Abstract

For a source node, \(v\), and target node, \(w\), the traceroute command iteratively issues “kth-hop” queries, for \(k = 1, 2, \ldots, \delta(v, w)\), which return the name of the \(k\)th vertex on a shortest path from \(v\) to \(w\), where \(\delta(v, w)\) is the distance between \(v\) and \(w\), that is, the number of edges in a shortest-path from \(v\) to \(w\). The traceroute command is often used for network mapping applications, the study of the connectivity of networks, and it has been studied theoretically with respect to biases it introduces for network mapping when only a subset of nodes in the network can be the source of traceroute queries. In this paper, we provide efficient network mapping algorithms, that are based on kth-hop traceroute queries. Our results include an algorithm that runs in a constant number of parallel rounds with a subquadratic number of queries under reasonable assumptions about the sampling coverage of the nodes that may issue kth-hop traceroute queries. In addition, we introduce a number of new algorithmic techniques, including a high-probability parametric parallelization of a graph clustering technique of Thorup and Zwick, which may be of independent interest.

1 Introduction

Network mapping involves inferring the topology of a communication network, such as the Internet, from queries, e.g., see Figure 1 and [24,49]. A prominent technique for network mapping is active probing using the Unix traceroute command to perform queries that reveal routing-path information, e.g., see [24,32,49]. We formulate the network mapping problem as follows. Suppose we are given access to a subset, \(U \subseteq V\), of the vertices of a connected, undirected, unweighted graph, \(G = (V, E)\), so that the distance, \(\delta(u, v)\), between two vertices, \(u\) and \(v\), in \(G\) is defined as the number of edges on a shortest path joining \(u\) and \(v\) in \(G\). The \(n\) vertices in \(U\) are known, but the set of edges, \(E\), is unknown. The subset \(U\) represents vantage point nodes from which we may issue the following type of queries:

- \(k\text{-hop}(k, u, v)\): return the vertex, \(w\), that is the \(k\)th vertex on a shortest path from \(u\) to \(v\) in \(G\). If \(k \geq \delta(u, v)\), then return \(v\).

Note that for \(u, v \in U\), \(k\text{-hop}(k, u, v)\) returns vertices in a single shortest path from \(u\) to \(v\). Shortest paths in \(G\) are not necessarily unique, however. So, for example, if \(\delta(u, v) = \delta(u, w) + \delta(w, v)\), it is not necessarily the case that \(k\text{-hop}(\delta(u, w), u, v) = w\). In
the network mapping problem, we are interested in using $k$th-hop queries to learn the edges of the induced shortest-path graph, $H = (U, \tilde{E})$, such that there is an edge $(u, v) \in \tilde{E}$, for $u, v \in U$, if and only if no $k$th-hop($k, u, v$) query would return a vertex $w \in U$ other than $v$, that is, $k$th-hop($k, u, v$) would return vertices of a shortest path from $u$ to $v$ that does not include any other vertex in $U$. Thus, $H$ is a weighted, connected, undirected graph such that each edge $(u, v)$ in $H$ has weight $\delta(u, v)$.

Our motivation for focusing on $k$th-hop queries is that they form the “inner loop” of how traceroute works by default. In particular, by default traceroute works by sending a series of packets in a network from a source, $u$, to a destination, $v$, with the packets having increasing time-to-live (TTL) values, up to an upper bound for the diameter, $\text{diam}(G)$, of $G$, which traceroute typically sets to 30 or 64 by default depending on the underlying operating system. The TTL field in a packet is decremented with each hop it traverses and when it reaches 1, then that node sends an ICMP message to the source address (with message including the node’s address), e.g., see [1,2]. Thus, the traceroute tool can be viewed as first performing a $k$th-hop($1, u, v$) query, then a $k$th-hop($2, u, v$) query, and so on, until getting a response from the vertex $v$. In fact, one can use options with the traceroute command to issue a $k$th-hop query directly, e.g., to find the 5th hop from a node to example.com, one could use the command, "traceroute -m 5 -M 5 example.com".

Our formulation of the network mapping problem abstracts away certain system issues. In particular, we are implicitly assuming that messages in $G$ are routed along shortest paths, which is a widely used setting assumed by the prior work [4,20,26]. An important system issue that we do not abstract away, however, is that only vertices in $U \subseteq V$ may issue queries. Indeed, there is some interesting prior work regarding the sampling biases introduced by only being able to issue queries from a subset, $U$, of the set of vertices, $V$, in $G$. For example, Achlioptas, Clauset, Kempe, and Moore [4] show that traceroute sampling\footnote{Traceroute sampling samples the network graph as the union of paths that packets traverse in performing traceroute queries from a subset of the nodes in a network.} finds power-law degree distributions in both $\Delta$-regular and Poisson-distributed random graphs, even though these underlying graphs do not themselves have power-law degree distributions, which is a statistical finding in experiments by Lakhina, Byers, Crovella, and Xie [37]. Maciej,
Markopoulou, and Patrick [36] study ways to correct for this bias when sampling large graphs. Further, Zhang, Kolaczyk, and Spencer [50] and Flaxman and Vera [26] study ways to correct for this bias for estimating degree distributions. Interestingly, Barrat, Alvarez-Hamelin, Dall’Asta, Vázquez, and Vespignani [13] provide an analysis that power laws still exist in the Internet graph in spite of the traceroute sampling bias, which these authors show is related to betweenness (see also [20]).

In spite of this interesting prior work concerning the sampling biases inherent in performing traceroute queries only from the nodes in the subset, $U$, we are not familiar with any prior work on efficient algorithms for solving the network mapping problem. We focus on two complexity measures for a network mapping algorithm, $\mathcal{A}$, in terms of $n = |U|$: $Q(n)$: the query complexity of $\mathcal{A}$. This is the total number of $k$th-hop queries issued. This complexity measure comes from learning theory (e.g., see [5, 18, 22, 43]) and complexity theory (where it is also known as “decision-tree complexity,” e.g., see [16, 48]).

$R(n)$: the round complexity of $\mathcal{A}$. This is the number of rounds of querying performed by $\mathcal{A}$, where the queries issued in a round are given in a batch such that any query issued in a round may not depend on the response to any other query in that round (but each query may depend on results of queries from previous rounds).

**Prior Related Work.** As mentioned above, we are not aware of prior algorithmic work on network mapping. If we analyze the algorithm used in existing mapping systems that use active probing, this amounts to a brute-force quadratic algorithm implemented by cooperating nodes of the network, which perform a traceroute to every other known node in the network, e.g., see [23, 24, 33]. Viewed combinatorially, this algorithm has query complexity, $Q(n)$, that is $O(\text{diam}(G) \cdot n^2)$, and round complexity, $R(n)$, that is $O(\text{diam}(G))$, for $k$th-hop queries.

The network mapping problem is related to graph reconstruction, e.g., see [3, 6, 7, 9–12, 14, 15, 17, 18, 21, 27–30, 34, 35, 38, 40–42, 44, 46, 47]. In this problem, one is given a connected unweighted graph, $G = (V, E)$, for which $V$ is known and goal is to discover $E$ through queries, such as:

- $\text{distance}(u, v)$: return the distance, $\delta(u, v)$, between $u$ to $v$ in $G$.
- $\text{shortest-path}(u, v)$: return the vertices (in order) in a shortest path from $u$ to $v$ in $G$.

There is also work on other types of queries, including vertex-betweenness queries [3]; queries returning whether a given subset of vertices induce a given edge [9–12, 15, 17]; queries returning the number of edges induced by a given subset of vertices [18, 27–29]; queries returning all shortest paths from a given node to all other nodes [14, 42]; queries returning the distance between two leaves in a phylogenetic tree [6, 7, 30, 35, 40, 47]; and queries returning whether a given vertex is an ancestor of another given vertex in a rooted tree [6, 7, 46].

