $v \in \{x_i \mid i \in [r]\}$, and $\mathfrak{A} \models \text{U}(v)$ if, and only if, $v = 1$.
3. C_q for $q \in \mathbb{Z}_p$ are $(d+1)$ -ary relations, where d is the maximal degree of the polynomials in P . These encode P in matrix form; that is, $\mathfrak{A} \models \text{C}_q(u, v_1, \dots, v_d)$ if, and only if, $u \in P$, each v_i is equal to a variable or 1, and the coefficient of the monomial $v_1 v_2 \dots v_d$ in u is equal to q .

We now use a k -ary interpretation to obtain a structure whose universe is the set of multilinear polynomials of degree at most k . Formally, let $\text{POLY}_p^* = (\mathbf{A}_0, \mathbf{A}_1, \dots, \mathbf{A}_{p-1}, \text{U}^*, \text{Mon}, \text{Sub})$ be a vocabulary where Mon and U^* are unary relational symbols, Sub is a binary relational symbol, and \mathbf{A}_q are as in the vocabulary LIN_p . One can then define an interpretation \mathcal{J} from POLY_p into POLY_p^* such that:

1. The universe of $\mathcal{J}(\mathfrak{A})$ are elements $\vec{v} \in V^k$ where either all v_i are equal to 1, all v_i are variables, or v_1 is a polynomial in P and v_2, \dots, v_k are either all equal to 1 or are variables such that $|\{v_i \mid 2 \leq i \leq k\}| \leq k - \deg(v_1)$. The relation $\equiv_{\mathcal{J}}$ partitions the universe into equivalence classes uniquely determined by the set of entries of each tuple. If the entries of \vec{v} are all equal to 1, we indicate its class by X_{\emptyset} , and similarly, if $v_i = x_{a_i}$ for all $i \in [k]$, we indicate its class by X_A where $A = \{a_i \mid i \in [k]\}$. If $v_1 = f$ for some $f \in P$ and v_2, \dots, v_k are all equal to 1, we indicate the class of \vec{v} by f and if $v_i = a_i$ for $2 \leq i \leq k$, we indicate its class by the pair (X_A, f) where $A = \{a_i \mid 2 \leq i \leq k\}$. We leave it to the reader to check that such an equivalence relation can be defined with first-order formulae.
2. $\mathfrak{A} \models \text{U}(\vec{v})$ and $\mathfrak{A} \models \text{Mon}(\vec{v})$ if, and only if, the equivalence class of \vec{v} is X_{\emptyset} and X_A with $|A| \geq 1$ respectively.
3. $\mathfrak{A} \models \mathbf{A}_q(\vec{u}, \vec{v})$ if, and only if, the equivalence class of \vec{u} and \vec{v} are X_A and (X_B, f) for some $f \in P$ respectively, and the coefficient of X_A in $X_B f$ equals q .
4. $\mathfrak{A} \models \text{Sub}(\vec{u}, \vec{v})$ if, and only if, the equivalence classes of \vec{u} and \vec{v} are X_A and X_B respectively and $A \subseteq B$.

The last thing required for proving Lemma 13 is showing the definability of monomials in the set \mathcal{S} after each iteration of the **while** loop. In what follows, set $\mathcal{T} = \{X_A f \mid f \in P, A \subseteq [r], \deg(X_A f) \leq k\}$.

Proof of Lemma 13. Let $\psi(z)$ be some FPS(p) formula over the vocabulary POLY_p^* . There is an interpretation $\mathcal{K}(t)$ of POLY_p^* into LIN_p such that $\mathcal{K}(\mathcal{J}(\mathfrak{A}), t \mapsto X_A)$ encodes the system of linear equations determining whether X_A is in the \mathbb{Z}_p -span of the set

$$\mathcal{T}_{\psi} = \mathcal{T} \cup \{X_B \mid (\mathfrak{A}, z \mapsto X_B) \models \psi(z) \wedge \text{Mon}(z)\}.$$

By Lemma 14, there is a FPS(p) formula $\theta_{\psi}(z)$, depending on ψ , such that $(\mathcal{J}(\mathfrak{A}), z \mapsto X_A) \models \theta_{\psi}(z)$ if, and only if, the monomial X_A is in the \mathbb{Z}_p -span of \mathcal{T}_{ψ} .

37:12 On the Relative Power of Linear Algebraic Approximations of Graph Isomorphism

In particular, replacing ψ with some unary relational variable Z ,

$$(\mathcal{J}(\mathfrak{A}), z \mapsto X_A) \models \exists y. \theta_Z(y) \wedge \text{Sub}(y, z)$$

holds if, and only if, there is some $B \subseteq A$ such that X_B is in the \mathbb{Z}_p -span of \mathcal{T}_Z . Whence,

$$(\mathcal{J}(\mathfrak{A}), z' \mapsto X_\emptyset) \models \text{if}_{\mathbb{Z}_p, z}(\exists y. \theta_Z(y) \wedge \text{Sub}(y, z))(z') \quad (2)$$

if, and only if, there is an MC_k refutation of P over \mathbb{Z}_p . By applying the Interpretation Lemma to the above formula and the interpretation \mathcal{J} , the desired result follows. \blacktriangleleft

Note that in formula 2, the solvability quantifier is included in the formula $\theta_Z(y)$.

► **Corollary 15.** *For any $k \in \mathbb{N}$, there is some k' such that for any graph Γ on V and $\vec{u}, \vec{v} \in V^k$, if there is a MC_k refutation of $\text{Ax}(\Gamma_{\vec{u} \rightarrow \vec{v}})$ over \mathbb{Z}_p , then there is some $\text{FOS}_{k'}(p)$ formula $\phi(\vec{z})$ distinguishing $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{u})$ from $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v})$.*

Proof. By Lemma 13 the equivalence classes of $\equiv_{\text{MC}_k}^p$ are definable in $\text{FPS}(p)$ and hence, by the embedding of $\text{FPS}(p)$ in infinitary $\text{FOS}(p)$, the statement follows. \blacktriangleleft

Combining the latter with Theorem 10 and Lemma 7, one deduces Theorem 1.

5 Nullstellensatz refutations and S_k^p -stability

The focus of this section is the proof of the following statement.

► **Lemma 16.** *Let Γ be a graph on V and let $\gamma \in \mathcal{P}(V^k)$. If for all $\vec{u}, \vec{v} \in V^k$, $\gamma(\vec{u}) = \gamma(\vec{v})$ if, and only if, $\vec{u} \equiv_{\text{NC}_k}^p \vec{v}$, then γ is S_k^p -stable.*

Theorems 2 and 3 are its direct consequences.

5.1 Proof of Lemma 16

In what follows, $\gamma \in \mathcal{P}(V^k)$ satisfies the assumptions of Lemma 16, $\vec{u}, \vec{v} \in V^k$ and $\vec{\chi}$ and $\vec{\xi}$ are the (\vec{i}, \vec{u}) and (\vec{i}, \vec{v}) -character vectors of γ respectively, where we may assume without loss of generality that $\vec{i} = (k, k-1, \dots, k-2r+1) \in [k]^{(2r)}$, for some r with $2r \leq k$. For $\vec{w}, \vec{z} \in V^l$, denote by $X_{\vec{w}\vec{z}}$ the monomial $x_{w_1 z_1} x_{w_2 z_2} \dots x_{w_l z_l}$ (which need not be multilinear).

Recall that γ is $S_{k,r}^p$ -stable, if, and only if, for every \vec{u}, \vec{v} there is some matrix $T \in \mathfrak{P}_{V^r}(\mathbb{Z}_p)$ such that $\chi_\sigma T = T \xi_\sigma$, for all $\sigma \in \text{Im}(\gamma)$. That is, the following system of equations is solvable in the variables $T_{\vec{w}\vec{z}}$:

$$\sum_{\vec{a} \in V^r} (\chi_\sigma)_{\vec{w}\vec{a}} T_{\vec{a}\vec{z}} - \sum_{\vec{a} \in V^r} T_{\vec{w}\vec{a}} (\xi_\sigma)_{\vec{a}\vec{z}} = 0 \quad \text{for } \sigma \in \text{Im}(\gamma), \vec{w}, \vec{z} \in V^r$$

$$\sum_{\vec{a} \in V^r} T_{\vec{w}\vec{a}} - 1 = 0 \quad \text{and} \quad \sum_{\vec{a} \in V^r} T_{\vec{a}\vec{z}} - 1 = 0 \quad \text{for } \vec{w}, \vec{z} \in V^r,$$

where $(\chi_\sigma)_{\vec{w}\vec{a}}$ is equal to 1 if $\gamma(\vec{u} \langle \vec{i}, \vec{w} \cdot \vec{a} \rangle) = \sigma$ and 0 otherwise (similarly for ξ_σ).

We show that there is a NC_k derivation from $\text{Ax}(\Gamma_{\vec{v} \rightarrow \vec{u}})$ over \mathbb{Z}_p of the following multilinear polynomials (Lemma 19):

$$\sum_{\vec{a} | \gamma(\vec{u}(\vec{i}, \vec{w} \cdot \vec{a})) = \sigma} X_{\vec{a}\vec{z}} - \sum_{\vec{a} | \gamma(\vec{v}(\vec{i}, \vec{a} \cdot \vec{z})) = \sigma} X_{\vec{w}\vec{a}} \text{ for } \sigma \in \text{Im}(\gamma), \vec{w}, \vec{z} \in V^r \quad (3)$$

$$\sum_{\vec{a} \in V^r} X_{\vec{w}\vec{a}} - 1 \text{ and } \sum_{\vec{a} \in V^r} X_{\vec{a}\vec{z}} - 1 \text{ for } \vec{w}, \vec{z} \in V^r. \quad (4)$$

We may view each monomial (apart from the constant term) as a distinct linear variable, so that all of the above are linear polynomials. Since $\gamma(\vec{u}) = \gamma(\vec{v})$, there is no NC_k refutation of $\text{Ax}(\Gamma_{\vec{v} \rightarrow \vec{u}})$ and hence, no linear combination of 3 and 4 gives the constant polynomial 1. It follows that if viewed as linear polynomials, 3 and 4 have a common root, thus showing Lemma 16.

► **Lemma 17.** *If $\gamma(\vec{u}(\vec{i}, \vec{w} \cdot \vec{z})) \neq \gamma(\vec{v}(\vec{i}, \vec{w}' \cdot \vec{z}'))$, then there is a NC_k derivation over \mathbb{Z}_p from $\text{Ax}(\Gamma_{\vec{v} \rightarrow \vec{u}})$ of $X_{\vec{w}\vec{w}'} X_{\vec{z}\vec{z}'}$.*

Proof. Set $Y = X_{\vec{w}\vec{w}'} X_{\vec{z}\vec{z}'}$ and let $X_{\vec{u}'\vec{v}'}$ be the degree $k - 2r$ monomial where $u'_j = u_j$ and $v'_j = v_j$ for $j \in [k - 2r]$. Then, there is a NC_k derivation of $Y(X_{\vec{u}'\vec{v}'} - 1)$, for indeed

$$Y(X_{\vec{u}'\vec{v}'} - 1) = Y(x_{u_1 v_1} - 1) + Y x_{u_1 v_1} (x_{u_2 v_2} - 1) + \dots + Y (x_{u_1 v_1} \dots x_{u_{k-2r-1} v_{k-2r-1}}) (x_{u_{k-2r} v_{k-2r}} - 1).$$

By assumption, $\gamma(\vec{u}(\vec{i}, \vec{w} \cdot \vec{z})) \neq \gamma(\vec{v}(\vec{i}, \vec{w}' \cdot \vec{z}'))$ and hence, there is an NC_k derivation of $Y X_{\vec{u}'\vec{v}'}$. Subtracting the latter from $Y(X_{\vec{u}'\vec{v}'} - 1)$ yields the desired statement. ◀

► **Lemma 18.** *For any $\vec{w}, \vec{z} \in V^r$ and $\vec{s} \in V^t$ there is a NC_{t+r} derivation over \mathbb{Z}_p from $\text{Ax}(\Gamma_{\vec{v} \rightarrow \vec{u}})$ of*

$$X_{\vec{w}\vec{z}} \left(\sum_{\vec{a} \in V^t} X_{\vec{s}\vec{a}} - 1 \right) \text{ and } X_{\vec{w}\vec{z}} \left(\sum_{\vec{a} \in V^t} X_{\vec{a}\vec{s}} - 1 \right).$$

Proof. We proceed by induction on t . For $t = 1$, $X_{\vec{w}\vec{z}}(\sum_{a \in V} x_{sa} - 1)$ is the product of a monomial and an axiom, so has a NC_{r+1} derivation.

Assume $X_{\vec{w}\vec{z}}(\sum_{\vec{a} \in V^t} X_{\vec{s}\vec{a}} - 1)$ has a NC_{t+r} derivation. It can be easily verified that if a polynomial f has a NC_r derivation from some set of axioms, then xf has a NC_{r+1} derivation for any variable x . Thus, $x_{s'a'} X_{\vec{w}\vec{z}}(\sum_{\vec{a} \in V^t} X_{\vec{s}\vec{a}} - 1)$ has a NC_{t+r+1} derivation. Finally

$$\sum_{a' \in V} x_{s'a'} X_{\vec{w}\vec{z}} \left(\sum_{\vec{a} \in V^t} X_{\vec{s}\vec{a}} - 1 \right) = X_{\vec{w}\vec{z}} \left(\sum_{\vec{a} \in V^t, a' \in V} X_{(\vec{s}, s')(\vec{a}, a')} - 1 \right) = X_{\vec{w}\vec{z}} \left(\sum_{\vec{a} \in V^{t+1}} X_{(\vec{s}, s')\vec{a}} - 1 \right)$$

as required. ◀

► **Lemma 19.** *There is a NC_k derivation over \mathbb{Z}_p from $\text{Ax}(\Gamma_{\vec{v} \rightarrow \vec{u}})$ of the polynomials in formulae (3) and (4).*

Proof. For $\vec{a} \in V^r$, set $\mathcal{N}(\vec{u}, \vec{w}) = \{\vec{a} \in V^r \mid \gamma(\vec{u}(\vec{i}, \vec{w} \cdot \vec{a})) = \sigma\}$ and $\mathcal{N}(\vec{v}, \vec{z}) = \{\vec{a} \in V^r \mid \gamma(\vec{v}(\vec{i}, \vec{a} \cdot \vec{z})) = \sigma\}$ (note the slight asymmetry). By Lemma 18, there is a NC_{2r} (and hence, NC_k , since $2r \leq k$) derivation of $X_{\vec{a}\vec{z}}(\sum_{\vec{a}' \in V^r} X_{\vec{s}\vec{a}'} - 1)$ for every $\vec{a}, \vec{s}, \vec{z} \in V^r$. By subtracting from the above all monomials $X_{\vec{a}\vec{z}} X_{\vec{s}\vec{a}'}$ for which $\vec{a}' \notin \mathcal{N}(\vec{v}, \vec{z})$ (which have a NC_k derivation by Lemma 17) one gets $X_{\vec{a}\vec{z}}(\sum_{\vec{a}' \in \mathcal{N}(\vec{v}, \vec{z})} X_{\vec{s}\vec{a}'} - 1)$. Adding these for all $\vec{a} \in \mathcal{N}(\vec{u}, \vec{w})$ yields

$$\sum_{\vec{a} \in \mathcal{N}(\vec{u}, \vec{w})} X_{\vec{a}\vec{z}} \left(\sum_{\vec{a}' \in \mathcal{N}(\vec{v}, \vec{z})} X_{\vec{s}\vec{a}'} - 1 \right). \quad (5)$$

A similar argument shows that there is a NC_k derivation of

$$\sum_{\vec{a} \in \mathcal{N}(\vec{v}, \vec{z})} X_{\vec{w}\vec{a}} \left(\sum_{\vec{a}' \in \mathcal{N}(\vec{u}, \vec{w})} X_{\vec{a}'\vec{s}} - 1 \right). \quad (6)$$

Subtracting (5) from (6) yields (3).

The polynomials in (4) can be derived by setting $r = 0$ in Lemma 18. \blacktriangleleft

5.2 Generalized Cai-Fürer-Immerman constructions

In 1992, Cai, Fürer and Immerman provided, for $k \geq 1$, a family of pairs of non-isomorphic graphs $(\mathcal{G}_k, \mathcal{H}_k)$ which cannot be distinguished by \mathcal{C}_k -formulae. These graphs really encode a system of linear equations over \mathbb{Z}_2 , the solvability of which can be decided in polynomial time. These structures can be generalized to encode a systems of linear equations over an arbitrary finite field. Loosely speaking, the *generalized Cai-Fürer-Immerman* construction for the field \mathbb{Z}_p provides, for each $k \in \mathbb{N}$, p non-isomorphic 3-regular graphs $\mathcal{G}_k^{(1)}, \dots, \mathcal{G}_k^{(p)}$. These delimit the power of well known linear algebra based polynomial-time approximations of graph isomorphism. Let $\Gamma_{k,p}$ be the disjoint union of the graphs $\mathcal{G}_k^{(1)}, \dots, \mathcal{G}_k^{(p)}$ and let V denote its vertex set.

► **Theorem 20** (Theorems 8.1 and 8.2 in [10]). *If $\Gamma = \Gamma_{k,p}$ and $q \neq p$, then the equivalence classes of $[\alpha_{k,\Gamma}]^{\text{IM}_k^q}$ do not coincide with those of the k -orbit partition for Γ . If $q = p$, the equivalence classes of $[\alpha_{3,\Gamma}]^{\text{IM}_3^q}$ coincide with those of the 3-orbit partition for Γ .*

Originally, the generalized Cai-Fürer-Immerman constructions were introduced to delimit the expressive power of the extension of fixed point logics with rank operators over a finite field $\text{FPR}(p)$ and, correspondingly, the distinguishing power of the extension of first order logic by said operators, $\text{FOR}(p)$ (see Chapter 7 of [18]). The distinguishing power of the invertible map test in characteristic p is at least that of $\text{FOR}(p)$, so in one direction Theorem 20 provides a lower bound for this logic. In the other direction, we can show that the orbit partition on $\Gamma_{k,p}$ can already be defined in $\text{FPR}(p)$. Indeed, it can be defined in the apparently weaker logic $\text{FPS}(p)$, giving the following result, of which Theorem 3 is a direct consequence.

► **Theorem 21.** *Let $\Gamma = \Gamma_{k,p}$. If $p \neq q$, there exist $\vec{u}, \vec{v} \in V^k$ in different equivalence classes of the k -orbit partition of Γ , such that there are no $\text{FOS}_k(q)$ -formulae distinguishing $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{u})$ from $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v})$. If $q = p$ and $\vec{u}, \vec{v} \in V^2$, then $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{u})$ is distinguished from $(\mathfrak{A}_\Gamma, \vec{z} \mapsto \vec{v})$ by some $\text{FOS}_2(q)$ -formula if, and only if, \vec{u}, \vec{v} are in different equivalence classes of the 2-orbit partition of Γ .*

6 Conclusions: where does polynomial calculus lie?

The invertible map tests can be thought of a family of algorithms, each of which distinguishes tuples of vertices of graphs according to the most general linear algebraic invariants expressible with a bounded number of variables in a logic. As bounded degree PC, MC and NC refutations can be decided solely by using basic field operations, one expects that the equivalences defined by the invertible map tests simulate those defined by the above mentioned proof systems. Theorem 1 gives a partial proof of this conjecture, leaving it open as to whether the invertible map tests can simulate bounded degree PC refutations, when taken over some finite field.

Our approach to this question was to attempt to define the above proof systems in the simplest logics which could express the solvability of systems of linear equations. The proof of Lemma 13 hints at the flaws of this choice. Deciding whether or not there is a PC_k refutation of $P \subseteq \mathbb{F}[x_1, \dots, x_r]$ can be understood as the following procedure, similar to that in Section 4.2.

INPUT: $P \subset \mathbb{F}[x_1, \dots, x_r]$
 OUTPUT: REFUTE or NOREFUTE.
 Initialize $\mathcal{S} = \{X_A f \mid f \in P, \deg(X_A f) \leq k\}$.
while $\text{span}_{\mathbb{F}}\mathcal{S}$ has changed since last round or $1 \notin \text{span}_{\mathbb{F}}\mathcal{S}$ **do**
 Find a set \mathcal{B} generating the \mathbb{F} -space $\{f \in \text{span}_{\mathbb{F}}\mathcal{S} \mid \deg(f) < k\}$.
 $\mathcal{S} \leftarrow \mathcal{S} \cup \{X_A f \mid f \in \mathcal{B}, \deg(X_A f) \leq k\}$.
end while
if $1 \in \text{span}_{\mathbb{F}}\mathcal{S}$ **output** REFUTE. **then**
else **output** NOREFUTE
end if

This procedure runs in polynomial time, as one can find \mathcal{B} by using Gaussian elimination (there is no need to store the set $\text{span}_{\mathbb{F}}\mathcal{S}$ as a generating set suffices), and the number of iterations of the **while** loop is bounded by the number of monomials of degree at most k in the variables $\{x_1, \dots, x_r\}$. If \mathbb{F} is finite, this procedure is a priori *not* definable in FPS(p), as it is not immediate whether there is a canonical choice for the set \mathcal{B} (its counterpart in the procedure for monomial calculus refutations was the set \mathcal{M} of monomials in the span of \mathcal{S}). Put otherwise, defining the set \mathcal{B} requires defining the solution space of a system of linear equations over a field of positive characteristic p , rather than just determining the solvability of the system and it is not clear if this can be done in FPS(p). The FPC definability of bounded degree polynomial calculus over the field \mathbb{Q} (Theorem 4.9 in [17]) relies in fact on the FPC definability of solution spaces of linear equations over \mathbb{Q} (Theorem 4.11 in [17]).

Let us view the problem from the viewpoint of proof complexity. It follows from Lemma 16, that if PC_k refutations over \mathbb{Z}_p are definable in FPS(p), then for every k , there is some k' such that if $\text{Ax}(\Gamma_{\vec{u} \rightarrow \vec{v}})$ has a PC_k refutation over \mathbb{Z}_p , then it has a $\text{NC}_{k'}$ refutation over \mathbb{Z}_p . It is known that for all n and for any field, there is a set of axioms on $n(n+1)$ variables which can be refuted by PC_3 but require degree $\Omega(n)$ to be refuted by NC (Theorem 6 in [5]). Furthermore, this lower bound can be shown to be optimal. On the other hand, Buss et al. have shown that NC derivations can be used to simulate *tree-like* PC derivations (see Theorems 5.3 and 5.4 in [6]) with only a small increase in degree. For a set of axioms of the form $\text{Ax}(\Gamma_{\vec{u} \rightarrow \vec{v}})$, it is not known if any PC_k refutation of such can be converted into a tree-like refutation without incurring in an unbounded increase in degree.

Abstract

The computational complexity of the MAXCUT problem restricted to interval graphs has been open since the 80's, being one of the problems proposed by Johnson on his *Ongoing Guide to NP-completeness*, and has been settled as NP-complete only recently by Adhikary, Bose, Mukherjee and Roy. On the other hand, many flawed proofs of polynomiality for MAXCUT on the more restrictive class of unit/proper interval graphs (or graphs with interval count 1) have been presented along the years, and the classification of the problem is still not known. In this paper, we present the first NP-completeness proof for MAXCUT when restricted to interval graphs with bounded interval count, namely graphs with interval count 4.

1 Introduction

A *cut* is a partition of the vertex set of a graph into two disjoint parts and the *maximum cut problem* (denoted MAXCUT for short) aims to determine a cut with the maximum number of edges for which each endpoint is in a distinct part. The decision problem MAXCUT is known to be NP-complete since the seventies [15], and only recently its restriction to interval graphs has been announced to be hard [1], settling a long-standing open problem that appeared in the 1985 column of the *Ongoing Guide to NP-completeness* by David S. Johnson [17]. We refer the reader to a revised version of the table in [12], where one can also find a parameterized complexity version of said table.

An *interval model* is a family of closed intervals of the real line. A graph is an *interval graph* if there exists an interval model, for which each interval corresponds to a vertex of the graph, such that distinct vertices are adjacent in the graph if and only if the corresponding intervals intersect. Ronald L. Graham proposed in the 80's the study of the *interval count* of an interval graph as the smallest number of interval lengths used by an interval model of the graph. Interval graphs having interval count 1 are called *unit intervals* (can also be called proper interval, or indifference). Understanding the interval count, besides being an interesting and challenging problem by itself, can be also of value for the investigation of problems that are hard for general interval graphs, and easy for unit interval graphs (e.g. geodetic number [8,13], optimal linear arrangement [9,16], sum coloring [20,21]). The positive results for unit interval graphs usually take advantage of the fact that a representation for these graphs can be found in linear time [10,11]. Surprisingly, the recognition of interval graphs with interval count k is open, even for $k = 2$ [7]. Nevertheless, another generalization of unit interval graphs has been recently introduced which might be more promising in this aspect. These graphs are called *k-nested interval graphs*, introduced in [18], where the authors, among other things, give a linear time recognition algorithm.

In the same way that MAXCUT on interval graphs has evaded being solved for so long, the community has been puzzled by the restriction to unit interval graphs. Indeed, two attempts at solving it in polynomial time were proposed in [4,6] just to be disproved closely after [3,19]. In this paper, we give the first classification that bounds the interval count, namely, we prove that MAXCUT is NP-complete when restricted to interval graphs of interval count 4. This also implies NP-completeness for the newly generalized class of 4-nested graphs, and opens the search for a full polynomial/NP-complete dichotomy classification in terms of the interval count. It can still happen that the problem is hard even on graphs of interval count 1. We contribute towards filling the complexity gap between interval and unit interval graphs.

Next, we establish basic definitions and notation. Section 2 describes our reduction and Section 3 discusses the interval count of the interval graph constructed in [1].

1.1 Preliminaries

In this work, all graphs considered are simple. For missing definitions and notation of graph theory, we refer to [5]. For a comprehensive study of interval graphs, we refer to [14].

Let G be a graph. Let X and Y be two disjoint subsets of $V(G)$. We let $E_G(X, Y)$ be the set of edges of G with an endpoint in X and the other endpoint in Y . For every subset $S \subseteq V(G)$, we let $S^X = S \cap X$ and $S^Y = S \cap Y$. A *cut* of G is a partition of $V(G)$ into two parts $A, B \subseteq V(G)$, denoted by $[A, B]$; the edge set $E_G(A, B)$ is called the *cut-set* of G associated with $[A, B]$. For each two vertices $u, v \in V(G)$, we say that u and v are in a *same part* of $[A, B]$ if either $\{u, v\} \subseteq A$ or $\{u, v\} \subseteq B$; otherwise, we say that u and v are in *opposite parts* of $[A, B]$. Denote by $\text{mc}(G)$ the maximum size of a cut-set of G . The MAXCUT problem has as input a graph G and a positive integer k , and it asks whether $\text{mc}(G) \geq k$.

Let $I \subseteq \mathbb{R}$ be a closed interval of the real line. We let $\ell(I)$ and $r(I)$ denote respectively the minimum and maximum points of I , which we call the *left* and the *right endpoints* of I , respectively. We denote a closed interval I by $[\ell(I), r(I)]$. The *length* of an interval I is defined as $|I| = r(I) - \ell(I)$. An *interval model* is a finite multiset \mathcal{M} of intervals. The *interval count* of an interval model \mathcal{M} , denoted by $\text{ic}(\mathcal{M})$, is defined as the number of distinct lengths of the intervals in \mathcal{M} . Let G be a graph and \mathcal{M} be an interval model. An \mathcal{M} -*representation* of G is a bijection $\phi: V(G) \rightarrow \mathcal{M}$ such that, for every two distinct vertices $u, v \in V(G)$, we have that $uv \in E(G)$ if and only if $\phi(u) \cap \phi(v) \neq \emptyset$. If such an \mathcal{M} -representation exists, we

say that \mathcal{M} is an *interval model* of G . We note that a graph may have either no interval model or arbitrarily many distinct interval models. A graph is called an *interval graph* if it has an interval model. The *interval count* of an interval graph G , denoted by $\text{ic}(G)$, is defined as $\text{ic}(G) = \min\{\text{ic}(\mathcal{M}) : \mathcal{M} \text{ is an interval model of } G\}$. An interval graph is called a *unit interval graph* if its interval count is equal to 1.

Note that, for every interval model \mathcal{M} , there exists a unique (up to isomorphism) graph that admits an \mathcal{M} -representation. Thus, for every interval model $\mathcal{M} = \{I_1, \dots, I_n\}$, we let $\mathbb{G}_{\mathcal{M}}$ be the graph with vertex set $V(\mathbb{G}_{\mathcal{M}}) = \{1, \dots, n\}$ and edge set $E(\mathbb{G}_{\mathcal{M}}) = \{ij : I_i, I_j \in \mathcal{M}, I_i \cap I_j \neq \emptyset, i \neq j\}$. Since $\mathbb{G}_{\mathcal{M}}$ is uniquely determined (up to isomorphism) from \mathcal{M} , in what follows we may make an abuse of language and use graph terminologies to describe properties related to the intervals in \mathcal{M} . Two intervals $I_i, I_j \in \mathcal{M}$ are said to be *true twins* in $\mathbb{G}_{\mathcal{M}}$ if they have the same close neighborhood in $\mathbb{G}_{\mathcal{M}}$, i.e. $N_{\mathbb{G}_{\mathcal{M}}}(I_i) \cup \{I_i\} = N_{\mathbb{G}_{\mathcal{M}}}(I_j) \cup \{I_j\}$.

For each three positive integers $a, b, c \in \mathbb{N}_+$, we write $a \equiv_b c$ to denote that a modulo b is equal to c modulo b .

2 Our reduction

The following theorem is the main contribution of this work:

► **Theorem 1.** *MAXCUT is NP-complete on interval graphs of interval count 4.*

This result is a stronger version of that of Adhikary et al. [1]. To prove Theorem 1, we present a polynomial-time reduction from MAXCUT on cubic graphs, which is known to be NP-complete [2]. In order to explain the technical effort needed to push the construction of Adhikary et al. enabling our construction of a reduction graph that uses only four different lengths of intervals, we present our construction in three sections. First, we explain how the key gadget of Adhikary et al. relates the number of intervals of each size to the part where they are placed in a maximum cut. Second, we present our new gadget that organizes copies of the original key gadget into an escalator grid, which constitutes our key gadget to obtain a reduction graph that admits a model with an interval count bounded by a constant. Third, an outline of the proof explains how our use of the base gadgetry due to Adhikary et al. through the escalator allows us to relate maximum cuts of the input graph to maximum cuts of the reduction graph.

2.1 Grained gadget

The interval graph constructed in the reduction of [1] is strongly based on two types of gadgets, called *V-gadgets* and *E-gadgets*. In fact, these gadgets are the same, except for the amount of intervals of certain kinds contained in each of them. In this subsection, we present a generalization of such gadgets, rewriting their key properties to suit our purposes. In order to discuss the interval count of the reduction of [1], we describe it in details in Section 3.

Let x and y be two positive integers. An (x, y) -*grained gadget* is an interval model \mathcal{H} formed by y long intervals (called *left long*) intersecting in their right endpoint with other y long intervals (called *right long*), together with $2x$ short intervals, x of which intersect exactly the y left long ones (called *left short*), and x of which intersect exactly the y right long ones (called *right short*); see Figure 1. We write $\mathcal{LS}(\mathcal{H})$, $\mathcal{LL}(\mathcal{H})$, $\mathcal{RS}(\mathcal{H})$ and $\mathcal{RL}(\mathcal{H})$ to denote the left short, left long, right short and right long intervals of \mathcal{H} , respectively, and we omit \mathcal{H} when it is clear from the context.

Note that, if \mathcal{H} is an (x, y) -grained gadget, then $\mathbb{G}_{\mathcal{H}}$ is a split graph such that $\mathcal{LS} \cup \mathcal{RS}$ is an independent set of size $2x$, $\mathcal{LL} \cup \mathcal{RL}$ is a clique of size $2y$, $N_{\mathbb{G}_{\mathcal{H}}}(\mathcal{LS}) = \mathcal{LL}$ and $N_{\mathbb{G}_{\mathcal{H}}}(\mathcal{RS}) = \mathcal{RL}$. Moreover, the intervals in \mathcal{LL} are true twins in $\mathbb{G}_{\mathcal{H}}$; similarly, the intervals in \mathcal{RL} are true twins in $\mathbb{G}_{\mathcal{H}}$.

■ **Figure 1** General structure of an (x, y) -grained gadget.

Let \mathcal{M} be an interval model containing an (x, y) -grained gadget \mathcal{H} . The possible types of intersections between an interval $I \in \mathcal{M} \setminus \mathcal{H}$ and \mathcal{H} in our construction are depicted in Figure 2, using our notation. More specifically, the *cover intersection* intersects all the intervals, the *weak intersection to the left (right)* intersects exactly the left (right) long intervals, while the *strong intersection to the left (right)* intersects exactly the left (right) long and short intervals. We say that \mathcal{M} *respects the structure* of \mathcal{H} if I either does not intersect \mathcal{H} at all, or intersects \mathcal{H} as depicted in Figure 2.

■ **Figure 2** (a) Interval $I \in \mathcal{M} \setminus \mathcal{H}$ covering \mathcal{H} , (b-c) weakly intersecting \mathcal{H} to the left and to the right, and (d-e) strongly intersecting \mathcal{H} to the left and to the right.

The advantage of this gadget is that, by manipulating the values of x and y , we can ensure that, in a maximum cut, the left long and right short intervals are placed in the same part, opposite to the part containing the left short and right long intervals. The next lemma is a step in this direction. Denote by $c_{\mathcal{M}}(\mathcal{H})$ the number of intervals of \mathcal{M} that cover \mathcal{H} ; by $wkl_{\mathcal{M}}(\mathcal{H})$ (resp. $wkr_{\mathcal{M}}(\mathcal{H})$) the number of intervals of \mathcal{M} that weakly intersect \mathcal{H} to the left (resp. right); and by $stl_{\mathcal{M}}(\mathcal{H})$ (resp. $str_{\mathcal{M}}(\mathcal{H})$) the number of intervals of \mathcal{M} that strongly intersect \mathcal{H} to the left (resp. right).

► **Lemma 2.** *Let x and y be positive integers, \mathcal{H} be an (x, y) -grained gadget and \mathcal{M} be an interval model that respects the structure of \mathcal{H} . For every maximum cut $[A, B]$ of $\mathbb{G}_{\mathcal{M}}$, the following conditions hold:*

1. *if $y + stl_{\mathcal{M}}(\mathcal{H}) + c_{\mathcal{M}}(\mathcal{H}) \equiv_2 1$ and $x > 2y - 1 + wkl_{\mathcal{M}}(\mathcal{H}) + stl_{\mathcal{M}}(\mathcal{H}) + c_{\mathcal{M}}(\mathcal{H})$, then $\mathcal{LS}(\mathcal{H}) \subseteq A$ and $\mathcal{LL}(\mathcal{H}) \subseteq B$, or vice versa;*
2. *if $y + str_{\mathcal{M}}(\mathcal{H}) + c_{\mathcal{M}}(\mathcal{H}) \equiv_2 1$ and $x > 2y - 1 + wkr_{\mathcal{M}}(\mathcal{H}) + str_{\mathcal{M}}(\mathcal{H}) + c_{\mathcal{M}}(\mathcal{H})$, then $\mathcal{RS}(\mathcal{H}) \subseteq A$ and $\mathcal{RL}(\mathcal{H}) \subseteq B$, or vice versa.*

Now, we want to add conditions that, together with the ones from the previous lemma, ensure that the left long intervals will be put opposite to the right long intervals. Based on Lemma 2, we say that $(\mathcal{H}, \mathcal{M})$ is *well-valued* if Conditions (1) and (2) hold, in addition to the following inequality

$$y^2 > y \cdot \text{wkr}_{\mathcal{M}}(\mathcal{H}) + (x - y) \cdot (\text{str}_{\mathcal{M}}(\mathcal{H}) + c_{\mathcal{M}}(\mathcal{H})). \quad (1)$$

Let $[A, B]$ be a maximum cut of $\mathbb{G}_{\mathcal{M}}$. We say that \mathcal{H} is *A-partitioned* by $[A, B]$ if $\mathcal{L}\mathcal{S}(\mathcal{H}) \cup \mathcal{R}\mathcal{L}(\mathcal{H}) \subseteq A$, and $\mathcal{R}\mathcal{S}(\mathcal{H}) \cup \mathcal{L}\mathcal{L}(\mathcal{H}) \subseteq B$. Define *B-partitioned* analogously. The next lemma finally ensures what we wanted.

► **Lemma 3.** *Let x and y be positive integers, \mathcal{H} be an (x, y) -grained gadget, \mathcal{M} be an interval model and $[A, B]$ be a maximum cut of $\mathbb{G}_{\mathcal{M}}$. If \mathcal{M} respects the structure of \mathcal{H} and $(\mathcal{H}, \mathcal{M})$ is well-valued, then \mathcal{H} is either A-partitioned or B-partitioned by $[A, B]$.*

We have rewritten above in a more technical form the lemmas presented in [1], so that we are able to explicitly give the conditions that ensure the key property of their gadgets.

2.2 Reduction graph

In this subsection, we formally present our construction. Recall that we are making a reduction from MAXCUT on cubic graphs. So, consider a cubic graph G on n vertices and m edges. Intuitively, we consider an ordering of the edges of G , and we divide the real line into m regions, with the j -th region holding the information about whether the j -th edge is in the cut-set. For this, each vertex u will be related to a subset of intervals traversing all the m regions, bringing the information about which part u belongs to. Let $\pi_V = (v_1, \dots, v_n)$ be an ordering of $V(G)$, $\pi_E = (e_1, \dots, e_m)$ be an ordering of $E(G)$, and $\mathfrak{G} = (G, \pi_V, \pi_E)$.

■ **Figure 3** General structure of a region of the (n, m) -escalator. The rectangles represent the (p, q) -grained gadgets \mathcal{H}_i^j .

We first describe the gadgets related to the vertices. Please refer to Figure 3 to follow the construction. The values of p, q used next will be defined later. An (n, m) -escalator is an interval model \mathcal{D} formed by $m + 1$ (p, q) -grained gadgets for each v_i , denoted by $\mathcal{H}_i^1, \dots, \mathcal{H}_i^{m+1}$, together with $2m$ link intervals, L_i^1, \dots, L_i^{2m} , such that L_i^{2j-1} and L_i^{2j} weakly intersect \mathcal{H}_i^j to the right and weakly intersect \mathcal{H}_i^{j+1} to the left. Additionally, all the grained gadgets are mutually disjoint, and given $j \in \{1, \dots, m + 1\}$ and $i, i' \in \{1, \dots, n\}$ with $i < i'$, the grained gadget \mathcal{H}_i^j occurs to the left of $\mathcal{H}_{i'}^j$.

Now, we add the gadgets related to the edges. Please refer to Figure 4 to follow the construction. The values of p', q' used next will be defined later. For each edge $e_j = v_i v_{i'} \in E(G)$, with $i < i'$, create a (p', q') -grained gadget \mathcal{E}_j and intervals $C_j^1, C_j^2, C_j^3, C_j^4$ in such a way that \mathcal{E}_j is entirely contained in the j -th region (i.e., in the open interval between

the right endpoint of \mathcal{H}_n^j and the left endpoint of \mathcal{H}_1^{j+1} , C_j^1 and C_j^2 weakly intersect \mathcal{H}_i^j to the right and weakly intersect \mathcal{E}_j to the left, and C_j^3 and C_j^4 weakly intersect $\mathcal{H}_{i'}^j$ to the right and strongly intersect \mathcal{E}_j to the left. Denote the constructed model by $\mathcal{M}(\mathfrak{G})$.

■ **Figure 4** General structure of the constructed interval model $\mathcal{M}(\mathfrak{G})$ highlighting the intersections between the intervals of the (n, m) -escalator \mathcal{D} , the intervals of the (p, q') -grained gadget \mathcal{E}_j , and the intervals $C_j^1, C_j^2, C_j^3, C_j^4$.

2.3 Outline of the proof

As above, consider a cubic graph G on n vertices and $m = \frac{3n}{2}$ edges, and let $\pi_V = (v_1, \dots, v_n)$ be an ordering of $V(G)$, $\pi_E = (e_1, \dots, e_m)$ be an ordering of $E(G)$ and $\mathfrak{G} = (G, \pi_V, \pi_E)$. We give an outline of the proof that $\text{mc}(G) \geq k$ if and only if $\text{mc}(\mathbb{G}_{\mathcal{M}(\mathfrak{G})}) \geq f(G, k)$, where f is defined at the end of the subsection. As it is usually the case in this kind of reduction, constructing an appropriate cut of the reduction graph $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$, given a cut of G , is an easy task. On the other hand, constructing an appropriate cut $[X, Y]$ of G , from a given a cut $[A, B]$ of the reduction graph $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$, requires that the intervals in $\mathcal{M}(\mathfrak{G})$ behave in a way with respect to $[A, B]$ so that $[X, Y]$ can be inferred, a task achieved with the help of Lemmas 2 and 3. In order to use these lemmas, we choose next suitable values for p, q, p', q' , and we observe that $\mathcal{M}(\mathfrak{G})$ respects the structure of the involved grained gadgets. After ensuring that each grained gadget behaves well individually, we also need to ensure that \mathcal{H}_i^1 can be used to decide in which part of $[X, Y]$ we should put v_i , and for this it is necessary that all gadgets related to v_i agree with one another. In other words, for each v_i , we want that the behaviour of the first gadget \mathcal{H}_i^1 influence the behaviour of the subsequent gadgets $\mathcal{H}_i^2, \dots, \mathcal{H}_i^{m+1}$, as well as the behaviour of the gadgets related to edges incident to v_i . This is done by choosing the following values for our floating variables:

$$q = 60n^3 + 1, \quad p = 2q + 7n, \quad q' = 18n^3 + 1 \quad \text{and} \quad p' = 2q' + 5n. \quad (2)$$

These values indeed satisfy Conditions (1) and (2) of Lemma 2, as well as Inequality (1). As previously said, the idea behind this choice of values is to store information about v_i in the gadgets $\mathcal{H}_i^1, \dots, \mathcal{H}_i^{m+1}$. Now, given $e_j = v_i v_{i'}$, $i < i'$, a final ingredient is to ensure that \mathcal{E}_j is influenced only by the intervals C_j^3 and C_j^4 , which in turn are influenced by the vertex $v_{i'}$, in a way that the number of edges in the cut-set of $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$ increases when the edge $v_i v_{i'}$ is in the cut-set of G . All these ideas are captured in the definitions below.

Given $v_i \in V(G)$ and a cut $[A, B]$ of $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$, we say that *the gadgets of v_i alternate in $[A, B]$* if, for every $j \in [m]$, we get that \mathcal{H}_i^j is A -partitioned if and only if \mathcal{H}_i^{j+1} is B -partitioned. Also, we say that $[A, B]$ is *alternating partitioned* if the gadgets of v_i alternate in $[A, B]$, for every $v_i \in V(G)$, and the following conditions hold for every $e_j = v_i v_{i'} \in E(G)$, with $i < i'$:

- (i) If \mathcal{H}_i^j is A -partitioned by $[A, B]$, then $\{C_j^1, C_j^2\} \subseteq B$; otherwise, $\{C_j^1, C_j^2\} \subseteq A$; and
- (ii) If $\mathcal{H}_{i'}^j$ is A -partitioned by $[A, B]$, then $\{C_j^3, C_j^4\} \subseteq B$ and \mathcal{E}_j is A -partitioned by $[A, B]$; otherwise, $\{C_j^3, C_j^4\} \subseteq A$ and \mathcal{E}_j is B -partitioned by $[A, B]$.

The following lemma is a key element in our proof.

► **Lemma 4.** *If $[A, B]$ is a maximum cut of $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$, then $[A, B]$ is an alternating partitioned cut.*

Sketch. The proof of Conditions (i) and (ii) is similar to the proof of Lemma 3, and in fact the same ideas are also part of the proof in [1]. Our ability to bound the interval count is due mainly to the fact that the vertex gadgets alternate in $[A, B]$, so we focus on this part of the proof. Another skipped detail is the fact that the pairs of link intervals, and the pairs of *intervals of type C* always go together. More formally, for every $j \in \{1, \dots, m\}$, we have that C_j^1, C_j^2 are in the same part, as well as C_j^3, C_j^4 . Similarly, for every $j \in \{1, \dots, m\}$ and $i \in \{1, \dots, n\}$, the intervals L_i^{2j-1}, L_i^{2j} are in the same part. Just to give an idea for the latter types of intervals, this is due to the fact that the intervals in \mathcal{H}_i^j or \mathcal{H}_{i+1}^j outweigh the total number of *relevant* intervals intersecting L_i^{2j-1}, L_i^{2j} that are outside such vertex gadgets.

Denote $\mathcal{M}(\mathfrak{G})$ by \mathcal{M} for simplicity, and let \mathcal{M}_i be the set of all the intervals related to vertex v_i ; more formally, it contains the grained gadget \mathcal{H}_i^j , for every $j \in [m+1]$, the link interval L_i^j , for every $j \in \{1, \dots, 2m\}$, every interval of type C_j^h that intersects \mathcal{H}_i^j to the right (this happens if e_j has v_i as endpoint), and every interval in \mathcal{E}_j for e_j incident to v_i . We count the number f_i of edges of the cut incident to some interval in \mathcal{M}_i and argue that, if the gadgets of v_i do not alternate in $[A, B]$, then we can obtain a bigger cut by rearranging \mathcal{M}_i , thus getting a contradiction.

Denote by $\overline{\mathcal{M}}_i$ the set of intervals $\mathcal{M} \setminus \mathcal{M}_i$, and by \mathcal{L} the set of all link intervals. In what follows, we do the counting in terms of m, n, p, q, p', q' for simplicity, and we do not make an exact counting, since it would be tedious and not help so much in the understanding of the ideas behind the proof. Also, there will be some values that should be added to f_i that remain the same, independently from how \mathcal{M}_i is partitioned; we call these values *irrelevant* and do not add them to f_i . Recall that every (x, y) -grained gadget has exactly $x + y$ intervals in A and $x + y$ in B . Thus, for each $j \in \{1, \dots, 2m\}$, we know that the number of edges between L_i^j and intervals in $\overline{\mathcal{M}}_i$ that are within a grained gadget do not change if we switch L_i^j from A to B or vice-versa; in other words, these values are irrelevant. Additionally, because we are considering that Conditions (i) and (ii) hold, the number of edges of the cut within each grained gadget of \mathcal{M}_i , and between grained gadgets of type \mathcal{H}_i^j and intervals of \mathcal{M}_i of type C can also be considered irrelevant. So now, for each $j \in \{1, \dots, m\}$, denote by ℓ_A^j the number of intervals in $\overline{\mathcal{M}}_i \cap \mathcal{L} \cap A$ that intersect L_i^{2j} ; define ℓ_B^j similarly. Observe that $\ell_A^j + \ell_B^j \leq 4n$ since it includes all the link intervals in the j -th region, plus at most the link intervals of the $(j-1)$ -th region related to $v_{i'}$ for $i' > i$, and the link intervals of the $(j+1)$ -th region related to $v_{i'}$ for $i' < i$. Additionally, let a_j be equal to 1 if L_i^{2j} is opposite to the right long intervals of \mathcal{H}_i^j , and 0 otherwise; similarly, let b_j be equal to 1 if L_i^{2j} is opposite to the left long intervals of \mathcal{H}_i^{j+1} , and 0 otherwise. Now, let $e_{j_1}, e_{j_2}, e_{j_3}$ be the edges incident to v_i , and for each $h \in \{1, 2, 3\}$, write e_{j_h} as $v_i v_{i_h}$. For each $h \in \{1, 2, 3\}$,

observe that the non-irrelevant number of edges of the cut incident to \mathcal{E}_{j_h} is $2(p' + q')$ if \mathcal{H}_i^j and $\mathcal{H}_{i_h}^j$ are partitioned differently, and that it is equal to $2p'$ otherwise. Therefore, if we let c_h be equal to 1 if \mathcal{H}_i^j and $\mathcal{H}_{i_h}^j$ are partitioned differently, and 0 otherwise, we get that there are $2p' + 2q'c_h$ edges in the cut incident to \mathcal{E}_{j_h} . Because $2p'$ is added for each $h \in \{1, 2, 3\}$, there is an irrelevant value of $6p'$ that we ignore. Therefore, we get that (recall that L^{2j-1} and L^{2j} are true twins):

$$f_i \leq \sum_{j=1}^m (2q(a_j + b_j) + \ell_A^j + \ell_B^j) + \sum_{h=1}^3 2q'c_h. \quad (3)$$

If L_i^{2j} is on the same side as the right long intervals of \mathcal{H}_i^j and the left long intervals of \mathcal{H}_i^{j+1} , we can increase f_i simply by switching its side (together of course with L_i^{2j-1}). Indeed, in this case we would lose at most $\max\{\ell_A^j, \ell_B^j\} \leq 4n$ edges, while gaining $4q$, a positive exchange since $q > n$. Observe that this implies that $a_j + b_j \geq 1$. Note also that this type of argument can be always applied, i.e., whenever in what follows we switch sizes of some subset of intervals, we can suppose that this property still holds. Now, let j be the minimum value for which $a_j + b_j = 1$ (j is well defined since otherwise we get that the gadgets of v_i alternate in $[A, B]$ and there is nothing to prove). Observe that this means that either both \mathcal{H}_i^j and \mathcal{H}_i^{j+1} are A -partitioned, or both are B -partitioned. Suppose the former, without loss of generality, and note that this means that $\mathcal{RL}(\mathcal{H}_i^j) \subseteq A$, while $\mathcal{LL}(\mathcal{H}_i^{j+1}) \subseteq B$. Also, let $j' > j$ be the minimum value for which the left long intervals of $\mathcal{H}_i^{j'+1}$ are on the opposite side of the right long intervals of $\mathcal{H}_i^{j'}$; if it does not exist, let $j' = m + 1$. We switch sides of the following intervals: \mathcal{H}_i^h , for every $h \in \{j + 1, \dots, j'\}$; L_i^{2j-1}, L_i^{2j} if they are also in A ; L_i^{2h-1}, L_i^{2h} for each $h \in \{j + 1, \dots, j' - 1\}$; and $L_i^{2j'-1}, L_i^{2j'}$ if $j' < m + 1$ and they are on the same side as $\mathcal{LL}(\mathcal{H}_i^{j'+1})$. Also switch the intervals of type C and intervals in edge gadgets appropriately in order to maintain the desired properties. We prove that we gain at least $2q - 4n$ edges, while losing at most $4nm + 6q' = 6(n^2 + q')$ (recall that $m = \frac{3n}{2}$). As previously said, this is not the exact count but gives an idea as how to choose the values for p, q, p', q' . Indeed, it suffices to choose values in a way as to ensure that the number of gained edges is bigger than the number of lost edges.

Observe that if we did not need to switch L_i^{2j-1}, L_i^{2j} , then, concerning these intervals, we gain at least $2q$ edges and lose none; otherwise, we gain $2q$ edges but lose at most $\ell_B^j \leq 4n$; thus we gain at least $2q - 4n$. As for the intervals L_i^{2h-1}, L_i^{2h} for $h \in \{j + 1, \dots, j' - 1\}$, by the definition of j' we know that we lose at most $\max\{\ell_A^h, \ell_B^h\} \leq 4n$, while maintaining the same number between them and the vertex gadgets. And if $j' < m + 1$, then we either gain $2q$ more edges if we did not need to change the side of $L_i^{2j'-1}, L_i^{2j'}$, or we gain $2q$ more edges while losing at most $\max\{\ell_A^{j'}, \ell_B^{j'}\} \leq 4n$. Hence, concerning the link intervals in \mathcal{M}_i , in total we lose at most $4nm = 6n^2$. As for the $6q'$ value, it suffices to see that, in the worst case scenario, $\{j_1, j_2, j_3\} \subseteq \{j + 1, \dots, j'\}$ and all the values c_h were previously equal to 1, and are now equal to 0 (observe again Inequality 3). \blacktriangleleft

Now, if $[A, B]$ is an alternating partitioned cut of $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$, we let $\Phi(A, B) = [X, Y]$ be the cut of G such that, for each vertex $v_i \in V(G)$, we have $v_i \in X$ if and only if \mathcal{H}_i^1 is A -partitioned by $[A, B]$. Note that $[X, Y]$ is well-defined and uniquely determined by $[A, B]$. On the other hand, given a cut $[X, Y]$ of G , there is a unique alternating partitioned cut $[A, B] = \Phi^{-1}(X, Y)$ of $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$ such that $[X, Y] = \Phi(A, B)$. Therefore, it remains to relate the sizes of these cut-sets. Basically we can use the good behaviour of the cuts in $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$ to prove that the size of $[A, B]$ grows as a well-defined function on the size of $\Phi(A, B)$. More formally, we can prove that the function f previously referred to is given by (recall that k is part of the input on the original problem):

$$f(G, k) = \left(\frac{3n^2}{2} + n\right)(2pq + q^2) + \frac{3n}{2}(2p'q' + (q')^2) + 6nq(n+1) \\ + (3n^2 + 3n)(n-1)(p+q) + 3n^2(p'+q') + 3n((k+1)q' + p') + 4k. \quad (4)$$

The above value is obtained using counting arguments much similar to the ones given in the proof of Lemma 4. The only downside is that we are not able to give an exact value for $|E_{\mathbb{G}_{\mathcal{M}(\mathfrak{G})}}(A, B)|$ as a function of $|E_G(X, Y)|$ and n, p, q, p', q' . For instance, note that the number of edges between link intervals within a region depend on the size of A and B , instead of the size of $E_G(X, Y)$. Nevertheless, we know that the range of values that $|E_{\mathbb{G}_{\mathcal{M}(\mathfrak{G})}}(A, B)|$ can assume, given that $|E_G(X, Y)| = k$, is distinct for each value of k , as the following lemma states.

► **Lemma 5.** *Let G be a cubic graph on n vertices, $\pi_V = (v_1, \dots, v_n)$ be an ordering of $V(G)$, $\pi_E = (e_1, \dots, e_{\frac{3n}{2}})$ be an ordering of $E(G)$, $\mathfrak{G} = (G, \pi_V, \pi_E)$, $[A, B]$ be an alternating partitioned cut of $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$ and $[X, Y] = \Phi(A, B)$. If $k = |E_G(X, Y)|$, then $f(G, k) \leq |E_{\mathbb{G}_{\mathcal{M}(\mathfrak{G})}}(A, B)| < f(G, k')$ for any integer $k' > k$.*

Sketch. Since $[A, B]$ is an alternating partitioned cut of $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$, we shall count the edges in the cut-set $E_{\mathbb{G}_{\mathcal{M}(\mathfrak{G})}}(A, B)$ according to the following three types of intervals incident to these edges: the edges in the cut-set that have an endpoint in a (p, q) -grained gadget; the edges in the cut-set that have an endpoint in a (p', q') -grained gadget; and the edges in the cut-set that have both endpoints in a link interval and/or an interval of the type C_j^ℓ .

First, we count the edges in the cut-set that have an endpoint in a (p, q) -grained gadget. The possible combinations are as follows.

- (1.1) Edges within (p, q) -grained gadgets related to vertices. There are exactly $(\frac{3n^2}{2} + n)(2pq + q^2)$ such edges.
- (1.2) Edges between link intervals L_i^{2j-1} and L_i^{2j} , and the (p, q) -gadgets related to vertices. There are exactly $m \cdot n \cdot (2q + 2q) = 6n^2q$ such edges.
- (1.3) Edges between intervals C_j^1, \dots, C_j^4 and the (p, q) -grained related to the vertices incident to edge e_j . There are exactly $\frac{3n}{2}(2q + 2q) = 6nq$ such edges.
- (1.4) Edges between (p, q) -grained gadgets related to vertices, and link intervals covering them. There are exactly $mn(n-1)(2p + 2q) = 3n^2(n-1)(p+q)$ such edges.
- (1.5) Edges between intervals C_j^1, \dots, C_j^4 and (p, q) -grained gadgets covered by them. There are exactly $\sum_{i \in [n]} 6(n-i)(p+q) = 3n(n-1)(p+q)$ such edges.

Second, we count the edges in the cut-set that have an endpoint in a (p', q') -grained gadget. The possible combinations are as follows.

- (2.1) Edges within (p', q') -grained gadgets related to edges. There are exactly $\frac{3n}{2}(2p'q' + (q')^2)$ such edges.
- (2.2) Edges between (p', q') -grained gadgets related to edges and the link intervals covering them. There are exactly $3n^2(p' + q')$ such edges.
- (2.3) Edges between (p', q') -grained gadget \mathcal{E}_j and intervals C_j^1, \dots, C_j^4 . There are exactly $\frac{3n}{2}(2kq' + 2(p' + q')) = 3n((k+1)q' + p')$ such edges (recall that $k = |E_G(X, Y)|$).

Third, we count the edges in the cut-set that have both endpoints in a link interval and/or an interval of the type C_j^ℓ for some $\ell \in \{1, \dots, 4\}$ and $j \in [m]$.

38:10 Maximum Cut on Interval Graphs of Interval Count Four Is NP-Complete

- (3.1) Edges between intervals C_j^1, C_j^2 and C_j^3, C_j^4 . There are exactly $4k$ such edges.
- (3.2) Edges between pairs of intervals $L_1^{2j-1}, L_1^{2j}, \dots, L_n^{2j-1}, L_n^{2j}$. There are *at most* $\sum_{j \in [m]} n^2 = mn^2 = \frac{3n^3}{2}$ such edges.
- (3.3) Edges between intervals $L_1^{2j-1}, L_1^{2j}, \dots, L_n^{2j-1}, L_n^{2j}$ and intervals in C_j^1, \dots, C_j^4 . There are *at most* $\sum_{j \in [m]} 8(n-1) = 8m(n-1) = 12n(n-1) = 12n^2 - 12n$ such edges.
- (3.4) Edges between link intervals in consecutive regions of the escalator. There are *at most*

$$\begin{aligned} \sum_{j \in \{2, \dots, m\}} \sum_{i \in [n]} 4(n-i) &= \sum_{j \in \{2, \dots, m\}} 2n(n-1) = 2(m-1)n(n-1) \\ &= 3n^2(n-1) - 2n(n-1) = 3n^3 - 5n^2 + 2n \end{aligned}$$

such edges.

- (3.5) Finally, edges between intervals C_j^1, \dots, C_j^4 and link intervals in the previous regions of the escalator. There are *at most* $\sum_{i \in [n]} 12(n-i) = 6n^2 - 6n$ such edges.

Therefore, summing up the number of edges in the cut-set $E_{\mathbb{G}_{\mathcal{M}(\mathfrak{G})}}(A, B)$ according to three types described above, except for the edges described in Cases (3.2)–(3.5) which, as we have seen, do not give exact values, we obtain that

$$\begin{aligned} |E_{\mathbb{G}_{\mathcal{M}(\mathfrak{G})}}(A, B)| &\geq \left(\frac{3n^2}{2} + n\right) (2pq + q^2) + \frac{3n}{2} (2p'q' + (q')^2) + 6nq(n+1) \\ &\quad + (3n^2 + 3n)(n-1)(p+q) + 3n^2(p'+q') \\ &\quad + 3n((k+1)q' + p') + 4k \\ &= f(G, k). \end{aligned}$$

On the other hand, note that the number of edges in Cases (3.2)–(3.5) is upper bounded by $\frac{9n^3}{2} + 13n^2 - 16n$. Thus, since $q' > \frac{9n^3}{2} + 13n^2 - 16n$, we have:

$$f(G, k) \leq |E_{\mathbb{G}_{\mathcal{M}(\mathfrak{G})}}(A, B)| \leq f(G, k) + \frac{9n^3}{2} + 13n^2 - 16n < f(G, k) + q'.$$

As a result, because there is a factor kq' in $f(G, k)$, we obtain that $f(G, k') > |E_{\mathbb{G}_{\mathcal{M}(\mathfrak{G})}}(A, B)|$ for any $k' > k$. \blacktriangleleft

The next lemma together with Lemma 7 stated next in Section 2.4 complete the proof of Theorem 1.

► **Lemma 6.** *Let G be a cubic graph on n vertices, $\pi_V = (v_1, \dots, v_n)$ be an ordering of $V(G)$, $\pi_E = (e_1, \dots, e_{3n})$ be an ordering of $E(G)$ and $\mathfrak{G} = (G, \pi_V, \pi_E)$. For each positive integer k , $\text{mc}(G) \geq k$ if and only if $\text{mc}(\mathbb{G}_{\mathcal{M}(\mathfrak{G})}) \geq f(G, k)$.*

Proof. First, suppose that $\text{mc}(G) \geq k$. Then, there is a cut $[X, Y]$ of G such that $|E_G(X, Y)| \geq k$. Let $[A, B]$ be the unique alternating partitioned cut of $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$ that, for each $i \in [n]$, satisfies the following condition: if $v_i \in X$, then \mathcal{H}_i^1 is A -partitioned; otherwise, \mathcal{H}_i^1 is B -partitioned. One can verify that $[A, B] = \Phi^{-1}(X, Y)$. Therefore, it follows from Lemma 5 that $\text{mc}(\mathbb{G}_{\mathcal{M}(\mathfrak{G})}) \geq |E_{\mathbb{G}_{\mathcal{M}(\mathfrak{G})}}(A, B)| \geq f(G, k)$. Conversely, suppose that $\text{mc}(\mathbb{G}_{\mathcal{M}(\mathfrak{G})}) \geq f(G, k)$. Then, there exists a cut $[A, B]$ of $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$ such that $|E_{\mathbb{G}_{\mathcal{M}(\mathfrak{G})}}(A, B)| \geq f(G, k)$. Assume that $[A, B]$ is a maximum cut of $\mathbb{G}_{\mathcal{M}(\mathfrak{G})}$. It follows from Lemma 4 that $[A, B]$ is an alternating partitioned cut. Consequently, by Lemma 5, $[X, Y] = \Phi(A, B)$ is a cut of G such that $|E_G(X, Y)| \geq k$. Indeed, if $|E_G(X, Y)| < k$, then $|E_{\mathbb{G}_{\mathcal{M}(\mathfrak{G})}}(A, B)| < f(G, k)$. Therefore, $\text{mc}(G) \geq k$. \blacktriangleleft

2.4 Bounding the interval count

Consider a cubic graph G on n vertices and $m = \frac{3n}{2}$ edges, and orderings π_V, π_E of the vertex set and edge set of G . Denote the triple (G, π_V, π_E) by \mathfrak{G} . We want to prove that the interval count of our constructed interval model $\mathcal{M}(\mathfrak{G})$ is at most 4. But observe that the construction of $\mathcal{M}(\mathfrak{G})$ is actually not unique, since the intervals are not uniquely defined; e.g., given such a model, one can obtain a model satisfying the same properties simply by adding $\epsilon > 0$ to all points defining the intervals. In this section, we provide a construction of a uniquely defined interval model related to \mathfrak{G} that satisfies the desired conditions and has interval count 4.

Consider our constructed interval model $\mathcal{M}(\mathfrak{G})$, and denote, for each $j \in [m]$, $\mathcal{S}_j = \mathcal{E}_j \cup \bigcup_{\ell \in [4]} C_j^\ell \cup \bigcup_{i \in [n]} (\mathcal{H}_i^j \cup \{L_i^{2j} \cup L_i^{2j-1}\})$. We show how to accommodate \mathcal{S}_1 within $[0, 6n - 2]$ in such a way that the same pattern can be adopted in the subsequent regions of $\mathcal{M}(\mathfrak{G})$ too, each time starting at multiples of $4n$. More specifically, letting $t = 4n$, we will accommodate \mathcal{S}_j within $[t \cdot (j - 1), 6n - 2 + t \cdot (j - 1)]$. Assume $e_1 = v_h v_{h'}$, with $h < h'$. Below, we say exactly which closed interval of the line corresponds to each interval $I \in \mathcal{S}_1$.

- For each $i \in [n]$, the left long intervals of \mathcal{H}_i^1 are equal to $[2i - 2, 2i - \frac{3}{2}]$ and the left short intervals are any choice of q distinct points within the open interval $(2i - 2, 2i - \frac{3}{2})$, whereas the right long intervals of \mathcal{H}_i^1 are equal to $[2i - \frac{3}{2}, 2i - 1]$ and the right short intervals are any choice of q distinct points within the open interval $(2i - \frac{3}{2}, 2i - 1)$. Note that open intervals are used to locate the closed intervals of length zero, but that the short intervals themselves are not open.
- C_1^1 and C_1^2 are equal to $[2h - 1, 2h + 2n - 2]$.
- C_1^3 and C_1^4 are equal to $[2h' - 1, 2h' + 2n - 2]$.
- The left long intervals of \mathcal{E}_1 are equal to $[2n, 4n - 1]$.
- The left short intervals of \mathcal{E}_1 are any choice of q' distinct points in the open interval $(2h + 2n - 2, 2h' + 2n - 2)$. Again, the open interval is used just to locate the closed intervals of length zero.
- The right long intervals of \mathcal{E}_1 are equal to $[4n - 1, 4n - \frac{1}{2}]$ and the right short intervals are any choice of q' distinct points within the corresponding open interval.
- For each $i \in [n]$, intervals L_i^1, L_i^2 are equal to $[2i - 1, 4n + 2(i - 1)]$.

■ **Figure 5** The closed intervals in $\mathcal{S}_1 \cup \bigcup_{i=1}^4 \mathcal{H}_i^2$ of a graph on 4 vertices. We consider e_1 to be equal to $v_3 v_4$. Each colour represents a different interval size. The short intervals are represented by the dots located inside the open interval. Vertical lines mark the endpoints of the intervals in $\mathcal{S}_1 \setminus \mathcal{L}$, while the green vertical line marks the beginning of the intervals in \mathcal{S}_2 .

The suitable chosen lengths of the above defined closed intervals are (see Figure 5, where we denote by \mathcal{L} the set of link intervals):

1. 0: short intervals of all grained gadgets (dots in Figure 5);
2. $1/2$: left long and right long intervals of each \mathcal{H}_i^1 , and right long intervals of \mathcal{E}_1 (red intervals in Figure 5);
3. $2n - 1$: intervals C_1^1, \dots, C_1^4 , and left long intervals of \mathcal{E}_1 (blue intervals in Figure 5);
4. $4n - 1$: intervals L_i^1 and L_i^2 , for every $i \in [n]$ (orange intervals in Figure 5).

Now, let $\mathcal{M}'(\mathfrak{G})$ be the interval model where each \mathcal{S}_j is defined exactly as \mathcal{S}_1 , except that we shift all the intervals to the right in a way that point 0 now coincides with point $t \cdot (j - 1)$. More formally, an interval I in \mathcal{S}_j corresponding to the copy of an interval $[\ell, r]$ in \mathcal{S}_1 is defined as $[\ell + t \cdot (j - 1), r + t \cdot (j - 1)]$. Also, we assign the intervals in the $(m + 1)$ -th grained gadgets to be at the end of this model, using the same sizes of intervals as above; i.e., \mathcal{H}_i^{m+1} is within the interval $[2i - 2 + t \cdot m, 2i - 1 + t \cdot m]$.

We have shown above that $\mathcal{M}'(\mathfrak{G})$ has interval count 4. The following lemma shows that the above chosen intervals satisfy the properties imposed in Subsections 2.1 and 2.2 on our constructed interval model $\mathcal{M}(\mathfrak{G})$.

► **Lemma 7.** *Let G be a cubic graph. Then, there exists an interval model $\mathcal{M}(\mathfrak{G})$ with interval count 4 for $\mathfrak{G} = (G, \pi_V, \pi_E)$, for every ordering π_V and π_E of the vertex set and edge set of G , respectively.*

3 The interval count of Adhikary et al.'s construction

We provided in Section 2 a reduction from the MAXCUT problem having as input a cubic graph G into that of MAXCUT in an interval graph G' having $\text{ic}(G') \leq 4$. Although our reduction requires the choice of orderings π_V and π_E of respectively $V(G)$ and $E(G)$ in order to produce the resulting interval model, we have established that we are able to construct an interval model with interval count 4 regardless of the particular choices for π_V and π_E (Lemma 7). Our reduction was based on that of [1], strengthened in order to control the interval count of the resulting model.

This section is dedicated to discuss the interval count of the original reduction [1]. Although the interval count was not of concern in [1], in order to contrast the reduction found there with the presented in this work, we investigate how interval count varies in the original reduction considering different vertex/edge orderings. First, we establish that the original reduction yields an interval model corresponding to a graph G' such that $\text{ic}(G') = O(\sqrt[4]{|V(G')|})$. Second, we exhibit an example of a cubic graph G for which a choice of π_V and π_E yields a model \mathcal{M}' with interval count $\Omega(\sqrt[4]{|V(G')|})$, proving that this bound is tight for some choices of π_V and π_E . For bridgeless cubic graphs, we are able in Lemma 8 to decrease the upper bound by a constant factor, but to the best of our knowledge $O(\sqrt[4]{|V(G')|})$ is the tightest upper bound. Before we go further analysing the interval count of the original reduction, it is worthy to note that a tight bound on the interval count of a general interval graph G as a function of its number of vertices n is still open. It is known that $\text{ic}(G) \leq \lfloor (n + 1)/2 \rfloor$ and that there is a family of graphs G for which $\text{ic}(G) = (n - 1)/3$ [7, 14]. That is, the interval count of a graph can achieve $\Theta(n)$.

In the original reduction, given a cubic graph G , an interval graph G' is defined through the construction of one of its models \mathcal{M} , described as follows:

1. let $\pi_V = (v_1, v_2, \dots, v_n)$ and $\pi_E = (e_1, e_2, \dots, e_m)$ be arbitrary orderings of $V(G)$ and $E(G)$, respectively;
2. for each $v_i \in V(G)$, $e_j \in E(G)$, let $\mathcal{G}(v_i)$ and $\mathcal{G}(e_j)$ denote respectively a (p, q) -grained gadget and a (p', q') -grained gadget, where:
 - $q = 200n^3 + 1$, $p = 2q + 7n$, and
 - $q' = 10n^2 + 1$, $p' = 2q' + 7n$;

3. for each $v_k \in V(G)$, insert $\mathcal{G}(v_k)$ in \mathcal{M} such that $\mathcal{G}(v_i)$ is entirely to the left of $\mathcal{G}(v_j)$ if and only if $i < j$. For each $e_k \in E(G)$, insert $\mathcal{G}(e_k)$ in \mathcal{M} entirely to the right of $\mathcal{G}(v_n)$ and such that $\mathcal{G}(e_i)$ is entirely to the left of $\mathcal{G}(e_j)$ if and only if $i < j$;
4. for each $e_j = (v_i, v_{i'}) \in E(G)$, with $i < i'$, four intervals $I_{i,j}^1, I_{i,j}^2, I_{i',j}^1, I_{i',j}^2$ are defined in \mathcal{M} , called *link* intervals, such that:
 - $I_{i,j}^1$ and $I_{i,j}^2$ (resp. $I_{i',j}^1$ and $I_{i',j}^2$) are true twin intervals that weakly intersect $\mathcal{G}(v_i)$ (resp. $\mathcal{G}(v_{i'})$) to the right;
 - $I_{i,j}^1$ and $I_{i',j}^1$ (resp. $I_{i,j}^2$ and $I_{i',j}^2$) weakly intersect (resp. strongly intersect) $\mathcal{G}(e_j)$ to the left.

By construction, therefore, $I_{i,j}^1$ and $I_{i,j}^2$ (resp. $I_{i',j}^1$ and $I_{i',j}^2$) cover all intervals in grained gadgets associated to a vertex v_ℓ with $\ell > i$ (resp. $\ell > i'$) or an edge e_ℓ with $\ell < j$.

Note that the number of intervals in \mathcal{M} is invariant under the particular choices of π_V and π_E and, therefore, so is the number of vertices of G' . Let $n' = |V(G')|$. Since G is cubic, $m = \frac{3n}{2}$. By construction,

$$n' = n(2p + 2q) + m(2p' + 2q') + 4m = 1200n^4 + 90n^3 + 25n^2 + 21n$$

and thus $n = \Theta(\sqrt[4]{n'})$. Since the set of intervals covered by any link interval depends on π_V and π_E , distinct sequences yield distinct resulting graphs G' having distinct interval counts.

We show next that $\text{ic}(G') = O(\sqrt[4]{n'})$. Note that

- the intervals of all gadgets $\mathcal{G}(v_i)$ and $\mathcal{G}(e_j)$ can use only two interval lengths (one for all short intervals, another for all the long intervals);
- for each $e_j = v_i v_{i'} \in E(G)$, with $i < i'$, both intervals $I_{i,j}^1$ and $I_{i,j}^2$ may be coincident in any model, and therefore may have the same length. The same holds for both intervals $I_{i',j}^1$ and $I_{i',j}^2$.

Therefore, $\text{ic}(G') \leq 2m + 2 = 3n + 2 = \Theta(\sqrt[4]{n'})$. Therefore, the NP-completeness result derived from the original reduction in [1] can be strengthened to state that MAXCUT is NP-complete for interval graphs G having interval count $O(\sqrt[4]{|V(G)|})$.

Second, we show that there is a resulting model \mathcal{M}' produced in the reduction, defined in terms of particular orderings π_V, π_E for which $\text{ic}(\mathcal{M}') = \Omega(\sqrt[4]{n'})$. Consider the cubic graph G depicted in Figure 6(a) which consists of an even cycle (v_1, v_2, \dots, v_n) with the addition of the edges $(v_i, v_{i+\frac{n}{2}})$ for all $1 \leq i \leq n/2$. For the ordering $\pi_V = (v_n, v_{n-1}, \dots, v_1)$ and any ordering π_E in which the first n edges are the edges of the cycle (v_1, v_2, \dots, v_n) , in this order, the reduction yields a model \mathcal{M}' for which there is a chain $I_{1,1}^1 \subset I_{2,2}^1 \subset \dots \subset I_{n,n}^1$ of nested intervals (see Figure 6(b)), which shows that $\text{ic}(\mathcal{M}') \geq n$, and thus $\text{ic}(\mathcal{M}') = \Omega(\sqrt[4]{n'})$.

■ **Figure 6** (a) A cubic graph G , and (b) a chain of nested intervals in the model \mathcal{M}' .

It can be argued from the proof of NP-completeness for MAXCUT when restricted to cubic graphs [2] that the constructed cubic graph may be assumed to have no bridges. This fact was not used in the original reduction of [1]. In an attempt to obtain a model \mathcal{M} having

fewer lengths for bridgeless cubic graphs, we have derived Lemma 8. Although the number of lengths in this new upper bound has decreased by the constant factor of $4/9$, it is still $\Theta(n) = \Theta(\sqrt[4]{n'})$.

► **Lemma 8.** *Let G be a cubic bridgeless graph with $n = |V(G)|$. There exist particular orderings π_V of $V(G)$ and π_E of $E(G)$ such that:*

1. *there is a resulting model \mathcal{M} produced in the original reduction of MAXCUT such that $\text{ic}(\mathcal{M}) \leq \frac{4n}{3} + 3$.*
2. *for all such resulting models \mathcal{M} , we have that $\text{ic}(\mathcal{M}) \geq 5$ if G is not a Hamiltonian graph.*

As a concluding remark, we note that the interval count of the interval model \mathcal{M} produced in the original reduction is highly dependent on the assumed orderings of $V(G)$ and $E(G)$, and may achieve $\text{ic}(\mathcal{M}) = \Omega(\sqrt[4]{n'})$. The model \mathcal{M}' produced in our reduction enforces that $\text{ic}(\mathcal{M}') = 4$ which is invariant for any such orderings. On the perspective of the problem of interval count 2 and beyond, for which very little is known, our NP-completeness result on a class of bounded interval count graphs is also of interest.

Abstract

We introduce a very natural generalization of the well-known problem of simultaneous congruences. Instead of searching for a positive integer s that is specified by n *fixed remainders* modulo integer divisors a_1, \dots, a_n we consider *remainder intervals* R_1, \dots, R_n such that s is feasible if and only if s is congruent to r_i modulo a_i for *some* remainder r_i in interval R_i for all i .

This problem is a special case of a 2-stage integer program with only two variables per constraint which is closely related to directed Diophantine approximation as well as the mixing set problem. We give a hardness result showing that the problem is NP-hard in general.

By investigating the case of *harmonic divisors*, i.e. a_{i+1}/a_i is an integer for all $i < n$, which was heavily studied for the mixing set problem as well, we also answer a recent algorithmic question from the field of real-time systems. We present an algorithm to decide the feasibility of an instance in time $\mathcal{O}(n^2)$ and we show that if it exists even the *smallest* feasible solution can be computed in strongly polynomial time $\mathcal{O}(n^3)$.

1 Introduction

In the recent past there was a great interest in the so-called *n-fold* integer programs [10, 17, 19] and *2-stage* integer programs [18, 20]. The matrix \mathcal{A} of a 2-stage integer program is constructed by block matrices $A^{(1)}, \dots, A^{(n)} \in \mathbb{Z}^{r \times k}$ and $B^{(1)}, \dots, B^{(n)} \in \mathbb{Z}^{r \times t}$ as follows:

$$\mathcal{A} = \begin{pmatrix} A^{(1)} & B^{(1)} & 0 & \dots & 0 \\ A^{(2)} & 0 & B^{(2)} & \ddots & \vdots \\ \vdots & \vdots & \ddots & \ddots & 0 \\ A^{(n)} & 0 & \dots & 0 & B^{(n)} \end{pmatrix}$$

For an objective vector $c \in \mathbb{Z}_{\geq 0}^{k+nt}$, a right-hand side $b \in \mathbb{Z}^{nr}$, and bounds $\ell, u \in \mathbb{Z}_{\geq 0}^{k+nt}$ the 2-stage integer program is formulated as

$$\max \{ c^T x \mid \mathcal{A}x = b, \ell \leq x \leq u, x \in \mathbb{Z}^{k+nt} \}.$$

A special case of a 2-stage integer program is given by the problem MIXING SET [6, 7, 15] (with only two variables in each constraint) where especially $r = k = t = 1$ and $A^{(1)} = \dots = A^{(n)}$. Remark that 2-variable integer programming problems were extensively studied by various

39:2 Fuzzy Simultaneous Congruences

authors, e.g. [3, 22] or [12] (with two variables in total). MIXING SET plays an important role for example in integer programming approaches for production planning [26]. Given vectors $a, b \in \mathbb{Q}^n$ one aims to compute

$$\min \{ f(s, x) \mid s + a_i x_i \geq b_i \forall i = 1, \dots, n, (s, x) \in \mathbb{Z}_{\geq 0} \times \mathbb{Z}^n \} \quad (1)$$

for some objective function f . Conforti et al. [8] pose the question whether the problem can be solved in polynomial time for linear functions f . Unless $P = NP$ this was ruled out by Eisenbrand and Rothvoß [13] who proved that optimizing any linear function over MIXING SET is NP-hard. However, the problem can be solved in polynomial time if $a_i = 1$ [15, 24] or if the capacities a_i fulfil a *harmonic* property [30], i.e. a_{i+1}/a_i is integer for all $i < n$. The case of harmonic capacities was intensively studied - see [8, 9] for simpler approaches.

More recently, real-time systems with harmonic tasks (the periods are integer multiples of each other) have received increased attention [5] and also harmonic periods have been considered before [2, 11, 27, 29]. Now a recent manuscript in the field of real-time systems by Nguyen et al. [25] gives rise to the study of a new problem. Nguyen et al. present an algorithm for the worst-case response time analysis of harmonic tasks with constrained release jitter running in polynomial time. The release jitter of a task is the maximum difference between the arrival times and the release times over all jobs of the task. Their algorithm uses heuristic components to solve an integer program that can be stated as a bounded version of MIXING SET with additional upper bounds B_i as follows.

BOUNDED MIXING SET (BMS)

Given capacities $a_1, \dots, a_n \in \mathbb{Z}$ and bounds $b, B \in \mathbb{Z}^n$ find $(s, x) \in \mathbb{Z}_{\geq 0} \times \mathbb{Z}^n$ such that

$$b_i \leq s + a_i x_i \leq B_i \quad \forall i = 1, \dots, n.$$

In particular they depend on minimizing the value of s which can be achieved in linear time in case of MIXING SET. While BMS may look artificial at first sight it is not; in fact, leading to a very natural generalization it can be restated in the well-known form of *simultaneous congruences*.

FUZZY SIMULTANEOUS CONGRUENCES (FSC)

Given divisors $a_1, \dots, a_n \in \mathbb{Z} \setminus \{0\}$ and remainder intervals $R_1, \dots, R_n \subseteq \mathbb{Z}$ and an interval $S \subseteq \mathbb{Z}_{\geq 0}$ find a number $s \in S$ such that

$$\exists r_i \in R_i : s \equiv r_i \pmod{a_i} \quad \forall i = 1, \dots, n.$$

Obviously, this also generalizes over the well-known problem of the Chinese Remainder Theorem (CRT). Here we give its generalized form (cf. [21]).

► **Theorem 1 (Generalized Chinese Remainder Theorem).** *Given divisors $a_1, \dots, a_n \in \mathbb{Z}_{\geq 1}$ and remainders $r_1, \dots, r_n \in \mathbb{Z}_{\geq 0}$ the system of n simultaneous congruences $s \equiv r_i \pmod{a_i}$ admits a solution $s \in \mathbb{Z}$ if and only if $r_i \equiv r_j \pmod{\gcd(a_i, a_j)}$ for all $i \neq j$.*

Furthermore, Leung and Whitehead [23] showed that k -Simultaneous Congruences (k -SC) is NP-complete in the weak sense. Given divisors $a_1, \dots, a_n \in \mathbb{Z}_{\geq 1}$ and remainders $r_1, \dots, r_n \in \mathbb{Z}_{\geq 0}$ the task is to find a number $s \in \mathbb{Z}_{\geq 0}$ and a subset $I \subseteq \{1, \dots, n\}$ with $|I| = k$ s.t. $s \equiv r_i \pmod{a_i}$ for all $i \in I$. Later it was shown by Baruah et al. [4] that k -SC also is NP-complete in the strong sense.

■ **Figure 1** The two possibilities for the modular projection of an interval.

Both problems BMS and FSC are interchangeable formulations of the same problem (see Section 2). Therefore, we will use them as synonyms and we especially assume formally that $R_i = [b_i, B_i]$. Interestingly and to the best of our knowledge, FSC/BMS was not considered before. However, the investigation of simultaneous congruences has always been of transdisciplinary interest connecting a variety of fields and applications, e.g. [1, 14, 16].

Our Contribution

- (a) We show that BMS is NP-hard for general capacities a_i . For the reduction from DIRECTED DIOPHANTINE APPROXIMATION we refer to the appendix. Compared to MIXING SET this is a stronger hardness result as BMS by itself only asks for an *arbitrary* feasible solution. Remark that every feasible instance of MIXING SET may be solved by $s = \|b\|_\infty, x = \mathbf{0}$.
- (b) In the case of harmonic capacities (i.e. a_{i+1}/a_i is an integer for all $i < n$), which was heavily studied for MIXING SET as mentioned before, we give an algorithm exploiting a merge idea based on modular arithmetic on intervals to decide the feasibility problem of FSC in time $\mathcal{O}(n^2)$. See Section 3.1 for the details.
- (c) Furthermore, for a feasible instance of FSC with harmonic capacities we present a polynomial algorithm as well as a strongly polynomial algorithm to compute the smallest feasible solution to FSC in time $\mathcal{O}(\min\{n^2 \log(a_n), n^3\}) \leq \mathcal{O}(n^3)$. See Section 3.2 for the details.
- (d) Our algorithm gives a strongly polynomial replacement for the heuristic component (which may fail to compute a solution) in the algorithm of Nguyen et al. [25]. However, we present an algorithm to solve the problem in linear time. See Section 4 for the details.

2 Notation and General Properties

For the sake of readability we write $X^{[\alpha]} = (X \bmod \alpha)$ for numbers X as well as $X^{[\alpha]} = \{z \bmod \alpha \mid z \in X\}$ for sets X (of numbers) to denote the modular projection of some number or interval, respectively. Extending the usual notation we also write $X \equiv Y \pmod{\alpha}$ if $X^{[\alpha]} = Y^{[\alpha]}$ for sets X, Y . Notice that on the one hand $(X \cup Y)^{[\alpha]} = X^{[\alpha]} \cup Y^{[\alpha]}$ but on the other hand be aware that $(X \cap Y)^{[\alpha]} \neq X^{[\alpha]} \cap Y^{[\alpha]}$ in general (cf. Lemma 9). Figure 1 depicts the structure of $v^{[\alpha]}$ if $v = [l_v, u_v]$ is an interval in \mathbb{Z} .

The empty set is denoted by \emptyset . Also we use the well-tried notation $t+X = \{t+z \mid z \in X\}$ to express the *translation* of a set of numbers X by some number t . For a set of sets \mathcal{S} we write $\bigcup \mathcal{S}$ to denote the union $\bigcup_{S \in \mathcal{S}} S$. Furthermore, we identify constraints by their indices. So for $i \leq n$ we say that “ $b_i \leq s + a_i x_i \leq B_i$ ” is constraint i .

Identity of BMS and FSC

It is important to notice that BMS allows zero capacities while FSC cannot allow zero divisors since $(\text{mod } 0)$ is undefined. However, consider a constraint i of BMS with $a_i \neq 0$. Let $b_i \leq s + a_i x_i \leq B_i$ be satisfied and set $r_i = s + a_i x_i$. Then $r_i^{[a_i]} = s^{[a_i]}$ and $r_i \in [b_i, B_i] = R_i$. Vice-versa let $r_i \in R_i$ s.t. $r_i \equiv s \pmod{a_i}$. Then there is an $x_i \in \mathbb{Z}$ s.t. $s + a_i x_i = r_i \in R_i = [b_i, B_i]$.

A constraint i that holds $a_i = 0$ simply demands that $s \in R_i$. Hence, if $a_i = a_j = 0$ for two constraints $i \neq j$ they can be replaced by one new constraint k defined by $R_k = R_i \cap R_j$. Therefore, one may assume that there is at most one constraint i with a zero capacity a_i . However, as all our results can be lifted back to the general case with low effort we will assume in terms of BMS that all capacities are non-zero and for FSC we make the equivalent assumption that $S = \mathbb{Z}_{\geq 0}$.

With our notation we may easily express the feasibility of a value s for a single constraint i as follows.

► **Observation 2.** *A value s satisfies constraint i if and only if $s^{[a_i]} \in R_i^{[a_i]}$.*

Proof. It holds that $\exists r_i \in R_i : r_i \equiv s \pmod{a_i}$ iff $\exists r_i \in R_i : r_i^{[a_i]} = s^{[a_i]}$ iff $s^{[a_i]} \in R_i^{[a_i]}$. ◀

By simply swapping the signs of the x_i we may assume that $a_i \geq 0$ for all i . We may also assume that the intervals are small in the sense that $B_i - b_i + 1 < a_i$ holds for all i . Assume that $B_i - b_i + 1 \geq a_i$ for an i and let $s \geq 0$ be an arbitrary integer. Then $b_i \leq B_i - a_i + 1$ and constraint i may always be solved by setting $x_i = \lceil (b_i - s)/a_i \rceil$ which satisfies

$$b_i \leq s + a_i \underbrace{\lceil \frac{b_i - s}{a_i} \rceil}_{x_i} \leq s + a_i \lceil \frac{B_i - a_i + 1 - s}{a_i} \rceil = s + a_i \lfloor \frac{B_i - s}{a_i} \rfloor \leq B_i.$$

Hence, constraint i is redundant and may be omitted. As a direct consequence there can be at most one feasible value for each x_i for a given guess s . In fact, we can decide the feasibility of a guess s in time $\mathcal{O}(n)$ as for all constraints i and values x_i it holds $b_i \leq s + a_i x_i \leq B_i$ if and only if $\lceil (b_i - s)/a_i \rceil = x_i = \lfloor (B_i - s)/a_i \rfloor$. So a guess s is feasible if and only if $\lceil (b_i - s)/a_i \rceil = \lfloor (B_i - s)/a_i \rfloor$ holds for all constraints i . Another consequence is that BMS is a generalization of MIXING SET as one can always add trivial upper bounds. By s_{\min} we denote the smallest feasible solution s that satisfies all constraints.

► **Observation 3.** *For feasible instances it holds that $s_{\min} < \text{lcm}(a_1, \dots, a_n)$.*

Proof. Let $\varphi = \text{lcm}(a_1, \dots, a_n)$. Remark that φ/a_i is integral for all i . Assume that (s, x) is a solution with $s = s_{\min} \geq \varphi$. Let $t = s - \varphi$ and $y_i = x_i + \varphi/a_i$ f.a. i . Then $0 \leq t < s_{\min}$ and $t + a_i y_i = s + a_i x_i$ f.a. i . So (t, y) is a solution that contradicts the optimality. ◀

3 Harmonic Divisors

Here we consider harmonic divisors in the sense that a_{i+1}/a_i is an integer for all $i < n$.

As we investigate some kind of a generalization of the setting of the Chinese Remainder Theorem, it is natural to ask for a CRT for *harmonic* (instead of the usually coprime) divisors and of course the (generalized) CRT answers this question; in this case we have $\text{gcd}(a_i, a_n) = a_i$ and so Theorem 1 reveals that if the system of n simultaneous congruences $s \equiv r_i \pmod{a_i}$ admits a solution then $r_i \equiv r_n \pmod{a_n}$ which says that if there is any solution then the set of all solutions is $a_n \mathbb{Z} + r_n^{[a_n]}$. However, it turns out that the investigation of FSC is a lot more complicated.

■ **Figure 2** $36a_1 = 18a_2 = 6a_3 = 3a_4 = a_5$. The guess s is not feasible for constr. 3 and 5.

In this section we present an algorithm to decide the feasibility of an instance of FSC. Also we show how optimal solutions can be computed in (strongly) polynomial time. Both of these results are based on the fine-grained interconnection between modular arithmetic on sets and the harmonic property. For some intuition Figure 2 gives a perspective on s as an anchor for 1-dimensional lattices with basis a_i which have to “hit” the intervals R_i . For example, in the figure it holds that $s + a_2 \cdot (-1) = s - a_2 \in R_2$, so the 1-dimensional lattice $(s + a_2z)_{z \in \mathbb{Z}}$ hits interval R_2 . Therefore, the choice of s satisfies constraint 2.

3.1 Deciding feasibility

The idea for our first algorithm will be to decide the feasibility problem by iteratively computing modular projections from constraint $i = n$ down to $i = 1$. In the following we will say that an interval $w \subseteq \mathbb{Z}$ represents a set $M \subseteq \mathbb{Z}$ (modulo α) if $w^{[\alpha]} = M^{[\alpha]}$. Also a set of intervals \mathcal{R} represents a set $M \subseteq \mathbb{Z}$ (modulo α) if $M^{[\alpha]} = \bigcup_{w \in \mathcal{R}} w^{[\alpha]}$. Given an integer $\alpha \geq 1$ and two intervals v, w we need to study the structure of the intersection $v^{[\alpha]} \cap w^{[\alpha]} \subseteq [0, \alpha)$. To express it let $v = [\ell_v, u_v], w = [\ell_w, u_w]$ and we define the basic intervals

$$\varphi_\alpha(v, w) = [\ell_v^{[\alpha]}, u_w^{[\alpha]}] \quad \text{and} \quad \psi_\alpha(v, w) = [\max\{\ell_v^{[\alpha]}, \ell_w^{[\alpha]}\}, \alpha + \min\{u_v^{[\alpha]}, u_w^{[\alpha]}\}]$$

for all intervals v, w . The former may be thought as the cases where $v^{[\alpha]}$ and $w^{[\alpha]}$ are two overlapping intervals while the intuition for the latter are situations where $v^{[\alpha]}$ and $w^{[\alpha]}$ both consist of two intervals which are in pairs overlapping. Remark that $\psi_\alpha(w, v) = \psi_\alpha(v, w)$ is always true.

► **Lemma 4.** *Given an integer $\alpha \geq 1$ and two intervals $v, w \subseteq \mathbb{Z}$ it holds that*

$$v^{[\alpha]} \cap w^{[\alpha]} \in \{ \emptyset, v^{[\alpha]}, w^{[\alpha]}, \psi_\alpha(v, w)^{[\alpha]}, \varphi_\alpha(v, w), \varphi_\alpha(w, v), \\ \varphi_\alpha(v, w) \dot{\cup} \varphi_\alpha(w, v), \varphi_\alpha(v, w) \dot{\cup} \psi_\alpha(v, w)^{[\alpha]}, \varphi_\alpha(w, v) \dot{\cup} \psi_\alpha(v, w)^{[\alpha]} \}.$$

The important intuition is that such a “modulo α intersection” can always be represented by at most two intervals. Remark that the sets in the second row are the only ones which are represented by $2 > 1$ intervals. Due to space reasons for the case distinction to prove Lemma 4 we refer to Appendix B and especially to Figure 6.

While Lemma 4 gives structure to intersections of two modular projections of intervals, the next lemma reveals how many intervals will be required to represent a *one-to-many* intersection. We will use this bound in every step of our algorithm. We want to add that both of these lemmas and even Lemma 6 do not depend on the harmonic property by themselves. However, they turn out to be especially useful in this setting.

► **Lemma 5.** *Let $\alpha \geq 1$, let v be an interval and let Q be a set of $k \geq 1$ intervals. Then there is a set R of at most $k+1$ intervals s.t. $v^{[\alpha]} \cap (\bigcup Q)^{[\alpha]} = (\bigcup R)^{[\alpha]}$.*

39:6 Fuzzy Simultaneous Congruences

Proof. We simply obtain that

$$v^{[\alpha]} \cap \left(\bigcup Q \right)^{[\alpha]} = \bigcup_{w \in Q} (v^{[\alpha]} \cap w^{[\alpha]}) = \bigcup_{\substack{w \in Q \\ w^{[\alpha]} \subseteq v^{[\alpha]}}} w^{[\alpha]} \cup \bigcup_{w \in D} (v^{[\alpha]} \cap w^{[\alpha]})$$

where $D = \{ w \in Q \mid w^{[\alpha]} \not\subseteq v^{[\alpha]}, w^{[\alpha]} \cap v^{[\alpha]} \neq \emptyset \}$ denotes the subset of intervals that cause the interesting intersections with $v^{[\alpha]}$ (cf. Lemma 4). Obviously, all other intersections can be represented by at most one interval each. So we study the intersections with D . In fact, everything gets simple if there are $w_1, w_2 \in D$ such that $v^{[\alpha]} \cap w_1^{[\alpha]} = \varphi_\alpha(v, w_1) \dot{\cup} \psi_\alpha(v, w_1)^{[\alpha]}$ and $v^{[\alpha]} \cap w_2^{[\alpha]} = \varphi_\alpha(w_2, v) \dot{\cup} \psi_\alpha(v, w_2)^{[\alpha]}$. By simply adapting the inequalities of the first case distinction in the proof of Lemma 4 we find

$$\begin{aligned} & (v^{[\alpha]} \cap w_1^{[\alpha]}) \cup (v^{[\alpha]} \cap w_2^{[\alpha]}) \\ &= ([0, u_v^{[\alpha]}] \dot{\cup} [\ell_v^{[\alpha]}, u_{w_1}^{[\alpha]}] \dot{\cup} [\ell_{w_1}^{[\alpha]}, \alpha]) \cup ([0, u_{w_2}^{[\alpha]}] \dot{\cup} [\ell_{w_2}^{[\alpha]}, u_v^{[\alpha]}] \dot{\cup} [\ell_v^{[\alpha]}, \alpha]) \\ &= [0, u_v^{[\alpha]}] \dot{\cup} [\ell_v^{[\alpha]}, \alpha] = v^{[\alpha]} \end{aligned}$$

which implies that $v^{[\alpha]} \cap \left(\bigcup Q \right)^{[\alpha]} = v^{[\alpha]}$ can be represented by only one interval, namely v . Therefore, in order to get an upper bound we assume that these two types of intersections do not come together. In more detail, we may assume by symmetry that $D = D_1 \dot{\cup} D_2$ where

$$\begin{aligned} D_1 &= \{ w \in D \mid v^{[\alpha]} \cap w^{[\alpha]} = \varphi_\alpha(v, w) \dot{\cup} \varphi_\alpha(w, v) \} \text{ and} \\ D_2 &= \{ w \in D \mid v^{[\alpha]} \cap w^{[\alpha]} = \varphi_\alpha(v, w) \dot{\cup} \psi_\alpha(v, w)^{[\alpha]} \}. \end{aligned}$$

It turns out that

$$\begin{aligned} \bigcup_{w \in D_1} (v^{[\alpha]} \cap w^{[\alpha]}) &= \bigcup_{w \in D_1} ([\ell_v^{[\alpha]}, u_w^{[\alpha]}] \dot{\cup} [\ell_w^{[\alpha]}, u_v^{[\alpha]}]) \\ &= [\ell_v^{[\alpha]}, \max_{w \in D_1} u_w^{[\alpha]}] \cup [\min_{w \in D_1} \ell_w^{[\alpha]}, u_v^{[\alpha]}] \text{ and} \\ \bigcup_{w \in D_2} (v^{[\alpha]} \cap w^{[\alpha]}) &= \bigcup_{w \in D_2} ([\ell_v^{[\alpha]}, u_w^{[\alpha]}] \dot{\cup} [\ell_w^{[\alpha]}, \alpha + u_v^{[\alpha]}]^{[\alpha]}) \\ &= [\ell_v^{[\alpha]}, \max_{w \in D_2} u_w^{[\alpha]}] \cup [\min_{w \in D_2} \ell_w^{[\alpha]}, \alpha + u_v^{[\alpha]}]^{[\alpha]} \end{aligned}$$

which finally joins up to

$$\bigcup_{w \in D} (v^{[\alpha]} \cap w^{[\alpha]}) = [\ell_v^{[\alpha]}, \max_{w \in D} u_w^{[\alpha]}] \cup [\min_{w \in D} \ell_w^{[\alpha]}, \alpha + u_v^{[\alpha]}]^{[\alpha]}.$$

Hence, all intersections with intervals in D may be represented by at most two intervals in total while each other intersection can be represented by at most one interval. Thus, if $|D| = 0$ then the whole intersection can be represented by at most k intervals. If $|D| \geq 1$ then there are at most $2 + |Q| - |D| \leq 2 + k - 1 = k + 1$ intervals required. \blacktriangleleft

Let S_i denote the set of all solutions $s \in \mathbb{Z}_{\geq 0}$ that are feasible for each of the constraints $i, i + 1, \dots, n$. We set $S_{n+1} = \mathbb{Z}_{\geq 0}$ to denote the feasible solutions to an empty set of constraints. The correctness of Algorithm 1 is implied by the following fundamental lemma. See Figure 3 for an example of a step inside the algorithm.

► Lemma 6. *It holds true that $S_i^{[a_i]} = R_i^{[a_i]} \cap S_{i+1}^{[a_i]}$ for all $i = 1, \dots, n$.*

■ **Figure 3** A step from $i+1$ to i ; modular projection to $[0, a_i)$ and intersection with $R_i^{[a_i]}$.

if $\bigcup Q_1 = \emptyset$ **then**

return “infeasible”

else

return “feasible”

Proof. Let $r \in S_i^{[a_i]}$. So there is a solution $s \in S_i$ such that $r = s^{[a_i]} \in R_i^{[a_i]}$. It holds that $S_i \subseteq S_{i+1}$ which implies $s \in S_{i+1}$ and thus $r = s^{[a_i]} \in S_{i+1}^{[a_i]}$.

Vice-versa let $r \in R_i^{[a_i]} \cap S_{i+1}^{[a_i]}$. So there is a solution $s \in S_{i+1}$ with $s^{[a_i]} = r$. From $r \in R_i^{[a_i]}$ we get $s^{[a_i]} \in R_i^{[a_i]}$. Hence, $s \in S_i$ and $r = s^{[a_i]} \in S_i^{[a_i]}$. ◀

▶ **Theorem 7.** *Algorithm 1 decides the feasibility of an instance in time $\mathcal{O}(n^2)$.*

Proof. We show that $\bigcup Q_i \equiv S_i \pmod{a_i}$ for all $i = n, \dots, 1$. This will prove the algorithm correct since then $\bigcup Q_1 \equiv S_1 \pmod{a_1}$ and that means $\bigcup Q_1$ is empty if and only if S_1 is empty. Obviously it holds that $\bigcup Q_n \equiv S_n \pmod{a_n}$ since $\bigcup Q_n = R_n$. Now suppose that $\bigcup Q_{i+1} \equiv S_{i+1} \pmod{a_{i+1}}$ for some $i \geq 1$. We have that $(\bigcup Q_i)^{[a_i]} = R_i^{[a_i]} \cap (\bigcup Q_{i+1})^{[a_i]}$ where the harmonic property implies $(\bigcup Q_{i+1})^{[a_i]} = ((\bigcup Q_{i+1})^{[a_{i+1}]})^{[a_i]} = (S_{i+1}^{[a_{i+1}]})^{[a_i]} = S_{i+1}^{[a_i]}$. Together with Lemma 6 this yields $(\bigcup Q_i)^{[a_i]} = R_i^{[a_i]} \cap S_{i+1}^{[a_i]} = S_i^{[a_i]}$ and that proves the algorithm correct. Using Lemmas 4–6 each set Q_i can be computed in time $\mathcal{O}(n)$ and this yields a total running time of $\mathcal{O}(n^2)$. ◀

3.2 Optimal solutions

Unfortunately, Algorithm 1 neither calculates a solution nor it directly implies one. Here we present an algorithm to compute the smallest feasible solution s_{\min} to FSC. However, by searching in the opposite direction the same technique also applies to the computation of the largest feasible solution $s_{\max} < a_n$. We start with a simple binary search approach.

▶ **Corollary 8.** *For feasible instances s_{\min} can be computed in time $\mathcal{O}(n^2 \log(a_n))$.*

This can be achieved by introducing an additional constraint measuring the value of s as follows. Let β be a positive integer. We extend the problem instance by a new constraint with number $n + 1$ defined by $a_{n+1} = 2 \cdot a_n$, $b_{n+1} = 0$, and $B_{n+1} = \beta$. Remark that this

β -instance admits the same set of solutions as the original instance as long as β is large enough, e.g. $\beta = a_n$ (cf. Observation 3). Consider a feasible solution to the β -instance where $\beta \leq a_n$. It holds that

$$2a_n x_{n+1} = a_{n+1} x_{n+1} \leq s + a_{n+1} x_{n+1} \leq B_{n+1} = \beta \leq a_n$$

which implies $x_{n+1} \leq \lfloor \frac{1}{2} \rfloor = 0$. However, if $x_{n+1} < 0$ then $s \geq a_{n+1} \cdot |x_{n+1}|$ and therefore the solution $s' = s + a_{n+1} x_{n+1}$ with $x'_{n+1} = 0$ and $x'_i = x_i - (a_{n+1}/a_i)x_{n+1}$ for all $i = 1, \dots, n$ is better than s and $x'_{n+1} = 0$.

Thus we may assume generally that $x_{n+1} = 0$ which allows us to measure the value of s using the upper bound β . We use β to do a binary search in the interval $[0, a_n]$ using Algorithm 1 to check the β -instance for feasibility. The smallest possible value for β then states the optimum value and that proves Corollary 8. However, with additional ideas we are able to achieve strongly polynomial time. We want to give some helpful intuition first.

Clearly, after revealing the intervals in Q_1 with Algorithm 1 a straightforward idea is to try tracing them back to a small solution for s , but routing through the modulus operations appears to become a non-polynomial bottleneck.

However, the following idea is a first step to end up with a constraint aggregation approach. Given the projections $A^{[ab]}$ and $B^{[a]}$ of two sets $A, B \subseteq \mathbb{Z}$ one can compute the intersection $A^{[a]} \cap B^{[a]}$ in at least two ways; primitively we compute $(A^{[ab]})^{[a]} = A^{[a]}$ and then intersect it with $B^{[a]}$, but also we can intersect $A^{[ab]}$ with b translated copies $B^{[a]}, a + B^{[a]}, \dots, (b-1)a + B^{[a]}$ of $B^{[a]}$ before computing the $[a]$ -projection. In fact, the following lemma seems to be a characteristic property of modular arithmetic on sets.

► **Lemma 9.** For all numbers $a, b \in \mathbb{Z}_{\geq 1}$ and sets $A, B \subseteq \mathbb{Z}$ it holds

$$A^{[a]} \cap B^{[a]} = \left(A^{[ab]} \cap \bigcup_{i=0}^{b-1} (ia + B^{[a]}) \right)^{[a]}.$$

Proof. Let x be a number. Then it holds

$$\begin{aligned} x \in \left(A^{[ab]} \cap \bigcup_{i=0}^{b-1} (ia + B^{[a]}) \right)^{[a]} &\Leftrightarrow \exists y \in A^{[ab]} : y \in \bigcup_{i=0}^{b-1} (ia + B^{[a]}) \wedge x = y^{[a]} \\ &\Leftrightarrow \exists y \in A^{[ab]} : y^{[a]} \in B^{[a]} \wedge x = y^{[a]} \\ &\Leftrightarrow x \in A^{[a]} \cap B^{[a]} \end{aligned}$$

where the last equivalence follows from $(A^{[ab]})^{[a]} = A^{[a]}$. ◀

Since the right side can be written as the modular projection of a *union of intersections* we can find a sensible strengthening; in fact, for arbitrary sets X, M_0, \dots, M_{m-1} it holds that

$$\bigcup_{i=0}^{m-1} (X \cap M_i) = \bigcup_{i=0}^{m-1} (X \cap (M_i \setminus \bigcup_{j=0}^{i-1} (X \cap M_j))).$$

While the left-hand side may not, the right-hand side is always a *disjoint* union. Taking into account the modular projections this leads to the following corollary.

► **Corollary 10.** For all numbers $a, b \in \mathbb{Z}_{\geq 1}$ and sets $A, B \subseteq \mathbb{Z}$ it holds $A^{[a]} \cap B^{[a]} = (\bigcup_{i=0}^{b-1} D_i)^{[a]}$ where $D_i = A^{[ab]} \cap Y_i$ and $Y_i = ia + (B^{[a]} \setminus \bigcup_{j=0}^{i-1} D_j^{[a]})$ for all $i = 0, \dots, b-1$.

■ **Figure 4** An example of four required intervals to represent $R_{n-1}^{[a_{n-1}]} \cap R_n^{[a_n]}$ in Lemma 13.

We will use Corollary 10 to aggregate constraints in order to reduce the problem size. The following observation gives a first bound for the smallest feasible solution s_{\min} .

► **Observation 11.** *For feasible instances it holds that $s_{\min} \in R_n^{[a_n]}$.*

This is true since in the harmonic case $s_{\min} < \text{lcm}(a_1, \dots, a_n) = a_n$ due to Observation 3 which then implies that $s_{\min} = s_{\min}^{[a_n]} \in R_n^{[a_n]}$ using Observation 2. Motivated by Observation 11 the idea is to search for s_{\min} in the modular projection $R_n^{[a_n]}$ by aggregating the penultimate constraint $n - 1$ into the last constraint n . In fact, the number of required intervals to represent both constraints can be bounded by a constant. A fine-grained construction then enforces the algorithm to efficiently iterate the feasibility test on aggregated instances to find the optimum value.

► **Theorem 12.** *For feasible instances s_{\min} can be computed in time $\mathcal{O}(n^3)$.*

Remark that the set of feasible solutions for the last two constraints is $S_{n-1} = R_{n-1}^{[a_{n-1}]} \cap (R_n^{[a_n]})^{[a_{n-1}]} = R_{n-1}^{[a_{n-1}]} \cap R_n^{[a_{n-1}]}$. Therefore, the next lemma states the crucial argument of the algorithm.

► **Lemma 13.** *The intersection $R_{n-1}^{[a_{n-1}]} \cap R_n^{[a_{n-1}]}$ can always be represented by the disjoint union $U \subseteq R_n^{[a_n]}$ of only constant many intervals in $R_n^{[a_n]}$ such that*

(a) $U^{[a_{n-1}]} = R_{n-1}^{[a_{n-1}]} \cap R_n^{[a_{n-1}]}$ and

(b) $u \equiv r \pmod{a_{n-1}}$ implies $u \leq r$ for all $u \in U$, $r \in R_n^{[a_n]}$.

Here the former property states that indeed the intervals in U are a proper representation for the last two constraints. The important property is the latter; in fact, it ensures that U is the best possible representation in the sense that U consists of the *smallest* intervals possible (see Figure 4).

Proof of Lemma 13. (a). By defining $D_i = Y_i \cap R_n^{[a_n]}$ and

$$Y_i = ia_{n-1} + (R_{n-1}^{[a_{n-1}]} \setminus \bigcup_{j=0}^{i-1} D_j^{[a_{n-1}]})$$

for all $i \in \{0, \dots, a_n/a_{n-1} - 1\}$ Corollary 10 proves the claim (cf. Figure 4). (b) follows by construction.

It remains to show that $\bigcup_i D_i$ is the union of only constant many disjoint intervals. Apparently, the intervals are disjoint by construction.

We claim that there are at most three non-empty sets D_i . Assume there are at least four non-empty translates D_i , namely D_i, D_j, D_k, D_ℓ . Then, since R_n is an interval it holds for at least two $p, q \in \{i, j, k, \ell\}$ that the *full interval translates* $F_p = [pa_{n-1}, (p+1)a_{n-1})$ and $F_q = [qa_{n-1}, (q+1)a_{n-1})$ are subsets of $R_n^{[a_n]}$. For p (and also for q) we get

$$D_p^{[a_{n-1}]} = \underbrace{(Y_p \cap R_n^{[a_n]})^{[a_{n-1}]}}_{\subseteq F_p} = Y_p^{[a_{n-1}]} = R_{n-1}^{[a_{n-1}]} \setminus \bigcup_{j=0}^{p-1} D_j^{[a_{n-1}]}$$

which implies with $\bigcup_{j=0}^{p-1} D_j^{[a_{n-1}]} \subseteq R_{n-1}^{[a_{n-1}]}$ that

$$\bigcup_{j=0}^p D_j^{[a_{n-1}]} = D_p^{[a_{n-1}]} \cup \bigcup_{j=0}^{p-1} D_j^{[a_{n-1}]} = R_{n-1}^{[a_{n-1}]}.$$

Then it follows $\bigcup_{j=0}^p D_j^{[a_{n-1}]} = R_{n-1}^{[a_{n-1}]} = \bigcup_{j=0}^q D_j^{[a_{n-1}]}$. W.l.o.g. let $p < q$. Then $D_q = Y_q \cap R_n^{[a_n]}$ is empty since

$$Y_q = qa_{n-1} + \left(R_{n-1}^{[a_{n-1}]} \setminus \bigcup_{j=0}^{q-1} D_j^{[a_{n-1}]} \right) \subseteq qa_{n-1} + \left(R_{n-1}^{[a_{n-1}]} \setminus R_{n-1}^{[a_{n-1}]} \right)$$

is empty and we have a contradiction.

Using the same case distinctions as in the proof of Lemma 4 one can show that each set D_i consist of at most two intervals. Therefore, all the non-empty sets D_i consist of at most $3 \cdot 2 = 6$ intervals in total. In fact, one can improve this bound to a total number of at most 4 intervals (see Figure 4) by a more sophisticated case distinction. ◀

This admits an algorithm using an aggregation argument as follows. For constraints n and $n - 1$ we use Lemma 13 to compute disjoint intervals $E_1, \dots, E_k \subseteq R_n^{[a_n]}$ (representing the constraints n and $n - 1$) where $k \leq C$ for a small constant C . If $k \geq 1$ then use Algorithm 1 to check the feasibility of the instances $\mathcal{I}_1, \dots, \mathcal{I}_k$ defined by

$$(\mathcal{I}_j) \quad \min \{ s \mid s^{[a_i]} \in R_i^{[a_i]} \forall i = 1, \dots, n-2, s^{[a_n]} \in E_j^{[a_n]}, s \in \mathbb{Z}_{\geq 0} \}.$$

If none of the instances $\mathcal{I}_1, \dots, \mathcal{I}_k$ admits a solution then the original instance can not be feasible. Assume that there is at least one feasible instance. Now, since E_1, \dots, E_k are disjoint exactly one of them contains the optimum value for s . W.l.o.g. assume that $E_1 < \dots < E_k$. Then there is a smallest index j such that \mathcal{I}_j is feasible and we solve \mathcal{I}_j recursively to find the optimum value. Together this yields an algorithm running in time $n \cdot C \cdot \mathcal{O}(n^2) = \mathcal{O}(n^3)$.

4 Uniprocessor Real-Time Scheduling

In real-time systems an important question is to ask for the *worst-case response time* of a task system. While the complexity is pseudo-polynomial in general [28], Nguyen et al. proposed a new algorithm [25] to compute it in polynomial time for preemptive sporadic tasks τ_1, \dots, τ_n with harmonic periods $T_i \geq 0$ and job processing times $C_i \geq 0$ running on a uniprocessor platform. The worst-case response time is the first point in time where $t = C_n + \sum_{i=1}^{n-1} C_i \cdot \lceil t/T_i \rceil$. Be aware that they assume the harmonic property in the opposite direction, i.e. $T_i/T_{i+1} \in \mathbb{Z}$. Their algorithm even allows the task execution to be delayed by some release jitter J_i . However, their algorithm depends on a heuristic component which may fail to compute correct solutions [25, Section 5.5, 6]. In fact, the fundamental computation problem can be expressed as a BMS instance which immediately implies a robust approach in time $\mathcal{O}(n^3)$ with our algorithm. Nevertheless, it can be solved even more efficiently in time $\mathcal{O}(n)$ which we describe here. The overall result will be the following theorem.

► **Theorem 14.** *The worst-case response time of a harmonic task real-time system with constrained release jitter can be computed in polynomial time.*

We adapt the notation of Nguyen et al. and extend it to our needs. The jobs of task τ_i have the processing time C_i and we define $c_i = \sum_{t=i+1}^{n-1} C_t$ to accumulate the last of them. The utilization of task τ_i is denoted by $U_i = C_i/T_i$ and it holds that $\sum_{t=1}^{n-1} U_t < 1$. In [25, Section 5.4.1] Nguyen et al. describe that also $x_1 = 1$ may be assumed. The system to solve (eq. (55), (56)) is described in [25, Section 5.5]:

$$\begin{aligned} \min \{ x_n \mid & J_i + T_i x_i \leq J_n + T_n x_n, \\ & J_n + T_n x_n - c_i \leq J_i + T_i x_i \quad \forall i \leq n-1 \} \end{aligned} \quad (2)$$

which can be formulated as the following BMS instance:

$$\min \left\{ x_n \mid \left\lceil \frac{J_i - J_n}{T_n} \right\rceil \leq x_n - \frac{T_i}{T_n} x_i \leq \left\lfloor \frac{J_i - J_n + c_i}{T_n} \right\rfloor \quad \forall i \leq n-1 \right\} \quad (3)$$

► **Lemma 15.** *If $i < j \leq n$ and $(c_i + c_j)/T_j < 1$ then in terms of variable x_i there is at most one feasible value for variable x_j .*

Proof. If $j < n$ then by combining the constraints for i and j in (2) we find

$$\begin{aligned} T_i x_i + J_i - J_n &\leq T_j x_j + J_j - J_n + c_j \quad \text{and} \\ T_j x_j + J_j - J_n &\leq T_i x_i + J_i - J_n + c_i \end{aligned}$$

which with the harmonic property and the integrality of x_j yields

$$\frac{T_i}{T_j} x_i + \left\lceil \frac{J_i - J_j - c_j}{T_j} \right\rceil \leq x_j \leq \frac{T_i}{T_j} x_i + \left\lfloor \frac{J_i - J_j + c_i}{T_j} \right\rfloor. \quad (4)$$

However, if $j = n$ then $c_j = \sum_{t=n+1}^{n-1} C_t = 0$ and thus (4) follows from (2) too (cf. (3)). Now by simply dropping the roundings we obtain in both cases that

$$\frac{T_i}{T_j} x_i + \left\lfloor \frac{J_i - J_j + c_i}{T_j} \right\rfloor - \left(\frac{T_i}{T_j} x_i + \left\lceil \frac{J_i - J_j - c_j}{T_j} \right\rceil \right) \leq \frac{c_i + c_j}{T_j} < 1$$

which proves the claim. ◀

According to (4) we define interval bounds $\ell_j^{(i)}(z)$ and $u_j^{(i)}(z)$ to denote the feasible values for variable x_j in terms of variable x_i where z states a value for variable x_i , i.e.

$$\ell_j^{(i)}(z) = \frac{T_i}{T_j} z + \left\lceil \frac{J_i - J_j - c_j}{T_j} \right\rceil \quad \text{and} \quad u_j^{(i)}(z) = \frac{T_i}{T_j} z + \left\lfloor \frac{J_i - J_j + c_i}{T_j} \right\rfloor.$$

Thus, (4) is equivalent to $x_j \in [\ell_j^{(i)}(x_i), u_j^{(i)}(x_i)]$ and if $(c_i + c_j)/T_j < 1$ then it either holds that $\ell_j^{(i)}(x_i) = x_j = u_j^{(i)}(x_i)$ or there is no solution at all.

Fortunately, there is always a sequence of variables such that the value of every next variable can be determined by the value of the current variable. The following lemma is crucial.

► **Lemma 16.** *If $i < n$ and $k = \max \{ t \leq n \mid T_{i+1} = T_t \}$ then there is at most one feasible value for variable x_k .*

39:12 Fuzzy Simultaneous Congruences

■ **Figure 5** The variable revealing flow with vertical lines between blocks of equal periods.

Proof. If $k < n - 1$ then it holds by the harmonic property and the maximality of k that $T_k \geq 2T_{k+1} \geq 2T_{k+2} \geq \dots \geq 2T_{n-1}$ and thus $T_t/T_k \leq 1/2$ for all $t = k + 1, \dots, n - 1$. Hence,

$$\frac{c_i + c_k}{T_k} = \sum_{t=i+1}^{n-1} U_t \frac{T_t}{T_k} + \sum_{t=k+1}^{n-1} U_t \frac{T_t}{T_k} = \sum_{t=i+1}^k U_t \underbrace{\frac{T_t}{T_k}}_{=1} + 2 \sum_{t=k+1}^{n-1} U_t \underbrace{\frac{T_t}{T_k}}_{\leq 1/2} \leq \sum_{t=i+1}^{n-1} U_t < 1.$$

If otherwise $k \geq n - 1$ then $c_k = 0$ and hence

$$\frac{c_i + c_k}{T_k} = \frac{c_i}{T_k} = \sum_{t=i+1}^{n-1} U_t \underbrace{\frac{T_t}{T_k}}_{=1} = \sum_{t=i+1}^{n-1} U_t < 1.$$

By Lemma 15 this proves the claim. ◀

This gives rise to the following algorithm. By iterating Lemma 16 and starting with $x_1 = 1$ we can reveal the last variable of each block of indices of equal periods (cf. Figure 5). Finally, this reveals the variable x_n and we only need to assure that the value of x_n admits feasible values for variables which are not revealed so far. Apparently we may restate the constraints of (2) as

$$\left\lfloor \frac{J_n - J_j - c_j + T_n x_n}{T_j} \right\rfloor \leq x_j \leq \left\lfloor \frac{J_n - J_j + T_n x_n}{T_j} \right\rfloor \quad \forall j = 1, \dots, n - 1.$$

Therefore, we can simply compare these bounds to assure the existence of a feasible value for each variable x_j . See Algorithm 2 for a formal description.

■ **Algorithm 2** Variable revealing flow.

```

procedure REVEAL
   $x_1 \leftarrow 1$ 
   $k \leftarrow 1$ 
  while  $k < n$  do
     $i \leftarrow k$ 
     $k \leftarrow \max \{ t \leq n \mid T_{i+1} = T_t \}$ 
    if  $\ell_k^{(i)}(x_i) \neq u_k^{(i)}(x_i)$  then
      return -1
    else
       $x_k \leftarrow \ell_k^{(i)}(x_i)$  ▷ Lemma 16
    for  $j = 1, \dots, n - 1$  do
      if  $\left\lfloor \frac{J_n - J_j - c_j + T_n x_n}{T_j} \right\rfloor > \left\lfloor \frac{J_n - J_j + T_n x_n}{T_j} \right\rfloor$  then ▷ no feasible solution for  $x_j$ 
      return -1
  return  $x_n$ 

```

► **Observation 17.** *By a more sophisticated investigation the number of index blocks of equal periods can be bounded by a constant and thus, the `while` loop reveals x_n in constant time. Therefore, the final feasibility test appears to be the only computational bottleneck.*

A Hardness of BMS

We reduce from DIRECTED DIOPHANTINE APPROXIMATION with *rounding down*. For any vector $v \in \mathbb{R}^n$ let $\lfloor v \rfloor$ denote the vector where each component is rounded down, i.e. $(\lfloor v \rfloor)_i = \lfloor v_i \rfloor$ for all $i \leq n$.

DIRECTED DIOPHANTINE APPROXIMATION with rounding down (DDA[↓])
 Given: $\alpha_1, \dots, \alpha_n \in \mathbb{Q}_+$, $N \in \mathbb{Z}_{\geq 1}$, $\varepsilon \in \mathbb{Q}$, $0 < \varepsilon < 1$
 Decide whether there is a $Q \in \{1, \dots, N\}$ such that $\|Q\alpha - \lfloor Q\alpha \rfloor\|_\infty \leq \varepsilon$.

Eisenbrand and Rothvoß proved that DDA[↓] is NP-hard [13]. In fact, every instance of DDA[↓] can be expressed as a BMS instance, which yields the following theorem.

► **Theorem 18.** BMS is NP-hard (even if $b_i = 0$ for all i with $a_i \neq 0$).

Proof. Write $\alpha_i = \beta_i/\gamma_i$ for integers $\beta_i \geq 0, \gamma_i \geq 1$ and set $\lambda = \prod_j \beta_j$. Then $\lambda/\alpha_i = (\lambda/\beta_i)\gamma_i \geq 0$ is integer. Let \mathcal{M} denote the following instance of BMS:

$$0 \leq Q' - (\lambda/\alpha_i) \cdot y_i \leq \lfloor (\lambda/\alpha_i) \cdot \varepsilon \rfloor \quad \forall i = 1, \dots, n \quad (5)$$

$$\lambda \leq Q' - 0 \cdot y_{n+1} \leq \lambda \cdot N \quad (6)$$

$$0 \leq Q' - \lambda \cdot y_{n+2} \leq 0 \quad (7)$$

$$Q', y_i \in \mathbb{Z} \quad \forall i = 1, \dots, n+2$$

■ **Figure 6** Examples for the cases of the case distinction in the proof of Lemma 4.

So let $Q \in \{1, \dots, N\}$ with $\|Q\alpha - \lfloor Q\alpha \rfloor\|_\infty \leq \varepsilon$ be given. We obtain readily that $Q' = \lambda Q$ and $y = (\lfloor Q\alpha_1 \rfloor, \dots, \lfloor Q\alpha_n \rfloor, 0, Q)$ defines a solution of \mathcal{M} since

$$0 \leq Q\alpha_i - \lfloor Q\alpha_i \rfloor \leq \varepsilon \quad \text{if and only if} \quad 0 \leq \underbrace{\lambda Q - (\lambda/\alpha_i) \cdot \lfloor Q\alpha_i \rfloor}_{\in \mathbb{Z}} \leq (\lambda/\alpha_i) \cdot \varepsilon.$$

Vice-versa let (Q', y) be a solution to \mathcal{M} . We see that (5) implies that

$$0 \leq Q' - (\lambda/\alpha_i) \cdot y_i \leq \lfloor (\lambda/\alpha_i) \cdot \varepsilon \rfloor \leq (\lambda/\alpha_i) \cdot \varepsilon$$

and by (7) we get $Q' = \lambda \cdot y_{n+2}$ which then implies $0 \leq y_{n+2}\alpha_i - y_i \leq \varepsilon < 1$ for all $i \leq n$. Now, since y_i is integer, there can be only one value for y_i , i.e. $y_i = \lfloor y_{n+2}\alpha_i \rfloor$. By $Q' = \lambda \cdot y_{n+2}$ and (6) we get $y_{n+2} \in \{1, \dots, N\}$ and by setting $Q = y_{n+2}$ this yields $\|Q\alpha - \lfloor Q\alpha \rfloor\|_\infty \leq \varepsilon$ and that proves the claim. ◀

B Omitted proofs

Proof of Lemma 4. We do a case distinction (see Figure 6) as follows. We only look at the non-trivial case, i.e. $v^{[\alpha]} \cap w^{[\alpha]} \notin \{\emptyset, v^{[\alpha]}, w^{[\alpha]}\}$, which especially implies $|v| < \alpha$ and $|w| < \alpha$.

We start with the case that neither $v^{[\alpha]}$ nor $w^{[\alpha]}$ is an interval, i.e. $u_v^{[\alpha]} < \ell_v^{[\alpha]}$ and $u_w^{[\alpha]} < \ell_w^{[\alpha]}$. Then it cannot be that $u_w^{[\alpha]} \geq \ell_v^{[\alpha]}$ and $u_v^{[\alpha]} \geq \ell_w^{[\alpha]}$ since that implies $\ell_v^{[\alpha]} \leq u_w^{[\alpha]} < \ell_w^{[\alpha]} \leq u_v^{[\alpha]}$. Hence, there are three cases as follows.

CASE 1.1. $u_w^{[\alpha]} < \ell_v^{[\alpha]}$ and $u_v^{[\alpha]} < \ell_w^{[\alpha]}$. Then the intersection equals

$$\begin{aligned} [0, \min\{u_v^{[\alpha]}, u_w^{[\alpha]}\}] \cup [\max\{\ell_v^{[\alpha]}, \ell_w^{[\alpha]}\}, \alpha] &= [\max\{\ell_v^{[\alpha]}, \ell_w^{[\alpha]}\}, \alpha + \min\{u_v^{[\alpha]}, u_w^{[\alpha]}\}]^{[\alpha]} \\ &= \psi_\alpha(v, w)^{[\alpha]}. \end{aligned}$$

CASE 1.2. $u_w^{[\alpha]} \geq \ell_v^{[\alpha]}$ and $u_v^{[\alpha]} < \ell_w^{[\alpha]}$. Then the intersection equals

$$[0, u_v^{[\alpha]}] \cup [\ell_v^{[\alpha]}, u_w^{[\alpha]}] \cup [\ell_w^{[\alpha]}, \alpha] = [\ell_v^{[\alpha]}, u_w^{[\alpha]}] \cup [\ell_w^{[\alpha]}, \alpha + u_v^{[\alpha]}]^{[\alpha]} = \varphi_\alpha(v, w) \cup \psi_\alpha(v, w)^{[\alpha]}.$$

CASE 1.3. $u_w^{[\alpha]} < \ell_v^{[\alpha]}$ and $u_v^{[\alpha]} \geq \ell_w^{[\alpha]}$. By symmetry we get $v^{[\alpha]} \cap w^{[\alpha]} = \varphi_\alpha(w, v) \cup \psi_\alpha(v, w)^{[\alpha]}$.

Now, w.l.o.g. assume that $v^{[\alpha]}$ is an interval, i.e. $\ell_v^{[\alpha]} \leq u_v^{[\alpha]}$, while $w^{[\alpha]}$ consists of two intervals, i.e. $u_w^{[\alpha]} < \ell_w^{[\alpha]}$. Then there are three cases as follows.

39:16 Fuzzy Simultaneous Congruences

CASE 2.1. $\ell_v^{[\alpha]} \leq u_w^{[\alpha]} < u_v^{[\alpha]} < \ell_w^{[\alpha]}$. Then the intersection equals $[\ell_v^{[\alpha]}, u_w^{[\alpha]}] = \varphi_\alpha(v, w)$.

CASE 2.2. $u_w^{[\alpha]} < \ell_v^{[\alpha]} < \ell_w^{[\alpha]} \leq u_v^{[\alpha]}$. Then the intersection equals $[\ell_w^{[\alpha]}, u_v^{[\alpha]}] = \varphi_\alpha(w, v)$.

CASE 2.3. $\ell_v^{[\alpha]} \leq u_w^{[\alpha]} < \ell_w^{[\alpha]} \leq u_v^{[\alpha]}$. Then the intersection is

$$[\ell_v^{[\alpha]}, u_w^{[\alpha]}] \dot{\cup} [\ell_w^{[\alpha]}, u_v^{[\alpha]}] = \varphi_\alpha(v, w) \dot{\cup} \varphi_\alpha(w, v).$$

Clearly, if both $v^{[\alpha]}$ and $w^{[\alpha]}$ are intervals (CASE 3) (which are not disjoint) then their intersection is either $\varphi_\alpha(v, w)$ or $\varphi_\alpha(w, v)$. ◀

Pebble Transducers with Unary Output

Gaëtan Douéneau-Tabot ✉

IRIF, Université de Paris, France

Abstract

Bojańczyk recently initiated an intensive study of deterministic pebble transducers, which are two-way automata that can drop marks (named “pebbles”) on their input word, and produce an output word. They describe functions from words to words. Two natural restrictions of this definition have been investigated: marble transducers by Douéneau-Tabot et al., and comparison-free pebble transducers (that we rename here “blind transducers”) by Nguyen et al.

Here, we study the decidability of membership problems between the classes of functions computed by pebble, marble and blind transducers that produce a unary output. First, we show that pebble and marble transducers have the same expressive power when the outputs are unary (which is false over non-unary outputs). Then, we characterize 1-pebble transducers with unary output that describe a function computable by a blind transducer, and show that the membership problem is decidable. These results can be interpreted in terms of automated simplification of programs.

1 Introduction

Regular languages can be described by several models such as deterministic, non-deterministic, or two-way (the reading head can move in two directions) finite automata [12]. A natural extension consists in adding an output mechanism to finite automata. Such machines, called *transducers*, describe functions from words to words (or relations when non-deterministic) and provide a natural way to model simple programs that produce outputs. The particular model of a *two-way transducer* consists in a two-way automaton enhanced with an output function. It describes the class of *regular functions* which has been intensively studied for its fundamental properties: closure under composition [5], logical characterization by monadic second-order transductions [7], decidable equivalence problem [9], etc.

Pebble transducers and their variants. The model of k -pebble transducer can be defined as an inductive extension of two-way transducers. A 0-pebble transducer is just a two-way transducer. For $k \geq 1$, a k -pebble transducer \mathcal{T} is a two-way transducer that, when in a given configuration, can “call” an *external function* f , computed by some $(k-1)$ -pebble transducer. \mathcal{T} gives as argument to f its input word together with a mark, named “pebble”, on the position from which the call was performed, and uses the output of f within its own output.

The behavior of a 1-pebble transducer is depicted in Figure 1. Intuitively, a k -pebble transducer is some recursive program whose recursion depth is at most $k+1$. Equivalently, it can be seen as an iterative algorithm with “two-way for-loops”, such that the maximal depth of nested loops is $k+1$. A k -pebble transducer can only produce an output whose

length is polynomial in its input's length, more precisely $\mathcal{O}(n^{k+1})$ when n is the input's length (this is intuitive from the “nested loops” point of view). The functions computed by a k -pebble transducer for some $k \geq 0$ are thus called *polyregular functions* [3]. Several properties of polyregular functions have been investigated: closure under composition [3], logical characterization by monadic second-order interpretations [4], etc. The equivalence problem (given two machines, do they compute the same function?) is however still open.

■ **Figure 1** Behavior of a 1-pebble transducer.

Recently, two natural restrictions of pebble transducers have been introduced. First, the *k-marble transducers* of [6] only give as argument to their external function the prefix of the input word which ends in the calling position (see Figure 4). Second, the *k-blind transducers*¹ of [11] give the whole input word, but no pebble on the calling position (see Figure 3). The classes of functions they compute are strict subclasses of polyregular functions [6, 11].

Class membership problems. These various models of transducers raise several membership problems: given a function computed by a machine of model X , can it be computed by some machine of model Y ? When Y is a restriction of X , this problem reformulates as a program optimization question: given a “complex” algorithm in a class X , can we build an equivalent “simpler” one in class Y ? Thus it is of a foremost interest in practice.

Given a function f computed by an ℓ -pebble transducer, one can ask whether it is computable by a k -pebble transducer for a given $k < \ell$. The problem is decidable [10], and it turns out that a necessary and sufficient condition for this membership is that $|f(w)| = \mathcal{O}(|w|^{k+1})$. Using the “nested loops” interpretation of pebble transducers, it means that an output of size $\mathcal{O}(|w|^{k+1})$ can always be produced with at most $k+1$ nested loops. Similar results have been obtained in [6] and [11] for their variants, with the same conclusion: an output of size $\mathcal{O}(|w|^{k+1})$ can always be produced with depth at most $k+1$.

Contributions. In this paper, we study a different membership problem: can a function given by a k -pebble transducer be computed by a k -marble or k -blind transducer? It turns out to be a more difficult question, since there is no intuitive and machine-independent candidate for a membership condition (such as the size of the output). In general, membership problems for transducers are difficult, since contrary to regular languages, there is no “canonical” object known to represent a regular function. Hence, there can be several seemingly unrelated manners to produce the same function, and moving from one to another can be technical.

We focus on *transducers whose output alphabet is unary*, and our proof techniques are new. The first main result is that (when the outputs are unary) k -pebble transducers and k -marble transducers compute the same functions (one direction is obvious since k -marble is a restriction of k -pebble). The transformation is effective, but the way of producing the output must sometimes be completely modified (the transformation modifies the *origin semantics*, in the sense of [2]), which creates an additional difficulty. The correspondence fails as soon as the output is not over a unary alphabet, as detailed in Example 1.

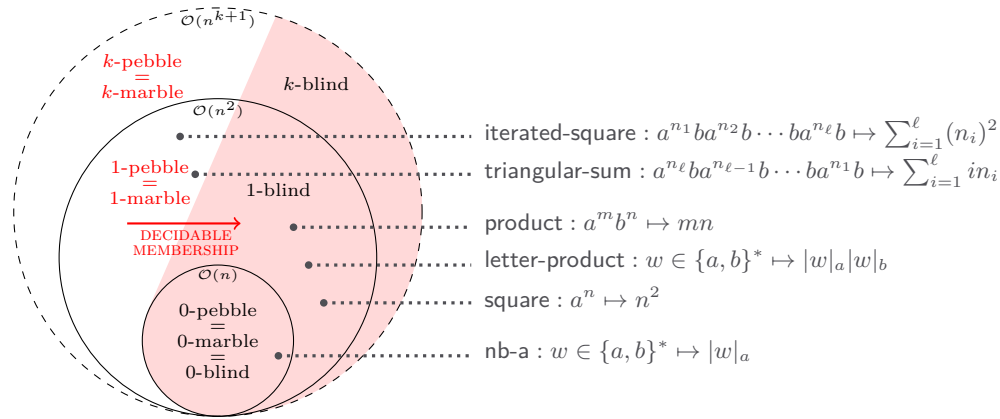

¹ The original terminology of [11] is *comparison-free pebble transducers*, but we strongly believe that the term “blind” is more adapted, since there are no pebbles in this model.

► **Example 1** ([6, 11]). The partial function $\{a, b\}^* \rightarrow \{a, b\}^*, a^m b^n \mapsto (b^n a)^m$ can be computed by a 1-pebble transducer, but not by a k -marble for any $k \geq 0$.

Since the equivalence problem is decidable for marble transducers, it follows from our result that it is also decidable for pebble transducers with unary output.

As a second main result, we show how to decide (when the outputs are unary) whether a function given by 1-pebble (\equiv 1-marble) transducer can be computed by a 1-blind transducer, or more generally by a k -blind transducer for some $k \geq 0$. The technical proof also gives a syntactical characterization of 1-marble transducers whose function verify this property: it describes a kind of “symmetry” in the production of the machine on its input. Furthermore, the conversion is effective when possible, but once more the manner of producing the output can be strongly modified. Our techniques heavily rely on the theory of *factorization forests*; this is, to our knowledge, the first time this notion is used for membership problems of transducers, and we believe this approach to be fruitful.

Our results are summarized in red in Figure 2. We also give some examples of functions (their outputs are non-negative integers, since we identify $\{a\}^*$ with \mathbb{N}).

■ **Figure 2** Classes of functions with unary output and results of this paper.

Outline. We first recall in Section 2 the definitions of k -pebble, k -marble and k -blind transducers, simplified for the case of unary outputs. In Section 3, we define the notions of k -pebble, k -marble and k -blind bimachines, and show their equivalence with the transducer models. Bimachines are easier to handle in the proofs, due to the fact that they avoid two-way moves. In Section 4, we show that k -marble and k -pebble transducers are equivalent. Finally, we solve in Section 5 the class membership problem from 1-pebble to 1-blind. Due to space constraints, several proofs are sketched in the main paper, and we focus on the most significant lemmas and characterizations.

2 Preliminaries

\mathbb{N} is the set of nonnegative integers. If $0 \leq i \leq j$, the set $[i:j]$ denotes $\{i, i+1, \dots, j\} \subseteq \mathbb{N}$ (empty if $j < i$). Capital letters A, B denote finite sets of letters (alphabets). The empty word is denoted ε . If $w \in A^*$, let $|w| \in \mathbb{N}$ be its length, and for $1 \leq i \leq |w|$ let $w[i]$ be its i -th letter. If $I = \{i_1 < \dots < i_\ell\} \subseteq \{1, \dots, |w|\}$, let $w[I] := w[i_1] \dots w[i_\ell]$. If $a \in A$, we denote by $|w|_a$ the number of letters a occurring in w . Given $A = \{a, \dots\}$, let $\underline{A} := \{\underline{a}, \dots\}$ be a

disjoint copy of A . For $1 \leq i \leq |w|$, we define $w \uparrow i := w[1:i-1] \underline{w[i]} w[i+1:|w|]$ as “ w in which position i is underlined”. We assume that the reader is familiar with the basics of automata theory, in particular the notion of two-way deterministic automaton.

Two-way transducers. A deterministic two-way transducer is a deterministic two-way automaton enhanced with the ability to produce outputs along its run. The class of functions described by these machines is known as *regular functions* [5, 7].

- **Definition 2.** A (deterministic) two-way transducer $(A, B, Q, q_0, F, \delta, \lambda)$ is:
- an input alphabet A and an output alphabet B ;
 - a finite set of states Q with an initial state $q_0 \in Q$ and a set $F \subseteq Q$ of final states;
 - a (partial) transition function $\delta : Q \times (A \uplus \{\vdash, \dashv\}) \rightarrow Q \times \{\triangleleft, \triangleright\}$;
 - a (partial) output function $\lambda : Q \times (A \uplus \{\vdash, \dashv\}) \rightarrow B^*$ with same domain as δ .

When given as input a word $w \in A^*$, the two-way transducer disposes of a read-only input tape containing $\vdash w \dashv$. The marks \vdash and \dashv are used to detect the borders of the tape, by convention we denote them as positions 0 and $|w|+1$ of w . Formally, a *configuration* over $\vdash w \dashv$ is a tuple (q, i) where $q \in Q$ is the current state and $0 \leq i \leq |w|+1$ is the position of the reading head. The *transition relation* \rightarrow is defined as follows. Given a configuration (q, i) , let $(q', \star) := \delta(q, w[i])$. Then $(q, i) \rightarrow (q', i')$ whenever either $\star = \triangleleft$ and $i' = i - 1$ (move left), or $\star = \triangleright$ and $i' = i + 1$ (move right), with $0 \leq i' \leq |w|+1$. A *run* is a sequence of configurations $(q_1, i_1) \rightarrow \dots \rightarrow (q_n, i_n)$. Accepting runs are those that begin in $(q_0, 0)$ and end in a configuration of the form $(q, |w|+1)$ with $q \in F$ (and it never visits such a configuration before). The function $f : A^* \rightarrow B^*$ computed by the machine is defined as follows. Let $w \in A^*$, if there exists an accepting run on $\vdash w \dashv$, then $f(w)$ is the concatenation of the $\lambda(q, w[i])$ along this unique run on $\vdash w \dashv$. To make f a total function, we let $f(w) := \varepsilon$ if there is no accepting run (the language of words having an accepting run in a two-way transducer is regular [12], hence the domain does not matter).

- **Example 3.** $\text{reverse} : A^* \rightarrow A^*$, $abac \mapsto caba$ can be computed by a two-way transducer.

From now on, the output alphabet of the machines will always be a singleton. Up to identifying $\{a\}^*$ and \mathbb{N} , we assume that $\lambda : Q \times (A \uplus \{\vdash, \dashv\}) \rightarrow \mathbb{N}$ and $f : A^* \rightarrow \mathbb{N}$.

External functions. We now extend the notion of output function λ : it will not give directly an integer, but performs a call to an *external function* which returns an integer. For pebbles, the output of the external functions depends on the input word and the current position.

- **Definition 4.** A two-way transducer with external pebble functions $(A, Q, q_0, F, \delta, \mathfrak{F}, \lambda)$ is:
- an input alphabet A ;
 - a finite set of states Q with an initial state $q_0 \in Q$ and a set $F \subseteq Q$ of final states;
 - a (partial) transition function $\delta : Q \times (A \uplus \{\vdash, \dashv\}) \rightarrow Q \times \{\triangleleft, \triangleright\}$;
 - a finite set \mathfrak{F} of external functions $\mathfrak{f} : (A \uplus \underline{A})^* \rightarrow \mathbb{N}$;
 - a (partial) output function $\lambda : Q \times (A \uplus \{\vdash, \dashv\}) \rightarrow \mathfrak{F}$ with same domain as δ .

Configurations (q, i) and runs of two-way transducers with external functions are defined as for classical two-way transducers. The function $f : A^* \rightarrow \mathbb{N}$ computed by the machine is defined as follows. Let $w \in A^*$ such that there exists an accepting run on $\vdash w \dashv$. If $\lambda(q, w[i]) = \mathfrak{f} \in \mathfrak{F}$, we let $\nu(q, i) := \mathfrak{f}(w \uparrow i)$, that is the result of \mathfrak{f} applied to w marked in i . Finally, $f(w)$ is defined as the sum of the $\nu(q, i)$ along this unique accepting run on $\vdash w \dashv$. We similarly set $f(w) = 0$ if there is no accepting run.

► Remark 5. If the external functions are constant, we exactly have a two-way transducer.

► Example 6. Let $a, b \in A$, $f_b : w \in (A \uplus \underline{A})^* \mapsto |w|_b$ and $f_0 : w \in (A \uplus \underline{A})^* \mapsto 0$. The two-way transducer with external pebble functions, which makes a single pass on its input and calls f_b if reading a and f_0 otherwise, computes **letter-product** : $w \in A \mapsto |w|_a|w|_b$.

We define two other models. Their definition is nearly the same, except that the external functions of \mathfrak{F} have type $A^* \rightarrow \mathbb{N}$ and $\nu(q, i)$ is defined in a slightly different way:

- in a *two-way transducer with external blind functions*, we define $\nu(q, i) := f(w)$. The external function is applied to w without marking the current position;
- in a *two-way transducer with external marble functions*, we define $\nu(q, i) := f(w[1:i])$. The external function is applied to the prefix of w stopping at the current position.

Pebble, blind and marble transducers. We now describe the transducer models using the formalism of external functions. These are not the original definitions from [3, 6, 11] (we are closer to the nested transducers of [10]), but the correspondence is straightforward, as soon as we know that pebble automata can only recognize regular languages.

► Definition 7. For $k \geq 0$, a k -pebble (resp. k -blind, k -marble) transducer is:

- if $k = 0$, a two-way transducer;
- if $k \geq 1$, a two-way transducer with external pebble (resp. blind, marble) functions that are computed by $(k-1)$ -pebble (resp. $(k-1)$ -blind, $(k-1)$ -marble) transducers.

The intuitive behavior of a 1-pebble transducer is depicted in Figure 1 in Introduction. We draw in Figure 3 the behavior of a 1-blind transducer, which is the same except that the calling position is not marked for the machine computing the external function.

■ Figure 3 Behavior of a 1-blind transducer.

■ Figure 4 Behavior of a 1-marble transducer.

► Example 8. By restricting the functions f_b and f_0 of Example 6 to A^* , we see that **letter-product** : $w \in A^* \mapsto |w|_a|w|_b$ can be computed by a 1-blind transducer.

The intuitive behavior of a 1-marble transducer is depicted in Figure 4.

► Example 9. The function **letter-product** : $w \in A^* \mapsto |w|_a|w|_b$ can be computed by a 1-marble transducer as follows. Assume that $a \neq b$, let $f_a : w \mapsto |w|_a$ and $f_b : w \mapsto |w|_b$. The machine calls f_b when reading a and f_a when reading b . This way, each a is “counted” $|w|_b$ times (from the call of f_b starting in this a which computes all the b before it, plus each time it is seen in a call of f_a starting from some b after this a).

The strategy for computing letter-product is really different between Examples 8 and 9. This illustrates the difficulty to obtain a “canonical” form for a transduction.

3 From two-way transducers to bimachines

Since we consider a commutative output monoid, the order in which the production is performed does not matter. It is thus tempting to simplify a two-way transducer in a one-way machine which visits each position only once. This is exactly what we do with bimachines, with the subtlety that they are able to check regular properties of the prefix (resp. suffix) starting (resp. ending) in the current position. From now on, we consider only total functions of type $A^+ \rightarrow \mathbb{N}$ (the output on ε can be treated separately and does not matter).

- **Definition 10.** A bimachine with external pebble functions $(A, M, \mu, \mathfrak{F}, \lambda)$ consists of:
- an input alphabet A ;
 - a morphism into a finite monoid $\mu : A^* \rightarrow M$;
 - a finite set \mathfrak{F} of external functions $\mathfrak{f} : (A \uplus \underline{A})^+ \rightarrow \mathbb{N}$;
 - a total output function $\lambda : M \times A \times M \rightarrow \mathfrak{F}$.

Given $1 \leq i \leq |w|$ a position of $w \in A^*$, let $\mathfrak{f}_i := \lambda(\mu(w[1:i-1]), w[i], \mu(w[i+1:|w|])) \in \mathfrak{F}$. The bimachine defines a function $f : A^+ \rightarrow \mathbb{N}$ as follows:

$$f(w) := \sum_{1 \leq i \leq |w|} \mathfrak{f}_i(w \uparrow i).$$

As before, we can define *bimachines with external blind* (resp. *marble*) functions (in this case we have $\mathfrak{f}_i : A^+ \rightarrow \mathbb{N}$). We then let:

$$f(w) := \sum_{1 \leq i \leq |w|} \mathfrak{f}_i(w) \left(\text{resp. } f(w) := \sum_{1 \leq i \leq |w|} \mathfrak{f}_i(w[1:i]) \right).$$

As for two-way transducers, we define bimachines (without external functions) by setting $\lambda : M \times A \times M \rightarrow \mathbb{N}$. Equivalently, it corresponds to bimachines with external constant functions $\mathfrak{f} : w \mapsto n$. Going further, we define k -pebble bimachines by induction.

- **Definition 11.** For $k \geq 0$, a k -pebble (resp. k -blind, k -marble) bimachine is:
- if $k = 0$, a bimachine (without external functions);
 - if $k \geq 1$, a bimachine with external pebble (resp. blind, marble) functions which are computed by $(k-1)$ -pebble (resp. $(k-1)$ -blind, $(k-1)$ -marble) bimachines.

► **Example 12.** The function *triangular-sum* : $a^{n\ell} b a^{n\ell-1} b \dots b a^{n1} b \mapsto \sum_{i=1}^{\ell} i n_i$ can be computed by a 1-marble bimachine. It uses the singleton monoid $M = \{1_M\}$ and the morphism $\mu : a, b \mapsto 1_M$ in all its bimachines. The output function of the main bimachine is defined by $\lambda(1_M, a, 1_M) := \mathfrak{f}_a$ and $\lambda(1_M, b, 1_M) := \mathfrak{f}_b$. For computing $\mathfrak{f}_a : w \mapsto 0$ we use output $\lambda_{\mathfrak{f}_a}(1_M, a, 1_M) := 0$ and $\lambda_{\mathfrak{f}_a}(1_M, b, 1_M) := 0$, and for computing $\mathfrak{f}_b : w \mapsto |w|_a$ we use output $\lambda_{\mathfrak{f}_b}(1_M, a, 1_M) := 1$ and $\lambda_{\mathfrak{f}_b}(1_M, b, 1_M) := 0$.

Standard proof techniques allow to relate bimachines and transducers.

- **Proposition 13.** k -pebble (resp. k -blind, k -marble) bimachines and k -pebble (resp. k -blind, k -marble) transducers compute the same functions, and both conversions are effective.

Proof sketch. Both directions are treated by induction. From bimachines to transducers, we show that a bimachine with external pebble functions can be transformed in an equivalent two-way transducer with the same external pebble functions (we use a *lookaround* [7] to simulate μ). From transducers to bimachines, the induction step shows that a two-way transducer with external pebble functions can be transformed in an equivalent bimachine with external pebble functions, by adapting the classical reduction from two-way to one-way automata [12]. However the new external functions can be linear combinations of the former ones, since we produce “all at once” the results of several visits in a position. We only need to use a finite number of combinations, since in its accepting runs, a two-way transducer can only visit each position a bounded number of times. ◀

4 Equivalence between k -pebble and k -marble transducers

The main goal of this section is to show equivalence between k -pebble and k -marble transducers, over unary outputs. We shall use another model which is equivalent to marble transducers [6]: a *streaming string transducer (with unary output)*, which consists in a deterministic automaton with a finite set \mathfrak{X} of registers that store integers. At each letter read, the values of the registers are updated by doing a linear combination of their former values, whose coefficients depend on the current state of the automaton. In our definition we focus on the registers and forget about the states, which corresponds to a weighted automaton over the semiring $(\mathbb{N}, +, \times)$ (it is shown in [6] that both models are equivalent). The update is represented by a matrix from $\mathbb{N}^{\mathfrak{X} \times \mathfrak{X}}$, which is chosen depending on the letter read.

► **Definition 14.** A streaming string transducer (SST) $\mathcal{T} = (A, \mathfrak{X}, I, T, F)$ is:

- an input alphabet A and a finite set \mathfrak{X} of registers;
- an initial row vector $I \in \mathbb{N}^{\mathfrak{X}}$;
- a register update function $T : A \rightarrow \mathbb{N}^{\mathfrak{X} \times \mathfrak{X}}$;
- an output column vector $F \in \mathbb{N}^{\mathfrak{X}}$.

T can be extended as a monoid morphism from A^* to $(\mathbb{N}^{\mathfrak{X} \times \mathfrak{X}}, \times)$. Given $w \in A^*$, the vector $IT(w)$ intuitively describes the values of the registers after reading w . To define the function $f : A^* \rightarrow \mathbb{N}$ computed by \mathcal{T} , we combine these values by the output vector:

$$f(w) := IT(w)F.$$

► **Example 15.** The function *triangular-sum* : $a^{n_\ell} b a^{n_{\ell-1}} b \cdots b a^{n_1} b \mapsto \sum_{i=1}^{\ell} i n_i$ can be computed by an SST. We use two registers x, y and allow constants in the updates for more readability: x is initialized to 0 and updated $x \leftarrow x + 1$ on a and $x \leftarrow x$ on b , and y is initialized to 0 and updated $y \leftarrow y$ on a and $y \leftarrow y + x$ on b . Finally we output y .

We are now ready to state the main results of this section.

► **Theorem 16.** Given a k -pebble bimachine, one can build an equivalent SST.

The proof is done by induction on $k \geq 0$. Consider a bimachine whose external functions are computed by $(k-1)$ -pebble bimachines. By hypothesis, we can compute these functions by SSTs. The induction step is shown by Lemma 17, which uses new proof techniques.

► **Lemma 17.** Given a bimachine with external pebble functions computed by SSTs, one can build an equivalent SST (with no external functions).

Proof idea. Let \mathcal{T} be the SST computing an external function f . On input $w \in A^+$, the bimachine calls f on several positions $1 \leq i_1 < \dots < i_\ell \leq |w|$, which induces executions of \mathcal{T} on $w \uparrow i_1, \dots, w \uparrow i_\ell$. These executions are very similar: they only differ when reading the marked letter. Thus we build an SST which computes “simultaneously” all these executions, by keeping track of the sum of the values of the registers of \mathcal{T} along them. \blacktriangleleft

As a consequence of Theorem 16, we obtain equivalence between pebbles and marbles over unary outputs. The result is false over non-unary output alphabets [6, 11]. We also relate these functions with those computed by SST, assuming that the output is bounded by a polynomial in the input’s length.

► **Corollary 18.** *For all $k \geq 0$ and $f : A^* \rightarrow \mathbb{N}$, the following conditions are equivalent:*

1. f is computable by a k -pebble transducer;
2. f is computable by a k -marble transducer;
3. f is computable by an SST and $f(w) = \mathcal{O}(|w|^{k+1})$.

Furthermore the transformations are effective.

Proof. Clearly a k -pebble transducer can simulate a k -marble transducer, hence $2 \Rightarrow 1$. Let f be computed by a k -pebble transducer, we have $f(w) = \mathcal{O}(|w|^{k+1})$ and by Theorem 16 one can build an SST for f . Thus $1 \Rightarrow 3$. Finally $3 \Rightarrow 2$ is shown in [6]. \blacktriangleleft

Another important consequence is that we can decide equivalence of pebble transducers with unary output, since we can do so for marble transducers [6].

► **Corollary 19.** *One can decide if two pebble transducers compute the same function.*

This has been an open question since [3], and it is still open for generic output alphabets.

5 Deciding if 1-pebble is 1-blind

Since the equivalence between marbles and pebbles is established, we now compare 1-pebble (which are 1-marble) transducers with 1-blind transducers. It turns out that 1-pebble are strictly more expressive; the main goal of this section is to show Theorem 20.

► **Theorem 20 (Membership).** *One can decide if a function given by a 1-marble (or 1-pebble) transducer can be computed by a k -blind transducer for some $k \geq 0$. If this condition holds, one can build a 1-blind transducer which computes it.*

Let us fix a function $f : A^+ \rightarrow \mathbb{N}$ described by a 1-marble bimachine $\mathcal{T} = (A, M, \mu, \mathfrak{F}, \lambda)$. For $f \in \mathfrak{F}$, let $\mathcal{T}_f := (A, M, \mu, \lambda_f)$ be the bimachine which computes it. We enforce the morphism μ to be surjective (up to considering the co-restriction to its image) and the same in all machines (up to taking the product of all morphisms used). Our goal is to give a decidable condition on \mathcal{T} for f to be computable by a 1-blind transducer. For this purpose, we define the notion of *bitype*. Intuitively, it describes two disjoint factors in an input word, together with a finite abstraction of their “context”.

Let $\Lambda := 3|M|$ (it will be justified by Theorem 27).

► **Definition 21.** *A bitype $\Phi := m \langle \mathbf{u}_1 \rangle m' \langle \mathbf{u}_2 \rangle m''$ consists in $m, m', m'' \in M$, $\mathbf{u}_1, \mathbf{u}_2 \in A^+$.*

We can define “the production performed in \mathbf{u}_1 by the calls from \mathbf{u}_2 ”, in Φ . For $1 \leq i \leq |\mathbf{u}_1|$ and $1 \leq j \leq |\mathbf{u}_2|$, let $\Phi(i, j) := \lambda_{f_j}(m\mu(\mathbf{u}_1[1:i-1]), \mathbf{u}_1[i], \mu(\mathbf{u}_1[i+1:|\mathbf{u}_1|]))m'\mu(\mathbf{u}_2[1:j])) \in \mathbb{N}$ where $f_j := \lambda(m\mu(\mathbf{u}_1)m'\mu(\mathbf{u}_2[1:j-1]), \mathbf{u}_2[j], \mu(\mathbf{u}_2[j+1:|\mathbf{u}_2|]))m''$). Then we set:

$$\text{prod}(m \langle \mathbf{u}_1 \rangle m' \langle \mathbf{u}_2 \rangle m'') := \sum_{\substack{1 \leq i \leq |\mathbf{u}_1| \\ 1 \leq j \leq |\mathbf{u}_2|}} \Phi(i, j) \in \mathbb{N}.$$

► **Definition 22.** The 1-marble bimachine \mathcal{T} is symmetrical whenever $\forall m, n, m_1, n_1, m_2, n_2 \in M$ and $u_1, u_2 \in A^+$ such that $|u_1|, |u_2| \leq 2^\Lambda$, $e_1 := \mu(u_1)$, $e_2 := \mu(u_2)$ and $e := m_1 e_1 n_1 = m_2 e_2 n_2$ are idempotents, there exists $K \geq 0$ such that $\forall p \in M$:

- if $m_1 e_1 p e_2 n_2 = e$, $e m_1 e_1 p e_2 = e m_2 e_2$ and $e_1 p e_2 n_2 e = e_1 n_1 e$, then $\text{prod}(m e m_1 e_1 \langle u_1 \rangle e_1 p e_2 \langle u_2 \rangle e_2 n_2 e n) = K$;
- if $m_2 e_2 p e_1 n_1 = e$, $e m_2 e_2 p e_1 = e m_1 e_1$ and $e_2 p e_1 n_1 e = e_2 n_2 e$, then $\text{prod}(m e m_2 e_2 \langle u_2 \rangle e_2 p e_1 \langle u_1 \rangle e_1 n_1 e n) = K$.

(a) Bitype $m e m_1 e_1 \langle u_1 \rangle e_1 p e_2 \langle u_2 \rangle e_2 n_2 e n$.

(b) Bitype $m e m_2 e_2 \langle u_2 \rangle e_2 p e_1 \langle u_1 \rangle e_1 n_1 e n$

■ **Figure 5** The bitypes used to define a symmetrical 1-marble bimachine.

Symmetry means that, under some idempotent conditions, $\text{prod}(m \langle u_1 \rangle m' \langle u_2 \rangle m'')$ only depends on $m, m'', m' \mu(u_2) m''$ and $m \mu(u_1) m'$, that are the “contexts” of u_1 and u_2 , but not on the element m' which separates them. The same holds if we swap u_1 and u_2 . The bitypes considered in Definition 22 are depicted in Figure 5, together with the equations they satisfy.

Symmetry is the decidable condition we are looking for, as shown in Theorem 23. Recall that f is the function computed by the 1-marble bimachine \mathcal{T} .

► **Theorem 23 (Characterization).** The following conditions are equivalent:

1. f is computable by a k -blind transducer for some $k \geq 0$;
2. f is computable by a 1-blind transducer;
3. \mathcal{T} is symmetrical.

Theorem 20 follows from Theorem 23, since it suffices to check whether the machine is symmetrical, which can be decided by ranging over all monoid elements (including idempotents) and words of length at most 2^Λ .

► **Example 24.** Let us show that the bimachine of Example 12 computing triangular-sum is not symmetrical. Let $u_1 := a$, $u_2 := b$, $m, n, m_1, n_1, m_2, n_2, p, e = 1_M$, $e_1 := \mu(u_1) = 1_M$ and $e_2 := \mu(u_2) = 1_M$. Then $\text{prod}(m e m_1 e_1 \langle u_1 \rangle e_1 p e_2 \langle u_2 \rangle e_2 n_2 e n) = \text{prod}(1_M \langle a \rangle 1_M \langle b \rangle 1_M) = 1$ and $\text{prod}(m e m_2 e_2 \langle u_2 \rangle e_2 p e_1 \langle u_1 \rangle e_1 n_1 e n) = \text{prod}(1_M \langle b \rangle 1_M \langle a \rangle 1_M) = 0$. Furthermore the equations of Definition 22 hold, thus triangular-sum is not computable by a k -blind bimachine.

Lemma 25 shows $1 \Rightarrow 3$ in Theorem 23. It allows to show that some function cannot be computed by a k -marble transducer. Its proof is technical; a coarse intuition is that a 1-blind bimachine which makes a production on u_1 when called from u_2 cannot see the monoid element m' between u_1 and u_2 (since u_2 is not marked, its position is “forgotten”).

► **Lemma 25.** If f is computable by a k -blind bimachine, then \mathcal{T} is symmetrical.

Since $2 \Rightarrow 1$ in Theorem 23 is obvious, it remains to show that if \mathcal{T} is symmetrical, then f is effectively computable by a 1-blind bimachine. This is the goal of the two following subsections. The main tool for the proof is the notion of factorization forest: using Lemma 36, it allows us to compute the function f without directly referring to a machine.

5.1 Factorization forests

Recall that $\mu : A^+ \rightarrow M$ is a fixed monoid morphism. A *factorization forest* [1] of $w \in A^+$ is an unranked tree structure which decomposes w following the image of its factors by μ .

- **Definition 26** ([13, 1]). A factorization (forest) of $w \in A^+$ is a tree defined as follows:
 - if $w = a \in A$, it is a leaf a ;
 - if $|w| \geq 2$, then $(\mathcal{F}_1) \cdots (\mathcal{F}_n)$ is a factorization of w if each \mathcal{F}_i is a factorization of some $w_i \in A^+$ such that $w = w_1 \cdots w_n$, and either:
 - $n = 2$: the root is a binary node;
 - or $n \geq 3$ and $\mu(w_1) = \cdots = \mu(w_n)$ is an idempotent: the root is an idempotent node.

The set of factorizations over w is denoted $\text{Fact}(w)$. Recall that $\Lambda = 3|M|$.

- **Theorem 27** ([13, 1]). For all $w \in A^+$, there is $\mathcal{F} \in \text{Fact}(w)$ of height at most Λ .

Let $\widehat{A} := A \uplus \{(\cdot, \cdot)\}$. We have defined $\text{Fact}(w)$ as a set of tree structures, but we can assume that $\text{Fact}(w) \subseteq \widehat{A}^+$. Indeed, in Definition 26, a factorization of w can also be seen as “the word w with parentheses”. There exists a rational function which computes factorizations, under this formalism. We reformulate this statement in Proposition 28 using a two-way transducer (which, exceptionally in this paper, has a non-unary output alphabet \widehat{A}).

- **Proposition 28** (Folklore). One can build a two-way transducer which computes a function $A^+ \rightarrow \widehat{A}^+, w \mapsto \mathcal{F} \in \text{Fact}(w)$ for some \mathcal{F} of height at most Λ .

We denote by $\text{Nodes}(\mathcal{F})$ the set of (idempotent or binary) nodes of \mathcal{F} . In order to simplify the statements, we identify a node with the subtree rooted in this node. Thus $\text{Nodes}(\mathcal{F})$ can also be seen as the set of subtrees of \mathcal{F} , and $\mathcal{F} \in \text{Nodes}(\mathcal{F})$. We shall use the standard tree vocabulary of “height” (a leaf is a tree of height 1), “parent node”, “descendant” and “ancestor” (defined in a non-strict way: a node is itself one of its ancestors), “branch”, etc.

- **Example 29.** Let $A = \{a, b, c\}$, $M = \{1_M, 2_M, 3_M\}$ with $2_M^2 = 1_M$, 3_M absorbing, $\mu(a) := 2_M$ and $\mu(b) := \mu(c) := 3_M$. Then $\mathcal{F} := (aa)(bc(a(cbbcb)))b \in \text{Fact}(aacacbbcb)$ (we dropped the parens around single letters for more readability) is depicted in Figure 6. Idempotent nodes are drawn using a horizontal line.

■ **Figure 6** The factorization $(aa)(bc(a(cbbcb)))b$ of $aacacbbcb$.

We define $\text{Iterable-nodes}(\mathcal{F}) \subseteq \text{Nodes}(\mathcal{F})$ as the set of nodes which are the middle child of an idempotent node. Intuitively, such nodes can be copied without modifying their “context”.

► **Definition 30.** Let $\mathcal{F} \in \text{Fact}(w)$, we define the set of iterable nodes of \mathcal{F} by induction:

- if $\mathcal{F} = a \in A$ is a leaf, $\text{Iterable-nodes}(\mathcal{F}) := \emptyset$;
- if $\mathcal{F} = (\mathcal{F}_1) \cdots (\mathcal{F}_n)$ is a binary or idempotent node, then:

$$\text{Iterable-nodes}(\mathcal{F}) := \{\mathcal{F}_i : 2 \leq i \leq n-1\} \bigsqcup_{1 \leq i \leq n} \text{Iterable-nodes}(\mathcal{F}_i).$$

On the contrary, we now define sets of nodes which cannot be duplicated individually.

► **Definition 31.** Let $\mathcal{F} \in \text{Fact}(w)$, we define the dependency of \mathcal{F} as follows:

- if $\mathcal{F} = a \in A$ is a leaf, then $\text{Dep}(\mathcal{F}) := \{a\}$;
- if $\mathcal{F} = (\mathcal{F}_1) \cdots (\mathcal{F}_n)$ is binary or idempotent, then $\text{Dep}(\mathcal{F}) := \{\mathcal{F}\} \cup \text{Dep}(\mathcal{F}_1) \cup \text{Dep}(\mathcal{F}_n)$.

Intuitively, $\text{Dep}(\mathcal{F}) \subseteq \text{Nodes}(\mathcal{F})$ contains all the nodes of \mathcal{F} except those which are descendant of a middle child. If $\mathcal{I} \in \text{Nodes}(\mathcal{F})$, we consider $\text{Dep}(\mathcal{I}) \subseteq \text{Nodes}(\mathcal{I})$ as a subset of $\text{Nodes}(\mathcal{F})$. We then define the frontier of \mathcal{I} , denoted $\text{Fr}_{\mathcal{F}}(\mathcal{I}) \subseteq \{1, \dots, |w|\}$ as the set of positions of w which belong to $\text{Dep}(\mathcal{I})$ (when seen as leaves of \mathcal{F}).

► **Example 32.** In Figure 6, the top-most red node \mathcal{I} is iterable. Furthermore $\text{Dep}(\mathcal{I})$ is the set of red nodes, $\text{Fr}_{\mathcal{F}}(\mathcal{I}) = \{5, 6, 10\}$ and $w[\text{Fr}_{\mathcal{F}}(\mathcal{I})] = acb$.

The relationship between iterable nodes and dependencies is detailed below. We denote by $\text{Part}(\mathcal{F}) := \text{Iterable-nodes}(\mathcal{F}) \uplus \{\mathcal{F}\}$, the set of iterable nodes plus the root.

► **Lemma 33.** Let $\mathcal{F} \in \text{Fact}(w)$, then $\{\text{Dep}(\mathcal{I}) : \mathcal{I} \in \text{Part}(\mathcal{F})\}$ is a partition of $\text{Nodes}(\mathcal{F})$; and $\{\text{Fr}_{\mathcal{F}}(\mathcal{I}) : \mathcal{I} \in \text{Part}(\mathcal{F})\}$ is a partition of $\{1, \dots, |w|\}$.

We define $\text{prod}(i, j)$ in w as “the production performed in i when called from j ”.

► **Definition 34.** Let $w \in A^+$ and $1 \leq i \leq j \leq |w|$ two positions of w . We define $\text{prod}(i, j) \in \mathbb{N}$ as $\lambda_{\mathfrak{f}_j}(\mu(w[1:i-1]), w[i], \mu(w[i+1:j]))$, where $\mathfrak{f}_j := \lambda(\mu(w[1:j-1]), w[j], \mu(w[j+1:|w|]))$.

We extend this definition to pairs of nodes: given $\mathcal{I}, \mathcal{J} \in \text{Nodes}(\mathcal{F})$, we define $\text{prod}(\mathcal{I}, \mathcal{J})$ “the sum of all productions performed in the frontier of \mathcal{I} , when called from the frontier of \mathcal{J} ” as follows (we have to ensure that the calling positions are “on the right”).

► **Definition 35.** Let $w \in A^+$, $\mathcal{F} \in \text{Fact}(w)$ and $\mathcal{I}, \mathcal{J} \in \text{Nodes}(\mathcal{F})$. We define:

$$\text{prod}(\mathcal{I}, \mathcal{J}) := \sum_{\substack{i \in \text{Fr}_{\mathcal{F}}(\mathcal{I}) \\ j \in \text{Fr}_{\mathcal{F}}(\mathcal{J}) \\ i \leq j}} \text{prod}(i, j) \in \mathbb{N}.$$

If \mathcal{I} is an ancestor of \mathcal{J} (or the converse) then $\text{Fr}_{\mathcal{F}}(\mathcal{I})$ and $\text{Fr}_{\mathcal{F}}(\mathcal{J})$ are interleaved, hence we can have both $\text{prod}(\mathcal{I}, \mathcal{J}) \neq 0$ and $\text{prod}(\mathcal{J}, \mathcal{I}) \neq 0$. However, if \mathcal{I} and \mathcal{J} are not on the same branch, we have either $\text{prod}(\mathcal{I}, \mathcal{J}) = 0$ or $\text{prod}(\mathcal{J}, \mathcal{I}) = 0$.

Applying Lemma 33, it is not hard to compute $f(w)$ using the $\text{prod}(\mathcal{I}, \mathcal{J})$.

► **Lemma 36.** Let $w \in A^+$, $\mathcal{F} \in \text{Fact}(w)$. Then:

$$f(w) = \sum_{\mathcal{I}, \mathcal{J} \in \text{Part}(\mathcal{F})} \text{prod}(\mathcal{I}, \mathcal{J}).$$

5.2 Typology of pairs of nodes

We intend to compute (if possible) f using a 1-blind transducer. Following Lemma 36, it is enough to consider the productions performed on the pairs of nodes of a factorization. For this study, we split the pairs depending on their relative position in the tree.

40:12 Pebble Transducers with Unary Output

Pairs separated by the frontier of the root. The frontier of the root $\text{Fr}_{\mathcal{F}}(\mathcal{F})$ plays a very specific role with respect to blind transducers. Indeed, over factorizations of height at most Λ , the size of the frontier is bounded, hence it splits the word in a bounded number of distinguishable “blocks”. Formally, we define the notion of *basis*.

► **Definition 37.** *An idempotent node is a basis if it belongs to the dependency of the root.*

The following result is shown by induction.

► **Lemma 38.** *Let $w \in A^+$ and $\mathcal{F} \in \text{Fact}(w)$. Given $\mathcal{I} \in \text{Iterable-nodes}(\mathcal{F})$, there exists a unique basis, denoted $\text{basis}_{\mathcal{F}}(\mathcal{I})$, such that \mathcal{I} is the descendant of a middle child of $\text{basis}_{\mathcal{F}}(\mathcal{I})$.*

► **Definition 39.** *Given $w \in A^+$ and $\mathcal{F} \in \text{Fact}(w)$, we define $D(\mathcal{F}) \subseteq \text{Part}(\mathcal{F}) \times \text{Part}(\mathcal{F})$ by:*

$$D(\mathcal{F}) := \{(\mathcal{I}, \mathcal{J}) : \mathcal{I}, \mathcal{J} \in \text{Iterable-nodes}(\mathcal{F}) \text{ and } \text{basis}_{\mathcal{F}}(\mathcal{I}) \neq \text{basis}_{\mathcal{F}}(\mathcal{J})\}.$$

Intuitively $\text{basis}_{\mathcal{F}}(\mathcal{I}) \neq \text{basis}_{\mathcal{F}}(\mathcal{J})$ means that $\text{Fr}_{\mathcal{F}}(\mathcal{I})$ and $\text{Fr}_{\mathcal{F}}(\mathcal{J})$ belong to two different “blocks” of the input. Lemma 40 is shown by building a 1-blind bimachine which visits successively each basis \mathcal{B} , and for each iterable \mathcal{J} such that $\text{basis}_{\mathcal{F}}(\mathcal{J}) = \mathcal{B}$, calls a submachine which visits the \mathcal{I} such that $\text{basis}_{\mathcal{F}}(\mathcal{I}) \neq \mathcal{B}$ and produces $\text{prod}(\mathcal{I}, \mathcal{J})$. The key element for doing this operation without pebbles is that the number of bases is bounded.

► **Lemma 40.** *One can build a 1-blind bimachine computing:*

$$f_D : (\widehat{A})^+ \rightarrow \mathbb{N}, \mathcal{F} \mapsto \begin{cases} \sum_{(\mathcal{I}, \mathcal{J}) \in D(\mathcal{F})} \text{prod}(\mathcal{I}, \mathcal{J}) & \text{if } \mathcal{F} \text{ factorization of height at most } \Lambda; \\ 0 & \text{otherwise.} \end{cases}$$

Linked pairs. Let $U(\mathcal{F}) := \text{Part}(\mathcal{F}) \times \text{Part}(\mathcal{F}) \setminus D(\mathcal{F})$, it corresponds to the pairs of $\text{Iterable-nodes}(\mathcal{F})$ which have the same basis, plus all the pairs $(\mathcal{F}, \mathcal{I})$ and $(\mathcal{I}, \mathcal{F})$ for $\mathcal{I} \in \text{Part}(\mathcal{F})$. We now study the pairs of $U(\mathcal{F})$ which are “linked”, in the sense that one node is (nearly) the ancestor of the other.

► **Definition 41.** *Let $w \in A^+$, $\mathcal{F} \in \text{Fact}(w)$. Let $L(\mathcal{F})$ be the set of all $(\mathcal{I}, \mathcal{J}) \in U(\mathcal{F})$ such that \mathcal{I} (or \mathcal{J}) is either the ancestor of, or the right/left sibling of an ancestor of \mathcal{J} (or \mathcal{I}).*

In particular, we have $(\mathcal{F}, \mathcal{F}), (\mathcal{I}, \mathcal{F}), (\mathcal{F}, \mathcal{I}), (\mathcal{I}, \mathcal{I}) \in L(\mathcal{F})$ for all $\mathcal{I} \in \text{Part}(\mathcal{F})$. If \mathcal{F} has height at most Λ , there are at most 3Λ nodes which are either an ancestor or the right/left sibling of an ancestor of \mathcal{I} . Lemma 42 follows from this boundedness.

► **Lemma 42.** *One can build a 0-blind bimachine computing:*

$$f_L : (\widehat{A})^+ \rightarrow \mathbb{N}, \mathcal{F} \mapsto \begin{cases} \sum_{(\mathcal{I}, \mathcal{J}) \in L(\mathcal{F})} \text{prod}(\mathcal{I}, \mathcal{J}) & \text{if } \mathcal{F} \text{ factorization of height at most } \Lambda; \\ 0 & \text{otherwise.} \end{cases}$$

Independent nodes. The remaining sum is the most interesting, since it is the only case where we use the assumption that \mathcal{T} to be symmetrical (and this assumption is crucial). Let $\mathcal{F} \in \text{Fact}(w)$, we define the set $I(\mathcal{F}) := U(\mathcal{F}) \setminus L(\mathcal{F})$. It contains the pairs $(\mathcal{I}, \mathcal{J})$ of iterable nodes such that $\text{basis}_{\mathcal{F}}(\mathcal{I}) = \text{basis}_{\mathcal{F}}(\mathcal{J})$ (i.e. they descend from a common “big” idempotent), and \mathcal{I} (or \mathcal{J}) is not an ancestor of \mathcal{J} (or \mathcal{I}), nor the left or right sibling of its ancestor.

► **Lemma 43.** *If \mathcal{T} is symmetrical, one can build a 1-blind bimachine computing:*

$$f_I : (\widehat{A})^+ \rightarrow \mathbb{N}, \mathcal{F} \mapsto \begin{cases} \sum_{(\mathcal{I}, \mathcal{J}) \in I(\mathcal{F})} \text{prod}(\mathcal{I}, \mathcal{J}) & \text{if } \mathcal{F} \text{ factorization of height at most } \Lambda; \\ 0 & \text{otherwise.} \end{cases}$$

Proof idea. We define $\text{type}_{\mathcal{F}}(\mathcal{I})$ for $\mathcal{I} \in \text{Iterable-nodes}(\mathcal{F})$ as a bounded abstraction of \mathcal{I} which describes the frontier and the location of \mathcal{I} in \mathcal{F} and in $\text{basis}_{\mathcal{F}}(\mathcal{I})$. Using symmetry, we show that for $(\mathcal{I}, \mathcal{J}) \in I(\mathcal{F})$, $\text{prod}(\mathcal{I}, \mathcal{J})$ only depends on $\text{type}_{\mathcal{F}}(\mathcal{I})$ and $\text{type}_{\mathcal{F}}(\mathcal{J})$, but not on their relative positions. Hence we build a 1-blind bimachine, whose main bimachine ranges over all possible \mathcal{J} and computes $\text{type}_{\mathcal{F}}(\mathcal{J})$, and whose submachines range over all possible \mathcal{I} (a special treatment has to be done to avoid \mathcal{I} such that $(\mathcal{I}, \mathcal{J}) \in L(\mathcal{F})$), compute $\text{type}_{\mathcal{F}}(\mathcal{I})$ and output $\text{prod}(\mathcal{I}, \mathcal{J})$. The submachines do not need to “see” \mathcal{J} . ◀

We finally show $3 \Rightarrow 2$ in Theorem 23. Given $w \in A^+$ we first compute \mathcal{F} of height at most Λ by Proposition 28. Then we use the machines from Lemmas 40, 42 and 43 and build a 1-blind transducer computing the sum of their outputs. The original function can be recovered since 1-blind transducers are closed under composition with two-way [11].

6 Conclusion and outlook

As a conclusion, we discuss future work. This paper introduces new proof techniques, in particular the use of factorization forests to study the productions of transducers. We believe that these techniques give a step towards other membership problems concerning pebble transducers. Among them, let us mention the membership problem from k -pebble to k -blind, at first over unary alphabets. Similarly, the membership from k -pebble to k -marble over non-unary alphabets is worth being studied (the answer seems to rely on combinatorial properties of the output, since unary outputs can always be produced using marbles).

A Proof of Lemma 17

We show that given a bimachine with external pebble functions, which are computed by SSTs, one can build an equivalent SST.

A.1 SST with lookahead

We first define a variant of SST with the same expressive power. Intuitively, this model is similar to bimachines, in the sense that the register update not only depends on the current letter, but also on a finite abstraction of the prefix and suffix.

► **Definition 44.** An SST with lookahead $\mathcal{T} = (A, \mathfrak{X}, M, \mu, I, \lambda, F)$ is:

- an input alphabet A and a finite set \mathfrak{X} of registers;
- a morphism into a finite monoid $\mu : A^* \rightarrow M$;
- an initial row vector $I \in \mathbb{N}^{\mathfrak{X}}$;
- a register update function $\lambda : M \times A \times M \rightarrow \mathbb{N}^{\mathfrak{X} \times \mathfrak{X}}$;
- an output column vector $F \in \mathbb{N}^{\mathfrak{X}}$.

Let us define its semantics. Intuitively, in position i of $w \in A^+$, we perform the register update $\lambda(\mu(w[1:i-1]), w[i], \mu(w[i+1:|w|]))$. Formally, for $0 \leq i \leq |w|$, we define $\mathcal{T}^{w,i} \in \mathbb{N}^{\mathfrak{X}}$ (“the values of the registers after reading $w[1:i]$ ”²) as follows:

- $\mathcal{T}^{w,0} := I$;
- for $i \geq 1$, $\mathcal{T}^{w,i} := \mathcal{T}^{w,i-1} \times \lambda(\mu(w[1:i-1]), w[i], \mu(w[i+1:|w|]))$.

To define the function $f : A^+ \rightarrow \mathbb{N}$ computed by \mathcal{T} , we combine the final values by the output vector:

$$f(w) := \mathcal{T}^{w,|w|} F.$$

It is known that SST with lookahead are equivalent to SST (the proof is roughly a “determinisation” procedure for eliminating the rightmost argument of λ , and an encoding of the monoid in the registers for eliminating the leftmost argument).

► **Lemma 45 ([8]).** Given an SST with lookahead, we can build an equivalent SST.

Hence, it is sufficient to build an SST with lookahead.

² Due to the fact that λ looks “on the right”, $\mathcal{T}^{w,i}$ depends on the whole w and not only on $w[1:i]$.

A.2 Main proof of Lemma 17

Let $\mathcal{T} = (A, M, \mu, \lambda, \mathfrak{F})$ be the bimachine with external pebble functions. Each $f \in \mathfrak{F}$ is computed by an SST $\mathcal{T}_f := (A \uplus \underline{A}, \mathfrak{X}_f, I_f, T_f, F_f)$.

► **Example 46** (Running example). Let $\mathcal{T} = (A, M, \mu, \lambda, \{f\})$ with $M = \{1_M\}$ singleton and $\lambda(1_M, a, 1_M) = f$ for $a \in A$. Let \mathcal{T}_f have two registers x, y with x initialized to 1 and y initialized to 0. When reading $a \in A \uplus \underline{A}$ it performs $x \leftarrow x, y \leftarrow y + x$. Finally it outputs y . Then $f(w) = |w|$ and \mathcal{T} computes $f : w \mapsto |w|^2$.

► **Definition 47.** Let $w \in A^*$ and $f \in \mathfrak{F}$. We define $\text{Calls}(w, f)$ as the set of positions of w in which f is called, that is $\{1 \leq j \leq |w| : \lambda(\mu(w[1:j-1]), w[j], \mu(w[j+1:|w|])) = f\}$.

For $1 \leq j \leq i \leq |w|$, $I_f T_f(w[1:i] \uparrow j)$ corresponds to the value of the registers of \mathcal{T}_f in position i when the call to f is performed from position j .

▷ **Claim 48.** For all $w \in A^*$, the following holds:

$$f(w) = \sum_{f \in \mathfrak{F}} \sum_{\substack{1 \leq j \leq |w| \\ j \in \text{Calls}(w, f)}} I_f T_f(w \uparrow j) F_f$$

Proof. By definition of external pebble functions we have:

$$f(w) := \sum_{1 \leq j \leq |w|} f_j(w \uparrow j)$$

where $f_j := \lambda(\mu(w[1:j-1]), w[j], \mu(w[j+1:|w|]))$ is “the external function called in j ”. Hence by partitioning the sum depending on the external functions it follows:

$$f(w) := \sum_{f \in \mathfrak{F}} \sum_{\substack{1 \leq j \leq |w| \\ j \in \text{Calls}(w, f)}} f(w \uparrow j)$$

And finally we note that $f(w \uparrow j) = I_f T_f(w \uparrow j) F_f$. ◁

Idea of the construction. Let us fix an external function f . Following Claim 48, we want to build an SST with lookahead \mathcal{U} which computes the values of the vector:

$$\sum_{\substack{1 \leq j \leq |w| \\ j \in \text{Calls}(w, f)}} I_f T_f(w \uparrow j) \in \mathbb{N}^{\mathfrak{X}}.$$

For this, it will keep track when in position i of the values of:

$$\sum_{\substack{1 \leq j \leq i \\ j \in \text{Calls}(w, f)}} I_f T_f(w[1:i] \uparrow j) \in \mathbb{N}^{\mathfrak{X}}$$

and these values will be updated when going from i to $i + 1$.

► **Example 49** (Running example). We have $I_f T_f(w[1:i] \uparrow j)(x) = 1$ and $I_f T_f(w[1:i] \uparrow j)(y) = i$. Hence $\sum_{\substack{1 \leq j \leq i \\ j \in \text{Calls}(w, f)}} I_f T_f(w[1:i] \uparrow j)(x) = i$ and $\sum_{\substack{1 \leq j \leq i \\ j \in \text{Calls}(w, f)}} I_f T_f(w[1:i] \uparrow j)(y) = i^2$.

40:16 Pebble Transducers with Unary Output

Formal construction. Let $\mathcal{U} = (A, \mathfrak{X}, M, \mu, I, \kappa, F)$ be an SST with lookahead with:

- the set $\mathfrak{X} := \bigsqcup_{\mathfrak{f} \in \mathfrak{F}} \{\text{Sum}_x : x \in \mathfrak{X}_{\mathfrak{f}}\} \sqcup \{\text{Old}_x : x \in \mathfrak{X}_{\mathfrak{f}}\}$ of registers;
- the morphism $\mu : A^* \rightarrow M$ used in \mathcal{T} ;
- an initial column vector $I \in \mathbb{N}^{\mathfrak{X}}$ such that for all $\mathfrak{f} \in \mathfrak{F}$ and $x \in \mathfrak{X}_{\mathfrak{f}}$:
 - $I(\text{Sum}_x) = 0$;
 - $I(\text{Old}_x) = I_{\mathfrak{f}}(x)$;
- the update $\kappa : M \times A \times M \rightarrow \mathbb{N}^{\mathfrak{X} \times \mathfrak{X}}$ as follows. Let $(m, a, n) \in M \times A \times N$ and $\mathfrak{f} := \lambda(m, a, n)$. Then $\kappa(m, a, n)$ performs the following updates:
 - for all $\mathfrak{g} \neq \mathfrak{f}$ and $x \in \mathfrak{X}_{\mathfrak{g}}$:
 - * $\text{Sum}_x \leftarrow \sum_{y \in \mathfrak{X}_{\mathfrak{g}}} \alpha_y \text{Sum}_y$;
 - * $\text{Old}_x \leftarrow \sum_{y \in \mathfrak{X}_{\mathfrak{g}}} \alpha_y \text{Old}_y$;
 where $x \leftarrow \sum_{y \in \mathfrak{X}_{\mathfrak{g}}} \alpha_y y$ is the update performed by $\mathcal{T}_{\mathfrak{g}}$ when reading a ;
 - for all $x \in \mathfrak{X}_{\mathfrak{f}}$:
 - * $\text{Sum}_x \leftarrow \sum_{y \in \mathfrak{X}_{\mathfrak{f}}} \alpha_y \text{Sum}_y + \sum_{y \in \mathfrak{X}_{\mathfrak{f}}} \beta_y \text{Old}_y$;
 - * $\text{Old}_x \leftarrow \sum_{y \in \mathfrak{X}_{\mathfrak{f}}} \alpha_y \text{Old}_y$;
 where $x \leftarrow \sum_{y \in \mathfrak{X}_{\mathfrak{f}}} \alpha_y y$ is the update performed by $\mathcal{T}_{\mathfrak{f}}$ when reading a ;
 and $x \leftarrow \sum_{y \in \mathfrak{X}_{\mathfrak{f}}} \beta_y y$ is the update performed by $\mathcal{T}_{\mathfrak{f}}$ when reading a .
 Intuitively, the sum with the β_y corresponds to what is “added” by the new call to \mathfrak{f} .
- the output line vector $F \in \mathbb{N}^{\mathfrak{X}}$ such that for all $\mathfrak{f} \in \mathfrak{F}$ and $x \in \mathfrak{X}_{\mathfrak{f}}$:
 - $F(\text{Sum}_x) = F_{\mathfrak{f}}(x)$;
 - $F(\text{Old}_x) = 0$.

► **Example 50** (Running example). \mathcal{U} performs the following updates:

- $\text{Old}_x \leftarrow \text{Old}_x$, $\text{Old}_y \leftarrow \text{Old}_y + \text{Old}_x$;
- $\text{Sum}_x \leftarrow \text{Sum}_x + \text{Old}_x$, $\text{Sum}_y \leftarrow \text{Sum}_y + \text{Sum}_x + \text{Old}_y + \text{Old}_x$.

We can check that $\mathcal{U}^{w,i}(\text{Old}_x) = 1$, $\mathcal{U}^{w,i}(\text{Old}_y) = i$ and $\mathcal{U}^{w,i}(\text{Sum}_x) = i$, $\mathcal{U}^{w,i}(\text{Sum}_y) = i^2$.

Correctness of the construction. As the registers Old_x for $x \in \mathfrak{X}_{\mathfrak{f}}$ are updated following the updates of $\mathcal{T}_{\mathfrak{f}}$, it follows immediately that:

▷ **Claim 51.** Given $x \in \mathfrak{X}_{\mathfrak{f}}$, for all $w \in A^+$ and $1 \leq i \leq |w|$ we have:

$$\mathcal{U}^{w,i}(\text{Old}_x) = I_{\mathfrak{f}} T_{\mathfrak{f}}(w[1:i])(x).$$

We can finally show that the registers Sum_x store the information we wanted.

▷ **Claim 52.** Given $x \in \mathfrak{X}_{\mathfrak{f}}$, for all $w \in A^+$ and $0 \leq i \leq |w|$ we have:

$$\mathcal{U}^{w,i}(\text{Sum}_x) = \sum_{\substack{1 \leq j \leq i \\ j \in \text{Calls}(w, \mathfrak{f})}} I_{\mathfrak{f}} T_{\mathfrak{f}}(w[1:i] \uparrow j)(x).$$

Proof. We proceed by induction on $0 \leq i \leq |w|$. For $i = 0$ both terms equal 0. For the induction step with $i \geq 1$ let $\mathfrak{f} \in \mathfrak{F}$ and $x \in \mathfrak{X}_{\mathfrak{f}}$.

Suppose that $\lambda(\mu(w[1:i-1]), w[i], \mu(w[i+1:|w|])) = \mathfrak{f}$ (the case when they differ is similar and even easier), then:

$$\sum_{\substack{1 \leq j \leq i \\ j \in \text{Calls}(w, \mathfrak{f})}} I_{\mathfrak{f}} T_{\mathfrak{f}}(w[1:i] \uparrow j)(x) = I_{\mathfrak{f}} T_{\mathfrak{f}}(w[1:i] \uparrow i)(x) + \sum_{\substack{1 \leq j \leq i-1 \\ j \in \text{Calls}(w, \mathfrak{f})}} I_{\mathfrak{f}} T_{\mathfrak{f}}(w[1:i] \uparrow j)(x). \quad (1)$$

- Let $x \leftarrow \sum_{y \in \mathfrak{X}_i} \alpha_y y$ be the update performed by \mathcal{T}_i when reading a .
Then for $j \leq i - 1$, $I_i \mathcal{T}_i(w[1:i] \uparrow j)(x) = \sum_{y \in \mathfrak{X}_i} \alpha_y \times I_i \mathcal{T}_i(w[1:i-1] \uparrow j)(y)$.
- Let $x \leftarrow \sum_{y \in \mathfrak{X}_i} \beta_y y$ be the update performed by \mathcal{T}_i when reading \underline{a} .
Then $I_i \mathcal{T}_i(w[1:i] \uparrow i)(x) = \sum_{y \in \mathfrak{X}_i} \beta_y \times I_i \mathcal{T}_i(w[1:i-1])(y)$.

Hence we can rewrite Equation 1 using values in position $i-1$. By Claim 51 and the induction hypothesis, this sum coincides with the update in \mathcal{U} . \triangleleft

The fact that \mathcal{U} computes f follows from the definition of F and Claim 48.

Graph Characterization of the Universal Theory of Relations

Amina Doumane ✉

CNRS, ENS Lyon, France

Abstract

The equational theory of relations can be characterized using graphs and homomorphisms. This result, found independently by Freyd and Scedrov and by Andr eka and Bredikhin, shows that the equational theory of relations is decidable. In this paper, we extend this characterization to the whole universal first-order theory of relations. Using our characterization, we show that the positive universal fragment is also decidable.

1 Introduction

Binary relations are a versatile mathematical object, used to model graphs, programs, databases, etc. It is then a natural task to understand the laws governing them. Since the seminal work of Tarski [14], this task has occupied researchers for several decades [15, 12, 3, 9, 11, 10, 2, 4, 13].

Relations usually come with a certain number of standard operations: union \cup , intersection \cap , composition \cdot , converse $^\circ$ etc. We are interested in containment between terms built with these operations with respect to their relational interpretations. When a containment between two terms t and u holds, we say that $t \geq u$ is a *valid inequation for relations* and write $\mathcal{R}el \models t \geq u$. For instance, an emblematic valid inequation is the following one:

$$(a \cdot b) \cap (a \cdot c) \geq a \cdot (b \cap c)$$

This law is valid because no matter how we interpret the letters a, b and c as relations, the relation denoted by the term $a \cdot (b \cap c)$ will be contained in the relation denoted by the term $(a \cdot b) \cap (a \cdot c)$. A very simple way to check that this inequation is valid relies on the following characterization ([1, Thm. 1], [7, p. 208]):

$$\mathcal{R}el \models t \geq u \quad \Leftrightarrow \quad \mathcal{G}(t) \triangleright \mathcal{G}(u) \quad (\star)$$

In this theorem, $\mathcal{G}(t)$ and $\mathcal{G}(u)$ are finite graphs associated to the terms t and u respectively, and \triangleright denotes the existence of a *graph homomorphism*. For example, the validity of the law above is witnessed by this homomorphism (in red) from the graph of $(a \cdot b) \cap (a \cdot c)$ to the graph of $a \cdot (b \cap c)$:

Using this characterization, we can show that relational validity of inequations is decidable.

As maybe noticed by the reader, inequations are implicitly universally quantified. They actually form a fragment of the more general *universal first-order* formulas. The latter comprises *universal positive formulas* which are basically disjunctions of inequations, and *Horn formulas* which are implications between inequations.

Universal first-order formulas have received a lot of attention in the model theory community. They enjoy for example the Łoś–Tarski theorem [8, Thm.5.4.4], which states that the set of universal first-order formulas is exactly the set of first-order formulas preserved under taking substructures.

In this paper, we give a graph characterization for those universal first-order formulas which are valid for relations, generalizing the characterization (\star). To this end, we proceed in three steps. First, we provide a characterization of relational validity for positive universal formulas. Based on this, we show that relational validity is decidable for this fragment. As a second step, we characterize relational validity for Horn formulas. Finally we combine the techniques used for both fragments to characterize validity for all universal first-order formulas. Before presenting our results, we start by recalling some background in Section 2.

2 Preliminaries

2.1 Universal theory of relations

We let $a, b \dots$ range over the letters of an alphabet A . *Terms* are generated by this syntax:

$$t, u ::= t \cdot u \mid t \cap u \mid t^\circ \mid 1 \mid \top \mid a \quad a \in A$$

We denote the set of terms by \mathcal{T} . We often write tu for $t \cdot u$, and assign priorities to symbols so that $ab \cap c$, $a \cap b^\circ$ and ab° parse respectively as $(a \cdot b) \cap c$, $a \cap (b^\circ)$ and $a \cdot (b^\circ)$.

First-order formulas are generated by the following syntax:

$$\varphi, \psi ::= t \geq u \mid \neg(t \geq u) \mid \varphi \vee \psi \mid \varphi \wedge \psi \mid \exists a. \varphi \mid \forall a. \varphi \quad t, u \in \mathcal{T}, a \in A.$$

Formulas of the form $t \geq u$ are called *inequations*. We extend the operation of negation \neg to all formulas in the standard way, for instance $\neg(\varphi \wedge \psi) = \neg\varphi \vee \neg\psi$. Implication $\varphi \Rightarrow \psi$ is a shortcut for $\neg\varphi \vee \psi$. Free and bound variables are defined as usual, and we call *sentence* a formula without free variables.

A *universal formula* is a formula from the syntax above which does not use existential quantification. A *generalized Horn formula* is a formula of the following form, where $\forall \vec{a}$ denotes a sequence of universal quantifications:

$$\forall \vec{a}. \bigwedge_{j \in J} (v_j \geq w_j) \Rightarrow \bigvee_{i \in I} (t_i \geq u_i)$$

We generally write it as follows, where \mathcal{H} is the set of inequations $\{v_j \geq w_j, j \in J\}$:

$$\forall \vec{a}. \mathcal{H} \Rightarrow \bigvee_{i \in I} (t_i \geq u_i)$$

We call \mathcal{H} its *hypothesis* and $\bigvee_{i \in I} (t_i \geq u_i)$ its *conclusion*. A *Horn formula* is a generalized Horn formula whose conclusion contains a single disjunct. We write it like this:

$$\forall \vec{a}. \mathcal{H} \Rightarrow t \geq u$$

A *Positive universal formula* is a generalized Horn formula whose set of hypothesis is empty. It looks like this:

$$\forall \vec{a}. \bigvee_{i \in I} (t_i \geq u_i)$$

A *universal inequation* is a positive universal formula with a single disjunct. We will sometimes call it simply inequation. It looks like this:

$$\forall \vec{a}. t \geq u$$

In the rest of the paper, we will be interested only on universal sentences, this is why we will omit the universal quantification in front of our formulas.

Note that every universal formula can be written as the conjunction of generalized Horn formulas. In the rest of the paper, we will mainly focus on the latter.

Let us define *relational validity* for generalized Horn sentences. An *interpretation* σ is a function $\sigma : A \rightarrow \mathcal{P}(B \times B)$ mapping letters into relations over a base set B . We can extend σ to all terms $\sigma : \mathcal{T} \rightarrow \mathcal{P}(B \times B)$, by interpreting the operations $\cdot, \cap, \circ, 1$ and \top on relations as follows:

$$\begin{aligned} R \cdot S &= \{(x, y) \mid \exists z. (x, z) \in R \text{ and } (z, y) \in S\} && \text{(Composition)} \\ R \cap S &= \{(x, y) \mid (x, y) \in R \text{ and } (x, y) \in S\} && \text{(Intersection)} \\ R^\circ &= \{(x, y) \mid (y, x) \in R\} && \text{(Converse)} \\ 1 &= \{(x, x) \mid x \in B\} && \text{(Identity)} \\ \top &= \{(x, y) \mid x, y \in B\} && \text{(Full relation)} \end{aligned}$$

Let σ be an interpretation as above. An inequation $t \geq u$ is *true under* σ , noted $\sigma \models t \geq u$, if $\sigma(t) \supseteq \sigma(u)$. A set of inequations \mathcal{H} are *true under* σ , noted $\sigma \models \mathcal{H}$, if this is the case for every inequation in \mathcal{H} . A generalized Horn sentence

$$\varphi := (\mathcal{H} \Rightarrow \bigvee_{i \in I} (t_i \geq u_i))$$

is *true under* σ , noted $\sigma \models \varphi$ if either $\sigma \not\models \mathcal{H}$ or there exists $i \in I$ such that $\sigma \models t_i \geq u_i$. We say that φ is *valid* for relations, noted $\mathcal{R}el \models \varphi$, if φ is true under all interpretations, using all possible base sets B .

Here are respectively a universal inequation (1), a positive universal sentence (2), and a Horn sentence (3), that are all valid for relations:

$$a(ba \cap 1)b \geq ab \cap 1 \tag{1}$$

$$(\top c \top \cap ab \cap ad \geq a(b \cap d)) \vee (d \geq ac) \tag{2}$$

$$ef^\circ \geq \top \Rightarrow (ae \cap cf)(e^\circ b \cap f^\circ d) \geq ab \cap cd \tag{3}$$

We will see in the upcoming sections how to check their validity.

2.2 Graph characterization of the inequational theory of relations

Let A be an alphabet. A *2-pointed labeled graph* is a structure (V, E, ι, o) where V is a set of vertices, $E \subseteq V \times A \times V$ is a set of edges and ι and o are two distinguished vertices called the *input* and *output*. We simply call them *graphs* in the sequel; we depict them as expected, with unlabeled ingoing and outgoing arrows to denote the input and the output, respectively. We denote by $\mathcal{G}r$ the set of finite graphs. If G is a graph and x, y two of its vertices, we denote by (x, G, y) the graph obtained from G by forgetting the original input and output of G , and considering x and y as the new input and output respectively.

41:4 Graph Characterization of the Universal Theory of Relations

We define the following operations of graphs.

$$G \cap H = \begin{array}{c} \circ \\ \swarrow G \\ \circ \quad \circ \\ \searrow H \\ \circ \end{array} \quad G \cdot H = \circ \rightarrow G \rightarrow \circ \rightarrow H \rightarrow \circ \quad G^\circ = \circ \leftarrow G \rightarrow \circ$$

We associate to every term $t \in \mathcal{T}$ a graph $\mathcal{G}(t)$ called the *graph of t* , by letting

$$\mathcal{G}(a) = \circ \xrightarrow{a} \circ \quad \mathcal{G}(1) = \circ \rightarrow \circ \quad \mathcal{G}(\top) = \circ \quad \circ \rightarrow$$

and by interpreting the operations \cdot, \cap and $^\circ$ on graphs as above.

► **Example 1.** The graphs $\mathcal{G}(\top \circ \top \cap ab)$, $\mathcal{G}(ab \cap 1)$ and $\mathcal{G}(bd^\circ)$ are respectively the following:

Graph homomorphisms play a central role in the paper, they are defined as follows:

► **Definition 2** (Graph homomorphism). *Given two graphs $G = \langle V, E, \iota, o \rangle$ and $G' = \langle V', E', \iota', o' \rangle$, a (graph) homomorphism $h : G \rightarrow H$ is a mapping from $V \rightarrow V'$ that preserves labeled edges, ie. if $(x, a, y) \in E$ then $(h(x), a, h(y)) \in E'$, and preserves input and output, ie. $h(\iota) = \iota'$ and $h(o) = o'$.*

The image of G by h , denoted $h(G)$, is the graph $\langle h(V), E'', \iota', o' \rangle$ where

$$E'' = \{(h(x), a, h(y)) \mid (x, a, y) \in E\}.$$

We write $G \triangleright H$ if there exists a graph homomorphism from G to H , and $G \hookrightarrow H$ if there exists an injective graph homomorphism from G to H . In the later case, we usually consider G as an actual subgraph of H .

Our starting point was this characterization of the inequational theory of relations:

► **Theorem 3** ([1, Thm. 1], [7, p. 208]). *For all terms u, v ,*

$$\mathcal{R}el \models u \geq v \quad \text{iff} \quad \mathcal{G}(u) \triangleright \mathcal{G}(v)$$

2.3 Graphs and interpretations

We state below the main lemma (Lemma 6) that was used to prove Theorem 3, which will be useful for us too. But first, let us explicit a link between graphs and interpretations.

► **Definition 4** (Graphs and interpretations). *Let $\sigma : A \rightarrow \mathcal{P}(B \times B)$ be an interpretation. The graph associated to σ , $\mathcal{G}(\sigma)$, is the graph whose set of vertices is B and*

$$(x, a, y) \text{ is an edge of } \mathcal{G}(\sigma) \quad \text{iff} \quad (x, y) \in \sigma(a).$$

Conversely if $G = (V, E)$ is a graph, the interpretation associated to G , $\mathcal{I}(G)$, is the function

$$\begin{aligned} A &\rightarrow \mathcal{P}(V \times V) \\ a &\mapsto \{(x, y) \mid (x, a, y) \in E\} \end{aligned}$$

In the above definition, graphs are considered without distinguished input and output.

► **Remark 5.** The functions \mathcal{G} and \mathcal{I} are inverses of each other: $\mathcal{I} \circ \mathcal{G}$ and $\mathcal{G} \circ \mathcal{I}$ are the identity function on interpretations and graphs respectively.

Recall that (x, G, y) is the graph G where x and y are chosen to be the input and output.

► **Lemma 6** ([1, Lemma 3]). *Let t be a term, $\sigma : A \rightarrow \mathcal{P}(B \times B)$ be an interpretation and $x, y \in B$. We have that:*

$$\sigma(t) \ni (x, y) \quad \text{iff} \quad \mathcal{G}(t) \triangleright (x, \mathcal{G}(\sigma), y)$$

3 Characterizing the positive universal theory of relations

Given two graphs G and H , we define $G \oplus H$ as the disjoint union of G and H , whose input and output are those of G . Note that \oplus is associative, but not commutative. However, note that the following holds:

$$G \oplus H \oplus K = G \oplus K \oplus H$$

$$G \triangleright H \oplus H \oplus K \Leftrightarrow G \triangleright H \oplus K$$

Now we can state our first characterization theorem:

► **Theorem 7.** For all terms t_i, u_i where $i \in [1, n]$, the following holds

$$\mathcal{R}el \models \bigvee_{i \in [1, n]} (t_i \geq u_i) \quad \text{iff} \quad \bigvee_{i \in [1, n]} (\mathcal{G}(t_i) \triangleright \mathcal{G}(u_i) \oplus G)$$

where $G = \mathcal{G}(u_1) \oplus \dots \oplus \mathcal{G}(u_n)$.

Using the remark above, the case of two disjuncts can be formulated as follows

$$\mathcal{R}el \models (t_0 \geq u_0) \vee (t_1 \geq u_1) \quad \text{iff} \quad \mathcal{G}(t_0) \triangleright \mathcal{G}(u_0) \oplus \mathcal{G}(u_1) \quad \text{or} \quad \mathcal{G}(t_1) \triangleright \mathcal{G}(u_1) \oplus \mathcal{G}(u_0)$$

Before proving Theorem 7, let us see an example of its application.

► **Example 8.** The validity of the following positive universal sentence

$$(\top c \top \cap ab \cap ad \geq a(b \cap d)) \vee (d \geq ac) \quad (2)$$

is witnessed by this homomorphism depicted below:

► **Remark 9.** Surprisingly, this characterization tells us that only one left-hand-side (lhs) of the disjuncts of a positive universal sentence plays a role in its validity. For instance, in the sentence (2) above, we can replace the lhs of the second inequation, d , by any term without affecting the validity.

Proof. We show here the case of binary disjunctions to lighten notations. The general case works exactly in the same way.

(\Rightarrow) Suppose that $\mathcal{R}el \models (t_0 \geq u_0) \vee (t_1 \geq u_1)$, let us show that either

$$\mathcal{G}(t_0) \triangleright \mathcal{G}(u_0) \oplus \mathcal{G}(u_1) \quad \text{or} \quad \mathcal{G}(t_1) \triangleright \mathcal{G}(u_1) \oplus \mathcal{G}(u_0)$$

Let G be the graph (without specified input and output) which is the disjoint union of $\mathcal{G}(u_0)$ and $\mathcal{G}(u_1)$, and let σ be the interpretation associated to G . We denote by G_0 the graph $\mathcal{G}(u_0) \oplus \mathcal{G}(u_1)$ and by G_1 the graph $\mathcal{G}(u_1) \oplus \mathcal{G}(u_0)$. To conclude the proof of this direction, we show that, for $i = 0, 1$:

$$\sigma(t_i) \supseteq \sigma(u_i) \quad \Rightarrow \quad \mathcal{G}(t_i) \triangleright G_i$$

41:6 Graph Characterization of the Universal Theory of Relations

Suppose that $\sigma(t_0) \supseteq \sigma(u_0)$, the other case is treated symmetrically. Let ι and o be respectively the vertices corresponding to the input and output of $\mathcal{G}(u_0)$ in G . We have that $\mathcal{G}(u_0) \triangleright (\iota, G, o)$, then by Lemma 6, $\sigma(u_0) \ni (\iota, o)$. Thus, $\sigma(t_0) \ni (\iota, o)$ and again by Lemma 6, $\mathcal{G}(t_0) \triangleright (\iota, G, o)$. But (ι, G, o) is G_0 and this remark concludes the proof.

(\Leftarrow) Suppose that $G(t_0) \triangleright \mathcal{G}(u_0) \oplus \mathcal{G}(u_1)$ and let us show that:

$$\mathcal{R}el \models (t_0 \geq u_0) \vee (t_1 \geq u_1)$$

The other case is treated symmetrically. Let $\sigma : A \rightarrow \mathcal{P}(B \times B)$ be an interpretation, and let G be its graph. We distinguish two cases. We have either:

$$\forall x, y \in B, \quad \mathcal{G}(u_1) \not\triangleright (x, G, y)$$

In this case, by Lemma 6, there is no pair (x, y) such that $(x, y) \in \sigma(u_1)$, hence $\sigma(t_1) \supseteq \sigma(u_1)$ is vacuously true.

Suppose now that there is x_1 and y_1 in B such that $\mathcal{G}(u_1) \triangleright (x_1, G, y_1)$, let h_1 be such homomorphism. Notice the following:

$$\forall x, y \in B, \quad \mathcal{G}(u_0) \triangleright (x, G, y) \Rightarrow \mathcal{G}(u_0) \oplus \mathcal{G}(u_1) \triangleright (x, G, y) \quad (\dagger)$$

Indeed, if h_0 is a homomorphism from $\mathcal{G}(u_0)$ to (x, G, y) , then we can combine it with h_1 to get a homomorphism from $\mathcal{G}(u_0) \oplus \mathcal{G}(u_1)$ to (x, G, y) .

Let us show that $\sigma(t_0) \supseteq \sigma(u_0)$. If $\sigma(u_0) \ni (x, y)$, then by Lemma 6, we have that $\mathcal{G}(u_0) \triangleright (x, G, y)$. Using the remark (\dagger), we get that $\mathcal{G}(u_0) \oplus \mathcal{G}(u_1) \triangleright (x, G, y)$. By our hypothesis, we know that $\mathcal{G}(t_0) \triangleright \mathcal{G}(u_0) \oplus \mathcal{G}(u_1)$, thus $\mathcal{G}(t_0) \triangleright (x, G, y)$. We conclude that $\sigma(t_0) \ni (x, y)$, and this ends the proof of our first characterization theorem. \blacktriangleleft

Testing the existence of a homomorphism between finite graphs is decidable. Hence, we get as a corollary of Theorem 7 that:

► **Theorem 10.** *The positive universal theory of relations is decidable.*

4 Characterizing the Horn theory of relations

To give a characterization of the Horn theory of relations, we need to generalize the homomorphism relation between graphs to take into account some set of hypothesis.

A *context* is a graph with a distinguished edge labeled by a special letter \bullet , called its *hole*. If G is a graph and C a context, then $C[G]$ is the graph obtained by “plugging G in the hole” of C , that is, $C[G]$ is the graph obtained as the disjoint union of G and C , where we identify the input (resp. output) of G with the input (resp. output) of the edge labeled by \bullet in C , and we remove the edge of C labeled \bullet .

► **Definition 11** (The relation $\triangleright_{\mathcal{H}}$). *Let \mathcal{H} be a set of inequations. We define the relation $\triangleright_{\mathcal{H}}$ on graphs as follows. We set $G \triangleright_{\mathcal{H}} H$ if and only if there is a context C and an inequation $(t \geq u) \in \mathcal{H}$ such that*

$$G = C[\mathcal{G}(t)] \quad \text{and} \quad H = C[\mathcal{G}(u)]$$

We define $\triangleright_{\mathcal{H}}$ as the transitive closure of $\triangleright \cup \triangleright_{\mathcal{H}}$.

In the definition above, the graphs G , H and C are not necessarily the graphs of some terms.

We can state now the main theorem of this section:

► **Theorem 12.** For all terms t, u and set of inequations \mathcal{H} , we have:

$$\mathcal{R}el \models (\mathcal{H} \Rightarrow t \geq u) \quad \text{iff} \quad \mathcal{G}(t) \triangleright_{\mathcal{H}} \mathcal{G}(u)$$

Hence, in order to show that a Horn sentence $(\mathcal{H} \Rightarrow t \geq u)$ is valid, we need to find a sequence of graphs G_0, \dots, G_n such that $G_0 = \mathcal{G}(t)$, $G_n = \mathcal{G}(u)$ and for every $i \in [0, n - 1]$ the graphs G_i and G_{i+1} are either related by homomorphism or by the relation $\triangleright_{\mathcal{H}}$. We say that this sequence *witnesses* the validity of this Horn sentence.

► **Example 13.** The validity of the following Horn sentence:

$$ef^\circ \geq \top \Rightarrow (ae \cap cf)(e^\circ b \cap f^\circ d) \geq ab \cap cd \quad (3)$$

is witnessed by the following sequence:

We start by applying a homomorphism represented by the dotted lines, then we factorize the obtained graph into a context (in green) and an inner graph (in red) which is the graph of ef° , the lhs of the hypothesis $ef^\circ \geq \top$. We replace it by the graph of the rhs \top , which is the empty graph. Doing so, we get the graph of $ab \cap cd$

Notice that the intermediary graph is *not* the graph of a term.

► **Remark 14.** One may wonder whether Theorem 12 leads to a decidability result for the Horn theory of relations. Actually, the latter is undecidable, as it subsumes the word problem for monoids [6, Thm.4.5].

The next two subsections are dedicated to the proof of Theorem 12.

4.1 From $\triangleright_{\mathcal{H}}$ to validity

In this section we prove the right-to-left implication of Theorem 12. But first, let us show the following lemma, which says that $\triangleright_{\mathcal{H}}$ collapses to \triangleright if the target graph is the graph of an interpretation making \mathcal{H} true.

► **Lemma 15.** Let \mathcal{H} be a set of inequations and σ an interpretation. If the inequations \mathcal{H} are true under σ , then for every graph G :

$$G \triangleright_{\mathcal{H}} (x, G(\sigma), y) \quad \text{iff} \quad G \triangleright (x, G(\sigma), y)$$

Proof. The right-to-left direction is trivial. We prove the other direction by induction on the length of a sequence witnessing that $G \triangleright_{\mathcal{H}} (x, G(\sigma), y)$. The most interesting base case is when, for some graph H :

$$G \triangleright_{\mathcal{H}} H \triangleright (x, G(\sigma), y) \quad (\text{BC})$$

The other two base cases are: $G \triangleright (x, G(\sigma), y)$, which is trivial, and $G \triangleright_{\mathcal{H}} (x, G(\sigma), y)$, which can be seen as a particular case of the interesting base case, by taking H to be $(x, G(\sigma), y)$. The inductive step is easy, as the composition of two homomorphisms is a homomorphism. Now, let us prove the interesting base case. Suppose that there is a graph H satisfying (BC), and let us find a homomorphism from G to $(x, G(\sigma), y)$.

41:8 Graph Characterization of the Universal Theory of Relations

Since $G >_{\mathcal{H}} H$, there is an inequation $(t \geq u) \in \mathcal{H}$ and a context C such that $G = C[\mathcal{G}(t)]$ and $H = C[\mathcal{G}(u)]$. We have also that $H \triangleright (x, G(\sigma), y)$, so let h be a homomorphism:

$$h : C[\mathcal{G}(u)] \rightarrow (x, G(\sigma), y)$$

Let x' and y' be respectively the image of the input and the output of $\mathcal{G}(u)$ by h . By considering the restriction of h to $\mathcal{G}(u)$, we have that $\mathcal{G}(u) \triangleright (x', G(\sigma), y')$. Hence, by Lemma 6, we have that $(x', y') \in \sigma(u)$. As \mathcal{H} is true under σ , we have also that $(x', y') \in \sigma(t)$, and again by Lemma 6, $\mathcal{G}(t) \triangleright (x', G(\sigma), y')$. Let us denote by k a homomorphism:

$$k : \mathcal{G}(t) \rightarrow (x', G(\sigma), y')$$

With these ingredients, we construct a homomorphism f from $G = C[\mathcal{G}(t)]$ to $(x, G(\sigma), y)$ as follows: the restriction of f to C is h and the restriction of f to $\mathcal{G}(t)$ is k . It is easy to check that f is indeed an homomorphism, and this ends the proof. \blacktriangleleft

We can now prove the right-to-left direction of Theorem 12.

Proof of Theorem 12 (\Leftarrow). Suppose that $\mathcal{G}(t) \triangleright_{\mathcal{H}} \mathcal{G}(u)$. Let σ be an interpretation satisfying \mathcal{H} and suppose that $(x, y) \in \sigma(u)$.

$\sigma(u) \ni (x, y)$	$\Rightarrow \mathcal{G}(u) \triangleright (x, G(\sigma), y)$	Lem. 6
	$\Rightarrow \mathcal{G}(t) \triangleright_{\mathcal{H}} (x, G(\sigma), y)$	By hypothesis
	$\Rightarrow \mathcal{G}(t) \triangleright (x, G(\sigma), y)$	Lem. 15
	$\Rightarrow \sigma(t) \ni (x, y)$	Lem. 6 \blacktriangleleft

4.2 From validity to $\triangleright_{\mathcal{H}}$

The main ingredient to prove the left-to-right direction of Theorem 12 is to construct, given a set of hypothesis \mathcal{H} , an interpretation making them true. For that we start from an arbitrary graph and “saturate” it by the hypothesis \mathcal{H} , then we iterate this construction ω -times and take the *limit graph*. The desired interpretation will be the interpretation associated to this graph. In the sequel, we define the notions of graph limit and saturation, then we proceed to the proof of our theorem.

4.2.1 Limit of a sequence of graphs

When we consider an increasing sequence of graphs $(G_i)_{i \in \omega}$, that is, $G_i \hookrightarrow G_{i+1}$ for every $i \in \omega$, the notion of limit is clear: it is just the union of the graphs G_i , its input and output being respectively the common input and output of the graphs G_i ; we denote it by $\lim_{i \in \omega} G_i$. We denote by $\theta_i : G_i \rightarrow \lim_{i \in \omega} G_i$ the natural injection of G_i into the limit graph, we call it the *limit injection for G_i* . Here is an illustration of this construction:

In the following, we extend this notion of limit to the case where the graphs G_i and G_{i+1} are related by an arbitrary homomorphism, not necessarily an injective one. Let us start with an observation.

Let $G_0 \xrightarrow{h_0} G_1 \xrightarrow{h_1} G_2 \dots$ be a sequence of *finite* graphs related by homomorphism. Let $(H_i)_{i \in \omega}$ be the successive images of G_0 by these homomorphisms, that is:

$$H_0 = G_0, \quad \text{and} \quad H_{i+1} = h_i(H_i) \quad \text{for } i \geq 0.$$

At some point, the image of G_0 will stabilize, in other words there is an index s such that, for all $i > s$ the function $k_i : H_i \rightarrow H_{i+1}$, the restriction of h_i to H_i is a bijection. We call *stabilization index* of G_0 the least index s satisfying this property, we denote it by s_0 . We call *stable image* of G_0 the graph H_{s_0} and we denote it by $S(G_0)$.

We define in the same way the *stabilization index* of G_i , and denote it s_i : it is the least index starting from which the homomorphisms h_j for $j > s_i$ do not merge nodes coming from G_i . We define similarly the stable image of G_i and denote it by $S(G_i)$.

Note that if $i \leq j$ then $s_i \leq s_j$ and $S(G_i) \hookrightarrow S(G_j)$. By considering the sequence of the stable images of the graphs G_i , we can now define the limit of this sequence:

► **Definition 16** (Limit of a sequence of graphs). *Let $(G_i)_{i \in \omega}$ be a sequence of finite graphs such that there is a homomorphism $h_i : G_i \rightarrow G_{i+1}$ for every $i \in \omega$. As the sequence of stable images $(S(G_i))_{i \in \omega}$ is increasing, its limit $\lim_{i \in \omega} S(G_i)$ is well defined. For every $i \in \omega$, let θ_i be the limit injection $\theta_i : S(G_i) \rightarrow \lim_{i \in \omega} S(G_i)$.*

We define the limit of the sequence $(G_i)_{i \in \omega}$ as follows:

$$\lim_{i \in \omega} G_i = \lim_{i \in \omega} S(G_i)$$

For every $i < j \in \omega$, we denote by $h_{[i,j]}$ the homomorphism $h_{[i,j]} : G_i \rightarrow G_j$ obtained as the composition $h_{j-1} \circ \dots \circ h_i$. We denote by $\pi_i : G_i \rightarrow \lim_{i \in \omega} G_i$ the homomorphism $\theta_{s_i} \circ h_{[i,s_i]}$. We call π_i the limit homomorphism for G_i .

► **Example 17.** Consider the sequence of terms $(t_i)_{i \in \omega}$ defined by:

$$t_i = \left(\bigcap_{k=0}^i a_k \cdot \bigcap_{k=0}^i b_k \right) \cap (a_{i+1} \cdot b_{i+1}).$$

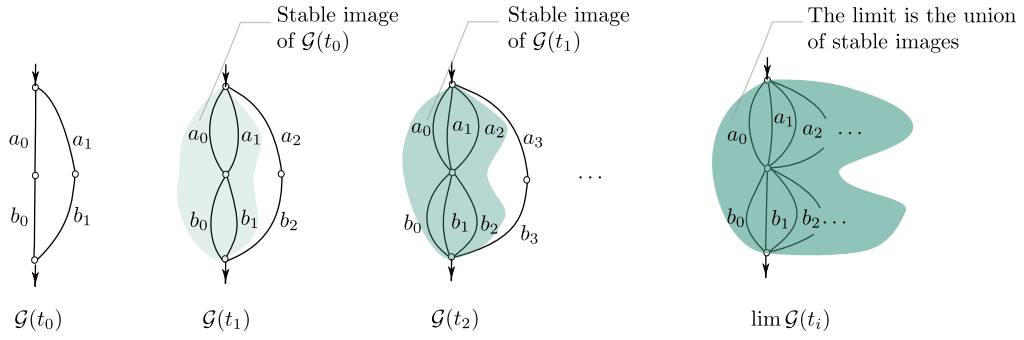

There is a (unique) homomorphism $h_i : \mathcal{G}(t_i) \rightarrow \mathcal{G}(t_{i+1})$. The limit of the sequence of graphs $(\mathcal{G}(t_i))_{i \in \omega}$ related by the homomorphisms $(h_i)_{i \in \omega}$, converges to the graph of this “term”¹:

$$\bigcap_{k=0}^{\infty} a_k \cdot \bigcap_{k=0}^{\infty} b_k$$

Here is an illustration of this example:

¹ This is not really a term since it contains infinite intersections, but it is clear how to define the graphs of such generalized terms.

41:10 Graph Characterization of the Universal Theory of Relations

Note that the limit does not depend only on the sequence of graphs, but also on the homomorphisms relating them. Consider for instance the following sequence of terms.

$$u_i = \left(\bigcap_{k=0}^i a_k \cdot \bigcap_{k=0}^i b_k \right) \cap \bigcap_{k=0}^{i+1} (a_k \cdot b_k).$$

If we consider the injections $\iota_i : \mathcal{G}(u_i) \rightarrow \mathcal{G}(u_{i+1})$, then the sequence $(\mathcal{G}(u_i))_{i \in \omega}$ related by the homomorphisms $(\iota_i)_{i \in \omega}$ converges to the graph of this “term”:

$$\left(\bigcap_{k=0}^{\infty} a_k \cdot \bigcap_{k=0}^{\infty} b_k \right) \cap \bigcap_{k=0}^{\infty} (a_k \cdot b_k)$$

But if we consider the homomorphisms $k_i : \mathcal{G}(u_i) \rightarrow \mathcal{G}(u_{i+1})$ which merges all the inner nodes² of $\mathcal{G}(u_i)$, we obtain as limit the graph of this “term”:

$$\bigcap_{k=0}^{\infty} a_k \cdot \bigcap_{k=0}^{\infty} b_k$$

► **Remark 18.** This notion of limit is a well known concept of category theory. Since the category of graphs and graph homomorphisms is cocomplete, every infinite sequence of homomorphisms has a colimit, unique up to isomorphism. We made the choice to give an explicit definition for the readers which are, as the author, not familiar with category theory.

Here are some properties satisfied by the limit of a sequence of graphs.

► **Proposition 19.** Let $(G_i)_{i \in \omega}$ be a sequence of graphs, and $h_i : G_i \rightarrow G_{i+1}$. Let G_ω be their graph limit, π_i be the limit homomorphism for G_i and H be a finite graph.

1. For every $i \in \omega$, if $H \triangleright (x, G_i, y)$ then $H \triangleright (\pi_i(x), G_\omega, \pi_i(y))$.
2. Conversely, if $H \triangleright (x, G_\omega, y)$ then $H \triangleright (x', G_i, y')$ for some i, x', y' satisfying $\pi_i(x') = x$ and $\pi_i(y') = y$.
3. In particular, we have that: $H \triangleright G_\omega \Leftrightarrow \exists i \in \omega, H \triangleright G_i$.

Proof. Property (1) is trivial. Indeed, if $h : H \rightarrow (x, G_i, y)$ is a homomorphism then $h_i \circ h : H \rightarrow (\pi_i(x), G_\omega, \pi_i(y))$ is also a homomorphism.

Suppose that $H \triangleright (x, G_\omega, y)$. Since H is finite, there is $i \in \omega$ such that $H \triangleright (x', S(G_i), y')$ where $\pi_i(x') = x$ and $\pi_i(y') = y$. But $S(G_i)$ is a subgraph of some G_j , where $j \in \omega$. Hence $H \triangleright (x', G_j, y')$. ◀

² That is, nodes different from the input and the output.

4.2.2 Saturation by hypothesis

Let $G, H \in \mathcal{Gr}$ and let x, y be two vertices of G . We denote by $G[H/xy]$ the graph obtained from G by merging the input of H with x and its output with y . The input and output of $G[H/xy]$ are those of G .

► **Remark 20.** Note that if the input and output of H are equal, then the operation $G[H/xy]$ merges the nodes x, y . Note also that $G \triangleright G[H/xy]$, but this homomorphism is not necessarily injective because of the possible merge of x and y .

► **Definition 21 (Saturation).** Let \mathcal{H} be a finite set of inequations, $G \in \mathcal{Gr}$ and V its set of vertices. Let $T \subseteq V \times V \times \mathcal{Gr}$ be the set of triplets satisfying:

$$(x, y, H) \in T \quad \text{iff} \quad \exists (t \geq u) \in \mathcal{H}, \quad \mathcal{G}(u) \triangleright (x, G, y) \quad \text{and} \quad H = \mathcal{G}(t)$$

Let $(x_i, y_i, H_i)_{i \leq n}$ be an enumeration of T . The saturation of G by \mathcal{H} is the graph denoted $Sat_{\mathcal{H}}(G)$ and defined as:

$$Sat_{\mathcal{H}}(G) = G[H_0/x_0y_0] \dots [H_n/x_ny_n]$$

In words, a triplet (x, y, H) is in T means that in the graph G , we “identified” the graph $\mathcal{G}(u)$, the rhs of a hypothesis in \mathcal{H} , between the nodes x and y . The graph H is $\mathcal{G}(t)$, the graph of the lhs of this hypothesis. To make G “agree” with hypothesis \mathcal{H} , we need to plug H between x and y . When we do that for all the triplets in T , we obtain the saturation of G by \mathcal{H} . Now, let us make some properties of saturation explicit.

► **Proposition 22.** Let G be a graph and \mathcal{H} a set of inequations.

1. For every inequation $(t \geq u) \in \mathcal{H}$, we have:

$$\mathcal{G}(u) \triangleright (x, G, y) \Rightarrow \mathcal{G}(t) \triangleright (x, Sat_{\mathcal{H}}(G), y)$$

2. $G \triangleright Sat_{\mathcal{H}}(G)$.

3. $Sat_{\mathcal{H}}(G) \triangleright_{\mathcal{H}} G$.

Proof. To prove (1), suppose that $(t \geq u) \in \mathcal{H}$ and $\mathcal{G}(u) \triangleright (x, G, y)$. This means that the triplet $(x, y, \mathcal{G}(t))$ is in the set T of Definition 21. Hence $Sat_{\mathcal{H}}(G)$ is of the form $K[\mathcal{G}(t)/xy]$. It is clear then that $\mathcal{G}(t) \triangleright (x, Sat_{\mathcal{H}}(G), y)$.

Property (2) is a consequence of Remark 20 above. For property (3), we will show that if $(x, y, H) \in T$, where T is as in definition 21, then $G[H/xy] \triangleright_{\mathcal{H}} G$. The result will be an iteration of this argument for all elements of T . By definition of T , there is a hypothesis $(t \geq u)$ such that $\mathcal{G}(u) \triangleright (x, G, y)$ and $H = \mathcal{G}(t)$. Let us denote by k a homomorphism from $\mathcal{G}(u)$ to (x, G, y) . Let C be the context obtained from G by adding an edge labeled \bullet between x and y . We have that:

$$G[H/xy] = C[\mathcal{G}(t)] \triangleright_{\mathcal{H}} C[\mathcal{G}(u)] \triangleright G$$

Indeed, the equality and inequation $\triangleright_{\mathcal{H}}$ are trivially true. To justify the \triangleright inequation, we define a homomorphism from $C[\mathcal{G}(u)]$ to G as follows: its restriction to $\mathcal{G}(u)$ is the homomorphism k , and its restriction to C is the identity. ◀

Now, we can define the ω -saturation of a graph by a set of hypothesis.