There are a number of important differences between the network mapping problem and graph reconstruction, however. Most significantly, the graph reconstruction problem assumes queries can be performed for any vertices in $V$, whereas in the network mapping problem we may only issue $k$th-hop queries for nodes in the subset $U \subseteq V$. In addition, even if we restrict the network mapping problem to the case where $U = V$, previous work on graph reconstruction has not considered $k$th-hop queries, which, as we mentioned above, form the “inner-loop” for how traceroute works and are distinct from distance and shortest-path queries. For example, it doesn’t seem possible to simulate a $k$th-hop query with fewer than $\Theta(n)$ distance queries, while a distance query can be simulated with $O(\log \text{diam}(G))$ $k$th-hop queries via binary search. Also, although it is trivial to simulate a $k$th-hop query with a single shortest-path query, it takes $\Theta(\text{diam}(G))$ $k$th-hop queries to simulate a single shortest-path query. Thus, $k$th-hop queries are strictly weaker than shortest-path queries while being better at capturing the true message complexity of the traceroute command.
Another difference between the network mapping problem and graph reconstruction is that previous work on graph reconstruction has mostly focused on how to sequentially reconstruct the graph, $G$, whereas the network mapping problem is inherently parallel, due to the motivation from mapping real-world networks, where each node is a computer. In terms of previous work on graph reconstruction in parallel, Mathieu and Zhou [38] recently provided a simple algorithm to reconstruct a connected, unweighted graph $G$, using an expected number of $\tilde{O}(N^{3/2})$ distance queries in 2 rounds. They also show that their algorithm takes an expected number of $\tilde{O}(N)$ distance queries to reconstruct a random $\Delta$-regular graphs.

The most relevant prior work on graph reconstruction, however, is by Kannan, Mathieu, and Zhou [34], who show how to reconstruct a connected, unweighted graph $G$, using an expected number of $O(\Delta^3 N^{3/2} \log^2 N \log \log N)$ distance queries, or an expected number of $N^{1+O(\tau(N))}$ shortest-path queries, where $N = |V|$ and $\tau(N) = \sqrt{(\log \log N + \log \Delta)/\log N}$, which is $o(1)$ when $\Delta$, the maximum degree of $G$, is $N^{o(1)}$. They also show that verifying a given set of edges can be done using $O(N^{1+O(\tau(N))})$ expected distance queries.

Our Results. A preliminary announcement of some of this paper’s results, using distance queries for graph reconstruction, where queries can be performed for any vertices in $V$, was presented in [8].

In Section 2, we introduce a new technique that may be of independent interest, where we provide a new parallel implementation of a well-known graph clustering technique of Thorup and Zwick [45] with round complexity of $O(1)$, while their original implementation implies an expected round complexity of $O(\log n)$. In doing so, we introduce a parameter that allows to trade off parallel time and cluster size. Moreover, we show that our complexity bounds hold with high probability, whereas Thorup and Zwick proved their complexity bounds only in expectation. In Section 3, we will use this new construction to compute a graph-theoretic Voronoi diagram in our network mapping algorithm. On the other hand, our graph clustering technique can be applied to other problems, such as that studied by Honiden, Houle, and Sommer [31] for balancing graph-theoretic Voronoi diagrams, to reduce the number of centers to $O(s)$ from $O(s \log n)$.

In Section 3, we provide the first non-trivial algorithmic results for the network mapping problem. Our query complexities and round complexities are characterized in terms of $n = |V|$ and some interesting parameters that capture the sampling coverage provided by the set $U$. For example, in addition to characterizing complexities in terms of $\Delta$, the maximum degree of the graph, $H$, we introduce a distance coverage parameter, $\delta_{\text{max}}$, which is the maximum weight for an edge in $H$, and a nearby-vertices parameter, $\mu$, which is an upper bound on the number of vertices within a distance of $2\delta_{\text{max}}$ of any given vertex $v \in U$. As we show, these parameters are required for the sake of efficiency, for we show that without these parameters the network mapping problem has a quadratic query-complexity lower bound. For example, under reasonable assumptions regarding these parameters, we are the first to give a constant-round network-mapping algorithm with query complexity better than the trivial brute-force algorithm.

In Section 4, we introduce a greedy approach for network mapping that is based on parallel greedy approximate set cover, which allows us to achieve a near-quasilinear query complexity (when $\Delta$ is $n^{o(1)}$). As with a related sequential greedy graph reconstruction result of Kannan, Mathieu, and Zhou [34], our query and round complexity bounds are parameterized in terms

---

2 The notation $\tilde{O}(f(N))$ is equivalent with $O(f(N) \cdot \text{polylog}(f(N)))$.

3 We say an event holds with high probability (w.h.p.) if it occurs with probability at least $1 - 1/n$. 
of the best sequential query complexity for verifying the edges of a graph using distance queries (without knowing the exact value of this query complexity). Further, for small values of the parameters, $\delta_{\max}$ and $\Delta$, our greedy approach uses a near-quasilinear number of $k$th-hop queries, which are strictly weaker than the shortest-path queries used by Kannan, Mathieu, and Zhou. We summarize our results in Table 1.

\end{table}

### 2 Parallel Graph Clustering

Thorup and Zwick [45] introduced a graph clustering technique in presenting a stretch\(^4\) 3 network routing scheme. We begin by describing our parallel graph clustering algorithm, which may be of independent interest, as it provides a parameterized parallel extension of the one by Thorup and Zwick [45]. Also, whereas Thorup and Zwick establish their bounds in expectation, we establish ours with high probability. In Section 3, we apply our parallel graph clustering algorithm in creating a graph-theoretic Voronoi diagram for our network mapping algorithm.

We begin with some review from Thorup and Zwick [45]. Let $G = (V, E)$ be a connected, undirected $n$-vertex graph, and let $\delta(u, v)$ denote the distance between vertices $u$ and $v$ in $G$. In this section, we allow $G$ to be weighted, where $\delta(u, v)$ is the sum of weights on a shortest path (lowest weight path) from $u$ to $v$, but in our algorithms for parallel network mapping, we assume $G$ is unweighted, in which case $\delta(u, v)$ is the number of edges on a shortest path from $u$ to $v$. For a subset $A \subseteq V$, let $\delta(A, v) = \min_{a \in A} \delta(a, v)$, and, for vertices $w, v \in V$, let $C_A(w)$ be the cluster of $w$ and $B_A(v)$ be the bunch of $v$ with respect to $A$, defined as follows:

$$C_A(w) = \{ v \in V \mid \delta(w, v) < \delta(A, v) \} \quad \text{and} \quad B_A(v) = \{ w \in V \mid \delta(w, v) < \delta(A, v) \}.$$

Note that if $w \in A$, then $C_A(w) = \emptyset$. Also, observe that bunches and clusters are “inverses” of each other, in that $v \in C_A(w)$ if and only if $w \in B_A(v)$. In addition, notice that clusters and bunches can only shrink as we add vertices to $A$; that is, if $A' \subseteq A$, then $C_A(w) \subseteq C_{A'}(w)$ and $B_A(v) \subseteq B_{A'}(v)$, for all $v$ and $w$ in $V$.

Now, let $\beta \in [4, n)$, be a “parallelism” parameter and let $s \in [4 \ln n, n)$ be a “size” parameter. Define a subset, $A \subseteq V$, to be a set of $(\beta, s)$-balanced centers if $|C_A(w)| \leq \beta n/s$, for all $w \in V$. Thorup and Zwick [45] give a sequential algorithm for finding a set of $(4, s)$-balanced centers of expected size $O(s \log n)$. In Algorithm 1, we give a parallel algorithm for finding a set of $(\beta, s)$-balanced centers of size $O(s \log_\beta n)$ in $O(\log_\beta n)$ rounds w.h.p. Thus, the parameter $\beta$ allows one to trade off parallel time and cluster size.

\footnote{Routing Stretch is the worst ratio between the length of a path on which a message is routed and the length of the shortest path in the network from the source to the destination.}
4:6 Mapping Networks via Parallel kth-Hop Traceroute Queries

Algorithm 1 parallel-centers($V, s, \beta$).

1. $A \leftarrow \emptyset$, $W \leftarrow V$
2. while $|W| > 0$ do
3.   $A' \leftarrow \text{Sample}(W, s)$ // a random sample of expected size $s$ (or $W$ if $s \geq |W|$)
4.   $A \leftarrow A \cup A'$
5.   for $w \in W$ do in parallel
6.     $C_A(w) \leftarrow \{v \in V : \delta(w, v) < \delta(A, v)\}$
7.   $W \leftarrow \{w \in W : |C_A(w)| > \beta n/s\}$
8. return $A$

Our algorithm (Algorithm 1) takes a graph $G = (V, E)$ as input and initializes $A$, the eventual output of the algorithm, to be empty, and $W$, the set of nodes $v \in V$ where $|C_A(v)| > \beta n/s$, to be $V$. Then, we iteratively add Sample($W, s$) to $A$, and replace $W$ with vertices $w \in W$ such that $|C_A(w)| > \beta n/s$, in parallel, where the function, Sample($W, s$), returns $W$ if $|W| \leq s$ and, otherwise, returns a set of elements from $W$ such that each element in $W$ is selected independently at random with probability $s/|W|$. We continue in this way until $W = \emptyset$.