41:12 Graph Characterization of the Universal Theory of Relations

► **Definition 23** (ω -saturation). If G is a graph and \mathcal{H} a set of inequations, we define the sequence $(Sat_{\mathcal{H}}^i(G))_{i \in \omega}$ as the successive iterations of G by saturation by the hypothesis \mathcal{H} :

$$Sat_{\mathcal{H}}^0(G) = G, \quad Sat_{\mathcal{H}}^{i+1}(G) = Sat(Sat_{\mathcal{H}}^i(G)) \quad (i \in \omega).$$

By Proposition 22 (2), we have that $Sat_{\mathcal{H}}^i(G) \triangleright Sat_{\mathcal{H}}^{i+1}(G)$. The limit is then well defined by Definition 16. We define the ω -saturation of G by \mathcal{H} as the graph:

$$Sat_{\mathcal{H}}^{\omega}(G) = \lim_{i \in \omega} Sat_{\mathcal{H}}^i(G).$$

The ω -saturation satisfies the following property. It says that given a set of inequations \mathcal{H} , if we start from an arbitrary graph G (so in general, the inequations of \mathcal{H} are not true under the interpretation associated to G) and we ω -saturate it by \mathcal{H} , then the inequations from \mathcal{H} are true under the interpretation associated to the obtained graph.

► **Proposition 24.** Let \mathcal{H} be a set of inequations, G be a graph, and σ the interpretation associated to $Sat_{\mathcal{H}}^{\omega}(G)$. The inequations from \mathcal{H} are true under σ .

Proof. We denote by G^{ω} the graph $Sat_{\mathcal{H}}^{\omega}(G)$, by G^i the graph $Sat_{\mathcal{H}}^i(G)$ for every $i \in \omega$ and by σ the interpretation associated to G^{ω} . By Remark 5, the graph associated to σ is G^{ω} . Let $\pi_i : G^i \rightarrow G^{\omega}$ be the limit homomorphism for G_i .

Let $(t \geq u) \in \mathcal{H}$, let us show that $\sigma(t) \supseteq \sigma(u)$. Suppose that $\sigma(u) \ni (x, y)$.

$$\begin{aligned} \sigma(u) \ni (x, y) &\implies \mathcal{G}(u) \triangleright (x, G^{\omega}, y) && \text{Lem. 6} \\ &\xrightarrow{\exists i, x', y'} \mathcal{G}(u) \triangleright (x', G^i, y'), \quad x = \pi_i(x') \text{ and } y = \pi_i(y') && \text{Prop. 19 (2)} \\ &\implies \mathcal{G}(t) \triangleright (x', G^{i+1}, y') && \text{Prop. 22 (1)} \\ &\implies \mathcal{G}(t) \triangleright (x, G^{\omega}, y) && \text{Prop. 19 (1)} \\ &\implies \sigma(t) \ni (x, y) && \text{Lem. 6} \end{aligned}$$

And this concludes the proof. ◀

We can go back to the proof of Theorem 12.

Proof of Theorem 12 (\Leftarrow). Suppose that $\mathcal{R}el \models \mathcal{H} \Rightarrow t \geq u$ and let us show that $\mathcal{G}(t) \triangleright_{\mathcal{H}} \mathcal{G}(u)$. We denote by $\mathcal{G}(u)^{\omega}$ the graph $Sat_{\mathcal{H}}^{\omega}(\mathcal{G}(u))$, by $\mathcal{G}(u)^i$ the graph $Sat_{\mathcal{H}}^i(\mathcal{G}(u))$ for every $i \in \omega$, and by σ be the interpretation associated to $\mathcal{G}(u)^{\omega}$. By Proposition 24, the inequations \mathcal{H} are true under σ . Note that the graph associated to σ is $\mathcal{G}(u)^{\omega}$ and that the input and output of $\mathcal{G}(u)^{\omega}$ are those of $\mathcal{G}(u)$, let us denote them by ι and o respectively.

By Proposition 19 (1), we have $\mathcal{G}(u) \triangleright \mathcal{G}(u)^{\omega}$. It follows that:

$$\begin{aligned} \mathcal{G}(u) \triangleright \mathcal{G}(u)^{\omega} &\Rightarrow \sigma(u) \ni (\iota, o) && \text{Lem. 6} \\ &\Rightarrow \sigma(t) \ni (\iota, o) && \text{By hypothesis} \\ &\Rightarrow \mathcal{G}(t) \triangleright \mathcal{G}(u)^{\omega} && \text{Lem. 6} \\ &\Rightarrow \mathcal{G}(t) \triangleright \mathcal{G}(u)^i \text{ for some } i \in \omega && \text{Prop. 19 (3)} \\ &\Rightarrow \mathcal{G}(t) \triangleright_{\mathcal{H}} \mathcal{G}(u) && \text{Prop. 22 (3)} \end{aligned}$$

This ends the proof of Theorem 12. ◀

4.3 Characterizing the universal theory of relations

We characterize now the validity of the generalized Horn sentences. The proof is a mix of the techniques used to prove Theorems 7 and 12.

► **Theorem 25.** *For all terms t_i, u_i where $i \in [1, n]$, and set of inequations \mathcal{H} , the following holds:*

$$\mathcal{R}el \models \mathcal{H} \Rightarrow \bigvee_{i \in [1, n]} (t_i \geq u_i) \quad \text{iff} \quad \bigvee_{i \in [1, n]} (\mathcal{G}(t_i) \triangleright_{\mathcal{H}} \mathcal{G}(u_i) \oplus G)$$

where $G = \mathcal{G}(u_1) \oplus \dots \oplus \mathcal{G}(u_n)$.

Proof. As for Theorem 7, we prove this result in the case of binary disjunctions, that is:

$$\mathcal{R}el \models \mathcal{H} \Rightarrow (t_0 \geq u_0) \vee (t_1 \geq u_1) \quad \text{iff} \quad G(t_0) \triangleright_{\mathcal{H}} \mathcal{G}(u_0) \oplus G(u_1) \text{ or } G(t_1) \triangleright_{\mathcal{H}} \mathcal{G}(u_1) \oplus G(u_0)$$

(\Rightarrow) Suppose that $\mathcal{R}el \models \mathcal{H} \Rightarrow (t_0 \geq u_0) \vee (t_1 \geq u_1)$, let us show that either

$$G(t_0) \triangleright_{\mathcal{H}} \mathcal{G}(u_0) \oplus G(u_1) \quad \text{or} \quad G(t_1) \triangleright_{\mathcal{H}} \mathcal{G}(u_1) \oplus G(u_0)$$

We set $G = \mathcal{G}(u_0) \oplus \mathcal{G}(u_1)$, and let G^ω denote the graph $Sat_{\mathcal{H}}^\omega(G)$, G^i denote the graph $Sat_{\mathcal{H}}^i(G)$ for every $i \in \omega$, and let σ be the interpretation associated to G^ω . By Proposition 24, the inequations \mathcal{H} are true under σ . Hence, we have either $\sigma(t_0) \supseteq \sigma(u_0)$ or $\sigma(t_1) \supseteq \sigma(u_1)$. Let us study the former case, the latter being symmetric.

Suppose that $\sigma(t_0) \supseteq \sigma(u_0)$. Let ι and o be respectively the input and output of G^ω . Notice that $\mathcal{G}(u_0) \triangleright (\iota, G^\omega, o)$, it follows that:

$$\begin{aligned} \mathcal{G}(u_0) \triangleright (\iota, G^\omega, o) &\Rightarrow \sigma(u_0) \ni (\iota, o) && \text{Lem. 6} \\ &\Rightarrow \sigma(t_0) \ni (\iota, o) && \text{By hypothesis} \\ &\Rightarrow \mathcal{G}(t_0) \triangleright G^\omega && \text{Lem. 6} \\ &\Rightarrow \mathcal{G}(t_0) \triangleright G^i \text{ for some } i \in \omega && \text{Prop. 19 (3)} \\ &\Rightarrow \mathcal{G}(t_0) \triangleright_{\mathcal{H}} G && \text{Prop. 22 (3)} \end{aligned}$$

This concludes the proof of this direction.

(\Leftarrow) Suppose that $G(t_0) \triangleright_{\mathcal{H}} \mathcal{G}(u_0) \oplus G(u_1)$ and let us show that:

$$\mathcal{R}el \models \mathcal{H} \Rightarrow (t_0 \geq u_0 \vee t_1 \geq u_1)$$

Note that the other case is symmetric. Let $\sigma : A \rightarrow \mathcal{P}(B \times B)$ be an interpretation under which \mathcal{H} is true, and let G be its graph. We distinguish two cases. We have either:

$$\forall x, y \in B, \quad \mathcal{G}(u_1) \not\triangleright (x, G, y)$$

In this case, by Lemma 6, there is no pair (x, y) such that $(x, y) \in \sigma(u_1)$, hence $\sigma(t_1) \supseteq \sigma(u_1)$ is vacuously true.

Suppose now that there is x_1 and y_1 in B such that $\mathcal{G}(u_1) \triangleright (x_1, G, y_1)$. Notice the following:

$$\forall x, y \in B, \quad \mathcal{G}(u_0) \triangleright (x, G, y) \Rightarrow \mathcal{G}(u_0) \oplus \mathcal{G}(u_1) \triangleright (x, G, y)$$

By using Lemma 6 and this remark, we get that if $\sigma(u_0) \ni (x, y)$ then $\mathcal{G}(t_0) \triangleright_{\mathcal{H}} (x, G, y)$. By Lemma 15, and since the inequations \mathcal{H} are true under σ , we have that $\mathcal{G}(t_0) \triangleright (x, G, y)$. Hence, by Lemma 6, we get $\sigma(t_0) \ni (x, y)$ which concludes the proof. ◀

As every universal sentence can be written as the conjunction of some generalized Horn sentences, Theorem 25 gives us a characterization of the validity of all universal sentences.

5 Conclusion

We end this paper by some concluding remarks and open problems.

By characterizing the universal theory of relations, we characterized also their existential theory. Now, can we characterize the full first-order theory of relations using graphs and homomorphisms?

Another direction of work is to extend the syntax of terms. For instance, we could add the operations of union and Kleene star. In this case, terms are interpreted, not by a single graph as we did here, but by a set of graphs as in [4, Def. 4]. Graph homomorphism is generalized to the relation \blacktriangleright between sets of graphs as follows:

$$C \blacktriangleright D \quad \Leftrightarrow \quad \forall H \in D, \exists G \in C, G \triangleright H$$

With these interpretations, Theorem 7 can be easily adapted when union is added to the syntax. However, it is not clear how to adapt it in the presence of the Kleene star. Theorem 12 seems hard to adapt both for the union and the Kleene star extensions.

Even if Theorems 12 and 25 do not give decidability for the corresponding theories, we can wonder whether it can be obtained under some restrictions on the hypothesis \mathcal{H} . For instance, is it the case when the hypothesis \mathcal{H} form a Noetherian rewriting system?

We can easily adapt this work to the realm of conjunctive queries. Indeed, terms can be replaced by conjunctive queries and inequations between terms by equivalence between conjunctive queries $Q_1 \equiv Q_2$. For example, by adapting Theorem 7 we get the decidability of the following problem:

Input: Conjunctive queries Q_1, Q_2, Q_3 and Q_4 .
Output: Do we have $(Q_1 \equiv Q_2) \vee (Q_3 \equiv Q_4)$?

which generalizes the result of Chandra and Merlin [5].

Abstract

Clique-width and treewidth are two of the most important and useful graph parameters, and several problems can be solved efficiently when restricted to graphs of bounded clique-width or treewidth. Bounded treewidth implies bounded clique-width, but not vice versa. Problems like LONGEST CYCLE, LONGEST PATH, MAXCUT, EDGE DOMINATING SET, and GRAPH COLORING are fixed-parameter tractable when parameterized by the treewidth, but they cannot be solved in FPT time when parameterized by the clique-width unless $FPT = W[1]$, as shown by Fomin, Golovach, Lokshtanov, and Saurabh [SIAM J. Comput. 2010, SIAM J. Comput. 2014]. For a given problem that is fixed-parameter tractable when parameterized by treewidth, but intractable when parameterized by clique-width, there may exist infinite families of instances of bounded clique-width and unbounded treewidth where the problem can be solved efficiently. In this work, we initiate a systematic study of the parameters co-treewidth (the treewidth of the complement of the input graph) and co-degeneracy (the degeneracy of the complement of the input graph). We show that LONGEST CYCLE, LONGEST PATH, and EDGE DOMINATING SET are FPT when parameterized by co-degeneracy. On the other hand, GRAPH COLORING is para-NP-complete when parameterized by co-degeneracy but FPT when parameterized by the co-treewidth. Concerning MAXCUT, we give an FPT algorithm parameterized by co-treewidth, while we leave open the complexity of the problem parameterized by co-degeneracy. Additionally, we show that PRECOLORING EXTENSION is fixed-parameter tractable when parameterized by co-treewidth, while this problem is known to be $W[1]$ -hard when parameterized by treewidth. These results give evidence that co-treewidth is a useful width parameter for handling dense instances of problems for which an FPT algorithm for clique-width is unlikely to exist. Finally, we develop an algorithmic framework for co-degeneracy based on the notion of Bondy-Chvátal closure.

1 Introduction

Treewidth and *clique-width* are two of the most important and useful graph parameters. Families of graphs of bounded treewidth include cactus graphs, outerplanar graphs, series-parallel graphs, Halin graphs, Apollonian networks [3], and graphs of bounded branch-width [45]. Graph classes with bounded clique-width include cographs [10], distance-hereditary graphs [35], and graphs of bounded treewidth [20]. Additionally, the clique-width of a graph is asymptotically equivalent to its rank-width [43].

An algorithmic meta-theorem due to Courcelle, Makowsky and Rotics [15] states that any problem expressible in the monadic second-order logic of graphs (MSO_1) can be solved in $f(cw) \cdot n$ time, i.e., it is fixed-parameter tractable when parameterized by the clique-width, cw , of the input graph. Originally this required a clique-width expression as part of the input. This restriction was removed when Oum and Seymour [43] gave an FPT algorithm, parameterized by the clique-width of the input graph, that finds a $2^{\mathcal{O}(cw)}$ -approximation of an optimal clique-width expression. In addition, Courcelle [16] states that any problem expressible in the monadic second-order logic of graphs with edge set quantifications (MSO_2) can be solved in time $f(tw) \cdot n$, where tw is the treewidth of the input graph. Clearly, every MSO_1 property is also a MSO_2 property. However, there are MSO_2 properties like “ G has an Hamiltonian cycle” that are not MSO_1 expressible [18]. These results have been extended a number of times [1, 9, 15, 37]. In particular, the MSO meta-theorems mentioned above were extended to LinEMSO by allowing the expressibility of optimization problems concerning maximum or minimum sets (LinEMSO properties are equivalent to MSO properties for optimization problems which can be expressed as searching for sets of vertices/edges that are optimal concerning some linear evaluation functions) [1, 17, 15]. From these meta-theorems, it follows that several problems can be efficiently solved when restricted to graphs of bounded clique-width or treewidth. Many optimization problems are LinEMSO_2 -expressible, but GRAPH COLORING , the problem of determining the chromatic number of the input graph is not a LinEMSO problem [41]. However, on graphs G with bounded treewidth, the chromatic number of G is also bounded; therefore, in this specific case, the problem is Turing-reducible to a MSO_1 problem (k - COLORING for fixed k).

Bounded treewidth implies bounded clique-width [13] but the opposite implication is not valid, as in the case of complete graphs. On the other hand, LinEMSO_2 is more expressive than LinEMSO_1 , and there exist LinEMSO_2 -expressible problems like MAXCUT , LONGEST CYCLE , LONGEST PATH and $\text{EDGE DOMINATING SET}$ that cannot be FPT when parameterized by clique-width [28, 29, 30, 31], unless $\text{FPT} = \text{W}[1]$. Additionally, GRAPH COLORING is also an FPT problem concerning treewidth parameterization that cannot be FPT when parameterized by clique-width, unless $\text{FPT} = \text{W}[1]$, see [30].

For problems that are fixed-parameter tractable when parameterized by treewidth, but intractable when parameterized by clique-width, the identification of tractable classes of instances of bounded clique-width and unbounded treewidth becomes a fundamental quest. The goal of this work is to show that *co-treewidth*, that is to say, the treewidth of the complement of the input graph, is a parameter that fulfills this quest. More precisely, we will show that several natural problems that are unlikely to be in FPT when parameterized by clique-width can be solved in FPT time when parameterized by co-treewidth. Examples of such problems are LONGEST PATH , LONGEST CYCLE , MAXCUT , $\text{EDGE DOMINATING SET}$, and GRAPH COLORING . In addition, since bounded treewidth implies bounded degeneracy (the degeneracy of a graph is upper bounded by its treewidth), we also consider the degeneracy of the complement graph, called *co-degeneracy*, as a parameter.

Let us say that a parameter x is weaker than parameter y , and y stronger than x , if the set of graph classes where x is bounded is a subset of those where y is bounded. In 2016, Saether and Telle [46] considered a graph parameter called *sm-width* which is stronger than *treewidth* and weaker than *clique-width*. They showed that *MAXCUT*, *GRAPH COLORING*, *HAMILTONIAN CYCLE* and *EDGE DOMINATING SET* are FPT when parameterized by *sm-width*. However, *co-treewidth* and *sm-width* are incomparable since trees have bounded *sm-width* but unbounded *co-treewidth*, and the complements of paths have bounded *co-treewidth* but unbounded *sm-width*. Also, note that *neighborhood diversity* [40], *twin-cover* [33], *shrub-depth* [34], and *modular-width* [32] are all weaker than *clique-width*, but none of them are stronger than *co-treewidth*. Gajarský, Lampis, and Ordyniak [32] showed that *GRAPH COLORING* and *HAMILTONIAN PATH* are $W[1]$ -hard parameterized by *shrub-depth* but FPT parameterized by *modular-width* (which is stronger than *neighborhood diversity* and *twin-cover*), they also leave as an open problem the complexity of *MAXCUT* and *EDGE DOMINATING SET* parameterized by *modular-width*. Besides, also in the context “between *treewidth* and *clique-width*”, Eiben, Ganian, Hamm, and Kwon [26] develop hybrid parameters (\mathcal{H} -*treewidth*) combining advantages of *treewidth* and modulators, the aim of \mathcal{H} -*treewidth* is to capture the *treewidth* of a modulator to the class \mathcal{H} (see [26]).

In 2016, Dvořák, Knop, and Masařík [25] showed that *k-PATH COVER* is FPT when parameterized by the *treewidth* of the complement of the input graph (i.e., the *co-treewidth* of the input). This implies that *HAMILTONIAN PATH* is FPT when parameterized by *co-treewidth*. In 2017, Knop, Koutecký, Masařík, and Toufar [38] asked about the complexity of deciding graph problems Π on the complement of G considering a parameter p of G (i.e., with respect to $p(G)$), especially for sparse graph parameters such as *treewidth*. In this paper, by showing that *LONGEST PATH*, *LONGEST CYCLE*, *MAXCUT*, *EDGE DOMINATING SET*, and *GRAPH COLORING* are all FPT when parameterized by *co-treewidth*, we exemplify that *co-treewidth* is a useful width parameter for dealing with problems for which an FPT algorithm for *clique-width* is unlikely. Besides, to the best of our knowledge, this is the first work dealing with *co-degeneracy* parameterization.

It is also natural to consider the *clique-width* of the complement graph as parameter, however, Courcelle and Olariu [20] proved that for every graph G we have $cw(\bar{G}) \leq 2 \cdot cw(G)$. Therefore, the notion of “*co-clique-width*” is redundant from the point of view of parameterized complexity. On the other hand, the notion of *co-treewidth* seems to be interesting given that bounded *co-treewidth* implies bounded *clique-width*; and *treewidth* and *co-treewidth* are incomparable parameters. Moreover, although *co-degeneracy* is incomparable with *clique-width*, it is stronger than *co-treewidth* and a useful parameter for handling some problems on dense instances. In this paper, we show that *LONGEST PATH*, *LONGEST CYCLE*, and *EDGE DOMINATING SET* are FPT when parameterized by *co-degeneracy*, while *GRAPH COLORING* is para-NP-hard. The complexity of *MAXCUT* parameterized by *co-degeneracy* is left open.

Finally, we also remark that for some graph problems, *co-treewidth* can be a parameter more useful than *treewidth*. For instance, *EQUITABLE COLORING* and *PRECOLORING EXTENSION* are well-known $W[1]$ -hard problems concerning *treewidth*; however, we remark that both problems are fixed-parameter tractable when parameterized by *co-treewidth*.

1.1 Preliminaries

We use standard graph-theoretic and parameterized complexity notation, and we refer the reader to [21, 24] for any undefined notation.

The *degeneracy* of a graph G is the least k such that every induced subgraph of G contains a vertex with degree at most k . Equivalently, the *degeneracy* of G is the least k such that its vertices can be arranged into a sequence so that each vertex is adjacent to most

k vertices preceding it in the sequence. We denote by $\text{co-deg}(G)$ the co-degeneracy of G , i.e., the degeneracy of \overline{G} . Also, for a graph G , we denote by $\text{co-tw}(G)$ the co-treewidth of G , i.e., the treewidth of \overline{G} . For short, we use *co-deg* and *co-tw* whenever the graph G is implicit.

In general, for a tree decomposition $(T, \{X_t\}_{t \in V(T)})$ it is common to distinguish one vertex r of T which will be the root of T . This introduces natural parent-child and ancestor-descendant relations in the tree T [21]. It is useful to design dynamic programming algorithms based on tree decompositions to obtain rooted tree decompositions that satisfy some auxiliary conditions. Such decompositions are so-called *nice tree decompositions*.

► **Definition 1.** A tree decomposition $(T, \{X_t\}_{t \in V(T)})$ with root node X_r is nice, if the following conditions are satisfied:

- $X_r = \emptyset$; (the root is an empty bag of T)
- If X_ℓ is a leaf node of T , then $X_\ell = \emptyset$; (each leaf X_ℓ is an empty bag of T)
- Every non-leaf node of T is of one of the following three types:
 1. Introduce node: a node t with exactly one child t' such that $X_t = X_{t'} \cup \{v\}$ for some vertex $v \notin X_{t'}$; we say that v is introduced at t .
 2. Forget node: a node t with exactly one child t' such that $X_t = X_{t'} \setminus \{w\}$ for some vertex $w \in X_{t'}$; we say that w is forgotten at t .
 3. Join node: a node t with two children t_1, t_2 such that $X_t = X_{t_1} = X_{t_2}$.

Let G be a graph and let $(T, \{X_t\}_{t \in V(T)})$ be a nice tree-decomposition of the graph G . For each node t of T , we denote by T_t the subtree of T rooted by t . Also, we denote by G_t the subgraph of G induced by the set of vertices contained in some bag of T_t .

Based on the following results, we can assume that we are given a nice tree decomposition of G without loss of generality.

► **Theorem 2** ([5]). There exists an algorithm that, given an n -vertex graph G and an integer k , runs in time $2^{O(k)} \cdot n$ and either outputs that the treewidth of G is larger than k , or constructs a tree decomposition of G of width at most $5k + 4$.

► **Lemma 3** ([21]). Given a tree decomposition $(T, \{X_t\}_{t \in V(T)})$ of G of width at most k , one can in time $O(k^2 \cdot \max(|V(T)|, |V(G)|))$ compute a nice tree decomposition of G of width at most k that has at most $O(k \cdot |V(G)|)$ nodes.

The *clique-width* of a graph is another parameter that we will mention very often, and therefore, we briefly define this parameter for completeness. Given a graph G , the clique-width of G , denoted by $\text{cw}(G)$, is defined as the minimum number of labels needed to construct G , using the following four operations: create a single vertex v with an integer label ℓ (denoted by $\ell(v)$); take the disjoint union (i.e., co-join) of two graphs (denoted by \oplus); join by an (arc) edge every vertex labeled i to every vertex labeled j for $i \neq j$ (denoted by $\eta(i, j)$); relabel all vertices with label i by label j (denoted by $\rho(i, j)$). An algebraic term representing such a construction of G and using at most k labels is a *k-expression* of G . The clique-width of G is the minimum k for which G has a k -expression.

Given a graph G and a vertex $v \in V(G)$, $N(v)$ denotes the (open) neighborhood of v , $N[v]$ denotes the closed neighborhood of v ($N[v] = N(v) \cup \{v\}$), and $d(v)$ denotes the degree of v ($d(v) = |N(v)|$).

We say that two vertices v, w of G have the same type if $N(v) \setminus \{w\} = N(w) \setminus \{v\}$.

A graph G has neighborhood diversity at most k , if there exists a partition of $V(G)$ into at most k sets, such that all the vertices in each set have the same type. We denote by $\text{nd}(G)$ (or just nd when the graph G is implicit) the least k such that G has neighborhood diversity at most k .

A set $S \subseteq V(G)$ is a *vertex cover* of a graph G if for each edge of G at least one of its endpoints is in S . The *vertex cover number* of G , denoted by $vc(G)$, is the least k such that G has a vertex cover of size k . It is well known that if a graph G has vertex cover at most k , then $nd(G) \leq 2^k + k$ (c.f. [40]).

A *path cover* \mathcal{P} of a graph G is a set of vertex-disjoint paths of G such that each vertex in $V(G)$ belongs to a path in \mathcal{P} .

A graph G is *Hamiltonian* if there is a cycle which includes every vertex of G (such a cycle is called a *Hamiltonian cycle*). A graph G is said *k-Hamiltonian* if the deletion of at most k vertices from G results in a Hamiltonian graph.

Finally, we denote by n the number of vertices of the graph under consideration.

2 Monadic second-order logic for graphs with bounded co-treewidth

Dvořák, Knop, and Masařík [25] asked whether it is possible to extend the meta-theorem for MSO_2 for the complementary setting – i.e. to allow quantification over sets of non-edges. As shown by Courcelle, Makowsky and Rotics [15] (assuming $P \neq NP$ on unary languages), it is not possible to allow quantification over sets of edges as well as quantification over sets of non-edges, under the requirement that for the target parameter the complete graphs should have bounded width. However, as observed by Knop, Kouřtecký, Masařík, and Toufar [38], the result that k -PATH COVER² is FPT when parameterized by co-treewidth suggests that at least sometimes some extension of MSO theorem can be useful to decide properties of the complement graph. Next, by way of illustration, we show that this is precisely the case of BALANCED CO-BICLIQUE, the problem of determining the maximum integer k for which the input graph G has a pair of cliques K_1, K_2 such that $|K_1| = |K_2| = k$ and there is no edge from K_1 to K_2 . Such a pair of cliques is the complement of a balanced complete bipartite graph (balanced biclique).

Let LinEMSO_2 be the extension of LinEMSO_1 , where quantification is allowed over sets of non-edges, but quantification over sets of edges is not allowed. It is easy to see that LinEMSO_2 -expressible problems are FPT concerning co-treewidth since LinEMSO_2 -expressible problems are FPT concerning treewidth. Note that expressing a property in LinEMSO_2 is equivalent to expressing the complementary property in LinEMSO_2 .

► **Lemma 4.** *Finding the maximum balanced biclique of a graph is LinEMSO_2 -expressible.*

Proof. Given a graph G and set of vertices S_1 , it is easy to express in MSO_1 the existence of a disjoint set S_2 such that S_1 and S_2 form an induced complete bipartite subgraph: S_1 and S_2 must be independent sets, and G must contain all possible edges from S_1 to S_2 . Although comparing the cardinality of sets is not allowed in LinEMSO_2 , in this particular case, it would still be possible by verifying the existence of a perfect matching in the subgraph induced by $S_1 \cup S_2$. Thus, the problem of finding the largest S_1 meeting these conditions is LinEMSO_2 -expressible. ◀

From Lemma 4 and the LinEMSO_2 meta-theorem for optimization problems parameterized by treewidth [19], it follows that Corollary 5 holds.

► **Corollary 5.** *BALANCED CO-BICLIQUE is fixed-parameter tractable when parameterized by the co-treewidth of G .*

² k -PATH COVER is the problem of finding a path cover of size k , where k is fixed.

3 Bondy-Chvátal closure, stability and co-degeneracy

Let G be a graph with n vertices and let u and v be distinct nonadjacent vertices of G such that $d(u) + d(v) \geq n$. Ore's theorem states that G is hamiltonian if and only if $G + uv$ is hamiltonian. In 1976, Bondy and Chvátal [8] generalized Ore's theorem and defined a helpful tool: the *closure* of a graph.

Let ℓ be an integer. The $(n + \ell)$ -closure $cl_{n+\ell}(G)$ of a graph G is obtained from G by recursively adding an edge between pairs of nonadjacent vertices whose degree sum is at least $n + \ell$ until no such pair remains. Bondy and Chvátal showed that $cl_{n+\ell}(G)$ is uniquely determined by G and that G is hamiltonian if and only if $cl_n(G)$ is hamiltonian.

First, observe that the classes of graphs with bounded co-degeneracy and bounded co-treewidth are both closed under completion (edge addition), just as bounded degeneracy and treewidth are closed under edge removals. Therefore, regarding HAMILTONIAN CYCLE on graphs with co-degeneracy or co-treewidth k , without loss of generality, we can assume that $G = cl_n(G)$.

Dvořák, Knop and Masařík [25] showed that if a graph G has co-treewidth k and $G = cl_n(G)$ (that is, closed under Bondy-Chvátal closure) then G has neighborhood diversity bounded by $2^{2(k^2+k)} + 2(k^2 + k)$. Below we present some stronger results.

We call by *co-vertex cover* any set of vertices whose removal makes the resulting graph complete, i.e., a vertex cover in the complement. The *co-vertex cover number*, $co-vc(G)$, of a graph G is the minimum cardinality of a co-vertex cover in G . Recall that $co-vc(G)$ is also called *distance to clique*, and a co-vertex cover set is also called a *clique modulator*.

► **Theorem 6.** *Let $\ell \geq 0$ be an integer. If a graph G has co-degeneracy k and $G = cl_{n+\ell}(G)$ then G has co-vertex cover number bounded by $2k + \ell + 1$. In addition, a co-vertex cover of G with size at most $2k + \ell + 1$ can be found in polynomial time.*

Proof. Let G be a graph such that $G = cl_{n+\ell}(G)$ and $co-deg(G)=k$.

We may assume that G has at least $2k + \ell + 2$ vertices.

Let $v_1, v_2, v_3, \dots, v_n$ be an ordering of the vertices of \overline{G} obtained by repeatedly removing the minimum-degree vertex of \overline{G} . For each $t \in \{1, 2, \dots, n\}$ we denote by G^t the subgraph of G induced by $\{v_i : 1 \leq i \leq t\}$.

Note that G^1 is a complete graph (i.e., a K_1). Therefore, $t = 1$ is the base case.

Now, let t be an integer such that $2 \leq t \leq n$ and $|V(G) \setminus V(G^t)| \geq 2k + \ell + 1$.

Suppose by hypothesis that G^{t-1} is a complete graph. At this point, it remains to prove that G^t is also a complete graph.

Since $V(G^{t-1}) = \{v_1, \dots, v_{t-1}\}$ is a clique of G and $co-deg(G)=k$, it holds that each vertex of $V(G^{t-1})$ has degree at least $n - k - 1$ in G . Also, the vertex v_t has at least $k + \ell + 1$ neighbors in $V(G) \setminus V(G^t)$, because $|V(G) \setminus V(G^t)| \geq 2k + \ell + 1$, and by the co-degeneracy the vertex v_t has at most k non-neighbors in $V(G) \setminus V(G^t)$. Finally, as $G = cl_{n+\ell}(G)$ it holds that v_t is adjacent to all vertices of G^{t-1} in the graph G , which implies that $V(G^t)$ is also a clique of G .

Thus, in a left-right manner according the ordering, $v_1, v_2, v_3, \dots, v_n$, we can observe that each $V(G^t)$ induces a clique until meeting the first vertex v_j such that $|V(G) \setminus V(G^j)| < 2k + \ell + 1$. This implies that $\{v_j, v_{j+1}, \dots, v_n\}$ is a co-vertex cover of G with size at most $2k + \ell + 1$, and it can be computed in polynomial time. ◀

As a corollary we improve the Dvořák-Knop-Masařík bound with respect to neighborhood diversity for $\ell = 0$.

► **Corollary 7.** *Let $\ell \geq 0$ be an integer. If a graph G has co-degeneracy k and $G = cl_{n+\ell}(G)$ then G has neighborhood diversity bounded by $2^{2k+\ell+1} + 2k + \ell + 1$.*

In [25], from the fact that if $G = cl_n(G)$ then the neighborhood diversity is bounded by a function of the co-treewidth, it is claimed that HAMILTONIAN PATH is in FPT concerning co-treewidth. For an FPT algorithm for HAMILTONIAN PATH parameterized by the neighborhood diversity (nd), they point to the seminal paper of Lampis [40], which uses an algorithm of Cosmadakis and Papadimitriou [14] resulting in solving the problem in time $O^*(2^{nd \cdot \log nd})$. Recall that this strategy implies a solution for HAMILTONIAN PATH in double exponential time with respect to the co-treewidth. Below we present a much more efficient algorithm. First, we consider co-vertex cover number parameterization.

► **Lemma 8.** *LONGEST PATH and LONGEST CYCLE can be solved in time $2^{O(k \cdot \log k)} \cdot n^{O(1)}$ where k is the co-vertex cover number of the input graph.*

Proof. Let S, K be a partition of the vertices of a graph G into a co-vertex cover S and a clique K , where $|S| = k$. We assume that $|K| > 2|S|$; otherwise we can “guess”, in single-exponential time, the vertices in the longest path/cycle, so one can solve both problems using single-exponential exact algorithms for HAMILTONIAN CYCLE (or TSP), such as the Bellman–Held-Karp algorithm [2, 36].

Since $|K| > 2|S|$, there is a longest cycle and a longest path containing all vertices of K , otherwise any longest cycle/path either has no edge between two vertices of K (therefore, it has size at most $2|S|$), or it has an edge uv where $u, v \in K$, implying that there is a larger cycle/path obtained by replacing uv by a uv -path containing as internal vertices the vertices of K that were not in the cycle/path, both cases contradict the fact that the cycle/path is the longest. Also, note that LONGEST PATH can be reduced to LONGEST CYCLE by adding one universal vertex. Therefore, we focus on LONGEST CYCLE.

Now, in time $2^{O(|S|)}$ one can branch by guessing the set S_x of vertices of S that are not in the longest cycle, and then removing S_x . After that, we may assume that we are dealing with an instance G' of the HAMILTONIAN CYCLE problem, where $V' = V(G) \setminus S_x$, $G' = G[V']$, $K' = K$, and $S' = S \setminus S_x$ is a co-vertex cover of G' .

Let k' be the cardinality of S' . Recall that $k' \leq k$. Now, we branch by guessing a permutation $s_1, s_2, \dots, s_{k'}$ of the vertices of S' representing a circular order of visits of the vertices of S' in the Hamiltonian cycle C (if any). Given such a permutation $s_1, s_2, \dots, s_{k'}$, we guess the edges s_i, s_{i+1} of G' that are in C . Note that these branching steps take $O(k! \cdot 2^k)$ time. Recall that $O(k! \cdot 2^k) = 2^{O(k \log k)}$. At this point, we have guessed the set of subpaths of C induced by S' . Let P_1, P_2, \dots, P_r be the circular order of visits of such paths according to the guessed permutation.

For each pair of consecutive paths P_i, P_{i+1} either their corresponding endpoints are connected by a common neighbor in C or there is a path of vertices of K between them in such a cycle. Again, we branch by guessing in time $2^{O(k)}$ the pairs connected by a common neighbor. After that, we can construct a bipartite graph B with bipartition $V(B) = (B_1, B_2)$ where: each vertex of B_1 represents either a pair of endpoints of the paths that must have a common neighbor in C , or an endpoint that has a distinct neighbor inside K along C ; B_2 is the set of vertices of the clique K , and $E(B)$ is defined according to the edges from S' to K (for vertices representing pairs of endpoints, the neighborhood is the vertices of K that are neighbors of both endpoints). Clearly, if the guessed structures are feasible for obtaining a Hamiltonian cycle C then B has a matching of size $|B_1|$. Let M be such a matching, if any.

Since $|K| > 2|S|$ we assume that for at least one pair P_i, P_{i+1} its corresponding endpoints do not have a common neighbor in C . Hence, having the matching M and such a path cover P_1, \dots, P_r of $G'[S']$, a Hamiltonian cycle can be easily obtained for G' . Therefore, LONGEST CYCLE and LONGEST PATH can be solved in time $2^{O(k \log k)} \cdot n^{O(1)}$, where $k = co-deg(G)$. ◀

Since HAMILTONIAN PATH can be reduced to HAMILTONIAN CYCLE by adding a universal vertex, from Bondy-Chvátal Theorem, Theorem 6 and Lemma 8, the following holds.

► **Corollary 9.** HAMILTONIAN CYCLE and HAMILTONIAN PATH can be solved in time $2^{O(k \log k)} \cdot n^{O(1)}$, where k is the co-degeneracy of the input graph.

In order to extend the previous result to PATH COVER, LONGEST CYCLE, and LONGEST PATH as well as considering the same strategy for other properties, it becomes necessary to introduce the notion of stability.

3.1 The stability of a property

A property P defined on all graphs of order n is said to be $(n + \ell)$ -stable if for any graph G of order n that does not satisfy P , the fact that uv is not an edge of G and that $G + uv$ satisfies P implies $d(u) + d(v) < n + \ell$. In other words, if $uv \notin E(G)$, $d(u) + d(v) \geq n + \ell$ and $G + uv$ has property P , then G itself has property P (c.f. [12]). We denote by $s(P)$ the smallest integer $n + \ell$ such that P is $(n + \ell)$ -stable, and call it the *stability* of P .

Note that if a graph property P is $(n + \ell)$ -stable then edges between pair of vertices u, v such that $d(u) + d(v) \geq n + \ell$ can be added without destroying such a property P .

Our co-degeneracy+closure+co-vertex cover framework is based on the following facts:

1. If a property P is $(n + \ell)$ -stable and $cl_{n+\ell}(G)$ satisfies P , then G itself satisfies P .
2. If a property P is $(n + \ell)$ -stable, regarding the problem of recognizing property P parameterized by co-degeneracy we can assume without loss of generality that $G = cl_{n+\ell}(G)$.
3. If $G = cl_{n+\ell}(G)$ and G has co-degeneracy k then G has a co-vertex cover of size at most $2k + \ell + 1$. In particular, we are interested in cases where ℓ is bounded by a function of k .
4. Many problems are easily solved in FPT-time concerning co-vertex cover parameterization.

Next, we list the stability of some graph properties P (see [8, 11, 12]):

Longest Cycle: “ G has circumference k ” satisfies $s(P) = n$. (Thm. 4 in [11])

Longest Path: “ G contains a P_k ” satisfies $s(P) = n - 1$ for $4 \leq k \leq n$. (Thm. 2.40 in [12])

Path Cover: “ G has a path cover of size at most k ” satisfies $s(P) = n - k$. (Thm. 9.13 in [8])

k -Hamiltonian: “ G is k -Hamiltonian” satisfies $s(P) = n + k$. (Thm. 2.25 in [12])

At this point, it is easy to see that Corollary 10 holds.

► **Corollary 10.** LONGEST CYCLE/PATH can be solved in time $2^{O(\text{co-deg} \log \text{co-deg})} \cdot n^{O(1)}$, and k -Hamiltonian graphs can be recognized in time $2^{O((\text{co-deg}+k) \log(\text{co-deg}+k))} \cdot n^{O(1)}$.

Proof. By the stability of the properties regarding the computation of the longest cycle, longest path, and recognition of k -Hamiltonian graphs, it holds that one can assume that G is closed under Bondy-Chvátal closure for an appropriated integer ℓ ($G = cl_{n+\ell}(G)$). By Theorem 6, it holds that G has a co-vertex cover S of size $O(\text{co-deg})$, or $O(\text{co-deg} + k)$ in the k -Hamiltonian case, and such a co-vertex cover can be obtained in polynomial time.

Given a co-vertex cover S of G , in time $2^{O(|S|)}$ one can “guess” the vertices of S that must be removed or are not in the longest cycle/path. After that, the proof follows as in Lemma 8. ◀

Next, we deal with the PATH COVER problem.

► **Corollary 11.** PATH COVER can be solved in time $2^{O(\text{co-deg} \log \text{co-deg})} \cdot n^{O(1)}$.

Proof. By the stability of the property P of having a path cover of size at most k (see [8]), without loss of generality, we can assume $G = cl_{n-k}(G)$. Note that $E(G) \subseteq E(cl_n(G)) \subseteq E(cl_{n-k}(G))$. Thus, from Theorem 6 it holds that G has co-vertex cover number at most $2k+1$, where $k = co-deg(G)$. In addition, such a co-vertex cover S can be found in polynomial time. Thus, G has a path cover of size at most $2k+2$, because one can use a trivial path for each vertex of the co-vertex cover, and a single path for the remaining vertices (they induce a clique). So, the path cover number of a graph G is bounded by $2k+2$. At this point, it is enough to determine the least $r \in [1, 2k+2]$ for which G has an r -path cover (path cover of size r). Since one can reduce the problem of finding an r -path cover to HAMILTONIAN PATH by adding $r-1$ universal vertices, and the addition of universal vertices preserve the co-vertex cover number of the input graph, by Corollary 9 it holds that PATH COVER can also be solved in time $2^{O(k \log k)} \cdot n^{O(1)}$, where $k = co-deg(G)$. ◀

4 Edge Dominating Set parameterized by co-degeneracy

An edge dominating set of a graph G is a set $Q \subseteq E(G)$ such that every edge of G is either in Q or incident to at least one edge of Q . The EDGE DOMINATING SET problem consists of determining the size of a minimum edge dominating set.

In [30], Fomin et al. showed that EDGE DOMINATING SET parameterized by clique-width is W[1]-hard. In [29, 31], they showed that EDGE DOMINATING SET cannot be solved in time $f(cw) \cdot n^{o(cw)}$, unless ETH fails.

In this section, we present a single-exponential FPT algorithm for EDGE DOMINATING SET parameterized by the co-degeneracy.

▶ **Theorem 12.** EDGE DOMINATING SET can be solved in time $2^{O(co-deg)} \cdot n^{O(1)}$.

Proof. First, we observe the following key property.

▷ **Claim 13.** The problem of finding a minimum edge dominating set is equivalent to finding the smallest vertex cover S such that $G[S]$ contains a perfect matching.

Proof. Yannakakis and Gavril [49] showed that given a minimum edge dominating set Q of G , one could find a minimum maximal matching with $|Q|$ edges. Since every maximal matching is an edge dominating set, the size of a minimum edge dominating set equals the size of a minimum maximal matching.

Now, let Q be a minimum edge dominating set that is also a minimum maximal matching. Since Q is a maximal matching then $V(Q)$ is a vertex cover inducing a graph having perfect matching. In addition, there is no vertex cover smaller than $V(Q)$ that also induces a graph having perfect matching; otherwise, Q is not a minimum maximal matching.

Conversely, let S be the smallest vertex cover S of G such that $G[S]$ contains a perfect matching. Let Q be such a perfect matching of $G[S]$. Since S is a vertex cover of G then $V \setminus S$ is an independent set, which implies that Q is a maximal matching of G . In addition, Q must be a minimum maximal matching, otherwise using the previous argument we obtain a vertex cover smaller than S also having a perfect matching, a contradiction. ◀

Now, recall that enumerating vertex covers in G is the same as enumerating independent sets in the same graph, which is equivalent to enumerating the cliques of \overline{G} .

Since \overline{G} has degeneracy k , we can enumerate all cliques containing some vertex of degree at most k (such a vertex must exist and there are at most 2^k cliques containing it); by deleting this vertex and continuing the enumeration in the remaining graph, we can enumerate every clique of \overline{G} .

Therefore, if a graph G has co-degeneracy k , then G has at most $2^k \cdot n$ distinct vertex covers which we can enumerate in time $O(2^k \cdot n^{O(1)})$. Thus, by checking the existence of perfect matchings, one can find the minimum edge dominating set in time $2^k \cdot n^{O(1)}$. ◀

5 MaxCut parameterized by co-treewidth

A cut $[S, V \setminus S]$ of a graph $G = (V, E)$ is a partition of V into two subsets S and $V \setminus S$. The *size* of the cut $[S, V \setminus S]$ is the number of edges crossing it, i.e., the cardinality of the cut-set $\{uv \in E \mid u \in S, v \in V \setminus S\}$. In the MAXCUT problem, we are given an unweighted undirected graph $G = (V, E)$, and our goal is to find a cut of maximum size.

From the parameterized complexity point of view, to determine if G has a cut of size at least k is fixed-parameter tractable when parameterized by either k or $k - \lfloor \frac{|E|}{2} \rfloor$ (c.f. [42, 44]). In addition, in 2000, Bodlaender and Jansen [6] showed that MAXCUT can be solved in FPT time when parameterized by the treewidth, and, in 2013, Bodlaender, Bonsma, and Lokshantov presented an $O(2^{tw} \cdot n)$ time algorithm for the problem, where tw is the treewidth of the input graph. On the other hand, Fomin, Golovach, Lokshantov and Saurabh [29, 31] showed that MAXCUT cannot be solved in time $f(cw) \cdot n^{o(cw)}$, unless ETH fails, where cw is the clique-width of the input graph G .

Regarding co-degeneracy parameterization we left the complexity of MAXCUT open. To the best of our knowledge, the complexity of MAXCUT is unknown even for co-planar graphs (the class of planar graphs is a subclass of the 5-degenerate graphs).

Concerning co-treewidth, it is not clear whether MAXCUT can be expressed in LinEMSO_2 . Given a cut $[S, V \setminus S]$ of a graph G , the complement of the cut-set of $[S, V \setminus S]$ is the set of non-edges that have one endpoint in each subset of the partition. The main challenge to express MAXCUT using just quantification over sets of vertices and sets of non-edges is that the size of $[S, V \setminus S]$ is given by $(|S| \cdot |V \setminus S|) - |\{uv \notin E \mid u \in S, v \in V \setminus S\}|$, thus, the natural objective function is not linear, and it is not appropriate to express the problem in LinEMSO . However, using a nice tree decomposition of the complement graph, we can find the maximum cut of the input graph in single-exponential time concerning the co-treewidth.

Given a graph G and a nice tree-decomposition $(T, \{X_t\}_{t \in V(T)})$ of G , our goal is to use $(T, \{X_t\}_{t \in V(T)})$ in order to find a maximum cut of \overline{G} . Recall that for each node t of T , we denote by G_t the subgraph of G induced by the set of vertices contained in some bag of T_t . Also, for each X_t the set of forgotten vertices in G_t is denoted by F_t ($F_t = V(G_t) \setminus X_t$).

Given a cut $[S, V \setminus S]$, we say that S is left part of the partition defined by the cut, and $V \setminus S$ is the right part.

Let $C[t, S, \ell]$ be the size of a maximum cut of the subgraph $\overline{G_t}$, where S are the vertices of X_t to the left part of the partition defined by the cut, and $X_t \setminus S$ are the vertices of X_t on the right part. Also, ℓ represents how many forgotten vertices are in the left part of this cut.

At this point, it is sufficient to show how to compute in a bottom-up manner the entries of the matrix (which is regarding \overline{G} (not G)) according to each type of node of the nice tree decomposition of G . Note that the maximum size of a cut in \overline{G} equals $\max_{0 \leq \ell \leq n} \{C[r, \emptyset, \ell]\}$, where r is the root of the tree decomposition.

For each node t of T we denote by t' and t'' the children of t (if any), and for each bag X_t we denote by $E(X_t)$ the set of edges with both endpoints in X_t . Thus, we proceed as follows:

Leaf: Since $X_t = \emptyset$, it holds that $S = \emptyset$, $\ell = 0$, and $C[t, S, \ell] = 0$.

Introduce vertex: $X_t = X_{t'} \cup \{v\}$. Recall that we are working with the tree decomposition of G , so the size of cuts of \overline{G} is given by non-edges of G .

$$C[t, S, \ell] = \begin{cases} C[t', S \setminus \{v\}, \ell] + |X_t \setminus S| - |\{uv \in E(X_t) : u \notin S\}| + (|F_{t'}| - \ell) & \text{if } v \in S \\ C[t', S, \ell] + |S| - |\{uv \in E(X_t), u \in S\}| + \ell & \text{if } v \notin S \end{cases} \quad (1)$$

Note that $|F_{t'}| - \ell$ is the number of vertices forgotten to the right part of the cut.

Forget vertex: $X_t = X_{t'} \setminus \{v\}$. In this case, we take the best of two possibilities: v in the left or right part of the cut.

$$C[t, S, \ell] = \max\{C[t', S \cup \{v\}, \ell - 1], C[t', S, \ell]\} \quad (2)$$

Join: $X_t = X_{t'} = X_{t''}$. In this case we have to do the union of two partial solutions. Since non-edges of $G[X_t]$ are non-edges of both $G_{t'}$ and $G_{t''}$, they must not be counted twice. In addition, there are non-edges between forgotten vertices of $G_{t'}$ and $G_{t''}$ that must be counted, so:

$$C[t, S, \ell] = \max_{0 \leq i \leq \ell} \{C[t', S, i] + C[t'', S, \ell - i] - (|S| \cdot |X_t \setminus S| - |\{uv \in E(X_t) : u \in S, v \notin S\}|) + i \cdot (|F_{t''}| - (\ell - i)) + (|F_{t'}| - i) \cdot (\ell - i)\} \quad (3)$$

Since the correctness of the recurrences is straightforward, the matrix has size $2^{\mathcal{O}(\text{co-tw})} \cdot n^2$, and each entry can be computed in time $\mathcal{O}(n)$, the following theorem holds.

► **Theorem 14.** *MAXCUT can be solved in $2^{\mathcal{O}(\text{co-tw})} \cdot n^3$.*

6 Treewidth vs. co-treewidth

In the previous sections we showed that PATH COVER, LONGEST CYCLE, LONGEST PATH, MAXCUT, and EDGE DOMINATING SET are all FPT concerning co-treewidth parameterization. These results contrast with the intractability of such problems regarding clique-width parameterization. Since all of these problems are also fixed-parameter tractable when parameterized by treewidth, it becomes interesting to identify problems that are tractable for co-treewidth but intractable concerning treewidth, as well as the opposite.

The TSP problem is NP-hard on complete graphs (co-treewidth equal to zero) but fixed-parameter tractable when parameterized by treewidth [4]. On the other hand, Fellows et al. [27] showed that PRECOLORING EXTENSION and EQUITABLE COLORING are W[1]-hard when parameterized by treewidth; next, we contrast these results by remarking that both problems are fixed-parameter tractable using co-treewidth as the parameter.

6.1 Coloring and covering problems

Each color class of a proper coloring of a graph G is an independent set, i.e., each color class is a clique in the complement. So, to solve GRAPH COLORING working with the complement graph, we must solve CLIQUE COVER in \overline{G} . Therefore, GRAPH COLORING parameterized by co-degeneracy/co-treewidth is equivalent to CLIQUE COVER parameterized by degeneracy/treewidth. It is known that GRAPH COLORING and CLIQUE COVER are NP-hard on planar graphs [39, 22]. Thus, they are para-NP-hard with respect to co-degeneracy.

Regarding co-treewidth, it is not clear if CLIQUE COVER can be solved using the $MSOL_2$ framework because in contrast with GRAPH COLORING, the size of the solution is unbounded on bounded treewidth graphs. However, in [47], van Rooij, Bodlaender, van Leeuwen, Rossmanith, and Vatshelle present an FPT algorithm for γ -CLIQUE COVER parameterized by treewidth. The γ -CLIQUE COVER problem is a generalization of CLIQUE COVER where the goal is to find a minimum collection C of disjoint cliques covering $V(G)$ such that the size of every clique in C is contained in γ (a set of integers). They showed a FPT algorithm that computes the size and number of minimum γ -clique covers of G . Preliminary parts of [47] have appeared in [7, 48]. Thus, GRAPH COLORING is FPT concerning co-treewidth.

The EQUITABLE COLORING problem is a variation of GRAPH COLORING where we are asked to find the minimum integer k for which the input graph G admits a proper k -coloring such that the sizes of any two color classes differ by at most one. Again, to solve EQUITABLE COLORING one can consider the complementary problem, i.e., EQUITABLE CLIQUE COVER parameterized by treewidth. In the EQUITABLE CLIQUE COVER problem, we are asked to find the minimum integer k such that the input graph G admits a clique cover of size k such that the sizes of any two cliques of the cover differ by at most one. Thus, one can use the algorithm for γ -CLIQUE COVER to solve EQUITABLE CLIQUE COVER, considering that all the cliques must have size either ℓ or $\ell - 1$ ($\gamma = \{\ell, \ell - 1\}$). Using the folklore fact that for a graph G , every clique of G is contained in some bag of a tree decomposition of G , it follows that we only need to consider ℓ in $[2, tw(G) + 1]$. Therefore, the running time of the algorithm increases by a factor of at most $tw(G)$, and EQUITABLE COLORING can also be solved in FPT time concerning co-treewidth. Besides, Gomes, Lima and dos Santos [23], using fast subset convolution as in [47], also showed an FPT-algorithm concerning treewidth for counting clique covers of G having only cliques of size ℓ and $\ell - 1$.

6.1.1 Precoloring Extension parameterized by co-treewidth

PRECOLORING EXTENSION is a generalization of GRAPH COLORING, where we are given a graph $G = (V, E)$ with a subset $P \subseteq V$ of precolored vertices, a precoloring c_P of the vertices of P , and asked to determine the minimum integer k for which G admits a proper k -coloring c which extends c_P (that is, $c(v) = c_P(v)$ for all $v \in P$).

Again, we work with the complementary problem, which we propose to call CLIQUE COVER EXTENSION. In such a problem the input is the same as in PRECOLORING EXTENSION, and the goal is to determine the minimum size of a clique cover for which vertices with the same color are in the same clique, and no clique has a pair of precolored vertices v, u such that $c_P(v) \neq c_P(u)$.

Next, we present a standard dynamic programming based on nice tree decompositions to solve CLIQUE COVER EXTENSION parameterized by treewidth. The proposed algorithm has a single-exponential dependency on the treewidth and preserves linearity with respect to n .

First, we assume that each color class induces a clique; otherwise, there is no solution. Thus, in the forget node t of a precolored vertex v it holds that all vertices precolored with color $c_P(v)$ belong to the graph G_t .

Let $C[t, S]$ be the minimum number of cliques needed to cover the vertices of $V(G_t) \setminus S$ in G_t (the subgraph rooted by the node t) according to the constraints of CLIQUE COVER EXTENSION, where S is a subset of X_t . Since each clique is contained in some bag, we assume that each clique is formed when its last vertex is introduced. Therefore, the matrix is filled in a bottom-up manner as follows.

Leaf: $X_t = \emptyset$, thus $S = \emptyset$ and $C[t, S] = 0$.

Introduce vertex: We are introducing the vertex v and all its edges. Thus, we have two possibilities: $v \in S$ or $v \notin S$. In the second case, v forms a new clique which either has size one or is formed by v together with some non-covered neighbors in $G_{t'}$.

$$C[t, S] = \begin{cases} C[t', S \setminus \{v\}], & \text{if } v \in S \\ \min_{\substack{W \\ v \in W}} \{C[t', S \cup W]\} + 1, & \text{if } v \notin S \end{cases} \quad (4)$$

where the minimum is taken over all possible $W \subseteq N(v) \cap (X_t \setminus S)$ such that $G[W]$ is a clique (including the empty set) and:

- $W \cup \{v\}$ contains no pair of precolored vertices u, w such that $c_P(u) \neq c_P(w)$;
- if $W \cup \{v\}$ contains a precolored vertex then it contains all vertices precolored with the same color.

Forget vertex: In this node the vertex v is forgotten. Since this vertex must be covered with a clique of $G_{t'}$, we have the following

$$C[t, S] = C[t', S]$$

Join: In this case, we are joining solutions of the graphs rooted by nodes $X_{t'}$ and $X_{t''}$. Every vertex of $V(G_t) \setminus S$ should be covered by a clique in either $G_{t'}$ or $G_{t''}$. To avoid counting twice some cliques of $G[X_t]$, it is sufficient to note that if a vertex of X_t is covered in $G_{t'}$, then we can assume that it is not covered in $G_{t''}$, and vice versa. This implies that for each pair of solutions to be analyzed (one from each child), the cliques of $G[X_t]$ are considered in at most one of them.

$$C[t, S] = \min_{\substack{S', S'' \\ S = S' \cap S'', S' \cup S'' = X_t}} \{C[t', S'] + C[t'', S'']\}$$

where the minimum is taken over all possible S', S'' such that $S = S' \cap S'', S' \cup S'' = X_t$.

Since the matrix has size $\mathcal{O}(2^{tw(G)} \cdot tw(G) \cdot n)$, and each entry can be computed in $\mathcal{O}(2^{tw(G)})$, the following holds.

► **Theorem 15.** CLIQUE COVER EXTENSION can be solved in $2^{\mathcal{O}(tw(G))} \cdot n$.

► **Corollary 16.** PRECOLORING EXTENSION can be solved in $2^{\mathcal{O}(co-tw(G))} \cdot n$.

7 Concluding Remarks

LONGEST CYCLE, LONGEST PATH, PATH COVER, MAXCUT, EDGE DOMINATING SET and GRAPH COLORING are all fixed-parameter tractable when parameterized by treewidth, but they are W[1]-hard when parameterized by clique-width. To handle dense instances of problems that are hard when parameterized by clique-width, we have considered the notions of co-degeneracy and co-treewidth of a graph.

We have proposed a framework based on Bondy-Chvátal closure for working with co-degeneracy. Using this framework we showed that LONGEST CYCLE, LONGEST PATH and PATH COVER are FPT when parameterized by co-degeneracy. Additionally, using a different approach, we showed that EDGE DOMINATING SET is also FPT when parameterized by co-degeneracy. Conversely, we remark that GRAPH COLORING is para-NP-hard regarding co-degeneracy parameterization while the complexity of MAXCUT is left open. On the other hand, both GRAPH COLORING and MAXCUT are FPT when parameterized by co-treewidth.

We also have shown that PRECOLORING EXTENSION is fixed-parameter tractable taking the co-treewidth as parameter, while it is known to be W[1]-hard when parameterized by treewidth (see [27]). The same holds for EQUITABLE COLORING. In contrast, CLIQUE COVER EXTENSION and EQUITABLE CLIQUE COVER are FPT when parameterized by treewidth and W[1]-hard when parameterized by co-treewidth.

These results, which are summarized in Table 1, give evidence that co-degeneracy and co-treewidth are handy width parameters for dealing with problems for which FPT algorithms parameterized by clique-width are unlikely to exist.

■ **Table 1** Parameterized complexity concerning treewidth, co-treewidth, co-degeneracy, and clique-width of graph problems addressed in this work. Courcelle and Olariu [20] proved that for every graph G we have $cwd(\overline{G}) \leq 2 \cdot cwd(G)$, thus the W[1]-hardness of CLIQUE COVER is implied from GRAPH COLORING. Also, the indicated para-NP-hardness are inherited from GRAPH COLORING or CLIQUE COVER. The main results presented in this work are highlighted in red.

	<i>tw</i>	<i>co-tw</i>	<i>co-deg</i>	<i>cw</i>
LONGEST PATH	FPT	FPT	FPT	W[1]-h
LONGEST CYCLE	FPT	FPT	FPT	W[1]-h
EDGE DOMINATING SET	FPT	FPT	FPT	W[1]-h
MAXIMUM CUT	FPT	FPT	open	W[1]-h
GRAPH COLORING	FPT	FPT	para-NP-h	W[1]-h
CLIQUE COVER	FPT	FPT	para-NP-h	W[1]-h
PRECOLORING EXTENSION	W[1]-h	FPT	para-NP-h	W[1]-h
EQUITABLE COLORING	W[1]-h	FPT	para-NP-h	W[1]-h
CLIQUE COVER EXTENSION	FPT	W[1]-h	para-NP-h	W[1]-h
EQUITABLE CLIQUE COVER	FPT	W[1]-h	para-NP-h	W[1]-h

We remark that $\min\{\text{treewidth}, \text{co-treewidth}\}$ seems to be a nice parameter between treewidth and clique-width. Note that every problem which can be expressed in both LinEMSO_2 and LinEMSO_2 is solvable in FPT-time when parameterized by $\min\{\text{treewidth}, \text{co-treewidth}\}$. Therefore, co-treewidth is a powerful tool to manipulate dense graphs.

We left the complexity of MAXCUT parameterized by co-degeneracy as an open problem. We remark that determining the complexity of MAXCUT seems to be a challenge even for co-planar graphs. Also, investigating the applicability of co-treewidth for problems that are hard when parameterized by treewidth is an interesting research direction. In particular, the complexity of LIST COLORING parameterized by co-treewidth is another interesting question.

Finally, we note that one can also consider parameters between co-degeneracy and co-treewidth such as co-contraction degeneracy, which is defined as the maximum degeneracy of a minor of the complement of G .

Isometric Embeddings in Trees and Their Use in Distance Problems

Guillaume Ducoffe

University of Bucharest, Romania

Abstract

We present powerful techniques for computing the diameter, all the eccentricities, and other related distance problems on some geometric graph classes, by exploiting their “tree-likeness” properties. We illustrate the usefulness of our approach as follows:

- We propose a subquadratic-time algorithm for computing all eccentricities on partial cubes of bounded lattice dimension and isometric dimension $\mathcal{O}(n^{0.5-\varepsilon})$. This is one of the first positive results achieved for the diameter problem on a subclass of partial cubes beyond median graphs.
- Then, we obtain almost linear-time algorithms for computing all eccentricities in some classes of face-regular plane graphs, including benzenoid systems, with applications to chemistry. Previously, only a linear-time algorithm for computing the diameter and the center was known (and an $\tilde{\mathcal{O}}(n^{5/3})$ -time¹ algorithm for computing all the eccentricities).
- We also present an almost linear-time algorithm for computing the eccentricities in a polygon graph with an additive one-sided error of at most 2.
- Finally, on any cube-free median graph, we can compute its absolute center in almost linear time. Independently from this work, Bergé and Habib have recently presented a linear-time algorithm for computing all eccentricities in this graph class (*LAGOS’21*), which also implies a linear-time algorithm for the absolute center problem.

Our strategy here consists in exploiting the existence of some embeddings of these graphs in either a system or a product of trees, or in a single tree but where each vertex of the graph is embedded in a subset of nodes. While this may look like a natural idea, the way it can be done efficiently, which is our main technical contribution in the paper, is surprisingly intricate.

1 Introduction

This paper is about classic location problems on graphs and metric spaces. Although we focus on unweighted undirected graphs in what follows, it should be clear to the reader that most of our results could also be applied to discrete metric spaces. For standard graph terminology, see [12, 33]. The distance in a graph $G = (V, E)$ between two vertices $u, v \in V$ equals the minimum number of edges in a uv -path, and is denoted $d_G(u, v)$. For any vertex u in G , let $e_G(u) := \max_{v \in V} d_G(u, v)$ be its eccentricity. The diameter and the radius of G are the maximum and minimum eccentricities of a vertex. We denote the former and the latter

¹ The $\tilde{\mathcal{O}}(\cdot)$ notation suppresses poly-logarithmic factors.

by $\text{diam}(G)$ and $\text{rad}(G)$, respectively. The center of G contains all vertices with minimum eccentricity. We study the problem of computing all eccentricities in Sec. 2. Finally, to any graph G we can associate a continuous metric space (X_G, d) : obtained from G by replacing every edge with a unit-length geodesic. Motivated by the problem of locating the “switching center” in a communication network, Hakimi’s absolute center problem consists in, being given G , computing all points of X_G that minimize their largest distance to a vertex of G [59]. We investigate this problem in Sec. 5.

Related work. There is a naive algorithm for computing all the eccentricities, resp. the absolute center, in an n -vertex m -edge graph in total $\mathcal{O}(nm)$ time. Conversely, assuming the so-called Strong-Exponential-Time Hypothesis (SETH), if an algorithm computes all the eccentricities in a graph, or even just the diameter, in $\mathcal{O}(n^a m^b)$ time, then we must have $a + b \geq 2$ [70]. In what follows, by *truly subquadratic* we mean $\mathcal{O}(n^a m^b)$ time where $a + b < 2$. The problem of finding truly subquadratic algorithms for the diameter problem on some special graph classes has been addressed in many papers [1, 14, 15, 17, 18, 23, 30, 31, 42, 46, 47, 45, 51, 55, 69]. There are comparatively much fewer results for the absolute center problem, *e.g.*, see [60, 63, 65] for previous results on trees and cacti.

As it is often the case, such problems become much easier for the graphs with a suitable “tree-like” representation such as: bounded tree-width graphs [17] and bounded clique-width graphs [44]. In the context of Metric Graph Theory (hereafter called MGT), one natural way to define tree-likeness of a graph is by using embeddings in trees. Recall that, if (X, d_X) and (Y, d_Y) are metric spaces, then an embedding is simply an injective function $\varphi : X \rightarrow Y$. Its distortion is the least $\alpha \geq 1$ s.t., for all $x, x' \in X$, we have $\alpha^{-1}d_X(x, x') \leq d_Y(\varphi(x), \varphi(x')) \leq \alpha d_X(x, x')$. The stretch is the least $\beta \geq 0$ s.t., for all $x, x' \in X$, we have $|d_X(x, x') - d_Y(\varphi(x), \varphi(x'))| \leq \beta$. An isometric embedding is one s.t. $\alpha = 1$, or equivalently $\beta = 0$. A quasi isometric embedding is one such that $\alpha = \mathcal{O}(1)$, or even better $\beta = \mathcal{O}(1)$. If we are given an isometric embedding of a graph in a tree (resp., a quasi isometric embedding), then we can solve exactly (resp., approximately) the diameter problem in linear time. Unfortunately, the graph classes to which this nice result can be applied are rather restricted. *E.g.*, the graphs that can be *isometrically* embedded in a *weighted* tree are exactly the block graphs [4, 61]. See also [5, 9] for an efficient recognition of tree metrics. More generally, all the metric spaces that embed in a tree with constant distortion have a bounded Gromov hyperbolicity: a polynomial-time computable parameter from geometric group theory that is inspired by the four-point characterization of tree metrics [58]. While many real-life networks are known to have bounded hyperbolicity [2], this is *not* the case for important classes in MGT such as: *median graphs* (even of dimension at most two), *Helly graphs* (even of strong isometric dimension at most two) and ℓ_1 -*graphs*. We refer to [3] for their respective definitions (median graphs are defined in Sec. 5).

Thus, we need to consider stronger notions of tree embeddings, or embeddings in more complicated “tree-like” spaces. Recall that the *Cartesian product* of graphs G_1, G_2 , denoted by $G_1 \square G_2$, has vertex-set $V(G_1) \times V(G_2)$ and edge-set $\{(u_1, u_2)(u_1, v_2) \mid u_2 v_2 \in E(G_2)\} \cup \{(u_1, u_2)(v_1, u_2) \mid u_1 v_1 \in E(G_1)\}$. In [21], Chepoi studied the benzenoid systems: a subclass of planar graphs with applications to chemistry, and he proved that they can be isometrically embedded in linear time in the Cartesian product of three trees. In a subsequent work [23], Chepoi et al. used this nice property in order to compute the diameter, and even the center, of these graphs in linear time. However, they also needed certain “total monotonic” property to hold for the distance-matrix of the graphs considered. To our best knowledge, the problem of computing all the eccentricities within benzenoid systems in almost linear time has been open until our work. Furthermore, we point out that the existence of similar embeddings as the one in [23], in a product or a system of constantly many trees, has been thoroughly

investigated for many graph classes [8, 6, 7, 25, 20, 35, 36, 37, 38, 39, 40, 41, 48, 68]. While it is NP-hard in general to decide whether such an embedding exists [8], we note that several of these above previous works have presented almost linear-time algorithms for this problem on some special cases.

Our results. We first prove that, for any fixed k , we can compute all eccentricities in a graph in quasi linear time if it is isometrically embedded in the Cartesian product of k trees (Theorem 1). This improves on Chepoi et al. [23] since we needn't any additional assumption on the distance-matrix and we solve a more general problem than just computing the diameter or the center. We apply this very general result to the following geometric graph classes:

- the triangular systems and hexagonal systems (*a.k.a.*, benzenoids), see Sec. 2.2;
- and the graphs of bounded lattice dimension, that can be isometrically embedded in the product of constantly many paths (with an additional technical assumption needed for computing the embedding), see Sec. 2.1.

Our actual result for Theorem 1 is even more general than what we stated above, since it can also be applied to other types of tree embeddings. If the embedding is not isometric but it has $\mathcal{O}(1)$ stretch or distortion, then our above approach leads to approximation algorithms for computing all the eccentricities. In particular,

- we prove that for any fixed k , all eccentricities in a k -polygon graph can be approximated in almost linear time within an additive one-sided error of at most 2, see Sec. 2.3.

In the second part of the paper, we consider a different type of tree embedding: from a graph G to a single tree T , but where each vertex u of G is mapped to a *subset* of nodes $U \subseteq V(T)$. This is similar to the notion of clan embedding, introduced in [52]. It leads us to solve a more general eccentricity problem on trees, that may be of independent interest for k -facility location problems [64, 73]. This is our second main technical contribution in the paper. More precisely, given an n -node tree T , the eccentricity of a node-subset U is defined as $e_T(U) = \max_{v \in V(T)} \min_{u \in U} d_T(v, u)$.

- We prove that after an $\mathcal{O}(n \log n)$ -time pre-processing, the eccentricity of any node-subset U can be computed in $\mathcal{O}(|U| \log^2 n)$ query time. See Theorem 9. These running times are optimal up to polylogarithmic factors.

Let $k \in \mathbb{N}$ and $\varepsilon \in (0; 1)$ be arbitrary. We observe that, combined to Theorem 1 in [52], our result implies a data structure for computing, for any graph G and any vertex-subset U (up to pre-processing), a $16k$ -approximation of $e_G(U)$ (resp., an $\tilde{\mathcal{O}}\left(\frac{\log n}{\varepsilon}\right)$ -approximation) in expected $\tilde{\mathcal{O}}(|U|n^{1/k})$ time (resp., in expected $\tilde{\mathcal{O}}((1 + \varepsilon) \cdot |U|)$ time). See Sec. 5.1.

We give another application of Theorem 9, in the context of distance and routing labelling schemes. Indeed, a successful approach for computing such schemes with small label sizes on geometric graph classes is as follows. Roughly, the vertices of a graph get partitioned recursively into convex subgraphs. At each step, the vertices of such convex subgraphs are projected to their respective boundary, so as to hit all shortest-paths to vertices in nearby convex subgraphs of the decomposition. Then, by mimicking the recursive construction of the labels, if the projections to the boundaries have some nice properties then, it becomes possible to compute all eccentricities, as well as to solve other related distance problems. It turns out that such embeddings are often *tree-like*, in the sense of either Theorem 1 or Theorem 9. We illustrate this with the case of cube-free median graphs (formally defined in Sec. 5). The cube-free median graphs properly contain the partial double trees (which can be isometrically embedded in the Cartesian product of two trees), and if their maximum degree is Δ then, they can be isometrically embedded in the Cartesian product of $\Delta^{\mathcal{O}(1)}$

trees [25]. However, in general they cannot be embedded in the product of constantly many trees, and so, Theorem 1 cannot be applied. We overcome this issue by relying on a recursive partition scheme as above, where the boundaries induce *isometric trees*, see [26]. Doing so, ■ we present the first almost linear-time algorithm for computing the absolute center of cube-free median graphs, see Theorem 10. Our approach can also be used in order to compute all eccentricities in this graph class.

Recently, Bergé and Habib have presented a linear-time algorithm for computing all eccentricities within the median graphs of bounded dimension (generalizing cube-free median graphs) [11]. A reviewer observed that the absolute center of a median graph is always: either its center if it is an independent set, or the middle points of all edges with their both ends in the center. As a result, we can also compute the absolute center of cube-free median graphs in linear time. That being said, we think that our alternative algorithm, although it is slightly slower, has the potential to be generalized to other graph classes beyond the median graphs. Indeed, to prove Theorem 10, we use some deep structural properties obtained recently for cube-free median graphs [26]. We point out that very similar properties have been obtained in the past for completely unrelated graph classes, such as planar graphs of non-positive combinatorial curvature [24, 29, 28]. Thus, there is room for generalizing our approach far beyond the cube-free median graphs.

Since both Theorems 1 and 9 are very general, we expect them to find applications beyond the classes studied in the paper.

Organization of the paper. In Sec. 2 we state Theorem 1, then we summarize our results obtained for subclasses of partial cubes, planar graphs and circle graphs. We postpone the proof of Theorem 1 to Sec. 3, due to its technicality. Our algorithms in Sec. 3 have an exponential dependency on the number k of trees considered. In Sec. 4, we give simple *conditional lower bounds* showing their near optimality. Finally, in Sec. 5, we address the problem of computing the eccentricity of k -subsets of nodes in a tree, and its application to the absolute center problem for cube-free median graphs.

Due to lack of space, several proofs are omitted from the following technical sections.

2 Eccentricity computation in some geometric graph classes

This section is devoted to the applications of our Theorem 1, which we formally state in what follows. We defined the Cartesian product of two graphs in Sec. 1. The *strong product* of graphs G_1, G_2 , denoted by $G_1 \boxtimes G_2$, is a supergraph of the Cartesian product with additional edge-set $\{(u_1, u_2)(v_1, v_2) \mid u_1v_1 \in E(G_1), u_2v_2 \in E(G_2)\}$. Finally, an embedding of a graph $G = (V, E)$ in a *system* of trees T_1, T_2, \dots, T_k is defined as k projections $\varphi_i : V \rightarrow V(T_i)$, $1 \leq i \leq k$. Then, the distortion of this embedding (resp. its stretch) is defined as the least α s.t., $\forall x, y \in X$, $\alpha^{-1}d(x, y) \leq \min_i d_{T_i}(\varphi_i(x), \varphi_i(y)) \leq \alpha d(x, y)$ (resp., as the least β s.t. $\forall x, y \in X$, $|d(x, y) - \min_i d_{T_i}(\varphi_i(x), \varphi_i(y))| \leq \beta$). We consider quasi-isometric embeddings of graphs and metric spaces in: Cartesian products of trees, strong products of trees, and systems of trees.

► **Theorem 1.** *Let $G = (V, E)$ be a graph and let T_1, T_2, \dots, T_k be a collection of k trees, where $N := \sum_{i=1}^k |V(T_i)|$.*

1. *If we are given an isometric embedding of G in either the system or the Cartesian product of these k trees, then we can compute all eccentricities in G in $\mathcal{O}(2^{\mathcal{O}(k \log k)}(N + n)^{1+o(1)})$ time².*

² See [17, Lemma 5] for a more careful analysis of the running time.

2. If we are given an embedding of G with distortion α (resp., with stretch β) in either the system or the Cartesian product of these k trees, then we can compute an α^2 -approximation (resp., an $+2\beta$ -approximation) of all eccentricities in G in $\mathcal{O}(2^{\mathcal{O}(k \log k)}(N+n)^{1+o(1)})$ time. It can be improved to an α -approximation (resp., a $+\beta$ -approximation) if the embedding only has one-sided distance errors.
3. All the results above also hold if we are given an embedding of G in the strong product of these k trees, with an improved runtime in $\mathcal{O}(N+kn)$.

See Sec. 3 for a sketch of the proof. We left open whether our approach could be generalized to, say, the direct product or the layered cross product [50] of constantly many trees. In what follows, we apply Theorem 1 to several geometric graph classes.

2.1 Partial cubes

The lattice dimension of a graph is the smallest k such that it isometrically embeds in the Cartesian product of k paths. This parameter only exists for partial cubes, *a.k.a.*, isometric subgraphs of hypercubes (where, by a hypercube, we mean a Cartesian product of edges). The isometric dimension of a partial cube is the least τ such that it isometrically embeds in the τ -dimensional hypercube.

► **Theorem 2.** *All eccentricities in an n -vertex partial cube with lattice dimension k and isometric dimension τ can be computed in $\mathcal{O}((\tau^2 + 2^{\mathcal{O}(k \log k)}) \cdot n^{1+o(1)})$ time.*

This is truly subquadratic provided $k = o(\log n)$ and $\tau = \mathcal{O}(n^{0.5-\varepsilon})$, for some $\varepsilon > 0$.

Proof. Let $G = (V, E)$ be a partial cube. It is well-known that E can be partitioned in so-called θ -classes, where each class represents a dimension of the smallest hypercube in which G can be isometrically embedded [34, 75]. Furthermore, given an edge, we can compute its θ -class in linear time (see Sec. 3 in [49]). Therefore, we can isometrically embed G in a smallest hypercube in $\tilde{\mathcal{O}}(\tau n)$ (here, we implicitly use that G only has $\tilde{\mathcal{O}}(n)$ edges, see Lemma 2 in [49]). Being given such an embedding, Eppstein's algorithm computes an embedding of G in the Cartesian product of a least number of paths in $\mathcal{O}(\tau^2 n)$ time [48]. Then, we are done applying Theorem 1 to the resulting embedding. ◀

2.2 Triangular and hexagonal systems

A *triangular system* is a subgraph of the regular triangular grid which is induced by the vertices lying on a simple circuit and inside the region bounded by this circuit. Similarly, a hexagonal system (*a.k.a.*, benzenoid) is a subgraph of the regular hexagonal grid bounded by a simple circuit. Improving on two prior works [21, 23], but at the price of a slightly slower running time, we prove that:

► **Theorem 3.** *All eccentricities in an n -vertex triangular system can be computed in $\tilde{\mathcal{O}}(n)$ time. All eccentricities in an n -vertex hexagonal system can be computed in $\tilde{\mathcal{O}}(n)$ time.*

Proof. Every hexagonal system can be isometrically embedded in the Cartesian product of three trees, in linear time [21]. Then, we are done applying Theorem 1. The same holds for triangular system, but it is a scale embedding: all distances in the tree are multiplied by two [23]. As it shall become clearer in Sec. 3.2, our framework easily accommodates to this more general type of embeddings. ◀

2.3 Polygon graphs

A circle graph is the intersection graph of chords in a cycle. For every $k \geq 2$, a k -polygon graph is the intersection graph of chords in a convex k -polygon where the ends of each chord lie on two different sides. Note that the k -polygon graphs form an increasing hierarchy of all the circle graphs. We obtain:

► **Theorem 4.** *All eccentricities in an n -vertex m -edge k -polygon graph can be computed in $\mathcal{O}(2^{\mathcal{O}(k)}(n+m)^{1+o(1)})$ time, within an additive one-sided error of at most two.*

Proof. Every k -polygon graph can be embedded in a system of $2 \log_{3/2} k + 7$ spanning trees with stretch two. Furthermore, such a system can be computed in linear time, if the graph is given together with its intersection model [36]. It was observed in [72] that an intersection model can be computed in $\mathcal{O}(4^k(n+m)\alpha(n+m))$ time, where $\alpha(\cdot, \cdot)$ denotes the Ackermann inverse function. We are now done applying Theorem 1 to the system (for $k' = \mathcal{O}(\log k)$). ◀

3 Proof of Theorem 1

We devote this section to the proof of our first main result in the paper (Theorem 1). In Sec. 3.1, we reduce to a more general query-answering problem on trees. We then solve this problem in Sec. 3.2.

3.1 Reductions

It turns out that *all* three types of embeddings that are considered in Theorem 1 can be reduced to the design of an efficient data structure for some abstract problem over a system of trees. In what follows, \odot denotes a binary associative operation over the nonnegative real numbers (*e.g.*, the addition, minimum or maximum of two numbers).

► **Problem 1** (\odot -ECCENTRICITIES).

Global Input: A system $(T_i)_{1 \leq i \leq k}$ of trees, and a subset $S \subseteq \prod_{i=1}^k V(T_i)$.

Query Input: $v = (v_1, v_2, \dots, v_k) \in \prod_{i=1}^k V(T_i)$

Query Output: $e_{\odot}(v, S) := \max\{d_{T_1}(s_1, v_1) \odot d_{T_2}(s_2, v_2) \odot \dots \odot d_{T_k}(s_k, v_k) \mid (s_1, s_2, \dots, s_k) \in S\}$.

Due to lack of space, formal reductions are omitted from the paper. Let us only sketch one of them (we stress that all these reductions are pretty similar to each other). Specifically, let φ be an isometric embedding of a graph $G = (V, E)$ (or of a discrete metric space) to the Cartesian product of the trees T_1, T_2, \dots, T_k . We set $S := \varphi(V)$, and then, for every $u \in V$ we obtain: $e_+(\varphi(u)) = \max_{v \in V} \sum_{i=1}^k d_{T_i}(\varphi_i(u), \varphi_i(v)) = \max_{v \in V} d_{\square_{i=1}^k T_i}(\varphi(u), \varphi(v))$, where \square stands for the Cartesian product and, for every $1 \leq i \leq k$, φ_i denotes the projection of φ to $V(T_i)$. In particular, $e_+(\varphi(u))$ is equal to the eccentricity of u . Similarly, we can reduce the eccentricity problem in systems and strong products of trees to min- and max-ECCENTRICITIES, respectively. We also stress that being given a *quasi* isometric embedding, our above approach leads to approximation algorithms for computing all the eccentricities.

3.2 A range-query framework

Our main result in this section is as follows:

► **Theorem 5.** For every $(T_i)_{1 \leq i \leq k}$ and S , let $N := \sum_{i=1}^k |V(T_i)|$. We can solve min-ECCENTRICITIES (resp., +-ECCENTRICITIES) with $\mathcal{O}(2^{\mathcal{O}(k \log k)}(N+|S|)^{1+o(1)})$ pre-processing time and $\mathcal{O}(2^{\mathcal{O}(k \log k)}(N+|S|)^{o(1)})$ query time.

We need to introduce two useful tools. First, let V be a set of k -dimensional points, and let $f : V \rightarrow \mathbb{R}$. A *box* is the Cartesian product of k intervals. A range query asks, given a box \mathcal{R} , for a point $\vec{p} \in V \cap \mathcal{R}$ s.t. $f(\vec{p})$ is maximized. Up to some pre-processing in $\mathcal{O}(|V| \log^{k-1} |V|)$ time, such query can be answered in $\mathcal{O}(\log^{k-1} |V|)$ time [74]. The corresponding data structure is called a k -dimensional range tree. Furthermore, note that for any $\varepsilon > 0$, $\forall x > 0$, $\log^k x \leq 2^{\mathcal{O}(k \log k)} x^\varepsilon$ [17].

Second, for an n -node tree $T = (V, E)$, a *centroid* is a node whose removal leaves subtrees of order at most $n/2$. A classic theorem from Jordan asserts that such node always exists [62]. Furthermore, we can compute a centroid in $\mathcal{O}(n)$ time by dynamic programming (e.g., see [56]). A *centroid decomposition* of T is a rooted tree T' , constructed as follows. If $|V(T)| \leq 1$, then $T' = T$. Otherwise, let c be a centroid. Let T'_1, T'_2, \dots, T'_p be centroid decompositions for the subtrees T_1, T_2, \dots, T_p of $T \setminus \{c\}$. We obtain T' from T'_1, T'_2, \dots, T'_p by adding an edge between c and the respective roots of these rooted subtrees, choosing c as the new root. Note that we can compute a centroid decomposition in $\mathcal{O}(n)$ time [32]. We rather use the folklore $\mathcal{O}(n \log n)$ -time algorithm since, for any node v , we also want to store its path $P(v)$, in T' , until the root, and the distances $d_T(v, c_i)$, in T , for any $c_i \in P(v)$.

Sketch proof of Theorem 5. Due to lack of space, we only give a proof for the case $\odot = +$. During a pre-processing phase, we compute a centroid decomposition for each tree T_i , $1 \leq i \leq k$ separately, in total $\mathcal{O}(N \log N)$ time. Then, we iterate over the elements $s = (s_1, s_2, \dots, s_k) \in S$. For every $1 \leq i \leq k$, let $P(s_i)$ be the path of s_i to the root into the centroid decomposition T'_i computed for T_i . We consider all possible k -sequences $c = (c_1, c_2, \dots, c_k)$ s.t., $\forall 1 \leq i \leq k$, $c_i \in P(s_i)$. Since the length of each path $P(s_i)$ is in $\mathcal{O}(\log N)$, there are $\mathcal{O}(\log^k N)$ possibilities. W.l.o.g., all nodes have a unique identifier. Throughout the remainder of the proof, we identify the nodes with their identifiers, thus treating them as numbers. For any sequence c , we create an $2k$ -dimensional point $\vec{p}_c(s)$, as follows: for every $1 \leq i \leq k$, the $(2i-1)^{th}$ and $2i^{th}$ coordinates are equal to c_i and the unique neighbour of c_i onto the $c_i s_i$ -path in T'_i , respectively (if $c_i = s_i$, then we may set both coordinates equal to s_i). The construction of all these $\mathcal{O}(|S| \log^k N)$ points takes time $\mathcal{O}(k|S| \log^k N)$. We include these points $\vec{p}_c(s)$, with an associated value $f(\vec{p}_c(s))$ (to be specified later in the proof) in some $2k$ -dimensional range tree. It takes $\mathcal{O}(|S| \log^k N) \log^{2k-1}(|S| \log^k N) = \mathcal{O}(2^{\mathcal{O}(k \log k)}(N+|S|)^{1+o(1)})$ time.

Then, in order to answer a query, let $v = (v_1, v_2, \dots, v_k)$ be the input. As before, for every $1 \leq i \leq k$, let $P(v_i)$ be the path of v_i to the root into T'_i . We iterate over all the k -sequences $c = (c_1, c_2, \dots, c_k)$ s.t., $\forall 1 \leq i \leq k$, $c_i \in P(v_i)$. Let $S_c \subseteq S$ contain every (s_1, s_2, \dots, s_k) s.t. $\forall 1 \leq i \leq k$, c_i is the least common ancestor of v_i and s_i in T'_i . The subsets S_c partition S , and so, $e_+(v, S) = \max_c e_+(v, S_c)$. We are left explaining how to compute $e_+(v, S_c)$ for any fixed c . For that, we observe that c_i is the least common ancestor of v_i and s_i in T'_i if and only if $c_i \in P(s_i) \cap P(v_i)$, and either $c_i \in \{v_i, s_i\}$ or the two neighbours of c_i onto the $c_i v_i$ -path and $c_i s_i$ -path in T'_i are different. In the latter case, let us denote by u_i the neighbour of c_i onto the $c_i v_i$ -path in T'_i . We can check these above conditions, for every $1 \leq i \leq k$, with the following constraints, over the $2k$ -dimensional points $\vec{p} = (p_1, p_2, \dots, p_{2k})$ constructed during the pre-processing phase: $\forall 1 \leq i \leq k$, $p_{2i-1} = c_i$ and if $c_i \neq v_i$, $p_{2i} \neq u_i$. Since $p_{2i} \neq u_i$ is equivalent to $p_{2i} \in (-\infty, u_i) \cup (u_i, +\infty)$, each inequality can be replaced by two range constraints over the same coordinate. In

particular, since there are $\leq k$ such inequalities, we can transform these above constraints into $\mathcal{O}(2^k)$ range queries. Therefore, we can output a point $\vec{p}_c(s)$, for some $s \in S_c$, maximizing $f(\vec{p}_c(s))$, in $\mathcal{O}(2^k \log^{2k-1}(|S| \log^k N)) = \mathcal{O}(2^{\mathcal{O}(k \log k)}(N + |S|)^{o(1)})$ time. Let $f(\vec{p}_c(s)) = \sum_{i=1}^k d_{T_i}(s_i, c_i)$. Since we have $s \in S_c$, $d_{T_i}(s_i, v_i) = d_{T_i}(s_i, c_i) + d_{T_i}(c_i, v_i)$ [54]. As a result: $e_+(v, S_c) = f(\vec{p}_c(s)) + \sum_{i=1}^k d_{T_i}(c_i, v_i)$. There are $\mathcal{O}(\log^k N)$ possible c , and so, the final query time is in $\mathcal{O}(2^{\mathcal{O}(k \log k)}(N + |S|)^{o(1)})$.

For the case when $\odot = \min$, we need points with $\mathcal{O}(k)$ more coordinates in order to correctly identify some index i s.t. $d_{T_i}(v_i, s_i) = \min_{1 \leq j \leq k} d_{T_j}(v_j, s_j)$. This is a similar trick as the one used in [1, 17, 19]. \blacktriangleleft

In contrast to Theorem 5, the distance between two vertices in the strong product of k trees equals the maximum distance between their k respective projections. Hence, we can process each tree of the system separately, and we obtain:

► **Lemma 6.** *For every $(T_i)_{1 \leq i \leq k}$ and S , let $N := \sum_{i=1}^k |V(T_i)|$. We can solve max-ECCENTRICITIES with $\mathcal{O}(N + k|S|)$ pre-processing time and $\mathcal{O}(k)$ query time.*

Proof. For every $1 \leq i \leq k$, let $\varphi_i : S \rightarrow V(T_i)$ be the projection of S to T_i . We stress that the projections $\varphi_i(S)$, $1 \leq i \leq k$, can be computed in total $\mathcal{O}(k|S|)$ time. Then, we iteratively remove from T_i the leaves that are not in $\varphi_i(S)$. Let T'_1, T'_2, \dots, T'_k be the k subtrees resulting from this above pre-processing. Note that, for every $1 \leq i \leq k$, $T_i \setminus T'_i$ is a forest whose each subtree can be rooted at some node adjacent to a leaf of T'_i , and so, adjacent to a node of $\varphi_i(S)$. For every node $v_i \in V(T_i) \setminus V(T'_i)$, let $\phi(v_i)$ be the unique leaf of T'_i s.t. the subtree of $T_i \setminus T'_i$ that contains v_i also contains a neighbour of $\phi(v_i)$. We compute, and store, the distance $d_{T_i}(v_i, \phi(v_i))$. Since, for doing so, we only need to perform breadth-first searches on disjoint subtrees, the total running time of this step is in $\mathcal{O}(N)$. Finally, we compute, for $1 \leq i \leq k$, all eccentricities in T'_i . Again, this can be done in total $\mathcal{O}(N)$ time (e.g., see [22, 43]). This concludes the pre-processing phase.

In order to answer a query, let us consider some input $v = (v_1, v_2, \dots, v_k)$. Our key insight here is that we have:

$$e_{\max}(v, S) = \max_{1 \leq i \leq k} \{ \max_{(s_1, s_2, \dots, s_k) \in S} d_{T_i}(v_i, s_i) \} = \max_{1 \leq i \leq k} \{ \max_{s_i \in \varphi_i(S)} d_{T_i}(v_i, s_i) \}.$$

Therefore, in order to compute $e_{\max}(v, S)$ in $\mathcal{O}(k)$ time, it suffices to compute $\max\{d_{T_i}(v_i, s_i) \mid s_i \in \varphi_i(S)\}$ in $\mathcal{O}(1)$ time for every $1 \leq i \leq k$. If $v_i \in V(T'_i)$ then, since $\varphi_i(S) \subseteq V(T'_i)$ and furthermore all the leaves of T'_i are in $\varphi_i(S)$, we get $\max\{d_{T_i}(v_i, s_i) \mid s_i \in \varphi_i(S)\} = e_{T'_i}(v_i)$. Otherwise, $\max\{d_{T_i}(v_i, s_i) \mid s_i \in \varphi_i(S)\} = d_{T_i}(v_i, \phi(v_i)) + e_{T'_i}(\phi(v_i))$. \blacktriangleleft

Theorem 1 now follows from our reductions in Sec. 3.1 combined with Theorem 5 and Lemma 6.

4 Hardness results

We complete the positive results of Theorem 1 with two conditional lower bounds. Both theorems follow from a “SETH-hardness” result in order to compute the diameter of *split graphs* with a logarithmic³ clique-number [13], and from the observation that every split graph with a maximal clique K embeds in any system of $|K|$ shortest-path trees rooted at the vertices of K .

³ The logarithmic upper bound is not explicitly stated in [13], but it easily follows from the sparsification lemma applied to k -SAT.

► **Theorem 7.** *For any $\varepsilon > 0$, there exists a $c(\varepsilon)$ s.t., under SETH, we cannot compute the diameter of n -vertex graphs in $\mathcal{O}(n^{2-\varepsilon})$ time, even if we are given as input an isometric embedding of the graph in a system of at most $c(\varepsilon) \log n$ spanning trees. In particular, under SETH, there is no data structure for min-ECCENTRICITIES with $\mathcal{O}(2^{o(k)}(N + |S|)^{1-o(1)})$ pre-processing time and $\mathcal{O}(2^{o(k)}(N + |S|)^{o(1)})$ query time, where $N := \sum_{i=1}^k |V(T_i)|$.*

We believe our Theorem 7 to be important since the embeddings of graphs in systems of tree spanners are well-studied in the literature [35, 36, 37, 38, 39, 40, 41].

► **Theorem 8.** *For any $\varepsilon > 0$, there exists a $c(\varepsilon)$ s.t., under SETH, we cannot compute the diameter of n -point metric spaces in $\mathcal{O}(n^{2-\varepsilon})$ time, even if we are given as input an isometric embedding of the space in a Cartesian product of at most $c(\varepsilon) \log n$ tree factors. In particular, under SETH, there is no data structure for +-ECCENTRICITIES with $\mathcal{O}(2^{o(k)}(N + |S|)^{1-o(1)})$ pre-processing time and $\mathcal{O}(2^{o(k)}(N + |S|)^{o(1)})$ query time, where $N := \sum_{i=1}^k |V(T_i)|$.*

Proof. Recall that for any $\varepsilon > 0$, there exists a $c(\varepsilon)$ s.t., under SETH, we cannot compute the diameter in $\mathcal{O}(n^{2-\varepsilon})$ time on the split graphs of order n and clique-number at most $c(\varepsilon) \log n$ [13]. Let $G = (K \cup I, E)$ be a split graph, where K and I are a clique and a stable set, respectively. If it is not given, such a bipartition of $V(G)$ can be computed in linear time [57]. For every $u \in K$, we construct a tree T'_u , and an embedding φ_u of G into the latter, as follows. We start from a single-node tree, to which we map vertex u . Then, for every $v \in N_G(u)$, we add a leaf into the tree, adjacent to the image of u , to which we map the vertex v . We add another node u^* in T'_u , that is also adjacent to the image of u (note that u^* is *not* the image of a vertex of G). Finally, for every vertex $v \in V(G) \setminus N_G[u]$, we add a leaf node, to which we map vertex v , that we connect to u^* by a path of length two. Let $\varphi : V(G) \rightarrow V(\square_{u \in K} T'_u)$ be s.t., for every $v \in V(G)$, $\varphi(v) = (\varphi_u(v))_{u \in K}$. The metric space considered is $(\varphi(V(G)), d)$, where d is the sub-metric induced by $d_{\square_{u \in K} T'_u}$ (distances in the Cartesian product). Indeed, let $v, v' \in V(G)$. For every $u \in K$, by construction we have $\text{diam}(T'_u) = 4$, and so, $d_{T'_u}(\varphi_u(v), \varphi_u(v')) \leq 4$. Specifically, if $u \in \{v, v'\}$ then $d_{T'_u}(\varphi_u(v), \varphi_u(v')) \leq 3$; if $v, v' \in N_G(u)$ then $d_{T'_u}(\varphi_u(v), \varphi_u(v')) = 2$; otherwise, $d_{T'_u}(\varphi_u(v), \varphi_u(v')) = 4$. Altogether combined, if $d_G(v, v') = 3$ (in particular, $v, v' \in I$) then we get $d(\varphi(v), \varphi(v')) = 4|K|$, otherwise we get $d(\varphi(v), \varphi(v')) \leq 3 + 4(|K| - 1) = 4|K| - 1$. ◀

5 One-to-many tree embeddings

We end up discussing a different type of tree-like embedding than in Sec. 2. First we present an algorithm for computing all eccentricities being given such an embedding (Sec. 5.1). We then propose, in Sec 5.2, an application of our result to the absolute center problem in a subclass of median graphs.

5.1 Computation of subset-eccentricities

We now address the problem of computing the eccentricity of *subsets* of nodes, in *one* tree:

► **Theorem 9.** *Let T be any n -node tree, and let $\alpha : V(T) \rightarrow \mathbb{R}$. After a pre-processing in $\mathcal{O}(n \log n)$ time, for any subset U of nodes and function $\beta : U \rightarrow \mathbb{R}$, we can compute the value $e_{T,\alpha}(U, \beta) = \max_{v \in V(T)} \min_{u \in U} (\alpha(v) + d_T(v, u) + \beta(u))$ in $\mathcal{O}(|U| \log^2 n)$ time.*

In particular, after an $\mathcal{O}(n \log n)$ -time pre-processing we can compute $e_T(U)$ in $\mathcal{O}(|U| \log^2 n)$ time by setting $\alpha(v) = 0$ for every node $v \in V(T)$ and $\beta(u) = 0$ for every node $u \in U$. The proof of Theorem 9 is technical, and we omit it due to lack of space. It is based

on a completely different processing method of the tree than in Sec. 3.2: using heavy-path decomposition [71] and the local computation of so-called Cartesian trees for maximum range queries [53].

Here is a possible application of our Theorem 9 for general graphs. By a clan embedding of a graph $G = (V, E)$ in a tree T , we mean a one-to-many embedding $S : V \rightarrow 2^{V(T)}$ such that, to each vertex $v \in V$, we also associate a leader $\chi(v) \in S_v$ in its corresponding node-subset of T . This embedding must further satisfy $d_T(S_u, S_v) \geq d_G(u, v)$ for every $u, v \in V$. The distortion of a clan embedding can be defined as $t := \max_{u \neq v} d_T(\chi(u), S_v) / d_G(u, v)$.

For each node x of T , we set $\alpha(x)$ to 0 if $x = \chi(u)$ for some vertex $u \in V$; otherwise, we set $\alpha(x)$ to some large enough *negative* value. Then, for any subset $U \subseteq V$, we can apply Theorem 9 to $\bigcup_{u \in U} S_u$ in order to compute a t -approximation of $e_G(U)$. We refer to [52] for various trade-offs between the size of the subsets S_u and the resulting distortion t .

5.2 Application to a distance-labelling scheme

We devote our last section to cube-free median graphs. Recall that a graph $G = (V, E)$ is called *median* if, for any triple $x, y, z \in V$, there exists a unique vertex c that is simultaneously on some shortest xy -, yz - and zx -paths. This class is ubiquitous in Theoretical Computer Science. Indeed, the median graphs are exactly the 1-skeletons of CAT(0) cube complexes [58], the domains of event structures [67] and the solution sets of 2-SAT formulas [66], among many characterizations. The *dimension* of a median graph G is the largest $d \geq 1$ such that G contains a d -cube (hypercube of dimension d) as an induced subgraph. In particular, the median graphs of dimension 1 are exactly the trees. The median graphs of dimension at most 2, *a.k.a.*, *cube-free median graphs*, have already received some attention in the literature [7, 16, 25, 26, 27].

In what follows, we abusively call eccentricity of a point $x \in X_G$, denoted by $e_G(x)$, its maximum distance to a vertex of G .

► **Theorem 10.** *There is an $\tilde{O}(n)$ -time algorithm for computing the absolute center of n -vertex cube-free median graphs. More generally, the algorithm encodes in $\mathcal{O}(n)$ space the eccentricity of all the points of X_G .*

The remainder of this section is devoted to the proof of Theorem 10. Given any point $x \in X_G$, if $W \subseteq V$ then, let $e_G(x, W) = \max_{w \in W} d(x, w)$. We observe that:

► **Lemma 11.** *For a bipartite graph $G = (V, E)$ and an edge $uv \in E$, let $W_{u,v} = \{w \in V \mid d(u, w) < d(v, w)\}$. If x is a point of the edge uv such that $d(u, x) = t$, then, we have $e(x) = \max\{t + e(u, W_{u,v}), 1 - t + e(v, W_{v,u})\}$.*

Proof. We have $V = W_{u,v} \cup W_{v,u}$ because G is bipartite. Let $w \in W_{u,v}$. Every xw -path going by vertex v would have length $1 - t + d(v, w) = 2 - t + d(u, w) > t + d(u, w)$, and therefore, it cannot be a shortest xw -path. In the same way, let $w \in W_{v,u}$. Every xw -path going by vertex u would have length $t + d(u, w) = 1 + t + d(v, w) > 1 - t + d(v, w)$, and therefore, it cannot be a shortest xw -path either. ◀

As a result of Lemma 11, we are left computing the values $e(u, W_{u,v})$ and $e(v, W_{v,u})$ for every edge uv . Since the cube-free median graphs are sparse [26], there are only $\mathcal{O}(n)$ values to be stored. Furthermore, for median graphs, the subsets $W_{u,v}$ are called half-spaces and they induce convex subgraphs. Thus, in a way, we could reduce the absolute center problem to the computation of all eccentricities in various convex subgraphs of the input. However, the number of subgraphs to be considered is in general super-constant, even for the cube-free

median graphs. Since by Lemma 11, a point in the absolute center must be either a vertex or at the middle of an edge, we could also reduce the absolute center problem to computing all eccentricities in the subdivision of G . Unfortunately, median graphs are not closed by taking subdivisions. We take an alternative approach in what follows.

For that, we first recall some notions and results from [26]. These results are specific to cube-free median graphs but, as we pointed it out in Sec. 1, similar structural decomposition theorems were proved in [24, 29, 28] for completely unrelated geometric graph classes.

In what follows, let $G = (V, E)$ be a cube-free median graph. A *centroid* is any vertex minimizing the sum of its distances to all other vertices. Recently, it was shown that a centroid in a median graph can be computed in linear time [10]. So, let $c \in V$ be a centroid.

A subgraph H of G is *gated* if, for every $v \in V \setminus V(H)$, there exists a $v^* \in V(H)$ s.t., $\forall u \in V(H)$, $d_G(u, v) = d_G(u, v^*) + d_G(v^*, v)$. We define the *fibers* $F(x) = \{x\} \cup \{v \in V(G \setminus H) \mid x \text{ is the gate of } v \text{ in } H\}$. The fibers $F(x)$, $x \in V(H)$ partition the vertex-set of G , and each induces a gated subgraph [26].

For any $z \in V$, the *star* $St(z)$ of z is the subgraph of G induced by all edges and squares of G incident to z . Any such star $St(z)$ is gated and, if furthermore $z = c$, every fiber $F(x)$, $x \in St(c)$ contains at most $|V|/2$ vertices [26].

A fiber $F(x)$ of the star $St(c)$ is a *panel* if $x \in N_G(c)$, and a *cone* otherwise. We say that two fibers $F(x), F(y)$ are *neighboring* if there exists an edge with an end in $F(x)$ and the other end in $F(y)$. If two fibers are neighboring then one must be a panel and the other must be a cone; furthermore, a cone has two neighboring panels [26]. Two fibers are *2-neighboring* if they are cones adjacent to the same panel. Finally, two fibers that are neither neighboring nor 2-neighboring are called *separated*.

The subset of vertices in $F(x)$ with a neighbour in $F(y)$ is denoted by $\partial_y F(x)$ (with the understanding that $\partial_y F(x) = \emptyset$ when $F(x), F(y)$ are not neighboring). The *total boundary* of $F(x)$ is defined as $\partial^* F(x) = \cup_y \partial_y F(x)$.

For a set of vertices A , an *imprint* of a vertex u is a vertex $a \in A$ such that there is no vertex of A (but a itself) on any shortest au -path. A subgraph H of G is *quasigated* if every vertex of $V(G \setminus H)$ has at most two imprints. It is known that for each fiber $F(x)$ of a star $St(z)$, the total boundary $\partial^* F(x)$ is an isometric quasigated tree [26].

► **Lemma 12** ([26]). *Let $G = (V, E)$ be a cube-free median graph, let $c \in V$ be a centroid, and let $F(x), F(y)$ be two fibers of the star $St(c)$. The following hold for every $u \in F(x)$, $v \in F(y)$.*

- *If $F(x)$ and $F(y)$ are separated, then $d_G(u, v) = d_G(u, c) + d_G(c, v)$;*
- *If $F(x)$ and $F(y)$ are neighboring, $F(x)$ is a panel and $F(y)$ is a cone, then let u_1, u_2 be the two (possibly equal) imprints of u on the total boundary $\partial^* F(x)$, and let v^* be the gate of v in $F(x)$. We have $d_G(u, v) = \min\{d_G(u, u_1) + d_G(u_1, v^*) + d_G(v^*, v), d_G(u, u_2) + d_G(u_2, v^*) + d_G(v^*, v)\}$;*
- *If $F(x)$ and $F(y)$ are 2-neighboring, then let $F(w)$ be the panel neighboring $F(x)$ and $F(y)$. Let u^* and v^* be the gates of u and v in $F(w)$. Then $d_G(u, v) = d_G(u, u^*) + d_G(u^*, v^*) + d_G(v^*, v)$.*

Sketch proof of Theorem 10. We compute for each edge $uv \in E$ two values, denoted by $f_G(u, v)$ and $f_G(v, u)$, so that: $f_G(u, v) \leq e_G(u, W_{u,v})$, $f_G(v, u) \leq e_G(v, W_{v,u})$ and, for each point x of the edge such that $d(u, x) = t$, $e_G(x) = \max\{t + f_G(u, v), 1 - t + f_G(v, u)\}$. If $E = \{uv\}$ then, we set $f_G(u, v) = f_G(v, u) = 0$. Otherwise, we compute a centroid c and we use an algorithmic procedure from [26] in order to compute in $\mathcal{O}(n)$ time the vertex-set and the edge-set of all fibers $F(x)$, $x \in St(c)$. We enumerate all the fibers $F(x)$, $x \in St(c)$, and we compute $D(x) = \max_{v \in F(x)} d_G(v, c)$. It can be done in total $\mathcal{O}(n)$ time by performing a

BFS rooted at c . Also, for each $x \in St(c)$, let G_x be induced by $F(x)$. Since, $F(x)$ is gated, and so convex, G_x is a cube-free median graph. In particular, we can apply our algorithm recursively on it in order to compute the values $f_{G_x}(\cdot, \cdot)$ associated to its edges. Then, we apply the following steps (some of which not being detailed due to lack of space):

Step 1. We consider all edges with their both ends in $St(c)$ and we compute the corresponding values $f_G(\cdot, \cdot)$. Roughly, it can be done in total $\mathcal{O}(n \log n)$ time if we order the vertices of $St(c)$ by non-decreasing $D(\cdot)$ value, and if we keep track for each $x \in St(c)$ of its neighbours in the star. To illustrate this, consider for example some edge xc . Then, $W_{x,c} = \bigcup \{F(y) \mid y \in N[x] \cap (St(c) \setminus \{c\})\}$, and so it becomes possible to compute $f_G(x, c), f_G(c, x)$ from the $D(\cdot)$ values. In the same way for an edge xy , where $x \in N(c), y \in St(c) \setminus N[c]$, we have $W_{y,x} = F(y) \cup F(x')$ where $F(x), F(x')$ are the two panels neighboring $F(y)$, and so, we can proceed as in the previous case for computing $f_G(x, y), f_G(y, x)$. Thus from now on, we only consider edges with at least one end not in $St(c)$.

Step 2. We consider each remaining edge uv sequentially, where $d(u, c) < d(v, c)$. Let $x, y \in St(c)$ satisfy $u \in F(x), v \in F(y)$. Let A be the union of all the fibers $F(z)$ s.t. $F(z)$ is separated from both $F(x)$ and $F(y)$. By Lemma 12, we have $A \subseteq W_{u,v}$. We want to compute $\max_{w \in A} d_G(u, w)$. There are three cases: $x = y$ and $F(x)$ is a panel; $x = y$ and $F(x)$ is a cone; $x \neq y$. Due to lack of space, we only detail the first case (the other two cases can be handled with similar techniques). Specifically, let $z \neq x$ be such that $F(z)$ is a panel and $D(z)$ is maximized. It can be computed in constant-time assuming the panels were ordered during a pre-processing phase. Recall that two panels are always separated. Therefore, the maximum distance between u and a vertex of A in a panel is equal to $d(u, c) + D(z)$. The case of separated cones is more complicated, and it requires some pre-processing. Specifically, we assign to all the fibers $F(z)$ pairwise different positive numbers, that we abusively identify with the vertices z of the star $St(c)$. Then, we enumerate the cones $F(z')$, $z' \in St(c) \setminus N_G[c]$. Let $F(z_1), F(z_2)$ be the two panels neighboring $F(z')$. We create a point $\vec{p}(z') = (z_1, z_2)$, to which we associate the value $f(\vec{p}(z')) = D(z')$. To complete the pre-processing, we put these points and their associated values in a 2-dimensional range tree, that takes $\mathcal{O}(n \log n)$ time. Now, to compute the maximum value between u and a vertex of A in a cone, it suffices to compute a point $\vec{p}(z') = (p_1, p_2)$ such that:

$$\begin{cases} p_1 \neq x, p_2 \neq x \\ f(\vec{p}(z')) \text{ is maximized for these above properties.} \end{cases}$$

Indeed, this maximum distance is exactly $d_G(u, c) + D(z') = d_G(u, c) + f(\vec{p}(z'))$. Furthermore, since each inequality gives rise to two disjoint intervals to which the corresponding coordinate must belong, a point $\vec{p}(z')$ as above can be computed using four range queries. It takes $\mathcal{O}(\log n)$ time. As a result, the total running time of this step is in $\mathcal{O}(n \log n)$.

Step 3. We consider each edge uv with at least one end not in $St(c)$ and such that $u \in F(x)$ for some panel $F(x)$. In what follows, for any $z, z' \in St(c)$, we write $z \sim z'$ if $F(z), F(z')$ are neighboring. Let $B = \bigcup \{F(y) \mid x \sim y \text{ and } v \notin F(y)\}$. Intuitively, what we try to do at this step is to compute $e(u, W_{u,v} \cap B)$ and $e(v, W_{v,u} \cap B)$. There are two cases: either $v \notin F(x)$ or $v \in F(x)$. In both cases, we reduce our computations to some suitable eccentricity problem on the tree $T = \partial^* F(x)$. Next, we detail the case $v \in F(x)$, which is the one to which we need to apply Theorem 9 (the case $v \notin F(x)$ is solved by using a rather standard dynamic

programming approach on the tree T). For each node $z \in V(T)$, let $\alpha(z)$ be the maximum distance between z and any vertex w in a neighboring cone $F(y)$ of which z is the gate in $F(x)$ (with the understanding that, if no vertex has z as its gate, then $\alpha(z)$ is a sufficiently large *negative* value, say $\alpha(z) = -|V(T)|$). All these nodes weights can be pre-computed in $\mathcal{O}(\sum_{y|x \sim y} |F(y)|)$ time. Furthermore, note that a cone is neighboring two panels [26]. As a result, if we consider each panel $F(x)$ sequentially then, we scan each cone only twice, and the total running-time of this pre-computation phase is in $\mathcal{O}(n)$.

We compute $e_G(u, B)$, $e_G(v, B)$ and $e_G(\{u, v\}, B) =^{def} \max_{w \in B} d_G(w, \{u, v\})$. For that, let $u_1, u_2 \in V(T)$ be the two (possibly equal) imprints of u , and similarly let $v_1, v_2 \in V(T)$ be the imprints of v . Set $\beta(u_1) = d_G(u, u_1)$, $\beta(u_2) = d_G(u, u_2)$ and in the same way $\beta(v_1) = d_G(v, v_1)$, $\beta(v_2) = d_G(v, v_2)$. Since T is isometric, then it follows from the distance formulae in Lemma 12 that the values to be computed are exactly $e_{T,\alpha}(\{u_1, u_2\}, \beta)$, $e_{T,\alpha}(\{v_1, v_2\}, \beta)$ and $e_{T,\alpha}(\{u_1, v_1, u_2, v_2\}, \beta)$. By Theorem 9, the latter can be computed in $\mathcal{O}(\log^2 n)$ time, up to some initial pre-processing of T in $\mathcal{O}(|V(T)| \log |V(T)|) = \mathcal{O}(|F(x)| \log |F(x)|)$ time. Overall, the running-time of this step is in $\mathcal{O}(n \log^2 n)$.

Let $e_G(u, B) = p_1$, $e_G(v, B) = p_2$ and $e_G(\{u, v\}, B) = p$. W.l.o.g., $p_1 \leq p_2$. It implies $p_2 = p + 1$. Then, $e_G(u, B \cap W_{u,v}) = p$. In the same way, if $p_1 = p + 1$ then we also have $e_G(v, B \cap W_{v,u}) = p$. From now on, we assume $p_1 < p + 1$. In particular, $p_1 = p$. But then, $e_G(v, B \cap W_{v,u}) \leq p - 1$, and therefore we needn't compute this value (*i.e.*, because we always have $t + p \geq 1 - t + e_G(v, B \cap W_{v,u})$ for any $t \in (0; 1)$).

Step 4. Finally, consider each edge uv with at least one end not in $St(c)$ and such that $v \in F(y)$ for some cone $F(y)$. Let $C = \bigcup \{F(y') \mid F(y) \text{ and } F(y') \text{ are either neighboring or 2-neighbouring, and } u \notin F(y')\}$. We would like to compute $e_G(u, W_{u,v} \cap C)$ and $e_G(v, W_{v,u} \cap C)$. There are two cases: either $u \in F(y)$ or $u \notin F(y)$. Consider the case $u \in F(y)$ (the other case can be dealt with similarly). We consider each x s.t. $F(x)$ is a panel neighboring $F(y)$ sequentially (there are only two such x). Let C_x contain $F(x)$ and all cones of C that are neighboring $F(x)$. We now consider $T = \partial^* F(x)$ which we assume to be pre-processed as during the previous Step 3. Let $u^*, v^* \in V(T)$ be the respective gates of u, v . Indeed, by Lemma 12 there is always a shortest-path between u (resp., v) and any vertex of C_x that goes by u^* (resp., by v^*). This part is solved through a delicate case analysis which depends on: some values $f_{G_x}(\cdot, \cdot)$ (obtained by applying our algorithm recursively to G_x) and some eccentricity functions computed for T during Step 3.

Overall, each fiber contains at most $n/2$ vertices, and so there are $\mathcal{O}(\log n)$ recursive stages. Since a stage runs in $\mathcal{O}(n \log^2 n)$ time (the bottleneck being Step 3), the total running time for computing all the values $f_G(\cdot, \cdot)$ is in $\mathcal{O}(n \log^3 n)$. ◀

Open problem. To which other graph classes can our framework in this section be applied? A good candidate could be the planar graphs of non positive combinatorial curvature [24], and especially the trigraphs [29]. To our best knowledge, it is open whether the eccentricities in a trigraph can be computed in almost linear time (there exists a linear-time algorithm for computing the diameter and the center [53]).

On Computing the Average Distance for Some Chordal-Like Graphs

Guillaume Ducoffe  

National Institute of Research and Development in Informatics, Bucharest, Romania
University of Bucharest, Romania

Abstract

The Wiener index of a graph G is the sum of all its distances. Up to renormalization, it is also the average distance in G . The problem of computing this parameter has different applications in chemistry and networks. We here study when it can be done in truly subquadratic time (in the size $n + m$ of the input) on n -vertex m -edge graphs. Our main result is a complete answer to this question, assuming the Strong Exponential-Time Hypothesis (SETH), for all the hereditary subclasses of chordal graphs. Interestingly, the exact same result also holds for the diameter problem. The case of non-hereditary chordal subclasses happens to be more challenging. For the chordal Helly graphs we propose an intricate $\tilde{O}(m^{3/2})$ -time algorithm for computing the Wiener index, where m denotes the number of edges. We complete our results with the first known linear-time algorithm for this problem on the dually chordal graphs. The former algorithm also computes the median set.

1 Introduction

This paper is about the fine-grained complexity of computing the average distance in a graph, a fundamental distance problem. For any undefined graph terminology, see [4, 20]. Unless stated otherwise, we only consider graphs that are simple, loopless, unweighted undirected, and more importantly connected. Let $G = (V, E)$ be such a graph. Throughout the paper, let $n = |V|$ and $m = |E|$. The distance between two vertices $x, y \in V$ equals the minimum number of edges on a xy -path in G . We denote it by $d_G(x, y)$, or simply by $d(x, y)$ whenever the graph G is clear from the context. The Wiener index of a graph G is $W(G) = \sum_{x, y \in V} d(x, y)$. Let also $\text{diam}(G) = \max_{x, y \in V} d(x, y)$ be the diameter of G . Note that $\text{diam}(G)$ and $\frac{1}{n(n-1)}W(G)$ represent the maximum and average distances in G . Although we focus in this work on computing $W(G)$, as it turns out, this problem is closely related to computing $\text{diam}(G)$. One of our objectives with this paper is to make clearer the connection between both problems.

The study of both parameters has applications in the fields of network optimization and analysis. For instance, delays are amongst the main causes of QoS degradation in a network. Roughly, if we further assume the network is subject to uniformly distributed demand, then we can approximate delays in the networks by distances in the underlying graph. In particular, with this interpretation in mind, the diameter and the (normalized) Wiener index would correspond to the maximum and average delays in the network, respectively. On a different note, for the analysis of social networks, and of more general complex networks with a core-periphery structure, various centrality indices have been introduced in order to measure the importance of a node. One of them, the so-called eccentricity centrality [34],

is tightly related to the diameter: in fact, with respect to this centrality measurement, the most peripheral vertices are exactly the diametral vertices (whose eccentricity equals the diameter). In the same way, the Wiener index is related to the closeness centrality [34]. In chemistry, relations were also shown between some quantities of molecules and the Wiener index of their chemical graph representation [42].

By a straightforward reduction to All-Pairs Shortest-Paths (APSP), the Wiener index and the diameter of a graph can both be computed in $\mathcal{O}(nm)$ time. Somehow, this is optimal, even for sparse graphs. Indeed, assuming the Strong Exponential-Time Hypothesis (SETH) [32], one cannot decide in $\tilde{\mathcal{O}}(n^{2-\epsilon})$ time, for any $\epsilon > 0$, whether a graph with $\tilde{\mathcal{O}}(n)$ edges has diameter either 2 or 3 [39]. The former implies that one cannot compute either the Wiener index of such graph in $\tilde{\mathcal{O}}(n^{2-\epsilon})$ time, for any $\epsilon > 0$ [12]. If we allow approximation algorithms, then the situation is completely different. Indeed, while for any fixed ε we can compute an $(1 + \varepsilon)$ -approximation of the Wiener index in almost linear time [27], a long line of recent works has ruled out such possibility for the diameter problem, establishing various trade-off between the allowed running-time and the best possible approximation factor [1, 5, 6, 18, 36]. In what follows, we only consider exact computations, but on restricted graph classes rather than on general graphs.

Let us call an algorithm truly subquadratic if it runs in $\tilde{\mathcal{O}}(n^a m^b)$ time, for some non negative a, b such that $a + b < 2$. On sparse graphs, such running time becomes $\tilde{\mathcal{O}}(n^{a+b})$ which for the Wiener index and the diameter problem is ruled out by SETH. For dense graphs, the running time becomes $\tilde{\mathcal{O}}(n^{a+2b})$, that may be worse than the classic $\mathcal{O}(nm) = \mathcal{O}(n^3)$ -time algorithm for APSP if $a + 2b > 3$. Therefore, so as to avoid this caveat, we are especially interested in running times in $\tilde{\mathcal{O}}(n^a m)$, for some non negative $a < 1$. Algorithms with such running times are known, for the diameter problem, on many graph classes [22, 24]. However, so far, we lack a good picture about the (non)existence of truly subquadratic-time algorithms for the Wiener index and the diameter problems within special graph classes. Indeed, the systematic study of the (non)existence of such algorithms is quite recent, motivated by the hardness results obtained in [7, 39]. Most prior works were about the (non)existence of almost linear-time algorithms, a much more restricted case [17]. We here make progress toward getting such good picture for the subclasses of chordal graphs.

Recall that, in what follows, most of our results apply to the Wiener index. What is remarkable, we think, is that many recent results for the Wiener index were obtained as a byproduct of similar results for the diameter [12, 14, 26]. Said otherwise, many SETH-hardness results for the diameter also apply to the Wiener index and, conversely, many truly subquadratic-time algorithms for computing the diameter can be modified in order to also compute the Wiener index (although this is not the case for all of them, *e.g.*, see [2, 24, 28]). It would be interesting to identify relevant graph classes where the complexity of the Wiener index and the diameter problem are different. One of our results in the paper, obtained for the subclass of chordal Helly graphs, may be a first step in this direction.

Our results. A graph is *chordal* if it has no induced cycle of length at least four. We here propose linear-time and truly subquadratic-time algorithms for computing the Wiener index, on subclasses of chordal graphs and related graph classes. First, in Sec. 2, we consider dually chordal graphs (*a.k.a.*, the clique-graphs of chordal graphs). The former are not chordal graphs in general, but they generalize strongly chordal graphs, and so, directed path graphs and interval graphs [11]. A linear-time algorithm for computing the diameter of dually chordal graphs was presented in [9] (it was recently extended to the computation of all eccentricities, see [21]). We propose a simple linear-time algorithm for computing the Wiener index in this class of graphs (Theorem 1). Doing so, we obtain the first linear-time

algorithm for computing the Wiener index on strongly chordal graphs, and on even larger chordal subclasses such as doubly chordal graphs. Then, in Sec. 3, we design a general divide-and-conquer method on the clique-tree of any chordal graph in order to compute its Wiener index. We give applications of this method in Sec. 4 and 5. Our main result is proved in Sec. 4, where under SETH we completely characterize the hereditary subclasses of chordal graphs for which we can compute the diameter, resp. the Wiener index, in truly subquadratic time. These subclasses turn out to be the same and they can be characterized via a VC-dimension argument or, in more graph-theoretic terms, as those subclasses excluding at least one split graph. See our Theorem 7 for details. Doing so, we get a simple criterion for the existence of truly subquadratic-time algorithms, both for the Wiener index and the diameter, on *many* subclasses of chordal graphs that have been considered in the literature (Corollary 13). Our characterization for the diameter problem follows from several previous works, although to our best knowledge it has not been observed before. Our main technical contribution in Sec. 4 is to prove that the same characterization also holds for the Wiener index. Finally, in Sec. 5, we end up studying the Wiener index for chordal Helly graphs, a prominent non-hereditary subclass of chordal graphs. – Recall that a graph is Helly if any family of pairwise intersecting balls (of arbitrary centers and radii) have a nonempty common intersection. – We state a few open questions in Sec. 6.

Due to lack of space, some proofs are omitted from the following technical sections.

2 Warm-up: Maximum neighbourhood orderings

Let $G = (V, E)$ be a graph. Recall that for a vertex v , $N(v) = \{u \in V \mid uv \in E\}$ denotes its open neighbourhood, while we call $N[v] = N(v) \cup \{v\}$ its closed neighbourhood. A maximum neighbour of a vertex v is some $u \in N[v]$ (possibly, $u = v$) such that $N[w] \subseteq N[u]$ for every $w \in N[v]$. We call a graph G dually chordal if its vertex-set can be totally ordered as (v_1, v_2, \dots, v_n) so that, for every $1 \leq i \leq n$, vertex v_i has a maximum neighbour in the induced subgraph $G \setminus \{v_1, v_2, \dots, v_{i-1}\}$ [11]. Such ordering is sometimes called a MNO (Maximum Neighbourhood Ordering), and it can be computed in linear time [9]. In what follows, we implicitly use the fact that, if a vertex v has a maximum neighbour $u \neq v$, then $G \setminus v$ is an isometric (distance-preserving) subgraph of G .

► **Theorem 1.** *The Wiener index of a dually chordal graph can be computed in linear time.*

Proof. Fix a MNO (v_1, v_2, \dots, v_n) for G . Let $G_0 = G$ and, for every $1 \leq i < n$, let $G_i = G \setminus \{v_1, v_2, \dots, v_i\}$. We observe that, for a vertex in G_{i-1} to be its own maximum neighbour, it must be a universal vertex. Since such a universal vertex can always be chosen last in a MNO of G_{i-1} , we assume from now on that every v_i , $i < n$ has a maximum neighbour $u_i \neq v_i$ in G_{i-1} . In what follows, we scan the ordering once in order to define some variables S_i and functions $\pi_i := V(G_i) \rightarrow \mathbb{N}$. Then, we reverse scan the MNO to compute, for every i and every $u \in V(G_i)$,

$$D_i(u) = S_i + \sum_{w \in V(G_i)} \pi_i(w) \cdot d(u, w).$$

Initially, let $S_0 = 0$ and, for every $v \in V$, let $\pi_0(v) = 1$. Doing so, we ensure that at the end of the algorithm we have $W(G) = \sum_{v \in V} D_0(v)$. Then, let us assume S_{i-1} and π_{i-1} to be known, for some $i > 0$. Let $u_i \in N_{G_{i-1}}(v_i)$ have maximum degree in the (isometric) subgraph G_{i-1} . Note that by maximality of $|N_{G_{i-1}}(u_i)|$, this vertex u_i must be a maximum neighbour of v_i in G_{i-1} . We set $S_i = S_{i-1} + \pi_{i-1}(v_i)$, $\pi_i(u_i) = \pi_{i-1}(u_i) + \pi_{i-1}(v_i)$ and $\pi_i(w) = \pi_{i-1}(w)$ for every other $w \in V(G_i) \setminus \{u_i\}$.

44:4 On Computing the Maximum and Average Distances for Some Chordal-Like Graphs

We now reverse scan the MNO. Clearly, $D_{n-1}(v_n) = S_{n-1}$. Let us assume the values $D_i(u)$ to be known. We set:

$$D_{i-1}(v_i) = D_i(u_i) + n - 2\pi_{i-1}(v_i) - \left(\sum_{w \in N_{G_{i-1}}(v_i) \setminus \{u_i\}} \pi_{i-1}(w) \right)$$

and we proceed to the following update for every $w \in N_{G_{i-1}}(v_i) \setminus \{u_i\}$: $D_{i-1}(w) = D_i(w) - \pi_{i-1}(v_i)$. Indeed, as it shall become clearer in the remainder of our proof, this update is because these are the only vertices $x \in V(G_i)$ for which we do not have $d_{G_{i-1}}(v_i, x) = d_{G_{i-1}}(u_i, x) + 1$. For every other vertex $x \in V(G_{i-1})$, $D_{i-1}(x) = D_i(x)$.

All the above operations can be performed in total $\sum_i \mathcal{O}(|N_{G_{i-1}}(v_i)|) = \mathcal{O}(m+n)$ time. Furthermore, if all values $D_i(x)$ are correctly computed, then we get $D_0(x) = \sum_{y \in V} d(x, y)$. In particular, $W(G) = \sum_{x \in V} D_0(x)$. Let us assume in what follows all the values $D_i(x)$ to be correctly computed, for some $i > 0$. Since u_i is a maximum neighbour of v_i we have $d(v_i, x) = d(u_i, x) + 1$ for every $x \notin N_{G_{i-1}}[v_i]$. In particular:

$$\begin{aligned} D_{i-1}(x) &= S_{i-1} + \sum_{y \in V(G_{i-1})} \pi_{i-1}(y) \cdot d(y, x) \\ &= S_{i-1} + \pi_{i-1}(v_i) \cdot d(x, v_i) + \pi_{i-1}(u_i) \cdot d(x, u_i) + \sum_{y \in V(G_i) \setminus \{u_i\}} \pi_{i-1}(y) \cdot d(y, x) \\ &= S_{i-1} + \pi_{i-1}(v_i) \cdot (d(x, u_i) + 1) + \pi_{i-1}(u_i) \cdot d(x, u_i) + \sum_{y \in V(G_i) \setminus \{u_i\}} \pi_i(y) \cdot d(y, x) \\ &= S_{i-1} + \pi_{i-1}(v_i) + (\pi_{i-1}(v_i) + \pi_{i-1}(u_i)) \cdot d(x, u_i) + \sum_{y \in V(G_i) \setminus \{u_i\}} \pi_i(y) \cdot d(y, x) \\ &= S_i + \sum_{y \in V(G_i)} \pi_i(y) \cdot d(y, x) = D_i(x). \end{aligned}$$

In the same way (using $d(u_i, u_i) = 0$),

$$\begin{aligned} D_{i-1}(u_i) &= S_{i-1} + \pi_{i-1}(v_i) + \sum_{y \in V(G_{i-1}) \setminus \{v_i\}} \pi_{i-1}(y) \cdot d(y, u_i) \\ &= S_i + \sum_{y \in V(G_i)} \pi_i(y) \cdot d(y, u_i) \\ &= D_i(u_i). \end{aligned}$$

However, for every $w \in N_{G_{i-1}}(v_i) \setminus \{u_i\}$, $\pi_{i-1}(v_i) \cdot d(v_i, w) = \pi_{i-1}(v_i)$ is counted twice in $D_i(w)$: once in S_i , and once in $\pi_i(u_i) \cdot d(u_i, w) = \pi_i(u_i) = \pi_{i-1}(u_i) + \pi_{i-1}(v_i)$. In particular, we obtain $D_{i-1}(w) = D_i(w) - \pi_{i-1}(v_i)$.

We are left proving that $D_{i-1}(v_i)$ is correctly computed. By induction, $\forall j, \sum_x \pi_j(x) = n$. Then, we have:

$$\begin{aligned} D_{i-1}(v_i) &= S_{i-1} + \sum_y \pi_{i-1}(y) \cdot d(y, v_i) = S_i + \left(\sum_y \pi_{i-1}(y) \cdot d(y, v_i) \right) - \pi_{i-1}(v_i) \\ &= S_i + \left(\sum_{w \in N_{G_{i-1}}(v_i) \setminus \{u_i\}} \pi_{i-1}(w) + \sum_{y \notin N_{G_{i-1}}(v_i) \setminus \{u_i\}} \pi_{i-1}(y) \cdot (d(y, u_i) + 1) \right) - \pi_{i-1}(v_i) \\ &= S_i + \left(\sum_{y \notin N_{G_{i-1}}(v_i) \setminus \{u_i\}} \pi_{i-1}(y) \cdot d(y, u_i) \right) + \left(\sum_{y \neq v_i} \pi_{i-1}(y) \right) - \pi_{i-1}(v_i) \end{aligned}$$

$$\begin{aligned}
&= S_i + \left(\sum_{y \notin N_{G_{i-1}}(v_i) \setminus \{u_i\}} \pi_i(y) \cdot d(y, u_i) \right) + n - 2\pi_{i-1}(v_i) \\
&= S_i + \left(\sum_y \pi_i(y) \cdot d(y, u_i) \right) - \left(\sum_{w \in N_{G_{i-1}}(v_i) \setminus \{u_i\}} \pi_{i-1}(w) \right) + n - 2\pi_{i-1}(v_i) \\
&= D_i(u_i) - \left(\sum_{w \in N_{G_{i-1}}(v_i) \setminus \{u_i\}} \pi_{i-1}(w) \right) + n - 2\pi_{i-1}(v_i). \quad \blacktriangleleft
\end{aligned}$$

A vertex v is a median if it minimizes $\sum_{u \in V} d(u, v)$. The median set of a graph G contains all its medians. With the same proof as for Theorem 1, we obtain:

► **Corollary 2.** *The median set of a dually chordal graph can be computed in linear time.*

Finally, a graph G is doubly chordal if it is both chordal and dually chordal [37]. Note that doubly chordal graphs properly contain the strongly chordal graphs, and so, the directed path graphs and the interval graphs.

► **Corollary 3.** *The Wiener index and the median set of a doubly chordal graph (and so, of a strongly chordal graph, resp. directed path graph, resp. interval graph) can be computed in linear time.*

We refer to [19] for a previous linear-time algorithm for the interval graphs. In contrast to our own algorithm, the former is taking an interval representation of the graph as input.

3 A framework for chordal graphs

We introduce a general method for computing the Wiener index of chordal graphs. We recall that a graph is called a split graph if its vertex-set can be bi-partitioned into a clique and a stable set [29]. In the SPLIT-WEIGHTED-WIENER problem, we are given as input a tuple $(\mathcal{P}(V), E', \alpha, \beta)$ where, for some split graph $H = (V, E)$:

- $\mathcal{P}(V) = (K, S^1, S^2, \dots, S^c)$ is a partition of the vertex-set V , where K is a clique and $S := \bigcup_{i=1}^c S^i$ is a stable set.
- $E' = \{uv \mid u \in K, v \in S\} \subseteq E$.
- $\alpha, \beta : V \rightarrow \mathbb{N}_{\geq 1}$ are weight functions.

We call H the underlying input split graph.

The output is equal to $\sum_{i \neq j} \sum_{x \in S^i, y \in S^j} [\beta(y)\alpha(x) + \beta(x)\beta(y)d(x, y) + \beta(x)\alpha(y)]$.

► **Theorem 4.** *There is an $\tilde{O}(m + n)$ -time reduction from computing the Wiener index on a chordal graph G to the SPLIT-WEIGHTED-WIENER problem on some instances $(\mathcal{P}(V_k), E'_k, \alpha_k, \beta_k)$. Furthermore, each underlying split H_k is obtained from some induced subgraph of G by removing the edges with their both ends in the same group S_k^i of the partition.*

We need to introduce a few additional notions and related intermediate results.

First, recall that a clique-tree of a graph G is a tree T of which the nodes are the maximal cliques of G , and such that for every vertex v the set of all the maximal cliques that contain v induces a connected subtree. It is known that G is chordal if and only if it has a clique-tree [13, 30, 41] and, furthermore, a clique-tree can be computed in linear time [40]. – See also [3, 10] and the references therein. – We may see a clique-tree T as a node-weighted tree where, for any maximal clique C , $w(C) = |C|$. Then, let $w(T) := \sum_C w(C)$. For a chordal graph, $w(T) = \mathcal{O}(n + m)$ [3].

For a set S and a vertex x , let us define $Pr(x, S) = \{y \in S \mid d(x, y) = d(x, S)\}$. Let also $I(x, y) = \{z \in V \mid d(x, y) = d(x, z) + d(z, y)\}$ for every vertices x and y . The following two results will be useful in our proofs:

► **Lemma 5** ([15]). *In a chordal graph G , if C is a clique and $x \notin C$, then there exists a vertex $g(x) \in \bigcap \{I(x, y) \mid y \in Pr(x, C)\}$ that is adjacent to all vertices from $Pr(x, C)$. This vertex $g(x)$ is sometimes called a gate of x .*

► **Lemma 6** ([22]). *If T is a clique-tree of a chordal graph G then, for every (not necessarily maximal) clique C of G , for every $v \notin C$ we can compute $d_G(v, C)$ and a corresponding gate v^* in total $\mathcal{O}(w(T))$ time, where $w(T)$ denotes the sum of cardinalities of all the maximal cliques of G .*

Finally, for an n -node tree $T = (V, E)$, a centroid is a node whose removal leaves subtrees of order at most $n/2$. A classic theorem from Jordan asserts that such node always exists [33]. Furthermore, we can compute a centroid in $\mathcal{O}(n)$ time by dynamic programming (e.g., see [31]).

Proof of Theorem 4. Up to additional $\mathcal{O}(n + m)$ -time pre-processing, we may assume each input graph G to be given under the form of a clique tree T . Our reduction is recursive. Consider first the following two base cases:

- **Case $|V(T)| = 1$.** Then, G is a clique, and we have $W(G) = n(n - 1)$.
- **Case $|V(T)| = 2$.** Then, G is the union of two intersecting cliques X and X' . In particular, $diam(G) = 2$, and so (see [12]), we have $W(G) = 2n(n - 1) - 2m$. Note that $n = |X| + |X'| - |X \cap X'|$ and $2m = |X| \cdot (|X| - 1) + |X'| \cdot (|X'| - 1) - |X \cap X'| \cdot (|X \cap X'| - 1)$ (computable by scanning once the maximal cliques of G).

From now on, $|V(T)| \geq 3$. We compute X a centroid of T . Let T_1, T_2, \dots, T_c be the subtrees of $T \setminus \{X\}$. For each i , let G_i be induced by the vertices contained in at least one node of T_i . By the properties of a clique-tree, each G_i is an isometric subgraph of G .

(1) Computation of the $W(G_i)$'s. We apply our reduction to G_1, G_2, \dots, G_c (encoded by their respective clique-trees T_1, T_2, \dots, T_c). Doing so (throughout one-to-many reductions to the SPLIT-WEIGHTED-WIENER problem), we computed their respective Wiener indices $W(G_1), W(G_2), \dots, W(G_c)$.

(2) Computation of a first (non definitive) instance $(\mathcal{P}, E', \alpha, \beta)$. We apply Lemma 6 in order to compute, for every $v \notin X$, $d(v, X)$ and a gate $g(v)$, whose existence is ensured by Lemma 5. For every i , let $U_i = \{g(v_i) \mid v_i \in V(G_i) \setminus X\}$. We set, for every $u_i \in U_i$:

$$\alpha(u_i) = \sum \{d(v_i, X) - 1 \mid g(v_i) = u_i\}, \text{ and } \beta(u_i) = \#\{v_i \in V(G_i) \setminus X \mid g(v_i) = u_i\}.$$

We consider the following instance $(\mathcal{P}, E', \alpha, \beta)$ where we have:

- $\mathcal{P} = (X, U_1, U_2, \dots, U_c)$;
- $E' = E \cap (X \times V \setminus X)$ (edges between X and the neighbours of X);
- and α, β as they were previously defined in the proof.

We claim that by solving the SPLIT-WEIGHTED-WIENER problem on this above instance, one computes the sum of all distances $d(v_i, v_j)$ for $v_i \in V(G_i) \setminus X$, $v_j \in V(G_j) \setminus X$ and $i \neq j$. Indeed, let $v_i \in V(G_i) \setminus X$ and $v_j \in V(G_j) \setminus X$, for some $i \neq j$. Every $v_i v_j$ -path crosses X . Furthermore, since X is a clique, there is a shortest $v_i v_j$ -path such that the vertex of X closest to v_i (resp., to v_j) is in $Pr(v_i, X)$ (resp., in $Pr(v_j, X)$). As a result, we have $d(v_i, v_j) = d(v_i, g(v_i)) + d(g(v_i), g(v_j)) + d(g(v_j), v_j)$. For v_i fixed, we get:

$$\begin{aligned}
\sum_{v_j \in V(G_j) \setminus X} d(v_i, v_j) &= \sum_{v_j \in V(G_j) \setminus X} (d(v_i, g(v_i)) + d(g(v_i), g(v_j)) + d(g(v_j), v_j)) \\
&= \sum_{u_j \in U_j} \sum_{v_j | g(v_j) = u_j} (d(v_i, g(v_i)) + d(g(v_i), u_j) + d(u_j, v_j)) \\
&= \sum_{u_j \in U_j} (\beta(u_j) \cdot (d(v_i, g(v_i)) + d(g(v_i), u_j)) + \alpha(u_j)).
\end{aligned}$$

If we sum the above over all the v_i 's, we obtain:

$$\begin{aligned}
\sum_{v_i \in V(G_i) \setminus X} \sum_{v_j \in V(G_j) \setminus X} d(v_i, v_j) &= \sum_{v_i \in V(G_i) \setminus X} \sum_{u_j \in U_j} (\beta(u_j) \cdot (d(v_i, g(v_i)) + d(g(v_i), u_j)) + \alpha(u_j)) \\
&= \sum_{u_i \in U_i} \sum_{u_j \in U_j} (\beta(u_j) \cdot (\alpha(u_i) + \beta(u_i)d(u_i, u_j)) + \beta(u_i)\alpha(u_j)) \\
&= \sum_{u_i \in U_i} \sum_{u_j \in U_j} (\beta(u_j)\alpha(u_i) + \beta(u_j)\beta(u_i)d(u_i, u_j) + \beta(u_i)\alpha(u_j)).
\end{aligned}$$

(3) Computation of a reduced instance. The problem with the above instance $(\mathcal{P}, E', \alpha, \beta)$ is that, in order to fit with our claimed running time for the reduction, we further need to have $|E'| = \mathcal{O}(w(T))$, that may not be the case in general. Thus, we need to reduce the instance. For that, let $U := \bigcup_i U_i$. For every $u \in U$, there is a maximal clique that contains $\{u\} \cup (N(u) \cap X)$. Thus, in order to relate u with its neighbours in X , it suffices to compute amongst all maximal cliques containing u one X_u maximizing $|X_u \cap X|$. We can do so, in $\mathcal{O}(w(T))$ time, as follows:

- We scan all the maximal cliques $X' \neq X$ in order to compute $|X' \cap X|$.
- We order the maximal cliques $X' \neq X$ by non increasing value of $|X' \cap X|$. It can be done by using, *e.g.*, counting sort.
- We scan all the ordered maximal cliques X' . Initially, all the vertices are left unmarked. When scanning a maximal clique X' , we set $X_u = X'$ for every $u \in X' \cap U$ unmarked. Then, we mark all vertices in X' .

Let $u, u' \in U$ be such that $X_u = X_{u'}$. Since u and u' are adjacent, there is an i such that $u, u' \in U_i$. Since furthermore, $N(u) \cap X = N(u') \cap X$ (these vertices are twins in the underlying split graph H), we may remove u' from U and update $\alpha(u), \beta(u)$ as follows: $\alpha(u) := \alpha(u) + \alpha(u')$, $\beta(u) := \beta(u) + \beta(u')$. Doing so until it can no more be done, we end up with a smaller set U^* such that no two vertices $u \in U^*$ are associated to the same maximal clique X_u . For every i , let us replace U_i in the above instance for SPLIT-WEIGHTED-WIENER by the subset $S_i = U_i \cap U^*$. Then, for $E^* = \{uv \mid u \in U^*, v \in X\}$ we obtain $|E^*| < \sum_{u \in U^*} |X_u| = \mathcal{O}(w(T))$, as desired.

From now on, we assume to be given $W_0 := \sum_{i \neq j} \sum_{v_i \in V(G_i) \setminus X, v_j \in V(G_j) \setminus X} d(v_i, v_j)$ (*i.e.*, by the above reduction to one instance of SPLIT-WEIGHTED-WIENER).

(4) Computation of the sum of distances between X and $V \setminus X$. Next, we compute $W_X := \sum_{x \in X, v \notin X} d(x, v)$. For that, recall that we computed the set $U = \bigcup_i U_i$ of all the gates, and the weight functions α, β . Furthermore, for each $x \in X$ and index i we have:

$$\sum_{v_i \in V(G_i) \setminus X} d(x, v_i) = \sum_{v_i \in V(G_i) \setminus X} (d(x, g(v_i)) + d(g(v_i), v_i)) = \sum_{u_i \in U_i} (\beta(u_i)d(x, u_i) + \alpha(u_i)).$$

Note that, for every $u \in U$, $d(u, x) \in \{1, 2\}$. Hence, we get:

$$\sum_{v \notin X} d(x, v) = 2 \cdot \left(\sum_{u \in U} \beta(u) \right) - \left(\sum_{u \in N(x) \cap U} \beta(u) \right) + \left(\sum_{u \in U} \alpha(u) \right).$$

The two sums $\sum_{u \in U} \beta(u)$ and $\sum_{u \in U} \alpha(u)$ can be pre-computed in $\mathcal{O}(|U|) = \mathcal{O}(w(T))$ time. Therefore, in order to compute W_X , we are left computing $\sum_{u \in N(x) \cap U} \beta(u)$ for every $x \in X$.

- For each $x \in X$, let $\gamma(x) = 0$ (at the end of the procedure, we shall have $\gamma(x) = \sum_{u \in N(x) \cap U} \beta(u)$).
- We root T arbitrarily and we start a BFS from the root.
- When we reach some maximal clique X' during the search, we further assume to have access to its intersection $Y = X' \cap p(X')$ with its parent node ($Y = \emptyset$ if X' is the root). For every $x \in (X \cap X') \setminus Y$, we increment $\gamma(x)$ by $\sum_{u \in U \cap X'} \beta(u)$. However, in order to avoid overcounting, for every $x \in X \cap Y$, we increment $\gamma(x)$ by $\sum_{u \in (U \cap X') \setminus Y} \beta(u)$.
- After processing each X' , we scan all the maximal cliques X'' that are children nodes of X' in order to compute $X' \cap X''$.

Since each maximal clique is scanned $\mathcal{O}(1)$ times, the total running time is in $\mathcal{O}(w(T))$.

(5) A formula for computing $W(G)$. At this point of the reduction, we are almost done for computing $W(G)$. However, if we sum all the partial estimates computed so far, there are a few distances overcounted. Specifically, let $Y_i = X \cap V(G_i)$. We have:

$$\begin{aligned} W(G) &= W_0 + \left(\sum_{i=1}^c W(G_i) \right) + |X| \cdot (|X| - 1) + 2W_X \\ &\quad - \sum_{i=1}^c \left(|Y_i| \cdot (|Y_i| - 1) + 2 \cdot \sum_{y_i \in Y_i} \sum_{v_i \in V(G_i) \setminus X} d(v_i, y_i) \right) \end{aligned}$$

Each set Y_i above can be computed as the intersection between X and the unique maximal clique $X_i \in V(T_i) \cap N_T(X)$. Furthermore, for $y_i \in Y_i$ fixed, we have:

$$\sum_{v_i \in V(G_i) \setminus X} d(v_i, y_i) = 2 \cdot \left(\sum_{u_i \in U_i} \beta(u_i) \right) - \left(\sum_{u_i \in N(y_i) \cap U_i} \beta(u_i) \right) + \left(\sum_{u_i \in U_i} \alpha(u_i) \right).$$

Hence, we are left computing $\gamma_i(y_i) = \sum_{u_i \in U_i \cap N(y_i)} \beta(u_i)$ for every $y_i \in Y_i$. This can be done in $\mathcal{O}(w(T_i))$ time, by using the same procedure as for computing the values $\gamma(x)$, but restricted to the clique-subtree T_i . Since all the T_i 's are disjoint, the total running time is still in $\mathcal{O}(w(T))$.

Complexity. Since we use in our reduction a centroid decomposition of the clique-tree T , there are $\mathcal{O}(\log |V(T)|) = \mathcal{O}(\log n)$ recursive stages. At each recursive stage, we proceed on disjoint clique-subtrees T' . Therefore, each recursive stage takes $\mathcal{O}(w(T))$ time (excluding the calls to an oracle solving SPLIT-WEIGHTED-WIENER). The total running time of the reduction, excluding the calls of the oracle, is in $\mathcal{O}(w(T) \log n) = \mathcal{O}(m \log n)$. ◀

We shall use the heavy machinery presented above in the next two sections.

4 Application: Hereditary subclasses of chordal graphs

Recall that a class of graphs is called hereditary if it is stable by induced subgraph. The complexity of the diameter problem has been studied for many hereditary subclasses of chordal graphs [9, 17, 25, 22, 23, 38]. For the special case of the interval graphs, a linear-time algorithm for computing the Wiener index is also known [19] (which we extended to the strongly chordal graphs in Sec. 2). However, even for the hereditary subclass of split graphs, under SETH there is no truly subquadratic algorithm for computing the diameter nor the Wiener index. In this section, we exactly characterize the hereditary subclasses of chordal graphs for which such algorithms exist (conditioned on SETH).

Recall that a hypergraph is a pair $\mathcal{H} = (X, \mathcal{R})$ such that each element of \mathcal{R} (called a hyperedge) is a subset of X (the elements of X are called vertices, by analogy to graphs). A vertex-subset $Y \subseteq X$ is shattered by \mathcal{H} if, for any possible subset $Z \subseteq Y$, there exists an $e \in \mathcal{R}$ such that $e \cap Y = Z$. The VC-dimension of \mathcal{H} is the largest cardinality of a shattered subset. For a graph, its VC-dimension is the VC-dimension of its neighbourhood hypergraph $\mathcal{N}(G) = (V, \{N[v] \mid v \in V\})$. Finally, a class of graphs has bounded VC-dimension if there exists a constant d such that every graph in the class has VC-dimension at most d .

► **Theorem 7.** *Under SETH, for any hereditary subclass \mathcal{C} of chordal graphs, the following statements are equivalent:*

1. *There is a truly subquadratic algorithm for computing the Wiener index within \mathcal{C} .*
2. *There is a truly subquadratic algorithm for computing the diameter within \mathcal{C} .*
3. *There is a truly subquadratic algorithm for deciding if a graph in \mathcal{C} has diameter ≤ 2 .*
4. *\mathcal{C} does not contain all the split graphs.*
5. *\mathcal{C} has bounded VC-dimension.*

The above theorem follows from previous works in the literature, and a new result on our own in Sec. 4.1. Specifically, we will use the following lemmas in our proof:

► **Lemma 8** ([7]). *For any $\varepsilon > 0$, there exists a $c(\varepsilon)$ s.t., under SETH, we cannot compute the diameter in $\mathcal{O}(n^{2-\varepsilon})$ time on the split graphs of order n and clique-number at most $c(\varepsilon) \log n$.*

► **Lemma 9** ([22]). *If \mathcal{C} is a subclass of chordal graphs of bounded VC-dimension, then there exists a randomized truly subquadratic-time algorithm for computing the diameter of the graphs in \mathcal{C} .*

The next result of Bousquet et al. [8] shows that for any hereditary chordal subclass, either Lemma 8 or Lemma 9 can be applied.

► **Lemma 10** ([8]). *Let \mathcal{C} be a hereditary class. If \mathcal{C} has infinite VC-dimension, then \mathcal{C} must contain either all the bipartite graphs, or all the co-bipartite graphs, or all the split graphs.*

We also prove a quantitative version of Lemma 10, for chordal graphs. Note that the worst-case running time of the algorithms presented in Lemma 9 and in Sec. 4.1 depends on the largest VC-dimension of a graph in the class \mathcal{C} .

► **Lemma 11.** *If H is a split graph, then every H -free chordal graph has VC-dimension at most $|V(H)| - 1$.*

In Sec. 4.1, we prove that:

► **Theorem 12.** *If \mathcal{C} is a subclass of chordal graphs of bounded VC-dimension, then there exists a deterministic truly subquadratic-time algorithm for computing the Wiener index of the graphs in \mathcal{C} .*

We are finally ready to prove our main result:

Proof of Theorem 7. Let $G \in \mathcal{C}$ be arbitrary. It is known [12] that $W(G) \leq 2n(n-1) - 2m$ if and only if $\text{diam}(G) \leq 2$. Therefore, (1) \implies (3). We also have (2) \implies (3). Since the diameter of a split graph is at most three, we get by Lemma 8 that (3) \implies (4). Furthermore, since not all bipartite graphs and co-bipartite graphs are chordal, by Lemma 10 we get that (4) \implies (5). Finally, by Lemma 9 we have (5) \implies (2), and by Theorem 12 we have (5) \implies (1). ◀

► **Corollary 13.** *The following subclasses of chordal graphs admit truly subquadratic algorithms for the Wiener index and the diameter problem: chordal bull-free graphs, chordal claw-free graphs, block graphs, interval graphs [38], strongly chordal graphs [9], directed path graphs [17], undirected path graphs [22], chordal dominating pair graphs [25], hereditary Helly graphs [22], k -separator chordal graphs [35], chordal graphs of bounded interval number, chordal graphs of bounded asteroidal number [25].*

To our best knowledge, our results are new for chordal bull-free graphs, chordal claw-free graphs, k -separator chordal graphs and chordal graphs of bounded interval number, both for the Wiener index and the diameter problem (references to prior works are given in the statement of Corollary 13). For the Wiener index only, our results are also new for the subclasses of strongly chordal graphs (see also Sec. 2 for a faster algorithm), directed path graphs, undirected path graphs, chordal dominating pair graphs, hereditary Helly graphs and chordal graphs of bounded asteroidal number. This above listing is far from exhaustive.

4.1 Sketch Proof of Theorem 12

In what follows, let $G = (V, E) \in \mathcal{C}$. By Theorem 4, computing the Wiener index of G can be reduced in $\tilde{O}(m+n)$ time to solving the SPLIT-WEIGHTED-WIENER problem on some instances $(\mathcal{P}(V_k), E'_k, \alpha_k, \beta_k)$. Let d be the maximum VC-dimension of a graph in \mathcal{C} . We prove below that each instance $(\mathcal{P}(V_k), E'_k, \alpha_k, \beta_k)$ can be solved in $\tilde{O}(|E'_k| \cdot |V_k|^{1-\varepsilon_d})$ time, where ε_d is a constant that only depends on d . Note that $\sum_k |E'_k| = \tilde{O}(m+n)$ since it is the total running time of our reduction. Furthermore, since by Theorem 4 each V_k is a subset of V , $\max_k |V_k| = \mathcal{O}(n)$. Hence, our result below implies an $\tilde{O}(\sum_k |E'_k| \cdot |V_k|^{1-\varepsilon_d}) = \tilde{O}(mn^{1-\varepsilon_d})$ running time in order to compute $W(G)$.

For the remainder of the proof, let $(\mathcal{P}(V_k), E'_k, \alpha_k, \beta_k)$ be fixed. Recall (see Sec. 3) $\mathcal{P}(V_k) = (K_k, S_k^1, S_k^2, \dots, S_k^{c_k})$ with K_k a clique of G . Let $S_k = \bigcup_j S_k^j = V_k \setminus K_k$. By Theorem 4, $E'_k = E(G) \cap (K_k \times S_k)$ (*i.e.*, there is no edge added or removed between K_k and S_k compared to G). We start with a simple observation:

► **Lemma 14.** *Let $G = (V, E)$ have VC-dimension at most d , and let $X, Y \subseteq V$. The hypergraph $\mathcal{H} = (X, \{N_G[y] \cap X \mid y \in Y\})$ also has VC-dimension at most d .*

Proof. Any subset shattered by \mathcal{H} is shattered by the neighbourhood hypergraph of G . ◀

We apply Lemma 14 to $X = S_k$ and $Y = K_k$. Let \mathcal{H}_k be the corresponding hypergraph.

A spanning path of a hypergraph \mathcal{H} is a total order of its vertex-set. The stabbing number of such spanning path is the least t such that every hyperedge of \mathcal{H} is the union of at most t intervals onto the path. The following result is based on a prior work of Chazelle and Welzl about range queries [16]:

► **Lemma 15** ([24]). *For every $d > 0$, there exists a constant $\varepsilon_d \in (0; 1)$ such that in $\tilde{\mathcal{O}}(m+n^{2-\varepsilon_d})$ deterministic time, for every n -vertex hypergraph $\mathcal{H} = (X, \mathcal{R})$ of VC-dimension at most d and size $m = \sum_{e \in \mathcal{R}} |e|$, we can compute a spanning path of stabbing number $\tilde{\mathcal{O}}(n^{1-\varepsilon_d})$. Moreover, $\varepsilon_d = \frac{1}{2^{d+1} \lceil c(d+1) - 1 \rceil + 1}$ for some constant $c > 2$.*

Apply Lemma 15 to \mathcal{H}_k . Doing so, for every $u \in K_k$, $N_H(u) \cap S_k$ is the union of $\tilde{\mathcal{O}}(|S_k|^{1-\varepsilon_d})$ intervals of the resulting spanning path of \mathcal{H}_k . Then, for every $s \in S_k$, define $N_k^2(s)$ to be the set of all vertices in S_k at distance two from s in the underlying split graph $(K_k \cup S_k, E'_k \cup (K_k \times K_k))$. We have that $N_k^2(s)$ is the union of $\tilde{\mathcal{O}}(|N_G(s) \cap K_k| \cdot |S_k|^{1-\varepsilon_d})$ intervals of the spanning path computed for \mathcal{H}_k .

One more ingredient is needed in our proof. Consider a set Q of 2-dimensional points. Each point $(x, y) \in Q$ is assigned some weight $f(x, y)$. A box is the Cartesian product of two intervals (we also allow intervals that are infinite, semi-finite, or reduced to a singleton). Note that each box defines a rectangle in the plane (possibly, a line or a point if some intervals are reduced to a singleton). A (counting) range query asks, for a given box, the sum of the weights of all points in Q that are contained into this rectangle.

► **Lemma 16** ([43]). *Let Q be a set of 2-dimensional points. After a pre-processing in $\mathcal{O}(|Q| \log |Q|)$ time, one can answer any range query in $\mathcal{O}(\log |Q|)$ time.*

Let $\sigma_k : S_k \rightarrow \{1, 2, \dots, |S_k|\}$ be the mapping of S_k to the nodes of the spanning path. For each $1 \leq i \leq c_k$ and $s_i \in S_k^i$, we create a point $(\sigma_k(s_i), i)$ with weight $f(\sigma_k(s_i), i) = \beta_k(s_i)$. Let Q_k be the resulting 2-dimensional point-set. We apply Lemma 16 in order to compute, for each i and $s_i \in S_k^i$, the weighted sum $\Phi(s_i) = \sum \{\beta_k(s') \mid s' \in N_k^2(s_i) \setminus S_k^i\}$; indeed, for any fixed s_i , this operation can be reduced to $\tilde{\mathcal{O}}(|N_G(s_i) \cap K_k| \cdot |S_k|^{1-\varepsilon_d})$ range queries, by using the interval representation of $N_k^2(s_i)$.

Finally, for every j , define $\alpha^j = \sum_{s' \in S_k^j} \alpha_k(s')$ and $\beta^j = \sum_{s' \in S_k^j} \beta_k(s')$. Let also $\alpha^* = \sum_{j=1}^{c_k} \alpha^j$ and $\beta^* = \sum_{j=1}^{c_k} \beta^j$. All the values α^j, β^j , $1 \leq j \leq c_k$ and α^*, β^* can be pre-computed in total $\mathcal{O}(|S_k|)$ time. Since in the underlying split graph H_k , the distance $d(s, s')$ between two different vertices $s, s' \in S_k$ in the stable set is either two or three, we may rewrite the output of SPLIT-WEIGHTED-WIENER as follows:

$$\begin{aligned} & \sum_{i \neq j} \sum_{s \in S_k^i, s' \in S_k^j} [\beta_k(s') \alpha_k(s) + \beta_k(s) \beta_k(s') d(s, s') + \beta_k(s) \alpha_k(s')] = \\ & \sum_i \sum_{s \in S_k^i} \left[(\beta^* - \beta^i) \cdot \alpha_k(s) + \beta_k(s) \cdot \left(\sum_{s' \notin S_k^i} \beta_k(s') d(s, s') \right) + \beta_k(s) \cdot (\alpha^* - \alpha^i) \right] \\ & = \left[\sum_i (\beta^* - \beta^i) \alpha^i \right] + \left[\sum_i \sum_{s \in S_k^i} \beta_k(s) \cdot \left(\sum_{s' \notin S_k^i} \beta_k(s') d(s, s') \right) \right] + \left[\sum_i \beta^i (\alpha^* - \alpha^i) \right] \\ & = \left[\sum_i (\beta^* - \beta^i) \alpha^i \right] + \left[\sum_i \sum_{s \in S_k^i} \beta_k(s) \cdot (3(\beta^* - \beta^i) - \Phi(s)) \right] + \left[\sum_i \beta^i (\alpha^* - \alpha^i) \right] \\ & = \left[\sum_i (\beta^* - \beta^i) (\alpha^i + 3\beta^i) \right] - \left[\sum_{s \in S_k} \beta_k(s) \Phi(s) \right] + \left[\sum_i \beta^i (\alpha^* - \alpha^i) \right]. \end{aligned}$$

Now, given the pre-computed values $\alpha^i, \beta^i, \alpha^*, \beta^*$ and $\Phi(s)$, we can compute the desired output in additional $\mathcal{O}(|S_k|)$ time. ◀

5 Application: Chordal Helly graphs

We end up our study investigating the complexity of the Wiener index on non-hereditary subclasses of chordal graphs. The chordal Helly graphs are a prominent such subclass. Indeed, they are a strict generalization of doubly chordal graphs, and so, of strongly chordal graphs, interval graphs, etc. Recently, a linear-time algorithm for computing the diameter of this subclass of graphs was proposed [22].

► **Theorem 17.** *There is an $\tilde{O}(m^{3/2})$ -time algorithm for computing the Wiener index of chordal Helly graphs.*

Proof. Let $G = (V, E)$ be a chordal Helly graph. We apply Theorem 4 in order to reduce the computation of $W(G)$ to solving the SPLIT-WEIGHTED-WIENER problem on some instances $(\mathcal{P}(V_k), E'_k, \alpha_k, \beta_k)$. Write $\mathcal{P}(V_k) = (K_k, S_k^1, S_k^2, \dots, S_k^{c_k})$. We also know from Theorem 4 that K_k is a clique of G . In what follows, we present an algorithm for solving the instance $(\mathcal{P}(V_k), E'_k, \alpha_k, \beta_k)$ in $\mathcal{O}(|K_k| \cdot |E'_k|)$ time. Doing so, we can compute $W(G)$ in $\sum_k \mathcal{O}(|K_k| \cdot |E'_k|)$ time. Since we further have $\sum_k |E'_k| = \tilde{O}(n + m)$ (time of the reduction of Theorem 4) and $\max_k |K_k| = \mathcal{O}(m^{1/2})$ because each subset K_k is a clique, we get a running time in $\tilde{O}(m^{3/2})$.

Throughout the remainder of the proof, let $(\mathcal{P}(V_k), E'_k, \alpha_k, \beta_k)$ be fixed. Let also $S_k = \bigcup_{i=1}^{c_k} S_k^i = V_k \setminus K_k$. We write $s \sim s'$ if there exists an i such that $s, s' \in S_k^i$. Then, our goal is to compute the following value:

$$\Psi_k := \sum \{\beta_k(s)\beta_k(s') \mid s \not\sim s' \text{ and } d(s, s') = 2\}.$$

Indeed, let us define $\alpha^i = \sum_{s \in S_k^i} \alpha_k(s)$ and $\beta^i = \sum_{s \in S_k^i} \beta_k(s)$ for every i . Similarly, let $\alpha^* = \sum_i \alpha^i$ and $\beta^* = \sum_i \beta^i$. All these values can be pre-computed in total $\mathcal{O}(|S_k|) = \mathcal{O}(|E'_k|)$ time. Then, the desired output $\sum_{i \neq j} \sum_{s \in S_k^i, s' \in S_k^j} [\beta_k(s')\alpha_k(s) + \beta_k(s)\beta_k(s')d(s, s') + \beta_k(s)\alpha_k(s')]$ can be rewritten as:

$$\sum_i (\beta^* - \beta^i)\alpha^i + \left(\sum_{i \neq j} \sum_{s \in S_k^i, s' \in S_k^j} \beta_k(s)\beta_k(s')d(s, s') \right) + \sum_i \beta^i(\alpha^* - \alpha^i).$$

Since in the underlying split graph, the distance between two distinct vertices in the stable set S_k is either two or three, we get:

$$\sum_{i \neq j} \sum_{s \in S_k^i, s' \in S_k^j} \beta_k(s)\beta_k(s')d(s, s') = 3 \left(\sum_i \beta^i(\beta^* - \beta^i) \right) - \Psi_k.$$

The algorithm. Let us define the adjacency lists $N_k(u) = \{s \in S_k \mid us \in E'_k\}$, for every $u \in K_k$. In the same way, let us define the adjacency lists $N_k(s) = \{u \in K_k \mid us \in E'_k\}$, for every $s \in S_k$. We set initially $\Psi_k := 0$. Then, let $K_k = (u_1, u_2, \dots, u_{|K_k|})$ be totally ordered. We consider each $u_i \in K_k$ sequentially, and in order from $i = 1$ to $i = |K_k|$. At step i , let us define for every $u' \in K_k$ the subset $N_{k,i}(u') := N_k(u') \setminus \left(\bigcup_{j < i} N_k(u_j) \right)$. For each $s \in S_k \setminus \left(\bigcup_{j < i} N_k(u_j) \right)$, let t be such that $s \in S_k^t$. We select a vertex $u' \in N_k(s)$ such that $|(N_{k,i}(u') \cap N_{k,i}(u_i)) \setminus S_k^t|$ is maximized. Then, we increment Ψ_k by:

$$\begin{cases} \beta_k(s) \cdot \sum \{\beta_k(s') \mid s' \in (N_{k,i}(u_i) \cap N_{k,i}(u')) \setminus S_k^t\} & \text{if } s \in N_{k,i}(u_i) \\ 2\beta_k(s) \cdot \sum \{\beta_k(s') \mid s' \in (N_{k,i}(u_i) \cap N_{k,i}(u')) \setminus S_k^t\} & \text{if } s \notin N_{k,i}(u_i). \end{cases}$$

Correctness. We first need to observe that $N_{k,1}(u_1)$ ($= N_k(u_1)$), $N_{k,2}(u_2), \dots, N_{k,i}(u_i), \dots$ is a partition of S_k . Therefore in order to prove correctness of the algorithm, it suffices to prove that at each step i , we increment Ψ_k by twice the sum of all $\beta_k(x)\beta_k(y)$ with $x \in N_{k,i}(u_i)$, $y \in S_k \setminus \left(\bigcup_{j < i} N_k(u_j)\right)$, $x \not\sim y$ and $d(x, y) = 2$. For that, let $s \in S_k \setminus \left(\bigcup_{j < i} N_k(u_j)\right)$ be arbitrary and such that $s \in S_k^t$ for some t . We prove next that for the vertex u' selected for s , all the vertices in $N_{k,i}(u_i) \setminus S_k^t$ and at distance two from s are also in $N_{k,i}(u')$. In particular, all the desired pairs (x, y) are enumerated: twice if $x, y \in N_{k,i}(u_i)$, and only once otherwise, thus proving correctness of our above formula for incrementing Ψ_k .

By maximality of u' , it is sufficient to prove the existence of a vertex $u^* \in N_k(s)$ such that all the vertices of $N_{k,i}(u_i) \setminus S_k^t$ that are at distance two from s are also contained into $N_{k,i}(u^*)$. We do so by reasoning on the whole graph G . Specifically, let $\mathcal{F} = \{N_G[x] \mid x = s \text{ or } (x \in N_{k,i}(u_i) \setminus S_k^t \text{ and } d(s, x) = 2)\}$. The balls in \mathcal{F} pairwise intersect. Therefore, by the Helly property, all balls in \mathcal{F} contain some common vertex z . We claim that $z \in K_k$. Note that it will prove the existence of the desired vertex u^* because in such a case we can always choose $u^* = z$. It follows from the proof of Theorem 4 that S_k^t and $S_k \setminus S_k^t$ are in separate connected components of $G \setminus K_k$, thus immediately proving the claim.

Implementation and Complexity. As a starter, we observe that all the lists $N_k(u)$, for $u \in K_k$ (resp., all the lists $N_k(s)$, for $s \in S_k$) can be constructed in $\mathcal{O}(|E'_k|)$ time. Throughout the algorithm, we maintain an $|S_k|$ -size array \mathbf{A} , whose entries are indexed by S_k and are initialized to 0 (at the end of the algorithm, we have for all $s \in N_{k,i}(u_i)$ that $\mathbf{A}[s] = i$). We also store two auxiliary matrices of dimensions $|K_k| \times (c_k + 1)$, denoted by \mathbf{Int} and \mathbf{Sum} , whose entries are indexed by $K_k \times \{0, 1, 2, \dots, c_k\}$ and of which we ensure that all entries equal 0 at the beginning of any step i . Finally, we find more convenient for certain operations to maintain a stack \mathbf{Stack} and a boolean $|K_k|$ -size array $\mathbf{InStack}$ whose entries are indexed by K_k ; before each step, we ensure that the stack is emptied and that all entries in $\mathbf{InStack}$ are set to False. Note that all the above data structures can be constructed in $\mathcal{O}(|S_k| + |K_k| \cdot c_k) = \mathcal{O}(|K_k| \cdot |S_k|) = \mathcal{O}(|K_k| \cdot |E'_k|)$ time.

We proceed as follows during any step i . First, we scan $N_k(u_i)$ and, for every $s \in N_k(u_i)$ such that $\mathbf{A}[s] = 0$, we set $\mathbf{A}[s] = i$. Furthermore, if we set $\mathbf{A}[s] = i$, then we add every $u' \in N_k(s)$ in \mathbf{Stack} (we use the auxiliary array $\mathbf{InStack}$ in order to avoid adding twice a vertex). Then, we consider each vertex in \mathbf{Stack} sequentially, until we emptied the stack. For every vertex u' considered, we scan the list $N_k(u')$. If $s \in N_k(u')$ is such that $\mathbf{A}[s] = i$ (equivalently, if $s \in N_{k,i}(u_i)$) then, we increment $\mathbf{Int}[u'][0]$ by one (intersection size with $N_{k,i}(u_i)$). Similarly, we increment $\mathbf{Sum}[u'][0]$ by $\beta_k(s)$. For the unique t such that $s \in S_k^t$, we also increment $\mathbf{Int}[u'][t]$ by one and $\mathbf{Sum}[u'][t]$ by $\beta_k(s)$, respectively. Finally, we apply our above formula in order to increment Ψ_k :

1. For every $s \in N_k(u_i)$, if $\mathbf{A}[s] = i$, then let t be the unique index such that $s \in S_k^t$. We increment Ψ_k by $\beta_k(s) \times (\mathbf{Sum}[u_i][0] - \mathbf{Sum}[u_i][t])$.
2. For every $s \in S_k$ such that $\mathbf{A}[s] = 0$, let also t be the unique index such that $s \in S_k^t$. We scan the list $N_k(s)$ in order to find some u' maximizing $\mathbf{Int}[u'][0] - \mathbf{Int}[u'][t]$. Then, we increment Ψ_k by $2\beta_k(s) \times (\mathbf{Sum}[u'][0] - \mathbf{Sum}[u'][t])$.

The whole step only takes $\mathcal{O}(|E'_k|)$ time because each adjacency list is scanned $\mathcal{O}(1)$ times. ◀

Although it is a truly subquadratic algorithm (in the size $n + m$ of the input), our algorithm does not perform better than the classic $\mathcal{O}(nm)$ -time algorithm for general graphs if $m = \Theta(n^2)$. This is in sharp contrast with our results in Sec. 4, for hereditary chordal subclasses, where all our algorithms run in $\tilde{\mathcal{O}}(n^a m)$ time, for some $a < 1$. It would be very interesting to improve the running time of Theorem 17, and to bring it much closer to the linear-time complexity of the diameter problem on this subclass of graphs.

6 Open problems

We left open whether there are there relevant graph classes where the complexity of the Wiener index and the diameter are different. In particular, are both problems subquadratic equivalent? Another interesting question is whether we could compute the Wiener index of Helly graphs in truly subquadratic time. In this paper, we only managed to find such algorithm for the subclasses of dually chordal graphs and chordal Helly graphs.

Abstract

We consider the TRIVIALY PERFECT EDITING problem, where one is given an undirected graph $G = (V, E)$ and a parameter $k \in \mathbb{N}$ and seeks to *edit* (add or delete) at most k edges from G to obtain a trivially perfect graph. The related TRIVIALY PERFECT COMPLETION and TRIVIALY PERFECT DELETION problems are obtained by only allowing edge additions or edge deletions, respectively. Trivially perfect graphs are both chordal and cographs, and have applications related to the tree-depth width parameter and to social network analysis. All variants of the problem are known to be NP-complete [6, 29] and to admit so-called polynomial kernels [13, 23]. More precisely, the existence of an $O(k^3)$ vertex-kernel for TRIVIALY PERFECT COMPLETION was announced by Guo [23] but without a stand-alone proof. More recently, Drange and Pilipczuk [13] provided $O(k^7)$ vertex-kernels for these problems and left open the existence of cubic vertex-kernels. In this work, we answer positively to this question for all three variants of the problem.

Introduction

A broad range of optimization problems on graphs are particular cases of so-called modification problems. Given an arbitrary graph $G = (V, E)$ and an integer k , the question is whether G can be turned into a graph satisfying some desired property by at most k *modifications*. By modifications we mean, according to the problem, vertex deletions (as for VERTEX COVER and FEEDBACK VERTEX SET where we aim to obtain graphs with no edges, or without cycles respectively) or edge deletions and/or additions (as for MINIMUM FILL-IN, also known as CHORDAL COMPLETION, where the goal is to obtain a chordal graph, with no induced cycles with four or more vertices, by adding at most k edges).

Here we consider edge modifications problems, that can be split in three categories, depending whether we allow only edge additions, only edge deletions, or both operations, in which case we speak of edge editing. Consider a family \mathcal{H} of graphs, called *obstructions*. In the \mathcal{H} -FREE EDITING problem we seek to edit at most k edges of G to obtain a graph that does not contain any obstruction from \mathcal{H} as an induced subgraph. One can similarly define \mathcal{H} -FREE COMPLETION and \mathcal{H} -FREE DELETION variants of this problem by only allowing the addition or deletion of edges, respectively. E.g., MINIMUM FILL-IN corresponds to \mathcal{H} -FREE COMPLETION, where \mathcal{H} is formed by all cycles with at least four vertices. For most families \mathcal{H} , all three versions are NP-complete, but thinking of k as of some suitably small quantity, they have been intensively studied in the framework of *parameterized complexity* (see [11] for

a comprehensive survey). The aim of parameterized complexity is to determine whether it is possible to decide the instance at hand in time $f(k) \cdot n^{O(1)}$ for some computable function f . Such problems are said to be FPT (*fixed-parameter tractable*). With a simple but elegant and powerful argument, Cai [7] proved that whenever \mathcal{H} is finite all three variants are FPT. Basically, whenever the graph contains one of the obstructions (graphs of \mathcal{H}), the algorithm branches on all possible modifications to destroy it, and makes the recursive calls with a lesser parameter k . When the family \mathcal{H} contains all cycles with at least four vertices, the corresponding edition problem CHORDAL EDITING was shown to be FPT relatively recently [10]. The completion variant, i.e., the MINIMUM FILL-IN, was known to be FPT since the 90's [7, 25].

We consider an equivalent definition of fixed-parameter tractability, namely *kernelization*. Given a parameterized problem Π , a *kernelization algorithm* for Π (or *kernel* for short) is an algorithm that given any instance (I, k) of Π runs in time polynomial in $|I|$ and k and outputs an equivalent instance (I', k') of Π such that $|I'| \leq h(k)$ and $k' \leq g(k)$ for some computable functions g and h . Whenever h is polynomial, we say that Π admits a *polynomial kernel*. A kernelization algorithm uses a set of polynomial-time computable *reduction rules* to *reduce* the instance at hand. We say that a reduction rule is *safe* whenever its application on an instance (I, k) of Π results in an equivalent instance (I', k') of Π . It is well-known that a parameterized problem is FPT if and only if it admits a kernelization algorithm [17]. While many polynomial kernels are known to exist for editing problems (see [11] or [27] for surveys), it is known that some editing problems are unlikely to admit polynomial kernels under reasonable complexity-theoretic assumptions [8, 22, 26]. When \mathcal{H} contains only a single obstruction, several results towards a dichotomy regarding the existence of polynomial kernels have been obtained [1, 8, 28]. Very recently, Marx and Sandeep [28] narrowed down the problem for obstructions containing at least 5 vertices to only nine distinct obstructions. In other words, the non-existence of polynomial kernels for \mathcal{H} -FREE EDITING for all such obstructions would imply the non-existence of polynomial kernels for any obstruction with at least 5 vertices. When \mathcal{H} contains several obstructions, a very natural setting is to include all cycles of length at least 3 in \mathcal{H} , thus targeting a subclass of chordal graphs. Indeed, editing (and especially completion) problems towards such classes cover classical problems with both theoretical and practical interest [15, 21, 24, 25, 33]. Notice that many known polynomial kernels for editing problems concern such classes [3, 4, 13, 23, 25]. For completion and deletion versions, polynomial kernels are often used as a first step in the design of subexponential parameterized algorithms [5, 12, 18, 19].

In this work, we focus on editing problems towards trivially perfect graphs, that is $\mathcal{H} = \{P_4, C_4\}$ (respectively a path and a cycle on 4 vertices). This problem is known as TRIVIALY PERFECT EDITING in the literature. By allowing edge addition or edge deletion only, we obtain the TRIVIALY PERFECT COMPLETION and TRIVIALY PERFECT DELETION problems, respectively.

Related work

While the NP-Completeness of TRIVIALY PERFECT COMPLETION and TRIVIALY PERFECT DELETION has been known for some time [6], the complexity of TRIVIALY PERFECT EDITING remained open until a work of Nastos and Gao [29]. Trivially perfect graphs have recently regained attention since they are related to the well-studied width parameter *tree-depth* [20, 30] which corresponds to the size of the largest clique of a trivially perfect supergraph of G with the smallest clique number. Moreover, Nastos and Gao [29] proposed a new definition for

community structure based on small obstructions. In particular, the authors emphasized that editing a given graph into a trivially perfect graph *yields meaningful clusterings in real networks* [29]. Trivially perfect graphs also correspond to chordal cographs and admit a so-called *universal clique decomposition* [12]. Polynomial kernels with $O(k^7)$ vertices have been obtained for all variants of the problem by Drange and Pilipczuk [13]. The technique used relies on a reduction rule bounding the number of vertices in any trivially perfect *module* and the computation of a so-called *vertex modulator*, that is a maximal packing of obstructions with additional properties. Combined with sunflower-like reduction rules and a careful analysis of the graph remaining apart from the vertex modulator, the authors managed to provide polynomial kernels. They then asked whether the $O(k^7)$ bound could be improved, and qualify as “really challenging question” whether one can match the $O(k^3)$ bound for TRIVIALLY PERFECT COMPLETION claimed by Guo [23].

Our contribution

We answer positively to this question and provide kernels with $O(k^3)$ vertices for all considered problems. To be complete, a quadratic vertex-kernel for the completion version only is claimed in [2, 9]. While our kernelization algorithm shares similarities with the work of Drange and Pilipczuk [13], our technique differs in several points. In particular, we do not rely on the computation of a vertex modulator, a useful technique to design polynomial kernels but somehow responsible for the large bound obtained. To circumvent this issue, we only rely on the so-called universal clique decomposition of trivially perfect graphs. This decomposition partitions the vertices of trivially perfect graph G into cliques, the bags being structured as nodes of a rooted forest such that two vertices are adjacent in G if and only they are in a same bag, or in two bags such that one is an ancestor of the other in the forest. For any positive instance of the problem, at most $2k$ bags contain vertices incident to modified edges. Informally, the rest of the bags can be regrouped into two types of ‘chunks’. Some correspond to trivially perfect modules of the input graph (which are known to be reducible to small sizes by [13]), others have a more complicated but still particular structure, similar to the *combs* of [13]. We show how to reduce the size of these combs. Altogether we believe that our rules not only improve the size of the kernel but also significantly simplify the kernelization algorithm of [13]. Last but not least, we think that this approach based on tree-like decompositions and the analysis of large chunks of the graph that are not affected by the modified edges might be exploitable for other editing problems. Indeed the technique has strong similarities with the notion of branches introduced by Bessy et al. [3] for modification to 3-leaf power graphs, a closely related graph class.

Outline

We begin with some preliminaries definitions and results about trivially perfect graphs (Section 1). We then introduce the notion of combs and provide the set of reduction rules needed to obtain an $O(k^3)$ vertex-kernel for TRIVIALLY PERFECT EDITING (Section 2). The combinatorial bound on the kernel size is provided in Section 3. We explain how these results can be adapted to obtain similar kernels for TRIVIALLY PERFECT COMPLETION and TRIVIALLY PERFECT DELETION (Section 4). The Conclusion section summarizes the results and suggests further developments. Proofs of statements labeled with (\star) are omitted in this extended abstract. The interested reader may refer to [14] for a full version of this paper.

1 Preliminaries

We consider simple, undirected graphs $G = (V, E)$ where V denotes the *vertex set* and $E \subseteq (V \times V)$ the *edge set* of G . We will sometimes use $V(G)$ and $E(G)$ to clarify the context. Given a vertex $u \in V$, the *open neighborhood* of u is the set $N_G(u) = \{v \in V : uv \in E\}$. The *closed neighborhood* of u is defined as $N_G[u] = N_G(u) \cup \{u\}$. A vertex $u \in V$ is *universal* if $N_G[u] = V$, and two vertices u and v are *true twins* if $N_G[u] = N_G[v]$. The set of universal vertices forms a clique and is called the *universal clique* of G . Given a subset of vertices $S \subseteq V$, $N_G[S]$ is the set $\cup_{v \in S} N_G[v]$ and $N_G(S)$ is the set $N_G[S] \setminus S$. We will omit the mention to G whenever the context is clear. The subgraph *induced* by S is defined as $G[S] = (S, E_S)$ where $E_S = \{uv \in E : u \in S, v \in S\}$. For the sake of readability, given a subset $S \subseteq V$ we define $G \setminus S$ as $G[V \setminus S]$. A subset of vertices $C \subseteq V$ is a *connected component* of G if $G[C]$ is a maximal connected subgraph of G . A subset of vertices $M \subseteq V$ is a *module* of G if and only if $N_G(u) \setminus M = N_G(v) \setminus M$ holds for every $u, v \in M$. A maximal set of true twins $K \subseteq V$ is a *critical clique*. Notice that $G[K]$ is a clique module and that the set $\mathcal{K}(G)$ of critical cliques of any graph G partitions its vertex set $V(G)$. Notice that the universal clique is a critical clique.

Trivially perfect graphs

A graph $G = (V, E)$ is trivially perfect if and only if it does not contain any P_4 (a path on 4 vertices) nor C_4 (a cycle on 4 vertices) as an induced subgraph (see Figure 1). We consider the following problem.

TRIVIALY PERFECT EDITING

Input: A graph $G = (V, E)$, a parameter $k \in \mathbb{N}$

Question: Does there exist a set of pairs $F \subseteq (V \times V)$ of size at most k such that the graph $H = (V, E \Delta F)$ is trivially perfect, with $E \Delta F = (E \setminus F) \cup (F \setminus E)$?

Given an instance $(G = (V, E), k)$ of TRIVIALY PERFECT EDITING, a set $F \subseteq (V \times V)$ such that $H = (V, E \Delta F)$ is trivially perfect is an *edition* of G . When F is constrained to be disjoint from (resp. contained in) E , we say that F is a *completion* (resp. a *deletion*) of G . The corresponding problems are TRIVIALY PERFECT COMPLETION and TRIVIALY PERFECT DELETION, respectively. For the sake of simplicity, given an edition (resp. completion, deletion) F of G , we use $G \Delta F$, $G + F$ and $G - F$ to denote the graphs $(V, E \Delta F)$, $(V, E \cup F)$ and $(V, E \setminus F)$, respectively. A vertex is *affected* by F whenever it is contained in some pair of F . The set F is a *k-edition* (resp. *k-completion*, *k-deletion*) whenever $|F| \leq k$. Finally, we say that such a set F is *optimal* whenever it is minimum-sized.

■ **Figure 1** The C_4 , P_4 and claw graphs, respectively. The claw will be useful in some of our proofs.

Trivially perfect graphs are hereditary and closed under true twin addition. This property will be useful to deal with critical cliques, as stated by the following result. Recall that critical cliques are maximal sets of true twins (or, equivalently, maximal clique modules), they will play a central role throughout this paper.

► **Lemma 1** ([3]). *Let \mathcal{G} be a hereditary class of graphs closed under true twin addition. For every graph $G = (V, E)$, there exists an optimal edition (resp. completion, deletion) F into a graph of \mathcal{G} such that for any two critical cliques K and K' either $(K \times K') \subseteq F$ or $(K \times K') \cap F = \emptyset$.*

Several characterizations are known to exist for trivially perfect graphs. We will mainly use the following ones.

► **Proposition 2** ([32]). *The class of trivially perfect graphs can be defined recursively as follows:*

- a single vertex is a trivially perfect graph.
- Adding a universal vertex to a trivially perfect graph results in a trivially perfect graph.
- The disjoint union of two trivially perfect graphs results in a trivially perfect graph.

► **Definition 3** (Universal clique decomposition, [12]). *A universal clique decomposition (UCD) of a connected graph $G = (V, E)$ is a pair $\mathcal{T} = (T = (V_T, E_T), \mathcal{B} = \{B_t\}_{t \in V_T})$ where T is a rooted tree and \mathcal{B} is a partition of the vertex set V into disjoint nonempty subsets, such that:*

- if $vw \in E$ and $v \in B_t, w \in B_s$ then s and t are on a path from a leaf to the root, with possibly $s = t$, and
- for every node $t \in V_T$, the set of vertices B_t is the universal clique of the induced subgraph $G[\bigcup_{s \in V(T_t)} B_s]$, where T_t denotes the subtree of T rooted at t .

The vertices of T are called *nodes* of the decomposition, while the sets of \mathcal{B} are called *bags*. We will sometimes abuse notation and identify nodes of T with their corresponding bags in \mathcal{B} . Notice moreover that in a universal clique decomposition, every node t of T that is not a leaf has at least two children since otherwise B_t would not contain *all* universal vertices of $G[\bigcup_{s \in V(T_t)} B_s]$.

► **Lemma 4** ([12]). *A connected graph G admits a universal clique decomposition if and only if it is trivially perfect. Moreover, such a decomposition is unique up to isomorphisms.*

One can observe that finding a universal clique decomposition can be done in polynomial time by iteratively identifying universal cliques and connected components. Finally, both Definition 3 and Lemma 4 can be naturally extended to *disconnected* trivially perfect graphs by considering a *rooted forest* instead of a rooted tree. More precisely, the universal clique decomposition of a disconnected graph $G = (V, E)$ is a rooted forest of universal clique decompositions of its connected components. Such a graph is thus trivially perfect if and only if it admits a universal clique decomposition shaped like a rooted forest.

We conclude this section by providing a new characterization of trivially perfect graphs in terms of maximal cliques and nested families.

► **Definition 5** (Nested family). *Let U be a universe and $\mathcal{F} \subseteq 2^U$ a family of subsets of U . The family \mathcal{F} is nested if and only if for every $A, B \in \mathcal{F}$, $A \subseteq B$ or $B \subseteq A$ holds.*

► **Lemma 6** (*). *Let $G = (V, E)$ be a graph, $S \subseteq V$ a maximal clique of G and K_1, \dots, K_r the connected components of $G \setminus S$. The graph G is trivially perfect if and only if the following conditions are verified:*

- (i) $G[S \cup K_i]$ is trivially perfect for every $1 \leq i \leq r$,
- (ii) $\bigcup_{1 \leq i \leq r} \{N_G(K_i)\}$ is a nested family,
- (iii) $(K_i \times N_G(K_i)) \subseteq E$ for every $1 \leq i \leq r$.

2 Kernelization algorithm for Trivially Perfect Editing

We begin this section by providing a high-level description of our kernelization algorithm. As mentioned in the introductory section, we use the universal clique decomposition of trivially perfect graphs to bound the number of vertices of a reduced instance. Let us consider a positive instance $(G = (V, E), k)$ of TRIVIALY PERFECT EDITING, F a suitable solution and $H = G \Delta F$. Denote by $\mathcal{T} = (T, \mathcal{B})$ the universal clique decomposition of H as described Definition 3. Since $|F| \leq k$, we know that at most $2k$ bags of \mathcal{T} may contain affected vertices. Let A be the set of such bags, and let A' denote the lowest common ancestor closure of A in forest T (Definition 17). As we shall see later, the size of A' is also linear in k (Lemma 18). The removal of every bag of A' from T will disconnect the forest T into several components (see Figure 2).

Such a connected component D of $T \setminus A'$ may see zero, one or two nodes of A' in the forest T (Lemma 4). If D has no neighbour in A' , the union of all bags of D corresponds to a connected component of H and of G , inducing a trivially perfect graph in G , and will be eliminated by a reduction rule. We shall see that the union of all components D_a of the second type, seeing a unique bag $a \in A'$ in the forest T , corresponds to a trivially perfect module of graph G . We use the reductions rules of [13] to shrink such a module to $O(k^2)$ vertices, which boils down to a total $O(k^3)$ vertices since $|A'| = O(k)$.

Our efforts will be focused on components D seeing two bags $a_1, a_2 \in A'$, one of them being ancestor of the other in forest T . We call such a structure D a *comb* (Definition 9 and Figure 2).

Figure 2 Analysis of a universal clique decomposition of a connected trivially perfect graph. Black vertices represent bags of A , gray vertices bags of A' and triangles are connected trivially perfect subgraphs of G . The leftmost rectangle is a comb of G , the rightmost a trivially perfect module. Note that any group of triangles rooted at a same bag is a trivially perfect module.

Such combs (the union of their bags) induce, in graph G , a trivially perfect subgraph that can be partitioned with regard to critical cliques and trivially perfect modules with nice inclusion properties on their neighborhoods. We provide two distinct reduction rules on these structures. Rule 4 reduces the so-called shaft of the comb (intuitively, the path strictly between a_1 and a_2 in T) to length $O(k)$. Rule 5 reduces the size of the whole comb (the union of its bags) to $O(k^2)$. Altogether, the reduced instance cannot contain more than $O(k^3)$ vertices.

We would like to note that the combs considered in this work are similar to the ones defined by Drange and Pilipczuk [13] and thus named after them. However, the two structures are not strictly identical, in particular since they were originally defined with respect to a vertex modulator (i.e. a packing of obstructions), and thus their neighborhood towards the rest of the graph was structured differently.

In the remaining of this section we assume that we are given an instance $(G = (V, E), k)$ of TRIVIALY PERFECT EDITING.

2.1 Reducing critical cliques and trivially perfect modules

We first give a classical reduction rule when dealing with modification problems. This rule is trivially safe for trivially perfect graphs.

► **Rule 1.** *Let $C \subseteq V$ be a subset of vertices such that $G[C]$ is a trivially perfect connected component of G . Remove C from G .*

We now give known reduction rules that deal with critical cliques and trivially perfect modules. The safeness of Rule 2 comes from the fact that trivially perfect graphs are hereditary and closed under true twin addition combined with Lemma 1. The safeness and polynomial-time application of Rule 3 was proved by Drange and Pilipczuk [13]. We would like to mention that while the statement of their rule assumes the instance at hand to be reduced by classical *sunflower* rules, this is actually not needed to prove the safeness of the rule. Altogether, we have the following.

► **Rule 2.** *Let $K \subseteq V$ be a set of true twins of G such that $|K| > k + 1$. Remove $|K| - (k + 1)$ arbitrary vertices in K from G .*

► **Rule 3.** *Let $M \subseteq V$ be a module of G such that $G[M]$ is trivially perfect and M contains an independent set I of size at least $2k + 5$. Remove all vertices of $M \setminus I$ from G .*

► **Lemma 7** (Folklore, [3, 13]). *Rules 1 to 3 are safe and can be applied in polynomial time.*

Using a structural result on trivially perfect graphs where critical cliques and independent sets have bounded size, Drange and Pilipczuk [13] proved the following.

► **Lemma 8** ([13]). *Let $(G = (V, E), k)$ be an instance of TRIVIALY PERFECT EDITING reduced under Rules 2 and 3. Then for every module $M \subseteq V$ such that $G[M]$ is trivially perfect, $|M| = O(k^2)$.*

2.2 Reducing shafts of combs

We now consider the main structure of our kernelization algorithm, namely *combs*. Recall that such structures are similar to the ones defined by Drange and Pilipczuk [13] but not strictly identical. More precisely, the inner part of the structure is the same but not their neighborhoods towards the rest of the graph. We however choose to use the same name since it is well-suited to illustrate the structure (see Figure 3).

► **Definition 9** (Comb). *Let $G = (V, E)$ be a graph and $C, R \subseteq V$ be such that C is a clique which can be partitioned into l critical cliques $\{C_1, \dots, C_l\}$ and R can be partitioned into l non-empty and non-adjacent trivially perfect modules $\{R_1, \dots, R_l\}$. The pair $P = (C, R)$ is a comb if and only if:*

- *there exist $V_f, V_p \subseteq V(G) \setminus \{C, R\}$, $V_f \neq \emptyset$ such that $\forall x \in C$, $N_G(x) \setminus (C \cup R) = V_p \cup V_f$ and $\forall y \in R$, $N_G(y) \setminus (C \cup R) = V_p$,*
- *$N_G(C_i) \cap R = \bigcup_{j=i}^l R_j$ and $N_G(R_i) \cap C = \bigcup_{j=1}^i C_j$ for $1 \leq i \leq l$.*

By the following property, given a comb (C, R) of graph $G = (V, E)$, the subgraph $G[C \cup R]$ is trivially perfect, and has a universal clique decomposition in which critical cliques (C_1, \dots, C_l) are arranged in a path starting from the root, the *shaft* of the comb, and the decomposition of

■ **Figure 3** Illustration of a comb, with shaft C and teeth R . The edges between V_p and V_f can be anything. Every tooth R_i induces a (possibly disconnected) trivially perfect module.

each *tooth* R_i is attached to C_i ; see Figure 3. The length of (C, R) is l , the number of critical cliques in C . We can observe that $N_G[C_i] \subsetneq \cdots \subsetneq N_G[C_1]$ and $N_G(R_1) \subsetneq \cdots \subsetneq N_G(R_l)$ because for $1 \leq i \leq l$, $N_G[C_i] = (\bigcup_{j=i}^l R_j) \cup V_p \cup V_f$ and $N_G(R_i) = (\bigcup_{j=1}^i C_j) \cup V_p$.

► **Proposition 10** (\star). *Given a comb (C, R) of graph $G = (V, E)$, the subgraph $G[C \cup R]$ is trivially perfect. Moreover the sets V_p and V_f , and the ordered partitions (C_1, \dots, C_l) of C and (R_1, \dots, R_l) of R are uniquely determined.*

► **Lemma 11**. *Given an instance $(G = (V, E), k)$ of TRIVIALY PERFECT EDITING and a comb (C, R) of length $l \geq 2k + 2$ of G , there is no optimal k -edition that affects vertices in $C \cup R$.*

Proof. Consider a k -edition F of G and $H = G \Delta F$. Denote by $F' \subseteq F$ the subset of pairs from F which does not contain any vertex from $C \cup R$ and let $H' = G \Delta F'$. Since $|F| \leq k$ and (C, R) is a comb of length at least $2k + 2$, there exist $i \neq j \in \{1, \dots, l\}$ such that C_i, R_i, C_j and R_j do not include affected vertices of F . Let us take $c_1 \in C_i, r_1 \in R_i, c_2 \in C_j$ and $r_2 \in R_j$.

Suppose that H' is not trivially perfect, then there exists an obstruction W of H' such that $A = W \cap (C \cup R) \neq \emptyset$. Since pairs of F' do not contain vertices of $C \cup R$, (C, R) is a comb in H' and $|A| = 4$ is impossible since $H'[C \cup R] = G[C \cup R]$ is trivially perfect by Proposition 10. We show that $|A| = 3$ is also impossible. If $|A| = 3$ then the vertex $x \in W \setminus (C \cup R)$ is in the set $V_p \cup V_f$, otherwise the obstruction W would not be connected. We now show that $H'[W]$ is a claw, contains a triangle (as subgraph) or is not connected. If $x \in V_p$, then by construction x is adjacent to every vertex of the comb and $H'[W]$ would be a claw. If $x \in V_f$ and A contains at least two vertices in C , then these vertices would induce a triangle with x . If $x \in V_f$ and A contains at least two vertices $r', r'' \in R$, then x is not adjacent to any of them (since V_f does not see R in G). If r' and r'' are not adjacent in H' , either the fourth vertex of W sees r', r'' and x so $H'[W]$ is a claw, or $H'[W]$ is disconnected. If r' and r'' are adjacent in H' , they must belong to a same module R_i . Again the fourth vertex of W must either see them both thus forming a triangle, or none of them and $H'[W]$ is disconnected. In any case, A cannot be an obstruction and we conclude that either $|A| = 1$ or $|A| = 2$. We shall now construct an obstruction $W' = (W \setminus A) \cup A'$ such that $H'[W]$ and $H'[W']$ are isomorphic and $A' \subseteq \{c_1, r_1, c_2, r_2\}$. We can observe that W must contain a vertex from V_p or V_f .

■ If $|A| = 1$, take $x \in A$. If $x \in R$ then let $A' = \{r_1\}$, else let $A' = \{c_1\}$. Since (C, R) is a comb, $H'[W]$ and $H'[W']$ are isomorphic.

- If $|A| = 2$, denote by x and y the elements of A . If $x, y \in C$, then $H[W]$ contains a triangle. If $x \in C$ and $y \in R$, in the subcase $xy \in E(H')$ let $A' = \{c_1, r_1\}$ and observe that $c_1 r_1 \in E(H')$, hence $H'[W]$ and $H'[W']$ are isomorphic; in the other subcase $xy \notin E(H')$, take $A' = \{c_2, r_1\}$, so $c_2 r_1 \notin E(H')$ thus again $H'[W]$ and $H'[W']$ are isomorphic. Eventually consider the last case $x, y \in R$. If $xy \in E(H')$ then $H[W]$ contains a triangle, else $xy \notin E(H')$, so let $A' = \{r_2, r_1\}$ and note that $r_2 r_1 \notin E(H')$ thus $H'[W]$ and $H'[W']$ are isomorphic.

The set W' is an obstruction of H' and since the vertices in $\{c_1, r_1, c_2, r_2\}$ are not incident to any pair of F , W' is also an obstruction of H . Therefore H is not trivially perfect, which is a contradiction, concluding the proof of the Lemma. ◀

► **Rule 4.** *Given a comb (C, R) of length $l \geq 2k + 2$ of G , remove from G the vertices in $C_i \cup R_i$ for $2k + 2 < i \leq l$.*

► **Lemma 12** (*). *Rule 4 is safe.*

2.3 Reducing the teeth

► **Lemma 13.** *Let $(G = (V, E), k)$ be a yes-instance of TRIVIAALLY PERFECT EDITING, and (C, R) be a comb of G such that there exist $a, b \in \{1, \dots, l\}$ with $\sum_{a \leq i \leq l} |R_i| \geq 2k + 1$ and $\sum_{b \leq i < a} |R_i| \geq 2k + 1$. Then there exists an optimal k -edition F of G such that for every $m \in \{1, \dots, b - 1\}$, the vertices of R_m are all adjacent to the same vertices of $V(G) \setminus R_m$ in $G \Delta F$, and F contains no pair of vertices of R_m .*

Proof. Let F be an optimal k -edition of G and $H = G \Delta F$. There exist $v_2 \in (R_a \cup R_{a+1} \cup \dots \cup R_l)$ and $v_1 \in (R_b \cup R_{b+1} \cup \dots \cup R_{a-1})$ unaffected by F . The neighborhood of v_1 in $H \setminus R$ must be a clique: indeed, if there exist $x, y \in N_G(v_1) \setminus R$ such that $xy \notin E(H)$, then since $(N_G(v_1) \setminus R) \subseteq (N_G(v_2) \setminus R)$, the vertices $\{v_1, x, v_2, y\}$ would induce a C_4 . Let $1 \leq m < b$, we will construct an edition F_m such that $|F_m| \leq |F|$, F_m contains no pair of vertices included in R_m and the vertices of R_m are all adjacent to the same vertices in $G \Delta F_m$. Applying this construction iteratively to each R_m , $1 \leq m < b$ will yield an edition F^* that verifies the desired properties.

Let S be a maximal clique in H that contains $N_G(v_1) \setminus R$ and v_1 , and let K_1, \dots, K_r be the connected components of $H \setminus S$. Observe that K_1, \dots, K_r respect the conditions i, ii and iii of Lemma 6 with S . Let $v_m \in R_m$ be a vertex contained in the least number of pairs of F with the other element in S .

Denote by N the set of vertices of S adjacent to v_m in graph H . Let H' be the graph constructed from $H \setminus R_m$ and $G[R_m]$ by adding the edges $N \times R_m$, and F_m be the edition such that $H' = G \Delta F_m$. By construction $|F_m| \leq |F|$, we will now show that H' is trivially perfect.

We can observe that $R_m \cap S = \emptyset$ (because v_1 is unaffected by F and is non-adjacent with R_m in G) and therefore that S is a maximal clique of $H \setminus R_m$.

By construction of H' , S is also a maximal clique of H' and R_m is a connected component of $H_m \setminus S$. Let $K'_1, \dots, K'_{r'}$ be the connected components of $(H \setminus R_m) \setminus S$. Sets $K'_1, \dots, K'_{r'}$ verify the conditions i, ii and iii of Lemma 6 with respect to S in $H \setminus R_m$ and thus also in H' . Moreover $H'[S \cup R_m]$ is trivially perfect and $(N_{H'}(R_m) \times R_m) \subseteq E(H')$ by construction. The family $\bigcup_{1 \leq i \leq r} \{N_H(K_i)\}$ is nested according to Lemma 6, and, by construction of H' , $\bigcup_{1 \leq i \leq r'} \{N_{H'}(K'_i)\} \subseteq \bigcup_{1 \leq i \leq r} \{N_H(K_i)\}$. We also have that $N \in \bigcup_{1 \leq i \leq r} \{N_H(K_i)\}$. Indeed, let $\bar{K}(v_m)$ the connected component of $H \setminus S$ containing v_m , according to condition iii from Lemma 6 we have $N_H(\bar{K}(v_m)) = N_H(v_m) \cap S = N$. Therefore the family $\bigcup_{1 \leq i \leq r'} \{N_{H'}(K'_i)\} \cup \{N\}$ is also nested. By Lemma 6 applied on H' and S , graph H' is trivially perfect.

45:10 A Cubic Vertex-Kernel for Trivially Perfect Editing

As mentioned previously, we can apply this construction iteratively to each R_m , $1 \leq m < b$ and obtain an edition F^* that verifies the desired properties. \blacktriangleleft

► **Rule 5.** *Given a comb (C, R) of G such that there exist $a, b \in \{1, \dots, l\}$ with $\sum_{a \leq i \leq l} |R_i| \geq 2k + 1$ and $\sum_{b \leq i < a} |R_i| \geq 2k + 1$. Then for every $i \in \{1, \dots, b - 1\}$, replace R_i by a clique of size $\min(|R_i|, k + 1)$ with the same neighborhood.*

► **Lemma 14** (\star). *Rule 5 is safe.*

► **Lemma 15** (\star). *Let $(G = (V, E), k)$ be an instance of TRIVIALY PERFECT EDITING such that Rules 2 to 5 are not applicable. Then, for every comb (C, R) of G , $|C \cup R| = O(k^2)$.*

► **Lemma 16** (\star). *Given an instance $(G = (V, E), k)$ of TRIVIALY PERFECT EDITING, Rules 4 and 5 can be exhaustively applied in polynomial time.*

3 Bounding the size of a reduced instance

We now prove thoroughly that any reduced yes-instance of TRIVIALY PERFECT EDITING contains $O(k^3)$ vertices. To that end, we need the following definition and result.

► **Definition 17** (LCA-closure [16]). *Let $T = (V, E)$ be a rooted tree and $A \subseteq V(T)$. The lowest common ancestor-closure (LCA-closure) A' of A is obtained as follows. Initially, set $A' = A$. Then, as long as there exist $x, y \in A'$ whose lowest common ancestor w is not in A' , add w to A' . The LCA-closure of A is the last set A' obtained using this process.*

► **Lemma 18** ([16]). *Let $T = (V, E)$ be a rooted tree, $A \subseteq V(T)$ and $A' = \text{LCA-closure}(A)$. Then $|A'| \leq 2 \cdot |A|$ and for every connected component C of $T \setminus A'$, $|N_T(C)| \leq 2$.*

► **Theorem 19.** *TRIVIALY PERFECT EDITING admits a kernel with $O(k^3)$ vertices.*

Proof. Let $(G = (V, E), k)$ be a reduced yes-instance of TRIVIALY PERFECT EDITING and F a k -edition of G . Let $H = G \triangle F$ and $\mathcal{T} = (T, \mathcal{B})$ the universal clique decomposition of H . The graph G is not necessarily connected, thus T is a forest. Let A be the set of nodes $t \in V(T)$ such that the bag B_t contains a vertex affected by F . Since $|F| \leq k$, we have $|A| \leq 2k$. Let $A' \subseteq V(T)$ be the set containing the nodes of $\text{LCA-closure}(A)$ and the root of each connected component of T (in case the closure does not contain them). According to Lemma 18 and Rule 1 which implies that there are at most $2k$ connected components in G and thus $2k$ roots, we have $|A'| \leq 6k$.

Let D be a connected component of $T \setminus A'$. We can observe that, by construction of A' (which for every pair of nodes, contains also the smallest common ancestor in T), only three cases are possibles (see Figure 4):

- $N_T(D) = \emptyset$ (D is a connected component of T).
- $N_T(D) = \{a\}$ (D is a subtree of T whose parent is $a \in A'$).
- $N_T(D) = \{a_1, a_2\}$ with one of the nodes $a_1, a_2 \in A'$ being an ancestor of the other in T .

We will say that these connected components are respectively of type 0, 1 or 2. For $D \subseteq V(T)$, we denote by $W(D) = \bigcup_{t \in D} B_t$ the set of vertices of G corresponding to bags of D .

There is no connected component of type 0 or else $W(D)$ would be a connected component of G inducing a trivially perfect graph. Rule 1 would have been applied to this component, contradicting the fact that G is a reduced instance.

Now consider the set of type 1 components D_1, D_2, \dots, D_r of $T \setminus A'$ attached in T to the same node $a \in A'$. We show that $W_a = W(D_1) \cup W(D_2) \cup \dots \cup W(D_r)$ is a trivially perfect module of G . In the graph H , W_a is by construction a module of the decomposition. Since

■ **Figure 4** (Left) universal clique decomposition of a connected component of H . (Right) shape of a reduced comb.

no vertex of W_a was affected by the edition F , W_a is also a module of G , trivially perfect by heredity. By Lemma 8, we have $|W_a| = O(k^2)$. There are at most $|A'| \leq 6k$ such sets W_a , thus the set of vertices of G in bags of type 1 components is of size $O(k^3)$.

Now consider the type 2 connected components D of $T \setminus A'$ which have two neighbors in T . Let a_1 and a_2 be these neighbors, one being the ancestor of the other, say a_1 is the ancestor of a_2 . Let t_1, \dots, t_l be the nodes of the tree on the path from a_1 to a_2 , in this order. The component D can be seen as a comb of shaft $(B_{t_1}, \dots, B_{t_l})$. More precisely, by construction of the universal clique decomposition, $W(D)$ can be partitioned into a comb (C, R) of H : the critical clique decomposition of C is $(C_1 = B_{t_1}, \dots, C_l = B_{t_l})$, and each R_i corresponds to the union of bags of the subtrees rooted at t_i which do not contain t_{i+1} , for $1 \leq i < l$, and to the union of bags of the subtrees rooted at t_l which do not contain a_2 , for $i = l$. Since (C, R) was not affected by F , it is also a comb of G . Thus for each type 2 component D , $W(D)$ contains $O(k^2)$ vertices by Lemma 15. Since T is a forest, it can contain at most $|A'| - 1 \leq 6k - 1$ such components in $T \setminus A$. Therefore the set of bags containing type 2 connected components of $T \setminus A$ contains $O(k^3)$ vertices.

It remains to bound the set of vertices of G which are in bags of A' . The vertices corresponding to nodes of $A' \setminus A$ are critical cliques of G , and are hence of size at most $k + 1$ by Rule 2. Thus the set of vertices in bags of $A' \setminus A$ is of size $O(k^2)$. The vertices corresponding to nodes of A are critical cliques in H but not necessarily of G . Let B_a be a bag corresponding to a node $a \in A$. We will show that B_a is covered by at most $2k + 1$ critical cliques of G , which by Rule 2 will imply that B_a contains $O(k^2)$ vertices of G , and thus the set of vertices in bags of A' is of size $O(k^3)$.

To see this, observe that B_a is a critical clique of H , and that G is obtained from H by editing at most k pairs of vertices. A result from [31] claims that, starting from a graph H and editing an edge, we add at most two critical cliques. The same arguments allow to claim that if B is a set of vertices covered by at most p critical cliques in H , and if H' is obtained by editing a pair of vertices x, y of H , then $p + 2$ critical cliques are enough to cover B in H' . To be complete, we now show this claim. Let $C_1, C_2, \dots, C_p, \dots, C_q$ be the critical cliques of H , suppose that B is covered by the first p cliques C_1, \dots, C_p . For each i , $1 \leq i \leq q$, the set $C''_i = C_i \setminus \{x, y\}$ is a clique module (not necessarily maximal) of H' . In particular, each C''_i is contained in a critical clique C'_i of H (the C'_i are not necessarily distinct). Let $C'(x)$ and $C'(y)$ be the critical cliques of H' containing respectively x and y . Clearly, the critical cliques $C'_1, \dots, C'_p, C'(x)$ and $C'(y)$ of H' cover the vertices of B , showing our claim. By applying this argument k times (one for each pair of F) to the bag B_a , which was a critical clique of H , we conclude that it is covered by at most $2k + 1$ critical cliques of G . Thus $|B_a| = O(k^2)$ by Rule 2.

45:12 A Cubic Vertex-Kernel for Trivially Perfect Editing

We conclude that $|V(G)| = O(k^3)$. Finally, we claim that a reduced instance can be computed in polynomial time. Indeed, Lemma 7 states that it is possible to reduce exhaustively a graph under Rules 2 to 3. Once this is done, it remains to apply exhaustively Rules 4 and 5 which is ensured by Lemma 16. ◀

4 Kernels for trivially perfect completion/deletion

In this section we show that the rules used for TRIVIALY PERFECT EDITING are safe for TRIVIALY PERFECT COMPLETION and TRIVIALY PERFECT DELETION. First Rules 1, 2 and 3 are safe for both problems. Indeed, the safeness of Rule 2 directly follows from Lemma 1 and Rule 3 was shown safe in [13].

We will now argue that Rules 4 and 5 are also safe. Lemma 11 states that no trivially perfect edition for an instance $(G = (V, E), k)$ of TRIVIALY PERFECT EDITING affects a comb of G of length at least $2k + 2$. This is also true when allowing only edge addition or edge deletion, implying the safeness of Rule 4 in both cases. In the proof of Lemma 13, for a trivially perfect edition F we construct another edition $F' \subseteq F$. In case F consists only of edge additions or deletions, it is also the case for F' , thus Lemma 13 holds for TRIVIALY PERFECT COMPLETION and TRIVIALY PERFECT DELETION and Rule 5 is safe for these problems.

The proof for the size of the kernel is the same as the proof of Theorem 19. Altogether, we obtain the following result.

► **Theorem 20.** *TRIVIALY PERFECT COMPLETION and TRIVIALY PERFECT DELETION admits a kernel with $O(k^3)$ vertices.*

5 Conclusion

We have provided a kernelization algorithm for TRIVIALY PERFECT EDITING, producing a cubic vertex-kernel, hence improving upon the $O(k^7)$ -size kernel of [13]. The techniques extend to the deletion and completion versions of the problem, within the same bounds. A natural question is whether the size of the kernel for TRIVIALY PERFECT EDITING can still be reduced – note that for TRIVIALY PERFECT COMPLETION, Bathie et al. claim a quadratic kernel [2].

Some ideas used in this work remind of very similar techniques applied to kernelization problems for edge editing towards classes of graphs \mathcal{G} having a tree-like decomposition. The simplest case – like here or for the class of so-called 3-leaf power graphs, see [3] – is when the vertices of the graph can be partitioned into bags inducing modules, and these bags can be structured as nodes of a forest T , with specific adjacency rules. If an arbitrary graph G can be turned into a graph of class \mathcal{G} by editing at most k pairs of vertices, the edited pairs are in some set A of at most $2k$ bags. Again by taking the lowest common ancestor closure A' of A , set A' is of size $O(k)$ and its removal from forest T will produce some chunks attached in T to 0, 1 or 2 nodes of A' (e.g., in [3], the authors speak of 1 and 2-branches, playing similar roles to modules and combs in this article). Kernelization algorithms can be obtained if we are able to reduce the bags themselves as well as the chunks, which hopefully have good structural properties. It is natural to wonder how general are these techniques, especially on subclasses of chordal graphs.

Abstract

For a DFA, a word *avoids* a subset of states, if after reading that word the automaton cannot be in any state from the subset regardless of its initial state. A subset that admits an avoiding word is *avoidable*. The *k-avoiding threshold* of a DFA is the smallest number such that every avoidable subset of size k can be avoided with a word no longer than that number. We study the problem of determining the maximum possible k -avoiding thresholds. For every fixed $k \geq 1$, we show a general construction of strongly connected DFAs with n states and the k -avoiding threshold in $\Theta(n^k)$. This meets the known upper bound for $k \geq 3$. For $k = 1$ and $k = 2$, the known upper bounds are respectively in $\mathcal{O}(n^2)$ and in $\mathcal{O}(n^3)$. For $k = 1$, we show that $2n - 3$ is attainable for every number of states n in the class of strongly connected synchronizing binary DFAs, which is supposed to be the best possible in the class of all DFAs for $n \geq 8$. For $k = 2$, we show that the conjectured solution for $k = 1$ (an upper bound in $\mathcal{O}(n)$) also implies a tight upper bound in $\mathcal{O}(n^2)$ on 2-avoiding threshold. Finally, we discuss the possibility of using k -avoiding thresholds of synchronizing automata to improve upper bounds on the length of the shortest reset words.

1 Introduction

A *deterministic finite complete semi-automaton* (called simply *automaton*) is a 3-tuple (Q, Σ, δ) , where Q is a finite set of *states*, Σ is an *input alphabet*, and $\delta: Q \times \Sigma \rightarrow Q$ is the *transition function*. The transition function is naturally extended to a function $Q \times \Sigma^* \rightarrow Q$. Throughout the paper, by n we always denote the number of states in Q .

Given a subset $S \subseteq Q$, the *image* of S under the action of a word $w \in \Sigma^*$ is $\delta(S, w) = \{\delta(q, w) \mid q \in S\}$. The *preimage* of S under the action of w is $\delta^{-1}(S, w) = \{q \in Q \mid \delta(q, w) \in S\}$.

The *rank* of a word w is the cardinality of the image $\delta(Q, w)$. A word w is *reset* if it has rank 1, i.e., its action maps all the states to one state. If an automaton admits a reset word, then it is called *synchronizing*, and its *reset threshold* is the length of the shortest reset word.

The central problem in the theory of synchronizing automata is the famous Černý conjecture, which states that every synchronizing n -state automaton has reset threshold at most $(n-1)^2$. Fig. 1 shows the 4-state automaton from the well-known Černý series [2], which

meets the conjectured upper bound for every n . The Černý conjecture is one of the most longstanding open problems in automata theory, with constantly growing literature around the topic; see an old survey [15] and a recent special issue dedicated to the problem [17]. The best known general upper bound on reset threshold is cubic and equals $\sim 0.1654n^3 + o(n^3)$ [11]. Better bounds are known for many subclasses of automata.

■ **Figure 1** The Černý automaton with $n = 4$ states.

1.1 Avoiding words

Avoiding words are defined similarly to reset words. For a state $q \in Q$, a word w is *avoiding* if $q \notin \delta(Q, w)$, i.e., no state is mapped by the action of w to q . More generally, a word w *avoids* a subset $S \subset Q$ if $\delta(Q, w) \cap S = \emptyset$. Note that a word of rank $n - k$ is also a word avoiding some subset S of size k . In this way, a reset word is a specific case of an avoiding word.

A subset S is *avoidable* if there exists an avoiding word for S . Then, the *S -avoiding threshold* is the length of the shortest words avoiding S . The *k -avoiding threshold* is the maximum S -avoiding threshold over all subsets $S \subset Q$ of size k . In other words, every avoidable subset of size k can be avoided with a word of length not exceeding the k -avoiding threshold.

Obviously, a k -avoiding threshold is never larger than the $(k + 1)$ -avoiding threshold. In a synchronizing automaton, every subset of size $\leq n - 1$ is avoidable.

For example, for the automaton from Fig. 1, the k -avoiding thresholds for $k = 1, 2, 3$ are respectively equal to 4, 8, 12. For instance, the shortest word avoiding subset $\{q_2, q_3\}$ is ba^3ba^3 , and no other subset of size two requires a longer word.

Avoiding words are closely related to reset words and can be interesting as such for similar reasons. Yet, so far the focus was put on their application to bounding reset thresholds.

Originally, the concept was first used by Trahtman as a tool for improving the cubic upper bound on the reset threshold [14]. This turned out to be wrong as is based on the claim that 1-avoiding threshold is at most n , whereas it can be larger [5]. Nevertheless, the idea of applying avoiding words has been shown to be useful. A non-trivial quadratic upper bound on 1-avoiding threshold already led to the first improvement [12] of the old and well-known upper bound on the reset threshold [8]. This was later refined to $\sim 0.1654n^3 + o(n^3)$ [11], using the same method but improving the counting argument.

Better upper bounds on avoiding thresholds should lead to better upper bounds on reset thresholds. Yet, the problem of avoiding may be of similar difficulty.

Avoiding a subset is closely related to subset reachability. The latter is the question for a given subset $T \subseteq Q$, are there and how long are words w such that $\delta(Q, w) = T$. It is known that the decision problem is PSPACE-complete even if the automaton is strongly connected [18] and the shortest such words can have a length larger than $2^n/n$ [4]. It

holds similarly in the weaker *included* version where w is such that $\delta(Q, w) \subseteq T$ [4]. This is equivalent to avoiding the complement of T : $\delta(Q, w) \subseteq T$ is equivalent to $\delta(Q, w) \cap (Q \setminus T) = \emptyset$. It is also equivalent to that w is *totally extending*, i.e., $\delta^{-1}(T, w) = Q$, which was shown to be PSPACE-complete even if the automaton is strongly connected and binary [1]. It follows that avoiding a subset, in general, should require exponentially long words, but precise bounds were not shown so far. In particular, these results do not say what happens in the case of a synchronizing automaton nor if the size of the subset S to avoid is small. Yet, as we note, these cases are particularly important.

1.2 Known upper bounds

For the 1-avoiding threshold, the best known upper bound is quadratic in n . It is derived through linear algebraic methods applied to automata.

► **Theorem 1** (rephrased [12, Corollary 5]). *For an n -state automaton, the 1-avoiding threshold is at most $(n - 2)(n - 1) + 2$.*

In the general case, for k -avoiding threshold, we have the following asymptotic bound:

► **Theorem 2** (rephrased [1, Theorem 12]). *Let $\mathcal{A} = (Q, \Sigma, \delta)$ be an n -state automaton, let r be the minimal rank in \mathcal{A} over all words, and let m be the length of the shortest words of the minimal rank. Then the k -avoiding threshold is at most $\mathcal{O}(n^{\min(r,k)} + m)$.*

Since for m we have only a cubic upper bound $\mathcal{O}(n^3)$, this component is dominating for $k = 1$ and $k = 2$. In these cases, it is unlikely to be tight. There is also the well-known rank (Pin-Černý) conjecture [8] stating that $m \leq (n - r)^2$.

No better bounds on avoiding thresholds are known in the case of a synchronizing and/or strongly connected automaton. Except for the obvious fact that for a synchronizing automaton $\mathcal{O}(n^3)$ is an upper bound on every k -avoiding threshold, and $\mathcal{O}(n^2)$ would be an upper bound if the (weak version of) Černý conjecture holds.

We note that it is also an easy exercise to prove that avoiding thresholds are small (at most linear) for many subclasses of automata. For example, for Eulerian automata, the k -avoiding threshold is at most $k(n - 1)$ [6]. For aperiodic automata [13, 16], or more generally, for automata with letters whose transitions contain only trivial cycles (self-loops), it is at most $n - 1$.

1.3 Known lower bounds

Concerning automata with the largest possible avoiding thresholds, only a few particular examples of automata were described so far. Moreover, they were limited to 1-avoiding threshold.

The first such example is a 4-state automaton with the 1-avoiding threshold equal to 6, which was found as a counterexample to the conjecture that the 1-avoiding threshold is bounded above by the number of states [5]. Later experiments [7] revealed several other examples with $n \leq 11$ states, suggesting that $2n - 2$ may be an upper bound.

It is also known that deciding whether 1-avoiding threshold or $\{q\}$ -avoiding threshold (for a given q) is smaller than a given integer is NP-complete [1].

1.4 Contribution

We tackle the problem of constructing automata with large avoiding thresholds. In this paper, we summarize our efforts.

First, we show that 1-avoiding threshold can be equal to $2n - 3$, for every number of states $n \geq 2$, and this is met by a series of strongly connected synchronizing automata. We conjecture that it is best possible, except for finitely many examples meeting $2n - 2$.

For the general case, we show a series of automata with k -avoiding thresholds in $\Theta(n^k)$. These automata are strongly connected but not synchronizing. This matches the asymptotic upper bound for $k \geq 3$, leaving open the cases $k = 2$ and $k = 1$. Yet, we show that the case of $k = 2$ can be reduced to a possible solution of the case of $k = 1$.

Finally, we note the potential of avoiding words for improving upper bounds on the reset threshold. So far, only an application of 1-avoiding threshold was considered; being in $\mathcal{O}(n)$, it would imply an upper bound on the reset threshold equal to $7/48n^3 + \mathcal{O}(n^2)$ [14]. However, with the generalized concept of avoiding subsets of size k , we can achieve more. If the k -avoiding threshold is subquadratic for all k bounded by any growing function in n (e.g., if for all $k \leq \log n$, the k -avoiding threshold is $o(n^2)$), then the reset threshold is subcubic.

2 1-avoiding threshold

We show a series of binary strongly connected synchronizing automata with 1-avoiding threshold equal to $2n - 3$. The existence of the series has been mentioned several times ([7, 12]), but it has not been described yet.

For each $n \geq 5$, we define $\mathcal{A}_n = (Q = \{q_1, \dots, q_n\}, \Sigma = \{a, b\}, \delta)$, which is shown in Fig. 2. The transition function is defined as follows: $\delta(q_1, a) = q_2; \delta(q_1, b) = q_1; \delta(q_2, a) = q_1; \delta(q_2, b) = q_3; \delta(q_3, a) = q_1; \delta(q_3, b) = q_4; \delta(q_i, a) = \delta(q_i, b) = q_{i+1}$ for all $i \in \{4, \dots, n-1\}; \delta(q_n, a) = q_4; \delta(q_n, b) = q_2$.

■ **Figure 2** The binary automaton \mathcal{A}_n with the 1-avoiding threshold equal to $2n - 3$.

► **Proposition 3.** *For $n \geq 5$, the automaton \mathcal{A}_n is strongly connected and synchronizing, and its reset threshold is at most $3n - 4$.*

Proof. We can avoid all even-indexed states on the a -cycle by word $(ab)^k$ for some k :

$$Q \xrightarrow{ab} Q \setminus \{q_4\} \xrightarrow{ab} Q \setminus \{q_4, q_6\} \xrightarrow{ab} \dots \xrightarrow{ab} \{q_1, q_2, q_3\} \cup \{q_5, q_7, \dots\}.$$

Moreover, if n is even, then we can continue applying word ab to avoid also all odd-indexed states on the a -cycle:

$$\{q_1, q_2, q_3\} \cup \{q_5, q_7, \dots\} \xrightarrow{ab} \{q_1, q_2, q_3\} \cup \{q_7, q_9, \dots\} \xrightarrow{ab} \dots \xrightarrow{ab} \{q_1, q_2, q_3\} \xrightarrow{ab} \{q_1, q_3\}.$$

If n is odd, then we can apply one additional a letter to avoid all odd-number states and repeat the procedure of avoiding even-number states, that is:

$$\begin{aligned} \{q_1, q_2, q_3\} \cup \{q_5, q_7, \dots\} &\xrightarrow{a} \{q_1, q_2, q_3\} \cup \{q_4, q_6, \dots\} \xrightarrow{ab} \{q_1, q_2, q_3\} \cup \{q_6, q_8, \dots\} \\ &\xrightarrow{ab} \dots \xrightarrow{ab} \{q_1, q_2, q_3, q_{n-1}\} \xrightarrow{ab} \{q_1, q_2, q_3\}. \end{aligned}$$

Overall, we can compress the automaton to the set $\{q_1, q_2, q_3\}$ using a word of length at most $2(n-3)$ for an even and $2(n-3)+1$ for an odd n , since each ab application decreases the size of the image by 1 until there are only three states left. The set $\{q_1, q_2, q_3\}$ can be easily synchronized to q_1 by the word $ab^{n-3}aba$. ◀

Informally, the key property of the construction is the following. To avoid q_1 , we must avoid both q_2 and q_3 . But to do so, we must first avoid two consecutive states in the cycle q_4, \dots, q_n on a . This requires one full round on this cycle. In particular, the avoided states on the cycle will be always q_4 and q_5 at some point. Then, we need a second round to map these two gaps to q_2 and q_3 , respectively. Hence, the shortest avoiding words for q_1 have length $\sim 2n$.

► **Theorem 4.** For $n \geq 7$, the 1-avoiding threshold of \mathcal{A}_n equals $2n-3$.

Proof. We show that the length of the shortest avoiding words for state q_1 is $2n-3$.

If n is even, then $(ab)^{n-3}bba$ is an avoiding word for q_1 of length $2n-3$. We have:

$$Q \xrightarrow{(ab)^{n-3}} \{q_1, q_2, q_3\} \xrightarrow{bba} \{q_2, q_4, q_5\}.$$

If $n \geq 9$ is odd, then $aba^{n-5}bab^{n-3}a$ is the desired word. We have:

$$Q \xrightarrow{ab} Q \setminus \{q_4\} \xrightarrow{a^{n-5}} Q \setminus \{q_3, q_{n-1}\} \xrightarrow{ba} Q \setminus \{q_3, q_4, q_5\} \xrightarrow{b^{n-3}} Q \setminus \{q_n, q_2, q_3\} \xrightarrow{a} Q \setminus \{q_1, q_4, q_3\}$$

For $n=7$, a shortest avoiding word is $abaabaaabba$.

To prove the lower bound, we start with an auxiliary claim.

Claim 1: If a word v avoids state q_n , then $|v| \geq n-2$. It follows because the only state that can be avoided with one letter (a) is q_3 , and the shortest words with an action mapping q_3 to q_n have length $n-3$.

Let w be a shortest word avoiding state q_1 . Since $\delta(q_1, b) = q_1$, $\delta(q_1, aa) = q_1$, and $\delta(q_1, aba) = q_1$, it follows that w must end with bba , as otherwise it would not be a shortest such word. Let write $w = w'bba$. We have $\delta(q_n, bba) = \delta(q_{n-1}, bba) = q_1$, which implies that w' must avoid both q_n and q_{n-1} . From Claim 1, $|w'| \geq n-2$, so we can write $w = w''xyubba$, where $|u| = n-5$, $|x| = |y| = 1$, and $|w''| \geq 1$. Since $w' = w''xyu$ avoids both q_n and q_{n-1} , and these states are mapped respectively to q_n and q_{n-1} by the action of every word of length $n-5$, we know that $w''xy$ avoids both q_5 and q_4 .

We consider three cases:

1. If $y = a$, then $w''x$ must avoid q_n (as $\delta(q_n, a) = q_4$). From Claim 1, we get that $|w''x| \geq n - 2$, hence $|w| \geq (n - 2) + 1 + (n - 5) + 3 = 2n - 3$.
2. If $y = b$ and $x = a$, then w'' must avoid q_n (as $\delta(q_n, ab) = q_5$). Similarly as in the previous case, we get that $|w| \geq 2n - 2$.
3. If $y = b$ and $x = b$, then w'' must avoid both q_2 and q_3 . Then, however, $w''a$ would avoid q_1 , which contradicts that w is a shortest such word. ◀

The proof covers the cases $n \geq 7$, whereas the lower bound for the cases $n \leq 6$ was confirmed by experiments [7].

Automata \mathcal{A}_n have another extremal property: The quadratic upper bound on the 1-avoiding threshold is derived by an iterative application of [12, Lemma 3], which for a given subset S gives a word w of length at most $n - |S| + 1$ that either avoids a fixed state $q \in Q$ or compresses S (i.e., $|\delta(S, w)| < |S|$). In the worst case, we must apply this lemma a linear number of times, hence a quadratic upper bound follows. The automata \mathcal{A}_n demonstrate that this may be the case: we may be forced to apply the lemma $\Theta(n)$ times obtaining each time the word $w = ba$, which compresses the subset. On the other hand, ba is very short compared to the linear upper bound $n - |S| + 1$. Yet, it would be possible that also this bound can be met. There also exists another series of automata (similar to the automaton from Fig. 4) showing that the upper bound $n - |S| + 1$ on the length of shortest avoiding or compressing word is tight for each $n \geq |S| \geq 1$. However, it is an open question whether both these bounds can be met simultaneously.

2.1 Exceptional examples

■ **Figure 3** An automaton with the 1-avoiding threshold equal to $2n - 2 = 12$ (for state q_1).