Since the size of a cluster, $|C_A(w)|$, does not increase as we add more vertices to $A$, the set $A$ returned by our algorithm is a set of $(\beta, s)$-balanced centers. Also, the Sample function returns a sample of size at most $2s$ with probability at least $1 - e^{-s/3}$, which holds with high probability across all iterations when $s \geq 4 \ln n$, by a standard Chernoff bound, e.g., see [39, p. 69]. Incidentally, Thorup and Zwick use the same Sample function, but don’t bound its maximum size as we do. This high-probability upper bound for the sample size is not sufficient to achieve a high-probability bound, however, for the entire parallel graph clustering algorithm.

To that end, we define a parameter, $\alpha$, as follows:

$$\alpha = \begin{cases} 2 & \text{if } \beta \leq ((4/3)e)^4 \\ (4/3)e^{1/2} & \text{otherwise} \end{cases}$$

where $e \approx 2.71828$ is Euler’s number. This definition of $\alpha$ is made so that we may achieve high probability bounds for a range of $\beta$ values.

Let $W_i$ denote the set $W$ at the beginning of iteration $i$, let $A'_i$ denote the set $A'$ that was added in iteration $i$, and let $A_i$ denote the set $A$ in this iteration, including the set, $A'_i$, i.e., $A_i = A_{i-1} \cup A'_i$, for $i = 1, 2, \ldots$, where $A_0 = \emptyset$. Say that iteration $i$ is “bad” if the following inequality holds:

$$\sum_{w \in W_i} |C_{A'_i}(w)| > \frac{\alpha n |W_i|}{s},$$

and that otherwise it is “good”. Note that, since $W_i$ is a given for iteration $i$, whether iteration $i$ is good or bad depends only on $A'_i$.

Lemma 1 (Thorup-Zwick [45], Lemma 3.2). Let $W \subseteq V$, let $1 \leq s \leq n$, and let $A' \leftarrow \text{Sample}(W, s)$. Then, for every $v \in V$, $E[|B_{A'}(v) \cap W|] \leq |W|/s$.

This implies the following:

$$E \left[ \sum_{w \in W_i} |C_{A'_i}(w)| \right] = E \left[ \sum_{v \in V} |B_{A'_i}(v) \cap W_i| \right] \leq \frac{n |W_i|}{s}.$$
Therefore, by Markov’s inequality, an iteration is bad with probability at most $1/\alpha$.

Let $W_{i+1}$ denote the set of vertices, $W$, whose clusters have size at least $\beta n/s$ at the end of a good iteration $i$. As $W_{i+1} \subseteq W_i$, and $C_{A_i}(w) \subseteq C_{A'_i}(w)$, for all $w \in V$, in a good iteration we have:

$$\frac{\beta n |W_{i+1}|}{s} \leq \sum_{w \in W_i} |C_{A_i}(w)| \leq \sum_{w \in W_i} |C_{A'_i}(w)| \leq \frac{\alpha n |W_i|}{s};$$

hence, $|W_{i+1}| \leq (\alpha/\beta)|W_i|$ in a good iteration. Thus, the number of good iterations of our algorithm is $O(\log(\beta/\alpha) n)$, which is $O(\log_2 n)$ for either choice of $\alpha$. Moreover, because an iteration is good independent of whether any other iteration is good or bad, we may use standard and non-standard Chernoff bounds to show that the number of bad iterations is also $O(\log_2 n)$ w.h.p., for either value of $\alpha$. (See Appendix A.1.) This gives us the following:

\textbf{Theorem 2.} Given an undirected, connected graph, $G = (V, E)$, we can find a set, $A$, of $(\beta, s)$-balanced centers of size $O(s \log_2 n)$ in $O(\log_2 n)$ parallel rounds w.h.p.

For example, if $\beta = 4$, then $A$ is constructed to have size $O(s \log n)$ in $O(\log n)$ rounds; if $\beta = n^\epsilon$, for constant $0 < \epsilon < 1/2$, then $A$ is constructed to have size $O(s)$ in $O(1)$ rounds.

## 3 Our Fast Parallel Network Mapping Algorithms

In this section, we provide our fast parallel network mapping algorithms for a connected, undirected, unweighted network, $G = (V, E)$, given a subset $U \subseteq V$ from which we may perform $k$th-hop queries. We denote the size of $U$ by $n$ and the size of $V$ by $N$. Let $H$ be the graph induced by the shortest paths in $G$ between pairs of vertices in $U$. That is, $H$ has vertex set $U$ and there is an edge $(u, v)$ in $H$, for $u, v \in U$, if the shortest path between $u$ and $v$ in $G$ determined by $k$th-hop queries contains no other vertex in $U$ besides $u$ and $v$. The weight of each edge $(u, v)$ in $H$ is the distance, $\delta(u, v)$, between $u$ and $v$ in $G$. The goal of network mapping is to determine the edges of $H$ (which can then be used to easily determine the vertices in $G$ in a shortest path corresponding to each edge $(u, v)$ in $H$ in a single round of $\delta(u, v)$ $k$th-hop queries). We assume we know the value of $\delta_{\text{max}}$, which is the weight of a maximum-weight edge in $H$. For example, if $U = V$, then $\delta_{\text{max}} = 1$. In the worst case, $\delta_{\text{max}}$ is equal to the diameter of $G$, but in real-world network mapping applications, $\delta_{\text{max}}$ is likely to be a constant.

We perform all the queries needed in our parallel network mapping algorithms in a subroutine, $\text{Distances}(v, W)$, which determines the distance, $\delta(v, w)$, for a given $v \in U$ and every other $w \in W \subseteq U$. We describe two possible implementations for $\text{Distances}(v, W)$, which we choose between depending on our desired goals. In our first implementation, we perform a simple binary search using $k$th-hop$(k, v, w)$ queries to determine $\delta(v, w)$, for each $w$. This requires $O(\log \diam(G))$ rounds and a total of $O(|W| \log \diam(G))$ $k$th-hop queries, and this implementation doesn’t require any assumptions about $W$. Note that we assume that we know $\diam(G)$, and if this is not the case, we can instead perform a doubling binary search with the same query complexity. In our second implementation, we perform $\delta_{\text{max}}$ $k$th-hop$(k, v, w)$ queries in parallel, for each $w$, for $k = 1$ to $\delta_{\text{max}}$. This implementation requires a single round of $O(\delta_{\text{max}} |W|)$ $k$th-hop queries, and it requires that $v \in W$, and the nodes in $W$ induce a connected subgraph of $H$ that contains the shortest path in $H$ from each $w$ in $W$ to $v$, and that we are only interested in finding the edges of this subgraph. This set of queries finds all the edges of a breadth-first search (BFS) tree, $B_v$, rooted at $v$, in the induced graph, $H$, since a shortest path from $w$ to $v$ is also a shortest path from $v$.
Algorithm 2. Our parallel querying algorithm, estimated-parallel-centers\((U, s, \beta)\), for finding a set of \((\beta, s)\)-balanced centers \(A\).

\[\begin{align*}
A & \leftarrow \emptyset, \ W \leftarrow U \\
T & \leftarrow c_1(s/\beta) \log n \quad // \quad c_1 \text{ is a constant set in the analysis} \\
3 & \text{while } |W| > 0 \text{ do} \\
4 & \quad A' \leftarrow \text{Sample}(W, s) \\
5 & \quad A \leftarrow A \cup A' \\
6 & \quad R \leftarrow \text{a random subset with } v \in U \text{ chosen independently with probability } T/n \\
7 & \quad \text{for each } r \in R \text{ do in parallel} \\
8 & \quad \text{Distances}(r, U) \\
9 & \text{for } w \in W \text{ do in parallel} \\
10 & \quad S(w) \leftarrow \{v \in R : \delta(w, v) < \delta(A, v)\} \quad // \quad S(w) = C_A(w) \cap R \\
11 & \quad W \leftarrow \{w \in W : |S(w)| > 2\beta T/s\} \quad // \quad \text{that is, } |S(w)|(n/T) > 2\beta n/s \\
12 & \quad \text{return } A
\end{align*}\]

to \(w\), and a subpath of any shortest path is a shortest path for its endpoints. Thus, in this second implementation, we can determine \(\delta(v, w)\), for each \(w \in U\), from \(B_v\), by summing the weights of the edges from \(v\) to \(w\) in \(B_v\) (which doesn’t require any additional queries). This gives us the following lemma.