There are several particular examples of synchronizing automata with 1-avoiding threshold equal to $2n - 2$. For instance, for the automaton \mathcal{A}_5 it is 8. Another example is shown Fig. 3, which is a largest known automaton meeting this bound.

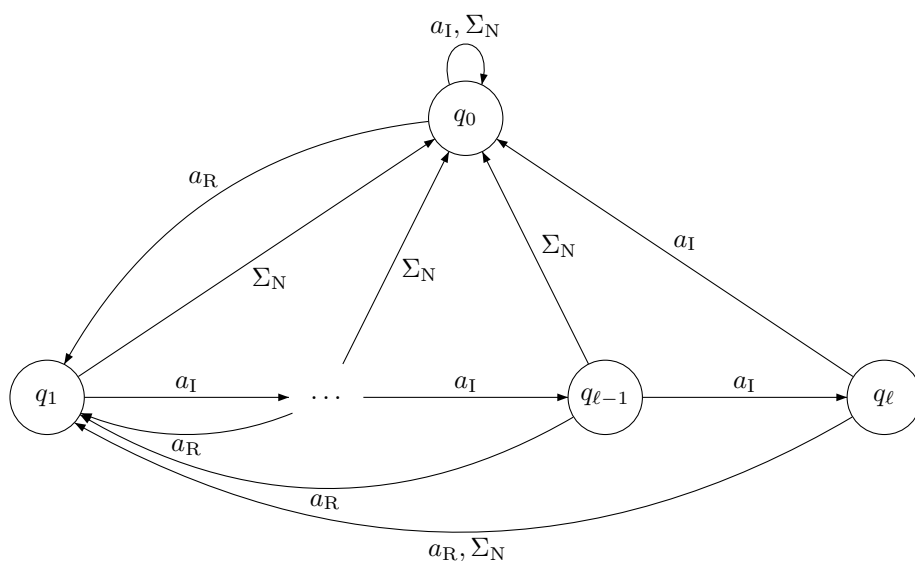

No such example seems to belong to a series keeping that 1-avoiding threshold. It is known that there are no binary synchronizing automata exceeding 1-avoiding threshold $2n - 3$ in range $n \in \{8, 9, 10, 11\}$ [7] (the case of $n = 11$ was verified later).

3 k -avoiding thresholds

3.1 General lower bound

For every fixed $k \geq 1$, we show an infinite series of (non-synchronizing) automata such that their k -avoiding threshold is in $\Theta(n^k)$. The construction is built from gadgets of two types.

3.1.1 One-track counting gadget

■ **Figure 4** The one-track counting gadget. The identity action of Σ_P is not drawn.

Let $\ell \geq 2$ be an integer, Σ_P, Σ_N be disjoint sets of letters, and $a_R, a_I \notin \Sigma_P \cup \Sigma_N$ be two other distinct letters. We define the *one-track counting gadget* $\mathcal{T}(\ell, a_R, \Sigma_P, a_I, \Sigma_N)$ (shown in Fig. 4), which is the automaton $(Q_{\mathcal{T}}, \Sigma_{\mathcal{T}}, \delta_{\mathcal{T}})$, where $P = \{q_0, q_1, \dots, q_{\ell}\}$, $\Sigma_{\mathcal{T}} = \{a_R, a_I\} \cup \Sigma_P \cup \Sigma_N$ and $\delta_{\mathcal{T}}$ is defined as follows. Letter a_R is the *reset letter* with the action mapping all the states to q_1 :

$$\delta_{\mathcal{T}}(q_i, a_R) = q_1 \text{ for } i \in \{0, 1, \dots, \ell\}.$$

Letter a_I is the *incrementing letter* with the action shifting the states q_1, \dots, q_{ℓ} :

$$\delta_{\mathcal{T}}(q_i, a_I) = q_{i+1} \text{ for } i \in \{1, \dots, \ell - 1\}; \quad \delta_{\mathcal{T}}(q_{\ell}, a_I) = q_0; \quad \delta_{\mathcal{T}}(q_0, a_I) = q_0.$$

The letters from Σ_P are called *previous letters* and they all act as the identity. The letters from Σ_N are called *next letters*; they have the same action mapping all the states to q_0 except q_{ℓ} , which is mapped to q_1 :

$$\delta_{\mathcal{T}}(q_i, a) = q_0 \text{ for } i \in \{0, 1, \dots, \ell - 1\}, a \in \Sigma_N; \quad \delta_{\mathcal{T}}(q_{\ell}, a) = q_1 \text{ for } a \in \Sigma_N.$$

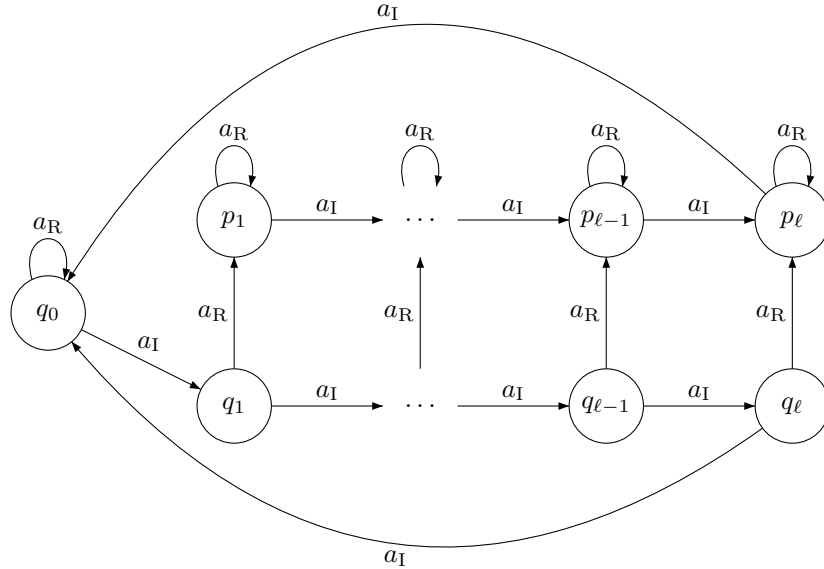

The mechanism of the gadget is that, in order to avoid q_0 , applications of next letters are restricted. We must start with a_R and then keep applying $a_I^{\ell-1}$ alternatingly with one next letter. Additionally, previous letters can be applied interleaving at any time. Formally, we have the following:

► **Lemma 5.** *Consider \mathcal{F} and a word $w \in (\{a_I\} \cup \Sigma_P \cup \Sigma_N)^*$. If the word $a_R w$ avoids q_0 , then in w , the number of occurrences of a_I is at least $\ell - 1$ times larger than the total number of occurrences of letters from Σ_N .*

Proof. In the analysis, we can ignore the occurrences of Σ_P and assume equivalently that $w \in (\{a_I\} \cup \Sigma_N)^*$.

Since w does not contain a_R and this is the only letter with the action mapping q_0 to another state, for every prefix w' of w , $a_R w'$ must also avoid q_0 . In the beginning, $\delta_{\mathcal{F}}(Q_{\mathcal{F}}, a_R) = \{q_1\}$. The only possibility to keep q_0 avoided is to apply $a_I^{\ell-1}$, which must be followed by a letter from Σ_N . We end with the singleton $\{q_1\}$ and the argument repeats, keeping the proportion between the numbers of occurrences of a_I and of letters from Σ_N . ◀

3.1.2 Two-track counting gadget

■ **Figure 5** The two-track counting gadget. The identity action of Σ_P is not drawn.

Let $\ell \geq 1$ be an integer, Σ_P be a set of letters, and a_R, a_I be two other distinct letters. We define the *two-track counting gadget* $\mathcal{D}(\ell, a_R, \Sigma_P, a_I)$ (shown in Fig. 5), which is the automaton $(Q_{\mathcal{D}}, \Sigma_P \cup \{a_R, a_I\}, \delta_{\mathcal{D}})$, where $Q_{\mathcal{D}} = \{q_0, q_1, \dots, q_\ell, p_1, \dots, p_\ell\}$, and $\delta_{\mathcal{D}}$ is defined as follows. Letter a_R is the *reset letter*, whose action maps the corresponding states q_i to p_i :

$$\delta_{\mathcal{D}}(q_i, a_R) = p_i \text{ for } i \in \{1, \dots, \ell\}; \quad \delta_{\mathcal{D}}(p_i, a_R) = p_i \text{ for } i \in \{1, \dots, \ell\}; \quad \delta_{\mathcal{D}}(q_0, a_R) = q_0.$$

Letter a_I is the *incrementing letter* acting as follows:

$$\delta_{\mathcal{D}}(q_i, a_I) = q_{i+1}, \quad \delta_{\mathcal{D}}(p_i, a_I) = p_{i+1} \text{ for } i \in \{1, \dots, \ell - 1\}; \quad \delta_{\mathcal{D}}(p_\ell, a_I) = \delta_{\mathcal{D}}(q_\ell, a_I) = q_0.$$

Finally, the letters from Σ_P act as identity.

The point of the gadget is that, in order to avoid p_ℓ , we have to apply $\ell - 1$ times letter a_I without applying letter a_R in between.

► **Lemma 6.** For \mathcal{D} , if a word $w \in \Sigma_{\mathcal{D}}^*$ avoids p_ℓ , then w contains at least ℓ occurrences of a_I without any occurrence of a_R in between.

Proof. Observe that for every word $u \in \Sigma_{\mathcal{D}}^*$, we have $\delta_{\mathcal{D}}(Q_{\mathcal{D}}, ua_R) = \{q_0, p_1, \dots, p_\ell\}$. Thus, if p_ℓ is avoided by w , then w must contain a subword (factor) $w' \in \Sigma_{\mathcal{D}} \setminus \{a_R\}$ such that $p_\ell \notin \delta_{\mathcal{D}}(\{q_0, p_1, \dots, p_\ell\}, v)$. Ignoring the letters from Σ_P , the only such words are a_i^i for $i \geq \ell$. ◀

3.1.3 The construction

We build the construction as a union of gadgets. For each $k \geq 1$ and $\ell \geq 2$, we build the automaton $\mathcal{K}(k, \ell) = (Q_{\mathcal{K}(k, \ell)}, \Sigma_{\mathcal{K}(k, \ell)}, \delta_{\mathcal{K}(k, \ell)})$. Let $\Sigma_{\mathcal{K}(k, \ell)} = \{a_R, a_1, \dots, a_k\}$ be the input alphabet. The automaton is the disjoint union of the following gadgets:

$$\begin{aligned} \mathcal{D} &= \mathcal{D}(\ell, a_R, \{a_k, \dots, a_2\}, a_1); \\ \mathcal{F}_i &= \mathcal{F}(\ell, a_R, \{a_k, \dots, a_{i+1}\}, a_i, \{a_{i-1}, \dots, a_1\}) \text{ for all } i \in \{2, \dots, k\}. \end{aligned}$$

As it contains states from several gadgets, when denoting a state, we specify the owning gadget in the superscript. Finally, we define the subset to be avoided:

$$S_k = \{p_\ell^{\mathcal{D}}\} \cup \bigcup_{i \in \{1, \dots, k-1\}} \{q_0^{\mathcal{F}_i}\}.$$

Observe that the number of states n of $\mathcal{K}(k, \ell)$ equals $(k-1)(\ell+1) + (1+2\ell) = k\ell + k + \ell = \ell(k+1) + k$.

Note that for every k , we have $Q_{\mathcal{K}(k, \ell)} \subsetneq Q_{\mathcal{K}(k+1, \ell)}$, $\Sigma_{\mathcal{K}(k, \ell)} \subsetneq \Sigma_{\mathcal{K}(k+1, \ell)}$, $\delta_{\mathcal{K}(k, \ell)} \subsetneq \delta_{\mathcal{K}(k+1, \ell)}$, and also $S_k \subsetneq S_{k+1}$. Hence, every letter of $\mathcal{K}(k, \ell)$ acts the same on the same common states in every $\mathcal{K}(k+i)$ for $i \geq 0$.

For every word $u \in \Sigma^*$, further applying a_R yields the same fixed image, that is:

$$\delta_{\mathcal{K}(k, \ell)}(Q_{\mathcal{K}(k, \ell)}, ua_R) = \delta_{\mathcal{K}(k, \ell)}(Q_{\mathcal{K}(k, \ell)}, a_R) = \{q_0^{\mathcal{D}}\} \cup \bigcup_{j \in \{1, \dots, \ell\}} \{p_j^{\mathcal{D}}\} \cup \bigcup_{i \in \{1, \dots, k\}} \{q_1^{\mathcal{F}_i}\}. \quad (1)$$

► **Lemma 7.** For $\mathcal{K}(k, \ell)$, the subset S_k is avoidable and the length of the shortest avoiding words for S_k equals $1 + \ell^k$ (and ℓ if $k = 1$).

Proof. For $k = 1$, the shortest avoiding word for S_1 is a_1^ℓ . For the remaining part, assume that $k \geq 2$.

Let w_k be a shortest avoiding word for S_k in $\mathcal{K}(k, \ell)$. First, we observe that w_k must contain a_R , since otherwise the states $q_0^{\mathcal{F}_i}$ could not be avoided. From (1), we know that w_k may contain only one occurrence of a_R and it must appear at the beginning; otherwise, there would exist a shorter avoiding word.

To show that S_k is avoidable with a word of length $1 + \ell^k$, we use induction on k . We show that there is an avoiding word w_k from $a_R \{a_1, \dots, a_k\}^*$ of the required length. For $k = 1$, there is only the gadget \mathcal{D} , and the word $w_1 = a_R a_1^\ell$ does the job. Assuming the statement for k , we show that it holds for $k+1$. Then w_k acts the same in $\mathcal{K}(k+1, \ell)$ as in $\mathcal{K}(k, \ell)$ on the common states. Let w_{k+1} be the word obtained from w_k by inserting $a_{k+1}^{\ell-1}$ before each occurrence of every letter from $\{a_1, \dots, a_k\}$. Since a_{k+1} works as the identity in the gadgets $\mathcal{D}, \mathcal{F}_1, \dots, \mathcal{F}_k$, S_k is avoided. Also, we can see that $\delta_{\mathcal{K}(k+1, \ell)}(\{q_0^{\mathcal{F}_{k+1}}, \dots, q_\ell^{\mathcal{F}_{k+1}}\}, w_{k+1}) = \{q_1^{\mathcal{F}_{k+1}}\}$. Thus w_{k+1} avoids S_{k+1} and has length $1 + \ell^k \cdot \ell = 1 + \ell^{k+1}$.

To show that there are no shorter avoiding words, we also use induction on k . We show that every avoiding word for S_k contains at least ℓ^k occurrences of letters from $\{a_1, \dots, a_k\}$. For $k = 1$, by Lemma 6, w has at least ℓ occurrences of a_1 . Assuming the statement for k ,

we show that it holds for $k + 1$. Let $w_{k+1} = a_R w'_{k+1}$ be a shortest avoiding word for S_{k+1} . Since $S_k \subset S_{k+1}$, w_{k+1} also avoids S_k . Let w'_k be the word obtained from w'_{k+1} by removing every occurrence of a_{k+1} . Then, $a_R w'_k$ is over the alphabet of $\mathcal{K}(k, \ell)$ and is an avoiding word for S_k in $\mathcal{K}(k, \ell)$. Thus, by the inductive assumption, it has at least ℓ^k occurrences of letters from $\{a_1, \dots, a_k\}$. Then w'_{k+1} contains them as well. By Lemma 4 for the last gadget \mathcal{T}_{k+1} , where the set of the next letters is $\{a_1, \dots, a_k\}$, we get that w'_{k+1} also must contain at least $(\ell - 1) \cdot \ell^k$ occurrences of a_{k+1} . Altogether, w'_{k+1} contains at least ℓ^{k+1} occurrences of letters from $\{a_1, \dots, a_{k+1}\}$. ◀

3.1.4 Strong connectivity

Each particular gadget is already strongly connected. We can make the whole construction strongly connected by redefining the special action of a_R so that its transitions work cyclically on the gadgets. Let

$$\begin{aligned} \delta_{\mathcal{K}(k, \ell)}(q_0^{\mathcal{D}}, a_R) &= q_1^{\mathcal{T}_1}; \\ \delta_{\mathcal{K}(k, \ell)}(q_j^{\mathcal{T}_i}, a_R) &= q_1^{\mathcal{T}_{i+1}} \text{ for } i \in \{1, \dots, k-1\}, j \in \{0, \dots, \ell\}; \\ \delta_{\mathcal{K}(k, \ell)}(q_j^{\mathcal{T}_k}, a_R) &= q_0^{\mathcal{D}} \text{ for } j \in \{0, \dots, \ell\}; \end{aligned}$$

and the action is left unchanged for the other states of \mathcal{D} : $q_1^{\mathcal{D}}, \dots, q_\ell^{\mathcal{D}}, p_1^{\mathcal{D}}, \dots, p_\ell^{\mathcal{D}}$.

Since (1) still holds for the modified construction, Lemma 7 works as well. We conclude the construction with the following:

► **Theorem 8.** *For every $k \geq 2$, there exists an infinite series of strongly connected automata such that its k -avoiding threshold is at least $1 + \left(\frac{n-k}{k+1}\right)^k$. For a fixed k , its k -avoiding threshold is in $\Theta(n^k)$.*

Proof. For an integer $k \geq 2$, we build the automata $\mathcal{K}(k, \ell)$ for all $\ell \geq 2$. Each $\mathcal{K}(k, \ell)$ has $n = \ell(k+1) + k$ states and its k -avoiding threshold is at least $1 + \ell^k$, thus we get the lower bound.

Note that a_R is the shortest word of the minimal rank, so for a fixed k , the lower bound asymptotically coincides with the upper bound from Theorem 2 for $k \geq 2$, thus the k -avoiding threshold is in $\Theta(n^k)$. ◀

3.2 2-avoiding threshold reduction

The bound $\mathcal{O}(n^k)$ is asymptotically tight for $k \geq 3$, but the cases of $k = 1$ and $k = 2$ remain open. This is due to the cubic upper bound on the length of the shortest minimal-rank words. However, we can reduce the problem for $k = 2$ to the case of $k = 1$. If 1-avoiding threshold is bounded by $f(n)$, then 2-avoiding threshold is at most $\mathcal{O}(n^2 + n \cdot f(n))$. Thus, if 1-avoiding threshold is at most linear, then 2-avoiding threshold is at most quadratic, which would be a tight bound.

A similar result, but restricted to strongly connected synchronizing automata, was shown in [12, Lemma 13]. Here, we show it in the general case, which in essence combines both techniques behind Theorem 8 and Theorem 4.

► **Theorem 9.** *For every n -state automaton, if the 1-avoiding threshold is at most $f(n)$ for some function f , then the 2-avoiding threshold is at most $\mathcal{O}(n^2 + n \cdot f(n))$.*

Proof. A *strongly connected bottom component* is a minimal non-empty set of states $X \subseteq Q$ such that for every word w we have $\delta(X, w) \subseteq X$. A synchronizing automaton has exactly one strongly connected bottom component, whereas a non-synchronizing automaton can have many of them. Let z be a shortest word such that all states in $\delta(Q, z)$ are in the strongly connected bottom components of the automaton. It is well-known that the length of z is in $\mathcal{O}(n^2)$ [9].

Let $\{q_1, q_2\}$ be a subset to avoid. States q_1 and q_2 are either in the same strongly connected component or in separate ones. In any case, we can ignore every other strongly connected component, since their states cannot be mapped to q_1 or q_2 . Let C_1 and C_2 be these components, respectively of q_1 and q_2 . From now, consider the automaton containing only C_1 and C_2 .

Let u_1 and u_2 be avoiding words respectively for q_1 and q_2 , both of length at most $f(n)$.

We build iteratively some words w_1, w_2, \dots, w_{n-1} . Each w_i will be of length $\mathcal{O}(i(n+f(n)))$. Let $w_0 = \varepsilon$.

Assume that we have built w_i , and let $X = \delta(Q, w_i)$. Now, we use a linear algebraic argument to infer that one of three possibilities hold:

- (1) there exists a word v of length at most $n - 1$ such that $q_1 \notin \delta(X, vu_2)$, or
- (2) there exists a word v of length at most $n - 1$ such that there are at least two distinct states $r_1, r_2 \in X$ such that $\delta(r_1, vu_2) = \delta(r_2, vu_2) = q_1$, or
- (3) there does not exist any word v (of any length) satisfying (1) or (2).

We omit to repeat the argument here since it follows in the same way as in the proof of [12, Lemma 13] and requires introducing many linear algebraic definitions. In [12, Lemma 13], however, (3) cannot happen due to the assumption that the automaton is synchronizing and strongly connected, so such a word v always exist.

If (1) holds, then $w_i vu_2$ is an avoiding word for $\{q_1, q_2\}$ and it has a desired length. If (2) holds, then let $w_{i+1} = w_i vu_2$, which is longer than w_i by at most $n - 1 + f(n)$. If (3) holds, then it means that w_i in the automaton restricted to C_1 has the minimal rank. Otherwise, we could map two distinct states from $X \cap C_1$ to the same state, and then map it to q_1 . In this case, we also stop with w_i .

If we have stopped with (3), then we repeat the construction symmetrically for q_2 . If we also do not find an avoiding word, then we obtain a word w'_i that has the minimal rank in the automaton restricted to C_2 . Altogether, $w_i w'_i$ has the minimal rank the automaton with both C_1 and C_2 .

Then, it remains to use the upper bound from Theorem 2. Since the length of $w_i w'_i$ is an upper bound on m , we get the upper bound $\mathcal{O}(n^2 + n \cdot f(n))$.

Finally, we have to add z at the beginning to construct an avoiding word in the original automaton, and the length of z is also at most $\mathcal{O}(n^2)$. ◀

4 Bounding reset threshold with avoiding words

If 1-avoiding threshold is subquadratic, it would yield an upper bound on reset threshold equal to $7/48n^3 + o(n^3)$. However, the application of 1-avoiding threshold to bound reset threshold can be generalized to the usage of k -avoiding thresholds, if they are small enough. It turns out that, in a synchronizing automaton, a subquadratic value of k -avoiding thresholds already for small values of k is enough to imply a subcubic upper bound on the reset threshold. In the following calculations, we disregard particular constants and focus only on asymptotic bounds.

46:12 Lower Bounds on Avoiding Thresholds

► **Lemma 10.** *Let (Q, Σ, δ) be an n -state synchronizing automaton and w be a word of rank $r \geq 2$. There exist at least one state $q \in \delta(Q, w)$ such that $|\delta^{-1}(\{q\}, w)| \leq \lfloor n/r \rfloor$.*

Proof. For each q , the states in $\delta^{-1}(\{q\}, w)$ are pairwise disjoint and they cover the whole Q . As we have r states in R , there exist a state $q \in R$ such that the cardinality of $\delta^{-1}(\{q\}, w)$ is at most n/r . ◀

► **Lemma 11.** *Let (Q, Σ, δ) be an n -state synchronizing automaton and w be a word of rank $r \geq 2$. There is a word of rank at most $r - 1$ and of length at most $|w| + d$, where d is the $\lfloor n/r \rfloor$ -avoiding threshold.*

Proof. We take the state q from Lemma 10. Since $r \geq 2$, so $\lfloor n/r \rfloor < n$, thus every subset of that size is avoidable. We first avoid the subset $\delta^{-1}(\{q\}, w)$ by a word u of length at most d , and then apply w . We have $\delta(Q, uw) \subseteq \delta(Q, w)$ and $q \in \delta(Q, w)$, but also $q \notin \delta(Q, uw)$, thus we obtain that $\delta(Q, uw) \subsetneq \delta(Q, w)$. ◀

Taking the usual notation, $\omega(1)$ is the set of $\mathbb{R} \rightarrow \mathbb{R}$ functions growing faster than a constant.

► **Theorem 12.** *If there exists a function $f \in \omega(1)$ such that for every n -state synchronizing automaton and every $k \leq f(n)$, the k -avoiding threshold is at most $\mathcal{O}(n^2)/f(n)$, then the reset threshold is in $o(n^3)$.*

Proof. We build a reset word in two phases. First, we start with the empty word and iteratively apply Lemma 11 until the built word reaches a rank of at most $n/f(n)$. Thus, there are at most $n - n/f(n)$ applications of the lemma. The rank is at least $n/f(n)$ every time, so we need the k -avoiding threshold for $k \leq n/(n/f(n)) = f(n)$. Hence, d from the lemma is bounded above by $\mathcal{O}(n^2)/f(n)$ from the assumption of the theorem. It follows that the resulted word of rank $n/f(n)$ has length at most $(n - n/f(n)) \cdot \mathcal{O}(n^2)/f(n) = \mathcal{O}(n^3)/f(n)$.

In the second phase, we use the usual pair compression [8]. We need to compress a pair at most $n/f(n) - 1$ times, each time appending a word of length smaller than n^2 . Thus, the word from this phase also has length at most $\mathcal{O}(n^3)/f(n)$.

Altogether, our reset word has length at most $n^3/f(n)$, which is in $o(n^3)$. ◀

5 Conclusions, discussion, and open problems

In the general case of an automaton and its k -avoiding threshold, we have a complete asymptotic solution for $k \geq 3$. The cases of $k = 2$ and $k = 1$ are open, yet a conjectured solution to the latter would solve also the former.

As for now, determining the maximum 1-avoiding threshold is the core problem, in particular in the class of synchronizing automata, but the general case of an automaton does not seem different for $k = 1$. Here, we considered a precise bound and have shown that $2n - 3$ is attainable for every $n \geq 2$. Yet, a few isolated examples reach $2n - 2$. We have the following conjecture:

A *trivial extension* of an automaton (Q, Σ, δ) is any automaton $(Q, \Sigma \cup \Sigma', \delta \cup \delta')$ such that each letter from Σ' act either as an identity or as a letter from Σ .

► **Conjecture 13.** *For an n -state automaton, the 1-avoiding threshold is at most $2n - 3$, except for a finite number of cases and their trivial extensions, where it is equal to $2n - 2$.*

A weak version (with any linear bound) of Conjecture 13 implies the following:

► **Conjecture 14.** *For an n -state automaton, a tight upper bound on 2-avoiding threshold is $\mathcal{O}(n^2)$.*

Conjecture 13 was verified for small cases [7], in particular up to 11 states for binary synchronizing automata. We have also experimented with the case of $k = 2$. The maximum 2-avoiding threshold of an n -state binary synchronizing automaton for $n = 3, \dots, 10$ equals respectively 6, 8, 12, 17, 19, 23, 25, and 28. However, for this problem, the range is much too small to reveal the tendency.

The case of synchronizing automata is much harder, and the problem remains open for all k . We have the trivial upper bound $\mathcal{O}(n^3)$, thus the situation is surely different than in the general case already for $k \geq 4$ and most likely already for $k \geq 2$.

We have made an effort to find a lower bound on the maximum possible k -avoiding threshold also for $k \geq 2$. We have not found any series of automata that would exceed the upper bound $\mathcal{O}(kn)$ (when k is a variable). This bound is easily met, for example by the well-known Rystsov series [10] with a sink (zero) state and reset threshold $n(n-1)/2$. We should consider the following:

► **Conjecture 15.** *For an n -state synchronizing automaton, the k -avoiding threshold is at most $\mathcal{O}(kn)$ (when k is a variable).*

It turns out that this is a weaker (by several means) version of the disproved Don's conjecture [3, Conjecture 18], which states that if a subset T is reachable, then it is reachable with a word of length at most $n(n - |T|)$. We know that Conjecture 15 does not hold for non-synchronizing automata, and even for synchronizing automata with the original non-asymptotic bound (by e.g., Theorem 4 for $k = 1$). On the other hand, if the reset threshold is at most quadratic, then the conjecture trivially holds for $k \in \Theta(n)$.

Finally, we have noted that a subquadratic upper bound on k -avoiding threshold of a synchronizing automaton for small, but non-constant, values of k , is enough to imply a subcubic upper bound on reset threshold. This should motivate further efforts on bounding avoiding thresholds. Since the current upper bound on 1-avoiding threshold is quadratic, this requires both decreasing it and generalizing to k -avoiding thresholds for small k . We know that a subquadratic upper bound for $k = 2$ is not possible in the class of non-synchronizing automata. Yet, our conjectures are much stronger than the required upper bound to give further improvements.

Abstract

Temporal logics for the specification of information-flow properties are able to express relations between multiple executions of a system. The two most important such logics are HyperLTL and HyperCTL*, which generalise LTL and CTL* by trace quantification. It is known that this expressiveness comes at a price, i.e. satisfiability is undecidable for both logics.

In this paper we settle the exact complexity of these problems, showing that both are in fact highly undecidable: we prove that HyperLTL satisfiability is Σ_1^1 -complete and HyperCTL* satisfiability is Σ_1^2 -complete. These are significant increases over the previously known lower bounds and the first upper bounds. To prove Σ_1^2 -membership for HyperCTL*, we prove that every satisfiable HyperCTL* sentence has a model that is equinumerous to the continuum, the first upper bound of this kind. We prove this bound to be tight. Finally, we show that the membership problem for every level of the HyperLTL quantifier alternation hierarchy is Π_1^1 -complete.

1 Introduction

Most classical temporal logics like LTL and CTL* refer to a single execution trace at a time while information-flow properties, which are crucial for security-critical systems, require reasoning about multiple executions of a system. Clarkson and Schneider [13] coined the term *hyperproperties* for such properties which, structurally, are sets of *sets* of traces. Just like ordinary trace and branching-time properties, hyperproperties can be specified using temporal logics, e.g. HyperLTL and HyperCTL* [12], expressive, but intuitive specification languages that are able to express typical information-flow properties such as noninterference, noninference, declassification, and input determinism. Due to their practical relevance and theoretical elegance, hyperproperties and their specification languages have received considerable attention during the last decade [1, 2, 5, 6, 7, 10, 12, 13, 14, 16, 26, 28, 31, 32, 39].

HyperLTL is obtained by extending LTL [34], the most influential specification language for linear-time properties, by trace quantifiers to refer to multiple executions of a system. For example, the HyperLTL formula

$$\forall\pi. \forall\pi'. \mathbf{G}(i_\pi \leftrightarrow i_{\pi'}) \rightarrow \mathbf{G}(o_\pi \leftrightarrow o_{\pi'})$$

expresses input determinism, i.e. every pair of traces that always has the same input (represented by the proposition i) also always has the same output (represented by the proposition o). Similarly, HyperCTL* is the extension of the branching-time logic CTL* [17] by path quantifiers. HyperLTL only allows formulas in prenex normal form while HyperCTL* allows arbitrary quantification, in particular under the scope of temporal operators. Consequently, HyperLTL formulas are evaluated over sets of traces while HyperCTL* formulas are evaluated over transition systems, which yield the underlying branching structure of the traces.

All basic verification problems, e.g. model checking [18, 25], runtime monitoring [3, 8, 11, 24], and synthesis [9, 21, 22], have been studied. Most importantly, HyperCTL* model checking over finite transition systems is decidable and TOWER-complete for a fixed transition system [25, 33]. However, for a small number of alternations, efficient algorithms have been developed and were applied to a wide range of problems, e.g. an information-flow analysis of an I2C bus master [25], the symmetric access to a shared resource in a mutual exclusion protocol [25], and to detect the use of a defeat device to cheat in emission testing [4].

But surprisingly, the exact complexity of the satisfiability problems for HyperLTL and HyperCTL* is still open. Finkbeiner and Hahn proved that HyperLTL satisfiability is undecidable [19], a result which already holds when only considering finite sets of ultimately periodic traces and $\forall\exists$ -formulas. In fact, Finkbeiner et al. showed that HyperLTL satisfiability restricted to finite sets of ultimately periodic traces is Σ_1^0 -complete [20] (i.e. complete for the set of recursively enumerable problems). Furthermore, Hahn and Finkbeiner proved that the $\exists^*\forall^*$ -fragment has decidable satisfiability [19] while Mascle and Zimmermann studied the HyperLTL satisfiability problem restricted to bounded sets of traces [33]. The latter work implies that HyperLTL satisfiability restricted to finite sets of traces (even non ultimately periodic ones) is also Σ_1^0 -complete. Finally, Finkbeiner et al. developed tools and heuristics [20, 23].

As every HyperLTL formula can be turned into an equisatisfiable HyperCTL* formula, HyperCTL* satisfiability is also undecidable. Moreover, Rabe has shown that it is even Σ_1^1 -hard [35], i.e. it is not even arithmetical. However, both for HyperLTL and for HyperCTL* satisfiability, only lower bounds, but no upper bounds, are known.

Our Contributions. In this paper, we settle the complexity of the satisfiability problems for HyperLTL and HyperCTL* by determining exactly how undecidable they are. That is, we provide matching lower and upper bounds in terms of the analytical hierarchy and beyond, where decision problems (encoded as subsets of \mathbb{N}) are classified based on their definability by formulas of higher-order arithmetic, namely by the type of objects one can quantify over and by the number of alternations of such quantifiers. We refer to Roger's textbook [36] for fully formal definitions. For our purposes, it suffices to recall the following classes. Σ_1^0 contains the sets of natural numbers of the form

$$\{x \in \mathbb{N} \mid \exists x_0 \cdots \exists x_k. \psi(x, x_0, \dots, x_k)\}$$

where quantifiers range over natural numbers and ψ is a quantifier-free arithmetic formula. The notation Σ_1^0 signifies that there is a single block of existential quantifiers (the subscript 1) ranging over natural numbers (type 0 objects, explaining the superscript 0). Analogously, Σ_1^1

is induced by arithmetic formulas with existential quantification of type 1 objects (functions mapping natural numbers to natural numbers) and arbitrary (universal and existential) quantification of type 0 objects. Finally, Σ_1^2 is induced by arithmetic formulas with existential quantification of type 2 objects (functions mapping type 1 objects to natural numbers) and arbitrary quantification of type 0 and type 1 objects. So, Σ_1^0 is part of the first level of the arithmetic hierarchy, Σ_1^1 is part of the first level of the analytical hierarchy, while Σ_1^2 is not even analytical.

In terms of this classification, we prove that HyperLTL satisfiability is Σ_1^1 -complete while HyperCTL* satisfiability is Σ_1^2 -complete, thereby settling the complexity of both problems and showing that they are highly undecidable. In both cases, this is a significant increase of the lower bound and the first upper bound.

First, let us consider HyperLTL satisfiability. The Σ_1^1 lower bound is a reduction from the recurrent tiling problem, a standard Σ_1^1 -complete problem asking whether $\mathbb{N} \times \mathbb{N}$ can be tiled by a given finite set of tiles. So, let us consider the upper bound: Σ_1^1 allows to quantify over type 1 objects: functions from natural numbers to natural numbers, or, equivalently, over sets of natural numbers, i.e. countable objects. On the other hand, HyperLTL formulas are evaluated over sets of infinite traces, i.e. uncountable objects. Thus, to show that quantification over type 1 objects is sufficient, we need to apply a result of Finkbeiner and Zimmermann proving that every satisfiable HyperLTL formula has a countable model [26]. Then, we can prove Σ_1^1 -membership by expressing the existence of a model and the existence of appropriate Skolem functions for the trace quantifiers by type 1 quantification. We also prove that the satisfiability problem remains Σ_1^1 -complete when restricted to ultimately periodic traces, or, equivalently, when restricted to finite traces.

Then, we turn our attention to HyperCTL* satisfiability. Recall that HyperCTL* formulas are evaluated over (possibly infinite) transition systems, which can be much larger than type 2 objects whose cardinality is bounded by \mathfrak{c} , the cardinality of the continuum. Hence, to obtain our upper bound on the complexity we need, just like in the case of HyperLTL, an upper bound on the size of minimal models of satisfiable HyperCTL* formulas. To this end, we generalise the proof of Finkbeiner and Zimmermann to HyperCTL*, showing that every satisfiable HyperCTL* formula has a model of size \mathfrak{c} . We also exhibit a satisfiable HyperCTL* formula $\varphi_{\mathfrak{c}}$ whose models all have at least cardinality \mathfrak{c} , as they have to encode all subsets of \mathbb{N} by disjoint paths. Thus, our upper bound \mathfrak{c} is tight.

With this upper bound on the cardinality of models, we are able to prove Σ_1^2 -membership of HyperCTL* satisfiability by expressing with type 2 quantification the existence of a model and the existence of a winning strategy in the induced model checking game. The matching lower bound is proven by directly encoding the arithmetic formulas inducing Σ_1^2 as instances of the HyperCTL* satisfiability problem. To this end, we use the formula $\varphi_{\mathfrak{c}}$ whose models have for each subset $A \subseteq \mathbb{N}$ a path encoding A . Now, quantification over type 0 objects (natural numbers) is simulated by quantification of a path encoding a singleton set, quantification over type 1 objects (which can be assumed to be sets of natural numbers) is simulated by quantification over the paths encoding such subsets, and existential quantification over type 2 objects (which can be assumed to be subsets of $2^{\mathbb{N}}$) is simulated by the choice of the model, i.e. a model encodes k subsets of $2^{\mathbb{N}}$ if there are k existential type 2 quantifiers. Finally, the arithmetic operations can easily be implemented in HyperLTL, and therefore also in HyperCTL*.

After settling the complexity of satisfiability, we turn our attention to the HyperLTL quantifier alternation hierarchy and its relation to satisfiability. Rabe remarks that the hierarchy is strict [35], and Mascle and Zimmermann show that every HyperLTL formula has

a polynomial-time computable equi-satisfiable formula with one quantifier alternation [33]. Here, we present a novel proof of strictness by embedding the FO[<] alternation hierarchy, which is also strict [15, 37]. We use our construction to prove that for every $n > 0$, deciding whether a given formula is equivalent to a formula with at most n quantifier alternations is Π_1^1 -complete (i.e. the co-class of Σ_1^1).

All proofs omitted due to space restrictions can be found in the full version [27].

2 Preliminaries

Fix a finite set AP of atomic propositions. A *trace* over AP is a map $t: \mathbb{N} \rightarrow 2^{\text{AP}}$, denoted by $t(0)t(1)t(2)\dots$. It is *ultimately periodic*, if $t = x \cdot y^\omega$ for some $x, y \in (2^{\text{AP}})^+$, i.e. there are $s, p > 0$ with $t(n) = t(n+p)$ for all $n \geq s$. The set of all traces over AP is $(2^{\text{AP}})^\omega$.

A transition system $\mathcal{T} = (V, E, v_I, \lambda)$ consists of a set V of vertices, a set $E \subseteq V \times V$ of (directed) edges, an initial vertex $v_I \in V$, and a labelling $\lambda: V \rightarrow 2^{\text{AP}}$ of the vertices by sets of atomic propositions. A path ρ through \mathcal{T} is an infinite sequence $\rho(0)\rho(1)\rho(2)\dots$ of vertices with $(\rho(n), \rho(n+1)) \in E$ for every $n \geq 0$.

HyperLTL. The formulas of HyperLTL are given by the grammar

$$\varphi ::= \exists \pi. \varphi \mid \forall \pi. \varphi \mid \psi \qquad \psi ::= a_\pi \mid \neg \psi \mid \psi \vee \psi \mid \mathbf{X} \psi \mid \psi \mathbf{U} \psi$$

where a ranges over atomic propositions in AP and where π ranges over a fixed countable set \mathcal{V} of (*trace*) *variables*. Conjunction, implication, and equivalence are defined as usual, and the temporal operators eventually **F** and always **G** are derived as $\mathbf{F} \psi = \neg \psi \mathbf{U} \psi$ and $\mathbf{G} \psi = \neg \mathbf{F} \neg \psi$. A *sentence* is a formula without free variables.

The semantics of HyperLTL is defined with respect to a *trace assignment*, a partial mapping $\Pi: \mathcal{V} \rightarrow (2^{\text{AP}})^\omega$. The assignment with empty domain is denoted by Π_\emptyset . Given a trace assignment Π , a variable π , and a trace t we denote by $\Pi[\pi \rightarrow t]$ the assignment that coincides with Π everywhere but at π , which is mapped to t . Furthermore, $\Pi[j, \infty)$ denotes the trace assignment mapping every π in Π 's domain to $\Pi(\pi)(j)\Pi(\pi)(j+1)\Pi(\pi)(j+2)\dots$, its suffix from position j onwards.

For sets T of traces and trace assignments Π we define

- $(T, \Pi) \models a_\pi$ if $a \in \Pi(\pi)(0)$,
- $(T, \Pi) \models \neg \psi$ if $(T, \Pi) \not\models \psi$,
- $(T, \Pi) \models \psi_1 \vee \psi_2$ if $(T, \Pi) \models \psi_1$ or $(T, \Pi) \models \psi_2$,
- $(T, \Pi) \models \mathbf{X} \psi$ if $(T, \Pi[1, \infty)) \models \psi$,
- $(T, \Pi) \models \psi_1 \mathbf{U} \psi_2$ if there is a $j \geq 0$ such that $(T, \Pi[j, \infty)) \models \psi_2$ and for all $0 \leq j' < j$: $(T, \Pi[j', \infty)) \models \psi_1$,
- $(T, \Pi) \models \exists \pi. \varphi$ if there exists a trace $t \in T$ such that $(T, \Pi[\pi \rightarrow t]) \models \varphi$, and
- $(T, \Pi) \models \forall \pi. \varphi$ if for all traces $t \in T$: $(T, \Pi[\pi \rightarrow t]) \models \varphi$.

We say that T *satisfies* a sentence φ if $(T, \Pi_\emptyset) \models \varphi$. In this case, we write $T \models \varphi$ and say that T is a *model* of φ . Although HyperLTL sentences are required to be in prenex normal form, they are closed under Boolean combinations, which can easily be seen by transforming such formulas into prenex normal form. Two HyperLTL sentences φ and φ' are equivalent if $T \models \varphi$ if and only if $T \models \varphi'$ for every set T of traces.

HyperCTL*. The formulas of HyperCTL* are given by the grammar

$$\varphi ::= a_\pi \mid \neg\varphi \mid \varphi \vee \varphi \mid \mathbf{X}\varphi \mid \varphi \mathbf{U}\varphi \mid \exists\pi. \varphi \mid \forall\pi. \varphi$$

where a ranges over atomic propositions in AP and where π ranges over a fixed countable set \mathcal{V} of (*path*) *variables*, and where we require that each temporal operator appears in the scope of a path quantifier. Again, other Boolean connectives and temporal operators are derived as usual. Sentences are formulas without free variables.

Let \mathcal{T} be a transition system. The semantics of HyperCTL* is defined with respect to a *path assignment*, a partial mapping Π from variables in \mathcal{V} to paths of \mathcal{T} . The assignment with empty domain is denoted by Π_\emptyset . Given a path assignment Π , a variable π , and a path ρ we denote by $\Pi[\pi \rightarrow \rho]$ the assignment that coincides with Π everywhere but at π , which is mapped to ρ . Furthermore, $\Pi[j, \infty)$ denotes the path assignment mapping every π in Π 's domain to $\Pi(\pi)(j)\Pi(\pi)(j+1)\Pi(\pi)(j+2)\cdots$, its suffix from position j onwards.

For transition systems \mathcal{T} and path assignments Π we define

- $(\mathcal{T}, \Pi) \models a_\pi$ if $a \in \lambda(\Pi(\pi)(0))$, where λ is the labelling function of \mathcal{T} ,
- $(\mathcal{T}, \Pi) \models \neg\psi$ if $(\mathcal{T}, \Pi) \not\models \psi$,
- $(\mathcal{T}, \Pi) \models \psi_1 \vee \psi_2$ if $(\mathcal{T}, \Pi) \models \psi_1$ or $(\mathcal{T}, \Pi) \models \psi_2$,
- $(\mathcal{T}, \Pi) \models \mathbf{X}\psi$ if $(\mathcal{T}, \Pi[1, \infty)) \models \psi$,
- $(\mathcal{T}, \Pi) \models \psi_1 \mathbf{U}\psi_2$ if there exists a $j \geq 0$ such that $(\mathcal{T}, \Pi[j, \infty)) \models \psi_2$ and for all $0 \leq j' < j$: $(\mathcal{T}, \Pi[j', \infty)) \models \psi_1$,
- $(\mathcal{T}, \Pi) \models \exists\pi. \varphi$ if there exists a path ρ of \mathcal{T} , starting in $\text{rcnt}(\Pi)$, such that $(\mathcal{T}, \Pi[\pi \rightarrow \rho]) \models \varphi$, and
- $(\mathcal{T}, \Pi) \models \forall\pi. \varphi$ if for all paths ρ of \mathcal{T} starting in $\text{rcnt}(\Pi)$: $(\mathcal{T}, \Pi[\pi \rightarrow \rho]) \models \varphi$.

Here, $\text{rcnt}(\Pi)$ is the initial vertex of $\Pi(\pi)$, where π is the path variable most recently added to Π , and the initial vertex of \mathcal{T} if Π is empty.¹ We say that \mathcal{T} *satisfies* a sentence φ if $(\mathcal{T}, \Pi_\emptyset) \models \varphi$. In this case, we write $\mathcal{T} \models \varphi$ and say that \mathcal{T} is a *model* of φ .

Complexity Classes for Undecidable Problems. A type 0 object is a natural number $n \in \mathbb{N}$, a type 1 object is a function $f: \mathbb{N} \rightarrow \mathbb{N}$, and a type 2 object is a function $f: (\mathbb{N} \rightarrow \mathbb{N}) \rightarrow \mathbb{N}$. As usual, predicate logic with quantification over type 0 objects (first-order quantifiers) is called first-order logic. Second- and third-order logic are defined similarly.

We consider formulas of arithmetic, i.e. predicate logic with signature $(0, 1, +, \cdot, <)$ evaluated over the natural numbers. With a single free variable of type 0, such formulas define sets of natural numbers (see, e.g. Rogers [36] for more details):

- Σ_1^0 contains the sets of the form $\{x \in \mathbb{N} \mid \exists x_0 \cdots \exists x_k. \psi(x, x_0, \dots, x_k)\}$ where ψ is a quantifier-free arithmetic formula and the x_i are variables of type 0.
- Σ_1^1 contains the sets of the form $\{x \in \mathbb{N} \mid \exists x_0 \cdots \exists x_k. \psi(x, x_0, \dots, x_k)\}$ where ψ is an arithmetic formula with arbitrary (existential and universal) quantification over type 0 objects and the x_i are variables of type 1.
- Σ_1^2 contains the sets of the form $\{x \in \mathbb{N} \mid \exists x_0 \cdots \exists x_k. \psi(x, x_0, \dots, x_k)\}$ where ψ is an arithmetic formula with arbitrary (existential and universal) quantification over type 0 and type 1 objects and the x_i are variables of type 2.

Note that there is a bijection between functions of the form $f: \mathbb{N} \rightarrow \mathbb{N}$ and subsets of \mathbb{N} , which is implementable in arithmetic. Similarly, there is a bijection between functions of the

¹ For the sake of simplicity, we refrain from formalising this notion properly, which would require to keep track of the order in which variables are added to Π 's domain.

form $f: (\mathbb{N} \rightarrow \mathbb{N}) \rightarrow \mathbb{N}$ and subsets of $2^{\mathbb{N}}$, which is again implementable in arithmetic. Thus, whenever convenient, we use quantification over sets of natural numbers and over sets of sets of natural numbers, instead of quantification over type 1 and type 2 objects; in particular when proving lower bounds. We then include \in in the signature.

3 HyperLTL satisfiability is Σ_1^1 -complete

In this section we settle the complexity of the satisfiability problem for HyperLTL: given a HyperLTL sentence, determine whether it has a model.

► **Theorem 1.** *HyperLTL satisfiability is Σ_1^1 -complete.*

We should contrast this result with [20, Theorem 1], which shows that HyperLTL satisfiability by *finite* sets of ultimately periodic traces is Σ_1^0 -complete. The Σ_1^1 -completeness of HyperLTL satisfiability in the general case implies that, in particular, the set of satisfiable HyperLTL sentences is neither recursively enumerable nor co-recursively enumerable. A semi-decision procedure, like the one introduced in [20] for finite sets of ultimately periodic traces, therefore cannot exist in general.

The Σ_1^1 upper bound relies on the fact that every satisfiable HyperLTL formula has a countable model [26]. This allows us to represent these models, and Skolem functions on them, by sets of natural numbers, which are type 1 objects. In this encoding, trace assignments are type 0 objects, as traces in a countable set can be identified by natural numbers. With some more existential type 1 quantification one can then express the existence of a function witnessing that every trace assignment consistent with the Skolem functions satisfies the quantifier-free part of the formula under consideration.

► **Lemma 2.** *HyperLTL satisfiability is in Σ_1^1 .*

Proof. Let φ be a HyperLTL formula, let Φ denote the set of quantifier-free subformulas of φ , and let Π be a trace assignment whose domain contains the variables of φ . The expansion of φ on Π is the function $e_{\varphi, \Pi}: \Phi \times \mathbb{N} \rightarrow \{0, 1\}$ with

$$e_{\varphi, \Pi}(\psi, j) = \begin{cases} 1 & \text{if } \Pi[j, \infty) \models \psi, \text{ and} \\ 0 & \text{otherwise.} \end{cases}$$

The expansion is completely characterised by the following consistency conditions:

- $e_{\varphi, \Pi}(a_{\pi}, j) = 1$ if and only if $a \in \Pi(\pi)(j)$.
- $e_{\varphi, \Pi}(\neg\psi, j) = 1$ if and only if $e_{\varphi, \Pi}(\psi, j) = 0$.
- $e_{\varphi, \Pi}(\psi_1 \vee \psi_2, j) = 1$ if and only if $e_{\varphi, \Pi}(\psi_1, j) = 1$ or $e_{\varphi, \Pi}(\psi_2, j) = 1$.
- $e_{\varphi, \Pi}(\mathbf{X}\psi, j) = 1$ if and only if $e_{\varphi, \Pi}(\psi, j + 1) = 1$.
- $e_{\varphi, \Pi}(\psi_1 \mathbf{U} \psi_2, j) = 1$ if and only if there is a $j' \geq j$ such that $e_{\varphi, \Pi}(\psi_2, j') = 1$ and $e_{\varphi, \Pi}(\psi_2, j'') = 1$ for all j'' in the range $j \leq j'' < j'$.

Every satisfiable HyperLTL sentence has a countable model [26]. Hence, to prove that the HyperLTL satisfiability problem is in Σ_1^1 , we express, for a given HyperLTL sentence encoded as a natural number, the existence of the following type 1 objects (relying on the fact that there is a bijection between finite sequences over \mathbb{N} and \mathbb{N} itself):

- A countable set of traces over the propositions of φ encoded as a function T from $\mathbb{N} \times \mathbb{N}$ to \mathbb{N} , mapping trace names and positions to (encodings of) subsets of the set of propositions appearing in φ .

- A function S from $\mathbb{N} \times \mathbb{N}^*$ to \mathbb{N} to be interpreted as Skolem functions for the existentially quantified variables of φ , i.e. we map a variable (identified by a natural number) and a trace assignment of the variables preceding it (encoded as a sequence of natural numbers) to a trace name.
- A function E from $\mathbb{N} \times \mathbb{N} \times \mathbb{N}$ to \mathbb{N} , where, for a fixed $a \in \mathbb{N}$ encoding a trace assignment Π , the function $x, y \mapsto E(a, x, y)$ is interpreted as the expansion of φ on Π , i.e. x encodes a subformula in Φ and y is a position.

Then, we express the following properties using only type 0 quantification: For every trace assignment of the variables in φ , encoded by $a \in \mathbb{N}$, if a is consistent with the Skolem function encoded by S , then the function $x, y \mapsto E(a, x, y)$ satisfies the consistency conditions characterising the expansion, and we have $E(a, x_0, 0) = 1$, where x_0 is the encoding of the maximal quantifier-free subformula of φ . We leave the tedious, but standard, details to the industrious reader. ◀

Now, we prove hardness.

► **Lemma 3.** *HyperLTL satisfiability is Σ_1^1 -hard.*

Proof. By a reduction from the *recurring tiling problem* which is given as follows. A *tile* is a function $\tau: \{\text{east, west, north, south}\} \rightarrow \mathcal{C}$ that maps directions into a finite set \mathcal{C} of colours. Given a finite set \mathcal{T} of tiles, a *tiling of the positive quadrant* with \mathcal{T} is a function $T: \mathbb{N} \times \mathbb{N} \rightarrow \mathcal{T}$ with the property that:

- if $T(i, j) = \tau_1$ and $T(i + 1, j) = \tau_2$, then $\tau_1(\text{east}) = \tau_2(\text{west})$ and
- if $T(i, j) = \tau_1$ and $T(i, j + 1) = \tau_2$ then $\tau_1(\text{north}) = \tau_2(\text{south})$.

The *recurring tiling problem* is to determine, given a finite set \mathcal{T} of tiles and a designated $\tau_0 \in \mathcal{T}$, whether there is a tiling T of the positive quadrant with \mathcal{T} such that there are infinitely many $j \in \mathbb{N}$ such that $T(0, j) = \tau_0$. This problem is known to be Σ_1^1 -complete [29], so if we reduce it to HyperLTL satisfiability this will establish the desired hardness result.

In our reduction, each x -coordinate in the positive quadrant will be represented by a trace, and each y -coordinate by a point in time.² In order to keep track of which trace represents which x -coordinate, we use one designated atomic proposition x that holds on exactly one time point in each trace: x holds at time i if and only if the trace represents x -coordinate i .

For this purpose, let \mathcal{T} be given, and define the following formulas over $\text{AP} = \{x\} \cup \mathcal{T}$:

- Every trace has exactly one point where x holds:

$$\varphi_1 = \forall \pi. (\neg x_\pi \mathbf{U}(x_\pi \wedge \mathbf{X} \mathbf{G} \neg x_\pi))$$

- For every $i \in \mathbb{N}$, there is a trace with x in the i -th position:

$$\varphi_2 = (\exists \pi. x_\pi) \wedge (\forall \pi_1. \exists \pi_2. \mathbf{F}(x_{\pi_1} \wedge \mathbf{X} x_{\pi_2}))$$

- If two traces represent the same x -coordinate, then they contain the same tiles:

$$\varphi_3 = \forall \pi_1. \forall \pi_2. (\mathbf{F}(x_{\pi_1} \wedge x_{\pi_2}) \rightarrow \mathbf{G}(\bigwedge_{\tau \in \mathcal{T}} (\tau_{\pi_1} \leftrightarrow \tau_{\pi_2})))$$

² Note that this means that if we were to visually represent this construction, traces would be arranged vertically.

47:8 HyperLTL Satisfiability Is Σ_1^1 -Complete, HyperCTL* Satisfiability Is Σ_1^2 -Complete

- Every time point in every trace contains exactly one tile:

$$\varphi_4 = \forall \pi. \mathbf{G} \bigvee_{\tau \in \mathcal{T}} (\tau_\pi \wedge \bigwedge_{\tau' \in \mathcal{T} \setminus \{\tau\}} \neg(\tau')_\pi)$$

- Tiles match vertically:

$$\varphi_5 = \forall \pi. \mathbf{G} \bigvee_{\tau \in \mathcal{T}} (\tau_\pi \wedge \bigvee_{\tau' \in \{\tau' \in \mathcal{T} \mid \tau(\text{north}) = \tau'(\text{south})\}} \mathbf{X}(\tau')_\pi)$$

- Tiles match horizontally:

$$\varphi_6 = \forall \pi_1. \forall \pi_2. (\mathbf{F}(x_{\pi_1} \wedge \mathbf{X}x_{\pi_2}) \rightarrow \mathbf{G} \bigvee_{\tau \in \mathcal{T}} (\tau_{\pi_1} \wedge \bigvee_{\tau' \in \{\tau' \in \mathcal{T} \mid \tau(\text{east}) = \tau'(\text{west})\}} (\tau')_{\pi_2}))$$

- Tile τ_0 occurs infinitely often at x -position 0:

$$\varphi_7 = \exists \pi. (x_\pi \wedge \mathbf{GF} \tau_0)$$

Finally, take $\varphi_{\mathcal{T}} = \bigwedge_{1 \leq i \leq 7} \varphi_i$. Technically $\varphi_{\mathcal{T}}$ is not a HyperLTL formula, since it is not in prenex normal form, but it can be trivially transformed into one. Collectively, subformulas φ_1 – φ_3 are satisfied in exactly those sets of traces that can be interpreted as $\mathbb{N} \times \mathbb{N}$. Subformulas φ_4 – φ_6 then hold if and only if the $\mathbb{N} \times \mathbb{N}$ grid is correctly tiled with \mathcal{T} . Subformula φ_7 , finally, holds if and only if the tiling uses the tile τ_0 infinitely often at x -coordinate 0. Overall, this means $\varphi_{\mathcal{T}}$ is satisfiable if and only if \mathcal{T} can recurrently tile the positive quadrant.

The Σ_1^1 -hardness of HyperLTL satisfiability therefore follows from the Σ_1^1 -hardness of the recurring tiling problem [29]. ◀

The Σ_1^1 -completeness of HyperLTL satisfiability still holds if we restrict to ultimately periodic traces.

► **Theorem 4.** *HyperLTL satisfiability restricted to sets of ultimately periodic traces is Σ_1^1 -complete.*

Proof. The problem of whether there is a tiling of $\{(i, j) \in \mathbb{N}^2 \mid i \geq j\}$, i.e. the part of $\mathbb{N} \times \mathbb{N}$ below the diagonal, such that a designated tile τ_0 occurs on every row, is also Σ_1^1 -complete [29].³ We reduce this problem to HyperLTL satisfiability on ultimately periodic traces.

The reduction is very similar to the one discussed above, with the necessary changes being: (i) every time point beyond x satisfies the special tile “null”, (ii) horizontal and vertical matching are only checked at or before time point x and (iii) for every π_1 there is a π_2 such that π_2 has designated tile τ_0 at the time where π_1 satisfies x (so τ_0 holds at least once in every row).

Membership in Σ_1^1 can be shown similarly to the proof of Lemma 2. So, the problem is Σ_1^1 -complete. ◀

³ The proof in [29] is for the part *above* the diagonal with τ_0 occurring on every column, but that is easily seen to be equivalent.

4 The HyperLTL Quantifier Alternation Hierarchy

The number of quantifier alternations in a formula is a crucial parameter in the complexity of HyperLTL model-checking [25, 35]. A natural question is then to understand *which* properties can be expressed with n quantifier alternations, that is, given a sentence φ , determine if there exists an equivalent one with at most n alternations. In this section, we show that this problem is in fact exactly as hard as the HyperLTL unsatisfiability problem (which asks whether a HyperLTL sentence has no model), and therefore Π_1^1 -complete. Here, Π_1^1 is the co-class of Σ_1^1 , i.e. it contains the complements of the Σ_1^1 sets.

Formally, the HyperLTL quantifier alternation hierarchy is defined as follows. Let φ be a HyperLTL formula. We say that φ is a Σ_0 - or a Π_0 -formula if it is quantifier-free. It is a Σ_n -formula if it is of the form $\varphi = \exists\pi_1 \cdots \exists\pi_k. \psi$ and ψ is a Π_{n-1} -formula. It is a Π_n -formula if it is of the form $\varphi = \forall\pi_1 \cdots \forall\pi_k. \psi$ and ψ is a Σ_{n-1} -formula. We do not require each block of quantifiers to be non-empty, i.e. we may have $k = 0$ and $\varphi = \psi$. By a slight abuse of notation, we also let Σ_n denote the set of hyperproperties definable by a Σ_n -sentence, that is, the set of all $L(\varphi) = \{T \subseteq (2^{\text{AP}})^\omega \mid T \models \varphi\}$ such that φ is a Σ_n -sentence of HyperLTL.

► **Theorem 5** ([35, Corollary 5.6.5]). *The quantifier alternation hierarchy of HyperLTL is strict: for all $n > 0$, $\Sigma_n \subsetneq \Sigma_{n+1}$.*

The strictness of the hierarchy also holds if we restrict our attention to sentences whose models consist of finite sets of traces that end in the suffix \emptyset^ω , i.e. that are essentially finite.

► **Theorem 6.** *For all $n > 0$, there exists a Σ_{n+1} -sentence φ of HyperLTL that is not equivalent to any Σ_n -sentence, and such that for all $T \subseteq (2^{\text{AP}})^\omega$, if $T \models \varphi$ then T contains finitely many traces and $T \subseteq (2^{\text{AP}})^* \emptyset^\omega$.*

This fact is a necessary ingredient for our argument that membership at some fixed level of the quantifier alternation hierarchy is Π_1^1 -hard. It could be derived from a small adaptation of the proof in [35], and we provide an alternative proof in the extended version [27] by exhibiting a connection between the HyperLTL quantifier alternation hierarchy and the quantifier alternation hierarchy for first-order logic over finite words, which is known to be strict [15, 38].

Our goal is to prove the following.

► **Theorem 7.** *Fix $n > 0$. The problem of deciding whether a HyperLTL sentence is equivalent to some Σ_n -sentence is Π_1^1 -complete.*

The easier part is the upper bound, since a corollary of Theorem 1 is that the problem of deciding whether two HyperLTL formulas are equivalent is Π_1^1 -complete. The lower bound is proven by reduction from the HyperLTL unsatisfiability problem. The proof relies on Theorem 6: given a sentence φ , we are going to combine φ with some Σ_{n+1} -sentence φ_{n+1} witnessing the strictness of the hierarchy, to construct a sentence ψ such that φ is unsatisfiable if and only if ψ is equivalent to a Σ_n -sentence. Intuitively, the formula ψ will describe models consisting of the “disjoint union” of a model of φ_{n+1} and a model of φ . Here “disjoint” is to be understood in a strong sense: we split both the set of traces and the time domain into two parts, used respectively to encode the models of φ_{n+1} and those of φ .

To make this more precise, let us introduce some notations. We assume a distinguished symbol $\$ \notin \text{AP}$. We say that a set of traces $T \subseteq (2^{\text{AP} \cup \{\$\}})^\omega$ is *bounded* if there exists $b \in \mathbb{N}$ such that $T \subseteq (2^{\text{AP}})^b \cdot \{\$\}^\omega$.

■ **Figure 1** Example of a split set of traces where each row represents a trace and $b = 3$.

► **Lemma 8.** *There exists a Π_1 -sentence φ_{bd} such that for all $T \subseteq (2^{\text{AP} \cup \{\$\}})^\omega$, we have $T \models \varphi_{bd}$ if and only if T is bounded.*

Proof. We let

$$\varphi_{bd} = \forall \pi. \forall \pi'. (\neg \$_\pi \mathbf{U} \mathbf{G} \$_\pi) \wedge \bigwedge_{a \in \text{AP}} \mathbf{G}(\neg(a_\pi \wedge \$_\pi)) \wedge \mathbf{F}(\neg \$_\pi \wedge \neg \$_{\pi'} \wedge \mathbf{X} \$_\pi \wedge \mathbf{X} \$_{\pi'}).$$

The conjunct $(\neg \$_\pi \mathbf{U} \mathbf{G} \$_\pi) \wedge \bigwedge_{a \in \text{AP}} \mathbf{G}(\neg(a_\pi \wedge \$_\pi))$ ensures that every trace is in $(2^{\text{AP}})^* \cdot \{\$\}^\omega$, while $\mathbf{F}(\neg \$_\pi \wedge \neg \$_{\pi'} \wedge \mathbf{X} \$_\pi \wedge \mathbf{X} \$_{\pi'})$ ensures that the $\$\text{'s}$ in any two traces π and π' start at the same position. ◀

We say that T is *split* if there exist $b \in \mathbb{N}$ and T_1, T_2 such that $T = T_1 \uplus T_2$, $T_1 \subseteq (2^{\text{AP}})^b \cdot \{\$\}^\omega$, and $T_2 \subseteq \{\$\}^b \cdot (2^{\text{AP}})^\omega$. Note that b is unique here. Hence, we define the left and right part of T as $T_\ell = T_1$ and $T_r = \{t \in (2^{\text{AP}})^\omega \mid \{\$\}^b \cdot t \in T_2\}$, respectively (see Figure 1).

It is easy to combine HyperLTL specifications for the left and right part of a split model into one global formula.

► **Lemma 9.** *For all HyperLTL sentences φ_ℓ, φ_r , one can construct a sentence ψ such that for all split $T \subseteq (2^{\text{AP} \cup \{\$\}})^\omega$, it holds that $T_\ell \models \varphi_\ell$ and $T_r \models \varphi_r$ if and only if $T \models \psi$.*

Proof of Lemma 9. Let $\widehat{\varphi}_r$ denote the formula obtained from φ_r by replacing:

- every existential quantification $\exists \pi. \varphi$ with $\exists \pi. ((\mathbf{F} \mathbf{G} \neg \$_\pi) \wedge \varphi)$;
 - every universal quantification $\forall \pi. \varphi$ with $\forall \pi. ((\mathbf{F} \mathbf{G} \neg \$_\pi) \rightarrow \varphi)$;
 - the quantifier-free part φ of φ_r with $\$_\pi \mathbf{U}(\neg \$_\pi \wedge \varphi)$, where π is some free variable in φ .
- Here, the first two replacements restrict quantification to traces in the right part while the last one requires the formula to hold at the first position of the right part. We define $\widehat{\varphi}_\ell$ by similarly relativizing quantifications in φ_ℓ . The formula $\widehat{\varphi}_\ell \wedge \widehat{\varphi}_r$ can then be put back into prenex normal form to define ψ . ◀

Conversely, any HyperLTL formula that only has split models can be decomposed into a Boolean combination of formulas that only talk about the left or right part of the model. This is formalised in the lemma below.

► **Lemma 10.** *For all HyperLTL Σ_n -sentences φ there exists a finite family $(\varphi_\ell^i, \varphi_r^i)_i$ of Σ_n -sentences such that for all split $T \subseteq (2^{\text{AP} \cup \{\$\}})^\omega$: $T \models \varphi$ if and only if there is an i with $T_\ell \models \varphi_\ell^i$ and $T_r \models \varphi_r^i$.*

We are now ready to prove Theorem 7.

Proof of Theorem 7. The upper bound is an easy consequence of Theorem 1: Given a HyperLTL sentence φ , we express the existence of a Σ_n -sentence ψ using first-order quantification and encode equivalence of ψ and φ via the formula $(\neg \varphi \wedge \psi) \vee (\varphi \wedge \neg \psi)$, which is unsatisfiable if and only if φ and ψ are equivalent. Altogether, this shows membership in Π_1^1 , as Π_1^1 is closed under existential first-order quantification (see, e.g. [30, Page 82]).

We prove the lower bound by reduction from the unsatisfiability problem for HyperLTL. So given a HyperLTL sentence φ , we want to construct ψ such that φ is unsatisfiable if and only if ψ is equivalent to a Σ_n -sentence.

We first consider the case $n > 1$. Fix a Σ_{n+1} -sentence φ_{n+1} that is not equivalent to any Σ_n -sentence, and such that every model of φ_{n+1} is bounded. The existence of such a formula is a consequence of Theorem 6. By Lemma 9, there exists a computable ψ such that for all split models T , we have $T \models \psi$ if and only if $T_\ell \models \varphi_{n+1}$ and $T_r \models \varphi$.

First, it is clear that if φ is unsatisfiable, then ψ is unsatisfiable as well, and thus equivalent to $\exists\pi. a_\pi \wedge \neg a_\pi$, which is a Σ_n -sentence since $n \geq 1$.

Conversely, suppose towards a contradiction that φ is satisfiable and that ψ is equivalent to some Σ_n -sentence. Let $(\psi_\ell^i, \psi_r^i)_i$ be the finite family of Σ_n -sentences given by Lemma 10 for ψ . Fix a model T_φ of φ . For a bounded T , we let \bar{T} denote the unique split set of traces such that $\bar{T}_\ell = T$ and $\bar{T}_r = T_\varphi$. For all T , we then have $T \models \varphi_{n+1}$ if and only if T is bounded and $\bar{T} \models \psi$. Recall that the set of bounded models can be defined by a Π_1 -sentence φ_{bd} (Lemma 8), which is also a Σ_n -sentence since $n > 1$. We then have $T \models \varphi_{n+1}$ if and only if $T \models \varphi_{bd}$ and there exists i such that $T \models \psi_\ell^i$ and $T_\varphi \models \psi_r^i$. So φ_{n+1} is equivalent to

$$\varphi_{bd} \wedge \bigvee_{i \text{ with } T_\varphi \models \psi_r^i} \psi_\ell^i,$$

which, since Σ_n -sentences are closed (up to logical equivalence) under conjunction and disjunction, is equivalent to a Σ_n -sentence. This contradicts the definition of φ_{n+1} .

We are left with the case $n = 1$. Similarly, we construct ψ such that φ is unsatisfiable if and only if ψ is unsatisfiable, and if and only if ψ is equivalent to a Σ_1 -sentence. However, we do not need to use bounded or split models here. Every satisfiable Σ_1 -sentence has a model with finitely many traces. Therefore, a simple way to construct ψ so that it is not equivalent to any Σ_1 -sentence (unless it is unsatisfiable) is to ensure that every model of ψ contains infinitely many traces.

Let $x \notin \text{AP}$, and $T_\omega = \{\emptyset^n \{x\} \emptyset^\omega \mid n \in \mathbb{N}\}$. As seen in the proof of Lemma 3, T_ω is definable in HyperLTL: There is a sentence φ_ω such that $T \subseteq (2^{\text{AP} \cup \{x\}})^\omega$ is a model of φ_ω if and only if $T = T_\omega$. By relativising quantifiers in φ_ω and φ to traces with or without the atomic proposition x , one can construct a HyperLTL sentence ψ such that $T \models \psi$ if and only if $T_\omega \subseteq T$ and $T \setminus T_\omega \models \varphi$.

Again, if φ is unsatisfiable then ψ is unsatisfiable and therefore equivalent to $\exists\pi. a_\pi \wedge \neg a_\pi$, a Σ_1 -sentence. Conversely, all models of ψ contain infinitely many traces and therefore, if ψ is equivalent to a Σ_1 -sentence then it is unsatisfiable, and so is φ . ◀

5 HyperCTL* satisfiability is Σ_1^2 -complete

Here, we consider the HyperCTL* satisfiability problem: given a HyperLTL sentence, determine whether it has a model \mathcal{T} (of arbitrary size). We prove that it is much harder than HyperLTL satisfiability. As a key step of the proof, we also prove that every satisfiable sentence admits a model of cardinality at most \mathfrak{c} (the cardinality of the continuum), and conversely, we exhibit a satisfiable sentence whose models are all of cardinality at least \mathfrak{c} .

► **Theorem 11.** *HyperCTL* satisfiability is Σ_1^2 -complete.*

On the other hand, HyperCTL* satisfiability restricted to finite transition systems is Σ_1^0 -complete. The upper bound follows from HyperCTL* model checking being decidable [12] (therefore, the problem is recursively enumerable and thus in Σ_1^0) while the matching lower bound is inherited from HyperLTL [19].

47:12 HyperLTL Satisfiability Is Σ_1^1 -Complete, HyperCTL* Satisfiability Is Σ_1^2 -Complete

Upper bound. We begin by proving membership in Σ_1^2 . The first step is to obtain a bound on the size of minimal models of satisfiable HyperCTL* sentences. For this, we use an argument based on Skolem functions, which is a transfinite generalisation of the proof that all satisfiable HyperLTL sentences have a countable model [26].

In the following, we use ω and ω_1 to denote the first infinite and the first uncountable ordinal, respectively, and write \aleph_0 and \aleph_1 for their cardinality.

► **Lemma 12.** *Each satisfiable HyperCTL* sentence φ has a model of size at most \mathfrak{c} .*

Proof sketch. Suppose φ has a model \mathcal{T} of arbitrary size, and fix Skolem functions witnessing this satisfaction. We then create a transfinite sequence of transition systems \mathcal{T}_α . We start by taking \mathcal{T}_0 to be any single path from \mathcal{T} starting in the initial vertex, and obtain $\mathcal{T}_{\alpha+1}$ by adding to \mathcal{T}_α all vertices and edges of the paths that are the outputs of the Skolem functions when restricted to inputs from \mathcal{T}_α . If α is a limit ordinal we take \mathcal{T}_α to be the union of all previous transition systems.

This sequence does not necessarily stabilise at ω , since \mathcal{T}_ω may contain a path ρ such that $\rho(i)$ was introduced in \mathcal{T}_i . This would result in \mathcal{T}_ω containing a path that was not present in any earlier model \mathcal{T}_i with $i < \omega$, and therefore we could have $\mathcal{T}_{\omega+1} \neq \mathcal{T}_\omega$.

The sequence does stabilise at ω_1 , however. This is because every path ρ contains only countably many vertices, so if every element $\rho(i)$ of ρ is introduced at some countable α_i , then there is a countable α such that all of ρ is included in \mathcal{T}_α . It follows that \mathcal{T}_{ω_1} does not contain any “new” paths that were not already in some \mathcal{T}_α with $\alpha < \omega_1$, and therefore the Skolem function f does not generate any “new” outputs either.

In each step of the construction at most \mathfrak{c} new vertices are added, so \mathcal{T}_{ω_1} contains at most \mathfrak{c} vertices. Furthermore, because \mathcal{T}_{ω_1} is closed under the Skolem functions, the satisfaction of φ in \mathcal{T} implies its satisfaction in \mathcal{T}_{ω_1} . ◀

With the upper bound at hand, we can place HyperCTL* satisfiability in Σ_1^2 , as the existence of a model of size \mathfrak{c} can be captured by quantification over type 2 objects.

► **Lemma 13.** *HyperCTL* satisfiability is in Σ_1^2 .*

Proof. As in the proof of Theorem 1. Because every HyperCTL* formula is satisfied in a model of size at most \mathfrak{c} , these models can be represented by objects of type 2. Checking whether a formula is satisfied in a transition system is equivalent to the existence of a winning strategy for Verifier in the induced model checking game. Such a strategy is again a type 2 object, which is existentially quantified. Finally, whether it is winning can be expressed by quantification over individual elements and paths, which are objects of types 0 and 1. Checking the satisfiability of a HyperCTL* formula φ therefore amounts to existential third-order quantification (to choose a model and a winning strategy) followed by a second-order formula to verify that φ holds on the model. Hence HyperCTL* satisfiability is in Σ_1^2 .

Formally, we encode the existence of a winning strategy for Verifier in the HyperCTL* model checking game $\mathcal{G}(\mathcal{T}, \varphi)$ induced by a transition system \mathcal{T} and a HyperCTL* formula φ . This game is played between Verifier and Falsifier, one of them aiming to prove that $\mathcal{T} \models \varphi$ and the other aiming to prove $\mathcal{T} \not\models \varphi$. It is played in a graph whose positions correspond to subformulas which they want to check (and suitable path assignments of the free variables): each vertex (say, representing a subformula ψ) belongs to one of the players who has to pick a successor, which represents a subformula of ψ . A play ends at an atomic proposition, at which point the winner can be determined.

Formally, a vertex of the game is of the form (Π, ψ, b) where Π is a path assignment, ψ is a subformula of φ , and $b \in \{0, 1\}$ is a flag used to count the number of negations encountered along the play; the initial vertex is $(\Pi_\emptyset, \varphi, 0)$. Furthermore, for until-subformulas ψ , we need auxiliary vertices of the form (Π, ψ, b, j) with $j \in \mathbb{N}$. The vertices of Verifier are

- of the form $(\Pi, \psi, 0)$ with $\psi = \psi_1 \vee \psi_2$, $\psi = \psi_1 \mathbf{U} \psi_2$, or $\psi = \exists\pi. \psi'$,
- of the form $(\Pi, \forall\pi. \psi', 1)$, or
- of the form $(\Pi, \psi_1 \mathbf{U} \psi_2, 1, j)$.

The moves of the game are defined as follows:

- A vertex (Π, a_π, b) is terminal. It is winning for Verifier if $b = 0$ and $a \in \lambda(\Pi(\pi)(0))$ or if $b = 1$ and $a \notin \lambda(\Pi(\pi)(0))$, where λ is the labelling function of \mathcal{T} .
- A vertex $(\Pi, \neg\psi, b)$ has a unique successor $(\Pi, \psi, b + 1 \bmod 2)$.
- A vertex $(\Pi, \psi_1 \vee \psi_2, b)$ has two successors of the form (Π, ψ_i, b) for $i \in \{1, 2\}$.
- A vertex $(\Pi, \mathbf{X}\psi, b)$ has a unique successor $(\Pi[1, \infty), \psi, b)$.
- A vertex $(\Pi, \psi_1 \mathbf{U} \psi_2, b)$ has a successor $(\Pi, \psi_1 \mathbf{U} \psi_2, b, j)$ for every $j \in \mathbb{N}$.
- A vertex $(\Pi, \psi_1 \mathbf{U} \psi_2, b, j)$ has the successor $(\Pi[j, \infty), \psi_2, b)$ as well as successors $(\Pi[j', \infty), \psi_1, b)$ for every $0 \leq j' < j$.
- A vertex $(\Pi, \exists\pi. \psi, b)$ has successors $(\Pi[\pi \mapsto \rho], \psi, b)$ for every path ρ of \mathcal{T} starting in $\text{rnt}(\Pi)$.
- A vertex $(\Pi, \forall\pi. \psi, b)$ has successors $(\Pi[\pi \mapsto \rho], \psi, b)$ for every path ρ of \mathcal{T} starting in $\text{rnt}(\Pi)$.

A play of the model checking game is a finite path through the graph, starting at the initial vertex and ending at a terminal vertex. It is winning for Verifier if the terminal vertex is winning for her. Note that the length of a play is bounded by $2d$, where d is the depth⁴ of φ , as the formula is simplified during each move.

A strategy σ for Verifier is a function mapping each of her vertices v to some successor of v . A play $v_0 \cdots v_k$ is consistent with σ , if $v_{k'+1} = \sigma(v_{k'})$ for every $0 \leq k' < k$ such that $v_{k'}$ is a vertex of Verifier. A straightforward induction shows that Verifier has a winning strategy for $\mathcal{G}(\mathcal{T}, \varphi)$ if and only if $\mathcal{T} \models \varphi$.

Recall that every satisfiable HyperCTL* sentence has a model of cardinality \mathfrak{c} (Lemma 12). Thus, to place HyperCTL* satisfiability in Σ_1^2 , we express, for a given natural number encoding a HyperCTL* formula φ , the existence of the following type 2 objects (using suitable encodings):

- A transition system \mathcal{T} of cardinality \mathfrak{c} .
- A function σ from V to V , where V is the set of vertices of $\mathcal{G}(\mathcal{T}, \varphi)$. Note that a single vertex of V is a type 1 object.

Then, we express that σ is a strategy for Verifier, which is easily expressible using quantification over type 1 objects. Thus, it remains to express that σ is winning by stating that every play (a sequence of type 1 objects of bounded length) that is consistent with σ ends in a terminal vertex that is winning for Verifier. Again, we leave the tedious, but standard, details to the reader. ◀

Lower bound. We first describe a satisfiable HyperCTL* sentence $\varphi_{\mathfrak{c}}$ that does not have any model of cardinality less than \mathfrak{c} (more precisely, the initial vertex must have uncountably many successors), thus matching the upper bound from Lemma 12. We construct $\varphi_{\mathfrak{c}}$ with one particular model $\mathcal{T}_{\mathfrak{c}}$ in mind, defined below, though it also admits other models.

⁴ The depth is the maximal nesting of quantifiers, Boolean connectives, and temporal operators.

■ **Figure 2** A depiction of \mathcal{T}_c . Vertices in black (on the left including the initial vertex) are labelled by **fbt**, those in red (on the right, excluding the initial vertex) are labelled by **set**.

The idea is that we want all possible subsets of $A \subseteq \mathbb{N}$ to be represented in \mathcal{T}_c in the form of paths ρ_A such that $\rho_A(i)$ is labelled by 1 if $i \in A$, and by 0 otherwise. By ensuring that the first vertices of these paths are pairwise distinct, we obtain the desired lower bound on the cardinality. We express this in HyperCTL* as follows: First, we express that there is a part of the model (labelled by **fbt**) where every reachable vertex has two successors, one labelled with 0 and one labelled with 1, i.e. the unravelling of this part contains the full binary tree. Thus, this part has a path ρ_A as above for every subset A , but their initial vertices are not necessarily distinct. Hence, we also express that there is another part (labelled by **set**) that contains a copy of each path in the **fbt**-part, and that these paths indeed start at distinct successors of the initial vertex.

We let $\mathcal{T}_c = (V_c, E_c, t_\varepsilon, \lambda_c)$ (see Figure 2), where

$$V_c = \{t_u \mid u \in \{0, 1\}^*\} \cup \{s_A^i \mid i \in \mathbb{N} \wedge A \subseteq \mathbb{N}\}$$

$$\lambda_c(t_\varepsilon) = \{\mathbf{fbt}\} \quad \lambda_c(t_{u.0}) = \{\mathbf{fbt}, 0\} \quad \lambda_c(t_{u.1}) = \{\mathbf{fbt}, 1\} \quad \lambda_c(s_A^i) = \begin{cases} \{\mathbf{set}, 0\} & \text{if } i \notin A \\ \{\mathbf{set}, 1\} & \text{if } i \in A \end{cases}$$

$$E_c = \{(t_u, t_{u0}), (t_u, t_{u1}) \mid u \in \{0, 1\}^*\} \cup \{(t_\varepsilon, s_A^0) \mid A \subseteq \mathbb{N}\} \cup \{(s_A^i, s_A^{i+1}) \mid A \subseteq \mathbb{N}, i \in \mathbb{N}\}.$$

► **Lemma 14.** *There is a satisfiable HyperCTL* sentence φ_c that has only models of cardinality at least c .*

Proof. The formula φ_c is defined as the conjunction of the formulas below:

1. The label of the initial vertex is $\{\mathbf{fbt}\}$ and the labels of non-initial vertices are $\{\mathbf{fbt}, 0\}$, $\{\mathbf{fbt}, 1\}$, $\{\mathbf{set}, 0\}$, or $\{\mathbf{set}, 1\}$:

$$\forall \pi. (\mathbf{fbt}_\pi \wedge \neg 0_\pi \wedge \neg 1_\pi \wedge \neg \mathbf{set}_\pi) \wedge \mathbf{XG}((\mathbf{set}_\pi \leftrightarrow \neg \mathbf{fbt}_\pi) \wedge (0_\pi \leftrightarrow \neg 1_\pi))$$

2. All **fbt**-labelled vertices have a successor with label $\{\mathbf{fbt}, 0\}$ and one with label $\{\mathbf{fbt}, 1\}$, and all **fbt**-labelled vertices that are additionally labelled by 0 or 1 have no **set**-labelled successor:

$$\forall \pi. \mathbf{G}(\mathbf{fbt}_\pi \rightarrow ((\exists \pi_0. \mathbf{X}(\mathbf{fbt}_{\pi_0} \wedge 0_{\pi_0})) \wedge (\exists \pi_1. \mathbf{X}(\mathbf{fbt}_{\pi_1} \wedge 1_{\pi_1}))) \wedge ((0_\pi \vee 1_\pi) \rightarrow \forall \pi'. \mathbf{X} \mathbf{fbt}_{\pi'}))$$

3. For every path of **fbt**-labelled vertices starting at a successor of the initial vertex, there is a path of **set**-labelled vertices (also starting at a successor of the initial vertex) with the same $\{0, 1\}$ labelling:

$$\forall \pi. ((\mathbf{X} \mathbf{fbt}_\pi) \rightarrow \exists \pi'. \mathbf{X}(\mathbf{set}_{\pi'} \wedge \mathbf{G}(0_\pi \leftrightarrow 0_{\pi'})))$$

4. Any two paths starting in the same **set**-labelled vertex have the same sequence of labels:

$$\forall \pi. \mathbf{G}(\mathbf{set}_\pi \rightarrow \forall \pi'. \mathbf{G}(0_\pi \leftrightarrow 0_{\pi'})).$$

It is easy to check that $\mathcal{T}_c \models \varphi_c$. Note however that it is not the only model of φ_c : for instance, some paths may be duplicated, or merged after some steps if their label sequences share a common suffix. So, consider an arbitrary transition system $\mathcal{T} = (V, E, v_I, \lambda)$ such that $\mathcal{T} \models \varphi_c$. By condition 2, for every set $A \subseteq \mathbb{N}$, there is a path ρ_A starting at a successor of v_I such that $\lambda(\rho_A(i)) = \{\mathbf{fbt}, 1\}$ if $i \in A$ and $\lambda(\rho_A(i)) = \{\mathbf{fbt}, 0\}$ if $i \notin A$. Condition 3 implies that there is also a **set**-labelled path ρ'_A such that ρ'_A starts at a successor of v_I , and has the same $\{0, 1\}$ labelling as ρ_A . Finally, by condition 4, if $A \neq B$ then $\rho'_A(0) \neq \rho'_B(0)$. ◀

Before moving to the proof that HyperCTL* satisfiability is Σ_1^2 -hard, we introduce one last auxiliary formula that will be used in the reduction, showing that addition and multiplication can be defined in HyperCTL*, and in fact even in HyperLTL, as follows: Let $\text{AP} = \{\mathbf{arg1}, \mathbf{arg2}, \mathbf{res}, \mathbf{add}, \mathbf{mult}\}$ and let $T_{(+, \cdot)}$ be the set of all traces $t \in (2^{\text{AP}})^\omega$ such that

- there are unique $n_1, n_2, n_3 \in \mathbb{N}$ with $\mathbf{arg1} \in t(n_1)$, $\mathbf{arg2} \in t(n_2)$, and $\mathbf{res} \in t(n_3)$, and
- either $\mathbf{add} \in t(n)$ for all n and $n_1 + n_2 = n_3$, or $\mathbf{mult} \in t(n)$ for all n and $n_1 \cdot n_2 = n_3$.

► **Lemma 15.** *There is a HyperLTL sentence $\varphi_{(+, \cdot)}$ which has $T_{(+, \cdot)}$ as unique model.*

To establish Σ_1^2 -hardness, we give an encoding of formulas of existential third-order arithmetic into HyperCTL*. As explained in Section 2, we can (and do for the remainder of the section) assume that first-order (type 0) variables range over natural numbers, second-order (type 1) variables range over sets of natural numbers, and third-order (type 2) variables range over sets of sets of natural numbers.

► **Lemma 16.** *Suppose $\varphi = \exists x_1 \dots \exists x_n. \psi$, where x_1, \dots, x_n are third-order variables, and ψ is a formula of second-order arithmetic. One can construct a HyperCTL* formula φ' such that $(\mathbb{N}, 0, 1, +, \cdot, <, \in)$ is a model of φ if and only if φ' is satisfiable.*

Proof. The idea of the proof is as follows. We represent sets of natural numbers as infinite paths with labels in $\{0, 1\}$, so that quantification over sets of natural numbers in ψ can be replaced by HyperCTL* path quantification. First-order quantification is handled in the same way, but using paths where exactly one vertex is labelled 1. In particular we encode first- and second-order variables x of φ as path variables π_x of φ' . For this to work, we need to make sure that every possible set has a path representative in the transition system (possibly several isomorphic ones). This is where formula φ_c defined in Lemma 14 is used. For arithmetical operations, we rely on the formula $\varphi_{(+, \cdot)}$ from Lemma 15. Finally, we associate with every existentially quantified third-order variable x_i an atomic proposition a_i , so that for a second-order variable y , the atomic formula $y \in x_i$ is interpreted as the atomic proposition a_i being true on π_y . This is all explained in more details below.

Let $\text{AP} = \{a_1, \dots, a_n, 0, 1, \mathbf{set}, \mathbf{fbt}, \mathbf{arg1}, \mathbf{arg2}, \mathbf{res}, \mathbf{mult}, \mathbf{add}\}$. Given an interpretation $\nu : \{x_1, \dots, x_n\} \rightarrow 2^{(2^{\mathbb{N}})}$ of the third-order variables of φ , we denote by \mathcal{T}_ν the transition system over AP obtained as follows: We start from \mathcal{T}_c , and extend it with an $\{a_1, \dots, a_n\}$ -labelling by setting $a_i \in \lambda(\rho_A(0))$ if $A \in \nu(x_i)$; then, we add to this transition system all traces in $T_{(+, \cdot)}$ as disjoint paths below the initial vertex.

From the formulas φ_c and $\varphi_{(+, \cdot)}$ defined in Lemmas 14 and 15, it is not difficult to construct a formula $\varphi_{(c, +, \cdot)}$ such that:

- For all $\nu : \{x_1, \dots, x_n\} \rightarrow 2^{(2^{\mathbb{N}})}$, the transition system \mathcal{T}_ν is a model of $\varphi_{(c, +, \cdot)}$.
- Conversely, in any model $\mathcal{T} = (V, E, v_I, \lambda)$ of $\varphi_{(c, +, \cdot)}$, the following conditions are satisfied:

47:16 HyperLTL Satisfiability Is Σ_1^1 -Complete, HyperCTL* Satisfiability Is Σ_1^2 -Complete

1. For every path ρ starting at a **set**-labelled successor of the initial vertex v_I , the vertex $\rho(0)$ has a label of the form $\lambda(\rho(0)) = \{\mathbf{set}, b\} \cup \ell$ with $b \in \{0, 1\}$ and $\ell \subseteq \{a_1, \dots, a_n\}$, and every vertex $\rho(i)$ with $i > 0$ has a label $\lambda(\rho(i)) = \{\mathbf{set}, 0\}$ or $\lambda(\rho(i)) = \{\mathbf{set}, 1\}$.
2. For every $A \subseteq \mathbb{N}$, there exists a **set**-labelled path ρ_A starting at a successor of v_I such that $1 \in \lambda(\rho_A(i))$ if $i \in A$, and $0 \in \lambda(\rho_A(i))$ if $i \notin A$. Moreover, all such paths have the same $\{a_1, \dots, a_n\}$ labelling; this can be expressed by the formula

$$\forall \pi. \forall \pi'. \mathbf{X} \left(\mathbf{G}(\mathbf{set}_\pi \wedge \mathbf{set}_{\pi'} \wedge (1_\pi \leftrightarrow 1_{\pi'})) \rightarrow \bigwedge_{a \in \{a_1, \dots, a_n\}} a_\pi \leftrightarrow a_{\pi'} \right).$$

3. For every path ρ starting at an **add**- or **mult**-labelled successor of the initial vertex, the label sequence $\lambda(\rho(0))\lambda(\rho(1)) \dots$ of ρ is in $T_{(+, \cdot)}$.
4. Conversely, for every trace $t \in T_{(+, \cdot)}$, there exists a path ρ starting at a successor of the initial vertex such that $\lambda(\rho(0))\lambda(\rho(1)) \dots = t$.

We then let $\varphi' = \varphi_{(\mathbf{c}, +, \cdot)} \wedge \exists \pi_0. \exists \pi_1. \mathbf{X}(1_{\pi_0} \wedge \mathbf{X} \mathbf{G} 0_{\pi_0} \wedge 0_{\pi_1} \wedge \mathbf{X} 1_{\pi_1} \wedge \mathbf{X} \mathbf{X} \mathbf{G} 0_{\pi_1}) \wedge h(\psi)$, where π_0 and π_1 are used to encode the constants 0 and 1, and $h(\psi)$ is defined inductively from the second-order body ψ of φ as follows:

- $h(\psi_1 \vee \psi_2) = h(\psi_1) \vee h(\psi_2)$ and $h(\neg \psi_1) = \neg h(\psi_1)$.
- If x ranges over sets of natural numbers, $h(\exists x. \psi_1) = \exists \pi_x. ((\mathbf{X} \mathbf{set}_{\pi_x}) \wedge h(\psi_1))$, and $h(\forall x. \psi_1) = \forall \pi_x. ((\mathbf{X} \mathbf{set}_{\pi_x}) \rightarrow h(\psi_1))$.
- If x ranges over natural numbers, $h(\exists x. \psi_1) = \exists \pi_x. ((\mathbf{X} \mathbf{set}_{\pi_x}) \wedge \mathbf{X}(0_{\pi_x} \mathbf{U}(1_{\pi_x} \wedge \mathbf{X} \mathbf{G} 0_{\pi_x}))) \wedge h(\psi_1)$, and $h(\forall x. \psi_1) = \forall \pi_x. ((\mathbf{X} \mathbf{set}_{\pi_x}) \wedge \mathbf{X}(0_{\pi_x} \mathbf{U}(1_{\pi_x} \wedge \mathbf{X} \mathbf{G} 0_{\pi_x}))) \rightarrow h(\psi_1)$.
- If y ranges over sets of natural numbers, $h(y \in x_i) = \mathbf{X}(a_i)_{\pi_y}$.
- If x ranges over natural numbers and y over sets of natural numbers, $h(x \in y) = \mathbf{F}(1_{\pi_x} \wedge 1_{\pi_y})$.
- $h(x < y) = \mathbf{F}(1_{\pi_x} \wedge \mathbf{X} \mathbf{F} 1_{\pi_y})$.
- $h(x \cdot y = z) = \exists \pi. (\mathbf{X} \mathbf{add}_\pi) \wedge \mathbf{F}(\mathbf{arg}1_{\pi} \wedge 1_{\pi_x}) \wedge \mathbf{F}(\mathbf{arg}2_{\pi} \wedge 1_{\pi_y}) \wedge \mathbf{F}(\mathbf{res}_\pi \wedge 1_{\pi_z})$, and $h(x + y = z) = \exists \pi. (\mathbf{X} \mathbf{mult}_\pi) \wedge \mathbf{F}(\mathbf{arg}1_{\pi} \wedge 1_{\pi_x}) \wedge \mathbf{F}(\mathbf{arg}2_{\pi} \wedge 1_{\pi_y}) \wedge \mathbf{F}(\mathbf{res}_\pi \wedge 1_{\pi_z})$.

If ψ is true under some interpretation ν of x_1, \dots, x_n as sets of sets of natural numbers, then the transition system \mathcal{T}_ν defined above is a model of φ' . Conversely, if $\mathcal{T} \models \varphi'$ for some transition system \mathcal{T} , then for all sets $A \subseteq \mathbb{N}$ there is a path ρ_A matching A in \mathcal{T} , and all such paths have the same $\{a_1, \dots, a_n\}$ -labelling, so we can define an interpretation ν of x_1, \dots, x_n by taking $A \in \nu(x_i)$ if and only if $a_i \in \lambda(\rho_A(0))$. Under this interpretation ψ holds, and thus φ is true. \blacktriangleleft

► **Lemma 17.** *HyperCTL* satisfiability is Σ_1^2 -hard.*

Proof. Let N be a Σ_1^2 set, i.e. $N = \{x \in \mathbb{N} \mid \exists x_0 \dots \exists x_k. \psi(x, x_0, \dots, x_k)\}$ for some second-order arithmetic formula ψ with existentially quantified third-order variables x_i . For every $n \in \mathbb{N}$, we define a sentence

$$\varphi_n = \exists x_0 \dots \exists x_k. (\exists x. x = \underbrace{0+1+1+\dots+1}_{n \text{ times}} \wedge \psi(x, x_0, \dots, x_k)).$$

Then φ_n is true if and only if $n \in N$. Combining this with Lemma 16, we obtain a computable function that maps any $n \in \mathbb{N}$ to a HyperCTL* formula φ'_n such that $n \in N$ if and only if φ'_n is satisfiable. \blacktriangleleft

6 Conclusion

In this work, we have settled the complexity of the satisfiability problems for HyperLTL and HyperCTL*. In both cases, we significantly increased the lower bounds, i.e. from Σ_1^0 and Σ_1^1 to Σ_1^1 and Σ_1^2 , respectively, and presented the first upper bounds, which are tight in both cases. Along the way, we also determined the complexity of restricted variants, e.g. HyperLTL satisfiability restricted to ultimately periodic traces (or, equivalently, to finite traces) is still Σ_1^1 -complete while HyperCTL* satisfiability restricted to finite transition systems is Σ_1^0 -complete. As a key step in this proof, we showed a tight bound of c on the size of minimal models for satisfiable HyperCTL* sentences. Finally, we also show that deciding membership in any level of the HyperLTL quantifier alternation hierarchy is Π_1^1 -complete.

Abstract

A pattern α is a string of variables and terminal letters. We say that α matches a word w , consisting only of terminal letters, if w can be obtained by replacing the variables of α by terminal words. The matching problem, i.e., deciding whether a given pattern matches a given word, was heavily investigated: it is NP-complete in general, but can be solved efficiently for classes of patterns with restricted structure. In this paper, we approach this problem in a generalized setting, by considering approximate pattern matching under Hamming distance. More precisely, we are interested in what is the minimum Hamming distance between w and any word u obtained by replacing the variables of α by terminal words. Firstly, we address the class of regular patterns (in which no variable occurs twice) and propose efficient algorithms for this problem, as well as matching conditional lower bounds. We show that the problem can still be solved efficiently if we allow repeated variables, but restrict the way the different variables can be interleaved according to a locality parameter. However, as soon as we allow a variable to occur more than once and its occurrences can be interleaved arbitrarily with those of other variables, even if none of them occurs more than once, the problem becomes intractable.

1 Introduction

A *pattern* (with variables) is a string which consists of *terminal letters* (e.g., a, b, c), treated as constants, and *variables* (e.g., x_1, x_2). A pattern is mapped to a word by substituting the variables by strings of terminals. For example, $x_1x_1babx_2x_2$ can be mapped to **aaaababbb** by the substitution ($x_1 \rightarrow \mathbf{aa}, x_2 \rightarrow \mathbf{b}$). If a pattern α can be mapped to a string of terminals w , we say that α matches w . The problem of deciding whether there exists a substitution which maps a given pattern α to a given word w is called the *matching problem*.

Patterns with variables and their matching problem appear in various areas of theoretical computer science. In particular, the matching problem is a particular case of the satisfiability problem for word equations. These are equations whose both sides are patterns with variables and whose solutions are substitutions that map both sides to the same word [37]; in the pattern matching problem, one side of the input equation is a string of terminals. Patterns with variables occur also in combinatorics on words (e.g., unavoidable patterns [38]), stringology (e.g., generalized function matching [2]), language theory (e.g., pattern languages [3]), or

database theory (e.g., document spanners [27, 26, 19, 44]). In a more practical setting, patterns with variables are used in connection to extended regular expressions with backreferences [14, 29, 25, 28], used in various programming languages.

The *matching problem* is NP-complete [3] in general. This is especially unfortunate for some computational tasks on patterns which implicitly solve the matching problem and are thus intractable as well. For instance, in algorithmic learning theory, this is the case for the task of computing *descriptive patterns* for finite sets of words [3, 21]. Such descriptive patterns are useful for the inductive inference of pattern languages, a prominent example of a language class which can be inferred from positive data (see, the survey [46] and the references therein). This and many other applications of pattern matching provide a good motivation to identify cases in which the matching problem becomes tractable. A natural approach to this task is to consider restricted classes of patterns. A thorough analysis [42, 45, 23, 24, 22, 43] of the complexity of the matching problem has provided several subclasses of patterns for which the matching problem is in P, when some structural parameters of patterns are bounded by constants. Prominent examples in this direction are patterns with a bounded number of repeated variables occurring in a pattern, patterns with bounded scope coincidence degree [42], or patterns with bounded locality [18]. The formal definitions of these parameters are given in Section 4, and corresponding efficient matching algorithms be found in [22, 18], but, to give an intuition, we mention that they are all numerical parameters which describe the structure of patterns and parameterize the complexity of the matching algorithms. That is, in all cases, if the respective parameter equals k , the matching algorithm runs in $O(n^{ck})$ for some constant c , and, moreover, the matching problem can be shown to be $W[1]$ -hard w.r.t. the respective parameter. A more general approach [42] introduces the notion of treewidth of patterns, and shows that the matching problem can be solved in $O(n^{2k+4})$ time for patterns with bounded treewidth k . The algorithms resulting from this general theory are less efficient than the specialized ones, while the matching problem remains $W[1]$ -hard w.r.t. treewidth of patterns. See also the survey [39].

In this paper, we extend the study of patterns which can be matched efficiently to the case of approximate matching: we allow mismatches between the word w and the image of α under a substitution. More precisely, we consider two problems. In the decision problem MisMatch_P we are interested in deciding, for a given pattern α from a class P , a given word w , and a non-negative integer Δ whether there exists a variable-substitution h such that the word $h(\alpha)$ has at most Δ mismatches to the word w ; in other words, the Hamming distance $d_{\text{HAM}}(h(\alpha), w)$ between $h(\alpha)$ and w is at most Δ . Alternatively, we consider the corresponding minimisation problem MinMisMatch_P of computing $d_{\text{HAM}}(\alpha, w) = \min\{d_{\text{HAM}}(h(\alpha), w) \mid h \text{ is a substitution of the variables in } \alpha\}$.

As most real-world textual data (e.g., involving genetic data or text written by humans) contains errors, considering string-processing algorithms in an approximate setting is natural and has been heavily investigated. See, e.g., the recent papers [16, 32, 31, 47], and the references therein, as well as classical results such as [1, 41, 35]. Closer to the topic of this paper, the problem of approximate pattern matching was also considered in the context of regular expression matching – see [6, 41] and the references therein. Continuing this line of research, we initiate a study of approximate matching problems for patterns with variables. Intuitively, in our problems, we ask if the input word w is a few mismatches away from matching the pattern α , i.e., if w can be seen as a slightly erroneous version of a word which exactly matches α .

■ **Table 1** Our results are listed in columns 3 and 4. We assume $|w| = n$, $|\alpha| = m$, $|\text{var}(\alpha)| = p$.

Class	$\text{Match}(w, \alpha)$	$\text{MisMatch}(w, \alpha, \Delta)$	$\text{MinMisMatch}(w, \alpha)$
Reg	$O(n)$ [folklore]	$O(n\Delta)$ matching cond. lower bound	$O(nd_{\text{HAM}}(\alpha, w))$ matching cond. lower bound
1Var	$O(n)$ [folklore]	$O(n)$	$O(n)$
NonCross	$O(nm \log n)$ [22]	$O(n^3 p)$	$O(n^3 p)$
1RepVar $k = \# x$ -blocks	$O(n^2)$ [22]	$O(n^{k+2} m)$ W[1]-hard w.r.t. k	$O(n^{k+2} m)$, PTAS W[1]-hard w.r.t. k no FPTAS (if $FPT \neq W[1]$)
kLOC	$O(mkn^{2k+1})$ [18] W[1]-hard w.r.t. k	$O(n^{2k+2} m)$ W[1]-hard w.r.t. k	$O(n^{2k+2} m)$ W[1]-hard w.r.t. k no FPTAS (if $FPT \neq W[1]$)
kSCD	$O(m^2 n^{2k})$ [22] W[1]-hard w.r.t. k	NP-hard for $k \geq 2$	NP-hard for $k \geq 2$
kRepVar	$O(n^{2k})$ [22] W[1]-hard w.r.t. k	NP-hard for $k \geq 1$	NP-hard for $k \geq 1$
k -bounded treewidth	$O(n^{2k+4})$ [42] W[1]-hard w.r.t. k	NP-hard for $k \geq 3$	NP-hard for $k \geq 3$

Our Contribution. Our results are summarized in Table 1. In that table, we describe the results we obtained for the problems MisMatch_P and MinMisMatch_P (introduced informally above and formally in Section 2) for a series of classes P of patterns for which the matching problem Match can be solved in polynomial time. The classes P we consider are the following: The class **Reg** of regular patterns, which contain at most one occurrence of any variable; the class **1Var** of unary patterns, which contain several occurrences of a single variable and terminals; the class **NonCross** of non-cross-patterns, which can be factorized in multiple **1Var**-patterns whose variables are pairwise different; the class **1RepVar** of one-repeated-variables, where only one variable (say x) is allowed to occur more than once; the classes **kLOC** of k -local patterns and **kSCD** of patterns with scope coincidence degree at most k , defined formally in Section 4; the class **kRepVar** of k -repeated-variables, where only k variables are allowed to occur more than once. We also (indirectly) obtain a lower bound for the complexity of MisMatch and MinMisMatch in the case of patterns with treewidth at most k .

Interestingly, for **Reg** we obtain matching upper and conditional lower bounds. As regular patterns are, in fact, a particular case of regular expressions, it is worth mentioning that, due to the conditional lower bounds from [4] on exact regular expression matching, it is not to be expected that the general case of matching regular-expressions under Hamming distance can be solved as efficiently as the case of regular patterns. Regarding patterns with repeated variables, we note that while in the case when the number of repeated variables, the scope coincidence degree, or the treewidth was bounded by a constant, polynomial-time algorithms for the exact matching problem were obtained. This does not hold in our approximate setting, unless $P=NP$. Only the locality measure has the same behaviour as in the case of exact matching: $\text{MisMatch}_{\text{kLOC}}$ and $\text{MinMisMatch}_{\text{kLOC}}$ can still be solved in polynomial time for constant k . In the simpler case of **1RepVar**-patterns, the locality corresponds to the number of x -blocks, so, if this is bounded by a constant, the two problems we consider can be solved in polynomial time.

The paper is organized as follows: after some preliminaries, we present in detail the results on **Reg**-patterns. Then we overview the results on patterns with repeated variables.

Future Work. While our results paint a detailed image of the complexity of `MisMatch` and `MinMisMatch` for some prominent classes of patterns for which the matching problem can be solved efficiently, some continuations of this work can be easily identified. Following [22], it would be interesting to try to optimise the algorithms for all classes from the table (except `Reg`, where the upper and conditional lower bounds match). In the case of `Reg`, it would be interesting to consider the problem for regular patterns with a constant number of variables; already in the case of two variables (also known as approximate string matching under Hamming distance) the known complexity upper and lower bounds do not match anymore [31, 47]. Another direction is to consider the two problems for other distance functions (e.g., edit distance) instead of the Hamming distance. Finally, it would be interesting if the applications of pattern matching in the area of algorithmic learning theory can be formulated (and still remain interesting) in this approximate setting.

2 Preliminaries

Let Σ be a finite alphabet of *terminal letters*. Let Σ^* be the set of all words and ε the empty word. The concatenation of k words w_1, w_2, \dots, w_k is written $\prod_{i=1}^k w_i$. The set Σ^+ is defined as $\Sigma^* \setminus \{\varepsilon\}$. For $w \in \Sigma^*$ the length of w is defined the number of symbols of w , and denoted as $|w|$. Further, let $\Sigma^n = \{w \in \Sigma^* \mid |w| = n\}$ and $\Sigma^{\leq n} = \bigcup_{i=0}^n \Sigma^i$. The letter on position i of w , for $1 \leq i \leq |w|$, is denoted by $w[i]$. For $w \in \Sigma^+$ and $x, y, z \in \Sigma^*$, the word y is a factor of w , if $w = xyz$; moreover, if $x = \varepsilon$ (respectively, $z = \varepsilon$), then y is called a prefix (respectively, suffix) of w . Let $w[i : j] = w[i] \cdots w[j]$ be the factor of w starting on position i and ending on position j ; if $i > j$ then $w[i : j] = \varepsilon$. By $[i : j]$ we denote the set $\{i, i + 1, \dots, j\}$ and $D[i : j]$ denotes a subarray of D whose positions are indexed by the numbers in $[i : j]$.

Let $\mathcal{X} = \{x_1, x_2, x_3, \dots\}$ be a set of *variables*. For the set of terminals Σ and the set of variables \mathcal{X} with $\Sigma \cap \mathcal{X} = \emptyset$, a pattern α is a word containing both terminals and variables, i.e., an element of $PAT_\Sigma = (\mathcal{X} \cup \Sigma)^+$. The set of all patterns, over all terminal-alphabets, is denoted $PAT = \bigcup_\Sigma PAT_\Sigma$. Given a word or a pattern γ , for the smallest sets (w.r.t. inclusion) $B \subseteq \Sigma$ and $Y \subseteq \mathcal{X}$ with $\gamma \in (B \cup Y)^*$, define the set of terminal symbols in γ , denoted by $\text{alph}(\gamma) = B$, and the set of variables of γ , denoted by $\text{var}(\gamma) = Y$. For any symbol $t \in \Sigma \cup \mathcal{X}$ and $\alpha \in PAT_\Sigma$, $|\alpha|_t$ denotes the number of occurrences of t in α .

A substitution (on the variables of α) is a mapping $h : \text{var}(\alpha) \rightarrow \Sigma^*$. For every $x \in \text{var}(\alpha)$, we say that x is substituted by $h(x)$ and $h(\alpha)$ denotes the word obtained by substituting every occurrence of a variable x in α by $h(x)$ and leaving all the terminals unchanged. We say that the pattern α matches a word $w \in \Sigma^+$, if there exists a substitution $h : \text{var}(\alpha) \rightarrow \Sigma^*$ such that $h(\alpha) = w$. The Matching Problem is defined for any family of patterns $P \subseteq PAT$:

Exact Matching Problem for P : **Match_P**

Input: A pattern $\alpha \in P$, with $|\alpha| = m$, a word w , with $|w| = n$.

Question: Is there a substitution h with $h(\alpha) = w$?

In this paper, we will consider an extension of the Matching Problem, in which we allow mismatches between the image of the pattern under a substitution and the matched word.

For words $w_1, w_2 \in \Sigma^*$ with $|w_1| = |w_2|$, the Hamming distance between w_1 and w_2 is defined as $d_{\text{HAM}}(w_1, w_2) = |\{i \mid w_1[i] \neq w_2[i] \wedge 1 \leq i \leq |w_1|\}|$. The Hamming distance describes, therefore, the number of mismatches between two words. For a pattern α and a word w , we can define the Hamming distance between α and w as $d_{\text{HAM}}(\alpha, w) = \min\{d_{\text{HAM}}(h(\alpha), w) \mid h \text{ is a substitution of the variables of } \alpha\}$. With these definitions we can introduce two new pattern matching problems for families of patterns $P \subseteq PAT$. In the first problem, we allow

for a certain distance Δ between the image $h(\alpha)$ of α under a substitution h and the target word w instead of searching for an exact matching. In the second problem, we are interested in finding the substitution h such that the number of mismatches between $h(\alpha)$ and the target word w is minimal, over all possible choices of h .

Approximate Matching Decision Problem for P : **MisMatch $_P$**

Input: A pattern $\alpha \in P$, with $|\alpha| = m$, a word w , with $|w| = n$, an integer $\Delta \leq m$.

Question: Is $d_{\text{HAM}}(\alpha, w) \leq \Delta$?

Approximate Matching Minimisation Problem for P : **MinMisMatch $_P$**

Input: A pattern $\alpha \in P$, with $|\alpha| = m$, a word w , with $|w| = n$.

Question: Compute $d_{\text{HAM}}(\alpha, w)$.

When analysing the number of mismatches between $h(\alpha)$ and w we need to argue about the number of mismatches between corresponding factors of $h(\alpha)$ and w , i.e., the factors occurring between the same positions i and j in both words. To simplify the presentations, for a substitution h that maps a pattern α to a word of the same length as w , we will call the factors $h(\alpha)[i : j]$ and $w[i : j]$ aligned under h . We omit h when it is clear from the context. Moreover, saying that we align a factor $\alpha[i : j]$ to a factor $w[i' : j']$ with a minimal number of mismatches, we mean that we are looking for a substitution h such that $|h(\alpha)| = |w|$, $h(\alpha[i : j])$ is aligned to $w[i' : j']$ under h , and the resulting number of mismatches between $h(\alpha[i : j])$ and $w[i' : j']$ is minimal w.r.t. all other choices for the substitution h .

We make some preliminary remarks. Firstly, in all the problems we consider here, we can assume that the pattern α starts and ends with variables, i.e., $\alpha = x\alpha'y$, with α' pattern and x and y variables. Indeed, if this would not be the case, we could simply reduce the problems by considering them for inputs α' and the word w' obtained by removing from w the prefix and suffix aligned, respectively, to the maximal prefix of α which contains only terminals and the maximal suffix of α which contains only terminals. Clearly, in the case of the exact-matching problem the respective prefixes (suffixes) of w and α must match exactly, while in the case of the approximate-matching problems one needs to account for the mismatches created by these prefixes and suffixes. So, from now on, we will work under the assumption that the patterns we try to align to words start and end with variables.

Secondly, solving **Match $_P$** is equivalent to solving **MisMatch $_P$** for $\Delta = 0$. Also, in a general framework, **MinMisMatch $_P$** can be solved by combining the solution of the decision problem **MisMatch $_P$** with a binary search on the value of Δ . Given that the distance between α and w is at most $n = |w|$, one needs to use the solution for **MisMatch $_P$** a maximum of $\log n$ times in order to find the exact distance between α and w . Sometimes this can be done even more efficiently, as shown in Theorem 3.4. On the other hand, solving **MinMisMatch $_P$** leads directly to a solution for **MisMatch $_P$** .

3 Matching Regular Patterns with Mismatches

A pattern α is *regular* if $\alpha = w_0 \prod_{i=1}^M (x_i w_i)$, with $w_i \in \Sigma^*$. The class of regular patterns is denoted by **Reg**. For example, the pattern $\alpha_0 = \text{abxabyzbaab}$, with $\text{var}\alpha = \{x, y, z\}$ is in **Reg**.

In this section we consider **MisMatch $_{\text{Reg}}$** and **MinMisMatch $_{\text{Reg}}$** .

As mentioned already, a solution for **MisMatch $_{\text{Reg}}$** with distance $\Delta = 0$ is a solution to **Match $_{\text{Reg}}$** . The latter problem can be solved in $\mathcal{O}(n)$ by a greedy approach. As noted in Section 2, we can assume that $w_0 = w_M = \varepsilon$, so $\alpha = (\prod_{i=1}^{M-1} x_i w_i) x_M$. Thus, we identify the last occurrence $w[\ell + 1 : \ell + |w_{M-1}|]$ of w_{M-1} in w , assign the string $w[\ell + |w_{M-1}| + 1 : n]$ to x_M , and then recursively match the pattern $\alpha = (\prod_{i=1}^{M-2} x_i w_i) x_{M-1}$ to $w[1 : \ell]$.

In the following, we propose a solution for $\text{MinMisMatch}_{\text{Reg}}$ which generalizes this approach. Further, we will show a matching lower bound for any algorithm solving $\text{MinMisMatch}_{\text{Reg}}$.

An equivalent formulation of $\text{MinMisMatch}_{\text{Reg}}$ is to find factors $w[\ell_i + 1 : \ell_i + |w_i|]$, with $1 \leq i \leq M-1$, such that $\sum_{i=1}^{M-1} d_{\text{HAM}}(w_i, w[\ell_i + 1 : \ell_i + |w_i|])$ is minimal and $\ell_i + |w_i| + 1 \leq \ell_{i+1}$, for all $i \in \{1, \dots, M-2\}$. In other words, we want to find the $M-1$ factors $w[\ell_i + 1 : \ell_i + |w_i|]$, with i from 1 to $M-1$, such that these factors occur one after the other without overlapping in w , they correspond (in order, from left to right) to the words w_i , for i from 1 to $M-1$, and the total sum of mismatches between $w[\ell_i + 1 : \ell_i + |w_i|]$ and w_i , added up for i from 1 to $M-1$, is minimal.

To approach this problem we need the following data-structures-preliminaries.

Given a word w , of length n , we can construct in $O(n)$ -time *longest common suffix*-data structures which allow us to return in $O(1)$ -time the value $LCS_w(i, j) = \max\{|v| \mid v \text{ is a suffix of both } w[1 : i] \text{ and } w[1 : j]\}$. See [33, 34] and the references therein. Given a word w , of length n , and a word u , of length m , we can construct in $O(n+m)$ -time data structures which allow us to return in $O(1)$ -time the value $LCS_{w,u}(i, j) = \max\{|v| \mid v \text{ is a suffix of both } w[1 : i] \text{ and } u[1 : j]\}$. This is achieved by constructing LCS_w -data structures for wu , as above, and noting that $LCS_{w,u}(i, j) = \min(LCS_w(i, n+j), j)$.

The following two lemmas are based on the data structures defined above and the technique called kangaroo-jump [35]. Their respective proofs can be found in the Appendix B.

► **Lemma 3.1.** *Let w and u , with $|w| = |u| = n$, be two words and δ a non-negative integer. Assume that, in a preprocessing phase, we have constructed $LCS_{w,u}$ -data structures. We can compute $\min(\delta + 1, d_{\text{HAM}}(u, w))$ using $\delta + 1$ $LCS_{w,u}$ queries, so in $O(\delta)$ time.*

► **Lemma 3.2.** *Given a word w , with $|w| = n$, a word u , with $|u| = m < n$, and a non-negative integer δ , we can compute in $O(n\delta)$ time the array $D[m : n]$ with $n - m + 1$ elements, where $D[i] = \min(\delta + 1, d_{\text{HAM}}(w[i - m + 1 : i], u))$.*

The following result is the main technical tool of this section.

► **Theorem 3.3.** *$\text{MisMatch}_{\text{Reg}}$ can be solved in $O(n\Delta)$ time. For an accepted instance w, α, Δ of $\text{MisMatch}_{\text{Reg}}$ we also compute $d_{\text{HAM}}(\alpha, w)$ (which is upper bounded by Δ).*

Proof. Assume $\alpha = \prod_{i=1}^{M-1} (x_i w_i) x_M$ and let $\alpha_\ell = \prod_{i=\ell}^{M-1} (x_i w_i) x_M$, for $\ell \in \{1, \dots, M-1\}$.

A first observation is that the problem can be solved in a standard way by dynamic programming in $O(nm)$ time.

We only give the main idea behind this approach. We can compute the minimum number of mismatches $T[i][j]$ which can be obtained when aligning the suffix of length i of w to the suffix of length j of α , for all $i \leq n$ and $j \leq m$. Clearly, $T[i][j]$ can be computed based on the values $T[i+1][j+1]$ and, if $\alpha[j]$ is a variable, $T[i+1][j]$. The full technicalities of this standard approach are easy to obtain so we do not go into further details.

We present a more efficient approach below.

Our efficient algorithm starts with a preprocessing phase, in which we compute $LCS_{w,u}$ -data structures, where $u = \prod_{i=\ell}^{M-1} w_i$. This allows us to retrieve in constant time answers to LCS_{w,w_i} -queries, for $1 \leq i \leq M-1$.

In the main phase of our algorithm, we compute an $(M-1) \times \Delta$ matrix $\text{Suf}[\cdot][\cdot]$, where, for $\ell \leq M-1$ and $d \leq \Delta$, we have $\text{Suf}[\ell][d] = g$ if and only if $w[g..n]$ is the shortest suffix of w with $d_{\text{HAM}}(\alpha_\ell, w[g : n]) \leq d$.

Once more, we note that the elements of $\text{Suf}[\cdot][\cdot]$ can be computed by a relatively straightforward dynamic programming approach in $O(nM\Delta)$ time. But, the strategy we present here is more efficient than that.

In our algorithm, we first use Lemma 3.2 to compute $Suf[M-1][\cdot]$ in $O(n\Delta)$ time. We simply run the algorithm of that lemma on the input strings w and w_{M-1} and the integer Δ . We obtain an array $D[\cdot]$, where $D[i] = \min(\Delta + 1, d_{\text{HAM}}(w[i - |w_{M-1}| + 1 : i], w_{M-1}))$. We now go with j from $|w_{M-1}|$ to n and, if $D[j] \leq \Delta$, we set $Suf[M-1][D[j]] = j - |w_{M-1}| + 1$. It is clear that $h = Suf[M-1][d]$ will be the starting position of the shortest suffix $w[h : n]$ of w such that $d_{\text{HAM}}(w_{M-1}x_M, w[h : n]) \leq d$. Thus, $Suf[M-1][\cdot]$ was correctly computed, and the time needed to do so is $O(n\Delta)$.

Further, we describe how to compute $Suf[\ell][\cdot]$ efficiently, based on $Suf[\ell+1][\cdot]$ (for ℓ from $M-2$ down to 1). We use the following approach. We go through the positions i of w from right to left and maintain a queue Q . When i is considered, Q stores all elements d such that $Suf[\ell][d]$ was not computed yet until reaching that position, but $i < Suf[\ell+1][d]$. Accordingly, the fact that d is in Q means that with a suitable alignment of w_ℓ ending on position i , we could actually find an alignment with $\leq d$ mismatches of α_ℓ with $w[i - |w_\ell| + 1 : n]$: when Q contains $d, \dots, d - t$, for some $t \geq 0$, an alignment of w_ℓ to $w[i - |w_\ell| + 1 : i]$ with $\leq t$ mismatches would lead to an alignment of α_ℓ with $w[i - |w_\ell| + 1 : n]$ with $\leq d$ mismatches by extending the alignment of $\alpha_{\ell+1}$ to $w[Suf[\ell+1][d-t] : n]$. The values d present in Q at some point are ordered increasingly (the older values are larger), the array $Suf[\ell+1][\cdot]$ is also monotonically increasing, and, as $Suf[\ell][d]$ cannot be set before $Suf[\ell][d']$, for any d and d' such that $d' < d$, the queue Q is actually an interval of integers $[new : old]$, where new is the newest element of Q , and old the oldest one. When we consider position i of the word, if the alignment of w_ℓ ending on position i causes t mismatches, then to be able to set a value $Suf[\ell][d]$, with $d \in Q$, we need to have that $Suf[\ell+1][d-t] > i$. As $Suf[\ell+1][d] > Suf[\ell+1][d-t]$ and $d \in Q$, this means that $d-t \in Q$, so the number of mismatches t must be strictly upper bounded by $|Q|$, in order to be useful. Accordingly, when considering position i , we compute the number $t \leftarrow \min\{d_{\text{HAM}}(w_\ell, w[i - |w_\ell| + 1 : i]), |Q|\}$, and if $t < |Q|$ we set $Suf[\ell][d] \leftarrow i - |w_\ell| + 1$ for all d such that $d-t \in Q$; we also eliminate all these elements d from the queue. Before considering a new position i , we check if $i = Suf[\ell+1][new-1]$, and, if yes, we insert $new-1$ in Q and update $new \leftarrow new-1$.

This computation of $Suf[\ell][\cdot]$ is implemented in the following algorithm:

1. Initialization: We maintain a queue Q , which initially contains only the Δ .
Let $new \leftarrow \Delta$ (this is the top element of the queue).
2. Iteration: For $i = Suf[\ell+1][\Delta] - 1$ down to $|w_\ell|$ we execute the steps a, b, and c:
 - a. Using Lemma 3.1 we compute $t \leftarrow \min(d_{\text{HAM}}(w_\ell, w[i - |w_\ell| + 1 : i]), |Q|)$.
 - b. If $t < |Q|$, we remove from Q all elements d , such that $d-t \geq new$, and set, for each of them, $Suf[\ell][d] \leftarrow i - |w_\ell| + 1$.
 - c. If $Suf[\ell+1][top-1] = i$ then we insert $top-1$ in Q and $top \leftarrow top-1$. Else, if $Suf[\ell+1][top-1] = 0$ then set $i \leftarrow 0$ and exit the loop.
3. Filling-in the remaining positions: Set all the positions of $Suf[\ell][\cdot]$ which were not filled during the above while-loop to 0.

The matrix $Suf[\cdot][\cdot]$ is computed correctly by the above algorithm, as it can be shown by the following inductive argument.

To show that $Suf[\ell][\cdot]$ is computed correctly by our algorithm, under the assumption that $Suf[\ell+1][\cdot]$ was correctly computed, we make several observations.

Firstly, it is clear that $Suf[\ell+1][d] \leq Suf[\ell+1][d+1]$. Secondly, when computed correctly, $Suf[\ell][d]$ should be the rightmost position g of w such that $d_{\text{HAM}}(w[g : n], w_\ell) = t \leq d$ and $Suf[\ell+1][d-t] \geq g + |w_\ell|$. Clearly, if $Suf[\ell][d+1] \neq 0$, then $Suf[\ell][d] < Suf[\ell][d+1]$.

Regarding the algorithm described in the main part of the paper, it is important to observe that the queue Q is ordered increasingly (i.e., the newer is an element in Q , the smaller it is) and the elements of Q form an interval $[new : old]$.

Now, let us show the correctness of the algorithm.

Let d be a non-negative integer, $d \leq \Delta$. Assume that our algorithm sets $Suf[\ell][d] = g$, with $g > 0$.

This means that d was removed from the queue in step 2.b when the for-loop was executed for $i = g + |w_\ell| - 1$. The reason for this removal was that $d_{\text{HAM}}(w[g : g + |w_\ell| - 1], w_\ell) = t \leq |Q| - 1$. Hence, in this step we have removed exactly those elements δ such that $new \leq \delta - t$. Accordingly, we also have that $new \leq d - t$ holds. Let $g' = Suf[\ell + 1][new]$. We thus have $g' > i = g + |w_\ell| - 1$, $d_{\text{HAM}}(\alpha_{\ell+1}, w[g' : n]) \leq new$, and $d_{\text{HAM}}(w_\ell x_\ell, w[g : g' - 1]) = t$. Putting this all together, we get that $d_{\text{HAM}}(\alpha_\ell, w[g : n]) \leq new + t \leq d$.

Now, assume for the sake of a contradiction, that there exists $g'' > g$ such that $d_{\text{HAM}}(\alpha_\ell, w[g'' : n]) \leq d$, i.e., $w[g : n]$ is not the shortest suffix s of w such that $d_{\text{HAM}}(\alpha_\ell, s) \leq d$. In this case, there exists d'' such that $g'' + |w_\ell| - 1 < Suf[\ell + 1][d'']$ and $d'' + d_{\text{HAM}}(w[g'' : g'' + |w_\ell| - 1], w_\ell) \leq d$. Because d is in Q when $i = g + |w_\ell| - 1$ is reached in the for-loop, then d must also be in Q when $i'' = g'' + |w_\ell| - 1$ is reached in the for-loop, because $i < i'' < Suf[\ell + 1][d''] \leq Suf[\ell + 1][d]$. In fact, as $Suf[\ell + 1][d] \geq Suf[\ell + 1][d''] > i''$, it follows that d'' must also be in Q when i'' is reached. Thus, $g \geq d - d''$ and, as we have seen above, $d - d'' \geq d_{\text{HAM}}(w[g'' : g'' + |w_\ell| - 1], w_\ell)$. Moreover, if new'' is the element on the top of the queue when i'' is reached, we have that $new'' \leq d''$. Hence, $new'' + d_{\text{HAM}}(w[g'' : g'' + |w_\ell| - 1], w_\ell) \leq d'' + d_{\text{HAM}}(w[g'' : g'' + |w_\ell| - 1], w_\ell) \leq d$. Therefore, when i'' was reached, all the conditions needed to remove d from Q and set $Suf[\ell][d] \leftarrow g''$ were met. We have reached a contradiction with our assumption that $g'' > g$.

In conclusion, if our algorithm sets $Suf[\ell][d] = g$, with $g > 0$, then $w[g : n]$ is the shortest suffix of w such that $d_{\text{HAM}}(w[g : n], w_\ell) \leq d$. By an analogous argument as the one used above in our proof by contradiction, we can show that if our algorithm sets $Suf[\ell][d] = 0$ then there does not exist any suffix $w[g : n]$ of w such that $d_{\text{HAM}}(w[g : n], w_\ell) \leq d$.

This means that our algorithm computing $Suf[\cdot][\cdot]$ is correct.

To finalize the proof of the theorem, we note that, after computing the entire matrix $Suf[\cdot][\cdot]$, we can accept the instance w, α, Δ of $\text{MisMatch}_{\text{Reg}}$ if and only if there exists $d \leq \Delta$ such that $Suf[1][d] \neq 0$. Moreover, $d_{\text{HAM}}(\alpha, w) = \min(\{d \mid Suf[1][d] \neq 0\} \cup \{+\infty\})$.

In the following we show that this algorithm works in $O(n\Delta)$ time. We will compute the complexity of this algorithm using amortized analysis. Firstly, we observe that the complexity of the algorithm is proportional to the total number of LCS_{w, w_ℓ} -queries we compute in step 2.a, for each $\ell \leq M$ or, in other words, over all executions of the algorithm. Now, we observe that when position i of w is considered (for a certain ℓ), we do $|Q|$ many LCS_{w, w_ℓ} -queries. So, this means that we do one query per each current element of Q (and none if $|Q| = 0$). Thus, the number of queries corresponding to each pair (ℓ, d) which appears in Q at some point equals the number of positions considered between the step when it was inserted in Q and the step when it was removed from Q . This means $O(Suf[\ell + 1][d] - Suf[\ell][d])$ queries corresponding to (ℓ, d) . Summing this up for a fixed d and ℓ from 1 to $M - 2$ we obtain that the overall number of queries corresponding to a fixed δ is $O(Suf[M - 1][d]) = O(n)$. Adding this up for all $d \leq \Delta$, we obtain that the number of LCS -queries performed in our algorithm is $O(n\Delta)$. So, together with the complexity of the initialization of $Suf[M - 1][\cdot]$, the complexity of this algorithm is $O(n\Delta)$.

This algorithm outperforms the other two algorithms solving $\text{MinMisMatch}_{\text{Reg}}$ which we mentioned, and, for $\Delta = 0$, it is a reformulation of the greedy algorithm solving $\text{Match}_{\text{Reg}}$. ◀

► **Theorem 3.4.** $\text{MinMisMatch}_{\text{Reg}}$ can be solved in $O(n\Phi)$ time, where $\Phi = d_{\text{HAM}}(\alpha, w)$.

Proof. We use the algorithm of Theorem 3.3 for $\Delta = 2^i$, for increasing values of i starting with 1 and repeating until the algorithm returns a positive answer and computes $\Phi = d_{\text{HAM}}(\alpha, w)$. The algorithm is clearly correct. Moreover, the value of i which was considered last is such that $2^{i-1} < \Phi \leq 2^i$. So $i = \lceil \log_2 \Phi \rceil$, and the total complexity of our algorithm is $O(n \sum_{i=1}^{\lceil \log_2 \Phi \rceil} 2^i) = O(n\Phi)$. ◀

In order to show that $\text{MinMismatch}_{\text{Reg}}$ and $\text{Mismatch}_{\text{Reg}}$ cannot be solved by algorithms running polynomially faster than the algorithms from Theorems 3.3 and 3.4, we will reduce the Orthogonal Vectors problem OV [10] to $\text{Mismatch}_{\text{Reg}}$. The overall structure of our reduction is similar to the one used for establishing hardness of computing edit distance [5, 11] or LCS [12], however we needed to construct gadgets specific to our problem. We recall the OV problem.

Orthogonal Vectors: OV

Input: Two sets U, V consisting each of n vectors from $\{0, 1\}^d$, where $d \in \omega(\log n)$.

Question: Do vectors $u \in U, v \in V$ exist, such that u and v are orthogonal, i.e., for all $1 \leq k \leq d$, $v[k]u[k] = 0$ holds?

In general, for a vector $u = (u[1], \dots, u[d]) \in \{0, 1\}^d$, the bits $u[i]$ are called coordinates. It is clear that, for input sets U and V as in the above definition, one can solve OV trivially in $\mathcal{O}(n^2d)$ time. The following conditional lower bound is known for OV .

► **Lemma 3.5 (OV-Conjecture).** *OV can not be solved in $\mathcal{O}(n^{2-\epsilon}d^c)$ for any $\epsilon > 0$ and constant c , unless the Strong Exponential Time Hypothesis (SETH) fails.*

See [10, 48] and the references therein for a detailed discussion regarding conditional lower bounds related to OV . In this context, we can show the following result.

► **Theorem 3.6.** *$\text{Mismatch}_{\text{Reg}}$ can not be solved in $\mathcal{O}(|w|^h \Delta^g)$ time (or in $\mathcal{O}(|w|^h |\alpha|^g)$ time) with $h + g = 2 - \epsilon$ for some $\epsilon > 0$, unless the OV -Conjecture fails.*

Proof. We reduce OV to $\text{MinMismatch}_{\text{Reg}}$. For this, we consider an instance of OV : $U = \{u_1, \dots, u_n\}$ and $V = \{v_1, \dots, v_n\}$, with $U, V \subset \{0, 1\}^d$. We transform this OV -instance into a $\text{Mismatch}_{\text{Reg}}$ -instance (α, w, Δ) , where $\Delta = n(d+1) - 1$. More precisely, we ensure that for the respective $\text{Mismatch}_{\text{Reg}}$ -instance, there exists a way to replace the variables with strings leading to exactly $n(d+1)$ mismatches between the image of α and w if and only if no two vectors u_i and v_j are orthogonal. But, if there exists at least one orthogonal pair of vectors u_i and v_j , there also exists a way to replace the variables of α such that the resulting string has strictly less than $n(d+1)$ mismatches to w . Both $|w|$ and $|\alpha|$ are in $\mathcal{O}(nd)$, and can be built in $\mathcal{O}(nd)$ time. The reduction consists of three main steps. First we will present a gadget for encoding the single coordinates of vectors u_i and v_i from U and V , respectively. Then we will show another gadget to encode a full vector of each respective set. And, finally, we will show how to assemble these gadgets of the vectors from set U into the word w and from V into α .

First gadget. Let $u_i = (u_i[1], u_i[2], \dots, u_i[d]) \in U, v_j = (v_j[1], v_j[2], \dots, v_j[d]) \in V$ and let k be a position of these vectors. We define the following gadgets:

$$A'(i_k) = \begin{cases} 001, & \text{if } u_i[k] = 0. \\ 100, & \text{if } u_i[k] = 1. \end{cases} \quad B'(j_k) = \begin{cases} 000, & \text{if } v_j[k] = 0. \\ 011, & \text{if } v_j[k] = 1. \end{cases}$$

Note that, when aligned, the pair of strings $(A'(i_k), B'(j_k))$ produces exactly one mismatch if and only if $u_i[k] \cdot v_j[k] = 0$; otherwise it produces three mismatches. So, $A'(i_k)$ and $B'(j_k)$ encode the single coordinates of u_i and v_j respectively.

48:10 Matching Patterns with Variables Under Hamming Distance

Further, we construct a gadget $X' = 010$ that produces always one mismatch if aligned to any of the strings $B'(j_k)$ corresponding to coordinates $v_j[k]$. See also Figure 1.

■ **Figure 1** Gadgets for the encoding of single coordinates of the vectors. On each edge we wrote the number of mismatches between the strings in the nodes connected by that edge.

Second gadget. The gadget $A(i)$ encodes the vector u_i , for $1 \leq i \leq n$, while the gadget $B(j)$ encodes the vector v_j , for $1 \leq j \leq n$. We construct these gadgets such that aligning $B(j)$ to $A(i)$ with a minimum number of mismatches yields exactly d mismatches, if the two corresponding vectors are orthogonal, and exactly $d + 1$ mismatches, otherwise. Moreover, we show that any other alignment of the gadgets $B(j)$ with other factors of w yields more mismatches.

In order to assemble the gadgets $A(i)$ and $B(j)$, for $1 \leq i, j \leq n$, we extend the terminal alphabet by three new symbols $\{\mathbf{a}, \mathbf{b}, \#\}$, as well as use two fresh variables x_j, y_j for each vector v_j . The gadgets $A(i)$, for all i , and, respectively, the gadgets $B(j)$, for all j , consist of the concatenation of the coordinate gadgets $A'(i_k)$ and, respectively, $B'(j_k)$ from left to right, in ascending order of k . Each two such consecutive gadgets $A'(i_k)$ and $A'(i_{k+1})$ (respectively, $B'(j_k)$ and $B'(j_{k+1})$) are separated by $\#\#\#$. We prepend to $A(i)$ the string \mathbf{bba} and append the string $\mathbf{bbb}X$, where $X = (X'\#\#\#)^{d-1}X'$. In the case of $B(j)$, we prepend $x_j\mathbf{bba}$ and append y_j . The full gadgets $A(i)$ and $B(j)$ are defined as follows.

- $A(i) = \mathbf{bba}A'(i_1)\#\#\#A'(i_2)\#\#\# \dots A'(i_d)\mathbf{bbb}X$
- $B(j) = x_j\mathbf{bba}B'(j_1)\#\#\#B'(j_2)\#\#\# \dots B'(j_d)y_j$.

For simplicity of the exposure, let $B'(j) = \mathbf{bba}B'(j_1)\#\#\#B'(j_2)\#\#\# \dots \#\#\#B'(j_d)$.

Note that $|A(i)|$ is the same for all i , so we can define $M = |A(i)|$.

Final assemblage. To define the word w , we use a new terminal $\$$. The word w is:

- $w = \$^M A(1)\$^M A(2)\$^M \dots A(n)\$^M A(1)\$^M A(2) \dots \$^M A(n)\M

To define α , we use two new fresh variables x and y . The pattern α is:

- $\alpha = x\$^M B(1)\$^M B(2)\$^M \dots \$^M B(n)\$^M y$.

The correctness of the reduction. We show that there exists a way to align α with w with $< n(d + 1)$ mismatches if and only if a pair of orthogonal vectors $u_i \in U$ and $v_j \in V$ exists. Otherwise, there exists an alignment of α to w with exactly $n(d + 1)$ mismatches.

To formally prove that the reduction fulfills this requirement, we proceed as follows.

A general idea: the repetition of the gadgets $A(i)$ in the word w guarantees that, if needed, a pair of gadgets $A(i)$ and $B(j)$, corresponding to the vectors $u_i \in U$ and, respectively, $v_j \in V$, can be aligned. More precisely, we can align $B'(j)$ to $\mathbf{bba}A'(i_1)\#\#\# \dots A'(i_d)$. The variables x, y and x_j, y_j , for $j \in \{1, \dots, n\}$, act as spacers: they allow us to align a string $B'(j)$ to the desired factor of w . This kind of alignment is enough for our purposes, as we only need to find one orthogonal pair of vectors, not all of them; however, we need enough space in w for the factors of α occurring before and after $B'(j)$, thus the repetition of the $A(i)$ gadgets.

We now analyse how a factor $B'(j)$ can be aligned to a factor of w . The main idea is to show that if there are no orthogonal vectors, then any alignment of $B'(j)$ to a factor of w creates at least $d + 1$ mismatches. Otherwise, we can align it with d mismatches only.

Case 1: $B'(j)$ is aligned to a factor $w[i : h]$ of w which starts with \$. Then the prefix **ba** of $B'(j)$ causes at least two mismatches, as the first **b** in **ba** is aligned to a \$ letter, while the **a** is aligned to either a **b** letter (from a **ba** factor) or a \$ letter. The rest of $B'(j)$ causes, overall, at least d mismatches, one per each group $B'(j_k)$. So, in this case, we have at least $d + 2$ mismatches caused by $B'(j)$.

Case 2: $B'(j)$ is aligned a factor $w[i : h]$ of w which ends with \$. Then, its prefix **ba** cannot be aligned to a factor **ba** of w . So, the **a** of the prefix **ba** of $B'(j)$ produces one mismatch, while the suffix $B'(j_d)$ causes at least 2 mismatches. The rest of $B'(j)$ causes at least $d - 1$ mismatches, one per each remaining group $B'(j_k)$. So, in this case, we have again at least $d + 2$ mismatches caused by $B'(j)$.

Case 3: $B'(j)$ is aligned exactly to the factor **ba** $A'(i_1)$ ###... $A'(i_d)$ and u_i and v_j are orthogonal, then $B'(j)$ causes exactly d mismatches.

Case 4: $B'(j)$ is aligned exactly to the factor **ba** $A'(i_1)$ ###... $A'(i_d)$ and u_i and v_j are not orthogonal, then $B'(j)$ causes at least $d + 2$ mismatches.

Case 5: $B'(j)$ is aligned exactly to the factor **bb** X , then $B'(j)$ causes $d + 1$ mismatches.

Case 6: $B'(j)$ is aligned to a factor starting strictly inside **ba** $A'(i_1)$ ###... $A'(i_d)$, then the prefix **ba** of $B'(j)$ cannot be aligned to a factor **ba** of w , so it causes at least two mismatches (from the alignment of **ba**). The rest of $B'(j)$ causes at least d mismatches, one per each group $B'(j_k)$. So, overall, $B'(j)$ causes at least $d + 2$ mismatches in this case.

To ease the understanding, cases 3 and 4 are illustrated in the following table: when aligning $A(i)$ to $B(j)$, to obtain the desired number of mismatches, we can match the parts of $A(i)$ to the parts of $B(j)$ as described in this table in the two cases 3. and 4.

Gadget	I	II	III	IV	mismatches
$A(i) =$	ε	ba $A'(i_1)$ ###...### $A'(i_d)$	bb X' ###...### X'	ε	
3. $B(j) =$	x_j	ba $B'(j_1)$ ###...### $B'(j_d)$	y_j	ε	d (in II)
4. $B(j) =$	ε	x_j	ba $B'(j_1)$ ###...### $B'(j_d)$	y_j	$d + 1$ (in IV)

Wrapping up, there are no other ways than those described in cases 1-6 above in which $B'(j)$ can be aligned to a factor of w . In particular, in order to reach an alignment with at most $n(d + 1) - 1$ mismatches, at least one $B'(j)$ should be aligned to a factor of w such that it only causes d mismatches (as in case 3). Thus, in that case we would have a pair of orthogonal vectors. Conversely, if there exist u_i and v_j which are orthogonal and $i \geq j$, then we can align $B'(j)$ to the occurrence of **ba** $A'(i_1)$ ###... $A'(i_d)$ from the first $A(i)$ and all the other gadgets $B'(\ell)$ to factors **bb** X , and obtain a number of $n(d + 1) - 1$ mismatches. Note that such an alignment is possible as there exist at least $j - 1$ factors **bb** X before the first $A(i)$ and at least n more occurrences of **bb** X after it; moreover the variables x_ℓ and y_ℓ can be used to align as desired the strings $B'(v_\ell)$ to the respective **bb** X factors of w . If there exist u_i and v_j which are orthogonal and $i < j$, then we can align $B'(j)$ to the occurrence of **ba** $A'(i_1)$ ### $A'(i_2)$ ###... $A'(i_d)$ from the second $A(i)$ and all the other gadgets $B'(\ell)$ to factors **bb** X , and obtain again a number of $n(d + 1) - 1$ mismatches. This is possible for similar reasons to the ones described above.

This shows that our reduction is correct. The instance of **OV** defined by U and V contains two orthogonal vectors if and only the instance of **MisMatch_{Reg}** defined by w, α , and $\Delta = n(d + 1) - 1$ can be answered positively. Moreover, the instance of **MisMatch_{Reg}** can be constructed in $O(nd)$ time and we have that $|w|, |\alpha|, \Delta \in \Theta(nd)$.

Assume now that there exists a solution of $\text{MisMatch}_{\text{Reg}}$ running in $O(|w|^g|\alpha|^h)$ with $g+h=2-\epsilon$ for some $\epsilon < 0$. This would lead to a solution for OV running in $O(nd+(nd)^{2-\epsilon})$, a contradiction to the OV -conjecture. Similarly, if there exists a solution of $\text{MisMatch}_{\text{Reg}}$ running in $O(|w|^g\Delta^h)$ with $g+h=2-\epsilon$ for some $\epsilon < 0$, then there exists a solution for OV running in $O(nd+(nd)^{2-\epsilon})$, a contradiction to the OV -conjecture. This proves our statement. \blacktriangleleft

► **Remark 3.7.** An immediate consequence of the previous theorem is that $\text{MinMisMatch}_{\text{Reg}}$ can not be solved in $\mathcal{O}(n^h d_{\text{HAM}}(\alpha, w)^g)$ time (or in $\mathcal{O}(|w|^h|\alpha|^g)$ time) with $h+g=2-\epsilon$ for some $\epsilon > 0$, unless the OV -Conjecture fails. Thus, as $d_{\text{HAM}}(\alpha, w) \leq |\alpha|$, $\text{MinMisMatch}_{\text{Reg}}$ and $\text{MisMatch}_{\text{Reg}}$ cannot be solved polynomially faster than our algorithms, unless the OV -Conjecture fails.

4 Patterns with Repeated Variables

In Section 3 we have shown that if no variable occurs more than once in the input pattern α , then the problems MisMatch and MinMisMatch can be solved in polynomial time. Let us now consider patterns where variables are allowed to occur more than once, i.e., patterns with repeated variables. Firstly, we recall two measures of the structural complexity of patterns.

For every variable $x \in \text{var}(\alpha)$, the scope of x in α is defined by $\text{sc}_\alpha(x) = [i : j]$, where i is the leftmost and j the rightmost occurrence of x in α . The scopes of the variables $x_1, \dots, x_k \in \text{var}(\alpha)$ coincide in α if $\bigcap_{i=1}^k \text{sc}(x_i) \neq \emptyset$. By $\text{scd}(\alpha)$ we denote the scope coincidence degree of α : the maximum number of variables in α whose scopes coincide. By kSCD we denote the class of patterns whose scope coincidence degree is at most k .

Given a pattern α , with p variables, a marking sequence of α is an ordering $x_1 < x_2 < \dots < x_p$ of $\text{var}(\alpha)$. The skeleton α_{var} of α is obtained from α by removing all the terminals. A marking of α_{var} w.r.t. a marking sequence $x_1 < x_2 < \dots < x_p$ of α is a p -steps procedure: in step i we mark all occurrences of variable x_i . The pattern α is called k -local if and only if there exists a marking sequence of $x_1 < x_2 < \dots < x_p$ of α such that, for i from 1 to p , the variables marked in the first i steps of the marking of α_{var} w.r.t. this marking sequence form at most k non-overlapping length-maximal factors in α_{var} ; the respective marking sequence is called witness for the k -locality of α . By kLOC we denote the class of k -local patterns. See [18, 15] for an extended discussion and examples regarding k -locality.

Several more particular classes which we consider in this context are the following:

- The class of unary patterns 1Var : $\alpha \in \text{1Var}$ if there exists $x \in X$ such that $\text{var}(\alpha) = \{x\}$; example: $\alpha_1 = \text{abxabxxbaab} \in \text{1Var}$.
- The class of one-repeated-variable patterns 1RepVar : $\alpha \in \text{1RepVar}$ if there exists at most one variable $x \in X$ such that $|\alpha|_x > 1$; example: $\alpha_2 = \text{abxyabzxxbaabv} \in \text{1RepVar}$.
- The class $\text{NonCross} = \text{1SCD}$, called the class of non-cross patterns; as examples, consider $\alpha_3 = \text{abxxyabzzbbvvvabvu} \in \text{NonCross} \setminus \text{1RepVar}$ and $\alpha_4 = \text{abxyabzxxbbvabx} \in \text{1RepVar} \setminus \text{NonCross}$. Note that $\alpha \in \text{NonCross}$ if and only if α can be written as the concatenation of several 1Var -patterns, whose variables are pairwise distinct. Thus, NonCross -patterns are 1-local.

Note that in a NonCross -pattern α , for any two variables $x, y \in \text{var}(\alpha)$, where the last occurrence of y is to the right of the first occurrence of x in α , we can actually write $\alpha = \beta x \gamma y \delta$ such that $x, y \notin \text{var}(\gamma)$, $x \notin \text{var}(\delta)$, and $y \notin \text{var}(\beta)$. In other words, there are no interleaved occurrences of two variables. Moreover, if $\alpha \in \text{NonCross}$, then α is 1-local: the marking sequence is obtained by ordering the variables according to the position of their first

occurrence. Clearly, $1\text{Var} \subset 1\text{RepVar}$ and $1\text{Var} \subset \text{NonCross}$, but 1RepVar and NonCross are incomparable. Indeed, if $\alpha \in \text{NonCross}$ then α is 1-local and 1RepVar contains patterns α with $\text{scd}(\alpha) = 2$.

Further, if α is a pattern and $x \in \text{var}(\alpha)$, then an x -block is a factor $\alpha[i : j]$ such that $\alpha[i : j] \in 1\text{Var}$ with $\text{var}(\alpha[i : j]) = x$ and it is length-maximal with this property: it cannot be extended to the right or to the left without introducing a variable different from x .

The next lemma is fundamental for the results of this section.

► **Lemma 4.1.** *Given a set of words $w_1, \dots, w_p \in \Sigma^m$, we can find in $O(|\Sigma| + mp)$ a median string for $\{w_1, \dots, w_p\}$, i.e. a string w such that $\sum_{j=1}^p d_{\text{HAM}}(w_i, w)$ is minimal.*

Proof. We will use an array C with Σ elements, called counters, indexed by the letters of Σ , and all initially set to 0. For each i between 1 and m , we count how many times each letter of Σ occurs in the multi-set $\{w_1[i], w_2[i], \dots, w_p[i]\}$ using C . Let $w[i]$ be the most frequent letter of this multi-set. After computing $w[i]$, we reset the counters which were changed in this iteration, and repeat the algorithm for $i + 1$. After going through all values of i , we return the word $w = w[1]w[2] \dots w[m]$ as the answer to the problem. The correctness of the algorithm is immediate, while its complexity is clearly $O(|\Sigma| + mp)$. ◀

The typical use of this lemma is the following: we identify the factors of w to which a repeated variable is aligned, and then compute the optimal assignment of this variable. Based on this, the following theorem can now be shown. The corresponding proof can be found in the full version of this paper [30].

► **Theorem 4.2.** $\text{MinMismatch}_{1\text{Var}}$ and $\text{Mismatch}_{1\text{Var}}$ can be solved in $O(n)$ time.

By a standard dynamic programming approach, we use the previous result to obtain a polynomial-time solution for $\text{MinMismatch}_{\text{NonCross}}$ based on the solution for $\text{MinMismatch}_{1\text{Var}}$ (in the statement, $p = |\text{var}(\alpha)|$). The corresponding proof can be found in the full version of this paper [30].

► **Theorem 4.3.** $\text{MinMismatch}_{\text{NonCross}}$ and $\text{Mismatch}_{\text{NonCross}}$ can be solved in $O(n^3p)$ time.

The results presented so far show that MinMismatch_P and Mismatch_P can be solved in polynomial time, as long as we do not allow interleaved occurrences of variables in the patterns of the class P . We now consider the case of 1RepVar -patterns, the simplest class of patterns which permits interleaved occurrences of variables. For simplicity, in the results regarding 1RepVar we assume that the variable which occurs more than once in the input pattern is denoted by x . The corresponding proof and the proof of the following more general result can be found in the Appendix B.

► **Theorem 4.4.** $\text{MinMismatch}_{1\text{RepVar}}$ and $\text{Mismatch}_{1\text{RepVar}}$ can be solved in $O(n^{k+2}m)$ time, where k is the number of x -blocks in the input pattern α .

► **Theorem 4.5.** $\text{MinMismatch}_{\text{kLOC}}$ and $\text{Mismatch}_{\text{kLOC}}$ can be solved in $O(n^{2k+2}m)$ time.

Note that NonCross -patterns are 1-local, while the locality of an 1RepVar -pattern is upper bounded by the number of x -blocks. However, the algorithms we obtained in those particular cases are more efficient than the ones which follow from Theorem 4.5.

The fact that Lemma 4.1 is used as the main building block for our results regarding Mismatch_P and MinMismatch_P for $P \in \{1\text{RepVar}, \text{kLOC}\}$, suggests that these problems could be closely related to the following well-studied problem [36, 20, 7, 13].

Consensus Patterns: CP

Input: k strings $w_1, \dots, w_k \in \Sigma^\ell$, integer $m \in \mathbb{N}$ with $m \leq \ell$, an integer $\Delta \leq mk$.

Question: Do the strings s , of length m , and s_1, \dots, s_k , factors of length m of each w_1, \dots, w_k , respectively, exist, such that $\sum_{i=1}^k d_{\text{HAM}}(s_i, s) \leq \Delta$?

Exploiting this connection, and following the ideas of [36], we can show the following theorem. In this theorem we restrict to the case when the input word w of $\text{MinMisMatch}_{1\text{RepVar}}$ is over $\Sigma = \{1, \dots, \sigma\}$ of constant size σ .

► **Theorem 4.6.** *For each constant $r \geq 3$, there exists an algorithm with run-time $O(n^{r+3})$ for $\text{MinMisMatch}_{1\text{RepVar}}$ whose output distance is at most $\min \left\{ 2, \left(1 + \frac{4\sigma-4}{\sqrt{\epsilon}(\sqrt{4r+1}-3)} \right) \right\} d_{\text{HAM}}(\alpha, w)$.*

The proof can be found in the Appendix B. It remains open whether other algorithmic results related to CP (such as those from, e.g., [8, 9, 40]) apply to our setting too.

In the following we show two hardness results which explain why the algorithms in Theorems 4.4 and 4.6 are interesting.

► **Theorem 4.7.** *$\text{MisMatch}_{1\text{RepVar}}$ is $W[1]$ -hard w.r.t. the number of x -blocks.*

Proof. We reduce CP to $\text{MisMatch}_{1\text{RepVar}}$, such that an instance of CP with k different input strings is mapped to an instance of $\text{MisMatch}_{1\text{RepVar}}$ with $k+1$ x -blocks (where x is the repeated variable), each containing exactly one occurrence of x .

Hence, we consider an instance of CP which consists of k strings $w_1, \dots, w_k \in \Sigma^\ell$ of length ℓ and two integer m, Δ defining the length of the target factors and the number of allowed mismatches, respectively.

The instance of $\text{MisMatch}_{1\text{RepVar}}$ which we construct consists of a text w and a pattern α , such that α contains $k+1$ x -blocks, each with exactly one occurrence of x , and is of polynomial size w.r.t. the size of the CP-instance. Moreover, the number of mismatches allowed in this instance of $\text{MisMatch}_{1\text{RepVar}}$ is $\Delta' = m + \Delta$. That is, if there exists a solution for the CP-instance with Δ allowed mismatches, then, and only then, we should be able to find a solution of the $\text{MisMatch}_{1\text{RepVar}}$ -instance with $\Delta + m$ mismatches.

The construction of the $\text{MinMisMatch}_{1\text{RepVar}}$ is realized in such a way that the word w encodes the input strings, while α creates the mechanism for selecting the string s and corresponding factors s_1, \dots, s_k . The general idea is that x should be mapped to s , and the factors to which the occurrences of x are aligned should correspond to the strings s_1, \dots, s_k .

The structure of the word w and that of the pattern α ensure that, in an alignment of α with w which cannot be traced back to a admissible solution for the CP-instance (that is, the occurrences of x are not aligned to factors of length m of the words w_1, \dots, w_k or x is not mapped to a string of length m) we have at least $M \gg \Delta'$ mismatches, hence it cannot lead to a positive answer for the constructed instance of $\text{MisMatch}_{1\text{RepVar}}$.

The reduction consists of three main steps. Firstly, we present a pair of gadgets to encode the relation of the strings w_i and their factors s_i , for i from 1 to k . Then, we present a second pair of gadgets, which ensures that, in a positive solution of $\text{MisMatch}_{1\text{RepVar}}$, the variable x can only be mapped to a string of length m , corresponding to the string s . Finally, we show how to assemble these gadgets into the input word w and the input pattern α for $\text{MisMatch}_{1\text{RepVar}}$.

First pair of gadgets. We introduce the new letters $\{a, b\}$, not contained in the input alphabet of the CP-instance, as well as the variable x and two fresh variables y_i, z_i , for each i from 1 to k . We construct the following two gadgets for each input string w_i with $1 \leq i \leq k$.

- A gadget to be included in w : $g_i = w_i \overbrace{a^M b^M \dots a^M b^M}^M$.
- A gadget to be included in α : $f_i = y_i x z_i \overbrace{a^M b^M \dots a^M b^M}^M$.

These gadgets allows us to align the i^{th} occurrence of x to an arbitrary factor of the word w_i , for i from 1 to k .

Second pair of gadgets. In this case, we use three new letters $\{c, d, \$\}$ which are not contained in the input alphabet of CP. Also, let $M = (k\ell)^2$. We define two new gadgets.

- A gadget to be included in w : $A_w = \overbrace{c^M d^M \dots c^M d^M}^M \m .
- A gadget to be included in α : $A_\alpha = \overbrace{c^M d^M \dots c^M d^M}^M x$.

These gadgets enforce that, in an alignment of α and w , the variable x is mapped to a string of length m , at the cost of exactly m extra mismatches. Note that, because $\Delta \leq km$, we have that $M \gg \Delta$.

Final assemblage. The word w and the pattern α are defined as follows.

- $w = g_1 g_2 \dots g_k A_w$ and $\alpha = f_1 f_2 \dots f_k A_\alpha$.

To wrap up, the instance of $\text{MinMismatch}_{1\text{RepVar}}$ is defined by $w, \alpha, \Delta + m$.

The correctness of the reduction. We will show that our reduction is correct by a detailed case analysis. We consider an alignment of α and w with minimal number of mismatches, and we make the following observations.

- A. Firstly, if every g_i is aligned to f_i , for i from 1 to k , it is immediate that x is mapped to a string of length m , as the last occurrence of x will be aligned to the $\m suffix of w . Thus, the total number of mismatches between α and w in an alignment with a minimum number of mismatches is upper-bounded by $(k+1)m$.
- B. Secondly, we assume, for the sake of a contradiction, that the length of the image of x is not m . If $|x| > m$ (respectively, $|x| < m$) then the prefix $(c^M d^M)^M$ of A_α is aligned to a factor of w which starts strictly to the left of (respectively, to the right of) the first position of the prefix $(c^M d^M)^M$ of A_w . It is not hard to see that this causes at least M mismatches. Indeed, in the case when $|x| > m$, if the factor $(c^M d^M)^M$ of α is aligned to a factor that starts at least M position to the left of the factor $(c^M d^M)^M$ of w , the conclusion is immediate; if the factor $(c^M d^M)^M$ starts less than M positions to the left of the factor $(c^M d^M)^M$ of w , then each group c^M in α will be aligned to a factor of w that includes at least a d letter, so we again reach the conclusion. In the case when $|x| < m$, then, again, each group c^M in α will be aligned to a factor of w that includes at least a d letter, so the alignment leads to at least M mismatches.

So, we can assume from now on that x is mapped to a string of length m . This also implies that A_α and A_w are aligned, so we will largely neglect them from now on.

- C. Thirdly, we assume that there exists i such that $|h(y_i)| + |h(z_i)| \neq |w_i| - m$. Let $j = \min\{i \leq k \mid |h(y_i)| + |h(z_i)| \neq |w_i| - m\}$. Then the suffixes $(a^M b^M)^M$ of g_j and f_j do not align perfectly to each other. If $|h(y_j)| + |h(z_j)| < |w_j| - m$, then the suffix $(a^M b^M)^M$ of f_j is aligned to a factor of w which starts inside w_j . This immediately causes at least M mismatches, as each group a^M will overlap to a group of which contains at least one b letter. If $|h(y_j)| + |h(z_j)| > |w_j| - m$, then the suffix $(a^M b^M)^M$ of f_j is aligned to a factor of w which starts strictly to the right of the factor w_j . However, because $M = (k\ell)^2 \gg k\ell$,

and f_j and g_j are followed by the same number of factors $(\mathbf{a}^M \mathbf{b}^M)^M$ (until the factors A_α and A_w are reached), the factor corresponding to the suffix $(\mathbf{a}^M \mathbf{b}^M)^M$ of f_j cannot start more than $k\ell$ positions to the right of w_j . It is then immediate that this factor $(\mathbf{a}^M \mathbf{b}^M)^M$ of f_j will cause at least M mismatches: each group \mathbf{a}^M will overlap to a group of which contains at least one \mathbf{b} letter.

So, from now on we can assume that the factors $(\mathbf{a}^M \mathbf{b}^M)^M$ of g_j and f_j are aligned.

- D. At this point, it is clear that in each alignment of α and w which fulfils the conditions described in items B and C: the variable x is mapped to a string of length m , and its first k occurrences are aligned to factors of the words w_1, \dots, w_k . We will now show that for each alignment of α and w in which the image of x contains a $\$$ symbol and fulfils the conditions above, there exists an alignment of α and w with at most the same number of mismatches, in which the image of x does not contain a $\$$ symbol and, once more, fulfils the conditions B and C. Assume that in our original alignment x is mapped to a string u_x of length m such that $u_x[i] = \$$. Let u_1, \dots, u_k be the factors of w_1, \dots, w_k , respectively, to which the first occurrences of the variable x are aligned. Consider the string u'_x which is obtained from u_x by simply replacing the $\$$ symbol on position i by $u_1[i]$. And then consider the alignment of α and w which is obtained from the original alignment by changing the image of x to u'_x instead of u_x . When compared to the original alignment, the new alignment has an additional mismatch caused by the occurrence of x aligned to $\m , but at least one less mismatch caused by the alignments of the first k occurrences of x . Indeed, in the original alignment, the i^{th} position of u_x was a mismatch to the i^{th} position of any string u_1, \dots, u_k , but now at least the i^{th} positions of w_1 and u'_x coincide. This shows that our claim holds. A similar argument shows that for any alignment in which x is mapped to a string containing other letters than the input letters from the CP-instance there exists an alignment in which x is mapped to a string containing only letters from the CP-instance.

Hence, from now on we can assume that the factors $(\mathbf{a}^M \mathbf{b}^M)^M$ of g_j and f_j are aligned and that the image of x has length m and is over the input alphabet of CP-instance.

Based on the observations A-D, we can show that the reduction has the desired properties. If the CP-instance admits a solution s, s_1, \dots, s_k which causes a number of mismatches less or equal to Δ , then we can produce an alignment of α to w as follows. We map x to s and, for i from 1 to k , we map x_i and y_i to the prefix of w_i occurring before s_i and, respectively, the suffix of w_i occurring after s_i . This leads to $\Delta + m$ mismatches between α and w , so the input $(w, \alpha, \Delta + m)$ of $\text{MisMatch}_{1\text{RepVar}}$ is accepted. Conversely, if we have an alignment of α and w with at most $\Delta + m$ mismatches, then we have an alignment with the same number of mismatches which fulfils the conditions summarized at the end of item D above. Hence, we can define s as the image of x in this alignment, and the strings s_1, \dots, s_k as the factors of w aligned to the first k occurrences of x from α . Clearly, for i between 1 and k , s_i is a factor of w_i . As m mismatches of the alignment were caused by the alignment of the last x to $\m , we get that $\sum_{i=1}^k d_{\text{HAM}}(s, s_i) \leq \Delta$. Thus, the instance of CP is accepted.

This concludes the proof of the correctness of our reduction. As M is clearly of polynomial size w.r.t. the size of the CP-instance, it follows that both w and α are of polynomial size $\mathcal{O}(kM^2)$. Therefore, the instance of $\text{MinMisMatch}_{1\text{RepVar}}$ can be computed in polynomial time, and our entire reduction is done in polynomial time. Moreover, we have shown that the instance $(w, \alpha, \Delta + M)$ of $\text{MinMisMatch}_{1\text{RepVar}}$ is answered positively if and only if the original instance of CP is answered positively. Finally, as the number of x blocks in α is $k + 1$, where k is the number of input strings in the instance of CP, and CP is $W[1]$ -hard with respect to this parameter, it follows that $\text{MinMisMatch}_{1\text{RepVar}}$ is also $W[1]$ -hard when the number of k -blocks in α is considered as parameter. This completes our proof. \blacktriangleleft

Note that the pattern α constructed in the reduction above is $k-1$ -local (and not k -local): a witness marking sequence is $z_1 < y_2 < z_2 < y_3 < \dots < z_{k-1} < y_k < x < y_1 < z_k$. Thus, $\text{MisMatch}_{1\text{RepVar}}$ is $W[1]$ -hard w.r.t. locality of the input pattern as well. Also, it is easy to see that $\text{scd}(\alpha) = 2$, and, by the results of [42], this shows that the treewidth of the pattern α , as defined in the same paper, is at most 3. Thus, even for classes of patterns with constant scd , number or repeated variables, or treewidth, the problems MisMatch_P and MinMisMatch_P can become intractable. In Theorem 4.6 we have shown that $\text{MinMisMatch}_{1\text{RepVar}}$ admits a polynomial time approximation scheme (for short, PTAS). We will show in the following that it does not admit an efficient PTAS (for short, EPTAS), unless $FPT = W[1]$. This means that there is no PTAS for $\text{MinMisMatch}_{1\text{RepVar}}$ such that the exponent of the polynomial in its running time is independent of the approximation ratio. To show this, we consider an optimisation variant of the problem CP, denoted minCP . In this problem, for k strings $w_1, \dots, w_k \in \Sigma^\ell$ of length ℓ and an integer $m \in \mathbb{N}$ with $m \leq \ell$, we are interested in the smallest non-negative integer Δ for which there exist strings s , of length m , and s_1, \dots, s_k , factors of length m of each w_1, \dots, w_k , respectively, such that $\sum_{i=1}^k d_{\text{HAM}}(s_i, s) = \Delta$. In [7], it is shown that minCP has no EPTAS unless $FPT = W[1]$. We can use this result and the reduction from the Theorem 4.7 to show the following result (see Appendix B).

► **Theorem 4.8.** $\text{MinMisMatch}_{1\text{RepVar}}$ has no EPTAS unless $FPT = W[1]$.

A Computational Model

The computational model we use to describe our results is the standard unit-cost RAM with logarithmic word size: for an input of size n , each memory word can hold $\log n$ bits. Arithmetic and bitwise operations with numbers in $[1 : n]$ are, thus, assumed to take $O(1)$

time. Numbers larger than n , with ℓ bits, are represented in $O(\ell/\log n)$ memory words, and working with them takes time proportional to the number of memory words on which they are represented. In all the problems, we assume that we are given a word w and a pattern α , with $|w| = n$ and $|\alpha| = m \leq n$, over a terminal-alphabet $\Sigma = \{1, 2, \dots, \sigma\}$, with $|\Sigma| = \sigma \leq n$. The variables are chosen from the set $\{x_1, \dots, x_n\}$ and can be encoded as integers between $n + 1$ and $2n$. That is, we assume that the processed words are sequences of integers (called letters or symbols), each fitting in $O(1)$ memory words. This is a common assumption in string algorithms: the input alphabet is said to be *an integer alphabet*. For instance, the same assumption was also used for developing efficient algorithms for `Match` in [21]. For a more detailed general discussion on this model see, e.g., [17].

B Proofs

► **Lemma 3.1.** *Let w and u , with $|w| = |u| = n$, be two words and δ a non-negative integer. Assume that, in a preprocessing phase, we have constructed $LCS_{w,u}$ -data structures. We can compute $\min(\delta + 1, d_{\text{HAM}}(u, w))$ using $\delta + 1$ $LCS_{w,u}$ queries, so in $O(\delta)$ time.*

Proof. Let $a = b = m$ and $d = 0$. While $a > 0$ and $d \leq \delta$ execute the following steps. Compute $h = LCS_{w,u}(a, b)$. If $h < b$, then increment d by 1, set $a \leftarrow a - h - 1$ and $b \leftarrow b - h - 1$, and start another iteration of the while-loop. If $h = b$, then set $b \leftarrow 0$ and exit the while-loop.

It is not hard to note that before each iteration of the while loop it holds that $d = d_{\text{HAM}}(w[a + 1 : m], u[b + 1 : m])$. When the while loop is finished, $d = \min(d_{\text{HAM}}(w[i - m + 1 : i], u[1 : m]), \delta + 1)$. In each iteration we first identify the length h of the longest common suffix of $w[1 : a]$ and $u[1 : b]$. Then, we jump over this suffix, as it causes no mismatches, and have either traversed completely the words w and u (and we do not need to do anything more), or we have reached a mismatch between w and u , on position $a - h = b - h$. In the latter case, we count this mismatch, jump over it, and repeat the process (but only if the number of mismatches is still at most δ). So, in other words, we go through the mismatches of w and u , from right to left, and jump from one to the next one using $LCS_{w,u}$ queries. If we have more than δ mismatches, we do not count all of them, but stop as soon as we have met the $(\delta + 1)^{\text{th}}$ mismatch. Accordingly, the algorithm is correct. Clearly, we only need $\delta + 1$ $LCS_{w,u}$ -queries and the time complexity of this algorithm is $O(\delta)$, once the $LCS_{w,u}$ -data structures are constructed. ◀

► **Lemma 3.2.** *Given a word w , with $|w| = n$, a word u , with $|u| = m < n$, and a non-negative integer δ , we can compute in $O(n\delta)$ time the array $D[m : n]$ with $n - m + 1$ elements, where $D[i] = \min(\delta + 1, d_{\text{HAM}}(w[i - m + 1 : i], u))$.*

Proof. We first construct, in linear time, the $LCS_{w,u}$ -data structures for the input words. Note that the $LCS_{w,u}$ -data structure can be directly used as $LCS_{w[i:i+m-1],u}$ data structure, for all $i \leq n - m + 1$.

Then, for each position i of w , with $i \leq m$, we use Lemma 3.1 to compute, in $O(\delta)$ time the value $d = \min(d_{\text{HAM}}(u, w[i - m + 1 : i]), \delta + 1)$. We then set $D[i] \leftarrow d$. By the correctness of Lemma 3.1, we get the correctness of this algorithm. Clearly, its time complexity is $O(n\delta)$. ◀

► **Theorem 4.4.** *$\text{MinMisMatch}_{1\text{RepVar}}$ and $\text{MisMatch}_{1\text{RepVar}}$ can be solved in $O(n^{k+2}m)$ time, where k is the number of x -blocks in the input pattern α .*

Proof. Once more, we only show how $\text{MinMismatch}_{1\text{RepVar}}$ can be solved. The result for $\text{Mismatch}_{1\text{RepVar}}$ follows then immediately.

In $\text{MinMismatch}_{1\text{RepVar}}$, we are given a word w , of length n , and a pattern α , of length m , which, as stated above, has exactly k x -blocks. Thus $\alpha = \prod_{i=1}^k (\gamma_{i-1}\beta_i)\gamma_k$, where the factors β_i , for $i \in \{1, \dots, k\}$, are the x -blocks of α . It is easy to observe that $\text{var}(\gamma_i) \cap \text{var}(\gamma_j) = \emptyset$, for all i and j , and $\gamma = \gamma_0\gamma_1 \cdots \gamma_k$ is a regular pattern.

When aligning α to w we actually align each of the patterns γ_j and β_i , for $0 \leq j \leq k$ and $1 \leq i \leq k$, to respective factors of the word w . Moreover, the factors to which these patterns are respectively aligned are completely determined by the length ℓ of the image of x , and the starting positions h_i of the factors aligned to the patterns β_i , for $1 \leq i \leq k$. Knowing the length ℓ of the image of x , we can also compute, for $1 \leq i \leq k$, the length ℓ_i of β_i , when x is replaced by a string of length ℓ . In this case, γ_0 is aligned $u_0 = w[1..h_1 - 1]$ and, for $1 \leq i \leq k$, β_i is aligned to $w_i = w[h_i : h_i + \ell_i - 1]$ and γ_i is aligned $u_i = w[h_i + \ell_i : h_{i+1} - 1]$ (where $h_{k+1} = n + 1$). Thus, $\beta_1 \cdots \beta_k$ matches $w_1 \cdots w_k$ and we can use Theorem 4.2 to determine $d_{\text{HAM}}(\beta_1 \cdots \beta_k, w_1 \cdots w_k)$ (or, in other words, determine the string u_x that should replace x in order to realize this Hamming distance). Further, we can use Theorem 3.4 to compute $d_{\text{HAM}}(\gamma_i, u_i)$, for all $i \in \{0, \dots, k\}$. Adding all these distances up, we obtain a total distance $D_{\ell, h_1, \dots, h_k}$; this value depends on ℓ, h_1, \dots, h_k .

So, we can simply iterate over all possible choices for ℓ, h_1, \dots, h_k and find $d_{\text{HAM}}(\alpha, w)$ as the minimum of the numbers $D_{\ell, h_1, \dots, h_k}$.

By the explanations above, it is straightforward that the approach is correct: we simply try all possibilities of aligning α with w . The time complexity is, for each choice of ℓ, h_1, \dots, h_k , $O(\sum_{i=1}^k |w_i|) \subseteq O(n)$ for the part corresponding to the computation of the optimal alignment between the factors β_i and the words w_i , and $O(\sum_{i=0}^k |u_i| d_{\text{HAM}}(\gamma_i, u_i)) \subseteq O(nm)$ for the part corresponding to the computation of the optimal alignment between the factors γ_i and the words u_i . So, the overall complexity of this algorithm is $O(n^{k+2}m)$. ◀

► **Theorem 4.5.** $\text{MinMismatch}_{\text{kLOC}}$ and $\text{Mismatch}_{\text{kLOC}}$ can be solved in $O(n^{2k+2}m)$ time.

Proof. We only present the solution for $\text{MinMismatch}_{\text{kLOC}}$ (as it trivially works in the case of $\text{Mismatch}_{\text{kLOC}}$ too).

Let us note that, by the results in [18], we can compute a marking sequence of α in $O(m^{2k}k)$ time. So, after such a preprocessing phase, we can assume that we have a word w , a k -local pattern α (with p variables) with a witness marking sequence $x_1 \leq \dots \leq x_p$ for the k -locality of α , and we want to compute $d_{\text{HAM}}(\alpha, w)$.

Generally, the main idea behind matching kLOC -patterns is that when looking for possible ways to align such a pattern α to a word w we can consider the variables in the order given by the marking sequence, and, when reaching variable x_i , we try all possible assignments for x_i . The critical observation here is that after each such assignment of a new variable, we only need to keep track of the way the $t \leq k$ length-maximal factors of α , which contain only marked variables and terminals, match (at most) $t \leq k$ factors of w .

We will use this approach in our algorithm for $\text{MinMismatch}_{\text{kLOC}}$.

The first step of this algorithm is the following. We go through α and identify all x_1 -blocks: $\beta_{1,1}, \dots, \beta_{1,j_1}$. Because α is k -local, we have that $j_1 \leq k$. For each $2j_1$ -tuple (i_1, \dots, i_{2j_1}) of positions of w , we compute the minimum number of mismatches if we align (simultaneously) the patterns β_g to the factors $w[i_{2g-1} : i_{2g}]$, for g from 1 to j_1 , respectively. This reduces to finding an assignment for x_1 which aligns optimally the patterns $\beta_{1,g}$ to the respective factors, and can be done in $O(n)$ time using Theorem 4.2. For each $2j_1$ -tuple (i_1, \dots, i_{2j_1}) of

positions of w , we denote by $M_1(i_1, \dots, i_{2j_1})$ the minimum number of mismatches resulting from the (simultaneous) alignment of the patterns $\beta_{1,g}$ to the factors $w[i_{2g-1} : i_{2g}]$, for g from 1 to j_1 , respectively. Clearly, M_1 can be seen as a j_1 -dimensional array.

Assume that after $h \geq 1$ steps of our algorithm we have computed the factors $\beta_{h,1}, \dots, \beta_{h,j_h}$ of α , which are length-maximal factors of α which only contain the variables x_1, \dots, x_h and terminals (i.e., extending them to the left or right would introduce a new variable x_ℓ with $\ell > h$); as α is k -local, we have $j_h \leq k$. Moreover, for each $2j_h$ -tuple (i_1, \dots, i_{2j_h}) of positions of w , we have computed $M_h(i_1, \dots, i_{2j_h})$, the minimum number of mismatches if we align (simultaneously) the patterns $\beta_{h,g}$ to the factors $w[i_{2g-1} : i_{2g}]$, for g from 1 to j_h , respectively. M_h is implemented as a j_h dimensional array, and this assumption clearly holds after the first step.

We now explain how step $h + 1$ is performed.

1. We compute the factors $\beta_{h+1,1}, \dots, \beta_{h+1,j_{h+1}}$ of α , which are length-maximal factors of α which only contain the variables x_1, \dots, x_{h+1} and terminals (i.e., extending them to the left or right would introduce a new variable x_ℓ with $\ell > h + 1$). Clearly, $\beta_{h+1,r}$ is either an x_{h+1} -block or it has the form $\beta_{h+1,r} = \gamma_{r,0}\beta_{h,a_r}\gamma_{r,1} \cdots \beta_{r,a_r+b_r}\gamma_{r,b_r+1}$ where the patterns $\gamma_{r,t}$ contain only the variable x_{h+1} and terminals and extending $\beta_{h+1,r}$ to the left or right would introduce a new variable x_ℓ with $\ell > h + 1$.
2. We initialize the values $M_{h+1}(i_1, \dots, i_{2j_{h+1}}) \leftarrow \infty$, for each $2j_{h+1}$ -tuple $(i_1, \dots, i_{2j_{h+1}})$ of positions of w .
3. For each $\ell \leq n$ (where ℓ corresponds to the length of the image of x_{h+1}) and each $2j_h$ -tuple (i_1, \dots, i_{2j_h}) of positions of w such that $M_h(i_1, \dots, i_{2j_h})$ is finite do the following:
 - a. We compute the tuple $(i'_1, \dots, i'_{2j_{h+1}})$ such that $\beta_{h+1,g}$ is aligned to the factor $w[i'_{2g-1} : i'_{2g}]$, for g from 1 to j_{h+1} , respectively. This can be computed based on the fact that the factors $\beta_{h,g}$ are aligned to the factors $w[i_{2g-1} : i_{2g}]$, for g from 1 to j_h , respectively, and the image of x_{h+1} has length ℓ .
 - b. We compute the factors of w aligned to x_{h+1} in the alignment computed in the previous line. Then, we can use the algorithm from Theorem 4.2 and the value of $M_h(i_1, \dots, i_{2j_h})$ to compute an assignment for x_{h+1} which aligns optimally the patterns $\beta_{h+1,g}$ to the corresponding factors of w .
 - c. If the number of the mismatches in this alignment is smaller than the current value of $M_{h+1}(i'_1, \dots, i'_{2j_{h+1}})$, we update $M_{h+1}(i'_1, \dots, i'_{2j_{h+1}})$.

This dynamic programming approach is clearly correct. In $M_{h+1}(i_1, \dots, i_{2j_{h+1}})$ we have the optimal alignment of the patterns $\beta_{h+1,1}, \dots, \beta_{h+1,j_{h+1}}$ to $w[i_1 : i_2], \dots, w[i_{2j_{h+1}-1} : i_{2j_{h+1}}]$, respectively. As far as the complexity is concerned, the lines 1, 3.a, 3.b, 3.c can be implemented in linear time, while the for-loop is iterated $O(n^{2k+1})$ times. Line 2 takes $O(n^{2k})$ times. The whole computation in step $h + 1$ of the algorithm takes, thus, $O(n^{2k+1})$ time.

Now, we execute the procedure described above for h from 2 to m , and, in the end, we compute the array M_m . The answer to our instance of the problem $\text{MinMismatch}_{\text{KLOC}}$ is $M_m(1, n)$. The overall time complexity needed to perform this computation is $O(mn^{2k+1})$ time. The preprocessing phase, in which the marking sequence and the array M_1 were computed, takes also $O(mn^{2k+1})$ time. So, the complexity stated in the statement is reached by our algorithm. \blacktriangleleft

► Theorem 4.6. *For each constant $r \geq 3$, there exists an algorithm with run-time $O(n^{r+3})$ for $\text{MinMismatch}_{1\text{RepVar}}$ whose output distance is at most $\min \left\{ 2, \left(1 + \frac{4\sigma-4}{\sqrt{e}(\sqrt{4r+1}-3)} \right) \right\} d_{\text{HAM}}(\alpha, w)$.*

Proof. We first note that there exists a relatively simple algorithm solving $\text{MinMisMatch}_{1\text{RepVar}}$ such that the output distance is no more than $2d_{\text{HAM}}(\alpha, w)$ (which also works for integer alphabets).

Indeed, assume that we have a substitution h for which $d_{\text{HAM}}(h(\alpha), w) = d_{\text{HAM}}(\alpha, w)$. Assume that the repeated variable x is mapped by h to a string u and the t occurrences of x are aligned, under h , to the factors w_1, w_2, \dots, w_t of w . Now, let w_i be such $d_{\text{HAM}}(u, w_i) \leq d_{\text{HAM}}(u, w_j)$ for all $j \neq i$. Let us consider now the substitution h' which substitutes x by w_i and all the other variables exactly as h did. We claim that $d_{\text{HAM}}(h'(\alpha), u) \leq 2d_{\text{HAM}}(h(\alpha), u)$. It is easy to see that $d_{\text{HAM}}(h'(\alpha), w) - d_{\text{HAM}}(h(\alpha), w) = \sum_{j=i}^t (d_{\text{HAM}}(w_i, w_j) - d_{\text{HAM}}(u, w_j)) \leq \sum_{j=i}^t (d_{\text{HAM}}(w_i, u) + d_{\text{HAM}}(u, w_j) - d_{\text{HAM}}(u, w_i))$ (where the last inequality follows from the triangle inequality for the Hamming distance). Thus, $d_{\text{HAM}}(h'(\alpha), w) - d_{\text{HAM}}(h(\alpha), w) \leq \sum_{j=i}^t d_{\text{HAM}}(w_i, u) \leq \sum_{j=i}^t d_{\text{HAM}}(w_j, u) \leq d_{\text{HAM}}(h(\alpha), u)$. So our claim holds.

A consequence of the previous observation is that there exists a substitution h' that maps x to a factor of w and produces a string $h'(\alpha)$ such that $d_{\text{HAM}}(h'(\alpha), u) \leq 2d_{\text{HAM}}(\alpha, u)$. So, for each factor u of w , we x by u in α to obtain a regular pattern α' , then use Theorem 3.4 to compute $d_{\text{HAM}}(\alpha', w)$. We return the smallest value $d_{\text{HAM}}(\alpha', w)$ achieved in this way. Clearly, this is at most $2d_{\text{HAM}}(\alpha, w)$. The complexity of this algorithm is $O(n^4)$, as it simply uses the quadratic algorithm of Theorem 3.4 for each factor of w .

We will now show how this algorithm can be modified to produce a value closer to $d_{\text{HAM}}(\alpha, w)$, while being less efficient.

The algorithm consists of the following main steps:

1. For $\ell \leq n/r$ and r factors u_1, \dots, u_r of length ℓ of w do the following:
 - a. Compute u_{u_1, \dots, u_r} the median string of u_1, \dots, u_r using Lemma 4.1.
 - b. Let α' be the regular pattern obtained by replacing x by u_{u_1, \dots, u_r} in α .
 - c. Compute the distance $d_{u_1, \dots, u_r} = d_{\text{HAM}}(\alpha', w)$ using Theorem 3.4.
2. Return the smallest distance d_{u_1, \dots, u_r} computed in the loop above.

Clearly, for $r = 1$ the above algorithm corresponds to the simple algorithm presented in the beginning of this proof. Let us analyse its performance for an arbitrary choice of r .

The complexity is easy to compute: we need to consider all possible choices for ℓ and the starting positions of u_1, \dots, u_r . So, we have $O(n^{r+1})$ possibilities to select the non-overlapping factors u_1, \dots, u_r of length ℓ of w . The computation done inside the loop can be performed in $O(n^2)$ time. So, overall, our algorithm runs in $O(n^{r+3})$ time.

Now, we want to estimate how far away from $d_{\text{HAM}}(\alpha, w)$ is the value this algorithm returns. In this case, we will make use of the fact that the input terminal-alphabet is constant. We follow closely (and adapt to our setting) the approach from [36].

Firstly, a notation. In step 1.b of the algorithm above, we align α' to w with a minimal number of mismatches. In this alignment, let d'_{u_1, \dots, u_r} be the total number of mismatches caused by the factors u_{u_1, \dots, u_r} which replaced the occurrences of the variable x in α .

Now, assume that we have a substitution h for which $d_{\text{HAM}}(h(\alpha), w) = d_{\text{HAM}}(\alpha, w) = d_{\text{opt}}$. Assume also that the repeated variable x is mapped by h to a string u_{opt} of length L and the t occurrences of x are aligned, under h , to the factors w_1, w_2, \dots, w_t of w . Let d'_{opt} be the number of mismatches caused by the alignment of the images of the t occurrences of x under h to the factors w_1, w_2, \dots, w_t . Finally, let $\rho = 1 + \frac{4\sigma-4}{\sqrt{e}(\sqrt{4r+1}-3)}$.

Note that, for $\ell = L$, u_1, \dots, u_r correspond to a set of randomly chosen numbers i_1, \dots, i_r from $\{1, \dots, n\}$: their starting positions. We will show in the following that $E[d'_{u_1, \dots, u_r}] \leq \rho d'_{\text{opt}}$. If this inequality holds, then we can apply the probabilistic method: there exists at least a choice of u_1, \dots, u_r of length L such that $d'_{u_1, \dots, u_r} \leq \rho d'_{\text{opt}}$. As we try all possible lengths ℓ and all variants for choosing u_1, \dots, u_r of length ℓ , we will also consider

the choice of u_1, \dots, u_r of length L such that $d'_{u_1, \dots, u_r} \leq \rho d'_{opt}$, and it is immediate that, for that, for the respective u_1, \dots, u_r we also have that $d_{u_1, \dots, u_r} \leq \rho d_{opt}$. Thus, the value returned by our algorithm is at most ρd_{opt} .

So, let us show the inequality $E[d'_{u_1, \dots, u_r}] \leq \rho d'_{opt}$.

For $\mathbf{a} \in \Sigma$, let $f_j(\mathbf{a}) = |\{i \mid 1 \leq i \leq t, w_i[j] = \mathbf{a}\}|$. Now, for an arbitrary string s of length L , we have that $\sum_{i=1}^t d_{\text{HAM}}(w_i, s) = \sum_{j=1}^L (t - f_j(s[j]))$. So, for $s = u_{opt}$ we get $\sum_{i=1}^t d_{\text{HAM}}(w_i, u_{opt}) = \sum_{j=1}^L (t - f_j(u_{opt}[j]))$, and for $s = u_{u_1, \dots, u_r}$ we have that $d'_{opt} = \sum_{i=1}^t d_{\text{HAM}}(w_i, u_{u_1, \dots, u_r}) = \sum_{j=1}^L (t - f_j(u_{u_1, \dots, u_r}[j]))$.

Therefore, $E[d'_{u_1, \dots, u_r}] = E\left[\sum_{j=1}^L (t - f_j(u_{u_1, \dots, u_r}[j]))\right] = \sum_{j=1}^L E[t - f_j(u_{u_1, \dots, u_r}[j])]$.

Consequently, $E[d'_{u_1, \dots, u_r} - d'_{opt}] = \sum_{j=1}^L (E[t - f_j(u_{u_1, \dots, u_r}[j])] - t + f_j(u_{opt}[j]))$.

That is, $E[d'_{u_1, \dots, u_r} - d'_{opt}] = \sum_{j=1}^L E[f_j(u_{opt}[j]) - f_j(u_{u_1, \dots, u_r}[j])]$.

By Lemma 7 of [36], we have that $E[f_j(u_{opt}[j]) - f_j(u_{u_1, \dots, u_r}[j])] \leq (\rho - 1)(t - f_j(u_{opt}[j]))$.

Hence, $E[d'_{u_1, \dots, u_r} - d'_{opt}] \leq (\rho - 1) \sum_{j=1}^L (t - f_j(u_{opt}[j])) = (\rho - 1)d'_{opt}$.

So, we indeed have that $E[d'_{u_1, \dots, u_r}] \leq \rho d'_{opt}$.

In conclusion, the statement of the theorem holds. \blacktriangleleft

► **Theorem 4.8.** $\text{MinMisMatch}_{1\text{RepVar}}$ has no EPTAS unless $FPT = W[1]$.

Proof. Assume, for the sake of a contradiction, that $\text{MinMisMatch}_{1\text{RepVar}}$ has an EPTAS. That is, for an input word w and an 1RepVar -pattern α , there exists a polynomial time algorithm which returns as answer to $\text{MinMisMatch}_{1\text{RepVar}}$ a value $\delta' \leq (1 + \epsilon)d_{\text{HAM}}(\alpha, w)$, and the exponent of the polynomial in its running time is independent of ϵ .

An algorithm for minCP would first implement the reduction in Theorem 4.7 to obtain a word w and a pattern α . Then it uses the EPTAS for $\text{MinMisMatch}_{1\text{RepVar}}$ to approximate the distance between α and w with approximation ratio $(1 + \frac{\epsilon}{2m})$. Assuming that this EPTAS returns the value D , the answer returned by this algorithm for the minCP problem is $D - m$.

As explained in the proof of Theorem 4.7, it is easy to see that the distance between the word w and the pattern α constructed in the respective reduction is $m + \Delta$, if Δ is the answer to the instance of the minCP problem. Thus, the value D returned by the EPTAS for $\text{MinMisMatch}_{1\text{RepVar}}$ fulfils $m + \Delta \leq D \leq (1 + \frac{\epsilon}{2m})(m + \Delta)$. So, we have $\Delta \leq D - m \leq \frac{\epsilon}{2} + (1 + \frac{\epsilon}{2m})\Delta$. We get that $\Delta \leq D - m \leq (1 + \frac{\epsilon}{2m} + \frac{\epsilon}{2\Delta})\Delta \leq (1 + \epsilon)\Delta$. So, indeed, $D - m$ would be a $(1 + \epsilon)$ -approximation of Δ .

Therefore, this would yield an EPTAS for minCP . This is a contradiction to the results reported in [7], where it was shown that such an EPTAS does not exist, unless $FPT = W[1]$. This concludes our proof. \blacktriangleleft

Keyboards as a New Model of Computation

Abstract

We introduce a new formalisation of language computation, called keyboards. We consider a set of atomic operations (writing a letter, erasing a letter, going to the right or to the left) and we define a keyboard as a set of finite sequences of such operations, called keys. The generated language is the set of words obtained by applying some non-empty sequence of those keys. Unlike classical models of computation, every key can be applied anytime. We define various classes of languages based on different sets of atomic operations, and compare their expressive powers. We also compare them to rational, context-free and context-sensitive languages. We obtain a strict hierarchy of classes, whose expressiveness is orthogonal to the one of the aforementioned classical models. We also study closure properties of those classes, as well as fundamental complexity problems on keyboards.

1 Introduction

We present a new formalisation of languages, called keyboards. A keyboard K is a finite set of keys, which are finite sequences of atomic operations, such as writing or erasing a letter, going one position to the right or to the left... The language of K is the set of words obtained by applying a sequence of its keys on an initially empty writing space. The idea comes from the image of a malfunctioning keyboard, in which a key does a sequence of operations instead of just one (for instance the key 'a' writes b then c , and then goes to the left).

Studying the set generated by a set of algebraic operations is far from new: many works exist on the sets generated by a subset of elements of an algebraic structure, for instance in the context of semigroup and group theory [2, 7], of matrix monoids [1, 8] or the theory of codes [3]. There is however, to the best of the author's knowledge, no previous work on a model resembling the one presented here.

The atomic operations we use in this paper are the base of other models of computation, such as forgetting automata and erasing automata [4, 5, 9]. The use of those operations was originally to simulate some analysis strategies in linguistics. As a first study of the model, we chose the actions of the operations (backspace and arrows) to behave like an actual keyboard in a text editor.

We can define various classes of languages based on the set of atomic operations we consider, and compare their expressive powers between them, and to well-known classes of languages. We obtain a strict hierarchy of classes, with a wide range of expressiveness and difficulty of comprehension. The expressiveness of keyboards seems to be overall orthogonal to the ones of classical models of computation, which we explain by two key differences with the latter.

First, keyboards are blind and memoryless, in that they do not have states and cannot read the tape at any point. Second, because of this weakness, we can allow operations such as moving in the word or erasing letters without blowing up their expressive power too much.

The main interests of keyboards are: 1. to obtain many deep and complex mathematical questions from a deceptively simple model, and 2. that their expressiveness is very different from the ones of classical models. A language that is simple to express with a keyboard may be more complicated for automata, and vice versa. This paper is meant as a first step in the study and comprehension of keyboards and their languages.

The paper is organised as follows. In Sections 2 and 3 we establish notations and basic definitions. Section 4 and 5 are dedicated to building properties and tools necessary to the study of keyboards. In Section 6 we dive into the specific properties of each keyboard class, and prove the inclusions of some of them in regular, context-free and context-sensitive languages. Then in Section 7, we study the inclusions between those classes, in particular showing that they are all different. Some complexity results are given in Section 8. Finally, in Section 9 we show that keyboard classes are not stable by union or intersection, and that some (but not all) of them are stable by mirror.

We do not provide full proofs, but only sketch of proofs for some results. The technical details can be found in the full version.

2 Preliminaries

Given a finite alphabet A , we note A^* the set of finite words over A and A^+ for the set of non-empty ones. Given a word $w = a_1 \cdots a_n \in A^*$, we write $|w|$ for its length and, for all $a \in A$, $|w|_a$ the number of occurrences of a in w . For all $1 \leq i, j \leq n$ we use the notation $w[i]$ for the i^{th} letter of w (i.e. a_i) and $w[i, j]$ for its factor $a_i \cdots a_j$ (and ε if $j < i$). We denote the mirror of w by $\tilde{w} = a_n \cdots a_1$.

We write $\text{Pref}(w)$ for the set of prefixes of w , $\text{Suff}(w)$ for its set of suffixes, $\text{Fact}(w)$ for its set of factors and $\text{Sub}(w)$ for its set of subwords.

We represent a finite automaton A as a tuple $(Q, \Delta, \text{Init}, \text{Fin})$ with Q a finite set of states, $\Delta : Q \times A \rightarrow 2^Q$ a transition function, and $\text{Init}, \text{Fin} \subseteq Q$ sets of initial and final states.

We represent a pushdown automaton on A as a tuple $(Q, \Gamma, \perp, \Delta, \text{Init}, \text{Fin})$ with

- Q a finite set of states ;
- Γ a finite stack alphabet ;
- $\perp \in \Gamma$ an initial stack symbol ;
- $\Delta : Q \times A \times (\Gamma \cup \{-\})^2 \rightarrow 2^Q$ a transition function ;
- Init and Fin sets of initial and final states.

We accept a word on final states with an empty stack. We write transitions as follows:

$$s_1 \xrightarrow[\text{op}_1, \text{op}_2]{a} s_2$$

with

- $\text{op}_1 = \uparrow\gamma$ if we pop $\gamma \in \Gamma$, and $\text{op}_1 = -$ if we do not pop anything.
- $\text{op}_2 = \downarrow\gamma$ if we push $\gamma \in \Gamma$ on the stack, and $\text{op}_2 = -$ if we do not push anything.

We will use ε -transitions in both finite and pushdown automata to simplify some proofs.

For more details and properties of those models, we refer the reader to [6].

3 Definitions

We fix a finite alphabet A and the following special symbols, taken out of A :

The backspace : \leftarrow The left arrow : \blacktriangleleft The right arrow : \blacktriangleright

The set of all symbols is $S \triangleq A \cup \{\leftarrow, \blacktriangleleft, \blacktriangleright\}$. An element of S is called an *atomic operation*.

► **Definition 1.** A configuration is a pair of words $(u, v) \in A^* \times A^*$. We will use $\mathcal{C}(A)$ to denote the set of configurations over A , and $\langle u|v \rangle$ to denote the configuration (u, v) .

We define the notation $\langle u|v \rangle_i$ as the letter at position i in the configuration with respect to the cursor: $\langle u|v \rangle_i = \tilde{u}[-i]$ if $i < 0$ and $v[i]$ if $i > 0$.

► **Definition 2.** The action of an atomic operation $\sigma \in S$ on a configuration $\langle u|v \rangle$ is written $\langle u|v \rangle \cdot \sigma$ and is defined as follows:

$$\begin{aligned} \langle u|v \rangle \cdot a &= \langle ua|v \rangle \text{ if } a \in A. \\ \langle \varepsilon|v \rangle \cdot \leftarrow &= \langle \varepsilon|v \rangle \quad \text{and} \quad \langle u'a|v \rangle \cdot \leftarrow = \langle u'|v \rangle \\ \langle \varepsilon|v \rangle \cdot \blacktriangleleft &= \langle \varepsilon|v \rangle \quad \text{and} \quad \langle u'a|v \rangle \cdot \blacktriangleleft = \langle u'|av \rangle \\ \langle u|\varepsilon \rangle \cdot \blacktriangleright &= \langle u|\varepsilon \rangle \quad \text{and} \quad \langle u|av' \rangle \cdot \blacktriangleright = \langle ua|v' \rangle \end{aligned}$$

We will sometimes write $\langle u|v \rangle \xrightarrow{\sigma} \langle u'|v' \rangle$ for $\langle u'|v' \rangle = \langle u|v \rangle \cdot \sigma$.

► **Example 3.** By applying the following sequence of atomic operations $\leftarrow, a, \blacktriangleright, \blacktriangleright, b$ to the configuration $\langle c|d \rangle$, we obtain the following rewriting derivation:

$$\langle c|d \rangle \xrightarrow{\leftarrow} \langle \varepsilon|d \rangle \xrightarrow{a} \langle a|d \rangle \xrightarrow{\blacktriangleright} \langle ad|\varepsilon \rangle \xrightarrow{\blacktriangleright} \langle ad|\varepsilon \rangle \xrightarrow{b} \langle adb|\varepsilon \rangle.$$

► **Definition 4.** We define other semantics for atomic operations, called effective semantics. The difference with the previous ones is that we forbid application of atomic operations without effect (such as backspace when the left word of the configuration is empty). Formally, given $u, v \in A^*, a \in A$ we have:

$$\begin{aligned} \langle u|v \rangle &\xrightarrow{a}_e \langle ua|v \rangle & \langle u'a|v \rangle &\xrightarrow{\leftarrow}_e \langle u'|v \rangle \\ \langle u'a|v \rangle &\xrightarrow{\blacktriangleleft}_e \langle u'|av \rangle & \langle u|av' \rangle &\xrightarrow{\blacktriangleright}_e \langle ua|v' \rangle \end{aligned}$$

We also define the operator \odot by $\langle u|v \rangle \odot \sigma = \langle u'|v' \rangle$ if and only if $\langle u|v \rangle \xrightarrow{\sigma}_e \langle u'|v' \rangle$.

► **Definition 5.** A key is a sequence of atomic operations, seen as a word on S . We will use $\mathcal{T}(S)$ to denote the set of keys on S (variables k, t, \dots), or \mathcal{T} if there is no ambiguity.

► **Definition 6.** The action of a key over a configuration is defined inductively as follows:

$$\begin{cases} \langle u|v \rangle \cdot \varepsilon = \langle u|v \rangle \\ \langle u|v \rangle \cdot (\sigma t) = (\langle u|v \rangle \cdot \sigma) \cdot t \end{cases}$$

We extend the notation $\langle u|v \rangle \xrightarrow{t} \langle u'|v' \rangle$ to keys. We define $\langle u|v \rangle \xrightarrow{t}_e \langle u'|v' \rangle$ and $\langle u|v \rangle \odot t$ analogously.

► **Remark 7.** We will also consider sequences of keys $\tau = t_1 \dots t_n$. The action of τ is obtained by composing the actions of the t_i , hence applying τ has the same effect as applying sequentially t_1, \dots, t_n . Note that τ is seen as a word on $\mathcal{T}(S)$ (and not on S), thus $|\tau|$ is n .

49:4 Keyboards

► **Definition 8.** The length of a key t , written $|t|$, is its length as a word on S . Further, given $\sigma \in S$, we note $|t|_\sigma$ the number of occurrences of σ in t . The size of a configuration $\langle u|v \rangle$ is defined as $|\langle u|v \rangle| = |u| + |v|$.

► **Definition 9.** Two keys t and t' are equivalent, denoted $t \sim t'$, if for all $u, v \in A^*$, $\langle u|v \rangle \cdot t = \langle u|v \rangle \cdot t'$.

► **Example 10.** ε is equivalent to $a\leftarrow$ for all $a \in A$, but not to $\blacktriangleright\blacktriangleleft$, as we have $\langle a|\varepsilon \rangle \cdot \blacktriangleright\blacktriangleleft = \langle \varepsilon|a \rangle$ whereas $\langle a|\varepsilon \rangle \cdot \varepsilon = \langle a|\varepsilon \rangle$.

Example 10 illustrates how \blacktriangleleft , \blacktriangleright and \leftarrow act differently if one side of the configuration is empty. We will see that these “edge effects” add some expressiveness compared to the effective semantics, but make proofs more complex.

► **Definition 11 (Automatic Keyboard).** An automatic keyboard is a finite subset of $\mathcal{T}(S)$.

► **Definition 12.** An execution of an automatic keyboard K on a configuration $c_0 \in \mathcal{C}$ is a **non-empty** finite sequence $\rho = (t_1, c_1), \dots, (t_{n+1}, c_{n+1}) \in (K \times C)^{n+1}$ ($n \in \mathbb{N}$) such that

$$\forall i \in \llbracket 1; n+1 \rrbracket, c_{i-1} \xrightarrow{t_i} c_i.$$

By default, we take as initial configuration $c_0 = \langle \varepsilon|\varepsilon \rangle$. We usually write $c_0 \xrightarrow{\tau} c_{n+1}$ to mean the execution $(\tau[1], c_0 \cdot \tau[1]), \dots, (\tau[n+1], c_0 \cdot \tau[1, n+1])$.

► **Definition 13.** A word $w \in A^*$ is recognised by an automatic keyboard K if there exist $u, v \in A^*$ and an execution $\langle \varepsilon|\varepsilon \rangle \xrightarrow{\tau} \langle u|v \rangle$ such that $w = uv$. The language $\mathcal{L}(K)$ of K is the set of words recognised by K .

We now define keyboards as automatic keyboards to which we added some final keys “with entry”, which mark the end of the execution.

► **Definition 14 (Keyboard (with entry)).** A keyboard K on S is a pair (T, F) of finite sets $T, F \subset \mathcal{T}(S)$. We call the elements of F the final keys of K and the elements of T its transient keys.

► **Definition 15 (Accepting execution of a keyboard).** Let $K = (T, F)$ be a keyboard and $c_0 = \langle u_0|v_0 \rangle$ an initial configuration. An accepting execution of K on c_0 is a finite sequence $\rho = (t_1, c_1), \dots, (t_{n+1}, c_{n+1}) \in (T \times C)^n \cdot (F \times C)$ ($n \in \mathbb{N}$) such that

$$\forall i \in \llbracket 1; n+1 \rrbracket, c_{i-1} \xrightarrow{t_i} c_i.$$

By default, an accepting execution is on the empty configuration $\langle \varepsilon|\varepsilon \rangle$.

► **Definition 16.** A word $w \in A^*$ is recognised by a keyboard K if there exist $u, v \in A^*$ and an execution $\langle \varepsilon|\varepsilon \rangle \xrightarrow{\tau} \langle u|v \rangle$ such that $w = uv$. The language $\mathcal{L}(K)$ of K is the set of words recognised by K .

► **Example 17.** The keyboard with one transient key \mathbf{aa} and one final key \mathbf{a} , recognises sequences of a of odd length.

► **Remark 18.** Let K_a be an automatic keyboard, then $\mathcal{L}(K_a)$ is recognised by the keyboard with entry (K_a, K_a) . In all that follows, we will thus see automatic keyboards as a subclass of keyboards.

► **Definition 19** (Size of a keyboard). *The size of a keyboard $K = (T, F)$ is defined as*

$$\|K\|_\infty = \max\{|t| \mid t \in T \cup F\}.$$

We may also use another measure $|K|$ of the size of K for complexity purposes:

$$|K| = \sum_{t \in T \cup F} (|t| + 1).$$

► **Definition 20** (Minimal keyboard). *A minimal keyboard K is an automatic keyboard without any operation besides writing letters. It can therefore be seen as a finite subset of A^* . We will note MK the class of minimal keyboards.*

► **Remark 21.** We construct our keyboard classes through the sets of special operations we allow. Class names are obtained by adding B (for \leftarrow), E (for the entry, noted \blacksquare), L (for \blacktriangleleft) and A (for \blacktriangleleft and \blacktriangleright) to K. We obtain these classes.

MK : $\{\}$	LK : $\{\blacktriangleleft\}$	AK : $\{\blacktriangleleft, \blacktriangleright\}$
EK : $\{\blacksquare\}$	LEK : $\{\blacktriangleleft, \blacksquare\}$	EAK : $\{\blacktriangleleft, \blacktriangleright, \blacksquare\}$
BK : $\{\leftarrow\}$	BLK : $\{\blacktriangleleft, \leftarrow\}$	BAK : $\{\blacktriangleleft, \blacktriangleright, \leftarrow\}$
BEK : $\{\leftarrow, \blacksquare\}$	BLEK : $\{\blacktriangleleft, \leftarrow, \blacksquare\}$	BEAK : $\{\blacktriangleleft, \blacktriangleright, \leftarrow, \blacksquare\}$

► **Remark 22.** We do not consider classes with \blacktriangleright without \blacktriangleleft because, without the \blacktriangleleft operator, we can only reach configurations of the form $\langle u|\varepsilon \rangle$ and thus \blacktriangleright never has any effect.

► **Remark 23.** We use the class names above to designate both keyboard classes and language classes. For instance, we will write that L is in AK if there exists a keyboard $K \in \text{AK}$ such that $L = \mathcal{L}(K)$.

4 General properties

In this section, we establish some properties on keyboard. Although most of them are quite intuitive, we take the time to be as formal as possible in order to build solid bases for the study of keyboards.

Our first lemma states that applying a key can only affect a bounded part of the word around the cursor.

► **Lemma 24** (Locality). *Let $t = \sigma_1 \dots \sigma_n$ be a key. If $\langle u|v \rangle \xrightarrow{t} \langle u'|v' \rangle$, then $u[1, |u| - n]$ is a prefix of u' and $v[n + 1, |v|]$ is a suffix of v' .*

Furthermore, $u'[1, |u'| - n]$ is a prefix of u and $v'[n + 1, |v'|]$ is a suffix of v .

Then we formalize the fact that if the cursor is far enough from the extremities of the word, then we do not have edge effects.

► **Lemma 25** (Effectiveness far from the edges). *Let $t = \sigma_1 \dots \sigma_n$ be a key, $\langle u|v \rangle$ a configuration and $\langle u_n|v_n \rangle = \langle u|v \rangle \cdot t$. If $n \leq \min(|u|, |v|)$, then $\langle u|v \rangle \xrightarrow{t}_e \langle u_n|v_n \rangle$, meaning that all the arrows and backspaces are applied effectively.*

The two next lemmas bound the variation in length of the configuration when applying a key.

► **Lemma 26** (Bounds on the lengths). *Let $t = \sigma_1 \dots \sigma_n$ be a key, $\langle u|v \rangle$ a configuration and $\langle u_n|v_n \rangle = \langle u|v \rangle \cdot t$. Then*

$$|uv| - |t|_{\leftarrow} + \sum_{x \in A} |t|_x \leq |u_n v_n| \leq |uv| + \sum_{x \in A} |t|_x.$$

In particular $||u_n v_n| - |uv|| \leq n$. Moreover $||u_n| - |u|| \leq n$ and $||v_n| - |v|| \leq n$.

► **Lemma 27** (Length evolution without left edge effects). *Let $t = \sigma_1 \dots \sigma_n$ be a key, $\langle u|v \rangle$ a configuration such that $|u| \geq n$. Let $\langle u_n|v_n \rangle = \langle u|v \rangle \cdot t$, then*

$$|u_n v_n| = |uv| - |t|_{\leftarrow} + \sum_{x \in A} |t|_x.$$

Then, we obtain the following lemma that can be used to show that some languages are not recognised by a keyboard.

► **Lemma 28.** *Let K be a keyboard with language L . Let $(\ell_n)_{n \in \mathbb{N}}$ be the sequence obtained by sorting the lengths of the words in L by increasing order. Then $(\ell_{n+1} - \ell_n)_{n \in \mathbb{N}}$ is bounded by $3\|K\|_\infty$.*

► **Example 29.** The languages $\{a^{n^2} \mid n \in \mathbb{N}\}$ and $\{a^p \mid p \text{ prime}\}$ are not recognised by a keyboard.

The two following lemmas will be useful when studying effective executions.

► **Lemma 30.** *Let $t = \sigma_1 \dots \sigma_n$ be a key such that $\langle u|v \rangle \xrightarrow{t}_e \langle u_n|v_n \rangle$. Then, for all words x, y , $\langle xu|vy \rangle \xrightarrow{t}_e \langle xu_n|v_n y \rangle$.*

► **Lemma 31.** *Let $t = \sigma_1 \dots \sigma_n$ be a key, $\langle u|v \rangle$ and $\langle x|y \rangle$ configurations such that $|u| = |x|$ and $|v| = |y|$. Then t acts efficiently from $\langle u|v \rangle$ if and only if it acts efficiently from $\langle x|y \rangle$.*

5 Key behaviour

This section aims at providing tools to describe the behaviour of a key. How can we formally express the intuitive fact that the i^{th} symbol of $c \cdot t$ was written by t or that the i^{th} symbol of c was moved by t ? We are going to distinguish letters from t and c in order to keep track of where t writes its letters and how the letters of c were affected.

► **Definition 32** (Tracking function). *Let \mathbb{Z}_t and \mathbb{Z}_c be two duplicates of \mathbb{Z} . We denote by \bar{k} the elements of \mathbb{Z}_c and by \hat{k} the elements of \mathbb{Z}_t .*

We define the tracking functions, one for keys $f_t: S^ \rightarrow (S \cup \mathbb{Z}_t)^*$, defined as follows: $f_t(\sigma_1 \dots \sigma_n) = \sigma'_1 \dots \sigma'_n$ where*

$$\sigma'_i = \begin{cases} \hat{i} & \text{if } \sigma_i \in A \\ \sigma_i & \text{otherwise} \end{cases}$$

and one for configurations $f_c: \mathcal{C}(A) \rightarrow \mathbb{Z}_c^ \times \mathbb{Z}_c^*$ defined by*

$$f_c(a_1 \dots a_k, b_1 \dots b_j) = \langle \bar{-k} \dots \bar{-1} \mid \bar{1} \dots \bar{j} \rangle.$$

By applying $f_t(t)$ to $f_c(c)$, we can keep track of which letters of the configuration and of the key were written, erased, or displaced, and where. We need two copies of \mathbb{Z} to differentiate between the symbols of $f_t(t)$ (added by the key) and $f_c(c)$ (already in the configuration).

► **Definition 33.** Let $\langle u|v \rangle$ be a configuration and t a key. We note $\langle u'|v' \rangle = \langle u|v \rangle \cdot t$ and $\langle x|y \rangle = f_c(u, v) \cdot f_t(t)$. We say that t writes its k^{th} symbol at position i from $\langle u|v \rangle$ if $\langle x|y \rangle_i = \widehat{k}$.

► **Remark 34.** Let $t = \sigma_1 \dots \sigma_n$ be a key, $\langle u|v \rangle$ a configuration and $1 \leq j < k \leq n$ integers. Then t writes its k^{th} symbol at position i from $\langle u|v \rangle$ if and only if $\sigma_{j+1} \dots \sigma_n$ writes its $(k-j)^{\text{th}}$ symbol at position i from $\langle u|v \rangle \cdot \sigma_1 \dots \sigma_j$. In particular, t writes its k^{th} symbol at position i from $\langle u|v \rangle$ if and only if $\sigma_k \dots \sigma_n$ writes its 1^{st} symbol from $\langle u|v \rangle \cdot \sigma_1 \dots \sigma_{k-1}$.

We defined an intuitive notion of writing the k^{th} symbol of t . In particular, if t writes its k^{th} symbol in i^{th} position from $\langle u|v \rangle$, then $\langle u'|v' \rangle_i = t_k$, as stated below.

► **Proposition 35.** Let $t = \sigma_1 \dots \sigma_n$ be a key, $\langle u|v \rangle$ a configuration. We note

$$\begin{aligned} \langle u_n|v_n \rangle &= \langle u|v \rangle \cdot t & \langle x'_n|y'_n \rangle &= f_c(u, v) \cdot t \\ \langle u'_n|v'_n \rangle &= \langle u|v \rangle \cdot f_t(t) & \langle x_n|y_n \rangle &= f_c(u, v) \cdot f_t(t) \end{aligned}$$

Then $|u_n| = |x_n| = |u'_n| = |x'_n|$ and $|v_n| = |y_n| = |v'_n| = |y'_n|$. And for all $a \in A$,

$$\begin{aligned} \langle u_n|v_n \rangle_j = a &\text{ iff } \langle x_n|y_n \rangle_j = \bar{k} \text{ and } \langle u|v \rangle_k = a && \text{ or } \langle x_n|y_n \rangle_j = \widehat{k} \text{ and } t_k = a \\ &\text{ iff } \langle u'_n|v'_n \rangle_j = a && \text{ or } \langle u'_n|v'_n \rangle_j = \widehat{k} \text{ and } t_k = a \\ &\text{ iff } \langle x'_n|y'_n \rangle_j = \bar{k} \text{ and } \langle u|v \rangle_k = a && \text{ or } \langle x'_n|y'_n \rangle_j = a \\ &(\text{iff } a \text{ already in configuration} && \text{ or } a \text{ added by } t). \end{aligned}$$

Tracking functions are a convenient formalism to show some results on keyboards. Besides, they permit to take multiples points of view.

► **Corollary 36.** Let t be a key and $\langle u|v \rangle$ a configuration. Then t writes its k^{th} symbol at position i from $\langle u|v \rangle$ if and only if $(\langle u|v \rangle \cdot f_t(t))_i = \widehat{k}$.

► **Definition 37.** Let t be a key, $\langle u|v \rangle$ a configuration. We say that t writes an a in i^{th} position from $\langle u|v \rangle$ if there exists k such that $t_k = a$ and t writes its k^{th} symbol in position i from $\langle u|v \rangle$. We say that t writes an a from $\langle u|v \rangle$ if t writes an a in some position from $\langle u|v \rangle$.

Then, we obtain some results, which are direct consequences of Proposition 35.

► **Proposition 38.** If t writes its k^{th} symbol in i^{th} position from $\langle u|v \rangle$ then $(\langle u|v \rangle \cdot t)_i = t_k$. In particular, if t writes an a in i^{th} position from $\langle u|v \rangle$ then $(\langle u|v \rangle \cdot t)_i = a$ and if t writes an a from $\langle u|v \rangle$ then $\langle u|v \rangle \cdot t$ contains an a .

► **Proposition 39.** Let t be a key and $\langle u|v \rangle, \langle u'|v' \rangle$ two configurations such that $|u| = |u'|$ and $|v| = |v'|$. Then t writes its k^{th} symbol in i^{th} position from $\langle u|v \rangle$ if and only if t writes its k^{th} symbol in i^{th} position from $\langle u'|v' \rangle$. In particular, t writes an a in j^{th} position from $\langle u|v \rangle$ if and only if t writes an a in j^{th} position from $\langle x|y \rangle$, and t writes an a from $\langle u|v \rangle$ if and only if t writes an a from $\langle x|y \rangle$.

This proposition makes explicit the fact that keys cannot read the content of a configuration. This leads to the following characterization.

► **Proposition 40.** Let t be a key, $a \in A$ and $\langle u|v \rangle$ a configuration containing no a . Let $\langle u'|v' \rangle = \langle u|v \rangle \cdot t$. t writes an a in position i from $\langle u|v \rangle$ if and only if $\langle u'|v' \rangle_i = a$. In particular, t writes an a from $\langle u|v \rangle$ if and only if $\langle u'|v' \rangle$ contains an a .

Clearly, if the number of a 's in a configuration increases after applying a key then this key writes an a .

► **Proposition 41.** *Let t be a key and $\langle u|v \rangle$ a configuration. If $|\langle u|v \rangle|_a < |\langle u|v \rangle \cdot t|_a$, then t writes an a from $\langle u|v \rangle$.*

Note that if a key behaves differently from two configurations, then there must be some edge effects. In what follows we focus on effective executions.

► **Proposition 42.** *Let t be a key and $\langle u|v \rangle$ and $\langle x|y \rangle$ two configurations on which t acts effectively. Then t writes its k^{th} symbol in i^{th} position from $\langle u|v \rangle$ if and only if t writes its k^{th} symbol in i^{th} position from $\langle x|y \rangle$. Therefore, t writes an a in position i from $\langle u|v \rangle$ if and only if t writes an a in position i from $\langle x|y \rangle$.*

In other words, a key always behaves the same way far from the edges of the configuration.

► **Definition 43.** *Let t be a key. We say that t ensures an a in position i far from the edges if there exists a configuration $\langle u|v \rangle$ such that t acts effectively on $\langle u|v \rangle$ and t writes an a in position i from $\langle u|v \rangle$.*

Then, we immediately obtain the following propositions.

► **Proposition 44.** *Let t be a key and $u, v \in A^*$ such that $|u| \geq |t|$ and $|v| > |t|$. Then t ensures an a far from the edges if and only if t writes an a from $\langle u|v \rangle$.*

► **Proposition 45.** *Let t be a key and $u, v \in A^*$ such that $|u| \geq |t|$ and $|v| \geq |t|$. If $|\langle u|v \rangle|_a < |\langle u|v \rangle \cdot t|_a$, then t ensures an a far from the edges.*

► **Proposition 46.** *Let t be a key which ensures an a far from the edges and $\langle u|v \rangle$ such that $|u| \geq |t|$ and $|v| \geq |t|$. Then $\langle u|v \rangle \cdot t$ contains an a .*

6 Characterisation of the classes

6.1 Languages of BEK (without the arrows)

To begin, we study keyboards that do not contain any arrows. As these keyboards has no \blacktriangleleft operation, the right component of a configuration in an execution of $K \in \text{BEK}$ (starting from $\langle \varepsilon|\varepsilon \rangle$) is always empty. Thus, in this part, we will sometimes denote u for the configuration $\langle u|\varepsilon \rangle$.

6.1.1 MK and EK

MK and EK are quite easy to understand. Indeed, since a key of a minimal keyboard K is just a word on A , $K \subset A^*$.

► **Remark 47.** Let $K = \{w_1, \dots, w_n\}$ be a minimal keyboard. Then $\mathcal{L}(K) = (w_1 + \dots + w_n)^+$.

EK languages are rather similar.

► **Lemma 48.** *Let $K = (T, F)$ be a EK keyboard. Then, $\mathcal{L}(K) = T^*F$ and this regular expression can be computed in $O(|K|)$.*

Thus, we can build in linear time a regular expression that recognises $\mathcal{L}(K)$.

6.1.2 BK and BEK

Some of the expressiveness of BEK comes from edge effects. For instance, finite languages are recognised by BK keyboards.

► **Example 49.** Let L be a finite language and $M = \max\{|w| \mid w \in L\}$. Then L is recognised by $K = \{\leftarrow^M w \mid w \in L\}$.

These edge effects could make BEK languages quite complex. On the other hand, we show that BEK keys can be put in a particular form.

► **Lemma 50 (Normal form).** *Let $t \in S^*$ be a key from BEK. Then there exist $m \in \mathbb{N}$ and $w \in A^*$ such that $t \sim \leftarrow^m w$. Further, m and w can be computed from t in polynomial time.*

Using this normal form, we understand that the action of a BEK key always consists in deleting a bounded number of letters at the end of the word, then adding a bounded number of letters. This reminds us of stacks. Following this intuition, we can easily encode the behaviour of a BEK keyboard into a pushdown automaton.

However, BEK is even more narrow since all languages of BEK are regular.

► **Theorem 51.** *Let K be a BEK keyboard. Then, $\mathcal{L}(K)$ is regular, and we can build an NFA $\mathcal{A}(K)$ recognising $\mathcal{L}(K)$ in polynomial time.*

► **Remark 52.** There are several ways to prove this result. One of them is to apply the pushdown automaton construction from the proof of Theorem 57 (presented later in the paper) in the particular case of BEK. The language of the BEK keyboard is then essentially the stack language of this automaton. A slight adaptation of the classical proof that the stack language of a pushdown automaton is rational then yields the result.

We choose to include another proof in this work, as it is elementary, not much longer than the one aforementioned, and seems more elegant to the authors.

We first show the result for languages of BK. Let K be an BK keyboard. The key idea is that at any point of the execution, we can split the word into:

- a prefix v of letters that will never be erased,
- a suffix x of letters which will eventually be erased.

As an example, in order to write abb with the keys $\leftarrow^2 abcc$, $\leftarrow^3 b$ and $\leftarrow^2 cbc$, we can write ab with t_1 and the remaining b with t_2 . However, when applying t_1 and then t_2 , t_2 erases too many letters and we obtain ab instead of abb . We therefore need a sequence of keys which does not erase the prefix ab , but replaces the two c by three letters, allowing us to apply t_2 . This is done by applying t_3 , replacing cc with cbc . We can therefore write abb with the sequence $t_1 t_3 t_2$.

Given a keyboard K of BK, we construct an automaton following this idea. Its states are integers from 0 to $\|K\|_\infty$, state i meaning that we have i extra letters to be erased at the end of the current word.

- A transition from i to j labelled by $w \in A^+$ means there exists a key erasing i letters and writing wx with $|x| = j$ (w is a part of the word we are trying to recognise and x is a suffix of extra letters to be erased).
- A transition from i to j labelled by ε means there exists a sequence of keys turning the suffix of extra letters of length i into one of length j , without erasing any of the other letters.

■ **Figure 1** Automaton corresponding to keyboard $\{\leftarrow\text{abc}, \leftarrow^4\text{bb}\}$.

Figure 1 shows the automaton obtained from keyboard $\{\leftarrow\text{abc}, \leftarrow^4\text{bb}\}$ with this construction (slightly simplified as we erased some useless states).

The red transitions (full arrows) are the ones we can do with $\leftarrow\text{abc}$ and the blue (dashed) ones those we can do by applying $\leftarrow^4\text{bb}$. The black (dotted) transitions, are the ones we use to switch from i to j extra letters.

As an example, let us see how we can recognise *babababb* with this automaton and this keyboard. We decompose it into $b \cdot a \cdot b \cdot ab \cdot abc$.

- We write a b with $\leftarrow^4\text{bb}$, leading us to state 1 (we need to erase the second b before to write the rest of the word).
- The key $\leftarrow\text{abc}$ then allows us to erase the second b and write a , leading to state 2 (we need to erase the bc suffix).
- A sequence of keys then allows us to switch from two extra letters (state 2 in the automaton) to four (state 4).
- The key $\leftarrow^4\text{bb}$ then allows us to erase four letters and write b , leaving us in state 1.
- The key $\leftarrow\text{abc}$ erases b and writes ab , leaving us in state 1.
- The key $\leftarrow\text{abc}$ erases the last letter and writes abc , with no extra letters, leaving us in state 0 in the automaton, where we can accept.

We need to construct the transitions of our NFA recognising the language of an BK keyboard. The construction of the transitions labelled by letters is rather straightforward, whereas the construction of the ε -transitions requires some arithmetic arguments, which are detailed in the full version of this paper.

We slightly adapt this construction to obtain an automaton for a keyboard of BEK.

- The state 0 is no longer final, and we add a final state Fin .
- For all states i and $t_f = \leftarrow^i w \in F$, we add a transition from i to Fin labelled by w . This simulates the action of, after producing vx (with $|x| = i$) with T , applying t_f .
- For all $t_f = \leftarrow^r w \in F$, we add a transition from Init to Fin labelled by w .

6.2 Languages of BLEK (without the right arrow)

In this section, we allow the use of \blacktriangleleft . With this symbol, we have the possibility to move into the word, and then erase or write letters. It opens a new complexity level.

Moreover, we provide a non-regular language of BLEK, hence showing that it is more expressive than BEK (see Theorem 51).

► **Example 53.** Let $K = \{aa\blacktriangleleft, bb\blacktriangleleft\}$. Then, $\mathcal{L}(K) = \{u\tilde{u} \mid u \in (a+b)^+\}$, that is, K recognises the non-empty palindromes of even length.

Thus, we can represent context-free non-regular languages with BLEK (one can observe that the keyboard of Example 53 is actually even in LK).

However, a basic observation helps us to understand the behaviour of a key of BLEK: as we do not have the symbol \blacktriangleright , we cannot go back to the right and all the letters to the right of the cursor are written forever. The following lemma can be proven easily by induction.

► **Lemma 54.** *Let $t = \sigma_1 \dots \sigma_n$ be a sequence of atomic operations, and $\langle u|v \rangle$ a configuration. Then, $\langle u|v \rangle \cdot t$ is of the form $\langle u'|v' \rangle$.*

Then, we can make some assertions about a key observing its result over a configuration.

► **Lemma 55 (Independence from position).** *Let t be a key of BLEK and $\langle u|v \rangle$ a configuration. If t writes an a from $\langle u|v \rangle$, then for all configurations $\langle u'|v' \rangle$, t writes an a from $\langle u'|v' \rangle$.*

Proof. We set $t = \sigma_1 \dots \sigma_n$. Let $\langle x|y \rangle$ be a configuration. By Proposition 39, we can assume it does not contain any a and by Remark 34, we can assume $\sigma_1 = a$ and t writes its first symbol from $\langle u|v \rangle$. We then define for all $1 \leq i \leq n$

$$\langle u_i|v_i \rangle = \langle u|v \rangle \cdot \sigma_1 \dots \sigma_i \quad \text{and} \quad \langle x_i|y_i \rangle = \langle x|y \rangle \cdot \sigma_1 \dots \sigma_i.$$

Let i be the smallest index such that u_i or x_i is empty, and $i = n$ if such an index does not exist (note that $i > 1$ as u_1 and x_1 contain the a written by σ_1). As t writes its first symbol from $\langle u|v \rangle$, $\sigma_1 \dots \sigma_i$ writes an a from $\langle u|v \rangle$ in some position j .

Further, $\sigma_1 \dots \sigma_i$ acts efficiently on $\langle u|v \rangle$ and on $\langle x|y \rangle$, thus by Proposition 42, t writes an a from $\langle x|y \rangle$ at position j . If $i = n$, the result is proven.

Otherwise, as either u_i or x_i is empty, we have $j > 0$ and $y_i[j] = v_i[j] = a$. By Lemma 54, y_n contains an a , while $\langle x|y \rangle$ does not by assumption, showing the result by Proposition 40. \blacktriangleleft

Moreover, we can refine Lemma 54.

► **Theorem 56 (BLEK fundamental).** *Let $t = \sigma_1 \dots \sigma_n$ be a sequence of atomic operations, and $\langle u|v \rangle$ a configuration. We set $\langle x_n|y_n \rangle = \langle \varepsilon|\varepsilon \rangle \cdot t$. Then $\langle u|v \rangle \cdot t$ is of the form $\langle u_n x_n|v_n v \rangle$ with y_n a subword of v_n and u_n a prefix of u .*

These observations help us to better understand BLEK. A key observation is that we can see the left part of the configuration as a stack, which can be modified, and the right part as the fixed one, just as the prefix of a word that has been read by an automaton. We can then recognise (the mirror of) a BLEK language with a pushdown automaton which guesses a sequence of keys, maintains the left part of the configuration in the stack and reads the right part of the configuration.

► **Theorem 57.** *Let K be a BLEK keyboard. Then, $\mathcal{L}(K)$ is context-free, and we can build a non-deterministic pushdown automaton $\mathcal{A}(K)$ recognising $\mathcal{L}(K)$ in polynomial time.*

The idea is to use the fact that what is written to the right of the cursor is unaffected by a key without right arrows (see Theorem 56).

We construct a pushdown automaton maintaining the invariant “After simulating the application of keys t_1, \dots, t_n we have read a word v and have as stack content a word u such that $\langle \varepsilon | \varepsilon \rangle \cdot t_1 \cdots t_n = \langle u | \tilde{v} \rangle$ ”.

Atomic operations are easily translated to satisfy that invariant. Writing a letter comes down to pushing it on the stack, applying a backspace to deleting the stack head, and applying a left arrow to popping and reading the stack head.

After simulating a sequence of keys, the automaton pops and reads the content of its stack before to accept. At this point, the automaton has read the mirror of the word produced by this sequence of keys. We then simply construct a pushdown automaton recognising the mirror of the language of the previous one.

6.3 Languages of EAK (without backspace)

A third interesting class is EAK, where the backspace is not allowed. Thus, the size of a configuration does not decrease along an execution. The execution of such a keyboard can therefore be easily simulated on a linear bounded automaton, as stated in Theorem 60.

In all the proofs of this section we will say that t writes an a when t contains an a (as we have no \leftarrow if t contains an a then this a will not be erased when applying t).