Lemma 3. Distances\((v, W)\) can be implemented in \(O(\log \text{diam}(G))\) rounds using a total of \(O(|W| \log \text{diam}(G))\) \(k\)-hop queries. Alternatively, if \(v \in W\), and the subgraph of \(H\) induced by \(W\) is connected and we are interested only in finding the edges of this subgraph, then Distances\((v, W)\) can be implemented in 1 round with \(O(\delta_{\max}|W|)\) \(k\)-hop queries.

Let the cluster of vertex \(w\) with respect to centers \(A\) be \(C_A(w) = \{v \in U \mid \delta(w, v) < \delta(A, v)\}\). The key idea of our parallel network mapping algorithm is to first find a set, \(A\), of \((\beta, s)\)-balanced centers, using our parallel algorithm from the previous section, and then use this set of centers to compute a graph-theoretic Voronoi diagram \([25,31]\) for \(G\), from which we may efficiently then perform a brute-force querying step for each Voronoi region. This approach is similar in spirit to the one by Kannan, Mathieu, Zhou \([34, \text{Section 2}]\), with some key important differences: i) the restriction of our queries to the vantage point \(U \subseteq V\) and the parameters capturing sampling coverage of set \(U\), ii) the usage of \(k\)-hop queries, and iii) our parallel graph clustering that allows us to trade off between round complexity and query complexity.

The initial center-finding step builds a set, \(A\), of size \(O(s \log_\beta n)\) such that each vertex in \(U\) has a cluster with respect to \(A\) of size at most \(\beta n/s\). One of the challenges in implementing this algorithm efficiently in parallel using \(k\)-hop queries is that we need to determine cluster sizes for all vertices in \(U\) in each iteration, which would take many queries to compute exactly. So, rather than compute such sizes exactly, we instead build a global random set, \(R\), which we use to approximate the size of each cluster. We give the details in Algorithm 2.

Lemma 4. Our estimated-parallel-centers algorithm constructs a set, \(A\), of \((3\beta, s)\)-balanced centers of size \(O(s \log_\beta n)\). Suppose Distances\((r, U)\) executes in \(R(n)\) rounds and \(Q(n)\) \(k\)-hop queries. Then estimated-parallel-centers algorithm executes in \(O(R(n) \log_\beta n)\) rounds and \(O(Q(n)/(s/\beta) \log n \log_\beta n)\) \(k\)-hop queries, w.h.p.

Proof. See Appendix A.2.
Now that we have defined and analyzed the function \texttt{estimated-parallel-centers}(U, s, \beta), let us next turn to our parallel algorithm for mapping a connected, undirected graph, \( G = (V, E) \), given a subset, \( U \subseteq V \), from which we can perform \texttt{kth-hop} queries. This algorithm takes as input the vertex set \( U \), and outputs, \( \tilde{E} \), the set of edges of the induced graph, \( H \), defined by the vertex set \( U \) and the shortest paths in \( G \) returned by \texttt{kth-hop} queries.

Let \( A \subseteq U \) be a set of centers, which in our network mapping algorithm will come from a call to our \texttt{estimated-parallel-centers}(U, s, \beta) algorithm, but a graph-theoretic Voronoi diagram can be defined for any weighted graph and any set of centers. Given a center, \( a \in A \), define the Voronoi cell, \( \text{Vor}_A(a) \), for \( a \) in \( H \) as \( \text{Vor}_A(a) = \{ v \in U : \delta(a, v) \leq \delta(A \setminus \{a\}, v) \} \). The graph-theoretic Voronoi diagram for \( A \) in \( U \) consists of the union of Voronoi cells, \( \text{Vor}_A(a) \), for each center, \( a \in A \). We say that an edge \((v, w) \in \tilde{E}\) is an interior edge if \( v, w \in \text{Vor}_A(a) \), for some center \( a \in A \), and it is a boundary edge if \( v \in \text{Vor}_A(a) \) and \( w \in \text{Vor}_A(b) \), where \( a \neq b \). If we were to perform a set of \texttt{kth-hop} queries for every pair of vertices in a Voronoi cell, then we are guaranteed to discover every internal edge in \( \text{Vor}_A(a) \), but we will miss boundary edges going between two Voronoi cells. Thus, we need to “branch out” a little bit from the vertices of \( \text{Vor}_A(a) \) in order to discover all the boundary edges. To facilitate this, for any center, \( a \in A \), let \( N_{2\delta_{\text{max}}}(a) \) be the set of “nearby” vertices in \( H \), that is, vertices that are within a distance of \( 2\delta_{\text{max}} \) of a. Formally,

\[
N_{2\delta_{\text{max}}}(a) = \{ v \in U : \delta(a, v) \leq 2\delta_{\text{max}} \}.
\]

We assume we know \( \mu \), the maximum size of \( N_{2\delta_{\text{max}}}(a) \), for any \( a \in A \). Of course, \( \mu < n \).

The following lemma shows that it is sufficient to consider these nearby neighbors, for each center \( a \in A \), in order to cover all the edges in \( H \), including interior edges and boundary edges. (See also Figure 2.)

We give the details of our network mapping algorithm in Algorithm 3. Through a call to \texttt{estimated-parallel-centers}(U, s, \beta), we find a set of \((O(\beta), s)\)-balanced centers, \( A \). Next, we build a BFS tree from each vertex \( a \in A \) to be able to identify nodes in \( N_{2\delta_{\text{max}}}(a) \). Then, our mapping algorithm, \texttt{map}, constructs graph-theoretic Voronoi diagram for the centers in \( A \), and then “branches out” from each center \( a \in A \) by considering the nodes in \( N_{2\delta_{\text{max}}}(a) \) and the clusters defined by nodes in \( N_{2\delta_{\text{max}}}(a) \). Finally, after having done this Voronoi decomposition, our algorithm performs exhaustive searches in each cluster in parallel. This part of the algorithm uses a method, \texttt{Exhaustive-Query}(W), which finds all the edges of \( H \) between vertices in \( W \) by calling \texttt{Distances}(v, W), for each \( v \in W \).

The following lemmas establish the correctness and performance complexities for our network mapping algorithm.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{voronoi_diagram}
\caption{This figure represents a partial structure of our Voronoi Diagram. Blue vertices represent centers from \( A \). The circle centered at \( a \in A \) represents the vertices of distance at most \( 2\delta_{\text{max}} \) from \( a \). We use clusters of nearby vertices of \( a \) to discover boundary edges. For simplicity, we draw only two clusters for two arbitrary nodes \( w_1, w_2 \in N_{2\delta_{\text{max}}}(a) \).}
\end{figure}
Algorithm 3 Parallel network mapping using k-th-hop queries.

1 Function map(U):
2 A ← estimated-parallel-centers(U, s, β)
3 for each a ∈ A do in parallel
4 Distances(a, U)  // gives us $N_{2\delta_{\text{max}}}(a)$ as well
5 for each a ∈ A do in parallel
6 $E_a$ ← Exhaustive-Query($N_{2\delta_{\text{max}}}(a)$)
7 for b ∈ $N_{2\delta_{\text{max}}}(a)$ do in parallel
8 Distances(b, U)
9 $C_A(b) \leftarrow \{v \in U : \delta(b, v) < \delta(A, v)\}$
10 $E_{a,b}$ ← Exhaustive-Query($C_A(b)$)
11 return $\bigcup_{a \in A} (E_a \cup \bigcup_{b \in N_{2\delta_{\text{max}}}(a)} E_{a,b})$

Lemma 5. Let $(u, v)$ be an edge in $H$. Then there exists a center, $a \in A$, such that $u$ and $v$ are both in $N_{2\delta_{\text{max}}}(a)$ or both in $C_A(b)$, for some $b \in N_{2\delta_{\text{max}}}(a)$.

Proof. Let $(u, v)$ be an edge in $H$, and note that, by definition, $\delta(u, v) \leq \delta_{\text{max}}$. Assume, without loss of generality, that $\delta(A, u) \leq \delta(A, v)$. Also, let $a$ be a vertex in $A$ such that $\delta(a, u) = \delta(A, u)$. If $\delta(a, u) \leq \delta_{\text{max}}$, then both $u$ and $v$ are in $N_{2\delta_{\text{max}}}(a)$, by the triangle inequality. So, suppose $\delta(a, u) > \delta_{\text{max}}$. Let $b$ be a vertex in $U$ on a shortest path from $a$ to $u$ such that $\delta_{\text{max}} < \delta(a, b) \leq 2\delta_{\text{max}}$. Note that $b$ must exist, since no edge in $H$ has weight more than $\delta_{\text{max}}$ (it is possible that $b = u$). Further, $b$ is in $N_{2\delta_{\text{max}}}(a)$ and $\delta(a, u) = \delta(a, b) + \delta(b, u)$. Also, $\delta(b, u) < \delta(a, u) = \delta(A, u)$; hence, $u$ is in $C_A(b)$.