► **Lemma 58.** *Let $K = (T, F)$ be a EAK keyboard. Let $u, v \in A^*$, let $\tau \in (T \cup F)^*$ and let $\langle u' | v' \rangle = \langle u | v \rangle \cdot \tau$. Then uv is a subword of $u'v'$. In particular $|uv| \leq |u'v'|$.*

► **Lemma 59.** *Let $K = (T, F)$ be a EAK keyboard, let $w \in \mathcal{L}(K)$. There exists an execution $\tau = t_1 \cdots t_n \in T^*F$ such that $\langle \varepsilon | \varepsilon \rangle \cdot \tau = \langle u | v \rangle$ with $uv = w$ and $n \leq |w|^2 + 1$.*

Proof. Let $w \in \mathcal{L}(K)$, and let $u, v \in A^*$, $\tau = t_1 \cdots t_n \in T^*F$ be such that $w = uv$ and $\langle \varepsilon | \varepsilon \rangle \cdot \tau = \langle u | v \rangle$.

We show that if $n > |w|^2 + 1$ then there exists a shorter execution writing $\langle u | v \rangle$.

Suppose $n > |w|^2 + 1$, and for all $0 \leq i \leq n$ let $k_i = |\langle \varepsilon | \varepsilon \rangle \cdot t_1 \cdots t_i|$ and $\langle u_i | v_i \rangle = \langle \varepsilon | \varepsilon \rangle \cdot t_1 \cdots t_i$. By Lemma 58, the sequence (k_i) is nondecreasing. As $n > |w|^2 + 1$ and $k_n = |w|$, there exists $0 \leq i \leq n - |w|$ such that $k_i = k_{i+1} = \cdots = k_{i+|w|}$. Again by Lemma 58, we have $u_i v_i = u_{i+1} v_{i+1} = \cdots = u_{i+|w|} v_{i+|w|}$. If $u_i v_i = w$ then the execution $t_1 \cdots t_i$ writes w .

If $u_i v_i \neq w$ then $k_i < |w|$. There are $|w| > k_i$ configurations $\langle u' | v' \rangle$ such that $u'v' = u_i v_i$, thus there exist $i \leq j_1 < j_2 \leq i + |w|$ such that $\langle u_{j_1} | v_{j_1} \rangle = \langle u_{j_2} | v_{j_2} \rangle$.

As a result, the execution $t_1 \cdots t_{j_1} t_{j_2+1} \cdots t_n$ writes w .

The lemma is proven. ◀

► **Theorem 60.** *For all keyboards $K = (T, F)$ of EAK we can construct a linear bounded automaton $\mathcal{A}(K)$ of polynomial size recognising $\mathcal{L}(K)$.*

Proof. We construct $\mathcal{A}(K)$ the linear bounded automaton which, given an input w , proceeds as follows:

- It divides the tape in three parts: one to memorize the input (of linear size), one to simulate an execution of K (of linear size as well by Lemma 58) and one containing a counter (of logarithmic size).
- It guesses a sequence of keys of T followed by a key of F and computes their effect on the fly. After the application of each key, the counter is incremented.

- If the counter goes beyond $|w|^2 + 1$, then the automaton rejects.
- If not, the automaton compares the obtained word to w , accepts if they are equal, and rejects otherwise.

This machine guesses a sequence of at most $|w|^2 + 1$ keys and accepts if the word obtained by their actions is the input.

Clearly if a word is accepted by $\mathcal{A}(K)$ then it is in $\mathcal{L}(K)$. Conversely, if a word w is in $\mathcal{L}(K)$ then by Lemma 59 there exists an execution of length at most $|w|^2 + 1$ accepting it, thus $\mathcal{A}(K)$ can guess this execution and accept w .

As a result, $\mathcal{L}(K) = \mathcal{L}(\mathcal{A}(K))$. ◀

7 Comparison of the keyboard classes

The characterisations that we provide give us some information about each class independently. We now compare the subclasses of BEAK in order to find out which inclusions hold between them. One of these inclusions, between BAK and BEAK, is especially interesting since it shows that keyboards with entry are strictly more powerful than automatic ones.

We decompose our results into the following propositions. Those establish that a class is included in another if and only if that same inclusion holds between their sets of operators, except possibly for the inclusion of EK and BEK in BAK, which we do not prove or disprove.

To start with, we show that a class containing the left arrow cannot be included in a class lacking it. This is a direct consequence of Example 53 and Theorem 51 as we have a language of LK which is not rational, and thus not in BEK.

► **Proposition 61.** $LK \not\subseteq BEK$.

We continue with the two next propositions, showing that a class containing the entry cannot be included in a class excluding it, except possibly for BAK.

► **Proposition 62** ($EK \not\subseteq BLK$). *EK is not included in BLK.*

► **Proposition 63** ($EK \not\subseteq AK$). *EK is not included in AK.*

Then we prove that a class with \leftarrow cannot be included in a class without \leftarrow .

► **Proposition 64** ($BK \not\subseteq EAK$). *BK is not included in EAK.*

The next proposition states that a class containing \blacktriangleright cannot be included in a class lacking it.

► **Proposition 65** ($AK \not\subseteq BLEK$). *AK is not included in BLEK.*

And finally we show that, except possibly for EK and BEK, a class with entry cannot be included in a class without entry.

► **Proposition 66** ($LEK \not\subseteq BAK$). *LEK is not included in BAK.*

The inclusion Hasse diagram of all subclasses of BEAK and traditional language classes is displayed in Figure 2.

■ **Figure 2** Hierarchy of language classes.

8 Complexity results

In this section we establish some complexity upper bounds on the membership and universality problems for various keyboard classes. The following three propositions are direct consequences of the known complexity bounds of the models which we translated keyboards into (in Remark 47, Lemma 48, Theorem 51 and Theorem 57).

► **Proposition 67.** *The membership problem on MK and EK is in PTIME. The universality problem is in PTIME on MK and PSPACE on EK.*

The problem for EK seems simple: it amounts to deciding, given two finite sets of words T and F , if T^*F is universal.

► **Proposition 68.** *The membership problem over BEK is in PTIME, and the universality problem over BEK in PSPACE.*

► **Proposition 69.** *The membership problem over BLEK is in PTIME.*

For BK keyboards, we prove that there exists a word not accepted by a given BK keyboard if and only if there exists one of polynomial length.

► **Proposition 70.** *The universality problem for BK keyboards is in CONP.*

For EAK keyboards, we know by Lemma 59 that every word w recognised by a EAK keyboard can be written with an execution of length polynomial in $|w|$, hence this proposition:

► **Proposition 71.** *The membership problem for EAK keyboards is in NP.*

9 Closure properties

In this section, we study closure properties of keyboard classes. We selected three operators, the union and the intersection, as they are the most natural closure operators, and the mirror, under which some classes are stable.

► **Proposition 72 (Mirror).** *MK, AK and EAK are stable by mirror. EK, BK, BEK and BLK are not stable by mirror.*

► **Proposition 73** (Intersection). *None of the keyboard language classes are stable by intersection.*

► **Proposition 74** (Union). *None of the keyboard language classes are stable by union.*

We end this section with an undecidability result, showing that intersecting keyboards can lead to highly complex languages. This shows another link with context-free languages, as the emptiness of the intersection of two context-free languages is undecidable as well.

► **Proposition 75** (Intersection emptiness problem). *The following problem is undecidable:*

Input: K_1, K_2 two LK keyboards.

Output: Is $\mathcal{L}(K_1) \cap \mathcal{L}(K_2)$ empty?

10 Conclusion

A natural question when it comes to models of computation is what we can do without any memory or any information on the current state of the system. We initiated a line of research aiming at studying such “blind” models. The one we considered here, keyboards, proved to be mathematically complex and interestingly orthogonal in expressiveness to several of the most classical models. We have established a number of properties of keyboards, as well as a vocabulary facilitating their study. We separated almost all classes and compared their expressiveness, thereby uncovering the lattice of their power.

Future work

As keyboards are a completely new model, there are many open problems we are working on or intend to address. We conjecture that EK is not included in BAK, but we do not have a proof. We also conjecture that not all AK languages are algebraic (the language generated by $\{a\blacktriangleright\blacktriangleright, b\blacktriangleleft\blacktriangleleft\}$ is a candidate as a counter-example) and that BEAK does not contain all rational languages ($a^* + b^*$ being a potential counter-example). We plan on extending the set of operations to add, for instance, a right erasing operator, symmetric to \leftarrow . It could also be interesting to study the semantics in which we forbid non-effective operations. Finally, we could equip the model with states and transitions labelled with keys. We would then have more control over which keys are applied at which times, thus increasing the expressiveness of the model and facilitating its study.

A Comparisons between classes

► **Proposition 62** (EK $\not\subseteq$ BLK). EK is not included in BLK.

Proof. The language $L = (a^2)^*(b + b^2)$ is clearly in EK. We first show that a keyboard K of BLK recognising L does not use the \blacktriangleleft operation. The idea is that if we could reach a configuration with letters to the right of the cursor, we could then apply a sequence of keys writing b^2 from $\langle \varepsilon | \varepsilon \rangle$, which would yield a word with letters after the second b (thus not in L) by Theorem 56.

K is therefore an BK keyboard which can write b^2 , hence there exists a sequence of keys of K whose normal form is $\leftarrow^k b^2$ for some k . We reach a contradiction by considering a word $w \in L$, applying τ , and distinguishing cases according to the parity of k . ◀

► **Proposition 63** (EK $\not\subseteq$ AK). EK is not included in AK.

Proof. Consider the language $\{a\}$. It is recognised by the keyboard $(\emptyset, \{a\})$ of EK.

Suppose there exists K a keyboard of AK recognising $\{a\}$. Then there exists $t \in K$ exactly containing an a . As K does not contain any \leftarrow , applying t twice from $\langle \varepsilon | \varepsilon \rangle$ yields a configuration with two a , and thus a word outside of $\{a\}$. We obtain a contradiction. ◀

Proof of Proposition 64

Define $t_a = \leftarrow a \diamond \blacklozenge$ and $t_b = \leftarrow \leftarrow b \diamond \blacklozenge \blacklozenge$, and $L_{\diamond \blacklozenge}$ as the language recognised by the keyboard $\{t_a, t_b\}$. $L_{\diamond \blacklozenge}$ is in BK, and we show that it is not in EAK using mainly the non-erasing property of EAK keyboards.

In all that follows, we will use the notations $t_a = \leftarrow a \diamond \blacklozenge$ and $t_b = \leftarrow \leftarrow b \diamond \blacklozenge \blacklozenge$.

We define $L_{\diamond \blacklozenge}$ as the language recognised by the BK keyboard $\{t_a, t_b\}$.

► **Lemma 76.** Let $x = x_1 \cdots x_n \in \{a, b\}^+$, we have

$$\langle \varepsilon | \varepsilon \rangle \cdot t_{x_1} \cdots t_{x_n} = x_1 w_{x_1 x_2} x_2 w_{x_2 x_3} x_3 \cdots w_{x_{n-1} x_n} x_n v_{x_n}$$

with $w_{aa} = w_{bb} = \diamond$, $w_{ab} = \varepsilon$, $w_{ba} = \diamond \blacklozenge$, $v_a = \diamond \blacklozenge$ and $v_b = \diamond \blacklozenge \blacklozenge$.

In particular, for all $u_1, u_2, u_3 \in A^*$, if $u_1 b u_2 a u_3 \in L_{\diamond \blacklozenge}$ then u_2 contains a \blacklozenge .

► **Proposition 64** (BK $\not\subseteq$ EAK). BK is not included in EAK.

Proof. Suppose there exists a keyboard $K = (T, F)$ of EAK recognising $L = L_{\diamond \blacklozenge}$. In this proof, we will use the letter k to denote keys of K , in order to avoid confusion with the keys t_a and t_b .

As $a \diamond \blacklozenge \in L$, there exists $\tau_f \in T^* F$ yielding that word.

Moreover, $w = (a\Diamond)^{3\|K\|_\infty} a\Diamond \in L$ (obtained by applying t_a $3\|K\|_\infty$ times). Hence, there exists an execution of K writing that word. By Lemma 58, as $|k|_a \leq \|K\|_\infty$ for all $k \in T \cup F$, this execution contains at least three keys containing an a , including at least two in T (as the execution only has one final key).

As w contains a single \Diamond , there exists a key k_a of T writing an a , but writing neither \Diamond nor b . By applying k_a then τ_f , we obtain a word of L containing a single \Diamond and no b . By lemma Lemma 76 this word must be of the form $(a\Diamond)^i a\Diamond$. We infer that k_a contains as many a and \Diamond . Let n be its number of a .

We can similarly show, using the word $(b\Diamond)^{3\|K\|_\infty} b\Diamond$, that there exists $k_b \in T$ containing as many b and \Diamond but neither \Diamond nor a . Let m be its number of b (and of \Diamond).

Let $\tau = k_a k_b$. We write

$$\langle u|v \rangle = \langle \varepsilon|\varepsilon \rangle \cdot \tau \quad \text{and} \quad \langle u'|v' \rangle = \langle u|v \rangle \cdot \tau_f$$

We have that $u'v'$ contains a single \Diamond . As $u'v' \in L$, $u'v'$ has to be of the form $wa\Diamond$ with w not containing any \Diamond , $|w|_a = n$, $|w|_b = m$ and $|w|_\Diamond = n + m$.

As wa contains at least a b , wa is of the form $u_1 b u_2 a$, thus by Lemma 76, u_2 contains a \Diamond , yielding a contradiction. As a conclusion, $L \notin \text{EAK}$. \blacktriangleleft

Proof of Proposition 65

Consider the keyboard $K = \{\mathbf{a} \blacktriangleleft^2 \blacktriangleright \mathbf{b}\}$.

By applying $\mathbf{a} \blacktriangleleft^2 \blacktriangleright \mathbf{b}$ on $\langle \varepsilon|\varepsilon \rangle$ we obtain $\langle ab|\varepsilon \rangle$, and by applying it on a configuration of the form $\langle ub|v \rangle$ we obtain $\langle ubb|av \rangle$. Hence, after applying it n times on $\langle \varepsilon|\varepsilon \rangle$ we get $ab^{n+1}a^n$. The language of K is therefore $L = \{ab^{n+1}a^n \mid n \in \mathbb{N}\}$.

► **Lemma 77.** *Let K be a keyboard of BLEK. If K recognises L then, for all $\tau \in T^*$, $\langle \varepsilon|\varepsilon \rangle \cdot \tau$ is of the form $\langle u|a^k \rangle$.*

Proof. As $abba \in L$, there exists $\tau \in T^*$ and $t_f \in F$ such that $\langle \varepsilon|\varepsilon \rangle \cdot \tau t_f = \langle x|y \rangle$ with $xy = abba$.

Let $\langle u|v \rangle$ be a configuration reachable by a sequence of keys of τ with v containing a b . By Theorem 56, $\langle u|v \rangle \cdot \tau t_f$ is of the form $\langle u'x|v'v \rangle$ with y a subword of v' . As a consequence, $abba$ is a subword of $u'xv'v$. With the assumption, we get that $abbab$ is a subword of $u'xv'v$, which contradicts the fact that $u'xv'v \in L$. \blacktriangleleft

► **Proposition 65** (AK $\not\subseteq$ BLEK). *AK is not included in BLEK.*

Proof. Let $K = (T, F)$ be a keyboard of BLEK, suppose it recognises L . Let $\tau \in T^*$ and $t_f \in F$. We set:

$$\langle x|y \rangle = \langle \varepsilon|\varepsilon \rangle \cdot t_f \quad \text{and} \quad \langle u|v \rangle = \langle \varepsilon|\varepsilon \rangle \cdot \tau.$$

There exists $n \in \mathbb{N}$ such that $xy = ab^{n+1}a^n$. By Theorem 56, $\langle \varepsilon|\varepsilon \rangle \cdot \tau t_f = \langle u|v \rangle \cdot t_f$ is of the form $\langle u'x|v'v \rangle$ with y a subword of v' .

As $ab^{n+1}a^n$ is a subword of xv' and $u'xv'v \in L$, u' is necessarily empty (otherwise u' would contain an a and as ab is a subword of xv' , aab would be a subword of $u'xv'v$, contradicting $u'xv'v \in L$).

By Lemma 26, $|v'v| - |v| \leq |t| \leq \|K\|_\infty$, i.e., $|v'| \leq \|K\|_\infty$. Furthermore, again by Lemma 26, $|x| \leq \|K\|_\infty$.

By Lemma 77, v is of the form a^k . Hence, all b in $u'xv'v$ are in xv' , thus $u'xv'v$ contains at most $2\|K\|_\infty$ b .

We have shown that all words in $\mathcal{L}(K)$ contain at most $2\|K\|_\infty$ b , contradicting $\mathcal{L}(K) = L$ as the number of b of words of L is unbounded. \blacktriangleleft

Proof of Proposition 66

Consider the following language over $A = \{a, b, c\}$:

$$L = L_1 \cup L_2 \text{ with } L_1 = \{wc\tilde{w} \mid w \in \{a, b\}^*\} \text{ and } L_2 = \{wcc\tilde{w} \mid w \in \{a, b\}^*\}.$$

We are going to prove that L is in LEK but not in BAK. L is recognised by $K = (\{aa\blacktriangleleft, bb\blacktriangleleft\}, \{c, cc\})$, then L is in LEK.

We now show that $L \notin \text{BAK}$. The intuition is as follows:

Suppose we have a keyboard K of BAK recognising L . As we want to recognise palindromes, we need to stay close to the centre in order to always modify both halves of the word.

If the word is large enough, this means that we have to get far from the edges. In particular, there is a key t writing an a far from the edges (even two a , as we have to stay in the language).

We study the behaviour of this key on $b^n cb^n$ and $b^n ccb^n$ with large n . The cursor being far from the edges, t behaves the same way in both cases. In particular, we make the following remarks:

- The maximal distance d between two a will be the same in both words. Thus, the resulting words have either both two c or both one c in the centre.
- In both cases the key adds a number of letters δ , and thus if $b^n cb^n$ is turned into a word of even length, then $b^n ccb^n$ is turned into a word of odd length, and vice-versa. As a result, they have different numbers of c in the centre.

As those facts are contradictory, we conclude that there cannot exist such a keyboard.

► **Proposition 66** (LEK $\not\subseteq$ BAK). LEK is not included in BAK.

B Complexity

Proof of Proposition 70

► **Lemma 78.** Let K be an BK keyboard. For all $\tau \in K^*$ there exists $\tau' \in K^*$ whose normal form is $\leftarrow^{k'} w'$ with $k' \leq \|K\|_\infty$ such that $\varepsilon \cdot \tau = \varepsilon \cdot \tau'$.

Proof. We proceed by induction on τ . The result hold for $\tau = \varepsilon$ (by taking $\tau' = \varepsilon$). Let $\tau \in K^*$, suppose there exists $\tau' \in K^*$ whose normal form is $\leftarrow^{k'} w'$ with $k' \leq \|K\|_\infty$ such that $\varepsilon \cdot \tau = \varepsilon \cdot \tau'$. Let $t \in K$, we study the sequence $t\tau$. We need to provide τ'' such that $\varepsilon \cdot t\tau = \varepsilon \cdot \tau''$ and with normal form $\leftarrow^{k''} w''$ with $k'' \leq \|K\|_\infty$.

There exist k and w such that $\leftarrow^k w$ is the normal form of t . Let $n = |w| - k'$.

- If $n > 0$, then $t\tau'$ is equivalent to $\leftarrow^k w[1, n]w'$ and we can set $\tau'' = t\tau'$ (as $n > 0$, we have $k' < |w| < \|K\|_\infty$).
- Otherwise, $\varepsilon \cdot t\tau = w \cdot \tau' = w \cdot \tau' = w' = \varepsilon \cdot \tau'$ and we can set $\tau'' = \tau'$.

The result is proven. ◀

► **Proposition 70.** The universality problem for BK keyboards is in CONP.

Proof. We prove that if a BK keyboard K is not universal, then there is a word of length at most $\|K\|_\infty + 1$ it does not recognise.

Let K be a keyboard of BK, suppose there exists $w \in A^*$ not recognised by K . We take w of minimal length. If $|w| \leq \|K\|_\infty + 1$ then the property holds.

If $|w| > \|K\|_\infty + 1$ then there exist $a \in A, v \in A^+$ such that $av = w$. As we assumed w to be of minimal length, v is recognised by K . By Lemma 78, there exist $k \leq \|K\|_\infty, \tau \in K^*$ whose normal form is $\leftarrow^k v$, such that $\varepsilon \cdot \tau = v$.

As $|a^{k+1}| = k + 1 \leq \|K\|_\infty + 1 < |w|$, a^{k+1} is recognised by K . Let τ' be such that $\varepsilon \cdot \tau' = a^{k+1}$, then we have $\varepsilon \xrightarrow{\tau'} a^{k+1} \xrightarrow{\tau} av = w$.

This contradicts the fact that w is not recognised by K . The property is proven. ◀

C Closure properties

Proof of Proposition 72

► **Proposition 72** (Mirror). *MK, AK and EAK are stable by mirror. EK, BK, BEK and BLK are not stable by mirror.*

For MK the result is clear as the mirror of $\mathcal{L}(K)$ is $\mathcal{L}(\tilde{K})$ when K is an MK keyboard.

As for AK and EAK, we first define the mirror of an atomic operation: the mirror of ◀ is ▶ (and vice-versa) and the mirror of a is $a\blacktriangleleft$. By turning every atomic operation in a keyboard into its mirror, we obtain a keyboard recognising the mirror language.

The language $L = b^*a$ is in EK and BK but its mirror is not in BEK, thus EK, BK and BEK are not stable under mirror.

The language $L = (b + b^2)a^*$ is recognised by the BLK keyboard

$$K = \{\leftarrow^2 a\blacktriangleleft b, \leftarrow^2 a\blacktriangleleft bb, \leftarrow^2 b, \leftarrow^2 bb\}$$

but its mirror $a^*(b + b^2)$ is not in BLK as is shown in the proof of Proposition 62.

Proof of Proposition 73

► **Proposition 73** (Intersection). *None of the keyboard language classes are stable by intersection.*

For MK and EK, we use the intersection of $(ab + ba + bb)^*$ and $(ba + b)^*$ as our counterexample.

For BK and BEK, we use again the language $L_{\diamond\blacklozenge}$ from the proof of Proposition 64. We also define $L' = (a + b + \diamond)^+\blacklozenge^2$ recognised by the BK keyboard

$$\{\leftarrow^2 a\blacklozenge^2, \leftarrow^2 b\blacklozenge^2, \leftarrow^2 \diamond\blacklozenge^2\}.$$

Thus L and L' are in BK, and we show that their intersection is not.

For the other classes, we show that $L = \{a^n b^n c^n \mid n \in \mathbb{N}\}$ is not in BEAK. Further, it is the intersection of the following LK languages:

- $(a + b)^* c^*$, recognised by $\{a, b, c\blacktriangleleft\}$,
- $a^*(b + c)^*$, recognised by $\{a, b\blacktriangleleft, c\blacktriangleleft\}$,
- $\{w \in (a + b + c)^* \mid |w|_a = |w|_b\}$, recognised by $\{ab, ba, c, \blacktriangleleft\}$,
- $\{w \in (a + b + c)^* \mid |w|_b = |w|_c\}$, recognised by $\{bc, cb, a, \blacktriangleleft\}$.

Proof of Proposition 74

► **Proposition 74** (Union). *None of the keyboard language classes are stable by union.*

To start with, we consider the languages a^* and b^* , both in MK, and prove that their union is neither in BLEK nor in EAK.

► **Lemma 79.** *The language $L = a^* + b^*$ is not in BLEK.*

Proof. Suppose there exists a keyboard $K = (T, F)$ of BLEK recognising L . Then there exists $\tau_a \in T^*$, $f_a \in F$ such that $\langle \varepsilon | \varepsilon \rangle \cdot \tau_a f_a = \langle u_a | v_a \rangle$ with $u_a v_a = a$.

There also exists $\tau_b \in T^*$, $f_b \in F$ such that $\langle \varepsilon | \varepsilon \rangle \cdot \tau_b f_b = \langle u_b | v_b \rangle$ with $u_b v_b = b^{1+\|K\|_\infty(|\tau_a|+2)}$.

By Lemma 24, applying τ_b to $\langle \varepsilon | \varepsilon \rangle$ yields a configuration with at least $1 + \|K\|_\infty(|\tau_a| + 1)$ b . We apply $\tau_b \tau_a f_a$ to $\langle \varepsilon | \varepsilon \rangle$, by Theorem 56 the resulting configuration contains an a , and as $\tau_a f_a$ can only erase at most $(|\tau_a| + 1)\|K\|_\infty$ letters, it contains a b . This is impossible, as the resulting word should be in L . ◀

► **Lemma 80.** *The language $L = a^* + b^*$ is not in EAK.*

Proof. Suppose there exists $K = (T, F)$ a keyboard of EAK recognising L . As $a^{\|K\|_\infty+1}$ and $b^{\|K\|_\infty+1}$ are both in L , there exist $t_a, t_b \in T$ such that t_a writes an a and t_b a b (and those letters are never erased, as we do not have \leftarrow). Let $f \in F$, $t_a t_b f$ writes a word containing both a and b , thus not in L . ◀

To finish, we define the language $L = L_a \cup L_b$ with $L_a = \{a^n c a^n \mid n \in \mathbb{N}\}$ and $L_b = \{b^n c b^n \mid n \in \mathbb{N}\}$. We can prove that L is not in BEAK, showing that all BAK and BEAK are not stable by intersection.

Proof of Proposition 75

► **Proposition 75** (Intersection emptiness problem). *The following problem is undecidable:*

Input: K_1, K_2 two LK keyboards.

Output: Is $\mathcal{L}(K_1) \cap \mathcal{L}(K_2)$ empty?

Proof. We reduce the Post Correspondence Problem. Let $(u_i, v_i)_{i \in \llbracket 1, n \rrbracket}$ be a PCP instance. For all $i \in \llbracket 1, n \rrbracket$, let u_i^\blacklozenge and v_i^\blacklozenge be u_i and v_i where we added a \blacklozenge at the right of every letter, i.e., if $u_i = a_1 a_2 \cdots a_n$ then $u_i^\blacklozenge = a_1 \blacklozenge a_2 \blacklozenge \cdots a_n \blacklozenge$.

We set for all $i \in \llbracket 1, n \rrbracket$, $t_i = u_i^\blacklozenge \widetilde{v_i^\blacklozenge} \blacktriangleleft^{2|v_i|}$. Let

$$K_{pal} = \{a a \blacktriangleleft \mid a \in A \cup \{\blacklozenge\}\} \cup \{\varepsilon\}$$

K_{pal} recognises the language of even palindromes over $A \cup \{\blacklozenge\}$. Now let

$$K = \{t_i \mid i \in \llbracket 1, n \rrbracket\}.$$

We easily show that $\mathcal{L}(K) \cap \mathcal{L}(K_{pal}) \neq \emptyset$ if and only if $(u_i, v_i)_{i \in \llbracket 1, n \rrbracket} \in \text{PCP}$. ◀

Quantum Speedups for Dynamic Programming on n -Dimensional Lattice Graphs

Abstract

Motivated by the quantum speedup for dynamic programming on the Boolean hypercube by Ambainis et al. (2019), we investigate which graphs admit a similar quantum advantage. In this paper, we examine a generalization of the Boolean hypercube graph, the n -dimensional lattice graph $Q(D, n)$ with vertices in $\{0, 1, \dots, D\}^n$. We study the complexity of the following problem: given a subgraph G of $Q(D, n)$ via query access to the edges, determine whether there is a path from 0^n to D^n . While the classical query complexity is $\tilde{\Theta}((D+1)^n)$, we show a quantum algorithm with complexity $\tilde{O}(T_D^n)$, where $T_D < D+1$. The first few values of T_D are $T_1 \approx 1.817$, $T_2 \approx 2.660$, $T_3 \approx 3.529$, $T_4 \approx 4.421$, $T_5 \approx 5.332$. We also prove that $T_D \geq \frac{D+1}{e}$ (here, $e \approx 2.718$ is the Euler's number), thus for general D , this algorithm does not provide, for example, a speedup, polynomial in the size of the lattice.

While the presented quantum algorithm is a natural generalization of the known quantum algorithm for $D=1$ by Ambainis et al., the analysis of complexity is rather complicated. For the precise analysis, we use the saddle-point method, which is a common tool in analytic combinatorics, but has not been widely used in this field.

We then show an implementation of this algorithm with time and space complexity $\text{poly}(n)^{\log^n T_D^n}$ in the QRAM model, and apply it to the SET MULTICOVER problem. In this problem, m subsets of $[n]$ are given, and the task is to find the smallest number of these subsets that cover each element of $[n]$ at least D times. While the time complexity of the best known classical algorithm is $O(m(D+1)^n)$, the time complexity of our quantum algorithm is $\text{poly}(m, n)^{\log^n T_D^n}$.

1 Introduction

Dynamic programming (DP) algorithms have been widely used to solve various NP-hard problems in exponential time. Bellman, Held and Karp showed how DP can be used to solve the TRAVELLING SALESMAN PROBLEM in $\tilde{O}(2^n)^1$ time using DP [5, 22], which still remains the most efficient classical algorithm for this problem. Their technique can be used to solve a plethora of different problems [16, 7].

The DP approach of Bellman, Held and Karp solves the subproblems corresponding to subsets of an n -element set, sequentially in increasing order of the subset size. This typically results in an $\tilde{\Theta}(2^n)$ time algorithm, as there are 2^n distinct subsets. What kind of speedups can we obtain for such algorithms using quantum computers?

It is natural to consider applying Grover's search, which is known to speed up some algorithms for NP-complete problems. For example, we can use it to search through the 2^n possible assignments to the SAT problem instance on n variables in $\tilde{O}(\sqrt{2^n})$ time. However, it is not immediately clear how to apply it to the DP algorithm described above. Recently, Ambainis et al. showed a quantum algorithm that combines classical precalculation with recursive applications of Grover's search that solves such DP problems in $\tilde{O}(1.817^n)$ time, assuming the QRAM model of computation [4].

In their work, the authors applied this result to obtain quantum speedups for the algorithms solving graph vertex ordering problems like PATHWIDTH and SUM CUT [7], and using a more involved analysis, for the GRAPH BANDWIDTH problem [12]. They also used similar ideas to provide speedups for the TRAVELLING SALESMAN, FEEDBACK ARC SET and MINIMUM SET COVER problems by combining the Divide & Conquer and DP techniques. Subsequently, these ideas have been used to construct quantum speedups for the GRAPH COLORING [29], MINIMUM STEINER TREE [26] and finding the optimal variable ordering for the binary decision diagrams (OBDDs) [30]. More surprisingly, [1] used the quantum speedup for the MINIMUM SET COVER to prove non-trivial conditional lower bounds for the k -SUM problem [1] (assuming the Set Cover Conjecture, which states that Minimum Set Cover cannot be solved classically in time $O((2 - \delta)^n)$ for any $\delta > 0$).

The $\tilde{O}(1.817^n)$ quantum speedup of Ambainis et al. for the aforementioned DP algorithm on the subsets of the n -element set examines the underlying transition graph, which can be seen as a directed n -dimensional Boolean hypercube, with edges connecting smaller weight vertices to larger weight vertices. A natural question arises, for what other graphs there exist quantum algorithms that achieve a speedup over the classical DP? In this work, we examine a generalization of the hypercube graph, the n -dimensional lattice graph with vertices in $\{0, 1, \dots, D\}^n$.

While the classical DP for this graph has running time $\tilde{\Theta}((D + 1)^n)$, as it examines all vertices, we prove that there exists a quantum algorithm (in the QRAM model) that solves this problem in time and space $\text{poly}(n)^{\log n} T_D^n$ for $T_D < D + 1$ (Theorems 4, 7). Our algorithm essentially is a generalization of the algorithm of Ambainis et al. We show the following running time for small values of D :

■ **Table 1** The complexity of the quantum algorithm.

D	1	2	3	4	5	6
T_D	1.81692	2.65908	3.52836	4.42064	5.33149	6.25720

¹ $f(n) = \tilde{O}(g(n))$ if $f(n) = O(\log^c(g(n))g(n))$ for some constant c .

A detailed summary of our numerical results is given in Section 5.3. Note that the case $D = 1$ corresponds to the hypercube, where we have the same algorithm and complexity as Ambainis et al. In our proofs, we extensively use the saddle point method from analytic combinatorics to estimate the asymptotic value of the combinatorial expressions arising from the complexity analysis.

It is interesting to compare our analysis and that of Ambainis et al. Their original algorithm is recursive, and solves instances of the problem of smaller size (on the subcubes of smaller dimensions). These instances are symmetrical, so the recursive calls can be analyzed identically, and the calculation of the complexity is relatively simple. However, this is not the case in our generalization for the n -dimensional lattice. To see this, consider, for example, the lattice $\{0, 1, 2\}^n$. In the recursive calls, our algorithm will examine sublattices $\{0, 1\}^{n_1} \times \{0, 1, 2\}^{n_2}$ with fixed maximum vertex weight $w = n_1 + 2n_2$. The first obstacle is that now there are many different cases (n_1, n_2) to analyze. The second obstacle is that recursively we have to solve the problem for a lattice $\{0, 1\}^{n_1} \times \{0, 1, 2\}^{n_2}$: now it becomes difficult to describe and analyze the sublattices examined in the recursion of depth at least 2. To solve these issues, we first make an ansatz that the exponential complexity of the algorithm on the lattice $\times_{d=1}^D \{0, 1, \dots, d\}^{n_d}$ can be expressed as $T_1^{n_1} T_2^{n_2} \dots T_D^{n_D}$, for some positive constants T_d . Then we make use of the saddle point method to find such optimal constants (that minimize T_D), and also prove that the ansatz is correct. Our analysis provides exactly the same $\tilde{O}(1.816\dots^n)$ complexity for the hypercube algorithm as by Ambainis et al.

Next, we also prove a lower bound on the query complexity of the algorithm for general D . Our motivation is to check whether our algorithm, for example, could achieve complexity $\tilde{O}((D+1)^{cn})$ for large D for some $c < 1$. We prove that this is not the case: more specifically, for any D , the algorithm performs at least $\tilde{\Omega}\left(\left(\frac{D+1}{e}\right)^n\right)$ queries (Theorem 5), where $e = 2.71828\dots$ is the Euler's number.

As an example application, we apply our algorithm to the SET MULTICOVER problem (SMC), which is a generalization of the SET COVER problem. In this problem, the input consists of m subsets of the n -element set, and the task is to calculate the smallest number of these subsets that together cover each element at least D times, possibly with overlap and repetition. While the best known classical algorithm has running time $O(m(D+1)^n)$ [27, 24], our quantum algorithm has running time $\text{poly}(m, n)^{\log^n T_D^n}$, improving the exponential complexity (Theorem 8).

The paper is organized as follows. In Section 2, we formally introduce the n -dimensional lattice graph and some of the notation used in the paper. In Section 3, we define the generic query problem that models the examined DP. In Section 4, we describe our quantum algorithm. In Section 5, we establish the query complexity of this algorithm and prove the aforementioned lower bound. In Section 6, we discuss the implementation of this algorithm and establish its time complexity. Finally, in Section 7, we show how to apply our algorithm to SMC, and discuss other related problems.

2 Preliminaries

The n -dimensional lattice graph is defined as follows. The vertex set is given by $\{0, 1, \dots, D\}^n$, and the edge set consists of directed pairs of two vertices u and v such that $v_i = u_i + 1$ for exactly one i , and $u_j = v_j$ for $j \neq i$. We denote this graph by $Q(D, n)$. Alternatively, this graph can be seen as the Cartesian product of n paths on $D + 1$ vertices. The case $D = 1$ is known as the Boolean hypercube and is usually denoted by Q_n .

We define the *weight* of a vertex $x \in V$ as the sum of its coordinates $|x| := \sum_{i=1}^n x_i$. Denote $x \leq y$ iff for all $i \in [n]$, $x_i \leq y_i$ holds. If additionally $x \neq y$, denote such relation by $x < y$.

Throughout the paper we use the standard notation $[n] := \{1, \dots, n\}$. In Section 7.1, we use notation for the superset $2^{[n]} := \{S \mid S \subseteq [n]\}$ and for the characteristic vector $\chi(S) \in \{0, 1\}^n$ of a set $S \in [n]$ defined as $\chi(S)_i = 1$ iff $i \in S$, and 0 otherwise.

We write $f(n) = \text{poly}(n)$ to denote that $f(n) = O(n^c)$ for some constant c . We also write $f(n, m) = \text{poly}(n, m)$ to denote that $f(n, m) = O(n^c m^d)$ for some constants c and d .

For a multivariable polynomial $p(x_1, \dots, x_m)$, we denote by $[x_1^{c_1} \cdots x_m^{c_m}]p(x_1, \dots, x_m)$ its coefficient at the multinomial $x_1^{c_1} \cdots x_m^{c_m}$.

3 Path in the hyperlattice

We formulate our generic problem as follows. The input to the problem is a subgraph G of $Q(D, n)$. The problem is to determine whether there is a path from 0^n to D^n in G . We examine this as a query problem: a single query determines whether an edge (u, v) is present in G or not.

Classically, we can solve this problem using a dynamic programming algorithm that computes the value $\text{dp}(v)$ recursively for all v , which is defined as 1 if there is a path from 0^n to v , and 0 otherwise. It is calculated by the Bellman, Held and Karp style recurrence [5, 22]:

$$\text{dp}(v) = \bigvee_{(u,v) \in E} \{\text{dp}(u) \wedge ((u, v) \in G)\}, \quad \text{dp}(0^n) = 1.$$

The query complexity of this algorithm is $O(n(D+1)^n)$. From this moment we refer to this as the *classical dynamic programming algorithm*.

The query complexity is also lower bounded by $\tilde{\Omega}((D+1)^n)$. Consider the sets of edges E_W connecting the vertices with weights W and $W+1$,

$$E_W := \{(u, v) \mid (u, v) \in Q(D, n), |u| = W, |v| = W+1\}.$$

Since the total number of edges is equal to $(D+1)^{n-1}Dn$, there is such a W that $|E_W| \geq (D+1)^{n-1}Dn/Dn = (D+1)^{n-1}$ (in fact, one can prove that the largest size is achieved for $W = \lfloor nD/2 \rfloor$ [13], but it is not necessary for this argument). Any such E_W is a cut of H_D , hence any path from 0^n to D^n passes through E_W . Examine all G that contain exactly one edge from E_W , and all other edges. Also examine the graph that contains no edges from E_W , and all other edges. In the first case, any such graph contains a desired path, and in the second case there is no such path. To distinguish these cases, one must solve the OR problem on $|E_W|$ variables. Classically, $\Omega(|E_W|)$ queries are needed (see, for example, [8]). Hence, the classical (deterministic and randomized) query complexity of this problem is $\tilde{\Theta}((D+1)^n)$. This also implies $\tilde{\Omega}(\sqrt{(D+1)^n})$ quantum lower bound for this problem [6].

4 The quantum algorithm

Our algorithm closely follows the ideas of [4]. We will use the well-known generalization of Grover's search:

► **Theorem 1** (Variable time quantum search (VTS), Theorem 3 in [3]). *Let $\mathcal{A}_1, \dots, \mathcal{A}_N$ be quantum algorithms that compute a function $f : [N] \rightarrow \{0, 1\}$ and have query complexities t_1, \dots, t_N , respectively, which are known beforehand. Suppose that for each \mathcal{A}_i , if $f(i) = 0$, then $\mathcal{A}_i = 0$ with certainty, and if $f(i) = 1$, then $\mathcal{A}_i = 1$ with constant success probability. Then there exists a quantum algorithm with constant success probability that checks whether $f(i) = 1$ for at least one i and has query complexity $O\left(\sqrt{t_1^2 + \dots + t_N^2}\right)$. Moreover, if $f(i) = 0$ for all $i \in [N]$, then the algorithm outputs 0 with certainty.*

Even though Ambainis formulates the main theorem for zero-error inputs, the statement above follows from the construction of the algorithm.

Now we describe our algorithm. We solve a more general problem: suppose $s, t \in \{0, 1, \dots, D\}^n$ are such that $s < t$ and we are given a subgraph of the n -dimensional lattice

$$\times_{i=1}^n \{s_i, \dots, t_i\},$$

and the task is to determine whether there is path from s to t . We need this generalized problem because our algorithm is recursive and is called for sublattices.

Define $d_i := t_i - s_i$. Let n_d be the number of indices $i \in [n]$ such that $d_i = d$. Note that the minimum and maximum weights of the vertices of this lattice are $|s|$ and $|t|$, respectively.

We call a set of vertices with fixed total weight a *layer*. The algorithm will operate with K layers (numbered 1 to K), with the k -th having weight $|s| + W_k$, where $W_k := \left\lfloor \sum_{d=1}^D \alpha_{k,d} n_d \right\rfloor$. Denote the set of vertices in this layer by

$$\mathcal{L}_k := \{v \mid |v| = |s| + W_k\}.$$

Here, $\alpha_{k,d} \in (0, 1/2)$ are constant parameters that have to be determined before we run the algorithm. The choice of $\alpha_{k,d}$ does not depend on the input to the algorithm, similarly as it was in [4]. For each $k \in [K]$ and $d \in [D]$, we require that $\alpha_{k,d} < \alpha_{k+1,d}$. In addition to the K layers defined in this way, we also consider the $(K+1)$ -th layer \mathcal{L}_{K+1} , which is the set of vertices with weight $|s| + W_{K+1}$, where $W_{K+1} := \left\lfloor \frac{|t| - |s|}{2} \right\rfloor$. We can see that the weights W_1, \dots, W_{K+1} defined in this way are non-decreasing.

The informal description of the algorithm (PATH) is as follows. First, we use the classical dynamic programming to calculate which vertices v with weight $|v| \leq |s| + W_1$ are reachable from s . Then, we store all of these answers in memory. Symmetrically, we also calculate from which vertices v with weight $|v| \geq |t| - W_1$ we can reach t , and also store this in memory. We refer to these steps as the classical precalculation part.

Next, we use VTS to search for a vertex $v^{(K+1)}$ in the layer \mathcal{L}_{K+1} such that there is path from s to $v^{(K+1)}$ and from v to t . The LAYERPATH function is then used to detect whether there is a path from s to $v^{(K+1)}$. First, we use VTS to search for a vertex $v^{(K)} \in \mathcal{L}_K$ such that: (1) there exists a path from $v^{(K)}$ to $v^{(K+1)}$; (2) there exists a path from s to $v^{(K)}$. The first condition we can check using PATH recursively for the lattice bounded by the vertices $v^{(K)}$ and $v^{(K+1)}$. The second condition is checked recursively using LAYERPATH in a similar fashion. Finally, for the vertex $v^{(1)} \in \mathcal{L}_1$, the LAYERPATH will need to check whether there is a path from s to $v^{(1)}$: this can be then simply read out from the memory, using the results of the precalculation part. We then similarly find whether t is reachable from $v^{(K)}$.

5 Query complexity

For simplicity, let us examine the lattice

$$\times_{i=1}^n \{0, \dots, t_i - s_i\},$$

as the analysis is identical.

Let the number of positions with maximum coordinate value d be n_d . We make an ansatz that the exponential complexity can be expressed as

$$T(n_1, \dots, n_D) := T_1^{n_1} T_2^{n_2} \cdot \dots \cdot T_D^{n_D}$$

■ **Algorithm 1** The quantum algorithm for detecting a path in the hyperlattice.

PATH(s, t):

1. Calculate n_1, \dots, n_D , and W_1, \dots, W_{K+1} . If $W_k = W_{k+1}$ for some k , determine whether there exists a path from s to t using classical dynamic programming and return.
2. Otherwise, first perform the precalculation step. Let $\text{dp}(v)$ be 1 iff there is a path from s to v . Calculate $\text{dp}(v)$ for all vertices v such that $|v| \leq |s| + W_1$ using classical dynamic programming. Store the values of $\text{dp}(v)$ for all vertices with $|v| = |s| + W_1$. Let $\text{dp}'(v)$ be 1 iff there is a path from v to t . Symmetrically, we also calculate $\text{dp}'(v)$ for all vertices with $|v| = |t| - W_1$.
3. Define the function $\text{LAYERPATH}(k, v)$ to be 1 iff there is a path from s to v such that $v \in \mathcal{L}_k$. Implement this function recursively as follows.
 - $\text{LAYERPATH}(1, v)$ is read out from the stored values.
 - For $k > 1$, run VTS over the vertices $u \in \mathcal{L}_{k-1}$ such that $u < v$. The required value is equal to

$$\text{LAYERPATH}(k, v) = \bigvee_u \{\text{LAYERPATH}(k-1, u) \wedge \text{PATH}(u, v)\}.$$

4. Similarly define and implement the function $\text{LAYERPATH}'(k, v)$, which denotes the existence of a path from v to t such that $v \in \mathcal{L}'_k$ (where \mathcal{L}'_k is the layer with weight $|t| - W_k$). To find the final answer, run VTS over the vertices in the middle layer $v \in \mathcal{L}_{K+1}$ and calculate

$$\bigvee_v \{\text{LAYERPATH}(K+1, v) \wedge \text{LAYERPATH}'(K+1, v)\}.$$

for some values $T_1, T_2, \dots, T_D > 1$ (we also can include n_0 and T_0 , however, $T_0 = 1$ always and doesn't affect the complexity). We prove it by constructing generating polynomials for the precalculation and quantum search steps, and then approximating the required coefficients asymptotically. We use the saddle point method that is frequently used for such estimation, specifically the theorems developed in [9].

5.1 Generating polynomials

First we estimate the number of edges of the hyperlattice queried in the precalculation step. The algorithm queries edges incoming to the vertices of weight at most W_1 , and each vertex can have at most n incoming edges. The size of any layer with weight less than W_1 is at most the size of the layer with weight exactly W_1 , as the size of the layers is non-decreasing until weight W_{K+1} [13]. Therefore, the number of queries during the precalculation is at most $n \cdot W_1 \cdot |\mathcal{L}_1| \leq n^2 D |\mathcal{L}_1|$, as $W_1 \leq nD$. Since we are interested in the exponential complexity, we can omit n and D , thus the exponential query complexity of the precalculation is given by $|\mathcal{L}_1|$.

Now let $P_d(x) := \sum_{i=0}^d x^i$. The number of vertices of weight W_1 can be written as the coefficient at x^{W_1} of the generating polynomial

$$P(x) := \prod_{d=0}^D P_d(x)^{n_d}.$$

Indeed, each $P_d(x)$ in the product corresponds to a single position $i \in [n]$ with maximum value d and the power of x in that factor represents the coordinate of the vertex in this position. Therefore, the total power that x is raised to is equal to the total weight of the vertex, and coefficient at x^{W_1} is equal to the number of vertices with weight W_1 . Since the total query complexity of the algorithm is lower bounded by this coefficient, we have

$$T(n_1, \dots, n_D) \geq [x^{W_1}]P(x). \tag{1}$$

Similarly, we construct polynomials for the LAYERPATH calls. Consider the total complexity of calling LAYERPATH recursively until some level $1 \leq k \leq K$ and then calling PATH for a sublattice between levels \mathcal{L}_k and \mathcal{L}_{k+1} . Define the variables for the vertices chosen by the algorithm at level i (where $k \leq i \leq K + 1$) by $v^{(i)}$. The PATH call is performed on a sublattice between vertices $v^{(k)}$ and $v^{(k+1)}$, see Fig. 1.

■ **Figure 1** The choice of the vertices $v^{(i)}$ and the application of PATH on the sublattice.

Define

$$S_{k,d}(x_{k,k}, \dots, x_{k,K+1}) := \sum_{i=0}^d T_i^2 \cdot \sum_{\substack{p_k, \dots, p_{K+1} \in [0,d] \\ p_{k+1} \leq \dots \leq p_{K+1} \\ p_{k+1} - p_k = i}} \prod_{j=k}^{K+1} x_{k,j}^{p_j}.$$

Again, this corresponds to a single coordinate. The variable $x_{k,j}$ corresponds to the vertex $v^{(j)}$ and the power p_j corresponds to the value of $v^{(j)}$ in that coordinate.

Examine the following multivariate polynomial:

$$S_k(x_{k,k}, \dots, x_{k,K+1}) := \prod_{d=0}^D S_{k,d}^{m_d}(x_{k,k}, \dots, x_{k,K+1}).$$

We claim that the coefficient

$$[x_{k,k}^{W_k} \cdots x_{k,K+1}^{W_{K+1}}] S_k(x_{k,k}, \dots, x_{k,K+1})$$

is the required total complexity squared.

First of all, note that the value of this coefficient is the sum of t^2 , where t is the variable for the running time of PATH between $v^{(k)}$ and $v^{(k+1)}$, for all choices of vertices $v^{(k)}, v^{(k+1)}, \dots, v^{(K+1)}$. Indeed, the powers p_j encode the values of coordinates of $v^{(j)}$, and a factor of T_i^2 is present for each multinomial that has $p_{k+1} - p_k = i$ (that is, $v_i^{(k+1)} - v_i^{(k)} = i$ for the corresponding position i).

Then, we need to show that the sum of t^2 equals the examined running time squared. Note that the choice of each vertex $v^{(j)}$ is performed using VTS. In general, if we perform VTS on the algorithms with running times s_1, \dots, s_N , then the total squared running time

is equal to $s_1^2 + \dots + s_N^2$ by Theorem 1. By repeating this argument in our case inductively at the choice of each vertex $v^{(j)}$, we obtain that the final squared running time indeed is the sum of all t^2 .

Therefore, the square of the total running time of the algorithm is lower bounded by

$$T(n_1, \dots, n_D)^2 \geq \left[x_{k,k}^{W_k} \cdots x_{k,K+1}^{W_{K+1}} \right] S_k(x_{k,k}, \dots, x_{k,K+1}). \quad (2)$$

Together the inequalities (1) and (2) allow us to estimate T . The total time complexity of the quantum algorithm is twice the sum of the coefficients given in Eq. (1) and (2) for all $k \in [K]$ (twice because of the calls to LAYERPATH and its symmetric counterpart LAYERPATH'). This is upper bounded by $2K$ times the maximum of these coefficients. Since $2K$ is a constant, and there are $O(\log n)$ levels of recursion (see Appendix A), in total this contributes only $(2K)^{O(\log n)} = \text{poly}(n)$ factor to the total complexity of the quantum algorithm.

5.2 Saddle point approximation

In this section, we show how to describe the tight asymptotic complexity of $T(n_1, \dots, n_D)$ using the saddle point method (a detailed review can be found in [15], Chapter VIII). Our main technical tool will be the following theorem.

► **Theorem 2.** *Let $p_1(x_1, \dots, x_m), \dots, p_D(x_1, \dots, x_m)$ be polynomials with non-negative coefficients. Let n be a positive integer and b_1, \dots, b_D be non-negative rational numbers such that $b_1 + \dots + b_D = 1$ and $b_d n$ is an integer for all $d \in [D]$. Let $a_{i,d}$ be rational numbers (for $i \in [m], d \in [D]$) and $\alpha_i := a_{i,1} b_1 + \dots + a_{i,D} b_D$. Suppose that $\alpha_i n$ are integer for all $i \in [m]$. Then*

$$(1) \quad [x_1^{\alpha_1 n} \cdots x_m^{\alpha_m n}] \prod_{d=1}^D p_d(x_1, \dots, x_m)^{b_d n} \leq \left(\inf_{x_1, \dots, x_m > 0} \prod_{d=1}^D \left(\frac{p_d(x_1, \dots, x_m)}{x_1^{a_{1,d}} \cdots x_m^{a_{m,d}}} \right)^{b_d} \right)^n$$

$$(2) \quad [x_1^{\alpha_1 n} \cdots x_m^{\alpha_m n}] \prod_{d=1}^D p_d(x_1, \dots, x_m)^{b_d n} = \Omega \left(\left(\inf_{x_1, \dots, x_m > 0} \prod_{d=1}^D \left(\frac{p_d(x_1, \dots, x_m)}{x_1^{a_{1,d}} \cdots x_m^{a_{m,d}}} \right)^{b_d} \right)^n \right),$$

where Ω depends on the variable n .

Proof. To prove this, we use the following saddle point approximation.²

► **Theorem 3** (Saddle point method, Theorem 2 in [9]). *Let $p(x_1, \dots, x_m)$ be a polynomial with non-negative coefficients. Let $\alpha_1, \dots, \alpha_m$ be some rational numbers and let n_i be the series of all integers j such that $\alpha_k j$ are integers and $[x_1^{\alpha_1 j} \cdots x_m^{\alpha_m j}] p(x_1, \dots, x_m)^j \neq 0$. Then*

$$\lim_{i \rightarrow \infty} \frac{1}{n_i} \log([x_1^{\alpha_1 n_i} \cdots x_m^{\alpha_m n_i}] p(x_1, \dots, x_m)^{n_i}) = \inf_{x_1, \dots, x_m > 0} \log \left(\frac{p(x_1, \dots, x_m)}{x_1^{\alpha_1} \cdots x_m^{\alpha_m}} \right).$$

Let $p(x_1, \dots, x_m) := \prod_{d=1}^D p_d(x_1, \dots, x_m)^{b_d}$, then

$$\frac{p(x_1, \dots, x_m)}{x_1^{\alpha_1} \cdots x_m^{\alpha_m}} = \frac{\prod_{d=1}^D p_d(x_1, \dots, x_m)^{b_d}}{x_1^{\alpha_1} \cdots x_m^{\alpha_m}} = \prod_{d=1}^D \frac{p_d(x_1, \dots, x_m)^{b_d}}{x_1^{a_{1,d} b_d} \cdots x_m^{a_{m,d} b_d}} = \prod_{d=1}^D \left(\frac{p_d(x_1, \dots, x_m)}{x_1^{a_{1,d}} \cdots x_m^{a_{m,d}}} \right)^{b_d}.$$

² Setting $\gamma = 1$ in the statement of the original theorem.

For the first part, as $p(x_1, \dots, x_m)^n$ has non-negative coefficients, the coefficient at the multinomial $x_1^{\alpha_1 n} \dots x_m^{\alpha_m n}$ is upper bounded by

$$\inf_{x_1, \dots, x_m > 0} \frac{p(x_1, \dots, x_m)^n}{x_1^{\alpha_1 n} \dots x_m^{\alpha_m n}} = \left(\inf_{x_1, \dots, x_m > 0} \frac{p(x_1, \dots, x_m)}{x_1^{\alpha_1} \dots x_m^{\alpha_m}} \right)^n$$

The second part follows directly by Theorem 3. ◀

5.2.1 Optimization program

To determine the complexity of the algorithm, we construct the following optimization problem. Recall that the Algorithm 1 is given by the number of layers K and the constants $\alpha_{k,d}$ that determine the weight of the layers, so assume they are fixed known numbers. Assume that $\alpha_{k,d}$ are all rational numbers between 0 and $1/2$ for $k \in [K]$; indeed, we can approximate any real number with arbitrary precision by a rational number. Also let $T_0 = 1$ and $\alpha_{K+1,d} = 1/2$ for all $d \in [D]$ for convenience.

Examine the following program $\text{OPT}(D, K, \{\alpha_{k,d}\})$:

$$\begin{aligned} \text{minimize } T_D \quad \text{s.t.} \quad & T_d \geq \frac{P_d(x)}{x^{\alpha_{1,d}}} && \forall d \in [D] \\ & T_d^2 \geq \frac{S_{k,d}(x_{k,k}, \dots, x_{k,K+1})}{x_{k,k}^{\alpha_{k,d}} \dots x_{k,K+1}^{\alpha_{K+1,d}}} && \forall d \in [D], \forall k \in [K] \\ & T_d \geq 1 && \forall d \in [D] \\ & x > 0 \\ & x_{k,j} > 0 && \forall k \in [K], \forall j \in \{k, \dots, K+1\} \end{aligned}$$

Let $n := n_1 + \dots + n_D$ and $\alpha_k := \frac{\sum_{d=1}^D \alpha_{k,d} n_d}{n}$. Suppose that T_1, \dots, T_D is a feasible point of the program. Then by Theorem 2 (1) (setting $b_i := n_i/n$ and $a_{i,d} := \alpha_{i,d} n_d$) we have

$$[x^{\alpha_1 n}]P(x) \leq \inf_{x > 0} \prod_{d=1}^D \left(\frac{P_d(x)}{x^{\alpha_{1,d} n_d}} \right)^{n_d} \leq T_1^{n_1} \dots T_D^{n_D}.$$

Similarly,

$$\begin{aligned} [x_{k,k}^{\alpha_{k,n}} \dots x_{k,K+1}^{\alpha_{K+1,n}}] S_k(x_{k,k}, \dots, x_{k,K+1}) &\leq \inf_{x_{k,k}, \dots, x_{k,K+1} > 0} \prod_{d=1}^D \left(\frac{S_{k,d}(x_{k,k}, \dots, x_{k,K+1})}{x_{k,k}^{\alpha_{k,d} n_d} \dots x_{k,K+1}^{\alpha_{K+1,d} n_d}} \right)^{n_d} \\ &\leq (T_1^{n_1} \dots T_D^{n_D})^2. \end{aligned}$$

Therefore, the program provides an upper bound on the complexity. There are two subtleties that we need to address for correctness: firstly, what happens when $\alpha_k n$ is not an integer; secondly, the case when $W_k = W_{k+1}$ for some k . We show that both do not raise an issue in Appendix B.

5.2.2 Optimality of the program

In the start of the analysis, we made an assumption that the exponential complexity $T(n_1, \dots, n_D)$ can be expressed as $T_1^{n_1} \dots T_D^{n_D}$. In Appendix C, using the lower bound of Theorem 3 (2), we show that $\text{OPT}(D, K, \{\alpha_{k,d}\})$ (which gives an upper bound on the complexity) can indeed achieve such value and also gives the best possible solution.

5.2.3 Total complexity

Finally, in Appendix D we argue that there exists a choice for the parameters $\{\alpha_{k,d}\}$ such that $\text{OPT}(D, K, \{\alpha_{k,d}\}) < D + 1$. Therefore, putting all together, we have the main result:

► **Theorem 4.** *There exists a bounded-error quantum algorithm that solves the path in the n -dimensional lattice problem using $\tilde{O}(T_D^n)$ queries, where $T_D < D + 1$. The optimal value of T_D can be found by optimizing $\text{OPT}(D, K, \{\alpha_{k,d}\})$ over K and $\{\alpha_{k,d}\}$.*

5.3 Complexity for small D

To find the estimate on the complexity for small values of D and K , we have optimized the value of $\text{OPT}(D, K, \{\alpha_{k,d}\})$ using Mathematica (minimizing over the values of $\alpha_{k,d}$). Table 2 compiles the results obtained by the optimization. In case of $D = 1$, we recovered the complexity of the quantum algorithm from [4] for the path in the hypercube problem, which is a special case of our algorithm.

■ **Table 2** The complexity of the quantum algorithm for small values of D and K .

	$D = 1$	$D = 2$	$D = 3$	$D = 4$	$D = 5$	$D = 6$
$K = 1$	1.86793	2.76625	3.68995	4.63206	5.58735	6.55223
$K = 2$	1.82562	2.67843	3.55933	4.46334	5.38554	6.32193
$K = 3$	1.81819	2.66198	3.53322	4.42759	5.34059	6.26840
$K = 4$	1.81707	2.65939	3.52893	4.42148	5.33263	6.25862
$K = 5$	1.81692	2.65908	3.52836	4.42064	5.33149	6.25720

For $K = 1$, we were able to estimate the complexity for up to $D = 18$. Figure 2 shows the values of the difference between $D + 1$ and T_D for this range.

■ **Figure 2** The advantage of the quantum algorithm over the classical for $K = 1$.

Our Mathematica code used for determining the values of T_D can be accessed at <https://doi.org/10.5281/zenodo.4603689>. In Appendix E, we list the parameters for the case $K = 1$.

5.4 Lower bound for general D

Even though Theorem 4 establishes the quantum advantage of the algorithm, it is interesting how large the speedup can get for large D . In this section, we prove that the speedup cannot be substantial, more specifically:

► **Theorem 5.** *For any fixed integers $D \geq 1$ and $K \geq 1$, Algorithm 1 performs $\tilde{\Omega}\left(\left(\frac{D+1}{e}\right)^n\right)$ queries on the lattice $Q(D, n)$.*

Proof. The structure of the proof is as follows. First, we prove that if $\alpha_{1,D} > \frac{1}{4}$, then the number of queries used in the algorithm during the precalculation step 2 is at least $\tilde{\Omega}((0.664554(D+1))^n)$ queries. Then, we prove that if $\alpha_{1,D} \leq \frac{1}{4}$, then the quantum search part in steps 3 and 4 performs at least $\tilde{\Omega}\left(\left(\frac{D+1}{e}\right)^n\right)$ queries. Therefore, depending on whether $\alpha_{1,D} > \frac{1}{4}$, one of the precalculation or the quantum search performs $\tilde{\Omega}((c(D+1))^n)$ queries for constant c , and the claim follows, since $\frac{1}{e} < 0.664554$. Due to space limitations, the proof can be accessed online in the full version of the paper [18] (Appendix B). ◀

6 Time complexity

In this section we examine a possible high-level implementation of the described algorithm and argue that there exists a quantum algorithm with the same exponential time complexity as the query complexity.

Firstly, we assume the commonly used QRAM model of computation that allows to access N memory cells in superposition in time $O(\log N)$ [17]. This is needed when the algorithm accesses the precalculated values of dp . Since in our case N is always at most $(D+1)^n$, this introduces only a $O(\log((D+1)^n)) = O(n)$ additional factor to the time complexity.

The main problem that arises is the efficient implementation of VTS. During the VTS execution, multiple quantum algorithms should be performed in superposition. More formally, to apply VTS to algorithms $\mathcal{A}_1, \dots, \mathcal{A}_N$, we should specify the *algorithm oracle* that, given the index of the algorithm i and the time step t , applies the t -th step of \mathcal{A}_i (see Section 2.2 of [11] for formal definition of such an oracle and related discussion). If the algorithms \mathcal{A}_i are unstructured, the implementation of such an oracle may take even $O(N)$ time (if, for example, all of the algorithms perform a different gate on different qubits at the t -th step).

We circumvent this issue by showing that it is possible to use only Grover's search to implement the algorithm, retaining the same exponential complexity (however, the sub-exponential factor in the complexity will increase). Nonetheless, the use of VTS in the query algorithm not only achieves a smaller query complexity, but also allowed to prove the estimate on the exponential complexity, which would not be so amiable for the algorithm that uses Grover's search.

6.1 Implementation

The main idea of the implementation is to fix a “class” of vertices for each of the $2K+1$ layers examined by the algorithm, and do this for all $r = O(\log n)$ levels of recursion. We will essentially define these classes by the number of coordinates of a vertex in such layer that are equal to 0, 1, \dots , D . Then, we can first fix a class for each layer for all levels of recursion classically. We will show that there are at most n^{D^2} different classes we have to consider at each layer. Since there are $2K+1$ layers at one level of recursion, and $O(\log n)$ levels of recursion, this classical precalculation will take time $n^{O(D^2 K \log n)}$. For each such choice of classes, we will run a quantum algorithm that checks for the path in the hyperlattice constrained on these classes of the vertices the path can go through. The advantage of

the quantum algorithm will come from checking the permutations of the coordinates using Grover’s search. The time complexity of the quantum part will be $n^{O(K \log n)} T_D^n$ (T_D^n as in the query algorithm, and $n^{O(K \log n)}$ from the logarithmic factors in Grover’s search), therefore the total time complexity will be $n^{O(D^2 K \log n)} \cdot n^{O(K \log n)} T_D^n = n^{O(D^2 K \log n)} T_D^n$, thus the exponential complexity stays the same.

6.2 Layer classes

In all of the applications of VTS in the algorithm, we use it in the following scenario: given a vertex x , examine all vertices y with fixed weight $|y| = W$ such that $y < x$ (note that VTS over the middle layer \mathcal{L}_{K+1} can be viewed in this way by taking x to be the final vertex in the lattice, and VTS over the vertices in the layers symmetrical to \mathcal{L}_{K+1} can be analyzed similarly).

We define a *class* of y ’s (in respect to x) in the following way. Let $n_{a,b}$ be the number of $i \in [n]$ such that $y_i = a$ and $x_i = b$, where $a \leq b$. All y in the same class have the same values of $n_{a,b}$ for all a, b . Also define a *representative* of a class as a single particular y from that class; we will define it as the lexicographically smallest such y .

As mentioned in the informal description above, we can fix the classes for all layers examined by the quantum algorithm and generate the corresponding representatives classically. Note that in our quantum algorithm, recursive calls work with the sublattice constrained on the vertices $s \leq y \leq t$ for some $s < t$, so for each position of y_i we should have also $y_i \geq s_i$; however, we can reduce it to lattice $0^n \leq y' \leq x$, where $x_i := t_i - s_i$ for all i . To get the real value of y , we generate a representative y' , and set $y_i := y'_i + s_i$.

Consider an example for $D = 2$. The following figure illustrates the representative y (note that the order of positions of x here is lexicographical for simplicity, but it may be arbitrary).

$$\begin{array}{l}
 x = 00 \dots 011 \dots \dots \dots 122 \dots \dots \dots 2 \\
 y = \underbrace{00 \dots 0}_{n_{0,0}} \underbrace{00 \dots 0}_{n_{0,1}} \underbrace{11 \dots 1}_{n_{1,1}} \underbrace{00 \dots 0}_{n_{0,2}} \underbrace{11 \dots 1}_{n_{1,2}} \underbrace{22 \dots 2}_{n_{2,2}}
 \end{array}$$

■ **Figure 3** The (lexicographically smallest) representative for y for $D = 2$.

Note that $n_{a,b}$ can be at most n . Therefore, there are at most n^{D^2} choices for classes at each layer. Thus the total number of different sets of choices for all layers is $n^{O(D^2 K \log n)}$. For each such set of choices, we then run a quantum algorithm that checks for a path in the sublattice constrained on these classes.

6.3 Quantum algorithm

The algorithm basically implements Algorithm 1, with VTS replaced by Grover’s search. Thus we only describe how we run the Grover’s search. We will also use the analysis of Grover’s search with multiple marked elements.

► **Theorem 6** (Grover’s search). *Let $f : S \rightarrow \{0, 1\}$, where $|S| = N$. Suppose we can generate a uniform superposition $\frac{1}{\sqrt{N}} \sum_{x \in S} |x\rangle$ in $O(\text{poly}(\log N))$ time, and there is a bounded-error quantum algorithm \mathcal{A} that computes $f(x)$ with time complexity T . Suppose also that there is a promise that either there are at least k solutions to $f(x) = 1$, or there are none. Then there exists a bounded-error quantum algorithm that runs in time $O(T \log N \sqrt{N/k})$, and detects whether there exists x such that $f(x) = 1$.*

Proof. First, it is well-known that in the case of k marked elements, Grover's algorithm [21] needs $O(\sqrt{N/k})$ iterations. Second, the gate complexity of one iteration of Grover's search is known to be $O(\log N)$. Finally, even though \mathcal{A} has constant probability of error, there is a result that implements Grover's search with a bounded-error oracle without introducing another logarithmic factor [23]. ◀

Now, for a class \mathcal{C} of y 's (for a fixed x) we need to generate a superposition $\frac{1}{\sqrt{|\mathcal{C}|}} \sum_{y \in \mathcal{C}} |y\rangle$ efficiently to apply Grover's algorithm. We will generate a slightly different superposition for the same purposes. Let I_1, \dots, I_D be sets $I_d := \{i \in [n] \mid x_i = d\}$ and let $n_d := |I_d|$. Let $y_{\mathcal{C}}$ be the representative of \mathcal{C} . We will generate the superposition

$$\bigotimes_{d=0}^D \frac{1}{\sqrt{n_d!}} \sum_{\pi \in S_{n_d}} |\pi(y_{\mathcal{C}_{I_d}})\rangle |\pi\rangle, \quad (3)$$

where $y_{\mathcal{C}_{I_d}}$ are the positions of $y_{\mathcal{C}}$ in I_d .

We need a couple of procedures to generate such state. First, there exists a procedure to generate the uniform superposition of permutations $\frac{1}{\sqrt{n!}} \sum_{\pi \in S_n} |\pi_1, \dots, \pi_n\rangle$ that requires $O(n^2 \log n)$ elementary gates [2, 10]. Then, we can build a circuit with $O(\text{poly}(n))$ gates that takes as an input $\pi \in S_n$, $s \in \{0, 1, \dots, D\}^n$ and returns $\pi(s)$. Such a circuit essentially could work as follows: let $t := 0^n$; then for each pair $i, j \in [n]$, check whether $\pi(i) = j$; if yes, let $t_j \leftarrow t_j + s_{\pi(i)}$; in the end return t . Using these two subroutines, we can generate the required superposition using $O(\text{poly}(n))$ gates (we assume D is a constant).

However, we do not necessarily know the sets I_d , because the positions of x have been permuted by previous applications of permutations. To mitigate this, note that we can access this permutation in its own register from the previous computation. That is, suppose that x belongs to a class \mathcal{C}' and $x = \sigma(x_{\mathcal{C}'})$, where $x_{\mathcal{C}'}$ is the representative of \mathcal{C}' generated by the classical algorithm from the previous subsection. Then we have the state $|\sigma(x_{\mathcal{C}'})\rangle |\sigma\rangle$.

We can then apply σ to both $\pi(y_{\mathcal{C}})$ and π . That is, we implement the transformation

$$|\pi(y_{\mathcal{C}})\rangle |\pi\rangle \rightarrow |\sigma(\pi(y_{\mathcal{C}}))\rangle |\sigma\pi\rangle.$$

Such transformation can also be implemented in $O(\text{poly}(n))$ gates. Note that now we store the permutation $\sigma\pi$ in a separate register, which we use in a similar way recursively.

Finally, examine the number of positive solutions among $\pi(y_{\mathcal{C}})$. That is, for how many π there exists a path from $\pi(y)$ to x ? Suppose that there is a path from y to x for some $y \in \mathcal{C}$. Examine the indices I_d ; for $n_{a,d}$ of these indices i we have $y_i = a$. There are exactly $n_{a,d}!$ permutations that permute these indices and don't change y . Hence, there are $\prod_{a=0}^D n_{a,d}!$ distinct permutations $\pi \in S_{n_d}$ such that $\pi(y) = y$.

Therefore, there are $k := \prod_{d=0}^D \prod_{a=0}^d n_{a,d}!$ distinct permutations π among the considered such that $\pi(y) = y$. The total number of considered permutations is $N := \prod_{d=0}^D n_d!$. Among these permutations, either there are no positive solutions, or at least k of the solutions are positive. Grover's search then works in time $O(T \log N \sqrt{N/k})$. In this case, N/k is exactly the size of the class \mathcal{C} , because $\frac{n_d!}{n_{0,d}! \dots n_{d,d}!}$ is the number of unique permutations of $y_{\mathcal{C}_{P_d}}$, the multinomial coefficient $\binom{n_d}{n_{0,d}, \dots, n_{d,d}}$. Hence the state Eq. (3) effectively replaces the need for the state $\frac{1}{\sqrt{|\mathcal{C}|}} \sum_{y \in \mathcal{C}} |y\rangle$.

6.4 Total complexity

Finally, we discuss the total time complexity of this algorithm. The exponential time complexity of the described quantum algorithm is at most the exponential query complexity because Grover's search examines a single class \mathcal{C} , while VTS in the query algorithm examines

all possible classes. Since Grover's search has a logarithmic factor overhead, the total time complexity of the quantum part of the algorithm is what is described in Section 5 multiplied by $n^{O(K \log n)}$, resulting in $n^{O(K \log n)} T_1^{n_1} \dots T_D^{n_D}$.

Since there are $n^{O(D^2 K \log n)}$ sets of choices for the classes of the layers, the final total time complexity of the algorithm is $n^{O(D^2 K \log n)} T_1^{n_1} \dots T_D^{n_D}$.

For the space complexity, note that the precalculation step requires asymptotically the same exponential amount of space as time, thus $T_1^{n_1} \dots T_D^{n_D}$ is also the exponential space complexity of the algorithm.

Therefore, we have the following result.

► **Theorem 7.** *Assuming QRAM model of computation, there exists a quantum algorithm that solves the path in the n -dimensional lattice problem with time and space complexity $\text{poly}(n)^{D^2 \log n} \cdot T_D^n$.*

7 Applications

7.1 Set multicover

As an example application of our algorithm, we apply it to the SET MULTICOVER problem (SMC). This is a generalization of the MINIMUM SET COVER problem. The SMC problem is formulated as follows:

Input: A set of subsets $\mathcal{S} \subseteq 2^{[n]}$, and a positive integer D .

Output: The size k of the smallest tuple $(S_1, \dots, S_k) \in \mathcal{S}^k$, such that for all $i \in [n]$, we have $|\{j \mid i \in S_j\}| \geq D$, that is, each element is covered at least D times (note that each set $S \in \mathcal{S}$ can be used more than once).

Denote this problem by SMC_D , and $m := |\mathcal{S}|$. This problem has been studied classically, and there exists an exact deterministic algorithm based on the inclusion-exclusion principle that solves this problem in time $\tilde{O}(m(D+1)^n)$ and polynomial space [27, 24]. While there are various approximation algorithms for this problem, we are not aware of a more efficient classical exact algorithm.

There is a different simple classical dynamic programming algorithm for this problem with the same time complexity (although it uses exponential space), which we can speed up using our quantum algorithm. For a vector $x \in \{0, 1, \dots, D\}^n$, define $\text{dp}(x)$ to be the size k of the smallest tuple $(\mathcal{C}_1, \dots, \mathcal{C}_k) \in \mathcal{S}^k$ such that for each i , we have $|\{j \in [k] \mid i \in \mathcal{C}_j\}| \geq x_i$. It can be calculated using the recurrence

$$\text{dp}(0^n) = 0, \quad \text{dp}(x) = 1 + \min_{S \in \mathcal{S}} \{\text{dp}(x')\},$$

where x' is given by $x'_i = \max\{0, x_i - \chi(S)_i\}$ for all i . Consequently, the answer to the problem is equal to $\text{dp}(D^n)$. The number of distinct x is $(D+1)^n$, and $\text{dp}(x)$ for a single x can be calculated in time $O(nm)$, if $\text{dp}(y)$ has been calculated for all $y < x$. Thus the time complexity is $O(nm(D+1)^n)$ and space complexity is $O((D+1)^n)$.

Note that even though the state space of the dynamic programming here is $\{0, 1, \dots, D\}^n$, the underlying transition graph is not the same as the hyperlattice examined in the quantum algorithm. A set $S \in \mathcal{S}$ can connect vertices that are $|S|$ distance apart from each other, unlike distance 1 in the hyperlattice. We can essentially reduce this to the hyperlattice-like transition graph by breaking such transition into $|S|$ distinct transitions.

More formally, examine pairs (x, S) , where $x \in \{0, 1, \dots, D\}^n$, $S \in \mathcal{S}$. Let $e(x, S) := \min\{i \in S \mid x_i > 0\}$; if there is no such i , let $e(x, S)$ be 0. Define a new function

$$\text{dp}(x, S) = \begin{cases} 0, & \text{if } x = 0^n, \\ \text{dp}(x - \chi(\{e(x, S)\}), S), & \text{if } e(x, S) > 0, \\ 1 + \min_{T \in \mathcal{S}, e(x, T) > 0} \{\text{dp}(x - \chi(\{e(x, T)\}), T)\}, & \text{if } e(x, S) = 0. \end{cases}$$

The new recursion also solves SMC_D , and the answer is equal to $\min_{S \in \mathcal{S}} \{\text{dp}(D^n, S)\}$.

Examine the underlying transition graph between pairs (x, S) . We can see that there is a transition between two pairs (x, S) and (y, T) only if $y_i = x_i + 1$ for exactly one i , and $y_i = x_i$ for other i . This is the n -dimensional lattice graph $Q(D, n)$. Thus we can apply our quantum algorithm with a few modifications:

- We now run Grover's search over (x, S) with fixed $|x|$ for all $S \in \mathcal{S}$. This adds a $\text{poly}(m, n)$ factor to each run of Grover's search.
- Since we are searching for the minimum value of dp , we actually need a quantum algorithm for finding the minimum instead of Grover's search. We can use the well-known quantum minimum finding algorithm that retains the same query complexity as Grover's search [14]³. It introduces only an additional $O(\log n)$ factor for the queries of minimum finding to encode the values of dp , since $\text{dp}(x, S)$ can be as large as Dn .
- A single query for a transition between pairs (x, S) and (y, T) in this case returns the value of the value added to the dp at transition, which is either 0 or 1. If these pairs are not connected in the transition graph, the query can return ∞ . Note that such query can be implemented in $\text{poly}(m, n)$ time.

Since the total number of runs of Grover's search is $O(K \log n)$, the additional factor incurred is $\text{poly}(m, n)^{O(K \log n)}$. This provides a quantum algorithm for this problem with total time complexity

$$\text{poly}(m, n)^{O(K \log n)} \cdot n^{O(D^2 K \log n)} T_D^n = m^{O(K \log n)} n^{O(D^2 K \log n)} T_D^n.$$

Therefore, we have the following result.

► **Theorem 8.** *Assuming the QRAM model of computation, there exists a quantum algorithm that solves SMC_D in time and space $\text{poly}(m, n)^{\log n} T_D^n$, where $T_D < D + 1$.*

7.2 Related problems

We are also aware of a couple of other works that implement the dynamic programming on the $\{0, 1, \dots, D\}^n$ n -dimensional lattice.

Psarftis examined the job scheduling problem [28], with application to aircraft landing scheduling. The problem requires ordering n groups of jobs with D identical jobs in each group. A cost transition function is given: the cost of processing a job belonging to group j after processing a job belonging to group i is given by $f(i, j, d_1, \dots, d_n)$, where d_i is the number of jobs left to process. The task is to find an ordering of the nD jobs that minimizes the total cost. This is almost exactly the setting for our quantum algorithm, hence we get $\text{poly}(n)^{\log n} T_D^n$ time quantum algorithm. Psarftis proposed a classical $O(n^2(D+1)^n)$ time

³ Note that this algorithm assumes queries with zero error, but we apply it to bounded-error queries. However, it consists of multiple runs of Grover's search, so we can still use the result of [23] to avoid the additional logarithmic factor.

dynamic programming algorithm. Note that if $f(i, j, d_1, \dots, d_n)$ are unstructured (can be arbitrary values), then there does not exist a faster classical algorithm by the lower bound of Section 3.

However, if $f(i, j, d_1, \dots, d_n)$ are structured or can be computed efficiently by an oracle, there exist more efficient classical algorithms for these kinds of problems. For instance, the many-visits travelling salesman problem (MV-TSP) asks for the shortest route in a weighted n -vertex graph that visits vertex i exactly D_i times. In this case, $f(i, j, d_1, \dots, d_n) = w(i, j)$, where $w(i, j)$ is the weight of the edge between i and j . The state-of-the-art classical algorithm by Kowalik et al. solves this problem in $\tilde{O}(4^n)$ time and space [32]. Thus, our quantum algorithm does not provide an advantage. It would be quite interesting to see if there exists a quantum speedup for this MV-TSP algorithm.

Lastly, Gromicho et al. proposed an exact algorithm for the job-shop scheduling problem [20, 31]. In this problem, there are n jobs to be processed on D machines. Each job consists of D tasks, with each task to be performed on a separate machine. The tasks for each job need to be processed in a specific order. The time to process job i on machine j is given by p_{ij} . Each machine can perform at most one task at any moment, but machines can perform the tasks in parallel. The problem is to schedule the starting times for all tasks so as to minimize the last ending time of the tasks. Gromicho et al. give a dynamic programming algorithm that solves the problem in time $O((p_{\max})^{2n}(D+1)^n)$, where $p_{\max} = \max_{i,j} \{p_{ij}\}$.

The states of their dynamic programming are also vectors in $\{0, 1, \dots, D\}^n$: a state x represents a partial completion of tasks, where x_i tasks of job i have already been completed. Their dynamic programming calculates the set of task schedulings for x that can be potentially extended to an optimal scheduling for all tasks. However, it is not clear how to apply Grover's search to calculate a whole set of schedulings. Therefore, even though the state space is the same as in our algorithm, we do not know whether it is possible to apply it in this case.

A Depth of recursion

Note that the algorithm stops the recursive calls if for at least one k , we have $W_k = W_{k+1}$, in which case it runs the classical dynamic programming on the whole sublattice at step 1. That happens when

$$\left| \sum_{d=1}^D \alpha_{k,d} dn_d \right| = \left| \sum_{d=1}^D \alpha_{k+1,d} dn_d \right|.$$

If this is true, then we also have $\sum_{d=1}^D \alpha_{k+1,d} dn_d - \sum_{d=1}^D \alpha_{k,d} dn_d = c$ for some constant $c < 1$. By regrouping the terms, we get

$$\sum_{d=1}^D (\alpha_{k+1,d} - \alpha_{k,d}) dn_d = c.$$

Denote $h := \min_{d \in [D]} \{\alpha_{k+1,d} - \alpha_{k,d}\}$. Then $\sum_{d=1}^D dn_d \leq \frac{c}{h}$. Note that the left hand side is the maximum total weight of a vertex. However, at each recursive call the difference between the vertices with the minimum and maximum total weights decreases twice, since the VTS call at step 4 runs over the vertices with weight half the current difference. Since c and h is constant, after $O(\log(nD)) = O(\log n)$ recursive calls the recursion stops. Moreover, the classical dynamic programming then runs on a sublattice of constant size, hence adds only a factor of $O(1)$ to the overall complexity.

Lastly, we can address the contribution of the constant factor of VTS from Theorem 1 to the complexity of our algorithm. At one level of recursion there are $K + 1$ nested applications of VTS, and there are $O(\log n)$ levels of recursion. Therefore, the total overhead incurred is $O(1)^{O(K \log n)} = \text{poly}(n)$, since K is a constant.

B Complexity technicalities of the optimization program

For correctness, we need to address the following two subtleties.

- The numbers $\alpha_k n$ might not be integer; in Algorithm 1, the weights of the layers are defined by $W_k = \lfloor \alpha_k n \rfloor$. This is a problem, since the inequalities in the program use precisely the numbers $\alpha_{k,d}$. Examine the coefficient $[x_1^{\lfloor \alpha_1 n \rfloor} \cdots x_m^{\lfloor \alpha_m n \rfloor}] p(x_1, \dots, x_m)$ in such general case (when we need to round the powers). Let $\delta_k := \alpha_k n - \lfloor \alpha_k n \rfloor$, here $0 \leq \delta_k < 1$. Then, by Theorem 2 (1),

$$[x_1^{\lfloor \alpha_1 n \rfloor} \cdots x_m^{\lfloor \alpha_m n \rfloor}] p(x_1, \dots, x_m)^n \leq \inf_{x_1, \dots, x_m \geq 0} \frac{p(x_1, \dots, x_m)^n}{x_1^{\alpha_1 n - \delta_1} \cdots x_m^{\alpha_m n - \delta_m}}. \quad (4)$$

Now let $\hat{x}_1, \dots, \hat{x}_m$ be the arguments that achieve $\inf_{x_1, \dots, x_m \geq 0} \frac{p(x_1, \dots, x_m)}{x_1^{\alpha_1} \cdots x_m^{\alpha_m}}$. Since $0 \leq \delta_k < 1$, we have $\hat{x}_k^{\delta_k} \leq \max\{\hat{x}_k, 1\}$. Hence, (4) is at most

$$(\hat{x}_1^{\delta_1} \cdots \hat{x}_m^{\delta_m}) \cdot \frac{p(\hat{x}_1, \dots, \hat{x}_m)^n}{\hat{x}_1^{\alpha_1 n} \cdots \hat{x}_m^{\alpha_m n}} \leq \left(\prod_{k=1}^m \max\{\hat{x}_k, 1\} \right) \cdot \left(\inf_{x_1, \dots, x_m \geq 0} \frac{p(x_1, \dots, x_m)}{x_1^{\alpha_1} \cdots x_m^{\alpha_m}} \right)^n.$$

As the additional factor is a constant, we can ignore it in the complexity.

- The second issue is when $W_k = W_{k+1}$ for some k . Then according to Algorithm 1, we run the classical algorithm with complexity $\tilde{\Theta}((D+1)^n)$. However, in that case n is constant (see Appendix A), which gives only a constant factor to the complexity.

C Proof of the optimality of the optimization program

- First, we prove that $\text{OPT}(D, K, \{\alpha_{k,d}\})$ has a feasible solution. For that, we need to show that all polynomials in the program can be upper bounded by a constant for some fixed values of the variables.

First of all, $\frac{P_d(x)}{x^{\alpha_{1,d}}}$ is upper bounded by $d + 1$ (setting $x = 1$). Now fix k and examine the values $\frac{S_{k,d}(x_{k,k}, \dots, x_{k,K+1})}{x_{k,k}^{\alpha_{k,d}} \cdots x_{k,K+1}^{\alpha_{K+1,d}}}$. Examine only such assignments of the variables $x_{k,j}$ that $x_{k,k} x_{k,k+1} = 1$ and $x_{k,j} = 1$ for all other $j > k + 1$. Now we write the polynomial as a univariate polynomial $S_{k,d}(y) := S_{k,d}(1/y, y, 1, \dots, 1)$. Note that for any summand of $S_{k,d}(y)$, if it contains some T_i^2 as a factor, then it is of the form $x_{k,k}^{p_k} x_{k,k+1}^{p_{k+1}} \cdot T_i^2 = y^i T_i^2$. Hence the polynomial can be written as $S_{k,d}(y) = \sum_{i=0}^d c_i y^i T_i^2$ for some constants c_1, \dots, c_d . From this we can rewrite the corresponding program inequality and express T_d^2 :

$$T_d^2 \geq \frac{\sum_{i=0}^d c_i y^i T_i^2}{y^{(\alpha_{k+1,d} - \alpha_{k,d})d}} \quad (5)$$

$$T_d^2 \geq \frac{\sum_{i=0}^{d-1} c_i y^i T_i^2}{y^{(\alpha_{k+1,d} - \alpha_{k,d})d}} + y^{(1 - \alpha_{k+1,d} + \alpha_{k,d})d} c_d T_d^2$$

$$T_d^2 \geq \frac{1}{1 - y^{(1 - \alpha_{k+1,d} + \alpha_{k,d})d} c_d} \cdot \frac{\sum_{i=0}^{d-1} c_i y^i T_i^2}{y^{(\alpha_{k+1,d} - \alpha_{k,d})d}}.$$

Note that c_d are constants that do not depend on T_i . If the right hand side is negative, then it follows that the original inequality Eq. (5) does not hold. Thus we need to pick such y that the right hand side is positive for all d . Hence we require that

$$y < \left(\frac{1}{c_d} \right)^{\frac{1}{(1-\alpha_{k+1,d}+\alpha_{k,d})^d}}.$$

Since the right hand side is a constant that does not depend on T_i , we can pick such y that satisfies this inequality for all d . Then it follows that all T_i is also upper bounded by some constants (by induction on i).

- Now the question remains whether the optimal solution to $\text{OPT}(D, K, \{\alpha_{k,d}\})$ gives the optimal complexity. That is, is the complexity $T_1^n \cdots T_D^{nD}$ given by the optimal solution of the optimization program such that T_D is the smallest possible?

Suppose that indeed the complexity of the algorithm is upper bounded by $T_1^n \cdots T_D^{nD}$ for some T_1, \dots, T_D . We will derive a corresponding feasible point for the optimization program.

Examine the complexity of the algorithm for $n_1 = b_1 n, \dots, n_D = b_D n$ for some fixed rational b_i such that $b_1 + \dots + b_D = 1$. The coefficients of the polynomials P and S_k give the complexity of the corresponding part of the algorithm (precalculation, and quantum search until the k -th level, respectively). Such coefficients are of the form $[x_1^{\alpha_1 n} \cdots x_m^{\alpha_m n}] \prod_{d=1}^D p_d(x_1, \dots, x_m)^{n_d}$. Let $A_d := T_d$, if $p = P$, and $A_d := T_d^2$, if $p = S_k$. Then we have

$$A_1^{n_1} \cdots A_D^{n_D} \geq [x_1^{\alpha_1 n} \cdots x_m^{\alpha_m n}] \prod_{d=1}^D p_d(x_1, \dots, x_m)^{n_d}. \quad (6)$$

On the other hand, (6) is at least

$$\Omega \left(\left(\inf_{x_1, \dots, x_m > 0} \prod_{d=1}^D \left(\frac{p_d(x_1, \dots, x_m)}{x_1^{a_{1,d}} \cdots x_m^{a_{m,d}}} \right)^{b_d} \right)^n \right)$$

when n grows large by Theorem 2 (2) (setting $a_{i,d} := \alpha_{i,d} d$). Then, in the limit $n \rightarrow \infty$, we have

$$A_1^{b_1} \cdots A_D^{b_D} \geq \inf_{x_1, \dots, x_m > 0} \prod_{d=1}^D \left(\frac{p_d(x_1, \dots, x_m)}{x_1^{a_{1,d}} \cdots x_m^{a_{m,d}}} \right)^{b_d}. \quad (7)$$

Now let Δ_{D-1} be the standard D -simplex defined by $\{b \in \mathbb{R}^D \mid b_1 + \dots + b_D = 1, b_d \geq 0\}$. Define $F_d(x) := \frac{p_d(x_1, \dots, x_m)}{x_1^{a_{1,d}} \cdots x_m^{a_{m,d}}}$, and $F(b, x) := \prod_{d=1}^D F_d(x)^{b_d}$ for $b \in \Delta_{D-1}$ and $x \in \mathbb{R}_{>0}^m$.

First, we prove that that for a fixed b , the function $F(b, x)$ is strictly convex. Examine the polynomial $p_d(x_1, \dots, x_m)$, which is either $P_d(x)$ or $S_{k,d}(x_{k,k}, \dots, x_{k,K+1})$. It was shown in [19], Theorem 6.3 that if the coefficients of $p_d(x_1, \dots, x_m)$ are non-negative, and the points (c_1, \dots, c_m) , at which

$$[x_1^{c_1} \cdots x_m^{c_m}] p_d(x_1, \dots, x_m) > 0,$$

linearly span an m -dimensional space, then $\log(F_d(x))$ is a strictly convex function. If $p_d = P_d$, then this property immediately follows, because there is just one variable x and the polynomial is non-constant. For $p_d = S_{k,d}$, the polynomial consists of summands of the form $T_{c_{k+1}-c_k}^2 x_{k,k}^{c_k} x_{k,k+1}^{c_{k+1}} \cdots x_{k,K+1}^{c_{K+1}}$, for $c_k \leq c_{k+1} \leq \dots \leq c_{K+1}$. Note that the

coefficient $T_{c_{k+1}-c_k}^2$ is positive. Thus the points $(c_k, \dots, c_{K+1}) = (0, \dots, 0, 1, \dots, 1)$ indeed linearly span a $(K - k + 2)$ -dimensional space. Therefore, $\log(F_d(x))$ is strictly convex. Then also the function $\sum_{d=1}^D b_d \log(F_d(x)) = \log(F(b, x))$ is strictly convex (for fixed b), as the sum of strictly convex functions is convex. Therefore, $F(b, x)$ is strictly convex as well.

Therefore, the argument $\hat{x}(b)$ achieving $\inf_{x \in \mathbb{R}_{>0}^m} F(b, x)$ is unique. Let $\hat{F}_d(b) := F_d(\hat{x}(b))$ and define D subsets of the simplex $C_d := \{b \in \Delta_{D-1} \mid \hat{F}_d(b) \leq A_d\}$. We will apply the following result for these sets:

► **Theorem 9** (Knaster-Kuratowski-Mazurkiewicz lemma [25]). *Let the vertices of Δ_{D-1} be labeled by integers from 1 to D . Let C_1, \dots, C_D be a family of closed sets such that for any $I \subseteq [D]$, the convex hull of the vertices labeled by I is covered by $\cup_{d \in I} C_d$. Then $\cap_{d \in [D]} C_d \neq \emptyset$.*

We check that the conditions of the lemma apply to our sets. First, note that $F(b, x)$ is continuous and strictly convex for a fixed b , hence $\hat{x}(b)$ is continuous and thus $\hat{F}_d(b)$ is continuous as well. Therefore, the “threshold” sets C_d are closed.

Secondly, let $I \subseteq [D]$ and examine a point b in the convex hull of the simplex vertices labeled by I . For such a point, we have $b_d = 0$ for all $d \notin I$. For the indices $d \in I$, for at least one we should have $\hat{F}_d(b) \leq A_d$, otherwise the inequality in Eq. (7) would be contradicted. Note that it was stated only for rational b , but since $\hat{F}_d(b)$ are continuous and any real number can be approximated with a rational number to arbitrary precision, the inequality also holds for real b . Thus indeed any such b is covered by $\cup_{d \in I} C_d$.

Therefore, we can apply the lemma and it follows that there exists a point $b \in \Delta_{D-1}$ such that $A_d \geq \hat{F}_d(b)$ for all $d \in [D]$. The corresponding point $\hat{x}(b)$ is a feasible point for the examined set of inequalities in the optimization program.

D Proof of the quantum speedup

Examine the algorithm with only $K = 1$; the optimal complexity for any $K > 1$ cannot be larger, as we can simulate K levels with $K + 1$ levels by setting $\alpha_{2,d} = \alpha_{1,d} + \epsilon$ for $\epsilon \rightarrow 0$ for all $d \in [D]$. For simplicity, denote $\alpha_d := \alpha_{1,d}$.

- Now examine the precalculation inequalities in $\text{OPT}(D, 1, \{\alpha_{1,d}\})$. For any values of $\alpha_{1,d}$, if we set $x = 1$, we have $\frac{P_d(x)}{x^{\alpha_d}} = \frac{\sum_{i=0}^d x^i}{x^{\alpha_d}} = d + 1$. The derivative is equal to

$$\left(\frac{\sum_{i=0}^d x^i}{x^{\alpha_d}} \right)' = \frac{x^{\alpha_d} \cdot \sum_{i=1}^d i x^{i-1} - \alpha_d x^{\alpha_d-1} \cdot \sum_{i=0}^d x^i}{x^{2\alpha_d}} = \frac{d(d+1)}{2} - \alpha_d d(d+1)$$

at point $x = 1$. Thus when $\alpha_d < \frac{1}{2}$, the derivative is positive. It means that for arbitrary $\alpha_d < \frac{1}{2}$, there exists some $x(d)$ such that $\frac{P_d(x)}{x^{\alpha_d}} < d + 1$, and $\frac{P_d(x)}{x^{\alpha_d}}$ monotonically grows on $x \in [x(d), 1]$. Thus, for arbitrary setting of $\{\alpha_d\}$ such that $\alpha_d < \frac{1}{2}$ for all $d \in [D]$, we can take $\hat{x} := \max_{d \in [D]} \{x(d)\}$ as the common parameter, in which case all $\frac{P_d(\hat{x})}{\hat{x}^{\alpha_d}} < d + 1$.

- Now examine the set of the quantum search inequalities. Let $y := x_{1,1}$ and $z := x_{1,2}$ for simplicity. Then such inequalities are given by

$$T_d^2 \geq S_{1,d}(y, z) = \frac{\sum_{i=0}^d T_i^2 \sum_{p=0}^{d-i} y^p z^{p+i}}{y^{\alpha_d} z^{d/2}}.$$

50:22 Quantum Speedups for Dynamic Programming on n -Dimensional Lattice Graphs

Now restrict the variables to condition $yz = 1$. In that case, the polynomial above simplifies to

$$S_{1,d}(z) := \frac{\sum_{i=0}^d T_i^2 \sum_{p=0}^{d-i} z^i}{y^{\frac{d}{2}+d(\alpha_d-\frac{1}{2})} z^{d/2}} = \left(\sum_{i=0}^d T_i^2 (d-i+1) z^i \right) \cdot z^{d(\alpha_d-\frac{1}{2})}.$$

We now find such values of z and $\alpha_1, \dots, \alpha_D$ so that $S_{1,d}(z) < (d+1)^2$ for all $d \in [D]$, where T_1, \dots, T_D are any values such that $T_d \leq d+1$ for all $d \in [D]$. Denote $\hat{S}_{1,d}(z)$ to be $S_{1,d}(z)$ with $T_d = d+1$ for all $d \in [D]$, then $\hat{S}_{1,d}(z) < (d+1)^2$ as well. Now let T_d be the maximum of $\frac{P_d(\hat{x})}{\hat{x}^{\alpha_d d}}$ from the previous bullet and $\hat{S}_{1,d}(z)$. Then, $T_d < d+1$, and we have both $T_d \geq \frac{P_d(\hat{x})}{\hat{x}^{\alpha_d d}}$ and $T_d^2 \geq \hat{S}_{1,d}(z) \geq S_{1,d}(z)$, since $S_{1,d}(z)$ cannot become larger when T_d decrease.

Now we show how to find such z and $\alpha_1, \dots, \alpha_D$. Examine the sum in the polynomial $\hat{S}_{1,d}(z)$

$$\sum_{i=0}^d (i+1)^2 (d-i+1) z^i = (d+1) + \sum_{i=1}^d (i+1)^2 (d-i+1) z^i.$$

Examine the second part of the sum. We can find a sufficiently small value of $z \in (0, 1)$ such that this part is smaller than any value $\epsilon > 0$ for all $d \in [D]$. Now, let $\alpha_d = \frac{1}{2} - \frac{c}{d}$ for some constant $c > 0$. Then

$$z^{d(\alpha_d-\frac{1}{2})} = z^{-c}$$

for all $d \in [D]$. Thus, the total value of the sum now is at most $(d+1+\epsilon)z^{-c}$. As $z^{-1} > 1$, take a sufficiently small value of c so that this value is at most $(d+1)^2$.

A Note on the Join of Varieties of Monoids with \mathbf{LI}

Nathan Grosshans   

Fachbereich Elektrotechnik/Informatik, University of Kassel, Germany

Abstract

In this note, we give a characterisation in terms of identities of the join of \mathbf{V} with the variety of finite locally trivial semigroups \mathbf{LI} for several well-known varieties of finite monoids \mathbf{V} by using classical algebraic-automata-theoretic techniques. To achieve this, we use the new notion of essentially- \mathbf{V} stamps defined by Grosshans, McKenzie and Segoufin and show that it actually coincides with the join of \mathbf{V} and \mathbf{LI} precisely when some natural condition on the variety of languages corresponding to \mathbf{V} is verified.

This work is a kind of rediscovery of the work of J. C. Costa around 20 years ago from a rather different angle, since Costa's work relies on the use of advanced developments in profinite topology, whereas what is presented here essentially uses an algebraic, language-based approach.

Acknowledgements I want to thank Thomas Place, who suggested the link between essentially- \mathbf{V} stamps and $\mathbf{V} \vee \mathbf{LI}$, but also Luc Segoufin who started the discussion with Thomas Place and encouraged me to write the present article. My thanks go as well to the anonymous referees for their helpful comments and suggestions. Finally, I want to mention that the introductions of Jean-Éric Pin's future book on algebraic automata theory and of Marc Zeitoun's works cited in the references have been helpful inspirations for my own introduction.

1 Introduction

One of the most fundamental problems in finite automata theory is the one of *characterisation*: given some subclass of the class of regular languages, find out whether there is a way to characterise those languages using some class of finite objects. This problem is often linked to and motivated by the problem of *decidability*: given some subclass of the class of regular languages, find out whether there exists an algorithm testing the membership of any regular language in that subclass. The obvious approach to try to find a characterisation of a class of regular languages would be to look for properties shared by all the minimal finite automata of those languages. If we find such characterising properties, we can then ask whether they can be checked by an algorithm to answer the problem of decidability for this class of languages. However, one of the most fruitful approaches of those two problems has been the *algebraic approach*, in which we basically replace automata with morphisms into monoids: a language L over an alphabet Σ is then said to be recognised by a morphism φ into a monoid M if and only if L is the inverse image by φ of a subset of M . Under this notion of recognition, each language has a minimal morphism recognising it, the *syntactic morphism* into the *syntactic monoid* of that language, that are minimal under some notion of division. The fundamental result on which this algebraic approach relies is that a language is regular if and only if its syntactic monoid is finite. One can thus try to find a characterisation of some class of regular languages by looking at the algebraic properties of the syntactic monoids of these languages.

And many such characterisations that are decidable were indeed successfully obtained since Schützenberger's seminal work in 1965 [18]. His famous result, that really started the field of *algebraic automata theory*, states that the star-free regular languages are exactly

those whose syntactic monoids are finite and aperiodic. Another important early result in that vein is the one of Simon [19] characterising the piecewise testable languages as exactly those having a finite \mathfrak{J} -trivial syntactic monoid. Eilenberg [12] was the first to prove that such algebraic characterisations actually come as specific instances of a general bijective correspondence between varieties of finite monoids and varieties of languages – classes of, respectively, finite monoids and regular languages closed under natural operations. Thus, a class of regular languages can indeed be characterised by the syntactic monoids of these languages, as soon as it verifies some nice closure properties. Eilenberg’s result was later completed by Reiterman’s theorem [17], that uses a notion of identities defined using profinite topology and states that a class of finite monoids is a variety of finite monoids if and only if it is defined by a set of profinite identities. Therefore, one can always characterise the variety of finite monoids associated to a variety of languages by a set of profinite identities and, additionally, this characterisation often leads to decidability, especially when this set is finite. A great deal of research works have been conducted to characterise varieties of finite monoids or semigroups by profinite identities (see the book of Almeida [3] for an overview; see also the book chapter by Pin [15] for more emphasis on the “language” part).

A kind of varieties of finite monoids or semigroups that has attracted many research efforts aiming for characterisations through identities are the varieties defined as the join of two other varieties. Given two varieties of finite monoids \mathbf{V} and \mathbf{W} , the *join of \mathbf{V} and \mathbf{W}* , denoted by $\mathbf{V} \vee \mathbf{W}$, is the least variety of finite monoids containing both \mathbf{V} and \mathbf{W} . One of the main motivations to try to understand $\mathbf{V} \vee \mathbf{W}$ is that the variety of languages corresponding to it by the Eilenberg correspondence, $\mathcal{L}(\mathbf{V} \vee \mathbf{W})$, is the one obtained by considering direct products of automata recognising languages from both $\mathcal{L}(\mathbf{V})$ and $\mathcal{L}(\mathbf{W})$, the varieties of languages corresponding to, respectively, \mathbf{V} and \mathbf{W} . This is a fundamental operation on automata, and while it is straightforward that $\mathcal{L}(\mathbf{V} \vee \mathbf{W})$ is simply the least variety of languages containing both $\mathcal{L}(\mathbf{V})$ and $\mathcal{L}(\mathbf{W})$, this does not at all furnish a decidable characterisation of $\mathcal{L}(\mathbf{V} \vee \mathbf{W})$, let alone a set of identities defining $\mathbf{V} \vee \mathbf{W}$. Generally speaking, the problem of finding a set of identities defining $\mathbf{V} \vee \mathbf{W}$ is difficult (see [3, 23]): in fact, there exist two varieties of finite semigroups that have a decidable membership problem but whose join has an undecidable membership problem [1]. However, sets of identities have been found for many specific joins: have a look at [2, 4, 6, 22, 21, 7, 9, 10] for some examples.

In this paper, we give a general method to find a set of identities defining the join of an arbitrary variety of finite monoids \mathbf{V} and the *variety of finite locally trivial semigroups* \mathbf{LI} , as soon as one has a set of identities defining \mathbf{V} and \mathbf{V} verifies some criterion. Joins of that sort have been studied quite a lot in the literature we mentioned in the previous paragraph (e.g. in [6, 21, 9, 10]), but while these works usually rely heavily on profinite topology with some in-depth understanding of the structure of the elements of the so-called free pro- \mathbf{V} monoids and free pro- \mathbf{LI} semigroups, we present a method that reduces the use of profinite topology to the minimum and that relies mainly on algebraic and language-theoretic techniques. The variety \mathbf{LI} is well-known to correspond to the class of languages for which membership only depends on bounded-length prefixes and suffixes of words. In [13], McKenzie, Segoufin and the author introduced the notion of *essentially- \mathbf{V}* stamps (surjective morphisms $\varphi: \Sigma^* \rightarrow M$ for Σ an alphabet and M a finite monoid) to characterise the built-in ability that programs over monoids in \mathbf{V} have to treat separately some constant-length beginning and ending of a word. Informally said, a stamp is *essentially- \mathbf{V}* when it behaves like a stamp into a monoid of \mathbf{V} as soon as a sufficiently long beginning and ending of the input word has been fixed. Our method builds on two results, that we prove in this article.

1. The first result is a characterisation in terms of identities of the class **EV** of essentially-**V** stamps given a set of identities E defining **V**: a stamp is in **EV** if and only if it satisfies all identities $x^\omega yuzt^\omega = x^\omega yvzt^\omega$ for $u = v$ an identity in E and where x, y, z, t do appear neither in u nor in v .
2. The second result says that **EV** and $\mathbf{V} \vee \mathbf{LI}$ do coincide if and only if **V** verifies some criterion, that can be formulated in terms of quotient-expressibility in $\mathcal{L}(\mathbf{V})$: any language $L \in \mathcal{L}(\mathbf{V})$ must, for an arbitrary choice of x, y , be such that the quotient $u^{-1}Lv^{-1}$ for u and v long enough can be expressed as the quotient $(xu)^{-1}K(vy)^{-1}$ for a $K \in \mathcal{L}(\mathbf{V})$.

Using these results, we can find a set of identities defining $\mathbf{V} \vee \mathbf{LI}$ as soon as a set of identities defining **V** is known by proving that **V** verifies the criterion in point 2. Note that actually, for technical reasons, we work with the so-called *ne*-variety of stamps corresponding to $\mathbf{V} \vee \mathbf{LI}$ rather than directly with the variety of finite semigroups $\mathbf{V} \vee \mathbf{LI}$, but this is not a problem since a variety of finite semigroups can always be seen as an *ne*-variety of stamps and vice versa. We apply this method to reprove characterisations of the join of **LI** with each of the well-known varieties of finite monoids **R**, **L**, **J** and any variety of finite groups.

The author noticed after proving those results that his work actually forms a kind of rediscovery of the work of J. C. Costa in [9]. He defines an operator U associating to each set of identities E the exact same new set $U(E)$ of identities as in point 1. Costa then defines a property of cancellation for varieties of finite semigroups such that for any **V** verifying it, $U(E)$ defines $\mathbf{V} \vee \mathbf{LI}$ for E defining **V**. He finally uses this result to derive characterisations of $\mathbf{V} \vee \mathbf{LI}$ for all the cases we are treating in our paper and many more.

What is, then, the contribution of our article? In a nutshell, it does mainly use algebraic and language-theoretic techniques while Costa's work relies heavily on profinite topology. In our setting, once the stage is set, all proofs are quite straightforward without real difficulties and rely on classical language-theoretic characterisations of the varieties under consideration. This is to contrast with Costa's work, that for instance draws upon the difficult analysis of the elements of free pro-**R** monoids by Almeida and Weil [5] to characterise $\mathbf{R} \vee \mathbf{LI}$.

Organisation of the article. Section 2 is dedicated to the necessary preliminaries. In Section 3, we recall the definition of essentially-**V** stamps and prove the characterisation by identities of point 1 above. Section 4 is then dedicated to the necessary and sufficient criterion for **EV** and $\mathbf{V} \vee \mathbf{LI}$ to coincide presented in point 2 and finally those results are applied to specific cases in Section 5. We finish with a short conclusion.

2 Preliminaries

We briefly introduce the mathematical material used in this paper. For the basics and the classical results of automata theory, we refer the reader to the two classical references of the domain by Eilenberg [11, 12] and Pin [14]. For definitions and results specific to varieties of stamps and associated profinite identities, see the articles by Straubing [20] and by Pin and Straubing [16]. We also assume some basic knowledge of topology.

General notations. Let $i \in \mathbb{N}$ be a natural number. We shall denote by $[i]$ the set of all natural numbers $n \in \mathbb{N}$ verifying $1 \leq n \leq i$.

Words and languages. Let Σ be a finite alphabet. We denote by Σ^* the set of all finite words over Σ . We also denote by Σ^+ the set of all finite non empty words over Σ , the empty word being denoted by ε . Our alphabets and words will always be finite, without further

mention of this fact. Given a word $w \in \Sigma^*$, we denote its length by $|w|$ and the set of letters it contains by $\text{alph}(w)$. Given $n \in \mathbb{N}$, we denote by $\Sigma^{\geq n}$, Σ^n and $\Sigma^{< n}$ the set of words over Σ of length, respectively, at least n , exactly n and less than n .

A *language over Σ* is a subset of Σ^* . A language is *regular* if it is recognised by a deterministic finite automaton. The *quotient of a language L over Σ relative to the words u and v over Σ* is the language, denoted by $u^{-1}Lv^{-1}$, of the words w such that $u w v \in L$.

Monoids, semigroups and varieties. A *semigroup* is a non-empty set equipped with an associative law that we will write multiplicatively. A *monoid* is a semigroup with an identity. An example of a semigroup is Σ^+ , the free semigroup over Σ . Similarly Σ^* is the free monoid over Σ . A *morphism φ from a semigroup S to a semigroup T* is a function from S to T such that $\varphi(xy) = \varphi(x)\varphi(y)$ for all $x, y \in S$. A morphism of monoids additionally requires that the identity is preserved. A semigroup T is a *subsemigroup* of a semigroup S if T is a subset of S and is equipped with the restricted law of S . Additionally the notion of submonoids requires the presence of the identity. A semigroup T *divides* a semigroup S if T is the image by a semigroup morphism of a subsemigroup of S . Division of monoids is defined in the same way. The *Cartesian (or direct) product* of two semigroups is simply the semigroup given by the Cartesian product of the two underlying sets equipped with the Cartesian product of their laws. An element s of a semigroup is *idempotent* if $ss = s$.

A *variety of finite monoids* is a non-empty class of finite monoids closed under Cartesian product and monoid division. A *variety of finite semigroups* is defined similarly. When dealing with varieties, we consider only finite monoids and semigroups, so we will drop the adjective finite when talking about varieties in the rest of this article.

Varieties of stamps. Let $f: \Sigma^* \rightarrow \Gamma^*$ be a morphism from the free monoid over an alphabet Σ to the free monoid over an alphabet Γ , that we might call an *all-morphism*. We say that f is an *ne-morphism* (non-erasing morphism) whenever $f(\Sigma) \subseteq \Gamma^+$.

We call *stamp* a surjective morphism $\varphi: \Sigma^* \rightarrow M$ for Σ an alphabet and M a finite monoid. We say that a stamp $\varphi: \Sigma^* \rightarrow M$ *all-divides* (respectively *ne-divides*) a stamp $\psi: \Gamma^* \rightarrow N$ whenever there exists an *all-morphism* (respectively *ne-morphism*) $f: \Sigma^* \rightarrow \Gamma^*$ and a surjective morphism $\alpha: \mathfrak{Im}(\psi \circ f) \rightarrow M$ such that $\varphi = \alpha \circ \psi \circ f$. The *direct product* of two stamps $\varphi: \Sigma^* \rightarrow M$ and $\psi: \Sigma^* \rightarrow N$ is the stamp $\varphi \times \psi: \Sigma^* \rightarrow K$ such that K is the submonoid of $M \times N$ generated by $\{(\varphi(a), \psi(a)) \mid a \in \Sigma\}$ and $\varphi \times \psi(a) = (\varphi(a), \psi(a))$ for all $a \in \Sigma$.

An *all-variety of stamps* (respectively *ne-variety of stamps*) is a non-empty class of stamps closed under direct product and *all-division* (respectively *ne-division*).

We will often use the following characteristic index of stamps, defined in [8]. Consider a stamp $\varphi: \Sigma^* \rightarrow M$. As M is finite there is a $k \in \mathbb{N}_{>0}$ such that $\varphi(\Sigma^{2k}) = \varphi(\Sigma^k)$: this implies that $\varphi(\Sigma^k)$ is a semigroup. The least such k is called the *stability index* of φ .

Varieties of languages. A language L over an alphabet Σ is *recognised by a monoid M* if there is a morphism $\varphi: \Sigma^* \rightarrow M$ and $F \subseteq M$ such that $L = \varphi^{-1}(F)$. We also say that φ *recognises L* . It is well known that a language is regular if and only if it is recognised by a finite monoid. The *syntactic congruence* of L , denoted by \sim_L , is the equivalence relation on Σ^* defined by $u \sim_L v$ for $u, v \in \Sigma^*$ whenever for all $x, y \in \Sigma^*$, $xuy \in L$ if and only if $xvy \in L$. The quotient Σ^*/\sim_L is a monoid, called *the syntactic monoid of L* , that recognises L via the *syntactic morphism η_L of L* sending any word u to its equivalence class $[u]_{\sim_L}$ for \sim_L . A stamp $\varphi: \Sigma^* \rightarrow M$ recognises L if and only if there exists a surjective morphism $\alpha: M \rightarrow \Sigma^*/\sim_L$ verifying $\eta_L = \alpha \circ \varphi$.

A class of languages \mathcal{C} is a correspondence that associates a set $\mathcal{C}(\Sigma)$ to each alphabet Σ . A (all-)variety of languages (respectively an *ne-variety of languages*) \mathcal{V} is a non-empty class of regular languages closed under Boolean operations, quotients and inverses of *all*-morphisms (respectively *ne*-morphisms). A classical result of Eilenberg [12, Chapter VII, Section 3] says that there is a bijective correspondence between varieties of monoids and varieties of languages: to each variety of monoids \mathbf{V} we can bijectively associate $\mathcal{L}(\mathbf{V})$ the variety of languages whose syntactic monoids belong to \mathbf{V} . This was generalised by Straubing [20] to varieties of stamps: to each *all*-variety (respectively *ne*-variety) of stamps \mathbf{V} we can bijectively associate $\mathcal{L}(\mathbf{V})$ the *all*-variety (respectively *ne*-variety) of languages whose syntactic morphisms belong to \mathbf{V} . Given two *all*-varieties (respectively *ne*-varieties) of stamps \mathbf{V}_1 and \mathbf{V}_2 , we have $\mathbf{V}_1 \subseteq \mathbf{V}_2 \Leftrightarrow \mathcal{L}(\mathbf{V}_1) \subseteq \mathcal{L}(\mathbf{V}_2)$.

For \mathbf{V} a variety of monoids, we define $\langle \mathbf{V} \rangle_{all}$ the *all*-variety of all stamps $\varphi: \Sigma^* \rightarrow M$ such that $M \in \mathbf{V}$. Of course, in that case $\mathcal{L}(\mathbf{V}) = \mathcal{L}(\langle \mathbf{V} \rangle_{all})$. Similarly, for \mathbf{V} a variety of semigroups, we define $\langle \mathbf{V} \rangle_{ne}$ the *ne*-variety of all stamps $\varphi: \Sigma^* \rightarrow M$ such that $\varphi(\Sigma^+) \in \mathbf{V}$. In that case, we consider $\mathcal{L}(\mathbf{V})$ to be the *ne*-variety of languages corresponding to $\langle \mathbf{V} \rangle_{ne}$. The operations $\langle \cdot \rangle_{all}$ and $\langle \cdot \rangle_{ne}$ form bijective correspondences between varieties of monoids and *all*-varieties of stamps and between varieties of semigroups and *ne*-varieties of stamps, respectively (see [20]).

Identities. Let Σ be an alphabet. Given $u, v \in \Sigma^*$, we set

$$r(u, v) = \min\{|M| \mid \exists \varphi: \Sigma^* \rightarrow M \text{ stamp s.t. } \varphi(u) \neq \varphi(v)\}$$

and $d(u, v) = 2^{-r(u, v)}$, using the conventions that $\min \emptyset = +\infty$ and $2^{-\infty} = 0$. Then d is a metric on Σ^* . The completion of the metric space (Σ^*, d) , denoted by $(\widehat{\Sigma^*}, \widehat{d})$, is a metric monoid called the *free profinite monoid on Σ^** . Its elements are all the formal limits $\lim_{n \rightarrow \infty} x_n$ of Cauchy sequences $(x_n)_{n \geq 0}$ in (Σ^*, d) and the metric d on Σ^* extends to a metric \widehat{d} on $\widehat{\Sigma^*}$ defined by $\widehat{d}(\lim_{n \rightarrow \infty} x_n, \lim_{n \rightarrow \infty} y_n) = \lim_{n \rightarrow \infty} d(x_n, y_n)$ for Cauchy sequences $(x_n)_{n \geq 0}$ and $(y_n)_{n \geq 0}$ in (Σ^*, d) . Note that, when it is clear from the context, we usually do not make the metric explicit when talking about a metric space. One important example of elements of $\widehat{\Sigma^*}$ is given by the elements $x^\omega = \lim_{n \rightarrow \infty} x^{n!}$ for all $x \in \Sigma^*$.

Every finite monoid M is considered to be a complete metric space equipped with the discrete metric d defined by $d(m, n) = \begin{cases} 0 & \text{if } m = n \\ 1 & \text{otherwise} \end{cases}$ for all $m, n \in M$. Every stamp

$\varphi: \Sigma^* \rightarrow M$ extends uniquely to a uniformly continuous morphism $\widehat{\varphi}: \widehat{\Sigma^*} \rightarrow M$ with $\widehat{\varphi}(\lim_{n \rightarrow \infty} x_n) = \lim_{n \rightarrow \infty} \varphi(x_n)$ for every Cauchy sequence $(x_n)_{n \geq 0}$ in Σ^* . Similarly, every *all*-morphism $f: \Sigma^* \rightarrow \Gamma^*$ extends uniquely to a uniformly continuous morphism $\widehat{f}: \widehat{\Sigma^*} \rightarrow \widehat{\Gamma^*}$ with $\widehat{f}(\lim_{n \rightarrow \infty} x_n) = \lim_{n \rightarrow \infty} f(x_n)$ for every Cauchy sequence $(x_n)_{n \geq 0}$ in Σ^* .

For $u, v \in \widehat{A^*}$ with A an alphabet, we say that a stamp $\varphi: \Sigma^* \rightarrow M$ *all-satisfies* (respectively *ne-satisfies*) the identity $u = v$ if for every *all*-morphism (respectively *ne*-morphism) $f: A^* \rightarrow \Sigma^*$, it holds that $\widehat{\varphi} \circ \widehat{f}(u) = \widehat{\varphi} \circ \widehat{f}(v)$. Given a set of identities E , we denote by $\llbracket E \rrbracket_{all}$ (respectively $\llbracket E \rrbracket_{ne}$) the class of stamps *all*-satisfying (respectively *ne*-satisfying) all the identities of E . When $\llbracket E \rrbracket_{all}$ (respectively $\llbracket E \rrbracket_{ne}$) is equal to an *all*-variety (respectively *ne*-variety) of stamps \mathbf{V} , we say that E *all-defines* (respectively *ne-defines*) \mathbf{V} .

► **Theorem 1** ([16, Theorem 2.1]). *A class of stamps is an all-variety (respectively ne-variety) of stamps if and only if it can be all-defined (respectively ne-defined) by a set of identities.*

To give some examples, the classical varieties of monoids **J**, **R** and **L** can be characterised by identities in the following way:

$$\begin{aligned} \langle \mathbf{R} \rangle_{all} &= \llbracket (ab)^\omega a = (ab)^\omega \rrbracket_{all} = \llbracket (ab)^\omega a = (ab)^\omega \rrbracket_{ne} \\ \langle \mathbf{L} \rangle_{all} &= \llbracket b(ab)^\omega = (ab)^\omega \rrbracket_{all} = \llbracket b(ab)^\omega = (ab)^\omega \rrbracket_{ne} \\ \langle \mathbf{J} \rangle_{all} &= \llbracket (ab)^\omega a = (ab)^\omega, b(ab)^\omega = (ab)^\omega \rrbracket_{all} = \llbracket (ab)^\omega a = (ab)^\omega, b(ab)^\omega = (ab)^\omega \rrbracket_{ne} . \end{aligned}$$

Finite locally trivial semigroups and the join operation. The variety **LI** of finite locally trivial semigroups is well-known to verify $\langle \mathbf{LI} \rangle_{ne} = \llbracket x^\omega y x^\omega = x^\omega \rrbracket_{ne}$ and to be such that for any alphabet Σ , the set $\mathcal{L}(\mathbf{LI})(\Sigma)$ consists of all Boolean combinations of languages of the form $u\Sigma^*$ or Σ^*u for $u \in \Sigma^*$, or equivalently of all languages of the form $U\Sigma^*V \cup W$ with $U, V, W \subseteq \Sigma^*$ finite (see [14, p. 38]).

Given a variety of monoids **V**, the join of **V** and **LI**, denoted by $\mathbf{V} \vee \mathbf{LI}$, is the inclusion-wise least variety of semigroups containing both **V** and **LI**. In fact, a finite semigroup S belongs to $\mathbf{V} \vee \mathbf{LI}$ if and only if there exist $M \in \mathbf{V}$ and $T \in \mathbf{LI}$ such that S divides the semigroup $M \times T$. (See [12, Chapter V, Exercise 1.1].) We can prove the following adaptation to *ne*-varieties of the classical results about joins (see the appendix for the proof).

► **Proposition 2.** *Let **V** be a variety of monoids. Then $\langle \mathbf{V} \vee \mathbf{LI} \rangle_{ne}$ is the inclusion-wise least *ne*-variety of stamps containing both $\langle \mathbf{V} \rangle_{all}$ and $\langle \mathbf{LI} \rangle_{ne}$. Moreover, $\mathcal{L}(\mathbf{V} \vee \mathbf{LI})$ is the inclusion-wise least *ne*-variety of languages containing both $\mathcal{L}(\mathbf{V})$ and $\mathcal{L}(\mathbf{LI})$ and verifies that $\mathcal{L}(\mathbf{V} \vee \mathbf{LI})(\Sigma)$ is the Boolean closure of $\mathcal{L}(\mathbf{V})(\Sigma) \cup \mathcal{L}(\mathbf{LI})(\Sigma)$ for each alphabet Σ .*

3 Essentially-**V** stamps

In this section, we give a characterisation of essentially-**V** stamps (first defined in [13]), for **V** a variety of monoids, in terms of identities. We first recall the definition.

► **Definition 3.** *Let **V** be a variety of monoids. Let $\varphi: \Sigma^* \rightarrow M$ be a stamp and let s be its stability index.*

*We say that φ is essentially-**V** whenever there exists a stamp $\mu: \Sigma^* \rightarrow N$ with $N \in \mathbf{V}$ such that for all $u, v \in \Sigma^*$, we have*

$$\mu(u) = \mu(v) \Rightarrow (\varphi(xuy) = \varphi(xvy) \quad \forall x, y \in \Sigma^s) .$$

*We will denote by **EV** the class of all essentially-**V** stamps.*¹

Now, we give a characterisation for a stamp to be essentially-**V**, based on a specific congruence depending on that stamp.

¹ Essentially-**V** stamps are called that way by analogy with quasi-**V** stamps and the class of essentially-**V** stamps is denoted by **EV** by analogy with **QV**, the notation for the class of quasi-**V** stamps. This makes sense since the initial motivation for the definition of essentially-**V** stamps was to capture the class of stamps into monoids of **V** that have the additional ability to treat separately some constant-length beginning and ending of a word. This ability can indeed be seen as orthogonal to the additional ability of stamps into monoids in **V** to perform modular counting on the positions of letters in a word, which is often handled by considering quasi-**V** stamps. (See [13] for more.) Our definition of **EV** does unfortunately not coincide with the usual definition of **EV**, that classically denotes the variety of monoids M such that the submonoid generated by the idempotents of M is in **V**. (This comes, among others, from the fact that the obtained variety of monoids does always contain at least all finite groups.)

► **Definition 4.** Let $\varphi: \Sigma^* \rightarrow M$ be a stamp and let s be its stability index. We define the equivalence relation \equiv_φ on Σ^* by $u \equiv_\varphi v$ for $u, v \in \Sigma^*$ whenever $\varphi(xuy) = \varphi(xvy)$ for all $x, y \in \Sigma^{\geq s}$.

► **Proposition 5.** Let $\varphi: \Sigma^* \rightarrow M$ be a stamp. Then \equiv_φ is a congruence of finite index and for any variety of monoids \mathbf{V} , we have $\varphi \in \mathbf{EV}$ if and only if $\Sigma^*/\equiv_\varphi \in \mathbf{V}$.

Proof. Let us denote by s the stability index of φ .

The equivalence relation \equiv_φ is a congruence because given $u, v \in \Sigma^*$ verifying $u \equiv_\varphi v$, for all $\alpha, \beta \in \Sigma^*$, we have $\alpha u \beta \equiv_\varphi \alpha v \beta$ since for any $x, y \in \Sigma^{\geq s}$, it holds that $\varphi(x\alpha u \beta y) = \varphi(x\alpha v \beta y)$ because $x\alpha, \beta y \in \Sigma^{\geq s}$. Furthermore, this congruence is of finite index because for all $u, v \in \Sigma^*$, we have that $\varphi(u) = \varphi(v)$ implies $u \equiv_\varphi v$.

Let now \mathbf{V} be a variety of monoids. Assume first that $\Sigma^*/\equiv_\varphi \in \mathbf{V}$. It is quite direct to see that $\varphi \in \mathbf{EV}$, as the stamp $\mu: \Sigma^* \rightarrow \Sigma^*/\equiv_\varphi$ defined by $\mu(w) = [w]_{\equiv_\varphi}$ for all $w \in \Sigma^*$ witnesses this fact. Assume then that $\varphi \in \mathbf{EV}$. This means that there exists a stamp $\mu: \Sigma^* \rightarrow N$ with $N \in \mathbf{V}$ such that for all $u, v \in \Sigma^*$, we have

$$\mu(u) = \mu(v) \Rightarrow (\varphi(xuy) = \varphi(xvy) \quad \forall x, y \in \Sigma^s) .$$

Now consider $u, v \in \Sigma^*$ such that $\mu(u) = \mu(v)$. For any $x, y \in \Sigma^{\geq s}$, we have that $x = x_1 x_2$ with $x_1 \in \Sigma^*$ and $x_2 \in \Sigma^s$ as well as $y = y_1 y_2$ with $y_1 \in \Sigma^s$ and $y_2 \in \Sigma^*$, so that $\varphi(xuy) = \varphi(x_1)\varphi(x_2 u y_1)\varphi(y_2) = \varphi(x_1)\varphi(x_2 v y_1)\varphi(y_2) = \varphi(xvy)$. Hence, $u \equiv_\varphi v$. Therefore, for all $u, v \in \Sigma^*$, we have that $\mu(u) = \mu(v)$ implies $u \equiv_\varphi v$, so we can define the mapping $\alpha: N \rightarrow \Sigma^*/\equiv_\varphi$ such that $\alpha(\mu(w)) = [w]_{\equiv_\varphi}$ for all $w \in \Sigma^*$. It is easy to check that α is actually a surjective morphism. Thus, we can conclude that Σ^*/\equiv_φ , which divides N , belongs to \mathbf{V} . ◀

Using this characterisation, we prove that given a set of identities ne -defining $\langle \mathbf{V} \rangle_{all}$ for a variety of monoids \mathbf{V} , we get a set of identities ne -defining \mathbf{EV} .

► **Proposition 6.** Let \mathbf{V} be a variety of monoids and let E be a set of identities such that $\langle \mathbf{V} \rangle_{all} = \llbracket E \rrbracket_{ne}$. Then \mathbf{EV} is an ne -variety of stamps and

$$\mathbf{EV} = \llbracket x^\omega y u z t^\omega = x^\omega y v z t^\omega \mid u = v \in E, x, y, z, t \notin \text{alph}(u) \cup \text{alph}(v) \rrbracket_{ne} .$$

Proof. Let

$$F = \{x^\omega y u z t^\omega = x^\omega y v z t^\omega \mid u = v \in E, x, y, z, t \notin \text{alph}(u) \cup \text{alph}(v)\} .$$

Central to the proof is the following claim.

▷ **Claim 7.** Let $\varphi: \Sigma^* \rightarrow M$ be a stamp. Consider the stamp $\mu: \Sigma^* \rightarrow \Sigma^*/\equiv_\varphi$ defined by $\mu(w) = [w]_{\equiv_\varphi}$ for all $w \in \Sigma^*$. It holds that for all $u, v \in \widehat{\Sigma}^*$,

$$\widehat{\mu}(u) = \widehat{\mu}(v) \Leftrightarrow (\widehat{\varphi}(\alpha^\omega \beta u \gamma \delta^\omega) = \widehat{\varphi}(\alpha^\omega \beta v \gamma \delta^\omega) \quad \forall \alpha, \beta, \gamma, \delta \in \Sigma^+) .$$

Before we prove Claim 7, we use it to prove that $\mathbf{EV} = \llbracket F \rrbracket_{ne}$.

Inclusion from left to right. Let $\varphi: \Sigma^* \rightarrow M$ be a stamp in \mathbf{EV} . Consider the stamp $\mu: \Sigma^* \rightarrow \Sigma^*/\equiv_\varphi$ defined by $\mu(w) = [w]_{\equiv_\varphi}$ for all $w \in \Sigma^*$. Since $\varphi \in \mathbf{EV}$, Proposition 5 tells us that $\Sigma^*/\equiv_\varphi \in \mathbf{V}$, hence $\mu \in \langle \mathbf{V} \rangle_{all}$.

Let us consider any identity $x^\omega y u z t^\omega = x^\omega y v z t^\omega \in F$. It is written on an alphabet B that is the union of the alphabet A on which $u = v \in E$ is written and of $x, y, z, t \in B \setminus A$. Let $f: B^* \rightarrow \Sigma^*$ be an ne -morphism. Since $\mu \in \langle \mathbf{V} \rangle_{all}$, we have that μ ne -satisfies the

identity $u = v$, so that $\widehat{\mu}(\widehat{f}(u)) = \widehat{\mu}(\widehat{f}(v))$. Notice that we have that $\widehat{f}(x^\omega) = f(x)^\omega$ as well as $\widehat{f}(t^\omega) = f(t)^\omega$ and that $f(x), f(y), f(z), f(t) \in \Sigma^+$ because f is non-erasing. Therefore, we have

$$\begin{aligned} \widehat{\varphi}(\widehat{f}(x^\omega y u z t^\omega)) &= \widehat{\varphi}(f(x)^\omega f(y) \widehat{f}(u) f(z) f(t)^\omega) \\ &= \widehat{\varphi}(f(x)^\omega f(y) \widehat{f}(v) f(z) f(t)^\omega) \\ &= \widehat{\varphi}(\widehat{f}(x^\omega y v z t^\omega)) \end{aligned}$$

by Claim 7. As this holds for any ne -morphism $f: B^* \rightarrow \Sigma^*$, we can conclude that φ ne -satisfies the identity $x^\omega y u z t^\omega = x^\omega y v z t^\omega$.

This is true for any identity in F , so $\varphi \in \llbracket F \rrbracket_{ne}$. In conclusion, $\mathbf{EV} \subseteq \llbracket F \rrbracket_{ne}$.

Inclusion from right to left. Let $\varphi: \Sigma^* \rightarrow M$ be a stamp in $\llbracket F \rrbracket_{ne}$. Consider the stamp $\mu: \Sigma^* \rightarrow \Sigma^*/\equiv_\varphi$ defined by $\mu(w) = [w]_{\equiv_\varphi}$ for all $w \in \Sigma^*$. We are now going to show that $\mu \in \langle \mathbf{V} \rangle_{all}$.

Take any identity $u = v \in E$ written on an alphabet A . There exists an identity $x^\omega y u z t^\omega = x^\omega y v z t^\omega \in F$ written on an alphabet B such that $A \subseteq B$ and $x, y, z, t \in B \setminus A$. Let $f: A^* \rightarrow \Sigma^*$ be an ne -morphism.

Take any $\alpha, \beta, \gamma, \delta \in \Sigma^+$. Let us define the ne -morphism $g: B^* \rightarrow \Sigma^*$ as the unique one which extends f by letting $g(x) = \alpha$, $g(y) = \beta$, $g(z) = \gamma$ and $g(t) = \delta$. Observe in particular that $\widehat{g}(w) = \widehat{f}(w)$ for any $w \in \widehat{A^*}$ and that $\widehat{g}(x^\omega) = g(x)^\omega = \alpha^\omega$ as well as $\widehat{g}(t^\omega) = \delta^\omega$. Now, as φ ne -satisfies $x^\omega y u z t^\omega = x^\omega y v z t^\omega$, we have that

$$\widehat{\varphi}(\alpha^\omega \beta \widehat{f}(u) \gamma \delta^\omega) = \widehat{\varphi}(\widehat{g}(x^\omega y u z t^\omega)) = \widehat{\varphi}(\widehat{g}(x^\omega y v z t^\omega)) = \widehat{\varphi}(\alpha^\omega \beta \widehat{f}(v) \gamma \delta^\omega) .$$

Since this holds for any $\alpha, \beta, \gamma, \delta \in \Sigma^+$, by Claim 7, we have that $\widehat{\mu}(\widehat{f}(u)) = \widehat{\mu}(\widehat{f}(v))$.

Therefore, $\widehat{\mu}(\widehat{f}(u)) = \widehat{\mu}(\widehat{f}(v))$ for any ne -morphism $f: A^* \rightarrow \Sigma^*$, which means that μ ne -satisfies $u = v$.

Since this holds for any $u = v \in E$, we have that $\mu \in \langle \mathbf{V} \rangle_{all}$, which implies that $\Sigma^*/\equiv_\varphi \in \mathbf{V}$ and thus $\varphi \in \mathbf{EV}$ by Proposition 5. In conclusion, $\llbracket F \rrbracket_{ne} \subseteq \mathbf{EV}$.

The claim still needs to be proved.

Proof of Claim 7. Let $\varphi: \Sigma^* \rightarrow M$ be a stamp of stability index s . Consider the stamp $\mu: \Sigma^* \rightarrow \Sigma^*/\equiv_\varphi$ defined by $\mu(w) = [w]_{\equiv_\varphi}$ for all $w \in \Sigma^*$. We now want to show that for all $u, v \in \widehat{\Sigma^*}$,

$$\widehat{\mu}(u) = \widehat{\mu}(v) \Leftrightarrow (\widehat{\varphi}(\alpha^\omega \beta u \gamma \delta^\omega) = \widehat{\varphi}(\alpha^\omega \beta v \gamma \delta^\omega) \quad \forall \alpha, \beta, \gamma, \delta \in \Sigma^+) .$$

Let $u, v \in \widehat{\Sigma^*}$. There exist two Cauchy sequences $(u_n)_{n \geq 0}$ and $(v_n)_{n \geq 0}$ in Σ^* such that $u = \lim_{n \rightarrow \infty} u_n$ and $v = \lim_{n \rightarrow \infty} v_n$. As Σ^*/\equiv_φ and M are discrete, we have that all four Cauchy sequences $(\mu(u_n))_{n \geq 0}$, $(\varphi(u_n))_{n \geq 0}$, $(\mu(v_n))_{n \geq 0}$ and $(\varphi(v_n))_{n \geq 0}$ are ultimately constant. So there exists $k \in \mathbb{N}$ such that $\widehat{\mu}(u) = \mu(u_k)$, $\widehat{\varphi}(u) = \varphi(u_k)$, $\widehat{\mu}(v) = \mu(v_k)$ and $\widehat{\varphi}(v) = \varphi(v_k)$.

Assume first that $\widehat{\mu}(u) = \widehat{\mu}(v)$. Take any $\alpha, \beta, \gamma, \delta \in \Sigma^+$. Since M is discrete, both Cauchy sequences $(\varphi(\alpha^{n!}))_{n \geq 0}$ and $(\varphi(\delta^{n!}))_{n \geq 0}$ are ultimately constant. So there exists $l \in \mathbb{N}$ such that for all $m \in \mathbb{N}, m \geq l$, we have $\widehat{\varphi}(\alpha^\omega) = \varphi(\alpha^{m!})$ and $\widehat{\varphi}(\delta^\omega) = \varphi(\delta^{m!})$. Hence, taking $m \in \mathbb{N}, m \geq l$ such that $|\alpha^{m!} \beta| \geq s$ and $|\gamma \delta^{m!}| \geq s$, it follows that

$$\widehat{\varphi}(\alpha^\omega \beta u \gamma \delta^\omega) = \varphi(\alpha^{m!} \beta u_k \gamma \delta^{m!}) = \varphi(\alpha^{m!} \beta v_k \gamma \delta^{m!}) = \widehat{\varphi}(\alpha^\omega \beta v \gamma \delta^\omega)$$

because $[u_k]_{\equiv_\varphi} = \widehat{\mu}(u) = \widehat{\mu}(v) = [v_k]_{\equiv_\varphi}$. Thus, we have that

$$\widehat{\varphi}(\alpha^\omega \beta u \gamma \delta^\omega) = \widehat{\varphi}(\alpha^\omega \beta v \gamma \delta^\omega)$$

for all $\alpha, \beta, \gamma, \delta \in \Sigma^+$.

Assume then that $\widehat{\varphi}(\alpha^\omega \beta u \gamma \delta^\omega) = \widehat{\varphi}(\alpha^\omega \beta v \gamma \delta^\omega)$ for all $\alpha, \beta, \gamma, \delta \in \Sigma^+$. Take any $\alpha, \beta \in \Sigma^{\geq s}$. Since $\varphi(\Sigma^s)$ is a finite semigroup and verifies that $\varphi(\Sigma^s) = \varphi(\Sigma^s)^2$, by a classical result in finite semigroup theory (see e.g. [14, Chapter 1, Proposition 1.12]), we have that there exist $\alpha_1, e, f, \beta_2 \in \Sigma^s$ and $\alpha_2, \beta_1 \in \Sigma^{\geq s}$ such that $\varphi(\alpha_1 e \alpha_2) = \varphi(\alpha)$ and $\varphi(\beta_1 f \beta_2) = \varphi(\beta)$ with $\varphi(e)$ and $\varphi(f)$ idempotents. Now, since $\varphi(e)$ is idempotent, we have that

$$\widehat{\varphi}(e^\omega) = \widehat{\varphi}(\lim_{n \rightarrow \infty} e^{n!}) = \lim_{n \rightarrow \infty} \varphi(e^{n!}) = \lim_{n \rightarrow \infty} \varphi(e)^{n!} = \varphi(e)$$

and similarly, $\widehat{\varphi}(f^\omega) = \varphi(f)$. So it follows that

$$\begin{aligned} \varphi(\alpha u_k \beta) &= \varphi(\alpha_1 e \alpha_2 u_k \beta_1 f \beta_2) \\ &= \widehat{\varphi}(\alpha_1 e^\omega \alpha_2 u \beta_1 f^\omega \beta_2) \\ &= \widehat{\varphi}(\alpha_1 e^\omega \alpha_2 v \beta_1 f^\omega \beta_2) \\ &= \varphi(\alpha_1 e \alpha_2 v_k \beta_1 f \beta_2) \\ &= \varphi(\alpha v_k \beta). \end{aligned}$$

As this is true for any $\alpha, \beta \in \Sigma^{\geq s}$, by definition it holds that $u_k \equiv_\varphi v_k$, hence $\widehat{\mu}(u) = \mu(u_k) = \mu(v_k) = \widehat{\mu}(v)$. \triangleleft

This concludes the proof of the proposition. \blacktriangleleft

4 Essentially- \mathbf{V} stamps and the join of \mathbf{V} and \mathbf{LI}

In this section, we establish the link between essentially- \mathbf{V} stamps and $\mathbf{V} \vee \mathbf{LI}$ and give a criterion that characterises exactly when they do correspond.

More precisely, consider the following criterion for a variety of monoids \mathbf{V} .

► **Criterion (A).** For any $L \in \mathcal{L}(\mathbf{V})(\Sigma)$ with Σ an alphabet, we have $xLy \in \mathcal{L}(\mathbf{V} \vee \mathbf{LI})(\Sigma)$ for all $x, y \in \Sigma^*$.

It is a kind of mild closure condition that appears to be a sufficient and necessary condition for \mathbf{EV} and $\mathbf{V} \vee \mathbf{LI}$ to correspond.

► **Proposition 8.** *Let \mathbf{V} be a variety of monoids. Then $\langle \mathbf{V} \vee \mathbf{LI} \rangle_{\text{ne}} \subseteq \mathbf{EV}$ and equality holds if and only if \mathbf{V} verifies criterion (A).*

Why this proposition is useful to give characterisations of $\mathbf{V} \vee \mathbf{LI}$ in terms of identities will become clear in the next section. For now, we focus on its proof, that entirely relies on the following characterisation of the languages recognised by essentially- \mathbf{V} stamps.

► **Proposition 9.** *Let \mathbf{V} be a variety of monoids. For any alphabet Σ , the set $\mathcal{L}(\mathbf{EV})(\Sigma)$ consists of all Boolean combinations of languages of the form xLy for $L \in \mathcal{L}(\mathbf{V})(\Sigma)$ and $x, y \in \Sigma^*$.*

Proof. Let \mathcal{C} be the class of languages such that for any alphabet Σ , the set $\mathcal{C}(\Sigma)$ consists of all Boolean combinations of languages of the form xLy for $L \in \mathcal{L}(\mathbf{V})(\Sigma)$ and $x, y \in \Sigma^*$.

Let Σ be an alphabet. We need to show that $\mathcal{L}(\mathbf{EV})(\Sigma) = \mathcal{C}(\Sigma)$.

Inclusion from right to left. Let $L \in \mathcal{L}(\mathbf{V})(\Sigma)$ and $x, y \in \Sigma^*$. Let $\mu: \Sigma^* \rightarrow N$ be the syntactic morphism of L : this implies that $N \in \mathbf{V}$ and that there exists $F \subseteq N$ such that $L = \mu^{-1}(F)$. Let also $\varphi: \Sigma^* \rightarrow M$ be the syntactic morphism of the language $xLy = x\Sigma^*y \cap \Sigma^{|x|}\mu^{-1}(F)\Sigma^{|y|}$ and let s be its stability index. We then consider $u, v \in \Sigma^*$ such that $\mu(u) = \mu(v)$. Take any $x', y' \in \Sigma^*$ such that $|x'| \geq |x|$ and $|y'| \geq |y|$. We clearly have that $x'uy' \in x\Sigma^*y$ if and only if $x'vy' \in x\Sigma^*y$. Moreover, $x' = x'_1x'_2$ for $x'_1 \in \Sigma^{|x|}$ and $x'_2 \in \Sigma^*$ and $y' = y'_1y'_2$ for $y'_1 \in \Sigma^*$ and $y'_2 \in \Sigma^{|y|}$, so that

$$\begin{aligned} x'uy' \in \Sigma^{|x|}\mu^{-1}(F)\Sigma^{|y|} &\Leftrightarrow \mu(x'_2uy'_1) \in F \\ &\Leftrightarrow \mu(x'_2vy'_1) \in F \\ &\Leftrightarrow x'vy' \in \Sigma^{|x|}\mu^{-1}(F)\Sigma^{|y|} . \end{aligned}$$

Hence, $x'uy' \in xLy$ if and only if $x'vy' \in xLy$ for all $x', y' \in \Sigma^*$ such that $|x'| \geq |x|$ and $|y'| \geq |y|$, so that, by definition of the stability index s of φ and as φ is the syntactic morphism of xLy , we have $\varphi(x'uy') = \varphi(x'vy')$ for all $x', y' \in \Sigma^s$. Thus, it follows that $\varphi \in \mathbf{EV}$.

This implies that $xLy \in \mathcal{L}(\mathbf{EV})(\Sigma)$. Therefore, since this is true for any $L \in \mathcal{L}(\mathbf{V})(\Sigma)$ and $x, y \in \Sigma^*$ and since $\mathcal{L}(\mathbf{EV})(\Sigma)$ is closed under Boolean operations, we can conclude that $\mathcal{C}(\Sigma) \subseteq \mathcal{L}(\mathbf{EV})(\Sigma)$.

Inclusion from left to right. Let $L \in \mathcal{L}(\mathbf{EV})(\Sigma)$ and let $\varphi: \Sigma^* \rightarrow M$ be its syntactic morphism: it is an essentially- \mathbf{V} stamp. Given s its stability index, this means there exists a stamp $\mu: \Sigma^* \rightarrow N$ with $N \in \mathbf{V}$ such that for all $u, v \in \Sigma^*$, we have

$$\mu(u) = \mu(v) \Rightarrow (\varphi(xuy) = \varphi(xvy) \quad \forall x, y \in \Sigma^s) .$$

For each $m \in N$ and $x, y \in \Sigma^s$ consider the language $x\mu^{-1}(m)y$. For any two words $w, w' \in x\mu^{-1}(m)y$, we have $w = xuy$ and $w' = xvy$ with $\mu(u) = \mu(v) = m$, so that $\varphi(w) = \varphi(w')$. By definition of the syntactic morphism, this means that for all $m \in N$ and $x, y \in \Sigma^s$, either $x\mu^{-1}(m)y \subseteq L$ or $x\mu^{-1}(m)y \cap L = \emptyset$. Therefore, there exists a set $E \subseteq N \times \Sigma^s \times \Sigma^s$ such that $L \cap \Sigma^{\geq 2s} = \bigcup_{(m,x,y) \in E} x\mu^{-1}(m)y$, hence

$$L = \bigcup_{(m,x,y) \in E} x\mu^{-1}(m)y \cup F$$

for a certain $F \subseteq \Sigma^{<2s}$.

Take $w \in F$. We have that $\{w\} = w\Sigma^* \cap \bigcap_{a \in \Sigma} (\Sigma^* \setminus wa\Sigma^*)$ with $\Sigma^* \in \mathcal{L}(\mathbf{V})(\Sigma)$. Thus, the singleton language $\{w\}$ belongs to $\mathcal{C}(\Sigma)$ and since this is true for any $w \in F$ and F is finite, we can deduce from this that F is in $\mathcal{C}(\Sigma)$, as the latter is trivially closed under Boolean operations.

Now, for all $m \in N$, the language $\mu^{-1}(m)$ belongs to $\mathcal{L}(\mathbf{V})(\Sigma)$, so we finally have $L \in \mathcal{C}(\Sigma)$. This is true for any $L \in \mathcal{L}(\mathbf{EV})(\Sigma)$, so in conclusion, $\mathcal{L}(\mathbf{EV})(\Sigma) \subseteq \mathcal{C}(\Sigma)$. \blacktriangleleft

Proposition 8 then follows from the two next lemmata, that are both easy consequences of Proposition 9. For completeness, we give the proofs in the appendix.

► **Lemma 10.** *Let \mathbf{V} be a variety of monoids. Then $\langle \mathbf{V} \vee \mathbf{LI} \rangle_{\text{ne}} \subseteq \mathbf{EV}$.*

► **Lemma 11.** *Let \mathbf{V} be a variety of monoids. Then $\mathbf{EV} \subseteq \langle \mathbf{V} \vee \mathbf{LI} \rangle_{\text{ne}}$ if and only if \mathbf{V} verifies criterion (A).*

5 Applications

In this last section, we use the link between essentially- \mathbf{V} stamps and $\mathbf{V} \vee \mathbf{LI}$ to reprove some characterisations of joins between \mathbf{LI} and some well-known varieties of monoids in terms of identities.

One thing seems at first glance a bit problematic about proving that a variety of monoids \mathbf{V} satisfies criterion (A). Indeed, to this end, one needs to prove that certain languages belong to $\mathcal{L}(\mathbf{V} \vee \mathbf{LI})$; however, this poses a problem when one's goal is precisely to characterise $\mathbf{V} \vee \mathbf{LI}$, because one shall a priori not know more about $\mathcal{L}(\mathbf{V} \vee \mathbf{LI})$ than what is given by Proposition 2. Nevertheless, there is a natural sufficient condition for criterion (A) to hold that depends only on $\mathcal{L}(\mathbf{V})$: if given any language $L \in \mathcal{L}(\mathbf{V})(\Sigma)$ and any $x, y \in \Sigma^*$ with Σ an alphabet, there exists a language $K \in \mathcal{L}(\mathbf{V})(\Sigma)$ such that L is equal to the quotient $x^{-1}Ky^{-1}$, then \mathbf{V} verifies criterion (A). We don't know whether this quotient-expressibility condition that solely depends on the variety \mathbf{V} (without explicit reference to \mathbf{LI}) is actually equivalent to it satisfying criterion (A), but we can prove such an equivalence for a weaker quotient-expressibility condition for \mathbf{V} . The proof is to be found in the appendix.

► **Proposition 12.** *Let \mathbf{V} be a variety of monoids. Then \mathbf{V} satisfies criterion (A) if and only if for any $L \in \mathcal{L}(\mathbf{V})(\Sigma)$ and any $x, y \in \Sigma^*$ with Σ an alphabet, there exist $k, l \in \mathbb{N}$ such that for all $u \in \Sigma^k, v \in \Sigma^l$, there exists a language $K \in \mathcal{L}(\mathbf{V})(\Sigma)$ verifying $u^{-1}Lv^{-1} = (xu)^{-1}K(vy)^{-1}$.*

This quotient-expressibility condition appears to be particularly useful to prove that a variety of monoids \mathbf{V} does not satisfy criterion (A) without needing to understand what $\mathcal{L}(\mathbf{V} \vee \mathbf{LI})$ is. We demonstrate this for the variety of finite commutative and idempotent monoids \mathbf{J}_1 .

► **Proposition 13.** \mathbf{J}_1 does not satisfy criterion (A).

Proof. Given an alphabet Σ , the set $\mathcal{L}(\mathbf{J}_1)(\Sigma)$ consists of all Boolean combinations of languages of the form $\Sigma^*a\Sigma^*$ for $a \in \Sigma$ (see [14, Chapter 2, Proposition 3.10]).

Let $L = \{a, b\}^*b\{a, b\}^* \in \mathcal{L}(\mathbf{J}_1)(\{a, b\})$ and $x = b, y = \varepsilon$. Take any $k, l \in \mathbb{N}$ and set $u = a^k$ and $v = a^l$. Consider a $K \in \mathcal{L}(\mathbf{J}_1)(\{a, b\})$. We have that $xuavy \in K \Leftrightarrow xuabvy \in K$ so that $a \in (xu)^{-1}K(vy)^{-1} \Leftrightarrow ab \in (xu)^{-1}K(vy)^{-1}$. But $a \notin u^{-1}Lv^{-1}$ and $ab \in u^{-1}Lv^{-1}$, hence $u^{-1}Lv^{-1} \neq (xu)^{-1}K(vy)^{-1}$ and this holds for any choice of K . So for any $k, l \in \mathbb{N}$, there exists $u \in \Sigma^k, v \in \Sigma^l$ such that no $K \in \mathcal{L}(\mathbf{J}_1)(\{a, b\})$ verifies $u^{-1}Lv^{-1} = (xu)^{-1}K(vy)^{-1}$.

In conclusion, by Proposition 12, \mathbf{J}_1 does not satisfy criterion (A). ◀

We now prove the announced characterisations of joins between \mathbf{LI} and some well-known varieties of monoids in terms of identities.

► **Theorem 14.** *We have the following.*

1. $\langle \mathbf{R} \vee \mathbf{LI} \rangle_{\text{ne}} = \mathbf{ER} = \llbracket x^\omega y(ab)^\omega azt^\omega = x^\omega y(ab)^\omega zt^\omega \rrbracket_{\text{ne}}$.
2. $\langle \mathbf{L} \vee \mathbf{LI} \rangle_{\text{ne}} = \mathbf{EL} = \llbracket x^\omega yb(ab)^\omega zt^\omega = x^\omega y(ab)^\omega zt^\omega \rrbracket_{\text{ne}}$.
3. $\langle \mathbf{J} \vee \mathbf{LI} \rangle_{\text{ne}} = \mathbf{EJ} = \llbracket x^\omega y(ab)^\omega azt^\omega = x^\omega y(ab)^\omega zt^\omega, x^\omega yb(ab)^\omega zt^\omega = x^\omega y(ab)^\omega zt^\omega \rrbracket_{\text{ne}}$.
4. $\langle \mathbf{H} \vee \mathbf{LI} \rangle_{\text{ne}} = \mathbf{EH}$ for any variety of groups \mathbf{H} .

Proof. In each case, we prove that the variety of monoids under consideration satisfies criterion (A) using Proposition 12. We then use Propositions 8 and 6.

Proof of 1. It is well-known that given an alphabet Σ , the set $\mathcal{L}(\mathbf{R})(\Sigma)$ consists of all languages that are disjoint unions of languages that are of the form $A_0^*a_1A_1^*\cdots a_kA_k^*$ where $k \in \mathbb{N}$, $a_1, \dots, a_k \in \Sigma$, $A_0, A_1, \dots, A_k \subseteq \Sigma$ and $a_i \notin A_{i-1}$ for all $i \in [k]$ (see [14, Chapter 4, Theorem 3.3]).

Let Σ be an alphabet and take a language $A_0^*a_1A_1^*\cdots a_kA_k^*$ where $k \in \mathbb{N}$, $a_1, \dots, a_k \in \Sigma$, $A_0, A_1, \dots, A_k \subseteq \Sigma$ and $a_i \notin A_{i-1}$ for all $i \in [k]$. Take $x, y \in \Sigma^*$. Observe that y can be uniquely written as $y = zt$ where $z \in A_k^*$ and $t \in \{\varepsilon\} \cup (\Sigma \setminus A_k)\Sigma^*$. We have

$$A_0^*a_1A_1^*\cdots a_kA_k^* = x^{-1} \left(xA_0^*a_1A_1^*\cdots a_kA_k^*t \cap \bigcap_{v \in A_k^{<|z|}} (\Sigma^* \setminus xA_0^*a_1A_1^*\cdots a_kv t) \right) y^{-1}$$

using the convention that $xA_0^*a_1A_1^*\cdots a_kv t = xvt$ for all $v \in A_k^{<|z|}$ when $k = 0$. The language $xA_0^*a_1A_1^*\cdots a_kA_k^*t \cap \bigcap_{v \in A_k^{<|z|}} (\Sigma^* \setminus xA_0^*a_1A_1^*\cdots a_kv t)$ does belong to the set $\mathcal{L}(\mathbf{R})(\Sigma)$ because the latter is closed under Boolean operations and by definition of z and t . Thus, we can conclude that for each $L \in \mathcal{L}(\mathbf{R})(\Sigma)$ and $x, y \in \Sigma^*$, there exists $K \in \mathcal{L}(\mathbf{R})(\Sigma)$ such that $L = x^{-1}Ky^{-1}$ by using the characterisation of $\mathcal{L}(\mathbf{R})(\Sigma)$, the fact that quotients commute with unions [14, p. 20] and closure of $\mathcal{L}(\mathbf{R})(\Sigma)$ under unions.

Proof of 2. It is also well-known that given an alphabet Σ , the set $\mathcal{L}(\mathbf{L})(\Sigma)$ consists of all languages that are disjoint unions of languages that are of the form $A_0^*a_1A_1^*\cdots a_kA_k^*$ where $k \in \mathbb{N}$, $a_1, \dots, a_k \in \Sigma$, $A_0, A_1, \dots, A_k \subseteq \Sigma$ and $a_i \notin A_i$ for all $i \in [k]$ (see [14, Chapter 4, Theorem 3.4]). The proof is then dual to the previous case.

Proof of 3. Given an alphabet Σ , for each $k \in \mathbb{N}$, we define the equivalence relation \sim_k on Σ^* by $u \sim_k v$ for $u, v \in \Sigma^*$ whenever u and v have the same set of subwords of length at most k . This relation is a congruence of finite index on Σ^* . Simon proved [19] that a language belongs to $\mathcal{L}(\mathbf{J})(\Sigma)$ if and only if it is equal to a union of \sim_k -classes for a $k \in \mathbb{N}$.

Let Σ be an alphabet and take $L \in \mathcal{L}(\mathbf{J})(\Sigma)$ as well as $x, y \in \Sigma^*$. Thus, there exists $k \in \mathbb{N}$ such that L is a union of \sim_k -classes. Define the language $K = \bigcup_{w \in L} [xwy]_{\sim_{|xy|+k}}$: it belongs to $\mathcal{L}(\mathbf{J})(\Sigma)$ by construction. We now show that $L = x^{-1}Ky^{-1}$, which concludes the proof. Let $w \in L$: we have that $xwy \in [xwy]_{\sim_{|xy|+k}} \subseteq K$, so that $w \in x^{-1}Ky^{-1}$. Let conversely $w \in x^{-1}Ky^{-1}$. This means that $xwy \in K$, which implies that there exists $w' \in L$ such that $xwy \sim_{|xy|+k} xw'y$. Actually, it holds that any $u \in \Sigma^*$ of length at most k is a subword of w if and only if it is a subword of w' , because xuy is a subword of xwy if and only if it is a subword of $xw'y$. Hence, $w \sim_k w'$, which implies that $w \in L$.

Proof of 4. Consider any variety of groups \mathbf{H} . Take a language $L \in \mathcal{L}(\mathbf{H})(\Sigma)$ for an alphabet Σ and let $x, y \in \Sigma^*$. Consider the syntactic morphism $\eta: \Sigma^* \rightarrow M$ of L : we have that M is a group in \mathbf{H} . Define the language $K = \eta^{-1}(\eta(x)\eta(L)\eta(y))$: it belongs to $\mathcal{L}(\mathbf{H})(\Sigma)$. We now show that $L = x^{-1}Ky^{-1}$, which concludes the proof. Let $w \in L$: we have that $\eta(xwy) \in \eta(x)\eta(L)\eta(y)$, so that $w \in x^{-1}Ky^{-1}$. Conversely, let $w \in x^{-1}Ky^{-1}$. We have that $xwy \in K$, which means that $\eta(xwy) = \eta(x)\eta(w')\eta(y)$ for a $w' \in L$, so that $\eta(w) = \eta(w') \in \eta(L)$, as any element in M is invertible. Thus, $w \in L$. ◀

6 Conclusion

The general method presented in this paper actually allows to reprove in a straightforward language-theoretic way even more characterisations of the join of **LI** with some variety of finite monoids. This can for instance be done for the variety of finite commutative monoids **Com** or the variety of finite commutative aperiodic monoids **ACom**.

In fact, as already observed in some sense by Costa [9], many varieties of finite monoids seem to verify criterion (A). The main question left open by this present work is to understand better what exactly those varieties are. Another question left open is whether Proposition 12 can be refined by using the stronger quotient-expressibility condition alluded to before the statement of the proposition. The answers to both questions are unclear to the author, but making progress on them may also lead to a better understanding of joins of varieties of finite monoids with **LI**.

A Missing proofs

Proof of Proposition 2. Let \mathbf{W} be an ne -variety of stamps such that $\langle \mathbf{V} \rangle_{all} \cup \langle \mathbf{LI} \rangle_{ne} \subseteq \mathbf{W}$. There exists a variety of semigroups \mathbf{W}' such that $\langle \mathbf{W}' \rangle_{ne} = \mathbf{W}$.

Let $S \in \mathbf{V} \cup \mathbf{LI}$. We denote by S^1 the monoid S if S is already a monoid and the monoid $S \cup \{1\}$ otherwise. Then the evaluation morphism $\eta_S: S^* \rightarrow S^1$ such that $\eta_S(s) = s$ for all $s \in S$ verifies $\eta_S(S^+) = S$ and additionally $S^1 = S$ when $S \in \mathbf{V}$. This implies that $\eta_S \in \langle \mathbf{V} \rangle_{all} \cup \langle \mathbf{LI} \rangle_{ne} \subseteq \mathbf{W}$. But by definition of \mathbf{W}' , it must be that $S = \eta_S(S^+) \in \mathbf{W}'$.

Therefore, \mathbf{W}' contains both \mathbf{V} and \mathbf{LI} , which implies that $\mathbf{V} \vee \mathbf{LI} \subseteq \mathbf{W}'$ by inclusion-wise minimality of $\mathbf{V} \vee \mathbf{LI}$. By definition, we can then conclude that $\langle \mathbf{V} \vee \mathbf{LI} \rangle_{ne} \subseteq \langle \mathbf{W}' \rangle_{ne} = \mathbf{W}$. So $\langle \mathbf{V} \vee \mathbf{LI} \rangle_{ne}$ is the inclusion-wise least ne -variety of stamps containing both $\langle \mathbf{V} \rangle_{all}$ and $\langle \mathbf{LI} \rangle_{ne}$.

Let now \mathcal{W} be an ne -variety of languages such that $\mathcal{L}(\mathbf{V}) \cup \mathcal{L}(\mathbf{LI}) \subseteq \mathcal{W}$. It holds that $\mathcal{W} = \mathcal{L}(\mathbf{W})$ for an ne -variety of stamps \mathbf{W} . We have that $\langle \mathbf{V} \rangle_{all}$, which is in particular an ne -variety of stamps, is included in \mathbf{W} because $\mathcal{L}(\langle \mathbf{V} \rangle_{all}) = \mathcal{L}(\mathbf{V}) \subseteq \mathcal{W} = \mathcal{L}(\mathbf{W})$, but also that $\langle \mathbf{LI} \rangle_{ne}$ is included in \mathbf{W} because $\mathcal{L}(\langle \mathbf{LI} \rangle_{ne}) = \mathcal{L}(\mathbf{LI}) \subseteq \mathcal{W} = \mathcal{L}(\mathbf{W})$. By inclusion-wise minimality of $\langle \mathbf{V} \vee \mathbf{LI} \rangle_{ne}$, it follows that $\langle \mathbf{V} \vee \mathbf{LI} \rangle_{ne} \subseteq \mathbf{W}$. Hence, using again the above fact on the Eilenberg correspondence, we can conclude that $\mathcal{L}(\mathbf{V} \vee \mathbf{LI}) = \mathcal{L}(\langle \mathbf{V} \vee \mathbf{LI} \rangle_{ne}) \subseteq \mathcal{L}(\mathbf{W}) = \mathcal{W}$. So $\mathcal{L}(\mathbf{V} \vee \mathbf{LI})$ is the inclusion-wise least ne -variety of languages containing both $\mathcal{L}(\mathbf{V})$ and $\mathcal{L}(\mathbf{LI})$.

Consider now the class of languages \mathcal{C} such that $\mathcal{C}(\Sigma)$ is the Boolean closure of $\mathcal{L}(\mathbf{V})(\Sigma) \cup \mathcal{L}(\mathbf{LI})(\Sigma)$ for each alphabet Σ . By closure under Boolean operations of $\mathcal{L}(\mathbf{V} \vee \mathbf{LI})$, we have that $\mathcal{C} \subseteq \mathcal{L}(\mathbf{V} \vee \mathbf{LI})$. Now, as Boolean operations commute with both quotients [14, p. 20] and inverses of ne -morphisms [14, Proposition 0.4], by closure of $\mathcal{L}(\mathbf{V})$ and $\mathcal{L}(\mathbf{LI})$ under quotients and inverses of ne -morphisms, we actually have that \mathcal{C} is an ne -variety of languages. Therefore, by inclusion-wise minimality of $\mathcal{L}(\mathbf{V} \vee \mathbf{LI})$, we can conclude that $\mathcal{L}(\mathbf{V} \vee \mathbf{LI}) = \mathcal{C}$. ◀

Proof of Lemma 10. We actually have that $\mathcal{L}(\mathbf{V}) \cup \mathcal{L}(\mathbf{LI}) \subseteq \mathcal{L}(\mathbf{EV})$, which allows us to conclude by inclusion-wise minimality of $\mathcal{L}(\mathbf{V} \vee \mathbf{LI})$ (Proposition 2) and by the fact that $\mathcal{L}(\mathbf{EV})$ is an ne -variety of languages (Proposition 6).

Let Σ be an alphabet. The fact that $\mathcal{L}(\mathbf{V})(\Sigma) \subseteq \mathcal{L}(\mathbf{EV})(\Sigma)$ follows trivially from Proposition 9. Moreover, for all $u \in \Sigma^*$, since necessarily $\Sigma^* \in \mathcal{L}(\mathbf{V})(\Sigma)$, we have that both $u\Sigma^*$ and Σ^*u belong to $\mathcal{L}(\mathbf{LI})(\Sigma)$. Thus, as $\mathcal{L}(\mathbf{EV})(\Sigma)$ is closed under Boolean operations, it follows that $\mathcal{L}(\mathbf{LI})(\Sigma) \subseteq \mathcal{L}(\mathbf{EV})(\Sigma)$.

This concludes the proof, since it holds for any alphabet Σ . ◀

Proof of Lemma 11. Assume that $\mathbf{EV} \subseteq \langle \mathbf{V} \vee \mathbf{LI} \rangle_{ne}$. For any $L \in \mathcal{L}(\mathbf{V})(\Sigma)$ and any $x, y \in \Sigma^*$ with Σ an alphabet, by Proposition 9, we have that $xLy \in \mathcal{L}(\mathbf{EV})(\Sigma) \subseteq \mathcal{L}(\mathbf{V} \vee \mathbf{LI})(\Sigma)$. Hence, \mathbf{V} verifies criterion (A).

Conversely, assume that \mathbf{V} verifies criterion (A). For any alphabet Σ , the set $\mathcal{L}(\mathbf{V} \vee \mathbf{LI})(\Sigma)$ contains all languages of the form xLy for $L \in \mathcal{L}(\mathbf{V})(\Sigma)$ and $x, y \in \Sigma^*$, so it contains all Boolean combinations of languages of that form, since it is closed under Boolean operations. Therefore, by Proposition 9, we have $\mathcal{L}(\mathbf{EV}) \subseteq \mathcal{L}(\mathbf{V} \vee \mathbf{LI})$, so that $\mathbf{EV} \subseteq \langle \mathbf{V} \vee \mathbf{LI} \rangle_{ne}$. ◀

Proof of Proposition 12. Let us first observe that given any alphabet Σ , given any language K on that alphabet and given any two words $x, y \in \Sigma^*$, we have that $x(x^{-1}Ky^{-1})y = x\Sigma^*y \cap K$ and $x^{-1}(xKy)y^{-1} = K$.

Implication from right to left. Assume that for any $L \in \mathcal{L}(\mathbf{V})(\Sigma)$ and any $x, y \in \Sigma^*$ with Σ an alphabet, there exist $k, l \in \mathbb{N}$ such that for all $u \in \Sigma^k, v \in \Sigma^l$, there exists a language $K \in \mathcal{L}(\mathbf{V})(\Sigma)$ verifying $u^{-1}Lv^{-1} = (xu)^{-1}K(vy)^{-1}$. Take $L \in \mathcal{L}(\mathbf{V})(\Sigma)$ for an alphabet Σ and take $x, y \in \Sigma^*$. Consider also $k, l \in \mathbb{N}$ that are guaranteed to exist by the assumption we just made.

For all $u \in \Sigma^k, v \in \Sigma^l$, there exists a language $K \in \mathcal{L}(\mathbf{V})(\Sigma)$ verifying $u^{-1}Lv^{-1} = (xu)^{-1}K(vy)^{-1}$, so that by our observation at the beginning of the proof, we have

$$x(u\Sigma^*v \cap L)y = xu(u^{-1}Lv^{-1})vy = xu((xu)^{-1}K(vy)^{-1})vy = xu\Sigma^*vy \cap K .$$

Using Proposition 2, we thus have that $x(u\Sigma^*v \cap L)y \in \mathcal{L}(\mathbf{V} \vee \mathbf{LI})(\Sigma)$ for all $u \in \Sigma^k, v \in \Sigma^l$. Moreover, since we have that the set of words of L of length at least $k + l$ is

$$\Sigma^{\geq k+l} \cap L = \bigcup_{u \in \Sigma^k, v \in \Sigma^l} (u\Sigma^*v \cap L)$$

and since

$$L = (\Sigma^{\geq k+l} \cap L) \cup F$$

where F is a finite set of words on Σ of length less than $k + l$, we have that

$$xLy = x((\Sigma^{\geq k+l} \cap L) \cup F)y = \bigcup_{u \in \Sigma^k, v \in \Sigma^l} x(u\Sigma^*v \cap L)y \cup xFy .$$

We can thus conclude that $xLy \in \mathcal{L}(\mathbf{V} \vee \mathbf{LI})(\Sigma)$ since $xFy \in \mathcal{L}(\mathbf{LI})(\Sigma)$ and because $\mathcal{L}(\mathbf{V} \vee \mathbf{LI})(\Sigma)$ is closed under unions.

Implication from left to right. Assume that \mathbf{V} satisfies criterion (A). Take $L \in \mathcal{L}(\mathbf{V})(\Sigma)$ for an alphabet Σ and take $x, y \in \Sigma^*$. By hypothesis, we know that $xLy \in \mathcal{L}(\mathbf{V} \vee \mathbf{LI})(\Sigma)$.

By Proposition 2, this means that xLy is a Boolean combination of languages in $\mathcal{L}(\mathbf{V})(\Sigma) \cup \mathcal{L}(\mathbf{LI})(\Sigma)$. Further, this implies that xLy can be written as the union of intersections of languages of $\mathcal{L}(\mathbf{V})(\Sigma)$ and $\mathcal{L}(\mathbf{LI})(\Sigma)$ or their complements, which in turn implies, by closure of $\mathcal{L}(\mathbf{V})(\Sigma)$ and $\mathcal{L}(\mathbf{LI})(\Sigma)$ under Boolean operations, that xLy can be written as a finite union of languages of the form $K \cap (U\Sigma^*V \cup W)$ with $K \in \mathcal{L}(\mathbf{V})(\Sigma)$ and $U, V, W \subseteq \Sigma^*$ finite. Since any word in xLy must be of length at least $|xy|$ and have x as a prefix and y as a suffix, we can assume that any language $K \cap (U\Sigma^*V \cup W)$ appearing in a finite union as described above verifies that $U \subseteq x\Sigma^*$, that $V \subseteq \Sigma^*y$ and that $W \subseteq x\Sigma^*y$. Now, if we take $k, l \in \mathbb{N}$ big enough, we thus have that

51:16 A Note on the Join of Varieties of Monoids with LI

$$xLy = \bigcup_{u \in \Sigma^k, v \in \Sigma^l} (K_{u,v} \cap xu\Sigma^*vy) \cup F$$

where $K_{u,v} \in \mathcal{L}(\mathbf{V})(\Sigma)$ for all $u \in \Sigma^k, v \in \Sigma^l$ and $F \subseteq \Sigma^{<|xy|+k+l}$. Hence, for all $u \in \Sigma^k, v \in \Sigma^l$, we have

$$\begin{aligned} u^{-1}Lv^{-1} &= u^{-1}(x^{-1}(xLy)y^{-1})v^{-1} \\ &= (xu)^{-1} \left(\bigcup_{u' \in \Sigma^k, v' \in \Sigma^l} (K_{u',v'} \cap xu'\Sigma^*v'y) \cup F \right) (vy)^{-1} \\ &= \bigcup_{u' \in \Sigma^k, v' \in \Sigma^l} (xu)^{-1} \left(xu'((xu')^{-1}K_{u',v'}(v'y)^{-1})v'y \right) (vy)^{-1} \cup \\ &\quad (xu)^{-1}F(vy)^{-1} \\ &= (xu)^{-1}K_{u,v}(vy)^{-1}, \end{aligned}$$

using classical formulae for quotients [14, p. 20] and observing that $(xu)^{-1}K(vy)^{-1} = \emptyset$ for any $K \subseteq \Sigma^*$ such that $K \cap xu\Sigma^*vy = \emptyset$. ◀

Optimal Regular Expressions for Palindromes of Given Length

Hermann Gruber 

Knowledgepark GmbH, München, Germany

Markus Holzer¹ 

Institut für Informatik, University of Giessen, Germany

Abstract

The language P_n (\tilde{P}_n , respectively) consists of all words that are palindromes of length $2n$ ($2n - 1$, respectively) over a fixed binary alphabet. We construct a regular expression that specifies P_n (\tilde{P}_n , respectively) of alphabetic width $4 \cdot 2^n - 4$ ($3 \cdot 2^n - 4$, respectively) and show that this is optimal, that is, the expression has minimum alphabetic width among all expressions that describe P_n (\tilde{P}_n , respectively). To this end we give optimal expressions for the first k palindromes in lexicographic order of odd and even length, proving that the optimal bound is $2n + 4(k - 1) - 2S_2(k - 1)$ in case of odd length and $2n + 3(k - 1) - 2S_2(k - 1) - 1$ for even length, respectively. Here $S_2(n)$ refers to the Hamming weight function, which denotes the number of ones in the binary expansion of the number n .

1 Introduction

During the last two decades or so, literally hundreds of research papers have been investigating deterministic and nondeterministic state complexity of regular languages. Here, general purpose lower bound techniques are available, and in many cases, upper and lower bounds can be obtained that match exactly, not only asymptotically. For recent surveys, see, e.g., [8, 15].

The situation is less desirable if we investigate the minimum required size of regular expressions describing a regular language. While several different lower bound techniques are available, often the best known upper and lower bounds match only asymptotically. For illustration, the size blow-up when going from finite automata over a binary alphabet to regular expressions is at least c^n for some $c > 1$ for large enough n , cf. [12]. The current record holder for the upper bound is $O(1.682^n)$, see [5]. This gives a “tight” bound of $2^{\Theta(n)}$, which is on closer inspection a bit loose. To our knowledge, exactly matching upper and lower bounds for the minimum required expression size are known only for very few nontrivial language families: Namely, the Boolean n -bit parity function [7, 14], the less-than relation on an n -set [2], given as $\{ij \mid 1 \leq i < j \leq n\}$, and the permutations of an n -set [23].

The set of all palindromes over the alphabet $\{a, b\}$ is context-free but not regular; virtually every computer science student in the world will learn this during their curriculum. Not surprisingly, this basic observation is as old as the Chomsky hierarchy itself [3]. Of course, if we consider only palindromes of a given length, the set thus obtained is finite, and therefore

¹ Corresponding author.

regular. We exactly determine the optimum regular expressions for this set, for every given length. In the course of the proof, we also determine the optimum regular expressions for the lexicographically first k palindromes of a given length, for every k . The difficulty of course lies in establishing a matching lower bound. To this end, we use and expand a method from [23] to obtain a recurrent lower bound. The recurrence thus obtained involves a “minvolution” in the sense of [11] and the minimum operator of course yields a nonlinear recurrence. A long line of research concerns asymptotic and exact solutions of recurrences involving minimum and maximum functions, see, e.g., [18] and references therein. Our recurrence falls into neither of the known categories. So we develop a tailor-made strategy for solving the recurrence, and derive a novel identity involving sums of Hamming weights. We hope that this will serve as a helpful example for researchers in need of solving similar nonlinear recurrences.

Some of our results contribute to the knowledge about integer sequences: We give a characterization of the number of multiplications to compute the $(n + 1)$ th power by the ancient Indian Chandah-sutra method in terms of Hamming weights (Lemma 8). Also, we find a new recurrence for the numbers having a partition into distinct Mersenne numbers greater than zero (Lemma 10). The functions giving the optimal lengths of the regular expressions we consider can be enumerated in lexicographic order; accompanying submissions to the On-line Encyclopedia of Integer Sequences (OEIS) are in preparation, since these sequences are not yet covered by OEIS.

With some extra effort, all of our results can be generalized to larger alphabet sizes. These results will be presented in the full version of this paper.

2 Preliminaries

We assume that the reader is familiar with the basic notions of formal language theory as contained in [16]. In particular, let Σ be an *alphabet* and Σ^* the *set of all words over the alphabet* Σ , including the *empty word* ϵ . The *length of a word* w is denoted by $|w|$, where $|\epsilon| = 0$, and the total number of occurrences of the alphabet symbol a in w is denoted by $|w|_a$. In this paper, we mainly deal with finite languages. The *order* of a finite language L is the length of a longest word belonging to L . A finite language L is *homogeneous* if all words in the language have the same length. In order to fix the notation, we briefly recall the definition of regular expressions and the languages described by them.

The *regular expressions* over an alphabet Σ are defined inductively in the usual way:² \emptyset , ϵ , and every letter a with $a \in \Sigma$ is a regular expression; and when E and F are regular expressions, then $(E + F)$, $(E \cdot F)$, and $(E)^*$ are also regular expressions. The language defined by a regular expression E , denoted by $L(E)$, is defined as follows: $L(\emptyset) = \emptyset$, $L(\epsilon) = \{\epsilon\}$, $L(a) = \{a\}$, $L(E + F) = L(E) \cup L(F)$, $L(E \cdot F) = L(E) \cdot L(F)$, and $L(E^*) = L(E)^*$. The *alphabetic width* or *size* of a regular expression E over the alphabet Σ , denoted by $\text{awidth}(E)$, is defined as the total number of occurrences of letters of Σ in E . For a regular language L , we define its alphabetic width, $\text{awidth}(L)$, as the minimum alphabetic width among all regular expressions describing L .

² For convenience, parentheses in regular expressions are sometimes omitted and the concatenation is simply written as juxtaposition. The priority of operators is specified in the usual fashion: concatenation is performed before union, and star before both product and union.

3 A Lower Bound for Palindromes of Even Length

For a nonnegative integer n , let $P_n = \{ww^R \mid w \in \{a, b\}^n\}$ denote the set of palindromes of length $2n$. In this section, we give a tight bound on the required regular expression size of P_n . For our toolbox, we need to investigate the concatenation of homogeneous languages.

► **Lemma 1.** *Let L_1 and L_2 be homogeneous languages. Then $\text{awidth}(L_1 \cdot L_2) = \text{awidth}(L_1) + \text{awidth}(L_2)$.*

Inspired by the method recently used to exactly determine the alphabetic width of the set of permutations [23], define $\ell(n, k)$ to be the minimum alphabetic width of a regular expression describing a subset of P_n , where the subset has cardinality at least k . Note that $\ell(n, k)$ is monotone in k by definition, that is, $\ell(n, k) \leq \ell(n, k')$, for $k \leq k'$.

► **Lemma 2.** *Let $n \geq 0$ and $1 \leq k \leq 2^n$. Then $\ell(n, k)$ obeys the following recurrence:*

$$\ell(n, k) \geq \min\{\ell(n-1, k) + 2, \min_{1 \leq i < k} \{\ell(n, i) + \ell(n, k-i)\}\}, \text{ for } n \geq 2 \text{ and } 2 \leq k \leq 2^{n-1},$$

$$\ell(n, k) \geq \min_{1 \leq i < k} \{\ell(n, i) + \ell(n, k-i)\}, \text{ for } n \geq 1 \text{ and } k > 2^{n-1},$$

and

$$\ell(n, 1) = 2n.$$

Proof. In the case $k = 1$, each regular expression describing a nonempty subset of $\{a, b\}^{2n}$ must have alphabetic width at least $2n$. For $n \geq 1$, the expression a^{2n} describes at least one word in P_n . For $n = 0$, ϵ is an optimal regular expression describing the only nonempty subset of $\{a, b\}^0 = \{\epsilon\}$. Thus we have $\ell(n, 1) = 2n$ for all $n \geq 0$.

For $n \geq 1$ and $2 \leq k \leq 2^n$, let E be a regular expression denoting a subset of P_n which has cardinality at least k . The language P_n is homogeneous, so we may safely assume that neither ϵ nor \emptyset occur in E , and the same holds for the Kleene star, see, e.g., [14]. Thus, E is of the form $F + G$ or of the form $F \cdot G$, and each of F and G have alphabetic width at least 1.

If $E = F + G$, then both F and G denote subsets of P_n , say of sizes k_1 and k_2 , respectively. Then $k_1 + k_2 \geq k$, and, by minimality, $k_1, k_2 < k$. We thus obtain the following recurrence in the case of union:

$$\begin{aligned} \ell(n, k) &\geq \ell(n, k_1) + \ell(n, k_2) \\ &\geq \ell(n, k_1) + \ell(n, k - k_1) \\ &\geq \min_{1 \leq i < k} \{\ell(n, i) + \ell(n, k - i)\}, \end{aligned}$$

where we used the monotonicity of $\ell(n, k)$ with respect to k for the second estimation.

The other case is that $E = F \cdot G$. We may assume that the words in F have length at most n – otherwise, we apply the argument to $E^R = G^R \cdot F^R$, and note that $\text{awidth}(E) = \text{awidth}(E^R)$. Let n_1 denote the length of the words in F . Then we have $1 \leq n_1 \leq n$. We claim that $L(F)$ must be a singleton language, that is, $L(F) = \{w\}$ for some word w . For the sake of contradiction, assume $L(F)$ contains another word x with $x \neq w$. Since E describes P_n and $L(E) = L(F) \cdot L(G)$, the language $L(E)$ contains a word of the form wzw^R , for some infix z . Since there is only one way to write wzw^R as product of words in $L(F)$ and $L(G)$, the word zw^R must be in $L(G)$. But then the non-palindromic word xzw^R is a member of $L(E)$, which yields the desired contradiction to establish the claim.

52:4 Optimal Regular Expressions for Palindromes of Given Length

Further, we can assume that $n_1 = 1$ without loss of generality. This can be seen as follows. By Lemma 1, $\text{awidth}(L(E)) = \text{awidth}(L(F)) + \text{awidth}(L(G))$. For $1 \leq i \leq n_1$, let a_i denote the i th letter in w . Since $L(F) = \{w\}$, we have $\text{awidth}(L(F)) = n_1$. Thus, if we replace the subexpression F of E with the expression $\tilde{f} = a_1 \cdot (a_2 \cdots a_{n_1})$, the expression \tilde{E} thus obtained is again minimal. By applying the associative law for concatenation to \tilde{E} , we obtain yet another minimal expression $\tilde{E}' = \tilde{f}' \cdot G''$ with $\tilde{f}' = a_1$ and $G'' = (a_2 \cdots a_{n_1} \cdot G)$.

Since all words in P_n are palindromic, $L(G'') = S \cdot a_1$, for some subset S of P_{n-2} . Also, set S must be of the same cardinality as $L(E)$. We thus obtain the following recurrence in the case of concatenation:

$$\ell(n, k) \geq \ell(n-1, k) + 2.$$

Observe that k can be at most 2^{n-1} in this case, since there are no more than 2^{n-1} palindromes of length $2(n-1)$. Also, we must have $n \geq 2$ in the case of concatenation, since both $k \geq 2$ and $k \leq 2^{n-1}$ hold.

Either the case of union or of concatenation applies – because E has no Kleene star, and we obtain the recurrence relation

$$\ell(n, k) \geq \min\{\ell(n-1, k) + 2, \min_{1 \leq i < k} \{\ell(n, i) + \ell(n, k-i)\}\}, \text{ for } n \geq 2 \text{ and } 2 \leq k \leq 2^{n-1},$$

and

$$\ell(n, k) \geq \min_{1 \leq i < k} \{\ell(n, i) + \ell(n, k-i)\}, \text{ for } n \geq 1 \text{ and } 2^{n-1} < k \leq 2^n,$$

as desired. ◀

In the above proof, we derived a recursive lower bound on $\ell(n, k)$. Let f denote the integer-valued function which is defined by that recurrence, that is,

$$f(n, k) = \min\{f(n-1, k) + 2, \min_{1 \leq i < k} \{f(n, i) + f(n, k-i)\}\}, \text{ for } n \geq 2 \text{ and } 2 \leq k \leq 2^{n-1},$$

$$f(n, k) = \min_{1 \leq i < k} \{f(n, i) + f(n, k-i)\}, \text{ for } n \geq 1 \text{ and } 2^{n-1} < k \leq 2^n,$$

and

$$f(n, 1) = 2n.$$

The recursive definition can be simplified with the aid of the following lemma.

► **Lemma 3.** $f(n, k) = f(n-1, k) + 2$, for $n \geq 2$ and $2 \leq k \leq 2^{n-1}$.

Proof. Recall the recursive definition of f in this parameter range is

$$f(n, k) = \min\{f(n-1, k) + 2, \min_{1 \leq i < k} \{f(n, i) + f(n, k-i)\}\},$$

for $n \geq 2$ and $2 \leq k \leq 2^{n-1}$, so the inequality $f(n, k) \leq f(n-1, k) + 2$ is immediate. For the converse inequality, we claim that

$$\min_{1 \leq i < k} \{f(n, i) + f(n, k-i)\} \geq f(n-1, k) + 2.$$

We prove this by lexicographic induction on (n, k) . To show the statement for $n \geq 2$ and $k \geq 2$, we assume that the statement holds for all pairs (n', k') with $n' < n$, as well as for all pairs with $n' = n$ and $k' < k$. Observe, that by the induction hypothesis on (n, k) we also can safely assume that $f(n', k') \geq f(n'-1, k') + 2$, which follows from the recursive definition of f . The base case $(2, 2)$ is easily verified with

$$\min_{1 \leq i < 2} \{f(2, i) + f(2, 2-i)\} = f(2, 1) + f(2, 1) = 4 + 4 \geq 4 + 2 = f(1, 2) + 2,$$

because $f(1, 2) = \min_{1 \leq i < 2} \{f(1, i) + f(1, 2 - i)\} = f(1, 1) + f(1, 1) = 2 + 2 = 4$. For the induction step, we apply the induction hypothesis and $f(n, k) \geq f(n - 1, k) + 2$ twice to obtain

$$\begin{aligned} \min_{1 \leq i < k} \{f(n, i) + f(n, k - i)\} &\geq \min_{1 \leq i < k} \{(f(n - 1, i) + 2) + (f(n - 1, k - i) + 2)\} \\ &\geq \min_{1 \leq i < k} \{f(n - 1, i) + f(n - 1, k - i)\} + 4 \\ &\geq f(n - 1, k) + 6, \end{aligned}$$

which means that $\min_{1 \leq i < k} \{f(n, i) + f(n, k - i)\} \geq f(n - 1, k) + 2$ as desired.

Having established the claim, the equality of $f(n, k)$ with $f(n - 1, k) + 2$ now follows immediately. This completes the proof of the lemma. ◀

Still, the second recurrence equation entails the full history of the parameter k . One might hope that f is convex in the parameter k , and that the minimum in the formula $\min_{1 \leq i < k} \{f(n, i) + f(n, k - i)\}$ is always attained in the middle, i.e., $\arg \min i = \lfloor \frac{k}{2} \rfloor$. Compare, e.g., [21, p. 366] on convex recurrences. But this is, unfortunately, not the case: for instance, we have $f(3, 6) = \min_{1 \leq i < 6} \{f(3, i) + f(3, 6 - i)\} = f(3, 2) + f(3, 4) = 8 + 14 = 22$, while $2 \cdot f(3, 3) = 2 \cdot (f(2, 3) + 2) = 2 \cdot (10 + 2) = 24$. In fact, computations for small ranges of n and k suggest a nontrivial behavior of f – see Table 1.

■ **Table 1** Some $f(n, k)$ values for small n and k .

	$k = 1$	$k = 2$	$k = 3$	$k = 4$	$k = 5$	$k = 6$	$k = 7$	$k = 8$	$k = 9$	$k = 10$	$k = 11$	$k = 12$	$k = 13$	$k = 14$	$k = 15$	$k = 16$
$n = 1$	2	4														
$n = 2$	4	6	10	12												
$n = 3$	6	8	12	14	20	22	26	28								
$n = 4$	8	10	14	16	22	24	28	30	38	40	44	46	52	54	58	60

At least, we are interested only in the value of $f(n, 2^n)$. Once we put forward a suitable induction hypothesis (which admittedly is somewhat flabbergasting), we can establish a simple closed form for $f(n, 2^n)$ with a laborious lexicographic induction.

▶ **Lemma 4.** $f(n, 2^n) = 2^{n+2} - 4$.

Proof. For the upper bound, observe that $f(n, 2^n) \leq 2 \cdot f(n, 2^{n-1})$ easily follows from the recurrence equations defining f and with the help of Lemma 3 we obtain

$$f(n, 2^n) \leq 2 \cdot (f(n - 1, 2^{n-1}) + 2).$$

With $f(1, 2) = 4$, this boils down to an inhomogeneous linear recurrence with variable n , which can be solved as $f(n, 2^n) \leq 4(2^n - 1) = 2^{n+2} - 4$.

The lower bound will follow immediately once we have established the following claim.

▷ **Claim 5.** Let $n \geq 1$ and $1 \leq k \leq 2^n$. Then

$$f(n, k) \geq \begin{cases} 4k & \text{if } k < 2^{n-1}, \\ 4k - 2 & \text{if } k \text{ is not a power of two and } k > 2^{n-1}, \text{ and} \\ 4k - 4 + 2n - 2 \log k & \text{if } k \text{ is a power of two.} \end{cases}$$

The remaining part of the proof is a lexicographic induction on (n, k) , which tedious details are left to the reader. ◀

4 Some Digit Theory

Now that our appetite is whetted, we want to solve the recurrence also in the general case where k is not a power of two. In this section, we develop the necessary tools regarding “digit theory,” that is, mathematical properties of digit sums, that we will need for the analysis. Let $S_2(n)$ denotes the “digit sum to base 2” function. This function is often referred to as the *Hamming weight function* and denotes the number of ones in the binary expansion of the number n . Throughout the rest of this paper, for a nonnegative integer n , we refer to the function $\lambda(n)$ defined as

$$\lambda(n) = \begin{cases} 0, & \text{if } n = 0 \\ \lfloor \log_2 n \rfloor, & \text{otherwise.} \end{cases}$$

Here $\log_2 n$ refers to the logarithm to base 2. For the digit sum to base 2 we find the following equations useful whenever powers of 2 are involved somehow.

► **Lemma 6.** *Let n be a nonnegative integer. Then*

1. $S_2(2^n - 1) = n$ and
2. $S_2(n - 2^{\lambda(n)}) = S_2(n) - 1$.

Next we recall an alternative characterization of the digit sum to base 2 that proves useful in the forthcoming calculations.

► **Lemma 7.** *Let n be a nonnegative integer. Then*

$$S_2(n) = n - \sum_{i=1}^{\infty} \left\lfloor \frac{n}{2^i} \right\rfloor.$$

Observe, that the sum contains only a finite number of non-zero summands.

More generally, for prime q the sum $\sum_{i=1}^{\infty} \left\lfloor \frac{n}{q^i} \right\rfloor$ is famously known to be equal to the largest power of q that divides $n!$ (Legendre’s formula [22]). For non-prime q , the latter equality ceases to hold in general, because for $n = 8$ and $q = 4$ the largest integer power of 4 that divides $8!$ is 3, because $8! = (2 \cdot 4) \cdot 7 \cdot (2 \cdot 3) \cdot 5 \cdot 4 \cdot 3 \cdot 2 \cdot 1 = 7 \cdot 5 \cdot 4^3 \cdot 3^2 \cdot 2$, while the sum evaluates to 2.

The study of the following maximization problem

$$\max_{0 \leq i \leq n} \{S_2(i) + S_2(n - i)\}$$

is essential for our main result. Remarkably, the formula on the right-hand side of the identity in Lemma 8 below is famously known as the number of multiplications to compute the $(n + 1)$ th power by the ancient Indian *Chandah-sutra method*. This appears as sequence A014701 in the On-line Encyclopedia of Integer Sequences, and is referred to as the *left-to-right binary method*³ in [20, Chap. 4.6.3].

► **Lemma 8.** *Let n be a nonnegative integer. Then*

$$\max_{0 \leq i \leq n} \{S_2(i) + S_2(n - i)\} = \lambda(n + 1) + S_2(n + 1) - 1.$$

³ We note that the formula given in [20, p. 463] refers to the *right-to-left binary method*. As explained there, the latter takes one more multiplication than the left-to-right binary method.

Proof. Observe, that $S_2(n)$ denotes the Hamming weight of n , that is, the number of ones in the binary expansion of the number n . We shall prove first the easier inequality, namely $\max_{0 \leq i \leq n} \{S_2(i) + S_2(n - i)\} \geq \lambda(n + 1) + S_2(n + 1) - 1$. It suffices to find a suitable decomposition $n = j + (n - j)$ for some j , which attains the bound. We choose $j = n + 1 - 2^{\lambda(n+1)}$. Then j is equal to $n + 1$ modulo $2^{\lambda(n+1)}$, and thus their binary expansions differ only in the highest order bit. In other words, $S_2(j) = S_2(n + 1) - 1$ by Lemma 6.2. Also, by the finite geometric series expansion,

$$n - j = n - \left(n + 1 - 2^{\lambda(n+1)}\right) = 2^{\lambda(n+1)} - 1 = \sum_{i=0}^{\lambda(n+1)-1} 1 \cdot 2^i,$$

and thus $S_2(n - j) = \lambda(n + 1)$ – see Lemma 6.1.

The converse inequality requires more effort, namely to prove that

$$\max_{0 \leq i \leq n} \{S_2(i) + S_2(n - i)\} \leq \lambda(n + 1) + S_2(n + 1) - 1.$$

Our strategy is as follows. Given any decomposition $n = x + y$ with $x, y \geq 0$, we write x and y in binary positional notation $x_{\lambda(x)} \cdots x_1 x_0$ and $y_{\lambda(y)} \cdots y_1 y_0$. Then we shall apply a certain set of rules to x and y such that

- after each rule application, the sum of the two summands x' and y' thus obtained is n , that is, $x' + y' = n$,
- after each rule application, the sum of their Hamming weights is not decreased, that is, $S_2(x') + S_2(y') \geq S_2(x) + S_2(y)$, and
- after the last rule application, in the larger summand thus obtained, all bits are equal to 1.

This will of course suffice to show that the decomposition into j and $n - j$, as described at the beginning of the proof of this lemma, attains the maximum.

When looking at the bits of x and y , there are several constellations that need to be addressed. The first rule concerns the case $x_0 = y_0 = 0$, that is, the lowest order bits are both zero. Assume x is greater than or equal to y , otherwise we exchange the roles of x and y . Let ℓ denote the lowest order nonzero bit position of x , that is $x_\ell = 1$ and $x_k = 0$, for all k with $0 \leq k < \ell$. Then decreasing the number x by 1 amounts to setting $x_\ell = 0$ and $x_k = 1$, for all k with $0 \leq k < \ell$. Also, increasing the number y by 1 amounts to setting $y_0 = 1$, while all other bits of y remain unchanged. Observe, that this maneuver increases the Hamming weight of both summands. Also, the two summands thus obtained add up to n , and both summands have their lowest order bit set to 1. For an illustration of this situation we refer the reader to the left drawing of Figure 1.

We now generalize this to the case $x_i = y_i = 0$, for $0 \leq i < \lambda(x)$. Here again, we assume that $x \geq y$; otherwise we exchange the roles of x and y . Here essentially the same mechanism applies, but, roughly speaking, we need to “multiply everything” by 2^i . In the same spirit as above, let ℓ denote the lowest order nonzero bit position of x above i , that is $x_\ell = 1$ and $x_k = 0$, for all k with $i \leq k < \ell$. Note that ℓ is guaranteed to exist, since $x \geq y$. Observe, that decreasing the number x by 2^i amounts to setting $x_\ell = 0$ and $x_k = 1$, for all k with $i \leq k < \ell$. Also, increasing the number y by 2^i amounts to setting $y_i = 1$, while all other bits of y remain unchanged. So this maneuver increases the Hamming weight of both summands. Also, the obtained summands sum up to n , and both summands have their i th bit set to 1. This completes the description of the first rule. For an illustration of this situation we refer to the right drawing of Figure 1.

■ **Figure 1** First bit manipulation rule for the decomposition of n into x and y for the first situation (left), i.e., $x_0 = y_0 = 0$, and the general situation (right), i.e., $x_i = y_i = 0$, for $0 \leq i < \lambda(x)$.

We iteratively apply this rule to the resulting pair of summands from the previous round, for each i in increasing order, requiring that $x \geq y$ at the beginning at every round; otherwise the rôles of x and y are exchanged. After the $(i + 1)$ th round, no constellations remain with $x_r = y_r = 0$, for $0 \leq r \leq i$. Finally, for every i with $0 \leq i \leq \lambda(x)$, no constellations remain with $x_i = y_i = 0$.

When y denotes the smaller summand obtained by the above procedure, the constellations where $y_i = 1$ do not need to be fixed. The remaining constellations are those where $y_i = 0$ and $x_i = 1$, for some $i \leq \lambda(x)$. The second rule is to exchange the bit values, that is, we set $y_i = 1$ and $x_i = 0$. It is clear that the two summands thus obtained add up to n . Also, the sum of the Hamming weights is unaffected. We apply the second rule as often as needed, and the number of these rule applications is of course bounded by $\lambda(x) + 1$. For an illustration of the second rule we refer to Figure 2.

■ **Figure 2** Second bit manipulation rule for the decomposition of n into x and y that is applied as often as needed.

After all applications of the second rule, we end up with the larger summand having all bits set to 1. Since the other two conditions are invariant under application of both rules, this completes the proof. ◀

5 Optimal Expressions for the first k Palindromes in Lexicographic Order

Now that we have collected the necessary tools, we aim to solve the recurrence $f(n, k)$ also for the case where k is not a power of two. Recall that Lemma 3 allows us to write up the recurrence in simplified form, as follows:

$$f(n, k) = f(n - 1, k) + 2, \text{ for } n \geq 2 \text{ and } 2 \leq k \leq 2^{n-1},$$

$$f(n, k) = \min_{1 \leq i < k} \{f(n, i) + f(n, k - i)\}, \text{ for } n \geq 1 \text{ and } 2^{n-1} < k \leq 2^n,$$

and

$$f(n, 1) = 2n.$$

We transform this recurrence into a recurrence on one unknown within two steps. In the first step, we define another function in two unknowns in terms of $f(n, k)$.

► **Lemma 9.** *Let $g(n, k) := \frac{1}{2}f(n, k) - n$. Then $g(n, k)$ satisfies the recurrence*

$$g(n, k) = g(n - 1, k), \text{ for } n \geq 2 \text{ and } 2 \leq k \leq 2^{n-1},$$

$$g(n, k) = n + \min_{1 \leq i < k} \{g(n, i) + g(n, k - i)\}, \text{ for } n \geq 1 \text{ and } 2^{n-1} < k \leq 2^n,$$

and

$$g(n, 1) = 0.$$

We shall apply the second transformation only for the “interesting” parameter range of k , that is, when k is in the upper half of the admissible range. Namely, we observe, that whenever $2^{n-1} < k \leq 2^n$, then we can express n in terms of k as $n = 1 + \lambda(k - 1)$. Recalling that $\lambda(0) = 0$, we set

$$h(k) := g(1 + \lambda(k - 1), k), \text{ for } k \geq 1.$$

Then we find the following situation:

► **Lemma 10.** *Let $h(k) := g(1 + \lambda(k - 1), k)$, for $k \geq 1$. Then $h(k)$ satisfies the recurrence*

$$h(1) = 0$$

$$h(k) = 1 + \lambda(k - 1) + \min_{1 \leq i < k} \{h(i) + h(k - i)\} \text{ for } k \geq 2,$$

and it has the solution $h(k) = 2(k - 1) - S_2(k - 1)$.

It is worth mentioning that the formula in Lemma 10 implies that the values of the recurrence h , starting from $h(1)$, coincide with the (zero-based) sequence A005187 in the On-Line Encyclopedia of Integer Sequences – the numbers having a partition into distinct Mersenne numbers greater than zero.

Now let’s undo both transformations. We first determine $g(n, k)$ by using $h(k)$ and its explicit solution. Then, by elementary calculations we arrive at an alternative recurrence for $f(n, k)$.

► **Lemma 11.** *The function $f(n, k)$ satisfies the recurrence*

$$f(n, k) = f(n - 1, k) + 2, \text{ for } n \geq 2 \text{ and } 2 \leq k \leq 2^{n-1},$$

$$f(n, k) = 2n + 4(k - 1) - 2S_2(k - 1), \text{ for } n \geq 1 \text{ and } 2^{n-1} < k \leq 2^n,$$

and

$$f(n, 1) = 2n$$

and it has the solution $f(n, k) = 2n + 4(k - 1) - 2S_2(k - 1)$.

Proof. In order to undo both transformations, we first determine $g(n, k)$ by using $h(k)$ and its explicit solution from Lemma 10. We find

$$g(n, k) = g(n - 1, k), \text{ for } n \geq 2 \text{ and } 2 \leq k \leq 2^{n-1},$$

$$g(n, k) = 2(k - 1) - S_2(k - 1), \text{ for } n \geq 1 \text{ and } 2^{n-1} < k \leq 2^n,$$

and

$$g(n, 1) = 0,$$

52:10 Optimal Regular Expressions for Palindromes of Given Length

because, for $k > 2^{n-1}$ we have

$$\begin{aligned} g(n, k) &= g(1 + \lambda(k - 1), k) \\ &= h(k) \\ &= 2(k - 1) - S_2(k - 1). \end{aligned}$$

Finally, recall that $f(n, k) = 2(g(n, k) + n)$, which results in

$$f(n, k) = f(n - 1, k) + 2, \text{ for } n \geq 2 \text{ and } 2 \leq k \leq 2^{n-1},$$

and for $k > 2^{n-1}$ we calculate

$$\begin{aligned} f(n, k) &= 2(g(n, k) + n) \\ &= 2(2(k - 1) - S_2(k - 1) + n) \\ &= 2n + 4(k - 1) - 2S_2(k - 1). \end{aligned}$$

For the terminating cases of the recurrence, we simply recall those from the original recurrence defining $f(n, k)$:

$$f(n, 1) = 2n,$$

and this completes the proof.

It remains to solve the alternative recurrence, which is now done with ease. The statement is proved by lexicographic induction on (k, n) . Let $k = 1$, then $2n + 4(k - 1) - 2S_2(k - 1) = 2n$ is obviously an solution for any n . To show the statement for $k \geq 2$ and $n \geq 1$, we assume that the statement holds for all pairs (k', n') with $k' < k$, as well as for all pairs with $k' = k$ and $n' < n$. Then for the case $k > 2^{n-1}$ we have nothing to prove and in case $2 \leq k \leq 2^{n-1}$, we apply the induction hypothesis and get

$$\begin{aligned} f(n, k) &= f(n - 1, k) + 2 \\ &= 2(n - 1) + 4(k - 1) - 2S_2(k - 1) + 2 \\ &= 2n + 4(k - 1) - 2S_2(k - 1) \end{aligned}$$

as desired. ◀

With the lower bound in place, it remains to give an optimal regular expression matching the lower bound. The expression $E_{n,k}$ describes the lexicographically first k palindromes of length $2n$, and is defined recursively as follows:

$$\begin{aligned} E_{n,k} &= a \cdot E_{n-1,k} \cdot a, \text{ for } n \geq 1 \text{ and } 1 \leq k \leq 2^{n-1}, \\ E_{n,k} &= a \cdot E_{n-1,2^{n-1}} \cdot a + b \cdot E_{n-1,k-2^{n-1}} \cdot b, \text{ for } n \geq 1 \text{ and } 2^{n-1} < k \leq 2^n, \end{aligned}$$

and

$$E_{0,1} = \epsilon.$$

We can prove by induction that this recursive upper bound on the alphabetic width meets the lower bound:

► **Lemma 12.** For $n \geq 0$ and $k \geq 1$, $\text{awidth}(E_{n,k}) = f(n, k)$.

It remains to show that the definition of $E_{n,k}$ is semantically correct, in the sense that it describes exactly the set of the lexicographically first k palindromes.

► **Lemma 13.** *Let n, k be integers with $n \geq 0$ and $1 \leq k \leq 2^n$. Then the regular expression $E_{n,k}$ describes the lexicographically first k palindromes of length $2n$.*

Proof. We begin with a natural bijection between palindromes of length $2n$, for $n \geq 1$, and the nonnegative integers in the range $0, 1, \dots, 2^n - 1$: for a nonnegative integer j with $0 \leq j < 2^n$, with binary expansion $\sum_{r=0}^{\infty} j_r 2^r = k$, let $\rho : \{0 \mapsto a, 1 \mapsto b\}$, and let $\rho_n(j) = \rho(j_{n-1})\rho(j_{n-2}) \cdots \rho(j_0)$ denote the usual n -bit binary representation of j in positional notation – with leading zeros if needed. Define the family of functions σ_n by letting $\sigma_n(j) = \rho_n(j)\rho_n(j)^R$. Whenever n is understood from the context, we shall drop the subscript and write $\rho(j)$ instead of $\rho_n(j)$, and similarly for σ . Observe, that, among the palindromes of length $2n$, the word $\sigma(j)$ is the $(j+1)$ th palindrome in lexicographic order. Conversely, for a palindrome w of length $2n$, the preimage $\sigma^{-1}(w)$ equals the (zero-based) lexicographic index of w among the palindromes of length $2n$. For convenience, we extend the definition of σ_n to the case $n = 0$ by letting $\sigma_0(0) = \epsilon$.

We claim that, given $n \geq 1$ and k with $1 \leq k \leq 2^n$, as well as a nonnegative integer $j < k$, the word $\sigma(j)$ is in $L(E_{n,k})$. This claim will be proven by induction on n . The base case is $n = 0$. We thus have $k = 1$. Here, $\sigma_0(0) = \epsilon$, and $E_{0,1} = \epsilon$. For the induction step, we now assume $n \geq 1$. We consider two cases:

Case 1. Consider first the case $j < 2^{n-1}$. Then $\sigma_n(j) = a \cdot \sigma_{n-1}(j) \cdot a$. By the induction hypothesis, $\sigma_{n-1}(j) \in L(E_{n-1,k})$, and by the recursive definition of the regular expression $E_{n,k}$, we have $a \cdot L(E_{n-1,k}) \cdot a \subseteq L(E_{n,k})$. Hence, $\sigma(j) \in L(E_{n,k})$ in this case.

Case 2. The other case is $j \geq 2^{n-1}$. Then $\sigma_n(j) = b \cdot \sigma_{n-1}(j - 2^{n-1}) \cdot b$. Observe, that also $k > 2^{n-1}$ holds, since $j < k$. Let $k' = k - 2^{n-1}$ and $j' = j - 2^{n-1}$. Then $k' \geq 1$ and $j' \geq 0$, as well as $n - 1 \geq 0$. Using the induction hypothesis, we have $\sigma_{n-1}(j') \in L(E_{n-1,k'})$. In other words, $\sigma_{n-1}(j - 2^{n-1}) \in L(E_{n-1,k-2^{n-1}})$. Now, by the recursive definition of the regular expression $E_{n,k}$, we obtain $b \cdot L(E_{n-1,k-2^{n-1}}) \cdot b \subseteq L(E_{n,k})$. Hence, $\sigma(j) \in L(E_{n,k})$ also in this case.

This completes the induction, and the claim is established.

It remains to show that no other words are described by $E_{n,k}$. To this end, we note first that the recursive definition of $E_{n,k}$ ensures that it describes no non-palindromic words, and only words of length $2n$. Now let w be any word that is described by $E_{n,k}$. Recall that $\sigma^{-1}(w)$ is equal to the lexicographic index of w among all palindromes of length $2n$.

We shall prove by induction on n that the lexicographic index of every w described by $E_{n,k}$ is at most $k - 1$. In the base case $n = 0$, we must have $k = 1$ and $w = \epsilon$, and $\sigma^{-1}(w) = 0 = k - 1$ in this case. Now assume $n \geq 1$. We distinguish two cases:

Case 1. Consider first the case that the word w is the form axa . We need to consider two subcases. The first subcase is $k \leq 2^{n-1}$. Here, by definition of $E_{n,k}$, the word x is in $L(E_{n-1,k})$. Bearing in mind that $\sigma^{-1}(x) = \sigma_{n-1}^{-1}(x)$ and $\sigma^{-1}(w) = \sigma_n^{-1}(w)$ denote two different functions, we will again drop the subscripts for convenient reading. By the induction assumption, $\sigma^{-1}(x) \leq k - 1$. Recalling the bijection between natural numbers and palindromes, we have $\sigma^{-1}(axa) = \sigma^{-1}(x)$. With $axa = w$, we obtain $\sigma^{-1}(w) = \sigma^{-1}(x)$ in this subcase. The second subcase is $k > 2^{n-1}$. Here, by definition of $E_{n,k}$, the word x is in $L(E_{n-1,2^{n-1}})$. By the induction assumption, $\sigma^{-1}(x) \leq 2^{n-1} \leq k - 1$, and using again the bijection between natural numbers and palindromes, $\sigma^{-1}(w) = \sigma^{-1}(x)$.

Case 2. Now consider the case that the word w is of the form $bx b$. By the recursive definition of $E_{n,k}$, we can conclude that $x \in L(E_{n-1,k-2^{n-1}})$ – and that $k > 2^{n-1}$. By the induction assumption, $\sigma^{-1}(x) \leq k - 2^{n-1} - 1$. Recalling the bijection between natural numbers and palindromes, we have $\sigma^{-1}(bx b) = 2^{n-1} + \sigma^{-1}(x)$. Taking these two facts together, we obtain $\sigma^{-1}(w) = 2^{n-1} + \sigma^{-1}(x) \leq 2^{n-1} + k - 2^{n-1} - 1 \leq k - 1$, as desired.

This completes the proof of the second claim, and the proof of the lemma is completed. ◀

52:12 Optimal Regular Expressions for Palindromes of Given Length

We thus can summarize our findings about palindromes of even length in the last three lemmata in the following statement.

► **Theorem 14.** *Let k and n be integers, with $n \geq 0$ and $1 \leq k \leq 2^n$. Then the set of the lexicographically first k palindromes of length $2n$ over a binary alphabet requires regular expressions of alphabetic width exactly $2n + 4(k - 1) - 2S_2(k - 1)$.*

6 Alphabetic Width of Palindromes of Odd Length

We turn to palindromes of odd length. The recurrences essentially differ only in the terminating cases. But changing the starting conditions of a nonlinear system may, or may not, change everything. We thus provide a careful writeup.

To this end, for positive integer n , let \tilde{P}_n denote the set of palindromes of length $2n - 1$ over a binary alphabet. Now define $\tilde{\ell}(n, k)$ to be the minimum alphabetic width of a regular expression describing a subset of \tilde{P}_n , where the subset has cardinality at least k . Again by definition, $\tilde{\ell}(n, k)$ is monotone with respect to the parameter k .

► **Lemma 15.** *Let $n \geq 1$ and $1 \leq k \leq 2^n$. Then $\tilde{\ell}(n, k)$ obeys the following recurrence:*

$$\begin{aligned} \tilde{\ell}(n, k) &\geq \min\{\tilde{\ell}(n-1, k) + 2, \min_{1 \leq i < k} \{\tilde{\ell}(n, i) + \tilde{\ell}(n, k-i)\}\}, \text{ for } n \geq 2 \text{ and } 2 \leq k \leq 2^{n-1}, \\ \tilde{\ell}(n, k) &\geq \min_{1 \leq i < k} \{\tilde{\ell}(n, i) + \tilde{\ell}(n, k-i)\}, \text{ for } n \geq 1 \text{ and } k > 2^{n-1}, \end{aligned}$$

and

$$\tilde{\ell}(n, 1) = 2n - 1.$$

In analogy to the definition of the function f , let \tilde{f} denote the integer-valued function which is defined by that recurrence, that is,

$$\begin{aligned} \tilde{f}(n, k) &= \min\{\tilde{f}(n-1, k) + 2, \min_{1 \leq i < k} \{\tilde{f}(n, i) + \tilde{f}(n, k-i)\}\}, \text{ for } n \geq 2 \text{ and } 2 \leq k \leq 2^{n-1}, \\ \tilde{f}(n, k) &= \min_{1 \leq i < k} \{\tilde{f}(n, i) + \tilde{f}(n, k-i)\}, \text{ for } n \geq 1 \text{ and } 2^{n-1} < k \leq 2^n, \end{aligned}$$

and

$$\tilde{f}(n, 1) = 2n - 1.$$

We estimate the values of the function $\tilde{f}(n, k)$ as follows:

► **Lemma 16.** *Let $n \geq 1$ and $1 \leq k \leq 2^n$. Then $\tilde{f}(n, k) = f(n, k) - k$.*

Thus, we immediately obtain:

► **Lemma 17.** $\tilde{f}(n, 2^n) = 3 \cdot 2^n - 4$.

With the lower bound in place, it remains to give an optimal regular expression matching the lower bound. The expression $\tilde{E}_{n,k}$ is defined recursively as follows.

$$\begin{aligned} \tilde{E}_{n,k} &= a \cdot \tilde{E}_{n-1,k} \cdot a, \text{ for } n \geq 2 \text{ and } 1 \leq k \leq 2^{n-1}, \\ \tilde{E}_{n,k} &= a \cdot \tilde{E}_{n-1,2^{n-1}} \cdot a + b \cdot \tilde{E}_{n-1,k-2^{n-1}} \cdot b, \text{ for } n \geq 2 \text{ and } 2^{n-1} < k \leq 2^n, \end{aligned}$$

and

$$\tilde{E}_{1,1} = a \text{ as well as } \tilde{E}_{1,2} = a + b.$$

The semantic correctness proof runs along the lines of the proof of Lemma 13.

► **Lemma 18.** *Let n, k be integers with $n \geq 1$ and $1 \leq k \leq 2^n$. Then the regular expression $\tilde{E}_{n,k}$ describes the lexicographically first k palindromes of length $2n - 1$.*

It remains to show that the alphabetic width of $\tilde{E}_{n,k}$ meets the lower bound. An easy induction reduces this to the case of even length palindromes, in a similar vein as we did it in Lemma 16.

► **Lemma 19.** *Let n, k be integers with $n \geq 1$ and $1 \leq k \leq 2^n$. Then $\text{awidth}(\tilde{E}_{n,k}) = \text{awidth}(E_{n,k}) - k$.*

We thus can summarize our findings about palindromes of odd length in the following theorem – compare with Theorem 14.

► **Theorem 20.** *Let k and n be integers, with $n \geq 1$ and $1 \leq k \leq 2^n$. Then the set of the lexicographically first k palindromes of length $2n - 1$ over a binary alphabet requires regular expressions of alphabetic width exactly $2n + 3(k - 1) - 2S_2(k - 1) - 1$.*

We conclude this section with a curious observation, which was contributed by an anonymous reviewer. Recall that

$$\tilde{\ell}(n, k) = \min_{\substack{|L| \geq k \\ L \subseteq \tilde{P}_n}} \{\text{awidth}(L)\},$$

that is, $\tilde{\ell}(n, k)$ denotes the minimum alphabetic width of a regular expression describing a subset of \tilde{P}_n , where the subset has cardinality at least k . Then the analysis in the present work establishes that the minimum is attained by the set of the lexicographically first k palindromes, and a corresponding statement holds in the even length case. This observation is summarized in the following theorem (which no longer needs to distinguish between even and odd length):

► **Theorem 21.** *For $n \geq 0$ and $1 \leq k \leq 2^{\lceil n/2 \rceil}$, let Pal_n denote the set of palindromes of length n , and let $\text{Lex}_{n,k}$ denote the set of the lexicographically first k palindromes of length n . Then*

$$\text{Lex}_{n,k} \in \underset{\substack{|L| \geq k \\ L \subseteq \text{Pal}_n}}{\text{argmin}} \text{awidth}(L).$$

As the reviewer pointed out, this is reminiscent of the Kruskal-Katona Theorem from extremal combinatorics, see, e.g., [19]. Among several equivalent formulations of that theorem, one of them deals with minimization of the size of shadows in layers of the Boolean hypercube. The Kruskal-Katona Theorem then states that initial segments with respect to a version of the lexicographic ordering form sets with the smallest shadow possible.

7 Conclusion

Most lower bound proofs for regular expression size can be put into the following three categories: proofs based on (arithmetic) circuit complexity, e.g., [4, 7, 14], proofs based on the star height lemma, e.g., [9, 12, 13], and specialized proofs that are tailor-made for a specific language family, e.g., [2, 6, 10, 23]. While the present work falls into the third category, the lower bound method is quite similar to the one for permutations [23]. We expect that the method can be expanded to further families of finite languages, where the best known regular expressions have a divide-and-conquer flavor. A few examples from the literature come to mind:

- First, the binomial language $B_{n,k} = \{w \in \{0,1\}^n : |w|_1 = k\}$. A regular expression of divide-and-conquer flavor having size $n^{O(\log k)}$ for this language was proposed in [7], and the question of optimality was posed as an open problem. In [4], methods from arithmetic circuit complexity are utilized to derive a lower bound of $nk^{\Omega(\log k)}$.
- Regarding larger alphabets, the less-than relation on an n -set is given as $\{ij \mid 1 \leq i < j \leq n\}$. For this language, the minimum required regular expression size was determined exactly in [2], which implies a lower bound on the complexity of rectifier networks. This language naturally generalizes to the set of increasing sequences of length k over an n -set. For this an arithmetic formula lower bound was derived in [17]. As pointed out in [4], that result transfers to lower bounds on regular expression size.
- For the set of permutations of an n -set, the exact bound was determined in [23], and an asymptotic lower bound is given in [4] using a different method. Its natural generalization is the set of k -permutations of an n -set. The nondeterministic state complexity of this language is studied in [1]. Their motivation is that a lower bound on nondeterministic state complexity gives lower bounds on the running time for parameterized algorithms following the divide-and-conquer paradigm. We claim that, by the well-nested nature of divide-and-conquer, a (potentially higher) lower bound on regular expression size would serve this goal equally well.

The cited examples witness a lot of cross-fertilization between lower bound methods on various models of computation, including arithmetic circuits, rectifier networks, families of parameterized algorithms, and, of course, regular expressions.

Abstract

We study the expressiveness and succinctness of good-for-games pushdown automata (GFG-PDA) over finite words, that is, pushdown automata whose nondeterminism can be resolved based on the run constructed so far, but independently of the remainder of the input word.

We prove that GFG-PDA recognise more languages than deterministic PDA (DPDA) but not all context-free languages (CFL). This class is orthogonal to unambiguous CFL. We further show that GFG-PDA can be exponentially more succinct than DPDA, while PDA can be double-exponentially more succinct than GFG-PDA. We also study GFGness in visibly pushdown automata (VPA), which enjoy better closure properties than PDA, and for which we show GFGness to be EXPTIME-complete. GFG-VPA can be exponentially more succinct than deterministic VPA, while VPA can be exponentially more succinct than GFG-VPA. Both of these lower bounds are tight.

Finally, we study the complexity of resolving nondeterminism in GFG-PDA. Every GFG-PDA has a positional resolver, a function that resolves nondeterminism and that is only dependant on the current configuration. Pushdown transducers are sufficient to implement the resolvers of GFG-VPA, but not those of GFG-PDA. GFG-PDA with finite-state resolvers are determinisable.

1 Introduction

Nondeterminism adds both expressiveness and succinctness to deterministic pushdown automata. Indeed, the class of context-free languages (CFL), recognised by nondeterministic pushdown automata (PDA), is strictly larger than the class of deterministic context-free languages (DCFL), recognised by deterministic pushdown automata (DPDA), both over finite and infinite words. Even when restricted to languages in DCFL, there is no computable bound on the relative succinctness of PDA [15, 38]. In other words, nondeterminism is remarkably powerful, even for representing deterministic languages. The cost of such succinct representations is algorithmic: problems such as universality and solving games with a CFL winning condition are undecidable for PDA [11, 19], while they are decidable for DPDA [39].

Intermediate forms of automata that lie between deterministic and nondeterministic models have the potential to mitigate some of the disadvantages of fully nondeterministic automata while retaining some of the benefits of the deterministic ones.

Unambiguity and bounded ambiguity, for example, restrict nondeterminism by requiring words to have at most one or at most k , for some fixed k , accepting runs. Holzer and Kutrib survey the noncomputable succinctness gaps between unambiguous PDA and both PDA and DPDA [18], while Okhotin and Salomaa show that unambiguous visibly pushdown automata are exponentially more succinct than DPDA [31]. Universality of unambiguous PDA is decidable, as it is decidable for unambiguous context-free grammars [33], which are effectively equivalent [17]. However, to the best of our knowledge, unambiguity is not known to reduce the algorithmic complexity of solving games with a context-free winning condition.

Another important type of restricted nondeterminism that is known to reduce the complexity of universality and solving games has been studied under the names of good-for-games (GFG) nondeterminism [16] and history-determinism [10]. Intuitively, a nondeterministic automaton is GFG if its nondeterminism can be resolved on-the-fly, i.e. without knowledge of the remainder of the input word to be processed.

For finite automata on finite words, where nondeterminism adds succinctness, but not expressiveness, GFG nondeterminism does not even add succinctness: every GFG-NFA contains an equivalent DFA [6], which can be obtained by pruning transitions from the GFG-NFA. Thus, GFG-NFA cannot be more succinct than DFA. But for finite automata on infinite words, where nondeterminism again only adds succinctness, but not expressiveness, GFG coBüchi automata can be exponentially more succinct than deterministic automata [23]. Finally, for certain quantitative automata over infinite words, GFG nondeterminism adds as much expressiveness as arbitrary nondeterminism [10].

Recently, pushdown automata on infinite words with GFG nondeterminism (ω -GFG-PDA) were shown to be strictly more expressive than ω -DPDA, while universality and solving games for ω -GFG-PDA are not harder than for ω -DPDA [25]. Thus, GFG nondeterminism adds expressiveness without increasing the complexity of these problems, i.e. pushdown automata with GFG nondeterminism induce a novel and intriguing class of context-free ω -languages.

Here, we continue this work by studying the expressiveness *and* succinctness of PDA over finite words. While the decidability results for ω -GFG-PDA on infinite words also hold for GFG-PDA on finite words, the separation argument between ω -GFG-PDA and ω -DPDA depends crucially on combining GFG nondeterminism with the coBüchi acceptance condition. Since this condition is only relevant for infinite words, the separation result does not transfer to the setting of finite words.

Nevertheless, we prove that GFG-PDA are more expressive than DPDA, yielding the first class of automata on finite words where GFG nondeterminism adds expressiveness. The language witnessing the separation is remarkably simple, in contrast to the relatively subtle argument for the infinitary result [25]: the language $\{a^i a^j b^k \mid k \leq \max(i, j)\}$ is recognised by a GFG-PDA but not by a DPDA. This yields a new class of languages, those recognised by GFG-PDA over finite words, for which universality and solving games are decidable. We also show that this class is incomparable with unambiguous context-free languages.

We then turn our attention to succinctness of GFG-PDA. We show that the succinctness gap between DPDA and GFG-PDA is at least exponential, while the gap between GFG-PDA and PDA is at least double-exponential. These results hold already for finite words.

To the best of our knowledge, both our expressiveness and our succinctness results are the first examples of good-for-games nondeterminism being used effectively over finite, rather than infinite, words (recall that all GFG-NFA are determinisable by pruning). Also, this

is the first succinctness result for good-for-games automata that does not depend on the infinitary coBüchi acceptance condition, which was used to show the exponential succinctness of GFG coBüchi automata, as compared to deterministic ones [23].

We then study an important subclass of GFG-PDA, namely, GFG visibly pushdown automata (VPA), in which the stack behaviour (push, pop, skip) is determined by the input letter only. GFG-VPA enjoy the good closure properties of VPA (to which they are expressively equivalent): they are closed under complement, union and intersection. We show that there is an exponential succinctness gap between deterministic VPA (DVPA) and GFG-VPA, as well as between GFG-VPA and VPA. Both of these are tight, as VPA, and therefore GFG-VPA as well, admit an exponential determinisation procedure [2]. Furthermore, we show that GFGness of VPA is decidable in EXPTIME. This makes GFG-VPA a particularly interesting class of PDA as they are recognisable, succinct, have good closure properties and deciding universality and solving games are both in EXPTIME. In contrast, solving ω -VPA games is 2EXPTIME-complete [27]. We also relate the problem of checking GFGness with the *good-enough synthesis* [1] or *uniformization* problem [9], which we show to be EXPTIME-complete for DVPA and GFG-PDA.

Nondeterminism in GFG automata is resolved on-the-fly, i.e. the next transition to be taken only depends on the run prefix constructed so far and the next letter to be processed. Thus, the complexity of a resolver, mapping run prefixes and letters to transitions, is a natural complexity measure for GFG automata. For example, finite GFG automata (on finite and infinite words) have a finite-state resolver [16]. For pushdown automata with their infinite configuration space, the situation is markedly different: On one hand, we show that GFG-PDA admit positional resolvers, that is, resolvers that depend only on the current configuration, rather than on the entire run prefix produced so far. Note that this result only holds for GFG-PDA over finite words, but not for ω -GFG-PDA. Yet, positionality does not imply that resolvers are simple to implement. We show that there are GFG-PDA that do not admit a resolver implementable by a pushdown transducer. In contrast, all GFG-VPA admit pushdown resolvers, again showing that GFG-VPA are better behaved than general GFG-PDA. Finally, GFG-PDA with finite-state resolvers are determinisable.

All proofs omitted due to space restrictions can be found in the full version [14].

Related work

The notion of GFG nondeterminism has emerged independently several times, at least as Colcombet's history-determinism [10], in Piterman and Henzinger's GFG automata [16], and as Kupferman, Safra, and Vardi's nondeterminism for recognising derived languages, that is, the language of trees of which all branches are in a regular language [24]. Related notions have also emerged in the context of XML document parsing. Indeed, preorder typed visibly pushdown languages and 1-pass preorder typeable tree languages, considered by Kumar, Madhusudan, and Viswanathan [21] and Martens, Neven, Schwentick, and Bex [28] respectively, also consider nondeterminism which can be resolved on-the-fly. However, the restrictions there are stronger than simple GFG nondeterminism, as they also require the typing to be unique, roughly corresponding to unambiguity in automata models and grammars. This motivates the further study of unambiguous GFG automata, although this remains out of scope for the present paper. The XML extension AXML has also inspired Active Context Free Games [29], in which one player, aiming to produce a word within a target regular language, chooses positions on a word and the other player chooses a rewriting rule from a context-free grammar. Restricting the strategies of the first player to moving from left to right makes finding the winner decidable [29, 5]; however, since the player still knows the future of the word, this restriction is not directly comparable to GFG nondeterminism.

Unambiguity, or bounded ambiguity, is an orthogonal way of restricting nondeterminism by limiting the number of permitted accepting runs per word. For regular languages, it leads to polynomial equivalence and containment algorithms [37]. Minimization remains NP-complete for both unambiguous automata [20, 4] and GFG automata [35] (at least when acceptance is defined on states, see [32]). On pushdown automata, increasing the permitted degree of ambiguity leads to both greater expressiveness and unbounded succinctness [17]. Finally, let us mention two more ways of measuring—and restricting—nondeterminism in PDA: bounded nondeterminism, as studied by Herzog [17] counts the branching in the run-tree of a word, while the minmax measure [34, 13] counts the number of nondeterministic guesses required to accept a word. The natural generalisation of GFGness as the *width* of an automaton [22] has not yet, to the best of our knowledge, been studied for PDA.

2 Preliminaries

An alphabet Σ is a finite nonempty set of letters. The empty word is denoted by ε , the length of a word w is denoted by $|w|$, and the n^{th} letter of w is denoted by $w(n)$ (starting with $n = 0$). The set of (finite) words over Σ is denoted by Σ^* , the set of nonempty (finite) words over Σ by Σ^+ , and the set of finite words of length at most n by $\Sigma^{\leq n}$. A language over Σ is a subset of Σ^* .

For alphabets Σ_1, Σ_2 , we extend functions $f: \Sigma_1 \rightarrow \Sigma_2^*$ homomorphically to words over Σ_1 via $f(w) = f(w(0))f(w(1))f(w(2)) \cdots$.

2.1 Pushdown automata

A pushdown automaton (PDA for short) $\mathcal{P} = (Q, \Sigma, \Gamma, q_I, \Delta, F)$ consists of a finite set Q of states with the initial state $q_I \in Q$, an input alphabet Σ , a stack alphabet Γ , a transition relation Δ to be specified, and a set F of final states. For notational convenience, we define $\Sigma_\varepsilon = \Sigma \cup \{\varepsilon\}$ and $\Gamma_\perp = \Gamma \cup \{\perp\}$, where $\perp \notin \Gamma$ is a designated stack bottom symbol. Then, the transition relation Δ is a subset of $Q \times \Gamma_\perp \times \Sigma_\varepsilon \times Q \times \Gamma_\perp^{\leq 2}$ that we require to neither write nor delete the stack bottom symbol from the stack: If $(q, \perp, a, q', \gamma) \in \Delta$, then $\gamma \in \perp \cdot (\Gamma \cup \{\varepsilon\})$, and if $(q, X, a, q', \gamma) \in \Delta$ for $X \in \Gamma$, then $\gamma \in \Gamma^{\leq 2}$. Given a transition $\tau = (q, X, a, q', \gamma)$ let $\ell(\tau) = a \in \Sigma_\varepsilon$. We say that τ is an $\ell(\tau)$ -transition and that τ is a Σ -transition, if $\ell(\tau) \in \Sigma$. For a finite sequence ρ over Δ , the word $\ell(\rho) \in \Sigma^*$ is defined by applying ℓ homomorphically to every transition. We take the size of \mathcal{P} to be $|Q| + |\Gamma|$.¹

A stack content is a finite word in $\perp\Gamma^*$ (i.e. the top of the stack is at the end) and a configuration $c = (q, \gamma)$ of \mathcal{P} consists of a state $q \in Q$ and a stack content γ . The initial configuration is (q_I, \perp) .