By the triangle inequality, and the above observations,

$$
\delta(b, v) \leq \delta(b, u) + \delta(u, v) \\
\leq \delta(b, u) + \delta_{\text{max}} \\
= \delta(a, u) - \delta(a, b) + \delta_{\text{max}} \\
< \delta(a, u) - \delta_{\text{max}} + \delta_{\text{max}} \\
= \delta(a, u) \\
= \delta(A, u).
$$

Therefore, $\delta(b, v) < \delta(A, v)$; hence, $v$ is also in $C_A(b)$.

Lemma 6. If Distances$(v, W)$ executes in $R(|W|)$ rounds using $Q(|W|)$ k-th-hop queries, then Algorithm 3 uses $O(Q(n)(s/\beta)\log \beta n \log_{\beta} n + \mu Q(n) + (\beta n/s) Q(\beta n/s) s \log_{\beta} n)$ queries in $O(R(n) \log_{\beta} n)$ rounds, w.h.p., where $\mu = \max_{a \in A} |N_{2\delta_{\text{max}}}(a)|$.

Proof. By Lemma 4, estimated-parallel-centers$(U, s, \beta)$ executes in $O(R(n) \log_{\beta} n)$ rounds and $O(Q(n)(s/\beta)\log \beta n \log_{\beta} n)$ k-th-hop queries, and returns a set of $(3\beta, s)$-balanced centers of size $O(s \log_{\beta} n)$, w.h.p. The parallel Distances calls in line 4 thus executes in $O(R(n))$ rounds using $O(Q(n) s \log_{\beta} n)$ k-th-hop queries, w.h.p., and the calls to Exhaustive-Query in line 6 execute in $O(R(\mu))$ rounds using a total of $O(\mu Q(\mu) s \log_{\beta} n)$ k-th-hop queries, but these bounds are dominated by the Distances calls in line 8, all of which execute in $O(R(n))$ rounds using $O(\mu Q(n) s \log_{\beta} n)$ k-th-hop queries, w.h.p. Finally, the calls to Exhaustive-Query in line 10 execute in $O(R(\beta n/s))$ rounds using $O(\mu(\beta n/s) Q(\beta n/s) s \log_{\beta} n)$ k-th-hop queries, w.h.p.
Plugging in our derived bounds for Distances, we get the following theorem.

Theorem 7. Given a connected graph, \( G = (V,E) \), and subset, \( U \subseteq V \), one can map the \( n \)-vertex induced shortest-path graph, \( H \), with respect to \( G \) and \( U \) in \( O(1) \) rounds using \( O(\delta_{max}^\mu n^{3/2+\epsilon}) \) \( k \)-hop queries, for constant \( 0 < \epsilon < 1/2 \), w.h.p. Alternatively, one can map \( H \) in \( O(\log n \cdot \log \text{diam}(G)) \) rounds using \( O(\mu n^{3/2} \log^{1.2} n \cdot \log \text{diam}(G)) \) queries, w.h.p.

Proof. For the first result, set \( \beta = n^\epsilon \) and \( s = n^{1/2+\epsilon} \), and let us use the implementation of Distances that executes in 1 round using \( O(\delta_{max}^\mu n) \) \( k \)-hop queries from Lemma 3. For the second result, set \( \beta = 4 \) and \( s = (n/\log n)^{1/2} \) and let us use the implementation of Distances that executes in \( O(\log \text{diam}(G)) \) rounds using \( O(n \log \text{diam}(G)) \) \( k \)-hop queries from Lemma 3. The bounds follow by Lemma 6.

For example, depending on the values of \( \delta_{max} \) and \( \mu \), the above theorem establishes an improvement over the brute-force querying algorithm for solving the parallel network mapping problem in \( O(1) \) rounds. The following theorem shows that bounding the parameters \( \delta_{max} \) and \( \mu \) is needed in order to do better than a quadratic number of \( k \)-hop queries.

Theorem 8. There is an infinite family of \( n \)-vertex graphs, \( G \), such that mapping the induced shortest-path graph, \( H \), for a set, \( U \), of \( O(n) \) vertices requires \( \Omega(n^2) \) \( k \)-hop queries, when \( \mu = \Theta(n) \) and \( \delta_{max} = \Theta(\log n) \), even if \( G \) has maximum degree 3.

Proof. Let \( G \) be the graph of a complete binary tree with \( n \) nodes and let \( U \) be the set of leaves of \( G \). Thus, the distance in \( H \) between any node, \( v \), in the left subtree of \( G \), and a node, \( w \), in the right subtree of \( G \), is \( 2 \log n \). Thus, \( \delta_{max} = 2 \log n \) and \( \mu = \Theta(n) \). Now, let \( G' \) be \( G \) plus a single path in \( G \) of length \( (2 \log n) - 1 \) between two vertices, \( v \) and \( w \), in \( U \) such that \( v \) is in the left subtree of \( G \) and \( w \) is in the right subtree of \( G \). Thus, there is an edge with weight \( (2 \log n) - 1 \) joining \( v \) and \( w \) in the induced shortest-path graph, \( H' \), for \( G' \), and otherwise \( H' \) has the same edge set as \( H \). But there are \( \Omega(n^2) \) such possible pairs and the only way to discover the edge \((v,w)\) in \( H \) is to perform a \( k \)-hop query. Any other type of \( k \)-hop query cannot distinguish between \( H \) and \( H' \).

4 A Greedy Network Mapping Algorithm

Kannan, Methieu, and Zhou [34] introduce a proof technique that sequentially uses a verification algorithm for unweighted graphs as an oracle for issuing shortest-path queries in a greedy graph reconstruction algorithm. In this section, we show how to adapt this proof technique to a parallel setting and apply it to map the weighted graph, \( H \). For example, our algorithm uses \( k \)-hop queries and provides parallelism according to a parameter, \( 1 \leq p < n \).

Our greedy algorithm is based on performing steps of the classic greedy set cover algorithm in parallel batches. Recall that in this problem, one is given a collection of sets, \( S_1, S_2, \ldots, S_m \), whose union is the universe \( \mathcal{U} \), and the goal is to find a smallest sub-collection of sets whose union is \( \mathcal{U} \), that is, a sub-collection that covers \( \mathcal{U} \). The greedy algorithm repeatedly chooses the set covering the maximum number of uncovered items in \( \mathcal{U} \), and this results in a number of sets that is at most an \( O(\log n) \) factor more than optimum [19].

Let \( f(n, \Delta) \) be the query complexity of the best sequential algorithm for the problem of graph verification for any connected unweighted graph of \( n \) vertices and maximum degree \( \Delta \) via distance queries, that is, for determining whether an unknown graph, \( G = (V,E) \), is equal to a given graph, \( \hat{G} = (V, \hat{E}) \). For example, Kannan, Methieu, and Zhou [34] show that \( f(n, \Delta) \) is \( n^{1+O(\tau(n))} \), where \( \tau(n) = \sqrt{(\log \log n + \log \Delta)/\log n} \). The function, \( f(n, \Delta) \), is used only in our analysis, where we show that, given a parallelism parameter, \( 1 \leq p < n \), our parallel network mapping algorithm can be tuned to have the desired query complexity, \( Q(n) \), and round complexity, \( R(n) \).
The distance queries in an unweighted graph verification algorithm perform two functions – confirming that edges in $\hat{E}$ are actually in $E$ and confirming that edges not in $\hat{E}$ are also not in $E$, that is, confirming every $(u,v) \notin \hat{E}$ is not in $E$. To that latter end, let $\delta_h(u,v)$ denote the hop-count (number of edges) distance between $u$ and $v$ based on the edges in $\hat{E}$, and let $\hat{E}^c$ denote the set of non-edges in $\hat{G}$, that is, the set of pairs, $(u,v)$, such that $u \neq v$ and $(u,v) \notin \hat{E}$. Similarly, let $E^c$ denote the set of non-edges in $G$. For any set of tentative edges, $\hat{E}$, define the following set for each pair of vertices, $(u,v) \in \hat{E}^c$: $\delta_{\hat{E}}(u,v) = \{(x,y) \in \hat{E}^c | \delta_h(u,x) + \delta_h(y,v) + 1 < \delta_h(u,v)\}$.

Kannan, Methieu, and Zhou [34] prove the following two lemmas.

**Lemma 9.** Suppose $\hat{E} \subseteq E$. For any $(u,v) \in \hat{E}^c$, if $\delta_h(u,v) = \hat{\delta}_h(u,v)$, where $\delta_h(u,v)$ denotes the hop-count distance between $u$ and $v$ in $G$, then $\delta_{\hat{E}}(u,v) \subseteq E^c$, that is, each pair in $\delta_{\hat{E}}(u,v)$ is a non-edge in $G$.

**Lemma 10.** If a set of distance queries, $T$, verifies that every non-edge of $\hat{G}$ is a non-edge of $G$, then $\bigcup_{(u,v) \in T} \delta_{\hat{E}}(u,v) = \hat{E}^c$.

We present our parallel greedy algorithm for mapping $H = (U, \hat{E})$ in $G = (V,E)$, for when $U \subset V$, that is, we incrementally build our tentative edge set $\hat{E} \subseteq E$:

1. We initialize a set of tentative edges, $\hat{E}$, to a spanning tree of $H$ by calling $k$th-hop($k$, $v$, $u$) from every vertex, $v \in U$, to an arbitrarily chosen vertex, $u \in U$, for $k = 1, \ldots, \text{diam}(G)$, in parallel. We initialize a set of confirmed non-edges of $H$, $F \leftarrow \emptyset$. Note that we always maintain that $F \subseteq \hat{E}^c$. This requires 1 round of $O(\text{diam}(G)n)$ kth-hop queries.

2. We compute all the $\delta_{\hat{E}}(u,v)$ sets, for pairs $(u,v) \in \hat{E}^c$, which requires no queries.

3. We perform $p$ steps of the greedy set-cover algorithm applied to the sets, $\delta_{\hat{E}}(u,v)$ in parallel, to determine the actual hop-count distances, $\delta_h(u_i,v_i)$, between $u_i$ and $v_i$ in $H$, for each $i = 1, 2, \ldots, p$ in parallel. This step requires $O(1)$ rounds of $O(p \cdot \text{diam}(G))$ kth-hop queries in total.

4. For each $i$ such that $\delta_h(u_i,v_i) = \hat{\delta}_h(u_i,v_i)$, we add all the pairs in $\delta_{\hat{E}}(u_i,v_i)$ to $F$. If $F = \hat{E}^c$, then we are done, by Lemma 10.

5. Otherwise, if $F \neq \hat{E}^c$ and $\delta_h(u_i,v_i) = \hat{\delta}_h(u_i,v_i)$, for all $i = 1, 2, \ldots, p$, then we repeat the above process, performing another $p$ steps of greedy set cover, looping back to Step 3.

6. If, on the other hand, $F \neq \hat{E}^c$ and $\delta_h(u_i,v_i) < \hat{\delta}_h(u_i,v_i)$, for some $i$, then there must be at least one edge on a shortest path from $u_i$ to $v_i$ that is in $\hat{E}$ but not yet in $\hat{E}$. In this case, we add all such edges (which were discovered when we performed the $\text{diam}(G)$ kth-hop($k$, $u_i$, $v_i$) queries) to $\hat{E}$, and repeat the above greedy searching for this updated set, $\hat{E}$, of candidate edges, returning to Step 2.

This gives us the following result.

**Theorem 11.** Let $f(n,\Delta)$ be the query complexity of an optimal sequential algorithm for graph verification for any unweighted connected graph with $n$ vertices and maximum degree $\Delta$ using distance queries. Then, for $1 \leq p < n$, our parallel network mapping algorithm has kth-hop query complexity, $Q(n) \in O((\Delta np + f(n,\Delta) \log n) \text{diam}(G))$ and round complexity, $R(n) \in O((\Delta n + (f(n,\Delta)/p) \log n)$, if $U \subset V$, or $Q(n) \in O((\Delta np + f(n,\Delta) \log n) \log n)$ and round complexity, $R(n) \in O((\Delta n + (f(n,\Delta)/p) \log n) \log n)$, if $U = V$.

**Proof.** See Appendix A.3.
Thus, setting $p$ to be $n^{O(r(n))}$ gives us the following.

**Corollary 12.** One can solve the network mapping problem with query complexity, $Q(n)$, that is $\text{diam}(G) \cdot n^{1+O(r(n))}$ and round complexity, $R(n)$, that is $O(\Delta n)$, if $U \subset V$, or with $Q(n)$ that is $n^{1+O(r(n))}$ and round complexity, $R(n)$, that is $O(\Delta n \log n)$, if $U = V$.

This query complexity is within an $n^{o(1)}$ factor of optimal when $\Delta$ is $n^{o(1)}$, by the following simple lower bound.

**Theorem 13.** Solving the network mapping problem for an $n$-vertex graph, $G$, with maximum degree, $\Delta$, requires $\Omega(\Delta n \log n)$ $k$th-hop queries, even if $H$ has only $n$ edges.

**Proof.** Let $H$ be a caterpillar (i.e., a tree where every leaf is at distance 1 from a vertex on a central path), such that every internal node has degree $\Delta$. Choose any pair, $u$ and $v$, of sibling leaves and connect them with an edge. The only way to discover the edge, $(u,v)$, is to perform a kth-hop $(k,u,v)$ query, for $k \geq 1$. Thus, in expectation, any graph reconstruction algorithm must perform a query for over half of the pairs of siblings in $H$, that is, at least $\Omega((n/\Delta)\Delta^2) = \Omega(\Delta n)$ queries, in order to discover all the edges of $H$.

### 5 Conclusion

We have given efficient algorithms for solving the network mapping problem in parallel. Such algorithms show the effectiveness of kth-hop queries, even though they are weaker than shortest-path queries. Our methods assume knowledge of $\delta_{\max}$ and $\mu$, but this assumption can be relaxed at the expense of increasing the round complexity by an $O(\log n)$ factor, while keeping the query complexity unchanged, by using our algorithm as a blackbox to perform a doubling search for the values of these parameters. Our methods also assume kth-hop $(k,u,v)$ remains same in the algorithm, which is a reasonable assumption in static routing. In our network mapping formulation, we abstracted away some system issues such that when the TTL field of a packet reaches 1, the node sends an ICMP message to the source address; however, in the real Internet, some nodes may have their ICMP responses switched off. Therefore, a direction to extend this work would be to design algorithms addressing such system issues.

We have also given new, parallel implementations for graph clustering, which provide tradeoffs between the number of center vertices and the sizes of clusters. Even for sequential algorithms, this result may prove useful for applications where minimizing the number of center points is a primary optimization goal. For instance, one can apply our construction to the problems studied by Honiden et al. [31] for balancing graph-theoretic Voronoi diagrams to shave a $O(\log n)$ factor of the number of centers. It seems likely, therefore, that this result will have other applications as well.

4:14 Mapping Networks via Parallel kth-Hop Traceroute Queries

Mapping Networks via Parallel kth-Hop Traceroute Queries

A Omitted Proofs

Here, we provide proofs that were omitted in the body of this paper.

A.1 Bounding the number of Bad Iterations for Parallel Graph Clustering

Recall that we chose $\alpha$ in our parallel graph clustering algorithm according to the formula

$$\alpha = \begin{cases} 
2 & \text{if } \beta \leq ((4/3)e)^4 \\
(4/3)e^{\beta/2} & \text{else,}
\end{cases}$$

where $\beta$ is the ratio of the number of edges in the current partition to the number of edges in the final partition.
and we said an iteration is “bad” if \( \sum_{w \in W_i} |C_{A_i}(w)| > \frac{2n|W_i|}{\alpha} \) and otherwise it is “good.” We also noted, by Markov’s inequality, that an iteration is bad with probability at most \( \alpha \).

Further, note that \( L = \log_{\beta}(\frac{\alpha}{\theta}) n = O(\log_{\beta} n) \) is the maximum number of good iterations, for either choice for \( \alpha \). We wish to show that the number of bad iterations is \( O(L) \) w.h.p.

Since \( W_i \) is a given for iteration \( i \), whether iteration \( i \) is good or bad depends only on \( A_i \); therefore, an iteration is good independent of whether any other iteration is good or bad, so, for the sake of analysis, consider a set of \( c_0L \) iterations (i.e., padding out with “dummy” iterations if necessary) where \( c_0 \geq 4 \) is a constant chosen below and each iteration is bad independently with probability \( 1/\alpha \). Let \( X \) denote the number of bad iterations in this set. So \( E[X] = c_0L/\alpha \); hence, the probability that over \( 3/4 \) of our iterations are bad can be bounded as \( p = \Pr(X > (3/4)c_0L) = \Pr(X > (3/4)\alpha \cdot E[X]) \). Thus, at least \( L \) of our iterations are good with probability at least \( 1 - p \).