The set of modes of \mathcal{P} is $Q \times \Gamma_\perp$. A mode (q, X) enables all transitions of the form (q, X, a, q', γ') for some $a \in \Sigma_\varepsilon$, $q' \in Q$, and $\gamma' \in \Gamma_\perp^{\leq 2}$. The mode of a configuration $c = (q, \gamma X)$ is (q, X) . A transition τ is enabled by c if it is enabled by c 's mode. In this case, we write $(q, \gamma X) \xrightarrow{\tau} (q', \gamma\gamma')$, where $\tau = (q, X, a, q', \gamma')$.

A run of \mathcal{P} is a finite sequence $\rho = c_0\tau_0c_1\tau_1 \cdots c_{n-1}\tau_{n-1}c_n$ of configurations and transitions with c_0 being the initial configuration and $c_{n'} \xrightarrow{\tau_{n'}} c_{n'+1}$ for every $n' < n$. The run ρ is a run of \mathcal{P} on $w \in \Sigma^*$, if $w = \ell(\rho)$. We say that ρ is accepting if it ends in a configuration whose state is final. The language $L(\mathcal{P})$ recognized by \mathcal{P} contains all $w \in \Sigma^*$ such that \mathcal{P} has an accepting run on w .

¹ Note that we prove exponential succinctness gaps, so the exact definition of the size is irrelevant, as long as it is polynomial in $|Q|$ and $|\Gamma|$. Here, we pick the sum for the sake of simplicity.

■ **Figure 1** The PDA \mathcal{P} from Example 2. Grey states are final, and X is an arbitrary stack symbol.

► **Remark 1.** Let $c_0\tau_0c_1\tau_1\cdots c_{n-1}\tau_{n-1}c_n$ be a run of \mathcal{P} . Then, the sequence $c_0c_1\cdots c_{n-1}c_n$ of configurations is uniquely determined by the sequence $\tau_0\tau_1\cdots\tau_{n-1}$ of transitions. Hence, whenever convenient, we treat a sequence of transitions as a run if it indeed induces one (not every such sequence does induce a run, e.g. if a transition $\tau_{n'}$ is not enabled in $c_{n'}$).

We say that a PDA \mathcal{P} is deterministic (DPDA) if

- every mode of \mathcal{P} enables at most one a -transition for every $a \in \Sigma \cup \{\varepsilon\}$, and
- for every mode of \mathcal{P} , if it enables some ε -transition, then it does not enable any Σ -transition.

Hence, for every input and for every run prefix on it there is at most one enabled transition to continue the run. Still, due to the existence of ε -transitions, a DPDA can have more than one run on a given input. However, these only differ by trailing ε -transitions.

The class of languages recognized by PDA is denoted by CFL, the class of languages recognized by DPDA by DCFL.

► **Example 2.** The PDA \mathcal{P} depicted in Figure 1 recognizes the language $\{ac^nd^na \mid n \geq 1\} \cup \{bc^nd^{2n}b \mid n \geq 1\}$. Note that while \mathcal{P} is nondeterministic, $L(\mathcal{P})$ is in DCFL.

2.2 Good-for-games Pushdown Automata

Here, we introduce good-for-games pushdown automata on finite words (GFG-PDA for short), nondeterministic pushdown automata whose nondeterminism can be resolved based on the run prefix constructed so far and on the next input letter to be processed, but independently of the continuation of the input beyond the next letter.

As an example, consider the PDA \mathcal{P} from Example 2. It is nondeterministic, but knowing whether the first transition of the run processed an a or a b allows the nondeterminism to be resolved in a configuration of the form $(q, \gamma N)$ when processing a d : in the former case, take the transition to state q_1 , in the latter case the transition to state q_2 . Afterwards, there are no nondeterministic choices to make and the resulting run is accepting whenever the input is in the language. This automaton is therefore good-for-games.

Formally, a PDA $\mathcal{P} = (Q, \Sigma, \Gamma, q_I, \Delta, F)$ is good-for-games if there is a (nondeterminism) resolver for \mathcal{P} , a function $r: \Delta^* \times \Sigma \rightarrow \Delta$ such that for every $w \in L(\mathcal{P})$, there is an accepting run $\rho = c_0\tau_0\cdots\tau_n c_n$ on w that has no trailing ε -transitions, i.e.

1. $n = 0$ if $w = \varepsilon$ (which implies that c_0 is accepting), and
2. $\ell(\tau_0\cdots\tau_{n-1})$ is a strict prefix of w , if $w \neq \varepsilon$,
and $\tau_{n'} = r(\tau_0\cdots\tau_{n'-1}, w(|\ell(\tau_0\cdots\tau_{n'-1})|))$ for all $0 \leq n' < n$. If w is nonempty, then $w(|\ell(\tau_0\cdots\tau_{n'-1})|)$ is defined for all $0 \leq n' < n$ by the second requirement. Note that ρ is unique if it exists.

Note that the prefix processed so far can be recovered from r 's input, i.e. it is $\ell(\rho)$. However, the converse is not true due to the existence of ε -transitions. This is the reason that the run prefix and not the input prefix is the argument for the resolver. We denote the class of languages recognised by GFG-PDA by GFG-CFL.

Intuitively, every DPDA *should* be good-for-games, as there is no nondeterminism to resolve during a run. However, in order to reach a final state, a run of a DPDA on some input w may traverse *trailing* ε -transitions after the last letter of w is processed. On the other hand, the run of a GFG-PDA on w consistent with any resolver has to end with the transition processing the last letter of w . Hence, not every DPDA recognises the same language when viewed as a GFG-PDA. Nevertheless, we show, using standard pushdown automata constructions, that every DPDA can be turned into an equivalent GFG-PDA. As every GFG-PDA is a PDA by definition, we obtain a hierarchy of languages.

► **Lemma 3.** $DCFL \subseteq GFG-CFL \subseteq CFL$.

Instead of requiring that GFG-PDA end their run with the last letter processed, one could add an end-of-word marker that allows traversing trailing ε -transitions after the last letter has been processed. In Appendix A.1, we show that this alternative definition does not increase expressiveness, which explains our (arguably simpler) definition.

Finally, let us remark that GFGness of PDA and context-free languages is undecidable. These problems were shown to be undecidable for ω -GFG-PDA and ω -GFG-CFL by reductions from the inclusion and universality problem for PDA on finite words [25]. The same reductions also show that these problems are undecidable over PDA on finite words.

► **Theorem 4.** *The following problems are undecidable:*

1. Given a PDA \mathcal{P} , is \mathcal{P} a GFG-PDA?
2. Given a PDA \mathcal{P} , is $L(\mathcal{P}) \in GFG-CFL$?

2.3 Games and Universality

One of the motivations for GFG automata is that solving games with winning conditions given by a GFG automaton is easier than for nondeterministic automata. This makes them appealing for applications such as the synthesis of reactive systems, which can be modelled as a game between an antagonistic environment and the system. Solving games is undecidable for PDA in general [11], both over finite and infinite words, while for ω -GFG-PDA, it is EXPTIME-complete [25]. As a corollary, universality is also decidable for ω -GFG-PDA, while it is undecidable for PDA, both over finite and infinite words [19].

Here, we consider Gale-Stewart games [12], abstract games induced by a language in which two players alternately pick letters, thereby constructing an infinite word. One player aims to construct a word that is in the language while the other aims to construct one that is not in the language. Note that these games are different, but related, to games played on configuration graphs of pushdown automata [39].

Formally, given a language $L \subseteq (\Sigma_1 \times \Sigma_2)^*$ of sequences of letter pairs, the game $G(L)$ is played between Player 1 and Player 2 in rounds $i = 0, 1, \dots$ as follows: At each round i , Player 1 plays a letter $a_i \in \Sigma_1$ and Player 2 answers with a letter $b_i \in \Sigma_2$. A play of $G(L)$ is an infinite word $\binom{a_0}{b_0} \binom{a_1}{b_1} \dots$ and Player 2 wins such a play if and only if each of its prefixes is in the language L . A strategy for Player 2 is a mapping from Σ_1^+ to Σ_2 that gives for each prefix played by Player 1 the next letter to play. A play agrees with a strategy σ if for each i , $b_i = \sigma(a_0 a_1 \dots a_i)$. Player 2 wins $G(L)$ if she has a strategy that only agrees with plays that are winning for Player 2. Observe that Player 2 loses whenever the projection of L onto its first component is not universal. Finally, universality reduces to solving these games: \mathcal{P} is universal if and only if Player 2 wins $G(L)$ for $L = \{ \binom{w(0)}{\#} \dots \binom{w(n)}{\#} \mid w(0) \dots w(n) \in L(\mathcal{P}) \}$.

We now argue that solving games for GFG-PDA easily reduces to the case of ω -GFG-PDA, which are just GFG-PDA over infinite words, where acceptance is not determined by final state, since runs are infinite, but rather by the states or transitions visited infinitely often.

Here, we only need safety ω -GFG-PDA, in which every infinite run is accepting (i.e. rejection is implemented via missing transitions). The infinite Gale-Stewart game over a language L of infinite words, also denoted by $G(L)$, is as above, except that victory is determined by whether the infinite word built along the play is in L .

► **Lemma 5.** *Given a GFG-PDA \mathcal{P} , there is a safety ω -GFG-PDA \mathcal{P}' no larger than \mathcal{P} such that Player 2 wins $G(L(\mathcal{P}))$ if and only if she wins $G(L(\mathcal{P}'))$.*

Proof. Let \mathcal{P}' be the PDA obtained from \mathcal{P} by removing all transitions (q, X, a, q', γ) of \mathcal{P} with $a \in \Sigma$ and with non-final q' .

With a safety condition, in which every infinite run is accepting, \mathcal{P}' recognises exactly those infinite words whose prefixes are all accepted by \mathcal{P} . Hence, the games $G(L(\mathcal{P}))$ and $G(L(\mathcal{P}'))$ have the same winning player. Note that the correctness of this construction crucially relies on our definition of GFG-PDA, which requires a run on a finite word to end as soon as the last letter is processed. Then, the word is accepted if and only if the state reached by processing this last letter is final.

Finally, since \mathcal{P} is GFG, so is \mathcal{P}' . Consider an infinite input in $L(\mathcal{P}')$. Then, every prefix w has an accepting run of \mathcal{P} induced by its resolver, which implies that the last transition of this run (which processes the last letter of w) is not one of those that are removed to obtain \mathcal{P}' . Now, an induction shows that the same resolver works for \mathcal{P}' as well, relying on the fact that if w and w' with $|w| < |w'|$ are two such prefixes, then the resolver-induced run of \mathcal{P} on w is a prefix of the resolver-induced run of \mathcal{P} on w' . ◀

Our main results of this section are now direct consequences of the corresponding results on ω -words [25].

► **Corollary 6.** *Given a GFG-PDA \mathcal{P} , deciding whether $L(\mathcal{P}) = \Sigma^*$ and whether Player 2 wins $G(L(\mathcal{P}))$ are both in EXPTIME.*

2.4 Closure properties

Like ω -GFG-PDA, GFG-PDA have poor closure properties.

► **Theorem 7.** *GFG-PDA are not closed under union, intersection, complementation, set difference and homomorphism.*

The proofs are similar to those used for ω -GFG-PDA and relegated to the full version [14]. There, we also study the closure properties under these operations with regular languages: If L is in GFG-CFL and R is regular, then $L \cup R$, $L \cap R$ and $L \setminus R$ are also in GFG-CFL, but $R \setminus L$ is not necessarily in GFG-CFL.

3 Expressiveness

Here we show that GFG-PDA are more expressive than DPDA but less expressive than PDA.

► **Theorem 8.** $DCFL \subsetneq GFG-CFL \subsetneq CFL$.

To show that GFG-PDA are more expressive than deterministic ones, we consider the language $B_2 = \{a^i \$ a^j \$ b^k \$ \mid k \leq \max(i, j)\}$. It is recognised by the PDA \mathcal{P}_{B_2} depicted in Figure 2, hence $B_2 \in CFL$. The first two states q_1 and q_2 deterministically push the input onto the stack, until the occurrence of the second $\$$. When the second $\$$ is processed, there is a nondeterministic choice to move to p_1 or p_2 and erase along ε -transitions 1 or 0 blocks

■ **Figure 2** A PDA \mathcal{P}_{B_2} recognising B_2 . Grey states are final, and X is an arbitrary stack symbol.

from the stack, so that the 1st or 2nd block of a 's respectively remains at the top of the stack. Then, the automaton compares the length of the b -block in the input with the length of the a -block at the top of the stack and accepts if the b -block is shorter, i.e. the third $\$$ is processed before the whole a -block is popped off the stack. If the input has not the form $a^i\$a^j\$b^k\$\$, then it is rejected.

We show that $B_2 \in \text{GFG-CFL}$ by proving that \mathcal{P}_{B_2} is good-for-games: the nondeterministic choice between moving to p_1 or to p_2 can be made only based on the prefix $a^i\$a^j$ processed so far. This is straightforward, as a resolver only needs to know which of i and j is larger, which can be determined from the run prefix constructed thus far. Then, in order to show that B_2 is not in DCFL , we prove that its complement B_2^c is not a context-free language. Since DCFL is closed under complementation, this implies the desired result.

Finally, to show that PDA are more expressive than GFG-PDA, we consider the language $L = \{a^n b^n \mid n \geq 0\} \cup \{a^n b^{2n} \mid n \geq 0\}$. We note that $L \in \text{CFL}$ while we show below $L \notin \text{GFG-CFL}$.

Unambiguous context-free languages, i.e. those generated by grammars for which every word in the language has a unique leftmost derivation, are another class sitting between DCFL and CFL . Thus, it is natural to ask how unambiguity and GFGness are related: To conclude this section, we show that both notions are independent.

► **Theorem 9.** *There is an unambiguous context-free language that is not in GFG-CFL and a language in GFG-CFL that is inherently ambiguous.*

An unambiguous grammar for the language $\{a^n b^n \mid n \geq 0\} \cup \{a^n b^{2n} \mid n \geq 0\} \notin \text{GFG-CFL}$ is easy to construct and we show that the language $B = \{a^i b^j c^k \mid i, j, k \geq 1, k \leq \max(i, j)\}$ is inherently ambiguous. Its inclusion in GFG-CFL is easily established using a similar argument as for the language $B_2 = \{a^i\$a^j\$b^k\$\mid k \leq \max(i, j)\}$ above. The dollars add clarity to the GFG-PDA but are cumbersome in the proof of inherent ambiguity.

4 Succinctness

We show that GFG-PDA are not only more expressive than DPDA, but also more succinct. Similarly, we show that PDA are more succinct than GFG-PDA.

► **Theorem 10.** *GFG-PDA can be exponentially more succinct than DPDA, and PDA can be double-exponentially more succinct than GFG-PDA.*

We first show that GFG-PDA can be exponentially more succinct than DPDA. To this end, we construct a family $(C_n)_{n \in \mathbb{N}}$ of languages such that C_n is recognised by a GFG-DPDA of size $O(n)$, yet every DPDA recognising C_n has at least exponential size in n .

Let $c_n \in (\{0, 1\}^n)^*$ be the word describing an n -bit binary counter counting from 0 to $2^n - 1$. For example, $c_2 = \$00\$01\$10\11 . We consider the family of languages $C_n = \{w \in \{0, 1, \$, \#\}^* \mid w \neq c_n\#\} \subseteq \{0, 1, \$, \#\}^*$ of bad counters.

We show that the language C_n is recognised by a GFG-PDA of size $O(n)$ and that every DPDA \mathcal{D} recognising C_n has exponential size in n . Observe that this result implies that even GFG-PDA that are equivalent to DPDA are not determinisable by pruning. In contrast, for NFA, GFGness implies determinisability by pruning [6].

We conclude this section by showing that PDA can be double-exponentially more succinct than GFG-PDA. We show that there exists a family $(L_n)_{n>0}$ of languages such that L_n is recognised by a PDA of size $O(\log n)$ while every GFG-PDA recognising this language has at least exponential size in n .

Formally, we set $L_n = (0+1)^*1(0+1)^{n-1}$, that is, the n^{th} bit from the end is a 1. We count starting from 1, so that the last bit is the 1st bit from the end. Note that this is the standard example for showing that NFA can be exponentially more succinct than DFA, and has been used for many other succinctness results ever since.

5 Good-for-games Visibly Pushdown Automata

One downside of GFG-PDA is that, like ω -GFG-PDA, they have poor closure properties and checking GFGness is undecidable. We therefore consider a well-behaved class of GFG-PDA, namely GFG visibly pushdown automata, GFG-VPA for short, that is closed under union, intersection, and complementation.

Let Σ_c, Σ_r and Σ_{int} be three disjoint sets of *call* symbols, *return* symbols and *internal* symbols respectively. Let $\Sigma = \Sigma_c \cup \Sigma_r \cup \Sigma_{\text{int}}$. A *visibly pushdown automaton* [2] (VPA) $\mathcal{P} = (Q, \Sigma, \Gamma, q_I, \Delta, F)$ is a restricted PDA that pushes onto the stack only when it reads a call symbol, it pops the stack only when a return symbol is read, and does not use the stack when there is an internal symbol. Formally,

- a letter $a \in \Sigma_c$ is only processed by transitions of the form (q, X, a, q', XY) with $X \in \Gamma_{\perp}$, i.e. some stack symbol $Y \in \Gamma$ is pushed onto the stack.
- A letter $a \in \Sigma_r$ is only processed by transitions of the form $(q, X, a, q', \varepsilon)$ with $X \neq \perp$ or (q, \perp, a, q', \perp) , i.e. the topmost stack symbol is removed, or if the stack is empty, it is left unchanged.
- A letter $a \in \Sigma_{\text{int}}$ is only processed by transitions of the form (q, X, a, q', X) with $X \in \Gamma_{\perp}$, i.e. the stack is left unchanged.
- There are no ε -transitions.

Intuitively, the stack height of the last configuration of a run processing some $w \in (\Sigma_c \cup \Sigma_r \cup \Sigma_s)^*$ only depends on w .

We denote by GFG-VPA the VPA that are good-for-games. Every VPA (and hence every GFG-VPA) can be determinised, i.e. all three classes of automata recognise the same class of languages, denoted by VPL, which is a strict subset of DCFL [2]. However, VPA can be exponentially more succinct than deterministic VPA (DVPA) [2]. We show that there is an exponential gap both between the succinctness of GFG-VPA and DVPA and between VPA and GFG-VPA. The proof of the former gap again uses a language of bad counters, similar to C_n used in Theorem 10, which we adapt for the VPA setting by adding a suffix allowing the automaton to pop the stack. Furthermore, for the gap between VPA and GFG-VPA, we similarly adapt the language L_n of words where the n^{th} bit from the end is a 1, from the proof of Theorem 10, by making sure that the stack height is always bounded by 1. Then, a GFG-VPA is essentially a GFG-NFA, and therefore determinisable by pruning, which means that it is as big as a deterministic automaton for the language.

► **Theorem 11.** *GFG-VPA can be exponentially more succinct than DVPA and VPA can be exponentially more succinct than GFG-VPA.*

We now turn to the question of deciding whether a given VPA is GFG. We show decidability using the *one-token game*, introduced by Bagnol and Kuperberg [3]. It modifies the game-based characterisation of GFGness of ω -regular automata by Henzinger and Piterman [16]. While the one-token game does not characterise the GFGness of Büchi automata, here we show that it suffices for VPA. The matching lower bound follows from a reduction from the inclusion problem for VPA, which is EXPTIME-hard [2], to GFGness (see [25] for details of the reduction in the context of ω -GFG-PDA).

► **Theorem 12.** *The following problem is EXPTIME-complete: Given a VPA \mathcal{P} , is \mathcal{P} GFG?*

We first define the *one-token game*, introduced by Bagnol and Kuperberg [3] in the context of regular languages, for VPA. Given a VPA $\mathcal{P} = (Q, \Sigma, \Gamma, q_I, \Delta, F)$, the positions of the one-token game consist of pairs of configurations (c_i, c'_i) , starting from the initial configuration of \mathcal{P} . At each round i :

- Player 1 picks a letter $a_i \in \Sigma$,
- Player 2 picks an a_i -transition $\tau_i \in \Delta$ enabled in c_i , leading to a configuration c_{i+1} ,
- Player 1 picks an a_i -transition $\tau'_i \in \Delta$ enabled in c'_i , leading to a configuration c'_{i+1} ,
- The game proceeds from the configuration (c_{i+1}, c'_{i+1}) .

A play consists of an infinite word $a_0 a_1 \dots \in \Sigma^\omega$ and two sequences of transitions $\tau_0 \tau_1 \dots$ and $\tau'_0 \tau'_1 \dots$ built by Players 2 and 1 respectively. Player 1 wins if for some n , $\tau'_0 \dots \tau'_n$ is an accepting run of \mathcal{P} over $a_0 \dots a_n$ and $\tau_0 \dots \tau_n$ is not. Recall that VPA do not have ε -transitions, so the two runs proceed in lockstep.

Observe that this game can be seen as a safety game on a visibly pushdown arena and can therefore be encoded as a Gale-Stewart game with a DCFL winning condition. This in turn is solvable in EXPTIME [39]. To prove Theorem 12, it now suffices to argue that this game characterises whether the VPA \mathcal{P} is GFG.

Proof. We now argue that \mathcal{P} is GFG if and only if Player 2 wins the one-token game on \mathcal{P} . One direction is immediate: if \mathcal{P} is GFG, then the resolver is also a strategy for Player 2 in the one-token game.

For the converse direction, consider the family of *copycat strategies* for Player 1 that copy the transition chosen by Player 2 until she plays an a -transition from a configuration c to a configuration c' such that there is a word aw that is accepted from c but w is not accepted from c' . We call such transitions non-residual. If Player 2 plays such a non-residual transition, then the copycat strategies stop copying and instead play the letters of w and the transitions of an accepting run over aw from c .

If Player 2 wins the one-token game with a strategy s , she wins, in particular, against this family of copycat strategies for Player 1. Observe that copycat strategies win any play along which Player 2 plays a non-residual transition. Therefore s must avoid ever playing a non-residual transition. We can now use s to induce a resolver r_s for \mathcal{P} : r_s maps a sequence of transitions over a word w to the transition chosen by s in the one-token game where Player 1 played w and a copycat strategy. Then, r_s never produces a non-residual transition. As a result, if a word w is in $L(\mathcal{P})$, then the run induced by r_s over every prefix v of w leads to a configuration that accepts the remainder of w . This is in particular the case for w itself, for which r_s induces an accepting run. This concludes our argument that r_s is indeed a resolver, and \mathcal{P} is therefore GFG.

Thus, to decide whether a VPA \mathcal{P} is GFG it suffices to solve the one-token game on \mathcal{P} , which can be done in exponential time. ◀

Finally, we relate the GFGness problem to the *good-enough synthesis* problem [1], also known as the *uniformization* problem [9], which is similar to the Church synthesis problem, except that the system is only required to satisfy the specification on inputs in the projection of the specification on the first component.

Let $w \in \Sigma_1$ and $w' \in \Sigma_2$ with $|w| = |w'|$. Then, for the sake of readability, we write $\binom{w}{w'}$ for the word $\binom{w(0)}{w'(0)} \cdots \binom{w(|w|-1)}{w'(|w|-1)}$ over $\Sigma_1 \times \Sigma_2$.

► **Definition 13** (GE-synthesis). *Given a language $L \subseteq (\Sigma_1 \times \Sigma_2)^*$, is there a function $f : \Sigma_1^* \rightarrow \Sigma_2$ such that for each $w \in \{w \mid \exists w' \in \Sigma_2^*. \binom{w}{w'} \in L\}$ the word $\binom{w}{w'}$ is in L , where $w'(n) = f(w(0) \cdots w(n))$ for each $0 \leq n < |w|$.*

We now prove that the GE-synthesis problem for GFG-VPA and DVPA is as hard as the GFGness problem for VPA, giving us the following corollary of Theorem 12.

► **Corollary 14.** *The GE-synthesis problem for inputs given by GFG-VPA, and in particular for DVPA, is EXPTIME-complete.*

Proof. We first reduce the good-enough synthesis problem to the GFGness problem. Given a GFG-VPA $\mathcal{P} = (Q, \Sigma_1 \times \Sigma_2, \Gamma, q_I, \Delta, F)$, with resolver r , let \mathcal{P}' be \mathcal{P} projected onto the first component: $\mathcal{P}' = (Q, \Sigma_1, \Gamma, q_I, \Delta', F)$ has the same states, stack alphabet and final states as \mathcal{P} , but has an a -transition for some $a \in \Sigma_1$ whenever \mathcal{P} has the same transition over $\binom{a}{b}$ for some $b \in \Sigma_2$. Let each transition of \mathcal{P}' be annotated with the Σ_2 -letter of the corresponding \mathcal{P} -transition. Thus \mathcal{P}' recognises the projection of $L(\mathcal{P})$ on the first component.

A resolver for \mathcal{P}' induces a GE-synthesis function for \mathcal{P} by reading the Σ_2 -annotation of the chosen transitions in \mathcal{P}' . Indeed, the resolver produces an accepting run with annotation w' of \mathcal{P}' for every word w in the projection of $L(\mathcal{P})$ on the first component. The same run is an accepting run in \mathcal{P} over $\binom{w}{w'}$ which is therefore in $L(\mathcal{P})$. Conversely a GE-synthesis function f for \mathcal{P} , combined with r , induces a resolver r' for \mathcal{P}' by using f to choose output letters and r to choose which transition of \mathcal{P} to use; together these uniquely determine a transition in \mathcal{P}' . Then, if $w \in L(\mathcal{P}')$, f guarantees that the annotation of the run induced by r' in \mathcal{P}' is a witness w' such that $\binom{w}{w'} \in \mathcal{P}$, and then r guarantees that the run is accepting, since the corresponding run in \mathcal{P} over $\binom{w}{w'}$ must be accepting.

We now reduce the GFGness problem of a VPA $\mathcal{P} = (Q, \Sigma, \Gamma, q_I, \Delta, F)$ to the GE-synthesis problem of a DVPA $\mathcal{P}' = (Q, \Sigma \times \Delta, \Gamma, q_I, \Delta', F)$. The deterministic automaton \mathcal{P}' is as \mathcal{P} except that each transition τ over a letter a in Δ is replaced with the same transition over $\binom{a}{\tau}$ in Δ' . In other words, \mathcal{P}' recognises the accepting runs of \mathcal{P} and its GE-synthesis problem asks whether there is a function that constructs on-the-fly an accepting run for every word in $L(\mathcal{P})$, that is, whether \mathcal{P} has a resolver. ◀

In contrast, for LTL specifications, the GE-synthesis problem is 2EXPTIME-complete [1].

6 Resolvers

The definition of a resolver does not put any restrictions on its complexity. In this section we study the complexity of the resolvers that GFG-PDA need. We consider two somewhat orthogonal notions of complexity: memory and machinery. On one hand, we show that resolvers can always be chosen to be *positional*, that is, dependent on the current state

and stack configuration only. Note that this is not the case for ω -regular automata², let alone ω -GFG-PDA. On the other hand, we show that they are not always implementable by pushdown transducers.

More formally, a resolver r is positional, if for any two sequences ρ and ρ' of transitions inducing runs ending in the same configuration, $r(\rho, a) = r(\rho', a)$ for all $a \in \Sigma$.

► **Lemma 15.** *Every GFG-PDA has a positional resolver.*

Proof. Let r' be a (not necessarily positional) resolver for \mathcal{P} . We define a resolver r such that for each configuration and input letter, it makes a choice consistent with r' for some input leading to this configuration. In other words, for every reachable configuration c , let ρ_c be an input to r' inducing a run ending in c . Then, we define $r(\rho, a) = r(\rho_c, a)$, where c is the last configuration of the run induced by ρ .

We claim that r , which is positional by definition, is a resolver. Towards a contradiction, assume that this is not the case, i.e. there is a word $w \in L(\mathcal{P})$ such that the run ρ induced by r is rejecting. Since this run is finite and $w \in L(\mathcal{P})$, there is some last configuration c along the run ρ from which the rest of the word, say u , is accepted³ (by some other run of \mathcal{P} having the same prefix as ρ up to configuration c). Let τ be the next transition along ρ from c . Since r chose τ , the resolver r' also chooses τ after some history leading to c , over some word v . Since u is accepted from c , the word vu is in $L(\mathcal{P})$; since r' is a resolver, there is an accepting run over u from c starting with τ , contradicting that c is the last position on ρ from where the rest of the word could be accepted. ◀

Contrary to the case of finite and ω -regular automata, since GFG-PDA have an infinite configuration space, the existence of positional resolvers does not imply determinisability. On the other hand, if a GFG-PDA has a resolver which only depends on the mode of the current configuration, then it is *determinisable by pruning*, as transitions that are not used by the resolver can be removed to obtain a deterministic automaton. However, not all GFG-PDA are determinisable by pruning, e.g. the GFG-PDA for the languages C_n used to prove Theorem 10.

We now turn to how powerful resolvers for GFG-PDA need to be. First, we introduce transducers as a way to implement a resolver. A transducer is an automaton with outputs instead of acceptance, i.e., it computes a function from input sequences to outputs. A pushdown resolver is a pushdown transducer that implements a resolver.

Note that a resolver has to pick enabled transitions in order to induce accepting runs for all inputs in the language. To do so, it needs access to the mode of the last configuration. However, to keep track of this information on its own, the pushdown resolver would need to simulate the stack of the GFG-PDA it controls. This severely limits the ability of the pushdown resolver to implement computations on its own stack. Thus, we give a pushdown resolver access to the current mode of the GFG-PDA via its output function, thereby freeing its own stack to implement further functionalities.

Formally, a pushdown transducer (PDT for short) $\mathcal{T} = (\mathcal{D}, \lambda)$ consists of a DPDA \mathcal{D} augmented with an output function $\lambda : Q^{\mathcal{D}} \rightarrow \Theta$ mapping the states $Q^{\mathcal{D}}$ of \mathcal{D} to an output alphabet Θ . The input alphabet of \mathcal{T} is the input alphabet of \mathcal{D} .

² A positional resolver for ω -regular automata implies determinisability by pruning, and we know that this is not always possible [6].

³ Observe that this is no longer true over infinite words as an infinite run can stay within configurations from where an accepting run exists without being itself accepting. In fact, the lemma does not even hold for coBüchi automata [23] as the existence of positional resolvers implies determinisability by pruning.

■ **Figure 3** The PDA \mathcal{P}_{B_3} for B_3 . Grey states are final, and X is an arbitrary stack symbol.

Then, given a PDA $\mathcal{P} = (Q, \Sigma, \Gamma, q_I, \Delta, F)$, a pushdown resolver for \mathcal{P} consists of a pushdown transducer $\mathcal{T} = (\mathcal{D}, \lambda)$ with input alphabet Δ and output alphabet $Q \times \Gamma_{\perp} \times \Sigma \rightarrow \Delta$ such that the function $r_{\mathcal{T}}$, defined as follows, is a resolver for \mathcal{P} : $r_{\mathcal{T}}(\tau_0 \dots \tau_k, a) = \lambda(q_{\mathcal{T}})(q_{\mathcal{P}}, X, a)$ where

- $q_{\mathcal{T}}$ is the state of the last configuration of the longest run of \mathcal{D} on $\tau_0 \dots \tau_k$ (recall that while \mathcal{D} is deterministic, it may have several runs on an input which differ on trailing ϵ -transitions);
- $(q_{\mathcal{P}}, X)$ is the mode of the last configuration of the run of \mathcal{P} induced by $\tau_0 \dots \tau_k$.

In other words, a transducer implements a resolver by processing the run so far, and then uses the output of the state reached and the state and top stack symbol of the GFG-PDA to determine the next transition in the GFG-PDA.

We now give an example of a GFG-PDA which does not have a pushdown resolver. The language in question is the language $B_3 = \{a^i \$ a^j \$ a^k \$ b^l \$ \mid l \leq \max(i, j, k)\}$. Compare this to the language B_2 in Section 3 which *does* have a pushdown resolver. Let \mathcal{P}_{B_3} be the automaton in Figure 3, which works analogously to the automaton for B_2 in Figure 2.

This automaton recognises B_3 : for a run to end in the final state, the stack, and therefore the input, must have had an a -block longer than or equal to the final b -block; conversely, if the b -block is shorter than or equal to some a -block, the automaton can nondeterministically pop the blocks on top of the longest a -block off the stack before processing the b -block. Furthermore, this automaton is GFG: the nondeterminism can be resolved by removing from the stack all blocks until the *longest* a -block is at the top of the stack, and this choice can be made once the third $\$$ is processed.

We now argue that this GFG-PDA needs more than a pushdown resolver. The reason is that a pushdown resolver needs to be able to determine which of the three blocks is the longest while processing a prefix of the form $a^* \$ a^* \$ a^*$. However, at least one of the languages induced by these three choices is not context-free, yielding the desired contradiction.

► **Lemma 16.** *The GFG-PDA \mathcal{P}_{B_3} has no pushdown resolver.*

Proof. Towards a contradiction, assume that there is a pushdown resolver r for \mathcal{P}_{B_3} , implemented by a PDT $\mathcal{T} = (\mathcal{D}, \lambda)$.

From \mathcal{T} , for each $i \in \{1, 2, 3\}$, we can construct a PDA \mathcal{D}_i that recognises the language of words $w \in a^* \$ a^* \$ a^*$ such that \mathcal{T} chooses from q_3 the transition of \mathcal{P}_{B_3} going to p_i when constructing a run on $w \$$: this is simply the pushdown automaton \mathcal{D} underlying \mathcal{T} where transitions of \mathcal{D} processing non- ϵ transitions τ of \mathcal{P}_{B_3} are modified to now process $\ell(\tau) \in \{a, b, \$\}$, transitions of \mathcal{D} processing ϵ -transitions of \mathcal{P}_{B_3} are removed, and states q of \mathcal{D} such that $\lambda(q)(q_3, X, \$) = (q_3, \$, X, p_i, X)$ are made final, intersected with a DFA checking that the input is in $a^* \$ a^* \$ a^*$.

Since \mathcal{T} implements a resolver for \mathcal{P} , each \mathcal{D}_i only accepts words of the form $a^{m_1}\$a^{m_2}\a^{m_3} such that $\max(m_1, m_2, m_3) = m_i$. Furthermore, at least for one $i \in \{1, 2, 3\}$, \mathcal{D}_i accepts $a^m\$a^m\a^m for infinitely many m .

To reach a contradiction, we now argue that this \mathcal{D}_i recognises a language that is not context-free. Indeed, if it were, then by applying the pumping lemma for context-free languages, there would be a large enough m such that the word $a^m\$a^m\$a^m \in L(\mathcal{D}_i)$ could be decomposed as $uvwyz$ such that $|vy| \geq 1$ and $uv^nwy^n z$ is in the language of \mathcal{D}_i for all $n \geq 0$. In this decomposition, v and y must be $\$$ -free. Then, if either v or y occurs in the i^{th} block and is non-empty, by setting $n = 0$ we obtain a contradiction as the i^{th} block is no longer the longest. Otherwise, we obtain a similar contradiction by setting $n = 2$. In either case, this shows that \mathcal{T} is not a pushdown resolver for \mathcal{P} . ◀

Another restricted class of resolvers are finite-state resolvers, which can be seen as pushdown resolvers that do not use their stack. Similarly to the case of ω -GFG-PDA [26], the product of a GFG-PDA and a finite-state resolver yields a DPDA for the same language.

► **Remark 17.** Every GFG-PDA with a finite-state resolver is determinisable.

Note that the converse does not hold. For example, consider the regular, and therefore deterministic context-free, language L_{10} of words $w\#$ with $w \in \{a, b\}^*$ with infix a^{10} . A GFG-PDA \mathcal{P}_{10} recognising L_{10} can be constructed as follows: \mathcal{P}_{10} pushes its input onto its stack until processing the first $\#$. Before processing this letter, \mathcal{P}_{10} uses ε -transitions to empty the stack again. While doing so, it can nondeterministically guess whether the next 10 letters removed from the stack are all a 's. If yes, it accepts; in all other cases (in particular if the input word does not end with the first $\#$ or the infix a_{10} is not encountered on the stack) it rejects. This automaton is good-for-games, as a resolver has access to the whole prefix before the first $\#$ when searching for a^{10} while emptying the stack. This is sufficient to resolve the nondeterminism. On the other hand, there is no finite-state resolver for \mathcal{P}_{10} , as resolving the nondeterminism, intuitively, requires to keep track of the whole prefix before the first $\#$ (recall that a finite-state resolver only has access to the topmost stack symbol).

In Appendix A.2 we consider another model of pushdown resolver, namely one that does not only have access to the mode of the GFG-PDA, but can check the full stack for regular properties. We show that this change does not increase the class of good-for-games context-free languages that are recognised by a GFG-PDA with a pushdown resolver.

Finally, for GFG-VPA, the situation is again much better. The classical game-based characterisation of GFGness of ω -regular automata by Henzinger and Piterman [16] can be lifted to VPA. Then, using known results [27] about VPA games having VPA strategies, we obtain our final theorem.

► **Theorem 18.** *Every GFG-VPA has a (visibly) pushdown resolver.*

Proof. Fix a VPA $\mathcal{P} = (Q, \Sigma, \Gamma, q_I, \Delta, F)$ and consider the following two-player game $\mathcal{G}(\mathcal{P})$, introduced by Henzinger and Piterman to decide GFGness of ω -automata [16]. In each round, first Player 1 picks a letter from Σ or ends the play. If he has not ended the play, then Player 2 picks a transition of \mathcal{P} . Hence, once Player 1 has stopped the play, Player 1 has picked an input word w over Σ^* and Player 2 has indicated a run ρ of \mathcal{P} . A finite play with outcome (w, ρ) is winning for Player 2 if either $w \notin L(\mathcal{P})$ or ρ induces an accepting run of \mathcal{P} on w . A strategy for Player 2 in this game is a mapping $\sigma: \Sigma^+ \rightarrow \Delta$ and an outcome $(w(0) \cdots w(k), \rho(0) \cdots \rho(k))$ is consistent with σ , if $\rho(j) = \sigma(w(0) \cdots w(j))$ for every $0 \leq j \leq k$. We say that σ is winning for Player 2, if every outcome of a finite play that is consistent with σ is winning for her (note that we disregard infinite plays).

Now, Player 2 wins $\mathcal{G}(\mathcal{P})$ if and only if \mathcal{P} is a GFG-VPA. This follows as every winning strategy for Player 2 can be turned into a resolver and vice versa.

Now, as the class of languages recognized by VPA, is closed under complementation and union [2], one can encode $\mathcal{G}(\mathcal{P})$ as a Gale-Stewart game with a VPL winning condition. Such games can be solved effectively [27] and the winner always has a winning strategy implemented by a (visibly) PDT. Thus, if \mathcal{P} is a GFG-VPA, i.e. Player 2 wins $\mathcal{G}(\mathcal{P})$, then she has a winning strategy implemented by a (visibly) PDT, which can easily be turned into a (visibly) pushdown resolver for \mathcal{P} . ◀

7 Conclusion

We have continued the study of good-for-games pushdown automata, focusing on expressiveness and succinctness. In particular, we have shown that GFG-PDA are not only more expressive than DPDA (as had already been shown for the case of infinite words), but also more succinct than DPDA: We have introduced the first techniques for using GFG nondeterminism to succinctly represent languages that do not depend on the coBüchi condition. Similarly, for the case of VPA, for which deterministic and nondeterministic automata are equally expressive, we proved a (tight) exponential gap in succinctness.

Solving games and universality are decidable for GFG-PDA, but GFGness is undecidable and GFG-PDA have limited closure properties. On the other hand, GFGness for VPA is decidable and they inherit the closure properties of VPA, e.g. union, intersection and complementation, making GFG-VPA an exciting class of pushdown automata. Finally, we have studied the complexity of resolvers for GFG-PDA, showing that positional ones always suffice, but that they are not always implementable by pushdown transducers. Again, GFG-VPA are better-behaved, as they always have a resolver implementable by a VPA.

Let us conclude by mentioning some open problems raised by our work.

- It is known that the succinctness gap between PDA and DPDA is noncomputable [15, 38], i.e. there is no computable function f such that any PDA of size n that has some equivalent DPDA also has an equivalent DPDA of size $f(n)$. Due to our hierarchy results, at least one of the succinctness gaps between PDA and GFG-PDA and between GFG-PDA and DPDA has to be uncomputable, possibly both.
- We have shown that some GFG-PDA do not have pushdown resolvers. It is even open whether every GFG-PDA has a computable resolver.
- On the level of languages, it is open whether every language in GFG-CFL has a GFG-PDA recognising it with a resolver implementable by a pushdown transducer.
- We have shown that GFGness is undecidable, both for PDA and for context-free languages. Is it decidable whether a given GFG-PDA has an equivalent DPDA?
- Equivalence of DPDA is famously decidable [36] while it is undecidable for PDA [19]. Is equivalence of GFG-PDA decidable?
- Does every GFG-PDA that is equivalent to a DPDA have a finite-state resolver with regular stack access (see Appendix A.2 for definitions)?
- There is a plethora of fragments of context-free languages one can compare GFG-CFL to, let us just mention a few interesting ones: Height-deterministic context-free languages [30], context-free languages with bounded nondeterminism [17] and preorder typeable visibly pushdown languages [21].

A Appendix

A.1 Resolvers with End-of-word Markers

As mentioned in the main part, GFG-PDA are by definition required to end their run with the last letter of the input word. Instead, one could also consider a model where they are allowed to take some trailing ε -transitions after the last input letter has been processed. As a resolver has access to the next input letter, which is undefined in this case, we need resolvers with end-of-word markers to signal the resolver that the last letter has been processed. In the following, we show that GFG-PDA with end-of-word resolvers are as expressive as standard GFG-PDA, albeit exponentially more succinct.

Fix some distinguished end-of-word-marker $\#$, which takes the role of the next input letter to be processed, if there is none after the last letter of the input word is processed. Let $\mathcal{P} = (Q, \Sigma, \Gamma, q_I, \Delta, F)$ be a PDA with $\# \notin \Sigma$. An EoW-resolver for \mathcal{P} is a function $r: \Delta^* \times (\Sigma \cup \{\#\}) \rightarrow \Delta$ such that for every $w \in L(\mathcal{P})$, there is an accepting run $c_0\tau_0 \cdots \tau_n c_n$ on w such that $\tau_{n'} = r(\tau_0 \cdots \tau_{n'-1}, w\#(|\ell(\tau_0 \cdots \tau_{n'-1})|))$ for all $0 \leq n' < n$. Note that the second argument given to the resolver is a letter of $w\#$, which is equal to $\#$ if the run prefix induced by $\tau_0 \cdots \tau_{n'-1}$ has already processed the full input w .

► **Lemma 19.** *GFG-PDA with EoW-resolvers are as expressive as GFG-PDA.*

Proof. A (standard) resolver can be turned into an EoW-resolver that ignores the EoW-marker. Hence, every GFG-PDA is a GFG-PDA with EoW-resolver recognizing the same language. So, it only remains to consider the other inclusion.

To this end, let $\mathcal{P} = (Q, \Sigma, \Gamma, q_I, \Delta, F)$ be a PDA with EoW-resolver. The language

$$C_{acc} = \{\gamma q \mid q \in F \text{ and } \gamma \in \perp\Gamma^*\} \subseteq \perp\Gamma^*Q$$

encoding final configurations of \mathcal{P} is regular. Hence, the language

$$C = \{\gamma q \in \perp\Gamma^*Q \mid \text{there is a run infix } (q, \gamma)\tau_0 \cdots \tau_{n-1}c_n \\ \text{with } \ell(\tau_0 \cdots \tau_{n-1}) = \varepsilon \text{ and } c_n \in C_{acc}\}$$

can be shown to be regular as well by applying saturation techniques [7]⁴ to the restriction of \mathcal{P} to ε -transitions. If \mathcal{P} reaches a configuration $c \in C$ after processing an input w , then $w \in L$, even if c 's state is not final.

Let $\mathcal{A} = (Q_{\mathcal{A}}, \Gamma_{\perp} \cup Q, q_I^{\mathcal{A}}, \delta_{\mathcal{A}}, F_{\mathcal{A}})$ be a DFA recognizing C . We extend the stack alphabet of \mathcal{P} to $\Gamma \times Q_{\mathcal{A}} \times (Q_{\mathcal{A}} \cup \{u\})$, where u is a fresh symbol. Then, we extend the transition relation such that it keeps track of the unique run of \mathcal{A} on the stack content: If \mathcal{P} reaches a stack content $\perp(X_1, q_1, q'_1)(X_2, q_2, q'_2) \cdots (X_s, q_s, q'_s)$, then we have

$$q_j = \delta_{\mathcal{A}}^*(q_I^{\mathcal{A}}, \perp X_1 \cdots X_j)$$

for every $1 \leq j \leq s$ as well as $q'_j = q'_{j-1}$ for every $2 \leq j \leq s$ and $q'_1 = u$. Here, $\delta_{\mathcal{A}}^*$ is the standard extension of $\delta_{\mathcal{A}}$ to words. The adapted PDA is still good-for-games, as no new nondeterminism has been introduced, and keeps track of the state of \mathcal{A} reached by processing the stack content as well as the shifted sequence of states of \mathcal{A} , which is useful when popping the top stack symbol: If the topmost stack symbol (X, q, q') is popped of the stack then q' is the state of \mathcal{A} reached when processing the remaining stack.

⁴ Also, see the survey by Carayol and Hague [8] for more details.

Now, we double the state space of \mathcal{P} , making one copy final, and adapt the transition relation again so that a final state is reached whenever \mathcal{P} would reach a configuration in C . Whether a configuration in C is reached can be determined from the current state of \mathcal{P} being simulated, as well as the top stack symbol containing information on the run of \mathcal{A} on the current stack content. The resulting PDA \mathcal{P}' recognizes $L(\mathcal{P})$ and has on every word $w \in L(\mathcal{P})$ an accepting run without trailing ε -transitions. Furthermore, an EoW-resolver for \mathcal{P} can be turned into a (standard) resolver for \mathcal{P}' , as the tracking of stack contents and the doubling of the state space does not introduce nondeterminism. ◀

As \mathcal{A} has at most exponential size, \mathcal{P}' is also exponential (both in the size of \mathcal{P}). This exponential blowup incurred by removing the end-of-word marker is in general unavoidable. In Theorem 10, we show that the language L_n of bit strings whose n^{th} bit from the end is a 1 requires exponentially-sized GFG-PDA. On the other hand, it is straightforward to devise a polynomially-sized GFG-PDA \mathcal{P}_{EoW} with EoW-marker recognizing L_n : the underlying PDA stores the input word on the stack, guesses nondeterministically that the word has ended, uses n (trailing) ε -transitions to pop of the last $n - 1$ letters stored on the stack, and then checks that the topmost stack symbol is a 1. With an EoW-resolver, the end of the input does not have to be guessed, but is marked by the EoW-marker. Hence, \mathcal{P}_{EoW} is good-for-games.

A.2 Pushdown Resolvers with Regular Stack Access

Recall that pushdown transducers implementing a resolver have access to the mode of the GFG-PDA whose nondeterminism it resolves. Here, we consider a more general model where the transducer can use information about the whole stack when determining the next transition. More precisely, we consider a regular abstraction of the possible stack contents by fixing a DFA running over the stack and allowing the transducer to base its decision on the state reached by the DFA as well.

Then, given a PDA $\mathcal{P} = (Q, \Sigma, \Gamma, q_I, \Delta, F)$, a pushdown resolver with regular stack access $\mathcal{T} = (\mathcal{D}, \mathcal{A}, \lambda)$ consists a DPDA \mathcal{P} with input alphabet Δ , a DFA \mathcal{A} over Γ_{\perp} with state set $Q^{\mathcal{A}}$, and an output function λ with output alphabet $Q \times Q^{\mathcal{A}} \times \Sigma \rightarrow \Delta$ such that the function $r_{\mathcal{T}}$ defined as follows, is a resolver for \mathcal{P} :

$$r_{\mathcal{T}}(\tau_0 \dots \tau_k, a) = \lambda(q_{\mathcal{T}})(q_{\mathcal{P}}, q_{\mathcal{A}}, a)$$

where

- $q_{\mathcal{T}}$ is the state of the last configuration of the longest run of \mathcal{D} on $\tau_0 \dots \tau_k$ (recall that while \mathcal{D} is deterministic, it may have several runs on an input which differ on trailing ε -transitions).
- Let c be the last configuration of the run of \mathcal{P} induced by $\tau_0 \dots \tau_k$. Then, $q_{\mathcal{P}}$ is the state of c and $q_{\mathcal{A}}$ is the state of \mathcal{A} reached when processing the stack content of c .

Every pushdown resolver with only access to the current mode is a special case of a pushdown resolver with regular stack access. On the other hand, having regular access to the stack is strictly stronger than having just access to the mode. However, by adapting the underlying GFG-PDA, one can show that the *languages* recognised by GFG-PDA with pushdown resolvers does not increase when allowing regular stack access.

► **Lemma 20.** *Every GFG-PDA with a pushdown resolver with regular stack access can be turned into an equivalent GFG-PDA with a pushdown resolver.*

53:20 A Bit of Nondeterminism Makes Pushdown Automata Expressive and Succinct

Proof. Let $\mathcal{P} = (Q, \Sigma, \Gamma, q_I, \Delta, F)$ be a GFG-PDA and let $(\mathcal{D}, \mathcal{A}, \lambda)$ be a pushdown resolver with stack access for \mathcal{P} . We keep track of the state \mathcal{A} reaches on the current stack as in the proof of Lemma 19: If a stack content $\perp(X_1, q_1) \cdots (X_s, q_s)$ is reached, then q_j is the unique state of \mathcal{P} reached when processing $\perp X_1 \cdots X_j$. Now, it is straightforward to turn $(\mathcal{D}, \mathcal{A}, \lambda)$ into a pushdown resolver for \mathcal{P} that has only access to the top stack symbol. ◀

Perfect Forests in Graphs and Their Extensions

University of Johannesburg, South Africa

Abstract

Let G be a graph on n vertices. For $i \in \{0, 1\}$ and a connected graph G , a spanning forest F of G is called an i -perfect forest if every tree in F is an induced subgraph of G and exactly i vertices of F have even degree (including zero). An i -perfect forest of G is proper if it has no vertices of degree zero. Scott (2001) showed that every connected graph with even number of vertices contains a (proper) 0-perfect forest. We prove that one can find a 0-perfect forest with minimum number of edges in polynomial time, but it is NP-hard to obtain a 0-perfect forest with maximum number of edges. We also prove that for a prescribed edge e of G , it is NP-hard to obtain a 0-perfect forest containing e , but we can find a 0-perfect forest not containing e in polynomial time. It is easy to see that every graph with odd number of vertices has a 1-perfect forest. It is not the case for proper 1-perfect forests. We give a characterization of when a connected graph has a proper 1-perfect forest.

1 Introduction

In this paper all graphs are finite, undirected, have no parallel edges or loops. We use standard terminology and notation, see e.g. [5]. The number of vertices (edges, respectively) of a graph G is called its *order* (*size*, respectively). The degree of a vertex x in a graph G is denoted by $d_G(x)$. A vertex x of a graph G is a *cut-vertex* if $G - x$ has more connected components than G . A maximal connected subgraph of a graph G without a cut-vertex is called a *block*. Thus, every block of G is either a maximal 2-connected subgraph or a bridge (including its vertices) or an isolated vertex, implying that a block of odd order in a connected graph of order at least 3, must be a maximal 2-connected subgraph.

A spanning forest F of G is called a *semiperfect forest* if every tree of F is an induced subgraph of G . Let G be a graph and let $f: V(G) \rightarrow \{0, 1\}$ be a function such that $\sum_{v \in V(G)} f(v)$ is even (we will call such a function *even-sum*). A subgraph H in G where $d_H(x) \equiv f(x) \pmod{2}$ for all $x \in V(G)$, is called an *f -parity subgraph*. Note that the requirement that f is even-sum is necessary as otherwise an f -parity subgraph does not exist. An f -parity subgraph H of G is called an *f -parity perfect forest* if H is a semiperfect forest.

For $i \in \{0, 1\}$ and a graph G , an f -parity perfect forest is called an *i -perfect forest* if $f(x) = 1$ for all vertices of G for $i = 0$, and for all vertices of G apart from one for $i = 1$. An i -perfect forest of G is *proper* if it has no vertices of degree zero. Note that every 0-perfect forest (called a perfect forest in [3, 9] and a pseudo-matching in [18]) is proper. For examples of 0-perfect and 1-perfect forests, see Figures 1 and 2.

54:2 Perfect Forests in Graphs and Their Extensions

■ **Figure 1** A graph G is shown in (a) and a 0-perfect forest of G is shown in (b) (as all degrees are odd and the trees are induced in G).

■ **Figure 2** The graph H is shown in (a), a (non-proper) 1-perfect forest of H is shown in (b), and a proper 1-perfect forest of H is shown in (c).

Clearly, every connected graph with a 0-perfect forest is of even order. Scott [17] proved that somewhat surprisingly the opposite implication is also true.

► **Theorem 1.** *Every connected graph of even order contains a 0-perfect forest.*

The proof of Theorem 1 in [17] is graph-theoretical and relatively long. A short proof using basic linear algebra is obtained in [9] and two short graph-theoretical proofs are given in [3]. All the proofs of Theorem 1 are constructive and yield polynomial algorithms for finding 0-perfect forests. Intuitively, it is clear that a 0-perfect forest can provide a useful structure in a graph and, in particular, this notion was used by Sharan and Wigderson [18] to prove that the perfect matching problem for bipartite cubic graphs belongs to the complexity class \mathcal{NC} . Semiperfect forests were used in the proofs of three theorems in [7]. Gutin and Yeo [11] studied extensions of a 0-perfect forest to directed graphs.

Since a 0-perfect forest is a generalization of a matching, it is natural to study the following two problems for a connected graph G of even order n :

- (1) Find a 0-perfect forest of G of minimum size. (Clearly, the minimum size is $n/2$ if and only if G has a perfect matching.)
- (2) Find a 0-perfect forest of G of maximum size. (This is of interest in matching-like edge-decompositions of G .)

The following theorem solves the first problem.

► **Theorem 2.** *In polynomial time, we can find a 0-perfect forest of minimum size.*

Theorem 2 follows immediately from the next theorem by letting $f(x) = 1$ for all $x \in V(G)$. Theorem 3 shows usefulness of extending Problem 1 to f -parity perfect forests. Theorem 3 is proved in Section 2.

► **Theorem 3.** *Let G be a connected graph and let $f: V(G) \rightarrow \{0, 1\}$ be an even-sum function. We can in polynomial time find an f -parity perfect forest H in G , such that $d_H(x) \equiv f(x) \pmod{2}$ for all $x \in V(G)$ and $|E(H)|$ is minimized.*

As the following theorem shows, the second problem cannot be solved in polynomial time unless $P=NP$.

► **Theorem 4.** *It is NP-hard to find a 0-perfect forest of maximum size.*

Let $n = |V(G)|$. Theorem 4 follows from the next result proved in Section 3. Theorem 5 is optimal in the following sense. The problem of finding a 0-perfect forest of size at least $n - 1$ is polynomial-time solvable because G has a 0-perfect forest of size at least $n - 1$ if and only if G is a tree in which every vertex is of odd degree.

► **Theorem 5.** *It is NP-hard to decide whether a connected graph contains a 0-perfect forest with at least $n - 2$ edges.*

It is easy to show that Theorem 5 holds if we replace $n - 2$ by $n - k$ for any integer $k \geq 2$. Indeed, add two new vertices x and y to a graph G as well as two edges xy and yu , where u is any vertex in G . The resulting graph is denoted by G' . Observe that there is a 0-perfect forest of size $|V(G)| - k$ in G if and only if there is a 0-perfect forest of size $|V(G')| - (k + 1)$ in G' .

Since the problem of finding a 0-perfect forest of maximum size is NP-hard, it is natural to study its parameterized complexity using appropriate parameterizations e.g. the parameterization below the tight upper bound $n - 1$ and the parameterization above the tight upper bound $n/2$. In other words, we can ask whether there is a 0-perfect forest of size at least $n - k$ ($n/2 + k$, respectively), where k is the parameter. (Above-tight-lower-bound and below-tight-upper-bound parameterizations were studied for many graph-theoretical and constraint satisfaction problems, see e.g. [1, 4, 10, 13, 14].) Theorem 5 shows that the parameterization $n - k$ is **para-NP-complete** (for an introduction to **para-NP-completeness**, see e.g. [6]). We do not know the answer to the following question. Is the parameterization $n/2 + k$ fixed-parameter tractable?¹

Here is another pair of natural problems on 0-perfect forests. They both are clearly polynomial-time solvable when restricted to perfect matchings. For a graph G of even order and an edge e in G ,

- (1') find a 0-perfect forest containing e ;
- (2') find a 0-perfect forest not containing e .

For Problem 1', we prove the following result in Section 4.

► **Theorem 6.** *The following problem is NP-hard. Given a connected graph G and an edge $e \in E(G)$, decide whether G has a 0-perfect forest containing e .*

For Problem 2', we have the next result, which follows immediately from Theorem 8, by letting $f(x) = 1$ for all x in G . Theorem 8 again demonstrates usefulness of f -parity perfect forests. It is proved in Section 5.

► **Theorem 7.** *Given a graph G and an edge $e \in E(G)$ we can in polynomial time decide whether G has a 0-perfect forest not containing e .*

► **Theorem 8.** *The following problem is polynomial time solvable. Given a graph G , an edge $e \in E(G)$ and an even-sum function $f: V(G) \rightarrow \{0, 1\}$, decide whether G has an f -parity perfect forest not containing e .*

¹ While working on the final version of this paper, we obtained a proof that the parameterized problem is W[1]-hard. We will include the proof in a journal version of the paper.

Since an odd order connected graph cannot have a 0-perfect forest, it is natural to ask whether every connected graph of odd order has a 1-perfect forest (recall that a 1-perfect forest has only one vertex of even degree). The answer is positive and the proof is trivial. In fact, it is not hard to show the following strengthening of this observation, which will be useful in the proof of Theorem 10.

► **Proposition 9.** *Let x be an arbitrary vertex of a connected graph G of odd order. Then G has a 1-perfect forest F such that $d_F(x)$ is even.*

Proof. Create a new graph H by adding a new vertex y to G and adding the edge xy . By Theorem 1, H has a 0-perfect forest, F_H . Deleting the vertex y from F_H , results in the desired 1-perfect forest of G where x is the only vertex of even degree. ◀

Note that not every connected graph of odd order has a proper 1-perfect forest. For example, no complete graph of odd order has such a forest. Thus, a more interesting question with a potentially more useful answer is when a connected graph of odd order has a proper 1-perfect forest? This question is answered in the following characterization proved in Section 6.

► **Theorem 10.** *Let \mathcal{B} be the set of all connected graphs where every block is a complete graph of odd order. If G is a connected graph of odd order $n \geq 3$ then G contains a proper 1-perfect forest if and only if $G \notin \mathcal{B}$.*

Using this theorem and a linear-time algorithm for computing biconnected components in a graph [12], in polynomial time we can decide whether a connected graph G of odd order contains a proper 1-perfect forest. If $G \notin \mathcal{B}$, the proof by induction of Theorem 2 yields a polynomial-time recursive algorithm to construct a proper 1-perfect forest.

Our proof of Theorem 10 is graph-theoretical and so are the proofs of Theorem 1 in [17] and [3]. Recall that Gutin [9] gave a linear-algebraic proof of Theorem 1. It would be interesting to see whether Theorem 10 can be proved using a linear-algebraic approach, too.

2 Proof of Theorem 3

► **Lemma 11.** *Let G be a connected graph and let $f: V(G) \rightarrow \{0, 1\}$ be an even-sum function. If H is an f -parity subgraph of G of minimum size, then H is an f -parity perfect forest.*

Proof. Assume that H is an f -parity subgraph with minimum possible $|E(H)|$. Clearly H contains no cycles, as removing the edges of a cycle would contradict the minimality of $|E(H)|$. Assume that some tree T of H is not an induced tree in G . Let xy be an edge of G , not belonging to T but with $\{x, y\} \subseteq V(T)$. Remove the unique (x, y) -path in T from H and add the edge xy to H . This decreases the number of edges in H without changing the parity of the degree of any vertex, contradicting the minimality of $|E(H)|$. Therefore H is indeed an f -parity perfect forest. ◀

Lemma 11 implies the following:

► **Theorem 12.** *Let G be a connected graph and let $f: V(G) \rightarrow \{0, 1\}$ be an even-sum function. Then there exists an f -parity perfect forest F in G .*

Proof. Let $x_1, x_2, \dots, x_k, y_1, y_2, \dots, y_k$ be the vertices in G with f -value equal to one. Let P_i be any (x_i, y_i) -path in G for all $i = 1, 2, \dots, k$, which exists as G is connected. Let H be the spanning subgraph of G such that an edge $e \in E(G)$ belongs to H if and only if e

belongs to an odd number of paths in P_1, P_2, \dots, P_k . Let $x \in V(G)$. Observe that $d_H(x)$ is odd if and only if x is incident with an odd number of edges in $\cup_{i=1}^k E(P_i)$, which is if and only if x is the endpoint of one of the paths i.e. $f(x) = 1$. Thus, H is an f -parity subgraph of G . Lemma 11 now implies that if H is the f -parity subgraph of G of minimum size, then H is an f -parity perfect forest. \blacktriangleleft

Note that Theorem 12 generalizes Theorem 1: set $f(x) = 1$ for all $x \in V(G)$. Thus, Theorem 12 provides an alternative proof of Theorem 1.

► Theorem 3. *Let G be a connected graph and let $f: V(G) \rightarrow \{0, 1\}$ be an even-sum function. We can in polynomial time find an f -parity perfect forest H in G , such that $d_H(x) \equiv f(x) \pmod{2}$ for all $x \in V(G)$ and $|E(H)|$ is minimized.*

Proof. Let G be a connected graph and let $f: V(G) \rightarrow \{0, 1\}$ be an even-sum function. Let $V(G) = \{v_1, v_2, \dots, v_n\}$. We will construct a weighed auxillary graph H as follows. Let $V(H) = \cup_{i=1}^n X_i$, where for every $i \in [n]$, $|X_i| \in \{n-1, n\}$ and $|X_i| \equiv f(v_i) \pmod{2}$. For all $1 \leq i < j \leq n$ and all $u \in X_i$ and $v \in X_j$, we let $uv \in E(H)$ if and only if $v_i v_j \in E(G)$. Finally add a matching $M_i = \{e_1^i, e_2^i, \dots, e_{\lfloor |X_i|/2 \rfloor}^i\}$ to X_i for all $i \in [n]$. Let the weight of all the edges within each X_i (i.e. the edges in M_i) be zero and let all edges between different X_i 's have weight one.

We first show that H contains a perfect matching. As $\sum_{v \in V(G)} f(v)$ is even we may assume that $\{v_1, v_2, \dots, v_{2k}\}$ are the vertices of G with an f -value of one for some integer k with $0 \leq k \leq n/2$. Assume that $y_i \in X_i$ is the unique vertex in X_i that is not saturated by M_i for all $i \in [2k]$ and start of by letting M be the matching containing all M_i 's.

Let $P_i = v_i v_{p_1^i} v_{p_2^i} \dots v_{p_{i-1}^i} v_{i+k}$ be any path in G from v_i to v_{i+k} where $i \in [k]$. It is not difficult to see that there exists an M -augmenting path, Q_i , in H starting in y_i and ending in y_{i+k} and containing exactly the edges $e_{i-1}^{p_1^i}, e_{i-2}^{p_2^i}, \dots, e_i^{p_{i-1}^i}$ from M . Also observe that Q_1, Q_2, \dots, Q_k are vertex disjoint, which implies that we can use all Q_i to increase the matching M thereby obtaining a perfect matching in H .

We will now show the following claim. The *size* of a multiset S is the total number of elements in S , where if an element $e \in S$ is of multiplicity r , then e is counted r times.

▷ **Claim A.**

- (a) If there exists a perfect matching in H with weight w^* then there exists a multiset of edges E^* in G of size w^* , such that $d_{E^*}(x) \equiv f(x) \pmod{2}$ for all $x \in V(G)$.
- (b) Conversely if E^* is a multiset of edges in G of size w^* , such that $d_{E^*}(x) \equiv f(x) \pmod{2}$ for all $x \in V(G)$, then there exists a perfect matching in H with weight at most w^* .

Proof of Claim A. First assume that we have a multiset of edges E^* in G of size $w^* \leq W_{\max}$, such that $d_{E^*}(x) \equiv f(x) \pmod{2}$ for all $x \in V(G)$. Let $M^* = \emptyset$. For every $v_i v_j \in E^*$ we will add edges between X_i and X_j to M^* as follows: if $v_i v_j$ is of multiplicity r in E^* , then we add an edge between X_i and X_j to M^* if and only if r is odd. Since we will add $2k_i + f(v_i)$ edges that are incident to X_i for each $i \in [n]$ (where k_i is some integer), we can add these edges such that their endvertices are $V(e_1^i) \cup V(e_2^i) \cup \dots \cup V(e_{k_i}^i)$ if $f(v_i) = 0$ and $\{y_i\} \cup V(e_1^i) \cup V(e_2^i) \cup \dots \cup V(e_{k_i}^i)$ if $f(v_i) = 1$ for each $i \in [n]$, where $V(e_j^i)$ denotes the pair of endvertices of e_j^i . We can now extend M^* to a perfect matching by adding $M_i \setminus \{e_1^i, e_2^i, \dots, e_{k_i}^i\}$ for each $i \in [n]$. This gives us a perfect matching in H with weight at most $|E^*|$ as desired.

Conversely assume that there exists a perfect matching M^* in H with weight w^* . Initially let $E^* = \emptyset$. For every $xy \in M^*$ with weight one (i.e. $x \in X_i$ and $y \in X_j$ for some $i \neq j$), add $v_i v_j$ to E^* . This gives us the desired multiset E^* , thereby completing the proof of Claim A. \blacktriangleleft

We have proved that H has a perfect matching. Let M_{\min} be a minimum weight perfect matching in H which can be determined in polynomial time using Edmonds' blossom algorithm as a subroutine, see e.g. [15]. Let W_{\min} be the weight of M_{\min} . By Claim A(a), using M_{\min} , in polynomial time we can find a multiset of edges E^* in G of size W_{\min} , such that $d_{E^*}(x) \equiv f(x) \pmod{2}$ for all $x \in V(G)$. By Claim A(b), since W_{\min} is the minimum weight of a perfect matching in H , W_{\min} is minimum size of a multiset of edges E^{**} , such that $d_{E^{**}}(x) \equiv f(x) \pmod{2}$ for all $x \in V(G)$.

Note that no edge is in E^* more than once, since if some edge, e , appears twice, then we can delete two copies of e from E^* , thereby contradicting the minimality of $|E^*|$. Let F be the spanning subgraph of G with edge set E^* . By Lemma 11 we note that F is an f -parity perfect forest, which completes the proof of the theorem. ◀

3 Proof of Theorem 5

We will reduce from the *not-all-equal 3-SAT* problem, abbreviated to NAE-3-SAT, which is the problem of determining whether an instance of 3-SAT has a truth assignment to its variables such that every clause contains both a true and a false literal. If this is the case we say that the instance is *NAE-satisfied*. NAE-3-SAT is known to be NP-hard to solve [16]. Let I be an instance of NAE-3-SAT with clauses C_1, C_2, \dots, C_m and variables v_1, v_2, \dots, v_n . We will construct a graph G such that G contains a 0-perfect forest with at least $n - 2$ edges if and only if I is NAE-satisfied.

We first create a gadget H_i for each $i = 1, 2, \dots, n$ as follows. Let

$$V(H_i) = \{x_1^i, z_1^i, y_1^i, x_2^i, z_2^i, y_2^i\}$$

and add all possible edges to H_i , except $x_1^i y_1^i$ and $x_2^i y_2^i$. For all $i = 1, 2, \dots, n - 1$ we then add all edges between $\{y_1^i, y_2^i\}$ and $\{x_1^{i+1}, x_2^{i+1}\}$. Now add a pendent edge to each vertex in $V(H_i) \setminus \{x_1^i, x_2^i, y_1^i, y_2^i\}$ for all $i = 1, 2, \dots, n$. See Figure 3 for an illustration of this part of G , which is denoted by Q . We will now complete our construction of G .

Figure 3 The gadgets H_1, H_2, \dots, H_n and the edges connecting these. The resulting graph is denoted by Q .

Let $V(G) = V(Q) \cup \{c_1, c_2, \dots, c_m\} \cup \{c'_1, c'_2, \dots, c'_m\}$. For each $j = 1, 2, \dots, m$ we will add an edge from both c_j and c'_j to y_2^i if and only if v_i is a literal in the clause C_j . We will furthermore add an edge from both c_j and c'_j to y_1^i if and only if \bar{v}_i is a literal in the clause C_j . This completes the construction of G . See Figure 4 depicting G for $I = (v_1, v_2, \bar{v}_3)$.

We will now show that G contains a 0-perfect forest of size at least $n - 2$ if and only if I is NAE-satisfied. First assume that I is NAE-satisfied and consider a truth assignment τ NAE-satisfying I . We will construct two vertex-disjoint induced trees, T_1 and T_2 , in G , such that all degrees in the trees T_i are odd for $i \in [2]$. If v_i is true in τ then add the vertices in

■ **Figure 4** The graph G if $I = (v_1, v_2, \bar{v}_3)$.

$\{x_1^i, z_1^i, y_1^i\}$ to T_1 and the vertices in $\{x_2^i, z_2^i, y_2^i\}$ to T_2 . Conversely, if v_i is false in τ then add the vertices in $\{x_1^i, z_1^i, y_1^i\}$ to T_2 and the vertices in $\{x_2^i, z_2^i, y_2^i\}$ to T_1 . We furthermore add all vertices of degree one to the same tree as their neighbour. Note that the vertices we have added so far to T_i (for $i \in [2]$) induce a tree in G , where every vertex has odd degree in T_i .

Finally as I is NAE-satisfied we note for $j \in [m]$, each of c_j and c'_j has one edge into one of the T_i 's and two edges into the other T_i . Add each of c_j and c'_j to the T_i with which it is only connected by one edge. We note that after this operation the vertices we have added so far to T_i (for $i \in [2]$) still induces a tree in G where every vertex has odd degree in T_i . After doing the above operation for all $j \in [m]$ we have obtained the desired trees T_1 and T_2 whose union form a 0-perfect forest in G with $|V(G)| - 2$ edges. See Figure 5 for the found T_1 and T_2 if the instance of NAE-3-SAT is $I = (v_1, v_2, \bar{v}_3)$ and the truth assignment is to set all variables equal to true.

■ **Figure 5** The trees T_1 and T_2 if $I = (v_1, v_2, \bar{v}_3)$ and $v_1 = v_2 = v_3 = \text{true}$.

Conversely, assume that G contains a 0-perfect forest with at least $|V(G)| - 2$ edges. As G is not a tree this implies that G contain two vertex-disjoint trees T_1 and T_2 such that each T_i is an induced tree in G of order at least 2, all degrees in each T_i are odd, and $V(T_1)$ and $V(T_2)$ partition $V(G)$. We will now prove the following claims where Claim C completes the proof of the theorem.

▷ **Claim A.** For each $i \in [n]$ one of the following cases hold.

- A.1:** $\{x_1^i, z_1^i, y_1^i\} \in V(T_1)$ and $\{x_2^i, z_2^i, y_2^i\} \in V(T_2)$.
- A.2:** $\{x_1^i, z_2^i, y_1^i\} \in V(T_1)$ and $\{x_2^i, z_1^i, y_2^i\} \in V(T_2)$.
- A.3:** $\{x_1^i, z_1^i, y_1^i\} \in V(T_2)$ and $\{x_2^i, z_2^i, y_2^i\} \in V(T_1)$.
- A.4:** $\{x_1^i, z_2^i, y_1^i\} \in V(T_2)$ and $\{x_2^i, z_1^i, y_2^i\} \in V(T_1)$.

Proof of Claim A. As the only two non-edges in H_i are $x_1^i y_1^i$ and $x_2^i y_2^i$ we note that there exist a 4-cycle on every set of 4 vertices in H_i . Therefore $|V(T_j) \cap V(H_i)| \geq 4$ is not possible for any $j \in [2]$ and $i \in [n]$. So $|V(T_j) \cap V(H_i)| = 3$ for $j \in [2]$ and $i \in [n]$.

As there is no 3-cycle in $G[V(T_j)]$ for $j \in [2]$ we note that x_1^i and y_1^i must belong to one of the trees, say T_j , and x_2^i and y_2^i must belong to the other tree, T_{3-j} . So if $x_1^i \in V(T_1)$ then $y_1^i \in V(T_1)$ and $\{x_2^i, y_2^i\} \subseteq V(T_2)$ and we are in case A.1 or A.2. On the other hand if $x_1^i \in V(T_2)$ then $y_1^i \in V(T_2)$ and $\{x_2^i, y_2^i\} \subseteq V(T_1)$ and we are in case A.3 or A.4. This completes the proof of Claim A. \triangleleft

\triangleright **Claim B.** For $i = 1, 2$, $G[V(Q) \cap V(T_i)]$ is a tree where all vertices have odd degree.

Proof of Claim B. Any vertex in G with degree one must belong to the same tree, T_j , as its neighbour, as both T_1 and T_2 have order at least two. By Claim A, we therefore note that $G[V(Q) \cap V(T_i)]$ is a path of length $3n$ with a pendent edge attached to each non-endpoint of the path. This implies that $G[V(Q) \cap V(T_i)]$ is a tree where all vertices have odd degree (as all degrees are either 1 or 3). This completes the proof of Claim B. \triangleleft

\triangleright **Claim C.** The instance I is NAE-satisfiable.

Proof of Claim C. Assume that the vertex c_j belongs to T_1 . First suppose that $|N_G(c_j) \cap V(T_1)| = 0$. In this case c_j has no neighbours in T_1 , a contradiction, as T_1 is a tree with order at least two. So $|N_G(c_j) \cap V(T_1)| \geq 1$. Assume that $|N_G(c_j) \cap V(T_1)| \geq 2$. As T_1 is an induced tree in G , c_j must have at least two neighbours, say x and y , in T_1 . However, by Claim B, there exists a (x, y) -path in T_1 using only vertices from $V(Q)$, which implies that there is a cycle in T_1 , a contradiction. Therefore $|N_G(c_j) \cap V(T_1)| = 1$.

Analogously, we can show that $|N_G(c_j) \cap V(T_2)| = 1$, whenever $c_j \in V(T_2)$. So each clause C_j ($j \in [m]$) has either exactly one literal that is false (if $c_j \in V(T_1)$) or exactly one literal that is true (if $c_j \in V(T_2)$). This implies that I is NAE-satisfiable, which completes the proof of Claim C and the theorem. \triangleleft

4 Proof of Theorem 6

To prove Theorem 6, we will use the following result. The proof of Theorem 4 follows the same approach as the proof that it is NP-hard to determine whether there is an induced cycle of odd length through a prescribed vertex, given in [2] by Bienstock. The proof is not given here but can be found in the appendix of [8].

\blacktriangleright **Theorem 4.** *It is NP-hard to determine whether a graph contains an induced cycle through two given edges.*

\blacktriangleright **Theorem 6.** *The following problem is NP-hard. Given a connected graph G and an edge $e \in E(G)$, decide whether G has a 0-perfect forest containing e .*

Proof. Let G be a graph and let $e_1 = u_1v_1$ and $e_2 = u_2v_2$ be distinct edges of G . We will construct an auxiliary graph H with an edge $e'_2 \in E(H)$, such that H contains a 0-perfect forest containing e'_2 if and only if G contains an induced cycle, C , such that $e_1, e_2 \in E(C)$. This will complete the proof by Theorem 4.

Let H be obtained from G by adding a pendent edge to each vertex in $V(G) \setminus \{u_1, v_1\}$ and deleting the edge e_1 . Let E_P denote the set of all the pendent edges we just added to G . Let $e'_2 = u_2v_2$ and note that $e'_2 \in E(H)$. This completes the construction of H .

Assume that there exists an induced cycle, C , in G such that $e_1, e_2 \in E(C)$. Let $E' = E_P \cup E(C) \setminus e_1$. Note that the edges in E' induce a 0-perfect forest in H containing the edge e'_2 .

Conversely assume that there is a 0-perfect forest, F , in H containing e'_2 . Clearly F contains all edges in E_P as each pendent edge is incident with a vertex of degree one. Let Q be the subgraph of H induced by the edges in $E(F) \setminus E_P$. Note that Q is a perfect forest

where u_1 and v_1 have odd degree and all other vertices have even degree. As Q is a perfect forest all components are induced trees, and as u_1 and v_1 are the only vertices of odd degree, this implies that Q is an induced path between u_1 and v_1 . Adding the edge e_1 to Q gives us an induced cycle in G containing both e_1 and e_2 (as $e'_2 \in E(F)$).

Therefore we have proven that H contains a 0-perfect forest containing e'_2 if and only if G contains an induced cycle, C , such that $e_1, e_2 \in E(C)$, as desired. ◀

5 Proof of Theorem 8

Let G be a graph and $e = uv$ an edge of G . Let $f: V(G) \rightarrow \{0, 1\}$ be an even-sum function. Our polynomial-time algorithm will follow from the four claims proved below. At the end of the proof, we briefly discuss how the claims are used in the algorithm.

▷ **Claim A.** Suppose that G contains a cut-vertex x , which may or may not belong to $\{u, v\}$. Let C be the component in $G - x$ intersecting $\{u, v\}$ (there is exactly one such component as $uv \in E(G)$) and let $G' = G[V(C) \cup \{x\}]$. Let $f'(w) = f(w)$ for all $w \in V(C)$ and define $f'(x) \in \{0, 1\}$ such that $\sum_{z \in V(G_i)} f'(z)$ is even. Then G has an f -parity perfect forest not containing e if and only if G' has an f' -parity perfect forest not containing e .

Proof of Claim A. Let G contain a cut-vertex x and let C_1, C_2, \dots, C_k be the components in $G - x$. Without loss of generality, assume that C_1 is the component intersecting $\{u, v\}$. Let $G_i = G[V(C_i) \cup \{x\}]$ for all $i \in [k]$.

For each $i \in [k]$ we will let $f_i: V(G_i) \rightarrow \{0, 1\}$ be defined such that $f_i(w) = f(w)$ for all $w \in V(C_i)$ and $\sum_{z \in V(G_i)} f_i(z)$ is even (this defines the value of $f_i(x)$). We will show that G has an f -parity perfect forest not containing e if and only if G_1 has an f_1 -parity perfect forest not containing e , which will complete the proof of Claim A.

First assume that G_1 has an f_1 -parity perfect forest F_1 not containing e . By Theorem 12 there exists an f_i -parity perfect forest, F_i , in G_i for all $i = 2, 3, \dots, k$. Now $F_1 \cup F_2 \cup \dots \cup F_k$ is an f -parity perfect forest of G not containing e , as desired.

Conversely assume that G has an f -parity perfect forest F not containing e . If we restrict F to $V(G_1)$, then we obtain an f_1 -parity perfect forest of G_1 not containing e . ◀

▷ **Claim B.** If G is 2-connected and $f(u) = 0$ or $f(v) = 0$ then G has an f -parity perfect forest not containing e .

Proof of Claim B. Assume without loss of generality that $f(u) = 0$. As G is 2-connected $G - u$ is connected and $\sum_{z \in V(G-u)} f(z)$ is even. Therefore, by Theorem 12, there exists an f -parity perfect forest in $G - u$, which is also an f -parity perfect forest in G not containing the edge e . ◀

▷ **Claim C.** If G is 2-connected and $f(u) = f(v) = 1$ then G has a f -parity perfect forest if and only if $\sum_{z \in V(G)} f(z) \geq 4$.

Proof of Claim C. Let $S = \sum_{z \in V(G)} f(z)$. As f is even-sum, S is even. Since $f(u) = f(v) = 1$, we have $S \geq 2$. If $S = 2$ and F is an f -parity perfect forest in G , then u and v must be leaves of the same tree in F (as they are the only vertices with an f -value of one). Therefore $e \in E(F)$, as otherwise the tree containing u and v is not induced in G . So, if $S = 2$ then G has no f -parity perfect forest F in G with $e \notin E(F)$.

We may therefore assume that $S \geq 4$ and let $w \in V(G) \setminus \{u, v\}$ have $f(w) = 1$. As G is 2-connected there exists a (u, v) -path, P , in G with $w \in V(P)$. (To see it, consider two internally disjoint paths from w to w' where w' is a new vertex added to G such that

54:10 Perfect Forests in Graphs and Their Extensions

$N(w') = \{u, v\}$.) We now create a spanning tree T in G , such that $E(P) \subseteq E(T)$ and $d_T(w) = 2$, as follows. Initially let $T = P$. While $V(T) \neq V(G)$ let $q \in V(G) \setminus V(T)$ be arbitrary such that q has an edge into $V(T) \setminus \{w\}$ (which exists as G is 2-connected). Add q and an edge from q into $V(T) \setminus \{w\}$ to T . When $V(T)$ becomes equal to $V(G)$ we have our desired tree T .

Let T_1 and T_2 be the two trees in $T - w$ (there are exactly two trees in $T - w$ as $d_T(w) = 2$). Let $S_1 = \sum_{z \in V(T_1)} f(z)$ and let $S_2 = \sum_{z \in V(T_2)} f(z)$. As $f(w) = 1$ and $V(T_1) \cup V(T_2) = V(G) \setminus \{w\}$, we note that $S_1 + S_2$ is odd. If S_i is odd then add w to T_i ($i \in [2]$), using the edge from w to $V(T_i)$ in T . This results in two trees, say T'_1 and T'_2 , where $\sum_{z \in V(T'_i)} f(z)$ is even for $i \in [2]$. Furthermore, as $w \in V(P)$ and $E(P) \subseteq E(T)$, we note that u and v do not belong to the same tree T'_i . By Theorem 12 there exists an f -parity perfect forest, F'_i , of $G[V(T'_i)]$ for $i \in [2]$ (as T'_i is a spanning tree in $G[V(T'_i)]$, $G[V(T'_i)]$ is connected). Now $F'_1 \cup F'_2$ is an f -parity perfect forest of G not containing e . This completes the proof of Claim C. \triangleleft

It is easy to see that the following algorithm is of polynomial time. Keep reducing the graph (see Claim A) as long as there exists a cut-vertex and when there are no more cut-vertices then the answer is “no” if the endpoints of e have an f -value of one and all other vertices have an f -value of zero and “yes”, otherwise (see Claims B and C). See Figure 6 for an illustration of the algorithm.

Figure 6 An illustration of the algorithm given in Theorem 8, where the values on the nodes indicate the f -values. As in the final graph the endpoints of e have an f -value of one and all other vertices have an f -value of zero there is no f -parity perfect forest in G' avoiding the edge e and therefore not in G either.

6 Proof of Theorem 10

Theorem 10 follows from Theorem 2 and Lemma 3 proved in this section. To prove Theorem 2, we will use the following:

► **Lemma 4.** *Let G be a connected graph of even order and let $xy \in E(G)$ such that $G - \{x, y\}$ is connected. If $G - x \in \mathcal{B}$ and $G - y \in \mathcal{B}$ then $N[x] = N[y]$.*

Proof. Let G be a connected graph of even order and let $xy \in E(G)$ be chosen such that $G - \{x, y\}$ is connected. Let $G_y = G - x$ and let $G_x = G - y$ and assume that $G_y \in \mathcal{B}$ and $G_x \in \mathcal{B}$. Let $C_1^x, C_2^x, \dots, C_{l_x}^x$ be the blocks of G_x and without loss of generality assume that $x \in V(C_1^x)$. Analogously, let $C_1^y, C_2^y, \dots, C_{l_y}^y$ be the blocks of G_y and without loss of generality assume that $y \in V(C_1^y)$.

▷ **Claim A.** $N_{G_x}[x] = V(C_1^x)$ and C_1^x is a complete graph of odd order and $C_1^x - x$ is a block in $G - \{x, y\}$. Analogously, $N_{G_x}[y] = V(C_1^y)$ and C_1^y is a complete graph of odd order and $C_1^y - y$ is a block in $G - \{x, y\}$.

Proof of Claim A. For the sake of contradiction assume that $u_1, u_2 \in N_{G_x}(x)$ but u_1 and u_2 belong to different blocks of G_x . In this case there is a cut-vertex in G_x separating u_1 and u_2 , which must be x (as u_1xu_2 is a path in G_x). However x does not separate u_1 and u_2 as $G - \{x, y\}$ is connected. This contradiction implies that all vertices in $N_{G_x}(x)$ belong to the same block of G_x .

Therefore, $N_{G_x}[x] \subseteq V(C_1^x)$ as x is not a cut-vertex in G_x (as $G - \{x, y\}$ is connected) and hence x only belongs to one block of G_x . As $G_x \in \mathcal{B}$ we note that C_1^x is a complete graph of odd order. As $|V(C_1^x)| \geq 3$ (as all blocks contain at least two vertices, and $|V(C_1^x)|$ is odd) and x is not a cut-vertex in G_x we note that $C_1^x - x$ is a block in $G - \{x, y\}$. This completes the proof of Claim A. ◁

We now return to the proof of the lemma. By Claim A we note that $C_1^y - y$ is a block in $G - \{x, y\}$ which furthermore is a complete graph of even order. If $C_1^x - x$ and $C_1^y - y$ are different blocks in $G - \{x, y\}$, then $C_1^y - y$ is a block of even order in G_x , a contradiction to $G_x \in \mathcal{B}$. So, $C_1^x - x$ and $C_1^y - y$ are the same block in $G - \{x, y\}$. By Claim A, we have the following chain of equalities, which completes the proof of the lemma.

$$N_G[x] = V(C_1^x - x) \cup \{x, y\} = V(C_1^y - y) \cup \{x, y\} = N_G[y] \quad \blacktriangleleft$$

► **Theorem 2.** *Every connected graph, $G \notin \mathcal{B}$, of odd order $n \geq 3$ contains a proper 1-perfect forest.*

Proof. The proof is by induction over odd integers $n \geq 3$. For $n = 3$, we have $G \cong P_3$, the path of order 3, which is a proper 1-perfect forest. Now we assume that G is a connected graph of odd order $n \geq 5$ such that $G \notin \mathcal{B}$. Let us consider two cases.

Case 1: G is not 2-connected. Assume that G has a cut-vertex x such that $G - x$ has a component C_1 of even order. Let $G_1 = G[V(C_1) \cup \{x\}]$ and let $G_2 = G - V(C_1)$. Note that both G_1 and G_2 are connected graphs of odd order. Furthermore the set of blocks of G is exactly the union of the blocks in G_1 and G_2 . As $G \notin \mathcal{B}$ (and therefore some block in G is not a complete graph of odd order) we note that either $G_1 \notin \mathcal{B}$ or $G_2 \notin \mathcal{B}$ (or both).

Let $i \in \{1, 2\}$ be defined such that $G_i \notin \mathcal{B}$ and let $j = 3 - i$. By induction hypothesis, there exists a proper 1-perfect forest F_i in G_i . By Theorem 9 there also exists a (not necessarily proper) 1-perfect forest, F_j , in G_j , where x is the vertex of even degree in F_j . We now note that $F_i \cup F_j$ is a proper 1-perfect forest of G , where the only vertex of even degree is the vertex of even degree in F_i . Thus, we may assume that G has no cut-vertex x such that some component in $G - x$ is of even order.

Now assume that G contains a cut-vertex x . By the previous assumption, all components in $G - x$ are of odd order, and let C_1 be a component of $G - x$. Let $G_1 = G[V(C_1) \cup \{x\}]$ and let $G_2 = G - V(C_1)$. Note that both G_1 and G_2 are connected graphs of even order. By Theorem 1 there exists a 0-perfect forest F_1 in G_1 and a 0-perfect forest F_2 in G_2 . Note that $F_1 \cup F_2$ is now a proper 1-perfect forest of G , where the only vertex of even degree is x .

Case 2: G is 2-connected.

► **Definition A.** As $G \notin \mathcal{B}$ and G has odd order, we note that G is not a complete graph. Therefore there exists an induced path $p_1p_2p_3$ in G (that is, $p_1p_2, p_2p_3 \in E(G)$ and $p_1p_3 \notin E(G)$). Let C_1, C_2, \dots, C_l be the components in $G - \{p_2, p_3\}$, such that $p_1 \in C_1$.

Assume first that $|V(C_1)|$ is odd. By Theorem 9 there exists a 1-perfect forest F_1 in C_1 , such that p_1 (see Definition A) is the vertex of even degree in F_1 . Let $G' = G - V(C_1)$ and note that G' is connected and of even order. Therefore, by Theorem 1, there exists a 0-perfect forest, F' , in G' .

If $d_{F_1}(p_1) > 0$ then $F_1 \cup F'$ is a proper 1-perfect forest in G . Now consider the case when $d_{F_1}(p_1) = 0$. As $N(p_1) \cap V(G') = \{p_2\}$ (as $p_1p_2p_3$ is an induced path in G) we note that adding the edge p_1p_2 to $F_1 \cup F'$ gives us a proper 1-perfect forest in G (where p_2 is the only vertex of even degree). Thus, in the rest of the proof, we may assume that $|V(C_1)|$ is even.

Let $G' = G[V(C_1) \cup \{p_2, p_3\}]$ and note that G is connected and of even order. Furthermore $G' - \{p_2, p_3\}$ is connected (as $G' - \{p_2, p_3\} = C_1$). As p_1 is adjacent to p_2 but not to p_3 we note that $N_{G'}[p_2] \neq N_{G'}[p_3]$. By Lemma 4 we must therefore have $G' - p_2 \notin \mathcal{B}$ or $G' - p_3 \notin \mathcal{B}$. Let $i \in \{2, 3\}$ be chosen such that $G' - p_i \notin \mathcal{B}$, which by induction hypothesis implies that there is a proper 1-perfect forest F_1 in $G' - p_i$.

As G is 2-connected, we note that p_{5-i} is not a cut-vertex of G . Therefore every component in $G - \{p_2, p_3\}$ has an edge to p_i , which implies that $G - V(F_1)$ is connected and of even order (as both G and F_1 are of odd order). By Theorem 1 there exists a 0-perfect forest, F_2 , in $G - V(F_1)$. Now $F_1 \cup F_2$ is a proper 1-perfect forest in G . This completes the proof. ◀

A semiperfect forest F of G is called a *2-perfect forest* if exactly two vertices of F have even degree.

► **Lemma 3.** If G is a connected graph of odd order and $G \in \mathcal{B}$ then G does not contain a proper 1-perfect forest.

Proof. Let G be a connected graph of odd order and let $G \in \mathcal{B}$. We will prove that G contains no proper 1-perfect forest. We will prove this using induction on the number of blocks in G .

If G contains only one block then G is a complete graph of odd order. In this case, any forest where all trees are induced, can only contain trees of order 2 (and 1 if we allow isolated vertices). This implies that G cannot contain a proper 1-perfect forest as G has odd order. This completes the base case.

Now assume that G contains at least two blocks, which implies that G contains a cut-vertex, x . Let C_1, C_2, \dots, C_l be the components in $G - x$ and let $G_i = G[V(C_i) \cup \{x\}]$ for $i \in [l]$. For the sake of contradiction suppose that G contains a proper 1-perfect forest F and let F_i denote F restricted to G_i for $i \in [l]$. As F is a proper 1-perfect forest we note that $d_F(x) \geq 1$. Without loss of generality, assume that $d_{F_1}(x) \geq 1$. This implies that F_1 is a proper i -forest in G_1 where $i \in \{0, 1, 2\}$. However as $|V(G_1)|$ is odd (as $G \in \mathcal{B}$) this implies that F_1 is a proper 1-perfect forest in G_1 . This is a contradiction to $G_1 \in \mathcal{B}$ (as $G \in \mathcal{B}$). ◀

Abstract

Given an existential formula Φ of linear arithmetic over p -adic integers together with valuation constraints, we study the p -universality problem which consists of deciding whether Φ is satisfiable for all primes p , and the analogous problem for the closely related existential theory of Büchi arithmetic. Our main result is a coNEXP upper bound for both problems, together with a matching lower bound for existential Büchi arithmetic. On a technical level, our results are obtained from analysing properties of a certain class of p -automata, finite-state automata whose languages encode sets of tuples of natural numbers.

1 Introduction

In the light of the undecidability of Hilbert's tenth problem, the decidability of the Diophantine problem for addition and divisibility established by Lipshitz [20] is a non-trivial and interesting result. The latter problem consists of deciding whether a system of divisibility constraints of the form $p(\mathbf{x}) \mid q(\mathbf{x})$, with p and q being linear polynomials, has a solution over the integers. Lipshitz' proof of decidability relies on a local-to-global principle. He showed that every such system can be transformed into an equi-satisfiable one that has a solution if and only if an associated restricted system of linear equations with simple p -adic valuation constraints is satisfiable over the p -adic integers for every prime p . We call the latter problem the *p -universality problem*. To decide p -universality for the restricted class he considered, Lipshitz showed that it suffices to only check satisfiability for all primes p up to a certain threshold that can be computed from the input. One main result of this paper is to show that the latter result can be generalised: p -universality is decidable in coNEXP for *arbitrary* systems of linear equations over p -adic integers together with *general* linear p -adic valuation constraints. For linear equations with first-order variables ranging over the whole field of the p -adic numbers and restricted valuation constraints that allow to impose a partial order on the p -adic valuations of the first-order variables, a quantifier-elimination procedure was given by Dolzmann and Sturm from which it is possible to derive a coNEXP upper bound for p -universality in this setting [8]. Their result also shows that, in their setting, the set of those primes for which a solution exists is either finite or co-finite.

Linear arithmetic over p -adic integers with valuation constraints is closely related to *Büchi arithmetic*. Büchi arithmetic of base $p \geq 2$, p not necessarily prime, is the first-order theory of the structure $(\mathbb{N}, +, =, V_p)$, an extension of Presburger arithmetic with a unary V_p function

such that $V_p(a) = b$ if and only if b is the largest power of p dividing a without remainder, i.e., there is some $k \in \mathbb{N}$ such that $b = p^k$, $b \mid a$ and $p \cdot b \nmid a$. Büchi showed that this theory is decidable using an automata-based approach, and conversely that Büchi arithmetic of base p defines the sets of numbers recognisable by p -automata, finite-state automata defining tuples of natural numbers encoded as words of tuples over the alphabet $\{0, \dots, p-1\}$ [5], though the latter result was incorrectly stated by Büchi and later correctly stated and proved by Bruyère [3]. One central line of research in Büchi arithmetic has been to understand the properties of this theory when the base p is variable. For instance, the celebrated Cobham-Semënov theorem states that if a set $M \subseteq \mathbb{N}^d$ is separately definable in Büchi arithmetic of multiplicatively independent bases p and q , then M is definable in Presburger arithmetic [7, 26]. Another main result of this paper is to show coNEXP-completeness of the analogue of p -universality for existential Büchi arithmetic: given an existential formula Ψ of Büchi arithmetic, decide whether Ψ is satisfiable in all bases $p \geq 2$. Note that p -universality does not imply definability in Presburger arithmetic as, for instance, the formula $V_p(x) = y$ is not definable in Presburger arithmetic, but it is p -universal.

Both coNEXP upper bounds are obtained by establishing doubly-exponential upper bounds on the smallest p for which a given formula becomes unsatisfiable. As a structural result, we obtain that for linear equations over p -adic integers with valuation constraints, the set of those primes p for which a given instance is satisfiable is precisely contained in an ultimately periodic set. On a technical level, our results are obtained by analysing properties of p -automata. While the latter have been studied for decades, only recently have they been instrumental in obtaining tight complexity bounds for long-standing open problems about the complexity of the satisfiability problem of the existential theories of the two arithmetic theories we consider in this paper [11]. A key observation we exploit for our approach is that the set of states of a p -automaton accepting the solutions of a system of linear Diophantine equations does *not* depend on p . Note that the quantifier-elimination approach employed by Dolzmann and Sturm [8] does not seem applicable in our setting as it works over the whole p -adic numbers and relies on them being a field. Moreover, Büchi arithmetic does not have a quantifier-elimination procedure, even when extended with additional predicates definable in existential Büchi arithmetic [13].

2 Preliminaries and main results

The symbols \mathbb{Z} , \mathbb{N} and \mathbb{Q} denote the set of integers, natural and rational numbers, respectively. We write \mathbb{P} for the set of prime numbers, and $\overline{\mathbb{Z}}$ to denote the set of integers extended with the symbol ∞ such that $n \leq \infty$ for all $n \in \mathbb{Z}$. All numbers are assumed to be encoded in binary, unless otherwise stated. For any object, we denote by $\langle \cdot \rangle$ the size of its encoding.

Linear arithmetic constraints over p -adic integers. Let $p \geq 2$ be a fixed prime number. Given a non-zero rational number $q \in \mathbb{Q}$, the p -adic valuation $v_p(q)$ is defined as the unique integer $k \in \mathbb{Z}$ such that $q = p^k \cdot \frac{a}{b}$ for $a, b \in \mathbb{Z}$ not divisible by p , and $v_p(0) = \infty$. The valuation v_p induces the p -adic absolute value $|\cdot|_p$ defined as $|q|_p = p^{-v_p(q)}$. The field of p -adic numbers \mathbb{Q}_p is obtained as the Cauchy completion of the field of the rational numbers under $|\cdot|_p$. Any p -adic number different from 0 has a unique p -adic expansion as an infinite power series $\sum_{i=k}^{\infty} a_i p^i$ for some $k \in \mathbb{Z}$, $a_k \neq 0$ and $a_i \in [0, p-1]$ for all $i \geq k$. The ring \mathbb{Z}_p of p -adic integers consists of all p -adic numbers for which this k is non-negative. By *linear arithmetic constraints over p -adic integers*, we refer to the first-order theory of the two-sorted structure $(\{\mathbb{Z}_p, \overline{\mathbb{Z}}\}, 0, 1, +, =, <, v_p)$. All constants, relational and functional symbols have their natural

semantics, and v_p is the p -adic valuation mapping p -adic integers to the valuation ring $\overline{\mathbb{Z}}$. For simplicity, we view the constants 0 and 1 as well as binary addition $+$ as being defined for both sorts. However, addition is restricted between elements of the *same* sort. The equality relation $=$ is defined on both $\overline{\mathbb{Z}}$ and \mathbb{Z}_p , whereas the less-than relation $<$ is restricted to the valuation ring $\overline{\mathbb{Z}}$. Usually, the letters u, v refer to first-order variables interpreted over \mathbb{Z}_p , and x, y, z refer to variables over $\overline{\mathbb{Z}}$. We rely on the axiom system for integer arithmetic enriched with infinity presented in [17] to treat linear terms over the valuation ring containing the symbol ∞ .

Note that we allow arbitrary Boolean combinations of linear inequalities to constraint valuations of the variables from \mathbb{Z}_p , whereas Dolzmann and Sturm [8] as well as Lipshitz [20] only allow restricted constraints of the form $v_p(u) \leq v_p(v)$.

Büchi arithmetic. Let $p \geq 2$ be a fixed integer. *Büchi arithmetic* of base p is the first-order theory of the structure $(\mathbb{N}, 0, 1, +, =, V_p)$, where the constants 0 and 1 and the relations $+$ and $=$ are interpreted in their natural semantics, and V_p is the unary function mapping every non-zero integer x to the largest power of p that divides x without remainder as defined in the introduction. For the purpose of this paper, as in [4] we define $V_p(0) = 1$, though other definitions such $V_p(0) = \infty$ are possible, but they do not change the sets of numbers definable in Büchi arithmetic. The decidability of Büchi arithmetic rests on the fact that Büchi arithmetic is an automatic structure in the sense of [14, 16, 2]. While full Büchi arithmetic is TOWER-complete [25], its existential fragment is only NP-complete [11].

Main decision problems and results. Both Büchi arithmetic and linear arithmetic constraints over p -adic integers are defined with respect to a fixed base $p \in \mathbb{N}$. In this paper, we treat p as a parameter, and, for a given formula Φ of *existential* Büchi arithmetic or *existential* linear arithmetic constraints over p -adic integers mentioning p , are interested in the following two decision problems:

- p -EXISTENCE: Is Φ satisfiable for *some* $p \geq 2$?
- p -UNIVERSALITY: Is Φ satisfiable for *every* $p \geq 2$?

When Φ is a formula of linear arithmetic constraints over p -adic integers, p above is additionally restricted to be a prime number. For the complexity of those decision problems, we stipulate that the V_p and v_p functions count as a single symbol in $\langle \Phi \rangle$ for any formula Φ . Note that p -universality and p -existence are not the complement of one and another: the formula $x \neq 2 \vee V_p(x) = 2$ of Büchi arithmetic has a solution for $p = 2$, but its negation is not p -universal. As the main results of this paper, we show:

► **Theorem 1.** *For both Büchi arithmetic and linear arithmetic constraints over p -adic integers, p -existence and p -universality are decidable in NEXP and coNEXP, respectively.*

► **Theorem 2.** *Deciding p -universality for Büchi arithmetic is coNEXP-hard.*

Further general notation. For an arbitrary set A , we write $\#A$ for its cardinality. If A is infinite, then $\#A = \infty$. For $a, b \in \mathbb{Z}$, we write $[a, b]$ for the set $\{a, a + 1, \dots, b\}$. Given a matrix $\mathbf{A} \in \mathbb{Z}^{n \times d}$ with components $a_{i,j} \in \mathbb{Z}$ ($i \in [1, n]$ and $j \in [1, d]$), the ∞ -norm of \mathbf{A} is defined as $\|\mathbf{A}\|_\infty \stackrel{\text{def}}{=} \max_{i=1, j=1}^{n, d} |a_{i,j}|$. We extend $\|\cdot\|_\infty$ to vectors in \mathbb{Z}^d by viewing them as elements of $\mathbb{Z}^{d \times 1}$. The $(1, \infty)$ -norm of \mathbf{A} is defined as $\|\mathbf{A}\|_{1, \infty} \stackrel{\text{def}}{=} \max_{i=1}^n \sum_{j=1}^d |a_{i,j}|$. Given a finite set $A \subseteq \mathbb{Z}^n$ of d integer vectors, we write $A^{\mathbf{M}}$ to denote the $n \times d$ matrix whose columns are the vectors in A , ordered following a lexicographic ordering. When clear from the context, we shall abbreviate $A^{\mathbf{M}}$ simply as \mathbf{A} . We write $\|A\|_\infty$ for $\|\mathbf{A}\|_\infty$.

Let $S: \mathbf{A} \cdot \mathbf{x} \geq \mathbf{c}$ be a system of linear inequalities with $\mathbf{A} \in \mathbb{Z}^{n \times d}$ and $\mathbf{c} \in \mathbb{Z}^n$. We write $\llbracket S \rrbracket$ for the solution set of S , that is the set of all $\mathbf{v} \in \mathbb{Z}^d$ such that $\mathbf{A} \cdot \mathbf{v} \geq \mathbf{c}$. We use $\llbracket S \rrbracket_{\geq 0}$ as a shorthand for $\llbracket S \rrbracket \cap \mathbb{N}^d$. Moreover, we define $\|S\| \stackrel{\text{def}}{=} \max(\|\mathbf{A}\|_\infty, \|\mathbf{c}\|_\infty)$. Finally, given a formula Φ of either Büchi arithmetic or linear arithmetic constraints over p -adic integers, we write $\|\Phi\|$ for the maximum absolute value of an integer appearing in Φ .

Deterministic p -automata and linear Diophantine equations. A central technical tool underlying the results of Theorem 1 are p -automata, a class of finite-state automata whose languages encode sets of natural numbers, see e.g. [4]. Given an integer $p \geq 2$, a p -automaton is a deterministic automaton over an alphabet $\Sigma_p^d := [0, p-1]^d$ for some positive integer d . A finite word $w = \mathbf{u}_k \cdots \mathbf{u}_0 \in (\Sigma_p^d)^*$ over Σ_p^d can be seen as encoding a d -tuple of non-negative integers in base p . We consider a *msd-first encoding* $\llbracket \cdot \rrbracket^*$, in which the most significant digit is on the left. Formally, $\llbracket w \rrbracket^* \in \mathbb{N}^d$ is defined as $\sum_{j=0}^k p^k \cdot \mathbf{u}_j$. Also note that for $w = \varepsilon$, the empty word, we have $\llbracket w \rrbracket^* = \mathbf{0}$.

Following [29], we define a p -automaton whose language is the msd-first encoding of all non-negative integer solutions of a system of linear equations.

► **Definition 3.** Let $S: \mathbf{A} \cdot \mathbf{x} = \mathbf{c}$ be a system of linear Diophantine equations with $\mathbf{A} \in \mathbb{Z}^{n \times d}$ and $\mathbf{c} \in \mathbb{Z}^n$. We define a p -automaton corresponding to S as $\mathcal{A}_p^*(S) \stackrel{\text{def}}{=} (Q, \Sigma_p^d, \delta, \mathbf{q}_0, F)$ with a set of states $Q = \mathbb{Z}^n$, transitions $\delta(\mathbf{q}, \mathbf{u}) = p \cdot \mathbf{q} + \mathbf{A} \cdot \mathbf{u}$ for all $\mathbf{q} \in Q$ and $\mathbf{u} \in \Sigma_p^d$, initial state $\mathbf{q}_0 = \mathbf{0}$, and final state $F = \{\mathbf{c}\}$.

For states $\mathbf{s}, \mathbf{t} \in Q$ and $\mathbf{u} \in \Sigma_p^d$, we write $\mathbf{s} \xrightarrow{\mathbf{u}}_{\mathbf{A}, p} \mathbf{t}$ whenever $\delta(\mathbf{s}, \mathbf{u}) = \mathbf{t}$. This notation is extended to words in the usual way: for a word $w \in (\Sigma_p^d)^*$, $\mathbf{s} \xrightarrow{w}_{\mathbf{A}, p} \mathbf{t}$ whenever there is $\mathbf{q} \in Q$ such that $\mathbf{s} \xrightarrow{w}_{\mathbf{A}, p} \mathbf{q} \xrightarrow{\mathbf{u}}_{\mathbf{A}, p} \mathbf{t}$. We write $\mathbf{s} \rightarrow_{\mathbf{A}, p} \mathbf{t}$ if $\mathbf{s} \xrightarrow{w}_{\mathbf{A}, p} \mathbf{t}$ holds for some $w \in (\Sigma_p^d)^*$, and omit the subscripts \mathbf{A} or p from $\rightarrow_{\mathbf{A}, p}$ when clear from the context.

As usual, under *regular* acceptance condition, a finite word $w \in (\Sigma_p^d)^*$ is accepted by the automaton $\mathcal{A} = \mathcal{A}_p^*(S)$ whenever $\mathbf{q}_0 \xrightarrow{w} \mathbf{f}$ for some $\mathbf{f} \in F$. The language $\mathcal{L}^*(\mathcal{A})$ of \mathcal{A} is the set of all words that are accepted by \mathcal{A} . Even though the automaton \mathcal{A} has infinitely many states, $\mathcal{L}^*(\mathcal{A})$ is a regular language since only finitely many *live states* can reach an accepting state.

► **Proposition 4** ([11], Prop. 5). Given the automaton $\mathcal{A}_p^*(S)$, only states $\mathbf{q} \in Q$ such that $\|\mathbf{q}\|_\infty \leq \max(\|\mathbf{A}\|_{1, \infty}, \|\mathbf{c}\|_\infty)$ can reach an accepting state.

Proposition 4 implies a bound on the cardinality of the set L of live states of the p -automaton $\mathcal{A}_p^*(S)$ as defined in Definition 3:

$$\#L \leq 2^n \cdot \max(\|\mathbf{A}\|_{1, \infty}, \|\mathbf{c}\|_\infty)^n \quad (1)$$

Observe that Proposition 4 also gives us a first key insight into deciding p -universality, as it shows that the set of live states of a p -automaton $\mathcal{A}_p^*(S)$ does *not* depend on the base p , but only on the system S . Deciding reachability in a p -automaton reduces to finding non-negative solutions to a certain system of Diophantine equations, as shown by the following proposition.

► **Proposition 5** ([11]). Given $\mathbf{s}, \mathbf{t} \in Q$, $k \in \mathbb{N}$ and $w \in (\Sigma_p^d)^k$, $\mathbf{s} \xrightarrow{w} \mathbf{t}$ iff $\mathbf{t} = p^k \cdot \mathbf{s} + \mathbf{A} \cdot \llbracket w \rrbracket^*$.

In view of the bounds on the set of live states given in (1), the length of the shortest word w witnessing $\mathbf{s} \rightarrow \mathbf{t}$ is exponential in $\langle S \rangle$. Of course, when $\mathbf{s} = \mathbf{0}$ and $\mathbf{t} = \mathbf{c}$, this bound is non-optimal, as von zur Gathen and Sieveking [27] have shown that any feasible system of

linear Diophantine equations S has a solution whose bit-size is polynomially bounded in $\langle S \rangle$. However, in the context of the p -universality problem, this bound on w is sufficient for us to establish the complexity upper bounds given by Theorem 1.

ω -regular acceptance condition and systems of equations over p -adic integers. A similar connection as in the previous paragraph can be established for systems of equations over p -adic integers [11]. In this setting, we consider infinite words $w = \mathbf{u}_0\mathbf{u}_1 \cdots \in (\Sigma_p^d)^\omega$ over Σ_p^d and view them as *lsd-first encodings* of d -tuples of p -adic integers in which the least significant digit is on the left. Formally, we define $\llbracket w \rrbracket^\omega \in \mathbb{Z}_p^d$ as $\sum_{j=0}^{\infty} p^j \cdot \mathbf{u}_j$.

Let $S: \mathbf{A} \cdot \mathbf{x} = \mathbf{c}$ be a system of linear equations with $\mathbf{A} \in \mathbb{Z}^{n \times d}$ and $\mathbf{c} \in \mathbb{Z}^n$, and let $w = \mathbf{u}_0\mathbf{u}_1 \cdots \in (\Sigma_p^d)^\omega$. We have $\mathbf{A} \cdot \llbracket w \rrbracket^\omega = \mathbf{c}$ if and only if $\mathbf{A} \cdot \llbracket w \rrbracket^\omega = \mathbf{c} \pmod{p^k}$ for all $k \in \mathbb{N}$. It follows, and was also discussed in [11], that $\mathbf{A} \cdot \llbracket w \rrbracket^\omega = \mathbf{c}$ if and only if for every $k \in \mathbb{N}$ there is $\mathbf{r} \in \mathbb{Z}^n$ such that $\mathbf{A} \cdot \llbracket \mathbf{u}_{k-1}\mathbf{u}_{k-2} \cdots \mathbf{u}_0 \rrbracket^* + \mathbf{r} \cdot p^k = \mathbf{c}$. By Proposition 5, the right hand side of this double implication expresses that the state \mathbf{r} can reach \mathbf{c} in the p -automaton $\mathcal{A}_p^*(S)$ by reading the word $\mathbf{u}_{k-1}\mathbf{u}_{k-2} \cdots \mathbf{u}_0$. So, $\mathbf{A} \cdot \llbracket w \rrbracket^\omega = \mathbf{c}$ is satisfied whenever the Büchi automaton obtained from $\mathcal{A}_p^*(S)$ by reversing every transition and making all states accepting has a non-empty language for the initial state \mathbf{c} . This ω -regular acceptance condition can equivalently be formulated as follows:

► **Proposition 6.** *For all $w = \mathbf{u}_0\mathbf{u}_1 \cdots \in (\Sigma_p^d)^\omega$, $\mathbf{A} \cdot \llbracket w \rrbracket^\omega = \mathbf{c}$ iff there is $\mathbf{r} \in \mathbb{Z}^n$ and a strictly ascending sequence $(\lambda_i)_{i \in \mathbb{N}}$ such that $\mathbf{r} \xrightarrow{\mathbf{u}_{\lambda_0-1} \cdots \mathbf{u}_{\lambda_0}}_{\mathbf{A}, p} \mathbf{c}$ and $\mathbf{r} \xrightarrow{\mathbf{u}_{\lambda_{j+1}} \cdots \mathbf{u}_{\lambda_j}}_{\mathbf{A}, p} \mathbf{r}$ for all $j \in \mathbb{N}$.*

Semi-linear set and ultimately periodic sets. Together with p -automata, to prove Theorem 1 we rely on well-known connections between solutions of systems of linear Diophantine equations and semi-linear sets. For $\mathbf{b} \in \mathbb{Z}^d$ and a finite set $P \subseteq \mathbb{Z}^d$ consisting of n elements, $L(\mathbf{b}, P)$ defines the *linear set* $\{\mathbf{x} \in \mathbb{Z}^d : \mathbf{x} = \mathbf{b} + \mathbf{P} \cdot \boldsymbol{\lambda} \text{ for some } \boldsymbol{\lambda} \in \mathbb{N}^n\}$. For a finite set $B \subseteq \mathbb{Z}^d$, $L(B, P)$ defines the *hybrid-linear set* $\bigcup_{\mathbf{b} \in B} L(\mathbf{b}, P)$. A *semi-linear set* is a finite union of hybrid-linear sets.

We use the following bound on the magnitude of the *bases* B and *periods* P of the set of solutions of a system of linear Diophantine equations, which is derived from [23].

► **Proposition 7** ([6], Prop. 4). *Let $\mathbf{A} \in \mathbb{Z}^{n \times d}$, $\mathbf{c} \in \mathbb{Z}^n$ and $S: \mathbf{A} \cdot \mathbf{x} = \mathbf{c}$. Then $\llbracket S \rrbracket_{\geq 0} = L(B, P)$ where $\|B\|_\infty \leq ((d+1) \cdot \|\mathbf{A}\|_\infty + \|\mathbf{c}\|_\infty + 1)^n$ and $\|P\|_\infty \leq (d \cdot \|\mathbf{A}\|_\infty + 1)^n$.*

Eventually, deciding p -existence and p -universality reduces to characterising the set of bases p for which an existential formula of Büchi arithmetic (or linear arithmetic constraints over p -adic integers) is satisfiable. This leads us to consider semi-linear sets in \mathbb{N} , which are equivalent to *ultimately periodic sets*, i.e., sets of definable as $F \cup L(T, q)$, where $q \in \mathbb{N}$ is the *period* of the ultimately periodic set, $F \subseteq \mathbb{N}$ is a finite set such that $\max F < \min T$, and $T \subseteq [t, t+q-1]$, where $t \in \mathbb{N}$ is the *threshold* of the ultimately periodic set.

Following [28], the essential building block leading to this change of representation, from one-dimensional semi-linear sets to ultimately periodic sets, is given by the proposition below.

► **Proposition 8.** *Let $M = L(B, P) \subseteq \mathbb{N}$. Then M is an ultimately periodic set with period $\text{gcd } P$ and threshold bounded by $\|B\|_\infty + \|P\|_\infty^2$.*

We recall bounds on union, intersection and set difference of ultimately periodic sets.

► **Proposition 9.** *Let M and N be two ultimately periodic sets with periods and thresholds respectively (p_1, t_1) and (p_2, t_2) . Then, $M \cup N$, $M \cap N$ and $M \setminus N$ are ultimately periodic sets with period $\text{lcm}(p_1, p_2)$ and threshold $\max(t_1, t_2)$.*

Since $\mathbb{N} = L(0, 1)$, Proposition 9 shows that the complement $\mathbb{N} \setminus M$ of an ultimately periodic set M is itself ultimately periodic, and has the same period and threshold as M .

For linear arithmetic constraints over p -adic integers, p -existence and p -universality restrict p to be prime numbers. We handle this restriction by using a variant of Linnik's theorem [19] to guarantee the existence of small primes on arithmetic progressions.

► **Proposition 10.** *There is a constant $c > 0$ such that for all co-prime $b, q \in \mathbb{N}$ there is some $p \in L(b, q) \cap \mathbb{P}$ such that $p \leq c \cdot (b \cdot r)^5$.*

Proof. Under the assumption that $b \in [1, q - 1]$, Linnik's theorem states that $L(b, q)$ contains a prime in $[1, d \cdot p^L]$ for fixed $d > 0$ and $L \in \mathbb{N}$. The best known bound for L is 5, as shown by Xylouris in [30]. To get rid of this additional restriction on b , consider a prime $s \in [b+1, 2(b+1)]$, whose existence follows from Bertrand's postulate [22]. From the primality of $s > b$ and the co-primality of b and q , we derive $\gcd(b, s \cdot q) = 1$ and $b < s \cdot r$. We can now safely apply Linnik's theorem, and derive that $L(b, s \cdot r) \subseteq L(b, q)$ contains a prime bounded by $c \cdot (b \cdot r)^5$ for some constant $c > 0$. ◀

Observe that every element of $L(b, q)$ is by definition divided by $\gcd(b, q)$. Hence, in the case where b and q are not co-prime, the only possible prime number appearing in $L(b, q)$ is b .

3 Exponential witnesses for p -existence and p -universality

For an existential formula Φ of either Büchi arithmetic or linear arithmetic constraints over p -adic integers, parametric in their base p , we write $\mathcal{B}(\Phi)$ for the set of bases $p \geq 2$ for which Φ is satisfiable. Note that, in defining $\mathcal{B}(\Phi)$ for linear arithmetic constraints over p -adic integers, we temporarily lift the primality condition on p . In this section, we establish the following result, which represents a crucial step in showing that the p -existence and p -universality problems are decidable in NEXP and coNEXP, respectively, proven in Section 4.

► **Theorem 11.** *Let Φ be an existential formula from Büchi arithmetic (resp. from linear arithmetic constraints over p -adic integers).*

- *If it exists, the smallest base $p \geq 2$ (resp. p prime) in $\mathcal{B}(\Phi)$ is bounded by $2^{2^{\mathcal{O}((\Phi)^2)}}$,*
- *If it exists, the smallest base $p \geq 2$ (resp. p prime) not in $\mathcal{B}(\Phi)$ is bounded by $2^{2^{\mathcal{O}((\Phi)^2)}}$.*

Whereas members of $\mathcal{B}(\Phi)$ are certificates of p -existence, a certificate for the non-universality of $\mathcal{B}(\Phi)$ can be retrieved from the “bases complement” $\overline{\mathcal{B}(\Phi)} \stackrel{\text{def}}{=} \mathbb{N} \setminus (\mathcal{B}(\Phi) \cup \{0, 1\})$. Consequently, a proof of Theorem 11 follows as soon as we show the following proposition.

► **Proposition 12.** *$\mathcal{B}(\Phi)$ is an ultimately periodic set with period and threshold in $2^{2^{\mathcal{O}((\Phi)^2)}}$.*

By Proposition 9, this result implies that $\overline{\mathcal{B}(\Phi)}$ is an ultimately periodic set with the same period and threshold as $\mathcal{B}(\Phi)$. Notice that for linear arithmetic constraints over p -adic integers the primality of the certificates can be obtained by an application of Linnik's theorem: consider the ultimately periodic representation $F \cup L(T, q)$ of $\mathcal{B}(\Phi)$, and suppose that it contains a prime. If $F \cup T$ contains a prime, then it is bounded by $2^{2^{\mathcal{O}((\Phi)^2)}}$. Otherwise, there is some $t \in T$ such that $L(t, q)$ contains a prime. So, t and q are co-prime (as $t \notin \mathbb{P}$), and by Linnik's theorem $L(t, q)$ has a prime bounded by $2^{2^{\mathcal{O}((\Phi)^2)}}$. Analogously, if $\mathcal{B}(\Phi)$ avoids a prime, then $\overline{\mathcal{B}(\Phi)}$ has a prime in $2^{2^{\mathcal{O}((\Phi)^2)}}$.

Proof of Proposition 12: Büchi arithmetic. Let Φ be a formula of existential Büchi arithmetic with parametric base p . To show Proposition 12, we introduce an abstraction of p -automata that we call *support graphs*. Support graphs are graphs that, while being independent from the base p , may correspond to paths of a p -automaton for a linear system $S: \mathbf{A} \cdot \mathbf{x} = \mathbf{c}$, and integrate auxiliary systems of inequalities that we use to enforce the satisfaction of formulae of the form $V_p(x) = y$, again independently of the choice of p .

► **Definition 13.** Let $n \in \mathbb{N}$, and consider a tuple of variables \mathbf{x} . A support graph on (n, \mathbf{x}) is a finite directed graph (V, E) with vertices $V \subseteq \mathbb{Z}^n$ and edges E of the form $\mathbf{s} \rightarrow_T \mathbf{t}$, where $\mathbf{s}, \mathbf{t} \in V$ and T is a system of linear inequalities with variables from \mathbf{x} .

A support graph can have multiple edges over the same two vertices, labelled with different systems of linear inequalities. We evaluate a support graph to the set of bases p for which it can be embedded into a p -automaton. Given $\mathbf{s}, \mathbf{t} \in V$ and a matrix $\mathbf{A} \in \mathbb{Z}^{n \times d}$, we define

$$\llbracket \mathbf{s} \rightarrow_T \mathbf{t} \rrbracket_{\mathbf{A}} \stackrel{\text{def}}{=} \{z \in \mathbb{N} : \mathbf{t} = \mathbf{s} \cdot z + \mathbf{A} \cdot \mathbf{x}, z \geq 2 \text{ and } \|\mathbf{x}\|_{\infty} < z, \text{ for some } \mathbf{x} \in \llbracket T \rrbracket_{\geq 0}\}.$$

Notice that $\llbracket \mathbf{s} \rightarrow_{\top} \mathbf{t} \rrbracket_{\mathbf{A}}$, where \top is a (trivial) system of inequalities such that $\llbracket \top \rrbracket_{\geq 0} = \mathbb{N}^d$, corresponds to the set of bases $p \geq 2$ for which the p -automaton $\mathcal{A}_p^*(S)$ has a one-step transition from \mathbf{s} to \mathbf{t} . As we only look at non-negative values for z and \mathbf{x} , we can introduce slack variables to translate the inequalities $z \geq 2$, $\|\mathbf{x}\|_{\infty} < z$, as well as all the ones in T , into equalities. This allows us to apply Proposition 7, followed by Proposition 8, to characterise $\llbracket \mathbf{s} \rightarrow_T \mathbf{t} \rrbracket_{\mathbf{A}}$ as an ultimately periodic set. Below, let $\|\mathbf{s} \rightarrow_T \mathbf{t}\|_{\infty} \stackrel{\text{def}}{=} \max(\|\mathbf{s}\|_{\infty}, \|\mathbf{t}\|_{\infty}, \|T\|)$.

► **Lemma 14.** Let $\mathbf{A} \in \mathbb{Z}^{n \times d}$, $\mathbf{s}, \mathbf{t} \in \mathbb{Z}^n$ and let T be a linear system of m inequalities. The set $\llbracket \mathbf{s} \rightarrow_T \mathbf{t} \rrbracket_{\mathbf{A}}$ is an ultimately periodic set with period and threshold bounded by $U^{\mathcal{O}(k \log k)}$, where $k = n + d + m$ and $U = \max(2, \|\mathbf{A}\|_{\infty}, \|\mathbf{s} \rightarrow_T \mathbf{t}\|_{\infty})$.

Given a support graph \mathcal{G} with edges e_1, \dots, e_{ℓ} , we write $\llbracket \mathcal{G} \rrbracket_{\mathbf{A}}$ for $\bigcap_{i \in [1, \ell]} \llbracket e_i \rrbracket_{\mathbf{A}}$, i.e. the set of $p \geq 2$ such that, for every edge $\mathbf{s} \rightarrow_T \mathbf{t}$ of \mathcal{G} , the transition $\mathbf{s} \xrightarrow{\mathbf{u}}_{p, \mathbf{A}} \mathbf{t}$ holds for some tuple $\mathbf{u} \in \Sigma_p^d$ satisfying T . By Proposition 9 and Lemma 14, $\llbracket \mathcal{G} \rrbracket_{\mathbf{A}}$ is ultimately periodic.

To prove Proposition 12, we first translate the formula Φ (possibly by introducing slack variables to replace inequalities with equalities) in a disjunctive normal form with $2^{\mathcal{O}(\langle \Phi \rangle)}$ disjuncts have the form $\mathbf{A} \cdot \mathbf{x} = \mathbf{c} \wedge \bigwedge_{i \in I} V_p(x_i) = y_i$, where $\mathbf{A} \in \mathbb{Z}^{n \times d}$, $\mathbf{c} \in \mathbb{Z}^n$, and all variables are among the ones in \mathbf{x} . We further manipulate each of these disjuncts by considering all linear orderings among the variables y_i ($i \in I$). Variables that are set to be equal in an ordering can be substituted accordingly, so that Φ is found to be equivalent to a disjunction of $2^{\mathcal{O}(\langle \Phi \rangle \log \langle \Phi \rangle)}$ formulae of size $\mathcal{O}(\langle \Phi \rangle)$ that have the form

$$\mathbf{A} \cdot \mathbf{x} = \mathbf{c} \wedge \bigwedge_{(i,j) \in J} V_p(x_i) = y_j \wedge \bigwedge_{j \in [1, m]} y_j < y_{j-1} \quad (2)$$

where $J \subseteq I \times [0, m]$ is a binary relation that is functional and surjective on its first component.

Let ψ be a formula of the form in (2). We aim at characterising $\mathcal{B}(\psi)$ as an ultimately periodic set. Recall that, by Proposition 5, solutions of the system $S: \mathbf{A} \cdot \mathbf{x} = \mathbf{c}$ are values $\llbracket w \rrbracket^* \in \mathbb{N}^d$ for some $w \in (\Sigma_p^d)^*$ such that $\mathbf{0} \xrightarrow{w}_{\mathbf{A}, p} \mathbf{c}$. Moreover, a constraint $V_p(x) = y$ restricts the variables x and y to be such that, in their base- p msd representation, $y \in \{0\}^{\ell} \cdot \{1\} \cdot \{0\}^r$ and $x \in [0, p-1]^{\ell} \cdot [1, p-1] \cdot \{0\}^r$, for some $\ell, r \in \mathbb{N}$. Consequently, in order for $\llbracket w \rrbracket^*$ to be a solution of (2), the word w must admit a decomposition $w_0 \cdot \mathbf{u}_0 \cdot w_1 \cdots w_m \cdot \mathbf{u}_m \cdot w_{m+1}$ such that $\mathbf{u}_0, \dots, \mathbf{u}_m \in \Sigma_p^d$,

$$\mathbf{0} = \mathbf{s}_0 \xrightarrow{w_0}_{\mathbf{A}, p} \mathbf{t}_0 \xrightarrow{\mathbf{u}_0}_{\mathbf{A}, p} \mathbf{s}_1 \cdots \mathbf{s}_m \xrightarrow{w_m}_{\mathbf{A}, p} \mathbf{t}_m \xrightarrow{\mathbf{u}_m}_{\mathbf{A}, p} \mathbf{s}_{m+1} \xrightarrow{w_{m+1}}_{\mathbf{A}, p} \mathbf{t}_{m+1} = \mathbf{c}, \quad (3)$$

where $\mathbf{s}_1, \dots, \mathbf{s}_{m+1}, \mathbf{t}_0, \mathbf{t}_m$ are (intermediate) live states, and every \mathbf{u}_j and w_j with $j \in [0, m]$ shall satisfy the constraints induced by the function V_p together with the ordering on the variables y_j . In particular, following the aforementioned decomposition for the variables x and y appearing in a constraint $V_p(x) = y$, for every $j \in [0, m]$ the values of \mathbf{u}_j for the variables $x_1, \dots, x_{\#I}$ and y_1, \dots, y_m shall satisfy the system U_j :

$$\begin{cases} y_j = 1, & x_i \geq 1 \quad : i \in I \text{ and } V_p(x_i) = y_j \text{ occurs in (2),} \\ y_k = 0 \quad : k \in [1, m] \setminus \{j\}, & x_i = 0 \quad : i \in I \text{ and } V_p(x_i) = y_k \text{ occurs in (2) for some } k < j. \end{cases}$$

whereas at each position of the word w_j ($j \in [0, m+1]$) shall satisfy the system W_j :

$$\begin{cases} y_k = 0 \quad : k \in [1, m], & x_i = 0 \quad : i \in I \text{ and } V_p(x_i) = y_k \text{ occurs in (2), for some } k < j. \end{cases}$$

Hence, paths as in (3) can be abstracted into support graphs with vertices from the set of live states of $\mathcal{A}_p^*(S)$ and having the form

$$\mathbf{0} = \mathbf{s}_0 \xrightarrow{W_0^j} \mathbf{t}_0 \xrightarrow{U_0} \mathbf{s}_1 \dots \mathbf{s}_m \xrightarrow{W_m^j} \mathbf{t}_m \xrightarrow{U_m} \mathbf{s}_{m+1} \xrightarrow{W_{m+1}^{j_{m+1}}} \mathbf{t}_{m+1} = \mathbf{c}, \quad (4)$$

where $\mathbf{s} \xrightarrow{j} \mathbf{t}$ is short for a path of length j going from \mathbf{s} to \mathbf{t} , and with arrows labelled by the system of inequalities T , and for every $i \in [0, m+1]$, j_i is the length of w_i .

► **Lemma 15.** *Let ψ be a formula as in (2).*

- *For every support graph \mathcal{G} of the form described in (4), $[\mathcal{G}]_{\mathbf{A}} \subseteq \mathcal{B}(\psi)$.*
- *For every $p \in \mathcal{B}(\psi)$ there is a support graph \mathcal{G} as in (4) such that $p \in [\mathcal{G}]_{\mathbf{A}}$.*

Proof. Let \mathbb{G} be the set of support graphs of the form in (4). The lemma equivalently states that $\mathcal{B}(\psi) = \bigcup_{\mathcal{G} \in \mathbb{G}} [\mathcal{G}]_{\mathbf{A}}$. Below, we refer to the first and second points in the lemma as the two inclusions \supseteq and \subseteq of this equality.

(\supseteq): Let \mathcal{G} be a support graph in \mathbb{G} , and consider $p \in [\mathcal{G}]_{\mathbf{A}}$. Notice that, by definition, this means that for every edge $\mathbf{s} \xrightarrow{T} \mathbf{t}$ of \mathcal{G} there is $\mathbf{u} \in \Sigma_p^d$ such that $\mathbf{s} \xrightarrow{\mathbf{u}}_{\mathbf{A}, p} \mathbf{t}$ and $\mathbf{u} \in [T]$. From (4), there is a path

$$\mathbf{0} = \mathbf{s}_0 \xrightarrow{w_0}_{\mathbf{A}, p} \mathbf{t}_0 \xrightarrow{\mathbf{u}_0}_{\mathbf{A}, p} \mathbf{s}_1 \dots \mathbf{s}_m \xrightarrow{w_m}_{\mathbf{A}, p} \mathbf{t}_m \xrightarrow{\mathbf{u}_m}_{\mathbf{A}, p} \mathbf{s}_{m+1} \xrightarrow{w_{m+1}}_{\mathbf{A}, p} \mathbf{t}_{m+1} = \mathbf{c},$$

where $w \stackrel{\text{def}}{=} w_0 \cdot \mathbf{u}_0 \cdot w_1 \cdot \dots \cdot w_m \cdot \mathbf{u}_m \cdot w_{m+1} \in (\Sigma_p^d)^*$, $\mathbf{u}_0, \dots, \mathbf{u}_m \in \Sigma_p^d$, every \mathbf{u}_j satisfies U_j and every symbol in w_j satisfies W_j . Clearly, $\mathbf{A} \cdot [w] = \mathbf{c}$. From the definition of the systems U_0, \dots, U_m and W_0, \dots, W_{m+1} , we obtain that in w the value for the variable y_j ($j \in [0, m]$) has a base- p msd representation of the form $\{0\}^{\ell_j} \cdot \{1\} \cdot \{0\}^{r_j}$, for some $\ell_j, r_j \in \mathbb{N}$ such that $\ell_j + 1 + r_j$ corresponds to the length of w . This means that every y_j is a power of p . Moreover, $r_{j-1} > r_j$ for every $j \in [1, m]$, and therefore $y_j < y_{j-1}$. Lastly, consider $(i, j) \in J$, so that $V_p(x_i) = y_j$ appears in ψ . The systems U_0, \dots, U_m and W_0, \dots, W_{m+1} force the base- p msd encoding of x_i to belong to the language $[0, p-1]^{\ell_j} \cdot [1, p-1] \cdot \{0\}^{r_j}$. We conclude that the formula $V_p(x_i) = y_j$ holds. So, ψ is satisfiable with respect to the base p , i.e., $p \in \mathcal{B}(\psi)$.

(\subseteq): Follows conversely to the other inclusion. Suppose ψ satisfiable with respect to the base p . Consider a word $w \in (\Sigma_p^d)^*$ such that $[w]^*$ is a solution of ψ . From $\bigwedge_{(i,j) \in J} V_p(x_i) = y_j$ we conclude that the base- p msd encodings of x_i and y_j belong to $\{0\}^{\ell_j} \cdot \{1\} \cdot \{0\}^{r_j}$ and $[0, p-1]^{\ell_j} \cdot [1, p-1] \cdot \{0\}^{r_j}$, respectively, for some ℓ_j and r_j such that $\ell_j + 1 + r_j$ corresponds to the length of w . From $y_j < y_{j-1}$ ($j \in [1, m]$), $r_{j-1} > r_j$. Hence, w admits a decomposition $w_0 \cdot \mathbf{u}_0 \cdot w_1 \cdot \dots \cdot w_m \cdot \mathbf{u}_m \cdot w_{m+1}$ such that $\mathbf{u}_0, \dots, \mathbf{u}_m \in \Sigma_p^d$,

$$\mathbf{0} = \mathbf{s}_0 \xrightarrow{w_0}_{\mathbf{A}, p} \mathbf{t}_0 \xrightarrow{\mathbf{u}_0}_{\mathbf{A}, p} \mathbf{s}_1 \dots \mathbf{s}_m \xrightarrow{w_m}_{\mathbf{A}, p} \mathbf{t}_m \xrightarrow{\mathbf{u}_m}_{\mathbf{A}, p} \mathbf{s}_{m+1} \xrightarrow{w_{m+1}}_{\mathbf{A}, p} \mathbf{t}_{m+1} = \mathbf{c},$$

where $s_1, \dots, s_{m+1}, t_0, t_m$ are live states. Moreover, every u_j is a solution of U_j and every symbol in the word w_j is a solution of W_j . Let \mathcal{G} be the support graph with edges $t_0 \rightarrow_{U_0} s_1, \dots, t_m \rightarrow_{U_j} s_{m+1}$ together with $i \rightarrow_{W_j} i'$, for every $j \in [0, m+1]$ and every two states i, i' such that $i \rightarrow_{\mathbf{A}, p} i'$ appears in the path going from s_j to t_j . The graph \mathcal{G} is of the form in (4), and $p \in \llbracket \mathcal{G} \rrbracket_{\mathbf{A}}$. \blacktriangleleft

Only finitely many support graphs have the form described in (4), as they all have vertices from the finite set of live states of $\mathcal{A}_p^*(S)$, and edges with labels from a finite set of linear systems. So, Lemma 15 implies that the set $\mathcal{B}(\psi)$ is equivalent to a finite union of $\llbracket \mathcal{G} \rrbracket_{\mathbf{A}}$, for which we can obtain an ultimately periodic representation according to Proposition 9 and Lemma 14.

► Lemma 16. *Let ψ be as in (2). Then $\mathcal{B}(\psi)$ is ultimately periodic with threshold in $U^{\mathcal{O}(k \log k)}$ and period in $U^{\mathcal{O}(\ell \cdot k \log k)}$, where $U = \max(2, \|\mathbf{A}\|_{1, \infty}, \|\mathbf{c}\|_{\infty})$, $k = n + 3d^2$ and $\ell = U^{4n}$.*

Proof. Let \mathbb{G} be the finite family of support graphs such that $\mathcal{B}(\psi) = \bigcup_{\mathcal{G} \in \mathbb{G}} \llbracket \mathcal{G} \rrbracket_{\mathbf{A}}$, according to Lemma 15. Every edge $s \rightarrow_T t$ of a support graph $\mathcal{G} \in \mathbb{G}$ is such that $\|s\|_{\infty}, \|t\|_{\infty} \leq \max(\|\mathbf{A}\|_{1, \infty}, \|\mathbf{c}\|_{\infty})$ and T is a system among $U_0, \dots, U_m, W_0, \dots, W_{m+1}$. Hence, all the graphs in $\bigcup_{j \in J} \mathbb{G}_j$ are built from a set E of $(2 \cdot \max(\|\mathbf{A}\|_{1, \infty}, \|\mathbf{c}\|_{\infty}))^{2n} \cdot (2m+3) \leq \mathcal{O}(\ell)$ edges (note: $m \leq \#I \leq d^2$). Each possible linear system T labelling an edge in E has at most $2d^2$ inequalities, with coefficients and constants in $\{0, 1\}$. By Lemma 14, each edge $e \in E$ is such that $\llbracket e \rrbracket_{\mathbf{A}}$ is an ultimately periodic set with period and threshold bounded by $U^{\mathcal{O}(k \log k)}$. By Proposition 9, taking unions and intersections of sets $\llbracket e \rrbracket_{\mathbf{A}}$ with $e \in E$, as for instance $\mathcal{B}(\psi) = \bigcup_{\mathcal{G} \in \mathbb{G}} \llbracket \mathcal{G} \rrbracket_{\mathbf{A}}$, always yields an ultimately periodic set with threshold in $U^{\mathcal{O}(k \log k)}$ and period in $U^{\mathcal{O}(\ell \cdot k \log k)}$. \blacktriangleleft

The bounds U , k and ℓ established in Lemma 16 for the threshold and the period of $\mathcal{B}(\varphi)$ can be restated in terms of the size of the initial formula Φ as follows: $U \leq 2^{\mathcal{O}(\langle \Phi \rangle)}$, $k \leq \mathcal{O}(\langle \Phi \rangle^2)$ and $\ell \leq 2^{\mathcal{O}(\langle \Phi \rangle^2)}$. This is sufficient to conclude that Proposition 12 holds. Indeed, the formula Φ is equivalent to a disjunction $\bigvee_{k \in K} \psi_k$ of formulae ψ_k of the form in (2), with $\#K \leq 2^{\mathcal{O}(\langle \Phi \rangle \log \langle \Phi \rangle)}$. This means that the set $\mathcal{B}(\Phi)$ is the union of all $\mathcal{B}(\psi_k)$ with $k \in K$. We apply Proposition 9 to obtain a representation of $\mathcal{B}(\Phi)$ as an ultimately periodic set with threshold bounded by $2^{\mathcal{O}(\langle \Phi \rangle^3 \log \langle \Phi \rangle)}$ and period bounded by $2^{2^{\mathcal{O}(\langle \Phi \rangle^2)}}$.

Proof of Proposition 12: Linear arithmetic constraints over p -adic integers. We now establish Proposition 12 for the case of Φ being an existential formula of linear arithmetic constraints over p -adic integers with parametric base p . For brevity, all proofs in this section are relegated to Appendix B. The crucial difference from the proof of Proposition 12 for Büchi arithmetic is that, differently from the V_p function, the p -adic valuation v_p induces constraints related to the relative lengths of subwords of the infinite words accepted by the p -automaton. For instance, to satisfy the formula $v_p(u) = 3 \cdot v_p(v) \wedge v_p(v) \geq 1$, the base- p lsd-first representation of u and v must obey the following constraints:

$$\begin{aligned} u &\in \{0\}^i \{0\} \quad \{0\}^{2i+1} [1, p-1] (\Sigma_p)^\omega, \\ v &\in \{0\}^i [1, p-1] (\Sigma_p)^{2i+1} \Sigma_p \quad (\Sigma_p)^\omega. \end{aligned}$$

where $i \geq 1$. In particular, we notice that the length of the maximal all-zeros prefix of v fixes the length of the maximal all-zeros prefix of u , and vice versa. This reflects in the proof of Proposition 12 where, instead of only considering support graphs that are linear structures in the sense of (4), we must consider arbitrary graphs and establish ultimately periodic representations of the lengths of their paths. To do so, we rely on the following

result on the lengths of words accepted by a *nondeterministic finite automaton* (NFA) over a *unary alphabet*. Recall that an NFA is a tuple $\mathcal{A} = (Q, \delta, I, F)$ where Q is a finite set of states, $\delta \subseteq Q \times Q$ is a transition relation, and $I, F \subseteq Q$ are set of initial and final states, respectively.

► **Proposition 17** ([24]). *Given an unary NFA $\mathcal{A} = (Q, \delta, I, F)$ with $s = \#Q$, one can construct in time $\mathcal{O}(s^2(s + \#\delta))$ a set $L = \bigcup_{k \in K} L(b_k, q_k)$ characterising the lengths of the words accepted by \mathcal{A} , with $\#K \leq \mathcal{O}(s^2)$, $b_k \leq (2 \cdot s + 1) \cdot s$ and $q_k \leq s$.*

Of course, other modifications with respect to the treatment of Büchi arithmetic are required: the support graphs must take into account the ω -regular acceptance condition defined in Proposition 6, and we also have to deal with the two-sorted structure of the theory.

Moving to the proof of Proposition 12, similarly to the case of Büchi arithmetic we start by manipulating the formula Φ and obtain a disjunctive normal form where each of the $2^{\mathcal{O}(\langle \Phi \rangle \log \langle \Phi \rangle)}$ disjuncts are of size $\mathcal{O}(\langle \Phi \rangle)$ and have the following form:

$$\mathbf{A} \cdot \mathbf{u} = \mathbf{c} \wedge \mathbf{B} \cdot \mathbf{x} \geq \mathbf{d} \wedge \bigwedge_{(i,j) \in J} v_p(u_i) = x_j \wedge \bigwedge_{j \in [1,r]} x_{j-1} < x_j \quad (5)$$

where $\mathbf{A} \in \mathbb{Z}^{n \times d}$, $\mathbf{c} \in \mathbb{Z}^n$, $\mathbf{B} \in \mathbb{Z}^{m \times e}$, $\mathbf{d} \in \mathbb{Z}^m$ and $J \subseteq I \times [0, r]$ is a binary relation that is functional and surjective on its first component. Each u_i with $i \in I$ is a variable among \mathbf{u} interpreted over \mathbb{Z}_p , and each x_j with $j \in [0, r]$ is a variable among \mathbf{x} , interpreted over \mathbb{Z} . Notice that restricting the interpretation of \mathbf{x} from \mathbb{Z} to \mathbb{Z} is without loss of generality: when bringing the formula Φ in disjunctive normal form, we can introduce tautologies of the form $x < \infty \vee x = \infty$, for each of the variables x in \mathbf{x} . Then, following the axiom system presented in [17], disjuncts where $x = \infty$ holds can be easily modified so that x is eliminated.

According to Proposition 6, solutions of the system $S: \mathbf{A} \cdot \mathbf{u} = \mathbf{c}$ over the p -adic integers are values $\llbracket w \rrbracket^\omega \in \mathbb{Z}_p^d$ for some infinite word $w = \mathbf{u}_0 \mathbf{u}_1 \dots \in (\Sigma_p^d)^\omega$ such that there is a live state $\mathbf{r} \in \mathbb{Z}^n$ of the p -automaton $\mathcal{A}_p^*(S)$ and an infinite sequence $\lambda_0 < \lambda_1 < \dots$ for which $\mathbf{r} \xrightarrow{\mathbf{u}_{\lambda_0-1} \dots \mathbf{u}_{\lambda_0}}_{\mathbf{A}, p} \mathbf{c}$ and $\mathbf{r} \xrightarrow{\mathbf{u}_{\lambda_{j+1}} \dots \mathbf{u}_{\lambda_j}}_{\mathbf{A}, p} \mathbf{r}$ for all $j \in \mathbb{N}$. Moreover, a constraint $v_p(u) = x$ restricts the variables u and x to be such that, in the base p lsd-first representation of u , we have $u \in \{0\}^x \cdot [1, p-1] \cdot [0, p-1]^\omega$. Consequently, in order for $(\llbracket w \rrbracket^\omega, \mathbf{x})$ to be a solution of (5), in addition to $\mathbf{B} \cdot \mathbf{x} \geq \mathbf{d}$, the word w must have a prefix of the form $w_0 \cdot \mathbf{v}_0 \cdot w_1 \dots w_r \cdot \mathbf{v}_r \cdot w_{r+1}$ such that $\mathbf{v}_0, \dots, \mathbf{v}_r \in \Sigma_p^d$, the word $w_0 \in (\Sigma_p^d)^*$ has length x_0 , each $w_i \in (\Sigma_p^d)^*$ with $i \in [1, r]$ has length $x_i - (x_{i-1} + 1) \geq 0$, and

$$\mathbf{r} = \mathbf{s}_{r+1} \xrightarrow{(w_{r+1})^R}_{\mathbf{A}, p} \mathbf{t}_{r+1} \xrightarrow{\mathbf{v}_r}_{\mathbf{A}, p} \mathbf{s}_r \dots \mathbf{s}_1 \xrightarrow{(w_1)^R}_{\mathbf{A}, p} \mathbf{t}_1 \xrightarrow{\mathbf{v}_0}_{\mathbf{A}, p} \mathbf{s}_0 \xrightarrow{(w_0)^R}_{\mathbf{A}, p} \mathbf{t}_0 = \mathbf{c} \quad (6)$$

where each $(w_i)^R$ with $i \in [0, r+1]$ is the reverse of the word w_i , and \mathbf{r} is a live state of $\mathcal{A}_p^*(S)$ for which the ω -regular condition of Proposition 6 is satisfied. Following the decomposition for the variable u appearing in a constraint $v_p(u) = x$ given above, for every $j \in [0, r]$ the values of \mathbf{v}_j for the variables $u_1, \dots, u_{\#I}$ shall satisfy the system U_j :

$$\begin{cases} u_i \geq 1 & : i \in I \text{ and } v_p(u_i) = x_j \text{ occurs in (5),} \\ u_i = 0 & : i \in I \text{ and } v_p(u_i) = x_k \text{ occurs in (5), for some } k \in [j+1, r]. \end{cases}$$

whereas at each position of the word w_j ($j \in [0, r+1]$) shall satisfy the system W_j :

$$\begin{cases} u_i = 0 & : i \in I \text{ and } v_p(u_i) = x_k \text{ occurs in (5), for some } k \in [j, r]. \end{cases}$$

■ **Figure 1** A support graphs for existential linear arithmetic constraints over p -adic integers.

Given a formula ψ of the form in (5), we abstract paths in the p -automaton $\mathcal{A}_p^*(S)$ induced by infinite words such as the word w above, by introducing a family of support graphs, denoted by $\mathbb{G}(\psi)$. Each support graph $\mathcal{G} \in \mathbb{G}(\psi)$ has live states of $\mathcal{A}_p^*(S)$ as vertices, and its set of edges can be partitioned in the following sets, for some *intermediate live states* $\mathbf{r}, \mathbf{s}_0, \dots, \mathbf{s}_{r+1}, \mathbf{t}_0, \dots, \mathbf{t}_{r+1}$ such that $\mathbf{r} = \mathbf{s}_{r+1}$ and $\mathbf{t}_0 = \mathbf{c}$:

- $C(\mathbf{r})$: a set of edges of the form $\mathbf{s} \rightarrow_{W_{r+1}} \mathbf{t}$ that describes a connected graph with a non-empty path from \mathbf{r} to itself (as required by the ω -regular condition of Proposition 6),
- $G_j(\mathbf{s}_j, \mathbf{t}_j)$, with $j \in [0, r+1]$: a set of edges of the form $\mathbf{s} \rightarrow_{W_j} \mathbf{t}$ that describes a connected graph with a (possibly empty) path going from \mathbf{s}_j to \mathbf{t}_j ,
- $\{\mathbf{t}_{j+1} \rightarrow_{U_j} \mathbf{s}_j\}$, for every $j \in [0, r]$.

As the set of live states of $\mathcal{A}_p^*(S)$ and the set of all linear systems U_j and W_j considered are finite, so is the set $\mathbb{G}(\psi)$. Figure 1 depicts a support graph from $\mathbb{G}(\psi)$. We say that \mathcal{G} *generates the length values* $(v_0, \dots, v_r) \in \mathbb{N}^{r+1}$ if \mathcal{G} has a path of the form

$$\mathbf{t}_{r+1} \rightarrow_{U_r} \mathbf{s}_r \xrightarrow{v_r - (v_{r-1} + 1)} \mathbf{t}_r \rightarrow_{U_{r-1}} \mathbf{s}_{r-1} \dots \mathbf{s}_1 \xrightarrow{v_1 - (v_0 + 1)} \mathbf{t}_1 \rightarrow_{U_0} \mathbf{s}_0 \xrightarrow{v_0} \mathbf{t}_0 = \mathbf{c} \quad (7)$$

Exactly as in the case of Büchi arithmetic, we aim at characterising $\mathcal{B}(\psi)$ as a union over a subset B of $\{\llbracket \mathcal{G} \rrbracket_{\mathbf{A}} : \mathcal{G} \in \mathbb{G}(\psi)\}$. According to the definition of $\mathcal{G} \in \mathbb{G}(\psi)$, the set $\llbracket \mathcal{G} \rrbracket_{\mathbf{A}}$ consists of some of the bases $p \geq 2$ for which, if we disregard the constraints imposed by the system of inequalities $\mathbf{B} \cdot \mathbf{x} \geq \mathbf{d}$, the formula ψ is satisfiable. To account for this system, we need to characterise the set of all length values that can be generated from \mathcal{G} , and check whether $\mathbf{B} \cdot \mathbf{x} \geq \mathbf{d} \wedge \bigwedge_{j \in [0, r]} x_j = v_j$ can be satisfied with respect to one of these length values (v_0, \dots, v_r) . This check, which we now formalise, does not depend on the base- p , so that either $\llbracket \mathcal{G} \rrbracket_{\mathbf{A}} \subseteq \mathcal{B}(\psi)$ or \mathcal{G} can be discarded when constructing the set B .

Consider $\mathcal{G} \in \mathbb{G}(\psi)$, with intermediate live states $\mathbf{s}_0, \dots, \mathbf{s}_{r+1} = \mathbf{r}, \mathbf{c} = \mathbf{t}_0, \dots, \mathbf{t}_{r+1}$. For every $j \in [0, r]$, we construct from the set of edges $G_j(\mathbf{s}_j, \mathbf{t}_j)$ the unary NFA (Q, δ, I, F) where Q is the set of live states appearing in some of the edges of $G_j(\mathbf{s}_j, \mathbf{t}_j)$, $I = \{\mathbf{s}_j\}$ and $F = \{\mathbf{t}_j\}$, and $\delta = \{(\mathbf{s}, \mathbf{t}) \in Q^2 : \mathbf{s} \rightarrow_{W_j} \mathbf{t} \in G_j(\mathbf{s}_j, \mathbf{t}_j)\}$. By Proposition 17, the set L_j of the lengths of the words accepted by this automaton is ultimately periodic. To obtain the length values that can be generated by \mathcal{G} , we combine the lengths of the sets L_0, \dots, L_r , and construct the following set $\oplus(L_0, \dots, L_r)$:

$$\oplus(L_0, \dots, L_r) \stackrel{\text{def}}{=} \left\{ \begin{pmatrix} \ell_0 \\ 1 + \ell_0 + \ell_1 \\ \dots \\ r + \sum_{i=0}^r \ell_i \end{pmatrix} \in \mathbb{N}^{r+1} : \ell_j \in L_j \text{ for all } j \in [0, r] \right\} \quad (8)$$

Below, we set $U \stackrel{\text{def}}{=} \max(2, \|\mathbf{A}\|_{1, \infty}, \|\mathbf{c}\|_{\infty})$, so that the live states of S are at most U^{2n} .

► **Lemma 18.** *The set $\oplus(L_0, \dots, L_r)$ contains all length values generated by \mathcal{G} . One can construct in time $\mathcal{O}(r^2) \cdot U^{\mathcal{O}(n \cdot r)}$ a representation of $\oplus(L_0, \dots, L_r)$ as a semi-linear set $\bigcup_{k \in K} L(\mathbf{b}_k, P_k)$, where $\#K \leq U^{\mathcal{O}(n \cdot r)}$, $\#P \leq r + 1$, $\|P\|_{\infty} \leq U^{2n}$ and $\|\mathbf{b}_k\|_{\infty} \leq \mathcal{O}(r \cdot U^{4n})$.*

As already stated, the set $L_{\mathcal{G}}$ allows us to characterise $\mathcal{B}(\psi)$ as a union over some of the sets in $\{\llbracket \mathcal{G} \rrbracket_{\mathbf{A}} : \mathcal{G} \in \mathbb{G}(\psi)\}$. This is formalised by the two following lemma, analogous to Lemma 15 established for Büchi arithmetic. For brevity, we write $\mathcal{G} \vdash \mathbf{B} \cdot \mathbf{x} \geq \mathbf{d}$ whenever there is a length value $(v_0, \dots, v_r) \in L_{\mathcal{G}}$ such that $\mathbf{B} \cdot \mathbf{x} \geq \mathbf{d} \wedge \bigwedge_{j \in [0, r]} x_j = v_j$ is satisfiable.

- **Lemma 19.** *Let ψ be a formula of the form given in (5).*
- *Given $\mathcal{G} \in \mathbb{G}(\psi)$, if $\mathcal{G} \vdash \mathbf{B} \cdot \mathbf{x} \geq \mathbf{d}$ then $\llbracket \mathcal{G} \rrbracket_{\mathbf{A}} \subseteq \mathcal{B}(\psi)$.*
- *For every $p \in \mathcal{B}(\psi)$, there is $\mathcal{G} \in \mathbb{G}(\psi)$ such that $\mathcal{G} \vdash \mathbf{B} \cdot \mathbf{x} \geq \mathbf{d}$ and $p \in \llbracket \mathcal{G} \rrbracket_{\mathbf{A}}$.*

Following the case of Büchi arithmetic, we then express $\mathcal{B}(\psi)$ as an ultimately periodic set.

- **Lemma 20.** *Let ψ be as in (5). The set $\mathcal{B}(\psi)$ is ultimately periodic, with threshold bounded by $U^{\mathcal{O}(k \log k)}$ and period bounded by $U^{\mathcal{O}(\ell \cdot k \log k)}$, with $k = n + 3d$ and $\ell = (r + 2) \cdot U^{4n+1}$.*

Together, Proposition 9 and Lemma 20 yield Proposition 12, as we recall that Φ is equivalent to a disjunction $\bigvee_{k \in K} \psi_k$ of formulae ψ_k of the form in (5), with $\#K \leq 2^{\mathcal{O}(\langle \Phi \rangle \log \langle \Phi \rangle)}$.

4 Deciding satisfiability when the base p is large

In view of the magnitude of the bases p established in Theorem 11, in order to prove Theorem 1, i.e., to show that the p -existence and p -universality problems are decidable in NEXP and coNEXP, respectively, it is sufficient to show the following statement.

- **Theorem 21.** *Let Φ be an existential formula of linear arithmetic constraints over p -adic integers (resp. Büchi arithmetic) with parametric base p . Then satisfiability of Φ with respect to a given value $p \in \mathbb{P}$ (resp. $p \geq 2$) can be decided in time $2^{\mathcal{O}(\langle \Phi \rangle^3)} \cdot \mathcal{O}(\langle p \rangle)$.*

This result cannot directly be obtained from [11], where it is shown that satisfiability of Φ with the base p given in binary is decidable NP, as it only gives a coNEXP^{NP} upper bound for p -universality when $\langle p \rangle$ is of exponential size. For our purposes, we require a decision procedure that runs in time polynomial in the size of the binary encoding of p provided as input. This can be achieved by appealing to a strongly polynomial-time algorithm for the feasibility problem of a system of linear Diophantine inequalities in a fixed dimension established in [9].

- **Proposition 22 ([9]).** *Let $S: \mathbf{A} \cdot \mathbf{x} \geq \mathbf{c}$ be a system of linear Diophantine inequalities, with $\mathbf{A} \in \mathbb{Z}^{n \times d}$ and $\mathbf{c} \in \mathbb{Z}^n$. Checking whether $\llbracket S \rrbracket \neq \emptyset$ can be decided using $d^{2.5d+o(d)} \cdot \langle S \rangle$ arithmetic operations, and space polynomial in $\langle S \rangle$.*

With this proposition at hand, proving Theorem 21 for both existential formulas of linear arithmetic constraints over p -adic integers and Büchi arithmetic, respectively, is not difficult. Any such formula can be converted in time $2^{\mathcal{O}(\langle \Phi \rangle \log \langle \Phi \rangle)}$ into a disjunctive normal form with disjuncts of the form given in (2) and (5), respectively. For every disjunct, we iterate in time $2^{\mathcal{O}(\langle \Phi \rangle^2)}$ over all decompositions of the form describe in (4) and (7), respectively, with each decomposition giving rise to family of systems of linear Diophantine equations whose number of variables is bounded by $\mathcal{O}(\langle \Phi \rangle^2)$ and whose coefficients are bounded by $\mathcal{O}(p + 2^{\langle \Phi \rangle})$. Proposition 22 then enables to decide any of such system with the required time bounds. Full details are deferred to Appendix C.

5 Büchi arithmetic: coNEXP lower bound for p -universality

Here, we prove Theorem 2 and show that the p -universality problem for existential Büchi arithmetic is coNEXP-hard. The proof is by a reduction from a coNEXP-complete generalisation of the quantified Boolean satisfiability problem, denoted by $\text{QO}\Pi_1\text{-SAT}$ (where QO stands for “quantified oracle”), that was introduced in [1] and later generalised in [21]. For $m \in \mathbb{N}$, let \mathcal{F}_m denote the set of all m -ary Boolean functions.

The $\text{QO}\Pi_1\text{-SAT}$ problem takes as input a tuple (m, n, φ) where $m, n \in \mathbb{N}$ are written in unary, and φ is a Boolean combination of $x_1, \dots, x_m, y_1, \dots, y_n$ and $f(x_1, \dots, x_m)$. The input is accepted if and only if for all $f \in \mathcal{F}_m$ there are $x_1, \dots, x_m, y_1, \dots, y_n \in \{0, 1\}$ such that φ is a valid.

Our reduction from $\text{QO}\Pi_1\text{-SAT}$ to the p -universality problem of existential Büchi arithmetic follows an approach for showing coNEXP hardness of the Π_2 -fragment of Presburger arithmetic [10, 12]. The main challenge is to show how to universally quantify over and suitably encode the doubly-exponential number of m -ary Boolean functions. Given $f \in \mathcal{F}_m$, we encode f via a number $z \in \mathbb{N}$ using a variant of Gödel encoding as follows:

$$f(b_0, \dots, b_{m-1}) = b \iff z \equiv b \pmod{q}, \text{ for all } q \in \mathbb{P} \cap [k^3, (k+1)^3), k = \sum_{i=0}^{m-1} 2^i \cdot b_i. \quad (9)$$

Note that Ingham’s theorem on prime gaps [15] guarantees that for sufficiently large $k \in \mathbb{N}$, there is at least one prime in the interval $[k^3, (k+1)^3)$. For technical convenience, to avoid adding a constant offset throughout our constructions, and as done in e.g. [10, 12], we apply Ingham’s theorem as if it was true for all $k \in \mathbb{N}$.

► **Lemma 23.** *For every $f \in \mathcal{F}_m$ there is some $z \in \mathbb{N}$ encoding f as specified in (9), and for all $i, j > 0$, p^i is a valid encoding if and only if p^j is a valid encoding.*

Proof. The first part immediately follows from the Chinese remainder theorem, and the second part follows from $b \in \{0, 1\}$ in (9). ◀

From [12] we can derive the existence of the following families of existential Presburger formulas polynomial-time computable in $m \in \mathbb{N}$ given in unary:

- $\Phi_m^{\text{prime}}(x)$ that evaluates to true if and only if $x < 2^m$ and $x \in \mathbb{P}$;
- $\Phi_m^{\text{pow}3}(x, y)$ that evaluates to true if and only if $x < 2^m$ and $y = x^3$;
- $\Phi_m^{\text{mod}}(x, y)$ that evaluates to true if and only if $y < 2^m$ and $x \equiv 0 \pmod{y}$; and
- $\Phi_m^{\text{invalid}}(x)$ that evaluates to true if and only if there are $q_1, q_2 \in \mathbb{P} \cap [k^3, (k+1)^3)$ for some $k < 2^m$ such that $(x \bmod q_1) \neq (x \bmod q_2)$ or $(x \bmod q_1) \notin \{0, 1\}$.

We define a family of existential formulas of Presburger arithmetic $\Phi_m^{\text{fun}}(\mathbf{x}, y, z)$ that hold if and only if $f(x_0, \dots, x_{m-1}) = y$, under the assumptions that z is a valid encoding of some $f \in \mathcal{F}_m$ as defined in Equation (9), $\mathbf{x} = (x_0, \dots, x_{m-1}) \in \{0, 1\}^m$ and $y \in \{0, 1\}$:

$$\begin{aligned} \Phi_m^{\text{fun}}(\mathbf{x}, y, z) \stackrel{\text{def}}{=} \exists x, k, k_0, k_1: & k = \sum_{i=0}^{m-1} 2^i \cdot x_i \wedge \Phi_m^{\text{pow}3}(k, k_0) \wedge \Phi_{m+1}^{\text{pow}3}(k+1, k_1) \\ & \wedge k_0 \leq x < k_1 \wedge \Phi_{3m+1}^{\text{prime}}(x) \wedge \Phi_{3m+1}^{\text{mod}}(z-y, x). \end{aligned}$$

For the final step of our reduction, given an instance $I = (m, n, \varphi)$ of $\text{QO}\Pi_1\text{-SAT}$, denote by $\tilde{\varphi}(\mathbf{x}, \mathbf{y}, y)$ the quantifier-free formula of Presburger arithmetic obtained from φ by replacing x_i and y_i by $x_i = 1$ and $y_i = 1$, respectively; $\neg x_i$ and $\neg y_i$ by $x_i = 0$ and $y_i = 0$, respectively; and $f(x_1, \dots, x_n)$ by $y = 1$ and $\neg f(x_1, \dots, x_n)$ by $y = 0$. We claim that I is a positive instance if and only if the following formula Ψ_p of existential Büchi arithmetic, with parametric base p and a single occurrence of a V_p function, is p -universal:

$$\Psi_p \stackrel{\text{def}}{=} \exists x \exists y \exists \mathbf{x} \exists \mathbf{y} \exists z: V_p(z) = z \wedge z > 1 \wedge 0 \leq x \leq 1 \wedge 0 \leq y \leq 1 \wedge \bigwedge_{i \in [1, m]} 0 \leq x_i \leq 1 \\ \wedge \bigwedge_{i \in [1, n]} 0 \leq y_i \leq 1 \wedge \Phi_m^{\text{fun}}(\mathbf{x}, \mathbf{y}, z) \wedge (\Phi_m^{\text{invalid}}(z) \vee \tilde{\varphi}(\mathbf{x}, \mathbf{y}, y)) ,$$

where $\mathbf{x} = (x_1, \dots, x_m)$ and $\mathbf{y} = (y_1, \dots, y_n)$. Theorem 2 is now an immediate consequence of the following proposition.

► **Proposition 24.** *Let $I = (m, n, \varphi)$ be an instance of $QO\Pi_1$ -SAT. Then I is a positive instance if and only if Ψ_p is p -universal.*

Proof. (\Rightarrow): By Lemma 23, any $f \in \mathcal{F}_m$ is encoded by some $p \in \mathbb{N}$. Choosing $z = p$ in Ψ_p and instantiating the x_j and y_j by those x_j and y_j making φ true for f , which exist by assumption, it follows that Ψ_p is p -universal.

(\Leftarrow): Suppose that Ψ_p is p -universal. By Lemma 23, for every $f \in \mathcal{F}_m$ there is some valid encoding p of f , and by assumption Ψ_p evaluates to true in base p for some choice $z = p^i$. By Lemma 23, p is a valid encoding of f as well, and hence the same x_j and y_j that make Ψ_p for $z = p^i$ and *a fortiori* $z = p$ true also make φ true for f . Hence I is a positive instance. ◀

6 Conclusion

There remains the open problems to what extent the coNEXP upper bound for p -universality for the p -adic integers stated in Theorem 1 is tight. The coNEXP lower bound for p -universality for existential Büchi arithmetic together with the bounds on the ultimately periodic representation of the set of bases satisfying a given formula obtained in Proposition 12 gives strong evidence that, should it be possible to improve the coNEXP upper bound for the p -adic integers, a different approach not based on p -automata will likely be required. Likewise, we do not know whether the NEXP upper bounds for p -existence can be improved.

The coNEXP lower bound for p -universality for Büchi arithmetic crucially relies on the presence of disjunction and conjunctive as Boolean connectives. It would be interesting to better understand the complexity of the conjunctive fragments of the logics we consider, at present we cannot obtain any better upper bounds. In particular, Lechner et al. have shown that the restricted formulas obtained in Lipshitz' decidability proof are p -universal if and only if they are satisfied for all primes p singly exponentially bounded in the input [18].

Another interesting open problem is to settle the decidability status of p -universality for full Büchi arithmetic. Given that Büchi arithmetic does not have quantifier elimination [13], this problem will also likely require new approaches and techniques.

A Missing proofs from Section 2

► **Proposition 6.** For all $w = \mathbf{u}_0 \mathbf{u}_1 \cdots \in (\Sigma_d^p)^\omega$, $\mathbf{A} \cdot \llbracket w \rrbracket^\omega = \mathbf{c}$ iff there is $\mathbf{r} \in \mathbb{Z}^n$ and a strictly ascending sequence $(\lambda_i)_{i \in \mathbb{N}}$ such that $\mathbf{r} \xrightarrow{\mathbf{u}_{\lambda_0-1} \cdots \mathbf{u}_0} \mathbf{A}, p \mathbf{c}$ and $\mathbf{r} \xrightarrow{\mathbf{u}_{\lambda_{j+1}} \cdots \mathbf{u}_{\lambda_j}} \mathbf{A}, p \mathbf{r}$ for all $j \in \mathbb{N}$.

Proof. Simple reformulation of the fact that $\mathbf{A} \cdot \llbracket w \rrbracket^\omega = \mathbf{c}$ holds if and only if for every $k \in \mathbb{N}$ there is $\mathbf{v} \in \mathbb{Z}^n$ such that $\mathbf{A} \cdot \llbracket \mathbf{u}_{k-1} \mathbf{u}_{k-2} \cdots \mathbf{u}_0 \rrbracket^* + \mathbf{v} \cdot p^k = \mathbf{c}$, where $w = \mathbf{u}_0 \mathbf{u}_1, \dots$. Indeed, as the set of live states of the p automaton for $\mathbf{A} \cdot \mathbf{u} = \mathbf{c}$ is finite (by Proposition 4), in the infinite sequence $\mathbf{v}_0, \mathbf{v}_1, \mathbf{v}_2, \dots$ where $\mathbf{A} \cdot \llbracket \mathbf{u}_{k-1} \mathbf{u}_{k-2} \cdots \mathbf{u}_0 \rrbracket^* + \mathbf{v}_k \cdot p^k = \mathbf{c}$ for every $k \in \mathbb{N}$, there must be a state \mathbf{r} that appears infinitely often. ◀

B Missing proofs from Section 3

Below, given a semi-linear set $M = \bigcup_{i \in I} L(B_i, P_i)$, we define $\|M\| \stackrel{\text{def}}{=} \max_{i \in I} (\|B_i\|_\infty, \|P_i\|_\infty)$.

► **Lemma 14.** Let $\mathbf{A} \in \mathbb{Z}^{n \times d}$, $\mathbf{s}, \mathbf{t} \in \mathbb{Z}^n$ and let T be a linear system of m inequalities. The set $\llbracket \mathbf{s} \rightarrow_T \mathbf{t} \rrbracket_{\mathbf{A}}$ is an ultimately periodic set with period and threshold bounded by $U^{\mathcal{O}(k \log k)}$, where $k = n + d + m$ and $U = \max(2, \|\mathbf{A}\|_\infty, \|\mathbf{s} \rightarrow_T \mathbf{t}\|_\infty)$.

Proof. Recall that $\llbracket \mathbf{s} \rightarrow_T \mathbf{t} \rrbracket_{\mathbf{A}}$ is the set of $z \in \mathbb{N}$ for which there is $\mathbf{x} = (x_1, \dots, x_d) \in \llbracket T \rrbracket_{\geq 0}$ satisfying the following system S of linear inequalities:

$$\begin{cases} \mathbf{s} \cdot z + \mathbf{A} \cdot \mathbf{x} = \mathbf{t} \\ z \geq 2 \\ x_i \leq z - 1 \quad \text{for every } i \in [1, d]. \end{cases}$$

As usual, when restricting a system to its non-negative solutions, we can replace inequalities with equalities by introducing slack variables, obtaining the system S' :

$$\begin{cases} \mathbf{s} \cdot z + \mathbf{A} \cdot \mathbf{x} = \mathbf{t} \\ z - z' = 2 \\ x_i + x'_i = z - 1 \quad \text{for every } i \in [1, d]. \end{cases}$$

where z', x'_1, \dots, x'_d are $(d+1)$ variables that shall be interpreted with non-negative integers. It is easy to verify that the set of solutions in $\llbracket S \rrbracket_{\geq 0}$ can be characterised by considering the set $\llbracket S' \rrbracket_{\geq 0}$ and projecting away the dimensions relatives to the slack variables z', x'_1, \dots, x'_d .

Notice that S' has $2 \cdot (d+1)$ variables and $n+d+1$ rows. A similar treatment can be applied to the system of inequalities T : by introducing at most m new slack variables, we obtain a system of equalities T' with m rows and $d+m$ variables. We apply Proposition 7, on the system made of S' and T' and conclude that $\llbracket S' \rrbracket_{\geq 0} \cap \llbracket T' \rrbracket_{\geq 0} = L(B, P)$ where

- $\|B\|_{\infty} \leq ((2 \cdot (d+1) + (d+m) + 2) \cdot U + 1)^{(n+d+1)+(d+m)}$,
- $\|P\|_{\infty} \leq ((2 \cdot (d+1) + (d+m)) \cdot U + 1)^{(n+d+1)+(d+m)}$.

Hence, $\|L(B, P)\| \leq U^{\mathcal{O}(k \log k)}$. Projecting $L(B, P)$ on the variable z yields $\llbracket \mathbf{s} \rightarrow_T \mathbf{t} \rrbracket_{\mathbf{A}}$. So, $\llbracket \mathbf{s} \rightarrow_T \mathbf{t} \rrbracket_{\mathbf{A}} = L(C, Q) \subseteq \mathbb{N}$ with $\|L(C, Q)\| \leq U^{\mathcal{O}(k \log k)}$. We now change representation: by Proposition 8, we characterise $\llbracket \mathbf{s} \rightarrow_T \mathbf{t} \rrbracket_{\mathbf{A}}$ as an ultimately periodic set with period $p \leq \gcd Q \leq U^{\mathcal{O}(k \log k)}$ and threshold $t \leq \|C\|_{\infty} + \|Q\|_{\infty}^2 \leq U^{\mathcal{O}(k \log k)}$. ◀

▶ **Lemma 18.** *The set $\oplus(L_0, \dots, L_r)$ contains all length values generated by \mathcal{G} . One can construct in time $\mathcal{O}(r^2) \cdot U^{\mathcal{O}(n \cdot r)}$ a representation of $\oplus(L_0, \dots, L_r)$ as a semi-linear set $\bigcup_{k \in K} L(\mathbf{b}_k, P_k)$, where $\#K \leq U^{\mathcal{O}(n \cdot r)}$, $\#P \leq r+1$, $\|P\|_{\infty} \leq U^{2n}$ and $\|\mathbf{b}_k\|_{\infty} \leq \mathcal{O}(r \cdot U^{4n})$.*

Proof. It is relatively straightforward to see that $\oplus(L_0, \dots, L_r)$ corresponds to the set of length values generated by \mathcal{G} . First, let $(v_0, \dots, v_r) \in \mathbb{N}^{r+1}$ be a length value generated by \mathcal{G} , which by definition means that \mathcal{G} has a path of the following form

$$\mathbf{t}_{r+1} \rightarrow_{U_r} \mathbf{s}_r \xrightarrow{W_r^{v_r - (v_{r-1} + 1)}} \mathbf{t}_r \rightarrow_{U_{r-1}} \mathbf{s}_{r-1} \dots \mathbf{s}_1 \xrightarrow{W_1^{v_1 - (v_0 + 1)}} \mathbf{t}_1 \rightarrow_{U_0} \mathbf{s}_0 \xrightarrow{W_0^{v_0}} \mathbf{t}_0 = \mathbf{c}.$$

Directly by definition of $G_j(\mathbf{s}_j, \mathbf{t}_j)$ and its related unary NFA, we have that $v_0 \in L_0$ and for every $j \in [1, r]$, $v_j - (v_{j-1} + 1) \in L_j$. By definition of $\oplus(L_1, \dots, L_r)$,

$$\begin{pmatrix} v_0 \\ 1 + v_0 + v_1 - (v_0 + 1) \\ \dots \\ i + v_0 + \sum_{j \in [1, i]} (v_j - (v_{j-1} + 1)) \\ \dots \\ r + v_0 + \sum_{j \in [1, r]} (v_j - (v_{j-1} + 1)) \end{pmatrix} = \begin{pmatrix} v_0 \\ v_1 \\ \dots \\ v_i \\ \dots \\ v_r \end{pmatrix} \in \oplus(L_1, \dots, L_r)$$

Conversely, suppose $(v_0, \dots, v_r) \in \oplus(L_1, \dots, L_r)$. This implies that there are ℓ_0, \dots, ℓ_r such that, for every $j \in [0, r]$, $\ell_j \in L_j$ and $v_j = j + \sum_{i \in [0, j]} \ell_i$. By definition of L_j , we conclude that \mathcal{G} has a path of the following form

$$\mathbf{t}_{r+1} \rightarrow_{U_r} \mathbf{s}_r \xrightarrow{W_r^{\ell_r}} \mathbf{t}_r \rightarrow_{U_{r-1}} \mathbf{s}_{r-1} \dots \mathbf{s}_1 \xrightarrow{W_1^{\ell_1}} \mathbf{t}_1 \rightarrow_{U_0} \mathbf{s}_0 \xrightarrow{W_0^{\ell_0}} \mathbf{t}_0 = \mathbf{c}.$$

We have $\ell_0 = v_0$ and, given $j \in [1, r]$, from $v_j = j + \sum_{i \in [0, j]} \ell_i = 1 + v_{j-1} + \ell_j$ we conclude that $\ell_j = v_j - (v_{j-1} + 1)$. Hence (v_0, \dots, v_r) is a length value generated by \mathcal{G} .

Let us now show how to construct a semi-linear representation of $\oplus(L_0, \dots, L_r)$. Recall that, by Proposition 17, for every $i \in [0, r]$ we have $L_i = \bigcup_{j \in J_i} L(b_j, p_j)$ with $\#J_i \leq \mathcal{O}(U^{4n})$, $b_j \leq (2 \cdot U^{2n} + 1) \cdot U^{2n}$ and $p_j \leq U^{2n}$. To compute $\oplus(L_0, \dots, L_r)$ we iterate over all $(j_0, \dots, j_r) \in J_0 \times \dots \times J_r$ and construct a linear set representation for

$$\oplus(L(b_{j_0}, p_{j_0}), \dots, L(b_{j_r}, p_{j_r})) \stackrel{\text{def}}{=} \left\{ \begin{pmatrix} \ell_0 \\ 1 + \ell_0 + \ell_1 \\ \dots \\ r + \sum_{i=0}^r \ell_i \end{pmatrix} \in \mathbb{N}^{r+1} : \forall i \in [0, r], \ell_i \in L(b_{j_i}, p_{j_i}) \right\}.$$

The set $\oplus(L_0, \dots, L_r)$ is then the union over all such linear sets. Hence, consider $(j_0, \dots, j_r) \in J_0 \times \dots \times J_r$ and the linear sets $L(b_{j_0}, p_{j_0}), \dots, L(b_{j_r}, p_{j_r})$. Given $i \in [0, r]$, we write $\mathbf{q}_i \in \mathbb{N}^{r+1}$ for the vector having zero in the first $i-1$ components, and p_{j_i} in the last $r+1-i$ components.

Moreover, let $\mathbf{b} \in \mathbb{N}^{r+1}$ be the vector with i th component set to $i + \sum_{k=0}^i b_{j_k}$. It is easy to see that $\oplus(L(b_{j_0}, p_{j_0}), \dots, L(b_{j_r}, p_{j_r})) = L(\mathbf{b}, \{\mathbf{q}_0, \dots, \mathbf{q}_r\})$. Due to the bound on each $L(b_{j_i}, p_{j_i})$, one can compute $L(\mathbf{b}, \{\mathbf{q}_0, \dots, \mathbf{q}_r\})$ in time $\mathcal{O}(r^2 \cdot \max_{i \in [0, r]} (\langle b_{j_i} \rangle, \langle p_{j_i} \rangle)) \leq \mathcal{O}(n \cdot r^2 \cdot \log U)$. Moreover, $\|\mathbf{q}_i\|_\infty \leq U^{2n}$ and $\|\mathbf{b}\|_\infty \leq \mathcal{O}(r \cdot U^{4n})$. When considering all $U^{\mathcal{O}(n \cdot r)}$ tuples, a semi-linear representation of $\oplus(L_0, \dots, L_r)$ can then be constructed in time $\mathcal{O}(r^2) \cdot U^{\mathcal{O}(n \cdot r)}$. \blacktriangleleft

► **Lemma 19.** *Let ψ be a formula of the form given in (5).*

- *Given $\mathcal{G} \in \mathbb{G}(\psi)$, if $\mathcal{G} \vdash \mathbf{B} \cdot \mathbf{x} \geq \mathbf{d}$ then $\llbracket \mathcal{G} \rrbracket_{\mathbf{A}} \subseteq \mathcal{B}(\psi)$.*
- *For every $p \in \mathcal{B}(\psi)$, there is $\mathcal{G} \in \mathbb{G}(\psi)$ such that $\mathcal{G} \vdash \mathbf{B} \cdot \mathbf{x} \geq \mathbf{d}$ and $p \in \llbracket \mathcal{G} \rrbracket_{\mathbf{A}}$.*

Proof. To show this result, we simply adapt the proof of Lemma 15. Let \mathbb{G} be the set of support graphs \mathcal{G} in $\mathbb{G}(\psi)$ such that $\mathcal{G} \vdash \mathbf{B} \cdot \mathbf{x} \geq \mathbf{d}$. The lemma equivalently states that $\mathcal{B}(\psi) = \bigcup_{\mathcal{G} \in \mathbb{G}} \llbracket \mathcal{G} \rrbracket_{\mathbf{A}}$. Below, we refer to the first and second points in the lemma as the two inclusions \supseteq and \subseteq of this equality.

(\supseteq): Let \mathcal{G} be a support graph in \mathbb{G} , and consider $p \in \llbracket \mathcal{G} \rrbracket_{\mathbf{A}}$. Moreover, let $(v_0, \dots, v_r) \in \mathbb{N}^{r+1}$ be a length value generated by \mathcal{G} such that $\mathbf{B} \cdot \mathbf{c} \geq \mathbf{d} \wedge \bigwedge_{i \in [0, r]} x_i = v_i$ is satisfiable. This means that \mathcal{G} has a path of the form

$$\mathbf{t}_{r+1} \rightarrow_{U_r} \mathbf{s}_r \xrightarrow{v_r - (v_{r-1} + 1)}_{W_r} \mathbf{t}_r \rightarrow_{U_{r-1}} \mathbf{s}_{r-1} \dots \mathbf{s}_1 \xrightarrow{v_1 - (v_0 + 1)}_{W_1} \mathbf{t}_1 \rightarrow_{U_0} \mathbf{s}_0 \xrightarrow{v_0}_{W_0} \mathbf{t}_0 = \mathbf{c}$$

Moreover, as $\mathcal{G} \in \mathbb{G}(\psi)$, there is $\mathbf{r} \in \mathbb{Z}^n$ such that \mathcal{G} has a path from \mathbf{r} to \mathbf{t}_{r+1} as well as a path from \mathbf{r} to itself. We recall that, by definition, for every edge $\mathbf{s} \rightarrow_T \mathbf{t}$ of \mathcal{G} there is $\mathbf{u} \in \Sigma_p^d$ such that $\mathbf{s} \xrightarrow{\mathbf{u}}_{\mathbf{A}, p} \mathbf{t}$ and $\mathbf{u} \in \llbracket T \rrbracket$. We conclude that there is an infinite word w such that $w = w_0 \cdot \mathbf{v}_0 \cdot w_1 \cdot \dots \cdot w_r \cdot \mathbf{v}_r \cdot \bar{w}$, where

1. $\mathbf{v}_0, \dots, \mathbf{v}_r \in \Sigma_p^d$, and for all $j \in [0, r]$, the prefix $w_0 \cdot \mathbf{v}_0 \cdot \dots \cdot w_j \in (\Sigma_p^d)^*$ of w has length v_j ,
2. $\mathbf{t}_{r+1} \xrightarrow{v_r}_{\mathbf{A}, p} \mathbf{s}_r \dots \mathbf{s}_1 \xrightarrow{(w_1)^R}_{\mathbf{A}, p} \mathbf{t}_1 \xrightarrow{v_0}_{\mathbf{A}, p} \mathbf{s}_0 \xrightarrow{(w_0)^R}_{\mathbf{A}, p} \mathbf{t}_0 = \mathbf{c}$,
3. $\bar{w} = \mathbf{u}_0 \mathbf{u}_1 \dots$ is an infinite suffix of w for which there is an infinite sequence $\lambda_0 < \lambda_1 < \dots$ such that $\mathbf{r} \xrightarrow{\mathbf{u}_{\lambda_0 - 1} \dots \mathbf{u}_0}_{\mathbf{A}, p} \mathbf{c}$ and for all $j \in \mathbb{N}$, $\mathbf{r} \xrightarrow{\mathbf{u}_{\lambda_{j+1}} \dots \mathbf{u}_{\lambda_j}}_{\mathbf{A}, p} \mathbf{r}$,
4. By definition of U_0, \dots, U_m and W_0, \dots, W_{m+1} , given $(i, j) \in J$, so that $v_p(u_i) = x_j$ appears in ψ , we have that $w_0 \cdot \mathbf{v}_0 \cdot \dots \cdot w_j$ projected on the encoding of u_i is in $\{0\}^*$, and v_j projected on the encoding of u_i is in $[1, p - 1]$.

Therefore, ψ admits a solution $(\llbracket w \rrbracket^\omega, \mathbf{x})$, where in \mathbf{x} for every $i \in [0, r]$ we have $x_i = v_i$. Indeed, from points 2 and 3, and by Proposition 6, $\mathbf{A} \cdot \llbracket w \rrbracket^\omega = \mathbf{c}$. From points 1 and 4, given $(i, j) \in J$, the l sd encoding of u_i is such that $v_p(u_i) = v_j$, hence $v_p(u_i) = x_j$. Lastly, by definition of (v_0, \dots, v_r) we have $x_0 < x_1 < \dots < x_r$, and we know that $\mathbf{B} \cdot \mathbf{c} \geq \mathbf{d} \wedge \bigwedge_{i \in [0, r]} x_i = v_i$ is satisfiable. This means that ψ is satisfiable with respect to the base p , i.e. $p \in \mathcal{B}(\psi)$.

(\subseteq): Follows conversely from the other inclusion. Briefly, suppose ψ satisfiable with respect to the base p . Consider a word $w \in (\Sigma_p^d)^\omega$ and $\mathbf{x} \in \mathbb{Z}^e$ such that $(\llbracket w \rrbracket^\omega, \mathbf{x})$ is a solution of ψ . As already said in the body of the paper, this means that w must have a prefix of the form $w_0 \cdot \mathbf{v}_0 \cdot w_1 \cdot \dots \cdot w_r \cdot \mathbf{v}_r \cdot w_{r+1}$ such that $\mathbf{v}_0, \dots, \mathbf{v}_r \in \Sigma_p^d$, the word $w_0 \in (\Sigma_p^d)^*$ has length x_0 , each $w_i \in (\Sigma_p^d)^*$ with $i \in [1, r]$ has length $x_i - (x_{i-1} + 1) \geq 0$,

$$\mathbf{r} = \mathbf{s}_{r+1} \xrightarrow{(w_{r+1})^R}_{\mathbf{A}, p} \mathbf{t}_{r+1} \xrightarrow{v_r}_{\mathbf{A}, p} \mathbf{s}_r \dots \mathbf{s}_1 \xrightarrow{(w_1)^R}_{\mathbf{A}, p} \mathbf{t}_1 \xrightarrow{v_0}_{\mathbf{A}, p} \mathbf{s}_0 \xrightarrow{(w_0)^R}_{\mathbf{A}, p} \mathbf{t}_0 = \mathbf{c}$$

and \mathbf{r} is a live state of $\mathcal{A}_p^*(S)$ for which the ω -regular condition of Proposition 6 is satisfied. Moreover, for every $j \in [0, r]$ the values of v_j for the variables $u_1, \dots, u_{\#I}$ satisfy the system U_j , whereas at each position of the word w_j ($j \in [0, r + 1]$) shall satisfy the system W_j .

Let \mathcal{G} be the support graph with edges $\mathbf{t}_1 \rightarrow_{U_0} \mathbf{s}_0, \dots, \mathbf{t}_{r+1} \rightarrow_{U_j} \mathbf{s}_r$ together with $\mathbf{i} \rightarrow_{W_j} \mathbf{i}'$, for every $j \in [0, r+1]$ and every two states \mathbf{i}, \mathbf{i}' such that $\mathbf{i} \rightarrow_{\mathbf{A}, p} \mathbf{i}'$ appears in the path going from \mathbf{s}_j to \mathbf{t}_j , and $\mathbf{i} \rightarrow_{W_{r+1}} \mathbf{i}'$, for every two states \mathbf{i}, \mathbf{i}' such that $\mathbf{i} \rightarrow_{\mathbf{A}, p} \mathbf{i}'$ appears in the path going from \mathbf{r} to itself. By definition, $\mathcal{G} \in \mathbb{G}(\psi)$ and $p \in \llbracket \mathcal{G} \rrbracket_{\mathbf{A}}$. Moreover, (x_0, \dots, x_r) is a length value generated by \mathcal{G} , which entails $\mathcal{G} \vdash \mathbf{B} \cdot \mathbf{x} \geq \mathbf{d}$. ◀

► **Lemma 20.** *Let ψ be as in (5). The set $\mathcal{B}(\psi)$ is ultimately periodic, with threshold bounded by $U^{\mathcal{O}(k \log k)}$ and period bounded by $U^{\mathcal{O}(\ell \cdot k \log k)}$, with $k = n + 3d$ and $\ell = (r+2) \cdot U^{4n+1}$.*

Proof. Analogous to the proof of Lemma 16. Consider the family of support graphs $\mathbb{G}(\psi)$. Since $\mathbb{G}(\psi)$ is finite, according to Lemma 19 we have $\mathcal{B}(\psi) = \bigcup_{G \in \mathbb{G}} \llbracket G \rrbracket_{\mathbf{A}}$ for some $G \subseteq \mathbb{G}(\psi)$. Every edge $\mathbf{s} \rightarrow_T \mathbf{t}$ of a support graph $\mathcal{G} \in G$ is such that $\|\mathbf{s}\|_\infty, \|\mathbf{t}\|_\infty \leq \max(\|\mathbf{A}\|_{1,\infty}, \|\mathbf{c}\|_\infty)$ and T is a system among $U_0, \dots, U_r, W_0, \dots, W_{r+1}$. Hence, all the graphs in G are built from a set E of $(2 \cdot \max(\|\mathbf{A}\|_{1,\infty}, \|\mathbf{c}\|_\infty))^{2n} \cdot (2r+3) \leq \ell$ edges. Each possible linear system T labelling an edge in E has at most $2d$ inequalities, with coefficients and constants in $\{0, 1\}$. By Lemma 14, each edge $e \in E$ is such that $\llbracket e \rrbracket_{\mathbf{A}}$ is an ultimately periodic set with period and threshold bounded by $U^{\mathcal{O}(k \log k)}$, where $k = n + 3d$. By Proposition 9, $\mathcal{B}(\psi) = \bigcup_{G \in \mathbb{G}} \llbracket G \rrbracket_{\mathbf{A}}$ is an ultimately periodic set with threshold in $U^{\mathcal{O}(k \log k)}$ and period in $U^{\mathcal{O}(\ell \cdot k \log k)}$. ◀

► **Theorem 21.** *Let Φ be an existential formula of linear arithmetic constraints over p -adic integers (resp. Büchi arithmetic) with parametric base p . Then satisfiability of Φ with respect to a given value $p \in \mathbb{P}$ (resp. $p \geq 2$) can be decided in time $2^{\mathcal{O}(\langle \Phi \rangle^3)} \cdot \mathcal{O}(\langle p \rangle)$.*

Proof. Consider an existential formula Φ of linear arithmetic constraints over p -adic integers, with parametric base q , and a concrete value $p \in \mathbb{P}$ for q . As done in Proposition 12, in time exponential in $\langle \Phi \rangle$ we manipulate Φ and obtain a disjunctive normal form where each of the $2^{\mathcal{O}(\langle \Phi \rangle \log \langle \Phi \rangle)}$ disjuncts are of size $\mathcal{O}(\langle \Phi \rangle)$ and the form in (5). We then iterate through each disjunct ψ of Φ , calling the procedure SAT(ψ) described in Algorithm 1. If the procedure returns true for some disjunct ψ , then Φ is satisfiable, otherwise it is unsatisfiable. Let us fix a disjunct ψ of Φ . We argue that SAT(ψ) is a decision procedure for the satisfiability problem of ψ that runs in time $2^{\mathcal{O}(\langle \psi \rangle^3)} \cdot \mathcal{O}(\langle p \rangle)$. As Φ has $2^{\mathcal{O}(\langle \Phi \rangle \log \langle \Phi \rangle)}$ many disjuncts of size $\mathcal{O}(\langle \Phi \rangle)$, this is sufficient to establish Theorem 21.

Let us sketch the correctness of the algorithm, which essentially follows by replaying some of the arguments that led to Proposition 12. Indeed, line 3 iterates through all possible tuples of intermediate live states, as done when considering the set of automatic support graphs $\mathbb{G}(\psi)$. Let $(\mathbf{s}_0, \mathbf{t}_0, \dots, \mathbf{s}_{r+1}, \mathbf{t}_{r+1})$ be one of these tuples. For every $j \in [0, r+1]$, the algorithm considers the unary NFA \mathcal{A}_j (line 6) whose arrows (\mathbf{s}, \mathbf{t}) corresponds to edges $\mathbf{s} \rightarrow_{W_j} \mathbf{t}$ of automatic support graphs for which $p \in \llbracket \mathbf{s} \rightarrow_{W_j} \mathbf{t} \rrbracket_{\mathbf{A}}$. The fundamental relation between \mathcal{A}_j and the p -automaton $\mathcal{A}_p^*(S)$ for the system $S: \mathbf{A} \cdot \mathbf{u} = \mathbf{c}$ is as follows:

$$(\mathbf{s}, \mathbf{t}) \in \delta \text{ if and only if there is } \mathbf{u} \in [0, p-1]^n \text{ such that } \mathbf{s} \xrightarrow{\mathbf{u}}_{\mathbf{A}, p} \mathbf{t} \text{ and } \mathbf{u} \in \llbracket W_j \rrbracket.$$

Therefore, if the checks performed in lines 7 and 8 are satisfied for all $j \in [0, r+1]$ (else, a new tuple in $Q^{2(r+1)}$ is considered), we conclude that $\mathcal{A}_p^*(S)$ contains a path of the form in (6). According to Proposition 6, line 9 then tests for the existence of a non-empty path in \mathcal{A}_{r+1} (equivalently, $\mathcal{A}_p^*(S)$) going from \mathbf{s}_{r+1} to itself. If such a path is found, then there is an infinite word $w \in (\Sigma_p^d)^\omega$ and $\mathbf{x} \in \mathbb{N}^e$ such that $(\llbracket w \rrbracket^*, \mathbf{x})$ is a solution for the subformula $\mathbf{A} \cdot \mathbf{u} = \mathbf{c} \wedge \bigwedge_{(i,j) \in J} v_p(u_i) = x_j \wedge \bigwedge_{j \in [1,r]} x_{j-1} < x_j$ of ψ . Lines 10 and 12 provides further analysis needed to check for the satisfaction of the system $\mathbf{B} \cdot \mathbf{x} \geq \mathbf{d}$. Again following what done for Proposition 12, line 10 computes the set L_j of lengths of words accepted by \mathcal{A}_j , that are then combined in the set $\oplus(L_0, \dots, L_r)$. Note that $\oplus(L_0, \dots, L_r)$ is empty if so is one set among L_0, \dots, L_r . If one element of $\oplus(L_0, \dots, L_r)$ satisfies $\mathbf{B} \cdot \mathbf{x} \geq \mathbf{d}$, then ψ is satisfiable, and the procedure returns true (line 12).

Let us discuss the time complexity of $\text{SAT}(\psi)$. First of all, the running time of the loop in line 5 is in $2^{\mathcal{O}(\langle \psi \rangle^2)} \cdot \mathcal{O}(\langle p \rangle)$. Indeed, notice that given $\mathbf{s}, \mathbf{t} \in Q$ and a system $T \in \{U_j, W_j, W_{r+1} : j \in [0, r]\}$, the membership problem $p \in \llbracket \mathbf{s} \rightarrow_T \mathbf{t} \rrbracket_{\mathbf{A}}$ correspond to the non-emptiness problem $\llbracket R \rrbracket \neq \emptyset$ of the linear system $R: \mathbf{t} = \mathbf{s} \cdot p + \mathbf{A} \cdot \mathbf{x} \wedge \|\mathbf{x}\| < p \wedge \mathbf{x} \in \llbracket T \rrbracket$, which by Proposition 22 can be decided in time $\langle \psi \rangle^{\mathcal{O}(\langle \psi \rangle)} \cdot \mathcal{O}(\langle p \rangle)$. Hence, by iterating over all pairs $(\mathbf{s}, \mathbf{t}) \in Q^2$, one constructs the automaton \mathcal{A}_j in time $2^{\mathcal{O}(\langle \psi \rangle^2)} \cdot \mathcal{O}(\langle p \rangle)$ (line 6). Line 7 runs in time $\langle \psi \rangle^{\mathcal{O}(\langle \psi \rangle)} \cdot \mathcal{O}(\langle p \rangle)$. Lines 8 and 9, can be implemented with a depth-first search on the automaton \mathcal{A}_j , which takes time bounded by the cardinality of the transition relation δ , that is bounded by $2^{\mathcal{O}(\psi)^2}$. Directly from Proposition 17, line 10 can be performed in time $2^{\mathcal{O}(\langle \psi \rangle^2)}$. Let us now look at line 12. By Lemma 18, computing $\oplus(L_0, \dots, L_r)$ as a semi-linear set can be done in time $2^{\mathcal{O}(\langle \psi \rangle^3)}$. This set is of the form $\bigcup_{k \in K} L(\mathbf{b}_k, P_k) \subseteq \mathbb{N}^{r+1}$, with $\#K \leq 2^{\mathcal{O}(\langle \psi \rangle^3)}$, $\|\mathbf{b}_k\|_\infty, \|P_k\|_\infty \leq 2^{\mathcal{O}(\langle \psi \rangle^2)}$ and $\#P_k \leq r+1$. Hence, to check for the non-emptiness of the intersection in line 12, it is sufficient to iterate over all $k \in K$ and check for the satisfiability of the system $\mathbf{y} = \mathbf{b}_k + P_k \cdot \boldsymbol{\lambda} \wedge \mathbf{B} \cdot \mathbf{x} \geq \mathbf{d}$, where \mathbf{y} is a subset of the variables appearing in \mathbf{x} . By Proposition 22, this can be done in time $\langle \psi \rangle^{\mathcal{O}(\langle \psi \rangle)}$. Overall, line 12 can be evaluated in $2^{\mathcal{O}(\langle \psi \rangle^3)}$, and hence the running time for the body of the for loop of line 3 is bounded by $2^{\mathcal{O}(\langle \psi \rangle^3)} \cdot \mathcal{O}(\langle p \rangle)$. As this loop iterates over $(2U)^{2(r+1)} \leq 2^{\mathcal{O}(\langle \psi \rangle^2)}$ tuples, the running time of $\text{SAT}(\psi)$ is in $2^{\mathcal{O}(\langle \psi \rangle^3)} \cdot \mathcal{O}(\langle p \rangle)$. ◀

In order to establish Theorem 21 for the case of existential Büchi arithmetic, it is sufficient to bring Φ into disjunctive normal form with disjuncts of the form in Equation (2), and call on each disjunct ψ the procedure $\text{SAT}(\psi)$ subject to the following updates: (I) reflecting (3), the iteration on line 3 is on tuples such that $\mathbf{s}_0 = \mathbf{0}$ and $\mathbf{t}_{r+1} = \mathbf{c}$, and the test in line 7 becomes $j > 0$ and $p \notin \llbracket \mathbf{t}_{j-1} \rightarrow_{U_j} \mathbf{s}_j \rrbracket_{\mathbf{A}}$; (II) the systems U_j and W_j in lines 6 and 7 are defined as introduced in Section 3 and (III) lines 4, 9, 10 and 12 are removed. The proof of Theorem 21 can be easily updated accordingly.

Obstructing Classification via Projection

Abstract

Machine learning and data mining techniques are effective tools to classify large amounts of data. But they tend to preserve any inherent bias in the data, for example, with regards to gender or race. Removing such bias from data or the learned representations is quite challenging. In this paper we study a geometric problem which models a possible approach for bias removal. Our input is a set of points P in Euclidean space \mathbb{R}^d and each point is labeled with k binary-valued properties. A priori we assume that it is “easy” to classify the data according to each property. Our goal is to obstruct the classification according to one property by a suitable projection to a lower-dimensional Euclidean space \mathbb{R}^m ($m < d$), while classification according to all other properties remains easy.

What it means for classification to be easy depends on the classification model used. We first consider classification by linear separability as employed by support vector machines. We use Kirchberger’s Theorem to show that, under certain conditions, a simple projection to \mathbb{R}^{d-1} suffices to eliminate the linear separability of one of the properties whilst maintaining the linear separability of the other properties. We also study the problem of maximizing the linear “inseparability” of the chosen property. Second, we consider more complex forms of separability and prove a connection between the number of projections required to obstruct classification and the Helly-type properties of such separabilities.

1 Introduction

Classification is one of the most basic data analysis operators: given a (very) large set of high-dimensional input data with a possibly large set of heterogeneous properties, we would like to classify the data according to one or more of these properties to facilitate further analysis and decision making. Machine learning and data mining techniques are frequently employed in this setting, since they are effective tools to classify large datasets. However, just as any data-driven techniques, they tend to preserve any bias inherent in the data,

for example, with regards to gender or race. Such bias arises from under-representation of minority groups in the data or is caused by historical data, which reflect outdated societal norms. Bias in the data might be inconsequential, for example in music recommendations, but it can be harmful when classification algorithms are used to make life-changing decisions on, for example, loans, recruitment, or parole [23].

Naturally, the identification and removal of bias receives a significant amount of attention, although the problem is still far from solved. For example, Mehrabi et al. [19] provide a taxonomy of fairness definitions and bias types. They list the biases caused by data and the types of discrimination caused by machine learning techniques. Many approaches have been considered to eliminate or reduce bias in machine learning models. Some researchers have used a statistical approach to address this problem (e.g., [13]), while others focus on data preprocessing or controlling the sampling to compensate for bias or under-representation in the data (e.g., [2, 15]). Another approach is to use an additional (adversarial) machine learning model to eliminate bias in the first model (e.g., [11, 18, 27]). One major problem of attempting to eliminate bias (or increasing fairness) in machine learning is that it may negatively affect the accuracy of the learned model. This trade-off has also been studied extensively (e.g., [3, 25]).

We are particularly interested in data that is represented by vectors in high-dimensional Euclidean space. Such data arises, for example, from word embeddings for textual data. Several studies show that the bias present in the training corpora is also present in the learned representation (e.g. [7, 8]). Abbasi et al. [1] recently introduced a geometric notion of stereotyping. In this paper we follow the same premise that bias is in some form encoded in the geometric or topological features of the high-dimensional vector representation and that manipulating this geometry can remove the bias. This premise has been the basis for many papers on algorithmic fairness (e.g., [11, 12, 26]).

Several papers investigate the theory that gender is captured in certain dimensions of the data. Bolukbasi et al. [5] postulate that the bias manifests itself in specific “particularly gendered” words and that equalizing distances to these special words removes bias. Zhao et al. [28] devise a model which attempts to represent gender in one dimension which can be removed after training to arrive at a (more) gender-neutral word representation. Bordia and Bowman [6] remove bias by minimizing the projection of the embeddings on the gender subspace (using a regularization term in the training process). Very recently, various papers [9, 10, 14, 22] explored the direct use of projection to remove sensitive properties of the data. In some cases the data is not projected completely, as removing sensitive properties completely may negatively affect the quality of the model.

In this paper we take a slightly more general point of view. We say that a property is present in the data representation if it is “easy” to classify the data according to that property. That is, a property (such as gender) can be described by more complicated geometric relations than a subspace. Given the premise that the geometry of word embeddings encodes important relations between the data, then any bias removal technique needs to preserve as much as possible of these relations. Hence we investigate the use of projection to eliminate bias while maintaining as many other relations as possible. We say that the relation of data points with respect to specific properties is maintained by a projection, if it is still easy to classify according to these properties after projection. Our paper explores how well projection can obstruct classification according to a specific property (such as gender) for certain classification models.

Problem statement. Our input is a set of n points $P = \{p_1, \dots, p_n\}$ in general position in \mathbb{R}^d . For convenience we identify the points with their corresponding vector. We model the various properties of the data (such as gender) as binary labels.¹ Hence, for all points in P we are also given k binary-valued *properties*, represented as functions $a_i: P \rightarrow \{-1, 1\}$ for $1 \leq i \leq k$. We denote the subset of points $p \in P$ with $a_i(p) = 1$ as P_+^i , and the subset of points $p \in P$ with $a_i(p) = -1$ as P_-^i for $1 \leq i \leq k$. For a point $p \in P$, we refer to the tuple $(a_1(p), \dots, a_k(p))$ as the *label* of p . Note that there are 2^k different possible labels. Generally speaking, we do not know which specific properties a dataset has. However, to study the influence of projection on all relevant properties of a dataset, we assume that these properties are given.

We assume that it is “easy” to classify the points in P according to the properties by using the point coordinates. Throughout the paper, we consider different definitions for what is considered easy or difficult to classify. Our goal is to compute a projection P' of P to lower dimensions such that the first property a_1 becomes difficult to classify in P' , and the other properties a_2, \dots, a_k remain easy to classify in P' . As a shorthand we use the notation $P_- = P_-^1$ and $P_+ = P_+^1$ for the point sets in which the special property a_1 is set to -1 and $+1$, respectively. Similarly, we use the notation P'_- and P'_+ for the point sets P_- and P_+ after projection. In most cases we will consider a projection along a single unit vector w ($\|w\| = 1$), mapping points in \mathbb{R}^d to points in \mathbb{R}^{d-1} . For a point $p_i \in P$, we denote its projection as $p'_i = p_i - (p_i \cdot w)w$, where $(p_i \cdot w)$ denotes the dot product between the vectors $p_i, w \in \mathbb{R}^d$. To assign coordinates to p'_i in \mathbb{R}^{d-1} , we need to establish a basis for the projected space. We therefore often consider p'_i to lie in the original space \mathbb{R}^d , where the coordinates of p'_i are restricted to the hyperplane that is orthogonal to w and passes through the origin. Sometimes we will consider projections along multiple vectors w_1, \dots, w_r . In that case we assume that $\{w_j\}_{j=1}^r$ form an orthonormal system, such that we can write the projection as $p'_i = p_i - \sum_{j=1}^r (p_i \cdot w_j)w_j$. Again, we assume that p'_i still lies in \mathbb{R}^d , but is restricted to the $(d - r)$ -dimensional flat that is orthogonal to w_1, \dots, w_r and passes through the origin.

We consider different models for defining what is easy or difficult to classify, resulting in different computational problems. These models typically rely on a form of “separability” between two point sets. For a specific definition of separability, using a slight abuse of notation, we will often state that a property a_i is separated in a point set P when we actually mean that P_-^i and P_+^i are separated (see Figure 1 for a simple example in \mathbb{R}^2). The specific models, along with the relevant definitions, are described in detail in the respective sections.

¹ Neither gender nor many other societally relevant properties are binary, however, we restrict ourselves to binary properties to simplify our mathematical model.

■ **Figure 1** Left: data points with two linearly-separable properties: shape and color. Middle: a projection which keeps shape separated, but not color. Right: a projection with the opposite effect.

Contributions and organization. In Section 2 we consider linear separability as the classification model. We first show that, if even one possible label is missing from P , then there may be no projection that eliminates the linear separability of a_1 whilst keeping the linear separability of the other properties. On the other hand, if all possible labels are present in the point set, then we show that it is always possible to achieve this goal. In Appendix A we discuss a related question: given a measure to quantify how far removed a labeled point set is from linear separability, how can we optimize this measure for a_1 after projection? We show that the optimal projection can be computed efficiently under certain specific conditions, but may be hard to compute efficiently in general. In Section 3 we introduce (b, c) -separability, which is a generalization of linear separability. Although a single projection is no longer sufficient to avoid (b, c) -separability of a_1 after projection, we show that, in general, the number of projections needed to achieve this is linked to the Helly number of the respective separability predicate. We then establish bounds on the Helly numbers of (b, c) -separability for specific values of b and c . Omitted proofs can be found in Appendix B.

2 Linear separability

In this section we consider linear separability for classification. For a point set P and property $a_i: P \rightarrow \{-1, 1\}$, we say that a_i is easy to classify on P if P_-^i and P_+^i are (strictly) linearly separable; we say that a_i is difficult to classify otherwise. Two point sets P and Q ($P, Q \subset \mathbb{R}^d$) are *linearly separable* if there exists a hyperplane H separating P from Q . The point sets are *strictly linearly separable* if we can additionally require that none of the points lie on H . Equivalently, the point sets P and Q are linearly separable if there exists a unit vector $v \in \mathbb{R}^d$ and constant $c \in \mathbb{R}$ such that $(v \cdot p) \leq c$ for all $p \in P$ and $(v \cdot q) \geq c$ for all $q \in Q$ (v is the normal vector of the hyperplane H). We say that P and Q are linearly separable *along* v . If the inequalities can be strict, then the point sets are strictly linearly separable.

One of the machine learning techniques that use linear separability for classification are *support vector machines* (SVMs). SVMs compute the (optimal) hyperplane that separates two classes in the training data (if linearly separable), and use that hyperplane for further classifications. Linear separability is therefore a good first model to consider for classification.

Let $CH(P)$ denote the convex hull of a point set P . By definition, we have that $x \in CH(P)$ if and only if there exist coefficients $\lambda_i \geq 0$ such that $x = \sum_{i=1}^n \lambda_i p_i$ and $\sum_{i=1}^n \lambda_i = 1$. We use the following basic results on convex geometry and linear algebra.

► **Fact 1.** *Two point sets P and Q are linearly separable iff $CH(P)$ and $CH(Q)$ are interior disjoint. P and Q are strictly linearly separable iff $CH(P) \cap CH(Q) = \emptyset$.*

► **Observation 2.** *Let $P' = \{p'_1, \dots, p'_n\}$ be the point set obtained from $P = \{p_1, \dots, p_n\}$ by projecting along a unit vector w . If $x = \sum_{i=1}^n \lambda_i p_i$ (for $\lambda_i \in \mathbb{R}$), then $x' = x - (w \cdot x)w = \sum_{i=1}^n \lambda_i p'_i$. Specifically, if $x \in CH(P)$, then $x' \in CH(P')$.*

► **Lemma 3.** *Let P and Q be two point sets. If we project both P and Q along a unit vector w to obtain P' and Q' , then P' and Q' are not strictly linearly separable iff there exists a line ℓ parallel to w that intersects both $CH(P)$ and $CH(Q)$. If ℓ intersects the interior of $CH(P)$ or $CH(Q)$, then P' and Q' are not linearly separable.*

Proof. Assume that the line ℓ exists, and it contains $x_P \in CH(P)$ and $x_Q \in CH(Q)$ (see Figure 2). By construction, $x' = x_P - (w \cdot x_P)w = x_Q - (w \cdot x_Q)w$. Hence, by Observation 2, $x' \in CH(P') \cap CH(Q')$. Thus, by Fact 1, P' and Q' are not strictly linearly separable.

■ **Figure 2** Line ℓ intersects $CH(P)$ and $CH(Q)$; after projection the convex hulls intersect.

For the other direction, choose $x' \in CH(P') \cap CH(Q')$. The line parallel to w and passing through x' must clearly intersect both $CH(P)$ and $CH(Q)$. The extension to (non-strict) linear separability is straightforward. ◀

Assume now that the properties a_1, \dots, a_k are strictly linearly separable in P . Can we project P along a unit vector w so that a_2, \dots, a_k are still strictly linearly separable in P' , but a_1 is not? We consider two variants: (1) *separation preserving* and (2) *separability preserving* projections. The former preserves a fixed set of separating hyperplanes H_2, \dots, H_k for properties a_2, \dots, a_k , the latter preserves only linear separability of a_2, \dots, a_k .

Lemma 4 proves there exist point sets using only $2^k - 1$ possible labels for which every separability preserving projection also keeps a_1 strictly linearly separable after projection. The idea is to use the properties a_2, \dots, a_k to sufficiently restrict the direction of a separability preserving projection to make it impossible for this projection to eliminate the linear separability of a_1 . A simple example for $d = k = 2$ is shown in Figure 3.

■ **Figure 3** A point set with 5 points and 2 properties: a_1 (color) and a_2 (shape). To keep a_2 linearly separable after projection, the projection vector w should be nearly vertical, but then a_1 will also remain linearly separable.

► **Lemma 4.** *For all $k > 1$ and $d \geq k$, there exist point sets P in \mathbb{R}^d with properties a_1, \dots, a_k using $2^k - 1$ labels such that any separability preserving projection along a unit vector w also keeps a_1 strictly linearly separable after projection.*

We now assume that all 2^k labels are used in P . Note that this assumption directly implies that $d \geq k$: take any set of k separating hyperplanes H_1, \dots, H_k for the k properties and consider the arrangement formed by the hyperplanes in \mathbb{R}^d . Clearly, all points in the same cell of the arrangement must have the same label. However, it is well-known that it is

■ **Figure 4** Theorem 5 in 2D: 4 points are needed to construct two intersecting convex hulls.

not possible to create 2^k cells in \mathbb{R}^d with only k hyperplanes if $d < k$. This has also interesting implications for the case when $d = k$: if we apply a separation preserving projection to P , then a_1 cannot be linearly separable in P' , since P' is embedded in \mathbb{R}^{k-1} .

We now show that, if $d \geq k$, then there always exists a separation preserving projection that eliminates the strict linear separability of a_1 (see Figure 4). Our proof uses Kirchner's theorem [16]. Below we restate this theorem in our own notation. We also include our own proof, since the construction in the proof is necessary for efficient computation of our result.

► **Theorem 5** ([16]). *Let P and Q be two points sets in \mathbb{R}^d such that $CH(P) \cap CH(Q) \neq \emptyset$. Then there exist subsets $P^* \subseteq P$ and $Q^* \subseteq Q$ such that $CH(P^*) \cap CH(Q^*) \neq \emptyset$ and $|P^*| + |Q^*| = d + 2$.*

Proof. Let $|P| = n$ and $|Q| = m$. We show that, if $n + m \geq d + 3$, then we can remove one of the points from either P or Q . Pick a point $x \in CH(P) \cap CH(Q)$. By definition, we can find coefficients $\lambda_1, \dots, \lambda_n \geq 0$ and $\mu_1, \dots, \mu_m \geq 0$ such that $\sum_{i=1}^n \lambda_i p_i = x = \sum_{j=1}^m \mu_j q_j$, $\sum_{i=1}^n \lambda_i = 1$, and $\sum_{j=1}^m \mu_j = 1$. If any of these coefficients is zero, then we can remove the corresponding point whilst keeping x in the intersection of the two convex hulls. Otherwise, we find nonzero coefficients a_1, \dots, a_n and b_1, \dots, b_m such that $\sum_{i=1}^n a_i p_i = \sum_{j=1}^m b_j q_j$, $\sum_{i=1}^n a_i = 0$, and $\sum_{j=1}^m b_j = 0$. As this is a linear system with $d + 2$ constraints and $n + m \geq d + 3$ variables, there must exist a set of nonzero coefficients that satisfy these constraints. Let $\rho_\lambda = \min\{\lambda_i/a_i \mid a_i > 0\}$, $\rho_\mu = \min\{\mu_j/b_j \mid b_j > 0\}$, and $\rho = \min(\rho_\lambda, \rho_\mu)$. Now consider the new coefficients $\lambda'_i = \lambda_i - \rho a_i$ and $\mu'_j = \mu_j - \rho b_j$. By construction we have that $\lambda'_i \geq 0$ for $1 \leq i \leq n$, $\mu'_j \geq 0$ for $1 \leq j \leq m$, $\sum_i \lambda'_i = \sum_j \mu'_j = 1$, and $\sum_i \lambda'_i p_i = \sum_j \mu'_j q_j = x'$. Additionally, one of the new coefficients is zero, and we can remove the corresponding point. We can repeat this process until $n + m = d + 2$. ◀

The following proof constructs a suitable projection vector using four main steps:

1. We project the points orthogonally onto the linear subspace A spanned by the normals of the separating hyperplanes H_2, \dots, H_k .
2. We argue that, since P uses all 2^k labels, a_1 is not linearly separable in A .
3. We find a small subset of points P^* for which a_1 is not linearly separable in A .
4. We construct a separation preserving projection that maps all points in P^* to an affine transformation of A . As a result, a_1 is not strictly linearly separable after projection.

We assume that the points in P , along with the chosen separating hyperplanes, are in *general position*. Specifically, we assume that any set of d vectors, where each vector is either a distinct difference vector of two points in P or the normal vector of one of the separating hyperplanes, is linearly independent. Note that, since all properties are initially strictly linearly separable, it is always possible to perturb the separating hyperplanes to ensure general position, assuming that P is also in general position.

► **Theorem 6.** *If P is a point set in \mathbb{R}^d in general position with $k \leq d$ strictly linearly separable properties a_1, \dots, a_k using all 2^k labels, then there exists a separation preserving projection along a unit vector w that eliminates the strict linear separability of a_1 .*

Proof. We provide an explicit construction of the vector w . Let H_2, \dots, H_k be any separating hyperplanes (in general position with P) for each of the properties a_2, \dots, a_k in P , respectively. Let v_i be the normal of hyperplane H_i for $2 \leq i \leq k$, and let $A \subset \mathbb{R}^d$ be the $(k-1)$ -dimensional linear subspace spanned by v_2, \dots, v_k . Furthermore, let $H^* = \bigcap_{i=2}^k H_i$ be the $(d-k+1)$ -dimensional flat that is the intersection of the separating hyperplanes. Note that a projection along a vector w is separation preserving if and only if w is parallel to H^* . Let $T(p)$ be the result of an orthogonal projection of a point $p \in P$ onto A . For ease of argument, we also directly apply an affine transformation that maps H^* (which intersects A in one point by construction) to the origin, and maps v_2, \dots, v_k to the standard basis vectors of \mathbb{R}^{k-1} .

Now define $Q_- = \{T(p) \mid p \in P_-\}$ and $Q_+ = \{T(p) \mid p \in P_+\}$. By construction, since all labels are used by P , both Q_- and Q_+ must have a point in each orthant of \mathbb{R}^{k-1} . If a point set Q has a point in each orthant, then $CH(Q)$ must contain the origin; because if it does not, then there exists a vector v such that $(v \cdot q) > 0$ for all $q \in Q$. But there must exist a point $q^* \in Q$ whose sign for each coordinate is opposite from that of v (or zero), which means that $(v \cdot q^*) \leq 0$, a contradiction. Thus, both $CH(Q_-)$ and $CH(Q_+)$ contain the origin, and $CH(Q_-) \cap CH(Q_+) \neq \emptyset$. We now apply Theorem 5 to Q_- and Q_+ to obtain Q_-^* and Q_+^* consisting of $k+1$ points in total. Let $P^* \subseteq P$ be the corresponding set of original points that map to $Q_-^* \cup Q_+^*$. We can now construct w as follows. Pick a point $p^* \in P^*$, and let F_1 be the unique $(k-1)$ -dimensional flat that contains the remaining points in P^* . Let F_2 be the flat obtained by translating H^* to contain p^* . Since F_1 is $(k-1)$ -dimensional and F_2 is $(d-k+1)$ -dimensional, $F_1 \cap F_2$ consists of a single point $r \in \mathbb{R}^d$ (assuming general position). The desired projection vector is now simply $w = r - p^*$ (normalized if necessary).

We finally show that the constructed vector w has the correct properties. First of all, w is parallel to H^* by construction, and hence the projection along w is separation preserving. Second, since $r \in F_1$ and p^* is projected to coincide with r (as $w = r - p^*$), all points in P^* will lie on the same $(k-1)$ -dimensional flat F_1' after projection. Also, since w is orthogonal to A , there exists an affine map from $Q_-^* \cup Q_+^*$ to P^* (after projection). Thus, we obtain that $CH(P_-') \cap CH(P_+') \neq \emptyset$; in particular, the convex hulls must intersect on F_1' . By Fact 1 this implies that a_1 is not strictly linearly separable after projection. ◀

The result of Theorem 6 has one shortcoming: the resulting projected point set P' is degenerate by construction and property a_1 may still be (non-strictly) linearly separable after projection. This is simply an artifact of the proof and can be avoided by slightly perturbing the projection vector w . The following lemma can be used to remedy this shortcoming. Here we again assume that, before projection, the point set P and the separating hyperplanes are in general position, and hence the only degeneracy in P' is the one introduced by construction.

► **Lemma 7.** *Let P and Q be two point sets in \mathbb{R}^d in general position and let P' and Q' be the point sets obtained by projecting P and Q along a vector w , respectively. If $CH(P') \cap CH(Q') \neq \emptyset$, then we can perturb w to obtain projections P'' and Q'' such that P'' and Q'' are not linearly separable and $P'' \cup Q''$ is in general position.*

Proof. Let $P = \{p_1, \dots, p_n\}$ and $Q = \{q_1, \dots, q_m\}$, and similarly $P' = \{p'_1, \dots, p'_n\}$ and $Q' = \{q'_1, \dots, q'_m\}$. We may assume that $m+n \geq d+1$, for otherwise P and Q do not really span \mathbb{R}^d . Since $CH(P') \cap CH(Q') \neq \emptyset$, there exist coefficients $\lambda_i \geq 0$ ($1 \leq i \leq n$) and $\mu_j \geq 0$ ($1 \leq j \leq m$) such that $\sum_i \lambda_i = 1$, $\sum_j \mu_j = 1$, and $\sum_i \lambda_i p'_i = \sum_j \mu_j q'_j$. We can ignore some

points with a zero coefficient so that we have exactly $d + 1$ points left, and we assume in the remainder of this proof that $m + n = d + 1$. Now assume w.l.o.g. that $\lambda_1 > 0$. We use the remaining points $(P' \cup Q') \setminus \{p'_1\}$ to set up a barycentric coordinate system for the points in $P' \cup Q'$. This has the advantage that only the coordinates of p_1 are affected when changing the projection vector w . Next, we slightly perturb the coefficients to obtain $\lambda'_i > 0$ ($1 \leq i \leq n$), $\mu'_j > 0$ ($1 \leq j \leq m$) with $\lambda'_1 = \lambda_1$, $\sum_i \lambda'_i = 1$ and $\sum_j \mu'_j = 1$ (this is clearly possible). There then exist a vector v (in barycentric coordinates) and $\epsilon > 0$ (ϵ can be arbitrarily small by scaling the perturbation of the coefficients) such that $\epsilon v + \sum_i \lambda'_i p'_i = \sum_j \mu'_j q'_j$. Now consider the point p_1^\perp which has the same barycentric coordinates as p'_1 , but then with the barycentric coordinate system defined by $(P \cup Q) \setminus \{p_1\}$. Then, by Observation 2, we must have that $p_1 - p_1^\perp = \alpha w$ for some constant $\alpha \neq 0$. Now we perturb p_1^\perp to p^* such that p^* has the same barycentric coordinates as $p'_1 + (\epsilon/\lambda_1)v$, but then again with the barycentric coordinate system defined by $(P \cup Q) \setminus \{p_1\}$. Additionally, we perturb w to $w' = p_1 - p^*$. Let $P'' = \{p''_1, \dots, p''_n\}$ and $Q'' = \{q''_1, \dots, q''_m\}$ be the point sets obtained by projecting P and Q along w' . We then have by construction that $\sum_i \lambda'_i p''_i = \sum_j \mu'_j q''_j$. Now assume for the sake of contradiction that P'' and Q'' are linearly separable by a hyperplane H . Then H must contain $CH(P'') \cap CH(Q'')$ and, consequently, all points that have a nonzero coefficient for the convex combination of a point $x \in CH(P'') \cap CH(Q'')$ (since all points of either P'' or Q'' lie on the same side of H). By construction there are $d + 1$ of these points in $P'' \cup Q''$. Since H is $(d - 2)$ -dimensional and we performed only a single projection, this also implies that there were $d + 1$ points on a $(d - 1)$ -dimensional hyperplane in $P \cup Q$. This contradicts the assumption that $P \cup Q$ is in general position. Finally, since $CH(P'')$ and $CH(Q'')$ are not interior disjoint by Fact 1, this property cannot be broken by slightly perturbing the projection vector w' . Thus, we can also ensure that $P'' \cup Q''$ is in general position. ◀

Computation. The proof of Theorem 6 is constructive and implies an efficient algorithm to compute the desired projection. Most steps in the construction involve simple linear algebra operations, like projections and intersecting flats (Gaussian elimination), which can easily be computed in polynomial time. The only nontrivial computational step is the application of Theorem 5, for which the proof is also constructive. If a point $x \in CH(P) \cap CH(Q)$ is given along with the coefficients for the convex combination, then we can simply obtain P^* and Q^* by repeatedly solving a linear system of equations and eliminating a point. Note that the linear system needs to involve only $d + 3$ points (arbitrarily chosen), so the linear system of equations can be solved in $O(d^3)$ time, and we can eliminate a point and update the coefficients in the same amount of time. Thus, we can compute P^* and Q^* in $O(nd^3)$ time, where $n = |P| + |Q|$ (similar arguments were used in [20]). If we are not given a point in $x \in CH(P) \cap CH(Q)$ along with the coefficients for the convex combination, then this must be computed first. This can be computed efficiently using linear programming.

The proof of Theorem 6 suggests how to check, if P does not use all 2^k labels, if there exists a separability preserving projection that eliminates the linear separability of a_1 : If we can find a set of separating hyperplanes H_2, \dots, H_k such that $CH(P_-)$ and $CH(P_+)$ intersect *after* projecting them orthogonally onto the space spanned by the normals of H_2, \dots, H_k , then the remainder of the proof holds. However, finding such suitable separating hyperplanes might be computationally hard in general.

3 Generalized separability

In this section we consider a generalization of linear separability for classification. One approach to achieve more complicated classification boundaries is to use clustering: the label of a point is determined by the label of the “nearest” cluster. If we use more than one

■ **Figure 5** Left: two point sets P (red) and Q (blue) that are $(1, 2)$ -separable, but not linearly separable. Right: two point sets that are $(2, 2)$ -separable, but not $(1, x)$ -separable for any value of x .

cluster per class, then the resulting classification is more expressive than classification by linear separation. This approach is also strongly related to nearest-neighbor classification, another common machine learning technique: the points decompose the space into convex subsets, each of which is associated with exactly one point; given enough clusters, we can thus exactly capture this behavior. But even with few clusters (convex sets), it may be possible to reasonably approximate the decomposition by using a single cluster to capture the same of many points with the same label. Hence, Our generalized definition of separability is inspired by such clustering-based classifications, with convex sets modeling the clusters.

Let P and Q be two point sets in \mathbb{R}^d . We say that P and Q are (b, c) -separable if there exist b convex sets S_1, \dots, S_b and c convex sets T_1, \dots, T_c such that for every point $p \in P$ we have that $p \in S = \bigcup_i S_i$, for every point $q \in Q$ we have that $q \in T = \bigcup_j T_j$, and that $S \cap T = \emptyset$ (see Figure 5). We can assume that $b \leq c$. Furthermore, we generally assume w.l.o.g. that any convex set S_i is the convex hull of its contained points. It is easy to see that linear separability and $(1, 1)$ -separability are equivalent.

Given a point set P along with k properties a_1, \dots, a_k , the goal is now to compute a separation preserving projection to a point set P' such that a_1 is not (b, c) -separable in P' . We again assume that all k properties are strictly linearly separable in P . To achieve this goal, we may need to project along multiple vectors w_1, \dots, w_r . As mentioned in Section 1, we assume that $\{w_j\}_{j=1}^r$ form an orthonormal system and that we can compute the projected points as $p'_i = p_i - \sum_{j=1}^r (w_j \cdot p_i) w_j$.

To extend Theorem 6 to (b, c) -separability, recall the four main steps of the proof described before Theorem 6. Step 3 is the most important. If a_1 was not linearly separable in A , then not even multiple separation preserving projections can eliminate the linear separability of a_1 . In that sense, A is the “worst we can do” with separation preserving projections. Step 3 is actually exploiting a Helly-type property [24] for linear separability: If two sets of points P and Q are not linearly separable, then there exist small subsets $P^* \subseteq P$ and $Q^* \subseteq Q$ such that P^* and Q^* are not linearly separable (Theorem 5). Hence, if we use a different type of separability that also has a Helly-type property, then we may be able to use the same approach as for linear separability. Generally speaking, let $F(P, Q)$ be a predicate that determines if point sets $P, Q \subseteq \mathbb{R}^d$ are “separable” (for some arbitrary definition of separable)². If, in the case that $F(P, Q)$ does not hold, there exist small (bounded by a constant) subsets $P^* \subseteq P$ and $Q^* \subseteq Q$ such that $F(P^*, Q^*)$ also does not hold, then F has the *Helly-type property*. The worst-case size of $|P^*| + |Q^*|$ often depends on the number of dimensions d of P and Q , and is referred to as the *Helly number* $m_F(d)$ of F . For technical reasons, we will require the following three natural conditions on F :

² We assume that F is defined independently from the dimensionality of P and Q (like (b, c) -separability). We do require that P and Q are embedded in the same space.

56:10 Obstructing Classification via Projection

1. If $F(P, Q)$ does not hold, then $F(P', Q')$ does not hold, where P' and Q' are obtained by projecting P and Q along a single unit vector, respectively.
2. If $P' \subseteq P$ and $Q' \subseteq Q$, then $F(P, Q)$ implies $F(P', Q')$.
3. If \mathcal{A} is an affine map, then $F(P, Q)$ holds if and only if $F(\mathcal{A}(P), \mathcal{A}(Q))$ holds.

We call a separation predicate F *well-behaved* if it satisfies these conditions. It is easy to see that (b, c) -separability is well-behaved. For Condition 1, note that any collection of convex sets for P' and Q' can easily be extended along the projection vector for P and Q without introducing an overlap between S and T . Condition 2 also holds, since we can simply use the same covering sets. Finally, Condition 3 holds since affine transformations preserve convexity. We summarize this generalization in the following generic theorem.