**Case 1:** \( \alpha = 2 \). In this case, \( \beta = O(1) \); hence, \( L = \Theta(\log_{\beta} n) = \Theta(\log n) \), since \( \beta \geq 4 \). Further, \( \Pr(X > (3/4)\alpha \cdot E[X]) = \Pr(X > (3/2) \cdot E[X]) \), and, by a standard Chernoff bound,\(^5\) e.g., see [39, p. 69],

\[
\Pr(X > (3/2) \cdot E[X]) \leq e^{-E[X]/12} = e^{-c_0L/24}.
\]

Thus, choosing \( c_0 \) so that \( c_0L/24 \geq 2 \ln n \), we will have more than \((3/4)c_0L \) bad iterations with probability at most \( 1/n^2 \).

**Case 2:** \( \alpha = (4/3)e^{\beta^{1/2}} \). In this case, \( (\alpha/\beta) \leq \beta^{-1/4} \); hence, \( L = O(\log_{\beta} n) \). Further, we have that \( \Pr(X > (3/4)c_0L) = \Pr(X > (3/4)\alpha \cdot E[X]) = \Pr(X > e^{\beta^{1/2}} \cdot E[X]) \), and, by a non-standard Chernoff bound,\(^6\) e.g., see [39, p. 70],

\[
\Pr(X > e^{\beta^{1/2}} \cdot E[X]) \leq \left( \frac{e}{e^{\beta^{1/2}}} \right)^{(3/4)c_0L} = \beta^{-(3/8)c_0L}.
\]

Thus, by choosing \( c_0 \) so that \((3/8)c_0L \geq 2 \log\beta n \), we will have more than \((3/4)c_0L \) bad iterations with probability at most \( 1/n^2 \).

Therefore, we have the following.

**Lemma 14.** The number of good and bad iterations in Algorithm 1 is \( O(\log_{\beta} n) \) w.h.p.

### A.2 The Complexity of the estimated-parallel-centers Algorithm

Recall that the estimated-parallel-centers algorithm uses a global random sample set, \( R \), for estimating cluster sizes, where \( R \) is a random subset of \( U \) of size \( T = c_1(s/\beta) \log n \). Recall that, for each vertex \( w \in W \), we defined \( S(w) \) such that \( S(w) = R \cap C_A(w) \). Thus, \( E[|S(w)|] = |C_A(w)|(T/n) \). We are interested in showing that w.h.p. this sample of \( C_A(w) \) is giving neither an over-estimate nor an under-estimate for the size of \( C_A(w) \), which we define respectively as follows:

- **Over-estimate event:** \( |C_A(w)| \leq \beta n/s \), but \( |S(w)| > 2\beta T/s \). In this case, we would be including \( w \) in \( W \) even though its cluster size is sufficiently small.
- **Under-estimate event:** \( |C_A(w)| > 3\beta n/s \), but \( |S(w)| \leq 2\beta T/s \). In this case, we would be excluding \( w \) from \( W \) even though its cluster size is big.

Let us consider each of these types of events in turn.

---

\(^5\) \( \Pr(X \geq (1 + \delta) \cdot E[X]) \leq e^{-E[X]/\delta^2/4} \), for \( 0 < \delta \leq 1 \).

\(^6\) \( \Pr(X \geq (1 + \delta) \cdot E[X]) \leq (e/(1 + \delta))^{(1+\delta)E[X]} \).
Over-estimate event. We wish to bound the probability that $|C_A(w)| \leq \beta n/s$ but $|S(w)| > 2\beta T/s$, where $T = c_1(s/\beta) \log n$. Let $X$ denote the sum of $|C_A(w)|$ indicator random variables for counting the members of $C_A(w) \cap R$, i.e., where each variable is 1 independently with probability $T/n$. Thus, $E[X] = E[|S(w)|] = |C_A(w)|(T/n)$. So

$$\Pr(|S(w)| > 2\beta T/s) = \Pr(X > 2\beta T/s) = \Pr\left(X > \frac{2\beta n}{s|C_A(w)|} \cdot E[X]\right)$$

$$= \Pr(X > (1 + \delta) \cdot E[X]),$$

where

$$\delta = \left(\frac{2\beta n}{s|C_A(w)|} - 1\right) > 1.$$

In addition,

$$\delta \cdot E[X] = \left(\frac{2\beta n}{s|C_A(w)|} - 1\right) \cdot \frac{|C_A(w)| T/n}{2\beta T/s} = \frac{2\beta T}{s} - \frac{|C_A(w)| T}{n} \geq \frac{2\beta T}{s} - \frac{c_1 \log n}{s}.$$

Thus, by a standard Chernoff bound, and the fact that $\delta > 1$,

$$\Pr(X \geq (1 + \delta) \cdot E[X]) \leq e^{-\delta \cdot E[X]/(2+\delta)} \leq e^{-\delta \cdot E[X]/3} \leq e^{-(c_1 \log n)/3} \leq \frac{1}{n^3},$$

for $c_1 \geq 9 \ln 2 \approx 6.24$.

Under-estimate event. We wish to bound the probability that $|C_A(w)| > 3\beta n/s$ but $|S(w)| \leq 2\beta T/s$, where $T = c_1(s/\beta) \log n$. Let $X$ denote the sum of $|C_A(w)|$ indicator random variables for counting the members of $C_A(w) \cap R$, i.e., where each variable is 1 independently with probability $T/n$. Thus, $E[X] = E[|S(w)|] = |C_A(w)|(T/n) > 3c_1 \log n$. So

$$\Pr(|S(w)| \leq 2\beta T/s) = \Pr(X \leq 2\beta T/s)$$

$$= \Pr\left(X \leq \frac{2\beta n}{s|C_A(w)|} \cdot E[X]\right) \leq \Pr(X \leq (2/3) \cdot E[X]).$$

Thus, by a standard Chernoff bound, e.g., see [39, p. 71],

$$\Pr(|S(w)| \leq 2\beta T/s) \leq e^{-(3c_1 \log n)/18} \leq \frac{1}{n^3},$$

when $c_1 \geq 18 \ln 2 \approx 12.48$.

Of course, $R$ is the same random sampling set for all our samples, $S(w)$, for $w \in W$. Nevertheless, by a union bound, the above analysis shows that $R$ causes an over-estimate event or an under-estimate event, for some $S(w)$, with probability at most $1/n^2$.

By the bound on over-estimate events, we have shown that w.h.p. every cluster with size over $\beta n/s$ is included in $W$ in any given iteration of our estimated-parallel-centers algorithm. In addition, by the bound on under-estimate events, we have shown that w.h.p. every vertex,

\footnote{Pr(X \geq (1 + \delta) \cdot E[X]) \leq e^{-\delta \cdot E[X]/(2+\delta)}, for \delta > 0, e.g., see \url{https://en.wikipedia.org/wiki/Chernoff_bound}.}

\footnote{Pr(X \leq (1 - \delta) \cdot E[X]) \leq e^{-\delta \cdot E[X]/2}, for 0 < \delta < 1.}
w, that we exclude from W has a cluster size of at most $3\beta n/s$. Thus, using essentially the same analysis as we gave for the proofs of Theorem 2 and Lemma 14, and noting that each iteration of our estimated-parallel-centers algorithm has round complexity $O(R(n))$ and query complexity $O(Q(n)(s/\beta) \log n)$, where $R(n)$ and $Q(n)$ are the respective round and query complexities for the Distances algorithm, we have the following.

**Lemma 15** (Lemma 4). Our estimated-parallel-centers algorithm constructs a set, A, of $(3\beta, s)$-balanced centers of size $O(s \log_\beta n)$. Suppose Distances($r, U$) executes in $R(n)$ rounds and $Q(n)$ kth-hop queries. Then estimated-parallel-centers algorithm executes in $O(R(n) \log_\beta n)$ rounds and $O(Q(n)(s/\beta) \log n \log_\beta n)$ kth-hop queries, w.h.p.

### A.3 Greedy Algorithm Proofs

Our description of our greedy algorithm given above in the body of our paper was for the case when $U \subset V$. For the case when $U = V$, we modify our algorithm to be the following (note that in this case, hop-count distance and graph distance are the same):

1. We initialize a set of tentative edges, $\hat{E}$, to a spanning tree of $H$ by calling kth-hop$(1, v, u)$ from every vertex, $v \in U$, to an arbitrarily chosen vertex, $u \in U$. We initialize a set of confirmed non-edges, $F \leftarrow \emptyset$. This requires 1 round of $O(n)$ kth-hop queries.

2. We compute all the $S_{u,v}(\hat{E})$ sets, for pairs $(u, v) \in \hat{E}$, which requires no queries.

3. We perform $p$ steps of the greedy set-cover algorithm applied to the sets, $S_{u,v}(\hat{E}) \setminus F$, with the goal of covering the remaining pairs, in $\hat{E}^c \setminus F$, in a greedy fashion, which also requires no queries. Let $\{(u_1, v_1), (u_2, v_2), \ldots, (u_p, v_p)\}$ denote the vertex pairs for the $S_{u,v}(\hat{E})$ sets chosen by these greedy steps.

4. We perform a binary search using kth-hop queries to determine the actual distance, $\delta(u_i, v_i)$, between $u_i$ and $v_i$ in $H$, for each $i = 1, 2, \ldots, p$ in parallel. This step requires $O(p \log n)$ rounds of at most $O(p \log n)$ kth-hop queries in total.

5. For each $i$ such that $\delta(u_i, v_i) = \hat{\delta}(u_i, v_i)$, we add all the pairs in $S_{u_i,v_i}(\hat{E})$ to $F$. If $F = \hat{E}^c$, then we are done, by Lemma 10.

6. Otherwise, if $F \neq \hat{E}^c$ and $\delta(u_i, v_i) = \hat{\delta}(u_i, v_i)$, for all $i = 1, 2, \ldots, p$, then we repeat the above process, performing another $p$ steps of greedy set cover, repeating a loop returning to Step 3.

7. If, on the other hand, $F \neq \hat{E}^c$ and $\delta(u_i, v_i) < \hat{\delta}(u_i, v_i)$, for some $i$, then there must be at least one edge on a shortest path from $u_i$ to $v_i$ that is in $E$ and not yet in $\hat{E}$. In this case, we perform a binary search, described below, to find at least one such an edge, add all such edges to $\hat{E}$, and repeat the above greedy searching for this updated set, $\hat{E}$, of candidate edges, returning to Step 2. This step requires $O(p \log n)$ rounds of at most $O(p \log n)$ kth-hop queries in total.

Before we give our analysis, let us describe the details for the binary search to find an undiscovered edge when $\delta(u_i, v_i) < \hat{\delta}(u_i, v_i)$, for some $i$. We begin with a query, kth-hop$(k, u_i, v_i)$, where $k = \lfloor \delta(u_i, v_i)/2 \rfloor$, and let $w$ denote the returned vertex. So, $\delta(u_i, w) = k$ and $\delta(u_i, v_i) = \hat{\delta}(u_i, v_i) - k$. Since $\delta(u_i, v_i) < \hat{\delta}(u_i, v_i)$, we know that $\delta(u_i, w) < \hat{\delta}(u_i, w)$ or $\delta(w, v_i) < \hat{\delta}(w, v_i)$. Thus, we recursively search for one of these until we discover a new edge not in $\hat{E}$, which must exist, since $\delta(u_i, v_i) < \hat{\delta}(u_i, v_i)$.

**Theorem 16** (Theorem 11). Let $f(n, \Delta)$ be the query complexity of an optimal sequential algorithm for graph verification for any unweighted connected graph with $n$ vertices and maximum degree $\Delta$ using distance queries. Then, for $1 \leq p < n$, our parallel network mapping algorithm has kth-hop query complexity, $Q(n) \in O((\Delta np + f(n, \Delta) \log n) \text{diam}(G))$.
and round complexity, \( R(n) \in O((\Delta n + (f(n, \Delta)/p) \log n)) \), if \( U \subseteq V \), or \( Q(n) \in O((\Delta np + f(n, \Delta) \log n) \log n) \) and round complexity, \( R(n) \in O((\Delta n + (f(n, \Delta)/p) \log n) \log n) \), if \( U = V \).

**Proof.** Building a spanning tree of \( H \) is a one-time expense taking \( O(n \cdot \text{diam}(G)) \) \( k \text{-hop} \) queries and a round complexity of \( O(1) \) (step 1), for the case when \( U \subseteq V \), or \( O(n) \) queries with a round complexity of \( O(1) \) (step 1), for the case when \( U = V \). Each iteration of our greedy algorithm takes \( O(p \cdot \text{diam}(G)) \) \( k \text{-hop} \) queries with a round complexity of \( O(1) \) (step 4), for the case when \( U \subseteq V \), or \( O(p \log n) \) \( k \text{-hop} \) queries with a round complexity of \( O(\log n) \) (step 4 and step 7), for the case when \( U = V \).

In the case when \( \delta_h(u_i, v_i) < \delta_h(u_i, v_i) \), for some \( i \in [1, p] \), we discover at least one new edge – let us charge the queries for this iteration to this edge. Thus, the total number of \( k \text{-hop} \) queries due to this case is \( O(\Delta np \cdot \text{diam}(G)) \), with \( O(\Delta n) \) rounds, for the \( U \subseteq V \) case, or \( O(\Delta np \log n) \), with \( O(\Delta n \log n) \) rounds, for the \( U = V \) case. So, let us consider the case when \( \delta_h(u_i, v_i) = \delta_h(u_i, v_i) \), for all \( i \in [1, p] \), which we call a “completely-greedy” iteration. We will provide an upper bound for the number of such iterations. Recall that in step 3, for the case when \( U \subseteq V \) (similarly in step 3, for the case when \( U = V \)) we performed \( p \) steps of greedy set-cover algorithm applied to the sets, \( S_{u,v}(\hat{E}) \setminus F \), with the goal of covering the remaining pairs, in \( \hat{E}^c \setminus F \) without additional queries. Let \( F_i \) denote the set of \( (x, y) \) pairs covered by the \( i \)-th step of this greedy set-cover algorithm, for \( i = 1, 2, \ldots, p \). Thus,

\[
|F_1| \geq |F_2| \geq \cdots \geq |F_p|,
\]

and at the moment we chose the subset \( F_i \) it was the largest subset covering the uncovered pairs in \( \hat{U} = \hat{E}^c \setminus (\bigcup_{j=1}^{i-1} F_j \cup F) \). The optimal sequential graph verification algorithm performs \( f(n, \Delta) \) distance queries and confirms all the pairs in \( \hat{E}^c \). Thus, in particular, this optimal algorithm must perform queries that cover \( \hat{U} \) as a part of its \( f(n, \Delta) \) queries; hence, because \( F_i \) is the subset for a distance query that covers the largest number of pairs in \( \hat{U} \), and the average number of pairs in \( \hat{U} \) covered by any distance query of the optimal algorithm is at least \( |\hat{U}|/f(n, \Delta) \), we have that

\[
|F_i| \geq \frac{|\hat{U}|}{f(n, \Delta)}.
\]

Thus, in any iteration of our algorithm, since we perform \( p \) greedy steps, the size of the remaining pairs in \( \hat{E}^c \setminus F \) is reduced by a multiplicative factor of

\[
\left(1 - \frac{1}{f(n, \Delta)}\right)^p \leq e^{-p/f(n, \Delta)}.
\]

Therefore, since \( \hat{E}^c \leq n(n-1) \) and by the end of our algorithm we cover every pair in \( \hat{E}^c \), the total number of completely-greedy iterations, \( g \), can be bounded above by the smallest value of \( g \) such that

\[
e^{-p/f(n, \Delta)g} < n^{-2};
\]

therefore, the total number of completely-greedy iterations, \( g \), is at most \( O((f(n, \Delta)/p) \log n) \). Note that the set \( \hat{E}^c \) is potentially growing during our algorithm, with completely-greedy iterations possibly interspersed with iterations that discover new edges in \( \hat{E} \). Nevertheless, the above analysis still holds, because (1) the function, \( f(n, \Delta) \) is a uniform bound for any connected graph with \( n \) nodes and maximum degree \( \Delta \), and (2) each time we (greedily)
confirm that \( \hat{\delta}(u, v) = \delta(u, v) \) for a set, \( S_{u,v}(\hat{E}) \), all the pairs in \( S_{u,v}(\hat{E}) \) are, in fact, non-edges in \( \hat{E}^c \). The claimed complexity bounds follow then, since each completely-greedy iteration requires \( O(p \cdot \text{diam}(G)) \) kth-hop queries with round complexity \( O(1) \), for the \( U \subset V \) case, or \( O(p \log n) \) kth-hop queries with round complexity \( O(\log n) \), for the \( U = V \) case.