► **Theorem 8.** *Let P be a point set in \mathbb{R}^d with k ($d \geq k$) properties a_1, \dots, a_k and let F be a well-behaved separation predicate in \mathbb{R}^d . Either we can use at most $\min(m_F(k-1)-k, d-k+1)$ separation preserving projections to eliminate $F(P_-, P_+)$, or this cannot be achieved with any number of separation preserving projections.*

Proof. Following the proof of Theorem 6, we first orthogonally project the points in P onto the $(k-1)$ -dimensional linear subspace A that is spanned by the normals v_2, \dots, v_k of the separating hyperplanes H_2, \dots, H_k of the properties a_2, \dots, a_k . Let $T(p)$ be the resulting projected point for a point $p \in P$. Now define $Q_- = \{T(p) \mid p \in P_-\}$ and $Q_+ = \{T(p) \mid p \in P_+\}$. If $F(Q_-, Q_+)$ holds, then no sequence of separation preserving projections can eliminate the separability (as defined by F) of a_1 , due to Condition 1 of a well-behaved separation predicate. Otherwise, we can find $Q_-^* \subseteq Q_-$ and $Q_+^* \subseteq Q_+$ such that $F(Q_-^*, Q_+^*)$ does not hold, and $|Q_-^*| + |Q_+^*| \leq m_F(k-1)$. Let $P^* \subseteq P$ be the set of original points that map to $Q_-^* \cup Q_+^*$. The points in P^* span a linear subspace B . Next, we construct an orthonormal basis $\{w_j\}_{j=1}^r$ for the set of vectors in B that are orthogonal to A (orthogonal to v_2, \dots, v_k). Since B has at most $m_F(k-1) - 1$ dimensions, and A has $k-1$ dimensions, we conclude that the orthonormal basis contains $r \leq m_F(k-1) - 1 - (k-1) = m_F(k-1) - k$ vectors. We then choose to project P along the vectors w_1, \dots, w_r . Since every w_j for $1 \leq j \leq r$ is orthogonal to A , these projections are all separation preserving. Furthermore, since we eliminate all vectors orthogonal to A from B , there exists an affine map from $Q_-^* \cup Q_+^*$ to P^* after projection. By using Condition 2 and Condition 3 of a well-behaved separation predicate, we can then conclude that $F(P'_-, P'_+)$ does not hold. Alternatively, we can simply project P to A , which requires $d - k + 1$ separation preserving projections. Hence, we need at most $\min(m_F(k-1) - k, d - k + 1)$ projections. ◀

We now focus on (b, c) -separability for different values of b and c . Unfortunately, not every form of (b, c) -separability has the Helly-type property.

► **Lemma 9.** *In $d \geq 2$ dimensions, $(1, 2)$ -separability does not have the Helly-type property.*

Proof. We prove the statement for $d = 2$, which automatically implies it for $d > 2$. Consider a set of n points $P = \{p_1, \dots, p_n\}$ equally spaced on the unit circle, where n is odd. For every point p_i we can define a wedge W_i formed between the rays from p_i to the two opposite points on the circle (which are well defined, since n is odd). By the Central Angle Theorem, the angle of this wedge is $\frac{\pi}{n}$. Furthermore, the distance of the rays to the origin is exactly $\sin(\frac{\pi}{n})$. Now, for some $\epsilon > 0$ and for each point p_i , we add a point q_i on the circle centered at the origin with radius $\sin(\frac{\pi}{n}) + \epsilon$, such that q_i lies outside of W_i to the left (counterclockwise). By construction there will also be a point q_j to the right of W_i , added by the point p_j that is the opposite point of p_i on the right (clockwise) side. We choose ϵ small enough such that any wedge W_i contains exactly $n - 2$ points from $Q = \{q_1, \dots, q_n\}$, having one point of Q outside of W_i on each side (see Figure 6).

■ **Figure 6** The construction for Lemma 9 with P in red and Q in blue.

Assume for the sake of contradiction that P and Q are $(1, 2)$ -separable. Since $Q \subset CH(P)$, we must cover Q with one set, and hence $S_1 = CH(Q)$. Now consider $P_1 = T_1 \cap P$ and $P_2 = T_2 \cap P$. Since the line segments between a point $p_i \in P_1$ and its opposite points p_j and p_{j+1} intersect $CH(Q)$, we get that p_j and p_{j+1} must both be in P_2 . We can repeat this argument for all points p_i to conclude that all pairs of consecutive points of P must be in the same set (P_1 or P_2). Since not all points in P can belong to the same set ($Q \subset CH(P)$), we obtain a contradiction. Thus, P and Q are not $(1, 2)$ -separable.

Now consider removing a single point p_i from P , and consider the line ℓ through the origin and p_i . The line ℓ splits $P \setminus \{p_i\}$ into two sets P_1 and P_2 . It is easy to see that, if we pick ϵ small enough, $CH(P_1)$ and $CH(P_2)$ do not intersect $CH(Q)$. Hence, $P \setminus \{p_i\}$ and Q are $(1, 2)$ -separable. If we remove a single point q_i from Q , then the line segment between p_i and one of its opposite points p_j does not intersect $CH(Q \setminus \{q_i\})$. We can again split P into P_1 and P_2 using the line ℓ through p_i and p_j (and shifted slightly towards the origin). Then it is again easy to see that, if we pick ϵ small enough, $CH(P_1)$ and $CH(P_2)$ do not intersect $CH(Q \setminus \{q_i\})$. Hence, P and $Q \setminus \{q_i\}$ are $(1, 2)$ -separable.

As a result, there exist no subsets of P and Q that are not $(1, 2)$ -separable. Thus, we get that the Helly number for $(1, 2)$ -separability is at least $|P| + |Q| = 2n$, and hence $(1, 2)$ -separability does not have the Helly-type property. ◀

Hence we cannot apply Theorem 8 to eliminate $(1, 2)$ -separability of a_1 in few separation preserving projections, if possible at all. However, this does not mean that it is not possible to provide this guarantee using different arguments. Nonetheless, we can use a similar construction as in the proof of Lemma 9 (using many more dimensions) to show that many separation preserving projections are needed to eliminate $(1, 2)$ -separability for a_1 (as many projections as needed to reach the 2-dimensional construction in the proof of Lemma 9).

Next, we consider $(1, \infty)$ -separability. This means that one of the point sets, say P , must be covered with one convex set, but we can use arbitrarily many convex sets to cover Q . Equivalently, P and Q are $(1, \infty)$ -separable if $CH(P) \cap Q = \emptyset$ or $P \cap CH(Q) = \emptyset$.

► **Lemma 10.** *In $d \geq 1$ dimensions, $(1, \infty)$ -separability has the Helly-type property with Helly number $2d + 2$.*

56:12 Obstructing Classification via Projection

■ **Figure 7** Lemma 10: constructing a small point set that is not $(1, \infty)$ -separable.

Proof. Let P and Q be point sets in \mathbb{R}^d such that P and Q are not $(1, \infty)$ -separable. Then there must be a point $p^* \in CH(Q)$ and a point $q^* \in CH(P)$. We can construct a star triangulation $\mathcal{T}(P)$ of $CH(P)$ with p^* as center (that is, all d -dimensional simplices have p^* as a vertex) and a star triangulation $\mathcal{T}(Q)$ of $CH(Q)$ with q^* as center (see Figure 7). We identify the unique simplex $\sigma_P \in \mathcal{T}(P)$ that contains q^* , and similarly the unique simplex $\sigma_Q \in \mathcal{T}(Q)$ that contains p^* . Now let $P^* \subseteq P$ be the vertices of σ_P and let $Q^* \subseteq Q$ be the vertices of σ_Q . Note that $p^* \in P^*$ and $q^* \in Q^*$. Then P^* and Q^* are not $(1, \infty)$ -separable, since $q^* \in CH(P^*) \cap Q^*$ and $p^* \in CH(Q^*) \cap P^*$. Finally, since a d -dimensional simplex contains $d + 1$ vertices, we obtain Helly number $2d + 2$. ◀

► **Corollary 11.** *Let P be a point set in \mathbb{R}^d with k ($d \geq k$) properties a_1, \dots, a_k . Either we can use at most $\min(k, d - k + 1)$ separation preserving projections to eliminate $(1, \infty)$ -separability of a_1 , or this cannot be achieved with any number of separation preserving projections.*

It may initially seem counter-intuitive that $(1, \infty)$ -separability has the Helly-type property (requiring only few projections to eliminate $(1, \infty)$ -separability), while the strictly stronger $(1, 2)$ -separability does not have the Helly-type property (and may require many projections to eliminate $(1, 2)$ -separability). Note however that Theorem 8 includes the clause that it simply may not be possible to eliminate separability of a_1 via any number of separation preserving projections. This case occurs more often with $(1, \infty)$ -separability than with $(1, 2)$ -separability, which explains why we can provide better guarantees on the number of projections for a strictly weaker separability condition.

We finally briefly consider $(2, \infty)$ -separability in \mathbb{R}^2 . Two point sets P and Q are not $(2, \infty)$ -separable in \mathbb{R}^2 if we need at least three convex sets disjoint from Q to cover P (and vice versa). This implies that $CH(P)$ must contain at least 3 points of Q ; if not, then we can draw a single line through all points in $Q \cap CH(P)$ to separate P into P_1 and P_2 , and $CH(P_1)$ and $CH(P_2)$ both cover P and are disjoint from Q . More generally, assume that we can cover P with two sets $CH(P_1)$ and $CH(P_2)$ that are disjoint from Q , and let ℓ be a line that separates $CH(P_1)$ and $CH(P_2)$ (Fact 1). Now consider the set of all triangles \mathcal{T}_P that are formed by three points of P such that a point of Q is contained in the triangle. We must have that ℓ transverses (intersects) all triangles in \mathcal{T}_P , otherwise the triangle is contained in P_1 or P_2 , and hence there is a point of Q in either $CH(P_1)$ or $CH(P_2)$. Furthermore, if there is point $q \in Q$ contained in, say, $CH(P_1)$, then there is also a triangle $\Delta \in \mathcal{T}_P$ in P_1 (Carathéodory's theorem), and hence ℓ does not intersect all triangles in \mathcal{T}_P . Thus, P and Q are $(2, \infty)$ -separable (assuming we cover P with 2 convex sets) if and only if there exists a line ℓ that transverses \mathcal{T}_P . As a result, if we can show a Helly-type property for line transversals of triangles, then we also obtain a Helly-type property for $(2, \infty)$ -separability. Unfortunately, there is no Helly-type property for line transversals of general sets of triangles [17]. We leave it as an open question to determine if there exists a Helly-type property for line transversals of these special sets of triangles \mathcal{T}_P .

4 Conclusion

We studied the use of projections for obstructing classification of high-dimensional Euclidean point data. Our results show that, if not all possible labels are present in the data, then it may not be possible to eliminate the linear separability of one property while preserving it for the other properties. This is not surprising if a property that we aim to keep is strongly correlated with the property we aim to hide. Nonetheless, one should be aware of this effect when employing projections in practice. When going beyond linear separability, we see that the number of projections required to hide a property increases significantly in theory, and we expect a similar effect when using, for example, neural networks for classification in practice. In other words, projecting a dataset once (or few times) may not be sufficient to hide a property from a smart classifier. Projection, as a linear transformation, can however be effective in eliminating certain linear relations in the data.

One potential direction of future work is to consider other separability predicates for labeled point sets, beyond linear separability and (b, c) -separability. Are there other types of separability that also have the Helly-type property used in Theorem 8? Or is there another way to show that few projections suffice to eliminate the separability of one of the properties? There are many other types of separability (for example, via boxes or spheres) for which this can be evaluated.

In this paper we focused on eliminating bias based on one property (such as gender). Intersectionality posits that discrimination due to multiple properties should be considered in a holistic manner, instead of one property at a time. In fact, any one property might not be a cause for discrimination, but their combination is. The following challenge arises: say we used projection successfully to eliminate the linear separability of gender. However, if we now restrict the data to one particular sub-class, for example black people, then the linear separability of gender might still be preserved within this subclass and hence discrimination against black women can still be possible. Under which conditions is it possible to eliminate the linear separability of one property not only in the full data, but also in specific (or all) subclasses? We leave this question as an open problem.

A Maximizing inseparability

In this section we consider the problem of not only eliminating the linear separability of a_1 , but additionally to maximize the “linear inseparability” (or overlap) of a_1 after projection. For that we need to define the overlap between two point sets P and Q . For a unit vector v , consider the intervals $I_P(v) = CH(\{v \cdot p_i \mid p_i \in P\})$ and $I_Q(v) = CH(\{v \cdot q_i \mid q_i \in Q\})$. We can then define the overlap between P and Q along v as the length of $I_P(v) \cap I_Q(v)$. Alternatively, we can define the overlap along v with the cost function used by soft-margin SVMs, which is designed for data that is not linearly separable (see [4] for more details). The overlap between two point sets P and Q is then defined as the minimum overlap over all (unit) vectors v . More precisely, for a given (projected) point set P , along with (implicit) property a_1 , we use the function $g(P, v)$ to describe the overlap of a_1 along the vector v , and we refer to g as the *overlap function*. The overlap of a_1 is then defined as $\min_v g(P, v)$. Our goal is to find the projection that maximizes this overlap after projection. More precisely, if we use $P' = \pi_w(P)$ to denote the projection of a point set P along the unit vector w , then the goal is to maximize the function $f(P, w) = \min_v g(\pi_w(P), v)$ over all separability/separation preserving projection vectors w . We consider the following two overlap functions $g(P, v)$ (although other options are possible):

Interval. For a point set P and unit vector v , let $I_- = CH(\{v \cdot p_i \mid p_i \in P_-\})$ and $I_+ = CH(\{v \cdot p_i \mid p_i \in P_+\})$. Then $g_{\text{int}}(P, v) = |I_- \cap I_+|$.

SVM. The goal of the soft-margin SVM optimization is to minimize $g_{\text{svm}}(P, v) = \lambda \|v\|^2 + \frac{1}{n} \sum_{i=1}^n \max(0, 1 - a_1(p_i)(v \cdot p_i - b))$. Note that g_{svm} also requires a parameter $b \in \mathbb{R}$, but we will often omit that dependence (we can assume that the overlap function minimizes over all $b \in \mathbb{R}$). Furthermore, $\lambda > 0$ is a parameter that can be set for g_{svm} . Finally, note that v does not need to be a unit vector.

We first consider the variant of the problem that aims to find the optimal separability preserving projection. The vector v that minimizes $g(P, v)$ for a given point set is typically computed using convex programming (in particular for SVMs, see [21]). Note that convex programming heavily relies on the fact that there exists only one local optimum (which hence must be the global optimum). We show that, for the problem of finding the optimal separability preserving projection, there may be multiple local optima for $f(P, w)$. This eliminates the hope of finding a convex programming formulation for this problem.

► **Theorem 12.** *There exists a point set P in \mathbb{R}^3 with 2 properties a_1, a_2 such that $f(P, w)$ with $g = g_{\text{svm}}$ has two local maxima when restricted to all separability preserving projection vectors w .*

■ **Figure 8** Illustration for Theorem 12: The domain for projections (x, y) with $\epsilon = 0.2$. Higher values in the overlap function are indicated with lighter colors. We can see two distinct local maxima.

Proof. The set P mostly consists of the vertices of a unit cube with side lengths 2 centered at the origin. We also add an extra point $p^* = (1 - \epsilon, 1 - \epsilon, 1)$ for some $\epsilon > 0$ (a point slightly moved inward from the point $p_8 = (1, 1, 1)$). Thus, P consists of nine points $\{p_1, \dots, p_8, p^*\}$. For property a_1 we choose that $a_1(p) = z(p)$ for all $p = (x(p), y(p), z(p)) \in P$. For property a_2 we have that $a_2(p) = a_1(p)$ for all $p \in P \setminus \{p_8\}$, and $a_2(p_8) = -1$. Now we limit and encode the space of possible projection vectors w to \mathbb{R}^2 as follows. For $w = (x(w), y(w), z(w))$ with $z(w) = 0$ it is clear that a projection along w will keep a_1 linearly separated, so we may encode all possible projections as $(x, y) = (x(w)/z(w), y(w)/z(w))$. Now consider the effect of using a projection (x, y) on P : we may assume that the x- and y-coordinates of points $p \in P$ with $z(p) = 1$ do not change and that for the other points we obtain a shifted square: $(x(p'), y(p')) = (x(p) + 2x, y(p) + 2y)$ for all $p \in P$ with $z(p) = -1$. Let $p_1 = (-1, -1, -1)$ such that $p'_1 = (-1 + 2x, -1 + 2y)$. Furthermore, let A consist of the projections of all points $p \in P$ with $a_1(p) = 1$, and let B consist of the projections of all points $p \in P$ with $a_2(p) = 1$. Note that A forms a square and B forms a square with one of the corners pushed inwards. By Fact 1, a projection (x, y) can only be separability preserving if $p'_1 \notin CH(B)$. By the same observation, a projection (x, y) with $x \geq 0$ and $y \geq 0$ preserves the linear separability of a_1 if $p'_1 \notin CH(A)$. Thus, we require that $p'_1 = (-1 + 2x, -1 + 2y) \in CH(A) \setminus CH(B)$. Note that $CH(A) \setminus CH(B)$ is a thin and nonconvex shape. The same thus holds for the domain of the projections (x, y) as shown in Figure 8, and hence the optimization problem is not convex. Furthermore, by evaluating the overlap function g_{svm} (using $\lambda = 10$) on this domain, we can see that there are two distinct local maxima: one close to $(0, 1)$ and one close to $(1, 0)$. ◀

Theorem 12 demonstrates that the constraint on projections to be separability preserving is generally not convex. We now consider the special case that we have only one property a_1 (hence no separability preserving constraint), and analyze if we can then efficiently maximize $f(P, w)$. For that, we first put a restriction on the overlap function $g(P, v)$. We say that $g(P, v)$ is *projectionable* if there exists a function $h: \mathbb{R}^n \times \mathbb{R}^d \rightarrow \mathbb{R}$ such that $g(P, v) = h(v \cdot P, v)$, where $v \cdot P = \{v \cdot p_i \mid p_i \in P\}$. In other words, g should only depend on P via the dot products of points in P with v . Note that both the Interval and SVM overlap functions are indeed projectionable. For projectionable overlap functions g we can redefine the optimization function f . In the following, let $v \perp w$ indicate that v and w are orthogonal.

■ **Figure 9** Illustration for Theorem 14 with $d = 2$: $H_+(t)$ can only intersect $R_{00} \cup R_{11}$ (orange, clipped to the unit disk) and $H_-(t)$ can only intersect $R_{01} \cup R_{10}$ (blue).

► **Lemma 13.** *If $g(P, v)$ is a projectionable overlap function, then $\max_w \min_v g(\pi_w(P), v) = \max_w \min_{v \perp w} g(P, v)$ for any point set $P \subset \mathbb{R}^d$.*

Proof. We will treat both w and v as a vector in \mathbb{R}^d . Since g is projectionable, there exists an equivalent function h that depends on v and the dot products between v and points in P . Now assume that $(v \cdot w) = 0$. Then we get

$$\begin{aligned} g(\pi_w(P), v) &= h(v \cdot \pi_w(P), v) \\ &= h(\{v \cdot (p_i - (w \cdot p_i)w) \mid p_i \in P\}, v) \\ &= h(\{v \cdot p_i \mid p_i \in P\}, v) \\ &= g(P, v). \end{aligned}$$

Since the vector v that minimizes $g(\pi_w(P), v)$ must be perpendicular to w , we obtain the desired equality. ◀

In the following we assume that the overlap function g is projectionable. Hence, by Lemma 13, we can rewrite f as $f(P, w) = \min_{v \perp w} g(P, v)$. This has the advantage that we can keep the point set P fixed while optimizing for w . We now aim to link properties of g to properties of f . As already discussed earlier, we can often find the vector v that minimizes $g(P, v)$ using convex programming. This implies that g has only one local minimum (for fixed P). We now use this fact to show that f has only one local maximum.

► **Theorem 14.** *If a function $g(P, v)$ has one local minimum for fixed P , then $f(P, w) = \min_{v \perp w} g(P, v)$ has one local maximum for fixed P .*

Proof. Note that $w \in \mathcal{S}^{d-1}$, where \mathcal{S}^{d-1} is the unit $(d - 1)$ -sphere, and $f(P, w) = f(P, -w)$, so we will treat w and $-w$ as equivalent. Similarly, if the local minimum of $g(P, v)$ is at $v = v^*$, then $v = -v^*$ may also be a local minimum, and together they will be counted as a single local minimum. For the sake of contradiction, assume that $f(P, w)$ has two distinct local maxima, one at $w = w_1^*$ and one at $w = w_2^*$ (and also at $w = -w_1^*$ and $w = -w_2^*$). We do not require that w_1^* and w_2^* are strict local maxima, but we do require that there exists no path $\gamma: [0, 1] \rightarrow \mathcal{S}^{d-1}$ with $\gamma(0) = w_1^*$ and $\gamma(1) = \pm w_2^*$ such that $f(P, \gamma(t)) \geq \min(f(P, \gamma(0)), f(P, \gamma(1)))$ for all $0 \leq t \leq 1$. Now consider the hyperplanes $H_1 = \{v \mid (v \cdot w_1^*) = 0\}$ and $H_2 = \{v \mid (v \cdot w_2^*) = 0\}$. Furthermore, let $\gamma_+: [0, 1] \rightarrow \mathcal{S}^{d-1}$ denote

the shortest (hyper)spherical interpolation from w_1^* to w_2^* , and let $\gamma_- : [0, 1] \rightarrow \mathcal{S}^{d-1}$ denote the shortest (hyper)spherical interpolation from w_1^* to $-w_2^*$. Note that γ_- and γ_+ are unique, since both w_1^* to w_2^* lie on a great circle on \mathcal{S}^{d-1} and $w_1^* \neq -w_2^*$. The hyperplanes H_1 and H_2 split \mathbb{R}^d into four parts (each hyperplane cuts \mathbb{R}^d into two parts): R_{00}, R_{01}, R_{10} , and R_{11} . Now let $x^* = \min(f(P, w_1^*), f(P, w_2^*))$ and consider the sublevel set $S = \{v \mid g(P, v) < x^*\}$. By definition of f , H_1 and H_2 are disjoint from S . Now consider a vector $\gamma_+(t)$ for some $0 < t < 1$, and let $H_+(t) = \{v \mid (v \cdot \gamma_+(t)) = 0\}$ be the corresponding hyperplane. Similarly define $H_-(t)$ for $\gamma_-(t)$. It is easy to see that $H_+(t)$ intersects either $R_{01} \cup R_{10}$ or $R_{00} \cup R_{11}$, but not both, and $H_-(t)$ intersects only the other region (see Figure 9). By assumption, there exist values t_-^* and t_+^* such that $f(P, \gamma_-(t_-^*)) < x^*$ and $f(P, \gamma_+(t_+^*)) < x^*$. Thus, by the definition of f , there must be two non-opposite regions, say R_{00} and R_{01} , that contain a point in S . These points cannot be in the same connected component, as they are separated by either H_1 or H_2 . Thus, S has multiple (non-opposite) connected components, and hence $g(P, v)$ must have at least two local minima. This contradicts our assumption, and hence $f(P, w)$ can have at most one local maximum. ◀

Following Theorem 14, we can use a hill-climbing approach to find the optimal projection vector w , if there is only one property a_1 . This same approach can be applied to find the optimal separation preserving projection for k properties. In that case, the corresponding separating hyperplanes H_2, \dots, H_k each take away a degree of freedom, but otherwise do not bound the domain of w . More precisely, if there is only one property a_1 , then $w \in \mathcal{S}^{d-1}$, where \mathcal{S}^d is the unit d -sphere. If there are k properties, then $w \in \mathcal{S}^{d-1} \cap H_2 \cap \dots \cap H_k = \mathcal{S}^{d-k}$. This reduction in dimensionality of the domain of w does not affect the proof of Theorem 14.

B Omitted proofs

► **Lemma 4.** *For all $k > 1$ and $d \geq k$, there exist point sets P in \mathbb{R}^d with properties a_1, \dots, a_k using $2^k - 1$ labels such that any separability preserving projection along a unit vector w also keeps a_1 strictly linearly separable after projection.*

Proof. We first construct the point set P for arbitrary k and $d = k$. Consider the vertices of a $(k - 1)$ -dimensional hypercube C_ϵ with side length $\epsilon > 0$ centered at the origin, for which all nonzero coordinates lie in the first $k - 1$ dimensions of \mathbb{R}^d . For each vertex p of C_ϵ , set

■ **Figure 10** Illustration for Lemma 4 with $d = k = 3$ and properties fill (a_1), color (a_2), and shape (a_3). Left: Q consisting of two copies of C_ϵ . Middle: a separability preserving projection must be nearly orthogonal to the (x, y) -plane. Right: the flat H separating property a_1 .

the properties of p based on its coordinates (p^1, \dots, p^d) : $a_1(p) = 1$, and $a_i(p) = \text{sgn}(p^{i-1})$ for $2 \leq i \leq k$, where $\text{sgn}(x)$ is the sign function. Next, create a copy of C_ϵ (along with the assigned properties) and place it around the coordinate $(0, \dots, 0, 1)$ (see Figure 10 left). Let the resulting point set be Q , and consider projecting Q along a unit vector w . Let $w = (w^1, \dots, w^d)$ and assume w.l.o.g. that $|w^1| \geq |w^i|$ for all $2 \leq i < k$. If $|w^1| > \epsilon$, then there always exists a line ℓ parallel to w that intersects both $CH(Q_-^2)$ and $CH(Q_+^2)$. By Lemma 3 this would imply that a_2 is not strictly linearly separable after projection along w , so we may assume that $|w^1| \leq \epsilon$ for any separability preserving projection (see Figure 10 middle).

Now consider a $(k-2)$ -dimensional flat H with the following properties: (1) it is not parallel to one of the first $k-1$ axes, (2) it lies in the first $k-1$ dimensions of \mathbb{R}^d (the other coordinates are zero), and (3) the distance from the origin to H is 1 (see Figure 10 right). Consider the orthants of the $(k-1)$ -dimensional subspace A spanned by the first $k-1$ axes. Based on the labels of the vertices of C_ϵ , each orthant is associated with a label for the properties a_2, \dots, a_k . Due to Property (1), H intersects all the first $k-1$ axes, either at the positive or the negative half-axis. Since there is exactly one orthant bounded by only the non-intersected half-axes, H intersects exactly $2^{k-1} - 1$ orthants. We now construct P by extending Q with an additional point in each of the intersected orthants, such that H separates this point from the origin. The label of each such point p has $a_1(p) = -1$ and is otherwise determined by the orthant. As a result, P uses $2^k - 1$ different labels.

Let v be the normal of H in the $(k-1)$ -dimensional subspace A . The margin for P_- and P_+ along v is at least $1 - k\epsilon$ (rough bound). For any separability preserving projection along unit vector w , we have that $|(w \cdot v)| \leq \epsilon$. Now consider any point $p \in P$ and its projection $p' = p - (w \cdot p)w$. We have that $(p' \cdot v) = (p \cdot v) - (w \cdot p)(w \cdot v) = (p \cdot v) \pm O(\epsilon)$, where we use the fact that $(w \cdot p) = O(1)$. Thus, the margin for property a_1 can be reduced by at most $O(\epsilon)$ by the projection, and hence the projection keeps a_1 strictly linearly separable if we choose ϵ small enough.

If $d > k$, then we can construct a simplex with side lengths 1 in the last $d - k + 1$ dimensions, and place a copy of C_ϵ around each of its vertices (for $d = k$ this simplex is simply an edge, as used above). With this construction we can still enforce w.l.o.g. that $|w^1| \leq \epsilon$ for any separability preserving projection along unit vector w , and the rest of the argument follows. \blacktriangleleft

Online Domination: The Value of Getting to Know All Your Neighbors

Abstract

We study the dominating set problem in an online setting. An algorithm is required to guarantee competitiveness against an adversary that reveals the input graph one node at a time. When a node is revealed, the algorithm learns about the entire neighborhood of the node (including those nodes that have not yet been revealed). Furthermore, the adversary is required to keep the revealed portion of the graph connected at all times. We present an algorithm that achieves 2-competitiveness on trees. We also present algorithms that achieve 2.5-competitiveness on cactus graphs, $(t - 1)$ -competitiveness on $K_{1,t}$ -free graphs, and $\Theta(\sqrt{\Delta})$ for maximum degree Δ graphs. We show that all of those competitive ratios are tight. Then, we study several more general classes of graphs, such as threshold, bipartite planar, and series-parallel graphs, and show that they do not admit competitive algorithms (i.e., when competitive ratio is independent of the input size). Previously, the dominating set problem was considered in a different input model (often together with the restriction of the input graph being always connected), where a vertex is revealed alongside its restricted neighborhood: those neighbors that are among already revealed vertices. Thus, conceptually, our results quantify the value of knowing the entire neighborhood at the time a vertex is revealed as compared to the restricted neighborhood. For instance, it was known in the restricted neighborhood model that 3-competitiveness is optimal for trees, whereas knowing the neighbors allows us to improve it to 2-competitiveness.

1 Introduction

Given an undirected simple graph $G = (V, E)$, a subset of vertices $D \subseteq V$ is called *dominating* if every vertex of V is either in D or is adjacent to some vertex in D . In the well-known \mathcal{NP} -hard dominating set problem, the goal is to find a dominating set of minimum cardinality. We study this problem in the online setting, where a graph is revealed one node at a time. When a node is revealed its entire neighborhood is revealed as well. An algorithm is required to make an irrevocable decision on whether to include the newly revealed vertex into the dominating set the algorithm is constructing or not. This decision must be made before the next vertex is revealed. Performance of an online algorithm is measured against an optimal

offline algorithm, i.e., an algorithm that knows the entire input in advance and has infinite computational resources. This measure is captured by the notion of competitive ratio and analysis, which is made precise below. For now, it suffices to note that competitive ratio is analogous to approximation ratio in the offline setting.

The dominating set problem has important practical and theoretical applications, such as establishing surveillance service ([1]), routing and transmission services in (wireless) networks ([5]), as well as broadcasting ([7, 8]). While the dominating set problem and its variants (connected dominating set, independent dominating set, weighted dominating set, etc.) have been extensively studied in the offline setting [1, 9, 11, 15, 16, 17], this problem has received little attention in the online algorithms community. The current paper attempts to fill in this gap, while making a quantitative comparison with another online model for dominating set.

Online dominating set problem has been studied in the vertex arrival model by Boyar et al. [3]. In that model, when a vertex is revealed only restricted neighborhood of that vertex is revealed as well, namely, those neighbors that appear among previously revealed vertices. Moreover, in the model considered by Boyar et al. decisions are only partially irrevocable, i.e., when a vertex arrives an algorithm may add this vertex together with *any of its neighbors from the restricted neighborhood* to the dominating set. Thus, the decision to include a vertex is irrevocable, while the decision not to include a vertex is only partially irrevocable – an algorithm has a chance to reconsider when any yet unrevealed neighbors arrive. The catch is that the algorithm does not know the input size and has to maintain a dominating set at all times. In the model considered in this paper, all decisions (to include or exclude a vertex from a dominating set) are irrevocable. Boyar et al. [3] considered the online dominating set problem in two settings, namely, with the restriction of an adversary being forced to maintain an always connected graph and without this restriction. For the fairness of comparison, when we talk about Boyar et al. results we refer to their results for the always-connected setting¹. To summarize, on one hand, our model is stronger for the adversary since it forces the algorithm to make an irrevocable decision at each step. On another hand, our model is weaker for the adversary than the model of Boyar et al. in the aspect of the adversary being forced to reveal all neighbors of a newly revealed vertex at once. Thus, our results when compared to those of the vertex arrival model can be viewed as quantifying the value of getting to know all neighbors of a vertex at the time of its revelation.

Perhaps somewhat surprisingly, we discover in several results that the benefit of knowing all neighbors outweighs the drawbacks of fully irrevocable decisions. Our results are summarized below, but in particular we show that in our model Δ -bounded degree graphs admit $O(\sqrt{\Delta})$ online algorithms, while Boyar et al. show that $\Omega(\Delta)$ is necessary in their model. Similarly, we analyze a 2-competitive algorithm for trees, while Kobayashi [13] shows a lower bound of 3 in the vertex arrival model. Our degree upper bound implies that $O(\sqrt{n})$ competitive ratio is tight for general graphs, whereas Boyar et al. showed the lower bound of $\Omega(n)$ in the vertex arrival model. This paints a picture that knowing all the neighbors improves not only precise constants, when graph classes allow for small competitive ratio algorithms, but also give asymptotic improvements for more “challenging” graph classes for algorithms.

Prior to summarizing our results, we give a brief overview of competitive analysis framework. For more details, an interested reader should consult excellent books [2, 14] and references therein. Let ALG be an algorithm for the online dominating set problem.

¹ In our model, two natural definitions of always-connected restriction are possible: (i) with respect to all vertices that the algorithm is aware of at any particular moment (this includes vertices that have arrived and their neighbors that have not yet arrived), and (ii) with respect to only those vertices that have arrived. Our work is in setting (ii). This distinction is absent in the vertex arrival model.

Let $ALG(G, \sigma)$ denote the set of vertices that are selected by ALG on the input graph G with its vertices revealed according to the order σ . We sometimes abuse the notation and omit G or σ (or both) when they are clear from the context. Abusing notation even more, we sometimes write $ALG(G, \sigma)$ to mean $|ALG(G, \sigma)|$. Similar conventions apply to an offline optimal solution denoted by OPT . We say that ALG has *strict competitive ratio* c if $ALG \leq c \cdot OPT$ on all inputs. We say that ALG has *asymptotic competitive ratio* c (or, alternatively, that ALG is c -competitive) if $\limsup_{OPT \rightarrow \infty} \frac{ALG}{OPT} \leq c$. The *competitive ratio* of ALG is the infimum over all c such that ALG is c -competitive. When we simply write “competitive ratio” we typically mean “asymptotic competitive ratio” unless stated otherwise.

We shall consider performance of algorithms with respect to restricted inputs, specified by various graph classes, such as trees, cactus graphs, series-parallel, etc. The above definitions of competitive ratios can be modified by restricting them to inputs coming from certain graph classes. We denote the competitive ratio of an algorithm ALG with respect to the restricted graph class $CLASS$ by $\rho(ALG, CLASS)$.

The following is a summary of our contributions with the section numbers where the results appear. Due to space considerations some of our results have been moved to appendix:

- tight competitive ratio 2 on trees (Section 3.1);
- tight competitive ratio $\frac{5}{2}$ on cactus graphs (Section 3.2);
- tight competitive ratio $\Theta(\sqrt{\Delta})$ on maximum degree Δ graphs (Section 3.3);
- tight competitive ratio $t - 1$ on $K_{1,t}$ -free graphs (Section 3.4);
- tight competitive ratio $\Theta(\sqrt{n})$ for threshold graphs (Section B.1), planar bipartite graphs (Section B.2), and series-parallel graphs (Section B.3).

We note that all our upper bounds are in terms of strict competitive ratios, and all our lower bounds, with the exception of $K_{1,t}$ -free graphs, are in terms of asymptotic competitive ratios.² Most of our upper bounds are established by charging arguments. Our charging schemes are natural and to analyze them we establish several combinatorial properties of relevant graph classes. We suspect that these (or similar) techniques can be used to extend the results to other graph classes, such as almost-tree(k). Our main contribution is conceptual: we begin a systematic study of a well known \mathcal{NP} -hard problem in an online setting that hasn’t been extensively considered before and which allows quantifying how much extra information about the neighborhood helps the competitive ratio.

2 Preliminaries

In this section we describe definitions and establish notations that will be used frequently in the rest of the paper. Let $G = (V, E)$ be a connected undirected graph on $n = |V| \geq 1$ vertices. The *closed neighborhood* of a subset of vertices $S \subseteq V$, denoted by $N[S]$, is defined as $S \cup \{v \in V \mid \exists u \in S, \{u, v\} \in E\}$.

The vertices V are revealed online in order (v_1, \dots, v_n) . Since we consider the online input model where vertices are revealed alongside their neighbors, we distinguish between two notions: those vertices that are revealed by a certain time and those that are visible. More precisely, we have the following:

² With the small caveat that the performance ratio for threshold graphs is measured as a function of input size for reasons provided later.

► **Definition 1.**

- v_i is revealed by time j if $i \leq j$.
- v_j is visible at time i if it is either revealed by time i or it is adjacent to some vertex revealed by time i .
- R_i denotes the set of all vertices revealed by time i .
- V_i denotes the vertices visible at time i (i.e. $V_i = N[R_i]$).

The adversary chooses the graph G as well as the revelation order of vertices; however, the adversary is restricted to those revelation orders that guarantee that the induced subgraph on R_i is connected for all i . Thus, we observe that the process of revelation of a graph by the adversary is a natural generalization of the breadth-first search (BFS) and depth-first search (DFS) explorations of the graph. Thus, we can define the *revelation tree* analogous to BFS and DFS trees. We need the following observation first:

► **Observation 2.** If $v_j \in V_i \setminus V_{i-1}$ with $j > i \geq 2$ then v_i is the unique neighbor of v_j at time i .

In the preceding observation, we say that v_j is a *child* of v_i and that v_i is the *parent* of v_j . The edge $\{v_i, v_j\}$ is called a *tree edge*. The subgraph induced on the tree edges is the *revelation tree*. Any edge $\{u, v\}$ where u is not the parent of v nor v the parent of u is called a *cross edge*.

After the vertex v_i is revealed together with its closed neighborhood $N[v_i]$, an online algorithm ALG must make a decision $d_i \in \{0, 1\}$, which indicates whether the algorithm takes this vertex to be in the dominating set or not. For a given online algorithm ALG we define the following:

► **Definition 3.**

- $S_i = \{v_k \mid d_k = 1, 1 \leq k \leq i\}$ is the set of revealed vertices selected by ALG after i decisions where $S_0 = \emptyset$.
- $D_i = N[S_i]$ is the set of visible vertices that are dominated after i decisions.
- $U_i = V_i \setminus D_{i-1}$ is the set of visible vertices undominated immediately before decision d_i where $U_0 = \emptyset$.

A series of figures are provided below which illustrate the preceding definitions. For these figures, and all others in this paper, the convention is that vertices that are shaded in gray are those selected by ALG , vertices with thicker boundaries belong to OPT , an edge that is dashed is a cross edge, and all the solid edges are tree edges.

■ **Figure 1** An example of vertices v_1, v_2, v_3, v_4 from some input graph being revealed in that order (from left to right). Empty vertices in this figure are visible but not yet revealed. The adversary must maintain the connectivity of revealed vertices (ignoring visible but not yet revealed vertices) at all times. The process continues until all vertices are revealed. An edge that is dashed is a cross edge and one that is solid is a tree edge.

Since an algorithm makes irrevocable decisions and must produce a feasible solution, there may be situations where an algorithm is forced to select a vertex v_j to be in the dominating set. This happens because v_j is the “last chance” to dominate some other vertex v_i . In this case, we say that v_j saves v_i or that v_j is the savior of v_i . Note that it is possible for a vertex v_j to save itself. The following definition makes the notion of “saving” precise.

► **Definition 4.** A vertex v_j saves a vertex v_i if $j = \max\{k \mid v_k \in N[v_i]\}$ and $N[v_i] \setminus \{v_j\}$ contains no vertices from S_{j-1} . Let $s(v_j)$ denote the set of vertices that v_j saves.

Observe that if a vertex is saved then it must be that every one of its neighbors (itself included) had a chance to dominate the said vertex.

► **Observation 5.** If v_i is saved then $v_i \in N[v_j] \cap U_j$ for any $v_j \in N[v_i]$.

All our upper bounds are established by either a GREEDY algorithm or a k -DOMINATE algorithm for some fixed integer value of parameter k :

- The algorithm GREEDY selects a newly revealed vertex if and only if the vertex is not currently dominated. Using the notation introduced above, GREEDY selects $v_i, i \geq 1$ if and only if $v_i \in U_i$.
- The algorithm k -DOMINATE (for some fixed integer parameter k) selects a newly revealed vertex if and only if either (1) the vertex has at least k undominated neighbors, or (2) the vertex saves at least one other vertex. Using the notation introduced before, v_i is selected if and only if either (1) $|N(v_i) \cap U_i| \geq k$, or (2) $|s(v_i)| \geq 1$.

Both GREEDY and k -DOMINATE give rise to rather efficient offline algorithms so that any of the positive results given in this paper may be realized as efficient offline approximation algorithms.

3 Competitive Graph Classes

3.1 Trees

In this section we establish the tight bound of 2 on the best competitive ratio when the input graph is restricted to be a tree. The upper bound is achieved by the 2-DOMINATE algorithm and is proved in Theorem 7 below. The lower bound on all online algorithms is established in Theorem 6. Within this section all of the formal statements implicitly assume that the input is a tree. We begin the section by proving the lower bound.

► **Theorem 6.** $\rho(\text{ALG}, \text{TREE}) \geq 2$ for any algorithm ALG .

Proof. Consider an arbitrary small $\epsilon > 0$. We will give an adversarial input that guarantees that $\text{ALG} \geq (2 - \epsilon)\text{OPT}$. Let $k = \lceil \frac{3}{\epsilon} \rceil \geq 4$. At the start, the adversary reveals v_1 with k children $\{c_1, \dots, c_k\}$. Then we start the process described in the next paragraph at c_1 . The process can terminate in two ways: (i) ALG stops selecting vertices to be in the dominating set, or (ii) ALG selects k vertices revealed after c_1 (inclusive). If the process terminates because of (i), then the adversary restarts the process at child c_2 of v_1 . The process again terminates either with (i) or (ii) with respect to c_2 . If it is due to (i), then the adversary restarts the process at c_3 , and so on. If the process terminates with (ii) with respect to c_i then we reveal c_j for $j > i$ as leaves of v_1 .

Next, we describe the process with respect to c_i . The adversary reveals c_i with 2 children and if ALG selects c_i then exactly one child of c_i is revealed with two additional children. If ALG selects the child then one of its children is revealed with two additional children, and so on. Let j_i be the number of these vertices that are selected by ALG . This process

terminates only if ALG stops selecting these vertices with two children ($j_i < k$) or when ALG selects k of them ($j_i = k$). At this point the subtree grown at c_i has some revealed vertices as well as visible, but not yet revealed vertices. To finish revealing the entire subtree, the adversary proceeds as follows.

If $j_i < k$ then the two children on the $(j_i + 1)$ 'st vertex are revealed to be leaves. Moreover, each of the j_i selected vertices have exactly one visible child that is not yet revealed. Reveal those j_i children, called *support vertices*, with an additional leaf child (i.e. the child is revealed to be a leaf after its parent is revealed). Including the 2 children of the $(j_i + 1)$ 'st vertex ALG must select at least $j_i + 2$ additional vertices to dominate these leaves for a total of $j_i + (j_i + 2) = 2(j_i + 1)$ selected vertices in this subtree. In this case, OPT can select the support vertices together with the $(j_i + 1)$ 'st vertex for a total $j_i + 1$ vertices to dominate the entire subtree.

If $j_i = k$ the procedure to finish revealing the entire subtree at c_i is similar: the k 'th vertex children are both revealed to be leaves and each of the other $k - 1$ selected vertices has the other child become a support vertex, i.e., revealed with an additional leaf child. The performance is similar here but ALG is not forced to select the two children of the k 'th vertex so ALG selects at least $k + (k - 1) = 2k - 1$. In this case, OPT needs only select the k 'th vertex together with the support vertices for a total of k vertices to dominate the subtree.

To finish the analysis, we consider the following two cases:

Case 1: for all i we have $j_i < k$. Then $ALG \geq 2(j_i + 1)$ on each subtree whereas $OPT \leq j_i + 1$ on each subtree. Summing over all subtrees and remarking that OPT might select v_1 we obtain that $ALG/OPT \geq (\sum 2(j_i + 1)) / (1 + \sum(j_i + 1)) \geq 2 - 2/k \geq 2 - \epsilon$.

Case 2: there exists ℓ such that $j_\ell = k$. Then OPT selects $j_i + 1$ vertices for $i < \ell$, k vertices for $i = \ell$, 0 vertices for $i > \ell$ per subtree, plus v_1 . Whereas ALG selects at least $2(j_i + 1)$ for $i < \ell$, $2k - 1$ for $i = \ell$, and 0 for $i > \ell$. By a similar calculation to **Case 1**, we obtain that $ALG/OPT \geq 2 - 3/k \geq 2 - \epsilon$. ◀

■ **Figure 2** An example of the process described in Theorem 6 where ALG selects $j_i = 3$ vertices on the subtree rooted at c_i . The top depicts the subtree immediately after revealing $c_{i,3}$ whereas the bottom shows the entirely revealed subtree.

Now that we have established an asymptotic lower bound of 2 for any algorithm we show that 2-DOMINATE is 2-competitive.

► **Theorem 7.** $\rho(2\text{-DOMINATE}, TREE) = 2$.

High level overview of the proof. Consider an arbitrary input $T = (V, E)$ on $n \geq 3$ vertices and let OPT denote a minimum dominating set of T which contains no vertices of degree 1 (i.e. any such vertex can be exchanged for its only neighbor). Recall that S is the set of vertices selected by 2-DOMINATE. Initially, we assign charge 1 to each vertex v in S and

charge 0 to each vertex v not in S . Thus, $|S| = \sum_{v \in S} ch_{init}(v)$ where $ch_{init}(v)$ denotes the initial charge of v . With a charging scheme described shortly, we spread the charge from the vertices in S to the vertices of V . Let $ch(v)$ denote the new charge associated with vertex v . We extend the functions ch_{init} and ch to subsets of vertices linearly, e.g., for $W \subseteq V$ we have $ch(W) = \sum_{v \in W} ch(v)$. We shall demonstrate that the procedure of spreading the charge satisfies two properties:

1. conservation property: $\sum_v ch_{init}(v) = \sum_v ch(v)$ meaning that the total charge is preserved; and
2. *OPT*-concentration property: for each $v \in OPT$ we have $ch(N[v]) \leq 2$.

With these two properties it follows that $2\text{-DOMINATE} \leq \sum_v ch_{init}(v) = \sum_v ch(v) \leq \sum_{v \in OPT} ch(N[v]) \leq 2OPT$, so 2-DOMINATE is strictly 2-competitive.

Before we proceed with this plan, we make a couple of useful observations:

► **Lemma 8.** *There are no cross edges incident on any vertex v_i . In particular, any vertex v_i has at most one neighbor before it is revealed.*

► **Corollary 9.** *If $\deg(v_i) \geq 3$ then $v_i \in S$.*

Now, we are ready to present formal details of the above plan. We spread the charges according to the following rule:

Consider any $v_i \in S$ with $X_i = N[v_i] \cap U_i$. Remarking that $X_i \neq \emptyset$ we then give each vertex in X_i an equal charge of $\frac{1}{|X_i|}$. That is, a vertex selected by 2-DOMINATE spreads its charge evenly to all the newly dominated vertices in its closed neighborhood. We say that each vertex in X_i is charged by v_i .

► **Observation 10.** *Every vertex is charged by exactly one vertex.*

The preceding observation immediately implies that any vertex has charge at most 1. This observation is tight in the sense that, on certain inputs, there are vertices with charge equal to 1. A vertex with charge 1 is a rather special case though. Suppose that a vertex v_i receives charge 1 from a vertex v_j where v_i and v_j are not necessarily distinct. Therefore we have that $|X_j| = |N[v_j] \cap U_j| = 1$ which implies that $|N(v_j) \cap U_j| \leq |N[v_j] \cap U_j| = 1 < 2$. Therefore when v_i receives charge it must be from a vertex $v_j \in S$ that was selected due to the “saviour” rule of 2-DOMINATE . Hence, v_j must have saved a vertex, and only one vertex since $|X_j| = 1$. Ultimately we conclude that if v_i has charge 1 then it must be saved by some vertex v_j where $X_j = \{v_i\}$ (this does not exclude the possibility that $v_i = v_j$). If v_i does not meet this condition then it must have charge at most $\frac{1}{2}$.

► **Lemma 11.** *If v_i and v_j both have charge equal to 1 then they share no common neighbors.*

Proof. Suppose for the sake of deriving a contradiction that $v_{i'}$ were a common neighbor of v_i and v_j . Since v_i is saved, by Observation 5 it must be that $v_i \in N(v_{i'}) \cap U_{i'}$. Similarly, we have that $v_j \in N(v_{i'}) \cap U_{i'}$. That is, $|N(v_{i'}) \cap U_{i'}| \geq 2$ and thus $v_{i'} \in S$. Moreover, $X_{i'} = N[v_{i'}] \cap U_{i'}$ contains v_i and v_j . In particular, we have that $|X_{i'}| \geq 2$ with $v_i, v_j \in X_{i'}$ and therefore v_i and v_j receive charge no larger than $\frac{1}{2}$, a contradiction. ◀

► **Lemma 12.** *If v_i and v_j both have charge equal to 1 then they are not adjacent.*

Proof. It is easy to see that v_1 cannot have charge 1 on any input with at least 2 vertices. Therefore we safely assume that $1 < i < j$ such that both v_i and v_j have a parent. We assume for the sake of deriving a contradiction that v_i and v_j are adjacent.

Now, since both v_i and v_j have charge 1 it follows that they are both saved vertices. First we show that both $v_i, v_j \notin S$. Notice that any saved vertex v_k has the property that $|N[v_k] \cap S| = 1$. Therefore, if we assume by way of contradiction that $v_i \in S$ we obtain that $N[v_i] \cap S = N[v_j] \cap S = \{v_i\}$ and therefore v_i saves itself and v_j . This yields that $X_i = N[v_i] \cap U_i$ contains v_i and v_j . In particular, we have that $|X_i| \geq 2$ with $v_i, v_j \in X_i$ and therefore v_i and v_j receive charge no larger than $\frac{1}{2}$, a contradiction. An identical argument will yield that $v_j \notin S$.

Therefore it must be that v_i is saved by some vertex $v_{i'}$ with $i' \notin \{i, j\}$. Moreover, we must have $i < j < i'$ since $i < j$ by assumption and $i' = \max\{k \mid v_k \in N[v_i]\}$. This implies that both $v_j, v_{i'}$ are children of v_i by Observation 8 yielding that $|N(v_i) \cap U_i| \geq 2$ but v_i cannot be in S . ◀

From the two preceding lemmas we have the immediate corollary.

► **Corollary 13.** *For any vertex v_i , at most one vertex in $N[v_i]$ has charge 1.*

Now, we finish the proof of 2-competitiveness of 2-DOMINATE on trees.

Proof of Theorem 7. The lower bound follows from Theorem 6. Let $v_i \in OPT$ be an arbitrary vertex in OPT . We consider two cases (1) $\deg(v_i) = 2$ or (2) $\deg(v_i) \geq 3$.

Case 1: Suppose that $\deg(v_i) = 2$ and hence $|N[v_i]| = 3$. By Corollary 13 it follows that at most one vertex in $N[v_i]$ has charge 1. If no vertices in $N[v_i]$ have charge 1 then $ch(x) \leq \frac{1}{2}$ for each $x \in N[v_i]$ and we obtain that $\sum_{x \in N[v_i]} ch(x) \leq 3(\frac{1}{2}) < 2$. If there is exactly one vertex $x' \in N[v_i]$ with charge 1 we therefore obtain that $\sum_{x \in N[v_i]} ch(x) =$

$$\sum_{x \in N[v_i] \setminus \{x'\}} ch(x) + ch(x') \leq \frac{2}{2} + 1 = 2.$$

Case 2: Suppose that $\deg(v_i) \geq 3$. By Corollary 9 it follows that $v_i \in S$ with at least 2 children. Let $C_i = V_i \setminus V_{i-1}$ denote the children of v_i and remark that $C_i \subseteq X_i$. That is, each child of v_i is charged by v_i and only v_i . Therefore the children of v_i can receive at most the full initial charge on v_i and thus attribute a charge of at most 1.

Now we claim that any vertex in $N[v_i] \setminus C_i$ has a charge of at most $\frac{1}{2}$. Indeed, suppose a vertex $v_{i'} \in N[v_i] \setminus C_i$ has charge 1 then it must be saved by v_i since $|N[v_{i'}] \cap S| = 1$ for any saved vertex $v_{i'}$. That is, there is exactly one vertex in its closed neighborhood that is selected and since v_i is selected it must be v_i . Thus, we must have that $v_{i'} \in X_i$ but since $C_i \subseteq X_i$ we know that $|X_i| \geq 2$ and thus $v_{i'}$ receives a charge of no more than $\frac{1}{2} < 1$, contradicting our assumption that $v_{i'}$ has charge 1.

Thus, by remarking that $|N[v_i] \setminus C_i| \leq 2$ we obtain that $\sum_{x \in N[v_i]} ch(x) = \sum_{v_j \in C_i} ch(v_j) + \sum_{v_{i'} \in N[v_i] \setminus C_i} ch(v_{i'}) \leq 1 + 2(\frac{1}{2}) = 2$ as desired. ◀

3.2 Cactus Graphs

A graph G is said to be a cactus graph if it is connected and every edge lies on at most one cycle. Hedetniemi, Laskar, and Pfaff [10] provide an exact offline algorithm that runs in linear time for finding a minimum dominating set of a cactus graph. Of course, an efficient offline algorithm does not guarantee that an online algorithm can perform well but fortunately, cactus graphs are a class of graphs for which an online algorithm can achieve

constant competitive ratio. In this section, we show that 2-DOMINATE is $\frac{5}{2}$ -competitive when inputs are restricted to cactus graphs, and that this is as well as any algorithm can perform. Within this section all of the formal statements implicitly assume that the input is a cactus graph.

■ **Figure 3** The cactus 2-gadget : The leftmost figure depicts the case where *ALG* does not select the root *r* and rightmost depicts the case where *ALG* selects *r*.

Before presenting a lower bound of $\frac{5}{2}$ on all online algorithms we describe a gadget that is used in the proof. The gadget itself is a cactus graph on $3 \leq n \leq 4$ vertices with the property that *OPT* selects exactly 1 vertex and any algorithm *ALG* selects at least 2 vertices. Consider revealing a root vertex *r* with 2 children *c* and *c'*. If *ALG* does not select *r* then both *c, c'* are revealed as only adjacent to *r* and *ALG* must select both whereas *OPT* selects only *r*. If *ALG* does select *r* then *c* is revealed as adjacent to *c'*, and *c'* is revealed with an additional child *x*. The vertex *x* is adjacent only to *c'* and thus *ALG* must select at least one of *c', x* whereas *OPT* selects only *c'* (both cases are depicted in Figure 3). Given any input cactus graph with a visible vertex *r* not yet revealed this gadget can be constructed with *r* as the root. Within the proof of the lower bound we call this a 2-gadget.

■ **Figure 4** The case described in Theorem 14 where *ALG* does not select $c_{1,1}$.

► **Theorem 14.** $\rho(\text{ALG}, \text{CACTUS}) \geq \frac{5}{2}$ for any algorithm *ALG*.

Proof. Consider an arbitrary small $\epsilon > 0$ and let $k = \lceil \frac{4}{\epsilon} \rceil \geq 5$. We will give an adversarial input that guarantees that $\text{OPT} \geq k$ and $\text{ALG} \geq (\frac{5}{2} - \epsilon)\text{OPT}$. To begin the input, the adversary reveals v_1 with k children $\{c_1, \dots, c_k\}$. Then we run an adversarial process starting with the child c_1 of v_1 . The process consists of rounds, where each round increases *OPT* by 2 while increasing *ALG* by 5. The process might terminate for one of two reasons: either (i) we guarantee strict competitive ratio at least $5/2$ on the subcactus rooted at c_1 , or (ii) k rounds starting at c_1 elapse. If the process terminates because of (i), then the adversary restarts the process at child c_2 of v_1 . The process again terminates either with (i) or (ii) with respect to c_2 . If it is due to (i), then the adversary restarts the process at c_3 , and so on. If the process terminates with (ii) with respect to c_i then we reveal c_j for $j > i$ as leaves. Below we describe the process starting at a child of v_1 although the first round of the process differs from the others that follow.

We now describe the first round starting at a child c of v_1 . Initially, we reveal c with 3 children. If ALG does not select c then each child of c is revealed as leaf and ALG must select all 3 children whereas OPT selects c . Suppose then that ALG selects c and let $c_{1,1}, c_{1,2}, c_{1,3}$ be the three children of c . Reveal $c_{1,1}$ as adjacent to $c_{1,2}$ along with 2 additional children. If ALG does not select $c_{1,1}$ then the children of $c_{1,1}$ are revealed as leaves, forcing ALG to select them and $c_{1,3}$ is revealed as the root of a 2-gadget ($c_{1,2}$ is revealed with no additional neighbors). Thus, $\frac{ALG}{OPT} \geq \frac{5}{2}$ in this case (see Figure 4). If instead ALG selects $c_{1,1}$ then $c_{1,2}$ and $c_{1,3}$ are revealed as the roots of two distinct 2-gadgets and since c is dominated by v_1 (we assume that $v_1 \in OPT$) we have that $\frac{ALG}{OPT} \geq \frac{5}{2}$ on this subcactus (excluding $c_{1,1}$) thus far (see Figure 5a). At this point, $c_{1,1}$ is selected by ALG and we start the second round (which is described below) with $c_{1,1}$ as the root. Every round that follows will be the same as the second and requires a root selected by ALG which has two children.

The second round starts at a selected root $c_{1,1}$ and we let $c_{2,1}, c_{2,2}$ be the 2 children of $c_{1,1}$. We reveal $c_{2,1}$ as adjacent to $c_{2,2}$ with 2 children $c_{3,1}, c_{3,2}$. If ALG does not select $c_{2,1}$ then $c_{3,1}, c_{3,2}$ are revealed as leaves and ALG selects $c_{1,1}, c_{3,1}, c_{3,2}$ and OPT can select $c_{2,1}$ for a performance of 3 along with the running performance of $\frac{5}{2}$ (see Figure 5b). If ALG does select $c_{2,1}$ then $c_{3,1}$ is revealed as adjacent to $c_{3,2}$ with two children $c_{4,1}, c_{4,2}$. If ALG does not select $c_{3,1}$ then $c_{4,1}, c_{4,2}$ are revealed as leaves and $c_{2,2}$ is revealed with an additional leaf neighbor $l_{2,2}$ so that ALG must select at least one of $c_{2,2}, l_{2,2}$. Thus, ALG here selects $c_{1,1}, c_{2,1}, c_{4,1}, c_{4,2}$ and at least one of $c_{2,2}, l_{2,2}$ whereas OPT can select $c_{3,1}$ and $c_{2,2}$ for a performance of $\frac{5}{2}$ (see Figure 6a). If instead ALG selects $c_{3,1}$ (thus far $c_{1,1}, c_{2,1}$ and $c_{3,1}$ are all selected) then $c_{2,2}$ is revealed with an additional leaf neighbor $l_{2,2}$ so that ALG must select at least one of $c_{2,2}, l_{2,2}$, and $c_{3,2}$ is revealed as the root of a 2-gadget so that $\frac{ALG}{OPT} \geq \frac{5}{2}$ on the subcactus thus far (excluding $c_{3,1}$) and we repeat the trap with $c_{3,1}$ as the selected root (see Figure 6b).

Let $j_i \geq 1$ denote the number of rounds that passed in the adversarial process starting at the child c_i . To finish the analysis, we consider the following two cases:

Case 1: For all i we have that $j_i < k$. Then $ALG \geq 5j_i$ on each subcactus whereas $OPT \leq 2j_i$ on each subcactus³. Summing over all subcacti and remarking that OPT selects v_1 we obtain that $ALG/OPT \geq (\sum 5j_i) / (1 + \sum 2j_i) \geq \frac{5}{2} - \frac{5}{2k} \geq \frac{5}{2} - \epsilon$.

Case 2: There exists ℓ such that $j_\ell = k$. In this case, there is an additional vertex $c_{j,1}$ with $j = 3(k-1)$ that was selected by ALG and must also be selected by OPT . (i.e. c_j is the root where a $(k+1)$ 'st round could start). Therefore, OPT selects $2j_i$ vertices for each process on child c_i with $i < \ell$, $2k+1$ vertices for $i = \ell$, 0 vertices for $i > \ell$ plus v_1 . Whereas ALG selects at least $5j_i$ for $i < \ell$, $5k+1$ for $i = \ell$, and 0 for $i > \ell$. Ultimately, we obtain that $ALG/OPT \geq (\sum 5j_i + 5k + 1) / (\sum 2j_i + 2k + 2) \geq \frac{5}{2} - 4/k \geq \frac{5}{2} - \epsilon$. ◀

► **Theorem 15.** $\rho(2\text{-DOMINATE}, \text{CACTUS}) = \frac{5}{2}$.

The proof can be viewed as an adaptation of our proof for trees to cactus graphs. We use a charging argument similar to the one given in the section on trees. Initially, a charge of 1 is given for each $v \in S$, the charge on each vertex is then spread to certain neighbors, and we then show that $\sum_{x \in N[v_i]} ch(x) \leq \frac{5}{2}$ for each $v_i \in OPT$. We spread the charge according

³ We have omitted the cases where ALG does not select the root c_i . These cases result in ALG selecting 3 vertices on the subcacti with OPT selecting only 1 and the result clearly still holds in this case.

(a) *ALG* does select $c_{1,1}$. The enclosed region contributes a performance of $\frac{5}{2}$. A trap is continued in this case with the root $c_{1,1}$.

(b) *ALG* does not select $c_{2,1}$.

■ **Figure 5** Two cases described in Theorem 14.

(a) *ALG* does not select $c_{3,1}$. The enclosed regions each contribute a performance of $\frac{5}{2}$.

(b) *ALG* does select $c_{3,1}$. The enclosed regions each contribute a performance of $\frac{5}{2}$. The trap that was used on a selected root $c_{1,1}$ is repeated with $c_{3,1}$ as the selected root.

■ **Figure 6** Two more cases described in Theorem 14.

to the same rule given in the preceding section and recall that Observation 10 (each vertex receives a new charge from one other vertex) still holds. In the analysis of how the charge gets reallocated, the structure of the underlying graph is of paramount importance. We begin with an analogue to Lemma 8.

► **Lemma 16.** *There is at most one cross edge incident on any v_i . In particular, v_i has at most 2 neighbors before it is revealed.*

Proof. Suppose that $v_i \neq v_1$ since the statement is clearly true for $v_i = v_1$. Suppose for the sake of deriving a contradiction that, at time $i - 1$, v_i has three neighbors v_h, v_{i_1}, v_{i_2} where v_h is the parent of v_i and $\{v_i, v_{i_1}\}, \{v_i, v_{i_2}\}$ are cross edges. Notice that v_{i_1} is visible at time $i - 1$ as otherwise would imply that $\{v_i, v_{i_1}\}$ were a tree edge. Thus, at time $i - 1$, v_{i_1} is visible and there is only one tree edge incident on v_i . In particular, this implies that there is a path consisting entirely of tree edges from v_{i_1} to v_h where said path does not contain the edge $\{v_h, v_i\}$ since it does not pass through v_i nor does it contain the edges $\{v_i, v_{i_1}\}, \{v_i, v_{i_2}\}$ since they are cross edges. Thus, by adding edges $\{v_h, v_i\}, \{v_i, v_{i_1}\}$ to this path we obtain a cycle (in the completely revealed input graph) that contains the edge $\{v_h, v_i\}$ but does not

contain the edge $\{v_i, v_{i_2}\}$. A similar argument yields that there is a path consisting of tree edges from v_{i_2} to v_h that does not contain the edges $\{v_h, v_i\}, \{v_i, v_{i_1}\}, \{v_i, v_{i_2}\}$ and hence by adding edges $\{v_h, v_i\}, \{v_i, v_{i_2}\}$ we obtain a cycle which contains the edge $\{v_h, v_i\}$ but does not contain the edge $\{v_i, v_{i_1}\}$. That is, two distinct cycles that share the common edge $\{v_h, v_i\}$, a contradiction. \blacktriangleleft

Since v_i has at most 2 neighbors before it is revealed then it has at least $\deg(v_i) - 2$ children. The following is analogous to Corollary 9 for trees.

► **Corollary 17.** *If $\deg(v_i) \geq 4$ then $v_i \in S$.*

► **Lemma 18.**

1. *If v_i and v_j both have charge equal to 1 then they share no common neighbors.*
2. *If v_i and v_j both have charge equal to 1 then they are not adjacent.*
3. *For any vertex v_i , at most one vertex in $N[v_i]$ has charge 1.*

Proof.

1. Follows identically to the proof of Lemma 11.
2. First, note that v_1 cannot have charge 1 on any input with at least 2 vertices. Therefore we safely assume that $1 < i < j$ such that both v_i and v_j have a parent. We assume for the sake of deriving a contradiction that v_i and v_j are adjacent.

Now, since both v_i and v_j have charge 1 it follows that they are both saved vertices. We first argue that both $v_i, v_j \notin S$. Notice that any saved vertex v_k has the property that $|N[v_k] \cap S| = 1$. Therefore, if we assume by way of contradiction that $v_i \in S$ we obtain that $N[v_i] \cap S = N[v_j] \cap S = \{v_i\}$ and therefore v_i saves itself and v_j . This yields that $X_i = N[v_i] \cap U_i$ contains v_i and v_j . In particular, we have that $|X_i| \geq 2$ with $v_i, v_j \in X_i$ and therefore v_i and v_j receive charge no larger than $\frac{1}{2}$, a contradiction. An identical argument will yield that $v_j \notin S$.

Thus, we assume that v_i is saved by a neighbor $v_{i'}$ and v_j is saved by a neighbor $v_{j'}$ where $i', j' \notin \{i, j\}$. Moreover, $i' \neq j'$ since v_i and v_j can share no common neighbors by part 1. Thus, we have that i, j, i', j' are all distinct with $i < j < i'$ and $i < j < j'$ since $i' = \max\{k \mid v_k \in N[v_i]\}$ and $j' = \max\{k \mid v_k \in N[v_j]\}$. As mentioned above v_i must have a parent v_h where $h < i < j < i'$. Therefore, $\deg(v_i) \geq 3$ and since $v_i \notin S$ it follows by Corollary 17 that $\deg(v_i) = 3$.

We are now in the situation where $v_i, v_j \notin S$ and v_i is incident on exactly 3 edges $\{v_h, v_i\}, \{v_i, v_j\}, \{v_i, v_{i'}\}$ where exactly one of the edges $\{v_i, v_j\}, \{v_i, v_{i'}\}$ is a tree edge (and the other a cross edge). We finish the proof by examining the two cases where **(1)** : $\{v_i, v_{i'}\}$ is a tree edge or **(2)** : $\{v_i, v_j\}$ is a tree edge.

Case 1: Suppose $\{v_i, v_{i'}\}$ is a tree edge so that $v_{i'}$ is a child of v_i . Therefore, $v_{i'} \in C_i \subseteq N(v_i) \cap U_i$, that is, $v_{i'}$ is an undominated neighbor of v_i when v_i is revealed. Since v_j is saved then by Observation 5 it follows that $v_j \in N(v_i) \cap U_i$, that is, v_j is also an undominated neighbor of v_i when v_i is revealed. That is, both $v_{i'}, v_j \in N(v_i) \cap U_i$ implying that $|N(v_i) \cap U_i| \geq 2$ but $v_i \notin S$, a contradiction.

Case 2: Suppose $\{v_i, v_j\}$ is a tree edge so that v_j is a child of v_i . First notice that $\{v_i, v_j\}$ is the only tree edge incident on v_j . Indeed, if there were a tree edge $\{v_j, v_l\}$ then v_l would be the child of v_j . Since v_i is saved we have $v_i \in N(v_j) \cap U_j$ by Observation 5 implying that $|N(v_j) \cap U_j| \geq 2$ but $v_j \notin S$. Thus, we are in the situation depicted in Figure 7a where $\{v_i, v_j\}$ is the only tree edge incident on v_j and by assumption $\{v_h, v_i\}, \{v_i, v_j\}$ are the only two tree edges incident on v_i . Therefore we have a path from $v_{i'}$ to v_h consisting of tree edges where said path does not contain the edges

(a) Case 2 of the second part of Lemma 18. (b) Resolution of the preceding case in Figure 7a. Two cycles sharing the common edge $\{v_h, v_i\}$.

■ **Figure 7** Figures used in the proof of Lemma 18.

$\{v_h, v_i\}, \{v_i, v_{i'}\}, \{v_i, v_j\}, \{v_j, v_{j'}\}$. Thus, by adding edges $\{v_h, v_i\}, \{v_i, v_{i'}\}$ to this path we obtain a cycle (in the completely revealed input) that contains the edge $\{v_h, v_i\}$ but does not contain the edge $\{v_j, v_{j'}\}$. Similarly, there is a path from $v_{j'}$ to v_h consisting of tree edges where said path does not contain the edges $\{v_h, v_i\}, \{v_i, v_{i'}\}, \{v_i, v_j\}, \{v_j, v_{j'}\}$ and by adding edges $\{v_h, v_i\}, \{v_i, v_j\}, \{v_j, v_{j'}\}$ we obtain a cycle (in the completely revealed input) that contains the edge $\{v_h, v_i\}$ but does not contain the edge $\{v_i, v_{i'}\}$. That is, two distinct cycles that share the common edge $\{v_h, v_i\}$, a contradiction.

3. Follows immediately from the previous parts. ◀

Now, we are ready to prove the upper bound for Theorem 15.

Proof of Theorem 15. The lower bound follows from Theorem 14. Let $v_i \in OPT$ be an arbitrary vertex in OPT . We consider two cases (1) $deg(v_i) \leq 3$ or (2) $deg(v_i) \geq 4$.

Case 1: Suppose that $deg(v_i) \leq 3$ and hence $|N[v_i]| \leq 4$. By Lemma 18 part 3 it follows that at most one vertex in $N[v_i]$ has charge 1. If no vertices in $N[v_i]$ have charge 1 then $ch(x) \leq \frac{1}{2}$ for each $x \in N[v_i]$ and we obtain that $\sum_{x \in N[v_i]} ch(x) \leq 4(\frac{1}{2}) = 2 < \frac{5}{2}$. If there is exactly one vertex $x' \in N[v_i]$ with charge 1 we therefore obtain that $\sum_{x \in N[v_i]} ch(x) =$

$$\sum_{x \in N[v_i] \setminus \{x'\}} ch(x) + ch(x') \leq \frac{3}{2} + 1 = \frac{5}{2}.$$

Case 2 : Suppose that $deg(v_i) \geq 4$. By Corollary 17 it follows that $v_i \in S$ with at least 2 children. Let $C_i = V_i \setminus V_{i-1}$ denote the children of v_i and remark that $C_i \subseteq X_i$. That is, each child of v_i is charged by v_i and only v_i . Therefore the children of v_i can receive at most the full initial charge on v_i and thus attribute a charge of at most 1.

Now we claim that any vertex in $N[v_i] \setminus C_i$ has a charge of at most $\frac{1}{2}$. Indeed, suppose a vertex $v_{i'} \in N[v_i] \setminus C_i$ has charge 1 then it must be saved by v_i since $|N[v_{i'}] \cap S| = 1$ for any saved vertex $v_{i'}$. That is, there is exactly one vertex in its closed neighborhood that is selected and since v_i is selected it must be v_i . Thus, we must have that $v_{i'} \in X_i$ but since $C_i \subseteq X_i$ we know that $|X_i| \geq 2$ and thus $v_{i'}$ receives a charge of no more than $\frac{1}{2} < 1$, contradicting our assumption that $v_{i'}$ has charge 1. Thus, by remarking that $|N[v_i] \setminus C_i| \leq 3$ we obtain that $\sum_{x \in N[v_i]} ch(x) = \sum_{v_j \in C_i} ch(v_j) + \sum_{v_{i'} \in N[v_i] \setminus C_i} ch(v_{i'}) \leq 1 + 3(\frac{1}{2}) = \frac{5}{2}$ as desired. ◀

3.3 Graphs of Bounded Degree

We study the problem when the inputs are restricted to graphs of bounded degree. That is, a positive integer $\Delta \geq 2$ is provided to the algorithm beforehand and the adversary is restricted to presenting graphs where every vertex has degree no larger than Δ . The problem of bounded degree graphs was explored in [3] although within the vertex arrival model described earlier. The authors show that a greedy strategy obtains a competitive ratio no larger than Δ and, when inputs are further restricted to be “always-connected” (i.e. each prefix of the input is connected) they provide a lower bound of $\Delta - 2$ for any algorithm.

By definition, any input belonging to our setting is “always-connected” yet the lower bound of $\Delta - 2$ does not apply. In particular, we show that $\lceil \sqrt{\Delta} \rceil$ -DOMINATE is $3\sqrt{\Delta}$ -competitive along with a lower bound of $\Omega(\sqrt{\Delta})$ for any online algorithm, essentially closing the problem in our setting. As previously mentioned, the authors in [12] consider a setting similar to ours where their adversary is not required to reveal visible vertices and they assume that an algorithm has additional knowledge of input size n . In this setting they provide an algorithm that achieves competitive ratio of $\Theta(\sqrt{n})$ for arbitrary graphs. For the upper bound below we follow a proof nearly identical to theirs modulo some minor details and definitions.

► **Definition 19.** A vertex $v_i \in S$ is said to be heavy if $|N(v_i) \cap U_i| \geq \lceil \sqrt{\Delta} \rceil$ and light otherwise. We let H and L denote the set of heavy and light vertices in S so that $|S| = |H| + |L|$.

To establish that $\lceil \sqrt{\Delta} \rceil$ -DOMINATE is $3\sqrt{\Delta}$ -competitive we use a charging argument, but it is quite different from the arguments in Sections 3.1 and 3.2. Initially, let $ch(v) = 1$ for each $v \in S$ so that $|S| = \sum_{v \in S} ch(v)$. Then spread the charge from S strictly to vertices in OPT so that $\sum_{v \in S} ch(v) = \sum_{v \in OPT} ch^*(v)$ where $ch^*(v)$ is the new charge on a vertex in OPT . We then show that $ch^*(v) \leq 2\sqrt{\Delta}$ for all $v \in OPT$ and thus $|S| = \sum_{v \in S} ch(v) =$

$\sum_{v \in OPT} ch^*(v) \leq |OPT|2\sqrt{\Delta}$ and the result then follows. We spread the charge from S to OPT according to the following rules:

1. If $v_i \in S \cap OPT$ then v_i keeps its full initial charge.
2. If $v_i \in H \setminus OPT$ then it spreads its initial charge evenly over all vertices in OPT . That is, each $v \in OPT$ obtains an additional charge of $\frac{1}{|OPT|}$ from v_i .
3. For each $v_i \in L \setminus OPT$, let $s(v_i)$ denote the set of vertices saved by v_i . Given a vertex $v_{i'} \in s(v_i)$ let opt be the mapping that maps $v_{i'}$ to itself if it is in OPT or to its earliest revealed neighbor in OPT otherwise. That is, $opt(v_{i'}) = v_{i'}$ if $v_{i'} \in OPT$ and $opt(v_{i'}) = v_k$ where $k = \min\{j \mid v_j \in N(v_{i'}) \cap OPT\}$ otherwise. For each $v_{i'} \in s(v_i)$, v_i spreads a charge of $\frac{1}{|s(v_i)|}$ to $opt(v_{i'})$.

► **Lemma 20.** If $v_i \in OPT$ then it receives charge from at most $\lceil \sqrt{\Delta} \rceil$ light vertices.

Proof. We consider two cases; (1) $v_i \in S$ or (2) $v_i \notin S$.

Case 1: Assume that $v_i \in S$, we show that v_i receives no charge from a distinct light vertex (therefore it receives charge from at most one light vertex, itself). Since $v_i \in S$ this implies that it is not saved by any $v_j, j \neq i$. Thus, if v_i were to receive charge from a light vertex it must be that $v_i = opt(v_{i'})$ for some $v_{i'}$ that is saved by some $v_k \in L$ different from v_i . More precisely, v_i must be adjacent to some $v_{i'}$ that is saved by some v_k with $k \neq i$. Yet, if $v_{i'} \in N(v_i)$ is saved then $N[v_{i'}] \cap S = \{v_i\}$ so this cannot be the case.

Case 2: Assume that $v_i \notin S$ and first remark that v_i is saved by at most one vertex so that it receives at most one charge from a light vertex in this way. If v_i receives charge from any other light vertex $v_k \in L$, it must be that v_i is adjacent to some vertex $v_{i'}$

that is saved by v_k . By Observation 5 it must be that $v_{i'} \in N(v_i) \cap U_i$, that is, is undominated when v_i is revealed. All this to say, that any light vertex that charges v_i determines at least one neighbor of v_i that is undominated at time i . Since $v_i \notin S$ we have $|N(v_i) \cap U_i| \leq \lceil \sqrt{\Delta} \rceil - 1$ and thus accounting for possibly one light vertex that charges v_i there are at most $\lceil \sqrt{\Delta} \rceil$ light vertices that charge v_i . ◀

► **Lemma 21.** $\frac{|H|}{|OPT|} \leq \sqrt{\Delta} + \frac{1}{\sqrt{\Delta}}$.

Proof. Since every vertex in H is selected because it dominated at least $\lceil \sqrt{\Delta} \rceil$ undominated vertices it follows that $|H| \leq \lfloor \frac{n}{\lceil \sqrt{\Delta} \rceil} \rfloor$. Moreover, by a standard result, first proved by Berge [1], a lower bound on OPT is $|OPT| \geq \lceil \frac{n}{\Delta+1} \rceil$. Ultimately this yields that $\frac{|H|}{|OPT|} \leq \frac{\lfloor \frac{n}{\lceil \sqrt{\Delta} \rceil} \rfloor}{\lceil \frac{n}{\Delta+1} \rceil} \leq \frac{\frac{n}{\lceil \sqrt{\Delta} \rceil}}{\frac{n}{\Delta+1}} \leq \frac{\Delta+1}{\sqrt{\Delta}} = \sqrt{\Delta} + \frac{1}{\sqrt{\Delta}}$. ◀

► **Theorem 22.** $\rho(\lceil \sqrt{\Delta} \rceil\text{-DOMINATE}, \Delta\text{-BOUNDED}) \leq 3\sqrt{\Delta}$.

Proof. Consider an arbitrary vertex $v_i \in OPT$. In light of Lemma 20 we see that it receives charge from at most $\lceil \sqrt{\Delta} \rceil$ light vertices, where each charge is no larger than 1. Moreover, by Lemma 21 the charge received by the heavy vertices is at most $\sqrt{\Delta} + \frac{1}{\sqrt{\Delta}}$ and v_i possibly receives charge from itself (it may be a heavy or light vertex). In particular we obtain that $ch(v_i) \leq \frac{|H|}{|OPT|} + \lceil \sqrt{\Delta} \rceil + 1 \leq (\sqrt{\Delta} + \frac{1}{\sqrt{\Delta}}) + \lceil \sqrt{\Delta} \rceil + 1 \leq 3\sqrt{\Delta}$. ◀

We now prove a lower bound $\Omega(\sqrt{\Delta})$ for any online algorithm. We should note that the adversarial input is bounded in size by a function of Δ . Although we have omitted the details, it is straightforward to extend the input so that the lower bound is in fact an asymptotic one.

► **Theorem 23.** $\rho(ALG, \Delta\text{-BOUNDED}) = \Omega(\sqrt{\Delta})$.

Proof. For simplicity we assume that Δ is a perfect square. Reveal v_1 with Δ children and reveal each child of v_1 with an additional $\sqrt{\Delta}$ children. Of the Δ children of v_1 , suppose that ALG selects exactly j where $0 \leq j \leq \Delta$. For the $\Delta - j$ vertices not selected, their $\sqrt{\Delta}$ neighbors are revealed to have degree 1 and ALG is forced to select each of these $(\Delta - j)(\sqrt{\Delta})$ vertices of degree 1.

Let S_j denote the set of the j selected vertices in $N(v_1)$ and $X = \bigcup_{v_i \in S_j} N(v_i)$. Since each vertex in S_j has $\sqrt{\Delta}$ children, it follows that $|X| = j\sqrt{\Delta}$. Partition the vertices of X into $\lceil \frac{j\sqrt{\Delta}}{\Delta} \rceil = \lceil \frac{j}{\sqrt{\Delta}} \rceil$ parts of size Δ (with at most one part having size $< \Delta$). Letting the parts be $X_1, X_2, \dots, X_{\lceil \frac{j}{\sqrt{\Delta}} \rceil}$ we reveal each vertex in a given part to a common vertex y_i (see figure 8 for an example). ALG must select at least one vertex for each part to dominate y_i and therefore at least an additional $\lceil \frac{j}{\sqrt{\Delta}} \rceil$ vertices are selected.

In total, ALG selects at least $j + (\Delta - j)(\sqrt{\Delta}) + \frac{j}{\sqrt{\Delta}}$ whereas OPT simply selects v_1 , the $\Delta - j$ vertices in $N(v_1) \setminus S_j$ and the $\frac{j}{\sqrt{\Delta}}$ vertices with labels y_i . Ultimately we have $\frac{ALG}{OPT} \geq \frac{j + (\Delta - j)(\sqrt{\Delta}) + \frac{j}{\sqrt{\Delta}}}{1 + (\Delta - j) + \frac{j}{\sqrt{\Delta}}} = \frac{j + j\sqrt{\Delta} + (\Delta - j)\Delta}{j + \sqrt{\Delta} + (\Delta - j)\sqrt{\Delta}} = \frac{\sqrt{\Delta}(j/\sqrt{\Delta} + j + (\Delta - j)\sqrt{\Delta})}{2(j/2 + \sqrt{\Delta}/2 + (\Delta - j)\sqrt{\Delta}/2)} \geq \frac{\sqrt{\Delta}}{2}$, where the last inequality follows from the fact that $j/2 + \sqrt{\Delta}/2 + (\Delta - j)\sqrt{\Delta}/2 \leq j/\sqrt{\Delta} + j + (\Delta - j)\sqrt{\Delta}$, since $\sqrt{\Delta}/2 \leq j/\sqrt{\Delta} + j/2 + (\Delta - j)\sqrt{\Delta}/2$, which can be seen since when $j < \Delta$ then the last term on the right hand side already is at least as large as the left hand side and when $j = \Delta$ then the middle term on the right hand side is at least the left hand side. ◀

■ **Figure 8** An instance described in the proof of Theorem 23 with $\Delta = 4$. The left depicts the graph after the children of v_1 have been revealed. Assuming that *ALG* selects $\{c_1, c_3, c_4\}$ above, the right depicts the completely revealed graph.

3.4 Graphs with Bounded Claws

In Appendix A we study $K_{1,t}$ -free graphs, which we also refer to as graphs with bounded “claws” (for $t = 3$, this graph class is known as “claw-free graphs”). We show that the competitive ratio $t - 1$ is both necessary and sufficient for this class of graphs. The upper bounds that we have demonstrated so far were all based on the k -DOMINATE algorithm for a suitable choice of parameter k . Interestingly, our upper bound on $K_{1,t}$ -free graphs is based on a conceptually simpler GREEDY algorithm. The analysis is no longer based on a charging scheme, but follows from combinatorial properties of graphs with bounded claws. For the details, one should consult the appendix.

4 Conclusions

In this paper we studied the minimum dominating set problem in an online setting where a vertex is revealed alongside all its neighbors. We also contrasted our results with those obtained by Boyar et al. [3] and Kobayashi [13] in a related vertex-arrival model. Dominating set is a difficult problem both offline and online. In our setting, the best achievable competitive ratio on general graphs is $O(\sqrt{n})$. This observation prompted us to study this problem with respect to more restrictive graph classes. Trees provide a natural graph class that usually allows for non-trivial competitive ratios. Indeed, we showed that in our model trees admit 2-competitive algorithms. There are several ways to try to extend this result to larger graph classes. We considered cactus graphs and showed that the optimal competitive ratio is 2.5 on them. Another way of generalizing trees is to consider graphs of higher treewidth. Unfortunately, once treewidth goes up to 2, competitive ratio jumps to $\Omega(\sqrt{n})$ (which is trivial in our setting due to $O(\sqrt{n})$ upper bound), as witnessed by series-parallel graphs. We also established non-trivial upper bounds on graphs of bounded degree, as well as graphs with bounded claws. When one moves to planar (even bipartite planar) graphs and threshold graphs, the competitive ratio jumps to $\Omega(\sqrt{n})$ again.

The above can be viewed as a larger program of developing a deeper understanding of the dominating set problem in an online setting. What are the main structural obstacles in graphs that prohibit online algorithms with small competitive ratios? Can one discover a family of graphs parameterized by some parameter t , which include cactus graphs, claw-free graphs, and bounded-degree graphs, such that the competitive ratio scales gracefully with t ? Lastly,

as another research direction, we mention that we have only considered the deterministic setting, so it would be of interest to extend our results to the randomized setting, as well as the setting of online algorithms with advice.

A Tight Bound for Graphs with Bounded Claws

Let $t \geq 3$, a graph G is said to be $K_{1,t}$ -free if it contains no induced subgraph isomorphic to $K_{1,t}$. When $t = 3$, this is the well-studied class of claw-free graphs. In this section we study $K_{1,t}$ -free graphs, which we also refer to as graphs with bounded “claws”.

From the preceding sections one might notice that the existence of an induced subgraph $K_{1,t}$ poses challenges for an algorithm. This section suggests that this intuition holds more than just a grain of truth. We show that, when inputs are restricted to $K_{1,t}$ -free graphs, the competitive ratio of every algorithm is bounded below by $t - 1$ and there is an algorithm that

achieves competitive ratio $t - 1$. The upper bounds that we have demonstrated so far were all based on the k -DOMINATE algorithm for a suitable choice of parameter k . Interestingly, our upper bound on $K_{1,t}$ -free graphs is based on a conceptually simpler GREEDY algorithm. The analysis is no longer based on a charging scheme, but follows from combinatorial properties of graphs with bounded claws.

► **Theorem 24.** $\rho(\text{ALG}, K_{1,t}\text{-FREE}) \geq t - 1$.

Proof. Reveal v_1 with $t - 1$ children. If ALG does not select v_1 then the input terminates as a star on t vertices (i.e. the $t - 1$ neighbors of v_1 are revealed with no additional neighbors). Any feasible algorithm must select the $t - 1$ neighbors of v_1 whereas OPT selects v_1 and the statement then follows. Suppose that ALG selects v_1 and let $c_i, 1 \leq i \leq t - 1$ be the children of v_1 . Reveal c_1 as adjacent to each child of v_1 and with an additional $t - 2$ children. If ALG does not select c_1 then the children of c_1 are revealed as leaves whereas the rest of the input is revealed to be a clique. That is, $N[v_1]$ is a clique and only c_1 has children. ALG selected v_1 and is forced to select the $t - 2$ children of c_1 whereas OPT selects only c_1 as a single dominating vertex. It is not hard to see that this input is $K_{1,t}$ -free and the result then follows (see Figure 9 for an example).

Suppose that ALG selects c_1 , the input then continues in the following way; For each $2 \leq j \leq t - 2$, (as long as ALG is accepting c_j) we reveal c_j as adjacent to every visible vertex and with an additional $t - 3$ children. That is, c_j is adjacent to each child $c_i, i \neq j$ of v_1 and the grandchildren of v_1 (i.e. the children of all the c_i with $1 \leq i \leq j$) so that c_j is a single dominating vertex of this prefix.

Case 1: If there is some $2 \leq j \leq t - 2$ such that ALG does not select c_j then the $t - 3$ children of

c_j are revealed as leaves, $N[v_i]$ is revealed as a clique, and the $(t - 2) + \sum_{i=2}^j (t - 3) = j(t - 3) + 1$ grandchildren of v_1 are revealed to form a clique. At this point, ALG has selected $\{v_1, c_1, \dots, c_{j-1}\}$ and is now forced to select the $t - 3$ children of c_j for an output of at least $j + (t - 3) \geq 2 + (t - 3) = t - 1$ whereas OPT selects only c_j so that $\frac{\text{ALG}}{\text{OPT}} \geq \frac{t-1}{1}$.

We now argue that this input is $K_{1,t}$ -free. Notice that for all v in this input we have $N(v) \subseteq N(c_j)$ so that if there is an induced $K_{1,t}$ with central vertex v then there is a claw with central vertex c_j . Therefore it is sufficient to show that is no claw with central vertex c_j to finish the claim. Suppose for contradiction's sake that there were an induced $K_{1,t}$ where c_j is the central vertex and the t neighbors of c_j are all pairwise non-adjacent. Let G denote the grandchildren of v_1 and remark that any neighbor of c_j is either a child of c_j , a grandchild of v_1 , or a vertex from $N[v_1] \setminus \{c_j\}$. Since there are t vertices and c_j only has $t - 3$ children by the pigeonhole principle we must have at least two vertices u, v that both are grandchildren of v_1 or both belong $N[v_1] \setminus \{c_j\}$. Yet, both the set of grandchildren of v_1 and $N[v_1] \setminus \{c_j\}$ are cliques. Therefore we have that u and v are adjacent, contradicting our assumption.

Case 2: If ALG selects each $c_i, 1 \leq i \leq t - 2$ then the $(t - 2)(t - 3) + 1$ grandchildren of v_1 are then revealed to form a clique ($N[v_1]$ has already been revealed as a clique). ALG has already selected $\{v_1, c_1, \dots, c_{t-2}\}$ and therefore has an output of at least $t - 1$ whereas OPT selects only c_{t-2} . An argument similar to the one above will yield that this input is $K_{1,t}$ -free and the result then follows. ◀

When inputs are restricted to $K_{1,t}$ -free graphs, we show that the online algorithm GREEDY is $(t - 1)$ -competitive. The crucial observation to make here is that the output of GREEDY is an independent set. We provide a result below that is a straightforward generalization of one given in [4]. The simplicity of the result suggests that it may have appeared in earlier work.

■ **Figure 9** An instance described in Theorem 24 with $t = 5$ where ALG does not select c_1 . The left depicts the graph at the moment c_1 was revealed and the right depicts the completely revealed graph.

■ **Figure 10** An instance described in Theorem 24 with $t = 5$ where ALG does not select c_2 . The left depicts the graph at the moment c_1 was revealed and the right depicts the completely revealed graph.

► **Lemma 25.** *Let $t \geq 3$, $G = (V, E)$ be a $K_{1,t}$ -free graph and I be any independent set in G . Then $|D| \geq \frac{|I|}{t-1}$ for any dominating set D in G .*

Proof. Suppose for the sake of deriving a contradiction that there is some dominating set D in G with $|D| < \frac{|I|}{t-1}$. Remarking that the vertices of D dominate the vertices of I as D is a dominating set we notice that there is some vertex $v \in D$ that dominates at least t vertices of I (i.e. if every vertex of D dominated at most $t - 1$ vertices then D would dominate at most $(t - 1)|D| < |I|$ vertices). Moreover, since v is adjacent to at least one of the $t \geq 3$ vertices of I it dominates, it cannot belong to I as I is independent. Therefore, the vertices of I dominated by $v \notin I$ are adjacent to v . In particular, at least t vertices of I , all pairwise non-adjacent, are neighbors of v and this induces $K_{1,t}$ in G . ◀

The preceding lemma shows that for any independent set I in a $K_{1,t}$ -free graph G , $|I| \leq (t - 1)\gamma(G)$. Given that GREEDY outputs an independent set we obtain the following result which is of interest to us.

► **Theorem 26.** $\rho(\text{GREEDY}, K_{1,t}\text{-FREE}) = t - 1$.

Proof. The upper bound is a consequence of Proposition 25 and the remarks that follow. The lower bound follows from Theorem 24. ◀

B Noncompetitive Graph Classes

Recall that the setting defined in [12] is nearly identical to ours except that an algorithm knows the input size n beforehand and the induced subgraph on the revealed vertices is not necessarily connected. Within this setting the authors establish a lower bound of $\Omega(\sqrt{n})$ for arbitrary graphs. Their proof can be augmented to show a lower bound of $\Omega(\sqrt{n})$ in our model, which is tight by our upper bound of $O(\sqrt{\Delta})$ on degree at most Δ graphs (applied

■ **Figure 11** An instance described in Theorem 24 with $t = 5$ where ALG does not select c_3 . The left depicts the graph at the moment c_3 was revealed and the right depicts the completely revealed graph.

to $\Delta = n - 1$). Instead, we strengthen such a result in several ways by showing that the lower bound of $\Omega(\sqrt{n})$ applies to several restricted classes such as threshold graphs⁴, planar bipartite graphs, and series-parallel graphs. Some of the proofs are omitted in this section due to space limitations. These proofs can be found in the full version of the paper [6].

B.1 Threshold Graphs

The graph join operation applied to two graphs G_1 and G_2 takes the disjoint union of the two graphs and adds all possible edges between the two graphs to the result (in addition to retaining the edges of G_1 and G_2). The class of threshold graphs can be described recursively as follows:

1. K_1 (i.e. a single isolated vertex) is a threshold graph.
2. If G is a threshold graph then the disjoint union $G \cup K_1$ is a threshold graph.
3. If G is a threshold graph then the graph join $G \oplus K_1$ is a threshold graph.

It is not hard to see that any connected threshold graph has a dominating set of size 1. Since our setting only allows for connected graphs we instead measure ALG as a function of input size n since $OPT \leq 1$ on every input. In particular, we show that for any algorithm there is an infinite family of threshold graphs for which this algorithm selects $\Omega(\sqrt{n})$ vertices (where the input has n vertices). Although OPT does not tend towards infinity, we consider this to be an asymptotic lower bound, but with input size n tending to infinity. In a sense, this is a stronger lower bound since the algorithm is guaranteed an input graph with a single dominating vertex, yet it still selects more than $\Omega(\sqrt{n})$ vertices in the input.

► **Theorem 27.** *For infinitely many values of n there is a threshold graph G_n such that $ALG(G_n) = \Omega(\sqrt{n})$.*

B.2 Planar Bipartite Graphs

Below is a lower bound of $\Omega(\sqrt{n})$ for planar bipartite graphs. We should mention that is strikingly similar to the lower bound on general graphs given in [12]. We provide a simple augmentation of their lower bound so that it not only consists of inputs that are revealed according to our model but inputs that are also planar bipartite graphs.

► **Theorem 28.** $\rho(ALG, PLANAR\ BIPARTITE) = \Omega(\sqrt{n})$.

⁴ With the caveat that, for threshold graphs, we instead consider the performance ratio as a function of input size.

B.3 Series-Parallel Graphs

In light of our 2-competitive algorithm for trees, it is natural to suppose that some class of graphs generalizing trees might admit competitive algorithms, that is, algorithms with bounded competitive ratio. One such generalization is graphs of bounded treewidth. Trees have treewidth 1, so the next step is to consider graphs of treewidth 2. Unfortunately, in this section we show that by increasing treewidth parameter from 1 to 2, the online dominating set problem becomes extremely hard for online algorithms. More specifically, we show that series-parallel graphs do not admit online algorithms with competitive ratio better than $\Omega(\sqrt{n})$. We remark that series-parallel graphs have treewidth at most 2.

We begin by recalling the definition of a series-parallel graph. It is defined with the help of the notion of a two-terminal graph (G, s, t) , which is a graph G with two distinguished vertices s , called a source, and t , called a sink. For a pair of two-terminal graphs (G_1, s_1, t_1) and (G_2, s_2, t_2) , there are two composition operations:

- *Parallel composition*: take a disjoint union of G_1 with G_2 and merge s_1 with s_2 to get the new source, as well as t_1 with t_2 to get the new sink.
- *Series composition*: take a disjoint union of G_1 with G_2 and merge t_1 with s_2 , which now becomes an inner vertex of the resulting two-terminal graph; s_1 becomes the new source and t_2 becomes the new sink.

A two-terminal series-parallel graph is a two-terminal graph that can be obtained by starting with several copies of the K_2 graph and applying a sequence of parallel and series compositions. Lastly, a graph is called series-parallel if it is a two-terminal series-parallel graph for some choice of source and sink vertices. Observe that intermediate graphs resulting in the construction of a series-parallel graph may have multiple parallel edges, so they are multigraphs. This is permitted, as long as the resulting overall graph is a simple undirected graph at the end.

Now, we are ready to prove the main result of this section.

► **Theorem 29.** $\rho(\text{ALG}, \text{SERIES-PARALLEL}) = \Omega(\sqrt{n})$.

Proof. Let $k \geq 2$ be an integer. The adversary reveals s with k neighbors c_1, \dots, c_k . Then c_1, \dots, c_k are revealed in this order with k new neighbors each. Let neighbors of c_i be d_{i1}, \dots, d_{ik} . Let $S \subseteq \{c_1, \dots, c_k\}$ be those vertices selected by *ALG*. For those $i \notin S$ we reveal their new neighbors in order d_{i1}, \dots, d_{ik} . Each such d_{ij} is revealed with a single new neighbor f_{ij} . For $i \in S$ we reveal their new neighbors in order d_{i1}, \dots, d_{ik} . Each such d_{ij} is revealed with a new neighbor t that is common to all these vertices. Then f_{ij} are revealed in arbitrary order with t as a new neighbor. Lastly t is revealed without any new neighbors.

Let $p = |S|$. Observe that in addition to these p vertices *ALG* must select at least one vertex from each of $\{d_{ij}, f_{ij}\}$ pairs for those $i \notin S$; otherwise, vertex d_{ij} would be undominated. Thus, $\text{ALG} \geq p + k(k - p)$. Also, observe that $\{s, t\} \cup \{c_i \mid i \notin S\}$ is a dominating set, so $\text{OPT} \leq k - p + 2$. The bound on the competitive ratio is $\frac{\text{ALG}}{\text{OPT}} \geq \frac{p + k(k - p)}{k - p + 2} = k - \frac{2k - p}{k - p + 2} \geq \frac{k}{2}$, where the last inequality is obtained as follows. For $k \geq 2$ we have $k^2 - kp \geq 2k - 2p$, which implies $k^2 - kp + 2k \geq 4k - 2p$. This in turn implies that $k(k - p + 2) \geq 2(2k - p)$, hence $(2k - p)/(k - p + 2) \leq k/2$. The quantitative part of the statement of this theorem follows from the fact that the total number of vertices is at most $2 + k + k^2 + k(k - p) = \Theta(k^2)$.

Lastly, we note that the adversarial graph thus constructed is, indeed, series-parallel. For each $i \notin S$ and $j \in \{1, \dots, k\}$ the path $c_i \rightarrow d_{ij} \rightarrow f_{ij} \rightarrow t$ is a series-composition of 3 copies of K_2 . These paths can be merged by a parallel composition to obtain the subgraph induced on $\{c_i, t\} \cup \{d_{ij}, f_{ij} \mid j \in \{1, \dots, k\}\}$ for each $i \notin S$. Each of these subgraphs is composed at c_i with another copy of K_2 with the new vertex playing the role of s . Similar argument holds to show that the subgraph induced on $\{s, c_i, t\} \cup \{d_{ij} \mid j \in \{1, \dots, k\}\}$ for $i \in S$ is a two-terminal series-parallel graph. Lastly, all these subgraphs are merged by a sequence of parallel compositions at s and t . ◀

A Linear-Time Nominal μ -Calculus with Name Allocation

Daniel Hausmann

Lutz Schröder  

Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

Abstract

Logics and automata models for languages over infinite alphabets, such as Freeze LTL and register automata, serve the verification of processes or documents with data. They relate tightly to formalisms over nominal sets, such as nondeterministic orbit-finite automata (NOFAs), where names play the role of data. Reasoning problems in such formalisms tend to be computationally hard. *Name-binding* nominal automata models such as *regular nondeterministic nominal automata (RNNAs)* have been shown to be computationally more tractable. In the present paper, we introduce a linear-time fixpoint logic $\text{Bar-}\mu\text{TL}$ for finite words over an infinite alphabet, which features full negation and freeze quantification via name binding. We show by a nontrivial reduction to *extended regular nondeterministic nominal automata* that even though $\text{Bar-}\mu\text{TL}$ allows unrestricted nondeterminism and unboundedly many registers, model checking $\text{Bar-}\mu\text{TL}$ over RNNAs and satisfiability checking both have elementary complexity. For example, model checking is in 2EXPSPACE , more precisely in parametrized EXPSPACE , effectively with the number of registers as the parameter.

1 Introduction

There has been longstanding interest in logics and automata models over infinite alphabets, such as the classical register automaton model [24] and Freeze LTL (e.g. [11,31]), or automata models over nominal sets [36] such as nondeterministic orbit-finite automata [2], in which *names* play the role of letters. Infinite alphabets may be seen as representing data. For example, nonces in cryptographic protocols [30], data values in XML documents [35], object identities [18], or parameters of method calls [23] can all be usefully understood as letters in infinite alphabets. A central challenge in dealing with infinite alphabets is that key decision problems in many logics and automata models are either undecidable or of prohibitively high complexity unless drastic restrictions are imposed (see the related work section). In a nutshell, the contribution of the present work is the identification of a linear-time fixpoint logic $\text{Bar-}\mu\text{TL}$ for *finite* words over infinite alphabets that

- allows both safety and liveness constraints (via fixpoints, thus in particular going beyond the expressiveness of LTL [17]) as well as full nondeterminism, and e.g. expresses the language “some letter occurs twice” (which cannot be accepted by deterministic or unambiguous register automata [2, 37]);
- imposes no restriction on the number of registers; and
- is closed under complement;

and nevertheless allows model checking and satisfiability checking in elementary complexity: Bar- μ TL model checking over regular nondeterministic nominal automata [38] (in the sense of checking that all words accepted by a given automaton satisfy a given formula) is in 2EXPSpace and more precisely in parametrized EXPSpace, with the maximal size of the support of states as the parameter (in the translation of nominal automata to register automata [2, 38], this corresponds to the number of registers); and satisfiability checking is in EXPSpace (and in parametrized PSPACE).

The tradeoff that buys this comparatively low complexity is a mild recalibration of the notion of freshness, which we base on explicit binding of names in strings in a nominal language model; depending on the exact discipline of α -renaming of bound names, one obtains either global freshness (w.r.t. all previous letters, as in session automata [3]) or local freshness (w.r.t. currently stored letters, as in register automata). This principle has been previously employed in the semantics of nominal Kleene algebra [16, 28] and in regular non-deterministic nominal automata (RNNAs) [38]. It carries the limitation that in the local freshness variant, letters can be required to be distinct only from such previous letters that are expected to be seen again – a restriction that seems reasonable in applications; that is, in many situations, one presumably would not need to insist on an object identifier, nonce, or process name b to be distinct from a previous name a if a is never going to be used again.

We introduce a dedicated finite-word automaton model, *extended regular nondeterministic nominal automata (ERNNAs)*, which extend RNNAs by \top -states, i.e. deadlocked universal states. We then base our results on mutual translations between Bar- μ TL and ERNNAs; the tableau-style logic-to-automata translation turns out to be quite nontrivial as it needs to avoid the accumulation of renamed copies of subformulae in automata states. Since RNNAs are, under global freshness, essentially equivalent to session automata [3], one consequence of our results is that session automata (which as such are only closed under *resource-bounded* complementation [3]) can be made closed under complement simply by allowing \top -states.

Proofs are mostly omitted or only sketched; full proofs are in the extended version [22].

Related work. *Automata:* Over infinite alphabets, the expressive power of automata models generally increases with the power of control (deterministic/nondeterministic/alternating) [25]. In deterministic models, language inclusion can often be decided in reasonable complexity; this remains true for unambiguous register automata [5, 34]. For nondeterministic register automata and the equivalent nondeterministic orbit-finite automata [2], emptiness is decidable but inclusion is undecidable unless one restricts to at most two registers [24]. Similarly, language inclusion (equivalently nonemptiness) of alternating register automata is undecidable unless one restricts to at most one register, and even then is not primitive recursive [11]. Automata models for infinite words outside the register paradigm include data walking automata [33], whose inclusion problem is decidable even under nondeterminism but at least as hard as reachability in Petri nets (equivalently vector addition systems) [7], as well as the highly expressive data automata [1], whose nonemptiness problem is decidable but, again, at least as hard as Petri net reachability. Note that by recent results [9], Petri net reachability is not elementary, and in fact Ackermann-complete [10, 32].

Logics: Bar- μ TL is incomparable to Freeze LTL. Satisfiability checking of Freeze LTL is by reduction to alternating register automata, and has the same high complexity even for the one-register case [11]. Satisfiability in the *safety* fragment of Freeze LTL over infinite words [31] is EXPSPACE-complete if the number of registers is restricted to at most one, while the refinement and model checking problems are decidable but not primitive recursive (all three problems become undecidable in presence of more than one register). The μ -calculus *with atoms* [26] is interpreted over Kripke models with atoms; its satisfiability problem is undecidable while its model checking problem is decidable, with the complexity analysis currently remaining open. It is related to the very expressive *first-order μ -calculus* [19, 20], for which model checking is only known to be semidecidable. The μ -calculus *over data words* [6, 8] works in the data walking paradigm. The satisfiability problem of the full calculus is undecidable; that of its ν -fragment, which translates into data automata, is decidable but elementarily equivalent to Petri net reachability. *Variable LTL* [21] extends LTL with a form of first-order quantification over data domains. The full language is very expressive and in particular contains full Freeze LTL [39]. Some fragments have decidable satisfiability or model checking problems (typically not both) [21, 39], occasionally in elementary complexity; these impose prenex normal form (reducing expressiveness) and restrict to quantifier prefixes that fail to be stable under negation. Decidable fragments will, of course, no longer contain full Freeze LTL; how their expressiveness compares to Bar- μ TL needs to be left open at present. *Flat Freeze LTL* [12] interdicts usage of the freeze quantifier in safety positions (e.g. the freeze quantifier can occur under F but not under G); its existential model checking problem over (infinite runs of) one-counter automata is NEXPTIME-complete, while the universal model checking problem is undecidable [4].

2 Preliminaries: Nominal Sets

Nominal sets offer a convenient formalism for dealing with names and freshness; for our present purposes, names play the role of data. We briefly recall basic notions and facts (see [36] for more details).

Fix a countably infinite set \mathbb{A} of *names*, and let G denote the group of finite permutations on \mathbb{A} , which is generated by the *transpositions* (ab) for $a \neq b \in \mathbb{A}$ (recall that (ab) just swaps a and b); we write 1 for the neutral element of G . A (left) *action* of G on a set X is a map $(-) \cdot (-): G \times X \rightarrow X$ such that $1 \cdot x = x$ and $\pi \cdot (\pi' \cdot x) = (\pi\pi') \cdot x$ for all $x \in X$, $\pi, \pi' \in G$. For instance, G acts on \mathbb{A} by $\pi \cdot a = \pi(a)$. A set $S \subseteq \mathbb{A}$ is a *support* of $x \in X$ if $\pi(x) = x$ for all $\pi \in G$ such that $\pi(a) = a$ for all $a \in S$. We say that x is *finitely supported* if x has some finite support, and *equivariant* if the empty set is a support of x , i.e. $\pi \cdot x = x$ for all $\pi \in G$. The *orbit* of $x \in X$ is the set $\{\pi \cdot x \mid \pi \in G\}$. The set of all orbits forms a partition of X , and X is *orbit-finite* if there are finitely many orbits.

A *nominal set* is a set X equipped with an action of G such that every element of X is finitely supported; e.g. \mathbb{A} itself is a nominal set. An early motivating example of a nominal set is the set of λ -terms with variable names taken from \mathbb{A} , and with the action of $\pi \in G$ given by replacing every variable name a with $\pi(a)$ as expected, e.g. $(ab) \cdot \lambda a.ba = \lambda b.ab$. Every element x of a nominal set has a least finite support, denoted $\text{supp}(x)$, which one may roughly think of as the set of names occurring (“freely”, see below) in x . A name $a \in \mathbb{A}$ is *fresh* for x if $a \notin \text{supp}(x)$. On subsets $A \subseteq X$ of a nominal set X , G acts by $\pi \cdot A = \{\pi \cdot x \mid x \in A\}$. Thus, $A \subseteq X$ is equivariant iff $\pi \cdot A \subseteq A$ for all $\pi \in G$. Similarly, A has support S iff $\pi \cdot A \subseteq A$ whenever $\pi(a) = a$ for all $a \in S$. We say that A is *uniformly finitely supported* if $\bigcup_{x \in A} \text{supp}(x)$ is finite [40], in which case A is also finitely supported [14, Thm. 2.29].

(The converse does not hold, e.g. the set \mathbb{A} is finitely supported but not uniformly finitely supported.) Uniformly finitely supported subsets of orbit-finite sets are always finite but in general, uniformly finitely supported sets can be infinite; e.g. for finite $B \subseteq \mathbb{A}$, the set $B^* \subseteq \mathbb{A}^*$ is uniformly finitely supported.

The Cartesian product $X \times Y$ of nominal sets X, Y is a nominal set under the componentwise group action; then, $\text{supp}(x, y) = \text{supp}(x) \cup \text{supp}(y)$. Given a nominal set X equipped with an equivalence relation \sim that is equivariant as a subset of $X \times X$, the quotient X/\sim is a nominal set under the group action $\pi \cdot [x]_{\sim} = [\pi \cdot x]_{\sim}$. A key role in the technical development is played by *abstraction sets*, which provide a semantics for binding mechanisms [15]:

► **Definition 2.1** (Abstraction set). Given a nominal set X , an equivariant equivalence relation \sim on $\mathbb{A} \times X$ is defined by

$$(a, x) \sim (b, y) \quad \text{iff} \quad (ac) \cdot x = (bc) \cdot y \text{ for some } c \in \mathbb{A} \text{ that is fresh for } (a, x, b, y)$$

(equivalently for all such c). The *abstraction set* $[\mathbb{A}]X$ is the quotient set $(\mathbb{A} \times X)/\sim$. The \sim -equivalence class of $(a, x) \in \mathbb{A} \times X$ is denoted by $\langle a \rangle x \in [\mathbb{A}]X$.

We may think of \sim as an abstract notion of α -equivalence, and of $\langle a \rangle$ as binding the name a . Indeed we have $\text{supp}(\langle a \rangle x) = \text{supp}(x) \setminus \{a\}$, as expected in binding constructs.

3 Data Languages and Bar Languages

As indicated, we use the set \mathbb{A} of names as the data domain, and capture freshness of data values via α -equivalence, roughly as follows. We work with words over \mathbb{A} where names may be preceded by the bar symbol “|”, which indicates that the next letter is bound until the end of the word (cf. Remark 3.2); such words are called *bar strings* [38]. Bar strings may be seen as patterns that govern how letters are read from the input word; broadly speaking, an occurrence of la corresponds to reading a letter from the input word, and binding this letter to the name a , while an undecorated occurrence of a means that the letter referred to by a occurs in the input word. (We loosely speak of the input word as consisting of letters, and of bar strings as consisting of names; formally, however, letters and names are the same, viz., elements of \mathbb{A} .) Bound names can be renamed, giving rise to a notion of α -equivalence; as usual, the new name needs to be sufficiently *fresh*, i.e. cannot already occur freely in the scope of the binding. For instance, in $albab$, the $|$ binds the letter b in $lbab$. The bar string $albab$ is α -equivalent to $alcac$ but not, of course, to $alaaa$. That is, we can rename the bound name b into c but not into a , as a already occurs freely in $lbab$; we say that renaming b into a is *blocked*.

We will see that bar strings modulo α -equivalence relate to formalisms for *global* freshness (a name is globally fresh if it has never been seen before), such as session automata [3]. Contrastingly, if we regard a bar string as representing all words over \mathbb{A} that arise by performing some α -equivalent renaming and then removing the bars, we arrive at a notion of *local* freshness, similar to freshness w.r.t. currently stored names as in register automata; precise definitions are given later in this section. For instance, the bar string $alba$ represents the set of words $\{cdc \mid c, d \in \mathbb{A}, c \neq d\} \subseteq \mathbb{A}^*$ under both local and global freshness semantics – in $alba$, a and b cannot be renamed into the same letter, since a occurs freely in the scope of lb . Contrastingly, lab represents the set $\{cd \mid c \neq d\} \subseteq \mathbb{A}^*$ under global freshness semantics, but under local freshness semantics it just represents the set \mathbb{A}^2 of all two-letter words, since lab is α -equivalent to $lala$. The impossibility of expressing the language $\{cd \mid c \neq d\}$ under local freshness is thus hardwired into our language model. We emphasize again that this

restriction seems reasonable in practice, since one may expect that freshness of new letters is often relevant only w.r.t. letters that are intended to be seen again later, e.g. in deallocation statements or message acknowledgements. Formal definitions are as follows.

► **Definition 3.1** (Bar strings). We put $\bar{\mathbb{A}} = \mathbb{A} \cup \{la \mid a \in \mathbb{A}\}$; we refer to elements $la \in \bar{\mathbb{A}}$ as *bar names*, and to elements $a \in \mathbb{A}$ as *plain names*. A *bar string* is a word $w = \sigma_1\sigma_2 \cdots \sigma_n \in \bar{\mathbb{A}}^*$, with *length* $|w| = n$; we denote the empty string by ϵ . We turn $\bar{\mathbb{A}}$ into a nominal set by putting $\pi \cdot a = \pi(a)$ and $\pi \cdot la = l\pi(a)$; then, $\bar{\mathbb{A}}^*$ is a nominal set under the pointwise action of G . We define α -*equivalence* on bar strings to be the least equivalence \equiv_α such that

$$wlav \equiv_\alpha wlbv \quad \text{whenever} \quad \langle a \rangle v = \langle b \rangle u \text{ in } [\mathbb{A}] \bar{\mathbb{A}}^*$$

(Definition 2.1) for $w, v, u \in \bar{\mathbb{A}}^*$, $a \in \mathbb{A}$. Thus, la binds a , with scope extending to the end of the word. Correspondingly, a name a is *free* in a bar string w if there is an occurrence of a in w that is to the left of any occurrence of la . We write $[w]_\alpha$ for the α -equivalence class of $w \in \bar{\mathbb{A}}^*$ and $\text{FN}(w) = \{a \in \mathbb{A} \mid a \text{ is free in } w\}$ ($= \text{supp}([w]_\alpha)$) for the set of free names of w . If $\text{FN}(w) = \emptyset$, then w is *closed*. A bar string w is *clean* if all bar names la in w are pairwise distinct and have $a \notin \text{FN}(w)$. For a set $S \subseteq \mathbb{A}$ of names, we write $\text{bs}(S) = \{w \in \bar{\mathbb{A}}^* \mid \text{FN}(w) \subseteq S\}$.

► **Remark 3.2.** Closed bar strings are essentially the same as the *well-formed symbolic words* that appear in the analysis of session automata [3]. Indeed, symbolic words consist of operations that read a letter into a register, corresponding to bar names, and operations that require seeing the content of some register in the input, corresponding to plain names. Symbolic words are normalized by a register allocation procedure similar to α -renaming. Well-formedness of symbolic words corresponds to closedness of bar strings.

Moreover, modulo the respective equational laws, bar strings coincide with the ν -strings [28, 29] that appear in the semantics of *Nominal Kleene Algebra (NKA)* [16]; cf. [38]. These are constructed from names in \mathbb{A} , sequential composition, and a binding construct $\nu a. w$, which binds the name a in the word w . In particular, the equational laws of ν -strings allow extruding the scope of every ν to the end of the word after suitable α -renaming. We note that **Bar- μ TL** and its associated automata models are more expressive than NKA as they express languages with unbounded nesting of binders [38].

We will work with three different types of languages:

► **Definition 3.3.**

1. *Data languages* are subsets of \mathbb{A}^* .
2. *Literal languages* are subsets of $\bar{\mathbb{A}}^*$, i.e. sets of bar strings.
3. *Bar languages* are subsets of $\bar{\mathbb{A}}^* / \equiv_\alpha$, i.e. sets of α -equivalence classes of bar strings.

A bar language L is *closed* if $\text{supp}(L) = \emptyset$.

Bar languages are the natural semantic domain of our formalisms, and relate tightly to data languages as discussed next. A key factor in the good computational properties of regular nominal nondeterministic automata (RNNA) [38] is that the bar languages they accept (cf. Section 5) are uniformly finitely supported, and we will design **Bar- μ TL** to ensure the same property. Note that a uniformly supported bar language is closed iff it consists of (equivalence classes of) closed bar strings. For brevity, we will focus the exposition on target formulae (in model checking) and automata that denote or accept, respectively, closed bar languages, with free names appearing only in languages accepted by non-initial states or denoted by proper subformulae of the target formula. (The treatment is easily extended to

bar languages with free names; indeed, such globally free names are best seen as a separate finite alphabet of constant symbols [29].) We will occasionally describe example bar languages as regular expressions over $\bar{\mathbb{A}}$ (i.e. as *regular bar expressions* [38]), meaning the set of all α -equivalence classes of instances of the expression.

To convert bar strings into data words, we define $\mathbf{ub}(a) = \mathbf{ub}(|a) = a$ and extend \mathbf{ub} to bar strings letterwise; i.e. $\mathbf{ub}(w)$ is the data word obtained by erasing all bars “|” from w . We then define two ways to convert a bar language L into a data language:

$$N(L) = \{\mathbf{ub}(w) \mid [w]_\alpha \in L, w \text{ clean}\} \quad \text{and} \quad D(L) = \{\mathbf{ub}(w) \mid [w]_\alpha \in L\}.$$

That is, N is a global freshness interpretation of $|$, while D provides a local freshness interpretation as exemplified above; e.g. as indicated above we have $D(|alba) = N(|alba) = \{aba \mid a, b \in \mathbb{A}, a \neq b\}$, while $N(|alb) = \{ab \mid a, b \in \mathbb{A}, a \neq b\}$ but $D(|alb) = \{ab \mid a, b \in \mathbb{A}\}$.

► **Remark 3.4.** In fact, the operator N is injective on closed bar languages, because \mathbf{ub} is injective on closed clean bar strings [37, 38]. This means that bar language semantics and global freshness semantics are essentially the same, while local freshness semantics is a quotient of the other semantics. It is immediate from [37, Lemma A.4] that N preserves intersection and complement of closed bar languages, the latter in the sense that $N(\mathbf{bs}(\emptyset) \setminus L) = \mathbb{A}^* \setminus N(L)$ for closed bar languages L . Both properties fail for the local freshness interpretation D ; the semantics of formulae should therefore be understood first in terms of bar languages, with D subsequently applied globally.

4 Syntax and Semantics of Bar- μ TL

We proceed to introduce a variant Bar- μ TL of linear temporal logic whose formulae define bar languages. This logic relates, via its local freshness semantics, to Freeze LTL. It replaces freeze quantification with name binding modalities, and features fixpoints, for increased expressiveness in comparison to the temporal connectives of LTL [17]. Via global freshness semantics, Bar- μ TL may moreover be seen as a logic for session automata [3].

Syntax. We fix a countably infinite set \mathbb{V} of (*fixpoint*) *variables*. The set **Bar** of *bar formulae* ϕ, ψ, \dots (in negation normal form) is generated by the grammar

$$\phi, \psi := \epsilon \mid \neg\epsilon \mid \phi \wedge \psi \mid \phi \vee \psi \mid \heartsuit_\sigma \phi \mid X \mid \mu X. \phi,$$

where $\heartsuit \in \{\diamond, \square\}$, $\sigma \in \bar{\mathbb{A}}$ and $X \in \mathbb{V}$. We define $\top = \epsilon \vee \neg\epsilon$ and $\perp = \epsilon \wedge \neg\epsilon$. We refer to \diamond_σ and \square_σ as σ -*modalities*. The meaning of the Boolean operators is standard; the fixpoint construct μ denotes unique fixpoints, with uniqueness guaranteed by a guardedness restriction to be made precise in a moment. The other constructs are informally described as follows. The constant ϵ states that the input word is empty, and $\neg\epsilon$ that the input word is nonempty. A formula $\diamond_a \phi$ is read “the first letter is a , and the remaining word satisfies ϕ ”, and $\square_a \phi$ is read dually as “if the first letter is a , then the remaining word satisfies ϕ ”. The reading of $|a$ -modalities is similar but involves α -renaming as detailed later in this section; as indicated in Section 3, this means that $|a$ -modalities effectively read fresh letters. They thus replace the freeze quantifier; one important difference with the latter is that $\diamond_{|a}$ consumes the letter it reads, i.e. advances by one step in the input word. A name a is *free* in a formula ϕ if ϕ contains an a -modality at a position that is not in the scope of any $|a$ -modality; that is, $|a$ -modalities bind the name a . We write $\mathbf{FN}(\phi)$ for the set of free names in ϕ , and $\mathbf{BN}(\phi)$ for the set of *bound names* in ϕ , i.e. those names a such that ϕ

mentions $!a$; we put $N(\phi) = \text{FN}(\phi) \cup \text{BN}(\phi)$, and (slightly generously) define the *degree* of ϕ to be $\text{deg}(\phi) = |N(\phi)|$. We write $\text{FV}(\phi)$ for the set of *free* fixpoint variables in ϕ , defined in the standard way by letting μX bind X ; a formula ϕ is *closed* if $\text{FV}(\phi) = \emptyset$. (We refrain from introducing terminology for formulae without free *names*.) As indicated above we require that all fixpoints $\mu X. \phi$ are *guarded*, that is, all free occurrences of X lie within the scope of some σ -modality in ϕ . We denote by $\text{cl}(\phi)$ the *closure* of ϕ in the standard sense [27], i.e. the least set of formulae that contains ϕ and is closed under taking immediate subformulae and unfolding top-level fixpoints; this set is finite. We define the *size* of ϕ as $|\phi| = |\text{cl}(\phi)|$.

For purposes of making Bar a nominal set, we regard every fixpoint variable X with enclosing fixpoint expression $\mu X. \phi$ as being annotated with the set $A = \text{FN}(\mu X. \phi)$; that is, we identify X with the pair (X, A) . We then let G act by replacing names in the obvious way; i.e. $\pi \cdot \phi$ is obtained from ϕ by replacing a with $\pi(a)$, $!a$ with $! \pi(a)$, and (X, A) with $(X, \pi \cdot A)$ everywhere. Otherwise, the definition is as expected:

► **Definition 4.1.** α -Equivalence \equiv_α on formulae is the congruence relation generated by

$$\diamond_{!a}\phi \equiv_\alpha \diamond_{!b}\psi \text{ and } \square_{!a}\phi \equiv_\alpha \square_{!b}\psi \quad \text{whenever } \langle a \rangle \phi = \langle b \rangle \psi$$

(cf. Definition 2.1).

► **Remark 4.2.** The point of implicitly annotating fixpoint variables with the free names of the enclosing μ -expression is to block unsound α -renamings: It ensures that, e.g., $\diamond_{!a}(\mu X. (\diamond_{!a} \epsilon \vee \diamond_{!b} X))$ is *not* α -equivalent to $\diamond_{!a}(\mu X. (\diamond_{!a} \epsilon \vee \diamond_{!a} X))$ (as X is actually $(X, \{a\})$), and is required to ensure stability of α -equivalence under fixpoint expansion, recorded next. We note that fixpoint expansion does *not* avoid capture of names; e.g. the expansion of $\mu X. (\diamond_{!a} \epsilon \vee \diamond_{!a} X)$ is $\diamond_{!a} \epsilon \vee \diamond_{!a}(\mu X. (\diamond_{!a} \epsilon \vee \diamond_{!a} X))$.

► **Lemma 4.3.** Let $\mu X. \phi \equiv_\alpha \mu X. \phi'$. Then $\phi[\mu X. \phi/X] \equiv_\alpha \phi'[\mu X. \phi'/X]$.

Proof. Immediate from the fact that by the convention that fixpoint variables are annotated with the free names of their defining formulae, X , $\mu X. \phi$, and $\mu X. \phi'$ have the same free names and hence allow the same α -renamings in the outer contexts ϕ and ϕ' , respectively. ◀

Semantics. We interpret each bar formula ϕ as denoting a uniformly finitely supported bar language, depending on a *context*, i.e. a finite set $S \subseteq \mathbb{A}$ such that $\text{FN}(\phi) \subseteq S$, which specifies names that are allowed to occur freely; at the outermost level, S will be empty (cf. Section 3). The context grows when we traverse modalities $\diamond_{!a}$ or $\square_{!a}$. Correspondingly, we define satisfaction $S, w \models \phi$ of a formula ϕ by a bar string $w \in \text{bs}(S)$ recursively by the usual clauses for the Boolean connectives, and

$$\begin{aligned} S, w \models \neg \epsilon &\Leftrightarrow w \neq \epsilon \\ S, w \models \epsilon &\Leftrightarrow w = \epsilon \\ S, w \models \mu X. \phi &\Leftrightarrow S, w \models \phi[\mu X. \phi/X] \\ S, w \models \diamond_a \phi &\Leftrightarrow \exists v. w = av \text{ and } S, v \models \phi \\ S, w \models \square_a \phi &\Leftrightarrow \forall v. \text{if } w = av \text{ then } S, v \models \phi \\ S, w \models \diamond_{!a} \phi &\Leftrightarrow \exists \psi \in \text{Bar}, v \in \overline{\mathbb{A}}^*, b \in \mathbb{A}. \\ &\quad w \equiv_\alpha !bv \text{ and } \langle a \rangle \phi = \langle b \rangle \psi \text{ and } S \cup \{b\}, v \models \psi \\ S, w \models \square_{!a} \phi &\Leftrightarrow \forall \psi \in \text{Bar}, v \in \overline{\mathbb{A}}^*, b \in \mathbb{A}. \\ &\quad \text{if } w \equiv_\alpha !bv \text{ and } \langle a \rangle \phi = \langle b \rangle \psi \text{ then } S \cup \{b\}, v \models \psi. \end{aligned}$$

Guardedness of fixpoint variables guarantees that on the right hand side of the fixpoint clause, $\mu X. \phi$ is evaluated only on words that are strictly shorter than w , so the given clause uniquely defines the semantics. Notice that $\diamond_{|a}$ and $\square_{|a}$ allow α -renaming of both the input word and the formula; we comment on this point in Remark 4.7. For a formula ϕ such that $\text{FN}(\phi) = \emptyset$, we briefly write

$$\llbracket \phi \rrbracket_0 = \{w \in \text{bs}(\emptyset) \mid \emptyset, w \models \phi\} \quad \text{and} \quad \llbracket \phi \rrbracket = \llbracket \phi \rrbracket_0 / \equiv_\alpha,$$

referring to $\llbracket \phi \rrbracket_0$ as the *literal language* and to $\llbracket \phi \rrbracket$ as the *bar language* of ϕ (variants with non-empty context and $\text{FN}(\phi) \neq \emptyset$ are technically unproblematic but require more notation). In particular, $\llbracket \phi \rrbracket$ is closed by construction. The *global* and *local freshness semantics* of ϕ are $N(\llbracket \phi \rrbracket)$ and $D(\llbracket \phi \rrbracket)$, respectively, where N and D are the operations converting bar languages into data languages described in Section 3.

► **Remark 4.4.** In $\text{Bar-}\mu\text{TL}$, fixpoints take on the role played by the temporal operators in Freeze LTL. In bar language semantics, the overall mode of expression in $\text{Bar-}\mu\text{TL}$, illustrated in Example 4.8, is slightly different from that of Freeze LTL, as in $\text{Bar-}\mu\text{TL}$ the input is traversed using modalities tied to specific letters rather than using a *next* operator \circ . In local freshness semantics, the effect of \circ is included in the name binding modality $\diamond_{|a}$. For instance, in local freshness semantics we can express LTL-style formulae $\phi U \psi$ (ϕ until ψ) as $\mu X. \psi \vee (\phi \wedge \diamond_{|a} X)$. In particular, $\mu X. \epsilon \vee \diamond_{|a} X$ defines the universal data language, so \top is not actually needed in local freshness semantics. Overall, Freeze LTL and $\text{Bar-}\mu\text{TL}$ (with local freshness semantics) intersect as indicated but are incomparable: On the one hand, Freeze LTL can express the language “the first two letters are different”, which as indicated in Section 3 is not induced by a bar language. On the other hand, $\text{Bar-}\mu\text{TL}$ features fixpoints, which capture properties that generally fail to be expressible using LTL operators, e.g. the language of all even-length words. The latter point relates to the fact that even over finite alphabets, LTL on finite words is only as expressive as first-order logic, equivalently star-free regular expressions (cf. [17]). Constrastingly, thanks to the fixpoint operators, $\text{Bar-}\mu\text{TL}$ is as expressive as its corresponding automata model (Theorem 6.6).

► **Remark 4.5.** As indicated previously, $\text{Bar-}\mu\text{TL}$ is closed under complement: By taking negation normal forms, we can define $\neg\phi$ so that $S, w \models \neg\phi$ iff $S, w \not\models \phi$.

We note next that literal languages of formulae are closed under α -equivalence, and that α -equivalent renaming of formulae indeed does not affect the semantics (cf. Remark 4.2):

► **Lemma 4.6.** For $\phi, \psi \in \text{Bar}$, $a \in \mathbb{A}$, $S \subseteq \mathbb{A}$, and $w, w' \in \overline{\mathbb{A}}^*$, we have:

1. If $S, w \models \psi$ and $w \equiv_\alpha w'$, then $S, w' \models \psi$.
2. If $S, w \models \psi$ and $\phi \equiv_\alpha \phi'$, then $S, w' \models \phi'$.

The proof is by induction along the recursive definition of the semantics; the case for fixpoints in Claim 2 is by Lemma 4.3.

► **Remark 4.7.** We have noted above that the semantics allows α -renaming of both words and formulae. Let us refer to an alternative semantics where the definition of $S, w \models \diamond_{|a} \phi$ is modified to require that there exists $w \equiv_\alpha lav$ such that $S \cup \{a\}, v \models \phi$ (without allowing α -renaming of $\diamond_{|a} \phi$), similarly for $\square_{|a}$, as the *rigid* semantics, and to the semantics defined above as the *actual* semantics. The rigid semantics is not equivalent to the actual semantics, and has several flaws. First off, claim 2 of the above Lemma 4.6 fails under the rigid semantics, in which, for example,

$$\emptyset, l|b|a \models \diamond_{|b} \diamond_{|a} \top \quad \text{but} \quad \emptyset, l|b|a \not\models \diamond_{|b} \diamond_{|b} \top$$

(the latter because $\{b\}, lab \not\models \diamond_{lb}\top$, as α -renaming of la into lb is blocked in lab). More importantly, the rigid semantics has undesirable effects in connection with fixpoints. For instance, in the actual semantics, the formula $\phi = \mu X. ((\neg\epsilon \wedge \square_{la}\perp) \vee \diamond_{la}X)$ has the intuitively intended meaning: A bar string satisfies ϕ iff it contains some plain name. In the rigid semantics, however, we unexpectedly have $\emptyset, labab \not\models \phi$; to see this, note that $\{a\}, labab \not\models \phi$ in the rigid semantics, since α -renaming of lb into la is blocked in $labab$.

► **Example 4.8.** We consider some Bar- μ TL formulae and their respective semantics under local and global freshness. (The local freshness versions are expressible in Freeze LTL in each case; recall however Remark 4.4.)

1. The bar language $\llbracket \top \rrbracket$ is the set of all closed bar strings (modulo α -equivalence, a qualification that we omit henceforth). Under both global and local freshness semantics, this becomes the set of all data words.
2. The bar language $\llbracket \diamond_{la}\square_a\epsilon \rrbracket$ is the language of all closed bar strings that start with a bar name la , and stop after the second letter if that letter exists and is the plain name a (e.g. $\llbracket \diamond_{la}\square_a\epsilon \rrbracket$ contains $la, laa, labab$ but not $laaa$). In both global and local freshness semantics, this becomes the language of all words that stop after the second letter if that letter exists and coincides with the first letter.
3. In context $\{a\}$, a bar string satisfies $\mu Y. ((\diamond_{lb}Y) \vee \diamond_a\top)$ iff it contains a free occurrence of a preceded only by bar names distinct from la . Thus, the bar language of

$$\mu X. (\diamond_{la}(X \vee \mu Y. ((\diamond_{lb}Y) \vee \diamond_a\top)))$$

consists of all closed bar strings that start with a prefix of bar names and eventually mention a plain name corresponding to one of these bar names. Under both local and global freshness semantics, this becomes the data language of all words mentioning some letter twice (which is not acceptable by deterministic or even unambiguous register automata [2, 37]). Notice that during the evaluation of the formula, the context can become unboundedly large, as it grows every time a bar name is read.

4. The bar language of the similar formula

$$\mu X. ((\diamond_{la}X) \vee (\diamond_{la}\mu Y. ((\diamond_{lb}Y) \vee \diamond_a\epsilon)))$$

consists of all closed bar strings where all names except the last one are bound names. Under global freshness semantics, this becomes the data language where the last letter occurs *precisely* twice in the word, and all other names only once. Under local freshness semantics, the induced data language is that of all words where the last letter occurs *at least* twice, with no restrictions on the other letters.

5. To illustrate both the mechanism of local freshness via α -equivalence and, once again, the use of \top , we consider the bar language of

$$\diamond_{la}\diamond_{lb}\mu X. ((\diamond_{lb}X) \vee \diamond_a\top),$$

which consists of all closed bar strings that start with a bar name la , at some later point contain a substring bab , and have only bar names distinct from la in between. Under global freshness semantics, this becomes the data language of all words where the first name a occurs a second time at the third position or later, all letters are mutually distinct until that second occurrence, and the letter preceding that occurrence is repeated immediately after. The local freshness semantics is similar but only requires the letters between the first and second occurrence of a to be distinct from a (rather than mutually distinct), that is, the substring bab is required to contain precisely the second occurrence of a .

5 Extended Regular Nondeterministic Nominal Automata

We proceed to introduce the nominal automaton model we use in model checking, *extended regular nondeterministic nominal automata* (ERNNAs), a generalized version of RNNAs [38] that allow for limited alternation in the form of deadlocked universal states.

Nominal automata models [2] generally feature nominal sets of states; these are infinite as sets but typically required to be orbit-finite. RNNAs are distinguished from other nominal automata models (such as *nondeterministic orbit-finite automata* [2]) in that they impose finite branching but feature *name-binding* transitions; that is, they have *free* transitions $q \xrightarrow{a} q'$ for $a \in \mathbb{A}$ as well as *bound* transitions $q \xrightarrow{la} q'$, both consuming the respective type of letter in the input bar string w . Bound transitions may be understood as reading fresh letters. RNNAs are a nondeterministic model, i.e. accept w if there *exists* a run on w ending in an accepting state. ERNNAs additionally feature \top -states that accept the current word even if it has not been read completely, and thus behave like the formula \top ; these states may be seen as universal states without outgoing transitions. Formal definitions are as follows.

► **Definition 5.1.** An *extended regular nondeterministic nominal automaton* (ERNNA) is a four-tuple $A = (Q, \rightarrow, s, f)$ that consists of

- an orbit-finite nominal set Q of *states* (whose orbits we also refer to as the *orbits of A*);
- an *initial state* $s \in Q$ such that $\text{supp}(s) = \emptyset$;
- an equivariant *transition relation* $\rightarrow \subseteq Q \times (\overline{\mathbb{A}} \cup \{\epsilon\}) \times Q$, with $(q, \sigma, q') \in \rightarrow$ denoted by $q \xrightarrow{\sigma} q'$; and
- an equivariant *acceptance function* $f: Q \rightarrow \{0, 1, \top\}$

such that \rightarrow is α -invariant (that is, $q \xrightarrow{la} q'$ and $\langle a \rangle q' = \langle b \rangle q''$ imply $q \xrightarrow{lb} q''$) and finitely branching up to α -equivalence (i.e. for each q , the sets $\{(a, q') \mid q \xrightarrow{a} q'\}$, $\{(\epsilon, q') \mid q \xrightarrow{\epsilon} q'\}$, and $\{\langle a \rangle q' \mid q \xrightarrow{la} q'\}$ are finite). Whenever $f(q) = \top$, we require $\text{supp}(q) = \emptyset$ and moreover that q is a deadlock, i.e. there are no transitions of the form $q \xrightarrow{\sigma} q'$. The *degree* $\text{deg}(A)$ of A is the maximal size of the support of a state in Q (in the translation of nominal automata into register automata, the degree corresponds to the number of registers [2, 38]). A state q is *accepting* if $f(q) = 1$, *non-accepting* if $f(q) = 0$, and a \top -state if $f(q) = \top$.

We extend the transition relation to words w over $\overline{\mathbb{A}}$, i.e. to bar strings, as usual; that is, $q \xrightarrow{w} q'$ iff there exist states $q = q_0, q_1, \dots, q_k = q'$ and transitions $q_i \xrightarrow{\sigma_{i+1}} q_{i+1}$ for $i = 0, \dots, k-1$ such that w is the concatenation $\sigma_1 \cdots \sigma_k$, where σ_i is regarded as a one-letter word if $\sigma_i \in \overline{\mathbb{A}}$, and as the empty word if $\sigma_i = \epsilon$. We define $L_{\text{pre}}(A) \subseteq \overline{\mathbb{A}}^* \times \{1, \top\}$ (for *prelanguage*) as

$$L_{\text{pre}}(A) = \{(w, f(q)) \mid s \xrightarrow{w} q, f(q) \in \{1, \top\}\}.$$

The *literal language* $L_0(A) \subseteq \overline{\mathbb{A}}^*$ accepted by an ERNNA A then is defined by

$$L_0(A) = \text{bs}(\emptyset) \cap (\{w \mid (w, 1) \in L_{\text{pre}}(A)\} \cup \{vu \mid (v, \top) \in L_{\text{pre}}(A), u \in \overline{\mathbb{A}}^*\});$$

that is, a closed bar string w is literally accepted if either w has a run ending in an accepting state or a prefix of w has a run ending in a \top -state. (Again, extending the treatment to bar strings with free names is technically unproblematic but heavier on notation.) The *bar language accepted by A* is the quotient

$$L_\alpha(A) = L_0(A) / \equiv_\alpha.$$

We say that A is ϵ -free if A contains no ϵ -transitions. If A is ϵ -free and contains no \top -states, then A is a *regular nondeterministic nominal automaton* (RNNA).

► **Remark 5.2.** The presence of \top -states makes ERNNAs strictly more expressive than RNNAs under bar language semantics (equivalently, under global freshness semantics). Indeed, the ERNNA consisting of a single \top -state accepts the universal bar language, which is not acceptable by an RNNNA [38]. On the other hand, under local freshness semantics, an accepting state with a $!a$ -self-loop accepts the universal data language (in analogy to the expressibility of \top by $\mu X. \epsilon \vee \diamond_{!a} X$ in $\text{Bar-}\mu\text{TL}$ under local freshness semantics, cf. Remark 4.4), so RNNAs are as expressive as ERNNAs under local freshness semantics.

Name dropping. Like for RNNAs, the literal language accepted by an ERNNA is not in general closed under α -equivalence. However, one can adapt the notion of name dropping [38] to ERNNA: Roughly speaking, an ERNNA is *name-dropping* if all its transitions may nondeterministically lose any number of names from the support of states (which corresponds to losing register contents in a register automaton). The literal language of a name-dropping ERNNA is closed under α -equivalence, and every ERNNA A can be transformed into a name-dropping ERNNA $\text{nd}(A)$, preserving the bar language. This transformation is central to the inclusion checking algorithm (see additional remarks in Section 7).

Representing ERNNAs. ERNNAs are, *prima facie*, infinite objects; we next discuss a finite representation of ERNNAs as *extended bar NFAs*, generalizing the representation of RNNAs as bar NFAs [38]. The intuition behind extended bar NFAs is similar to that of ERNNAs, except that extended bar NFAs are not closed under name permutation. In particular, extended bar NFAs feature deadlocked universal states:

► **Definition 5.3.** An *extended bar NFA* $A = (Q, \rightarrow, s, f)$ consists of

- a finite set Q of *states*;
- a *transition relation* $\rightarrow \subseteq (Q \times \bar{\mathbb{A}} \times Q)$, with $(q, \sigma, q') \in \rightarrow$ denoted by $q \xrightarrow{\sigma} q'$;
- an *initial state* $s \in Q$; and
- an *acceptance function* $f: Q \rightarrow \{0, 1, \top\}$

such that whenever $f(q) = \top$, then q is a deadlock, i.e. has no outgoing transitions. We extend the transition relation to words over $\bar{\mathbb{A}}$ (including the empty word) as usual. Similarly as for ERNNAs, we define $L_{\text{pre}}(A) \subseteq \bar{\mathbb{A}}^* \times \{1, \top\}$ by

$$L_{\text{pre}}(A) = \{(w, f(q)) \mid s \xrightarrow{w} q, f(q) \in \{1, \top\}\}.$$

The *literal language* $L_0(A)$ accepted by A is

$$L_0(A) = \{w \mid (w, 1) \in L_{\text{pre}}(A)\} \cup \{vu \mid (v, \top) \in L_{\text{pre}}(A), u \in \bar{\mathbb{A}}^*\}.$$

The *bar language* of A is then defined as the quotient $L_\alpha(A) = L_0(A)/\equiv_\alpha$. For ease of presentation, we only consider the case where $L_\alpha(A)$ is closed, which is easily checked syntactically (no a may be reached in A without passing $!a$). We generally write (A, q) for the extended bar NFA that arises by making $q \in Q$ the initial state of A , dropping however the requirement that the bar language accepted by (A, q) is closed. The set $\text{FN}(A, q)$ of *free names* of $q \in Q$ is then $\text{FN}(A, q) = \bigcup_{(w,b) \in L_{\text{pre}}(A,q)} \text{FN}(w)$. Slightly sharpening the original definition [38], we take the *degree* of A to be $\text{deg}(A) := \max_{q \in Q} |\text{FN}(A, q)|$.

► **Theorem 5.4.** *ERNNAs and extended bar NFAs accept the same bar languages; that is:*

1. *For a given extended bar NFA with n states and degree k , there exists a name-dropping ERNNA of degree k with $n \cdot 2^k$ orbits that accepts the same bar language.*
2. *For a given ERNNA with n orbits and degree k , there exists an extended bar NFA of degree k with $n \cdot k!$ states that accepts the same bar language.*

The key algorithmic task on ERNNAs is inclusion checking; we generalize the inclusion algorithm for RNNAs [38] to obtain

► **Theorem 5.5.** *Given a bar NFA A_1 and an extended bar NFA A_2 , the inclusion $L_\alpha(A_1) \subseteq L_\alpha(A_2)$ can be checked using space polynomial in the number of orbits of A_1 and A_2 , and exponential in $\deg(A_1)$ and $\deg(A_2)$. The same holds under local freshness semantics.*

6 Equivalence of Bar- μ TL and ERNNA

Our model checking algorithm will be based on translation of closed formulae into ERNNAs, in what amounts to a tableau construction that follows a similar spirit as the standard automata-theoretic translation of LTL, but requires a special treatment of \Box -formulae and $\neg\epsilon$, and moreover uses nondeterminism to bound the number of free names in automata states (which may be thought of as the number of registers) by guessing certain names, as explained in the following example.

► **Example 6.1.** Consider the formulae $\phi(b) = \mu Y. (\Box_b \perp \wedge \Box_{!c} Y)$ and $\psi = \mu X. (\Box_{!a} X \wedge \Box_{!b} \phi(b))$. The formula $\phi(b)$ states that the first plain name that occurs is not a free occurrence of b , and ψ thus states that none of the bar names have a free occurrence later on. When evaluating ψ over a bar string $w = |a_1 a_2 \dots |a_n a_i v$ consisting of n bar names $|a_i$ followed by the plain name a_i ($1 \leq i \leq n$) and a remaining bar string v (so w does not satisfy ψ), one eventually has to evaluate all the formulae $\phi(a_1), \dots, \phi(a_n)$ over the bar string $a_i v$. Thus, the number of copies of formulae that a naively constructed ERRNA for ψ needs to keep track of can in principle grow indefinitely. At a first glance, this seems to prohibit a translation of formulae into orbit-finite automata. However, we observe that when the letter a_i is read, all $\phi(a_j)$ for $i \neq j$ immediately evaluate to \top (since the conjuncts $\Box_{a_j} \perp$ and $\Box_{!c} \phi(a_j)$ of their fixpoint unfolding both hold vacuously), and only the evaluation of $\phi(a_i)$ becomes relevant (since the argument of $\Box_{a_i} \perp$ is actually evaluated). In fact, it is possible to let the ERRNA for ψ nondeterministically guess the first plain name a_i that occurs in the input bar string. Then it suffices to let the ERNNA keep track of $\phi(a_i)$ since as discussed, all other copies of $\phi(b)$ become irrelevant.

The idea from the previous example can be generalized to work for all formulae. To this end we introduce a recursive manipulation of formulae that uses annotations to explicitly restrict the support of formulae and to guess and enforce so-called distinguishing letters. When constructing an ERNNA from a formula, we will use such manipulated formulae to avoid the problem described in Example 6.1 by bounding the number of formulae that the constructed ERNNA has to track.

► **Definition 6.2.** Fix a marker element $* \notin \mathbb{A}$ (indicating absence of a name). Let ϕ be a formula, let B and C be sets of letters such that $B \subseteq C$, and let $a \in (C \setminus B) \cup \{*\}$. For $n \in \mathbb{N}$, we define $\phi_C^B(a)_n$ recursively (as termination measure of the recursive definition we use tuples $(|n|, \mathbf{u}(\phi), |\phi|)$, ordered by lexicographic ordering, where $\mathbf{u}(\phi)$ denotes the number of unguarded fixpoint operators in ϕ) by putting $\phi_C^B(a)_0 = \top$ and, for $n > 0$,

$$\begin{aligned} \epsilon_C^B(a)_n &= \epsilon & \neg\epsilon_C^B(a)_n &= \neg\epsilon \\ (\psi \wedge \chi)_C^B(a)_n &= \psi_C^B(a)_n \wedge \chi_C^B(a)_n & (\psi \vee \chi)_C^B(a)_n &= \psi_C^B(a)_n \vee \chi_C^B(a)_n \\ (\diamond_{!b} \psi)_C^B(a)_n &= \diamond_{!b} (\psi_{C \cup \{b\}}^{B \cup \{b\}}(a)_{n-1}) & (\Box_{!b} \psi)_C^B(a)_n &= \Box_{!b} (\psi_{C \cup \{b\}}^{B \cup \{b\}}(a)_{n-1}) \\ (\mu X. \psi)_C^B(a)_n &= (\psi[\mu X. \psi/X])_C^B(a)_n \end{aligned}$$

and

$$\begin{aligned}
 (\diamond_b \psi)_C^B(a)_n &= \begin{cases} \perp & b \notin C \\ \diamond_b(\psi_C^B(a)_{n-1}) & b \in C, b \in B \\ \diamond_b(\psi_{\text{FN}(\psi)}^\emptyset(*)_{n-1}) & b \in C, b \notin B \end{cases} \\
 (\square_b \psi)_C^B(a)_n &= \begin{cases} \top & b \notin C \\ \square_b(\psi_C^B(a)_{n-1}) & b \in C, b \in B \\ \chi(b)_C^B(a)_{n-1} & b \in C, b \notin B \end{cases}
 \end{aligned}$$

where

$$\chi(b)_C^B(a)_{n-1} = \begin{cases} \square_b(\psi_{\text{FN}(\psi)}^\emptyset(*)_{n-1}) & a = * \\ \epsilon \vee \diamond_{lc} \top \vee \bigvee_{d \in B} \diamond_d \top \vee \diamond_a(\psi_{\text{FN}(\psi)}^\emptyset(*)_{n-1}) & a = b \\ \epsilon \vee \diamond_{lc} \top \vee \bigvee_{d \in B \cup \{a\}} \diamond_d \top & * \neq a \neq b. \end{cases}$$

During this process, fixpoint formulae are unfolded before replacing any free modalities within their arguments; by guardedness of fixpoint variables, this happens at most n times. (We intend the number n as a strict upper bound on the length of bar strings over which $\phi_C^B(a)_n$ is meant to be evaluated; cf. Lemma 6.3.) The process replaces just the first freely occurring boxes whose index is in C but not in B ; hence, modal operators whose index comes from B are left unchanged. Intuitively, $\phi_C^B(a)_n$ is a formula that behaves like the restriction of ϕ to the support C on bar strings w such that $|w| < n$ and in which a is the first free name that is not contained in B (if any such name occurs in w ; in this case we refer to the letter a as *distinguishing letter*). Hence $\phi_C^B(a)_n$ is like the restriction of ϕ to support C , assuming that the distinguishing letter is a . Formally:

► **Lemma 6.3.** *Let B and C be sets of names such that $B \subseteq C$, let $a \in (C \setminus B) \cup \{*\}$, let ϕ be a formula, and let S be a context. Let v be a bar string such that if $a \neq *$, then each letter that has a free occurrence in v before the first free occurrence of a in v is contained in B . Also, suppose that if there is some freely occurring letter in v that is not contained in B and the first such letter d is in $\text{FN}(\phi)$, then $d \in C$. Under these assumptions, we have*

$$S, v \models \phi \iff S, v \models \phi_C^B(a)_n \quad \text{for all } n \text{ such that } |v| < n.$$

Proof sketch. Induction along the recursive definition of $\phi_C^B(a)_n$. ◀

Let ϕ be a formula, let B , C , and D be sets of names such that $B \subseteq C$, and let $a \in (C \setminus B) \cup D \cup \{*\}$. We put

$$\phi_C^B(a)_n^D = \begin{cases} \perp & \text{if } a \in D \\ \phi_C^B(a)_n & \text{if } a \notin D, \end{cases}$$

the intuition being that $\phi_C^B(a)_n^D$ encodes ϕ (restricted to support C) together with the guess that a is the distinguishing letter (and that all names freely occurring before a are from the set B), where guessing a letter from the set D is not allowed. This rules out the situation that a letter from D is used to satisfy a distinguishing box formula in ϕ . Using Lemma 6.3, we obtain:

► **Lemma 6.4.** *Let π, π' be permutations, let ϕ be a formula, let w be a bar string, let S be a context, and put $A := \text{FN}(\pi \cdot \phi)$, $A' := \text{FN}(\pi' \cdot \phi)$ and $B := A \cap A'$. Furthermore, let a be either the first freely occurring letter in w that is not in B if that letter exists and is in $A \cup A'$ (in which case we say that a is the distinguishing letter w.r.t B and w), and $a = *$ otherwise. Then $a \notin B$ and we have*

$$S, w \models (\pi \cdot \phi) \wedge (\pi' \cdot \phi) \iff S, w \models ((\pi \cdot \phi)_A^B(a)_{|w|+1}^{A'} \wedge (\pi' \cdot \phi)_B^\emptyset(*)_{|w|+1}^\emptyset) \vee ((\pi' \cdot \phi)_{A'}^B(a)_{|w|+1}^A \wedge (\pi \cdot \phi)_B^\emptyset(*)_{|w|+1}^\emptyset).$$

Relying on name restriction as in Lemma 6.4, we are able to translate formulae to ERRNAs.

► **Theorem 6.5.** *For every closed formula ϕ of size m and degree k , there is an ERNNA $A(\phi)$ with degree bounded exponentially in k and polynomially in m , and with number of orbits bounded doubly exponentially in k and singly exponentially in m , that accepts the bar language of ϕ , i.e. $L_\alpha(A(\phi)) = \llbracket \phi \rrbracket$.*

We sketch the construction of $A(\phi)$. Let $\text{cl}(\phi)$ denote the closure of ϕ , defined in the standard way. We put

$$\text{Cl} = \text{cl}(\phi) \cup \{\diamond_\sigma \psi \mid \square_\sigma \psi \in \text{cl}(\phi)\} \cup \{\epsilon, \perp\} \cup \{\diamond_b \top \mid b \in \text{BN}(\phi)\},$$

noting $|\text{Cl}| \leq 4m$ (recall that \perp and \top abbreviate $\epsilon \wedge \neg \epsilon$ and $\epsilon \vee \neg \epsilon$, respectively). Furthermore, we put

$$\text{formulae} = \{\psi_C^B(a) \mid \psi \in \text{Cl}, B \subseteq \text{N}(\phi), C \subseteq \text{FN}(\psi), a \in C \cup \{*\}\},$$

noting that the cardinality of formulae is linear in m and exponential in k ; specifically, $|\text{formulae}| \leq |\text{Cl}| \cdot (|\text{N}(\phi)| + 1) \cdot 2^{2|\text{N}(\phi)|} \leq 2^{2k} \cdot 4m(k+1) \leq 2^{2m} \cdot 5m^2$ since we have $|\text{FN}(\psi)| \leq |\text{N}(\phi)|$ for all $\psi \in \text{Cl}$ and since $k \leq m$. The set formulae contains formulae $\psi \in \text{Cl}$ that are annotated with a single name a (or $*$) and two sets B and C of names. The annotation with a is used to encode a guessed name (with $*$ denoting the situation that no name has been guessed yet) which we call *distinguishing letter*, while the set C encodes the restriction of the support of ψ to C and the set B denotes the names that are allowed to occur freely before the distinguishing letter does. This data will be used to bound the number of copies of subformulae that can occur in nodes of the constructed tableau. We construct an ERRNA $A(\phi) = (Q, \rightarrow, s, f)$ with carrier set

$$Q = \left\{ \left(\{(\pi_1 \cdot \phi_1, \dots, \pi_n \cdot \phi_n), a\} \mid \pi_1, \dots, \pi_n \in G, \right. \right. \\ \left. \left. \{\phi_1, \dots, \phi_n\} \subseteq \text{formulae}, a \in \mathbb{A} \cup \{*\} \right\},$$

where the π_i act on names as usual and we define $\pi_i(*) = *$. The bound on the number of orbits follows since each combination of a subset Φ of formulae, a name a and an equivalence relation on the set of free names of Φ and a gives rise to at most one orbit. We put $s = (\{\phi_{\text{FN}(\phi)}^\emptyset(*)\}, *)$. Given a state $(\Gamma, b) \in Q$, formulae $\pi \cdot (\psi_C^B(a)) \in \Gamma$ stand for instances of ψ in which the distinguishing letter is fixed to be $\pi \cdot a$, $\pi \cdot B$ is the set of free names that are allowed to occur before $\pi \cdot a$ does, and the support of ψ is restricted to $\pi \cdot C$. The shape of a formula $\pi \cdot (\psi_C^B(a))$ is just the shape of ψ ; for brevity, we omit the annotations with C, B, a when they are not relevant. To deal with box operators and $\neg \epsilon$, states also contain a separate name component b (which may be $*$) that denotes a guess of the last relevant free name after which the evaluation of formulae from Γ will stop. A state $(\Gamma, b) \in Q$ is *propositional* if Γ contains some formula of the shape $\psi_1 \vee \psi_2$, $\psi_1 \wedge \psi_2$, or $\mu X. \psi_1$; *quasimodal* if (Γ, b) is not propositional but Γ contains some formula of the form $\neg \epsilon$ or $\square_\sigma \phi$; and *modal* if (Γ, b) is

neither propositional nor quasimodal, i.e. if all elements of Γ are either of the shape ϵ or $\diamond_\sigma\phi$. We define the acceptance function $f: Q \rightarrow \{0, 1, \top\}$ by $f(\emptyset, b) = \top$, $f(\Gamma, b) = 1$ if $\Gamma \neq \emptyset$ and all elements of Γ are of the shape ϵ , and $f(\Gamma, b) = 0$ for all other states.

Transitions work roughly as follows. The component Γ of a state (Γ, b) plays the usual role: It records formulae that the automaton requires the remaining input word to satisfy. To bound the number of free names that have to be tracked, formulae are annotated with guesses for distinguishing letters. The transitions from propositional and modal states follow the standard tableau rules; e.g. given a propositional state $q = (\Gamma \cup \{\psi \wedge \chi\}, b)$, we have $q \xrightarrow{\epsilon} (\Gamma \cup \{\psi, \chi\}, b)$; given a modal state $q = (\{\diamond_a\psi_1, \dots, \diamond_a\psi_n\}, b)$, we have $q \xrightarrow{a} (\{\psi_1, \dots, \psi_n\}, b)$; and a modal state containing $\diamond_a\psi$ and $\diamond_b\chi$ for $a \neq b$ is a deadlock (the treatment of \diamond_{1a} is more involved). \Box -formulae and $\neg\epsilon$ are dealt with by ϵ -transitions from quasimodal states (Γ, b) to modal states. This process is straightforward if Γ contains some formula $\diamond_\sigma\psi$. The critical case is the remaining one: A formula $\Box_\sigma\psi$ in Γ can be satisfied by in fact satisfying $\diamond_\sigma\psi$, by ending the word, or by reading either a plain name c other than σ or a bar name (if $\sigma \in \mathbb{A}$), or by reading any plain name (if $\sigma \in \overline{\mathbb{A}}$). This is where the second component b of states comes in: The letter c must have previously appeared as a bar name; $A(\phi)$ guesses when this happens (in bound transitions from modal states), and records its guess in b , with $*$ representing the situation that no guess has yet been made.

When constructing transitions in $A(\phi)$ as explained above, the set of formulae to which a naively constructed transition leads may contain two instances $\pi \cdot (\psi_C^B(a))$ and $\pi' \cdot (\psi_C^B(a))$ of an annotated formula ψ . In this situation, the rest of the word has to satisfy both formulae, but the set Q can only contain one instance of $\psi_C^B(a)$. Here we use the above restriction technique and repeated application of Lemma 6.4 to ensure that only a single copy needs to be kept.

We also have a converse translation which goes via the equivalence of ERNNAs and extended bar NFAs, and associates a fixpoint variable to each state.

► **Theorem 6.6.** *For every ERNNA A there exists a formula ϕ such that $\llbracket \phi \rrbracket = L_\alpha(A)$.*

Notably, by Remark 4.5, the results of this section imply

► **Corollary 6.7.** *The class of closed bar languages definable by ERNNAs is closed under complement: for each ERNNA A there exists an ERNNA \bar{A} such that $L_\alpha(\bar{A}) = \text{bs}(\emptyset) \setminus L_\alpha(A)$.*

As mentioned previously, RNNAs are essentially equivalent to session automata [38], which are only closed under *resource-bounded* complement [3] for some resource bound k ; in our present terminology, this corresponds to complement within the set of closed bar strings, modulo α -equivalence, that can be written with at most k different bound names. It is maybe surprising that full complementation (of session automata or RNNAs) is enabled by simply allowing \top -states.

7 Reasoning for Bar- μ TL

Using Theorem 6.5, we reduce reasoning problems for Bar- μ TL to ERNNAs:

► **Definition 7.1** (Reasoning problems). A closed formula ϕ is *satisfiable* if $\llbracket \phi \rrbracket \neq \emptyset$, and *valid* if $\llbracket \phi \rrbracket = \text{bs}(\emptyset)$. A formula ψ *refines* ϕ if $\llbracket \psi \rrbracket \subseteq \llbracket \phi \rrbracket$. An RNNA A *satisfies* ϕ (written $A \models \phi$) if $L_\alpha(A) \subseteq \llbracket \phi \rrbracket$. The *model checking problem* is to decide whether $A \models \phi$. We sometimes emphasize that these problems refer to *bar languages* or, equivalently, *global freshness*. The corresponding problems for *local freshness* arise by applying the D operator (Section 3) to all bar languages involved; e.g. A *satisfies* ϕ *under local freshness* if $D(L_\alpha(A)) \subseteq D(\llbracket \phi \rrbracket)$.

The complexity of $\text{Bar-}\mu\text{TL}$ reasoning problems, obtained using in particular Theorem 6.5 and Theorem 5.5, is summed up as follows.

► **Theorem 7.2.**

1. Model checking $\text{Bar-}\mu\text{TL}$ over $RNNAs$ is in 2EXPSPACE , more precisely in para-EXPSPACE with the degree of the formula as the parameter, under both bar language semantics (equivalently global freshness) and under local freshness. The same holds for validity under local freshness.
2. The satisfiability problem for $\text{Bar-}\mu\text{TL}$ is in EXPSPACE , more precisely in para-PSPACE with the degree of the formula as the parameter, under both bar language semantics / global freshness and under local freshness. The same holds for validity and refinement under bar language semantics / global freshness.

We leave the complexity (and in fact the decidability) of refinement checking under local freshness semantics as an open problem.

8 Conclusions

We have defined a specification logic $\text{Bar-}\mu\text{TL}$ for finite words over infinite alphabets, modelled in the framework of nominal sets, which covers both local and global freshness. $\text{Bar-}\mu\text{TL}$ features freeze quantification in the shape of name-binding modalities, and as such relates to Freeze LTL. It combines comparatively low complexity of the main reasoning problems with reasonable expressiveness, in particular unboundedly many registers, full nondeterminism, and closure under complement. Freshness is based on α -equivalence in nominal words; this entails certain expressive limitations on local freshness, which however seem acceptable in relation to the mentioned good computational properties.

An important issue for future work is the behaviour of $\text{Bar-}\mu\text{TL}$ over infinite words; also, we will investigate whether our methods extend to languages of data trees (e.g. [13]).

Test of Quantumness with Small-Depth Quantum Circuits

Shuichi Hirahara

Abstract

Recently Brakerski, Christiano, Mahadev, Vazirani and Vidick (FOCS 2018) have shown how to construct a test of quantumness based on the learning with errors (LWE) assumption: a test that can be solved efficiently by a quantum computer but cannot be solved by a classical polynomial-time computer under the LWE assumption. This test has led to several cryptographic applications. In particular, it has been applied to producing certifiable randomness from a single untrusted quantum device, self-testing a single quantum device and device-independent quantum key distribution.

In this paper, we show that this test of quantumness, and essentially all the above applications, can actually be implemented by a very weak class of quantum circuits: constant-depth quantum circuits combined with logarithmic-depth classical computation. This reveals novel complexity-theoretic properties of this fundamental test of quantumness and gives new concrete evidence of the superiority of small-depth quantum circuits over classical computation.

1 Introduction

Background. A very active research area in quantum computing is proving the superiority of “weak” models of quantum computation, such as small-depth quantum circuits, over classical computation. The main motivation is that such models are expected to be much easier to implement than universal quantum computation (e.g., polynomial-size quantum circuits) – Indeed in the past years we have been witnessing the development of several small-scale quantum computers (see, e.g., [1] for information about current quantum computers).

Under assumptions such as the non-collapse of the polynomial hierarchy or the hardness of (appropriate versions of) the permanent, strong evidence of the superiority of weak classes of quantum circuits has been obtained from the 2000s [2, 3, 4, 6, 12, 13, 14, 18, 19, 20, 33, 39]. A recent breakthrough by Bravyi, Gosset and König [10], further strengthened by subsequent works [5, 11, 17, 21], showed an *unconditional* separation between the computational powers of quantum and classical small-depth circuits by exhibiting a computational task that can be solved by constant-depth quantum circuits but requires logarithmic depth for classical circuits. A major shortcoming, however, is that logarithmic-depth classical computation is a

relatively weak complexity class. Due to the notorious difficulty of proving superlogarithmic lower bounds on the depth of classical circuits, showing significantly stronger unconditional separations seems completely out of reach of current techniques.

Progress has nevertheless been achieved recently by modifying the concept of computational problem, and considering *interactive problems* (problems consisting of several rounds of interaction between the computational device and a verifier). Grier and Schaeffer [23], in particular, showed that there exists an interactive problem that can be solved by constant-depth quantum circuits but such that any classical device solving it would solve $\oplus\text{L}$ -problems. This is a stronger evidence of the superiority of constant-depth quantum circuits since the complexity class $\oplus\text{L}$ is expected to be significantly larger than logarithmic-depth classical computation. On the other hand, problems in $\oplus\text{L}$ are still tractable classically since they can be solved in polynomial time.¹

Another significant development was achieved by Brakerski, Christiano, Mahadev, Vazirani and Vidick [7] who proposed, using some techniques from [29], a test of quantumness based on the Learning with Errors (LWE) assumption, which states that the learning with error problem (informally, inverting a “noisy” system of equations) cannot be solved in polynomial time. (See also [8, 27] for variants of this test.) They showed that this test can be passed with high probability using a polynomial-time quantum device but cannot be solved by any polynomial-time classical device under the LWE assumption, which is a compelling evidence of the superiority of quantum computing.² A crucial property of this test is that checking if the computational device passes the test (which thus means checking if the computational device is quantum) can be done efficiently – this property is not known to be true for many other tests from prior works in quantum supremacy (e.g., [2, 3, 4, 6, 12, 13, 14, 18, 19, 20, 33, 39].) Finally, the test of quantumness from [7] has another fundamental property: it can be shown that the only way for a computationally bounded quantum prover to pass the test is to prepare precisely the expected quantum state.³ This property makes it possible to control a computationally bounded quantum prover, and has already lead to many cryptographic applications: producing certifiable randomness from a single untrusted (computationally bounded) quantum device [7], self-testing of a single quantum device [31] and device-independent key distribution [30].

Our results. In this paper we investigate complexity-theoretic aspects of quantum protocols passing the above test of quantumness based on LWE. While the quantum protocol from [7] can clearly be implemented in polynomial time, and while prior works discussed its practical realization and gave some promising numerical estimates on the number of qubits needed for its implementation (for instance, Ref. [7] mentioned 2000 qubits for a protocol providing 50 bits of security), to our knowledge several theoretical aspects, and in particular depth complexity, have not been investigated so far.

We first isolate the main computational task solved by a quantum protocol passing the test. This computational problem, which we denote **StateGeneration**, is presented in Section 3. Informally, it asks to prepare a quantum superposition of an arbitrary vector x and its shift $x - s$, where s denotes the solution of the “noisy” system of linear equations used in the LWE assumption. Our main technical contribution (the formal statement is in Section 3) shows that this problem can be solved by a constant-depth quantum circuit combined with efficient (low-complexity) classical computation:

¹ More precisely, we have the inclusions $\text{NC}_1 \subseteq \text{L} \subseteq \oplus\text{L} \subseteq \text{NC}_2 \subseteq \text{P}$.

² We stress that the quantum protocol that passes the test does not solve the learning with error problem.

³ The proof of this statement relies on the (standard) assumption that the learning with error problem is hard for computationally bounded quantum computation as well.

► **Theorem 1** (Informal version). *The computational task `StateGeneration` can be solved by a constant-depth quantum circuit combined with logarithmic-depth classical computation.*

The model of quantum circuits we consider in Theorem 1 is described formally in Section 2.4 and is reminiscent of some models used in prior works on measurement-based quantum computing (in particular Refs. [15, 16]). The primary motivation for considering this model is as follows: compared with the practical cost of implementing quantum computation, classical computation (and especially low-complexity computation such as logarithmic-depth classical computation) can be considered as a free resource and thus may not be included in the depth complexity. One possible criticism of our model is that the quantum states created by our constant-depth quantum circuits need to be kept coherent while the logarithmic-depth classical computation is performed, which may be an issue since in terms of decoherence waiting is essentially as difficult as performing quantum computation. We can however argue that classical logarithmic-depth classical computation should be implementable significantly faster than logarithmic-depth quantum computation, thus limiting the impact of decoherence.

As mentioned above, `StateGeneration` is the main computational task used in the test of quantumness based on LWE and its applications given in [7, 8, 30, 31] (the other quantum steps indeed only consist in measuring the state generated in an appropriate basis). As a consequence of Theorem 1, the whole test of quantumness and its applications to producing certifiable randomness, self-testing and device-independent key distribution can thus immediately be implemented by constant-depth quantum circuits combined with logarithmic-depth classical computation. For completeness, we describe in detail how to apply our construction with the whole test of quantumness from [7], which was actually only sketched in prior works (since those works focused on applications of the test), in Section 4.

Overview of our techniques. Our main technical contribution is Theorem 1, which shows how to solve `StateGeneration` using constant-depth quantum circuits (in our model allowing some low-complexity classical pre/processing). This is done by modifying the construction of prior works in two major ways.

Our first contribution is to show how to construct in constant depth a quantum state robust against small “noise”. In [7] the construction was done by considering a state with amplitudes taken from a wide-enough Gaussian distribution, and creating this state using the approach from the seminal paper by Regev [36], which itself relied on a technique by Grover and Rudolph [24]. To our knowledge, the resulting construction, while definitely implementable with quantum circuits of polynomial size, does not seem to be implementable in constant depth. Instead, our main idea (see Theorem 9 in Section 3) is to use a quantum state with amplitudes taken from a much simpler distribution (a wide-enough truncated uniform distribution) that can be implemented in constant depth.

The second contribution (Theorem 6 in Section 3) is analyzing carefully how to implement in the quantum setting the map used in the learning with error problem (note that in the quantum setting the map needs to be applied in superposition, which requires a quantum circuit). We observe that when given as input a state robust against small noise, the remaining computational task involves only algebraic operations modulo q , for some large integer q . We then show that prior works by Høyer and Spalek [25] and Takahashi and Tani [38] imply that implementing arithmetic operations modulo q exactly and generating a good approximation of the uniform superposition of all elements of $\{0, 1, \dots, q - 1\}$ can be done using constant-depth quantum circuits if unbounded fanout gates are allowed. We finally show that unbounded fanout gates can be implemented in our model using a technique called gate teleportation [22, 28, 34].

2 Preliminaries

2.1 General notations

In this paper the notation \log represents the logarithm in basis 2. For any integer q , we write $\mathbb{Z}_q = \{0, 1, \dots, q-1\}$. As usual in lattice-based cryptography, we will often identify \mathbb{Z}_q with the set of integers $\{-\lfloor q/2 \rfloor + 1, \dots, \lfloor q/2 \rfloor\}$. For any $a \in \mathbb{Z}_q$, we write $J(a) \in \{0, 1\}^{\lceil \log q \rceil}$ its binary representation, as in [7]. Given a vector $x \in \mathbb{Z}_q^m$, we write $\|x\| = \sqrt{\sum_{i=1}^m |x_i|^2}$ and $\|x\|_\infty = \max_{i \in \{1, \dots, m\}} |x_i|$, and write $J(x) = (J(x_1), \dots, J(x_m)) \in \{0, 1\}^{m \lceil \log q \rceil}$ its binary representation. Given a matrix $A \in \mathbb{Z}_q^{m \times n}$, we define the distance of A as the minimum over all the non-zero vectors $x \in \mathbb{Z}_q^m$, of the quantity $\|Ax\|$.

2.2 Lattice-based cryptography

For a security parameter λ , let m, n, q be integer functions of λ . Let χ be a distribution over \mathbb{Z}_q . The $\text{LWE}_{m,n,q,\chi}$ problem is to distinguish between the distributions $(A, As + e)$ and (A, u) , where $A \in \mathbb{Z}_q^{m \times n}$, $s \in \mathbb{Z}_q^n$ and $u \in \mathbb{Z}_q^m$ are uniformly random and $e \leftarrow \chi^m$. The corresponding hardness assumption is that no polynomial-time algorithm can solve this problem with non-negligible advantage in λ . As in [7], we write $\text{LWE}_{n,q,\chi}$ the task of solving $\text{LWE}_{m,n,q,\chi}$ for any function m that is at most a polynomial in $n \log q$.

The most usual distribution χ used in lattice-based cryptography is the truncated discrete Gaussian distribution, which we now introduce. For any positive integer q and any positive real number B , the truncated discrete Gaussian distribution over \mathbb{Z}_q with parameter B , which we denote $D_{q,B}$, is defined as $D_{q,B}(x) = (e^{-\pi|x|^2/B^2})/\gamma$ if $|x| \leq B$ and $D_{q,B}(x) = 0$ otherwise, for any $x \in \mathbb{Z}_q$, where γ is the normalization factor defined as $\gamma = \sum_{z \in \mathbb{Z}_q, |z| \leq B} e^{-\pi|z|^2/B^2}$.

As in [7], we will use the following theorem to generate instances of the learning with error problem.

► **Theorem 2** (Theorem 2.6 in [7] and Theorem 5.1 in [32]). *Let $m, n \geq 1$ and $q \geq 2$ be such that $m = \Omega(n \log q)$. There is an efficient randomized algorithm $\text{GENTRAP}(1^n, 1^m, q)$ that returns a matrix $A \in \mathbb{Z}_q^{m \times n}$ and a trapdoor t_A such that the distribution of A is negligibly (in n) close to the uniform distribution. Moreover, there is an efficient algorithm INVERT that, on input A , t_A and $Ax + e$ where $x \in \mathbb{Z}_q^n$ is arbitrary, $\|e\| \leq q/(C\sqrt{n \log q})$ and C is a universal constant, returns x with overwhelming probability over $(A, t_A) \leftarrow \text{GENTRAP}(1^n, 1^m, q)$.*

The matrix A generated by $\text{GENTRAP}(1^n, 1^m, q)$ has distance at least $2q/(C\sqrt{n \log q})$ with overwhelming probability. Also note that if $\|e\|_\infty \leq q/(C\sqrt{mn \log q})$, then the inequality $\|e\| \leq q/(C\sqrt{n \log q})$ holds. These two observations motivate the following definition: we define \mathcal{K} as the set of 5-tuples (m, n, q, A, u) such that m, n and q are positive integers, $A \in \mathbb{Z}_q^{m \times n}$ is a matrix of distance at least $2q/(C\sqrt{n \log q})$, where C is the constant from Theorem 2, and $u \in \mathbb{Z}_q^m$ is a vector that can be written as $u = As + e$ for some $s \in \mathbb{Z}_q^n$ and some $e \in \mathbb{Z}_q^m$ with $\|e\|_\infty \leq q/(C\sqrt{mn \log q})$. Informally, the set \mathcal{K} represents the set of good parameters for the version of LWE we will consider. For technical reasons, we also define the following variant, which enables us to set a stronger upper bound on $\|e\|_\infty$. For any $B_V > 0$, we define $\mathcal{K}_{B_V} \subseteq \mathcal{K}$ as the set of 5-tuples $(m, n, q, A, u) \in \mathcal{K}$ such that the following two conditions hold:

- (i) $q \geq B_V C \sqrt{mn \log q}$,
- (ii) u can be written as $u = As + e$ for some $s \in \mathbb{Z}_q^n$ and some $e \in \mathbb{Z}_q^m$ with $\|e\|_\infty \leq B_V$.

2.3 Quantum states: bounded and robust states

We assume that the reader is familiar with the basics of quantum computing and refer to, e.g., [35] for a good reference.

For any positive integer q , we write \mathcal{H}_q the complex Hilbert space of dimension q with basis $\{|x\rangle\}_{x \in \mathbb{Z}_q}$. Quantum states in \mathcal{H}_q are (implicitly) implemented using $\lceil \log q \rceil$ qubits, via the binary encoding of these basis vectors. For any integer $m \geq 1$, we also consider the Hilbert space $\mathcal{H}_q^{\otimes m}$ and associate to it the basis $\{|x\rangle\}_{x \in \mathbb{Z}_q^m}$. A quantum state $|\varphi\rangle$ in $\mathcal{H}_q^{\otimes m}$ can thus be written as $|\varphi\rangle = \sum_{x \in \mathbb{Z}_q^m} \alpha_x |x\rangle$, for complex numbers α_x such that $\sum_{x \in \mathbb{Z}_q^m} |\alpha_x|^2 = 1$. We write its support $\text{supp}(|\varphi\rangle) = \{x \in \mathbb{Z}_q^m \mid \alpha_x \neq 0\}$. We say that $|\varphi\rangle$ has real amplitudes if $\alpha_x \in \mathbb{R}$ for each $x \in \mathbb{Z}_q^m$. For any vector $e \in \mathbb{Z}_q^m$, we write $|\varphi + e\rangle = \sum_{x \in \mathbb{Z}_q^m} \alpha_x |x + e\rangle$, where the addition is performed modulo q .

We now introduce two crucial definitions on which our approach will be based.⁴

► **Definition 3.** *Let B be a positive real number. A quantum state $|\varphi\rangle \in \mathcal{H}_q^{\otimes m}$ is B -bounded if $\|x\|_\infty < B$ for any element $x \in \text{supp}(|\varphi\rangle)$.*

► **Definition 4.** *Let B, ε be two positive real numbers. A quantum state $|\varphi\rangle \in \mathcal{H}_q^{\otimes m}$ is (ε, B) -robust if $|\varphi\rangle$ has real amplitudes and, for any vector $e \in \mathbb{Z}_q^m$ such that $\|e\|_\infty \leq B$, the inequality $\langle \varphi | \varphi + e \rangle \geq 1 - \varepsilon$ holds.*

Finally, given two states $|\varphi\rangle$ and $|\psi\rangle$ in $\mathcal{H}_q^{\otimes m}$, and any positive real number ε , we say that $|\varphi\rangle$ and $|\psi\rangle$ are ε -close if $\| |\varphi\rangle - |\psi\rangle \|^2 \leq \varepsilon$. We also define the notion of ε -closeness to a subspace as follows.

► **Definition 5.** *Let \mathcal{H}' be a subspace of $\mathcal{H}_q^{\otimes m}$ and ε be a positive real number. We say that a state $|\varphi\rangle \in \mathcal{H}_q^{\otimes m}$ is ε -close to \mathcal{H}' if there exists a quantum state $|\psi\rangle \in \mathcal{H}'$ such that $\| |\varphi\rangle - |\psi\rangle \|^2 \leq \varepsilon$.*

2.4 Quantum circuits

Universal sets of quantum gates. As in the standard model of quantum circuits (see, e.g., [35]), in this paper we work with qubits. We consider two sets of elementary gates. We first consider the set $\mathcal{B}_r = \{H, T, CNOT\}$ where $H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ is the Hadamard gate, $T = \begin{pmatrix} 1 & 0 \\ 0 & e^{i\pi/4} \end{pmatrix}$ is the $\pi/8$ -phase operation and $CNOT = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}$ is the controlled-not gate. This is an universal set consisting of a finite number of gates that can approximate any quantum gate with good precision (see Section 4.5.3 of [35] for details). The second set we consider, which we denote \mathcal{B} , contains all the gates acting on 1 qubit and the $CNOT$ operator. Note that this set contains an infinite number of gates.

Our model. We now introduce the class of quantum circuits considered in this paper. Let r_1 and r_2 be two positive integers, and \mathcal{S} be a set of elementary quantum gates (e.g., $\mathcal{S} = \mathcal{B}_r$ or $\mathcal{S} = \mathcal{B}$).

⁴ We stress that these two definitions (as well as several definitions of the previous paragraph) are basis-dependent – we always refer to the canonical basis $\{|x\rangle\}_{x \in \mathbb{Z}_q^m}$. Also note that while Definition 4 can easily be written without the requirement that the state has real amplitude (by replacing $\langle \varphi | \varphi + e \rangle$ by $|\langle \varphi | \varphi + e \rangle|$, for instance), requiring that the state has real amplitudes will be enough for our purpose and will simplify later calculations.

A circuit in the class $\mathcal{C}(\mathcal{S}, r_1, r_2)$ acts on $r_1 + r_2$ qubits. These qubits are initialized to the state $|0\rangle^{\otimes(r_1+r_2)}$. The circuit consists of successive layers. Each layer consists of a constant-depth quantum circuit over the basis \mathcal{S} acting on these $r_1 + r_2$ qubits, which does not contain any measurement, followed by measurements in the computational basis of all the first r_1 qubits. Consider the i -th layer. Let $x_i \in \{0, 1\}^{r_1}$ denote the outcome of measuring the first r_1 qubits at the end of this layer. Then some classical function $f_i: \{0, 1\}^{r_1} \rightarrow \{0, 1\}^{r_1}$ is applied to the x_i , and the value $f_i(x_i)$ is given as input to the first r_1 qubits of the next layer, i.e., the r_1 qubits are reinitialized to the state $|f_i(x_i)\rangle$. We refer to Figure 1 for an illustration.

■ **Figure 1** A quantum circuit of the class \mathcal{C} consisting of three layers. Each rectangular box represents a quantum circuit (without measurements) of constant depth with gates in the set \mathcal{S} .

The complexity of a circuit in the class defined above depends on the number of qubits $r_1 + r_2$, the number of layers and the classical complexity of computing function f_i 's. We are mainly interested in circuits that have a constant number of layers and such that all functions can be computed efficiently classically. We formally define this class below.

We define the class $\mathcal{C}_0(\mathcal{S})$ of families of circuits $\{C_n\}_{n \in \mathbb{N}}$ such that the following conditions hold:

- for each $n \in \mathbb{N}$, we have $C_n \in \mathcal{C}(\mathcal{S}, r_1, r_2)$ for some integers r_1, r_2 such that $r_1 + r_2 = n$;
- for each $n \in \mathbb{N}$, the number of layers in C_n is constant (i.e., independent of n);
- for each $n \in \mathbb{N}$, all the functions f_i 's of C_n can be computed by a $O(\log n)$ -depth classical circuit.

We require that the family is logarithmic-space uniform, i.e., there exists a classical Turing machine that on input 1^n outputs a classical description of C_n (as well as descriptions of the circuits computing the functions f_i 's) in $O(\log n)$ space.

2.5 Clifford circuits and quantum arithmetic

Clifford circuits. Let us consider the Pauli gates $X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ and $Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ and the phase gate $S = \begin{pmatrix} 1 & 0 \\ 0 & i \end{pmatrix}$. A quantum circuit consisting only of gates from the set $\{X, Z, S, H, CNOT\}$ is called a Clifford circuit.⁵ Such a circuit can be implemented by a quantum circuit of class $\mathcal{C}_0(\mathcal{B}_r)$ acting on $\text{poly}(s)$ qubits, where s is the number of gates in the original circuit, via a technique called gate teleportation first introduced by Gottesman and Chuang [22] and then developed into a computational model by Leung [28] and Nielsen [34] (see also, e.g., [9, 26] for good presentations of this technique).

A concrete example, which we will actually heavily use, is the unbounded fanout gate over $\mathcal{H}_2^{\otimes m}$. This unitary gate maps the basis state $|x_1, x_2, \dots, x_{m-1}, x_m\rangle$ to $|x_1, x_1 \oplus x_2, \dots, x_1 \oplus x_{m-1}, x_1 \oplus x_m\rangle$, for any $x_1, \dots, x_m \in \{0, 1\}$. This gate can easily be written as a circuit

⁵ Since $X = S^2$ and $Z = HS^2H$, the two Pauli gates can actually be removed from this gate set.

consisting of $m - 1$ successive CNOT gates (the depth of such a circuit implementation is thus linear in m). Using the above approach, this gate can be implemented by a quantum circuit of class $\mathcal{C}_0(\mathcal{B}_r)$ acting on $\text{poly}(m)$ qubits. A concrete decomposition, which uses only two layers, is presented in Section 6 of [15].

Modular arithmetics. Let us consider the following unitary operations (where the arithmetic operations are performed modulo q and ω is a q -th root of unity):

- the quantum Fourier transform F_q over \mathcal{H}_q , such that $F_q|i\rangle = \frac{1}{\sqrt{q}} \sum_{j=0}^{q-1} \omega^{ij}|j\rangle$ for any $i \in \mathbb{Z}_q$;
- the unitary operation ADD_q over $\mathcal{H}_q^{\otimes 2}$ that maps $|i\rangle|j\rangle$ to $|i\rangle|i+j\rangle$ for any $i, j \in \mathbb{Z}_q$;
- the unitary operation MULT_q over $\mathcal{H}_q^{\otimes 3}$ that maps $|i\rangle|j\rangle|k\rangle$ to $|i\rangle|j\rangle|k+ij\rangle$ for any $i, j, k \in \mathbb{Z}_q$.

We now discuss how to obtain exact implementations for ADD_q and MULT_q , and also for arbitrary linear maps over \mathbb{Z}_q (exact implementation of these gates will be crucial for implementing our test of quantumness in constant depth). Takahashi and Tani [38] showed how to implement exactly ADD_q and MULT_q in constant depth by circuits that use gates in \mathcal{B} and unbounded fanout gates acting on $\text{poly}(\log q)$ qubits, by showing that quantum threshold gates, which are enough to implement all these operations (as first pointed out by Høyer and Spalek [25], based on prior works on classical threshold gates [37]), can be implemented in constant depth by such circuits. Since each unbounded fanout gate can be implemented by a quantum circuit of class $\mathcal{C}_0(\mathcal{B}_r)$ acting on $\text{poly}(\log q)$ qubits, as discussed above, these arithmetic operations can be exactly implemented by quantum circuits of class $\mathcal{C}_0(\mathcal{B})$ acting on $\text{poly}(\log q)$ qubits. As discussed in [25, 38], the same approach can be applied to implement iterated addition, and more generally any linear map $f: \mathbb{Z}_q^n \rightarrow \mathbb{Z}_q$, since such maps can be computed in constant depth using classical threshold gates as well. This can easily be further generalized to give implementation of any linear map $f: \mathbb{Z}_q^n \rightarrow \mathbb{Z}_q^m$ by a quantum circuit of class $\mathcal{C}_0(\mathcal{B})$ acting on $\text{poly}(m, n, \log q)$ qubits.

Unfortunately, it is still unknown if the operator F_q can be implemented exactly in constant depth with a circuit using only elementary gates in \mathcal{B} and unbounded fanout gates (see Section 6 of [38]). For the protocol constructed in this paper, however, we will only need to apply F_q to the state $|0\rangle \in \mathcal{H}_q$, i.e., we only need to prepare the state $F_q|0\rangle = \frac{1}{\sqrt{q}} \sum_{x \in \mathbb{Z}_q} |x\rangle$. Lemma 4.18 in [25] shows that this task can be implemented in constant depth with exponential precision (which will be enough for our purpose): there exists a constant-depth circuit of size $\text{poly}(\log q)$ using gates in \mathcal{B} and unbounded fanout gates that computes a state which is at distance at most $1/q^2$ of the state $F_q|0\rangle$. By converting each unbounded fanout gate, this circuit can immediately be converted into a circuit in the class $\mathcal{C}_0(\mathcal{B})$ acting on $\text{poly}(\log q)$ qubits.

3 Quantum State Generation using Small-Depth Circuits

In this section we describe the main computational task solved by a quantum prover in the test of quantumness based on LWE we present in Section 4 (as well as in prior works [7, 8, 30, 31]), and show how to solve it using a quantum circuit of small depth.

3.1 Statement of the problem

For any $B_V > 0$ and any $k = (m, n, q, A, u) \in \mathcal{K}_{B_V}$, where \mathcal{K}_{B_V} is the set of parameters defined in Section 2.2, let $\Lambda_k \subseteq \mathbb{Z}_q^m$ denote the set of vectors $y \in \mathbb{Z}_q^m$ such that there exists a vector $x \in \mathbb{Z}_q^n$ for which $\|Ax - y\| \leq q/(C\sqrt{n \log q})$. Note that such x is necessarily unique,

since A has distance at least $2q/(C\sqrt{n\log q})$. Let us write this vector x_y . Note that $x_u = s$ using the notations of Section 2.2, i.e., defining s as the (unique) vector in \mathbb{Z}_q^n such that u can be written as $u = As + e$ for $e \in \mathbb{Z}_q^m$ with $\|e\|_\infty \leq B_V$. For any $y \in \Lambda_k$, define the quantum state

$$|\Psi_y\rangle = \frac{1}{\sqrt{2}} (|0\rangle|x_y\rangle + |1\rangle|x_y - x_u\rangle).$$

Let \mathcal{H}_k be the subspace of $\mathcal{H}_2 \otimes \mathcal{H}_q^n \otimes \mathcal{H}_q^m$ generated by the states $\{|\Psi_y\rangle|y\rangle\}_{y \in \Lambda_k}$.

The computational problem we consider in this section, which we denote **StateGeneration**, has two parameters $\varepsilon, B_V > 0$, and is defined as follows. This is the main task solved by the quantum protocols passing our test of quantumness, as well as in the tests used in prior works [7, 8, 30, 31].

StateGeneration(ε, B_V).

Given $k \in \mathcal{K}_{B_V}$, create a quantum state ε -close to \mathcal{H}_k .

Here is our main theorem, which shows that the problem can be solved by a small-depth quantum circuit when q is large enough.

► **Theorem 1** (Formal version). *For any $\varepsilon, B_V > 0$, the problem **StateGeneration**(ε, B_V) can be solved, for all inputs $k \in \mathcal{K}_{B_V}$ such that $q \geq (8mB_VC\sqrt{mn\log q})/\varepsilon$, by a quantum circuit of class $\mathcal{C}_0(\mathcal{B})$ acting on $\text{poly}(m, n, \log q)$ qubits.*

Theorem 1 follows from Theorems 6 and 9 proved in Subsections 3.2 and 3.3.

3.2 Preparation procedure

In this subsection we present and analyze a quantum procedure that outputs a state close to \mathcal{H}_k when given as additional input an appropriate quantum state $|\varphi\rangle \in \mathcal{H}_q^{\otimes m}$. This procedure can be implemented by a small-depth quantum circuit. In subsection 3.3 we will show how to create efficiently such an appropriate state $|\varphi\rangle$.

The following theorem is the main contribution of this subsection.

► **Theorem 6.** *Let ε and B_V be any positive parameters. For any $k \in \mathcal{K}_{B_V}$ with $q \geq \sqrt{2n/\varepsilon}$, there exists a quantum circuit of class $\mathcal{C}_0(\mathcal{B})$ acting on $\text{poly}(m, n, \log q)$ qubits that receives a quantum state $|\varphi\rangle \in \mathcal{H}_q^{\otimes m}$, outputs a quantum state $|\Phi\rangle \in \mathcal{H}_2 \otimes \mathcal{H}_q^n \otimes \mathcal{H}_q^m$, and satisfies the following condition: if $|\varphi\rangle$ is $\frac{q}{C\sqrt{mn\log q}}$ -bounded and $(\varepsilon/2, B_V)$ -robust, then $|\Phi\rangle$ is ε -close to \mathcal{H}_k .*

Proof. We first describe the procedure. Let us write $|\varphi\rangle = \sum_{z \in \mathbb{Z}_q^m} \alpha_z |z\rangle$ the input state, where $\alpha_z \in \mathbb{R}$ for all $z \in \mathbb{Z}_q^m$ (remember that the definition of a robust state implies that the amplitudes are real). The procedure first prepares the state $|0\rangle|0\rangle|\varphi\rangle \in \mathcal{H}_2 \otimes \mathcal{H}_q^{\otimes n} \otimes \mathcal{H}_q^{\otimes m}$ and applies the unitary operator $H \otimes F_q^{\otimes n} \otimes I$ to this state to obtain

$$\frac{1}{\sqrt{2q^n}} \sum_{b \in \{0,1\}} \sum_{x \in \mathbb{Z}_q^n} |b\rangle|x\rangle|\varphi\rangle = \sum_{b \in \{0,1\}} \sum_{x \in \mathbb{Z}_q^n} \sum_{z \in \mathbb{Z}_q^m} \frac{\alpha_z}{\sqrt{2q^n}} |b\rangle|x\rangle|z\rangle.$$

Using the approach discussed in Section 2.5, this can be done by a quantum circuit of class $\mathcal{C}_0(\mathcal{B})$ acting on $\text{poly}(m, n, \log q)$ qubits with approximation error $\frac{n}{q^2} \leq \varepsilon/2$. Below we assume that this state has been done exactly – we will add the approximation error at the very end of the calculation. The procedure then converts this state to the state

$$|\Phi\rangle = \sum_{b \in \{0,1\}} \sum_{x \in \mathbb{Z}_q^n} \sum_{z \in \mathbb{Z}_q^m} \frac{\alpha_z}{\sqrt{2q^n}} |b\rangle|x\rangle|z + f_k(b, x)\rangle,$$

where $f_k: \{0, 1\} \times \mathbb{Z}_q^n \rightarrow \mathbb{Z}_q^m$ is the function defined as $f_k(b, x) = Ax + bu$ for any $(b, x) \in \{0, 1\} \times \mathbb{Z}_q^n$ (all the operations are performed modulo q). This operation can be implemented by a quantum circuit of class $\mathcal{C}_0(\mathcal{B})$ acting on $\text{poly}(m, n, \log q)$ qubits using the approach of Section 2.5 since f_k can be written as a linear map over $\mathbb{Z}_q \times \mathbb{Z}_q^n$ as follows: define the matrix $A' \in \mathbb{Z}_q^{m \times (n+1)}$ obtained by appending the vector u to the left of the matrix A and write $f_k(b, x) = A' \begin{pmatrix} b \\ x \end{pmatrix}$.

We now analyze this procedure. Let us write the output state in the following form:

$$|\Phi\rangle = \frac{1}{\sqrt{2q^n}} \sum_{x \in \mathbb{Z}_q^n} (|0\rangle|x\rangle|\Phi_{0,x}\rangle + |1\rangle|x\rangle|\Phi_{1,x}\rangle),$$

where

$$|\Phi_{0,x}\rangle = \sum_{z \in \mathbb{Z}_q^m} \alpha_z |Ax + z\rangle \quad \text{and} \quad |\Phi_{1,x}\rangle = \sum_{z \in \mathbb{Z}_q^m} \alpha_z |Ax + u + z\rangle = \sum_{z \in \mathbb{Z}_q^m} \alpha_z |A(x + s) + e + z\rangle.$$

Define the quantum state

$$|\Phi'\rangle = \frac{1}{\sqrt{2q^n}} \sum_{x \in \mathbb{Z}_q^n} (|0\rangle|x\rangle|\Phi'_{0,x}\rangle + |1\rangle|x\rangle|\Phi'_{1,x}\rangle),$$

where $|\Phi'_{0,x}\rangle = |\Phi_{0,x}\rangle$ and $|\Phi'_{1,x}\rangle = \sum_{z \in \mathbb{Z}_q^m} \alpha_z |A(x + s) + z\rangle$. We first show that the states $|\Phi\rangle$ and $|\Phi'\rangle$ are close.

▷ **Claim 7.** $\langle \Phi | \Phi' \rangle \geq 1 - \varepsilon/4$.

Proof. We have $u = As + e$ for some $s \in \mathbb{Z}_q^n$ and some vector $e \in \mathbb{Z}_q^m$ such that $\|e\|_\infty \leq B_V$. Since the state $|\varphi\rangle$ is $(\varepsilon/2, B_V)$ -robust, we thus have $\langle \Phi_{1,x} | \Phi'_{1,x} \rangle = \langle \varphi | \varphi + e \rangle \geq 1 - \varepsilon/2$ for any $x \in \mathbb{Z}_q^n$. We thus obtain $\langle \Phi | \Phi' \rangle = \frac{1}{2} + \frac{1}{2q^n} \sum_{x \in \mathbb{Z}_q^n} \langle \Phi_{1,x} | \Phi'_{1,x} \rangle \geq 1 - \varepsilon/4$, as claimed. ◀

We now show that the state $|\Phi'\rangle$ is in \mathcal{H}_k . The crucial property we will use is that the equality $|\Phi'_{0,x}\rangle = |\Phi'_{1,x-s}\rangle$ holds for any $x \in \mathbb{Z}_q^n$.

Let us decompose $|\Phi'\rangle$ as follows:

$$|\Phi'\rangle = \sum_{y \in \mathbb{Z}_q^m} \gamma_y |\Phi'_y\rangle |y\rangle,$$

for quantum states $|\Phi'_y\rangle$ and amplitudes γ_y such that $\sum_{y \in \mathbb{Z}_q^m} |\gamma_y|^2 = 1$. We now show the following claim.

▷ **Claim 8.** For any $y \in \mathbb{Z}_q^m$ such that $|\gamma_y| > 0$, we have $y \in \Lambda_k$ and $|\Phi'_y\rangle = |\Psi_y\rangle$.

Proof. Assume that $|\gamma_y| > 0$. Observe that in this case $y \in \text{supp}(|\Phi'_{0,x_0}\rangle)$ for some $x_0 \in \mathbb{Z}_q^n$. Since the state $|\varphi\rangle$ is $q/(C\sqrt{mn \log q})$ -bounded, we have $\|y - Ax_0\| \leq \sqrt{m} \cdot \|y - Ax_0\|_\infty \leq q/(C\sqrt{n \log q})$, and thus $y \in \Lambda_k$.

We show below that for any distinct $x, x' \in \mathbb{Z}_q^n$ we have $\text{supp}(|\Phi'_{0,x}\rangle) \cap \text{supp}(|\Phi'_{0,x'}\rangle) = \emptyset$, which implies that $|\Phi'_y\rangle = |\Psi_y\rangle$.

Indeed, assume that $\text{supp}(|\Phi'_{0,x}\rangle) \cap \text{supp}(|\Phi'_{0,x'}\rangle) \neq \emptyset$ and take an element r in the intersection. Since the state $|\varphi\rangle$ is B_P -bounded, we have $\|r - Ax\| \leq \sqrt{m} \cdot \|r - Ax\|_\infty \leq q/(C\sqrt{n \log q})$ and $\|r - Ax'\| \leq \sqrt{m} \cdot \|r - Ax'\|_\infty \leq q/(C\sqrt{n \log q})$, and thus $\|A(x - x')\| \leq 2q/(C\sqrt{n \log q})$. This is impossible, since by construction the matrix A has distance at least $2q/(C\sqrt{n \log q})$. ◀

Claim 8 implies that the state $|\Phi'\rangle$ is in \mathcal{H}_k . Since we have $\| |\Phi\rangle - |\Phi'\rangle \|^2 = 2 - 2\langle \Phi | \Phi' \rangle \leq \varepsilon/2$ from Claim 7, this concludes the proof of the theorem (the additional $\varepsilon/2$ term comes from the approximation error in the application of $F_q^{\otimes n}$). ◀

3.3 Creating the initial state

Brakerski et al. [7] have shown how to construct a quantum state that is B_P -bounded and (ε, B_V) -robust, for appropriate parameters $B_V \ll B_P$, using Gaussian distributions. In this subsection we present another quantum state that has similar properties, but can be created by a small-depth quantum circuit.

► **Theorem 9.** *For any $\varepsilon, B_V > 0$, any integer $m \geq 1$ and any $q \geq (8mB_VC\sqrt{mn\log q})/\varepsilon$, there exists a quantum circuit of class $\mathcal{C}_0(\mathcal{B})$ acting on $\text{poly}(m, \log q)$ qubits that generates a quantum state $|\varphi\rangle \in \mathcal{H}_q^{\otimes m}$ that is $\frac{q}{C\sqrt{mn\log q}}$ -bounded and $(\varepsilon/2, B_V)$ -robust.*

Proof. Let us write $r = \left\lceil \log_2 \left(\frac{q}{C\sqrt{mn\log q}} \right) \right\rceil$ and $I = \{-2^{r-1}, \dots, 0, \dots, 2^{r-1} - 1\}$.

We describe the construction. Starting with the quantum state $|0\rangle^{\otimes m} \in \mathcal{H}_q^{\otimes m}$, apply (in parallel) a Hadamard gate on the first r qubits of each copy of $|0\rangle$, in order to get the state

$$\left(\frac{1}{\sqrt{2^r}} \sum_{x \in \{0, \dots, 2^r - 1\}} |x\rangle \right)^{\otimes m}.$$

Then apply on each of the m copies the unitary operator over \mathcal{H}_q that maps $|i\rangle$ to $|i - 2^{r-1}\rangle$ for any $i \in \mathbb{Z}_q$ (the subtraction is done modulo q). As described in Section 2.5, these arithmetic operations can be implemented by a quantum circuit of class $\mathcal{C}_0(\mathcal{B})$ acting on $\text{poly}(m, \log q)$ qubits. This gives the state

$$\left(\frac{1}{\sqrt{2^r}} \sum_{x \in I} |x\rangle \right)^{\otimes m} = \frac{1}{\sqrt{2^{mr}}} \sum_{(x_1, \dots, x_m) \in I^m} |x_1, \dots, x_m\rangle.$$

For any vector $e = (e_1, \dots, e_m) \in \mathbb{Z}_q^m$, consider the state

$$|\varphi + e\rangle = \frac{1}{\sqrt{2^{mr}}} \sum_{(x_1, \dots, x_m) \in I^m} |x_1 + e_1, \dots, x_m + e_m\rangle.$$

The inner product of $|\varphi\rangle$ and $|\varphi + e\rangle$ is $\langle \varphi | \varphi + e \rangle = \frac{|S_e|}{2^{mr}}$, where S_e is the set of vectors $(x_1, \dots, x_m) \in I^m$ such that $(x_1 + e_1, \dots, x_m + e_m) \in I^m$. If $\|e\|_\infty \leq B_V$, then $\{-2^{r-1} + B_V, \dots, 2^{r-1} - 1 - B_V\}^m \subset S_e$ and thus

$$\langle \varphi | \varphi + e \rangle \geq \left(\frac{2^r - 2B_V}{2^r} \right)^m = \left(1 - \frac{B_V}{2^{r-1}} \right)^m \geq 1 - \frac{mB_V}{2^{r-1}} \geq 1 - \frac{4mB_VC\sqrt{mn\log q}}{q} \geq 1 - \varepsilon/2,$$

as claimed. ◀

4 Application: Test of Quantumness

In this section we describe and analyze the test of quantumness based on the LWE assumption that has been implicitly presented in [7], and show how to use the results from Section 3 to pass this test with small-depth quantum circuits.

We first define some sets $G_{s,b,x} \subseteq \{0, 1\}^{n \lceil \log q \rceil}$ exactly as in [7]. The definition is fairly technical and can actually be skipped on a first reading, since we will later only use the property that these sets are dense enough. For any $b \in \{0, 1\}$ and any $x \in \mathbb{Z}_q^n$, let $I_{b,x}: \{0, 1\}^{n \lceil \log q \rceil} \rightarrow \{0, 1\}^n$ be the map such that for any $d \in \{0, 1\}^{n \lceil \log q \rceil}$, each coordinate

of $I_{b,x}(d)$ is obtained by taking the inner product modulo 2 of the corresponding block of $\lceil \log q \rceil$ coordinates of d and of $J(x) \oplus J(x - (-1)^b \mathbf{1})$, where $\mathbf{1}$ denotes the vector in \mathbb{Z}_q^n where each coordinate is $1 \in \mathbb{Z}_q$. We define the set

$$G_{b,x} = \left\{ d \in \{0, 1\}^{n \lceil \log q \rceil} \mid \exists i \in \left\{ b \frac{n}{2}, \dots, b \frac{n}{2} + \frac{n}{2} \right\} : (I_{b,x}(d))_i \neq 0 \right\}.$$

For any $s \in \mathbb{Z}_q^m$, we then define $G_{s,0,x} = G_{0,x} \cap G_{1,x-s}$ and $G_{s,1,x} = G_{0,x+s} \cap G_{1,x}$. Note that these sets are dense: for any $s, x \in \mathbb{Z}_q^n$ and any $b \in \{0, 1\}$, we have $|G_{s,b,x}| \geq (1 - 2 \cdot 2^{-n \lceil \log q \rceil / 4}) 2^{n \lceil \log q \rceil}$.

Our test of quantumness is described in Figure 2. In Subsection 4.1 we explain how to pass the test when q is large enough using a quantum prover that can be implemented in constant depth. In Subsection 4.2 we then show that no classical computationally-bounded prover can pass this test with high probability under the LWE assumption, for a large range of parameters. A concrete test of quantumness can be obtained, for instance, by fixing $\varepsilon = 1/n$, setting $B_L = \Theta(n)$, $m = \Theta(n^2)$, choosing B_V superpolynomial in n and taking $q = \Theta(B_V n^{9/2})$. Theorem 10 shows that a small-depth quantum prover can pass the corresponding test of quantumness with probability close to $1 - 1/n$, while Theorem 11 shows that no polynomial-time classical prover can pass the test with probability significantly larger than $3/4$, under the LWE assumption (the gap between the success probabilities of classical and quantum provers can easily be further amplified using parallel repetitions).

Input: three positive integers m, n, q such that $q \geq B_V C \sqrt{mn \log q}$ holds.

1. The verifier applies the procedure $\text{GENTRAP}(1^n, 1^m, q)$ and gets a pair (A, t_A) . The verifier then takes a vector $s \in \mathbb{Z}_q^n$ uniformly at random, and a vector $e \in \mathbb{Z}_q^m$ by sampling each coordinate independently according to the distribution D_{q, B_V} . The verifier sends the pair $(A, As + e)$ to the prover.
2. The prover sends a vector $y \in \mathbb{Z}_q^m$ to the verifier.
3. The verifier chooses a random bit r uniformly at random and sends it to the prover.
4. If $r = 0$ then the prover sends a pair $(b, x) \in \{0, 1\} \times \mathbb{Z}_q^n$ to the verifier. If $r = 1$ then the prover sends a pair $(c, d) \in \{0, 1\} \times \{0, 1\}^{n \lceil \log q \rceil}$ to the verifier.
5. If $r = 0$ then the verifier accepts if and only if $\|Ax + bu - y\| \leq 2q / (C \sqrt{n \log q})$. If $r = 1$, then the verifier applies the procedure $\text{INVERT}(A, t_A, y)$ and get an output that we denote $x_0 \in \mathbb{Z}_q^n$. The verifier accepts if and only if the three conditions $\|Ax_0 - y\| \leq 2q / (C \sqrt{n \log q})$, $c = d \cdot (J(x_0) \oplus J(x_0 - s))$ and $d \in G_{s,0,x_0}$ all hold.

■ **Figure 2** Test of quantumness. Here $B_V > 0$ is a parameter.

4.1 Quantum protocol

Here is the main result of this subsection.

► **Theorem 10.** *Let ε and B_V be any positive parameters. There exists a quantum prover, which can be implemented by a circuit of class $\mathcal{C}_0(\mathcal{B})$ acting on $\text{poly}(m, n, \log q)$ qubits, that passes the test of Figure 2 with probability at least $1 - 3\sqrt{\varepsilon} - \delta$ for all values (m, n, q) such that $q \geq (8m B_V C \sqrt{mn \log q}) / \varepsilon$, where δ is some negligible function of the parameters.*

Proof. The 5-tuple $(m, n, q, A, As + e)$ is in \mathcal{K}_{B_V} with overwhelming probability (see the discussion after Theorem 2 in Section 2.2). We describe the quantum protocol under this assumption. After receiving the key at Step 1, the prover creates a state $|\varphi\rangle$ that is

59:12 Test of Quantumness with Small-Depth Quantum Circuits

$q/(C\sqrt{mn\log q})$ -bounded and $(\varepsilon/2, B_V)$ -robust using Theorem 9. Then the prover applies Theorem 6 using the state $|\varphi\rangle$ as input, which gives a state $|\Phi\rangle$ that is ε -close to some state in \mathcal{H}_k .

Let us first describe and analyze the remaining of the protocol under the assumption that $|\Phi\rangle$ is in \mathcal{H}_k (instead of being only close to \mathcal{H}_k). The prover measures the rightmost register of $|\Phi\rangle$. Let $y \in \mathbb{Z}_q^m$ denote the measurement outcome. The state after the measurement is

$$|\Psi_y\rangle = \frac{1}{\sqrt{2}} (|0\rangle|x_0\rangle + |1\rangle|x_0 - s\rangle) |y\rangle,$$

where $x_0 \in \mathbb{Z}_q^n$ is such that $\|Ax_0 - y\| \leq q/(C\sqrt{n\log q})$. At Step 2, the prover sends this value y . At Step 4, if the prover received $r = 0$, it measures the first two registers of the above state in the computational basis and simply sends to the verifier the measurement outcome (b, x) . This passes the verifier's check at Step 5 with certainty, since $\|Ax_0 - y\| \leq q/(C\sqrt{n\log q})$ and $A(x_0 - s) + u = Ax_0 + e$, with

$$\|Ax_0 + e - y\| \leq q/(C\sqrt{n\log q}) + \|e\| \leq q/(C\sqrt{n\log q}) + B_V\sqrt{m} \leq 2q/(C\sqrt{n\log q}).$$

If the prover received $r = 1$, it first applies an Hamadard gate on each qubit of the first two registers, which gives the state

$$\left(\frac{1}{2\sqrt{2^n}} \sum_{c \in \{0,1\}} \sum_{d \in \{0,1\}^n} \left((-1)^{J(x_0) \cdot d} + (-1)^{J(x_0 - s) \cdot d + c} \right) |c\rangle|d\rangle \right) |y\rangle.$$

The prover then measures the first two registers, and sends to the verifier the outcome (c, d) . Since (c, d) necessary satisfies the equality $J(x_0) \cdot d \equiv J(x_0 - s) \cdot d + c \pmod{2}$, and $d \in G_{s,0,x_0}$ with overwhelming probability due to the density of $G_{s,0,x_0}$, the verifier's check succeeds at Step 5 with overwhelming probability, i.e., probability at least $1 - \delta$ for some negligible function δ .

Since the actual state $|\Phi\rangle$ is only ε -close to \mathcal{H}_k (instead of being in \mathcal{H}_k as we assumed so far), using the triangular inequality we can conclude that the success probability on the actual state is at least $1 - \delta - \varepsilon - 2\sqrt{\varepsilon} \geq 1 - \delta - 3\sqrt{\varepsilon}$. ◀

4.2 Classical hardness

In this subsection we will use exactly the same parameters and hardness assumption as in [7].

Let λ be a security parameter. All the other parameters are functions of λ . Let q be a prime. Let $\ell, n, m \geq 1$ be polynomially bounded functions of λ , and B_L, B_V be positive integers such that the following conditions hold:

- $n = \Omega(\ell \log q)$ and $m = \Omega(n \log q)$,
- $2\sqrt{n} \leq B_L < B_V \leq q$,
- B_V/B_L is superpolynomial in λ .

Here is the main result of this subsection.

► **Theorem 11.** *Assume a choice of parameters as above. Assume the hardness assumption $\text{LWE}_{\ell,q,D_q,B_L}$ holds. No polynomial-time classical prover can pass the test of Figure 2 with probability greater than $3/4 + \mu$, for some negligible function μ of the security parameter λ .*

Proof. Consider a classical prover that passes the test with probability at least $3/4 + \mu$ for some function μ .

Let us write w the contents of the prover's memory and computation history at the end of Step 2 (note that y can be recovered from w). Let $\mathcal{A}_0(w)$ be the algorithm the prover applies when it receives 0 at Step 3, and $\mathcal{A}_1(w)$ be the algorithm the prover applies when it receives 1. Let consider the following strategy: Apply $\mathcal{A}_0(w)$ to get (b, x) , then rewind the computation and apply $\mathcal{A}_1(w)$ to get (c, d) , and finally output the 4-tuple (b, x, d, c) .

Let $p_0(w)$ denote the probability that the output of $\mathcal{A}_0(w)$ satisfies $\|Ax + bu - y\| \leq 2q/(C\sqrt{n \log q})$, and $p_1(w)$ denote the probability that the output of $\mathcal{A}_1(w)$ satisfies $c = d \cdot (J(x_0) \oplus J(x_0 - s))$ and $d \in G_{s,0,x_0}$. Our assumption implies that $\mathbb{E}_w[p_0(w)/2 + p_1(w)/2] \geq 3/4 + \mu$. Thus the overall probability that $\|Ax + bu - y\| \leq 2q/(C\sqrt{n \log q})$, $c = d \cdot (J(x_0) \oplus J(x_0 - s))$ and $d \in G_{s,0,x_0}$ all hold is at least

$$\mathbb{E}_w[1 - (1 - p_0(w)) - (1 - p_1(w))] = \mathbb{E}_w[(p_0(w) + p_1(w)) - 1] \geq 1/2 + 2\mu.$$

In this case we have $x_0 = x$ if $b = 0$ and $x_0 = x + s$ if $b = 1$, and thus $c = d \cdot (J(x) \oplus J(x - (-1)^b s))$ holds in both cases. Lemma 4.7 in [7], which we state for completeness in Appendix A, guarantees that μ must be negligible. ◀

A The Adaptive Hardcore Bit Lemma

For completeness, we reproduce below the statement of the adaptive hardcore bit lemma from [7] on which the proof of Theorem 11 is based.

► **Lemma 12** (Lemma 4.7 in [7]). *Assume a choice of parameters as in Section 4.2. Assume the hardness assumption $\text{LWE}_{\ell,q,D_q,B_L}$ holds. Let $s \in \{0,1\}^n$. Write*

$$H_s = \{(b, x, d, d \cdot (J(x) \oplus J(x - (-1)^b s)) \mid b \in \{0,1\}, x \in \mathbb{Z}_q^n, d \in G_{s,b,x}\}$$

$$\overline{H}_s = \{(b, x, d, c) \mid (b, x, d, c \oplus 1) \in H_s\}.$$

Consider a pair $(A, As + e)$ generated as follows: generate A using $\text{GENTRAP}(1^n, 1^m, q)$, then take $s \in \{0,1\}^n$ uniformly at random and e by sampling each coordinate independently according to the distribution $D_{\mathbb{Z}_q, B_V}$. Then for any polynomial-time algorithm \mathcal{A} that receives as input the pair $(A, As + e)$ there exists a negligible function $\mu(\lambda)$ such that

$$\left| \Pr[\mathcal{A}(A, As + e) \in H_s] - \Pr[\mathcal{A}(A, As + e) \in \overline{H}_s] \right| \leq \mu(\lambda).$$

On Search Complexity of Discrete Logarithm

Abstract

In this work, we study the discrete logarithm problem in the context of TFNP – the complexity class of search problems with a syntactically guaranteed existence of solutions for all instances. Our main results establish that suitable variants of the discrete logarithm problem are complete for the complexity class PPP, respectively PWPP, i.e., the subclasses of TFNP capturing total search problems with a solution guaranteed by the pigeonhole principle, respectively the weak pigeonhole principle. Besides answering an open problem from the recent work of Sotiraki, Zampetakis, and Zirdelis (FOCS’18), our completeness results for PPP and PWPP have implications for the recent line of work proving conditional lower bounds for problems in TFNP under cryptographic assumptions. In particular, they highlight that any attempt at basing average-case hardness in subclasses of TFNP (other than PWPP and PPP) on the average-case hardness of the discrete logarithm problem must exploit its structural properties beyond what is necessary for constructions of collision-resistant hash functions.

Additionally, our reductions provide new structural insights into the class PWPP by establishing two new PWPP-complete problems. First, the problem DOVE, a relaxation of the PPP-complete problem PIGEON. DOVE is the first PWPP-complete problem not defined in terms of an explicitly shrinking function. Second, the problem CLAW, a total search problem capturing the computational complexity of breaking claw-free permutations. In the context of TFNP, the PWPP-completeness of CLAW matches the known intrinsic relationship between collision-resistant hash functions and claw-free permutations established in the cryptographic literature.

1 Introduction

The discrete logarithm problem (DLP) and, in particular, its conjectured average-case hardness lies at the foundation of many practical schemes in modern cryptography. To day, no significant progress towards a generic efficient algorithm solving DLP has been made (see, e.g., the survey by Joux, Odlyzko, and Pierrot [17] and the references therein).

One of the distinctive properties of DLP is its *totality*, i.e., given a generator g of a cyclic group (G, \star) , we know that a solution x for DLP exists for any target element $t = g^x$ in the group. Thus, the perceived hardness of DLP does not stem from the uncertainty whether a

solution exists but pertains to the search problem itself. In this respect, DLP is not unique – there are various total search problems with unresolved computational complexity in many domains such as algorithmic game theory, computation number theory, and combinatorial optimization, to name but a few. More generally, the complexity of all total search problems is captured by the complexity class TFNP.

In order to improve our understanding of the seemingly disparate problems in TFNP, Papadimitriou [20] suggested to classify total search problems based on syntactic arguments ensuring the existence of a solution. His approach proved to be extremely fruitful and it gave rise to various subclasses of TFNP that cluster many important total search problems. For example,

PPAD: formalizes parity arguments on directed graphs and captures, e.g., the complexity of computing Nash equilibria in bimatrix games [7, 3].

PPA: formalizes parity arguments on *undirected* graphs and captures, e.g., the complexity of Necklace splitting [9].

PPP: formalizes the pigeonhole principle and captures, e.g., the complexity of solving problems related to integer lattices [22].

PWPP: formalizes the *weak* pigeonhole principle and captures, e.g., the complexity of breaking collision-resistant hash functions and solving problems related to integer lattices [22].

DLP and TFNP

DLP seems to naturally fit the TFNP landscape. Though, a closer look reveals a subtle issue regarding its totality stemming from the need to certify that the given element g is indeed a generator of the considered group (\mathbb{G}, \star) or, alternatively, that the target element t lies in the subgroup of (\mathbb{G}, \star) generated by g . If the order $s = |\mathbb{G}|$ of the group (\mathbb{G}, \star) is known then there are two natural approaches. The straightforward approach would be to simply allow additional solutions in the form of distinct $x, y \in [s] = \{0, \dots, s-1\}$ such that $g^x = g^y$. By the pigeonhole principle, either $t = g^x$ for some $x \in [s]$ or there exists such a non-trivial collision $x, y \in [s]$. The other approach would be to leverage the Lagrange theorem that guarantees that the order of any subgroup must divide the order of the group itself. If we make the factorization of the order s of the group a part of the instance then it can be efficiently tested whether g is indeed a generator.

Despite being a prominent total search problem, DLP was not extensively studied in the context of TFNP so far. Only recently, Sotiraki, Zampetakis, and Zirdelis [22] presented a total search problem motivated by DLP. They showed that it lies in the complexity class PPP and asked whether it is complete for the complexity class PPP.

1.1 Our Results

In this work, we study formalizations of DLP as a total search problem and prove new completeness results for the classes PPP and PWPP.

Our starting point is the discrete logarithm problem in “general groups” suggested by Sotiraki et al. [22]. Given the order $s \in \mathbb{Z}$, $s > 1$, we denote by $\mathbb{G} = [s] = \{0, \dots, s-1\}$ the canonical representation of a set with s elements. Any efficiently computable binary operation on \mathbb{G} can be represented by a Boolean circuit $f: \{0, 1\}^l \times \{0, 1\}^l \rightarrow \{0, 1\}^l$ that evaluates the operation on binary strings of length $l = \lceil \log(s) \rceil$ representing the elements of \mathbb{G} . Specifically, the corresponding binary operation \star on \mathbb{G} can be computed by first taking the binary representation of the elements $x, y \in \mathbb{G}$, evaluating f on the resulting strings, and mapping the value back to \mathbb{G} . Note that the binary operation \star induced on \mathbb{G} by f in this way might not satisfy the group axioms and, thus, we refer to (\mathbb{G}, \star) as the induced *groupoid* adopting the terminology for a set with a binary operation common in universal algebra.

Assuming that (\mathbb{G}, \star) is a cyclic group, we might be provided with the representations of the identity element $id \in \mathbb{G}$ and a generator $g \in \mathbb{G}$, which, in particular, enable us to efficiently access the group elements via an indexing function $\mathcal{I}_{\mathbb{G}}: [s] \rightarrow \mathbb{G}$ computed as the corresponding powers of g (e.g. via repeated squaring). An instance of a general DLP is then given by a representation (s, f) inducing a groupoid (\mathbb{G}, \star) together with the identity element $id \in \mathbb{G}$, a generator $g \in \mathbb{G}$, and a target $t \in \mathbb{G}$; a solution for the instance (s, f, id, g, t) is either an index $x \in [s]$ such that $\mathcal{I}_{\mathbb{G}}(x) = t$ or a pair of distinct indices $x, y \in [s]$ such that $\mathcal{I}_{\mathbb{G}}(x) = \mathcal{I}_{\mathbb{G}}(y)$. Note that the solutions corresponding to non-trivial collisions in $\mathcal{I}_{\mathbb{G}}$ ensure totality of the instance irrespective of whether the induced groupoid (\mathbb{G}, \star) satisfies the group axioms – the indexing function $\mathcal{I}_{\mathbb{G}}$ either has a collision or it is a bijection and must have a preimage for any t .

The general DLP as defined above can clearly solve DLP in specific groups with efficient representation such as any multiplicative group \mathbb{Z}_p^* of integers modulo a prime p , which are common in cryptographic applications. On the other hand, it allows for remarkably unstructured instances and the connection to DLP is rather loose – as we noted above, the general groupoid (\mathbb{G}, \star) induced by the instance might not be a group, let alone cyclic. Therefore, we refer to this search problem as INDEX (see Definition 15 in Section 4 for the formal definition).

A priori, the exact computational complexity of INDEX is unclear. Sotiraki et al. [22] showed that it lies in the class PPP by giving a reduction to the PPP-complete problem PIGEON, where one is asked to find a preimage of the 0^n string or a non-trivial collision for a function from $\{0, 1\}^n$ to $\{0, 1\}^n$ computed by a Boolean circuit given as an input. No other upper or lower bound on INDEX was shown in [22]. Given that DLP can be used to construct collision-resistant hash functions [6], it seems natural to ask whether INDEX lies also in the class PWPP, a subclass of PPP defined by the canonical problem COLLISION, where one is asked to find a collision in a shrinking function computed by a Boolean circuit given as an input.

However, a closer look at the known constructions of collision-resistant hash functions from DLP reveals that they crucially rely on the homomorphic properties of the function $g^x = \mathcal{I}_{\mathbb{G}}(x)$. Given that (\mathbb{G}, \star) induced by an arbitrary instance of INDEX does not necessarily possess the structure of a cyclic group, the induced indexing function $\mathcal{I}_{\mathbb{G}}$ is not guaranteed to have any homomorphic properties and it seems unlikely that INDEX could be reduced to any PWPP-complete problem such as COLLISION. In Section 4, we establish that the above intuition is indeed correct since our Theorem 1 shows that INDEX is PPP-complete:

► **Theorem 1.** *INDEX is PPP-complete.*

On the other hand, we show that, by introducing additional types of solutions in the INDEX problem, we can enforce sufficient structure on the induced groupoid (\mathbb{G}, \star) that allows for a reduction to the PWPP-complete problem COLLISION. First, we add a solution type witnessing that the coset of t is not the whole \mathbb{G} , i.e., that $\{t \star a \mid a \in \mathbb{G}\} \neq \mathbb{G}$, which cannot be the case in a group. Specifically, a solution is also any pair of distinct $x, y \in [s]$ such that $t \star \mathcal{I}_{\mathbb{G}}(x) = t \star \mathcal{I}_{\mathbb{G}}(y)$. Second, we add a solution enforcing some form of homomorphism in $\mathcal{I}_{\mathbb{G}}$ with respect to t . Specifically, a solution is also any pair of $x, y \in [s]$ such that $\mathcal{I}_{\mathbb{G}}(x) = t \star \mathcal{I}_{\mathbb{G}}(y)$ and $\mathcal{I}_{\mathbb{G}}(x - y \bmod s) \neq t$. The second type of a solution is motivated by the classical construction of a collision-resistant hash function from DLP by Damgård [6]. Notice that if there are no solutions of the second type then any pair x, y such that $\mathcal{I}_{\mathbb{G}}(x) = t \star \mathcal{I}_{\mathbb{G}}(y)$ gives rise to the preimage of t under $\mathcal{I}_{\mathbb{G}}$ by simply computing $x - y \bmod s$. We refer to the version of INDEX with the additional two types of solutions as DLOG (see Definition 5 in Section 3 for the formal definition), as it is in our opinion close enough to the standard DLP in cyclic groups.

Since DLOG is a relaxation of INDEX obtained by allowing additional types of solutions, it could be the case that we managed to reduce DLOG to COLLISION simply because DLOG is trivial. Note that this is not the case since DLOG is at least as hard as DLP in any cyclic group with an efficient representation, where DLP would naturally give rise to an instance of DLOG with a unique solution corresponding to the solution for the DLP. In Section 3, we establish that DLOG is at least as hard as the problem of finding a non-trivial collision in a shrinking function by proving Theorem 2 that shows that DLOG is PWPP-complete:

► **Theorem 2.** *DLOG is PWPP-complete.*

Implications for cryptographic lower bounds for subclasses of TFNP

It was shown already by Papadimitriou [20] that cryptographic hardness might serve as basis for arguing the existence of average-case hardness in subclasses of TFNP. A recent line of work attempts to show such cryptographic lower bounds for subclasses of TFNP under increasingly more plausible cryptographic hardness assumptions [16, 2, 10, 13, 11, 18, 4, 5, 8, 1, 19, 15]. However, it remains an open problem whether DLP can give rise to average-case hardness in subclasses of TFNP other than PWPP and PPP. Our results highlight that any attempt at basing average-case hardness in subclasses of TFNP (other than PWPP and PPP) on the average-case hardness of the discrete logarithm problem must exploit its structural properties beyond what is necessary for constructions of collision-resistant hash functions.

Witnessing totality of number theoretic problems

In the full version [12], we discuss some of the issues that arise when defining total search problems corresponding to actual problems in computational number theory. First, we highlight some crucial distinctions between the general DLOG as defined in Definition 5 and the discrete logarithm problem in multiplicative groups \mathbb{Z}_p^* . In particular, we argue that the latter is unlikely to be PWPP-complete.

Second, we clarify the extent to which our reductions exploit the expressiveness allowed by the representations of instances of DLOG and INDEX. In particular, both the reduction from COLLISION to DLOG and from PIGEON to INDEX output instances that induce groupoids unlikely to satisfy group axioms and, therefore, do not really correspond to DLP. Additionally, we revisit the problem BLICHFELDT introduced in [22] and show that it also exhibits a similar phenomenon in the context of computational problems on integer lattices.

Alternative characterizations of PWPP

Our PWPP-completeness result for DLOG is established via a series of reductions between multiple intermediate problems, which are thus also PWPP-complete. We believe this characterization will prove useful in establishing further PWPP-completeness results. These new PWPP-complete problems are defined in Section 3 and an additional discussion is provided in Section 5.

2 Preliminaries

We denote by $[m]$ the set $\{0, 1, \dots, m-1\}$, by \mathbb{Z}^+ the set $\{1, 2, 3, \dots\}$ of positive integers, and by \mathbb{Z}_0^+ the set $\{0, 1, 2, \dots\}$ of non-negative integers. For two strings $u, v \in \{0, 1\}^*$, $u \parallel v$ stands for the concatenation of u and v . When it is clear from the context, we omit the operator \parallel , e.g., we write $0x$ instead of $0 \parallel x$. The standard XOR function on binary strings of equal lengths is denoted by \oplus .

Bit composition and decomposition

Throughout the paper, we often make use of the bit composition and bit decomposition functions between binary strings of length k and the set $[2^k]$ of non-negative integers less than 2^k . We denote these functions bc^k and bd^k . Concretely, $\text{bc}^k : \{0, 1\}^k \rightarrow [2^k]$ and $\text{bd}^k : [2^k] \rightarrow \{0, 1\}^k$. Formally, for $x = x_1x_2 \dots x_k \in \{0, 1\}^k$, we define $\text{bc}^k(x) = \sum_{i=0}^{k-1} x_{k-i}2^i$. The function bc^k is bijective and we define the function bd^k as its inverse, i.e., for $a \in [2^k]$, $\text{bd}^k(a)$ computes the unique binary representation of a with leading zeroes such that its length is k . When clear from the context, we omit k and write simply bc and bd to improve readability. At places, we work with the output of bd^k without the leading zeroes. We denote by $\text{bd}_0 : \mathbb{Z}_0^+ \rightarrow \{0, 1\}^*$ the standard function which computes the binary representation without the leading zeroes.

TFNP and some of its subclasses

A *total NP search problem* is a relation $S \subseteq \{0, 1\}^* \times \{0, 1\}^*$ such that: 1) the decision problem whether $(x, y) \in S$ is computable in polynomial-time in $|x| + |y|$, and 2) there exists a polynomial q such that for all $x \in \{0, 1\}^*$, there exists a $y \in \{0, 1\}^*$ such that $(x, y) \in S$ and $|y| \leq q(|x|)$. The class of all total NP search problems is denoted by TFNP.

Let $S, T \subseteq \{0, 1\}^* \times \{0, 1\}^*$ be total search problems. A *reduction from S to T* is a pair of polynomial-time computable functions $f, g : \{0, 1\}^* \rightarrow \{0, 1\}^*$ such that, for all $x, y \in \{0, 1\}^*$ if $(f(x), y) \in T$ then $(x, g(y)) \in S$. In case there exists a reduction from S to T , we say that *S is reducible to T* . The above corresponds to so-called polynomial-time many-one (or Karp) reductions among decision problems in the context of search problems. In the rest of the paper, we consider only such reductions.

► **Definition 3** (PIGEON problem and PPP [20]).

INSTANCE: A Boolean circuit C with n inputs and n outputs.

SOLUTION: One of the following:

1. a string $u \in \{0, 1\}^n$ such that $C(u) = 0^n$,
2. distinct strings $u, v \in \{0, 1\}^n$ such that $C(u) = C(v)$.

The class of all total search problems reducible to PIGEON is called PPP.

► **Definition 4** (COLLISION problem and PWPP [16]).

INSTANCE: A Boolean circuit C with n inputs and m outputs with $m < n$.

SOLUTION: Distinct strings $u, v \in \{0, 1\}^n$ such that $C(u) = C(v)$.

The class of all total search problems reducible to COLLISION is called PWPP.

3 DLog is PWPP-complete

In this section, we define DLOG, a total search problem associated to DLP and show that it is PWPP-complete. Our reductions give rise to additional new PWPP-complete problems DOVE and CLAW, which we discuss further in Section 5.

Similarly to Sotiraki et al. [22], we represent a binary operation on $\mathbb{G} = [s] = \{0, \dots, s-1\}$ by a Boolean circuit $f : \{0, 1\}^l \times \{0, 1\}^l \rightarrow \{0, 1\}^l$, where $l = \lceil \log(s) \rceil$. Given such a representation (s, f) , we define a binary operator $f_{\mathbb{G}} : [s] \times [s] \rightarrow [2^l]$ for all $x, y \in [s]$ as $f_{\mathbb{G}}(x, y) = \text{bc}(f(\text{bd}(x), \text{bd}(y)))$. We denote by (\mathbb{G}, \star) the groupoid induced by f , where $\star : [s] \times [s] \rightarrow [s]$ is the binary operation closed on $[s]$ obtained by extending the operator $f_{\mathbb{G}}$ in some fixed way, e.g., by defining $x \star y = 1$ for all $x, y \in [s]$ such that $f_{\mathbb{G}}(x, y) \notin [s]$.

■ **Algorithm 1** Computation of the x -th power of the generator $g \in [s]$ of a groupoid (\mathbb{G}, \star) of size $s \in \mathbb{Z}_0^+$ induced by $f: \{0, 1\}^{2^{\lceil \log(s) \rceil}} \rightarrow \{0, 1\}^{\lceil \log(s) \rceil}$ with identity $id \in [s]$.

```

1: procedure  $\mathcal{I}_{\mathbb{G}}(x)$ 
2:    $(x_m, \dots, x_1) \leftarrow \text{bd}_0(x)$ 
3:    $r \leftarrow \text{bd}(id)$ 
4:    $g \leftarrow \text{bd}(g)$ 
5:   for  $i$  from  $m$  to 1 do
6:      $r \leftarrow f(r, r)$ 
7:     if  $x_i = 1$  then
8:        $r \leftarrow f(g, r)$ 
9:     end if
10:  end for
11:  return  $\text{bc}(r)$ 
12: end procedure

```

If the induced groupoid (\mathbb{G}, \star) was a cyclic group then we could find the indices of the identity element $id \in [s]$ and a generator $g \in [s]$. Moreover, we could use g to index the elements of the group (\mathbb{G}, \star) , e.g., in the order of increasing powers of g , and the corresponding *indexing function* $\mathcal{I}_{\mathbb{G}}: [s] \rightarrow [2^l]$ would on input x return simply the x -th power of the generator g . We fix a canonical way of computing the x -th power using the standard square-and-multiply method as defined in Algorithm 1. The algorithm first computes $(x_m, x_{m-1}, \dots, x_1) = \text{bd}_0(x)$, i.e., the binary representation of the exponent x without the leading zeroes for some $m \leq l$, and it then proceeds with the square-and-multiply method using the circuit f . As explained above, f implements the binary group operation. Hence, $f(r, r)$ corresponds to squaring the intermediate value r and $f(g, r)$ corresponds to multiplication of the intermediate value r by the generator g .

With the above notation in place, we can give the formal definition of DLOG.

► **Definition 5** (DLOG problem).

INSTANCE: A size parameter $s \in \mathbb{Z}^+$ such that $s \geq 2$ and a Boolean circuit $f: \{0, 1\}^{2^{\lceil \log(s) \rceil}} \rightarrow \{0, 1\}^{\lceil \log(s) \rceil}$ representing a groupoid (\mathbb{G}, \star) , and indices $id, g, t \in [s]$.

SOLUTION: One of the following:

1. $x \in [s]$ such that $\mathcal{I}_{\mathbb{G}}(x) = t$,
2. $x, y \in [s]$ such that $f_{\mathbb{G}}(x, y) \geq s$,
3. $x, y \in [s]$ such that $x \neq y$ and $\mathcal{I}_{\mathbb{G}}(x) = \mathcal{I}_{\mathbb{G}}(y)$,
4. $x, y \in [s]$ such that $x \neq y$ and $f_{\mathbb{G}}(t, \mathcal{I}_{\mathbb{G}}(x)) = f_{\mathbb{G}}(t, \mathcal{I}_{\mathbb{G}}(y))$,
5. $x, y \in [s]$ such that $\mathcal{I}_{\mathbb{G}}(x) = f_{\mathbb{G}}(t, \mathcal{I}_{\mathbb{G}}(y))$ and $\mathcal{I}_{\mathbb{G}}(x - y \bmod s) \neq t$.

The first type of a solution in DLOG corresponds to the discrete logarithm of t . Since we cannot efficiently verify that the input instance represents a group with the purported generator g , additional types of a solution had to be added in order to guarantee that DLOG is total. Note that any solution of these additional types witnesses that the instance does not induce a group, since for a valid group these types cannot happen. Nevertheless, the first three types of a solution are sufficient to guarantee the totality of DLOG. The last two types of a solution make DLOG to lie in the class PWPP and are crucial for correctness of our reduction from DLOG to COLLISION presented in Section 3.2. In Section 5, we provide further discussion of DLOG and some possible alternative definitions.

In Section 3.1, we show that DLOG is PWPP-hard. In Section 3.2, we show that DLOG lies in PWPP. Therefore, we prove Theorem 2.

► **Theorem 2.** *DLOG is PWPP-complete.*

3.1 DLog is PWPP-hard

To show that DLOG is PWPP-hard, we reduce to it from the PWPP-complete problem COLLISION (see Definition 4). Given an instance $C: \{0, 1\}^n \rightarrow \{0, 1\}^{n-1}$ of COLLISION, our reduction to DLOG defines a representation (s, f) of a groupoid (\mathbb{G}, \star) and the elements id, g , and t such that we are able to extract some useful information about C from any non-trivial collision $\mathcal{I}_{\mathbb{G}}(x) = \mathcal{I}_{\mathbb{G}}(y)$ in the indexing function $\mathcal{I}_{\mathbb{G}}$ computed by Algorithm 1. The main obstacle that we need to circumvent is that, even though the computation performed by $\mathcal{I}_{\mathbb{G}}$ employs the circuit f representing the binary operation in the groupoid, it has a very restricted form. In particular, we need to somehow define f using C so that there are no collisions in $\mathcal{I}_{\mathbb{G}}$ unrelated to solutions of the instance of COLLISION. To sidestep some of the potential issues when handling an arbitrary instance of COLLISION, we reduce to DLOG from an intermediate problem we call DOVE.

► **Definition 6** (DOVE problem).

INSTANCE: A Boolean circuit C with n inputs and n outputs.

SOLUTION: One of the following:

1. a string $u \in \{0, 1\}^n$ such that $C(u) = 0^n$,
2. a string $u \in \{0, 1\}^n$ such that $C(u) = 0^{n-1}1$,
3. distinct strings $u, v \in \{0, 1\}^n$ such that $C(u) = C(v)$,
4. distinct strings $u, v \in \{0, 1\}^n$ such that $C(u) = C(v) \oplus 0^{n-1}1$.

It is immediate that DOVE is a relaxation of PIGEON (cf. Definition 3) with two additional new types of a solution – the cases 2 and 4 in the above definition. Similarly to case 1, case 2 corresponds to a preimage of a fixed element in the range. Case 4 corresponds to a pair of strings such that their images under C differ only on the last bit. Permutations for which it is computationally infeasible to find inputs with evaluations differing only on a prescribed index appeared in the work of Zheng, Matsumoto, and Imai [23] under the term *distinction-intractable* permutations. Zheng et al. showed that distinction-intractability is sufficient for collision-resistant hashing. Note that we employ distinction-intractability in a different way than [23]. In particular, their construction of collision-resistant hash from distinction-intractable permutations could be leveraged towards a reduction from DOVE to COLLISION (proving DOVE is contained in PWPP) – we use DOVE as an intermediate problem when reducing from COLLISION to DLOG (proving PWPP-hardness of DLOG). In the overview of the reduction from DOVE to DLOG below, we explain why distinction-intractability seems as a natural choice for our definition of DOVE.

Reducing Dove to DLog

Let $C: \{0, 1\}^n \rightarrow \{0, 1\}^{n-1}$ be an arbitrary instance of DOVE. Our goal is to construct an instance $G = (s, f, id, g, t)$ of DLOG such that any solution to G provides a solution to the original instance C of DOVE. The key step in the construction of G is a suitable choice of the circuit f since it defines both $\mathcal{I}_{\mathbb{G}}$ and $f_{\mathbb{G}}$. Our initial observation is that, by the definition of $\mathcal{I}_{\mathbb{G}}$ (Algorithm 1), the circuit f is only applied on specific types of inputs during the computation of $\mathcal{I}_{\mathbb{G}}(x)$. Specifically:

- In each loop, $f(r, r)$ is computed for some $r \in \{0, 1\}^*$. We denote f restricted to this type of inputs by f_0 , i.e., $f_0(r) = f(r, r)$.
- If the corresponding bit of x is one then $f(g, r)$ is computed with fixed $g \in \{0, 1\}^*$ and some $r \in \{0, 1\}^*$. We denote f restricted to this type of inputs by f_1 , i.e., $f_1(r) = f(g, r)$.

Hence, using the above notation, the computation of $\mathcal{I}_G(x)$ simply corresponds to an iterated composition of the functions f_0 and f_1 depending on the binary representation of x evaluated on id (e.g., $\mathcal{I}_G(\text{bc}(101)) = f_1 \circ f_0 \circ f_0 \circ f_1 \circ f_0(\text{bd}(id))$). Exploiting the observed structure of the computation of \mathcal{I}_G , our approach is to define f_0 and f_1 (i.e., the corresponding part of f) using the circuit C so that we can extract some useful information about C from any non-trivial collision $\mathcal{I}_G(x) = \mathcal{I}_G(y)$ (i.e., from a solution to DLOG, case 3).

The straightforward option is to set $f_0(r) = f_1(r) = C(r)$ for all $r \in \{0, 1\}^n$. Unfortunately, such an approach fails since for all distinct $u, v \in \{0, 1\}^n$ with Hamming weight l , there would be an easy to find non-trivial collision $x = \text{bc}(u)$ and $y = \text{bc}(v)$ of the form $\mathcal{I}_G(x) = \text{bc}(C^{n+l}(id)) = \mathcal{I}_G(y)$, which might not provide any useful information about the circuit C . Hence, we define f_0 and f_1 such that $f_0 \neq f_1$.

On a high level, we set $f_0(r) = C(r)$ and $f_1(r) = C(h(r))$ for some function $h: \{0, 1\}^n \rightarrow \{0, 1\}^n$ that is not the identity as in the flawed attempt above. Then, except for some special case, a non-trivial collision $\mathcal{I}_G(x) = \mathcal{I}_G(y)$ corresponds to the identity $C(C(u)) = C(h(C(v)))$ for some $u, v \in \{0, 1\}^n$, which are not necessarily distinct. In particular, if $C(u) \neq h(C(v))$ then the pair of strings $C(u), h(C(v))$ forms a non-trivial collision for C . Otherwise, we found a pair u, v such that $C(u) = h(C(v))$ that, for the choice $h(y) = y \oplus 0^{n-1}1$, translates into $C(u) = C(v) \oplus 0^{n-1}1$, i.e., a pair of inputs breaking distinction-intractability of C , and corresponds to the fourth type of a solution in DOVE. Finally, the second type of a solution in DOVE captures the special case when there is no pair u, v such that $C(C(u)) = C(h(C(v)))$. The formal reduction from DOVE to DLOG establishing Lemma 7 below is given in the full version [12].

► **Lemma 7.** *DOVE is reducible to DLOG.*

PWPP-hardness of Dove. Next, we show that, by introducing additional types of solutions into the definition of PIGEON, we do not make the corresponding search problem too easy – DOVE is at least as hard as any problem in PWPP. Our reduction from COLLISION to DOVE is rather syntactic and natural. In particular, it results in instances of DOVE with only one type of solutions corresponding to collisions of the original instance of COLLISION. For the formal proof, see the full version [12].

► **Lemma 8.** *COLLISION is reducible to DOVE.*

Lemma 7 and Lemma 8 imply PWPP-hardness of DLOG as stated in the corollary below.

► **Corollary 9.** *DLOG is PWPP-hard.*

3.2 DLog Lies in PWPP

In order to establish that DLOG lies in PWPP, we build on the existing cryptographic literature on constructions of collision-resistant hash functions from the discrete logarithm problem. Specifically, we mimic the classical approach by Damgård [6] to first construct a family of *claw-free permutations* based on DLP and then define a collision-resistant hash using the family of claw-free permutations.¹ Recall that a family of claw-free permutations is an efficiently sampleable family of pairs of permutations such that given a “random” pair

¹ In principle, it might be possible to adapt any alternative known construction of collision-resistant hash from DLP such as the one of Ishai, Kushilevitz, and Ostrovsky [14], which goes through the intermediate object of *homomorphic one-way commitments*. However, this would necessitate not only the corresponding changes in the definition of DLOG but also an alternative proof of its PWPP-hardness.

h_0 and h_1 of permutations from the family, it is computationally infeasible to find a *claw* for the two permutations, i.e., inputs u and v such that $h_0(u) = h_1(v)$. We formalize the corresponding total search problem, which we call **CLAW**, below.

► **Definition 10** (**CLAW problem**).

INSTANCE: Two Boolean circuits h_0, h_1 with n inputs and n outputs.

SOLUTION: One of the following:

1. two strings $u, v \in \{0, 1\}^n$ such that $h_0(u) = h_1(v)$,
2. two distinct strings $u, v \in \{0, 1\}^n$ such that $h_0(u) = h_0(v)$,
3. two distinct strings $u, v \in \{0, 1\}^n$ such that $h_1(u) = h_1(v)$.

The first type of a solution in **CLAW** corresponds to finding a claw for the pair of functions h_0 and h_1 . As we cannot efficiently certify that both h_0 and h_1 are permutations, we introduce the second and third type of solutions which witness that one of the functions is not bijective. In other words, the second and third type of solution ensure the totality of **CLAW**.

Similarly to [6], our high-level approach when reducing from **DLOG** to **COLLISION** is to first reduce from **DLOG** to **CLAW** and then from **CLAW** to **COLLISION**. Although, we cannot simply employ his analysis since we have no guarantee that 1) the groupoid induced by an arbitrary **DLOG** instance is a cyclic group and 2) that an arbitrary instance of **CLAW** corresponds to a pair of permutations. It turns out that the second issue is not crucial. It was observed by Russell [21] that the notion of claw-free *pseudopermutations* is sufficient for collision-resistant hashing. Our definition of **CLAW** corresponds exactly to the worst-case version of breaking claw-free pseudopermutations as defined by [21]. As for the first issue, we manage to provide a formal reduction from **DLOG** to **GENERAL-CLAW**, a variant of **CLAW** defined below.

► **Definition 11** (**GENERAL-CLAW problem**).

INSTANCE: Two Boolean circuits h_0, h_1 with n inputs and n outputs and $s \in \mathbb{Z}^+$ such that $1 \leq s < 2^n$.

SOLUTION: One of the following:

1. two strings $u, v \in \{0, 1\}^n$ such that $\text{bc}(u) < s$, $\text{bc}(v) < s$ and $h_0(u) = h_1(v)$,
2. two distinct strings $u, v \in \{0, 1\}^n$ such that $h_0(u) = h_0(v)$,
3. two distinct strings $u, v \in \{0, 1\}^n$ such that $h_1(u) = h_1(v)$,
4. a string $u \in \{0, 1\}^n$ such that $\text{bc}(u) < s$ and $\text{bc}(h_0(u)) \geq s$,
5. a string $u \in \{0, 1\}^n$ such that $\text{bc}(u) < s$ and $\text{bc}(h_1(u)) \geq s$.

The main issue that necessitates the introduction of additional types of a solution in the definition of **GENERAL-CLAW** (compared to **CLAW**) is that the possible solutions to an instance of **DLOG** are not from the whole domain $[2^n]$ but they must lie in $[s]$.

The formal reductions proving Lemma 12 and Lemma 13 below are presented in the full version [12]. The two lemmata establish Corollary 14, which concludes the proof of Theorem 2.

► **Lemma 12.** *DLOG is reducible to GENERAL-CLAW.*

► **Lemma 13.** *GENERAL-CLAW is reducible to COLLISION.*

► **Corollary 14.** *DLOG is contained in PWPP.*

4 Index is PPP-complete

In this section, we study the complexity of a more restricted version of DLOG that we call INDEX. In the definition of INDEX, we use the notation from Section 3 introduced for the definition of DLOG. In particular, the function \mathcal{I}_G is the same as defined in Algorithm 1.

► **Definition 15** (INDEX problem).

INSTANCE: A size parameter $s \in \mathbb{Z}^+$ such that $s \geq 2$ and a Boolean circuit $f: \{0, 1\}^{2^{\lceil \log(s) \rceil}} \rightarrow \{0, 1\}^{\lceil \log(s) \rceil}$ representing a groupoid (G, \star) and indices $g, id, t \in [s]$.

SOLUTION: One of the following:

1. $x \in [s]$, such that $\mathcal{I}_G(x) = t$,
2. $x, y \in [s]$, such that $x \neq y$ and $f_G(x, y) \geq s$,
3. $x, y \in [s]$, such that $x \neq y$ and $\mathcal{I}_G(x) = \mathcal{I}_G(y)$.

It is immediate that DLOG is a relaxation of INDEX due to the additional types of solutions. In Section 4.1, we show that INDEX is PPP-hard. In Section 4.2, we show that INDEX lies in PPP. Therefore, we prove PPP-completeness of INDEX.

► **Theorem 1.** *INDEX is PPP-complete.*

4.1 Index is PPP-hard

The formal reduction from the PPP-complete problem PIGEON to INDEX is arguably the most technical. Given an instance $C: \{0, 1\}^n \rightarrow \{0, 1\}^n$ of PIGEON, the main idea is to define an instance $G = (s, f, id, g, t)$ of INDEX such that the induced indexing function \mathcal{I}_G carefully “emulates” the computation of the circuit C – so that any solution to G provides a solution to the original instance C of PIGEON. In order to achieve this, we exploit the structure of the computation induced by \mathcal{I}_G in terms of evaluations of the circuit f representing the binary operation in the groupoid (G, \star) . Specifically, the computation of \mathcal{I}_G gives rise to a tree labeled by the values output by \mathcal{I}_G and structured by the two special types of calls to f (i.e., squaring the intermediate value or multiplying it by the generator). Our reduction constructs f inducing \mathcal{I}_G with the computation corresponding to a sufficiently large such tree so that its leaves can represent all the possible inputs for the instance C of PIGEON and the induced indexing function \mathcal{I}_G outputs the corresponding evaluation of C at each leaf. Moreover, for the remaining nodes in the tree, \mathcal{I}_G results in a bijection to ensure there are no additional solutions of the constructed instance of INDEX that would be unrelated to the original instance of PIGEON. Below, we provide additional details of the ideas behind the formal reduction given in the full version [12].

Similarly to the reduction from DOVE to DLOG, the key step in our construction of G is a suitable choice of the circuit f since it determines the function \mathcal{I}_G . Recall the notation for f_0 and f_1 introduced in the reduction from DOVE to DLOG, i.e., $f_0(r) = f(r, r)$ and $f_1(r) = f(g, r)$. We start by describing a construction of an induced groupoid (G, \star) independent of the instance C of PIGEON but which serves as a natural step towards our reduction.

Constructing bijective \mathcal{I}_G

Our initial goal in the first construction is to define f_0 and f_1 and the elements $id, g \in [s]$ such that \mathcal{I}_G is the identity function, i.e., such that $\mathcal{I}_G(a) = a$ for all $a \in [s]$. To this end, our key observation is that, for many pairs of inputs $a, b \in [s]$, the computation of $\mathcal{I}_G(b)$ includes the whole computation of $\mathcal{I}_G(a)$ as a prefix (see Algorithm 1), e.g., for all $a, b \in [s]$ such that

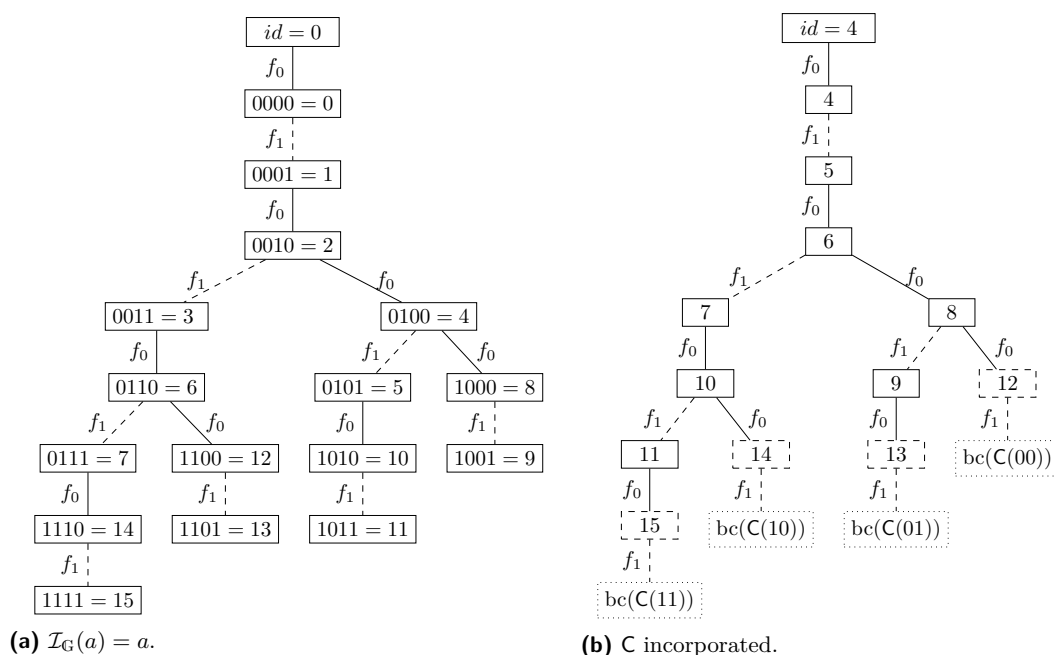

Figure 1 Trees induced by the computation of \mathcal{I}_G .

- either $bd_0(a)$ is a prefix of $bd_0(b)$
- or $bd_0(a) = y|0$ and $bd_0(b) = y|1$ for some $y \in \{0, 1\}^*$.

Specifically, if $bd_0(a) = y|0$ then $\mathcal{I}_G(a) = bc(f_0(bd(\mathcal{I}_G(bc(y)))))$, and if $bd_0(a) = y|1$ then $\mathcal{I}_G(a) = bc(f_1(bd(\mathcal{I}_G(bc(y|0)))))$.

Thus, we can capture the whole computation of \mathcal{I}_G on all the possible inputs from \mathbb{G} via a tree representing the successive calls to f_0 and f_1 based on the bit decomposition $bd_0(a)$ of the input a without the leading zeroes. In Figure 1a, we give a tree induced by the computation of \mathcal{I}_G in a groupoid of order $s = 16$ with $id = 0$. Solid lines correspond to the application of f_0 and dotted lines to application of f_1 . Except for the root labeled by the identity element id , each node of the tree corresponds to the point at which \mathcal{I}_G terminates on the corresponding input $a \in [s]$, where the second value in the label of the node is the input a and the first value is $bd(a)$, i.e., the binary representation of a with the leading zeroes.

Note that Figure 1a actually suggests which functions f_0 and f_1 induce \mathcal{I}_G such that $\mathcal{I}_G(a) = a$ for all $a \in [s]$. In particular, Algorithm 1 initializes the computation of \mathcal{I}_G with $r = bd(id) = bd(0) = 0^n$ and, thus, the desired traversal of the computation tree is achieved for all inputs $a \in [s]$ by 1) f_0 that performs a cyclic shift of the input r to the left and 2) f_1 that flips the last bit of the input r .

Similarly, the above observation allows to construct f'_0 and f'_1 such that for all $a \in [s]$ that $\mathcal{I}_G(a) = a + b \pmod s$ for some fixed $b \in [s]$, which can be performed simply by setting $id = b$ and consistently “shifting” the intermediate value r by the bit decomposition of the fixed value b before and after application of the above functions f_0 and f_1 .

Incorporating the Pigeon instance

The issue which makes it non-trivial to reduce from PIGEON to INDEX is that the functions f_0 and f_1 inducing the groupoid (\mathbb{G}, \star) are oblivious to the actual progress of the computation performed by \mathcal{I}_G . The above discussion shows that we have some level of control over the

60:12 On Search Complexity of Discrete Logarithm

computation of \mathcal{I}_G . However, it is a priori unclear how to meaningfully incorporate the PIGEON instance C into the above construction achieving that $\mathcal{I}_G(a) = a$ for all $a \in [s]$. For example, we cannot simply allow f_0 or f_1 to output $C(r)$ while at some internal node in the computation tree of \mathcal{I}_G as this would completely break the global structure of \mathcal{I}_G on the node and all its children and, in particular, could induce collisions in \mathcal{I}_G unrelated to the collisions in C . However, we can postpone the application of C to the leaves of the tree since, for all inputs a corresponding to a leaf in the tree, the computation of $\mathcal{I}_G(a)$ is not a part of the computation for $\mathcal{I}_G(b)$ for another input b .

Given that we are restricted to the leaves of the computation tree when embedding the computation of C into \mathcal{I}_G , we must work with a big enough tree in order to have as many leaves as the 2^n possible inputs of the circuit $C: \{0, 1\}^n \rightarrow \{0, 1\}^n$. In other words, the instance of INDEX must correspond to a groupoid of order s strictly larger than n . Note that for $s = 2^k$, the leaves of the tree correspond exactly to the inputs for \mathcal{I}_G from the set

$$A_o = \{a \in [2^k] \mid \exists y \in \{0, 1\}^{k-2}: \text{bd}(a) = 1\|y\|1\},$$

i.e., the set of *odd* integers between 2^{k-1} and 2^k , which has size 2^{k-2} . Thus, in our construction, we set $s = 2^{n+2}$ to ensure that there are 2^n leaves that can represent the domain of C .

Our goal is to define \mathcal{I}_G so that its restriction to the internal nodes of the tree (non-leaves) is a bijection between $[2^{n+2}] \setminus A_o$ and $[2^{n+2}] \setminus [2^n]$. In other words, when evaluated on any internal node of the tree, \mathcal{I}_G avoids the values in $[2^n]$ corresponding to bit composition of the elements in the range of C . If we manage to induce such \mathcal{I}_G then there are no non-trivial collisions in \mathcal{I}_G involving the internal nodes – the restrictions of \mathcal{I}_G to A_o and to its complement $[2^{n+2}] \setminus A_o$ would have disjoint images and, by the bijective property of the restriction to the internal nodes of the tree, any collision in \mathcal{I}_G would be induced by a collision in C . Our construction achieves this goal by starting with f_0 and f_1 inducing \mathcal{I}_G such that, for all $a \in [2^{n+2}]$, it holds that $\mathcal{I}_G(a) = a + 2^n \pmod{2^{n+2}}$, which we already explained above.

Note that the image of the restriction of \mathcal{I}_G to the set

$$A_e = \{a \in [2^{n+2}] \mid \exists y \in \{0, 1\}^n: \text{bd}(a) = 1\|y\|0\},$$

i.e., the set of *even* integers between 2^{n+1} and 2^{n+2} , has non-empty intersection with integers in $[2^n]$ corresponding to the range of C . Nevertheless, it is possible to locally alter the behaviour of f_0 and f_1 on A_e so that \mathcal{I}_G does not map to $[2^n]$ when evaluated on A_e . Then, we adjust the definition of f_0 and f_1 such that for all inputs $a \in A_o$ corresponding to a leaf of the tree, $\mathcal{I}_G(a) = \text{bc}(C(h(a)))$ for some bijection h between A_o and $\{0, 1\}^n$ (a natural choice is simply the function that drops the first and the last bit from the binary decomposition $\text{bd}(a)$ of a). Finally, we set the target in the resulting instance of INDEX to $t = 0$ to ensure that the preimage of t under \mathcal{I}_G corresponds exactly to a preimage of 0^n under C .

In Figure 1b, we illustrate the computation tree of \mathcal{I}_G corresponding to an instance of INDEX produced by our reduction on input $C: \{0, 1\}^n \rightarrow \{0, 1\}^n$ for $n = 2$. Accordingly, G is of size $s = 2^{n+2} = 16$ and its elements are represented by the nodes of the tree. When compared with the tree in Figure 1a, the label of each node in Figure 1b equals the value $\mathcal{I}_G(a)$, where a is the second value in the label of the node at the same position in the tree in Figure 1a. Nodes belonging to $[2^s] \setminus A_e \cup A_o$, A_e , and A_o are highlighted by differing styles of edges. Specifically, the labels of nodes with a solid edge correspond to evaluations of the inputs from $[2^{n+1}] = [8]$, the labels of nodes with a dashed edge correspond to evaluations of the inputs from A_e , and the labels of nodes with a dotted edge correspond to the evaluations

of the inputs from A_o . Since the image of $bc \circ C$ is $[2^n] = [4]$, it is straightforward to verify that any collision in \mathcal{I}_G depicted in Figure 1b must correspond to a collision in C and that any preimage of $t = 0$ under \mathcal{I}_G corresponds directly to a preimage of 0^n under C .

The formal reduction establishing Lemma 16 is given in the full version [12].

► **Lemma 16.** *PIGEON is reducible to INDEX.*

4.2 Index Lies in PPP

The main idea of our reduction from INDEX to PIGEON is analogous to the reduction in [22] from their discrete logarithm problem in “general groups” to PIGEON. Although, we need to handle the additional second type of a solution for INDEX, which corresponds to f_G outputting an element outside G . The formal reduction proving Lemma 17 is given in the full version [12]. Together, Lemma 16 and Lemma 17 establish Theorem 1.

► **Lemma 17.** *INDEX is reducible to PIGEON.*

5 New Characterizations of PWPP

Our results in Section 3.1 and Section 3.2 establish new PWPP-complete problems DLOG, DOVE, and CLAW. Below, we provide additional discussion of these new PWPP-complete problems.

DLog

Alternative types of violations. Since the last type of a solution in DLOG implies that the associative property does not hold for the elements $t, \mathcal{I}_G(x)$, and $\mathcal{I}_G(y)$, one could think about changing the last type of a solution to finding $x, y, z \in [s]$ such that $f_G(x, f_G(y, z)) \neq f_G(f_G(x, y), z)$ to capture violations of the associative property directly. However, our proof of PWPP-hardness would fail for such alternative version of DLOG and we do not see an alternative way of reducing to it from the PWPP-complete problem COLLISION. In more detail, any reduction from COLLISION to DLOG must somehow embed the instance C of COLLISION in the circuit f in the constructed instance of DLOG. However, a refutation of the associative property of the form $f(x, f(y, z)) \neq f(f(x, y), z)$ for some x, y , and z might simply correspond to a trivial statement $C(u) \neq C(v)$ for some $u \neq v$, which is unrelated to any non-trivial collision in C .

Explicit \mathcal{I}_G . A natural question about our definition of DLOG is whether its computational complexity changes if the instance additionally contains an explicit circuit computing the indexing function \mathcal{I}_G . First, the indexing function \mathcal{I}_G could then be independent of the group operation f and, thus, the reduction from COLLISION to such variant of DLOG would become trivial by defining the indexing function \mathcal{I}_G directly via the COLLISION instance C . On the other hand, the core ideas of the reduction from DLOG to COLLISION would remain mostly unchanged as it would have to capture also \mathcal{I}_G computed by Algorithm 1. Nevertheless, we believe that our version of DLOG with an implicit \mathcal{I}_G computed by the standard square-and-multiply algorithm strikes the right balance in terms of modeling an interesting problem. The fact that it is more structured than the alternative with an explicit \mathcal{I}_G makes it significantly less artificial and relevant to the discrete logarithm problem, which is manifested especially in the non-trivial reduction from DLOG to COLLISION in Section 3.2.

Dove

The chain of reductions in Section 3 shows, in particular, that DOVE (Definition 6) is PWPP-complete. The most significant property of DOVE compared to the known PWPP-complete problems (PIGEON or the weak constrained-SIS problem defined by Sotiraki et al. [22]) is that it is not defined in terms of an explicitly shrinking function. Nevertheless, it is equivalent to COLLISION and, thus, it inherently captures some notion of compression. Given its different structure than COLLISION, we were able to leverage it in our proof of PWPP-hardness of DLOG, and it might prove useful in other attempt at proving PWPP-hardness of other problems. We emphasize that all four types of a solution in DOVE are exploited towards our reduction from DOVE to DLOG and we are not aware of a more direct approach of reducing COLLISION to DLOG that avoids DOVE as an intermediate problem.

Claw

Russel [21] showed that a weakening of claw-free permutations is sufficient for collision-resistant hashing. Specifically, he leveraged claw-free *pseudopermutations*, i.e., functions for which it is also computationally infeasible to find a witness refuting their bijectivity. Our definition of CLAW ensures totality by an identical existential argument – a pair of functions with identical domain and range either has a claw or we can efficiently witness that one of the functions is not surjective.

CLAW trivially reduces to the PWPP-complete problem GENERAL-CLAW and, thus, it is contained in PWPP. Below, we provide also a reduction from COLLISION to CLAW establishing that it is PWPP-hard.

► **Lemma 18.** *COLLISION is reducible to CLAW.*

Proof of Lemma 18. We start with an arbitrary instance $C : \{0, 1\}^n \rightarrow \{0, 1\}^m$ of COLLISION with $m < n$. Without loss of generality, we can suppose that $m = n - 1$ since otherwise we can pad the output with zeroes, which preserves the collisions. We construct an instance of CLAW as follows:

$$h_0(x) = C(x)0$$

and

$$h_1(x) = C(x)1.$$

We show that any solution to this instance (h_0, h_1) of CLAW gives a solution to the original instance C of COLLISION. Three cases can occur:

1. $u, v \in \{0, 1\}^n$ such that $h_0(u) = h_1(v)$. Since the last bit of $h_0(u)$ is zero and the last bit of $h_1(v)$ is one, this case cannot happen.
2. $u, v \in \{0, 1\}^n$ such that $u \neq v$ and $h_0(u) = h_0(v)$. From the definition of h_0 , we get that $C(u)0 = h_0(u) = h_0(v) = C(v)0$, which implies that $C(u) = C(v)$. Hence, the pair u, v forms a solution to the original instance C of COLLISION.
3. $u, v \in \{0, 1\}^n$ such that $u \neq v$ and $h_1(u) = h_1(v)$. We can proceed analogously as in the previous case to show that the pair u, v forms a solution to the original instance C of COLLISION. ◀

A Homological Condition on Equational Unifiability

Mirai Ikebuchi ✉

Massachusetts Institute of Technology, Cambridge, MA, USA

Abstract

Equational unification is the problem of solving an equation modulo equational axioms. In this paper, we provide a relationship between equational unification and homological algebra for equational theories. We will construct a functor from the category of sets of equational axioms to the category of abelian groups. Then, our main theorem gives a necessary condition of equational unifiability that is described in terms of abelian groups associated with equational axioms and homomorphisms between them. To construct our functor, we use a ringoid (a category enriched over the category of abelian groups) obtained from the equational axioms and a free resolution of a “good” module over the ringoid, which was developed by Malbos and Mimram.

1 Introduction

Equational unification is the problem of solving a given equation modulo an equational theory. For example, if we consider the axioms of commutative rings with a multiplicative unit, the equational unification problem asks whether given a polynomial equation with integer coefficients has a solution in integers. The decidability of this problem was posed by David Hilbert (Hilbert’s tenth problem) and it was shown to be undecidable [12, 5]. There are specific theories such as the theory of abelian groups or the theory of boolean rings such that the equational unification is decidable (see [2, §3.4]). The problem is generally semi-decidable, but not generally decidable. *Narrowing* [6, 7] is a procedure that finds all solutions of the equation, but it may not terminate in general.

Our purpose is to provide a necessary condition of solvability of an equation. The condition is obtained from a homological invariant of equational theories. More precisely, we will define an abelian group $\mathcal{H}(E)$ for a set E of equations (or equational axioms) and an abelian group homomorphism $\mathcal{H}(E \rightarrow E') : \mathcal{H}(E) \rightarrow \mathcal{H}(E')$ for two sets E, E' of equations satisfying $E^* \subset E'^*$. Here, E^*, E'^* are the equational theories of E, E' , i.e., the sets of all equations that can be derived by E, E' . Then, we will prove the following theorem.

► **Theorem 1.** *Let Σ be a signature, E be a set of equations of $\text{Term}(\Sigma)$ and $t, s \in \text{Term}(\Sigma)$ be two terms. If t, s are E -unifiable, then $\mathcal{H}(E \rightarrow E \cup \{t \approx s\})$ is surjective.*

Although $\mathcal{H}(E)$ and $\mathcal{H}(E \rightarrow E')$ are defined using abstract algebra, Theorem 1 is restated in terms of rewriting and matrices if a complete TRS of $E \cup \{t \approx s\}$ is given. In that case, we can compute a matrix associated with E and $E \cup \{t \approx s\}$ and the surjectivity of $\mathcal{H}(E \rightarrow E \cup \{t \approx s\})$ can be checked by matrix operations. (Theorem 5). Therefore, we have

a sound procedure for non- E -unifiability; if we compute the matrix and if it does not have full rank, then we can conclude that t, s are not E -unifiable. We will see how this procedure works on some simple examples in Section 3.

Our contribution is not only presenting a new procedure for non- E -unifiability. Our abelian group $\mathcal{H}(E)$ and homomorphism $\mathcal{H}(E \rightarrow E')$ can provide an algebraic consideration of equational unification, equational logic, or rewriting. The abelian group $\mathcal{H}(E)$ is invariant under equivalence of E , that is, if two sets E, E' of equations are equivalent, then $\mathcal{H}(E)$ and $\mathcal{H}(E')$ are isomorphic. We define $\mathcal{H}(E)$ using homological algebra of equational theories. The homological algebra of equational theories we use in this paper is based on [10, 11, 8]. Also, we will prove that \mathcal{H} is a functor from the category of sets of equations over a fixed signature to the category of abelian groups.

The paper is organized as follows. In Section 2, we explain basic concepts of unifiability and rewriting. In Section 3, as mentioned earlier, we rephrase Theorem 1 under a certain case so that our condition is checkable by matrix computations. Then, we see some examples and consider equational unification problems on them. In Section 4, we define $\mathcal{H}(E)$ and $\mathcal{H}(E \rightarrow E')$ which appear in Theorem 1 and prove Theorem 1 and 5. In Section 5, we see how homological algebra has been applied to rewriting in other contexts and then we conclude in Section 6.

2 Preliminaries

A *signature* Σ is a set associated with a function $\alpha : \Sigma \rightarrow \mathbb{Z}_{\geq 0}$. For $f \in \Sigma$, we say that f is of *arity* n if $n = \alpha(f)$. Let V be a countably infinite set distinct from Σ . A *term* over Σ and V is a formal object defined inductively as follows:

1. Any element in V , called a *variable*, is a term.
2. For $f \in \Sigma$ of arity n , if t_1, \dots, t_n are terms, then $f(t_1, \dots, t_n)$ is also a term.

Here, $f(t_1, \dots, t_n)$ is a formal expression and not a function application, though its semantics is often treated as a function application. If $c \in \Sigma$ is of arity 0, we write just c for $c()$. For a signature Σ , let $\text{Term}(\Sigma, V)$ denote the set of terms over Σ and V . Also, in this paper, the variables we use are x_1, x_2, \dots , so we just write $\text{Term}(\Sigma)$ for $\text{Term}(\Sigma, \{x_1, x_2, \dots\})$. If f is a symbol of arity 2 that is usually written in infix notation (e.g., $+$, \times), we write $t_1 f t_2$ instead of $f(t_1, t_2)$. We write $\text{Var}(t)$ for the set of variables that occur in t .

A *substitution* is a function $V \rightarrow \text{Term}(\Sigma, V)$. For a term t and a substitution σ , $t\sigma$ denotes the term obtained by replacing all variables v in t with $\sigma(v)$. If a substitution σ satisfies $\sigma(v_1) = t_1, \dots, \sigma(v_n) = t_n$ and $\sigma(v) = v$ for any $v \neq v_1, \dots, v_n$, σ is written as $\{v_1 \mapsto t_1, \dots, v_n \mapsto t_n\}$. Two terms t, s are *unifiable* if there exists a substitution σ such that $t\sigma = s\sigma$. Such σ is called a *unifier*. A *most general unifier (mgu)* of unifiable terms t, s is a unifier σ of t, s satisfying that for any other unifier σ' of t, s , there exists a substitution τ such that $\sigma' = \sigma\tau$.

A *context* is a term in $\text{Term}(\Sigma, V \cup \{\square\})$ that has just one \square in it. For a context $C \in \text{Term}(\Sigma, V \cup \{\square\})$ and a term $t \in \text{Term}(\Sigma, V)$, $C[t]$ denotes the term $C\{\square \mapsto t\}$.

An *equation* is a pair of terms. Equations are written as $l \approx r$. A *rewrite rule* is an equation $l \approx r$ satisfying $\text{Var}(l) \supset \text{Var}(r)$. For rewrite rules, we write $l \rightarrow r$ instead of $l \approx r$. A *term-rewriting system (TRS)* is a set of rewrite rules. For an equation $l \approx r$ and a term t , we say that t is rewritten to s by $l \approx r$, denoted $t \xrightarrow[l \approx r]{} s$, if there is a context

C and a substitution σ such that $t = C[l\sigma]$ and $s = C[r\sigma]$. For a set of equations E and two terms t, s , we say that t is rewritten to s by E , denoted $t \rightarrow_E s$, if $t \xrightarrow[l \approx r]{*} s$ holds for some $l \approx r \in E$. The reflexive transitive closure of the relation \rightarrow_E is written as $\xrightarrow{*}_E$, and the reflexive symmetric transitive closure of \rightarrow_E is written as $\xleftrightarrow{*}_E$ or \approx_E . Two sets E, E' of equations are *equivalent* if $\approx_E = \approx_{E'}$. Two terms t, s are said to be *E -unifiable* if there exists a substitution σ such that $t\sigma \approx_E s\sigma$. Such a σ is called an *E -unifier*. If we consider the problem of finding an E -unifier of two terms t, s , we write $t \approx_E^? s$ for the problem.

A TRS R is *terminating* if there is no infinite path $t_1 \rightarrow_R t_2 \rightarrow_R t_3 \rightarrow_R \dots$.

Two terms t_1, t_2 are *joinable* by R if there exists a term s such that $t_1 \xrightarrow{*}_R s \xleftarrow{*}_R t_2$. A TRS R is *confluent* if, for any terms t, t_1, t_2 , $t_1 \xleftarrow{*}_R t \xrightarrow{*}_R t_2$ implies that t_1 and t_2 are joinable.

A TRS R is *complete* if R is terminating and confluent.

Let R be a TRS and $l_1 \approx r_1, l_2 \approx r_2 \in R$ be two rewrite rules. Suppose that the variables of $l_2 \approx r_2$ are renamed so that $\text{Var}(l_1) \cap \text{Var}(l_2) = \emptyset$. For some context C and nonvariable term t , if t and l_2 are unifiable with mgu σ and if $C[t] = l_1$, then the pair $(r_1\sigma, C[r_2\sigma])$ is called a *critical pair* of R . For example, suppose that we have two rules

$$\begin{aligned} A: & f(f(x_1, x_2), x_3) \approx f(x_1, f(x_2, x_3)) \\ B: & f(i(x_4), x_4) \approx e. \end{aligned}$$

The subterm $f(x_1, x_2)$ of the left-hand side of A and $f(i(x_4), x_4)$, the right-hand side of B , can be unified with the mgu $\sigma = \{x_1 \mapsto i(x_4), x_2 \mapsto x_4, x_4 \mapsto x_4\}$. Then, the corresponding critical pair is $(f(i(x_4), f(x_4, x_3)), e)$, as the following diagram shows.

$$\begin{array}{ccc} & f(f(i(x_4), x_4), x_3) & \\ & \swarrow A \quad \searrow B & \\ f(i(x_4), f(x_4, x_3)) & & e \end{array}$$

3 A Computable Necessary Condition

Let Σ be a signature. For a set E of equations and two terms t, s , if there exists a complete TRS R of $E \cup \{t \approx s\}$, Theorem 1 can be described more explicitly. To state the explicit version of the theorem, we need some definitions.

► **Definition 2.** Let E be a set of equations. The degree of E , denoted by $\text{deg}(E)$, is defined by $\text{deg}(E) = \text{gcd}\{\#_i l - \#_i r \mid l \approx r \in E, i = 1, 2, \dots\}$ where $\#_i t$ is the number of occurrences of x_i in t for $t \in T(\Sigma)$ and $\text{gcd}\{0\}$ is defined to be 0.

For example, $\text{deg}(\{f(x_1, x_2, x_2) \approx x_1, g(x_1, x_1, x_1) \approx e\}) = \text{gcd}\{0, 2, 3\} = 1$.

Let $R = \{l_1 \rightarrow r_1, \dots, l_n \rightarrow r_n\}$ be a TRS and $\text{CP}(R) = \{(t_1, s_1), \dots, (t_m, s_m)\}$ be the set of the critical pairs of R . For any $j \in \{1, \dots, m\}$, let a_j^R, b_j^R be the numbers in $\{1, \dots, n\}$ such that the critical pair (t_j, s_j) is obtained by $l_{a_j^R} \rightarrow r_{a_j^R}$ and $l_{b_j^R} \rightarrow r_{b_j^R}$, that is, $t_j = r_{a_j^R}\sigma \leftarrow l_{a_j^R}\sigma = C[l_{b_j^R}\sigma] \rightarrow C[r_{b_j^R}\sigma] = s_j$ for some substitution σ and single-hole context C after suitably renaming variables in $l_{a_j^R} \rightarrow r_{a_j^R}$ and $l_{b_j^R} \rightarrow r_{b_j^R}$. Suppose R is complete. We fix an arbitrary rewriting strategy and for a term t , let $\text{nr}_i^R(t)$ be the number of times $l_i \rightarrow r_i$ is used to reduce t into its R -normal form with respect to the strategy.

61:4 A Homological Condition on Equational Unifiability

For a natural number d , we write \mathbb{Z}_d for $\mathbb{Z}/d\mathbb{Z}$, the integers modulo d .

► **Definition 3.** Let $d = \deg(R)$. The matrix $D(R)$ is a $n \times m$ matrix over \mathbb{Z}_d whose (i, j) -th entry $D(R)_{ij}$ ($1 \leq i \leq n$, $1 \leq j \leq m$) is $[\text{nr}_i^R(s_j) - \text{nr}_i^R(t_j) + \delta(b_j^R, i) - \delta(a_j^R, i)] \in \mathbb{Z}_d$ where $\delta(x, y)$ is the Kronecker delta. (That is, $\delta(x, y) = 1$ if $x = y$ and 0 if $x \neq y$.)

In other words, the (i, j) -th entry of $D(R)$ is the difference between (1) the number of $l_i \rightarrow r_i$ in the upper path from t to \hat{t} in the diagram below, and (2) that in the lower path.

The degree $\deg(E)$ and the matrix $D(R)$ are introduced in [8] to give a lower bound of number of equational axioms that is needed to present a given equational theory.

► **Definition 4.** Let $E = \{l'_1 \approx r'_1, \dots, l'_{n'} \approx r'_{n'}\}$ be a set of equations and $R = \{l_1 \rightarrow r_1, \dots, l_n \rightarrow r_n\}$ be a complete TRS. Suppose $E^* \subset R^*$. Then, $U(E, R)$ is the $n \times n'$ matrix over \mathbb{Z}_d whose (i, j) -th entry is $[\text{nr}_i^R(l'_j) - \text{nr}_i^R(r'_j)] \in \mathbb{Z}_d$ where $d = \deg(R)$.

For a commutative ring A , two $n \times m$ matrices M, N over A are said to be *equivalent* if $N = PMQ$ for some invertible $n \times n$ matrix P and $m \times m$ matrix Q over A . We write $I_{n,m}$ for the $n \times m$ diagonal matrix whose diagonal elements are all 1.

Here is the explicit version of Theorem 1.

► **Theorem 5.** Let $E = \{u_1 \approx v_1, \dots, u_k \approx v_k\}$ be a set of equations and t, s be two terms. Suppose that there is a complete TRS $R = \{l_1 \rightarrow r_1, \dots, l_n \rightarrow r_n\}$ of $E \cup \{t \approx s\}$ and $\deg(R) \neq 1$. If t, s are E -unifiable, then the augmented matrix $(D(R)|U(E, R))$ is equivalent to $I_{n,m}$ and $n \leq m$ where m is the number of columns of $(D(R)|U(E, R))$.

We will prove Theorem 1 and how it implies Theorem 5 in Section 4 after introducing more algebraic tools.

► **Remark 6.** Although the matrices $D(R)$ and $U(E, R)$ depend on the choice of rewriting strategy, the necessary condition stated in Theorem 5 does not depend on the choice. We will prove this fact in Section 4.

► **Remark 7.** It is algorithmically checkable whether a matrix over \mathbb{Z}_d is equivalent to $I_{n,m}$ in polynomial time by computing the Smith normal form [4, Chapter 15]. Note that if the degree d is prime, since \mathbb{Z}_d is a field, it suffices to get a diagonal matrix by elementary row/column operations and see all diagonal elements are nonzero.

We shall see some examples.

► **Example 8.** Let E_1 be the set of equations

$$B_1 : 0 + x_1 \approx x_1, \quad B_2 : s(x_1) + x_2 \approx s(x_1 + x_2).$$

Consider the E_1 -unification problem $x_1 + x_1 \stackrel{?}{\approx}_{E_2} s(0)$. By applying Knuth-Bendix completion to $E_1 \cup \{x_1 + x_1 \rightarrow s(0)\}$, we obtain a complete TRS R_1 :

$$B_1 : 0 + x_1 \rightarrow x_1, \quad C_1 : x_1 + x_1 \rightarrow 0, \quad C_2 : s(x_1) \rightarrow x_1.$$

The degree of R_1 is 2 and R_1 has one critical pair $\Pi' : 0 \xleftarrow{B_1} 0 + 0 \xrightarrow{C_1} 0$ and the matrix $(D(R_1)|U(E_1, R_1))$ is given as

$$\begin{array}{c|cc} \Pi' & B_1 & B_2 \\ \hline B_1 & 1 & 0 \\ C_1 & 1 & 0 \\ C_2 & 0 & 0 \end{array}.$$

Here, each entry of $D(R_1|U(E_1, R_1))$ is thought of as an element in \mathbb{Z}_2 . Since it does not have full rank, $x_1 + x_1$ and $s(0)$ are not E_1 -unifiable.

We can also consider the E_1 -unification problem $x_1 + x_1 \approx_{E_2}^? 0$. It has an obvious solution $x_1 \mapsto 0$, so the matrix corresponding to this problem must be equivalent to $I_{n,m}$ for some n, m . We give a complete TRS for $E_1 \cup \{x_1 + x_1\}$, its critical pairs, and the corresponding matrix in the appendix.

More generally, consider the E_1 -unification problem $x_1 + x_1 \approx_{E_1}^? s^n(0)$ where $s^n(0) = s(\dots s(0)\dots)$. In fact, we can see that if n is odd, $E' = E_1 \cup \{x_1 + x_1 \approx s^n(0)\}$ is equivalent to $\underbrace{\overline{E_1}}_n \cup \{x_1 + x_1 \approx s(0)\}$ and if n is even, E' is equivalent to $E_1 \cup \{x_1 + x_1 \approx 0\}$.

► **Example 9.** Let $E_2 = \{a(b(b(a(x_1)))) \approx x_1\}$. It is known that E_2 does not have a complete TRS with a finite number of rewrite rules [9]. Consider the E_2 -unification problem $a(b(x_1)) \approx_{E_2}^? x_1$. Then, $E_2 \cup \{a(b(x_1)) \approx x_1\}$ has a complete TRS $R_2 = \{a(b(x_1)) \rightarrow x_1, b(a(x_1)) \rightarrow x_1\}$. Then, there are two critical pairs

$$\begin{array}{l} a(x_1) \xleftarrow{a(b(x_1)) \rightarrow x_1} a(b(a(x_1))) \xrightarrow{b(a(x_1)) \rightarrow x_1} a(x_1), \\ b(x_1) \xleftarrow{a(b(x_1)) \rightarrow x_1} b(a(b(x_1))) \xrightarrow{b(a(x_1)) \rightarrow x_1} b(x_1). \end{array}$$

It is easy to check that $(D(R_2)|U(E_2, R_2))$ is the 2×3 matrix whose entries are all 1 and so it is not equivalent to $I_{2,3}$. Therefore, $a(b(x_1))$ and x_1 are not E_2 -unifiable.

► **Remark 10.** As Example 9 indicates, it can be the case that it is difficult or impossible to find a complete TRS of the given set E of equations but a complete TRS of $E \cup \{t \approx s\}$ is easy to find. The basic version of narrowing, the main existing tool for E -unification for unspecified E , is applicable only when a complete TRS of E is given. So, it is notable that Theorem 5 does not require us to find a complete TRS of E .

4 Homological Algebra on Equational Theories

The aim of this section is to define $\mathcal{H}(E)$ and $\mathcal{H}(E \rightarrow E')$, and to prove Theorem 1 and Theorem 5. For that, we will construct some algebraic structures associated with E and applies homological algebra to them. First, let us see the notion of *resolution*, which is often used to define invariants of mathematical objects in many branches of mathematics. See [15] as an introductory text.

Let R be a ring. We say that the sequence

$$\dots \xrightarrow{f_{i+1}} M_{i+1} \xrightarrow{f_i} M_i \xrightarrow{f_{i-1}} M_{i-1} \xrightarrow{f_{i-2}} \dots$$

of left R -modules M_i and R -linear maps f_i is *exact* if $\ker f_i = \text{im } f_{i+1}$ holds. For a left R -module M , a *free resolution* of M is an exact sequence

$$\dots \xrightarrow{\partial_2} F_2 \xrightarrow{\partial_1} F_1 \xrightarrow{\partial_0} F_0 \xrightarrow{\epsilon} M \rightarrow 0$$

61:6 A Homological Condition on Equational Unifiability

where each F_i is free. It is known that for any left R -module M , free resolutions of M exist. A *partial free resolution* of M is an exact sequence of finite length

$$F_n \xrightarrow{\partial_n} \dots \xrightarrow{\partial_2} F_2 \xrightarrow{\partial_1} F_1 \xrightarrow{\partial_0} F_0 \xrightarrow{\epsilon} M \rightarrow 0$$

with free F_i s.

The notion of resolution is defined not only for modules over a ring but also for modules over a *ringoid*. In [11], Malbos and Mimram constructed a ringoid associated with a given equational theory and defined invariants called homology groups using a free resolution over that ringoid. We will also use the free resolution to define $\mathcal{H}(E)$ in Theorem 1. We shall see their construction in the subsections from 4.1 to 4.3, then provide the definitions of $\mathcal{H}(E)$, $\mathcal{H}(E \rightarrow E')$ and prove our main theorems.

4.1 Category of Bicontexts

We fix a signature Σ . Let $t = \langle t_1, \dots, t_n \rangle$ be an n -tuple of terms whose variables are in $\{x_1, \dots, x_m\}$ and $s = \langle s_1, \dots, s_m \rangle$ be an m -tuple of terms. We define their composition $t \circ s$ by $\langle t_1[s_1/x_1, \dots, s_m/x_m], \dots, t_n[s_1/x_1, \dots, s_m/x_m] \rangle$ where $t_i[s_1/x_1, \dots, s_m/x_m]$ is the term obtained by substituting s_j for x_j in t_i for each $j = 1, \dots, m$ in parallel.

► **Definition 11.** A bicontext is a pair (C, t) of a context C and n -tuple of terms $t = \langle t_1, \dots, t_n \rangle$.

For two bicontexts (C, t) and (D, s) , we define their composition $(C, t) \circ (D, s)$ by $(C[D \circ t], s \circ t)$ where $D \circ t = D[t_1/x_1, \dots, t_n/x_n]$ for $t = \langle t_1, \dots, t_n \rangle$.

► **Definition 12.** The category of bicontexts \mathbb{K} consists of

- *Objects:* natural numbers $0, 1, \dots$,
- *Morphisms* $\mathbb{K}(n_1, n_2)$: bicontexts (C, t) where t is an n_1 -tuple of terms such that the elements of t and C have variables in $\{x_1, \dots, x_{n_2}\}$ (except \square in C),
- *Identity:* $(\square, \langle x_1, \dots, x_n \rangle)$

and the composition is defined above.

4.2 Ringoids

We consider an algebraic structure called *ringoid*.

► **Definition 13.** A ringoid \mathcal{R} is a small **Ab**-enriched category. That is, each hom-set is equipped with abelian group structure $(\text{hom}_{\mathcal{R}}(a, b), +, 0)$ and satisfies the following rules.

$$0 \circ x = 0, \quad x \circ 0 = 0, \quad z \circ (x + y) = z \circ x + z \circ y, \quad (z + w) \circ x = z \circ x + w \circ x$$

where $x, y \in \text{hom}_{\mathcal{R}}(a, b)$, $z, w \in \text{hom}_{\mathcal{R}}(b, c)$.

A ringoid can be thought of as a “many-sorted” ring. If a ringoid has just a single object, its morphisms form a ring with addition $+$ and multiplication \circ . If a ringoid has multiple objects, each object can be thought of as a sort. We can add two morphisms $x : a_1 \rightarrow b_1$, $y : a_2 \rightarrow b_2$ only if $a_1 = a_2$ and $b_1 = b_2$. Also, we can multiply them as composition $y \circ x$ only if $b_1 = a_2$.

For any small category \mathcal{C} , there exists a ringoid $\mathbb{Z}\langle\mathcal{C}\rangle$ called the ringoid *freely generated by* \mathcal{C} . The ringoid $\mathbb{Z}\langle\mathcal{C}\rangle$ has the same objects as \mathcal{C} and the hom-set $\mathbb{Z}\langle\mathcal{C}\rangle(a, b)$ between objects a, b is the free abelian group generated by $\mathcal{C}(a, b)$. The composition of $\mathbb{Z}\langle\mathcal{C}\rangle$ is given by linearly extending the composition of \mathcal{C} as $(w + z) \circ (x + y) = w \circ x + w \circ y + z \circ x + z \circ y$.

We can define an ideal of a ringoid and a module over a ringoid.

► **Definition 14.** Let \mathcal{R} be a ringoid. An ideal of \mathcal{R} is a subfunctor of the hom-bifunctor $\mathcal{R}(-, -) : \mathcal{R} \times \mathcal{R} \rightarrow \mathbf{Ab}$. If I is an ideal of \mathcal{R} , then we can define the category \mathcal{R}/I whose objects are those of \mathcal{R} , morphisms are $(\mathcal{R}/I)(a, b) = \mathcal{R}(a, b)/I(a, b)$, and the composition is induced by that of \mathcal{R} . Also, a structure of ringoid of \mathcal{R}/I is induced by that of \mathcal{R} .

► **Definition 15.** Let \mathcal{R} be a ringoid.

- A left \mathcal{R} -module is a functor $M : \mathcal{R} \rightarrow \mathbf{Ab}$ satisfying $M(x+y) = M(x) + M(y)$, $M(0) = 0$ for any $x, y \in \mathcal{R}(a, b)$, $a, b \in \text{Obj}(\mathcal{R})$. We define the scalar multiplication $\cdot : \mathcal{R}(a, b) \times M(a) \rightarrow M(b)$ as $a \cdot m = M(a)(m)$.
- A right \mathcal{R} -module is a left \mathcal{R}^{op} -module.
- For two left \mathcal{R} -modules M_1, M_2 , an \mathcal{R} -linear map $f : M_1 \rightarrow M_2$ is a natural transformation. (We can define an \mathcal{R} -linear map between right \mathcal{R} -modules in the same manner.)

► **Definition 16.** Let M_1 be a left \mathcal{R} -module. A submodule of M_1 is a left \mathcal{R} -module M_2 such that there exists a monomorphism $\phi : M_2 \rightarrow M_1$ and $\phi_a : M_2(a) \rightarrow M_1(a)$ is an inclusion of sets for each object a of \mathcal{R} .

We define left free \mathcal{R} -modules over ringoids.

► **Definition 17.** Let P be a family of sets P_a ($a \in \text{Obj}(\mathcal{R})$). The left free \mathcal{R} -module generated by P , denoted by $\mathcal{R}\underline{P}$, is defined as follows. For each $a \in \text{Obj}(\mathcal{R})$, $(\mathcal{R}\underline{P})(a)$ is the abelian group consisting of formal finite sums $\sum_{x \in P_b, b \in \text{Obj}(\mathcal{R})} \lambda_x \underline{x}$, ($\lambda_x \in \mathcal{R}(b, a)$). Here, the underline for x above is added to emphasize the difference between λ_x and x . The scalar multiplication is given as $r \cdot (\sum_x \lambda_x \underline{x}) = \sum_x (r \circ \lambda_x) \underline{x}$ ($r \in \mathcal{R}(a, c)$).

For a ringoid \mathcal{R} , let $\mathbf{Mod}_{\mathcal{R}}$ denote the category of left \mathcal{R} -modules and \mathcal{R} -linear maps. The following proposition tells us that $\mathbf{Mod}_{\mathcal{R}}$ has good properties so that we can apply homological algebra to it.

► **Proposition 18** ([13]). $\mathbf{Mod}_{\mathcal{R}}$ is an abelian category and any left \mathcal{R} -module has a free resolution.

We do not give the details of this proposition, but one of the important consequences of being abelian is that we have the notions of kernel and image of an \mathcal{R} -linear map in the category.

► **Definition 19.** Let M_1, M_2 be two left \mathcal{R} -modules and $f : M_1 \rightarrow M_2$ be an \mathcal{R} -linear map. Then, the kernel and the image of f are defined as $(\ker f)(a) = \ker f_a$, $(\text{im } f)(a) = \text{im } f_a$ for each object a . Here, f_a is an abelian group homomorphism, so \ker and im in the right-hand sides are the kernel and the image for group homomorphisms.

Many other notions for modules over a ring can be generalized.

► **Definition 20.** Let M_1 be a left \mathcal{R} -module and M_2 be a submodule of M_1 . The quotient module M_1/M_2 is the left \mathcal{R} -module given as $(M_1/M_2)(a) = M_1(a)/M_2(a)$.

► **Definition 21.** Let M be a left \mathcal{R} -module. For an index set I , for each $i \in I$, let a_i be an object of \mathcal{R} and x_i be an element of $M(a_i)$. The submodule generated by $\{x_i\}_{i \in I}$ is the left \mathcal{R} -module N such that for each $a \in \text{Obj}(\mathcal{R})$, $N(a)$ is the abelian group consisting of finite sums $\sum_{i \in I} \lambda_i \cdot x_i$ ($\lambda_i \in \mathcal{R}(a, a_i)$).

► **Definition 22.** Let M_1 be a right \mathcal{R} -module and M_2 be a left \mathcal{R} -module. The tensor product $M_1 \otimes_{\mathcal{R}} M_2$ of M_1 and M_2 is defined as the coend $M_1 \otimes_{\mathcal{R}} M_2 = \int^a M_1(a) \otimes M_2(a)$. That is, an abelian group $M_1 \otimes_{\mathcal{R}} M_2$ is the tensor product of M_1, M_2 if there is an extranatural transformation $\zeta : M_1(-) \otimes M_2(-) \rightarrow M_1 \otimes_{\mathcal{R}} M_2$ such that for any abelian group A and any extranatural transformation $\gamma : M_1(-) \otimes M_2(-) \rightarrow A$, there exists a unique abelian group homomorphism $\phi : M_1 \otimes_{\mathcal{R}} M_2 \rightarrow A$ with $\gamma_a = \phi \circ \zeta_a$ for any $a \in \text{Obj}(\mathcal{R})$.

Explicitly, $M_1 \otimes_{\mathcal{R}} M_2$ is the abelian group $\left(\bigoplus_{a \in \text{Obj}(\mathcal{R})} M_1(a) \otimes M_2(a) \right) / R$ where R is the abelian group generated by $M_1(f \circ p)(x) \otimes y - x \otimes M_2(f)(y)$ for any $f : a \rightarrow a', x \in M_1(a'), y \in M_2(a), a, a' \in \text{Obj}(\mathcal{R})$.

Let M_1, M_2 be two left \mathcal{R} -modules and N_1, N_2 be two right \mathcal{R} -modules. For linear maps $f : M_1 \rightarrow M_2$ and $g : N_1 \rightarrow N_2$, we define $g \otimes f : N_1 \otimes_{\mathcal{R}} M_1 \rightarrow N_2 \otimes_{\mathcal{R}} M_2$ to be the abelian group homomorphism $(f \otimes g)(n \otimes m) = g(n) \otimes f(m)$. If $N_1 = N_2$ and g is the identity map, we write $N_1 \otimes f$ instead of $g \otimes f$.

The tensor product of modules over a ringoid satisfies many properties of tensor product of modules over a ring. In particular, we have

► **Lemma 23.** Let N be a right \mathcal{R} -module and M_1, M_2, M_3 be left \mathcal{R} -modules. If the sequence $M_1 \xrightarrow{f} M_2 \xrightarrow{g} M_3 \rightarrow 0$ is exact, then the sequence $N \otimes_{\mathcal{R}} M_1 \xrightarrow{N \otimes f} N \otimes_{\mathcal{R}} M_2 \xrightarrow{N \otimes g} N \otimes_{\mathcal{R}} M_3 \rightarrow 0$ is also exact.

4.3 Partial Free Resolutions

For the category of bicontexts \mathbb{K} , consider the ringoid $\mathbb{Z}\langle\mathbb{K}\rangle$. Then, we will define a ringoid \mathcal{R}^E such that any two equivalent sets E, E' of equations give rise to isomorphic ringoids $\mathcal{R}^E \simeq \mathcal{R}^{E'}$.

For a term t and a positive integer i , let $\kappa_i(t)$ be the linear combination of contexts given inductively by

$$\kappa_i(x_i) = \square, \quad \kappa_i(x_j) = 0 \quad (i \neq j), \quad \kappa_i(f(t_1, \dots, t_k)) = \sum_{j=1}^k f(t_1, \dots, \underbrace{\square}_{j\text{th}}, \dots, t_k) [\kappa_i(t_j)].$$

Application of linear combination of contexts to a context which appears in the last rule is defined by $C[D_1 + \dots + D_n] = C[D_1] + \dots + C[D_n]$. Also, for a term t , symbol $f \in \Sigma^{(n)}$, and n -uple of terms $u = \langle s_1, \dots, s_n \rangle$, let $\varphi_{f,u}(t)$ be the linear combination of all contexts C satisfying $C[f(s_1, \dots, s_n)] = t$.

We define the ideal I_E of $\mathbb{Z}\langle\mathbb{K}\rangle$. Let $I_E(m, n)$ be the subgroup of $\mathbb{Z}\langle\mathbb{K}\rangle(m, n)$ generated by elements of the form

$$(\kappa_i(s) - \kappa_i(t), w), \quad (\varphi_{f,vu}(t \circ v) - \varphi_{f,vu}(s \circ v) - \varphi_{f,u}(t) \circ v + \varphi_{f,u}(s) \circ v, w), \quad (\square, w_1) - (\square, w_2)$$

for any $s \approx_E t, w_1 \approx_E w_2$. Then, define \mathcal{R}^E to be $\mathbb{Z}\langle\mathbb{K}\rangle / I_E$.¹ For a morphism x of $\mathbb{Z}\langle\mathbb{K}\rangle$, we write $[x]^E$ or just $[x]$ for the equivalence class of x in \mathcal{R}^E . If we consider the free module $\mathcal{R}^E \underline{P}$ for a family P of sets P_0, P_1, \dots , we write $C_1 \underline{p}u_1 + \dots + C_k \underline{p}u_k$ for $[(C_1, u_1) + \dots + (C_k, u_k)] \underline{p} \in \mathcal{R}^E \underline{P}(i)$. By definition, for any E' equivalent to E , $\mathcal{R}^{E'}$ is isomorphic to \mathcal{R}^E .

¹ For the original definition of \mathcal{R}^E in [11], the generators $\varphi_{f,vu}(t \circ v) - \varphi_{f,vu}(s \circ v) - \varphi_{f,u}(t) \circ v + \varphi_{f,u}(s) \circ v$ of $I_E(m, n)$ was not given. However, we need these generators to prove $\partial_1(\hat{t}) = \varphi(\hat{t}) - \varphi(t)$ which is used to show $\partial_1 \circ \partial_2 = 0$ in Appendix A of [11]. We do not need to change the other parts of the proof.

Let $d = \deg(E)$. Consider the right \mathcal{R}^E -module that maps any object n to \mathbb{Z}_d and whose scalar multiplication $\cdot : \mathbb{Z}_d \times \mathcal{R}^E(m, n) \rightarrow \mathbb{Z}_d$ is given by $[1] \cdot [(C_1, t_1) + \dots + (C_k, t_k)] = [k]$. We write \mathbb{Z}_d also for this right \mathcal{R}^E -module. We show that the scalar multiplication is well-defined. If $C_1 + \dots + C_k = \kappa_i(s)$ and $D_1 + \dots + D_{k'} = \kappa_i(t)$ for some $s \approx t$, then $k - k' = \#_i s - \#_i t$ is divided by d by the definition of $\deg(E)$. Thus, $[1] \cdot [\sum_{i=1}^k (C_i, t) - \sum_{i=1}^{k'} (D_i, t)] = [0]$. Also, since the number of bicontexts in $\varphi_{f,u}(t)$ is the number of subterm $f(u)$ in t , for any $l \approx r \in E$, $f \in \Sigma$, $t \in T(\Sigma)$, the linear combination $\varphi_{f,u}(r \circ t) - \varphi_{f,u}(l \circ t) - \varphi_{f,u}(r) + \varphi_{f,u}(l)$ consists of da contexts for some nonnegative integer a . Therefore, $[1] \cdot [\varphi_{f,u}(r \circ t) - \varphi_{f,u}(l \circ t) - \varphi_{f,u}(r) + \varphi_{f,u}(l)] = [0]$, so the scalar multiplication for \mathbb{Z}_d is well-defined.

Let X_1 be a singleton set $\{\star\}$, X_i be the empty set for $i = 0$ or $i = 2, 3, \dots$, and X be the family consisting of X_i s. We define a left \mathcal{R}^E -module \mathcal{Z}^E to be the quotient $\mathcal{R}^E \underline{X} / N$ where N is the submodule of $\mathcal{R}^E \underline{X}$ generated by $\sum_{i=1}^m \kappa_i(u) \circ t \star t_i - \square_{\star} \langle u \circ t \rangle$ for every term u with $\text{Var}(u) \subset \{x_1, \dots, x_m\}$ and m -uple $t = \langle t_1, \dots, t_m \rangle$ of terms. Then, we construct a partial free resolution of \mathcal{Z}^E

$$\mathcal{R}^E \underline{\mathbf{P}}_2 \xrightarrow{\partial_2^E} \mathcal{R}^E \underline{\mathbf{P}}_1 \xrightarrow{\partial_1^E} \mathcal{R}^E \underline{\mathbf{P}}_0 \xrightarrow{\epsilon^E} \mathcal{Z}^E \rightarrow 0 \quad (1)$$

as follows. First, $\mathbf{P}_0, \mathbf{P}_1, \mathbf{P}_2^E$ are families of sets $(\mathbf{P}_0)_j, (\mathbf{P}_1)_j, (\mathbf{P}_2^E)_j$ given as

$$(\mathbf{P}_0)_j = \begin{cases} \{1\} & (j = 1) \\ \emptyset & (j \neq 1) \end{cases}, \quad (\mathbf{P}_1)_j = \Sigma^{(j)} = \{f \in \Sigma \mid f \text{ has arity } j\}$$

$$(\mathbf{P}_2^E)_j = \{l \approx r \in E \mid \text{Var}(l) \cup \text{Var}(r) \subset \{x_1, \dots, x_j\}\}.$$

Then, we define \mathcal{R}^E -linear maps $\epsilon^E, \partial_0^E, \partial_1^E$ as

$$\epsilon^E(\underline{1}) = \underline{\star}, \quad \partial_0^E(f) = \sum_{i=1}^n f(x_1, \dots, \underbrace{\square}_{i\text{th}}, \dots, x_n) \underline{1}\langle x_i \rangle - \underline{1}\langle f(x_1, \dots, x_n) \rangle,$$

$$\partial_1^E(l \approx r) = \varphi(r) - \varphi(l)$$

where $\varphi : \text{Term}(\Sigma) \rightarrow \mathcal{R}^E \underline{\mathbf{P}}_1$ is defined inductively as

$$\varphi(x_i) = 0, \quad \varphi(f(t_1, \dots, t_n)) = \underline{f}\langle t_1, \dots, t_n \rangle + \sum_{i=1}^n \underline{f}\langle t_1, \dots, \underbrace{\square}_{i\text{th}}, \dots, t_n \rangle \varphi(t_i).$$

If there is a complete TRS R of E , we can extend the sequence (1) to

$$\mathcal{R}^R \underline{\mathbf{P}}_3 \xrightarrow{\partial_3^R} \mathcal{R}^R \underline{\mathbf{P}}_2 \xrightarrow{\partial_2^R} \mathcal{R}^R \underline{\mathbf{P}}_1 \xrightarrow{\partial_1^R} \mathcal{R}^R \underline{\mathbf{P}}_0 \xrightarrow{\epsilon^R} \mathcal{Z}^R \rightarrow 0. \quad (2)$$

Here, \mathbf{P}_3^R is the family of sets $(\mathbf{P}_3^R)_j$ where each $(\mathbf{P}_3^R)_j$ consists of 5-uple $(l \rightarrow r, t, C, l' \rightarrow r', t')$ such that

- $l \circ t = C[l' \circ t']$ and $r \circ t \leftarrow l \circ t = C[l' \circ t'] \rightarrow C[r' \circ t']$ is a critical peak, and
- either $l \rightarrow r$ or $l' \rightarrow r'$ is in $(\mathbf{P}_2^R)_j$ and the other is in $(\mathbf{P}_2^R)_k$ for some $k \leq j$.

For such a 5-uple $\alpha = (l \rightarrow r, t, C, l' \rightarrow r', t')$, $\partial_2^R(\underline{\alpha})$ is defined as

$$\partial_2^R(\underline{\alpha}) = \underline{l' \rightarrow r' t'} - \underline{C l \rightarrow r t} + \widehat{\underline{r' \circ t'}} - \widehat{\underline{C[r \circ t]}}$$

where \hat{s} is defined for any term s as follows. Suppose s is rewritten to its normal form \hat{s} by rewrite rules $p_1 \rightarrow q_1, \dots, p_k \rightarrow q_k \in R$ as

$$s = C_1[p_1 \circ u_1], C_1[q_1 \circ u_1] = C_2[p_2 \circ u_2], \dots, C_{k-1}[q_{k-1} \circ u_{k-1}] = C_k[p_k \circ u_k], C_k[q_k \circ u_k] = \hat{s}$$

for some C_i s and u_i s. Then, $\hat{s} = \sum_{i=1}^k C_i \underline{p_i} \rightarrow q_i \underline{u_i}$.

61:10 A Homological Condition on Equational Unifiability

► **Theorem 24** ([11]). *If R is a complete TRS, the sequence (2) is exact.*

The following lemma is useful for the next subsection.

► **Lemma 25.** *Let E be a set of equations with degree d . For any family P of sets P_0, P_1, \dots , we have an abelian group isomorphism $\mathbb{Z}_d \otimes_{\mathcal{R}^E} \mathcal{R}^E \underline{P} \simeq \mathbb{Z}_d \underline{\uplus} P$ where $\underline{\uplus} P$ is the disjoint union of P_i s and the right-hand side is the free module generated by $\underline{\uplus} P$ over \mathbb{Z}_d as a ring.*

Proof. Consider the abelian group homomorphism $\psi : \mathbb{Z}_d \underline{\uplus} P \rightarrow \mathbb{Z}_d \otimes_{\mathcal{R}^E} \mathcal{R}^E \underline{P}$, $p \mapsto 1 \otimes p$. Then, ψ is surjective since $1 \otimes Cpu = 1 \cdot [(C, u)] \otimes p = 1 \otimes p$ for any $1 \otimes Cpu \in \mathbb{Z}_d \otimes_{\mathcal{R}^E} \mathcal{R}^E \underline{P}$. Let $\gamma_i : \mathbb{Z}_d \otimes (\mathcal{R}^E \underline{P}(i)) \rightarrow \mathbb{Z}_d \underline{\uplus} P$ be the abelian group homomorphism $1 \otimes Cpu \mapsto p$. We can check that γ_i s form an extranatural transformation γ , so we have $\phi : \mathbb{Z}_d \otimes_{\mathcal{R}^E} \mathcal{R}^E \underline{P} \rightarrow \mathbb{Z}_d \underline{\uplus} P$ with $\gamma_i = \phi \circ \zeta_i$ for $\zeta_i : \mathbb{Z}_d \otimes (\mathcal{R}^E \underline{P}(i)) \rightarrow \mathbb{Z}_d \otimes_{\mathcal{R}^E} \mathcal{R}^E \underline{P}$. Then, $\phi(\psi(p)) = \phi(\zeta_i(1 \otimes p)) = \gamma_i(1 \otimes p) = p$. Thus, ψ is an isomorphism. ◀

4.4 Invariant $\mathcal{H}(E)$

We are ready to define $\mathcal{H}(E)$.

► **Definition 26.** *For a set E of equations, we define the abelian group $\mathcal{H}(E)$ by*

$$\mathcal{H}(E) = \mathbb{Z}_d \otimes_{\mathcal{R}^E} \ker \partial_0^E = \mathbb{Z}_d \otimes_{\mathcal{R}^E} \text{im } \partial_1^E \quad (d = \text{deg}(E)).$$

If two sets E, E' of equations are equivalent, since \mathcal{R}^E and $\mathcal{R}^{E'}$ are isomorphic and $\partial_0^E = \partial_0^{E'}$, we have $\mathcal{H}(E) \simeq \mathcal{H}(E')$. That is, we can see that $\mathcal{H}(E)$ is invariant under the equivalence of E . (This holds especially since we are fixing a signature Σ .)

Let E, E' be sets of equations with $E^* \subset E'^*$. Then, the functor $\pi^{E, E'} : \mathcal{R}^E \rightarrow \mathcal{R}^{E'}$ given as $[(C_1, u_1) + \dots + (C_k, u_k)]^E \mapsto [(C_1, u_1) + \dots + (C_k, u_k)]^{E'}$ is well-defined. For a family of sets P , $\pi^{E, E'}$ extends to $\bar{\pi}_P^{E, E'} : \mathcal{R}^E \underline{P} \rightarrow \mathcal{R}^{E'} \underline{P}$. Then, we can see that the diagram

$$\begin{array}{ccc} \mathcal{R}^E \underline{\mathbf{P}}_1 & \xrightarrow{\partial_0^E} & \mathcal{R}^E \underline{\mathbf{P}}_0 \\ \downarrow \bar{\pi}_{\underline{\mathbf{P}}_1}^{E, E'} & & \downarrow \bar{\pi}_{\underline{\mathbf{P}}_0}^{E, E'} \\ \mathcal{R}^{E'} \underline{\mathbf{P}}_1 & \xrightarrow{\partial_0^{E'}} & \mathcal{R}^{E'} \underline{\mathbf{P}}_0 \end{array}$$

commutes. Therefore, if we restrict $\bar{\pi}_{\underline{\mathbf{P}}_1}^{E, E'}$ to $\ker \partial_0^E$, we get $\bar{\pi}_{\underline{\mathbf{P}}_1}^{E, E'}|_{\ker \partial_0^E} : \ker \partial_0^E \rightarrow \ker \partial_0^{E'}$. Let $d = \text{deg}(E)$ and $d' = \text{deg}(E')$. Since $E^* \subset E'^*$, d' divides d and we can define a group homomorphism $q^{d, d'} : \mathbb{Z}_d \rightarrow \mathbb{Z}_{d'}$ as $q^{d, d'}(n + d\mathbb{Z}) = n + d'\mathbb{Z}$. Consider the composition of abelian group homomorphisms

$$\mathbb{Z}_d \otimes (\ker \partial_0^E(k)) \xrightarrow{f_k} \mathbb{Z}_{d'} \otimes (\ker \partial_0^{E'}(k)) \xrightarrow{\zeta_k} \mathbb{Z}_{d'} \otimes_{\mathcal{R}^{E'}} \ker \partial_0^{E'}$$

where $f_k = q^{d, d'} \otimes (\bar{\pi}_{\underline{\mathbf{P}}_1}^{E, E'}|_{\ker \partial_0^E(k)})$ and ζ_k is the extranatural transformation given in the definition of tensor product. Since $\zeta_k \circ f_k$ ($k = 0, 1, \dots$) form an extranatural transformation, we get an abelian group homomorphism $\mathbb{Z}_d \otimes_{\mathcal{R}^E} \ker \partial_0^E \rightarrow \mathbb{Z}_{d'} \otimes_{\mathcal{R}^{E'}} \ker \partial_0^{E'}$ by naturality and let $\mathcal{H}(E \rightarrow E')$ denote it. That is, $\mathcal{H}(E \rightarrow E')$ makes the following diagram commute.

$$\begin{array}{ccc} \mathbb{Z}_d \otimes (\ker \partial_0^E(k)) & \xrightarrow{\zeta_k} & \mathbb{Z}_d \otimes_{\mathcal{R}^E} \ker \partial_0^E \\ \downarrow f_k & & \downarrow \mathcal{H}(E \rightarrow E') \\ \mathbb{Z}_{d'} \otimes (\ker \partial_0^{E'}(k)) & \xrightarrow{\zeta_k} & \mathbb{Z}_d \otimes_{\mathcal{R}^{E'}} \ker \partial_0^{E'} \end{array} \quad (3)$$

Thus, we have obtained an abelian group homomorphism $\mathcal{H}(E \rightarrow E') : \mathcal{H}(E) \rightarrow \mathcal{H}(E')$.

Now, we can prove Theorem 1.

Proof of Theorem 1. Let $F = E \cup \{t \approx s\}$. If $t\sigma \approx_E s\sigma$ for some σ , then E is equivalent to $E' = E \cup \{t\sigma \approx s\sigma\}$ and F is equivalent to $F' = F \cup \{t\sigma \approx s\sigma\}$. Since $\mathbb{Z}_d \otimes_{\mathcal{R}^{F'}} \mathcal{R}^{F'} \underline{\mathbf{P}}_2^{F'}$ is freely generated by $1 \otimes \underline{l \approx r}$ for $l \approx r \in F'$ (Lemma 25), $\mathcal{H}(F') = \mathbb{Z}_d \otimes_{\mathcal{R}^{F'}} \text{im } \partial_1^{F'}$ is generated by $1 \otimes \partial_1^{F'}(\underline{l \approx r})$ for $l \approx r \in F'$. For $l \approx r \in E'$, since $\mathcal{H}(E' \rightarrow F')(1 \otimes \partial_1^{E'}(\underline{l \approx r})) = 1 \otimes \partial_1^{F'}(\underline{l \approx r})$, to show the surjectivity of $\mathcal{H}(E' \rightarrow F')$, it suffices to check that $1 \otimes \partial_1^{F'}(\underline{t \approx s})$ is in $\text{im } \mathcal{H}(E' \rightarrow F')$. We have $1 \otimes \partial_1^{F'}(\underline{t \approx s} - \underline{t\sigma \approx s\sigma}) = 0 \in \mathbb{Z}_d \otimes \text{im } \partial_1^{F'}$ since

$$\begin{aligned} 1 \otimes \partial_1^{F'}(\underline{t \approx s} - \underline{t\sigma \approx s\sigma}) &= 1 \otimes (\varphi(s) - \varphi(t) - \varphi(s\sigma) + \varphi(t\sigma)) \\ &= 1 \otimes (\varphi(s) - \varphi(t)) - 1 \otimes (\varphi(s\sigma) - \varphi(t\sigma)) \\ &= 1 \otimes (\varphi(s)\sigma - \varphi(t)\sigma) - 1 \otimes (\varphi(s\sigma) - \varphi(t\sigma)) = 0. \end{aligned}$$

Therefore, $1 \otimes \partial_1^{F'}(\underline{t \approx s}) = 1 \otimes \partial_1^{F'}(\underline{t\sigma \approx s\sigma})$ in $\mathbb{Z}_d \otimes_{\mathcal{R}^{F'}} \text{im } \partial_1^{F'}$. Also, since $t\sigma \approx s\sigma \in E'$, we have $1 \otimes \partial_1^{F'}(\underline{t\sigma \approx s\sigma}) = \mathcal{H}(E' \rightarrow F')(1 \otimes \partial_1^{E'}(\underline{t\sigma \approx s\sigma}))$. Thus, $1 \otimes \partial_1^{F'}(\underline{t \approx s}) \in \text{im } \mathcal{H}(E' \rightarrow F')$. \blacktriangleleft

We show that Theorem 1 implies Theorem 5. Suppose R is a complete TRS with degree d . First, notice that if $d = 1$, then \mathbb{Z}_d is a trivial group and so is $\mathcal{H}(R)$. Hence Theorem 1 is not interesting in that case. We write $\check{\partial}_2^R$ for the map $\mathbb{Z}_d \otimes_{\mathcal{R}^R} \partial_2^R : \mathbb{Z}_d \otimes_{\mathcal{R}^R} \mathcal{R}^R \underline{\mathbf{P}}_3^R \rightarrow \mathbb{Z}_d \otimes_{\mathcal{R}^R} \mathcal{R}^R \underline{\mathbf{P}}_2^R$ and write $\check{\partial}_1^R$ for the map $\mathbb{Z}_d \otimes (\partial_1^R : \mathcal{R}^R \underline{\mathbf{P}}_2^R \rightarrow \text{im } \partial_1^R)$. Since the sequence

$$\mathbb{Z}_d \otimes_{\mathcal{R}^R} \mathcal{R}^R \underline{\mathbf{P}}_3^R \xrightarrow{\check{\partial}_2^R} \mathbb{Z}_d \otimes_{\mathcal{R}^R} \mathcal{R}^R \underline{\mathbf{P}}_2^R \xrightarrow{\check{\partial}_1^R} \mathbb{Z}_d \otimes_{\mathcal{R}^R} \text{im } \partial_1^R \rightarrow 0$$

is exact, $\mathcal{H}(E) = \mathbb{Z}_d \otimes_{\mathcal{R}^R} \text{im } \partial_1^R$ is isomorphic to $\text{coker } \check{\partial}_2^R = \mathbb{Z}_d \otimes_{\mathcal{R}^R} \mathcal{R}^R \underline{\mathbf{P}}_2^R / \text{im } \check{\partial}_2^R$.

Let E be a set of equations with degree d' and R be a complete TRS with degree d such that $E^* \subset R^*$. We define $h : \mathbb{Z}_{d'} \otimes_{\mathcal{R}^E} \mathcal{R}^E \underline{\mathbf{P}}_2^E \rightarrow \mathbb{Z}_d \otimes_{\mathcal{R}^R} \mathcal{R}^R \underline{\mathbf{P}}_2^R$ by $h(1 \otimes \underline{t \approx s}) = 1 \otimes (\hat{t} - \hat{s})$.

► Lemma 27. $\check{\partial}_1^R \circ h = \mathcal{H}(E \rightarrow R) \circ \check{\partial}_1^E$. That is, the following diagram commutes:

$$\begin{array}{ccc} \mathbb{Z}_{d'} \otimes_{\mathcal{R}^E} \mathcal{R}^E \underline{\mathbf{P}}_2^E & \xrightarrow{\check{\partial}_1^E} & \mathbb{Z}_{d'} \otimes_{\mathcal{R}^E} \text{im } \partial_1^E \\ \downarrow h & & \downarrow \mathcal{H}(E \rightarrow R) \\ \mathbb{Z}_d \otimes_{\mathcal{R}^R} \mathcal{R}^R \underline{\mathbf{P}}_2^R & \xrightarrow{\check{\partial}_1^R} & \mathbb{Z}_d \otimes_{\mathcal{R}^R} \text{im } \partial_1^R. \end{array}$$

Proof. First, we show, by induction, $\check{\partial}_1^R(1 \otimes \hat{t}) = 1 \otimes (\varphi(\hat{t}) - \varphi(t)) \in \mathbb{Z}_d \otimes_{\mathcal{R}^R} \text{im } \partial_1^R$ for any term t . If $\hat{t} = 0$, or equivalently, t is normal, then the equality trivially holds. If $\hat{t} = C\underline{l \approx ru} + \hat{t}'$ ($C[l \circ u] = t$, $C[r \circ u] = t'$) and $\check{\partial}_1^R(1 \otimes \hat{t}') = 1 \otimes (\varphi(\hat{t}') - \varphi(t'))$, then $\check{\partial}_1^R(1 \otimes \hat{t}) = 1 \otimes (\varphi(\hat{t}) - \varphi(t) + \varphi(r) - \varphi(l))$. Since $1 \otimes (\varphi(r) - \varphi(l)) = 1 \otimes (C\varphi(r)u - C\varphi(l)u) = 1 \otimes (\varphi(t') - \varphi(t))$, we have $\check{\partial}_1^R(\hat{t}) = 1 \otimes (\varphi(\hat{t}) - \varphi(t))$.

Now, we have $\check{\partial}_1^R(h(1 \otimes \underline{t \approx s})) = \check{\partial}_1^R(1 \otimes \hat{t}) - \check{\partial}_1^R(1 \otimes \hat{s}) = 1 \otimes (\varphi(s) - \varphi(t))$ and thus $\mathcal{H}(E \rightarrow R)(\check{\partial}_1^E(1 \otimes \underline{t \approx s})) = 1 \otimes (\varphi(s) - \varphi(t))$. \blacktriangleleft

61:12 A Homological Condition on Equational Unifiability

The above lemma implies that the map

$$\bar{h} : \mathbb{Z}_{d'} \otimes_{\mathcal{R}^E} \mathcal{R}^E \underline{\mathbf{P}}_2^E / \ker \check{\partial}_1^E \rightarrow \mathbb{Z}_d \otimes_{\mathcal{R}^R} \mathcal{R}^R \underline{\mathbf{P}}_2^R / \ker \check{\partial}_1^R, \quad [x] \mapsto [h(x)]$$

is well-defined since if $x \in \ker \check{\partial}_1^E$, then $\check{\partial}_1^R(h(x)) = \mathcal{H}(E \rightarrow R)(\check{\partial}_1^E(x)) = 0$. Also, $\mathcal{H}(E \rightarrow R)$ is surjective iff \bar{h} is surjective since we have the diagram

$$\begin{array}{ccc} \mathbb{Z}_{d'} \otimes_{\mathcal{R}^E} \mathcal{R}^E \underline{\mathbf{P}}_2^E / \ker \check{\partial}_1^E & \xrightarrow{\cong} & \mathbb{Z}_{d'} \otimes_{\mathcal{R}^E} \text{im } \partial_1^E \\ \downarrow \bar{h} & & \downarrow \mathcal{H}(E \rightarrow R) \\ \mathbb{Z}_d \otimes_{\mathcal{R}^R} \mathcal{R}^R \underline{\mathbf{P}}_2^R / \ker \check{\partial}_1^R & \xrightarrow{\cong} & \mathbb{Z}_d \otimes_{\mathcal{R}^R} \text{im } \partial_1^R. \end{array}$$

Theorem 5 follows from Theorem 1 and the lemma below.

► **Lemma 28.** *The map $\mathcal{H}(E \rightarrow R)$ is surjective iff the matrix $(D(E)|U(E, R))$ is equivalent to $I_{n,m}$ and $n \leq m$ where n (resp. m) is the number of rows (resp. columns) in $(D(R)|U(E, R))$.*

Proof. We can see that $U(E, R)$ is a matrix representation of h and $D(R)$ is a matrix representation of $\check{\partial}_2^R$. So, $(D(E)|U(E, R))$ is equivalent to $I_{n,m}$ and $n \leq m$ iff the map

$$(\mathbb{Z}_d \otimes_{\mathcal{R}^R} \mathcal{R}^R \underline{\mathbf{P}}_3^R) \times (\mathbb{Z}_d \otimes_{\mathcal{R}^E} \mathcal{R}^E \underline{\mathbf{P}}_2^E) \rightarrow \mathbb{Z}_d \otimes_{\mathcal{R}^R} \mathcal{R}^R \underline{\mathbf{P}}_2^R, \quad (x, y) \mapsto \check{\partial}_2^R(x) + h(y)$$

is surjective.

Suppose $\mathcal{H}(E \rightarrow R)$ is surjective. Then, \bar{h} is surjective and so for any $z \in \mathbb{Z}_d \otimes_{\mathcal{R}^R} \mathcal{R}^R \underline{\mathbf{P}}_2^R$, we have $y \in \mathbb{Z}_{d'} \otimes_{\mathcal{R}^E} \mathcal{R}^E \underline{\mathbf{P}}_2^E$ and $z' \in \ker \check{\partial}_1^R$ satisfying $z = h(y) + z'$. Since $\ker \check{\partial}_1^R = \text{im } \check{\partial}_2^R$, there exists x such that $\check{\partial}_2^R(x) = z'$. Therefore, the map $(x, y) \mapsto \check{\partial}_2^R(x) + h(y)$ is surjective. The converse can be shown in a similar way. ◀

The above lemma implies that the necessary condition stated in Theorem 5 is independent of the choice of rewriting strategy. (\because The map $\mathcal{H}(E \rightarrow R)$ is defined independently from rewriting strategies.)

4.5 Functoriality

For a signature Σ , consider the category \mathcal{E}_Σ such that its objects are sets of equations over Σ and for each pair of objects E, E' with $E^* \subset E'^*$, there exists exactly one morphism $E \rightarrow E'$. Then, we shall see that $\mathcal{H} : \mathcal{E}_\Sigma \rightarrow \mathbf{Ab}$ is a functor. It is straightforward to show that $\mathcal{H}(E \rightarrow E)$ is an identity map, so we show

$$\mathcal{H}(E' \rightarrow E'') \circ \mathcal{H}(E \rightarrow E') = \mathcal{H}(E \rightarrow E'') \quad (4)$$

for any E, E', E'' with $E^* \subset E'^* \subset E''^*$. Recall that $\mathcal{H}(E \rightarrow E')$ is defined using the functor

$$\pi^{E, E'} : \mathcal{R}^E \rightarrow \mathcal{R}^{E'}, \quad [(C_1, u_1) + \cdots + (C_k, u_k)]^E \mapsto [(C_1, u_1) + \cdots + (C_k, u_k)]^{E'}.$$

For a set E'' of equations with $E'^* \subset E''^*$, we can see $\pi^{E', E''} \circ \pi^{E, E'} = \pi^{E, E''}$ and so

$$q^{d', d''} \otimes \bar{\pi}_{\mathbf{P}_1}^{E', E''} \circ q^{d, d'} \otimes \bar{\pi}_{\mathbf{P}_1}^{E, E'} = q^{d, d''} \otimes \bar{\pi}_{\mathbf{P}_1}^{E, E''}. \quad (5)$$

As we saw that the diagram (3) commutes, we have the commutative diagram

$$\begin{array}{ccc}
 \mathbb{Z}_d \otimes (\ker \partial_0^E(k)) & \xrightarrow{\zeta_k} & \mathbb{Z}_d \otimes_{\mathcal{R}^E} \ker \partial_0^E \\
 \downarrow q^{d,d'} \otimes \overline{\pi}_{\mathbf{P}_1}^{E,E'} & & \downarrow \mathcal{H}(E \rightarrow E') \\
 \mathbb{Z}_{d'} \otimes (\ker \partial_0^{E'}(k)) & \xrightarrow{\zeta_k} & \mathbb{Z}_{d'} \otimes_{\mathcal{R}^{E'}} \ker \partial_0^{E'} \\
 \downarrow q^{d',d''} \otimes \overline{\pi}_{\mathbf{P}_1}^{E',E''} & & \downarrow \mathcal{H}(E' \rightarrow E'') \\
 \mathbb{Z}_{d''} \otimes (\ker \partial_0^{E''}(k)) & \xrightarrow{\zeta_k} & \mathbb{Z}_{d''} \otimes_{\mathcal{R}^{E''}} \ker \partial_0^{E''}
 \end{array}
 \begin{array}{l}
 \\
 \mathcal{H}(E \rightarrow E'') \\
 \leftarrow
 \end{array}$$

where $d = \deg(E)$, $d' = \deg(E')$, and $d'' = \deg(E'')$. By (5) and by the uniqueness of $\mathcal{H}(E \rightarrow E'')$, we obtain the equality (4).

5 Related Work

5.1 Free Resolutions in Rewriting

The partial free resolution (2) was given by Malbos and Mimram in [11] to compute invariants called homology groups of an equational theory. For a signature Σ and set E of equational theory over Σ , if we have a free resolution $\dots \xrightarrow{\delta_3} F_3 \xrightarrow{\delta_2} F_2 \xrightarrow{\delta_1} F_1 \xrightarrow{\delta_0} F_0 \xrightarrow{\eta} \mathcal{Z}^E \rightarrow 0$ of \mathcal{Z}^E , the i -th homology group $H_i(\Sigma, E)$ is defined as the abelian group $\ker(\mathbb{Z}_d \otimes \delta_{i-1}) / \text{im}(\mathbb{Z}_d \otimes \delta_i)$. As a general fact of homological algebra, it is shown that the homology groups do not depend on the choice of free resolution. Also, if E' is a set of equations over Σ' and (Σ', E') is Tietze equivalent (see [11] for the definition) to (Σ, E) , $H(\Sigma', E')$ is isomorphic to $H(\Sigma, E)$. The partial free resolution (2) is useful to compute the homology groups since each generating set \mathbf{P}_i is finite. Also, it is shown that for any signature Σ' and set E' of equations over Σ' , if (Σ', E') is Tietze equivalent to (Σ, E) , E' has at least $s(H_2(\Sigma, E))$ elements where $s(A)$ is the minimum number of generators of A . In [8], the author showed that for a set E' of equations over Σ which E is also over, if E' is equivalent to E (in the sense $E^* = E'^*$), E' has at least $s(H_2(\Sigma, E)) + s(\text{im}(\mathbb{Z}_d \otimes \partial_1))$ elements.

Homology groups are defined for many mathematical objects. Homology groups of a group, also called group homologies, have a close relationship with homology groups of an equational theory. For a group G , its homology $H_i(G)$ is defined as follows. Consider the group ring $\mathbb{Z}\langle G \rangle$ and a free resolution of \mathbb{Z} as a left $\mathbb{Z}\langle G \rangle$ -module

$$\dots \xrightarrow{\delta_3} F_3 \xrightarrow{\delta_2} F_2 \xrightarrow{\delta_1} F_1 \xrightarrow{\delta_0} F_0 \xrightarrow{\eta} \mathbb{Z} \rightarrow 0,$$

then $H_i(G) = \ker(\mathbb{Z} \otimes \delta_{i-1}) / \text{im}(\mathbb{Z} \otimes \delta_i)$. If a group G is presented by some generators $S = \{g_1, g_2, \dots\}$ and relations $T = \{r_1 = 1, r_2 = 1, \dots\}$, it is known that there is a partial free resolution

$$\mathbb{Z}\langle G \rangle \underline{T} \rightarrow \mathbb{Z}\langle G \rangle \underline{S} \rightarrow \mathbb{Z}\langle G \rangle \rightarrow \mathbb{Z} \rightarrow 0.$$

(See [3, Exercise 3 in §II.5] for example.)

In [14], Squier considered free resolutions of \mathbb{Z} as a module over the monoid ring $\mathbb{Z}\langle M \rangle$ for a monoid M . Also in this case, if M is presented by generators $S = \{g_1, g_1, \dots\}$ and relations $T = \{l_1 = r_1, l_2 = r_2, \dots\}$, we have a partial free resolution

$$\mathbb{Z}\langle M \rangle \underline{T} \rightarrow \mathbb{Z}\langle M \rangle \underline{S} \rightarrow \mathbb{Z}\langle M \rangle \rightarrow \mathbb{Z} \rightarrow 0.$$

Moreover, he showed that if the relations form a complete string rewriting system, the partial free resolution is extended to

$$\mathbb{Z}\langle M \rangle \underline{U} \rightarrow \mathbb{Z}\langle M \rangle \underline{T} \rightarrow \mathbb{Z}\langle M \rangle \underline{S} \rightarrow \mathbb{Z}\langle M \rangle \rightarrow \mathbb{Z} \rightarrow 0.$$

where U is the set of critical pairs. This resolution inspired our free resolution (2) for an equational theory.

5.2 Narrowing

For a TRS R , a term s is said to be *narrowable* into a term t if there exist a rule $l \rightarrow r \in R$, a context C , and non-variable term s' such that $s = C[s']$, s' and l are unifiable with the mgu σ , and $t = C[r]\sigma$. (We rename variables in l so that $\text{Var}(l) \cup \text{Var}(s) = \emptyset$.) In that case, we write $s \rightsquigarrow_{\sigma, R} t$. The sequence $t_0 \rightsquigarrow_{\sigma_1, R} t_1 \rightsquigarrow_{\sigma_2, R} \cdots \rightsquigarrow_{\sigma_n, R} t_n$ is abbreviated to $t_0 \rightsquigarrow_{\sigma, R}^* t_n$ for $\sigma = \sigma_0 \sigma_1 \dots \sigma_n$. For two substitutions σ, θ and a set X of variables, σ is *more general modulo R on X* than θ , denoted $\sigma \leq_R^X \theta$, if there exists a substitution τ such that $x\theta \approx_R x\sigma\tau$ for any $x \in X$. Then, it is known that narrowing is a complete procedure for R -unification:

- **Theorem 29** ([7]). *Suppose that R is complete and eq be a new symbol with arity 2.*
- *If $\text{eq}(s, t) \rightsquigarrow_{\sigma, R}^* \text{eq}(s', t')$ and s', t' are unifiable with the mgu τ , s, t are R -unifiable with the unifier $\sigma\tau$.*
 - *If s, t are R -unifiable with a unifier θ , then there exist a narrowing sequence $\text{eq}(s, t) \rightsquigarrow_{\sigma, R}^* \text{eq}(s', t')$ and an mgu τ of s', t' such that $\sigma\tau \leq_R^{\text{Var}(\text{eq}(s, t))} \theta$.*

Consider Example 1 again. We can say $x_1 + a$ and $x_1 + b$ are not E_1 -unifiable since $\text{eq}(x_1 + a, x_1 + b)$ is not narrowable by any rules in E_1 .

For Example 2, however, we have an infinite narrowing sequence from $\text{eq}(x_1 + x_1, s(0))$:

$$\begin{aligned} \text{eq}(x_1 + x_1, s(0)) &\rightsquigarrow_{x_1 \mapsto s(x_1), E_2} \text{eq}(s(x_1 + s(x_1)), s(0)) \\ &\rightsquigarrow_{x_1 \mapsto s(x_1), E_2} \text{eq}(s(s(x_1 + s(x_1))), s(0)) \\ &\rightsquigarrow_{x_1 \mapsto s(x_1), E_2} \cdots \end{aligned}$$

so we can see that narrowing is a semi-decision procedure of the problem of equational unification. It has been studied that what kind of restriction on a TRS ensures termination of narrowing [1].

6 Conclusion

We have obtained a functor $\mathcal{H} : \mathcal{E}_\Sigma \rightarrow \mathbf{Ab}$ where \mathcal{E}_Σ is the category of sets of equations and proved that E -unifiability of two terms t, s implies the surjectivity of the homomorphism $\mathcal{H}(E \rightarrow E \cup \{t \approx s\})$. In case where $E \cup \{t \approx s\}$ has a complete TRS, the surjectivity of $\mathcal{H}(E \rightarrow E \cup \{t \approx s\})$ is equivalent to the condition that the matrix $(D(R)|U(E, R))$ has full rank. Therefore, our theorem gives a sound procedure for checking non- E -unifiability.

A The matrix for $E_1 \cup \{x_1 + x_1 \approx 0\}$

The TRS $E_1 \cup \{x_1 + x_1 \approx 0\}$ has the following complete TRS R_3 :

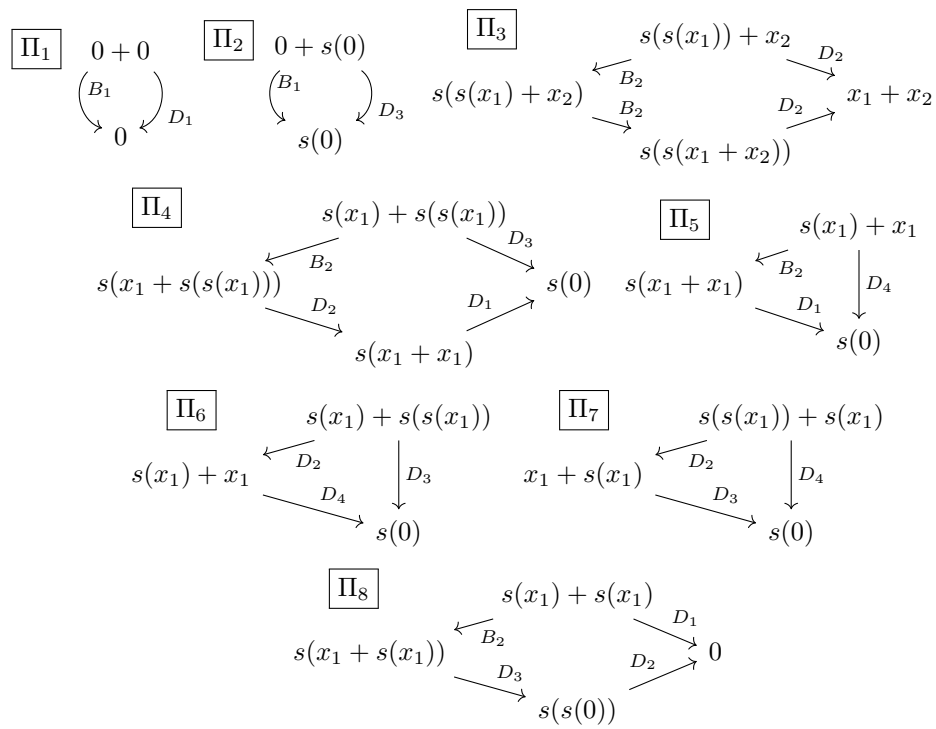

$$\begin{array}{llll} B_1 : 0 + x_1 \rightarrow x_1 & B_2 : s(x_1) + x_2 \rightarrow s(x_1 + x_2) & D_1 : x_1 + x_1 \rightarrow 0 \\ D_2 : s(s(x_1)) \rightarrow x_1 & D_3 : x_1 + s(x_1) \rightarrow s(0) & D_4 : s(x_1) + x_1 \rightarrow s(0). \end{array}$$

The critical pairs are listed in Fig. 1 and the matrix $(D(R_3)|U(E_1, R_3))$ is given as follows.

$$\begin{array}{cccccccccc|cc} & \Pi_1 & \Pi_2 & \Pi_3 & \Pi_4 & \Pi_5 & \Pi_6 & \Pi_7 & \Pi_8 & \Pi_9 & B_1 & B_2 \\ \begin{array}{l} B_1 \\ B_2 \\ D_1 \\ D_2 \\ D_3 \\ D_4 \end{array} & \left(\begin{array}{cccccccccc|cc} 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \end{array} \right) \end{array}$$

It is not too hard to check that it has full rank.

Abstract

Using a recently introduced algebraic framework for classifying fragments of first-order logic, we study the complexity of the satisfiability problem for several ordered fragments of first-order logic, which are obtained from the ordered logic and the fluted logic by modifying some of their syntactical restrictions.

1 Introduction

The study of computational properties of fragments of first-order logic is an active research area, which has been motivated by the general observation that most of the logics used in computer science applications, such as the description logics, can be translated into first-order logic [5]. The main goal of this area is to discover expressive fragments which have nice computational properties; in particular, their satisfiability problem – the problem of determining whether a given sentence of the fragment is satisfiable – should be decidable. Perhaps the most widely studied decidable fragments of first-order logic are the two-variable logic FO^2 and the guarded fragment GF, and their various extensions, see for example [2, 3, 11, 17]. Recently there has been an increasing interest on studying fragments that we refer to in this paper collectively as the *ordered fragments* [1, 12, 13, 14].

Informally speaking, we define a fragment of first-order logic to be ordered, if the syntax of the fragment restricts permutations of variables (with respect to some ordering of the variables) and the order in which the variables are to be quantified. To illustrate these restrictions, consider the sentence

$$\forall v_1(P(v_1) \rightarrow \exists v_2(R(v_1, v_2) \wedge \forall v_3 S(v_1, v_2, v_3))).$$

This sentence is ordered in the sense that variables occur in the right order in the atomic formulas, and they are quantified in the correct order. This particular sentence belongs to the most well-known member of this family of logics, namely the so-called fluted logic, which was proved to have a TOWER-complete satisfiability problem in [13].

Another important ordered fragment, which is also relevant for the present work, is the so-called ordered logic, which on the level of sentences is a fragment of fluted logic (for a formal definition of this logic we refer the reader to section 3). In [4] it was proved that the

complexity of the satisfiability problem of this logic is in PSPACE, by reducing this problem to the satisfiability problem of modal logic over serial frames. It turns out that the satisfiability problem of this fragment is also PSPACE-complete, and the proof for PSPACE-hardness can be found in the full version of this paper.

Thus the aforementioned syntactical restrictions, which guarantee that the formulas of the fragment are ordered, seem to guarantee that the underlying fragments are decidable. Another aspect that makes the ordered fragments of first-order logic interesting is that they are orthogonal in expressive power with respect to other well-known fragments of first-order logic, such as the guarded fragments. For instance, the formula $\forall v_1 \forall v_2 \forall v_3 R(v_1, v_2, v_3)$ is clearly ordered, but it expresses a property that is, for example, neither expressible in GF nor in FO^2 . Thus they form a genuinely new family of decidable fragments of first-order logic, and hence they provide us with a fresh perspective on the question of what makes a fragment of first-order logic decidable.

Ordered fragments can also be used to tame the complexity of decidable fragments. To give an example of what we mean by this, we mention the recent work conducted in [1] where the author showed, among other results, that even though the complexity of the satisfiability problem of GF is 2EXPTIME -complete, it becomes EXPTIME -complete if we restrict attention to the set of formulas that also belong to the fluted logic. More precisely the author introduced a new ordered fragment, namely the forward guarded fragment which contains as a proper subset the aforementioned intersection of GF and the fluted logic, and then proceeded to prove that the satisfiability problem of this stronger logic is EXPTIME -complete.

Since the syntax of ordered logics restricts heavily the permutations of variables and the order in which the variables are quantified, their syntax can often be presented naturally in a variable-free way. Indeed, the fluted logic was originally discovered by Quine as a by-product of his attempts to present the full syntax of first-order logic in a variable-free way by using the predicate functor logic [15, 16]. Interestingly, this approach was also adopted in the recent papers [12, 14], where the fluted logic was presented using its variable-free syntax.

Recently a research program was introduced in [6, 7, 10] for classifying fragments of first-order logic within an algebraic framework that is closely related to the aforementioned predicate functor logic. In a nutshell, the basic idea is to identify fragments of first-order logic with finite algebraic signatures (for more details, see the next section). The algebraic framework naturally suggests the idea of defining logics with limited permutations, and hence it is well suited for defining various logics that belong to the family of ordered fragments.

The main purpose of the present work is to apply the aforementioned algebraic framework to study how the complexities of ordered and fluted logic change, if we modify their syntax in various ways. The first question that we study in this paper is whether one could extend the syntax of ordered logic while maintaining the requirement that the complexity of the satisfiability problem remains relatively low. We will formalize different minimal extension of the ordered logic using additional algebraic operators and study the complexities of the resulting logics. The picture that emerges from our results seems to suggest that even if one modifies the syntax of the ordered logic in a very minimal way, the resulting logics will most likely have much higher complexity. For instance, if we relax even slightly the order in which the variables can be quantified, the resulting logic will have NEXPTIME -hard satisfiability problem. However, there are also exceptions to this rule, since the complexity of ordered logic with equality turns out to be the same as the complexity of the regular ordered logic.

Motivated by the recent study of one-dimensional guarded fragments conducted in [8], we will also study the one-dimensional fragments of fluted logic and ordered logic. Intuitively a logic is called one-dimensional if quantification is limited to applications of blocks of existential

(universal) quantifiers such that at most one variable remains free in the quantified formula. Imposing the restriction of one-dimensionality to fluted logic and ordered logic decreases quite considerably the complexity of the underlying logics: the complexity of the one-dimensional fluted logic is NEXPTIME-complete while the complexity of the one-dimensional ordered logic (even with equality) is NP-complete. In the case of one-dimensional fluted logic we are able to add some further algebraic operators into its syntax without increasing its complexity.

We will also prove that several natural extensions of the ordered logic and the fluted logic are undecidable. First, for the ordered logic we are able to show that if we allow variables to be quantified in an arbitrary order, then the resulting logic is undecidable. Secondly, we are able to show that if we lift the restrictions on how the variables in the atomic formulas can be permuted in the one-dimensional fluted logic, then the resulting logic is undecidable. Finally, in the case of the full fluted logic, we can show that if we relax only slightly the way variables can be permuted and the order in which variables can be quantified, then the resulting logic is undecidable.

2 Algebraic way of presenting logics

The purpose of this section is to present the algebraic framework introduced in [6, 7, 10] for defining logics in an algebraic way. We will be working with purely relational vocabularies with no constants and function symbols. In addition we will not consider vocabularies with 0-ary relation symbols. Throughout this paper we will use the convention where the domain of a model \mathfrak{A} will be denoted by the set A .

Let A be an arbitrary set. As usual, a k -**tuple** over A is an element of A^k . We will use ϵ to denote the 0-ary tuple. Given a non-negative integer k , a k -ary **AD-relation** over A is a pair $T = (X, k)$, where $X \subseteq A^k$. Here 'AD' stands for arity-definite. Given a k -ary AD-relation $T = (X, k)$ over A , we will use $(a_1, \dots, a_k) \in T$ to denote $(a_1, \dots, a_k) \in X$. Given an AD-relation T , we will use $ar(T)$ to denote its arity.

Given a set A , we will use $AD(A)$ to denote the set of all AD-relations over A . If $T_1, \dots, T_k \in AD(A)$, then the tuple (A, T_1, \dots, T_k) will be called an **AD-structure** over A . A bijection $g : A \rightarrow B$ is an **isomorphism** between AD-structures (A, T_1, \dots, T_k) and (B, S_1, \dots, S_k) , if for every $1 \leq \ell \leq k$ we have that $ar(T_\ell) = ar(S_\ell)$, and g is an ordinary isomorphism between the relational structures $(A, rel(T_1), \dots, rel(T_k))$ and $(B, rel(S_1), \dots, rel(S_k))$, where $rel(T)$ denotes the underlying relation of an AD-relation.

The following definition was introduced in [7], where it was called arity-regular relation operator.

► **Definition 1.** A k -ary **relation operator** F is a mapping which associates to each set A a function $F^A : AD(A)^k \rightarrow AD(A)$ and which satisfies the following requirements.

1. The operator F is isomorphism invariant in the sense that whenever two AD-structures (A, T_1, \dots, T_k) and (B, S_1, \dots, S_k) are isomorphic via g , the same mapping is also an isomorphism between the AD-structures $(A, F^A(T_1, \dots, T_k))$ and $(B, F^B(S_1, \dots, S_k))$.
2. There exists a function $\sharp : \mathbb{N}^k \rightarrow \mathbb{N}$ so that for every AD-structure (A, T_1, \dots, T_k) we have that the arity of the AD-relation $F^A(T_1, \dots, T_k)$ is $\sharp(ar(T_1), \dots, ar(T_k))$. In other words the arity of the output AD-relation is always determined fully by the sequence of arities of the input AD-relations.

Given a set of relation operators \mathcal{F} and a vocabulary τ , we can define a language $GRA(\mathcal{F})[\tau]$ as follows, where $R \in \tau$ and $F \in \mathcal{F}$:

$$\mathcal{T} ::= \perp \mid \top \mid R \mid F(\underbrace{\mathcal{T}, \dots, \mathcal{T}}_{ar(F) \text{ times}}).$$

Here “GRA” stands for general relational algebra. We sometimes use the infix notation instead of the prefix notation, if the infix notation is more conventional. Furthermore we will drop the brackets in the case where F is unary operator.

If the underlying vocabulary τ is clear from context or irrelevant, we will write $\text{GRA}(\mathcal{F})$ instead of $\text{GRA}(\mathcal{F})[\tau]$. The members of $\text{GRA}(\mathcal{F})$ will be referred to as **terms**. In the case where \mathcal{F} is a finite set $\{F_1, \dots, F_n\}$, we will use $\text{GRA}(F_1, \dots, F_n)$ to denote $\text{GRA}(\{F_1, \dots, F_n\})$.

Given a model \mathfrak{A} of vocabulary τ and $\mathcal{T} \in \text{GRA}(\mathcal{F})[\tau]$, we define its **interpretation** $\llbracket \mathcal{T} \rrbracket_{\mathfrak{A}}$ recursively as follows:

1. If $\mathcal{T} = \perp$, then we define $\llbracket \mathcal{T} \rrbracket_{\mathfrak{A}} := (\emptyset, 0)$, and if $\mathcal{T} = \top$, then we define $\llbracket \mathcal{T} \rrbracket_{\mathfrak{A}} := (\{\epsilon\}, 0)$.
2. If $\mathcal{T} = R \in \tau$, then we define $\llbracket R \rrbracket_{\mathfrak{A}} = (R^{\mathfrak{A}}, ar(R))$.
3. If $\mathcal{T} = F(\mathcal{T}_1, \dots, \mathcal{T}_k)$, then we define $\llbracket \mathcal{T} \rrbracket_{\mathfrak{A}} = F_A(\llbracket \mathcal{T}_1 \rrbracket_{\mathfrak{A}}, \dots, \llbracket \mathcal{T}_k \rrbracket_{\mathfrak{A}})$.

Note that the interpretation of a term over \mathfrak{A} is an AD-relation over A . The arity of this AD-relation (over some fixed model) is called the arity of the term \mathcal{T} and we will denote it by $ar(\mathcal{T})$. Note that by definition the arity of the output relation is independent of the underlying model, which guarantees that $ar(\mathcal{T})$ is well-defined.

Given two k -ary terms \mathcal{T} and \mathcal{P} over the same vocabulary, we say that \mathcal{T} is **contained** in \mathcal{P} , if for every model \mathfrak{A} over τ and for every $(a_1, \dots, a_k) \in A^k$ we have that if $(a_1, \dots, a_k) \in \llbracket \mathcal{T} \rrbracket_{\mathfrak{A}}$ then $(a_1, \dots, a_k) \in \llbracket \mathcal{P} \rrbracket_{\mathfrak{A}}$. We will denote this by $\mathcal{T} \models \mathcal{P}$. If \mathcal{T} is a 0-ary term and \mathfrak{A} is a model so that $\llbracket \mathcal{T} \rrbracket_{\mathfrak{A}} = (\{\epsilon\}, 0)$, then we denote this by $\mathfrak{A} \models \mathcal{T}$. Given a 0-ary term \mathcal{T} , we say that \mathcal{T} is **satisfiable** if there exists a model \mathfrak{A} so that $\mathfrak{A} \models \mathcal{T}$.

We will conclude this section by briefly indicating how we can compare the expressive power of algebras with fragments of FO. Let $k \geq 0$ and consider an FO-formula $\varphi(v_{i_1}, \dots, v_{i_k})$, where $(v_{i_1}, \dots, v_{i_k})$ lists all the free variables of φ , and $i_1 < \dots < i_k$. If \mathfrak{A} is a suitable model, then φ defines the AD-relation $\llbracket \varphi \rrbracket_{\mathfrak{A}} := (\{(a_1, \dots, a_k) \mid \mathfrak{A} \models \varphi(a_1, \dots, a_k)\}, k)$ over A . Given a k -ary term \mathcal{T} and FO-formula $\varphi(v_{i_1}, \dots, v_{i_k})$ over the same vocabulary, we say that \mathcal{T} is **equivalent** with φ if for every model \mathfrak{A} we have that $\llbracket \mathcal{T} \rrbracket_{\mathfrak{A}} = \llbracket \varphi \rrbracket_{\mathfrak{A}}$.

If \mathcal{F} is a set of relation operators and $\mathcal{L} \subseteq \text{FO}$, then we say that $\text{GRA}(\mathcal{F})$ and \mathcal{L} are **equivalent**, if for every $\mathcal{T} \in \text{GRA}(\mathcal{F})$ there exists an equivalent formula $\varphi \in \mathcal{L}$, and conversely for every formula $\varphi \in \mathcal{L}$ there exists an equivalent term $\mathcal{T} \in \text{GRA}(\mathcal{F})$. Similarly, we say that $\text{GRA}(\mathcal{F})$ and \mathcal{L} are **sententially equivalent**, if for every 0-ary term $\mathcal{T} \in \text{GRA}(\mathcal{F})$ there exists an equivalent sentence $\varphi \in \mathcal{L}$, and conversely for every sentence $\varphi \in \mathcal{L}$ there exists an equivalent 0-ary term $\mathcal{T} \in \text{GRA}(\mathcal{F})$.

3 Relevant fragments and complexity results

The purpose of this section is to present the relevant FO-fragments that we are going to study and to present the main complexity results that we are able to obtain. Through out this section (X, k) and (Y, ℓ) are AD-relations over some set A .

We are going to start by defining formally the ordered logic OL, which will form the backbone for the rest of fragments studied in this paper.

► **Definition 2.** Let $\bar{v}_\omega = (v_1, v_2, \dots)$ and let τ be a vocabulary. For every $k \in \mathbb{N}$ we define the set $\text{OL}^k[\tau]$ as follows.

1. Let $R \in \tau$ be an ℓ -ary relation symbol and consider the prefix (v_1, \dots, v_ℓ) of \bar{v}_ω containing precisely ℓ -variables. If $k \geq \ell$, then $R(v_1, \dots, v_\ell) \in \text{OL}^k[\tau]$.
2. Let $\ell \leq \ell' \leq k$ and suppose that $\varphi \in \text{OL}^\ell[\tau]$ and $\psi \in \text{OL}^{\ell'}[\tau]$. Then $\neg\varphi, (\varphi \wedge \psi) \in \text{OL}^k[\tau]$.
3. If $\varphi \in \text{OL}^{k+1}[\tau]$, then $\exists v_{k+1} \varphi \in \text{OL}^k[\tau]$.

Finally we define $\text{OL}[\tau] := \bigcup_k \text{OL}^k[\tau]$.

► **Remark 3.** The way we have presented the syntax of OL here is slightly different from the way it is often presented in the literature. The two logics are nevertheless equivalent on the level of sentences.

The syntax of this logic is somewhat involved, but it can be given a very nice algebraic characterization using just three relation operators $\{\neg, \cap, \exists\}$, which we are going to define next. Recalling that if F is a relation operator, then F^A denotes the function to which F maps the set A , we can define the relation operators as follows.

- ¬) We define $\neg^A(X, k) = (A^k \setminus X, k)$. We call \neg the **complementation** operator.
- ∩) If $k \neq \ell$, then we define $\cap^A((X, k), (Y, \ell)) = (\emptyset, 0)$. Otherwise we define

$$\cap^A((X, k), (Y, \ell)) = (X \cap Y, k).$$

We call \cap the **intersection** operator.

- ∃) If $k = 0$, then we define $\exists^A(X, k) = (X, k)$. Otherwise we define

$$\exists^A(X, k) = (\{(a_1, \dots, a_k) \mid (a_1, \dots, a_k, b) \in X, \text{ for some } b \in A\}, k - 1).$$

We call \exists the **projection** operator.

The following proposition establishes the promised characterization result.

► **Proposition 4.** *OL and $\text{GRA}(\neg, \cap, \exists)$ are sentimentally equiexpressive.*

The complexity of OL is rather low and thus it is natural to ask how it changes if we add additional operators to the syntax of the logic. The first operator that is studied in this paper is the operator E , which we define as follows.

- E) If $k < 2$, then we define $E^A(X, k) = (X, k)$. Otherwise we define

$$E^A(X, k) = (\{(a_1, \dots, a_k) \in X \mid a_{k-1} = a_k\}, k).$$

We call E the **equality** operator.

It turns out that the addition of equality does not increase the complexity of ordered logic. In our proof for the PSPACE upper bound, it will be convenient to extend the ordered logic with an additional operator I , which we define as follows.

- I) If $k \leq 1$, then we define $I^A(X, k) = (X, k)$, and otherwise we define

$$I^A(X, k) = (\{(a_1, \dots, a_{k-1}) \in A^{k-1} \mid (a_1, \dots, a_{k-1}, a_{k-1}) \in X\}, k - 1).$$

We call I the substitution operator.

In contrast with the equality operator, adding either of the following two operators to OL will result in a logic with NEXPTIME-hard satisfiability problem.

- s) If $k < 2$, then we define $s^A(X, k) = (X, k)$. Otherwise we define

$$s^A(X, k) = (\{(a_1, \dots, a_{k-2}, a_k, a_{k-1}) \mid (a_1, \dots, a_k) \in X\}, k).$$

We call s the **swap** operator.

C) If $k \neq 1$ and $\ell \leq 1$, then we define $C^A((X, k), (Y, \ell)) = (\emptyset, 0)$. In the case where $1 = k \leq \ell$ (the case $1 = \ell \leq k$ is defined similarly) we will define

$$C^A((Y, \ell), (X, k)) = (\{(a_1, \dots, a_\ell) \in Y \mid a_\ell \in X\}, \ell).$$

We call C the **one-dimensional intersection**.

The intuition behind the swap operator is clear: it lifts in a minimal way the ordering restriction on the syntax of ordered logic. The one-dimensional intersection may appear to be somewhat unnatural, but the underlying intuition is that we want to lift the uniformity imposed by \cap in a minimal way.

The other ordered fragment investigated in this paper is the fluted logic FL. We will not give a formal definition for this fragment here, but instead we will introduce its algebraic characterization using the operators $\{\neg, \dot{\cap}, \exists\}$, where $\dot{\cap}$ is defined as follows.

$\dot{\cap}$) If $m := \max\{k, \ell\}$, then we define

$$\dot{\cap}^A((X, k), (Y, \ell)) = (\{(a_1, \dots, a_m) \mid (a_{m-k+1}, \dots, a_m) \in X \text{ and } (a_{m-\ell+1}, \dots, a_m) \in Y\}, m),$$

We call $\dot{\cap}$ the **suffix intersection**.

The following result was proved in [7].

► **Proposition 5.** FL and $\text{GRA}(\neg, \dot{\cap}, \exists)$ are equiexpressive.

It was proved in [13] that the satisfiability problem for FL is TOWER-complete. The natural follow-up question is then to study what fragments of FL have more feasible complexity. In this paper we approach this question by studying the so-called *one-dimensional* fragment of fluted logic. To give this logic an algebraic characterization, we will need to introduce two additional operators, \exists_1 and \exists_0 , which we define as follows.

\exists_1) If $k < 2$, then we define $\exists_1^A(X, k) = (X, k)$. Otherwise we define

$$\exists_1^A(X, k) = (\{a \in A \mid \text{There exists } \bar{b} \in A^{k-1} \text{ such that } a\bar{b} \in X\}, 1)$$

\exists_0) If $k = 0$, then we define $\exists_0^A(X, k) = (X, k)$. Otherwise we define $\exists_0^A(X, k)$ to be $(\{\epsilon\}, 0)$, if X is non-empty, and $(\emptyset, 0)$, if X is empty.

We call collectively the operators \exists_1 and \exists_0 **one-dimensional projection** operators. These operators correspond to quantification which leaves at most one free-variable free. Now we define the algebra $\text{GRA}(\neg, \dot{\cap}, \exists_1, \exists_0)$ to be the one-dimensional fluted logic.

As one might expect, imposing the one-dimensionality requirement to formulas of FL will result in a logic with much lower complexity. The exact complexity of one-dimensional FL turns out to be NEXPTIME-complete, even for its extension with the swap and equality operators $\text{GRA}(s, E, \neg, \dot{\cap}, \exists_1, \exists_0)$. In this paper we also study the one-dimensional fragment of ordered logic with equality operator $\text{GRA}(E, \neg, \cap, \exists)$, for which the satisfiability problem turns out to be just NP-complete.

Besides just decidability results, we will also prove several undecidability results. To state some of these results, we will first define the following operator p .

p) If $k < 2$, then we define $p^A(X, k) = (X, k)$. Otherwise we define

$$p^A(X, k) = (\{(a_1, \dots, a_k) \mid (a_k, a_1, \dots, a_{k-1}) \in X\}, k).$$

We call p the **cyclic permutation** operator.

■ **Table 1** Complexities of the fragments. For each of the fragments the satisfiability problem is complete for the corresponding complexity class listed in the second column, excluding the case $\{s, E, \neg, C, \cap, \exists\}$ where the complexity is not known. All the results listed here are new.

$E, \neg, \cap, \exists_1, \exists_0$	NP
E, \neg, \cap, \exists	PSPACE
$s, \neg, C, \cap, \exists$	NEXPTIME
$E, \neg, C, \cap, \exists$	NEXPTIME
$s, E, \neg, C, \cap, \exists$?
$s, E, \neg, \hat{\cap}, \exists_1, \exists_0$	NEXPTIME
p, \neg, \cap, \exists	Π_1^0
$p, \neg, \hat{\cap}, \exists_1, \exists_0$	Π_1^0
$s, \neg, \hat{\cap}, \exists$	Π_1^0

Adding p to an ordered fragments correspondence essentially to the removal of the syntactical restriction that variables should be quantified in a specific order. The following theorem collects our undecidability results.

► **Theorem 6.** *Suppose that \mathcal{F} is a set of relation operators that contains $\{p, \neg, \cap, \exists\}$, $\{p, \neg, \hat{\cap}, \exists_1, \exists_0\}$ or $\{s, \neg, \hat{\cap}, \exists\}$. Now the satisfiability problem for $\text{GRA}(\mathcal{F})$ is Π_1^0 -hard.*

Let us conclude this section by mentioning briefly two complexity results that follow immediately from the literature and which complement the picture emerging from the results listed in Table 1. First, it is easy to verify that $\text{GRA}(p, s, E, \neg, C, \cap, \exists_1, \exists_0)$ is essentially equivalent with one-dimensional uniform fragment UF_1 , which was proved to be NEXPTIME-complete in [9]. The second result that we should mention is that the satisfiability problem for $\text{GRA}(E, \neg, \hat{\cap}, \exists)$ is TOWER-complete, since it contains FL and it can be translated to FL with equality, for which the satisfiability problem was recently proved in [14] to be TOWER-complete.

4 Tables and normal forms

In this paper we are going to perform several model constructions and hence it is useful to start by collecting some definitions and tools that we are going to need in the later sections.

► **Definition 7.** *Let $k \in \mathbb{Z}_+$ and $\mathcal{F} \subseteq \{I, s\}$. A k -table with respect to \mathcal{F} is a maximally consistent set of k -ary terms of the form \mathcal{T} or $\neg\mathcal{T}$, where $\mathcal{T} \in \text{GRA}(\mathcal{F})$. Given a model \mathfrak{A} and $\bar{a} \in A^k$, we will use $\text{tp}_{\mathfrak{A}}(\bar{a})$ to denote the k -table realized by \bar{a} .*

We will identify k -tables ρ with the terms $\bigcap_{\alpha \in \rho} \alpha$, which makes sense since all of the algebraic signatures that we are going to consider always include the operator \cap . This allows us to use notation such as $\rho \models \rho'$, where ρ and ρ' are k -tables. Furthermore, we will refer to 1-tables also as 1-types. We say that $a \in A$ is **king**, if there is no other element in the model that realizes the same 1-type.

Notice that there is almost no “overlapping” between tables. For instance, if we consider tables for \emptyset , then the table realized by a tuple (a_1, \dots, a_k) will not imply *anything* about the table realized by any non-identity permutation of the tuple (a_1, \dots, a_k) or any sub-tuple of (a_1, \dots, a_k) . And even if we are considering tables for $\{s\}$, the table realized by (a_1, \dots, a_k) will only imply something about the table realized by $(a_1, \dots, a_k, a_{k-1})$.

► **Definition 8.** Let \mathfrak{A} and \mathfrak{B} be models over the same vocabulary, and let \mathcal{F} be a subset of $\{I, s, E, \neg, C, \cap, \hat{\cap}\}$. Let $\bar{a} \in A^k$ and $\bar{b} \in B^k$, where $k \in \mathbb{Z}_+$. We say that \bar{a} and \bar{b} are similar with respect \mathcal{F} , if for every k -ary term $\mathcal{T} \in \text{GRA}(\mathcal{F})$ we have that $\bar{a} \in \llbracket \mathcal{T} \rrbracket_{\mathfrak{A}}$ if, and only if, $\bar{b} \in \llbracket \mathcal{T} \rrbracket_{\mathfrak{B}}$.

In what follows we will not mention the set \mathcal{F} explicitly, since it will always be clear from the context. For different subsets of $\{I, s, E, \neg, C, \cap, \hat{\cap}\}$ one can find explicit characterizations for when two tuples are similar using the notions of 1-types and tables. For example, if $\mathcal{F} = \{s, C, \neg, \cap\}$, then two tuples \bar{a} and \bar{b} are similar with respect to \mathcal{F} if and only if $tp_{\mathfrak{A}}(\bar{a}) = tp_{\mathfrak{B}}(\bar{b})$, $tp_{\mathfrak{A}}(a_{k-1}) = tp_{\mathfrak{B}}(b_{k-1})$ and $tp_{\mathfrak{A}}(a_k) = tp_{\mathfrak{B}}(b_k)$.

We will next introduce two Scott-normal forms for our logics. In the normal forms we will use the operator \cup which can be defined in a standard way in terms of \neg and \cap .

► **Definition 9.** Let $\mathcal{F} \subseteq \{I, s, E, C\}$.

■ We say that a term $\mathcal{T} \in \text{GRA}(\mathcal{F} \cup \{\neg, \cap, \exists\})$ is in normal form, if it has the following form

$$\bigcap_{1 \leq i \leq m_{\exists}} \exists \kappa_i \cap \bigcap_{1 \leq j \leq m_{\forall}} \forall \lambda_j \cap \bigcap_{1 \leq i \leq m_{\exists}} \forall^{n_i} (\neg \alpha_i^{\exists} \cup \exists \beta_i^{\exists}) \cap \bigcap_{1 \leq j \leq m_{\forall}} \forall^{n_j} (\neg \alpha_j^{\forall} \cup \forall \beta_j^{\forall}),$$

where κ_i , λ_j , α_i^{\exists} , β_i^{\exists} , α_j^{\forall} and β_j^{\forall} are terms of $\text{GRA}(\mathcal{F} \cup \{\neg, \cap\})$, and the terms κ_i and λ_j are unary. Here \forall is short-hand notation for $\neg \exists \neg$ and \forall^n stands for a sequence of \forall of length n .

■ We say that a term $\mathcal{T} \in \text{GRA}(\mathcal{F} \cup \{\neg, \cap, \hat{\cap}, \exists_1, \exists_0\})$ is in normal form, if it has the following form

$$\bigcap_{1 \leq i \leq m_{\exists}} \exists_0 \kappa_i \cap \bigcap_{1 \leq j \leq m_{\forall}} \forall_0 \lambda_j \cap \bigcap_{1 \leq i \leq m_{\exists}} \forall_0 (\neg \alpha_i^{\exists} \cup \exists_1 \beta_i^{\exists}) \cap \bigcap_{1 \leq j \leq m_{\forall}} \forall_0 (\neg \alpha_j^{\forall} \cup \forall_1 \beta_j^{\forall}),$$

where κ_i , λ_j , α_i^{\exists} , β_i^{\exists} , α_j^{\forall} and β_j^{\forall} are terms of $\text{GRA}(\mathcal{F} \cup \{\neg, \cap, \hat{\cap}\})$, and the terms κ_i and λ_j are unary. Here \forall_0 and \forall_1 are short-hand notations for $\neg \exists_0 \neg$ and $\neg \exists_1 \neg$ respectively.

In a rather standard fashion one can prove the following lemma.

► **Lemma 10.** Let $\mathcal{F} \subseteq \{I, s, E, C\}$.

1. There is a polynomial time nondeterministic procedure, taking as its input a term $\mathcal{T} \in \text{GRA}(\mathcal{F} \cup \{\neg, \cap, \exists\})$ and producing a term \mathcal{T}' in normal form (over extended signature), such that
 - if $\mathfrak{A} \models \mathcal{T}$, for some structure \mathfrak{A} , then there exists a run of the procedure which produces a term \mathcal{T}' in normal form so that $\mathfrak{A}' \models \mathcal{T}'$ for some expansion \mathfrak{A}' of \mathfrak{A} .
 - if the procedure has a run producing \mathcal{T}' and $\mathfrak{A} \models \mathcal{T}'$, for some \mathfrak{A} , then $\mathfrak{A} \models \mathcal{T}$.
2. There is a polynomial time nondeterministic procedure, which operates similarly as the above procedure with the exception that it takes as its input a term in $\mathcal{T} \in \text{GRA}(\mathcal{F} \cup \{\neg, \cap, \hat{\cap}, \exists_1, \exists_0\})$, and which satisfies the additional requirement that if \mathcal{T} does not contain the operator $\hat{\cap}$, then neither does any of the terms that this procedure produces.

To conclude this section, we will introduce some further notation and terminology which will be useful in the later sections of this paper. Consider a term \mathcal{T} in normal form. Subterms of \mathcal{T} that are of the form $\forall^{n_i} (\neg \alpha_i^{\exists} \cup \exists \beta_i^{\exists})$ or $\forall_0 (\neg \alpha_i^{\exists} \cup \exists_1 \beta_i^{\exists})$ are called **existential requirements** and we will denote them with \mathcal{T}_i^{\exists} . Similarly subterms of the form $\forall^{n_j} (\neg \alpha_j^{\forall} \cup \forall \beta_j^{\forall})$ or of the form $\forall_0 (\neg \alpha_j^{\forall} \cup \forall_1 \beta_j^{\forall})$ will be called **universal requirements** and we will denote them with \mathcal{T}_j^{\forall} . Consider a model \mathfrak{A} and an existential requirement \mathcal{T}_i^{\exists} . If

\mathcal{T}_i^{\exists} is of the form $\forall^{n_i}(\neg\alpha_i^{\exists} \cup \exists\beta_i^{\exists})$ and $\bar{a} \in \llbracket \alpha_i^{\exists} \rrbracket_{\mathfrak{A}}$, then an element $c \in A$ so that $\bar{a}c \in \llbracket \beta_i^{\exists} \rrbracket_{\mathfrak{A}}$ will be called a **witness** for \bar{a} and \mathcal{T}_i^{\exists} . Similarly, if \mathcal{T}_i^{\exists} is of the form $\forall_0(\neg\alpha_i^{\exists} \cup \exists_1\beta_i^{\exists})$ and $a \in \llbracket \alpha_i^{\exists} \rrbracket_{\mathfrak{A}}$, then a tuple $\bar{c} \in A^k$, where $k = ar(\beta_i^{\exists}) - 1$, is called a witness for a and \mathcal{T}_i^{\exists} .

5 Ordered logic with equality

In this section we will study the complexity of $\text{GRA}(E, \neg, \cap, \exists)$, i.e. ordered logic with equality. We will start by proving that this logic has a polynomially bounded model property, which means that each satisfiable term has a model of size at most polynomial with respect to the size of the term.

Before proceeding with the proof, we will first note that w.l.o.g. we can assume that if an element c is a witness for some existential requirement \mathcal{T}_i^{\exists} and a tuple (a_1, \dots, a_k) , then $a_k \neq c$. This follows from the observation that if \mathcal{T}_i^{\exists} is of the form $\forall^{n_i}(\neg\alpha_i^{\exists} \cup \exists\beta_i^{\exists})$ then it is equivalent with the following term $\forall^{n_i}(\neg(\alpha_i^{\exists} \cap \neg\exists E\beta_i^{\exists}) \cup \exists\beta_i^{\exists})$, where we can replace $\exists E\beta_i^{\exists}$ with $I\beta_i^{\exists}$.

► **Theorem 11.** *Let $\mathcal{T} \in \text{GRA}(I, E, \neg, \cap, \exists)$ and suppose that \mathcal{T} is satisfiable. Then \mathcal{T} has a model of size bounded polynomially in $|\mathcal{T}|$.*

Proof. Let $\mathcal{T} \in \text{GRA}(I, E, \neg, \cap, \exists)$ be a term in normal form. Let \mathfrak{A} be a model of \mathcal{T} . Without loss of generality we will assume that \mathfrak{A} contains at least two distinct elements. Our goal is to construct a bounded model $\mathfrak{B} \models \mathcal{T}$. As the domain of our model we will take the set

$$B = \{1, \dots, m\} \times \{0, 1\},$$

where $m = \max\{m_{\exists}^1, m_{\exists}\}$. To define the model, we just need to specify the tables for all the k -tuples of elements from B . This will be done inductively, and in such a way that the following condition is maintained: for every $\bar{b} \in B^k$ there exists $\bar{a} \in A^k$ so that \bar{b} is similar with \bar{a} . Maintaining this requirement will make sure that our model \mathfrak{B} will not violate any universal requirements.

We will start by defining the 1-types for all the elements of B . Since $\mathfrak{A} \models \bigcap_{1 \leq i \leq m_{\exists}^1} \exists \kappa_i$, for every $1 \leq i \leq m_{\exists}^1$ there exists $a_i \in A$ so that $tp_{\mathfrak{A}}(a_i) \models \kappa_i$. We will define that for every $(i, j) \in B$, $tp_{\mathfrak{B}}((i, j)) = tp_{\mathfrak{A}}(a_i)$. Suppose then that we have defined the tables for k -tuples and we wish to define the tables for $(k+1)$ -tuples. We will start by making sure that all the existential requirements are full-filled. So, let $1 \leq i \leq m_{\exists}$ and $\bar{b} \in B^k$ so that we have not assigned a witness for \bar{b} and \mathcal{T}_i^{\exists} . By construction we know that there exists $\bar{a} \in A^k$ which is similar to \bar{b} . Now there exists $a_k \neq c \in A$ so that $\bar{a}c \in \llbracket \beta_i^{\exists} \rrbracket$. If $b_k = (i', j)$, then we will use the element $d = (i, j + 1 \bmod 2)$ as a witness for \bar{b} by defining that $tp_{\mathfrak{B}}(\bar{b}d) = tp_{\mathfrak{A}}(\bar{a}c)$. Since we have reserved for every element $m_{\exists} \leq m$ distinct witnesses for the existential requirements, the process of providing witnesses can be done without conflicts.

Having provided witnesses for k -tuples, we will still need to do define the $(k+1)$ -tables for the remaining k -tables. So, let $\bar{b} \in B^k$ and $d \in B$ be elements so that the table of $\bar{b}d$ has not been defined. If $b_k = d$, then the table for $\bar{b}d$ is determined by the table for \bar{b} . Suppose then that $b_k \neq d$. Let $\bar{a} \in A^k$ be a k -tuple which is similar with \bar{b} . Pick an arbitrary $a_k \neq c \in A$ and define $tp_{\mathfrak{B}}(\bar{b}d) = tp_{\mathfrak{A}}(\bar{a}c)$. ◀

The above theorem can be used to show that if we assume that the underlying vocabulary to be bounded, i.e., there is a fixed constant bound on the maximum arity of relation symbols, then the complexity of the ordered logic is NP-complete.

► **Theorem 12.** *The satisfiability problem for $\text{GRA}(E, \neg, \cap, \exists)$ over bounded vocabularies is NP-complete.*

In the case where the vocabulary is not assumed to be bounded, the complexity of the ordered logic turns out to be PSPACE-complete. The complete proof can be found in the full version of this paper, but we will sketch the basic idea here. The PSPACE-hardness can be proved by reducing the satisfiability problem of modal logic over serial frames to that of $\text{GRA}(\neg, \cap, \exists)$. For the upper bound one can adapt the well-known algorithm of Ladner. The idea is to non-deterministically construct a model in a depth-first fashion by first guessing a set of 1-types of polynomial size (the domain of the model) and then guess tables for longer and longer tuples of elements.

► **Theorem 13.** *The satisfiability problem for $\text{GRA}(E, \neg, \cap, \exists)$ is PSPACE-complete.*

6 Further extensions of ordered logic

In this section we will study extensions of ordered logic which are obtained by adding either the swap or the one-dimensional intersection (or both) into its syntax. It turns out that we can deduce easily from the literature sharp lower bounds for the relevant fragments.

► **Proposition 14.** *Let \mathcal{F} be a set of relation operators that contains either $\{\neg, C, \cap, \exists\}$ or $\{s, \neg, \cap, \exists\}$. Now the satisfiability problem for $\text{GRA}(\mathcal{F})$ is NEXPTIME-hard.*

► **Remark 15.** We remark that the proof of the above proposition shows that the proposition holds even if we restrict attention to vocabularies which contain at most binary relation symbols. In particular, the satisfiability problems of $\text{GRA}(\neg, C, \cap, \exists_1, \exists_0)$ and $\text{GRA}(s, \neg, \cap, \exists_1, \exists_0)$ are also NEXPTIME-hard.

Now we will focus on proving the corresponding upper bounds on the complexities of $\text{GRA}(\neg, C, \cap, \exists)$ and $\text{GRA}(s, \neg, \cap, \exists)$ by showing that their least common extension $\text{GRA}(s, \neg, C, \cap, \exists)$ has the exponentially bounded model property. The core of the argument is the same as the proof of the exponential model property for FO^2 given in [3].

► **Theorem 16.** *Let $\mathcal{T} \in \text{GRA}(s, \neg, C, \cap, \exists)$ and suppose that \mathcal{T} is satisfiable. Then \mathcal{T} has a model of size bounded exponentially in $|\mathcal{T}|$.*

Proof. Let $\mathcal{T} \in \text{GRA}(s, \neg, C, \cap, \exists)$ be a term in normal form and let \mathfrak{A} be a model of \mathcal{T} . Our goal is to construct a bounded model \mathfrak{B} so that $\mathfrak{B} \models \mathcal{T}$. As the domain of the model \mathfrak{B} we will take the set

$$B := \{tp_{\mathfrak{A}}(a) \mid a \in A\} \times \{1, \dots, m\} \times \{0, 1, 2\},$$

where $m = \max\{m_{\exists}^1, m_{\exists}\}$. Clearly $|B| \leq 2^{O(|\mathcal{T}|)}$. Again, to construct the model, we will need to specify the tables for all the k -tuples of elements from B . We will follow the same strategy as in the proof of theorem 11, i.e. the tables will be specified inductively while maintaining the condition that for every $\bar{b} \in B^k$ for which $tp_{\mathfrak{B}}(\bar{b})$ has been specified, there exists $\bar{a} \in A^k$ which is similar to \bar{b} .

We will start with the 1-types. For every $b = (tp_{\mathfrak{A}}(a), i, j) \in B$ we define that $tp_{\mathfrak{B}}(b) := tp_{\mathfrak{A}}(a)$. Suppose then that we have defined the tables for k -tuples. We start defining the tables for $(k+1)$ -tuples by providing witnesses for all the relevant tuples. So, consider an existential requirement \mathcal{T}_i^{\exists} and a tuple $\bar{b} \in B^k$ so that $\bar{b} \in \llbracket \alpha_i \rrbracket_{\mathfrak{B}}$. Suppose that $b_k = (tp_{\mathfrak{A}}(a), i', j)$. By construction there exists a tuple $\bar{a} \in A^k$ so that \bar{b} and \bar{a} are similar. Thus $\bar{a} \in \llbracket \alpha_i \rrbracket_{\mathfrak{A}}$. Since

$\mathfrak{A} \models \mathcal{T}_i^{\exists}$, there exists an element $c \in A$ which is a witness for \bar{a} and \mathcal{T}_i^{\exists} . We will use the element $d = (tp_{\mathfrak{A}}(c), i, j+1 \bmod 3) \in B$ as a witness for \bar{b} by defining that $tp_{\mathfrak{B}}(\bar{b}d) := tp_{\mathfrak{A}}(\bar{a}c)$ and $tp_{\mathfrak{B}}((b_1, \dots, b_{k-1}, d, b_k)) := tp_{\mathfrak{A}}((a_1, \dots, a_{k-1}, c, a_k))$.

Before moving forward, let us argue that our method of assigning witnesses does not produce conflicts. Consider a tuple $\bar{b} = (b_1, \dots, b_k) \in B^k$ and $d \in B$ so that we used d as a witness for \bar{b} and some existential requirement \mathcal{T}_i^{\exists} . We will argue that the table for the tuple (\bar{b}, d) was not defined in two different ways. First we note that we have reserved distinct elements for each of the existential requirements, and thus we used d as a witness for \bar{b} only for the existential requirement \mathcal{T}_i^{\exists} . We then note that since we are assigning witnesses for tuples in a “cyclic” manner, we will not use b_k as a witness for the tuple (b_1, \dots, b_{k-1}, d) . Since these cases are the only possible ways that we might have defined the table of the tuple $\bar{b}d$ in two different ways, we conclude that it is only defined once.

We will now assign tables for the remaining $(k+1)$ -tuples. So, consider a tuple $\bar{b} \in B^k$ and $d = (tp_{\mathfrak{A}}(c), i, j) \in B$ so that we have not defined the table for the tuple $\bar{b}d$. By construction there exists a tuple $\bar{a} \in A^k$ which is similar to \bar{b} . Let $c \in A$ be an element that realizes the 1-type of d (and which is not necessarily distinct from a_k). Now we define that $tp_{\mathfrak{B}}(\bar{b}d) := tp_{\mathfrak{A}}(\bar{a}c)$ and that $tp_{\mathfrak{B}}((b_1, \dots, b_{k-1}, d, b_k)) = tp_{\mathfrak{A}}((a_1, \dots, a_{k-1}, c, a_k))$. ◀

► **Corollary 17.** *The satisfiability problem for $\text{GRA}(s, \neg, C, \cap, \exists)$ is NEXPTIME-complete.*

We will conclude this section by considering $\text{GRA}(E, \neg, C, \cap, \exists)$ and $\text{GRA}(s, E, \neg, C, \cap, \exists)$. An easy modification in the argument of theorem 11 yields a bounded model property for the first logic.

► **Theorem 18.** *Let $\mathcal{T} \in \text{GRA}(E, \neg, C, \cap, \exists)$ and suppose that \mathcal{T} is satisfiable. Then \mathcal{T} has a model of size bounded exponentially in $|\mathcal{T}|$.*

Proof. Let \mathcal{T} be a term in normal form and assume that \mathfrak{A} is a model of \mathcal{T} . If $K = \{tp_{\mathfrak{A}}(a) \mid a \text{ is a king}\}$, then one can take as the domain of the bounded model \mathfrak{B} the set

$$B := K \cup (\{tp_{\mathfrak{A}}(a) \mid a \text{ is not a king}\} \times \{1, \dots, m\} \times \{0, 1\}),$$

where $m = \max\{m_{\exists}^1, m_{\exists}\}$. One can now adapt the proof of theorem 11 to obtain a model \mathfrak{B} of \mathcal{T} with domain B . ◀

► **Corollary 19.** *The satisfiability problem for $\text{GRA}(E, \neg, C, \cap, \exists)$ is NEXPTIME-complete.*

The logic $\text{GRA}(s, E, \neg, C, \cap, \exists)$ turns out to be more tricky. We have not been able to verify whether this logic is undecidable, but we can show that it does not have the finite model property, see the full version of this paper.

7 One-dimensional ordered logics

In this section we consider logics that are obtained from the ordered logic and the fluted logic by imposing the restriction of one-dimensionality. We will first show that the satisfiability problem of the one-dimensional fluted logic, which has been extended with the operators s and E , is NEXPTIME-complete. As usual, we will prove this by showing that the logic has the bounded model property. The proof is heavily influenced by similar model constructions performed in [9] and [8], which were based on the classical construction of [3].

► **Theorem 20.** *Let $\mathcal{T} \in \text{GRA}(s, E, \neg, \dot{\cap}, \exists_1, \exists_0)$ and suppose that \mathcal{T} is satisfiable. Then \mathcal{T} has a model of size bounded exponentially in $|\mathcal{T}|$.*

62:12 Ordered Fragments of First-Order Logic

Proof. Let $\mathcal{T} \in \text{GRA}(s, E, \neg, \hat{\cap}, \exists_1, \exists_0)$ be a term in normal form and suppose that \mathcal{T} is satisfiable. Let us fix an arbitrary model \mathfrak{A} of \mathcal{T} , which we will use to construct a bounded model \mathfrak{B} for \mathcal{T} . Let $K \subseteq A$ denote the set of kings of A . For each existential requirement \mathcal{T}_i^\exists of \mathcal{T} and $k \in \llbracket \alpha_i^\exists \rrbracket_{\mathfrak{A}} \cap K$, we will pick some witness \bar{c} . Let C denote the resulting set. Next, we let P denote the set of non-royal 1-types realized by elements of \mathfrak{A} . Fix some function $f : P \rightarrow A$ with the property that $tp_{\mathfrak{A}}(f(\pi)) = \pi$, for every $\pi \in P$. For every existential requirement \mathcal{T}_i^\exists and $\pi \in P$ so that $\pi \models \alpha_i^\exists$, we will pick some witness $\bar{c}^{\pi,i}$. Let $W_{\pi,i}$ denote the set of elements occurring in $\bar{c}^{\pi,i}$ that are not kings.

As the domain of the bounded model \mathfrak{B} we will then take the following set

$$B = C \cup \bigcup_{\pi,i,j} W_{\pi,i,j},$$

where π ranges over P , i ranges over $\{1, \dots, m\}$, where $m = \max\{m_\exists^1, m_\exists\}$, and j ranges over $\{0, 1, 2\}$. The sets $W_{\pi,i,j}$ are pairwise disjoint copies of the sets $W_{\pi,i}$. Clearly $|B| \leq 2^{O(|\mathcal{T}|)}$. We will make $\mathfrak{B} \upharpoonright C$ isomorphic with $\mathfrak{A} \upharpoonright C$. Furthermore, we will make each of the structures $\mathfrak{B} \upharpoonright (K \cup W_{\pi,i,j})$ isomorphic with the corresponding structures $\mathfrak{A} \upharpoonright (K \cup W_{\pi,i})$.

We will then provide witnesses for elements of B . Since we have already provided witnesses for kings, we need to only provide witnesses for non-royal elements of the court and for elements in $(B \setminus C)$. We will start with the non-royal elements of the court. Consider an existential requirement \mathcal{T}_i^\exists and let $b \in (C \setminus K) \cap \llbracket \alpha_i^\exists \rrbracket_{\mathfrak{A}}$. If there exists a witness for b and \mathcal{T}_i^\exists in C , then nothing needs to be done. So suppose that there does not exist a witness for b and \mathcal{T}_i^\exists in C . If π is the 1-type of b in \mathfrak{B} , then we know that there exists a witness \bar{c} for $f(\pi)$ and \mathcal{T}_i^\exists . We have now two cases.

Suppose first that the length of \bar{c} is one, i.e. $\bar{c} = c$, for some $c \in A$. If $c = a$, then b is already a witness for itself in \mathfrak{B} . If $c \neq a$, then we define $tp_{\mathfrak{B}}(b, d) = tp_{\mathfrak{B}}(a, c)$ and $tp_{\mathfrak{B}}(d, b) = tp_{\mathfrak{B}}(c, a)$, where d denotes the single element of $W_{\pi,i,0}$ (note that d can't be a king, since otherwise b and \mathcal{T}_i^\exists would have had a witness in C). Suppose then that the length of \bar{c} is $k > 1$. If $\bar{d} \in (W_{\pi,i,0} \cup K)^k$ denotes the corresponding witness, then we define $tp_{\mathfrak{B}}(b\bar{d}) = tp_{\mathfrak{A}}(a\bar{c})$ and $tp_{\mathfrak{B}}(bd_1, \dots, d_k, d_{k-1}) = tp_{\mathfrak{A}}(ac_1, \dots, c_k, c_{k-1})$. Note that since b does not occur in \bar{d} and \bar{d} contains at least one non-royal element, the above definitions do not lead into any conflicts with the structure that we have assigned for $\mathfrak{B} \upharpoonright C$.

Thus we have managed to provide witnesses for elements in $C \setminus K$. To provide witnesses for elements of $(B \setminus C)$, we can do roughly the same as above with the exception that instead of $W_{\pi,i,0}$, we will use - assuming that $b \in W_{\pi',i',j}$ - the set $W_{\pi,i,j+1 \bmod 3}$. Let us then briefly argue that the above procedure for producing witnesses can be executed without conflicts. First we note that we do not face any conflicts when assigning witnesses for some b and \mathcal{T}_i^\exists and then for b and $\mathcal{T}_{i'}^\exists$, where $i \neq i'$, since for every j the sets $W_{\pi,i,j}$ and $W_{\pi,i',j}$ are disjoint. Secondly we note that we do not face any conflicts when assigning witnesses for some b and \mathcal{T}_i^\exists and then for $b \neq b'$ and \mathcal{T}_i^\exists , since in the first case we assign a table for the tuple $b\bar{d}$ and in the second case for $b'\bar{d}$, and neither of these tables imply anything about the other table. Finally we note that since we are assigning witnesses in a cyclic manner, if we use \bar{d} as a witness for $b \notin C$ and \mathcal{T}_i^\exists , then we are never using any tuple containing b as a witness for any of the elements in \bar{d} .

To complete the structure, for every k we need to define the tables for tuples $\bar{b} \in B^k$. We can do this inductively with respect to k as follows. Suppose first that there exists distinct elements $b, b' \in B$ so that we have not assigned table for the pair (b, b') . Now we choose a pair of distinct elements $a, a' \in A$ with the same 1-types as b and b' , and then define $tp_{\mathfrak{B}}(b, b') = tp_{\mathfrak{A}}(a, a')$ and $tp_{\mathfrak{B}}(b', b) = tp_{\mathfrak{A}}(a', a)$. Note that such elements a, a' exist even if the elements b, b' would have the same 1-types, since at least one of them is not a king.

Suppose then that we have defined the tables for every $\bar{d} \in B^k$. Let $b \in B$ and $\bar{d} \in B^k$ be so that we have not defined the table for the tuple (b, \bar{d}) . By construction there exists $\bar{c} \in A^k$ which is similar with \bar{d} . Let $a \in A$ be an arbitrary element which has the same 1-type as b . We then define $tp_{\mathfrak{B}}(b, \bar{d}) = tp_{\mathfrak{A}}(a, \bar{c})$ and $tp_{\mathfrak{B}}(b, d_1, \dots, d_k, d_{k-1}) = tp_{\mathfrak{A}}(a, c_1, \dots, c_k, c_{k-1})$. Continuing this way it is clear that we can define tables for all the tuples of B^k in such a way that we do not violate any of the universal requirements. ◀

► **Corollary 21.** *The satisfiability problem for $\text{GRA}(s, E, \neg, \dot{\cap}, \exists_1, \exists_0)$ is NEXPTIME-complete.*

We will conclude this section by considering the one-dimensional ordered logic with equality, which is the logic $\text{GRA}(E, \neg, \cap, \exists_1, \exists_0)$. Perhaps unsurprisingly, the satisfiability problem for this logic is NP-complete.

► **Theorem 22.** *The satisfiability problem for $\text{GRA}(E, \neg, \cap, \exists_1, \exists_0)$ is NP-complete.*

8 Conclusions

In this paper we have studied systematically how the complexities of various ordered fragments of first-order logic change if we modify slightly the underlying syntax. The general picture that emerges is that even if we relax only slightly the restrictions on the syntax, the complexity of the logic can increase drastically. On the other hand, we have seen that adding the further restriction of one-dimensionality on the logics can greatly decrease the complexity of the logic.

There are several directions in which the work conducted in this paper can be continued. Perhaps the most immediate technical problem is whether the logic $\text{GRA}(s, E, \neg, C, \cap, \exists)$ is decidable. As we have seen, this logic does not have the finite model property, and thus we don't expect that traditional model building techniques can be used to prove that it is decidable. On the other hand, we have not been able to prove that this logic is undecidable using standard tiling arguments.

Abstract

We introduce a new notion of \mathcal{C} -simple problems for a class \mathcal{C} of decision problems (i.e. languages), w.r.t. a particular reduction. A problem is \mathcal{C} -simple if it can be reduced to each problem in \mathcal{C} . This can be viewed as a conceptual counterpart to \mathcal{C} -hard problems to which all problems in \mathcal{C} reduce. Our concrete example is the class of *non-regular* deterministic context-free languages (DCFL'), with a truth-table reduction by Mealy machines. The main technical result is a proof that the DCFL' language $L_{\#} = \{0^n 1^n \mid n \geq 1\}$ is DCFL'-simple, and can be thus viewed as one of the simplest languages in the class DCFL', in a precise sense. The notion of DCFL'-simple languages is nontrivial: e.g., the language $L_R = \{wcw^R \mid w \in \{a, b\}^*\}$ is not DCFL'-simple.

By describing an application in the area of neural networks (elaborated in another paper), we demonstrate that \mathcal{C} -simple problems under suitable reductions can provide a tool for expanding the lower-bound results known for single problems to the whole classes of problems.

1 Introduction

We introduce a new notion of \mathcal{C} -simple problems for a class \mathcal{C} of decision problems (i.e. languages). A problem is \mathcal{C} -simple if it can be reduced to each problem in \mathcal{C} ; if this problem is, moreover, in \mathcal{C} , it can be viewed as a simplest problem in \mathcal{C} . The \mathcal{C} -simple problems are thus a conceptual counterpart to the common \mathcal{C} -hard problems (like, e.g., NP-hard problems) to which conversely any problem in \mathcal{C} reduces. These definitions (of \mathcal{C} -simple and \mathcal{C} -hard problems) are parametrized by a chosen reduction that does not have a higher computational complexity than the class \mathcal{C} itself. Therefore, it may be said that if a \mathcal{C} -hard problem has a (computationally) “easy” solution, then each problem in \mathcal{C} has an “easy” solution. On the other hand, if we prove that a \mathcal{C} -simple problem is not “easy”, in particular that it cannot be solved by machines of a type \mathcal{M} that can implement the respective reduction, then all problems in \mathcal{C} are not “easy”, that is, are not solvable by \mathcal{M} ; this extends a lower-bound result for one problem to the whole class of problems.

In this paper, we consider \mathcal{C} to be the class of non-regular deterministic context-free languages, which we denote by DCFL' ; we thus have $\text{DCFL}' = \text{DCFL} \setminus \text{REG}$ (where REG denotes the class of regular languages). We use a truth-table reduction by Mealy machines (which is motivated below). Hence a DCFL' -simple problem is a language $L_0 \subseteq \Sigma^*$ (over an alphabet Σ) that can be reduced to each DCFL' language $L \subseteq \Delta^*$ by a Mealy machine \mathcal{A} with an oracle L , denoted \mathcal{A}^L . More precisely, we have a finite-state transducer \mathcal{A} that transforms a given input word $w \in \Sigma^*$ to a word $\mathcal{A}(w) \in \Delta^*$ (a query prefix), and each state q of \mathcal{A} is associated with a finite tuple $\sigma_q = (s_{q,1}, s_{q,2}, \dots, s_{q,r_q})$ of r_q words from Δ^* (query suffixes), and with a truth table $f_q : \{0,1\}^{r_q} \rightarrow \{0,1\}$. The oracle-machine \mathcal{A}^L behaves like \mathcal{A} , hence it reads an input word w (translating it to $\mathcal{A}(w)$) by which it enters a state q , and then submits r_q queries, i.e. the words $\mathcal{A}(w) \cdot s_{q,i}$ for all $i \in \{1, 2, \dots, r_q\}$, to the oracle that for each $i \in \{1, 2, \dots, r_q\}$ decides whether or not $\mathcal{A}(w) \cdot s_{q,i}$ is in L (or, equivalently, whether or not $\mathcal{A}(w)$ belongs to the quotient $L/s_{q,i} = \{v \in \Delta^* \mid v \cdot s_{q,i} \in L\}$); the oracle-answers are then aggregated by the truth table f_q , which decides whether or not $w \in L_0$.

This truth-table reduction by Mealy machines induces a preorder on the class of languages; we denote this preorder by \leq_{tt}^A , using the superscript “A” to stress that our truth-table reduction is realized by simple *automata*, not by general Turing machines. The main technical result of this paper is that the DCFL' language $L_{\#} = \{0^n 1^n \mid n \geq 1\}$ (over the binary alphabet $\{0,1\}$) is DCFL' -simple, since $L_{\#} \leq_{tt}^A L$ for each language L in DCFL' . The class DCFLS of DCFL' -simple languages comprises REG and is a strict subclass of DCFL ; e.g., the DCFL' language $L_R = \{w c w^R \mid w \in \{a,b\}^*\}$ over the alphabet $\{a,b,c\}$ proves to be not DCFL' -simple. The closure properties of DCFLS are similar to that of DCFL as the class DCFLS is closed under complement and intersection with regular languages, while being not closed under concatenation, intersection, and union.

The above definition of DCFL' -simple problems has originally been motivated by the analysis of the computational power of neural network (NN) models which is known to depend on the (descriptive) complexity of their weight parameters [9, 12]. The so-called analog neuron hierarchy [10] of binary-state NNs with increasing number of α extra analog-state neurons, denoted as αANN for $\alpha \geq 0$, has been introduced for studying NNs with realistic weights between integers (finite automata) and rational numbers (Turing machines). We use the notation αANN also for the class of languages accepted by αANNs , which can clearly be distinguished by the context. The separation $1\text{ANN} \subsetneq 2\text{ANN}$ has been witnessed by the DCFL' language $L_{\#} \in 2\text{ANN} \setminus 1\text{ANN}$. The proof of $L_{\#} \notin 1\text{ANN}$ is rather technical (based on the Bolzano-Weierstrass theorem) which could hardly be generalized to other DCFL' languages, while it was conjectured that $L \notin 1\text{ANN}$ for all DCFL' languages L , that is, $\text{DCFL}' \subseteq (2\text{ANN} \setminus 1\text{ANN})$ (implying $1\text{ANN} \cap \text{DCFL} = 0\text{ANN} = \text{REG}$). An idea how to prove this conjecture is to show that $L_{\#}$ is in some sense the simplest problem in the class DCFL' , namely, to reduce $L_{\#}$ to any DCFL' language L by using a reduction that can be carried out by 1ANNs , which are at least as powerful as finite automata. If the composition of a 1ANN that carries out the reduction of $L_{\#}$ to L with a hypothetical 1ANN accepting L can be realized by another 1ANN , which would thus accept $L_{\#}$, we get that no 1ANN accepting L can exist, since $L_{\#}$ has been proven not to be accepted by 1ANNs .

The idea why $L_{\#}$ should serve as the simplest language in the class DCFL' comes from the fact that any reduced context-free grammar G generating a non-regular language $L \subseteq \Delta^*$ is *self-embedding* [4, Theorem 4.10]. This means that there is a so-called self-embedding nonterminal A admitting the derivation $A \Rightarrow^* xAy$ for some non-empty strings $x, y \in \Delta^+$. Since G is reduced, there are strings $v, w, z \in \Delta^*$ such that $S \Rightarrow^* vAz$ and $A \Rightarrow^* w$ where S is the start nonterminal in G , which implies $S \Rightarrow^* vx^mwy^mz \in L$ for every $m \geq 0$. It is thus

straightforward to suggest to reduce an input word $0^m 1^n \in \{0, 1\}^*$ where $m, n \geq 1$, to the string $vx^m wy^n z \in \Delta^*$ (while the inputs outside $0^+ 1^+$ are mapped onto some fixed string outside L) since $0^m 1^n \in L_{\#}$ entails $vx^m wy^n z \in L$.

However, the suggested (one-one) reduction from $L_{\#}$ to L is not consistent because $vx^m wy^n z \in L$ does not necessarily imply $0^m 1^n \in L_{\#}$. For example, consider the DCFL' language $L_1 = \{0^m 1^n \mid 1 \leq m \leq n\}$ over the binary alphabet $\Delta = \{0, 1\}$ for which there are no words $v, x, w, y, z \in \Delta^*$ such that $vx^m wy^n z \in L_1$ would ensure $m = n$. Nevertheless, we can pick two inputs $0^m 1^{n-1}$ and $0^m 1^n$ instead of one, that is, $x = 0$, $y = 1$, and $v = w = z = \varepsilon$ (ε denoting the empty string), which satisfy $0^m 1^n \in L_{\#}$ iff $m = n$ iff $vx^m wy^{n-1} z \notin L_1$ and $vx^m wy^n z \in L_1$.

It turns out that this can be generalized to any DCFL' language. Namely, we prove in this paper that for each DCFL' language $L \subseteq \Delta^*$, over an alphabet Δ , there are words $v, x, w, y, z \in \Delta^+$ and a language $L' \in \{L, \bar{L}\}$, where $\bar{L} = \Delta^* \setminus L$ is the complement of L , such that $0^m 1^n \in L_{\#}$ iff $vx^m wy^{n-1} z \notin L'$ and $vx^m wy^n z \in L'$. In fact, we even show that either for all $m, n \geq 0$ we have $vx^m wy^n z \in L'$ iff $m = n$, or for all $m, n \geq 0$ we have $vx^m wy^n z \in L'$ iff $m \leq n$. We note that this technical result seems interesting on its own since in the class DCFL it substantially strengthens the known result for context-free languages (CFL) [2, Theorem 2.10] that for any CFL' language $L \subseteq \Delta^*$ (where $\text{CFL}' = \text{CFL} \setminus \text{REG}$) there is a so-called non-degenerated iterative pair $(v, x, w, y, z) \in (\Delta^*)^5$ with non-empty xy , satisfying $vx^m wy^m z \in L$ for all $m \geq 0$ and $vx^m wy^n z \notin L$ for some $m \neq n$.

Hence the inconsistent many-one (in fact, one-one) reduction from $L_{\#}$ with one query to the oracle L is replaced by a truth-table reduction, that is, by a special Turing reduction in which all its finitely many (in our case two) oracle queries are presented at the same time and there is a Boolean function (a truth table) which, when given the answers to the queries, produces the final answer of the reduction. This truth-table reduction from $L_{\#}$ to L can be implemented by a deterministic finite-state transducer (a Mealy machine) \mathcal{A} with the oracle L : It transforms the input $0^m 1^n$ where $m, n \geq 1$ (the inputs outside $0^+ 1^+$ are rejected), to the output $vx^m wy^{n-1} \in \Delta^+$ and carries out two queries to L that arise by concatenation of this output with two fixed suffixes z and yz ; hence the queries are $vx^m wy^{n-1} z \stackrel{?}{\in} L$ and $vx^m wy^n z \stackrel{?}{\in} L$. The truth table is defined so that the input $0^m 1^n$ is accepted by \mathcal{A}^L iff the two answers to these queries are distinct and at same time, the first answer is negative in the case $L' = L$, and positive in the case $L' = \bar{L}$, which is equivalent to $0^m 1^n \in L_{\#}$.

It follows that the DCFL' language $L_{\#}$ is DCFL'-simple under the truth-table reduction by Mealy machines. Since this reduction can be implemented by 1ANNs, we achieve the desired stronger separation $\text{DCFL}' \subseteq (\text{2ANN} \setminus \text{1ANN})$ in the analog neuron hierarchy [10, 11]. This result constitutes a non-trivial application of the proposed concept of DCFL'-simple problem. Moreover, if we could generalize the result to (nondeterministic) CFL, e.g. by proving that some DCFL' language is CFL'-simple, which would imply that $L_{\#}$ is CFL'-simple by the transitivity of reduction, then we would achieve that even the intersection of CFL' and 1ANN is empty. We note the interesting fact that $L_{\#}$ cannot be CSL'-simple (under our reduction), since 1ANN accepts some context-sensitive languages outside CFL [10].

In general, if we show that some \mathcal{C} -simple problem under a given reduction cannot be computed by a computational model \mathcal{M} that implements this reduction, then all problems in the class \mathcal{C} are not solvable by \mathcal{M} either. The notion of \mathcal{C} -simple problems can thus be useful for expanding known (e.g. technical) lower-bound results for individual problems to the whole classes of problems at once, as it was the case of the DCFL'-simple problem $L_{\#} \notin \text{1ANN}$, expanding to $\text{DCFL}' \cap \text{1ANN} = \emptyset$. It seems worthwhile to explore if looking for \mathcal{C} -simple problems in other complexity classes \mathcal{C} could provide effective tools for strengthening known lower bounds.

We remark that the hardest context-free language by Greibach [3] can be viewed as CFL-hard under a special type of our reduction \leq_{tt}^A . Related line of study concerns the types of reductions used in finite or pushdown automata with oracle. For example, non-deterministic finite automata with oracle complying with many-one restriction have been applied to establishing oracle hierarchies over the context-free languages [8]. For the same purpose, oracle pushdown automata have been used for many-one, truth-table, and Turing reducibilities, respectively, inducing the underlying definitions also to oracle nondeterministic finite automata [14]. In addition, nondeterministic finite automata whose oracle queries are completed by the prefix of an input word that has been read so far and the remaining suffix, have been employed in defining a polynomial-size oracle hierarchy [1].

In the preliminary study [13], some considerations about the simplest DCFL' language have appeared, yet without formal definitions of DCFL'-simple problems, that included only sketches of incomplete proofs of weaker results based on the representation of DCFL by so-called deterministic monotonic restarting automata [6], which have initiated investigations of non-regularity degrees in DCFL [7].

In this paper we achieve a complete argument for $L_{\#}$ to be a DCFL'-simple problem, within the framework of deterministic pushdown automata (DPDA) by using some ideas on regularity of pushdown processes from [5]. We now give an informal overview of the proof. Given a DPDA \mathcal{M} recognizing a non-regular language $L \subseteq \Delta^*$, it is easy to realize that some computations of \mathcal{M} (from the initial configuration) must be reaching configurations where the stack is arbitrarily large while it can be (almost) erased afterwards. Hence the existence of words $v, x, w, y, z \in \Delta^+$ such that $vx^mwy^mz \in L$ for all $m \geq 0$ is obvious. However, we aim to guarantee that for all m, n the equality $m = n$ holds if, and only if, $vx^mwy^{n-1}z \notin L'$ and $vx^mwy^n z \in L'$, where L' is either the language L or its complement. This is not so straightforward but it is confirmed by our detailed analysis (in Section 3). We study the computation of \mathcal{M} on an infinite word $a_1a_2a_3 \dots$ that visits infinitely many pairwise non-equivalent configurations. We use a natural congruence property of language equivalence on the set of configurations, and avoid some tedious technical details by a particular use of Ramsey's theorem. This allows us to extract the required tuple $v, x, w, y, z \in \Delta^+$ from the mentioned infinite computation. We note that determinism of \mathcal{M} is essential in the presented proof; we leave open if it can be relaxed to show that $L_{\#}$ is even CFL'-simple.

The rest of the paper is organized as follows. In Section 2 we recall basic definitions and notation regarding DPDA and Mealy machines, introduce the novel concept of DCFL'-simple problems under truth-table reduction by Mealy machines and show some simple properties of the class DCFLS of DCFL'-simple problems. In Section 3 we present the proof of the main technical result which shows that $L_{\#}$ is DCFL'-simple. Finally, we summarize the results and list some open problems in Section 4.

2 DCFL'-Simple Problem Under Truth-Table Mealy Reduction

In this section we define the truth-table reduction by Mealy machines, introduce the notion of DCFL'-simple problems, show their basic properties, and formulate the main technical result (Theorem 1). But first we recall standard definitions of pushdown automata.

A *pushdown automaton (PDA)* is a tuple $\mathcal{M} = (Q, \Sigma, \Gamma, R, q_0, X_0, F)$ where Q is a finite set of states including the start state $q_0 \in Q$ and the set $F \subseteq Q$ of accepting states, while the finite sets $\Sigma \neq \emptyset$ and $\Gamma \neq \emptyset$ represent the input and stack alphabets, respectively, with the initial stack symbol $X_0 \in \Gamma$. In addition, the set R contains finitely many transition rules

$pX \xrightarrow{a} q\gamma$ with the meaning that \mathcal{M} in state $p \in Q$, on the input $a \in \Sigma_\varepsilon = \Sigma \cup \{\varepsilon\}$ (recall that ε denotes the empty string), and with $X \in \Gamma$ as the topmost stack symbol may read a , change the state to $q \in Q$, and pop X , replacing it by pushing $\gamma \in \Gamma^*$.

By a *configuration* of \mathcal{M} we mean $p\alpha \in Q \times \Gamma^*$, and we define relations \xrightarrow{a} for $a \in \Sigma_\varepsilon$ on $Q \times \Gamma^*$: each rule $pX \xrightarrow{a} q\gamma$ in R induces $pX\alpha \xrightarrow{a} q\gamma\alpha$ for all $\alpha \in \Gamma^*$; these relations are naturally extended to \xrightarrow{w} for $w \in \Sigma^*$. For a configuration $p\alpha$ we define $\mathcal{L}(p\alpha) = \{w \in \Sigma^* \mid p\alpha \xrightarrow{w} q\beta \text{ for some } q \in F \text{ and } \beta \in \Gamma^*\}$, and $\mathcal{L}(\mathcal{M}) = \mathcal{L}(q_0X_0)$ is the language accepted by \mathcal{M} . A PDA \mathcal{M} is *deterministic* (a DPDA) if there is at most one rule $pX \xrightarrow{a} ..$ for each tuple $p \in Q$, $X \in \Gamma$, $a \in \Sigma_\varepsilon$; moreover, if there is a rule $pX \xrightarrow{\varepsilon} ..$, then there is no rule $pX \xrightarrow{a} ..$ for $a \in \Sigma$. We also use the standard assumption that all ε -steps are popping, that is, in each rule $pX \xrightarrow{\varepsilon} q\gamma$ in R we have $\gamma = \varepsilon$.

The languages accepted by (deterministic) pushdown automata constitute the class of (*deterministic*) *context-free languages*; the classes are denoted by DCFL and CFL, respectively, whereas $\text{DCFL}' = \text{DCFL} \setminus \text{REG}$.

In the following theorem we formulate the main technical result: any language in DCFL' includes a certain “projection” of the language $L_\# = \{0^n1^n \mid n \geq 1\}$, which means that $L_\#$ is in some sense the simplest language in the class DCFL' . The theorem, whose proof will be presented in Section 3, thus provides an interesting property of DCFL' .

► **Theorem 1.** *Let $L \subseteq \Delta^*$ be a non-regular deterministic context-free language over an alphabet Δ . There exist non-empty words $v, x, w, y, z \in \Delta^+$ and a language $L' \in \{L, \bar{L}\}$ (where $\bar{L} = \Delta^* \setminus L$ is the complement of L) such that*

- *either for all $m, n \geq 0$ we have $vx^mwy^n z \in L'$ iff $m = n$,*
- *or for all $m, n \geq 0$ we have $vx^mwy^n z \in L'$ iff $m \leq n$;*

this entails that for all $m \geq 0$ and $n > 0$ we have

$$(vx^mwy^{n-1}z \notin L' \text{ and } vx^mwy^n z \in L') \quad \text{iff} \quad m = n. \quad (1)$$

In order to formalize the DCFL' -simple problems, we now define a *Mealy machine* \mathcal{A} with an *oracle*: it is a tuple $\mathcal{A} = (Q, \Sigma, \Delta, \delta, \lambda, q_0, \{(\sigma_q, f_q) \mid q \in Q\})$ where Q is a finite set of states including the start state $q_0 \in Q$, and the finite sets $\Sigma \neq \emptyset$ and $\Delta \neq \emptyset$ represent the input and output (oracle) alphabets, respectively. Moreover, $\delta : Q \times \Sigma \rightarrow Q$ is a (partial) state-transition function which extends to input strings as $\delta : Q \times \Sigma^* \rightarrow Q$ where $\delta(q, \varepsilon) = q$ for every $q \in Q$, while $\delta(q, wa) = \delta(\delta(q, w), a)$ for all $q \in Q$, $w \in \Sigma^*$, $a \in \Sigma$. Similarly, $\lambda : Q \times \Sigma \rightarrow \Delta^*$ is an output function which extends to input strings as $\lambda : Q \times \Sigma^* \rightarrow \Delta^*$ where $\lambda(q, \varepsilon) = \varepsilon$ for all $q \in Q$, and $\lambda(q, wa) = \lambda(q, w) \cdot \lambda(\delta(q, w), a)$ for all $q \in Q$, $w \in \Sigma^*$, $a \in \Sigma$. In addition, for each $q \in Q$, the tuple $\sigma_q = (s_{q,1}, s_{q,2}, \dots, s_{q,r_q})$ of strings in Δ^* contains r_q query suffixes, while $f_q : \{0, 1\}^{r_q} \rightarrow \{0, 1\}$ is a truth table that aggregates the answers to the r_q oracle queries.

The above Mealy machine \mathcal{A} starts in the start state q_0 and operates as a deterministic finite-state transducer that transforms an input word $w \in \Sigma^*$ to the output string $\mathcal{A}(w) = \lambda(q_0, w) \in \Delta^*$ written to a so-called oracle tape. The oracle tape is a semi-infinite, write-only tape which is empty at the beginning and its contents are only extended in the course of computation by appending the strings to the right. Namely, given a current state $q \in Q$ and an input symbol $a \in \Sigma$, the machine \mathcal{A} moves to the next state $\delta(q, a) \in Q$ and writes the string $\lambda(q, a) \in \Delta^*$ to the oracle tape, if $\delta(q, a)$ is defined; otherwise \mathcal{A} rejects the input. After reading the whole input word $w \in \Sigma^*$, the machine \mathcal{A} is in the state $p = \delta(q_0, w) \in Q$, while the oracle tape contains the output $\mathcal{A}(w) = \lambda(q_0, w) \in \Delta^*$.

Finally, the Mealy machine \mathcal{A} , equipped with an oracle $L \subseteq \Delta^*$, in this case denoted \mathcal{A}^L , queries the oracle whether $\mathcal{A}(w)$ belongs to the (right) quotient $L/s_{p,i} = \{u \in \Delta^* \mid u \cdot s_{p,i} \in L\}$, for each suffix $s_{p,i}$ in σ_p , and the answers are aggregated by the truth table f_p . Thus, the oracle Mealy machine \mathcal{A}^L accepts the input word $w \in \Sigma^*$ iff

$$f_p \left(\chi_{L/s_{p,1}}(\mathcal{A}(w)), \chi_{L/s_{p,2}}(\mathcal{A}(w)), \dots, \chi_{L/s_{p,r_p}}(\mathcal{A}(w)) \right) = 1$$

where $p = \delta(q_0, w)$ and $\chi_{L/s_{p,i}} : \Delta^* \rightarrow \{0, 1\}$ is the characteristic function of $L/s_{p,i}$, that is, $\chi_{L/s_{p,i}}(u) = 1$ if $u \cdot s_{p,i} \in L$, and $\chi_{L/s_{p,i}}(u) = 0$ if $u \cdot s_{p,i} \notin L$. The language accepted by the machine \mathcal{A}^L is defined as $\mathcal{L}(\mathcal{A}^L) = \{w \in \Sigma^* \mid w \text{ is accepted by } \mathcal{A}^L\}$.¹

We say that $L_1 \subseteq \Sigma^*$ is *truth-table reducible* to $L_2 \subseteq \Delta^*$ by a Mealy machine, which is denoted as $L_1 \leq_{tt}^A L_2$, if $L_1 = \mathcal{L}(\mathcal{A}^{L_2})$ for some Mealy machine \mathcal{A} running with the oracle L_2 . The following lemma shows that we can chain these reductions together since the relation \leq_{tt}^A is a preorder.

► **Lemma 2.** *The relation \leq_{tt}^A is reflexive and transitive.*

Proof. The relation \leq_{tt}^A is reflexive since $L = \mathcal{L}(\mathcal{A}^L) \subseteq \Sigma^*$ for the oracle Mealy machine $\mathcal{A}^L = (\{q\}, \Sigma, \Sigma, \delta, \lambda, q, \{(\sigma_q, f_q)\})$ where $\delta(q, a) = q$ and $\lambda(q, a) = a$ for every $a \in \Sigma$, $\sigma_q = (\varepsilon)$, and f_q is the identity.

Now we show that the relation \leq_{tt}^A is transitive. Let $L_1 \leq_{tt}^A L_2$ and $L_2 \leq_{tt}^A L_3$ which means $L_1 = \mathcal{L}(\mathcal{A}_1^{L_2}) \subseteq \Sigma^*$ and $L_2 = \mathcal{L}(\mathcal{A}_2^{L_3}) \subseteq \Delta^*$ for some oracle Mealy machines $\mathcal{A}_1^{L_2} = (Q_1, \Sigma, \Delta, \delta_1, \lambda_1, q_0^1, \{(\pi_q, g_q) \mid q \in Q_1\})$ and $\mathcal{A}_2^{L_3} = (Q_2, \Delta, \Theta, \delta_2, \lambda_2, q_0^2, \{(\varrho_q, h_q) \mid q \in Q_2\})$, respectively. We will construct the oracle Mealy machine $\mathcal{A}^{L_3} = (Q, \Sigma, \Theta, \delta, \lambda, q_0, \{(\sigma_q, f_q) \mid q \in Q\})$ such that $L_1 = \mathcal{L}(\mathcal{A}^{L_3}) \subseteq \Sigma^*$ which implies the transitivity $L_1 \leq_{tt}^A L_3$. We define $Q = Q_1 \times Q_2$ with $q_0 = (q_0^1, q_0^2)$, $\delta((q_1, q_2), a) = (\delta_1(q_1, a), \delta_2(q_2, \lambda_1(q_1, a)))$ and $\lambda((q_1, q_2), a) = \lambda_2(q_2, \lambda_1(q_1, a))$ for every $(q_1, q_2) \in Q$ and $a \in \Sigma$, which ensures $\mathcal{A}(w) = \lambda(q_0, w) = \lambda_2(q_0^2, \lambda_1(q_0^1, w)) = \mathcal{A}_2(\mathcal{A}_1(w)) \in \Theta^*$ for every $w \in \Sigma^*$. For each state $p = (p_1, p_2) \in Q$ in \mathcal{A} , we define the tuple of query suffixes from Θ^* ,

$$\sigma_p = (\lambda_2(p_2, s_{p_1,i}) \cdot s_{p_2(i),j} \mid i = 1, \dots, r_{p_1}, j = 1, \dots, r_{p_2(i)})$$

where $\pi_{p_1} = (s_{p_1,1}, s_{p_1,2}, \dots, s_{p_1,r_{p_1}}) \in \Delta^{r_{p_1}}$ and $\varrho_{p_2(i)} = (s_{p_2(i),1}, s_{p_2(i),2}, \dots, s_{p_2(i),r_{p_2(i)}}) \in \Theta^{r_{p_2(i)}}$ are the query suffixes associated with $p_1 \in Q_1$ and $p_2(i) = \delta_2(p_2, s_{p_1,i}) \in Q_2$ for $i \in \{1, \dots, r_{p_1}\}$, respectively, and the truth table $f_p = g_{p_1}(h_{p_2(1)}, \dots, h_{p_2(r_{p_1})})$ aggregates the answers to the corresponding oracle queries, which ensures $L_1 = \mathcal{L}(\mathcal{A}^{L_3}) \subseteq \Sigma^*$. ◀

We say that $L_0 \subseteq \Sigma^*$ is *DCFL'-simple* if $L_0 \leq_{tt}^A L$ for every non-regular deterministic context-free language $L \subseteq \Delta^*$. We show that Theorem 1 entails that the DCFL' language $L_\#$ is DCFL'-simple. In addition, we denote by DCFLS the class of DCFL'-simple problems and formulate its basic properties.

► **Corollary 3** (of Theorem 1). *The non-regular deterministic context-free language $L_\# = \{0^n 1^n \mid n \geq 1\}$ is DCFL'-simple.*

Proof. Let $L \subseteq \Delta^*$ be any DCFL' language. According to Theorem 1, there are $v, x, w, y, z \in \Delta^+$ and $L' \in \{L, \bar{L}\}$ such that condition (1) holds for L' . We define the Mealy machine $\mathcal{A}^L = (\{q_0, q_1, q_2\}, \{0, 1\}, \Delta, \delta, \lambda, q_0, \{(\sigma_q, f_q) \mid q \in Q\})$ with the oracle L , as $\delta(q_0, 0) = \delta(q_1, 0) = q_1$, $\delta(q_1, 1) = \delta(q_2, 1) = q_2$, $\lambda(q_0, 0) = vx$, $\lambda(q_1, 0) = x$, $\lambda(q_1, 1) = w$, $\lambda(q_2, 1) = y$, $\sigma_{q_0} = \sigma_{q_1} = ()$

¹ Note that the described protocol works also for non-prefix-free languages since for any input prefix that has been read so far, the output value from the truth table determines whether the oracle Mealy machine is in an “accepting” state, deciding about this prefix analogously as a deterministic finite automaton. The truth-table reduction only requires that the given oracle answers do not influence further computation when subsequent input symbols are read.

($r_{q_0} = r_{q_1} = 0$), $\sigma_{q_2} = (z, yz)$ ($r_{q_2} = 2$), $f_{q_0} = f_{q_1} = 0$, $f_{q_2}(0,0) = f_{q_2}(1,1) = 0$, and $f_{q_2}(1,0) = 1 - f_{q_2}(0,1)$ where $f_{q_2}(0,1) = 1$ iff $L' = L$. It is easy to verify that $L_{\#} = \mathcal{L}(\mathcal{A}^L)$, which implies $L_{\#} \leq_{tt}^A L$. Hence, $L_{\#}$ is DCFL'-simple. ◀

► **Proposition 4.**

1. $REG \subsetneq DCFLS$.
2. $DCFLS \subsetneq DCFL$, and $L_R = \{wcw^R \mid w \in \{a, b\}^*\} \in DCFL \setminus DCFLS$.
3. The class $DCFLS$ is closed under complement and intersection with regular languages.
4. The class $DCFLS$ is not closed under concatenation, intersection and union.

Proof (Sketch).

1. For any regular language L , consider a Mealy machine $\mathcal{A}^{L_{\#}}$ with the DCFL'-simple oracle $L_{\#}$, that simulates a deterministic finite automaton recognizing L , while its constant truth tables produce 1 iff associated with the accept states. Hence, $L \leq_{tt}^A L_{\#}$ which means L is DCFL'-simple according to Lemma 2 and Corollary 3 which also implies $REG \neq DCFLS$.
2. We first observe that $DCFLS \subseteq DCFL$. Let $L \in DCFLS$ be any DCFL'-simple language which ensures $L \leq_{tt}^A L_{\#}$ by an oracle Mealy machine $\mathcal{A}^{L_{\#}}$. The machine $\mathcal{A}^{L_{\#}}$ can be simulated by a DPDA \mathcal{M} which extends a suitable DPDA $\mathcal{M}_{\#}$ (e.g. with no ε -transitions) accepting $L_{\#} = \mathcal{L}(\mathcal{M}_{\#})$, so that the finite control of \mathcal{M} implements the finite-state transducer \mathcal{A} whose output is presented online as an input to $\mathcal{M}_{\#}$. Moreover, for each state q of \mathcal{A} , the finite control of \mathcal{M} evaluates the truth table f_q which aggregates the answers to the queries with r_q suffixes associated with q , by inspecting at most constant number of topmost stack symbols. Hence $L = \mathcal{L}(\mathcal{M}) \in DCFL$.

In order to show that $DCFLS \neq DCFL$, we prove that the DCFL $L_R = \{wcw^R \mid w \in \{a, b\}^*\}$ over the alphabet $\{a, b, c\}$ is not DCFL'-simple. For the sake of contradiction, suppose that $L_R \leq_{tt}^A L_{\#}$ by a Mealy machine $\mathcal{A}^{L_{\#}} = (Q, \{a, b, c\}, \{0, 1\}, \delta, \lambda, q_0, \{(\sigma_q, f_q) \mid q \in Q\})$ with the oracle $L_{\#} = \{0^n 1^n \mid n \geq 1\}$, which means $L_R = \mathcal{L}(\mathcal{A}^{L_{\#}})$. Consider all the 2^k possible prefixes $w \in \{a, b\}^k$ of inputs presented to $\mathcal{A}^{L_{\#}}$ that have the length $|w| = k$. These strings can bring $\mathcal{A}^{L_{\#}}$ into a finite number $|\{\delta(q_0, w) \mid w \in \{a, b\}^k\}| \leq |Q|$ of distinct states while the length $|\lambda(q_0, w)|$ of outputs written to the oracle tape is bounded by $O(k)$. For $\lambda(q_0, w)$ outside 0^*1^* , the acceptance of words wu where $u \in \{a, b, c\}^*$, depends only on the truth values $f_q(0, \dots, 0)$ associated with the states q from the finite set Q , due to $\lambda(q_0, wu) \notin L_{\#}/s$ for any $s \in \{0, 1\}^*$. On the other hand, the number of distinct outputs $\lambda(q_0, w)$ in 0^*1^* is bounded by $O(k)$. This means that for a sufficiently large $k \geq 1$, there must be two distinct prefixes $w_1, w_2 \in \{a, b\}^k$ such that $\delta(q_0, w_1) = \delta(q_0, w_2)$ and $\lambda(q_0, w_1) = \lambda(q_0, w_2)$ in 0^*1^* , which results in the contradiction $w_1 c w_2^R \in \mathcal{L}(\mathcal{A}^{L_{\#}}) \setminus L_R$.

3. The class $DCFLS$ is closed under complement since the truth tables can be negated. Furthermore, any oracle Mealy machine can be modified so that it simulates another given finite automaton in parallel and is forced to reject if this automaton rejects, which shows $DCFLS$ to be closed under intersection with regular languages.
4. Observe that $R = \{1\}^*$, $L_1 = \{0^m 1^m 0^n \mid m, n \geq 1\}$, $L_2 = \{0^m 1^n 0^n \mid m, n \geq 1\}$, and $L_3 = L_1 \cup (\{1\} \cdot L_2)$ are DCFL'-simple while $R \cdot L_3 \notin DCFL$, $L_1 \cap L_2 \notin CFL$, and $L_1 \cup L_2 \notin DCFL$ are not DCFL'-simple according to 2. ◀

3 Proof of the Main Result (Theorem 1)

Theorem 1 follows from the (more specific) next lemma that we prove in this section. (See Appendix for an informal overview with figures.)

By \mathbb{N} we denote the set $\{0, 1, 2, \dots\}$, and by $[i, j]$ the set $\{i, i+1, \dots, j\}$ (for $i, j \in \mathbb{N}$).

► **Lemma 5.** *Let $\mathcal{M} = (Q, \Sigma, \Gamma, R, p_0, X_0, F)$ be a DPDA where $L = \mathcal{L}(\mathcal{M}) = \mathcal{L}(p_0X_0)$ is non-regular (hence L belongs to DCF L'). There are $v \in \Sigma^*$, $x, w, y, z \in \Sigma^+$, $p, q \in Q$, $X \in \Gamma$, $\gamma \in \Gamma^+$, $\delta \in \Gamma^*$ such that the following four conditions hold:*

1. $p_0X_0 \xrightarrow{v} pX\delta$ and $pX \xrightarrow{x} pX\gamma$, which entails the infinite (stack increasing) computation

$$p_0X_0 \xrightarrow{v} pX\delta \xrightarrow{x} pX\gamma\delta \xrightarrow{x} pX\gamma\gamma\delta \xrightarrow{x} pX\gamma\gamma\gamma\delta \xrightarrow{x} \dots; \quad (2)$$

2. $pX \xrightarrow{w} q$;
3. $q\gamma \xrightarrow{y} q$, hence $q\gamma^\ell\delta' \xrightarrow{y^\ell} q\delta'$ for all $\ell \in \mathbb{N}$ and $\delta' \in \Gamma^*$;
4. one of the following cases is valid (depending on whether $z \in \mathcal{L}(q\delta)$ or $z \notin \mathcal{L}(q\delta)$):
 - a. $\mathcal{L}(q\gamma^k\delta) \ni y^\ell z$ iff $k = \ell$ (for all $k, \ell \in \mathbb{N}$), or $\mathcal{L}(q\gamma^k\delta) \ni y^\ell z$ iff $k \leq \ell$ (for all $k, \ell \in \mathbb{N}$);
 - b. $\mathcal{L}(q\gamma^k\delta) \ni y^\ell z$ iff $k \neq \ell$ (for all $k, \ell \in \mathbb{N}$), or $\mathcal{L}(q\gamma^k\delta) \ni y^\ell z$ iff $k > \ell$ (for all $k, \ell \in \mathbb{N}$).

We note that $p_0X_0 \xrightarrow{v} pX\delta \xrightarrow{x^m} pX\gamma^m\delta \xrightarrow{w} q\gamma^m\delta \xrightarrow{y^m} q\delta$ (for each $m \in \mathbb{N}$); hence $vx^mwy^mz \in L$ iff $z \in \mathcal{L}(q\delta)$ (since z is nonempty). Theorem 1 indeed follows from the lemma: there is $L' \in \{L, \bar{L}\}$ such that either $vx^mwy^mz \in L'$ iff $m = n$ (for all $m, n \in \mathbb{N}$), or $vx^mwy^mz \in L'$ iff $m \leq n$ (for all $m, n \in \mathbb{N}$). (In Theorem 1 we also stated that v is nonempty. If $v = \varepsilon$ here, then we simply take vx and yz as the new v, z , respectively.)

Proof of Lemma 5

In the rest of this section we provide a proof of Lemma 5, assuming a fixed DPDA $\mathcal{M} = (Q, \Sigma, \Gamma, R, p_0, X_0, F)$ where $L = \mathcal{L}(p_0X_0)$ is non-regular. The proof structure is visible from the auxiliary claims that we state and prove on the way.

Convention. W.l.o.g. we assume that \mathcal{M} always reads the whole input $u \in \Sigma^*$ from p_0X_0 . This can be accomplished in the standard way, by adding a special bottom-of-stack symbol \perp and a (non-accepting) fail-state. (Each empty-stack configuration $q\varepsilon$ becomes $q\perp$, and each originally stuck computation enters the fail-state where it loops. We also recall that all ε -steps are popping, and thus infinite ε -sequences are impossible.) Hence for any infinite word $a_1a_2a_3 \dots$ in Σ^ω there is a unique infinite computation of \mathcal{M} starting in p_0X_0 ; it stepwise reads the whole infinite word $a_1a_2a_3 \dots$.

The *left quotient of L by $u \in \Sigma^*$* is the set $u \setminus L = \{v \in \Sigma^* \mid uv \in L\}$; concatenation has priority over \setminus , hence $u_1u_2 \setminus L = (u_1u_2) \setminus L$. (The next claim is valid for any non-regular L .)

► **Claim 6.** We can fix an infinite word $a_1a_2a_3 \dots$ in Σ^ω ($a_i \in \Sigma$) such that $a_1a_2 \dots a_i \setminus L \neq a_1a_2 \dots a_j \setminus L$ for all $i \neq j$.

Proof. Let us consider the labelled transition system $\mathcal{T} = (\text{LQ}(L), \Sigma, (\xrightarrow{a})_{a \in \Sigma})$ where $\text{LQ}(L) = \{u \setminus L \mid u \in \Sigma^*\}$ and $\xrightarrow{a} = \{(L', a \setminus L') \mid L' \in \text{LQ}(L)\}$. (We recall that $L' = u \setminus L$ entails $a \setminus L' = ua \setminus L$.) Since L is non-regular, the set of states reachable from $L = \varepsilon \setminus L$ in \mathcal{T} is infinite. The out-degree of states in \mathcal{T} is finite (in fact, bounded by $|\Sigma|$), hence an application of König's lemma yields an infinite *acyclic* path $L \xrightarrow{a_1} L_1 \xrightarrow{a_2} L_2 \xrightarrow{a_3} \dots$. ◁

We call a *configuration* $p\alpha$ of \mathcal{M} *unstable* if $\alpha = Y\beta$ and R contains a rule $pY \xrightarrow{\varepsilon} q$ (we recall that ε -steps are only popping); otherwise $p\alpha$ is *stable*. Since \mathcal{M} is a *deterministic* PDA, for each unstable $p\alpha$ we can soundly define the *stable successor of $p\alpha$* as the unique stable

configuration $p'\alpha'$ where $p\alpha \xrightarrow{\varepsilon} p'\alpha'$ (α' being a suffix of α). If the path $p\alpha \xrightarrow{\varepsilon} p'\alpha'$ does not go via an accepting state (in F), then $\mathcal{L}(p\alpha) = \mathcal{L}(p'\alpha')$; otherwise $\mathcal{L}(p\alpha) = \{\varepsilon\} \cup \mathcal{L}(p'\alpha')$. (We note that the configurations in the computation (2) that start with pX are necessarily stable: since we have $pX \xrightarrow{x} pX\gamma$ for $x \in \Sigma^+$, we cannot have $pX \xrightarrow{\varepsilon} p'$.)

▷ **Claim 7.** Each configuration is visited at most twice by

$$\text{the computation of } \mathcal{M} \text{ from } p_0X_0 \text{ on } a_1a_2a_3 \cdots \text{ that is fixed by Claim 6.} \quad (3)$$

Proof. The computation (3) is infinite, stepwise reading the whole word $a_1a_2a_3 \cdots$, and it can be presented as

$$r_0\gamma_0 \xrightarrow{a_1} r_1\gamma_1 \xrightarrow{a_2} r_2\gamma_2 \xrightarrow{a_3} \cdots \quad (\text{for } r_0\gamma_0 = p_0X_0)$$

where each $r_i\gamma_i$ is stable; each segment $r_i\gamma_i \xrightarrow{a_{i+1}} r_{i+1}\gamma_{i+1}$ starts with a (visible) a_{i+1} -step that is followed by a (maybe empty) sequence of (popping) ε -steps via unstable configurations. Since such an ε -sequence might go through an accepting state, we can have $r_i\gamma_i = r_j\gamma_j$ for $i \neq j$ though $a_1a_2 \cdots a_i \setminus L \neq a_1a_2 \cdots a_j \setminus L$; in this case L contains precisely one of the words $a_1a_2 \cdots a_i$ and $a_1a_2 \cdots a_j$, and the languages $a_1a_2 \cdots a_i \setminus L$ and $a_1a_2 \cdots a_j \setminus L$ differ just on ε . Nevertheless, this reasoning entails that we cannot have $r_i\gamma_i = r_j\gamma_j = r_\ell\gamma_\ell$ for pairwise different i, j, ℓ .

Since each segment $r_i\gamma_i \xrightarrow{a_{i+1}} r_{i+1}\gamma_{i+1}$ visits any unstable configuration at most once and $r_{i+1}\gamma_{i+1}$ is the stable successor for all unstable configurations in the segment, we deduce that also each unstable configuration can be visited at most twice in the computation (3). ◁

▷ **Claim 8.** The computation (3) on $a_1a_2a_3 \cdots$ can be “stair-factorized”, that is, written

$$p_0X_0 \xrightarrow{v_0} p_1X_1\alpha_1 \xrightarrow{v_1} p_2X_2\alpha_2\alpha_1 \xrightarrow{v_2} p_3X_3\alpha_3\alpha_2\alpha_1 \xrightarrow{v_3} \cdots \quad (4)$$

so that for each $i \in \mathbb{N}$ we have $v_i \in \Sigma^+$ and $p_iX_i \xrightarrow{v_i} p_{i+1}X_{i+1}\alpha_{i+1}$ where α_{i+1} is a nonempty suffix of the right-hand side of a rule in R (i.e., a nonempty suffix of γ in a rule $pX \xrightarrow{a} q\gamma$).

Proof. We consider the computation (3), and call a stable configuration $pX\beta$ a *level*, with *position* $i \in \mathbb{N}$, if $p_0X_0 \xrightarrow{a_1 \cdots a_i} pX\beta$ and all configurations visited by the computation $pX\beta \xrightarrow{a_{i+1}a_{i+2} \cdots}$ after $pX\beta$ have the stack longer than $|X\beta|$; each level $pX\beta$ has thus a unique position which we denote $\text{POS}(pX\beta)$. Since each configuration is visited at most twice in (3), and the set of configurations with a fixed length is finite, we get that the set of levels is infinite, with elements $p'_0X'_0, p_1X_1\beta_1, p_2X_2\beta_2, \dots$ where $0 \leq \text{POS}(p'_0X'_0) < \text{POS}(p_1X_1\beta_1) < \text{POS}(p_2X_2\beta_2) < \dots$. The computation (3) can be thus presented as

$$p_0X_0 \xrightarrow{v'_0} p'_0X'_0 \xrightarrow{v''_0} p_1X_1\beta_1 \xrightarrow{v_1} p_2X_2\beta_2 \xrightarrow{v_2} p_3X_3\beta_3 \xrightarrow{v_3} \cdots$$

where $|v'_0| = \text{POS}(p'_0X'_0)$, and $|v_0v_1 \cdots v_{j-1}| = \text{POS}(p_jX_j\beta_j)$ for $j \geq 1$, putting $v_0 = v'_0v''_0$.

Each segment $pX\beta \xrightarrow{v} p'X'\beta'$ between two neighbouring levels can be obviously written as $pX\beta \xrightarrow{a} q\gamma_1\gamma_2\beta \xrightarrow{v'} p'X'\gamma_2\beta$ where $pX \xrightarrow{a} q\gamma_1\gamma_2$ is a rule in R , both γ_1 and γ_2 are nonempty, $v = av'$, and $q\gamma_1 \xrightarrow{v'} p'X'$. Hence the validity of the claim is clear. ◁

We define the natural *equivalence relation* \sim on the set of configurations of \mathcal{M} : we put $p\alpha \sim q\beta$ if $\mathcal{L}(p\alpha) = \mathcal{L}(q\beta)$.

We fix the presentation (4), calling $p_iX_i\alpha_i\alpha_{i-1} \cdots \alpha_1$ the *level-configurations* (for all $i \in \mathbb{N}$). Since we have $\mathcal{L}(p_iX_i\alpha_i\alpha_{i-1} \cdots \alpha_1) \setminus \{\varepsilon\} = (v_0v_1 \cdots v_{i-1} \setminus L) \setminus \{\varepsilon\}$, there cannot be three level-configurations in the same \sim -class (i.e., in the same equivalence class w.r.t. \sim).

63:10 The Simplest Non-Regular Deterministic Context-Free Language

Hence any infinite set of level-configurations represents infinitely many \sim -classes. Now we show a congruence-property that might enable to shorten a level-configuration while its \sim -class is preserved. We use the notation $\text{DS}(p\alpha)$ (the “down-states” of $p\alpha$), putting

$$\text{DS}(p\alpha) = \{q \mid p\alpha \xrightarrow{u} q \text{ for some } u \in \Sigma^*\}.$$

▷ **Claim 9.** If $q\gamma \sim q\gamma'$ for each $q \in \text{DS}(p\beta)$, then $p\beta\gamma \sim p\beta\gamma'$.

Proof. Let us consider $u \in \Sigma^*$. If $u \in \mathcal{L}(p\beta)$, then $u \in \mathcal{L}(p\beta\mu)$ for all $\mu \in \Gamma^*$. If $u \notin \mathcal{L}(p\beta)$ and there is no prefix u' of u such that $p\beta \xrightarrow{u'} q$, then $u \notin \mathcal{L}(p\beta\mu)$ for all $\mu \in \Gamma^*$. If $u \notin \mathcal{L}(p\beta)$ and $u = u'u''$ where $pX\beta \xrightarrow{u'} q$ (necessarily for some $q \in \text{DS}(pX\beta)$), then $u \in \mathcal{L}(p\beta\mu)$ iff $u'' \in \mathcal{L}(q\mu)$. Hence the claim is clear. ◁

The next claim is an immediate corollary.

▷ **Claim 10.** Any computation $p_0X_0 \xrightarrow{w_1} pX\beta_1 \xrightarrow{w_2} pX\beta_2\beta_1 \xrightarrow{w_3} p'X'\beta_3\beta_2\beta_1$ where $pX \xrightarrow{w_2} pX\beta_2$ ($w_2 \in \Sigma^+$), $pX \xrightarrow{w_3} p'X'\beta_3$, and $q\beta_2\beta_1 \sim q\beta_1$ for each $q \in \text{DS}(p'X'\beta_3)$ can be shortened to $p_0X_0 \xrightarrow{w_1} pX\beta_1 \xrightarrow{w_3} p'X'\beta_3\beta_1$ where $p'X'\beta_3\beta_1 \sim p'X'\beta_3\beta_2\beta_1$.

The i -th level-configuration in (4) is reached by the computation $p_0X_0 \xrightarrow{v_0v_1\cdots v_{i-1}} p_iX_i\alpha_i\alpha_{i-1}\cdots\alpha_1$. It can happen that there are j_1, j_2 , $0 \leq j_1 < j_2 \leq i$ such that $p_{j_1}X_{j_1} = p_{j_2}X_{j_2}$ and $q\alpha_{j_2}\alpha_{j_2-1}\cdots\alpha_1 \sim q\alpha_{j_1}\alpha_{j_1-1}\cdots\alpha_1$ for all $q \in \text{DS}(p_iX_i\alpha_i\alpha_{i-1}\cdots\alpha_{j_2+1})$. In this case we can shorten the computation as in Claim 10, where $v_{j_1}v_{j_1+1}\cdots v_{j_2-1}$ corresponds to the omitted w_2 . The resulting shorter computation might be possible to be repeatedly shortened further (if it can be presented so that the conditions of Claim 10 are satisfied). Now for each $i \geq 1$ we fix a (stair-factorized) computation

$$p_{i,0}X_{i,0} \xrightarrow{v_{i,0}} p_{i,1}X_{i,1}\alpha_{i,1} \xrightarrow{v_{i,1}} p_{i,2}X_{i,2}\alpha_{i,2}\alpha_{i,1} \cdots \xrightarrow{v_{i,n_i-1}} p_{i,n_i}X_{i,n_i}\alpha_{i,n_i}\alpha_{i,n_i-1} \cdots \alpha_{i,1} \quad (5)$$

that has arisen by a maximal sequence of the above shortenings of the prefix

$$p_0X_0 \xrightarrow{v_0v_1\cdots v_{i-1}} p_iX_i\alpha_i\alpha_{i-1}\cdots\alpha_1 \text{ of (4).}$$

Hence $p_{i,0}X_{i,0} = p_0X_0$, $p_{i,n_i}X_{i,n_i} = p_iX_i$, $\alpha_{i,n_i}, \alpha_{i,n_i-1}, \dots, \alpha_{i,1}$ is a subsequence of $\alpha_i, \alpha_{i-1}, \dots, \alpha_1$, and $p_{i,n_i}X_{i,n_i}\alpha_{i,n_i}\alpha_{i,n_i-1}\cdots\alpha_{i,1} \sim p_iX_i\alpha_i\alpha_{i-1}\cdots\alpha_1$.

▷ **Claim 11.** For each $\ell \in \mathbb{N}$ there is i such that $n_i > \ell$ (where n_i is from (5)).

Proof. As already discussed, the set of level-configurations represents infinitely many \sim -classes. The last configurations of computations (5) represent the same infinite set of \sim -classes, and their lengths thus cannot be bounded; since the lengths of all $\alpha_{i,j}$ are bounded (they are shorter than the longest right-hand sides of the rules in R), the claim is clear. ◁

Now we come to a crucial claim in our proof of Lemma 5. Besides the notation $\text{DS}(p\alpha)$ we also introduce $\text{ES}(p\alpha)$ (the by- ε -reached down-states of $p\alpha$), by putting

$$\text{ES}(p\alpha) = \{q \mid p\alpha \xrightarrow{\varepsilon} q\}.$$

Hence $\text{ES}(p\alpha) \subseteq \text{DS}(p\alpha)$, and $|\text{ES}(p\alpha)| \leq 1$ (due to the determinism of the DPDA \mathcal{M}).

We recall that $p\alpha \sim q\beta$ means $\mathcal{L}(p\alpha) = \mathcal{L}(q\beta)$. To handle the special case of the empty word ε , we also define a (much) coarser equivalence \sim_0 : we put $p\alpha \sim_0 q\beta$ if ε either belongs to both $\mathcal{L}(p\alpha)$ and $\mathcal{L}(q\beta)$, or belongs to none of them.

The next claim is rather technical but it captures some straightforward combinatorial observations that are handled by a simple use of Ramsey's theorem. Informally speaking, if n_i in the final configuration in (5) is sufficiently large, then we can find a convenient pumping segment in this configuration. (All this should be easily understandable after reading the informal overview with figures in Appendix.)

▷ **Claim 12.** There is a constant $B \in \mathbb{N}$ determined by the DPDA \mathcal{M} such that for all $i \in \mathbb{N}$ where $n_i > B$ the final configuration in (5) can be written as

$$p_{i,n_i} X_{i,n_i} \alpha_{i,n_i} \alpha_{i,n_i-1} \cdots \alpha_{i,1} = \bar{p}\bar{X}\beta\gamma\delta$$

where the following conditions hold:

1. $\gamma = \alpha_{i,j} \alpha_{i,j-1} \cdots \alpha_{i,j'+1}$ where $n_i \geq j > j' \geq n_i - B$ and $p_{i,j} X_{i,j} = p_{i,j'} X_{i,j'}$ (and $\beta = \alpha_{i,n_i} \alpha_{i,n_i-1} \cdots \alpha_{i,j+1}$, $\delta = \alpha_{i,j'} \alpha_{i,j'-1} \cdots \alpha_{i,1}$);
2. the sets $\text{DS}(\bar{p}\bar{X}\beta)$ and $\text{DS}(\bar{p}\bar{X}\beta\gamma)$ are equal, further being denoted by \bar{Q} ;
3. for each $q \in \bar{Q}$, if $\text{ES}(q\gamma) = \{q'\}$, then $\text{ES}(q'\gamma) = \{q'\}$ (and $q' \in \bar{Q}$);
4. each $q' \in \bar{Q}$ belongs to $\text{DS}(q\gamma)$ for some self-containing $q \in \bar{Q}$, where $q \in \bar{Q}$ is *self-containing* if $q \in \text{DS}(q\gamma)$;
5. there is a state $q' \in \bar{Q}$ for which $q'\gamma\delta \not\sim q'\delta$ and $q'\gamma\delta \sim_0 q'\delta$.

Proof. We fix some i with n_i larger than a constant B determined by \mathcal{M} as described below (there are such i by Claim 11). For convenience we put $p_{i,n_i} X_{i,n_i} = \bar{p}\bar{X}$, $n_i = n$, and $\alpha_{i,j} = \bar{\alpha}_j$, hence the final configuration in (5) is $p_{i,n_i} X_{i,n_i} \alpha_{i,n_i} \alpha_{i,n_i-1} \cdots \alpha_{i,1} = \bar{p}\bar{X}\bar{\alpha}_n \bar{\alpha}_{n-1} \cdots \bar{\alpha}_1$. We view the $n+1$ prefixes

$$\bar{p}\bar{X}, \bar{p}\bar{X}\bar{\alpha}_n, \bar{p}\bar{X}\bar{\alpha}_n\bar{\alpha}_{n-1}, \bar{p}\bar{X}\bar{\alpha}_n\bar{\alpha}_{n-1}\bar{\alpha}_{n-2}, \dots, \bar{p}\bar{X}\bar{\alpha}_n\bar{\alpha}_{n-1} \cdots \bar{\alpha}_1$$

as the vertices of a complete graph with coloured edges.

For $\bar{p}\bar{X}\bar{\alpha}_n\bar{\alpha}_{n-1} \cdots \bar{\alpha}_1 = \bar{p}\bar{X}\mu\nu\rho$, where $\mu = \bar{\alpha}_n\bar{\alpha}_{n-1} \cdots \bar{\alpha}_{j+1}$, $\nu = \bar{\alpha}_j\bar{\alpha}_{j-1} \cdots \bar{\alpha}_{j'+1}$, and $\rho = \bar{\alpha}_{j'}\bar{\alpha}_{j'-1} \cdots \bar{\alpha}_1$, $n \geq j > j' \geq 0$, the edge between the vertices $\bar{p}\bar{X}\mu$ and $\bar{p}\bar{X}\mu\nu$ has the following tuple as its *colour*:

$$\left(p_{i,j} X_{i,j}, p_{i,j'} X_{i,j'}, \text{DS}(\bar{p}\bar{X}\mu), \text{DS}(\bar{p}\bar{X}\mu\nu), (\text{DS}(q\nu), \text{ES}(q\nu))_{q \in \text{DS}(\bar{p}\bar{X}\mu)}, \mathbb{Q}_{\neq}, \mathbb{Q}_0 \right)$$

where $\mathbb{Q}_{\neq} = \{q' \in \text{DS}(\bar{p}\bar{X}\mu) \mid q'\nu\rho \not\sim q'\rho\}$ and $\mathbb{Q}_0 = \{q' \in \mathbb{Q}_{\neq} \mid q'\nu\rho \sim_0 q'\rho\}$ (and $p_{i,j} X_{i,j}, p_{i,j'} X_{i,j'}$ are taken from (5)).

Since the set of colours is bounded (by a constant determined by \mathcal{M}), Ramsey's theorem yields a bound B guaranteeing that there is a monochromatic clique of size 3 among the vertices $\bar{p}\bar{X}, \bar{p}\bar{X}\bar{\alpha}_n, \bar{p}\bar{X}\bar{\alpha}_n\bar{\alpha}_{n-1}, \dots, \bar{p}\bar{X}\bar{\alpha}_n\bar{\alpha}_{n-1} \cdots \bar{\alpha}_{n-B}$. (We have soundly chosen i so that $n = n_i$ is bigger than B .) We fix such a monochromatic clique MC, denoting its 3 vertices as

$$\bar{p}\bar{X}\beta, \bar{p}\bar{X}\beta\gamma, \bar{p}\bar{X}\beta\gamma\bar{\gamma}, \text{ and its colour as } C = (p'X', p'X', \bar{Q}, \bar{Q}, (\mathcal{D}_q, \mathcal{E}_q)_{q \in \bar{Q}}, Q', Q_0).$$

This is sound, since the fact that both edges $\{\bar{p}\bar{X}\beta, \bar{p}\bar{X}\beta\gamma\}$ and $\{\bar{p}\bar{X}\beta\gamma, \bar{p}\bar{X}\beta\gamma\bar{\gamma}\}$ have the same colour entails that the first component in this colour is the same as the second component, and the third component is the same as the fourth component.

We now show that the conditions 1–5 are satisfied for the presentation of $\bar{p}\bar{X}\bar{\alpha}_n\bar{\alpha}_{n-1} \cdots \bar{\alpha}_1$ as $\bar{p}\bar{X}\beta\gamma\delta$, where $\delta = \bar{\gamma}\bar{\alpha}_k\bar{\alpha}_{k-1} \cdots \bar{\alpha}_1$ for the respective k .

Conditions 1 and 2 are trivial (due to the colour C).

Condition 3: Let $q \in \bar{Q}$ and $\text{ES}(q\gamma) = \{q'\}$ (hence also $q' \in \bar{Q}$). Then $\mathcal{E}_q = \text{ES}(q\gamma) = \text{ES}(q\gamma\bar{\gamma}) = \{q'\}$ (since MC is monochromatic). This entails $\text{ES}(q'\bar{\gamma}) = \{q'\}$, hence $\mathcal{E}_{q'} = \{q'\}$, which in turn entails $\text{ES}(q'\gamma) = \{q'\}$.

Condition 4: We first note a general fact: $\text{DS}(p\mu\nu) = \bigcup_{q \in \text{DS}(p\mu)} \text{DS}(q\nu)$. Since $\bar{Q} = \text{DS}(\bar{p}\bar{X}\beta) = \text{DS}(\bar{p}\bar{X}\beta\gamma) = \text{DS}(\bar{p}\bar{X}\beta\gamma\bar{\gamma})$, for each $q' \in \bar{Q}$ there is thus $q \in \bar{Q}$ such that $q' \in \mathcal{D}_q$. We also have the following “transitivity”: if $q_1, q_2, q_3 \in \bar{Q}$, $q_1 \in \mathcal{D}_{q_2}$, and $q_2 \in \mathcal{D}_{q_3}$,

63:12 The Simplest Non-Regular Deterministic Context-Free Language

then $q_1 \in \mathcal{D}_{q_3}$ (since MC is monochromatic). For any $q' \in \bar{Q}$ there is clearly a “chain” $q' = q_1, q_2, q_3, \dots, q_\ell$ where $\ell > 1$, $q_j \in \mathcal{D}_{q_{j+1}}$ for all $j \in [1, \ell-1]$, and $q_j = q_\ell$ for some $j < \ell$. By the above transitivity, q_ℓ is self-containing ($q_\ell \in \mathcal{D}_{q_\ell}$ and thus $q_\ell \in \text{DS}(q_\ell\gamma)$) and $q' \in \mathcal{D}_{q_\ell}$ (hence $q' \in \text{DS}(q_\ell\gamma)$).

Condition 5: For any three configurations at least two belong to the same \sim_0 -class. Since the edges among the vertices $\bar{p}\bar{X}\beta, \bar{p}\bar{X}\beta\gamma, \bar{p}\bar{X}\beta\gamma\bar{\gamma}$ have the same Q'_0 in their colour C, we get that $Q'_0 = Q'$, and thus also $q'\gamma\delta \sim_0 q'\delta$ for all $q' \in \bar{Q}$ such that $q'\gamma\delta \not\sim q'\delta$. Now if for all $q' \in \bar{Q}$ we had $q'\gamma\delta \sim q'\delta$ (which includes the case $\bar{Q} = \emptyset$), then we would get a contradiction with our choice of (5) since it could have been shortened as in Claim 10. \triangleleft

Now we state a weaker version of Lemma 5:

\triangleright **Claim 13.** There are $v \in \Sigma^*, x, w, y, z \in \Sigma^+, p, q \in Q, X \in \Gamma, \gamma \in \Gamma^+, \delta \in \Gamma^*$ such that $p_0X_0 \xrightarrow{v} pX\delta, pX \xrightarrow{x} pX\gamma, pX \xrightarrow{w} q, q\gamma \xrightarrow{y} q$, and

- either $z \in \mathcal{L}(q\delta)$ and $z \notin \mathcal{L}(q\gamma^\ell\delta)$ for all $\ell > 0$,
- or $z \notin \mathcal{L}(q\delta)$ and $z \in \mathcal{L}(q\gamma^\ell\delta)$ for all $\ell > 0$.

Proof. We fix one $\bar{p}\bar{X}\beta\gamma\delta$ guaranteed by Claim 12 (satisfying the respective conditions 1–5). There are $v \in \Sigma^*, x, w, y, \bar{z} \in \Sigma^+, p, q \in Q, X \in \Gamma, \gamma \in \Gamma^+, \delta \in \Gamma^*, q' \in \text{DS}(q\gamma)$ such that

$p_0X_0 \xrightarrow{v} pX\delta, pX \xrightarrow{x} pX\gamma, pX \xrightarrow{w} q, q\gamma \xrightarrow{y} q$, and $\mathcal{L}(q'\gamma\delta)$ and $\mathcal{L}(q'\delta)$ differ on \bar{z} (i.e., $\bar{z} \in (\mathcal{L}(q'\gamma\delta) \setminus \mathcal{L}(q'\delta)) \cup (\mathcal{L}(q'\delta) \setminus \mathcal{L}(q'\gamma\delta))$).

Indeed: The respective computation (5) can be written $p_0X_0 \xrightarrow{v} pX\delta \xrightarrow{x} pX\gamma\delta \xrightarrow{w'} \bar{p}\bar{X}\beta\gamma\delta$ where x and γ are nonempty. The claimed q' and [nonempty] \bar{z} are guaranteed by 5 in Claim 12, and q is a respective self-containing state from 4. Since $q \in \text{DS}(\bar{p}\bar{X}\beta)$ and $q \in \text{DS}(q\gamma)$, we get $pX\gamma\delta \xrightarrow{w''} q\gamma\delta \xrightarrow{y} q\delta$, where $w'' \neq \varepsilon$. We also have $y \neq \varepsilon$, since otherwise $\text{DS}(q\gamma) = \text{ES}(q\gamma) = \{q\}$, $q' = q$, and we could not have $q\gamma\delta \not\sim q\delta$ and $q\gamma\delta \sim_0 q\delta$.

Since $q' \in \text{DS}(q\gamma)$, we can fix z' such that $q\gamma \xrightarrow{z'} q'$. Hence the languages $\mathcal{L}(q\gamma\gamma\delta)$ and $\mathcal{L}(q\gamma\delta)$ differ on $z = z'\bar{z}$; more generally, $\mathcal{L}(q\gamma^{\ell+1}\gamma\delta)$ and $\mathcal{L}(q\gamma^\ell\gamma\delta)$ differ on $y^\ell z$ for all $\ell \geq 0$. Now we aim to find out for which ℓ we have $z \in \mathcal{L}(q\gamma^\ell\delta)$.

We recall that $\bar{Q} = \text{DS}(\bar{p}\bar{X}\beta) = \text{DS}(\bar{p}\bar{X}\beta\gamma)$; hence $\bigcup_{\bar{q} \in \bar{Q}} \text{DS}(\bar{q}\gamma) = \bar{Q}$. Since $q \in \bar{Q}$, we get that $\text{DS}(q\gamma^d) \subseteq \bar{Q}$ for all $d \in \mathbb{N}$ (by induction). We now distinguish two cases:

1. For each prefix z_1 of z and each $d \leq |z|$ we have: if $q\gamma^d \xrightarrow{z_1} \bar{q}$, then $\text{ES}(\bar{q}\gamma) = \emptyset$.
2. There are a prefix z_1 of z , $d \leq |z|$, and $\bar{q}, q'' \in \bar{Q}$ such that $q\gamma^d \xrightarrow{z_1} \bar{q}$ and $\text{ES}(\bar{q}\gamma) = \{q''\}$.

In the case 1 we clearly have either $\forall \ell > |z| : z \in \mathcal{L}(q\gamma^\ell\delta)$ or $\forall \ell > |z| : z \notin \mathcal{L}(q\gamma^\ell\delta)$ (here δ plays no role). In the case 2 we recall that $\bar{q}\gamma \xrightarrow{\varepsilon} q''$ entails that $\bar{q}\gamma^k\delta \xrightarrow{\varepsilon} q''\delta$ for all $k \geq 1$ (since $\text{ES}(q''\gamma) = \{q''\}$ by 3 in Claim 12). Hence we have either $\forall \ell > |z| + 1 : z \in \mathcal{L}(q\gamma^\ell\delta)$ or $\forall \ell > |z| + 1 : z \notin \mathcal{L}(q\gamma^\ell\delta)$.

Since $\mathcal{L}(q\gamma^2\delta)$ and $\mathcal{L}(q\gamma\delta)$ differ on z , we deduce that there is $\ell_0 \geq 1$ such that either $z \in \mathcal{L}(q\gamma^{\ell_0}\delta)$ and $z \notin \mathcal{L}(q\gamma^\ell\delta)$ for all $\ell > \ell_0$, or $z \notin \mathcal{L}(q\gamma^{\ell_0}\delta)$ and $z \in \mathcal{L}(q\gamma^\ell\delta)$ for all $\ell > \ell_0$. Hence for $\bar{\delta} = \gamma^{\ell_0}\delta$ we have either $z \in \mathcal{L}(q\bar{\delta})$ and $z \notin \mathcal{L}(q\gamma^\ell\bar{\delta})$ for all $\ell > 0$, or $z \notin \mathcal{L}(q\bar{\delta})$ and $z \in \mathcal{L}(q\gamma^\ell\bar{\delta})$ for all $\ell > 0$. Since for $\bar{v} = vx^{\ell_0}$ we have $p_0X_0 \xrightarrow{\bar{v}} pX\bar{\delta}$, the claim is proven. \triangleleft

Claim 13 shows that there is $L' \in \{L, \bar{L}\}$ such that $vx^mwy^mz \in L'$ and $vx^mwy^n z \notin L'$ for $m > n$, which is a weaker version of Lemma 5. To handle the case $m < n$, we have to find out for which ℓ we have $y^\ell z \in \mathcal{L}(q\delta)$. We thus look at the computation from $q\delta$ on the infinite word y^ω (recalling our convention that this computation is infinite, stepwise reading the word $yyy\cdots$), and use the obvious fact that after a prefix this computation becomes “periodic” (either cycling among finitely many configurations, or increasing the stack forever).

▷ Claim 14. For any configuration $q\delta$ and words y, z there are numbers $s \geq 0$ (“shift”) and $P > 0$ (“period”) such that for all $\ell \geq s$ the remainder $(\ell \bmod P)$ determines whether or not $\mathcal{L}(q\delta) \ni y^\ell z$.

Proof. We assume $y \neq \varepsilon$ (otherwise the claim is trivial). For the infinite computation from $q\delta$ on $yyy \dots$ there are obviously $k_1 \geq 0$, $k_2 > 0$, $\bar{q} \in Q$, and $\rho, \mu, \nu \in \Gamma^*$ such that the computation can be written $q\delta \xrightarrow{y^{k_1}} \bar{q}\rho\nu \xrightarrow{y^{k_2}} \bar{q}\rho\mu\nu \xrightarrow{y^{k_2}} \bar{q}\rho\mu\mu\nu \xrightarrow{y^{k_2}} \bar{q}\rho\mu\mu\mu\nu \xrightarrow{y^{k_2}} \dots$ where $\bar{q}\rho \xrightarrow{y^{k_2}} \bar{q}\rho\mu$. (We have $\mu = \varepsilon$ if the computation visits only finitely many configurations, and otherwise we consider the stair-factorization of the computation.)

For each $j \in [0, k_2-1]$ we put $\bar{q}\rho \xrightarrow{y^j} \bar{q}_j\rho_j$, and we have two possible cases:

1. There is $d_0 \geq 0$ such that for all $d \geq d_0$ performing z from $\bar{q}_j\rho_j\mu^d\nu$ does not reach ν at the bottom.
2. There are $d_0 \geq 0$, a prefix z' of z , $q' \in Q$, and $\bar{d} \in [1, |Q|]$ such that $\bar{q}_j\rho_j\mu^{d_0} \xrightarrow{z'} q'$ and $q'\mu^{\bar{d}} \xrightarrow{\varepsilon} q'$.

In the case 1 either $\mathcal{L}(q\delta) \ni y^{d \cdot k_2 + j} z$ for all $d \geq d_0$, or $\mathcal{L}(q\delta) \not\ni y^{d \cdot k_2 + j} z$ for all $d \geq d_0$.

In the case 2, for each $d \geq 0$ we have $q'\mu^d \xrightarrow{\varepsilon} q_d$ where $q_{d_1} = q_{d_2}$ if $d_1 \equiv d_2 \pmod{\bar{d}}$. Hence for each $d \geq d_0$, the (non)membership of $y^{d \cdot k_2 + j} z$ in $\mathcal{L}(q\delta)$ is determined by $(d \bmod \bar{d})$.

The claim is thus clear. \triangleleft

Now we finish the proof of Lemma 5. We take the notation from Claim 13; for the respective $q\delta, y, z$ we add s, P from Claim 14. Let k_0 be a multiple of P that is bigger than s . We now view $x^{k_0}, y^{k_0}, \gamma^{k_0}$ as new x, y, γ , respectively. Claims 13 and 14 now yield the statement of Lemma 5.

4 Conclusion and Open Problems

In this paper, we have introduced a new notion of the \mathcal{C} -simple problem that reduces to each problem in \mathcal{C} , being thus a conceptual counterpart to the \mathcal{C} -hard problem to which each problem in \mathcal{C} reduces. We have illustrated this concept on the definition of the DCFL'-simple problem that reduces to each DCFL' language under the truth-table reduction by Mealy machines. We have proven that the DCFL' language $L_{\#} = \{0^n 1^n \mid n \geq 1\}$ is DCFL'-simple, and thus represents the simplest languages in the class DCFL'. This result finds its application in expanding the known lower bound for $L_{\#}$, namely that $L_{\#}$ cannot be recognized by the neural network model 1ANN, to all DCFL' languages. Moreover, the class DCFLS of DCFL'-simple problems containing the regular languages is a strict subclass of DCFL and has similar closure properties as DCFL.

We note that the hardest context-free language L_0 by Greibach [3], where each L in CFL is an inverse homomorphic image of L_0 or $L_0 \setminus \{\varepsilon\}$, can be viewed as CFL-hard w.r.t. a many-one reduction based on Mealy machines realizing the respective homomorphisms. Our aims in the definition of DCFL'-simple problems cannot be achieved by such a many-one reduction, hence we have generalized it to a truth-table reduction. We can alternatively consider a general Turing reduction that is implemented by a Mealy machine which queries the oracle at special query states, each associated with a corresponding query suffix, while its next transition from the query state depends on the given oracle answer. The oracle Mealy machine then accepts an input word if it reaches an accept state after reading the input. The language $L_{\#}$ proves to be DCFL'-simple under this Turing reduction allowing for an unbounded number of online oracle queries; this can be shown by Claim 13 (a weaker version of Lemma 5).

It is natural to try extending our result to non-regular nondeterministic (or at least unambiguous) context-free languages, by possibly showing that $L_{\#}$ is CFL'-simple. Another important challenge for further research is looking for \mathcal{C} -simple problems for other complexity classes \mathcal{C} and suitable reductions. This could provide an effective tool for strengthening lower-bounds results known for single problems to the whole classes of problems, which deserves a deeper study.

A Informal overview of Lemma 5 and of its proof

Given a DPDA \mathcal{M} accepting a non-regular language $L = \mathcal{L}(\mathcal{M}) = \mathcal{L}(p_0 X_0) \subseteq \Sigma^*$, Lemma 5 claims that there is a word $v \in \Sigma^*$ and nonempty words $x, w, y, z \in \Sigma^+$ with the properties depicted in Figure 1, which entail the following conditions:

Figure 1 DPDA computation scheme where either $vx^mwy^n z$ is (or is not) accepted iff $m = n$, or $vx^mwy^n z$ is (or is not) accepted iff $m \leq n$.

1. (the pumping condition)

$p_0X_0 \xrightarrow{v} pX\delta \xrightarrow{x^m} pX\gamma^m\delta \xrightarrow{w} q\gamma^m\delta \xrightarrow{y^m} q\delta$ for all $m \geq 0$ (since $pX \xrightarrow{x} pX\gamma$ and $q\gamma \xrightarrow{y} q$); hence $z \in \mathcal{L}(q\delta)$ entails $vx^mwy^m z \in L$ for all $m \geq 0$, and $z \notin \mathcal{L}(q\delta)$ entails $vx^mwy^m z \notin L$ for all $m \geq 0$;

2. (the prefix condition)

the prefix differs from $q\delta$ on z in the sense that the languages of all configurations reachable by vx^mwy^n where $m > n$ differ from $\mathcal{L}(q\delta)$ on z ; referring to Figure 1, $z \in \mathcal{L}(q\gamma^k\delta) \Delta \mathcal{L}(q\delta)$ for all $k > 0$, where $A \Delta B$ denotes $(A \setminus B) \cup (B \setminus A)$;

3. (the suffix condition)

the suffix (all configurations reachable by vx^mwy^n where $m < n$) either differs from, or coincides with, $q\delta$ on z ; referring to Figure 1, either $z \in \mathcal{L}(q\delta) \Delta \mathcal{L}(p'\xi(\gamma')^k\delta')$ for all $k \geq 0$, or $z \in \mathcal{L}(q\delta) \cap \mathcal{L}(p'\xi(\gamma')^k\delta')$ for all $k \geq 0$.

The prefix condition 2 implies that the stack segment γ is nonempty (while γ' might be empty). The conditions also imply that $q \in DS(q\gamma)$ and $ES(q\gamma) = \emptyset$, when we use the following definitions: $DS(r\alpha) = \{r' \mid r\alpha \xrightarrow{u} r' \text{ for some } u \in \Sigma^*\}$ (the “down-states” of $r\alpha$) and $ES(r\alpha) = \{r' \mid r\alpha \xrightarrow{\varepsilon} r' \}$ (which is either the empty set or a singleton containing the down-state reached by a sequence of ε -poppings from $r\alpha$). Hence $ES(r\alpha) \subseteq DS(r\alpha)$, and $ES(r\alpha) \neq \emptyset$ entails $ES(r\alpha) = DS(r\alpha) = \{r'\}$ for some r' . Figure 2 depicts an example of $DS(pX\gamma^5)$, using the obvious compositional approach based on $DS(pX)$ and $DS(q_i\gamma)$ and $ES(q_i\gamma)$ where $i \in \{1, 2, 3, 4, 5\}$, assuming that the state set of \mathcal{M} is $Q = \{q_1, q_2, q_3, q_4, q_5\}$ and $p = q_2$. (Here the stack is presented horizontally.)

Figure 2 Each directed path from the leftmost black point to the rightmost upper point shows that $q_1 \in DS(q_2X\gamma^5)$. The completely-dashed paths correspond to ε -sequences; e.g. $ES(q_5\gamma\gamma) = \{q_5\}$.

Getting tuples (v, x, w, y, z) satisfying the pumping condition 1

Since $L = \mathcal{L}(p_0X_0)$ is not regular, it is clear that from p_0X_0 the computations of \mathcal{M} can reach configurations with arbitrary stack-heights, more precisely configurations with arbitrarily long erasable stack-tops. (The stack-top α in a configuration $p\alpha\beta$ is erasable if $DS(p\alpha) \neq \emptyset$.)

■ **Figure 3** Stair-factorization.

Moreover, such long stack-tops must be also erasable by using many “solid-line” segments that use visible (i.e. non- ε) steps. Indeed: if all possible stack-erasings would in principle go along the dashed lines, i.e. by ε -popping, like from $q_1\gamma^k$ in Figure 2, then this would also entail regularity of L , since even long (erasable) stacks could be replaced with their equivalents of bounded lengths in such cases.

Using the above observations, it is standard to derive the existence of various tuples (v, x, w, y, z) satisfying the pumping condition 1. A crucial fact is that any computation $p_0X_0 \xrightarrow{u} r\alpha$ where the stack-content α is long can be *stair-factorized* into a long sequence of “stairs”, as depicted on the left in Figure 3: here $p_iX_i \xrightarrow{v_i} p_{i+1}X_{i+1}\alpha_{i+1}$ and α_{i+1} is a nonempty suffix of the right-hand side of a rewriting rule of \mathcal{M} (for $i = 0, 1, 2, \dots$). If a (long) stack $\alpha_k\alpha_{k-1}\dots\alpha_1$ is first built and then its (long) top $\alpha_k\alpha_{k-1}\dots\alpha_{j+1}$ gets erased, we let p'_i denote the state in which $\alpha_i\alpha_{i-1}\dots\alpha_j\alpha_{j-1}\dots\alpha_1$ is exposed during this erasing (for $i = k, k-1, \dots, j$); such p'_i are depicted on the right in Figure 3, assuming $j = 1$. By the pigeonhole principle, a triple (p, X, p') repeats in a sufficiently long sequence $(p_j, X_j, p'_j), (p_{j+1}, X_{j+1}, p'_{j+1}), \dots, (p_k, X_k, p'_k)$, which naturally yields a “pumping tuple” (v, x, w, y, z) .

Pumping-operation on (v, x, w, y, z) (preserving the conditions 1, 2, 3 that hold)

Looking at Figure 1, we observe that if the pumping condition 1 holds for a tuple (v, x, w, y, z) , then it is preserved by the *pumping-operation* on (v, x, w, y, z) that consists in replacing x and y with their “multiples” x^{k_0} and y^{k_0} , for any $k_0 \geq 1$. Moreover, if (v, x, w, y, z) also happens to satisfy the prefix condition 2, then also this condition is preserved by the pumping-operation (for any $k_0 \geq 1$). The same is true for the suffix condition 3.

Establishing the suffix condition 3 (by the pumping-operation for suitable k_0)

Given (v, x, w, y, z) that satisfies the pumping condition 1, we now show that the pumping-operation (for an appropriate number k_0) establishes the suffix condition 3. First we observe that if \mathcal{M} starts in $q\delta$ and processes $y^\omega = yyy\dots$, then the respective infinite computation necessarily enters a “cycle” after a “prelude”. This is depicted in Figure 1, but there both the prelude and the cycle process the word y . Generally, we would get a prelude $q\delta \xrightarrow{y^{k_1}} p'\xi\delta'$ and a cycle $p'\xi\delta' \xrightarrow{y^{k_2}} p'\xi\gamma'\delta'$ (where $p'\xi \xrightarrow{y^{k_2}} p'\xi\gamma'$ and γ' might be empty) for some numbers k_1, k_2 (where $k_2 > 0$). We now show that the set

$$A = \{\ell \in \mathbb{N} \mid z \in \mathcal{L}(C_\ell)\} \text{ where } C_\ell \text{ are the configurations satisfying } q\delta \xrightarrow{y^\ell} C_\ell \quad (6)$$

is ultimately periodic; i.e., for a *shift* $s \geq 0$ and a *period* $P > 0$ we have that for all $\ell \geq s$ the remainder $(\ell \bmod P)$ determines whether or not $\ell \in A$. Generally we cannot simply take $P = k_2$ as a suitable period, since z might “embark” on popping the γ' -segments along “dashed paths”: processing a prefix z_1 of z from $p'\xi\gamma'\gamma'\cdots\gamma'\delta'$ might reach a configuration $q'\gamma'\gamma'\cdots\gamma'\delta'$ like $q_1\gamma\gamma\gamma\cdots$ in Figure 2, in which case we have $q'\gamma'\gamma'\cdots\gamma'\delta' \xrightarrow{\varepsilon} r\delta'$, and it is the state r in which the bottom δ' is reached that determines whether z is accepted or not (i.e., whether $z_2 \in \mathcal{L}(r\delta')$ when $z = z_1z_2$). We thus might need to choose P as a multiple of k_2 , guaranteeing that the above mentioned state r (in which δ' is reached) is also repeating with the period P .

Having a shift s and a period P characterizing the ultimate periodicity of the set A defined by (6), we choose $k_0 \geq s$ that is a multiple of P . Then replacing x and y with x^{k_0} and y^{k_0} indeed guarantees the suffix condition 3; an important point is that the “suffix” might *differ from, or coincide with, $q\delta$* on z .

Establishing the prefix condition 2

Given a tuple (v, x, w, y, z) satisfying the pumping condition 1, if we aim to establish the prefix condition 2 by the pumping-operation, then it is natural to consider the “prefix-counterpart” of (6), namely the set

$$A' = \{\ell \in \mathbb{N} \mid z \in \mathcal{L}(q\gamma^\ell\delta)\} \quad (7)$$

(recall Figure 1). It is again clear that A' is ultimately periodic, but a problem is that we have to guarantee that the “prefix” has to *differ from $q\delta$* on z (unlike the “suffix” that can also coincide).

We now show that if A' is nontrivial ($\emptyset \subsetneq A' \subsetneq \mathbb{N}$), then we can establish the prefix condition 2 easily. Let s be the shift and P the period of a presentation of A' as an ultimately periodic set, and let $i_0 \in A'$ and $i_1 \notin A'$. Let $k_0 \geq \max\{i_0, i_1, s\}$ be a multiple of P , and let $j \in \{0, 1\}$ be such that i_j differs from k_0 on the membership in A' . Instead of (v, x, w, y, z) we now take (v', x', w, y', z) where $v' = vx^{i_j}$, $x' = x^{k_0}$, $y' = y^{k_0}$. Referring to Figure 1, by this change δ is replaced with $\bar{\delta} = \gamma^{i_j}\delta$, and γ is replaced with $\bar{\gamma} = \gamma^{k_0}$. We have $z \in \mathcal{L}(q\bar{\delta}) \triangle \mathcal{L}(q(\bar{\gamma})^k\bar{\delta})$ for all $k > 0$; hence the prefix condition 2 is indeed established.

It remains to explore if we can have the case that for each tuple (v, x, w, y, z) satisfying the pumping condition 1 the “prefix” set A' defined by (7) (when referring to the notation of Figure 1) is trivial. Since we can choose z freely, this case would, in fact, entail that $q\delta \sim q\gamma\delta \sim q\gamma\gamma\delta \sim \cdots$, where $C \sim C'$ stands for $\mathcal{L}(C) = \mathcal{L}(C')$ for any configurations C, C' . We now show that this case cannot happen since the language $L = \mathcal{L}(q_0X_0)$ is non-regular.

First, it is straightforward to derive that we can fix a *crucial infinite computation of \mathcal{M} from p_0X_0* , processing some word $a_1a_2a_3\cdots$, whose stair-factorization has infinitely many stairs and each stair represents its own equivalence class of \sim . We can view the left part of Figure 3 as a prefix of this crucial computation; we thus have $p_iX_i\alpha_i\alpha_{i-1}\cdots\alpha_1 \not\sim p_jX_j\alpha_j\alpha_{j-1}\cdots\alpha_1$ for all $i \neq j$. (The existence of such an infinite computation follows by the fact that the set of left quotients $\{u \setminus L \mid u \in \Sigma^*\}$, where $u \setminus L = \{u' \in \Sigma^* \mid uu' \in L\}$, is infinite since L is non-regular, and by König’s lemma since the tree of all computations of \mathcal{M} from p_0X_0 is finitely branching.)

We are not done, since even in this crucial infinite computation (with pairwise non-equivalent stairs) a “pumping” tuple (v, x, w, y, z) derived by the above-mentioned pigeonhole principle might not guarantee that $q\delta \not\sim q\gamma\delta$ (and we might have $q\delta \sim q\gamma\delta \sim q\gamma\gamma\delta \sim \cdots$). For instance, let us assume that in Figure 3 we have $p_1X_1 = p_3X_3$, and that $Q = \{q_1, q_2, q_3\}$ as depicted in Figure 4. We can have $q_2\alpha_1 \sim q_2\alpha_3\alpha_2\alpha_1$ (as denoted by the rectangles in

■ **Figure 4** Shortening of configurations (here $p_1X_1 = p_3X_3$).

Figure 4) and $q_3\alpha_1 \sim q_3\alpha_3\alpha_2\alpha_1$ (as denoted by the circles), but $q_1\alpha_1 \not\sim q_1\alpha_3\alpha_2\alpha_1$ (which causes that $p_1X_1\alpha_1 \not\sim p_3X_3\alpha_3\alpha_2\alpha_1$). By putting $pX = p_1X_1 = p_3X_3$, $\delta = \alpha_1$, $x = v_1v_2$ (referring to Figure 3), and $\gamma = \alpha_3\alpha_2$, we get a “pumping” $p_0X_0 \xrightarrow{v_0} pX\delta \xrightarrow{x} pX\gamma\delta \xrightarrow{x} pX\gamma\gamma\delta$ where $pX\gamma\gamma\delta$ is depicted as the third configuration in Figure 4. (We have omitted unreachable “black points.”) Here we indeed have $q\delta \sim q\gamma\delta \sim q\gamma\gamma\delta \sim \dots$, as is highlighted by the fourth configuration in Figure 4.

In our example we can also note that some configurations in the crucial infinite computation might be safely shortened while their equivalence classes are preserved. This is depicted on the right in Figure 4: we have $p_0X_0 \xrightarrow{v_0v_1v_2v_3} p_4X_4\alpha_4\alpha_3\alpha_2\alpha_1$, but we obviously have $p_4X_4\alpha_4\alpha_3\alpha_2\alpha_1 \sim p_4X_4\alpha_4\alpha_1$; this shorter representant of the equivalence class of $p_4X_4\alpha_4\alpha_3\alpha_2\alpha_1$ is reachable by omitting v_1v_2 , i.e., $p_0X_0 \xrightarrow{v_0v_3} p_4X_4\alpha_4\alpha_1$.

Nevertheless, the crucial computation visits infinitely many equivalence classes, so the sizes of the stair-configurations $p_iX_i\alpha_i\alpha_{i-1}\dots\alpha_1$ must grow above any bound even when we first shorten them maximally in the (repeated) described way. Let us now fix a stair-configuration that has been maximally shortened in the above way and is still sufficiently long. By straightforward combinatorial arguments (that can be presented as an application of Ramsey’s theorem to avoid tedious technicalities) we can derive that this (shortened) configuration can be written as $\bar{p}\bar{X}\bar{\beta}\gamma\delta$ where γ is nonempty, and

- γ can be pumped (having the same “lower” p_jX_j and “upper” $p_{j'}X_{j'}$, like $\gamma = \alpha_3\alpha_2$ in Figure 4);
- the sets $\text{DS}(\bar{p}\bar{X}\bar{\beta})$ and $\text{DS}(\bar{p}\bar{X}\bar{\beta}\gamma)$ are equal, further being denoted by \bar{Q} (e.g., in Figure 4 $p_4X_4\alpha_4\alpha_3\alpha_2\alpha_1 = \bar{p}\bar{X}\bar{\beta}\gamma\delta$ where $\bar{Q} = \{q_2, q_3\}$);
- there is $q' \in \bar{Q}$ for which $\mathcal{L}(q'\gamma\delta)$ and $\mathcal{L}(q'\delta)$ differ on a nonempty word \bar{z} (e.g., now let the circled $q_3\gamma\delta$ and $q_3\delta$ in Figure 4 differ in this way, hence we can choose $q' = q_3$);
- moreover, this $q' \in \bar{Q}$ belongs to $\text{DS}(q\gamma)$ for some self-containing $q \in \bar{Q}$, where $q \in \bar{Q}$ is *self-containing* if $q \in \text{DS}(q\gamma)$ (let $q = q_2$ in our example, though here also q_3 is possible).

It is then clear that $q\gamma \xrightarrow{y} q$ and $q\gamma \xrightarrow{z'} q'$ for some nonempty y, z' ; this entails $q\gamma\gamma\delta \not\sim q\gamma\delta$ since they differ on $z = z'\bar{z}$. (This is sufficient for us even if we cannot deduce that $q\gamma\delta \not\sim q\delta$.)

A formal proof is given in the main part of the paper.

On the Hardness of Compressing Weights

Abstract

We investigate computational problems involving large weights through the lens of kernelization, which is a framework of polynomial-time preprocessing aimed at compressing the instance size. Our main focus is the weighted CLIQUE problem, where we are given an edge-weighted graph and the goal is to detect a clique of total weight equal to a prescribed value. We show that the weighted variant, parameterized by the number of vertices n , is significantly harder than the unweighted problem by presenting an $\mathcal{O}(n^{3-\varepsilon})$ lower bound on the size of the kernel, under the assumption that $\text{NP} \not\subseteq \text{coNP/poly}$. This lower bound is essentially tight: we show that we can reduce the problem to the case with weights bounded by $2^{\mathcal{O}(n)}$, which yields a randomized kernel of $\mathcal{O}(n^3)$ bits.

We generalize these results to the weighted d -UNIFORM HYPERCLIQUE problem, SUBSET SUM, and weighted variants of Boolean CONSTRAINT SATISFACTION PROBLEMS (CSPs). We also study weighted minimization problems and show that weight compression is easier when we only want to preserve the collection of optimal solutions. Namely, we show that for node-weighted VERTEX COVER on bipartite graphs it is possible to maintain the set of optimal solutions using integer weights from the range $[1, n]$, but if we want to maintain the ordering of the weights of all inclusion-minimal solutions, then weights as large as $2^{\Omega(n)}$ are necessary.

1 Introduction

A prominent class of problems in algorithmic graph theory consist of finding a subgraph with certain properties in an input graph G , if one exists. Some variations of this problem can be solved in polynomial time (detecting a triangle), while the general problem is NP-complete since it generalizes the CLIQUE problem. In recent years, there has been an increasing interest in understanding the complexity of such subgraph detection problems in *weighted* graphs, where either the vertices or the edges are assigned integral weight values, and the goal is either to find a subgraph of a given form which optimizes the total weight of its elements, or alternatively, to find a subgraph whose total weight matches a prescribed value.

Incorporating weights in the problem definition can have a significant effect on computational complexity. For example, determining whether an unweighted n -vertex graph has a triangle can be done in time $\mathcal{O}(n^\omega)$ (where $\omega < 2.373$ is the exponent of matrix

multiplication) [14], while for the analogous weighted problem of finding a triangle of minimum edge-weight, no algorithm of running time $\mathcal{O}(n^{3-\varepsilon})$ is known for any $\varepsilon > 0$. Some popular conjectures in fine-grained complexity theory even postulate that no such algorithms exist [27]. Weights also have an effect on the best-possible exponential running times of algorithms solving NP-hard problems: the current-fastest algorithm for the NP-complete HAMILTONIAN CYCLE problem in undirected graphs runs in time $\mathcal{O}(1.66^n)$ [3], while for its weighted analogue, TRAVELING SALESPERSON, no algorithm with running time $\mathcal{O}((2 - \varepsilon)^n)$ is known for general undirected graphs (cf. [23]).

In this work we investigate how the presence of weights in a problem formulation affects the *compressibility* and *kernelization complexity* of NP-hard problems. Kernelization is a subfield of parameterized complexity [6, 9] that investigates how much a *polynomial-time* preprocessing algorithm can compress an instance of an NP-hard problem, without changing its answer, in terms of a chosen complexity parameter.

For a motivating example of kernelization, we consider the VERTEX COVER problem. For the unweighted variant, a kernelization algorithm based on the Nemhauser-Trotter theorem [25] can efficiently reduce an instance (G, k) of the decision problem, asking whether G has a vertex cover of size at most k , to an equivalent one (G', k') consisting of at most $2k$ vertices, which can therefore be encoded in $\mathcal{O}(k^2)$ bits via its adjacency matrix. In the language of parameterized complexity, the unweighted VERTEX COVER problem parameterized by the solution size k admits a kernelization (self-reduction) to an equivalent instance on $\mathcal{O}(k^2)$ bits. For the *weighted* variant of the problem, where an input additionally specifies a weight threshold $t \in \mathbb{N}_+$ and a weight function $w: V(G) \rightarrow \mathbb{N}_+$ on the vertices, and the question is whether there is a vertex cover of size at most k and weight at most t , the guarantee on the encoding size of the reduced instance is weaker. Etscheid et al. [10, Thm. 5] applied a powerful theorem of Frank and Tardős [12] to develop a polynomial-time algorithm to reduce any instance (G, w, k, t) of WEIGHTED VERTEX COVER to an equivalent one with $\mathcal{O}(k^2)$ edges, which nevertheless needs $\mathcal{O}(k^8)$ bits to encode due to potentially large numbers occurring as vertex weights. The WEIGHTED VERTEX COVER problem, parameterized by solution size k , therefore has a kernel of $\mathcal{O}(k^8)$ bits.

The overhead in the kernel size for the weighted problem is purely due to potentially large weights. This led Etscheid et al. [10] to ask in their conclusion whether this overhead in the kernelization sizes of weighted problems is necessary, or whether it can be avoided. As one of the main results of this paper, we will prove a lower bound showing that the kernelization complexity of some weighted problems is strictly larger than their unweighted counterparts.

Our results. We consider an edge-weighted variation of the CLIQUE problem, parameterized by the number of vertices n :

EXACT-EDGE-WEIGHT CLIQUE (EEWC)

Input: An undirected graph G , a weight function $w: E(G) \rightarrow \mathbb{N}_0$, and a target $t \in \mathbb{N}_0$.

Question: Does G have a clique of total edge-weight exactly t , i.e., a vertex set $S \subseteq V(G)$ such that $\{x, y\} \in E(G)$ for all distinct $x, y \in S$ and such that $\sum_{\{x, y\} \subseteq S} w(\{x, y\}) = t$?

Our formulation of EEWC does not constrain the cardinality of the clique. This formulation will be convenient for our purposes, but we remark that by adjusting the weight function it is possible to enforce that any solution clique S has a prescribed cardinality. Through such a cardinality restriction we can obtain a simple reduction from the problem with potentially negative weights to equivalent instances with weights from \mathbb{N}_0 , by increasing all weights by a suitably large value and adjusting t according to the prescribed cardinality.

Note that an instance of EEWC can be reduced to an equivalent one where G has all possible edges, by simply inserting each non-edge with a weight of $t + 1$. Hence the difficulty of the problem stems from achieving the given target weight t as the total weight of the edges spanned by S , not from the requirement that $G[S]$ must be a clique.

EEWC is a natural extension of ZERO-WEIGHT TRIANGLE [1], which has been studied because it inherits fine-grained hardness from both 3-SUM [29] and ALL PAIRS SHORTEST PATHS [28, Footnote 3]. EEWC has previously been considered by Abboud et al. [2] as an intermediate problem in their W[1]-membership reduction from k -SUM to k -CLIQUE. Vassilevska-Williams and Williams [29] considered a variation of this problem with weights drawn from a finite field. The related problem of detecting a triangle of negative edge weight is central in the field of fine-grained complexity for its subcubic equivalence [30] to ALL PAIRS SHORTEST PATHS. Another example of an edge-weighted subgraph detection problem with an exact requirement on the weight of the target subgraph is EXACT-EDGE-WEIGHT PERFECT MATCHING, which can be solved using algebraic techniques [22, §6] and has been used as a subroutine in subgraph isomorphism algorithms [21, Proposition 3.1].

The unweighted version of EEWC, obtained by setting all edge weights to 1, is NP-complete because it is equivalent to the CLIQUE problem. When using the number of vertices n as the complexity parameter, the problem admits a kernelization of size $\mathcal{O}(n^2)$ obtained by simply encoding the instance via its adjacency matrix. We prove the following lower bound, showing that the kernelization complexity of the edge-weighted version is a factor n larger. The lower bound even holds against *generalized* kernelizations (Definition 4).

► **Theorem 1.** *The EXACT-EDGE-WEIGHT CLIQUE problem parameterized by the number of vertices n does not admit a generalized kernelization of $\mathcal{O}(n^{3-\varepsilon})$ bits for any $\varepsilon > 0$, unless $\text{NP} \subseteq \text{coNP}/\text{poly}$.*

Intuitively, the lower bound exploits the fact that the weight value of each of the $\Theta(n^2)$ edges in the instance may be a large integer requiring $\Omega(n)$ bits to encode. We also provide a randomized kernelization which matches this lower bound.

► **Theorem 2.** *There is a randomized polynomial-time algorithm that, given an n -vertex instance (G, w, t) of EXACT-EDGE-WEIGHT CLIQUE, outputs an instance (G', w', t') of bitsize $\mathcal{O}(n^3)$, in which each number is bounded by $2^{\mathcal{O}(n)}$, that is equivalent to (G, w, t) with probability at least $1 - 2^{-n}$. Moreover, if the input is a YES-instance, then the output is always a YES-instance.*

The proof is based on the idea that taking the weight function modulo a random prime preserves the answer to the instance with high probability. We adapt the argument by Harnik and Naor [13] that it suffices to pick a prime of magnitude $2^{\mathcal{O}(n)}$. As a result, each weight can be encoded with just $\mathcal{O}(n)$ bits.

It is noteworthy that the algorithm above can produce only false positives, therefore instead of using randomization we can turn it into a co-nondeterministic algorithm which guesses the correct values of the random bits. The framework of cross-composition excludes not only deterministic kernelization, but also co-nondeterministic [8], thus the lower bound from Theorem 1 indeed makes the presented algorithm tight.

Together, Theorems 1 and 2 pin down the kernelization complexity of EXACT-EDGE-WEIGHT CLIQUE, and prove it to be a factor n larger than for the unit-weight case. For CLIQUE, the kernelization of $\mathcal{O}(n^2)$ bits due to adjacency-matrix encoding cannot be improved to $\mathcal{O}(n^{2-\varepsilon})$ for any $\varepsilon > 0$, as was shown by Dell and van Melkebeek [8].

We extend our results to the hypergraph setting, which is defined as follows: given a d -regular hypergraph ($d \geq 3$) with non-negative integer weights on the hyperedges, and a target value t , test if there is a vertex set S for which each size- d subset is a hyperedge (so

that S is a hyperclique) such that the sum of the weights of the hyperedges contained in S is exactly t . By a bootstrapping reduction using Theorem 1, we prove that EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE does not admit a generalized kernel of size $\mathcal{O}(n^{d+1-\varepsilon})$ for any $\varepsilon > 0$ unless $\text{NP} \subseteq \text{coNP}/\text{poly}$, while the randomized hashing technique yields a randomized kernelization of size $\mathcal{O}(n^{d+1})$.

We can view the edge-weighted (d -hyper)clique problem on (G, k, w, t) as a weighted constraint satisfaction problem (CSP) with weights from \mathbb{Z} , by introducing a binary variable for each vertex, and a weighted constraint for each subset S' of d vertices, which is satisfied precisely when all variables for S' are set to true. If S' is a (hyper)edge $e \in E(G)$ then the weight of the constraint on S' equals the weight of e ; if S' is not a hyperedge of G , then the weight of the constraint on S' is set to $-\infty$ to prevent all its vertices from being simultaneously chosen. Under this definition, G has a (hyper)clique of edge-weight t if and only if there is an assignment to the variables for which the total weight of satisfied constraints is t . Via this interpretation, the lower bounds for EEWC yield lower bounds on the kernelization complexity of weighted variants of CSP. We employ a recently introduced framework [17] of reductions among different CSPs whose constraint languages have the same maximum degree d of their characteristic polynomials, to transfer these lower bounds to other CSPs (see Section 3.3 for definitions). We obtain tight kernel bounds when parameterizing the exact-satisfaction-weight version of CSP by the number of variables, again using random prime numbers to obtain upper bounds. Our lower bounds for EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE transfer to all CSPs with degree $d \geq 2$. In degree-1 CSP each constraint depends on exactly one variable, therefore its exact-weighted variant is equivalent to the SUBSET SUM problem, for which we also provide a tight lower bound.

► **Theorem 3.** *SUBSET SUM parameterized by the number of items n does not admit a generalized kernelization of size $\mathcal{O}(n^{2-\varepsilon})$ for any $\varepsilon > 0$, unless $\text{NP} \subseteq \text{coNP}/\text{poly}$.*

Theorem 3 tightens a result of Etscheid et al. [10, Theorem 14], who ruled out (standard) kernelizations for SUBSET SUM of size $\mathcal{O}(n^{2-\varepsilon})$ assuming the Exponential Time Hypothesis. Our reduction, conditioned on the incomparable assumption $\text{NP} \not\subseteq \text{coNP}/\text{poly}$, additionally rules out generalized kernelizations that compress into an instance of a potentially different problem. Note that the new lower bound implies that the input data in SUBSET SUM cannot be efficiently encoded in a more compact way, whereas the previous lower bound relies on the particular way the input is encoded in the natural formulation of the problem. On the other hand, a randomized kernel of size $\mathcal{O}(n^2)$ is known [13].

The results described so far characterize the kernelization complexity of broad classes of weighted constraint satisfaction problems in which the goal is to find a solution for which the total weight of satisfied constraints is exactly equal to a prescribed value. We also broaden our scope and investigate the maximization or minimization setting, in which the question is whether there is a solution whose cost is at least, or at most, a prescribed value. Some of our upper-bound techniques can be adapted to this setting: using a procedure by Nederlof, van Leeuwen and de Zwaan [24] a maximization problem can be reduced to a polynomial number of exact queries. This leads, for example, to a *Turing* kernelization (cf. [11]) for the weight-maximization version of d -UNIFORM HYPERCLIQUE which decides an instance in randomized polynomial time using queries of size $\mathcal{O}(n^{d+1})$ to an oracle for an auxiliary problem. We do not have lower bounds in the maximization regime.

In an attempt to understand the relative difficulty of obtaining an exact target weight versus maximizing the target weight, we finally investigate different models of weight reduction for the WEIGHTED VERTEX COVER problem studied extensively in earlier works [5, 10, 24]. We consider the problem on *bipartite* graphs, where an optimal solution can be found in

polynomial time, but we investigate whether a weight function can be efficiently compressed while either preserving (a) the collection of minimum-weight vertex covers, or (b) the relative ordering of total weight for all *inclusion-minimal* vertex covers. We give a polynomial-time algorithm for case (a) which reduces to a weight function with range $\{1, \dots, n\}$ using a relation to b -matchings, but show that in general it is impossible to achieve (b) with a weight function with range $\{1, \dots, 2^{o(n)}\}$, by utilizing lower bounds on the number of different threshold functions.

Organization. We begin with short preliminaries with the crucial definitions. We prove our main Theorem 1 in Section 3 by presenting a cross-composition of degree 3 into EXACT-EDGE-WEIGHT CLIQUE and employing it to obtain kernelization lower bounds for d -uniform hypergraphs for $d \geq 2$. This section also contains the kernelization lower bound for SUBSET SUM as well as the generalization of these results to Boolean CSPs. Next, in Section 4 we focus on bipartite WEIGHTED VERTEX COVER and the difficulty of compressing weight functions. The proofs of statements marked with (★) are located in the appendix. The proofs of statements marked with (♠) can be found in the full version [16]. The proof of Theorem 2, together with Turing kernelization for maximization problems, is given in Appendix B. The kernel upper bounds for Boolean CSPs can be found in the full version [16].

2 Preliminaries

We denote the set of natural numbers including zero by \mathbb{N}_0 , and the set of positive natural numbers by \mathbb{N}_+ . For positive integers n we define $[n] := \{1, \dots, n\}$. For a set U and integer $d \geq 1$ we denote by $\binom{U}{d}$ the collection of all size- d subsets of U . All logarithms we employ have base 2. Given a set U and a weight function $w: U \rightarrow \mathbb{N}_0$, for a subset $S \subseteq U$ we denote $w(S) := \sum_{v \in S} w(v)$.

A graph G has a vertex set $V(G)$ and an edge set $E(G) \subseteq \binom{V(G)}{2}$. For $d \geq 2$, a d -uniform hypergraph G consists of a vertex set $V(G)$ and a set of hyperedges $E(G) \subseteq \binom{V(G)}{d}$, that is, each hyperedge is a set of exactly d vertices. Hence a 2-uniform hypergraph is equivalent to a standard graph. A *clique* in a d -uniform hypergraph G is a vertex set $S \subseteq V(G)$ such that for each $X \in \binom{S}{d}$ we have $X \in E(G)$: each possible hyperedge among the vertices of S is present. A *vertex cover* for a graph G is a vertex set $S \subseteq V(G)$ containing at least one endpoint of each edge. A vertex cover is *inclusion-minimal* if no proper subset is a vertex cover.

Parameterized complexity. A *parameterized problem* Q is a subset of $\Sigma^* \times \mathbb{N}_+$, where Σ is a finite alphabet.

► **Definition 4.** Let $Q, Q' \subseteq \Sigma^* \times \mathbb{N}_+$ be parameterized problems and let $h: \mathbb{N}_+ \rightarrow \mathbb{N}_+$ be a computable function. A generalized kernel for Q into Q' of size $h(k)$ is an algorithm that, on input $(x, k) \in \Sigma^* \times \mathbb{N}_+$, takes time polynomial in $|x| + k$ and outputs an instance (x', k') such that:

1. $|x'|$ and k' are bounded by $h(k)$, and
2. $(x', k') \in Q'$ if and only if $(x, k) \in Q$.

The algorithm is a kernel for Q if $Q = Q'$. It is a polynomial (generalized) kernel if $h(k)$ is a polynomial.

► **Definition 5 (Linear-parameter transformations).** Let P and Q be parameterized problems. We say that P is linear-parameter transformable to Q , if there exists a polynomial-time computable function $f: \Sigma^* \times \mathbb{N}_+ \rightarrow \Sigma^* \times \mathbb{N}_+$, such that for all $(x, k) \in \Sigma^* \times \mathbb{N}_+$, (a) $(x, k) \in P$ if and only if $(x', k') = f(x, k) \in Q$ and (b) $k' \leq \mathcal{O}(k)$. The function f is called a linear-parameter transformation.

We employ a linear-parameter transformation for proving the lower bound for SUBSET SUM. For other lower bounds we use the framework of cross-composition [4] directly.

► **Definition 6** (Polynomial equivalence relation, [4, Def. 3.1]). *Given an alphabet Σ , an equivalence relation \mathcal{R} on Σ^* is called a polynomial equivalence relation if the following conditions hold.*

- (i) *There is an algorithm that, given two strings $x, y \in \Sigma^*$, decides whether x and y belong to the same equivalence class in time polynomial in $|x| + |y|$.*
- (ii) *For any finite set $S \subseteq \Sigma^*$ the equivalence relation \mathcal{R} partitions the elements of S into a number of classes that is polynomially bounded in the size of the largest element of S .*

► **Definition 7** (Degree- d cross-composition). *Let $L \subseteq \Sigma^*$ be a language, let \mathcal{R} be a polynomial equivalence relation on Σ^* , and let $Q \subseteq \Sigma^* \times \mathbb{N}_+$ be a parameterized problem. A degree- d OR-cross-composition of L into Q with respect to \mathcal{R} is an algorithm that, given z instances $x_1, x_2, \dots, x_z \in \Sigma^*$ of L belonging to the same equivalence class of \mathcal{R} , takes time polynomial in $\sum_{i=1}^z |x_i|$ and outputs an instance $(x', k') \in \Sigma^* \times \mathbb{N}_+$ such that:*

- (i) *the parameter k' is bounded by $\mathcal{O}(z^{1/d} \cdot (\max_i |x_i|)^c)$, where c is some constant independent of z , and*
- (ii) *$(x', k') \in Q$ if and only if there is an $i \in [z]$ such that $x_i \in L$.*

► **Theorem 8** ([4, Theorem 3.8]). *Let $L \subseteq \Sigma^*$ be a language that is NP-hard under Karp reductions, let $Q \subseteq \Sigma^* \times \mathbb{N}_+$ be a parameterized problem, and let $\varepsilon > 0$ be a real number. If L has a degree- d OR-cross-composition into Q and Q parameterized by k has a polynomial (generalized) kernelization of bitsize $\mathcal{O}(k^{d-\varepsilon})$, then $\text{NP} \subseteq \text{coNP/poly}$.*

3 Kernel lower bounds

3.1 Exact-Edge-Weight Clique

In this section we show that EXACT-EDGE-WEIGHT CLIQUE parameterized by the number of vertices in the given graph n does not admit a generalized kernel of size $\mathcal{O}(n^{3-\varepsilon})$, unless $\text{NP} \subseteq \text{coNP/poly}$. We use the framework of cross-composition to establish a kernelization lower bound [4]. We will use the NP-hard RED-BLUE DOMINATING SET (RBDS) as a starting problem for the cross-composition. Observe that RBDS is NP-hard because it is equivalent to SET COVER and HITTING SET [19].

RED-BLUE DOMINATING SET (RBDS)

Input: A bipartite graph G with a bipartition of $V(G)$ into sets R (red vertices) and B (blue vertices), and a positive integer $d \leq |R|$.

Question: Does there exist a set $D \subseteq R$ with $|D| \leq d$ such that every vertex in B has at least one neighbor in D ?

The following lemma forms the heart of the lower bound. It shows that an instance of EEWC on $z \cdot N^{\mathcal{O}(1)}$ vertices can encode the logical OR of a sequence of z^3 instances of size N each. Roughly speaking, this should be interpreted as follows: when $z \gg N$, each of the roughly z^2 edge weights of the constructed graph encodes z useful bits of information, in order to allow the instance on $\approx z^2$ edges to represent all z^3 inputs.

► **Lemma 9.** *There is a polynomial-time algorithm that, given integers z, d, n, m and a set of z^3 instances $\{(G_{i,j,k}, R_{i,j,k}, B_{i,j,k}, d) \mid i, j, k \in [z]\}$ of RBDS such that $|R_{i,j,k}| = m$ and $|B_{i,j,k}| = n$ for each $i, j, k \in [z]$, constructs an undirected graph G' , integer $t > 0$, and weight function $w: E(G') \rightarrow \mathbb{N}_0$ such that:*

1. the graph G' contains a clique of total edge-weight exactly t if and only if there exist $i^*, j^*, k^* \in [z]$ such that G_{i^*, j^*, k^*} has a red-blue dominating set of size at most d ,
2. the number of vertices in G' is $\mathcal{O}(z(m + nd))$, and
3. the values of t and $|V(G')|$ depend only on z, d, n , and m .

Proof. We describe the construction of (G', w, t) ; it will be easy to see that it can be carried out in polynomial time. Label the vertices in each set $R_{i,j,k}$ arbitrarily as r_1, \dots, r_m , and similarly label the vertices in each set $B_{i,j,k}$ as b_1, \dots, b_n . We construct a graph G' with edge-weight function w and integer t such that G' has a clique of total edge weight exactly t if and only if some $G_{i,j,k}$ is a YES-instance of RBDS. In the following construction we interpret edge weights as vectors of length $nz + 1$ written in base $(m + d + 2)$, which will be converted to integers later. Starting from an empty graph, we construct G' as follows; see Figure 1.

1. For each $i \in [z]$, create a vertex b_i . The vertices b_i form an independent set, so that any clique in G' contains at most one vertex b_i .
2. For each $j \in [z]$, create a vertex set $R_j = \{r_1^j, r_2^j, \dots, r_m^j\}$ and insert edges of weight $\vec{0}$ between all possible pairs of R_j .
3. For each $k \in [z]$, create a vertex s_k . The vertices s_k form an independent set, so that any clique in G' contains at most one vertex s_k .
4. For each $j, k \in [z]$, for each $x \in [m]$, insert an edge between s_k and r_x^j of weight $\vec{0}$.

The next step is to ensure that the neighborhood of a vertex r_x in $G_{i,j,k}$ is captured in the weights of the edges which are incident on r_x^j in G' .

5. For each $i, j \in [z]$, for each $x \in [m]$, insert an edge between b_i and r_x^j .
6. The weight of each edge $\{b_i, r_x^j\}$ is a vector of length $nz + 1$, out of which the least significant nz positions are divided into z blocks of length n each, and the most significant position is 1. The numbering of blocks as well as positions within a given block start with the least significant position.

For each $i, j \in [z]$, for each $x \in [m]$, the weight of edge $\{b_i, r_x^j\}$ is defined as follows. For each $k \in [z]$, for each $q \in [n]$, the value $v_{k,q}(b_i, r_x^j)$ represents the value of the q^{th} position of the k^{th} block of the weight of $\{b_i, r_x^j\}$. The value is defined based on the neighborhood of vertex r_x in $G_{i,j,k}$ as follows:

$$v_{k,q}(b_i, r_x^j) = \begin{cases} 1 & \text{if } \{b_i, r_x\} \in E(G_{i,j,k}) \\ 0 & \text{otherwise.} \end{cases} \quad (1)$$

Intuitively, the vector representing the weight of edge $\{b_i, r_x^j\}$ is formed by a 1 followed by the concatenation of z blocks of length n , such that the k^{th} block is the 0/1-incidence vector describing which of the n blue vertices of instance $G_{i,j,k}$ are adjacent to r_x .

Note that the n blue vertices of an input instance $G_{i,j,k}$ are represented by a single blue vertex b_i in G' . The difference between distinct blue vertices is encoded via different positions of the weight vectors. The most significant position of the weight vectors, which is always set to 1 for edges of the form $\{b_i, r_x^j\}$, will be used to keep track of the number of red vertices in a solution to RBDS.

The graph constructed so far has a mechanism to select the first index i of an instance $G_{i,j,k}$ (by choosing a vertex b_i), to select the second index j (by choosing vertices r_x^j), and to select the third index k (by choosing a vertex s_k). The next step in the construction adds weighted

■ **Figure 1** Top-left: An instance $(G_{2,1,3}, R_{2,1,3}, B_{2,1,3}, 2)$ of RBDS with $m = 4, n = 5$, and $d = 4$. Right: Illustration of the EEWC instance created for a sequence of 3^3 inputs including the one on the left. For readability, only a subset of the edges is drawn. Bottom-left: For each type edge with non-zero weight, an example weight is shown in vector form.

edges $\{b_i, s_k\}$, of which a solution clique in G' will contain exactly one. The weight vector for this edge is chosen so that the domination requirements from all RBDS instances whose third index differs from k (and which are therefore not selected) can be satisfied “for free”.

7. For each $i, k \in [z]$, insert an edge between b_i and s_k .
8. As in Step 6, the weight of the edge $\{b_i, s_k\}$ is a $(1 + nz)$ -tuple consisting of the most significant position followed by z blocks of length n . There is a 0 at the most significant position, block k consists of n zeros, and the other blocks are filled with ones. Hence the weight of the edge $\{b_i, s_k\}$ is independent of i .

To be able to ensure that G' has a clique of exactly weight t if some input instance $G_{i,j,k}$ has a solution, we need to introduce padding numbers which may be used as part of the solution to EEWC.

9. For each position $v \in [nz + 1]$ of a weight vector, add a vertex set $P_v = \{p_1^v, p_2^v, \dots, p_{d-1}^v\}$ to G' . Recall that d is the upper bound on the solution size for RBDS.
10. For each $i \in [z]$, for each $v \in [nz + 1]$, for each $y \in [d - 1]$, add an edge $\{b_i, p_y^v\}$. The weight of edge $\{b_i, p_y^v\}$ has value 1 at the v^{th} position and zeros elsewhere.
11. For each $v \in [nz + 1]$, for each $y \in [d - 1]$, add an edge $\{p_y^v, u\}$ of weight $\vec{0}$ for all $u \in V(G') \setminus (\{b_i \mid i \in [z]\} \cup \{p_y^v\})$, i.e., for all vertices $u \neq p_y^v$ which were not already adjacent to p_y^v .

We define the target weight t to be the $(nz + 1)$ -length vector with value d at each position, which satisfies Condition 3. Observe that G' has $\mathcal{O}(z(m + nd))$ vertices: Steps 1 and 3 contribute $\mathcal{O}(z)$ vertices, Step 2 contributes $\mathcal{O}(zm)$, and Step 9 contributes $\mathcal{O}(d(nz))$. Hence Condition 2 is satisfied. It remains to verify that G' has a clique of total edge weight

exactly t if and only if some input instance $G_{i,j,k}$ has a solution of RED-BLUE DOMINATING SET of size at most d . Before proving this property, we show the following claim which implies that no carries occur when summing up the weights of the edges of a clique in G' .

▷ **Claim 10.** For any clique $S \subseteq V(G')$, for any position $v \in [nz + 1]$ of a weight vector, there are at most $d + m + 1$ edges of the clique $G'[S]$ whose weight vector has a 1 at position v , and all other weight vectors are 0 at position v .

Proof. By construction, the entries of the vector encoding an edge weight are either 0 or 1.

By Steps 1 and 3, a clique S in G' contains at most one vertex b_i and one vertex s_k . Since G' does not have edges between vertices in distinct sets R_j and $R_{j'}$ by Step 2, any clique in G' consists of at most one vertex b_i , one vertex s_k , a subset of one set R_j , and a subset of $\bigcup_{v \in [nz+1]} P_v$. For any fixed position $v \in [nz + 1]$, the only edge-weight vectors which can have a 1 at position v are the $d - 1$ edges from P_v to b_i , the edge $\{b_i, s_k\}$, and the m edges between R_j and b_i . As this yields $(d - 1) + 1 + m$ edges that possibly have a 1 at position v , the claim follows. ◁

The preceding claim shows that when we convert each edge-weight vector to an integer by interpreting the vector as its base- $(m + d + 2)$ -representation, then no carries occur when computing the sum of the edge-weights of a clique. Hence the integer edge-weights of a clique $S \subseteq V(G')$ sum to the integer represented by vector t , if and only if the edge-weight vectors of the edges in S sum to the vector t . In the remainder, it therefore suffices to prove that there is a YES-instance G_{i^*,j^*,k^*} of RBDS among the inputs if and only if G' has a clique whose edge-weight vectors sum to the vector t . We prove these two implications.

▷ **Claim 11.** If some input graph G_{i^*,j^*,k^*} has a red-blue dominating set of size at most d , then G' has a clique of edge-weight exactly t .

Proof. Let $S \subseteq R_{i^*,j^*,k^*}$ of size at most d be a dominating set of B_{i^*,j^*,k^*} . We define a vertex set $S' \subseteq V(G')$ as follows. Initialize $S' := \{b_{i^*}, s_{k^*}\}$, and for each vertex $r_x \in S$, add the corresponding vertex $r_x^{j^*} \in R_{j^*}$ to S' .

We claim that S' is a clique in G' . To see this, note that R_{j^*} is a clique by Step 2. Vertex s_{k^*} is adjacent to all vertices of R_{j^*} by Step 4. Vertex b_{i^*} is adjacent to all vertices of R_{j^*} by Step 5. By Step 8 there is an edge between b_{i^*} and s_{k^*} .

Let us consider the weight of clique S' . Since S is a dominating set of B_{i^*,j^*,k^*} , if we sum up the weight vectors of the edges $\{b_{i^*}, r_x^{j^*}\}$ for $r_x \in S$, then by Step 6 we get a value of at least one at each position of block k^* . The most significant position of the resulting sum vector has value $|S| \leq d$. By Step 8 the weight vector of the edge $\{b_{i^*}, s_{k^*}\}$ consists of all ones, except for block k^* and the most significant position, where the value is zero. Thus adding the edge weight of $\{b_{i^*}, s_{k^*}\}$ to the previous sum ensures that each block has value at least 1 everywhere, whereas the most significant position has value $|S|$. All other edges spanned by S have weight $\vec{0}$. Letting t' denote the vector obtained by summing the weights of the edges of clique S' , we therefore find that t' has value $|S|$ as its most significant position and value at least 1 everywhere else.

Next we add some additional vertices to the set S' to get a clique of weight exactly t . By Step 11, vertices from the sets P_v for $v \in [nz + 1]$ are adjacent to all other vertices in the graph and can be added to any clique. All edges incident on a vertex $p_y^v \in P_v$ have weight $\vec{0}$, except the edges to vertices of the form b_i whose weight vector has a 1 at the v^{th} position and 0 elsewhere. Since S' contains exactly one such vertex b_{i^*} , for any $v \in [nz + 1]$ we can add up to $d - 1$ vertices from P_v to increase the weight sum at position v from its value of at least 1 in t' , to a value of exactly d . Hence G' has a clique of edge-weight exactly t . ◁

▷ **Claim 12.** If G' has a clique of edge-weight exactly t , then some input graph G_{i^*,j^*,k^*} has a red-blue dominating set of size at most d .

Proof. Suppose $G'[S']$ is a clique whose total edge weight is exactly t . Note that only edges for which one of the endpoints is of the form b_i for $i \in [z]$ have positive edge weights. The remaining edges all have weight $\vec{0}$. Also, by Step 1 there is at most one b -vertex in S' . Hence since $t \neq \vec{0}$ there is exactly one vertex b_{i^*} in S' . By Step 9 and 10, the edges of type $\{b_{i^*}, p_y^v\}$ for $p_y^v \in P_v$ contribute at most $d-1$ to the value of each position $v \in [nz+1]$ of the sum. Hence for each position $v \in [nz+1]$ there is an edge in clique S' of the form $\{b_{i^*}, r_x^j\}$ or $\{b_{i^*}, s_k\}$ which has a 1 at position v . We use this to show there is an input instance with a red-blue dominating set of size at most d .

By Step 3, there is at most one s -vertex in S' . Let $k^* := 1$ if $S \cap \{s_1, \dots, s_z\} = \emptyset$, and otherwise let s_{k^*} be the unique s -vertex in S' . Since the weight of the edge $\{b_{i^*}, s_{k^*}\}$ has zeros in block k^* by Step 8, our previous argument implies that for each of the n positions of block k^* , there is an edge in clique S' of the form $\{b_{i^*}, r_x^j\}$ whose weight has a 1 at that position. Hence S' contains at least one r -vertex, and by Step 2 all r -vertices in the clique S' are contained in a single set R_{j^*} . We show that G_{i^*,j^*,k^*} has a red-blue dominating set of size at most d . Let $S := \{r_x | r_x^j \in S'\}$. Since for each of the n positions of block k^* there is an edge $\{b_{i^*}, r_x^j\}$ in S' with a 1 at that position, by Step 5 each blue vertex of B_{i^*,j^*,k^*} has a neighbor in S . Hence S is a red-blue dominating set. By Step 5, the most significant position of each edge between b_{i^*} and R_{j^*} has value 1. As the most significant position of the target t is set to d , it follows that $|S| \leq d$, which proves that G_{i^*,j^*,k^*} has a red-blue dominating set of size at most d . ◁

This completes the proof of Lemma 9. ◀

Lemma 9 forms the main ingredient in a cross-composition that proves kernelization lower bounds for EXACT-EDGE-WEIGHT CLIQUE and its generalization to hypergraphs. For completeness, we formally define the hypergraph version as follows.

EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE (EEW- d -HC)
Input: A d -uniform hypergraph G , weight function $w: E(G) \rightarrow \mathbb{N}_0$, and a positive integer t .
Question: Does G have a hyperclique of total edge-weight exactly t ?

The following theorem generalizes Theorem 1. The case $d = 2$ of the theorem follows almost directly from Lemma 9 and Theorem 8, as the construction in the lemma gives the crucial ingredient for a degree-3 cross-composition. For larger d , we essentially exploit the fact that increasing the size of hyperedges by one allows one additional dimension of freedom, as has previously been exploited for other kernelization lower bounds for d -HITTING SET and d -SET COVER [7, 8]. The proof is given in Appendix A.1.

► **Theorem 13.** (★) *For each fixed $d \geq 2$, EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE parameterized by the number of vertices n does not admit a generalized kernel of size $\mathcal{O}(n^{d+1-\varepsilon})$ for any $\varepsilon > 0$, unless $\text{NP} \subseteq \text{coNP/poly}$.*

3.2 Subset Sum

We show that SUBSET SUM parameterized by the number of items n does not have generalized kernel of bitsize $\mathcal{O}(n^{2-\varepsilon})$ for any $\varepsilon > 0$, unless $\text{NP} \subseteq \text{coNP/poly}$. We prove the lower bound by giving a linear-parameter transformation from EXACT RED-BLUE DOMINATING SET. We

use EXACT RED-BLUE DOMINATING SET rather than RED-BLUE DOMINATING SET as our starting problem for this lower bound because it will simplify the construction: it will avoid the need for “padding” to cope with the fact that vertices are dominated multiple times.

The SUBSET SUM problem is formally defined as follows.

SUBSET SUM (SS) Input: A multiset X of n positive integers and a positive integer t . Question: Does there exist a subset $S \subseteq X$ with $\sum_{x \in S} x = t$?	Parameter: n
---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	-----------------------

We use the following problem as the starting point of the reduction.

EXACT RED-BLUE DOMINATING SET (ERBDS) Input: A bipartite graph G with a bipartition of $V(G)$ into sets R (red vertices) and B (blue vertices), and a positive integer $d \leq R $. Question: Does there exist a set $D \subseteq R$ of size <i>exactly</i> d such that every vertex in B has exactly one neighbor in D ?	Parameter: $n := V(G) $
-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	---------------------------------

Jansen and Pieterse proved the following lower bound for ERBDS.

► **Theorem 14** ([15, Thm. 4.9]). *EXACT RED-BLUE DOMINATING SET parameterized by the number of vertices n does not admit a generalized kernel of size $\mathcal{O}(n^{2-\varepsilon})$ unless $\text{NP} \subseteq \text{coNP}/\text{poly}$.*

Actually, the lower bound they proved is for a slightly different variant of ERBDS where the solution D is required to have size *at most* d , instead of *exactly* d . Observe that the variant where we demand a solution of size *exactly* d is at least as hard as the *at most* d version: the latter reduces to the former by inserting d isolated red vertices. Therefore the lower bound by Jansen and Pieterse also works for the version we use here, which will simplify the presentation.

► **Theorem 3.** *SUBSET SUM parameterized by the number of items n does not admit a generalized kernelization of size $\mathcal{O}(n^{2-\varepsilon})$ for any $\varepsilon > 0$, unless $\text{NP} \subseteq \text{coNP}/\text{poly}$.*

Proof. Given a graph G with a bipartition of $V(G)$ into R and B with $R = \{r_1, r_2, \dots, r_{n_R}\}$, $B = \{b_1, b_2, \dots, b_{n_B}\}$, and target value d for ERBDS, we transform it to an equivalent instance (X, t) of SS such that $|X| = n_R$. We start by defining n_R numbers N_1, N_2, \dots, N_{n_R} in base $(n_B + 1)$. For each $i \in [n_R]$, the number N_i consists of $(n_B + 1)$ digits. We denote the digits of the number N_i by $N_i[1], \dots, N_i[n_B + 1]$, where $N_i[1]$ is the least significant and $N_i[n_B + 1]$ is the most significant digit. Intuitively, the number N_i corresponds to the red vertex r_i . See Figure 2 for an illustration.

For each $i \in [n_R]$, for each $j \in [n_B + 1]$, digit $N_i[j]$ of number N_i is defined as follows:

$$N_i[j] = \begin{cases} 1 & \text{if } j = n_B + 1 \\ 1 & \text{if } j \in [n_B] \text{ and } \{r_i, b_j\} \in E(G) \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

Hence the most significant digit of each number is 1, and the remaining digits of number N_i form the 0/1-vector indicating to which of the n_B blue vertices r_i is adjacent in G .

To complete the construction we set $X = \{N_1, N_2, \dots, N_{n_R}\}$ and we define t as follows:

$$t = d \underbrace{11 \dots 1}_{n_B \text{ times}} \quad (3)$$

■ **Figure 2** Left: An instance of ERBDS with $n_R = 4$, $n_B = 5$, and $d = 2$. Right: Illustration of the SS instance created for the given input. Note that $\{r_2, r_4\}$ and the numbers $\{N_2, N_4\}$ form a solution for ERBDS and SS, respectively. The leftmost column corresponds to the total count (ct) of the number of elements; the remaining columns correspond to blue vertices.

Observe that under these definitions, there are no carries when adding up a subset of the numbers in X , as each digit of each of the n_R numbers is either 0 or 1 and we work in base $n_R + 1$.

The number of items $|X|$ in the constructed instance of SS is n_R , upper bounded by the parameter $|V(G)|$ of ERBDS. It is easy to see that the construction can be carried out in polynomial time. To complete the linear-parameter transformation from ERBDS to SS, it remains to prove that G has a set $D \subseteq R$ of size exactly d such that every vertex in B has exactly one neighbor in D , if and only if there exist a set $S \subseteq X$ with $\sum_{x \in S} x = t$.

In the forward direction, suppose that there exists a set $D \subseteq R$ of size exactly d such that every vertex in B has exactly one neighbor in D . We claim that $\{N_i \mid r_i \in D\}$ is a solution to SS. The resulting sum has value d at the most significant digit since $|D| = d$. All other digits correspond to vertices in B . Since each blue vertex is adjacent to exactly one vertex from D it is easy to verify that all remaining digits of the sum are exactly one, implying that the numbers sum to exactly t .

For the reverse direction, suppose there is a set $S \subseteq X$ with $\sum_{x \in S} x = t$. Since the most significant digit of t is set to d and each number in X has a 1 as most significant digit, we have $|S| = d$ since there are no carries during addition. Define $D := \{r_i \mid N_i \in S\}$ as the set of the red vertices corresponding to the numbers in S . As $\sum_{x \in S} x = t$ and no carries occur in the summation, we have $\sum_{x \in S} x[j] = t[j] = 1$ for each $j \in [n_B]$. As the j -th digit of all numbers is either 0 or 1 by definition, there is a unique $N_i \in S$ with $N_i[j] = 1$, so that $r_i \in D$ is the unique neighbor of b_j in D . This shows that D is an exact red-blue dominating set of size d , concluding the linear-parameter transformation.

If there was a generalized kernelization for SS of size $\mathcal{O}(n^{2-\epsilon})$, then we would obtain a generalized kernelization for ERBDS of size $\mathcal{O}(n^{2-\epsilon})$ by first transforming it to SS, and then applying the generalized kernelization for the latter. Hence by contraposition and Theorem 14, the claim follows. ◀

3.3 Constraint Satisfaction Problems

In this section we extend our lower bounds to cover Boolean Constraint Satisfaction Problems (CSPs). We employ the recently introduced framework [17] of reductions among different CSPs to make a connection with EEW- d -HC. We start with introducing terminology necessary to identify crucial properties of CSPs.

Preliminaries on CSPs. A k -ary constraint is a function $f: \{0, 1\}^k \rightarrow \{0, 1\}$. We refer to k as the arity of f , denoted $\text{AR}(f)$. We always assume that the domain is Boolean. A constraint f is satisfied by an input $s \in \{0, 1\}^k$ if $f(s) = 1$. A constraint language Γ is a finite collection of constraints $\{f_1, f_2, \dots, f_\ell\}$, potentially with different arities. A *constraint application*, of a k -ary constraint f to a set of n Boolean variables, is a triple $\langle f, (i_1, i_2, \dots, i_k), w \rangle$, where the indices $i_j \in [n]$ select k of the n Boolean variables to whom the constraint is applied, and w is an integer weight. The variables can repeat in a single application.

A formula Φ of $\text{CSP}(\Gamma)$ is a set of constraint applications from Γ over a common set of variables. For an assignment x , that is, a mapping from the set of variables to $\{0, 1\}$, the integer $\Phi(x)$ is the sum of weights of the constraint applications satisfied by x . The considered decision problems are defined as follows.

<p>EXACT-WEIGHT $\text{CSP}(\Gamma)$</p> <p>Input: A formula Φ of $\text{CSP}(\Gamma)$ over n variables, an integer $t \in \mathbb{Z}$.</p> <p>Question: Is there an assignment x for which $\Phi(x) = t$?</p>	<p>Parameter: n</p>
--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	-----------------------------------------

<p>MAX-WEIGHT $\text{CSP}(\Gamma)$</p> <p>Input: A formula Φ of $\text{CSP}(\Gamma)$ over n variables, an integer $t \in \mathbb{Z}$.</p> <p>Question: Is there an assignment x for which $\Phi(x) \geq t$?</p>	<p>Parameter: n</p>
---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	-----------------------------------------

The compressibility of $\text{MAX-WEIGHT CSP}(\Gamma)$ has been studied by Jansen and Włodarczyk [17], who obtained essentially optimal kernel sizes for every Γ in the case where the weights are polynomial with respect to n . Even though the upper and lower bounds in [17] are formulated for $\text{MAX-WEIGHT CSP}(\Gamma)$, they could be adapted to work with $\text{EXACT-WEIGHT CSP}(\Gamma)$. The crucial idea which allows to determine compressibility of Γ is the representation of constraints via multilinear polynomials.

► **Definition 15.** For a k -ary constraint $f: \{0, 1\}^k \rightarrow \{0, 1\}$ its characteristic polynomial P_f is the unique k -ary multilinear polynomial over \mathbb{R} satisfying $f(x) = P_f(x)$ for any $x \in \{0, 1\}^k$.

It is known that such a polynomial always exists and it is unique [26].

► **Definition 16.** The degree of constraint language Γ , denoted $\text{deg}(\Gamma)$, is the maximal degree of a characteristic polynomial P_f over all $f \in \Gamma$.

The main result of Jansen and Włodarczyk [17] states that $\text{MAX-WEIGHT CSP}(\Gamma)$ with polynomial weights admits a kernel of $\mathcal{O}(n^{\text{deg}(\Gamma)} \log n)$ bits and, as long as the problem is NP-hard, it does not admit a kernel of size $\mathcal{O}(n^{\text{deg}(\Gamma)-\varepsilon})$, for any $\varepsilon > 0$, unless $\text{NP} \subseteq \text{coNP/poly}$. It turns out that in the variant when we allow both positive and negative weights the problem is NP-hard whenever $\text{deg}(\Gamma) \geq 2$ [18]. The lower bounds are obtained via linear-parameter transformations, where the parameter is the number of variables n . We shall take advantage of the fact that these transformations still work for an unbounded range of weights.

► **Lemma 17** ([17], Lemma 5.4). For constraint languages Γ_1, Γ_2 such that $2 \leq \text{deg}(\Gamma_1) \leq \text{deg}(\Gamma_2)$, there is a polynomial-time algorithm that, given a formula $\Phi_1 \in \text{CSP}(\Gamma_1)$ on n_1 variables and integer t_1 , returns a formula $\Phi_2 \in \text{CSP}(\Gamma_2)$ on n_2 variables and integer t_2 , such that

1. $n_2 = \mathcal{O}(n_1)$,
2. $\exists_x \Phi_1(x) = t_1 \iff \exists_y \Phi_2(y) = t_2$,
3. $\exists_x \Phi_1(x) \geq t_1 \iff \exists_y \Phi_2(y) \geq t_2$.

Kernel lower bounds for CSP. The lower bound of $\Omega(n^{\deg(\Gamma)-\varepsilon})$ has been obtained via a reduction from d -SAT (with $d = \deg(\Gamma)$) to MAX-WEIGHT CSP(Γ), combined with the fact that MAX d -SAT does not admit a kernel of size $\mathcal{O}(n^{d-\varepsilon})$ for $d \geq 2$ [8, 17]. We are going to show that when the weights are arbitrarily large, then the optimal compression size for EXACT-WEIGHT CSP(Γ) becomes essentially $\mathcal{O}(n^{\deg(\Gamma)+1})$, so the exponent is always larger by one compared to the case with polynomial weights. To this end, we are going to combine the aforementioned reduction framework with our lower bound for EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE.

Consider a constraint language Γ_{AND}^d consisting of a single d -ary constraint AND_d , which is satisfied only if all the arguments equal 1. The characteristic polynomial of AND_d is simply $P(x_1, \dots, x_d) = x_1 x_2 \cdots x_d$, hence the degree of Γ_{AND}^d equals d . We first translate our lower bounds for the hyperclique problems into a lower bound for EXACT-WEIGHT CSP(Γ_{AND}^d) for all $d \geq 2$, and then extend it to other CSPs.

► **Lemma 18.** *For all $d \geq 2$, EXACT-WEIGHT CSP(Γ_{AND}^d) does not admit a generalized kernel of size $\mathcal{O}(n^{d+1-\varepsilon})$, for any $\varepsilon > 0$, unless $\text{NP} \subseteq \text{coNP}/\text{poly}$.*

Proof. Consider an instance (G, w, t) of EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE. Let W be the sum of all weights, which are by the definition non-negative. We can assume $t \in [0, W]$, as otherwise there is clearly no solution. We create an instance Φ of EXACT-WEIGHT CSP(Γ_{AND}^d) with the variable set $V(G)$ as follows. For each potential hyperedge $e = \{v_1, \dots, v_d\}$, if $e \in E(G)$ we create a constraint application $\langle \text{AND}_d, (v_1, \dots, v_d), w(e) \rangle$ and if $e \notin E(G)$, we create a constraint application $\langle \text{AND}_d, (v_1, \dots, v_d), W + 1 \rangle$.

If $X \subseteq V(G)$ is a hyperclique with total weight t , then for the assignment $x(v) = [v \in X]$ it holds that $\Phi(x) = t$. In the other direction, if $\Phi(x) = t$ then x cannot satisfy any constraint application with weight $W + 1$. Hence, each size- d subset of 1-valued variables corresponds to a hyperedge in G and $X = \{v \in V(G) \mid x(v) = 1\}$ forms a hyperclique of total weight t .

We have constructed a linear-parameter transformation from EEW- d -HC to EXACT-WEIGHT CSP(Γ_{AND}^d). Therefore, any generalized kernel of size $\mathcal{O}(n^{d+1-\varepsilon})$ for the latter would entail the same bound for EEW- d -HC. The claim follows from Theorem 13. ◀

The lower bound for EXACT-WEIGHT CSP(Γ_{AND}^d) given by Lemma 18 yields a lower bound for general EXACT-WEIGHT CSP(Γ) using the reduction framework described above.

► **Theorem 19.** *For any Γ with $\deg(\Gamma) \geq 2$, EXACT-WEIGHT CSP(Γ) does not admit a generalized kernel of size $\mathcal{O}(n^{\deg(\Gamma)+1-\varepsilon})$, for any $\varepsilon > 0$, unless $\text{NP} \subseteq \text{coNP}/\text{poly}$.*

Proof. Consider an n -variable instance (Φ_1, t_1) of EXACT-WEIGHT CSP(Γ_{AND}^d), where $d = \deg(\Gamma)$. It holds that $\deg(\Gamma_{\text{AND}}^d) = d$. By Lemma 17, there is a linear-parameter transformation that translates (Φ_1, t_1) into an equivalent instance (Φ_2, t_2) of EXACT-WEIGHT CSP(Γ). If we could compress (Φ_2, t_2) into $\mathcal{O}(n^{d+1-\varepsilon})$ bits, this would entail the same compression for (Φ_1, t_1) . The claim follows from Lemma 18. ◀

This concludes the discussion of kernelization lower bounds. The kernelization upper bounds discussed in the introduction can be found in Appendix B (for hyperclique problems) and in the full version [16] (for CSPs).

4 Node-weighted Vertex Cover in bipartite graphs

Preserving all minimum solutions. For a graph G with node-weight function $w: V(G) \rightarrow \mathbb{N}_+$, we denote by $\mathcal{C}(G, w)$ the collection of subsets of $V(G)$ which are minimum-weight vertex covers of G . For n -vertex bipartite graphs there exists a weight function with range $[n]$ that preserves the set of minimum-weight vertex covers, which can be computed efficiently.

► **Theorem 20.** (♠) *There is an algorithm that, given an n -vertex bipartite graph G and node-weight function $w: V(G) \rightarrow \mathbb{N}_+$, outputs a weight function $w^*: V(G) \rightarrow [n]$ such that $\mathcal{C}(G, w) = \mathcal{C}(G, w^*)$. The running time of the algorithm is polynomial in $|V(G)|$ and the binary encoding size of w .*

The proof of the theorem is given in the full version [16]. It relies on the fact that a maximum b -matching (the linear-programming dual to VERTEX COVER) can be computed in strongly polynomial time in bipartite graphs by a reduction to MAX FLOW. The structure of a maximum b -matching allows two weight-reduction rules to be formulated whose exhaustive application yields the desired weight function. We also prove that the bound of n on the largest weight in Theorem 20 is best-possible.

Preserving the relative weight of solutions. For a graph G , we say that two node-weight functions w, w' are *vertex-cover equivalent* if the ordering of inclusion-minimal vertex covers by total weight is identical under the two weight functions, i.e., for all pairs of inclusion-minimal vertex covers $S_1, S_2 \subseteq V(G)$ we have $w(S_1) \leq w(S_2) \Leftrightarrow w'(S_1) \leq w'(S_2)$. While a minimum-weight vertex cover of a bipartite graph can be found efficiently, the following theorem shows that nevertheless weight functions with exponentially large coefficients may be needed to preserve the ordering of minimal vertex covers by weight.

► **Theorem 21.** (♠) *For each $n \geq 1$, there exists a node-weighted bipartite graph G_n on $2(n+1)$ vertices with weight function $w: V(G_n) \rightarrow \mathbb{N}_+$ such that for all weight functions $w': V(G) \rightarrow \mathbb{N}_+$ which are vertex-cover equivalent to w , we have: $\max_{v \in V(G_n)} w'(v) \geq 2^{\Omega(n)}$.*

5 Conclusions

We have established kernelization lower bounds for SUBSET SUM, EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE, and a family of EXACT-WEIGHT CSP problems, which make it unlikely that there exists an efficient algorithm to compress a single weight into $o(n)$ bits. This gives a clear separation between the setting involving arbitrarily large weights and the case with polynomially-bounded weights, which can be encoded with $\mathcal{O}(\log n)$ bits each. The matching kernel upper bounds are randomized and we leave it as an open question to derandomize them. For SUBSET SUM parameterized by the number of items n , a deterministic kernel of size $\mathcal{O}(n^4)$ is known [10].

Kernelization of weighted minimization/maximization problems is so far less understood. We are able to match the same kernel size as for the exact-weight problems, but only through Turing kernels. Using techniques from [10] one can obtain, e.g., a kernel of size $\mathcal{O}(n^8)$ for MAX-EDGE-WEIGHT CLIQUE. Improving upon this bound possibly requires a better understanding of the threshold functions. Our study of weighted VERTEX COVER on bipartite graphs indicates that preserving the order between all the solutions might be overly demanding and it could be easier to keep track only of the structure of the optimal solutions. Can we extend the theory of threshold functions so that better bounds are feasible when we just want to maintain a separation between optimal and non-optimal solutions?

A Kernel lower bounds

A.1 Omitted proof for Exact-Edge-Weight Clique

► **Theorem 13.** (★) *For each fixed $d \geq 2$, EXACT-EDGE-WEIGHT d -UNIFORM HYPER-CLIQUE parameterized by the number of vertices n does not admit a generalized kernel of size $\mathcal{O}(n^{d+1-\varepsilon})$ for any $\varepsilon > 0$, unless $\text{NP} \subseteq \text{coNP/poly}$.*

Proof. We give a degree- $(d + 1)$ OR-cross-composition (Definition 7) from RBDS to the weighted hyperclique problem using Lemma 9. We start by giving a polynomial equivalence relation \mathcal{R} on inputs of RBDS. Let two instances of RBDS be equivalent under \mathcal{R} if they have the same number of red vertices, the same number of blue vertices, and the same target value d . It is easy to check that \mathcal{R} is a polynomial equivalence relation.

Consider Z inputs of RBDS from the same equivalence class of \mathcal{R} . If Z is not a $(d + 1)^{\text{th}}$ power of an integer, then we duplicate one of the input instances until we reach the first number of the form $2^{(d+1)i}$, which is trivially such a power. This increases the number of instances by at most the constant factor 2^{d+1} and does not change whether there is a YES-instance among the instances. As all requirements on a cross-composition are oblivious to constant factors, from now on we may assume without loss of generality that $Z = z^{d+1}$ for some integer z . By definition of \mathcal{R} , all instances have the same number m of red vertices, the same number n of blue vertices, and have the same maximum size d of a solution.

64:18 On the Hardness of Compressing Weights

For $d = 2$, we can simply invoke Lemma 9 for the $z^{d+1} = z^3$ instances of RBDS and output the resulting instance (G', w, t) of EEWC, which acts as the logical OR. Since the encoding size N of an instance of RBDS with m red vertices, n blue vertices, and target value d satisfies $N \in \Omega(n + m + d)$, Lemma 9 guarantees that G' has $\mathcal{O}(z(m + nd)) \in \mathcal{O}(\sqrt[3]{Z} \cdot N^2)$ vertices, which is suitably bounded for a degree-3 cross-composition for the parameterization by the number of vertices. Hence the claimed lower bound for generalized kernelization then follows from Theorem 8.

In the remainder of the proof, we assume $d \geq 3$. Partition the z^{d+1} inputs in z^{d-2} groups $\{X_{i_1, \dots, i_{d-2}} \mid i_1, \dots, i_{d-2} \in [z]\}$ of size z^3 each. Apply Lemma 9 to each group $X_{i_1, \dots, i_{d-2}}$. This results in z^{d-2} instances $(G_{i_1, \dots, i_{d-2}}, w_{i_1, \dots, i_{d-2}}, t)$ of EEWC on a simple graph. Note that all instances share the same value of $t > 0$, as Lemma 9 ensures that t only depends on (z, d, n, m) which are identical for all groups. Similarly, all resulting instances have the same number of vertices. Hence we can re-label the vertices in each graph so that all graphs $G_{i_1, \dots, i_{d-2}}$ have the same vertex set \mathcal{V} of size $\mathcal{O}(z(m + nd))$. The YES/NO-answer to each composed instance is the disjunction of the answers to the RBDS instances in its corresponding group.

Build a d -uniform hypergraph G^* with weight function $w^*: E(G^*) \rightarrow \mathbb{N}_0$ and target value t^* as follows:

1. $V(G^*) = \mathcal{V} \cup Y_1 \cup \dots \cup Y_{d-2}$, where $Y_\ell = \{y_{\ell, j} \mid j \in [z]\}$ for $\ell \in [d-2]$.
2. A set $S \subseteq V(G^*)$ of exactly d vertices is a hyperedge of G^* if there is no $\ell \in [d-2]$ for which $|S \cap Y_\ell| > 1$.
3. The weight of a hyperedge S is equal to 0 if there exists $\ell \in [d-2]$ with $S \cap Y_\ell = \emptyset$. Otherwise, for each $\ell \in [d-2]$ let i_ℓ be the unique index j such that $y_{\ell, j} \in S$.
 - If $e_S := S \cap \mathcal{V}$ is an edge in graph $G_{i_1, \dots, i_{d-2}}$ then define $w^*(S) := w_{i_1, \dots, i_{d-2}}(e_S)$.
 - Otherwise, let $w^*(S) := t + 1$.
4. Set $t^* = t$.

Since $d \in \mathcal{O}(1)$, hypergraph G^* has $\mathcal{O}(z \cdot (m + nd)) + \mathcal{O}(z \cdot d) \in \mathcal{O}(Z^{1/(d+1)} \cdot (m + n)^{\mathcal{O}(1)})$ vertices. (We use here that $d \leq m$.) Hence the parameter value of the constructed EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE instance is indeed bounded by the $(d+1)$ -th root of the number of input instances times a polynomial in the maximum size of an input instance, satisfying the parameter bound of a degree- $(d+1)$ cross-composition.

It remains to verify that G^* has a hyperclique of weight t^* if and only if one of the input instances has a RBDS of size at most d . By the guarantee of Lemma 9, it suffices to show that G^* has a hyperclique of weight t^* if and only if one of the weighted standard graphs $(G_{i_1, \dots, i_{d-2}}, w_{i_1, \dots, i_{d-2}})$ obtained by applying that lemma to some group of z^3 inputs, has a clique of weight t .

First suppose there exists a weighted graph $(G_{i_1^*, \dots, i_{d-2}^*}, w_{i_1^*, \dots, i_{d-2}^*})$ that contains a clique S of total edge weight t . Let $I := \{y_{\ell, i_\ell^*} \mid \ell \in [d-2]\}$. Let $S' := S \cup I$. By Step 2, the set S' is a hyperclique in G^* . It remains to verify that its weight is $t^* = t$. By Step 3, for each edge e of the clique S the set $e \cup I$ is a hyperedge in G^* of the same weight. Additionally, each subset of S' that does not contain I has weight 0. Hence the weight of hyperclique S' is equal to the weight of clique S and is therefore $t^* = t$.

For the other direction, suppose G^* has a clique $G^*[S^*]$ of weight $t^* = t$. Since $t > 0$ and all hyperedges in G^* of nonzero weight contain exactly one vertex of each set Y_ℓ for $\ell \in [d-2]$, there exist i_1^*, \dots, i_{d-2}^* such that $S^* \cap Y_\ell = \{i_\ell^*\}$ for each $\ell \in [d-2]$. Let $I := \{y_{\ell, i_\ell^*} \mid \ell \in [d-2]\}$. We will show that $S^* \cap \mathcal{V}$ is a clique of weight t in $G_{i_1^*, \dots, i_{d-2}^*}$. Since $t^* = t > 0$ and edge-weights are non-negative, it follows that no hyperedge in S^* has weight $t + 1$. By Step 3, this implies each subset of $S^* \cap \mathcal{V}$ of size two is an edge of $G_{i_1^*, \dots, i_{d-2}^*}$, and hence $S^* \cap \mathcal{V}$ is a clique.

For each set $e \subseteq \mathcal{V}$ of size two, the weight of the hyperedge $e \cup I$ is equal to $w_{i_1^*, \dots, i_{d-2}^*}(e)$. As all other hyperedges in S^* have weight 0, it follows that the weight of the clique $S^* \cap \mathcal{V}$ equals that of hyperclique S^* , and is therefore equal to $t^* = t$. This implies $G_{i_1^*, \dots, i_{d-2}^*}$ has a clique of total edge weight $t = t^*$, which concludes the proof. \blacktriangleleft

B Kernel upper bounds

In this section, we present randomized kernel upper bounds for EEW- d -HC, which match the obtained lower bounds. For the maximization variant of EEW- d -HC, we present a Turing kernel with the same bounds. The results in this section follow from combining known arguments from Harnik and Naor [13] and Nederlof et al. [23] with gadgets that allow us to produce an instance of the same problem that is being compressed (so we obtain a true kernelization, not a generalized one).

Consider a family \mathcal{F} of subsets of a universe U and a weight function $w: \mathcal{F} \rightarrow [-N, N]$. For a subset $X \subseteq U$, we denote $w_{\text{SUM}}(X) = \sum_{Y \in \mathcal{F}, Y \subseteq X} w(Y)$. The following fact has been observed by Harnik and Naor [13, Claim 2.7] and for the sake of completeness we provide a proof for the formulation which is the most convenient for us.

► **Lemma 22.** *Let U be a set of size n , $\mathcal{F} \subseteq 2^U$ be a family of subsets, $w: \mathcal{F} \rightarrow [-N, N]$ be a weight function, and $t \in [-N, N]$. There exists a randomized polynomial-time algorithm that, given a real $\varepsilon > 0$, returns a prime number $p \leq 2^n \cdot \text{poly}(n, \log N, \varepsilon^{-1})$, such that if there is no $X \subseteq U$ satisfying $w_{\text{SUM}}(X) = t$, then*

$$\mathbb{P}\left(\text{there is } X \subseteq U \text{ satisfying } w_{\text{SUM}}(X) \equiv t \pmod{p}\right) \leq \varepsilon.$$

Proof. For a fixed function w , we say that p is *bad* if for some $X \subseteq U$ it holds that $w_{\text{SUM}}(X) \equiv t \pmod{p}$ but $w_{\text{SUM}}(X) \neq t$. This implies that p divides $|w_{\text{SUM}}(X) - t|$. We argue that the number of bad primes is bounded by $2^n \cdot (n + 1 + \log(N))$. Since $|w_{\text{SUM}}(X) - t| \leq 2^{n+1} \cdot N$, this number can have at most $\log(2^{n+1} \cdot N) = n + 1 + \log N$ different prime divisors. There are at most 2^n choices of X , which proves the bound.

We sample a random prime p among the set of the first $M = 2^n \cdot (n + 1 + \log(N)) \cdot \varepsilon^{-1}$ primes. It is known that the first M primes lie in the interval $[2, \mathcal{O}(M \log M)]$ and we can uniformly sample a prime number from this interval in time $(\log M)^{\mathcal{O}(1)} = (n + \log \log(N) + \log(\varepsilon^{-1}))^{\mathcal{O}(1)}$ [20]. By the argument above, the probability of choosing a bad prime is bounded by ε . \blacktriangleleft

► **Theorem 23.** *There is a randomized polynomial-time algorithm that, given an n -vertex instance (G, w, t) of EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE, outputs an instance (G', w', t') of bitsize $\mathcal{O}(n^{d+1})$, such that:*

1. *if (G, w, t) is a YES-instance, then (G', w', t') is always a YES-instance,*
2. *if (G, w, t) is a NO-instance, then (G', w', t') is a NO-instance with probability at least $1 - 2^{-n}$.*

Furthermore, each number in (G', w', t') is bounded by $2^{\mathcal{O}(n)}$.

Proof. Let us define $N = \max(t, \max_{e \in E(G)} w_e)$. We can assume $\log N \leq 2^n$, because otherwise the input length is lower bounded by 2^n and the brute-force algorithm for EEW- d -HC becomes polynomial.

We apply Lemma 22 to the weight function w , target t , and $\varepsilon = 2^{-n}$, to compute the desired prime $p \leq 2^n \cdot \text{poly}(n, \log N, \varepsilon^{-1}) = 2^{\mathcal{O}(n)}$. If there exists a hyperclique $X \subseteq V(G)$ satisfying $w_{\text{SUM}}(X) = t$ with respect to the weighted set family $E(G) \subseteq \binom{V(G)}{d}$, then clearly $w_{\text{SUM}}(X) \equiv t \pmod{p}$. Furthermore, with probability $1 - 2^{-n}$, the implication in the other direction holds as well. In particular, in this case p does not divide t .

Let us construct a new instance (G', w', t') of EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE with weights bounded by $p \cdot n^d$, which is bounded by $2^{\mathcal{O}(n)}$ for constant d . We set $w'(v) = w(v) \pmod{p}$ and $t_p = t \pmod{p}$. The condition $w_{\text{SUM}}(X) \equiv t \pmod{p}$ is equivalent to the existence of $i \in [0, n^d)$ for which $w'_{\text{SUM}}(X) = t_p + ip$, because the sum $w'_{\text{SUM}}(X)$ comprises of at most n^d summands from the range $[0, p)$.

We introduce a set U_Z of $d - 1$ new vertices and for each $j \in [0, d - 1]$ we introduce a set U_j of n new vertices. Intuitively, the sets U_j can be used to represent any number $i \in [0, n^d)$ in base n . For every j and every $v \in U_j$ we create a hyperedge $e = U_Z \cup \{v\}$ with weight $w'_e = n^j \cdot p$. For every other size- d subset containing at least one new vertex, we create a hyperedge with weight 0. Observe that for every integer $i \in [0, n^d]$, we can find a set $Y \subseteq U_Z \cup U_0 \cup \dots \cup U_{d-1}$ such that $w'_{\text{SUM}}(Y) = ip$. Let G' be the graph with the set of vertices $V(G) \cup U_Z \cup U_0 \cup \dots \cup U_{d-1}$ and hyperedges inherited from G plus these defined above. We set $t' = t_p + n^d \cdot p$.

Suppose now that $X \subseteq V(G)$ forms a hyperclique of total weight t in G . Then $w'_{\text{SUM}}(X) = t_p + ip$ for some $i \in [0, n^d)$. By the argument above, we can find a set $Y \subseteq U_Z \cup U_0 \cup \dots \cup U_{d-1}$ such that $w'_{\text{SUM}}(X \cup Y) = t'$ and $X \cup Y$ is a hyperclique in G' .

In the other direction, suppose we have successfully applied Lemma 22 and there is a hyperclique $X' \subseteq V(G')$ with total weight t' . Then p divides $w'_{\text{SUM}}(X' \setminus V(G))$, so since all hyperedges intersecting both $V(G)$ and $X' \setminus V(G)$ have weight 0, we have $w'_{\text{SUM}}(X' \cap V(G)) \equiv t \pmod{p}$ and $w_{\text{SUM}}(X' \cap V(G)) = t$, which gives a desired hyperclique in G .

The new instance has $\mathcal{O}(n)$ vertices and $\mathcal{O}(n^d)$ edges. The weight range is $[0, n^d \cdot p]$ and, since $p = 2^{\mathcal{O}(n)}$, each weight can be encoded with $\mathcal{O}(n)$ bits. The claim follows. \blacktriangleleft

We obtain Theorem 2 as a corollary by taking $d = 2$.

B.1 Turing kernel for Max Weighted Hyperclique

We turn our attention to the maximization variant of the weighted hyperclique problem. We consider the problem MAX-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE, which takes the same input as EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE, but the goal is to detect a hyperclique of total weight greater or equal to the target value t . Even though we are not able to compress the weight function as in Theorem 23, we present a Turing kernelization with the same size. We rely on a generic technique of reducing interval queries to exact queries.

► **Theorem 24** ([24], Theorem 1). *Let U be a set of cardinality n , let $w: U \rightarrow \mathbb{N}_0$ be a weight function, and let $l < u$ be non-negative integers with $u - l > 1$. There is a polynomial-time algorithm that returns a set of pairs $\Omega = (w_1, t_1), \dots, (w_K, t_K)$ with $w_i: U \rightarrow \mathbb{N}_0$ and integers t_1, t_2, \dots, t_K , such that:*

1. K is at most $(5n + 2) \cdot \log(u - l)$,
2. for every set $X \subseteq U$ it holds that $w(X) \in [l, u]$ if and only if there exist $i \in [1, K]$ such that $w_i(X) = t_i$.

A polynomial Turing kernel (cf. [11]) for a parameterized problem \mathcal{P} is a polynomial-time algorithm that decides any instance of \mathcal{P} with access to an oracle that answers instances of size polynomial with respect to the parameter. The size of a Turing kernel is the maximal size of the instances queried to the oracle. Note that if the classic problem underlying \mathcal{P} is NP-hard, then any query for a potentially different problem \mathcal{Q} can be translated into a query for \mathcal{P} whose size is only polynomially larger. Hence in many settings, including ours, it does not make a difference for the existence of polynomial-size Turing kernels whether the queries are for the same problem or for another problem contained in NP.

Observe that the number of calls to the oracle is not restricted, although it is polynomial in the input size since the overall procedure runs in polynomial time. The following theorem gives a one-sided error randomized Turing kernel of size $\mathcal{O}(n^{d+1})$ for MAX-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE parameterized by the number of vertices n .

► **Theorem 25.** *There is a randomized polynomial-time algorithm that, given an n -vertex instance (G, w, t) of MAX-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE, returns a family of K instances (G_i, w_i, t_i) , $i \in [K]$, of EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE, each of bitsize $\mathcal{O}(n^{d+1})$, such that:*

1. K is polynomial with respect to the input size,
2. if (G, w, t) is a YES-instance, then at least one instance (G_i, w_i, t_i) is a YES-instance,
3. if (G, w, t) is a NO-instance, then with probability $1 - 2^{-\Omega(n)}$ all the instances (G_i, w_i, t_i) are NO-instances.

Proof. We apply Theorem 24 with U being the set of hyperedges in G , $l = t$, and $u = n^d \cdot \max_{e \in E(G)} w_e$. We can assume that $l \leq u$, as otherwise there can be no solution. We obtain $K = \log(u - l) \cdot \mathcal{O}(n^d)$ many weight functions w^i and integers t_i , so that for each $X \subseteq U$ it holds $w_{\text{SUM}}(X) \geq t$ if and only if $w_{\text{SUM}}^i(X) = t_i$ for some $i \in [K]$. Observe that $\log(u - l)$ is upper bounded by the input size, so the condition (1) is satisfied.

The original problem thus reduces to a disjunction of polynomially many instances of EXACT-EDGE-WEIGHT d -UNIFORM HYPERCLIQUE. We use Theorem 23 to compress each of them to $\mathcal{O}(n^{d+1})$ bits. The probability that a single instance would be incorrectly compressed is bounded by 2^{-n} . By the union bound, the probability that any instance would be incorrectly compressed is $n^{\mathcal{O}(1)} \cdot 2^{-n} = 2^{-\Omega(n)}$. ◀

Griddings of Permutations and Hardness of Pattern Matching

Abstract

We study the complexity of the decision problem known as *Permutation Pattern Matching*, or PPM. The input of PPM consists of a pair of permutations τ (the “text”) and π (the “pattern”), and the goal is to decide whether τ contains π as a subpermutation. On general inputs, PPM is known to be NP-complete by a result of Bose, Buss and Lubiw. In this paper, we focus on restricted instances of PPM where the text is assumed to avoid a fixed (small) pattern σ ; this restriction is known as $\text{Av}(\sigma)$ -PPM. It has been previously shown that $\text{Av}(\sigma)$ -PPM is polynomial for any σ of size at most 3, while it is NP-hard for any σ containing a monotone subsequence of length four.

In this paper, we present a new hardness reduction which allows us to show, in a uniform way, that $\text{Av}(\sigma)$ -PPM is hard for every σ of size at least 6, for every σ of size 5 except the symmetry class of 41352, as well as for every σ symmetric to one of the three permutations 4321, 4312 and 4231. Moreover, assuming the exponential time hypothesis, none of these hard cases of $\text{Av}(\sigma)$ -PPM can be solved in time $2^{o(n/\log n)}$. Previously, such conditional lower bound was not known even for the unconstrained PPM problem.

On the tractability side, we combine the CSP approach of Guillemot and Marx with the structural results of Huczynska and Vatter to show that for any monotone-griddable permutation class \mathcal{C} , PPM is polynomial when the text is restricted to a permutation from \mathcal{C} .

1 Introduction

Permutation Pattern Matching, or PPM, is one of the most fundamental decision problems related to permutations. In PPM, the input consists of two permutations: τ , referred to as the “text”, and π , referred to as the “pattern”. The two permutations are represented as sequences of distinct integers. The goal is to determine whether the text τ contains the pattern σ , that is, whether τ has a subsequence order-isomorphic to σ (see Section 2 for precise definitions).

Bose, Buss and Lubiw [7] have shown that the PPM problem is NP-complete. Thus, most recent research into the complexity of PPM focuses either on parametrized or superpolynomial algorithms, or on restricted instances of the problem.

For a pattern π of size k and a text τ of size n , a straightforward brute-force approach can solve PPM in time $O(n^{k+1})$. This was improved by Ahal and Rabinovich [1] to $O(n^{0.47k+o(k)})$, and then by Berendsohn, Kozma and Marx [6] to $O(n^{k/4})$.

When k is large in terms of n , a brute-force approach solves PPM in time $O(2^{n+o(n)})$. The first improvement upon this bound was obtained by Bruner and Lackner [8], whose algorithm achieves the running time $O(1.79^n)$, which was in turn improved by Berendsohn, Kozma and Marx [6] to $O(1.6181^n)$.

Guillemot and Marx [11] have shown, perhaps surprisingly, that PPM is fixed-parameter tractable with parameter k , via an algorithm with running time $n \cdot 2^{O(k^2 \log k)}$, later improved to $n \cdot 2^{O(k^2)}$ by Fox [10].

Restricted instances

Given that PPM is NP-hard on general inputs, various authors have sought to identify restrictions on the input permutations that would allow for an efficient pattern matching algorithm. These restrictions usually take the form of specifying that the pattern must belong to a prescribed set \mathcal{C} of permutations (the so-called \mathcal{C} -PATTERN PPM problem), or that both the pattern and the text must belong to a set \mathcal{C} (known as \mathcal{C} -PPM problem). The most commonly considered choices for \mathcal{C} are sets of the form $\text{Av}(\sigma)$ of all the permutations that do not contain a fixed pattern σ .

Note that for the class $\text{Av}(21)$, consisting of all the increasing permutations, $\text{Av}(21)$ -PATTERN PPM corresponds to the problem of finding the longest increasing subsequence in the given text, a well-known polynomially solvable problem [17]. Another polynomially solvable case is $\text{Av}(132)$ -PATTERN PPM, which follows from more general results of Bose et al. [7].

In contrast, for the class $\text{Av}(321)$ of permutations avoiding a decreasing subsequence of length 3 (or equivalently, the class of permutations formed by merging two increasing sequences), $\text{Av}(321)$ -PATTERN PPM is already NP-complete, as shown by Jelínek and Kynčl [15]. In fact, Jelínek and Kynčl show that $\text{Av}(\sigma)$ -PATTERN PPM is polynomial for $\sigma \in \{1, 12, 21, 132, 231, 312, 213\}$ and NP-complete otherwise.

For the more restricted $\text{Av}(\sigma)$ -PPM problem, a polynomial algorithm for $\sigma = 321$ was found by Guillemot and Vialette [12] (see also Albert et al. [2]), and it follows that $\text{Av}(\sigma)$ -PPM is polynomial for any σ of length at most 3. In contrast, the case $\sigma = 4321$ (and by symmetry also $\sigma = 1234$) is NP-complete [15]. It follows that $\text{Av}(\sigma)$ -PPM is NP-complete whenever σ contains 1234 or 4321 as subpermutation, and in particular, it is NP-complete for any σ of length 10 or more.

In this paper, our main motivation is to close the gap between the polynomial and the NP-complete cases of $\text{Av}(\sigma)$ -PPM. We develop a general type of hardness reduction, applicable to any permutation class that contains a suitable grid-like substructure. We then verify that for most choices of σ large enough, the class $\text{Av}(\sigma)$ contains the required substructure. Specifically, we can prove that $\text{Av}(\sigma)$ -PPM is NP-complete in the following cases:

- Any σ of size at least 6.
- Any σ of size 5, except the symmetry type of 41352 (i.e., the two symmetric permutations 41352 and 25314).
- Any σ symmetric to one of 4321, 4312 or 4231.

Note that the list above includes the previously known case $\sigma = 4321$. Our hardness reduction, apart from being more general than previous results, has also the advantage of being more efficient: we reduce an instance of 3-SAT of size m to an instance of PPM of

size $O(m \log m)$. This implies, assuming the exponential time hypothesis (ETH), that none of these NP-complete cases of $\text{Av}(\sigma)$ -PPM can be solved in time $2^{o(n/\log n)}$. Previously, this lower bound was not known to hold even for the unconstrained PPM problem.

Grid classes

The sets of permutations of the form $\text{Av}(\sigma)$, i.e., the sets determined by a single forbidden pattern, are the most common type of permutation sets considered; however, such sets are not necessarily the most convenient tools to understand the precise boundary between polynomial and NP-complete cases of PPM. We will instead work with the more general concept of *permutation class*, which is a set \mathcal{C} of permutations with the property that for any $\pi \in \mathcal{C}$, all the subpermutations of π are in \mathcal{C} as well.

A particularly useful family of permutation classes are the so-called grid classes. When dealing with grid classes, it is useful to represent a permutation $\pi = \pi_1\pi_2 \cdots \pi_n$ by its *diagram*, which is the set of points $\{(i, \pi_i) \mid i = 1, \dots, n\}$. A grid class is defined in terms of a *gridding matrix* \mathcal{M} , whose entries are (possibly empty) permutation classes. We say that a permutation π has an \mathcal{M} -*gridding*, if its diagram can be partitioned, by horizontal and vertical cuts, into an array of rectangles, where each rectangle induces in π a subpermutation from the permutation class in the corresponding cell of \mathcal{M} . The permutation class $\text{Grid}(\mathcal{M})$ then consists of all the permutations that have an \mathcal{M} -gridding.

To a gridding matrix \mathcal{M} we associate a *cell graph*, which is the graph whose vertices are the entries in \mathcal{M} that correspond to infinite classes, with two vertices being adjacent if they belong to the same row or column of \mathcal{M} and there is no other infinite entry of \mathcal{M} between them.

In the griddings we consider in this paper, a prominent role is played by four specific classes, forming two symmetry pairs: one pair are the monotone classes $\text{Av}(21)$ and $\text{Av}(12)$, containing all the increasing and all the decreasing permutations, respectively. Note that any infinite class of permutations contains at least one of $\text{Av}(12)$ and $\text{Av}(21)$ as a subclass, by the Erdős–Szekeres theorem [9].

The other relevant pair of classes involves the so-called *Fibonacci class*, denoted $\oplus 21$, and its mirror image $\ominus 12$. The Fibonacci class can be defined as the class of permutations avoiding the three patterns 321, 312 and 231, or equivalently, it is the class of permutations $\pi = \pi_1\pi_2 \cdots \pi_n$ satisfying $|\pi_i - i| \leq 1$ for every i .

Griddings have been previously used, sometimes implicitly, in the analysis of special cases of PPM, where they were applied both in the design of polynomial algorithms [2, 12], and in NP-hardness proofs [15, 16]. In fact, all the known NP-hardness arguments for special cases of \mathcal{C} -PATTERN PPM are based on the existence of suitable grid subclasses of the class \mathcal{C} . In particular, previous results of the authors [16] imply that for any gridding matrix \mathcal{M} that only involves monotone or Fibonacci cells, $\text{Grid}(\mathcal{M})$ -PATTERN PPM is polynomial when the cell graph of \mathcal{M} is a forest, and it is NP-complete otherwise. Of course, if $\text{Grid}(\mathcal{M})$ -PATTERN PPM is polynomial then $\text{Grid}(\mathcal{M})$ -PPM is polynomial as well. However, the results in this paper identify a broad family of examples where $\text{Grid}(\mathcal{M})$ -PPM is polynomial, while $\text{Grid}(\mathcal{M})$ -PATTERN PPM is known to be NP-complete.

Our main hardness result, Theorem 2, can be informally rephrased as a claim that \mathcal{C} -PPM is hard for a class \mathcal{C} whenever \mathcal{C} contains, for each n and a fixed $\varepsilon > 0$, a grid subclass whose cell graph is a path of length n , and at least εn of its cells are Fibonacci classes. A somewhat less technical consequence, Corollary 4, says that $\text{Grid}(\mathcal{M})$ -PPM is NP-hard whenever the cell graph of \mathcal{M} is a cycle with no three vertices in the same row or column and with at least one Fibonacci cell.

Corollary 4 is, in a certain sense, best possible, since our main tractability result, Theorem 10, states that \mathcal{C} -PPM is polynomial whenever \mathcal{C} is *monotone-griddable*, that is, $\mathcal{C} \subseteq \text{Grid}(\mathcal{M})$, where \mathcal{M} contains only monotone (or empty) cells. Moreover, by a result of Huczynska and Vatter [13], every class \mathcal{C} that does not contain $\oplus 21$ or $\ominus 12$ is monotone griddable. Taken together, these results show that $\text{Grid}(\mathcal{M})$ -PPM is polynomial whenever no cell of \mathcal{M} contains $\oplus 21$ or $\ominus 12$ as a subclass.

2 Preliminaries

A *permutation of length n* is a sequence π_1, \dots, π_n in which each element of the set $[n] = \{1, 2, \dots, n\}$ appears exactly once. When writing out short permutations explicitly, we shall omit all punctuation and write, e.g., 15342 for the permutation 1, 5, 3, 4, 2. The *permutation diagram* of π is the set of points $S_\pi = \{(i, \pi_i) \mid i \in [n]\}$ in the plane. Observe that no two points from S_π share the same x - or y -coordinate. We say that such a set is in *general position*. Note that we blur the distinction between permutations and their permutation diagrams, e.g., we shall refer to “the point of π ”.

For a point p in the plane, we let $p.x$ denote its horizontal coordinate and $p.y$ its vertical coordinate. Two finite sets $S, R \subseteq \mathbb{R}^2$ in general position are *order-isomorphic*, or just *isomorphic* for short, if there is a bijection $f: S \rightarrow R$ such that for any pair of points $p \neq q$ of R we have $f(p).x < f(q).x$ if and only if $p.x < q.x$, and $f(p).y < f(q).y$ if and only if $p.y < q.y$; in such case, the function f is the *isomorphism* from S to R . The *reduction* of a finite set $S \subseteq \mathbb{R}^2$ in general position is the unique permutation π such that S is isomorphic to S_π .

A permutation τ *contains* a permutation π , denoted by $\pi \preceq \tau$, if there is a subset $P \subseteq S_\tau$ that is isomorphic to S_π . Such a subset is then called *an occurrence* of π in τ , and the isomorphism from S to P is an *embedding* of π into τ . If τ does not contain π , we say that τ *avoids* π .

A *permutation class* is any down-set \mathcal{C} of permutations, i.e., a set \mathcal{C} such that if $\pi \in \mathcal{C}$ and $\sigma \preceq \pi$ then also $\sigma \in \mathcal{C}$. For a permutation σ , we let $\text{Av}(\sigma)$ denote the class of all σ -avoiding permutations. We shall throughout use the symbols \boxplus and \boxminus as short-hands for the class of increasing permutations $\text{Av}(21)$ and the class of decreasing permutations $\text{Av}(12)$.

Observe that for every permutation π of length at most m , the permutation diagram S_π is a subset of the set $\{p \mid \frac{1}{2} < p.x < m + \frac{1}{2} \wedge \frac{1}{2} < p.y < m + \frac{1}{2}\}$, called *m -box*. This fact motivates us to extend the usual permutation symmetries to bijections of the whole m -box. In particular, there are eight symmetries generated by:

reversal which reflects the m -box through its vertical axis, i.e., the image of a point p is the point $(m + 1 - p.x, p.y)$,

complement which reflects the m -box through its horizontal axis, i.e., the image of a point p is the point $(p.x, m + 1 - p.y)$,

inverse which reflects the m -box through its ascending diagonal axis, i.e., the image of a point p is the point $(p.y, p.x)$.

We say that a permutation π is *symmetric* to a permutation σ if π can be transformed into σ by any of the eight symmetries generated by reversal, complement and inverse. The *symmetry type*¹ of a permutation σ is the set of all the permutations symmetric to σ .

¹ We chose the term “symmetry type” over the more customary “symmetry class”, to avoid possible confusion with the notion of permutation class.

The symmetries generated by reversal, complement and inverse can be applied not only to individual permutations but also to their classes. Formally, if Ψ is one of the eight symmetries and \mathcal{C} is a permutation class, then $\Psi(\mathcal{C})$ refers to the set $\{\Psi(\sigma) \mid \sigma \in \mathcal{C}\}$. We may easily see that $\Psi(\mathcal{C})$ is again a permutation class.

Consider a pair of permutations π of length n and σ of length m . The *inflation* of a point p of π by σ is the reduction of the point set

$$S_\pi \setminus \{p\} \cup \left\{ \left(p.x + \frac{q.x}{m+1}, p.y + \frac{q.y}{m+1} \right) \mid q \in S_\sigma \right\}.$$

Informally, we replace the point p with a tiny copy of σ .

The *direct sum* of π and σ , denoted by $\pi \oplus \sigma$, is the result of inflating the “1” in 12 with π and then inflating the “2” with σ . Similarly, the *skew sum* of π and σ , denoted by $\pi \ominus \sigma$, is the result of inflating the “2” in 21 with π and then inflating the “1” with σ . If a permutation τ cannot be obtained as direct sum of two shorter permutations, we say that τ is *sum-indecomposable* and if it cannot be obtained as a skew sum of two shorter permutations, we say that it is *skew-indecomposable*. Moreover, we say that a permutation class \mathcal{C} is *sum-closed* if for any $\pi, \sigma \in \mathcal{C}$ we have $\pi \oplus \sigma \in \mathcal{C}$. We define *skew-closed* analogously.

We define the *sum completion* of a permutation π to be the permutation class

$$\oplus\pi = \{\sigma_1 \oplus \sigma_2 \oplus \cdots \oplus \sigma_k \mid \sigma_i \preceq \pi \text{ for all } i \leq k \in \mathbb{N}\}.$$

Analogously, we define the *skew completion* $\ominus\pi$ of π . The class $\oplus 21$ is known as the *Fibonacci class*.

2.1 Grid classes

When we deal with matrices, we number their rows from bottom to top to be consistent with the Cartesian coordinates we use for permutation diagrams. For the same reason, we let the column coordinates precede the row coordinates; in particular, a $k \times \ell$ *matrix* is a matrix with k columns and ℓ rows, and for a matrix \mathcal{M} , we let $\mathcal{M}_{i,j}$ denote its entry in column i and row j .

A matrix \mathcal{M} whose entries are permutation classes is called a *gridding matrix*. Moreover, if the entries of \mathcal{M} belong to the set $\{\square, \square, \emptyset\}$ then we say that \mathcal{M} is a *monotone gridding matrix*.

A $k \times \ell$ -*gridding* of a permutation π of length n are two weakly increasing sequences $1 = c_1 \leq \cdots \leq c_{k+1} = n + 1$ and $1 = r_1 \leq \cdots \leq r_{\ell+1} = n + 1$. For each $i \in [k]$ and $j \in [\ell]$, we call the set of points $p \in S_\pi$ such that $c_i \leq p.x < c_{i+1}$ and $r_j \leq p.y < r_{j+1}$ the (i, j) -*cell* of π . An \mathcal{M} -*gridding* of a permutation π is a $k \times \ell$ -gridding such that the reduction of the (i, j) -cell of π belongs to the class $\mathcal{M}_{i,j}$ for every $i \in [k]$ and $j \in [\ell]$. If π has an \mathcal{M} -gridding, then π is said to be \mathcal{M} -*griddable*, and the *grid class* of \mathcal{M} , denoted by $\text{Grid}(\mathcal{M})$, is the class of all \mathcal{M} -griddable permutations.

The *cell graph* of the gridding matrix \mathcal{M} , denoted $G_{\mathcal{M}}$, is the graph whose vertices are pairs (i, j) such that $\mathcal{M}_{i,j}$ is an infinite class, with two vertices being adjacent if they share a row or a column of \mathcal{M} and all the entries between them are finite or empty. See Figure 1. We slightly abuse the notation and use the vertices of $G_{\mathcal{M}}$ for indexing \mathcal{M} , i.e., for a vertex v of $G_{\mathcal{M}}$, we write \mathcal{M}_v to denote the corresponding entry.

A *proper-turning path* in $G_{\mathcal{M}}$ is a path P such that no three vertices of P share the same row or column. Similarly, a *proper-turning cycle* in $G_{\mathcal{M}}$ is a cycle C such that no three vertices of C share the same row or column.

■ **Figure 1** A gridding matrix \mathcal{M} on the left and a permutation equipped with an \mathcal{M} -gridding on the right. Empty entries of \mathcal{M} are omitted and the edges of $G_{\mathcal{M}}$ are displayed inside \mathcal{M} .

Let π be a permutation, and let (c, r) be its $k \times \ell$ -gridding, where $c = (c_1, \dots, c_{k+1})$ and $r = (r_1, \dots, r_{\ell+1})$. A permutation π together with a gridding (c, r) form a *gridded permutation*. When dealing with gridded permutations, it is often convenient to apply symmetry transforms to individual columns or rows of the gridding. Specifically, the *reversal of the i -th column* of π is the operation which generates a new (c, r) -gridded permutation π' by taking the diagram of π , and then reflecting the rectangle $[c_i, c_{i+1} - 1] \times [1, n]$ in the diagram through its vertical axis, producing the diagram of the new permutation π' . Note that π' differs from π by having all the entries at positions $c_i, c_i + 1, \dots, c_{i+1} - 1$ in reverse order. If $c_{i+1} \leq c_i + 1$, then $\pi' = \pi$.

Similarly, the *complementation of the j -th row* of the (c, r) -gridded permutation π is obtained by taking the rectangle $[1, n] \times [r_j, r_{j+1} - 1]$ and turning it upside down, obtaining a permutation diagram of a new permutation.

Column reversals and row complementations can also be applied to gridding matrices: a reversal of a column i in a gridding matrix \mathcal{M} simply replaces all the classes appearing in the entries of the i -th column by their reverses; a row complementation is defined analogously.

We often need to perform several column reversals and row complementations at once. To describe such operations succinctly, we introduce the concept of $k \times \ell$ -orientation. A $k \times \ell$ -orientation is a pair of functions $\mathcal{F} = (f_c, f_r)$ with $f_c: [k] \rightarrow \{-1, 1\}$ and $f_r: [\ell] \rightarrow \{-1, 1\}$. To *apply* the orientation \mathcal{F} to a $k \times \ell$ -gridded permutation π means to create a new permutation $\mathcal{F}(\pi)$ by reversing in π each column i for which $f_c(i) = -1$ and complementing each row j for which $f_r(j) = -1$. Note that the order in which we perform the reversals and complementations does not affect the final outcome. Note also that \mathcal{F} is an involution, that is, $\mathcal{F}(\mathcal{F}(\pi)) = \pi$ for any $k \times \ell$ -gridded permutation π .

We may again also apply \mathcal{F} to a gridding matrix \mathcal{M} . By performing, in some order, the row reversals and column complementations prescribed by \mathcal{F} on the matrix \mathcal{M} , we obtain a new gridding matrix $\mathcal{F}(\mathcal{M})$. For instance, taking the gridding matrix $\begin{pmatrix} \boxtimes & \boxtimes \\ \boxtimes & \boxtimes \end{pmatrix}$ and applying reversal to its first column yields the gridding matrix $\begin{pmatrix} \boxtimes & \boxtimes \\ \boxtimes & \boxtimes \end{pmatrix}$. Observe that if (c, r) is an \mathcal{M} -gridding of a permutation π , then the same gridding (c, r) is also an $\mathcal{F}(\mathcal{M})$ -gridding of the permutation $\mathcal{F}(\pi)$.

Let \mathcal{M} be a monotone gridding matrix. An orientation \mathcal{F} of \mathcal{M} is *consistent* if all the nonempty entries of $\mathcal{F}(\mathcal{M})$ are equal to \boxtimes . For instance, the matrix $\begin{pmatrix} \boxtimes & \boxtimes \\ \boxtimes & \boxtimes \end{pmatrix}$ has a consistent orientation acting by reversing the first column and complementing the first row, while the matrix $\begin{pmatrix} \boxtimes & \boxtimes \\ \boxtimes & \boxtimes \end{pmatrix}$ has no consistent orientation. We remark that Vatter and Waton [18] have shown that any monotone gridding matrix whose cell graph is acyclic has a consistent orientation.

A vital role in our arguments is played by the concept of monotone griddability. We say that a class \mathcal{C} is *monotone-griddable* if there exists a monotone gridding matrix \mathcal{M} such that \mathcal{C} is contained in $\text{Grid}(\mathcal{M})$. Huczynska and Vatter [13] provided a neat and useful characterization of monotone-griddable classes.

► **Theorem 1** (Huczynska and Vatter [13]). *A permutation class \mathcal{C} is monotone-griddable if and only if it contains neither the Fibonacci class $\oplus 21$ nor its symmetry $\ominus 12$.*

Finally, a monotone grid class $\text{Grid}(\mathcal{C} \mathcal{D})$ where both \mathcal{C} and \mathcal{D} are non-empty is called a *horizontal monotone juxtaposition*. Analogously, a *vertical monotone juxtaposition* is a monotone grid class $\text{Grid}(\frac{\mathcal{C}}{\mathcal{D}})$ with both \mathcal{C} and \mathcal{D} non-empty. A *monotone juxtaposition* is simply a class that is either a horizontal or a vertical monotone juxtaposition.

2.2 Pattern matching complexity

In this paper, we deal with the complexity of the decision problem known as \mathcal{C} -PPM. For a permutation class \mathcal{C} , the input of \mathcal{C} -PPM is a pair of permutations (π, τ) with both π and τ belonging to \mathcal{C} . An instance of \mathcal{C} -PPM is then accepted if τ contains π , and rejected if τ avoids π . In the context of pattern-matching, π is referred to as the *pattern*, while τ is the *text*.

Note that an algorithm for \mathcal{C} -PPM does not need to verify that the two input permutations belong to the class \mathcal{C} , and the algorithm may answer arbitrarily on inputs that fail to fulfill this constraint. Decision problems that place this sort of validity restrictions on their inputs are commonly known as *promise problems*.

Our NP-hardness results for \mathcal{C} -PPM are based on a general reduction scheme from the classical 3-SAT problem. Given that \mathcal{C} -PPM is a promise problem, the reduction must map instances of 3-SAT to valid instances of \mathcal{C} -PPM, i.e., the instances where both π and τ belong to \mathcal{C} .

On top of NP-hardness arguments, we also provide time-complexity lower bounds for the hard cases of \mathcal{C} -PPM. These lower bounds are conditioned on the *exponential-time hypothesis* (ETH), a classical hardness assumption which states that there is a constant $\varepsilon > 0$ such that 3-SAT cannot be solved in time $O(2^{\varepsilon n})$, where n is the number of variables of the 3-SAT instance. In particular, ETH implies that 3-SAT cannot be solved in time $2^{o(n)}$.

Given an instance (π, τ) of \mathcal{C} -PPM, we always use n to denote the length of the text τ . We also freely assume that π has length at most n since otherwise the instance can be straightforwardly rejected. Following established practice, we express our complexity bounds for \mathcal{C} -PPM in terms of n . Note that inputs of \mathcal{C} -PPM of size n actually require $\Theta(n \log n)$ bits to encode.

3 Hardness of PPM

In this section, we present the main technical hardness result and then derive its several corollaries. However, we first need to introduce one more definition.

We say that a permutation class \mathcal{C} has the *\mathcal{D} -rich path property* for a class \mathcal{D} if there is a positive constant ε such that for every k , the class \mathcal{C} contains a grid subclass whose cell graph is a proper-turning path of length k with at least $\varepsilon \cdot k$ entries equal to \mathcal{D} . Moreover, we say that \mathcal{C} has the *computable \mathcal{D} -rich path property*, if \mathcal{C} has the \mathcal{D} -rich path property and there is an algorithm that, for a given k , outputs a witnessing proper-turning path of length k with at least $\varepsilon \cdot k$ copies of \mathcal{D} in time polynomial in k .

► **Theorem 2.** *Let \mathcal{C} be a permutation class with the computable \mathcal{D} -rich path property for a non-monotone-griddable class \mathcal{D} . Then \mathcal{C} -PPM is NP-complete, and unless ETH fails, there can be no algorithm that solves \mathcal{C} -PPM*

- *in time $2^{o(n/\log n)}$ if \mathcal{D} moreover contains any monotone juxtaposition,*
- *in time $2^{o(\sqrt{n})}$ otherwise.*

■ **Figure 2** The gridding matrix \mathcal{M} , the gridded permutation π (the pattern) and the gridded permutation τ (the text), used in the simplified overview of the proof of Theorem 2.

We remark, without going into detail, that the two lower bounds we obtained under ETH are close to optimal. It is clear that the bound of $2^{o(n/\log n)}$ matches, up to the $\log n$ term in the exponent, the trivial $2^{O(n)}$ brute-force algorithm for PPM. Moreover, the lower bound of $2^{o(\sqrt{n})}$ for \mathcal{C} -PPM also cannot be substantially improved without adding assumptions about the class \mathcal{C} . Consider for instance the class $\mathcal{C} = \left(\begin{array}{c|c} \square & \square \\ \oplus_{21} & \square \end{array} \right)$. As we shall see in Proposition 3, this class has the computable \oplus_{21} -rich path property, and therefore the $2^{o(\sqrt{n})}$ conditional lower bound applies to it. However, by using the technique of Ahal and Rabinovich [1], which is based on the concept of treewidth of permutations, we can solve \mathcal{C} -PPM (even \mathcal{C} -PATTERN PPM) in time $n^{O(\sqrt{n})}$. This is because we can show that a permutation $\pi \in \mathcal{C}$ of size n has treewidth at most $O(\sqrt{n})$. We omit the details of the argument here.

3.1 Overview of the proof of Theorem 2

The proof of Theorem 2 is based on a reduction from the well-known 3-SAT problem. The individual steps of the construction are rather technical and in view of the space constraints, we only present here a high-level overview of the construction, while some of the more technical aspects are described in the appendix.

Suppose that \mathcal{C} is a class with the computable \mathcal{D} -rich path property, where \mathcal{D} is not monotone griddable. This means that \mathcal{D} contains the Fibonacci class \oplus_{21} or its reversal \ominus_{12} as subclass. Suppose then, without loss of generality, that \mathcal{D} contains \oplus_{21} .

To reduce 3-SAT to \mathcal{C} -PPM, consider a 3-SAT formula Φ , with n variables x_1, \dots, x_n and m clauses. We may assume that each clause of Φ has exactly 3 literals.

Let $L = L(m, n)$ be an integer whose value will be specified later. By the \mathcal{D} -rich path property, \mathcal{C} contains a grid subclass $\text{Grid}(\mathcal{M})$ where the cell graph of \mathcal{M} is a path of length L , in which a constant fraction of cells is equal to \mathcal{D} .

To simplify our notation in this high-level overview, we will assume that the cell graph of \mathcal{M} corresponds to an increasing staircase. More precisely, the cells of \mathcal{M} representing infinite classes can be arranged into a sequence C_1, C_2, \dots, C_L , where C_1 is the bottom-left cell $\mathcal{M}_{1,1}$ of \mathcal{M} , each odd-numbered cell C_{2i-1} corresponds to the diagonal cell $\mathcal{M}_{i,i}$, and each even numbered cell $C_{2i,2i}$ corresponds to $\mathcal{M}_{i+1,i}$. All the remaining cells of \mathcal{M} are empty. To simplify the exposition even further, we will assume that each odd-numbered cell of the path is equal to \square and each even-numbered cell is equal to \mathcal{D} . See Figure 2.

With the gridding matrix \mathcal{M} specified above, we will construct two \mathcal{M} -gridded permutations, the pattern π and the text τ , such that π can be embedded into τ if and only if the formula Φ is satisfiable. We will describe π and τ geometrically, as permutation diagrams, which are partitioned into blocks by the \mathcal{M} -gridding. We let P_i denote the part of π corresponding to the cell C_i of \mathcal{M} , and similarly we let T_i be the part of τ corresponding to C_i .

■ **Figure 3** The constructions of simple gadgets. The tile Q_i is always on the left and the tile Q_{i+1} is on the right. The dotted lines show the relative vertical order of points.

To get an intuitive understanding of the reduction, it is convenient to first restrict our attention to *grid-preserving embeddings* of π into τ , that is, to embeddings which map the elements of P_i to elements of T_i for each i .

The basic building blocks in the description of π and τ are the *atomic pairs*, which are specific pairs of points appearing inside a single block P_i or T_i . It is a feature of the construction that in any grid preserving embedding of π into τ , an atomic pair inside a pattern block P_i is mapped to an atomic pair inside the corresponding text block T_i . Moreover, each atomic pair in π or τ is associated with one of the variables x_1, \dots, x_n of Φ , and any grid-preserving embedding will maintain the association, that is, atomic pairs associated to a variable x_j inside π will map to atomic pairs associated to x_j in τ .

To describe π and τ , we need to specify the relative positions of the atomic pairs in two adjacent blocks P_i and P_{i+1} (or T_i and T_{i+1}). These relative positions are given by several typical configurations, which we call *gadgets*. Several examples of gadgets are depicted in Figure 3. In the figure, the pairs of points enclosed by an ellipse are atomic pairs. The choose, multiply and merge gadgets are used in the construction of τ , while the pick and follow gadgets are used in π . The copy gadget will be used in both. We also need more complicated gadgets, namely the *flip gadgets* of Figure 4, which span more than two consecutive blocks. In all cases, the atomic pairs participating in a single gadget are all associated to the same variable of Φ .

The sequence of pattern blocks P_1, P_2, \dots, P_L , as well as their corresponding text blocks T_1, \dots, T_L , is divided into several contiguous parts, which we call *phases*. We now describe the individual phases in the order in which they appear.

The initial phase and the assignment phase. The initial phase involves a single pattern block P_1 and the corresponding text block T_1 . Both P_1 and T_1 consist of an increasing sequence of $2n$ points, divided into n consecutive atomic pairs $X_1^1, X_2^1, \dots, X_n^1 \subseteq P_1$ and $Y_1^1, Y_2^1, \dots, Y_n^1 \subseteq T_1$, numbered in increasing order. The pairs X_j^1 and Y_j^1 are both associated to the variable x_j . Clearly any embedding of P_1 into T_1 will map the pair X_j^1 to the pair Y_j^1 , for each $j \in [n]$.

The initial phase is followed by the assignment phase, which also involves only one pattern block P_2 and the corresponding text block T_2 . P_2 will consist of an increasing sequence of n atomic pairs $X_1^2, X_2^2, \dots, X_n^2$, where each X_j^2 is a decreasing pair, i.e., a copy of 21 . Moreover, $X_j^1 \cup X_j^2$ forms the pick gadget, so the first two pattern blocks can be viewed as a sequence of n pick gadgets stacked on top of each other.

■ **Figure 4** A flip text gadget on the left and a flip pattern gadget on the right. The first tile pictured is Q_i and the last tile is Q_j where $j = i + 3$. As before, the dotted lines show the relative order of points.

The block T_2 then consists of $2n$ atomic pairs $\{Y_j^2, Z_j^2; j \in [n]\}$, positioned in such a way that $Y_j^1 \cup Y_j^2 \cup Z_j^2$ is a choose gadget. Thus, $T_1 \cup T_2$ is a sequence of n choose gadgets stacked on top of each other, each associated with one of the variables of Φ .

In a grid-preserving embedding of π into τ , each pick gadget $X_j^1 \cup X_j^2$ must be mapped to the corresponding choose gadget $Y_j^1 \cup Y_j^2 \cup Z_j^2$, with X_j^1 mapped to Y_j^1 , and X_j^2 mapped either to Y_j^2 or to Z_j^2 . There are thus 2^n grid-preserving embeddings of $P_1 \cup P_2$ into $T_1 \cup T_2$, and these embeddings encode in a natural way to the 2^n assignments of truth values to the variables of Φ . Specifically, if X_j^2 is mapped to Y_j^2 , we will say that x_j is false, while if X_j^2 maps to Z_j^2 , we say that x_j is true. The aim is to ensure that an embedding of $P_1 \cup P_2$ into $T_1 \cup T_2$ can be extended to an embedding of π into τ if and only if the assignment encoded by the embedding satisfies Φ .

Each atomic pair that appears in one of the text blocks T_2, T_3, \dots, T_L is not only associated with a variable of Φ , but also with its truth value; that is, there are “true” and “false” atomic pairs associated with each variable x_j . The construction of π and τ ensures that in an embedding of π into τ in which X_j^2 is mapped to Y_j^2 (corresponding to setting x_j to false), all the atomic pairs associated to x_j in the subsequent stages of π will map to false atomic pairs associated to x_j in τ , and conversely, if X_j^2 is mapped to Z_j^2 , then the atomic pairs of π associated to x_j will only map to the true atomic pairs associated to x_j in τ .

The multiplication phase. The purpose of the multiplication phase is to “duplicate” the information encoded in the assignment phase. Without delving into the technical details, we describe the end result of the multiplication phase and its intended behaviour with respect to embeddings. Let d_j be the number of occurrences (positive or negative) of the variable x_j in Φ . Note that $d_1 + d_2 + \dots + d_n = 3m$, since Φ has m clauses, each of them with three literals. Let P_k and T_k be the final pattern block and text block of the multiplication phase. Then P_k is an increasing sequence of $3m$ increasing atomic pairs, among which there are d_j atomic pairs associated to x_j . Moreover, the pairs are ordered in such a way that the d_1 pairs associated to x_1 are at the bottom, followed by the d_2 pairs associated to x_2 and so on. The structure of T_k is similar to P_k , except that T_k has $6m$ atomic pairs. In fact, we may obtain T_k from P_k by replacing each atomic pair $X_i^k \subseteq P_k$ associated to a variable x_j by two adjacent atomic pairs Y_i^k, Z_i^k , associated to the same variable, where Y_i^k is false and Z_i^k is true.

It is useful to identify each pair $X_i^k \subseteq P_k$ as well as the corresponding two pairs $Y_i^k, Z_i^k \subseteq T_k$ with a specific occurrence of x_j in Φ . Thus, each literal in Φ is represented by one atomic pair in P_k and two adjacent atomic pairs of opposite truth values in T_k .

The blocks P_3, \dots, P_k and T_3, \dots, T_k are constructed in such a way that any embedding of π into τ that encodes an assignment in which x_j is false has the property that all the atomic pairs in P_k associated to x_j are mapped to the false atomic pairs of T_k associated to x_j , and similarly, when x_j is encoded as true in the assignment phase, the pairs of P_k associated to x_j are only mapped to the true atomic pairs of T_k . Thus, the mapping of any atomic pair of P_k encodes the information on the truth assignment of the associated variable.

The multiplication phase is implemented by a combination of multiply gadgets and flip text gadgets in τ , and copy gadgets and flip pattern gadgets in π . It requires no more than $O(\log m)$ blocks in π and τ , i.e., $k = O(\log m)$.

The sorting phase. The purpose of the sorting phase is to rearrange the relative positions of the atomic pairs. While at the end of the multiplication phase, the pairs representing occurrences of the same variable appear consecutively, after the sorting phase, the pairs representing literals belonging to the same clause will appear consecutively. More precisely, letting P_ℓ and T_ℓ denote the last pattern block and the last text block of the sorting phase, P_ℓ has the same number of atomic pairs associated to a given variable x_j as P_k , and similarly for T_ℓ and T_k . If K_1, \dots, K_m are the clauses of Φ , then for each clause K_j , P_ℓ contains three consecutive atomic pairs corresponding to the three literals in K_j , and T_ℓ contains the corresponding six atomic pairs, again appearing consecutively. Similarly as in P_k and T_k , each atomic pair in P_ℓ must map to an atomic pair in T_ℓ representing the same literal and having the correct truth value encoded in the assignment phase.

To prove Theorem 2, we need two different ways to implement the sorting phase, depending on whether the class \mathcal{D} contains a monotone juxtaposition or not. The first construction, which we call *sorting by gadgets*, does not put any extra assumptions on \mathcal{D} . However, it may require up to $\Theta(m)$ blocks to perform the sorting, that is $\ell = \Theta(m)$.

The other implementation of the sorting phase, which we call *sorting by juxtapositions* is only applicable when \mathcal{D} contains a monotone juxtaposition, and it can be performed with only $O(\log m)$ blocks. The difference between the lengths of the two versions of sorting is the reason for the two different lower bounds in Theorem 2.

The evaluation phase. The final phase of the construction is the evaluation phase. The purpose of this phase is to ensure that for any embedding of π into τ , the truth assignment encoded by the embedding satisfies all the clauses of Φ . For each clause K_j , we attach suitable gadgets to the atomic pairs in P_ℓ and T_ℓ representing the literals of K_j . Using the fact that the atomic pairs representing the literals of a given clause are consecutive in P_j and T_j , this can be done for all the clauses simultaneously, with only $O(1)$ blocks in π and τ . This completes an overview of the hardness reduction proving Theorem 2.

When the reduction is performed with sorting by gadgets, it produces permutations π and τ of size $O(m^2)$, since we have $L = O(m)$ blocks and each block has size $O(m)$. When sorting is done by juxtapositions, the number of blocks drops to $L = O(\log m)$, hence π and τ have size $O(m \log m)$. ETH implies that 3-SAT with n variables and m clauses cannot be solved in time $2^{o(m+n)}$ [14]. From this, the lower bounds from Theorem 2 follow.

Further details of the reduction, as well as the correctness proof, are presented in the appendix A.

3.2 Consequences

In the rest of this section, we focus on presenting examples of classes that satisfy the technical “rich path” property, which is the backbone of all our hardness arguments.

■ **Figure 5** Illustration of the proof of Proposition 3. Left: a gridding matrix \mathcal{M} whose cell graph is a cycle with a single entry equal to \mathcal{D} . The numbers along the bottom and the left edge form an orientation that maps each entry to a sum-closed class. Right: a gridding matrix whose grid class is contained in $\text{Grid}(\mathcal{M})$ and whose cell graph is a path. The endvertices of the path are highlighted in gray, and the first and last few steps of the path are shown as dashed lines. The numbers along the edges are the labels forming the characteristic of each entry.

► **Proposition 3.** *Let \mathcal{D} be a non-monotone-griddable class that is sum-closed or skew-closed. If \mathcal{M} is a gridding matrix whose cell graph $G_{\mathcal{M}}$ contains a proper-turning cycle with at least one entry equal to \mathcal{D} , then $\text{Grid}(\mathcal{M})$ has the computable \mathcal{D} -rich path property.*

Proof. We note that the proof closely follows a proof of a similar claim for monotone grid classes by Jelínek et al. [16, Lemma 3.5].

We may assume, without loss of generality, that the cell graph of \mathcal{M} consists of a single cycle, that it contains a unique entry equal to \mathcal{D} , and that all the remaining nonempty entries are equal to \boxplus or to \boxminus . This is because each infinite permutation class contains either \boxplus or \boxminus as a subclass, and replacing an entry of \mathcal{M} by its infinite subclass can only change $\text{Grid}(\mathcal{M})$ into its subclass. If we can establish the \mathcal{D} -rich path property for the subclass, then it also holds for the class $\text{Grid}(\mathcal{M})$ itself.

We may also assume that \mathcal{D} is sum-closed, since the skew-closed case is symmetric. In particular, \mathcal{D} contains $\oplus 21$ as a subclass.

Let L be a given integer. We show how to obtain a grid subclass of $\text{Grid}(\mathcal{M})$ whose cell graph is a proper-turning path of length at least L that contains a constant fraction of \mathcal{D} -entries. Refer to Figure 5. Suppose \mathcal{N} is a $k \times \ell$ gridding matrix whose every entry is either sum-closed or skew-closed. The refinement $\mathcal{N}^{\times q}$ of \mathcal{N} is the $qk \times q\ell$ matrix obtained from \mathcal{N} by replacing the entry $\mathcal{N}_{i,j}$ with

- a $q \times q$ diagonal matrix with all the non-empty entries equal to $\mathcal{N}_{i,j}$ if $\mathcal{N}_{i,j}$ is sum-closed,
- a $q \times q$ anti-diagonal matrix with all the non-empty entries equal to $\mathcal{N}_{i,j}$ if $\mathcal{N}_{i,j}$ is skew-closed.

It is easy to see that $\text{Grid}(\mathcal{N}^{\times q})$ is a subclass of $\text{Grid}(\mathcal{N})$. We call the submatrix of $\mathcal{N}^{\times q}$ formed by the entries $\mathcal{N}_{a,b}^{\times q}$ for $q \cdot i < a \leq (q + 1) \cdot i$ and $q \cdot j < b \leq (q + 1) \cdot j$ the (i, j) -block of $\mathcal{N}^{\times q}$.

Importantly, it follows from the work of Albert et al. [3, Proposition 4.1] that for every monotone gridding matrix \mathcal{N} , there exists a consistent orientation of the refinement $\mathcal{N}^{\times 2}$. Translating it to our setting, we can assume that there is a $k \times \ell$ orientation \mathcal{F} such that the image of $\mathcal{M}_{i,j}$ under \mathcal{F} is sum-closed for every $i \in [k]$ and $j \in [\ell]$. If that is not the case for \mathcal{M} , we simply start with $\mathcal{M}^{\times 2}$ instead.

Given such an orientation $\mathcal{F} = (f_c, f_r)$, we label the rows and columns of the refinement $\mathcal{M}^{\times L}$ using the set $[L]$. The L -tuple of columns created from the i -th column of \mathcal{M} is labeled in the increasing order from left to right if $f_c(i)$ is positive and right to left otherwise. Similarly, the L -tuple of rows created from the j -th row of \mathcal{M} is labeled in the increasing order from bottom to top if $f_r(j)$ is positive and top to bottom otherwise. The *characteristic of an entry* in $\mathcal{M}^{\times L}$ is the pair of labels given to its column and row. Observe that each non-empty entry in $\mathcal{M}^{\times L}$ has a characteristic of the form (s, s) for some $s \in [L]$ by the choice of orientation. Therefore, $G_{\mathcal{M}^{\times L}}$ consists exactly of L connected components, each corresponding to a copy of \mathcal{M} .

We pick an arbitrary non-empty monotone entry $\mathcal{M}_{i,j}$ of \mathcal{M} and obtain a matrix \mathcal{M}_L by replacing the (i, j) -block in $\mathcal{M}^{\times q}$ with the $q \times q$ matrix whose only non-empty entries are the ones with characteristic $(s, s+1)$ for all $s \in [L-1]$ and they are all equal to $\mathcal{M}_{i,j}$. $\text{Grid}(\mathcal{M}_L)$ is a subclass of $\text{Grid}(\mathcal{M})$ since the modified (i, j) -block corresponds to shifting the original (anti-)diagonal matrix by one row either up or down, depending on the orientation of the j -th row of \mathcal{M} .

Observe that we connected all the L copies of \mathcal{M} into a single long path. Moreover, the path contains $L-1$ entries in the (i, j) -block and L entries in every other non-empty block. Therefore, a constant fraction of its entries belong to the (a, b) -block such that $\mathcal{M}_{a,b} = \mathcal{D}$ and thus are equal to \mathcal{D} . It is easy to see that the described procedure is constructive and can easily be implemented to run in polynomial time. Therefore, $\text{Grid}(\mathcal{M})$ indeed has the computable \mathcal{D} -rich path property. \blacktriangleleft

Combining Proposition 3 with Theorem 2, we get the following corollary. Note that in the corollary, if \mathcal{D} fails to be sum-closed or skew-closed, we may simply replace it with $\oplus 21$ or $\ominus 12$, since at least one of these two classes is its subclass by Theorem 1.

► Corollary 4. *Let \mathcal{D} be a non-monotone-griddable class. If \mathcal{M} is a gridding matrix whose cell graph contains a proper-turning cycle with one entry equal to \mathcal{D} , then $\text{Grid}(\mathcal{M})$ -PPM is NP-complete. Moreover, unless ETH fails, there can be no algorithm for $\text{Grid}(\mathcal{M})$ -PPM running*

- *in time $2^{o(n/\log n)}$ if \mathcal{D} additionally contains any monotone juxtaposition and is either sum-closed or skew-closed,*
- *in time $2^{o(\sqrt{n})}$ otherwise.*

Three symmetry types of patterns of length 4 can be tackled with a special type of grid classes. The k -step increasing $(\mathcal{C}, \mathcal{D})$ -staircase, denoted by $\text{St}_k(\mathcal{C}, \mathcal{D})$ is a grid class $\text{Grid}(\mathcal{M})$ of a $k \times (k+1)$ gridding matrix \mathcal{M} such that the only non-empty entries in \mathcal{M} are $\mathcal{M}_{i,i} = \mathcal{C}$ and $\mathcal{M}_{i,i+1} = \mathcal{D}$ for every $i \in [k]$. In other words, the entries on the main diagonal are equal to \mathcal{C} and the entries of the adjacent lower diagonal are equal to \mathcal{D} . The increasing $(\mathcal{C}, \mathcal{D})$ -staircase, denoted by $\text{St}(\mathcal{C}, \mathcal{D})$, is the union of $\text{St}_k(\mathcal{C}, \mathcal{D})$ over all $k \in \mathbb{N}$.

Observe that if \mathcal{C} and \mathcal{D} are two infinite classes and one of them contains $\oplus 21$ or $\ominus 12$ then Theorem 2 applies and $\text{St}(\mathcal{C}, \mathcal{D})$ -PPM is NP-complete. Furthermore, if it also contains a monotone juxtaposition as a subclass, then the almost linear lower bound under ETH follows. We proceed to show that three symmetry types of classes avoiding a pattern of length 4 actually contain such a staircase subclass.

► **Proposition 5.** *For any sum-indecomposable permutation σ , the class $\text{St}(\boxplus, \text{Av}(\sigma))$ is contained in the class $\text{Av}(1 \oplus \sigma)$.*

Proof. Suppose for a contradiction that $\sigma' = 1 \oplus \sigma$ belongs to $\text{St}(\boxplus, \text{Av}(\sigma))$. In particular it belongs to $\text{St}_k(\boxplus, \text{Av}(\sigma))$ for some k and there is a witnessing gridding. If the first element is not mapped to one of the \boxplus -entries on the upper diagonal, then the whole σ' must lie in a single $\text{Av}(\sigma)$ -entry on the lower diagonal, which is clearly not possible. Therefore, the first element must be mapped to one of the \boxplus -entries. Notice that the rest of σ' cannot be mapped to any of the \boxplus -entries as it lies below and to the right of the first element. However, it cannot lie in more than one $\text{Av}(\sigma)$ -entry; otherwise, we could express σ as a direct sum of two shorter permutations. Hence, there must be an occurrence of σ in an $\text{Av}(\sigma)$ -entry which is clearly a contradiction. ◀

A direct consequence of Proposition 5 is that taking σ to be 321, 312 or 231, we see that $\text{St}(\boxplus, \text{Av}(321)) \subseteq \text{Av}(4321)$, $\text{St}(\boxplus, \text{Av}(231)) \subseteq \text{Av}(4231)$ and $\text{St}(\boxplus, \text{Av}(312)) \subseteq \text{Av}(4312)$. Note that the first inclusion is rather trivial and the latter two have been previously observed by Berendsohn [5].

We may easily observe that for any pattern σ of size 3, the class $\text{Av}(\sigma)$ contains the Fibonacci class or its reversal, as well as a monotone juxtaposition. Combining Proposition 5 with Theorem 2 yields the following consequence.

► **Corollary 6.** *For any permutation σ that contains a pattern symmetric to 4321, to 4231, or to 4312, the problem $\text{Av}(\sigma)$ -PPM is NP-complete, and unless ETH fails, it cannot be solved in time $2^{o(n/\log n)}$.*

We verified by computer that there are only five symmetry types of patterns of length 5 that do not contain any of 4321, 4213, 4312 or their symmetries – represented by 14523, 24513, 32154, 42513 and 41352. Of these five, four can be handled by Corollary 4 since they contain a specific type of cyclic grid classes, as we now show.

► **Proposition 7.** *The class $\text{Av}(\sigma)$ contains the class $\text{Grid}(\mathcal{M})$ for the gridding matrix*

$$\mathcal{M} = \begin{pmatrix} \boxplus & \boxplus \\ \text{Av}(\pi) & \boxplus \end{pmatrix} \text{ whenever}$$

- $\pi = 132$ and $\sigma = 14523$, or
- $\pi = 231$ and $\sigma = 24513$, or
- $\pi = 321$ and $\sigma \in \{32154, 42513\}$.

Proof. Suppose that σ and π are one of the listed cases. Observe that $\text{Grid}(\mathcal{M})$ is a subclass of $\text{Av}(\sigma)$ if and only if σ is not in $\text{Grid}(\mathcal{M})$. For contradiction, suppose that the class $\text{Grid}(\mathcal{M})$ contains σ . Therefore, there exists a witnessing \mathcal{M} -gridding $1 = c_1 \leq c_2 \leq c_3 = 6$ and $1 = r_1 \leq r_2 \leq r_3 = 6$ of σ .

Let us consider the four choices of σ separately, starting with $\sigma = 14523$: if $c_2 \leq 3$ and $r_2 \leq 3$, the cell $(2, 2)$ of the gridding contains the pattern 21, if $c_2 \leq 4$ and $r_2 \geq 4$, the cell $(2, 1)$ contains 12, if $c_2 \geq 4$ and $r_2 \leq 4$, the cell $(1, 2)$ contains 12, and if $c_2 \geq 5$ and $r_2 \geq 5$, the cell $(1, 1)$ contains 132. In all cases we get a contradiction with the properties of the \mathcal{M} -gridding. The same argument applies to $\sigma = 14513$, except in the last case we use the pattern 231 instead of 132.

For $\sigma = 32154$, the four cases to consider are $c_2 \leq 4 \wedge r_2 \leq 4$, $c_2 \geq 5 \wedge r_2 \leq 3$, $c_2 \leq 3 \wedge r_2 \geq 5$, and $c_2 \geq 4 \wedge r_2 \geq 4$, in each case getting contradiction in a different cell of the gridding. For $\sigma = 42513$, the analogous argument distinguishes the cases $c_2 \leq 3 \wedge r_2 \leq 3$, $c_2 \geq 4 \wedge r_2 \leq 4$, $c_2 \leq 4 \wedge r_2 \geq 4$, and $c_2 \geq 5 \wedge r_2 \geq 5$. ◀

It is easy to see that every σ of length at least 6 contains a pattern of size 5 which is not symmetric to 41352. Therefore, $\text{Av}(\sigma)$ -PPM is NP-complete for all permutations σ of length at least 4 except for one symmetry type of length 5 and for four out of seven symmetry types of length 4. As $\text{Av}(\sigma)$ -PPM is polynomial-time solvable for any σ of length at most 3, these are, in fact, the only cases left unsolved.

► **Corollary 8.** *If σ is a permutation of length at least 4 that is not in symmetric to any of 3412, 3142, 4213, 4123 or 41352, then $\text{Av}(\sigma)$ -PPM is NP-complete, and unless ETH fails, it cannot be solved in time $2^{o(n/\log n)}$.*

To conclude this section, we remark that the suitable grid subclasses were discovered via computer experiments facilitated by the Permuta library [4].

4 Polynomial-time algorithm

We say that a permutation π is *t-monotone* if there is a partition $\Pi = (S_1, \dots, S_t)$ of S_π such that S_i is a monotone point set for each $i \in [t]$. The partition Π is called a *t-monotone partition*.

Given a *t-monotone* partition $\Pi = (S_1, \dots, S_t)$ of a permutation π and a *t-monotone* partition $\Sigma = (S'_1, \dots, S'_t)$ of τ , an embedding ϕ of π into τ is a (Π, Σ) -embedding if $\phi(S_i) \subseteq S'_i$ for every $i \in [t]$. Guillemot and Marx [11] showed that if we fix a *t-monotone* partitions of both π and τ , the problem of finding a (Π, Σ) -embedding is polynomial-time solvable.

► **Proposition 9** (Guillemot and Marx [11]). *Given a permutation π of length m with a *t-monotone* partition Π and a permutation τ of length n with a *t-monotone* partition Σ , we can decide if there is a (Π, Σ) -embedding of π into τ in time $O(m^2n^2)$.*

We can combine this result with the fact that there is only a bounded number of ways how to grid a permutation, and obtain the following counterpart to Corollary 4.

► **Theorem 10.** *\mathcal{C} -PPM is polynomial-time solvable for any monotone-griddable class \mathcal{C} .*

Proof. Let \mathcal{M} be a $k \times \ell$ monotone gridding matrix such that $\text{Grid}(\mathcal{M})$ contains the class \mathcal{C} . We have to decide whether π is contained in τ for two given permutations π of length m and τ of length n , both belonging to the class \mathcal{C} .

First, we find an \mathcal{M} -gridding of τ . We enumerate all possible $k \times \ell$ gridgings and for each, we test if it is a valid \mathcal{M} -gridding. Observe that there are in total $O(n^{k+\ell-2})$ such gridgings since they are determined by two sequences of values from the set $[n]$, one of length $k - 1$ and the other of length $\ell - 1$. Moreover, it is straightforward to test in time $O(n^2)$ whether a given $k \times \ell$ gridding is in fact an \mathcal{M} -gridding. Note that we are guaranteed to find an \mathcal{M} -gridding as τ belongs to $\mathcal{C} \subseteq \text{Grid}(\mathcal{M})$. We set Σ to be the $(k \cdot \ell)$ -monotone partition of τ into the monotone sequences given by the individual cells of the gridding.

In the second step, we enumerate all possible \mathcal{M} -griddings of π . As with τ , we enumerate all possible $O(m^{k+\ell-2})$ $k \times \ell$ gridgings of π and check for each gridding whether it is actually an \mathcal{M} -gridding in time $O(m^2)$. For each \mathcal{M} -gridding found, we let Π be the $(k \cdot \ell)$ -monotone partition of π given by the gridding, and we apply Proposition 9 to test whether there is a (Π, Σ) -embedding in time $O(m^2n^2)$.

If there is an embedding ϕ of π into τ , there is a $(k \cdot \ell)$ -monotone partition Σ' of π such that ϕ is a (Π, Σ') -embedding. Therefore, the algorithm correctly solves \mathcal{C} -PPM in time $O(n^{k+\ell} + m^{k+\ell}n^2)$ – polynomial in n, m . ◀

Notice that if \mathcal{M} is a gridding matrix whose every entry is monotone griddable, or equivalently no entry contains the Fibonacci class or its reverse as a subclass, then the class $\text{Grid}(\mathcal{M})$ is monotone griddable as well. It follows that for such \mathcal{M} , the $\text{Grid}(\mathcal{M})$ -PPM problem is polynomial-time solvable. We also note that recent results on \mathcal{C} -PATTERN PPM [16] imply that if a gridding matrix \mathcal{M} has an acyclic cell graph, and if every nonempty cell is either monotone or symmetric to a Fibonacci class, then $\text{Grid}(\mathcal{M})$ -PATTERN PPM, and therefore also $\text{Grid}(\mathcal{M})$ -PPM, is polynomial-time solvable as well. These two tractability results contrast with our Corollary 4, which shows that for any gridding matrix \mathcal{M} whose cell graph is a cycle, and whose nonempty cells are all monotone except for one Fibonacci cell, $\text{Grid}(\mathcal{M})$ -PPM is already NP-hard.

5 Open problems

We have presented a hardness reduction which allowed us to show that the $\text{Av}(\sigma)$ -PPM problem is NP-complete for every permutation σ of size at least 6, as well as for most shorter choices of σ . Nevertheless, for several symmetry types of σ , the complexity of $\text{Av}(\sigma)$ -PPM remains open. We collect all the remaining unresolved cases as our first open problem.

► **Open problem 1.** *What is the complexity of $\text{Av}(\sigma)$ -PPM, when σ is a permutation from the set $\{3412, 3142, 4213, 4123, 41352\}$?*

Our hardness results are accompanied by time complexity lower bounds based on the ETH. Specifically, for our NP-hard cases, we show that under ETH, no algorithm may solve \mathcal{C} -PPM in time $2^{o(\sqrt{n})}$. The lower bound can be improved to $2^{o(n/\log n)}$ under additional assumptions about \mathcal{C} . This opens the possibility of a more refined complexity hierarchy within the NP-hard cases of \mathcal{C} -PPM. In particular, we may ask for which \mathcal{C} can \mathcal{C} -PPM be solved in subexponential time.

► **Open problem 2.** *Which cases of \mathcal{C} -PPM can be solved in time $2^{O(n^{1-\varepsilon})}$? Can the general PPM problem be solved in time $2^{o(n)}$?*

A The proof of Theorem 2

Our job is to construct a pair of permutations π and τ , both having a gridding corresponding to a \mathcal{D} -rich path, with the property that the embeddings of π into τ will simulate satisfying assignments of a given 3-SAT formula. First, we introduce the concept of \mathcal{F} -assembly which enables us to describe constructions of gridded permutations from a grid class $\text{Grid}(\mathcal{M})$ somewhat independently from the actual shape of \mathcal{M} .

A.1 \mathcal{F} -assembly

A finite subset P of the m -box in general position is called an m -tile and a $k \times \ell$ family of m -tiles is a set $\mathcal{P} = \{P_{i,j} \mid i \in [k], j \in [\ell]\}$ where each $P_{i,j}$ is an m -tile. Let $\mathcal{F} = (f_c, f_r)$ be a $k \times \ell$ orientation and let \mathcal{P} be a family of m -tiles $P_{i,j}$ for $i \in [k], j \in [\ell]$. The \mathcal{F} -assembly of \mathcal{P} is the point set S defined as follows.

We define for every $i \in [k], j \in [\ell]$ the point set $P'_{i,j} = \{p + (i \cdot m, j \cdot m) \mid p \in \Phi_i(\Psi_j(P_{i,j}))\}$ where Φ_i is an identity if $f_c(i) = 1$ and reversal otherwise, while Ψ_j is an identity if $f_r(j) = 1$ and complement otherwise. We set $S = \bigcup P'_{i,j}$ to be the \mathcal{F} -assembly of \mathcal{P} . If S is not in general position, we rotate it clockwise by a tiny angle to a general position without changing the order of any points that originally did not share a common coordinate.

Let \mathcal{M} be a $k \times \ell$ gridding matrix. We say that the *image of $\mathcal{M}_{i,j}$ under \mathcal{F}* is the class $\Phi_i(\Psi_j(\mathcal{M}_{i,j}))$. The *\mathcal{F} -image of \mathcal{M}* , denoted by $\mathcal{F}(\mathcal{M})$, is then the $k \times \ell$ gridding matrix defined as $\mathcal{F}(\mathcal{M})_{i,j} = \Phi_i(\Psi_j(\mathcal{M}_{i,j}))$.

► **Observation 11.** *Let \mathcal{M} be a $k \times \ell$ gridding matrix, let \mathcal{F} be a $k \times \ell$ orientation and \mathcal{P} a $k \times \ell$ family of m -tiles. If for every $i \in [k]$ and $j \in [\ell]$ the reduction of $P_{i,j}$ belongs to the class $\mathcal{F}(\mathcal{M})_{i,j}$ then the reduction of the \mathcal{F} -assembly of \mathcal{P} belongs to $\text{Grid}(\mathcal{M})$.*

Furthermore, if the cell graph $G_{\mathcal{M}}$ of a monotone gridding matrix \mathcal{M} is acyclic, we can always find an orientation \mathcal{F} such that the image $\mathcal{F}(\mathcal{M})_{i,j}$ of every non-empty entry $\mathcal{M}_{i,j}$ is the class \square . We say that such \mathcal{F} is a *consistent orientation* for the gridding matrix \mathcal{M} . The existence of consistent orientations is guaranteed for matrices with acyclic cell graphs.

► **Lemma 12** (Vatter and Waton [18]). *There exists a consistent $k \times \ell$ orientation \mathcal{F} for any monotone $k \times \ell$ gridding matrix \mathcal{M} whose cell graph $G_{\mathcal{M}}$ is acyclic.*

A.2 The reduction

Let Φ be a given 3-CNF formula with n variables x_1, x_2, \dots, x_n and m clauses K_1, K_2, \dots, K_m each containing exactly three literals. Let \mathcal{M} be a $g \times h$ gridding matrix such that $\text{Grid}(\mathcal{M})$ is a subclass of \mathcal{C} , the cell graph $G_{\mathcal{M}}$ is a proper-turning path of sufficient length to be determined later with a constant fraction of its entries is equal to \mathcal{D} .

First, we label the vertices of the path as p_1, p_2, p_3, \dots choosing the direction such that at least half of the \mathcal{D} -entries share a row with their predecessor. By application of Lemma 12, there is a $g \times h$ orientation \mathcal{F} such that the class $\mathcal{F}(\mathcal{M})_{i,j}$ is equal to \square for every monotone entry $\mathcal{M}_{i,j}$ and the class $\mathcal{F}(\mathcal{M})_{i,j}$ contains $\oplus 21$ for every \mathcal{D} -entry $\mathcal{M}_{i,j}$. Our plan is to simultaneously construct two $g \times h$ families of tiles \mathcal{P} and \mathcal{T} and then set π and τ to be the \mathcal{F} -assemblies of \mathcal{P} and \mathcal{T} , respectively. We abuse the notation and for any $g \times h$ family of tiles \mathcal{Q} (in particular for \mathcal{P} and \mathcal{T}), we use Q_i instead of Q_{p_i} to denote the tile corresponding to the i -th cell of the path.

For now, we will only consider restricted embeddings. We say that an embedding of π into τ where π is an \mathcal{F} -assembly of \mathcal{P} and τ is an \mathcal{F} -assembly of \mathcal{T} , is *grid-preserving* if the image of tile $P_{i,j}$ is mapped to the image of $T_{i,j}$ for every i and j . We slightly abuse the notation in the case of grid-preserving embeddings and say that a point q in the tile $P_{i,j}$ is mapped to a point r in the tile $T_{i,j}$ instead of saying that the image of q under the \mathcal{F} -assembly is mapped to the image of r under the \mathcal{F} -assembly. We say that a pair of points r, q in the tile Q_i *sandwiches* a set of points A in the tile Q_{i+1} if for every point $t \in A$ $r.y < t.y < q.y$ in case p_i and p_{i+1} occupy a common row or otherwise, if the same holds for the x -coordinates.

A.2.1 Gadgets

We construct the tiles from gadgets consisting of pairs of points that we call *atomic pairs*. We assume that the tiles are formed as direct sums of the individual gadgets. Consequently, if $A, B \subseteq Q_i$ are point sets of two different gadgets, then either whole A lies to the right and above B or vice versa. We describe the gadgets in the case when p_i and p_{i+1} share a common row and p_i is to the left of p_{i+1} , as the other cases are symmetric. The gadgets are fully described by the relative positions of their points, therefore we refer the reader to Figure 3 for their definitions.

We say that the copy, pick and follow gadgets connect the pair A to the pair B and the multiply gadget multiplies the pair A to B_1 and B_2 . The choose gadget is said to branch the pair A to B_1 and B_2 and the merge gadget merges the pairs A_1 and A_2 into the pair B . We follow with two observations about the behavior of these gadgets.

► **Observation 13.** *Suppose there is a choose gadget branching an atomic pair A^T in the tile T_i to two atomic pairs B_1^T and B_2^T in the tile T_{i+1} , and a pick gadget in \mathcal{P} connecting an atomic pair A^P in the tile P_i to an atomic pair B^P in the tile P_{i+1} . In any grid-preserving embedding of π into τ , if A^P is mapped to A^T then B^P is mapped either to B_1^T or to B_2^T .*

► **Observation 14.** *Suppose there is a merge gadget merging atomic pairs A_1^T and A_2^T in the tile T_i into an atomic pair B^T in the tile T_{i+1} , and a follow gadget connecting an atomic pair A^P in the tile P_i to an atomic pair B^P in the tile P_{i+1} . In any grid-preserving embedding of π into τ , if A^P is mapped to A_α^T for some $\alpha \in \{1, 2\}$ then B^P is mapped to B^T .*

The flip gadget

We proceed to define two gadgets – a flip text gadget and a flip pattern gadget. It is insufficient to consider just two neighboring tiles as we need two \mathcal{D} -entries for the construction. To that end, let i and j be indices such that both p_{i+1} and p_j are \mathcal{D} -entries and there is no other \mathcal{D} -entry between them.

As before, suppose that A_1 and A_2 are two atomic pairs in Q_i . The *flip text gadget* attached to the atomic pairs A_1 and A_2 consists of two points s_1^{i+1}, s_2^{i+1} in the tile Q_{i+1} and two atomic pairs B_1^k and B_2^k in each tile Q_k for every $k \in [i+2, j] = \{i+2, i+3, \dots, j\}$. The points s_1^{i+1}, s_2^{i+1} form an occurrence of 21 and s_α^{i+1} is sandwiched by A_α for each $\alpha \in \{1, 2\}$.

The atomic pairs B_1^k, B_2^k for $k \in [i+2, j-1]$ are set such that B_2^k lies to the left and below of B_1^k , and together, they form an occurrence of 1234. The only difference in the case of atomic pairs B_1^j, B_2^j is that they form an occurrence of 2143. For every $k \in [i+3, j]$ and $\alpha \in \{1, 2\}$, the pair B_α^k sandwiches the pair B_α^{k-1} and moreover, the pair B_α^{i+2} sandwiches the point s_α^{i+1} . We say that the flip text gadget flips the pairs A_1, A_2 in Q_i to the pairs B_2^j, B_1^j in Q_j . See the left part of Figure 4.

We define the *flip pattern gadget* as a set of points isomorphic to the pairs B_1^k for all k together with the point s_1^{i+2} . See the right part of Figure 4.

Observe that flip gadget propagates the mapping properties while switching the order of the pairs. However, it can also be used to test if only one of its initial atomic pairs is used in the embedding. We omit proofs of the following lemmas due to space constraints.

► **Lemma 15.** *Suppose there is a flip pattern gadget connecting an atomic pair \bar{A} in P_i with an atomic pair \bar{B} in P_j . Furthermore, suppose that there is a flip text gadget flipping atomic pairs A_1 and A_2 in T_i to atomic pairs B_2 and B_1 in T_j . In any grid-preserving embedding of π into τ , if \bar{A} is mapped to A_α for some $\alpha \in \{1, 2\}$ then \bar{B} is mapped to B_α .*

► **Lemma 16.** *Suppose that there are two flip pattern gadgets connecting an atomic pair A_α^P in P_i to an atomic pair B_α^P in P_j for $\alpha \in \{1, 2\}$. Suppose that there is a flip text gadget in \mathcal{T} that flips atomic pairs A_1^T and A_2^T in T_i to atomic pairs B_2^T and B_1^T in T_j . There cannot exist a grid-preserving embedding ϕ of π into τ that maps A_α^P to A_α^T for each $\alpha \in \{1, 2\}$.*

Note that all the gadgets except for the copy and multiply ones require a non-monotone entry and thus, we need to somehow bridge the segments of the path consisting only of monotone entries. By *attaching a gadget* to the pair A , we mean connecting to A a chain of copy gadgets leading all the way to its first non-monotone entry and then attaching the desired gadget at the end of this chain.

A.2.2 Constructing the \mathcal{C} -PPM instance

We define the initial tile P_1 to contain atomic pairs X_k^0 for $k \in [n]$ and the initial tile T_1 to contain atomic pairs Y_k^0 for $k \in [n]$ where each X_k^0 and Y_k^0 form an occurrence of 12 and X_i^0 (Y_j^0) lies to the left and below of X_j^0 (Y_i^0) for every $i < j$. Any grid-preserving embedding of π into τ must obviously map X_k^0 to Y_k^0 for every $k \in [n]$. We describe the rest of the construction in four distinct phases.

Assignment phase. In the first phase, we simulate the assignment of truth values to the variables. To that end, we attach to each pair Y_k^0 for $k \in [n]$ a choose gadget that branches Y_k^0 to two atomic pairs $Y_{k,1}^1$ and $Z_{k,1}^1$ and we attach to each pair X_k^0 for $k \in [n]$ a pick gadget that connects X_k^0 to an atomic pair $X_{k,1}^1$. The properties of choose and pick gadgets imply that in any grid-preserving embedding, $X_{k,1}^1$ is either mapped to $Y_{k,1}^1$ or to $Z_{k,1}^1$.

Multiplication phase. Our next goal is to multiply the atomic pairs corresponding to a single variable into as many pairs as there are occurrences of this variable in the clauses. We describe the gadgets dealing with each variable individually.

Fix $k \in [n]$ and let m_k for $k \in [n]$ denote the total number of occurrences of x_k and $\neg x_k$ in Φ . We are going to describe the construction inductively in $\lceil \log m_k \rceil$ steps. Fix $i \geq 1$. We add for each $j \in [2^i]$ three multiply gadgets, one that multiplies the atomic pair $X_{k,j}^i$ to atomic pairs $\tilde{X}_{k,2j-1}^{i+1}$ and $\tilde{X}_{k,2j}^{i+1}$, one that multiplies the pair $Y_{k,j}^i$ to $\tilde{Y}_{k,2j-1}^{i+1}$ and $\tilde{Y}_{k,2j}^{i+1}$, and finally one that multiplies $Z_{k,j}^i$ to $\tilde{Z}_{k,2j-1}^{i+1}$ and $\tilde{Z}_{k,2j}^{i+1}$. Observe that the properties of gadgets imply that for arbitrary $j \in [2^{i+1}]$, $\tilde{X}_{k,j}^{i+1}$ maps either to $\tilde{Y}_{k,j}^{i+1}$ or to $\tilde{Z}_{k,j}^{i+1}$. However in the text, we have the quadruple $\tilde{Y}_{k,2j-1}^{i+1}, \tilde{Y}_{k,2j}^{i+1}, \tilde{Z}_{k,2j-1}^{i+1}, \tilde{Z}_{k,2j}^{i+1}$ in this specific order.

To solve this, we add for each $j \in [2^i]$ a flip text gadget that flips $\tilde{Y}_{k,2j}^{i+1}, \tilde{Z}_{k,2j-1}^{i+1}$ to atomic pairs $Z_{k,2j-1}^{i+1}, Y_{k,2j}^{i+1}$. The properties of flip gadgets (Lemma 15) guarantee that for every $j \in [2^{i+1}]$, the pair $X_{k,j}^{i+1}$ is mapped either to $Y_{k,j}^{i+1}$ or to $Z_{k,j}^{i+1}$. Moreover, the order of atomic pairs in the text now alternates between Y and Z as desired. It follows that we need in total $O(\log m)$ \mathcal{D} -entries for the multiplication phase.

Sorting phase. The multiplication phase ended with atomic pairs $X_{k,j}^i$ in the pattern ordered lexicographically by (k, j) , i.e., bundled in blocks by the variables. The goal of the sorting phase is to rearrange them such that they become bundled by clauses.

First, we remark that it is possible to flip the order of any two neighboring pairs in the pattern using only a $O(1)$ layers of gadgets. Unfortunately, the space constraints make it impossible to include the description here as it is quite involved and technical. Using this approach, we can flip an arbitrary set of neighboring pairs in $O(1)$ layers of gadgets and thus, we can arbitrarily reshuffle the atomic pairs of the pattern in $O(m)$ layers.

On the other hand, we describe how we can do the sorting phase using significantly fewer fewer tiles if the class \mathcal{D} contains a monotone juxtaposition. We shall discuss here only the case when \mathcal{D} contains the juxtaposition $\mathcal{B} = \text{Grid}(\square \square)$ as the other cases can be solved using the same technique. Let p_i be an entry such that $\mathcal{F}(\mathcal{M})_{p_i}$ contains \mathcal{B} and recall that we assumed that p_i shares a common row with p_{i-1} . We construct a tile Q_i from two increasing sets Q_i^1 and Q_i^2 placed next to each other. In particular, we can attach to any atomic pair A in Q_{i-1} a copy gadget connecting A to an atomic pair B and choose arbitrarily whether B lies in Q_i^1 or Q_i^2 .

Figure 6 Example of one sorting step using Grid($\square \square$) and a partition $\{1, 2, 3\} = \{1, 3\} \cup \{2\}$.

Let J_1 and J_2 be a partition of the set $[3m]$. We attach a copy gadget ending in Q_i^α to each X_j, Y_j and Z_j with $j \in J_\alpha$ for each $\alpha \in \{1, 2\}$. In this way, we rearranged the atomic pairs in \mathcal{P} such that first we have all pairs X_j such that $j \in J_1$ followed by all pairs X_j for $j \in J_2$. Similarly in \mathcal{T} , we have Y_j, Z_j for $j \in J_1$ followed by Y_j, Z_j for $j \in J_2$. See Figure 6.

Notice that the described operation simulates a stable bucket sort with two buckets. Therefore, we can simulate radix sort and rearrange the atomic pairs into arbitrary order given by σ by iterating this operation $O(\log m)$ times. In this way, the whole sorting phase uses only $O(\log m)$ entries equal to \mathcal{D} .

Evaluation phase. In the evaluation phase, we test whether each clause $K_j = (x_a \vee x_b \vee x_c)$ is satisfied. We consider the case when K_j contains only positive literals as clauses with negative literals can be handled with minor modifications of the argument. Suppose X_a, X_b and X_c are the three neighboring atomic pairs in \mathcal{P} that correspond to the three literals in K_j . In \mathcal{T} , there are six neighboring atomic pairs $Y_a, Z_a, Y_b, Z_b, Y_c, Z_c$ such that in any grid-preserving embedding, the pair X_α is mapped to either Y_α or Z_α for every $\alpha \in \{a, b, c\}$.

We abuse the notation and use the same letters to denote atomic pairs in different tiles so that the gadgets carry the names through. First, we add (i) a choose gadget that branches Z_b to \bar{Z}_b and \tilde{Z}_b , and (ii) pick gadgets to $Y_a, Z_a, Y_b, Y_c, Z_c, X_a, X_b$ and X_c . We continue with adding two layers of flip gadgets, modifying the order of atomic pairs in the text as follows

$$Y_a Z_a \overleftrightarrow{Y_b} \bar{Z}_b \tilde{Z}_b \overleftrightarrow{Y_c} Z_c \rightarrow Y_a \overleftrightarrow{Z_a} \bar{Z}_b Y_b \tilde{Z}_b \overleftrightarrow{Z_c} Y_c \rightarrow Y_a \bar{Z}_b Z_a Y_b Z_c \tilde{Z}_b Y_c.$$

Observe that either X_b is mapped to Y_b and thus K_j is satisfied, or X_b is mapped to one of \bar{Z}_b and \tilde{Z}_b . Subsequently, the order of pairs in the final tile guarantees by Lemma 16 that simultaneously, X_a cannot map to Z_a and X_c to Z_c and thus, K_j must be satisfied.

That concludes the construction of \mathcal{P} and \mathcal{T} . Observe that each tile in both \mathcal{P} and \mathcal{T} contains $O(m)$ points. If \mathcal{D} contains a monotone juxtaposition, then $|\pi|, |\tau| \in O(m \log m)$ and otherwise, $|\pi|, |\tau| \in O(m^2)$. This gives rise to the two different conditional lower bounds.

Beyond grid-preserving embeddings. First, we modify both π and τ such that any embedding that maps the image of P_1 to the image of T_1 must already be grid-preserving. To that end, we add atomic pairs A_1, A_2 to the initial tile P_1 such that A_1 is to the left and below everything else and A_2 is to the right and above everything else. We then attach to both A_1, A_2 a chain of copy gadgets going all the way to the last tile of the path. We modify \mathcal{T} , in the same way, using chains of copy gadgets originating in the atomic pairs B_1 and B_2 . Observe that in any embedding that sends P_1 to T_1 , the image of A_α is mapped to the image of B_α for each $\alpha \in \{1, 2\}$. The chain of copy gadgets attached to A_α then must map to the chain of gadgets attached to B_α and these chains force the embedding to be grid-preserving.

Finally, we modify π and τ to obtain permutations π' and τ' such that any embedding of π' into τ' can be translated to an embedding of π into τ that maps P_1 to T_1 and vice versa. Let r and q be the lowest and topmost points in P_1 and similarly, let s and t be the lowest and topmost points of T_1 . The family of tiles \mathcal{P}' is obtained from \mathcal{P} by inflating both r and q with an increasing sequence of length $|\tau| + 1$ and similarly, the family \mathcal{T}' is obtained from \mathcal{T} by inflating both s and t . We call the points obtained by inflating r and q *lower anchors* and the ones obtained by inflating s and t *upper anchors*. We let π' and τ' be the \mathcal{F} -assemblies of \mathcal{P}' and \mathcal{T}' . Observe that these modifications did not change the asymptotic size of the input as $|\pi'| = O(|\tau|)$ and $|\tau'| = O(|\tau'|) = O(|\tau|)$.

A.3 Correctness

The “only if” part. Let Φ be a satisfiable formula and fix arbitrary satisfying assignment. We map the image of P_1 to the image of T_1 . In the assignment phase, we map the pair $X_{k,1}^1$ to $Y_{k,1}^1$ if x_k is set to true, otherwise we map it to $Z_{k,1}^1$. The embedding of the multiplication and sorting phase is uniquely determined by the gadgets. It is easy to check that for each satisfied clause K_j there is a way to extend the mapping to the evaluation phase.

The “if” part. Let ϕ be an embedding of π' into τ' . The total length of the anchors in both π' and τ' is $2|\tau| + 2$. Therefore, at least $|\tau| + 2$ points of the anchors in π' must be mapped to the anchors in τ' and in particular, there is at least one point in each anchor of π' that maps to corresponding anchor in τ' . The chains of copy gadgets attached to A_1 and A_2 force the rest of the embedding to be grid-preserving, and thus it straightforwardly translates to a grid-preserving embedding of π into τ .

Using the grid-preserving embedding, we define a satisfying assignment $\rho: [n] \rightarrow \{T, F\}$. We set $\rho(k) = T$ if the pair $X_{k,1}^1$ is mapped to $Y_{k,1}^1$ and we set $\rho(k) = F$ if it is mapped to $Z_{k,1}^1$. This property is clearly maintained throughout the multiplication and sorting phases due to the properties of the gadgets. Finally, we already argued that our construction of evaluation phase guarantees that all three literals in a given clause cannot be negative.

Sets of Linear Forms Which Are Hard to Compute

Abstract

We present a uniform description of sets of m linear forms in n variables over the field of rational numbers whose computation requires $m(n - 1)$ additions. Our result is based on bounds on the height of the annihilating polynomials in the Perron theorem and an effective form of the Lindemann–Weierstrass theorem which is due to Sert (1999).

1 Introduction

Evaluating a set of a linear forms is a natural computation task that frequently appears in both theory and applications. For a matrix

$$\Delta = \begin{pmatrix} \delta_{1,1} & \delta_{1,2} & \cdots & \delta_{1,n} \\ \delta_{2,1} & \delta_{2,2} & \cdots & \delta_{2,n} \\ \vdots & \vdots & & \vdots \\ \delta_{m,1} & \delta_{m,2} & \cdots & \delta_{m,n} \end{pmatrix} \quad (1)$$

and a column vector

$$\mathbf{x} = (x_1, \dots, x_n)^T \quad (2)$$

linear forms are presented as a matrix-vector product

$$\Delta \mathbf{x} = (\delta_{j,1}x_1 + \dots + \delta_{j,n}x_n)_{j=1}^m \quad (3)$$

in which the matrix entries $\delta_{s,t}$ are fixed values and the vector entries x_s are varying inputs and computations are by means of *linear* algorithms. As expected, the complexity of a linear algorithm is its number of additions and we are interested in sets of linear forms of high complexity.

Obviously, the set of linear forms (3) can be computed in $m(n - 1)$ additions. However, in finite fields, this trivial upper bound is not the best possible. Namely, over a finite field of q elements, it can be computed in $O(mn/\log_q m)$ additions, see [10, Theorem 1], where the implied constants are absolute. On the other hand (in finite fields), when $m = O(n)$, there exist $\delta_{s,t}$, $s = 1, \dots, m$ and $t = 1, \dots, n$, for which any computation of (3) requires $\Omega(mn/\log_q m)$ additions, cf. [10, Section 5]. In fact, this lower bound holds for almost all

$m \times n$ matrices with $m = O(n)$, see Appendix B.2 for the precise statement and the proof by a *counting argument*. Thus, for each pair of positive integers m and n such that $m = O(n)$, the entries of such a matrix can be effectively computed, but to describe them uniformly (in m and n) is a very difficult open problem. Even no example of a non-linear complexity is known from the literature.

The situation is quite different when the underlying field is infinite. By a *transcendence degree argument*, it is easy to see that, over the field of real numbers \mathbb{R} , say, when the coefficients of the linear forms are algebraically independent, the computation of (3) requires $m(n-1)$ additions (cf. [4, Section 5.2]). This leads to a natural question: what about the field of rational numbers \mathbb{Q} ? Refining the transcendence degree argument we establish the existence of sets of linear forms (3) over \mathbb{Q} whose computation requires $m(n-1)$ additions. Moreover, as it is shown in Appendix B.3, almost all sets of linear forms (3) are of such complexity. The main result of our paper is a uniform description of such a set.

Namely, we show that, if the entries of a matrix Δ are algebraically independent and Γ is “sufficiently close” to Δ , then computing $\Gamma\mathbf{x}$ also requires $m(n-1)$ additions. However, an estimate of the above “sufficiently close” and, as a corollary, uniform description of such matrices are based on very non-trivial number-theoretic tools [11] and also involves lengthy and somewhat tedious calculations. Furthermore, we believe that some of our results, such as bounds on the height of the annihilating polynomials in the Perron theorem, are of independent interest and may find further applications.

This paper is organized as follows. In Section 2 we present the definition of a linear algorithm and its associated graph and in Section 3, we normalize linear algorithms and state some simple basic complexity results. In Section 4, we prove the existence of a set of linear forms of the maximal complexity over \mathbb{Q} . Then, in Section 5, we present an alternative proof of the existence of such a set and outline an example. In Section 6 we estimate the height of the polynomial¹ appearing in the alternative proof and in Section 7 we recall an effective version of the *Lindemann-Weierstrass theorem* of Sert [11], which makes the existence proof constructive.² Finally, in Section 8, we present an example of a set of m linear forms in n variables over \mathbb{Q} whose computation requires $m(n-1)$ additions.

To shorten the calculations and to simplify the final result, we use very crude estimates routinely applying inequalities of the form $N^N + N \leq 2N^N$, $e^{N^N} < N^{N^2}$ and similar. Nevertheless these estimation are still sufficient to make the point and to illustrate the approach.

Throughout the paper we adhere the convention that our main results are called “*Theorems*”, our auxiliary results are “*Propositions*”, while all previously known results (regardless of their depth and importance) are called “*Lemmas*”.

2 Linear algorithms and their associated graphs

A *linear algorithm* over a field \mathbb{F} in *indeterminates* x_1, x_2, \dots, x_n consists of a sequence of operations $u_i \leftarrow \alpha_i u_{j_i} + \beta_i u_{k_i}$, $i = 1, \dots, C$, where

- $\alpha_i, \beta_i \in \mathbb{F}^*$ are the algorithm coefficients;
- u_i is the algorithm *variable* that does not appear in a previous step;

¹ That is, the maximum of the absolute values of the polynomial coefficients.

² The Lindemann–Weierstrass theorem states that if algebraic numbers $\alpha_1, \dots, \alpha_N$ are linearly independent over \mathbb{Q} , then $e^{\alpha_1}, \dots, e^{\alpha_N}$ are algebraically independent.

- u_{j_i} and u_{k_i} are either indeterminates or the algorithm variables appearing in a previous step (that is, if u_{j_i} and u_{k_i} are the algorithm variables appearing at step i , then $j_i, k_i < i$).

With each algorithm variable u in a linear algorithm we associate the following linear form $\ell(u)$:

- if u is an indeterminate x_t , then $\ell(u)$ is x_t ;
- if u is the left-hand side of an operation $u \leftarrow \alpha v + \beta w$, then $\ell(u)$ is the linear form $\alpha\ell(v) + \beta\ell(w)$.

A linear algorithm *computes* a linear form $\ell(x_1, \dots, x_n)$, if there is a variable, or an indeterminate, u of the algorithm and a *constant* $\gamma \in \mathbb{F}$ such that $\ell(x_1, \dots, x_n) = \gamma\ell(u)$ (thus, linear algorithms compute linear forms up to scaling by a constant) and a linear algorithm computes a set linear forms

$$\mathcal{L}(x_1, \dots, x_n) = \{\ell_s(x_1, \dots, x_n) : s = 1, \dots, m\}$$

if it computes each form $\ell_s(x_1, \dots, x_n) \in \mathcal{L}(x_1, \dots, x_n)$.

The number n of the variables and the number m of linear forms are fixed throughout this paper.

► **Definition 1.** *The complexity $|\mathcal{A}|$ of a linear algorithm \mathcal{A} is the length C of its sequence of operations.*

► **Definition 2.** *The (additive) complexity of a set of linear forms is the minimal complexity of a linear algorithm that computes the set and algorithms of that minimal complexity are called optimal.*

It is known from [13] that if a set of linear forms over an infinite field can be computed in C additions by a *straight-line* algorithm (see [1, Section 12.2]), then it also can be computed in C additions by a linear algorithm. In other words, multiplications and divisions “cannot replace additions”.

With a linear algorithm \mathcal{A} we associate a labelled directed acyclic graph $G_{\mathcal{A}}(V_{\mathcal{A}}, E_{\mathcal{A}})$, whose set of vertices is the union of $\{x_1, \dots, x_n\}$ and the set of the variables of \mathcal{A} and there is an edge from vertex v to vertex u , if there is an operation of the form $u \leftarrow \alpha v + \beta w$ or the form $u \leftarrow \alpha w + \beta v$. In the former case, the edge is labelled α and, in the latter case, it is labelled β . We denote the label of edge e by $\lambda(e)$.

By definition, $|V_{\mathcal{A}}| = n + |\mathcal{A}|$ and the number of vertices of $G_{\mathcal{A}}$ of the in-degree 2 is $|\mathcal{A}|$.

Let $\pi = e_1, \dots, e_k$ be a path of edges in $G_{\mathcal{A}}$. The *weight* $w(\pi)$ of π is defined, recursively, as follows.

- If π is of length zero, then $w(\pi) = 1$;
- $w(\pi, e) = w(\pi)\lambda(e)$, where π, e is the path π extended with edge e .

The following correspondence between linear algorithms and their associated graphs is well-known from the literature.

► **Lemma 3** (See, e.g., [4, Remark 13.19]). *Let*

$$\mathcal{A} = \{u_i \leftarrow \alpha_i u_{j_i} + \beta_i u_{k_i} : i = 1, \dots, C\}$$

be a linear algorithm and let $\Pi_{\mathcal{A}}(x_t, u_i)$ denote the set of all paths of edges from the indeterminate x_t to the algorithm variable u_i in $G_{\mathcal{A}}$. Then

$$\ell(u_i) = \sum_{t=1}^n \left(\sum_{\pi \in \Pi_{\mathcal{A}}(x_t, u_i)} w(\pi) \right) x_t, \quad i = 1, \dots, C. \quad (4)$$

3 Normalized linear algorithms

In this section we introduce a subclass of linear algorithms called *normalized* linear algorithms. These algorithms have the same computation power, but are more convenient for dealing with complexity issues.

► **Definition 4.** *A linear algorithm is normalized if in each its operation*

$$u_i \leftarrow \alpha_i u_{j_i} + \beta_i u_{k_i}$$

the coefficient α_i of u_{j_i} is 1. The coefficient β_i of u_{k_i} is called a proper coefficient.

We say that a label is *proper* if it is a proper coefficient of the algorithm.

The result below immediately follows from Definition 4 and the definition of the associated graph $G_{\mathcal{A}}$ of an algorithm \mathcal{A} .

► **Proposition 5.** *The additive complexity of a normalized linear algorithm \mathcal{A} equals to the number of proper labels of its associated graph $G_{\mathcal{A}}$.*

Furthermore, we also have the following results.

► **Proposition 6.** *For each linear algorithm there is a normalized linear algorithm of the same complexity that computes the same set of linear forms.*

Proof. Let

$$\mathcal{A} = \{u_i \leftarrow \alpha_i u_{j_i} + \beta_i u_{k_i} : i = 1, \dots, C\}$$

be a linear algorithm. It suffices to show that there exists a normalized linear algorithm

$$\tilde{\mathcal{A}} = \{\tilde{u}_i \leftarrow \tilde{u}_{j_i} + \tilde{\beta}_i \tilde{u}_{k_i} : i = 1, \dots, C\}$$

and constants $\gamma_i \in \mathbb{F}$, $i = 1, \dots, C$, such that $\ell(u_i) = \gamma_i \ell(\tilde{u}_i)$, $i = 1, \dots, C$.

We convert \mathcal{A} to $\tilde{\mathcal{A}}$ and define the constants γ_i by recursion on $i = 1, \dots, C$.

The first addition of \mathcal{A} is $u_1 \leftarrow \alpha_1 x_s + \beta_1 x_t$, implying $\ell(u_1) = \alpha_1 x_s + \beta_1 x_t$. We put

$$\tilde{\beta}_1 = \frac{\beta_1}{\alpha_1} \quad \text{and} \quad \gamma_1 = \alpha_1.$$

Then

$$\ell(u_1) = \alpha_1 x_s + \beta_1 x_t = \alpha_1 \left(x_s + \frac{\beta_1}{\alpha_1} x_t \right) = \gamma_1 (x_s + \tilde{\beta}_1 x_t) = \gamma_1 \ell(\tilde{u}_1).$$

The $(i+1)$ -st addition of \mathcal{A} is $u_{i+1} \leftarrow \alpha_{i+1} u_{j_{i+1}} + \beta_{i+1} u_{k_{i+1}}$, implying

$$\ell(u_{i+1}) = \alpha_{i+1} \ell(u_{j_{i+1}}) + \beta_{i+1} \ell(u_{k_{i+1}}).$$

We put

$$\tilde{\beta}_{i+1} = \frac{\beta_{i+1} \gamma_{k_{i+1}}}{\alpha_{i+1} \gamma_{j_{i+1}}} \quad \text{and} \quad \gamma_{i+1} = \alpha_{i+1} \gamma_{j_{i+1}}.$$

Then

$$\begin{aligned} \ell(u_{i+1}) &= \alpha_{i+1} \ell(u_{j_{i+1}}) + \beta_{i+1} \ell(u_{k_{i+1}}) \\ &= \alpha_{i+1} \gamma_{j_{i+1}} \ell(\tilde{u}_{j_{i+1}}) + \beta_{i+1} \gamma_{k_{i+1}} \ell(\tilde{u}_{k_{i+1}}) \\ &= \alpha_{i+1} \gamma_{j_{i+1}} \ell\left(\tilde{u}_{j_{i+1}} + \frac{\beta_{i+1} \gamma_{k_{i+1}}}{\alpha_{i+1} \gamma_{j_{i+1}}} \tilde{u}_{k_{i+1}}\right) \\ &= \gamma_{i+1} \ell(\tilde{u}_{j_{i+1}} + \tilde{\beta}_{i+1} \tilde{u}_{k_{i+1}}) \\ &= \gamma_{i+1} \ell(\tilde{u}_{i+1}), \end{aligned}$$

which concludes the proof. ◀

From now on, we assume that all linear algorithms under consideration are over \mathbb{R} and by Proposition 6, we assume that they are normalized.

We represent a linear form $\ell(x_1, \dots, x_n) = \sum_{t=1}^n \delta_t x_t$ by the product $(\delta_1, \dots, \delta_n)\mathbf{x}$, where \mathbf{x} is the (column) vector of the indeterminates x_1, \dots, x_n as in (2). Similarly, we represent a set of linear forms

$$\ell_s(x_1, \dots, x_n) = \sum_{t=1}^n \delta_{s,t} x_t, \quad s = 1, \dots, m,$$

by a matrix-vector product $\Delta\mathbf{x}$, where the s th row of the matrix Δ is the row vector $(\delta_{s,1}, \dots, \delta_{s,n})$ of the coefficients of $\ell_s(x_1, \dots, x_n)$, see (3).

4 Computation of linear forms over \mathbb{R} and \mathbb{Q}

In this section we prove the existence of a matrix $\Delta \in \mathbb{Q}^{m \times n}$ such that computing the set of linear forms $\Delta\mathbf{x}$ requires $m(n-1)$ additions. As a preliminary step, we consider matrices with entries from \mathbb{R} .

► **Theorem 7** (Cf. [4, Theorem 13.10]). *If all the coefficients of the linear forms (3) are algebraically independent, then the additive complexity of (3) is $m(n-1)$.*³

Proof. Let \mathcal{A} be a linear algorithm that computes (3) and let $G_{\mathcal{A}} = (V_{\mathcal{A}}, E_{\mathcal{A}})$ be its associated labelled graph.

Let u_{i_s} and γ_s , $s = 1, \dots, m$, be the algorithm variables and the respective constants such that

$$\ell_s(x_1, \dots, x_n) = \sum_{t=1}^n \delta_{s,t} x_t = \gamma_s \ell(u_{i_s}).$$

Then, by Lemma 3,

$$\delta_{s,t} = \gamma_s \sum_{\pi \in \Pi_{\mathcal{A}}(x_t, u_{i_s})} w(\pi) = P_{s,t}(\gamma_s, \beta_1, \dots, \beta_{|\mathcal{A}|})$$

for some polynomials $P_{s,t}(Y_s, X_1, \dots, X_{|\mathcal{A}|})$, $s = 1, \dots, m$ and $t = 1, \dots, n$.

If the number $|\mathcal{A}|$ of the proper labels is less than $m(n-1)$, then the total number of β and γ variables is less than mn , implying that these mn polynomials are algebraically dependent, see Proposition 5.

Let $P(Z_{1,1}, \dots, Z_{m,n})$ be a polynomial over \mathbb{Q} such that

$$P(P_{1,1}(Y_1, X_1, \dots, X_{|\mathcal{A}|}), \dots, P_{m,n}(Y_m, X_1, \dots, X_{|\mathcal{A}|})) = 0. \quad (5)$$

Then

$$P(P_{1,1}(\gamma_1, \beta_1, \dots, \beta_{|\mathcal{A}|}), \dots, P_{m,n}(\gamma_m, \beta_1, \dots, \beta_{|\mathcal{A}|})) = 0,$$

implying

$$P(\delta_{1,1}, \dots, \delta_{m,n}) = 0. \quad (6)$$

That is, the matrix entries $\delta_{s,t}$ are algebraically dependent, in contradiction with the condition of the theorem. ◀

³ In [4] this result is attributed to [16], but the proof in [16] is very implicit.

66:6 Sets of Linear Forms Which Are Hard to Compute

Recall that we aim to find an $m \times n$ matrix over \mathbb{Q} that defines the set of linear forms of complexity $m(n-1)$. The existence of such a matrix is shown below (see Theorem 15), but to describe its entries is not straightforward at all and we do this in Section 8.

To proceed with our proof of existence we first need to introduce a number of definitions and auxiliary results.

► **Definition 8.** We say that $P(Z_1, \dots, Z_N) \in \mathbb{Z}[Z_1, \dots, Z_N]$ is an annihilating polynomial of $P_k(X_1, \dots, X_{N-1}) \in \mathbb{Z}[X_1, \dots, X_{N-1}]$, $k = 1, \dots, N$, if P is a non-zero polynomial and

$$P(P_1(X_1, \dots, X_{N-1}), \dots, P_N(X_1, \dots, X_{N-1})) = 0.$$

► **Definition 9.** We say that the polynomial $P_{s,t}(Y_s, X_1, \dots, X_{|\mathcal{A}|})$, $s = 1, \dots, m$ and $t = 1, \dots, n$, defined in the proof of Theorem 7 is associated with the (s, t) -th entry of Δ via \mathcal{A} .

► **Definition 10.** We say that a polynomial P is (m, n) -associated if for some $m \times n$ matrix Δ , some $s = 1, \dots, m$, some $t = 1, \dots, n$ and some algorithm \mathcal{A} with $|\mathcal{A}| < m(n-1)$ that computes (3), P is associated with the (s, t) -th entry of Δ via \mathcal{A} .

► **Proposition 11.** The set of (m, n) -associated polynomials is finite.

Proof. By (4), the coefficients of $P_{s,t}(Y_s, X_1, \dots, X_{|\mathcal{A}|})$ are zero or one and, by definition, $|\mathcal{A}| < m(n-1)$. Therefore

$$\deg P_{s,t}(Y_s, X_1, \dots, X_{|\mathcal{A}|}) < m(n-1),$$

where $s = 1, \dots, m$ and $t = 1, \dots, n$, and the result follows. ◀

► **Definition 12.** The polynomial $P(Z_{1,1}, \dots, Z_{m,n}) \in \mathbb{Q}[Z_{1,1}, \dots, Z_{m,n}]$ satisfying (5), that is, an annihilating polynomial of

$$P_{1,1}(Y_1, X_1, \dots, X_{|\mathcal{A}|}), \dots, P_{m,n}(Y_m, X_1, \dots, X_{|\mathcal{A}|}),$$

is called an \mathcal{A} - Δ -annihilating polynomial.

► **Definition 13.** We say that a set of polynomials \mathfrak{Q} is (m, n) -complete if for each $m \times n$ matrix Δ and each algorithm \mathcal{A} with $|\mathcal{A}| < m(n-1)$ that computes (3), \mathfrak{Q} contains an \mathcal{A} - Δ -annihilating polynomial.

For our specific example we shall look for a common non-zero of all polynomials in an (m, n) -complete set. This resembles the approach in [14], see also [4, Section 9.4].

► **Proposition 14.** Let \mathfrak{Q} be a minimal with respect to inclusion (m, n) -complete set of polynomials. Then \mathfrak{Q} is finite.

Proof. This is because number of polynomials in \mathfrak{Q} does not exceed the number of all k -tuples, $k < m(n-1)$ of (m, n) -associated polynomials and by Proposition 11 the number of such tuples is finite. ◀

In what follows, for a matrix A we denote by $|A|$ its *Frobenius norm*, that is, the square root of the sum of squares of its entries. Similarly, for a vector α we use $|\alpha|$ to denote its *Euclidean norm*.

► **Theorem 15.** There exists an $m \times n$ matrix over \mathbb{Q} that defines the set of linear forms of complexity $m(n-1)$.

Proof. Let $\Delta_1, \Delta_2, \dots$, be a sequence of $m \times n$ matrices over \mathbb{Q} that converges (in the Frobenius norm) to the matrix $\Delta = (\delta_{s,t})$ from the proof of Theorem 7. That is, $\lim_{i \rightarrow \infty} |\Delta_i - \Delta| = 0$.

Let $\Delta_i = (\delta_{s,t,i})$, $i = 1, 2, \dots$. Then

$$\lim_{i \rightarrow \infty} \delta_{s,t,i} = \delta_{s,t} \quad s = 1, \dots, m \text{ and } t = 1, \dots, n. \quad (7)$$

Assume to the contrary that for each $i = 1, 2, \dots$, there is an algorithm \mathcal{A}_i , $|\mathcal{A}_i| < m(n-1)$, that computes $\Delta_i \mathbf{x}$. Let Ω be a finite (m, n) -complete set provided by Proposition 14. Then, like in the proof of Theorem 7, it can be shown that for each $i = 1, 2, \dots$, there is an \mathcal{A}_i - Δ_i -annihilating polynomial $P_i(Z_{1,1}, \dots, Z_{m,n}) \in \Omega$ such that $P_i(\delta_{1,1,i}, \dots, \delta_{m,n,i}) = 0$.

Thus, there is a subsequence $\tilde{\Delta}_1, \tilde{\Delta}_2, \dots$ of $\Delta_1, \Delta_2, \dots$ with the same annihilating polynomial $P(Z_{1,1}, \dots, Z_{m,n})$, implying $P(\tilde{\delta}_{1,1,i}, \dots, \tilde{\delta}_{m,n,i}) = 0$, $i = 1, 2, \dots$, which, by (7), implies (6). However, the latter contradicts the algebraic independence of the entries of Δ . \blacktriangleleft

5 An alternative proof of Theorem 15 and an outline of an example

Here we present an alternative and more constructive approach of the existence of a set of m linear forms in n variables over \mathbb{Q} of complexity $m(n-1)$ and outline our example. To simplify the calculations, we look for a matrix Γ defining such a set in the ball of radius 1 centered at Δ . We show in Section 7 that this condition is redundant.

Theorem 16 below is in the background of our example of linear forms which are hard to compute.

► **Theorem 16.** *Let Ω be an (m, n) -complete set of polynomials. Let $\Gamma = (\gamma_{s,t})$ and $\Delta = (\delta_{s,t})$ be $m \times n$ matrices, where $\delta_{s,t}$, $s = 1, \dots, m$ and $t = 1, \dots, n$, are algebraically independent and $|\Delta - \Gamma| < 1$. Let $\gamma = (\gamma_{1,1}, \dots, \gamma_{m,n})$ and let $\delta = (\delta_{1,1}, \dots, \delta_{m,n})$. If*

$$|\delta - \gamma| < \min_{Q \in \Omega} \min_{|\mu| < 1} \left\{ \frac{|Q(\delta)|}{|\nabla Q(\delta + \mu)|} \right\}, \quad (8)$$

then computing $\Gamma \mathbf{x}$ requires $m(n-1)$ additions.

The proof of Theorem 16 is based on the following lemma.

► **Lemma 17** (The mean value theorem for several variables, see, e.g., [2, Chapter 12, Example 1]). *Let $F : \mathbb{R}^N \rightarrow \mathbb{R}$ be a differentiable function and $\alpha_1, \alpha_2 \in \mathbb{R}^N$. Then, for some $\vartheta \in [0, 1]$,*

$$F(\alpha_2) - F(\alpha_1) = \nabla F(\alpha_1 + \vartheta(\alpha_2 - \alpha_1)) \cdot (\alpha_2 - \alpha_1),$$

where ∇F denotes the gradient of F .

Proof of Theorem 16. Assume to the contrary that the set of linear forms $\Gamma \mathbf{x}$ can be computed in less than $m(n-1)$ additions by an algorithm \mathcal{A} . Then, since Ω is (m, n) -complete, there is an \mathcal{A} - Γ -annihilating polynomial $Q \in \Omega$ such that $Q(\gamma) = 0$.

By Lemma 17, for some $\vartheta \in [0, 1]$

$$Q(\delta) - Q(\gamma) = \nabla Q(\gamma + \vartheta(\delta - \gamma)) \cdot (\delta - \gamma). \quad (9)$$

Since

$$\gamma + \vartheta(\delta - \gamma) = \vartheta\delta + (1 - \vartheta)\gamma = \vartheta\delta + (1 - \vartheta)(\delta + \gamma - \delta) = \delta + (1 - \vartheta)(\gamma - \delta)$$

66:8 Sets of Linear Forms Which Are Hard to Compute

and $|(1 - \vartheta)(\gamma - \delta)| < 1$, by (9), for $\mu = (1 - \vartheta)(\gamma - \delta)$, we have

$$Q(\delta) = \nabla Q(\delta + \mu) \cdot (\delta - \gamma) \quad (10)$$

because $Q(\gamma) = 0$. It follows from (10), by the Cauchy–Schwarz inequality, that

$$|Q(\delta)| \leq |\nabla Q(\delta + \mu)| |\delta - \gamma|,$$

which contradicts (8). ◀

Note that, since the components of δ are algebraically independent, $Q(\delta) \neq 0$. Thus, for a finite (m, n) -complete set of polynomials Ω , the right-hand side of (8) is positive.

Using the trivial inequality

$$|\delta - \gamma| \leq \sqrt{mn} \max\{|\delta_{s,t} - \gamma_{s,t}| : s = 1, \dots, m, t = 1, \dots, n\}$$

we see that Theorem 16 yields the corollary below.

► **Corollary 18.** *Let Ω be an (m, n) -complete set of polynomials. Let $\Gamma = (\gamma_{s,t})$ and $\Delta = (\delta_{s,t})$ be $m \times n$ matrices, where $\delta_{s,t}$, $s = 1, \dots, m$ and $t = 1, \dots, n$, are algebraically independent and $|\Delta - \Gamma| < 1$. Let $\gamma = (\gamma_{1,1}, \dots, \gamma_{m,n})$ and $\delta = (\delta_{1,1}, \dots, \delta_{m,n})$. If*

$$\max\{|\delta_{s,t} - \gamma_{s,t}| : s = 1, \dots, m \text{ and } t = 1, \dots, n\} < \frac{1}{\sqrt{mn}} \min_{Q \in \Omega} \min_{|\mu| < 1} \left\{ \frac{|Q(\delta)|}{|\nabla Q(\delta + \mu)|} \right\},$$

then computing $\Gamma \mathbf{x}$ requires $m(n - 1)$ additions.

Following the above existence proof, for an example of a rational $m \times n$ matrix defining a set of linear forms of complexity $m(n - 1)$ we need a set of algebraically independent numbers $\delta_{s,t}$, $s = 1, \dots, m$ and $t = 1, \dots, n$, for which the right-hand side of (8) can be effectively estimated. Such a set is provided by an effective version of the Lindemann-Weierstrass theorem due to Sert [11], see Lemma 26 in Section 7.

6 The degree and the height of annihilating polynomials

In this section we estimate the denominator of the right-hand side of (8). For this we need to estimate the degree and the height of (m, n) -polynomials which are defined as follows.

► **Definition 19.** *A polynomial P is called an (m, n) -polynomial if for some $m \times n$ matrix Δ and some algorithm \mathcal{A} , $|\mathcal{A}| < m(n - 1)$, that computes (3), P is \mathcal{A} - Δ -annihilating.*

Recall that these polynomials arise from linear algorithms of the complexity less than $m(n - 1)$ and satisfy (5).

We start with the following result, that is essentially due to Perron.

► **Lemma 20** ([8], see also [9, Theorem 1.1] for a self-contained proof.). *Let*

$$P_k(X_1, \dots, X_{N-1}) \in \mathbb{Z}[X_1, \dots, X_{N-1}]$$

with $\deg P_k(X_1, \dots, X_{N-1}) = d_k$, $k = 1, \dots, N$. Then there exists an annihilating polynomial $P(Z_1, \dots, Z_N) \in \mathbb{Z}[Z_1, \dots, Z_N]$ of P_1, \dots, P_N such that

$$\deg P \leq \frac{d_1 \times \dots \times d_N}{\min\{d_1, \dots, d_N\}}.$$

Actually, in [8], the polynomial $P(Z_1, \dots, Z_N)$ has rational coefficients, but, multiplying them by their common denominator, we obtain a polynomial over \mathbb{Z} .

In the case of (m, n) -polynomials, $N = mn$ and $d_s \leq m(n-1)$, $i = 1, \dots, N$. Therefore, by Lemma 20, we may assume that the degree of (m, n) -polynomials under consideration does not exceed N^{N-1} .

Next, we are going to estimate the minimum height $h(P)$ of the polynomial $P(Z_1, \dots, Z_N)$ provided by Lemma 20. This can be done by solving a system of linear homogeneous equations, see [14, Lemma 2.2], [4, Lemma 9.28] or [9, Property 1.2].

We need some auxiliary results first. We start with recalling the following well-known upper bound on the height of a polynomial product.

► **Lemma 21** (See, e.g., [5, Lemma 1.2(1)(b)], where the logarithmic height $\ln h(P)$ is used.). Let $P_k \in \mathbb{Z}[X_1, \dots, X_{N-1}]$, $k = 1, \dots, \ell$. Then

$$h\left(\prod_{k=1}^{\ell} P_k\right) \leq N^{\sum_{k=1}^{\ell} \deg P_k} \prod_{k=1}^{\ell} h(P_k).$$

We also recall the classical *Siegel lemma*.

► **Lemma 22** ([12, Page 213, Hilfssatz], see also [3, 15] for further improvements and generalizations.). If a system of J linear homogeneous equations in $I > J$ variables

$$\sum_{i=1}^I b_{i,j} z_i = 0, \quad j = 1, \dots, J,$$

with $B = (b_{i,j})_{i,j=1}^{I,J} \in \mathbb{Z}^{I \times J}$, has a nonzero solution, then it has a nonzero integer solution $\mathbf{v} = (v_1, \dots, v_I)$ with

$$h(\mathbf{v}) \leq 1 + (Ih(B))^{J/(I-J)},$$

where

$$h(B) = \max\{|b_{i,j}| : i = 1, \dots, I, j = 1, \dots, J\}$$

and

$$h(\mathbf{v}) = \max\{|v_i| : i = 1, \dots, I\}. \quad (11)$$

We are now ready to estimate the height of an annihilating polynomial. More precisely we establish the following result.

► **Proposition 23.** Let $P(Z_1, \dots, Z_N) \in \mathbb{Z}[Z_1, \dots, Z_N]$ be an annihilating polynomial of

$$P_k(X_1, \dots, X_{N-1}) \in \mathbb{Z}[X_1, \dots, X_{N-1}], \quad k = 1, \dots, N.$$

There exists another annihilating polynomial $Q(Z_1, \dots, Z_N) \in \mathbb{Z}[Z_1, \dots, Z_N]$ of P_1, \dots, P_N of degree and height

$$\deg Q \leq \deg P,$$

$$h(Q) \leq 1 + \left(\binom{\deg P + N}{N} N^{d_{\max} \deg P} h_{\max}^{\deg P} \right)^{\binom{\deg P + N}{N} - 1},$$

respectively, where

$$d_{\max} = \max\{\deg P_k : k = 1, \dots, N\},$$

$$h_{\max} = \max\{h(P_k) : k = 1, \dots, N\}.$$

66:10 Sets of Linear Forms Which Are Hard to Compute

Proof. We employ the following notation:

- $\mathbf{X} = (X_1, \dots, X_{N-1})$ and $\mathbf{Z} = (Z_1, \dots, Z_N)$ are vectors of variables;
- $\mathbf{i} = (i_1, \dots, i_N)$ and $\mathbf{j} = (j_1, \dots, j_{N-1})$ are vectors of non-negative integers;
- $\mathbf{X}^{\mathbf{j}} = \prod_{s=1}^{N-1} X_s^{j_s}$ and $\mathbf{Z}^{\mathbf{i}} = \prod_{k=1}^N Z_k^{i_k}$ are multivariate monomials.

We search for a polynomial Q in the form

$$Q(Z_1, \dots, Z_N) = \sum_{\mathbf{i}: i_1 + \dots + i_N \leq \deg P} v_{\mathbf{i}} \mathbf{Z}^{\mathbf{i}}, \quad (12)$$

with unknown coefficients $v_{\mathbf{i}}$ to be determined.

To find the coefficients $v_{\mathbf{i}}$ of $Q(Z_1, \dots, Z_N)$, we substitute the polynomials $P_k(X_1, \dots, X_{N-1})$ for Z_k , $k = 1, \dots, N$, in (12), obtaining

$$\begin{aligned} Q(P_1(X_1, \dots, X_{N-1}), \dots, P_N(X_1, \dots, X_{N-1})) \\ = \sum_{\mathbf{i}: i_1 + \dots + i_N \leq \deg P} v_{\mathbf{i}} \prod_{k=1}^N P_k^{i_k}(X_1, \dots, X_{N-1}) = 0. \end{aligned} \quad (13)$$

Let

$$\prod_{k=1}^N P_k^{i_k}(X_1, \dots, X_{N-1}) = \sum_{\mathbf{j}: j_1 + \dots + j_{N-1} \leq d_{\max} \deg P} \mathbf{c}_{\mathbf{i}, \mathbf{j}} \mathbf{X}^{\mathbf{j}}.$$

Then, it follows from (13) that

$$\begin{aligned} \sum_{\mathbf{i}: i_1 + \dots + i_N \leq \deg P} v_{\mathbf{i}} \sum_{\mathbf{j}: j_1 + \dots + j_{N-1} \leq d_{\max} \deg P} \mathbf{c}_{\mathbf{i}, \mathbf{j}} \mathbf{X}^{\mathbf{j}} \\ = \sum_{\mathbf{j}: j_1 + \dots + j_{N-1} \leq d_{\max} \deg P} \mathbf{X}^{\mathbf{j}} \left(\sum_{\mathbf{i}: i_1 + \dots + i_N \leq \deg P} \mathbf{c}_{\mathbf{i}, \mathbf{j}} v_{\mathbf{i}} \right) = 0. \end{aligned}$$

That is, we have a system of linear homogeneous equations

$$\sum_{\mathbf{i}: i_1 + \dots + i_N \leq \deg P} \mathbf{c}_{\mathbf{i}, \mathbf{j}} v_{\mathbf{i}} = 0, \quad \mathbf{j}: j_1 + \dots + j_{N-1} \leq d_{\max} \deg P \quad (14)$$

in

$$I = \binom{\deg P + N}{N} \quad (15)$$

unknowns $v_{\mathbf{i}}$ (the coefficients of $P(Z_1, \dots, Z_N)$).

We also note that for the coefficients $\mathbf{c}_{\mathbf{i}, \mathbf{j}}$ of the system of linear equations (14) we have

$$\max_{\mathbf{i}, \mathbf{j}} |\mathbf{c}_{\mathbf{i}, \mathbf{j}}| \leq \max_{i_1 + \dots + i_N \leq \deg P} h \left(\prod_{k=1}^N P_k^{i_k} \right),$$

where \mathbf{i} and \mathbf{j} run through the vectors with $i_1 + \dots + i_N \leq \deg P$ and $j_1 + \dots + j_{N-1} \leq d_{\max} \deg P$, respectively

Hence, by Lemma 21 with $\ell = \deg P$,

$$\max_{\mathbf{i}, \mathbf{j}} |\mathbf{c}_{\mathbf{i}, \mathbf{j}}| \leq N^{d_{\max} \deg P} h_{\max}^{\deg P}. \quad (16)$$

Since, by our assumption on the polynomial Q , this system has a non-zero solution, we can select at most $J \leq I - 1$ linear equations forming a system of linear homogeneous equations, which is equivalent to (14). Hence combining the bound (16) with Lemma 22, we derive that (14) has a solution with

$$\max\{v_i : \mathbf{i} = (i_1, \dots, i_N) \text{ with } i_1 + \dots + i_N \leq \deg P\} \leq 1 + (IN^{d_{\max} \deg P} h_{\max}^{\deg P})^{I-1},$$

where I is given by (15), which concludes the proof. \blacktriangleleft

In what follows we renumber the (m, n) -associated polynomials $P_{s,t}$, $s = 1, \dots, m$ and $t = 1, \dots, n$, in (5) as P_1, \dots, P_N , that is, we write

$$\{P_1, \dots, P_N\} = \{P_{s,t} : s = 1, \dots, m, t = 1, \dots, n\}. \quad (17)$$

We remark that by Lemma 20, we can assume $\deg P \leq d_{\max}^{N-1}$ in the notation of Proposition 23. Furthermore, as we have noticed in the proof of Proposition 11, in the special case of (m, n) -associated polynomials we have

$$d_{\max} = N \quad \text{and} \quad h_{\max} = 1. \quad (18)$$

Thus, by Lemma 20, we can assume

$$\deg P \leq N^{N-1}. \quad (19)$$

► **Corollary 24.** *For any $N = mn \geq 4$ and polynomials (17), there exists an (m, n) -polynomial $Q(Z_1, \dots, Z_N)$ of degree and height satisfying*

$$\deg Q \leq N^{N-1} \quad \text{and} \quad h(Q) \leq N^{2N^{N^2}}, \quad (20)$$

respectively.

Proof. The bound on the degree follows directly from (19). Using the well known estimate

$$\binom{q}{r} \leq \frac{q^r}{r!} \leq (eq/r)^r,$$

which holds for arbitrary integers $q \geq r \geq 1$, we derive

$$\binom{N^{N-1} + N}{N} \leq (e(N^{N-2} + 1))^N = e^N N^{N(N-2)} (1 + 1/N^{N-2})^N \leq e^{N+1} N^{N^2-2N}.$$

Since for $N \geq 4$ we have $e^{N+1} < N^N$, we now obtain

$$\binom{N^{N-1} + N}{N} < N^{N^2-N}.$$

Substituting (18) and (19) in Proposition 23 and using the above estimate, we see that

$$h(Q) \leq 1 + \left(N^{N^N + N^2 - N}\right)^{N^{N^2-N}} = 1 + N^{(N^N + N^2 - N)N^{N^2-N}}.$$

We now use the crude estimate $N^N + N^2 - N < 2N^N$ and obtain

$$h(Q) < 1 + N^{2N^{N^2}}.$$

Since $h(Q)$ is an integer, this concludes the proof. \blacktriangleleft

66:12 Sets of Linear Forms Which Are Hard to Compute

Let $\mathfrak{Q}_{m,n}$ denote the class of annihilating (m,n) -polynomials Q with the degree and height satisfying 20, where $N = mn$. By Corollary 24, we see that for $N = mn \geq 4$, $\mathfrak{Q}_{m,n} \neq \emptyset$. Clearly, $\mathfrak{Q}_{m,n}$ is (m,n) -complete and, therefore, Corollary 18 can be applied with $\mathfrak{Q} = \mathfrak{Q}_{m,n}$.

We remark that the case of $N = mn \leq 3$ is trivial, as then $m = 1$ or $n = 1$. Hence the condition $N \geq 4$, which stems from Corollary 24, is not restrictive.

We also recall the definition of the naive height in (11).

► **Corollary 25.** *For any $N = mn \geq 4$ and $\delta \in \mathbb{R}^N$, we have*

$$\max_{Q \in \mathfrak{Q}_{m,n}} \max_{|\mu| < 1} |\nabla Q(\delta + \mu)| < N^{3N^{N^2}} (h(\delta) + 1)^{N^{N-1}}.$$

Proof. First we estimate

$$\frac{\partial Q}{\partial Z_k}(\delta + \mu), \quad k = 1, \dots, N.$$

The polynomial $\partial Q / \partial Z_k$ is of degree

$$\deg \partial Q / \partial Z_k < \deg Q \leq N^{N-1}$$

and thus, by Corollary 24, of height

$$h(\partial Q / \partial Z_k) \leq N^{N-1} h(Q) \leq N^{2N^{N^2} + N - 1}.$$

The number of monomials in N variables of degree less than N^{N-1} is less than $N^{N^2 - N}$. Thus, for $|\mu| \leq 1$ we have

$$\begin{aligned} \left| \frac{\partial Q}{\partial Z_k}(\delta + \mu) \right| &\leq N^{N^2 - N} h(\partial Q / \partial Z_k) (h(\delta) + 1)^{N^{N-1}} \\ &\leq N^{2N^{N^2} + N^2 - 1} (h(\delta) + 1)^{N^{N-1}} < N^{3N^{N^2}} (h(\delta) + 1)^{N^{N-1}}, \end{aligned}$$

and the result follows. ◀

7 Effective Lindemann–Weierstrass theorem

In this section we estimate the numerator of the right-hand side of (8). This, together with the estimation of the denominator of the right-hand side of (8) in the previous section, would make Theorem 16 constructive. The estimation of the numerator is based on an effective version of the Lindemann–Weierstrass theorem due to Sert [11] stated below. We precede the statement of the theorem with the necessary definitions and notations.

- K is a number field of degree D .
- M_K is the set of normalized absolute values of K , that is, the extensions onto K all the values on \mathbb{Q} (Archimedean and p -adic).
- The *absolute height* $h_a(\alpha)$ of an s -tuple $\alpha = (\alpha_1, \dots, \alpha_s) \in K^s$ is defined by

$$h_a(\alpha) = \prod_{\nu \in M_K} \max_{1 \leq k \leq s} \{1, |\alpha_k|_\nu\}^{D_\nu / D},$$

where D_ν is the local degree of K_ν , that is, the dimension of the ν -completion of K over \mathbb{R} , if ν is Archimedean, or the ν -completion of K over \mathbb{Q}_p , if ν is p -adic.

- Let $\{\beta_1, \dots, \beta_L\}$ be the set of all coefficients of a polynomial $P(x_1, \dots, x_N)$ over K . We denote by Δ_P the discriminant of $\mathbb{Q}(\beta_1, \dots, \beta_L)$.

- The *absolute height* of a multi-variate polynomial P is the absolute height of the tuple of the polynomial coefficients.

Our main technical tool is the following result of Sert.

► **Lemma 26** ([11, Theorem 3]). *Let $P \in K[Z_1, \dots, Z_N]$ be of degree $d \geq 1$ and of absolute height H and let $\alpha = (\alpha_1, \dots, \alpha_N) \in K^N$ be linearly independent over \mathbb{Q} . Then*

$$\begin{aligned} & \ln |P(e^{\alpha_1}, \dots, e^{\alpha_N})| \\ & \geq -c_0 d^N \left(\ln H + \frac{39}{328D} \ln |\Delta_P| + \exp(c_1 d^N + c_2 d^N \ln d + 72 \max\{1, h_a(\alpha)\}) \right), \end{aligned}$$

where

$$\begin{aligned} c_0 &= 41 \times 3^{2N} 2^{-N+1} D^{N+1} N^N, \\ c_1 &= 2^{2-N} 3^{2N+1} D^{N+1} N^N + (1 + 6D) 2^{4-N} 3^{2N} D^N N^N \ln(9DN) \\ & \quad + 2^{4-N} 3^{2N} D^{N+1} N^N (1 + 6N) \ln h_a(\alpha), \\ c_2 &= (1 + 6D) 2^{4-N} 3^{2N} D^N N^N. \end{aligned}$$

► **Remark 27.** As noticed by Sert [11, Page 100], if the coefficients of $P(Z_1, \dots, Z_N)$ are rational integers, then, in Lemma 26, we replace H with the ordinary height $h(P)$ of P and replace $\ln |\Delta_P|$ with zero.

The result below follows from Lemma 26 and Remark 27 by a straightforward substitution.

► **Corollary 28.** *Let $Q(Z_1, \dots, Z_N) \in \mathfrak{Q}_{m,n}$ and let $\alpha_1, \dots, \alpha_N$ be algebraic numbers linearly independent over \mathbb{Q} . Then, for $N \geq 4$,*

$$|Q(e^{\alpha_1}, \dots, e^{\alpha_N})| > \exp\left(-N^{2^{5N}} D^{N+1} N^{N^2+2(D+\max\{1, h_a(\alpha)\})}\right)$$

where D is the degree of the number field $\mathbb{Q}(\alpha_1, \dots, \alpha_N)$.

The proof of this corollary is presented in Appendix A.1.

Now, the substitution of the bound of Corollaries 28 and 25 for the numerator and the denominator of the right-hand side of (8), respectively, makes Theorem 16 constructive.

Finally, for the uniform example of a set of m linear forms in n variables over \mathbb{Q} of complexity $m(n-1)$ in the next section we need the estimation below.

► **Proposition 29.** *Let α be a positive integer such that $[\mathbb{Q}(\alpha^{1/N}) : \mathbb{Q}] = N$, where $N = mn \geq 4$ and $N > \alpha > 1$, and let $\gamma_{s,t}$, $s = 1, \dots, m$ and $t = 1, \dots, n$, be such that*

$$\left| e^{\alpha^{(s-1)n+t)/N}} - \gamma_{s,t} \right| < \exp\left(-N^{3N^2}\right). \quad (21)$$

Then, for $\Gamma = (\gamma_{s,t})$, computing $\Gamma \mathbf{x}$ requires $m(n-1)$ additions.

The proof of this proposition is presented in Appendix A.2.

8 An example

An example of an integer matrix $\Omega \in \mathbb{Z}^{m \times n}$ such that computing $\Omega \mathbf{x}$ requires $m(n-1)$ additions is based on Proposition 29 with $\alpha = 2$. We precede the example with a series of auxiliary calculations for which we need the propositions below.

Throughout we assume that $N \geq 4$.

We recall the definition of binomial coefficients for real arguments:

$$\binom{r}{i} = \frac{r(r-1) \cdots (r-i+1)}{i!}.$$

66:14 Sets of Linear Forms Which Are Hard to Compute

► **Proposition 30.** For $r \in (0, 1)$ and a non-negative integer j ,

$$\left| 2^r - \sum_{i=0}^j \binom{r}{i} \right| < \frac{1}{j+1}$$

Proof. For $x > 0$, the Taylor expansion (with the Lagrange remainder) of $(1+x)^r$ is

$$(1+x)^r = \sum_{i=0}^j \binom{r}{i} x^i + \binom{r}{j+1} \Theta^{j+1} \quad (22)$$

for some $\Theta \in (0, x)$. Substituting 1 for both x and Θ in (22), we obtain

$$\left| 2^r - \sum_{i=0}^j \binom{r}{i} \right| < \left| \binom{r}{j+1} \right| = \frac{|r(r-1)(r-2)\cdots(r-j)|}{(j+1)!} < \frac{j!}{(j+1)!} < \frac{1}{j+1},$$

and the result follows. ◀

By Proposition 30, we approximate $2^{((s-1)n+t)/N}$ by

$$r_{s,t} = \sum_{i=0}^j \binom{((s-1)n+t)/N}{i} \quad s = 1, \dots, m, \quad t = 1, \dots, n,$$

for an appropriate j , to be chosen later.

► **Proposition 31.** For $x \in (1, 2)$ and $k \geq 6$,

$$e^x - \sum_{i=0}^k \frac{x^i}{i!} < \frac{1}{k+1}.$$

Proof. For $x > 0$, the Taylor expansion (with the Lagrange remainder) of e^x is

$$e^x = \sum_{i=0}^k \frac{x^i}{i!} + \frac{\Theta^{k+1}}{(k+1)!}$$

for some $\Theta \in (0, x)$. Thus, using $k! \geq 2^{k+1}$ for $k \geq 6$, we obtain

$$e^x - \sum_{i=0}^k \frac{x^i}{i!} = \frac{\Theta^{k+1}}{(k+1)!} < \frac{2^{k+1}}{(k+1)!} < \frac{1}{k+1},$$

which concludes the proof. ◀

By Proposition 31, we approximate $e^{r_{s,t}}$ by

$$\gamma_{s,t} = \sum_{i=0}^k \frac{r_{s,t}^i}{i!}, \quad s = 1, \dots, m, \quad t = 1, \dots, n,$$

for an appropriate k , to be chosen later.

Our last auxiliary estimation is as follows.

► **Proposition 32.** Let $x \leq 2$ and $\varepsilon \in (-1, 1)$. Then

$$|e^x - e^{x+\varepsilon}| < 42\varepsilon.$$

Proof. By Lemma 17,

$$|e^x - e^{x+\varepsilon}| < \left| e^{x-|\varepsilon|} - e^{x+|\varepsilon|} \right| = 2\varepsilon e^{x+\Theta}$$

for some $\Theta \in (-\varepsilon, \varepsilon)$. Thus, $|e^x - e^{x+\varepsilon}| < 2e^3\varepsilon < 42\varepsilon$. \blacktriangleleft

To simplify the expressions in our example, recalling the bound of Proposition 29 it is now convenient to denote

$$E = \exp\left(N^{3N^2}\right). \quad (23)$$

We contend that for

$$j \geq 126E \quad \text{and} \quad k \geq 3E \quad (24)$$

we have the inequality

$$\left| e^{2^{((s-1)n+t)/N}} - \gamma_{s,t} \right| < \frac{2}{3E}. \quad (25)$$

Indeed, first we note that, by Propositions 31 and 32, we have

$$\begin{aligned} \left| e^{2^{((s-1)n+t)/N}} - \gamma_{s,t} \right| &= \left| e^{2^{((s-1)n+t)/N}} - \sum_{i=0}^k \frac{r_{s,t}^i}{i!} \right| \\ &\leq \left| e^{r_{s,t}} - \sum_{i=0}^k \frac{r_{s,t}^i}{i!} \right| + \left| e^{2^{((s-1)n+t)/N}} - e^{r_{s,t}} \right| \\ &< \frac{1}{k+1} + 42 \left| 2^{((s-1)n+t)/N} - r_{s,t} \right|. \end{aligned}$$

Now using Proposition 30 and recalling the choice of j and k in (24), we derive

$$42 \left| 2^{((s-1)n+t)/N} - r_{s,t} \right| \leq \frac{42}{j+1} \leq \frac{1}{3E} \quad \text{and} \quad \frac{1}{k+1} \leq \frac{1}{3E}$$

and (25) follows.

Thus, by (25) and Proposition 29, computing $\Gamma \mathbf{x}^T$, where

$$\Gamma = (\gamma_{s,t}) \in \mathbb{Q}^{m \times n}$$

requires $m(n-1)$ additions.

Of course, all of the above also holds for computations over \mathbb{C} and unbounded algorithm coefficients, whereas in [7] the algorithm coefficients are bounded by 1.

Even though,

$$\gamma_{s,t} \leq e^{2^{((s-1)n+t)/N}} + \frac{2}{3E} \leq e^2 + 1/6 < 8 \quad (26)$$

the numerator and the denominator of $\gamma_{s,t}$ are very large. The matrix

$$\tilde{\Gamma} = (\tilde{\gamma}_{s,t}) \in \mathbb{Q}^{m \times n} \quad (27)$$

with “smaller” entries such that computing $\tilde{\Gamma} \mathbf{x}^T$ requires $m(n-1)$ additions is defined by

$$\tilde{\gamma}_{s,t} = \frac{\lfloor 3\lfloor E+1 \rfloor \gamma_{s,t} \rfloor}{3\lfloor E+1 \rfloor}, \quad s = 1, \dots, m, \quad t = 1, \dots, n. \quad (28)$$

66:16 Sets of Linear Forms Which Are Hard to Compute

For the proof, by Proposition 29, it suffices to show that

$$\left| e^{2^{((s-1)n+t)/N}} - \tilde{\gamma}_{s,t} \right| < \frac{1}{E},$$

which is indeed so, because

$$\begin{aligned} \left| e^{2^{((s-1)n+t)/N}} - \tilde{\gamma}_{s,t} \right| &= \left| e^{2^{((s-1)n+t)/N}} - \frac{\lfloor 3\lfloor E+1 \rfloor \gamma_{s,t} \rfloor}{3\lfloor E+1 \rfloor} \right| \\ &= \left| e^{2^{((s-1)n+t)/N}} - \gamma_{s,t} - \frac{\{3\lfloor E+1 \rfloor \gamma_{s,t}\}}{3\lfloor E+1 \rfloor} \right| \\ &\leq \left| e^{2^{((s-1)n+t)/N}} - \gamma_{s,t} \right| + \frac{\{3\lfloor E+1 \rfloor \gamma_{s,t}\}}{3\lfloor E+1 \rfloor} \\ &\leq \frac{2}{3E} + \frac{1}{3\lfloor E+1 \rfloor} \leq \frac{1}{E}. \end{aligned}$$

By definition, the matrix

$$\Omega = 3\lfloor E+1 \rfloor \tilde{\Gamma} \in \mathbb{Z}^{m \times n}, \quad (29)$$

where $\tilde{\Gamma}$ is defined by (28), has integer entries and computing $\Omega \mathbf{x}^T$ also requires $m(n-1)$ additions. Thus we have the following.

► **Theorem 33.** *Let $N = mn \geq 4$. The matrix*

$$\Omega = (\omega_{s,t}) \in \mathbb{Z}^{m \times n},$$

given by (29) defines the set of linear forms of complexity $m(n-1)$ and has elements of size

$$0 \leq \omega_{s,t} \leq 25 \exp\left(N^{N^{3N^2}}\right).$$

Proof. From the above discussion it only remains to estimate the size of elements of Ω . From (26) we conclude that

$$0 \leq \omega_{s,t} \leq 8(3E+1) \leq 25E,$$

where E is defined by (23). As one easily verifies that under our assumption we have $E \geq 24$. ◀

It seems to be of interest to find an integer matrix with smaller entries, that defines the set of linear forms of the same complexity.
